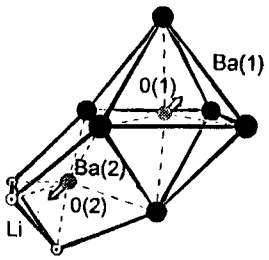
one is above the Li_3 prismane base, and three bridge the three BaLi prismane edges. The tetrahydrofuran oxygen centers are coordinated to the Ba centers that are not part of the prismane. If the O^{2-} inner centers are also considered, each polyhedron face is at least singly O-capped.

The polyion aggregate $\{[Ba_6Li_3O_2][OC(CH_3)_3]_{11}(O_3C_4H_8)\}$ contains 204 centers and 932 electrons. A model $\{[Ba_6Li_3O_2](OH)_{11}\}$, simplified by the substitution $(H_3C)_3 \rightarrow H$ and removal of the THF ligands still contains 33 centers and 460 electrons; nevertheless, calculations on this molecule are possible with the presently best-suited LCGTO-DF (Linear Combinations of Gaussian Type Orbitals Density Functional) method[4, 5] and a CRAY YMP. A more severely simplified model accentuating, however, the polyion character of the title compound is $\{[Ba_6Li_3O_2]^{11+}(e^-)_{11}\}$, in which the anions are represented by point charges, and which reduces the problem to 11 centers and (still) 350 electrons. The Kohn–Sham eigenvalue spectra calculated for both models (Fig. 2) provide essential information.



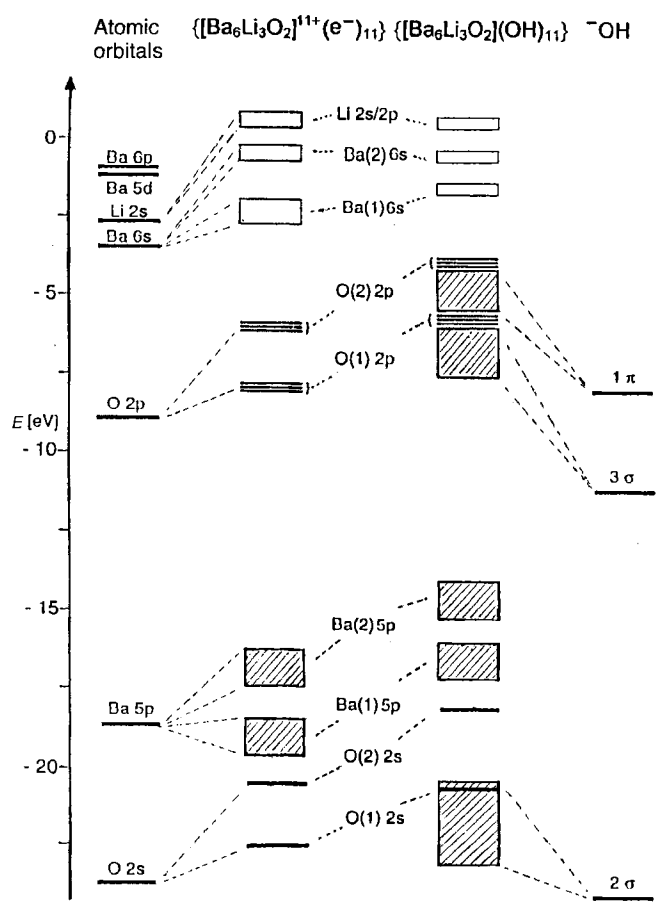


Fig. 2. Kohn–Sham eigenvalue spectra of LCGTO-DF-calculated valence orbitals [5] for both cluster models $\{[Ba_6Li_3O_2]^{11+}(e^-)_{11}\}$, and $\{[Ba_6Li_3O_2](OH)_{11}\}$ based on the spin-averaged Ba, Li, O atomic orbitals and OH molecular orbitals (filled and empty levels for Ba without spin/orbit splitting are represented by shaded and unshaded boxes, respectively).

The eigenvalues can be classified according to the basis orbital contributions Ba(1) for the centers of the outer Ba_3 triangle of the octahedron and Ba(2) for the shared Ba_3 face between octahedron and prismane, and in addition, the O^{-2} oxygen centers O(1) of the octahedron and O(2) of the prismane. Because of the O contacts on both sides, the contributions of Ba(2) to the molecular orbital energies are smaller than those of Ba(1). Furthermore, due to the smaller ionic character of the adjacent Li contacts, O(2) > O(1). In the $(OH)_{11}$ model the diversity of the 2σ, 3σ and 1π orbitals has to be taken into account. The electrostatic field of $(OH)_{11}$ predominantly shifts the occupied levels to higher energies and thereby reduces the HOMO–LUMO energy difference of 3.17 eV (102 a′ – 74 a″) in the $(e^-)_{11}$ model to 1.82 eV (137′ a′ – 138 a′). The bond energy of the individual OH ligands is calculated to be −25.1 eV for ionic dissociation to $^-$OH and −5.8 eV for homolytic clearage to $^\bullet$OH; comparable values for water are −18.1 eV ($H^+ + {}^-OH$) and −5.4 eV ($H^\bullet + {}^\bullet OH$). With respect to the electrostatic interaction in the $(e^-)_{11}$ model, each $^-$OH ligand stabilizes the cluster by 1 eV.

Special attention was focused on the two O^{2-} cluster oxygens. Hypersurface calculations within the $(e^-)_{11}$ model allow estimation of force constants[5] and vibrational frequencies and predict a weak O(1)···O(2) coupling of about 40 cm^{-1}. For the different charge distribution, a numerical integration over atomic lattice cells[5] yields −1.95 for O(1) and −1.68 for O(2). In the point charge approximation, satisfactory agreement is achieved by calculating the potential −24.2 eV at O(1) and −22.3 eV at O(2). The charges at the metal centers[5] obtained on numerical integration further confirm that the ionic contributions are more pronounced in the $Ba_o^{(2.1-2.2)+}$ octahedron than in the $Ba^{2.2+}Li^{0.8+}$ prismane. The analysis of the charge density distribution, therefore, supports the assignment as a polyion aggregate.

Despite of the information gathered both from crystallization and structure determination (Fig. 1) as well as from the LCGTO density functional calculations (Fig. 2), there are still numerous unanswered questions such as whether barium metal after dissolution in *tert*-butyl alcohol accompanied by H_2 evolution is already present as a $[Ba_6O]^{10+}$ octahedron.[6] Above all, it is of interest how the oxygen centers are incorporated. One possibility is, for instance, that it occurs as investigated almost 30 years ago[7] in the formation of the copper complexes $[Cu_4OL_4X_6]$ (L = amine, X = halide) containing an O^{2-} center in the Cu_4^{2+} tetrahedron. These and other facets of the intriguing novel lipophilically wrapped polyion aggregates are presently being explored.

isotropically with a riding model using individual displacement parameters ([U(H) = 1.5 U_{eq}(C-methyl)], [U(H) = 1.2 U_{eq}(C-methylene]). Three THF molecules were disordered and refined according to a split model. In one of these THF molecules the oxygen could not be localized unequivocally and was therefore refined as carbon. Further details of the crystal structure investigation are available on request from Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the deposition number CSD-58880.

[2] The following "lipophilically wrapped polyion aggregates" have been crystallized and characterized by structure: a) the hexameric sodium imido(tetraphenoxydiphosphate), a hydrocarbon ellipsoid $\{H_{120}C_{144}O_{24}[OP\text{-}N^-PONa^+]_6\}$ containing a Na_6O_{12} core (H. Bock, H. Schödel, Z. Havlas, E. Herrmann, *Angew. Chem.* **1995**, *107*, 1441; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 1355); b) $\{(H_{52}C_{44}O_4)^{3-}[Li_6^+(NH_3)_2]^{6+}(O_4C_{44}H_{52})^{3-}\}$, an edge-shared Li_6^+ double tetrahedron between calix[4]arene trianion half-shells (H. Bock, A. John, C. Näther, Z. Havlas, *J. Am. Chem. Soc.* **1995**, *117*, in press); c) $\{(H_8C_{12}C{=}NO_2)_6^{6-}K_6(OC_4H_8)_2(O_2C_4H_8)\}$, a hexameric aci-9-nitrofluorene potassium salt containing the coordination cluster K_6O_{12} (H. Bock, R. Dienelt, H. Schödel, Z. Havlas, *J. Chem. Soc. Chem. Commun.* **1995**, submitted); d) aluminumlithium-bis(catecholate)-penta(dimethoxyethane), a $C_{48}H_{76}$-wrapped infinite chain of $[O_3Li^+(O_4^-Al^{2+})(O_2Li^+O_2)(Al^{2+}O_4^-)Li^+O_3]$ links (H. Bock, R. Beck, H. Schödel, Z. Havlas, unpublished results); cf. R. Beck, Masters thesis, Universität Frankfurt, **1995**.

[3] The search through the Cambridge Crystallographic Data Bank for already known lipophilically wrapped polyion aggregates cannot be carried out in a single approach. The following isolated details were uncovered: a) D. Fenske, G. Longoni, G. Schmid summarized information on S- and Se-containing transition metal clusters ("Clusters and Colloids – From Theory to Applications" (Ed.: G. Schmid), VCH, Weinheim, **1994**, pp. 89–298); b) clusters of alkali metal oxides such as Rb_9O_2 or $Cs_{12}O_3$ consisting of O-filled Rb_6 or Cs_6 octahedra have been known since 1971 (A. Simon, *Struct. Bonding* **1979**, *36*, 81); c) isolated reports concern lithium-3,3-dimethyl-1-buten-2-olate-tetrahydrofuran (**A**; R. Amstutz, W. B. Schweizer, D. Seebach, J. D. Dunitz, *Helv. Chim. Acta* **1981**, *64*, 2617) and nonameric sodium-*tert*-butanolate (**B**; J. E. Davies, J. Kopf, E. Weiss, *Acta Crystallogr. Sect. B* **1982**, *38*, 2251; see also E. Weiss, *Angew. Chem.* **1993**, *105*, 1565; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1501. As the space-filling representations of **A** and **B** show, the $(Na^+O^-)_9$ double hexagon is less lipophilically wrapped than the $(Li^+O^-)_4$ cubane.

$[(H_3C)_3C\text{-}C(=CH_2)O^{\ominus}Li^{\oplus}(OC_4H_8)]_4$ $[(H_3C)_3CO^{\ominus}Na^{\oplus}]_9$

[5] Details of the LCGTO-DF-calculations: Basis sets Ba (18s, 13p, 8d, 1f), Li (9s, 4p), O^{2-} (11s, 7p, 1d), O (9s, 5p, 1d), H (6s, 1p) with generalized atom contractions of TZVP quality; the additional charge density and exchange correlation potential basis sets were designed according to standard procedures [4]. The three-dimensional numerical integration to determine the exchange correlation contributions to the total energy were performed using a cell grid of the ionic radii $r(Ba^{2+}) = 135$ pm, $r(Li^+) = 76$ pm, $r(O^{2-}) = 140$ pm, and $r(H) = 37$ pm. The eigenvalue scheme (Fig. 2) was supplemented by the calculated dipole moments of 29 D in the $(e^-)_{11}$ model and of 21 D in the $(^-OH)_{11}$ model, as well as by the different 1s-shifts relative to the atomic value of +7.7 eV for O(1) and of +9.2 eV for O(2) in the $(^-OH)_{11}$ model, which are predominantly due to the electrostatic potential difference of −1.9 eV between the centers O(1) and O(2). The force constants for the O(1)/O(2)-coupling are $f_{11} \approx f_{22} \approx 1.2$ and $f_{12} \approx 0.1$ mdyn Å^{-3}.

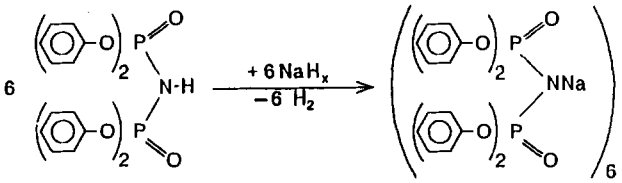
The Lipophilically Wrapped Polyion Aggregate $\{H_{120}C_{144}O_{24}(OP)_2N^-Na_6^+\}$, a Hexameric Sodium Tetraphenyl Imidodiphosphate Containing an $[Na_6O_{12}]$ Core in a Hydrocarbon Ellipsoid**

Hans Bock*, Holger Schödel, Zdenek Havlas, and Eckhard Herrmann*

Dedicated to Professor Peter Schuster

Tetraphenyl imidodiphosphate $HN[PO(OC_6H_5)_2]_2$[2a] with its $[OP\text{-}N\text{-}PO]^-$ chelate pincer is a Brønsted acid with advantages for complexation[2b] and extraction[2c] of metal ions. If salts are formed, not in water or alcohols[2] but in dry benzene, with sodium hydride, instead of the well-known[2d] monomeric chelate complexes $[Me^nL_n]$ a novel hexamer results [Eq. (a)].



(a)

The structure determination on the colorless prisms of the hexamer[3] (Fig. 1) reveals a "hydrocarbon skin" $H_{120}C_{144}$ composed of 24 phenyl rings (Fig. 1, top right), which lipophilically wraps a polyion aggregate with an $[Na_6O_{12}]^{6+}$ core within a circle of four imidodiphosphate ions (Fig. 1, bottom left), capped above and below by two others (Fig. 1, bottom right).

In the three-dimensional cluster core $[Na_6O_{12}]^{6+}$, the distances between the Na^+ ions and the deprotonated nitrogen centers of the anions are, on average, 370 pm; the complexation, therefore, is accomplished through the 223 to 250 pm long $Na\cdots O{=}P$ contacts (Fig. 1, bottom right). Every Na^+ ion is surrounded by four close O centers and is coordinated in addition to another at a larger distance (see legend of Fig. 1; values in brackets between 265 and 305 pm). The Na_6O_{12} network contains a center of inversion and a total of 24 stronger and 6 weaker $Na^+\cdots O^{\delta-}$ interactions. Of the stronger ones, 14 are located in the tetramer circle (dashed lines in Fig. 1, bottom left) and the other 10 connect the two capping tetraphenyl imido disphosphate ligands which bridge the metal centers Na1, Na2, Na3, Na1′, Na2′, and Na3′ (Fig. 1, bottom right, O50P5N3P6O60).

According to ab initio calculations with a "double zeta" basis set, the $Na^+\cdots O^{\delta-}$ interactions are largely ionic[4a] and support the designation of the compound as a polyion aggregate.

[**] Lipophilically Wrapped Polyion Aggregates, Part 2, and Interactions in Crystals, Part 70. The research project was supported by the Adolf-Messer-Foundation, the Deutsche Forschungsgemeinschaft, the State of Hesse, and the Fonds der Chemischen Industrie. Part 1 and Part 69: ref. [1].

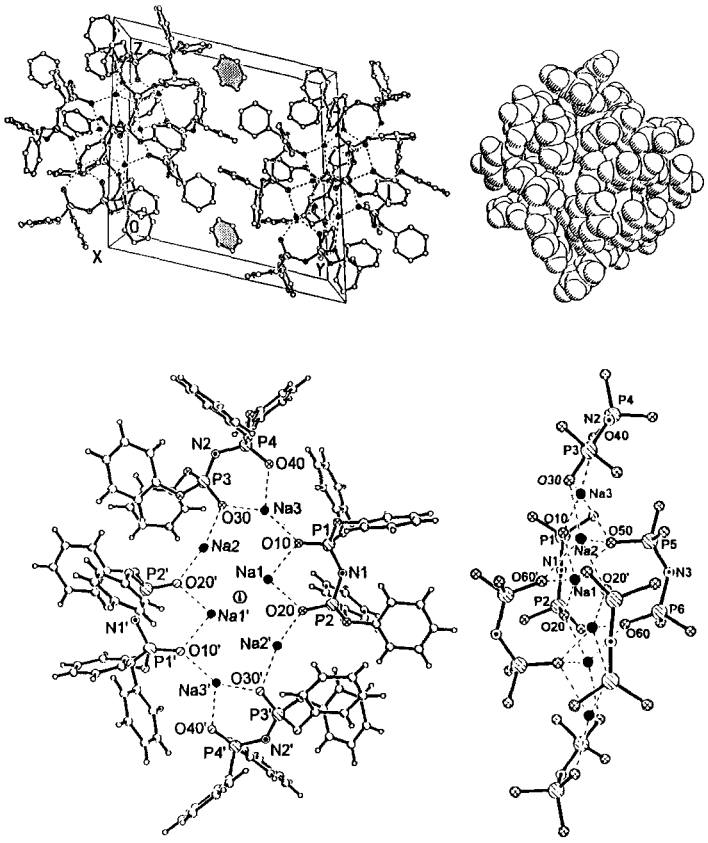

Fig. 1. Single-crystal structure of hexameric sodium tetraphenyl imidodiposphate at 200 K [3]. Top left: unit cell (triclinic $P\bar{1}$, $Z = 2$) viewed along the x direction with two molecules of benzene in crystal cavities per three formula units shaded; shortest non-bonded C···C distance to the phenyl substituents 360 pm). Top right: space-filling representation of the hexamer. Bottom left: View of a cut through the $[Na_6O_{12}]^{6+}$ core showing four of the six tetraphenyl imidodiphosphate ions encircling the cluster (ⓘ: center of inversion). Bottom right: side view of the polyion aggregate $[\{O_2(O)PN\text{-}P(O)O_2\}^-Na]_6$, without phenyl groups, around the three types of centers, Na1, Na2, and Na3. Selected bond lengths [pm] and angles [°]: Na1O10 234, Na1O20 223, Na1O50 226, Na1O60′ 230, Na1O60 (265), Na2O20′ 230, Na2O30 231, Na2O50 238, Na2O60′ 249, Na2O31 (284), Na3O10 228, Na3O30 229, Na3O40 223, Na3O50 238, Na3O52 (305), O10Na1O20 92, O10Na1O50 86, O10Na1O60 145, O20Na1O50 154, O20Na1O60 87, PN 156, P=O 148, P–O 160 PNP 132, OPO 105, 110, OPN 105, 120.

The formal charge separation $Na^+\cdots OPN^-$ impedes MNDO calculations of enthalpies of formation: Relative to $[\{(HO)_2OP\}_2N^-Na^+]_n$ with $n = 1$, for hexamerization ($n = 6$) a lower limit of $\Delta\Delta H_f^{MNDO} = -146\ kJ\,mol^{-1}$ per monomer is estimated, which on consideration of all contacts $Na^+\cdots O^{\delta-}$, increases to an average of $\Delta\Delta H_f^{MNDO} = -200\ kJ\,mol^{-1}$.[4c] The total enthalpy of formation calculated from the structural data (Fig. 1) of $\Delta H_f^{MNDO} = -9021\ kJ\,mol^{-1}$ includes a Coulomb repulsion contribution within the Na_6^+ network of $\Delta\Delta H_f^{MNDO} = 3942\ kJ\,mol^{-1}$.

The lipophilic $H_{120}C_{144}$ hydrocarbon skin of the hexameric tetraphenyl imidodiphosphate is composed of 24 phenyl rings whose interactions can be estimated. The starting point is the statistical structure analysis of 34 phenyl-containing proteins from the database of the Cambridge Crystallographic Data Centre,[5] which traces the formation of "phenyl clusters" to CH/π interactions: according to this analysis, two phenyl rings with an average centroid/centroid distance of 505 pm and a dihedral angle between their planes of 70° should contribute about $-5\ kJ\,mol^{-1}$ to the enthalpy of formation.[5a] In crystals of aromatic compounds with six-membered rings, these interactions can generate the known herringbone patterns. For benzene dimers in the gas phase, calculations with highly correlated wavefunctions predict a stabilization of at least $-9\ kJ\,mol^{-1}$[5c] for a parallel-shifted arrangement of C_6 rings 385 pm apart. For the "phenyl skin" of the polyion aggregate presented here (Fig. 1), an analysis of the structural data (Fig. 2) yields a distribution of the total of 62 ring intercentroid distances and angles between the planes of the 24 phenyl rings. The histograms show 44 intercentroid distances smaller than 600 pm and 29 arrangements with interplanar angles smaller than 60°. The average values are $\bar{d}_{R\cdots R} = 534$ pm and $\bar{\omega} = 35°$. Fitting the correlated calculation results for benzene dimers[5c] to a Morse potential curve yields an estimated $-1\ kJ\,mol^{-1}$ for parallel phenyl rings 500 pm apart and thus an overall cluster stabilization contribution by the phenyl wrapping of at most $-50\ kJ\,mol^{-1}$.[6]

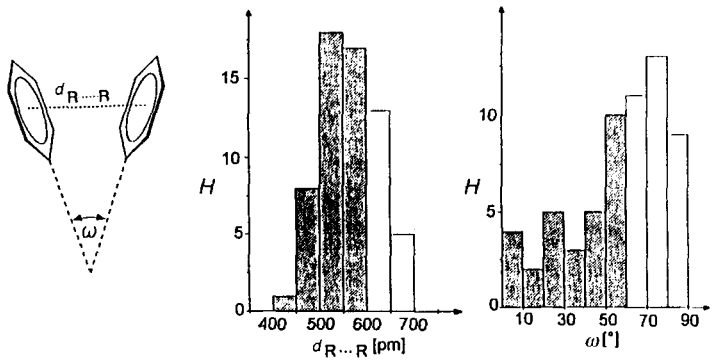

Fig. 2. Abundances H of distances d and angles ω between phenyl rings in the title compound.

Lipophilically wrapped polyion aggregates are characterized[1] by a cluster core of cations and anions that provides thermodynamic stability, and by a largely impenetrable hydrocarbon skin, which adds kinetic stability. A generalizable crystallization (self-organization) principle[1] now emerges. Within a few months, we succeeded in crystallizing and structurally characterizing the following polyion aggregates:

- $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$, an (octahedron + prismane) polyhedron,[1]
- $\{(H_{52}C_{44}O_4)^{3-}[Li_6^+(NH_3)_2](O_4C_{44}H_{52})^{3-}\}$, an edge-sharing double tetrahedron between calix[4]arene trianions,[7a]
- $\{[(H_8C_{12}C{=}NO_2)^-K^+]_6(OC_4H_8)_2(O_2C_4H_8)\}$, a hexameric aci-9-nitrofluorene potassium with a K_6O_{12} core,[7b] and
- $\{(H_{76}C_{48})[Li_4^+Al_2^{2+}O_8^-O_{10}]\}_\infty$, an aluminumlithium-bis(catecholate)-penta(dimethoxyethane) chain.[7c]

In the hexameric sodium tetraphenylimidodiphosphate presented here, the thermodynamic stability is analogously dominated by the energetically favorable ionic contacts ($Na^+\cdots O^{\delta-}$).[3] The lipophilic wrapping determines on one hand the selective crystallization of the hexamer because of the spatial demands of the 24 phenyl substituents, and on the other the kinetic stability because of its impermeability at least to larger molecules.

[3] The crystalline powder from reaction (a) was recrystallized from dry benzene at room temperature under argon. Crystal structure determination: $(C_{24}H_{20}NP_2O_6Na)_3(C_6H_6)_2$, $M_r = 1666.2$, crystal dimensions $0.66 \times 0.52 \times 0.40$ mm, colorless prisms, temperature 200 ± 1 K, $a = 1398.4(1)$, $b = 1758.5(1)$, $c = 1788.9(1)$ pm, $\alpha = 101.74(1)$, $\beta = 107.06(1)$, $\gamma = 95.37(1)^\circ$, $V = 4061.9(6)$, 10^6 pm^3, $Z = 2$, $\rho_{calcd} = 1.362$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 71.07$ pm, triclinic, space group $P\bar{1}$ (no. 2), Siemens P4 four-circle diffractometer, 14256 measured reflections within $3^\circ \leq 2\theta \leq 50^\circ$, 13631 independent reflections of which 10459 with $I > 2\sigma(I)$, structure solution by direct methods (SHELXS), 1043 parameters refined on F (SHELXTL PC), $R = 0.038$, $R_w = 0.039$, residual electron density $+0.27/-0.32$ e Å^{-3}, $S = 1.608$. C, N, O, P positions anisotropically refined, hydrogens in ideal positions (d(C-H) = 96 pm) and refined isotropically using a riding model with a temperature factor common to the phenyl rings. One molecule benzene is 33% disordered; its main position was refined anisotropically and minor positions refined isotropically as idealized hexagons. Further details for the crystal structure determination can be requested from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-58881.

[4] The calculations were performed with the programs GAMESS (M. W. Schmidt, K. K. Baldridge, J. A. Boatz, J. H. Jensen, S. Koseki, M. S. Gordon, K. A. Nguyen, T. L. Windus, S. T. Elbert, *QCPE Bull.* **1990**, *10*, 52) and MOPAC 6.00 (J. J. P. Stewart, QCPE Programm 455, Indiana University, Bloomington) on our work station IBM RISC 6000. The storage limit of 252 atoms required the replacement of the phenyl groups by hydrogen, because the hexamer contains 324 centers. a) The ab initio calculations started from the structural data and employed a "double zeta" basis set (S. Huzinaga, J. Andzelm, M. Klobukowski, E. Radzio-Andzelm, Y. Sakai, H. Tatewaki, *Gaussian Basis Sets for Molecular Orbital Calculations*, Elsevier, Amsterdam, **1984**). A potential energy plot yielded two preferred positions for Na^+ at the $[O(HO)_2P\text{-}N'\text{-}P(OH)_2O]^-$ anion: in the center of the chelate pincer with Na1 $\cdots$ O distances of 233 and 234 pm, and outside them with a distance of 228 pm between Na3 and each oxygen atom. The total energy differences amounted to -603 (Na1) and -462 kJ mol^{-1} (Na3), and the charges to $+0.94$ (Na1) and $+0.96$ (Na3); b) based on the structural data (Fig. 1) the following MNDO-enthalpies of formation (kJ mol^{-1}) were calculated: $[(HO)_2OP\text{-}N\text{-}PO(OH)_2Na]_n$ for $n = 1$ -1358 and for $n = 6$ -9021; for the difference $\Delta\Delta H_f^{MNDO}$ -873, for each monomer -146 and for 6 Na^+ $+4515$ and for $(Na^+)_6$ $+7835$; c) with the individual contributions of the fragments O10Na1O20, O30Na2O40, and O50Na3O60 of -1262, -1261, and -1251, respectively, an enthalpy difference $\Delta\Delta H_f^{MNDO}$ of 8734 kJ mol^{-1} for the complexation $(Na^+)_6 \rightarrow$ hexamer and -4792 for 6 $Na^+ \rightarrow$ hexamer (without Coulomb repulsion is calculated, that is, an average stabilization of -200 for each $Na^+ \cdots O^\delta$ contact.

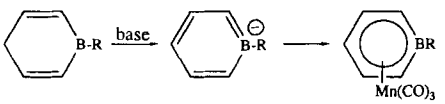
Aromatic Gallium Heterocycles: Synthesis of the First Gallatabenzene**

Arthur J. Ashe III,* Saleem Al-Ahmad, and Jeff W. Kampf

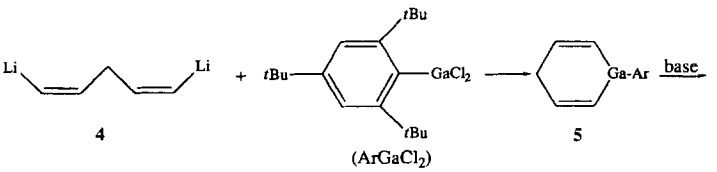
Dedicated to Professor Herbert Schumann on the occasion of his 60th birthday

Boratabenzene derivatives (**1**) have been intensely investigated for 25 years.[1-4] The high acidity of the precursor boracyclohexadienes (**2**),[5] and the close resemblance of boratabenzene metal complexes such as **3** with the corresponding cyclopentadienyl metal complexes[3, 4, 6] convincingly demonstrate that **1** is an anionic aromatic ring with six π electrons. Recent research suggests that boron's heavier congener gallium may also be able to form π bonds with carbon;[7, 8] thus an exploration of the chemistry of gallatabenzene should be of interest. We report here on the first synthesis of an arylgallatabenzene (**6**) and structural data for its $Mn(CO)_3$ complex (**7**).

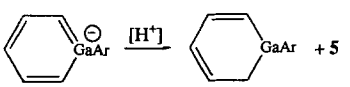


2 **1** **3**

In order to inhibit the Lewis acidity of the gallium atom we chose the highly hindered arylgallatabenzene **6** (Ar = tBu$_3$C$_6$H$_2$) as our target. The precursor gallacyclohexadiene **5** may be prepared by an adaption of the method used by Jutzi et al. to prepare silacyclohexadiene.[9] The reaction of (1*Z*,4*Z*)-1,5-dilithio-1,4-pentadiene (**4**) with 2,4,6-tri(*tert*-butyl)phenylgallium dichloride[10] gives **5** as air- and moisture-sensitive white crystals in 80% yield. The spectroscopic properties are completely consistent with the assigned structure. Compound **5** may be deprotonated with bases (tBuLi, Ph_3CLi, lithium diisopropylamide, or fluorenyllithium) in THF to afford yellow solutions of **6**. Treatment of **5** with one equivalent of indenyllithium in THF initially gives **6** and indene; however, on standing indenyllithium is reformed along with the conjugated gallacyclohexadiene **8**. Quenching **6** with excess cyclopentadiene affords a 1:1 mixture of **5** and **8**. Alternatively **5** may be completely converted to **8** by treatment with a trace of indenylithium in THF.



4 (ArGaCl$_2$) **5**



6 **8**

Thus, the acidity of **5** is bracketed between that of cyclopentadiene ($pK_a \approx 16$)[11] and that of indene ($pK_a \approx 21$),[11] while the more stable **8** is less acidic than indene. Since **5** is considerably

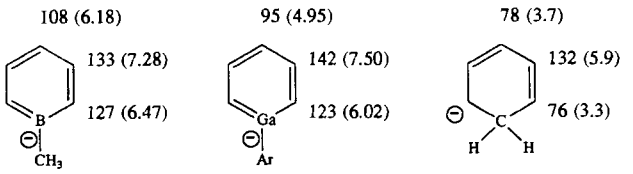
[**] This work was supported by the National Science Foundation.

more acidic than acyclic 1,4-dienes ($pK_a \approx 31$),[11, 12] there is a strong presumption that the gallium atom of **6** accepts π-electron density from the carbon atoms to form an aromatic ring with six π electrons. However under similar conditions **2** (R = Me) is more acidic than cyclopentadiene.[1b, 5] Thus the driving force for aromatization must be smaller for gallatabenzene than for boratabenzene.

The ^{1}H NMR spectrum of **6** in [D$_8$]THF shows a characteristic first-order [*AA'BB'C*] pattern for the signals of the five gallatabenzene ring protons, while the signals in the ^{13}C NMR spectrum can be unambiguously assigned by using selective ^{1}H-^{13}C decoupling. The ^{1}H and ^{13}C NMR chemical shift values of **1** (R = Me) and **6** are compared with those of the nonaromatic cyclohexadienide **9**[13] in Scheme 1. ^{13}C NMR chemical shift

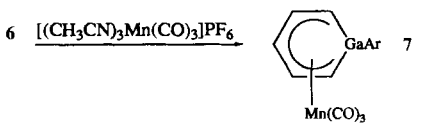


1 6 9

Scheme 1. Comparison of the ^{13}C NMR and the ^{1}H NMR (in parentheses) chemical shift values for anions **1** (R = Me), **6**, and **9** in [D$_8$]THF.

values have been used extensively to evaluate π-charge densities of carbanions[13, 14] and heterocarbanions.[15] The spectrum of cyclohexadienide (**9**) is typical for π-delocalized carbanions.[13] The signals for the negatively charged carbon atoms C1, C3, and C5 occur approximately 50 ppm higher field than those for the uncharged carbon atoms C2 and C4. The spectra of **1** (R = Me) and **6** deviate from this pattern in that the upfield shifts of the corresponding nuclei are much smaller, which is consistent with diminished negative charge at these carbon centers due to π-electron donation to the respective heteroatoms. In the same manner the ^{1}H NMR chemical shifts of the ring protons of **1** (R = Me) and **6** are shifted substantially downfield from the corresponding signals for **9**. This effect is consistent with ring current effects and/or diminished negative charge at carbon.[2] Thus the NMR spectra suggest that gallatabenzene **6** has aromatic character.

In order to explore further the chemistry of **6** we have prepared the Mn(CO)$_3$ complex **7**. The reaction of **6** with [Mn(CO)$_3$(CH$_3$CN)$_3$]PF$_6$ affords **7** in 46% yield as yellow air-



and moisture-sensitive crystals. An X-ray structural analysis allowed determination of the molecular structure of **7** as illustrated in Figure 1.[16] The structure of **7** shows that the gallatabenzene ring is η^5 coordinated through its planar pentadienyl moiety to the Mn(CO)$_3$ group. The ring is folded so that the C4-C5-C6-C7-C8 and C4-Ga-C8 planes intersect at 34.5°. While the five C–Mn bonds are of normal length (2.12–2.30 Å),[17] the Ga–Mn distance of 3.03 Å is much longer than the 2.50 Å reported for a Ga–Mn bond of a related complex.[18] The three C–Ga bond lengths of the trigonally surrounded Ga atom are not significantly different and fall in the expected range (1.94–1.96 Å) for single bonds. The plane of the aryl substituents is perpendicular to the C4-Ga-C8 plane. Thus the structure of **7** provides no evidence for Ga–C π bonding.

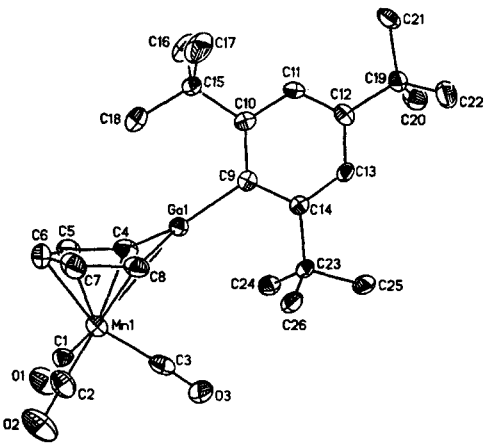

Fig. 1. Solid-state structure of **7** (ORTEP). Selected distances [Å] and angles [°]: Ga1-C8 1.936(3), Ga1-C4 1.942(4), Ga1-C9 1.961(3), Ga1-Mn1 3.0290(7), Mn1-C4 2.303(3), Mn1-C5 2.161(4), Mn1-C6 2.121(4), Mn1-C7 2.152(4), Mn1-C8 2.291(3), C4-C5 1.396(5), C5-C6 1.416(5), C6-C7 1.434(6), C7-C8 1.387(5); C9-Ga1-C4 132.75(15), C9-Ga1-C8 133.78(14), C4-Ga1-C8 93.5(2).

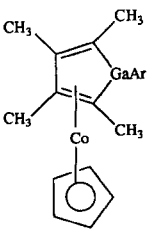
However, the electronic isolation of the Ga atom in **7** is a probable consequence of steric effects. A displacement of the Ga atom towards the ring plane, which is necessary to achieve η^6 coordination, would involve severe steric compression of the *ortho tert*-butyl group (C24, C26) and the carbonyl (C303). In a relevant related study Cowley et al. have found that the planar 1-(2,4,6-tri-*tert*-butylphenyl)-2,3,4,5-tetramethylgallole distorts on complexation to a CpCo group to form **10** by folding the Ga atom away from the metal.[8] We intend to prepare derivatives of **7** with smaller substituents on gallium which may show η^6 coordination.



10

Experimental Procedure

5: A solution of **4**, prepared from 5.25 mmol butyllithium in hexane (2.1 mL) and (1*Z*,4*Z*)-1,5-diiodohexa-1,4-diene (0.84 g, 2.63 mmol) in diethyl ether (30 mL), was added dropwise with stirring to a solution of ArGaCl$_2$ (1.01 g, 2.63 mmol) in diethyl ether (20 mL) at −78 °C. The reaction mixture was allowed to warm to 25 °C over 90 min, after which the solvent was removed under vacuum. The residue was extracted with pentane (40 mL). The volume of the extracts was reduced under re-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1212-1358 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 12

duced pressure to 15 mL. Cooling to −78 °C afforded 0.8 g (80%) of **5** as white crystals; m.p. 127 °C.

6: To a solution of **5** (20 mg, 0.051 mmol) in [D$_8$]THF (0.5 mL) at −78 °C was added a solution of *tert*-butyllithium (0.051 mmol) in pentane (30 μL). On warming to 25 °C the solution became yellow. The NMR spectrum was consistent with the formation of **6**. It showed only signals of **6**, the solvent, and the conjugate acid of the base. An identical spectrum was recorded for **6** prepared from **5** and fluorenyllithium. Compound **6** did not react with excess fluorene but was quenched to a 1:1 mixture of **5** and **8** by treatment with excess cyclopentadiene.

8: A solution of **5** (50 mg, 0.13 mmol) in THF (5 mL) was treated with a trace of indenyllithium (3 mg) for 24 h. Removal of solvent left a waxy solid which was recrystallized from pentane to give 42 mg (84%) of **8**; m.p. 159 °C.

7: A solution containing one equivalent of lithium diisopropylamide in diethyl ether (10 mL) was added dropwise to a stirred solution of **5** (0.4 g, 1.05 mmol) in diethyl ether (15 mL) at −78 °C. The reaction solution was allowed to warm to 25 °C affording a yellow solution, which was cooled to −78 °C and added dropwise to a suspension of [Mn(CO)$_3$(CH$_3$CN)$_3$]PF$_6$ (0.43 g, 1.05 mmol) in diethyl ether (10 mL) at −78 °C. The reaction mixture was allowed to warm to 25 °C and stirred for 3 h. The solvent was removed under reduced pressure, and the residue was extracted with pentane (40 mL). Reduction of the volume to 20 mL and cooling at −20 °C for 24 h afforded 0.25 g (46% yield) of yellow crystals of **7**; m.p. 189 °C.

Metal Oxo Cation Receptors: Multimode Coordination to the Dioxoosmium(VI) Cation**

A. S. Borovik, Justin Du Bois, and Kenneth N. Raymond*

The selective recognition of metal ions conventially has been achieved by using a host with an appropriately sized spherical cavity that matches the ionic radius of the metal guest.[1, 2] In contrast, the selective binding of nonspherical species often relies on combinations of weak and strong bonding interactions between a molecular host and its nonspherical guest.[3–6] Successful binding requires proper spatial alignment of recognition sites between the host and guest.

We are developing new molecular systems that utilize multimode coordination to bind nonspherical metal oxo cations.[7–9] The approach takes advantage of the chemical and morphological properties of the metal oxo cations by using ligands that can simultaneously stabilize the highly oxidized metal center through coordinate-covalent bonds, while interacting with the oxo moieties through intramolecular hydrogen bonds. To examine the requisite structural features for multimode binding to metal oxo cations, we have synthesized a series of tetraamidato ligands with appendages containing hydrogen bond donors. In this report we present electrochemical evidence showing that these ligands provide significant stabilization of the dioxoosmium(VI) cation. Furthermore, X-ray crystallographic results show that the orientation of the appended hydrogen bond donors can be varied and positioned toward the oxo moieties of a bound osmyl cation to achieve multimode binding.

The multimode bonding approach has proven successful for the selection and stabilization of metal–ligand adducts. Recent examples of molecular systems that combine covalent and intramolecular hydrogen bonds include an Fe^{II} porphyrin system that stabilizes an O_2 adduct,[10] uranyl Schiff base complexes that recognize $H_2PO_4^-$,[11] and a Pd^{II} macrocyclic species that selectively binds nucleobases.[12] The ligands described here have been constructed with a binding pocket composed of two *N*-acylated 1,2-diaminobenzene units fastened together with a diethyl malonyl strap. The strongly basic nitrogen atoms of the amidato ligands effectively stabilize highly oxidized metal centers, as has been shown by the elegant work of Collins et al.[13–16] The nitrogen atoms opposite the malonyl strap in the H_6-**1** and H_6-**2** ligands used here (Scheme 1) are components of urea groups whose function is twofold: the urea nitrogen atoms attached to the aryl supports can be deprotonated to complete the tetraamidato metal ion binding pocket, while the tethered C(O)NHR moieties provide hydrogen bond donors to the oxygen atoms of the oxo ligands of the osmyl cation. CPK models suggest that hexadentate chelate formation with intramolecular hydrogen bonds is energetically favored through a side-on approach of the appended ureas to the oxo oxygen atoms. To test these design concepts the osmyl complexes of H_6-**1** and H_6-**2** have been synthesized. These complexes have been used to examine both the oxidative stability of a high valent metal center in a tetraamidato pocket as well as the extent of intramolecular hydrogen bonding between the urea moieties

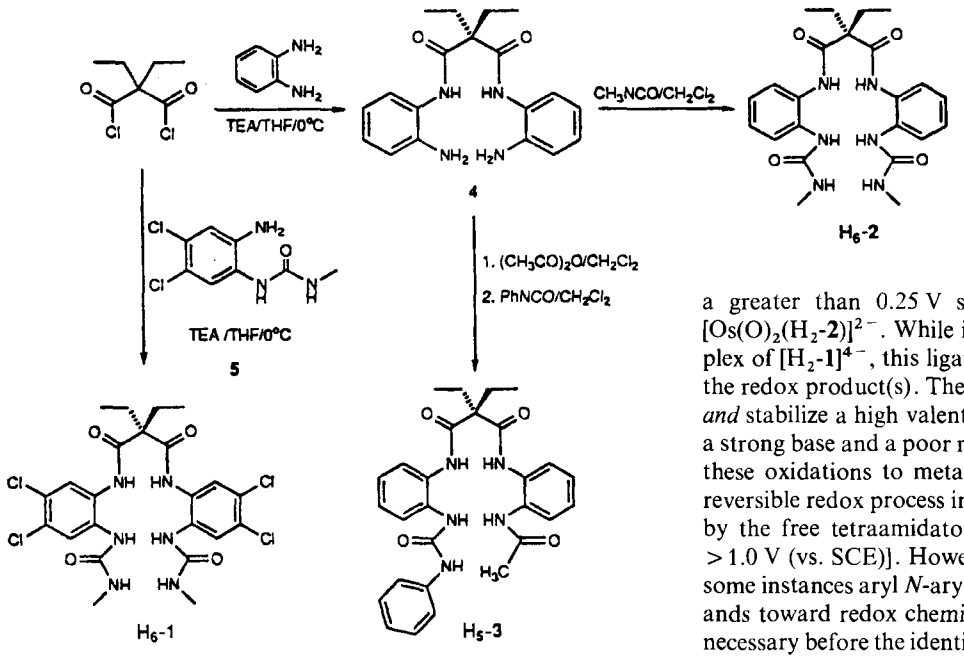
[**] Stereognostic Coordination Chemistry, Part 4 – Part 3: [9]. This research was supported by the United States National Science Foundation Grant no. CHE-8919207. We thank Dr. Fred Hollander and Dr. Sonya J. Franklin for their help in determining the solid-state structures.



Scheme 1. Synthesis of the ligands used. TEA = triethylamine.

and the oxo oxygen atoms. Additionally, an unsymmetrical complex, $[Os(O)_2(H\text{-}3)]^{2-}$, has been prepared which allows for analysis of the influence of adjacent groups (which lack hydrogen bond donors) on the orientation of the remaining urea moiety.

Ligand H_6-**1** was synthesized in a stepwise manner by treating 1,2-diamino-4,5-dichlorobenzene with one equivalent of methyl isocyanate to afford the urea species **5**, which was then treated with 2,2-diethyl malonyl dichloride to give the desired ligand in 21% yield (based on the starting diamine) (Scheme 1). H_6-**2** and H_5-**3** were synthesized in yields of 91 and 26%, respectively, from the diamide–diamine intermediate **4** (Scheme 1). Treatment of the ligands with a methanolic slurry of $K_2[Os(O)_2(OH)_4]$ afforded the osmyl complexes $[Os(O)_2(H_2\text{-}1)]^{2-}$ and $[Os(O)_2(H_2\text{-}2)]^{2-}$, which were further purified by metathesis with Ph_4P^+, and $K_2[Os(O)_2(H\text{-}3)]$, which was obtained in pure form after recrystallization. All of the dioxoosmium(VI) complexes are stable in air, both in solution and the solid state.

Cyclic voltammetry (CV) was used to assess the ability of the ligands to stabilize the oxidized forms of the osmyl cation: $[Os(O)_2(H_2\text{-}1)]^{2-}$ and $[Os(O)_2(H_2\text{-}2)]^{2-}$ exhibit two redox processes at potentials above zero volts. A one-electron redox wave is found for $[Os(O)_2(H_2\text{-}1)]^{2-}$ at 0.461 V (vs. SCE), while the corresponding couple for $[Os(O)_2(H_2\text{-}2)]^{2-}$ occurs at 0.206 V (vs. SCE) (Fig. 1a). For $[Os(O)_2(H_2\text{-}2)]^{2-}$, this couple only approaches reversibility at scan rates $>0.75\ Vs^{-1}$; at lower speeds there is significant loss of current for the return cathodic scan, which is characteristic of an electron transfer chemical reaction (EC) process. In contrast, this redox process in $[Os(O)_2(H_2\text{-}1)]^{2-}$ is reversible throughout the scan range studied (0.010 to $2.0\ Vs^{-1}$). The higher potential events are significantly less stable: a one-electron couple at 0.840 V (vs. SCE) is observed for $[Os(O)_2(H_2\text{-}1)]^{2-}$ that is only quasi-reversible at scan rates $>1.0\ Vs^{-1}$, whereas $[Os(O)_2(H_2\text{-}2)]^{2-}$ has an irreversible oxidation at 0.650 V (vs. SCE) (Fig. 1b). Finally, $[Os(O)_2(H_2\text{-}3)]^{2-}$, with one appended acetamido group, is the most unstable of the complexes when oxidized, having an irreversible oxidation at 0.385 V (vs. SCE).

$[Os(O)_2(H_2\text{-}2)]^{2-}$ is oxidized at relatively modest potentials; yet the oxidized product(s) are prone to decomposition under the conditions of the CV experiment. This suggests that $[H_2\text{-}2]^{4-}$ provides sufficient electron density to allow for the formation of highly oxidized metal species, but that the ligand itself can not stabilize the resulting products. Placing chloro substituents on each aryl ring of the ligand, as is done in $[Os(O)_2(H_2\text{-}1)]^{2-}$, causes a greater than 0.25 V shift in the oxidation compared to $[Os(O)_2(H_2\text{-}2)]^{2-}$. While it is harder to oxidize the osmyl complex of $[H_2\text{-}1]^{4-}$, this ligand is significantly better at stabilizing the redox product(s). These results show that in order to access *and* stabilize a high valent metal species, a ligand must be both a strong base and a poor reducing agent. It is tempting to assign these oxidations to metal-centered processes, particularly the reversible redox process in $[Os(O)_2(H_2\text{-}1)]^{2-}$. [This is supported by the free tetraamidato ligands having oxidation potentials >1.0 V (vs. SCE)]. However, Collins et al. have shown that in some instances aryl *N*-arylamidato donors are non-innocent ligands toward redox chemistry;[17] thus further experiments are necessary before the identity of these redox couples can be determined unambiguously.

The solid-state molecular structures of the osmyl complexes of $[H_6\text{-}1]$ and $[H_5\text{-}3]$ were determined by X-ray diffraction.[18] In $(Ph_4P)_2[Os(O)_2(H_2\text{-}1)]$ (Fig. 2A), the Os^{VI} center lies in the plane formed by the four N donor centers of the amidato ligands of the binding pocket. The average Os–N bond length is 2.058(11) Å.[18] The primary coordination sphere of the osmium center is completed by the two oxo oxygen atoms which are in the expected *trans* configuration (O1-Os-O2 angle is 179.5(5)°). The X-ray structural analysis of $[Os(O)_2(H_2\text{-}1)]^{2-}$ also reveals the near-symmetrical disposition of the appended C(O)NHMe fragments to opposite faces of the equatorial coordination plane. The twisting of these fragments by approximately 34° relative to the coordination plane results in the appropriate conformations for intramolecular hydrogen bonding between the appended HN moieties and the oxo ligands of the osmyl cation. The heavy atom N1–O1 and N2–O2 distances of 3.00 and 3.01 Å are within van der Waals contacts; approach angles,

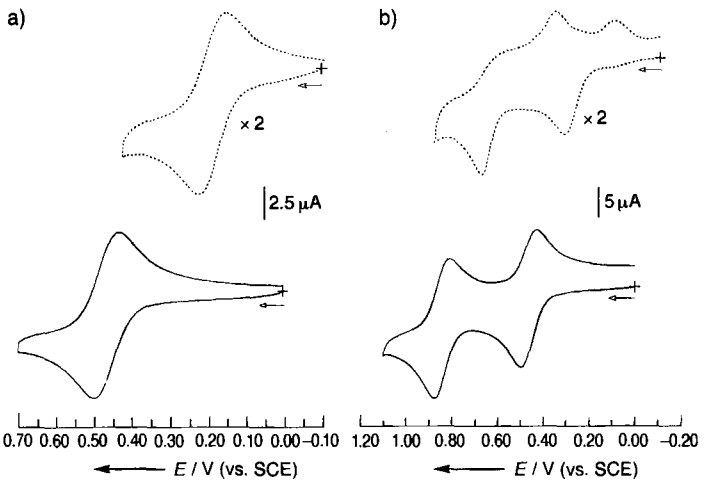


Fig. 1. a) Cyclic voltammograms of the first oxidative process for $[Os(O)_2(H_2\text{-}1)]^{2-}$ (—) and $[Os(O)_2(H_2\text{-}2)]^{2-}$ (---) at a scan rate of $0.75\ Vs^{-1}$. b) Cyclic voltammograms of $[Os(O)_2(H_2\text{-}1)]^{2-}$ (—) and $[Os(O)_2(H_2\text{-}2)]^{2-}$ (---) at a scan rate of $2.0\ Vs^{-1}$. Conditions: glassy carbon working electrode, platinum wire auxiliary electrode, SCE reference electrode, 0.1 M NBu_4PF_6 in CH_3CN. $E^{0'}$ for the ferrocinium/ferrocene couple was +0.42 mV under these conditions.

FT-IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3388 (s, br) (N-H, urea), 817 (s) ($Os(O)_2$ asym.). Elemental analysis for ($C_{71}H_{66}N_6P_2O_6Os$): calcd.: C 63.10, H 4.92, N 6.22; found: C 63.03, H 5.17, N 6.16.

$K_2[Os(O)_2(H_2\text{-}\mathbf{3})]$: ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C, TMS): δ = 9.58 (s, 1H; C(O)-NH), 8.20 (m, 3H; ArH), 7.74 (m, 2H; ArH), 7.43 (d, 2H; ArH), 7.20 (t, 2H; ArH), 6.70 (m, 4H; ArH), 2.39 (s, 3H; C(O)-(CH_3), 2.05 (unresolved q, 4H; $-CH_2-$), 0.73 (t, 6H; $-CH_3$). FT-IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 823 (s), 842 (w) ($Os(O)_2$ asym.). Elemental analysis for ($[C_{28}H_{27}K_2N_5O_6Os] \cdot 3.0\ H_2O$): calcd.: C 39.47, H 3.91, N 8.22; found: C 39.69, H 3.99, N 7.88.The water solvates were corroborated by ^{1}H NMR spectroscopy.

N-H-O_{oxo} and Os-O_{oxo}-N_{urea}, range between 135–140° and 88–93°, respectively. These data indicate weak, side-on intramolecular hydrogen bonds and constitute structural evidence that multimode binding can be achieved between a metal oxo cation and a single molecular species.

To maximize the affinity of these ligands for metal oxo cations the interactions between the appendages must be taken into account. In particular, how does an appended group influence the orientation(s) of a neighboring hydrogen bond donor? To investigate these orientational effects the unsymmetrical complex $[Os(O)_2(H_2\text{-}\mathbf{3})]^{2-}$ has been synthesized in which one urea group has been replaced with an acetamido group. The molecular structure of $[Os(O)_2(H_2\text{-}\mathbf{3})]^{2-}$ shows that the lone urea appendage is not oriented toward either oxo ligand of the bound osmyl cation; rather it is interacting with the appended acetamido ligand through an intramolecular hydrogen bond (Fig. 2B).[21] The preference of the urea of form hydrogen bonds to the more basic carbonyl oxygen produces an eight-membered ring with a N5–O5 distance of 2.781 Å and a N5–H–O5 angle of 160.9°.[21] ^{1}H NMR studies show that this conformation remains intact in solution. The signal for the urea hydrogen in $[Os(O)_2(H_2\text{-}\mathbf{3})]^{2-}$ is shifted significantly downfield compared to that in H_5-**3** [$\Delta\delta$ = 1.74 (CD_3CN) and $\Delta\delta$ = 0.575 in [D$_6$]DMSO], which is indicative of an urea hydrogen bond.[22]

In summary the strong σ bonds between metal centers and nitrogen atoms of deprotonated amides have been combined with weak hydrogen bonds to develop systems that stabilize the osmyl cation. Since the electronic and structural features of these systems can be readily tuned, a variety of different systems can be tailored to fit a given metal oxo cation. In addition, the system provides access to a variety of appended groups, allowing us to analyze structurally different hydrogen bond donors.

$S(NPMe_3)_4^{2+}$: The First Structure Determination of a Dication of Hexavalent Sulfur**

Hella Folkerts, Wolfgang Hiller, Martin Herker, Sergei F. Vyboishchikov, Gernot Frenking, and Kurt Dehnicke*

Cationic species of hexavalent sulfur like $H_3SO_4^+$ and $H_2SO_3F^+$ are important as "super acids" and "magic acids" and are employed as protonating agents for weak bases.[1, 2] However, compounds containing these cations have not been isolated to date.[2] Using the super acid systems HF/SbF_5, pentafluoro-λ^6-sulfanylamines can be converted to the sulfanylammonium salts **1** (n = 1, 2).[3] Several other monocations of hexavalent sulfur containing sulfur atoms with a coordination number 3, 4, or 5 are known,[4, 5] which usually are derived from dialkylamido and monoalkylamido derivatives. The oxo derivatives $OSF_3^+AsF_6^-$[6] and $OSF_2Cl^+AsF_6^-$[7] have been characterized by structure determinations. A dication of hexavalent sulfur, $SF_2(NMe_2)_2^{2+}$, characterized by NMR spectroscopy, was first reported in 1984.[8] No confirmed data are available for the S^{VI}-phosphorane iminato derivative $[S(NPPh_3)_3]Cl_3$.[9] Numerous examples of cations of tetravalent sulfur are known. They include cations of the general formula SX_3^+ with X = organic group, halide, CN, and other ligand atoms[10] as well as the monomeric SN^+ ion.[11]

$[Me_{3-n}H_nNSF_5]^+AsF_6^-$ **1**

Investigations of phosphorane iminato complexes of transition metals, [M] = N = PR_3, have shown that the ligand NPR_3^- can stabilize the elements M in high oxidation states, due to the large M–N bond orders.[12] We have now confirmed this observation for the reaction of disulfur dichloride with the silylated phosphorane imine $Me_3SiNPMe_3$. The reaction proceeds in boiling acetonitrile and leads to a disproportion according to Equation (a).

$$3S_2Cl_2 + 4Me_3SiNPMe_3 \longrightarrow \underset{\mathbf{2}}{[S(NPMe_3)_4]Cl_2} + {}^5/_8S_8 + 4ClSiMe_3 \quad (a)$$

Compound **2** · 4 CH_3CN was isolated as colorless needles after removal of the precipitated sulfur by filtration. If kept under vacuum the crystals loose the coordinated acetonitrile. The IR spectrum of **2** shows two intensive stretching vibrations of the symmetry species *E* at 1128 and 985 cm^{-1}, which can be assigned to ν_{as}(PN) and ν_{as}(SN). This is in agreement with the S_4 symmetry of the cation[13] as determined by X-ray crystallography. The related deformation vibrations are found at 480 and 413 cm^{-1}. The less intensive, IR-active vibrations of the symmetry species *B* are presumably hidden underneath the strong bands of the symmetry species *E*. The IR spectrum shows no evidence of a S–Cl stretching vibration. This is in agreement with the results of the crystal structure analysis[14] which suggests an ionic structure for **2**. In the dication $S(NPMe_3)_4^{2+}$ (Fig. 1) the sulfur atoms are surrounded by the N atoms of the phosphorane iminato ligands in a tetrahedral fashion. The S–N interatomic distances are 156.5 pm and correspond to double bonds; similar values are observed in cyclic sulfur–nitrogen cations[15] like $S_4N_3^+$[16] and $S_4N_4^{2+}$.[17] The S–N interatomic distances in tris(imino) derivatives **3** are even shorter (150.4 pm (E = Si) and 151.1 pm (E = C)[18]), which is due to the low coordination number (CN = 3) of the sulfur atom. In contrast, the S–N interatomic distances in $[S(NPPh_3)_3]Cl$, which contains tetravalent sulfur, are 163.5 pm[9b] and therefore considerably longer than those in **2**. The P–N interatomic distances in **2** are 162.1 pm corresponding to double bonds,[19] while the bond angles of 122.3° at the N atoms are indicative of sp^2 hybridization.

3, E = C, Si

The geometry of the parent compound $S(NPH_3)_4^{2+}$ (**2'**), which was derived from **2**, was optimized with an ab initio calculation at the Hartree–Fock level.[20] The calculation results in a structure possessing S_4 symmetry (Fig. 2) for **2'**, which is essentially identical with the skeleton geometry of **2**. The calculated interatomic distances and bond angles of **2'** are in good agreement with the values found for **2** (Table 1). A NBO analysis of **2'**[21] reveals a strongly positive partial charge at the

2' **4**

Fig. 2. Calculated structures of **2'** and **4**.

sulfur atom (+2.64) and at the phosphorus atoms (+1.27) and a strongly negative partial charge at the nitrogen atoms (−1.47). According to the calculation, the N–S and the N–P bonds each correspond to single bonds which are strongly polarized towards the more electronegative nitrogen atom (Table 1). The hybridization of the N orbitals is close to sp^2 for both bonds, while approximate sp^3 hybridization with a minor contribution of the d orbitals to the bonds is found for S and P. Two lone-pair orbitals are calculated for each nitrogen atom. The results of the NBO analysis of **2'** are in agreement with the classical ideas of the bonding situation, which is suggested by the experimentally determined geometry of **2**. The $S(NPMe_3)_4^{2+}$ ion contains polar covalent N–S and N–P single bonds, which as a result of strong charge attraction between the negatively charged nitrogen atom and the positively charged phosphorus and sulfur atoms, respectively, tend towards double bonds.

We have also calculated the structure of the parent compound $S(NH_2)_4^{2+}$ **4**. There is some evidence that **4** exists; however, its isolation and the determination of its geometry has not been reported to date. The calculated structure of **4** shows D_{2d} symmetry (Fig. 2). The recently isolated, isoelectronic $P(NH_2)_4^+$ ion also has D_{2d} symmetry as determined by X-ray structure analysis.[22] The calculated N-S-N bond angles of **4** are 102.4 and 124.7°, the analogous N-P-N bond angles of the $P(NH_2)_4^+$ ion are 102.7 and 124.2°[22]. The S–N interatomic distances of **4** are slightly longer (157.5 pm) than those of **2'**.

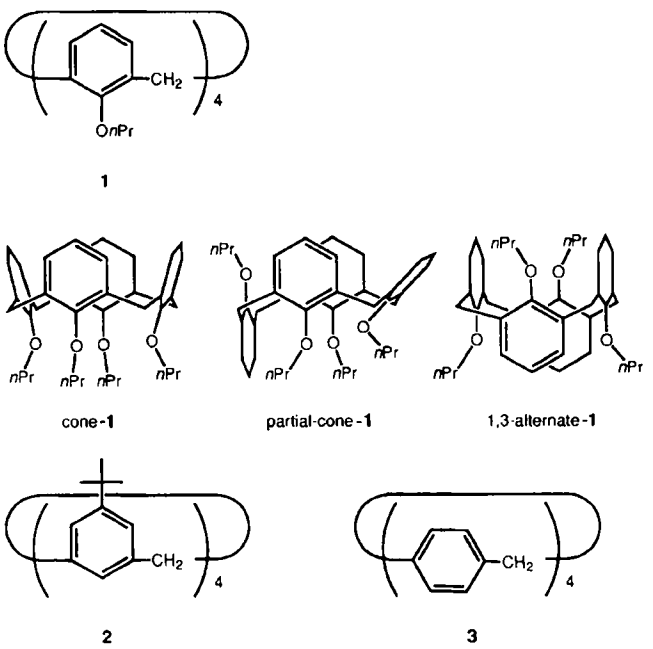
"Cation-π Interactions" Detected by Mass Spectrometry; Selective Recognition of Alkali Metal Cations by a π-Basic Molecular Cavity

Fumiaki Inokuchi, Yuji Miyahara, Takahiko Inazu, and Seiji Shinkai*

Recently, the "cation–π interaction" has been of interest as a new type of secondary valence force, which is thought to play a crucial role in biological systems.[1] Complementary results have been accumulated with several artificial systems.[2–6] Kebarle et al. showed for the first time by mass spectrometry that K^+ binds to benzene in the gas phase.[7] This finding stimulated the study of cation–π interactions between benzene and metal cations.[8–12] We report here on our studies with cyclophanes that complex metal cations in their π-basic cavities.[13–17] We recently noticed that appropriately charged host–guest-type complexes, the concentration of which is very low in solution, can be easily detected by mass spectrometry.[18] We tested three conformationally rigid conformers of 25,26,27,28-tetrapropoxycalix[4]arene (**1**) (cone-**1**, partial-cone-**1**, and 1,3-alternate-**1**),[16, 17] conformationally mobile 5,11,17,23-tetra-*tert*-butylcalix[4]arene (**2**),[19] and [1.1.1.1]paracyclophane (**3**).[20] We have found that the cation–π interaction is conveniently and selectively detectable by mass spectrometry (particularly, with **3**). Compounds **1**–**3** and the complexes with alkali metal and silver cations were analyzed by positive secondary ion mass spectrometry (positive SIMS), in which the sample is "dissolved" in a matrix, and by positive electrospray ionization mass spectrometry (positive ESI-MS), for which no matrix is needed.



1 **2** **3**

We have found that in solution the affinity of the conformers of **1** with K^+ and Ag^+ appears in the order of 1,3-alternate-**1** > partial-cone-**1** ≫ cone-**1**.[16, 17] The Ag^+ complexes provided clear evidence that the high affinity of 1,3-alternate-**1** and partial-cone-**1** to Ag^+ is ascribable to π-donor participation. The distance between two distal benzene rings in these conformers is very close to the diameter of the Ag^+ ion, and therefore they can sandwich Ag^+ without changing their structure.[16, 17] The signal intensity of $(\mathbf{1} + M)^+$ in the SI mass spectra (normalized relative to $(NBA + H)^+$; NBA = *m*-nitrobenzyl alcohol) for alkali metal cations appears in the order of $K^+ > Rb^+ > Cs^+ \gg Na^+ > Li^+$ and that for the conformers of **1** appears in the order of 1,3-alternate-**1** > partial-cone-**1** ≫ cone-**1** (Fig. 1).[21] These orders are completely consistent with those observed in solution.[16, 17] Since signals for the starting compounds and the solvent, which are useful for normalization, could not be detected, we used the absolute intensity of the signals of each metal complex. In the ESI mass spectra the trend in the signal intensities of $(\mathbf{1} + M)^+$ is very similar to that for SIMS (Fig. 1). The reproducibility is excellent (±5%) when the same measurement conditions are used. However, we found one significant difference between the two sets of experiments: the signal intensity for $(\text{cone-}\mathbf{1} + M)^+$ is much greater in the ESI mass spectra and the difference among three conformers is relatively small. This result implies that although the metal affinity of cone-**1** is weak in solution, it can compete with that of 1,3-alternate-**1** and partial-cone-**1** in a matrix-free system. Consistent with this proposal, the signal intensities in ESI mass spectra decrease with increasing NBA concentration. These results suggest the significant contribution of the cation-π interaction, but the propoxy groups may also be involved in the metal binding.

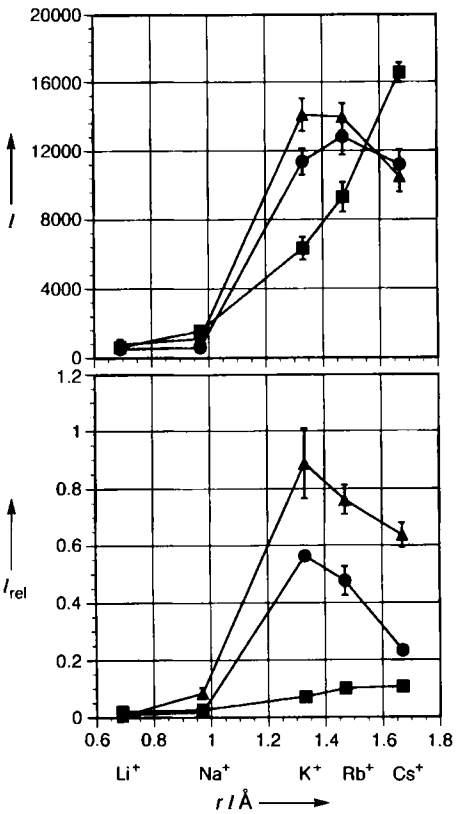


Fig. 1. Absolute signal intensities $I((1 + M)^+)$ in ESI mass spectra (top) and relative signal intensities $I_{rel}((1 + M)^+/(NBA + H)^+)$ in SI mass spectra (bottom) plotted versus the ionic radii *r* [Å] of M^+. ▲: $(\text{1,3-alternate-}\mathbf{1} + M)^+$; ●: $(\text{partial-cone-}\mathbf{1} + M)^+$; ■: $(\text{cone-}\mathbf{1} + M)^+$.

To exclude this possibility we used calix[4]arene without propoxy groups (**2**).[19] This molecule is conformationally mobile. Although the signals assignable to $(2 + M)^+$ ions could be detected in the SI mass spectra, the intensities were about two orders of magnitude less than those for $(1 + M)^+$, and significant metal ion selectivity was not observed (Fig. 2).[21] The result indicates that the freezing of the conformation is indispensable to efficient detection of the complex. In the ESI mass spectrum a strong peak was observed for $(2 + Cs)^+$. This could be expected based on the results with cone-**1**. Conceivably, when metal ions are not "solvated" in a matrix, the large, soft Cs^+ ion can be bound selectively to the π-basic cavity of **2**.

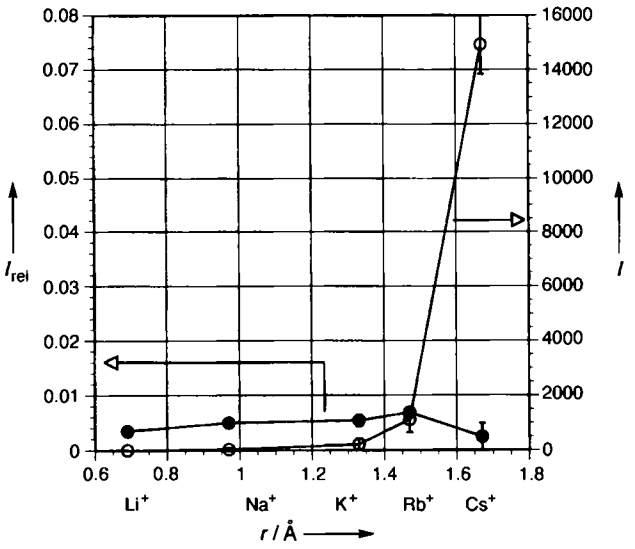

Fig. 2. Absolute signal intensities $I((2 + M)^+)$ in ESI mass spectra (○) and relative signal intensities $I_{rel}((2 + M)^+/(NBA + H)^+)$ in SI mass spectra (●) plotted versus the ionic radii r [Å] of M^+.

We also examined compound **3**, which has a well-defined cavity formed by four benzene rings and which is conformationally fixed.[20] The signals for $(3 + Li)^+$, $(3 + Na)^+$, and $(3 + K)^+$ were scarcely detectable by SIMS, whereas the signals due to $[3 + Rb]^+$ and $[3 + Cs]^+$ were very intense (Fig. 3).[21, 22] Very similar results were also obtained from ESI-MS. From semiempirical molecular orbital calculations (MOPAC version 6.0 PM3 Hamiltonian) on calixarene **3** we estimate that the distance from the center of a bridgehead carbon atom to the center of the cavity is 3.44 Å. This is very close to the sum of the ionic radius of Cs^+ (1.67 Å)[24] and the van der Waals radius of an aryl carbon atom (1.70 Å)[23]. For Rb^+ (1.47 Å)[24] this sum is slightly less, and for Li^+ (0.69 Å), Na^+ (0.97 Å), and K^+ (1.33 Å)[24] much less than 3.44 Å. Li^+, Na^+, and K^+ ions cannot interact with all four benzene rings in **3**, but the size of Rb^+ and Cs^+ ions is comparable with the size of the cavity in **3**. Cs^+, in particular, can nest exactly in the cavity and interact with the four benzene walls simultaneously. This finding can be rationalized only by the presence of the cation–π interaction.[25]

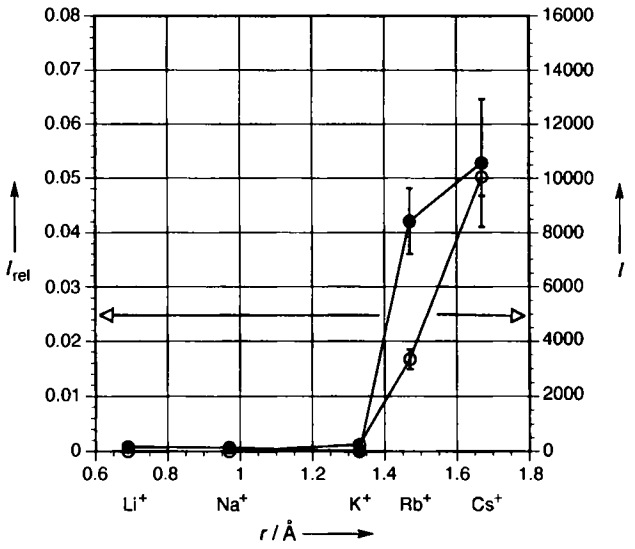

Fig. 3. Absolute signal intensities $I((3 + M)^+)$ in ESI mass spectra (○) and relative signal intensities $I_{rel}((3 + M)^+/(NBA + H)^+)$ in SI mass spectra (●) plotted versus the ionic radii r [Å] of M^+.

To further confirm the contribution of the cation–π interaction we examined the Ag^+ complexes of **1** and **3** by mass spectrometry. As expected from the data obtained in solution,[16, 17] the $[1 \cdot Ag]^+$ complexes gave very intense signals assignable to each conformer complex ($(1 + Ag)^+/(NBA + H)^+ = 0.16$ for 1,3-alternate-**1**, 0.25 for partial-cone-**1**, and 0.21 for cone-**1**). In contrast, the signal attributed to the $[3 \cdot Ag]^+$ complex could not be detected. Although the Ag^+ ion has a special affinity for carbon–carbon double bonds,[13–16] it is comparable in size to K^+ and smaller than the cavity in **3**. Thus Ag^+ cannot form a complex with **3**. In contrast, Cs^+ has no special affinity but fits into the cavity of **3** and forms a complex. These findings support the view that the metal ion selectivity in the present system is governed by the host–guest-type "hole-size selectivity".

By mass spectrometry it is very difficult to detect a complex that forms in solution through weak secondary valence forces. In fact, we could not obtain any sign of the complexes formed between **3** and alkali metal cations in solution. The difficulty is attributed firstly to competition between inclusion of the guest in the host molecule and solvation of the guest molecules, and secondly to competition between the enthalpy gain caused by the host–guest interaction and the entropy loss caused by the organization of the host molecule induced upon guest inclusion. Hence, weak host–guest-type complexation should be detectable when the solvation terms are eliminated and when the host molecule is well-preorganized. These requirements are satisfied in the by $[3 \cdot M]^+$ complexes in the gas phase.

Experimental Procedure

For the SIMS experiments (Hitachi M-2500 mass spectrometer) the host compound (0.01 M in 5 μL chloroform), *m*-nitrobenzyl alcohol (NBA) as matrix (15 μL), and the alkali metal chloride or silver nitrate (0.01 M in 5 μL methanol) were mixed. Then 1 μL of the mixture was loaded on the silver target. Xe^+ was employed as a primary ion and accelerated at 6.0 kV. Secondary ions were accelerated at 3.0 kV. The signal intensities were averaged over ten scans. ESI-MS experiments were performed on the same apparatus with an ESI ion source (M-2517). A chloroform solution (50 μL) containing the host compound (0.001 M) and a methanol solution (50 μL) containing a mixture of alkali metal chlorides (0.001 M each LiCl, NaCl, KCl, RbCl, and CsCl) were mixed. A portion of the solution (20 μL) was injected directly into the ESI source by syringe pump (Hitachi L-6200). General instrument settings: vaporization temperature 180 °C, mobile phase chloroform/methanol 1/1, flow rate 0.06 mL min^{-1}, N_2 gas pressure 1.0 kg cm^{-2} (Pneumatically Assisted ESI). The signal intensities were averaged over five scans and recorded as the sum of the corresponding isotopic peaks.

[21] Even when the signal intensities of $(1 + M)^+$ or $(1 + M)^+/1^+$ are plotted versus the ionic radius very similar plots are obtained. When an equimolar mixture of **1**, **2**, and **3** was analyzed in the absence of metal cations, the ratio of the signal intensities was $1^+:2^+:3^+ = 2.81:7.13:1.00$, indicating the relatively stability of the host cations.

[22] The attempt to detect $[3 \cdot Cs]^+$ in solution by ^1H NMR spectroscopy and solvent extraction failed.

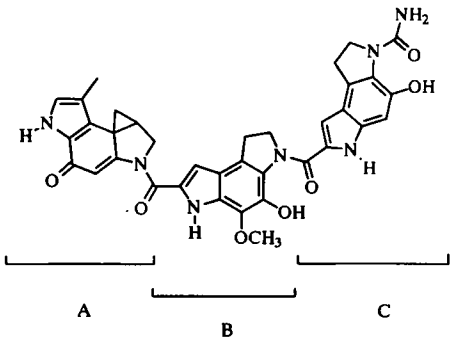
[25] Very recently, Ungaro et al. reported on cation-π interactions in a [calix[4]arene-crown-6 $\cdot$ Cs]$^+$ complex (R. Ungaro, A. Casnati, F. Ugozzoli, A. Pochini, J.-F. Dozol, C. Hill, H. Rouquette, *Angew. Chem.* **1994**, *106*, 1551; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1506). Although the X-ray crystal structure shows that the distance between benzene rings and Cs^+ is short, the presence of cation-interactions is doubtful due to the presence of many metal-coordinating oxygen atoms (as in the complexes $[1 \cdot M]^+$.

Efficient Total Synthesis of the Pharmacophore of the Anticancer Antibiotic CC-1065 by Zirconocene- and Palladium-Initiated Cyclizations**

Lutz F. Tietze* and Wilm Buhr

Dedicated to Professor Richard R. Schmidt on the occasion of his 60th birthday

The antibiotic CC-1065 (**1**), which was first isolated from *Streptomyces zelensis* in 1978, is one of the most potent antitumor agents known at present.[1] It contains three pyrrolo-[3,2-*e*]dihydroindole moieties; the A-unit with an unusual spirocyclopropyl group is the pharmacophore, whereas the B- and C-units are responsible for the strong binding to DNA. It has been shown that the A-unit of **1**, called CPI, selectively alkylates



CC-1065 1

AT-rich regions of the minor groove of double-stranded DNA.[2] However, **1** cannot be used as a drug because of delayed fatal hepatotoxicity. In contrast, derivatives of the CPI unit having similar antitumor activity do not show this negative property.[3]

For the design of selective anticancer agents[4] we have developed a new and highly efficient synthesis of the (N^2-benzenesulfonyl)-CPI derivative **2**. This synthesis is superior to the known procedures and is distinguished by its short reaction sequence. The key steps are two consecutive cyclizations mediated by organo transition metal complexes which allow the formation of first the pyrroline and then the pyrrole ring in **2**.

Retrosynthetically, **2** can be traced back to the N^2-benzenesulfonyl-*seco*-CPI **3**, which via **5** leads to the starting material **4**. The special feature of this synthesis is that not only is the pyrroline ring constructed in the first cyclization with zirconocene methyl chloride,[5f, 5g, 6a, b] but during the quenching with iodine, in addition to the formation of a iodomethyl group, a second iodine atom is simultaneously introduced at the arene. This can be used for the construction of the pyrrole ring in the subsequent Heck reaction.[7a-c]

Substrate **4** was synthesized in 66% yield in four steps starting from the commercially available 2-methoxy-4-nitroaniline through Pt-catalyzed hydrogenation in dioxane, twofold *N*-ben-

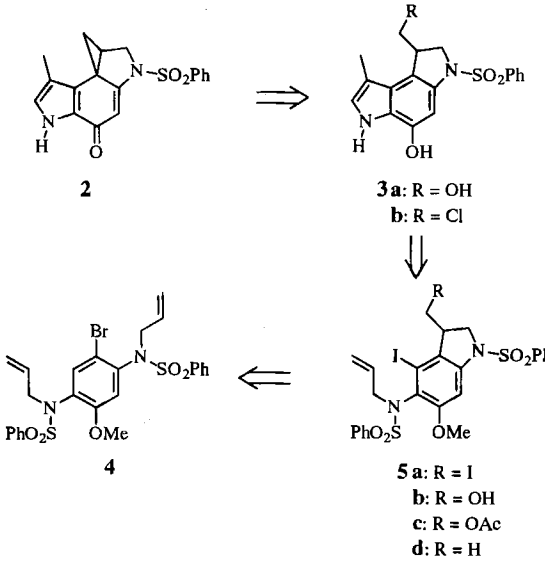
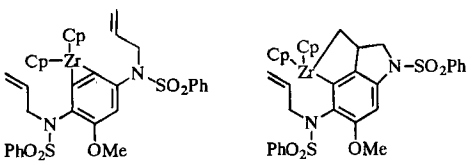
[**] Anticancer Agents, Part 22. This work was supported by the Fonds der Chemischen Industrie. We wish to thank the Degussa AG for their generous gifts of noble metal compounds. Part 21: ref. [4b].

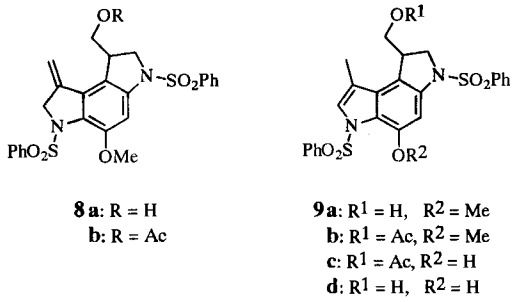


zenesulfonization with benzenesulfonyl chloride in pyridine,[8] bromination with *N*-bromosuccinimide in tetrahydrofuran, and double allylation with allyl bromide in the presence of tetrabutylammonium iodide also in tetrahydrofuran. Halogen–metal exchange in **4** with *t*BuLi in tetrahydrofuran and subsequent metal exchange with $[Cp_2ZrCl(CH_3)]$ proceeded supposedly through a zirconium–didehydrobenzene complex **6** to the zirconacyclopentene derivative **7**,[6c] which gave **5a** in 60% yield as a single product after quenching with two equivalents of iodine in dichloromethane. In the reaction of **7** with iodine, first the aryl–zirconium bond and then the alkyl–zirconium bond was cleaved. This was deduced from the reaction of **7** with only one equivalent of iodine followed by aqueous workup, which gave **5d** exclusively. Somewhat surprising is the high regioselectivity of the cyclization of **4**; the insertion of the alkene group in complex **6** occurs exclusively *para* to the methoxy group.[9]



Compound **5a** could not be used directly in the Heck reaction since both the iodobenzene moiety and the iodomethylpyrroline group react to form a methylpyrrole unit. For this reason **5a** was first converted into the hydroxymethyl derivative **5b** with silver oxide on silica gel in 90% yield (acetone/water, 20 °C, 24 h). The transformation of the iodomethyl group in **5a** caused many problems at the beginning since all attempts at nucleophilic substitution, for example with acetate, failed; instead elimination with partial isomerization of the formed double bond occurred.

The Heck reaction for the preparation of **3** can be carried out with **5b** as well as with **5c**, which is obtained quantitively from **5b** by acetylation with sodium acetate in acetic anhydride. With catalytic amounts of tetrakis(triphenylphosphane)palladium **5b** gave a 17:1 mixture of **8a** and **9a** in 90% yield (2 mol% $[Pd(PPh_3)_4]$, CH_3CN/Et_3N, 60 °C, 18 h). In contrast, reaction of **5c** with palladium acetate in the presence of silver carbonate led in 90% yield exclusively to **8b** (2 mol% $Pd(OAc)_2$, 1.5 equiv Ag_2CO_3, DMF, 20 °C, 2 h). Without further workup the respective mixtures of **8a**/**9a** and **8b** were isomerized with camphorsulfonic acid quantitively to give **9a** and **9b** (CH_2Cl_2, 20 °C, 1 h). The cleavage of the aryl methyl ether in **9b** to give **9c** was achieved with boron tribromide in 80% yield (CH_2Cl_2, −10 °C, 1 h); under these conditions **9a** provided only a mixture of products.



Solvolysis of **9c** in methanol in the presence of potassium carbonate afforded **9d**, and successive cleavage of the benzenesulfonyl group at the indole nitrogen with sodium bis(2-methoxyethoxy)dihydroaluminate (Red-Al) led to the desired *seco*-CPI **3a** with an overall yield of 70%. The conversion of **3a** to **2** is known[10] and was carried out not only by means of Mitsunobu's method[11] with diethyl azodicarboxylate, but also via the chloride **3b** with a subsequent base-induced cyclization.

In summary, the pharmacologically important CPI derivative **2** was prepared in 11 steps with an overall yield of 12% starting from commercially available 2-methoxy-4-nitroaniline. The double cyclization mediated by zirconocene and palladium complexes is of general synthetic value, and we are currently testing it for the construction of other complex bis-*ortho*-annelated arenes.

Experimental Procedure

To a solution of **4** (0.34 mmol) and $[Cp_2ZrCH_3Cl]$ (0.35 mmol) in dry THF (10 mL) was added slowly with stirring at −78 °C a solution of *tert*-butyllithium in hexane (0.70 mmol). Stirring was continued for 1 h at −78 °C and 18 h at 20 °C. The solvent was evaporated in vacuo and the residue dissolved in dry CH_2Cl_2 (20 mL) and cooled to 0 °C. To this solution was slowly added a suspension of iodine (0.72 mmol) in dry CH_2Cl_2 (20 mL), and the mixture was stirred for 1 h at 0 °C and 36 h at 20 °C. The reaction mixture was filtered through celite, washed with saturated Na_2SO_3 solution, water, and brine (10 mL each), dried over $MgSO_4$, and concentrated to dryness. After chromatography (petroleum ether/ethyl acetate 3:1) **5a** was obtained in 60% yield. Recrystallization from ethyl acetate gave colorless needles.

5a: M.p. 206.9 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.34 (dd, J = 10, 9.0 Hz, 1H, 3-CH_a), 3.32 (s, 3H, O-CH_3), 3.34–3.46 (m, 2H, 3-H, 3-CH_a), 3.85–4.00 (m, 2H, 2-H_a, 1'-H_a), 4.10 (d, J = 12 Hz, 1H, 2-H_b), 4.49 (dd, J = 13.5, 6.0 Hz, 1H, 1'-H_b), 4.93 (d, J = 6 Hz, 1H, *trans*-CH=CH_2), 4.98 (s, 1H, *cis*-CH=CH_2), 5.83–5.97 (cm, 1H, CH=CH_2), 7.14 (s, 1H, 7-H), 7.48–7.69 (m, 6H, Ph-H), 7.72–7.79 (m, 2H, Ph-H), 7.82 (d, J = 8.0 Hz, Ph-H).

9c: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.01 (s, 3H, OAc), 2.21 (s, 3H, 8-CH_3), 3.10 (dd, J = 10, 9.0 Hz, 1H, 1-CH_a), 3.52–3.78 (m, 2H, 1-H, 1-CH_b), 4.06 (dd, J = 11.5, 3.5 Hz, 1H, 2-H_a) 4.16 (d, J = 11.5 Hz, 2-H_b), 7.15 (s, 1H, 7-H), 7.37 (s, 1H, 4-H), 7.38–7.63 (m, 6H, Ph-H), 7.76 (d, J = 8.0 Hz, 2H, Ph-H), 7.85 (d, J = 8.0 Hz, 2H, Ph-H), 8.85 (s, 1H, Ph-OH).

Protection Rackets?

Tactics of Organic Synthesis. By *Tse-Lok Ho.* Wiley, Chichester, Great Britain, 1994. 450 pp., hardcover £ 49.50.—ISBN 0-471-59896-8

As the most recent offshoot of a series on modern organic synthesis, containing up to now five monographs, Tse-Lok Ho presents his most recent work "Tactics in Organic Synthesis". His self-declared aim is to provide a standardized overview on synthetic tactics based on selected examples. The term "tactics" can be understood as the skillful application of one or more individual reactions within the framework of an overall concept ("strategy"). The book consists of nine chapters, which deal successively with the topics of convergency, protective groups ("Activity Modulation, Group Protection, and Latent Functionalities"), Umpolung, tandem reactions, cyclic compounds ("Cyclic Arrays for Structural and Stereochemical Manipulations"), execution of intramolecular reactions, template and chelation effects, symmetry considerations, and various others ("Miscellaneous Tactics").

A wide range of tactics and methods is discussed in the individual chapters, in such a compressed form that can hardly be found anywhere else. Almost every class of natural product appears once in some connection or other, and almost every important fact on the regio- and stereoselective control of a reaction is treated somewhere. In spite of the division into chapters, the content nevertheless remains heterogeneous, and on reading the text one is occasionally unaware in which section one currently is. In view of the extensive amount of material (ca. 1400 literature references) it is difficult to criticize the choice, although almost inevitably one may occasionally regard another example as more important or more instructive. The almost exclusive restriction to references from the primary literature appears to me to be unfortunate, with the result that numerous important reviews can only be found after a long search or even not at all. The references in the text follow the general system [surname of the first named author, year], and correspond with an appropriate appendix to the complete list of citations at the end of the book. An author index is unfortunately not provided. Based on about 150 randomly selected references, the details were found to be predominantly reliable. The year of publication was found to be incorrect for only three examples. A reference given in the text (p. 264) as [B. A. Anderson, 1992] could not be found in the appendix, another was incorrectly cited (p. 14) as [J. Davies, 1981]. In a few cases references in the text were missing, for example, the work of Nicolaou's group on the endiandrinic acids (p. 97). I could not find the example shown on p. 78 for chelate control in the source given, [Masuyama, 1988]. Printing errors are kept within limits and are rarely so meaningful as the "wild intermediate" on p. 244 ("animal" rather than "aminal"). German-speaking authors are almost inevitably not spared the mutilation of their names (Hoffman, p. 416; Oppenaur, p. 81; Kauffman, p. 419; Vorbrügen, p. 206). Sentences such as "reactions... are under chelation control in THF, but not in THF" (p. 309) should have been eliminated on reading the proofs.

In terms of content, the book is based on a uniform pattern. The author first describes in a couple of sentences a tactical manoeuver on one molecule, and this is followed by a reaction scheme illustrating the reaction concerned. Such schemes (ca. 800) make up a large part of the book and are reproduced uniformly, largely based on those in the original publications. Those explanations that are not accompanied by the appropriate schemes are difficult to comprehend, as one can rarely understand, without visual aids, what it is actually all about. Generally, I found the text wooden and dry, sometimes long-winded. I found it distracting that reference was frequently made in the text to numbering (D-ring, C-14, etc.) that was not indicated in the formulas. One also wonders why schemes appear in identical form in two distinct places in the book (pp. 97/388, 98/191, 126/380, 192/388, 246/272, 255/395) and not simply cross-referenced on the corresponding page. The reaction schemes are so constructed that a key intermediate is presented, beginning with the starting material, without any indication of reaction conditions (double arrow), for which the tactical measures under discussion are being carried out. In the ideal case, the result of this procedure is that a single reaction arrow, inscribed with reagents and reaction conditions, leads to a product that is also displayed graphically. From there one manages to reach the target molecule of the synthesis via reactions conducted without further detail (double arrow). Unfortunately, the author frequently deviates from this ideal position. The key reaction arrow frequently covers several steps, and the reagents are not specified at all or only incompletely. Retrosynthetic arrows, which should be superfluous, sometimes appear within the schemes. As a result of these deficiencies, the diagrams are often difficult to grasp or ambiguous. The process of comprehension is interrupted, because one is forced to engage in speculation. This is exacerbated by the fact that a comparatively high percentage of the reaction equations contain errors. These include transposed symbols or groups (in 19 schemes, e.g., on p. 127, where a methyl ether erroneously undergoes a fragmentation in place of an alcohol), missing or superfluous groups (in 25 schemes, e.g., on p. 319, where a methylene group is forgotten in two equations), the wrong reagents (in 10 schemes, e.g., p. 377, where NaOMe is used for an isomerization in place of the NaHMDS used in the original publication) or wrong configurations (in 6 schemes, e.g., on p. 30, where the Mitsunobu reaction is erroneously shown as not leading to inversion), and factual discrepancies (in 10 schemes, e.g., on p. 293, where the course of the Heck reaction is not given correctly). Neverthe-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

less, the impression should not be created that the overall graphical presentation is poor. Many of the drawings are decidedly effective and show stereochemical relationships especially well. Statistically, however, every tenth figure is afflicted with a blemish. The book loses much of its charm as a consequence of the lack of attention paid to production of the figures.

In summary, I regard this book as a useful purchase, if one regards it as a hotch-potch of various, highly interesting key steps in organic synthesis and uses it as such. The use of individual chapters for graduate courses in organic synthesis can be considered after careful reworking. The book could serve as a textbook only in rare cases. For this purpose the wealth of material presented is too large and the presentation too condensed.

Protecting Groups. By *P. J. Kocienski.* Thieme, Stuttgart, 1994. 265 pp., paperback DM 60.00.—ISBN 3-13-135601-4

"Protection is not a principle, but an expedient." With this very apt comment Philip Kocienski begins his book on protecting groups in organic synthesis. Synthetic chemists would dearly like to be able to work without protecting groups, but are very glad that they exist. Without protecting groups there would be no syntheses of taxol, calicheamicin, Saragossa acid, or erythronolide, to name just a few recent highlights of synthetic chemistry.

The standard work on the subject up to now has been Theodora Greene's *Protective Groups in Organic Synthesis*, first published in 1981, followed in 1991 by an updated version (Greene and Wuts). Whereas the book by Greene and Wuts is set out rather in the form of an encyclopedia, treating over 700 different protecting groups, Kocienski limits his coverage to the 50 or so protecting groups that have been most proven in practice. In the author's words: "We felt the need for a critical survey of the subject, that focuses on the widely most protecting groups, for the most common functional groups, used by most organic chemists most of the time." Measured against these aims, Kocienski has done an excellent job in writing this book.

It begins with an introductory chapter on general aspects of the use of protecting groups. First Kocienski states the conditions that must be fulfilled by a good protecting group: it must be cheap, easy to introduce, stable over a wide range of conditions, capable of being detached selectively, and should not interfere unnecessarily with the analysis of the host molecule. The selective removal of a protecting group is more important than the conditions for introducing it. Many synthetic chemists are familiar with examples in which a total synthesis failed in its last stage because the protecting groups, whose importance is often underestimated, could not be detached in the desired way. Ideally one would like to be able to choose a set of protecting groups, each one of which can be selectively removed in the presence of all the other groups. Kocienski calls this an orthogonal set of protecting groups. Even though it is never possible in practice to fully realize the aim of choosing such a set, Kocienski names twelve deprotecting conditions which together come very close to achieving it. These twelve ways of detaching a protecting group are: basic solvolysis, action of acids, action of transition metals, action of fluorides, reductive elimination using zinc, β-elimination, hydrogenolysis, oxidation, action of Na/NH_3, use of S_N2 conditions, removal of allyl groups, and photochemical action. All these twelve conditions are described in the introductory chapter and illustrated by examples. Next the author discusses temporary protection (for example, of aldehydes in the form of α-amino-alkoxides), and the effects of neighboring groups on protecting groups; in particular it is pointed out that an apparently harmless protecting group can be transformed by the effects of neighboring groups into a highly reactive functional group.

This introductory chapter is followed by five separate chapters on protecting groups for alcohol, diol, carboxyl, carbonyl, and amino functions. In each case the most important and commonly used protecting groups are discussed, beginning with the methods for detaching these groups, followed by methods for preparing them. The use of each protecting group is illustrated by several recent examples, with clearly set out reaction schemes. These schemes are superior to those in the book by Greene and Wuts, both in their information content and in their clarity. NMR data are also given for each protecting group, information that will be of particular value for the practical user.

Reading the book is made more enjoyable by the author's peculiarly British brand of humor. An example of this is the introductory remarks to the chapter on amino-protecting groups: "Nitrogen is the element of faction neatly dividing organic chemists into camps. Those who have mastered its vagaries are undaunted by the prospect of contending with its reactivity. Then there are those in the minority antipodal camp (like the author) who respect that nitrogen is best confined to a cylinder and used to shield precious reactions and reagents from the ravages of air and moisture!"

Chapter 7 is in the form of an epilogue, in which the progress achieved in the chemistry of protecting groups is illustrated by describing the total synthesis of erythronolide. Also, as an outstanding example of the art of achieving a synthesis with as few protecting group stages as possible, Kocienski describes the synthesis of (9*S*)-dihydroerythronolide A, as reported in *Angewandte Chemie* by Hoffmann and Stürmer.

Each chapter ends with a comprehensive list of references. A detailed list of contents and a glossary of abbreviations are provided to help the reader.

Who should read this book? Certainly the advanced student who is already, or about to begin, working for a higher degree or doctorate in a research group using synthetic methods. Then every practicing chemist in industry or university who needs to know about protecting groups. The book should also be available in every chemistry library. The economical price of this paperback version will certainly not be an obstacle to buying it.

der Universität Marburg (Germany)

Der große Schwindel. By *F. DiTrocchio.* Campus, Frankfurt/New York, 1994. 221 pp., hardcover DM 48.00.—ISBN 3-593-35116-1

Like the Biblical deadly sins, dishonesty in science is officially condemned with a vehemence very like that with which in practice "in real life" it is tolerated and pursued. The "wink-of-an-eye" expression employed in the title of this book (translated: *The Great Swindle*; the harsher terms fraud and 'falsification' are reserved for the subtitle) speaks a language every bit as eloquent as certain international laboratory jargon that touches on the same theme, whether it be in English (When in doubt, throw it out; fudge factor), German ("π mal Daumen" and "eh er noch den Schmelzpunkt kannte, sand ers an die *Angewandte*") or French ("corriger la fortune"). To put it another way, science's exalted demands cannot

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1212-1370 $ 10.00+.25/0

always be met by (occasionally) weak mortals. Has this always been the case? Or has scientific fraud been increasing of late? If so, why? What causes scientists to practice fraud in the first place? What in fact *is* scientific fraud? Where does it begin and where does it end? Does it include the "cleaning up" of a set of data or providing inaccurate yield information (cf. yield, isolated yield, Swiss yield), summarizing a publication one has only skimmed, reviewing a book one has scarcely read? All questions worthy of academic consideration, ones the author logically proposes to address through establishment of the independent scientific discipline Defraudistics (something that heretofore has always been more akin to an art). *The Great Swindle* would admittedly not be the first monograph devoted to this discipline, but it would certainly soon join the ranks of the standard works, and for several reasons.

In the first place, the book represents a collection of examples of famous instances of falsification and fraud, including both authentic cases and others one might more properly define as borderline situations.

Among the authentic illustrations one would assuredly cite the case of Moewus (who proved that certain green algae exchange genetic material through copulation), that of Burt (who through his legendary investigation of twins decided once and for all the question of whether intelligence can be inherited), or the famous Piltdown case, to which is devoted an extensive chapter ("Improper Fossils and Missing Limbs") because of its great significance in the controversy surrounding Darwinian evolution. This chapter introduces in a critical way, one after another, all the relevant suspects including famous authors like Teilhard de Chardin and Sir Arthur Conan Doyle. Such clear-cut cases of fraud, even though the true guilty party in the Piltdown episode remains unidentified to this day, could easily be supplemented by chemists: starting with the Kögl case, proceeding with polywater and cold fusion, and perhaps culminating in the recently perpetrated fraud involving stereoselective synthesis in an NMR spectrometer.

I would characterize as "borderline cases" those described in the opening chapter ("Even Nobel Prize Winners Commit Fraud"), most of which more nearly resemble a scientific ride across Lake Constance than a calculated attempt at deceit. Newton provides a good example. Not only the present author but various other historians and theoreticians of science have accused Newton of "playing loose" with the accuracy required in his experiments and measurements in an attempt to substantiate his theoretical models, even adjusting his measured variables until he achieved the values prescribed by the models. This may well be the case, although it is not easily proven in specific instances; nonetheless, Newton's actual achievement is the fact that he managed to reach the shores of safety and thereby discover a new law of nature, one that has subsequently stood up to repeated testing. The situation is similar with E. Haeckel, who in the context of establishing the law of species also stands accused of perpetrating falsehoods (documented in *The Great Swindle*). The significance of Haeckel's research into the principles of the general morphology of organisms may thus be somewhat diminished, but it is certainly not negated. (Although from our current perspective a title like *Sandalion. An Open Response to the Falsification Claims by the Jesuits*, Frankfurt 1910, does leave one a bit skeptical.)

These particular frauds and others cited by DiTrocchio, which include Galileo, Millikan, and Einstein, differ quite drastically from the true falsifiers discussed at the outset. As Brecht observed in his powerful drama *Galileo*: Not everything a great man does is itself great.

DiTrocchio deals especially in the chapter entitled "Big Science or Big Fraud?" with the question of whether instances of fraud in science are on the increase. Reduced to a single sentence, the thesis he offers is that present-day fraud [is related to] the financing of research as introduced after World War II in the United States and subsequently [propagated] throughout the Western world. In other words: The science of falsification was essentially born when science was transformed from a calling into a profession. Put yet another way: Whereas Galileo practiced deceit in order to verify and disseminate a theory, Bruening [an American psychologist and notorious fraud] practiced deceit as a way of justifying in the eyes of the responsible agency [the National Institutes of Health] his receipt of financial support. In other words, on one hand a scientific Titan (with minor weaknesses), on the other a scientific mercenary for whom any means are regarded as legitimate. I do not believe this thesis is tenable. A gentleman scientist of the English leisure class, or a private scholar enjoying the patronage of an Italian prince, certainly appears more likely to have a "calling" than a modern-day professional scientist, who is obliged simultaneously to engage in the profane pursuit of a living. But the latter is not necessarily more inclined toward fraud. The actual number of fraud cases is of course unknown, but it may well be presumed to have risen in recent years; after all, the incidence of scientific fraud should be proportional in a general way to the number of active scientists. What is it, therefore, that motivates some (few) scientists to present falsified, improved, or freely invented results? The reasons are certainly very diverse, ranging from the humorous (cultivated particularly in Britain in the form of the hoax), through attempts to damage the reputations of others and cases of pathological ambition, all the way to megalomania and obsession with an *idée fixe*. Notwithstanding the above reservations, there may also be certain societal factors today that have the effect of stimulating fraud. An era like the present, so obsessed with individual success and being someone special, would presumably be more conducive to engendering fraud out of the (self-)recognition that one is in fact *not* particularly special than an era in which doubts about one's personal worth were less widespread. One of the remarkable facts associated especially with the most recent examples of fraud is the lack of attention on the part of the perpetrator to the question: Is this piece of deception worthwhile? Indeed, it is likely that this question was never even posed. The corresponding answer is quite straightforward: Fraud does not pay. There is no way to extract financial gain from scientific fraud because it cannot be marketed, certainly not over any prolonged period. The scientific fame one might perhaps be seeking will also not be achieved, because a spectacular experiment is certain to be repeated throughout the world, at which point the deception becomes obvious. Could fraud be motivated by the joy of having beaten the system through smuggling a piece of false data into the body of scientific wisdom? If so the victory would be a cheap one, because only the perpetrator of the fraud will be in a position to enjoy it, unless he or she invokes a kind of Rumpelstiltskin effect and plays an active role in disclosure of the deceit. Moreover, such a victory, especially in chemistry, is exceedingly easy to achieve. Thanks to modern methods of numerical calculation and the plethora of existing experimental data (e.g., spectral and structural data bases) it would be child's play today, for example, to describe a first synthesis of some new substance in such a convincing way that even a competent reviewer would be unlikely to recommend against publication of the work. But is that really falsification? Has it not always been an important

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1212-1371 $ 10.00+.25/0

goal to develop theoretical methods that permit one to predict physical and chemical properties with such precision that a real experiment leading to the same result becomes unnecessary?

DiTrocchio raises questions of this type in the last chapter of his book, entitled The Scientist as Deceiver, where he explicitly dismisses any interest in small-time fraud or simple falsification. In this intellectually stimulating discourse the author promotes the thesis that all scientists, but especially those not engaged in normal science according to Kuhn's use of the term, *must* engage in deception. In DiTrocchio's own words: "[Ever since Popper we know] that it is possible to provide proof only for that which is false, whereas one can never prove absolutely that something is true. This means that all the scientific theories we hold to be true cannot be regarded as true because their truth has actually been proven, but only because the scientists who formulated them succeeded in making such truth plausible to their colleagues and to us. This ordinarily includes the use of more or less serious falsifications or tricks, albeit ones that are not apparent, or only become apparent after a long period of time. In the end, scientists thus perpetrate fraud in the name of truth, because they are in no position to prove truth itself." In this particular quote I find the words falsification, tricks, and fraud somewhat disturbing. Scientists are in fact very much aware of the limits of their abilities. They know they are dealing with images, analogies, and metaphors (DiTrocchio speaks of science as a great illusion), which they formulate as accurately as possible within the confines of the knowledge available, their own personal creativity, and their imagination. The claim is never made (at least not any more) that one is presenting a comprehensive exposition of truth. Science remains an open endeavor and thus occasionally open to fraud and deceit, at least as defined in a court of law, but open also to the sort of high-level manoevering noted above, which one might better describe as un-deceiving in the sense of destroying an illusion. Otherwise the public is too likely to gain the impression that even science amounts to nothing but a big swindle. This may be precisely the message many of our contemporaries wish to hear, but it is not the case, nor is it the message the author wished to convey—or is he attempting to deceive us?

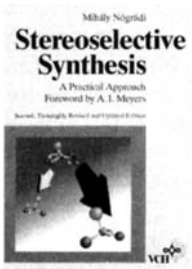
Stereoselective Synthesis. 2nd Edition. By *M. Nógrádi*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1994. 368 pp., paperback DM 68.00, $ 45.00.—ISBN 3-527-29243-8/1-56081-895-6

Like its first edition published in 1986, this enlarged and revised second edition of *Stereoselective Synthesis* has two purposes. Firstly it is intended for chemists involved in the synthesis of enantiomerically pure chiral natural products and active agents. Secondly it aims to provide advanced students and postgraduates with a clearly understandable account of basic principles and progress in the ever growing field of asymmetric synthesis.



Nógrádi's book describes the impressive developments that have occurred in stereoselective synthesis during the past 20 years. The earlier chapters contain a detailed account of the theoretical basis of methods for regio- and stereoselective synthesis. Recent discoveries and theories, such as the isoinversion principle, have been included in this new edition. The aspects treated in the following chapters include classical variants of methods for stereoselective functionalization, for example using chiral auxiliaries. The types of reactions discussed include such varied examples as stereoselective non-catalytic reductions, oxidations, nucleophilic additions, electrophilic additions, cycloadditions, and pericyclic reactions. The most recent published work (up to December 1992), such as the development of chiral reagents and innovations in the use of chiral auxiliaries, e.g. for 1,3-dipolar cycloadditions, is only partly covered in this new edition. Advances and new applications in the area of enantioselective catalysis are covered in greater detail. The trend away from stoichiometric methods to catalytic methods is impressively described, with examples from the areas of catalytic hydrogenations, epoxidations, and the *cis*-hydroxylation of olefins. The wide-ranging uses of chiral ligands and chiral Lewis acids are also discussed, as applied, for example, to enantioselective additions (the increasing success of organozinc reagents, and the catalysis of aldol reactions and ene reactions by chiral boron or aluminum Lewis acids). The reader wishing to study topics in greater depth has access in this edition to more than 1800 literature references, of which 831 are more recent (although these extend only up to December 1992!).

The choice of topics covered sometimes seems a little arbitrary and turns out to be incomplete, and the results reported are heavily concentrated on the best known research groups. Consequently the advanced reader who wants to avoid missing important recent developments will often need to refer to the original papers and follow up other references that these bring to light. However, since there have been so many new developments in asymmetric synthesis it is understandable that the author has not been able to include all the new work of the last few years.

To summarize, the appearance of a new edition of this book is well justified in view of the immense amount of published work and new developments in asymmetric synthesis in recent years, and this edition continues to give a good overall insight into this highly topical field of organic synthesis. The availability of a paperback version now means that students can afford to buy it, and it undoubtedly offers them welcome additional reading to accompany lecture courses on the subject.

My Search for Carbocations and Their Role in Chemistry (Nobel Lecture)**

George A. Olah*

Every generation of scientific men (i.e., scientists) starts where the previous generation left off, and the most advanced discoveries of one age constitute elementary axioms of the next.
Aldous Huxley

Introduction

Hydrocarbons are compounds of the elements carbon and hydrogen. They make up natural gas and oil and thus are essential for our modern life. Burning of hydrocarbons generates energy in our power plants and heats our homes. Derived gasoline and diesel oil propel our cars, trucks, airplanes. Hydrocarbons are also the feedstock for practically every synthetic material from plastics to pharmaceuticals. What nature gives us needs, however, to be processed and modified. We will eventually also need to make hydrocarbons ourselves, as our natural resources are depleted. Many of the processes used are acid-catalyzed, and the chemical reactions involved proceed through positive ion intermediates. Consequently, the knowledge of these intermediates and their chemistry is of substantial significance in both fundamental research and practical science.

Carbocations are the positive ions of carbon compounds. In 1901 Norris[1a] and Kehrmann and Wentzel[1b] independently discovered that colorless triphenylmethyl alcohol gave deep yellow solutions in concentrated sulfuric acid. Triphenylmethyl chloride similarly formed orange complexes with aluminum and tin chlorides. Adolf von Baeyer (Nobel laureate, 1905) should be credited for having recognized in 1902 the saltlike character of the products [Eq. (1)].[1c]

$$Ar_3C{-}X \rightleftharpoons Ar_3C^+ + X^- \qquad (1)$$

He then suggested a correlation between the appearance of color and salt formation—the so-called "halochromy". Gomberg[1d] (who had shortly before discovered the stable triphenylmethyl radical) as well as Walden[1e] contributed to the evolving understanding of the structure of related cationic dyes, such as malachite green **1**.

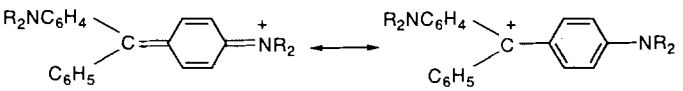
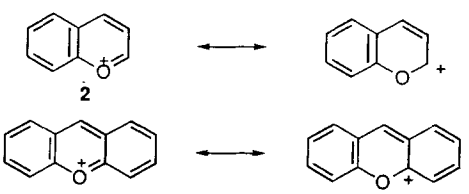
Stable carbocationic dyes were soon found to be present even in nature. The color of red wine as well as of many flowers, fruits, leaves, etc. is due in part to flavylium and anthocyanin compounds formed upon cleavage of their respective glycosides.



1

The elucidation of the constitution of flavylium and anthocyanin compounds developed from Robinson's and Willstätter's pioneering studies. Werner[1f] formulated the parent benzopyrilium or xanthylium salts **2** and **3** as oxonium salts, while Baeyer[1g] emphasized their great similarity to triarylmethylium salts and considered them carbenium salts. Time has indeed justified both points of view with the realization of the significance of the contribution of both oxonium and carbenium ion resonance forms.



2

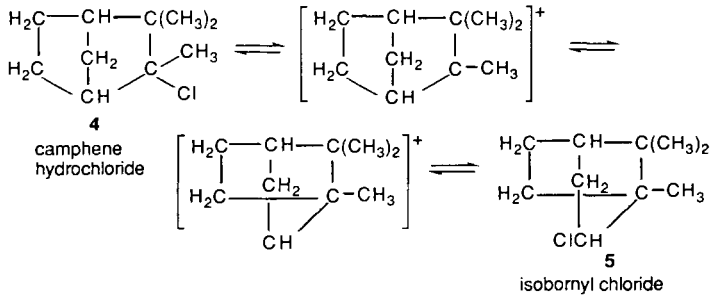
3

Whereas the existence of ionic triarylmethyl and related dyes was established at around the turn of the 20th century, the more general significance of carbocations in chemistry was long unrecognized. Triarylmethyl cations were considered as an isolated curiosity of chemistry, not unlike Gomberg's triarylmethyl radicals. Not only were simple hydrocarbon cations believed to be unstable, their fleeting existence was even doubted.

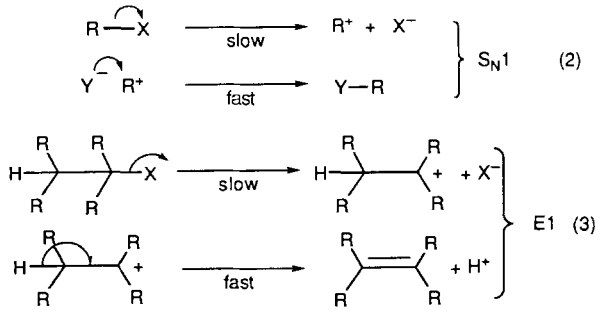
One of the most original and significant ideas in organic chemistry was the suggestion that carbocations (as we now call all the positive ions of carbon compounds) might be intermediates in the course of reactions that start from nonionic reactants and lead to nonionic covalent products.

It was Hans Meerwein[2] who, while studying the Wagner rearrangement of camphene hydrochloride to isobornyl chloride together with van Emster in 1922, found that the rate of the reaction increased with the dielectric constant of the solvent. Further, he found that certain Lewis acid chlorides such as $SbCl_5$, $SnCl_4$, $FeCl_3$, $AlCl_3$, and $SbCl_3$ (but not BCl_3 or $SiCl_4$)

as well as dry HCl, which promote the ionization of triphenylmethyl chloride by formation of carbocationic complexes, also considerably accelerated the rearrangement of camphene hydrochloride (**4**) to isobornyl chloride (**5**). Meerwein concluded that the isomerization actually does not proceed by way of migration of the chlorine atom but by a rearrangement of a cationic intermediate. Hence, the modern concept of carbocationic intermediates was born. Meerwein's views were, however, greeted with much skepticism by his peers in Germany, and he was discouraged from following up on these studies.



C. K. Ingold, E. H. Hughes, and their collaborators in England started in the late 1920s to carry out detailed kinetic and stereochemical investigations on what became known as nucleophilic substitution at saturated carbon and as polar elimination reactions.[3] Their work relating to unimolecular nucleophilic substitution and elimination called S_N1 and E1 reactions [Eq. (2) and (3)] laid the foundation for the role of electron-deficient carbocationic intermediates in organic reactions.



F. C. Whitmore[4] in the US in the thirties generalized these concepts to include many other organic reactions in a series of papers. Carbocations, however, were generally considered to be unstable and transient (short-lived), as they could not be directly observed. Many leading chemists, including Roger Adams, determinedly doubted their existence as real intermediates and strongly opposed even mentioning them. Whitmore consequently never was able in any of his publications in the prestigeous Journal of the American Chemical Society to use the notation of ionic R_3C^+. The concept of carbocations, however, slowly grew to maturity through kinetic, stereochemical, and product studies of a wide variety of reactions. Leading investigators such as P. D. Bartlett, C. D. Nenitzescu, S. Winstein, D. J. Cram, M. J. S. Dewar, J. D. Roberts, P. v. R. Schleyer, and others have contributed fundamentally to the development of modern carbocation chemistry. The role of carbocations as one of the basic concepts of modern chemistry was firmly established and is well reviewed.[5-7] With the advancement of mass spectrometry the existence of gaseous cations was proven, but this could give no indication of their structure or allow extrapolation to solution chemistry. Direct observation and study of stable, long-lived carbocations, such as of alkyl cations in the condensed state remained an elusive goal.

My involvement with the study of carbocations dates back to the fifties and resulted in the first direct observation of alkyl cations and subsequently the whole spectrum of carbocations as long-lived species in highly acidic (superacidic) solutions.[5, 8, 9] The low nucleophilicity of the counteranions (SbF_6^-, $Sb_2F_{11}^-$ etc.) greatly contributed to the stability of the carbocationic salts, which could in some instances even be isolated as crystalline salts. The techniques we developed with superacids to generate stable ions also gained wide application in the preparation of other ionic intermediates (nitronium, halonium, oxonium ions, etc.). At the same time the preparation and study of an ever increasing number of carbocations allowed a general concept of carbocations, which I suggested in a 1972 paper, to evolve. In the same paper I suggested that the cations of carbon compounds be termed "carbocations".[10] "Carbocations" is now the approved[11] (IUPAC) generic name for all cationic carbon compounds. Similarly, the anionic compounds are called "carbanions".

George A. Olah was born in 1927 and educated in Budapest, Hungary. He moved in 1957 first to Canada and then to the USA with the Dow Chemical Company. Since 1977 he has been Director of the Loker Hydrocarbon Research Institute and Distinguished Professor of Organic Chemistry at the University of Southern California, Los Angeles. He is a member of the US National Academy of Sciences, a Foreign Member of the Italian Academia dei Lincei, and an Honorary Member of the Hungarian Academy of Sciences. He received Honorary Doctorates from the University of Durham (England), the University of Munich, the University of Crete (Greece), and his alma mater, the Technical University of Budapest. He is the recipient of many awards including the American Chemical Society Awards in Petroleum Chemistry, Creative Work in Synthetic Organic Chemistry, the Roger Adams Award, and the Nobel Prize in Chemistry, 1994. His research interests are in the area of synthetic and mechanistic organic chemistry, reactive intermediates (carbocations), superacids, and hydrocarbon chemistry. He has published more than 1000 scientific papers, holds 100 patents, and authored or co-authored 15 monographs.

From Acyl Cations to Alkyl Cations

The transient nature of carbocations arises from their high reactivity towards reactive nucleophiles present in the system. The use of counterions with relatively low nucleophilicity, particularly tetrafluoroborate (BF_4^-), enabled Meerwein in the forties to prepare a series of oxonium and carboxonium ion salts, like $R_3O^+BF_4^-$ and $HC(OR)_2^+BF_4^-$, respectively.[12] These Meerwein salts are efficient alkylating agents; they transfer alkyl groups in S_N2-type reactions. However, no acyl ($RCO^+BF_4^-$) or alkyl cation salts ($R^+BF_4^-$) were obtained in Meerwein's studies.

Acetic acid and acetic anhydride were shown to form complexes with Lewis acids such as boron trifluoride. The behavior of acetic acid and acetic anhydride in strong protic acids (sulfuric acid, oleum, perchloric acid, etc.) was also extensively studied. None of these resulted, however, in the isolation or unequivocal characterization of the acetyl cation (or other related homologous acyl cations). F. Seel prepared acetylium tetrafluoroborate[13] for the first time in 1943 by treating acetyl fluoride with boron trifluoride [Eq. (4)].

$$CH_3COF + BF_3 \rightleftharpoons CH_3CO^+BF_4^- \quad (4)$$

In the early fifties, I became interested in organic fluorine compounds while working at the Organic Chemical Institute of the Technical University in Budapest led by the late Professor G. Zemplén, a noted carbohydrate chemist and former student of Emil Fischer (Nobel laureate, 1902) whose "scientific grandson" I can thus consider myself. Zemplén was not very impressed by my ideas, as he thought attempts to study fluorine compounds which necessitated "outrageous" reagents such as hydrogen fluoride to be extremely foolish. Eventually, however, I prevailed and was allowed to convert an open balcony at the rear of the top floor of the chemistry building into a small laboratory, where together with some of my early dedicated associates, A. Pavlath, S. Kuhn, we started up the study of organic fluorides as reagents. Seel's previous work particularly fascinated me. As Zemplén's interest was in glycoside synthesis and related carbohydrate chemistry, I thought that selective α- or β-glycoside synthesis could be achieved by treating either acetofluoroglucose (and other fluorinated carbohydrates) or their relatively stable, deacetylated fluorohydrins with the appropriate aglucons. In the course of the project -COF compounds were needed. As Seel did not seem to have followed up his earlier study, I became interested in exploring acylation with acyl fluorides in general. The work was subsequently extended to alkylation with alkyl fluorides with boron trifluoride as catalyst for Friedel-Crafts type reactions. These studies also aroused my interest in the mechanistic aspects of the reactions, including the complexes of RCOF and RF with BF_3 and subsequently with other Lewis acid fluorides [Eq. (5) and (6)]. Thus, my long fascination with the chemistry of carbocationic complexes began.

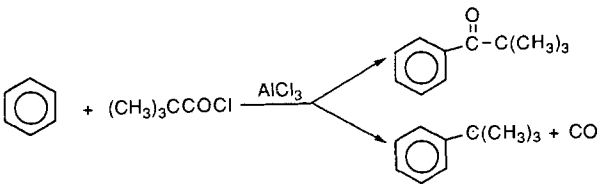
$$ArH + RCOF \overset{BF_3}{\rightleftharpoons} ArCOR + HF \quad (5)$$

$$ArH + RF \overset{BF_3}{\rightleftharpoons} ArR + HF \quad (6)$$

Carrying out such research in post-war Hungary was not easy. There was no access to such chemicals as anhydrous HF, FSO_3H, or BF_3, and we had to prepare them ourselves. HF was prepared from fluorspar (CaF_2) and sulfuric acid, and its reaction with SO_3 (generated from oleum) gave FSO_3H. By treating boric acid with fluorosulfuric acid we made BF_3. Handling these reagents and performing this chemistry in a laboratory equipped with the barest of necessities was indeed a challenge. It was only around 1955 through Meerwein, who read some of my early publications, started corresponding with me, and offered his help, that we received a cyclinder of BF_3 gas. What a precious gift it was![14]

My early work with acyl fluorides also involved formyl fluoride, HCOF,[15] which was first prepared by Nesmejanov and Kahn in the thirties,[16] but they did not pursue its use in synthesis. We also prepared a series of higher homologous acyl fluorides and studied their chemistry.[15]

In Friedel-Crafts chemistry when pivaloyl chloride is treated with aromatics in the presence of aluminum chloride, *tert*-butylated products were obtained besides the expected ketones [Eq. (7)].[17]



(7)

These were assumed to be formed by decarbonylation of the intermediate pivaloyl complex or cation. In the late fifties, now working at the Dow Chemical Company laboratory in Sarnia, Ontario (Canada), I was able to return to my investigations and extend them by using IR and NMR spectroscopy to study isolable complexes between acyl fluoride and Lewis acid fluoride, including those higher valency Lewis acid fluorides such as SbF_5, AsF_5, PF_5. Consequently, it was not unexpected that the $(CH_3)_3CCOF-SbF_5$ complex we generated showed substantial tendency toward decarbonylation.[18] What was exciting, however, was that we could follow this process by NMR spectroscopy and observe what turned out to be the first stable, long-lived alkyl cation salt, namely, *tert*-butyl hexafluoroantimonate.[18-20]

$$(CH_3)_3CCOF + SbF_5 \longrightarrow (CH_3)_3CCO^+SbF_6 \overset{-CO}{\longrightarrow} (CH_3)_3C^+SbF_6^- \quad (8)$$

This breakthrough was first reported in my 1962 papers[18-19] and was followed by studies that led to methods yielding long-lived alkyl cations in solution.[20] Before recollecting some of this exciting development, however, a brief review of the long quest for these elusive alkyl cations is in order.

Earlier Unsuccessful Attempts To Observe Alkyl Cations in Solution

Until the early sixties alkyl cations were considered only as transient species. Their existence had been indirectly inferred from kinetic and stereochemical studies.[3] No reliable spectro-

scopic or other physical measurements of simple alkyl cations in solution or in the solid state were reported despite decades of extensive studies (including conductivity and cryoscopic measurements). Gaseous alkyl cations had been investigated since the fifties by electron bombardment of alkanes, haloalkanes, and other precursors in mass spectrometric studies, but these investigations, of course, did not provide structural information.[21]

The existence of complexes between Friedel–Crafts alkyl halides and Lewis acid halides had been established from observations, such as Brown's study of the vapor pressure depression of CH_3Cl and C_2H_5Cl in the presence of gallium chloride.[22] The conductivity of aluminum chloride in alkyl chlorides[23] and of alkyl fluorides in boron trifluoride was measured,[24] and the effect of ethyl bromide on the dipole moment of aluminum bromide was studied.[25] However, in no case could well-defined, stable alkyl cation complexes be detected, even at very low temperatures.

Electronic spectra of alcohols and olefins in strong protic acids such as sulfuric acid were obtained by Rosenbaum and Symons.[26] They observed that several simple aliphatic alcohols and olefins give an absorption maximum around 290 nm and ascribed this characteristic absorption to the corresponding alkyl cations. Finch and Symons,[27a] on reinvestigation, however, showed that condensation products, formed with acetic acid (used as solvent for the precursor alcohols and olefins), were responsible for the spectra and not the simple alkyl cations. Moreover, protonated mesityl oxide was also identified as the absorbing species in the isobutylene/acetic acid/sulfuric acid system.

Deno and his coworkers[27b] carried out an extensive study of the fate of alkyl cations formed from alcohols or olefins in undiluted H_2SO_4 and oleum, and showed that equal amounts of a saturated hydrocarbon mixture (C_4 to C_{18}) insoluble in H_2SO_4 and a mixture of cyclopentenyl cations (C_9 to C_{20}) in the H_2SO_4 layer formed. These cations exhibit strong ultraviolet absorption around 300 nm. Olah, Pittman, and Symons subsequently reviewed and clarified the question of electronic spectra of carbocationic systems and the fate of various precursors in different acids.[27c]

At this stage it was clear that all earlier attempts to prove the existence of long-lived, well-defined alkyl cations were unsuccessful in acids such as sulfuric acid, perchloric acid, etc. and at best inconclusive in case of the interaction of alkyl halides with Lewis acid halides. Proton elimination from any alkyl cation formed as intermediate gives an olefin, which then reacts further and can lead to complex systems affecting conductivity, as well as other chemical and physical studies.

It was not realized till the breakthrough in superacid chemistry (see below) that in order to suppress the deprotonation of alkyl cations to olefins [Eq. (9)] and the subsequent formation of very complex systems by reactions such as alkylation, oligomerization, polymerization, and cyclization of olefins with alkyl cations, acids much stronger than those known and used at the time were needed.

$$(CH_3)_3C^+ \rightleftharpoons H^+ + (CH_3)_2C{=}CH_2 \qquad (9)$$

Finding such acids (called "superacids") turned out to be the key to obtaining stable, long-lived alkyl cations and carbocations in general. If any deprotonation were still to take place, however, the alkyl cation (a strong acid) would immediately react with the olefin (a good π-base) to give the multitude of mentioned reactions.

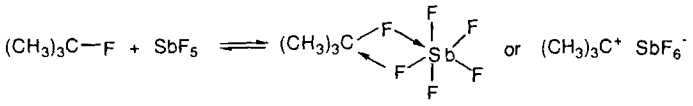
Long-Lived Alkyl Cations from Alkyl Fluorides in Antimony Pentafluoride and Related Conjugate Superacids

The idea that ionization of alkyl fluorides to stable alkyl cations could be possible with an excess of strong Lewis acid fluorides that serve as solvents first came to me while I was working in Hungary in the early fifties and studying the boron trifluoride catalyzed alkylation of aromatics with alkyl fluorides. In the course of these studies I attempted to isolate $RF{:}BF_3$ complexes. Realizing the difficulty to find suitable solvents that would allow ionization but at the same not react with developing, potentially highly reactive alkyl cations, we condensed neat alkyl fluorides with boron trifluoride at low temperatures. At the time I had no access to spectroscopic methods such as IR or NMR, which were still in their infancy. I remember a visit by Costin Nenitzescu (an outstanding but never fully recognized Rumanian chemist, who carried out much pioneering research on acid-catalyzed reactions). We commiserated our lack of access even to an IR spectrometer. (Nenitzescu later recalled sending a cyclobutadiene–Ag^+ complex on the Orient Express to a colleague in Vienna for IR studies, but it decomposed en route.) All we could do at the time on our $RF-BF_3$ systems were conductivity measurements. The results showed that methyl fluoride and ethyl fluoride gave only low conductivity complexes, whereas the isopropyl fluoride and *tert*-butyl fluoride complexes were highly conducting [Eq. (10)]. The latter systems, however, also showed some polymerization (from deprotonation of the involved carbocations to give olefins). Thus, the conductivity data must have been affected by acid formation.[24]

$$R{-}F + BF_3 \rightleftharpoons \overset{\delta+}{R}{-}F \rightarrow \overset{\delta-}{BF_3} \rightleftharpoons R^+BF_4^- \qquad (10)$$

After the defeat of the 1956 Hungarian revolution I escaped with my family and spent some months in London before moving to Canada, where I was able to continue my research at the Dow Chemical Company Research Laboratory in Sarnia, Ontario. After a prolonged, comprehensive search of many Lewis acid halides I finally hit on antimony pentafluoride.[18–20] It turned out to be an extremely strong Lewis acid and for the first time enabled the ionization of alkyl fluorides in solution to stable, long-lived alkyl cations. Neat SbF_5 solutions of alkyl fluorides are viscous, but diluted with liquid sulfur dioxide the solutions could be cooled and studied at $-78\,^{\circ}C$. Subsequently, I also introduced even lower nucleophilicity solvents such as SO_2ClF or SO_2F_2 which allowed studies at much lower temperatures. As sequel to the observation of the decarbonylation of the pivaloyl cation that gave the first spectral evidence for the tertiary butyl cation, *tert*-butyl fluoride was ionized in excess antimony pentafluoride. The solution of the *tert*-butyl cation turned out to be remarkably stable, allowing chemical and spectroscopic studies alike.[28, 29]

In the late fifties the research director of the Canadian Dow laboratories was not yet convinced about the usefulness of NMR spectroscopy. Consequently we had no such instrumentation of our own. Fortunately the Dow laboratories in Midland (Michigan) just 100 miles across the border had excellent facilities run by E. B. Baker, a pioneer of NMR spectroscopy, who offered his help. To probe whether our SbF_5 solution of alkyl fluorides indeed contained alkyl cations, we routinely drove with our samples in the early morning to Midland and watched Ned Baker obtain their NMR spectra. *tert*-Butyl fluoride itself shows a characteristic doublet in its ^1H NMR spectrum due to the fluorine–hydrogen coupling of $J_{H,F} = 20$ Hz. In SbF_5 solution the doublet disappeared and the methyl protons became significantly deshielded from about $\delta = 1.5$ to $\delta = 4.3$. This was very encouraging but not yet entirely conclusive to prove the presence of the *tert*-butyl cation. If one assumes that with SbF_5 *tert*-butyl fluoride forms only a polarized donor–acceptor complex, which undergoes fast fluorine exchange (on the NMR time scale), the fluorine–hydrogen coupling would be "washed out", while still a significant deshielding of the methyl protons would be expected. The differentiation of a rapidly exchanging, polarized donor–acceptor complex from the long sought-after, really ionic $t\text{-}C_4H_9^+SbF_6^-$ thus became a major challenge [Eq. (11)].



(11)

Ned Baker, despite being himself a physicist, showed great interest in our chemical problem. To solve it, he devised a means to obtain the ^{13}C NMR spectra of our dilute solutions, an extremely difficult task before the advent of Fourier transform NMR techniques. Labeling with carbon-13 was generally possible at the time only to about 50% level (from $Ba^{13}CO_3$). When we prepared 50% ^{13}C-labeled *tert*-butyl fluoride, we could obtain at best only 5% solutions in SbF_5. Thus, the ^{13}C content of the solution was highly diluted. Baker, however, undaunted devised an INDOR (INDOR = internuclear double resonance) method. Using the high sensitivity of the proton signal, he was able by the double resonance technique to observe the ^{13}C shifts of our dilute solutions—a remarkable achievement around 1960! To our great joy the tertiary carbon atom [$\delta(^{13}C) = 335.2$] in $(CH_3)_3CF–SbF_5$ turned out to be more than $\Delta\delta = 300$ deshielded from that of the covalent starting material! Such very large chemical deshielding (the most deshielded ^{13}C signal at the time) could not be reconciled with a donor–acceptor complex. It indicated rehybridization from sp^3 to sp^2 and at the same time showed the effect of significant positive charge on the carbocationic carbon center. For simplicity I am not discussing here the nature of the counterion, which can be a dimer ($Sb_2F_{11}^-$) or even an oligomer, or questions of ion-pairing and separation (concepts developed by Winstein).

Besides the *tert*-butyl cation we also succeeded in preparing and studying the related *sec*-isopropyl and the *tert*-amyl cations [Eq. (12) and (13)]. The isopropyl cation was of particular interest. Whereas in the *tert*-butyl cation the methyl protons are attached to carbons that are adjacent only to the carbocationic center, in the isopropyl cation a proton is directly attached to it. When we obtained the proton NMR spectrum of the $i\text{-}C_3H_7F–SbF_5$ system, the CH proton showed up as an enormously deshielded septet at $\delta = 13.5$, ruling out the possibility of a polarized donor–acceptor complex and indicating the formation of $(CH_3)_2CH^+$ ion. The ^{13}C NMR spectrum was also conclusive showing a very highly deshielded (by $\Delta\delta > 300$) ^+C atom (chemical shift: $\delta(^{13}C) = 320.6$). The spectrum of the *tert*-amyl cation showed an additional interesting feature in the strong long-range H–H coupling of the methyl protons adjacent to the carbocationic center with the methylene protons. If only the donor–acceptor complex were involved, such long range coupling through an sp^3 carbon would be small (1–2 Hz). Instead the observed significant coupling ($J_{H,H} = 10$ Hz) indicated that the species studied indeed had an sp^2 center through which the long-range H–H coupling became effective. Figure 1 reproduces the ^1H NMR spectra of the *tert*-butyl, *tert*-amyl, and isopropyl cations. These original spectra are framed and hung in my office as a momento, as is the ESCA spectrum of the norbornyl cation (see below).

$$(CH_3)_2CHF + SbF_5 \longrightarrow (CH_3)_2CH^+SbF_6^- \quad (12)$$

$$(CH_3)_2CFCH_2CH_3 + SbF_5 \longrightarrow (CH_3)_2\overset{+}{C}CH_2CH_3SbF_6^- \quad (13)$$

Our studies also included an IR spectroscopic investigation of the observed ions (Fig. 2).[29] John Evans, at the time a spectroscopist at the Midland Dow laboratories, offered his cooperation and was able to obtain and analyze the vibrational spectra of our alkyl cations. It is rewarding to see that some thirty years later FTIR spectra obtained by Denis Sunko and his colleagues in Zagreb with low-temperature matrix-deposition techniques and Schleyer's calculations of the spectra show good agreement with

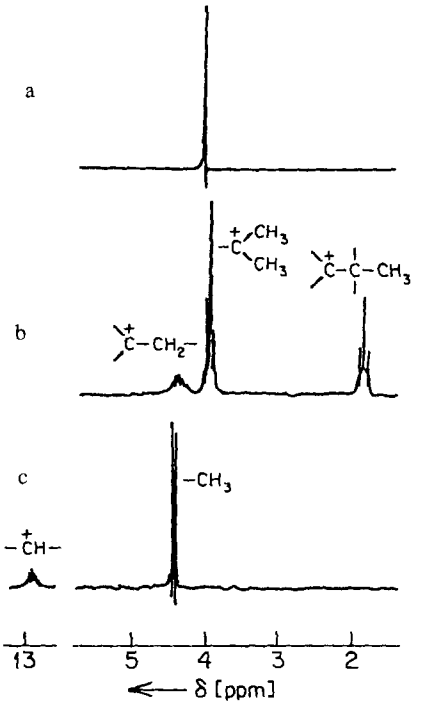


Fig. 1. ^1H NMR spectra (60 MHz, in SbF_5/SO_2ClF solution, −60 °C) of a) the *tert*-butyl cation [trimethylcarbenium ion, $(CH_3)_3C^+$], b) the *tert*-amyl cation [ethyldimethylcarbenium ion, $(CH_3)_2C^+–C_2H_5$], and c) the isopropyl cation [dimethylcarbenium ion, $(CH_3)_2C^+–H$].

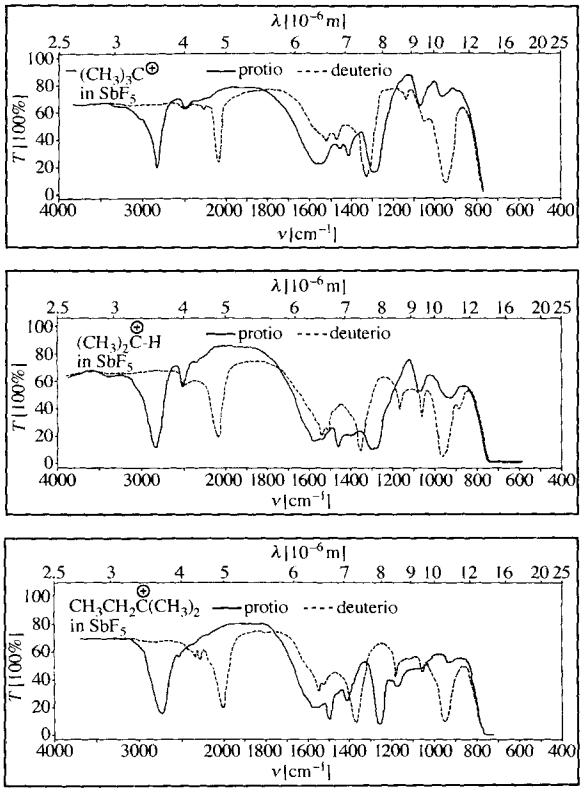

Fig. 2. IR spectra of *tert*-butyl (top), isopropyl (center), and *tert*-amyl (bottom) cations. T = transmission.

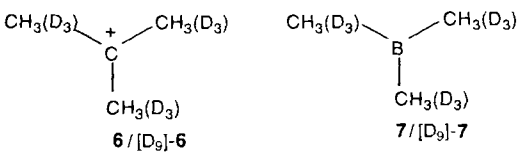
our early work, even though our work was carried out in neat SbF_5 at room temperature long before the advent of the FTIR methods.[30]

Subsequently in 1968–1970 with Jack DeMember and August Commeyras[31] we were able to carry out more detailed IR and laser Raman spectroscopic studies of alkyl cations. Comparison of the data of unlabeled and deuterium-labeled *tert*-butyl cations (**6**) with those of isoelectronic trimethylboron (**7**) proved the planar structure of carbocation **6** (Table 1).



6 / [D9]-**6** **7** / [D9]-**7**

This was also an early example of the realization that for nearly all carbocations there exist neutral isoelectronic isostructural boron analogues, which later in the hands of R. E. Williams and others proved so useful.

When in the summer of 1962 I was able for the first time to present our work in public at the Brookhaven Organic Reaction Mechanism Conference[28a] and subsequently in a number of other presentations and publications,[28b–e, 29] I had convincing evidence to substantiate that after a long and frequently frustrating search stable, long-lived alkyl cations had finally been obtained in superacidic solutions.

The chemistry of stable, long-lived carbocations as they became known, began and its progress became fast and wide spread. In an industrial laboratory, publication of research is not always easy. I would therefore like to thank the Dow Chemical Company for allowing me not only to carry out the work, but also to publish the results.

After successful preparation of long-lived, stable carbocations in antimony pentafluoride solutions, the work was extended to a variety of other superacids. Protic superacids such as FSO_3H (fluorosulfuric acid) and CF_3SO_3H (triflic acid) as well as conjugate acids such as $HF–SbF_5$, $FSO_3H–SbF_5$ (Magic Acid), $CF_3SO_3H–SbF_5$, and $CF_3SO_3H–B(O_3SCF_3)_3$, were extensively used to ionize precursors, including alcohols. Superacids based on fluorides such as AsF_5, TaF_5, and NbF_5, and other strong Lewis acids such as $B(O_3SCF_3)_3$ were also successfully introduced. The name Magic Acid for the $FSO_3H–SbF_5$ system was given by J. Lukas, a German post-doctoral fellow working with me in Cleveland in the sixties, who after a laboratory party put remainders of a Christmas candle into the acid. The candle dissolved and the resulting solution gave an excellent NMR spectrum of the *tert*-butyl cation. This observation understandably evoked much interest, and hence he termed the acid "Magic". The name stuck in our laboratory. I think it was Ned Arnett who subsequently introduced the name into the literature where it increasingly became used. When a former graduate student of mine, J. Svoboda, started a small company (Cationics) to make some of our ionic reagents commercially, he obtained trade name protection for Magic Acid, and it has been marketed as such since.

Many contributed to the study of long-lived carbocations. The field rapidly expanded and allowed successful study of practically any carbocationic system. Time does not allow crediting here all my former associates and the many researchers around the world who contributed so much to the development of the field. Their work can be found in the extensive literature. I would like, however, to specifically mention the pioneering work of D. M. Brouwer and H. Hogeveen, as well as their colleagues at the Shell Laboratories in Amsterdam in the sixties and seventies. They contributed fundamentally to the study of long-lived carbocations and related superacidic hydrocarbon chemistry. The first publication from the Shell laboratories on alkyl cations appeared in *Chemical Communications* in 1964,[32] following closely my initial reports of 1962–1964. Similarly,

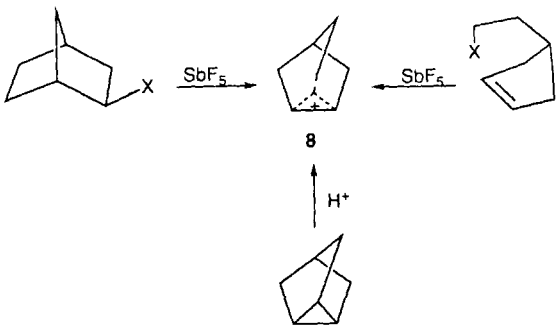
I would like to emphasize the fundamental contributions of R. J. Gillespie to strong acid (superacid) chemistry[33] and also his generous help while I was working at the Dow Laboratories in Canada. I reestablished contact with him during this time after we first met in the winter of 1956 at University College in London where he worked with C. K. Ingold. Subsequently, he moved to McMaster University in Hamilton, Ontario. In the late fifties he already had an NMR spectrometer and in our study of SbF_5 containing highly acidic systems of carbocations we were gratified by his help to run some of our spectra on his instrument. His long-standing interest in fluorosulfuric acid and our studies in SbF_5-containing systems found common ground in studies of FSO_3H–SbF_5 systems.[34] It was also Gillespie who suggested calling protic acids stronger than 100% sulfuric acid as superacids.[33] This arbitrary, but most useful definition is now generally used. It should be pointed out, however, that the name "superacid" goes back to J. B. Conant of Harvard who used it in 1927 to denote acids such as perchloric acid, which he found stronger than conventional mineral acids and capable of protonating even such weak bases as carbonyl compounds.[35] Our book "Superacids" published in 1985 with Surya Prakash and Jean Sommer[33c] was appropriately dedicated to the memory of Conant. Few of today's chemists are aware of his contributions to this field.

My memories of the already mentioned 1962 Brookhaven Mechanism Conference,[28a] where I first reported on long-lived carbocations in public, are still clear in my mind. The scheduled "main event" of the meeting was the continuing debate between Saul Winstein and Herbert C. Brown (the pioneer of hydroboration chemistry, Nobel laureate, 1979) on the classical or nonclassical nature of some carbocations (or carbonium ions as they were still called at the time).[36] It must have come to them and others in the audience as quite a surprise that a young chemist from an unknown industrial laboratory was invited to give a major lecture and claimed to have obtained and studied stable, long-lived "carbonium" ions (i.e., carbocations) by the simple new method of using a highly acidic (superacidic) system. I remember being called aside separately by both Winstein and Brown during the conference and cautioned that a young chemist should be exceedingly careful making such claims. Each pointed out that most probably I was mistaken and could not have obtained long-lived carbonium ions. Just in case, however, my method should turn out to be real, I certainly would obtain evidence for the "nonclassical" or "classical" nature, of the much disputed 2-norbornyl cation (**8**, see Scheme 1). Their much heralded controversy[36b, c] centered around the question whether the experimentally observed, significant rate enhancement of the hydrolysis of 2-*exo*- over 2-*endo*-norbornyl esters and high *exo* selectivity in the system were caused, as suggested by Winstein, by σ participation of the C_1–C_6 single bond with delocalization to a bridged nonclassical ion or only by steric hindrance in the *endo* system and involving equilibrating classical trivalent ions. Nonclassical ions, a term first used by J. D. Roberts,[37] were suggested by P. D. Bartlett to contain too few electrons to allow a pair for each "bond", that is, in the ground state they must contain delocalized σ electrons.[36a] As my method allowed us to prepare carbocations as long-lived species, clearly the opportunity was given to decide the question experimentally through direct observation of the ion. At the time I had obtained only the proton spectrum of 2-norbornyl fluoride in SbF_5 at room temperature, which displayed a single, broad peak indicating complete equilibration through hydride shifts and Wagner–Meerwein rearrangement (well-known in solvolysis reactions and related transformations of 2-norbornyl systems). However, my curiosity was aroused and subsequently when in 1964 I transferred to Dow's Eastern Research Laboratory (established under Fred McLafferty as laboratory director first in Framingham, MA, and then moved to Weyland, MA), the work was further pursued in cooperation with Paul Schleyer from Princeton University and Marty Saunders from Yale University.[38a] Paul, who became a life-long friend, had, even at that time, a knack of acting as the catalyst to initiate cooperative efforts. Using SO_2 as solvent, we were able to lower the temperature of our solution to $-78\,^{\circ}C$ and also prepared the ion by ionization of cyclopentenylethyl fluorides or by protonation of nortricyclene in $FSO_3H/SbF_5/SO_2ClF$ (Scheme 1).



Scheme 1.

I still did not have access to suitable low temperature instrumentation to carry out needed NMR studies, but Marty Saunders did. Thus, our samples now traveled the Massachusetts turnpike to New Haven, where Saunders was able to study solutions of the norbornyl cation at increasingly low temperatures using his own home-built NMR instrumentation housed in the basement of the Yale chemistry building. We were able to obtain NMR spectra of the ion at $-70\,^{\circ}C$, where the 3,2-hydride shift was frozen out. It took, however, till 1969 following my move to Cleveland to Case Western Reserve University to develop efficient low-temperature techniques with solvents such as SO_2ClF and SO_2F_2, to obtain high resolution ^1H and ^{13}C NMR spectra of the 2-norbornyl cation eventually down to $-159\,^{\circ}C$ in supercooled solutions.[38b, c] Both 1,2,6-hydride shifts and the Wagner–Meerwein rearrangement could be frozen out at such a low temperature and the static, bridged ion was observed (Figs. 3a and 3b).[38c]

The differentiation of bridged, nonclassical from rapidly equilibrating classical carbocations based on NMR spectroscopy is difficult, since NMR is a relatively slow physical method with a limited time scale. We addressed this question in some detail in our work by comparing estimated shifts of the two systems with model systems.[38b, c] Of course these days this task is greatly simplified by highly efficient theoretical methods such as IGLO and GIAO to calculate NMR shifts of ions and comparing them with the experimental data.[38d] It is rewarding

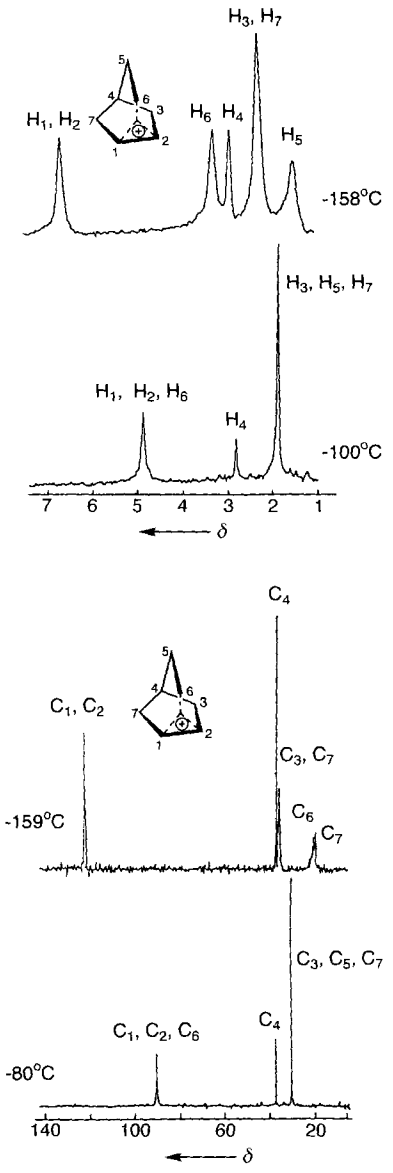


Fig. 3. Top: 395 MHz ^{1}H NMR spectra of the 2-norbornyl cation in $SbF_5/SO_2ClF/SO_2F_2$ solution. Bottom: 50 MHz, proton-decoupled ^{13}C NMR spectra of 2-norbornyl cation (^{13}C enriched) in $SbF_5/SO_2ClF/SO_2F_2$ solution.

to see that our results and conclusions stood up well to comparison with all the more recent studies.

As mentioned, we carried out IR studies (using fast vibrational spectroscopy) early in our work on carbocations. In our studies of the norbornyl cation we also obtained Raman spectra,[38b] and although at the time it was not possible to calculate the spectra theoretically, comparison with model compounds (2-norbornyl system and notricyclene) indicated the symmetrical, bridged nature of the ion. Sunko and Schleyer recently were able to obtain the FTIR spectrum in elegant studies and compare it with theoretical calculations.[30]

Kai Siegbahn's (Nobel laureate in Physics, 1981) core electron spectroscopy (ESCA) was another fast physical method we applied to resolve the question of bridged vs. rapidly equilibrating ions. We were able to study carbocations in the late sixties by this method, adapting it to superacidic matrixes. George Mateescu and Louise Riemenschneider in my Cleveland laboratory established ESCA instrumentation and the needed methodology for obtaining the ESCA spectra of a number of carbocations, including the *tert*-butyl and the 2-norbornyl cation in SbF_5-based superacidic matrixes (Fig. 4).[39] These studies again convincingly showed the nonclassical nature of the 2-norbornyl cation, because no trivalent carbenium ion center was observed in the ESCA spectrum characteristic of a classical ion, such as is the case for the *tert*-butyl cation. Although again some criticism was leveled at our work by proponents of the equilibrating classical-ion concept, subsequent studies by Dave Clark fully justified our results and conclusions.[39c] So did a comparison of theoretical calculations with the experimental data.

It is proper to mention here some significant, more recent studies. Saunders's studies showed the absence of deuterium

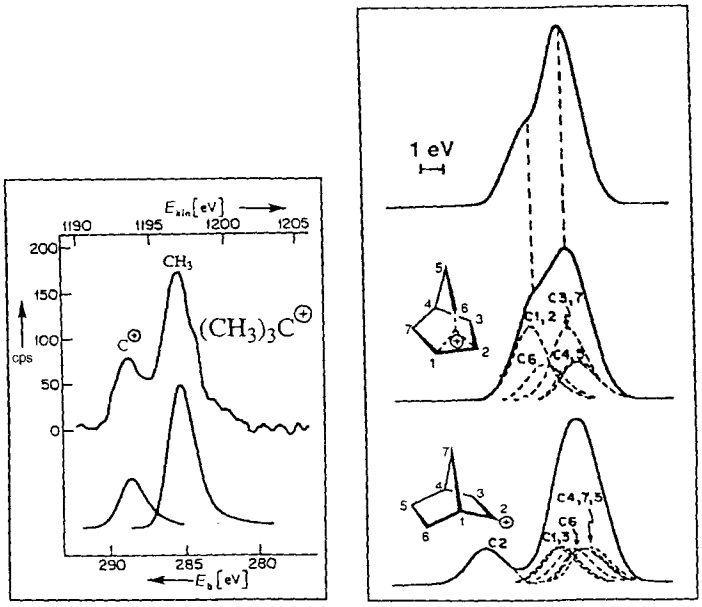

Fig. 4. Left: Carbon 1s photoelectron spectrum of the *tert*-butyl cation (top curve from experiment; bottom curve calculated). Right: 1s core-hole-state spectra for the 2-norbornyl cation (top), and Clark's simulated spectra for the classical (center) and nonclassical ions (bottom).

isotopic perturbation, as anticipated for a classical equilibrating system.[40] Myhre and Yannoni[41] at very low (5 K!) temperatures were able to obtain solid state ^{13}C NMR spectra that showed no indication of freezing out any equilibrating classical ions; the barriers at this temperature should be as low as 200 cal mol^{-1} (the energy of a vibrational transition). Laube was able to carry out single crystal X-ray structural studies on substituted 2-norbornyl cations.[42] Schleyer's theoretical studies,[38d] includng IGLO and related calculation of NMR shifts and their comparison with experimental data, contributed further to the understanding of σ-bridged carbonium ion nature of the 2-norbornyl cation. (The classical 2-norbornyl cation was not even found to be an energetically high-lying intermediate!) So did Arnett's calorimetric studies.[43] In a 1983 paper entitled "Conclusion of the Norbornyl Ion Controversy" with Prakash and Saunders we were able to state[44] that "all these studies unequivocally ended the so-called nonclassical-ion controversy". Winstein's original views were fully justified by the extensive structural studies made possible through my "stable ion" chemistry.

Although many believe that too much effort was expended on this problem, in my view the norbornyl ion controversy had significant consequences for chemistry. It not only helped to extend the limits of available techniques for structural studies and theoretical calculations, but also laid the foundation for the chemistry of C–H and C–C single bonds with electrophiles and thus of saturated hydrocarbons (see below).

Intensive, critical studies of a controversial topic always help to eliminate the possibility of any errors. One of my favorite quotations is that by Georg von Békésy (Nobel laureate in Physiology and Medicine, 1961).[45]

> "[One] way of dealing with errors is to have friends who are willing to spend the time necessary to carry out a critical examination of the experimental design beforehand and the

results after the experiments have been completed. An even better way is to have an enemy. An enemy is willing to devote a vast amount of time and brain power to ferreting out errors both large and small, and this without any compensation. The trouble is that really capable enemies are scarce; most of them are only ordinary. Another trouble with enemies is that they sometimes develop into friends and lose a good deal of their zeal. It was in this way the writer lost his three best enemies. Everyone, not just scientists, need a few good enemies!"

Clearly there was no lack of devoted adversaries (perhaps a more proper term than enemies) on both sides of the norbornyl controversy. It is to their credit that we know probably more today about the structure of carbocations such as the norbornyl cation than of any other chemical species. Their efforts resulted in the most rigorous studies and the development or improvement of many techniques.

To me the most significant consequence of the norbornyl cation studies was the realization that C–H and C–C single bonds can act as two-electron σ donors not only in intramolecular but also in intermolecular transformations and electrophilic reactions. Two-electron, three-center (2e–3c) bonding (familiar in boron and organometallic chemistry) is the key for these reactions. Much new chemistry rapidly evolved, and the broad scope and significance of the chemistry of hypercoordinated carbon compounds (in short hypercarbon) was recognized.[46]

The General Concept of Carbocations

The study of carbocations by direct observation of long-lived species and related superacid chemistry made it apparent that the carbocation concept is wider than previously thought and needed a more general definition, which I offered in a 1972 paper.[10] The definition takes into account the existence of two major limiting classes of carbocations with a continuum of species with different degrees of delocalization bridging them.

a) Trivalent "classical" carbenium ions contain an sp^2-hybridized electron-deficient carbon atom, which tends to be planar in the absence of constraining skeletal rigidity or steric interference. (It should be noted that sp-hybridized, linear oxocarbonium ions and vinyl cations also show substantial electron deficiency on carbon). The carbenium carbon center contains six valence electrons and is thus highly electron deficient. The structure of trivalent carbocations can always be adequately described by using only two-electron, two-center bonds (Lewis valence bond structures). CH_3^+ is the parent trivalent ion.

b) Pentacoordinated (or higher coordinated) "nonclassical" carbonium ions, which contain five (or more coordinated carbon atoms. They cannot be described by two-electron, two-center single bonds alone, but also necessitate the use of two-electron, three- (or multi-) center bonding. The carbocation center is always surrounded by eight electrons, but overall the carbonium ions are electron-deficient because two electrons are shared between three (or more) atoms. CH_5^+ can be considered the parent for carbonium ions.

Subsequently in 1977 Brown and Schleyer offered a related definition:[36c]

"A nonclassical carbonium ion is a positively charged species which cannot be represented adequately by a single Lewis structure. Such a cation contains one or more carbon or hydrogen bridges joining the two electron-deficient centers. The bridging atoms have coordination numbers higher than usual, typically five or more for carbon and two or more for hydrogen. Such ions contain two-electron, three- (or multiple-) center bonds including a carbon or hydrogen bridge."

Lewis's concept that a covalent chemical bond consists of a pair of electrons shared between the two atoms became a cornerstone of structural chemistry. Chemists tend to brand compounds as anomalous if their structures cannot be depicted in terms of such bonds alone. Carbocations with too few electrons to allow a pair for each "bond" came to be referred to as nonclassical, a name first used by J. D. Roberts[37] for the cyclopropylcarbinyl cation and adapted by Winstein to the norbornyl cation.[47] The name is still used even though it is now recognized that like other compounds, they adopt the structures appropriate for the number of electrons they contain with two-electron, two- or three- (even multi-) center bonding (not unlike the bonding principles for boron compounds established by Lipscomb, Nobel laureate, 1976). The terms classical and nonclassical are expected, however, to fade away gradually as the general nature of bonding becomes recognized.

Whereas the differentiation of trivalent carbenium, and pentacoordinated carbonium ions serves a useful purpose to define them as limiting ions, it should be clear that in carbocationic systems varying degrees of delocalization always exist. This can involve participation by neighboring n-donor atoms, π-donor groups, or σ-donor C–H or C–C bonds.

Carbocations

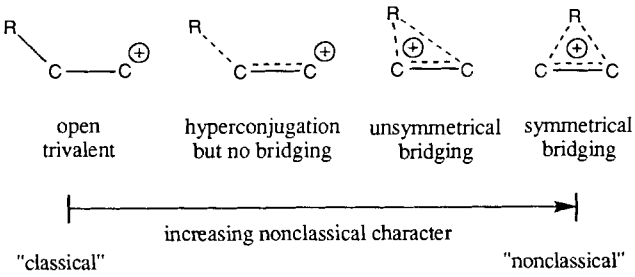
trivalent "classical" ions (carbenium ions) CH_3^+ is parent	pentacoordinated (or higher) "nonclassical" ions (carbonium ions) CH_5^+ is parent

Trivalent carbenium ions are the key intermediates in reactions of unsaturated π-donor hydrocarbons with electrophiles. At the same time pentacoordinated carbonium ions are the key to reactions of saturated σ-donor hydrocarbons with electrophiles. The ability of single bonds to act as electron donors lies in their ability to form carbonium ions by two-electron, three-center (2e–3c) bond formation.

Expansion of the carbon octet through 3d orbital participation does not seem possible; there can be only eight valence electrons in the outer shell of carbon, a small, first row element.[46] The valency of carbon cannot exceed four. Kekulé's concept of the tetravalency of carbon in bonding terms represents attachment of four atoms (or groups) involving 2e–2c Lewis-type bonding. There is, however, nothing that prevents carbon from also participating in multicenter bonding. Pentacoordination (or higher) of carbon implies five (or more) atoms or ligands simultaneously attached to it within reasonable bonding distance.[46]

Neighboring group participation with the vacant p orbital of a carbenium ion center contribute to its stabilization through

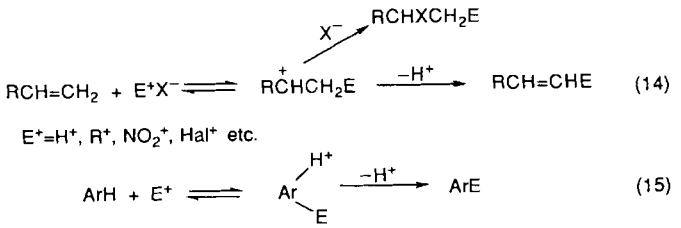
delocalization, which can involve atoms with unshared electron pairs (n-donors), π-electron systems (direct conjugative or allylic stabilization), bent σ-bonds (as in cyclopropylcarbinyl cations), and C–H and C–C σ-bond hyperconjugation. Trivalent carbenium ions, with the exception of the parent CH_3^+, therefore always show varying degrees of delocalization without becoming pentacoordinated carbonium ions. The limiting cases define the extremes of the spectrum of carbocations (Scheme 2).



Scheme 2.

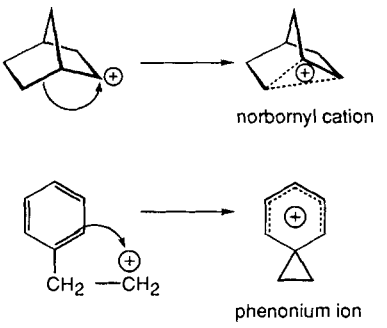
The Role of Carbocations in Electrophilic Reactions

Acid-catalyzed electrophilic reactions and transformations such as isomerization, alkylation, substitution, addition, elimination, rearrangements, etc. involve carbocationic intermediates. Many of these reactions also gained significance in industrial applications. Aromatic hydrocarbon chemistry and that based on acetylene laid the foundation for industrial organic chemistry a century ago. Subsequently olefin-based chemistry took on great significance. In all this chemistry reactive π-bonded systems are the electron donor substrates. In electrophilic reactions they readily form trivalent carbocationic intermediates [Eq. (14) and (15)].



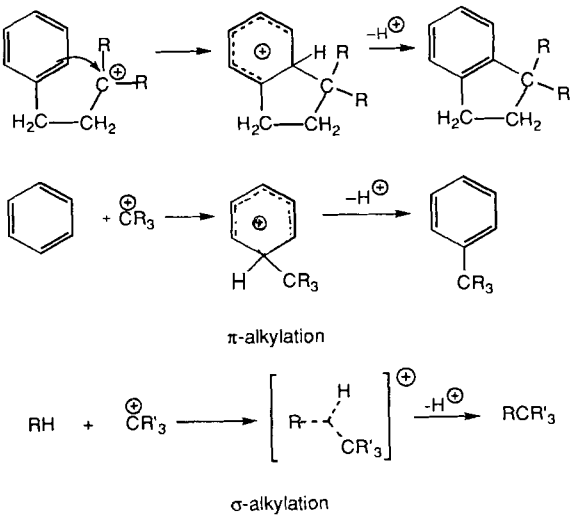
The discovery of pentacoordinate carbonium ions discussed previously led to the realization that they play an important role not only in understanding the structure of nonclassical ions, but more importantly as the key to electrophilic reactions at single bonds, for example, of saturated aliphatic hydrocarbons (alkanes and cycloalkanes). Such reactions include not only acid-catalyzed hydrocarbon isomerizations, fragmentations, cyclizations, but also substitutions and related electrophilic reactions and transformations.

In ionization of β-phenylethyl systems, neighboring π-orbital participation with the carbocationic center occurs, which can be considered as intramolecular π-alkylation giving Cram's phenonium ions. The corresponding ionization of 2-norbornyl systems involves participation of a properly oriented C–C single bond (that is, intramolecular σ-alkylation) giving the bridged ion (Scheme 3).



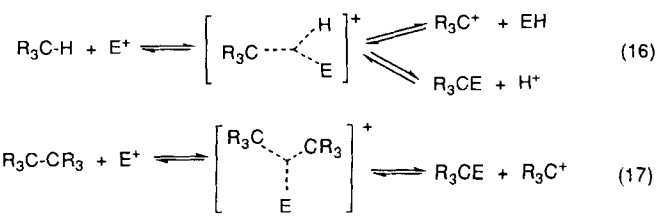
Scheme 3.

Alkylation of π systems in Friedel–Crafts type reactions (either by an inter- or intramolecular route) has long been widely known and well studied. To extend these relationships it was logical to ask why intermolecular alkylation (and other electrophilic reactions) of σ-donor hydrocarbons could not be affected (Scheme 4).



Scheme 4.

Our studies in the late sixties and early seventies for the first time provided evidence for the general reactivity of covalent C–H and C–C single bonds of alkanes and cycloalkanes in various protolytic processes as well as in hydrogen–deuterium exchange, alkylation, nitration, halogenation, etc. [Eq. (16) and (17)]. This reactivity is due to the σ-donor ability (σ basicity) of single bonds, which allows bonds to share their bonded electron pairs with an electron-deficient reagent in two-electron, three-center bond formation. The reactivity of single bonds thus stems from their ability to participate in the formation of pentacoordinate carbonium ions. Subsequent cleavage of the three-center



bond in a C H reaction results in formation of substitution products, whereas C–C reaction results in bond cleavage and formation of a fragment carbenium ion, which then can react further.

As bond-to-bond shifts can readily take place through the low barriers within five coordinate carbonium ions, the intermediates can be more complex but always involve interconverting carbonium ions.

Superacidic hydrocarbon chemistry under conditions favoring carbocationic intermediates is also gaining in significance in practical applications. Isomerization of alkanes at relatively low temperature, a much improved and environmentally adaptable alkylation, new approaches to the functionalization of methane and possibilities in its utilization as a building block for higher hydrocarbons and their derivatives, as well as moderate conditions for coal liquefaction are just a few examples to be mentioned here.[48]

Protosolvolytic Activation of Carbocationic Systems

Carbocations are electrophiles, that is, electron-deficient compounds. In electrophilic reactions of unsaturated, π-donor hydrocarbons and their derivatives (such as acetylenes, olefins, aromatics) the reaction with the electrophilic reagents is facilitated by the nucleophilic assistance of the substrates. In reactions with increasingly weaker (deactivated) π-donors and even more so with only weakly electron-donating saturated hydrocarbons (σ-donors), the electrophile itself must provide the driving force for the reactions. Hence the need for very strongly electron-demanding electrophiles and comparably low nucleophilicity reaction media (such as superacidic systems).

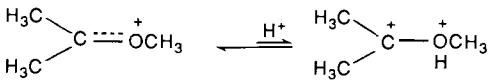
It was only more recently realized[49] that electrophiles capable of further interaction (coordination, solvation) with strong Brønsted or Lewis acids can be greatly activated. The resulting enhancement of reactivity can be very significant compared to that of the parent electrophiles under conventional conditions and indicates *superelectrophile* formation, that is, electrophiles with greatly enhanced electron deficiency (frequently of dipositive nature). I have reviewed[49] elsewhere the superelectrophilic activation of various electrophiles and will not discuss it here, except for some superelectrophilic activation which can also affect the reactivity of carbocations.

In carboxonium ions, originally studied by Meerwein, alkyl groups of an alkyl cation, such as the *tert*-butyl cation, are replaced by alkoxy, such as methoxy groups. The methoxy groups delocalize charge (by neighboring oxygen participation) and thus make these ions increasingly more stable:

$$(CH_3)_3C^+ < (CH_3)_2\overset{+}{C}OCH_3 < CH_3\overset{+}{C}(OCH_3)_2 < {}^+C(OCH_3)_3$$

At the same time their reactivity as carbon electrophiles decreases. For example, they do not alkylate aromatics or other hydrocarbons. Strong oxygen participation thus greatly diminishes the carbocationic nature.

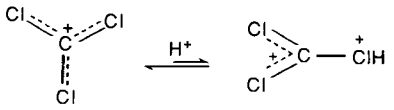
Neighboring oxygen participation, however, can be decreased if a strong acid protosolvates (or protonates) the nonbonded oxygen electron pairs [Eq. (18)]. Consequently, carboxonium ions (and related ions such as acyl cations) in superacidic media



(18)

show greatly enhanced carbon electrophilic reactivity indicative of dicationic nature.

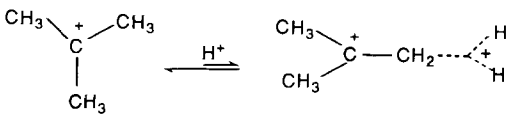
Similarly halogen-substituted carbocations, such as the trichloromethyl cation Cl_3C^+,[50] are greatly stabilized by n–p back donation (not unlike BCl_3). They can also be greatly activated by superacidic media, which protosolvate (protonate) the nonbonded halogen electron pairs, thus diminishing neighboring halogen participation [Eq. (19)].



(19)

This explains for example why carbon tetrachloride highly enhances the reactivity of protic superacids for alkane transformations. Lewis acids have similar activating effect.[49]

Alkyl cations themselves, in which only hyperconjugative C–H or C–C single bond interactions stabilize the electron-deficient center, are activated by superacidic solvation. Results of theoretical calculations and hydrogen–deuterium exchange of long-lived alkyl cations in deuterated superacids, under conditions where no deprotonation–reprotonation can take place substantiate the existence of these protoalkyl dications as real intermediates [Eq. (20)].[51]



(20)

The widely recognized high reactivity of alkanes for isomerization alkylation reactions in strongly acidic media is very probably assisted by protosolvation of the intermediate alkyl cations. Similar activation can be involved in other acid-catalyzed hydrocarbon transformations, which are preferentially carried out in solutions containing excess acid.

Activation by Solid Superacids and Possible Relevance to Enzymatic Systems

The chemistry of carbocations and their activation was discussed so far in superacidic solutions. However, superacidic systems are not limited to solution chemistry. Solid superacids, possessing both Brønsted and Lewis acid sites, are of increasing significance. They range from supported or intercalated systems, to highly acidic perfluorinated resinsulfonic acids (such as Nafion-H and its analogues) to certain zeolites (such as H-ZSM-5).

To explain why their remarkable activity, for example in catalytic transformations of alkanes (even methane), an appraisal of the de facto activity at the acid sites of such solid acids is called for.[49]

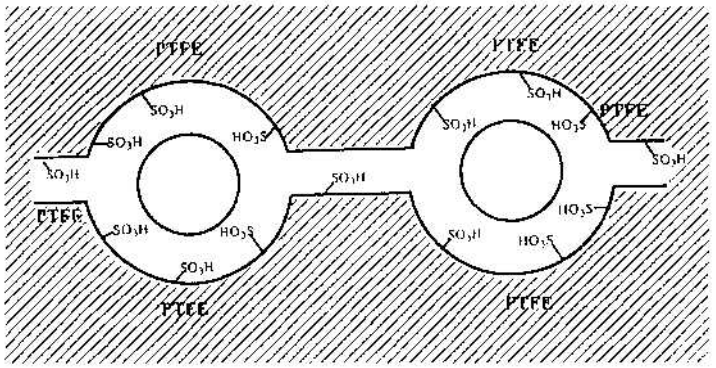


Fig. 5. Clustered SO_3H acid sites in a perfluorinated resinsulfonic acid.

Nafion-H is known to contain acidic SO_3H groups clustered together (Fig. 5).

H-ZSM-5, which also displays superacidic activity, was found by Haag et al.[52] to isomerize and alkylate alkanes readily (H_2 was observed as the protolytic by-product in stoichiometric amounts). In this zeolite, active Brønsted and Lewis acid sites are again in close proximity, approximately 2.5 Å apart (Fig. 6).

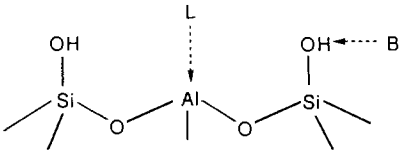

Fig. 6. Brønsted (B) and Lewis acid sites (L) in zeolites.

It is reasonable that in these (and other) solid superacid catalyst systems, bi- or multidentate interactions forming highly reactive intermediates is possible. This amounts to the solid-state equivalent of protosolvation (protonation).[49]

Nature is able to perform its own transformations in ways which chemists have only begun to understand and cannot yet come close to duplicating. At enzymatic sites many significant transformations take place which are acid-catalyzed (including electron-deficient metal-ion-catalyzed processes). Because of the unique structure at enzymatic sites bi- and multidentate interactions must be possible; the concepts discussed here thus may also have relevance to our understanding of some enzymatic processes.[49]

Conclusions

The chemistry of long-lived carbocations became a very active and fast developing field with contributions by researchers from all around the world. It is with understandable satisfaction that I look back at the progress achieved and the possibilities ahead. What started out as a for one of the most significant class of chemical reaction intermediates, the carbocations, as long-lived species and a study of their structure, led subsequently to the development of the general concept of the reactivity of single bonds, such as C–H and C–C bonds, with electrophiles and related superacidic hydrocarbon chemistry.

Despite all the progress that has been made I believe that most exciting chemistry in the field still lies ahead for future generations to explore. I wish them as much excitement and satisfaction in their work as I had.

The concept of the tetravalency of carbon stated by Kekulé well over a century ago remains an essential foundation of organic chemistry. Carbon, as a small first row element, cannot extend its valance shell, and the octet rule allows formation of only four two-electron, two-center (2e–2c) Lewis-type bonds (or their equivalent multiple bonds). It is, however, possible for one (or more) electron pair of carbon to be involved in two-electron, three-center (2e–3c) bonding.[46] This allows carbon to simultaneously bond five (or even six) atoms or groups. This is the case in carbonium ions which contain hypercarbon (hypercoordinate carbon). It also provides the key to understanding the rapidly emerging chemistry of saturated hydrocarbons with electrophiles, including that of the parent methane and of C–H and C–C bonds in general. Whereas hypercoordinate carbocations are 8e carbon systems that do not violate the octet rule, carbanionic S_N2 transition states $[Y\cdots CR_3\cdots X]^-$ are 10e systems and thus cannot be intermediates.

I wrote more than twenty years ago[9] "The realization of the electron donor ability of shared (bonded) electron pairs (single bonds) could one day rank equal in importance with G. N. Lewis' realization of the electron donor unshared (nonbonded) electron pairs (or for this reason I could add the electron pairs involved in multiple bonding). We can now not only explain the reactivity of saturated hydrocarbons and single bonds in general electrophilic reactions, but indeed use this understanding to explore new areas and reactions of carbocation chemistry." It is with some satisfaction that I feel this promise is being fulfilled.

I was fortunate to be able to build on the foundations laid by many. I would like to acknowledge particularly the fundamental contributions of Hans Meerwein (1879–1965) and Christopher Kelk Ingold (1893–1970), who recognized the role of carbocations in some chemical reactions, and Frank Whitmore (1887–1947), who generalized it to many others. I am also greatly indebted to all my former students and associates, whose dedication, hard work, and major scientific contributions made our joint effort possible. My wife Judy till her retirement was not only an integral part of our scientific effort. All those who ever worked in the Olah group appreciated greatly her warmth, caring, and concern for our "scientific family". In our 20 years of association from brilliant graduate student to trusted friend and colleague, G. K. Surya Prakash made invaluable contributions. The Loker Hydrocarbon Research Institute of the University of Southern California provided a wonderful home and support for our work in the last 15 years. The board of the Institute, particularly Mrs. Katherine Loker, Harold Moulton, and Carl Franklin are thanked for their support and friendship over the years. I also cherish close association with such wonderful colleagues and friends as Ned Arnett, Joseph Casanova, Paul Schleyer, Jean Sommer, Peter Stang, Ken Wade, and Robert Williams, who are senior distinguished fellows of the Loker Institute. The National Institutes of Health and the National Science Foundation gave support over the years to our studies of carbocations, and the Loker Institute mainly supported the work on hydrocarbon chemistry.

G Proteins and Regulation of Adenylate Cyclase (Nobel Lecture)**

Alfred G. Gilman*

Introduction

Earl Sutherland, a friend of my father, wrote to me in the spring of 1961 with a proposal to participate in what was then an educational adventure—a combined M.D.–Ph.D. training program that he had devised at Western Reserve University (now Case Western Reserve University) in Ohio. My reaction was entirely negative. I thanked him, politely I think, but the idea of spending seven years in Cleveland had little appeal. Happily, Sutherland was persistent. He wrote again in the fall of 1961 (the beginning of my last year in college), I decided the idea was worth a visit, and I had my first glimpse of cyclic AMP, for whose discovery, in 1957, Sutherland was later awarded the Nobel Prize (in 1971). Cyclic AMP, Sutherland, and the M.D.–Ph.D. Program all looked rather appealing. Thus, on my arrival in September, 1962, I was disappointed to learn that Sutherland was about to depart for Vanderbilt University. However, there was an attractive opportunity to work with Theodore Rall, Sutherland's younger collaborator, who had played a pivotal role in the crucial experiments of 1957. I entered the Rall lab, and in over 30 subsequent years have never escaped the lure of cyclic nucleotide research, despite occasional attempts to try. The most determined of these efforts came with my choice of Marshall Nirenberg's newly proclaimed neurobiology laboratory for postdoctoral training. However, in our first conversation after my arrival at the National Institutes of Health in Bethesda, Marshall asked me to establish an assay for cyclic AMP in his laboratory. I was trapped again, but I didn't fight back very vigorously.

Rall and Sutherland's discovery of cyclic AMP and adenylate cyclase (or adenylyl cyclase), the hormone-sensitive enzyme that synthesizes the cyclic nucleotide from ATP, gave birth to the concepts of transmembrane signaling and of hormone-regulated synthesis of intracellular second messengers (Fig. 1). Both men were trained as biochemists (Sutherland with Carl Cori, Rall with Albert Lehninger), and together they initiated a classical reductionistic approach to deciphering hormone action. In the 1950s, hormones could almost be defined as regulatory molecules that would act only on intact cells. Sutherland and Rall's

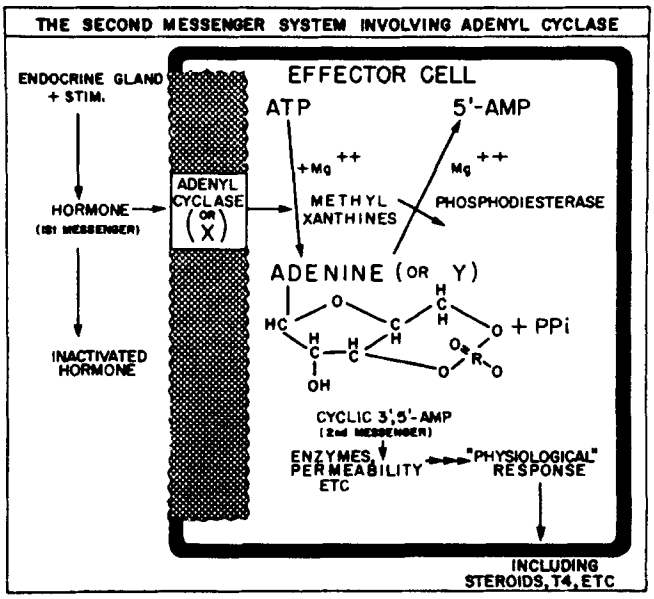

Fig. 1. An early pictorial formulation of Sutherland's second messenger concept.

coup was to assemble a system in which a characteristic effect of epinephrine and glucagon (activation of phosphorylase) could be observed in homogenates and then to dissect the system into its major components—hormone-stimulated synthesis of a factor, cyclic AMP, by the particulate fraction and subsequent action of the factor in the cytosol to activate phosphorylase.[1] An assay (albeit torturous) for adenylate cyclase was in hand, and hormone action could then be studied by adding ATP to plasma membranes.

Although the concept of receptors for endogenous regulatory molecules and drugs arose with the pharmacological experiments of Langley and Ehrlich in the late nineteenth and early twentieth centuries, the word evoked only metaphysical associations in many at the time of the discovery of cyclic AMP. The term receptor does not appear in the index of the 1955 edition of *The Pharmacological Basis of Therapeutics*, the standard textbook of pharmacology, but the following sentence is there: "Years ago, Langley named the differentiating substance the 'receptive substance'; this term is still widely employed, but it must be realized that the 'receptor' may not be a morphologically demonstrable structure." Rall and Sutherland's experiments provided test-tube assays for receptors, and the assays demonstrated that the receptors were authentic. The effects of epinephrine and congeners on adenylate cyclase were shown to

conform to Ahlquist's new conceptualization of β-adrenergic receptors (as distinguished from α receptors), and the effects were blocked with the first, newly discovered β-adrenergic antagonist.[2] Biochemical approaches to receptors were thus born, and the question arose of the relationship of the β-adrenergic receptor to adenylate cyclase. Could the enzyme be the receptor? Perhaps, but this model would demand the existence of a family of adenylate cyclases with distinct regulatory sites, because regulation of the enzyme was shown not to be restricted to epinephrine and glucagon; adrenocorticotropic hormone (ACTH), thyrotropin (TSH), lutinizing hormone (LH), alcohol dehydrogenase (ADH), and other stimulators were soon in evidence, as was inhibition of adenylate cyclase activity by cholinergic agonists.[3]

Over a decade after the discovery of adenylate cyclase, Martin Rodbell and colleagues provided reasonably compelling, although indirect, evidence that receptors and adenylate cyclases were distinct molecular entities. The adenylate cyclase of adipocytes is stimulated by a myriad of hormones. If there were distinct cyclases that each also served as a receptor, responses to maximally effective concentrations of hormones would be additive. They were not, implying that distinct receptors could interact with a common pool of adenylate cyclase.[4] The issue was resolved definitively in the 1970s with the advent of ligand binding assays for receptors. Receptors could finally be examined by methods that did not rely on detection of a functional response. It was then possible to solubilize and resolve adenylate cyclases from β-adrenergic receptors, proving that they were distinct macromolecules[5, 6]

Early Times for G Proteins

The question of the moment thus became the mechanism of interaction or "coupling" between receptors and adenylate cyclase. The relatively simple notion that an agonist–receptor complex could act as an allosteric regulator of the enzyme was also challenged by Rodbell, who first promulgated the notion of a "transducer" acting as an intermediary between receptors and adenylate cyclase.[7] Although this notion was at first based predominantly on excellent instinct and the lipid bilayer was named as a candidate transducer, supportive data for something more specific were soon forthcoming. Rodbell, Birnbaumer, and their colleagues made the surprising discovery that one regulatory ligand (the receptor agonist) was not sufficient to activate adenylate cyclase. A hormone could not activate the enzyme unless guanosine triphosphate (GTP) was also present.[8] This crucial observation had been missed for over a decade because of contamination of both membrane preparations and substrate ATP with sufficient (μM) concentrations of GTP to meet the requirement. It was subsequently determined that hormonal inhibition of adenylate cyclase activity was similarly dependent on GTP.[9] I will leave it to Rodbell to describe these observations in more detail.[*] However, it should be noted that there was considerable skepticism about the significance of the findings (Fig. 2), in part generated by difficulties in reproduction of the result; most biochemists were not working with the very nice membrane preparations available in the Rodbell laboratory.

Fig. 2. A cartoon from the 1970s, drawn by Dr. Pierre DeMeytes, suggested that not all investigators could readily observe the requirement for GTP in transmembrane signaling. (Printed with permission from Dr. DeMeytes.)

Several observations of the mid-1970s spoke to the undeniable importance of GTP in regulation of hormone-sensitive adenylate cyclase activity. Most significantly, Cassel and Selinger detected a hormone-stimulated GTPase activity that appeared to be associated with activation of adenylate cyclase, and, despite enormous technical difficulties, they correctly deduced (from kinetic analysis) the significance of the GTPase in terminating a hormonally mediated signal.[10] Consistent with

[*] See the following Nobel Lecture by M. Rodbell.

Alfred G. Gilman was born in New Haven, CT (USA) in 1941. He received his B.S. in biochemistry from Yale University in 1962 and his M.D./Ph.D. in pharmacology in 1969 from Case Western Reserve University in Cleveland, OH. He completed his postdoctoral training in the Laboratory of Biochemical Genetics at the National Institutes of Health in Bethesda, MD. In 1971 Gilman moved to the Department of Pharmacology at the University of Virgina, where he rose through the ranks (Assistant Professor 1971–1973, Associate Professor 1973–1977, Professor 1977–1981). Since 1981 he has been Chairman of Pharmacology at the University of Texas Southwestern Medical Center at Dallas. Gilman discovered, characterized, and purified a set of guanine nucleotide binding regulatory proteins (G proteins). His observations provided a firm molecular basis for understanding certain signal transduction processes present throughout nature. He has received a number of honors and awards for this work including the 1994 Nobel Prize for Medicine and Physiology.

these thoughts, Londos and Schramm and co-workers had noted that nonhydrolyzable analogs of GTP, such as Gpp(NH)p, activated adenylate cyclase dramatically and without the need for hormone.[11, 12] Michael Maguire, my first postdoctoral fellow, discovered that GTP decreased the affinity of receptors selectively for agonists, but not for antagonists.[13] The interpretation of this counterintuitive observation was not clear, but it surely appeared to be significant.

Throughout this time a few brave souls had attempted to solubilize and purify components of hormone-sensitive adenylate cyclase systems. All encountered great difficulties. Hormonal responsiveness was quickly lost on solubilization with detergents, and adenylate cyclase itself appeared to be remarkably labile. Eva Neer was perhaps the first to treat the enzyme as an approachable biochemical object, with a careful exploration of its hydrodynamic properties.[14] Despite this, a conventional biochemical approach to the system looked difficult indeed.

The turning point, for us, started with the description by Daniel et al. of the cytocidal effect of cyclic AMP on clonal S49 lymphoma cells.[15] Bourne and associates were soon able to isolate a variant (cyc$^-$) of these cells that appeared to lack adenylate cyclase,[16] despite continued expression of a normal number of β-adrenergic receptors.[17] We were able to select another S49 cell variant that intrigued us even more—an uncoupled (UNC) mutant that appeared to have normal receptors and adenylate cyclase but that failed to generate a cyclic AMP signal in response to appropriate hormones (β-adrenergic agonists or prostaglandins).[18] The availability of these genetic variants made the biochemistry appear more approachable, particularly to Elliott Ross, an extremely talented and well-trained membrane biochemist who joined my lab in 1975. Ross sought to reconstitute the cyc$^-$ mutant in vitro, first by extracting adenylate cyclase from cells that lacked β-adrenergic receptors and then by somehow coaxing the protein back into fruitful interactions with the receptors present in cyc$^-$ membranes. The experiment eventually worked; cyc$^-$ membranes were reconstituted to display catecholamine-sensitive adenylate cyclase activity.[19] We were pleased that we had taken the first step in resolution and reconstitution of the system, but we had little idea how quickly the investment would pay dividends. The reconstitution had not worked for the anticipated reasons. When we inactivated the adenylate cyclase in the detergent extract used for the reconstitution, we still observed undiminished levels of hormone-stimulated adenylate cyclase activity. That is, addition of a detergent extract devoid of adenylate cyclase activity to receptor-containing cyc$^-$ membranes (which also had no adenylate cyclase activity) led to restoration of the complete response (Fig. 3). Treatments with proteases quickly revealed that both the detergent extract and the cyc$^-$ membranes contained proteins that were necessary for observation of *any* adenylate cyclase activity—basal or that stimulated by hormones, fluoride, or guanine nucleotides. (We now know that the specific isoforms of adenylate cyclase that predominate in S49 cells have notably low basal activity.) Thus two proteins were required—the catalyst or adenylate cyclase itself, which in fact was present in so-called cyc$^-$ membranes, and a stimulatory protein, deficient in cyc$^-$ membranes, that had survived the mild conditions used to inactivate adenylate cyclase in the extract used for reconstitution. We proposed that the role of the hormone receptor

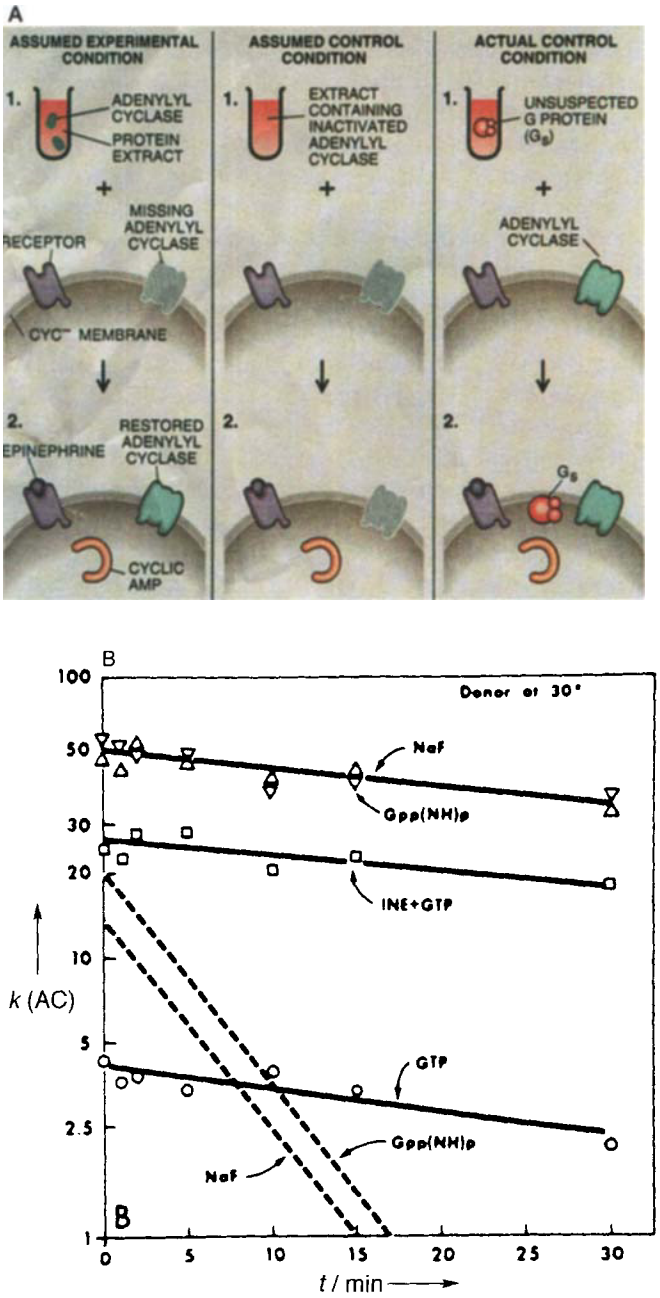

Fig. 3. Experiments leading to the discovery of G_s. A) Cartoon of the protocols. Left: 1. In the first experiments, Elliott M. Ross added a detergent extract of membrane proteins to so-called cyc$^-$ membranes, which were thought to lack adenylate cyclase. 2. Epinephrine stimulated cyclic AMP production, which seemed to indicate that adenylate cyclase had been inserted into the deficient membranes. Middle: In the control experiment, the adenylate cyclase in the extract was inactivated. Even without it, epinephrine caused the cyc$^-$ membranes to make cyclic AMP. Right: 1. This puzzling finding led to the discovery that the cyc$^-$ membranes did contain adenylate cyclase but lacked a third component necessary to activate it—a G protein that persisted in the extract after adenylate cyclase had been inactivated. Restoration of the G protein to the membranes enabled adenylate cyclase to synthesize cyclic AMP. (Reprinted with permission from ref. [154].) B) Data from these experiments. Reconstitution of hormone-sensitive adenylate cyclase by mixture of cyc$^-$ membranes with heat-inactivated wild-type membrane extracts. Detergent extracts of wild-type membranes were heated at 30 °C for the times indicated on the abscissa, chilled, and mixed with cyc$^-$ membranes. The NaF- and Gpp(NH)p-stimulated adenylate cyclase activities, k(AC) [pmol min^{-1} mL^{-1}] of the incubated extracts are shown by the dashed lines. Aliquots of the reconstituted mixtures, prepared with these incubated extracts, were assayed with GTP, isoproterenol (a congener of epinephrine) plus GTP, NaF, or Gpp(NH)p, as indicated. (Reprinted with permission from ref. [21].)

was to regulate the interaction between these two components.[20, 21] Coincidentally, Pfeuffer achieved partial resolution between adenylate cyclase and an activating protein that bound selectively to a guanine nucleotide based affinity resin.[22]

The novel protein became the object of our attentions, in part because of its more mysterious nature and in part because it was not as labile as adenylate cyclase. Additional experiments by Ross implied that the protein (at the time termed G/F, but eventually named G_s) was the site of action of guanine nucleotides (and fluoride),[21] and these hypotheses were strengthened by hydrodynamic characterization of the activity by Allyn Howlett; she detected Gpp(NH)p- and fluoride-induced alterations suggestive of subunit dissociation upon activation by these ligands.[23] The really hard work fell to Paul Sternweis and John Northup, who together undertook the task of purification. The good luck of G_s was its revelation by mutation in S49 cells and the existence of an easy assay for the protein by activation of adenylate cyclase. The bad luck, unknown at the time, was that G_s is among the least abundant of the G proteins. Nevertheless, perseverance (by all involved) and skill (by those doing the experiments) paid off, and G_s, with its unsuspected 35-kDa β subunit, finally emerged as a homogeneous guanine nucleotide binding protein, capable of activating adenylate cyclase in its Gpp(NH)p- or fluoride-activated forms (Fig. 4).[24, 25] The third, 8-kDa (γ) subunit went unnoticed at the time.

Further studies of G_s performed shortly thereafter revealed that one equivalent of guanine nucleotide bound to the α subunit of the oligomer, that activation by Gpp(NH)p or fluoride was in fact accompanied by subunit dissociation, and that the resolved Gpp(NH)p-bound α subunit was necessary and sufficient for activation of adenylate cyclase (Fig. 5).[26, 27] Additional work on the mechanism of activation of G_s by fluoride provided surprises and even amusement. The effect of fluoride, observable when experiments were performed in glass test tubes

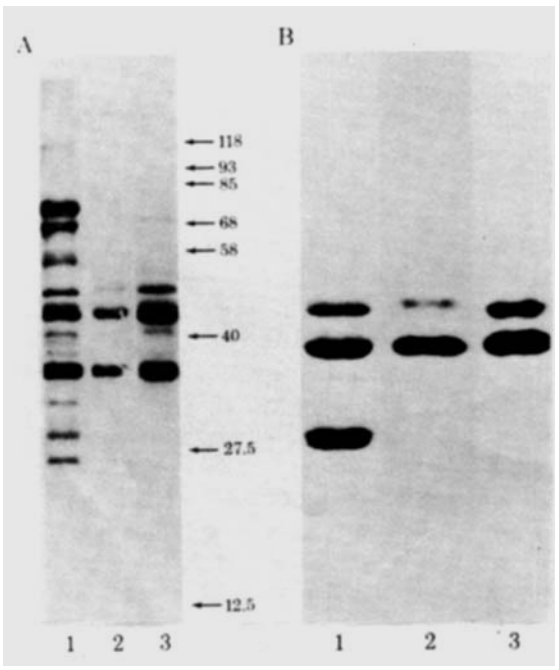

Fig. 4. A) Polyacrylamide gel electrophoresis of purified fractions of G_s. Lane 1: Protein from an intermediate step of purification. Lanes 2 and 3: Purified protein, 3 µg and 8 µg, respectively. B) Labeling of purified G_s with cholera toxin and [^{32}P]NAD. Lane 1: Purified protein stained with Coomassie blue. Lanes 2 and 3: Autoradiograms of the cholera toxin labeled protein, exposed for 16 and 48 h, respectively. The two higher molecular weight bands in the purified preparation, both of which are labeled with cholera toxin, are alternatively spliced forms of $G_{s\alpha}$. The lower molecular weight band is the β subunit. (Reprinted with permission from ref. [24].)

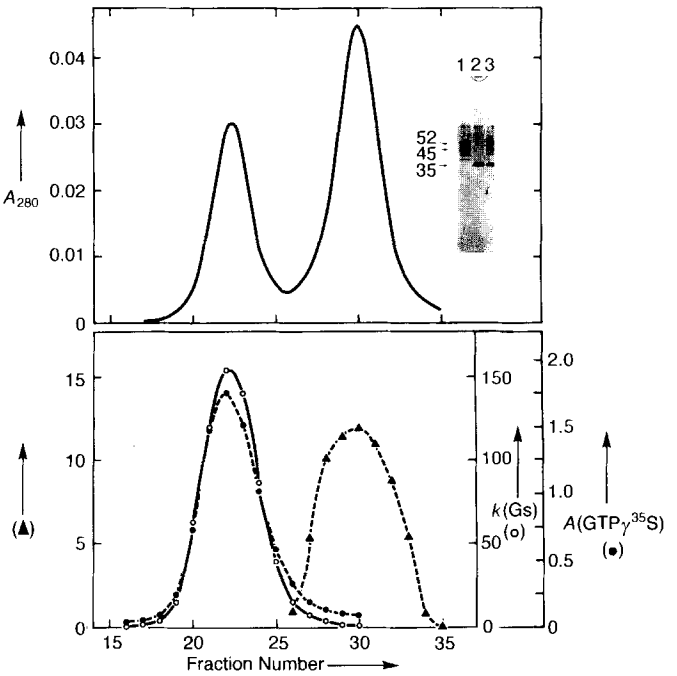

Fig. 5. Separation of the subunits of G_s by gel filtration. Purified G_s was labeled by incubation with [^{35}S]GTPγS. After removal of free nucleotide, the protein was subjected to high-performance gel filtration. The top panel shows the absorbance A (280 nm) of the eluted protein. The inset shows the silver staining pattern for sodium dodecylsulfate/polyacrylamide gel electrophoresis of the pooled peaks of protein (lane 1 = first peak, lane 2 = second peak) and of the protein applied (lane 3). The lower panel shows the activities assayed. G_s activity, $k(G_s)$ [nmol min^{-1}] (o), is quantified by activation of adenylate cyclase. The radioactivity A (GTPγ^{35}S) [10^6 counts min^{-1} mL^{-1}] (•) indicates high-affinity binding of the radioactive nucleotide. 35 K Activity A (35 K) at 14 min $- t_{1/2}$ (▲) is a measure of the activity of the $\beta\gamma$ subunit complex. Nucleotide binding activity and the capacity to activate adenylate cyclase were exclusively associated with the resolved α subunit of G_s, which dissociated from $\beta\gamma$ on activation with GTPγS. (Reprinted with permission from ref. [27].)

or in the presence of components of the adenylate cyclase assay (i.e. ATP), was lost in the absence of ATP when experiments were done in plastic test tubes.[28, 29] Another mystery factor was skillfully pursued by Paul Sternweis, who purified the coactivator from both ATP and from aqueous extracts of disposable glass test tubes. A metal seemed to be involved, and neutron-activation analysis revealed Al^{3+} as the culprit.[29] The significance and value of that observation has become particularly apparent a decade later.

An interesting side activity at this time was study of the ADP-ribosylation of G_s by cholera toxin. That this occurred was very strongly implied by the work of Gill,[30] Vaughan,[31] and Bourne,[32] and was proven with purification of the protein. However, as purification proceeded, the capacity of cholera toxin to ADP-ribosylate G_s was lost. This could be restored by addition of a protein factor[33] that was eventually purified, named ADP-ribosylation factor or ARF, and found to be a low-molecular-weight GTP binding protein.[34, 35] ARF is, of course, now leading a happy existence as an important regulator

of protein trafficking[36] and as an activator of phospholipase D.[37] Its association with cholera toxin and/or G_s remains to be explained.

Work in Japan in the late 1970s and early 1980s by Michio Ui and his colleagues resulted in characterization of islet-activating protein (IAP), a toxin from *Bordetella pertussis*. Treatment of cells or membranes with this toxin resulted in loss of hormonal inhibition of adenylate cyclase (and in some cases enhancement of hormonal stimulation of the enzyme).[38] Coincidentally, the toxin appeared to catalyze the incorporation of the ADP-ribosyl moiety of NAD into a 41-kDa membrane protein.[39] The parallel with cholera toxin was remarkable. Toshiaki Katada, Professor Ui's student, applied for a postdoctoral position in my lab and was quickly accepted. As Gary Bokoch, another newly arrived postdoc, and Katada began to work with Professor Ui's toxin, John Northup realized that he had frequently been plagued with a 41-kDa contaminant during purification of G_s. He even had fractions in the freezer that were enriched in this contaminant. Moral: never throw anything away! (This contaminant can be seen in Fig. 4). The obvious experiment worked beautifully on the first try; Northup's contaminant was a superb substrate for ADP-ribosylation by IAP. Our relatively tortuous experience with the purification of G_s then paid off, and purification of the true IAP substrate proceeded quickly,[40] aided by the fact that it is substantially more abundant than G_s. The hypothesis that the IAP substrate represented G_i, a homologous G protein responsible for inhibition of adenylate cyclase, was obvious, and its validity was established a year later with thorough characterization of G_i.[41-44] Nevertheless, the actual mechanisms (plural intended) of inhibition of adenylate cyclase by G_i remained elusive.

Throughout much of this time, Bitensky, who had detected a light-activated cyclic GMP phosphodiesterase in the retina,[45] called attention to parallels between the visual transduction pathway and hormone-sensitive adenylate cyclases. Particularly notable were descriptions of a light-activated GTPase[46] and a guanine nucleotide requirement for activation of the phosphodiesterase. These observations led to purification of transducin (G_t)[47,48] and appreciation that G_s, G_i, and G_t represented a family of structurally homologous guanine nucleotide binding proteins with related α subunits and very similar (or identical) β subunits[49] (Fig. 6). The existence of the γ subunit of the transducin heterotrimer was recognized early because of its great abundance. Poor avidity for stain delayed its recognition as a component of G_s and G_i.[41,50]

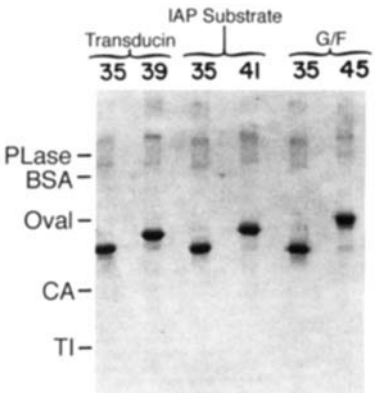

Fig. 6. Electrophoretic profile of the purified subunits of transducin (G_t), the IAP substrate (G_i), and G/F (G_s). The α subunits of the three G proteins have different molecular weights, while the β subunits appeared to be the same. Peptide mapping and analysis of amino acid compositions of the subunits indicated that the α subunits were distinct but related, while the β subunits were very similar or identical. PLase = pig liver esterase, BSA = bovine serum albumin, Oval = ovalbumin, CA = carboanhydrase, TI = soybean trypsin inhibitor. (Reprinted from ref. [49].)

For a brief period of time in the early 1980s it seemed that things might calm down. Guanine nucleotide mediated stimulation and inhibition of adenylate cyclase was in the hands of G_s and G_i, while transducin explained the observations in the visual system. In collaboration with Ross, we were able to observe hormonal stimulation of adenylate cyclase using three purified proteins—the β-adrenergic receptor, G_s, and adenylate cyclase—reconstituted into phospholipid vesicles.[51] What more was there? Major clues came quickly. Paul Sternweis,[52] now independently, and Eva Neer[53] discovered G_o as a startlingly abundant protein in brain; Fain[54] and Gomperts[55] observed hormone- and GTP-dependent stimulation of inositol trisphosphate synthesis; amino acid sequence homologies were detected between signal-transducing G proteins and the $p21^{ras}$ gene products;[56] and the cloners arrived.[57,58] It was clearly time to add some new technology to the repertoire and welcome many new people to the party.

G Proteins from Pheromones to Photons

It now seems appropriate to abandon the historical, storytelling approach and attempt to describe the current level of understanding of G protein mediated transmembrane signaling. It has become abundantly clear, particularly over the past decade, that this relatively large family of heterotrimeric GTP-binding and -hydrolyzing proteins plays an essential transducing role in linking hundreds of cell surface receptors to effector proteins at the plasma membrane. These systems are widely utilized in nature, controlling processes ranging from mating in yeast to cognition in man. Receptors that activate G proteins are correspondingly diverse and encompass proteins that interact with hormones, neurotransmitters, autacoids, odorants, tastants, pheromones, and photons. Several reviews of this area are recommended[59-70] and should also be consulted for references to the original literature.

Overview of G Protein Function and Structure

Although G proteins are structural heterotrimers, they function as dissociable dimers. The β and γ subunits exist as tightly associated complexes that function as a unit. The identity of the α subunit is currently used to define a given G protein oligomer. Although a number of different $\beta\gamma$ subunit complexes can apparently associate fruitfully and promiscuously with a variety of α subunits, it is unknown to what extent this occurs in vivo.

Sixteen distinct genes encode G protein α subunits in mammals; 20 or more proteins are synthesized, including the products that arise as a result of alternative splicing of mRNA. The commonly recognized subclassification of the α subunit family is based on structural relationships, but this scheme does reasonable justice to functional relationships as well[66] (Fig. 7). Four subfamilies are usually discussed: 1) the small G_s group (G_s and G_{olf}), best recognized as activators of adenylate cyclases; 2) the large and functionally diverse G_i group, whose members are pertussis toxin substrates with one exception (G_z); 3) the G_q group, activators of the several isoforms of phospholipase Cβ; and 4) the most recently recognized G_{12} group, whose

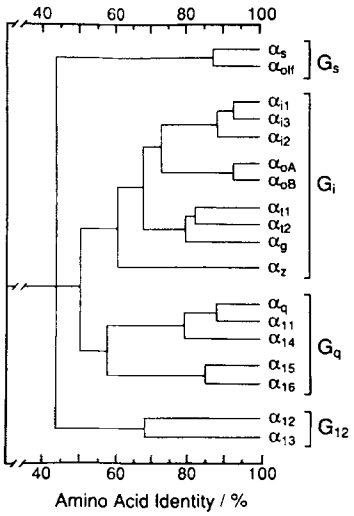

Fig. 7. Sequence relationships between α subunits of mammalian G proteins and family groupings. (Modified with permission from refs. [65, 66].)

functions are unknown. There are five known genes encoding β subunits and six for γ subunits. If all possible combinations of α, β, and γ subunits were allowed, we would need to consider at least 600 G protein oligomers. Although some combinations of β and γ subunits appear to be forbidden and there are some preferences of α subunits for specific $\beta\gamma$ dimers, the number is still likely to be very large.

Each G protein α subunit has a single high-affinity binding site for guanine nucleotide. The GDP-bound form of α is relatively inactive and has high affinity for $\beta\gamma$. Thus, GDP-$\alpha\beta\gamma$ constitutes the inactive oligomer. Receptor-catalyzed guanine nucleotide exchange results in formation of GTP-α, and resultant conformational changes cause dissociation of α from $\beta\gamma$ (see Fig. 8). Two regulators of downstream effectors, GTP-α and $\beta\gamma$, are thus liberated. G protein α subunits are themselves enzymes, albeit poor ones, with intrinsic GTPase activity. After a period of time characteristic of individual α subunits, GTP is hydrolyzed to GDP, subunits associate, and the basal state is restored. G proteins thus function as switches and timers. The high affinity of α (and particularly of the oligomer) for GDP holds the switch off; nucleotide exchange turns the switch on; hydrolysis of GTP turns it off again with a characteristic delay (seconds to perhaps minutes) as a result of slow catalysis; this constitutes the timer, which is an important element of signal amplification.

G protein subunits are subjected to a number of covalent modifications, both physiologically and pathologically. Lipid covalent modifications are particularly evident. Members of the G_i subfamily are myristoylated, with the C14 fatty acid incorporated in amide linkage to amino-terminal glycine residues.[71-73] This modification is an important determinant of the affinity of these α subunits for $\beta\gamma$ and of the affinity of the $G_{i\alpha}$ proteins for adenylate cyclase (see below).[74, 75] All α subunits with the exception of $G_{t\alpha}$ are palmitoylated, in some cases doubly so, and the C16 fatty acid is bound in thioester linkage to cysteine residues near the amino terminus.[76] In the case of members of the G_i family, the palmitoylated cysteine residue is immediately adjacent to the myristoylated glycine. While myristoylation presumably occurs cotranslationally and the modification is irreversible, palmitate is incorporated post-translationally and the bound fatty acid turns over relatively rapidly. Of particular interest, turnover of palmitate is a receptor-regulated phenomenon, with control apparently exerted at the level of removal of palmitate from the α subunit.[77, 78] The significance of this phenomenon is not yet fully appreciated, but it could represent part of a pathway for attenuation of transmembrane signaling. Finally, for the lipids, γ subunits contain typical CAAX boxes at their carboxyl termini and are prenylated; the γ_1 subunit, found in the retina, is farnesylated,[79] while the other γ subunits appear to be geranylgeranylated.[80, 81] Although prenylation is not essential for the formation of high-affinity $\beta\gamma$ dimers, it is crucial for the interactions of $\beta\gamma$ with α and with at least certain effectors (e.g. adenylate cyclases).[82] All of the lipid modifications may play important roles in localization of G protein subunits to membranes, although the mechanisms that dictate the specificities of these protein–membrane interactions remain to be discovered. We suspect that $G_{s\alpha}$ contains an as yet unidentified covalent modification. The natural protein (purified from liver or brain) has a substantially higher affinity for adenylate cyclase than does recombinant $G_{s\alpha}$ synthesized in bacteria.[83]

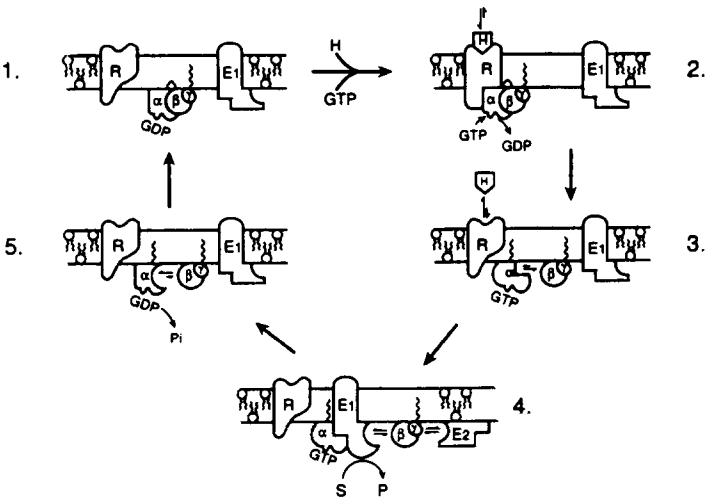

Fig. 8. G protein mediated transmembrane signaling. 1) In the basal state G proteins exist as heterotrimers with GDP bound tightly to the α subunit. The hormone receptor R is unoccupied, and the effector E is unregulated. 2) Upon binding of hormone H and receptor activation, the receptor interacts with the heterotrimer to promote a conformational change and dissociation of GDP from the guanine nucleotide binding site; at normal cellular concentrations of guanine nucleotides, GTP fills the site immediately. (Under experimental conditions where GTP is absent, the hormone has high affinity for the receptor and the H–R–G complex is stable.) 3) Binding of GTP to G_α induces a conformational change with two consequences. First, the G protein dissociates from the H–R complex, reducing the affinity of hormone for receptor and, in turn, freeing the receptor for another liaison with a neighboring quiescent G protein. Second, GTP binding also reduces the affinity of G_α for $G_{\beta\gamma}$, and subunit dissociation occurs. 4) This frees G_α–GTP to fulfill its primary role as a regulator of effectors and activate the enzymatic transformation of substrate S into product P. At least in some systems, the free $G_{\beta\gamma}$ complex also interacts directly with effectors (E_1) and modulates the activity of the active complex, or it acts independently at distinct effectors (E_2). 5) G_α possesses an intrinsic GTPase activity. The rate of this GTPase determines the lifetime of the active species and the associated physiological response. The G_α-catalyzed hydrolysis of GTP leaves GDP in the binding site and causes dissociation and deactivation of the active complex G_α–E_1. G_α–GDP has high affinity for $G_{\beta\gamma}$; subsequent reassociation of G_α–GDP with $G_{\beta\gamma}$ returns the system to the basal state (a). (Reprinted with permission from ref. [68].)

ADP-ribosylation of G protein α subunits by bacterial toxins is a particularly interesting, irreversible covalent modification of pathological significance. The diarrheagenic enterotoxin produced by *Vibrio cholerae* and the heat-labile toxin synthesized by certain strains of *E. coli* are ADP-ribosyltransferases with great specificity for $G_{s\alpha}$. NAD is the donor of the ADP-ribosyl moiety, which is attached to an active site arginine residue of the substrate.[84] The resultant inhibition of the GTPase activity of $G_{s\alpha}$ causes persistent activation of both $G_{s\alpha}$ and adenylate cyclase. Diarrhea is the dominant sign of disease because of the

local, enteric nature of the infection. A toxin (islet-activating protein) produced by *Bordetella pertussis* catalyzes ADP-ribosylation of a cysteine residue near the carboxyl-terminus of members of the G_i family of α subunits.[85] This results in inhibition of interactions between G proteins and receptors, effectively blocking the affected pathways, including those that cause inhibition of adenylate cyclase. As a sidelight, it is interesting to note that other microorganisms have developed different strategies for elevation of host cell concentrations of cyclic AMP. A toxin elaborated by *Bacillus anthacis* and a distinct *Bordetella pertussis* toxin are themselves calmodulin-activated adenylate cyclases that permeate mammalian cells.

High-resolution crystal structures of two G protein α subunits, $G_{t\alpha}$ and $G_{i\alpha 1}$, in different liganded states have been described recently.[86-88] We have been pleased to collaborate with Stephen Sprang in these efforts. The general architecture of these closely related proteins is essentially identical (Fig. 9).

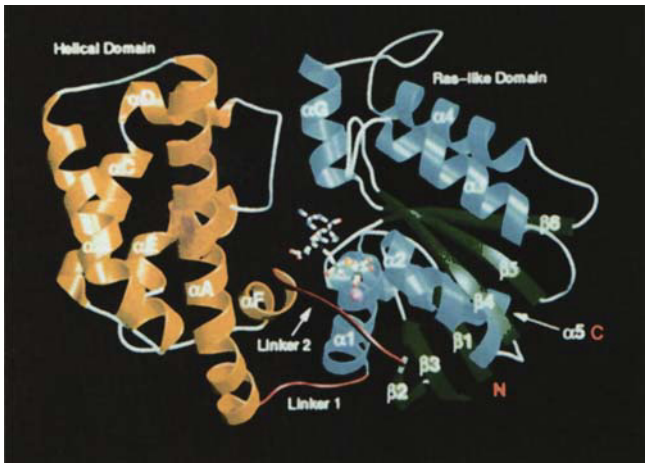

Fig. 9. Ribbon and coil representation of $G_{i\alpha 1}$ subunit. The helical domain is colored yellow, and the $p21^{ras}$-like domain is green and cyan. Linker-1 and linker-2 strands are colored red. The GTPγS is shown as a ball-and-stick model, and the magnesium ion is depicted as a magenta sphere. Secondary structure elements are labeled. The red letters N and C mark the positions of the first ordered residues at the N and C termini of the molecule. (Reprinted with permission from ref. [88].)

Each is constructed of two very distinct domains: a $p21^{ras}$-like $\alpha\beta$ domain that is flanked by a unique (to G proteins) α-helical domain. The two structures are connected by a pair of linker strands. Although all of the direct contacts between the protein and guanine nucleotide are formed with either the $p21^{ras}$-like domain or the linker-2 peptide, the nucleotide is virtually buried in the cleft between the two major domains. It is hypothesized that receptor-mediated conformational changes sufficient to permit guanine nucleotide exchange result in substantial separation of the helical and $p21^{ras}$-like structures.

Despite the existence of several superb crystal structures of $p21^{ras}$ proteins and of GTPase-deficient mutants of $p21^{ras}$, it has been difficult to deduce the mechanism of GTP hydrolysis, perhaps in large part because the proteins are such poor catalysts in the absence of activators (GTPase activating proteins or GAPS). The same is true of the structures of the GTPγS-bound forms of $G_{t\alpha}$ and $G_{i\alpha 1}$. Happily, however, the AlF_4^--bound conformations of these proteins are more illuminating. As noted above, Al^{3+} was unexpectedly found to be a cofactor necessary for activation of G proteins by F^-, and it had been deduced that AlF_4^- probably binds to G_α proteins in proximity to GDP, mimicking the γ-phosphoryl moiety of GTP.[29, 89, 90] The X-ray structure revealed this hypothesis to be nearly correct.[88] However, rather than simply mimicking GTP, GDP–AlF_4^- appears to be acting as a transition state analog, revealing critical roles played by active-site amino acid residues.

Two residues, Arg^{178} ($G_{i\alpha 1}$ numbering) and Gln^{204}, had been implicated in catalysis as the result of isolation or construction of GTPase-deficient proteins with mutations at these sites.[91-94] In addition, this Arg residue corresponds to the Arg in $G_{s\alpha}$ that is ADP-ribosylated by cholera toxin, and the Gln corresponds to Gln^{61} in $p21^{ras}$, a residue known to be critical for catalysis. (There is no homolog of Arg^{178} in $p21^{ras}$; Arg^{178} is in the linker-2 peptide.) Rearrangement of the positions of these two residues in the GDP–AlF_4^- structure (relative to their positions in the GTPγS-bound protein) reveals their roles in catalysis (Fig. 10). Gln^{204} appears to be stabilizing and orienting the hydrolytic water molecule in the trigonal–bipyramidal transition state, while Arg^{178} stabilizes the negative charge at the equatorial oxygen atoms of the pentacoordinate phosphate intermediate. Since this Arg residue is unique to G_α proteins, its presence may explain the higher hydrolytic activity of G_α proteins relative to those of members of the $p21^{ras}$ family.

Hydrolysis of GTP by $G_{i\alpha 1}$ is accompanied by relaxation of both the linker-2 strand and a twenty-residue segment that contains Gln^{204}. The loss of any ordered conformation in these residues (which are invisible in the electron density map) accounts for alterations in properties known to be characteristic of the GDP-bound form of the protein: loss of the Mg^{2+} binding site, a somewhat reduced affinity for guanine nucleotide, enhanced susceptibility to proteolysis in this region, and quenching of tryptophan fluorescence.

A surprising consequence of GTP hydrolysis is the assembly of the amino and carboxyl termini into a distinct, organized α-helical domain. This structural change occurs nearly 30 Å from the catalytic site, and it is difficult to discern an intramolecular pathway of conformational transition between these sites. Even more surprising is the discovery that the newly formed domain forms an exceedingly complimentary and extensive packing interface with the α-helical domain and the linker-2 strand of the neighboring molecule in the crystal lattice (Fig. 11). Thus, the transmission of structural changes between the GTP binding site and the amino and carboxyl terminii (which form part of the presumptive binding surface for the $\beta\gamma$ subunit complex) might be by means of intermolecular contacts.[95] Interestingly, these observations could be pertinent to recent speculations by Rodbell on the possibility of G protein oligomerization.[96]

Functions of α Subunits of G Proteins

Almost all known G protein α subunits and many distinct $\beta\gamma$ subunit complexes have been purified to homogeneity from tissue sources or purified after expression in heterologous systems (either *E. coli* or Sf9 cells) (Table 1). Properties of several subunits have also been inferred by application of new-wave bio-

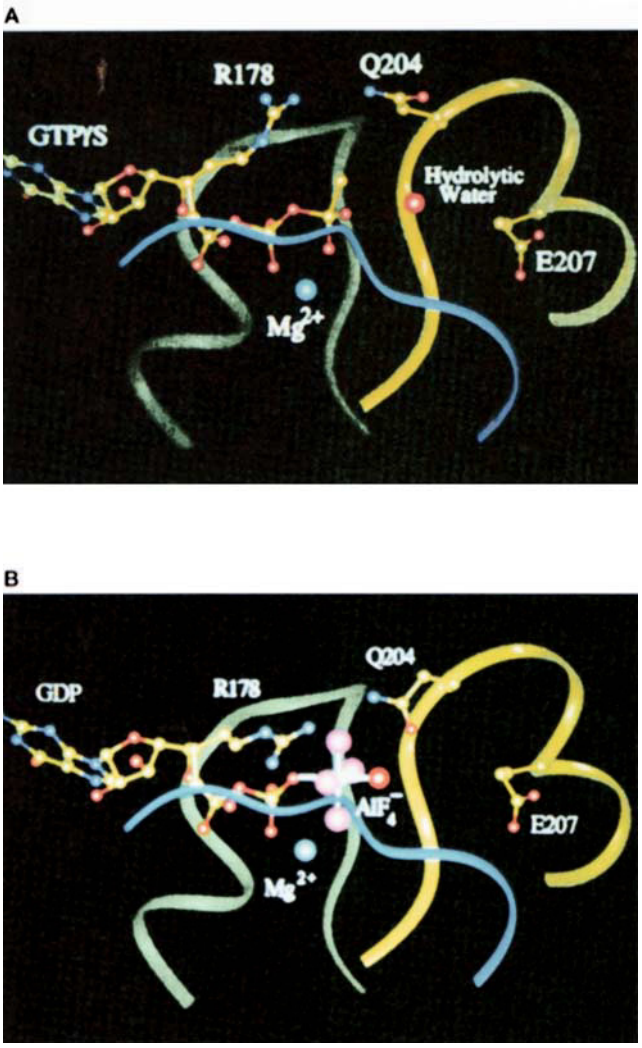

Fig. 10. A) A representation of the active site in the GTPγS–$G_{i\alpha 1}$ complex, showing the disposition of Arg^{178} and Gln^{204}; these residues are not within hydrogen-bonding distance of the nucleotide. The nucleophilic water molecule is *trans* axial to the O atom of the P–O–P bridge, and the O(H_2O)–P distance is 3.85 Å. The β_1–α_1 loop is colored green, the $\beta 2$–$\alpha 3$ switch peptide yellow, and the linker-2 strand blue. B) The GDP–AlF_4^- complex shown from the same perspective. Arg^{178} and Gln^{204} have rotated to contact the AlF_4^- cluster, and the nucleophilic water molecule has moved into the ligand field of the aluminum ion. C) Model of the active site of $G_{i\alpha 1}$ at the transition state of the phosphorolysis reaction, based on the structure of the GDP–AlF_4^- complex. (Reprinted with permission from ref. [88].)

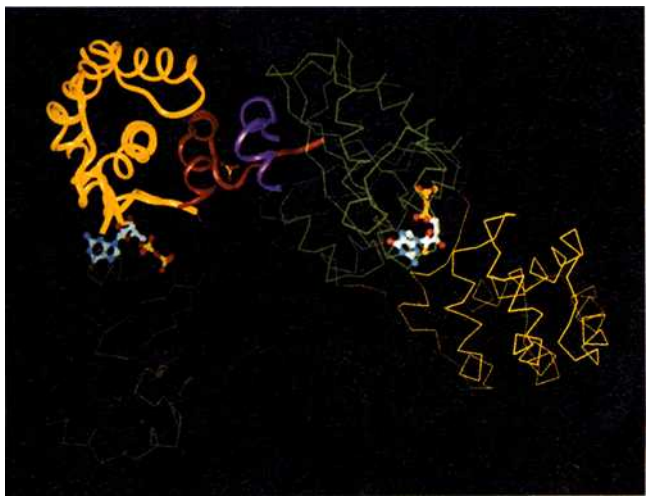

Fig. 11. Symmetry-related molecules of GDP–$G_{i\alpha 1}$ form a helical array in the crystalline state. The C- and N-termini of $G_{i\alpha 1}$ are disordered in the GTP complex but fold into a discrete protein microdomain comprising nearly 40 residues upon hydrolysis of the nucleoside triphosphate. A phosphate ion, which contacts three arginine residues from the amino terminus and lysine 180 from the linker-2 strand, may act as a nucleation center for the microdomain. (A sulfate ion serves this role in crystals of GDP–$G_{i\alpha 1}$.) This microdomain forms an extensive and complementary interface with the α-helical domain and the linker-2 strand of the neighboring molecule. The contact buries more than 1800 $Å^2$ of solvent-accessible surface, an area equivalent to that encompassed by many protein antigen–immunoglobulin complexes.

chemistry—experiments performed "in transfecto". Each system has advantages and disadvantages. While the *E. coli*-derived proteins may be missing certain covalent modifications (although myristoylation can be accomplished by coexpression of protein N-myristoyl transferase), they have the distinct advantage of being unambiguously free of other G protein subunits. This can be difficult to prove with G proteins isolated from other sources.

The members of the $G_{s\alpha}$ subfamily (α_s, α_{olf}) activate various adenylate cyclases, and they do so by direct interactions with these proteins. All known isoforms of membrane-bound mammalian adenylate cyclase are activated by $G_{s\alpha}$. $G_{s\alpha}$ is expressed as four distinct polypeptides (± residues encoded in exon 3; ± a serine residue at the splice junction) as a result of alternative splicing of a single precursor mRNA, but these variants have not been well distinguished functionally.[97–99] The α subunit of G_{olf} is expressed predominantly in olfactory neuroepithelium, where it presumably couples odorant receptors with a largely olfactory-specific isoform of adenylate cyclase (type III).[100] Purified $G_{s\alpha}$ also activates dihydropyridine-sensitive, voltage-gated Ca^{2+} channels in patches excised from skeletal and cardiac muscle[101] and inhibits cardiac Na^+ channels.[102] The physiological significance of these last two effects is difficult to judge. G_s is activated by receptors that stimulate adenylate cyclase activity; β-adrenergic receptors are prototypical.

Members of the G_i subfamily were first encountered as retinal transducins and then as substrates for islet-activating protein. The two isoforms of transducin are selectively expressed in retinal rods and cones.[103] They are activated by photolyzed rhodopsin or the cone opsins, and each stimulates a cyclic GMP specific phosphodiesterase, resulting in lowered intracellular concentrations of cyclic GMP on illumination. A transducin-like G protein, gusducin, is expressed selectively in taste

Table 1. Properties of mammalian G protein α subunits.

Family/ subunit	M_r [kDa]	Amino acid identity [%] [a]	Toxin [b]	Lipid [c]	Distribution in tissue	Representative receptors [d]	Effector/Role [f]

buds.[104] The relationship of gusducin to the transducins is sufficiently close that a cyclic nucleotide phosphodiesterase is hypothesized to be the effector in a pathway mediating response to certain tastants.

Three closely related genes encode the three $G_{i\alpha}$ subunits. These proteins are functionally very similar in vitro, although they differ in both their cellular and subcellular distribution. Demonstration of the direct involvement of these α subunits as inhibitors of adenylate cyclases was long delayed for several technical reasons, including a requirement for comparatively high concentrations, the need for myristoylation of the α subunit, and differential responses of different isoforms of adenylate cyclase.[75, 105] This role is now well established. Although the $G_{i\alpha}$ proteins were originally thought to activate K^+ channels in cardiac myocytes and neural tissue,[106] their role in this pathway is now more controversial and may be secondary to that played by the βγ subunit complex.[107] Evidence has also accumulated for a role of at least certain $G_{i\alpha}$ proteins in membrane trafficking.[108–110] Participation of these proteins in such apparently distinct cellular pathways is confusing.

$G_{z\alpha}$ differs substantially from the $G_{i\alpha}$ proteins, but it also inhibits adenylate cyclase activity in transfected cells[111] and in vitro.[112] Notably, $G_{z\alpha}$ is not a substrate for pertussis toxin and has a very slow rate of GTP hydrolysis.[113]

As mentioned previously, the discovery of G_o was an eye-opener because of its abundance in brain (1–2% of brain membrane protein) and apparent lack of involvement with known guanine nucleotide regulated systems. Although $G_{o\alpha}$ appears to play a major role as an inhibitor of voltage-sensitive Ca^{2+} channels,[114] I assume it has other extremely important roles. Hints are supplied by its high concentration in neural growth cones[115] and apparent interactions with GAP-43, a Ca^{2+}-binding protein that is also concentrated in these structures.[116]

Compelling evidence for regulation of phosphoinositide-specific phospholipase C activities was in hand well before the relevant G proteins could be identified.[54, 55] This is a pertussis toxin insensitive process in most cells, and the PCR-based cloning of members of the $G_{q\alpha}$ subfamily provided candidates for this role.[117] Nearly simultaneously, G proteins that serve this function were identified by classical reconstitutive techniques[118, 119] and by purification of novel α subunits using clever subunit affinity and exchange techniques.[120] All three paths merged with the identification of $G_{q\alpha}$ and then $G_{11\alpha}$, $G_{14\alpha}$, and $G_{15/16\alpha}$ as activators of the various isoforms of phospholipase Cβ. Purification of the relevant proteins proved that interactions of $G_{q\alpha}$ family members with the phospholipases are direct, and these appear to occur at carboxyl-terminal domains of the enzymes. Particularly interesting is the observation that the phospholipase Cβ subunits act as GAPs or GTPase-activating proteins towards $G_{q\alpha}$.[121] In the absence of the effector, the k_{cat} value for hydrolysis of GTP by these proteins is very low, but it is increased over 50-fold by the effector. The simplest interpretation of this effect is that phospholipase Cβ should block its own activation. However, kinetic analyses of these interactions suggest that receptor, G_q, and the phospholipase associate in a complex that binds and hydrolyzes GTP rapidly, such that there is substantial steady-state activation of phospholipase C associated with particularly rapid responses.

The roles of $G_{12\alpha}$ and $G_{13\alpha}$ are unknown. Both of these proteins are structurally related to the product of the *Drosophila*

concertina gene, which appears to play a role in gastrulation.[122] Transfection of NIH 3T3 cells with $G_{12\alpha}$ cDNA results in cellular transformation.[123, 124]

Functions of $\beta\gamma$ Subunits of G Proteins

General acceptance of downstream regulation of effectors by the $\beta\gamma$ subunit complex (Table 2) is relatively recent.[69, 70] These subunits were first assigned less glamorous roles. The binding of GDP and $\beta\gamma$ to α is positively cooperative. $\beta\gamma$ thus stabilizes the inactive GDP-bound form of α by markedly reducing the rate of dissociation of nucleotide.[125] As a result, $\beta\gamma$ acts as a noise suppressor.[126] By contrast, interactions of GTP and $\beta\gamma$ with α are negatively cooperative, and it was hypothesized that $\beta\gamma$ could speed deactivation of α and thereby cause inhibition of relevant downstream responses.[127] The significance of this possibility remains ill-defined, but the eventual observation of inhibitory effects of $G_{i\alpha}$ proteins on adenylate cyclase has obviated the "need" for this hypothesis. Receptor-catalyzed exchange of GDP for GTP on G_s requires $\beta\gamma$,[128] and $\beta\gamma$ can act catalytically in this role. The G protein heterotrimer is thus the form that is recognized by receptor, and reassociation of subunits is a requisite for activation.

The first strong evidence for interaction of $\beta\gamma$ with effectors came from Logothetis et al.,[107] who detected activation of K^+ channels in cardiac atrial myocytes with $\beta\gamma$ but not with $G_{i\alpha}$. Controversy about the interpretation of these observations kept $\beta\gamma$ at least partially in the closet for a few years, despite genetic evidence that $\beta\gamma$ was the primary mediator of downstream signaling in the pheromone response pathway of budding yeast.[129] Interesting and direct interactions between $\beta\gamma$ and effectors such as adenylate cyclases[130–132] and phospholipases[133, 134] have now been observed using simple biochemical assays that have been widely reproduced; the issue thus now seems to be settled. Effects of $\beta\gamma$ on different adenylate cyclases will be discussed below.

The issue of specificity among different species of $\beta\gamma$ subunits remains vexing. Other than observations that nonretinal α subunits and effectors appear to discriminate against retinal $\beta\gamma$ ($\beta_1\gamma_1$), little specificity is observed in examination of the interactions of a number of $\beta\gamma$ subunit complexes with a variety of α subunits and effectors.[82, 135, 136] These observations, made in vitro, fly in the face of striking observations of specificity made in intact cells by Kleuss and associates.[82, 135–139] Voltage-sensitive Ca^{2+} channels in GH_3 cells are inhibited by both M_4-muscarinic and somatostatin receptors. Selective suppression of either of the two splice variants of $G_{o\alpha}$ with antisense oligonucleotides demonstrates that the muscarinic response depends on the expression of $G_{o1\alpha}$ but not $G_{o2\alpha}$, while the response to somatostatin is selectively dependent on $G_{o2\alpha}$. Similar suppression of individual β or γ subunits also yielded striking results, consistent with muscarinic signaling through $\alpha_{o1}\beta_3\gamma_4$ and somatostatin signaling through $\alpha_{o2}\beta_1\gamma_3$. The best current guess is that this specificity is exerted at the level of receptor/G protein interactions, but demonstrations of such by reconstitution of purified components in vitro remains less than convincing.

Adenylate Cyclases

We have maintained our interest in adenylate cyclases throughout the "diversion" into G proteins, although "the job" of adenylate cyclase was for some time the domain of only one individualistic lab member. This situation changed and improved substantially in 1989.

Mammalian adenylate cyclases are activated by forskolin, a diterpene found in the roots of the plant *Coleus forskolii*. The development of a forskolin-affinity matrix by Pfeuffer and Metzger[140] made purification of the enzyme possible, but not simple. Smigel was the first in our laboratory to purify a calmodulin-sensitive form of adenylate cyclase from bovine brain by adapting Pfeuffer's techniques,[141] and Krupinski and coworkers[142] finally purified a sufficient amount of protein to obtain amino acid sequence. With the invaluable help of Randall Reed at Johns Hopkins, whose collaborative efforts we sought because of the abundance of adenylate cyclase in olfactory neuroepithelium, cDNAs encoding type I (by definition) adenylate cyclase were obtained from a bovine brain library. Several labs have now contributed to the isolation of six additional full-length clones (types II–VI and VIII) by application of low-stringency hybridization and PCR techniques; all of these proteins have been expressed, and their regulatory properties are being defined.[143–145]

Table 2. Properties of mammalian G protein β and γ subunits.

Subunit	M_r [kDa]	Amino acid identity [%] [a]	Tissue distribution	Effector/Role [b]
β				support of agonist-induced receptor phosphorylation and desensitization
β_1	37.3	100	ubiquitous	
β_2	37.3	90	nearly ubiquitous	required for G_s-receptor interaction
β_3	37.2	83	nearly ubiquitous	
β_4	37.2	89	nearly ubiquitous	inhibiton of G_t activation
β_5	38.7	52	brain	
γ				↑ or ↓ adenylate cyclase (isoform-specific responses)
γ_1	8.4	100	retinal rods	↑ phospholipase Cβ_2, β_3
γ_2	7.9	38	brain, adrenal	
γ_3	8.5	36	brain, testis	↑ K^+ channels
γ_4	(?partial)	(34)	(kidney, retina (?))	
γ_5	7.3	25	ubiquitous	↑ phospholipase A_2 (?)
γ_7	7.5	35	ubiquitous	

[a] Comparison is with the first-listed member of each family. [b] ↑ = activation; ↓ = inhibition.

Mammalian, membrane-bound adenylate cyclases have a complex (deduced) structure that is reminiscent of a variety of transporters and channels (Fig. 12). Their topographical relationship to the P glycoprotein and the cystic fibrosis transmembrane conductance regulator is striking, although they share no amino acid sequence homologies with these proteins. A short

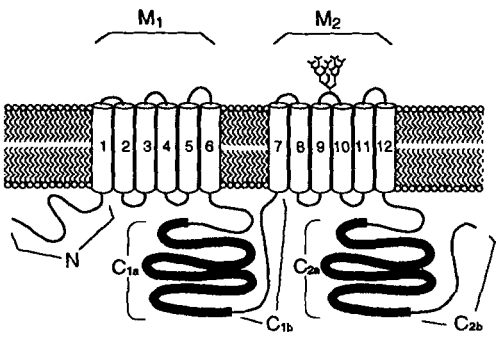

Fig. 12. Predicted topology of membrane-bound adenylate cyclases. Cylinders represent membrane-spanning regions, while bold lines indicate regions of high amino acid similarity among all members of the family. N: N-terminal domain; M_1, M_2: sets of membrane-spanning regions; C_{1a}, C_{1b}, C_{2a}, C_{2b}: large intracellular cytoplasmic domains. (Reprinted with permission from ref. [145].)

cytoplasmic amino terminus is followed by six putative transmembrane spans (designated M_1) and a roughly 40-kDa cytoplasmic domain (C_1). This apparent structural unit is then repeated: a second set of six transmembrane spans (M_2) is again followed by a second large cytoplasmic domain (C_2). Although this structure is unique for a "simple" enzyme, its significance is elusive. I find it fascinating that the regulatory motif for adenylate cyclases—activation by a GTP binding protein—is apparent in *Saccharomyces cerevisiae*. Although this mode of regulation is conserved from yeast to mammals, the molecular players are not. The adenylate cyclase of *Saccharomyces* is a very large peripheral membrane protein with little resemblance to its mammalian counterpart.[146] The GTP-binding protein in yeast responsible for stimulation of cyclic AMP synthesis is the resident homolog of mammalian $p21^{ras}$,[147] even though yeast has heterotrimeric G proteins. Evolution works in strange ways.

Two regions of roughly 200 amino acid residues each (C_{1a} and C_{2a}) are highly conserved among the mammalian adenylate cyclases, and this relationship also extends to the topographically similar enzymes of *Drosophila* and *Dictyostelium*. The C_{1a} and C_{2a} domains are also quite similar to each other and to the catalytic domains of both membrane-bound and soluble guanylate cyclases. These relationships indicate that one or both of these domains is a site of catalysis.

Unfortunately, it has not been possible to detect significant adenylate cyclase activity following expression of either of these putative catalytic domains as discrete proteins; the same is true if individual halves of the molecule are expressed in Sf9 cells. Nevertheless, concurrent expression of M_1C_1 and M_2C_2 results in appearance of a substantial level of adenylate cyclase activity that can be regulated characteristically by G protein subunits and, in the case of the type I enzyme, by calmodulin.[130] We tentatively assume that interaction between the C_1 and C_2 domains is necessary for catalysis. This is consistent with the facts that both subunits of heterodimeric, soluble guanylate cyclases are required for catalysis (each subunit contains sequences homologous to C_{1a} and C_{2a})[148] and that the membrane-bound guanylate cyclases are homo-oligomers.[149] It is also interesting that point mutations in either C_{1a} or C_{2a} can impair adenylate cyclase activity severely and that mutations in either domain can elevate the K_m value for ATP. Both domains may bind ATP; both might also catalyze cyclic AMP synthesis, or one may be the dominant catalyst while the other serves a regulatory role.

Regulation of Adenylate Cyclases by G Protein Subunits

All seven of the isoforms of adenylate cyclase identified to date are activated by $G_{s\alpha}$ (and forskolin). Surprisingly, these features (and so-called P-site inhibition by adenosine analogs) are the only shared regulatory motifs. The type I isoform is also activated by calmodulin, while it is strongly inhibited by the G protein $\beta\gamma$ subunit complex. Although this effect was originally attributed to sequestering of calmodulin by $\beta\gamma$, purification of the expressed cyclase has permitted demonstration of its direct interaction with $\beta\gamma$.[132] The three isoforms of $G_{i\alpha}$ and $G_{o\alpha}$ can also inhibit type I adenylate cyclase, but the effect is much less prominent than that of $\beta\gamma$ when calmodulin is the activator of the enzyme, and it nearly disappears when the cyclase is activated by $G_{s\alpha}$.[105]

Type I adenylate cyclase is the only isoform found to date that is inhibited by $\beta\gamma$. When we looked for such interactions with other isoforms, we were very surprised to find strong stimulation of enzymatic activity with the type II and type IV proteins.[131, 150] Particularly interesting, these stimulatory effects of $\beta\gamma$ are highly conditional. The subunits have little or no effect on adenylate cyclase activity when added alone, but the complex stimulates enzymatic activity five- to tenfold when $G_{s\alpha}$ is also present. Stimulation of type II and IV adenylate cyclases by $\beta\gamma$ requires substantially higher concentrations of $\beta\gamma$ than of $G_{s\alpha}$, and we presume that effective concentrations of both activators cannot arise by dissociation of oligomeric G_s. The source of $\beta\gamma$ is believed to be the G_i or G_o oligomers, both of which are present in high concentrations in brain. We thus envision type II and IV adenylate cyclases as molecules designed to detect coincidental activation of two regulatory pathways, marking such events with a distinctive signal. The biochemical properties of these adenylate cyclases provide an excellent explanation for phenomena described in the 1970s by Rall and associates,[151] who observed highly synergistic stimulation of cyclic AMP accumulation in brain slices after application of pairs of neurotransmitters now known to work through G_s- and G_i-regulated pathways. Given activation of type II adenylate cyclase by $\beta\gamma$, which presumably arises from G_i, it would be problematic if $G_{i\alpha}$ were to inhibit the enzyme; gratifyingly, it does not.

The first really believable demonstrations of inhibition of adenylate cyclases by $G_{i\alpha}$ were observed with the type V and type VI isoforms, where the effect is prominent.[75, 105] As noted above, it is dependent on myristoylation of these α subunits and requires fairly high, but we believe quite reasonable, concentrations of the proteins (high nM–μM). Type V and VI adenylate cyclases are thus regulated in the relatively simple way that was envisioned to be the general rule—activation by $G_{s\alpha}$ and inhibi-

tion by $G_{i\alpha}$. But even these isoforms provided surprises, in that they are inhibited by low (μM) concentrations of Ca^{2+}.

Three distinct patterns of regulation of mammalian adenylate cyclases are thus evident (Fig. 13). All isoforms are activated by $G_{s\alpha}$, and two other subclasses of G proteins, G_i and G_q, are implicated as well, either directly or indirectly. The effects of G_q family members are exerted through Ca^{2+}, either acting alone, with calmodulin, or with protein kinase C. G_i- and G_q-mediated pathways can both activate an adenylate cyclase (types II and probably IV) in concert with $G_{s\alpha}$, or they can both oppose such activation (types V and VI). The effects of G_i and G_q are antagonistic to each other with the type I enzyme. Even at this relatively early stage of investigation of the regulatory complexities of adenylate cyclases, it is clear that these enzymes have evolved to permit extensive integration and cross-talk between signaling pathways. The adenylate cyclases are focal points for the convergence of a great deal of regulatory information.

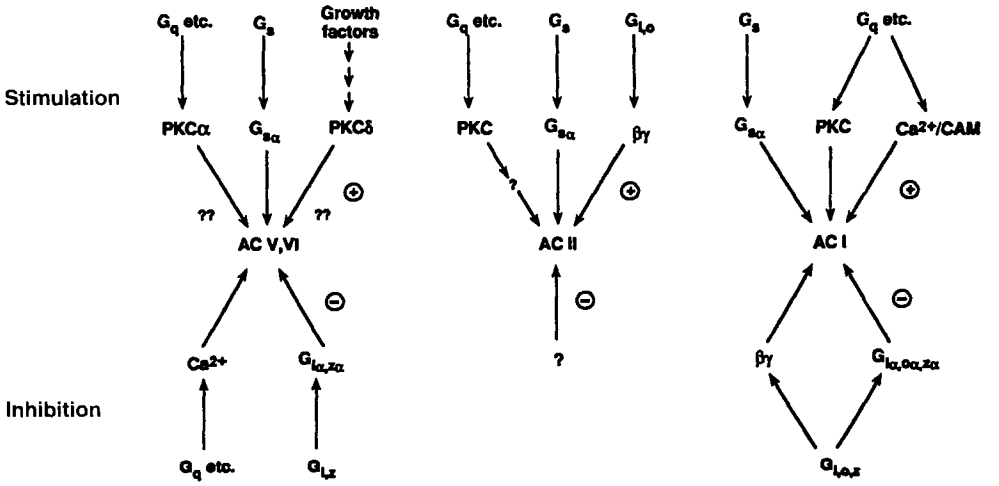

Fig. 13. Patterns of regulation of adenylate cyclase activity. PKC = protein kinase C; CAM = calmodulin; AC = adenylate cyclase. See text for discussion. (Reprinted with permission from ref. [145].)

Future Directions for Research on Adenylate Cyclase

Adenylate cyclases are labile intrinsic membrane proteins; their level of expression is low, even under artificial conditions. New tools are needed to probe their structures and mechanisms of regulation. With these thoughts in mind, Wei-Jen Tang has attempted to construct a soluble adenylate cyclase that would retain characteristic regulatory properties, be synthesized in large quantities, and be amenable to genetic analysis. He has recently succeeded in designing and synthesizing a molecule that may have all of these properties.[152] The current product is a chimera of the C_{1a} domain of type I adenylate cyclase, joined by a linker to the C_2 domain of type II adenylate cyclase. The molecule is synthesized by *E. coli*, where it accumulates in the cytoplasm. It is activated dramatically (from an extremely low basal activity) by $G_{s\alpha}$ and, surprisingly, forskolin. Cyclase-deficient strains of *E. coli* are dependent on expression and activation of the adenylate cyclase for growth on maltose. Genetic selection of mutants with informative phenotypes thus seems possible, as does purification, detailed characterization, and, hopefully, structural analysis. We hope that this approach will open the door for true understanding of these important proteins.

Why G Proteins?

One might well ask why G proteins are included in signaling pathways, and why the systems are so complex structurally. Transmembrane signaling is clearly accomplished with simpler (although usually oligomeric) molecular assemblages such as tyrosine kinases, ligand-gated ion channels, and receptor guanylate cyclases. I believe there are several reasons for the evolution of complex signaling systems. At a relatively simple level, the existence of these molecular switches and timers permits enormous amplification in the signaling process. A single agonist–receptor complex can catalyze the activation of many G proteins during the time that a single G protein α subunit remains active;[153] delayed deactivation of the α subunit permits further amplification at the level of catalytic effector molecules. There is also the possibility of substantial regulatory complexity, with opportunities to modulate both the quantitative and qualitative aspects of signaling by alterations in rates of synthesis and degradation of many gene products, as well as more acute regulation by covalent modification of these molecules. Most importantly, perhaps, the tripartite nature of these signaling systems permits enormous diversity of outputs. G protein regulated signaling pathways are characterized by both convergence and divergence at each step. Many different kinds of receptors can converge to activate a single type of G protein, while a single type of receptor can interact with more than one species of G protein to initiate several events. Similarly, different G proteins may converge on a single effector to alter its activity, either additively, synergistically, or antagonistically, while a single G protein may also interact with more than one effector. G proteins can also exert effects through either their α or βγ subunits. The complexity of the cellular switchboard thus appears sufficiently vast to permit each cell to design a highly customized signaling repertoire by expression of a relatively modest number of modular components. Identification of all of these components seems certain in the next decade or so. With this information in hand, we will be able to complete our understanding of the wiring diagram of the signaling switchboard in each type of cell. Such knowledge, coupled with both increasing sophistication in rational drug design and increasingly clever approaches to screen huge chemical libraries, will revolutionize both pharmacology and therapeutics.

There are many who have earned my most profound gratitude. My father encouraged a love of science by example, and it was carefully nurtured by my doctoral and postdoctoral mentors, Theodore W. Rall, who perhaps should have won a Nobel Prize, and Marshall W. Nirenberg, who did. All of the students and postdoctoral fellows who have worked in our laboratory have made substantial contributions. These individuals are (in alphabetical order): David Berman, Gary Bokoch, Lawrence Brunton, Patrick Casey, Francoise Coussen, Carmen Dessauer, Alex Duncan, Kenneth Ferguson, Michael Freissmuth, Boning Gao, Michael Graziano, Tatsuya Haga, Emanuel Hanski, Bruce Harris, John Hepler, Tsutomu Higashijima, Allyn Howlett, Jorge Iñiguez-Lluhi, Hiroshi Itoh, Richard Kahn, Toshiaki Katada, Christiane Kleuss, Tohru Kozasa, John Krupinski, Ethan Lee, Hsin Chieh (Calvin) Lin, Maurine Linder, Michael Maguire, David Manning, Pamela Middleton, Susanne Mumby, John Northup, Bruce Posner, Lynn Quarmby, Andre Raw, Janet Robishaw, Elliott Ross, Leonard Schleifer, Joseph Schwarzmeier, Murray Smigel, Paul Sternweis, Roger Sunahara, Wei-Jen Tang, Ronald Taussig, and Natsuo Ueda. Many members of our staff have also played crucial roles, but two long-term employees truly stand out—Pamela Sternweis and Wendy Deaner. Collaborations with others on our faculty and elsewhere have been invaluable. Particularly notable roles have been played by Susanne Mumby, Elliott Ross, Stephen Sprang, and Paul Sternweis. Our research has been supported continuously since 1972 by grants from the National Institutes of Health (first the National Institute of Neurological Disorders and Stroke and then the National Institute of General Medical Sciences) and, since 1977, by the American Cancer Society. Other invaluable sources of support have included Mr. and Mrs. Peter O'Donnell, the Lucille P. Markey Charitable Trust, the Raymond Willie Chair of Molecular Neuropharmacology, the Perot Family Foundation, the Meadows Foundation, and the Robert A. Welch Foundation.

Signal Transduction: Evolution of an Idea (Nobel Lecture)**

Martin Rodbell*

In general there is no set of observations conceivable which can give enough information about the past of a system to give complete information as to its future.
Norbert Wiener

Think simplicity; then discard it.
Alfred North Whitehead

Introduction

I was born in 1925, a time when there were no talking movies, when radio was just emerging as a popular listening device, newspapers printed important information, and libraries were sources of both pleasure and learning. My father's grocery store (above which we lived) was a community center where people from blocks away would come for their groceries and to gossip. We knew or knew about everyone in our neighborhood. In that atmosphere I grew up as a young man feeling the warmth of this community. Retrospectively, I have come to realize how important this long-gone community and the intense human relationships have been to my development as a scientist. My scientific neighborhood encompasses a place where cultural and language differences have been melded seamlessly and with synergy to promote communication, to expand knowledge with a kinship of purpose, and to create new thought. Nature, which we often equate with our genetic make up, and Nurture, which symbolizes our environment, interact mutually and synergistically in this community. These are the forces that have given meaning to life; the question of which comes first, the chicken or the egg, is not of biological importance.

My lecture reflects my interest in societal/cellular relationships and concerns the broad issues of biological communication. The first half will deal with the development of the concept of transducers and their role in cell signaling. Since this concept is still at an evolutionary phase, I will conclude with an hypothesis which in its simplest message argues that biological communication consists of a complex meshwork of structures in which G proteins, surface receptors, the extracellular matrix, and the vast cytoskeletal network within cells are joined in a community of effort, for which my life and those of my colleagues is a metaphor.

Receptors, Allostery, and the Second-Messenger Theory

The concept of receptors as sensory elements in biology has a long history. Early in this century Paul Ehrlich realized the importance of surface receptors and postulated a "lock-and-key" theory to explain their interactions with antigenic materials and drugs. Today, it is understood that receptors are proteins with the patterns of design and malleability of structure required for discriminating between an extraordinary variety of chemical signals. My interest in receptors began in the early 1960s, when I uncorked the means of freeing adipocytes from their tissue matrix by collagenase treatment and found that insulin at physiological concentrations stimulated glucose uptake.[1] Searching for the possible site of action of the hormone, I tested the effects of treating adipocytes with phospholipases and proteases on the assumption that, if the surface or plasma membrane contains insulin receptors, these digestive enzymes might prevent insulin action. Surprisingly, phospholipases mimicked the known actions of insulin on glucose utilization and protein synthesis.[2, 3] Based on such observations, I postulated that insulin might act by stimulating phospholipases,[4] not a bad hypothesis in view of the accumulated evidence of the importance of phospholipases in mediating the actions of a variety of hormones.[5]

During the 1960s two major theories influenced the course of my research on hormone receptors. One was the "second-messenger" theory.[6, 7] This theory suggested that extracellular or primary messengers in the form of hormones or neurotransmitters act through receptors that regulate the production of adenosine-3′,5′-monophosphate (cyclic AMP), considered to be the intracellular messenger that mediates the actions of hormones on all aspects of cellular metabolism, growth, and differentiation. The perceptions of Monod and colleagues that led to their incisive theory of allosteric regulation[8] blended beautifully with Sutherland's theory that receptors are structurally and functionally linked to the regulation of cyclic AMP production. Overwhelmingly persuasive was the notion that adenyl (now adenylate or adenylyl cyclase) is an allosterically regulated enzyme system containing two distinct sites for binding receptors and for triggering catalytic action. Located at the surface or plasma membrane of cells, the asymmetric positioning of these sites—the allosteric hormone-sensing sites on the exterior and ATP-utilizing catalytic sites at the interior surfaces of the membrane—provided a logical framework for investigating the molecular basis for hormone action. My attention shifted from

insulin to those hormones known to stimulate the production of cyclic AMP in fat cells.

The Multireceptor Adenylate Cyclase System in Adipocytes

At the time, the only specific assay for cyclic AMP production relied on a complicated, time-consuming bioassay. Krishna[9] and later Salomon[10] developed relatively simple chromatographic assays which for the first time allowed rapid, multiple assays of adenylate cyclase. When Lutz Birnbaumer arrived in my laboratory in 1967, that assay literally danced under his extraordinary prowess, yielding information that laid the foundation for the concept of transducers. Prior to his coming, I had developed a rapid method for obtaining fat cell membranes (called "ghosts") responsive not only to insulin but also to various hormones that stimulate cyclic AMP production and resultant lipolysis in fat cells.[11] These hormones included epinephrine, adrenocorticotropic hormone (ACTH), thyrotropin (TSH), lutinizing hormone (LH), and secretin, as well as glucagon and fluoride ions. The latter, shown previously to stimulate adenylate cyclase in a variety of cell membranes,[6] activated the fat cell system by a Mg^{2+}-dependent process displaying a Hill coefficient of 2.0, suggesting that the system may contain at least two sites of action for Mg ions, one certainly a Mg–ATP complex at the catalytic site. That a regulatory site for Mg ions exists was suggested by the finding that both ACTH and fluoride ions markedly reduced the concentration of Mg ions necessary for stimulation of activity.[12] The kinetics of ATP action proved too complicated for interpretation at the time. Not realizing that ATP was contaminated with GTP, we couldn't interpret what later proved to be the stimulatory and inhibitory actions of GTP on adenylate cyclase systems. The lesson is clear to me today: never attempt to interpret a hyperbolic curve; it describes the behavior of the entire universe!

Demonstration of Distinct Hormone Receptors

Much of our energy and time was devoted to delineating the receptors for the hormones that stimulated the cyclase system. The pharmacology of the peptide hormones receptor was essentially unknown and necessitated a variety of indirect tests, including the effects of proteases, inhibitory analogs, and differential ion dependencies, which in combination suggested that each of the hormones stimulated cyclase through distinct receptor types. Since the enzyme system and the receptors were contained in the same cell, these findings allowed us to test a fundamental question: do all of the hormones operate on the same enzyme or, as depicted in the Sutherland model, is each hormone receptor coupled to separate cyclase models? The various hormones were tested at maximal and submaximal concentrations alone or combined with the other hormones. Synergy was seen with some combinations but, most importantly, additivity of response was not obtained with maximal concentrations of the hormones.[13] Similar findings were reported simultaneously.[14] Although not proof, we argued that the fat cell cyclase system most likely consists of multiple receptors interacting with a common catalytic unit. Conceptually, the picture that emerged is that each receptor contains specific binding regions and some common structural element that interacts with the catalytic component to stimulate conversion of MgATP to cAMP. At that time we considered that the catalytic component contains the regulatory site for Mg ions and is the site of action of fluoride ion. Lipids were somehow involved in the structural interactions between receptors and catalytic unit, because, unlike fluoride action, hormone action was exquisitely sensitive to agents (phospholipases, detergents) that affect membrane structure.[15] It was clear that hormone action involved a more complex structural and regulatory enzyme system than originally thought. It was inconceivable to me that several hormone receptors could be structurally annealed to the same enzyme (I referred to this problem as "too many angels on a pinhead"). A new concept of hormone action had to be considered.

Martin Rodbell was born in 1925 in Baltimore, MD (USA) and studied biology and chemistry at Johns Hopkins University. He earned his PhD in biochemistry in 1954 at the University of Washington in Seattle for his research on the biosynthesis of lecithin in rat liver conducted under the direction of Prof. D. Hanaken. During subsequent postdoctoral studies with Dr. H. E. Carter at the University of Illinois in Urbana he examined the biosynthesis of chloramphenicol. He then worked with Dr. Anfinsen at the National Heart Institute in Bethesda, MD, where he studied lipoproteins. In 1960 he joined Prof. J. Brachet's research group at the Free University of Brussels, Belgium, and then moved to the laboratory headed by Dr. P. Gaillard in Leiden, The Netherlands. He returned to the U.S. in 1961 and was offered a position in the Laboratory of Nutrition and Endocrinology at the Institute of Arthritis and Metabolic Diseases in Bethesda, MD. Here he conducted research on lipoprotein lipases and insulin action on the utilization of glucose in fat cells. In the mid-1960s Rodbell's research interests were redirected by Earl Sutherland's "second-messenger" theory of hormone action and the role of cyclic AMP. In the next few years Rodbell and Lutz Birnbaumer developed the concept of transducers and principles of signal transduction. During the period 1967–1968 Rodbell focused his research efforts on the effect of hormones on ion and amino acid transport in fat cells. He served as interim Director of the Institut de Biochimie Clinique in Geneva, Switzerland, and was later appointed Professor at the Laboratory of Biochemistry at the University of Geneva (1981–1983), during which time he conducted research on the structure and function of glucagon.

Informational Processing: The Concept of Transduction

At that time my thinking on the subject of how hormonal information is transferred across the cell membrane and translated into action was greatly influenced by the theories of informational processing proposed by Norbert Wiener,[16] the originator of cybernetic theory. This subject was introduced to me by Oscar Hechter, who had previously proposed several important theoretical considerations concerning hormone action. He was the first to question the proposition that hormones act directly on the adenylate cyclase enzyme.[17] Through lengthy discussions at a downtown hotel bar in Washington D.C. prior to a meeting that I had organized at NIH to honor Sutherland, we arrived at the concept of transduction as a means of coupling information between signal-activated receptor and regulation of adenylate cyclase. Given the paucity of knowledge at that time, the concept of informational processing was put in abstract cybernetic terms: a discriminator representing the receptor, a transducer, and an amplifier representing adenylate cyclase because of the large increase in cyclic AMP generated when converted to its activated state. The transducer is a coupling device designed to allow communication between discriminator and amplifier. At the meeting I presented this idea, illustrated (but without participation of Mg ions and GTP at that time) in Figure 1. We considered the possibility that Mg ions and lipids participate in the transduction process, but we realized that the transducer concept required fleshing out with more evidence on the structure/functional relationships between receptor and enzyme.

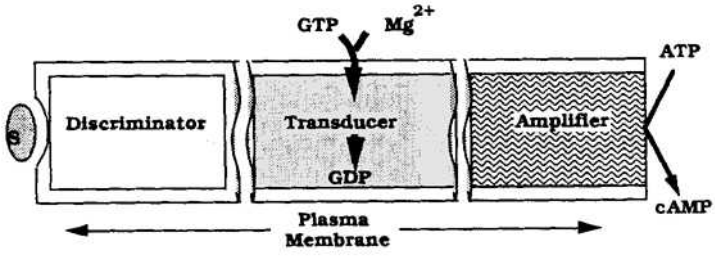

Fig. 1. Cybernetic description of signal transduction. S = signal.

The Actions of GTP and Glucagon on Liver Cyclase

Because of the experimental complexity of studying the multireceptor adenylate cyclase system in rat adipocytes, my colleagues (Birnbaumer, Pohl, Krans) and I turned our attention to the glucagon-sensitive adenylate cyclase system in liver. To some extent this change was made because of the historical significance of the hepatic system in hormone action and, coincidentally, because David Neville[18] at NIH had reported purification of rat liver plasma membranes by a relatively simple procedure. As importantly, we radio-labeled glucagon with ^{125}I making it possible to investigate both the nature of the glucagon receptor and the relationship between hormone binding and hormonal activation of adenylate cyclase.

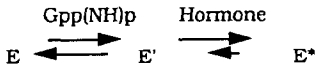
Michiel Krans began the glucagon-binding studies with our findings that hormonal activation of adenylate cyclase in liver membranes rises within seconds and falls rapidly when the hormone is displaced by an antagonist such as des-his-glucagon, which proved later to be a weak partial agonist. Our expectations were that binding of ^{125}I-labeled glucagon would proceed rapidly (within seconds) and would be reversed easily by washing the membranes free of medium containing the hormone. Instead, Krans observed that binding was extremely slow requiring at least 20 minutes before reaching a plateau. Extensive washing under a variety of conditions failed to remove the bound material. None of the binding characteristics fit with the kinetics of hormone action. However, the medium used for binding contained nothing but salt and buffer, whereas the cyclase assay medium contained multiple components including the substrate, MgATP. A dramatic change resulted when all of the cyclase ingredients were added to the hormone-binding medium. The level of bound hormone at "steady state" was drastically reduced; maximal binding was attained within seconds. We subsequently found that ATP was the principal culprit. Realizing from painful experience as a graduate student that commercial preparations of ATP contain a variety of contaminating nucleotides, I tested many types of purine and pyrimidine nucleotides. GTP, GDP, and ITP were the only nucleotides that mimicked the effects of ATP. Most importantly, the guanine nucleotides acted at concentrations much lower (two to three orders of magnitude) than ATP. GppCp, a poorly hydrolyzable analog, also acted, although its effects required much higher concentrations than those of GTP or GDP. Each of the nucleotides induced rapid release of prebound glucagon from its receptor. We established that guanine nucleotides act by lowering the affinity of receptor for the hormone.[19]

At that point the central question was the possible relationship of this effect of GTP on hormone binding to the actions of glucagon on adenylate cyclase activity. To avoid the problem of contaminating GTP in the assay for the enzyme, we prepared [^{32}P]APP(NH)p as substrate using a biosynthetic method. This analog proved stable to degradation by ATPases in the membrane. Under these conditions, glucagon did not stimulate adenylate cyclase unless GTP was present in approximately the same concentrations as those that affected the affinity of the receptor.[20] Subsequently, Michael Lin and Yoram Salomon[21] demonstrated that hormone and GTP concertedly and rapidly induced the active form of the enzyme. Glucagon, moreover, reduced the small lag in activation given by activating nucleotide alone. The die was cast; logically GTP acts at the transduction process along with Mg ions (Fig. 1). Although the components of the informational processing system remained unknown, there was little doubt in our minds that a transducer exists and that this crucial component mediates the transfer of information between receptor and enzyme.

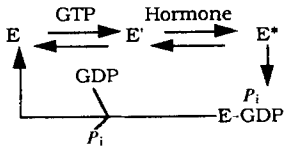
GTP Hydrolysis

Because GTP was susceptible to hydrolysis by nucleotidases in membranes, our next objective was to substitute GTP with a nonhydrolyzable derivative. Taking a cue from our experience with App(NH)p, Gpp(NH)p was synthesized. A few months later, we found that Gpp(NH)p caused the enzyme's activity to "take off" to an extent not even seen with fluoride ions. To our

amazement, the normally unstable cyclase system remained fully active even after three days at room temperature. We then tested Gpp(NH)p on a variety of cyclase systems using every cell membrane preparation we could obtain. All showed the same phenomenon.[22] Gpp(NH)p, unlike hormone plus GTP, stimulated activity following a rather lengthy lag period which was shortened considerably when hormone was added.[21] Yoram Salomon investigated the binding of [^{32}P]Gpp(NH)p to liver membranes and found substantial guanine nucleotide-specific binding, far in excess of the number of glucagon receptors.[23] These findings were discounted by others because of the seeming disparity in the levels of glucagon receptor and guanine nucleotide binding sites. However, it was not understood at the time that multiple types of receptors interact with several types of GTP-binding proteins; that story evolved nearly ten years later. The key elements of signal transduction gained from these findings were that Gpp(NH)p binds to the liver membranes in the absence of hormone, whereas glucagon accelerated the ability of the nucleotide to activate adenylate cyclase, not vice versa. These findings plus modeling of the kinetics of Gpp(NH)p/Mg[24] gave rise to a three-state model in which hormones act by promoting the conversion of the nucleotide-bound E′ state to the activated E* state [Eq. (1)]. However, as this model had 21 parameters and only two variables (Mg^{2+} and Gpp(NH)p concentrations), we realized that this yielded only an approximation of what must be a very complicated system.



(1)



(2)

At about the same time Michael Schramm, in a series of beautifully executed experiments, demonstrated that Gpp(NH)p acts in a pseudo-irreversible fashion; in other words, removal of the nucleotide from the medium after incubation resulted in retention of the high level of cyclase activity.[25] Based on this finding with Gpp(NH)p taken together with the inability of GTP alone to stimulate activity, we proposed that the transducer must have the capacity to hydrolyze GTP. When GTP was substituted for Gpp(NH)p in the modeling of the liver system's kinetics [Eq. (2)], the data fit with the hypothesis that the activated state E* is the state in which GTP was converted to GDP + P_i. In this fashion, it could be understood why activation by GTP and hormone involved essentially no lag period whereas with Gpp(NH)p + hormone, the lag was shortened but persisted. GTP turnover, in this model, is required for the rapid, reversible actions of the hormone. A few years later, Cassel and Selinger, in a brilliant set of experiments, showed conclusively that hormones stimulated the hydrolysis of GTP to GDP + P_i. From these findings, they elaborated the theory that hydrolysis of GTP to GDP is the "turn-off" reaction and the resultant bound GDP converts the transducer to its inhibitory state.[26] Hormones promote the displacement of GDP and its exchange with GTP; this exchange reaction is the key to hormonal activation of G proteins. Nucleotide exchange and GTP hydrolysis are fundamental to the regulation of all types of G proteins that have been examined to date. Not considered in this theory, however, is that the overall turnover of GTP is a complex set of reactions including hydrolysis and subsequent release of phosphate from a bound state. In a detailed study of the light-activated rhodopsin system,[27] it was suggested that hydrolysis of GTP is a very rapid process, whereas the rate-limiting step is the release of inorganic phosphate from its binding sites on transducin, the G protein responsible for activation of phosphodiesterase in outer segments of retinal rod cells. This proposal fits with the prolonged activation by fluoride ions (complexed with aluminum or magnesium ions) which most likely act by binding to the same Mg–phosphate binding sites on transducin.

Dual Stimulatory and Inhibitory Actions of GTP and Fluoride Ions

The multireceptor fat cell system proved invaluable not only for investigating the multiple actions of hormones. It provided the first insight that adenylate cyclase is both inhibited and stimulated by two independent processes involving GTP and fluoride ions. Hans Löw and Jim Harwood found that fluoride ions and both GTP and Gpp(NH)p induced stimulation and inhibition of the enzyme as the concentrations of these agents were increased.[28, 29] The mechanism was elusive until Hirohei Yamamura[30] noted marked differences in the properties of the stimulatory and inhibitory phases. Subsequent characterization of the dual process[31] and the discovery[32] that the fat cells contained adenosine receptors that induce inhibition of adenylate cyclase by means of a GTP-dependent process finally placed the inhibitory role of guanine nucleotides on the same level of importance as the stimulatory process. From these studies arose the new concept of dual regulation of adenylate cyclase by hormones, guanine nucleotides, and fluoride ions.[33] Implicit in the argument was the understanding that transduction involving stimulation and inhibition must be exercised through distinct GTP-binding proteins. We called them nucleotide regulatory proteins (abbreviated N) because ITP was also active. Thus arose the nomenclature N_s and N_i, now commonly known as G_s and G_i. One logical consequence of these findings is that G proteins are independent of both receptors and adenylate cyclase. Pfeuffer's purification of a 42 kDa protein that he could label by incubating membranes with [^{32}P]NAD and cholera toxin[34, 35] provided the first tangible evidence for the existence of G_s, the cyclase stimulatory transducer. It had been discovered earlier that cholera toxin greatly increased the production of cAMP in intestinal cells, suggesting that the toxin acts on the adenylate cyclase system (reviewed in ref. [36]). Later, pertussis toxin[37] provided the means for detecting and purifying G_i and G_o. Meanwhile, in the laboratory of Gordon Tompkins it was found that treatment of cultured lymphoma cells (rat S49) with cyclic AMP resulted in their death.[38] Based on this phenomenon they isolated surviving mutant forms; in one of these the enzyme could not be stimulated by Gpp(NH)p and fluoride ions, and

epinephrine action was also abolished.[39] Using the mutant called AC^- (because it was mistakenly thought to lack adenylate cyclase). Gilman and his colleagues[40,41] subsequently demonstrated that supplementation with extracts from wild-type cells restored both hormonal action in a GTP-dependent fashion and the actions of Gpp(NH)p and fluoride ions. This assay proved useful for the first purification of what was then called G/F factor, now known as G_s, the transduction protein(s) responsible for stimulating adenylate cyclase.

During this period, studies in the lab[42,43] showed that hormone receptors linked with G_s displayed very different physical and kinetic properties from those observed when adenylate cyclase was linked (after activation) with G_s, suggesting either different states or different forms of the GTP regulatory process. Finally, and perhaps most critical for our work was the discovery by Bitensky and colleagues[44] that light-activation of a cyclic GMP phosphodiesterase in outer segments of rod cells is mediated by a guanine nucleotide dependent process, similar to the actions of guanine nucleotides on adenylate cyclase. By 1980 it was clear that the actions of guanine nucleotides are not confined to the adenylate cyclase system. In a brief overview[33] I proposed that there must be several types of GTP-binding proteins, which I called N_s, N_i, N_t (now transducin), and N_x, that mediate the actions of hormones on a number of effector systems. N_x was postulated when I learned that GTP affected the binding of agonists to receptors known to alter calcium uptake in liver cells.[45] By 1990 those predictions were proven correct. However, the number and variety of GTP-binding proteins involved in signal transduction are now greater than I had imagined.

General Characteristics of Guanine Nucleotide Action

During the 1970s some of the fundamental characteristics of receptor systems coupled through GTP-binding proteins had been delineated. What followed in the ensuing 20 years was the elaboration of the types of G proteins, now numbering about 20. Beginning with transducin,[46] it emerged that G proteins are constructed of three types of subunits, an α subunit uniquely capable of binding and degrading GTP and a tightly knit complex of β and γ subunits. This discovery, eventually established for all G proteins coupled to receptors,[47] opened up a new chapter in signal transduction which, in recent years, has helped to explain the pleiotropic actions of hormones.

Dr. Gilman will present much of the work on detailed structures of G proteins, including the recent X-ray crystallographic studies of $G_{s\alpha}$.[*] I will now turn to a subject that has dominated my efforts for the past 15 years.

Topological Disposition of Components

One of the most difficult problems in membrane biology is to understand how components are organized or structured within the plane of the membrane. The topological relationship of membrane proteins to the exterior and interior components of the cell presents another major problem. The "mobile receptor" concept introduced the notion that receptor proteins are free to move rapidly within the membrane. In the case of receptors linked to G proteins, this concept gave rise to the hypothesis that hormones act by stimulating the engagement between receptors and G proteins. The "collision-coupling" model[48] attributes the rate of cyclase activation to the frequency and efficiency of collisions between agonist-bound receptors and G proteins. In this manner any one receptor can activate a number of G proteins due to the free mobility of each component. The rate of activation of G proteins (and adenylate cyclase) are directly proportional to the number of agonist-occupied receptors.

Although kinetic analysis can provide important insights into mechanism, in reality the fundamental question is how the different components are constructed and distributed in the plane of the membrane so that they interact with the observed efficiency and rapidity. The logistics of the encounters are obviously better if the membrane is packed with receptors, as in the case of rhodopsin in rods or cones, where the number of receptors is in large excess of G proteins and effectors. However, in most cells hormone receptors are present at relatively low concentrations.

For this reason, I thought that receptors and G proteins may be precoupled and that hormones act by altering the nature of the coupling process. This notion now seems justified based on biophysical studies which reveal that receptors are complexed with G proteins, and that such complexes are confined within matrix-like, specialized domains.[49] In fact, the structures involved in receptor-coupled signaling processes in general now seem more Buddha-like, both in their stationary setting and their multicomponent structures, which appear to interact in a flickering fashion more in keeping with the ephemeral relationship between action and inaction, between life and death.

The major concern in my laboratory starting in the late 1970s was the structure of the hormone-sensitive cyclase systems as they exist in their native membrane environment. I had learned of target or irradiation analysis from a report that target analysis might be useful for discerning the nature of the interactions between the components of the glucagon-sensitive system in liver membranes.[50] The interpretations of the data were based on the mobile receptor theory. Of major concern to us was the fact that irradiation studies were carried out with freeze-dried material. We had learned that freeze-drying of liver membranes, for example, leads to drastic reductions in hormonal regulation of adenylate cyclase. We decided to use this technique employing a different protocol not involving freeze-drying.

Fortunately, on the floor above my lab dwelled a scientist with the necessary credentials. Ellis Kempner had conducted his graduate thesis on the usage of irradiation analysis, knew both its promises and its faults, and became interested in our problem. As importantly, a young scientist from Switzerland trained in biophysics had just arrived in the lab looking for a suitable research problem. Werner Schlegel and Kempner began a project that became the focal point of our research for the next 15 years.

[*] See Nobel Lecture by A. G. Gilman.

Target Analysis

Schlegel and Kempner ultimately worked out procedures that fully preserved activity and, indeed, provided the first detailed "functional structure" of each component of the glucagon-sensitive system in liver membranes and the hormone-sensitive, stimulatory and inhibitory structures in rat adipocytes.[51, 52] I emphasize the phrase "functional structure" since the analysis measures the exponential decay in activity in relation to the energy input of electrons that bombard the system; this relationship provides the "functional mass". As reviewed recently by Kempner,[53] irradiation of complex, multicomponent enzyme systems does not cause disruption of complexes, but introduces breakages in the protein backbone along each chain of the complex. Thus, although activity is lost, the decrease in activity accurately reflects the loss in functional mass.

Most surprising and initially puzzling were the findings that irradiation of both the liver and adipocyte systems prior to exposure to regulatory ligands—hormones, fluoride ions, guanine nucleotides—gave functional target masses of about 1500 kDa for the stimulatory processes involving glucagon and GTP; an even larger functional mass was exhibited by the inhibitory phase of the adipocyte adenosine receptor mediated process. Such large sizes did not fit with the estimated masses of receptors, G proteins and adenylate cyclase. When the systems were exposed first to activating ligands and then analyzed for their target masses, dramatic reductions in functional mass were observed. For example, in the presence of glucagon and GTP, the functional mass was reduced to about 350 kDa. In the presence of fluoride ions or Gpp(NH)p, the mass was reduced to about 250 kDa. The mass of adenylate cyclase as measured with MnATP as substrate was about 120 kDa, and has now been confirmed by the structure of cloned cyclases.

Disaggregation Theory of Hormone/GTP Action

Out of these findings arose the postulate that the hormone-sensitive cyclase system is composed of an oligomeric complex of receptors and G proteins which, upon interaction with hormone and GTP, disaggregate into the receptor and G protein monomers.[33] Most importantly, target analysis led me to the conclusion that the primary signal emanating from the actions of hormones must be a protein, which had to consist, minimally, of a GTP-binding protein. Not knowing that G proteins were heterotrimers, we estimated the size of the monomer to range from about 120 kDa (fluoride or Gpp(NH)p activation) to about 220 kDa after glucagon treatment (correcting for the estimated mass of cyclase). The estimated values obtained after fluoride or Gpp(NH)p treatment were much larger than that of $G_{s\alpha}$ (43–50 kDa). The larger value obtained after glucagon treatment I conjectured as the combination of the receptor complexed with a monomer of G_s. The monomer complex, considered to be the true "messenger" of hormone action, reacts with adenylate cyclase resulting in either stimulation (by G_s) or inhibition (by G_i). This theory I termed the "Disaggregation Theory of Hormone Action".[33] Incorporated are the fundamental ideas that the structure of the receptor/G protein complex is a multimer of these components, that adenylate cyclase exists separately from the complex, and that a "monomeric" structure derived from the disaggregation is the messenger that communicates information from the hormone-bound receptor/G protein complex to the effector or enzyme.

In this model, I had assumed that receptors and G proteins exist in about equal amounts and are coupled stoichiometrically. Much later when accurate methods became available for measuring the concentrations of receptors and G proteins in cells, it became clear that in most cells, G proteins are present in excess of receptors, possibly in a ratio of as much as 10:1. Given this information, clearly the model must be altered; such that the largest portion of the mass of the glucagon-sensitive adenylate cyclase (or the adenosine-sensitive, inhibitory system in adipocytes) is attributed to G proteins; in other words, G proteins are most likely multimeric structures.

The disaggregation theory soon fell into disfavor because of the findings that heterotrimeric G proteins treated with Gpp(NH)p or the later more popular GTPγS dissociated into free α subunits and $\beta\gamma$ complexes.[54, 55] From this arose Gilman's "dissociation" theory in 1988. The disaggregation theory clearly needed biochemical evidence for the existence of multimeric forms of G proteins. We began the odyssey in this direction with two approaches: cross-linking experiments with synaptoneurosomes from rat brain and extraction of G proteins with various detergents followed by sucrose-gradient analysis of the hydrodynamic properties of the extracted material.

Cross-Linking Studies

Synaptoneurosome membranes were chosen for most of the studies because brain tissue contains the bulk of all known types of G proteins. We were greatly aided in these studies by generous contributions from several colleagues in the field (principally, Dr. Alan Spiegel at NIH) who had prepared polyclonal antibodies against peptide sequences of the α and β subunits of several types of G proteins (G_s, G_i, G_o, and G_q), including subspecies of these proteins.

We tested a variety of cross-linking agents for both their efficacy and selectivity of action at low concentrations. *N,N'*-(1,4-phenylene)dimaleimide (1,4-dimaleimidobenzene) proved the most satisfactory. In addition to all of the G proteins tested, multimeric tubulin and F actin were the only two types of membrane-associated proteins that were detectably cross-linked.[56] After cross-linking in their membrane environment, the G proteins were extracted with sodium dodecylsulfate and chromatographed on sieving columns that allow separation of proteins over a large range of sizes. In this manner it was found that both α and β subunits of G_s, G_i, G_o, and G_q were cross-linked to form structures comparable in size to cross-linked tubulin or actin. We concluded from these studies that G proteins, most likely intact heterotrimers, are multimeric structures in association with the plasma membrane. Such evidence provided substantial credence to our basic arguments for the disaggregation theory. Most importantly, it appeared that multimeric G proteins are responsible for the large ground state structures observed with target analysis.

Detergent Studies

The next stage necessitated some means of isolating the multimeric G proteins, a process requiring the use of detergents. Aware of the fact that detergents such as sodium cholate and Lubrol extract intact heterotrimeric structures,[57] in other words monomers of the putative multimers, we considered the possibility that these detergents may disrupt the multimeric structure. Accordingly, we tested a variety of detergents and determined the sizes of G protein structures extracted by using hydrodynamic properties on sucrose gradients as our assay. Of the seven detergents tested, octyl-β-glucoside (OG), tween 20, and digitonin yielded structures behaving hydrodynamically larger than those obtained with sodium cholate or Lubrol, after correction for the possible contributions of micellar forms of the detergents.[58] OG extracted from liver membranes gave structures that were heterodisperse; about 10% sedimented through sucrose gradients and the bulk remained soluble. When membranes were treated with cholera toxin in the presence of [^{32}P]NAD (the means of specifically labeling $G_{s\alpha}$, the majority of the labeled material appeared in the insoluble fraction.[59, 60] When such labeled material in the membranes was subjected to the combined actions of glucagon and low concentrations of GTPγS, a large portion of the insoluble material became soluble and appeared in a fraction similar to that of purified heterotrimeric G_s.

Based on the cross-linking and hydrodynamic studies we deduced that G_s is likely multimeric in liver and synaptoneurosome membranes, that only multimeric structures are altered by glucagon and low concentrations of GTPγS in liver membranes, and that one of the primary results of their action is the disaggregation of multimers to monomers, as predicted in the disaggregation theory. In synaptoneurosomes high concentrations of GTPγS caused the heterotrimeric G proteins to dissociate into free α and $\beta\gamma$ subunits when dissolved in Lubrol or sodium cholate but not in digitonin.[58] Hence, our suspicions were confirmed that the native structures of G proteins are not preserved with detergents used for purifying heterotrimeric forms of G proteins.

An Extended Disaggregation Theory of Hormone Action

Target analysis provided the initial impetus for the development of the disaggregation theory. However, it has become clear that the theory as originally presented has to be modified to account for the fact that G proteins are the major contributor to the large functional mass; that is, G proteins form multimeric structures. We had also established that there are marked differences between the regulation of G proteins by the coupled receptors and the regulation of adenylate cyclase by G proteins.[42, 43] When the structures and regulatory properties of adenylate cyclases became known,[61] particularly the fact that these are transmembrane proteins that have a two-cassette structure (i.e. two distinct domains on a 12 membrane-spanning structure), it became possible to construct a more coherent theory to explain the regulation of the cyclase system.[62] Regulatory cycles A for regulation of multimer to monomer G proteins and B for regulation of cyclase by a monomeric G protein (G_s) are illustrated in Figure 2.

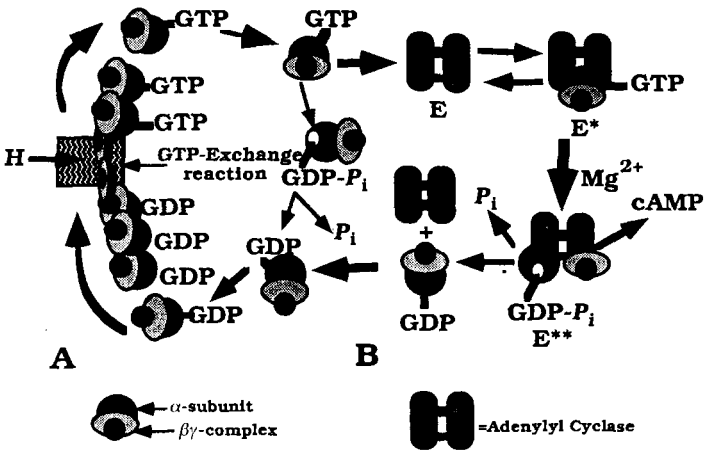


Fig. 2. Regulatory cycles for signal transduction. A) Receptor activation of G proteins. B) G_s-mediated activation of adenylate cyclase. H = hormone, E = enzyme (adenylate cyclase), E* = enzyme/G protein/GTP complex, E** = enzyme/G protein/GDP-P_i complex.

The excursion of receptor along the multimeric G protein chain is governed by the hormone-induced exchange of GTP and GDP. The GTP-occupied monomer at one end is released, allowing it either to interact with adenylate cyclase or to return (after hydrolysis of GTP to GDP) to the other terminus of the multimer. In cycle B the GTP-occupied monomer interacts with the enzyme E without necessarily inducing significant changes in enzyme activity (E*). Activity is governed by Mg^{2+}-dependent hydrolysis of bound GTP to GDP + P_i. In this scenario hydrolysis induces dissociation of the α subunit from the $\beta\gamma$ complex; the resultant separated subunits interact distinctively with the two cassettes or domains of adenylate cyclase (E**). Depending on the type of adenylate cyclase associated with the G protein, activity is governed solely by the α_s subunit, synergistically by the combination of α_s and $\beta\gamma$ subunits, or by inhibition of α_s stimulation by the $\beta\gamma$ subunit. Release of P_i from its binding site on α_s results in reassociation of α_s with $\beta\gamma$. The GDP-bound G_s protein then reassociates with the multimer to become part of the hormone-regulated cycle. It should be emphasized that both cycles occur in association with the surface membrane. The principal element that differs from other theories of hormone-regulated cyclase systems is that the concerted interactions of enzyme, Mg^{2+}, and GTPase are responsible for separation of the α_s and $\beta\gamma$ subunits. The extent and duration of enzyme stimulation are controlled by the independent actions of the separated subunits and the rate at which P_i is released following hydrolysis.

Most people in the field will argue that hydrolysis is not necessary for activation because nonhydrolyzable analogs of GTP are fully capable of stimulating cyclase activity. However, my view is that allosteric regulation by Gpp(NH)p, a slow, hysteretic process, may involve stabilization of a Mg^{2+}-induced disassociation of G_s that normally exists transiently and which does not require any participation by adenylate cyclase in the dissociative process. In this sense, the nonhydrolyzable analogs of GTP may have misguided many in the G protein field into thinking that energy derived from the splitting of GTP is not involved in signal transduction.

It should be noted in this extension of the disaggregation theory that disaggregation of multimers and dissociation of monomers are separate but interrelated phenomena, both contributing to the overall dynamics of signal transduction.

The Similar Structure and Regulation of G Proteins and Cytoskeletal Proteins

During these studies, my attention was drawn to the striking similarities of the properties of G proteins to those of tubulin and actin, the major cytoskeletal elements in cells (reviewed in ref. [63]). For example, G proteins, like actin and tubulin, are associated with the inner aspect of the surface membrane, adhering possibly both through intrinsic membrane proteins such as receptors and to membrane lipids. Of particular interest is the fact that all three types of multimeric proteins are subject to regulation by either GTP (G proteins and tubulin) or ATP (actin) and their hydrolytic products (dinucleotides and P_i). Receptors regulate exchange of bound nucleotides (GDP with GTP) and act catalytically in the process. Similarly, the excursion of a single myosin molecule during muscle contraction along the chain of actin multimers is governed by the exchange of bound ADP with ATP and the hydrolysis of ATP to ADP and P_i. As stated previously, GTP turnover (production of GDP + P_i) is essential for the rapid and sustained actions of hormones; release of P_i is the crucial rate-limiting process in the overall dynamics of signaling. The same is true for myosin/actin interactions.[64]

With these similarities in structure and regulation, G proteins can be classified as part of the cytoskeletal matrix. The primary functional difference is that G proteins serve as chemical signaling devices, whereas tubulin and actin serve as mechanical signaling devices. The release of monomers from multimers is the basis for chemical signaling by G proteins. Dynamic changes in the disaggregation–aggregation cycle of actin and tubulin multimers are also regulatory devices designed for regulating the interactions or movement between specialized components of cells. Based on evidence accumulated over the past decade,[63] all three types of cytoskeletal proteins are connected in some manner to a variety of signaling systems that adhere to the cytoskeletal matrix. These include heterotrimeric G proteins, so-called low molecular weight G proteins, protein kinases and phosphatases, and other proteins or systems that communicate between the surface membrane and the interior of cells. These components form weblike structures that possibly interact in a flickering manner in response to activation of membrane receptors, including those that are growth promoting.

Given the extraordinary complexity of signaling processes at the biochemical level, new investigatory tools are clearly needed. Already promising are the microscopic imaging techniques with immunofluorescent molecules for specifically tagging and viewing structures in their living environment. I suspect that the reductionists with their prowess in molecular biology and X-ray crystallography and those of us attempting to view the living process at the cellular level will merge with our assemblages of ideas and experiences. When this larger, multiplex community of effort finally is consummated, a bright new era in scientific discovery will certainly emerge.

This article and the following "poem" are dedicated to all my colleagues, former and present, who contributed heavily to the concept of signal transduction. Without their efforts, the field of G proteins would not have existed.

To My Friends: Thoughts from "On High"

Life on a roller coaster, oscillating from hither to yon,
no respite for the iconoclast, wandering from dusk to dawn.
Conjuring strange thoughts foreign and twice forbidden,
like Prometheus unbound, this Nobelist climbs in vain
to Andean peaks, seeking what most would proclaim insane.
Why, he ponders, are there no answers to protean questions
when others thinking cleanly and simply with Occam's sharp razor
proclaim what seems obvious given the beam of their unerring laser.
Nature, happily unfettered with philosophy, or with cunning, or with intent
moves relentlessly onward or even backward with energy unspent
while we mortals test and probe with twinkling machines
blinking precisely at each movement, striving to unravel
its irresolute randomness, its fathomless, unlimited, meaningless rush into spiraling chaos,
oblivious of its multitudinous trials & errors which we pontifically believe must be unerring truth & resolution.
The laugh is on those who, burdened with pretensions of truth, believe they can fathom within 15 minutes of human existence what has transpired over eons of space and time in this Universe.
So, I extol the intuitions encapsulated in the folds of my mind from whence occasionally they hurtle to the forebrain and in a twinkling of a proton's discharge bring to fruition a thought, an idea borne on the feathery appendages of teeming neurons wedded in a seamless synergy. Those fleeting moments are cherished, as are those precious impulses imparted by the innumerable individuals who nurtured and instilled unknowingly their encrypted thoughts in mine.
So, with these fanciful thoughts in mind I give praise to you—my friends, my colleagues, my soul-mates, my loved ones for letting my soul and thoughts meander hither and yonder in this attempt at philosophy and poetry. We now belong to the gods on high who praise us for our frailties and our achievements.

Fullerene Model Compounds: Bowl-Shaped Aromatic Hydrocarbons and Cyclophane-Based Cage Molecules

Rüdiger Faust*

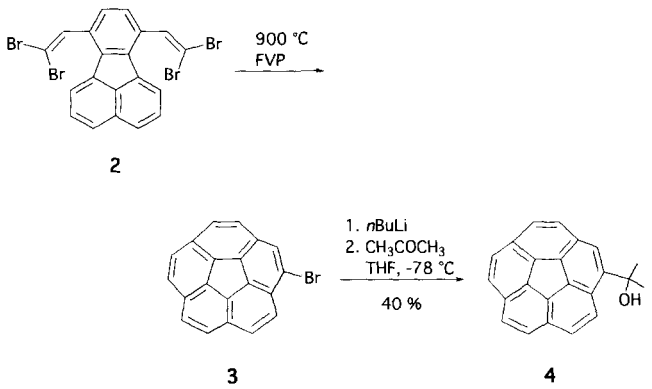
Despite the continuous stream of exciting reports about the chemistry of buckminsterfullerene C_{60},[1, 2] a classical total synthesis of this spherical molecular carbon allotrope remains a great intellectual and preparative challenge.[3] Meanwhile, the curved "aromatic" surface of the fullerene and the cavity it encapsulates have stimulated the investigation of model compounds that, besides being interesting in their own right, may ultimately prove to be suitable starting points for a flexible assembly of carbon spheres. Bowl-shaped aromatic hydrocarbons and cyclophane-based cage compounds are among the promising candidates, and some of the more recent results in these fields are highlighted in the following.

Corannulene **1**,[4] the archetypical bowl-shaped aromatic hydrocarbon (Fig. 1), was first synthesized by Barth and Lawton

1

Fig. 1. Corannulene **1**, the archetypical bowl-shaped aromatic hydrocarbon.

in the pre-fullerene era almost thirty years ago in a tedious, seventeen-step procedure. It was not until 1991 that Scott and co-workers[5] followed up on this milestone effort and reported a convenient access to **1** from simple fluoranthene precursors by flash vacuum pyrolysis techniques.[6] In addition to the attractive brevity of this protocol it proved to be of great generality (vide infra) and, furthermore, it is easily modified to provide substituted derivatives of **1**. Thus, starting from 7,10-bis(2,2-dibromovinyl)fluoranthene (**2**) (readily prepared from acenaphthenequinone and dimethyl 3-oxoglutarate), bromocorannulene **3** could be obtained in reasonable but variable yields (around 29% in one case) along with **1** and 1,6-dibromocorannulene (Scheme 1).[7] Reaction of the lithiated derivative of **3** with acetone resulted in the formation of the corresponding racemic 2-corannulenyl-2-propanol (**4**), whose diastereotopic methyl groups were used as probes to determine the equilibrium



Scheme 1. Pyrolytic synthesis of bromocorannulene **3** by flash vacuum pyrolysis (FVP) and its conversion to **4**.

of bowl-to-bowl inversion by dynamic NMR methods. Truly remarkable for a seemingly rigid framework as that of **1** consisting solely of sp^2-hybridized carbon atoms, the barrier to bowl inversion of **4** was determined to be $\Delta G^{\neq} = 10.2 \pm 0.2$ kcal mol^{-1} at $-64\,^{\circ}C$, indicating that at room temperature cup-shaped corannulene inverts more than 200000 times per second! Even greater flexibility was demonstrated for the 1,2-dihydro- and 1,2,5,6-tetrahydrocorannulene derivatives with $\Delta G^{\neq}$ values of 8.5 ± 0.5 and 6–7 kcal mol^{-1}, respectively.[6a]

The first metal complex of corannulene was obtained by treating it with excess lithium metal in [D_8]THF.[8] In agreement with theoretical predictions **1** was slowly converted into a stable, diamagnetic tetraanion in which the negative charge is distributed on the internal as well as on the peripheral carbons. One can therefore speculate that $\mathbf{1}^{4-}$ is best represented electronically as an aromatic cyclopentadienyl anion embedded in an aromatic 18 π electron [15]annulene trianion. Evidence for supramolecular phenomena of corannulene tetraanions and their counterions in solution was first detected when alkylated derivatives of **1** were treated with lithium metal.[9] Aggregation of the resulting monosubstituted corannulene tetraanions led to stereoisomeric dimers that were readily distinguished by ^{1}H NMR spectroscopy. It was therefore proposed that $\mathbf{1}^{4-}$ occurs as $[\{(Li^+)_4 \cdot \mathbf{1}^{4-}\}_2]$ in analogy. An elegant ^{7}Li NMR study further revealed that four of the eight Li cations are sandwiched between the two charged corannulenes, while two of the remaining four reside on each of the outer sides of the hydrocarbons (Fig. 2). Variable-temperature NMR experiments demonstrat-

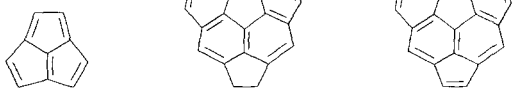
ed a rapid exchange between the exterior and the interior lithium cations at room temperature ($\Delta G^{\neq}$ = 13.2 kcal mol^{-1} at 265 K) and indicated that this process occurs without dissociation of the dimeric complex. MNDO calculations suggest that the two bowls prefer a convex–concave spatial relationship, like stacked cups in a cupboard. However, the magnetic equivalence of the two arenes and the four exterior lithium cations even at 190 K led to the conclusion that a rapid concerted bowl-to-bowl inversion process of the two corannulenes must occur.

An interesting comparison to the lithiated corannulenes is provided by the recent report of de Meijere, Stalke, and coworkers on the crystal structure of dilithiated acepentalene (**5**),[10] whose curved carbon framework constitutes a fragment



5 **6** **7**

of the smallest theoretically possible fullerene C_{20}. Similar to the corannulene tetraanions, acepentalenediide forms a dimeric aggregate in the solid state in which two dianionic hydrocarbon moieties are bridged by two lithium cations and one of the remaining two Li^+ ions resides on each of the two exterior sides of the dimer (Fig. 3). In contrast to the stacking pattern proposed for dimeric tetralithiocorannulene, the acepentalenediide units show a convex–convex spatial relationship in which the bottoms of the bowls are directed towards each other. This arrangement, however, does not seem to prevail in solution, where apparently either rapid fluctuation processes (e.g. bowl inversion, monomer–dimer equilibrium) occur or distinct monomers of dilithioacepentalenediide exist.

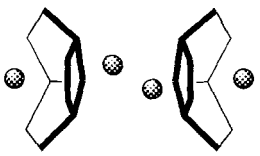


Fig. 3. Schematic representation of dimeric dilithioacepentalenediide in the solid state. The DME solvent molecules coordinated to the lithium cations are omitted for clarity.

The rate of inversion in bowl-shaped aromatic hydrocarbons can be effectively reduced by increasing the curvature of the bowl and/or deepening its cavity. This concept was explored by Rabideau et al. who showed that the ^{1}H NMR resonances of the ethano bridge hydrogens in dihydrocyclopenta[*bc*]corannulene **6** do not coalesce up to the observable temperature limit of 135 °C.[11] Spin polarization transfer experiments at 127 °C allowed the estimation of $\Delta G^{\neq}$ = 26 kcal mol^{-1} as the lower limit for the inversion barrier of **6**. This means that the molecule is essentially locked into one conformation of the cup even at elevated temperatures with a barrier to inversion that is more than twice as high as that of non-annelated **4** and hence **1**. The rigid structures of **6** and cyclopentacorannulene **7** also lead to interesting long-range packing effects in the solid state.[12] X-ray crystallographic analysis of **7** reveals that the molecules are stacked together in a concave–convex fashion as depicted schematically in Figure 4. The presence of weak π-stacking interac-

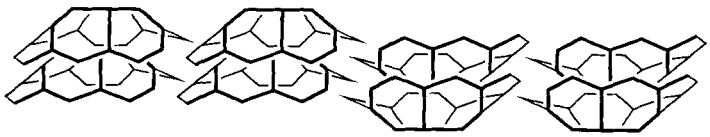

Fig. 4. Idealized representation of the stacking pattern of **7** in the solid state.

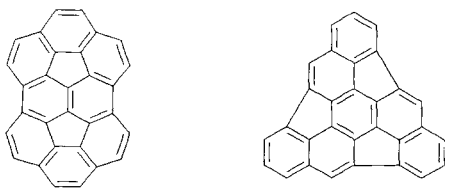
tions between the arenes is suggested by 24 intermolecular C–C distances that are shorter than the sum of the van der Waals radii of two carbon atoms. Such a regular stacking pattern is absent in the solid-state structure of **1**,[4c] where presumably rapid fluxional processes prevent a higher degree of orientation. In the gas phase, on the other hand, **1** seems to interact with curved aromatic surfaces, as implied by reactions between **1** and its radical cation, and between **1** and $C_{60}^{\cdot+}$.[13] Electrostatic considerations point to a dominantly concave–convex arrangement in $[\mathbf{1}\cdot\mathbf{1}]^{\cdot+}$, while some ambiguity remains about the structure of the $[\mathbf{1}\cdot C_{60}]^{\cdot+}$ complex.

With respect to a possible total synthesis of buckminsterfullerene, bowl-shaped aromatic hydrocarbons whose carbon skeletons constitute half of the C_{60} surface are particularly relevant as potential synthetic intermediates. These so-called semibuckminsterfullerenes[14] have recently attracted considerable attention, both from a synthetic and a theoretical point of view. Starting from 1,2,5,6-tetraoxopyracene and relying on pyrolytic methodology developed by Stang and co-workers, Rabideau et al. were able to synthesize **8** as the first member of this class of compounds.[15] Although the yellow needles of **8** (decomp. > 300 °C) were not suitable for X-ray diffraction studies, the bowl-shaped topology of **8** is convincingly supported by computational structure optimizations at the ab initio HF/3-21G level. Compared to smaller fullerene fragments, the depth of the bowl is significantly increased, leading to an estimated (computed) barrier of bowl-to-bowl inversion of 57 kcal mol^{-1}. The degree of curvature on the surface of **8** is predicted to be very close to that of C_{60}, suggesting that topologically **8** is indeed a good model for the fullerene. As a direct precursor for carbon spheres, however, **8** is of little value, since dimerization



8 **9**

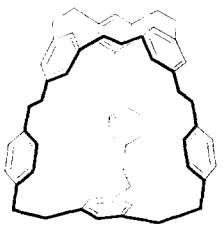
of this C_{30} unit would lead to a carbon cage with four pairs of adjacent five-membered rings, a structure that would violate the "pentagon rule" for stable fullerenes.

Another member of this class of semibuckminsterfullerenes is triindenotriphenylene **9**, a molecule whose carbon skeleton was

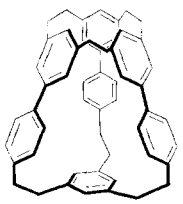
already suggested in 1987 by McKee and Herndon[16] as a possible intermediate in the formation of C_{60}. Although **9** is still elusive experimentally, it has received keen interest recently,[14, 17–19] partly because the rigidity of the bowl-shaped carbon frame should give rise to a large inversion barrier[17] (calculated to be 74 kcal mol^{-1}), rendering **9** a test case for competitive concave or convex metal complexation.[14, 18] While semiempirical calculations favor coordination of some cations (e.g. Li^+, Tl^+, and Pb^+) to the outside of the bowl, other metals (e.g. Na^+, K^+, Ga^+) are predicted to bind preferentially to the concave side of **9**. Ab initio calculations with the HF/6-31G*//3-21G basis set, on the other hand, suggest that the electron density inside the bowl is significantly greater than on the outside, but also indicate that the bias for binding most metal cations on either face of **9** is rather small and amounts to an energy difference of only 1–2 kcal mol^{-1}.[18b] Clearly, the true value of metal ion complexed, bowl-shaped aromatic hydrocarbons as models of exo- or endohedral fullerene derivatives will only be evident after much needed experimentation.

A different approach to fullerene model compounds was recently presented by Vögtle and co-workers.[20] They realized that certain cyclophane-based hydrocarbon cages define an almost spherical cavity which, in contrast to the inside of the fullerenes, can be accessed through custom-tailored openings on the surface of these "spheriphanes". In light of the finding that pyrolysis of simple aromatic compounds such as naphthalene leads to the formation of fullerenes,[21] concave cyclophane hosts with an appropriate number of carbon centers can be envisioned to serve as direct precursors for endohedral fullerene complexes[22] that are currently obtained by arc-discharge vaporization of doped graphite.

While this concept is still far from being practical, first steps in this direction have now been made with the synthesis of two "spherical" hydrocarbons, namely **10** (molecular formula $C_{60}H_{60}$) and the smaller, more rigid hydrocarbon cage **11**



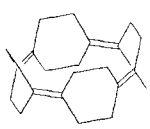
10



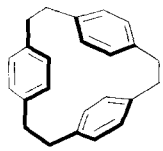
11

($C_{54}H_{48}$). Both compounds were obtained from simple benzene derivatives by established cyclophane methodology. Semiempirical structure optimizations predict that the cavity of **10** should be large enough to accommodate a variety of neutral, organic guests such as adamantylamine and *tert*-butylamine. Although cocrystallization experiments have proved to be unsuccessful so far, preliminary studies at high pressure indicate that such supramolecular inclusion complexes can indeed be obtained.

Quite remarkable is the complexation behavior of **10** towards silver cations. Extraction experiments show that 10^{-3} M chloroform solutions of **10** are able to extract 10% of the silver cations from aqueous $AgNO_3$ solutions. In comparison to other π-spherands like **12**[23] and **13**,[24] both of which are known to form stable inclusion complexes with Ag^+, the extracting power of **10** under these conditions is at least two times higher than that of **13** and exceeds those of the smaller cyclophane **11** and of **12** by one order of magnitude. In addition, the hydrocarbon cage **10** shows high selectivity for Ag^+ and almost ignores other metal ions like Na^+, Ca^{2+}, and Zn^{2+}, as well as Tl^+ and Hg^{2+}, which have ionic radii similar to that of Ag^+.



12



13

It is tempting to assume that the silver ion resides inside the deep cavity of **10**, but neither the exact composition of the complex nor the location of the metal ion could as yet be determined experimentally. However, the characterization of endohedral cyclophane complexes of **10** is clearly only a matter of time and will mark another step towards a rational assembly of "filled" fullerenes.[25]

Progress in Oligosaccharide Synthesis through a New Orthogonal Glycosylation Strategy**

Hans Paulsen*

Glycoconjugates have numerous important biological functions.[1, 2] For a better understanding of these functions, defined natural and modified glycoconjugates are needed. To this end, intensive efforts in the last few years have been aimed at the synthesis of glycoconjugates, resulting in remarkable progress in oligosaccharide synthesis. New glycosylation methods have been developed with efficient leaving groups, which lead to good yields and high stereoselectivity under mild conditions. The halide, thioglycoside, and trichloroacetimidate methods,[3–5] in modified forms, have proved to be especially effective. Chemical and enzymatic reactions can also be combined, as long as the glycosyl transferases and the activated nucleotide sugar are available.[6]

The most effective methods for the construction of larger oligosaccharides is block synthesis, in which blocks of di- or trisaccharides are coupled. The configuration of the anomeric centers is already fixed in the nonreducing block sequences.[7] One drawback here is that the anomeric center at the reducing unit of a block must be reactivated for subsequent coupling. Activation of the anomeric center should not require many steps or, better yet, should be direct. Thus 2-(trimethylsilyl)ethyl-glycosides, for example, have been prepared from blocks,[8] which are readily deprotected and converted into activated trichloroacetimidates.[5, 9] Glycal-type structures can also be activated by epoxidation, making renewed coupling possible.[10] However, use of stable thioglycosides at the anomeric center of the block is best, since a wide variety of structures and promoters is possible.

For the construction of an oligosaccharide building block a glycosylation reaction is also necessary. The synthesis of a thioglycoside-containing unit, for example, requires a different glycosylation procedure with a different leaving group for the donor, since the potentially activatable thioglycoside would be destroyed otherwise. Numerous strategies are available, which involve several or more additional reaction steps, depending on the blocking pattern. The coupling of donors activated by benzyl substituents with acceptors deactivated by acetyl groups has also been suggested.[11, 12] Ogawa et al. recently described an interesting and provocative strategy that starts with a set of two donors, which can be extended in an orthogonal glycosylation reaction.[13]

The approach was demonstrated with a model reaction sequence leading to long-chain $\beta(1 \rightarrow 4)$-glycosidically linked 2-acetamido-2-deoxy-D-glucose units (Scheme 1). Thioglycoside **1** and glycosyl fluoride **4** serve as the two building blocks. Thioglycoside **1** can be coupled with the deactylated glycosyl fluoride **3** without affecting fluorine at the anomeric center, and the resulting disaccharide **5** with the activated anomeric center can be used directly for further glycoside synthesis. Inversely, the reaction of glycosyl fluoride **4** with the deacetylated thioglycoside **2** yields disaccharide **7** in which the thioglycoside is unchanged. This disaccharide can also be employed directly in further glycosidation without any additional steps. This flexible method thus enables glycosidation without destruction of the active anomeric center at the acceptor. This promising strategy can be applied to other systems.

The phenylthioglycosides employed are activated with *N*-iodosuccinimide trifluoromethanesulfonic acid (NIS-TfOH) (or NIS-AgOTf), and the phenylthiogroup acts as a leaving group. In reactions with the glycosyl fluorides the promotor is the reagent Cp_2HfCl_2–$AgClO_4$. Thus larger oligosaccharide blocks can be constructed from the two monosaccharides **1** and **4** with these two reagents. Compounds **1** and **4** contain an *N*-phthaloyl group at C-2, which induces uniform β-glycosidic linkage.

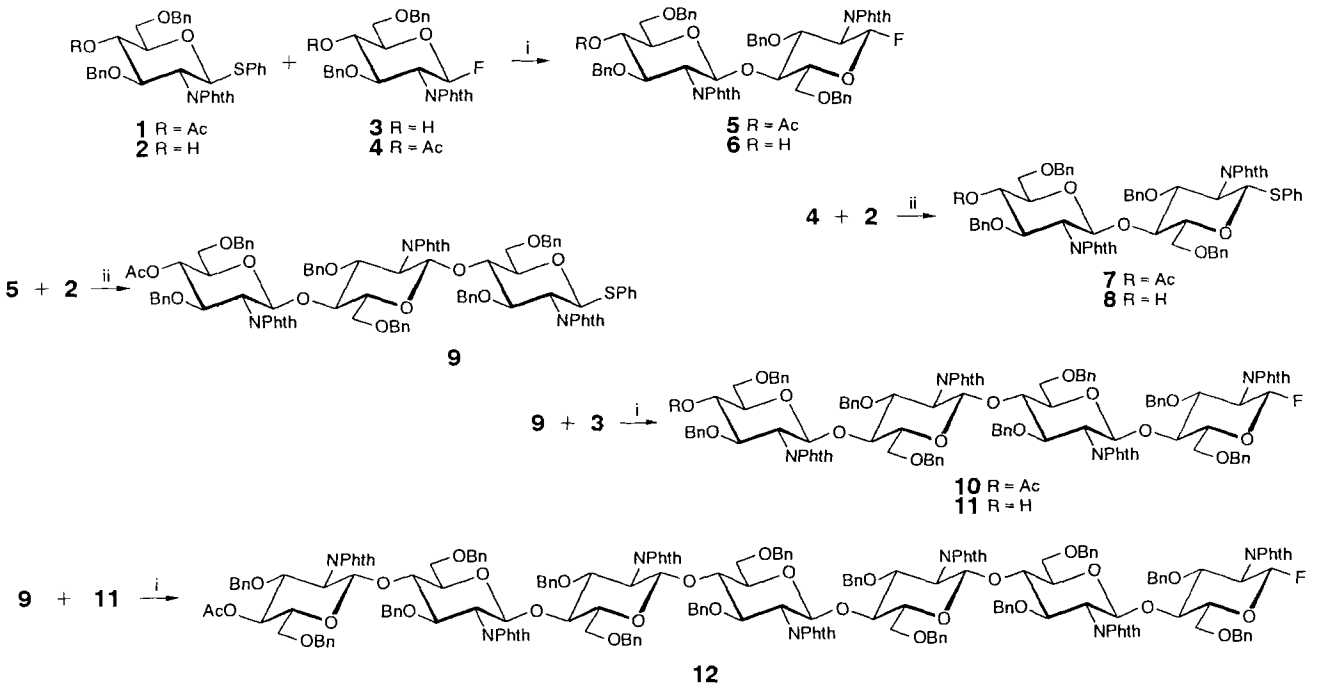
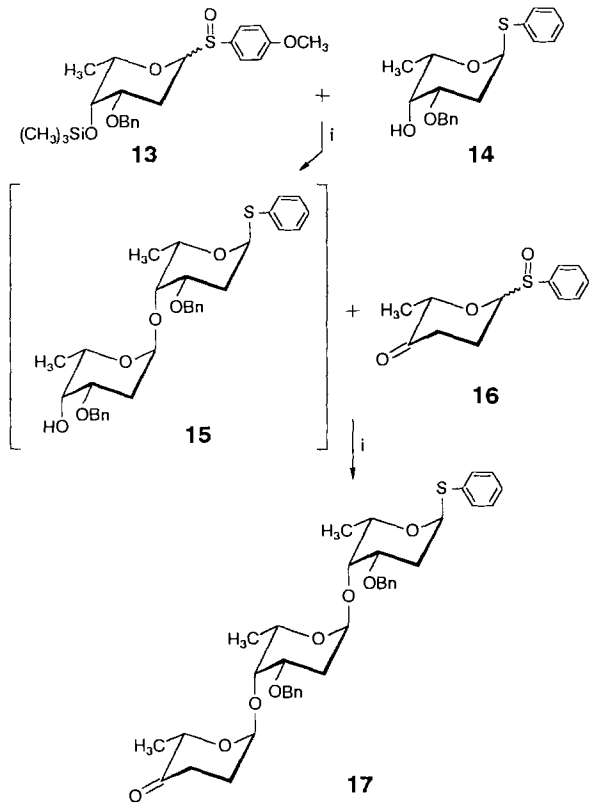


Scheme 1. i) NIS, TfOH (AgOTf); ii) Cp_2HfCl_2, $AgClO_4$.



Scheme 2. i) TfOH, $HC{\equiv}CCO_2CH_3$, −78 °C.

The approach was demonstrated with the following synthesis. Coupling of **1** and **3** affords disaccharide **5** (85%), whereas the reaction of donor **4** with **2** gives the disaccharide **7** (81%). Disaccharide **5** is treated with **2** to furnish trisaccharide **9** (72%). The subsequent coupling of **9** with **3** yields tetrasaccharide **10** (65%). Deacetylation of **10** to **11** can be followed by block condensation of trisaccharide **9** with **11**, which yields heptasaccharide **12** (67%). Phenylthioglycosides and glycosyl fluorides are used both as donors and as acceptors, and additional steps for activation of the anomeric center are not required in either case.

Kahne et al.[14] used a similar strategy in a very elegant synthesis of a trisaccharide in practically one step. The building blocks they used, the S-glycosides **13**, **14**, and **16**, have considerably different reactivities at the anomeric center (Scheme 2). Phenylthioglycoside **14** is definitely the least reactive, while phenyl sulfoxide **16** is considerably more reactive. The reactivity of **16** can be increased yet further by introduction of a methoxy substituent on the phenyl group, thus giving the highly reactive *p*-methoxyphenylsulfoxide **13**.

A solution of building blocks **13**, **14**, and **16** in Et_2O/CH_2Cl_2 is simply mixed in the presence of TfOH and $HC{\equiv}CCO_2CH_3$ at −78 to −70 °C, and trisaccharide **17** is isolated in 25% after 45 min. It is assumed that the modestly reactive **14** reacts first with the highly reactive **13** to give disaccharide **15**; the silyl ether is cleaved simultaneously, and **15** reacts with the moderately reactive **16** to provide **17**.

In view of the available arsenal of glycosylation reactions,[15, 16] these two examples should point the way for the development of similar strategies.

[WL(NO)(O)(CH$_3$)]—An Unusual Nitrosyltungsten Complex**

Jochen Böhmer, Karl Wieghardt,* and Bernhard Nuber

Recently we reported[1] the first example of a mononuclear nitrosyl(oxo)molybdenum(II) complex, [MoL(NO)(O)(OH)] (L = 1,4,7-triisopropyl-1,4,7-triazacyclononane), in which the strong π-acceptor ligand NO and the strong π-donor ligand O^{2-} are bound to the same metal ion in a *cis* arrangement. This 18e complex is of the $\{M\text{-}NO\}^4$ type; the terminal Mo=O and Mo=NO bonds are short and both have double-bond character. A synergistic bonding model has been proposed in which electron density is transferred from the filled p orbitals of the oxo ligands to the empty π* orbitals of the nitrosyl ligand thus weakening the N–O bond.[1] We report here on an unusual organometallic variant of this class of compound.[2]

Nitrosylation of [WL(CO)$_3$][3] with $NaNO_2$ and concentrated HCl in methanol, followed by addition of KPF_6, gave yellow air-stable crystals of [WL(NO)(CO)$_2$]PF$_6$ (**1**). Reduction of **1** with $LiAlH_4$ in dry THF under anaerobic conditions (Scheme 1) results in a blue solution from which, following hydrolysis with H_2O and filtration, blue crystals of [WL(NO)(CO)(CH$_3$)] (**2**) were isolated.[4] Complex **2** reacts quantitatively in CH_3CN with concentrated HCl in the absence of oxygen to yield one equivalent each of methane and [WL(NO)(CO)(NCCH$_3$)]Cl. The latter is converted with $NaClO_4$ to the perchlorate salt **3**, which is air stable in solution and in the solid state. The 18e complexes **1**–**3** are of the $\{W\text{-}NO\}^6$ type.[5]

Complex **2** reacts in acetone with oxygen within seconds at room temperature, as evidenced by a change in the color of the solution from blue to red. After removal of the solvent we obtained red microcrystals of [WL(NO)(O)(CH$_3$)] (**4**) in almost quantitative yield; this compound represents a complex of $\{W\text{-}NO\}^4$ type. In the IR spectrum, the NO and W=O stretching frequencies are observed at 1433 cm^{-1} (!) and 835 cm^{-1}, respectively. If the reaction is carried out in the presence of $^{18}O_2$ only the latter band shifts to lower wavenumbers (796 cm^{-1}), whereas the band attributable to NO does not shift. The observed value for the ν(NO) stretching frequency of **4** constitutes, to the best of our knowledge, the lowest wavenumber ever reported for a linear M–NO group.

The gaseous products that form when **2** is allowed to react with O_2 were analyzed quantitatively (GC, MS) and identified as CO_2 and CO; the combined amount of these two gases corresponds exactly to the one equivalent of CO ligand that has been displaced from **2** [Eqs. (a) and (b)]. The CO_2/CO ratio is

$$2[WL(NO)(CO)(CH_3)] + O_2 \xrightarrow{2} 2[WL(NO)(O)(CH_3)] + 2CO \quad (a)$$

$$[WL(NO)(CO)(CH_3)] + O_2 \rightarrow [WL(NO)(O)(CH_3)] + CO_2 \quad (b)$$

Table 1. Selected physical data for **1**–**4**.

1: ^{1}H NMR (CD_3CN, 400 MHz): δ = 3.59 (sep, 2H), 3.26 (sep, 1H), 3.20–2.87 (m, 12H), 1.34 (d, 6H), 1.33 (d, 6H), 1.21 (d, 6H); $^{13}C\{^1H\}$ NMR (CD_3CN, 106.22 MHz): δ = 221.21, 65.19, 63.05, 54.04, 53.43, 52.97, 18.82, 18.68, 18.43; IR: ν_{as}(CO) 2002, ν_s(CO) 1905, 1892, ν(NO) 1659, 1642 cm^{-1}; FAB-MS: *m/z* 525.1 $[M - PF_6]^+$; UV Vis (CH_3CN): λ_{max} (ε, L mol^{-1} cm^{-1}) = 240 (sh) (9000), 260 (8350), 338 (310), 391 (200), 460 (sh) nm (90)

2: ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 3.76 (sep, 1H), 3.67 (sep, 1H), 3.36 (sep, 1H), 3.15–2.42 (m, 12H), 1.43 (d, 3H), 1.38 (d, 6H), 1.30 (d, 3H), 1.14 (d, 3H), 1.02 (d, 3H), 0.06 (s/d, ^2J(W,H) = 7.32 Hz, 3H); IR: ν(CO) 1805, ν(NO) 1520 cm^{-1}; UV/Vis (CH_3CN): λ_{max} (ε, L mol^{-1} cm^{-1}) = 232 (4660), 319 (1050), 395 (140), 593 nm (60)

3: ^{1}H NMR (CD_3CN, 400 MHz): δ = 3.57 (sep, 1H), 3.47 (sep, 1H), 3.29 (sep, 1H), 3.19–2.79 (m, 12H), 2.67 (s, 3H), 1.41 (d, 3H), 1.30 (d, 3H), 1.29 (d, 3H), 1.28 (d, 3H), 1.21 (d, 3H), 1.16 (d, 3H); $^{13}C\{^1H\}$ NMR (CD_3CN, 106.22 MHz): δ = 206.29, 142.39, 67.13, 61.14, 60.56, 55.12, 54.04, 53.48, 52.13, 50.42, 19.92, 19.18, 18.72, 17.27, 15.97, 4.57; IR: ν(CO) 1871, 1863; ν(NO) 1593 cm^{-1}; FAB-MS: *m/z* 538.2 $[M - ClO_4]^+$; UV/Vis (CH_3CN): λ_{max} (ε, L mol^{-1} cm^{-1}) = 230 (8840), 274 (7380), 335 (1100), 396 (160), 522 (125)

4: ^{1}H NMR (CD_3OD, 400 MHz): δ = 4.13 (sep, 1H), 3.68 (sep, 1H), 3.29 (sep, 1H), 3.20–2.58 (m, 12H), 1.41 (d, 3H), 1.34 (d, 3H), 1.27 (d, 3H), 1.10 (d, 3H), 1.03 (d, 3H), 1.00 (d, 3H), 0.27 (s/d, ^2J(W,H) = 7.80 Hz, 3H); $^{13}C\{^1H\}$ NMR (CD_3OD, 106.22 MHz): δ = 62.21, 60.53, 60.38, 59.49, 59.22, 58.39, 46.15, 45.03, 44.39, 21.31, 21.17, 21.04, 19.49, 15.81, 15.48, 14.91; IR: ν(NO) 1433, ν(W^{16}O) 835, ν(W^{18}O) 796 cm^{-1}; FAB-MS: *m/z* 500.1 $[M^+]$; UV/Vis (CH_3CN) λ_{max} (ε, L mol^{-1} cm^{-1}) = 228 (4500), 330 (sh) (500), 385 (sh) (160), 548 (70)

dependent on the initial concentration of **2**: at 0.023 M [**2**] this ratio is approximately 80:20; whereas at [**2**] $< 10^{-3}$ M the only detectable gaseous reaction product is CO_2. When the reaction was carried with $^{18}O_2$, the isotopically labeled products $[WL(N^{16}O)(^{18}O)(CH_3)]$, $C^{18}O^{16}O$, and $C^{16}O$ could be identified by IR spectroscopy and mass spectrometry. The mechanistic interpretation of these results is shown in Scheme 1.[6] Kinetic studies aimed at the elucidation of the mechanism of the oxidation of **2** with O_2 are in progress.

The results of single-crystal X-ray diffraction analyses[7] of **2**·acetone and **4**·$C_2H_5OH \cdot 2H_2O$ confirm the mononuclear nature of these complexes (Figs. 1 and 2, respectively). The W=O bond in **4** is relatively short (1.826(9) Å) and has substantial double-bond character; it is slightly longer than those in octahedral oxotungsten(VI) complexes (1.67–1.76 Å).[8] The W–NO bond is also rather short (1.71 Å), whereas the N–O bond appears to be weak at 1.24(2) Å. In the solid state, the W=O group in **4** forms a strong hydrogen bond to one ethanol molecule ($O(1)\cdots O_{EtOH}$ 2.567(8) Å), whereas the oxygen atom of the nitrosyl ligand is bound to one molecule of water of crystallization ($O(4)\cdots O_{H_2O}$ 2.533 Å). The presence of O–H···O hydrogen bonds confirms the increased electron density and, therefore, the basicity of the two oxygen atoms in the neutral molecule of **4**.

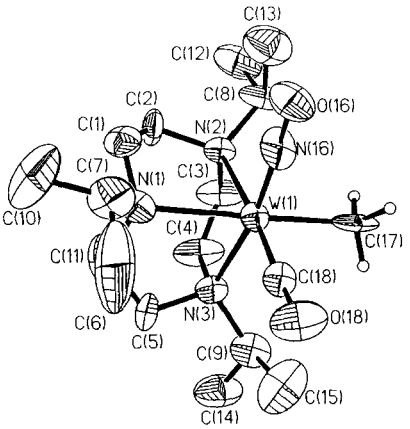

Fig. 1. Structure of the neutral complex in crystals of **2**·acetone. Selected bond lengths [Å] and angles [°]: W(1)-N(1) 2.35(2), W(1)-N(2) 2.38(2), W(1)-N(3) 2.34(2), W(1)-N(16) 1.80(2), W(1)-C(17) 2.29(2), W(1)-C(18) 1.87(2), N(16)-O(16) 1.21(3), C(18)-O(18) 1.21(3); N(16)-W(1)-C(18) 86.8(10), W(1)-N(16)-O(16) 173.6(22), W(1)-C(18)-O(18) 177.2(19).

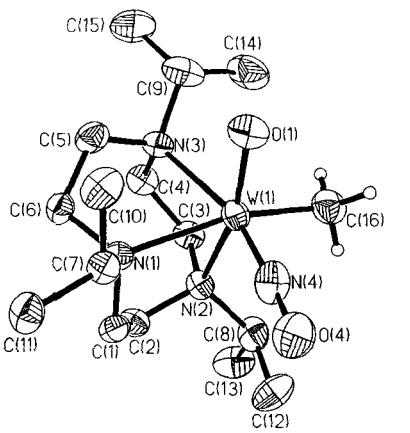

Fig. 2. Structure of the neutral complex in crystals of **4**·$C_2H_5OH \cdot 2H_2O$. Selected bond lengths [Å] and angles [°]: W(1)-N(1) 2.297(8), W(1)-N(2) 2.422(9), W(1)-N(3) 2.417(11), W(1)-N(4) 1.708(14), W(1)-O(1) 1.826(9), W(1)-C(16) 2.15(1), N(4)-O(4) 1.24(2); O(1)-W(1)-N(4) 101.5(5), O(1)-W(1)-C(16) 98.2(4), N(4)-W(1)-C(16) 93.9(5), W(1)-N(4)-O(4) 174.0(10).

Interestingly, ^{183}W satellite peaks are discernible in the 400 MHz ^1H NMR spectra of **2** (in CD_2Cl_2) and **4** (in CD_3OD); these satellite peaks are characteristic for $W-CH_3$ groups. The $^2J(W,H)$ coupling constants for **2** and **4** are 7.32 Hz and 7.80 Hz, respectively. For comparison, a coupling constant of 9.5 Hz has been reported for $[Tp^*W^{VI}(O)_2(CH_3)]$ (Tp* = tris(3,5-dimethyl-1-pyrazolyl)borate).[9] A correlation exists between the $^2J(W,H)$ coupling constant and the formal oxidation state of the tungsten center, which increases from zero in **2**, to two in **4**, and to six in $[Tp^*W(O)_2(CH_3)]$.

Complex **4** comprises the strong π-acceptor ligand NO, the very strong π-donor ligand O^{2-}, *and* one very strong σ-donor ligand, CH_3^-. All of these ligands are coordinated to the same metal ion in a *cis* arrangement. This shows once again the marked tendency of nitrosyl ligands to undergo (M–NO) π-backbonding with concurrent weakening of the N–O bond (ν(NO) at 1433 cm^{-1}). Compound **4** can be regarded as an 18e complex if one assumes the presence of a W=O double bond with the 4e donor O^{2-} as ligand. Alternatively, the electronic structure of **4** can be described in terms of an octahedrally coordinated W^{IV} center (d^2), an antiferromagnetically coupled NO ligand ($S = 1$), and one oxo and one methyl anion.[10] The presence of an oxophilic W^{IV} center in this formulation readily explains the remarkable stability of **4**.

Experimental Procedure

1: Concentrated HCl (10 mL) was slowly added (effervescence!) to a suspension of $[LW(CO)_3]$ (1 g, 1.9 mmol) and $NaNO_2$ (0.3 g, 4.3 mmol) in methanol (100 mL) resulting in a yellow solution. Insoluble material was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in water (100 mL) and the solution was filtered. The yellow product **1** was precipitated by adding a solution of KPF_6 (0.5 g, 2.7 mmol) in water (50 mL) to the filtrate. Yield: 1.15 g (90%).

2: A solution of **1** (1 g, 1.5 mmol) in THF (200 mL) was purged with argon, and $LiAlH_4$ (0.3 g, 7.9 mmol) was added in small portions. The mixture was stirred at room temperature until the solution had turned blue, whereupon unreacted $LiAlH_4$ was removed by filtration. Degassed water (30 mL) was slowly added to the filtrate and the resulting precipitate was collected by filtration under an inert argon atmosphere. The THF was removed under vacuum and the blue product **2** precipitated as a microcrystalline powder from water. Yield: 0.46 g (60%).

3: Under an inert argon atmosphere, **2** (0.3 g, 0.6 mmol) was dissolved in a solvent mixture of HCl/CH_3CN (1:3) (the solvent mixture was purged with argon prior to use) resulting in effervescence and a red solution. The solvent was removed under vacuum and the residue was dissolved in methanol (10 mL). Upon addition of $NaClO_4$ (0.1 g), the product **3** precipitated as a red, microcrystalline solid. Yield: 0.33 g (90%).

4: **2** (1.0 g, 2.0 mmol) was dissolved in CH_2Cl_2 (15 mL) in air. The color of the solution changed from blue to red. After removal of the solvent the red product **4** was obtained quantitatively. Yield: 0.95 g (95%).

All compounds gave satisfactory elemental analyses (C, H, N). Selected physical data for these complexes is summarized in Table 1.

Gladysz, *ibid.* **1982**, *104*, 141. h) We were subsequently able to show that this reaction can be applied to amine rhenium(I) complexes and have prepared [Re(tacn)(NO)(CO)(CH_3)] (tacn = 1,4,7-triazacyclononane) which was found to be stable toward oxygen: C. Pomp, K. Wieghardt, *Inorg. Chem.* **1988**, *27*, 3796.

[5] J. H. Enemark, R. D. Feltham, *Coord. Chem. Rev.* **1974**, *13*, 339.

[6] The proposed mechanism for the formation of **4** and $C^{16}O^{18}O$ involves the intramolecular rearrangement of a coordinated peracid ester and is formulated in analogy to mechanisms for the reaction of [IrCl(CO)(tdpme)] or [Os(NO)(CO)Cl(PPh_3)$_2$] with O_2 (tdpme = 1,1,1-tris(diphenylphosphanomethyl)-ethane). In both of these reactions an intermediate comprising a bidentate carbonato ligand has been identified. In the present reaction such a carbonato complex is also conceivable as an intermediate which subsequently decomposes to give **4** and CO_2. W. O. Siegl, S. J. Lapporte, J. P. Collman, *Inorg. Synthesis of Belt Cyclophanes**

Herbert Meier* and Klaus Müller

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

Cyclophanes[1, 2] and compounds with beltlike structures[3] are important themes in organic chemistry. We report here on the synthesis of novel belt cyclophanes. Their molecular basis is an [18]annulene anellated with arenes. The preparatively simple approach to these compounds is based on a highly stereoselective triple cyclocondensation of azomethines.[4, 5] The naphthalene, phenanthrene, and chrysene derivatives **1** are transformed by elimination of aniline under alkaline conditions into compounds **2** (Scheme 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In contrast to unsubstituted [18]annulene,[6] the areno-condensed [18]annulenes **2** are not planar but have a pyramidal structure with C_3 symmetry.[4] In this case the lowest energy structure corresponds to a compromise between the increased resonance stabilization in the planar structure and the simultaneously increased steric interaction of the six inner H atoms. Force field calculations (MMX, PC Model 4.0 Serena)[7] for $R^i = H$ ($i = 1...4$) indicated that the anellated compounds **2a–h** should be more planar than **2i–k**. Characteristic parameters are the torsion angles θ (C_8-C_9-C_{9a}-C_{29}), which are 25.1° in the first case and 33.2° in the second. The enthalpy of formation ΔH_f is correspondingly lower for the first set of compounds than for the second (208.7 versus 216.5 kcal mol^{-1}, $R^i = H$).

Compounds **2** have chromophores with interesting photochemical characteristics. The longest wavelength absorption maximum lies between 330 and 360 nm for the phenanthro-condensed systems, whereas for the more planarized naphtho-anellated systems it is red-shifted to 370–400 nm. The nature of the anellation also plays an important role, as the spectra of the isomeric tris(dodecyloxy) compounds **2h** and **2k** show. The long-wavelength maximum is bathochromically shifted in the more planar compound **2h** compared to that of **2k**.

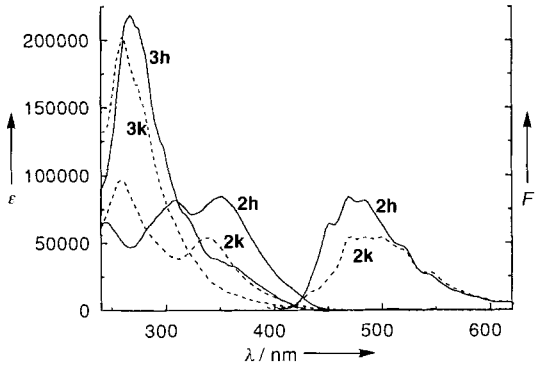

Fig. 1. UV/Vis spectra of compounds **2h** (—) and **2k** (- - -), as well as of the irradiation products **3h** (—) and **3k** (- - -), in *n*-hexane. Fluorescence spectra of **2h** and **2k** in *n*-hexane (intensities *F* in arbitrary units).

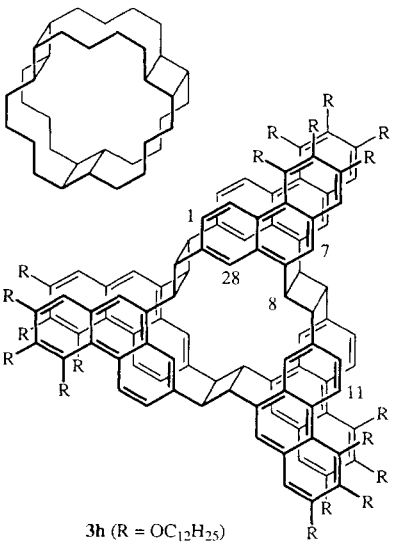
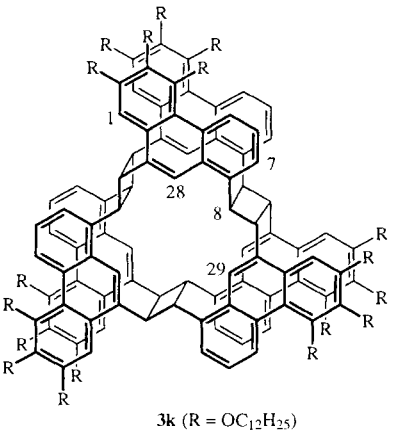
Irradiation ($\lambda \geq 290$ nm) of **2h** and **2k** in oxygen-free benzene (freeze-pump-thaw technique) leads to dimers **3h**[8] and **3k**[9] in 56 and 68% yield, respectively. These represent new cyclophane types. The belt structure shown in Scheme 2 results from a highly regio- and stereoselective triple [2π + 2π]cycloaddition. The phenanthrene systems are arranged opposite each other on each edge of the belt.

In comparison to the flexible 18-membered rings in the annulenes **2h,k**, the dimers are completely rigid. In the UV/Vis spectra the "phenanthrene transitions" (β-bands) are retained with a maximum at roughly 265 nm. It must be taken into account that the molar concentration of chromophores is doubled in **3h,k** compared to **2h,k**. The long-wavelength maxima of **2h,k** disappear after the dimerization; however, the long-wavelength absorption edges remain because electronic transitions typical for cyclophanes occur in this region.

An interesting structural question arises from considerations of whether **3** is formed from the preferred conformation or a higher energy conformation of **2**, in which the inner and outer protons 8-H/9-H, 17-H/18-H, 26-H/27-H have exchanged places. This can be determined by using isotopic labeling and NOE difference spectroscopy. With this in mind we synthesized (9-D,18-D,27-D)**2h** from the corresponding compound **1** with a deuterated phenyl imino group -CD=NC_6H_5. Irradiation of the ^{1}H NMR signal of the 8-H protons in the 18-membered ring in **3h,k** gave a positive NOE effect at 28-H, while irradiation of the signal of 9-H gave a positive NOE effect at 10-H and 7-H. This indicates that the preferred conformation of **2** also determines the stereochemistry of **3**. The S_1 state responsible for the photoreaction exerts no additional stereochemical changes. Analogous photodimerizations are observed with the other annulenes **2** irrespective of anellation mode; exceptions to this are compounds **2i,j**, which are photostable. R^4 Residues in **2i,j** cause a still stronger deviation from the planar arrangement. The torsion angle θ (C_{28a}-C_{7a}-C_8-C_9) is 129.1° in **2i** according to MMX calculations; that is, the olefinic bond is twisted out of the phenanthrene plane by 50.9°. This inhibits the formation of excimers, which are responsible for the regio- and stereospecific course of the photodimerization.[10]





Scheme 2.

In general, photodimerizations from electronically excited singlet states become inefficient below a concentration of 10^{-2} to 10^{-3} M, because the average lifetime of the S_1 state is not sufficient for dimerization partners to come together simply by diffusion.[10] Surprisingly, the dimerization of **2h,k** proceeds even in a 10^{-5} M solution. According to diffusion theory this would require an unrealistic lifetime for the singlet state of $\tau > 10^{-6}$ s. Due to the unusually strong concentration effect on the ^{1}H NMR shifts in **2h,k** ($\Delta\delta$ of up to 1), we assume that in the ground state these large disc-shaped molecules associate in solution.

The association of the discotic mesogens is crucial for the formation of columnar liquid crystals, which we have proved for **2h,k** by X-ray small-angle diffraction, differential scanning calorimetry (DSC), and polarization microscopy. The DSC measurements for **2k** are shown in Figure 2. The cooling and heating curves indicate an extremely wide range for the LC phase. Irradiation ($\lambda \geq 300$ nm) at 230 °C leads to a quantitative

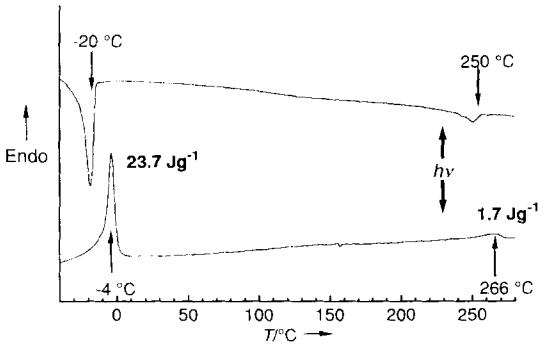


Fig. 2. DSC measurement of **2k** (upper cooling curve, lower heating curve, 20 K min^{-1} in each case).

formation of the belt cyclophane **3k**. The LC properties are irreversibly lost in the process. At lower temperatures the quantum yield drops to zero. At room temperature the LC phase is photostable. Compound **2h** shows analogous behavior. The large temperature effect on the photoreactivity cannot be explained by a thermal activation barrier in the S_1 state, since then the temperature dependence would also appear in the solution photolysis. We explain this effect by the temperature-dependent mobility. The photocyclodimerization requires not only a parallel orientation of the large discoid mesogens, but also a small separation of the olefinic centers. Only with the increased molecular mobility at higher temperatures and the thereby increased rotation about the column axis can a photodimerization take place in the LC phase. Under the described conditions this is even more efficient than in solution.

Silacyclopropene: Generation by High-Vacuum Flash Pyrolysis and Matrix-Spectroscopic Identification **

Günther Maier,* Harald Pacl, and Hans Peter Reisenauer

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

In 1961 Vol'pin et al. reported the synthesis of a compound with a silacyclopropene structure.[1] However, it was shown soon afterwards that the structure assignment was incorrect and that the isolated product was a 1,4-disilacyclohexa-2,5-diene.[2] This resulted in renewed attempts to produce silacyclopropenes.[3] These proved unsuccessful until 1976, when Gaspar et al. succeeded for the first time in preparing a substituted silacyclopropene.[4] Shortly afterwards the synthesis of further silacyclopropenes was reported.[5–7] At that time two methods were available for the synthesis of this class of substances. One enabled the formation of silacyclopropenes by the addition of substituted silanediyls (silylenes) to disubstituted alkynes,[4, 5] and the other by the photolysis of alkynyldisilanes.[6, 7] Recently silacyclopropene chemistry has experienced an upswing: the first stable silacyclopropenes monosubstituted at the double bond were prepared.[8] Sander et al. came close to the synthesis of the unsubstituted parent compound with the generation of 1,1-dimethylsilacyclopropene[9] by the photolysis of a bis(diazomethyl)silane. The first silacyclopropene not substituted at the double bond was obtained in this way.

Here we report on the first generation of the long-sought parent substance, the unsubstituted silacyclopropene **4**. At the same time a new route to this class of substances is presented. Silacyclopropene **4** is formed in the high-vacuum flash pyrolysis of 1,1,1-trimethyl-2-vinyldisilane **1** by elimination of trimethylsilane. This method, in which trimethylsilane is eliminated by pyrolysis leading to the generation of reactive species, has already been applied successfully in our group to the production of 1-silacyclopropenylidene as well as other C_2H_2Si isomers.[10] The precursor **1** can be obtained from 1,1,1-trimethyl-2-phenyldisilane:[11] the latter reacts with trifluoromethanesulfonic acid (pentane, 1 h, 0 °C) to give the corresponding triflate; treating this with vinylmagnesium chloride in THF yields **1**, which can be distilled and then isolated by preparative gas chromatography (silicone phase OV 101, 175 °C) in 70% yield.[12]

Silacyclopropene: Generation by High-Vacuum Flash Pyrolysis and Matrix-Spectroscopic Identification **

Günther Maier,* Harald Pacl, and Hans Peter Reisenauer

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

In 1961 Vol'pin et al. reported the synthesis of a compound with a silacyclopropene structure.[1] However, it was shown soon afterwards that the structure assignment was incorrect and that the isolated product was a 1,4-disilacyclohexa-2,5-diene.[2] This resulted in renewed attempts to produce silacyclopropenes.[3] These proved unsuccessful until 1976, when Gaspar et al. succeeded for the first time in preparing a substituted silacyclopropene.[4] Shortly afterwards the synthesis of further silacyclopropenes was reported.[5–7] At that time two methods were available for the synthesis of this class of substances. One enabled the formation of silacyclopropenes by the addition of substituted silanediyls (silylenes) to disubstituted alkynes,[4, 5] and the other by the photolysis of alkynyldisilanes.[6, 7] Recently silacyclopropene chemistry has experienced an upswing: the first stable silacyclopropenes monosubstituted at the double bond were prepared.[8] Sander et al. came close to the synthesis of the unsubstituted parent compound with the generation of 1,1-dimethylsilacyclopropene[9] by the photolysis of a bis(diazomethyl)silane. The first silacyclopropene not substituted at the double bond was obtained in this way.

Here we report on the first generation of the long-sought parent substance, the unsubstituted silacyclopropene **4**. At the same time a new route to this class of substances is presented. Silacyclopropene **4** is formed in the high-vacuum flash pyrolysis of 1,1,1-trimethyl-2-vinyldisilane **1** by elimination of trimethylsilane. This method, in which trimethylsilane is eliminated by pyrolysis leading to the generation of reactive species, has already been applied successfully in our group to the production of 1-silacyclopropenylidene as well as other C_2H_2Si isomers.[10] The precursor **1** can be obtained from 1,1,1-trimethyl-2-phenyldisilane:[11] the latter reacts with trifluoromethanesulfonic acid (pentane, 1 h, 0 °C) to give the corresponding triflate; treating this with vinylmagnesium chloride in THF yields **1**, which can be distilled and then isolated by preparative gas chromatography (silicone phase OV 101, 175 °C) in 70% yield.[12]

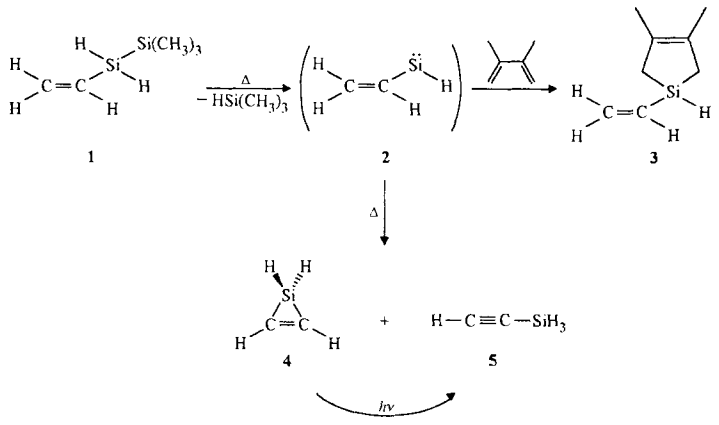
[**] Hetero π Systems, Part 21. This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft. – Part 20: ref. [10].



A high-vacuum flash pyrolysis (quartz tube: diameter 8 mm, length of heated zone 5 cm; ca. 10^{-3} mbar; 650 °C) was carried out on a gas mixture comprising disilane **1** and argon (1:1000). After leaving the hot zone the reaction products were directly condensed onto a CsI window at 10 K. Subsequently the matrix-isolated products were studied by IR and UV/Vis spectroscopy. The C_2H_4Si isomers ethynylsilane **5** and silacyclopropene **4** (Table 1) were detected in addition to trimethylsilane, acetylene, and small amounts of ethylene. Vinylsilanediyl **2** was not deposited onto the matrix holder, although its formation was expected in view of the structure of the precursor **1**. Indeed **2** is the primary product of the pyrolysis, since silacyclopentene **3** is obtained in 50 % yield as a trapping product from **2** in the copyrolysis of **1** with 2,3-dimethylbutadiene (quartz tube: length 33 cm, length of heated zone 25 cm, diameter 15 mm, filled with quartz Raschig rings; 450 °C; nitrogen as carrier gas).[13] Trapping products of the other C_2H_4Si isomers have not been detected. Evidently **4** and **5** are formed from the vinylsilanediyl **2** under the conditions used in the high-vacuum flash pyrolysis; presumably **5** does not arise directly from **2** but from the silacyclopropene **4** formed from **2**.

To explain the reaction mechanism and identify the C_2H_4Si species formed apart from **5**, we carried out a geometry optimization and a calculation of the vibrational spectra at the MP2/6-31G** level[14] for the C_2H_4Si isomers **2** and **4**–**9**. The resulting energy levels of the C_2H_4Si isomers increase in the order ethynylsilane **5** (global minimum) < silacyclopropene **4** < 1-silacyclopropylidene **6** < ethylidenesilanediyl **7** < *anti*- < *syn*-vinylsilanediyl **2** < 1-silaallene **8**. Particularly noteworthy is that the energy levels of all the isomers considered are extremely close to one another (Scheme 1). Compared with older calculations,[15] in which frequency calculations were not carried out, the relatively high energy content of **2** is particularly notable. As expected from the calculations, only the two lowest energy isomers, **4** and **5**, are actually formed in significant quantities in the pyrolysis.

Table 1. IR data of silacyclopropene **4** (experimental (Ar matrix, 10 K) as well as calculated (MP2/6-31G**) and corrected wavelengths [cm^{-1}]); integrated intensities (relative to the strongest band) are given in parentheses.

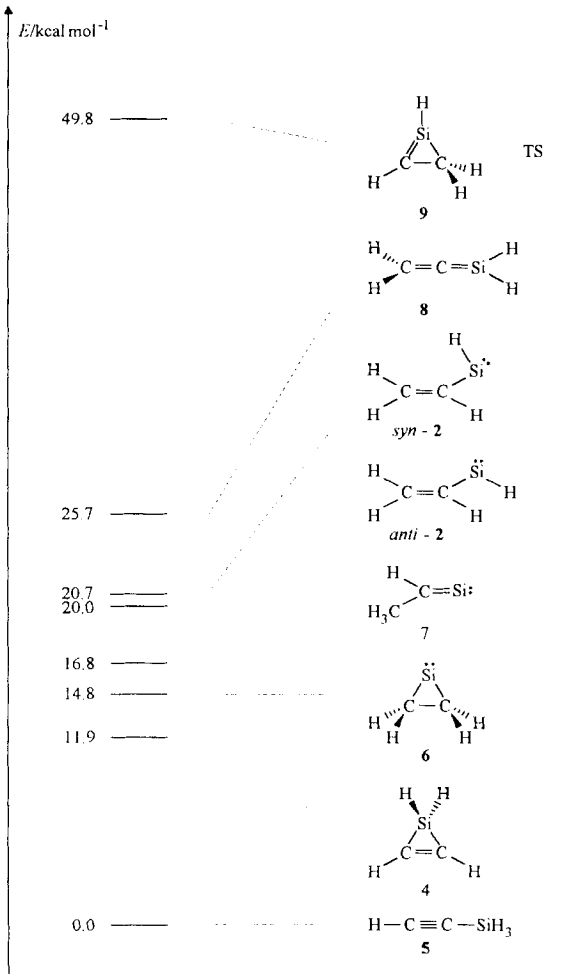
[a] $\tilde{\nu}_{corr.} = \tilde{\nu}_{exp.}(\mathbf{4}) / \tilde{\nu}_{calc.}(\mathbf{4}) \times \tilde{\nu}_{calc.}$(isotopomer). [b] The figures in these columns refer only to the nonlabeled silacyclopropene **4**. [c] Absolute intensity 182 km mol^{-1}. [d] The arithmetic mean of the two SiH stretching vibrations was used as the reference.



Scheme 1. Relative energies E [kcal mol^{-1}] of the C_2H_4Si isomers **2**, **4**–**8** (energy minima), and **9** (transition state TS) calculated at the MP2/6-31G** level taking into account the zero point vibrational energy.

Good agreement between the experimental and calculated IR spectra is found only for silacyclopropene **4** (Fig. 1, Table 1).[16] Thus, in accordance with the calculation, its IR spectrum shows two bands for the CH stretching vibrations (3061.2 and 3041.6 cm^{-1}), two for the SiH stretching vibrations (2176.3

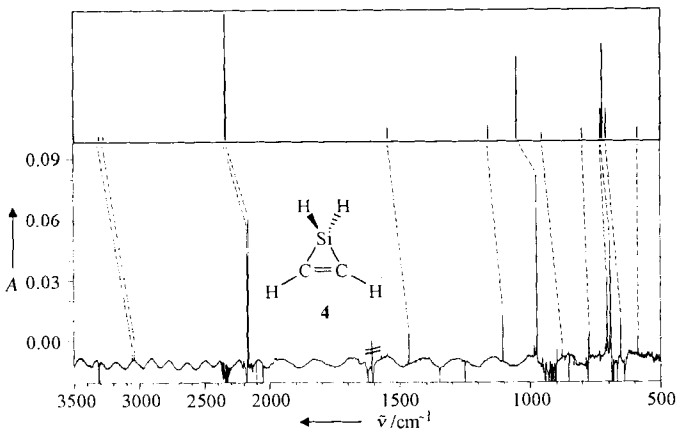


Fig. 1. Comparison of the experimental (bottom) and calculated IR spectra (MP2/6-31G**, top) of silacyclopropene **4**. The experimental spectrum (Ar matrix, 10 K) is the difference spectrum for the photoreaction **4** → **5**. The bands due to water have been crossed.

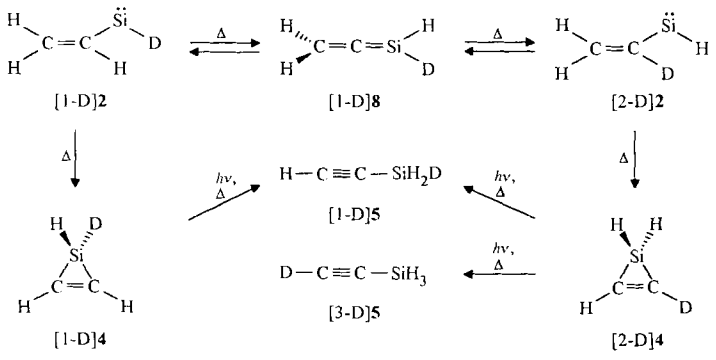
and 2166.7 cm^{-1}), and one for the CC stretching vibration (1467.2 cm^{-1}). In addition the pattern of the remaining eight lower lying absorption bands corresponds to the calculated ones. Particularly characteristic is the strong band arising from the SiH_2 deformation at 975.9 cm^{-1}. Irradiation of **4** with light of wavelength $\lambda = 254$ nm results in the selective rearrangement to **5**, even though **4** shows no UV maximum above 250 nm. 1,1-Dimethylsilacyclopropene behaves in a similar way.[9] Ethynylsilane **5** is photostable.

In addition to the unmarked precursor we have also investigated the deuterated analogue [2,2-D_2]**1**. This can be obtained from 1,1-dibromo-2,2,2-trimethyl-1-phenyldisilane[11b] by reduction with $LiAlD_4$ and subsequent conversion with trifluoromethanesulfonic acid and vinylmagnesium chloride as described above. The high-vacuum flash pyrolysis of [2,2-D_2]**1** led to two important findings: Firstly, the observed band shifts (see Table 1) confirm the reliability of the present structure assignment of **4**. Secondly, the results give an insight into the reaction mechanism. In the pyrolysis of [2,2-D_2]**1** the silacyclopropene isotopomers [1-D]**4** and [2-D]**4** are formed approximately in the ratio 1:1. The two ethynylsilanes [1-D]**5** and [3-D]**5** are also formed, but here the former predominates.

To explain these results we suggest the following mechanism: Pyrolysis results initially in the formation of vinylsilanediyl [1-D]**2** as confirmed by the trapping studies. This is in equilibrium with its isotopomer [2-D]**2** through the 1-silaallene intermediate [1-D]**8**. The energetically more favorable silacyclopropene isotopomers [1-D]**4** and [2-D]**4** are then formed in equal amounts from [1-D]**2** and [2-D]**2**.



The rearrangement **2** → **4** could be initiated by the addition of the silanediyl center to the C–C double bond. This reaction would be analogous to the well-known formation of cyclopropenes from vinylcarbenes. In our case, the 1-silacycloprop-1-ene **9** would have to be formed first under this assumption, followed by a 1,2-hydrogen shift. However, the structure of **9** does not represent an energy minimum according to the calculation, but rather **9** is a transition state with a relative energy of 49.8 kcal mol^{-1}. In principle the formation of **4** from **2** can also occur quite differently by the insertion of the silanediyl center in the C–H bond of the olefinic CH_2 group in **2**.

Under pyrolysis conditions the silacyclopropenes [1-D]**4** and [2-D]**4** are already partly opened to give the ethynylsilane isotopomers [1-D]**5** and [3-D]**5**, so that the global minimum is reached. The same ring-opening can also be photochemically induced.

First Steps Towards Ordered Monolayers of Ligand-Stabilized Gold Clusters**

Stefanie Peschel and Günter Schmid*

Dedicated to Professor Peter Paetzold on the occasion of his 60th birthday

The achievement of an ordered arrangement of chemically produced quantum dots is very important in the light of future applications in nanotechnology. Most of the work carried out in this field concerns the use of semiconductor quantum dots, since it is hoped that the transition of a semiconductor from the bulk state to the nanometer region, will give rise to novel physical properties, particularly in the field of electrooptics.[1] Apart from the difficulty of synthesizing semiconductor clusters with largely uniform size and defined structure, the main problem is to achieve a two- or three-dimensional arrangement of the particles, without them touching. Numerous attempts have been made to use zeolites or porous materials as host lattices.[2] Polymers have also been used to prevent a coalescence of the semiconductor particles. To date there has been no recognizable breakthrough in the practical effectiveness of these types of systems.

With the synthesis of ligand-stabilized transition metal clusters a different kind of approach to quantum dots has become possible, which has advantages over conventional systems: 1. uniform particle size, 2. the stabilization by largely inert ligand shells, 3. the equidistant arrangement as a result of defined ligand shells, 4. the avoidance of coalescence processes, 5. the possibility of varying the separation between the clusters by chemical modification of the ligand shell. Figure 1 illustrates these possibilities which are decisive for the utilization of quantum properties.

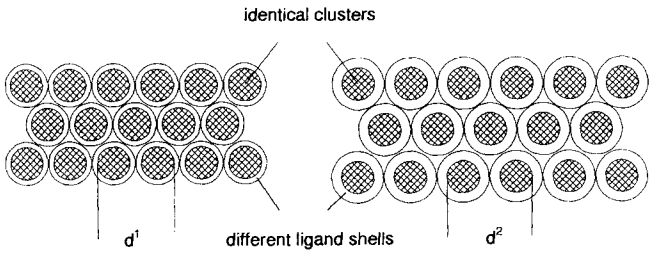

Fig. 1. The intermolecular distances and therefore the Coulomb barriers between the clusters can be modified by varying the ligand shell.

Recently, we were able to answer unequivocally the question of whether besides semiconductor clusters also metal clusters could be applied as quantum dots. Gold clusters of composition $[Au_{55}(PPh_3)_{12}Cl_6]$ are composed of a cluster core about 1.4 nm in diameter and a ligand shell 0.35 nm thick, which results in an approximately spherical particle with a total diameter of about 2.1 nm. In a close packed three-dimensional arrangement these clusters show conductivity, which is characterized by single-electron tunneling (SET) processes between the cluster cores separated by the ligand shells.[3] Investigations of clusters on the surface of pellets using scanning tunnel microscopy (STM) and scanning tunneling spectroscopy (STS) produce images which show that the ligand shells of the individual clusters are in contact, and in the current/voltage diagram there is not only the expected Coulomb barrier[4] but also, for the first time, energy fine line splitting of the electronic states in individual clusters at room temperature.[5] Therefore, ligand-stabilized metal clusters seem to fulfill the requirements for their application in the nanometer range.

In contrast to the readily synthesized, but complicated workings of three-dimensional cluster arrangements in crystals and pellets, ordered monolayers on suitable substrates should facilitate electronic investigations. This applies to an even greater extent to one-dimensional cluster arrangements (quantum wires), which we are currently trying to produce.

We were able to synthesize largely ordered monolayers of ligand-stabilized Au_{55} clusters for the first time. In order to accomplish this we used the established principle of self-assembly with the help of poly-electrolytes.[6] However, we could not use the $[Au_{55}(PPh_3)_{12}Cl_6]$ cluster itself but had to synthesize a derivative in which the PPh_3 was replaced by a $PPh_2(m\text{-}C_6H_4SO_3H)$ ligand. To this end we used the previously reported sodium salt $[Au_{55}\{PPh_2(m\text{-}C_6H_4SO_3Na)_{12}\}Cl_6]$[7] and converted it into the free acid by ion exchange. When a freshly prepared thin layer of poly(ethylenimine) (PEI) on a mica surface is immersed into a solution of the cluster there is a strongly attractive interaction between the sulfonic groups and the imino groups.

The coating is carried out by immersion of a mica platelet for 24 hours in a 10^{-4} molar aqueous solution of PEI. After intensive washing with distilled water and drying in vacuo, the coated platelet was then immersed in a 3×10^{-6} molar aqueous solution of the Au cluster. In order to remove any additional cluster molecules sticking to the surface, the platelet was washed with a total of 0.5 L of distilled water and dried in vacuo. Because of the ready solubility of the cluster, this procedure ensures that only the strongly adhesive monolayer produced by the acid–base interaction remains. Figure 2 is a simplified illustration of the principle of the cluster/PEI interaction.

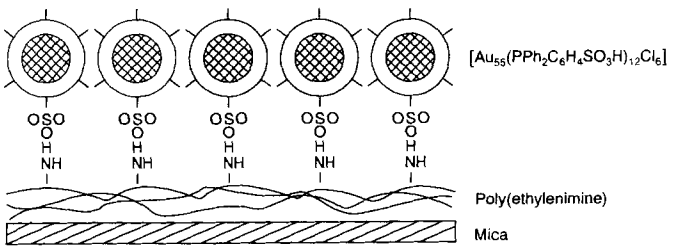

Fig. 2. Schematic illustration of the interaction between cluster molecules and poly(ethylenimine). A mica platelet (ca. 1 cm^2) coated with PEI, was immersed for 24 h in a 3×10^{-6} M aqueous cluster solution. As a consequence the sulfonic groups of the cluster ligands interact with the imino groups of the polymer.

Figure 3 (top) shows a three-dimensional atomic force microscopic (AFM) image[8] of a section of the cluster monolayer. Sections of comparable quality can be obtained from all areas of the approximately 1 cm^2 surface. Shorter reaction times between the PEI layer and the cluster solution, for example six or twelve hours, gave a relatively closely packed occupation, however, the level shown in Figure 3 top occurs only after 24 hours. Numerous cross-sections show that less than 5% of the surface is disordered or uncovered.

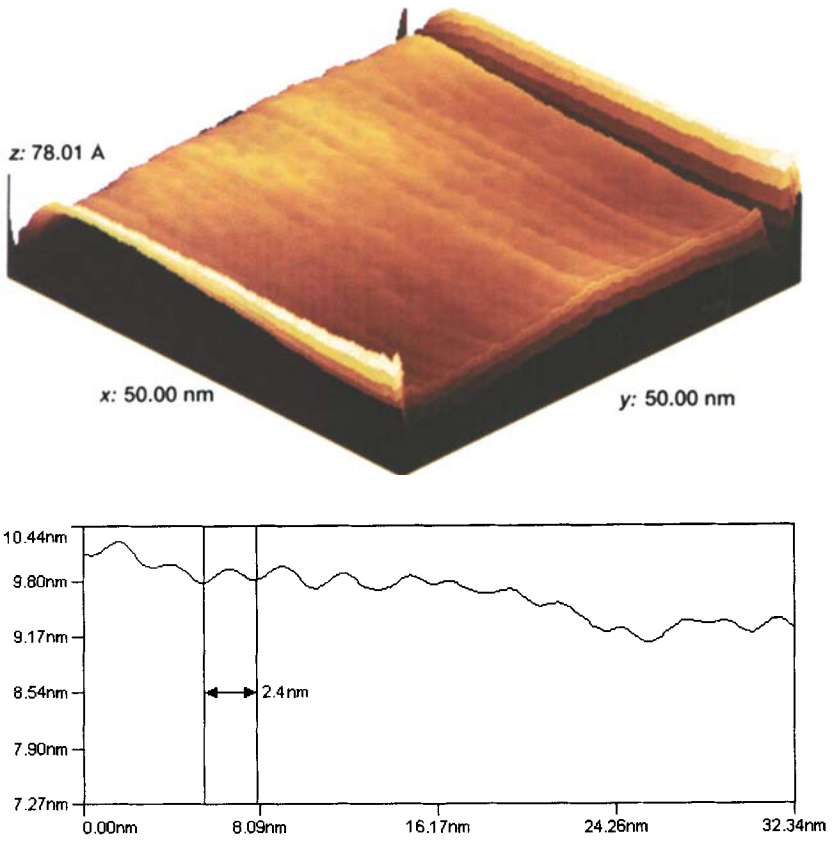

Fig. 3. Top: Three-dimensional representation of a largely ordered monolayer of $[Au_{55}\{PPh_2(m\text{-}C_6H_4SO_3H)_{12}\}Cl_6]$ on poly(ethylenimine). Bottom: Cross-section of a single cluster row. The separation between the clusters is 2.4 nm, which is in agreement with the calculated cluster size.

The equidistance of the clusters within a row and the resulting organization can be seen at the bottom of Figure 3 which shows a typical cross-section. The average distances of 2.4 $\pm$ 0.2 nm are in very good agreement with those expected for SO_3H-substituted clusters. These easily synthesized cluster monolayers can now be used to study electronic transitions in two-dimensional arrangements of quantum dots (cluster cores) separated by the ligand shells and spaced 1.4 nm apart, a distance which cannot be obtained either by the usual semiconductor technology or by the semiconductor clusters described above. Furthermore, this principle can be used for the formation of sandwich structures because the cluster monolayer can, in turn, be coated with PEI. Since it should be possible to synthesize the corresponding cluster monolayers with clusters from other metals, additional possibilities are available for the generation of multilayer systems with different metals.

Self-Assembly of a Ferromagnetically Coupled Manganese(II) Tetramer**

Angelo J. Amoroso, John C. Jeffery, Peter L. Jones, Jon A. McCleverty,* Peter Thornton, and Michael D. Ward*

We recently described the preparation of the podand ligand tris[3-(2′-pyridyl)pyrazol-1-yl]hydroborate, L^-.[1] This ligand contains three *N*,*N*-bidentate chelating arms linked at the apical boron atom and is the first example of a podand ligand based on the tris(pyrazol-1-yl)hydroborate core. The cavity size was found to be appropriate for lanthanide(III) ions (ionic radius ≈ 1 Å), and some 1:1 nine-coordinate complexes such as $[Eu(L)F(MeOH)_2]PF_6$ were prepared in which the lanthanide ion was located in the hexadentate ligand cavity.[1] We thought it would be of interest to see how the ligand behaved with first-row transition-metal dications (ionic radius ≈ 0.7–0.8 Å), which are both smaller than lanthanides and prefer lower coordination numbers. Molecular modeling studies indicated that 1:1 complexes with sensible metal–ligand bond lengths would involve considerable strain on the ligand; conversely if the ligand were allowed to adopt a strain-free conformation then the metal–pyridyl bond lengths would be unrealistically long (> 3 Å).

Crosby and Miss Kate Byrom for recording the electrospray mass spectra, and Dr. S. G. Carling and Prof. P. Day of the Royal Institution for assistance with recording the magnetic data.

Reaction of KL with one equivalent of $Mn(CH_3CO_2)_2 \cdot 4H_2O$ in methanol followed by treatment with KPF_6 afforded a yellow solid **1**.[2] Elemental analysis and fast-atom bombardment mass spectrometry (FAB-MS) both indicated the formulation $[MnL]PF_6$ for **1**. However an electrospray mass spectrum (ES-MS: solvent: $MeCN/H_2O$ (1/1); capillary voltage, 3.48 kV; cone voltage, 25 V; source temperature, 80 °C) gave an intense peak at 1996.4 Daltons, whose position and isotopic pattern were consistent with formation of a tetrameric species $[Mn_4L_4]^{4+}$. The crystal structure determination confirmed this,[3] and three views of the structure of the cation are in Figures 1–3. There is no crystallographically imposed symmetry within the tetrameric unit. The complex contains four crystallographically independent Mn^{II} ions which are arrayed approximately in a tetrahedron with Mn–Mn separations (all different) of between 6.218 and 6.293 Å. Each ligand L^- sits "above" one triangular face of this tetrahedron and donates one bidentate arm to each of the three metal ions on that face. Each ligand therefore interacts with three different metal ions (see Fig. 4a), and each metal ion is coordinated by one bidentate arm from each of three different ligands. The Mn–N distances lie in the range 2.17–2.38 Å and are typical of Mn^{II}–N(pyridyl) and Mn^{II}–N(pyrazolyl) bonds in high-spin complexes.[5] The coordination geometries of the metal ions are highly distorted octahedra (Fig. 3): the N-Mn-N angles lie in the range 72–110°; the bite angles of the bidentate chelating fragments are 72–73°. It is apparent from Figure 2 that aromatic π-stacking interactions between pyrazolyl rings are present, which may help to stabilize the structure of **1**. The interaction between the pyrazolyl rings from different ligands and attached to adjacent metals is shown in Figure 4b; the average separation between the overlapping areas is about 3.4 Å.

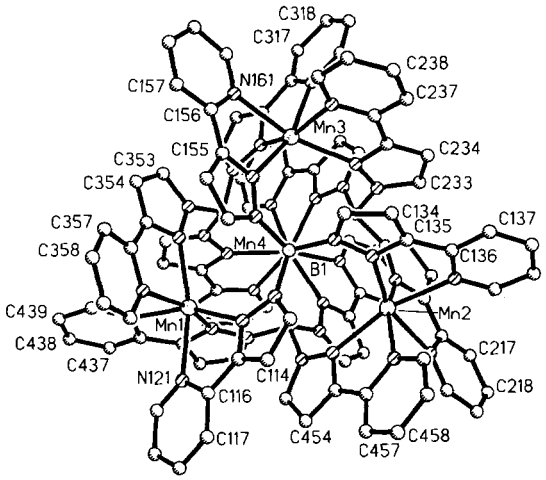

Fig. 1. Crystal structure of the cation of **1** with the numbering scheme. The Mn–N distances lie in the range 2.17–2.38 Å, N-Mn-N angles in the range 72–110°.

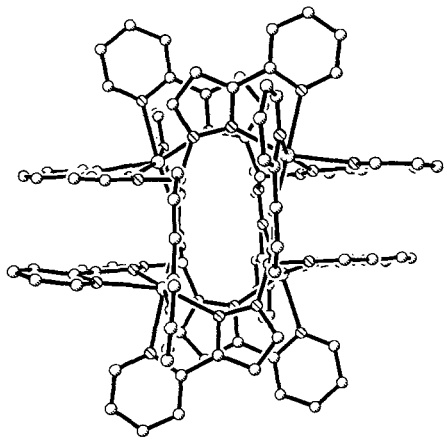

Fig. 2. Alternative view of the crystal structure of the cation of **1**.

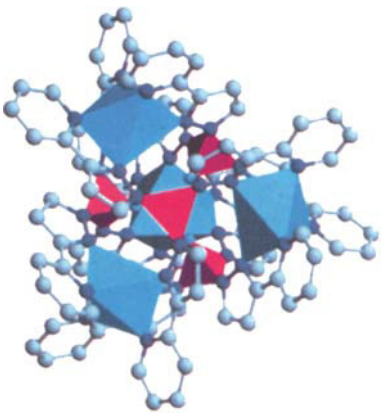

Fig. 3. Representation of the structure of **1** emphasizing the coordination polyhedra. The octahedra represent the coordination spheres of Mn^{II} centers, the smaller tetrahedra those of boron atoms, which have the B–H bonds directed inwards.

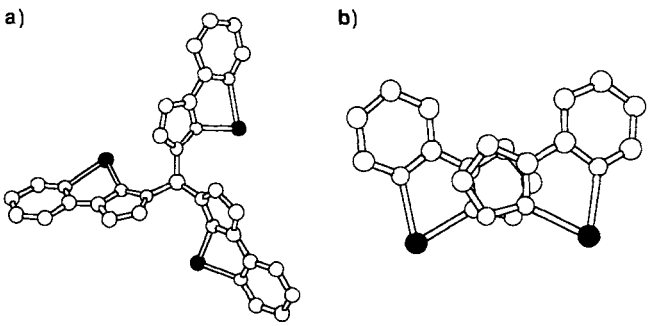

Fig. 4. Fragments of the crystal structure of **1** showing a) the disposition of a single ligand, and b) the π stacking of the pyrazolyl rings attached to adjacent metals.

The formation of this tetramer in high yield by assembly of eight components, involving formation of 24 metal–ligand bonds as well as additional noncovalent interactions, is an interesting example of how a relatively complicated molecule can form from simple components when there is an appropriate degree of complementarity between the properties of the metal (size, preference for a particular coordination geometry) and those of the ligand (number, arrangement and type of binding sites, steric limitations).[6] Appropriate combinations of carefully designed ligands with particular metal ions therefore can be considered to be "pre-programmed" to self-assemble in a specific and unique way, and such methods have resulted in the formation of complicated molecular architectures such as double[7] and triple[8] helices, cylinders,[9] capped cylinders,[10] and grids.[11] Ligand L^- is particularly versatile in that it can behave in quite different ways according to the properties of the metal ions it reacts with (lanthanide or first-row transition metal).

The EPR spectrum of **1** in MeCN at room temperature showed a single, featureless, very broad resonance at $g = 2.008$ with a peak–peak separation of 650 G. The lack of the usual hyperfine coupling and the breadth of the signal are consistent

with the presence of magnetic exchange effects. Low-temperature magnetic susceptibility measurements on **1** (5–300 K) confirm the presence of a weak ferromagnetic interaction. A plot of $1/\chi$ versus T is exactly linear over the whole range (correlation coefficient with best-fit straight line = 1.000) with a ferromagnetic θ value of 1.5 K. The magnetic moment μ per Mn^{II} center (Fig. 5) rises steadily from 5.83 μ_B at 300 K to 5.93 μ_B at 40 K.

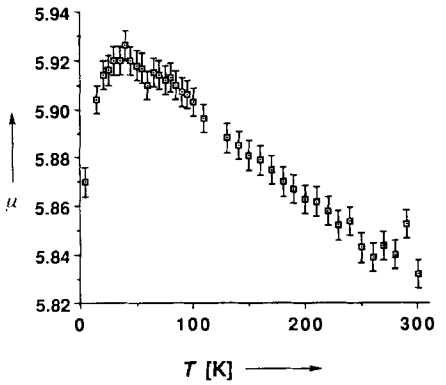

Fig. 5. Low-temperature magnetic data for **1**: a plot of μ per Mn^{II} center vs T.

The origin of the decrease in the value of μ at temperatures below 40 K is not clear and a fuller analysis will have to await field-dependency studies. That the limiting high-temperature value of μ is fractionally less than the spin-only value despite ferromagnetic exchange may be ascribed to trace diamagnetic impurities, but the overall trend is clear.

The presence of ferromagnetic exchange is surprising, as the Mn^{II} centers are too far apart to have any direct orbital overlap between them and there are no direct bridges linking pairs of Mn^{II} ions; magnetic exchange is commonly associated with, for example, phenolate bridges.[12] The shortest pathway linking each Mn^{II} ion to its neighbors is via the aromatic stacking interaction depicted in Figure 4b, and we suggest that this $\pi-\pi$ interaction offers a route for the transmission of magnetic effects, possibly by a McConnell spin-polarization mechanism, especially as the pyridyl and pyrazolyl groups are π-acidic and some of the unpaired electron density in the metal d(π) orbitals will therefore be delocalized onto the ligand fragments involved in the π stacking. Intermolecular exchange can be ruled out since the shortest intermolecular Mn–Mn contact is 12.00 Å and there is no bridging pathway comparable to that within the tetramer; in addition the EPR spectrum showed that the exchange interaction was maintained even in dilute solutions. Recently very weak ferromagnetic exchange between separate complex units in a crystal was ascribed solely to intramolecular $\pi-\pi$ overlap of terminal aromatic ligands;[13] thus, complex **1** represents the second example of this phenomenon. The ability to transmit magnetic exchange interactions through noncovalent interactions such as hydrogen bonding,[14] nonbonding van der Waals interactions,[13] and now π stacking is of considerable importance to the design and synthesis of bulk ferromagnets,[15, 16] particularly as these noncovalent interactions play important roles both in self-assembly of supramolecular complexes and the three-dimensional ordering in crystal structures.

Similar complexes of L^- have been obtained with Fe^{II}, Co^{II}, Ni^{II}, and Zn^{II}. In every case ES-MS indicated formation of tetrameric $[M_4L_4]^{4+}$ species. We have also determined the crystal structure of $[Zn_4L_4](PF_6)_4$, which, apart from small changes in bond lengths and angles and the presence of a threefold symmetry axis in the tetrameric cation, is the same as that of **1**.[17] Full details of this structure and of the magnetic properties of the other complexes will be the subject of a full paper in due course.

[1] A. J. Amoroso, A. M. Cargill Thompson, J. C. Jeffery, P. L. Jones, J. A. McCleverty, M. D. Ward, *J. Chem. Soc. Chem. Commun.* **1994**, 2751.

[2] A mixture of KL (0.241 g, 0.5 mmol) and $Mn(CH_3CO_2)_2 \cdot 4H_2O$ (0.123 g, 0.5 mmol) was dissolved in MeOH (20 mL) to give a pale yellow solution. Dropwise addition of excess aqueous KPF_6 precipitated an off-white solid which was filtered off and dried to give 0.28 g of **1** (87%). X-ray quality crystals were grown from $MeCN/Et_2O$. A satisfactory elemental analysis was obtained.

[3] Crystal data for $[Mn_4L_4](PF_6)_4 \cdot (MeCN)_4 \cdot (Et_2O)$: $C_{108}H_{98}B_4F_{24}Mn_4N_{40}OP_4$, $M = 2815.14$, pale yellow blocks, monoclinic, space group $P2_1/n$, $a = 21.778(8)$, $b = 20.352(6)$, $c = 28.898(9)$ Å, $\beta = 103.83(3)°$, $V = 12437(7)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.503$ g cm^{-3}, $\mu = 5.50$ cm^{-1}, $F(000) = 5720$. The crystal selected (0.75 × 0.75 × 0.6 mm) was mounted in a glass capillary tube in some of the recrystallization solvent as a precaution against facile solvent loss. Using a Siemens SMART diffractometer with a CCD area detector (graphite-monochromated $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $T = 293$ K) 42954 reflections were collected ($2\theta_{max} = 46.5°$, $-24 \le h \le 24$; $-21 \le k \le 22$; $-32 \le l \le 13$) of which 17194 were unique. Data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied (XEMP) based on multiple measurements of equivalent data. The structure was solved by direct methods using SHELXTL and refined (1673 parameters with 46 restraints) using SHELX93 by full-matrix least-squares on all F^2 data [4]. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were included in calculated positions and refined with fixed isotropic thermal parameters. Refinement converged at R_1 [$F > 4\sigma(F)$] = 0.064, wR_2 (all data) = 0.169. Maximum/minimum residual electron density: +0.652/−0.522 e Å^{-3}. The asymmetric unit contains four molecules of MeCN and one of Et_2O in addition to one tetrameric cation and four PF_6^- ions. Full details of the crystal structure determination are available on request from the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ, on quoting the full journal citation.

The Two-Dimensional Network Structure and Metamagnetic Properties of the 2:1 Complex of $[Mn(3\text{-MeOsalen})(H_2O)]ClO_4$ and $K_3[Fe(CN)_6]$**

Hitoshi Miyasaka, Naohide Matsumoto,* Hisashi Ōkawa, Nazzareno Re, Emma Gallo, and Carlo Floriani*

The field of molecular magnetism has shown quite spectacular advances in the last decade.[1] In particular ferro- and ferrimagnetic one-dimensional chain compounds based upon metal complexes have brought noteworthy success in the field of molecular design and synthesis, magnetism, and theoretical studies.[1] However, although it is easier to design the structure and synthesis of one-dimensional rather than two- or three-dimensional compounds, recent efforts have been directed at molecular design of multidimensional magnetic compounds, since the ferromagnetism itself is a three-dimensional property.[1, 2]

The cyanide system based on the Prussian blue family $CA^{II}[B^{III}(CN)_6]$ ($C = Cs^+$; A = Ni, Mn, Cr; B = Cr, Fe) exhibits an excellent basis for the molecular design of ferri- and ferromagnets, in which the $[B^{III}(CN)_6]^{3-}$ ion acts as a multidentate complex ligand and the A^{II} ion receives the donor atoms.[3] These cyanide compounds have rigid three-dimensional structures in which two magnetic centers alternate, and the CN^- ion bridges the two metal ions as a simple magnetic mediator. However, because of difficulties in obtaining single crystals, the details of the correlation between the magnetism and the crystal structure remain uncertain.

Manganese Schiff base complexes possess a high degree of structural versatility; variation in coordination geometry, nuclearity, and metal oxidation state are all possible.[4] Since manganese(III) complexes of salen analogs (H_2salen = *N*,*N*′-bis(salicylidene)ethylenediamine) can receive donor atoms at the apical sites, it was anticipated that the coupling of the manganese Schiff base complex to $[B^{III}(CN)_6]^{3-}$ ion might enable the formation of a novel family of magnetic compounds with potential control over the structure of the crystal lattice. We therefore examined the reaction of $[MnL(H_2O)]ClO_4$ (L = salen analogs) and $K_3[Fe(CN)_6]$. The products are easily crystallized and display a remarkable variety of magnetic behavior and a rich structural chemistry. One such compound, $K[Mn(3\text{-MeOsalen})]_2[Fe(CN)_6]$, has a unique two-dimensional structure and exhibits a spontaneous three-dimensional magnetic ordering.

An ORTEP drawing of this trinuclear molecule with the atom numbering scheme is given in Figure 1.[5] Since the space group

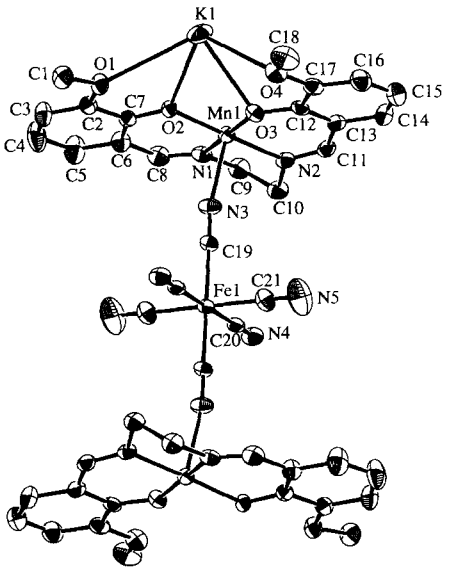

Fig. 1. Structure of the trinuclear unit of $K[Mn(3\text{-MeOsalen})]_2[Fe(CN)_6] \cdot 2DMF$ (ORTEP drawing) with the numbering scheme of the unique atoms (50% probability ellipsoids).

is $P2_1/c$ and the unit cell contains two trinuclear molecular units, the unsymmetrical unit is one half of the trinuclear molecular unit, and the Fe and K ions must occupy the special positions. The Fe ion is positioned at a center of symmetry (1/2,0,1/2) and surrounded octahedrally by six CN^- groups. Two CN^- groups of the $[Fe(CN)_6]^{3-}$ moiety bridge to the Mn ions to give a linear bridging unit of (3-MeOsalen)Mn-NC-Fe-CN-Mn(3-MeOsalen) with bond lengths of Fe–C19 = 1.932(5) Å, Mn–N3 = 2.290(5) Å, and C19–N3 = 1.150(7) Å and angles of Fe-C19-N3 = 177.2(5)° and C19-N3-Mn = 169.5(5)°. The Fe–C19 bond length of 1.932(5) Å within this bridging fragment is rather shorter than the other two iron–cyanide bonds [Fe–C20 of 1.943(6) Å and Fe–C21 of 1.941(7) Å]. A projection of the trinuclear complex along the Fe–Mn vector shows that the Fe–C20 and Fe–C21 bonds bisect the N1-Mn-N2 and N1-Mn-O2 angles, respectively. The K^+ ion positioned at the inversion center (1/2,0,0) interacts with eight oxygen atoms of the two Mn(3-MeOsalen) moieties of adjacent trinuclear units. The two methoxy groups at the 3-position of the (3-MeOsalen) ligand contribute to the formation of the sandwich structure and form a crown-ether-like sandwich structure around the K^+ ion, which produces a one-dimensional chain. The sandwich structure around K^+ and the dimensions of K–O [K–O2 of 2.721(4) and K–O3 of

(3-MeOsalen)$^{2-}$ = dianion of bis(3-methoxysalicylidene)ethylenediamine.

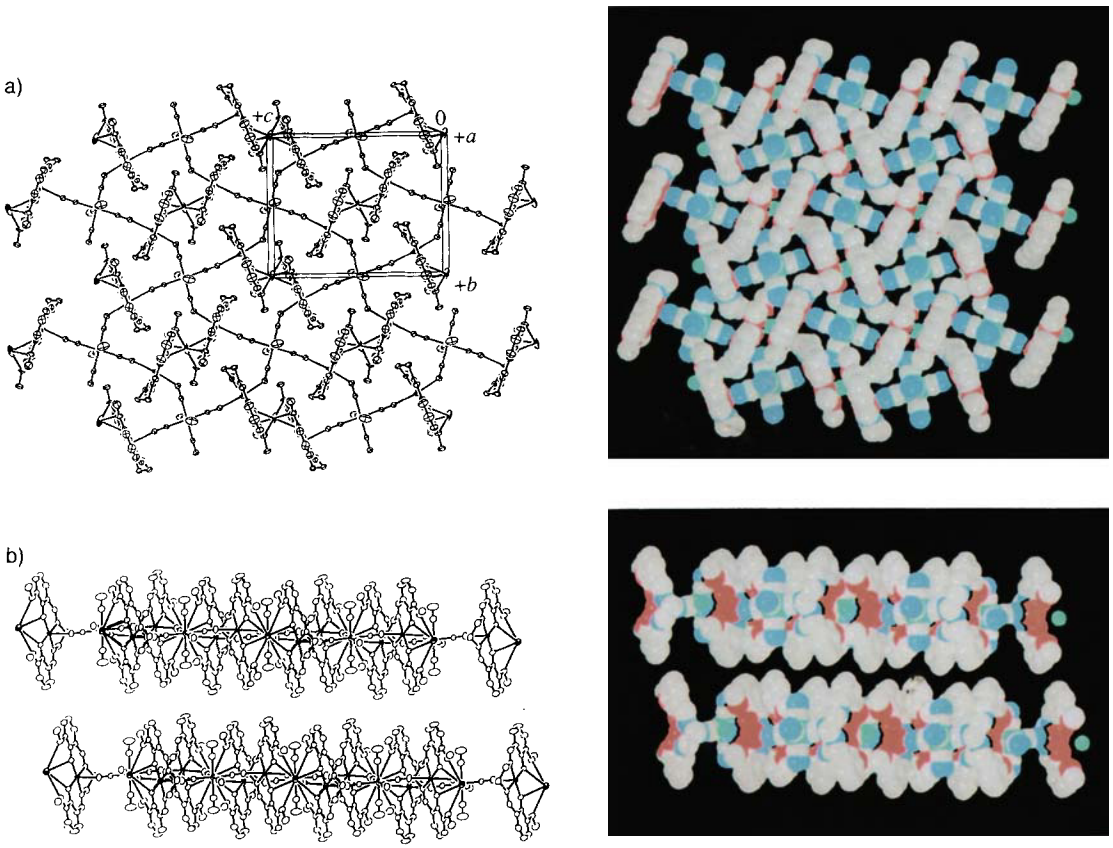

Fig. 2. a) Projection along the a axis, showing a two-dimensional network structure, in which a net unit is composed of a cyclic, octanuclear structure ($\cdots$Mn-NC-Fe-CN$\cdots)_4$ and involves a sandwich structure. b) Projection perpendicular to the a axis, showing stacking of the sheet structure by van der Waals contacts. In each case on the right are the corresponding space-filling representations of the two-dimensional network structure.

2.789(4) Å for the K-phenoxy oxygen atoms and K–O1 of 3.211(4) and K–O4 of 3.109(4) Å for K-methoxy oxygen atoms] are compatible with those of [K(benzo[15]crown-5)$_2$] and related crown ether compounds.[6]

The crystal structure projected onto the bc plane showing the two-dimensional structure is given in Figure 2a. Another two CN^- groups of the $Fe(CN)_6^{3-}$ moiety are bound to the Mn atoms of the adjacent chains with a Mn–N4 distance of 2.415(5) Å, which creates a two-dimensional network in which a net unit is composed of a cyclic octanuclear structure ($\cdots$Mn-NC-Fe-CN$\cdots)_4$ and internally bridged by a sandwich structure (see Fig. 2a). The interchain bridging unit Fe-C20-N4$\cdots$Mn*, where * indicates a symmetry operation of $(x, 1/2 - y, 1/2 + z)$, has bond lengths of Fe–C20 = 1.943(6), C20–N4 = 1.157(7), and N4$\cdots$Mn* = 2.415(5) Å, with angles of Fe-C20-N4 = 178.4(6) and C20-N4-Mn* = 137.2(4)°, indicating a large bending of the C–N$\cdots$Mn interaction. Because of the coordination of the CN^- group of the adjacent chain, the Mn ion is six-coordinate, assuming a square-bipyramidal geometry in which the two apical sites are occupied by nitrogen atoms N3 of the chain and N4 of the adjacent chain, and the equatorial sites by the N_2O_2 donor atoms of the quadridentate ligand (average bond lengths: (Mn–N) = 1.970(5), (Mn–O) = 1.873(4) Å). The two-dimensional sheet structure stacks along the a axis by a transformation, and on the basis of the interlayer distances, the interaction between the layers is attributable to van der Waals contacts.

The magnetic behaviors of the two samples prepared by Method A and Method B (see Experimental Procedure) are very similar, but they show a slight difference below about 250 G. In this communication, the magnetic behavior of the Method B sample is described.

The magnetic susceptibility was measured from 1.9 K to 300 K by a SQUID magnetometer (SQUID = superconducting quantum interference device) under the applied magnetic field of 800 G, and the plot of μ_{eff} vs. T is depicted in Figure 3. The effective magnetic moment per trinuclear unit is 7.33 μ_B at room temperature, which is slightly larger than the spin-only value 7.14 μ_B for the magnetically dilute, three-spin system (S_{Mn}, S_{Fe}, S_{Mn}) = (2, 1/2, 2). On lowering the temperature, μ_{eff} increases gradually and then sharply without a minimum, reaches the maximum value of 32.1 μ_B at 9 K, and finally decreases abruptly to 17.4 μ_B at 1.9 K.[7] The maximum value of μ_{eff} is very much larger than the spin-only value of the possible largest spin-state S_T = 9/2 for (S_{Mn}, S_{Fe}, S_{Mn}) = (2, 1/2, 2), μ_{so} = 9.95 μ_B.

The FCM curve (field-cooled magnetization M vs. T) was obtained by cooling the sample under a weak magnetic field of 0.5 G. On lowering the temperature, the magnetization shows a

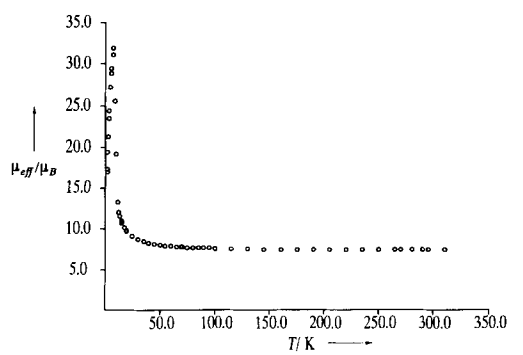

Fig. 3. Plot of the effective magnetic moments of K[Mn(3-MeOsalen)]$_2$[Fe(CN)$_6$] per Mn_2Fe unit against temperature.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1313-1447 $ 10.00+.25/0

rapid increase below about 10 K till the maximum at 9.2 K, and then a decrease. The abrupt increase of the magnetization indicates the on-set of long-range magnetic ordering due to the ferromagnetic coupling within each layer. The decrease below 9.2 K indicates the presence of interlayer antiferromagnetic interaction. The FCM curves were also measured under 100 G and 300 G. The M vs. T curve at 100 G still shows a sharp peak, whereas the curve at 300 G has no peak and remains constant after the abrupt increase at 9 K. This result is also indicative of interlayer antiferromagnetic interaction. The hysteresis loop at 4.5 K is shown in Figure 4, where the initial magnetization pro-

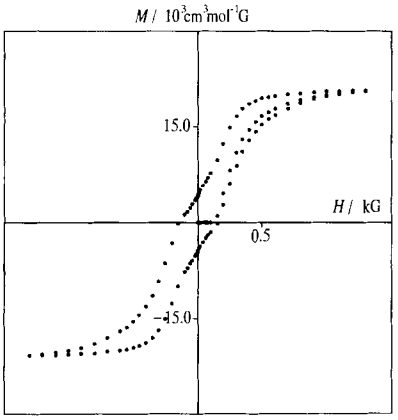

Fig. 4. Hysteresis loop (M vs. H) at 4.5 K.

cedure from 0 G to 300 G shows a metamagnetic character. The field dependence of the magnetization up to 5.5 T on a powder sample was measured at 4.2, 6.0, and 7.5 K. On increasing the applied magnetic field at 4.2 K, the magnetization value is close to zero below about 250 G, increases rapidly reaching the plateau region (about $M = 3\,N\mu_B$) around 1500 G, and then increases linearly to 6 $N\mu_B$ at 5.5 T. Since the saturation magnetization M_s is expected to be 9 $N\mu_B$ for this system (S_{Mn}, S_{Fe}, S_{Mn}) = (2, 1/2, 2) according to the equation $M_s = Ng\mu_B S$, the higher magnetic field than 5.5 T is necessary for the magnetic saturation of this compound. It can be also seen that the magnetization saturates more easily as the temperature increases. This behavior shows a metamagnetic character,[9] in which the coupling between magnetic metal ions is ferromagnetic within each layer, but the layers are antiferromagnetically coupled. The interlayer antiferromagnetic interaction of the compound prepared according to Method B is expected to be very weak as a result of the van der Waals contacts where DMF molecules of crystallization are positioned between the layers. Therefore, the magnetic difference below 250 G between the samples prepared by Method A and Method B can be ascribed to the slight difference in the interlayer interaction.

The compound in question possesses two favorable characteristics imparted by the component iron–cyanide and manganese Schiff base complexes. The cyanide system assumes a rigid cubic structure whose three-dimensional arrangement is essential for three-dimensional magnetic ordering, but the poor quality of the crystal has prevented a single-crystal X-ray analysis of the structure. The manganese(III) complex with the salen analogs can accommodate bridging ligands such as the CN^- ion at its axial sites, and the structure is sufficiently flexibile. As anticipated, the coupling of these two compounds gives a magnetic material with high crystallinity and multidimensional structure. Further studies are now in progress.

Experimental Procedure

Caution! Perchlorate salts are potentially explosive and should only be handled in small quantities.

The complex can be prepared by two methods, Method A and Method B.

Method A: To the solution of [Mn(3-MeOsalen)(H_2O)]ClO_4 (294 mg, 0.5 mmol) in methanol (50 mL) was added a solution of $K_3[Fe(CN)_6]$ (165 mg, 0.5 mmol) in water (5 mL) at room temperature. The resulting solution was left to stand for 1 h, and the reddish brown precipitate thus produced was collected by suction filtration, washed with 1:1 v/v methanol/water, and dried in vacuo. Anal.: calcd for $C_{42}H_{36}N_{10}O_8KFeMn_2$: C 49.77, H 3.58, N 13.18, Mn 10.84, Fe 5.51; found: C 49.63, H 3.68, N 13.57, Mn 10.63, Fe 5.03. IR(KBr): ν = 1601, 1624 (C=N), 2097, 2114 cm^{-1} (C≡N); m.p. > 300 °C.

Method B: A solution of $K_3[Fe(CN)_6]$ in 2-propanol/water (1:1 v/v, 0.25 mmol in 30 mL mixed solution) was allowed to diffuse into a solution of [Mn(3-MeOsalen)(H_2O)]ClO_4 (0.25 mmol) in *N*,*N*-dimethylformamide (30 mL). After one week at room temperature in the dark, thin, brown platelets were obtained. The crystals contain two *N*,*N*-dimethylformamide molecules per trinuclear unit as solvent of crystallization.

[7] A net unit in the two-dimensional structure is composed of a cyclic octanuclear structure $(\cdots Mn\text{-}NC\text{-}Fe\text{-}CN\cdots)_4$ involving a sandwich structure. In the cyclic tetramer there are two kind of magnetic paths between Mn^{III} and Fe^{III} ions through the CN^- group, that is, intratrimer (linear unit) and intertrimer paths, both exhibiting ferromagnetic interaction. The magnetic interaction through the K^+ ion between two manganese ions is negligible [8].

Macrobicyclic Titanium(IV) Complexes with C_3-Symmetric Synthetic Peptides**

Kay Severin, Wolfgang Beck,* Gunter Trojandt, Kurt Polborn, and Wolfgang Steglich*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

The synthesis of C_3-symmetric pseudo-peptides[1] has been achieved during studies related to the chemistry of electrophilic glycine equivalents. The tricarboxylic acid 2,2',2''-nitrilotris-[2-(benzoylamino)acetic acid], N(BzGly*OH)$_3$ **1** is accessible in a few further steps from the coupling of methyl α-bromohippurate with ammonia. This compound, which is stabilized by three intramolecular hydrogen bonds, has proven to be a suitable template for the synthesis of C_3-symmetric pseudo-peptides with defined geometry.[1] The coordination properties of this class of compound are of interest for several reasons. Firstly, applications as chiral ligands for stereoselective synthesis seem possible;[2] and secondly, peptides with a well-defined metal coordination site are model compounds for metalloenzymes.[3] The reaction of $[(\eta^5\text{-}C_5H_5)TiCl_3]$ or $[(\eta^5\text{-}C_5Me_5)TiCl_3]$[4] with the trianion of **1** (*RRR*/*SSS*) yields the complexes **2** and **3**. The

RRR/SSS

$[(\eta^5\text{-}C_5H_5)Ti(1)]$ **2**

$[(\eta^5\text{-}C_5Me_5)Ti(1)]$ **3**

X-ray structural analysis[5] of **3** (Fig. 1) shows the pseudo-amino acid functions as a pentadentate ligand: besides the titanatrane-like complexation,[6] coordination of a benzoyl O atom occurs.

If the Cp* ring is regarded as an unidentate ligand, the environment around the titanium atom can be described as distorted octahedral. The Ti atom resides slightly above the plane formed from the O atoms O1, O3, O4, and O7. The molecular structure also provides an explanation for the remarkable stability[7] of the complexes **2** and **3**: the ligand causes the complete sterical shielding of the Ti atom.

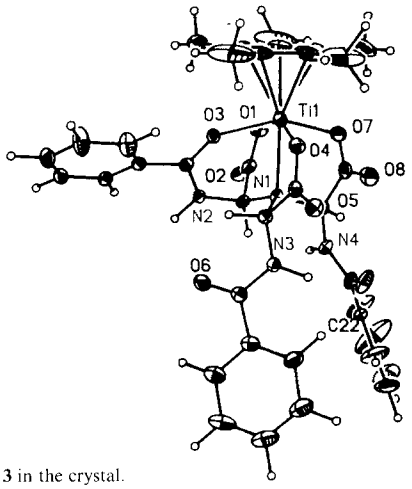

Fig. 1. Molecular structure of **3** in the crystal.

An important aspect of the structure of **3** is the stabilization by inter- and intramolecular hydrogen bonds. By coordination of the benzoyl group two of—in the free ligand three—intramolecular hydrogen bonds between the amide-N and -O atoms are broken. The amide N atoms N2 and N4 "released" by this coordination now form intermolecular hydrogen bonds: N2–H to a water molecule present in the crystal (not shown in Fig. 1), N4–H to the carboxylate-O atom of an adjacent molecule. This leads to a dimerization of the complex in the crystal (Fig. 2). Interestingly both enantiomers (*RRR* and *SSS*) are linked through hydrogen bonds.[8]

This structural type is consistent with the spectroscopic data also for **2**. The lowering of the ligand symmetry is manifested in the NMR spectra. They show separate signals for the three hippuric acid residues. The ^{1}H NMR signals of the amino acid ligand of **3** in [D$_6$]DMSO are substantially broadened at elevated temperatures. This coalescence phenomenon is presumably a consequence of an exchange between coordinated and free benzoyl groups. Treatment of the disodium salt of **1** with $[(\eta^5\text{-}C_5H_5)TiCl_2]$ in methanol also affords **2** as the major product (NMR-spectroscopic proof). Presumably a double substitution of carboxylato for chloro ligands occurs first, followed by an

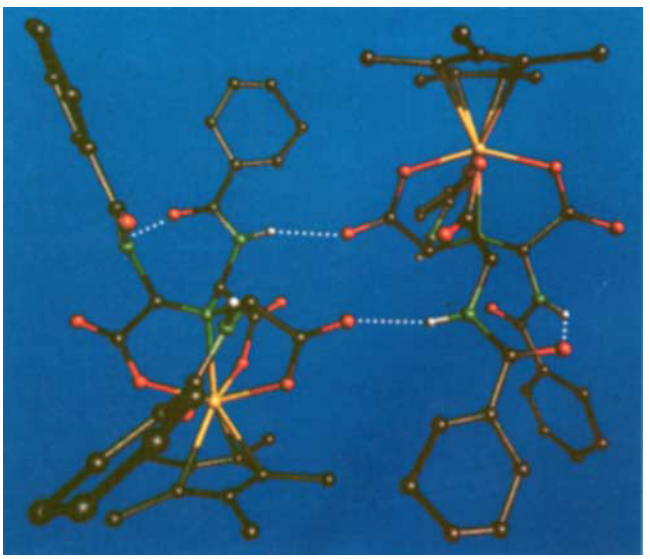

Fig. 2. Dimerization of **3** through hydrogen bonds.

intramolecular protolysis of a cyclopentadienyl ligand by the remaining acid function.

Pseudo-peptides, prepared starting from **1**, exhibit a uniform basic structure stabilized by hydrogen bonds in the crystalline state.[1] Hence they should be ideally preorganized for the formation of macrobicycles. Amino acids with sterically demanding side chains were chosen deliberately for the C-terminii; these shield the titanium atom, and consequently stabilize the complexes and prevent a di- or oligomerization through intermolecular coordination of the metal atom.

The reaction of the pseudo-nonapeptides $N(BzGly*GlyLeuOH)_3$, $N(BzGly*GlyPheOH)_3$, and $N(BzGly*LeuPheOH)_3$ with three equivalents of sodium methoxide in dichloromethane and subsequent treatment with $[Cp*TiCl_3]$ gives the complexes **4**–**6**, respectively (depicted schematically in Fig. 3). These complexes can be isolated by extraction with dichloromethane/ether (**4** and **5**) or dichloromethane/pentane (**6**). In this way, side products can be separated quantitatively. The yields of the reactions are above 50%. The pseudo-nonapeptides used for the synthesis of compounds **4** and **6** were purified by fractional crystallization before saponification. One of the two diastereoisomers is thereby separated. The absolute configuration of the ligands in these compounds (*RRR* in **4**; *SSS* in **6**) can be determined by recording the CD spectra.[11] A mixture of isomers (ca. 2.5:1) was used for the synthesis of **5**. During complexation and/or the subsequent workup procedures for **5** one diastereomer (*SSS*) becomes enriched (ca. 5:1).

Fig. 3. Schematic representation of the macrobicyclic $Cp*Ti^{IV}$ complexes **4**–**8** (AS = α-amino acid).

To record the NMR spectra of compounds **4**–**6**, low concentrations of the samples are required (below 0.8 mM), since at higher concentrations, considerable line broadening is observed, presumably due to aggregation. The spectra show one set of signals for the three peptide chains in each case. This proves that in solution the C_3 symmetry of the peptide ligands remains intact after complexation. An exact assignment of the ^1H NMR signals was achieved with the help of H-H-COSY spectra. The shifts of the amide protons of AS_1 and AS_2 indicate the presence of six intramolecular hydrogen bonds in **4**–**6**, similar to the situation in the uncomplexed pseudo-peptides. Only the amide protons of the C-terminal amino acids (AS_3) apparently do not form hydrogen bonds. The "Cp*Ti-lid" provides additional rigidity for the peptide frame. This becomes noticeable in the ^1H NMR spectra by the difference between the chemical shifts of diastereotopic protons.[9] Thus, the signals of the glycine methylene protons (AS_2) in the free ligand are separated by 0.6 ppm, those in **5** by 1.1 ppm. This effect is less marked for the diastereotopic methylene protons of the phenylalanine or leucine side chains.

Figure 4 shows a simulation of the molecular structure of **4**.[10] This was performed on the basis of structural data of $N(BzGly*GlyLeuOMe)_3$.[1] The basic framework fixed by hydrogen bonds was used unchanged, the carboxylate groups of the leucine residues were rotated (without change of symmetry) into a position favorable for complexation, and the methyl ester functions replaced by the Cp*Ti fragment. The lipophilic leucine side chains point away from the molecular axis and are an important reason for the good solubility of **4** in organic solvents. The same holds for the phenylalanine and leucine side chains of compounds **5** and **6**. As the three peptide chains are bound relatively close to each other through hydrogen bonds, the space inside the molecules appears too small for a hypothetical guest molecule.

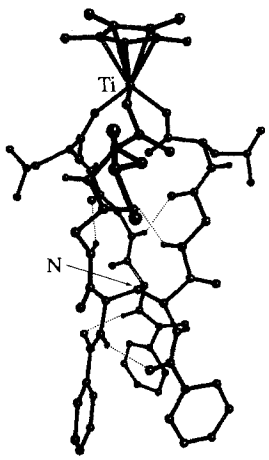

Fig. 4. Simulation of the molecular structure of **4**.

In Figures 3 and 4, the carboxylate groups are shown as unidentate ligands; however, an η^2-coordination with formation of four-membered chelate rings cannot be ruled out either on the basis of NMR or IR spectroscopic data. This holds for compounds **4**–**6** as well as for the following compounds **7** and **8**.

In order to explore the limitations of this synthetic concept, two pseudo-pentadecapeptides, $[N(BzGly*ValValGlyValOMe)_3$ and $N(BzGly*ValLeuGlyPheOMe)_3]$, were prepared. Also here amino acids with lipophilic side chains were chosen deliberately to increase the solubility. The synthesis of the macrobicyclic complexes **7** and **8** (ring size 32 atoms) was achieved analogously to that for **4**–**6**; however as expected the yields are lower (13% for **7**; 6% for **8**), the solubility in dichloromethane likewise. The molecular structures of **7** and **8** are shown schematically in Figure 3.

The cyclopentadienyl–Ti^{IV} complexes presented here are examples for the use of C_3-symmetric peptide bundles as ligands. We are currently investigating whether by suitable functionalization of the peptide chains it is possible to introduce other metal fragments into the peptide bundles.

Experimental Procedure

The pseudo-amino acid and peptide esters used were prepared as described in ref. [1], and subsequently saponified with LiOH in THF/water. The synthesis of complexes **2**–**8** was performed under argon with dry purified solvents. FAB mass

spectra were obtained for all complexes. The isotopic distribution corresponded to the calculated values within the precision limits of the experiment. All compounds gave satisfactory elemental analyses.

2: A solution of **1** (219 mg, 0.40 mmol) in methanol (10 mL) was treated with a methanolic NaOMe solution (1.20 mmol) and stirred for 45 min at room temperature. After addition of $[CpTiCl_3]$ (86 mg, 0.39 mmol) and 2.5 h stirring, a yellow precipitate formed from the originally clear solution. The suspension was concentrated in vacuo to 5 mL and stirred for 30 min at 0 °C. The precipitate was isolated by centrifugation and recrystallized from dichloromethane/hexane. Yellow crystals were obtained by layering an ethyl acetate solution with hexane. Yield 176 mg (66%), m.p. >175 °C (decomp).-IR (KBr): $\tilde{\nu} = 1673\ cm^{-1}$ vs and br. (CO_2 and CON), 1602 s, 1563 s and 1525 s (CON). – ^1H NMR (400 MHz, $CDCl_3$): $\delta = 4.87$ (d, $^3J = 6$ Hz, 1H, NHCH), 5.28 (d, $^3J = 7$ Hz, 1H, NHCH), 5.79 (d, $^3J = 9$ Hz, 1H, NHCH), 6.94 (s, 5H, Cp), 7.23–7.63 (m, 11H, Ph), 7.74 (d, $^2J = 9$ Hz, 1H, NHCH), 7.78 (dd, $^3J = 7$, $^4J = 1$ Hz, 2H, *o*-Ph), 7.95 (d, $^3J = 7$ Hz, 1H, NHCH), 7.99 (dd, $^3J = 8$, $^4J = 1$ Hz, 2H, *o*-Ph), 9.38 (d, $^3J = 6$ Hz, 1H, NHCH). – ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 66.24$, 69.63 and 77.81 (NHCH), 127.84, 127.88, 128.16, 128.43, 128.61, 129.91, 131.85, 132.05, 132.68, 132.73 and 135.65 (Cp and Ph), 168.24, 169.27, 169.49, 169.73, 170.55 and 170.70 (CO_2 and CON).

3: Synthesis analogous to that for **2** in methanol (20 h, room temperature). Purification by extraction with dichloromethane and recrystallization from ethyl acetate/hexane. Red crystals, yield 198 mg (68%), m.p. >197 °C (decomp).-IR (Nujol): $\tilde{\nu} = 1714\ cm^{-1}$ s (CON, coord.), 1670 s and 1647 s (CO_2 and CON), 1597 s, 1560 s and 1525 s (CON). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 2.21$ (s, 15H, Cp*), 4.79 (d, $^3J = 7$ Hz, 1H, NHCH), 5.11 (d, $^3J = 7$ Hz, 1H, NHCH), 5.64 (d, $^3J = 9$ Hz, 1H, NHCH), 6.82 (d, $^3J = 9$ Hz, 1H, NHCH), 7.22–7.62 (m, 11H, Ph), 7.73 (dd, $^3J = 8$, $^4J = 1$ Hz, 2H, *o*-Ph), 7.83 (d, $^3J = 7$ Hz, 1H, NHCH), 7.95 (dd, $^3J = 8$, $^4J = 1$ Hz, 2H, *o*-Ph), 8.77 (d, $^3J = 7$ Hz, 1H, NHCH). – ^{13}C NMR (100.5 MHz, CD_3OD): $\delta = 13.01$ [$C_5(CH_3)_5$], 67.05, 67.96 and 71.03 (NHCH), 128.63, 129.05, 129.10, 129.38, 129.50, 129.70, 130.46, 132.90, 133.22, 133.45, 134.11, 135.61 and 137.86 [$C_5(CH_3)_5$ and Ph], 170.56, 171.25, 172.50, 172.70, 173.50 and 173.91 (CO_2 and CON).

4: A solution of N(BzGly*GlyLeuOH)$_3$ (159 mg, 0.15 mmol) in dichloromethane (20 mL) was treated with a methanolic NaOMe solution (0.41 mmol) and stirred for 2 h at room temperature. Then a solution of $[Cp^*TiCl_3]$ (39 mg, 0.14 mmol) in dichloromethane (5 mL) was added slowly, the solution stirred for another 2 h and the solvent was evaporated in vacuo. The residue was extracted with a 1:1 mixture of dichloromethane and ether (15 mL). The resulting solution was concentrated in vacuo to about 1 mL. The product precipitated after addition of pentane (20 mL) and was washed with pentane (20 mL). Orange powder. Yield 104 mg (56%), m.p. >196 °C (decomp).-IR (KBr): IR (KBr): $\tilde{\nu} = 1659\ cm^{-1}$ vs (CO_2 and CON), 1525 vs (CON). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.95$ [d, $^3J = 6$ Hz, 9H, CH(CH_3)$_2$], 1.00 [d, $^3J = 7$ Hz, 9H, CH(CH_3)$_2$], 1.43–1.78 [m, 9H, CH(CH$_3$)$_2$ and CH$_2$-Leu], 2.12 (s, 15H, Cp*), 3.54 (dd, $^2J = 16$, $^3J = 3$ Hz, 3H, CH$_2$-Gly), 4.50 (dt, $^3J = 10$, $^3J = 10$, $^3J' = 5$ Hz, 3H, NHCH-Leu), 4.68 (dd, $^2J = 16$, $^3J = 9$ Hz, 3H, CH$_2$-Gly), 5.65 (d, $^3J = 10$ Hz, 3H, NH-Leu), 5.84 (d, $^3J = 10$ Hz, 3H, NHCHN), 7.11 (t, $^3J = 8$ Hz, 6H, *m*-Ph), 7.29 (t, $^3J = 8$ Hz, 3H, *p*-Ph), 7.37 (d, $^3J = 8$ Hz, 6H, *o*-Ph), 8.61 (d, $^3J = 10$ Hz, 3H, NHCHN), 8.70 (m, 3H, NHCH$_2$). – ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 12.05$ [$C_5(CH_3)_5$], 21.72, 23.16 and 24.72 [CH(CH$_3$)$_2$ and CH(CH_3)$_2$], 40.27, 42.50, 51.39 (CH$_2$-Leu, NHCH-Leu and CH$_2$-Gly), 62.85 (NHCHN), 127.47, 127.90, 131.13, 133.53 and 135.15 [$C_5(CH_3)_5$ and Ph], 166.94, 168.51 and 169.93 (CO_2 and CON).

5: Synthesis analogous to that for **4**; extraction with dichloromethane/ether (2:3) (20 mL). Orange powder. Yield 128 mg (53%), m.p. >194 °C (decomp).-IR (KBr): $\tilde{\nu} = 1658\ cm^{-1}$ vs (CO_2 and CON), 1524 vs (CON). – ^1H NMR (400 MHz, $CDCl_3$): $\delta = 2.04$ (s, 15H, Cp*), 2.80 (dd, $^2J = 15$, $^3J = 10$ Hz, 3H, CH$_2$-Phe), 3.14 (dd, $^2J = 15$, $^3J = 5$ Hz, 3H, CH$_2$-Phe), 3.33 (dd, $^2J = 16$, $^3J = 4$ Hz, 3H, CH$_2$-Gly), 4.41 (dd, $^2J = 16$, $^3J = 10$ Hz, 3H, CH$_2$-Gly), 4.66 (m, 3H, NHCH-Phe), 5.57 (d, $^3J = 9$ Hz, 3H, NH-Phe), 5.61 (d, $^3J = 9$ Hz, 3H, NHCHN), 6.98–7.24 (m, 30H, C_6H_5), 8.20 (m, 6H, NHCHN and NHCH$_2$). – ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 12.19$ [$C_5(CH_3)_5$], 37.18, 42.35 and 53.40 (CH$_2$-Gly, CH$_2$-Phe and NHCH-Phe), 62.84 (NHCHN), 127.33, 127.41, 127.88, 128.53, 128.75, 128.87, 131.16, 133.41 and 135.73 [$C_5(CH_3)_5$ and Ph], 166.94, 168.30 and 169.80 (CO_2 and CON).

6: Synthesis analogous to that for **4**; extraction with dichloromethane/pentane (20 mL) (1:1). Orange powder. Yield 110 mg (49%), m.p. >189 °C (decomp).-IR (KBr): $\tilde{\nu} = 1664\ cm^{-1}$ vs (CO_2 and CON), 1518 vs (CON). – ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.89$ [d, $^3J = 6$ Hz, 9H, CH(CH_3)$_2$], 0.94 [d, $^3J = 7$ Hz, 9H, CH(CH_3)$_2$], 1.37 [m, 3H, CH(CH$_3$)$_2$], 2.04 (m, 6H, CH$_2$-Leu), 2.13 (s, 15H, Cp*), 2.94 (dd, $^2J = 15$, $^3J = 10$ Hz, 3H, CH$_2$-Phe), 3.29 (dd, $^2J = 15$, $^3J = 5$ Hz, 3H, CH$_2$-Phe), 4.63–4.68 (m, 3H, NHCH-Phe), 4.69–4.75 (m, 3H, NHCH-Leu), 5.75 (d, $^3J = 9$ Hz, 3H, CH-Gly), 5.83 (d, $^3J = 8$ Hz, 3H, NH-Phe), 7.02–7.54 (m, 30H, Ph), 8.39 (d, $^3J = 9$ Hz, 3H, NH-Leu), 8.60 (d, $^3J = 9$ Hz, 3H, NH-Gly). – ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 12.10$ [$C_5(CH_3)_5$], 21.51, 23.53 and 24.84 [CH(CH$_3$)$_2$ and CH(CH_3)$_2$], 36.99 and 40.38 (CH$_2$-Leu and CH$_2$-Phe), 50.46 and 54.15 (NHCH-Phe and NHCH-Leu), 63.20 (NHCHN), 127.34, 127.52, 127.74, 127.86, 128.56, 128.94, 131.02, 133.42 and 135.34 [$C_5(CH_3)_5$ and Ph], 166.65, 167.70 and 171.92 (CO_2 and CON).

7: Synthesis analogous to that for **4**; extraction with dichloromethane/acetone (2:1) (30 mL). The slight difficulties in obtaining high-resolution spectra of complexes **4**–**6** became more dominant in compounds **7** and **8**; even at low concentrations only poorly resolved signals can be obtained. Orange powder. Yield 35 mg (13%), m.p. >203 °C (decomp). IR (KBr): $\tilde{\nu} = 1657\ cm^{-1}$ vs (CO_2 and CON), 1523 vs (CON).

8: Synthesis analogous to that for **4**; extraction with dichloromethane/ether (3:1) (20 mL). Orange powder. Yield 32 mg (6%), m.p. >189 °C (decomp).-IR (KBr): $\tilde{\nu} = 1657\ cm^{-1}$ vs (CO_2 and CON), 1523 vs (CON).

Rapid Water Diffusion in a Cage-Type Crystal Lattice: β-Cyclodextrin Dodecahydrate**

Thomas Steiner, Aida M. Moreira da Silva, José J. C. Teixeira-Dias, Jörn Müller, and Wolfram Saenger*

Crystalline β-cyclodextrin-dodecahydrate (β-CD · 12 H_2O) is an excellent model for research on hydrogen bonding and on water clusters.[1–6] In the crystal lattice, the β-CD molecules form molecular cages that host seven water molecules. These are statistically and dynamically distributed over eleven positions, between which they move with jump rates of around 10^{10}–10^{11} s^{-1}.[4–6] There is no direct connection between the cages, so that water diffusion through the crystal lattice should occur only slowly (or not at all) (for further structural information see ref. [7]). Recently, however, we have shown that the water content of β-CD hydrate adjusts itself to humidity changes in the atmosphere within minutes.[8] This requires exchange of water molecules with the surroundings and water diffusion within the crystals with a rate of about 1/1000 of that in pure water,[9] although the crystal structure is apparently densely packed (Fig. 1, see also legend). This rapid diffusion through the crystal lattice must be associated with structural fluctuations of the β-CD molecules, which temporarily open suitable diffusion paths. In the following, we investigate these phenomena by using a combination of H_2O/D_2O and $H_2{}^{16}O/H_2{}^{18}O$ exchange experiments.

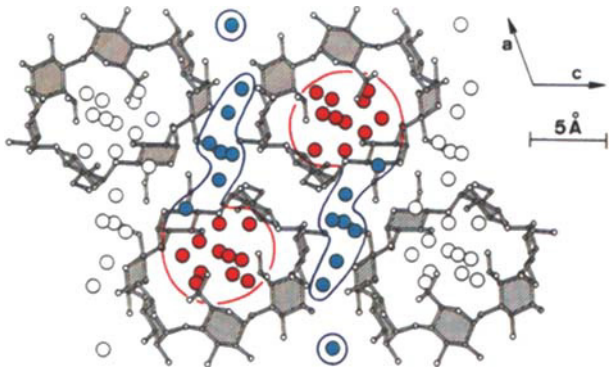

Fig. 1. Crystal structure of β-CD · 12 H_2O, projected along the monoclinic b axis (using coordinates from [3]). The eleven partially occupied water sites in the β-CD cavity are drawn red, and the eight water sites between the β-CD molecules are drawn blue. Red and blue envelope lines show the approximate "surface" of the water arrangement. The β-CD pyranose rings are shaded. The water cluster in the β-CD cavity is connected with a water chain between the β-CD molecules, but neither this chain nor the β-CD cavities are connected between neighboring crystal asymmetric units. In each asymmetric unit, one "solitary" water molecule is isolated from all other water molecules, and forms hydrogen bonds only to C–OH groups.

If crystalline β-CD · 12 H_2O is exposed to an atmosphere containing D_2O or $H_2{}^{18}O$, these "markers" diffuse into the sample. This can be followed by Raman spectroscopy and mass spectrometry, respectively. In the first experiment, microcrystalline β-CD hydrate[10] was exposed at room temperature to the atmosphere over a reservoir of D_2O, without having contact to the bulk liquid. After defined time periods, samples were quickly sealed in glass capillaries and the Raman spectra were recorded.[11] The bands of O–H and O–D stretching vibrations are very broad, but they are distinctly separated from all other bands[12] (ν_{OH} centered near 3400 cm^{-1}, ν_{OD} centered near 2500 cm^{-1}), and from their integrated intensities, the O–H/O–D ratio in the sample can be obtained. A typical series of spectra is shown in Figure 2: the H(O) concentration falls exponentially

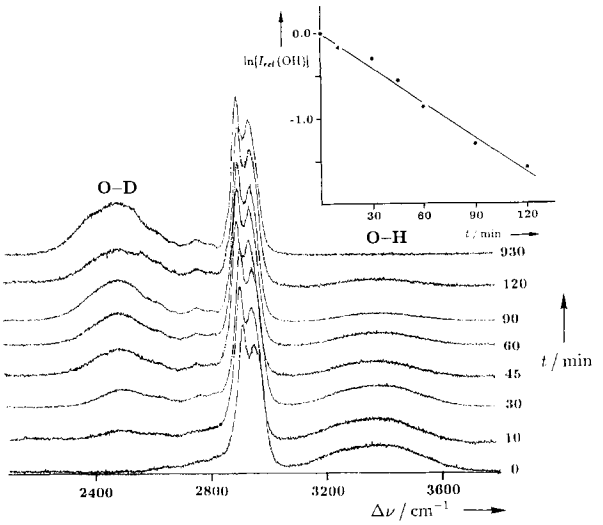

Fig. 2. H(O) → D(O) exchange. β-CD · 12 H_2O was exposed to D_2O vapor for defined time periods, and Raman spectra were then recorded. Typical series of spectra for hydrated commercial β-CD [10], sample ≈ 20 mg, only the relevant spectral region 2300–370 cm^{-1} is shown (invariable central peak: ν_{CH}). Drawn on a semi-logarithmic scale, the integrated relative intensity of the ν_{OH} band decreases linearly.

according to first order kinetics $c_H = c_{H,0}\, e^{-kt}$ (see the inset in Fig. 2 showing linearity of the semi-logarithmic plot). After few hours, *no*[13] H(O) is left in the sample. This kinetics is invariably observed for samples of different origin, and with different experimental arrangements. It must be stressed, however, that the macroscopic rate constant k is not an absolute value: due to shorter diffusion paths, the exchange is faster in small than in large samples (in Fig. 2: $k = 1.4 \times 10^{-2}$ min^{-1}; i.e. 50% exchange within 50 min). If deuterated samples are exposed to H_2O atmosphere, the back-exchange is equally rapid and complete.

The above experiment shows that D atoms diffuse into the sample and H atoms out, but it does not show the mechanism of transport: D and H atoms could be transported by diffusion of intact water molecules, but also by chains of proton (or deuteron) transfer processes. This question was answered by a complementary experiment, in which crystalline β-CD · 12 $H_2{}^{16}O$ was exposed to the atmosphere over a reservoir of $H_2{}^{18}O$.[14] After defined time periods, small samples were transferred into a mass spectrometer,[15] and gradually heated to 110 °C to expel the crystal water. The intensities of the mass signals m/z 18 for $H_2{}^{16}O$ and m/z 20 for $H_2{}^{18}O$ were continuously recorded, until all water was removed from the sample. After background subtraction, the integrated intensities

of these signals measure the relative $H_2{}^{16}O$ and $H_2{}^{18}O$ contents in the sample. The quantity $I_{18}/(I_{18}+I_{20})$ gives the percentage $H_2{}^{16}O$ of the total water content and falls exponentially with exposure time (Fig. 3). This shows that $H_2{}^{16}O$ is actually replaced by $H_2{}^{18}O$ from the atmosphere. For comparable sample dimensions, the exchange rates are similar to those for the H/D exchange experiment (for the example in Fig. 3: $k = 1.2\times10^{-2}\ min^{-1}$, corresponding to 50% exchange within 60 min). This exchange is also (almost[16]) complete, that is, it affects *all* water sites in the crystal.

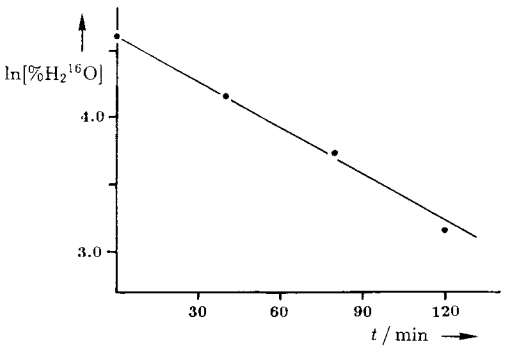

Fig. 3. $H_2{}^{16}O \rightarrow H_2{}^{18}O$ exchange. β-CD $\cdot 12H_2{}^{16}O$ samples were exposed to an $H_2{}^{18}O$ atmosphere for defined time periods, and the percentage of $H_2{}^{16}O$ in the crystal water was determined by mass spectrometry. To show the exponential behavior, the percentage $H_2{}^{16}O$ is drawn on a semi-logarithmic scale.

Since D and ^{18}O markers diffuse with comparable rates, these experiments indicate that intact water molecules diffuse through the crystal lattice. Although there are no continuous water channels, the diffusion is fast with macroscopic walks of $\approx$0.1 mm within minutes. This would be only in conflict with the crystal structure if the β-CD molecules are regarded as rigid objects. In fact, however, it is known from crystallographic displacement parameters[2] and from a molecular dynamics simulation study[4] that the C and O atoms in β-CD hydrate vibrate with amplitudes around 0.4 Å. These fluctuations are sufficient to transiently open passages through which water molecules can travel between adjacent crystal asymmetric units.

In the H/D exchange experiment, D is carried by intact water molecules over "long"[17] distances. Locally, D is transferred also to hydroxyl groups. The observation that the H/D exchange is complete has two important implications: 1) There is no H(O) atom in the crystal that is fixed in a "permanent" O–H $\cdots$ O hydrogen bond, and 2) since the H/D exchange also reaches those C–OH groups that are not sterically accessible for water molecules, there must be local chains of H/D transfer processes between hydroxyl groups. These involve *all* 21 O–H groups of the β-CD molecule, including those which appear to be ordered in the crystal structure determined by neutron diffraction.[2] This means that in the crystal lattice of β-CD $\cdot 12H_2O$, there is permanent internal transfer of protons and of water molecules.

The above dynamic processes are certainly associated with the structural disorder of hydroxyl groups and water molecules.[2] In crystalline α-CD $\cdot 6H_2O$ where all H_2O and C–OH groups are well ordered,[18] the H/D exchange is several orders of magnitude slower.

[7] β-CD is a macrocyclic oligosaccharide consisting of seven $\alpha(1\rightarrow4)$ linked D-glucopyranose units. From aqueous solution, it crystallizes as a dodecahydrate, β-CD $\cdot 12H_2O$, space group monoclinic $P2_1$. X-ray [3] and neutron [2] crystal structures show that *all* twelve H_2O are disordered to some degree. About seven H_2O are distributed over eleven partially occupied sites in the β-CD cavity; the other five H_2O molecules are distributed over eight sites in interstices. The β-CD molecules are packed in a herringbone arrangement, so that the H_2O molecules in neighboring crystal asymmetric units are sterically isolated from each other [3]. The β-CD molecule carries 21 O–H groups, of which only five have an ordered H position. The other 16 exhibit dynamic orientational disorder ("flip-flop" disorder [2]). Of these 16 disordered O–H groups, four are hydrogen-bonded only to other O–H groups and are consequently not directly accessible to water molecules.
[8] The water content varies continuously between 12.3 H_2O per β-CD at 100% ambient humidity (and crystals under mother liquor), $\approx$11.6 H_2O per β-CD at $\approx$60%, and $\approx$9.4 H_2O per β-CD at 15% humidity. This affects the water molecules enclosed in the β-CD cavity to a larger extent than those in interstitial sites. Commercially available β-CD hydrate has similar water content (if hydrated at humid atmosphere). Complete dehydration (for example in a desiccator) leads to collapse of the crystalline structure. The obtained substance fully re-hydrates at humid atmosphere; in the X-ray beam it shows a diffuse diffraction pattern indicating some residual crystalline order (Y. Nakai, K. Yamamoto, K. Terada, A. Kajiyama, I. Sasaki, *Chem. Pharm. Bull.* **1986**, *34*, 2178–2182).
[9] For a β-CD $\cdot 12H_2O$ crystal of $0.4\times0.3\times0.2\ mm^3$, dehydration was observed to follow e^{-kt} with $k = 0.33\ min^{-1}$, and was completed after $\approx$15 min [3]. This can serve to estimate an isotropic diffusion constant (which is only a very rough estimate because crystals are anisotropic): in isotropic diffusion, the mean square distance of random walks in a time period t is $\langle r^2\rangle = 6Dt$. Assuming that in the above experiment, most water molecules must have walked distances $\approx$0.1 mm within $t < 10$ min, a diffusion constant $D \approx 3\times10^{-8}\ cm^2s^{-1}$ is required (D in pure water: $2.2\times10^{-5}\ cm^2s^{-1}$ [19]).
[10] Samples for Raman spectroscopy: a) commercially available β-CD (Wacker-Chemie, München), hydrated by contact with the atmosphere. b) Ground crystals of β-CD $\cdot 12H_2O$ grown from solutions in H_2O.
[11] Jobin-Yvon T64000 Raman spectrometer (with software for determining band intensities), Coherent-Innova 300-05 Ar^+ laser, $\lambda = 514.5$ nm, 100 mW at the sample position, standard errors of measured wavenumbers $\approx 1\ cm^{-1}$. Samples sealed in capillary tubes with 0.8 mm inner diameter.
[12] O. Egyed, *Vibrational Spectroscopy* **1990**, *1*, 225–227.
[13] In Figure 2, the ν_{OH} band for $t = 0$ min exposure corresponds to $\approx$45 H(O) atoms per β-CD (21 C–OH, 12 H_2O). As estimated from the integrated intensities, the ν_{OH} band at 120 min represents 9.0 ± 1.0 H(O) atoms per β-CD ($=80\%$ exchange), and the flat spectrum (around 3400 cm^{-1}) for 930 min is compatible with less than 1.0 H(O) atom per β-CD.
[14] $H_2{}^{18}O$ from Isotec Inc., Miamisburg (Ohio), labeled as 97 atom %.
[15] Varian MAT311A mass spectrometer, modified by AMD Intectra, Kratos DS90 data system, EI (70 eV), ion accelerating voltage 5 kV, direct inlet probe, sample heating rate $\approx 5°\ min^{-1}$. Sample transfer into the spectrometer requires 1–2 minutes, in which slight back-exchange with atmospheric $H_2{}^{16}O$ cannot be avoided. Background intensity from contamination with atmospheric water in the sample crucible and in the spectrometer also cannot be completely avoided.
[16] The sample with longest exposure to $H_2{}^{18}O$, eight days, still contained 10% $H_2{}^{16}O$ (i.e. only 90% $H_2{}^{18}O$). For the water reservoir producing the vapor, a content of $\approx$8% $H_2{}^{16}O$ was measured. As the $^{16}O/^{18}O$ ratios in the water reservoir and in the sample were barely different, the exchange in the sample is actually better than 90%.
[17] This means that a given water molecule on the average performs many diffusion jumps between two H-(or D)-transfer processes. The distance walked between two such processes is therefore large compared to the jump distance. However, this distance need not be "macroscopic": it is assumed that during its journey from the surface to the interior of the crystal, a water molecule experiences many H-(or D)-transfer processes.

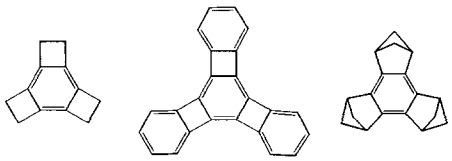
X-Ray Diffraction Evidence for a Cyclohexatriene Motif in the Molecular Structure of Tris(bicyclo[2.1.1]hexeno)benzene: Bond Alternation after the Refutation of the Mills–Nixon Theory**

Hans-Beat Bürgi,* Kim K. Baldridge, Kenneth Hardcastle, Natia L. Frank, Peter Gantzel, Jay S. Siegel,* and Joseph Ziller

For over 60 years, chemists have attributed bond length alternation in various types of benzenoid structures to the Mills–Nixon effect.[1] Originally, this theory was an attempt to account in structural terms for the observed regioselectivity of electrophilic substitution in tetralin and indan. A historical analysis of the development of this effect has shown that Mills and Nixon based their proposal on the incorrect Kekulé oscillation model for benzene, in which two D_{3h}-symmetric cyclohexatrienes are presumed to be in equilibrium; appropriate substitutions could then, in principle, shift the equilibrium to one side. Because the bond lengths and angles in this model are assumed to be dictated by van't Hoff tetrahedra, and the strain energy is thought to be described by Baeyer's theory,[2] the Mills–Nixon postulate has strong structural implications. Specifically, indan and related annelated benzenes are predicted to be cyclohexatriene-like, with double bonds positioned exocyclic to the five-membered ring; however, experimental structural data has never been available to support such speculations.

Given the postulate's faulty premises, it is wholly incorrect to interpret bond alternation in benzenoids in terms of the "theory" of Mills and Nixon. Nonetheless, the notion of angle-strain induced bond alternation in benzene has persisted even without experimental structural proof.[3] Semiempirical[4] and minimal basis set[5] calculations have predicted bond alternation to be common among trisannelated benzenes with exocyclic bond angles deviating significantly from 120°, and extreme for tri(cyclobuteno)benzene (**1**); however, experimental structure determinations of strained monocyclic annelated benzenes like **1**[6] have provided no evidence for this effect. Indeed, except for molecules like starphenylene **2**[7] where strong π effects are at play,[8] significant bond alternation in benzenoids has not been documented experimentally.[9] Ab initio computations at the Restricted Hartree–Fock 6-31G(D) level and higher predict a uniquely large bond alternation to be present in tris(bicyclo-[2.1.1]hexeno)benzene (**3**).[10] The present X-ray crystallographic analysis of **3** produces a molecular structure consistent with the computational predictions, and suggests a "bicyclic-strain" effect that is distinctly *not* a legacy of Mills and Nixon.



1 2 3

Wittig trimerization of 2-chlorobicyclo[2.1.1]hex-2-ene gave **3** in poor yield, but isolable quantity. Single crystals of **3** were grown by slow evaporation from benzene at room temperature.[11] The crystal lattice is built from molecular layers showing translational symmetry. The stacking of the layers manifests deviations from translational symmetry leading to an order–disorder crystal structure,[12] such that the molecular structure of **3** and its nearest neighbor relationships can be obtained from the diffraction data, but the crystal packing as a whole remains uncertain.

Compound **3** is the first bona fide mononuclear benzenoid hydrocarbon with a cyclohexatriene-like geometry. The central ring is planar and the internal angles are all 120° (Fig. 1); however, the two inequivalent bonds in the benzene ring differ

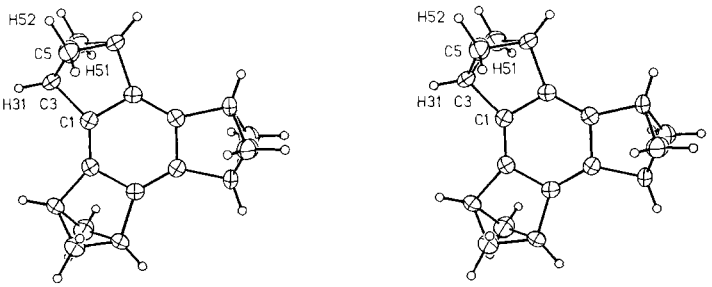


Fig. 1. Stereoview of **3** down the threefold symmetry axis.

by 0.089 Å (1.438(5)–1.349(6) Å). These lengths correspond to Pauling bond orders of 1.86 and 1.39 for the shorter and longer bond, respectively,[13] giving a bond order difference of roughly 0.5. In comparison, the difference in the bond order for the bonds in the central ring of **2** is 0.75, and in **1** it is less than 0.1. Although the average bond length in the benzene ring in **3** is "normal" compared to the average bond length for a hexasubstituted benzene (1.397 ± 0.009 Å),[9, 14] the *endo* bond is more than 4σ longer, and the *exo* bond is more than 4σ shorter.[9] Thus, either length alone would be remarkable. The radial bond from C(arom.) to C(methine) is quite normal (1.514(3) Å), as is the C(methine)–C(methylene) bond of the four-membered ring (1.558(8) Å).[15] The bicyclic annelation strongly constricts the C(arom.)-C(arom.)-C(methine) angle down to 102.3(2)°, and this angle distortion is presumed to be correlated to the manifestation of bond alternation.[16]

Ab initio computations at the Hartree–Fock 6-31G(D) level and higher, as well as Density Functional Theory (DFT) have predicted significant bond alternation in **3** (Fig. 2, Table 1).[17–23] Reasonable structures are obtained with gradient-corrected density functional methods, which inherently account for electron correlation, as well as from the Restricted Hartree–Fock 6-31G(D) basis set. Smaller basis sets or semiempirical quantum mechanical methods overestimate the degree of

bond localization. This preference for bond localization in lower basis set calculations has been noted in a computational study of the hypothetical all-*cis* conformation of cyclodecapentaene.[24]

Consecutive layers of **3** are related by local centers of symmetry leading to a nearest neighbor relationship in which the center of a molecule in one layer is situated over a hydrogen atom in the wing of a molecule in a neighboring layer (Fig. 3). This juxtaposition evokes thoughts of the polar/π interactions between benzenes with hydrogens.[25]

[9] In this context, significance is defined as follows: The length of a C(arom.)–C(arom.) bond for a hexasubstituted benzene is 1.397 Å, with $\sigma = 0.009$ Å; σ for all benzene derivatives is 0.013 Å. A value of $\pm 3\sigma$ (i.e. ± 0.027–0.039 Å) or greater is considered significant. The values for σ are taken from the Cambridge Crystallographic Database (F. H. Allen, O. Kennard, D. G. Watson, L. Brammer, A. G. Orpen, R. Taylor, *J. Chem. Soc. Perkin Trans. 2* **1987**, S1–S19).

[11] Crystallographic details for **3**: Precession photographs taken at room temperature showed a diffraction pattern with Laue symmetry 6/*mmm* but with diffuse diffraction streaks along c^* for $h - k + 3n$. The streaks are more intense around l odd than around l even. Reciprocal lattice lines along c^*, for which $h - k = 3n$, show sharp reflections for l even and systematic absences for l odd. These diffraction characteristics indicate an order–disorder structure [12]. Three sets of diffraction data had been collected before photographs were taken, one on an Enraf-Nonius CAD4 diffractometer equipped with a molybdenum tube, the second on a Siemens P4RA diffractometer equipped with a rotating Mo-anode, both at room temperature (hexagonal unit cell constants, $a = 9.007(5)$, $c = 17.802(11)$ Å, $V = 1250.7(21)$ Å^3) and the third at ca. 140 K on a Siemens P3 diffractometer with a molybdenum tube ($a = 8.74(4)$, $c = 17.736(8)$ Å, $V = 1237.0(16)$ Å^3). All three data sets show the following characteristics: reflections with $h - k = 3n$, $l = 2m$ are strong and show reasonable to excellent internal R-values when averaged with respect to 6/*mmm* symmetry; reflections with $h - k = 3n$, $l = 2m + 1$ are essentially absent; measurements with $h - k + 3n$ show poor internal R-values. The last observation is consistent with the fact that intensities measured by scanning across continuous diffraction streaks depend critically on the orientation of the crystal axes relative to the goniometer axes and on the unavoidable errors in the corresponding orientation matrix. As a consequence, measurements in symmetry-equivalent parts of reciprocal space may differ significantly. Sharp reflections are far less affected by these problems. The structure may be solved by first considering only the sharp reflections with $h - k = 3n$, $l = 2m$. These define a reduced hexagonal unit cell with $a' = (2a + b)/3$, $b' = (-a + b)/3$, $c' = c/2$ ($a' = b' = 5.200(3)$, $c' = 8.901(6)$ Å, $V = 208.4(4)$ Å^3). There are 1147 sharp reflections in the layers $-3 \le h' \le 6$, $-6 \le k' \le 3$, $-11 \le l' \le 11$. Averaging the second data set in 6/*mmm* symmetry leads to 114 uniques reflections with $R(\mathrm{int}) = 0.033$. The systematic absences of the reduced cell are $(00l')$, $l' = 2n + 1$ and $(h'h'l')$, $l' = 2n + 1$, thus indicating space group $P6_3/mmc$ for the reduced cell. Use of direct methods shows two molecules centered at 2/3, 1/3, 1/4 and 1/3, 2/3, 3/4 with site symmetry D_{3h} and related by a center of symmetry at 1/2, 1/2, 1/2. There are three carbon and three hydrogen atoms in the molecular asymmetric unit. Carbon atoms were refined anisotropically; C–H vectors were fixed in chemically meaningful directions. The C–H distances at C5 (see Fig. 1 for numbering) refined to 1.00(3) Å; the C–H distance at C3 was fixed at 0.95 Å. An isotropic displacement parameter, common to all hydrogen atoms, refined to 0.043(6) Å^2. The number of refined parameters is 22, including a scale and an extinction factor. Refinement converged smoothly at $R(|F|) = 0.028$, $wR(F^2) = 0.076$ and GOF = 1.222 for all 114 observations. All calculations were performed with the programs SHELX93 and XP. Treating the other two data sets in the same way leads to essentially the same, but less accurate results. In the original unit cell the molecular centers would be at 1/3, 1/3, z; $-1/3$, 0, z; 0, $-1/3$, z; 1/3, 0, $z + 1/4$; 0, 1/3, $z + 1/4$; $-1/3$, $-1/3$, $z + 1/4$ (with $z = 1/8$ and 5/8). For steric reasons and because the translational symmetry perpendicular to the threefold axis is a,b rather than a',b', only one of the three alternative positions can be occupied for a given value of z. The basic building blocks of the crystal structure are thus well-ordered layers of **3**, one per unit mesh in a,b, with their threefold axes perpendicular to the a,b-plane. The layer symmetry group is $p\bar{6}2m$. The layers above and below any given layer each have a choice governed by probability rules between three alternative, but well-defined positions; this will be elaborated elsewhere. However, no matter which alternative is chosen, the nearest neighbor relationship between molecules in adjacent layers is always as shown in Figure 2. Since the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1313-1455 $ 10.00+.25/0

stacking of consecutive layers is governed by a combination of probability rules and well-defined nearest neighbor relationships, the crystal shows the observed combination of diffuse and sharp scattering.

[13] L. Pauling, *The Nature of the Chemical Bond*, 3rd ed., Cornell University Press, Ithaca, NY, **1961**, pp. 239–40.

[14] Alternatively, the total bond order in **3** is 9.75, less than the bond order in benzene (10) but greater than that in hexasubstituted benzenes (9.54) based on the average bond lengths.

[15] The mean values and their estimated standard deviations listed in ref. [9] are 1.554(21) Å for cyclobutane (any substitution) and 1.510(14) Å for $R_2CH-C=C$.

[16] The angle distortion effect seems to be nullified in benzenes with monocyclic annelations, like **1**, perhaps due to "bent bonds" in those systems; the angular effect for bicyclics appears to be more effective. For an example of a related distortion in the norbornyne trimer, see: N. L. Frank, K. K. Baldridge, P. Gantzel, J. S. Siegel *Tetrahedron Lett.* **1995**, in press.

[17] Computational details: The molecular structure of **3** was determined at a variety of theoretical methods to determine self-consistency. Reported here are the split-valence 6-31G(D) [18] and triple-zeta valence TZV(D) [19] basis sets, employed at the restricted Hartree–Fock (RHF) self-consistent field (SCF) level of theory. These basis sets include a set of six d polarization functions on all heavy atoms. These calculations were performed with the aid of the analytically analytically determined gradients and search algorithms contained in GAMESS [20]. Additional calculations at the MP2/6-31G(D) and Density Functional Theory levels were performed to determine the effects of dynamical correlation. Calculations using the former method, a post-RHF method that incorporates correlation in terms of Møller-Plesset theory of order 2 (MP2) [21], were performed using the GAUSSIAN 92 suite of programs [22]. Calculations using Density Functional Theory (DFT) Methods, which inherently incorporate effects of correlation in their development, were performed with the aid of the numerical methods within Dmol [23]. A double numerical basis set augmented by polarization functions, comparable in size to the 6-31G(D) basis set of the traditional Hartree–Fock methods, was chosen for the DFT calculations.

Architectural Control in "Living" Free Radical Polymerizations: Preparation of Star and Graft Polymers**

Craig J. Hawker*

The ability to accurately control macromolecular architecture is becoming an increasingly important theme in polymer science with the interest being driven by the desire to prepare materials with new and/or improved properties.[1] One way to achieve these goals is to introduce branches into the polymer backbone. For example, graft and star systems have been shown to be useful as rheology control agents, compatabilizers for polymer blends, and emulsifiers.[2] Traditionally, graft and star polymers have been prepared by anionic[3] and cationic polymerization,[4] or by group transfer techniques.[5] However these techniques suffer from rigorous synthetic conditions, an inability to form many random copolymer systems, and incompatibility with a wide range of monomer units. One goal of synthetic polymer chemistry is to devise a free radical approach to the preparation of graft and star systems which has the same degree of macromolecular control as the above techniques but does not suffer from their synthetic drawbacks. Previous attempts at using free radical methods have not been entirely successful due to a lack of macromolecular control and combination reactions, which result in network formation.[6] In this report we describe a novel "living" free radical methodology which overcomes these problems and allows the synthesis of star and graft copolymers with controlled molecular weights and low polydispersities under mild conditions.

This new polymerization method is based on the use of novel initiators containing a covalent adduct of styrene and 2,2,6,6-tetramethylpiperidinyloxy (TEMPO).[7] Previously we have demonstrated that the molecular weight and chain ends of polystyrene can be accurately controlled by the use of **1** as an initiator.[8] These results, coupled with the pioneering work by Georges et al.[9] and Rizzardo et al.[10] suggest that the polymerization proceeds with little or no termination and may be considered living in nature. It is this lack of termination reactions, coupled with a high degree of macromolecular control, which may allow the synthesis of well-defined star and graft polymer systems using TEMPO-based initiators.

To investigate this question we examined the synthesis of a trifunctional initiator, **2**, which contains three initiating styrene-TEMPO groups. It was hoped that each of the three styrene-TEMPO groups of **2** would independently initiate a growing polymer chain and that these individual polymer chains would grow at approximately the same rate to give well-defined star macromolecules. It was found that the benzyl ester group of the starting material **1** could be hydrolyzed with potassium hydroxide to give the alcohol **3** in excellent yields. Reaction of **3** with 1,3,5-benzenetricarbonyl chloride (**4**) in the presence of 4-dimethylaminopyridine proceeded smoothly to give the desired trifunctional initiator **2** in 71% yield after purification (Scheme 1). Under the conditions developed previously,[7, 9] bulk polymerization of 200 equivalents of deuterated styrene with **2** at 130 °C for 72 h was found to give the polystyrene **5** in 84% yield with no detectable amounts of crosslinked or insoluble material (Scheme 2). Analysis of **5** revealed a molecular

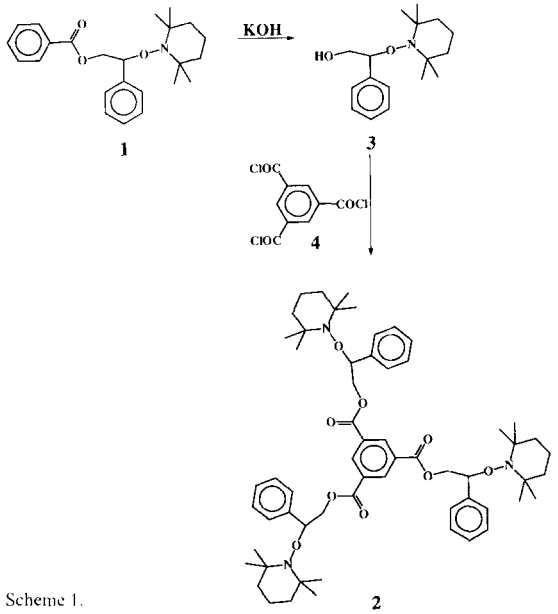
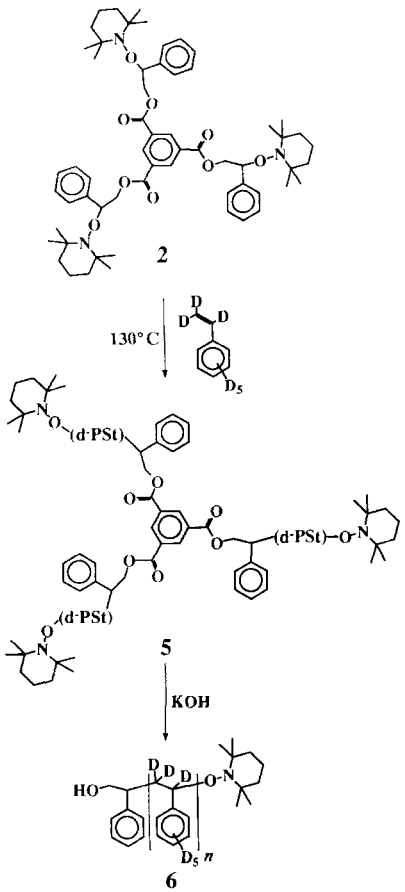


Scheme 1.



Scheme 2.

weight M_n of 16500 amu and a polydispersity (PD) of 1.20.[11] From the feed ratio, and assuming a three-arm star polymer is formed, the theoretical molecular weight M_n of **5** should be 21000 with each arm having a number average molecular weight of 7000. This discrepancy in molecular weights is, however, fully consistent with the proposed structure since the hydrodynamic volume of a star polymer is less than that of a comparable linear polymer. To determine the molecular weights of the individual arms of the star polystyrene, **5** was hydrolyzed with potassium hydroxide (Scheme 2). Significantly, the hydrolyzed product **6** was found to have a molecular weight M_n of 7600 (PD = 1.12) which agrees closely with the theoretical value for one arm of the star polymer ($M_n = 7000$). These results support the formation of a well-defined three-arm star macromolecule from **2**, the molecular weight of which can be accurately controlled by the initial feed ratio.

Further evidence for the proposed structures was obtained by comparing the ^{1}H NMR spectra of the trifunctional initiator **2** with that of the deuterated star polystyrene **5** and its hydrolyzed product **6**. As can be seen in Figure 1, the signals of the protons

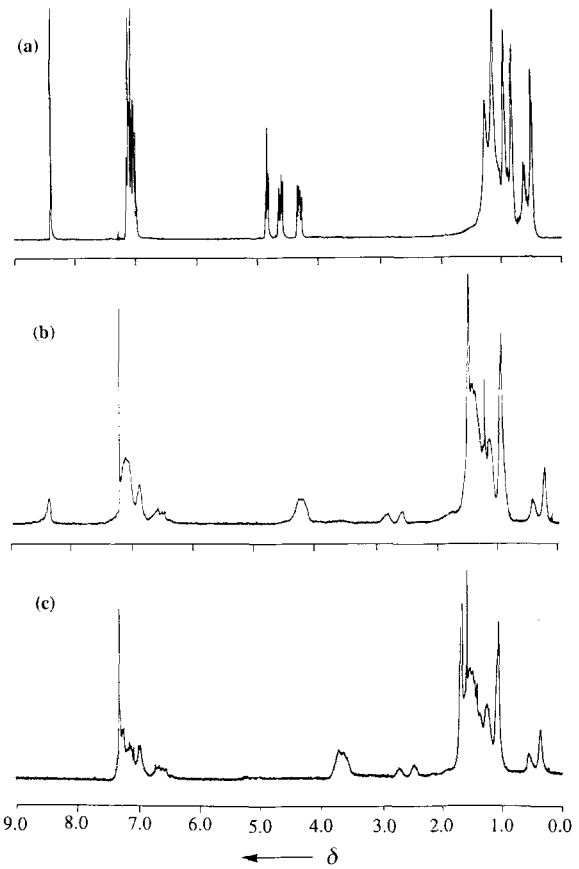


Fig. 1. a) ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of the trifunctional initiator **2**; b) ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of the three-arm deuterated polystyrene star **5**; c) ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of the hydrolysis product **6**.

H_a, H_b, and H_c, which stem from the styrene unit in **2**, appear as three AB quartets at $\delta = 4.30-5.10$, and the protons of the symmetrically substituted core unit appear as a singlet at $\delta = 8.20$. On reaction with [D_8]styrene the resonances for H_a, H_b, and H_c undergo upfield shifts which correlate with the insertion of deuterated styrene units between the TEMPO and styrenic units of **2**, while the resonance for the core unit remains as a singlet at $\delta = 8.16$. On hydrolysis the resonance for the core unit at about $\delta = 8.20$ disappears, and the resonances for H_a, H_b, and H_c undergo shifts which are consistent with the generation of a hydroxy end group. In fact the spectrum of **6** is identical to that obtained when the alcohol **3** is used to initiate the polymerization of deuterated styrene.[8] In all three spectra the resonances for the TEMPO group are observed at $\delta = 0.0-1.5$ which demonstrates the stability of the TEMPO linkage to hydrolysis conditions.

Repetition of the above polymerization/hydrolysis reactions with up to 1000 equivalents of styrene was found to give similar results and illustrates the usefulness of this technique for the preparation of high molecular weight materials. For example, reaction of **2** with 700 equivalents of styrene was found to give a three-arm star polystyrene in 88% yield which had a M_n of 53000 and a PD of 1.19. While this value is again less than the theoretical number average molecular weight of 73000, hydrolysis to give the individual arms resulted in much closer agreement ($M_n = 22000$; PD = 1.09) with the theoretical number average molecular weight of 24000. This high degree of macromolecular control coupled with a lack of crosslinked material supports a "living" nature for this novel polymerization process with no termination due to combination or disproportionation. The versatility and usefulness of this "living" free radical chemistry is also demonstrated by the ability to use monomers such as *p*-chloromethylstyrene as well as acrylates and methacrylates. For example, previously unreported star polymers containing narrow dispersity arms which are random copolymers of styrene and butyl acrylate can be prepared from **2**.

This lack of termination steps also opens up the possibility of using this polymerization process to prepare graft systems. In an effort to also investigate the compatibility of the styrene-TEMPO group with standard free radical procedures the synthetic strategy for preparation of the graft systems involved initial synthesis of a monomer unit incorporating the styrene-TEMPO group, copolymerization with styrene under normal free radical conditions, followed by a "living" free radical polymerization with a second feed of styrene. The synthesis of the polymeric initiator is outlined in Scheme 3. Reaction of **2** with *p*-chloromethylstyrene in the presence of sodium hydride was found to give the desired monomeric derivative **7** in 71% yield after purification. Copolymerization of **7** with styrene was conducted under normal conditions using azobisisobutyronitrile (AIBN) as an initiator in refluxing tetrahydrofuran. Significantly the polymerization proceeded smoothly to give the desired copolymer **8** ($M_n = 12000$; PD = 1.80) in 72% yield after purification. Analysis of the copolymer by ^1H and ^{13}C NMR spectroscopy showed the expected resonances for the styrene-TEMPO group, and comparison with the aromatic styrenic resonances for the backbone polymer permitted the ratio of monomer units to be determined. The experimentally determined value of 1:19 agrees with the feed ratio and shows that the styrene-TEMPO group has little effect on reactivity ratios. Bulk polymerization of a mixture of the copolymer **8** and 200 equivalents of styrene at 130 °C for 72 h resulted in polymerization of the added styrene to give the proposed graft system **9**. Comparison of the gel permeation chromatographic (GPC) traces for the starting polymer **8** and the graft system **9** clearly shows an increase in molecular weight for **9** and the absence of unreacted starting polymer (Fig. 2). In this case the nature of the grafted polymer chain **10** could not be probed by hydrolysis due to the stability of the ether linkage, and cleavage of this group was therefore accomplished by treatment of **9** with an excess of trimethylsilyl iodide (Scheme 4). This results in a dramatic change in the GPC trace for the isolated product, no peak for the starting graft system is observed, and the polydispersity of the sample is lowered from 2.01 to 1.26. Interestingly, the number average molecular weight for **10** was determined to be 23000, which agrees closely with the theoretical M_n for the grafted chains of 21000. These results demonstrate that a graft system is produced and that the TEMPO groups attached to the polystyrene backbone of **8** are capable of initiating the polymerization of styrene to give grafts of controlled molecular weight and low polydispersity. The small shoulder at lower molecular weight in the GPC trace for **10** correlates with the molecular weight of the starting polymer **8**, and is due to the cleaved backbone polymer, whose signal underlies the main peak for the grafted chain. This ability to conduct one free radical polymerization and then by simply increasing the temperature and adding new monomer, to conduct a second "living" free radical polymerization is intriguing and may open up new paths to unusual macromolecular architectures. As for the star polymers unusual graft copolymers can be readily prepared by this "living" free radical technique from monomers which cannot be polymerized by better known anionic or cationic techniques.

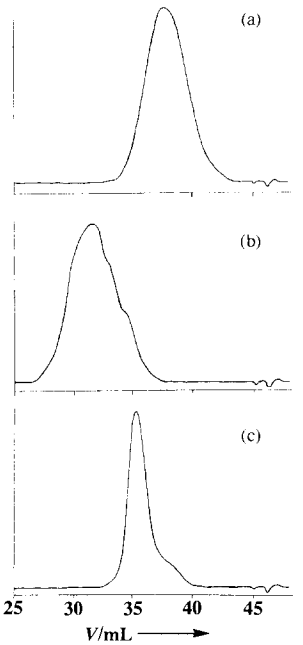

Fig. 2. a) Gel permeation chromatogram of the starting copolymer **8**; b) gel permeation chromatograph of the graft polymer **9**; c) gel permeation chromatogram of the cleaved graft polymer **10**.

In conclusion we have demonstrated that "living" free radical polymerizations based on TEMPO derivatives allow for the accurate control of macromolecular architecture. Star and graft copolymers can be prepared from the appropriate multifunctional initiators with no observation of crosslinking or termination by combination even under melt conditions. The molecular weights of the arms, or grafts, can be controlled by varying the equivalents of monomer added while maintaining very low polydispersities. We believe that this novel polymerization process offers the architectural control previously obtainable only under synthetically more rigorous anionic or cationic conditions.

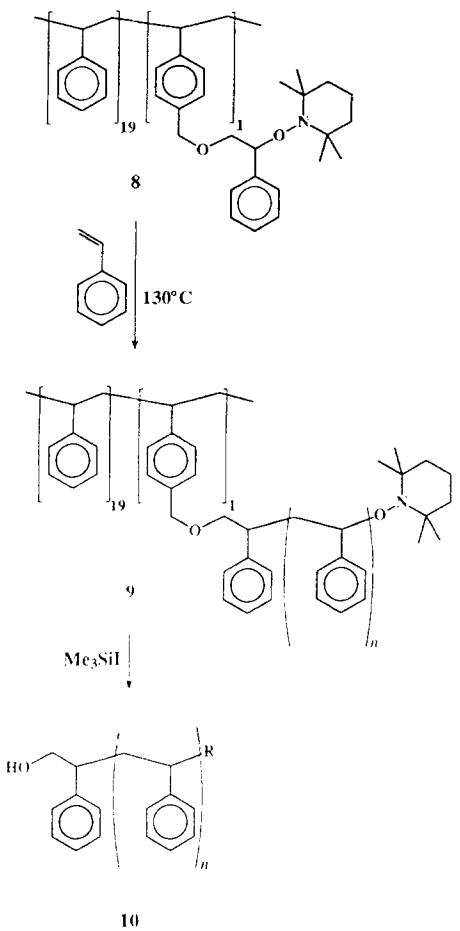

Scheme 4.

Experimental Procedure

2: To a solution of the alcohol **3** (1.0 g, 3.6 mmol) and **4** (290 mg, 1.1 mmol) in dry tetrahydrofuran (20 mL) was added dropwise a solution of 4-dimethylaminopyridine (50 mg, 0.4 mmol) and pyridine (300 mg, 3.8 mmol) in tetrahydrofuran (2.0 mL). The reaction mixture was stirred at room temperature under argon for 16 h and then evaporated to dryness. The residue was partitioned between dichloromethane (50 mL) and water (50 mL), and the aqueous layer extracted with dichloromethane (2 × 50 mL). The combined organic layers were dried, evaporated to dryness, and purified by flash chromatography eluting with 1:2 hexane/dichloromethane increasing to dichloromethane. This gave the trifunctional initiator **2** as a pale yellow oil. Yield 71%; ^{1}H NMR ($CDCl_3$): δ = 0.79, 1.03, 1.25, 1.62 (each brs, 12H, CH_3), 1.34 – 1.58 (m, 6H, CH_2), 4.60 (ABq, J = 6 Hz, 1H, C*H*H), 4.91 (ABq, J = 6 Hz, 1H, CH*H*), 5.14 (t, J = 3 Hz, 1H, C*H*), 7.25 – 7.52 (m, 5H, ArH), 8.20 (s, 3H, ArH); ^{13}C NMR ($CDCl_3$): δ = 17.17, 20.38, 34.12, 40.47, 60.15, 67.30, 83.89, 127.74, 128.18, 128.85, 130.92, 131.55, 134.53, 140.33, and 164.54; mass spectrum (EI) *m/z* 987; anal. calcd. for $C_{60}H_{81}N_3O_9$: C 72.9, H 8.26, N 4.25; found: C 73.2, H 7.99, N 4.43.

Preparation of three-arm polystyrene **5** from **2**: A solution of the trifunctional TEMPO initiator **2** (150 mg, 0.152 mmol) in [D_8]styrene (3.40 g, 30.4 mmol, 200 equiv) was heated at 130 °C with stirring under argon for 72 h. During this time the viscosity of the solution was observed to gradually increase and the clear reaction mixture eventually solidified. The reaction mixture was then dissolved in dichloromethane (25 mL) and precipitated into hexane (1 L) followed by re-precipitation into methanol (1 L). The three-arm polystyrene **5** was isolated as a white solid after drying. Yield 84%; M_n = 16500 and PD = 1.20; ^{1}H NMR ($CDCl_3$): δ = 0.40 (br d), 0.90 – 1.70 (br m), 2.65 and 2.90 (br d, H_c), 4.35 (m, 2H, H_a and H_b), 6.40 – 7.25 (br m), 8.40 (s, core H's); ^{13}C NMR ($CDCl_3$): δ = 17.10, 20.90, 39.4–43.8, 125.0 (br), 127.34 (br), 128.22, 129.42, 132.73, 144.8–145.8 (a number of resonances were too small to observe).

7: To a solution of the alcohol **3** (1.0 g, 3.6 mmol) in dry tetrahydrofuran (20 mL) was added sodium hydride (200 mg, 5.0 mmol) and the mixture stirred at room temperature for 10 min. A solution of *p*-vinylbenzyl chloride (1.52 g, 10.0 mmol, 3.0 equiv) was added and the mixture stirred at room temperature for 1 h, then heated at reflux for 16 h. The reaction mixture was then evaporated to dryness and partitioned between dichloromethane (50 mL) and water (50 mL) and the aqueous layer extracted with dichloromethane (2 × 50 mL). The combined organic layers were dried, evaporated to dryness and purified by flash chromatography eluting with 1:1 hexane/dichloromethane increasing to dichloromethane. This gave the styrene derivative **7** as a pale yellow oil. Yield 71%; ^{1}H NMR ($CDCl_3$): δ = 0.63, 1.01 (each brs, 6H, CH_3), 1.15 – 1.55 (m, 12H, 3 × CH_2 and 2 × CH_3), 3.65 (ABq, J = 6 Hz, 1H, C*H*H), 3.95 (ABq, J = 6 Hz, 1H, CH*H*), 4.41 (s, 2H, CH_2), 4.84 (d of d, J = 2 and 6 Hz, 1H, C*H*H), 5.20 (d of d, J = 2 and 7 Hz, 1H, =CH*H*), 5.71 (d of d, J = 2 and 6 Hz, 1H, =CH*H*), 6.66 (d of d, J = 6 and 7 Hz, 1H, =CH), 7.08 (d, 2H, Ar*H*), 7.25–7.52 (m, 7H, Ar*H*); ^{13}C NMR ($CDCl_3$): δ = 17.17, 20.56, 33.87, 40.48, 59.36, 72.74, 72.83, 85.41, 113.52, 126.04, 127.24, 127.53, 127.82, 127.88, 136.62, 138.14, and 141.79; mass spectrum (EI) *m/z* 393.

Copolymerization of **7** with styrene: A solution of the styrene-TEMPO monomer **7** (450 mg, 1.15 mmol), styrene (2.40 g, 23.0 mmol, 20 equiv), and AIBN (40 mg, 0.23 mmol) in dry tetrahydrofuran (20 mL) was heated at reflux under argon for 24 h. The reaction mixture was evaporated to dryness, redissolved in dichloromethane (10 mL) and precipitated into methanol (500 mL) followed by hexane (500 mL). The copolymer **8** was isolated as a white powder. Yield 72%; M_n = 12000 and PD = 1.80; ^{1}H NMR ($CDCl_3$): δ = 0.65, 0.90 – 1.70, 3.65, 3.95, 4.30, 4.82, 6.40 – 7.25 (br m); ^{13}C NMR ($CDCl_3$): δ = 17.25, 39.0 – 43.5, 125.3 (br), 127.5 (br), 128.30, 144.7 – 145.8 (a number of resonances were too small to observe).

Preparation of graft polystyrene **9**: A solution of the polymeric initiator **8** (200 mg, 0.085 mmol, 1.0 equiv) in styrene (1.82 g, 17.5 mmol, 200 equiv) was heated at 130 °C with stirring under argon for 72 h. During this time the viscosity of the solution was observed to gradually increase and the clear reaction mixture eventually solidified. The reaction mixture was then dissolved in dichloromethane (25 mL) and precipitated into hexane (1 L) followed by re-precipitation into methanol (1 L). The graft polystyrene **9** was isolated as a white solid after drying. Yield 80%; M_n = 86000 and PD = 2.01; ^{1}H NMR ($CDCl_3$): δ = 0.90 – 1.70 (br m), 6.40 – 7.25; ^{13}C NMR ($CDCl_3$): δ = 39.0 – 44.5, 125.0 (br), 127.5 (br), 144.5 – 146.0.

A Novel Chainlike Heteropolyanion Formed by Keggin Units: Synthesis and Structure of $(ET)_{8n}[PMnW_{11}O_{39}]_n \cdot 2nH_2O$**

José Ramón Galán-Mascarós, Carlos Giménez-Saiz, Smaïl Triki, Carlos J. Gómez-García, Eugenio Coronado,* and Lahcène Ouahab

Heteropolyanions with the general formula $[X_xM_mO_y]^{-q}$ (M = W, Mo, Nb, V etc.; X = Si, P, B, Co, Fe, Cu etc.), have been known for well over a century and constitute a large fundamental class of inorganic compounds[1] that in recent years have aroused increasing interest because of their relevance to several disciplines due to their topological and electronic versatilities.[2] In spite of the vast number of known polyoxoanions, the number of different structural types is relatively low. Most of them present discrete clusterlike structures of definite sizes and shapes. In fact, they can be viewed as molecular fragments of metal oxides formed by closed and highly symmetrical networks of MO_x polyhedra (usually octahedra and tetrahedra) sharing corners, edges, or faces.

The first characterized, and the best known, of these structural types is the Keggin polyoxoanion.[3] It consists of four M_3O_{13} groups (M = Mo, W) surrounding a central heteroatom in a tetrahedral cavity. Each M_3O_{13} group is formed by three octahedra sharing edges and having a common oxygen atom which is also shared with the central heteroatom. By removing one, two, or three M atoms in the Keggin structure it is possible to obtain the mono-, di-, and trivacant Keggin polyoxometalates.[4] These lacunary species can, generally, be reconstituted with ease by using their ability to form stable complexes with d-transition metals. The resulting mono-,[5] di-,[6] and trisubstituted[7] Keggin polyoxoanions, however, have shown discrete structures in all cases.

Structures of extended heteropolyanions have been observed very rarely. In these structures the metal heteroatoms (mainly rare earth metals) are linked to the external oxygen atoms of the polyoxoanion ligand to give chain structures in which the metal cation and the polyoxoanion alternate. Examples of this kind are the complexes formed from $[UMo_{12}O_{42}]^{8-}$ and Th^{4+} ions,[8] $[Mo_8O_{27}]^{6-}$ and Eu^{3+} ions,[9] and $[H_2W_{12}O_{42}]^{10-}$ and Co^{2+} ions.[10] However, none of the structures reported for Keggin anions or their derivatives has shown the existence of polymeric species.[11]

In this communication we report the synthesis and structure of the first characterized compound containing a chain of Keggin polyoxoanions: $(ET)_8[PMnW_{11}O_{39}] \cdot 2H_2O$, where ET is the organic donor bis(ethylenedithio)tetrathiafulvalene. This compound has been obtained as a part of our investigation on hybrid radical materials formed by conducting organic donors and magnetic inorganic polyoxoanions.[12, 14b] Single-crystals of the title compound **1** have been prepared by electro-oxidation of ET in presence of the monosubstituted Keggin anion

$(ET)_{8n}[PMnW_{11}O_{39}]_n \cdot 2nH_2O$ **1**

$[PMn(H_2O)W_{11}O_{39}]^{5-}$ (abbreviated to $PMnW_{11}$). Its structure[13] is related to those found in the α_1 and α_2 phases of radical salts $(ET)_8[XW_{12}O_{40}] \cdot (solv.)_n$ ($X = Co^{2+}$, Cu^{2+}, Fe^{3+}, $(H^+)_2$, B^{3+}, Si^{4+}).[14] It consists of alternate layers of the organic donor with the α packing mode[15] and the inorganic Keggin polyoxometalates. Nevertheless, the unit cell parameters and the molecular packing of the inorganic layers of **1** are different, so we prefer to call this new structure an α_3 phase.

The most striking feature of this new α_3 phase **1** lies in the fact that the undecatungsto complex of Mn^{2+} is connected by a common oxygen atom forming chains that run along the *c* axis (Fig. 1). This bridging oxygen atom connects two opposite positions of the Keggin unit occupied by Mn^{2+} and W^{6+} ions with an occupancy factor of one half (we name this position as Z).[16] From the structural point of view, it is important to note that the localization of the Mn atom over two of the twelve metal sites is quite unusual for this type of heteropolyanion. In many crystalline salts of the monosubstituted Keggin anions XMW_{11}, the metal atom M positions are fully disordered as a consequence of the cubic crystal structure.[17] The lower symmetry of **1** (monoclinic) has allowed the Mn atom to be located and distortions in the polyanion to be determined. In fact, the structure of the Keggin ion in **1** is elongated along the *c* axis as can be seen from the P–metal distances, which increase from 3.54–3.57 Å (for P–W) to 3.63 Å (for P–Z) (see Fig. 1). From the chemical point of view, the existence of this polymer involves a displacement of the molecule of H_2O coordinated to Mn in one Keggin unit by a terminal O atom on W in another unit. In this context, we have found that the Mn compound is the only

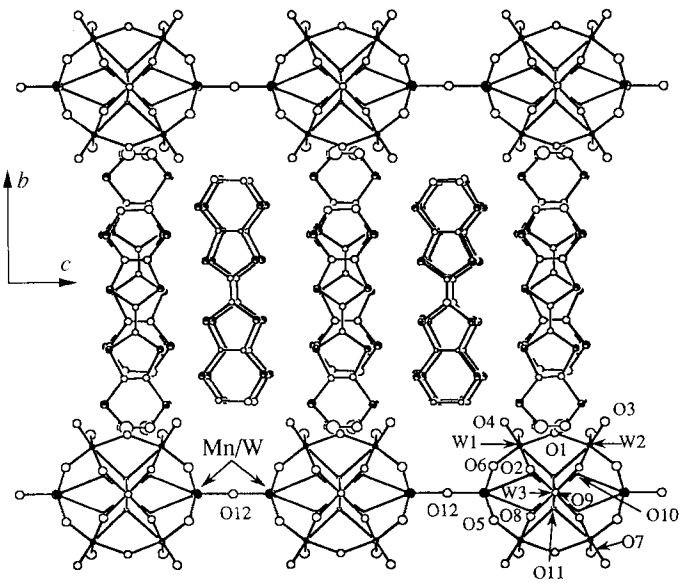

Fig. 1. Structure of the radical salt **1** showing the eclipsed and dimerized ET chains as well as the chains of Keggin polyoxometalates. J. G.), the Caja de Ahorros del Mediterráneo, and the CNRS. S. T. thanks the CICYT for a post-doctoral grant. ET = bis(ethylenedithio)tetrathiafulvalene.

member of the series $(ET)_8[XMW_{11}]$ ($XM = PMn^{2+}$, PNi^{2+}, PCo^{2+}, $SiCr^{3+}$, $SiFe^{3+}$) that gives rise to the polymeric chain anion. The other compounds belong to the α_2 phase, showing discrete Keggin anions.[18] A possible reason for this difference may be related with the larger size of Mn^{2+} compared with that of the other ions. In the case of manganese, the bridge can be formed with a smaller variation in the lattice parameters (c is reduced by ca. 1 Å when passing from α_2 to α_3 phases).

The structure of the organic layers in **1** exhibits the α mode of packing in the ET molecules. As in other α_1 and α_2 phases, these layers are formed by two kinds of ET chains (I and II in Fig. 2) that run along the [101] direction and alternate in the [$\bar{1}$01] direction. Three crystallographically independent molecules

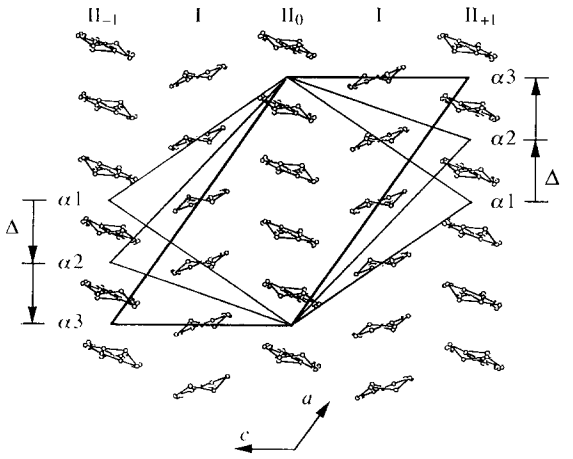

Fig. 2. Structure of the organic layer in the ac plane showing the α mode of packing and the structural relationship existing between this α phase (α_3) and the other two related phases (α_1 and α_2).

noted A, B, and C are present in the α_3 phase. Type I chains comprise alternating B and C molecules packed in an eclipsed way with intrachain S···S distances of 4.02 Å, whereas type II chains are formed by zigzag dimers of A molecules with similar intra- and inter-dimer S–S distances (3.79 Å and 3.90 Å, respectively). Each dimer is displaced by about 3.12 Å along the [010] direction (i.e., the direction of the central C=C bond) in such a way that six S atoms are eclipsed with the neighboring dimers. The shortest interchain S···S distances (3.41(2)–3.55(2) Å) are significantly shorter than the intrachain ones, emphasizing the bidimensional character of the packing. The ET molecules are tilted with respect to the axis of the chain giving rise to dihedral angles between ET molecules of neighboring chains of about 49° (in the other two α phases these angles are about 46°). A structural relationship exists between the three α modifications: Starting from a given α_i structure, the opposite displacements of two type II chains (II_{+1} and II_{-1}) with respect to a central chain (II_0) in the [101] direction by a distance of about 4 Å (which is the intrastack ET–ET separation), gives rise to the α_{i+1} structure (Fig. 2). These displacements are accompanied by the corresponding displacements in the inorganic sublattice, which give rise to a shortening in the distances between terminal oxygen atoms (Ot and Ot′ in Fig. 3) of neighboring Keggin units. Thus, the Ot–Ot′ distance decreases from 7.95 Å in α_1 to 3.70 in α_2, and to 0 Å in α_3 where neighboring Keggin anions are linked through an oxygen bridge (O12).

The nature of this new salt adds to the recent interest of polyoxometalates as inorganic components of organic–inorganic hybrid materials with interesting solid-state properties. In fact, preliminary physical characterization[19] has shown that

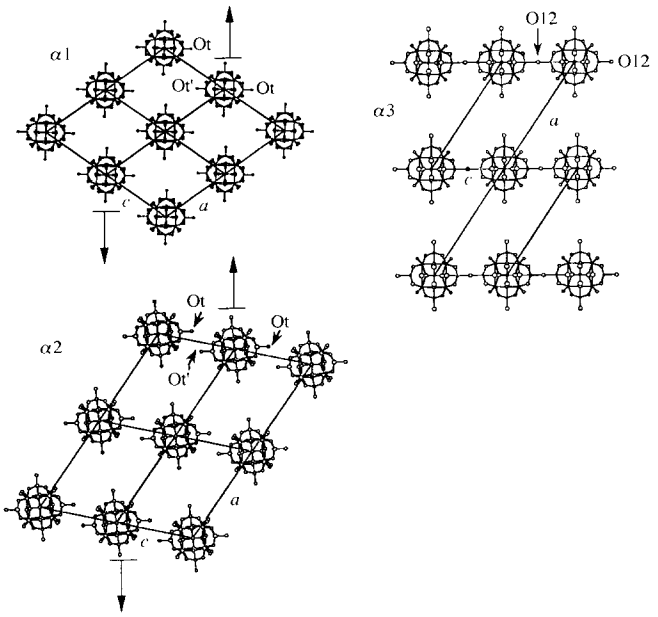

Fig. 3. Structure of the inorganic sublattice in the ac plane for the three α phases.

the compound is a magnetic semiconductor ($\sigma \approx 0.1$ S cm^{-1} at room temperature) which exhibits weak antiferromagnetic interactions between Mn^{2+} ions and the organic spin sublattice.[20] In this context it is to be noted that **1** represents the first member of a wide series of materials formed by monosubstituted Keggin anions and the organic radical; the Keggin anions show localized magnetic moments on their surface, the ET molecules delocalized electrons. The complete structural and physical characterization of this series of radical salts is under way.

Experimental Procedure

$[PM(H_2O)W_{11}O_{39}]$: All Keggin monosubstituted polyoxometalates $[PM(H_2O)W_{11}O_{39}]$ were synthesized by the following method: To a solution of $Na_8H[PW_9O_{34}] \cdot 19H_2O$[21] (3.6 mmol) in water (100 mL) was added glacial acetic acid (2 mL) and about a twofold excess of the transition metal salt (acetate, nitrate, or sulfate) as a solid. The pH of these solutions was set to approximately 5 by addition of small amounts of glacial acetic acid when necessary. These colored solutions were refluxed for at least two hours and filtered hot through paper to remove any insoluble material. An excess of solid Bu_4NBr was added with stirring to the clear solutions resulting in the immediate precipitation of a colored solid which was filtered, washed with water, and air dried overnight. These solids were recrystallized in acetonitrile and allowed to crystallize at room temperature. After about two days, the well-formed polyhedral-shaped single crystals were collected and air dried. The presence of the anion, as well as that of the Bu_4N^+ ion was confirmed by single-crystal X-ray studies and by the IR spectra, which were very similar for all compounds.

1: Single crystals of **1** were obtained by the electrochemical oxidation of ET (2.5×10^{-3} M in a mixture of wet $CHCl_2CH_2Cl/CH_3CN$ 1:1) in the presence of the Bu_4N^+ salt of the polyoxoanion (3×10^{-3} M in a mixture of wet $CHCl_2CH_2Cl/CH_3CN$ 1:1) in a U-shaped cell with Pt electrodes (1 mm in diameter) separated by a sintered-glass frit. The intensity of the current was fixed at 0.6 μA and after two weeks at 1.25 μA. After five weeks, shiny black prismatic single crystals of **1** were collected carefully, washed with CH_3CN, and air dried. The purity of the single crystals was checked by chemical analysis; this showed a Mn:W ratio of 1/11.

[10] We have obtained the chain $([H_2W_{12}O_{42}\{Co(H_2O)_4\}_2]^{6-})_\infty$, where the polyanion $[H_2W_{12}O_{42}]^{10-}$ is connected by two Co^{2+} atoms. C. Giménez-Saiz, J. R. Galán-Mascarós, S. Triki, E. Coronado, L. Ouahab, *Inorg. Chem.* **1995**, *34*, 524.

[11] We have very recently found out that T. J. R. Weakley and H. T. Evans obtained a polymeric structure for the Et_3NH^+ salts of the anions $PCoW_{11}$ and $AsCoW_{11}$. However, in their case the precision in the structure determinations has been limited by gross disorder of the Et_3NH^+ and H_2O, and also partial disorder of the W and Co atoms involved in the bridges (personal communication).

[18] The difference between the Mn undecatungsto complex and the other Keggin polyanions is only observed in the solid-state radical salts. In the precursor Bu_4N^+ salts of these polyanions, the substituted Keggin anions of Mn are present as discrete units as in the other members of the series XMW_{11}. In fact, all these Bu_4N^+ salts are isostructural exhibiting a cubic lattice with $a = 17.6$ 17.7 Å. Probably in nonaqueous solution the polyanions are also present as discrete species, and only when the lattice is formed the Mn complex polymerizes.

[20] The magnetic moment of **1** (6.6 BM at 300 K) shows a gradual decrease upon cooling down, approaching the value of one isolated Mn^{II} ion at low temperatures (4.92 BM at 6 K). These results support the presence of an ordered sequence Mn-O-W in the chain since no magnetic Mn Mn interaction is detected, thus eliminating the possibility of Mn-O-Mn bridges. Below 6 K the magnetic moment of the $(ET)_8[PMnW_{11}]$ radical salt crosses the curve of the $Bu_4N[PMnW_{11}]$ Keggin salt, suggesting the presence of very weak antiferromagnetic interactions between the two sublattices.

A Silicon Strand of More than 7 Å in Diameter in $Ba_2Eu_3Si_7$**

Christina Häußermann and Reinhard Nesper*

Dedicated to Professor Gerhard Fritz on the occasion of his 75th birthday

The binary compounds formed by silicon with alkaline-earth and rare-earth metals differ substantially in their crystal structures, as well as in their stoichiometries and physical properties. Barium forms the five stable silicides $BaSi_2$,[1] Ba_3Si_4,[2] BaSi,[3] Ba_5Si_3,[4] and Ba_2Si,[5] whereas only two europium compounds, $EuSi_2$[6] and EuSi[3], are yet known. Except for BaSi and EuSi, both of which crystallize in the CrB structural type with planar, one-dimensional zigzag chains $^1_\infty[Si^{2-}]$, there are no other direct structural relationships between Eu and Ba silicides. $BaSi_2$ contains isolated Si^{4-}_4 tetrahedra, whereas a three-dimensional Si skeleton of three-bonded (3b), trigonal-planar Si atoms is present in $EuSi_2$. A Si^{6-}_4 butterfly anion occurs in Ba_3Si_4, which according to the Zintl–Klemm concept is a reduced form of the tetrahedron.

Only a small number of ternary silicides $M_xM'_ySi$ have been reported.[7, 8] For our studies of magnetic interactions in diluted spin systems, we have begun to synthesize such three-component compounds. During investigations of the phase width of $Ba_xEu_{1-x}Si_2$, the title compound $Ba_2Eu_3Si_7$ was found and characterized. It is not a direct derivative of the binary silicides, because in these neither the stoichiometry nor the crystal structure is represented. $Ba_2Eu_3Si_7$ forms as gray metallic needles.[10] It decomposes peritectically at 1260 K, which makes it difficult to obtain a pure phase.

The crystal structure determination was performed on a single crystal by X-ray diffraction. $Ba_2Eu_3Si_7$ crystallizes hexagonally in the space group $P\bar{6}2m$-D^3_{3h} with one formula unit in the unit cell.[11] The structural type is new, and it contains a novel Zintl anion of silicon. The silicon atoms constitute one-dimensional infinite strands $^1_\infty[(Si(Si_3)Si_3)^{10-}]$ (Fig. 1). Corresponding to the charge transfer of ten electrons per formula unit, two-(2b) and three-bonded (3b) silicon atoms are present. Without exception the latter have trigonal-planar coordination and act as central Si–Si links, whereas the (2b)Si belong to the

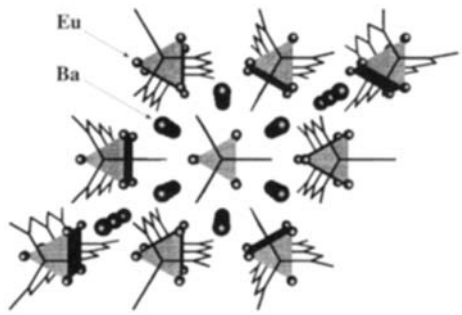

Fig. 1. Perspective view of the crystal structure of $Ba_2Eu_3Si_7$ in the [001] direction. The black lines represent Si Si bonds and the filled polyhedra Eu prisms. Ba atoms (large spheres) occupy the space between the $^1_\infty[(Eu_3Si_7)^{4-}]$ strands.

boundary, as can be seen in Figure 2a–c. Together, the (2b)Si and (3b)Si atoms also form planar arrangements.[12] The Si–Si bonds are slightly longer than expected for uncharged single bonds (2.409 and 2.437 Å). We know, however, that bond lengths in solids are significantly affected by charge repulsion and cation influences.[13–15] Strong variations have also been reported for Si–Si single bonds in molecules. These are explained in terms of influences of the ligands.[16]

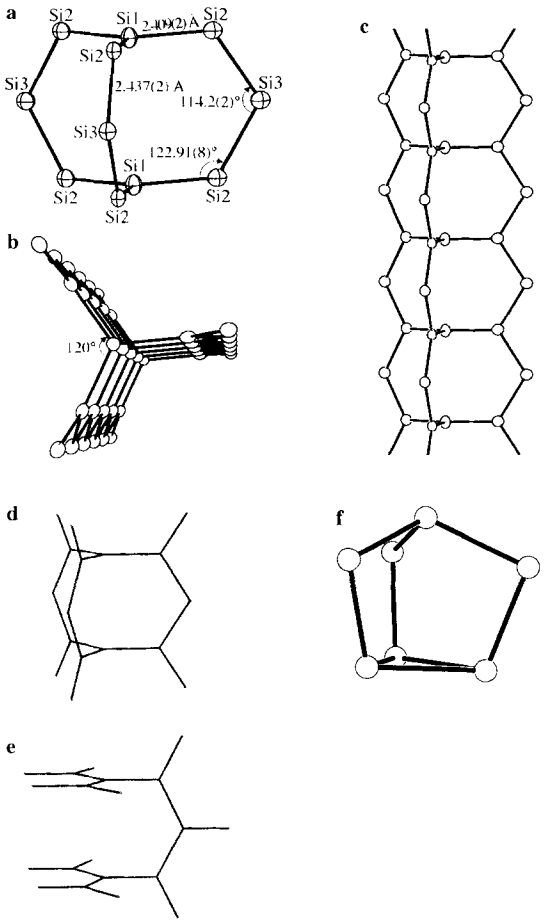

Fig. 2. a) Bicyclic Si_7 fragment (3,3,3-barrelane) from the one-dimensional Si chain in $Ba_3Eu_3Si_7$ (bond lengths and angles are given); b) perspective view along the chain; c) side view; d) section of the polyanion $^1_\infty[Si_7^{10-}]$; and e) corresponding section of the Si substructure in $EuSi_2$ for comparison; f) structure of P_7^{3-} and X_4Y_3 with X = P, As and Y = S, Se.

The angle at the three-bonded Si2 atom is not restricted by symmetry, yet deviates by less than three degrees from threefold symmetry, while an angle of 114° on the two-bonded Si3 appears to be somewhat large for an atom with two free electron pairs. We assume that the cation's influence is of importance also in this case.

This silicon strand with a diameter of approximately 7.5 Å is not very compact, if the silicon atoms alone are considered (Fig. 2c). Actually, it is the largest one-dimensional, polymeric strand of silicon ever synthesized in a well-defined compound.

The lone pairs on Si3 do not point directly at barium or europium atoms, but are directed toward regions between them. The barium atoms surround the central strand like an internal surface and are clearly separated from the europium sites (Fig. 1). The latter form trigonal prisms about the central Si atoms of the strand, whereas Ba atoms coordinate the terminal Si atoms (Fig. 1). Trigonal prismatic arrangements are rather typical for transition-metal and rare-earth-metal atoms in silicides, though several variants are possible. $EuSi_2$, for instance, crystallizes under normal conditions with the α-$ThSi_2$ structure,[6, 18] with prisms twisted by 90 degrees relative to one another along the c direction. The ternary compounds of the $Eu(Cu_xSi_{2-x})$ type, on the other hand, crystallize with the AlB_2 structure, in which all prisms are parallel.[18] The Zintl anions of silicon are particularly suitable for studying and, to some extent, controlling the various functional influences of cations upon the silicon substructure.[15]

The chemical reactivities and melting points indicate that Ba-silicides are distinctly more stable than Eu-silicides. This can be interpreted in terms of stronger interactions between the rare-earth metal and the silicon atoms, which makes the distribution of Eu atoms in the central strand plausible. Ba atoms evidently form a positively charged envelope for the $^1_\infty[(Eu_3Si_7)^{4-}]$ polymer. The Si-polyanion could be understood as part of the $EuSi_2$ structure in which two of the three (2b)Si atoms are twisted and joined to form end groups (compare Figures 2d and e). The third silicon atom remains unchanged. The impression on examining Figure 1 and 2 is of a $EuSi_2$-structure that is partly dissolved and coordinated by barium ligands. Attempts to isolate the silicon substructure are in progress.

Isoelectronic relatives to the Zintl anion Si_7^{10-} have been found among the pnictogen compounds X_7^{3-} and X_4Y_3 phases (X = P, As; Y = S, Se).[17] The connectivity in these compounds, however, is different; only two of the (3b)X atoms are linked to each other (Fig. 2f).

[10] According to differential-thermoanalytical investigations, $Ba_3Eu_3Si_7$ does not melt congruently, but undergoes peritectical decomposition at 1260 K. We have therefore obtained this phase in only approximately 50% yields. The synthesis was carried out from the pure elements (Ba rods, 99.5%, Eu rods, 99.5%; Si powder, 99.99%) in a 1:3:7 molar ratio in welded Nb ampoules under an argon atmosphere. In typical synthesis about 1 g of reactant is heated to 1570 K, and then cooled to room temperature at a rate of 50 K h^{-1}.

[12] The coplanar Si coordination in transition-metal and rare-earth-metal compounds is understood to be a result of d-orbital influences. However, silicides of heavy alkaline-earth metals have recently been found that also contain trigonal planar Si atoms (compare ref. [15]). There is at present no satisfactory explanation to this.

The Role of Dehydroalanine in Catalysis by Histidine Ammonia Lyase**

Martin Langer, Andrea Pauling, and János Rétey*

The conversion of L-histidine into urocanic acid, catalyzed by histidine ammonia lyase (HAL), is an unusual elimination reaction and poses a mechanistic challenge for chemists.[1] The stepwise and the concerted[1] reaction modes either lead to unlikely, energetically disfavored intermediates or are based on implausible assumptions. HAL catalyzes the first step in histidine degradation in most organisms, and its failure in humans causes histidinemia.[2] HAL and the important plant enzyme phenylalanine ammonia lyase are the only enzymes known to contain a catalytically essential dehydroalanine,[3, 4] which has been shown to arise posttranslationally from serine 143[5] and serine 202,[6] respectively. Because of the electrophilicity[3, 7] of this prosthetic group it has been suggested[1, 3] that the α-amino group of histidine attacks it as a nucleophile thus enhancing the leaving ability of the amino group. But such a mechanism is unsatisfactory for the following reasons:

1) It does not answer the question of how the β-H_{Re} atom[3, 8] is activated.
2) The leaving ability of the α-amino group could be also enhanced by simple protonation.
3) It does not explain the finding of Furuta et al.[9, 10] that HAL catalyzes not only the exchange of β-H_{Re} but also that of 5-H in the imidazole ring.
4) It does not explain why L-cysteine and L-homocysteine strongly inhibit HAL, while other amino acids do not.[11, 12]

Klee at al.[13] found that L-5-nitrohistidine is a moderately good substrate of HAL. While [β-$^2H_2$]histidine exhibits a kinetic deuterium isotope effect of $k_H/k_D \approx 1.5-2.0$,[13, 14] no such effect is observed with L-5-nitro[β-$^2H_2$]histidine. The obvious explanation for this finding is the activation of the β-H atoms by the nitro group (Scheme 1). As a consequence, proton abstraction by a basic group of the enzyme is no longer rate-limiting for the overall reaction.

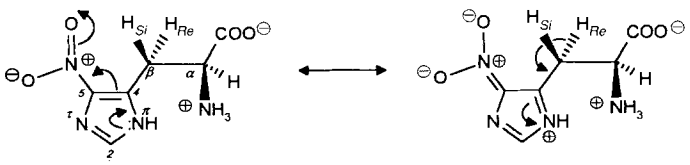


Scheme 1. Activation of the β-H atom by the nitro group in 5-nitrohistidine.

Recently we prepared mutants of HAL in which the codon for Ser 143 is exchanged with the codons of Ala and Thr.[5, 15] These mutants showed almost no activity with L-histidine as substrate. Here we report the results of experiments in which the activity of our HAL mutants, S143A and S143T, as well as of the sodium borohydride-treated wild-type histidase (HAL_{red}) was examined with both histidine and L-5-nitrohistidine as substrates and which suggest a novel mechanism for the HAL reaction.

First we compared the activities using L-5-nitrohistidine as substrate. The corresponding kinetic constants, K_m and V_{max}, are listed in Table 1. Surprisingly, the "inactive" mutants readily

Table 1. Michaelis constants K_m and V_{max} of wild-type, S143A, S143T, and HAL_{red} histidine ammonia lyases with L-5-nitrohistidine as substrate [a].

HAL	V_{max} [IU mg^{-1}] [b]	K_m [mM]
wild-type	0.85 ± 0.1	7.7 ± 1.5
S143A	0.87 ± 0.2	9.8 ± 3.0
S143T	0.87 ± 0.1	12.8 ± 2.9
HAL_{red}	0.79 ± 0.1	13.6 ± 3.9

[a] For the determination of K_m and V_{max} the substrate concentration in the enzyme assay was varied between 1 and 15 mM, and the increase of absorption was monitored at 400 nm [13]. The values were determined using Lineweaver-Burk diagrams. [b] IU = international enzyme unit.

accept L-5-nitrohistidine as substrate to the same extent that wild-type HAL does. Their kinetic constants differ only insignificantly. The slight increase of K_m for the S143T mutant may be due to unfavorable steric interactions between the methyl group of threonine and the nitro group of the substrate. Similarly, the slight impairment of both K_m and V_{max} in the case of the sodium borohydride-treated enzyme may arise from unspecific reactions by the reagent.

At this point it was necessary to reexamine the "inactivity" of our mutants with the natural substrate L-histidine. Using a much larger amount of HAL in the assay mixture (relative to the amount of 5-nitrohistidine used previously), we could determine the kinetic constants (Table 2). Whereas the K_m values of the mutants are on the same order of magnitude as those for wild-type HAL, the V_{max} values are about 1000 and 50000 times less.

Table 2. Michaelis constants K_m and V_{max} of wild-type, S143A, S143T, and HAL_{red} histidine ammonia lyases with L-histidine as substrate [a].

HAL	V_{max} [IU mg^{-1}] [b]	K_m [mM]	$\frac{V_{wild\text{-}type}}{V_{mutant}}$
wild-type	25	5.2 ± 0.8	1
S143A	0.0214	7.5 ± 0.9	1170
S143T	0.00047	3.1 ± 0.6	53100
HAL_{red}	<0.1	–	–

[a] For the determination of the K_m and V_{max} values the substrate concentration in the enzyme assay was varied between 0.5 and 34 mM, and the increase of absorption monitored at 277 nm. The values were determined using Lineweaver-Burk diagrams. [b] IU = international enzyme unit.

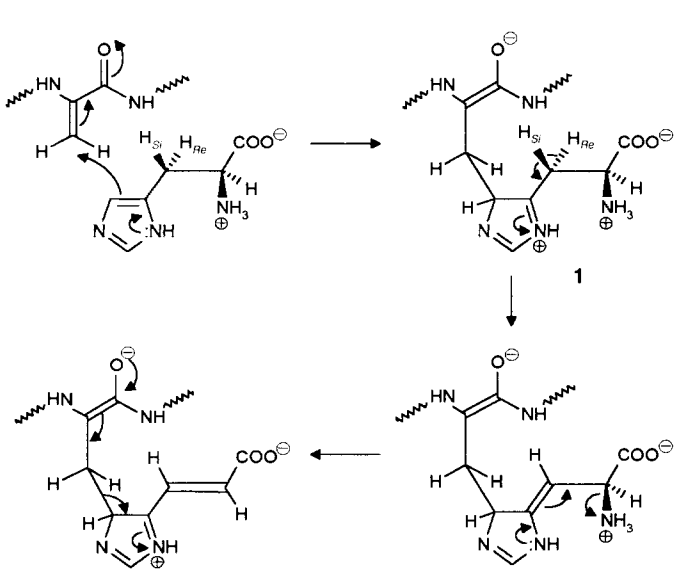
Two explanations could account for the slight activity of our mutants with L-histidine: 1) An error in the expression; in other words, misreading the GCC or ACC codons for the TCC codon (serine) could occasionally produce wild-type HAL.[16] 2) The mutants could catalyze a slow deamination of histidine even though they lack the prosthetic group. In the first case the unaltered K_m value would be obvious; in the second case one must postulate that the prosthetic dehydroalanine residue is not involved in the formation of the initial Michaelis complex.

Our conclusions rely on the more dramatic differences in the V_{max} values. While the absence of the dehydroalanine prosthetic group results in almost no activity with L-histidine as substrate, virtually no effect is seen when L-5-nitrohistidine is used as substrate. To make sure that the spectrophotometric enzyme assay does not simulate a conversion, the progress of the reaction was also monitored by ^{1}H NMR spectroscopy. All four HALs catalyzed the conversion of L-5-nitrohistidine into 5-nitrourocanate at a similar rate. However, the reaction slowed down with time and stopped when 5-nitrourocanate reached a concentration of about 1 mM. This product inhibition was verified by kinetic experiments using wild-type HAL as a catalyst and L-histidine as a substrate. 5-Nitrourocanate inhibited the reaction with a K_i value of 0.6 mM, which is about ten times lower than the K_m value for the substrate.

The conversion of L-5-nitrohistidine was also confirmed by preparative experiments with both the wild-type and the mutant histidine ammonia lyases. After denaturation and removal of the protein, the pH of the reaction mixture was adjusted to 1.0. In all three experiments about the same amount of 5-nitrourocanic acid crystallized as orange-brown cubes.[17]

The reactivity of the mutants lacking dehydroalanine and the sodium borohydride-treated enzyme with L-5-nitrohistidine as substrate rules out the mechanism in which the α-amino group of histidine attacks this electrophilic group.[1] The results of Klee et al.,[13] together with ours, suggest that the only function of the dehydroalanine prosthetic group lies in enhancing the acidity of the β-H_{Re} atom and hence facilitating the formation of the corresponding carbanion.

Besides its α-amino group histidine has still another nucleophilic site, namely the imidazole nucleus, which could react with the electrophilic dehydroalanine. The nucleophilic reactivity of imidazole in an enzymatic reaction was discovered several years ago.[18] In Scheme 2 a mechanism is shown starting with an electrophilic substitution at the 5-imidazole position by the dehydroalanine side chain. This leads to the immonium intermediate **1** in which the H atoms at the two carbon centers are activated. Abstraction of the β-H_{Re} proton by a basic group of the enzyme is followed by elimination of ammonia. In the last step (indicated only by arrows) the dehydroalanine–urocanate adduct fragments to urocanate and HAL under regeneration of the prosthetic group. Reversible abstraction of the likewise acidified 5-H atom in the immonium intermediate **1** could account for the exchange of this atom with solvent deuterium.[9, 10]



Scheme 2. Proposed mechanism of the HAL-catalyzed transformation of L-histidine into urocanic acid.

As mentioned earlier the activity of the imidazole 5-position is precedented in the urocanase reaction in which the electrophile is a prosthetic NAD^+ molecule.[18] Although in the case of HAL the postulated covalent adduct has not yet been observed directly, the indirect evidence and the chemical plausibility are very convincing. Such a mechanism is also in accord with the strong inhibition of HAL by L-cysteine and L-homocysteine.[11, 12] In these amino acids the sulfur nucleophile is positioned at the correct distance (compared with the imidazole 5-position of histidine) to attack the electrophilic dehydroalanine center. Recently we proposed a mechanism for the irreversible inhibition by these amino acids in the presence of oxygen.[15]

Since circular dichroism measurements indicate that the three-dimensional structure is not changed in our S143A and S143T mutants relative to that of wild-type HAL,[5, 15] their reactivity with L-5-nitrohistidine is readily explained by the more acidic nature of the β-H_{Re} proton in this substrate. Thus the nitro group fulfills the same task as the dehydroalanine prosthetic group and renders it unnecessary.

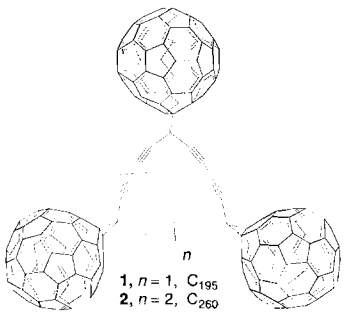
Solubilized Derivatives of C_{195} and C_{260}: The First Members of a New Class of Carbon Allotropes $C_{n(60+5)}$**

Lyle Isaacs, Paul Seiler, and François Diederich*

Dedicated to Professor Hans-Jürgen Bestmann on the occasion of his 70th birthday

As part of our program on the synthesis, chemistry, and material properties of new carbon allotropes,[1] we became interested in fullerene–acetylene hybrid systems.[2] As first targets we chose members of the family of allotropes with the molecular formula $C_{n(60+5)}$, which can be viewed as adducts of *cyclo*-C_n[3] and C_{60}, and synthesized by the oxidative cyclization of a diethynylmethanofullerene..[2] Thus, the smallest member in this family, C_{195} (**1**), consists of a *cyclo*-C_{15} core surrounded by three peripheral fullerenes, whereas C_{260} (**2**) is a *cyclo*-C_{20} derivative with four fullerenes attached. Structures related to the proposed carbon allotropes, in which the fullerene end-capping groups are exchanged for C_2H_4 fragments, have recently been reported by Scott, de Meijere, and coworkers.[4]



Although **1** and **2** were expected to be stable compounds, their synthesis by oxidative coupling of 61,61-diethynylmethanofullerene[60] failed, and resulted in an intractable mixture of insoluble compounds.[2] Therefore, we decided to prepare derivatives of **1** and **2** bearing solubilizing groups on the fullerene spheres. In order to avoid a mixture of diastereomeric macrocycles, solubilizing functional groups in the diethynylmethanofullerene cyclization component needed to be attached so that the two free ethynyl groups were chemically equivalent. Taking advantage of our recently developed tether-directed remote functionalization methodology,[5] we targeted a C_{2v}-symmetrical diethynylmethanofullerene, which would give isomerically pure derivatives of **1** and **2** upon oxidative cyclization. By this methodology we had previously prepared the hexaadduct **3**, whose X-ray crystal structure has now been solved. Here we give preliminary information on the solid-state structure of **3**, and report the preparation of **4** and **5**, the first derivatives of the carbon allotropes C_{195} (**1**) and C_{260} (**2**), as well as matrix-assisted laser-desorption-ionization time-of-flight (MALDI-TOF) mass spectrometric studies, which suggest that **4** and **5** may be direct precursors to the cyclocarbons *cyclo*-C_{15} (**6**) and *cyclo*-C_{20} (**7**).

A stereoview of the X-ray structure of **3** with its six addends, one of which is disordered, is shown in Figure 1.[6] The largest deformations on the C_{60} surface occur within the six-bridged pyracylene subunits, as expected. Bridgehead 6–6 bond lengths of the cyclopropane rings range from 1.591(3) Å to 1.617(3) Å; those of the cyclohexene rings amount to 1.596(3) Å. They are in good agreement with corresponding bond lengths between bridgehead atoms reported for other methanofullerenes[7] and fullerene Diels–Alder adducts.[8] Significant deformations also occur in the remaining part of the C_{60} skeleton. The eight six-

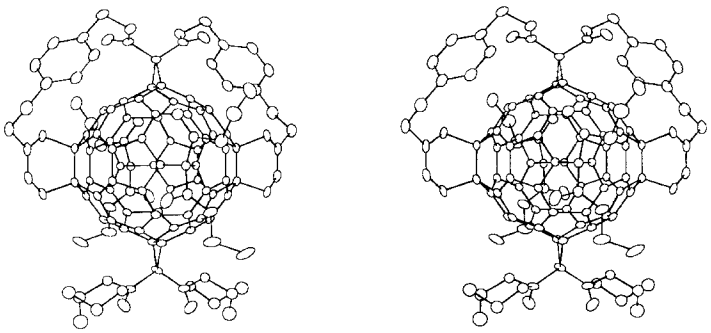

Fig. 1. Stereoview of the X-ray crystal structure of **3**.

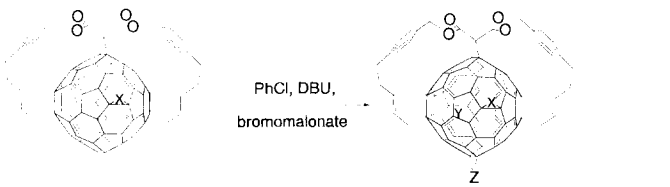
membered rings not bridged to any of the functional groups are located at the corners of a cubic cyclophane-type network. The average length of 6–6 and 6–5 bonds within these rings is 1.386 and 1.426 Å, respectively, and the inter-ring, biphenyl-type bond length averages 1.471 Å. With respect to an I_h C_{60}-skeleton, the bond length alternation in these six-membered rings is reduced from about 0.07 (in C_{60}) to 0.04 Å. The same trend has been observed in the crystal structures of two analogous hexaadducts[7d, 9] and interpreted as an indication that these six-membered rings have become more benzene-like.

As a starting material for the synthesis of solubilized derivatives of **1** and **2**, we initially chose the C_s-symmetrical tetraadduct **9**.[5] Its precursor, trisadduct **8**,[5] is now available in 1.3 g batches (60% yield) by performing the tether-directed double Diels–Alder reaction at about 0.6 mM concentration, a sixfold increase over the previously reported concentration. To prepare a C_{2v}-symmetrical pentaadduct for the subsequent introduction of a diethynylmethano group, **9** was treated with diethyl α-bromomalonate in PhCl at 20 °C in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)[5, 10] to give a mixture of two fullerene pentaadducts C_{2v} **11** and C_s **12** in a ratio of 80:20 (70%, Scheme 1). In CH_2Cl_2 at −40 °C a ratio of 75:25 was obtained, while in CCl_4 at 20 °C the selectivity was increased to 91:9.



Scheme 1. Synthesis of pentaadducts of C_{60}.

These results were relatively surprising since, to a first approximation, each of the two reactive 6–6 bonds has three addends located in equatorial positions, which were expected to exert similar activating effects.[11] Close examination of the molecular structure of **9** (Scheme 1) revealed that the more reactive bond is doubly e_{face} and singly e_{edge} while the less reactive bond is doubly e_{edge} and singly e_{face} with regard to the addends already in place (Fig. 2). This is the first experimental evidence for the enhanced reactivity of e_{face} bonds over e_{edge} bonds, which had been predicted in computational studies.[7d] Unfortunately, the R_f values of **11** and **12** were identical, and their chromatographic separation on SiO_2 was not possible.

We therefore decided to add the more polar bromomalonate **16**, prepared from **15** (Scheme 2), to trisadduct **8**, hoping to generate a larger difference in the R_f values of the isomeric C_{2v}- and C_s-symmetrical pentaadducts. Reaction of **16** with **8** following the reported procedure[5, 10] gave tetraadduct **10** in 70% yield. Also formed were trace quantities of three isomeric products which could be separated easily by chromatography on silica gel H (CH_2Cl_2). Further reaction of **10** with **16** (Scheme 1) gave the C_{2v}- and C_s-symmetrical pentaadducts **13** and **14** in a relative ratio of 71:29 along with trace quantities of a third product. Satisfyingly, separation of the isomeric mixture was readily achieved by column chromatography on silica gel H (CH_2Cl_2/AcOEt 100:1.5). The structures of C_{2v} **13** and C_s **14** are supported by the presence of 16 (17 expected) and 30 (32 expected) ^{13}C NMR resonances for the fullerene C atoms, as well as the presence of two chemically nonequivalent CH_2CO_2Et groups (in a 1:1 ratio) for **13** and three (in a 1:1:2 ratio) for **14** in the ^1H NMR spectra. In the MALDI-TOF spectrum of both compounds, the molecular ion appeared as the base peak at $m/z = 1712$ along with weaker peaks resulting from fragmentation of the malonate groups. The C_{2v} isomer **13** is pale orange, while the C_s isomer **14** is orange-red in CH_2Cl_2 solution; accordingly, the UV/Vis spectra of the two compounds are quite different: the end-absorption of **13** occurs at $\lambda = 550$ nm and of **14** at $\lambda = 590$ nm.[12]

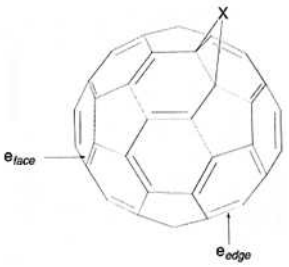


Fig. 2. Depiction of the difference between e_{face} and e_{edge} bonds in a hypothetical monoadduct $C_{60}X$. The e_{face} bond sees the face of the bridging addend, whereas the e_{edge} bond sees its edge.

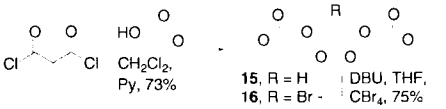
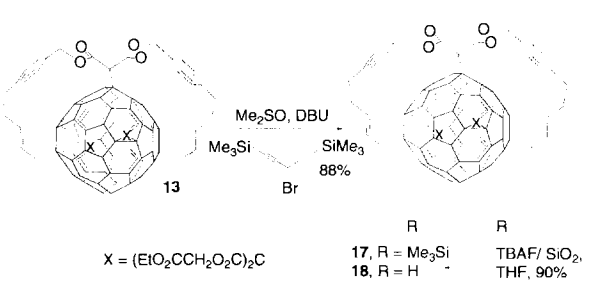


Scheme 2. Synthesis of a polar bromomalonate for the Bingel reaction.

The introduction of the diethynylmethano group was achieved by the reported ionic route[2a] via nucleophilic addition/elimination of 1,5-bis(trimethylsilyl)-3-bromopenta-1,4-diyne (Scheme 3). The reaction was found to be quite solvent dependent: under the conditions used for the monoaddition to C_{60} (toluene, 20 °C), no significant conversion of **13** occurred, and only partial conversion was achieved in THF as solvent. When the reaction was conducted in Me_2SO, however, a very



Scheme 3. Synthesis of the C_{2v}-symmetrical diethynylmethanofullerene **18**.

clean conversion was achieved, and the desired dialkynylmethanofullerene hexaadduct **17** was obtained in 88% yield (Scheme 3).

The ^{1}H NMR spectrum of **17** in $CDCl_3$ showed only a single Me_3Si resonance, and the presence of 17 fullerene C-atom resonances in the ^{13}C NMR spectrum provided conclusive proof of the depicted C_{2v} symmetry. The MALDI-TOF mass spectrum showed the expected molecular ion at $m/z = 1918$, but the base peak was the fragment at $m/z = 1711$ resulting from loss of the diethynylmethylene group from the molecule, which regenerates the pentaadduct ion **13**$^+$. Attempts to deprotect **17** under basic conditions (K_2CO_3, MeOH/THF) led to products resulting from cleavage of the ester groups. However, reaction of **17** with tetrabutylammonium fluoride (TBAF, 2.75 equiv) on SiO_2 in anhydrous THF gave the free diethynyl derivative **18** in 90% yield (Table 1) after chromatography on silica gel H (CH_2Cl_2/AcOEt 100:1.5). The successful use of TBAF illustrates that hexaadducts of C_{60} have dramatically reduced reactivity towards nucleophilic attack by fluoride anions, relative to the unsubstituted carbon sphere.

Oxidative cyclization of **18** ($c = 0.3$ mM) under Glaser–Hay conditions (CuCl, *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), air, CH_2Cl_2) failed to produce isolable amounts of cyclic oligomers. However, when a solution of **18** ($c = 0.16$ mM) was subjected to the Eglinton–Glaser coupling conditions[13] (200 equiv of anhydrous $Cu(OAc)_2$, dry pyridine, under Ar), two major products were detected by TLC (SiO_2, $R_f = 0.28$ and 0.15 in CH_2Cl_2/AcOEt 100:5). Isolation of the two yellow compounds was achieved by chromatography on silica gel H (CH_2Cl_2/AcOEt 100:5 then 100:8.5), and their structures were established as cyclic trimeric D_{3h}-**4** and cyclic tetrameric D_{4h}-**5**, based on their spectroscopic properties. The ^{1}H NMR spectra of both oligomers showed no peaks for terminal acetylenic H atoms, two independant sets of CH_2CO_2Et peaks, and one set of peaks for the tether-cyclohexene moiety. In the ^{13}C NMR spectrum, 17 resonances were visible for the fullerene C atoms. This implies local C_{2v} symmetry, which, when combined with a single peak for the bridging methano C atom and only two acetylenic carbon resonances, indicated overall D_{nh} symmetry. The shapes of the UV/Vis spectra of **4** and **5** are almost identical and very similar to those reported previously for fullerene hexaadducts[5, 7d] with the exception of the molar extinction coefficients, which increase as the number of fullerene moieties per molecule increases.

The size of the cyclic oligomers was determined by MALDI-TOF mass spectrometry. In the spectrum of **4** (Fig. 3) the expected molecular ion appeared at $m/z = 5317$ ($C_{348}H_{174}O_{60}$ requires 5314)[14] along with weaker peaks at higher masses, which can be ascribed to matrix adducts of the cyclic oligomer.

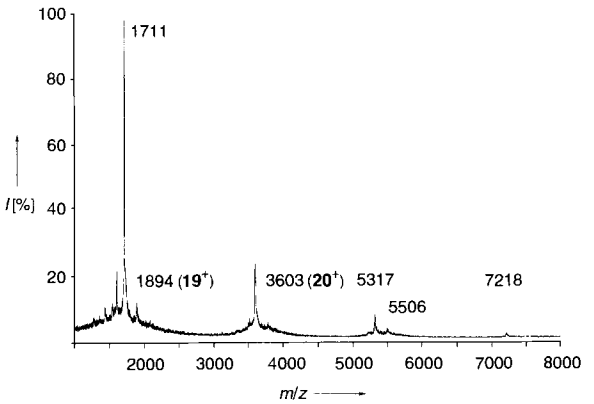


Fig. 3. MALDI-TOF mass spectrum of **4** measured in the linear positive ion mode at 25 kV acceleration voltage with α-cyano-4-hydroxycinnamic acid as the matrix. The peak at $m/z = 5506$ corresponds to a matrix adduct of **4** ($C_{359}H_{181}O_{63}N$ requires 5503), the peak at $m/z = 7218$ to an adduct of **4** with the matrix and fragment **13** ($C_{469}H_{239}O_{83}N$ requires 7214).

Strong fragment ions confirmed the large propensity of dialkynylmethanofullerenes to undergo retroaddition with loss of the fullerene, which was already noted for **17** and **18**. The base peak in the spectrum of **4** appeared at $m/z = 1711$, which corresponds to the fullerene pentaadduct ion **13**$^+$. This very interesting fragmentation also explains the relatively intense fragment ions at $m/z = 3603$ ($C_{237}H_{116}O_{40}$ requires 3602) and 1894 ($C_{126}H_{58}O_{20}$ requires 1891), which arise from the loss of one and two fullerene pentaadducts **13** to generate ions corresponding to bis- and monofullerene adducts of *cyclo*-C_{15}, respectively. Unfortunately, it was not possible to observe a peak for *cyclo*-C_{15}^+ itself, because matrix peaks severely obscured the spectrum in the mass region around $m/z = 180$. The corresponding spectrum recorded without matrix assistance did not yield further information since, at the required higher laser power, significant fragmentation of the solubilizing groups occurred, once again obscuring the mass region around $m/z = 180$.

The mass spectrum of the cyclization product with the lower R_f value did not give a molecular ion peak at masses expected for tetrameric, pentameric, or hexameric cyclic oligomers. However, a very weak peak was observed at $m/z = 5385$ ($C_{353}H_{174}O_{60}$ requires 5374) and a relatively strong one at

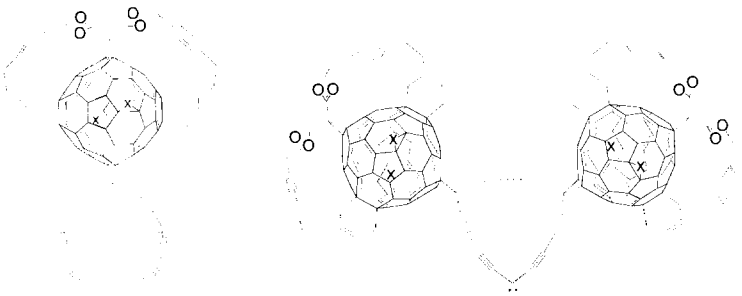
[a] MALDI-TOF MS spectra were measured using 2,5-dihydroxybenzoic acid or α-cyano-4-hydroxycinnamic acid as the matrix. [b] New compounds in Schemes 1 and 2 were fully characterized by ^{1}H and ^{13}C NMR, FT-IR, EI-MS, and correct elemental analysis or high-resolution MS.



$m/z = 3666$ ($C_{242}H_{116}O_{40}$ requires 3662). In analogy to the fragmentation pattern observed in the spectrum of cyclic trimeric **4**, these peaks correspond to ions formed by the loss of one and two molecules of pentaadduct **13** from cyclic tetrameric **5**. The peak at $m/z = 1952$ ($C_{131}H_{58}O_{20}$ requires 1951) results from the loss of a third equivalent of **13** and corresponds to the ion of an adduct between the fullerene derivative **13** and *cyclo*-C_{20}. These characteristic fragment peaks provide strong support for the cyclic tetrameric structure **5** assigned to the oligomer with the lower R_f value. Just as in the spectrum of the cyclic trimeric **4**, matrix peaks prevented the unambiguous observation of a peak for free *cyclo*-C_{20}^+. The formation and observation of free *cyclo*-C_{15} and *cyclo*-C_{20} ions, starting from **4** and **5** respectively, and their gas phase ion–molecule coalescence reactions are now being further investigated by Fourier-transform mass spectrometry (FT-MS), a technique that had previously been successfully applied to the study of other cyclocarbon molecules.[3b, 15] Continuing studies are also directed toward the synthesis of less highly and reversibly functionalized derivatives of C_{195} and C_{260} and, ultimately, target the preparation of the free carbon allotropes C_{195} (**1**) and C_{260} (**2**).

Experimental Procedure

4 and **5**: To a suspension of 4 Å molecular sieves (8 g) in pyridine (380 mL) containing anhydrous $Cu(OAc)_2$ (2.345 g, 12.91 mmol) under Ar was added **18** (114.4 mg, 0.065 mmol) in pyridine (20 mL) over 3.75 h by syringe pump. After 20 h the reaction mixture was poured into toluene (300 mL), washed with aqueous $CuSO_4$ and saturated aqueous NaCl, and dried ($MgSO_4$). Column chromatography (silica gel H) eluted with CH_2Cl_2/AcOEt 100:5 gave a yellow fraction of **4**, while elution with CH_2Cl_2/AcOEt 100:8.5 afforded a yellow fraction of **5**. Upon addition of cyclohexane and concentration, the products precipitated. Washing with cyclohexane gave **4** (37.1 mg, 32%), and **5** (23.8 mg, 21%), both as yellow solids.

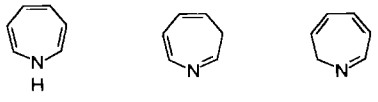
First Synthesis of 2*H*-Azepine**

Dieter Hamprecht, Kurt Polborn, and Wolfgang Steglich*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

Of the four possible azepine isomers only 1*H*-azepine **1** and 3*H*-azepine **2** are known so far, from pioneering work by Hafner[1] and Vogel et al.[2] Stimulated by the natural occurrence of 2*H*-azepines,[3] we have now developed a general synthesis for this type of heterocycle, which has led to the preparation of the previously unknown 2*H*-azepine **3**.



1 **2** **3**

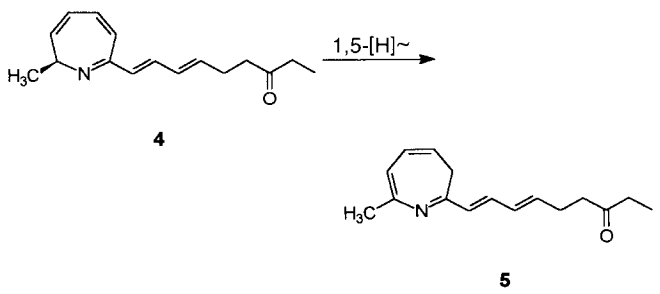
[**] We thank Dr. B. Steffan for carrying out the NMR experiments. D. H. thanks the Fonds der Chemischen Industrie for a Doktorandenstipendium.

Hitherto, substituted 2*H*-azepines have been obtained only in some special cases.[4] The pungent 2*H*-azepine alkaloid chalciporone **4** was isolated from the mushroom *Chalciporus piperatus*.[3] In solution **4** readily rearranges at room temperature to the 3*H*-azepine **5** (Scheme 1).



Scheme 1. Formation of the 3*H*-azepine isochalciporone **5** by rearrangement of the 2*H*-azepine chalciporone **4**.

The 2*H*-azepine **3** was synthesized starting from the *N*-Boc-glycine methoxymethylamide **6**,[5] which, according to Weinreb et al.,[6] reacts with 2.7 equivalents of lithiated 4-tetrahydropyranyloxy-1-butyne **7**[7] to give the alkynone **8** (Scheme 2); excess **7** can be recovered. Reduction of the carbonyl group and acetylation of the resulting alcohol gives a high yield of the protected diol **9**, which is then hydrogenated (Lindlar catalyst) to the (*Z*)-alkene. Cleavage of the tetrahydropyranyl ether by pyridinium *para*-toluenesulfonate (PPTS) catalyzed transacetalization with ethylene glycol yields the alcohol **10**.[8] The oxidation of **10** to the β,γ-unsaturated aldehyde **11** presented unexpected difficulties. For instance, the oxidation with pyridinium chlorochromate (PCC), PCC/NaOAc, DMSO/oxalyl chloride/NEt_3, or catalytic quantities of tetrapropylammonium perruthenate/*N*-methylmorpholine-*N*-oxide was unsuccessful; however, the problem of the oxidation was overcome by treating **10** with Dess–Martin periodinane.[9] Attempts to purify **11** by chromatography on silica gel or neutral alumina led to the formation of the (*E*,*E*)-dienal **12** by elimination of acetic acid. According to the ^{1}H NMR spectrum the crude oxidation product contains about 80% **11**. Treatment of this material with trifluoroacetic acid in dichloromethane at low temperature, followed by addition of a base [1,4-diazabicyclo[2.2.2]octane (DABCO) or 4-dimethylamino pyridine (DMAP)] leads to 2*H*-azepine **3** (Scheme 2). Under acidic reaction conditions, the Boc group is cleaved, and condensation to give the cyclic imine and the 1,4-elimination of acetic acid takes place. The cyclization of **11** is favored by the (*Z*)-configuration of the double bond. This is supported by the fact that under the above reaction conditions in the presence of a catalytic amount of iodine the (*E*,*E*)-dienal **12** forms only traces of **3**.

The 2*H*-azepin **3** is difficult to isolate because of its high volatility and instability in pure form. On careful evaporation of an ethereal solution of **3** at 0 °C, we observed a severe loss of product and rapid yellowing of the residue together with a pyridine-like odor. Thus, the yield of **3** is difficult to determine and amounts to approximately 1%, according to the ^{1}H NMR spectrum. For the NMR experiments a solution of **3** in deuterochloroform was obtained by condensation of the volatiles in a cold trap at −78 °C/2 mbar. In contrast to chalciporone **4** and other 2,7-disubstituted 2*H*-azepines, **3** is surprisingly stable in solution. After 48 h at room temperature or 30 min at 60 °C no trace of the thermodynamically favored[4d] 3*H*-azepine **2** could be detected. After standing at room temperature for one week the solution turned yellow. The structure of **3** was confirmed by NMR spectroscopy (^{1}H NMR: Fig. 1 and Table 1,

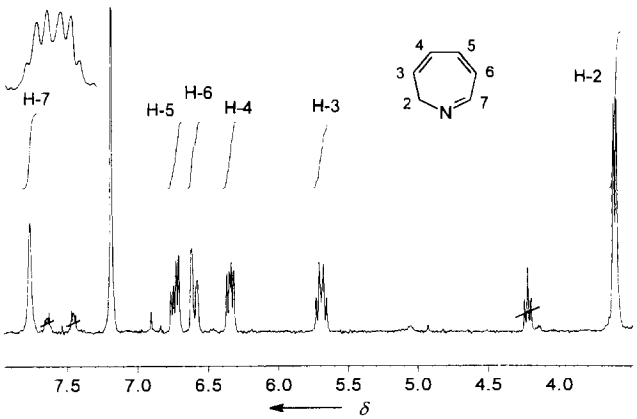


Fig. 1. ^{1}H NMR spectrum of **3** (300 MHz, $CDCl_3$). The signal of H-7, showing the complex coupling pattern, is enlarged (600 MHz, CD_2Cl_2, 270 K).

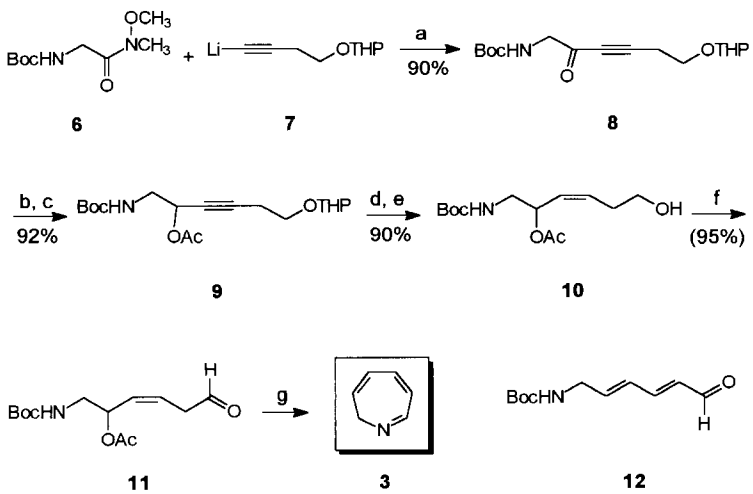

Scheme 2. Synthesis of 2*H*-azepine **3**. a) THF, −78 °C → −50 °C, 90 min, then dilute acetic acid; b) $NaBH_4$, MeOH, 0 °C, 1 h; c) Ac_2O, pyridine, cat. DMAP, CH_2Cl_2, 25 °C, 50 min; d) glycol, DME, cat. PPTS, 70 °C, 135 min (94% conversion); e) quinoline poisoned Lindlar catalyst, C_6H_6, H_2 (1 bar), 25 °C, 3 h; f) Dess–Martin periodinane, CH_2Cl_2, 25 °C, 30 min; g) trifluoroacetic acid, CH_2Cl_2 or $CDCl_3$, −10 °C, 4 h, then DMAP or DABCO.

Table 1. ^{1}H NMR data (300 MHz, $CDCl_3$; coupling constants *J* determined at 600 MHz in CD_2Cl_2) and ^{13}C NMR data (151 MHz, $CDCl_3$) of 2*H*-azepine **3**.

H	δ	Pattern	*J* [Hz]	C	δ

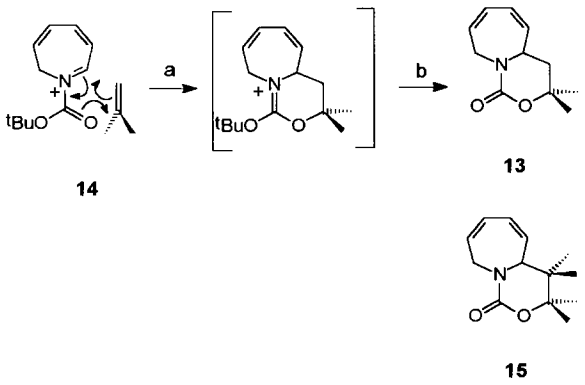
4	6.35	ddd	9.3, 5.4, 1.3	4	129.25
5	6.74	dddd	11.2, 5.4, 1.1, 1.1	5	136.73
6	6.60	dddd	11.2, 3.0, 1.1, 1.1	6	130.76
7	7.84	ddt	3.0, 1.2, 1.2	7	158.53

^{13}C NMR: Table 1, H-H-COSY, C-H-COSY, NOESY) and GC-MS. The signal of the atom H-7 is remarkable, resembling a broadened singlet; however, the coupling pattern of the signal is revealed upon observation of the ^{1}H NMR spectrum (600 MHz) of **3** at 270 K in dichlorodideuteromethane at higher resolution (Fig. 1).

From the nonvolatile residue of the reaction mixture 3,4,4a,9-tetrahydro-3,3-dimethyl-1*H*-[1,3]oxazino-[3,4-*a*]azepin-1-one **13** (Scheme 3) can be isolated in 5 to



Scheme 3. Proposed mechanism of the formation of **13**: a) [2 + 4]cycloaddition; b) liberation of isobutene and deprotonation.

10% yield from **11**. The structure of **13** was assigned by NMR spectroscopy (^{1}H NMR, ^{13}C NMR, H-H-COSY, DEPT) and mass spectrometry and confirmed by crystal structure analysis[10] (Fig. 2). It seems plausible that **13** results from a [2 + 4]cycloaddition between the isobutene formed in situ and

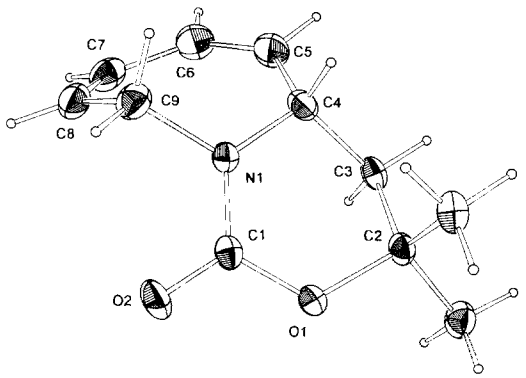


Fig. 2. ORTEP representation of the crystal structure of **13**.

the immonium ion **14** (Scheme 3). Similar Diels–Alder reactions of *N*-acylimmonium compounds are well known.[11] On addition of excess 2,3-dimethyl-2-butene to the reaction mixture, besides some **13** (**15**:**13** ≙ 7:1), 3,4,4a,9-tetrahydro-3,3,4,4-tetramethyl-1*H*-[1,3]oxazino[3,4-*a*]azepin-1-one **15** is formed in 11% yield. Surprisingly, the seven-membered ring can be formed prior to deprotection of the amino group.

Our synthetic route offers a flexible access to a variety of substituted 2*H*-azepines, including the natural product **4**, which will be reported at a later date.

Experimental Procedure

3: In a dry Schlenk flask **11** (0.16 g, 0.50 mmol; about 85% pure) in $CDCl_3$ (2.0 mL) was cooled to −11 °C. Trifluoroacetic acid (0.24 mL) and molecular sieves 4 Å (0.09 g) were added, and the red solution was stirred for 3.5 h at −11 °C (TLC control). Then the solution was cooled to −20 °C and DABCO (0.42 g, 3.7 mmol) was added, which caused the solution to turn yellow. The volatile components were distilled in vacuo (2 mbar) at room temperature and collected in a cold trap (−78 °C). The solution containing **3** was dried for a short time over $MgSO_4$ and used directly to determine the physical data. ^{1}H and ^{13}C NMR: Table 1; UV/Vis (Et_2O): λ_{max} = 306, 247, 214 nm; GC-MS: retention time = 5.1 min (column: Fissons DB 1701, 15 m × 0.25 mm, 30 °C, 15 psi He), *m/z* (%): 94.1 (7), 93.1 (100) [M^+], 92.1 (20), 78.1 (6), 67.1 (10), 66.1 (42), 65.1 (37), 63.1 (8), 51.0 (5), 41.0 (6), 40.0 (20), 39.0 (32), 38.0 (9).

13: The nonvolatile residue of the reaction mixture of **3** was dissolved in *tert*-butylmethyl ether, washed with water and brine, dried ($MgSO_4$), and the solvent was removed in vacuo. Flash-chromatography (silica gel) afforded **13** as a colorless solid (8 mg, 8%). Crystals suitable for crystal structure analysis (colorless needles) were obtained by slow crystallization from CH_2Cl_2/hexane. M.p. 79–81 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 6.27–6.34 (m, 1H; CH), 5.89–6.07 (m, 2H; 2 CH), 5.74–5.80 (m, 1H; CH), 4.38–4.47 (m, 1H; CH), 4.29 (dd, ^3J(H,H) = 14.6, 6.7 Hz, 1H, CH_2), 3.61 (dd, ^3J(H,H) = 14.6, 4.9 Hz, 1H; CH_2), 2.02 (dd, ^3J(H,H) = 13.8, 5.7 Hz, 1H; CH_2), 1.74 (dd, ^3J(H,H) = 13.8, 11.0 Hz, 1H; CH_2), 1.40 (s, 3H; CH_3), 1.37 (s, 3H; CH_3); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 152.90, 135.57, 132.01, 126.49, 126.89, 76.41, 56.10, 45.24, 39.43, 28.99, 24.97; IR (film): $\tilde{\nu}$ = 2980, 1690, 1370, 1170 cm^{-1}; FAB-MS: *m/z*: 194 [M + H$^+$].

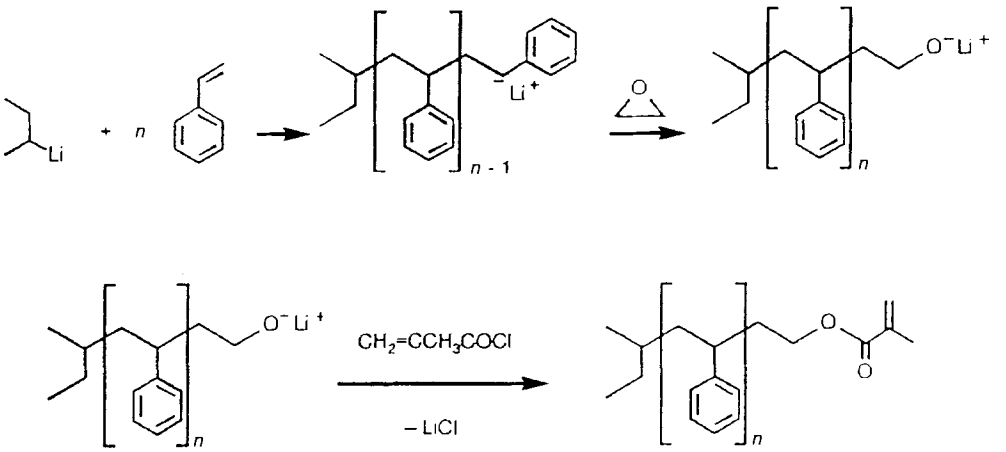
Lyotropic Phases Formed by "Molecular Bottlebrushes"**

Matthias Wintermantel, Karl Fischer, Markus Gerle, Roland Ries, Manfred Schmidt,* Kanji Kajiwara, Hiroshi Urakawa, and Isao Wataoka

The polymerization of macromonomers (that is, end-functionalized oligomers, Scheme 1) has been a matter of extensive research in order to prepare well-defined comblike polymers.[1]



Scheme 1. Reaction scheme for the preparation of the macromonomers.

However, the homopolymerization of macromonomers did not yield degrees of polymerization significantly exceeding the length of a macromonomer itself, unless copolymerized with conventional small monomers. A major breakthrough was achieved by Tsukahara et al., who in a radical mechanism homopolymerized anionically prepared oligostyrenes with molar masses between 10^3 and 10^4 g mol^{-1} that were end-functionalized with methacryloyl groups and obtained degrees of polymerization (weight average) P_w of up to 1000.[2] Recent structure characterization of such long-chain polymacromonomers revealed that the main chain exhibits an almost rodlike conformation as measured by the Kuhn statistical segment length of $l_k > 1000$ Å.[3] Apparently, the extended structure of the polymethacrylate (PMA) main chain is caused by the strong overcrowding of the oligostyrene side chains, which are only separated by a contour distance $l = 2.5$ Å at the polymer backbone. Also, because of the length of the side chains, the diameter or cross-section of this curved cylindrical macromolecule or "bottlebrush" is quite large ($d \approx 70-150$ Å for a side chain of molar mass $M_n = 3950$ g mol^{-1}, dependent on whether hydrodynamic data or X-ray investigations of the cross-sectional radius of gyration were used for the determination of diameter).[3] Still, the aspect ratio L_w/d (L_w is the weight-averaged contour length, $L_w = P_w \cdot l$, and d the diameter of the chain) is of the order of 10–50 for most of the samples, and accordingly, such polymers should form liquid-crystalline phases.

Here we report on X-ray scattering measurements of the polymacromonomers in toluene performed at the synchroton source in Tsukuba, Japan, which indeed show the formation of lyotropic phases, probably nematic, in semi-concentrated solution. The investigated polymacromonomer sample had a molar mass of $M_w = (2.2 \cdot 10^6)$ g mol^{-1} corresponding to a contour length $L_w = 1400$ Å. The polydispersity index determined by gel permeation chromatography (GPC) was $M_w/M_n \approx 1.5$, and the Kuhn statistical segment length (as measure of chain stiffness) $l_k = 1250$ Å.[3]

Figure 1 shows the X-ray scattering intensity $I(q)$ as a function of the scattering vector q [$q = (4\pi/\lambda \sin(\theta/2)$, where λ is the wavelength in the medium and θ the scattering angle) for polymacromonomer concentrations $0.2 \le c \le 30\%$ (w/w). In the dilute regime $c < 0.5\%$ the form factor $P(q)$ of a single chain is measured: the intensity is seen to decrease monotonically with increasing q. However, the q regime investigated here reflects the scattering pattern of the chain cross-section. With increasing concentrations a shoulder develops into a clearly resolved scattering peak.

Particularly at the highest measured concentration of 31.5%, the width of the scattering peak narrows drastically. The scattering peaks observed at higher concentrations cannot be explained by single-particle scattering but rather reflect the interparticle structure factor $S(q)$ originating from the intermolecular order of the molecules.

On application of Bragg's relation, a mean distance d_B between the scattering planes (100) of hexagonal order is obtained from the scattering peak at q_{max} [Eq. (a)]. The mean par-ticle distance d_2 is then derived from Equation (b). In order to

$$d_B = 2\pi/q_{max} \quad \text{(a)}$$

$$d_2 = 2d_B/\sqrt{3} \quad \text{(b)}$$

compare the present results with earlier investigations on the tabacco mosaic virus (TMV)[4] and on poly-γ-benzylglutamate (PBG),[5] a reduced plot of d_2/d_0 (d_2 is the mean distance between the particles and d_0 their "hard-core" diameter) versus the volume fraction of solute is shown in Figure 2. Since a hard-core

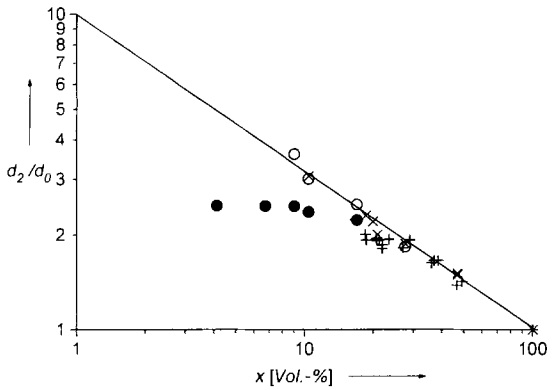

Fig. 2. Reduced interparticle distance d_2/d_0 vs. the volume fraction of polymer: × TMV [4], + PBG [5], ●, ○ polymacromonomer. The mean distance $\bar{d}_2$ is derived from $I(q)$ (×, +, ○) or from $S(q)$ (●) as explained in the text.

diameter for the polymacromonomer is impossible to define (because of the radially decaying segment density), a value of d_0 of 67 Å is assumed in order to obtain an approximate superposition with the other curves. This value of d_0 compares well with the cross-sectional radius of gyration $R_{g,c} = 36.4$ Å as determined by X-ray scattering ($d_{g,c} = 72.8$ Å[3]). For comparison, the hypothetical "hard-core" diameter of a molecule with the bulk density $\rho = 1.05\ g\,cm^{-3}$ of polystyrene would amount to $d_2 = 57$ Å, and the hydrodynamically effective cross-section as determined by diffusion measurements to $d_h = 150$ Å. The solid line shows the expected scaling relation for the packing of parallel cylinders [Eq. (c)].

$$d_2/d_0 \approx c^{-1/2} \qquad \text{(c)}$$

The observed agreement of the relative spacing as a function of the volume fraction for the polymacromonomer (PBG and TMV) is expected, because the aspect ratio L/d of all three systems is of the order of 15. Surprisingly, the data evaluation as described above does not give any evidence for the occurrence of a biphasic (isotropic/anisotropic) regime, which is theoretically predicted by Onsager[6] and Flory[7] at volume fractions between 10–20%, because in the biphasic region the mean distance is expected to be independent of the concentration of polymers.

Although the influence of the decaying single-particle form factor $P(q)$ might seriously influence the position of the maximum intensity, particularly at the lower q values, this has been ignored in the presentation of the data so far. For spherically symmetric particles, the total intensity $I(q)$ is expressed by the product of the particle scattering factor and the structure factor [Eq. (d)]. Equation (d) breaks down for anisotropic particles,

$$I(q) = P(q)\,S(q) \qquad \text{(d)}$$

because the structure factor $S(q)$ becomes a function of $P(q)$ as now the interparticle interference depends on the shape of the single particles, that is, on the spatial distribution of the scattering centers within one macromolecule. Unfortunately, there is no unique solution to this problem except to assume, a priori, a certain density distribution of the molecules and calculate the Fourier transform into q space.

For a preliminary treatment of more detailed data analysis we assume Equation (d) to be approximately valid for our system. Accordingly, the structure factor $S(q) = I(q)/P(q)$ is shown in Figure 3 for the concentrations $c \geq 4.93\%$. To reduce the noise

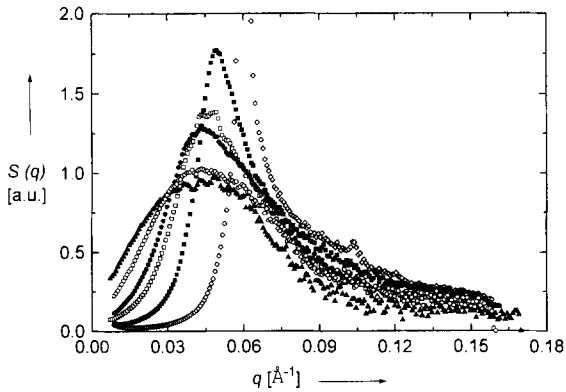

Fig. 3. The static structure factor $S(q)$ in arbitrary units as a function of the scattering vector q for different polymacromonomer concentrations in wt%: △ 4.93%, ○ 8.0%, ● 10.7%, □ 12.3%, ■ 19.8%, ◇ 31.5%. For the highest concentration even higher order peaks are observed with a relative spacing of $d_1:d_2:d_3 = 1:\sqrt{3}:2$, which supports the hexagonal packing.

in the data the single-particle form factor $P(q)$ was evaluated from the average intensities of the concentrations $c = 0.306\%$, 0.393%, and 0.481%. For $c < 12.3\%$ the maximum of the observed broad structure peaks remains approximately constant and increases in intensity with increasing concentration. This is exactly the result expected from the biphasic regime where the volume fraction of the anisotropic phase increases with increasing concentration but the interparticle distance within the ordered phase remains constant. From the position of the maximum, a mean distance of $d_2 = 156$ Å is calculated from Equations (a) and (b), which is interpreted as the mean distance of the cylinders in the ordered part of the biphasic region, that is, between the A and B points. The solution becomes fully anisotropic at concentrations above 12.8% (B point) as now the interparticle separation starts to decrease with increasing concentration as expected ($d_2 \approx c^{-1/2}$, solid line in Fig. 2).

The formation of lyotropic liquid crystals by polymacromonomers is also detected by polarized light microscopy on thin films that were prepared by slow evaporation of the solvent. The resulting pictures shown in Figure 4 (bottom) were developed by exposing the film for 10 min. This documentation of the small optical anisotropy of the particles is explained by an expanded, but still random conformation of the polystyrene side chains, which hardly contribute to the birefringence. Upon heating (see thermal history, Fig. 4 top), the birefringence of the film disappears at 140 °C, which lies significantly above the glass transition temperature of $T_g \approx 100$ °C and does not reappear on slow cooling (which may be due to kinetic effects).

We have reported on a new concept for preparing stiff polymers that form liquid crystals and consist of "commodity" monomers such as styrene and methacrylate. This concept is simply based on the overcrowding of bulky side chains

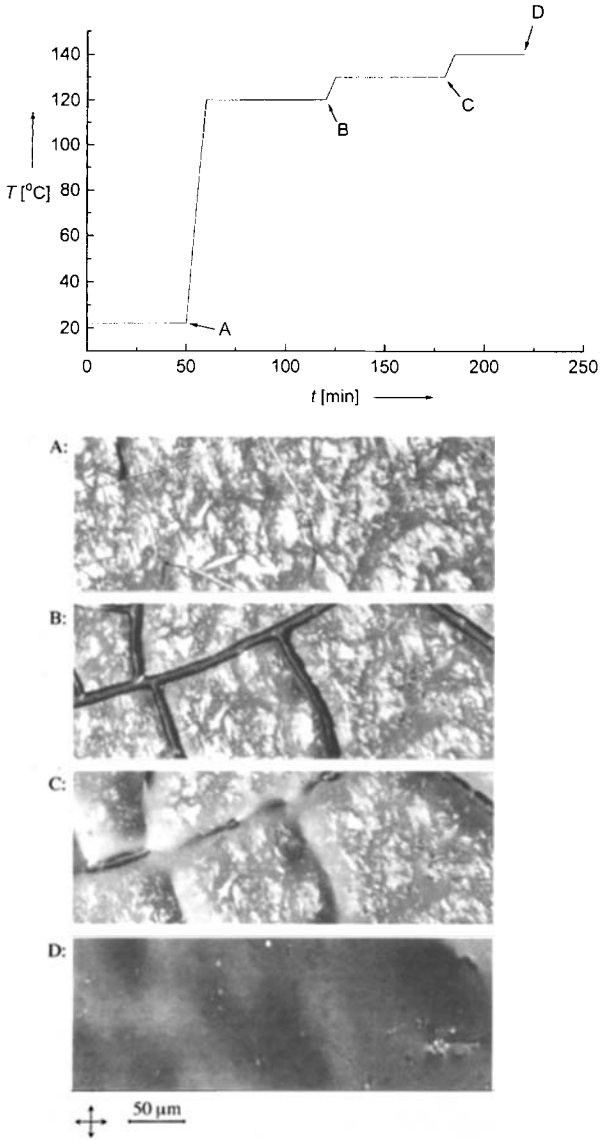

Fig. 4. Top: Thermal history of the anisotropic polymacromonomer film. Bottom: Polarization microscopy pictures at temperatures A–D as depicted above.

which forces the otherwise flexible main chain into a stretched conformation with significantly reduced degrees of freedom.

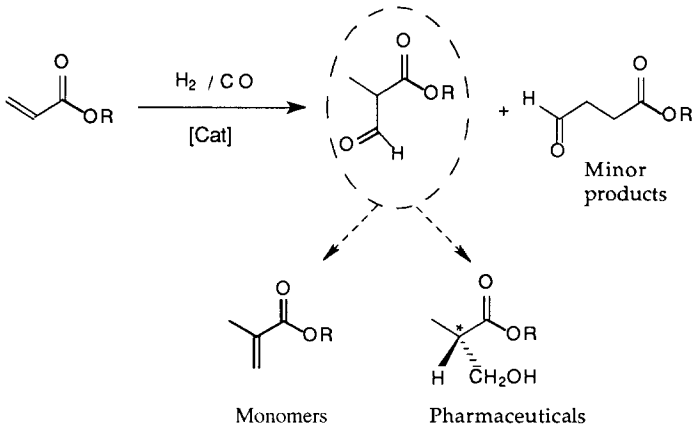
Enhancement of Catalytic Activity for Hydroformylation of Methyl Acrylate by Using Biphasic and "Supported Aqueous Phase" Systems**

Georges Fremy, Eric Monflier, Jean-François Carpentier, Yves Castanet, and André Mortreux*

Among the numerous hydroformylation reactions, those of α,β-unsaturated esters are of particular interest. In this area, much attention has been focused on the hydroformylation of acrylate esters to give 2-formylpropanoate esters, since the latter are used extensively for the synthesis of pharmaceuticals[1] and may also be considered a potential source of the extremely important methacrylate esters (Scheme 1).[2] Generally, rhodium-based homogeneous catalytic systems show good catalytic activities as well as high *iso*/*n* regioselectivities for acrylate esters, and



Scheme 1.

many examples have been reported.[3] However, due to the high cost of rhodium, alternative ways for recovering the catalyst have been developed for many hydroformylation reactions, for example through the use of biphasic[4] and "supported aqueous phase" (SAP)[5] systems using water-soluble phosphanes. Despite their advantages, these catalytic systems almost always suffer from poor activities; put simply, they are always far slower than analogous reactions in the homogeneous phase. However, very recently, an acceleration effect on the rhodium-based biphasic hydroformylation of 1-octene using trisulfonated triphenylphosphane (TPPTS) in the presence of triphenylphosphane (TPP) was reported.[6] Under these biphasic conditions, turnover frequencies (TOFs) were almost comparable to those obtained with homogeneous systems.[5e, 6] In this paper, we describe biphasic and heterogeneous catalytic systems for the hydroformylation of methyl acrylate which have much higher activities than the homogeneous variant.

7 [f]	TPPTS/SiO_2	40/0.9	120	3.0	97.0	149	870
8 [f]	TPPTS/SiO_2	40/6	12	5.1	94.9	136	4300
9 [f]	TPPTS/SiO_2	40/10	120	6.6	93.4	148	570

[a] Reaction conditions: 0.2 mmol of $[Rh(acac)(CO)_2]$, 2 mmol (equiv P) of phosphane, 100 mmol of methyl acrylate; $T = 50\,^{\circ}C$; $p = 50$ bar ($CO/H_2 = 1$). [b] Optimized time for total conversion of methyl acrylate. [c] Ratio α-aldehyde/β-aldehyde. [d] Defined as mole of initially converted methyl acrylate per mole of rhodium per hour. [e] $[HRh(CO)(TPPTS)_3]$ was used as catalyst. [f] SiO_2 (60 Å, 490 $m^2 g^{-1}$, 70–230 mesh): 9 g.

We first compared the activities and selectivities obtained with sulfonated phosphanes in the hydroformylation of methyl acrylate under conventional biphasic conditions with those obtained with triphenylphosphane (TPP) and 1,4-bis(diphenylphosphino)butane (DPPB), the ligands typically used under homogeneous conditions (Table 1). The (DPPB)Rh system is the most active and selective (entry 2),[3a] and served as a comparison.

The respective mono- and tetrasulfonated analogues (TPPMS and DPPBTS, respectively) gave lower activities and very poor chemo- and/or regioselectivities for the desired branched aldehyde (entries 3 and 6). This was particularly the case for DPPBTS which led to the predominant formation of the hydrogenated product. Surprisingly, when the trisulfonated triphenylphosphane (TPPTS) was used, we observed a significant increase in the reaction rate relative to that of the homogeneous reaction (cf. entries 1 and 4).[7] Selectivities for the hydroformylated products were similar, and both ligands led almost exclusively to the branched aldehyde. The hydridorhodium(I) species $[HRh(CO)(TPPTS)_3]$ gave comparable results (cf. entries 4 and 5). This indicated the rapid formation of the catalytic species from the precursors under our conditions. To our knowledge, such an increase in activity from the transposition of an homogeneous reaction to aqueous biphasic conditions has never been reported. In fact, catalytic rates under biphasic conditions, even with TPP as promoter ligand,[5e, 6] are almost always lower than those in a homogeneous medium.[4a, 8]

The above findings led us to examine the behavior of SAP systems, in which the catalyst precursors—a rhodium complex and a water-soluble phosphane—are deposited on silica gel with a variable amount of water. Under these conditions, the catalytic rates could be greatly improved. Methyl acrylate could be hydroformylated with an exceptionally high TOF of 2370 h^{-1} (entry 9) compared to 330 h^{-1} for DPPB (entry 2). Typical kinetic data for systems based on TPP derivatives are illustrated in Figure 1.

The results obtained with silica gel supported catalysts were strikingly dependent on the water content (entries 7–9, Fig. 2). The maximum initial activity (4300 h^{-1}) was obtained for a water content of 37% by weight[9] (entry 8); even slight deviations from this water content led to decreased activities. When larger amounts of water were present, the catalytic rates observed were similar to those found under classical biphasic conditions (cf. entries 4 and 9). These results are in sharp contrast with the previously reported examples in which these techniques were employed with higher α-olefins (e.g. heptene, tetradecene).[5] In these studies the activities of heterogeneous catalytic systems were much lower than the corresponding homogeneous systems. We assume that in our case, polar interactions between methyl acrylate and silica gel and/or the water phase supported on the silica gel surface may be responsible for the high catalytic rates observed. In line with this hypothesis, several hydroformylation experiments conducted with propylene, a nonpolar substrate, did not show increased rates of reaction on transposition from biphasic to SAP conditions. Further experiments to confirm the above hypothesis and extend the range of substrates are currently under way.

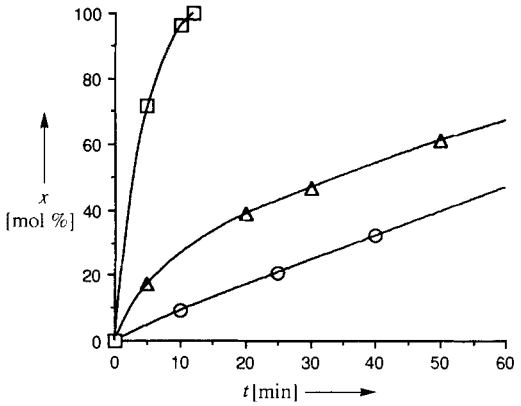

Fig. 1. Conversion x of methyl acrylate as a function of time for TPP (○), TPPTS (△), and TPPTS/SiO_2 (□) rhodium catalyst systems. See Experimental Procedure for reaction conditions.

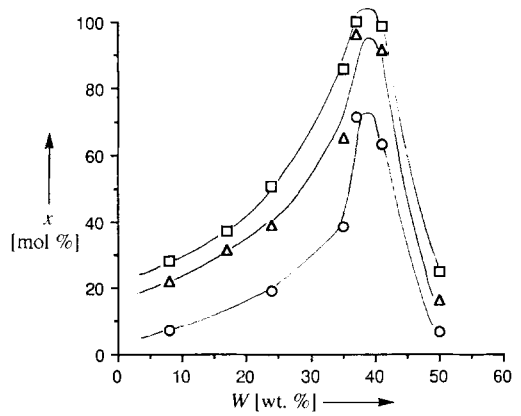

Fig. 2. Conversion x of methyl acrylate as a function of water content W for supported aqueous phase Rh/TPPTS/SiO_2 systems. Reaction times: 5 min (○), 10 min (△), and 15 min (□). See Experimental Procedure for reaction conditions.

Experimental Procedure

Preparation of the reaction mixtures. a) Homogeneous systems: Under an atmosphere of N_2, 0.2 mmol of the rhodium precursor [Rh(acac)$(CO)_2$], 2 mmol (equiv P) of phosphane, and 100 mmol of methyl acrylate were dissolved in 40 mL of toluene. b) Biphasic systems: 0.2 mmol of the rhodium precursor and 2 mmol (equiv P) of phosphane were stirred in 30 mL of water until total dissolution, and then 100 mmol of methyl acrylate in 40 mL of toluene was added. c) Silica gel supported systems: 0.2 mmol of the rhodium precursor and 2 mmol of TPPTS were stirred in 20 mL of water until total dissolution, and then added to 9 g of freshly dried silica. Water was then partially removed under vacuum until the desired water content was reached; this was precisely determined by gravimetric thermal analysis of an aliquot. The resulting powder was mixed with a solution of 100 mmol of methyl acrylate in 40 mL of toluene.

Catalytic reactions: A 100 mL stainless steel autoclave was charged under an atmosphere of N_2 with the reaction mixture, then heated at 50 °C, and pressurised with 50 bar of CO/H_2 (1/1). Mechanical stirring (1000 rpm) with a multipaddle unit was then started. The pressure was kept constant throughout the whole reaction by using a gas reservoir along with a pressure regulator. The reaction was monitored by quantitative gas chromatographic analysis (CP Si 5-CB, 25 m × 0.32 mm).

A Remarkable Effect of Silyl Substitution on Electrocyclization of Vinylallenes

Masahiro Murakami,* Hideki Amii, Kenichiro Itami, and Yoshihiko Ito*

Considerable attention has been directed toward the effects of silyl substituents,[1] which are now widely utilized in a variety of organic reactions.[2] Of these, β-cation stabilization in electrophilic reactions of organosilicon compounds is one of the most exploited. We now report a remarkable effect of silyl substitution on the kinetics and the thermodynamics of the thermal electrocyclization of vinylallenes.

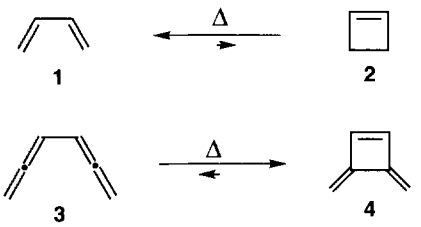
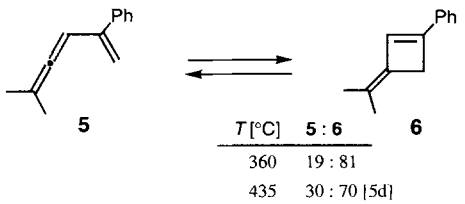
The electrocyclic ring closure of conjugated dienes has been a source of continuing interest from the viewpoints of both organic and theoretical chemistry. 1,3-Butadiene (**1**), an open-chain compound, is thermodynamically favored over cyclobutene (**2**).[3] In contrast, 3,4-bis(alkylidene)cyclobutene (**4**), a ring-closed compound, is favored over bis(allene) (**3**) despite the ring strain (Scheme 1).[4]



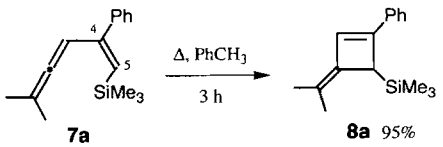
Scheme 1. The equilibrium of thermal electrocyclization of conjugated diene systems.

Interestingly vinylallene, which is structurally intermediate between **1** and **3**, also has an intermediate equilibrium position for the ring closure, and relatively high temperature is required for electrocyclization;[5] Pasto et al. reported that heating of vinylallene **5** produced an equilibrium mixture of **5**:**6** = 19:81 at 360 °C, and of **5**:**6** = 30:70 at 435 °C (Scheme 2).



Scheme 2. The thermal electrocyclization of non-silyl-substituted vinylallene **5**.

During the course of our study on the use of the silastannation reaction in synthesis,[6] we found that in marked contrast to **5**, the vinylallene **7a** that differs from **5** only in the silyl substituent at C5 underwent unidirectional electrocyclization[7] at about 145 °C to give (alkylidene)cyclobutene **8a** in 95% isolated yield (Scheme 3). None of **7a** remained after heating for 3 h.



Scheme 3. The facile and unidirectional electrocyclization of silyl-substituted vinylallene **7a**.

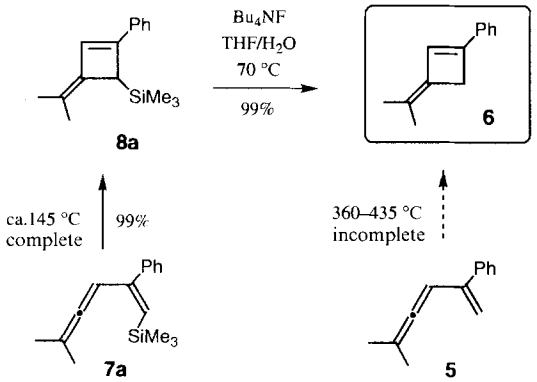
This result shows that the ring-closed product **8a** is thermodynamically much more stable than **7a**. Furthermore, the activation energy for electrocyclization is much smaller than that of non-silyl-substituted vinylallene **5**.

Other examples of facile and unidirectional electrocyclization of silyl-substituted vinylallenes are given in Table 1.[8] At reflux in xylene, both *cis* and *trans*-5-silyl-substituted vinylallenes **7** yield (alkylidene)cyclobutenes **8** in high yield.

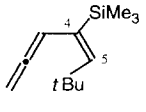
Table 1. Unidirectional electrocyclization of vinylallenes **7** in xylene at reflux (ca. 145 °).

7	t [h]	8	Yield [%]
 **7b**	2	 **8b**	99
 **7c**	2	 **8b**	90
 **7d**	15	 **8d**	95
 **7e**	12	 **8e**	98
 **7f**	21	 **8f**	85

The trimethylsilyl group of **8a** was removed on treatment with Bu_4NF to produce, in overall high yield from **7a**, (alkylidene)cyclobutene **6**, which was fairly stable up to at least 160 °C[5d] (Scheme 4). The direct electrocyclization of **5** failed to complete conversion.



Scheme 4. Efficient synthesis of **6** by electrocyclization of **7a** followed by desilylation.



9

The origin of this effect of silyl-substitution is of much interest. For comparison with **7d** and **7e**, vinylallene **9**, having a tertiary butyl group instead of a silyl group at C5, was heated at reflux in xylene. As no (alkylidene)cyclobutene was obtained after heating for 17 h, it is unlikely that electrocyclization is promoted by the steric factor of a silyl group. Besides, the silyl group at C4 does not promote the electrocyclization. Silyl-substituted (alkylidene)cyclobutene **8** has two C–C double bonds. The silyl group is located at the allylic position of both of them. Since hyperconjugation ($\sigma-\pi$ conjugation) is thought to raise the energy of the π system of an allylsilane,[9] it is also difficult to explain the stabilization of **8** in terms of the electronic effect of the silyl group.

Although the origin is equivocal, the present experimental finding exemplifies the significant effect of the introduction of silicon on the thermal electrocyclicization of vinylallenes. Precise theoretical studies on the origin of this effect are currently underway.

Experimental Procedure

7a,b,d, f: See ref. [6].

8a: A solution of **7a** (200 mg, 0.83 mmol) in xylene (3 mL) was heated at reflux for 12 h. The reaction mixture was cooled, reduced in volume, and purified by chromatography on silica gel (hexane) to afford **8a** (190 mg, 95%) as an oil. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.00$ (s, 9H), 1.71 (s, 3H), 1.79 (s, 3H), 3.19 (s, 1H), 6.60 (s, 1H), 7.15–7.40 (m, 5H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = -1.2$, 19.6, 20.3, 38.9, 117.2, 123.9, 125.5, 127.2, 128.1, 133.5, 135.0, 147.6; $C_{16}H_{22}Si$: calcd C 79.27, H 9.15; found C 79.53, H 9.14.

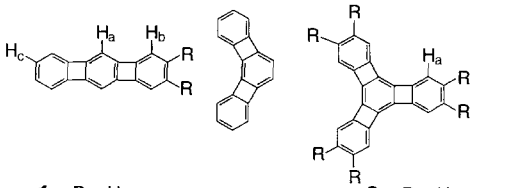
C_3-Symmetric Hexakis(trimethylsilyl)[7]phenylene ["Tris(biphenylenocyclobutadieno)cyclohexatriene"], a Polycyclic Benzenoid Hydrocarbon with Slightly Curved Topology**

Roland Boese,* Adam J. Matzger, Debra L. Mohler, and K. Peter C. Vollhardt*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The phenylenes constitute a new class of [4*n*]annuleno[4*n* + 2]-annulenes composed of alternating fused benzene and cyclobutadiene rings.[1] Several topologies may be envisaged, the simplest being represented by the purely linear, angular, and trigonal frames of **1**,[2] **2**,[3] and **3**.[4] Such π systems activated by



1a, R = H
1b, R = $Si(CH_3)_3$

2

3a, R = H
3b, R = $Si(CH_3)_3$

strain and electronic features are of intrinsic theoretical interest as unique subjects on which to study the relative contributions of σ and π electrons to the structure and reactivity of the "aromatic" benzene ring,[5] and as potential organic molecular magnetic and/or conducting materials.[6] While the linear[7] and angular[8] homologous series of **1** and **2** have been extended up to the [5]phenylenes, **3** is so far the only member with trigonal geometry. Yet, the symmetry of the latter is of particular interest because it leads to orbital degeneracy that, under certain conditions, may provide molecules with a stable triplet ground state, which, if correctly juxtaposed, could impart ferromagnetism on the bulk material.[9]

We present here the total synthesis of the hexasilylated trigonal [7]phenylene **9**, a comparison of its physical properties with those of **1**, **3**, and the unilaterally extended **6** and **7**, and its highly unusual bowed structure. The title compound **9** is the largest phenylene yet known, and model **7** represents a new isomer in the [5]phenylene series (the third of 12 possible structures). The syntheses of both necessitated the use of 1,6-bis(triisopropylsilyl)-1,3,5-hexatriyne (**4**) as the cocyclization partner in the crucial CpCo-catalyzed chain-extension steps,[7b] thus avoiding stepwise elaboration of **3b** in which the central ring is subject to electrophilic attack.

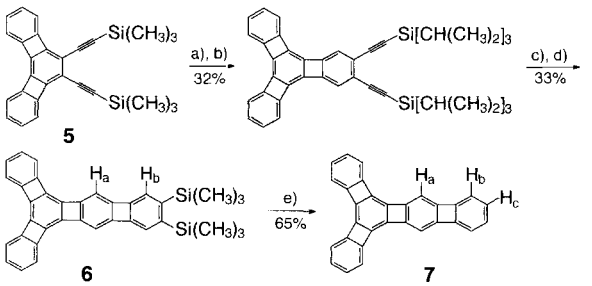
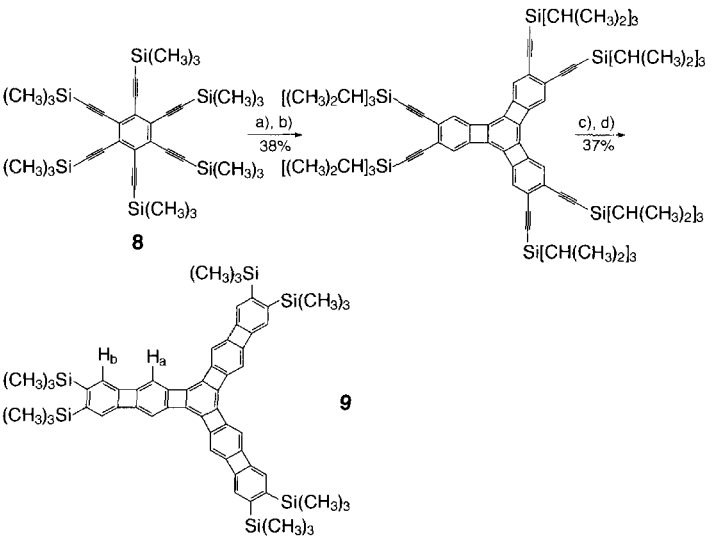
Matzger acknowledges a Syntex predoctoral fellowship (1994–1995). We thank Prof. A. Streitwieser for helpful discussions.

Schemes 1 and 2 detail the synthetic strategies toward **7** and **9**,[10] starting with the known precursors **5**[4] and **8**, respectively.[11] Noteworthy are the excellent yields in the transformation of **8** to **9** (equivalent to about 73% for each CpCo-catalyzed [2 + 2 + 2]cycloaddition) and the fact that of the thirteen rings in **9**, twelve are made by cobalt catalysis. No sign of the CpCo complexes[7] of **6** and **9** was detected in the cyclizations.



Scheme 1. a) $Bu_4N^+F^-$, THF, toluene, 23 °C, 2h; b) **4** (5 equiv), $[CpCo(CO)_2]$, toluene, Δ, *hv*, 16h; c) $Bu_4N^+F^-$, THF, 23 °C; d) $(CH_3)_3SiC\equiv CSi(CH_3)_3$, $[CpCo(CO_2)]$, THF, Δ, *hv*, 16 h; e) CF_3COOH, CH_2Cl_2, 23 °C, 16 h.



Scheme 2. a) $KF\cdot 2H_2O$, [18]crown-6, DME, 23 °C; b) **4** (7 equiv), $[CpCo(CO)_2]$, toluene, Δ, *hv*, 16 h; c) $Bu_4N^+F^-$, THF, 23 °C, 30 min; d) $(CH_3)_3SiC\equiv CSi(CH_3)_3$, $[CpCo(CO_2)]$, THF, Δ, *hv*, 16 h.

The comparison of the physical properties of the moderately air-stable [5]- and [7]phenylenes (Table 1) with each other and related substructures of the individual systems, in particular **3**, are of interest. It becomes immediately evident that the presence of one linear [3]phenylene unit (for example, **3a** → **7**) induces a relatively large bathochromic shift in the electronic spectrum [$\Delta\lambda_{max}$ (highest wavelength band) = 107 nm], whereas subsequent benzocyclobutadiene annelation causes a relatively attenuated change [for example, **3b** → **9**, corresponding $\Delta\lambda_{max}$ = 133 nm, or **6** → **9**, $\Delta\lambda_{max}$ = 37 nm; the slight incongruence is a consequence of the different degree of silyl substitution]. Similarly, the diagnostic proton chemical shifts for H_a ($CDCl_3$) from **3a** through **6** to **9** decrease by greatly differing increments (δ = 7.18, 6.68, 6.56, respectively), though the corresponding values for H_b in **6** and **9** are almost identical. The observations suggest that there is only a relatively small interaction of the three "outside" biphenylene units in **9** across the central cyclo-

hexatriene, not unlike the situation encountered in **3**.[4] Alternatively, one could interpret the topologies of **6**, **7**, and **9** essentially as perturbed linear [3]phenylenes in which one of the terminal benzene rings (namely that representing the internal core of the **3**-subunit) has been forced into complete bond alternation (as indicated in the resonance structures chosen to depict **6**, **7**, and **9**; see also the X-ray data below). This model leads to the prediction of reduced paratropism in the cyclobutadienoid rings and the expectation that H_a–H_c would be significantly deshielded relative to the corresponding hydrogens in **1a** or **1b** (as references for **7** or **6** and **9**, respectively).[2] Such an effect is indeed observed ($\Delta\delta$ values in $CDCl_3$): (**7**–**1a**) for H_a: 0.41, H_b: about 0.15, H_c: about 0.10; (**6**–**1b**) for H_a: 0.37, H_b: about −0.04; (**9**–**1b**) for H_a: 0.25, H_b: about −0.02. Consistent with this view, the actual chemical shifts of H_a–H_c in **6**, **7**, and **9** are the same as or very close to those in biphenylene and 2,3-bis(trimethylsilyl)biphenylene.[2]

As expected, such subtle trends are not reflected in the ^{13}C NMR data, which are less diagnostic of the presence of ring current effects. Rather, the ^{13}C chemical shifts are readily computed by taking into account cumulative incremental changes along the series of phenylenes **1**–**3**. As exceptions, the central cyclohexatriene carbon atoms in **3b** (δ = 131.23) experience a "long-range shielding effect" of increasing benzocyclobutadiene annelation to **6** (δ = 128) and **9** (δ = 122.37). Considering that the cyclobutadienoid carbon atoms in biphenylene resonate at δ = 151.9, these smaller chemical shifts are remarkable and most likely the result of unusual hybridization at these positions to accommodate σ strain and minimize antiaromatic π contributions.[5a–c]

To gain further insight into how the strain is accommodated in the molecules reported, X-ray structural investigations were performed. Unfortunately in the case of **6**, severe twinning prevented a refinement of the structure beyond its gross features. Gratifyingly, better data were obtained on the more important **9** (Fig. 1).[12] In the unit cell, two molecules stack in a staggered cofacial arrangement with offset centers, seemingly to enable π–π interactions[13] between two internal biphenylene units. The distance between the atoms C12A and C21B of the symmetry related (inversion center) molecules is 3.39 Å, the corresponding value between the two planes of the four-membered rings C5, C6, C19, C24 (ring I) is 3.52 Å, comparable to related separations in biphenylene[14a] and its charge transfer complexes.[14b] There is one molecule of THF associated with (but not contacting) each molecule of **9**.

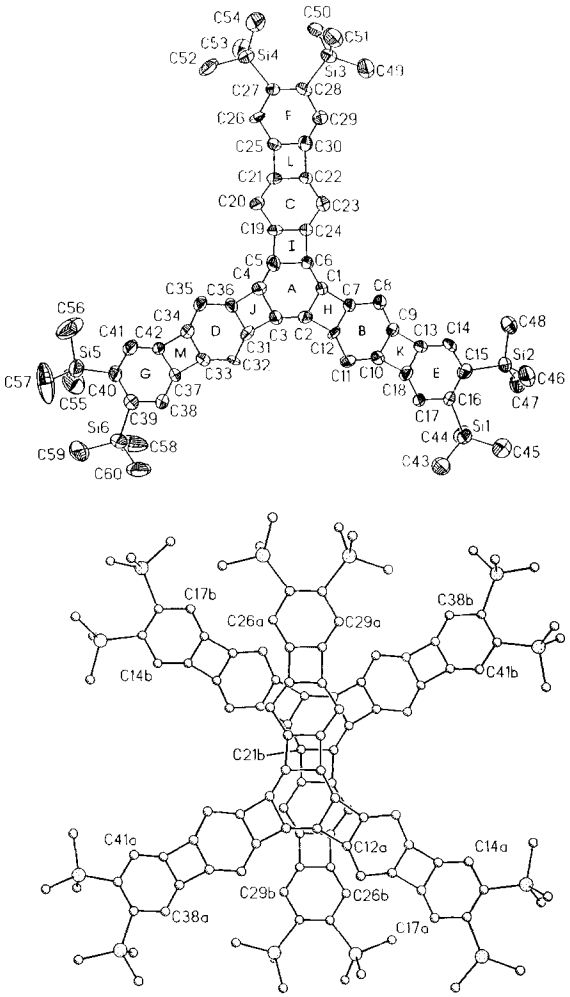

Fig. 1. Molecular structure of **9** (top) and arrangement of the two molecules in the unit cell (bottom).

Most instructive is Figure 2 which depicts the changes that occur on trisbenzocyclobutadiene annelation of **3b** or, alternatively, enforcing bond alternation at one of the terminal benzene rings of **1** by bisbenzocyclobutadiene annelation. In the first comparison, it is immediately apparent that the central six-membered ring in **9** is completely bond localized (1.326, 1.509 Å), arguably (from standard deviations) even more so than that in **3b** (1.335, 1.494 Å).[22] Moreover, the rectangular nature of rings H, I, J is slightly reduced (1.419, 1.485 Å vs. 1.408, 1.501 Å), and the order of bond alternation of the non-fused bonds in rings B, C, D inverted (1.405, 1.377 Å vs. 1.368, 1.417 Å). The terminal benzene rings adopt a geometry close to those of the two reference compounds and even biphenylene itself[15] [when one corrects for the effect of *ortho*-bis(trimethylsilyl) substitution].[16] Taking the tetrasilyl[3]phenylene as a reference point, conversion to the framework of **9** causes a structural alteration in the direction that might be expected from a biphenylene attached to a cyclobutacyclohexatriene. Bearing the caveat of standard deviations and the relatively qualitative nature of such comparisons in mind, but encouraged

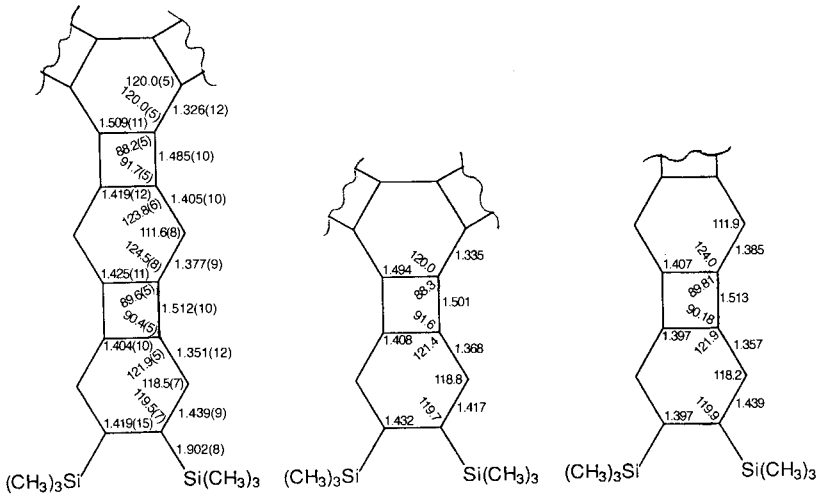

Fig. 2. Averaged (for idealized symmetry) selected bond distances [Å] and angles [°] of **9** (left), **3b** (middle)[4], and **1b** with two additional silyl substituents (2,3,7,8-tetrakis(trimethylsilyl)[3]phenylene [2], right).

by the internal consistency with the ^{1}H NMR data, we feel that **9** can be loosely described as a tris(biphenylenocyclobutadieno)cyclohexatriene.

Perhaps most striking is the observation that **9** is not planar, but (slightly) bowl-shaped, and that the two molecules in the unit cell are stacked in a concave–concave manner (Fig. 3). It is

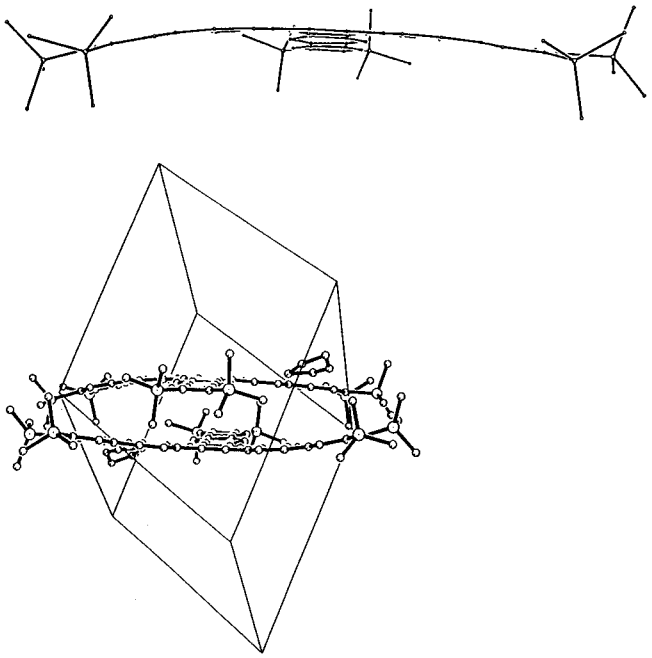

Fig. 3. Side view of a single molecule of **9** (top) and of the unit cell with THF molecules of crystallization (bottom).

difficult to quantitate the extent of deplanarization in **9** in a simple manner, because the planes of neighboring rings are not only bent with respect to each other but also twisted.[12] A best attempt at specifying the degree of curvature is the deviation of the perimeter atoms C15, C16, C27, C28, C39, and C40 from the plane of the central ring A, which varies from 0.20 to 1.08 Å, with a mean value of 0.63 Å. The "arm" A–F is bent the least, very likely because the two molecules are mutually offset along this axis (see Fig. 1). As there are no obvious crystal packing reasons for the observed curving of **9**, it appears that the molecule "voluntarily" adopts a non-flat conformation. Indeed, it is possible that this phenomenon may be general for (some of) the (higher) phenylenes. Thus, while **2** is completely planar,[3] its linear analog appears sinusoidal,[2] and, more significantly, the trigonal **3b** distorts in exactly the same manner as **9**,[4] although crystal packing forces were invoked at the time to explain these observations.

Calculations at the highest level (6-31G*) that can be reasonably performed on **3a** show that symmetrical bending of the planes of the fused cyclobutadienes and benzene rings with respect to the central core is energetically remarkably inexpensive.[17] It is noteworthy in this connection that: 1) one of the molecules in the unit cell of biphenylene is slightly nonplanar, bent by 1.9° (interplanar angle);[14a] 2) the biphenylene nucleus can be forced to deplanarize by [*d*,*e*,*f*]-fusion[18a] and incorporation into a cyclophane framework;[18b] 3) fused benzenoid hydrocarbons are flat, unless forced to exist otherwise by nonbonding interactions[19] or specific annelation as (most dramatically) exemplified by the buckybowls corannulene and semibuckminsterfullerene;[20] 4) there may be a driving force towards deplanarization in phenylenes on enthalpic (accommodation of ring strain and decrease in antiaromatic overlap) and entropic (degrees of freedom) grounds; and 5) should point 4) be borne out by further experiments, it may have ramifications for the stability and hence synthetic accessibility of cyclobutadienoid fullerenes,[21a,b] in particular the spherical phenylenes described by a truncated cuboctahedron, C_{48}, and a truncated icosidodecahedron, C_{120} ("archimedene").[21c]

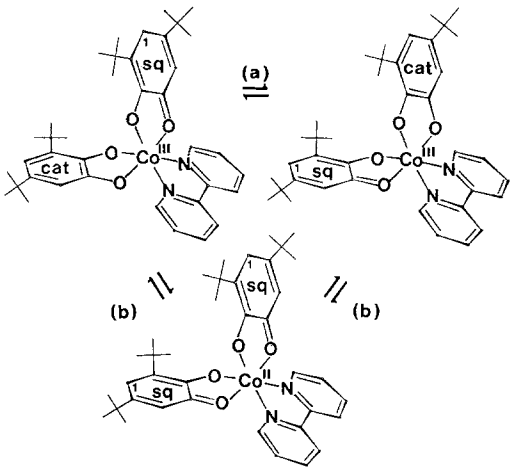
Photoinduced Valence Tautomerism in Cobalt Complexes Containing Semiquinone Anion as Ligand: Dynamics of the High-Spin $[Co^{II}(3,5\text{-dtbsq})_2]$ to Low-Spin $[Co^{III}(3,5\text{-dtbsq})(3,5\text{-dtbcat})]$ Interconversion **

David M. Adams, Bulang Li, John D. Simon,* and David N. Hendrickson*

Cobalt complexes with two semiquinone-derived ligands have been shown[1-3] to undergo a valence tautomeric interconversion between high-spin $[Co^{II}(\overset{\frown}{N\ N})(sq)_2]$ and low-spin $[Co^{III}(\overset{\frown}{N\ N})(sq)(cat)]$ forms, where $\overset{\frown}{N\ N}$ is a chelating diiminium ligand such as 2,2′-bipyridine (bpy). In these molecules, an intramolecular electron transfer converts the high-spin Co^{II} ion to a low-spin Co^{III} ion, and one of the ligands is reduced by one electron from a semiquinone anion ligand (sq^-) to a catecholato (cat^{2-}) ligand. There are two different mixed-valence isomers of the Co^{III} complex. The dynamical processes that are possible for such a valence-tautomeric complex are summarized in Scheme 1.



Scheme 1. Possible intramolecular electron transfer processes present in a cobalt complex with two semiquinone anion ligands.

The valence tautomeric interconversion (process b) can be thermally driven. In solution[1, 3, 4] it occurs gradually over a large temperature range of about 100 K, whereas in the solid state[1, 2] the interconversion can occur abruptly in a range of about 10 K. The valence tautomeric transformation is accompanied by structural changes (bond lengths between the cobalt ion and the ligands) and large changes in the optical and magnetic properties of the complexes. There are two important motivations for studying these cobalt complexes. First, they are excellent model systems for elucidating factors that control intramolecular electron transfer. In particular, the influence of the spin change (low-spin vs. high-spin Co) on electron transfer (Scheme 1, process b) can be explored. Second, these valence

[**] This work was supported by the U. S. National Science Foundation (CHE-9306485 (J. D. S.), CHE-9115286 and CHE-9420322 (D. N. H.)) and the National Institutes of Health (HL13652 (D. N. H.)). 3,5-dtbsq = 3,5-di-*tert*-butylbenzosemiquinone; 3,5-dtbcat = 3,5-di-*tert*-butylcatecholate.

tautomeric complexes could serve as fast optical switching devices.[5, 6]

In this communication we report results of the first picosecond time-resolved optical experiments on valence-tautomeric cobalt complexes. We have studied the Co^{III} complexes **1** and **2**,

[Co(dpbpy)(3,5-dtbsq)(3,5-dtbcat)] **1**

[Co(dmbpy)(3,5-dtbsq)(3,5-dtbcat)] **2**

where dpbpy is 4,4'-diphenyl-2,2'-bipyridine, dmbpy is 4,4'-dimethyl-2,2'-bipyridine, and 3,5-dtbsq$^-$ and 3,5-dtbcat^{2-} are the semiquinone anion and catecholate forms of 3,5-di-*tert*-butyl-1,2-benzoquinone, respectively. Valence tautomeric complexes, like spin-crossover complexes,[7] are particularly suitable for photophysical investigations since the electronic absorption spectra of the ground and the lowest energy excited state can be obtained by varying the temperature. Figure 1 shows the temperature dependence of the spectrum of the dpbpy complex **1** in tetrahydrofuran over the temperature range 298–348 K. The ligand-to-metal charge transfer (LMCT) band at 600 nm, characteristic of the low-spin Co^{III} species, decreases at elevated temperatures and is replaced by the two transitions at 540 nm and 770 nm which are associated with the high-spin Co^{II} species. The transient picosecond "pump/probe" apparatus has been described elsewhere.[8] A pump pulse in the visible range (532 nm, $\approx$70 ps pulse width, 0.2 mJ per pulse) into the LMCT band of the Co^{III} tautomer results in a transient absorption monitored at 720 nm and a corresponding transient bleach monitored at 600 nm. Figure 2 displays the transient curves obtained for a solution of complex **1** in toluene (1.63×10^{-3} M) at 298 K. Least-squares fitting (solid lines) shows that these transients are well described by single-exponential functions with the same time constant, $\tau_{obs}=1.15$ ns. The observation of a bleach and absorption with identical kinetics around an isosbestic point indicates that we are looking at a light-induced population of the high-spin $[Co^{II}(\overset{\frown}{N}\,\overset{\frown}{N})(sq)_2]$ state, followed by relaxation back to equilibrium. It should be noted that valence tautomers are in thermal equilibrium in solution according to Equation (a). Thus the

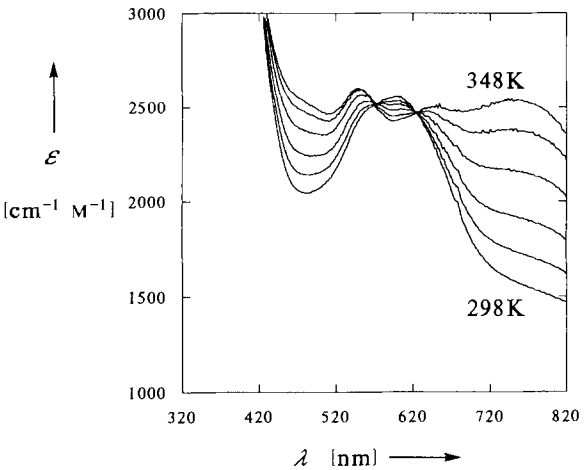

Fig. 1. Temperature dependence of the electronic absorption spectrum of a solution of **1** in tetrahydrofuran at $T=298$, 308, 318, 328, 338, and 348 K. The molar extinction coefficent ε is plotted versus wavelength λ.

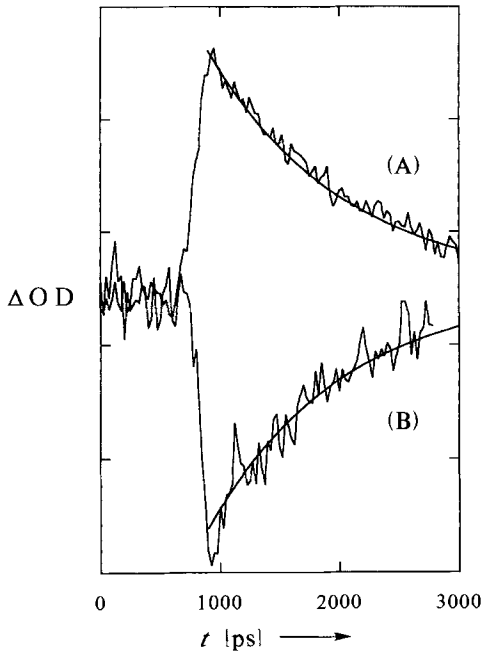

Fig. 2. A) Changes in the transient absorption (ΔOD = difference in absorption) of **1** in toluene at 298 K monitored at 720 nm after excitation at 532 nm. B) Transient bleach monitored at 600 nm after excitation at 532 nm. The solid line represents a least-squares fit to single exponential and gives the value of $\tau_{obs}=1.1$ ns for both data sets.

tautomerization involves a reversible first-order reaction, where $K_{eq}=k_1/k_{-1}$ and $\tau_{obs}=1/k_1+1/k_{-1}$. Since we see no indication of a rise time, the high-spin Co^{II} state is formed within the experimental resolution (70 ps).

The solvent dependence of the valence tautomeric relaxation has been examined. For the dpbpy complex the observed lifetimes of the excited state are 1.1 (toluene), $\approx$2.0 (tetrahydrofuran), and $\approx$10 ns (dichloromethane). Figure 3 shows the traces obtained after photoperturbation ($\lambda_{pump}=532$ nm and $\lambda_{probe}=720$ nm) of solutions of the dpbpy complex in THF (1.09×10^{-3} M) and in CH_2Cl_2 (1.64×10^{-3} M). Variable-temperature UV/Vis spectroscopy of this complex in various solvents suggests that the critical temperature (T_c) of the valence

(a)

tautomeric conversion shifts to lower temperatures in polar solvents.[9] This implies that the zero-point energy difference between tautomers decreases when changing to more polar solvents. The T_c decreases by about 25 K on changing from toluene to THF. Since τ_{obs} in these solvents increases from 1.1 ns to 2 ns, respectively, it would appear that as the driving force decreases the rate decreases. However, it must be kept in mind that τ_{obs} is the sum of $1/k_1$ and $1/k_{-1}$. In order to make quantitative correlations between the driving force and the rate of back valence tautomerization k_{-1}, it is necessary to determine K_{eq}.[10] Solution magnetic susceptibility determinations of K_{eq} are currently in progress.

It has been previously established that the counter-ligand provides a subtle handle for controlling the zero-point energy differences between valence tautomers.[1, 3] We have also investigated the rate of the valence tautomerization of the dmpby complex **2**. This complex is known to have a smaller energy gap between tautomers than the dpbpy complex **1**.[1] The observed lifetime of the excited state for a solution of the dmbpy complex **2** in toluene (1.10×10^{-3} M) at 298 K following photoexcitation ($\lambda_{pump} = 532$ nm and $\lambda_{probe} = 720$ nm) is ≈ 8 ns. Furthermore, we have investigated the kinetics of the dmbpy complex doped into a polystyrene polymer film ($M_w = 250000$) g mol^{-1}).[11] Relative to toluene, the polymer provides a less polar environment for the complex and thus tends to increase the energy separation between the tautomers. Consequently, the observed lifetime of the excited state decreases to about 2 ns. Since similar relaxation behavior is observed in doped polymer films and in solution, it is likely that we are observing a single molecule process.

A relaxation time of 1–10 ns for the valence tautomerization (process b in Scheme 1) is interesting in view of the fact that this process involves separate or concomitant metal-to-ligand electron transfer and a spin change at the cobalt ion. $\Delta S = 2$ spin-crossover relaxation times in solution at room temperature are on the order of 30–150 ns for Fe^{II} complexes and 2–10 ns for Fe^{III} complexes.[12] The spin-crossover transformation for a Co^{II} complex is a $\Delta S = 1$ process where the high- and low-spin states interact through a first-order spin-orbit interaction and short relaxation times are expected. Spin-crossover relaxation times for $[Co(terpy)_2]^{2+}$ (terpy = 2,2′:6′,2″-terpyridine) are reported[13] to be on the order of 0.1 ns. The valence-tautomeric conversion is from a high-spin $Co^{II}(sq)_2$ to a low-spin $Co^{III}(sq)(cat)$ complex, where the latter has an $S = 1/2$ ground state resulting from the single unpaired electron on the one sq^- ligand. There is a very weak[14] magnetic exchange interaction between the sq^- ligands and the $S = 3/2$ high-spin Co^{II} ion. Thus, the $Co^{II}(sq)_2$ complexes have one $S = 1/2$, two $S = 3/2$, and one $S = 5/2$ states in close energy proximity. Since the valence-tautomerization (process b in Scheme 1) is slow relative to spin-crossover in simple Co^{II} complexes, it must be that the intramolecular electron transfer also affects the rate of reaction.

Further studies aimed at understanding the way in which factors such as the driving force, ligands, temperature, and solvent influence the excited state dynamics of these valence tautomeric complexes are currently in progress.

Burial of Hydrocarbon Causes Cooperative Enhancement of Electrostatic Binding**

Gary J. Sharman, Mark S. Searle, Bellinda Benhamu, Patrick Groves, and Dudley H. Williams*

The hydrophobic effect, involving the burial of hydrocarbon formerly exposed to water, provides a major driving force in molecular recognition, and is fundamental to our understanding of the structure and function of biological systems. The desire to rationalize the forces involved in molecular complexation[1, 2] and the stabilization of highly ordered molecular assemblies[3, 4] has led to attempts to correlate the magnitude of the hydrophobic free energy with the nonpolar surface area no longer accessible to solvent.[5] This approach potentially provides a useful

numerical estimate for assessing binding contributions in molecular recognition studies.[2, 4, 6] However, data from protein engineering experiments[4, 6] and ligand binding studies[2] suggest that the hydrophobic effect promotes binding in aqueous solution to a larger extent than is estimated from solvent transfer measurements.[7] An explanation for this discrepancy has been sought, at least partially, in terms of changes in volume entropy in the two sets of experiments.[7] In the present work we show that burial of hydrocarbon in a molecular recognition site can lead to the strengthening of adjacent electrostatic interactions.

The electrostatic binding of a peptide C-terminal carboxylate group, an interaction crucial to cell wall recognition by glycopeptide antibiotics, is conveniently monitored through the ^{1}H NMR chemical shifts of several glycopeptide backbone NH groups (w_2 and w_3 in Fig. 1), which undergo large downfield

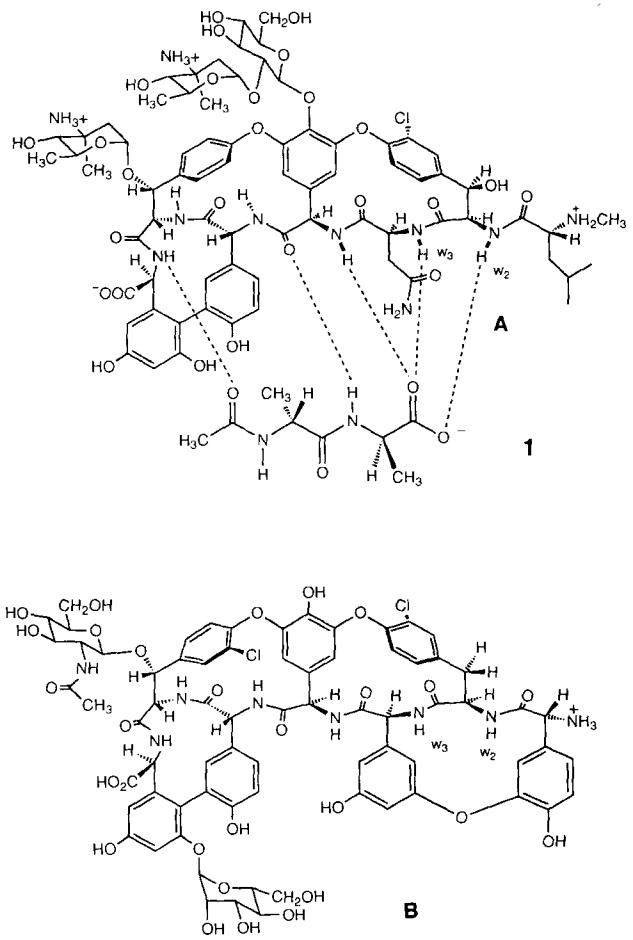

Fig. 1. Structures of eremomycin (**A**) and teicoplanin A_3-1 (**B**). An exploded view of the complex of eremomycin with the dipeptide cell wall analogue *N*-Ac-D-Ala-D-Ala is shown. Dotted lines represent hydrogen bonds.

shifts in the presence of cell wall peptides (up to $\Delta\delta \approx 3.5$ for w_2). In studies with the antibiotics eremomycin (**A**) and teicoplanin A_3-1 (**B**) (Fig. 1),[8] we have systematically deleted ligand methyl interactions through the synthesis of a series of Gly- and D-Ala-containing dipeptides (Fig. 2) and measured their binding properties.[9] Each alanine methyl group buries hydrocarbon surface area from solvent;[10] the increase in dipeptide binding affinity can be accounted for in terms of contributions from the classical hydrophobic effect and possibly van der Waals interactions that are stronger in the complex than

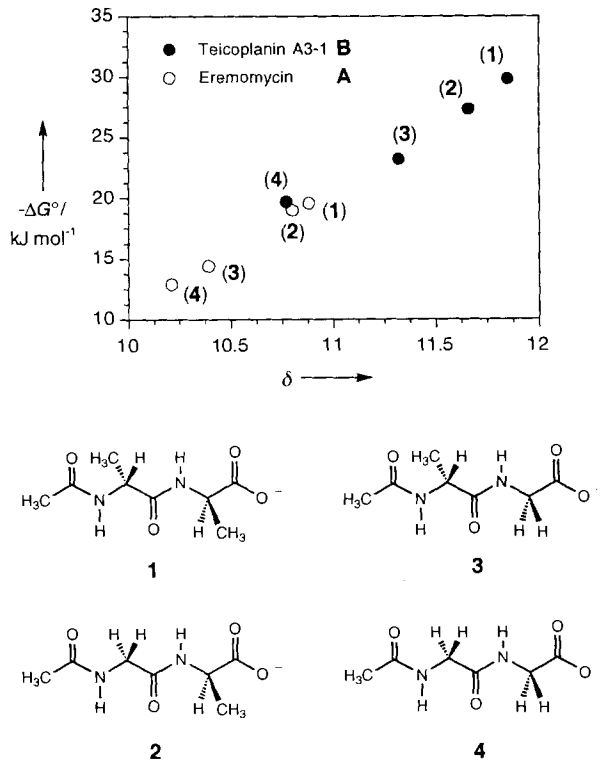

Fig. 2. Dipeptide ligands considered in this study. Plot of ligand binding energy ΔG° (pH 4.5, 298 K) to eremomycin (**A**) and teicoplanin A_3-1 (**B**) versus limiting ^{1}H NMR chemical shift of amide NH group w_2. For eremomycin the limiting chemical shift represents the average of the w_2 shifts in the two nonequivalent dimer binding sites that differ by $\Delta\delta < 0.1$. Errors in ΔG° values are less than reflected in the size of the data points.

with solvent. Each dipeptide in the series (Fig. 2) shares a completely analogous set of hydrogen bonding interactions with the glycopeptide. Molecular modeling studies of all the complexes, based upon NOE data, establish that the hydrogen bonding arrangements of the bound ligands do not vary significantly, nor do the structures of the antibiotics, which are relatively inflexible on account of extensive cross-linking of aromatic amino acid side chains (Fig. 1). Thus, there are no clear changes in binding geometries or antibiotic structure that are likely to result in significant differences in the observed ^{1}H NMR chemical shifts of w_2 amongst the various ligands. Indeed ^{13}C NMR data have recently been used to show that a wide range of ligands bearing carboxylate groups all bind with similar arrangements.[11] We conclude that the strength of the carboxylate binding interaction is reflected in the limiting NMR chemical shift of w_2 (at ligand concentrations in which <95% of the antibiotic is bound), and this has been monitored as a function of the overall ligand binding energy ΔG° (Fig. 2). It is evident that as ΔG° becomes more negative, through the introduction of alanine methyl groups, the limiting shift of w_2 (and w_3, not shown) also increases. We interpret the change in limiting shift of w_2 as reflecting a structure with binding interactions over shorter distances,[12] such that a cooperative enhancement of the electrostatic binding energy of the carboxylate group arises through the burial of hydrocarbon in an adjacent site. Thus, when the restriction of motion of the carboxylate group is aided by the burial of hydrocarbon, or through other electrostatic interactions such as hydrogen bonds, as previously described,[13] then on average the carboxylate group will occupy a deeper position in its electrostatic (enthalpic) well corresponding to a greater binding exothermicity.[14]

These observations may account for the fact that the burial of hydrocarbon appears to give a larger free energy change when measured in systems in which the hydrocarbon is "anchored" into a molecular recognition site than in the solvent transfer model, where translational and rotational freedom is unaffected.[7] While protein engineering experiments[4, 6] and ligand binding studies[2] have indicated surface area dependent free energy contributions from burial of hydrocarbon of 0.19–0.25 kJ mol^{-1} Å^{-2}, the value from the solvent transfer model is approximately half this value, 0.08–0.13 kJ mol^{-1} Å^{-2}.[7, 15] One possible explanation for this discrepancy is suggested by the above results: the introduction of the hydrocarbon entity may strengthen adjacent polar interactions, such that the burial of hydrocarbon in experiments with proteins[4, 6] and antibiotics[2] may derive some favorable free energy increment (over that of the solvent transfer model) through an electrostatic (enthalpic) term, whereas the solvent transfer portion (the classical hydrophobic effect) is essentially entropy-driven at room temperature.[15] We have shown that this is the case for one specific neighboring interaction, but the extra binding energy is likely to arise from a cooperative enhancement of all interactions.

The results presented suggest that the assignment of enthalpic contributions to specific interactions (implied through changes in ^{1}H NMR chemical shifts) are subject to cooperative enhancement. By monitoring a specific binding interaction, we have illustrated a cooperative interplay between hydrophobic and electrostatic contributions to binding in a molecular recognition site.

[8] Glycopeptide antibiotics have been shown to dimerize in aqueous solution: J. P. Waltho, D. H. Williams, *J. Am. Chem. Soc.* **1989**, *111*, 2475; U. Gerhard, J. P. Mackay, R. A. Maplestone, D. H. Williams, *ibid.* **1993**, *115*, 232; J. P. Mackay, U. Gerhard, D. A. Beauregard, R. A. Maplestone, D. H. Williams, *ibid.* **1994**, *116*, 4573. This dimerization has been proposed to play an important role in mediating biological activity: J. P. Mackay, U. Gerhard, D. A. Beauregard, M. S. Westwell, M. S. Searle, D. H. Williams, *ibid.* **1994**, *116*, 4581. To show that the observed trends in w_2 ^{1}H NMR chemical shifts are independent of the ability of the antibiotics to dimerize, we present results for both eremomycin (**A**) and teicoplanin A_3-1 (**B**). The former has a large dimerization constant ($K_{dim} \approx 10^6$ M^{-1}), while the latter shows no measurable tendency to dimerize. In addition, dimerization of eremomycin and ligand binding are cooperative phenomena; K_{dim} is roughly a factor of 100 greater in the presence of ligands.
[9] Binding constants were measured in triplicate by UV difference spectroscopy at antibiotic concentrations between 50 and 200 μM at pH 4.5 and 298 K in 100 mM sodium phosphate/1 M NaCl buffer. NMR spectra were recorded in 90% H_2O/10% D_2O solution using a 1-1 binomial solvent suppression sequence; exchangeable protons were assigned in all cases using 2D NOE experiments.
[10] Cell wall analogues are bound within a shallow surface cleft on the antibiotic such that the deletion of methyl groups (Ala → Gly) results in exposure of the previously buried hydrocarbon of the antibiotic to solvent, rather than creating a vacant cavity.

[14] It is of course also true that the peptide ligands containing one or more methyl groups will be less flexible than those containing only Gly residues. However, the term "burial of hydrocarbon" must include changes in flexibility in the bound state as well as the classical hydrophobic effect since the variables are inseparable.

Novel, Blue-Transparent Frequency Doublers Based on 1,8-Di(hetero)arylnaphthalenes**

André Bahl, Walter Grahn,* Stefan Stadler, Franz Feiner, Grant Bourhill, Christoph Bräuchle, Axel Reisner, and Peter G. Jones

Dedicated to Professor Wolfgang Lüttke on the occasion of his 75th birthday

Nonlinear optics (NLO)[1] has become a focus of attention for material scientists in the expectation that revolutionary progress will be associated with the transition from electronics to photonics.[2] The preparation of many photonic devices requires materials with high non-linear optical susceptibilities χ[2], which on the molecular level depend on the first hyperpolarizability β. A series of organic compounds have shown themselves to be particularly suitable in terms of their high β values, and other positive properties such as low optical loss and facile handling.[1c, 3]

A technically important application of NLO is frequency doubling, [second harmonic generation (SHG)] for example, of light of wavelengths 800–830 nm (working wavelengths of diode lasers).[4] Materials that are to exploit this process effectively must simultaneously be transparent at 830 (λ) and 415 nm ($\lambda/2$) and display high NLO activity.[5] However, the necessary high β values—consistent with predictions based on the usual models[6]—have so far only been observed for NLO-(chromo)phores of the charge transfer (CT)-type **1**, which ab-

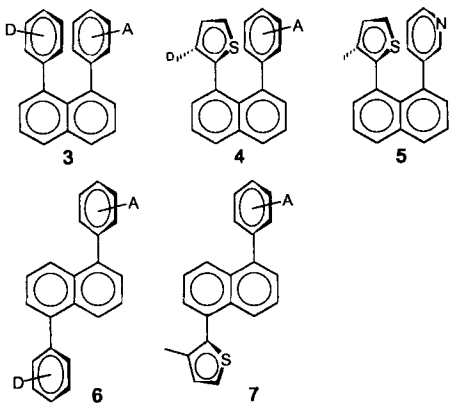
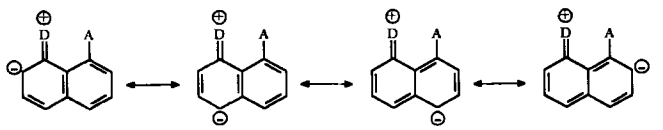
sorb at long wavelengths.[7] Despite many promising developments[5a, 8] it has not yet proved possible to find an optimal compromise between the linear and nonlinear optical properties for the conventional NLO-phores (**1**).

We have decided on a fundamentally different approach to the improvement of the efficiency–transparency trade-off,[5b] by choosing the basic structure **2**, thus avoiding a direct conjugation between the donor (D) and acceptor (A). Compounds of this type are distinguished by higher energy electronic transitions and offer potential noncovalent interactions between the opposing surfaces of the D/A π-electron systems.[9] Through-space interactions have scarcely been investigated or realised as a basis for NLO activity,[10] although quantum-chemical calculations by Ratner, Marks, et al. indicate that CT complexes should be NLO-active.[11]

As the subject of our investigations we have chosen the 1,8-di(hetero)arylnaphthalenes **3**–**5** in which one aryl substituent is rendered electron-rich by an electron donor and/or heteroarene,



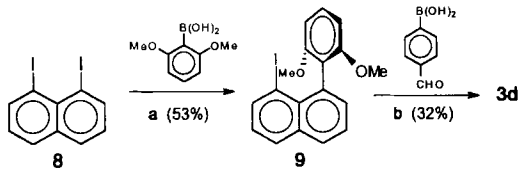
while the other has reduced electron density as a result of an electron-withdrawing group or heteroarene. The 1,5-di(hetero)-arylnaphthalenes **6** and **7** are suitable reference compounds, since like **1** they may display conjugative CT through the π-electron system, which is not possible with a 1,8 substitution pattern of naphthalene (Scheme 1).



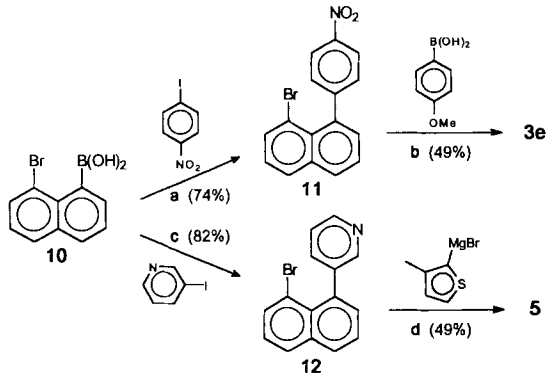
Scheme 1. Resonance structures of 1,8-disubstituted naphthalenes.

Few 1,8-di(hetero)arylnaphthalenes are known, consistent with the lack of a general synthesis. The preparation of known derivatives[12] cannot be generalized, because the methods either do not allow an unsymmetrical functionalization and/or greatly restrict the range of substituents.

The Suzuki reaction[13] provides a method of aryl–aryl cross-coupling with a wide range of applications. 1,8-Diiodonaphthalene (**8**)[12g] can be selectively transformed into the corresponding 8-aryl-1-iodonaphthalenes such as **9** by Pd-catalyzed coupling with an aryldihydroxyborane (Scheme 2 reaction a). These, and their bromo analogues, react smoothly with another (different) arylboronic acid (in spite of considerable steric hindrance) to form **3** (Scheme 2 reaction b and Scheme 3 reaction b). Such consecutive Suzuki couplings were used to synthesize



Scheme 2. Synthesis of **3d**: a) [Pd(PPh$_3$)$_4$], NaHCO$_3$, benzene/EtOH/H$_2$O, reflux; b) as a), but Na$_2$CO$_3$ as base in toluene/EtOH/H$_2$O.



Scheme 3. Synthesis of **3e** and **5**: a–c) [Pd(PPh$_3$)$_4$], Na$_2$CO$_3$, toluene/EtOH/H$_2$O, reflux; d) [NiCl$_2$(dppp)] (dppp = 1,3-bis(diphenylphosphano)propane), Et$_2$O/THF, 0 °C, then heated at reflux.

most of the unsymmetrically substituted diarylnaphthalenes such as **3a**–**d**.

Problems with the preparation and stability of some arylboronic acids led us to incorporate the organometallic function into the naphthalene coupling component. This "Umpolung" is typified by the synthesis of 1-(8-bromonaphthyl)dihydroxyborane (**10**),[14] a key compound in the general synthesis of 1,8-di(hetero)arylnaphthalenes. As an example, **10** can be monoarylated with 1-iodo-4-nitrobenzene or 3-iodopyridine to form **11** or **12** in good yield (Scheme 3 reaction a or c).

Compound **5** is best prepared by Grignard cross-coupling of **11** with 2-(3-methylthienyl)magnesium bromide (Scheme 3 reaction d), since in this case no functional groups restrict the use of organomagnesium compounds.

The X-ray structure analysis of **3e**[15] (Fig. 1) shows that both phenyl rings subtend an angle of 62.6° with the plane of the naphthalene. Similarly high torsion angles are observed in other diarylnaphthalenes[16] and lead to the face-to-face arrangement of the π-electron systems indicated in general structure **2**. The very close approach of the two phenyl rings in 1,8 arrangement is noteworthy: the value of 298.5 pm (C9–C18) is smaller than in 1,8-diphenylnaphthalene (299.3 pm) and markedly smaller than the van der Waals distance for parallel aromatic systems (about 340 pm).[16b]

Characteristic for this arrangement of the aryl rings are the significant high-field shifts ($\Delta\delta$ = 0.5–0.6 for various **3**) of the ^{1}H NMR signals of both 1,8-aryl substituents relative to those for corresponding 1-arylnaphthalenes. This effect, which has been attributed to an electronic interaction, is also observed for the paracyclophanes, with analogous arrangement of aryl rings (stereological[17a] molecules),[17b] and similar compounds.[12]

The lack of D/A conjugation means that compounds of the type **3**–**5** have relatively small dipole moments. This property, together with possible D–A/D–A stacking, tends to favor the formation of acentric structures. Thus **3e** crystallizes in the noncentrosymmetric space group $P2_1$,[15] which confers a

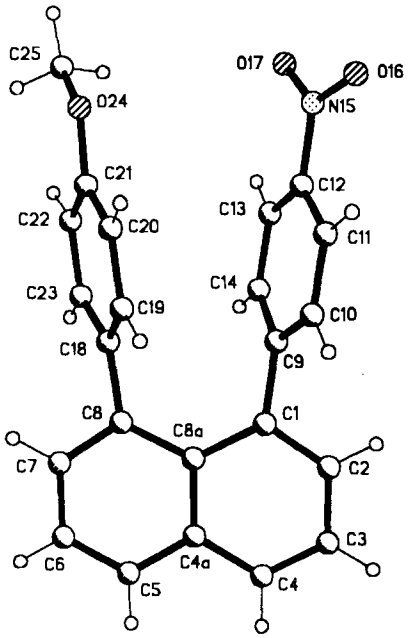


Fig 1. Crystal structure of **3e** [15]. Selected distances [pm]: C1–C8 257.7(5), C4–C5 243.1(5), C9–C18 298.5(4), C12–C21 377.9(5). Interplanar angles [°]: C1–C8a/C9–C14 62.56(10), C1–C8a/C18–C23 62.65(9).

macroscopic nonlinearity upon the crystals and renders them candidates for a frequency-doubling function.

The β values of compounds **3**–**7**[18] (presented in Table 1) were measured by means of hyper-Rayleigh-scattering (HRS),[19] since this method covers all components of the β tensor.

Table 1. Longest wavelength absorption maxima λ_{max} with extinction coefficients ε_{max} and transparency limits ($\lambda_{cut\ off}$) in $CHCl_3$, and first hyperpolarizibilities β (HRS measurements at 1064 nm in $CHCl_3$) for **3**–**7**.

No.	A [a]	D [a]	λ_{max} [nm]	$\lambda_{cut\ off}$ [nm]	ε_{max}	$10^{30} \times \beta_{HRS}$ [c] [esu]

	PNA [b]		350	428	14200	17

[a] In the 4-position, if not otherwise indicated. [b] Paranitroaniline (PNA) served as external reference. [c] Error limits approximately ± 15%.

Apart from the nitroarene **3e**, all 1,8-diarylnaphthalenes **3**–**5** display the necessary transparency ($\lambda_{cut-off} < 380$ nm) and are markedly more NLO-active than the colored *p*-nitroaniline (PNA). Compounds **4a** and **4c** display the highest β values (44 and 42×10^{-30} esu, respectively), which are those of the highly active blue-transparent representatives of the conventional NLO-systems **1** (40,[8a] 60[5a] and $80^{[8c]} \times 10^{-30}$ esu).

In order to increase the molecular hyperpolarizability β of **3** and **4**, the most promising D/A combinations according to the "two-level" model[6] were tested: the linear optical properties show the expected dependency on the D/A strength. The methoxy derivatives **3b** and **3e** show that a stronger acceptor (**3b**: CN, **3e**: NO_2) leads, as expected, to bathochromism and increased extinction. In contradiction of the accepted structure–property relations[17] for NLO-phores of type **1** and of the two-level model, the nonlinear optical properties are, however, scarcely affected.

In this context it is remarkable that the CT bands in the UV/Vis spectra of **3**–**5** are always overlapped, never isolated. If a transannular $\pi-\pi$ interaction of the two 1,8-aryl rings is nevertheless (partly) responsible for the observed NLO activity, the 1,8-diarylnaphthalenes should be more NLO-active than the comparably substituted 1,5-isomers! Despite a clear hypso- and hypochromism of their light absorption, compounds **3b** and **4d** do indeed display considerably higher β values than their *conjugated* analogues **6** and **7b**.

Because of their high nonlinearity, transparency, and thermal stability, the novel NLO-phores **3**, **4**, and **5** represent fascinating alternatives to the conventional extended conjugated systems **1** for the development of blue-transparent frequency-doubling devices. We hope that our newly won knowledge of these chromophores and the corresponding models will enable us to achieve still higher efficiencies β without reducing transparency.

Experimental Procedure

All reactions were carried out under a N_2 atmosphere [18].

10: A solution of **9** (1.25 g, 5.00 mmol) [14], 1-iodo-4-nitrobenzene (1.49 g, 6.00 mmol), Na_2CO_3 (1.27 g, 12.00 mmol), and $[Pd(PPh_3)_4]$ (173 mg, 0.17 mmol) in a mixture of toluene (15 mL), ethanol (15 mL), and water (10 mL) was heated at reflux for 48 h. The mixture was then freed from solvent, taken up in $CHCl_3$, washed three times with 1 M NaOH and once with water, and dried over Na_2SO_4. Chromatography on 180 g silica gel (Merck KG-60 Art. No. 7734, $CHCl_3$) gave **10** as the second fraction; it was recrystallized analytically pure from *n*-hexane. Yield 1.21 g (74%). M.p. 124 °C.

11: As for **10**, starting from **9** (1.25 g, 5.00 mmol) and 3-iodopyridine (1.23 g, 6.00 mmol), but taken up in Et_2O and extracted with 1 M HCl. The aqueous phase was made alkaline with 2 M NaOH, taken up again in Et_2O, dried over K_2CO_3, and the solvent was removed in vacuo. Kugelrohr distillation (180 °C/0.3 mbar) yields **11** (82%) as a colorless, viscous oil (1.17 g).

3e: A solution of **10** (0.64 g, 2.00 mmol), (4-methoxyphenyl)dihydroxyborane (0.47 g, 3.00 mmol), Na_2CO_3 (0.64 g, 6.00 mmol), and $[Pd(PPh_3)_4]$ (69 mg, 0.06 mmol), in a mixture of toluene (6 mL), ethanol (6 mL), and water (4 mL) was heated at reflux for 48 h. Workup as for **10** gave, after TLC (silica gel KG-60, $CHCl_3$, third fraction) and recrystallization (*n*-hexane with a little ethyl acetate), 0.35 g (49%) of yellow crystals, m.p. 183–184 °C; ^{1}H NMR: δ = 8.90 (dd, ^3J = 8.2, ^4J = 1.4 Hz, 1H; 4-H), 7.95 (dd, ^3J = 8.2, ^4J = 1.4 Hz, 1H; 5-H), 7.73 (AA'XX', N = 8.8 Hz, 2H; 17/19-H), 7.58 (m, 1H; 6-H), 7.56 (m, 1H; 3-H), 7.44 (dd, ^3J = 7.1, ^4J = 1.4 Hz, 1H; 7-H), 7.37 (dd, ^3J = 7.1, ^4J = 1.4 Hz, 1H; 2-H), 7.07 (AA'XX', N = 8.8 Hz, 2H; 16/20-H), 6.84 (AA'XX', N = 8.7 Hz, 2H; 10/14-H), 6.47 (AA'XX', N = 8.7 Hz, 2H; 11/13-H), 3.63 (s, 3H; OCH_3); ^{13}C NMR: δ = 158.4 (C-12), 150.3 (C-15), 145.5 (C-18), 139.5 (C-8), 138.0 (C-1), 135.4 (C-4a), 131.0 (C-10/14) 131.0 (C-7), 130.9 (C-2), 130.4 (C-16/20), 130.0 (C-4), 129.3 (C-8a), 128.5 (C-5), 125.7 (C-6), 125.0 (C-3), 122.1 (C-17/19), 113.1 (C-11/13), 55.3 (OCH_3).

6: A solution of 2-(3-methylthienyl)magnesium bromide (from Mg turnings (0.15 g, 6.3 mmol) and 2-bromo-3-methylthiophene (1.02 g, 5.7 mmol) in diethyl ether (12 mL)) was added at 0 °C over 15 min to a suspension of **11** (0.82 g, 2.9 mmol) and $[NiCl_2(dppp)]$ (31.2 mg, dppp = 1,3-bis(diphenylphosphano)propane) in Et_2O/THF (1:1, 20 mL). After 1 h at room temperature with constant stirring, the mixture was heated at reflux for 4 h. After hydrolysis with NH_3/NH_4Cl and removal of solvent by distillation, the residue was taken up in Et_2O, washed with NH_3/NH_4Cl solution and water, dried over K_2CO_3, and the solvent again removed by distillation. Column chromatography (80 g basic Al_2O_3 Act. 1; $CHCl_3$) gave **6** as the third fraction; it was recrystallized from *n*-hexane. Yield 430 mg (49%) of yellowish crystals, m.p. 125.5 °C; ^{1}H NMR ($CDCl_3$): δ = 8.53 (m), 8.31 (m), 8.27 (m), 7.97 (m), 7.95 (m), 7.55–7.51 (m), 7.47 (m), 7.30 (m), 7.25 6.86 (m), 6.32 (m), 6.31 (m), 1.76 (s), 1.69 (s); ^{13}C NMR ($CDCl_3$): 24 signals in the range δ = 150.5–121.1.

Yellow prism $0.9 \times 0.8 \times 0.8$ mm, Siemens P4 diffractometer, 3479 intensities to $2\theta_{max}$ 50°, 3250 independent. Structure solution: direct methods. Structure refinement: anisotropic on F^2 (program SHELXL-93, G. M. Sheldrick, University of Göttingen); H atoms with riding model; $wR(F^2)$ 0.094, with conventional $R(F)$ 0.042, for 489 parameters and 505 restraints; max. $\Delta\rho$ 163 e nm^{-3}. The structure could also be solved and refined in the orthorhombic space group $P2_12_12_1$; the apparent higher symmetry must, however, be regarded as pseudosymmetry, because the β angle deviates too far from 90° (in general, maximum deviations from genuine 90° angles are about 0.02°). To check the cell constants, those of another crystal were measured on a different diffractometer at −130 °C: β was 90.14(2)°. The assumption of a genuine deviation from orthorhombic symmetry was thus strengthened, but routine diffractometer measurements will probably not give unambiguous proof. Further details can be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-401564.

The Active Sites of the Native Cytochrome-c Oxidase from Bovine Heart Mitochondria: EXAFS-Spectroscopic Characterization of a Novel Homobinuclear Copper Center (Cu_A) and of the Heterobinuclear Fe_{a3}-Cu_B Center**

Gerald Henkel,* Arnd Müller, Stefan Weissgräber, Gerhard Buse, Tewfik Soulimane, Guy C. M. Steffens, and Hans-Friedrich Nolting

Cytochrome-c oxidase [E. C. 1.9.3.1] catalyzes the reduction of molecular oxygen to water in the respiratory chain and converts the redox energy to an electrochemical proton potential across the plasma or mitochondrial membrane. Owing to its important function, the metalloenzyme has been the subject of numerous investigations. The membrane-spanning protein is composed of 13 subunits and contains in addition to two heme-A groups (Fe_a and Fe_{a3}) two copper centers (Cu_A and Cu_B) as well as a zinc and a magnesium ion. While the Cu_A center has been shown to act as the primary electron acceptor, the catalytic reduction of oxygen takes place at the binuclear center Fe_{a3}-Cu_B.[1]

According to the results of homologous classifications of numerous sequences from subunit II and molecular biological studies of the expressed soluble Cu_A domain from *Paracoccus denitrificans*, the amino acid ligands for the Cu_A center are most probably two histidine and two cysteine residues. In addition, one methionine residue is also conserved.[2, 3] The precise copper content of the protein was not established until quite recently. Whereas earlier assumptions proposed that the native enzyme contained two copper ions, Buse and co-workers were recently able to demonstrate the presence of a third, specifically bound copper ion.[4] After a short and somewhat controversial discussion in the literature (see e.g. ref. [5]), the existence of the third copper ion is now considered to be correct.[6] EPR studies indicate its presence as an integral constituent of the Cu_A center.[7, 12] On the basis of the results of a recent EXAFS (EXAFS = extended X-ray absorption fine structure) investigation on the expressed soluble Cu_A domain from subunit II of the caa_3-cytochrome-c oxidase from *Bacillus subtilis* and on a mixed-valence reference complex, the authors proposed a binuclear center containing a direct copper–copper bond without any bridging ligands.[8, 9]

In an attempt to characterize the metal centers, we performed high-resolution X-ray absorption measurements in the K edge regions of copper, iron, and zinc by using intact preparations of cytochrome-c oxidase from bovine heart mitochondria. They were shown to contain three copper and two iron atoms as well as one zinc and one magnesium atom by precise metal content analyses (ICP-AES). In this paper we report the analysis of the EXAFS regions of the copper and iron edges. The experimentally determined EXAFS functions are shown in Figure 1.

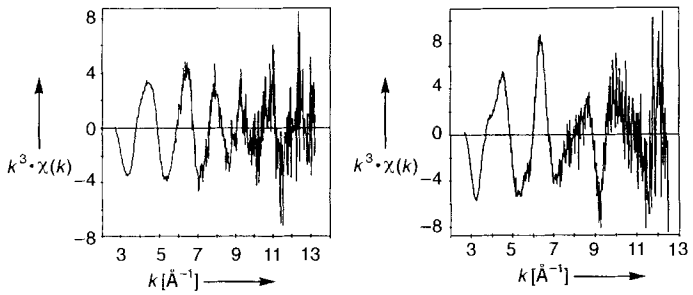

Fig. 1. Left: Experimental copper EXAFS (k^3-weighted); right: Experimental iron EXAFS (k^3-weighted).

Based on the results of the curve fitting procedure, the Cu_A center of the intact cytochrome-c oxidase from bovine heart mitochondria is a novel homobinuclear complex with a copper–copper distance of 2.46 Å. Though the enzyme has already been the subject of several EXAFS investigations,[10] a backscatterer contribution in the range between 2.4 and 2.7 Å has only been reported in connection with measurements on membrane-oriented layers.[10k] This contribution was assigned to a copper–methionine interaction; at the time the Cu_A center was thought to be mononuclear.

In order to evaluate the data, the copper EXAFS (Fig. 1, left) was Fourier-filtered in the distance range between 1.45 and 4.35 Å. The characteristic Fourier transform observed in this region could be modeled with an appropriate set of ligand atoms taking multiple scattering effects into account (see Fig. 2c and 2d).

During the initial steps of the structure refinement based on the Fourier-filtered EXAFS function, the first coordination sphere of Cu was modeled with a ligand set composed of nitrogen and sulfur donor atoms at distances of about 1.98 and 2.30 Å, respectively. Inspection of the Fourier transform, revealed an additional significant backscatterer at a distance of about 2.5 Å. The backscattering contributions at about 3 and 4 Å (see Fig. 2) were also not covered by this model. They are characteristic features of complexes with coordinated five-membered imidazole-type rings, representing the backscattering contributions of the α-carbon atoms (at ca. 3 Å) and the sum of the contributions of the atoms in β-positions (carbon and nitrogen atoms) and of multiple scattering effects within the five-membered ring (at ca. 4 Å).[11] The introduction of a total of three coordinating histidine groups in the structural model led to a distinct improvement of the fitting result. However, the deficiency in the backscattering density at 2.5 Å in the Fourier transform remains (Fig. 2a and 2b). The modeling of this contribution is best achieved with the phase and amplitude functions of a scatterer from the series of electron-rich 3d metals. Since in our opinion the metal–metal distance within the binuclear Fe_{a3}–Cu_B center must be at least 1 Å longer than 2.5 Å due to the steric shielding of the iron atom by the porphyrin ring, only copper is suitable as the backscatter atom in this case. A further convincing argument for this interpretation can be derived from the occupation numbers, which clearly favor a total of two copper–copper interactions (fit-index 0.234) over only one copper–iron contact. The refinement of the complete structural model results in a copper–copper distance of 2.46 Å.

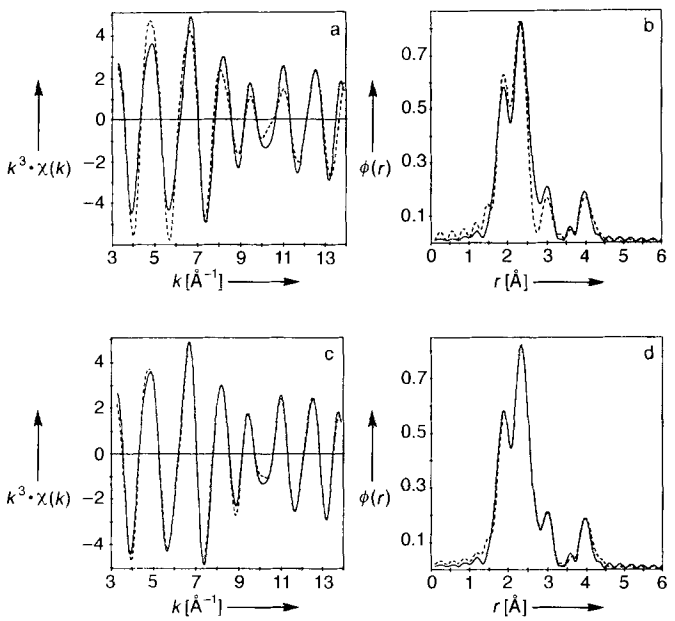

Fig. 2. a) Fourier-filtered copper EXAFS (solid line) and theoretically fitted curve (three histidine residues, four N/O and five S/Cl donor functions, dashed line) and b) corresponding Fourier transform (solid line: experiment; dashed line: model); fit-index: 1.262; c) Fourier-filtered copper EXAFS and theoretically fitted curve as in Fig. 2a, but including additional copper and iron backscatterer contributions (complete model, see Table 1) and d) corresponding Fourier transform; fit-index: 0.176.

Attempts to fit this contribution with an additional sulfur instead of a nitrogen atom led to a negative Debye–Waller factor (Cu–S = 2.60 Å, $2\sigma^2 = -0.004$ Å^2). Combined with the slightly worse fit-index of 0.255, the physically not meaningful value clearly supports a model with an electron-rich 3d transition metal backscatterer in accordance with our interpretation as copper atom. However, the existence of an additional, weakly bonded methionine residue in a distance range from about 2.6 to 3.1 Å cannot be ruled out completely as its contribution would be masked by the copper in this constellation.

In order to account for a backscattering contribution to the peak at 4 Å not yet considered, the structural model was completed by addition of an iron atom at a distance of about 3.9 Å from the copper atom. The final structural model consists of a set of backscatterers of the type O and/or N, a set of imidazole fragments from the histidine residues, a set of sulfur atoms from the cysteine residues as well as a set of copper and iron atoms in the local environment of the copper atoms. It should be mentioned that possible backscattering contributions of chloro ligands are modeled by the sulfur ligand shell due to very similar amplitude and phase functions (Fig. 2c and 2d).

During the final cycles of the structure refinement, the occupation numbers of the individual coordination spheres were varied in integral units under preservation of the coordination number four. For each set of possible occupation numbers generated, a common value for E_0, the distances of the individual shells from the central atom as well as their averaged Debye–Waller factors were refined taking multiple scattering effects into account. During the refinements, the imidazole rings were treated as rigid groups. The results for the set with the best fit index are listed in Table 1.

The interpretation of the results is complicated by the fact that the Cu EXAFS is a superposition of the contributions from all three copper atoms. On average, each copper atom has four directly bonded ligands, and a total of five copper–sulfur(chlorine) interactions is observed.

According to sequence classifications[2] and investigations by Lappalainen and Saraste,[3] two cysteine and two histidine residues are available to bind to copper in the homobinuclear center Cu_A. The conserved methionine residue probably does not belong to the first coordination sphere of copper.[3] Since

Table 1. Results of the curve fitting procedure for the Fourier-filtered EXAFS data of the copper K edge [a].

Shell	Occupation number	Distance [Å]	Debye–Waller factor [Å^2]

N_{His}	1.00 (3/3)	4.11	0.015
C_{His}	1.00 (3/3)	4.21	0.034

[a] The occupation number is normalized to one copper atom (total coordination number four); the atoms of the histidine residues are refined as a rigid unit; estimated error in distances: 0.03 Å.

five Cu–S(Cl) bonds are detected in this study, both cysteine residues within the Cu_A center must be present as bridging ligands, because the coordination of Cu_B is dominated by N and/or O donor ligands in accordance with its redox properties as a high-potential center ($E_{1/2}$ ca. 0.34 V). As the Cu_A center is the primary electron acceptor which transfers an electron to the active site, the native enzyme could contain mixed-valence $Cu^{1.5+}$ centers. Evidence for this hypothesis was recently found by comparative EPR investigations of N_2O reductase and cytochrome-c oxidase,[12] thus a tetrahedral ligand environment of both copper atoms is assumed to be most likely.

The surprisingly short Cu···Cu distance within the binuclear Cu_A center raises the question of a plausible structural model for the complete homobinuclear complex. In fact, synthetic binuclear copper compounds with mixed tetrahedral sulfur–nitrogen ligand spheres and comparably short copper–copper distances are unknown to date.[9] To our knowledge there is only one binuclear complex of a 3d metal with tetrahedral coordination and alkanethiolato bridges known so far, where the metal–metal distance is shorter than 2.5 Å. This is the complex ion $[Co_2(SC_3H_7)_5]^-$, in which the two MS_4 tetrahedra share a common face.[13] Since the metal–metal distances in similar complexes with coordination tetrahedra sharing common edges are invariably longer,[14] we propose a structural unit that contains a third bridging function in addition to the two cysteine bridges as the model for the homobinuclear Cu_A center of cytochrome-c oxidase. This third bridge could be the oxygen atom of a water molecule or of an aspartic acid residue, which invariably occurs in the peptide sequence at a suitable position. The tetrahedral coordination of each copper atom is completed by two terminally bonded histidine residues leading to an ideally linear N–Cu···Cu–N chain. The proposed structural model is shown in Figure 3. The short Cu···Cu distance does of course not rule out a direct metal–metal bond. However, magnetic investigations on $[Co_2(SC_3H_7)_5]^-$ and on its selenium-substituted counterpart, $[Co_2(SeC_3H_7)_5]^-$, indicate that the unpaired 3d electrons are coupled through superexchange mechanisms and not through direct metal–metal bonds.[15]

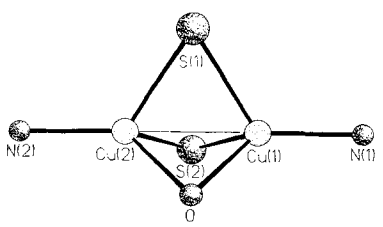

Fig. 3. Model for the homobinuclear Cu_A center of the cytochrome-c oxidase from bovine heart mitochondria (ball and stick model).

Accordingly, one histidine residue, one sulfur or chlorine, and two nitrogen and/or oxygen donor functions remain available for the coordination of copper within the Cu_B center. However, we cannot rule out the possibility that one of the remaining nitrogen or oxygen donor functions belongs to another histidine residue. The interpretation is not completely conclusive in this respect, since similar fit indices result for the alternative structural models. We favor the model with a total of three imidazole residues because the Debye–Waller factors of the ring atoms in β positions are of an order comparable to those of the α carbon atoms.

The Cu EXAFS yields a copper–iron distance of 3.89 Å. This value corresponds to that one expected for a tetrahedrally coordinated copper site linked to a heme unit through a ligand bridge. The bridge most probably is a sulfur or chlorine atom, since a corresponding iron–sulfur or iron–chlorine contact could be identified on evaluating the fine structure of the iron edge.

Different interpretations of the copper EXAFS have led to contradictory descriptions in the literature about the copper–iron distance within the Fe_{a3}-Cu_B center of cytochrome-c oxidase. The value derived by Powers et al. is 3.8 Å,[10a] while the distance found by Scott et al. (3.0 Å) is considerably shorter.[10f] A similar short distance was also described by George et al.[10k] These values are rather uncertain, because in the evaluation of the EXAFS data no attempts were made to model the multiple scattering pathways within the imidazole fragments. In a recent EXAFS investigation of a aa_3-quinol oxidase from *Bacillus subtilis* containing a Fe_{a3}-Cu_B center but no Cu_A center, a copper–iron distance of 3.7 Å was described.[16]

In analogy to Cu, the Fe EXAFS analysis was carried out by using a Fourier-filtered function (Fig. 4, left) which accounts for

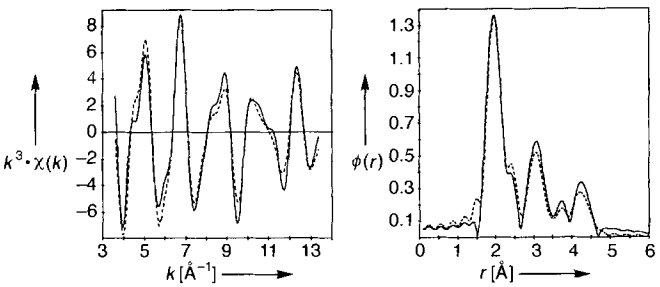

Fig. 4. Left: Fourier-filtered iron EXAFS (solid line) and theoretically fitted curve (complete model, dashed line); right: Corresponding Fourier transform.

all backscattering contributions in a distance range between 1.50 and 4.65 Å (Fig. 4, right). The first coordination sphere can be modeled quite well with a ligand set of nitrogen and sulfur donor atoms. The backscattering contributions with peaks at about 3.0 and 4.2 Å (Fig. 4 right) are essentially caused by the non-coordinated ring atoms of the tetrapyrrole and imidazole fragments. These contributions were taken into account by considering multiple scattering effects during the subsequent curve-fitting procedure. The contribution of a copper atom to the fine structure of the iron K edge becomes apparent in a destructive interference at about 3.9 Å. The complete structural model consists of a set of imidazole fragments from the histidine residues, a set of tetrapyrrole fragments, a set of bridging methine-C atoms, a set of sulfur or chlorine atoms as well as a set of copper atoms in the local environment of the iron atoms.

During the final cycles of the structure refinement, the occupation numbers of the individual coordination spheres were

varied in integral units under preservation of the coordination number six. For each set of possible occupation numbers generated, a common value for E_0, the distances of the individual shells from the central atom as well as their averaged Debye–Waller factors were refined taking multiple scattering effects into account. During the refinements, the imidazole rings and the tetrapyrrole fragments were treated as rigid groups. The results for the set with the best fit-index are listed in Table 2. The

[a] The occupation number is normalized to one iron atom (total coordination number six); the atoms of the histidine and porphine residues are refined as rigid units; estimated error in distances: 0.03 Å

iron–copper distance within the Fe_{a3}-Cu_B center derived from the Fe EXAFS is 4.04 Å and thus slighly longer than the corresponding distance derived from the Cu EXAFS. The deviation can be explained by uncertainties in modeling the five-membered rings and the multiple scattering effects within the ligand frameworks, which arise from the application of averaged geometries for the five-membered ring systems of the imidazole and tetrapyrrole residues. Here we appear to have reached the limits of the method, which demonstrates that the iron–copper distance determined has a relatively high error. The backscattering contribution at 2.31 Å is the result of a sulfur or chlorine donor function, which has to be formulated as a bridge between Cu_B and Fe_{a3}. Further statements, for example about the separation between the metal centers in different subunits of the enzyme, are not possible due to the limited range of the method, which usually does not exceed 4 to 5 Å in biomolecules.

While the work described in this paper was in the last stages of evaluation,[17] the results of an EXAFS investigation on the soluble Cu_A domain from subunit II of the caa_3-cytochrome-c oxidase from *Bacillus subtilis* expressed in *Escherichia coli* were published.[8] They confirm the results of this work with regard to the distance between the copper atoms within the homobinuclear center. Despite this fact, there are significant differences, especially with respect to the total number of copper–sulfur contacts. Whereas the interpretation of the EXAFS data of the intact cytochrome-c oxidase from bovine heart mitochondria requires the assumption of two cysteine bridges, the number of copper–sulfur bonds for the soluble Cu_A domain of the bacterial cytochrome-c oxidase was determined with only two (i.e. bridging ligands excluded).[8] It should also be mentioned that the characteristic imidazole backscattering contributions found in the Cu EXAFS of the complete mitochondrial cytochrome-c oxidase are almost completely lacking in the spectrum of the soluble Cu_A domain. Because it is highly unlikely that the Cu_A centers of the bacterial cytochrome-c oxidases differ characteristically from the Cu_A centers of the corresponding oxidases in mammals, there might be significant differences between the domain reconstructed by gene technology and the native enzyme. The structural model proposed by Blackburn et al.[8] is based on measurements on samples with excess copper contents and contains a copper–copper bond without any bridging ligands. This model, however, refers to the reconstructed domain and is hence not readily transferable to the Cu_A center of the intact cytochrome-c oxidase from bovine heart mitochondria.

The structural models for the homobinuclear Cu_A as well as for the heterobinuclear Fe_{a3}-Cu_B center derived from our EXAFS experiments are depicted schematically in Figure 5.

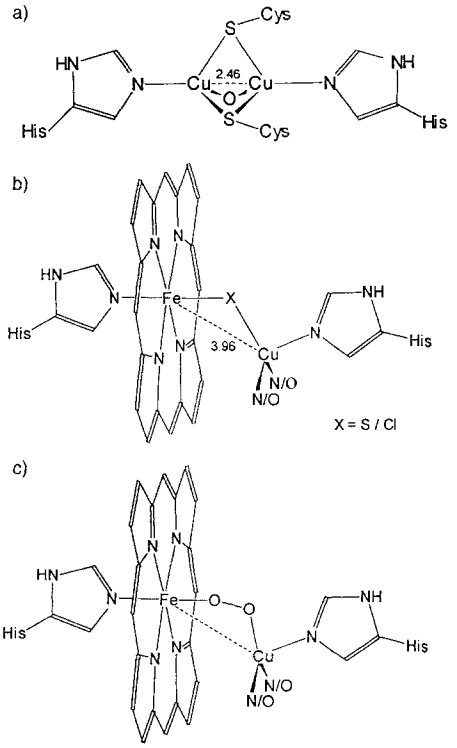

Fig. 5. Models for the metal centers of cytochrome-c oxidase in schematic representation: the homobinuclear center Cu_A (a), the heterobinuclear center Fe_{a3}-Cu_B (b), and the proposed binding situation of the O_2 molecule (c).

Since the enzyme in its examined form readily reacts with oxygen without any activation phase, the metal atoms of the Fe_{a3}-Cu_B center should already be in the catalytically relevant position. Based on this assumption, we propose a model for the binding of the O_2 molecule which is shown in Figure 5c. In this model, the O_2 molecule is bound in a *cis*-μ-1,2 arrangement to both the iron and the copper atom.

Experimental Procedure

Cytochrome-c oxidase was isolated from bovine heart mitochondria as described and purified on Q-Sepharose FF (Pharmacia) in 0.1% Triton TX-100, 10 mM Tris/HCl (pH 7.6) in the final step [18]. The enzyme exists as a monodisperse dimer under these conditions and reacts rapidly and monophasically with cyanide; the maximal activity corresponds to the activity in situ, that is, in its membranous environment. The chemical purity of the protein was checked by SDS-polyacrylamide gel electrophoresis, amino acid analysis, and quantitative determination of the N-terminal amino acids by Edman degradation. The metal content was determined by ICP-AES [18].

The enzyme solution used for X-ray absorption spectroscopy was concentrated by ultrafiltration in Centricon-100 (Amicon) to 800 µM. The samples were filled in polystyrene cuvettes with Kapton windows (layer thickness 1 mm, volume 150 µL), shock frozen in a cryogenic bath with ethanol/dry ice (195 K), and subsequently

cooled down to 77 K. During the measurements the samples were kept in a helium cryostate at 20 K.

The X-ray absorption spectra in the region of the iron, copper, and zinc K edges were recorded with the EXAFS spectrometer of the European Molecular Biology Laboratory (EMBL) in the Hamburger Synchrotronstrahlungslabor (HASYLAB) at the Deutsches Elektronen-Synchrotron (DESY, Hamburg) center using the synchrotron radiation from the storage ring DORIS II (4.5 GeV; average beam current 50 mA) [19]. The optical system of the EXAFS spectrometer consists of a Si(111) double crystal monochromator and a focussing toroidal mirror. Selected Bragg reflections of a suitably mounted Si crystal simultaneously recorded with the spectrum are used for the absolute calibration of the energy axis [20].

The spectra were recorded by measuring the fluorescence radiation in a range from 6915 to 7780 eV (Fe) and from 8725 to 9710 eV (Cu) with a 13-element solid-state detector (Canberra). The measuring time was 1–2 s per point with about 1400 points per spectrum. A total of 34 (Fe edge) and 23 (Cu edge) single scans, repectively, were averaged after individual energy calibration. The EXAFS functions were isolated from these spectra by literature procedures [21], and the determination of the background was achieved with a spline function. The data evaluation was carried out with the program packages EXPROG (energy calibration and data reduction) [22] and EXCURV88 (curve fitting procedures employing theoretical amplitude and phase functions) [23].

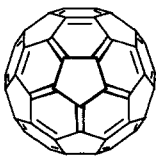
Dilithium Acepentalenediide: An Unusual Dimer of Contact Ion Triplets with Bowl-Shaped Dianions**

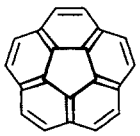
Rainer Haag, Roland Fleischer, Dietmar Stalke,* and Armin de Meijere*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

New allotropic forms of carbon like C_{60} **1** and higher fullerenes are currently a popular research topic.[1] Alkali metal doped C_{60}-fullerenes, in particular, have attracted considerable attention due to their superconductivity at low temperatures.[2] Corannulene **2**,[3] the smallest complete subunit of C_{60} with a curved molecular surface, consists of a five-membered ring fully surrounded by six-membered rings. Its alkali metal derivatives have also been studied extensively.[4]

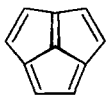


1



2

3



4

The smallest conceivable fullerene is C_{20} **3**, which is made up of five-membered rings only. Both dodecahedradecaene **3**[5] and acepentalene **4**,[6] the smallest curved subunit of **3**, have been targets for synthesis in spite of their obviously exceedingly high strain. The $C_{10}H_6$ hydrocarbon **4** is even more strained than the $C_{20}H_{10}$ corannulene **2** and has been predicted to be a triplet diradical in the ground state.[7] However, this electronic destabilization can be overcome, and the corresponding closed-shell dianion **6** has been obtained with remarkable ease by treating triquinacene **5** with a superbasic mixture[8] of *n*-butyllithium, potassium *tert*-pentoxide, and TMEDA[9] (Scheme 1). Although **6** has been characterized unequivocally by its spectroscopic data and trapping reactions with electrophiles, its structure remained unknown, because the dipotassium salt **6a** initially formed from **5** could not be purified sufficiently.

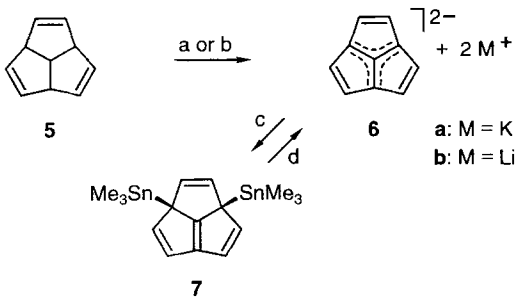
[**] This work was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie, as well as by BASF, Bayer, and Hüls AG through generous gifts of chemicals. We are grateful to Mr. W. Zolke, Göttingen, for recording the ^{7}Li CP-MAS NMR spectra and Prof. M. Rabinovitz, Jerusalem, for helpful discussions. R. H. is indebted to the Gottlieb-Daimler and Karl-Benz-Stiftung for a travel grant.



Scheme 1.

We have now succeeded in preparing and purifying 4,7-bis(trimethylstannyl)dihydroacepentalene **7** by sublimation. From **7**, pure dilithium acepentalenediide **6b** can be obtained by a cleanly proceeding transmetalation with methyllithium in dimethoxyethane (DME) at −60 °C. Compound **6b** crystallized very well from a solution in DME at low temperatures (−30 °C), and a single-crystal structure analysis was performed at 153 K.[10] In the crystal, **6b** forms dimers consisting of two bowl-shaped $C_{10}H_6$ dianions whose convex surfaces face each other (Fig. 1). Two lithium counterions, Li2 and Li2A, each of

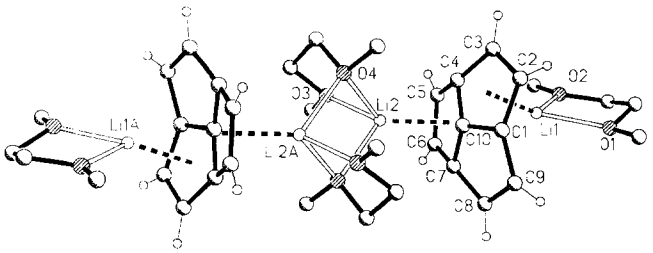


Fig. 1. The solid-state structure of **6b**; selected bond lengths [pm]: Li1-C 232.9(4), Li2-C 237.2(4), Li1-O1 204.1(4), Li1-O2 202.1(4), Li2-O3 200.8(4), Li2-O4 213.2(4), Li2A-O4 223.5(4), Li1-C_5(center) 198.9, Li2-C_5(center) 203.9. For averaged structural parameters of the CH skeleton see Fig. 2.

which coordinate one molecule of dme, are sandwiched between the two convex surfaces, but with different distances to each of them. The remaining two lithium counterions are located on the outward pointing concave faces of the bowl-shaped dianions (Li1 and Li1A in Fig. 1). These cations each coordinate one of the three angularly fused five-membered rings in an almost ideal η^5 fashion; the Li–C distances range from 225.9 (Li–C1) to 238.9 pm (Li–C3). The coordination spheres of Li1 and Li1A are also completed by dme donor molecules with average Li–O distances of 203.1 pm.

The lithium ions on the convex faces of the dianions also have ideal η^5 coordination, but each one to a second five-membered ring (C4, C5, C6, C7, C10) with distances between 227.0 (Li2–C10) and 241.7 pm (Li2–C4). In addition, the inner lithium atoms Li2 and Li2A each coordinate one dme molecule, but not in the same fashion as the coordination of dme by Li1 and Li1A. Both oxygen atoms chelate the same lithium atom, and one oxygen atom (O4) forms an μ_2 bridge between the two inner metal atoms, resulting in a four-membered, central Li_2O_2 ring. The crystallographic inversion center is located in the middle of that ring. Because of the different bonding modes, the Li–O distances in this ring are not equal. While Li2–O3 is 200.8 pm, the bonds to O4 are longer (Li2–O4 213.2, Li2–O4A 223.5 pm) due to unequal electron distribution between both electropositive lithium atoms. Because Li2 gets electron density from three oxygen atoms and Li1 only from two, the carbanionic fragment is more attractive to Li1, resulting in a shorter distance between the Li1 atom and the center of the five-membered ring (198.9 pm) than that between Li2 and the corresponding five-membered ring (203.9 pm).[13]

Although the structure of **6b** should be regarded as a contact ion triplet with all the implications of ion pairing phenomena,[14] the $C_{10}H_6$ dianion adopts almost ideal local C_3 symmetry with C10 on the threefold axis. The coordination sphere of C10 is considerably pyramidalized (26.3 pm out of the plane of the three neighboring atoms; sum of the three bond angles: 349.7°). The three central C–C bonds are of equal length (140.4 pm)[15] within error limits, and despite the negative charges in the molecule they are only marginally shorter than those in the central five-membered ring of corannulene **2** (141.1 pm[16]). The six C–C(H) bonds in **6b** are 5 pm longer (av. 145.5 pm) and the three peripheral C(H)–C(H) about the same length (av. 141.1 pm) as those in **2**. Unlike corannulene **2**, in which the central five-membered ring is completely regular with all bond angles equal to 108°, in **6b** the endocyclic bond angles range from 101.9° (average) for the C-C-C(H) angles and 109.6° (average) for C-C(H)-C(H) to 116.6° (average) for C-C-C angles at the central carbon C10 (Fig. 2). Yet all three five-membered rings in **6b** are almost ideally planar with a maximum deviation of only 2.8 pm from the best plane in each case.

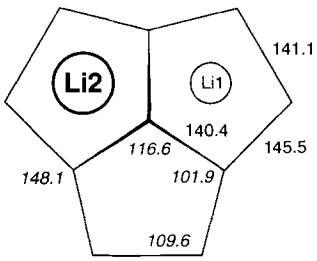

Fig. 2. Structural parameters of the CH skeleton of **6b**. Geometrically equivalent bond lengths [pm] and angles [°] are averaged; angles are in italics.

Unexpectedly, the structural parameters of the single five-membered ring of the $C_{10}H_6$ unit not coordinated to a lithium ion are basically the same as those of the other two. Like in Ph_3CM (M = Li, Na)[17] contact ion pairs, the two lithium ions in **6b** do not affect the bonding parameters in the carbon skeleton. It would be interesting to see whether structural distortion would be more pronounced in higher alkali metal derivatives of acepentalene, since in such derivatives of Ph_3CM (M = K, Rb, Cs)[18] with η^6 coordination of one of the three phenyl rings by the metal, the bond between this ring and the central carbon atom is considerably shorter than that to the other two.[19]

An analogous dimeric assembly, in solution however, has also been deduced from NMR spectroscopic studies of the tetraanion of corannulene, $C_{20}H_{10}^{4-}$ **2**$^{4-}$, with lithium counterions.[4] In contrast to the arrangement of the two $C_{10}H_6Li_2$ units in the crystal of **6b**, the two $C_{20}H_{10}$ subunits in the dimer of $C_{20}H_{10}Li_4$ are postulated to face each other with one convex and one concave side ("stacked-bowl" arrangement) with rapid inversions of both.[4] Another remarkable difference between $(C_{20}H_{10}Li_4)_2$ **2**$^{4-}$ and $(C_{10}H_6Li_2)_2$ **6b** is that the solid-state structure of the latter could not be verified in solution. The ^7Li and ^1H NMR spectra of **6b** in solution ([D$_8$]THF, −60 °C) show single signals at $\delta_{LiBr} = -8.2$ and $\delta_{TMS} = 6.16$, respectively. The three different types of carbon atoms in **6b** give rise to three signals [δ_{TMS} = 108.5 (d, C-2(3,5,6,8,9), 116.2 (s, C-1(4,7), 151.8 (s, C-10)] in the ^{13}C NMR spectrum ([D$_8$]THF, −60 °C).[20] This indicates C_3 symmetry of the molecules of **6b** in solution, which may either be caused by fluxional behavior in the dimer (rapid exchange of inside and outside positions, e.g. by inversion), by a rapid dimer–monomer equilibrium, or by the sole occurrence of a stable monomer of **6b** in solution. Even

at $-110\,^{\circ}C$ it was not possible to resolve the signals of different ^{1}H, ^{7}Li, and ^{13}C nuclei in the respective NMR spectra in solution. However, in the ^{7}Li CP-MAS NMR spectrum of solid **6b**, two different resonances were observed at $\delta = -4.9$ and -9.8 (ext. LiCl), similar to that reported for other oligolithio compounds in the solid state.[21] Because of its chemical shift and shape, the broad signal at lower field is tentatively assigned to the outer lithium ions Li1/Li1A in the dimer, and the other to the inner ones (Li2/Li2A). This is in line with the observed ^{7}Li chemical shifts of the tetralithium corannulene $\mathbf{2}^{4-}$ in solution.[4e] Unfortunately, different signals for the carbon atoms could not be resolved in the ^{13}C CP-MAS NMR spectrum of **6b**, possibly due to the relatively high quadrupole moment of the coordinated ^{7}Li nuclei or a dynamic process of the lithium counterions even in the solid state. This difficulty might be overcome by studying the corresponding ^{6}Li-enriched derivative, which is currently being prepared.

It is also noteworthy that unlike $\mathbf{2}^{4-}$ and **6b**, the dilithium pentalenediide, which can be considered a subunit of dilithium acepentalenediide **6b**, does not form a dimer.[22] Instead it is a monomeric "ion triplet" with the two lithium ions on opposite sides of the planar hydrocarbon skeleton. Such ion triplets are known for a number of lithium derivatives of conjugated hydrocarbons.[23] Also, "reverse" ion triplets with a single lithium ion between two organic anions are known.[24] But aggregates larger than the one reported here for **6b** and for corannulene tetraanion $\mathbf{2}^{4-}$,[4] in which several lithium ions are sandwiched between two hydrocarbon polyanions, are relatively rare.[25, 26] It remains to be seen whether the curved shape of acepentalenediide **6b** is static or easily inverted like the corannulene molecule **2**[3c] and its tetraanion $\mathbf{2}^{4-}$.[4]

[10] Crystal data of **6b**: $C_{18}H_{20}Li_2O_4$, $M = 320.3$, monoclinic, space group $P2_1/c$, $a = 1333.5(3)$, $b = 847.3(2)$, $c = 1578.9(3)$ pm, $\beta = 91.57(3)^{\circ}$, $V = 1.7833(6)$ nm^3, $Z = 4$, $\rho_{calcd} = 1.193$ Mg m^{-3}, $F(000) = 688$, $\lambda = 71.073$ pm, $T = 153$ K, $\mu(Mo_{K\alpha}) = 0.080$ mm^{-1}. Data were collected on a Stoe-AED diffractometer. A suitable crystal ($0.6 \times 0.4 \times 0.4$ mm) in a drop of oil [11] was cooled rapidly and mounted at $-80\,^{\circ}C$. Intensities were collected by the $2\theta/\omega$ methods in the range $5 < 2\theta < 50^{\circ}$. Of a total of 5666 reflections 3097 were independent; largest difference peak and hole: 643 and -288 e nm^{-3}, $R1(I > 2\sigma(I)) = \Sigma \, ||F_o| - |F_c|| / \Sigma \, |F_o| = 0.065$ und $wR2 = \{\Sigma \, [w(F_o^2 - F_c^2)^2] / \Sigma \, [w(F_o^2)^2]\}^{0.5} = 0.211$ based on F^2 for all data. The structure was solved by direct methods (SHELXS92) [12a] and refined by full-matrix least squares on F^2 (SHELXL93) [12b]. The hydrogen atom positions were refined with a riding model with the CH_3 groups free to rotate about their local threefold axes. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

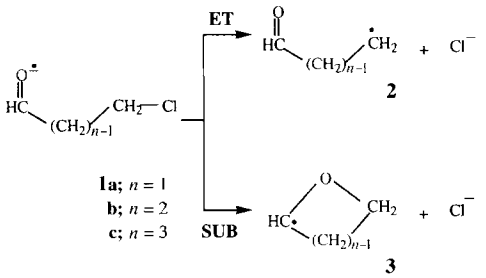
Electron Transfer and Polar Reactions of Cyclizable Anion Radicals: Structural Consequences of Orbital Selection Rules and Chain-Length Constraints**

G. Narahari Sastry, A. Chandrasekhar Reddy, and Sason Shaik*

To be or not to be bonded is a fundamental question for the transition state (TS) of an electron transfer (ET) reaction of an electrophile nucleophile combination that also has a classical polar (bond-forming) pathway available to it.[1] Valence bond configuration mixing (VBCM) analysis predicts that when either the nucleophile or the electrophile is an ion radical, both the ET and polar pathways may have TS structures with strong bonding interactions governed by reaction-specific orbital selection rules.[2, 3] These orbital selection rules determine the resonance energies of the respective transition states and thereby exert stereo- and regiospecific requirements. According to the VBCM analysis,[2] when the reactive fragments involve a carbonyl anion radical moiety and a carbon–halide moiety (C–X), the orbital selection rule for the ET-TS dictates a structure that optimizes the overlap between the singly occupied π^* orbital of the anion radical moiety and the σ^* orbital of the C–X moiety. In contrast, the TS structure for the polar (substitution) mechanism requires the optimum overlap between the doubly occupied oxygen lone-pair orbital of the anion radical and the σ^* orbital of C–X. The reaction-specific orbital interactions provide structural rules for the dichotomy of ET and polar mechanisms in ion radical chemistry. The role of the orbital selection rules has been corroborated in a recent ab initio study[4] of the intermolecular ET and substitution (SUB) reactions in a simple model system: the formaldehyde anion radical and methyl chloride. It was found that the structures of both the ET and SUB transition states have strong bonding interactions and possess distinct regio- and orientational selectivity in accord with the selection rules.

What is still missing for establishing the dichotomy of ET and polar mechanisms on solid structural foundations is a clear demonstration that the orbital selection rules are indeed at work in systems or models thereof that are known to display both ET and polar mechanisms, and in which the selection rules pose stringent structural constraints for the ET-TS. The opportunity is provided by recent elegant studies of Kimura et al.,[5, 6] who showed that the anion radicals of ω-haloalkyl phenyl ketone undergo competitive ET and SUB reactions and exhibit intriguing trends such as a common activation driving force law and a alternating dependence of the relative efficiency on the chain length. We report on ab initio computational studies of the intramolecular ET and SUB reactions of ω-chloroalkanal anion radicals (Scheme 1), models of compounds used by Kimura et al. The computational results provide structural and energetic evidence for the dominating influence of reaction-specific orbital selection rules and for the specific bonding features that are established in the ET-TS even when the anion radicals have adverse structural constraints.



Scheme 1.

The ab initio MO computations used the split-valence plus polarization (6-31G*) basis set at the unrestricted Hartree–Fock level, and employed standard geometry optimization and characterization procedures.[7–9] This level was chosen after the ET and SUB processes for **1b** had been tested at UHF and UMP2 levels of theory with the 6-31G* and 6-31 + G* basis sets. Calculations at all of these levels showed identical mechanistic details and also the same trends in the relative energies. Moreover, previous studies for the reactions between formaldehyde anion radical and methyl chloride had shown an identical mechanistic dichotomy at the UHF, ROHF, and post-HF levels up to CCSD(T).[4, 10] The invariance of the trends indicates that the mechanistic conclusions reached at the UHF level of theory are very unlikely to change at higher levels, and this allows us to study the computationally more demanding system **1c**.

The calculations reported are at UHF/6-31G* level, which is the highest common level employed here for **1a**–**1c**. Anion radical **1a** ($n = 1$) is unstable and dissociates without an activation barrier to give exclusively the ET product **2a**. An experimental study on a substituted analogue of **1a** arrived at an identical result.[6] In contrast, **1b** ($n = 2$) and **1c** ($n = 3$) are stable and react according to ET and SUB mechanisms to yield corresponding products as shown in Scheme 1. The optimized structures of reactants (**1b**, **1c**), ET transition states (**4b**, **4c**), and SUB transition states (**5b**, **5c**), for for both reactions (with $n = 2$ and $n = 3$) are depicted in Figure 1, and are seen to exhibit an identical mechanistic dichotomy. In all cases both the ET and SUB transition states involve backside attack on the C–Cl bond. However, while for all systems the C–C–Cl unit in the ET-TS is oriented preferentially perpendicular to the plane of the HC=O unit, in the twin SUB-TS the O–C–Cl group is in the same plane as the carbonyl group. It is intriguing that the

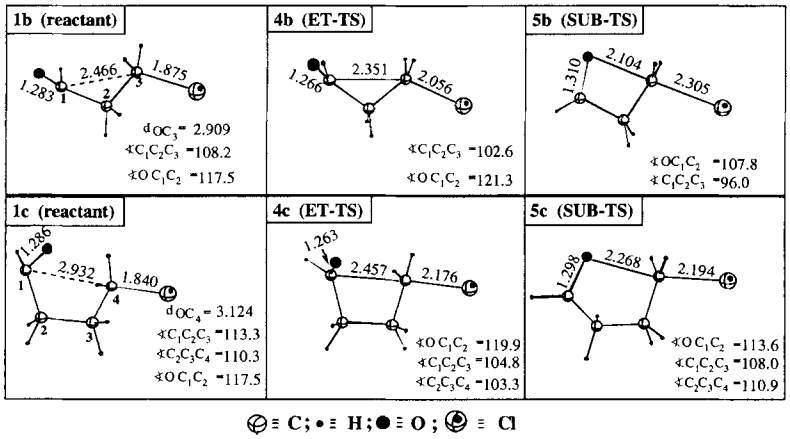

Fig. 1. UHF/6-31G*-optimized structures of the reactants (**1b**, **1c**) and the ET (**4b**, **4c**) and SUB transition states (**5b**, **5c**) for $n = 2$ and 3 (Scheme 1). Only important structural parameters are specified (angles in [°], distances in [Å]).

ET process takes place through the C end of the carbonyl group despite the fact that the extra negative charge is on oxygen![11] Attempts to find alternative pathways for the ET process starting from **1b** and **1c**, for example through the O end or in different trajectories, have either failed or resulted in the C-oriented ET-TS structures in Figure 1. No direct C-alkylation pathway could be found from the reactant, which is in full agreement with the experimental observation of only the O-alkylation product besides the ET product.[5, 6] As seen in Figure 2, these findings all follow the VBCM orbital selection rules, which dictate that the structure of the ET-TS is determined by optimizing the overlap between the π^* (CO) and the σ^* (CCl) orbitals, whereas the structure of the SUB-TS is determined by the overlap requirements between oxygen's lone pair n(O) and the σ^* (CCl) orbitals.

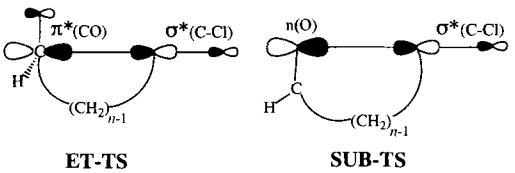

Fig. 2. Sketch of overlapping orbitals showing the resonance interactions in the ET-TS (left) and SUB-TS (right), as predicted by VBCM analysis [2]. Note the different orientations of the HCO moiety in the two transition states.

Table 1 lists the computed energies and isotope effects for the SUB and ET pathways. The activation barriers are dramatically different for the two systems, reflecting the effect of the orbital selection rules imposed on the chain-length constraints. Thus, for **1b** with $n = 2$ the ET barrier is smaller than that for the SUB process. In contrast, for **1c** with $n = 3$ the exact opposite is found. While the first trend (entries 1, 2) follows the relative thermodynamics of the ET and SUB pathways, the second trend (entries 3, 4) does not. Therefore the trends in Table 1 reflect very specific structural effects on the twin transition states, which are independent of the thermodynamic effect.

A close look at the optimized structures of reactant **1b** and the corresponding ET and SUB transition states (**4b** and **5b**) reveals why ET is the favored pathway (Fig. 1). The C–C distance between the carbonyl carbon and the terminal carbon is already short in reactant **1b**. Consequently, ET-TS **4b** requires only a little reorganization for achieving the necessary C–C bonding in the carbonyl π plane, since the carbonyl moiety is already appropriately oriented in reactant **1b** with respect to the C–Cl bond. The shortening of the C–C distance in the ET-TS (from 2.466 Å in **1b** to 2.351 Å in **4b**) is an indication that the ET-TS tries to achieve π^*(CO)–σ^*(CCl) bonding as strong as possible. In contrast, the SUB-TS **5b** requires major reorganization to achieve the requisite bonding via a strained four-membered ring. Thus, due to the constraints of the $n = 2$ chain, the orbital selection rule requirement is easily met for ET process of **1b** ($n = 2$), while for the corresponding SUB-TS the bonding requirement is met at the expense of high ring strain.

An increase in the length of the methylene chain by one unit to **1c** ($n = 3$) dramatically reverses the barrier for the ET and SUB mechanisms (Table 1, entries 3, 4), because chain-length constraints now operate against the orbital selection rule for the ET pathway. Thus, the π^*(CO)–σ^*(CCl) bonding for the ET pathway requires ET-TS **4c** to assume a strained four-membered ring structure with very small C-C-C angles (Fig. 1). On the other hand, the n(O)–σ^*(CCl) selection rule for the SUB-TS requires an almost strain-free five-membered ring structure (with close to normal bond angles; Fig. 1).[5] As already mentioned, it is intriguing that although the extra electron resides on oxygen,[11] the ET process takes place through the C end of the carbonyl group; the seemingly available, favorable five-membered ring arrangement that would be expected if ET were to proceed at the O end is avoided. The computed strained C orientation is therefore a strong indication that the ET-TS has a specific bonding requirement that has to be met despite structural constraints imposed by the intervening chain.

Table 1. Computed energies [a] and kinetic isotope effects [b] at the UHF/6-31G* level.

Reaction	$\Delta E^{\neq}$	ΔE_{rxn} [c]	$\alpha(CH_2/CD_2)$	$\alpha(C^{12/13})$
(1) ET ($n = 2$)	2.0	−34.9 (−46.9)	1.059	1.030
(2) SUB ($n = 2$)	12.6	−12.7 (−21.3)	0.996	1.040
(3) ET ($n = 3$)	8.2	−37.9 (−50.5)	1.141	1.045
(4) SUB ($n = 3$)	3.4	−38.6 (−46.9)	0.992	1.046

[a] All values are in kcal mol^{-1}. [b] Using the Eyring equation at the UHF/6-31G* level with frequencies scaled by 0.8929. The α position is designated with respect to Cl. [c] ΔE values refer to the conversion of particular reactant to give the respective products. The values in parentheses correspond to conversion of reactants to clusters of products.

Kinetic isotope effects can be used to distinguish the two mechanisms and to unravel their bonding properties. As shown in Table 1, the $\alpha(CH_2/CD_2)$ isotope effects, which are inverse for SUB mechanism and normal for ET pathway, may be used as criteria.[12] The $\alpha(C^{12/13})$ isotope effect, which is a measure of the tightness of a transition state,[13] is seen to be normal for both mechanisms. The calculated normal and large $\alpha(C^{12/13})$ isotope effect indicates that the ET transition states for $n = 2$ and $n = 3$ have strong bonding interactions much like their twin SUB transition states.

The present computational study demonstrates that the dichotomy between ET and polar mechanisms in ion radical chemistry can be explained by bonding principles derived from

mechanism-specific orbital selection rules. It is demonstrated that the orbital selection rules set stringent structural requirements on the geometries of both the ET-TS and the twin SUB-TS, and determine all of their stereochemical information—stereospecificity, regiospecificity, orientational specificity—and the consequent activation barriers. Thus, the ET-TS is found to possess a robust stereochemistry that follows the maximum bonding principle allowed by the selection rule. The existence of kinetic isotope effects for the ET-TS may help establish or challenge the structured ET-TS presented here, and put it in perspective with the traditional notion of weak bonding in the outer sphere model.[14–17]

New Nonlinear Optical Materials: Expedient Topotactic Self-Assembly of Acentric Chromophoric Superlattices**

Wenbin Lin, Shlomo Yitzchaik, Weiping Lin, Amit Malik, Mary K. Durbin, Andrew G. Richter, George K. Wong, Pulak Dutta, and Tobin J. Marks*

Although molecule-based assemblies offer many attractions for the construction of efficient second-order nonlinear optical materials (large nonresonant response, ultrafast response times, low dielectric constants/losses, and intrinsic tailorability), significant synthetic challenges have impeded the realization of optimum materials.[1, 2] These challenges include maximizing chromophore hyperpolarizability and number density as well as maximizing the degree and thermal/temporal stability of induced microstructural acentricity. An attractive alternative to electric field poled glassy polymers[2, 3] and Langmuir–Blodgett films[4] is a self-assembly[5] approach in which acentric chromophoric superlattices[6] are built up in a layer-by-layer fashion through the formation of covalent bonds.[6, 7] In the past, the efficiency of this approach has been limited by the slow rate (days) at which the large hyperpolarizability stilbazolium chromophore layers[6] could be assembled and the resulting, less than optimum superlattice structural regularity. We report here a new topotactic "molecular layer assembly approach in which the key assembly step is effected in either a solvent-free solid state or chemical vapor deposition mode, which in combination with other building block modifications, allows the expedient assembly of robust chromophoric architectures with high structural regularity and with very large nonlinear optical response. The results suggest that other self-assembly routes to multilayer structures could be achieved in a similar manner.

The present approach to acentric chromophoric superlattices utilizes the sequential repetition of three layer-building steps (Fig. 1), beginning upon a clean, hydroxylated surface (e.g., SiO_2 or single-crystal silicon). The progress of the assembly process is monitored by X-ray photoelectron spectroscopy (XPS), advancing aqueous contact angle (θ_a) measurements,

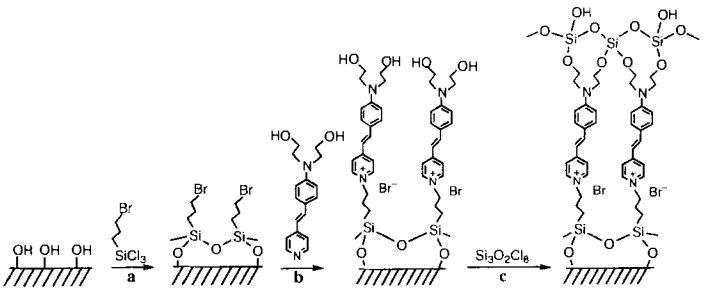

Fig. 1. Schematic representation of the self-assembly of covalent chromophoric superlattices. Conditions: see Experimental Procedure. The steps **a**–**c** can be repeated.

transmission optical spectroscopy, polarized second harmonic generation (SHG; $\lambda_0 = 1064$ nm), and specular X-ray reflectivity (XRR).[8]

Step **a** introduces a bromoalkyl functionality, the presence of which is evident from Br 3d XPS (peak at 70.4 eV, characteristic of a bromoalkane),[9] an appropriate hydrophobic change in θ_a (increases from 15° for SiO_2 to 75°), and an XRR monolayer thickness of about 10 Å. The cure component of this step is designed to achieve maximum intrafilm and film–substrate crosslinking.

Step **b** can be effected in either of two efficient modes. 1) A thin layer (≈ 1000 Å) of the stilbazolium chromophore precursor, 4-(*N*,*N*-dihydroxyethylamino)stilbazole,[6] is spin-coated onto the bromoalkyl-functionalized surface, followed by brief heating in vacuo to effect quaternization and removal of excess reagent (130 °C/0.4 Torr). 2) The precursor vapor can be passed over the heated substrate in a chemical vapor deposition (CVD) process. The course of the quaternization/assembly is verified by quantitative formation of Br^- in the Br 3d XPS (68.0 eV), the appearance of amine and pyridinium N1s XPS signals (399.5, 401.6 eV; 1:1 intensity ratio), an appropriate hydrophilic change in θ_a (75° → 50°), an increased film thickness to about 30 Å in the XRR (consistent with molecular models), and an extremely large SHG response from the anchored, high-hyperpolarizability[10] stilbazolium chromophore, $\chi^{(2)}_{zzz} = 7 \times 10^{-7}$ esu. Angular-dependent SHG measurements reveal an average tilt angle of the chromophore β_{zzz} direction of $40 \pm 3°$ away from the surface normal, in good agreement with earlier results.[6]

The course of step **b**, as monitored by in situ SHG measurements (Fig. 2) reveals the onset of chromophore formation at about 120 °C, far below the melting point of 4-(*N*,*N*-dihydroxyethylamino)stilbazole (194 °C), and suggestive of an interfacial

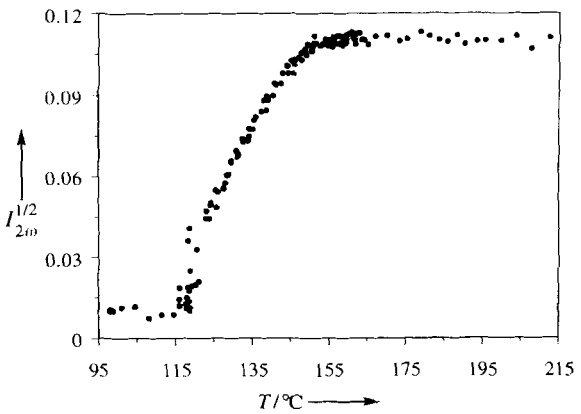

Fig. 2. In situ monitoring of the quaternization/chromophore formation step **b** in Fig. 1 by transmission second harmonic generation ($\lambda_0 = 1064$ mn). Temperature ramp rate: 25–160 °C, 1 °C min^{-1}; 160-215 °C, 3 °C min^{-1}. $I^{1/2}_{2\omega}$ data are in arbitrary units.

solid-state reaction. The quaternization process is complete by about 150 °C. It can also be seen by the persistence of the SHG response that the monolayer is stable under these conditions to 215 °C.

Step **c** is designed to provide lateral structural stabilization/planarization through interchromophore crosslinking and to provide a substrate for the subsequent iterative superlattice assembly process. The course can be ascertained from the expected hydrophilic change in θ_a (50° → 17°) and the additional thickness detected in the XRR (≈ 7 Å).

In the present admittedly crude, first-generation embodiment, about three to five complete iterations (trilayer assemblies) of steps **a**–**c** can be achieved per day—an increase in growth efficiency of about 30-fold over earlier work.[6] The degree to which this scheme produces a regular superlattice microstructure without loss of acentricity (deleterious randomization of chromophore orientation) and diminution of SHG efficiency, was investigated as a function of the number of added layers (steps **a**–**c**) by XRR, transmission optical spectroscopy, and SHG. The superlattice thicknesses calculated from the XRR data (Fig. 3a) show a smooth, monotonic increase as a

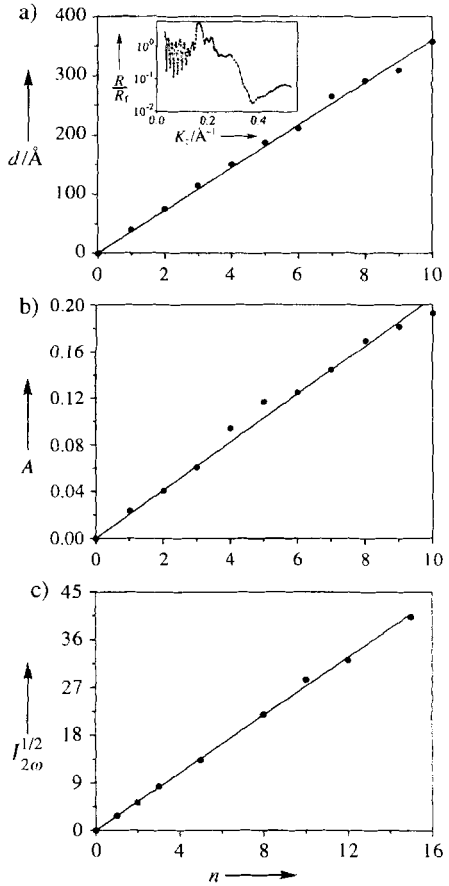

Fig. 3. Dependence of several characteristics of the chromophoric superlattice of Fig. 1 on the number of layers n, each composed of steps **a**–**c**. a) Thickness d derived from specular X-ray reflectivity measurements. Inset: normalized X-ray reflectance plotted versus wave vector for a specimen with 10 layers. b) Transmission optical absorbance A at 480 nm. c) Square root of the 532 nm second harmonic generation intensity (arbitrary units, $\lambda_0 = 1064$ nm).

function of the total number of assembled layers, consistent with a high degree of structural regularity. XRR data for a typical sample are shown in Figure 3a (inset). The maximum at $K_z = 0.17$ Å^{-1} is a "Bragg" peak due to scattering from individual layers; the interlayer spacing calculated from this peak position is 36 ± 1 Å, in good agreement with the thickness data and molecular models. The closely spaced minima in the data are due to interference between reflections from the superlattice–substrate and superlattice–air interfaces.

Further evidence for the buildup of regular superlattice layers with uniform chromophore orientation comes from the linear dependence of the 480 nm stilbazolium chromophore HOMO → LUMO longitudinal charge-transfer excitation[11] ab-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1313-1498 $ 10.00+.25/0

sorbance on the number of assembled layers (Fig. 3b). A final test of the present superlattice regularity comes from the SHG response as a function of the number of layers. Because the film thicknesses are small compared to the wavelength of the incident light, the intensity of the SHG light from a regular structure should scale quadratically with the number of layers. The observed linear dependence of the square root of the second harmonic response on the number of layers (Fig. 3c) indicates both structural regularity in layer thicknesses as well as uniform alignment of the chromophore molecules. From the slope, $\chi^{(2)}_{zzz} \approx 5 \times 10^{-7}$ esu (≈ 200 pm V^{-1}) can be deduced; this value is slightly lower than the aforementioned monolayer result (see above) due to the added thickness imparted by the siloxane layer introduced in step **c**. Although it is probably resonance-enhanced,[11] this level of frequency doubling efficiency rivals or exceeds those under the same conditions of the most efficient poled polymers and Langmuir–Blodgett films reported to date.[1, 2] In addition to the information in Figure 2, aging studies still in progress indicate complete thermal stability of the SHG response over many months at 25 °C and some decay over the course of several hundred hours at 100 °C.

It is interesting to note that chromophoric superlattices of the present type can also be assembled if siloxane capping step **c** is deleted. Although XRR and optical spectroscopy indicate the buildup of a regular superlattice (as in Figs. 3a and b), the response of SHG intensity with the number of layers is not quadratic (in contrast to Fig. 3c). When the number of layers exceeds three, the SHG intensity begins to fall. This result indicates that in the absence of the lateral stabilization imparted by step **c**, randomization of chromophore alignment, perhaps induced by chromophore dipole–dipole repulsions, destroys the microstructural acentricity. In conclusion, these results demonstrate an expeditious and probably generalizable route to robust, intrinsically acentric (not requiring an electric poling field) and structurally regular, self-assembled superlattices exhibiting very large second-order nonlinear optical responses. Further elaboration of this chemistry and application to device structures[12] is in progress.

Experimental Procedure

All the operations were carried out using standard Schlenck techniques. Pentane and heptane (Fisher Scientific) were distilled from Na/K alloy immediately before use. (3-bromopropyl)trichlorosilane (Lancaster) was purified by vacuum distillation. Octachlorotrisiloxane was prepared by controlled hydrolysis of $SiCl_4$; 4-(*N*,*N*-dihydroxyethylamino)stilbazole was prepared according to the procedures in ref. [6].

Step **a**: Freshly cleaned glass or silicon single-crystal substrates were immersed in a 1:100 (v/v) solution of (3-bromopropyl)trichlorosilane in heptane for 20 min, and then washed with copious amounts of pentane, followed by sonication in acetone for 1 min. The samples were then air-cured at 110 °C for 10 min.

Step **b**: 1) The silylated substrates (after step **a**) were spin-coated with a 4 mM solution of 4-(*N*,*N*-dihydroxyethylamino)stilbazole in methanol at 4000 rpm and then heated at 130 °C in a vacuum oven (0.4 Torr) for 30 min. 2) The silylated substrates were placed directly above a petri dish containing 4-(*N*,*N*-hydroxyethylamino)stilbazole in a vacuum oven (0.4 Torr) at 130 °C for 30 min.

Step **c**: The glass and silicon single-crystal substrates (after step **a** and step **b** treatments) were immersed in a 1:150 (v/v) solution of octachlorotrisiloxane in heptane for 30 min and then washed with copious amounts of pentane, followed by sonication in acetone for 1 min. The samples were then air-cured at 110 °C for 10 min.

The X-ray reflectivity measurements were performed at Beam Line X23B of the National Synchrotron Light Source at Brookhaven National Laboratory in Upton, NY, USA, using the instrumentation and analysis procedures described in ref. [8]. Polarized second harmonic generation measurements were carried out as described in ref. [6b].

Structure Organization of Aluminosilicate Polyanions with Surfactants: Optimization of Al Incorporation in Aluminosilicate Mesostructural Materials

Guoyi Fu, Colin A. Fyfe,* Wilhelm Schwieger, and George T. Kokotailo

Recently a new family of silicate-surfactant mesostructural materials, discovered by researchers at Mobil Corporation, has drawn considerable attention due to their potential applications as either highly ordered mesoporous molecular sieves, organic-inorganic nanocomposites or materials with biomimetic importance.[1–5] One member of this family, designated MCM-41, has highly ordered mesoscopic channels in a hexagonal arrangement, whose size may be engineered to be greater than 100 Å. For this type of mesoporous material to be practically useful as a catalyst, it is essential to incorporate a suitable amount of a metallic element into the silicate framework. The incorporation of vanadium or titanium oxides into the silicate framework of MCM-41 has been reported, and the resulting materials have been found to show promising activities in certain oxidation reactions.[6] For the aluminosilicate MCM-41 materials, efforts have been made to increase the framework Al content by using

alternative aluminum sources, such as sodium aluminate or aluminum alkoxides, to replace pseudo-boehmite alumina which is commonly used in these syntheses.[7]

In a recent paper,[8] we described a new two-step synthetic approach using well-characterized silicate polyanions, specifically the well-known double four-ring (D4R) silicate, $Si_8O_{20}^{8-}$ (Si_8), as precursors. Firstly, the mutual structure organization of the silicate species and the surfactant molecules, governed by electrostatic interactions, leads to mesophasic precipitates with layer or rod-based structures. Further structure ordering of these precipitates can then be achieved by vapor phase treatment. A critical difference between this procedure and previous syntheses is that the materials are isolated after precipitation in the first step and then treated under quite different conditions in the second. Using this approach, we have cleanly synthesized the hexagonal, the cubic, and the lamellar mesostructures and also, for the first time, observed the phase transformations between these mesophases in a systematic manner. Herein, we extend this new synthetic route to the analogous aluminosilicate system focusing on maximizing the aluminum incorporation in the mesostructural framework by using well-characterized aluminosilicate polyanions as precursors.

The aluminosilicate precursor used was $Al_4Si_4(OH)_8O_{12}^{4-}$ (Al_4Si_4), which has a similar cubelike structure to the D4R silicate, but with four Al replacing four Si atoms in alternating corners of the cube. This has been characterized in solution by NMR spectroscopy and also as the crystalline tetramethylammonium (TMA) salt by NMR spectroscopy and X-ray diffraction techniques.[9, 10] The structure of the Al_4Si_4 anion is shown schematically in Figure 1. Three different surfactants were used in the present work, namely, hexadecyltrimethyl ammonium chloride (C_{16}TACl), dodecyltrimethylammonium bromide (C_{12}TABr) and dodecylammonium chloride (C_{12}AMCl).

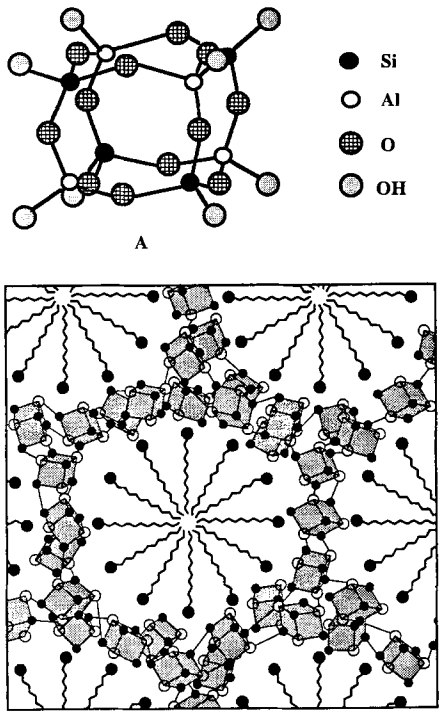

Fig. 1. Top: Schematic representation of the $Al_4Si_4O_{12}(OH)_8^{4-}$ structure; bottom: Schematic representation of the structure of the Al_4Si_4-C_nTA hexagonal phase (AS-H_1) in the plane perpendicular to the cylindrical channels showing the arrangement of templates and precursor cubes. Note that the walls in the real material may be thicker than the single layer of cubes shown here and the cubes themselves may be distorted to differing degrees by the condensation reactions.

The X-ray diffraction pattern (Fig. 2a) of the Al_4Si_4-C_{16}TA precipitate indicates that it is dominated by a rod-based mesophase similar to that observed for the Si_8-C_{16}TA system in acidic media (H_0 phase).[8] As we have rationalized for the Si_8-C_{16}TA system, this precipitate phase is formed by silicate- (aluminosilicate in this case) coated surfactant mesoscopic rods with

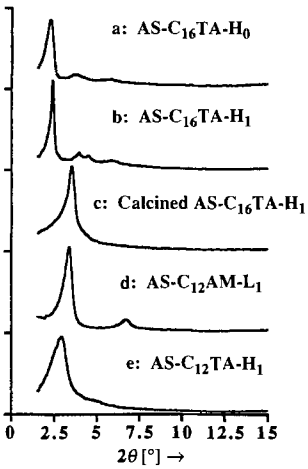

Fig. 2. X-ray diffraction patterns obtained on a Rigaku Rotaflex rotating anode diffractometer using $Cu_{K\alpha}$ radiation of a) the aluminosilicate precipitate phase (AS-H_0) formed by mixing Al_4Si_4 and C_{16}TACl solutions; b) the aluminosilicate hexagonal phase (AS-H_1) obtained from AS-H_0 by vapor phase treatment at 110 °C for 3 days; c) the AS-H_1 phase calcined by slowly increasing the temperature to 500 °C with a stream of N_2 passing through the sample and then maintaining the temperature at 500 °C for 3 h with a stream of air passing through the sample; d) the lamellar phase (AS-L_1) obtained by first precipitating Al_4Si_4 with $C_{12}NH_3^+$ in solution and then treating the precipitate in refluxing isopropyl alcohol for 24 h; and e) the hexagonal phase of Al_4Si_4-C_{12}TA obtained by a similar procedure as for the Al_4Si_4-C_{16}TA system.

poorly ordered hexagonal packing. We denote this aluminosilicate phase here as AS-H_0. From AS-H_0, more ordered hexagonal phases (AS-H_1) can be obtained by vapor phase treatment (Fig. 2b). The schematic structure model of this hexagonal phase is shown in Figure 1 top. The ^{29}Si NMR spectrum of the TMA crystals (Fig. 3a) shows a very strong resonance in the

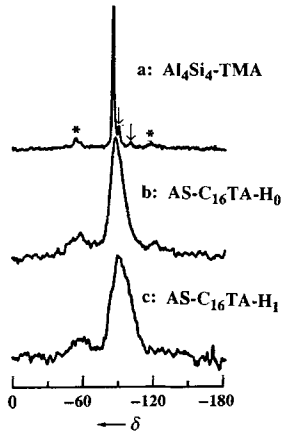

Fig. 3. ^{29}Si MAS NMR spectra obtained with a spinning rate of 3 kHz using a Bruker AM-400 spectrometer and a home-made MAS probe. a) Spectrum of $(NMe_4)_4Al_4Si_4O_{12}(OH)_8 \cdot xH_2O$ (^{29}Si NMR peaks indicated with arrows are thought to be due to a very small amounts of Al_3Si_5); b) and c) the AS-H_0 and AS-H_1 phases described in Fig. 2a and Fig. 2b, respectively. The ^{29}Si NMR chemical shifts are referenced to TMS using Q_8M_8 as an intermediate reference. The peaks indicated with an asterisk are spinning sidebands.

Q^3(3 Al) region ($\delta = -85$) and two very weak peaks in Q^3(2 Al,1 Si) and Q^3(3 Si) regions ($\delta = -90$ and -100, respectively), indicating that the Al_4Si_4 species is dominant with a minimal amount of Al_3Si_5 ($\approx 5\%$) also present. The broadened, unresolved ^{29}Si NMR peaks for the AS-H_0 and AS-H_1 phases (Fig. 3b and c) are due to condensations between Al_4Si_4 cubes, which result in new Si environments, such as Q^4(4 Al) and Q^4(3 Al,1 Si) sites, in addition to uncondensed Q^3 sites, and also to line broadening caused by variable site distortion. Line broadening is also observed for the ^{27}Al resonances of the mesophases (Fig. 4) compared to that of the TMA crystals

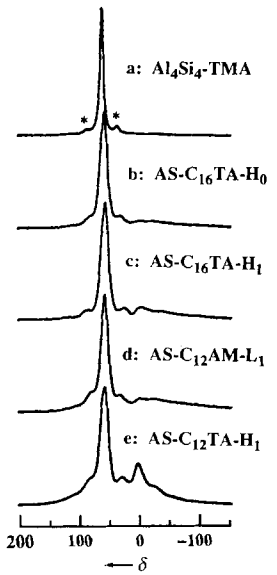

Fig. 4. ^{27}Al MAS NMR spectra obtained with a spinning rate of 3 kHz using a Bruker AM-400 spectrometer and a home-made MAS probe. The spectra in Fig. 4a–c are of the same materials as in Fig. 3a–c; the spectra in Fig. 4d and e are of the same materials as in Fig. 2d and e. The ^{27}Al NMR chemical shifts are referenced to the $Al(H_2O)_6^{3+}$ resonance of a 1 M solution of $Al(NO_3)_3 \cdot 6H_2O$. The peaks indicated with an asterisk are spinning sidebands.

(Fig. 4a) due to similar distribution of T-site geometries. The ^{27}Al NMR spectra (Fig. 4) also show that these mesostructures contain a number of octahedrally (O_h) coordinated Al centers. Janicke et al.[7c] have recently suggested that the resonance for the octahedrally coordinated Al centers in the ^{27}Al NMR spectrum of an aluminosilicate (Si/Al = 16/1) MCM-41 structure obtained from aluminum isopropoxide precursors is due to framework Al, since these Al sites were converted to tetrahedrally coordinated ones after calcination. The small amount of octahedrally coordinated Al observed in our mesophases is possibly from the same kind of framework Al. It has been reported[4] that if Catapal-B alumina is used as the Al source, complete incorporation of Al cannot be achieved even if only a small amount of alumina is used. With sodium aluminate as the Al source, a Si/Al ratio of as low as 8.5/1 without contamination from unreacted alumina has been recently reported for an MCM-41 structure.[7a] Clearly, the nature of the Al source is important in determining the amount of Al incorporated into a mesostructure. Using Al_4Si_4 as precursor, we have achieved a Si/Al ratio very close to 1/1, the lowest ratio possible for an aluminosilicate with tetrahedrally coordinated Al centers without the formation of unstable Al-O-Al linkages. Clearly, in comparison to the commonly used methods based on gel precursors, it is advantageous to incorporate aluminum at the oligomer stage using aluminosilicate polyanions as precursors.

Although Al_4Si_4 has the same cubic structure as Si_8, its charge is only half that of Si_8 according to the single crystal X-ray diffraction results.[10] Also, in the Al_4Si_4 structure all the terminal groups are OH rather than O^- groups as in Si_8. These differences make these two precursors behave differently in both the initial structural organization and the extended mesostructure formation (condensation) processes. It is clear that the charge density balance at the inorganic-surfactant interfaces is one of the important factors that determine the mesophasic structure formed.[2, 3, 8] The lower charged Al_4Si_4 requires a larger head-to-chain volume ratio of the surfactant assembly and therefore promotes the formation of a structure with curved interfaces. As a result, only the rod-based AS-H_0 can be obtained as a major phase for the Al_4Si_4-C_{16}TA system even under basic conditions although, under such conditions, a layer-based mesophase (L_0) is dominant for the more highly charged Si_8 precursor. In addition, the terminal OH groups in Al_4Si_4 condense much more readily than the O^- groups in Si_8, which makes it unnecessary to use acid to promote the condensation during the vapor phase treatment and also makes the time of the treatment much shorter than for the corresponding Si_8-C_{16}TA system. Furthermore, using only water rather than acid in the vapor phase treatment increases the possibility of the Al_4Si_4 precursor remaining intact in the final mesostructural materials. Preliminary results from a dipolar-based ^{27}Al-^{29}Si solid-state NMR connectivity experiment[11] on the Al_4Si_4-C_{16}TA system indicates that the Si-O-Al linkage remains intact in the hexagonal mesophases. It should be noted that Al_4Si_4 is the stable species under the conditions of the initial precipitations, and that they are stable in solution to 90 °C and in the solid state to temperatures above 100 °C as monitored by solid-state NMR spectroscopy.

Interestingly, a lamellar phase is obtained for the Al_4Si_4-C_{12}AM system (Fig. 2d and Fig. 4d) although it cannot be prepared with the surfactants with quaternary ammonium groups. This may be understood by considering that, in contrast to the quaternary ammonium ions, the primary ammonium (C_{12}AM) ions can become partially deprotonated during the precipitation process when they are mixed with the basic TMA-Al_4Si_4 solution (pH ≈ 11). The effective structure organizing agent in this case will be a mixture of charged ammonium ions and neutral amine molecules, which will decrease the head-to-chain volume ratio of the surfactant arrays and make the formation of a layered mesostructure favorable. The existence of amine functionalities, which are basic in aqueous solution, in the precipitated mesophases makes it inappropriate to carry out water vapor treatment because the base could be deleterious for the aluminosilicate framework. Instead, the precipitate can be refluxed with organic solvents (e.g., isopropyl alcohol) to achieve better structure ordering and condensation. The different behavior of surfactants with primary and quaternary ammonium ions in the organization of the Al_4Si_4 polyanions strongly suggests that not only can the charge density of the inorganic precursors be adjusted to achieve a desired mesostructure as we have done for the Si_8-C_{16}TA system,[8] it is also possible to adjust the surfactant component to modify the charge density at the interfaces. This example also provides further evidence that the charge density balance at the interface determines the mesostructure formed.

In addition to the Al_4Si_4 species, aluminosilicate polyanions with the same cubic structure, $AlSi_7$, Al_2Si_6 (two isomers), and Al_3Si_5 have also been reported and characterized[12] and could be used as precursors. Moreover, the incorporation of Al into the cubic Si_8 structure can be achieved with the bulk Si/Al ratio continuously varying from infinity (in the pure Si_8 case) to 1/1 (in the pure Al_4Si_4 case) by the procedure given above starting from TMA silicate and TMA aluminate solutions with an appropriate silicate to aluminate molar ratio. It is also known that other polysilicates such as double three-ring (D3R), double five-ring (D5R) silicates, etc., exist in certain systems with quaternary ammonium groups.[12] Partial substitution of Si in these structures with Al is also possible. Incorporation of other metallic elements in the Si_8 structure should also be possible, and this will considerably enrich the chemistry of these mesostructural materials and extend their possible applications. By selection of appropriate precursor species in terms of both structure and composition, it should be possible to synthesize mesostructural and mesoporous materials with desired properties and a degree of local structure.

Calcination of the AS-H_1 phase by slowly heating the sample under N_2 to 500 °C over a period of five hours, and then heating it in air at 500 °C for another five hours leads to a considerable contraction of the structure. The X-ray diffraction patterns

show that the $d(100)$ value decreases from about 36 Å for AS-C_{16}TA-H_1 (Fig. 2b) to about 25 Å for the calcined material (Fig. 2c). The ^{27}Al NMR spectra of calcined samples indicate some of the tetrahedrally coordinated Al centers are converted to octahedrally coordinated ones. Partial dealumination is not unexpected for an aluminosilicate structure with such a high Al content, but it is also possible that these Al centers are still relatively strongly bound to the framework and the walls have become thicker and the pores smaller. We are currently exploring the structural details of these calcined materials and the possibility of removing the templates by other, less destructive, procedures.

In summary, this work, together with our previous results on the Si_8 precursor demonstrates that it is possible to organize inorganic oligomers with surfactants step by step into mesostructural materials. Incorporation of metallic elements, and other modifications in structure and composition can be carried out more easily and more effectively at the oligomer stage than with gel precursors. It is also possible to achieve true materials design and structure-tailoring through such a synthetic pathway by using suitable structure building blocks (e.g., oligomers) and by effectively controlling the structure assembling processes (e.g., condensation).

Experimental Procedure

Crystalline TMA-Al_4Si_4 was prepared according to the literature procedure by slowly evaporating a solution containing TMA silicate and TMA aluminate in a 1:1 Si/Al ratio [9]. The TMA-silicate solution was prepared by dissolving Ludox silica into a TMAOH solution to obtain a final concentration of 1 M for both Si and TMA. The TMA aluminate solution used was freshly prepared by hydrolyzing aluminum isopropoxide in a TMAOH solution to a final Al concentration of 0.3 M and a TMA/Al ratio of 1.5/1. The precipitation of Al_4Si_4 with surfactants was performed by mixing an Al_4Si_4 solution (typically, TMA-Al_4Si_4 crystals (10 g) dissolved in H_2O(100 g)) and a solution of a surfactant (for example, 12.3% C_{16}TACl (200 mL)). The C_{12}AM solution was prepared by dissolving dodecylamine in an aqueous solution containing an equivalent amount of hydrochloric acid. The precipitate-mother liquor mixtures were aged overnight to equilibrate the condensation, and the precipitates were then isolated by filtration, washed with distilled water at room temperature and air-dried. The vapor phase treatments of the resulting Al_4Si_4-C_nTA ($n = 16$, 12) precipitates were carried out by using the procedure given in reference [8] but water alone was used in the present work rather than the HCl solution used for the Si_8-C_{16}TA systems. The Al_4Si_4-C_{12}AM precipitate was treated in refluxing isopropyl alcohol ($T = 90$ °C) for 24 hours to achieve further condensation.

One-Electron Redox Reactions of CoASH Esters in Anaerobic Bacteria—A Mechanistic Proposal**

Wolfgang Buckel* and Reinhart Keese

In his seminal work on the structure and function of acetyl-coenzyme A (acetyl-CoA), Feodor Lynen recognized already in 1951 that the thioester moiety of CoASH esters has properties similar to those of aldehydes and ketones.[1] This concept was further developed by Sir John W. Cornforth in 1959[2] and later confirmed by ^{13}C NMR spectroscopy. The chemical shift of the C atom in the thioester functional group was shown to be similar to that of aldehydes ($\delta \approx 195$), whereas signals for C atoms in the carboxyl group of typical oxygen esters are found at a higher field ($\delta \approx 160$). The ketone-like carbon of thioesters is readily attacked by nucleophiles such as amines, alcohols, and enolates. Furthermore, it lowers the pK_a value of a C–H bond of an adjacent carbon atom from roughly 30 (in carboxylate anions) to about 21,[3] thereby enhancing the rate of deprotonation. These two properties are relevant to many of the known reactions of thioesters in biology. The first property is exploited by a variety of enzymes catalyzing the transfer of the acyl groups of CoA esters to water, alcohols, amines, carboxylates, and thiols (thioester hydrolases EC 3.1.2., acyltransferases EC 2.3.1., and CoA-transferases EC 2.8.3.) as well as to hydrides derived from nicotinamide adenine dinucleotide phosphate (NAD(P)H) (aldehyde dehydrogenases, CoA-acylating, EC 1.2.1.). The second property, the enolization, is used by enzymes catalyzing Claisen condensations (e.g. citrate synthases, EC 4.1.3.7/28) and thioester condensations (e.g. thiolase, acetyl-CoA C-acetyltransferase, EC 2.3.1.9), as well as β-eliminations (e.g. acyl-CoA

dehydrogenases such as EC 1.3.99.2/3 and 3-hydroxyacyl-CoA dehydratases such as EC.4.1.2.17).

In recent years, however, five different enzymatic reactions of CoA derivatives have been discovered that do not fit into the generalizations mentioned above. These are dehydrations, reductions, and oxidations that occur only in certain bacteria growing under anaerobic conditions: 1) the reversible *syn*-dehydration of (*R*)-2-hydroxyacyl-CoA **1** to (*E*)-enoyl-CoA **2** (see Fig. 2 and ref. [4]); 2) the reversible dehydration of 4-hydroxybutyryl-CoA **3** to crotonyl-CoA **4** (see Fig. 3);[5, 6] 3) the oxidation of phenylacetyl-CoA **5** to mandelyl-CoA **6** (see Fig. 4);[7] 4) the reduction of benzoyl-CoA **7** to cyclohexa-1,5-diene-1-carboxyl-CoA **8** (see Fig. 5);[8] 5) the reduction of 4-hydroxybenzoyl-CoA **9** to benzoyl-CoA **7** (see Fig. 6).[9]

The dehydration of (*R*)-2-hydroxyacyl-CoA giving (*E*)-enoyl-CoA **2** is of considerable mechanistic interest since it requires the abstraction of a nonactivated β-hydrogen atom with a pK_a of $\geqslant 30$. The (*R*)-lactyl-CoA dehydratase from *Clostridium propionicum* (Fig. 2, R = H, CH_3)[10–14] and the (*R*)-2-hydroxyglutaryl-CoA dehydratases from *Acidaminococcus fermentans* and *Fusobacterium nucleatum* (R = CH_2COO^-)[15–20] have been purified to homogeneity. The enzymes have been characterized as extremely oxygen-sensitive ($t_{1/2}$ in air about 10 s) and contain reduced flavin mononucleotide (FMN) and riboflavin, as well as iron–sulfur clusters. The enzymes require activation by a reducing agent, preferentially titanium(III) citrate ($E' \approx -600$ mV),[21] as well as $MgCl_2$ and catalytic amounts of adenosine triphosphate (ATP), which is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate. In the proposed mechanism the nonactivated β-hydrogen is abstracted by the oxidized flavin as a hydride, as in acyl-CoA dehydrogenases.[4, 14, 19] In order to provide oxidized flavin, it was assumed that the hydroxyl group is displaced by a hydride derived from the reduced flavin present in the enzyme. This S_N2 reaction is facilitated by the adjacent electron-withdrawing thioester, similar to the facile nucleophilic substitution of the bromine in phenacylbromide. Furthermore, the nucleofugicity of the hydroxyl group could be enhanced by coordination to the iron–sulfur cluster, which may be regarded as a biological analogue of a tosylation agent, as shown by Beinert and Kennedy[22a] for aconitase (EC 4.2.1.3), an enzyme from the citric acid cycle. Although this mechanism appears to be plausible and explains the presence of flavins and iron–sulfur clusters in the dehydratases, the reduction of (*R*)-2-hydroxyacyl-CoA to acyl-CoA remains problematic. Thus, for S_N2 displacements with hydride, which would be conducted with $NaBH_4$ or even $LiAlH_4$ in organic chemistry, NADH ($E^{\circ\prime} = -320$ mV) would be a much better hydride donor than $FMNH^-$ ($E^{\circ\prime} \geq -200$ mV). In addition, neither (*R*)-lactyl-CoA dehydratase nor (*R*)-2-hydroxyglutaryl-CoA dehydratases are able to function as electron acceptors and catalyze the respective oxidation and dehydration of the putative intermediates propionyl-CoA and glutaryl-CoA, respectively, by ferricenium ion.[22b]

In this paper an alternative mechanism is presented, for which α-hydroxyketones (**10**; Fig. 1) may serve as models for 2-hydroxyacyl-CoA derivatives. There are several examples of reactions in which tosylated or acetylated α-hydroxyketones are reduced to the corresponding unsubstituted ketones (**11**) by single-electron donors such as zinc in acetic acid, chomium(II) and dithionite.[23] Samarium(II) ions are even able to reductively eliminate the hydroxy group of α-hydroxy esters.[24] It is suggested that the carbonyl group in **10** is first reduced by one electron to a ketyl group (**12**; only one resonance structure is shown in Fig. 1). The electron pair at the former carbonyl carbon atom displaces the adjacent hydroxyl group with the formation of a

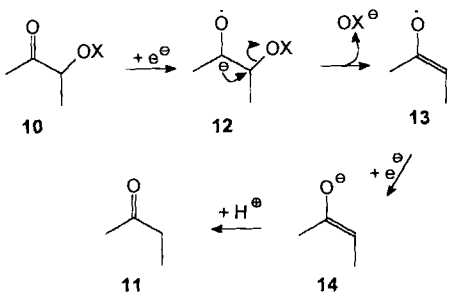

Fig. 1. Reduction of α-hydroxyketones **10** to unsubstituted ketones **11** by one-electron donors. X = H, acetyl, tosyl, etc.

enoxy radical **13**. A second one-electron reduction then leads to enolate **14**, which is protonated to give ketone **11**. Abstraction of a β-hydrogen atom from enolate **14** as a hydride rather than protonation at the enolate α-carbon, however, would yield a vinyl ketone, an analogue of enoyl-CoA **2**. This mechanism proposed for the reversible dehydration of (*R*)-2-hydroxyacyl-CoA **1** to (*E*)-enoyl-CoA **2** is shown in Figure 2.

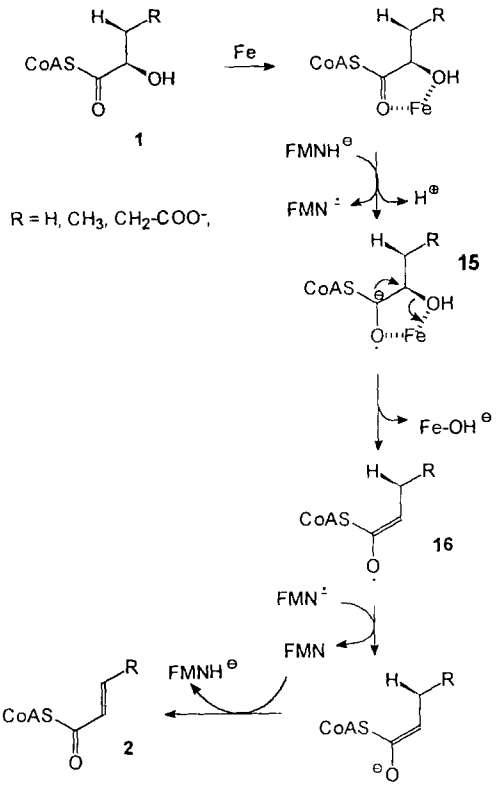

Fig. 2. Reversible *syn*-dehydration of (*R*)-2-hydroxyacyl-CoA **1** to (*E*)-enoyl-CoA **2**. Fe = [4Fe-4S] cluster like that in aconitase [22a] (see also ref. [24]).

The mechanism has following features: 1) It is based on the assumption that thioesters can be regarded as analogues of aldehydes or ketones.[1, 2] 2) It accounts for the ability of flavins not only to accept hydride ions, but also to act as donors and acceptors of single electrons, forming semiquinones.[25] 3) It assumes that ketyls derived from thioesters (**15**, Fig. 2) are as stable as those obtained from ketones. The latter are isoelectronic to the indefinitely stable nitroxyl radicals.[26] 4) The two sequential one-electron reductions of the thioester avoid the accumulation of two negative charges, which would be the case if both elec-

trons were delivered simultaneously. On the other hand, the transfer of two electrons together with a proton, or as a hydride, would lead to the reduction of the thioester to give the aldehyde. 5) It avoids saturated acyl-CoA derivatives as intermediates. 6) It is consistent with stereochemical investigations, which indicate that a freely rotating methylene radical (R = H)[27] or a less freely rotating methine radical (R = CH_3) in the β-position is unfavored.[14]

A probable variant of this mechanism would be the removal of the β-hydrogen as a *proton* already from the enoxy radical **16**, yielding the corresponding ketyl of enoyl-CoA, which is consequently oxidized to the product. Thereby a cycle is formed in which a single, high-energy electron is turned over many times. This would also explain the catalytic activation: Titanium(III) citrate supplies the electron, which is energized by hydrolysis of ATP[28b] as shown for nitrogenase.[28a]

A similar mechanism can be postulated for the reversible dehydration of 4-hydroxybutyryl-CoA **3** to crotonyl-CoA **4** (Fig. 3). Again the C–H bond at the β-carbon is not activated

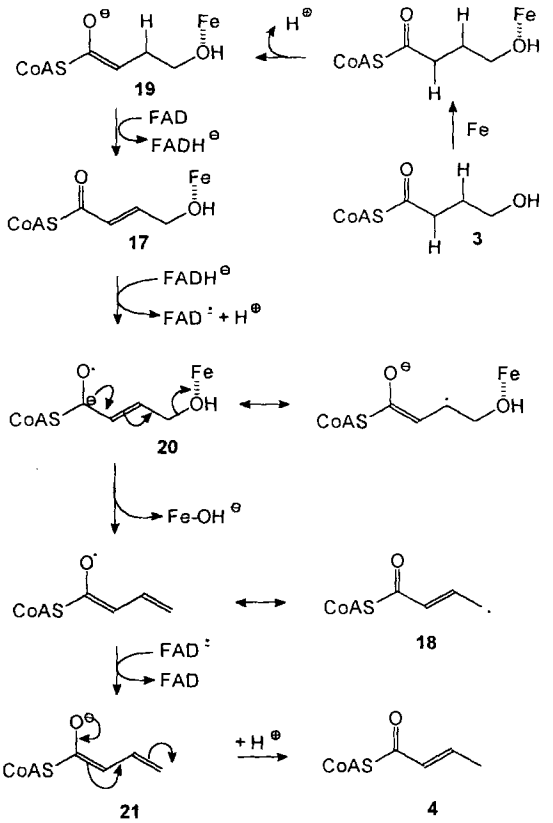

Fig. 3. Reversible dehydration of 4-hydroxybutyryl-CoA **3** to crotonyl-CoA **4**.

and hence cannot be deprotonated. The 4-hydroxybutyryl-CoA dehydratases from *Clostridium aminobutyricum*[5] and *C. kluyveri*[6] contain iron–sulfur clusters and FAD in the oxidized state. Reduction of the flavin inactivates the enzyme, which is reactivated by oxidation with hexacyanoferrate(III). Oxygen, however, irreversibly inactivates the enzyme, probably due to the destruction of the iron–sulfur cluster. The dehydration may be initiated by an FAD-dependent α,β-oxidation of 4-hydroxybutyryl-CoA **3** to 4-hydroxycrotonyl-CoA **17**. In turn, compound **17**, a vinylogous 2-hydroxyacyl-CoA, is reduced to crotonyl-CoA via ketyl intermediates, whereby FAD is regenerated. In the course of this reaction the methylene group at C-4 of 4-hydroxybutyryl-CoA is converted into the methyl group of crotonyl-CoA. Hence, introduction of all three hydrogen isotopes might lead to a "chiral methyl group".[29, 30] In the proposed γ-crotonyl radical intermediate **18** rotation of the methylene group most likely has a substantial barrier. It is expected, therefore, that one enantiomer of the chiral methyl group will be formed preferentially. In analogy to the dehydration of 2-hydroxyacyl-CoA, the dehydration of 4-hydroxybutyryl-CoA could also proceed by a one-electron cycle, in which the removal of a hydride from enolate **19** by FAD is replaced by a one-electron oxidation followed by deprotonation to give ketyl **20**. After elimination of the hydroxide ion, the resulting dienoxy radical **18** would be reduced to dienolate **21** followed by protonation to give crotonyl-CoA **4**. In contrast to the dehydration of 2-hydroxyacyl-CoA, this reverted one-electron cycle should turn over on a much lower energy level due to the conjugated intermediates, which agrees well with its lack of ATP requirement.

The oxidation of phenylacetyl-CoA **5** to phenyl(hydroxyacetyl)-CoA **6** (mandelyl-CoA; Fig. 4) should proceed as the

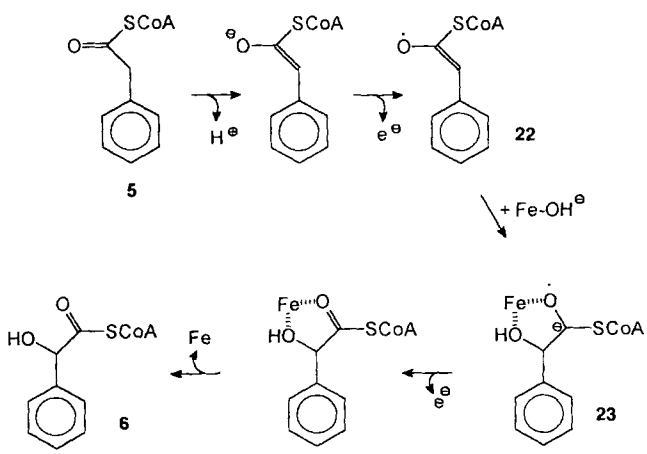

Fig. 4. Oxidation of phenylacetyl-CoA **5** to mandelyl-CoA **6**.

reversal of the reduction of a 2-hydroxyketone (Fig. 1). The mechanism predicts the presence of an iron–sulfur cluster facilitating the addition of the hydroxyl group to the enoxy radical **22**, whereby the ketyl **23** is formed. In contrast to the dehydratases (see Figs. 2 and 3), involvement of a flavin is not necessary, since hydrides are not transferred and other compounds such as ferredoxins could serve as one-electron acceptors.

The recently discovered reduction of benzoyl-CoA **7** to cyclohexa-1,5-diene-1-carboxy-CoA **8** in the bacterium *Thauera aromatica* can also be explained by stepwise addition of two electrons (Fig. 5). This reaction could proceed via radical anions in analogy to the Birch reduction of arenes. Calculations have shown that the *para* position of the radical anion of benzaldehyde, a close analogue of the radical anion of benzoyl-CoA, is the most electron-rich position and thus subject to preferential protonation.[31] A similar mechanism can be proposed for the 1,4- or 2,5- addition of two hydrogens to benzoyl-CoA **7**, which was observed by Gibson and Gibson.[32a] The thioester group thus serves as the entrance for the electrons into the aromatic ring, while the position of protonation is controlled by the enzyme. This new function for the thioester was not considered in an earlier proposal also involving one-electron transfers.[8] The stoichiometric ATP hydrolysis[32b] coupled to this reduction is necessary to reduce the redox potential of unidentified biologi-

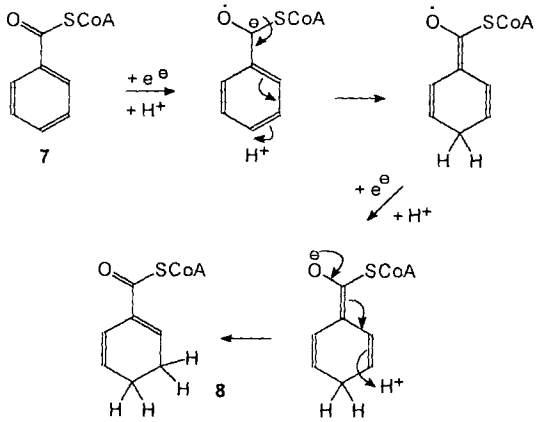

Fig. 5. Reduction of benzoyl-CoA 7 to cyclohexa-1,5-diene-1-carboxyl-CoA 8.

cal electron donors to at least -550 mV (see also 2-hydroxyacyl-CoA dehydratase). As mentioned above, for the same purpose, stoichiometric amounts of ATP are required for the biological fixation of nitrogen.[28]

In a similar way, 4-hydroxybenzoyl-CoA 9 may be reduced to benzoyl-CoA 7 (Fig. 6). The 4-hydroxybenzoyl-CoA reductase

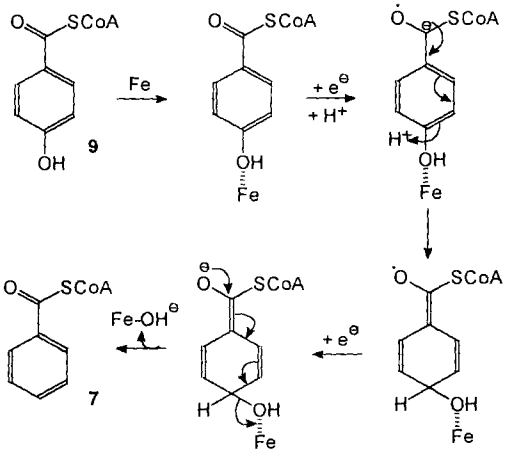

Fig. 6. Reduction of 4-hydroxybenzoyl-CoA 9 to benzoyl-CoA 7.

has been purified to homogeneity and characterized as an iron–sulfur enzyme. Flavin could not be detected.[9] With this type of mechanism the removal of the hydroxyl groups from 2-hydroxybenzoyl-CoA (salicylyl-CoA), and the amino group from 2-aminobenzoyl-CoA (anthranilyl-CoA) may also be explained. It is of interest that the reduction of 3-chlorobenzoate to benzoate does not proceed at the thioester level.[33]

All the five reactions discussed here, for which one-electron transfers have been postulated, are extremely oxygen-sensitive. This can be explained by the high reactivity of oxygen towards single "energy-rich" electrons at low potential. Under aerobic conditions, one-electron transfers are only found at potentials ≥ 0 mV. At lower potentials all reductions are two-electron steps, the lowest being that by NADH ($E^{\circ\prime} = -320$ mV). The research group of W. Buckel is currently investigating these single-electron transfers by EPR spectroscopy.

It has been demonstrated in this paper that the reduction of a ketone to a ketyl results in an umpolung of the electrophilic carbonyl carbon into a nucleophilic one. Another example of an umpolung is the oxidative decarboxylation of pyruvate to acetyl-CoA catalyzed by pyruvate ferredoxin oxidoreductase (pyruvate synthase, EC 1.2.7.1) from *Halobacterium halobium*. In this reaction a free radical, indeed a ketyl, has been detected and characterized by EPR spectroscopy (Fig. 6).[34] The umpolung is achieved by addition of pyruvate to thiamine diphosphate. The addition product reversibly decarboxylates to give hydroxyethyl-thiamine diphosphate. It has been shown that the hydroxyethyl moiety of the latter is oxidized by an iron–sulfur cluster with the removal of one electron to the ketyl (Fig. 6). Further oxidation of the ketyl to acetylthiamine diphosphate,[35] followed by an acetyl transfer to CoASH yields the final product acetyl-CoA (Fig. 7).

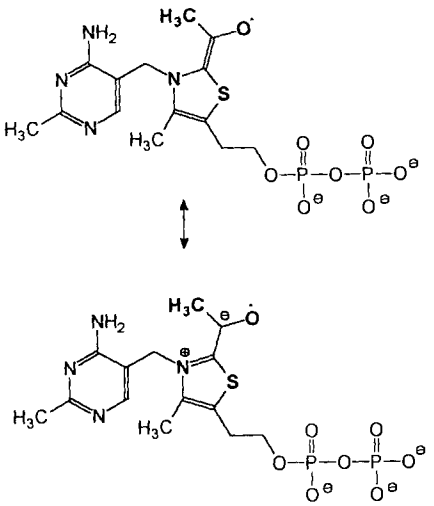

Fig. 7. A ketyl as an intermediate of the pyruvate ferredoxin oxidoreductase.

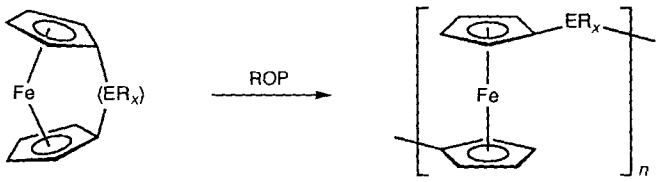
Synthesis and Structure of the First Sulfur-Bridged [1]Ferrocenophane**

John K. Pudelski, Derek P. Gates, Ron Rulkens, Alan J. Lough, and Ian Manners*

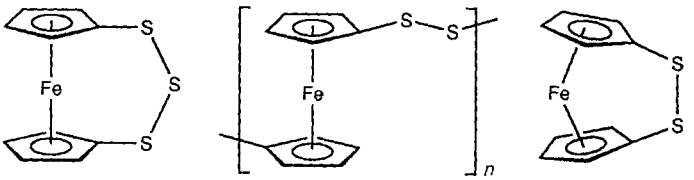
[1]Ferrocenophanes have attracted attention because of their interesting structures and reactivity,[1] their applications as surface derivatization agents,[2] and very recently as precursors to novel transition-metal-based polymers through ring-opening polymerization (ROP).[3] The first [1]ferrocenophane, **1** ($ER_x = SiPh_2$), was isolated by Osborne et al. in 1975 from the reaction of dilithioferrocene·tmeda (tmeda = tetramethylethylenediamine) and Ph_2SiCl_2.[4] This species was shown to possess an unusual, strained structure in which the planes of the cyclopentadienyl ligands were tilted with respect to one another by about 19°.[5] Germanium-bridged [1]ferrocenophanes **1** (E = Ge) have been subsequently reported and possess slightly less strained structures.[1, 6] Group 15 elements such as phosphorus and arsenic have also been successfully incorporated into the bridge structure,[1, 6–8] and the cyclopentadienyl ring-tilts for species **1** (E = P or As) are greater (about 23–27°).[6, 8] In 1992 we reported the discovery that silicon-bridged [1]ferrocenophanes undergo facile thermally induced ROP reactions to afford high molecular weight ($M_n > 10^5$) poly(ferrocenylsilanes) **2** (E = Si, $R_x = Me_2$, Ph_2) (Scheme 1).[9] We have also observed that related [1]ferrocenophanes with germanium or phosphorus in the bridge polymerize thermally and that ROP can be induced in solution by using anionic initiators.[3, 10–12]

[1]Ferrocenophanes containing Group 16 elements in the bridge are unknown at present, but would be expected to possess even more strained, ring-tilted structures[13] than their Group 14 and 15 analogues and might also function as precursors to novel polymers. Trithio-bridged [3]ferrocenophanes such as **3** have been previously prepared from the reactions of dilithiated ferrocenes with elemental sulfur.[14, 15] Although essentially unstrained (tilt angles smaller than 4.5°),[16, 17] Rauchfuss and co-workers have recently reported an elegant ROP reaction of these species, induced by sulfur atom abstraction with PBu_3, which affords polymers such as **4**.[17–19] Strained dithio-bridged [2]ferrocenophanes **5** have been proposed as possible intermediates in these polymerization reactions but have not been identified or isolated to date. In this paper we report the first example of a sulfur-bridged [1]ferrocenophane.[20]



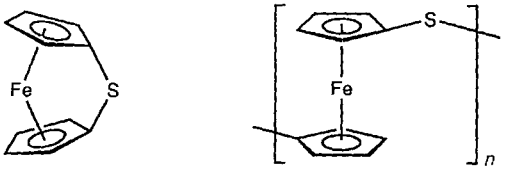
1 **2**

Scheme 1.



3 **4** **5**

We attempted to prepare the sulfur-bridged [1]ferrocenophane **6** by the low temperature reaction of dilithioferrocene·tmeda with $(PhSO_2)_2S$ in THF.[21, 22] Removal of the $LiSO_2Ph$ by-product followed by vacuum sublimation of the crude product residue afforded a purple sublimate contaminated with a trace quantity of ferrocene. Recrystallization of this sublimate from hexanes at −30 °C afforded **6**, free of ferrocene, as a purple crystalline material in 14% yield.



6 **7**

Characterization of **6** by NMR and UV/Vis spectroscopy confirmed the assigned structure and provided interesting insight into the strained nature of this species. For example, the ^1H NMR spectrum (in C_6D_6) of **6** consists only of a pair of widely separated pseudo triplets at $\delta = 3.96$ and 4.61, assigned to the α and β cyclopentadienyl protons. In the ^{13}C NMR spectrum (in C_6D_6) (Fig. 1), the *ipso* cyclopentadienyl carbon atom of **6** resonates at the highest field yet observed ($\delta = 14.3$) for the *ipso* carbons of a [1]ferrocenophane[23] and clearly reflects structural distortion at these sites.[1] In hexanes, **6** exhibits a UV/Vis absorbance at 504 nm, which is considerably red-shifted

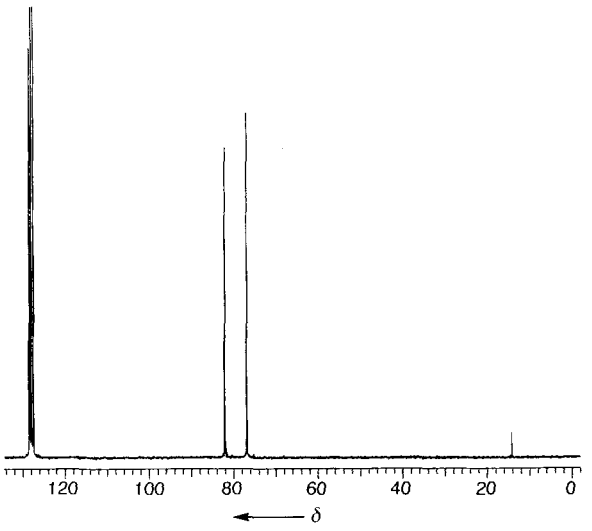

Fig. 1. ^{13}C NMR spectrum of **6** (50.3 MHz, C_6D_6).

relative to the 440 nm absorbance of ferrocene and is indicative of highly tilted cyclopentadienyl rings.[1, 24]

A single crystal X-ray diffraction study of **6** was undertaken in order to probe the structure of this novel species.[25] A suitable crystal was obtained by cooling a solution of **6** in hexanes to −30 °C; the resulting structure diagram is shown in Figure 2.

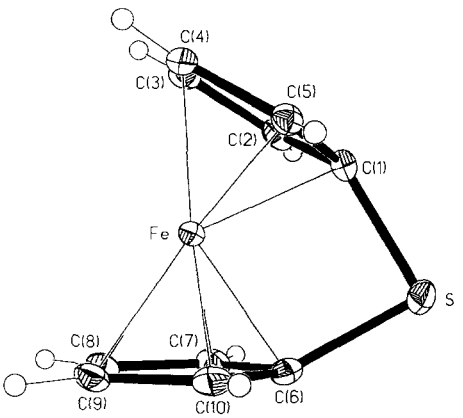

Fig. 2. Crystal structure of **6**. Selected bond lengths [Å] and angles [°]: S–C(1) 1.807(2), S–C(6) 1.805(2), Fe–C(1) 1.969(2), Fe–C(2) 2.005(2), Fe–C(5) 2.018(2), Fe–C(3) 2.074(2), Fe–C(4) 2.082(2), Fe–C(6) 1.967(2), Fe–C(7) 2.021(2), Fe–C(10) 2.010(2), Fe–C(8) 2.091(2), Fe–C(9) 2.083(2), C(1)-S-C(6) 89.03(9).

The most striking structural feature of **6** is the unprecedented 31.05(10)° tilt angle between the planes of the cyclopentadienyl rings. This tilt angle is the largest yet reported for a [1]ferrocenophane and the first over 30° for any Group 8 [*n*]metallocenophane.[26] Cyclopentadienyl ring tilting is accompanied by a RC1-Fe-RC2 angle (RC = ring centroid) of 156.9(1)° compared to 180° in ferrocene and a 0.326(2) Å displacement of the iron atom from the line joining the two ring centroids. The tilted cyclopentadienyl rings maintain an eclipsed conformation with a C1-RC1-RC2-C6 torsion angle of 0.4(3)°. Additional structural distortions include angles of 29.1(1)° and 28.8(1)° between the cyclopentadienyl ring planes and the exocyclic C–S bonds. The C1-S-C6 angle of 89.03(9)° is smaller than the analogous angles in silicon-bridged [1]ferrocenophanes (about 96°–99°) and similar to the angles found in phosphorus-bridged species (about 91°). The S–C bond lengths (average, 1.806(3) Å) are typical of C–S single bonds, although slightly elongated relative to analogous bonds in trithio-bridged [3]ferrocenophanes (about 1.75–1.76 Å).

Despite its highly strained structure, **6** is stable as a solid and in solution (C_6D_6) at room temperature in the absence of air or moisture. Cyclic voltammetric analysis[27] of **6** showed a quasi-reversible oxidation ($I_{red}/I_{ox} = 0.74$) at 500 mVs^{-1} in contrast to silicon-bridged [1]ferrocenophanes, which, under identical conditions, exhibit reversible oxidations.[28] Preliminary studies reveal that when **6** is heated at 150 °C a orange-brown solid product, insoluble in common organic solvents (such as THF, toluene), is obtained. Mass spectrometric analysis of this solid showed peaks that could be assigned to oligomeric $[(\eta\text{-}C_5H_4)Fe(\eta\text{-}C_5H_4)S]_n$ species of up to four repeat units in length, which is consistent with the proposed polymeric structure **7**.[29]

Further studies of the reactivity of **6** and attempts to prepare soluble polymeric materials by ROP are in progress.

Experimental Procedure

To a mixture of dilithioferrocene·tmeda (1.07 g, 3.41 mmol) and $(PhSO_2)_2S$ (1.16 g, 3.69 mmol) cooled to −196 °C by a liquid N_2 bath was added dry THF (30 mL) precooled to −78 °C. The resulting red mixture was allowed to warm slowly to room temperature. Solvent was removed in vacuo, and the resulting residue was extracted with dry hexanes (3 × 10 mL). The extracts were passed through a fritted glass disk, and the red filtrate was concentrated in vacuo. The resulting residue was sublimed at 25 °C (0.01 mm Hg), and 0.15 g of crude **6** was collected on a cold probe (−40 °C). Two successive recrystallizations from hexanes at −30 °C afforded 0.10 g (14 %) of **6** as a dark purple crystalline solid: m.p. 104 °C; ^1H NMR (200 MHz, C_6D_6): $\delta = 4.61$ (ps t, $J = 2$ Hz, 4H), 3.96 (ps t, $J = 2$ Hz, 4H); ^{13}C NMR (50.3 MHz, C_6D_6): $\delta = 82.1$ (cyclopentadienyl), 76.9 (cyclopentadienyl), 14.3 (*ipso*-cyclopentadienyl); UV/Vis (hexanes): λ_{max} (ε) = 504 nm (343 $Lcm^{-1}mol^{-1}$); HR-MS calcd for $C_{10}H_8{}^{56}FeS$ 215.9696, found 215.9689.

Synthesis and X-Ray Powder Structure of a Novel Porous Uranyl Phenylphosphonate Containing Unidimensional Channels Flanked by Hydrophobic Regions**

Damodara M. Poojary, Daniel Grohol, and Abraham Clearfield*

A variety of metal phosphonate compounds have been synthesized and examined in view of their applications in catalysis, sorption, ion exchange, intercalation chemistry, etc. These systems generally form mononuclear coordination complexes,[1, 2] linear one-dimensional structures,[3, 4] or layered compounds.[5–7] The layered compounds are of special interest because of the ordered arrangement of organic groups on either side of the metal–phosphonate layers, which provide a highly organized media for specific reactions of the type mentioned above.[7, 8] Metal–phosphonate compounds showed further promise in their diverse applications when porous compounds similar to zeolites were discovered: aluminum methylphosphonate[9] and copper methylphosphonate[10] have inorganic frameworks and unidimensional channels similar to those in zeolites. In these structures the methyl groups are projected towards the center of the channels resulting in hydrophobic channels. In this communication we describe the structure of the uranyl phenylphosphonate $UO_2(O_3PC_6H_5)\cdot 0.7H_2O$,[11] which has similar unidirectional pores; the most remarkable feature of this structure, however, is that the phenyl groups are arranged on the outer periphery of isolated channels and the channel is lined with uranyl oxygen atoms.

Step scanned X-ray powder diffraction data were collected on a Rigaku automated diffractometer ($Cu_{K\alpha}$, 50 kV, and 180 mA), and the pattern was indexed by Ito methods.[12] The systematic absences were consistent with either the space group *P*6/*mcc* or *P*6*cc*. The initial choice of the centric space group was found to be correct from the successful solution and refinement of the structure. Integrated intensities were extracted from the profile, and a Patterson map was computed by using 74 unambiguously indexed reflections. The position of the uranium atom was located from this map. Constrained refinement against this data set and subsequent difference Fourier maps revealed the positions of the P and all the oxygen atoms. This structural model was then entered into GSAS[13] for Rietveld refinement. Subsequent Fourier maps revealed the positions of all the carbon atoms of the phenyl group. Two positions were identified for lattice water molecules. O(W1) is located at the center of the pore and is at hydrogen-bonding distance (2.39 Å) from O(W2). Since symmetry-related O(W2) positions are close to each other (1.6 Å), they cannot exist with full occupancy. The corresponding occupancy refined to about 0.5 thus totally accounting for 0.67 moles of water, which is close to the amount of water loss (2.7%) determined by thermogravimetric analysis. This low water content is probably dictated by the strain energy imposed by the curvature of the channels. The crystallographic data are given in reference [14] and Table 1. The observed and calculated powder patterns are shown in Figure 1.

walls of these pores but no such linkages exist between neighboring channels. This structure therefore is different from the copper[10] and aluminum[9] methylphosphonates which contain three-dimensional networks. The pore in the present structure consists of a 12-ring in which six uranium and six phosphorus centers alternate; the distance between the adjacent uranium atoms in this ring is about 6.1 Å (i.e. distance between U atoms in a or b direction). All the atoms except one of the phosphonate oxygens (O3) lie on a mirror plane at $z = 0.0$ and 1/2. The uranium atoms are arranged in the form of a zigzag chain along the wall of the channels with an intermetallic distance of about 4.1 Å (i.e. distance between U atoms in c direction). The oxygen atoms (O3) are involved both in chelation and bridging the metals along the c axis. This leads to double chains with alternating four-membered rings along the wall of the pore; one consisting of two U atoms and two O atoms, the other of two O atoms, a U atom, and a P atom. These double chains are linked together by the phosphonate oxygens O4 along the a (or b) direction (Fig. 3). This type of metal–phosphonate binding is

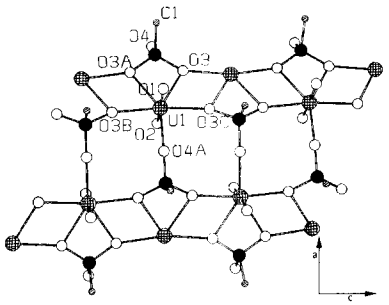

Fig. 3. Arrangement of uranyl phosphonate double chains along the wall of the pore.

strikingly similar to that observed for $UO_2(O_3PCH_2Cl)$,[15] although the latter compound is layered; the organic groups point on either side of the layer. The coordination geometry about the U atom is thus a pentagonal bipyramid, in which the five phosphonate oxygen atoms form the basal plane and the uranyl oxygen atoms (O1 and O2) occupy the axial sites. One of the uranyl oxygen atoms projects towards the center of the pore. The phenyl groups are arranged on the outside of the pore and they are held together by stacking interactions.[16] This grouping of the phenyl groups thus creates isolated channels whose arrangement is dictated by the packing forces.

The distance between the diagonally opposite U atoms in the 12-ring is 12.2 Å. Since one of the uranyl oxygen atoms (O2) is in the same plane of the ring and is directed roughly towards the center of the channel, the diameter of the pore is reduced by a factor equivalent to about two U=O bond lengths. Taking this and the van der Waals radius of O(1.4 Å) into account, the calculated diameter of the available pore is about 7.3 Å. The compound is stable up to about 350 °C. The d spacing of the dehydrated sample is nearly the same as the starting material, indicating the porous structure of the compound. Investigations on intercalation reactions and other physicochemical studies are in progress.

Experimental Procedure

Uranyl nitrate hexahydrate (5.0 g, 10.0 mmol) was dissolved in distilled water (160 mL), filtered, and 50% HF(1.75 mL, 60 mmol) was added. Phenylphosphonic acid (2.37 g, 15.0 mmol) was dissolved in water (160 mL) and added to the uranyl nitrate solution. The total volume of the mixture was then adjusted to 350 mL with distilled water and the temperature was raised to 90 °C. After 1–2 h a yellow powder started to precipitate, which was filtered off after about 5 h, washed with distilled water and air-dried. Thermogravimetric analysis was carried out at a rate of 10 °C min^{-1} under a flow of O_2. The weight loss up to 150 °C was 2.7% and the total weight loss up to 500 °C was 19.5%. Elemental analysis: Found: P 6.13, C 17.51, H 1.67; calc. for $UO_2(O_3PC_6H_5)\cdot 0.67\,H_2O$: P 7.07, C 16.44, H 1.46.

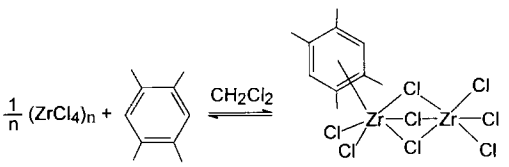
[16] The phenyl rings are grouped about the sixfold axes, in such a way that three rings are in one plane (at $z = 0$) and the other three at a plane with $z = 1/2$ and vice versa. For a given phenyl group, there are two nearest neighboring phenyl groups, both at a plane shifted half along the c axis. The interactions between the groups from the same channel involve C2 and C3 atoms (C2···C2′ 3.78, C3···C3′ 3.9 Å), while that between neighboring channels involve C4 and C5 atoms (C4–C4′ 3.5, C5–C5′ 3.6, C4–C5′ 3.8, and C5–C4′ 3.8 Å). The C6 atoms of the adjacent phenyl rings are separated further apart to accommodate one of the uranyl oxygen atoms O1.

Hydrocarbon Activation with Metal Halides: Catalysis of the Jacobsen Rearrangement by $(ZrCl_4)_n$ in the Presence of Aromatic Hydrocarbons**

Euro Solari, Fabrizio Musso, Richard Ferguson, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

The metal-promoted rearrangement of hydrocarbons involving C–C bond cleavage and formation is of major interest.[1] Amongst the more interesting approaches, though not frequently employed, is the use of acidic metal electrophiles such as early transition metal halides.[2, 3] This approach has a parallel in organic chemistry—reactions with super acidic compounds.[4] A significant advantage of acidic metals over expensive, low-valent metals in elaborate coordination environments[1] is their straightforward preparation, low cost, and stability towards oxygen.

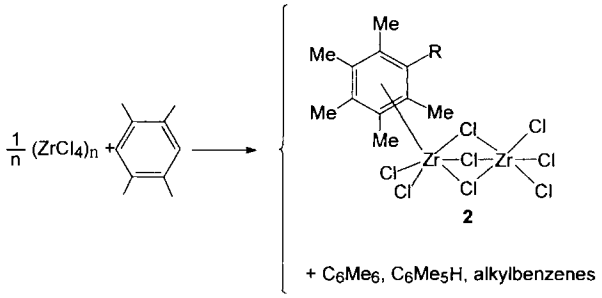
We report here on a number of observations concerning the interaction of alkylbenzenes with $ZrCl_4$. Although $ZrCl_4$ is extremely insoluble in noncoordinating solvents, it is very soluble in CH_2Cl_2 in the presence of a stoichiometric amount of 1,2,4,5-$Me_4C_6H_2$ (durene). The ^1H NMR spectrum of the reaction mixture in CD_2Cl_2 initially shows the presence of an unshifted singlet for the Me groups of durene, but after some time numerous peaks of increasing intensity appear in its vicinity. Addition of THF to the solution results in $[ZrCl_4(thf)_2]$, in addition to durene and a small amount of other alkylbenzenes. The dissolution of $ZrCl_4$ promoted by durene has been interpreted according to Reaction (a).



1 (a)

The solubility of $ZrCl_4$ is also increased in the presence of other alkylbenzenes, although the hydrocarbon:$ZrCl_4$ ratio depends on the arene. In the case of mesitylene[5] the dissolution occurs with an arene:$ZrCl_4$ ratio of 2:1, which reflects the lower basicity of mesitylene compared to that of durene. However, this technique cannot be extended to C_6Me_5H and C_6Me_6, because, though they react with $ZrCl_4$, they form insoluble compounds.

When the CH_2Cl_2 solution of $ZrCl_4$–durene was left standing for several weeks, significant amounts of C_6HMe_5, C_6Me_6, $C_6Me_4H_2$, and $C_6Me_3H_3$ formed, along with some insoluble compounds. This conversion continued until the starting durene is completely consumed. Thus the transformation of the $ZrCl_4$–durene system in CH_2Cl_2 solution can be summarized by Scheme 1.



Scheme 1. **2**: R = H (50%), Me (50%).

We isolated compound **2**, $[(\eta^6\text{-}Me_5C_6R)Zr_2Cl_8]$ (R = H, 50%; R = Me, 50%), as a crystalline solid. Its structure, identical to that of **1** and $[(\eta^6\text{-}C_6Me_6)Zr_2Cl_8]$ (**3**), and its composition have been proved by an X-ray analysis and by analysis of the decomposition products arising from the reaction with THF. To avoid the statistical presence of the C_6Me_6 and C_6Me_5H

ligands in **2**, we synthesized the analogous complex **3** from pure C_6Me_6 and $ZrCl_4$ in 1,2-$Cl_2C_6H_4$. The ^1H NMR spectrum of **3** in CD_2Cl_2 shows two singlets at $\delta = 2.20$ (low intensity) and $\delta = 2.55$ corresponding to free C_6Me_6 and zirconium-coordinated C_6Me_6, respectively. The structure of **3** is shown in Figure 1[6] with some selected structural parameters. Some distantly related examples of (η^6-arene)zirconium(IV) complexes have been reported recently.[7]

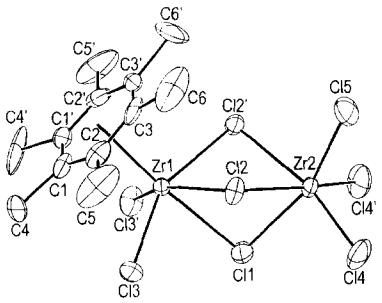

Fig. 1. ORTEP view of complex **3** (ellipsoids at 30% probability). Selected distances [Å]: Zr1 Cl1 2.762(2), Zr1 Cl2 2.587(2), Zr1 Cl3 2.375(2), Zr1 · Cb1 2.367(6), Zr1 C1 2.739(6), Zr1 · C2 2.725(8), Zr1–C3 2.768(7), Zr2–Cl1 2.519(3), Zr2 Cl2 2.609(2), Zr2–Cl4 2.347(3), Zr2–Cl5 2.357(4). Bond angles [°]: Cl3-Zr1-Cl3' 94.0(1), Cl2-Zr1-Cl3 151.4(1), Cl2-Zr1-Cl2' 78.2(1), Cl1-Zr1-Cb1 174.7(2), Cl4'-Zr2-Cl4 99.4(1), Cl2-Zr2-Cl4 91.0(1), Cl1-Zr2-Cl2 76.6(1), Cl1-Zr2-Cl5 161.4(1). Primed atoms denote a transformation of x, $0.5 - y$, z. Cb1 refers to the centroid of the aromatic ring.

Complex **3** has a crystallographic mirror plane passing through both Zr atoms, Cl1, and Cl5. The assignment of an η^6 bonding mode to the hexamethylbenzene fragment is supported by the narrow range of the Zr–C distances [2.725(8)–2.768(7) Å]. The terminal Zr–Cl bonds have an average length of 2.365(9) Å, while significant asymmetry is observed for the bridging chlorine atoms; the longest Zr–Cl distance is to Cl1, which is *trans* to the η^6-C_6Me_6 ligand [Zr1–Cl1 2.762(2) Å].[8] This chlorine atom should therefore be the easiest to ionize. Indeed, complexes **1**–**3** should be considered as models of the precursors for the formation of $[(\eta^6\text{-}C_6Me_6)TiCl_3]^+[Ti_2Cl_9]^-$, which is generated from the reaction of C_6Me_6 with a large excess of $TiCl_4$ in CH_2Cl_2.[9] The large ionic radius and the greater acidity of zirconium versus titanium allow the isolation of the neutral arene complexes **2** and **3** prior to subsequent ionization processes.

We have investigated the possible roles played by CH_2Cl_2, including whether it serves as the source of methyl groups. To rule out this hypothesis, we performed the same durene rearrangement in other solvents such as 1,2-$C_6H_4Cl_2$, $C_2H_2Cl_4$, and *n*-octane.[10] In addition, when the reaction was carried out in CD_2Cl_2 we did not observe incorporation of deuterated methyl groups into the final alkylbenzenes.

The reaction in Scheme 1 is catalytic, albeit to only a limited extent. Furthermore, complexes **2** and **3** dissolved in CH_2Cl_2 are also able to promote the disproportionation of durene. The $ZrCl_4$-assisted rearrangement of C_6Me_5H is quite similar to that discussed for durene. The rates of both reactions can be increased considerably by conducting the reaction in 1,2-$Cl_2C_6H_4$ at 60 °C, or by using a higher $ZrCl_4$:hydrocarbon ratio. We should mention at this stage that the isomerization of durene was observed previously by action of concentrated sulfuric acid, the so-called Jacobsen reaction.[11, 12a, 12b]

The mechanism of the reaction in Scheme 1 is open. Contrary to our results, in the alkylation and dealkylation reactions promoted either by H_2SO_4 or Lewis acids such as H^+, BF_3, and AlX_3, the methyl migration occurs almost exclusively in an intramolecular fashion.[12c] Such reactions are believed to proceed via a carbocation intermediate, as is the case in alkylbenzene rearrangements promoted by the $TaCl_5/CH_2Cl_2$ system[13a] and in alkane isomerization assisted by CX_4/AlX_3.[13b] Unlike these cases, we believe that in our reaction a methyl group is transferred intermolecularly from a methyl donor to a methyl-accepting arene, and this probably does not require a carbocation intermediate. As a matter of fact, when we performed the reaction at 100 °C in 1,2-$Cl_2C_6H_4$ with C_6Me_6, we observed the formation of partially methylated benzenes and alkylated solvent.[14]

Studies in progress are aimed at extending these reactions to the functionalization of hydrocarbons and other kinds of hydrocarbon rearrangements, and to making these reactions catalytic in zirconium. In addition, we should mention that the solution of durene–$ZrCl_4$ in CH_2Cl_2 can be used as a source of a soluble, weakly solvated form of dimeric $ZrCl_4$.

Experimental Procedure

1: A solution of $ZrCl_4$ (40.0 g, 171.7 mmol) and durene (23.05 g, 171.7 mmmol) in CH_2Cl_2 (100 mL) gave a red-violet solution after 15–18 h. THF (5.0 mL) was added to a 5.0 mL aliquot of the solution and $[ZrCl_4(thf)_2]$ was isolated. Durene was identified as the major organic product (by GC-MS) along with significant amounts of C_6Me_5H and C_6Me_6, and all the $C_6H_2Me_4$ isomers. After a reaction time of six months at room temperature, we found that the initial durene was completely converted into C_6Me_5H and C_6Me_6 in a 4:3 molar ratio with an overall yield of 90%; the durene isomers amounted to only 1%, and we did not determine the amounts of the other demethylated species such as the mesitylene isomers and the insoluble products. We indirectly proved that insoluble diarylmethanes containing bridging CD_2 units form from benzene and toluene by the action of CD_2Cl_2 assisted by $ZrCl_4$. The addition of THF to the final solution gave $[ZrCl_4(thf)_2]$ (95%).

2: A $ZrCl_4$–durene solution in CH_2Cl_2 was left standing at room temperature for one month, then concentrated to dryness. The solid was recrystallized from 1,2-$Cl_2C_6H_4$ to give **2** (93%). Anal. calcd for $C_{23}H_{34}Cl_{16}Zr_4$: C 22.23, H 2.76; found: C 23.01, H 2.95. Compound **2** decomposed on treatment with THF giving a 1:1 mixture of C_6Me_5H and C_6Me_6. Crystal data for **2**: $[Zr_2Cl_8(C_{12}H_{18})_{0.5}(C_{11}H_{16})_{0.5}]$, orthorhombic, space group *Pnma*, $a = 19.514(3)$, $b = 13.266(3)$, $c = 8.130(6)$ Å, $V = 2104.6(1.7)$ Å^3, $Z = 4$.

3: A suspension of $ZrCl_4$ (2.50 g, 10.7 mmol) in 1,2-$Cl_2C_6H_4$ (150 mL) and C_6Me_6 (0.865 g, 5.30 mmol) was heated to boiling until it became a clear solution. The solution was then allowed to cool to ambient temperature, affording **3** as a microcrystalline solid (90%). Anal. calcd for $C_{12}H_{18}Cl_8Zr_2$: C 22.94, H 2.89; found: C 23.01, H 2.97.

Isomerization of durene: A moderately catalytic isomerization of durene to C_6Me_6 and C_6Me_5H in CH_2Cl_2 was observed when high durene:$ZrCl_4$ ratios were used. The conversion of durene to C_6Me_6 and C_6Me_5H was roughly 40% complete in one day when a durene:$ZrCl_4$ ratio of 10:1 was used. To accelerate the reaction and demonstrate catalysis, we used a high $ZrCl_4$:substrate ratio. With a $ZrCl_4$:durene ratio of 4:1, durene in CH_2Cl_2 was completely converted in one day. The first addition of durene was followed by several others while maintaining the same ratio, with no noticeable loss in activity. In every case complete conversion required one day. In this way the conversion of durene assisted by $ZrCl_4$ extends to more than 20 times the stoichiometric value.

[5] $ZrCl_4$ (10.0 g, 42.9 mmol) can be dissolved in 100 mL of CH_2Cl_2 in the presence of mesitylene (10.32 g, 85.9 mmol) in 15–20 h.

[6] Crystal data for **3**: $C_{12}H_{18}Cl_8Zr_2$, orthorhombic, space group *Pnma*; $a = 19.524(4)$, $b = 13.218(3)$, $c = 8.355(4)$ Å, $V = 2156.2(12)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.936$ g cm^{-3}; $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $\mu_{MoK\alpha} = 19.48$ cm^{-1}; crystal dimensions $0.21 \times 0.30 \times 0.38$ mm. The structure was solved by the heavy-atom method starting from a Patterson map calculated using SHELX-76 and refined anisotropically for all non-hydrogen atoms. The high values of the U_{ij} thermal parameters of the methyl carbons suggested the presence of some disorder due to a possible noncentrosymmetric structure. We tried to refine the structure in the noncentrosymmetric space group $Pna2_1$, but we did not succeed because of strong correlations between pseudosymmetry-related parameters. The centrosymmetric refinement was then considered satisfactory and the high anisotropic thermal parameters attributed to some rotation of the hexamethylbenzene molecule in the plane perpendicular to the Zr–centroid direction. The hydrogen atoms were ignored. The refinement was based on the unique total data and carried out using SHELX-92. For 1948 unique total reflections [$I > 2\sigma(I)$] collected at room temperature ($6 < 2\theta < 50^\circ$) and corrected for absorption, the final *wR2* was 0.092 ($R = 0.042$ for 1098 unique observed reflections). All calculations were done on an Encore 91 computer. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

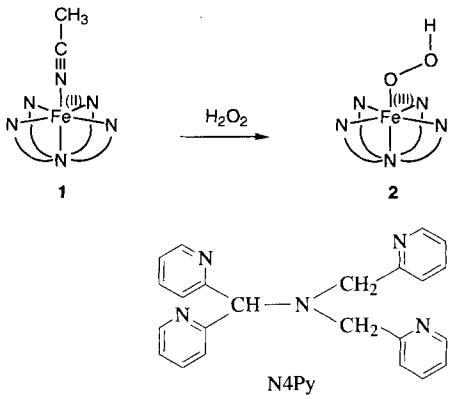
[14] Complete transformation of C_6Me_6 (1.73 g, 10.7 mmol) was observed when the reaction was conducted at 100 °C in 1,2-$Cl_2C_6H_4$ (100 mL) for 2–3 days with $ZrCl_4$ (5.0 g, 21.5 mmol). The GC-MS analysis showed the presence of pentamethylbenzene, durene and isodurene, mesitylene isomers, and *o*-dichloro(methyl)benzene isomers, all of them in the same ratio.

Nonheme Iron Centers in Oxygen Activation: Characterization of an Iron(III) Hydroperoxide Intermediate**

Marcel Lubben, Auke Meetsma, Elizabeth C. Wilkinson, Ben Feringa,* and Lawrence Que, Jr.*

Peroxoiron(III) complexes are increasingly being considered as potential intermediates in oxidations catalyzed by nonheme iron centers in biology, because of anticipated difficulties in stabilizing high-valent iron-oxo species in the absence of porphyrins.[1] For example, spectroscopic studies of "activated bleomycin" (BLM[2]), an antitumor drug that effects the oxidative cleavage of DNA and the oxidation of hydrocarbons,[3] cumulatively support its formulation as a low-spin hydroperoxidoiron(III) species.[4] A model for "activated BLM" has been synthesized that mimics its reactivity and gives rise to the same optical and EPR spectra;[5] however, more detailed spectroscopic data is not yet available. In a related area, alkylperoxoiron(III) complexes have been implicated in hydrocarbon oxidations;[6] several have been stabilized at low temperature and spectroscopically characterized.[7] To date, however, "activated BLM" remains the only characterized iron hydroperoxide complex in a nonheme environment. Our own efforts have been directed at generating analogous species in different but related nonheme ligand environments. We thus present here the synthesis and X-ray structure of **1**, an iron(II) complex of a new pentadentate ligand ("N4Py"). Complex **1** reacts with H_2O_2 to generate a transient purple species **2** which is characterized as a low-spin hydroperoxoiron(III) complex. (The compound numbers **1** and **2** are used both for the Fe^{II} and Fe^{III} cations, respectively, and also for their perchlorate salts.)



Treatment of N4Py with one equivalent of $Fe(ClO_4)_3 \cdot 10\,H_2O$ in a CH_3OH/CH_3CN mixture followed by vapor diffusion of ethyl acetate yielded dark red crystals of [Fe(N4Py)(CH_3CN)]-

$(ClO_4)_2$ (**1**). The structure of **1** shows a six-coordinate iron(II) center surrounded by N atoms from four equatorial pyridine ligands and the apical positions are occupied by the N atom of the tertiary amine and that of acetonitrile (Fig. 1).[8] The four pyridine rings are all positioned *perpendicular* to the basal plane

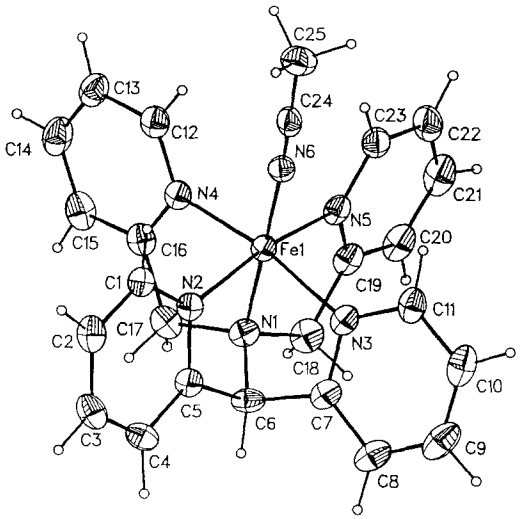

Fig. 1. Structure of the cation of **1** (ORTEP plot) showing 50% probability ellipsoids; hydrogen atoms have been omitted for clarity. Selected distances [Å]: Fe1–N1 1.961(3), Fe1–N2 1.976(3), Fe1–N3 1.967(3), Fe1–N4 1.968(3), Fe–N5 1.975(3), Fe–N6 1.915(3).

of coordination, a situation markedly different from porphyrin systems where the pyrrole groups are within the basal plane. Complex **1** has a low-spin iron(II) center as indicated by the short Fe–N bond lengths of 1.91–1.98 Å.[9] Furthermore all its protons can be accounted for by features in the diamagnetic region of its ^{1}H NMR spectrum, consistent with a low-spin iron(II) complex. The thermodynamic stability of this low-spin iron(II) center is probably the driving force for the reduction of the initially formed iron(III) complex in the synthetic procedure. The ability of the N4Py ligand to stabilize the iron(II) state is supported by the cyclic voltammetry of **1** in CH_3CN which shows a reversible oxidation at 990 mV vs the normal hydrogen electrode (NHE) corresponding to the Fe^{III}/Fe^{II} couple.

Complex **1** exhibits a UV/Vis spectrum with a distinct band at 458 nm ($\varepsilon = 4000\,M^{-1}cm^{-1}$) in acetone (Fig. 2). Treatment of **1** in acetone with an excess (80 equiv) of H_2O_2 at $-8\,^\circ C$ causes the appearance of a purple species ($\lambda_{max} = 530$ nm, $\varepsilon \approx 1100\,M^{-1}cm^{-1}$) with a half-life of 45 min (Fig. 2). At 25 °C however, the purple color disappears within minutes due to disproportionation of H_2O_2, but reappears by the addition of more H_2O_2. A UV/Vis titration of **1** with H_2O_2 shows that the characteristic band for **1** completely disappears with the addition of 0.5 equiv H_2O_2 before the purple color of **2** appears with further addition of H_2O_2, indicating that **1** is first converted to an iron(III) species prior to forming **2**.

The intermediate **2** exhibits an EPR spectrum with g values at 2.17, 2.12, and 1.98 (Fig. 2 inset), indicative of a low-spin iron(III) species. Its signal intensity accounts for as much as 80% of the iron present and correlates directly with the intensity of the purple chromophore. We ascribe the purple color of **2** to a peroxide-to-iron(III) charge transfer transition, but, unlike for high-spin peroxoiron(III) complexes,[10] this assignment could not be corroborated by resonance Raman spectroscopy due to the photoinstability of **2**. Other low-spin peroxoiron(III) species such as "activated BLM" and its Fe(pma) analogue also appear to decompose with laser irradiation.[5]

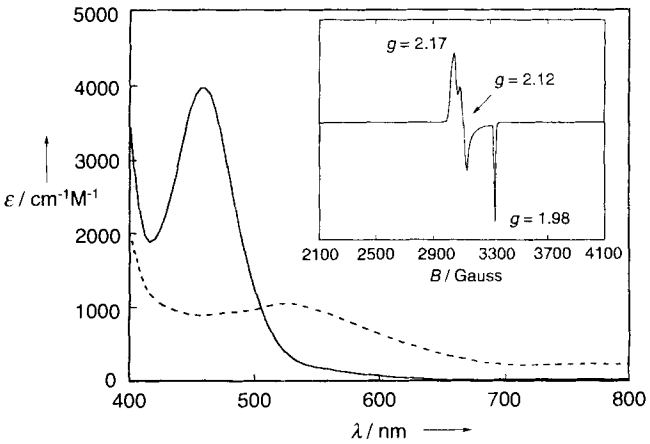

Fig. 2. UV/Vis spectra of **1** (dashed line) and **2** (solid line) in acetone at $-8\,^\circ C$. Inset: X-band EPR spectrum of **2** in acetone at 4 K.

Insight into the nature of **2** has been obtained from electrospray ionization mass spectrometric analysis. Introduction of a cold solution of **2** into a Sciex API III spectrometer affords positive and negative ion mass spectra with the most prominent peak clusters at m/z 555 and 753, respectively. These features correspond to the ions, $\{[(N4Py)FeOOH]ClO_4\}^+$ and $\{[(N4Py)FeOOH](ClO_4)_3\}^-$ and exhibit isotope intensity patterns that match calculated patterns for their formulae (Fig. 3).

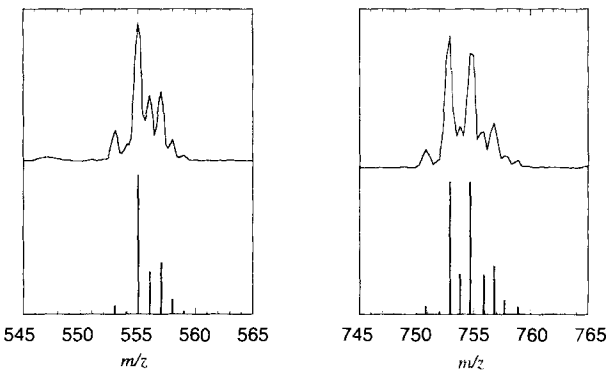

Fig. 3. Electrospray ionization mass spectrometric features of **2** at m/z + 555 and −753, corresponding to the ions $\{[(N4Py)FeOOH]ClO_4\}^+$ and $\{[(N4Py)FeOOH](ClO_4)_3\}^-$, respectively; calculated isotope patterns are represented by bars under each peak cluster.

Furthermore, the intense purple color of **2** is maintained throughout the course of the mass spectrometric experiment, showing that the complex has not decomposed. It is thus clear from these data that **2** is best formulated as $[Fe(N4Py)OOH]^{2+}$; given the pentadentate nature of N4Py and the available coordination site, we favor an end-on coordination mode for the bound hydroperoxide in **2**. This represents the first mass spectrometric evidence for a synthetic hydroperoxoiron(III) intermediate and lends strong support for the formulation of "activated BLM" as $[Fe^{III}(BLM)OOH]^{2+}$.[4, 11]

The intermediate **2** is able to oxidize alkanes. Treatment of **1** with 100 equiv H_2O_2 in the presence of 1000 equiv cyclohexane results in the formation of 13 equiv cyclohexanol and 5 equiv cyclohexanone with respect to **1** within 0.5 h. This corresponds to 36 turnovers per hour and represents an alkane functionaliza-

tion activity comparable to those observed for Fe(tpa) and Fe(bpy) complexes[6] and the "Gif" family of catalysts,[12] which are the best nonheme iron oxidation catalysts reported thus far. Intermediate **2** is observed in the presence of substrate, and cyclohexane oxidation ceases upon disappearance of the purple color, suggesting the involvement of **2** in the catalytic oxidation of cyclohexane. Further experiments to establish the exact role of **2** in catalysis are in progress.

In summary, using the novel pentadentate N4Py ligand we have characterized an air-stable low-spin iron(II) complex that reacts with H_2O_2 to form a transient low-spin iron(III) intermediate **2** in high yield. The intermediate **2** was stable enough to be characterized by electrospray ionization mass spectrometry as $[(N4Py)Fe^{III}OOH]^{2+}$. Furthermore **2** can hydroxylate cyclohexane efficiently. Our studies thus demonstrate that such hydroperoxy complexes can be formed without the participation of an amidate ligand as found in bleomycin and support the notion that an Fe^{III}-OOH moiety can be a viable alternative for high-valent iron-oxo species in mechanisms proposed for nonheme iron oxygenases.[11]

Experimental Procedure

Caution: Complexes with organic ligands and perchlorate anions are potentially **explosive**!

N4Py: Picolyl chloride hydrochloride (6.8 g, 41.5 mmol) was added to an aqueous solution of NaOH (5 M, 8.3 mL) at 0 °C. After stirring for 10 min, this solution was added to bis(2-pyridyl)methylamine (4.13 g, 20.75 mmol) and another portion of aqueous NaOH (5 M, 8.3 mL). This solution was allowed to stir for 48 h at 25 °C, and then concentrated $HClO_4$ was added to precipitate a yellow solid, which was recrystallized from hot water. Treatment of this perchlorate salt with 2.5 M NaOH solution and extraction with dichloromethane yielded the free amine of 4NPy (2.84 g, 37% yield). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.97 (s, 4 H, CH_2), 5.35 (s, 1 H, CH), 7.13 (m, 4 H, Py), 7.63 (m, 8 H, Py), 8.51 (d, 2 H, J = 4.8 Hz, Py), 8.57 (d, 2 H, J = 4.7 Hz, Py).

1: $Fe(ClO_4)_3 \cdot 10H_2O$ (0.215 g, 0.403 mmol) was added to a solution of N4Py (0.144 g, 0.392 mmol) in methanol/acetonitrile (1:1). The solution was allowed to stir for 5 min, and then was placed in an ethyl acetate bath. The red crystalline product was collected and washed with ethyl acetate to yield **1** as dark, red crystals (0.178 g, 65% yield). ^{1}H NMR (300 MHz, CD_3CN, 25 °C): δ = 4.27 (d, 2 H, J = 18.1 Hz, CH_2), 4.40 (d, 2 H, J = 18.1 Hz, CH_2), 6.34 (s, 1 H, CH), 7.06 (d, 2 H, J = 7.8 Hz, Py), 7.33 (m, 4 H), 7.68 (m, 2 H, Py), 7.88 (m, 4 H, Py), 8.90 (d, 2 H, J = 5.4 Hz, Py), 9.03 (d, 2 H, J = 5.4 Hz, Py). UV/Vis (acetone): λ_{max} (ε) = 382 (5700), 458 (4000); anal. calcd for $C_{25}H_{28}Cl_2FeN_6O_{10}$: C 42.94, H 4.04, N 12.02; found: C 43.21, H 3.76, N 12.02.

The pH-Dependent Synthesis and Structural Study of Dimer and Cyclic Trimer Complexes of 9-Methyl- or 9-Ethylhypoxanthine Nucleobases with (η^5-Pentamethylcyclopentadienyl)-rhodium Aqua Complexes**

Hong Chen, Marilyn M. Olmstead, David P. Smith, Marcos F. Maestre, and Richard H. Fish*

Recently there has been a dramatic new focus on the reactions of organometallic complexes with biologically important ligands, and interestingly, the majority have been performed in aqueous solution.[1] In our own bioorganometallic chemistry studies, we have been investigating the unique coordination chemistry of Cp*Rh aqua complexes (Cp* = C_5Me_5) with DNA/RNA nucleobases, nucleosides, nucleotides, and oligonucleotides in both organic and aqueous solutions.[1a–e] In one of these studies, we reported on a structure of a monomeric Cp*Rh-9-methylhypoxanthine (9-MH) complex (**1**, OTf = OSO_2CF_3) obtained from the reaction of one equivalent of 9-MH with $[Cp^*Rh(MeOH)_3](OTf)_2$ generated in situ in MeOH.[1d]

$[Cp^*Rh\{\eta^1(N^7)\text{-}9\text{-}MH\}(MeOH)_2](OTf)_2$ **1**

[**] Bioorganometallic Chemistry, Part 6. The studies at LBL were generously supported by NIH Grant A I 08427 to M. F. M. and by LBL Laboratory Directed Research and Development Funds to M. F. M. and R. H. F., and the U. S. Department of Energy (No. DE-ACO3-76SF00098). Part 5: [1e].

An ^{1}H NMR pH titration profile of **1** in D_2O clearly defined the role of pH in the conversion of this monomer to presumed cyclic trimer and dimer complexes. By observing the H8 and H2 regions of the ^{1}H NMR spectra at various pD values (pD = pH + 0.4), we found that **1** remained unchanged from pD 2.45 to 5.13 (signal broadened slightly at the latter pH); however, an equilibrium process occurred when the pD values were increased to 6.45, 7.96, and 10.50 (Fig. 1). At pD 6.45 the ^{1}H NMR spectrum showed the dramatic chemical shifts diagnostic for the formation of cyclic trimers,[1a, d] while at pD 10.50, a new complex was formed with significant upfield shifts of H8 and H2 that were reminiscent of a $[\{Cp^*Rh(\mu\text{-}OH)(L)\}_2]$ dimer (L = 1-methylcytosine).[1b]

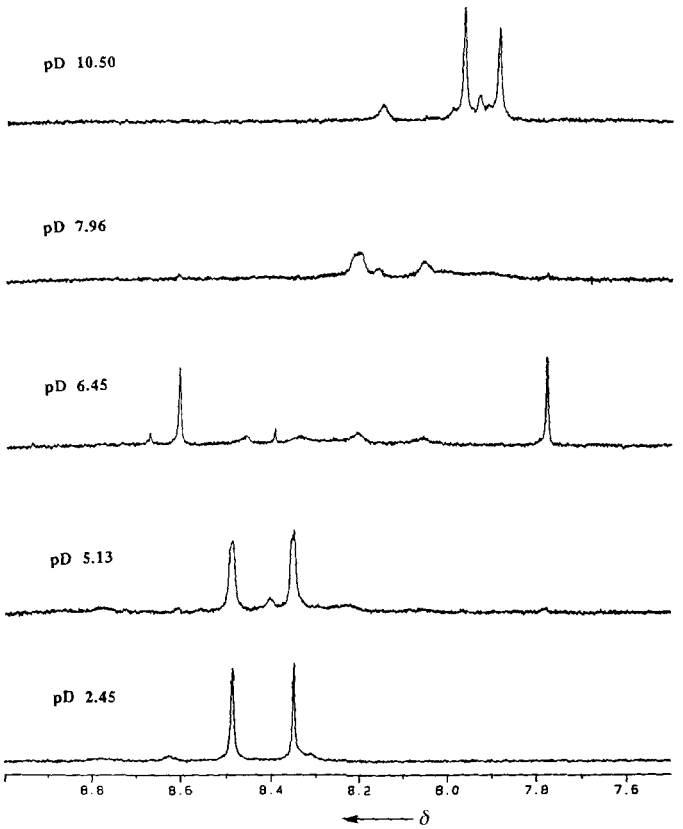

Fig. 1. ^{1}H NMR (400 MHz) spectra of **1** at ambient temperature and different pH values.

In this communication we report on several novel bonding modes of the nucleobase, 9-MH, and an ethyl analogue, 9-ethylhypoxanthine (9-EH), on coordination to Cp*Rh aqua complexes at intermediate and high pH values. Thus, we were able to isolate a new cyclic trimer at a pH of 6.1, the complex **2**,[2] as well as another new complex (**3**)[3] at a pH of 10.2, that were both unequivocally characterized by single-crystal X-ray crystallography studies.

$[\{Cp^*Rh[\mu_2\text{-}\eta^1(N^1)\text{:}\eta^2(N^7,O^6)\text{-}9\text{-}EH]\}_3](OTf)_3$ **2**

$[\{Cp^*Rh[\eta^1(N^1)\text{-}9\text{-}MH](\mu\text{-}OH)\}_2]$ **3**

The cyclic trimer **2**, a racemic mixture, was obtained as yellow crystals from $MeOH/H_2O$, and the cation of one enantiomer of **2** has the X-ray crystal structure shown in Figure 2.[4] A key feature is the simultaneous $\eta^2(N^7,O^6)$ and $\eta^1(N^1)$ ligation of

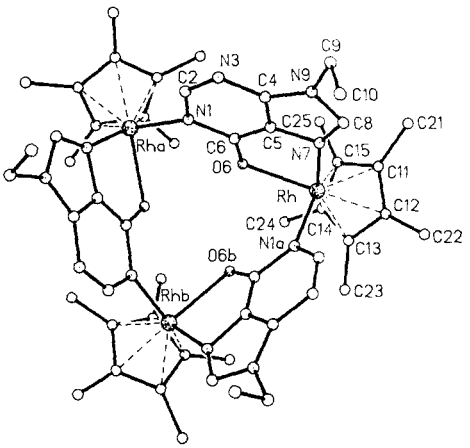

Fig. 2. Structure of $2 \cdot 3.33\,CH_3OH$. Selected bond lengths [Å] and angles [°]: Rh-C15, 2.115(26); Rh-N1a, 2.135(14); Rh-N7, 2.133(16); Rh-O6, 2.240(14); O6-Rh-N7, 80.2(6); O6-Rh-N1a, 88.1(6); N7-Rh-N1a, 85.0(7); Rh-O6-C6, 106.9(14); Rh-N7-C5, 106.0(14); N7-Rh-C15, 116.8(9); O6-C6-C5, 122.3(20); C6-C5-N7, 123.6(17); C2-N1-C6, 114.8(21); N1-C6-C5, 114.1(18); N1-C6-O6, 123.6(22); C5-N7-C8, 102.2(17).

9-EH, which is unprecedented in comparison to a great majority of N7 monodentate complexes,[5] and the few examples of $\eta^2(N^7,O^6)$ binding modes of 9-substituted guanine and hypoxanthine derivatives found in the literature.[6] It is interesting to note, for comparison, the $\eta^2(N^7, N^6)$ and $\eta^1(N^1)$ ligation of 9-methyladenine with [Cp*Rh] that we previously reported.[1a]

Two other structural features of **2** merit comment. First, the cation of **2** has a triangular dome-like cavity; three Cp* groups stretch out from the top of the dome, three ethyl groups point to the bottom, three hypoxanthine planes form the surrounding shell, and three Rh atoms are embedded on the top of the dome. The view shown in Figure 2 is from the bottom of this cavity along the C_3 axis, which passes from the top of the dome to the bottom. Second, the C6–O6 bond distance of 1.296(24) Å falls between the single-bond length of 1.42 Å found in an alcohol,[7] and the double-bond length of 1.233(4) and 1.230(7) Å in inosine,[8] and the $\eta^1(N^7)$ monodentate monomer **1**, respectively. This result suggests that a significant amount of multiple-bond character still exists in the C6–O6 bond of **2**, an argument supported by the long C6–N1 bond (1.401(29) Å) in **2**, relative to a typical C4–N3 double-bond length of 1.358(10) Å that was found in the *trans*-$[\{Cp^*Rh[\eta^1\text{-}(N^3)\text{-}1\text{-methylcytosine}](\mu\text{-}OH)\}_2]^{2+}$ complex.[1b]

The structure of the orange dimer **3**, isolated from its aqueous reaction mixture at pH 10.2, is shown in Figure 3.[4] The main structural features of interest are the unique $\eta^1(N^1)$,[5] rather than $\eta^1(N^7)$ or $\eta^2(N^7,O^6)$ binding mode of 9-MH, and the intramolecular hydrogen bonding between

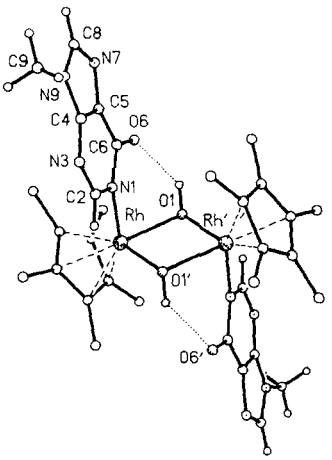

Fig. 3. Structure of **3**, $[\{Cp^*Rh(9\text{-}MH)(OH)\}_2]\cdot 18H_2O$. Selected bond lengths [Å] and angles [°]: Rh-O1, 2.136(4); Rh-N1, 2.148(5); H1···O6, 1.99(1), O1-H1···O6, 140(1); O1-Rh-N1, 86.4(2); Rh-O1-Rh', 102.1(1); Rh-N1-C6, 118.1(4); Rh-N1-C2, 119.8(4); C2-N1-C6, 121.1(5); N1-C6-C5, 113.3(5); N1-C6-O6, 121.3(6); O6-C6-C5, 125.5(5); C6-C5-N7, 130.8(5); C5-N7-C8, 103.1(5).

the μ-OH groups and O6 of this nucleobase. These binding arrangements are in sharp contrast to those in **1** and **2**, as well as other reported metal complexes of 9-substituted guanine and hypoxanthine derivatives,[6] but precedented as shown by the studies of Lippert and co-workers on the $\eta^1(N^1)$ binding of 9-methylguanine to Pt^{II}.[5] However, this $\eta^1(N^1)$-9-methylguanine–Pt^{II} complex was not formed directly, but was prepared via the [μ-$\eta^1(N^7)$:$\eta^1(N^1)$-9-methylguanine]diplatinum(II) complex by selective cleavage of the Pt^{II} atom at N7 with CN^-. We wish to note that guanosine formed a mononuclear [Cp*Rh] complex with $\eta^1(N^7)$ coordination[1a] rather than a cyclic trimer like 9-EH, and thus, unlike Pt^{II}, the [Cp*Rh] group appears to be too sterically demanding to form $\eta^1(N^1)$ complexes with the guanine nucleus; that is, the adjacent NH_2 group at C2 might prevent this type of bonding.

Dimeric complex **3** represents a rare example in which the μ-OH group is involved in intramolecular hydrogen bonding.[1b] The C6–O6 bond of 1.259(7) Å is slightly longer than those observed in inosine (1.233(4) Å), **1** (1.230(7) Å), and a typical aldehyde (1.22 Å),[7] which indicates the primary double-bond character of this C6–O6 group. The elongation of this bond is presumably due to the intramolecular H-bond between O6 and the μ-OH group as well as the intermolecular H-bond between O6 and the H_2O molecules present in the crystal lattice.

The core structure of **3** is similar to the *cis*-[9] and *trans*-$[\{Cp^*Rh(\eta^1\text{-}L)(\mu\text{-}OH)\}_2]^{2+}$[1b] dimeric complexes with heteroaromatic nitrogen ligands (*cis*: L = quinoline, **4**; *trans*: L = 1-methylcytosine, **5**); however, some slight differences merit comment. The planar $Rh_2(\mu\text{-}OH)_2$ fragment of **3** has an O-Rh-O angle of 77.9(1)°, which is in between that of **5** (78.8(2)°), and **4** (75.1(1), 74.8(1)°), and an Rh-O-Rh angle of 102.1(1)°, which is larger than that of **5** (101.2(2)°), yet smaller than that of **4** (105.0(1)°). These structural features are consistent with the intermediate Rh···Rh distance of 3.309(1) Å for **3** relative to those observed for **4** (3.322(1) Å) and **5** (3.290(2) Å). These slight structural differences between **3**, **4**, and **5** are presumably caused by the different numbers of intramolecular H-bonds in these three complexes. Complex **3** has two intramolecular H-bonds in which the $Rh_2(\mu\text{-}OH)_2$ core acts only as H donors, whereas complex **5** has four intramolecular H-bonds in which the $Rh_2(\mu\text{-}OH)_2$ core acts both as a H donor and a H acceptor, and complex **4** has no intramolecular H-bonds. The four intramolecular H-bonds in **5** possibly cause the two μ-OH groups to be further apart, thus providing the largest O-Rh-O angle and shortest Rh···Rh distance amongst these three dimeric complexes.

Although the exact mechanism of the formation of **3** is still not known, it is conceivable that the deprotonation of NH1 ($pK_a = 9.5$)[10] at pH 10.2 makes the N1 site much more nucleophilic than N7 or O6, and in addition, the intramolecular H-bonding between O6 and the μ-OH group stabilizes the dimeric arrangement of **3**. Moreover, at pH 6.1 the construction of the cyclic trimer **2** might emanate from the more favorable $\eta^2(N^7,O^6)$ bidentate five-membered ring complex, since N7 is more nucleophilic at this pH than NH1, and presumably, this $\eta^2(N^7,O^6)$ coordination is more thermodynamically favored. The facile deprotonation of NH1 was followed by formation of the third binding site to an adjacent [Cp*Rh] moiety, a [Cp*Rh{$\eta^2(N^7,O^6)$-9-MH}](OTf) intermediate complex, since the NH1 would be more acidic upon the formation of the $\eta^2(N^7,O^6)$ bidentate five-membered ring.

In conclusion, the novel cyclic trimer **2** and dimer **3** complexes of 9-EH and 9-MH were synthesized in aqueous solution at pH 6.1 and 10.2, respectively, and their structures were verified by single-crystal X-ray crystallography. Finally, the formation of dramatically different structures at various pH values could be explained by the changes in the nucleophilicity of N7, O6, and N1 binding sites. We are pursuing other examples of unique structures for [Cp*Rh]–nucleobase complexes as a function of pH.

Experimental Procedure

2: To a solution of $[Cp^*RhCl_2]_2$ (0.075 g, 0.12 mmol) in H_2O (14 mL, degassed once) was added AgOTf (0.13 g, 0.51 mmol). The reaction mixture was stirred at ambient temperature for 3 h and then filtered. To the filtrate was added 9-EH (0.040 g, 0.24 mmol), and after all the 9-EH had dissolved, the pH was adjusted to 6.1 by the addition of 0.10 N NaOH. The final reaction mixture was degassed and stirred at 25 °C overnight and then at 50 °C for 45 min. The solvent was removed in vacuo, and the yellow residue was taken up in MeOH (5 mL). The product precipitated from MeOH, was collected on a frit, washed with small amounts of MeOH, and dried in vacuo to give 60 mg yellow microcrystals (yield, 45%). FAB-MS, $[M + H-OTf]^+$ (15.2%), $[\{Cp^*Rh(9\text{-}EH)\}_2(OTf)]^+$ (20%), and $[\{Cp^*Rh(9\text{-}EH)\}_2]^+$ (45%). Elemental analysis for $C_{54}H_{66}F_6N_{12}O_{12}Rh_2S_2 \cdot 2H_2O$, calcd C 38.4, H 4.15, N 9.97; found, C 38.1, H 3.97, N 9.71. ^1H NMR (400 MHz, [D$_4$]MeOH, 25 °C): δ = 8.86 (s, 1H, H8), 7.80 (s, 1H, H2), 4.20 (q, ^3J(H,H) = 7 Hz, 2H, CH_2), 1.89 (s, 15H, Cp*), and 1.44 (t, ^3J(H,H) = 7 Hz, 3H, CH_3).

3 was prepared as for **2**, except that the pH was adjusted to 10.2, and the X-ray quality product crystallized on concentration of the aqueous reaction mixture (yield, 60%). FAB/MS, $[M-2CH_3]^+$ (3.3%), $[M-2CH_3-Cp^* + 2H]^+$ (3%), $[M/2-3H]^+$ (3%), and $[M/2-2CH_3-H]^+$ (100%). Elemental analysis for $C_{32}H_{42}N_8O_4Rh_2 \cdot 3H_2O$, calcd C 44.5, H 5.57, N 12.99; found, C 44.3, H 5.29, N 12.56. ^1H NMR (400 MHz, [D$_4$]MeOH, 25 °C) δ = 8.17 (s, 1H, H8), 7.81 (s, 1H, H2), 3.70 (s, 3H, CH_3), 1.76 (s, 15H, Cp*).

Single-Crystal X-Ray Structure of the Metastable Aryne Precursor Tetrafluorophenyllithium and of 1,2,3,4-Tetrafluorobenzene**

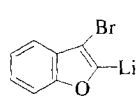
Thomas Kottke, Kuangsen Sung, and Richard J. Lagow*

Dedicated to Paul von Ragué Schleyer on the occasion of his 65th birthday

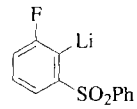
The development of a dehydrobenzene concept can be traced back to the studies of the reaction of phenyllithium with fluorobenzene performed by Wittig in 1942.[1] The existence of benzyne (1,2-didehydrobenzene) and related arynes as intermediates was later established by Roberts,[2] Huisgen,[3] and Wittig.[4] Ever since, dehydrobenzene chemistry has played a major part in many laboratories and is well-documented by numerous review articles.[5] The formation of arynes generally involves the β-elimination of appropriately positioned substituents from an aromatic precursor. Suitable synthetic methods are the fragmentation of benzo-fused cyclic systems, the elimination of nitrogen and carbon dioxide from benzenediazonium carboxylates or related compounds, and the elimination of halide ions from "aryl anion"[6] intermediates.

A prime example of the halide-ion elimination is the elimination of metal halides from metalated aryl halides, the classical procedure for the generation of arynes. The reaction mostly proceeds under mild conditions, particularly when organolithium intermediates are involved. Apart from solvent effects, the stability of those intermediates has essentially been attributed to the character of the substituents as well as to the nature of the leaving halogen. Substituents that inductively stabilize the negative charge of the intermediate "aryl anion" reduce the tendency to lose halide.[5b, 7] The ease of aryne formation with respect to the nature of the leaving halide follows the order $F < Cl < Br$.[5b, 8]

Recently, Boche and co-workers introduced geometric parameters which may structurally reflect the reactivity of metalated aryl halides towards β-elimination when they determined the crystal structures of two potential aryne precursors:[9] 3-bromo-2-lithiobenzofuran **1**, and 3-fluoro-2-lithio-1-phenylsulfonylbenzene **2**. Although both compounds contain lithium and halogen on neighboring carbon atoms, only in **2** can elimination of lithium halide be initiated. Based on a comparison with average C_{aryl}–X bond lengths (X = halogen), the authors correlated the difference in reactivity with the extent of the C–X bond lengthening apparent in the solid-state structures. Relative to the C–Br bond in **1**, **2** has an elongated C–F bond, and in addition, a shorter intramolecular Li–X distance. Moreover, ab initio MO calculation of unsolvated *ortho*-fluorophenyllithium revealed a remarkably long C–F bond (142.2 pm vs. 133.8 pm in *para*-fluorophenyllithium) as a consequence of an intramolecular Li–F coordination.[10]

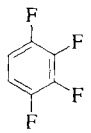


1

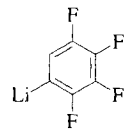


2

To determine the magnitude of C–X bond lengthening accurately and to investigate a possible involvement of solid-state Li···F interactions we have determined the crystal structures[11] of 1,2,3,4-tetrafluorobenzene (**3**) and of THF-solvated tetrafluorophenyllithium (**4**). Because of the low melting point of **3** (−42 °C) and the decomposition of solid **4** at −22 °C (the colorless crystals turn black within seconds), low temperature crystallization and mounting techniques had to be applied to facilitate structural characterization.[12]



3



4

As expected, within the standard deviation, the bond lengths and angles of the planar ring system in **3** are symmetrical with respect to the axis bisecting the C2–C3 and the C5–C6 bond (Fig. 1). Minor differences between the geometric parameters along this axis are due to substituent effects (as discussed below): The carbon skeleton of the ring shows slightly alternating bond lengths; the longest is C5–C6 (138.6(2) pm), and the shortest C1–C6 and C4–C5 (136.9(2) pm each). The ring bond angles at C1 and C4 (121.3(1) and 121.4(1)°, respectively) are slightly larger than the others (119.2(1)–119.5(1)°). The molecules are packed in layers, which

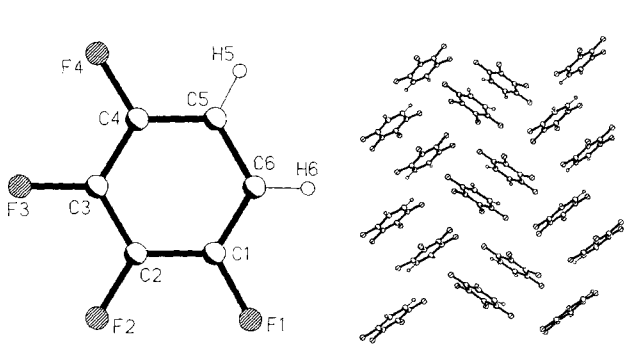


Fig. 1. Molecular structure of **3** (left), and the packing in the crystal (right, one layer is shown). Selected bond lengths [pm] and angles [°]: C1–F1 134.9(2), C1–C2 137.9(2), C2–F2 134.1(2), C2–C3 137.3(2), C3–F3 134.1(2), C3–C4 137.6(2), C4–F4 134.9(2), C4–C5 136.9(2), C5–C6 138.6(2), C6–C1 136.9(2), C6-C1-C2 121.3(1), C1-C2-C3 119.5(1), C2-C3-C4 119.3(1), C3-C4-C5 121.4(1), C4-C5-C6 119.3(1), C5-C6-C1 119.2(1).

resemble a chessboard in which each field is formed by a pair of molecules oriented parallel to each other (Fig. 1, right).

Metalation of **3** with *n*BuLi in THF yields the benzyne precursor **4**. LiF elimination from **4** occurs in solution at temperatures above −40 °C, in contrast to + 60 °C observed in **2**. This is in agreement with the less marked stabilizing effect of the fluorine substituents vs. a phenylsulfonyl group.[5b, 9] The X-ray structure analysis reveals that **4** is a monomer in the solid state (Fig. 2).

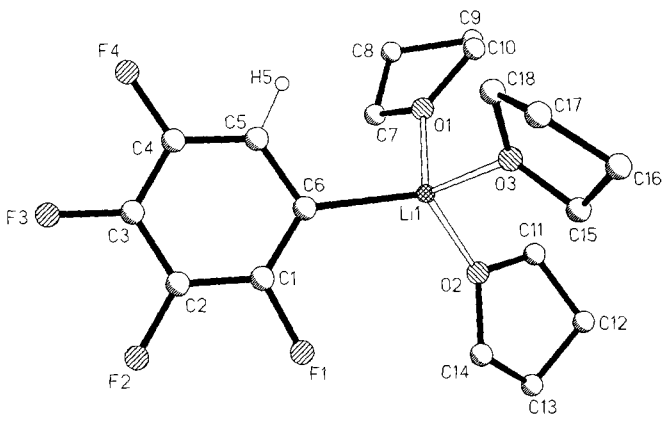

Fig. 2. Molecular structure of **4**. Selected bond lengths [pm] and angles [°]: Li1–C6 213.6(5), Li1–O1 195.6(4), Li1–O2 195.1(4), Li1–O3 196.4(4), C1–F1 138.2(3), C1–C2 136.9(4), C2–F2 136.3(3), C2–C3 136.8(3), C3–F3 134.7(3), C3–C4 137.3(4), C4–F4 136.8(3), C4–C5 136.5(4), C5–C6 141.5(3), C6–C1 136.7(3); C6-C1-C2 125.7(2), C1-C2-C3 119.3(2), C2-C3-C4 118.1(2), C3-C4-C5 121.3(2), C4-C5-C6 122.4(2), C5-C6-C1 113.1(2).

The lithium atom is positioned nearly in the plane defined by the aromatic carbon atoms (torsion angle C2-C1-C6-Li1 = 173.3(3)°). The coordination sphere of Li1 is made up of three THF molecules and the deprotonated carbon atom C6. The Li1–C6 bond length of 213.6(5) pm falls within the range of corresponding Li–C distances observed in the few known examples of monomeric aryllithium structures (207.4–213.5 pm).[13]

The structure of the attached benzene ring shows the typical distortions earlier ascertained in aryllithium structures.[13, 14] The narrowing of the *ipso* angle along with the widening of the *ortho* angles has been explained in terms of a rehybridization of the *ipso*-carbon atom.[14c, 15] While electropositive substituents decrease the corresponding ring angle and slightly elongate the $C_{ipso}-C_{ortho}$ bond lengths, electronegative substituents have the opposite effect. The presence of electropositive and unsymmetrically arranged electronegative substituents make a complex combination of both effects a crucial feature in **4**, causing the remarkably large C_{ortho} angles and different $C_{ipso}-C_{ortho}$ lengths. The nonbonding Li1–F1 distance of 344.8(4) pm is smaller than in **2** (367.2(7) pm[9]). However, it is significantly larger than nonbonding Li–F distances observed in compounds with obvious Li···F interactions (for example, an Li–F distance of 225.2 pm[16] has been observed in dimeric, ether-solvated 2,4,6-tris(trifluoromethyl)phenyllithium). Furthermore, it by far exceeds the Li–F distance in the calculated structure of unsolvated 1-fluoro-2-lithiobenzene (190.1 pm[10]), which could be considered as a lower limit of Li–F distances in related structures.

The longest C–F bond in **4** is 138.2(3) pm (C1–F1), which is indeed the one adjacent to the C–Li bond. However, the difference with respect to the other C–F bond lengths is not very pronounced. In fact, comparison with **3** reveals an elongation of all C–F bonds. This effect becomes less significant at the positions further away from the "anionic" carbon atom. The involvement of all C–F bonds indicates that the "anionic character" of the phenyl group is responsible for the bond lengthening rather than an Li···F interaction affecting per se only one C–F bond. This interpretation is supported by the exterior bond angles at C1 and C6. F1-C1-C6 (119.4(2)°) and Li1-C6-C1 (129.9(2)°) are each larger than their counterparts (F1-C1-C2 = 114.9(2)° and Li1-C6-C5 = 116.7(2)°, respectively), which is probably due to the steric influence of the THF ligands and the short C1–C6 distance (136.7(3) pm vs. 141.5(3) pm for C6–C5). A dominant Li···F interaction in **4** would lead to a somewhat different geometry. A possible explanation for the longer C–F bonds may be a partial distribution of the negative charge over the ring skeleton—enhanced by the electron-withdrawing effect of the fluorine substituents—reducing the polarity of the C–F bonds and consequently resulting in bond elongation.

The structures of **3** and **4** do not suggest a correlation between solid-state Li–F distances and the reactivity of aryne precursors towards LiF elimination. Although the Li–F distance is 313.3(3) pm in the crystal structure of monomeric THF-solvated pentafluorophenyllithium,[17] which is significantly shorter than Li1–F1 in **4**, LiF elimination occurs only above −6 °C in the solid state and slowly at −10 °C[7a] in etheral solution; this is in agreement with the greater number of stabilizing fluorine substituents.

Experimental Procedure

3: A solution of 1,2,3,4-tetrafluorobenzene (2.1 g, 14 mmol) in a mixture of pentane (15 mL) and toluene (5 mL) was maintained at −90 °C for several hours. The initially formed crystals were redissolved leaving only a few crystallites in the solution. After 2–3 days at −78 °C colorless blocks, suitable for X-ray structure analysis, had grown.

4: Following the procedure reported earlier [18], **3** (2 g, 13 mmol) dissolved in THF (50 mL) were treated with *n*BuLi (33 mmol, 13.2 mL, 2.5 M solution in hexane) for 2 h at −70 °C. Within one week single crystals had grown after treatment of the reaction solution as described for **3**.

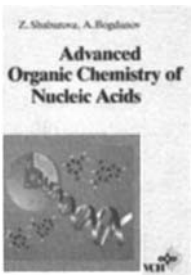
A Nucleus of Modern Chemical Techniques

Advanced Organic Chemistry of Nucleic Acids. By *Z. A. Shabarova* and *A. A. Bogdanov*. VCH Verlagsgesellschaft, Weinheim, 1994. 588 pp., hardcover DM 248.00.—ISBN 3-527-29021-4

Alongside the classical disciplines of organic, inorganic, and physical chemistry, a number of related disciplines are nowadays increasing in importance. One of these is bioorganic chemistry. Whereas it was formerly regarded as just a minor branch of biology, or at best accepted as biochemistry and perhaps tolerated at the periphery of organic chemistry, this field is now, with good reason, being seen as increasingly important. The growth of interest in this interdisciplinary area is gaining further momentum from the rapid advances in research into the molecular mechanisms that determine life. In particular the developments in protein and nucleic acid chemistry are the pacemakers.



During the last few years several monographs dealing with these topics at a specialist level have appeared. In contrast, the existing textbooks are not up-to-date. The book reviewed here, by the Russian authors Zoe Shabarova and Alexey Bogdanov, is the most recent treatment of nucleic acid chemistry. As indicated by the title, the subject of the book is the organic chemistry of this class of natural compounds. In the preface the authors make it clear that their main aim was to produce a textbook specifically for students.

The book is a completely revised English version of the textbook originally published by the same authors in 1978 in Russian under the title "The Chemistry of Nucleic Acids and their Compounds". Much new material has been added, including a chapter on the highly topical subject of ribozymes.

The book is divided into 11 chapters (588 pages), most of which have been written by Z. Shabarova. First the structure of nucleosides is described (Chapter 1: pyrimidines and purines, importance of the configuration of the anomeric center, nucleoside antibiotics). Their properties are then discussed (Chapter 2: tautomeric structures, reactions with nucleophiles and electrophiles, addition reactions, stability of the glycosidic bond). The following chapters describe the nucleotides which are the building blocks of DNA and RNA (Chapters 3 and 4: acid/base behavior, properties of the phosphate group(s), reactions at the phosphate group). Beginning on page 187, Chapter 5 deals with the primary structure of the nucleic acids DNA and RNA. The nomenclature of nucleic acids is explained, followed by a discussion of the action of nucleases and methods for determining the nucleoside sequence. In Chapter 6 ("Determination of the Primary Structure of Nucleic Acids") the methods of sequencing are treated in greater detail, including DNA-mapping, chemical sequencing, and enzymatic sequencing. Also included here is the method of sequencing on a solid support, as well as the highly topical polymerase chain reaction (PCR) method. Chapter 7 deals with the basic features of the secondary structure of nucleic acids, including the conformational characteristics of nucleotide monomers and single-strand oligonucleotides. The macromolecular structure of DNA and RNA, starting with the Watson–Crick model, is treated in Chapter 8. Supercoiled DNA and other unusual DNA structures such as G-tetrads and "hairpins" are described, followed by the secondary structures of the t-RNAs and high molecular mass RNAs. In the following chapter the student is introduced to the chemical properties of polynucleotides and to modifications of nucleic acids, e.g., involving the carbohydrate or aglycon moieties. The chapter ends with short descriptions of two studies of conformational changes in DNA and four-stranded G4-DNA. As mentioned earlier, Chapter 10 deals with the highly topical field of ribozyme chemistry. This very readable book ends with a chapter on a very "chemical" aspect: the synthesis of nucleic acids. This consists of about 100 pages in which not only chemo-enzymatic methods but also the different chemical strategies of oligonucleotide synthesis are discussed in detail. The chapter is completed by a description of the preparation of synthetic genes and the technique of cloning. Literature references are listed at the end of each chapter.

After reading this well-written book nobody can really doubt that the chemistry of nucleosides and nucleic acids is an intrinsic part of organic chemistry. Although some of the formula schemes are unconventional and take a little time to get used to, the authors are to be congratulated on the quality of their work. As a textbook this is a very successful effort. My only complaint is that the publishers need to introduce a cheaper paperback version as soon as possible, because the price of DM 248 is not affordable to students. I fear that until that is remedied, the high price will limit the distribution of this excellent book.

Modern Electroorganic Chemistry. By *D. Kyriacou*. Springer, Heidelberg, 1994. 228 pp., hardcover DM 98.00.—ISBN 3-540-57504-9

During the last twenty years there have been enormous developments in electroorganic chemistry and many books and review articles have appeared. In this book D. Kyriacou has aimed to give a systematic presentation of current knowledge in the area of electroorganic chemistry. There are five chapters: an introduction (17 pp.), followed by chapters on

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

anodic, cathodic, and indirect electroorganic reactions (92, 56, and 26 pp. respectively), and finally a chapter on various interesting special areas of electrosynthesis (33 pp.).

The introductory chapter presents the fundamental principles needed for an understanding of electroorganic reactions. The basic components required to achieve a successful electrochemical reduction or oxidation are described (the electrodes, the electrolytic cell, the conducting electrolyte, and the potentiostat), and the author explains concepts such as direct and indirect electrochemical reactions, electron transfer, electrode potential, equilibrium potential, and overvoltage.

The anodic reactions discussed in Chapter 2 include oxidation of hydrocarbons, alcohols, phenols, carboxylic acids, amines, amides, ethers, esters, N-heterocycles, and organosulfur compounds. Thus, for example, the author describes the oxidation of alkanes in the presence of acetonitrile (acetamidation), the anodic coupling of arenes, the Kolbe synthesis for preparing ω,ω'-disubstituted alkanes, and the synthesis of poly(2,6-dimethyl-1,4-phenyleneoxide) from 2,6-dimethylphenol. The anodic substitution reactions described include cyanidation, acetoxylation, halogenation, hydroxylation, and alkoxylation.

The cathodic reactions discussed in Chapter 3 are electrochemical hydrogenations and reductions of carbonyl, organohalogen, organonitro, and organosulfur compounds and of N-heterocycles, and also electrocarboxylation. Thus, for example, cyclopropanes are synthesized from alkenes in the presence of methylene bromide at a graphite cathode, which is combined with a zinc sacrificial anode in an unpartitioned cell. The reduction and hydrolysis of purine gives 4-aminomethyl-5-amino-2-imidazoline, and the electrocarboxylation of ethene gives succinic acid. Carbon dioxide is converted to methanol in a photoelectrochemical reduction using leuco-indigo, and the indigo thus generated is then reduced back to leuco-indigo. The latter process forms the basis of a recently developed solar cell.

In cases where the electron exchange in an electrochemical oxidation takes place via a mediator the reaction is said to be indirect. Chapter 4 deals with indirect electroorganic reactions, under the headings of oxidative and reductive indirect reactions. Species that can be used as oxidative mediators are the transition metal ions Ce^{4+} and Ru^{4+}, the halogen cations I^+ and Br^+, and tris(*p*-bromophenyl)-amine. Metal ions in low oxidation states, such as Fe^{2+}, Cr^{2+}, and Sn^{2+}, are effective as reductive mediators. Anthracene is used as an organic reductive mediator.

The final chapter collects together a number of special areas of electroorganic synthesis, such as electropolymerization and the synthesis of natural products.

This book covers all the important modern developments in electroorganic synthesis, and by providing a wealth of literature references enables the reader to study this interesting field in greater depth. The inclusion of laboratory recipes for the electrochemical synthesis of many different compounds is especially useful. Moreover, all the information in the book is very clearly presented. There are few errors, and those that have occurred do not detract from the very high quality of the book. For example, it was undesirable to use the same symbol Q for quantity of charge (p. 14) and for the quotient of the activities in the Nernst equation (p. 8). For consistency the formula chosen for naphthalene on page 95, with five double bonds (ten π-electrons), should also have been used on page 27.

Derivative Spectrophotometry. Low and Higher Order. By *G. Talsky*. VCH Verlagsgesellschaft, Weinheim, 1994. 228 pp., hardcover DM 248.00.—ISBN 3-527-28294-7

I approached this book with high expectations, hoping to learn about important applications of derivative methods to spectroscopic interpretation. However, my first impressions were that the publishers had not made a very good job of language-polishing, and also that the text ought have been checked by a proof-reader with a mathematical background. For me there were many small points that rankled. The impression is given that the infrared region ends at 2.5 μm, thus: "Higher energies are necessary though, for electron excitation." Sometimes things are expressed in an awkward way, as in "...the curve is computet", or "...derivative orders contribute only littel..." In stating the Lambert–Beer law the mention of Bouguer as the earlier discoverer is wrongly spelt, and Volkmann is wrongly cited as the author of a book on "infrared spectrophotometry". These printing errors are mildly amusing, but the mistakes in the mathematical formulas are pure carelessness, and several times I had to overcome a strong temptation to abandon the book. Sometimes plus signs, sub- and superscripts are missing, while in other cases a symbol that should be a subscript is printed at normal height. Occasionally the wrong result is given for an elementary operation such as differentiation or calculation of a logarithm—sorry, such mistakes just cannot be tolerated. Proportional is not the same as equals!

The chapter on derivatives, for example those of the Gaussian function, is unnecessarily awkward and labored. I cannot understand why the author has not kept to a consistent nomenclature (there was already a hint of this in the discussion of the various symbols for differentiation). It seems a little strange that extinction coefficients and band distances are given in millimeters. And since when is the Lorentzian band-shape an exponential function? The Savitzky–Golay smoothing equation (Eq. 3–22) contains printing errors. Certain general recursion formulas are cited without mentioning the restrictions stated in the original publications.

I was often reminded of old times when the author referred to cutting out peaks and weighing to determine their areas, and again in the descriptions of instrumentation. Even graphical methods of estimating tangents are included. The literature references too are a little antiquated. What is the purpose of the short digression on the binary system?—It is hardly necessary to point out that modern computers still use it. I certainly did not think that analog and hybrid methods still have an important role in differentiation routines. The literature on digital methods of smoothing and differentiation is well covered. However, references to some recent monographs on this subject area should certainly have been included (e.g., P. Gans, *Data Fitting in the Chemical Sciences*, Wiley, Chichester, **1992**). One would also expect to find a mention of recent publications on the suppression or elimination of "spikes".

The treatment of practical aspects begins with Chapter 4. However, the choice of examples to illustrate the advantages of derivative spectroscopy seems to me unconvincing. With regard to the fundamental question of what is the optimal order of differentiation, the author's answer is that every shoulder and turning point in the original spectrum must appear in the derivative as an extreme value. It would also have been useful to compare the derivative method with alternative procedures that have grown in importance in the last few years, for example resolution enhancement using techniques such as the maximum entropy method or self-deconvolution; these avoid the interference by satellites that can arise in derivative spec-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1313-1524 $ 10.00+.25/0

troscopy. Regrettably, the literature coverage extends only to 1990. On the other hand, the survey of the applications of derivative spectroscopy, which are summarized in the form of 57 tables, is impressive. Looking through these and noting the order of differentiation, one finds that, with very few exceptions, the derivative spectra are of lower orders with fourth order as the maximum. Even after reading this (very expensive) book, it seems to me that the use of higher orders has little to recommend it.

H. Michael Heise

Enzymes in Synthetic Organic Chemistry. (Tetrahedron Organic Chemistry Series, Vol. 12.) By *C.-H. Wong* and *G. M. Whitesides*. Elsevier, Oxford, 1994. 370 pp., hardcover £ 55.00/paperback £ 25.00.—ISBN 0-08-035942-6/0-08-035941-8

During the last ten years there has been a great increase in the use of enzymes in organic synthesis; a survey of the wide-ranging areas of application of such methods will therefore be welcomed by everyone interested in using these powerful catalysts to solve problems of synthesis.

This book on the subject contains six chapters: an introductory one explaining the basic general principles of enzymatic catalysis and a further five treating important types of reactions. The first chapter deals with the physicochemical principles whereby enzymatic catalysis increases reaction rates, with the kinetics of such reactions, and with the effects of the solvent, temperature, and pH on the specificity of the enzyme. Further aspects treated here are the important problem of cofactor regeneration, and the behavior of enzymes in organic solvents. The second chapter describes the use of hydrolyzing enzymes for the formation or breaking of carbon–nitrogen and carbon–oxygen bonds in amides, peptides, esters, nitriles, and epoxides; the enzymes used are amidases, proteases, esterases, lipases, phosphatases, nitrilases, and epoxide-hydrolases. The effectiveness of these enzymes, especially for peptide synthesis and for preparing enantiomerically pure carboxylic acid derivatives and hydroxy compounds, is illustrated by describing results from about 400 published studies. Chapter 3 is devoted to the use of enzymes in redox reactions. As such reactions usually depend on nicotinamide cofactors, the question of cofactor regeneration is discussed in detail. The basic principles of stereoselectivity in redox reactions mediated by NAD(P) are also explained. Many of the examples of reductions and oxidations described here involve horse-liver alcohol dehydrogenase, but the discussion also extends to applications of other alcohol dehydrogenases and of numerous keto-acid dehydrogenases, as well as metal-mediated enolate reductases, galactose oxidase, lipooxygenase, arene dioxygenase, and various monooxygenases. Chapter 4 is concerned with carbon–carbon bond formation reactions, a topic of great importance for organic synthesis. In describing typical applications the authors devote special attention to enzyme-catalyzed aldol reactions, but they also explain how cyanohydrins, acyloins, and polycyclic compounds such as isoprenoids and steroids can be prepared using the appropriate enzymes. The current state of knowledge on the use of aldolases for stereoselective syntheses of monosaccharides, neuraminic acid, and related polyhydroxy compounds with many chiral centers is well described with numerous examples.

The growth in understanding of the role of carbohydrates in the functions of the bacterial cell wall and of their importance for cell adhesion, cell differentiation, and cell development has led to a great upsurge of interest in the synthesis of oligo- and polysaccharides. For solving the various regio- and stereochemical problems of such syntheses, enzymatic methods are becoming ever more important. The influence of these developments is evident in Chapter 5, which is concerned with the formation of glycosidic bonds by enzymatic catalysis. Reactions for converting monosaccharides into the reactive nucleoside phosphates needed for glycoside formation, and the use of glycosyl transferases, are described in detail. Here we see that, in this area especially, the use of these enzymes on a preparative scale is still severely handicapped by the difficulty of obtaining them. Chapter 6 deals with enzyme-catalyzed addition and elimination reactions, and the use of enzymes to catalyze the transfer of phosphate, methyl, sulfate, and amino groups. In view of the central importance of phosphoric acid esters in biochemical conversion reactions, much space is devoted to the regeneration of ATP and the synthesis of phosphorylated carbohydrates.

The book does not claim to provide a general introduction to the principles of enzymology or of biochemistry. However, by treating the applications in five chapters devoted to important types of reactions it should enable every synthetic organic chemist to gain a quick overview of the current state of the art in enzymatic catalysis as an aid to organic synthesis. By using this book, with the approximately 1500 literature references provided, the interested reader will be able to discover quickly whether there is a good prospect of solving a particular synthetic problem by such methods. It can therefore be recommended to everyone seeking to exploit the great potential of enzymatic catalysis in his or her work.

Structure and Bonding in Organometallic Anions of Heavy Group 14 and 15 Elements

Michael A. Paver, Christopher A. Russell, and Dominic S. Wright*

Alkali metal organometallic complexes (containing C–metal bonds) and the frequently structurally related alkali metal amides and alkoxides have been investigated extensively both in the solid state and in solution in the past two decades. However, until recently, the related complexes containing the heavier metallic and semi-metallic p block elements and the alkali and alkaline earth metals had rarely been studied in their own right. Recent solid-state structural studies have illustrated the immense structural diversity and bonding modes to be found within these species. One of the principal focuses of recent studies has been complexes containing organometallic anions of p block metals (e.g., triorganostannates, containing R_3Sn^-) in which metal–metal bonds occur between the heavy p block metal and the alkali or alkaline earth metal and the investigation of the nature of this bonding. The development of new synthetic routes has also allowed the preparation of a variety of anionic ligands with p block metal centers which promise new opportunities in coordination chemistry. In addition, the synthesis of a family of homologous anionic π complexes has given a fresh direction in the chemistry of p block metal metallocene complexes.

Keywords: antimony compounds · bismuth compounds · lead compounds · thallium compounds · tin compounds

1. Introduction

In the past twenty years or so there has been a great deal of interest in the structures and reactivity of organometallic reagents used in organic synthesis. This is particularly true of the organolithium compounds (containing C–Li bonds)[1] and of the structurally related amide, imide (with N–Li bonds),[2] and alkoxide complexes (with O–Li bonds).[3] All these compounds are widely employed as potent deprotonation reagents (sterically demanding bases) and as "anion equivalents" (nucleophilic sources of R^-) in standard organic syntheses. Extensive data is now available on the structures in solution and in the solid state of oligomeric (ring, cage, and ladder[1–3]) complexes containing organic anions linked by such *nonmetallic* p block elements (C, N, P, O, S) to alkali and alkaline earth metals.

Complexes containing alkali metals and *metallic* or *semi-metallic* p block elements have been known for many years.[4] For example, triorganostannates, commonly formulated as "$MSnR_3$" or as $M^+SnR_3^-$, are used to promote the formation of Sn–C bonds by their reactions with electrophilic organic substrates.[5] However, few such complexes containing metals or semi-metals have been investigated in their own right in the solid state or in solution, although many of these species are commonly generated in situ as precursors by organic chemists to perform a variety of transformations. Recently, there has been a renewed interest in complexes containing organometallic anions, alkoxides, or amides and low valent p block metals and semi-metals. Such studies have been made possible mainly by modern handling techniques and, particularly, by improved techniques for the low-temperature X-ray characterization of these commonly thermally unstable compounds.[6] Although this is still a relatively under-developed area, recent studies have shown that such compounds exhibit a wealth of novel bonding situations and exciting new structures in the solid state. The work carried out to date provides the basis for a developing new area of coordination chemistry and the fuel for many theoretical studies probing the nature of the bonding in these compounds.

Our interests in this field were stimulated by the lack of structural information on complexes containing bonds between "early" main group metals (groups 1 and 2) and metallic p block elements. Initially, we were interested in probing the nature of the metal–metal interactions (ionic vs. covalent) and of the bonding in the complex anions with p block metal centers. A second, and perhaps more general interest, stemmed from the desire to develop mild synthetic strategies to potentially unstable complexes containing anions of p block metals, utilizing nucleophilic addition reactions to neutral precursors and acid/base reactions. These initial goals have led us to broader investigations of the interaction of a variety of anionic p block metal amides with main group and transition metals and to the synthesis of new organometallic π complexes derived from neutral p block metal cyclopentadienides.

2. Complexes Containing Bonds between Alkali and Alkaline Earth Metal and Heavy p Block Metals

Early work on the reactions of organometallic halides of heavy p block metals with alkali metals in liquid ammonia showed that a variety of salts containing alkali metal cations and p block metal organometallic anions could be prepared. For example, "$NaSnMe_3$" was first prepared by the reaction of Me_3SnBr and Na in liquid ammonia in 1922 as a yellow-tan powder[7] and "$NaSbPh_2$" was synthesized in 1941 by the reaction of Ph_2SbI with Na in liquid ammonia.[8] These species are extremely air- and moisture-sensitive and many, for example the triorganoplumbates, are not stable for prolonged periods at room temperature and are in some cases light sensitive, for example, the dioranostibanes.[4] Organic chemists have made frequent use of these species as "soft" organometallic nucleophiles in syntheses.[5] The favored method of synthesis of these reagents has depended on the particular heavy p block metal involved. The main synthetic strategies to such complexes are 1) the reaction of metal–halogen bonds with an alkali metal [Eq. (a)], 2) the rection of a metal–hydrogen bond with an alkali metal organometallic compound [Eq. (b)], and 3) the cleavage of a p block metal–metal bond with a group 1 or 2 metal organometallic compound [Eq. (c)] or with the metals themselves [Eq. (d)].[4, 5] Additionally, the reaction of a labile metal–carbon bond is valuable in certain circumstances, for example in the in situ synthesis of $NaPbPh_3$ from Ph_4Pb.[4] Evidently for the heaviest elements (Pb and Bi), whose hydrides are unstable or cannot be prepared, cleavage of E–E bonds or E–X bonds are the best approaches.

$$R_nE\text{-}X + 2M \longrightarrow R_nE\text{-}M + MX \quad (a)$$

$$R_nEH + R'M \longrightarrow R_nE\text{-}M + R'H \quad (b)$$

$$R_nE\text{-}ER_n + R'M \longrightarrow R_nE\text{-}M + R_nR'E \quad (c)$$

$$R_nE\text{-}ER_n + 2M \longrightarrow 2R_nE\text{-}M \quad (d)$$

Despite the potential for the formation of metal–metal bonds between the alkali or alkaline earth metals and the p block metals in these compounds, it was not until recently that the existence of such bonding has been unequivocally demonstrated by X-ray analysis. This development has come about by employing aprotic (aromatic and ethereal) solvents as the reaction media and, generally, by making use of Lewis base donor solvation of the alkali and alkaline earth metal cations to solublize complexes and aid crystallization. The area remains one in which a great deal of synthetic and structural work still has to be done. Surprisingly, even for the semi-metal silicon only a few alkali metal bonded complexes have been structurally characterized[9] and there are no examples of such metal–metal bonded complexes of germanium.

The first truly metal–metal bonded complex to be characterized in the solid state, [Ph_3SnLi(pmdeta)] **1** (pmdeta = $MeN(CH_2CH_2NMe_2)_2$) was prepared by the reaction of *n*BuLi with Ph_3SnH and pmdeta (molar ratio 1:1:1) in toluene.[10] The complex (Fig. 1) contains a Sn–Li bond whose length is slightly greater than the sum of the covalent radii of Sn and Li (average over two independent molecules 2.817 Å; the sum of covalent radii of Sn and Li is 2.74 Å).

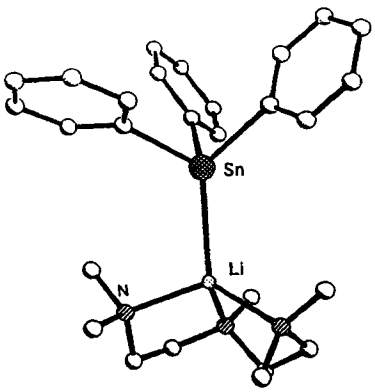

Fig. 1. Crystal structure of the monomeric molecules of **1**.

The Pb complex analogous to **1**, [Ph_3PbLi(pmdeta)] (**2**), is prepared from the reaction of Ph_3Pb–$PbPh_3$ with *n*BuLi and pmdeta (molar ratio 1:1:1).[11] It is stable for only about 12 h under N_2 at room temperature. The thermal decomposition pathway appears to involve the migration of a phenyl group as indicated by the formation of Ph_4Pb and elemental Pb. The essential structural features of **2** are very similar to those of **1**. The Pb–Li distance is slightly greater than the sum of the covalent radii of Pb and Li (average over both independent molecules 2.858 Å; sum of covalent radii of Pb and Li is 2.81 Å). The Ph_3Pb moiety of **2** is, however, more pyramidal than the Ph_3Sn unit of **1** and the Ph_3Si unit of [$Ph_3SiLi(thf)_3$] (**3**) (average

Dominic S. Wright was born in Gosport, Hampshire, England, in 1964. He studied chemistry at the University of Strathclyde in Glasgow (1982–1986), and then moved to Cambridge University where he obtained a Ph.D. in 1989 under the supervision of Dr. Ronald Snaith. He was elected a Research Fellow in Cambridge at Gonville and Caius College (1989) and was made a member of staff at Cambridge University in 1991. In 1993 he received the Meldola Medal, a prize awarded by the Royal Society of Chemistry in conjunction with the Society of Maccabaeans, for developments in the organometallic chemistry of the alkali and alkaline earth metals. His research interests include various aspects of main group organometallic chemistry.

C-Si-C angle in **3** 101.3°,[9f] average C-Sn-C angle in **1** 96.1°,[10] average C-Pb-C angle in **2** 94.3°[11]). The significant distortion in the Ph_3E units of **1**, **2**, and **3** away from a tetrahedral geometry is consistent with the expected increase in effective energetic separation of the s and p orbitals on descending group 14. This results in the metals progressively preferring to use predominantly p orbitals to bond to the C centers and the E–Li bonds largely involving the metal *n*s orbital. The pyramidal geometries of the Ph_3E moieties in **1**–**3** and in the ion-separated complex $[([18]crown-6)]K^+ \cdots Ph_3Sn^-]$ (**4**),[12] contrast with the near planar geometry found for the ion-separated Ph_3C^- ion where, as a result of more energetically favorable orbital mixing, the C atom is sp^2 hybridized.[13]

Concerning the nature of the bonding and the question of which orbitals of the heavy p block metal are used in the bonds between alkali metals and heavy p block metals of **1** and **2**, ab initio MO calculations show that the Sn–Li and Pb–Li bonds of Ph_3SnLi and Ph_3PbLi involve the p_z orbitals of Sn and Pb (which are directed along the metal–metal bonds) as well as their s orbitals (Fig. 2).[11]

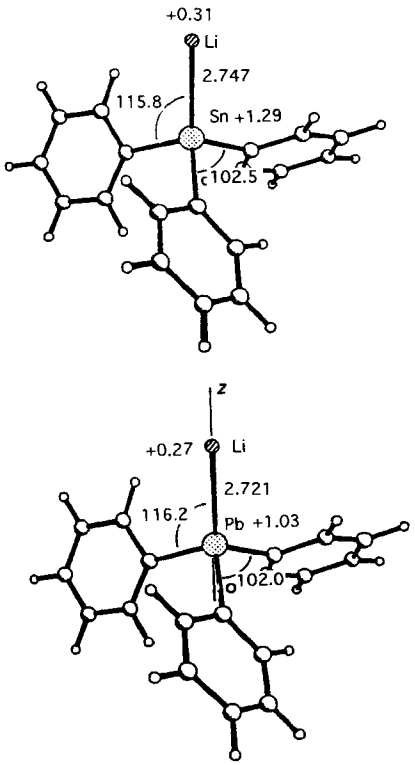

Fig. 2. Structures of Ph_3SnLi (top) and Ph_3PbLi (bottom) optimized by ab initio calculations.

The effect of solvation of the alkali metals in the above models is, not surprisingly, to elongate the E–Li bonds towards those found experimentally. Although limited in terms of mimicking the steric demands present in **1** and **2**, calculations on ion-contacted H_3PbLi and ion-separated H_3Pb^- illustrate that the coordination geometry about the heavy p block metal tends towards pyramidal (i.e. away from tetrahedral) as the contact to the alkali metal is broken (H-Pb-H 101.2° in H_3Pb-Li and 93.2° in H_3Pb^-). Thus the geometry of the p block metal center can be used to gauge the strength of the metal–metal interaction. The distinctly pyramidal geometries of the Sn and Pb anions in **1** and **2**, respectively, imply that such metal–metal bonding is very weak.

The weakness of the bonds between these heavy p block and early main group metals is further emphasized by the outcomes of the reactions of Ph_3SnH with *n*BuLi in the presence of other Lewis base donors. If one equivalent of monodentate HMPA ($O=P(NMe_2)_3$) or bidentate TMEDA ($(Me_2NCH_2)_2$) are present, the ion-separated complexes $[Li_2(hmpa)_5]^{2+}[Ph_3Sn]_2^-$ (**5**)[14] and $[Li(tmeda)_2]^+[Ph_3Sn]^-$ (**6**),[15] respectively, in which more than one equivalent of each donor is incorporated in to the product, are formed favorably. Solvation of the alkali metals by the Lewis base donor ligands clearly competes with the bonding between early main group metals and heavy p block metals. The Ph_3Pb units in transition metal complexes, for example in $[Ph_3PbV(CO)_6]$ (**7**) (C-Pb-C ca. 106.2°)[16] and in *cis*-$[Pt(Ph_3Pb)(PPh_3)_2Ph]$ (**8**) (C-Pb-C average 106.6°),[17] are distinctly more tetrahedral than that in **2**; thus together with the results of the calculations mentioned above on ion-paired and ion-separated H_3Pb^- systems, this illustrates that the interactions between alkali metals and p block metals are weaker than those between alkali metals and transition metals.

Cryoscopic molecular mass measurements in benzene show that **1** is monomeric and that the Sn–Li bond is therefore sustained in solution. Low-temperature ^7Li NMR studies of **1** (−90 °C) exhibit a large combined ^{117}Sn- and ^{119}Sn–Li coupling ($^1J_{Sn-Li}$ = 412 Hz) (Fig. 3).[10] Recently values of ^{119}Sn–^7Li coupling constants as high as 466 Hz have been recorded for

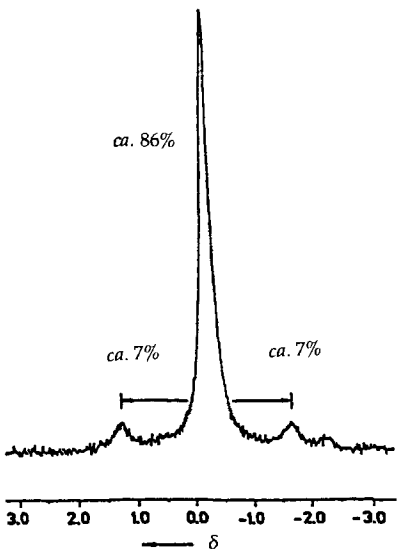

Fig. 3. ^7Li NMR spectrum of **1** at −90 °C in $[D_8]$toluene.

$n Bu_3SnLi$ in HMPA.[18] Rather than implying that there is a significant amount of covalent character in these Sn–Li bonds, the large coupling constants observed are most probably symptomatic of the employment of a predominantly 5s orbital in the Sn–Li bonds. The magnitude of these coupling constants, although significantly greater than the Si–Li coupling constants in covalent silyllithium compounds (ca. 50 Hz[9f, 19]), are in the

range expected on the basis of the trend observed previously for a variety of group 14 triorgano metal complexes in solution.[20]

The stannyl potassium compound $[(Me_3CCH_2)_3SnK(toluene)_3]$ **10**, in which a Sn–K bond is present (Sn–K 3.32–3.72 Å), shows a range of fascinating structural features in the solid-state (Fig. 4).[21] The complex **10** is prepared by the cleavage of the Sn–Sn bond of $(Me_3CCH_2)_3SnSn(CH_2CMe_3)_3$ (**9**)[21] with K metal in THF. Remarkably, the K^+ cation of **10**

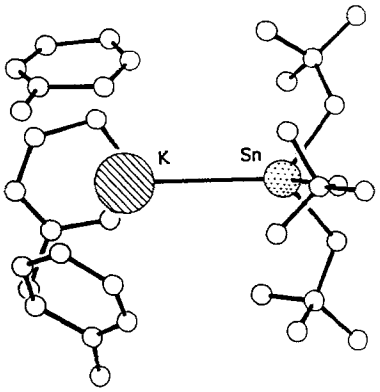

Fig. 4. Crystal structure of the monomeric molecules in **10**.

is solvated by three π-bonded toluene molecules. Thus, complex **10** is the first example of a complex containing a bond between an early main group metal and a heavy p block metal in which the alkali metal ion is not stabilized by heteroatom (O, N, etc.) donors.

The presence of the Sn–K bond in **10** is also manifest in its cross-polarization magic angle spinning (CP-MAS) solid-state ^{119}Sn NMR spectrum in which ^{119}Sn–^{39}K coupling is seen for the first time.[21]

Although the structural work on complexes containing semi-metallic p block elements of group 15 (As) and group 16 (Se, Te) is far less well developed than those containing the nonmetallic elements (N[2] and O[3]), it is clear that the same aggregation principles are observed with these complexes. The occurrence of monomers ($n = 1$),[22–27] dimers ($n = 2$),[22, 28–30] trimers ($n = 3$, i.e., the boat-shaped trimer $[\{Li[\mu\text{-}AsCH(SiMe_3)_2]\}_3]$ **11**[31]), and hexamers ($n = 6$, i.e., $[\{Li\{\mu_3\text{-}TeSi(SiMe_3)_3\}\}_6]$ (**12**)[30]) containing $(AsM)_n$, $(SeM)_n$, and $(TeM)_n$ frameworks illustrates the greater structural diversity of these complexes compared to those of Sn and Pb. The higher degrees of oligomerization attained stem from the apparently greater strengths of the semi-metallic bonds to the early main group metals. This greater tendency for association is manifest in the complexes $[\{(thf)Li[\mu\text{-}As(AstBu_2)(tBu)]\}_2]$ (**13**)[28] and $[\{(dme)Li[\mu\text{-}TeSi(SiMe_3)_3]\}_2]$ (**14**) (dme = $MeOCH_2CH_2OMe$),[32] in which despite solvation of the Li^+ ions by Lewis bases oligomerization into dimers occurs rather than dissociation (in a manner akin to the ion-separated complexes **5** and **6**).

Until recently there were no examples of molecular compounds with Sb–Li or Bi–Li bonds.[33] The structure of the complex $[cy_2SbLi(pm,deta)]$ (**15**) (cy = cyclohexyl) (Fig. 5)[34] was found to contain an Sb–Li bond (2.84 Å) which, like the E–Li bonds in the monomeric complexes **1** and **2** with Sn–Li and Pb–Li bonds is slightly longer than the sum of the covalent

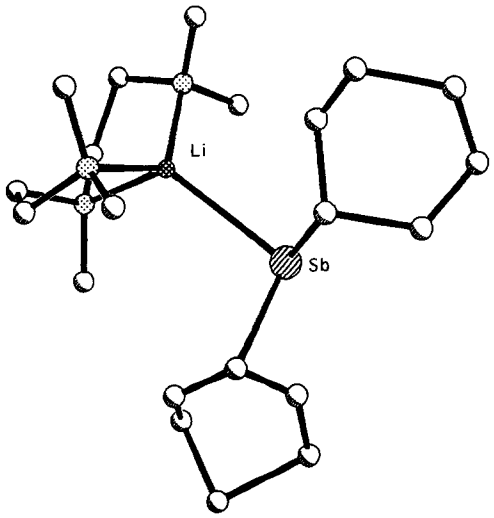

Fig. 5. Crystal structure of the monomeric molecules of **15**.

radii of Sb and Li (2.77 Å). The fact that this bond is sustained even in THF solutons is an indication that Sb–Li bonds are more stable than Sn–Li and Pb–Li bonds.

Perhaps the greatest challenge for the future in this area is the synthesis and characterization of complexes with bonds between metallic p block elements and early main group metals containing larger frameworks (rings and cages, etc.), since all the structurally characterized compounds so far are monomers. As alluded to above, bearing in mind the weakness of E–Li bonds where E is a metallic element, avoiding strong Lewis base solvation will be a key consideration in future investigations. A further area of developing interest is the application of Sn derivatives of alkaline earth metals in the synthesis of alkaline earth metal organometallic complexes. This is exemplified by the recent structural characterization of the monomeric Ca complex *trans*-$[Ca(SnMe_3)_2(thf)_4]$ **16**.[35] The cleavage of the weak Ca–Sn bonds of **16** with organometallic nucleophiles may well provide a key synthetic route in the syntheses of such organometallic compounds.[35]

3. New Anionic Ligands

Amides and alkoxides containing the heavy p block metals of groups 14 and 15 (Sn, Pb, Sb, Bi) exhibit a very diverse coordination chemistry. Such ions are being increasingly employed as novel ligands to a range of main group and transition metals.

Probably the most well-known and most simple examples of alkoxide or amide complexes are those of group 14. These generally have a trigonal bipyramidal structure in which the group 14 elements are linked through bridging heteroatoms to an early main group metal.[36a] Such a design is particularly common for alkoxide cages of Ge, Sn, and Pb.[36–40] The discrete cage complex $[Li(\mu\text{-}2,6\text{-}Ph_2C_6H_3O)_3Sn]$ **17** (Li–Sn 2.784 Å)[37] typifies this structural design and the basic bonding pattern present within these species (Fig. 6). The Li^+ ion and the Sn^{II} center of **17** are held together solely by μ-O alkoxide bridges. Since the lone pair on Sn points away from the Li^+ ion

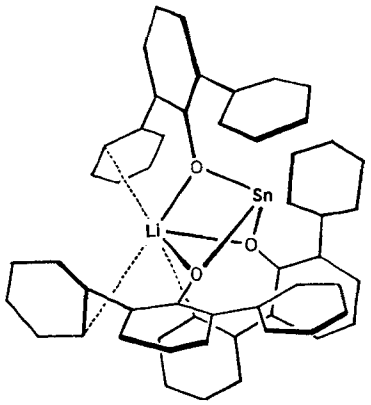

Fig. 6. Crystal structure of the monomers of **17**.

there is little or no Sn–Li bonding present (despite the presence of a close Sn···Li contact in **17**).

The flexibility of alkoxystannates as ligands is evident from the aggregation of the basic trigonal bipyramidal building units upon increasing the metallic radii of the alkali metal ion thus satisfying the increased coordination sphere of the cation. This is seen in the series of complexes $[\{Sn(OtBu)_3M\}]_n$ (M = Li (**18**), Na (**19**), $n = 2$; M = K (**20**), Cs (**21**), Rb (**22**), $n = \infty$)[39] in which structural ammendment occurs from dimers consisting of fused rings with fourfold coordination of Li and Na for **18** and **19** (Fig. 7), to polymeric structures based on SnO_3M trigonal bipyramids which are associated by additional intermonomer M–O bonds for **20**–**22**.[39a,d] Veith et al. have demonstrated that the $(tBu_3O)_3Sn^{:-}$ ion can, by utilizing both the μ-O linkage and the Sn lone pair, act as a bifunctional tripod ligand to main group and transition metals.[36b] Veith has written an extensive review on main group metal cage compounds and their coordination chemistry.[36a]

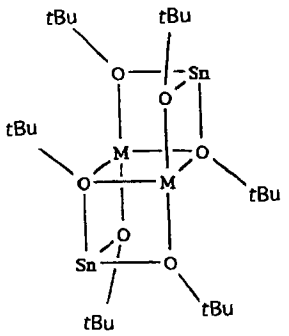

Fig. 7. Schematic structure of the fused dimers of **18** and **19**.

For the anionic tris-pyrazolyltin and -germanium compounds which have recently been investigated,[40,41] an unprecedented alternative to the aggregation noted for **18**–**22** is found. Dimerization rather than polymerization is the result of coordination to Na^+ in the structure of $[\{(Pz)_3SnNa(thf)_2(PzH)\}_2]$ (**23**). Two of the pyrazolyl groups of each $[(Pz)_3Sn]^-$ ion link the alkali metal ions together and the third is uncoordinated (Fig. 8). This bonding mode contrasts with the more conventional tridentate attachment observed in the Ge analogue which has the conventional monomeric trigonal bipyramidal structure. Such "claw" tris-pyrazolyl ligands $(Pz)_3E^-$ (E = Sn, Ge) are very flexible in their coordination to a range of metal ions and promise to be an exciting new area in the future.[41] This study also points the way forward for the design of selective ligands by tailoring the heteroatomic center within such anionic ligands (i.e., by varying the hardness/softness, steric demands of the organic group, and ligand bite) to the coordination environment suitable for a particular metal.

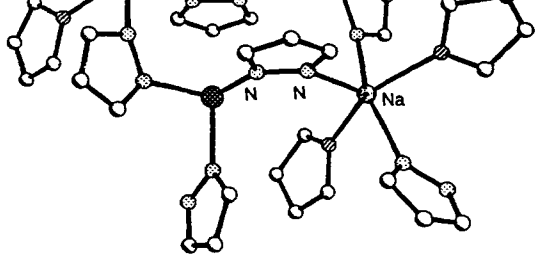

Fig. 8. Cyclic dimer structure of **23**.

The conventional synthesis of amide and alkoxide complexes is by nucleophilic substitution of the metal halides with the appropriate organic anion. However, the development of nucleophilic substitution of Cp_2E (E = Sn, Pb) allows the syntheses of a host of such anions in the absence of potential interference by halide ions.[42–44] In the light of their applications as selective ligands mentioned above, this new approach is of importance in broadening the range of complexes accessible. The reactions of more potent (imino, amido, or organometallic) nucleophiles with Cp_2E appear to occur by an associative (addition–elimination mechanism) rather than by a concerted pathway. This is shown by the isolation of $[Cp(Me_3Si)_2NSn(\mu\text{-}Cp)Li(pmdeta)]$ (**24**) from the 1:1 reaction of Cp_2Sn with $(Me_3Si)_2NLi$ in the presence of PMDETA.[45] The complex is best regarded as a "loose-contact" complex of the neutral components $[Cp(Me_3Si)_2NSn\cdots(\mu\text{-}Cp)Li(pmdeta)]$ as is shown by its dissociation into the neutral fragments in aromatic solvents even at room temperature.[45] As such, complex **24** can be regarded as a model intermediate for such nucleophilic substitution.

In contrast to the development of group 14 alkoxide and amide derivatives as ligands, the derivatives of group 15 have received far less attention. However, very recently a series of polyamidoantimonate complexes have been prepared by stepwise metalation of primary amines employing $(Me_2N)_3Sb$ as a metalating source. An example of this "mixed-metalation" procedure is the reaction of $Li[Sb(NHCy)]_4$ with $(Me_2N)_3Sb$ (molar ratio 1:2) which gives the unusual polynuclear amidoantimonate complex $[LiSb_3(Ncy)_4(NMe_2)_2]$ **25**. This complex contains a Sb_3N_6Li "deck-chair" core (Fig. 9 left).[46] Using a similar method $[\{Li_2Sb_2(Ncy)_4\}_2]$ (**26**),[47] consisting of a core of two interlocked broken cubes (Fig. 9 middle), and $[\{(PhCH_2CH_2NLi)_3Sb(thf)\}_2]$ (**27**),[46] containing a fourteen-membered polyhedral core (Fig. 9 right), can also be synthesized. The polyimidoantimonate ions of **25**, **26**, and **27** are potential ligands to a range of main group and transition metals.

The robust nature of this new type of ligand is confirmed by the recent synthesis of $[Cu_4\{Sb_2(Ncy)_4\}_2]$ (**28**) from the transmetalation of **26** with CuCl (Fig. 10).[48] In contrast to **26** which contains a roughly tetrahedral array of Li atoms in the central portion of the molecule, complex **28** contains an almost ideal square-planar Cu_4 core. The function of the $[Sb_2(Ncy)_4]^{2-}$ ligands of **28** is similar to that observed recently in $[Cu_4\{C_6H_4O_2(Me_2SiNtBu)_2\}_2]$ (**29**), which also contains a square-planar Cu_4 core.[49]

The solution behavior of **26** is of interest. Cryoscopic molecular mass measurements and variable-temperature ^7Li NMR spectroscopy show that the complex is involved in a dissociative

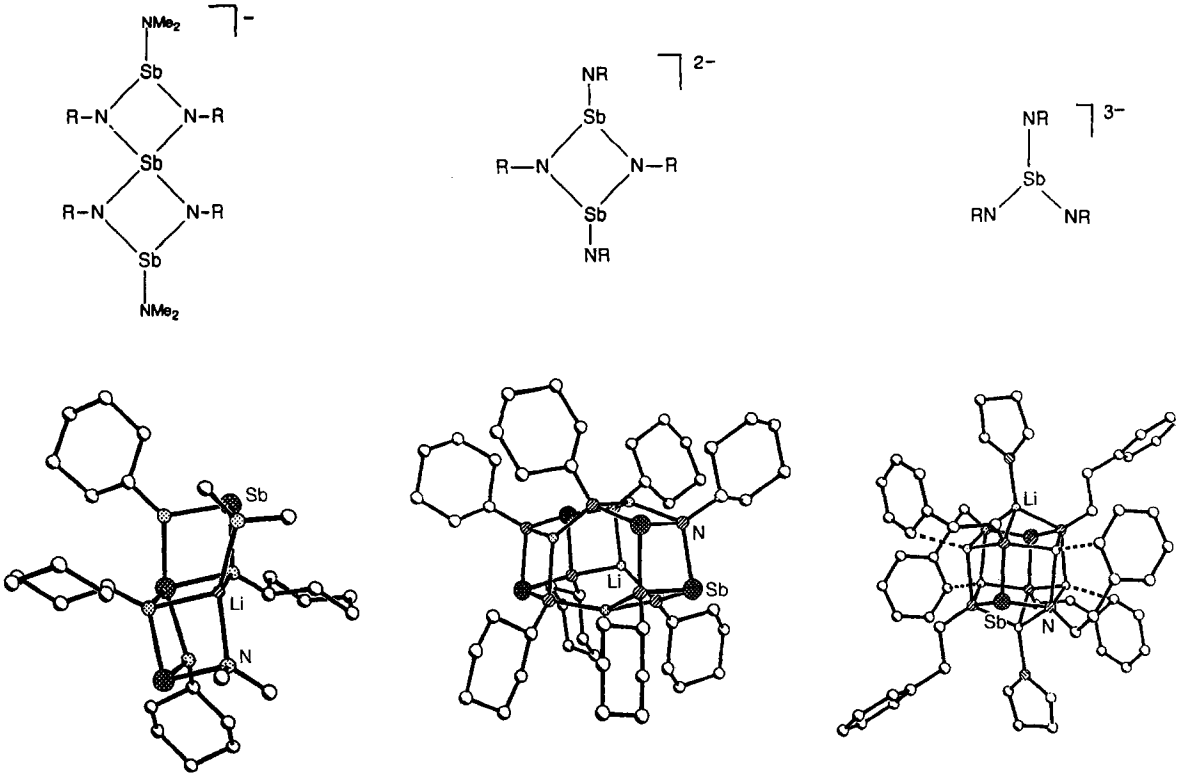

Fig. 9. Polyamidoantimonate ions of **25**–**27** (top) and their cage structures (bottom).

equilibrium in which the cubane halves of the core are formed, that is $[\{Li_2Sb_2(Ncy)_4\}_2] \rightleftarrows 2[Li_2Sb_2(Ncy)_4]$.[47b] Such symmetrical dissociation is relevant to the ability of these polyamido antimonate complexes to capture other metal salts. This is seen in the cage expansion reaction of the fourteen-membered polyhedral complex $[\{(cyNLi)_3Sb\}_2]$ **30**, whose structure is similar to that of **27**, with *t*BuOK (molar ratio 1:3) in toluene. The resulting twenty-membered cage complex is $[\{(cyNLi)_3Sb\}_2(t\text{BuOK})_3(\eta\text{-toluene})_2(\text{toluene})_2]$ (**31**) (Fig. 11 bottom).[50] The formation of **31** can be visualized as occurring by symmetrical cleavage of the precursor cage followed by cocomplexation with a $[K_3(\mu\text{-O})_3]$ ring (Fig. 11 top). The development of the mixed-metalation procedure to other p block metals of group 14 (Sn, Pb) and 15 (Bi, As) provides some exciting new possibilities as regards the coordination chemistry of related anions in the synthesis of bimetallic and trimetallic complexes by transmetalation and cocomplexation reactions.

4. Anions from p Block Metals and Cyclopentadienyl Ligands

Cyclopentadienyl derivatives of the heavy p block metals have been investigated extensively in the past thirty years or so.[51] An examination of the solid-state and gas-phase structures and of the formal electron counts of the metals in these complexes [CpE, E = In (**32**), Tl (**33**);[52,53] Cp_2E, E = Si (**34**), Ge (**35**), Sn (**36**);[54-56] Cp_3E, E = Sb (**37**), Bi (**38**)[57]] provides a useful predictive tool in assessing the possible occurrence of anionic and cationic[58,59] species generated from them. As illustrated in Figure 12, nucleophilic addition of Cp^- would potentially produce a family of anionic species which are isolelectronic with the neutral cyclopentadienyl complex of a neighboring group.

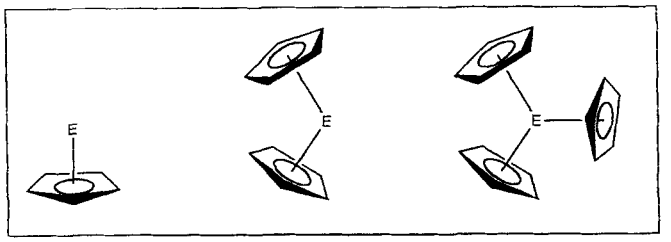

Fig. 12. Isoelectronic and isostructural relationships between neutral, anionic, and cationic cyclopentadienyl species.

Addition of Cp^- to CpE (E = In, Tl) should result in an isolated 14e anion Cp_2E^-, whose electron count corresponds to that of the neutral Cp_2E in group 14 (Fig. 12). In practice addition of CpLi and Cp_2Mg to polymeric $[(\mu\text{-}\eta^5\text{-Cp})Tl]_\infty$ does indeed "extrude" a 14e unit of this lattice.[60] The structures of ion-contacted [CpTl(μ-Cp)Li(pmdeta)] (**39a**) and ion-separated [CpMg(pmdeta)] [Cp_2Tl] (**39b**) (Fig. 13) have been determined in the solid state and contain bent thallocene anions (average $Cp_{centroid}$-Tl-$Cp_{centroid}$ 153.3° in **39a** and 156.7° in **39b**) which are isoelectronic with stannocene.

While the Tl center of $[(\eta^5\text{-Cp})_2Tl]^-$ in **39b** is attached almost equivalently to the η^5-Cp ligands, in **39a** the terminal η^5-Cp contact (Tl–$Cp(a)_{centroid}$ 2.60 Å) is significantly shorter than that made with the Li^+–bridging μ-Cp ligand. In **39a** the Li^+ ion competes with the Tl^I center for the electron density of the bridging Cp ligand and pulls this Cp away from the Tl^I center. There is a compensatory enhancement in the interaction between the terminal η^5-Cp ligand and Tl, and the Tl–$Cp(a)_{centroid}$ distance approaches that found in the gas phase structure of monomeric $[(\eta^5\text{-Cp})Tl]$.[53]

Ab initio MO calculations on various isomers of the discrete $[(\eta^5\text{-Cp})_2Tl]^-$ ion show that the association of Cp^- and CpTl is reasonably favorable (-28.0 kcal mol^{-1} for the ECP-DZ basis set). Furthermore, results at higher levels of calculation (MP2, MP3, MP4) illustrate that the most stable bent structure (with C_s symmetry) is only marginally more favorable than the most stable linear structure (with D_{5d} symmetry) (e.g., only 0.82 kcal mol^{-1} at the MP4 level). These results suggest, contrary to findings of calculations on Cp_2Ge (**40**), where orbital admixing of the antibonding a_{1g}^* MO with the metal p_x atomic orbital leads to a significantly greater stability of the bent structure,[61] that orbital admixing is ineffective in the discrete $[(\eta^5\text{-Cp})_2Tl]^-$ ion. This view is confirmed by the fact that an essentially spherical (s-like) lone pair is present on the Tl center of the bent $[(\eta^5\text{-Cp})_2Tl]^-$ ion. Examination of the electron density in the bent structure also suggests that the interactions of the Tl atom with the two Cp ligands are not equivalent and that the anion is probably best regarded as a "close-contact" complex between CpTl and Cp^-.

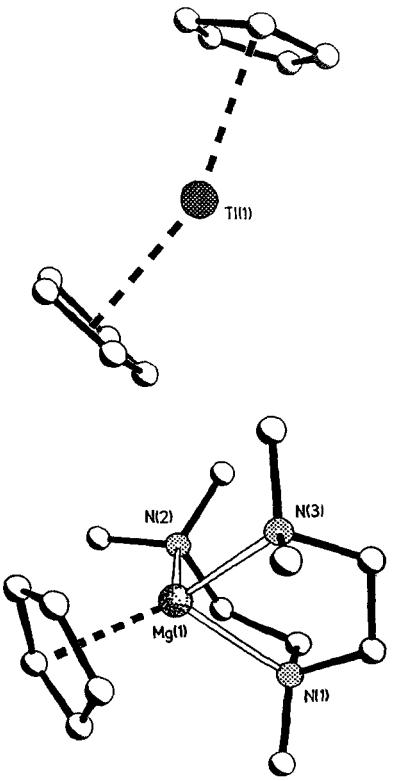

Fig. 13. Crystal structure of **39b**.

The nucleophilic addition of CpNa and Cp_2Mg to Cp_2Sn and $[Cp_2Pb]_\infty$ produce a range of ion-paired $[(\eta^5\text{-Cp})_2E(\mu\text{-}\eta^5\text{-Cp})Na(pmdeta)]$, E = Sn (**41**),[62] Pb (**42**)[63] (Fig. 14 top) and ion-separated $[Mg(thf)_6][(\eta^3\text{-Cp})_3E]_2$, E = Sn (**43**),[43] Pb (**44**),[63] (Fig. 14 bottom) complexes. These species contain highly unusual nearly planar "paddle-wheel" triorganostannate and plumbate ions whose geometries are in marked contrast to the classic pyramidal structures discussed above for ion-separated and ion-paired Ph_3E^- complexes.[10,12,14,15,22] This unique structural modification is of interest with respect to the applications of triorganostannates as reagents in organic synthesis, since it is likely that the nucleophilicity of the Sn center (which now appears to be sp^2-hybridized) will also be modified.

The E(μ-Cp)Na bridges of the ion-contacted complexes **41** and **42** (Fig. 14 top) can be rationalized in a similar way to the Tl(μ-Cp)Li bridge of **39a**. Interestingly, the ion-separated complexes **43** and **44** contain Cp_3E^- ions that are distinctly more pyramidal than the ion-paired species. The latter, and the change in hapticity of the Cp rings from η^5 in **41** and **42** to η^3 in **43** and **44** appears, at least on geometrical grounds, to reflect an increase in Sn and Pb lone pair character upon ion-separation. In respect to the trend outlined earlier for isoelectronic and isostructural species, the Cp_3E^- ions of complexes **41**–**44** can be seen as being related to 20e Cp_3E (E = Sb and Bi[57]), and the

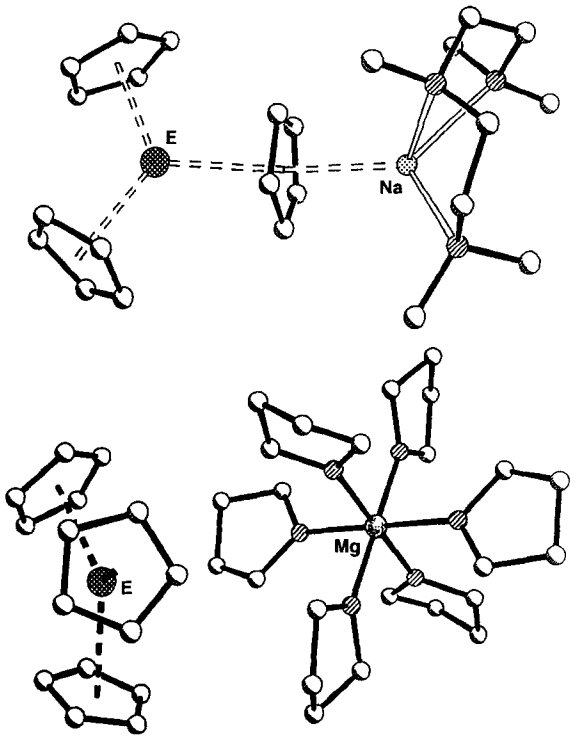

Fig. 14. Top: Structure of **41** and **42**, and bottom: structure of **43** and **44**.

ion-separated and ion-paired Pb complexes (**42** and **44**, respectively) can be regarded as extruded fragments of the $[Cp_2Pb]_\infty$ lattice. The observation of an ion-separated Cp_3Pb^- ion in **44** suggests that the 1:1 electrolyte produced when Cp_2Pb is dissolved in THF is most likely $[CpPb(thf)_x]^+[Cp_3Pb]^-$ (**45**), as opposed to the previously suggested $CpPb^+$ and discrete Cp^- ion.[64]

Ab initio MO calculations show the importance of Na^+ ion solvation in influencing the nature of the ion-contacted species; whether best considered as loose-contact $[Cp_2E\cdots CpNa(pmdeta)]$ or as close-contact complexes $(Cp_2E-Cp^{\delta-}\cdots Na^{\delta+})$.[63] Calculations on $[Cp_2E(\mu\text{-}Cp)Na]$, as models for **41** and **42**, show that in the absence of solvation these species are best regarded as loose-contact complexes. However, solvation of Na^+ diminishes the competition between this cation and the Sn and Pb centers for the electron density of the bridging Cp ligand and tips the balance towards closer and closer interaction of Sn and Pb with the bridging Cp ring. Calculations on Cp_3E^- in ion-separated complexes illustrate, in a similar way to the results on the $[(\eta^5\text{-}Cp)_2Tl]^-$ ion in complexes with separated ions,[60] that even here one of the E–Cp interactions is weaker than the other two. The results of the calculations are largely consistent with those from solid-state ^{119}Sn MAS-NMR studies on the Sn complexes; according to these NMR studies the Cp_2Sn character is more pronounced in the ion-paired complex **41** than in the ion-separated complex **43**.[63]

The view of the $[(\eta^5\text{-}Cp)_2Tl]^-$ ion mentioned above as an extruded fragment of the parent $[(\eta^5\text{-}Cp)Tl]_\infty$ lattice is confirmed by the recent synthesis of $[Li([12]crown\text{-}4)_2]^+[(\eta^5\text{-}Cp)Tl(\mu\text{-}Cp)Tl(\eta^5\text{-}Cp)]^-$ (**46**) (Fig. 15).[65] The complex contains an extended anion which is the next homologue of the bis(cyclopentadienyl)thallate ion, and the first homometallic

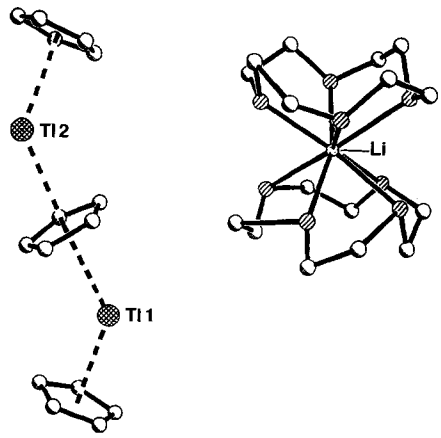

Fig. 15. Crystal structure of **46**.

main group metal triple-decker sandwich complex. This result suggested that yet higher chain homologues of $[(\eta^5\text{-}Cp)_2Tl]^-$ and of $[(\eta^3\text{-}Cp)_3E]^-$ (E = Sn and Pb) should be possible. Very recently this expectation has been confirmed: The reaction of Cp_2Pb with CpLi and [12]crown-4 (2:1:2) was carried out in an attempt to prepare the $[Cp_5Pb_2]^-$ ion (the next highest homologue of the $[Cp_3Pb]^-$ ion).[66] However, the only isolated product has an empirical formula $[Li([12]crown\text{-}4)_2]^+[Cp_7Pb_3]^-$. A subsequent X-ray study showed that the complex has the structural formula $[Li([12]crown\text{-}4)_2]_2^+[Cp_5Pb_2]^-[Cp_9Pb_4]^-$ (**47**) (Fig. 16),[66] containing the second and fourth homologues of the Cp_3Pb^- ion rather than the third (as might have been suggested from the empirical formula).

5. Concluding Remarks and Outlook

Complexes containing p block metal organometallic anions as well as corresponding alkoxides and amides are a highly diverse family of compounds. With the development and greater availability of low-temperature X-ray crystallography and with modern handling procedures, many of these unstable materials can now be structurally characterized. Such investigations have illustrated the exceptionally diverse bonding patterns to be

found in this class of complex and have set the stage for the development of the coordination chemistry and of detailed theoretical investigations of these species.

The unequivocal characterization of monomeric compounds containing bonds between early main group metals and heavy p block metals has laid the foundations for studies of more structurally elaborate oligomers containing frameworks with metal–metal bonds. One problem to be overcome in the synthesis of such compounds is that these metal–metal interactions are weaker than those between non-metallic or semi-metallic elements and early main group metals. The development of new synthetic approaches to anionic p block alkoxides and amides provides the basis for a great deal of future work on selective ligands to a range of metals. Simple derivatives of group 14 [containing R_3E^- units, with R bearing a heteroatom-centered (E) organic group] constitute a highly versatile class of readily prepared ligands in which variation of the metal or hardness and softness of the heteroatom center can be used to change the affinity of the anion for a particular metal. The synthesis of more complicated polyamido anions of group 15 by "mixed-metalation" (employing the Me_2NM derivatives) promises a greater ligand versatility and the potential, by using a similar synthetic route, to prepare a new class of related group 14 anions. Finally, the syntheses of a family of anions by nucleophilic addition of Cp^- to the cyclopentadienyl derivatives of the heavier p block metals gives rise to a variety of new synthetic challenges. Higher linear and cyclic homologues as well as mixed-metal derivatives will be future goals.

We would like to thank Dr. D. R. Armstrong (Strathclyde), Dr. D. Barr and Dr. S. Cook (Associated Octel), Dr. M. G. Davidson (Cambridge), Dr. A. J. Edwards (Cambridge), Dr. D. Moncrieff (Florida State), Dr. P. R. Raithby (Cambridge), Dr. D. Reed (Edingburgh), M.-A. Rennie (Cambridge), Dr. D. Stalke (Göttingen), and Dr. A. Steiner (Göttingen) for their valuable contributions to much of the work discussed in this review. D. S. W. would also like to thank Dr. Ronald Snaith (Cambridge) for his support and guidance throughout his carreer. We would also like to thank The Engineering and Physical Sciences Research Council (UK), The Nuffield Research Council, The Royal Society, Associated Octel (Ellesmere Port, UK), and The Cambridge Crystallographic Data Centre for financial support.

26th INTERNATIONAL SYMPOSIUM ON ENVIRONMENTAL ANALYTICAL CHEMISTRY

Vienna, Austria, 9 - 12 April 1996

Organization: Austrian Society for Analytical Chemistry,
Vienna University of Technology,
International Association of Environmental Analytical Chemistry

Chairmen: M. Grasserbauer (Vienna), J. Tarradellas (Lausanne)

The Symposium will cover the following major topics:

- development of new analytical techniques, instrumentation and procedures for environmental studies
- application of analytical techniques to environmental problems

Program highlights covered by invited lectures of leading scientists will include:

• sampling strategies and sample preparation (e.g. SFE, SPE, SPME) • hyphenated techniques (e.g. LC-GC, GC-MS, GC-AES, HPLC-MS) • elemental analysis, inorganic speciation and organic trace analysis • sensors for environmental monitoring • biochemical detection techniques • multiresidue (screening) procedures • quality assurance in environmental analysis • air, water and soil analysis • transnational environmental problems in Europe • environmental pollution in sensitive ecosystems

Scientific contributions on all topics related to environmental analytical chemistry will be considered for oral or poster presentation !

FOR INFORMATION PLEASE CONTACT: Dr. Erwin Rosenberg, Institute of Analytical Chemistry, Vienna University of Technology, Getreidemarkt 9/151, A- 1060 Vienna, Austria; Fax: (+43-1) 586 7813

Patterns in Hydrogen Bonding: Functionality and Graph Set Analysis in Crystals**

Joel Bernstein,* Raymond E. Davis,* Liat Shimoni, and Ning-Leh Chang

Whereas much of organic chemistry has classically dealt with the preparation and study of the properties of *individual* molecules, an increasingly significant portion of the activity in chemical research involves understanding and utilizing the nature of the *interactions between* molecules. Two representative areas of this evolution are supramolecular chemistry and molecular recognition. The interactions between molecules are governed by intermolecular forces whose energetic and geometric properties are much less well understood than those of classical chemical bonds between atoms. Among the strongest of these interactions, however, are hydrogen bonds, whose directional properties are better understood on the local level (that is, for a single hydrogen bond) than many other types of nonbonded interactions. Nevertheless, the means by which to characterize, understand, and predict the consequences of many hydrogen bonds among molecules, and the resulting formation of molecular aggregates (on the microscopic scale) or crystals (on the macroscopic scale) has remained largely enigmatic. One of the most promising systematic approaches to resolving this enigma was initially developed by the late M. C. Etter, who applied graph theory to recognize, and then utilize, patterns of hydrogen bonding for the understanding and design of molecular crystals. In working with Etter's original ideas the power and potential utility of this approach on one hand, and on the other, the need to develop and extend the initial Etter formalism was generally recognized. It with that latter purpose that we originally undertook the present review.

Keywords: hydrogen bonds · self organization · solid-state structures

I perceived that you had acquired some knowledge in those matters from others, and that you were perplexed and bewildered; yet you sought to find out a solution to your difficulty. I urged you to desist from this pursuit, and enjoined you to continue your studies systematically; for my object was that the truth should present itself in connected order, and that you should not hit upon it by mere chance.[1]

1. Introduction

In a number of papers we have advocated the use of graph sets for the analysis of hydrogen-bonding patterns in organic crystals.[2–6] There has been considerable interest in this method,[7] and there appeared to be a need to expand upon our earlier formal presentation of the rules for determining the graph sets. Moreover, during the past few years we gained experience in our own use of graph sets, and as a result of numerous inquiries from others who have attempted to apply these methods, we have become aware of a number of problems, misunderstandings, and ambiguities in the prescriptions we had provided for determining the graph sets.[3, 5] We therefore thought it fitting to review those rules here in more practical terms than those presented earlier, and to present a number of worked examples that might provide additional assistance and guidelines for those who wish to apply the method.

We are particularly aware that for the graph set approach to be of any utility, its language must be straightforward and consistent. Assignments from different research groups must be arrived at according to readily understood and commonly accepted rules, they must be easy to make, and they must be identical. One way to guarantee such a situation is to provide widely available computer programs for use in making the graph set assignments. This is certainly a goal to which we aspire, and we are currently working to design software that will meet these objectives. In the meantime, it is of crucial importance to prevent the spread of misunderstandings and misconceptions about the use and applications of the method, as well as to avoid the proliferation of incorrectly assigned graph sets.

With that purpose in mind we undertook the writing of this paper. We will first review briefly the essential features of the graph set approach, recalling that a more formal approach has been given earlier. We then present a number of worked examples of graph set assignments, noting some difficulties and pitfalls and how they may be avoided. Finally, we will discuss the utility of graph set analysis in discovering hydrogen-bond pattern functionalities that cross the traditional boundaries of chemical functionality.

2. Graph Set Definitions

Perhaps the most remarkable feature of the graph set approach to analysis of hydrogen-bond patterns is the fact that even complicated networks can be reduced to combinations of four simple patterns, each specified by a designator: chains (**C**), rings (**R**), intramolecular hydrogen-bonded patterns (**S**), and other finite patterns (**D**). Specification of a pattern is augmented by a subscript designating the number of hydrogen-bond donors **d** (in the most common case covalently bonded hydrogens, but certainly not limited to them), and a superscript giving the number of hydrogen-bond acceptors **a**. In addition, the number of atoms **n** in the pattern is called the degree of the pattern and is specified in parentheses. The graph set descriptor is then given as $\mathbf{G}_{\mathbf{d}}^{\mathbf{a}}(\mathbf{n})$,[*] where **G** represents one of the four possible designators.

These four patterns and their descriptors are best illustrated by examples. A chain whose "link" is composed of four atoms as in **1** would be specified as **C(4)**. When no subscript and superscript are given, one donor and one acceptor are implied. Similarly, the intramolecular hydrogen bond in **2** would be specified as **S(6)**, for the six atoms comprising the intramolecular pattern. When the donor and acceptor are from two (or more) *discrete* entities (molecules or ions), as in **3**, the designation of the hydrogen bond is **D**. The entities, as we will demon-

Joel Bernstein was born in Cleveland, Ohio, in 1941. After obtaining a B. A. at Cornell University, he earned a Ph.D. in physical chemistry at Yale University for research on the solid-state spectroscopy of organic compounds. Following two-year postdoctoral stints in X-ray crystallography with Ken Trueblood at UCLA and in organic solid-state chemistry with the late Gerhardt Schmidt at the Weizmann Institute of Science in Rehovoth, Israel, he joined the faculty of the newly established Ben-Gurion University of the Negev, where he is now Professor of Chemistry. His research interests center on the organic solid state, with particular emphasis on understanding and utilizing polymorphism, structure–property relations, and organic conducting materials. His career has been punctuated by visiting professorships at the University of Illinois, Cornell University, and most recently at the University of Minnesota, where he continued a long cooperation with the late Margaret C. Etter.

Raymond E. Davis was born in Hobbs, New Mexico, in 1938. Following his B. S. in Chemistry at the University of Kansas, he obtained a Ph.D. in physical chemistry at Yale University for research in the structures of organic compounds by X-ray crystallography. He then spent two years in the laboratory of David Harker at the Center for Crystallographic Research, Roswell Park Memorial Institute, Buffalo, New York. In 1966, he joined the faculty of the University of Texas at Austin, where is now Professor of Chemistry and Biochemistry. He has received many awards for teaching excellence and is the co-author of a widely used general chemistry textbook. His research has involved structural studies of organic and organometallic compounds, emphasizing π complexes, phosphorus macrocycles, and metal–phosphorus cluster compounds. More recently he has turned his attention to organic solid-state chemistry, especially studies of packing in molecular crystals and methods for crystal engineering.

strate below, may differ on chemical grounds (that is, the molecules or ions involved are two different chemical entities) or on crystallographic grounds (that is, chemically identical molecules not related by a crystallographic symmetry operation). In **3** there is only one donor and one acceptor, and the pattern involves only the hydrogen bond; in this case other atoms need not be counted, and the degree of the pattern **(2)** may be omitted.[8] Finally, the fourth possible pattern is the ring **4**. In the example shown, the two hydrogen atoms in the ring are not different (they are related by the crystallographic inversion center indicated in the diagram), but they could be.[9] The pattern contains a total of eight atoms, two of them donors and two acceptors, and hence is designated $\mathbf{R_2^2(8)}$.

The analysis of hydrogen-bonding patterns into these four simple categories can lead to important insights regarding the patterns of recognition between both like and unlike molecules. Cataloguing these patterns for particular functional groups can lead to a language describing their interaction and self-recognition similar to that of organic chemists for the reactivity of those same functional groups. Just as widely differing chemical groups may exhibit similar reactivities with respect to particular reagents, so differing functional groups may be seen as having similar hydrogen-bonding characteristics based on the patterns recognized through an analysis with these descriptors (Table 1).

Table 1. Glossary of terms

degree (of a pattern)	the number of atoms in the pattern
designator, **G** (of a pattern)	one of four letters designating the fundamental type of pattern: **C** (chain), **R** (ring), **S** (intramolecular pattern), **D** (other finite patterns)
descriptor, $\mathbf{G_d^a(n)}$ (of a pattern)	a notation summarizing the pattern: **G**: the pattern designator; **d**: a subscript describing the number of donors in the pattern; **a**: a superscript describing the number of acceptors in the pattern; **n**: the degree of the pattern
motif	a hydrogen-bonded pattern in which only one type of hydrogen bond is present
unitary graph set, $\mathbf{N_1}$[a]	a listing of the descriptors for all of the motifs in a structure
binary graph set, $\mathbf{N_2}$ [b]	a descriptor of a pattern in which two types of hydrogen bonds are present
basic/complex graph set	(for a *particular set* of hydrogen bonds) basic: the graph set of lowest degree for those hydrogen bonds; complex: any graph set of higher degree involving those hydrogen bonds

[a] Alternative terminology: first-level graph set. [b] Alternative terminology: second-level graph set.

3. Terminology and Notation

A motif is a pattern containing only one type of hydrogen bond.[3] Specifying the motif for each different hydrogen bond in a network according to one of the four pattern descriptors in the preceding section leads to a description of the network in the form of a list of the motifs. In earlier papers we specified this as a first-order graph set ($\mathbf{N_1}$), and followed that specification, when the chemical or structural problem required it, with the definition of higher order graph sets. In retrospect the choice of the term "order" seems to be unfortunate. In theoretical chemistry, "of increasingly higher order" often implies "of increasingly less importance". That implication was by no means intended in the language of graph sets. On the contrary, the intent was to specify "of increasing size or increasing complexity" in terms of the number of atoms and/or hydrogen bonds in the particular pattern. We now feel that the designation *order* should be replaced by *level*, and we will henceforth make use of the latter term exclusively. Hence, specifying the motifs for the different hydrogen bonds according to a prescribed hierarchy[3] defines the *unitary*, or first-level, graph set $\mathbf{N_1}$.

The chemically interesting or topologically characteristic patterns of a system often appear when more than one type of hydrogen bond is included in the description, that is, in higher level graph sets.[5, 6] This will be true for **S**, **D**, and **C** patterns. Suppose a structure contains three distinct hydrogen bonds, designated *a*, *b*, and *c*. There will now be several possible *binary* (or second-level) graph sets, each one describing a pattern formed by two of these H-bonds—that is, $\mathbf{N_2}(ab)$, $\mathbf{N_2}(ac)$, $\mathbf{N_2}(bc)$. Note further that we now advocate the notation $\mathbf{N_2}$ for any binary graph set (that is, a set containing exactly two types of hydrogen bonds); we believe that this is more systematic and thus more readily reproducible by different workers than the previous notation of somewhat arbitrarily assigning subscripts based on the accidental order in which the graph sets were worked out.[6] The *ternary* or third-level graph sets (there might be more than one possible—see Section 12) are those that involve all three H-bonds, that is, $\mathbf{N_3}(abc)$.

Different pathways might also be found that include the same set of H-bonds, but with different degrees (**n**). To describe this situation, we suggest the term *basic* to describe the graph set of *lowest degree* and the term *complex* to describe ones of *higher degree*. Consideration of some of the choices for the binary graph set for α-glycine[10] illustrates this point (Fig. 1). The shortest path involving H-bonds *a* and *b* gives the binary graph set $\mathbf{C_2^2(6)}$; this is the *basic* binary graph set for *a* and *b*. A longer chain, $\mathbf{C_2^2(10)}$, represents a *complex* binary graph set for the same two H-bonds. Neither of these, however, describes the most obvious feature of this array, the ring structure; this is denoted by another complex binary graph set, $\mathbf{R_4^4(16)}$. In addi-

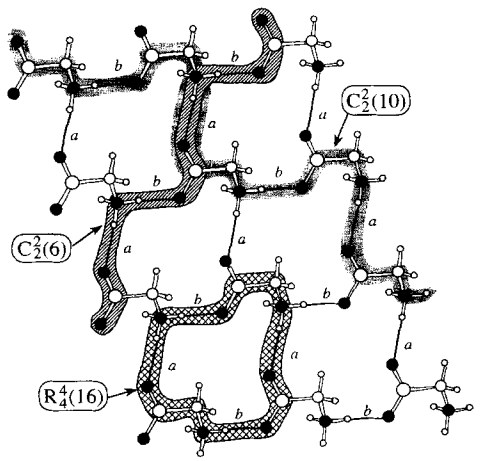

Fig. 1. Graph set assignments for the binary level of α-glycine. In this and many figures that follow, different types of hydrogen bonds (solid lines) are distinguished by labeling with italic lower case letters; carbon and hydrogen atoms are shown as open circles, oxygen atoms as solid circles, and nitrogen atoms as shaded circles.

tion, for extended **R** patterns that contain at least one edge (that is, one bond) in common, it is also possible to define an infinite number of increasingly larger ring systems. It is possible to generate binary graph sets for infinitely higher degrees (additional complex sets) for the two H-bonds in Figure 1, each one representing an increasingly larger pattern (Scheme 1).

$\mathbf{R}_6^6(26)$ with sequence $\overline{\lceil aabaab \rceil}$

$\mathbf{R}_6^6(26)$ with sequence $\overline{\lceil abbabb \rceil}$

$\mathbf{R}_8^8(36)$ with sequence $\overline{\lceil abbaabab \rceil}$

$\mathbf{R}_8^8(36)$ with sequence $\overline{\lceil aabbaabb \rceil}$

Scheme 1. Examples of complex graph sets.

This is the graph set manifestation of the "chicken wire" structure: a two-dimensional network of rings that have at least one bond (valence bond or hydrogen bond) in common.[11] Hence, the general protocol for defining graph sets must also include the possibility of increasing the degree (**n**) of the pattern, as well as the number of different hydrogen bonds (the level). Patterns that might later seem "characteristic" of a series of structures sometimes show up at higher levels or in more complex graph sets (or both). This point will be further exemplified in Sections 8 and 9.

4. The Hydrogen Bond—A Working Definition

The discussion in this section will refer specifically to hydrogen bonds, although in principle, of course, other types of interactions, for example, S···S, C–Cl···O, may be analyzed in precisely the same manner. Graph set analysis of hydrogen-bond networks is generally quite straightforward, and our experience has taught us that confusion can generally be avoided by proceeding in a systematic manner.

Assigning the descriptors to hydrogen-bond patterns requires first isolating the *hydrogen bonds* in the structural unit under study and *not* just the hydrogen atoms that participate in hydrogen bonding. The structural unit in question will generally be the crystallographic asymmetric unit and may be a single molecule, a number of the same molecules, part of a molecule, a complex, more than one molecule in a cocrystal, a molecule plus solvent molecule, etc. For that unit it is necessary to determine how many different hydrogen-bonding hydrogen atoms are to be considered. This is not a trivial question. Commonly recognized hydrogen bonds are those connecting oxygen and nitrogen atoms (for example O–H···N or O–H···O), but certainly C–H···O and C–H···N interactions are now included in hydrogen bonding,[12] and in cases where they play a clear role in the interactions among molecules it may be desirable to incorporate them in the graph set analysis. The decision on which hydrogen atoms are to be considered for inclusion may, in fact, vary from problem to problem, depending again on the chemical or structural questions being asked.

The hydrogen atoms to be considered as participants in hydrogen bonding interactions having been defined, it then becomes necessary to define the hydrogen bonds in which they participate. At this juncture the indication of whether a hydrogen bond exists or not will be based on a geometric (distance) criterion, although later we will definitely want to consider other criteria as well. Determining the geometric criterion for inclusion of an interaction as a hydrogen bond is a crucial, and by no means trivial step in the process. As a result of statistical surveys of the crystallographic literature and of structures in the Cambridge Structural Database, it has been possible to define characteristic values for many kinds of interactions, including hydrogen bonds.[13–15] These geometric characteristics are of immense value as the basis for theoretical calculations of molecular electronic structure, in, for instance, molecular mechanics and molecular dynamics, in modeling studies, protein structure determination, and the derivation of new potential energy functions. However, it has been shown that the application of geometric criteria, in particular that of a DH···A or D···A distance test as the strict test for the presence or absence of a hydrogen bond is not justifiable.[16] For instance, in a survey of amino acids Jeffrey and Maluszynska[17] have demonstrated that there are most probable DH···A and D···A distances for hydrogen bonds, but a smooth decrease in the distribution curve beyond that most probable value to about 3.0 Å for D···A distances. Beyond that distance, H···H van der Waals interactions begin to appear; the most frequent distance for these is 3.5 Å.

Dependence on a strict test for the presence or absence of a hydrogen bond is, in many ways, contrary to the philosophy of the graph set approach and hence fraught with dangers. As noted above, one of the principal advantages of the graph set approach is the facility for recognizing *patterns* of hydrogen bonding. Simply stated, patterns do not always have strict geometrical limitations. Hence, putting a limit of, say, 3.20 Å on the O···O or O···N distance might lead to ignoring a pattern for which the distance is 3.21 Å, but which is of no less importance in the overall scheme of hydrogen bonding. The limit to this reasoning is an infinite distance, but in practice nominal limiting distances can be defined; these are, however, considerably greater than those currently in vogue or based on van der Waals radii. Such distances should be considered as variable, depending on the system under study. Very large interaction distances are not to be expected ("nature abhors a vacuum"), so, as a result of interactions other than hydrogen bonding, other atoms will be present. Moreover, we wish to urge flexibility in setting arbitrary geometric criteria to determine hydrogen-bond interactions to ensure the recognition of patterns.

This interest in recognizing and defining hydrogen-bond patterns leads us to an operational definition of hydrogen bonds that incorporates their organizational consequences[2] rather than exclusively their geometrical characteristics. It is worth repeating here that definition, which parallels Pauling's definition of a chemical bond:[18]

> "A hydrogen bond is an interaction that directs the association of a covalently bound hydrogen atom with one or more other atoms, groups of atoms, or molecules into an aggregate structure that is sufficiently stable to make it convenient for the chemist to consider it as an independent chemical species."

In summary, then, in most cases it will be convenient for the chemist to employ some yes/no geometric criterion to test for hydrogen bonds. However, there is an increasing recognition of the subtlety of intermolecular interactions of many different types,[19] and for the time being at least, the best way to recognize these is to *look for* them and to *look at* them. Fortunately, in the age of desk top computer graphics, the ability to do this is within the reach of an increasingly large segment of the scientific community.

The C–H···O hydrogen bond is particularly illustrative in this regard. In his chapter titled "Selected Topics in Hydrogen Bonding" in the 1968 Festschrift[20] marking Linus Pauling's 65th birthday, Jerry Donohue included a section subheaded "The C–H···O Hydrogen Bond: What Is It?" Following a survey of the admittedly scant crystallographic information then available on such interactions, Donohue rather bluntly concluded the section with the sentence, "It appears to me that the answer to the question in the title of this section is: 'It isn't'". It is perhaps not an exaggeration to suggest that this statement traumatized virtually an entire generation of chemists and crystallographers, who subsequently avoided use of the term "hydrogen bond" when referring to C–H···O interactions. For at least the next decade, discussions of hydrogen bonds were limited to those involving a hydrogen atom bonded to an oxygen or nitrogen atom while the other atom was a hydrogen bond acceptor.

Nevertheless, there was considerable structural evidence for the presence of similar interactions between a hydrogen atom bonded to carbon when oxygen was the acceptor. For instance, in the structure of triclinic quinhydrone[21] (the 1:1 complex between quinone and hydroquinone, Fig. 2) there are clearly

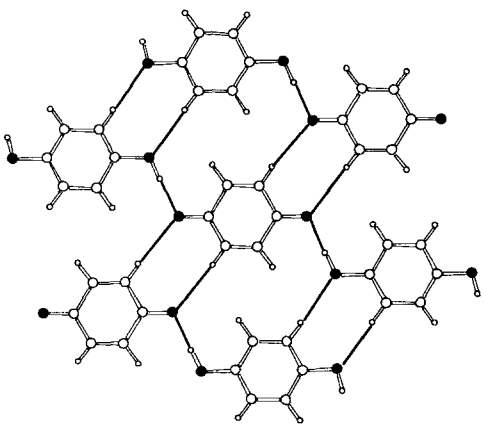

Fig. 2. Triclinic quinhydrone; view of the layer structure normal to the central benzoquinone molecule (based on Sakurai [21]). The figure shows shows C–H···$O_{carbonyl}$, C–H···$O_{hydroxyl}$, and O–H···$O_{carbonyl}$ contacts [22].

interactions between C–H groups and carbonyl or hydroxy groups, in addition to the expected O–H···O interactions. The first form centrosymmetric $\mathbf{R_2^2(8)}$ rings reminiscent of those in benzoic acid (**4**); these rings persist in the structure of 1,4-naphthoquinone[23] (Fig. 3) in which there are no hydroxyl hydrogen atoms. Examination of many more structures of this type confirms beyond any doubt the presence of a C–H···O interaction, which has been geometrically characterized and which is

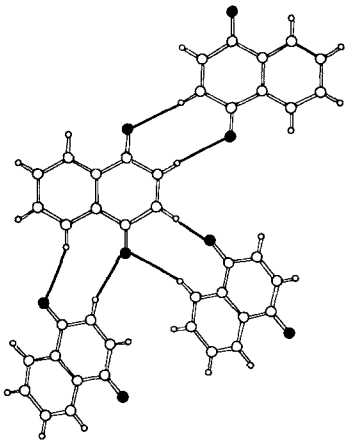

Fig. 3. View of the structure of 1,4-naphthoquinone normal to the molecular plane, showing C–H···O contacts [22]. Based on Gaultier and Hauw [23].

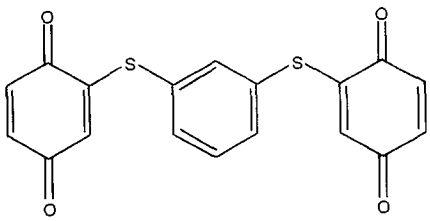
now perfectly acceptable in the growing family of hydrogen bonds.[12] The characteristic H···O distance is in the range 2.16–2.65 Å with a mean value of 2.45 Å.[12, 17] In many cases this centrosymmetric (at least topologically so) $\mathbf{R_2^2(8)}$ ring arrangement is found, which is clearly a hydrogen-bonding *pattern* that is common to this type of interaction. Such a pattern is distinctly recognizable, for instance, in the crystal structure of *meta*-(dithienylquinone) benzene (**5**),[24] as shown in Figure 4,



5

even though the O···H distance is 2.8 Å. In fact, there apparently is no other specific interaction in this structure. In looking at crystal structures of hydrogen-bonded systems we will try to recognize patterns with such ideas in mind.

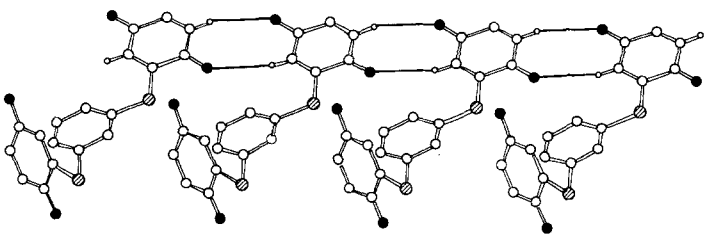


Fig. 4. View of the structure of **5**. Oxygen atoms are shown as solid circles; hydrogen atoms on the benzene ring have been omitted for clarity. The C–H···O distance is 2.8 Å. Taken from ref. [24].

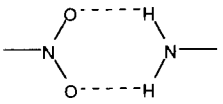
5. A Reminder and a Caveat

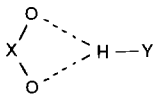
Many of the problems in assigning graph sets that have been brought to our attention stem from a lack of adherence to the fundamental definition of a hydrogen-bonding motif. We repeat that definition here and follow with an example.

A motif is a hydrogen-bonded set in which only one type of hydrogen bond is present.

The crucial point in this definition is the presence of only one *type of hydrogen bond*, not one *hydrogen atom*. Thus, in **6a**, if the two hydrogen atoms are not crystallographically equivalent, the unitary level graph set $\mathbf{N}_1$ would be **DD**, and the binary level would be $\mathbf{R}_2^2(6)$. Similarly, the two branches of a three-centered ("bifurcated") hydrogen bond such as **6b** should be treated as



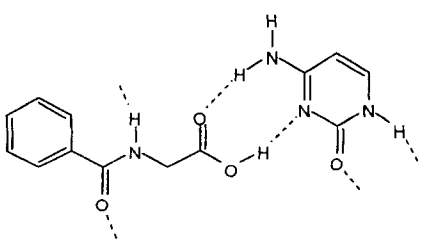
6a



6b

two different hydrogen bonds if the two branches are not crystallographically equivalent; the description of such an arrangement would appear at the binary level as $\mathbf{R}_1^2(4)$. Although this approach may appear at first to complicate the process of assigning graph sets, we believe that the contrary is true. As we will show in a number of examples below, strict adherence to this procedure will remove ambiguities from the process of assigning graph sets. Admittedly, this rigorous approach does sacrifice some of the aesthetic appeal of the whole procedure, in that the characteristic and distinguishing patterns will often appear later on in the formal process of assigning graph sets. However, those characteristic patterns that distinguish and relate different materials and that make the whole method so appealing are by no means lost; they simply appear at higher levels. Put another way, first identifying patterns "by eye" and then assigning their graph sets without regard to issues of crystallographic dependence/independence, level, and so on, limits the utility of the graph set approach to a *descriptive* function; by contrast, following a procedure and allowing the graph set descriptions of the patterns to develop systematically gives the approach a *diagnostic* as well as a descriptive dimension. The rigor advocated here has developed in part as a result of considering the design of algorithms for programming an automatic procedure that can be integrated into existing programs for plotting crystal structures and into structural databases, such as the Cambridge Structural Database.

As one illustration, in the complex **7** the two molecules are chemically different. Considering for the moment only the donors and acceptors involved in forming the ring, the two hydrogen bonds that participate in the ring are different; so in this case the first-level graph set is $\mathbf{N}_1 = \mathbf{DD}$. What will generally be considered the truly interesting chemical and essence-bearing pattern, again $\mathbf{R}_2^2(8)$, is found only at the binary level, which, by definition, contains two types of hydrogen bonds.



7

6. A Protocol for Assigning Graph Sets

Working independently in Austin and in Beer Sheva we have found that there is a natural protocol for assigning the graph set to a hydrogen-bonded system.[25] All investigators, of course, will find shortcuts and conveniences inherent in their own software, and perhaps even their own scientific background and interests, but the following procedure should make the assignment of hydrogen-bond graph sets relatively straightforward and, more importantly, consistent.

Two computer programs are essential: one that can calculate geometry, including intermolecular distances based on space group symmetry operations and translations, and a second that can plot crystal structures, preferably in stereo, and can easily accommodate addition and removal of molecules related by symmetry and translation, and rotation of the view. We often take our structures for study from the Cambridge Structural Database (CSD), and find it most convenient when the geometry calculation and plotting programs can use CSD entries without further modification.[26]

It is particularly helpful for the remainder of the process if all of the calculations are based on sets of fractional coordinates that define recognizable chemical units; otherwise it is easy to get lost in a maze of symmetry operations. After selection of the hydrogen atoms that are to be considered as possible participants in hydrogen bonding, the first program is used to calculate the possible hydrogen-bonding distances. A decision must then be made about which interactions should be included as hydrogen bonds; the nominal distance values cited above would serve as reasonable starting criteria. At this point intramolecular **S** motifs should be identified.

Through use of the symmetry positions of the calculated acceptor atoms for intermolecular hydrogen bonds, the molecular environment of the hydrogen bonds can be constructed. This is done by first generating on the graphics output both the original reference molecule(s) (whose coordinates were originally stored for computer plotting and geometry calculations) and, if necessary, a neighboring molecule that is connected to the first by a hydrogen bond. The presence of a crystallographic inversion center (or less commonly a $\bar{3}$, $\bar{4}$, or $\bar{6}$ axis) that relates the molecules that are hydrogen-bonded to each other prescribes an **R** motif. An **R** motif could also be generated by a two-fold rotation or by mirror reflection; however, for reasons related to packing efficiency such arrangements are extremely rare in the crystal structures of organic molecules.[27] The absence of inversion symmetry suggests that the motif is probably either a **C** or a **D**; the former is generated by unit cell translations or by symmetry operations of the second kind (screw axis or glide plane), and the latter arises in the absence of any symmetry relating the two molecules. Being finite, first-level **D** motifs are relatively easy to identify. Having determined the pattern designator, the degree of the pattern must be determined by counting the number of atoms. For **C** motifs we generally start at a hydrogen atom, traverse the hydrogen bond, and continue until reaching the same hydrogen atom in a symmetry-related molecule. It is particularly enlightening to carry out this procedure one molecule at a time, carefully labeling each new molecule as it is added to the graphic display. The repetition of a symmetry operation may be necessary to complete or extend a particular

hydrogen-bonding motif. In this way it is possible to generate each motif, one at a time. Generating hard copy and highlighting the motifs in different colors is a convenient way of preserving a permanent record of the graph set analysis.

After the initial assignment of the motifs and then the first-level graph set, higher level graph sets can be determined, if necessary, by systematically taking combinations of the different hydrogen bonds. We denote the motifs as *a*, *b*, *c*, etc. according to the hierarchy specified[3] for the first-level graph set. Binary (that is, pairs of hydrogen-bond types) graph sets, $\mathbf{N_2}(ab)$, $\mathbf{N_2}(ac)$, $\mathbf{N_2}(bc)$, etc. are then generated. For example, for three hydrogen bonds we would generate three basic unitary motif descriptors and three basic binary graph sets; four hydrogen bonds would correspond to four basic motif descriptors and six basic binary graph sets. The bookkeeping for this process is facilitated by use of a summary table in the form of a matrix in which the unitary motif descriptors appear on the diagonal and the second-level graph set descriptors appear off the diagonals. This is illustrated for anthranilic acid (Table 2 in Section 10) and iminodiacetic acid (Table 3 in the appendix). Higher level sets—ternary, quaternary, etc.—can then be generated as desired. As already discussed, the graph set description of complex networks can often yield insight into the characteristic chemical and structural features of the hydrogen bonding.

For the time being, at least, we have not addressed the problem of the directionality of hydrogen-bonding patterns. Even for a pairwise combination of motifs, say **DD**, the possibility of directionality certainly exists. In cyclic systems **R** that are generated by a crystallographic rotation axis, a number of possibilities exist, depending on the nature of the unique unit from which the **R** is generated and the presence or absence of symmetry elements in addition to the rotation axis. The distinction between homodromic and heterodromic patterns in cyclic systems has also been discussed by Jeffrey and Saenger.[16] Specifying the sense of such patterns would require an additional index in the pattern descriptor, and at this point we prefer to keep the notation to a minimum.

7. Structural Aspects As Motivation for Graph Set Analysis

In the remainder of this review, we raise, and attempt to resolve, some questions that have arisen in our attempts to use the graph set formalism to shed light on similarities and differences in packing patterns of related structures. Because many of the examples we cite arise from that work, it might be useful to elaborate briefly on its motivation, by giving but two illustrations of areas in which the graph set approach shows promise.

The focus in Beer Sheva has been on the study of polymorphic systems, with the additional goal of providing some guidelines for understanding the changes in hydrogen-bonding networks that result from the transformation from one polymorphic form to another. Two published examples have established the usefulness of the method of graph set analysis of hydrogen bonding in such systems.[5, 6] One area of work in Austin involves the comparison of hydrogen-bonding patterns for the same substance in enantiomeric and racemic crystalline forms—a relationship similar to that in polymorphism—with an eye to issues of resolution, racemic vs. conglomerate crystallization, etc. A subset of this work deals with amino acids; chemical similarities within this set of structures provide another thread of relationships that we can pursue with graph sets.

Clearly, one raison d'être of polymorphic forms in organic crystals is the possibility of the formation of different patterns of hydrogen bonding, and in many cases this is indeed manifested in differences in the graph sets found for polymorphs of a substance.[28] Similarly, the possibility of different patterns of hydrogen bonding is surely a potential factor in determining relative stabilities of racemic vs. enantiomeric crystals for a substance. However, there are also cases for which the graph sets of a racemate/enantiomer pair or of two polymorphs are identical at all levels. In such cases, the different structures clearly are not attributable directly to differences in hydrogen-bonding *patterns*, but rather to the subtleties of hydrogen-bonding *energetics* within the networks, and to further subtleties of non-hydrogen-bonding energetics between the hydrogen-bonding networks.

As an example of a pair of structures in which the enantiomeric and the racemic structures have identical hydrogen-bonding patterns at all levels, consider the structures of D,L-alanine[29] (Fig. 5, top) and L-alanine[30] (Fig. 5, bottom). A comparison of these diagrams suggests that the hydrogen-bonding patterns for the two structures are identical in all regards, an impression that is reinforced by the unitary graph sets, **C(5)C(5)C(5)**. Higher

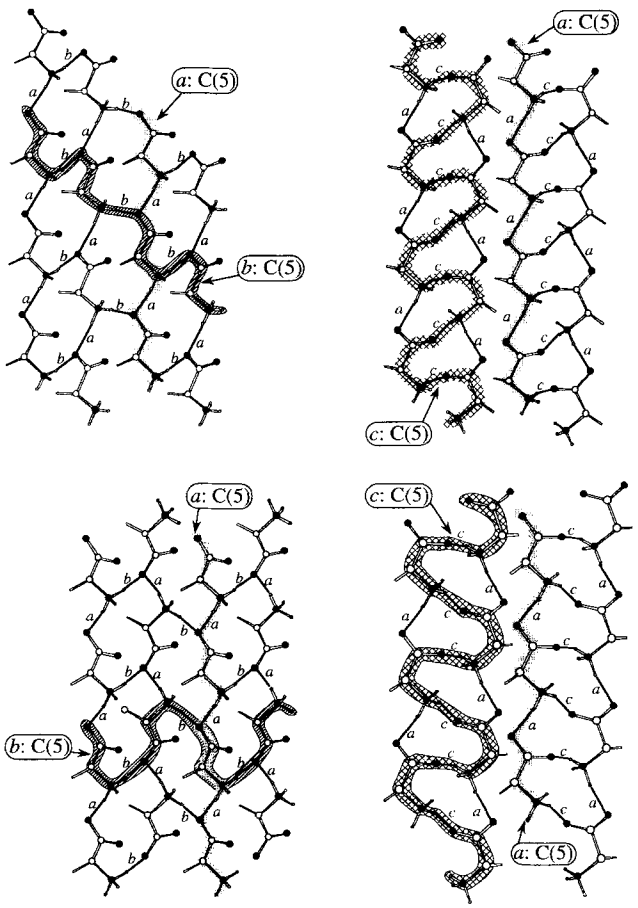


Fig. 5. Hydrogen-bond patterns of the structure of D,L-alanine (top) and L-alanine (bottom), showing the three hydrogen bonds: on the left those labeled *a* and *b*, and on the right those labeled *a* and *c*.

level graph sets, not marked in the figures, also correspond—$\mathbf{C_2^1(4)}$ for the basic (a,b) graph set, $\mathbf{R_4^4(14)}$ and rings of higher degree for complex (a,b) graph sets (analogous to α-glycine, see Fig. 1), $\mathbf{C_2^2(6)}$ for the basic (a,c) graph set, and so on.

A similar situation is seen for the two polymorphic structures α-D,L-methionine[31] (Fig. 6, top) and β-D,L-methionine[31] (Fig. 6, bottom). The unitary graph sets for both are **C(5)C(5)C(5).** The only significant difference between these two structures is in the conformation of the terminal CH_3S group. Higher level graph sets, again not marked in the figures, agree—$\mathbf{C_2^1(4)}$ for the basic (a,b) graph set, $\mathbf{R_4^4(12)}$ and rings of higher degree for complex (a,b) graph sets (again analogous to α-glycine, see Fig. 1), $\mathbf{R_4^4(12)}$ for the basic (a,c) graph set, and so on.

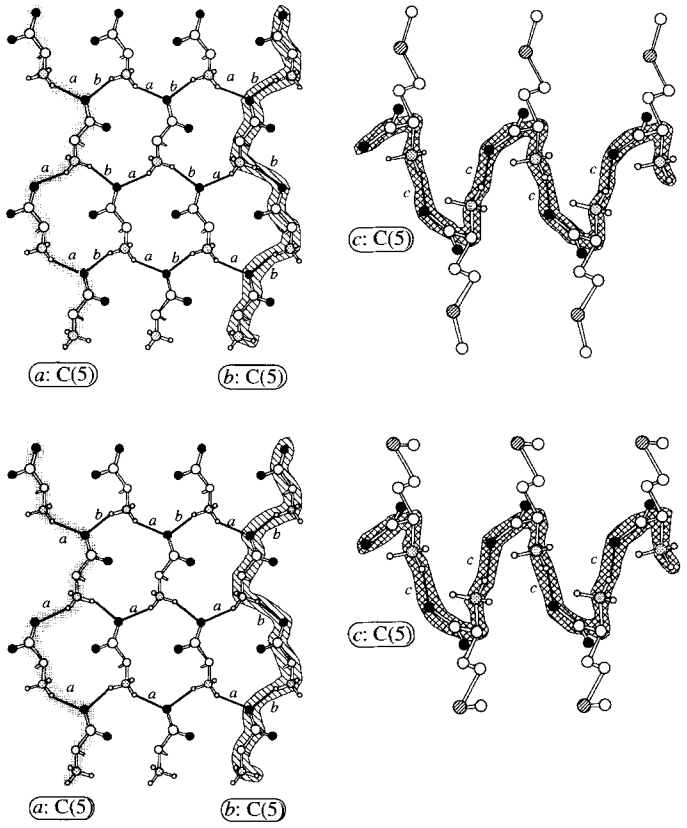

Fig. 6. Hydrogen-bond patterns of the structure of α-D,L-methionine (top) and β-D,L-methionine (bottom), showing the three hydrogen bonds: on the left those labeled *a* and *b*, and on the right those labeled *c*.

Comparison of the four structures just discussed and α-glycine (Fig. 1) exemplifies one essential point: Identical graph set notations at one level—for example, first-level graph sets **C(5)C(5)C(5)** for these five structures—*do not ensure* that the patterns are identical at all levels. The figures and, with even greater certainty, the higher-level graph sets as formally deduced, show clearly that three different structural arrangements are represented in these five structures. If differences in the graph sets of patterns appear, the conclusion that the patterns are different necessarily follows; however, one should conclude that patterns are identical only after establishing that *all graph sets, both basic and complex, at all levels* are the same for the structures.[32] Thus, we must emphasize again that the diagnostic power of the graph set approach would be diminished or lost without a systematic, thorough analysis, probably facilitated by computer algorithms in all but the simplest cases.

8. Rings or Chains or Both?

In many structures the hydrogen-bonding pattern clearly consists of chains whose "links" contain rings. Such a pattern appears in the triclinic form of tetramethyl-β-oxoglutaric acid (TOXGLU10) (Fig. 7a). There is no crystallographic symmetry within the molecule; the hydrogen-bonded rings at the ends of

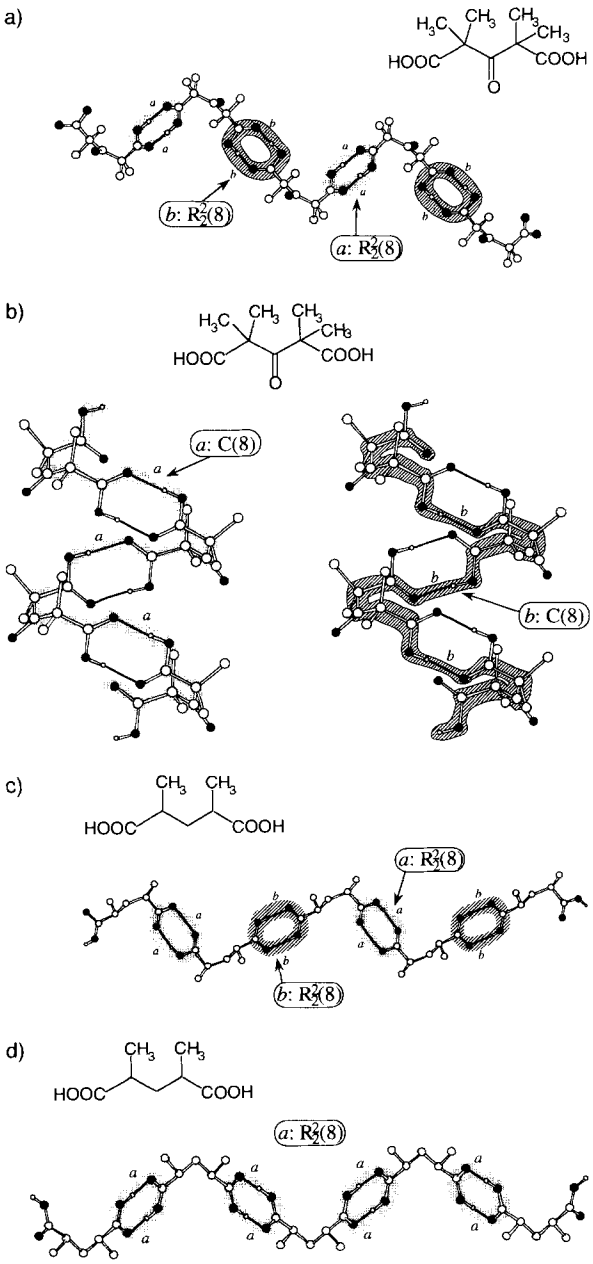

Fig. 7. a), b) Hydrogen-bond patterns for the triclinic form of tetramethyl-β-oxoglutaric acid, showing the two crystallographically independent rings in the chain (a) and the two alternatives for constructing chains (b). c) Hydrogen-bond patterns for *meso*-α,α′-dimethylglutaric acid, showing the two crystallographically independent rings in the chain. d) Hydrogen-bond pattern for *rac*-α,α′-dimethylglutaric acid, showing the effect of symmetry, which makes all $\mathbf{R_2^2(8)}$ equivalent.

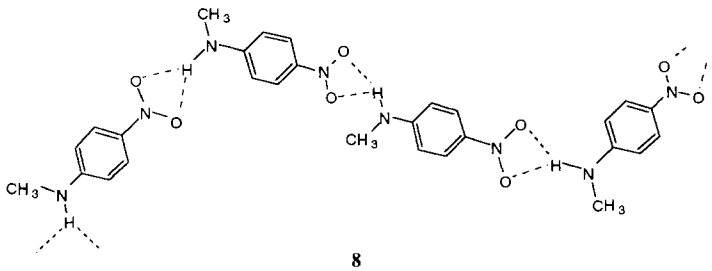
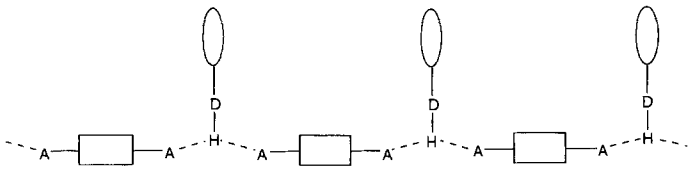
the molecule occur around different inversion centers, so each carboxylic acid dimer appears at the unitary level. The motifs are $\mathbf{R_2^2(8)}$ and $\mathbf{R_2^2(8)}$ for the two H-bonds *a* and *b*, giving the *basic* unitary graph set $\mathbf{R_2^2(8)R_2^2(8)}$. The basic binary graph set is $\mathbf{C_2^2(16)}$, counting through only one branch of each dimer ring. However, this basic representation does not adequately point to the presence of the ring as a characteristic topological element that distinguishes this hydrogen bonding pattern from a simple chain pattern; we might term this pattern a "chain of rings". We advocate a notation in which the ring designation is appended in square brackets to the chain designation: the extended notation for this pattern is thus $\mathbf{C_2^2(16)[R_2^2(8)]}$.[3]

Another such case is schematically represented for *N*-methylaniline[33a] in **8**, for which the basic binary graph set is $\mathbf{R_1^2(4)}$.[33b] Designating the chain by the complex binary notation $\mathbf{C_1^2(8)}$ would not be unique, however, because one could imagine a hypothetical (to the best of our knowledge) pattern such as **9** with the same designation. Using the square brackets notation introduced above, the full designation for the structure **8** is $\mathbf{C_1^2(8)[R_1^2(4)]}$.



8



9

Some ways that a chain of rings could arise are shown schematically as **10**–**13**, in which the designations *a* to *d* each represent a hydrogen bond. In **10**, all hydrogen bonds are crystallographically equivalent, which implies symmetry both within and between molecules; thus this chain of rings appears at the unitary level. Examples of such chains are the *β* form of oxalic acid (see Section 9), *rac*-dimethylglutaric acid (RADMGA, Section 9), and *β*-ketoglutaric acid.[34] If the molecule contains no symmetry but each ring is formed around a symmetry element (most commonly an inversion center), pattern **11** arises, in which the chain of rings appears at the binary level. Instances of pattern **11** include *meso*-dimethylglutaric acid (GLUTAC10, Section 9), triclinic tetramethyloxoglutaric acid (TOXGLU10, above), and Form I of amobarbital (Section 10). The absence of symmetry within either the molecule or the ring can give rise to the pattern **12**, again at the binary level, as in, for example, monoclinic tetramethyloxoglutaric acid (TOXGLU11, Section 9). Pattern **13**, would appear only at the quaternary level, because four different hydrogen bonds are involved. This could occur, for instance, when adjacent residues in the chain are crystallographically distinct, for example, in a cocrystal (including solvates), an ionic structure, or a structure with more than one formula unit per asymmetric unit ($Z' > 1$). Form II of amobarbital (Section 10) provides an example of such a pattern.

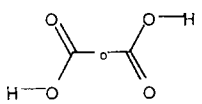
9. Crystallographic Symmetry Within and Between Molecules

In the previous section, we touched on the effects of crystallographic symmetry between and/or within molecules. In a similar vein, we noted above in Section 2 that for benzoic acid (**4**) the ring structure is due to the presence of a crystallographic inversion center. In that case, the two hydrogen bonds are identical, related by the inversion center; this resulted in the now-familiar $\mathbf{R_2^2(8)}$ ring as the basic unitary graph set.



14

In the *β* form of oxalic acid (**14**),[35] the asymmetric unit is composed of only one half of the molecule; the full molecule is generated by a crystallographic inversion center, so there is only *one* crystallographically independent OH group in this structure. An additional inversion center, operating in the same manner as in the benzoic acid structure, generates the $\mathbf{R_2^2(8)}$. The crystal structure, shown in Figure 8, clearly contains chains composed of rings linked through the molecule so the pattern at the unitary level is fully specified as $\mathbf{C(5)[R_2^2(8)]}$.

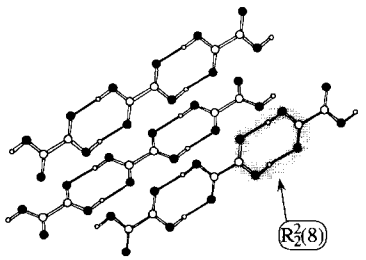


Fig. 8. The structure of the *β* form of oxalic acid, indicating the $\mathbf{R_2^2(8)}$ ring pattern typical of many carboxylic acids. The difunctionality of the molecule leads to a chain structure.

The glutaric acid derivatives shown in Figure 7 further illustrate the ideas of this and preceding sections.

TOXGLU10: As discussed in Section 8, the motifs for the triclinic form of tetramethyl-*β*-oxoglutaric acid (Fig. 7a)[36] are $\mathbf{R_2^2(8)}$ for the two H-bonds *a* and *b*, giving the *basic* unitary graph set $\mathbf{R_2^2(8)R_2^2(8)}$. The basic binary graph set is $\mathbf{C_2^2(16)}$, with the extended notation $\mathbf{C_2^2(16)[R_2^2(8)]}$.

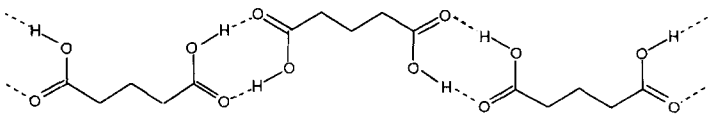
TOXGLU11: The monoclinic form of tetramethyl-*β*-oxoglutaric acid (Fig. 7b)[37] has no crystallographic symmetry within the molecule or relating the two H-bonds per molecule. The motifs are **C(8)** for the two H-bonds *a* and *b*, giving the *basic* unitary graph set **C(8)C(8)**. Because the carboxylic acid dimer

involves two crystallographically independent H-bonds, its familiar notation appears in the basic binary graph set, $\mathbf{R_2^2(8)}$.

GLUTAC10: The triclinic form of *meso*-a,a'-dimethylglutaric acid[38] (Fig. 7c) has the same symmetry and packing pattern as TOXGLU10. The basic unitary graph set is $\mathbf{R_2^2(8)R_2^2(8)}$ and the basic binary graph set $\mathbf{C_2^2(16)}$, with the extended notation $\mathbf{C_2^2(16)[R_2^2(8)]}$.

RADMGA: In *rac*-α,α'-dimethylglutaric acid[39] (Fig. 7d) the molecule lies on a crystallographic symmetry element (a twofold rotation axis), and the hydrogen bonding at each end occurs around an inversion center. Thus there is only one crystallographically independent H-bond. The motif could be described either as $\mathbf{R_2^2(8)}$ to emphasize the ring or **C(8)** to emphasize the chain. At present, the protocol for assigning graph sets does not specify a priority of assignment when two or more alternatives are of the same degree, here 8. We recommend the "chain of rings" notation discussed in the preceding section, $\mathbf{C(8)[R_2^2(8)]}$.

The common pattern in these four glutaric acid derivatives is the chain of rings shown as **15**. This consists of a chain with



15

periodicity eight, containing an eight-membered ring, or $\mathbf{C(8)[R_2^2(8)]}$. In the formal analysis of RADMGA, this notation appears directly as the unitary graph set. In the other three structures, it would show up in the complex binary graph sets with periodicity 16 and containing *two* $\mathbf{R_2^2(8)}$ rings, or $\mathbf{C_2^2(16)[R_2^2(8)]}$; we recognize this as *twice* the fundamental $\mathbf{C(8)[R_2^2(8)]}$ pattern. This illustrates again that a formal, systematic approach eventually leads to recognizably similar graph set designations when common features are present. It also points up the additional necessity of inspecting the graph sets not just for common features but also for *multiples* of common features.

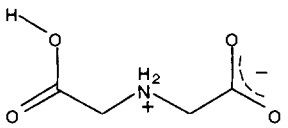
10. Structures with More than One Molecule in the Asymmetric Unit ($Z' > 1$)

A significant number of crystal structures contain more than one molecule in the asymmetric unit. In such cases, the structural/chemical question is: do the different molecules in the asymmetric unit have identical or different hydrogen-bond patterns? If the patterns differ, and the structure is one of a set of related structures, is there any commonality of patterns between different molecules in the asymmetric unit and the other structures?

Crystallographically, two or more molecules in the asymmetric unit are totally independent. If they have different hydrogen-bonding patterns as revealed from the graph set analysis, then they are exhibiting different properties of molecular recognition. When crystallographically nonequivalent molecules have the same hydrogen-bond environment, is it necessary to define the graph set for each? On the other hand, if they do not have the same environment, what is the prescription for defining the graph set in the general case?

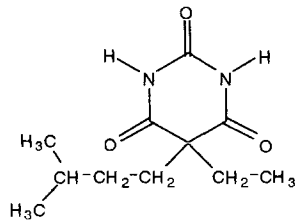
We have recently carried out a survey of polymorphic structures in which at least one of the structures contains more than one molecule in the asymmetric unit. Though this survey was not exhaustive, it did suggest the variety of cases possible. The examples we present here will serve as a prescription for defining the graph sets in many such cases.[40]

Our first encounter with this problem came with the analysis of trimorphic iminodiacetic acid (**16**).[5] In this case Form 2 contains two molecules with identical hydrogen-bond patterns in the asymmetric unit. Hence the two molecules were treated as identical, and the graph set was assigned for one of them. Although the chemical implications of that analysis are not altered, in light of our subsequent experience we realize that each of the molecules in the asymmetric unit should have been treated individually. A reanalysis of the graph sets for iminodiacetic acid Form 2 with the protocols developed here appears in the Appendix.



16

The problem and its solution are demonstrated in the two known polymorphic forms of amobarbital (5-ethyl-5-isoamylbarbituric acid) (**17**). Form I contains one molecule in the asymmetric unit, and Form II contains two.[42] The molecule has two hydrogen atoms that can participate in hydrogen bonding and the three potential hydrogen-bond acceptor carbonyl groups. In the unitary graph set for Form I (Fig. 9a), each of these forms a centrosymmetric $\mathbf{R_2^2(8)}$: the unitary graph set is thus simply $\mathbf{N_1 = R_2^2(8)R_2^2(8)}$.



17

For Form II there are now four different hydrogen atoms that must be accounted for in the unitary graph set. The representative part of the structure is shown in Figure 9b. The two hydrogen atoms from molecule A form hydrogen bonds with carbonyl groups from molecule B and vice versa. Each one of these combinations is a **D** motif; hence the unitary graph set for Form II is $\mathbf{N_1 = DDDD}$. Even a cursory comparison of Figures 9a and b indicates a great similarity between the two, which is not reflected so far in the unitary graph sets. Two of the binary graph sets for Form II, (*a*,*b*) and (*c*,*d*), will be $\mathbf{R_2^2(8)}$ (Fig. 9c), which does, of course, reflect the identity with the first level for Form I. These graph set assignments assist in demonstrating the great similarities between the two structures. These similarities will continue at higher levels. For instance, the obvious "chain-of-rings" feature that is described at the binary level in Form I would appear at the quaternary level in Form II. Because of the presence of twice as many hydrogen atoms in Form II as in Form I there will be twice as many possible levels for the former than for the latter, and the formal identities in graph set assignments would never appear at the same level. Nevertheless, a combination of systematic graph set assignment and careful visual inspection will reveal those similarities.

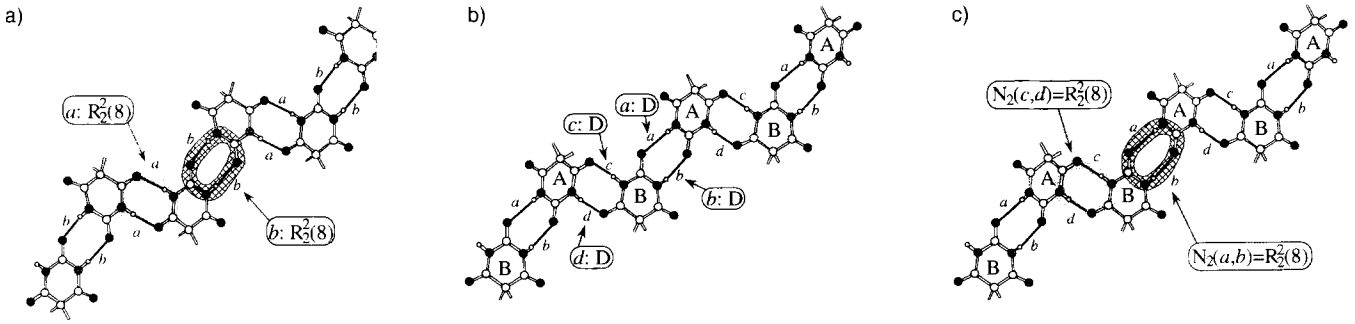


Fig. 9. Graph set assignments for the two polymorphs of amobarbital (**17**). Pendant groups have been omitted for clarity. a) Form I, first-level motifs. b) Form II, first-level motifs; A and B designate the two different molecules in the asymmetric unit. c) Form II, two of the binary graph sets.

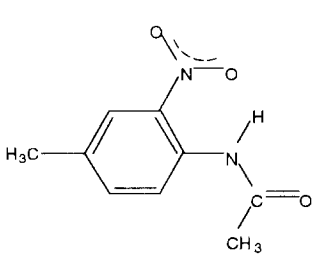
Another example is trimorphic 4-methyl-2-nitroacetanilide (**18**).[43-45] Polymorphs 1 and 2 each contain one molecule in the asymmetric unit; polymorph 3 has two. The molecule clearly has one hydrogen that can participate in a hydrogen bond. The most likely acceptor for that hydrogen is the carbonyl oxygen, although those on the nitro group are also somewhat basic in character. Unless the hydrogen participates in two different hydrogen bonds, the first-level graph set should be defined by one motif for Forms 1 and 2 and by two motifs for Form 3. The graph sets are given in Figure 10. Form 1 is distinguished by a **C(4)** motif from an N–H···O=C hydrogen bond, whereas the single molecule in the asymmetric unit in Form 2, and the two molecules in Form 3 all exhibit an **S(6)** motif resulting from an intramolecular N–H···O–N hydrogen bond.[46] In this case the unitary graph sets of the two molecules in the asymmetric unit of Form 3 are identical, and are the same as that for Form 2.



18

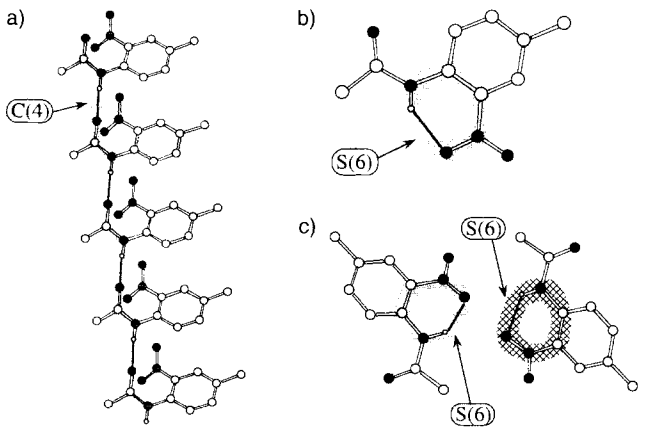


Fig. 10. First-level graph sets for the three polymorphs of 4-methyl-2-nitroacetanilide (**18**). Relevant parts of the crystal structure are shown for Form 1. The two molecules in the asymmetric unit of Form 3 are shown in their true crystallographic relationship to each other (see text). a) Form 1. b) Form 2. c) Form 3.

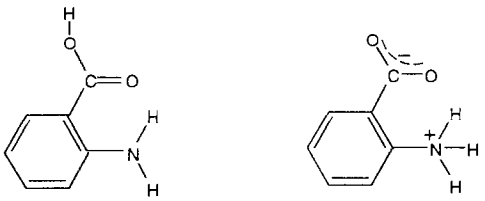
The situation differs in anthranilic acid (**19**), another trimorphic material whose structural chemistry has been widely studied.[47-54] This case illustrates a number of aspects in the choice of cutoff distance as criterion for defining the hydrogen-bond network. The molecule may exist in either the neutral **19a** or zwitterionic **19b** form. In either case each molecule has three



19a **19b**

hydrogen atoms that can participate in hydrogen bonds. For the neutral molecule the carbonyl oxygen atom is the obvious candidate as best hydrogen acceptor; the hydroxyl oxygen atom is considerably less suitable. For the zwitterionic case, both oxygen atoms are equally good acceptors.

These structures and their graph sets are presented in Figure 11. In Forms II and III the one molecule in the asymmetric unit is in the neutral form; in Form I there are two molecules per asymmetric unit, one neutral and one zwitterionic. In Form II (Fig. 11a), the hydrogen atom of the carboxyl group forms the now familiar ring structure $\mathbf{R_2^2(8)}$ about a crystallographic inversion center. One of the amino hydrogen atoms participates in an intramolecular motif **S(6)**. The closest acceptor to the second amino hydrogen is 2.38 Å. Hence by "normal" standards it might not be considered as participating in a hydrogen bond. However, that hydrogen atom clearly points in the direction of a carbonyl oxygen atom, and although the latter must then be counted as participating in three hydrogen bonds, we believe that the pattern exhibited here warrants including this in the hydrogen-bond network description as a chain, **C(6)**. Thus the first-level graph set is $\mathbf{N_1 = C(6)S(6)R_2^2(8)}$ (diagonal terms in Table 2).

In Form III (Fig. 11b) once again the carboxylic acid forms the $\mathbf{R_2^2(8)}$ ring about a crystallographic inversion center. One amino hydrogen atom is intramolecularly hydrogen-bonded to the carboxyl carbonyl oxygen atom to again yield **S(6)**, and the second amino hydrogen atom is hydrogen-bonded, this time to

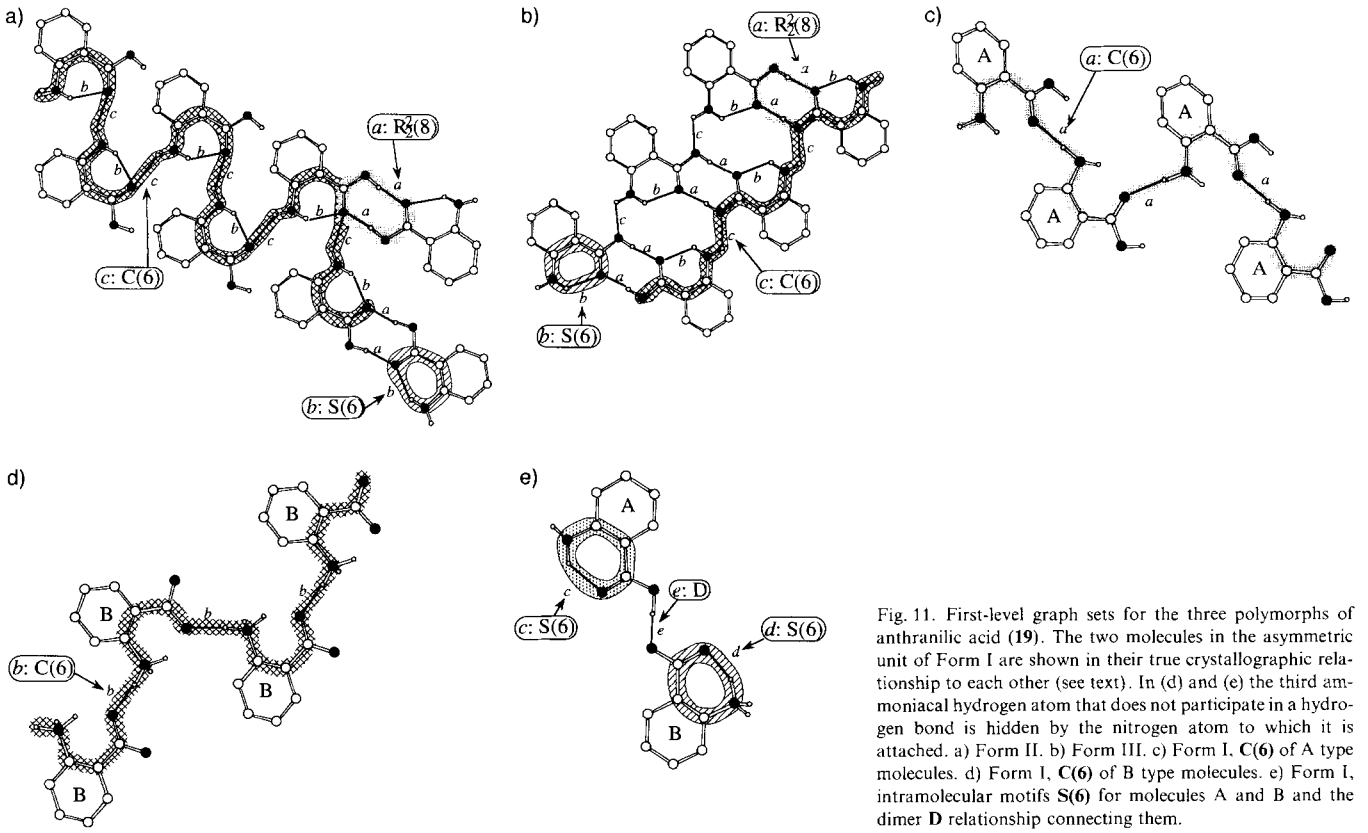


Fig. 11. First-level graph sets for the three polymorphs of anthranilic acid (**19**). The two molecules in the asymmetric unit of Form I are shown in their true crystallographic relationship to each other (see text). In (d) and (e) the third ammoniacal hydrogen atom that does not participate in a hydrogen bond is hidden by the nitrogen atom to which it is attached. a) Form II. b) Form III. c) Form I, **C(6)** of A type molecules. d) Form I, **C(6)** of B type molecules. e) Form I, intramolecular motifs **S(6)** for molecules A and B and the dimer **D** relationship connecting them.

the carboxy hydroxyl oxygen atom to form the chain **C(6)**. In the first level the graph sets are identical: $\mathbf{N_1}$ = **C(6)S(6)R_2^2(8)**.

The two molecules in the asymmetric unit of Form I can be distinguished chemically. Neutral molecule A forms a **C(6)** motif using an amino hydrogen and a carboxyl carbonyl oxygen atom (Fig. 11c); the zwitterion B has the same motif with an ammoniacal hydrogen and a carboxylate oxygen atom (Fig. 11d). As in the other two polymorphs, a second hydrogen atom on the nitrogen leads to an **S(6)** motif for each of the molecules in the asymmetric unit (Fig. 11e). Molecules A and B are linked together through an $O-H\cdots O_{carboxylate}$ bond, a **D** motif. The sixth hydrogen atom (that is, the remaining ammoniacal one on molecule B) is not involved in hydrogen bonding, at least for $O\cdots H$ distances less than 3 Å. Hence the first-level graph set for Form 1 is $\mathbf{N_1}$ = **C(6)C(6)S(6)S(6)D**.

To distinguish between Forms II and III we turn to the binary graph sets. In principle three hydrogen bonds can be combined pairwise in three different ways (that is, the off-diagonal terms in Table 2). The resulting $\mathbf{C_2^1(4)}$ for Form II is shown in Figure 12a, which reflects the fact that the same carbonyl oxygen atom participates in both hydrogen bonds in the chain. For

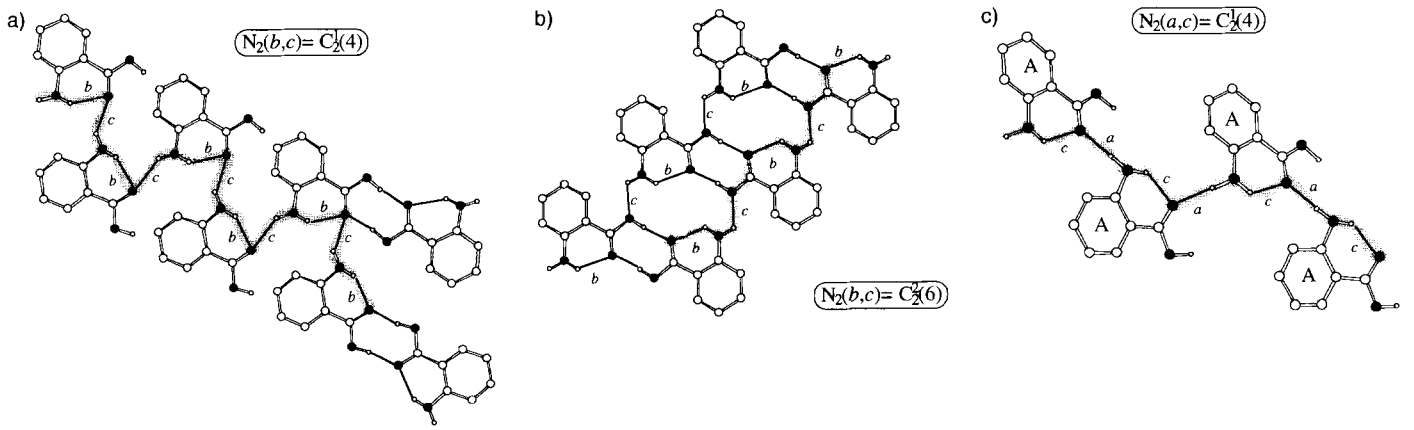

Fig. 12. Second-level graph set for anthranilic acid (**19**). General comments in the legend of Fig. 11 apply here, too. a) Form II. b) Form III. c) Form I, molecule A.

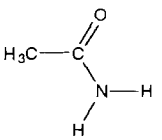
Form III (Fig. 12b) the chain $C_2^2(6)$ goes through both oxygen atoms of the carboxyl group; hence two acceptors and two more atoms in each "link". The binary graph set for Form I, $C_2^1(4)$ (Fig. 12c), is identical to that of Form II, but it is important to note that only A type molecules are present in this pattern.

This example demonstrates some more of the important aspects of graph set analysis of hydrogen-bonding networks: 1) the distance cutoff for the definition of a hydrogen bond must be flexible; 2) the crystal structures must be examined carefully when deciding on the presence or absence of hydrogen bonds in borderline cases; 3) higher level graph sets are needed to distinguish between those that are identical at the first level; 4) different molecules in the asymmetric unit must be clearly distinguished and treated separately; 5) a simple and straightforward analysis leads to readily identifiable similarities and differences among the polymorphs; 6) the resulting representation of the structure is readily comparable with that of other structures.

11. "Cyclic" Systems Generated by a Rotational Symmetry Element

The two forms of acetamide (**20**) demonstrate a number of principles in the assignment of graph sets, and also the simplification in understanding the similarities and differences between them. Acetamide crystallizes in an orthorhombic form with two molecules in the asymmetric unit[55] and a relatively unusual rhombohedral form with one molecule in the asymmetric unit.[56] The presence of two molecules (A and B) in the asymmetric unit in the orthorhombic form means that motifs must be defined for the hydrogen bonds formed by four hydrogen atoms. In the first-level graph set (Fig. 13a) A and B molecules each form a **C(4)** motif, and one A molecule as hydrogen donor is paired with a B molecule as hydrogen acceptor and vice versa in two **D** motifs. The first-level graph set is therefore N_1 = **C(4)C(4)DD**. The first-level graph set of the rhombohedral form (Fig. 13b) is generated by hydrogen bonds formed by the two amido hydrogen atoms, each leading to a **C(4)** motif, and N_1 = **C(4)C(4).**



20

The basic binary graph set for the orthorhombic structure is obtained by combining the two **D** motifs, leading to $R_2^2(8)$ (Fig. 13c). In the rhombohedral form, the hydrogen bonds from the two amido hydrogen atoms are arranged around the threefold axis, leading to the binary-level ring pattern $R_6^3(12)$ (Fig. 13d). The generation of an $R_6^3(12)$ ring by the threefold axis is analogous to the generation of an $R_2^2(8)$ ring by the center of symmetry.

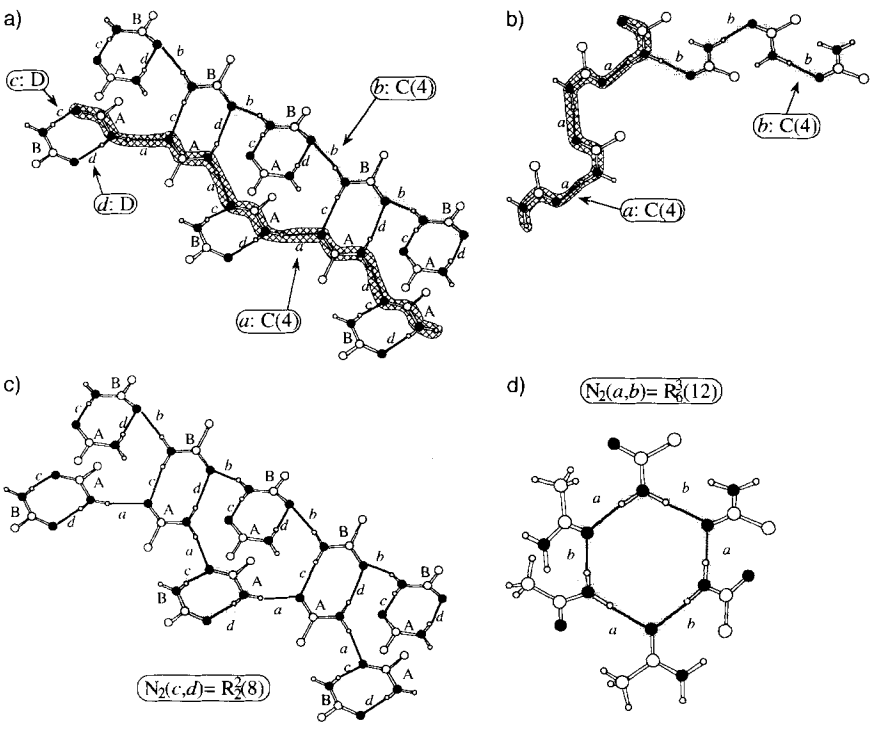


Fig. 13. Graph sets for the two polymorphs of acetamide (**20**). a) Orthorhombic form, first level; A and B designate the two different molecules in the asymmetric unit. b) Rhombohedral form, first level. c) Orthorhombic form, second level. d) Rhombohedral form, second level.

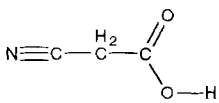
12. Does D Ever Contain More than Two Units? (and Other Curiosities)

All the examples of **D** (or "discrete") patterns we have encountered to this point have included only two molecules. There are however, many cases in which the finite **D** unit contains more than two molecules. Although we have not made any systematic analysis of the saccharides, this class of compounds appears to be particularly rich in patterns of this type.[57] One example of a **D** pattern composed of more than two molecules appears in dimorphic cyanoacetic acid (**21**), which is also of interest because both polymorphs have several molecules in the asymmetric unit: the α form[58] with three molecules per asymmetric unit (A, B, C) and the β form[59] with two (A, B). The presence of one hydrogen-bond donor and two hydrogen-bond acceptors on a single molecule provides various hydrogen-bonding possibilities.



21

The first-level graph set of the α form (Fig. 14a) is composed of a **C(6)** motif of A molecules linked by an O–H···N hydrogen bond; the same motif is observed for B molecules. In the C molecules, on the other hand, the carboxyl groups form the O–H···O hydrogen bond, leading to the common $R_2^2(8)$ motif. The first-level graph set is then N_1 = **C(6)C(6)**$R_2^2(8)$**.** The presence of both of these hydrogen bonds in the same structure suggests a similar basicity for the carboxyl carbonyl and the cyano nitrogen atoms. Additional evidence for this observation is provided in the hydrogen bonding of the β form (Fig. 14b). The A molecules

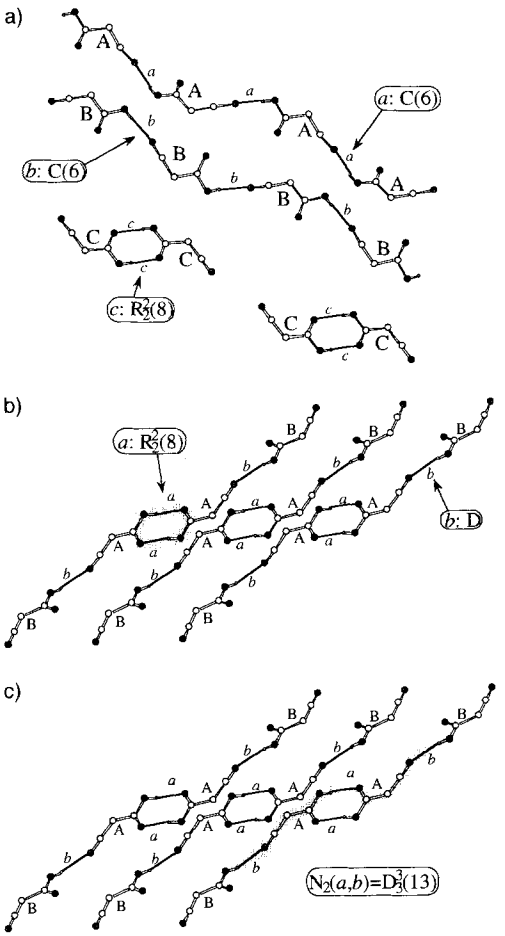


Fig. 14. Graph sets of the two polymorphs of cyanoacetic acid (**21**). a) α form, first level. b) β form, first level. c) β form, second level.

are in an $\mathbf{R_2^2(8)}$ motif typical of carboxylic acids, and the carboxylic hydrogen atom of a B molecule forms a hydrogen bond with the nitrogen atom of an A molecule. The first-level graph set is thus $\mathbf{N_1 = DR_2^2(8)}$.

The α form of **21** provides the first example we have presented here for which there are no graph sets beyond the first level, because no links between motifs exist. In the β form the combination of the two hydrogen bonds described by $\mathbf{N_1}$ leads to a finite pattern at the binary level (hence **D**, Fig. 14c) for which a suitable description is $\mathbf{D_3^3(13)}$.[60] In light of the discussion in Section 8, however, an extended notation would additionally make note of the fact that the $\mathbf{R_2^2(8)}$ ring is present in this pattern by augmenting the pattern descriptor: $\mathbf{D_3^3(13)[R_2^2(8)]}$.

The **D[R]** pattern is not as unusual as we thought at first. In a study of hydrogen-bonding patterns in nine derivatives of trimethoprim (**22**),[61] we have found 21 occurrences of patterns of this type at the binary level. In addition to four more occurrences of $\mathbf{D_3^3(13)[R_2^2(8)]}$, that study yielded multiple occurrences of each of the graph sets listed in Scheme 2.

$\mathbf{D_3^3(9)[R_2^2(8)]}$	$\mathbf{D_3^3(11)[R_2^2(16)]}$	$\mathbf{D_3^3(13)[R_2^2(16)]}$
$\mathbf{D_3^3(13)[R_2^2(18)]}$	$\mathbf{D_3^3(14)[R_2^2(18)]}$	$\mathbf{D_3^3(15)[R_2^2(4)]}$
$\mathbf{D_3^3(15)[R_2^2(8)]}$	$\mathbf{D_3^3(16)[R_2^2(18)]}$	$\mathbf{D_3^3(17)[R_2^2(16)]}$
$\mathbf{D_3^3(20)[R_2^2(18)]}$		

Scheme 2. Examples of **D[R]** patterns for nine derivatives of **22**.

It is clear that hydrogen-bonding patterns in centrosymmetric crystals with crystallographically distinct moieties, for example, ionic structures, solvated structures, and those with $Z' > 1$, will be replete with the **D[R]** binary graph sets.

13. Toward a Hydrogen-Bond Pattern Functionality

We have demonstrated that graph set analysis provides the tools for a systematic analysis of the patterns of hydrogen-bonded networks. Moreover, in principle, the methodology for this analysis is straightforward. The actual process of analysis is still not automated, although efforts in this direction are now under way. However, the potential of such automated analyses is already evident, and we present here some examples.

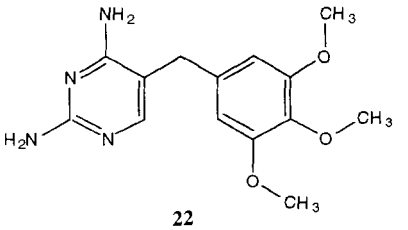
As a natural consequence of the historical development of chemistry over the last century, in particular organic chemistry, chemists have been taught to think in terms of chemical functional groups or chemical functionality. Virtually every basic organic chemistry text is organized according to this classification. The mention of aldehydes, ketones, amides, amines, or nitriles, for instance, evokes a whole series of mental associations such as group composition, group structure, methods of preparation, types of reactions, and physical properties. Similarly, associations elicited by the use of reaction mechanism notations (SN_1, E_2, etc.) convey a wealth of commonly understood and accepted information about a particular reaction mechanism, such as the types of molecules that can and cannot participate in a reaction type, the limiting conditions, expected products, stereochemistry, and many other characteristics and properties.

Graph set analysis of hydrogen-bonded systems potentially provides a means for analyzing a large number of structures and for seeking systematic correlations between the resultant patterns that demonstrate a *hydrogen bond pattern functionality*. This pattern functionality can be easily recognized in the concept of *isographic* relationships, as originally defined by Etter[2] (that is, chemically different functional groups having the same graph set are described as isographic).

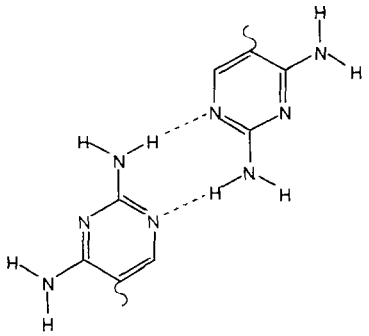
Because hydrogen bonding is perhaps the most dominant mechanism for molecular recognition, such a classification scheme will allow us to define the hydrogen-bonding patterns by which molecules "recognize" each other. Cataloguing the hydrogen-bond graph sets for a wide variety of hydrogen-bonding groups can illuminate hydrogen bond pattern functionality, which can cut across the traditional boundaries of chemical functionality. In the same manner that chemical functionality can be used to predict reaction products and stereochemistry, and to design molecules and synthetic routes, so hydrogen bond pattern functionality might then be employed to predict the three-dimensional structure of a compound or complex, or to design substances with a desired and predetermined structure.

Some of these functionalities have been revealed almost as a matter of course in the preceding discussion. For instance, the homodromic[116] $\mathbf{R_2^2(8)}$ pattern—in a variety of different forms—is pervasive, the best-known example probably being the hydrogen-bonded carboxylic acid dimer. It was the presence of the $\mathbf{R_2^2(8)}$ pattern that prompted our recognition of the C–H $\cdots$ O hydrogen bonding in **5** (Fig. 4). In addition to the many

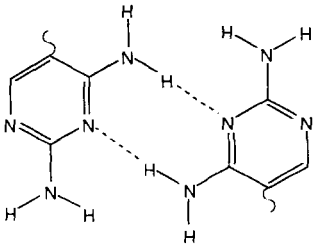
examples included here, the $\mathbf{R_2^2(8)}$ pattern also appears in Watson–Crick base pairing.[3] Our study[61] of trimethoprim (**22**) has yielded many more instances of this pattern that involve 2,4-diaminopyrimidine hydrogen bonding at the unitary level, arranged either as **23a** or **23b**.[62]



22

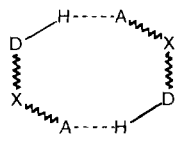


23a



23b

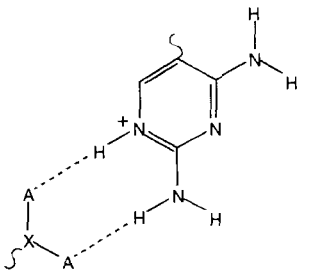
Our curiosity piqued by the frequent occurrences of homodromic $\mathbf{R_2^2(8)}$ just cited, we carried out a preliminary survey of the CSD for the centrosymmetric (or pseudocentrosymmetric) $\mathbf{R_2^2(8)}$ pattern **24**, in which D represents a donor, A represents an acceptor, X is any element, and the X–A and X–D bonds are of any order. This survey revealed more than 2800 occurrences of pattern **24** in more than 2400 structures including more than 80 different element combinations represented by D, X, and A. Though we have just begun to analyze the chemical functional groups represented, it is already clear that dozens of chemical functionalities are represented in this single hydrogen-bond pattern.



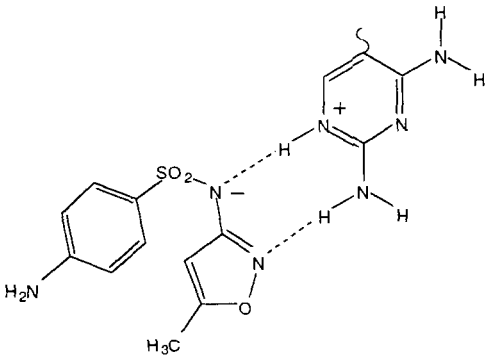
24

In trimethoprim salts, the 2,4-diaminopyrimidinium group is often involved in binary-level heterodromic[116] $\mathbf{R_2^2(8)}$ arrangements in which both donors are on the protonated trimethoprim and both acceptors are on the anion; these are shown schematically as **25a** and **25b**. In the three trimethoprim structures of type **25a**, the anions are all different; A–X–A represents, variously, O–C–O of benzoate or of acetate and O–S–O of ethylsulfonate. Yet another trimethoprim derivative, a cocrystal with barbital,[63] gives a more involved pattern (**26**) but still one based at the binary level on $\mathbf{R_2^2(8)}$.

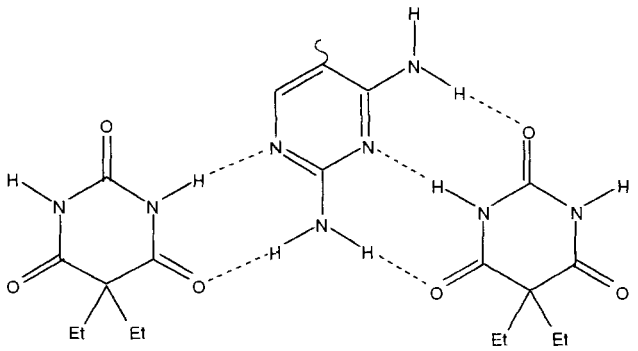
The potential power of the concept of hydrogen bond pattern functionality is further demonstrated by considering the pattern $\mathbf{R_4^2(8)}$ (**27**), which is a characteristic binary graph of primary amides (Fig. 15a). Because this pattern generally involves four molecules routine searches for the presence of individual hydrogen bonds would not easily reveal it. $\mathbf{R_4^2(8)}$ also appears when primary amides form cocrystals, for example in (*N*-acetyl-



25a

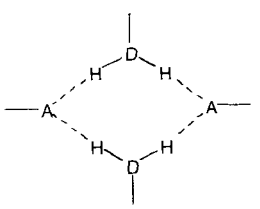


25b



26

acetamide)–(4-hydroxybenzamide) structure (Fig. 15b). We have also seen this in the chemically very different compound, iminodiacetic acid (**16**), in particular in the quaternary graph set of Form 2 (Fig. 15c; also see Appendix). We can go even farther afield chemically with, for example, the complex (1-methylcytosine)–(5-fluorouracil) (Fig. 15d),[64] and with a series of cocrystals between nitroanilines and triphenylphosphine oxide and its derivatives (Fig. 15e).[65] Our exposure to this pattern from these structures made it readily recognizable in α-$Me_4NOH \cdot 2H_2O$, in which D is $O(H_2O)$ and A is OH^-. The same pattern is observed when the hydrogen-bond acceptor is changed from oxygen (neutral or charged) to a halide (D is $O(H_2O)$, and A is X^- in $[Zn(en)_3]F_2 \cdot H_2O$, $Et_4NCl \cdot H_2O$, and $[(CH_2)_6N_4CH_3]Br \cdot H_2O$]).[66–69] In his thorough survey of interactions of water and ionic halides, Rowland has observed the same



27

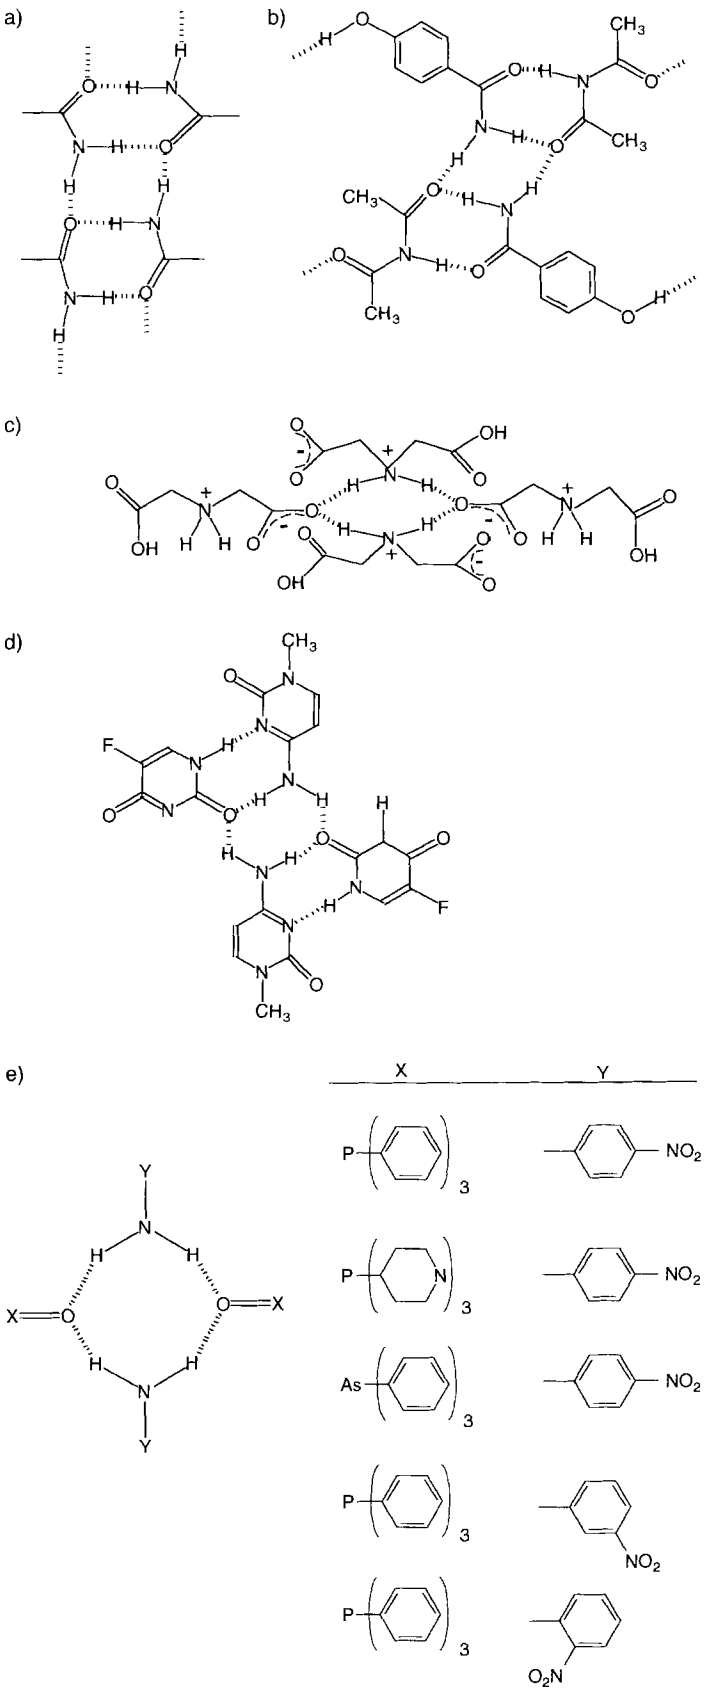


Fig. 15. The $\mathbf{R_4^2(8)}$ hydrogen bond pattern functionality in a variety of compounds. a) The second-level graph set of benzamide (benzene rings have been omitted); b) the fourth-level graph set of the cocrystal of (*N*-acetylacetamide)–(4-hydroxybenzamide); c) the quaternary graph set of iminodiacetic acid (**16**), polymorph 2; d) the cocrystal (1-methylcytosine)–(5-fluorouracil); e) the series of five cocrystals between nitroanilines and some R_3(P,As) oxides.

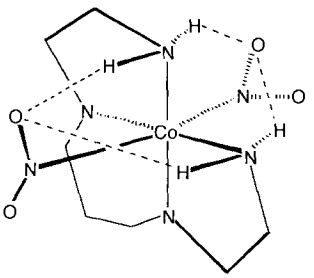
pattern (D is $O(H_2O)$, A is Cl^-).[70] Salts of trimethoprim[61] in which D is $N(NH_2)$, and A is $-O^-$ (in the benzoate)[71] or $^-O\text{-}SO_2CH_2CH_3$ (in the ethyl sulfonate[72]) further illustrate the pervasiveness of the $\mathbf{R_4^2(8)}$ pattern, even though the anions and the crystal structures are very different. The intramolecular manifestation of $\mathbf{R_4^2(8)}$, denoted as $\mathbf{S_4^2(8)}$, is also seen, for example, at the quaternary level in *trans*-dinitro(1,10-diamino-4,7-diazadecane)cobalt(III) bromide (**28**).[73] Even from this relatively small sampling of structures we can already see that $\mathbf{R_4^2(8)}$, together with its intramolecular analogue $\mathbf{S_4^2(8)}$, is a pattern that includes many traditionally classified chemical functionalities.



28

Until now, recognition of the patterns of hydrogen bonding has depended a great deal on serendipity: on which structures were being analyzed, usually for other reasons, and the chance possibility of human recognition of some unexpected, but persistent pattern. The steps we are taking to automate and to systematize the process of assigning graph sets will facilitate application of this methodology in a diagnostic as well as a descriptive mode. The incorporation of pattern-recognition software into structural search software should largely obviate the need for the arbitary human intervention and chemical intuition that was previously the order of the day. This will allow chemists more readily to recognize and correlate patterns that characterize hydrogen bond pattern functionality, which we believe holds great promise for analyzing and understanding the way molecules aggregate both in crystals and in solution.

14. Summary and Outlook

This paper reviews much of our current thinking on the use of graph sets in interpreting and understanding hydrogen-bonding patterns. We have demonstrated that it already allows rather complicated networks to be described in an efficient shorthand manner for the comparison and cataloguing of a large variety of structures. Moreover, we have found that the very process of working out the graph sets for any particular structure yields considerable insight into the nature of the hydrogen bonding in particular and the packing in general. We expect that as more specific software becomes available for generating the hydrogen-bond networks and their corresponding graph sets and presenting them in a convenient way, the method will become an even more useful tool for the diagnosis, analysis, understanding, and prediction of supramolecular aggregates dominated by hydrogen bonds.

There is still much to be done to develop this methodology for more complex systems. For instance, there are additional features of molecular and crystal structures in general, and hydrogen-bonded structures in particular, that one would like to include in the shorthand notation described here. These include branched chains, "ladder"-type chains, ribbons, sheets, double layers, and helices. Many of these can indeed be described using

the current nomenclature, but there appear to be distinguishing characteristics between similar structures, say sheets of various kinds, that are not immediately apparent from the graph set description as we have developed it to this point. Just as the work presented here represents progress due to our accumulated experience in working out problems encountered in the recent past, we expect that the solutions to many of the challenges mentioned above will come as we continue to expand the application of the method to increasingly knotty problems.

Appendix - A Reanalysis of Iminodiacetic Acid

At a number of points we have referred here to the graph set analysis of trimorphic iminodiacetic acid (**16**). This comprised one of our early attempts to use the methodology described here to define the differences and similarities among polymorphs characterized by rather complex hydrogen-bond networks.[5] In polymorph Form 2 of this system there are two molecules in the asymmetric unit. At the time we carried out this analysis we were not aware of the importance of considering crystallographically independent hydrogen atoms (and hydrogen bonds) separately as we have prescribed here. This was due in part to the fact that in this system the pairs of chemically equivalent hydrogen atoms on the two independent molecules have the same hydrogen bonding properties (as noted in ref. [5]). We now know that Form 2 must be analyzed in terms of six, rather than three, hydrogen atoms that participate in hydrogen bonds. That analysis and a comparison with the earlier results are presented here.

Each of the six independent hydrogen atoms participates in one hydrogen bond (Fig. 16). Hence the first-level graph set

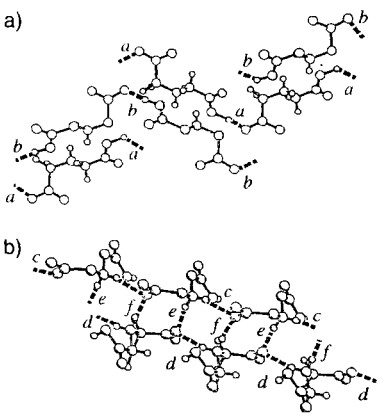


Fig. 16. Hydrogen-bond patterns of Form 2 of iminodiacetic acid (**16**), adapted from ref. [3]. The pattern is best understood from two separate drawings: a) the **C(8)** motifs for the two crystallographically independent carboxylic hydrogen atoms; b) the four motifs for the four amino hydrogen atoms. The six motifs combine to give the unitary network.

contains six motif descriptors, $\mathbf{N_1}$ = **DDC(5)C(5)C(8)C(8).** The identical hydrogen-bonding properties of the chemically equivalent hydrogen atoms on the two molecules are suggested here. At the binary level there are fifteen possible unique, pairwise combinations of the six hydrogen bonds. As indicated in Table 3, four of those are not defined, because all paths connecting the two hydrogen bonds traverse other hydrogen bonds. The chemical equivalency of the hydrogen bonds from the two molecules is reflected in the commutative identity of the graph sets of five pairs of combinations. The remaining binary graph set is $\mathbf{R_2^2(10)}$, which appeared at the unitary level in the earlier analysis that ignored the crystallographic nonequivalence of the two molecules.

Table 3. Unitary motifs (on-diagonal) and binary graph sets (off-diagonal) for iminodiacetic acid, Form 2.

Type of H-Bond Participating atomo	*a* H(1)A···O	*b* H(1)B···O	*c* H(2)A···O	*d* H(2)B···O	*e* H(3)A···O	*f* H(3)B···O
a H(1)A···O	**C(8)**					
b H(1)B···O	[a]	**C(8)**				
c H(2)A···O	$\mathbf{C_2^2(10)}$	[a]	**C(5)**			
d H(2)B···O	[a]	$\mathbf{C_2^2(10)}$	[a]	**C(5)**		
e H(3)A···O	$\mathbf{D_2^2(8)}$	$\mathbf{D_2^2(10)}$	$\mathbf{D_3^3(10)}$	$\mathbf{D_3^3(8)}$	**D**	
f H(3)B···O	$\mathbf{D_2^2(10)}$	$\mathbf{D_2^2(8)}$	$\mathbf{D_3^3(8)}$	$\mathbf{D_3^3(10)}$	$\mathbf{R_2^2(10)}$	**D**

[a] No link at binary level.

It is recalled that for Form 1 $\mathbf{N_1}$ = **C(5)C(8)$\mathbf{R_2^2}$(10)** and for Form 3 $\mathbf{N_1}$ = **C(5)C(5)C(8),** so the earlier analysis of Form 2 as **C(5)C(8)$\mathbf{R_2^2}$(10)** had indicated at the unitary level that Form 1 and Form 2 were equivalent. This is no longer true. Further, the graph set feature that did distinguish between them, $\mathbf{R_4^2(8)}$, now appears at the quaternary level for Form 2 (hydrogen bonds *c*, *e*, *d*, *f*), rather than at the binary level.

I do not presume to think that this treatise settles every doubt in the minds of those who understand it, but I maintain that it settles the greater part of their difficulties. No intelligent man will require and expect that on introducing any subject I shall completely exhaust it; or that on commencing the exposition of a figure, I shall explain all its parts. Such a course could not be followed by a teacher in a viva voce exposition, much less by an author in writing a book, without becoming a target for every foolish conceited person to discharge the arrows of folly at him.[11]

We were introduced to the realm of graph set analysis of hydrogen bonds by the late Margaret C. Etter, whose insight was inspirational and whose enthusiasm was contagious. We had the good fortune to discuss many of the aspects of this work with her prior to her death on June 10, 1992. In some ways this paper is but a very modest attempt to perpetuate a part of her considerable scientific legacy, achieved in a tragically shortened scientific career. While many of the ideas were thrashed out in our discussions and correspondence with her, the full responsibility for this work lies with us. We hope we are true to her spirit. J. B. and R. E. D. thank Dr. Olga Kennard for her hospitality at the Cambridge Crystallographic Data Center where early drafts of this paper were prepared and discussed. J. B. acknowledges a grant from the Israel Academy of Sciences (Jerusalem). Part of the work of L. S. was also supported by the US-Israel Binational Science Foundation (Jerusalem). The work in Austin (R. E. D., N-L. C.) was supported in part by the Robert A. Welch

Foundation (Grant F-233). John MacDonald of Professor Etter's group at the University of Minnesota provided advice, corrections, criticism, and encouragement throughout the development of our ideas and this work; we are indeed grateful to him. Dr. Geoffrey Khan of the Cambridge University Library assisted in locating the preambulary and postscript quotations from Maimonides.

[8] Note that a hydrogen bond from a cation to an anion, or from a molecule to a cocrystallized solvent molecule must be denoted in the first level as **D**. A discrete set that involves more than one hydrogen bond (binary or higher level) would necessarily have more than one donor and/or acceptor and more than two atoms in the pattern, so the subscript, superscript, and parenthetic notation of degree would all be required.
[9] This would correspond to a different *level* of the graph set assignment (see Section 3).

[11] The appearance of these more complex ring notations in some automatic fashion, for example, in a computerized graph set assignment procedure, would be an indication of such an extended ring pattern. The ring system shown here is a pervasive feature in crystal structures of the amino acids.

[25] The following discussion is based on the assumption of the availability of rather primitive software for calculating geometry and plotting crystal structures. Surprisingly, very few of the currently available molecular modeling software packages have convenient means for displaying and analyzing *crystal* structures, as opposed to *molecular* structures.
[26] One of the problems in developing the graph sets stems from the necessity in most cases to generate rather extended descriptions of the *crystal structure*, including the hydrogen bonding, rather than simply the *molecular* structure or the "view of the packing" that are sometimes automatically generated. The latter generally does not include sufficient numbers of molecules to portray all the specific intermolecular interactions. In many cases, a single view of the crystal structure, even in stereo, is difficult to interpret. Software for readily generating and rotating crystal structures with a number of unit cells considerably facilitates this task, and will make the examination of crystal structures and the assignment of their hydrogen-bonding graph sets a much more common practice.

[60] The original graph set specifications [3] prescribed the degree of a **D** motif as "the number of atoms in the entire length of the hydrogen-bonded set starting with the proton of the first hydrogen bond, proceeding along the shortest pathway, and ending with the acceptor atom in the last hydrogen bond of the set". Following those instructions would lead to degree 12 for the binary pattern shown in Fig. 14c; that description would mislead, as it does not encompass all the hydrogen bonds that link the discrete cluster. The guideline should be amended so that the degree **n** includes counting through all hydrogen bonds, that is, including all donors and acceptors. The same conclusion was reached by J. C. MacDonald (Ph.D. Dissertation, University of Minnesota, **1993**).

Exciting Results from the Field of Homogeneous Two-Phase Catalysis

Boy Cornils*

With the advent of two-phase catalysis, the last and in fact inherent disadvantage of homogeneous catalysis relative to its heterogeneous counterpart appears to have been swept away. This breakthrough has been achieved by arranging the process such that, at least when reaction is complete, the organometallic complex serving as a catalyst on one hand, and the reaction product (and residual starting material) on the other, are located in different phases, so a simple phase separation is sufficient for isolating the product from the catalyst (which may then be introduced immediately into another catalyst cycle).[1] The catalyst is situated in a mobile phase which, because it is confined within the reactor, also serves as an immobilization medium. Interestingly, quite atypically, the principle itself was implemented on a large (ca. 10^6 tonnes per annum) scale in industry in the Shell higher olefins process (SHOP), as well as the Ruhrchemie/Rhône–Poulenc oxo process even prior to the onset of comprehensive scientific investigation, initiated later by a number of academic research groups.[2] An indication of the significance of the process as far as the scientific world is concerned is the fact that the "standard ligand" for aqueous two-phase catalysis, triphenylphosphane trisulfonate (TPPTS), now appears in the Aldrich Catalogue of Fine Chemicals.

This elegant approach to catalyst separation has in turn led to intense preoccupation with possible laboratory and industrial applications of two-phase catalysis, as well as extension of the process into new areas. A series of important contributions to the literature has recently cast a rather bright spotlight in this direction.

Not surprisingly, the ideal form of the process is *aqueous* two-phase catalysis, in which the organometallic two-phase catalyst resides in a stationary aqueous solution in the reaction system. This is not only the most convenient arrangement on both the laboratory and industrial scale, but also the optimal modification with respect to cost and environmental considerations. Use of water as the second phase has its limitations, however, especially when the water solubility of the starting materials proves too low, preventing adequate transfer of organic substrate into the aqueous phase or at the phase boundary, and consequently reducing the reaction rate to such an extent that it becomes unacceptable. Cases like this can be dealt with by introducing a surfactant (or by using ligands that confer surfactant properties), but other alternatives include addition of a solvating agent that produces a quasi "mechanical" effect, or use perhaps of a cosolvent, two measures that presumably increase either the mutual solubility of the components or mobility across the phase boundaries. The effectiveness of additives of this type has been the subject of much controversy in the literature, and it depends heavily on such specific factors as the ligands and their purity, the nature and behavior of the substrate, the presence of miscibility gaps, and precise reaction conditions. From an engineering and economic standpoint it is also important to remember that any "foreign" additive will inevitably increase the difficulty and cost of purification, thereby mitigating the clear advantages associated with two-phase catalysis in its purest form.

Chaudhari et al.[3] were the first to suggest introducing "promoter ligands" soluble exclusively in the organic phase, thus altering the solubility of the complex *internally*. These authors were able to show through hydroformylation of the extremely water-insoluble 1-octene (equilibrium solubility in water at 298 K: 2.408×10^{-5} kmol m^{-3}; cf. propene, with a solubility of ca. 7×10^3 kmol m^{-3}) with $[HRh(CO)(TPPTS)_3]$ as catalyst that addition of triphenylphosphane to the 1-octene increases the reaction rate by a factor of 10–50. Ligand exchange during the course of the reaction leads to the formation of isolable mixed-ligand complexes of the type $[HRh(CO)(TPPTS)_{3-x}(TPP)_x]$ ($x = 0$–3). These display activities somewhat greater than is observed for catalysts modified only with TPPTS, though still inferior to the activity obtained by simple physical addition of TPP alone, a result that indicates the importance of as yet unexplained effects at the boundary surfaces of the two reaction phases (cf. Fig. 1).

With respect to the development of an industrial process for the hydroformylation of higher olefins (a challenge not yet met) it must of course be noted that the suggestion by Chaudhari et al. of adding a promoter ligand once again raises the problem of a "foreign substance," with the resulting need for a costly separation step. Nevertheless, these experiments do suggest that a search for ligands with carefully matched hydrophilic and hydrophobic characteristics may lead to a solution to the problem, provided the electronic characteristics of the oxo catalyst can be optimized simultaneously.

The foreign additive problem is avoided in an approach suggested by Jin, Fell, et al.,[4, 5] who have proposed a two-phase hydroformylation of higher olefins (up to 1-dodecene) based on replacing the ligands in $[HRh(CO)_4]$ with

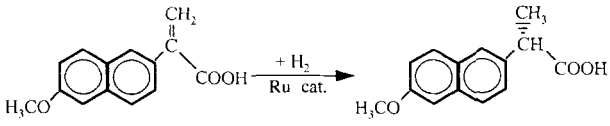
ethoxylated tris(*p*-hydroxyphenyl)phosphanes of the structure indicated in **1**.

The corresponding Chemical Abstracts entry fails to provide any indication of the real novelty involved in the Chinese work, but the German version of the paper makes it clear that this particular oxo catalyst takes advantage of a temperature-dependent "cloud point" associated with the phosphorus-bound poly(alkylene glycol ether) ligands. Thus, above the cloud point the ligand (and thus the complex catalyst) loses its hydration shell, just as in the case of other compounds of this type, causing the two-phase reaction mixture normally obtained when olefin is added to the catalyst solution to merge into a single phase, thereby initiating a rapid transformation that is no longer impeded by material-transport problems. Subsequent lowering of the temperature causes the hydration shell to be reversibly restored, inducing the complex catalyst solution once again to separate this time from the reaction product (the desired higher aldehydes) as an independent phase. Since the agent responsible for the merger and subsequent separation of the phases is the appropriately custom-designed ligand itself, there is no call for investing extra effort in the removal and recycling of a foreign additive, and this must therefore be regarded as a promising avenue for further exploration on a commercially realistic scale.

Results reported in two other papers by Bergbreiter et al.[6] and Wan and Davis[7] take advantage of similar effects. Bergbreiter et al. applied the designation "smart ligands" in describing certain phosphorus-bound poly(alkylene oxide) oligomers that together with rhodium precursors form complexes with the structure **2**, complexes that display both hydrogenation and oxo activity. Here again, an inverse temperature dependency of the complex catalyst's solubility leads at high temperature to single-phase behavior and correspondingly increased reaction rates.

$[Rh(Cl)\{Ph_2P(CH_2CH_2O)_nCH_2CH_2PPh_2\}_{1.5}]$ **2**

Wan and Davis combined the possibilities inherent in the supported liquid phase catalysis (SLPC) and supported aqueous phase catalysis (SAPC) techniques with a modified water-soluble (and thus hydrophilic) ruthenium catalyst dissolved in ethylene glycol in their demonstration of an enantioselective hydrogenation of 2-(6′-methoxy-2′-naphthyl)-acrylic acid (**3**). The reaction leads to (*S*)-naproxene (**4**) with *ee* values as high as 96%. Ligand modification was accomplished with tetrasulfonated BINAP [2,2′-bis(diphenylphosphino)-1,1′-binaphthyl], which in conjunction with ruthenium chloride generates the active hydrogenation complex $[Ru(BINAP\text{-}4\text{-}SO_3Na)(C_6H_6)Cl]Cl$ (Scheme 1).



3 **4**

Scheme 1. Homogeneous hydrogenation of the acrylic acid derivative **3** to give (*S*)-naproxene (**4**).

The substrate is dissolved in the hydrophobic solvent mixture cyclohexane/chloroform. This combination forms a second phase in the presence of the highly polar supported-catalyst solution, which is in turn immiscible with organic liquids. Wan and Davis attempted in this way to achieve a double "heterogenization" or "immobilization" of a complex catalyst that would otherwise be homogeneous: Deposition on the selected support CPG (controlled-pore glass) causes the catalyst to become *heterogeneous*, and the two-phase technique results in its further *immobilization*. The success reported in conjunction with this remarkable experiment is quite astounding. It will certainly be worth waiting a bit to see if the success proclaimed[8] can be confirmed with other substrates, and whether the indirect "proofs" cited for localized retention of the ruthenium catalyst in fact withstand closer scrutiny. Given all the previous experience with liquid–solid phase catalysts and their susceptibility to "leaching" this would seem somewhat unlikely.

Another approach to two-phase catalysis and the immobilization of homogeneous catalysts has been suggested by Horváth and Rábai at Exxon. Following preliminary conference reports[9] and an article in *Science*,[10] a corresponding European Patent application has now been published as well.[11] Horváth and Rábai discuss their new "fluorous biphase system" (or "fluorous multiphase system" as it is characterized in the broader set of claims constituting the patent application) also in the context of the hydroformylation reaction as an illustrative example. Thus, a modified oxo catalyst bearing partially fluorinated ligands bound via phosphorus, such as that illustrated in structure **5**, is introduced into certain perfluoro (or partially fluorinated) solvents with which ordinary organic substrates and solvents are immiscible.

$[HRh(CO)\{P[CH_2CH_2(CF_2)_5CF_3]_3\}_3]$ **5**

Proper "tailoring" of the ligands is said to be extraordinarily important. For example, the methylene group located between the phosphorus atom and the perfluoro end group in **5** is alleged

to be responsible for controlling the influence of the electron-withdrawing end groups ("fluorous ponytails"[12]) and fine-tuning their effect to the appropriate level. The two-phase mixture consisting of catalyst phase and olefin becomes homogeneous at higher temperature, causing the catalytic process itself to occur with a correspondingly high rate of reaction in a single phase. The system is subsequently cooled, permitting one to take advantage of a thermally defined miscibility gap in order to separate the reaction product from the catalyst, which then becomes available for immediate reuse.

The practical applicability on an industrial scale of this rather exotic two-phase system remains to be demonstrated. Doing so will require a clarification of such basic issues as activity, cost, catalyst lifetimes (and thus catalyst life and economic feasibility), toxicity, concerns regarding the ozone depletion potential (ODP) and greenhouse warming potential (GWP) values of the corresponding fluorinated compounds, etc. There is also the possibility of competitive extraction of fluorinated hydrocarbons by the aldehyde phase in the oxo reaction (leading to potential problems in subsequent hydrogenation to the plasticizer alcohols that are in fact the desired products).

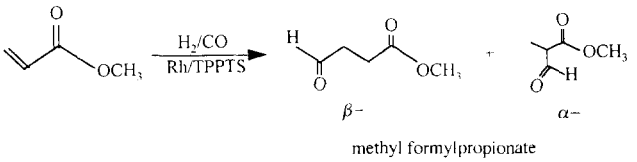
The professional world will also follow with some interest the future course of the patent application itself and the possibility that there may be appeals, since at least part of the basic idea underlying the Exxon process was described previously in a 1991 dissertation by M. Vogt entitled "Zur Anwendung perfluorierter Polyether bei der Immobilisierung homogener Katalysatoren" (On the Application of Perfluorinated Polyethers in the Immobilization of Homogeneous Catalysts).[13] Vogt was attempting to develop ligands based on hexafluoropropene oxide (HFPO) oligomers for subsequent complexation with appropriate cobalt or nickel precursors, and to exploit the latter for oligomerization or polymerization reactions. It did indeed prove possible in principle to bind HFPO oligomers to homogeneous transition-metal catalysts, conferring upon the modified complexes the solvophobic properties characteristic of this class of compounds. The result was a two-phase reaction procedure conducted in a perfluoropolyether medium facilitating separation of the product from the catalyst.

There now exists evidence for the extension of two-phase catalysis into a new area, suggesting interesting possibilities in an entirely different field of application. Gassner and Leitner[14] have described a hydrogenation of carbon dioxide to formic acid [Eq. (a)] that is accompanied by astonishingly high

$$H_{2(aq)} + CO_2(aq) = HCOOH_{(aq)} \qquad (a)$$

turnover values in aqueous solution in the presence of TPPTS-modified rhodium catalysts. This potentially relevant process will certainly generate considerable interest if it proves feasible to carry out a selective transformation of "technical grade" carbon dioxide (i.e., without prior purification) at "industrial concentrations" (meaning a CO_2 content in the range of a few percent). The high specificity associated with two-phase processes makes rapid progress in this regard appear likely as well.

The specificity of biphase catalyst systems (in conjunction with activities comparable to those anticipated with single-phase systems) has been illustrated in an elegant way by Mortreux et al.[15] In a regioselective hydroformylation of methyl acrylate to give α-formylpropionic acid with the catalyst $[HRh(CO)(TPPTS)_3]$, these authors observed an aldehyde yield comparable to that achieved with TPP, as well as an α/β product ratio of the expected order of magnitude and an even higher turnover frequency (TOF) (Scheme 2).



methyl formylpropionate

Scheme 2. Hydroformylation of methyl acrylate.

A $[HRh(CO)(TPPTS)_3]$ catalyst of the SAPC type on SiO_2 led to TOF values that were higher still, exceeding those obtainable with the homogeneous single-phase $[HRh(CO)(TPP)_3]$ system by a factor of 220 depending on experimental conditions. This is impressive evidence of the fact that it is dangerous to make predictions about reaction rates with biphasic catalyst systems, and that the nature of the associated substrate must always be taken into account.

New Dimensions in the Sol–Gel Process

Hans Reuter* and Maria-Theresia Brandherm

One of the characteristics of our modern, fast-moving age is certainly the fact that, as consumers, we take for granted many of the things which we find very practical and useful every day without thinking more deeply about them. It is therefore not surprising that the general public does not realize that chemical processes play a decisive role in the production of many products of everyday life, especially since the press more often than not only publishes articles on the negative aspects of chemistry. However, these critics also appreciate the advantages of a dazzle-free rear-view mirror in a car or of an office which is nicely flooded by daylight but at the same time the temperature inside is still normal because of windows with solar reflecting glass.

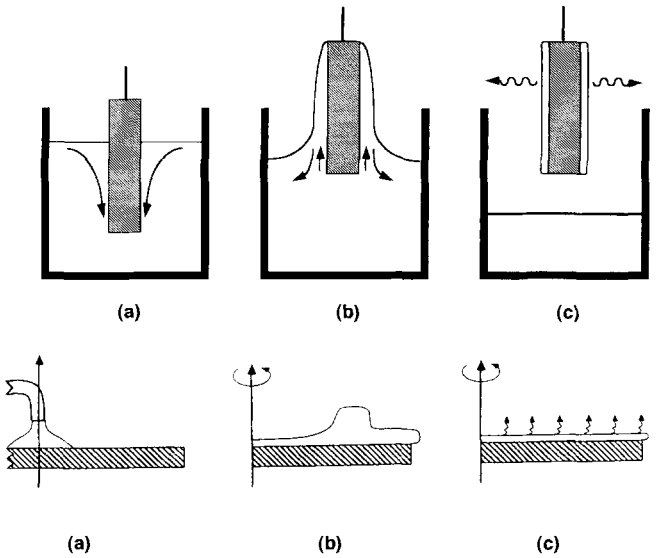
How many people are aware that these amenities are the products of high-tech chemistry[1] and are based on a procedure whose underlying principles were already known more than a hundred years ago[2] but whose technological application has achieved its breakthrough only in the last fifteen years.[3] The procedure referred to here is the so-called solution–sol–gel process (SSG process),[4] which involves the hydrolysis of metal alkoxides in solution, followed by formation of a sol and its subsequent gelation. The gel is then converted into the corresponding metal oxide after heat treatment.

The advantages[5] of the SSG process over other methods for the production of ceramics lies in the comparatively low temperatures required for the preparation of the oxide, the high purity of the starting materials, the ease with which the process can be undertaken, and the possibility, in principle, to carry out the shaping already at the solution or sol stage in the fluid phase.

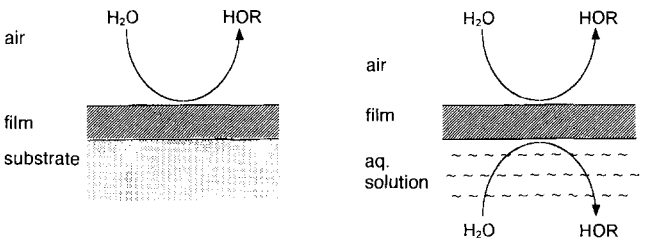
With regard to the shaping, the production of thin oxide films on various substrates in particular has proved successful in technical applications[6] such as those mentioned above. The spreading of the fluid phase takes place either after the so-called dip-coating or after the spin-coating procedure. The course of these procedures is outlined in the steps shown in Scheme 1. Layer thicknesses of between 50 and 100 nm can be achieved in this way, and thicker layers can be readily obtained by repeating the coating procedure several times.

The fact that the technological breakthrough of a procedure does not necessarily mean that the relevant research comes to a standstill is evident from two recent publications which have attracted a great deal of attention. In one of the articles I. Moriguchi et al.[7] describe their studies on—as the authors call it—the two-dimensional sol–gel process.

In the preparation of a film by the SSG process, the solution of the metal alkoxide is usually spread *onto the substrate* and is hydrolyzed only thereafter, whereas in the two-dimensional sol–gel process a solution of the metal alkoxide as a film is spread *onto an aqueous phase*. As shown in Scheme 2 the novelty of this procedure is that the hydrolysis can occur on both the lower and upper side of the film.



Scheme 1. Flow diagram of the principal course of the dip-coating (top) and spin-coating procedure (bottom) for the spreading of metal alkoxide solutions or sols according to the SSG process. In the dip-coating procedure the substrate initially dipped in the solution of the precursor (a), on removal (b) the solution flows off from the substrate under the influence of gravity until only a thin film remains; in the final step (c) the solvent is evaporated and the metal alkoxide is hydrolyzed to the gel. In the spin-coating procedure the solution of the precursor is spread in the middle of the substrate (a) and subsequently (b) distributed evenly as a thin film by rapid rotation of the substrate; in the final step (c) the solvent is evaporated and the alkoxide is hydrolyzed.



Scheme 2. The direction of attack of the hydrolysis in the preparation of films according to traditional (left) and two-dimensional solution sol–gel process (right).

In the present case a solution of tetrabutoxytitanium in chloroform was spread on a surface of water, and the formation and morphology of the condensate film was studied with fluorescence spectroscopy. It was shown that initially a lot of floating islands made up of solid material were formed on the water surface. These islands later gather together and eventually form a featureless, homogeneous layer. Since the observed apparent molecular area is significantly smaller than that of the precursor, the authors conclude that this condensate film is not the molecular monolayer of the precursor.

In the traditional solution–sol–gel process it is known that acetic acid and acetylacetonate suppress the hydrolysis and condensation of the metal alkoxides in solution because they form chelate complexes with the metal atom.[8] In the present case such a suppression effect is also encountered in the 2D sol–gel process since an increase of the apparent molecular area

is observed on addition of these two reagents to the aqueous phase. The condensate films obtained in this way are considerably more stable.

For subsequent application it is important that the resulting nanometer-thick TiO_2 films can be transferred onto substrates such as CaF_2 or quartz. This was achieved by using the Langmuir–Blodgett technique, in which the chelate-stabilized films can be transferred considerably more easily and safer than the films prepared on pure water. According to the authors the original homogeneous state of the condensate film is preserved. The film deposited on CaF_2, also shows C–H and Ti-O-C vibrations in the IR spectrum. However, the C and H contents determined from the elemental analysis of the vacuum-dried film are considerably lower than values expected for the precursor.

These results were interpreted as indicating that the precursor hydrolyzes on the water surface, condenses, and then undergoes two-dimensional aggregation; this process results in some residual butoxy groups. The authors further speculate that the hydrophobicity of the butoxy groups and probably also their moderate reactivity are indispensible in the formation of such floating condensate films.

The films transferrred onto the substrates can be densified by conventional methods by heat treatment. Thermogravimetric measurements on the powders scraped off the surface showed that the conversion of the gel to crystalline TiO_2, that is dehydration and elimination of the remaining butoxy groups, is completed at 723 K. The IR bands of the organic ligands already disappear after heat treatment at 573 K for 30 min. X-ray diffraction (XRD) and scanning electron microscopy (SEM) proved ineffective in characterizing the films. However, the thickness of the TiO_2 layer was determined to be 4.3 nm by depth-profiling X-ray photoelectron spectroscopy (XPS). In the UV spectrum an absorption edge was found at 337 nm, which is significantly blue-shifted compared to quantum-size TiO_2.[9]

The second article by Nakamura and Matsui[10] takes us from two-dimensional layers to one-dimensional *tubes*. The preparation of *fibers* by the SSG process has already been possible for several years;[11] however, the preparation of hollow fibers is described here for the first time. The tubes were formed in a process in which silicon tetraethoxide was hydrolyzed in a mixture of ethanol, ammonia, water, and tartaric acid. The reaction products were washed on a net with fine pores with a large amount of water to remove impurities. Interestingly, most of the tubes had a square cross section with an outer diameter of 0.8–1.0 μm and were 200–300 μm in length; the inner diameter and wall thickness lie in the range 0.02–0.8 and 0.15–0.3 μm, respectively. Only a few tubes had an oval cross section with a circular inner channel. Furthermore, the authors established that the diameter decreased with falling process temperature. Thus, the finest tube had an outer diameter of 0.05–0.1μm.

The authors also report on a remarkable substrate selectivity for the formation of the nanotubes. Only the racemate of the tartaric acid and a mixture of L- and D-tartaric acid yield this product; the L, D, and *meso* isomer alone were ineffective. According to their calculations the authors attribute this to a system of hydrogen bonds, whose relative position to one another is considered to be favorable in the first case and unfavorable in the second. However, the reaction mechanism for the formation is still unkown.

These gel tubes could be converted to glass tubes at 800–1000 °C in air. In the IR spectrum the band of the Si–OH vibration diminishes, whereas the Si–O band adopted the shape and position found for that band in the correspondingly treated SiO_2 glass. The SiO_2 tubes thus obtained proved to be X-ray amorphous.

The two publications show that the solution–sol–gel process still has a few surprises in store even after more than a hundred years of research and development, which only at first sight appear to be alchemistic since we know too little about the "background" chemistry. It remains rewarding and exciting to follow further developments in this highly topical field of research,[12] not least because of the numerous overlaps with other areas of chemistry.

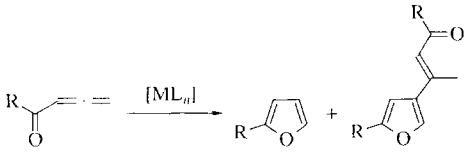
Transition Metal Catalyzed Dimerization of Allenyl Ketones**

A. Stephen K. Hashmi*

Furans are present in many natural products and important pharmaceuticals as well as in flavorings and fragrances.[1] Furthermore, they are very popular synthetic building blocks.[2] Therefore a great deal of effort has been devoted to the development of new synthetic methods for the formation of furans.[1-3]

A milestone in the area of transition metal catalyzed syntheses of furans was the discovery by Marshall[4] that the readily available allenyl ketones **1**[5] can be isomerized selectively to furans by using Rh^I or Ag^I catalysts. Several years prior to this discovery, similar rearrangements had been observed by Jullien et al.[6] and Huntsman et al.[7] when allenyl ketones were subjected to flash vacuum thermolysis.

We have found that the terminal allenyl ketones **1** are not only converted into the expected isomerization products **2**, but also into the dimers **3**; the product ratio **2**:**3** is strongly dependent on



1 **2** **3**

a, R = Me
b, R = Pr
c, R = $CH(CH_2)_4$
d, R = *t*Bu
e, R = Ph
f, R = CH_2Cl
g, R = 2-IC_6H_4
h, R = 3,4-$(MeO)_2C_6H_3$
i, R = OEt

the catalyst used. The most efficient conversion of **1a** into **3a** (Table 1) was achieved by using tetrakis(2,2,2-trifluoroethoxycarbonyl)palladacyclopentadiene ($TCPC^{TFE}$), which was introduced by Trost.[8] When $AgNO_3$, $[Rh_2(OAc)_4]$, or $[RuCl_2(CO)_3]_2$ were employed, **2a** was formed exclusively, whereas the use of Cu^ICl led to the predominant formation of **2a** along with traces of **3a** (see Table 3). The structure of **3a** was elucidated by HETCOR, 1D-INADEQUATE, and NOE NMR experiments.[9] The C,C coupling constants and NOE data are listed in Scheme 1.

The selectivity of the dimerization to **3a** is remarkable. Since the transformation proceeds readily at room temperature, Diels-Alder reactions between the allenyl ketone and a furyl group in one of the products do not occur.[10] Furthermore,

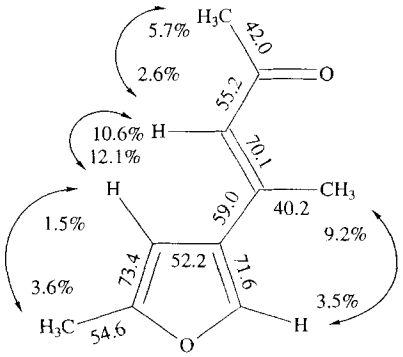


Scheme 1. C,C coupling constants and NOE data for **3a**.

[2 + 2] cycloadducts are not formed as seen in transition metal catalyzed dimerizations of unfunctionalized allenes.[11] The trisubstituted double bond in **3a** is formed selectively with (*E*)-configuration. Moreover, when Pd^{II} catalysts were used with a turnover number (TON) of >1100, the substrate/catalyst ratios (0.05–0.1 mol%) were much higher than with Ag^I (TON = 5.6)[4c, 12] or Rh^I (TON = 8.5)[4a, 12] catalysts. As a result, it was possible to convert multigram quantities of **1a** with the Pd catalyst. The catalytic activity of Pd is inhibited by phosphane ligands.

Similar results were obtained with the allenyl ketones **1b–e** (Table 2). On increasing the bulkiness of the substituent R, the

Table 2. $TCPC^{TFE}$-catalyzed reactions of **1b–e** in $[D_6]$acetone at room temperature.

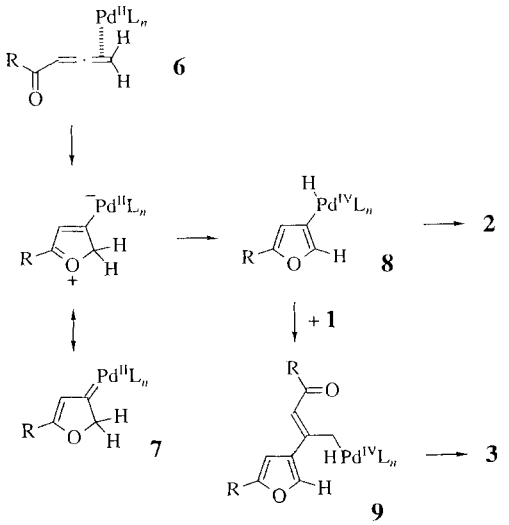
Allenyl ketone	**2**:**3** [a]	Yield of **3** [%] [b]
1b	1.0:4.7	76
1c	1.0:3.0	67
1d	1.0:1.0	33
1e	1.0:6.1	81
1f	1.0:2.2	60
1g	- [c]	91

[a] Determined by ^1H NMR spectroscopy. [b] Due to its volatility, **2** cannot be separated from the solvent. [c] Not determined.

amount of monomer **2** increases and the yield of **3** decreases. Even compounds such as α-chloroketone **1f** could be cyclized, which is not feasible with Ag catalysts. The reaction of aryl iodide **1g** is an example that exhibits interesting chemoselectivity. We did not observe any products derived from either an oxidative addition followed by an inter- or intramolecular carbometalation of the allene[13] or a deactivation of the catalyst. Therefore it should be possible to perform interesting tandem reactions. Only one additional substituent at the allene, as in **4**, is sufficient to suppress the dimerization completely. Thus, **5** is formed in quantitative yield (NMR spectroscopy) using only 0.1 mol% of the Pd catalyst. Ester **1i** did not react with the Pd catalyst at room temperature; at higher temperatures it polymerized.

4 **5**

The mechanism of the formation of **3** is probably related to the Marshall cycloisomerization of **1** to **2**.[4d] The coordination of the Pd atom by the allene (complex **6**) is presumably followed by an intramolecular oxypalladation of the terminal double bond. In this way the γ-donor substituted vinyl carbene complex **7** would form as an intermediate. In cross-over experiments



between **1a**, which is monodeuterated at the terminal methylene group of the allene, and nondeuterated **1h** (and between monodeuterated **1h** and nondeuterated **1a**), a statistical mixture was formed that included the monomers **2a** and **2h**, the dimers **3a** and **3h**, as well as both mixed dimers. A deuterium distribution indicating H/D exchange was not obtained; however, we observed a deuterium isotope effect of $k_H/k_D = 3.1$ (22 °C). On the other hand, an H/D exchange with a protic solvent as described by Marshall was observed, but only to a minor extent. The cyclization of **1a** in acetone in the presence of 12 equivalents of D_2O gave rise to only 36% of the product monodeuterated at the desired position and 64% of the nondeuterated product. These findings are consistent with a β-H-elimination, which would lead to the furyl-hydrido species **8**.[14] Because of the low concentration of **8**, only the slow H/D exchange with D_2O, which is present in high concentration, can be observed and not, however, the exchange between deuterated and nondeuterated **8**.

Compound **8** can either form product **2** by a reductive elimination or can be converted to **9** by a carbopalladation of an additional molecule of **1** followed by a reductive elimination to form dimer **3**. The electrophilic character of the Pd^{IV} atom in **8** appears to be crucial for the high selectivity of the carbopalladation at the electron-rich, terminal double bond of the cumulene.[15] The selective formation of the (*E*)-configurated double bond can be explained by an addition of the Pd atom to the side of the double bond pointing away from the acyl substituent.

In conclusion, the cyclization of allenyl ketones to furans is not limited to the use of Rh^I and Ag^I compounds as catalysts, but can also be carried out successfully with Pd compounds, which catalyze these reactions much more efficiently. Furthermore, a novel reaction pathway has been established in the transformation of terminal allenyl ketones with Pd^{II} catalysts, namely the cycloisomerization/dimerization to **3**. Product **3** was formed under mild conditions and in preparatively useful amounts. Since allenyl ketones are readily available, the formation of **3** with its dendralene-like double bond system[16] presents a simple way to starting materials for "diene-transmissive" Diels–Alder reactions.[17]

Experimental Procedure

Typical synthesis: TCPC^{TFE} (6.6 mg, 10 μmol) was added to **1a** (1.64 g, 20.0 mmol) in absolute acetone (20 mL) under an inert gas atmosphere. After complete conversion (NMR monitoring), the solvent was removed in vacuo and the residue was purified by chromatography on silica gel with hexanes/ethyl acetate (6/1) (**3a**: 1.24 g, 76%).

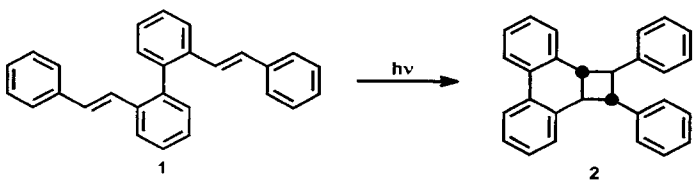
A Cycloaddition–Cyclodehydrogenation Route from Stilbenoids to Extended Aromatic Hydrocarbons

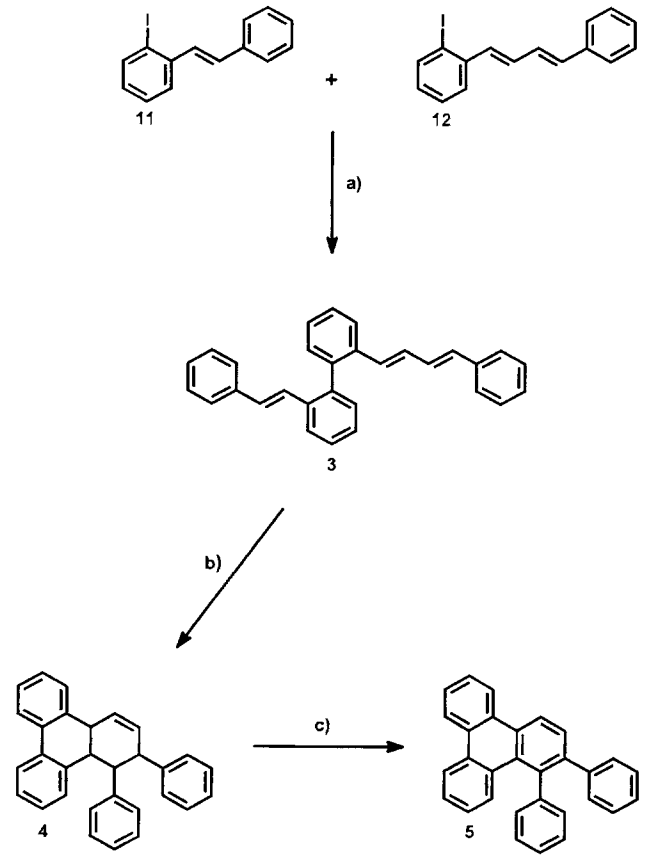
Markus Müller, Heike Mauermann-Düll, Manfred Wagner, Volker Enkelmann, and Klaus Müllen*

Dedicated to Professor Wolfram Grimme on the occasion of his 65th birthday

The photochemical conversion of 2,2′-distyrylbiphenyl (**1**) both in solution[1] and as a film[2] yields cyclobutane **2** by a stereoselective [2 + 2] cycloaddition. We were interested in preparing a thermally active stilbene derivative analogous to **1** not only for synthetic and mechanistic reasons but also for structuring thin layers. An intramolecular [4 + 2] cycloaddition would require the previously unknown all-*trans*-2(4-phenylbuta-1,3-dienyl)-2′-styrylbiphenyl (**3**). We describe here the synthesis of **3**, its thermal cyclization under mild conditions to give cyclohexene **4**, and the subsequent dehydrogenation affording triphenylene **5** (Scheme 1).



1 **2**



Scheme 1. a) 1. **11**, BuLi, THF, −78 °C; 2. $ZnBr_2$, THF, −78 °C; 3. **12**, tris(dibenzylidenacetone)dipalladium(0) [$Pd_2(dba)_3$], THF, −78 → 25 °C; b) toluene, 100 °C; c) DDQ, benzene, 78 °C.

The general importance of the synthetic scheme described here leading to extended polyaryl compounds is demonstrated by the application of the strategy to a homologue of **3**. The extended phenylenevinylene compound **6** undergoes a double Diels–Alder cycloaddition affording **7**, which in turn can be dehydrogenated to furnish hydrocarbon **8** (Scheme 2).

We show that the most important consequence of the cycloaddition is that the products, triphenylenes **5** and **8**, undergo multiple electron transfer induced cyclodehydrogenations to give extended planar graphitic sections[3] such as **9** and **10** in high yields.

Compound **3** was synthesized from *trans*-2-iodostilbene (**11**) and *trans,trans*-2′-iodo-1,4-diphenylbuta-1,3-diene (**12**) by aryl–aryl coupling via zincates according to the method of Knochel et al.[4] (75% yield). The coupling partners **11** and **12** were constructed readily by Wittig reaction of 2-iodobenzyltriphenylphosphonium chloride with benzaldehyde and *trans*-cinnamaldehyde, respectively. The mixtures of configurational isomers that resulted were converted into the thermodynamically more stable *trans* isomers by heating in toluene at 110 °C with

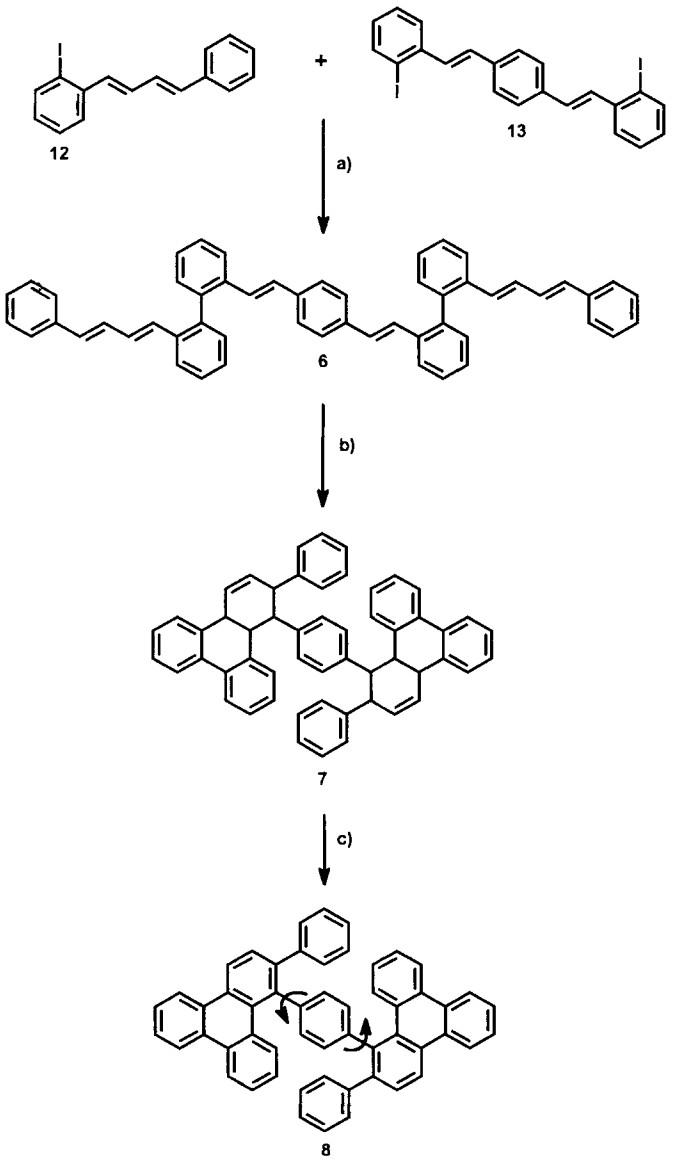

Scheme 2. a) 1. **12**, BuLi, THF, −78 °C; 2. $ZnBr_2$, THF, −78 °C; 3. **13**, $[Pd_2(dba)_3]$, THF, −78 → 25 °C; b) toluene, 100 °C; c) DDQ, 1,1,2,2-tetrachloroethane, 140 °C.

catalytic amounts of iodine in the absence of light. Photocyclization products did not form.

When compound **3**, which contains both a dienophile and a diene, was heated in toluene at 100 °C, an intramolecular Diels–Alder reaction resulted in the quantative formation of 1,2,4a,12b-tetrahydro-1,2-diphenyltriphenylene (**4**) (as a mixture of stereoisomers, see below). When the intermolecular [4 + 2] cyclization of *trans,trans*-1,4-diphenylbuta-1,3-diene and *trans*-stilbene was attempted under the same conditions, no conversion was observed even after reaction times of over 100 h. The cyclohexene ring in compound **4** was dehydrogenated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) with aromatization to give 1,2-diphenyltriphenylene (**5**) (75% yield). Compound **5** was previously observed as a side product (9% isolated yield) in investigations of the photochemistry of the Diels–Alder product formed from tetraphenylfuran and maleic anhydride.[5]

In the synthesis of **6** the aryl–aryl couplings of two equivalents of the 2′-iodophenylbutadiene component **12** with the central *trans,trans*-1,4-di(2′-iodostyryl)benzene (**13**) also proceed via an activated zinc species; in this case compound **12** undergoes iodine–zinc exchange. The relatively low yield of **6** (32%) in this biscoupling can be explained by the low reaction temperature, which is necessary to avoid premature intramolecular Diels–Alder reactions.

The *para*-distyryl-substituted benzene **13**, the "double" dienophile component in the subsequent thermally induced [4 + 2] cycloaddition, was synthesized by the double Wittig reaction of 2-iodobenzyltriphenylphosphonium chloride and terephthaldialdehyde and, like the Wittig products **11** and **12**, was transformed into the thermodynamically stable all-*trans* isomer. In analogy to the reaction of **3**, heating compound **6** in toluene at 100 °C provided **7** in 94% yield. Because several chiral centers are formed in this reaction, **7** was obtained as a mixture of isomers, which were not separated. The crude mixture of **7** was dehydrogenated by treatment with DDQ, in analogy to the synthesis of **5**, affording 1,4-di(2-phenyltriphenylen-1-yl)benzene (**8**) in 98% yield. Important physical and spectroscopic data for compounds **3**–**10** are listed in Table 1.

Table 1. Physical and spectroscopic data for **3**–**10**.

3: ^{1}H NMR (500 MHz, $CDCl_3$, 30 °C): δ = 7.82, 7.76 (each d, ^3J(H,H) = 9.3 and 9.8 Hz, each 1H; H6, H6′, biphenyl), 7.45–7.36 (m, 2H; H5, H5′, biphenyl), 7.34–7.18 (m, 14H), 7.02, 6.83 (each d, ^3J(H,H) = 16.2 Hz, each 1H; AB, olef. Fig. 1. X-ray structure of **3**.

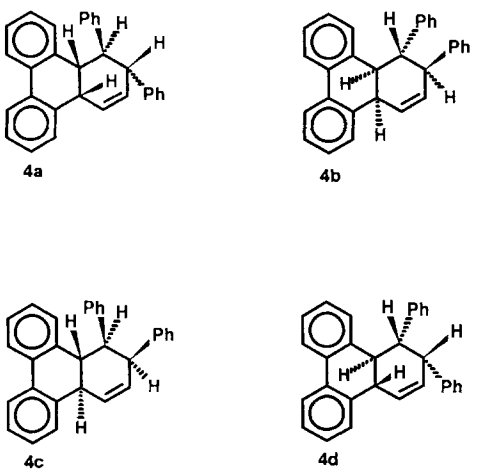
The X-ray crystal structure of **3** (Fig. 1)[6] reveals that the biphenyl unit is twisted by 69°. The corresponding angle in analogue **1** is considerably greater (115°), such that the two styryl groups in **1** have an *anti* arrangement.[2]

One of the requirements of the intramolecular Diels–Alder reaction of **3** is free rotation about the central σ bond of the biphenyl unit, since the double bonds approach each other only when the interplanar angle within the biphenyl unit is sufficiently small. Another requirement of the reaction is the conversion of the transoid conformation of the *trans,trans*-butadiene unit found in the crystal into a cisoid arrangement. In the concerted Diels–Alder cycloaddition of **3** two diastereomeric pairs of enantiomers **4a/b** and **4c/d** are possible products.[7]



NMR spectroscopic analyses (NOE experiments, ^{1}H,^{1}H-COSY, ^{13}C,^{1}H-COSY measurements) showed that the **4c/d** pair of enantiomers is the main product of the [4 + 2] cyclization (**4a/b**:**4c/d** = 1:5). The relative configuration of **4c** was confirmed by the X-ray structure determined for a single crystal obtained from the reaction mixture (Fig. 2).[6]

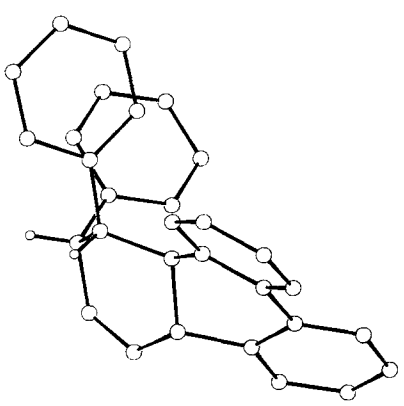


Fig. 2. X-ray structure of **4c**.

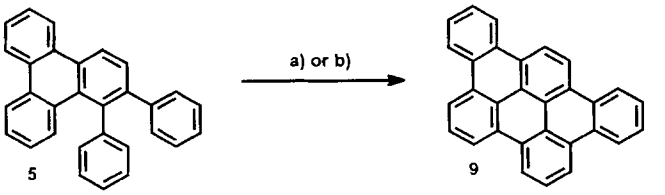
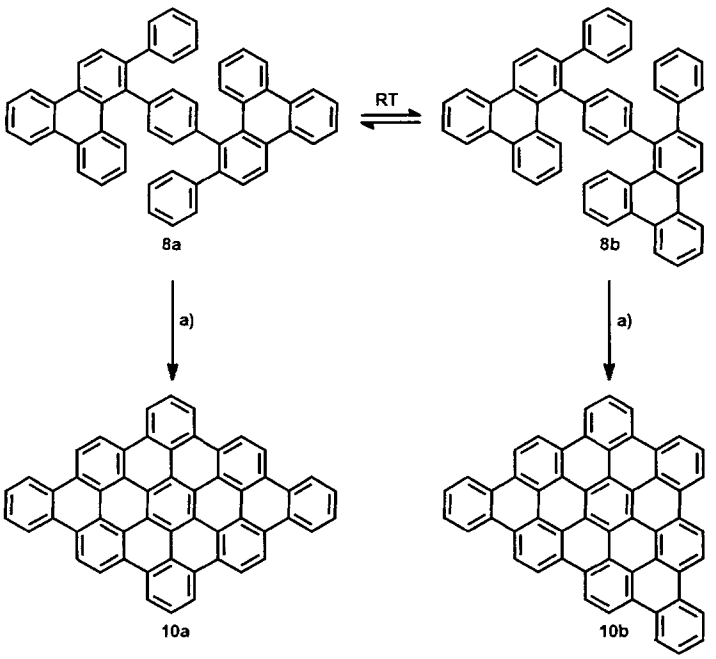
The synthesis of graphitic sections described here relies on the cyclodehydrogenation of **5** giving tribenzo[*b,n,pqr*]perylene (**9**)[8] (Scheme 3). This conversion was possible by reduction of a solution of **5** in 1,2-dimethoxyethane at 5 °C with a potassium mirror for several days and subsequent



Scheme 3. a) 1. K, 1,2-dimethoxyethane, 5 °C; 2. I_2, toluene; b) $AlCl_3$, $CuCl_2$, CS_2, room temperature.

oxidation with iodine in toluene (yield 47%, after twofold recrystallization from nitrobenzene). Alternatively, oxidation of **5** with copper dichloride and aluminum trichloride in carbon disulfide provided **9** (room temperature, 2 d, 77% yield). The latter procedure can be used for larger scale preparation of **9**.

The oxidative cyclodehydrogenation of **8** was conducted in analogy to the cyclization of triphenylene **5** (99% yield; Scheme 4). The loss of 12 hydrogen atoms, proved by FD- and



Scheme 4. a) $AlCl_3$, $CuCl_2$, CS_2, room temperature.

LD-TOF mass spectrometry, indicates formation of six new aryl–aryl bonds and complete planarization of the polybenzenoid arene **8**. Since the cyclodehydrogenated, polycyclic arene **10** is extremely insoluble in all standard solvents, more extensive characterization was not possible. Thus we have not yet determined which of the two isomers, **10a** or **10b**, results. The formation of **10a** or **10b** should depend on whether the extremely twisted polyaryl compound **8** assumes the planar conformation **8a** or **8b** in the oxidative cyclodehydrogenation. We will describe an independent synthesis of **10a** shortly as conclusive structural proof.

The cycloaddition–cyclodehydrogenation sequence described here offers a new, surprisingly simple route to extended aromatic hydrocarbons. The application of the Diels–Alder cyclization developed with biphenyl **3** to its homologue **6** suggests that poly(phenylenevinylene) compounds can be employed that contain suitable ene and diene units; such compounds could undergo multiple Diels–Alder reactions and subsequent aroma-

tization and cyclodehydrogenation. This would be an especially attractive approach for the preparation of larger graphitic sections.

[6] Crystal structure analyses were conducted with a Nonius CAD-4 diffractometer with graphite-monochromated $Cu_{K\alpha}$ radiation ($\lambda = 1.5418$ Å) at room temperature. Lattice parameters were obtained from 25 reflections by least squares analysis ($\theta > 25°$). The intensities were measured with $\theta/2\theta$ scans. The structures were solved by direct methods, the C atoms refined with anisotropic deflection parameters, and the H atoms treated with a riding model. Empirical absorption correction; programs used: Molen, SIR, ORTEP. **3** ($C_{30}H_{24}$): monoclinic, $C2/c$, $a = 43.530(9)$, $b = 5.632(3)$, $c = 18.770(3)$ Å, $\beta = 111.232(9)°$, $V = 4289.5$ Å^3, $Z = 8$, $\rho_{calcd} = 1.191$ g cm^{-3}, $\mu = 4.736$ cm^{-1}, 3011 reflections, of which 1799 were observed ($I > 3\sigma(I)$), $R = 0.043$, $R_w = 0.047$. **4c** ($C_{30}H_{24}$): orthorhombic, $P2_12_12_1$, $a = 10.286(1)$, $b = 11.433(1)$, $c = 17.911(1)$ Å, $V = 2106.2(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.213$ g cm^{-3}, $\mu = 4.823$ cm^{-1}, 1568 reflections, of which 1330 were observed ($I > 3\sigma(I)$), $R = 0.033$, $R_w = 0.031$. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-58920.
[7] In the HPLC separation a minor fraction (7 area%) was isolated, whose UV absorption maxima are red-shifted relative to those of the two diastereomeric pairs of enantiomers. This can be explained by a twofold 1,3-hydrogen shift converting the Diels–Alder product **4** into a phenanthrene. This phenanthrene derivative also yields diphenyltriphenylene **5** on dehydrogenation.

$XeOF_5^-$, an Anion with Pentagonal-Pyramidal Structure**

Arkady Ellern and Konrad Seppelt*

$XeOF_4$ and IF_5 have strikingly similar physical, chemical, and structural properties. Both have a square-pyramidal structure[1, 2] and show distinct intermolecular interactions in condensed phase. With fluoride acceptors they form the cations IF_4^+ and $XeOF_3^+$, which have a similar structure.[3, 4] Alkali metal fluorides dissolve in IF_5 and $XeOF_4$ to form the crystalline associates $F^- \cdot 3IF_5$ and $F^- \cdot 3XeOF_4$, which also display almost identical structures in which the three square-pyramidal IF_5 and $XeOF_4$ units solvate the F^- ion, but themselves remain structually virtually unaltered.[5, 6] Removal of IF_5 or $XeOF_4$ from these associates in vacuum yields the anions IF_6^- and $XeOF_5^-$. Because the salts always form as powders, structural investigations were difficult. $(CH_3)_4N^+IF_6^-$ could, however, be obtained in the form of single crystals. The structure of the anion IF_6^- is an octahedron strongly distorted towards C_{3v} symmetry. Because of its steric effect the nonbonding lone electron pair lies on the threefold axis. With the small cation NO^+ as counterion an $I_4F_{24}^{4-}$ cluster is obtained,[7] which resembles the tetramer found in solid XeF_6 and its solutions.[8, 9]

No exact data on the structure of $XeOF_5^-$ have yet been obtained. After analysis of the IR and Raman data, Holloway, Schrobilgen et al. assumed a low-symmetry C_s structure.[6] Christe et al. reported that ab initio calculations and a new analysis of the IR and Raman data showed a pentagonal-pyramidal structure with C_{5v} symmetry.[10]

Initially during studies of the anions XeF_7^- and XeF_8^{2-} we serendipitously obtained crystals of $NO^+XeOF_5^-$, which were apparently formed by hydrolysis. $NO^+XeOF_5^-$ is formed directly from NOF and $XeOF_4$ and crystallizes from the liquid phase below room temperature in millimeter long, colorless crystals. During the study of the NOF/$XeOF_4$ system a long time ago the existence of a 1:1 compound was established.[11]

Our precise single-crystal structural analysis of $NO^+XeOF_5^-$ gave a structure (Fig. 1a) that resembles neither the C_{3v}-symmetric structure of $(CH_3)_4N^+IF_6^-$ nor the cluster structure of

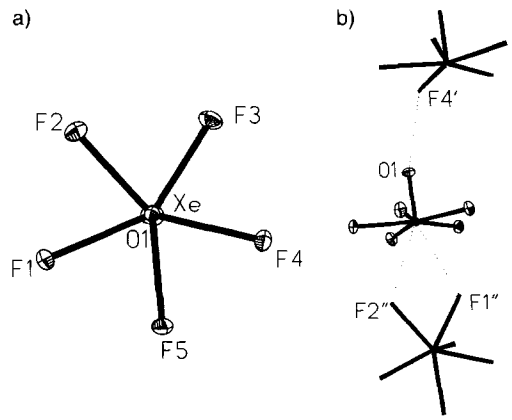

Fig. 1. Structure of the $XeOF_5^-$ ion in crystals of $NO^+XeOF_5^-$ (ORTEP representation, 50% probability). View onto the average plane through the five fluorine atoms. Distances [pm]: Xe–O 171.0(2), Xe–F1 203.2(2), Xe–F2 197.8(2), Xe–F3 195.6(2), Xe–F4 199.9(2), Xe–F5 201.1(2). The oxygen atom lies slightly off the ideal fivefold axis. b) View about perpendicular to the fivefold axis. Interanionic interactions are indicated by dotted lines. Distances [pm]: Xe···F1" 278, Xe···F2" 299, O···F4' 285.

$(NO^+IF_6^-)_4$. The $XeOF_5^-$ ion has a pentagonal-pyramidal structure with the oxygen atom in apical position. This structure is not only exceptionally aesthetic and unique in fluorine chemistry, but is also extremely regular. The lengths of all Xe–F bonds lie between 195.6(2) and 203.2(2) pm. The small variations can be explained by intramolecular interactions (Fig. 1b). The Xe–O bond of 171.0(2) pm is short as anticipated from its apical position. The xenon atom is situated merely 2.5(1) pm above the best plane through the five fluorine atoms; that is, the O-Xe-F angles are, with only one exception (89.1(1)°), slightly larger than 90° (90.6–91.8(1)°). The fluorine atoms, however, deviate up to 2.9(2) pm from this best plane. These slight deviations from ideal C_{5v} symmetry can also be explained by intermolecular interactions. The F-Xe-F angles lie between 71.2(1) and 74.0(1)°, thus showing minimal scatter about the ideal value of 72° for a planar XeF_5 unit.

Why does $XeOF_5^-$ behave so differently from IF_6^-? The oxygen–xenon bond must occupy substantially more space

than the fluorine atoms because of its partial double-bond character; the apical position of a pentagonal pyramid is well suited for such particularly large ligands; the nonbonding electron pair can occupy the *trans* apical position. In contrast to the central atom in BrF_6^- and XeF_8^{2-},[12, 13] the xenon atom in $XeOF_5^-$ is coordinatively unsaturated. It forms intermolecular Xe–F contacts (278.4 and 298.5 pm) with two fluorine atoms of adjacent anions. This additional coordination still leaves enough space for the nonbonding lone pair. On the other hand, these intermolecular interactions are comparatively weak and have no strong structure-determining influence. We had not previously found a suitable solvent for high-resolution NMR measurements of $NO^+XeOF_5^-$. $NO^+XeOF_5^-$ dissolves in acetonitrile; in the ^{19}F NMR spectrum at $-40\,^{\circ}C$ a broad signal (600 Hz) is observed at $\delta = 141$; this is explained by an intermolecular fluorine exchange.

Experimental Procedure

$XeOF_4$ and NOF (in the approximate ratio 1:1) were condensed under vacuum (stainless steel vacuum apparatus) into a perfluoroethene–propene (Teflon–FEP) tube, which was then sealed. The liquid phase solidified slightly below room temperature to form large crystals that were partly formed by sublimation as well. Crystal structure analysis: A suitable crystal with dimensions $0.4 \times 0.4 \times 0.4$ mm was mounted at low temperature ($T = -153\,^{\circ}C$) on an Enraf–Nonius CAD4 diffractometer; space group $P2_1/n$ (no. 14), $a = 669.8(1)$, $b = 551.0(1)$, $c = 1425.1(2)$ pm, $\beta = 101.2(2)^{\circ}$, $V = 515.9(1)$ pm^3, $Z = 4$, $2\theta_{max} = 90^{\circ}$, $Mo_{K\alpha}$, 71.069 pm, ω scan, 4275 measured reflections of which 4169 were independent and 4150 used, Lorentz polarization correction, Difabs absorption correction [14], $\mu = 68.3$ mm^{-1}, min./max. correction 0.73/1.10, structure solved with the program SHELXS-86 [15], structure refinement with SHELXL-93 [16], 83 parameters, $R_1 = 0.0296$, $wR_2 = 0.0806$, extinction coefficient 0.0114(9), residual electron density 2.7 e $\times 10^6$ pm^{-3} (80 pm from xenon atom). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-58969.

Hydroxylation of Alkanes with Molecular Oxygen Catalyzed by a New Ruthenium-Substituted Polyoxometalate, $[WZnRu_2^{III}(OH)(H_2O)(ZnW_9O_{34})_2]^{11-}$**

Ronny Neumann,* Alexander M. Khenkin, and Mazal Dahan

The utilization of dioxygen in liquid-phase oxidation of hydrocarbons is currently an important research goal due to its availibility and its benign effect on the environment. Since dioxygen has a triplet ground state, direct oxidation of organic compounds is not possible. Common modes of dioxygen "activation" thus include a) formation of hydrocarbon radicals leading to formation of reactive hydroperoxides by free-radical autoxidation mechanisms,[1] b) photoexcitation of dioxygen to form highly reactive singlet oxygen,[2] c) use of dioxygen as a secondary oxidant in metal-ion-catalyzed mechanisms as in Wacker-type processes,[3] and d) reductive cleavage of transition-metal dioxygen complexes to form highly active metal–oxo intermediates as in manganese porphyrins[4] and the various Gif systems.[5] A more desirable mode of activation would be the direct use of dioxygen to elicit oxygenation without formation of hydrocarbon radicals, or use of photoexcitation or reducing agents. A few such examples exist including alkene epoxidation with ruthenium porphyrins[6] and alkane hydroxylation with perfluorinated iron porphyrins,[7] although recently evidence has been put forward claiming that the latter is a free-radical autoxidation.[8]

In this paper we report on the preparation of a diruthenium-substituted polyoxometalate **1** and its use as a catalyst for the

$[WZnRu_2^{III}(OH)(H_2O)(ZnW_9O_{34})_2]^{11-}$ **1**

hydroxylation of alkanes such as adamantane with molecular oxygen at atmospheric pressure. Hydroxylation takes place almost *exclusively* at the tertiary carbon positions. This regioselectivity indicates that the oxidaton is not a typical free-radical autoxidation and that the ruthenium-substituted polyoxometalate activates molecular oxygen in a non-radical pathway. Supportive of this conclusion are the findings that adamantane is more reactive than triphenylmethane, that the reaction is not inhibited by the presence of alkyl-radical scavengers such as *tert*-butylcatechol, and that oxidation with hydroperoxides (required intermediates in autoxidations) yield significantly different reaction selectivities.

The polyoxometalate may be viewed as a dimer of a truncated Keggin structure having a "belt" of W, Zn, and Ru cations sandwiched between the two B-XW_9O_{34} trivacant Keggin fragments (Fig. 1). This new ruthenium polyoxometalate is isostructural with other similar transition-metal-substituted compounds reported[9, 10] and used previously.[11] Temperature-dependent magnetic susceptibility measurments[12] and the EPR spectrum[13] of the polycrystalline solid both support the X-ray analysis, indicating that the polyoxometalate should be viewed as a compound with two hexacoordinate ruthenium(III) centers at the designated terminal positions with one labile aqua

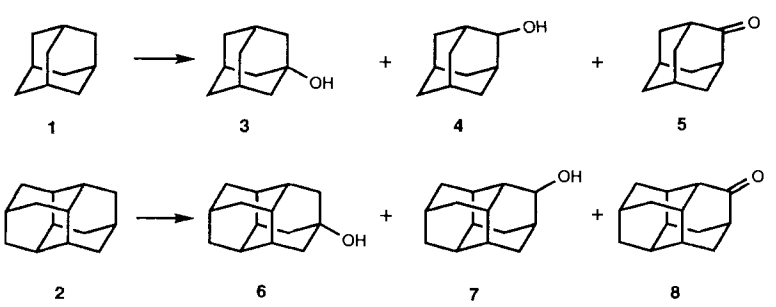
having both tertiary and secondary saturated carbon atoms that bear hydrogen atoms react virtually only at the tertiary position yielding 1-adamantanol (**3**) and 1-congressanol (**6**). Very little alcohol or ketone is formed at the secondary carbon.[14]



Further confirmation of this trend can be seen in the complete inactivity of alkanes with only secondary carbon centers such as cyclohexane and diphenylmethane. Under free-radical conditions, normal ratios of oxidation at tertiary vs. secondary positions is 3:1. Furthermore, addition of the alkyl-radical scavenger, *tert*-butylcatechol, even at four times the amount of alkane substrate, caused only a very slight decrease in catalytic activity.[15] Additionally, alkylaromatic compounds such as cumene and triphenylmethane, known to be relatively highly reactive to free-radical autoxidations, were inactive or only slightly active in the presence of the disubstituted ruthenium polyoxometalate. Finally, oxidations with of adamantane with *tert*-butylhydroperoxide yielded a ratio of oxidation tertiary/secondary of 6.7:1. Assuming similar regioselectivity of all tertiary hydroperoxides, this result would also seem to indicate that adamantane hydroperoxide, the expected intermediate in an autoxidation pathway, is not an intermediate in the oxidation with molecular oxygen. Other ruthenium-substituted polyoxometalates reported in the literature were inactive ($PRuW_{11}O_{39}^{4-}$,[16] $SiRuW_{11}O_{39}^{5-}$),[17] yielded the usual ratio of autoxidation products ($PRuMo_{11}O_{39}^{4-}$),[18] or are known to form μ-oxo dimers ($(P_2W_{17}O_{61}Ru)_2O^{16-}$).[19] It would presumptuous at this stage to give a mechanistic explanation for our findings; however, a variety of explanations ranging from formation of caged hydrocarbon radicals within **1** to formation of active ruthenium–oxo intermediates is to be explored. The mechanistic uncertainty, however, does not detract from the importance of the discovery of a new mode of dioxygen activation in the hydroxylation of alkanes by use of a novel "oxidatively stable"[20] ruthenium-substituted polyoxometalate.

Experimental Procedure

The ruthenium-disubstituted polyoxometalate Na_{11}-**1**·$42H_2O$ was prepared by adding $Ru[(CH_3)_2SO]_4Cl_2$ (4.0 g, 12.2 mmol) to a solution of $Na_{12}Zn_3(H_2O)_2Zn_2W_{19}O_{68}\cdot 46H_2O$ (23 g, 3.9 mmol) in water (10 mL) at 90 °C under argon. The solution was stirred at this temperature for 18 h, then cooled, and opened to air. When 2 g of KCl was added to the brown solution, 10.9 g of the desired compound precipitated. The product was recrystallized twice from hot water. Overall yield: 24%; anal. calcd for $K_{11}Ru_2Zn_3W_{19}O_{68}\cdot 15H_2O$: K 6.97, Ru 3.60, Zn 3.50, W 62.32, H_2O 4.82; found K 7.06, Ru 3.56, Zn 3.24, W 61.30, H_2O 4.69. Single crystals for X-ray analysis were obtained by recrystallizing 0.12 g of the potassium salt in 10 mL of 0.5 M NaCl solution.

A stock solution of 2.71×10^{-4} M $Q_{11-x}Na_x$-$\mathbf{1}_2$ (Q = tricaprylmethylammonium) was prepared by mixing Na_{11}-$\mathbf{1}_2$·$42H_2O$ (1 g) dissolved in water with tricaprylmethyammonium chloride (1 g) dissolved in 1,2-dichloroethane (10 mL), separating phases, and drying the organic phase with Na_2SO_4. Concentrations were determined by UV-Vis spectroscopy; $\lambda_{max}(\varepsilon) = 306$ nm($50000\,M^{-1}cm^{-1}$).

Hydroxylation reactions were carried out by holding a solution of substrate (0.25 mmol) and ruthenium polyoxometalate (0.25 μmol, 0.1 mol%) in 1,2-dichloroethane (0.5 mL) under dioxygen (10 mL, approximately 0.45 mmol) at atmospheric pressure at 80 °C for 24 h. After cooling, reaction mixtures were analyzed unambiguously by GLC with two different columns using reference samples; the product identity was crosschecked by GLC-MS.

The Crafts–Friedel Reaction: Aromatic Alkylation within the Complex Formed upon Addition of a Gaseous Arenium Ion to an Olefin**

Massimiliano Aschi, Marina Attinà, and Fulvio Cacace*

Alkylation of arenes with olefins, one of the most important industrial applications of Friedel–Crafts reactions, proceeds by preliminary protonation of the alkenes by Brønsted acids such as $H(BF_3OH)$, $H(AlCl_3OH)$, H_2SO_4, followed by addition of the carbenium ions formed, or their polarized complexes, to the arene [Eq. (a)].[1] An alternative route is conceivable, in which alkylation occurs within a complex formed upon addition of an arenium ion to the olefin [Eq. (b)].

$$C_3H_6 + HA \longrightarrow iC_3H_7^{\delta+} \cdots A^{\delta-} \xrightarrow{+C_6H_6} \mathbf{1} + A^- \quad (a)$$

$$C_6H_7^+ + C_3H_6 \longrightarrow [C_6H_7^+ \cdot C_3H_6] \rightleftharpoons [C_6H_6 \cdot iC_3H_7^+] \rightleftharpoons \mathbf{1} \quad (b)$$

2 **3**

Sequence (b) represents a distinct reaction pathway, with special kinetic and mechanistic features, only if alkylation occurs within the complex, without separation of the reagents. If, on the contrary, the carbenium ion escapes into the medium and reacts with the arene only at some later stage, the whole sequence is tantamount to a conventional Friedel–Crafts alkylation whose only peculiarity is that the acid used to protonate the olefin is an arenium ion.

Aromatic alkylation promoted by the reaction of arenium ions with olefins was envisaged long ago by Olah,[2] but because discrimination between the alternative pathway (b) and the conventional mechanism (a) is extremely difficult in solution, further developments were blocked. We report here the first demonstration that the alkylation mechanism outlined in sequence (b) is actually operative in the gas phase and present a preliminary account of its essential features, deduced from the joint application of mass spectrometry and radiolysis.[3]

To demonstrate operation of sequence (b) in the gas phase, preliminary FT-ICR experiments were performed, where $C_6H_6D^+$ benzenium ions ($m/z = 80$), obtained by chemical ionization of $[^{12}C]C_6H_6$ with CO/D_2 in the external ion source of the spectrometer, were driven into the resonance cell, isolated by multiple ejection techniques, and allowed to react with C_3H_6. As expected, at the low stationary pressure (less than 5×10^{-7} Torr) of the cell, the $C_9H_{12}D^+$ ion from sequence (b) could not be detected, owing to its fast back dissociation under conditions of inefficient collisional stabilization.

However, by using a pulsed valve one can obtain, albeit for a short time (5 ms), C_3H_6 pressures up to 5×10^{-5} Torr, which allows stabilization of a fraction of the $C_9H_{12}D^+$ ions, which can thus be positively identified by accurate mass measurements (Fig. 1). Despite their low relative abundance (< 5%) formation of the $C_9H_{12}D^+$ ions is significant, since it can only occur within the complex formed by the reactants. In fact, no C_6H_6 is introduced into the reaction cell, which excludes the role of any free $iC_3H_6D^+$ as a source of the $C_9H_{12}D^+$ ion observed.[4]

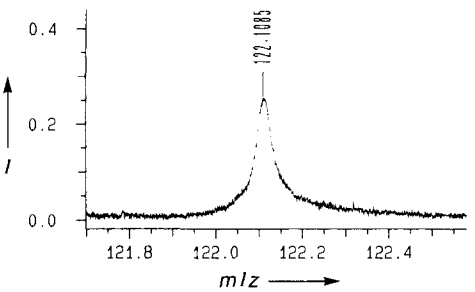

Fig. 1. Exact mass analysis of the $C_9H_{12}D^+$ adduct from the reaction of $C_6H_6D^+$ with C_3H_6 under the conditions given in the text. Relative ionic intensity in arbitrary units.

The FT-ICR results are consistent with, but do not prove the occurrence of sequence (b) since the data give no structural information, and it cannot be excluded that the $C_9H_{12}D^+$ ions observed are noncovalent complexes, like **2** and/or **3**, rather than protonated cumene **1**. More conclusive evidence was obtained from the radiolytic experiments (see Table 1).

In the experiments a bulk gas, for example, CH_3F at atmospheric pressure, containing small amounts of the reactants (C_6D_6 and C_3H_6), a radical scavenger (O_2), and a gaseous base such as $(CH_3)_2O$, is subjected to γ irradiation. According to a well-established reaction sequence,[5] ionization of CH_3F produces stable $(CH_3)_2F^+$ ions that react efficiently with C_6D_6 to give $C_6D_6CH_3^+$ ions,[6] which are largely converted by the base into $C_6D_5CH_3$, a major radiolytic product.[7] Those toluenium ions that escape deprotonation are available to promote iso-

Table 1. Alkylated products from the reaction with olefins of the arenium ions from the attack of radiolytically formed cations on C_6D_6.

T [°C]	Gas phase [a]	Olefin	Alkylated products (*o*:*m*:*p*)	Product ratio [b]
42	CH_3F	C_3H_6	$CH_3C_6D_4iC_3H_6D$	ca. 1.4×10^{-3}
80	CH_3F	C_3H_6	$CH_3C_6D_4iC_3H_6D$	6.0×10^{-3}
120	CH_3F	C_3H_6	$CH_3C_6D_4iC_3H_6D$ (50:25:25)	$\frac{CH_3C_6D_4iC_3H_6D}{C_6D_5CH_3} = 3.1\times10^{-2}$
135	CH_3F	C_3H_6	$CH_3C_6D_4iC_3H_6D$	3.6×10^{-2}
120	CH_3F	cC_6H_{10}	$CH_3C_6D_4cC_3H_{10}D$	$\frac{CH_3C_6D_4cC_6H_{10}D}{C_6D_5CH_3} = 5.6\times10^{-2}$
42	CF_4	C_3H_6	$CF_3C_6H_4iC_3H_6D$ (0:74:26)	0.13
80	CF_4	C_3H_6	$CF_3C_6H_4iC_3H_6D$	$\frac{CF_3C_6H_4iC_3H_6D}{C_6D_5CF_3} = 0.11$

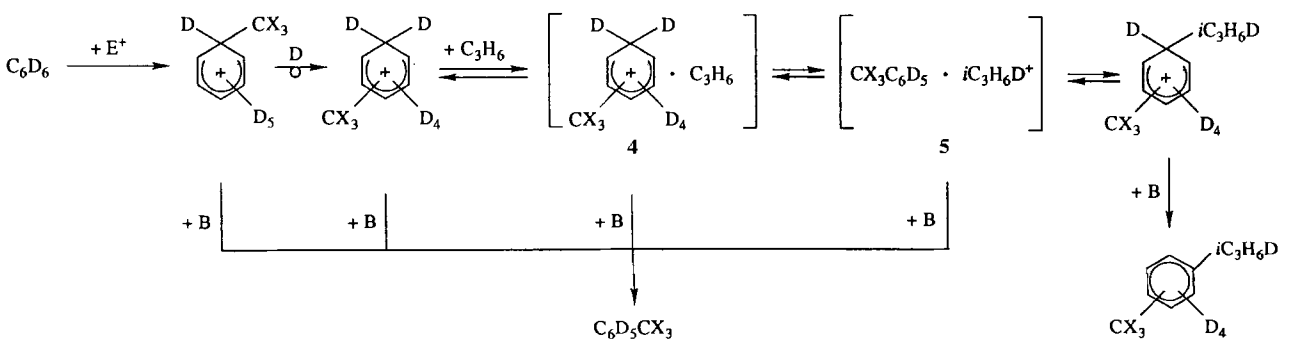
[a] All systems contained C_6D_6 (1.5–2.8 Torr), the olefin (5–10 Torr), O_2 (10 Torr), and a gaseous base (Me_2O, 1.1 Torr). Absorbed dose 1.3×10^4 Gy; dose rate 2×10^4 Gy h^{-1}. [b] Standard deviation of the ratio ±10%.

propylation (Scheme 1, X = H). The nature and the isomeric composition of the products, established by GC/MS, correspond exactly to the isomeric $CH_3C_6D_4iC_3H_6D$ cymenes expected from sequence (b). Furthermore, under the conditions prevailing in the radiolytic experiments, isopropylation necessarily occurs within an ion–molecule complex, which excludes a role for free $iC_3H_6D^+$ ions. The efficiency of the process, expressed by the cymenes/toluene ratio (last column of Table 1), undergoes a 26-fold increase as the reaction temperature is raised from 42 to 135 °C, and points to an activation barrier most likely associated with conversion of complex **4** into **5** (X = H), which is endothermic because toluene is more basic than propene. If the deprotonation rate of **4** by B is essentially independent of the temperature, a reasonable assumption for an exothermic proton transfer from an unhindered arenium ion to an n-type base, the activation energy for the conversion of **4** into **5** can be calculated from the dependence of the cymenes/toluene ratio on the temperature. The result ($E_a = 9.1\pm1.0$ kcal mol^{-1}) is significantly close to the difference in proton affinity between toluene and propene of 9.3 kcal mol^{-1}.[8]

It is noteworthy that the isomeric composition of the cymenes from (b) is the same as that in control experiments involving alkylation of toluene by free $iC_3H_7^+$ ions at the same temperature.[9] Replacing C_3H_6 with cC_6H_{10} yields an a isomeric mixture of $CH_3C_6D_4cC_6H_{10}D$ *cyclo*-hexyltoluenes, and it is apparent from Table 1 that the efficiency of the alkylation increases appreciably when the more basic cycloalkene is used.[10] Remarkably, no 1-methyl-cyclopentyl derivative was detected among the products: fast trapping within the [toluene–cyclohexylium ion] complex must prevent rearrangement of the cation, a reaction that is unavoidable in conventional bimolecular reactions even at pressures up to 1470 Torr in the presence of high concentrations of an efficient nucleophile.[11] Significantly, isodurenium ions from the methylation of mesitylene are completely unreactive toward C_3H_6 even at 135 °C. Finally, alkylation of C_6D_6 with CF_3^+ from the radiolysis of CF_4[12] promotes the reaction sequence outlined in Scheme 1, X = F, leading to formation of isomeric $CF_3C_6D_4iC_3H_6D$. This reaction displays a weakly negative temperature dependence and is considerably more efficient than for X = H, consistent with the lower basicity of $CF_3C_6D_5$ compared to that of $CD_3C_6D_5$, which reduces or cancels the endothermicity, and hence lowers the barrier for the conversion of **4** into **5** when X = F.

Despite their preliminary nature, the above results conclusively demonstrate operation of sequence (b) in the gas phase and provide a coherent picture of its peculiar features that allows sharp mechanistic discrimination from conventional Friedel–Crafts alkylation. For example, the seemingly paradoxical observation that the rate of formation of isopropylated trifluorotoluenes exceeds that of cymenes, whereas isopropylation of isodurene does not occur at all, that is, a trend that runs contrary to that prevailing in conventional Friedel–Crafts alkylation, is easily accommodated in the framework of sequence (b). In fact, in those cases where the **4** → **5** conversion is rate determining, the process is favored by a relatively low basicity, and hence by a low nucleophilicity of the arene, whereas this feature depresses the reactivity in conventional electrophilic alkylation (a).

The present results are of relevance to the theory of aromatic substitution, and outline a new class of electrophilic alkylation reactions, whose salient feature is the extremely short lifetime (down to the picosecond scale) of the alkylating cation prior to reaction. This widens the scope of aromatic alkylation by allowing substitution by unstable carbenium ions that would undergo isomerization in conventional bimolecular reactions. This work is also relevant to gas-phase ion chemistry, providing the first demonstration of an aromatic substitution occurring within an ion–molecule complex prepared by assembling ini-



Scheme 1. $E^+ = (CH_3)_2F^+$, X = H; $E^+ = CF_3^+$, X = F.

tially separate components. The role of ion–molecule complexes has long been postulated in mass spectrometry,[13] but was based, in general, on indirect evidence from the fragmentation pattern of excited species from the ionization of molecules in which the putative components of the complex were initially covalently bound. In the specific case of alkylbenzenes, irrefutable mass spectrometric evidence is lacking for complexes such as **2**; results of molecular orbital calculations[14] do not appear inconsistent with ours.

Experimental Procedure

The gaseous samples for the radiolytic experiments were prepared in sealed 135 mL glass vessels, irradiated in a 220 Gammacell (Nuclear Canada Ltd.), fitted with a thermostat. The gases and the chemicals used were research-grade products from commercial sources. The radiolytic products were analyzed by GC/MS (50 m long, 0.2 mm i.d. fused silica column, coated with a 0.5 μm methylsilicone film; VG Micromass TRIO quadrupole mass spectrometer). The FT-ICR experiments were performed with a Bruker Spectrospin Apex TM 47e spectrometer equipped with an external ion source.

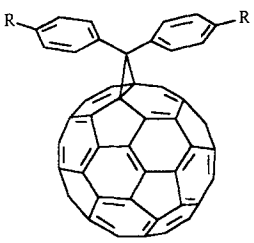
Electrochemical Evidence for Through-Space Orbital Interactions in Spiromethanofullerenes**

Matthias Eiermann, Robert C. Haddon, Brian Knight, Q. Chan Li, Michele Maggini, Nazario Martín, Toshinobu Ohno, Maurizio Prato, Toshiyasu Suzuki, and Fred Wudl*

While buckminsterfullerene C_{60}[1] can be converted efficiently into a remarkable number of methanofullerenes and fulleroids,[2] gaining control over its electronic properties still is an interesting and demanding goal[3] which might open up a broad variety of applications similar to achievements in classical benzene chemistry.

The cyclic voltammetry (CV) data of diphenylmethanofullerenes **1** with electron-donating groups (EDGs) and electron-withdrawing groups (EWGs) in the *p,p'* positions of the phenyl groups are independent of the functional groups.[4] In contrast, spiroannelated analogues show remarkable substituent effects which we suggested calling "periconjugation".[5] Here we describe our experimental evidence obtained from 1,1-(4-oxocyclohexa-2,5-dieno)- and 9,9-fluorenofullerenes and present the conclusions derived from the observations.



1 (R = EWG, EDG)

The most direct method for studying the influence of addends on the electronic properties of fullerene C_{60} is cyclic voltammetry. The CV measurements were carried out in *o*-dichlorobenzene, because the spiroannelated methanofullerenes are most soluble in this solvent[6] and four reduction waves of C_{60} can be detected. Since various irreversible processes can be observed in some of the cyclic voltammograms, peak potentials rather than the averaged data are given in Table 1 and in the discussion. All compounds described were prepared by known methods.[2, 7]

Since the 5/6- and 6/6-isomers of 1,1-(4-oxocyclohexano)-fullerene, **2a** and **2b**, respectively, can be separated, both could be characterized by CV individually. Their first reductions are fully reversible and occur at −1158 and −1164 mV (peak potentials, vs. ferrocene/ferrocenium), respectively, well within the expected range for "standard" methanofullerenes.[2, 8] In comparison, the reduction is facilitated by more than 70 mV (vs. **2b**)

4: R = *t*Bu
5: R = Me

All fluorenofullerenes **6**–**13** described in the following could be isolated exclusively as adducts on 6/6 junctions; no 5/6 isomers were detectable. Assuming that this is a general structural principle of fluorenofullerenes applicable to the conversion of a mono- into a bisadduct, no other regiochemical control besides steric repulsion seems to direct the location of the second addition relative to the first.[9] Thus all bis(fluoreno)fullerenes were obtained as mixtures of five (**12**: six) regioisomers,[10] which could be separated only partially by HPLC (Scheme 1).

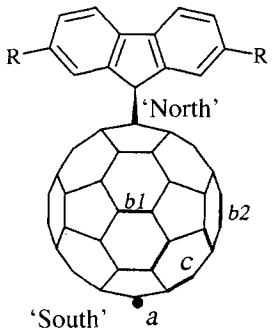

Scheme 1. Possible positions for a second addend on the "south pole" (*a*), on the "equator" (*b*1, *b*2), and in between (*c*, three possible positions)[10]. For clarity, symmetry-equivalent positions have been omitted.

The CV spectra of the spiroannelated methanofullerenes clearly demonstrate the striking influence of the addends on the C_{60} moiety. The positions (Table 1) of the first two reduction waves correlate with the electronic demand of the fluorenyl groups.[11] In the unsubstituted and the exclusively EDG-substituted[12] fluorenofullerenes (**6**, **7**, **9**, **10**), the first and the second reduction waves are strictly electrochemically reversible. The uptake of a third electron is electrochemically irreversible, exhibiting a scan rate dependent gap between reduction and reoxidation (Fig. 1).

The spiroannelated methanofullerenes bearing EWGs (**8**, **11**–**13**) give rise to CV curves that are more difficult to resolve.

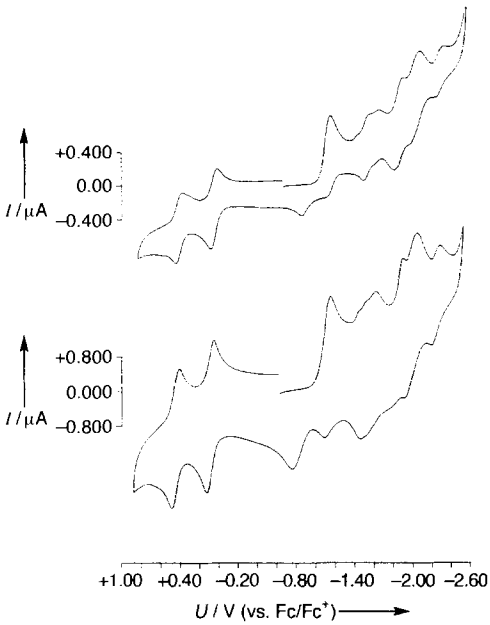

Fig. 2. Cyclic voltammograms of **12** (upper scan: $10\,mVs^{-1}$; lower scan: $100\,mVs^{-1}$; potential vs. Fc/Fc^+).

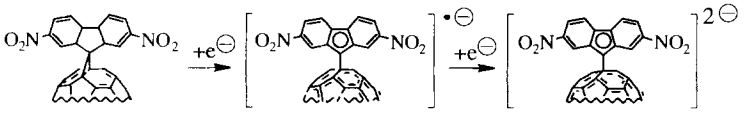
The first, second, and third reduction peaks are electrochemically irreversible, with complicated multiple reoxidation waves (Fig. 2). This behavior is not yet fully understood and will be the subject of further investigations; however it may be ascribed to the opening of a cyclopropane ring, as shown in Scheme 2.



Scheme 2.

The crucial structural difference between 9,9-fluorenofullerenes **6**–**13** and (diphenylmethano)fullerenes **1** is that in the latter the phenyl rings are free to rotate but prefer to lie "parallel" to the fullerene surface, whereas the aromatic rings in **6**–**13** are held rigidly perpendicular to the surface of the spheroid. The cyclohexadienone derivatives **3**–**5** have similar structures. Models show that there is a likelihood of unusual periconjugation, different from spiroconjugation,[13] between the p_z orbitals of the addends and the "p_z" orbitals of the fullerene carbon atoms adjacent to the bridge atom. Even though a spiro atom also separates the π systems in **3**–**13**, the mode of interaction of the corresponding p_z orbitals is geometrically completely different from spiroconjugation. This can be easily seen by looking at the relative orientations of the atomic orbitals involved (Fig. 3).

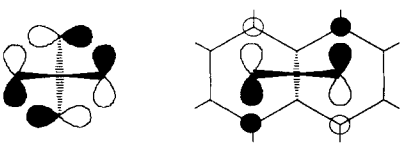


Fig. 3. Modes of orbital interaction in spiroconjugation (left) and periconjugation (right).

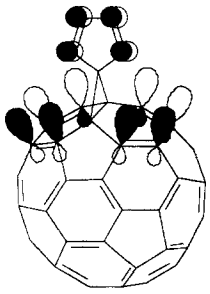
MNDO calculations on the spirocyclopentadiene compound **14** were used to model the interaction. In the fully optimized structure, which gives a transannular cyclopropane bond length of 1.602 Å,[14] the HOMO is bonding between the cyclopentadiene and C_{60} residues (Fig. 4). The LUMO has a_1 symmetry and is followed in energy by the b_2 and b_1 orbitals. When the length of the transannular cyclopropane bond is constrained to 2.0 Å, the energy is increased by 13 $kcal\,mol^{-1}$ and the HOMO is no longer bonding between the two moieties. The b_1 orbital then becomes the LUMO followed by the a_1 and b_2 orbitals. Since the b_1 orbital is antibonding with respect to the transannular cyclopropane bond, its population (e.g. by electrochemical reduction) will weaken the bond. These frontier orbital interactions may account for the complex findings in the electrochemical studies of **6**–**13**.



14

Fig. 4. HOMO interaction in cyclopentadienofullerene **14**. The remaining atomic orbitals contributing to the molecular HOMO are left out for clarity.

The ability to control the electron acceptor and donor strength of methanofullerenes—a fine-tuning of the electrochemical properties—opens up more possibilities for fullerene modification. Current research is aimed at an improved theoretical understanding of the effects as well as application of the results described here to the preparation of more electropositive and electronegative methanofullerenes.

[10] The number of isomers was deduced from the ^{1}H NMR spectra. If one designates the location of the first addition as the "north pole" of the fullerene, there are four different types of 6/6 junctions on the "southern" hemisphere including the "south pole", giving rise to four regioisomeric bisadducts. Two further types of 6/6 junctions on the "equator" lead to two additional bisadducts only if the second substituent is different from the first (a total of six regioisomers). Otherwise only one additional regioisomer is formed (a total of five regioisomers).

[11] In the cyclic voltammograms of all isomeric mixtures of bisadducts **9**–**12** the signal shapes are, in general, similar to those of the corresponding monoadducts, indicating that relative positions of the substituents has a surprisingly small effect on the redox potentials.

[12] All compounds with dibenzylamino groups (**7**, **10**, **12**) can be oxidized reversibly in two steps due to a charging of the amino-substituted fluorenyl moieties. Oxidation peak potentials: **7**: +114 mV, +463 mV; **10**: +147 mV, +473 mV (two-electron processes); **12**: +129 mV, +464 mV (see Figs. 1 and 2) (vs. ferrocene/ferrocenium). This behavior was also detected in 2,7-bis(dibenzylamino)-9-fluorenone.

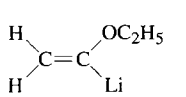
α-Ethoxyvinyllithium: An Unexpected Polymeric Structure—Tetrameric Subunits Linked by Li–C π Interactions**

Klas Sorger, Walter Bauer, Paul von Ragué Schleyer,* and Dietmar Stalke

Dedicated to Professor Heinz Viehe on the occasion of his 65th birthday

Serving as an acyl anion equivalent, α-ethoxyvinyllithium (**1**) is a widely used synthetic reagent.[1] We now report the complex X-ray structure of unsolvated **1**, as well as NMR spectroscopic evidence for its nature in THF. In general, organolithium systems with α-halogen or α-oxygen substituents (R^1R^2CXLi) have "carbenoid" character, with bridging lithium and elongated C–X bonds.[2–5]



1

Crystals of **1** (synthesized by tin/lithium exchange) were obtained from hexane in the absence of cosolvents. The structure of **1** adopts a self-assembled, polymeric chain in the solid state (Fig. 1).[6] The asymmetric unit contains six $H_2C{=}C(Li)OEt$ molecules. Four of them are aggregated to form a distorted cubic Li_4C_4 tetramer, the remaining two generate a second tetramer by a C_2 axis (Fig. 1a).

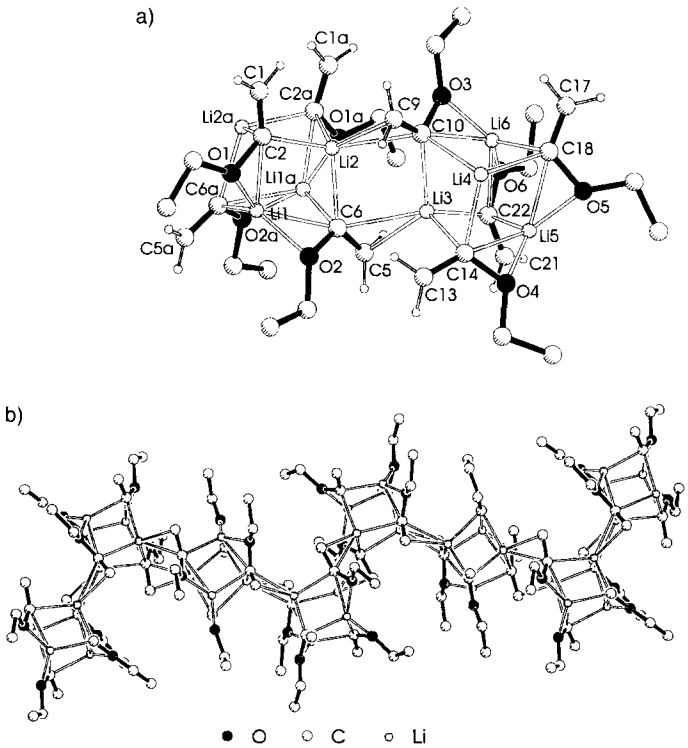


Fig. 1. a) Crystal structure of polymeric **1** showing the monoclinic unit cell. The methylene and methyl hydrogen atoms of the ethoxy groups have been omitted for clarity (the labels with a letter identify atoms which are related by a C_2 axis). b) Chain structure of polymeric **1** showing the tetrameric subunits linked by C–Li π-interactions. Selected bond lengths [pm] and angles [°]: Li1–O1 183.6(9), Li1–O2 189.8(9), Li1–C2 216.8(11), Li1–C6 245.9(10), Li1–C6a 222.1(10), Li2–C2 223.4(10), Li2–C2a 232.1 (10), Li2–C6 227.9(11), Li2–C9 244.6(10), Li2–C10 253.1(10), Li3–C10 225.1(11), Li3–C14 231.3(10), Li3–C22 227.4(10), Li3–C5 244.8(10), Li3–C6 251.8(10), Li4–C10 236.6(10), Li4–C14 223.0 (10), Li4–C18 227.2(11), Li4–C13a 242.5(10), Li4–C14a 251.5(10), Li5–O4 186.0(10), Li5–O5 188.0(10), Li5–C14 234.1(11), Li5–C18 230.1(12), Li5–C22 221.4(11), Li6–O3 187.9(9), Li6–O6 186.6(10), Li6–C10 231.3(11), Li6–C18 214.4(10), Li6–C22 228.3(11), Li bridged C=C (mean) 133.3(8), nonbridged C=C (mean) 131.9(8); C=C O (mean) 117.7, C1-C2-Li1 172.1(5), C5-C6-Li1 149.0(4), C9-C10-Li6 156.5(5), C13-C14-Li5 156.2(5), C17-C18-Li5 163.8(6), C21-C22-Li6 158.0(5).

The Li/oxygen carbenoid character of **1** is shown by the elongated C_α–O bond (142.1(6)–143.6(6) pm, mean: 142.8(7) pm;[3, 5a–d] the C_{vinyl}–O bond length in vinylethers is about 136 pm (Fig. 2 bottom[7]). Similar elongations of 6.8 and 8.5 pm were observed in α-lithiobenzofuran[5d] and 3-bromo-2-lithiobenzofuran,[5b] respectively. The C_α–O bond of monomeric α-methoxyvinyllithium (computed ab initio at the Becke3LYP/6-311 + G**[8] level) is even longer (13 pm, Fig. 2 top) which can be attributed to the absence of other lithium ligands. Due to the unfavorable lone pair repulsions in the s-*cis* form, the α-methoxyvinyl anion favors the *s-trans* conformation (Fig. 2 middle). Both the conformation of α-methoxyvinyllithium and

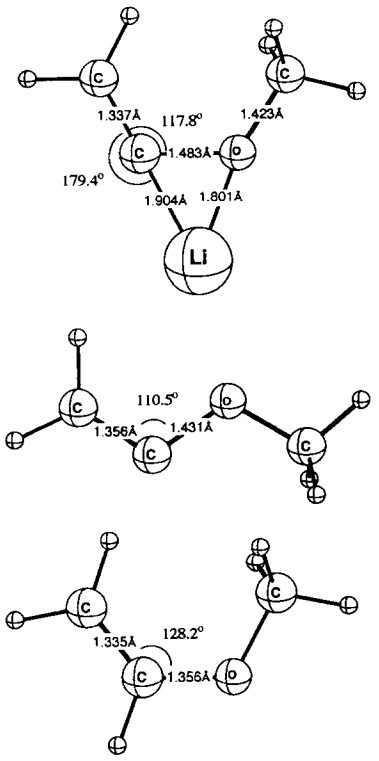

Fig. 2. Becke3LYP/6-311 + G** optimized C_s geometries (energy minima) of monomeric α-methoxyvinyllithium (top), the *s-trans* α-methoxyvinyl anion (middle), and *s-cis* methylvinylether (bottom). The different conformational preferences and the C–O bond lengths are noteworthy.

the *s-cis* form of the methylvinyl ether differ from the conformation of the anion. The C_α–O bond elongation of 7.5 pm in the anion is much less than that computed for the lithium derivative. This emphasizes the effect of ion pairing.[9]

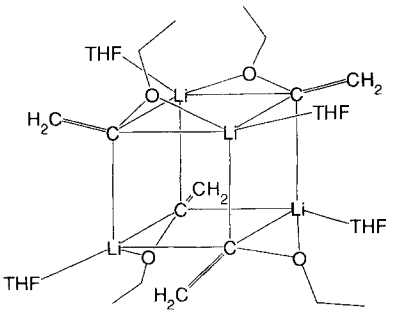
The lithium cations in the polymeric solid-state structure of **1** bridge the C–O bonds in notable ways: two lithium atoms in each tetramer coordinate simultaneously to *two* oxygen atoms, namely, Li1 to O1 and O2, Li1a to O1a and O2a, Li5 to O4 and O5, Li6 to O3 and O6 [Li–O distance: 183.6(9) – 189.8(9), mean: 187.0(10) pm] (Fig. 1a), resulting in pentacoordinate lithium centers. Similar double-coordination of lithium to two heteroatoms is found in 1-lithio-2-methoxybenzene,[10] in which lithium bridges an anionic carbon atom and a β-oxygen atom.

The two other lithium cations in each tetramer, Li2 and Li2a (as well as Li3 and Li4 in the polymeric chain), do *not* have oxygen contacts. Instead, these cations exhibit π interactions to the C=C double bonds of α-ethoxyvinyllithium units in the neighboring tetramer (Fig. 1). Consequently, these lithium atoms are σ-bonded to three vinylic carbon atoms [C–Li distance: 223.4(10)–236.6(10) pm] and are η^2-coordinated to a C–C π bond. Hence, there are two different lithium environments in polymeric **1**: pentacoordination with contacts to two oxygen atoms and pentacoordination to five carbon atoms, two of them π-bound.

The unusual manner in which neighboring tetrameric subunits are connected –through Li–C_{vinyl} η^2-interactions—is intriguing (Fig. 1b).[11] The Li–C π contacts in the solid-state structure of **1** saturate the coordination sphere of the lithium cations and link the tetramers into a polymeric chain. In contrast, the Li_4C_4 tetramers in polymeric [(PhC≡CLi)$_4$(tetramethylhexanediamine)$_2$][12] are linked by the diamine ligands to form helices. Since the π electrons are polarized towards the terminal carbon (C_β) upon lithiation (i.e., ethylvinylether vs **1**),[19] the Li–C_β distances are significantly shorter [242.5(10)–244.8(10) pm] than the Li–C_α distances [251.5(10)–253.1(10) pm]. However, both distances are within the range of Li–C bond lengths observed for π-bonded lithium.[11, 13]

Consistent with computational findings,[14] the lithium-bridged C=C bonds [mean: 133.3(8) pm] are 1.4 pm (marginally but systematically) *longer* than the nonbridged C=C bonds [mean: 131.9(8) pm]. At the Becke3LYP/6-311 + G** level,[8] the C=C bond elongation in the Li^+–ethylene C_{2v} π complex is 1.2 pm.

A low-temperature ^{13}C NMR spectrum of α-ethoxyvinyllithium (**1** – ^{6}Li) reveals that the solid-state structure is not retained in [D$_8$]THF solution. At −90 °C, a well-resolved seven-line ^{13}C multiplet due to ^{13}C-^{6}Li scalar coupling is observed for the lithiated carbon. This is consistent with a static tetramer ($^1J(^{13}C$-$^6Li)$ = 5.0 Hz).[15, 19] The lithiated carbon C_α couples with three *equivalent* lithium cations.[15, 19] A tetramer **2**[16]



2

with lithium bridging the C–O bond is confirmed by ^{6}Li-^{1}H heteronuclear Overhauser effect spectroscopy (HOESY):[17] under the same conditions, however, in the presence of one equivalent of undeuterated THF per lithium atom, ^{6}Li cross peaks with nearly identical intensities to *all* hydrogens of **1**, as well as to the THF α-hydrogens are found. Close contacts between lithium and the methylene, and even the methyl hydrogen atoms of the ethoxy group, demonstrate the lithium bridging of the C_α–O bond in solution. Close contacts between lithium and the THF α-hydrogens indicate the coordination of THF to lithium.

The downfield shift of the ^{13}C NMR signal of the lithiated carbon in **1** relative to the $\delta(^{13}C(1))$ of H_2C=CHOEt, $\Delta\delta$ = 60.7,[18] is typically large for carbenoids.[4c, 5c, 19, 20] This downfield shift exceeds that of "non-carbenoid" tetrameric vinyllithium[17] ($\Delta\delta$ = 54.4). The C(Li)O carbenoid character of **1** is thus confirmed both by the C–O bond elongation and by the ^{13}C NMR characteristics.

Experimental Procedure

n-Butyllithium (3.30 mmol, 2.06 mL of a 1.6 M solution in hexane) was added to a solution of tributyl(1-ethoxyvinyl)stannane [1.19 g, 3.30 mmol, prepared [1e] by reaction of α-ethoxyvinylpotassium [21] with tributyltin chloride (yield 90%)] in hexane (17.0 mL) at −40 °C. The solution was then stirred for 5 h at 0 °C. The product, a white precipitate, was warmed into solution (50 °C). Cooling to 8 °C yielded the crude product which was recrystallized from *n*-hexane at room temperature. This resulted in the formation of long, but very thin, colorless needles, which, under these conditions, are stable only for about 12 h. After several attempts, a single-crystal suitable for X-ray analysis was obtained. The crystal was selected and transported to the diffractometer at −50 °C [22]. ^{1}H NMR [25] (400 MHz, [D$_8$]THF, c = 3.4, −50 °C): δ = 4.85 (s, 1H, H_{trans}), 3.96 (s, 1H, H_{cis}), 3.58 (q, ^3J(H,H) = 13.4 Hz, 2H, CH_2), 1.29 (t, ^3J(H,H) = 13.4 Hz, 3H, CH_3); ^{13}C NMR see ref. [18]; ^{6}Li NMR ([D$_8$]THF, c = 3.4, −90 °C, referenced to 1 M LiBr in [D$_8$]THF): δ = −0.20 (s).

[6] Crystal data of polymeric **1** $[LiC_4H_7O]_6$: $M = 468.22$, monoclinic, space group $C2/c$, $a = 3322(2)$, $b = 976.7(7)$, $c = 2491(2)$ pm, $\beta = 130.47(3)^\circ$, $V = 6.149(8)$ nm^3, $Z = 8$, $\rho_c = 1.011$ Mg m^{-3}, $F(000) = 2016$, $\lambda = 0.71073$ Å, $\mu(Mo_{K\alpha}) = 0.066$ mm^{-1}, $T = 153$ K. data were collected on a Stoe-Siemens-AED. Intensities of a $0.9 \times 0.1 \times 0.05$ mm rapidly cooled crystal in an oil drop [22] were collected by the $2\theta/\omega$ method in the range of $8^\circ \leq 2\theta \leq 45^\circ$. Of a total of 5121 refections, 4028 were independent and 4024 used to refine 368 parameters, largest difference peak and hole: 223 and -195 e nm^{-3}, $R1(F > 4\sigma(F)) = 0.079$ and $wR2 = 0.230$ (all data) with $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR2 = (\Sigma\omega(F_o^2 - F_c^2)^2/\Sigma\omega(F_o^2)^2)^{0.5}$. The structure was solved with direct methods (SHELXS-90 [23]) and refined by full-matrix least-squares on F^2 (SHELXL-93 [24]). The hydrogen atom positions of the CH_2 groups were refined freely with the C–H bond length restrained to be the same while a riding model was applied to refine the hydrogen atom positions of the other groups. Further details of the crystal sructure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), by quoting the full journal citation.

A New Family of Chiral Binaphthyl-Derived Cyclophane Receptors: Complexation of Pyranosides**

Sally Anderson, Ulf Neidlein, Volker Gramlich, and François Diederich*

Dedicated to Professor Dr. Manfred Regitz on occasion of his 60th birthday

Carbohydrate recognition is central to many biological processes, including the transmission of disease and the operation of the immune system.[1] Carbohydrates are suitable molecules for recognition, because they have a much greater capacity to store information than other biopolymers.[2] The study of these recognition processes can be either carried out directly on biological systems, for example by analyzing the interactions in protein–carbohydrate complexes by X-ray crystallography[3] or in enzyme-linked immunosorbent assays,[4] or by synthesizing simpler analogous receptors whose binding properties can be systematically varied and analyzed.[5] We targeted the chiral receptors **1a–d** (Scheme 1), which show a remarkable degree of

Jens Cuntze for the NMR titrations.

preorganization: six, eight, or ten OH groups converge upon a central cavity providing a ring of H-bonding sites for carbohydrate recognition.[6] These receptors, derived from the 3,3′-diethynyl-1,1′-binaphthyl-2,2′-diol spacer **2**, allow economy in the synthesis of a wide range of hosts. The introduction of linking groups X between the acetylenes would widen the cavity and provide enough space either to replace the convergent OH groups with other H-bonding residues or to bind di- and higher oligosaccharides. These linking groups could also offer a foundation on which to attach a hydrophobic floor parallel to the plane of H-bonding sites; Lemieux[7] has convincingly shown that hydrophobic desolvation and van der Waals interactions are at least as important for biological carbohydrate binding in aqueous solution as the H-bonding interactions. Varying the divergent R groups at the periphery should lead to receptors soluble in solvents of any desired polarity, including water. Here we report the synthesis of the neutral receptors (*R*,*R*,*R*)-(−)-**3** and (*R*,*R*,*R*,*R*)-(−)-**4**, and of the tetraanionic receptor (*R*,*R*,*R*,*R*)-(−)-**5**, as well as preliminary binding studies with pyranosides.

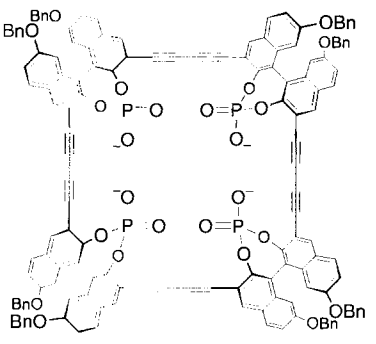
(*R*,*R*,*R*,*R*,*R*)-(−)-**18**	3	Bz



(*R*,*R*,*R*,*R*)-(−)-**5**

The synthesis of the novel receptors started with the preparation of the optically active cyclization component (*R*)-(+)-**6** (Scheme 2). Differential O-protection and O-deprotection of 2-bromo-3,6-naphthalenediol[8] (**7** → **8** → **9** → **10**) followed by oxidative coupling afforded the racemic dibrominated 1,1′-binaphthyl-2,2′-diol **11**, whose constitution was confirmed by single crystal X-ray diffraction.[9] Optical resolution of **11** was accomplished via the (L)-menthyl phosphite **12**: diastereoisomer (−)-**12**[10] (diastereomeric excess > 99.5%)[11] crystallized readily, whereas (+)-**12** failed to crystallize from the filtrate even after concentration. The menthyl phosphite was readily cleaved[10] with K_2CO_3 in MeOH/$CHCl_3$ to give diol (−)-**11**. To show that (−)-**11** was the *R* enantiomer, the diol was debrominated, benzylated to give (−)-**13**, and the optical rotation of (−)-**13** ($[\alpha]_D^{22} = -15.2$, $c = 0.5$, CH_2Cl_2; Table 1) compared with that of (*S*)-(+)-**13** ($[\alpha]_D^{22} = +15.2$, $c = 0.5$, CH_2Cl_2), derived from benzylation of (*S*)-(+)-7,7′-bis(benzyloxy)-1,1′-binaphthyl-2,2′-diol, whose absolute configuration had been previously determined.[12]

Table 1. Optical rotations of nonmacrocyclic precursors.

	$[\alpha]_D^{22}$	*c* (in CH_2Cl_2)
(*R*)-(+)-**6**	+26.6	1.0
(*R*)-(−)-**11**	−79.4	1.0
(*R*)-(−)-**12**	−394.5	1.0
(*R*)-(−)-**13**	−15.2	0.5
(*R*)-(+)-**14**	+8.0	1.0
(*R*)-(+)-**15**	+1.6	1.0

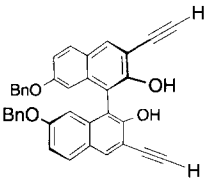
The OH groups in (*R*)-(−)-**11** were benzoylated to give (*R*)-(+)-**14**, and Stille coupling[13] with Me_3Si-C≡C-$SnMe_3$ afforded (*R*)-(+)-**15** containing two silylethynyl groups. Deprotection with K_2CO_3 in MeOH/THF gave, without attack at the ester protecting groups, the cyclization component (*R*)-(+)-**6**. Neither Stille nor Heck coupling[14] with unprotected (*R*)-(−)-**11** gave the desired dialkynylated product.

Oxidative Glaser–Hay coupling (air, CuCl, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA)) of (*R*)-(+)-**6** ($c = 4 \times 10^{-4}$ mol L^{-1}) in CH_2Cl_2 rapidly led to a product mixture from which the cyclic trimeric oligomer (*R*,*R*,*R*)-(−)-**16** (20%), tetrameric (*R*,*R*,*R*,*R*)-(−)-**17** (20%), and pentameric

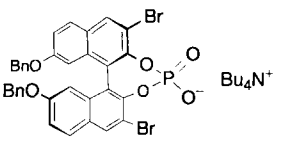
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1515-1597 $ 10.00+.25/0

(*R,R,R,R,R*)-(−)-**18** (3%) were isolated by flash chromatography (SiO_2, cyclohexane/AcOEt) (Table 2). Fast atom bombardment (FAB) mass spectra with positive ion detection gave strong molecular ions indicating the size of the oligomers, and the ^{13}C NMR spectra showed the required 22 peaks for cyclic oligomers of this type. Importantly, two signals were observed between $\delta = 75$ and 85, corresponding to the C atoms in the butadiyne links. Further confirmation of the butadiyne groups was obtained from the IR spectra, where both symmetric and antisymmetric stretches were observed in the region between 2100 and 2250 cm^{-1}. The ^1H NMR spectra of the three cyclic oligomers were very similar, except for the aromatic signals from the benzoyl protecting groups; presumably the observed differences in the positions of the benzoyl resonances reflect the different degrees of crowdedness in the three cavities.

Benzoyl ester hydrolysis of (*R,R,R*)-(−)-**16** and (*R,R,R,R*)-(−)-**17** proceeded smoothly with KOH in MeOH/THF and yielded the targeted neutral receptors (*R,R,R*)-(−)-**3** (90%) and (*R,R,R,R*)-(−)-**4** (92%). Similarly, (*R*)-(−)-**19** was prepared by deprotection of (*R*)-(+)-**6** as a control for binding experiments.[15] Since ionic hydrogen bonding is known to contribute greatly to strong carbohydrate binding in biological and synthetic receptors,[3, 5a] we have also prepared the tetraphosphate receptor (*R,R,R,R*)-(−)-**5** by treating (*R,R,R,R*)-(−)-**4** for 3 h at 20 °C with $POCl_3$ in dry CH_2Cl_2 in the presence of NEt_3, followed by hydrolysis with THF/H_2O for 12 h at 40 °C and ion exchange chromatography (Dowex 50WX8, Bu_4N^+, $CHCl_3$/CH_3CN 1:1) (67%). As a control for the binding experiments, monophosphate (*R*)-(−)-**20** was obtained in a similar way from (*R*)-(−)-**11**.



(*R*)-(−)-**19**



(*R*)-(−)-**20**

CPK models and computer modeling showed that the binding site of (*R,R,R*)-(−)-**3** is complementary in size and shape to a hexopyranose ring. ^1H NMR titration studies with (*R,R,R*)-(−)-**3** and pyranosides in dry $CDCl_3$[16] ($T = 300$ K), in which the change in chemical shift of the receptor OH protons was monitored as a function of the concentration of guest, showed the formation of stable 1:1 complexes. The association constants K_a between 90 and 370 L mol^{-1} (Table 3) for the complexes of 1-*O*-octyl glucopyranosides **21**–**23** were obtained by nonlinear least-squares curve fitting of the titration data.[17] Under the same conditions, no significant complexation of these substrates was observed in control runs with (*R*)-(−)-**19**, which demonstrates that OH groups from more than one of the three

Table 2. Selected physical data of (*R,R,R*)-(−)-**3**, (*R,R,R,R*)-(−)-**4**, (*R,R,R,R*)-(−)-**5**, (*R,R,R*)-(−)-**16**, (*R,R,R,R*)-(−)-**17**, and (*R,R,R,R,R*)-(−)-**18** [a].

binaphthyl spacers in (*R,R,R*)-(−)-**3** participate in the binding to the pyranoside in the macrocyclic cavity. The stronger binding of octyl β-D-glucopyranoside (**23**) compared to its anomer **21** seems to reflect the greater amount of intramolecular H-bonding in the unbound α-anomer.[5n, 18] (*R,R,R*)-(−)-**3** shows a modest selectivity between the two enantiomers of octyl α-glucopyranoside.

Binding between (*R,R,R*)-(−)-**3** and 1-*O*-octyl α-D-mannopyranoside **24**[19] was also investigated, but the receptor OH-signal was too broad at ambient temperature; variable temperature studies on this system showed that the complex formed is in exchange with its free components at an intermediate rate on the NMR time scale at room temperature and can be forced into fast exchange by heating to 330 K. Cooling to 240 K gives rise to a very complicated spectrum in which the signals of bound host and guest are very broad, since the low symmetry of the pyranoside is imposed on the resonances of the trimeric receptor. The surprisingly slow exchange kinetics, relative to those observed for pyranoside binding to cleft-type receptors,[5a, n] supports a complex geometry in which the sugar substrate must fully penetrate into the receptor cavity rather than docking onto one of the two receptor faces.

In preliminary studies we have also explored the complexation between the tetraanionic macrocycle (*R,R,R,R*)-(−)-**5** (with four convergent phosphodiester groups) and octyl β-D-glucopyranoside (**23**). The formation of ionic host–guest hydrogen bonds between the phosphates of the receptor and the OH groups of the substrate dramatically increases the complexation strength, which becomes too large to be evaluated by ^{1}H NMR titrations in pure CD_3CN, a much more competitive solvent than $CDCl_3$ for the H-bonding centers of the binding partners.[5a] Complexation occurred even in the presence of a protic cosolvent, and host–guest binding was observed by ^{1}H NMR in CD_3CN solutions containing up to 20% v/v of CD_3OD. The ^{1}H NMR signals of all sugar protons were considerably shifted upfield on complexation: for example at equal concentrations of host and guest of 1.0 mmol L^{-1}, the anomeric CH signal of **23** moved upfield from $\delta = 4.197$ to $\delta = 3.787$ in pure CD_3CN to $\delta = 3.903$ in CD_3CN/CD_3OD 98:2 (v/v), and to $\delta = 4.116$ in CD_3CN/CD_3OD 90:10 (v/v). Attempts at quantitative binding titrations in CD_3CN/CD_3OD 98:2 (v/v) rapidly showed that the receptor tends to form complexes with higher, presumably 1:2 host–guest stoichiometry. When pyranoside **23** was present in excess over the receptor, higher complexation clearly predominated as indicated by the shape of the titration curves.[5a] A host–guest complexation ratio of 1:2 can be readily rationalized by the eight phosphate ester O atoms forming H-bonds to four OH groups of two sugars that presumably dock from opposite faces onto the receptor. At low concentrations with an excess of host (c = 0.5 to 2 mmol L^{-1}) over guest (c = 0.5 mmol L^{-1}), binding titration curves and Job plots suggested the predominant formation of a stable 1:1 complex, and evaluation of the upfield complexation shifts of the anomeric proton H-C(1) ($\Delta\delta_{sat} = 0.27$) and proton H-C(2) ($\Delta\delta_{sat} = 0.15$) yielded a preliminary association constant of $K_a = 15000 \pm 5000$ L mol^{-1} ($\Delta G^\circ = -5.7$ kcal mol^{-1}, $T = 300$ K). In the presence of CD_3OD as a cosolvent, comparison compound (*R*)-(−)-**20** did not show detectable binding to **23**, whereas a weak 1:1 complex was formed in pure CD_3CN ($K_a = 170 \pm 20$ L mol^{-1}, $\Delta G^0 = -3.1$ kcal mol^{-1}).

The preparation of this first class of receptors from the chiral binaphthyl (*R*)-(+)-**6** illustrates the synthetic potential of the large receptor family shown in Scheme 1, and the preliminary binding studies show their recognition potential. The observed complexation of neutral carbohydrates in the presence of a protic cosolvent suggests that, with appropriately designed receptors from this family, complexation of these substrates in aqueous solutions may be achieved in the near future.

Experimental Procedure

Glaser–Hay coupling to form (*R,R,R*)-(−)-**16**, (*R,R,R,R*)-(−)-**17**, and (*R,R,R,R,R*)-(−)-**18**: CH_2Cl_2 (1.0 L, freshly distilled over CaH_2) was added to a mixture of (*R*)-(+)-**6** (150 mg, 0.4 mmol) and freshly prepared [20] copper(I) chloride (2.71 g, 27 mmol). The mixture was stirred under dry air for 10 min (vigorous stirring at this stage reduces the particle size of the copper(I) chloride, which accelerates the reaction when TMEDA is added). TMEDA (4.21 mL, 3.24 g, 28 mmol) was then added, and the reaction mixture turned dark green. After 20 min, TLC analysis (SiO_2, cyclohexane/AcOEt 80:20) showed that there was no starting material left. The reaction was quenched with H_2O (1.0 L) and exhaustively washed with H_2O (3 × 1.0 L) until the CH_2Cl_2 phase was yellow and most of the copper salts had been removed. After evaporation, the product mixture was separated by flash column chromatography (SiO_2, cyclohexane, then cyclohexane/AcOEt 85:15, then cyclohexane/AcOEt 80:20), to give (*R,R,R*)-(−)-**16** (31 mg, 20%), (*R,R,R,R*)-(−)-**17** (31 mg, 20%), and (*R,R,R,R,R*)-(−)-**18** (5 mg, 3%).

Jasmonic Acid and Coronatin Induce Odor Production in Plants

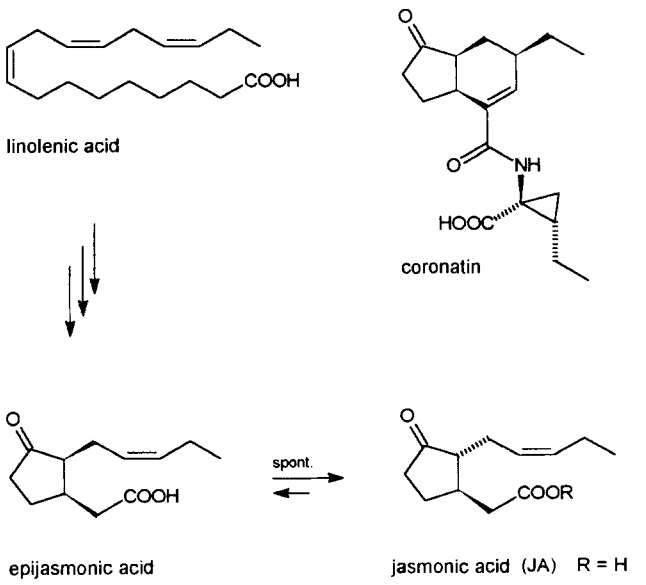
Wilhelm Boland,* Jörn Hopke, Jens Donath, Jörg Nüske, and Friedemann Bublitz

Dedicated to Professor Dieter G. Müller on the occasion of his 60th birthday

Jasmonic acid (JA) and certain derivatives (e.g. methyl jasmonate, JA-Me) play a key role as phytohormones, elicitors, and signal transducers.[1] They are formed from linolenic acid through a known sequence of reactions (Scheme 1)[2] and induce the expression of specific genes in the form of proteins (Jasmonate Induced Proteins, JIPs),[3] which are responsible for a number of effects including defoliation, senescence promotion,[4] and emission of ethylene.[5] Similar, adverse results can be induced by application of the structurally related phytotoxin coronatin, which has been previously isolated from culture filtrates of pathogenic strains of *Pseudomonas syringae*[6] and *Xanthomonas campestris*.[7] Again, the typical effects are chlorose, senescence, and enhanced ethylene production.[8]

In recent years JA has been found to stimulate a number of other effects. Among them, tomato tuber induction,[9] tendril coiling,[10] and the induction of secondary metabolite biosynthesis[11] in cell suspension cultures of *Escholtzia californica* and *Rauvolfia canescens* are particularly noteworthy. Again, similar effects can be triggered by coronatin.[12] Moreover, JA and JA-Me appear to be important stress signals, or signal transducers, in plants' defense against herbivores, since both induce the biosynthesis of proteinase inhibitors.[13,14] Plant defense also involves the release of volatile substances which may act inter alia as intra- or interspecific "SOS signals",[15] attracting predators that prey on herbivores.[16,17]

We report here that the biosynthesis and emission of volatiles can be triggered in many plant species by application of JA and coronatin. The effect is demonstrated in Figure 1 for *Nicotiana tabacum*. Leaves from untreated tobacco plants release volatiles at relatively low levels (Fig. 1A). However, following 30 h of incubation with JA (10 $\mu mol\,mL^{-1}$), supplied through the petiole of a freshly detached leaf, a dramatic increase in the production of a number of volatiles is seen (Fig. 1B). The effect can still be triggered with roughly 100 $nmol\,mL^{-1}$ of JA. An overview of the JA-treated plants, the type of volatiles produced, and the extent to which individual compounds or compound classes are triggered is presented in Table 1. As previously shown for *Phaseolus lunatus* (lima bean) and *Zea mays* (maize), the maximum rate of volatile emission is reached within 20–30 h after application of JA.[18] The volatile substances released can be divided into three classes of compounds: 1) mevalogenins,



Scheme 1. Synthesis of jasmonic acid and methyl jasmonate from linolenic acid and the structure of coronatin.

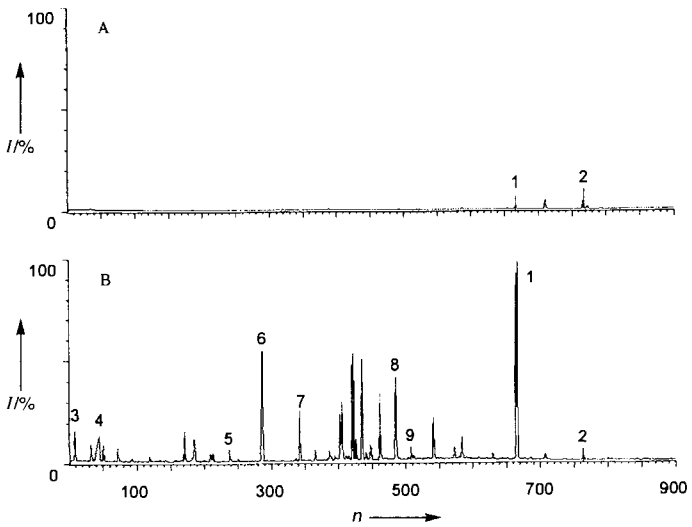


Fig. 1. Gas chromatographic analysis of volatiles from tobacco leaves (*Nicotiana tabacum*) A) untreated, B) after treatment with jasmonic acid. The relative signal intensity *I* is plotted against the number *n* of the scan (1 scan per second). Compounds identified: neophytadiene (**1**), $C_{20}H_{32}$ **2**, (3*Z*)-hex-3-enyl acetate (**3**), oct-1-en-3-ol (**4**), indole (**5**), (3*Z*)-hex-3-enyl tiglate (**6**), β-elemene (**7**), (3*Z*)-hex-3-enyl benzoate (**8**), 4,8,12-trimethyltrideca-1,3,7,11-tetraene (**9**).

mainly mono- and sesquiterpenes; 2) acetogenins, degradation products of fatty acid hydroperoxides (e.g. esters of leaf alcohols and oct-1-ene-3-ol); 3) aromatic compounds (alcohols, esters, and indole).

While the leaves of most plants show significant characteristics of senescence (withering, browning along the vascular bundles) after treatment with JA (>10 μmol mL^{-1}), similar adverse effects failed to appear after treatment with coronatin (50 and 100 nmol mL^{-1}). Experiments were carried out with the lima bean (*P. lunatus*) and maize (*Z. mays*) as two typical representatives of mono- and dicotyledonous plants. In general, coronatin proved to be the superior inducing agent; the threshold concentration for odor induction was roughly 1 nmol mL^{-1}. The pattern of the induced volatiles corresponds to that from treatment with JA, but owing to the low concentrations of coronatin used (50 and 100 nmol mL^{-1}) no senescence promotion was observed.

Strong odor induction by JA in the fern *Dryopteris filixmas* indicates that this signal transduction pathway may be an archetypal development within the phylogeny of plants, which apparently persists even in modern dicotyledonous plants like *N. tabacum* and *P. lunatus*. This is also supported by JA induction of volatiles in the leaves of the pharmacologically interesting gingko tree (*Ginkgo biloba*), the last representative of the genus *Ginkoopsida*. Leaves of the willow tree (*Salix alba*) likewise release volatiles after treatment with JA.

It must be emphasized, however, that the application of JA does not always result in the production and emission of novel compounds; in several cases only the relative composition of the mixture of volatiles is altered (Table 1, *Brassica oleracea*, *Eucalyptus globulus*). It remains to be established whether the production of volatiles is due to activation of the defense genes within the various plants, or if it is a concomitant effect of senescence. Irrespective of the signaling pathway within the plant, it is interesting to see that the JA- or coronatin-induced volatiles from the lima bean (*P. lunatus*) and maize (*Z. mays*) correspond to those typically released in response to an attacking herbivore.[16–18]

The emission of methyl jasmonate (JA-Me) from some of the JA-treated plants (cf. Table 1) appears significant, since gaseous JA-Me has been shown to induce defense reactions in neighboring plants like, for example, the synthesis of proteinase inhibitors[13] and phytoalexins.[10,19] In this respect, the emission of JA-Me may be taken as additional evidence for the involvement of volatile jasmonates in interplant communication. In a similar fashion volatile methyl salicylate (Table 1, *P. lunatus*) may activate defense genes,[20] but this effect still remains to be established.

Odor induction by JA and coronatin provides interesting perspectives. Since the biosynthesis of most of the volatile compounds in Table 1 is known, their detection after JA or coronatin treatment should allow preliminary extrapolations to the enzymatic level and may provide valuable hints for the identification of still unknown JIPs. Other interesting applications may include the attraction of useful insects into crop fields[16,17] threatened by herbivores by preventive induction of volatile synomones and/or resistance genes,[20] and the enhanced production of valuable flavor compounds. Preliminary induction experiments with JA in cell suspension cultures of *N. tabacum* and *P. lunatus* demonstrated, however, that emission of volatiles remains restricted to only a few compounds and does not show the full pattern of compounds from the JA- or coronatin-treated differentiated, intact plant.

Experimental Procedure

Freshly detached plantlets (with 2–5 leaves) of the plants listed in Table 1 were placed in solutions of racemic *trans*-JA (10 μmol mL^{-1}) or coronatin (50 and 100 nmol mL^{-1}) in tap water. Following 10 h of preincubation, the plants were placed in a closed system (ca. 750 mL), and the volatiles were collected on a small charcoal trap (1.5 mg) by air circulation [21] over 20 h. After desorption of the volatiles from the charcoal with dichloromethane (30 μL), the compounds were analyzed by GC-MS (DB1 silica gel capillary column, 10 m × 0.31 mm; temperature program: 50 °C (2 min), then an increase of 10 °C min^{-1} to 200 °C; detection: Fisons MD 800 mass spectrometer, GC interface at 260 °C, scan range: 35–300 Da s^{-1}. The mixture of compounds released from freshly detached plantlets placed in water served as a control. Plants: *P. lunatus* and *Z. mays* were cultivated as described in ref. [18]. *Gerbera jamesonii*, cv. *Sirtaki* was kindly provided by Prof. Dr. M. Dicke, Agricultural University, Wageningen, The Netherlands. All other plants were from the Botanical Garden of the University of Bonn.

Pericyclic Reactions in Nature: Spontaneous Cope Rearrangement Inactivates Algae Pheromones**

Wilhelm Boland,* Georg Pohnert, and Ingo Maier

Dedicated to Professor Hans-Jürgen Bestmann on the occasion of his 70th birthday

Female gametes of marine brown algae use olefinic C_{11} hydrocarbons as chemical signals to trigger the release of and/or attract conspecific flagellated motile male sex cells.[1, 2] In 1971 Müller et al.[3] isolated ectocarpene (**2a**), the pheromone of the cosmopolitan brown algae *Ectocarpus siliculosus*. It soon proved to be the prototype of a whole series of structurally related 6-substituted cyclohepta-1,4-dienes, which attract male gametes or induce their mass release (release factors). The most frequently occurring compounds include dictyotene (**1**),[4] desmarestene (**3**),[5] and lamoxirene (**4**).[6, 7] The latter is typical for the highly evolved order Laminariales, in which the pheromone induces spermatozoid release prior to attraction. The threshold concentration of male response towards the signal is typically found in the range of 10 nmol L^{-1} to 0.01 nmol L^{-1}, depending upon algae species and pheromone function.

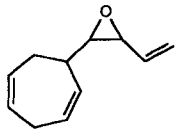
3



4

Recently we have shown that female gametes of marine brown algae use C_{20} fatty acids as starting materials in the biosynthesis of **1** and **2a** (Scheme 1).[8, 9] The precursor of dictyotene (**1**) was shown to be arachidonic acid, whereas ectocarpene (**2a**) was found to originate from *cis*-eicosa-5,8,11,14,17-pentaenic acid (**5**). The first steps of fatty acid activation remain unknown, but by analogy with the biogenesis of **2** in higher plants,[10] a 9-hydroperoxy fatty acid **6** (9-HPEPE) is implicated as the first O-functionalized intermediate. A hydroperoxide lyase could cleave the reactive intermediate 9-HPEPE **6** directly to give the thermally labile *cis*-disubstituted cyclopropane (1*R*,2*S*)-**7a** (C_{11}) and the C_9 dicarbonyl fragment **8** (Scheme 1). Divinylcyclopropanes of type **7** are thermally labile and rearrange in a spontaneous [3,3] sigmatropic reaction

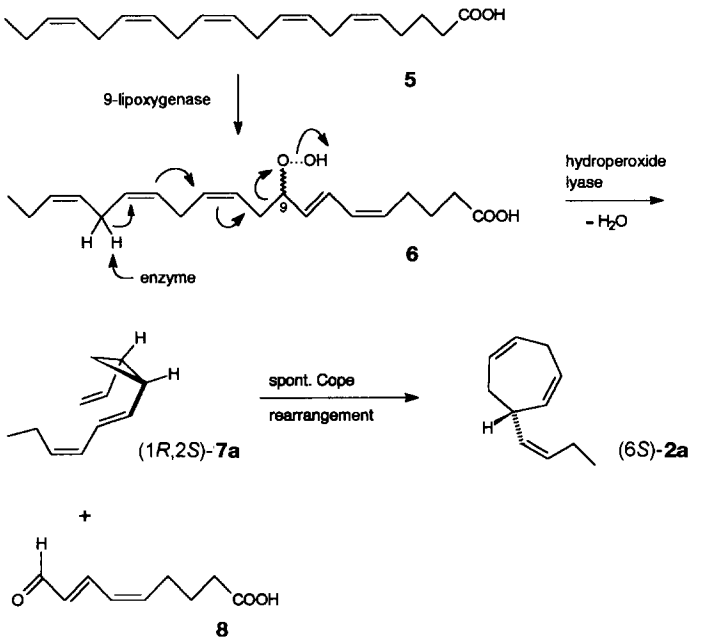
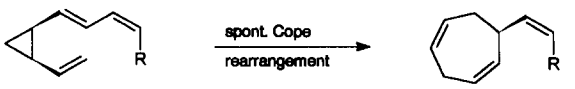


Scheme 1. Postulated mechanism of the biosynthesis of ectocarpene (6*S*)-**2a** from all-*cis*-eicosa-5,8,11,14,17-pentaenic acid (**5**). Activation of **5** by a lipoxygenase yields the 9-hydroperoxide (**6**). Oxidative cleavage of the hydroperoxide by a hydroperoxide lyase is assumed to formally give the C_{11} fragment (1*R*,2*S*)-**7a** and the dicarbonyl compound **8**.

(Cope rearrangement) yielding cyclohepta-1,4-dienes **1**–**4**.[1, 11]

To verify this hypothesis we developed a synthesis of the thermolabile cyclopropanes (1*R*,2*S*)-**7a**, (1*R*,2*S*)-**7b**, and (1*R*,2*S*)-**7c**[12, 13] and determined the activation energies of the Cope rearrangements yielding (6*S*)-**2a**, (6*R*)-**3**, and (6*S*)-**2b**, respectively.[14] Table 1 lists the Arrhenius parameters and half-lives

Table 1. Activation parameters and half-lives for the Cope rearrangement of cyclopropanes (1*R*,2*S*)-**7**.



(1*R*,2*S*)-**7**

Cyclopropane	Cycloheptadiene	R	E_a [kJ mol^{-1}]	ln *A*	$t_{1/2}$(8 °C) [min]	$t_{1/2}$(18 °C) [min]
(1*R*,2*S*)-**7a**	(6*S*)-**2a**	C_2H_5	63.8±1.2	18.9±0.4	56	21
(1*R*,2*S*)-**7b**	(6*R*)-**3**	$CH{=}CH_2$	62.6±1.5	18.5±0.5	45	18
(1*R*,2*S*)-**7c**	(6*S*)-**2b**	H	64.9±1.2	19.0±0.4	77	30

for these transformations at two temperatures typical for the surroundings of marine brown algae (spring temperatures in Arctic and Mediterranean regions). The activation energies are in accord with published data for the unsubstituted *cis*-divinylcyclopropane.[15, 16] In light of these relatively long half-lives for the rearrangement of divinylcyclopropane derivatives (18 to 77 min), the actual nature of the pheromone had to be verified. The cyclohepta-1,4-dienes **1**–**4** had been thought to be the signaling agent, but the question arose as to whether thermolabile precursors like (1*R*,2*S*)-**7a** were actually the active pheromones. Comparative bioassays with male gametes of *Ectocarpus siliculosus* (clone PAr 27a) using (1*R*,2*S*)-**7a** and **2a** showed that only the unstable cyclopropane (1*R*,2*S*)-**7a** was an effective pheromone. In previous work a threshold concentration of approximately 10 nmol L^{-1} of (6*S*)-**2a** in seawater was determined.[17, 18] In contrast, that of (1*R*,2*S*)-**7a** was found to be significantly lower, around 5 pmol L^{-1} (Fig. 1). Even the accumulation factor at the highest available concentration Q_{max} (quotient of the number of cells within a standard area on a pheromone-containing droplet and that on a blank control droplet) for (1*R*,2*S*)-**7a** ($Q_{max} \approx 15$) is significantly higher than that reported for (6*S*)-**2a** ($Q_{max} \approx 2.2$).[17] The efficiency is comparable to that of other known thermostable pheromones of marine brown algae.[18–20]

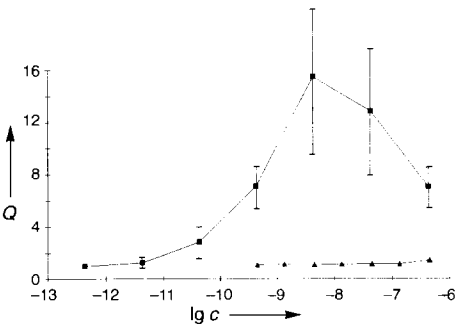


Fig. 1. Biological activity test [21] of (1*R*,2*S*)-**7a** (■) and (6*S*)-**2** (▲) with male gametes of *Ectocarpus siliculosus* (clone PAr-27a♂). The diagram shows a plot of the accumulation factor *Q* against the logarithm of the concentration *c* of (1*R*,2*S*)-**7a** and of (6*S*)-**2** in seawater [19, 22]. Male gametes of the clone used in this test only respond to the highest available concentration of (6*S*)-**2a**.

Pheromone release by female gametes, chemotactic orientation of male gametes, and fusion of the sexual cells all occur within only a few minutes. Thus (6*S*)-**2a**, the rearrangement product of the unstable pheromone (1*R*,2*S*)-**7a**, cannot assume a time-dependent role as a chemical signal; the half-life for the rearrangement of (1*R*,2*S*)-**7a** is significant longer than time required for sexual encounter in algae.

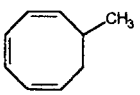
The plot in Figure 1 clearly shows the biological effect of the Cope rearrangement in the rapid, temperature-dependent degradation of the cyclopropyl pheromones. Further (a)biotic degradation to the completely inactive oxygenated products progresses significant slower, taking from hours to days.[1] In their sexual cycle marine brown algae have developed the fastest and most effective mechanism known for spontaneous inactivation of attractant and/or release factors. Furthermore, this is the only known signal system in which deactivation occurs by a [3,3] sigmatropic reaction.

The high biological activity of the disubstituted cyclopropane (1*R*,2*S*)-**7a** provides strong evidence for the proposed model of cycloheptadiene biosynthesis (see Scheme 1) in marine brown algae. In fact, the release of (1*R*,2*S*)-**7a** can even be proved directly by HPLC analysis. An extract from a dense suspension of freshly released female gametes of *E. siliculosus* (ca. 5×10^7 cells) was analyzed by HPLC (RP-18 column). A transient signal was observed, which had the same retention volume and UV absorption (λ_{max} = 246 nm) as the synthetic reference (1*R*,2*S*)-**7a**. In addition, the half-life of the signal given by the natural product corresponded with the decrease in the signal of synthetic (1*R*,2*S*)-**7a** caused by rearrangement to (6*S*)-**2a** (see Table 1).

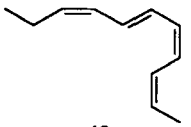
These results suggest that systems in which cycloheptadienes were identified as pheromones or release factors should be reexamined; thermally labile cyclopropyl precursors of type **7** may be the actual pheromones and have even lower threshold con-

centratons. First results on bioassays with fertile male gametophytes of the North Atlantic brown algae *Desmarestia aculeata*, using a thermally stable analogue of **7b** (CH_2OCH_3 instead of $CH{=}CH_2$ at C(2)[19]), showed high activity. Thus for another algal pheromone, a cyclopropane derivative is implicated as an active substance.

A large variety of pericyclic and electrocyclic rearrangements were shown to occur in the biosynthesis of marine brown algae pheromones. For example, 7-methylcycloocta-1,3,5-triene (**9**), a trace component in the pheromone blend of the Mediterranean brown algae *Cutleria multifida*, is believed to be derived from the linear (1,3*Z*,5*Z*,7*E*)-nonatetraene by means of an 8π electrocyclic ring closure reaction. In addition, thalli of fertile *Giffordia mitchellae* release (2*Z*,4*Z*,6*E*,8*Z*)-undeca-2,4,6,8-tetraene (**10**, giffordene). The unusual geometry of this tetraene is produced by a [1,7]-hydrogen shift, which occures spontaneously at ambient temperatures.[1, 20]



9



10

Experimental Procedure

Fertile female gametophytes of *Ectocarpus siliculosus* (ca. 2.1 g fresh weight) were kept for ca. 16 h at 2 °C. Gamete release was then induced by increasing the temperature to 18 °C and exposing the sample to light. In order to obtain a significant accumulation of pheromone, the cell suspension (5.2×10^7 cells in 10 mL of seawater) was concentrated by removing excess seawater and kept under light for 4 h at 4 °C (ca. 70 $\mu mol\,m^{-2}\,s^{-1}$). The suspension was treated with 4 mL of MeOH (0 °C) and extracted with 5 mL of CH_2Cl_2 (0 °C). The organic layer was concentrated to 1 mL at 0 °C and analyzed immediately by HPLC (LiChrospher 100, RP 18, 25 × 0.4 cm; eluent: MeOH:H_2O 9:1; flow rate: 0.5 mL min^{-1}; injection volume: 100 μL; detection: 244 nm). The rearrangement of the thermolabile precursor was followed by stopping the flow at the peak maximum. Comparison of the rate of the extinction decay with the synthetic reference leads to the identification of the natural product.

[22] The actual concentration of the pheromone in seawater is calculated from the concentration of the substance in a biologically inert solvent (perfluorohydrocarbon FC 72, 3M Company, Düsseldorf) and the partition coefficient *K*(FC 72/seawater). The partition coefficient of the unstable (1*R*,2*S*)-**7a** can only be estimated, *K*(FC 72/seawater) ≈ 2000; that of the stable *trans* isomer is 2700. (For comparison: The partition coefficients of the *cis*- and *trans*-disubstituted cyclopentene pheromones [19] are 4800 and 6200, respectively.)

Photoswitchable Electrical Communication of Glucose Oxidase and Glutathione Reductase with Electrode Surfaces through Photoisomerizable Redox Mediators**

Mazzi Lion-Dagan, Sharon Marx-Tibbon, Eugenii Katz, and Itamar Willner*

Reversible photochemical activation and deactivation of biomaterials, especially of enzymes, has recently been a subject of extensive research activity.[1] Photochemical control of enzyme activities was accomplished by chemical modification of the biocatalysts with photoisomerizable components,[2, 3] immobilization of the biocatalysts in photoisomerizable polymers,[4] and by selective association of redox proteins with photoisomerizable monolayer interfaces.[5] Photoswitchable redox enzymes were applied for the amperometric transduction of optical signals and their amplification.[5, 6] Electron transfer communication between redox proteins, for example glucose oxidase or nitrate reductase, and electrode surfaces is mediated by electron relays such as ferrocenes, bipyridinium salts, and quinones.[7–9] The design of photoisomerizable electron mediators could provide a novel means of photochemically controlling redox enzymes, since the photoisomer states of the mediator could be recognized differentially by the biocatalyst. Here we report on the reversible photochemical activation–deactivation of the electrical communication of the redox proteins of glucose oxidase (GOD) and glutathione reductase (GR) with electrode surfaces, using the ferrocene–nitrospiropyran **1a**[10] (for GOD) and *N*,*N*′-bipyridinium-nitrospiropyran **2a**[12] (for GR) as photoisomerizable electron mediators.

The enzymes GOD and GR were organized as multilayer arrays on a base self-assembled monolayer on a rough gold electrode[14] (Scheme 1). The roughness factor corresponded to

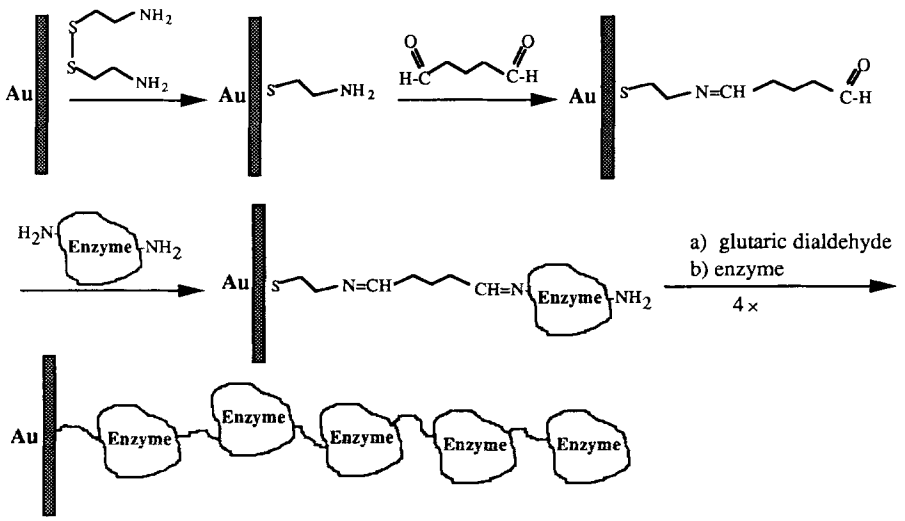

Scheme 1. Organization of enzyme monolayer arrays on the surface of the Au electrode.

20. A cystamine monolayer was assembled on the electrode and subsequently reacted with glutaric dialdehyde. The resulting monolayer was then treated with the respective enzyme. By a two-step procedure involving modification of the enzyme layer with glutaric dialdehyde followed by the reaction with the biocatalyst, a defined number of enzyme layers was constructed onto the base enzyme layer. For the experiments employing GOD and GR, five layers of the respective enzyme were immobilized on the electrodes. It should be noted that this procedure leads to a cross-linked network of the enzyme layers; however, the surface density of the enzyme is similar in each of the assembled layers.[7b]

Ferrocene–nitrospiropyran **1a** and *N,N'*-bipyridinium–nitrospiropyran **2a** can be photoisomerized reversibly. Irradiation of **1a** or **2a** ($360 < \lambda < 380$ nm) results in photoisomerization to the redox-relay merocyanine states **1b** and **2b**, respectively. Further illumination of the merocyanine isomer states with visible light ($\lambda > 475$ nm) restores the ferrocene– and bipyridinium–nitrospiropyrans **1a** and **2a**, respectively. Cyclic voltammetry experiments revealed that the ferrocene–nitrospiropyran **1a** exhibits a reversible oxidation wave at $E^\circ = +0.44$ V (vs. SCE). The bipyridinium–nitrospiropyran **2a** displays a quasi-reversible reduction wave at $E^\circ = -0.535$ V (vs. SCE). The cyclic voltammograms of the ferrocene (Fig. 1) and bipyridinium redox units were unaffected by photoisomerization to **1b** or **2b**, respectively.

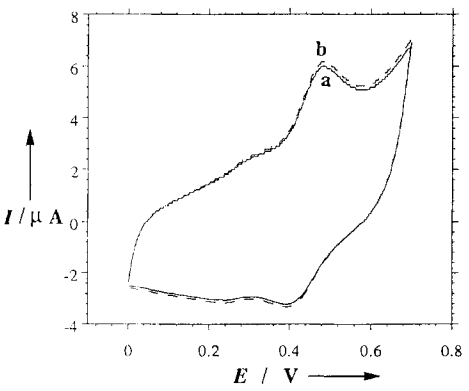

Fig. 1. Cyclic voltammograms of a) ferrocene–nitrospiropyran **1a** (1×10^{-4} M); b) ferrocene–nitromerocyanine **1b** (1×10^{-4} M), Na_2SO_4 (0.05 M), and 0.01 M phosphate buffer, pH 7.0, and 10% v/v ethanol, using the GOD-modified electrode as working electrode. Potential scan rate 100 mV s^{-1}.

Figure 2 shows the steady-state amperometric responses of the GOD multilayer electrode in the presence of the photoisomerizable electron mediator **1** and in the presence of added glucose.[15] In the presence of the electron mediator in the ferrocene–spiropyran state **1a**, addition of 4 mM glucose (addition time indicated by arrow) results in current development in the electrochemical cell (curve a). This implies that electrochemically oxidized **1a** mediates the oxidation of the GOD redox center that biocatalyzes the oxidation of glucose. Irradiation of the electrolyte solution ($360 < \lambda < 380$ nm) followed by isomerization of **1a** to **1b** results in background current (curve b). This result indicates that ferrocene–merocyanine **1b** does not act as electron mediator for GOD, even though it is effectively oxidized to ferrocene–spiropyran cation. Further photoisomerization of **1b** to **1a** by

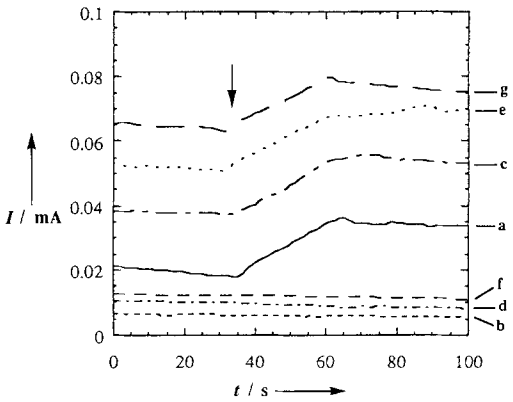

Fig. 2. Amperometric responses of the GOD-modified electrode upon multiple addition of glucose (4 mM; time of addition indicated by arrow). Curves a, c, e, and g correspond to the steady-state currents in the presence of electron mediator **1a** (1×10^{-4} M). Curves b, d, and f correspond to the steady-state currents in the presence of electron mediator **1b** (1×10^{-1} M). Electrolyte solution consists of 0.01 M phosphate buffer, pH 7.0, and 0.1 M Na_2SO_4. Applied potential corresponds to +0.55 V (vs. SCE).

irradiation ($\lambda > 475$ nm) results in the initial amperometric response as a result of electrochemically biocatalyzed oxidation of glucose. Further addition of glucose causes an increase in the current developed in the system (curve c), reconfirming that **1a** acts as electron mediator for the biocatalyst. Subsequent isomerization of **1a** to **1b** restores the background current (curve d). It can be seen that the layered GOD array exhibits electrical communication with the electrode surface when the electron mediator is in the ferrocene–spiropyran state **1a**, whereas electrical interaction is prohibited in the photoisomer state **1b**. The electrical communication of the biocatalyst with the electrode interface can be switched on and off reversibly by photoisomerization of the electron relay. As noted, the redox potential of the ferrocene units in **1a** and **1b** is identical. Hence, only the structural isomerization of the relay units yield the "ON–OFF" electrocatalytic activation and deactivation of GOD.

The activity of glutathione reductase has been photochemically regulated in a similar manner by the application of the

N,N'-bipyridinium–spiropyran **2a** as electron transfer mediator. Previous studies[7c, 16] indicated that the *N,N'*-bipyridinium radical cation acts as an electron transfer mediator for the enzyme that stimulates the reduction of oxidized glutathione [Eq. (a); GSSG = oxidized glutathione, GSH = glutathione, GR = glutathione reductase, V^{2+} = *N,N'*-bipyridinium relay]. The GR multilayered Au electrode (five layers) was used as the working electrode in the electrochemical cell.[15]

$$GSSG + 2V^{\bullet+} + 2H^+ \xrightarrow{GR} 2GSH + 2V^{2+} \quad (a)$$

In the presence of *N,N'*-bipyridinium–nitrospiropyran **2a** in the electrochemical cell, effective electrochemically biocatalyzed reduction of GSSG occurs ($v \approx 6$ mM s^{-1}). Photoisomerization of **2a** to **2b** ($360 < \lambda < 380$ nm) blocks the formation of GSH, implying that the enzyme GR does not electrically communicate with **2b**. Subsequent photoisomerization of **2b** to **2a** restores the electrochemically biocatalyzed reduction of GSSG. Reversible electrical activation–deactivation of the enzyme by photoisomerization of the electron relay through states **2a** and **2b** is feasible (Fig. 3).[17]

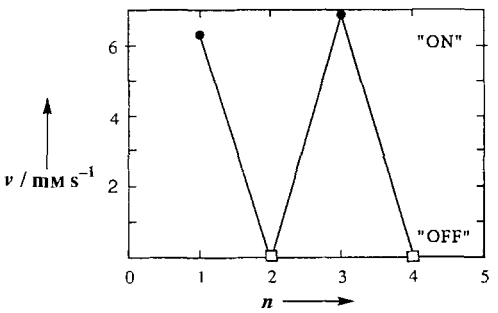

Fig. 3. Cyclic photochemically stimulated formation of GSH by the GR electrode. ●: In the presence of **2a** (1×10^{-4} M); □: in the presence of **2b** (1×10^{-4} M). Applied potential corresponds to −0.62 V (vs. SCE); n = number of cycles; v = rate of GSH formation.

We thus conclude that the application of photoisomerizable redox relays provides a novel means of controlling the electrical communication of redox proteins with electrode surfaces. The photoisomer states linked to the electron mediator control the redox interactions of the charge carrier with the protein (Scheme 2). The specific origin for the lack of electrical interactions between the respective proteins and the redox relay in the merocyanine state is at present unknown. We assume that steric constraints or electrostatic repulsive interactions between the isomers and the proteins or their active-site surroundings prevent the intimate contact of the mediator and the enzyme redox center required for electrical communication.

Reversible Template-Directed Activation of Equatorial Double Bonds of the Fullerene Framework: Regioselective Direct Synthesis, Crystal Structure, and Aromatic Properties of T_h-$C_{66}(COOEt)_{12}$**

Iris Lamparth, Cäcilia Maichle-Mössmer, and Andreas Hirsch*

Multiple additions to the fullerene core are remarkably regioselective.[1, 2] By successive cyclopropanations of equatorial (*e*) 6–6 double bonds we were able to synthesize the T_h symmetric hexaadduct $C_{66}(COOEt)_{12}$ (**1**).[2, 3] The preferred attack of 6–6 double bonds in *e* positions (Fig. 1) relative to addends already bound to the fullerene core can be explained by a consideration of both the thermodynamic stability of the different regioisomers and the enhanced orbital coefficients of frontier orbitals in *e* positions of the corresponding precursor molecules.[2] Meanwhile, other hexaadducts with an analogous addition pattern were synthesized by Diederich et al.,[4] who used spacer-controlled functionalization, and by Kräutler et al.[5] through six [4 + 2] cycloadditions. The facile access to high yields of stable and highly symmetric oligoadducts of C_{60}, which can be further functionalized, plays a very important role, for example, in the field of material science and biological applications of fullerene derivatives and is still one of the major synthetic challenges in fullerene chemistry. In this work we report for the first time on a new and very simple concept of a template-directed activation of the C_{60} framework, which allows the direct synthesis of **1** with very high regioselectivity and yields of up to 50%, as well as on its crystal structure and enhanced aromatic character relative to C_{60}. Furthermore, we show that the stable compound **1** can be transformed quantitatively into the corresponding hexamalonic acid **2**, which is of great importance with regard to modifications of the side chain.

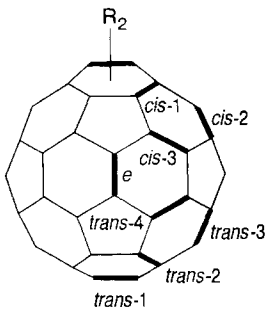

Fig. 1. Positional relationships of the eight different double bonds in a C_{60} monoadduct relative to the 6–6 bond carrying the first addend R_2 (R_2, for example, methylene).

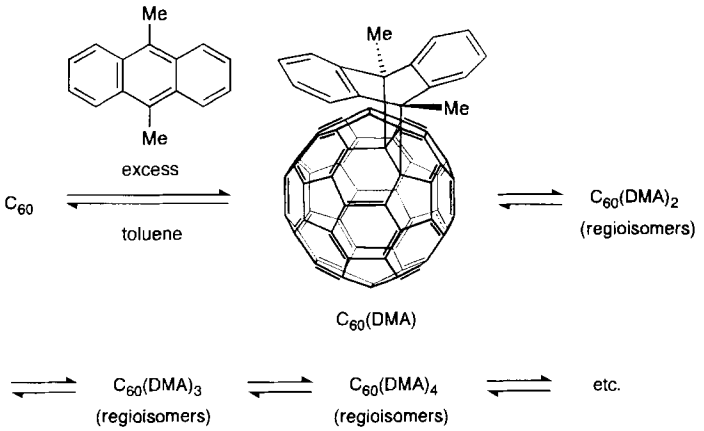
The regioselectivity of attacks to *e* double bonds becomes even more pronounced as the number of addends already bound in *e* positions increases. This is expressed, for example, by further enhanced orbital coefficients in the LUMOs as well as in the HOMOs in these positions.[2] If the formation of adducts is reversible, besides kinetic control, thermodynamic control[6] gains importance. At equilibrium, adducts with incomplete octahedral addition patterns predominate. They can serve as template or matrix for irreversible *e* additions or addend-substitution reactions. Looking for a suitable template intermediate, we found that the reaction of C_{60} and 9,10-dimethylanthracene (DMA) is reversible already at room temperature. Addition of DMA to a solution of C_{60} in toluene causes a slow change in color from purple to chestnut-brown as the corresponding Diels–Alder adducts $C_{60}(DMA)_n$ are formed (Scheme 1). After



Scheme 1.

the equilibrium was established, the dependence of the distribution of adducts on the concentration of DMA was investigated quantitatively with HPLC. The peaks in the chromatograms can be assigned to particular adducts by their UV/Vis spectra,[1, 2] which were recorded simultaneously by diode array scans. An increasing concentration of DMA causes a shift of the equilibrium towards higher adducts. Whereas the addition of only one equivalent of DMA yields C_{60} (40%) and the monoadduct $C_{60}(DMA)$ (48%) as major components besides traces of $C_{60}(DMA)_2$ (7%), the equilibrium shifts towards the higher adducts $C_{60}(DMA)_2$ (52%) and $C_{60}(DMA)_3$ (24%) when 10 equivalents of DMA are added, and no unmodified C_{60} can be detected. The adducts $C_{60}(DMA)_n$ are mixtures of regioisomers predominantly consisting of adducts with an octahedral addition pattern, for example, the C_3 symmetric *e,e,e* isomer in the case of $C_{60}(DMA)_3$, as UV/Vis spectra show. Elevated reaction temperatures shift the equilibrium towards unmodified C_{60}. DMA can be removed from the equilibrium by the reaction with oxygen in laboratory light or with dimethyl acetylenedicarboxylate under formation of the cycloadducts **3** and **4** and of unmodified C_{60} (Scheme 2). The facile formation of the endo-

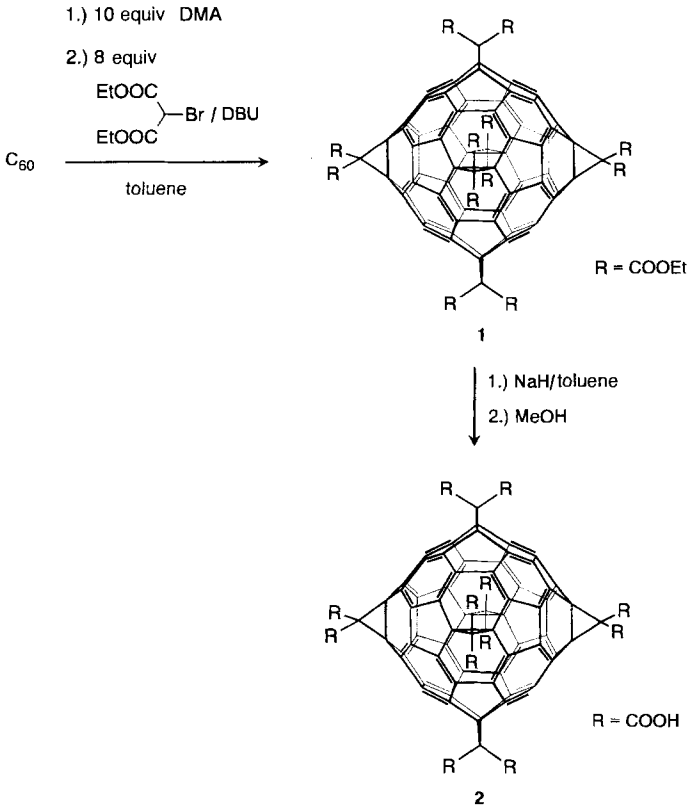
peroxide **3** is promoted by the efficient photosensitizing properties of C_{60} and its derivatives.[7]

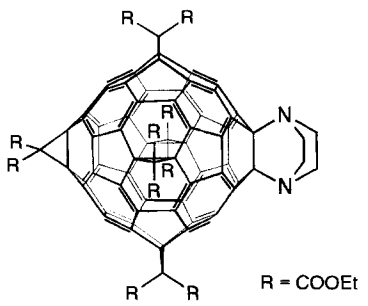
The synthesis of **1** by successive cyclopropanation[1,2,8] of C_{60} with diethyl bromomalonate and NaH without template activation, isolating all intermediate products, gives a total yield of 0.2%. After template activation with DBU (DBU = 1,5-diazabicyclo[4.3.0]non-5-ene) as a base and 10 equiv DMA, the one-step reaction (with 8 equiv diethyl bromomalonate) yields 37% (HPLC) of **1** as the only regioisomeric hexaadduct. Thus, the yield is increased by a factor of 120 (Scheme 3). In addition, a



Scheme 3.

considerable amount of C_{2v}-$C_{65}(COOEt)_{10}$[2] and C_s-$C_{64}(COOEt)_8$[2] with an incomplete octahedral addition pattern is obtained, which can undergo further cyclopropanation and yield another 11% of **1** (total yield 48%). Compound **1** can be isolated from the reaction mixture simply by flash chromatography followed by recrystallization from $CHCl_3$/bromobenzene (1:1). The majority of the free DMA can be recovered. This procedure gives an overall yield of **1** of 23% (based on amount of C_{60}) as light yellow rhombic crystals.

The one-step reaction of C_{60} with 8 equiv diethyl bromomalonate/DBU without template activation proceeds with decreased regioselectivity and with a significantly lower yield of **1** (14%). A considerable amount of $C_{65}(COOEt)_{10}$ possessing a "wrong" (that is, not octahedral) addition pattern and of $C_{67}(COOEt)_{14}$ having C_1 symmetry and not being formed from **1**[9] is obtained. Without template activation a pronounced proportion of the successive cyclopropanation of C_{60} proceeds along different channels. This is plausible, as the least regioselective step is the formation of the bisadducts $C_{62}(COOEt)_4$.[1] Among eight possible regioisomers the *e* isomer C_s-$C_{62}(COOEt)_4$, a precursor molecule of **1**, is the main product (relative yield 38%), but 60% of the products are five other isomers from which **1** can not be formed.[10] Thus, the decisive advantage of template activation of C_{60} with DMA is that the reversible formation of adducts guarantees large amounts of *e*-$C_{60}(DMA)_2$ and *e,e,e*-$C_{60}(DMA)_3$ from which **1** can be formed with very high regioselectivity. Furthermore, if, for example, *e,e,e*-$C_{60}(DMA)_3$ is cyclopropanated in a position other than *e*, the DMA addends can rearrange to an isomer with complete octahedral addition pattern because of the reversibility of adduct formation. The principle of template activation offers facile access to the high-yield synthesis of mixed adducts with octahedral addition patterns. For example, the reaction of the monoadduct C_{2v}-$C_{60}(N_2C_4H_8)$[11] (fulleropiperazine) with diethyl bromomalonate/DBU in the presence of 10 equiv DMA gives a 27% yield (according to HPLC) of the mixed hexaadduct **5**.[12]



The crystals of **1** grown from a $CHCl_3$/bromobenzene solution are in the triclinic space group $P\bar{1}$ and contain two molecules of bromobenzene in the unit cell.[13] The molecular structure (Fig. 2) confirms the results of NMR investigations[2] of **1** according to which the cyclopropanated bonds of C_{60} are single bonds ($d = 1.59$ Å), and the fullerene core is closed. Very remarkable is the bonding in the remaining π-electron system of

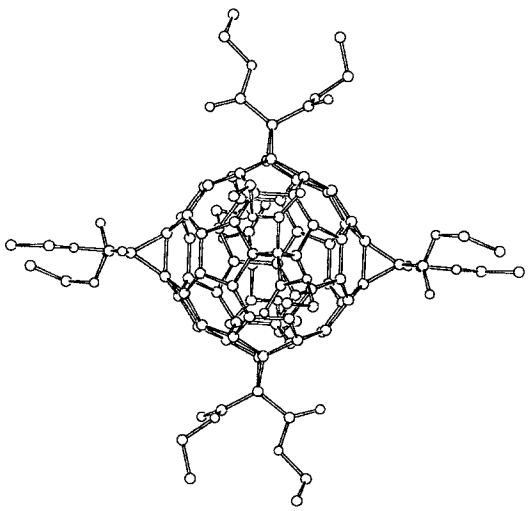


Fig. 2. Crystal sructure of **1**. The two bromobenzene molecules per unit cell are omitted for clarity.

1 which is a new type of an oligocyclophane[2,4-6] (Fig. 3). The alternation of bond lengths between 6–6 bonds and 5–6 bonds characteristic of unmodified C_{60}[14] is reduced by half to approximately 0.03 Å in **1**. A resulting increase of the benzenoid character is manifested in the optical properties of compound **1**. Relative to solutions of C_{60} (purple) or its adducts $C_{61}(COOEt)_2$ to $C_{65}(COOEt)_{10}$ (red to orange) the light yellow solutions of **1** show only weak absorption bands in the visible region of the spectrum ($\varepsilon_{vis} < 2400$). The mixed adduct **5** has

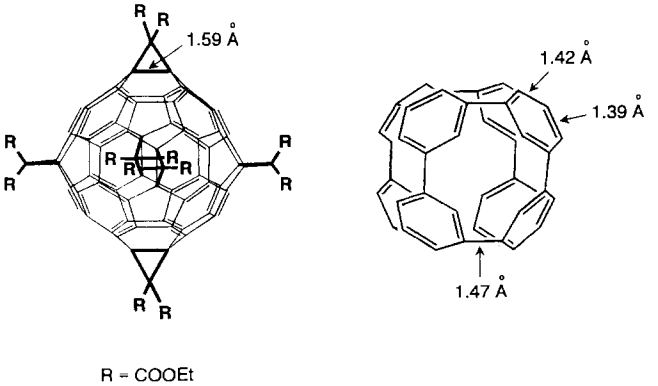

Fig. 3. Schematic illustration of **1** with selected bond lengths and of the remaining benzenoid π-electron system.

similar optical properties. Remarkably, the color of C_1-$C_{67}(COOEt)_{14}$ is again orange, because no truly benzenoid substructures can be formed within the fullerene framework.

The hexamalonate $C_{66}(COOEt)_{12}$ (**1**) is stable towards light, air, and moisture. This is essential for further side-chain chemistry as well as for potential practical applications. In fact, if **1** is treated with NaH and methanol[15] it can be transformed easily and quantitatively into the corresponding highly water-soluble hexamalonic acid derivative **2**[16] (Scheme 3). This compound has ideal features for use as a building block for dendrimers, as a buffer system, or as a starting molecule for the synthesis of biologically active fullerene derivatives.

Diodelike Current–Voltage Curves for a Single Molecule—Tunneling Spectroscopy with Submolecular Resolution of an Alkylated, *peri*-Condensed Hexabenzocoronene**

Andreas Stabel, Peter Herwig, Klaus Müllen,* and Jürgen P. Rabe*

The spectroscopy of single molecules in a defined environment is of relevance not only as a tool in future molecular electronics.[1] A single molecule dispersed amongst many others in an amorphous matrix can be selected by laser spectroscopy on account of its specific surroundings.[2] Single molecule detection is achieved by optical spectroscopy in an extremely small sample volume of a highly diluted substance. In the nearfield optical microscope this volume can be as small as 100 nm^3, which is still sufficient for a satisfactory distinction from the background.[3] These methods do, however, not allow for a spatial localization of the molecule. One method that circumvents this shortcoming is the local excitation of luminescence with the help of a scanning tunneling microscope.[4] Another method is tunneling spectroscopy of single molecules. At submolecular resolution this technique offers a way to chemically identify individual molecular moieties. It consists of immobilizing the molecules on a solid surface, imaging them by scanning tunneling *microscopy* (STM), and then performing tunneling *spectroscopy* (STS) at a specific location. While scanning tunneling microscopy of molecules has evolved into a precise and widespread method,[5] few reliable results have been published for spatially resolved tunneling spectroscopy. Most of them concern investigations on Si and GaAs in ultrahigh vacuum, for which detailed spectroscopic data obtained by classical methods of surface science

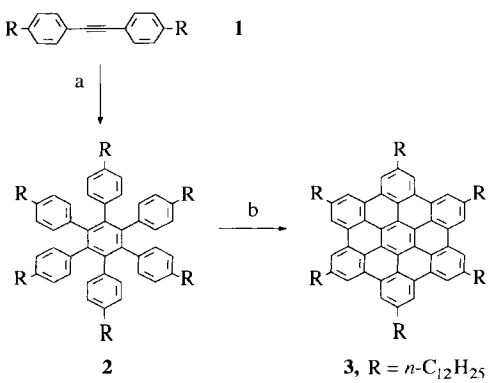
were already available.[6] Tunneling spectroscopy investigations on molecular systems were commonly presented without concomitant molecular resolution STM imaging.[7, 8] This limitation arises because, in general, the sharpest, highest resolution tips are the most likely to give unreliable tunneling spectra.[9] One possible reason for this behavior is the strong influence that an unusually bound single atom at the very end of the tip has on tunneling spectra. In the case of a blunter tip, the influence of such an atom diminishes. These tips are therefore the most likely to give consistent current–voltage (*IV*) curves. The price for reproducible tunneling spectra is therefore paid in a reduced spatial resolution and, consequently, in the limitation to spatially extended molecular moieties.

We therefore set out to obtain reproducible tunneling spectra of molecules exhibiting two electronically different and spatially extended moieties. We chose alkylated polycyclic arenes. The energy of the molecular electronic states of the alkyl part of these molecules is far from that of the Fermi level of the electrodes, while the energy of the highest occupied molecular orbital (HOMO) of the aromatic core can quite easily come close to it.

1,4-Didodecylbenzene,[10] 1,5-dihexadecyloxynaphthalene,[11] and hexakis(hexadecyloxy)triphenylene[12] had already been shown to adsorb from organic solutions onto the basal plane of graphite in ordered two-dimensional structures. In our search for spatially more extended molecules, we investigated 3,10-didodecylperylene.[13] Tunneling spectroscopic investigations from +1.5 V to −1.5 V reveal that the *IV* curves are asymmetric, with a higher current at positive tip bias. These characteristic curves can be unequivocally and reproducibly distinguished from *IV* curves of simple alkanes. However, we could not unambiguously assign different *IV* curves to the alkyl and the aromatic moieties. This led us to synthesize a spatially even more extended, alkylated polycyclic arene. The alkyl side chains should, on one hand, guarantee the processability of the substance from solution, and on the other, favor the formation of adlayers on graphite. We decided to synthesize an alkyl-substituted, *peri*-condensed hexabenzocoronene (**3**). This substance was until now only known in its unsubstituted, insoluble form.[14]

The synthesis (Scheme 1) begins with 4,4′-di-*n*-dodecyltolane (**1**),[15] which is easily obtainable in four steps.[16] Tolane **1** is then cyclotrimerized[17] under the catalytic action of $[Co_2(CO)_8]$. The resulting hexa(4-dodecylphenyl)benzene (**2**)[18] is readily soluble in organic solvents. In the next step **2** is cyclodehydrated under oxidative conditions ($Cu(CF_3SO_3)_2/AlCl_3$, CS_2, 25 °C).[19] The yield of the target molecule **3** is relatively low (49%), because intermolecular aryl–aryl couplings and dealkylation could not be suppressed. The new substance **3** is soluble in various organic solvents at room temperature already and can therefore be comprehensively characterized (see Experimental). The cyclovoltammetric determination of the first reduction potentials shows the reversible formation of the mono- and dianion ($E^1_{1/2} = -2.12$ V, $E^2_{1/2} = -2.36$ V). Oxidation occurs at $E^1 = +1.01$ V and $E^2 = +1.42$ V and is irreversible, because an insoluble film forms on the electrode.



Scheme 1. a) $[Co_2(CO)_8]$, dioxane, 100 °C (92% yield); b) $Cu(CF_3SO_3)_2/AlCl_3$, CS_2, 25 °C (49%).

Structural investigations by electron diffraction experiments (LEED) of monolayers of unsubstituted *peri*-condensed hexabenzocoronene (R = H in **3**) on highly oriented pyrolytic graphite (HOPG) have been reported.[20] Since it lacks an aliphatic moiety, however, this molecule is not suited for locally differentiating tunneling spectroscopy. In the STM images of the alkylated *peri*-condensed hexabenzocoronene **3** (Fig. 1a), the bright areas (high tunneling current) correspond to the aromatic cores, while the dark areas (low tunneling current) correspond to the aliphatic part of the two-dimensional lattice.[5] As indicated in Figure 1b, the adsorbed alkyl chains have a preferential direction parallel to one of the main axes of the underlying graphite lattice. Because the depicted packing results in some free volume, the alkyl chains fill this space dynamically by utilizing the thermal energy kT at room temperature. The unit cell drawn in Figure 1 ($a = 1.94$ nm, $b = 2.64$ nm, $\gamma = 80°$) reveals that the sixfold symmetry of the molecule has been reduced to a twofold symmetry of the adsorbate lattice. This phenomenon of symmetry reduction was previously known from the system hexakis(hexadecyloxy)triphenylene–HOPG.[12] The current–voltage curve **a** in Figure 2 was taken above the aliphatic part marked by A in Figure 1a. The broken black lines show the *IV* curves with the bias values scanned from minus to plus; the grey lines document the backscans. Curve **a** is symmetric with respect to the origin. It can therefore not be distinguished from an *IV* curve taken on pure graphite covered only by a thin film of solvent.[13] The energy of the highest occupied molecular orbitals (HOMO) of alkanes is so far from that of the Fermi level of the electrodes that a coupling of these states during a scan of ±1.5 V to the tunneling current seems extremely unlikely.[21] The curve **b** in Figure 2 was taken above the aromatic core of a molecule of **3** marked by B in Figure 1a. Contrary to curve **a**, it exhibits a strong asymmetry. The diodelike shape reveals a factor of asymmetry of approximately one order of magnitude with respect to the maximal current values.

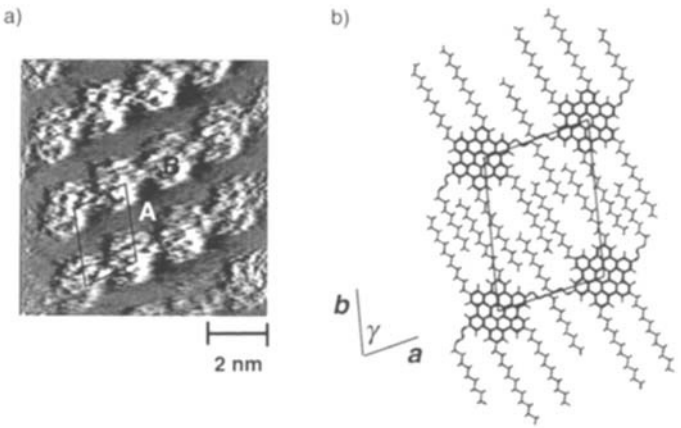


Fig. 1. a) STM image of **3** on HOPG with unit cell depicted. $U_T = 0.9$ V, $I_T = 0.5$ nA. b) Close packed model of a two-dimensional crystal of **3**.

A detailed explanation has still to be elaborated; nevertheless, two factors seem to be responsible for the observed asymmetric

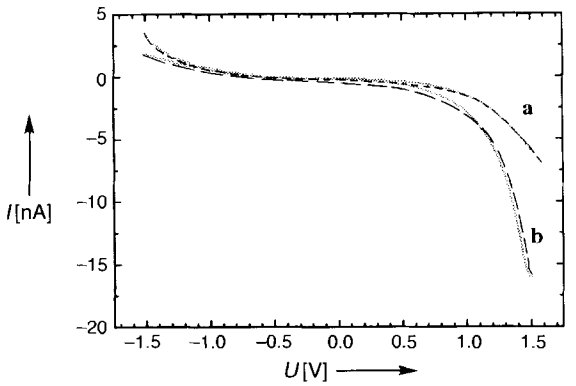

Fig. 2. a) Current–voltage curve of **3**: **a)** symmetric for the alkyl part; **b)** diodelike curve for the aromatic part of the molecule.

behavior.[13] The position of the HOMO within a range of ± 1.5 V about the Fermi level of the electrodes makes a resonant tunneling current possible.[22] This has been demonstrated by Fischer et al. who investigated a Langmuir–Blodgett film consisting of a few monolayers of an octasubstituted palladium–phthalocyanine (PcPd) and a perylene 3,4,9,10-tetracarboxydiimide (PTCDI) sandwiched between two evaporated gold electrodes.[23] The HOMO of **3** lies within a few tenths of an electron volt from the HOMO of PTCDI and PcPd.[23–25] The Fermi level of the employed Pt/Ir electrodes is also close to that of gold (about 5 eV). A resonant amplification of the tunneling current is therefore possible in the present case. Secondly, the asymmetric position of the benzocoronene layer in the tunneling gap plays an important role. At a relatively high tunneling resistance (in our case approx. 650 MΩ before the interruption of the feedback loop), the adsorbate layer is closer to the substrate than to the tip.[26] In contrast with the symmetric experiments of Fischer et al., who obtained symmetric *IV* curves, the break in geometric symmetry in our experiment entails an asymmetric current response of the system.

The observed asymmetry is similar to the one detected by Pomerantz et al. for copper–phthalocyanine on oxidatively modified graphite.[7] They could not, however, image the molecules with STM and were therefore not able to present laterally resolved *IV* spectra on a molecular scale. The present work on the other hand proves that STS can, in principle, be employed for chemical recognition of extended molecular moieties. Furthermore it could be shown that an *IV* curve, caused by the properties of a single molecule of *peri*-condensed hexabenzocoronene in contact with two electrodes, resembles that of a diode.

Experimental Procedure

Spectroscopic data of **3**: ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.14(s, 12H), 2.90(t, 12H), 1.93(m, 12H), 1.63(m, 12H), 1.54(m, 12H), 1.40(m, 84H), 0.90(t, 18H); ^{13}C NMR(125 MHz, $CDCl_3$): δ = 138.2, 128.1, 121.7, 119.5, 117.8, 36.1, 31.4, 30.9, 29.1, 28.9, 28.88, 28.8, 28.7, 28.3, 21.6, 13.0); UV/Vis: λ_{max} (ε) [nm] = 447 (2930), 440 (3044), 391 (53682), 374 (193444), 352 (101007).

For a tunneling spectroscopic investigation, a monolayer of **3** adsorbed on graphite from solution is first imaged by STM. For this a drop of a saturated solution of **3** in 1,2,4-trichlorobenzene is placed on the basal plane of graphite by means of a Pasteur pipette. The two-dimensional crystallization was induced by a bias pulse between tip and sample (10 V/150 ns). The STM images were obtained with a home-built instrument [27] in the constant height mode under ambient conditions (scan rate: 0.3 Hz/image, tip bias: positive, Pt/Ir tip; cut). They were recorded on videotape in real time and digitalized later. No digital image processing was performed.

In the dynamic scan mode the molecular moiety to be analyzed is brought into the center of the image. The x and y scanning is then reduced stepwise to zero. As a consequence, the tip slides into the center of the image. The feedback loop is then interrupted, and the tip fixed at a constant distance of a few nanometers from the sample. Subsequently a voltage ramp between -1.5 V to $+1.5$ V is applied, and the current response registered on a digital oscilloscope (LeCroy9400). The ramp is repeated between twelve and sixteen times within a time slot of 60 ms to 80 ms. The current signal that has been read out is then subdivided into the individual cycles, which are then used to compute an averaged *IV* curve. After the measurement the feed back loop is reactivated, and scanning in both x and y directions picked up again. An image appears again. A complete cycle image measurement–image takes about eight seconds.

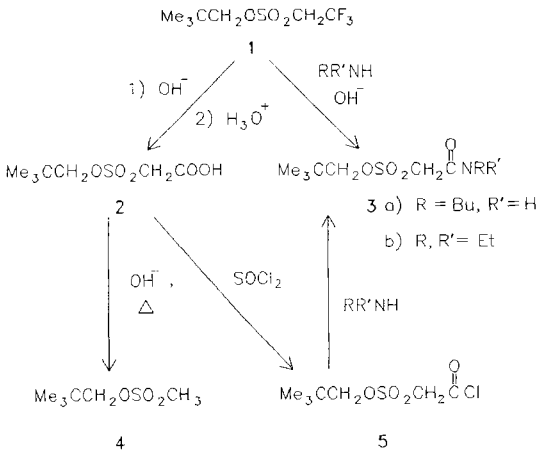
Reactions of Neopentyl 2,2,2-Trifluoroethanesulfonate (Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose**

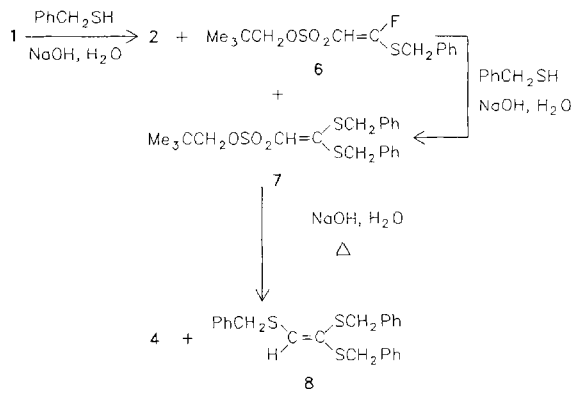
James F. King* and Manjinder Singh Gill

Recently, Demiroglou et al.[1] presented evidence for the need to revise the previously held picture of the reactions of 2,2,2-trifluoroethanesulfonyl (tresyl) agarose with nucleophiles such as hydroxide, thiolate anions, and primary amines. Though they showed clearly that the reaction does not go by a simple S_N2 displacement at carbon, the revised structures that they proposed for the coupled products, an alkylsulfuric acid, a dialkyl thiosulfate, and a dialkyl sulfamate, respectively, appeared to us to be incorrect, justifiable neither by precedent nor by the well-established principles of reaction mechanisms. It seemed much more likely that the attachment of nucleophiles would occur by way of some form of the β-elimination/Michael-type addition sequence shown by Stirling[2] for compounds of the general structure $-SO_2-\underset{|}{C}H-\underset{|}{C}-Lg$ (Lg = leaving group). Related conversions, for example, of tresyl fluoride into sulfoacetic acid and related products,[3] and a tresylate ester into a mesylate ester have been reported.[4] We now describe experiments with neopentyl tresylate (**1**), a model system chosen to 1) avoid the problems of determining the structures of polymers, 2) be unlikely to show S_N2 reactions at the primary carbon,[5] and hence 3) be well set up to show the coupling reactions of tresyl agarose with amines and thiols.

The reactions of **1** and further interconversions of the products are shown in Schemes 1 and 2; structural assignments of new compounds are supported by ^1H NMR, ^{13}C NMR, and IR spectra and exact mass determinations (Table 1). Structure **2** for the product of the reaction of **1** with hydroxide follows from its decarboxylation to neopentyl mesylate (**4**). Conversion of **2** via the acid chloride **5** into the amides **3a** and **3b** confirm these as the products of the reaction of **1** with butylamine and diethylamine, respectively.



Scheme 1. Reactions of neopentyl tresylate (**1**) with amines and hydroxide, and further transformations.



Scheme 2. Reactions of **1** with phenylmethanethiol and hydroxide, and further reactions.

Table 1. Characterization of new compounds.

[a] Prepared by the general procedure in ref. [7].

The composition of the product from reaction of **1** with NaOH and phenylmethanethiol varied with the relative amounts of the reactants. With one equivalent of the thiol the product mixture consisted of **2**, the stereoisomeric fluoromonosulfides (*E*)-**6** and (*Z*)-**6**, and the ketene dithioacetal **7** in a 3:3:1:3 ratio. With three equivalents of the thiol the product was mainly **7** (80% yield). The structure of **7** follows from its mode of formation and spectra, as well as its slow transformation with NaOH in hot aqueous dioxane into neopentyl

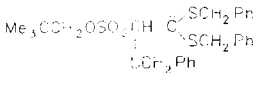
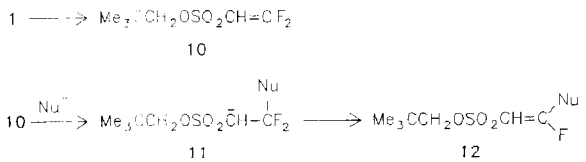
mesylate (**4**); this reaction presumably takes place by way of **2**, which readily yields **4** under these conditions. The structure of **6** is clear from spectra and its ready conversion with the thiolate to **7**; the *trans* orientation ((*E*)-**6**) of the hydrogen and fluorine atoms is assigned to the isomer with the larger H–F coupling. Formation of **8** is readily accounted for by reaction of **7** with $PhCH_2S^-$ (produced along with **4**), presumably by way of **9** formed by addition of $PhCH_2S^-$ to **7**, followed by loss of the alkylsulfite anion. In a separate experiment, **7** on reaction with $PhCH_2SH$ and aqueous NaOH, gave **8** in good yield. The identity of **8** was confirmed by synthesis from trichloroethylene and $PhCH_2S^-$ by a known general method.[8]



9

The production of **2**, **3**, **6**, and **7** from **1** is easily rationalized by assuming initial conversion of **1** by an E1cB process into **10** (Scheme 3), which may undergo Michael-type addition–elimination as in the sequence **1**→**10**→**11**→**12**; repetition of the addition–elimination and (or) hydrolysis leads to the products.



Scheme 3. The initial elimination–addition sequence of the reactions of **1**.

Although any extension of our solution chemistry to the solid phase must be made with caution, we conclude that in the light of our results with neopentyl tresylate the structures proposed by Demiroglou et al.[1] are extremely unlikely. The published information[1] on the products of the reactions of tresyl agarose appears to be consistent with their having the structures $RO\text{-}SO_2CH_2COOH$ (reaction with NaOH), $ROSO_2CH_2CONHBu$ (reaction with $BuNH_2$), and almost equal amounts of $RO\text{-}SO_2CH{=}C(SBu)_2$ and $ROSO_2CH_2COOH$ (reaction with BuSH).[9] These model experiments provide critical information for the understanding of the tresyl agarose reactions and the basis of the chromatographic utility of these products.

Experimental Procedure

Except where otherwise noted the reaction products were characterized by at least ^1H and ^{13}C NMR spectra (see Table 1).

1 → **2**: A mixture of **1** (112 mg, 0.48 mmol), 1 M aqueous NaOH (2 mL), and dioxane (1 mL) was stirred at room temperature for 1 h; workup gave **2** as a white solid (90 mg, 90%).

2 → **4**: A mixture of **2** (13.2 mg, 0.06 mmol), 1 M NaOH (0.3 mL),and dioxane (0.5 mL) was heated at reflux for 2 h. The reaction mixture was cooled and extracted with $CDCl_3$ (1 mL). The ^1H NMR spectrum showed signals due to **4**; comparison of their integrals with those from added toluene (7 μL) showed the yield of **4** to be 60%. Evaporation of the solvent gave a clear liquid; its ^1H NMR spectrum showed only **4** with a trace of unconverted **2**.

1 → **3**: A solution of **1** (255 mg, 1.09 mmol) in dioxane (0.8 mL) was added to a stirred solution of 1 M NaOH (2 mL) and butylamine (0.1 mL, 1.0 mmol) at 0 °C. The mixture was stirred for 1 h and then worked up to give an oil; its ^1H NMR spectrum showed it to be a 1:1 mixture of **2** and **3a**. Preparative thin-layer chromatography (tlc) (silica gel) with elution with a 1:2 mixture of EtOAc and petroleum ether (b.p. 30–60 °C) gave **3a** as a white solid (80 mg, 28%), which was recrystallized from ether/petroleum ether; m.p. 48–50 °C. A similar mixture of **1** (67 mg, 0.29 mmol) 1 M NaOH (0.72 mL), diethylamine (90 μL, 0.87 mmol) in dioxane (0.7 mL), after 40 min reaction, gave a clear liquid, its ^1H NMR spectrum showing the presence of **3a** with traces of **2**; removal of the latter by washing with aqueous NaOH (pH 12–13) gave **3b** (60 mg, 80%).

2 → **5** → **3**. Thionyl chloride (5 mL) containing **2** (288 mg, 1.37 mmol) was heated at 50–55 °C with stirring for 4.5 h. The excess $SOCl_2$ was removed under reduced pressure to leave **5** as a light brown solid (228 mg, 73%). A solution of **5** (100 mg, 0.44 mmol) in CH_2Cl_2 (1 mL) added dropwise with stirring to butylamine (0.22 mL, 2.2 mmol) in CH_2Cl_2 at 0 °C gave, after 3 h, **3a** (81 mg, 75%). Similar reaction of **5** with Et_2NH gave **3b** (75 mg, 65%).

1 → **2** + **6** + **7**: A dioxane solution (1 mL) of **1** (200 mg, 0.85 mmol) was added with stirring to $PhCH_2SH$ (100 μL, 0.85 mmol) in a mixture of 1 M NaOH (1.9 mL) and dioxane (0.5 mL) at room temperature. Workup after 1 h gave an oil (0.30 g); its ^1H NMR spectrum showed it to consist of **2**, (*E*)-**6**, (*Z*)-**6**, and **7** in a 3:3:1:3 ratio. The acid (**2**, 50 mg, 28%) was removed by washing a CH_2Cl_2 solution with 0.25 M NaOH, and the neutral components were separated by preparative tlc; elution with a 1:8 mixture of EtOAc and petroleum ether (b.p. 35–60 °C) gave (*Z*)-**6** (17 mg, 6%) as the faster moving band and a mixture of (*E*)-**6** and **7** as the slower. The latter mixture was separated into (*E*)-**6** (faster) (43 mg, 16%) and **7** (75 mg, 21%) on further tlc (elution three times with CH_2Cl_2/petroleum ether 1:2).

1 → **7**: A dioxane solution (1 mL) of **1** (106 mg, 0.45 mmol) was added to $PhCH_2SH$ (160 μL, 1.36 mmol) in 1 M NaOH (1.14 mL). A white precipitate appeared after 3–5 min; workup after 15 min, and recrystallization from Et_2O gave **7** (154 mg, 80%).

7 → **4** + **8**. A mixture of **7** (36 mg, 0.09 mmol), 6.6 M NaOH (6.5 mL, 43 mmol) and dioxane (3 mL) after 6 h at reflux gave a product identified by its ^1H NMR spectrum as a 1:4:4 mixture of **4**, **7**, and **8**.

7 → **8**. A dioxane solution (1 mL) of **7** (36 mg, 0.09 mmol) was added to a solution of $PhCH_2SH$ (68 μL, 0.58 mmol) in 6.6 M NaOH (1 mL) under N_2, and the mixture was heated at reflux for 2 h; the oily product on tlc (elution with EtOAc/petroleum ether, 1:10) gave **8** as a light yellow oil (25 mg, 74%), identical to that prepared by heating a mixture of trichloroethene (1.37 g, 10 mmol) in absolute EtOH (15 mL) at reflux with $PhCH_2S^-Na^+$ (38 mmol) for 21 h under N_2 [8].

(*Z*)-**6** → **7**. A solution of (*Z*)-**6** (10 mg, 0.03 mmol) in dioxane (50 μL) was added to a mixture of 1 M NaOH (140 μL) and $PhCH_2SH$ (20 μL, 0.15 mmol). Workup after 15 min gave a product (10 mg, 75%) with a ^1H NMR spectrum identical to that of **7**.

(*E*)-**6** → **2** + **7**. A mixture of (*E*)-**6** (14 mg, 0.04 mmol), 1 M NaOH (100 μL), and dioxane (50 μL) was stirred at room temperature for 11 h, giving on workup a product (12 mg) that showed ^1H NMR signals appropriate for unconverted (*E*)-**6**, **2**, and **7** in a 1:1:1 ratio.

[5] Recently we found that the use of a bulky group to suppress the S_N2 reaction at carbon is unnecessary, and that ethyl, isobutyl, and octyl tresylates give reactions like those in Schemes 1 and 2. Genuine S_N2 reactions at the carbon atom of a primary tresylate with relatively weakly basic nucleophiles (azide anion, thiourea) are known [6].

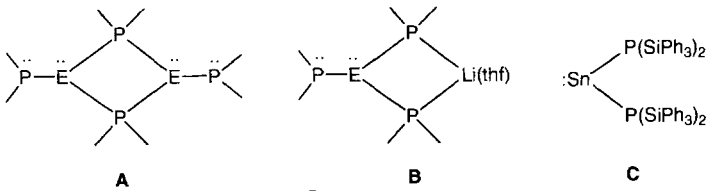
[9] Among other more likely structures for possible components of the thiolate reaction are $ROSO_2CH{=}CF(SBu)$, the analogue of **6** that would account for residual fluorine in the product, and $RSO_2CH_2C(SBu)_3$, the trithioorthoester, an analogue of which is found as a minor product from isobutyl tresylate and the major product (53% vs 41% for the ketene dithioacetal) in the reaction of ethyl tresylate with three equivalents of $PhCH_2S^-$ (cf. ref. [5]); the ^1H NMR spectrum of this last product also indicated the presence of a small amount (about 6%) of the simple thioether, $EtSCH_2Ph$. Prof. H. P. Jennissen has kindly shown us solid phase ^{13}C NMR spectra that he obtained from the *N*-butyl and *S*-butyl agarose materials. The spectrum of the former appears in accord with the amide structure ($ROSO_2CH_2CONHBu$) along with a smaller amount of the acid ($ROSO_2CH_2COOH$). The *S*-butyl agarose spectrum shows fewer well-defined signals, perhaps suggesting (when taken with other information) that the product composition may be complex, including probably $RO\text{-}SO_2CH_2COOH$, and some (or all) of the following: $ROSO_2CH{=}CF(SBu)$, $ROSO_2CH{=}C(SBu)_2$, $ROSO_2CH_2C(SBu)_3$, $ROSO_2CH_2COSBu$, and even possibly the thioether, RSBu.

Diphosphanyl- and Diarsanyl-Substituted Carbene Homologues: Germanediyls, Stannanediyls, and Plumbanediyls with Remarkable Electronic Structures**

Matthias Driess,* Rudolf Janoschek,* Hans Pritzkow, Stefan Rell, and Uwe Winkler

Dedicated to Professor Egon Uhlig on the occasion of his 65th birthday

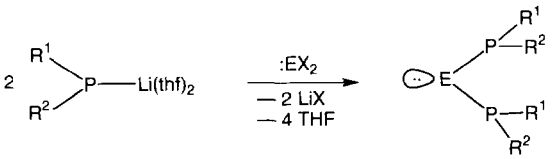
Compounds with multiple bonds (π-electron systems)[1] and subvalent compounds (carbene analogues)[2] of the heavy main group elements (period > 3) differ fundamentally from those of the elements of the second period with respect to their electronic structure.[3] This is illustrated impressively, for example, by carbene homologues which, in contrast to methanediyl, have a singlet ground state (S_0). The synthesis of thermally stable compounds of the form $:EX_2$ with η^1-bound ligands X (germanediyls,[4] stannanediyls,[5] and plumbanediyls[6]) has enabled extensive preparative and theoretical investigations.[7] The focus of these studies has been the influence of the electronic structure (singlet triplet (S/T) separation) on the reactivity (dimerization and cycloaddition behavior). The results have demonstrated that the carbene homologues are monomeric and show no tendency to oligimerize when they have a relatively large S/T separation and the ligands X are particularly bulky and/or function as intramolecular donor centers. To date, alkyl, aryl, OR, SR, and NR_2 groups have been used as the ligand X, and the structures of several of these colored, diamagnetic carbene homologues have also been characterized.[8] A phosphanyl-substituted monomeric carbene analogue was not known until now. Instead, despite the incorporation of bulky $P(SiMe_3)_2$[9] and $PtBu_2$[10] groups, phosphorus-bridged dimers **A** or ate complexes **B** were formed. The recently reported stannanediyl **C** was characterized by its ^1H and ^{31}P NMR spectroscopy and cryoscopy.[11]



A **B** **C**

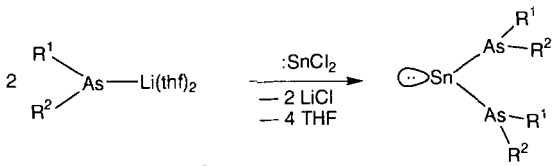
E = Ge, Sn, Pb

Herein, we report on the syntheses and crystal and electronic structures of a complete series of thermally stable, homoleptic phosphanyl-substituted carbene analogues of germanium, tin, and lead (**2**–**4**). In addition, we describe the first diarsanyl-substituted stannanediyl **5**, whose structure was also determined by a crystal structure analysis. These compounds were synthesized within the framework of our investigations into P- and As-metalated (fluorosilyl)silylphosphanes and -arsanes, which are suitable precursors for the synthesis of thermally stable Si=P and Si=As compounds.[12] During the transmetalation of the sterically demanding lithium (fluorosilyl)silylphosphanides **1a,b**, we observed that both compounds react with GeI_2, $SnCl_2$, and $PbCl_2$ in toluene at −78 °C. The germanediyl, stannanediyl, and plumbanediyl derivatives **2**–**4** can be obtained in the form of dark green crystals. In contrast to **1a,b**, these compounds are stable in toluene up to 90 °C and decompose at higher temperature with the elimination of Ge, Sn, and Pb metal, respectively.



1a: R^1 = Si(Is)$_2$F; R^2 = Si*i*Pr$_3$
1b: R^1 = Si(*t*Bu)(Is)F; R^2 = Si*i*Pr$_3$
Is = 2,4,6-*i*Pr$_3$C$_6$H$_2$

2: E = Ge, R^1 = Si(Is)$_2$F
3a: E = Sn, R^1 = Si(Is)$_2$F
3b: E = Sn, R^1 = Si(*t*Bu)(Is)F
4: E = Pb, R^1 = Si(*t*Bu)(Is)F



6: R^1 = Si(*t*Bu)(Is)F; R^2 = Si*i*Pr$_3$

5

The compounds were characterized by multinuclear NMR spectroscopy and elemental analysis. In the ^{31}P NMR spectra of **2**, **3a**, and **3b**, singlets are observed at $\delta = -62.1$, −102.5, and −121.3. The resonances for **3a** and **3b** show Sn satellites ($^1J(^{119}Sn,P) = 1682$, 1628 Hz); the positions of the signals are barely influenced by the polarity and donor character of the solvent. The magnitudes of the coupling constants are significantly larger than the values for compounds with Sn^{IV}–P^{III} single bonds (700–1000 Hz)[13] and dimeric carbene analogues **A** and **B** (1250–1360 Hz).[8, 9] By far the largest $^1J(Sn,P)$ coupling constants (2199–2200 Hz) were observed for phosphanylidenestannanes ($R_2Sn{=}PR$).[14] It is still unclear to what extent these larger values for **3a,b** can be interpreted in terms of increased Sn–P π interactions. Because of the limited solubility of **3b**, only **3a** could be characterized by ^{119}Sn NMR spectroscopy. The spectrum of **3a** shows a triplet at comparably low field ($\delta = 1551$ ($^1J(Sn,P) = 1682$ Hz)) which supports the fact that monomeric stannanediyl molecules, without stabilization by a donor, are present in solution. For OR, SR, or NR_2-substituted stannanediyls, the ^{119}Sn NMR signals are shifted to significantly higher field (90–900 ppm).[5, 8]

The ^{31}P NMR spectrum of the plumbanediyl **4** surprisingly shows two broad signals in a 1:1 ratio at $\delta = -88.8$ and −95.6 (298 K) with ^{207}Pb satellites ($^1J(Pb,P) = 1995$, 1979 Hz). This indicates that two diastereomeric forms, which show no coalescence up to 90 °C, are present; however, these chemical shifts are strongly temperature dependent. In contrast, the $^1J(Pb,P)$ coupling constants for dimeric plumbanediyls of forms **A** and **B** have values of 1260–1660 Hz and 1770 Hz, respectively.[10] Both diastereomers are formed when single crystals of **4**, which is present as only one diastereomer (see crystal structure analysis; Fig. 1), are dissolved in toluene. This is presumably attribut-

ed to the fact that the phosphorus inversion barrier in **4** is higher than that for the tin analogue **3b**.

The colors of the carbene analogues **2**, **3a,b**, and **4** are unusual. With the exception of **3b** (dark yellow-brown), they are intense green in solution (toluene, hexane, CH_2Cl_2, and THF); in the solid state **3b** is also dark green. This finding is reflected in the UV/Vis spectra (λ_{max} values) (Table 1).

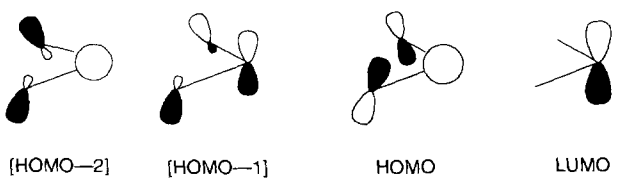
Calculations of electronic transitions were carried out at the CIS level with the ab initio Los Alamos pseudopotential method (LANL1DZ),[15] which had been implemented in the Gaussian92 program.[16] The transitions for the parent compound :$E[P(SiH_3)_2]_2$ (E = Ge, Sn) are in very good agreement with the experimental S_1 values (deviations 0.2–0.4 eV). However, the calculations show that the λ_{max} values (S_1) are strongly dependent on the dihedral angle. A rotation of the E–P bond can lead to a signal in the range 300–800 nm. The results for the transitions for :$E[P(SiH_3)_2]_2$ (E = Ge, Sn, (Table 2)) are based on the

Table 2. Orbital energies [eV], Mulliken net atomic charges Q(Sn) [e], and S_1 excitation energies [eV] of several stannanediyls.

	:SnH_2	:$Sn[N(SiH_3)_2]_2$	:$Sn[P(SiH_3)_2]_2$
LUMO	−0.39	0.27	−0.45
HOMO	−8.52	−8.93	−7.51
Q(Sn)	0.507	1.269	0.683
S_1	2.50	4.13	2.27

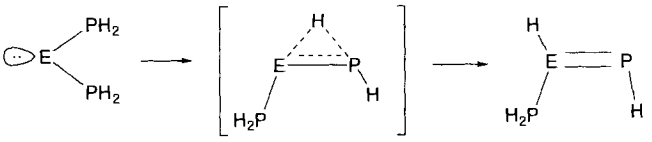
experimentally determined geometries for **2** and **3**. The calculated S_1 transition for :$Sn[N(SiH_3)_2]_2$ is, in contrast to that for :$Sn[P(SiH_3)_2]_2$, hypochromically shifted by 245 nm. The unusual color of the phosphanyl-substituted carbene analogues **2**–**4** is evidently due to the destabilization of the HOMO. A comparison with :SnH_2 shows that charge depletion at the Sn atom by the ligands also plays a role (Table 2). In fact, all stannanediyls known to date have an absorption at significantly lower wavelength and are, therefore, yellow or red (λ_{max} 380–495 nm).[5]

The three lone pairs of electrons in :$E[P(SiH_3)_2]_2$ (E = Ge, Sn) fill three molecular orbitals which are made up of the 4s, 4p (Ge), 5s, 5p (Sn), and 3s,3p (P) valence orbitals (Scheme 1). We have also calculated (MP2/DZ + POL//RHF/DZ + ZPE)[15, 16] the reaction profile for the isomerization of :$E(PH_2)_2$ (E = Si, Ge, Sn, Pb) **D** via the transition state **E** to the



Scheme 1. Selected frontier orbitals for :$E[P(SiH_3)_2]_2$ (E = Ge, Sn).

tautomer **F** with an E=P bond, and observe that the carbene-like form **D** is increasingly preferred over **F** in the series Si, Ge, Sn, Pb (Scheme 2, Table 3).



Scheme 2. Calculated reaction pathway for the isomerization of **D** to **F** via the intermediate **E**. E = Si, Ge, Sn, Pb.

Table 3. Relative enthalpies $\Delta H(0)$ [kcal mol^{-1}] for the reaction profile of the **D** → **E** → **F** isomerization; calculated with the ab initio pseudopotential method.

E	**D**	**E** (TS)	**F**
Si	0.0	29.2	−18.2
Ge	0.0	40.4	−2.1
Sn	0.0	54.6	14.8
Pb	0.0	70.6	32.4

Bonding behavior like that in the diphosphanyl compounds **2**–**4** is also observed for the diarsanylstannanediyl **5**, which is obtained in 74% yield by the reaction of lithium arsanide **6** with $SnCl_2$. Green crystals of **6** yield, as with **3b**, a yellow-brown solution, whose signal due to the S_1 transition indicates high dispersion.

The monomeric carbene homologous molecules have a V-shaped P-E-P (E = Ge, Sn, Pb) or a As-Sn-As arrangement, even in the solid state; this was confirmed by X-ray structure analyses for **2**–**5** (Fig. 1).[17] Due to disordering, a discussion of

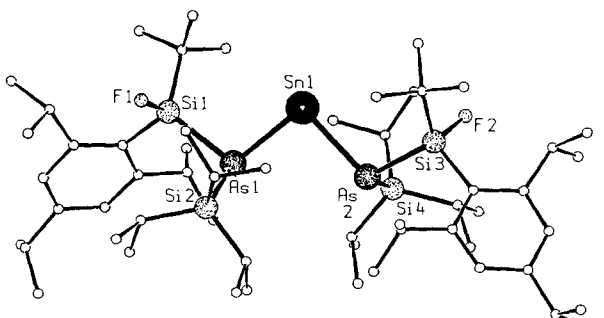


Fig. 1. Molecular structure of **5** in the crystal. The compounds **3b** and **4** are isotypic with **5**. The two crystallographically independent molecules differ only slightly. Selected distances [Å] and angles [°] for **5**: Sn-As 2.652(1), As-Si(F) 2.380(2), As-Si(*i*Pr) 2.388(2), Si-F 1.647(2); As-Sn-As 94.64(4), Sn-As-Si(F) 105.64(5) Sn-As-Si(*i*Pr) 105.62(5). **3b**: Sn-P 2.567(1), P-Si(F) 2.270(2), P-Si(*i*Pr) 2.286(2), Si-F 1.615(2); P-Sn-P 98.78(4), Sn-P-Si(F) 107.05(5), Sn-P-Si(*i*Pr) 108.45(5). **4**: Pb-P 2.654(4), P-Si(F) 2.263(5), P-Si(*i*Pr) 2.278(5), Si-F 1.613(8); P-Pb-P 97.88(4), Pb-P-Si(F) 106.76(5), Pb-P-Si(*i*Pr) 107.89(5).

the structures of **2** and **3a** is not meaningful. As a result, only the crystal structures of **3b**, **4**, and **5** will be discussed here. These compounds are isotypic; the same enantiomeric form is present in each case.

There is a relatively small angle at tin (**3b**: 98.78(4)°, **5**: 94.64(4)°, average values) and lead (**4** 97.84(4)°) despite the fact that there are bulky phosphanyl and arsanyl substituents present. This is due to the "reluctance to hybridize" which is found among these heavy main group elements.[3] Identical angles have been obtained for the amino analogues.[4] The P and As atoms are pyramidally coordinated (average sum of angles: **3b**: 320.9, **4**: 320.5, and **5**: 315.2°) and the average Sn–P (2.567(1) Å), Pb–P (2.654(4) Å), and Sn–As (2.652(1) Å) distances are significantly shorter than the corresponding values in the dimeric[10] and hypervalent[18] stannanediyls and plumbanediyls. The Sn–P and Pb–P distances in the Sn^{IV}–P^{III} and Pb^{IV}–P^{III} compounds are shorter (2.51 Å vs. 2.61 Å)[19] due to the partial charge at the center.

Experimental Procedure

2: A slurry of GeI_2 (0.60 g, 1.83 mmol) in toluene (50 mL) was treated at −78 °C with **1a** (2.91 g, 3.66 mmol) The reaction mixture was warmed to room temperature over 12 h during which time an intense green solution was formed. After the LiI was removed by filtration, the filtrate was concentrated to about 10 mL and left at 10 °C for crystallization. Yield: 1.1 g (0.8 mmol, 44%) green, cubic crystals; m.p. 110 °C (decomp.).

Compounds **3**–**5** were prepared analogously.

3a: $SnCl_2$ (0.54 g, 2.87 mmol) and **1a** (4.55 g, 5.75 mmol) yielded dark green crystals (3.01 g, 2.15 mmol, 75%); m.p. 131 °C (decomp.).

3b: $SnCl_2$ (0.31 g, 1.61 mmol) and **1b** (2.08 g, 3.22 mmol) yielded green cubes (1.50 g, 1.35 mmol, 84%) after crystallization from hexane; m.p. 158 °C (decomp.).

4: $PbCl_2$ (0.44 g, 1.58 mmol) and **1b** (2.04 g, 3.16 mmol) yielded green cubes (1.10 g, 0.92 mmol, 58%) after crystallization from hexane; m.p. 53 °C (decomp.).

5: $SnCl_2$ (0.19 g, 1.02 mmol) and **6** (1.40 g, 2.04 mmol) yielded green cubes (0.90 g, 0.75 mmol, 74%) after crystallization from hexane at −20 °C; m.p. 136 °C (decomp.).

Biosyntheses of Novel Emycins from the Mutant Strain *Streptomyces cellulosae* ssp. *griseoincarnatus* 1114-2**

Martin Gerlitz, Györgyi Udvarnoki, and Jürgen Rohr*

The development of concepts for the search for structurally novel natural products which may eventually serve as lead structures for pharmaceutical or other indications is a permanent challenge, increased by resistance problems. This challenge may be faced in particular in academic research institutions, since sufficient test assays established on the industrial side are waiting for use.[1] Parallel to the concept of creating novel natural products through targeted genetic modifications of polyketide-producing streptomycetes,[2] we also use the often faster approach of arbitrarily genetically modifying selected streptomycetes. In this context we are particularly interested in those polyketide producers whose product spectra are obviously influenced by oxidoreductases. A good example is *Streptomyces cellulosae* ssp. *griseoincarnatus* (FH-S 1114),[4] an angucyclinone[5] producer yielding elmycin D (**1**) as the major product, the known antibiotics ochromycinone (**2**)[5] and deoxyrabelomycin (**3**)[5] as minor products, and, among others, emycin A (**4**) as trace products.[6] From this product spectrum one can assume a biosynthetic relationship between these four metabolites resulting from oxidoreductase activities. Oxygenases are especially able to markedly modify a primary biosynthetic molecular backbone, as known from the biosynthesis of the polyether antibiotic monensin[7a, b] or prostaglandins.[7c] Thus a mutation of a strain showing intense oxidoreductase activities may result in a whole spectrum of novel products.

Indeed, a mutant (strain 1114-2) showing a significantly changed product spectrum (TLC, HPLC)[3] was obtained readily by NTG (NTG = *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine) treatment[3] of the wild-type strain FH-S 1114. Besides the wild-type strain products **1**, **2**, and **4** (major products), the production of four novel metabolites, namely the emycins C (**5**) (small side product), D (**6**), E (**7**), and F (**8**) could be observed, the latter three being also major products of *S. cellulosae* ssp. *griseoincarnatus* 1114-2 (Fig. 1). The structure elucidation of the

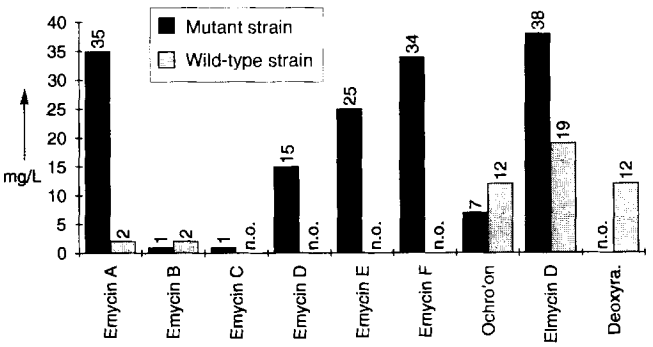

Fig. 1. Comparison of the products of the wild-type strain S-1114 and of the mutant strain 1114-2.

new compounds **5**–**8** by spectroscopic methods[8] (NMR data: see Tables 1 and 2) yielded the surprising result that two of the compounds, namely emycins D (**6**) and E (**7**), each appear as a pair of nonseparable diastereoisomers (see NMR data), which complicated the interpretation of the spectra. The constitution of the novel emycins was mainly established through $^{n}J_{C,H}$

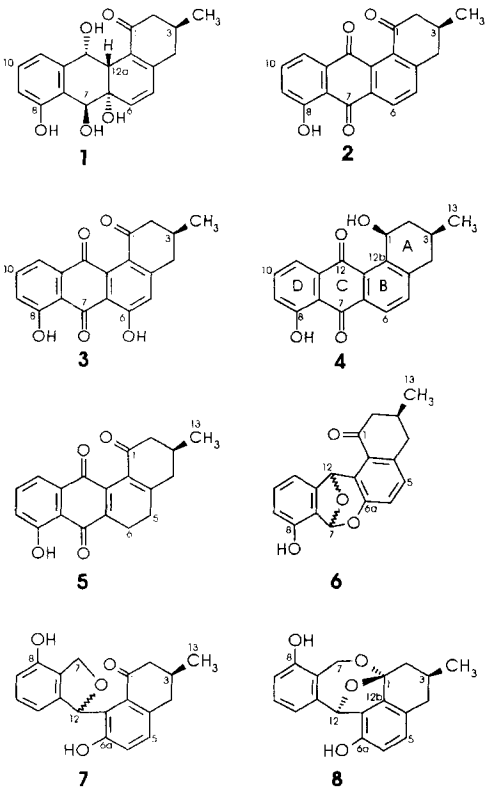

Table 1. ^{1}H NMR data of the novel emycins C (**5**), D (**6**), E (**7**), and F (**8**), (relative to internal TMS, at 500 MHz, *J* in Hz). Additional NMR data of the diastereoisomers of **6** and **7** (Diast.) are given as footnotes.

long-range couplings from the HMBC NMR experiment (HMBC = *H*etero *M*ultiple *B*ond *C*onnectivity Spectroscopy) and the COLOC NMR experiment (COLOC = *Co*rrelation Spectroscopy via *Lo*ng-Range Couplings) (Fig. 2). The absolute configurations of the structures of **6**–**8** were determined by X-ray analyses.[8, 9]

The molecular frameworks of the emycins D (**6**), E (**7**), and F (**8**) are unprecedented; thus, we attempted to elucidate their

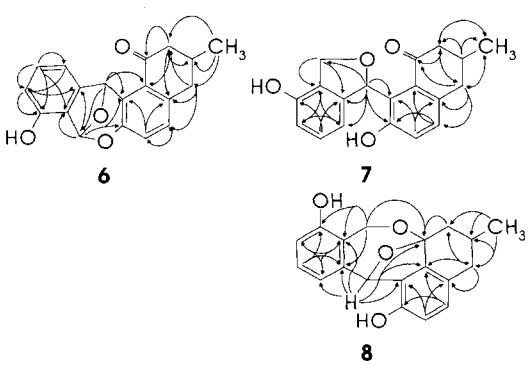

Fig. 2. Observed $^nJ_{C-H}$ long-range couplings of emycins D (**6**), E (**7**), and F (**8**) (HMBC and COLOC spectra, respectively).

generation through biosynthetic investigations. In all three novel structures, rings A, B, and D of the benz[*a*]anthracene framework of the angucyclinones[5] (see emycin A (**4**)) turned out to be largely unchanged in comparison with the wild-type strain products, and thus a biosynthetic relationship to the wild-type strain products seemed evident. Labeling experiments using [1-^{13}C]-, [1,2-$^{13}C_2$]-, and [1-^{13}C,$^{18}O_2$]acetate as well as a fermentation carried out under an ^{18}O-enriched atmosphere revealed the biosynthetic sources of all carbon and oxygen atoms of the major products of mutant strain *S. cellulosae* ssp. *griseoincarnatus* (1114-2). For the typical angucyclinones **1**, **2**, and **4** the expected acetate incorporation pattern was found, namely construction from a single polyketide chain assembled from ten acetate units starting at C-13 and ending at C-2 (under decarboxylation of the last acetate unit).[10] There were also no unexpected results with respect to the biogenetic origin of the oxygen atoms, that is there was no evidence for prearomatic deoxygenation steps as were found recently for some multicyclic aromatic polyketides.[10d, 10e, 11] In the biosyntheses of the novel emycins D (**6**), E (**7**), and F (**8**), the fourth acetate unit is cleaved, since carbons C-6a and C-7 appear as enriched singlets (instead of a coupling pair) in the ^{13}C NMR spectrum after the feeding experiment with the doubly labeled [1,2-$^{13}C_2$]acetate. Thus an oxidative carbon–carbon split between C-6a and C-7 must have occurred. This was supported by the fermentation

Table 3. ^{13}C NMR upfield shifts ($\Delta\delta$) after the incorporation experiments with ^{18}O-labeled precursors: elmycin D (**1**), ochromycinone (**2**), emycins A (**4**), D (**6**), E (**7**), and F (**8**); **A**: incorporation of [1-^{13}C,$^{18}O_2$]acetate (99% ^{13}C, 55% ^{18}O); **B**: fermentation under an $^{18}O_2$ (50% ^{18}O)-enriched atmosphere; (% relative ^{18}O-enrichment [a]).

experiment in an $^{18}O_2$-enriched atmosphere, in which 6a-O was labeled in all three compounds **6**–**8**, proving its origin from atmospheric oxygen. The results are summarized in Figure 3 (only elmycin D (**1**) is shown as an example of a common angucyclinone) as well as in Tables 2 and 3.

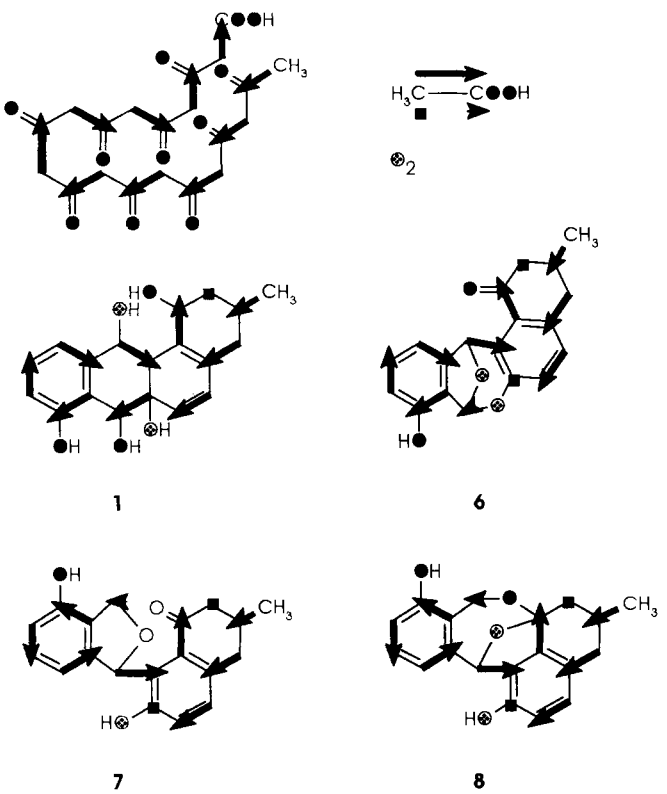

Fig. 3. Results of the incorporation experiments with ^{13}C- and ^{18}O-labeled precursors.

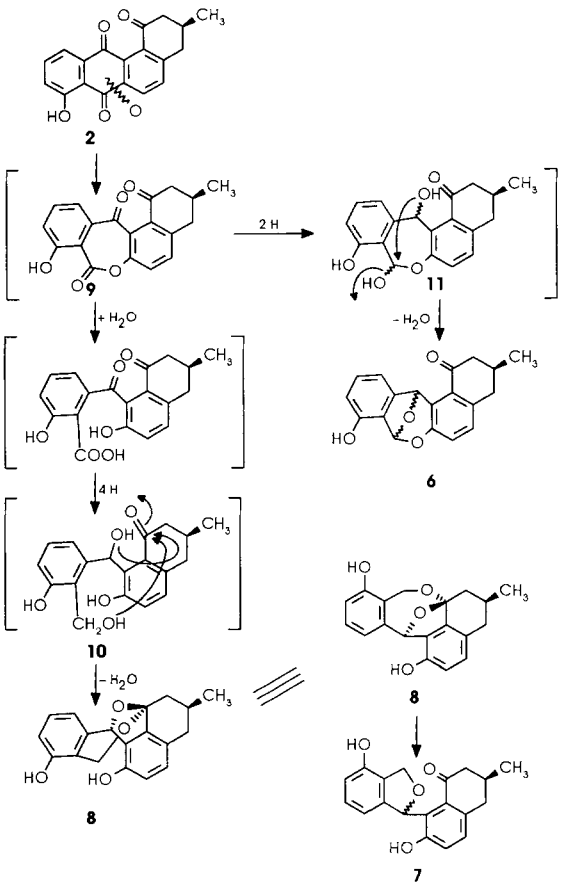
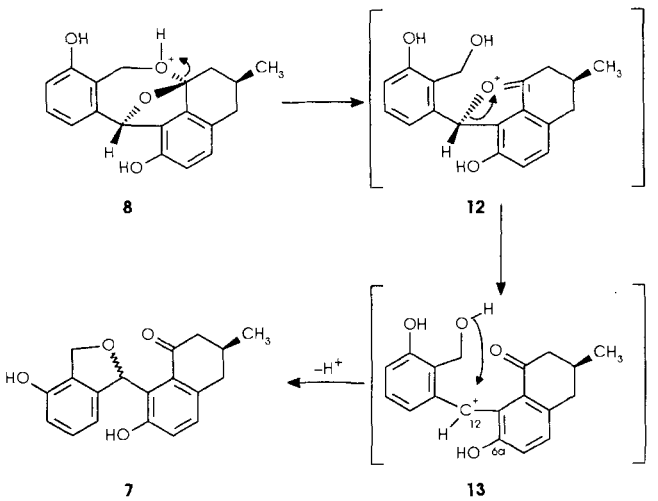


Scheme 1. Hypothetical biosynthesis cascade for the generation of the unusual emycins D (**6**), E (**7**), and F (**8**).

A hypothetical biosynthesis scheme (Scheme 1) was deduced from the results of the biosynthetic investigations that explains the generation of the novel molecular frameworks of emycins D–F (**6**–**8**) in a plausible way: starting with an enzymatic Baeyer–Villiger oxidation on a quinone precursor,[11a] presumably with ochromycinone (**2**), which results in the lactone intermediate **9**, and continues through the opening of the lactone **9** and the subsequent reduction to give the intermediate **10**, an intramolecular ketalization into emycin F (**8**) takes place as a key biosynthetic step. This finally rearranges (under participation of non-enzymatic steps?) into the thermodynamically more stable emycin E (**7**). The intramolecular ketalization of the dialcohol intermediate **10** is possible because of the free rotation about the C-12/C-12a axis after cleavage of the lactone and the reduction. This step must be catalyzed by an enzyme, since **8** appears as a sole diastereoisomer. Emycin D (**6**) is probably a shunt product, whose formation may start at lactone **9**. Both carbonyl carbons C-7 and C-12 of **9** have to be reduced into the hemiacetal and secondary alcohol, respectively, to form intermediate **11** which can be intramolecularly cyclized into the

acetal emycin D (**6**). That **6** emerges as a diastereomeric mixture (with C-7 and C-12 in *R*, or both stereocenters in *S* configuration;[8] *R,R* : *S,S* = 1:1) is unexpected and intriguing, since this has to be caused by an unspecific oxidoreductase (dehydrogenase) reducing the C-12 keto function into a stereochemically inconsistently configurated alcohol (Scheme 1). We are currently investigating the formation of **6**. The last step of the biosynthetic cascade of the emycins is a novel type of rearrangement, initiated by the protonation of 7-O, which eases the cleavage of the C-1/7-O bond. The resulting carbenium ion with the positive charge at C-1 in **12** induces the second necessary scission between C-12 and its adjacent oxygen atom; in this way the C-1 keto function is regenerated and a more stable carbenium ion with the positive charge at C-12 in **13** is formed (Scheme 2). The



Scheme 2. Rearrangement of emycin F (**8**) into emycin E (**7**).

C atom, which carries the positive charge in **13**, lies in the benzylic position to both neighboring arene units; in this arrangement the 6-OH group in particular contributes a stabilizing neighboring group effect. Therefore the carbenium ion at C-12 can be intramolecularly attacked on both sides by the oxygen atom of the primary alcohol group at C-7 with the formation of the dihydrofuran moiety, leading to emycin E (**7**) as a diastereomeric mixture (Scheme 2). The quantitative rearrangement of emycin F (**8**) into emycin E (**7**) could also be performed in a model reaction, namely stirring **8** at pH 1 for 24 h. Since such a low pH neither occurs during the fermentation of *S. cellulosae* ssp. *griseoincarnatus* (1114-2) nor during the workup procedure, this rearrangement has to be caused by a similar acidic milieu inside the cells, or under the participation of an enzyme. Within the rearrangement of **8** into **7** a hydrate structure (not shown in Scheme 2) at C-1 probably occurs as an intermediate, since the ^{18}O label (from the fermentation in $^{18}O_2$) disappears during the rearrangement, or is introduced, if the reaction is carried out in $H_2{}^{18}O$.

The work described here shows that genetic modifications can cause a significant change in the secondary metabolite spectrum of streptomycetes and lead to the production of considerable quantities of novel compounds (see Fig. 1). Furthermore, oxidoreductases play a significant role in these reactions. Nevertheless, it is not certain whether the mutation effected one or more oxidoreductases directly or whether it caused a regulatory change through which, for example, ochromycinone **2** is produced in higher yields and could thus serve as a substrate for the oxygenase responsible for the Baeyer–Villiger oxidation. The latter alternative is more likely, since we also found the novel emycins D, E, and F in the wild-type strain, but only in traces ($< 1\ mg\ L^{-1}$). Interesting structure modifications of angucyclinones induced by oxidating enzymes were also reported recently by S. Gould et al.[12]

Experimental Procedure

Bacterial strain, cultivation, and isolation of the products: Mutant strain *S. cellulosae* ssp. *griseoincarnatus* (1114-2) was prepared by NTG-mutation [3]. Its cultivation as well as the isolation of the products will be described elsewhere [8].

Instruments/NMR methods: see refs. [2b,3,11a].

Labeled compounds and incorporation experiments: [1-^{13}C]- and [1,2-$^{13}C_2$]acetate (each 99% ^{13}C) was obtained from CIL (Cambridge Isotope Laboratories, Cambridge, MA, USA), $^{18}O_2$ (98% ^{18}O) from Isotec Inc. (Miamisburg, OH, USA), [1-^{13}C,$^{18}O_2$]acetate was synthesized as described before [13]. The labeled acetates were fed in five equal portions (1 g each, H_2O solutions) to a growing culture of strain 1114-2, 45, 53, 61, 69, and 77 h after inoculation of the fermentor. To avoid O-exchange with the solvent, the [1-^{13}C,$^{18}O_2$]acetate was always dissolved immediately before feeding. The $^{18}O_2$ was diluted with $^{16}O_2$ to 50% in our closed system apparatus [13a], which was connected here to a 1 L-fermentor, from 45 h after inoculation to the end of the fermentation (96 h).

Emycin C (**5**): $C_{19}H_{16}O_4$ (308.33); $[\alpha]_D^{20} = +108.1$ ($c = 0.007$, MeOH); EI-MS (70 eV): *m/z* (%) 308 (35, M^+, HR calcd. for $C_{19}H_{16}O_4$ and found: 308.1048), 266 (60), 94 (100); ^{1}H NMR: see Table 1; ^{13}C NMR (125.7 MHz, $CDCl_3$): $\delta = 194.6$ (s, C-1), 46.0 (t, C-2), 29.5 (d, C-3), 39.8 (t, C-4), 129.0 (s, C-4a), 29.1 (t, C-5), 19.0 (t, C-6), 141.6 (s, C-6a), 188.7 (s, C-7), 114.8 (s, C-7a), 161.0 (s, C-8), 119.3 (d, C-9*), 136.2 (d, C-10*), 123.5 (d, C-11*), 133.0 (s, C-11a), 182.0 (s, C-12), 141.9 (s, C-12a), 130.5 (C-12b), 21.0 (q, C-13); * assignments are interchangeable.

Emycin D (**6**): $C_{19}H_{16}O_4$ (308.33); $[\alpha]_D^{20} = -34.9$ ($c = 0.072$, $CHCl_3$); EI-MS (70 eV): *m/z* (%) 308 (60, M^+, HR calcd. for $C_{19}H_{16}O_4$ and found 308.1049), 279 (30), 239 (100); ^{1}H and ^{13}C NMR: see Tables 1 and 2, respectively.

Emycin E (**7**): $C_{19}H_{18}O_4$ (310.35); $[\alpha]_D^{20} = +49.0$ ($c = 0.071$, MeOH); EI-MS (70 eV): *m/z* (%) 310 (100, M^+, HR calcd. for $C_{19}H_{18}O_4$ and found: 310.1207), 295 (85), 239 (70); ^{1}H and ^{13}C NMR: see Tables 1 and 2, respectively.

Emycin F (**8**): $C_{19}H_{18}O_4$ (310.35); $[\alpha]_D^{20} = +209.9$ ($c = 0.016$, MeOH); EI-MS (70 eV): *m/z* (%) 310 (100, M^+, HR calcd. for $C_{19}H_{18}O_4$ and found 310.1205), 295 (85), 239 (30); ^{1}H and ^{13}C NMR: see Tables 1 and 2, respectively.

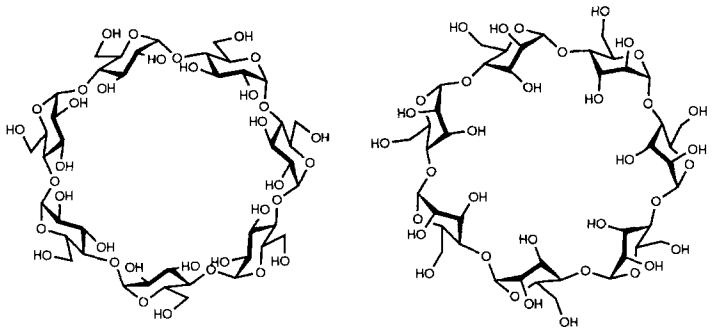
β-Cycloaltrin: A Cyclooligosaccharide Consisting of Seven α(1 → 4)-Linked Altropyranoses**

Kahee Fujita,* Hideaki Shimada, Kazuko Ohta, Yasuyoshi Nogami, Kyoko Nasu, and Toshitaka Koga

Cyclodextrins, for example β-cyclodextrin (**1**) (Scheme 1), are cyclic oligosaccharides made up of 1,4-linked D-glucopyranose units in $^4C_1$ chair conformation. They can include a wide variety of substrates in their hydrophobic cavities. The formation of inclusion complexes and reactions constrained to the cavities have been studied extensively.[1] Several cyclooligosaccharides uniformly composed of sugars other than glucose have been reported such as the inulin-derived α-cyclofructin,[2] α- and β-cyclomannins, synthesized chemically,[3] and α-cyclogalactin, which so far has been characterized by molecular modeling only.[4] In this paper, we report the preparation of a novel cyclooligosaccharide constituted of seven α(1 → 4)-linked altropyranoses, which we designate, in accord with a recent proposal for simplified nomenclature,[4] as β-cycloaltrin (**3**) (Scheme 1).



1 **3**

Scheme 1. Structures of **1** and **3** ($^4C_1$ conformation).

product with $R_f = 0.19$, which has distinctly different mobility from that of **1** and **2** ($R_f = 0.32$ and 0.84, respectively). Reversed-phase column chromatography gave the novel cyclooligosaccharide **3** in 72.9% yield. The FAB mass spectrum showed **3** to have the same molecular weight as **1**; however, the NMR data (Fig. 1) are clearly different. The assignment of the

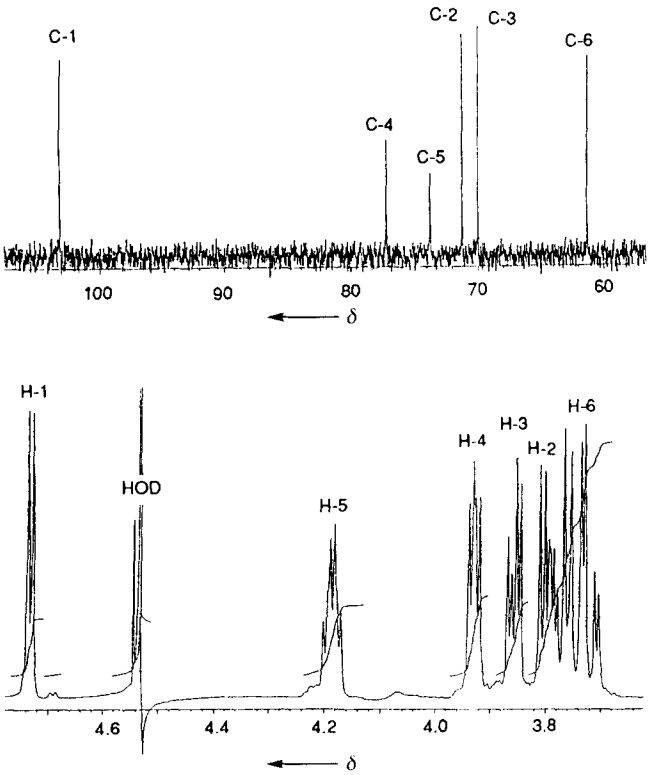


Fig. 1. Top: ^{13}C NMR spectrum of **3** (125 MHz, D_2O, 40 °C, CH_3CN). Bottom: ^1H NMR spectrum of **3** (500 MHz, D_2O, 40 °C, CH_3CN).

signals of **3** relied on ^1H, ^1H- and $^1H,^{13}C$-COSY NMR spectra, and indicates that **3** consists of altropyranoses. The coupling constants (e.g. J(H-1, H-2) = 4.5 Hz) indicate that **3** is a mixture of at least two rapidly interconverting[6] conformations, $^1C_4$ and $^4C_1$ chair conformations (see Scheme 1). Alternatively, **3** assumes a single fixed conformation, for example, in which the altropyranose units have a twist conformation, since the vicinal coupling constant J(H-1, H-2) is intermediate between that of

[8] For a pyranoid $^1C_4$ conformation $^3J_{1,2}$ should be around 8 Hz. Therefore, the pyranose rings in **3** may be closer to a $^4C_1$ rather than the $^1C_4$ form.
[9] The purity of **2** is very important for the reaction; contamination by even a small amount of benzenesulfonates, which are intermediates in the epoxidation leading to **2**, is very harmful for the present reaction, since **3** is hydrolyzed by sulfonic acid produced during the reaction.

Novel Biological Copper Proteins through Anion Addition to the Mutant Met121Gly of *Pseudomonas aeruginosa* Azurin**

Momcilo Vidakovic and Juris P. Germanas*

Blue copper proteins are widely distributed in nature, where they function as electron-transfer mediators in important biochemical processes such as photosynthesis and metabolism.[1] The unique spectrochemical properties of these proteins have long attracted the attention of bioinorganic chemists.[2] For proteins in the oxidized state [copper(II)], these characteristics include an intense absorption band centered around 600 nm ($\varepsilon = 2000-6000\ M^{-1}cm^{-1}$), an EPR spectrum with an unusually small copper hyperfine splitting ($I = 3/2$, $A_{\parallel} \leq 70 \times 10^{-4}\ cm^{-1}$), and anomalously high redox potentials for the Cu^{II}/Cu^{I} couple [180–680 mV versus the normal hydrogen electrode (NHE)]. Crystallographic analysis has revealed that the copper(II) ion in these proteins is coordinated to two histidine residues and one cysteine residue in an approximately trigonal planar geometry.[3] Besides these three strong interactions, weaker axial interactions between the copper ion and other ligands are generally present. For example, in azurin and plastocyanin, the thioether sulfur atom of a methionine residue interacts with the copper center, while in stellacyanin, a glutamine carboxamide oxygen is thought to coordinate to the metal.[4] The nature of the axial interaction is believed to significantly influence the spectrochemical characteristics of metal centers of the blue copper proteins.[5] To probe the effect of various axial ligands on the spectroscopic and electrochemical properties of these copper sites, we have prepared by site-directed mutagenesis a variant of *Pseudomonas aeruginosa* azurin, Met121Gly,[6] in which the weakly coordinating ($R_{S-Cu} = 3.1$ Å) thioether side chain of Met121 is replaced by a hydrogen atom. This creates a cavity that can be occupied by exogenous ligands.[7] In this communication we report the preparation and characterization of unique biological copper species, obtained through addition of the anions N_3^-, SCN^-, and CN^- to Met121Gly azurin. Their spectroscopic properties are distinct from those of any known naturally occurring copper proteins.[8]

The UV-Vis spectra of blue copper proteins display a characteristic absorption band at about 600 nm, due to a $S_{cys}(\pi)$ to Cu^{II} charge transfer (LMCT) transition, along with another band at about 450 nm from a S_{cys} (pseudo-σ) to Cu^{II} LMCT.[9] The relative intensities of the two bands vary, depending on the protein. A correlation between the relative intensity of the band at 450 nm and the axial displacement of the copper atom from the plane formed by the His_2Cys ligand set has been reported for a number of blue copper proteins.[10] Upon titration of Met121Gly azurin with azide, thiocyanate, or cyanide, the intense absorption band at 614 nm of the uncomplexed protein disappeared, and a new, weaker band at approximately 420 nm arose, along with a feature at about 590 nm (Table 1).[11] The wavelengths of the transitions at 420 nm were dependent on the specific anion, indicating that the anion ligated directly to the

copper(II) ion. From the greater intensities of the 420 nm bands relative to those of the 590 nm bands in the spectra of the protein–ligand adducts, we inferred a larger separation between the copper(II) ion and the plane of the protein's His_2Cys ligand set than in the uncomplexed form.[10] The formation constants of the 1:1 complexes, determined spectrophotometrically, revealed the cyanide adduct to be substantially more stable than the azide or thiocyanate adducts (Table 1).

Resonance Raman spectra of Met121Gly azurin and its anion adducts were recorded with excitation wavelengths of 568 nm (without exogenous ligand) or 413 nm (with exogenous ligand). The set of four strong bands in the spectrum of the uncomplexed protein[12] was replaced in the spectrum of the anion adducts by a pair of peaks at lower energy (Fig. 1). Since the most intense band in the resonance Raman spectra of blue copper proteins results from a predominantly Cu–S stretching vibrational mode,[12] the shift of the intense band in the spectra of the anion adducts to lower wavenumber indicated that the anion complexes possessed weaker, and consequently longer, Cu–S bonds than the uncomplexed protein (Table 1). The appearance of bands attributable to bond-stretching modes of azide and thiocyanate in the spectra of the specific adducts further confirmed that these anions coordinated directly to the copper(II) ion of Met121Gly azurin (Fig. 1).

The EPR data of spectra of the 1:1 complexes also reflected a change in coordination environment at the copper site in the protein–anion adducts. The copper(II) centers of the adducts displayed EPR spectra with axial symmetry, in contrast to the uncomplexed protein, which displayed an EPR spectrum with rhombic symmetry (Fig. 2). Strikingly, the values for the copper

hyperfine coupling constant ($A_{\parallel}$) of the complexes (Table 1) were well above the range of values observed for typical blue copper sites ($\leq 70 \times 10^{-4}$ cm^{-1}).[2] Furthermore the $A_{\parallel}$ values for the adducts were considerably smaller than those seen for common tetragonal, or type 2, copper compounds ($160-220 \times 10^{-4}$ cm^{-1}).[2] Plots of $g_{\parallel}$ versus $A_{\parallel}$ for copper complexes often produce linear correlations for compounds of similar structural or electronic origin.[13] When the values of $g_{\parallel}$ for the Met121Gly–anion adducts were plotted against the values of $A_{\parallel}$, a linear correlation was obtained ($R = 0.95$), which was distinct from the correlations seen for blue or type 2 (tetragonal) copper centers. Differences in the precise values of the adduct's EPR parameters reflected small structural variations in the ligand environment of the copper atom of each adduct.[13]

The redox potentials of Met121Gly azurin and its anion complexes were determined by potentiometric titration. Binding of thiocyanate or azide to the copper(II) ion of the protein pro-

duced species with lower redox potentials than the free protein (Table 1). The midpoint potential of the cyanide adduct could not be determined by this method because of competitive oxidation of cyanide. The lower potentials of the two anion adducts relative to Met121Gly azurin could be rationalized by inferring electrostatic stabilization of the higher copper oxidation state by the negatively charged ligands.

The spectroscopic properties of the Met121Gly azurin–anion adducts indicate the presence of a novel form of protein-bound copper having spectroscopic properties distinct from those of either blue or type 2 copper proteins. According to a computer-generated model of the Met121Gly active site,[14] coordination of external ligands to the copper(II) ion in the space previously occupied by the Met121 side chain should result in a distorted tetrahedral environment for the metal center. Binding of anionic species to the copper(II) ion should also result in lengthening of the other metal–ligand bonds. Absorption and resonance Raman spectra of the Met121Gly azurin–anion complexes reflect substantial axial displacement of the copper atom from the plane of the His_2Cys ligand set along with elongation of the S_{cys}–Cu bond.[10, 12] The values for the parallel hyperfine splittings in the EPR spectra of the 1:1 complexes are consistent with diminished covalency in the S_{cys}–Cu bond relative to the uncomplexed form, resulting from S–Cu bond lengthening.[15] In natural blue copper proteins with distorted tetrahedral metal centers and short axial interactions with neutral ligating atoms, absorption spectra display intense bands at about 450 nm, and EPR spectra suggest a rhombic g tensor.[2] Absorption spectra with λ_{max} at about 420 nm and EPR spectra with axial symmetry for the Met121Gly azurin–anion adducts signify a unique electronic structure of the copper centers in these proteins as a result of the anionic character of the axial ligands. Further support for the proposed model of the Met121Gly azurin–anion adduct copper centers comes from properties of structurally characterized, pseudo-tetrahedral copper complexes, which display spectroscopic characteristics remarkably similar to those of the adducts reported here.[16]

A variety of unusual copper proteins can be easily created through addition of anions to the azurin mutant Met121Gly. The ability to create ligand-accessible metal centers in coordinatively saturated metalloproteins by directed mutagenesis holds promise for the preparation of metalloproteins with selective ion-sensing capabilities. Further studies aimed at detailed characterization of the electronic and geometric structure, as well as the electron-transfer properties of the active sites of these unusual proteins are in progress.

A Redox-Switchable Hemilabile Ligand: Electrochemical Control of the Coordination Environment of a Rh^I Complex**

Elizabeth T. Singewald, Chad A. Mirkin,* and Charlotte L. Stern

We report the synthesis and characterization of a redox-switchable hemilabile ligand (RHL), $FcOCH_2CH_2PPh_2$ (**1**, $Fc = (\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$, and its complexation to Rh^I to form the square-planar, *cis*-phosphane, *cis*-ether Rh^I complex **2** (Scheme 1). This new ligand type can yield electrochemical con-

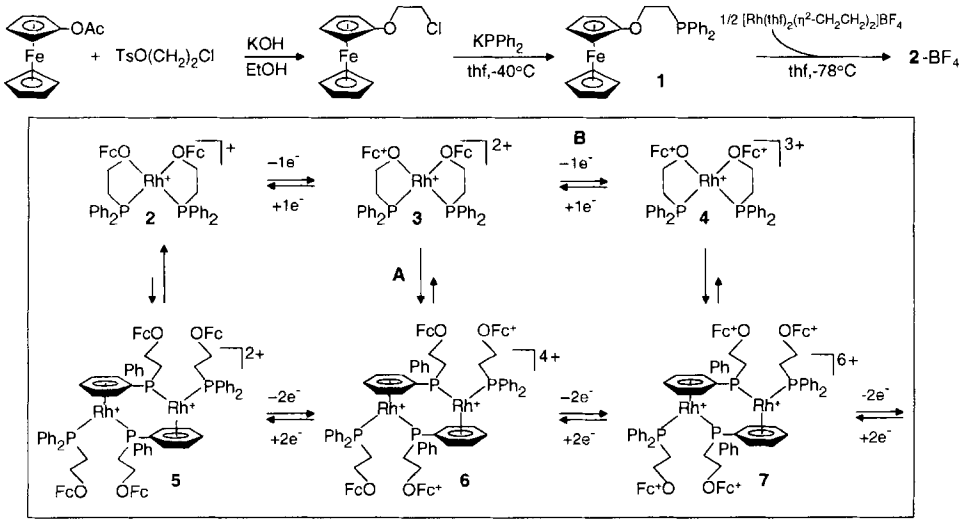
M. acknowledges a Dreyfus Foundation New Faculty Award (1991–1996), a Beckman Young Investigator Award (1992–1994), a Naval Young Investigator Award (1994–1997), a National Science Foundation Young Investigator Award (1993–1998), and an A. P. Sloan Fellowship (1995–1997) for partial support of this research.



Scheme 1. Synthesis of ligand **1** and complex **2** (top) and proposed electrochemical transformations for **2** (in frame). Formal charges are denoted at appropriate atoms; overall charge is denoted outside the bracket.

trol over the electronic and steric environments of the Rh^I center. Bidentate ligand **1**, which was designed for complexation to late transition metals, has two important characteristics. First, for the example reported herein (**2**), ligand **1** is hemilabile because the phosphane moiety binds strongly to Rh^I to form a substitutionally inert bond, while the ether functionality forms a weak bond to Rh^I, which is substitutionally labile; hemilabile ligands have been studied extensively.[1] Second, the ferrocenyl group in **1** is covalently attached to the ether moiety; therefore, the binding affinity of the O atom for Rh is dependent on the oxidation state of the ferrocenyl group. With this RHL design, coordination sites at the transition-metal center to which **1** is chelated can be labilized selectively by applying a potential that can oxidize the ferrocenyl group, thereby yielding electrochemical control over transition-metal coordination environment. Electrochemical control over the coordination environment of the transition-metal complex controls the reactivity of the complex and in principle, its catalytic properties. To this end, we are designing a series of new electrocatalysts based on the RHL concept. This work complements the work of others involving 1) the design of redox-switchable ligands for sensor probes and ion transport membranes[2] and 2) the use of *substitutionally inert* redox-active ligands to tune the reactivity of transition metals.[3] The approach reported herein is fundamentally different from the latter work, because it focuses on controlling ligand binding characteristics rather than the electronic character of the transition-metal center to which the redox-active ligands are bound.[4]

The synthesis of **2**-BF_4 begins with the reaction between ferrocenylacetate[5] (5.8 mmol), KOH (5.8 mmol), and $TsOCH_2CH_2Cl$ (Ts = *p*-$(CH_3C_6H_4)SO_2$, 23 mmol) in ethanol (30 mL) at reflux for 20 h to form $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4OCH_2CH_2Cl)]$ in 65% yield (Scheme 1). The reaction of $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4OCH_2CH_2Cl)]$ (6.9 mmol) with one equivalent of $KPPh_2$ in 60 mL of THF at −40 °C gives ligand **1** in 92% yield. Compound **2** is then formed from the reaction between ligand **1** (0.52 mmol) and $[(\eta^2\text{-}C_2H_4)_2Rh(thf)_2]BF_4$[6] (0.26 mmol) in THF (100 mL) at −78 °C. Compound **2**-BF_4 was isolated in 55% yield as an orange-red crystalline salt by recrystallization from CH_2Cl_2/pentane.

Spectroscopic data for **2**-BF_4 in dilute CD_2Cl_2 solutions (10 mM) are fully consistent with its proposed structure (see Experimental). For example, the ^{31}P NMR resonance signal and Rh–P coupling constant are highly diagnostic of a square-planar *cis*-phosphane, *cis*-ether Rh^I complex[1, 7a] and compare well with the ^{31}P NMR data for crystallographically characterized, isoelectronic $[Rh(\eta^4\text{-}(\{\eta^5\text{-}C_5H_4\}OCH_2CH_2PPh_2)_2Fe)]BF_4$, ($^{31}P\{^1H\}$ NMR: $\delta = 61.2$, d, $J_{Rh,P} = 210.6$ Hz).[7b]

Slow diffusion of pentane into a CH_2Cl_2 solution of **2** (0.9 mM) yielded X-ray quality single crystals. Surprisingly, a single crystal X-ray diffraction study shows that **2** forms a μ_2-η^6-arene dimer (**5**) in the solid state (Fig. 1).[12] Bis(phosphane), η^6-arene pianostool dimers similar to **5** have been reported by others, although all of these examples involve chelating bis(phosphane) ligands.[8] Significantly, upon dissolving 2 mg of crystalline **5** in CD_2Cl_2 (0.5 mL), it cleanly reverts to the monomeric species **2** as shown by its ^{31}P NMR spectrum. Apparently **2** and **5** are in equilibrium (Fig. 1), and at high concentrations (for example, single crystals) the dimer **5** is favored over the monomer **2**.

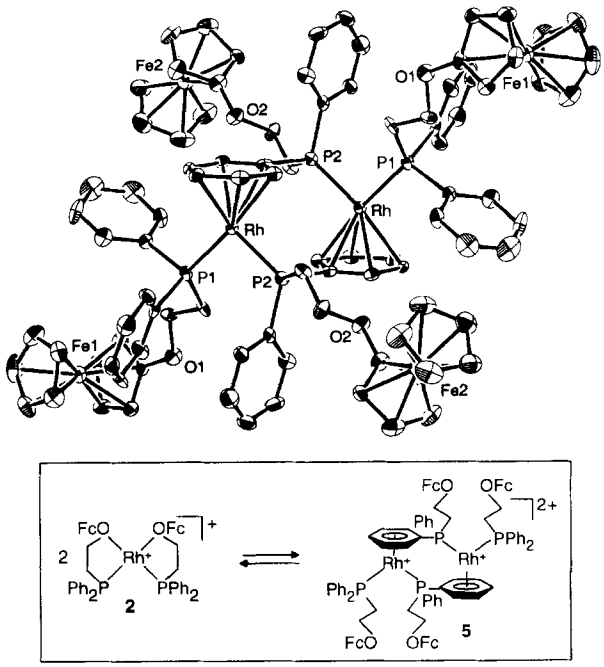


Fig. 1. Structure of **5** (ORTEP drawing; thermal ellipsoids are drawn at 50% probability; BF_4 anions and CH_2Cl_2 molecules are omitted for clarity). Selected distances [Å] and angles [°]: Rh–Rh 4.238(2), Rh–P1 2.260(3), Rh–P2 2.239(3), Rh–C(centroid) 1.423; P1-Rh-P2 95.08(9).

Cyclic voltammetry of complex **2** at concentrations at which only **2** is detected in solution by spectroscopy (1 mM) is dependent on the scan rate (Fig. 2). At a sweep rate of 20 mVs^{-1} the cyclic voltammogram of **2** exhibits two reversible waves at 260 mV and 980 mV vs. Ag wire (Fig. 2A). Initially, one might be inclined to assign the wave at 260 mV, a two-electron transfer

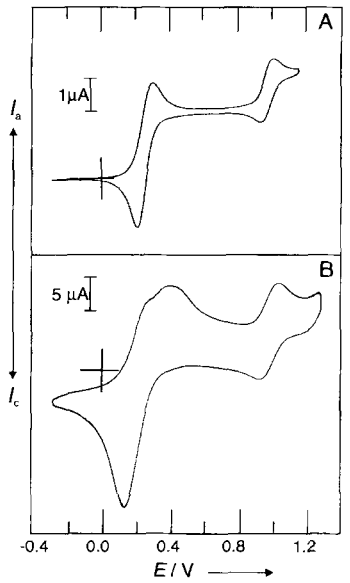

Fig. 2. Cyclic voltammogram for **2**-BF_4 (1 mM) with 0.1 M nBu_4NPF_6 in CH_2Cl_2 as supporting electrolyte, a Au disk as working electrode (0.03 cm^2), and a Ag reference electrode: A) sweep rate 20 mVs^{-1}, B) 1 Vs^{-1}.

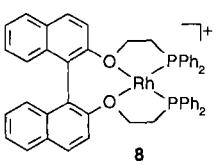
process (see below), to the oxidation of the two Fc groups of **2** and the wave at 980 mV to a one-electron, Rh-centered oxidation/reduction of 2^{2+} (that is, **4** in Scheme 1). However, a reversible Rh^I/Rh^{II} redox couple for **4** would be highly unusual since there are only a few examples of mononuclear Rh^{II} complexes. Although some of these compounds have square-planar geometry around Rh, there are no examples of square-planar *cis*-phosphane, *cis*-ether Rh^{II} complexes.[9] In fact, a model Rh^I tetrafluoroborate compound (**8**), which is isoelectronic with **2**, exhibits an *irreversible* Rh-centered oxidation (E_p = 890 mV vs. Ag wire).[10] Therefore, we conclude that the species being oxidized at 980 mV in Figure 2A is *not* a square-planar *cis*-phosphane, *cis*-ether Rh^I complex.



8

For compound **2**, as the scan rate is increased to 1 Vs^{-1}, the oxidative wave assigned to the two Fc-centered oxidations at 20 mVs^{-1} broadens and then splits into two distinct waves (Fig. 2B). On the reverse scan only one cathodic wave is observed for the Fc/Fc^+ couples. At 1 Vs^{-1} the wave assigned to Rh oxidation also appears reversible (Fig. 2B).

The electrochemical response for compound **2** is highly consistent with an electrochemically induced, haptotropic rearrangement and dimerization that ultimately results in the formation of complex **7** (Scheme 1). According to our proposed scheme, at a sweep rate of 20 mVs^{-1}, **2** undergoes a Fc-centered oxidation to form **3**. This weakens the Fc^+O–Rh bond, and on the time scale of the experiment, the Fc^+O group of **3** along with its FcO group are displaced by an arene ligand in a dimerization reaction to form **6** (path A in Scheme 1). Once displaced, the unoxidized FcO groups in **6** are immediately oxidized, which results in the formation of compound **7**. If on the time scale of the electrochemical experiment the dimerization is fast, a single wave associated with oxidation of two Fc groups per Rh center for **2** would be expected (Fig. 2A). The spontaneous oxidation of the uncomplexed FcO groups in **6** is reasonable; they should be more electron-rich than the Rh^+-complexed FcO group in **3** and therefore more easily oxidized. The wave at 980 mV is attributed to a Rh^I/Rh^{II} redox couple for **7** (Fig. 2A). Note that the Rh centers of complex **7** are not square-planar ones but have adopted piano-stool geometries. We have shown that a series of isoelectronic mononuclear *cis*-phosphane, η^6-arene piano-stool complexes exhibit reversible Rh^I/Rh^{II} redox couples.[11] A comparison of the current passed for the oxidation of **7** (Scheme 1 and Fig. 2) and the current associated with the **7** to **5** conversion (1:2) indicates that oxidation of **7** is a two-electron transfer process. The nature of the product formed from the oxidation of **7** is currently under investigation.

At 1 Vs^{-1} (Fig. 2B), the electrochemical reaction sequence for **2** follows a different pathway (path B in Scheme 1), but ultimately yields the same dimer (**7**) that formed in path A. The first step is a Fc-centered oxidation of **2** to form **3**, but before dimerization occurs, a second Fc-centered oxidation forms **4**. Since the Fc^+O group in **3** remains bound to Rh on the time scale of the electrochemical experiment, the FcO group in **3** is oxidized at a more positive potential than the FcO group(s) in **2** (or **6** in path A, Scheme 1). In short, at fast scan rates the second FcO group in **2** is more difficult to oxidize than the first because they are in electronic communication with each other through their interaction with the Rh center. Compound **4** then dimerizes by arene displacement of its labile Fc^+O groups to form **7**. As at a sweep rate of 20 mVs^{-1}, the oxidation of **7** at 1 Vs^{-1} is a reversible process. On the return sweep at both 20 mVs^{-1} and 1 Vs^{-1}, all Fc^+O groups of **7** are reduced at one potential to form **5**, because all are dissociated from the Rh centers and therefore are not in electronic communication with each other. Once **5** is formed, it deoligomerizes to reform **2**, which makes the entire electrochemical sequence a chemically reversible process. This deoligomerization step is analogous to the dissolution of crystals of **5** in CD_2Cl_2 to form **2** (see above).

These experiments clearly show that RHLs may be used to control transition-metal coordination environment (both steric and electronic), and in the case of **2**–**7**, they may be used to control the position of the monomer/dimer equilibrium.

Experimental Procedure

All NMR spectra were recorded on a Varian Gemini 300 MHz spectrometer at 20 °C. For all ^{31}P NMR spectra 85% H_3PO_4 was the external reference.

(2-chloroethyl)ferrocenyl ether: ^1H NMR (C_6D_6): δ = 3.20 (t, J(H,H) = 5.6 Hz, 2H, CH_2Cl), 3.50 (t, J(H,H) = 5.6 Hz, 2H, CH_2O), 3.62 (t, J(H,H) = 1.9 Hz, 2H, Fc protons), 3.89 (t, J(H,H) = 1.9 Hz, 2H, Fc protons), 4.08 (s, 5H, Fc protons); MS(EI) (60 eV, 190 °C): m/z 264 [M^+]. Elemental analysis: calcd for $C_{12}H_{13}ClFeO$: C 54.49, H 4.95; found: C 54.67, H 4.98.

1: ^1H NMR (C_6D_6): δ = 2.43 (t, J(H,H) = 7.5 Hz, 2H, CH_2P), 3.63 (t, J(H,H) = 1.9 Hz, 2H, Fc protons), 3.86 (dt, J(H,H) = J(H,P) = 7.6 Hz, 2H, CH_2O), 3.92 (t, J(H,H) = 1.9 Hz, 2H, Fc protons), 4.02 (s, 5H, Fc protons), 7.00–7.45 (m, 10H, Ph); ^{31}P NMR (C_6D_6): δ = −21.3 (s); FAB-MS: m/z 414 [M^+]. Elemental analysis: calcd for $C_{24}H_{23}FeOP$: C 69.58, H 5.59; found: C 69.78, H 5.67.

2: ^1H NMR (CD_2Cl_2): δ = 2.78 (m, 4H, CH_2P), 3.82 (m, 4H, Fc protons), 3.98 (s, 10H, Fc protons), 4.20 (m, 8H, CH_2O and Fc protons), 7.27–7.42 (m, 20H, Ph); ^{31}P NMR (CD_2Cl_2): δ = 61.0 (d, J(Rh,P) = 211.3 Hz); FAB-HRMS: m/z calcd 931.0727 [M^+], found 931.0703 [M^+].

[12] Crystal data for **5**-$(BF_4)_2$: $C_{96}H_{92}Fe_4B_2F_8O_4P_4Rh_2 \cdot 4CH_2Cl_2$, $M_r = 2206.34$, $0.29 \times 0.14 \times 0.05$ mm, triclinic, space group $P\bar{1}$, $a = 10.934(2)$, $b = 14.322(3)$, $c = 16.956(4)$ Å, $\alpha = 73.29(2)$, $\beta = 83.43(2)$, $\gamma = 81.66(2)$ Å, $V = 2509(2)$ Å^3, $\rho_{calcd} = 1.460$ g cm^{-3}, $Z = 1$, $\theta_{max} = 22.60°$, $\mu(Mo_{K\alpha}) = 11.11$ cm^{-1}, $\lambda = 0.71069$ Å, $F(000) = 1120$. Data were collected on an Enraf-Nonius CAD-4 diffractometer at -120 ± 1 °C using the ω–θ scan technique ($2\theta \leq 45.9°$). The data were corrected for Lorentz and polarization effects. In addition, an analytical absorption correction was applied with transmission factors ranging from 0.84–0.95. The structure was solved by direct methods (SHELXS-86). Of the 6959 reflections, 4065 with $I > 3.00\sigma(I)$ were used in the refinement. Refinement of 589 variable parameters (TEXAN 5.0) converged with the residuals of $R = 0.051$ and $R_w = 0.052$. Four dichloromethane solvent molecules were found in the unit cell; two remained disordered after refinement. The highest peaks left in the final difference map were located in the vicinity of the disordered solvent molecules. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

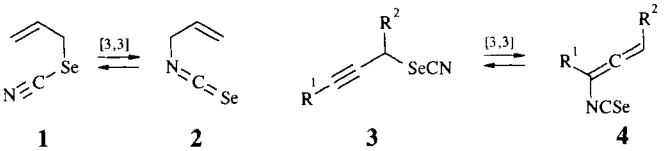
Synthesis and Reactions of Vinyl Isoselenocyanates**

Klaus Banert* and Christoph Toth

Dedicated to Professor Harald Günther on the occasion of his 60th birthday

The existence of isoselenocyanates ("seleno mustard oils") was doubted for a long time,[1] but the synthesis of several aryl and alkyl derivatives has been achieved in recent years.[2] To the best of our knowledge, however, vinyl isoselenocyanates have not yet been prepared. We now report on isomerization reactions that are derived from the known equilibration[3] of allyl selenocyanate **1** and allyl isoselenocyanate **2**, but direct the isoselenocyanato function to a *vinylic* position for the first time. These [3,3]sigmatropic rearrangements provide access to the highly reactive allenyl isoselenocyanates **4** and the isoselenocyanate-substituted 1,3-butadienes **11** and **15**.

An equilibrium of prop-2-ynyl selenocyanates **3** and allenes **4** is established on gas-phase thermolysis[4] of **3**[5] (Scheme 1). Due to their pronounced tendency to polymerize, the isoselenocyanates **4** can only be handled in solution. They can nevertheless be purified by flash chromatography (SiO_2, hexane/Et_2O 10:1; for characterization of **4**, see Table 1). The equilibrium **3a** ⇌ **4a**[6] is verified by renewed gas-phase thermolysis of **4a**.



1 **2** **3** **4**

Scheme 1. **3a**, **4a**: $R^1 = R^2 = H$; **3b**, **4b**: $R^1 = H$, $R^2 = Me$; **3c**, **4c**: $R^1 = Me$, $R^2 = H$; yields based on converted **3**: **4a** 80%, **4b** 82%, **4c** 76%; ratios at equilibrium: **3a**/**4a** = 37:63; **3b**/**4b** = 17:83; **3c**/**4c** = 79:21.

Table 1. Selected physical data of compounds **4a–c**, **5**, and **9** [a].

4a: ^{1}H NMR: $\delta = 5.44$ (d, $^4J = 6.4$, 2 H; H-3), 6.16 (t, $^4J = 6.4$, 1 H; H-1); ^{13}C NMR: $\delta = 86.30$ (t; C-3), 89.51 (br. d; C-1), 128.40 (v. br. s; NCSe), 210.88 (s; C-2); GC-MS: *m/z* (%): 145 (82) [M^+], 118 (38) [$M^+ - HCN$], 39 (100) [$C_3H_3^+$]; IR (CCl_4): $\tilde{\nu} = 2080$ (NCSe).

4b: ^{1}H NMR: $\delta = 1.79$ (dd, $^3J = 7.4$, $^5J = 2.7$, 3 H; H-4), 5.80 (dq, $^3J = 7.4$, $^4J = 5.9$, 1 H; H-3), 6.03 (dq, $^4J = 5.9$, $^5J = 2.7$, 1 H; H-1); ^{13}C NMR: $\delta = 13.62$ (q; C-4), 87.94 (br. d; C-1), 97.63 (d; C-3), 126.90 (br. s; NCSe), 206.26 (s; C-2).

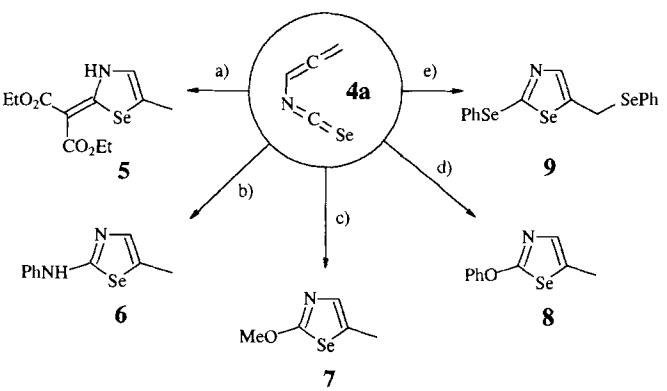
4c: ^{1}H NMR: $\delta = 1.96$ (t, $^5J = 3.2$, 3 H; CH_3), 5.24 (q, $^5J = 3.2$, 2 H; CH_2); ^{13}C NMR: $\delta = 18.97$ (q; CH_3), 83.73 (t; CH_2), 98.75 (br. s; *c*-NCSe), 128.18 (br. s; NCSe), 208.03 (s; C-2).

5: yellow crystals: m.p. 128 °C; ^{1}H NMR: $\delta = 1.35$ (t, $^3J = 7.1$, 6 H; CH_2CH_3), 2.37 (d, $^4J = 1.5$, 3 H; 5-CH_3), 4.27 (q, $^3J = 7.1$, 4 H; CH_2), 6.92 (q, $^4J = 1.5$, 1 H; H-4), 12.70 (s, 1 H; NH); ^{13}C NMR: $\delta = 13.68$ (q, 2 C; CH_2CH_3), 14.36 (q; 5-CH_3), 60.10 (t, 2 C; CH_2CH_3), 87.62 (s; $C(CO_2Et)_2$), 122.48 (d; C-4), 128.40 (s; C-5), 168.00 (s), 175.00 (s); IR (CCl_4): $\tilde{\nu} = 1650$ (C=O), 1620 (C=O), 1250 (C–O); correct elemental analysis based on $C_{11}H_{15}NO_4Se$.

9: light-red, viscous liquid: ^{1}H NMR: $\delta = 4.21$ (d, $^4J = 0.9$, 2 H; CH_2), 7.20–7.80 (m, 11 H; 2 × Ph and H-4); ^{13}C NMR: $\delta = 25.35$ (t; CH_2), 127.85 (d; Ph), 128.56 (s; C-5), 129.34 (d; Ph), 129.50 (d; Ph), 129.80 (d; Ph), 133.80 (d; Ph), 135.98 (d; Ph), 142.37 (d; C-4), 143.59 (s; *i*-Ph), 146.15 (s; *i*-Ph), 164.85 (s; C-2); correct elemental analysis of the picrate based on $C_{22}H_{16}N_4O_7Se_2$.

[a] ^{1}H NMR ($CDCl_3$, 300 or 200 MHz, *J* in Hz), ^{13}C NMR ($CDCl_3$, 75 or 50 MHz, *J* in Hz), MS (EI, 70 eV, correct isotopic distribution), IR ($\tilde{\nu}$ in cm^{-1}), elemental analyses (C,H,N).

In contrast to allenyl isocyanates[7] but similar to allenyl isothiocyanates,[8] compounds **4** afford heterocyclic products on treatment with carbon-, nitrogen-, oxygen-, or seleno-containing nucleophiles (Scheme 2). The syntheses of selenazoles[9] **5**–**9** (Table 1) show that **4a** reacts distinctly more slowly with nucleophiles than the unusually reactive allenyl isothiocyanate.[8]



Scheme 2. Reactions of **4a** with nucleophiles to give the selenazoles **5**–**9**; a) NaH, THF, $CH_2(CO_2Et)_2$, then **4a**, 20 °C, 2 h, then NH_4Cl, H_2O (65%); b) $PhNH_2$, Et_2O, hexane, 60 °C, 17 h (60%); c) MeOH, 60 °C, 24 h (50%); d) PhOH, NEt_3, Et_2O, hexane, 60 °C, 48 h (88%); e) NaH, THF, Ph_2Se_2 (excess), 75 °C, 1.5 h, then **4a** 40 °C, 5 h and 20 °C, 16 h, then NH_4Cl, H_2O (50%).

[**] Rearrangement Reactions, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 4: K. Banert, S. Groth, H. Hückstädt, K. Vrobel, *Phosphorus, Sulfur, Silicon Relat. Elem.* **1994**, *95–96*, 323–324.

Not only the prop-2-ynyl selenocyanates **3** but also the buta-2,3-dienyl selenocyanates **10b** and **10d**, which are easily accessible from the respective precursors **10a**[10] or **10c**[11] and potassium selenocyanate, are suitable reactants for rearrangements that direct an isoselenocyanate function to a vinylic position. The buta-1,3-dienes **11a** and **11b** are formed by gas-phase thermolysis[4] in a virtually irreversible reaction (in the case of **10d** thermolysis is also possible in solution). On treatment with the reactive dienophiles **12**, **11b** undergoes [4 + 2] cycloadditions to give **13** (Scheme 3, Table 2).

Heating of a very dilute solution of **14**[12] in toluene causes a double [3,3]sigmatropic isomerization to produce the bis(isoselenocyanate) **15** (yield 12%, Table 2), which can be separated from unconverted **14** (26%) by flash chromatography (SiO_2, hexane/Et_2O 10:1). In this case, gas-phase thermolysis entails considerable decomposition on attempts to evaporate the precursor and provides unsatisfactory yields (about 1%) due to the low volatility of **14** and the extreme tendency of **15** to polymerize.

The bis(isocyanide) **16a** is produced in a rapid and smooth reaction on treatment of **15** with triethyl phosphite, triphenylphosphane, or polymer-supported triphenylphosphane. This 2,3-diisocyanobuta-1,3-diene constitutes the central structural element of the xanthocillines **16b**,[13] a group of natural antibiotics. Deselenizations **11a** → **17a**, **11b** → **17b**, and **4a** → **18**[14] are performed analogously (Scheme 4, Table 2). Isonitrile **17b** can be distilled under vacuum whereas **17a** possesses a distinctly lower stability; **16a** can be handled only in solution. As yet we have not succeeded in synthesizing the isonitriles on desulfurization of the corresponding isothiocyanates.[8]

Table 2. Selected physical data of compounds **11a,b**, **15**, **16a** and **17a,b** [a].

11a: ^{1}H NMR: δ = 5.17 (br. s, 1 H; H-1), 5.31 (br. s, 1 H; H-1), 5.37 (dd, ^3J = 10.3, ^5J = 1.5, 0.8, 1 H; *E*-H-4), 5.59 (d, ^3J = 16.7, 1 H; *Z*-H-4), 6.27 (dd, ^3J = 16.7, 10.3, 1 H; H-3); ^{13}C NMR: δ = 114.68 (dd; CH_2), 117.97 (dd; CH_2), 128.46 (br. s; NCSe), 131.18 (d; C-3), 134.28 (s; C-2).

[4] The selenocyanates were passed at a pressure of about 0.1–0.01 Torr without carrier gas through a glass tube (about 45 × 1.5 cm) filled with Raschig rings and heated to 350–400 °C. To prevent polymerization the products were collected in a cold trap and diluted with an inert solvent before thawing. Gas-phase thermolyses of **3** performed at temperatures lower than 350 °C resulted in incomplete equilibration (increased ratio **3**:**4**), whereas temperatures higher than 400 °C led to a constant **3**:**4** ratio (see Scheme 1) but also to several (volatile) products of successive reactions. With optimized conditions **3** could be evaporated nearly without residue, but it was not possible to avoid the deposition of decomposition products in the pyrolysis tube completely.

[5] All selenocyanates were prepared on treatment of halogen compounds or sulfonates with potassium selenocyanate in DMSO. Under these conditions the

formation of S_N2' products, for example, the reaction of 1-methylprop-2-ynyl tosylate ("3-tosyloxy-1-butyne") to give 1-selenocyanatobuta-1,2-diene, could be repressed to a large extent. Yields: **3a** 80% from the bromide, b.p. 55–60 °C at 2 Torr; **3b** 80% from the tosylate, b.p. 60–61 °C at 3 Torr; **3c** 33% from the tosylate, b.p. 50 °C at 0.1 Torr.

[6] For comparison: The equilibration of the allyl compounds resulted in a **1**:**2** ratio of 73:27 (^{1}H NMR, 80 °C, $CDCl_3$).

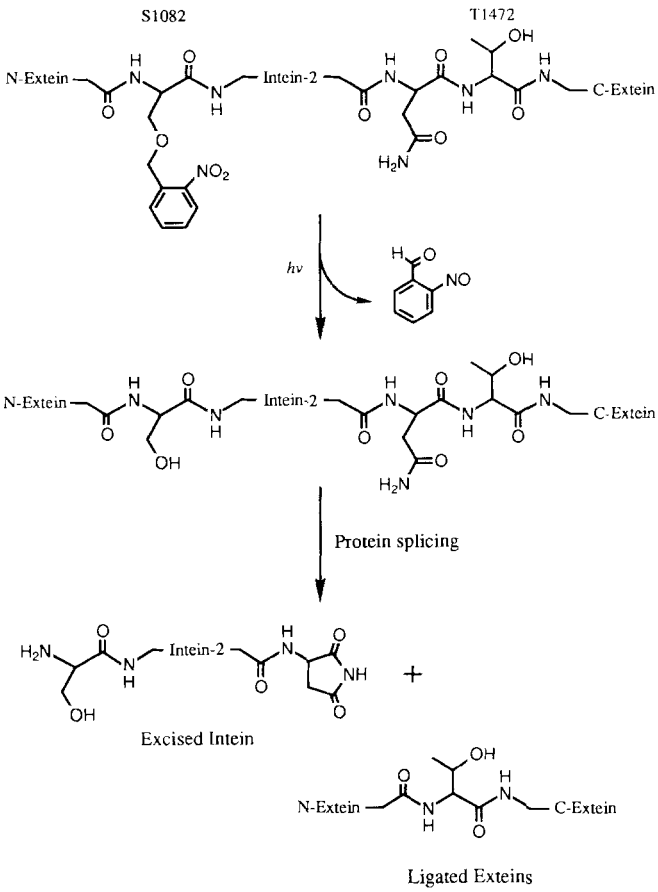
Photochemically Initiated Protein Splicing**

Sandra N. Cook, William E. Jack, Xiaofeng Xiong, Lora E. Danley, Jonathan A. Ellman, Peter G. Schultz, and Christopher J. Noren*

Protein splicing is a post-translational rearrangement process in which an internal polypeptide segment (intein)[1] is excised from a primary translation product, with concomitant ligation of the flanking polypeptides (exteins).[2] This process results in the production of two protein products from a single precursor polypeptide: the intein (often a homing endonuclease thought to initiate lateral transmission of the intein coding sequence)[3] and the ligated exteins.

A substantially purified precursor protein has been shown to splice in vitro, which indicates that protein splicing is autocatalytic.[4] Expression of intein coding sequences in foreign genetic contexts has demonstrated that all of the residues required for splicing reside within the intein except for the first residue of the C-extein.[4–6] Comparison of seven examples of self-splicing proteins revealed several conserved features, including small nucleophilic residues (Cys, Ser, or Thr) immediately following both splice junctions and the sequence His–Asn immediately preceding the downstream junction.[2] Substitutions for the Ser/Cys/Thr residues at either junction abolished splicing,[2e, i, 5–7] which has led to the proposal of splicing mechanisms in which either or both of these residues play a role analogous to that of the active site nucleophiles of serine and cysteine proteases.[2e, h, i, 4, 8] We have begun to probe the mechanism of this novel biochemical reaction using the method of unnatural amino acid mutagenesis and now report the generation and characterization of a photochemically initiated self-splicing reaction.

Intein-2 from the DNA polymerase of *Thermococcus litoralis* (*Tli pol*, Vent polymerase) was chosen for initial studies. This protein has a serine at the upstream splice junction and a threonine at the downstream junction.[2d] In order to cage the unspliced precursor protein, the 2-nitrobenzyl ether of serine was substituted for the conserved Ser1082 residue at the upstream splice junction (Scheme 1).[9] Upon irradiation at 300–350 nm, 2-nitrobenzyl ethers undergo rapid conversion to the



Scheme 1. Initiation of protein splicing of truncated *Thermococcus litoralis* DNA polymerase by photolysis of 2-nitrobenzyl ether at the upstream splice junction.

free alcohol and 2-nitrosobenzaldehyde,[10] so the wild-type sequence should be restored upon photolysis and splicing should proceed normally. Incorporation of the caged serine analog *O*-(2-nitrobenzyl)serine was accomplished by in vitro suppression of the corresponding amber nonsense mutation with a chemically aminoacylated suppressor tRNA.[11, 12] To simplify analysis of splicing products, the Ser1082 → amber (Ser1082*am*) mutation was introduced into a truncated construct (pANY5) in which the 45.3 kDa *Tli pol* intein-2 is flanked by only 2.2 kDa of the N-extein and 8.3 kDa of the C-extein.[13]

When expressed in an *E. coli* coupled transcription/translation system[11, 14] (Fig. 1), the wild-type construct pANY5 yielded the expected 55.8 kDa precursor and the 45.3 kDa excised intein (the endonuclease PI-*Tli*I), which were detected by Western analysis using an anti-PI-*Tli*I antibody.[15] The yield of spliced product was approximately 70%, which is in agreement with reported results for archaea inteins expressed in *E. coli*.[2e, 4] This presumably reflects an incorrectly folded subpop-

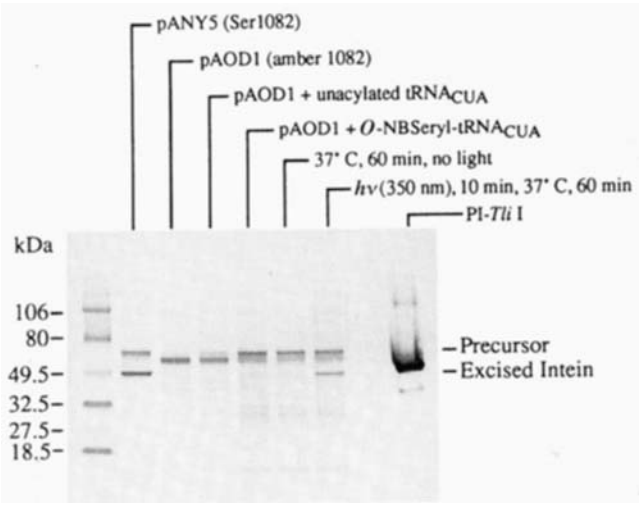

Fig. 1. Western blot analysis of in vitro suppression and photochemically initiated splicing. In vitro transcription/translation reactions [14] (30 μL) contained 3 μg of the expression vector pANY5 (2.2 kDa N-extein/45.3 kDa intein/8.3 kDa C-extein) or the upstream amber mutant pAOD1 (S1082*am*) as indicated, and were supplemented with 8.5 μL of S-30 extract from *E. coli* D-10, 450 units T7 RNA polymerase, 3 μg rifampicin, and, where indicated, 4 μg unacylated $tRNA_{CUA}$ [11c] or 10 μg *O*-NB-seryl-$tRNA_{CUA}$ [11b]. Reactions were incubated 30 min in the dark at 37 °C with shaking. A 5 μL portion of each reaction was withdrawn and precipitated with acetone for later gel analysis. Translation was then arrested in the *O*-NB-Ser-suppressed reactions with RNase A (0.3 mg mL^{-1}), and protein splicing was photoinitiated by irradiating half of each reaction on ice with a 275 watt tungsten lamp equipped with a UV filter (GE model RSK6B) at a distance of 20 cm for 10 min, while the other half was kept in the dark as a control. Both portions were then incubated in the dark for 60 min at 37 °C to allow the splicing reaction to take place, after which 5 μL of each was precipitated with acetone for gel analysis. All samples were denatured and electrophoresed on a 10–20% gradient SDS-tricine gel (NOVEX), transferred to nitrocellulose membrane, and probed with anti-PI-*Tli*I antibody (mouse polyclonal serum, C. Carlow) [2d]. Blots were developed with goat anti-mouse IgG/alkaline phosphatase conjugate, using NBT/BCIP as colorimetric substrate [15]. Purified intein-2 (PI-*Tli*I, NEB) was used as a Western standard.

ulation of precursor molecules due to the lower growth temperature of *E. coli*. Expression of the upstream amber mutant pAOD1 (S1082*am*) in the absence of added suppressor tRNA produced a 53 kDa product, consistent with reinitiation of translation following the amber codon. As expected, the intensity of this band was diminished in the presence of aminoacylated suppressor tRNA. Readthrough of the amber codon by endogenous aminoacyl-tRNA (yielding full-length 56 kDa precursor) was insignificant under the conditions employed.

The dinucleotide pdCpA was acylated with *N*-biphenylisopropyloxycarbonyl (BPOC)-protected *O*-(2-nitrobenzyl) serine (*O*-NB-Ser) and ligated to truncated $tRNA_{CUA}$(-CA)[11c] using T4 RNA ligase.[11d, 12a] In vitro transcription/translation of the Ser1082 amber mutant pAOD1 in the presence of deprotected *O*-NB-seryl-$tRNA_{CUA}$ yielded the 55.8 kDa precursor protein (Fig. 1). No 45.3 kDa product corresponding to the excised intein was observed, which indicates that the 2-nitrobenzyl group on the serine hydroxyl group quantitatively blocked the splicing reaction. Brief irradiation of the blocked precursor, followed by further incubation to allow the splicing reaction to occur, resulted in excision of the 45.3 kDa intein with an efficiency comparable to that of the wild-type construct (about 50%). No excision was observed in a control reaction in which the irradiation step was omitted; the excision process is thus absolutely dependent upon irradiation. Attempts to detect the 10 kDa ligation product were unsuccessful, possibly because of the proteolytic sensitivity of *T. litoralis* DNA polymerase in *E. coli*.[2e] Nonetheless, since the wild-type amino acid sequence is liberated upon photolysis, we know from previous studies that intein excision is coupled to extein ligation.[2e, 4]

These results demonstrate that the *O*-NB-Ser-$tRNA_{CUA}$ efficiently suppresses the Ser1082 amber mutant to produce a full-length precursor protein in which splicing can be initiated by brief photolysis. These experiments should make possible a range of time-resolved studies relevant to dissecting the mechanism of the protein splicing reaction.

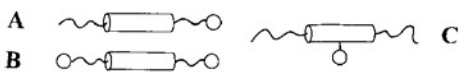
Mesogenic Properties of Amphiphilic Liquid Crystals with an Unusual Head-Group Topology**

Frank Hildebrandt, Jörg Andreas Schröter, Carsten Tschierske,* Reinhard Festag, Ralf Kleppinger, and Joachim Heinz Wendorff

Liquid crystalline phases may be displayed by anisotropic as well as by amphiphilic molecules. Anisotropic (calamitic or discotic) molecules are arranged with their long axes parallel to each other to give thermotropic smectic or columnar liquid-crystalline phases. In contrast, the driving force of the self-organization of amphiphilic molecules is their ability to segregate incompatible (for example, hydrophilic and hydrophobic) parts of the individual molecules. This gives rise to large aggregates which form the basis of lamellar, columnar, or cubic thermotropic and lyotropic mesophases. A combination of these two structural principles can provide new liquid-crystalline materials, consisting of rigid units connected with one, two, or even more hydrophilic groups at the termini of their alkyl chains.[1] The segregation of the different parts of the molecules is facilitated by the parallel arrangement of the rigid cores and visa versa. In amphiphilic polyhydroxy compounds this gives rise to significant mesophase stabilization.[2, 3] The question arose: What happens if a hydrophilic group is not terminally (Fig. 1, A), but laterally (C) attached to a rigid core? The two



different organizing forces of liquid-crystalline phases would be perpendicularly directed to each other in these compounds, and the parallel arrangement of the calamitic units would disturb the segregation of hydrophilic and hydrophobic parts of the molecules and visa versa. We have therefore synthesized novel amphiphilic compounds with hydrophilic groups laterally attached to a rigid 4,4″-didecyloxy-*p*-terphenyl core.

The glycerol ether **3** (Fig. 2, see also Table 1)[4] is the first compound containing this molecular structure. Polarization microscopy established that it is a liquid-crystalline material. On cooling from the isotropic melt at 114 °C the transition to a liquid-crystalline phase can be seen by the formation of batonnets that rapidly coalesce to a focal conic fan texture with pseudoisotropic areas indicating a mesophase of the smectic A type, which crystallizes at 36 °C. No additional phase transition was detected in this temperature range. Reheating gives a melting point of 83 °C.

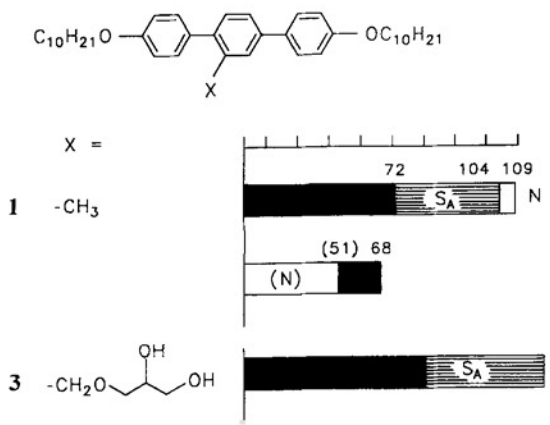

Fig. 2. The influence of lateral substituents on the mesophase behavior of 2′-substituted 4,4″-didecyloxy-terphenyl derivatives. The transition temperatures are displayed as columns: black areas indicate the crystalline state and hatched or blank areas correspond to liquid-crystalline phases (S_A and N, respectively). If the liquid-crystalline phase appears below the melting point, these are metastable (monotropic) mesophases; they were detected by cooling from the isotropic melt. The numbers above the bars indicate that phase-transition temperatures as determined by polarization microscopy. Values in brackets refer to monotropic phase transitions. Abbreviations: N = nematic mesophase, S_A = smectic A Phase. In the case of **1** a monotropic smectic C phase occurs at 70 °C.

In addition the mesophase of compound **3** was investigated with X-ray scattering. The X-ray pattern shows several sharp reflections in the small-angle region, which can be attributed to a layered structure: the peaks can be indexed to the third order. An amorphous halo occurs in the wide-angle region. The compound **3** thus displays a smectic layer structure without long-range order in the layers (S_A phase). A layer thickness of 3.13 nm (at 92 °C) results. Using CPK models and assuming an all-*trans* conformation of the alkyl chains, the molecular length was estimated to be 3.8 nm. The individual molecules are thus arranged parallel to each other in the layers, and the diol groups are placed between the terphenyl groups. The thickness of the smectic layers is significantly smaller than the length of the individual molecules. This can be attributed to a partial intercalation of the terminal alkyl chains. Because the lateral groups are comparatively large, the terphenyl groups are forced apart. The additional free space between the alkyl chains allows a deep interdigitation, which results in a layer distance significantly lower than the molecular length.

A comparison of the diol compound **3** with the 4,4″-didecyloxy-2′-methylterphenyl (**1**, Fig. 2)[5] indicates an influence of the bulky lateral diol group that stabilizes the mesophase. It is indeed very surprising that although the diol **3** has a significantly larger lateral substituent, it displays the greater mesophase stability. This mesophase stabilization is especially evident from the comparison of the diol **3** with compound **2** carrying a lateral substituent of comparable size but without hydroxyl groups; it is contradictory to all previous experience. Until now it was well established that larger substituents in the lateral position of the rigid core of calamitic liquid crystals give rise to a more or less significant destabilization of the liquid-crystalline phases.[6]

We therefore have to assume, that hydrogen bonding between the diol groups is responsible for the unexpected mesophase stabilization of compound **3**.

Although the mesophase stabilization by hydrogen bonding is well documented for amphiphilic diols with terminal diol groups,[2] the mesophase stabilization by lateral diol groups is rather surprising. The formation of a smectic layer structure can only be explained if one assumes a parallel arrangement of the terphenyl units with the diol groups placed between the rigid

cores within the layers. This arrangement contrasts with the usually observed segregation of hydrophilic and hydrophobic parts of amphiphilic molecules and should disturb the hydrogen bonding.

The IR spectra of compound **3** display a broad absorption in the frequency range of the O–H stretching vibrations, indicating the presence of large hydrogen bonding networks. Temperature-dependent measurements of the pure compound show an unusually large shift of its frequency with increasing temperature (Fig. 3). This temperature dependence can be attributed to a successiv collapse of intermolecular hydrogen bonding with increasing temperature. Intermolecular H-bonding is dominant in the crystalline state ($\tilde{\nu}_{max}$ = 3360 cm^{-1}) and also in the liquid-crystalline state. The aggregates are significantly smaller in the liquid state, and an absorption at 3580 cm^{-1} indicates the presence of a substantial number of single molecules with intramolecular hydrogen bonding between the OH groups within the diol unit. The arrangement of the molecules in layers seems to allow the most efficient intermolecular hydrogen bonding and any disturbence of the longitudinal order causes their breakdown.

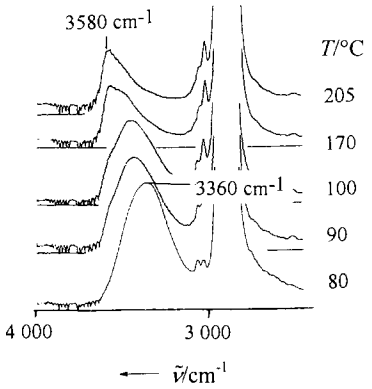

Fig. 3. Sections of the temperature-dependent IR spectra of compound **3** in the range 2500–4000 cm^{-1}, measured with a BIORAD-FTS-40 spectrophotometer, in a heated thermal cell SPECEC P/N 21.500.

In order to estimate the influence of the lateral hydrogen bonding on the molecular order within the smectic mesophase, the nonamphiphilic compound **1** was also investigated by X-ray scattering. In the S_A phase the layer thickness is 3.47 nm (at 85 °C). This is a little bit surprising, because this distance is larger than that of compound **3**. However, the lateral side group of compound **1** is only a methyl group and thus much smaller than the bulky 2-oxa-4,5-dihydroxypentyl group of compound **3**. The possibilities for interdigitation are reduced, and the thickness is consequently much closer to the molecular length. Another remarkable finding is the smaller number of small-angle peaks (three distinct peaks for compound **3** and only two at compound **1**). This indicates a better longitudinal order of the layers built up by the diol derivative **3**. The better ordering is evidently due to the formation of hydrogen bonds between the diol groups. The position of these groups and therefore of the hydrogen bonds between the rigid cores leads to an enhancement of the longitudinal ordering of those cores.

We must conclude that the liquid-crystalline phases of calamitic mesogens can be stabilized by lateral substituents that strongly interact with each other by hydrogen bonding. In order to verify this hypothesis, the chemical structure of these new amphiphilic liquid crystals has been varied by changing the lateral hydrophilic group. The thermotropic liquid crystalline properties of the amides **5**–**8**[7] are compared in Figure 4 (for spectroscopic data of **7** and **8**, see Table 1). It indicates that the mesophase stability of the S_A phase indeed rises with increasing number of hydroxyl groups in the growing lateral chain. The "glucamide" **8** (1-[2,5-bis(4-decyloxyphenyl)benzoylamido]-1-deoxy-D-sorbitol) represents the first example of an entirely novel type of liquid-crystalline carbohydrates.[8] The microscopic texture of the

[a] Correct C,H analyses and ^{1}H NMR spectra are available for all compounds.

mesophase between 112 °C and 147 °C is typical for a smectic A phase. The X-ray pattern exhibits a sharp Bragg reflection and the corresponding reflections of second and third order (Fig. 5). The d value amounts approximately 3.3 nm, which again corresponds to a smectic layer structure in which the terphenyl units are arranged parallel to each other.

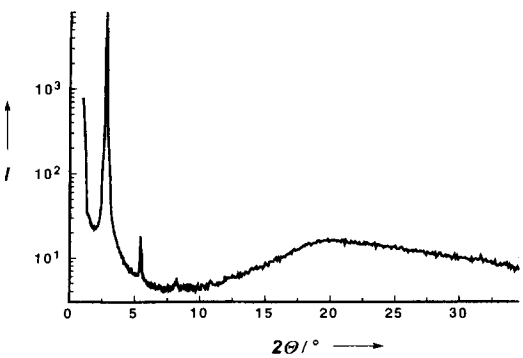

Fig. 5. X-ray scattering of compound **8** in the mesophase at 116 °C. I = intensity in arbitary units.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1515-1632 $ 10.00+.25/0

Though no detailed miscibility studies have been carried out, preliminary contact preparations suggest that the smectic A phases of compounds **1** and **3** and those of the compounds **3** and **8** are completely miscible.

Intermolecular hydrogen bonding is also found in carboxylic acids that are known to form dimers. In Figure 6 the carboxylic acid **10** is compared with its acid chloride **9** and the methyl carboxylate **4**. Again the carboxylic acid (the compound that

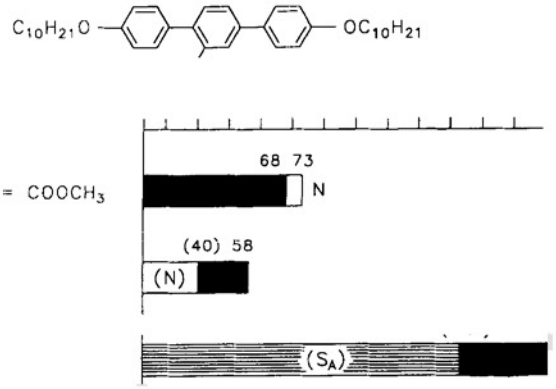

Fig. 6. Comparison of the phase-transition temperatures T/°C of 2,5-bis(4-decyloxyphenyl)benzoic acid (**10**) and the corresponding acid chloride **9** and methyl benzoate **4** (determined by polarization microscopy).

can form hydrogen bonding) displays the higher mesophase stability. The recently described laterally connected siamese twin mesogens[9] and also the covalent, laterally connected trimesogens[5] may be looked upon as examples for covalent, laterally fixed molecules. These compounds also display higher mesophase stabilities compared with structurally related calamitic single mesogens.

If one compares the compounds **1**–**10** it is obvious that lateral fixing of calamitic molecules by hydrogen bonding also increases the structural order, which stabilizes the layered smectic A phase with respect to the nematic phase (N) of the nonamphiphilic compounds. These new compounds also differ in this respect from laterally alkyl substituted calamitic compounds which usually favor the nematic phase.[6]

In summary, we have shown that there is an ambivalent influence of hydrophilic lateral substituents. Their steric requirements tend to separate the rigid cores from each other, which decreases the molecular order and should thus give rise to a significant mesophase destabilization. However, attractive forces between these substituents—such as hydrogen bonding—strongly fix the individual molecules to each other. If these attractive forces exceed the repulsive forces, the longitudinal order of the molecules is increased, and smectic liquid-crystalline phases are stabilized. In this way, lateral fixing of calamitic mesogens by hydrogen bonding is a new approach to smectic materials with broad mesomorphic ranges.

Furthermore, these new amphiphilic diol derivatives resemble an amphiphilic architecture which closely resembles that of the naturally occurring cholic acid salts and some peptides;[10] both consist of rigid stuctures with surfaces of different polarity. The biomimetic potential of these facial amphiphiles makes it exciting to study their ability to form other self-organizing supramolecular systems, such as lyotrophic mesophases, micelles, and thin films. These investigations are under way.

Bromides of Rare Earth Metal Boride Carbides —A System of Building Blocks**

Hansjürgen Mattausch and Arndt Simon*

Only a few metal-rich rare earth metal halides MX_n with $n \leq 2$ are known namely M_2X_3[1–3] and LaI.[4] Other compounds described as binary phases and accessible in low yields, however, finally turned out to be "stabilized" by interstitial atoms.[5] Due to the electropositive nature of the rare earth metals these interstitial atoms have anionic character.

Addition of H, C, N, O in experiments to reduce rare earth trihalides led to numerous new ternary compounds, whose structures could be systematized in terms of a condensation of characteristic building units[6]: M_4O tetrahedra, M_6N_2 double tetrahedra, M_4H tetrahedra, and M_6H_2 octahedra as well as M_6C and M_6C_2 octahedra were repeatedly found. These units can be combined as was demonstrated recently with compounds containing the interstitial atoms C/H,[7] C/O,[8, 9] and C/N[10, 11] simultaneously. Here we report new phases with B/C which particularly well illustrate this building block principle.

$Gd_4Br_3C_2B$, $La_3Br_2C_2B$, and $Ce_6Br_3C_3B_2$ are the first members of a presumably large class of compounds. They can be

obtained as black needles or bars by heating stoichiometric amounts of MBr_3, M, C, and B for several days.[12]

Figure 1 shows the building blocks that occur in the structures of $Gd_4Br_3C_2B$, $La_3Br_2C_2B$, and $Ce_6Br_3C_3B_2$.[13] In these building blocks discrete C atoms are always octahedrally coordinated by M atoms, and B–C units are formed with a trigonal prism around the B atoms connected to a tetragonal pyramid around C. The structure of $Gd_4Br_3C_2B$ contains molecular B–C units with $d_{B-C} = 156$ pm and discrete C atoms (Fig. 1a, 1b).

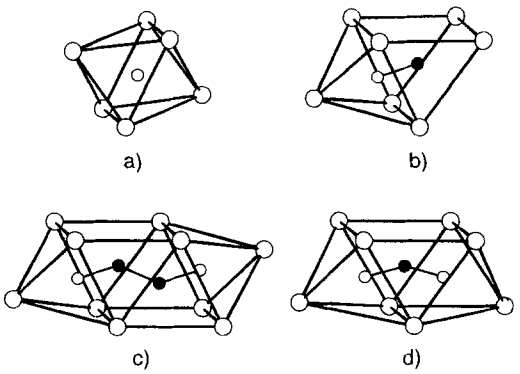

Fig. 1. Monomeric units in the structures of $Gd_4Br_3C_2B$, $La_3Br_2C_2B$, and $Ce_6Br_3C_3B_2$. B: small filled circles, C: small open circles, M: large circles. a) Octahedral coordination of discrete C atoms by M atoms; b) B–C unit with the B atom residing in a trigonal prism and the C atom in a tetragonal pyramid; c) Condensation of two B–C (cf. Fig. 1b) units to form a C-B-B-C group. d) C-B-C unit with the B atom residing in a trigonal prism around and both C atoms in tetragonal pyramids.

In the structure of $Ce_6Br_3C_3B_2$ single C atoms occur together with C-B-B-C groups (Fig. 1a, 1c) which form by condensation of two units of the building blocks shown in Figure 1b through the prism faces. The distances in the B_2C_2 group are $d_{C-B} = 153$ pm and $d_{B-B} = 164$ pm; the C-B-B angle is 139°. The structure of $La_3Br_2C_2B$ contains exclusively BC_2 units characterized by a d_{B-C} distance of 149 pm and C-B-C angle of 148°.

The units shown in Figure 1 are condensed in layers according to Figures 2–4.[15] The space between the layers is filled by Br atoms which belong to a single layer in $Ce_6Br_3C_3B_2$ and $La_3Br_2C_2B$, but some of them interconnect layers in $Gd_4Br_3C_2B$. In the chosen projection of the structure of $Gd_4Br_3C_2B$ the layers are composed of alternating double chains of the building blocks shown in Figures 1a and 1b. The octahedra and prisms are condensed through edges and square faces, respectively. The expansion of these faces leads to long distances between neighboring B–C units ($d_{B-B} = 208$ pm). In the chosen projection for $Ce_6Br_3C_3B_2$ and $La_3Br_2C_2B$ the prisms condensed through their triangular faces are clearly visible. The resulting chains of prisms alternate with chains of octahedra in the case of $Ce_6Br_3C_3B_2$ and are directly coupled in $La_3Br_2C_2B$. The interatomic distances between adjacent B–C groups exceed 380 pm.

The described discrete B-C, C-B-B-C, and C-B-C units are characteristic fragments of the structures of boride carbides of transition metals, lanthanoids, and actinoids. For example, the B_2C_2 units characteristic for $Ce_6Br_3C_3B_2$ are linked to give chains in the structures of UBC[16] and ThBC[17] by the formation of B–B bonds, and the structure of $Th_3B_2C_3$ ($= Th_3C(BC)_2$)[18] contains C-B-B-C units and discrete C atoms. The incorporation of halogen atoms, leads to a breakdown of such three-dimensional networks into layers. The

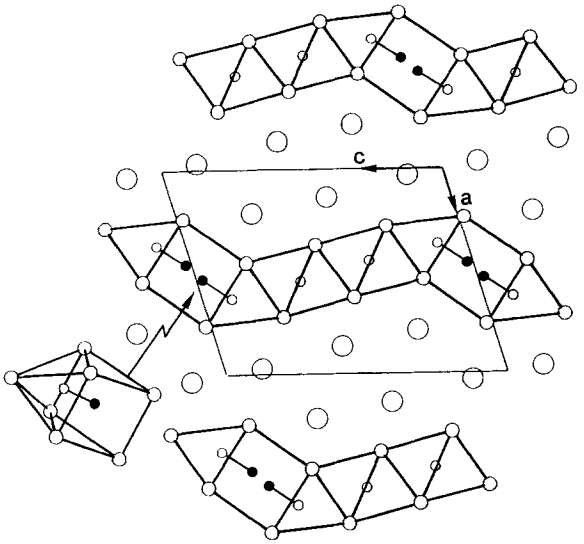

Fig. 2. Projection of the structure of $Gd_4Br_3C_2B$ along [010]. Units (1a) and (1b) (see Fig. 1) are condensed into layers with Br atoms (large circles) arranged between the layers. To illustrate the environment of the B–C unit the prisms and the tetragonal pyramids are drawn separately on the lower left-hand side. The unit cell is outlined.

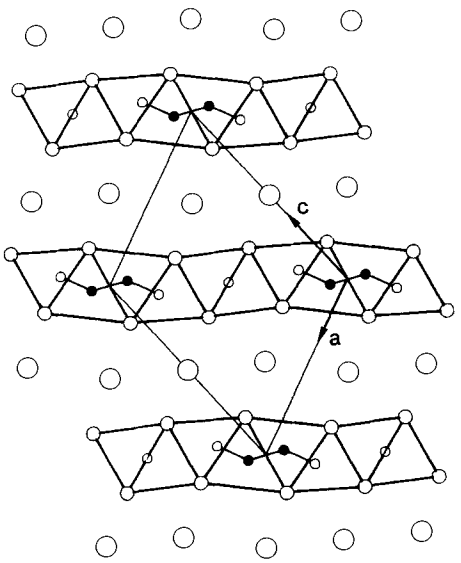

Fig. 3. Projection of the structure of $Ce_6Br_3C_3B_2$ along [010]. Alternating strings of units (1a) and (1c) (see Fig. 1) are condensed into layers which are linked through Br atoms. The unit cell is outlined.

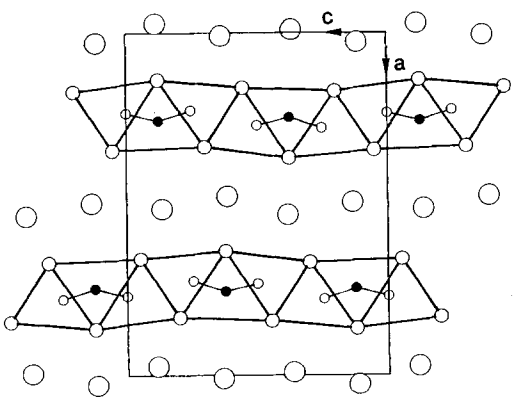

Fig. 4. Projection of the structure of $La_3Br_2C_2B$ along [010]. Slightly corrugated layers, parallel to (001) are composed of unit (1d) (see Fig. 1) and separated by Br atoms. The unit cell is outlined.

fragmentation gives access to a local description of the complex bonding situation in carbide borides.

The structural units found in $Gd_4Br_3C_2B$ can be discussed within the Zintl–Klemm concept as $(Gd^{3+})_4(Br^-)_3(C^{4-})(CB^{5-})$. The B–C distance of 155 pm is in agreement with that calculated for the "methyl borane"-derived BC^{5-} anion.[19] However, it is clear from the low electrical resistivity (van der Pauw method[20]) of this compound, $\rho = 8$ mΩcm in the range between 50 and 300 K, that the treatment of chemical bonding in terms of localized electrons is only applicable in certain cases. In fact, the distance $d_{B-B} = 208$ pm corresponds to a Pauling bond order of 0.22.[19] The existence of weak bonds between B atoms of adjacent B–C units is verified by COOP (COOP = crystal orbital overlap population) analysis on the basis of extended Hückel calculations.[21] Although the "intermolecular" distances between B_2C_2 units in $Ce_6Br_3C_3B_2$ are sufficiently large to exclude bonding interactions, the question remains, whether $B_2C_2^{11-}$ anions can be formulated or whether electrons are partially delocalized in bands exhibiting metal–metal bonding character. For $La_3Br_2C_2B$ the anionic species BC_2^{7-}, which is isoelectronic with SO_2, can be derived according to the Zintl–Klemm concept $(La^{3+})_3(Br^-)_2(BC_2^{7-})$. The BC_2 unit, however, is less bent than SO_2 ($\sphericalangle$O-S-O = 119°, $\sphericalangle$C-B-C = 148°). In Sc_2BC_2 the BC_2 unit is even linear. Evidently, in agreement with the metallic conductivity[22] and the results of band structure calculations[23] one electron per formula unit is delocalized in bands with M–M bonding character in accordance with the formulation $(Sc^{3+})_2(BC_2^{5-})e^-$. $La_3Br_2C_2B$ also shows metallic conductivity so that a partial delocalization of electrons in bands with La character is also expected in this metallic phase.

In the structures of rare earth metal carbide halides zero-, one- and two-dimensional fragments of the three-dimensional carbide structures are realized. We aim to develop a similar structural chemistry with carbide borides.

A New Application of Capillary Zone Electrophoresis: Determination of Energy Barriers of Configurationally Labile Chiral Compounds**

Gerald Weseloh, Christian Wolf, and Wilfried A. König*

Various techniques may be applied in the investigation of configurationally labile compounds. The racemates may be resolved into their enantiomers, and the energy barrier of enantiomerization investigated by chiroptical methods. Alternatives avoiding enantiomeric enrichment or separation are dynamic NMR spectroscopy, HPLC, or GC.[1] Kinetic parameters must, however, be determined by computer simulation of the experimental data.

We describe a new procedure for the determination of energy barriers of enantiomerization reactions based on capillary zone electrophoresis (CZE).[2] With this method enantiomerization reactions may be investigated in the temperature range 25 °C–95 °C by using small amounts of racemic samples, which are typical for CZE. Subsequent computer simulation is unnecessary.

4,4′-Diamino-2,2′-diisopropylbiphenyl **1**, which is present as its diammonium dication in the buffer of pH 3.0, is excellently resolved into its enantiomers by the chiral additive heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in the electrophoretic buffer. Figure 1 shows sche-

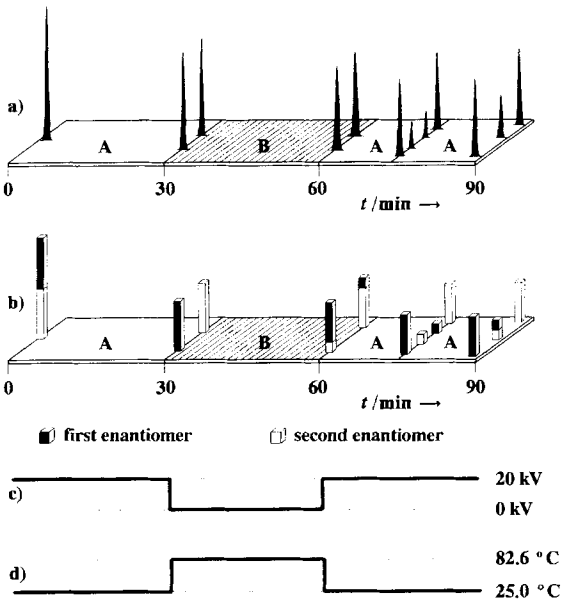

Fig. 1. Schematic illustration of the separation procedure in the capillary over the whole experiment including the enantiomerization time (a) and the enantiomeric composition of each peak (b). In section A the separation proceeds, whereas in section B enantiomerization takes place. The voltage during the experiment is given by (c), and the temperature in the capillary by (d).

matically the analytic method and illustrates the experimental voltage and temperature program. Initially the separation procedes at low temperature to the middle of the capillary. At this point the voltage is switched off. The sample is already completely resolved into the enantiomers. The temperature is increased to a certain value, and the separated enantiomers are left to interconvert for a certain period. The capillary is then cooled to the original temperature, and by switching on the voltage, electrophoresis is continued in the second half of the capillary. In the detector the newly formed racemate is recorded as a new signal located exactly between the signals of the two enantiomers. A correction of the peak area, which is usually indispensable in CZE because of the difference in speed of the sample components is not necessary.[3] Figure 2 shows a typical electropherogram of an enantiomerization experiment.

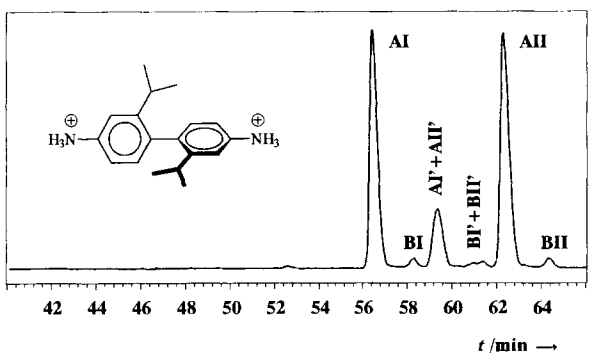

Fig. 2. Electropherogram of an enantiomerization experiment. The duration of enantiomerization is not accounted for in the time axis. AI and AII are the signals of the two enantiomers of **1**. AI' + AII' is the signal corresponding to the interconverted sample. BI, BII, and BI' + BII' are the signals of a structural isomer of **1**. Capillary length: 130 cm; distance to the detector 110 cm; buffer: 30 mM H_3PO_4/NaH_2PO_4 (pH 3.0) to which 0.05% hydroxyethylcellulose had been added as well as heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (30 mM) as a chiral selector; field strength: 154 Vcm^{-1}; separation temperature: 25 °C; temperature of enantiomerization: 82.6 °C. The sample (0.1 mmolar solution) was electrokinetically injected (3 sec at 20 kV).

For the determination of the rotational barriers, experiments with different periods of enantiomerization were performed (Fig. 3). The energy barrier was calculated according to first-order reaction kinetics.

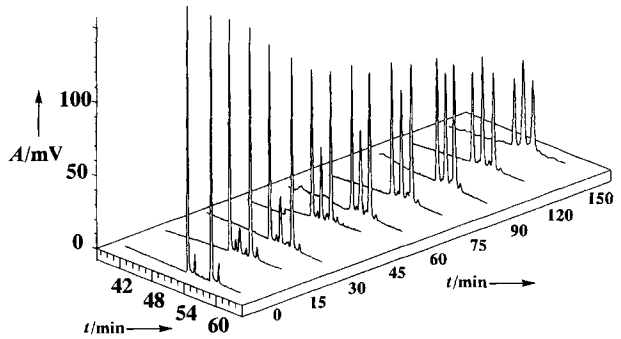

Fig. 3. Comparison of separations with different enantiomerization times.

The rotational energy barrier of the dication of **1** determined by this procedure was 115.2 ± 0.2 $kJmol^{-1}$ at 82.6 °C. Polarimetric investigations of the enantiomerically enriched dication of **1** in ethanol/HCl gave 112.8 ± 0.1 kJ^{-1} at 86.9 °C. Since the energy barrier was determined at comparable temperatures and in similar solvent systems with both methods, the difference of 2.4 $kJmol^{-1}$ may be ascribed to a stabilizing interaction with the cyclodextrin derivative.

The procedure introduced here allows the determination of rotational energy barriers of compounds that cannot be investigated by dynamic GC, HPLC, or NMR spectroscopy. The method can be applied easily on minute sample amounts. No preseparation of the racemate into enantiomers is required. The peak areas are directly correlated with the interconverted sample amount. Thus, in contrast to dynamic methods, a computer simulation is unnecessary.

Experimental Procedure

All experiments were performed with a capillary electrophoresis System 100 (Grom, Herrenberg). The capillary was kept at constant temperature by a water thermostat Julabo Paratherm FT 20B electronic and by a mgw Lauda RC20 cryostat. The sampling system was modified to accommodate sample vials. For recording the detector signals (UV at 210 nm) an Atari-ST computer with a data system from F & A Gibau (Hamburg) was used.

After installation the capillary was rinsed for 10 min each with 1 M NaOH, 0.1 M NaOH, and fully deionized water (Millipore RO_{10}Plus). Before each experiment it was rinsed for 5 min with the buffer used. All solutions were filtered through a 0.45 µm syringe filter (Sartorius RC 15 and Lida 0.45 µm Nylon). To avoid the formation of air bubbles in the capillary during the heating period, the buffer was degassed with helium directly prior to electrophoresis.

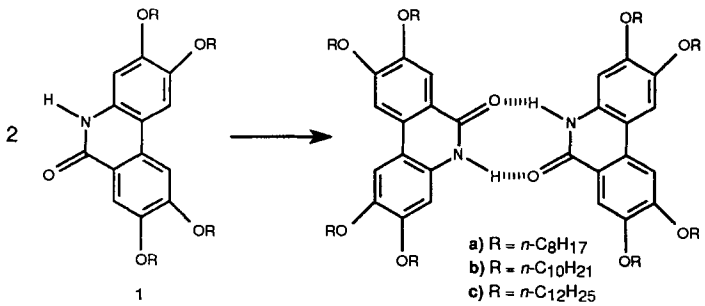
Self-Assembling Discotic Mesogens**

Ralf Kleppinger, C. Peter Lillya,* and Changqing Yang

Since their discovery in 1977[1] many varieties of discotic liquid crystals have been described.[2] While there are many examples of calamitic (rod-shaped) mesogens that self-assemble by hydrogen bonding,[3] there are few examples of columnar mesophase formation by well-defined supramolecules. Some neat soaps,[4] diisobutylsilane diol,[5] Lattermann's monoaryl esters of *cis,cis*-1,3,5-cyclohexanetriol,[6] and Praefcke's inositol derivatives[7] form columnar mesophases as a consequence of amphiphilic interactions. Rationally planned association is apparent in examples reported by Malthête et al.[8] (carboxylic acid dimerization), by Lehn et al.[9] (complementary base pairing), and by Matsunaga et al.[10] (hydrogen bonding parallel to the column axes). None of these examples involves a self-assembled supramolecule with a predictable composition and a persistent disklike shape. Malthête's and Lehn's examples come the closest, but their supramolecules must act in pairs to simulate disks, behavior which would not have been predicted on the basis of molecular structure. We report below the first example of rational molecular design of a predictable self-assembled disklike supramolecule that forms a columnar mesophase.

Our strategy takes advantage of the strong tendency of α-pyridones to form hydrogen-bonded dimers, a phenomenon elegantly exploited by Wuest in his design and study of techtons and other self-assembling species.[11] We surmised that suitably substituted 6(5*H*)-phenanthridinones (**1**) would form persistent disklike dimers (Scheme 1) and consequently would behave as discotic mesogens.



Scheme 1. Dimerization of 6(5*H*)-phenanthridinone derivatives.

To test this hypothesis we synthesized three tetraalkoxy-6(5*H*)-phenanthridinones (**1a–c**, Table 1) via the tetramethoxybiphenylcarboxylate intermediate **2** (Scheme 2), the synthesis of which was previously reported by Dow.[12] Phenanthridinone derivatives **1a–c** exhibited reproducible behavior over multiple DSC heating and cooling cycles[17] (Table 2). The octyl derivative **1a** exhibits several transitions on cooling only, but the decyl (**1b**) and dodecyl (**1c**) derivatives each show two endotherms on heating and two exotherms on cooling. The transitions at the higher temperatures exhibit small enthalpies, consistent with mesophase–isotropic phase transitions.[13] The large enthalpies and supercooling values of the lower temperature transitions are consistent with crystallization.[14]

Table 1. Physical data for compounds **1a–c** [a].

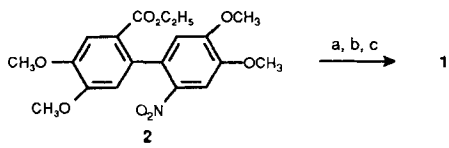
1c: IR (KBr): $\tilde{\nu}$ = 3400 (br., N–H str.), 1670 cm^{-1} (C=O, str.); ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 9.89 (br. s, 1H; N*H*), 7.88 (s, 1H; H_5), 7.49 (s, 1H; H_{10}), 7.41 (s, 1H; H_1), 6.73 (s, 1H; H_4), 4.24–4.06 (m, 8H; OCH_2), 1.90 (m, 8H; OCH_2CH_2), 1.5–1.3 (m, 72H; CH_2), 0.88 (t, ^3J = 6.3 Hz, 12H; CH_3); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): δ = 162.2, 153.7, 151.3, 149.0, 145.4, 130.8, 129.7, 118.4, 111.4, 110.0, 108.9, 104.3, 100.7, 71.0, 69.3, 69.2, 31.9, 29.72, 29.68, 29.53, 29.46, 29.39, 29.2, 26.1, 22.7, 14.1; MS: *m/z* = 931.8028 [*M*$^+$], 932.8101 [*M*$^+$ + H].

[a] Mass spectrometry results were obtained from the Midwest Center for Mass Spectrometry at the University of Nebraska, Lincoln.



Scheme 2. Synthesis of 6(5*H*)-phenanthridinones **1a–c**. Reagents: a) 1. BBr_3/CH_2Cl_2, −78 °C to room temperature; 2. CH_3OH. b) RBr/KI/K_2CO_3/4-methyl-2-pentanone, reflux, 3 days. c) Fe/AcOH, 100 °C, 12 h. Overall yield: 20–25%.

Table 2. Phase transition temperatures of **1a–c**, determined by DSC [a].

	1a		**1b**		**1c**	
	K–M	M–I	K–M	M–I	K–M	M–I
Heating *T* [°C]	114.2 [b]		98.8	118.4	88.3	108.0
ΔH [J g^{-1}]	68.0 [b]	–	66.7	2.8	40.5	1.8
Cooling *T* [°C]	90.4	111.2	78.8	104.7	69.3	103.1
ΔH (J g^{-1}]	66.0	2.3	69.0	2.7	57.9	2.0

[a] K = crystalline phase; M = mesophase; I = isotropic phase. Heating and cooling at 10 °C min^{-1}. [b] K→*I* transitions.

Examination by polarizing optical microscopy[17] confirmed that **1a** forms a monotropic mesophase on cooling, while **1b** and **1c** form enantiotropic mesophases. In the mesophase **1a–c** exhibit focal conic textures. Cooling all three compounds from the isotropic phase caused the dendritic mesophase growth that is a common feature of columnar phase formation[14] (Fig. 1).

In variable-temperature FT-IR measurements[15] on **1c** over a temperature range from 70 °C to 170 °C only hydrogen-bonded phenanthridinone could be detected. At all temperatures the N–H absorption was broad with no high frequency components, while the carbonyl absorption appeared near 1670 cm^{-1}.

The original ideas were developed while C. P. L. enjoyed the hospitality of Prof. H. Ringsdorff's research group at the Institut für Organische Chemie at the Universität Mainz, Germany. R. K. thanks the Deutsche Forschungsgemeinschaft for a fellowship grant (KL 954/1-1).

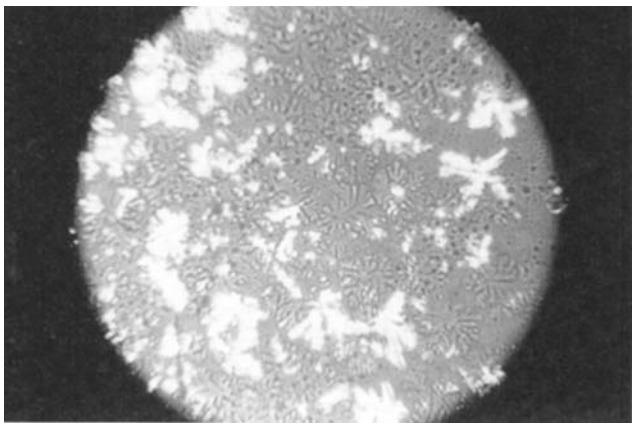

Fig. 1. Photomicrograph of dendritic mesophase growth of **1b**, cooled from isotropic phase to 105 °C. Photo with nearly parallel polarizers, 100×.

X-ray diffraction patterns[16] of the unoriented mesophase of **1b** revealed sharp reflections corresponding to Bragg spacings of 26, 15, and 13 Å, consistent with hexagonal packing of columns. Indeed, small angle diffraction patterns of properly oriented samples resolved into six hexagonally oriented spots on annealing in the mesophase (Fig. 2). The wide-angle region revealed a

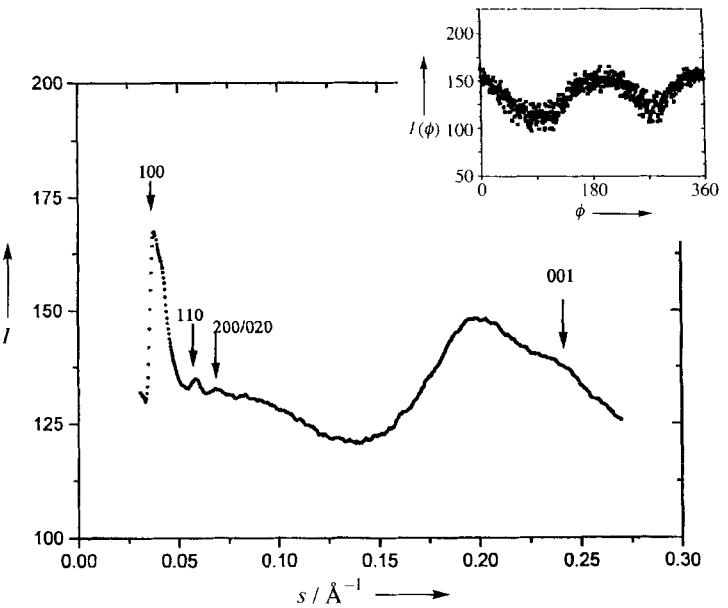

Fig. 2. X-ray scattering diagram of mesophase of **1b**. The radial intensity distribution (I in arbitrary units, $s = (2\sin\theta)/\lambda$ [Å]$^{-1}$) displays reflections from inter- (100, 110, 200/020) and intracolumnar order (001). The insert shows the azimuthal intensity distribution $I(\phi, s = 0.25$ Å$^{-1})$ of the intracolumnar reflection, derived from a densitometer scan performed on a flat-chamber X-ray diagram. The original X-ray pattern was taken from an oriented sample in the mesophase at 110 °C.

halo (max. at 4.5 Å) arising from the liquidlike alkyl side chains, and a broad reflection at 3.6 Å, corresponding to the average distance between disks in the stack. These observations are consistent with a hexagonal columnar phase (D_h), with an intercolumnar distance of 31 Å, and an intracolumnar disk stacking distance of 3.6 Å. Using these lattice parameters, we calculated a mesophase density of 0.45 g cm^{-3} if the mesogenic entity is the monomer but 0.90 g cm^{-3} if the mesogenic entity is a dimer. Only the latter value is tenable; thus phenanthridinone derivatives **1a–c** form the predicted disk-shaped dimers, which, in turn, form hexagonal columnar mesophases.

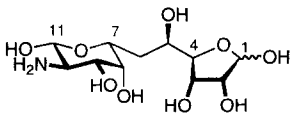
Disaccharide Mimetics by Enzymatic Tandem Aldol Additions**

Oliver Eyrisch and Wolf-Dieter Fessner*

Dedicated to Professor R. R. Schmidt on the occasion of his 60th birthday

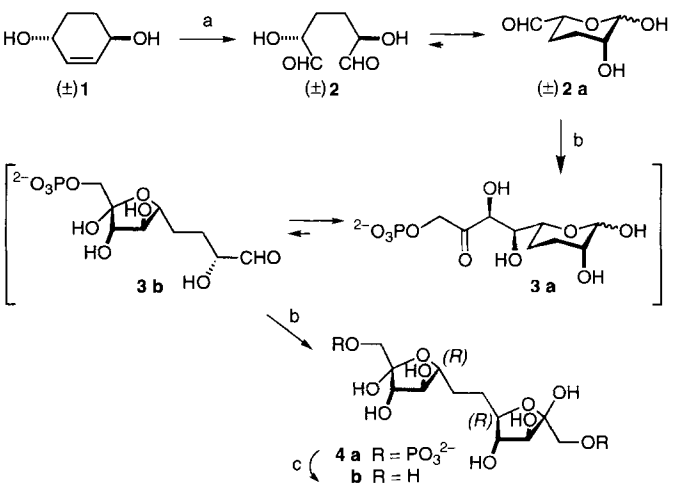
The increasing amount of detailed knowledge on the mode of action of complex oligosaccharides in biological recognition phenomena and the occurrence of longer chain sugars as the bioactive principle of compounds like the tunicamycins have placed the synthesis of higher homologous sugars containing 8–13 carbons and their derivatives in the focus of modern carbohydrate chemistry.[1] Of particular interest are *C*-disaccharides[2] as nonhydrolyzing antimetabolites, that is, potential inhibitors of glycoside-processing enzymes. Classical synthetic strategies—iterative chain elongation or convergent block condensations on the basis of available pentoses or hexoses—require the free, unmasked carbonyl group of the sugars and thus intensive protecting group manipulations. Limited availability or reactivity of suitably configurated precursors from the "chiral pool" are obvious further restrictions.



Tunicamine

In the context of the developing enzymatic de novo syntheses of simple sugars[3] and extending their chains by a C_3 unit to form C_8 and C_9 homologues by using aldolases,[4, 5] we present a new procedure: twofold chain elongation ("tandem" aldolization[6]) of simple, readily available dialdehydes afford dodeco-2,11-diuloses of doubly furanoid or pyranoid nature[7]—formally derived from ketohexoses by C-coupling tail to tail—in a highly stereoselective fashion and with deliberately variable substitution patterns.

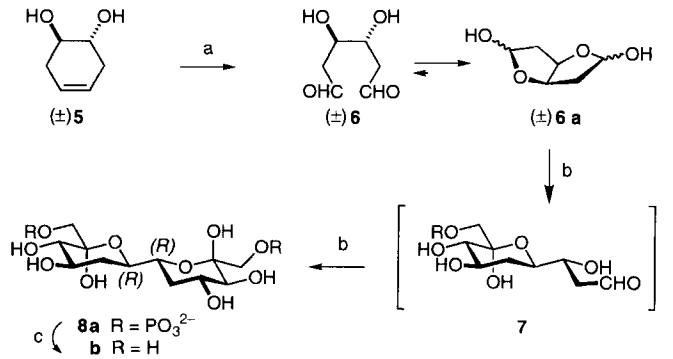
The enzyme-mediated aldol reaction of dihydroxyacetone phosphate (DHAP) and 2- or 3-hydroxylated aldehydes leads to ketofuranoses or ketopyranoses, respectively, while the absolute and relative configurations of all stereocenters in the products can be controlled by the choice of the aldolase (C-3, C-4)[8] and by adopting a kinetically[9a] or thermodynamically selective[9b] reaction mode (C-5, C-6). In principle, such a process should also be applicable to difunctional aldehydes.[10] A plausible candidate for initial tests was 2,5-dihydroxyhexanedial (**2**). Dial **2** is smoothly formed by ozonolysis of racemic cyclohex-2-ene-1,4-diol (**1**)[11] followed by reductive workup and, according to an NMR analysis, exists in solution as a mixture of several constitutional isomers (hydrates, hemiacetals; mostly **2a**) (Scheme 1). Its FruA-catalyzed[8] coupling with DHAP, generated in situ by retroaldolization of fructose 1,6-bisphosphate (FBP), proceeded at a satisfactory rate (about 10% rel. v_{max}) with transient formation of a monoadduct (**3**; TLC analysis). The secondary addition to form **4a** may be at a certain kinetic disadvantage, because in the equilibrium the pyranose form **3a** with a masked aldehyde group is presumably more stable than **3b**, a furanose having a free aldehyde (hydrate) group, but the intermediate is



Scheme 1 [8]. a) O_3/MeOH, −78 °C; Me_2S, room temperature (RT). b) 1.3 equiv FBP, FruA (125 U), triosephosphate isomerase (250 U), pH 7.2, 2 days. c) Acid phosphatase (25 U), pH 5.8, 3 days; 37% **4b** from *rac*-**1**.

practically completely consumed in the presence of a slight excess of DHAP (FBP). After enzymatic dephosphorylation of **4a** with acid phosphatase, chromatography on Ca^{2+} ion-exchange resin, and crystallization from water–acetone, a bisadduct was isolated in 37% overall yield (based on *rac*-**1**; 74% based on (*R,R*)-**1**), which according to its spectra is unequivocally the C_2-symmetrical, all-*trans*-configurated **4b**,[12] a 6,6′-linked dimer of D-fructose. In the crude product mixture no significant amounts of the diastereomer stemming from the (*S,S*) antipode of **2** were detectable ($\leq 5\%$), which is expected to be significantly less stable owing to a twofold *cis*-vicinal substitution.

3,4-Dihydroxyhexanedial (**6**) was generated by oxidative ring cleavage of doubly homoallylic diol *rac*-**5**[13] (Scheme 2) and



Scheme 2 [8]. a) O_3/MeOH, −78 °C; Me_2S, RT. b) 1.0 equiv FBP, FruA (500 U), triosephosphate isomerase (500 U), pH7.2, 7 days; 40% conversion. c) Acid phosphatase (50 U), pH 5.8, 16 h; 13% **8b** from *rac*-**5**.

shown by NMR spectroscopy to exist in aqueous solution as mixed bicyclic anomers **6a** ($\alpha\alpha$:$\alpha\beta$:$\beta\beta$ = 7:9:2), with no indication of a prevalence of a linear species ($\leq 2\%$). Accordingly, the primary aldolization step with DHAP/FruA proceeded considerably more sluggishly than the addition to **2**. The intermediate (presumably mainly pyranose **7**) was not detectable, and the only bisphosphate product was isolated after 7 days of reaction. Dephosphorylation provided in 13% total yield (based on *rac*-**5**; 26% based on (*R,R*)-**5**; about 60–70% when corrected for conversion) the crystalline bipyranoid diketose **8b**. Its C_2-symmetry and the bisequatorial connection between the rings

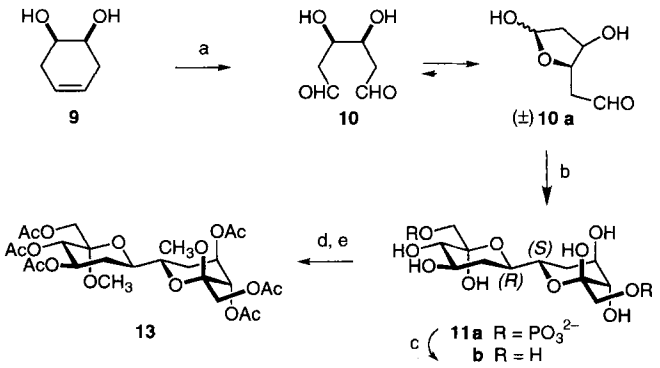
[**] Enzymes in Organic Synthesis, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft (Grant Fe 244/2-2) and the Schwerpunktsprogramm "Synthese-Enzyme" from the state of Baden-Württemberg. We thank Christina Schütte for experimental assistance. Part 9: [5].

are conclusively corroborated by the simple NMR spectra[12] and by the typical occurrence of a pseudo-quartet for the axial protons 5-H and 8-H with almost identical geminal and vicinal couplings of approximately 12 Hz. Despite the use of an excess of DHAP (as FBP) no adduct of the (*S,S*) enantiomer of **6** had been formed. Its constitution (demanding a diaxial linkage) thus seems to be thermodynamically highly disadvantageous even relative to the furanoid FBP.

The *meso*-dialdehyde **10** can stabilize itself only by single cyclization (**10a**, Scheme 3) and therefore should display much better substrate qualities. Indeed, relatively rapidly a bisadduct

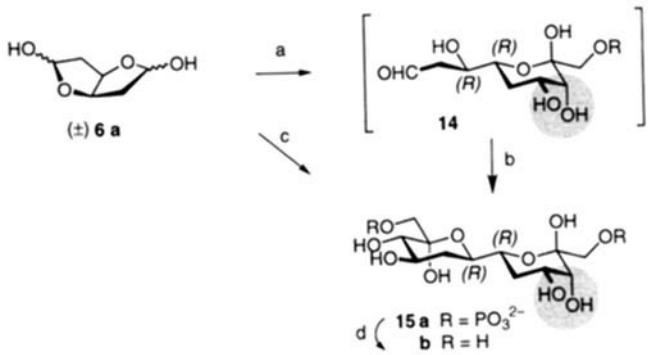


Scheme 3 [8]. a) O_3/MeOH, −78 °C; Me_2S, RT. b) 1.0 equiv FBP, FruA (250 U), triosephosphate isomerase (500 U), pH7.2, 16 h. c) Acid phosphatase (50 U), pH 5.8, 16 h; 71% from **9**. d) **11b** + MeOH, Dowex 50W-X8, reflux; 87% **12** (corresponds to **13**, where H replaces Ac). e) Ac_2O/py, RT; 91% **13**.

accumulated directly from the enzymatic reaction with DHAP/FruA; consequently a potential kinetic preference of the aldolase for the 3-(*S*)- or 3-(*R*)-hydroxyaldehyde moieties within **10** could not be uncovered. Neither phosphate ester **11a**, nor the free syrupy sugar **11b**, obtained in 70% overall yield by conventional processing, allowed a satisfactory NMR analysis to be carried out, because a complex equilibrium of anomers and/or conformers was apparently established, further complicated by the unequivocal participation of partially acyclic forms. Complete signal[12] and conformational analysis was possible for **13**, which was obtained by peracetylation of the sparingly soluble dimethyl glycoside **12** (87%). This revealed that the pyranose subunit stemming from the (*S*)-configurated part of the dialdehyde has to tolerate two axial *O*-acyl substituents at C-3′/C4′ in order to obviate an unfavorable equatorial to axial ring connection.

An application of the RhuA, stereocomplementary to FruA,[8] tested with **6** as example, furnished two rather startling results (Scheme 4): 1) Rapid consumption of DHAP abruptly ceased with formation of a monoadduct **14**, from which a bisadduct (**15a**) could only be obtained upon addition of the FruA enzyme; 2) NMR analysis[12] of **15b** unambiguously established a *cis*-vicinal substitution pattern in one of the two rings, rather than the expected two *trans* forms.

The failure of the RhuA enzyme in the second addition step has to be assigned to the anionic charge of the phosphate ester moiety in the intermediate **14a** (likewise, glyceraldehyde 3-phosphate is not accepted[14]). According to molecular models this charge can be oriented spatially close to the aldehyde group. Since on the other hand the FruA preferentially converts anionic substrates[4] but accepts **6** only reluctantly, the two biocatalysts complement each other almost perfectly for usage in a one-pot synthesis in which **15a** is indeed generated by simulta-



Scheme 4 [8]. a) 2.5 equiv. of DHAP, RhuA, pH 6.8. b) + FruA. c) 0.75 equiv. of FBP, RhuA (150 U), FruA (150 U), triosephosphate isomerase (500 U), pH7.2, 20 h. d) Acid phosphatase (50 U), pH 5.8, 16 h; 46% **15b** from *rac*-**6**.

neous action of both aldolases on **6** and on FBP with high selectivity (≥90% content of **15a** in the crude product; 46% total yield of **15b**). NMR analysis of the adduct and spectral comparison with **8b** substantiated the diequatorial ring connection, an all-equatorially substituted pyranose, and an axially oriented 3-OH group in the second ring ($J_{3,4}$ = 9.4, $J_{3',4'}$ = 3.2 Hz). Because of the employment of *rac*-**6** and "enantiogenic" aldolases, the *cis*-configuration could, in principle, have been created by either of the two enzymes (*epi*-4 OH by RhuA, *epi*-3 OH by FruA; **15** or *ent*-**15**, respectively), but may more plausibly be rationalized merely as the result of an incorrect binding of the aldehyde by the RhuA, since mechanistic arguments suggest enantiospecificity of all DHAP-dependent aldolases for C-3,[15] whereas a limited diastereoselectivity of the RhuA at C-4 for certain types of substrates has been documented.[16] Equilibration at longer reaction times probably allows the erroneously connected *cis*-adduct to accumulate.

The yields of the tandem reactions, some of which need improvement, on one hand reflect the inferior substrate qualities of aldehydes masked as hemiacetals and presumably having high apparent K_m values, and on the other hand the as yet nonoptimized reaction conditions, which, particularly due to the choice of fructose 1,6-bisphosphate as the source for DHAP, may have potential weaknesses in the slow attainment of equilibria of unknown nature; oxidative generation of DHAP in situ[17] seems to be a reasonable alternative. However, the fact that enantiomerically pure complex sugar skeletons of high structural variability can be made from readily accessible, racemic starting materials in a single synthetic step with creation of four new asymmetric centers and differentiation of two more (one of which is independent), makes enzymatic tandem aldolizations highly attractive.

[10] Although several attempts of additions to α,ω-dialdehydes (glyoxal, glutaric dialdehyde) have been reported in the literature, in no case has a product been characterized [18]. Our extensive studies corroborate that enzymatic assays indicate consumption of DHAP, but no defined products result (TLC, NMR analysis). Another problem is the cross-linking by aliphatic dialdehydes, which irreversibly destroys enzymatic activity. We attribute the success of the experiments presented here to the formation of stable hemiacetals by hydroxylated dialdehydes; relative rates of enzyme deactivation, however, have not been determined.

closo-$[B_5H_4PPh_3\{Fe(CO)_3\}\{Ir(CO)_2PPh_3\}]$: The First Structurally Characterized *closo*-Heterobimetallaheptaborane System**

Jonathan Bould, Nigam P. Rath, and Lawrence Barton*

nido-Metallahexaboranes, that is species in which a metal moiety replaces a BH group in *nido*-B_6H_{10}, are convenient starting materials for reactions of hexaboranes since they are easier to handle than B_6H_{10} itself.[1] Two metallahexaboranes can be easily prepared in high yield: *nido*-$[B_5H_9\{Os(CO)(PPh_3)_2\}]$[2] and *nido*-$[B_5H_8\{Ir(CO)(PPh_3)_2\}]$ (**1**).[2,3] While some reactions with osmahexaborane have been reported,[4] other than recent calculations[5] and our own preliminary report of the preparation of $[B_5H_6\{Ir(CO)(PPh_3)_2\}(\mu\text{-}H)\{PtCl(PMe_2Ph)\}]$,[6] nothing has been published about the reactivity of the iridahexaborane cluster since its synthesis was first reported in 1979.[3] This contrasts with, for example, metalladecaboranes which have been extensively studied and which show great similarities to the parent decaboranes.[7]

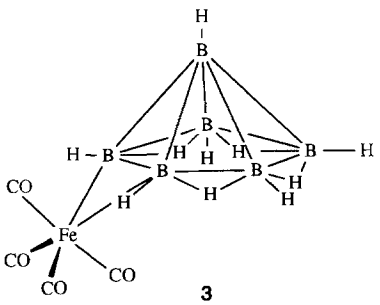
2



3

The B_6H_{10} cluster **2** contains a basal B–B bond with a high degree of basic character.[8] This is a feature that has been exploited in the formation of a number of compounds with iron,[9a–d] iridium,[9b] rhodium,[9b] and platinum,[9e] in which this bond donates two electrons to the metal. Thus for iron the reaction of B_6H_{10} with $[Fe_2(CO)_9]$ affords $[B_6H_{10}\{\mu\text{-}Fe(CO)_4\}]$ (**3**). It was therefore of interest to see if the iridahexaborane analogue **1**, which has a similar basal B–B bond as determined by single-crystal X-ray diffraction (B–B distance 1.65 Å vs. 1.63 Å in B_6H_{10}),[3,10] would undergo an analogous reaction.

[**] We thank the National Science Foundation, the Missouri Research Board, and the University of Missouri-St. Louis for financial support of this work and the Johnson Mathey Company for a loan of $IrCl_3 \cdot 3H_2O$.

Compound **1** was stirred with $[Fe_2(CO)_9]$ (molar ratio 1:1) in CH_2Cl_2 for 24 h. Thin-layer chromatography of the resultant mixture afforded the title compound **5** in approximately 1% yield. NMR[11] and IR[12] spectroscopic investigations suggested a *closo*-iridapentaborane cluster with iron incorporated, and this was confirmed by a single-crystal X-ray diffraction study.[13] The structure of **5** (Fig. 1) reveals a *closo*-bimetallaheptaborane cluster with an $Fe(CO)_3$ moiety in the axial position and an $[Ir(CO)_2(PPh_3)]$ moiety in an equatorial position. As such, **5** is both the first pentagonal-bipyramidal metallaheptaborane to be structurally characterized (two others, $[B_6H_6Cp^*Ni]^{2-}$ [14] and $[B_5H_7(Cp^*Co)_2]$[15] ($Cp^* = C_5Me_5$) have been proposed from NMR evidence) and also the first iridaferraborane. The presence of both first- and third-row transition elements in a metallaborane cluster is also rare.

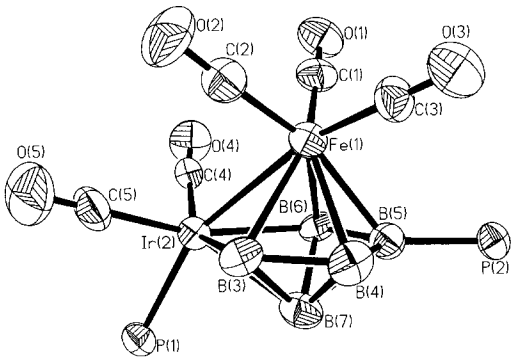

Fig. 1. The molecular structure of **5**. Phenyl rings have been omitted for clarity. There is a terminal hydrogen atom on each boron atom except B(5) as shown by ^1H-{^{11}B} NMR spectroscopy. Selected interatomic distances [Å] and angles [°]: Fe(1)–Ir(2) 2.706(2), Fe(1)–B(3) 2.234(13), Fe(1)–B(4) 2.218(13), Fe(1)–B(5) 2.124(12), Fe(1)–B(6) 2.238(11), Fe(1)–C(1) 1.792(12), Fe(1)–C(2) 1.769(12), Fe(1)–C(3) 1.752(12), Ir(2)–B(3) 2.169(14), Ir(2)–B(6) 2.155(12), Ir(2)–B(7) 2.29(2), Ir(2)–P(1) 2.332(3), Ir(2)–C(4) 1.927(12), Ir(2)–C(5) 1.919(12), B–B 1.57(2)–1.85(2); C-Fe(1)-C 95.5(5)–99.8(5), C(1/2)-Fe(1)-Ir(2) 95.3(3)/88.1(4), C(5)-Ir(2)-C(4) 104.5(5), P(1)-Ir(2)-C(4/5) 92.2(3)/92.4(4).

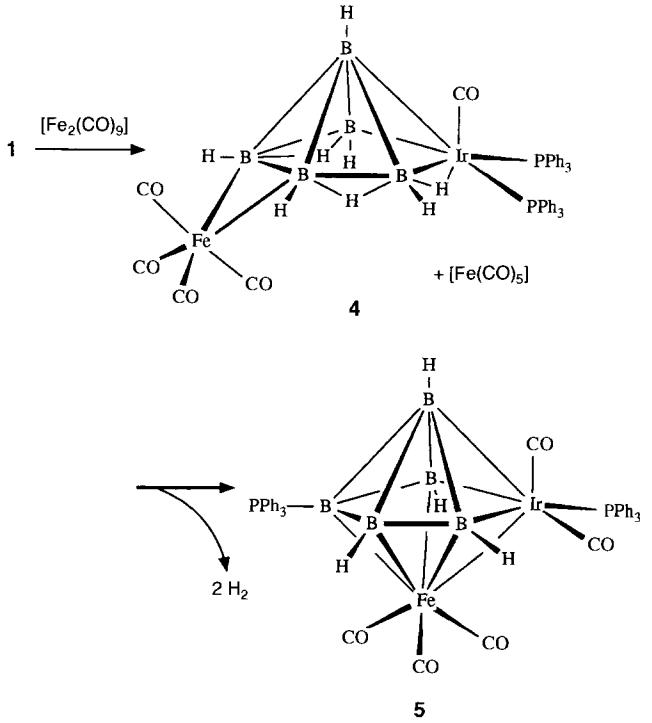
The Fe–Ir distance in **5** (2.706(2) Å) is slightly longer than the sum of the covalent radii and lies in the center of the range of Ir–Fe distances in iron–iridium metal clusters and bridged binuclear complexes that has been taken in these compounds to indicate a significant bonding interaction.[16] The Fe–B distances of 2.12–2.23 Å, which are similar to or longer than the $Ir-B_{(equatorial)}$ distances of 2.16 and 2.17 Å, perhaps reflect the η^5 coordination of the iron center compared to the η^4 coordination of the iridium center. In line with this, the $Ir-B_{(axial)}$ distance of 2.29 Å is about 0.1 Å longer than the the $Ir-B_{(equatorial)}$ distances. Similarly, the $B_{(axial)}-B_{(equatorial)}$ distances (1.77–1.82 Å) are longer than the distances in the equatorial belt (1.57–1.69 Å). The $[B_5H_4\{Ir(CO)_2(PPh_3)\}]$ portion of the molecule retains much of the overall geometry of a *nido*-$[B_5H_8\{Ir(CO)(PPh_3)_2\}]$ cluster with the $\{Fe(CO)_3\}$ moiety effectively capping the open face of the IrB_5 cluster subunit.

In accordance with skeletal electron counting rules,[17] compound **5** is a 16-electron *closo*-polyhedron with seven vertices; the $[Fe(CO)_3]^{2+}$ vertex capping a formal *nido*-$[B_5H_4(PPh_3)\{Ir(CO)_2(PPh_3)\}]^{2-}$ unit. Although the analogy between BH and $Fe(CO)_3$ has been well documented,[18] as far as we are aware there is only one other metallaborane compound in which an $[Fe(CO)_3]$ moiety is η^5 bonded in a *closo*-borane; this is the recently described metallacarborane *closo*-$[C_2B_9H_{11}\{Fe(CO)_3\}]$.[19] It is possible, even though the yield is low and the reaction must be necessarily complex, that the product is formed by the initial addition of an $Fe(CO)_4$ moiety to the iridaborane, followed by ligand rearrangement in which a carbonyl group migrates to the iridium center, and the PPh_3 moiety migrates to the borane cage together with concurrent loss of hydrogen (Scheme 1). The product **5** is the first structurally characterized metallaheptaborane and is one of very few known heterobimetallaboranes based on a mid-sized borane template.



Scheme 1.

Experimental Procedure

A solution of $[B_5H_8\{Ir(CO)(PPh_3)_2\}]$ (200 mg, 0.25 mmol) and $[Fe_2(CO)_9]$ (90 mg, 0.25 mmol) in CH_2Cl_2 was stirred under nitrogen for 24 h. ^{11}B NMR spectra of the solution showed that the initial metallaborane had been completely consumed to give new borane-containing products and also that the title compound was present in the mixture. The solution was concentrated and purified by thin-layer chromatography on silica gel using CH_2Cl_2/pentane as the eluant. A number of bands were observed but only one was sufficiently stable to be isolated by this technique, and this was characterized as the title compound **5** (1.8 mg, 0.8% yield, elemental analysis for $C_{41}H_{34}B_5FeIrO_5P_2$, found (calculated) %: C 50.35 (50.73), H 3.36 (3.53). A crystal suitable for single-crystal X-ray diffraction analysis was obtained by pentane diffusion in to a CH_2Cl_2 solution of the compound.

Enantiospecific Syntheses of Valiolamine and its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid**

Tony K. M. Shing* and Leong H. Wan

Recently the chemotherapeutic potential of glycosidase inhibitors (for example, as anti-HIV agents) was recognized and is being exploited.[1] Natural product valiolamine (**1**), isolated from the fermentation broth of *Streptomyces hygroscopicus* subsp. *limoneus* IFO12703[2] that produces antibiotic validamycin, is the most potent α-glucosidase inhibitor among the amino pseudosugars (carbasugars)[3] valienamine, validamine, and hydroxyvalidamine obtained from chemical or microbial degradation[4] of validamycin. The structure of valiolamine (**1**) was deduced to be (2*S*)-(1,2,4,5/3)-5-amino-1-*C*-hydroxymethyl-1,2,3,4-cyclohexanetetraol on the basis of spectral studies,[5] and its absolute configuration was confirmed by a stereoselective transformation of valienamine or validamine into valiolamine.[6] The *N*-[2-hydroxy-1-(hydroxymethyl)ethyl]valiolamine, coded as AO-128, displayed higher activities than the parent valiolamine and is undergoing clinical trial for treatment of diabetes.[7] Scheme 1 shows the structural resemblance between **1** and α-D-glucose. Since **1** is a potent α-D-glucosidase inhibitor, its (1*R*) diastereomer **2** (1-*epi*-valiolamine) that possesses a β-amino group might be a β-D-glucosidase inhibitor. Along this line of reasoning, (2*R*) and (1*R*,2*R*) diastereomers of valiolamine (**3** and **4**) may inhibit α-D- or β-D-mannosidase, respectively. Three total syntheses of valiolamine (**1**) were achieved starting from a Diels–Alder (furan–acrylic acid) cycloadduct,[8] from D-glucose by a Ferrier rearrangement,[9] and from 2,3,4,6-tetra-*O*-benzyl-D-glucono-1,5-lactone involving an aldol reaction.[10] The last synthesis[10] can also be used to prepare **2**, but no syntheses of amino pseudosugars **3** and **4** have been reported. Our endeavors in pseudosugar synthesis from (−)-quinic acid (**5**) have already furnished 2-crotonyloxymethyl-(4*R*,5*R*,6*R*)-4,5,6-trihydroxycyclohex-2-enone (COTC),[11] pseudo-β-D-mannopyranose, pseudo-β-D-fructopyranose,[12] pseudo-α-D-

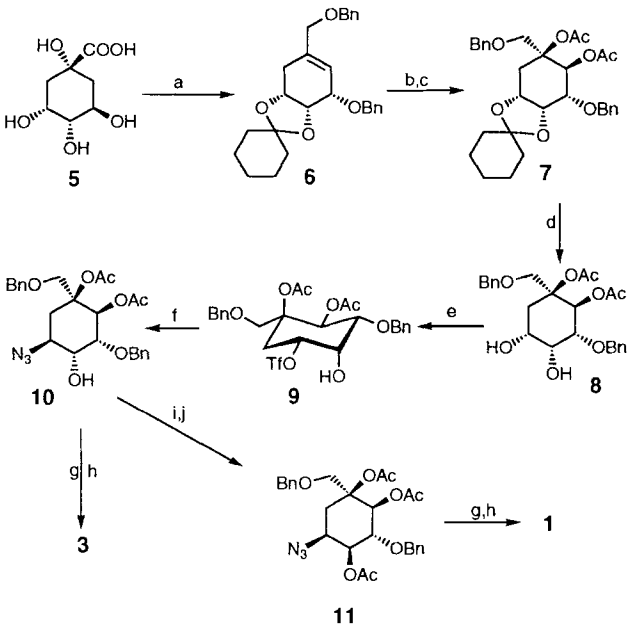
glucopyranose, pseudo-α-D-mannopyranose,[13] and cyclophellitol and its diastereomers.[14] This communication further demonstrates the versatility of this approach in facile syntheses of **1**–**4**.

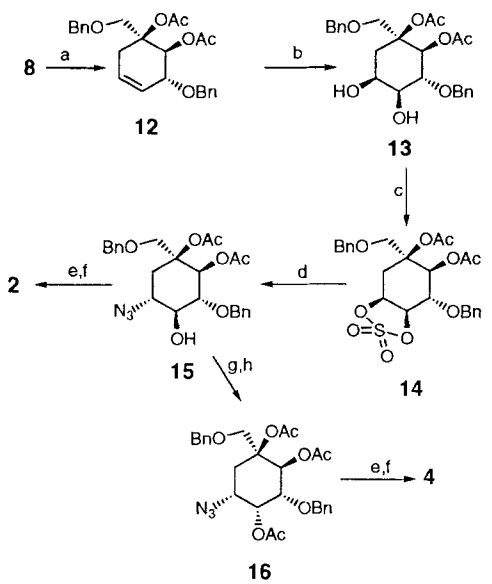
The route to valiolamine **1** and its (2*R*) diastereomer **3** is shown in Scheme 2. Our previous work[14] has indicated that (−)-quinic acid (**5**) could be easily converted into alkene **6** in five



Scheme 2. Syntheses of valiolamine (**1**) and 2-*epi*-valiolamine (**3**): a) 5 steps, 47%, see ref. [13]; b) OsO_4, H_2O, Me_3NO, pyridine, *t*BuOH, reflux, 75%; c) Ac_2O, DMAP, Et_3N, reflux, 90%; d) TFA, H_2O, CH_2Cl_2, 90%; e) Tf_2O (1 equiv), pyridine, CH_2Cl_2, 0 °C, 90%; f) NaN_3, benzo[15]crown-5, DMF, 60%; g) K_2CO_3, MeOH; h) H_2, $Pd(OH)_2$, EtOH, (two steps, 58% for **3**; 73% for **1**); i) Tf_2O, pyridine, CH_2Cl_2, 0 °C, 90%; j) nBu_4NOAc, THF, 80%.

steps with an overall yield of 47%. Catalytic OsO_4 dihydroxylation[15] of alkene **6** from the less hindered β face gave the β-diol, which was protected as diacetate **7**. Acidic removal of the cyclohexylidene acetal in **7** furnished diol **8**, $[\alpha]_D^{25} = -13.5$ ($c = 0.4$ in $CHCl_3$).[16] Selective esterification of the equatorial OH-1 in **8** with one equivalent of triflic anhydride in pyridine gave triflate **9** which reacted with NaN_3 to give azide **10**, $[\alpha]_D^{27} = +9.9$ ($c = 1.6$ in $CHCl_3$).[17] Deprotection of **10** yielded 2-*epi*-valiolamine (**3**) for the first time, $[\alpha]_D^{25} = -11.1$ ($c = 0.4$ in H_2O).[18] On the other hand, triflylation of the alcohol in **10** followed by nucleophilic displacement with nBu_4NOAc in THF provided azido triacetate **11**, $[\alpha]_D^{25} = -14.0$ ($c = 1.5$ in $CHCl_3$). Deprotection of **11** then afforded **1**, $[\alpha]_D^{22} = +15.4$ ($c = 2.2$ in H_2O) [literature value:[5] $[\alpha]_D^{20} = +18.8$ ($c = 1.0$ in H_2O)].

The route to 1-*epi*-valiolamine (**2**) and the ((1*R*,2*R*) diastereomer **4** is illustrated in Scheme 3. Alkene **12** was readily accessible from the diol **8** by a Corey–Winter[19] reaction in 64% overall yield. *cis*-Dihydroxylation of **12** with the catalyst osmium tetraoxide[15] was disappointing and gave 20% yield of β-diol **13**, 10% of the α-diol **8**, and 60% of the starting material **12**. It is noteworthy that our newly developed flash dihydroxylation procedure with catalytic RuO_4[20] afforded the desired β-diol **13**, m.p. 127–128 °C; $[\alpha]_D^{25} = +21.9$ ($c = 1.0$ in $CHCl_3$) in 80% yield! The diol **13** was then converted into the cyclic sulfate **14**, m.p. 61–67 °C; $[\alpha]_D^{21} + 42.2$ ($c = 3.9$ in $CHCl_3$), according to the Sharpless method.[21] Regioselective ring opening of **14** with azide occurred at the C-1 atom to form the desired azido alcohol



Scheme 3. Syntheses of 1-*epi*-valiolamine (**2**) and the (1*R*,2*R*) diastereomer **4**: a) 1,1′-thiocarbonyldiimidazole, toluene, reflux, then $P(OMe)_3$, reflux, 64% overall; b) $RuCl_3 \cdot H_2O$, $NaIO_4$, EtOAc, CH_3CN, H_2O, 0 °C, 80%; c) $SOCl_2$, Et_3N, CH_2Cl_2, 0 °C, then $RuCl_3$, $NaIO_4$, CCl_4, CH_3CN, H_2O, 0 °C, 74% overall; d) LiN_3, DMF, then 20% aq. H_2SO_4, THF, 50%; e) K_2CO_3, MeOH; f) H_2, $Pd(OH)_2$, EtOH (two steps, 75% for **2**; 68% for **4**; g) Tf_2O, pyridine, CH_2Cl_2, 0 °C, 78%; nBu_4NOAc, THF, 95%.

15, $[\alpha]_D^{27} = -3.4$ ($c = 0.9$ in $CHCl_3$). Deprotection of **15** thus afforded 1-*epi*-valiolamine (**2**), $[\alpha]_D^{20} = -27.9$ ($c = 0.5$ in H_2O) [literature value:[10] $[\alpha]_D^{24} = -23.2$ ($c = 0.5$ in H_2O)]. On the other hand, inversion of the C-2 configuration in **15** by triflylation and subsequent nucleophilic substitution with acetate afforded the azido triacetate **16**, $[\alpha]_D^{29} = -61.5$ ($c = 0.7$ in $CHCl_3$). Deprotection of **16** furnished the target molecule **4**, $[\alpha]_D^{19} = -13.7$ ($c = 0.5$ in H_2O).

In summary, we have described facile syntheses of amino pseudosugars valiolamine and its diastereomers from quinic acid. The application of this flexible strategy to the construction of valienamine, validamine, and hydroxyvalidamine is in progress.

Preparation of a Surface-Active Chiral Diphosphane and Its Use in the Hydrogenation of Prochiral Olefins**

Hao Ding, Brian E. Hanson,* and József Bakos

The synthesis of novel water-soluble phosphanes has attracted a great deal of attention recently.[1] Much of the effort has been directed toward the preparation of water-soluble chiral diphosphanes for two-phase asymmetric hydrogenation.[2–5] Syntheses of water-soluble diphosphanes that require sulfonation of phenyl groups directly bound to phosphorus suffer from relatively low yield due, in part, to oxidation of the phosphane.[6] It has recently been reported by Herrmann et al. that oxidation of the phosphane can be virtually eliminated during the sulfonation of phenylphosphanes when the reaction is carried out in the presence of orthoboric acid;[7] however, the new sulfonation conditions still require oleum and long reaction times. We describe here the high yield preparation of a chiral water-soluble diphosphane that contains four sulfonate groups. Furthermore, dynamic light scattering experiments demonstrate that this phosphane aggregates under certain conditions in water, and catalytic reactions in a two-phase system occur faster in the presence of the surface-active phosphane than with similar ligands that contain $P[C_6H_4\text{-}m\text{-}SO_3Na]_2$ groups.

Previously we reported that sulfonation of $P[C_6H_4\text{-}p\text{-}(CH_2)_3\text{-}C_6H_5]_3$ (**1**) occurs in high yield under remarkably mild conditions;[8] this reaction requires concentrated sulfuric acid (no oleum) and takes less than three hours at room temperature to go to completion [Eq. (a)]. The product, **2**, forms aggregates with a hydrodynamic radius of 20 Å in aqueous NaCl solution.[8]

$$\underset{\mathbf{1}}{P[C_6H_4(CH_2)_3C_6H_5]_3} \xrightarrow[\text{2. NaOH}]{\text{1. } H_2SO_4} \underset{\mathbf{2}}{P[C_6H_4(CH_2)_3C_6H_4SO_3Na]_3} \qquad \text{(a)}$$

Triarylphosphanes are readily cleaved by alkali metals under a variety of reaction conditions.[9] Mixed triarylphosphanes $PAr_{3-x}Ar'_x$ are reported to cleave at the most electron-withdrawing aryl group;[10] however, analysis of the cleavage products by NMR spectroscopy shows that in the case of Ar = Ph and Ar' = p-$C_6H_4NMe_2$ cleavage does not take place exclusively at the phenyl ring.[11] For this reason the phosphane **1** rather than a mixed triarylphosphane is used as the precursor to chiral chelating phosphanes that contain $P[C_6H_4\text{-}p\text{-}(CH_2)_3\text{-}C_6H_5]_2$ units. Cleavage of **1** is accomplished with excess lithium metal in THF [Eq. (b)]. The resulting lithium phosphide **3** may be isolated as a red oil upon addition of hexanes. The oil is used directly

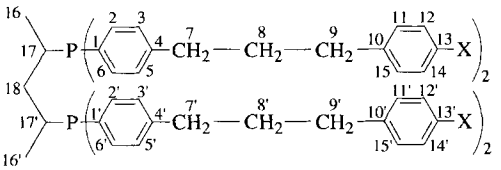
$$P[C_6H_4(CH_2)_3C_6H_5]_3 \xrightarrow[2.\ tBuCl]{1.\ Li} Li\{P[C_6H_4(CH_2)_3C_6H_5]_2\} \quad (b)$$

1 **3**

in reactions with chiral ditosylates. Hydrolysis of an aliquot of **3** with D_2O yields the corresponding deuterated secondary phosphane (^{31}P NMR, $\delta = -43.06$) ($^1J_{D,P} = 32.7$ Hz)).

The reaction of **3** with (*R*,*R*)-2,4-pentanediylditosylate leads to the bis(diphenylphosphino)pentane (BDPP) analog **4** in high yield as an oily pale yellow liquid. Sulfonation of **4** occurs under similar conditions as those for reaction (a). The tetrasulfonated product **5** (shown schematically in Fig. 1), is formed in high



4, X = H
5, X = SO_3Na

yield after six hours. Both the ^1H and ^{13}C NMR spectra are consistent with sulfonation in the *para* position; that is, only the AA'BB' pattern of the signals expected for *para* substitution in an aromatic ring is observed in the ^1H spectrum, and in the ^{13}C NMR spectrum four signals are observed for the ring ω to phosphorus rather than the six required for *ortho* or *meta* substitution.

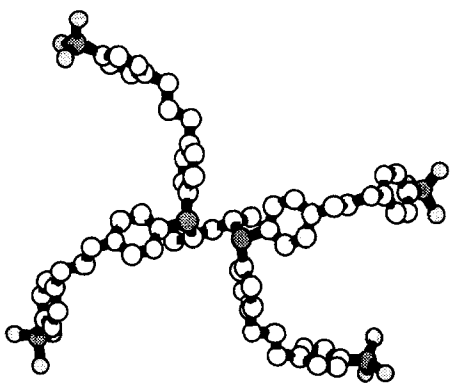


Fig. 1. Schematic representation of the ligand **5**. The ligand is drawn to scale and in the necessary conformation to form a skew chelate ring when bound to a metal.

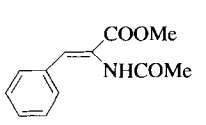
Dynamic light scattering experiments on **5** show that aggregates with a radius of 25 Å are formed in aqueous solutions that are 0.01 M in **5** and 0.25 M in NaCl.

As a test to see if the surface-active character of **5** influences its catalytic activity in a two-phase reaction, the hydrogenation of the prochiral olefin, (*Z*)-2-(*N*-acetamido)cinnamic acid ester (AACA-Me), was performed in a two-phase reaction medium consisting of either dichloromethane or ethyl acetate and water. The results of several of these reactions are collected in Table 1. For comparison results with BDPP[12] and tetrasulfonated BDPP (BDPPTS)[2] are included in the table.



AACA-Me

It is well-known that the BDPP ligand is not the best for the asymmetric hydrogenation of AACA-Me. With BDPP the maximum *ee* value reported is 72% with this substrate, while with diphosphane derivatives of methyl-α-D-glucopyranosides (glup) and related compounds as the ligand, *ee* values of > 95% are obtained in the presence of nonchiral surfactants.[13] The substrate AACA-Me was chosen to determine if a two-phase reaction medium could be modified with surface-active chiral ligands to improve reactivity and selectivity, since potential improvement in selectivity is best observed in a ligand and substrate system that begins with modest selectivity, as was observed with the glup ligands mentioned above.

Table 1. Hydrogenation of AACA-Me under various conditions [a].

Exp.	Ligand	Solvent	Pressure [atm]	Time [h]	Yield [%]	*ee* [%]
1	BDPP [b]	MeOH	1	0.20	100	72
2	**5** [c]	MeOH	1	0.75	100	75
3	BDPPTS	MeOH	15	1	100	72
4	**5** [b]	EtOAc/H_2O	1	1.5	100	69
5	**5** [d]	EtOAc/H_2O	1	1.5	100	66
6	**5** [e]	EtOAc/H_2O	1	20	67	35
7a	BDPPTS [f]	EtOAc/H_2O	15	not reported	100	45
7b	BDPPTS [g]	EtOAc/H_2O	15	1.3	100	44
8	BDPPTS [h]	EtOAc/H_2O	1	20	32	20
9	BDPPTS [i]	EtOAc/H_2O	1	20	36	18

[a] The reactions were carried out as follows: $T = 25$ °C, solvent EtOAc/H_2O = 1/1 (except in experiments 1–3); the catalyst was prepared from $[\{Rh(cod)Cl\}_2]$ and the water-soluble ligand in water. Optical purity was determined by optical rotation as described previously [4b]. [b] See ref. [11]. [c] 0.0025 M Rh, 0.0025 M **5**, AACA-Me/Rh = 100/1. [d] As in [c] + 0.05 M SDS. [e] As in [b] + 0.05 M Na_2HPO_4. [f] See ref. [2]. [g] Repeat of the experiment described in ref. [2]. [h] 0.0025 M Rh, 0.0025 M BDPPTS, AACA-Me/Rh = 1001/1. [i] As in [g] + 0.05 M SDS.

Nearly identical hydrogenation activity and selectivity are obtained with the rhodium complexes of **5** and of BDPP, when the reactions are carried out homogeneously in methanol (experiments 1–3). The selectivity with BDPPTS in a two-phase system is dependent on the nature of the organic phase. In EtOAc/H_2O 45% *ee* is obtained at 15 atm (entry 7 in Table 1). Furthermore, the reactions with BDPPTS in a two-phase system are relatively slow; in EtOAc/H_2O only 32% conversion is observed after 20 h at 1 atm (experiment 8). In contrast, in the same two-phase system, using catalysts based on **5** only 1.5 hours are required to reach 100% conversion and an enantiomeric excess of 69% is obtained (experiment 4). This value approaches that seen in methanol alone as the solvent and is an improvement over the BDPPTS ligand in the same solvent systems; however, all the reactions in two-phase systems are less selective and slower than the homogeneous reactions in methanol.

Addition of a salt, Na_2HPO_4, has the effect of decreasing reactivity of **5** (experiment 6). This result is not surprising in that there is no excess phosphane present to form micelles at high ionic strength. It has been observed in related systems that high ionic strength has the effect of decreasing reactivity in a two-phase system with a poorly water-soluble substrate in the absence of micelles. Addition of Na_2HPO_4 also decreases the selectivity perhaps due to formation of a monohydride species.[13] The selectivity is not improved if sodium dodecylsulfate (SDS) is added to the catalyst (experiment 5). This is somewhat surprising in light of the results of Selke et al.[14] They note that surfactants can induce a modest increase in selectivity as well as improve reactivity in the hydrogenation of cinnamic acid derivatives with the glup ligands in water.

In summary the surface-active ligand **5** gives catalytsts that show improved reactivity and similar selectivity to its nonmod-

ified analog BDPP. We conclude then that the incorporation of the easily sulfonated pendant group, *p*-(3-phenylpropyl)phenyl, into other diphosphanes will lead generally to chiral catalysts of improved activity in two-phase systems. The selectivity will be set by the parent chiral ligand system.

Experimental Procedure

The phosphanes **4** and **5** were synthesized under nitrogen by standard procedures for organophosphorus chemistry [8]. NMR measurements were done on a Bruker WP 200 at 200.13 MHz for ^{1}H, 50.323 MHz for ^{13}C, and 81.015 MHz for ^{31}P. An asterisk by the multiplicity data stands for pseudo. The numbering of the carbon atoms in the phosphanes can be taken from the formula of **5**.

4: Finely chopped lithium metal (0.14 g, 0.02 mol) was suspended in dry THF (10 mL), and tris-[*p*-(3-phenylpropyl)phenyl]phosphane (6.2 g, 0.01 mol) in THF (100 mL) was added from a dropping funnel over a period of about 10 min with vigorous stirring. The resulting deep red solution was stirred at room temperature for an additional 2 h. *tert*-Butyl chloride (0.93 g, 0.01 mol) was added and the reaction mixture was brought to reflux for 15 min. The volume of the solution was reduced to about 10 mL and dry degassed pentane (80 mL) was added. A dark red viscous residue (**3**) separated at −78 °C. The red oil was redissolved in THF (50 mL) and either (*S,S*)- or (*R,R*)-2,4-pentanediol-ditosylate (2.0 g, 0.0049 mol) in THF (10 mL) was added. After 10 h the solvent was removed to yield a pale yellow oil. The oil was redissolved in diethyl ether (40 mL) and washed three times with water (10 mL). The ether layer was dried over $MgSO_4$ and the volume reduced to about 10 mL; methanol (30 mL) was added to yield a pale yellow oil (**4**). Yield: 3.2 g, 71 %.

^{31}P NMR data for **3** and the deuterated secondary phosphane formed upon deuterolysis in THF: **3**: $\delta = -25.97$ (s); deuterium bis[*p*-(3-phenylpropyl)phenyl]-phosphane: $\delta = -43.06$ (t, ^1J(D,P) = 32.7 Hz).

Physical data for **4**: ^{1}H NMR ($CDCl_3$): $\delta = 0.87$ {dd, ^3J(H,H) = 6.7, ^3J(H,P) = 15.4 Hz, 6H, (16)CH_3 + (16′)CH_3}; 1.31 {* quin., ^3J(H,H) + ^3J(H,P) = 6.9 Hz, 2H, (18)CH_2}, 1.86 {m, 8H, (8)CH_2 + (8′)CH_2}; 2.37 {m, 2H, (17)CH + (17′)CH}; 2.53 {m, 16H, (7)CH_2 + (7′) CH_2 + (9)CH_2 + (9′)CH_2}; 7.01–7.30 (m, 36 H, aromatic protons); ^{13}C NMR ($CDCl_3$): 15.72 {d, ^2J(C,P) = 12.1 Hz, 2C, (16)CH_3 + (16′)CH_3}; 27.49 {*t, 2C, (17)CH + (17′)CH}; 32.64 {s, 4C, (8) CH_2 + (8′)CH_2}; 35.18 {s, 4C, (9) CH_2 + (9′)CH_2}; 35.42 {s, 4C, (7)CH_2 + (7′)CH_2}; 36.54 (br. s, 1C, (18)CH_2}; 125.72 {s, 4C, (13)CH + (13′)CH}; 128.26 {s, 8C, (12)CH + (12′)CH + (14)CH + (14′)CH}; 128.38 {s, 8C, (11)CH + (11′)CH + (15)CH + (15′)CH}; 133.62 {d, ^3J(C,P) = 21.1 Hz, 8C, (3)CH + (3′)CH + (5)CH + (5′)CH}; 142.51 {d, ^2J(C,P) = 50.3 Hz, 8C, (2)CH + (2′)CH + (6)CH + (6′)CH}; the signals for (1)C, (4)C, (10)C are not observed; ^{31}P NMR: δ (in $CDCl_3$) −1.80 (s); δ (in THF) −2.30 (s); MS(FAB$^+$): m/z = 913 (M + 1)

5: Compound **4** (5 g, 5.5 mmol) was placed into a 1000 mL flask, cooled to −78 °C; 96% H_2SO_4 (20 mL) was then added with stirring. The mixture was allowed to come to room temperature. The reaction mixture was neutralized by slow addition of 20% NaOH after 6 h. The pH was adjusted to 9 and the final volume was about 120 mL. Methanol (720 ml) was added and the mixture was heated to reflux for 30 min, filtered, and the precipitate extracted with hot methanol (200 mL). After two extractions, the filtrates were combined and the volume was reduced to about 45 mL. Acetone (270 mL) was added to precipitate **5** as a white solid which was collected and dried. Yield: 6.1 g, 84%.

Physical data for **5**: ^{1}H NMR (CD_3OD): $\delta = 0.82$ {dd, ^3J(H,H) = 6.5, ^3J(H,P) = 15.5 Hz, 6H, (16)CH_3 + (16′)CH_3}; 1.17 {m, 2H, (18)CH_2}; 1.81 {m, 8H, (8)CH_2 + (8′)CH_2} 2.38 {m, 2H (17)CH + (17′) CH}; 2.52 {m, 16 H, (7)CH_2 + (7′)CH_2 + (9)CH_2 + (9′)CH_2}; 7.02 {m, 8H} + 7.24 (m, 8H} {(12)CH + (12′)CH + (14′)CH + (14′)CH + (11)CH + (11′)CH + (15)CH + (15′)CH}; 7.14 {m, 8H} + 7.64 {m, 8H} {(2)CH + (2′)CH + (6)CH + (6′)CH + (3)CH + (3′)CH + (5)CH + (5′)CH}; ^{13}C NMR (CD_3OD): δ = 16.33 {d, ^2J(C,P) = 17.9 Hz, 2C, (16)CH_3 + (16′)CH_3}; 28.50 {*t, ^1J(P,C) + ^3J(P,C) = 8.4 Hz, 2C, (17)CH + (17′)CH}; 33.98 {s, 4C, (8)CH_2 + (8′)CH_2]; 36.10 {br. s, 8C, (9)CH_2 + (9′) CH_2 + (7)CH_2 + (7′)CH_2}; 36.97 {br. s, 1C (18)CH_2}; 127.08 {s, 8C, (11)CH + (11′)CH + (15)CH + (15′)CH}; 129.35 {s, 8C, (12)CH + (12′)CH + (14)CH + (14′)CH}; 129.52 {d, ^3J(C,P) = 7.7 Hz, 8C, (3)CH + (3′)CH + (5)CH + (5′)CH}; 134.78 {dd, ^2J(C,P) = 19.4 Hz, ^6J(C,P) = 10.0 Hz, 8C, (2)CH + (2′)CH + (6)CH + (6′)CH}; 142.09 {s, 4C, (10)C + (10′)C}; 143.89 {s, 4C, (4)C + (4′)C}; 144.38 {d, ^1J(C,P) = 4.2 Hz, 4C, (1)C + (1′)C}; 146.10 {s, 4C, (13)C + (13′)C}; ^{31}P NMR (CD_3OD): $\delta = -1.11$ (s); MS ($C_{65}H_{66}Na_4O_{12}P_2S_4$, R = $C_6H_4(CH_2)_3C_6H_4$; FAB$^+$): m/z: 1343 (M + Na$^+$), 1321 (M + H$^+$), 1241 (M − (SO_3^-)), 967 (MH$^+$ − R − (SO_3^-) − Na$^+$), 718 (M − PR_2 + Na$^+$), 648 (PR_2 + Na$^+$). Elemental analysis, calc. for the tetrahydrate: $C_{65}H_{74}Na_4O_{16}P_2S_4$: C 56.05, H 5.37; found: C 55.63, H 5.53.

$(CuI)_3P_{12}$: A Solid Containing a New Polymer of Phosphorus Predicted by Theory**

Arno Pfitzner* and Eva Freudenthaler

Despite numerous investigations on phosphanes and phosphides[1–3] since the determination of the crystal structure of Hittorf's phosphorus only assumptions have been made concerning the existence and especially the structure of further allotropic forms of red phosphorus.[4] A concrete model for this polymorph was put forward very recently by Häser and Böcker based on theoretical methods.[5] They proposed a thermodynamically stable helix consisting of condensed five- and six-membered rings only. Nevertheless, this allotrope has not yet been obtained in a crystalline state, possibly because difficulties associated in the packing of such helices result in amorphous solids.

Systematic investigations on new copper(I) ion conductors consisting of adducts of copper(I) halides and elemental phosphorus have yielded the new solid compound $(CuI)_3P_{12}$. The structure of the above-mentioned neutral phosphorus fragment has not been observed previously by experiment (but was predicted by theory). Evidently, the screws can be crystallized together with CuI which is known to show a large variety of compounds in which the copper atoms are coordinated differently.[6] Investigations on $CuTe_2X$, $CuSe_2X$, and CuSeTeX (X = Cl, Br, I) show the flexibility of the copper(I) halides coordinated to neutral polymeric chalcogen screws.[7–12] Recently

even a helical arrangement of face-sharing tetrahedra in $[(C_6H_5)_4P]^1_\infty[Cu_3I_4]$ has been reported.[13]

Here we present some of the results of experiments on the Cu-X-P (X = Cl, Br, I) systems. The only previously reported examples of this class of compounds are the ternary compound $Cu_2P_3I_2$,[14] which contains polymeric $^1_\infty[P^0_{12}]$ incorporated in CuI and is best expressed by the formula $(CuI)_8P_{12}$, and $Cu_3P_{15}I_2$, a copper(I) iodide phosphide containing $^1_\infty[P^-_{15}]$ ions, which we published recently.[15]

The crystal structure of the hitherto unknown compound $(CuI)_3P_{12}$ was determined by single-crystal X-ray diffraction.[16] It exhibits two crystallographically independent phosphorus strands (strands 1 and 2), which do not differ significantly (Fig. 1). In the crystal these strands are arranged in a rod packing, and are bound together by P-Cu-P interactions to form slabs parallel to (100). Cu-I-Cu bridges link these slabs along [001]. The copper atoms may be divided up into three different groups with respect to their coordination by iodine and phosphorus. The copper atoms are all tetrahedrally coordinated. Cu1 and Cu2 are each bonded to one phosphorus atom of strand 1 and three iodine atoms. The copper atoms Cu3–Cu6 are each bonded to two iodine and two phosphorus atoms; these phosphorus atoms belong to one (Cu3, Cu4) or two strands (Cu5, Cu6). The iodine atoms are bonded to two (I1–I4, $2.526(1) \le d_{Cu-I} \le 2.668(1)$ Å), or to three copper atoms (I5, I6, $2.568(1) \le d_{Cu-I} \le 2.718(1)$ Å).

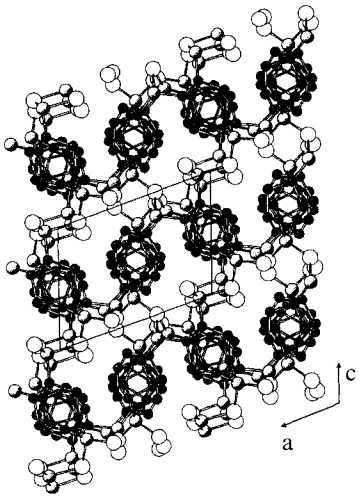

Fig. 1. Section of the crystal structure of $(CuI)_3P_{12}$. P: black, Cu: shaded, I: empty circles. View along [010].

The most remarkable features of the structure of $(CuI)_3P_{12}$ are the one-dimensional infinite strands of phosphorus, which stretch along the needle axis [010] and consist of five- and six-membered rings of phosphorus only. According to the theoretical calculations reported by Böcker and Häser,[5] this arrangement should be more stable than the $^1_\infty[P^0_{12}]$ chains in $Cu_2P_3I_2$, which additionally contain four-membered rings. The difference between the two crystallographically independent strands in $(CuI)_3P_{12}$ is a result of packing in the solid; that is, the strands differ with respect to their interactions to the surrounding copper atoms. In line with the nomenclature proposed by Böcker and Häser[5] the strands are named $^1_\infty([P10]P2[])^0$ (in comparison the $Cu_2P_3I_2$ contains linear $^1_\infty([P8]P4(4)[])^0$ units). The basic [P10] unit in $(CuI)_3P_{12}$ is shown in Figure 2a. Addition of a copper atom attached to the six-membered ring results in CuP_{10} units with pseudo "ufosane" structure. These P_{10} units are linked formally by P_2 fragments (P2 and P5 in strand 1, and P22 and P25 in strand 2), leading to the formation of infinite one-dimensional screws of phosphorus. The length of such a repeating unit ([P10]P2[]) in $(CuI)_3P_{12}$ is $b/2 = 6.93$ Å, which is about 1 Å less than observed for the linear strand ([P8]P4(4)[]) in $Cu_2P_3I_2$. This is in good agreement with the value of about 7.2 Å predicted by theory (SCF/SVP-level).[17] The extent to which the copper atoms contribute to the stabilization of the phosphorus helices $^1_\infty([P10]P2[])^0$ is the subject of theoretical studies. The formation of the phosphorus strands can alternatively be described by the linkage of P_7 norbornane-analogous fragments (Fig. 2b).

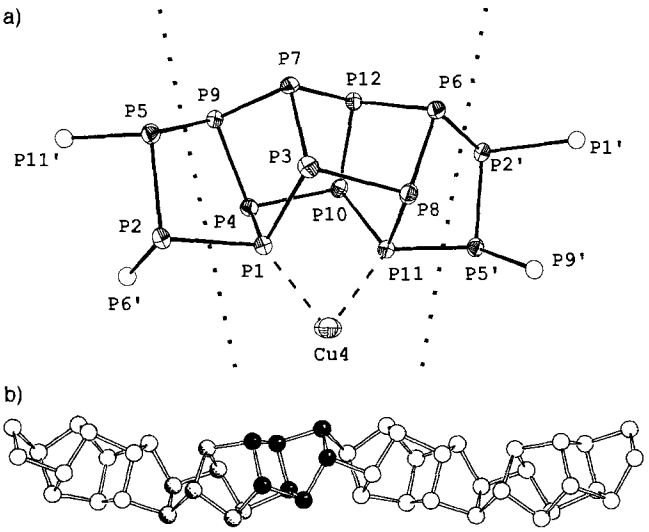

Fig. 2. a) CuP_{10} unit with pseudo "ufosane" structure in $(CuI)_3P_{12}$; these units are linked by P2, P5 in strand 1, and P2′ and P5′ in strand 2. b) Section of a phosphorus strand; two norbornane-analogous P_7 fragments are emphasized.

The phosphorus atoms in the strands each show three covalent bonds to neighboring phosphorus atoms; the d_{P-P} distances range from 2.18 to 2.28 Å. The d_{P-P} bond lengths do not vary significantly with the coordination of additional copper atoms. The distances between copper and phosphorus atoms all lie in the small range $2.27 < d_{Cu-P} < 2.32$ Å, similar to the situation in Cu_2P_7.[18] Our investigations on $Cu_3P_{15}I_2$[15] indicated that the d_{Cu-P} distance is not affected by a formal negative charge on the phosphorus atoms. The different coordination pattern of the two crystallographically independent strands leads to the conclusion that packing effects, which are supported by the great flexibility of the copper iodide substructure, are primarily responsible for the phosphorus structure observed here.

It seems reasonable to assume that the $^1_\infty[P^0_{12}]$ screws described in this work are formed in the reaction of CuI with P, regardless of whether amorphous red or white phosphorus are used as the starting material. The interesting question of whether these phosphorus chains are already present in elemental red phosphorus and may be extracted from it by reaction with copper iodide remains to be answered.

Experimental Procedure

$(CuI)_3P_{12}$ was prepared by reaction of CuI and P in the ratio CuI:P = 1:4 in evacuated silica tubes with an excess volume as small as possible (typical setup: 1 g in total, inner diameter of ampoule 12 mm, ampoule length ca. 3 cm). Depending on the use of white or red phosphorus as starting material the reaction temperature of 500 °C can be reached more or less quickly. No crystalline ternary product was obtained by applying much lower temperatures (e.g. 150 °C, P_4). After a few weeks flat shiny needles of $(CuI)_3P_{12}$, which are very sensitive to mechanical manipulations, can be separated from by products, such as $Cu_3P_{15}I_2$, and others which have not yet been completely characterized. Crystals freed from impurities by cleaning in water are stable in air for some time. Because of strong texture effects it was difficult to obtain X-ray powder patterns with sufficient quality for sample characterization. Up to now it has not been possible to obtain any useful ^{31}P solid-state NMR spectra.

Corrigendum

In a thorough reinvestigation T. J. Collins, E. Münck, et al. (*Angew. Chem.* **1995**, *34*, 1216–1219) have found that the values for the zero-field splitting parameter D in Table 1 should be corrected to 9 ± 2 for compound **1** and 3 ± 2 for compound **2**. The title of the communication should read "A Stable Aquairon Complex with $S = 1$: Structure and Spectroscopic Properties."

Making Connections: Update on Thin Metal Films

The Chemistry of Metal CVD. Edited by *T. T. Kodas* and *M. J. Hampden-Smith*. VCH Verlagsgesellschaft, Weinheim, 1994. 538 pp., hardcover DM 228.00.—ISBN 3-527-29071-0

Chemical vapor deposition (CVD) is a method of producing pure metal films for a wide variety of applications, and has become increasingly important in recent years. It was at first thought that thin metal films produced by MOCVD (metal organic chemical vapor deposition) would be contaminated by unacceptable levels of carbon (or hydrocarbon fragments) and that coatings obtained by this method would therefore be of only limited value. However, many examples have been found which contradict that view, causing a reassessment of the method. Nevertheless, progress continues to be hampered by poor communication between chemists, process technologists, materials scientists, and electrochemists. To help remedy that problem the editors of this book offer a comprehensive overview of the current state of research (with about 1470 references extending up to 1994), to serve the needs of a heterogeneous readership from different disciplines.

Chapter 1 is a short introduction concerned with aspects of the application of metal contacts to silicon-based semiconductor devices (diffusion barriers, contact between metal and silicon), likely future developments, and the advantages and disadvantages of currently used deposition techniques. Chapters 2–8 then deal in turn with the deposition of individual metals: aluminum (Ch. 2), tungsten (Ch. 3), copper from Cu^{II} precursors (Ch. 4), copper from Cu^{I} precursors (Ch. 5), gold and silver (Ch. 6), platinum, palladium, and nickel (Ch. 7), and lastly (Ch. 8) tantalum, chromium, molybdenum, iron, cobalt, rhodium, iridium, and some less common metals, intermetallic phases, and alloys. The chapters on aluminum CVD (M. G. Simmons and W. L. Gladfelter) and copper CVD (G. L. Griffin, A. W. Maverick, M. J. Hampden-Smith, and T. T. Kodas) are well-rounded, packed with information, and well-written from a learning standpoint, and are therefore suitable as material for incorporating into lecture courses on materials chemistry for students of appropriate disciplines. The concise, succinct, and very competent treatment covers a wealth of topics; to name just a few, it includes the interaction between surfaces and the chemistry of the gas phase, dependence of results on the details of the process (type of reactor, method of supplying energy, etc.), area-selective deposition, prenucleation in the gas phase, purity, and electrical and morphological properties. On the other hand Chapters 3, 6, 7, and 8 are written more in the style of literature surveys which, although thoroughly comprehensive, do not always include critical evaluation. The detailed chemical descriptions of organometallic compounds used as precursors are largely, if not entirely, superfluous for readers with a knowledge of chemistry. It would have helped the reader considerably if the authors had been more careful and selective in their treatment of the literature, as there are long passages of text which merely paraphrase the contents of tables. In this respect the discussions here differ only slightly from several recent review articles by other authors in various journals and progress report series. In Chapter 8 the authors have attempted a critical evaluation of the miscellaneous factual information that is drawn together here, but a few important aspects are missing. For example, there is little discussion of how likely it is that pure metallic films of titanium, chromium, vanadium, niobium, or tantalum can be produced by MOCVD, in view of the fact that all these readily form carbides. On the whole, well-established information about mechanisms is given in only a few cases. However, this is not so much an omission on the part of the authors as a reflection of the fact that the field is still in a state of rapid development, and therefore it is not surprising that many of the sections are of a very speculative nature. Chapter 9, "Overview of Metal CVD", is essentially a summary, in 70 pages, of the whole work, together with a brief outline of some process-orientated aspects (reactor design, precursor transport, kinetics of film growth, etc.). Compared with other treatments (e.g. Hitchman and Jensen, 1993; Vossen and Kern, 1991) this is limited to just the bare essentials. The overall structure of the book, treating individual elements or metals in turn, and the arrangement of the subject matter, has resulted in much repetition. The text could have been tightened up considerably and the factual information arranged more effectively under broad headings such as the incorporation of carbon, nucleation, selectivity, morphology, the influence of process variables, and so on.

The book is very handsomely produced and is virtually free of printing errors. It is certainly a valuable resource, both for the molecular chemist interested in this field and for the practical user, enabling the reader to get a rapid overview of the widely scattered original literature. Parts of it offer a good basis for preparing teaching courses. However, as the first comprehensive treatment in book form of this already well-established field of research, which the title appears to claim, it has some shortcomings. It is also by no means cheap for the information that it contains.

Phosphorus-31 NMR Spectral Properties in Compound Characterization and Structural Analysis. Edited by *L. D. Quin* and *J. G. Verkade*. VCH Publishers, New York, 1994. 450 pp., hardcover DM 260.00.—ISBN 1-56081-637-6

This volume on new developments in ^{31}P NMR spectroscopy is in principle

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

greatly to be welcomed, in view of the rapid growth of information on this and other methods of structure determination. Important new developments in this field include, for example, automation using robotic sample changers, multidimensional NMR experiments with heteronuclear chemical shift correlation (HETCOR), studies of phosphorus compounds of biological interest with multiple isotopic labeling, and solid-state NMR spectroscopy. However, the editors' treatment of the subject is not entirely satisfactory, as becomes especially evident on comparing the book with its predecessor (now no longer to be printed) in the series *Methods in Stereochemical Analysis*. That book began by laying the foundations of a sound understanding of the theory of the method (in several chapters with a comprehensive bibliography) and of the experimental techniques (construction of the spectrometer, etc.), thereby equipping the reader with the necessary knowledge to deal with problems of qualitative, quantitative, and structural analysis. In contrast the present book is unconvincing with regard to its conception and content. The contributors are well-recognized experts (experimentalists in many cases), and the articles treating the chemistry of their specialist areas from an analytical viewpoint are mostly very well illustrated. However, these are presented against a very sketchy and inadequate theoretical background, thus making it difficult for the reader to properly understand their contents and to appreciate the advances in techniques that have been achieved.

The book consists of nine chapters containing 33 individual contributions (each of about 10–18 pages including a bibliography), and has an author index and a subject index. In view of the many abbreviations and acronyms by which the various NMR procedures are known, it is unfortunate that no glossary of these has been provided. The book has been carefully produced, and the quality of the spectra that are reproduced varies from good to very good.

The first article, by D. B. Chesnut and B. E. Rusiloski, is on ab-initio calculations of ^{31}P chemical shifts. Chapter 2 consists of three contributions on the conformational analysis of phosphorus heterocycles. M. Mikolajczyk and P. P. Graczyk give a detailed account of work on 2-chalcogenophosphoranyl-substituted 1,3-dithianes. Next comes an article by R. R. Holmes and coauthors on phosphorus(III) and phosphorus(V) heterocycles (e.g. dibenzo[*d,f*]-1,3,2-dioxaphosphepine) which act as sterically selective phosphane ligands in metal-catalyzed reactions. The chapter ends with a contribution by W. G. Bentrude on the determination of $^{1}H,^{31}P$ coupling constants for the conformational analysis of three-, four-, and fivefold-coordinated 1,3,2-dioxaphosphorinanes. Mono- and polycyclic compounds are also the main theme of Chapter 3, the exception being R. H. Neilson's article on phosphino-substituted allenes, acetylenes, and dienes. The first paper on the main topic is by J.-P. Majoral and coauthors, who describe the unusual spectroscopic properties of 1,3-diaza-2,4-diphosphetidines in both their monomeric and oligomeric forms, including examples such as the phosphorus macrocycles and dendrimers that are currently attracting much interest. E. Fluck and G. Heckmann report on acyclic and cyclic $1\lambda^3,3\lambda^5$-phosphorylides. M. Baudler and coauthors describe the use of ^{31}P NMR spectroscopy to determine the structure of the bicyclic phosphide LiH_5P_8, which is an instructive example of the capabilities of the SPT (selective polarization transfer) experiment. The chapter ends with articles on the determination of the structures of cyclophosphazenes (C. W. Allen) and phosphazenes (M. Pomeranz), in which ^{15}N NMR measurements also play a part.

Chapter 4 is entirely devoted to the chemistry and spectroscopic properties of compounds with phosphorus in low-coordination states. M. Meisel and coauthors describe the use of donor-stabilized metaphosphates in the synthesis of heterocyclic compounds, and M. Regitz and coauthors report on the oligomerization products of *t*-butylphosphaacetylene and their identification by ^{31}P NMR spectroscopy. E. Niecke and D. Gudat discuss configurational and substituent effects on the ^{31}P NMR parameters of iminophosphanes, both in solution and in the solid state. M. Yoshifuji contributes an article on methylenephosphanes and diphosphenes. This chapter is completed by an article by R. W. Reed and G. Bertrand on the wide-ranging uses of the bis(diisopropylamino)-phosphino substituent for the stabilization of reactive compounds. Chapter 5 is concerned with spectroscopic studies of transition metal complexes with phosphane ligands. J. H. Nelson describes work on metal-mediated intramolecular [4 + 2]-cycloadditions of phospholes. E. Lindner and coauthors discuss the dynamic behavior of five-membered etherphosphane ligands and thermodynamic data on these. The article by J. F. Nixon and coauthors is concerned with metal-mediated syntheses of mono- and polycyclic phosphane ligands and the characterization of the products. A. H. Hughes describes work on determining the structures of homo- and heterobinuclear complexes with phosphorus-containing chelate ligands (such as dppm), with particular emphasis on the $^{31}P,^{31}P$ coupling constants.

Chapter 6 reports on advances in the structural analysis of biochemically important phosphorus compounds. G. Lowe discusses the stereochemical analysis of $[^{16}O,^{17}O,^{18}O]$-isotopically labeled chiral inorganic thiophosphates, and the introduction of these as terminal groups in adenosine triphosphate. D. G. Gorenstein describes the use of specific HETCOR and PAC pulse sequence experiments to yield information about the conformation of the phosphodiester backbone in oligonucleotides of moderate chain lengths (12–20 base pairs). T. Glonek describes techniques for obtaining phospholipid extracts, preparing samples from these, and analyzing them by ^{31}P NMR spectroscopy.

Chapter 7 is concerned with the investigation of reaction mechanisms. In the first article E. Vedejs and C. F. Marth describe a careful and thorough analysis of the λ^5-oxaphosphetane intermediate in the synthetically important Wittig reaction. In another very interesting contribution P. M. Cullis describes an investigation of the stereochemistry of the transfer of ^{17}O-labeled phosphoryl and thiophosphoryl groups by ADP. L. N. Markovsky and coauthors report on examples of reversible coordination isomerism involving proto-, halo-, and phosphotropic effects in inorganic compounds. Chapter 8 introduces some new areas of application of ^{31}P NMR spectroscopy and others where recent advances have occurred. First M. Murray gives an introduction to two-dimensional methods as applied to P,P and P,H correlation experiments. This is followed by a well-structured article by J. K. Gard on advances in the automation of such measurements (e.g. by using an automatic sample changer) and on the interpretation of results on oligophosphates of industrial importance. The contribution by J. G. Verkade is also likely to be of industrial interest, dealing with the analysis of coal constituents (alcohols, amines, acids) by first derivatizing these with simple phosphorus-containing reagents. M. J. Gallagher describes the spectroscopic characterization of the parent compounds of various phosphoric acid derivatives. The chapter ends with an interesting article in which G. H. Hägele describes the use of ^{31}P NMR measurements for monitoring titrations. The final chapter is devoted to solid-state ^{31}P NMR spec-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1515-1652 $ 10.00+.25/0

troscopy, which has advanced greatly in the last ten years, based on the CP/MAS method developed by Schaefer and Stejskal. First M. J. Potrzebowski and J. Michalski give a short introduction to this field. Taking a bis(phosphoryl)disulphide as an example, they compare the information yielded by CP/MAS measurements with that given by X-ray crystallography, and show correlations between the two (e.g. $\Delta\delta$ is correlated with the S–P–S bond angle). L. D. Quin describes how electrophilic compounds containing phosphorus in low-coordination states, supported on silica gel, are used as scavengers to prepare samples which are then analyzed by CP/MAS ^{31}P NMR spectroscopy. This last chapter ends with an introduction to MAS-frequency-dependent NMR spectroscopy by R. E. Wasylishen, illustrated by results on $Cd(PPh_3)(NO_3)_2$.

The book as a whole suffers from the defects already mentioned earlier and from those of conference reports in general, namely heterogeneity across the chapters and a relatively high price due to the short print run. However, it is certainly not redundant, since it collects together for the first time the many analytical capabilities of ^{31}P NMR spectroscopy, which can be used to investigate such widely different substances as highly reactive intermediates, nucleic acids, cyclotriphosphazenes, and derivatized coal constituents. The book can therefore be recommended not only for readers with interests in these topics but for others too.

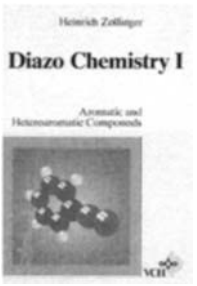
Diazo Chemistry I. By *H. Zollinger*. VCH Verlagsgesellschaft, Weinheim, 1994. 453 pp., hardcover DM 198.00.—ISBN 3-527-29213-6

Heinrich Zollinger, the author of this monograph on the chemistry of aromatic and heteroaromatic diazo compounds, is better qualified than virtually anyone else to write a comprehensive and critical work on the subject. Diazo compounds are of great industrial importance, and their chemistry raises difficult and challenging problems. The work reviewed here incorporates the knowledge gained from the author's experience in the industrial application of diazonium compounds and in research into their modes of reaction. Its predecessors are Zollinger's earlier books *Diazo and Azo Chemistry of Aliphatic and Aromatic Compounds* (1961) and *Color Chemistry* (1987, followed by a second edition in 1991). Part II of the present work, covering aliphatic and inorganic diazonium compounds, is to be published within a year following the first volume.



In thirteen chapters *Diazo Chemistry I* deals with all the important concepts and properties that make up the present understanding of the chemistry of aromatic and heteroaromatic diazo compounds. Chapter 1 (9 pp.) describes the historical development of the subject and explains the nomenclature for this group of compounds. Chapter 2 (21 pp.) deals with preparative methods, beginning with the most common procedure, the diazotization of amines by alkali metal nitrites in dilute mineral acids. Aspects of diazotization in concentrated mineral acids and under anhydrous conditions are then discussed. The author also deals briefly with the isolation of diazonium salts and draws attention to the special case of the diazotization of aminophenols, which are readily deprotonated to give diazoketones. Apart from the nitrosation of amines, there are only a few other methods for preparing diazonium salts, and this concludes the chapter. The third chapter (25 pp.) is concerned with the kinetics and mechanisms of diazotization. After critically reviewing the considerable literature on this subject, the author devotes special attention to the effects of different mineral acids and concentrations on the diazotization mechanism. Other aspects treated include the use of nucleophilic catalysis in diazotization, and the conversion of isolated *N*-nitrosamines to diazonium salts. Chapter 4 (23 pp.) deals with the structure of diazonium salts, reviewing the latest results from crystal structure determinations. Spectroscopic observations and the reactive properties of diazonium compounds are discussed and explained in the light of theoretical studies. In Chapters 5 and 6 (48 pp. altogether) the author discusses the addition of nucleophiles to aryldiazonium compounds. The effect of pH on the reaction of diazonium salts with water is treated in detail, followed by discussions of the reactions with O-, S-, N-, P-, and C-nucleophiles. These two chapters are completed by a section on intramolecular coupling reactions, which yield some interesting heterocyclic compounds. Chapter 7 (16 pp.) discusses the mechanism of the addition of nucleophiles to diazonium ions and the structures of the resulting compounds. Mechanistic aspects of the reactions of diazonium compounds involving loss of nitrogen are treated in Chapter 9 (48 pp.), and Chapter 10 (67 pp.) describes the synthetic applications of such reactions as a general method for introducing nucleophiles into non-activated arenes. Chapter 11 (15 pp.) deals briefly with host–guest complexes of arene-diazonium salts, then in Chapter 12 (78 pp.) the author treats what is undoubtedly the most important reaction of aromatic and heterocyclic diazonium compounds, the coupling reaction yielding azo dyes. The last chapter (19 pp.) is concerned with the formation and reactions of triazenes.

The author's comprehensive knowledge of aromatic and heteroaromatic diazonium compounds has resulted in a monograph which contains practically all the information that a specialist working in this field could wish for. The reader approaching the subject from a somewhat greater distance may find that the often very detailed treatment presents a rather formidable "energy barrier". Also many of the formula schemes are not very carefully prepared, in stark contrast to the precision of the text. As well as many errors of stoichiometry, the most serious problem is that in many cases insufficient care has been taken with the layout of the formulas. Better formula schemes presenting the information clearly would have greatly improved the book, especially for the non-specialist.

However, every chemist whose work is concerned with diazonium compounds, whether in industry or academia, will find this book indispensable. Furthermore, those whose research interests lie in other directions but who occasionally have to deal with diazonium compounds, especially in a teaching role, should certainly use this book at such times.

Scalar Coupling Constants—Their Analysis and Their Application for the Elucidation of Structures

Matthias Eberstadt, Gerd Gemmecker, Dale F. Mierke, and Horst Kessler*

Dedicated to Professor Richard R. Ernst

Since their discovery in the early fifties, scalar coupling constants have been of great interest to the NMR spectroscopist. Their impact on structure determination by NMR spectroscopy is founded on the fact that the size of the coupling constant is directly related to molecular conformation. Today, for most chemical substances the parameters for the Karplus relationship, which relates the vicinial (3-bond) coupling constant to the dihedral angle, have been determined. In addition to proton–proton distances, the application of coupling constants in modern conformational analysis is indispensable. In the study of larger molecules which are of current interest, more and more involved experiments are necessary in order to overcome signal overlap and increasing line widths. A large number of experimental techniques for the determination of coupling constants has been developed; however, for this reason the choice of the most appropriate experiment to use has become more difficult. This decision must be made carefully to maximize instrument usage and obtain the largest number of couplings with the greatest accuracy possible. Many of the computer programs used in structure calculations can directly apply coupling constant restraints, similar to proton–proton distances developed from NOEs. Therefore, not only is the quality of the structure improved, but the molecular motions (internal dynamics) are better described. In this article, we review the techniques that exist today with particular attention paid to helping the non-expert to choose the appropriate experiment for the problem at hand. In addition, the use of coupling constants in computer simulations are discussed.

Keywords: NMR spectroscopy · structure elucidation

1. Introduction

Since its discovery in the early days of NMR spectroscopy by Gutowsky et al.,[1, 2] as well as independently by Hahn and Maxwell,[3, 4] indirect scalar spin–spin coupling (J coupling) has been realized as an important structural parameter. As the coupling is mediated by bonding electrons, it provides important information about the constitution of molecules in terms of the connectivity of the coupled nuclei. The size of the coupling constant depends not only on the number of bonds that separate the coupled nuclei, but also on the configuration of the electrons and their spatial arrangement.[5, 6] The latter effect can be especially useful in the determination of stereochemistry (configuration and conformation) and will be one of the major points of this article.

Many J coupling constants illustrate a clear dependency on dihedral angles and therefore are an important source of conformational information. This relationship is particularly distinct for ^3J couplings and the so-called Karplus relation, which for example correlates the $^3J_{H^N,H^\alpha}$ coupling in amino acids with the ϕ dihedral angle (cf. Fig. 1a). Such J couplings were employed early on in the study of conformation; however, since that time they have become less important as distance parameters developed from NOE have taken on a dominating role.[7–9] Only recently has a renaissance of sorts been seen in the use of J coupling constants. This has been brought about by the development of a series of new methods which allow for a more exact determination of the size of coupling constants.[10–13] Simultaneously, coupling constants for very large molecules which were previously not accessible, can now be measured with the help of multidimensional methods.[14–16] In addition, new methods to use the value of the J couplings in structure calculations have been developed.[17–20] Thereby a larger set of experimental data is available, so that not only the dependability of structures determined by NMR spectroscopy can be increased but also information about flexibility and internal molecular dynamics becomes accessible. Both play an important part in understanding the interaction between molecules ("molecular recognition").

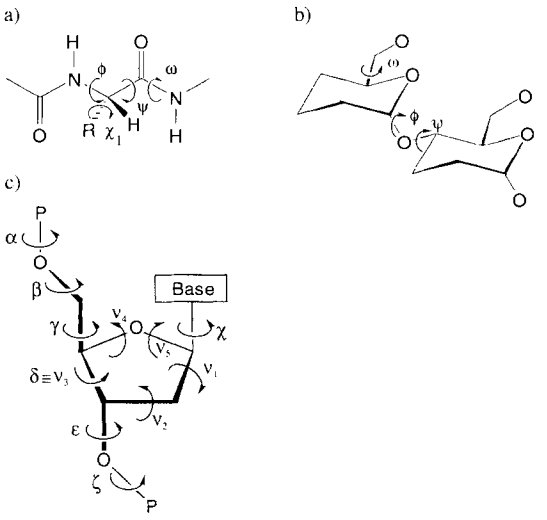

Fig. 1. Definitions of the dihedral angles in peptides, glycosides, and nucleic acids. a) Fragment of a peptide (L-amino acid) with the relevant dihedral angles for the peptide backbone and side chain using the IUPAC-IUB nomenclature. b) The dihedral angles ϕ, ψ, and ω in oligosaccharides: ϕ = H1-C1-O1-C_X, ψ = C1-O1-C_X-H_X, ω = C1-O1-C6-C5. c) Torsion angles of the sugar-phosphate backbone as well as of the glycosidic angle χ used to define the conformation of nucleic acids.

Here, the IUPAC-IUB definitions of the dihedral angles for the most important biopolymers (Fig. 1) are given for future reference.[23] Conformation and dynamics of these substances are at the center of interest in bioorganic chemistry and in this article we will concentrate on the measurement and utilization of the J couplings of these molecules. Based on these couplings (homo- and heteronuclear) the conformational preferences of most of these torsions can be characterized.

In the following we elucidate the fundamental principles which are necessary to understand the various methods to determine coupling constants. The exact procedure to use depends on the size of the molecule, type of coupling to be measured as well as the required precision and the possibility of isotopic enrichment. During the last few years numerous new multidimensional techniques have been developed. Because of the great variety of these experiments, it is not a trivial task to choose the optimal experiment for a specific question. It is our intent with this article to close the gap in the literature regarding this problem. The individual methods will then be combined in separate sections according to the method of determination, simplifying the survey of the existing procedures. After this we will touch upon several conformationally relevant dependencies which influence the size of the coupling constant and close with the employment of J values in distance geometry and molecular dynamics calculations.

2. The Determination of Coupling Constants

Basic Features

The scalar coupling of a nucleus A with nucleus X causes a splitting of the signal for A, a result from the different orienta-

Horst Kessler, born in 1940 in Suhl, Thüringen, studied in Leipzig and Tübingen, and received his doctorate in 1966 under the supervision of Eugen Müller for work on a preparative organic topic. He completed his habilitation in 1969 for work on the detection of inner molecular mobility by NMR spectroscopy. In 1971 he became a Professor for Organic Chemistry at the Unversität Frankfurt. In 1989 he moved to the Technische Universität München. He was awarded the Otto-Bayer-Preis in 1986 and the Max-Bergmann-Medaille for peptide chemistry in 1988. Guest professorships have taken him to Halifax, Tokyo, Madison, and Haifa. His research interests include rational molecule design based on the conformation, synthesis and structure of peptides and peptidomimetica, and the development of NMR techniques and calculational methods for the determination of molecular structures.

Dale F. Mierke, born in 1961 in Sacramento, California, received his Bachelor of Sciences in Physical Chemistry and Biology at the University of California, Irvine, in 1984. He obtained his doctorate under the supervision of Murray Goodman at the University of California, San Diego, for research on the structural properties of peptides. In 1990 he was awarded a Fulbright fellowship to work in the research group of Horst Kessler, where he remained until 1993. Since then he has worked at the Gustav H. Carlson School of Chemistry of Clark University and at the Pharmacology Department at the Medical Center of the University of Massachusetts in Worchester, Massachusetts.

Gerd Gemmecker, born in 1961 in Hanau am Main, studied chemistry from 1981 to 1986 in Frankfurt and received his doctorate in 1989 under the supervision of Horst Kessler for NMR studies of cyclic peptides. 1990/1991 he carried out post doctoral research with S. W. Fesik (Abbot Labs., USA) on the elucidation of the structures of the complexes cyclophilin/cyclosporin A and FKBP/ascomycin by NMR spectroscopy. From 1991 to 1993 he studied protein structures with NMR methods as a Liebig-Stipendiat at the TU München, since 1994 he has continued research there on NMR spectroscopic investigations of protein nucleic acid complexes within the framework of the Sonderforschungsbereich 369 "Grundlagen des Sekundärstoffwechsels".

Matthias Eberstadt, born in 1967 in Hof, Bayern, studied chemistry from 1986 to 1991 at the Technische Universität München, and completed his diploma thesis with work on the determination of coupling constants under the supervision of Horst Kessler. From 1992 to 1995 he carried out work in the same research group toward his doctorate. His interests include experimental and theoretical studies on the structures of proteins with the help of NMR spectroscopy.

tions (spin states) of the coupled spin X in a magnetic field. In the case of 1/2 spin nuclei, two spin states (often denoted α and β) are produced. The spin–spin coupling causes a splitting in the signal producing a doublet separated by the size of the coupling $J_{A,X}$. The size of the coupling constant, in contrast to chemical shifts, is independent of the strength of the external magnetic field. In this article we will deal only with weakly coupled spin systems (i.e. the coupling constant J is small in comparison to the difference in the chemical shifts, $\Delta\nu$, of the coupled atoms). For analysis of higher order spin systems, which is especially prevalent for low magnetic fields, we recommend the following textbooks given in references [24–29].

For first-order spin systems (with weak spin–spin coupling) the single multiplet lines are – in the simplest case – well-separated and the J value can be read directly from the one-dimensional (1D)-spectrum (see Fig. 2 top). If signals in the 1D spectrum overlap, the measurement of a two-dimensional (2D) spectrum is often helpful: as a rule the cross peaks contain the same multiplicity in their fine structure as the corresponding 1D signals. When dealing with well-separated multiplet lines, coupling constants can simply be read from the cross-section of a cross peak (usually in the direct dimension where a sufficient digital resolution can be easily obtained), although there are some 2D experiments whose cross peaks normally do not produce clean phases (e.g. the common TOCSY spectrum). For such occasions the insertion of a z-filter[30, 31] before the detection or the employment of selective pulses is helpful.[32] If one is interested in only a few coupling constants, the modified 1D equivalent of the 2D experiment (i.e. selective 1D experiments,[33, 34] chemical shift selective filters (CSSF) [35, 36]) can be utilized.

Regarding multidimensional spectra *active* and *passive* couplings must be distinguished. If the two nuclei A and X are coupled with each other the coupling constant $J_{A,X}$ makes possible a coherence transfer between the *active* nuclei A and X resulting in a corresponding cross peak (A,X). The coupling constant $J_{A,X}$ is therefore described as an active coupling. All

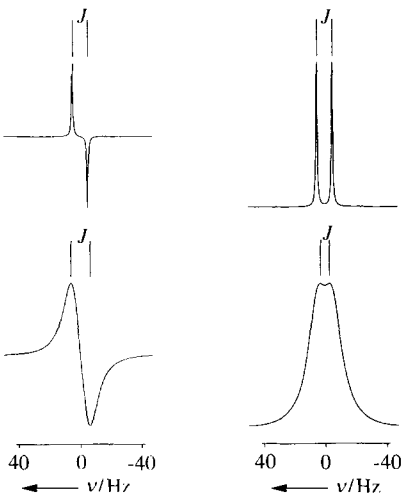

Fig. 2. Comparison of antiphase (left) and in-phase (right) doublets with a coupling constant J of 10.0 Hz and different line widths: width at half-height 1 Hz (top row) and 15 Hz (lower row). In the case with base line separation (top), both spectra lead to the correct coupling constant. In contrast, for larger line widths (below), the apparent coupling constant is too large for the antiphase and too small for the in-phase components.

further couplings involving these nuclei to a third nucleus M (e.g. $J_{A,M}$ or $J_{X,M}$), which are not responsible for the formation of the (A,X) cross signal, are described as passive couplings. Depending on the size of the spin system several passive couplings can come into existence. Active and passive couplings can differ by means of different phase in the spectrum: for example, in the 2D-COSY experiment the active coupling is antiphase, while the passive couplings are in-phase; whereas in the z-filtered 2D-TOCSY experiment all couplings are in-phase.[25] Examples of in-phase and antiphase signals are given in Figure 2.

In this article the most simple case (completely separated multiplet lines) will not be considered, but techniques will be presented which allow for the reliable extraction of coupling constants from signals with nonresolved fine structure.

Coupling constants are often within the range of the natural line widths of the signals. The line width mainly depends on the molecular weight of the substance under examination: small molecules, which reorientate quickly in solution, have relatively sharp lines (1 Hz or less), whereas the spectra of big molecules have broad lines (e.g. 20–30 Hz are common for medium-sized proteins). If the line width in comparison with the coupling constant is significant (i.e. is not small enough to be neglected), the single multiplet lines are no longer base-line separated and the distance between the lines (i.e. the distance between the maxima of the lines) does not exactly correspond to the coupling constant. As shown in Figure 2, the greater the line width the more the coupling constant is overestimated in the case of antiphase signals [37] and underestimated in the case of in-phase couplings. When choosing a technique for the determination of a coupling constant one should therefore pay heed to line width. Of course this is important for larger molecules, but also must be addressed with small molecules when measuring very small coupling constants or if the measurements are carried out at low temperatures or in viscous solvents.

Overview of Techniques for the Determination of Coupling Constants

To provide a better overview of the different experimental methods and the points mentioned above, we have divided the manuscript into three different sections according to the method of determination of the coupling constant. First, procedures which use the form of lines in one- or multidimensional spectra, including reference spectra in the analysis, will be discussed. Secondly, multidimensional methods which produce an E.COSY pattern, from which the passive coupling constant is determined, are developed. Finally methods in which the coupling constant is determined by the signal intensity in correlated spectra are given.

It is impossible to discuss all of the procedures that have been published for the determination of coupling constants, and therefore we will discuss only a few of the most important ones. The experiments, given in Tables 1–3, are organized according to the type of determination as outlined above: 1) form of the signal, 2) E.COSY-signal patterns, and 3) intensity of the signal. We want to state that most of the techniques can be improved by the application of pulsed-field gradients (see e.g. Section 2.3.4). However, for clarity we want to avoid describing all possible variations and instead concentrate on the ideas behind

Table 1. Measurement of coupling constants from line shape.

Name	Short description	Comments [a]	References
Homonulear coupling constants			
A) Coupling constants from 1D spectra			
a) z-filter spectra	pure phase, e.g. 2D-TOCSY	Ad.: 1D and 2D possible Dis.: increased measurement time because of z-filter	[30, 31]
b) selective decoupling [b]	sel. decoupling and spectra simulation	Ad.: exact method Dis.: limited to small molecules, selective decoupling required	[45]
c) J-doubling [b]	manipulation of measured data	Ad.: possible as multidimensional experiments, exact method Dis.: limited to small molecules	[41, 42]
B) Coupling constants from antiphase multiplets			
a) AX coupling constants from COSY [b]	fitting from calculated dispersive and absorptive spectra	Ad.: easy to carry out, also good for medium sized molecules Dis.: good signal-to-noise ratio required, only for AX spin systems	[38]
b) DISCO [b]	combination of antiphase [c] with other in-phase [d] or antiphase signals [c]	Ad.: complicated signal pattens and overlap can be addressed Dis.: interactive calculation of scaling factor	[11, 39, 40]
c) convolution of complementary multiplets [b]	similar to DISCO, but with computer fitting	Ad.: more exact than DISCO	[43]
C) Coupling constants from in-phase multiplets			
a) analysis of phase-multiplets after inverse FT [b]	mathematical manipulation of measured data of inphase multiplets	Ad.: signals from NOESY or HSQC, also good for large molecules Dis.: only for AX spin systems	[15]
b) HMQC with "purge"- pulse	^{15}N-HMQC spectrum	Ad.: sensitivity Dis.: large line widths lead to problems, ^{15}N-labeling required	
Heteronuclear coupling constants			
a) 2D-*J*-spectroscopy	heteronuclear coupling is read from multiplet in F_1	Dis.: only for small molecules, direct detection (sensitivity problems), no pure phase signal	[166-168]
b) selective INEPT	same as a)	Ad.: more sensitive than 2D-*J* Dis.: protons must be well resolved, only for small molecules, direct detection	[169]
c) DEPT-*J*-spectroscopy	same as a)	Ad.: editing of multiplets possible Dis.: same as for 2D-*J*	[170, 171]
d) HMBC with homonuclear reference spectrum [b]	convolution of hetero- and homonuclear multiplets; coupling constants is obtained from fitting procedure	Ad.: coupling constants to quaternary carbons possible, numerous couplings per spectrum, inverse detection Dis.: good signal-to-noise ratio (greater measurement time) required	[12, 48, 51]
e) FIDS-HSQC	heteronuclear coupling e.g. ^3J(C,P), ^3J(H,P) in nucleotides	Ad.: sensitive method Dis.: good signal-to-noise ratio required	[76]

[a] Ad. = advantages, Dis. = disadvantages. The comments are derived from our personal experience and will generally hold true. For special circumstances the disadvantages can be overcome or otherwise addressed. [b] Discussed in detail in the text. [c] For example, obtained from a COSY, P.COSY, E.COSY, P.E.COSY. [d] From a 1D signal or refocused COSY spectra with z-Filter, for example TOCSY spectra with z-Filter.

the methods referring only to the original literature. Therefore, in Sections 2.1 to 2.3 only details of the most important experiments are discussed.

2.1. Determination of Coupling Constants from the Shape of the Signal

In this section procedures which are employed mainly for small molecules and suited for the determination of homonuclear and heteronuclear coupling constants are given. For heteronuclear couplings it is important that the technique be as sensitive as possible and is suitable for samples in natural abundance.

In principle all these techniques attempt to correct or compensate for the partial overlapping of multiplet lines by either using additional parameters which depend on the shape of the signals or by fitting a model to the overlapping experimental signal (most often carried out by using a reference signal). However, this procedure presupposes that the line width is not significantly larger than the coupling constant and furthermore, the signals have a good signal-to-noise ratio, so that enough information for the correction can be obtained from the experimental signal form.

2.1.1. *A-X couplings from COSY Spectra*

As was shown in Figure 2, only a rough approximate value of the coupling constant can be determined from an antiphase (e.g. COSY) cross peak, which in principle is too large because of the reciprocal signal cancellation of the antiphase structure. If the line shape and width is known, it is relatively easy to obtain the actual coupling from simulated spectra that reproduce the experimental measurement (Fig. 3).

Kim and Prestegard[38] have described an especially simple method for the determination of coupling constants from AX spectra in which the line width is not explicitly required. Instead the coupling constant is calculated from two parameters, ν_a and ν_d, the splitting of the absorptive and dispersive signal, respectively, which can usually be easily determined (Fig. 4).

This procedure offers the advantage that no additional spectrum has to be recorded (a COSY spectrum is usually necessary for signal assignment in the study of biomolecules). Furthermore, no mathematical follow-up treatment of the raw data is required.

This method is based on the assumption of a Lorentzian line shape for the multiplet. For a complete description of a doublet, generally only two parameters are needed: the line width at half

Table 2. Experiments that utilize an E.COSY cross peak pattern.

Name	Short description	Comments [a]	References
Homonuclear coupling constants			
A) Coupling constants from homonuclear spectra			
E.COSY	passive coupling constants from combination of multiple quantum spectra	Ad.: homonuclear, good resolution Dis.: at least three coupled spins required	[11, 54, 55]
P.E.COSY	combination from β-COSY with reference spectrum	Ad.: easier and more sensitive than E.COSY Dis.: not as exact as E.COSY, less sensitive than E.COSY and P.E.COSY	[54, 59]
z-COSY	similar pulse sequence as NOESY with small flip angle pulses	Ad.: absorptive diagonal Dis.: complications from NOE cross peaks	[172]
soft-COSY	E.COSY signal produced by application of selective pulses	Ad.: more sensitive than E.COSY, only for small molecules Dis.: selective pulse, for more coupling constants many spectra required	[173, 174]
PICSY	selective pulse in TOCSY, E.COSY with in-phase signal component	Ad.: in-phase multiplets Dis.: selective pulse, only for small molecules	[44]
B) Coupling constants from heteronuclear spectra			
I) In natural abundance			
JHH-TOCSY	E.COSY signals produced with signal components in-phase or antiphase to each other	Ad.: utilization of ^1J(X,H) coupling constant, also good for ^{15}N-labeled proteins Dis.: only good for XH spin systems, does not work for XH_2	[175]
XLOC	uses of selective proton pulse	Ad.: coherence transfer does not depend on J(H,H), no requirements for spin systems	[176]
II) Isotopically enriched materials			
triple resonance experiments	for the determination of $^3J(H^N,H^\alpha)$ coupling constant in proteins or peptides	– first implementation increase in sensitivity – utilization of gradients and further increase in sensitivity	[13] [14] [177]
HCCH-E.COSY techniques	for the determination of ^3J(H,H) coupling constant in proteins and peptides e.g. $^3J(H^\alpha,H^\beta)$	– with β-pulse – with selective pulse – utilization of $^3J(H^\alpha,H^\beta)$ coupling constants in proteins with TOCSY for C,C-transfer	[87] [86] [89, 181] [88, 178]
Heteronuclear coupling constants			
I) In natural abundance			
soft-H, C-COSY	soft heteronuclear pulses to produce E.COSY-multiplet pattern	Dis.: low sensitivity, selective pulse	[179]
HSQC	heteronuclear coupling constants, for example ^3J(C,P) and ^3J(H,P) in nucleic acids		[75]
HETLOC [b]	ω_1-filtered TOCSY-spectrum	Ad.: simple pulse sequence, BIRD-pulse can be used to increase repetition rate Dis.: only coupling to heteroatoms that possess a directly bound proton	[62–65]
BIRD-3D-HSQC-TOCSY	$^3J(H^\beta,C^\delta)$ coupling constants	Ad.: natural abundance or "random labeling"	[180]
II) Isotopically enriched materials [c]			
homonuclear techniques	no heteronuclear decoupling	Ad.: very simple method Dis.: only for resolved heteroatoms (^{15}N)	[60, 61]
band-selective decoupling of homonuclear spectra	selective heteronuclear decoupling	Ad.: very easy method Dis.: selective decoupling	[181]
HYSEL-CH, REPAY-CH, CH_2	heteronuclear ^3J(C,H) coupling constants	Ad.: elimination of diagonal, editing possible	[189]
triple resonances experiments	for the determination of $^3J(H^N,C')$, $^3J(N(i), H^\alpha(i-1)$ or $^3J(H^N,C^\beta)$ coupling in peptides	Ad.: also suitable for large proteins	[4, 177, 183–188, 190, 194]
HCCH-E.COSY techniques	heteronuclear coupling e.g. $^3J(H^\beta,C')$ in peptides	Ad.: exact method, also good for large molecules Dis.: labeling required	[89, 182]

[a] See footnote in Table 1. [b] More detailed description can be found in the literature. [c] Of course, for higher natural abundance spins (for example ^{31}P), enrichment is not necessary.

Table 3. Measurement of coupling constants from signal intensity.

Name	Short description	Comments [a]	References
COLOC	constant-time experiment	Ad.: simple relationship between intensity and coupling constant Dis.: direct detection, sensitivity problems, most often coupling only qualitatively measured	[47]
HMBC	proton detected experiment for measurement of long-range connectivities	Ad.: sensitivity from inverse detection Dis.: consideration of homonuclear coupling necessary	[46]
selective HMBC	similar to HMBC, with selective ^{13}C-pulses	Ad.: better resolution than with HMBC Dis.: selective pulse necessary	[93]
[^{15}N,^{1}H]-COSY $^{3}J(H^{N},H^{\alpha})$	similar to HSQC, for $^{3}J_{H}N_{H}\alpha$ in peptides	Ad.: very precise method Dis.: long measurement time, ^{15}N enrichment required	[94, 95]
LRCC	hetero-hetero coupling constants, for example ^{3}J(C,C) in proteins	Ad.: otherwise very difficult to measure coupling constants Dis.: isotope enrichment required	[98]
LRCH	heteronuclear coupling constants, for example $^{3}J(C^{\gamma},H^{\beta})$ and $^{2}J(C^{\delta},H^{\gamma})$		[99]
CT-HSQC-Difference	constant-time-HSQC, coupled and decoupled spectra recorded; e.g. ^{n}J(C,N)	Ad.: sensitive, otherwise very difficult to measure coupling constants Dis.: possible disturbance from relaxation times	[104]
C-C Correlation	constant-time experiment, coupling constant is measured from ratio of two signals; e.g. ^{n}J(C,C)	Ad.: sensitive, otherwise very difficult to measure coupling constants Dis.: possible disturbance from relaxation times, ^{13}C enrichment required	[97]
$H_{N}NH_{AB}$-COSY	heteronuclear coupling constant; e.g. $^{3}J(N,H^{\beta})$		[191]
HNHA	$^{3}J(H^{N},H^{\alpha})$	Ad.: very sensitive, ^{15}N-labeling required Dis.: possible disturbances for relaxation times, not good for very large molecules	[16]

[a] See footnote in Table 1.

height $v_{1/2}$ and the scalar coupling constant J, which can be determined from two independent experimentally measurable parameters. For this purpose Kim and Prestegard use both the estimated coupling (v_a) (i.e. the distance of the maxima in the absorptive doublet) and the distance v_d of the two outer extremes in the 90° phase-shifted (i.e. dispersive) doublet (instead of the linewidth, which is not easily accessible from the doublet alone). By calculation of the analytical expression for these two values from the theoretical Lorentzian-line shape, an expression for J [Eq. (1)], which contains only the two experimentally available parameters v_a and v_d, can be developed. J can now be calculated from the square root of the only real root of this cubic equation.

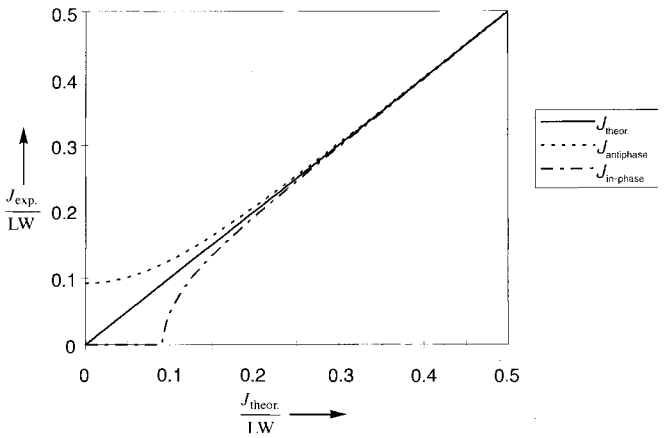

Fig. 3. The correlation of the measured splitting, J_{exp}/LW (LW = line width), with the theoretical coupling constant (J_{theor}/LW) for a Lorentzian doublet is shown for antiphase and in-phase multiplets. In the range of approximately 0.15–0.3 the coupling constant measured from the antiphase and in-phase doublets can be corrected to account for line shape. For values under 0.1, the J_{exp} measured from an antiphase multiplet is only slightly dependent of the measured splitting, while the correlation for couplings measured from in-phase multiplets completely disappears. For these cases, correction of the measured values is not possible.

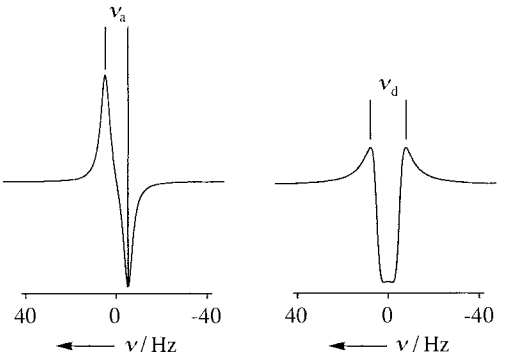

Fig. 4. The measurement of the separation of the signal maxima of an antiphase doublet for the absorptive (v_a) and dispersive (v_d) component. From these two parameters the coupling constant J can be calculated from the cubic Equation (1).

$$J^6 - v_d^2 J^4 - \left(\frac{9}{4}v_a^4 - \frac{3}{2}v_a^2 v_d^2 - \frac{3}{4}v_d^4\right)J^2 + \frac{81}{64}v_a^6 - \frac{9}{16}v_a^4 v_d^2 - \frac{21}{32}v_a^2 v_d^4 - \frac{1}{16}v_d^6 + \frac{v_d^8}{64 v_a^2} = 0 \quad (1)$$

This procedure is straightforward to perform and is recommended for the evaluation of COSY signals, for example, (H^{N},H^{α}) cross signals of peptides and proteins especially if signals in the 1D spectrum overlap. A good signal-to-noise ratio is necessary for the accurate determination of v_d. For signal-to-noise ratios of under 5 inaccuracies of v_a and especially v_d will result in significant errors for the calculated J values. Regarding apodization of the experimental signal, one is limited to the exponential function since the theoretical basis of the method requires a Lorentzian line shape. However, in practice other apodization functions cause only small errors.

2.1.2. The DISCO Procedure

The cross peaks of a nucleus in a COSY spectrum are differentiated by the fact that each time *one* coupling (namely the active coupling) is in antiphase, while all of the other couplings appear in-phase. The overlapping of the latter couplings often produces a complicated multiplet pattern, from which no coupling constants can be easily read. In this instance there is a series of procedures, which combine antiphase splitting with in-phase splitting so that the number of the multiplets diminish and the coupling constant can be read from the simplified fine structure. The required antiphase signals are available through COSY signals (Fig. 5a). The in-phase signals can be obtained in principle from the COSY diagonal signal or a 1D spectrum, or if signal overlap is a problem from the cross peak of a TOCSY experiment, in which phase distortions from dispersive antiphase contributions are minimized by using a z-filter (as discussed above).[30, 31]

By forming the *di*fference or the *s*um of cross signals in *COSY* spectra (DISCO) [11, 39, 40] one obtains a halving of the

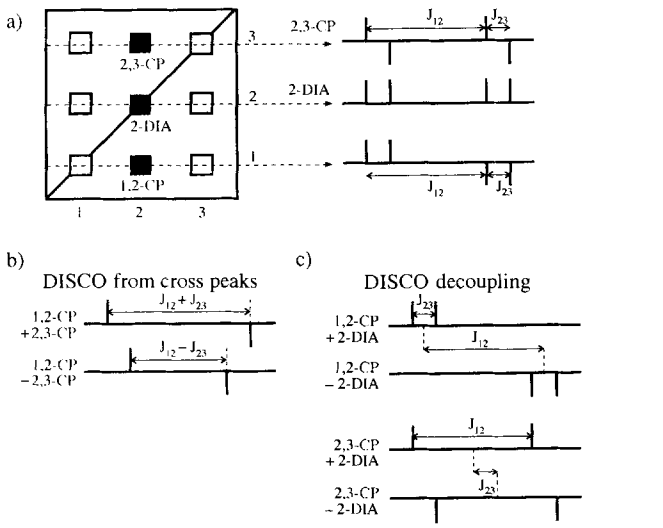

Fig. 5. a) DISCO experiment with cross peaks for spin 2 of a three-spin system. Left: schematic representation of a COSY spectrum; right: slices of the cross peaks between spins 1-2 and 2-3 (1,2-CP, 1,3-CP) along with the diagonal (2-DIA) in ω_2. b) DISCO method from addition and subtraction of the cross peaks. c) DISCO decoupling from addition and subtraction of the cross peak and diagonal signal.

number of multiplet components (Fig. 5b). From the traces of two cross peaks a multiplet can be obtained by addition (with proper weighting) which contains the sum of the two active coupling constants in antiphase. As a rule less overlapping occurs in such additions so that the distances between the lines can be determined more precisely. From the difference (negative combination) of the two traces, the differences between the active couplings of the cross peak can be obtained which is often difficult to measure because of the small size. The DISCO procedure is schematically depicted in Figure 6.

A variation referred to as decoupled-DISCO can be obtained by mixing antiphase multiplets (positive intensity) and in-phase multiplets (negative intensity) resulting in spectra "decoupled" with regard to the active coupling; each component is shifted to the left and right by half the coupling constant (Fig. 5c). Using this procedure coupling constants can be determined from multiplets with broad lines.

However, one problem with the DISCO procedure is that the correct scaling factor for the combination of the two spectra is unknown; this value must be determined interactively. In addition, the evaluation of complicated, strongly coupled spin systems remains difficult.

2.1.3. *J* Doubling

The procedure of *J* doubling[41] is founded on a purely mathematical follow-up treatment of the raw, experimental data. For this treatment, in-phase and antiphase signals have to be differentiated; here the discussion is limited to in-phase multiplets. We refer to the literature for an analogous analysis of antiphase signals.[42]

For this procedure the FID of a freely exposed, in-phase doublet is necessary (i.e. either the FID of the 1D spectrum or—for overlapping signals—a series of slices from a 2D spec-

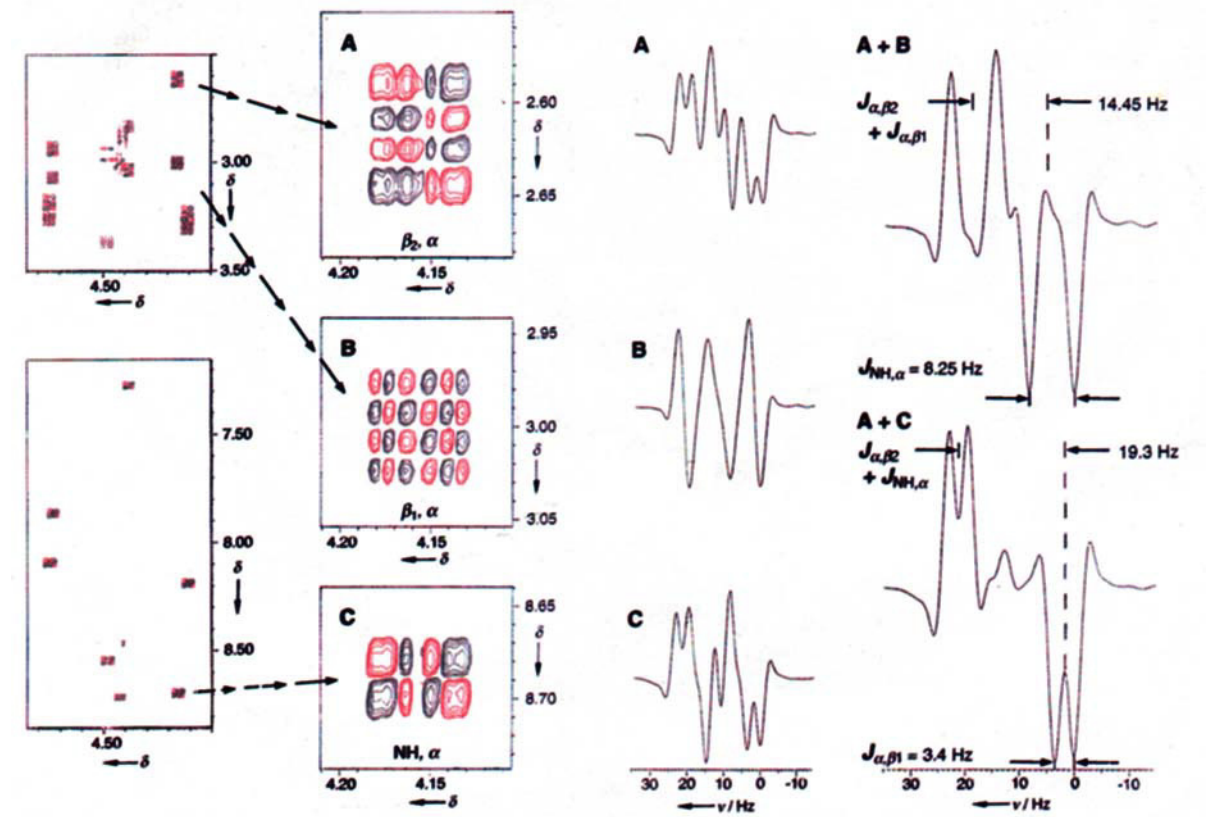

Fig. 6. Illustration of the DISCO method for the $\alpha\beta$ coupling in aromatic amino acids of a cyclic hexapeptide. First column: (H^{α},H^{β}) cross peak (top) and (H^{α},H^{N}) cross peak from a 2D-DQF-COSY spectrum. Second column: expanded portion of the cross peaks H^{α},$H^{\beta2}$ (A), H^{α},$H^{\beta1}$ (B), and H^{α},H^{N} (C). Third column: slice along the F_2 dimension through the corresponding cross peak. Fourth column: slices resulting from the sums of the slices A + B (top) and A + C (below). The sum of the coupling constants ($^3J(H^{\alpha},H^{\beta2})$ + $^3J(H^{\alpha},H^{\beta1})$ and ($^3JH^{\alpha},H^{\beta2}$) + $^3J(H^{\alpha},H^{N})$) can be measured with high accuracy.

trum containing a resolved cross peak which can afterwards be transformed into a corresponding pseudo-FID by inverse Fourier transformation (IFT). In the time domain an in-phase doublet corresponds to a damped harmonic vibration, which is modulated by a $\cos(\pi Jt)$ signal, in which J is the coupling constant to be determined. By multiplying this FID with a function $\sin(\pi J_{test}t)$ one obtains after Fourier transformation an additional antiphase splitting of size J_{test}. The two middle lines of the four resulting lines will exactly cancel out each other because of the antiphase character when $J = J_{test}$ (Fig. 7). The coupling J can therefore be determined by optimizing the parameter J_{test} in the FID modulation function until these multiplet lines disappear. This criterion of optimization is ideal for automated evaluation (e.g. the integral of the complete multiplet in absolute value representation is driven to a minimum).[42]

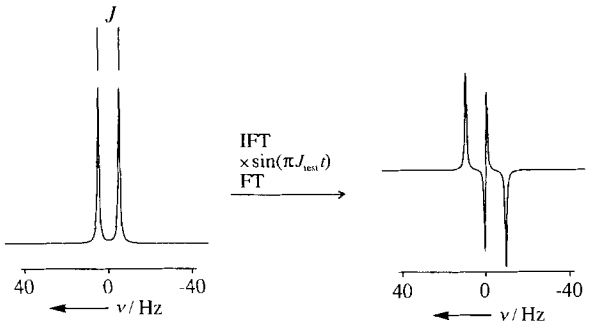

Fig. 7. The doubling of the coupling constant J for an in-phase multiplet. The FID from an IFT is multiplied by the function $\sin(\pi J_{test}t)$, which produces an antiphase doublet with a coupling constant of J_{test}. The value J_{test} is varied until the central antiphase doublet disappears and therefore $J_{test} = J$.

The procedure of J doubling can be performed in many different variations (e.g. the same cancellation of the central pair of lines can be obtained by modulating the FID with $\cos(\pi J_{test}t)$, corresponding to an additional in-phase splitting around J_{test}, starting from an antiphase doublet). By using more complex modulation functions for the FID, more complex line patterns can be generated, which are also greatly simplified by cancellation in the case of $J = J_{test}$. Finally the procedure is not limited to doublets: in the case of more complex multiplets several minima of the signal intensity will be obtained, corresponding to the different coupling constants included in the signal. It must be noted that by multiplication of the signal by the test coupling more lines are created, which can have the negative consequence of even greater signal overlap.

2.1.4. *Simulation of Line Forms with Reference Signals*

The fundamental idea for this technique is founded on the simulation of a complex, nonresolved multiplet starting out from various experimental multiplets. We begin this portion with the discussion of two relatively easy methods for obtaining homonuclear coupling constants and then discuss a very important variation for the measurement of a heteronuclear long-range coupling constant. As given in Section 2.1.3, a signal can be deconvoluted with an additional, in-phase (or antiphase) splitting by modulating the FID with $\cos(\pi J_{test}t)$ (or $\sin(\pi J_{test}t)$) (Fig. 8). By using a J_{test} that corresponds to an antiphase (or in-phase) multiplet the phase properties of the resulting spectrum can be manipulated: each signal then includes an in-phase

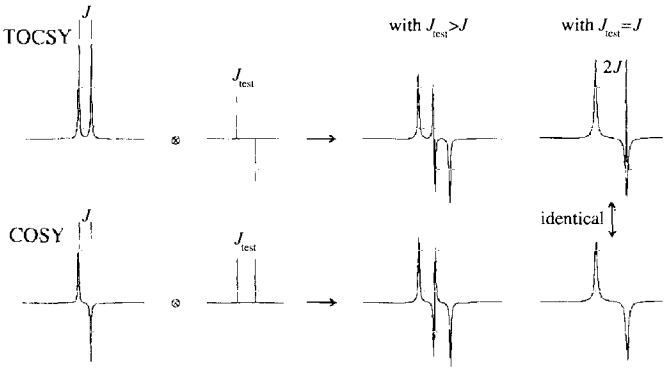

Fig. 8. Determination of a homonuclear coupling constant from COSY (antiphase) and TOCSY (in-phase) signals by convolution with a complementary multiplet coupling of J_{test} (see Fig. 7). When $J_{test} = J$, both of the multiplets are identical (far right), which can be used for a convergence criterium for the determination of the coupling constant J.

and an antiphase splitting of the same size $J = J_{test}$ (Fig 8, right). Therefore another criterion for optimization can be the similarity of the modulated multiplets obtained from both methods which can be determined with the help of the standard deviation of the two signals[43] or with vectorial algorithms.[44]

Another possibility, which is especially suited for the determination of homonuclear in-phase coupling constants, is the convolution of selectively decoupled spectra[45] with a test coupling which is then optimized. Two spectra serve as the data set: the conventional 1D spectrum (or a series of cross-sections taken from a 2D experiment containing a cross peak) and a further spectrum, in which the desired coupling $J_{B,D}$ was removed by irradiation of the frequency of the nucleus H_D (Fig. 9). The decoupled spectrum is again deconvoluted (i.e. the FID is multiplied by the function $\cos(\pi J_{test}t)$) resulting in an artificial in-phase coupling of size J_{test}. While varying J_{test}, the signal is compared with the decoupled spectrum either in the time or frequency domain until the deviation for $J = J_{test}$ is minimized. It is important to note that false minima can occur for sums or differences of the coupling constants included in the multiplet.

Such a selective decoupling is especially easy to perform if the coupling involves a heteronucleus. For example $^3J_{H,P}$ and $^3J_{C,P}$

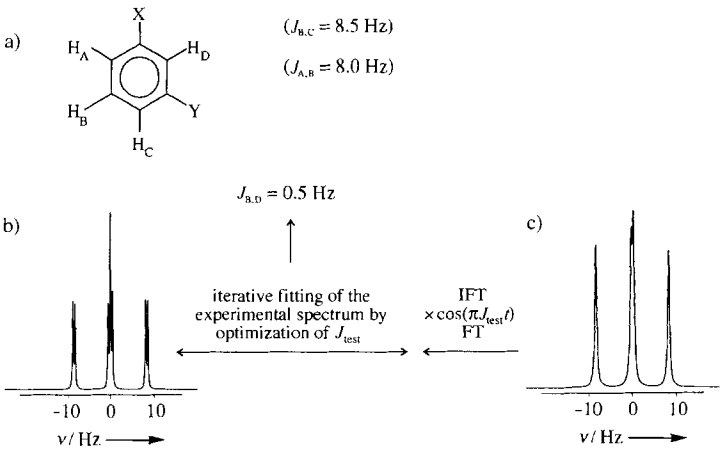

Fig. 9. Determination of the J(H,H) coupling constants for *meta*-disubstituted benzene (a). The values of the large ^3J coupling constants J(A,B) and J(B,C) can be read directly from the 1D spectrum (not shown). The multiplet of H_B coupled (b) and with selective decoupling of H_D (c). The selectively decoupled multiplet can be transformed into the coupled multiplet only when $J_{test} = J$.

in nucleic acids can be determined from two 2D-^{1}H,^{13}C-HSQC correlation spectra, one of which was recorded with ^{31}P decoupling (FIDS-HSQC).[76] The line widths in the ^{1}H (or ^{13}C) dimension in the two spectra differ from each other by the coupling of the proton (or carbon) atom to the phosphorus atom (Fig. 10).

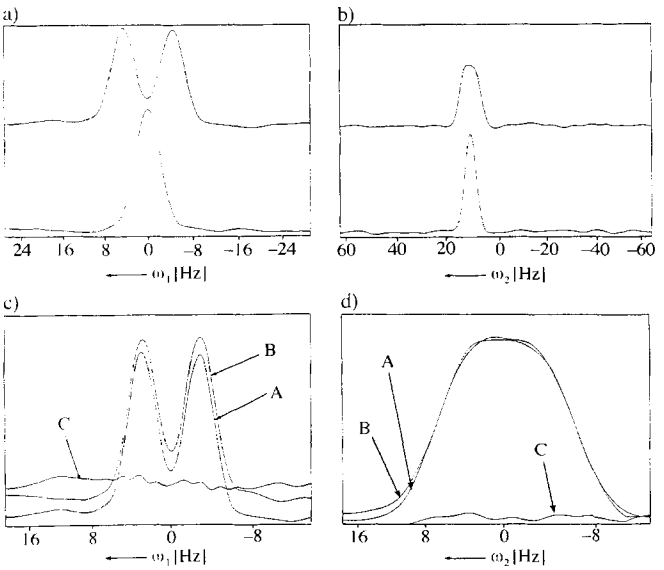

Fig. 10. FIDS-HSQC spectrum of a cyclic deoxyribose-methylphosphonate. a) Slices along the F_1 dimension (the ^{13}C dimension) through the (H5',C5') cross peak without (above) and with (below) ^{31}P-decoupling. b) Slices along the F_2 dimension (the ^{1}H dimension) through the (H3',C3') cross peak without (above) and with (below) ^{31}P-decoupling. c) Results from the simulation of the coupled multiplets (a) from the decoupled multiplet with the addition of the ^2J(C5',P) coupling; the optimal fit is obtained with ^2J(C5',P) = 8.9 Hz. d) Analogous to (c) from the multiplet shown in (b), producing ^3J(H3',P) = 4.5 Hz. A = experimental, B = simulated multiplet, C = difference (from ref. [76]).

These techniques have found widespread application in the determination of heteronuclear long-range coupling constants from HMBC (*h*eteronuclear *m*ulti-*b*ond *c*orrelation) cross peaks with samples with ^{13}C in natural abundance.[46] The major advantage is that the HMBC experiment is relatively sensitive because of inverse detection (e.g. compared to the COLOC experiment[47]) and that the identity of the heteronuclear long-range couplings directly ensues from the assignment of the 2D cross signals.[12, 48] The pulse sequence (including a low-pass J filter[49]) is shown in Figure 11.[12] The 180° ^{1}H pulse at the end of the sequence is not part of the standard HMBC experiment; it is only necessary in the determination of coupling constants with a homonuclear reference spectrum.

The HMBC experiment is a simple variation of the inverse heteronuclear correlation technique HMQC (*h*eteronuclear *m*ulti-*q*uantum *c*orrelation). During the time Δ_2 (in practice

Fig. 11. Pulse sequence for a HMBC experiment to determine heteronuclear coupling constants. The resulting spectrum correlates the protons through long-range coupling (i.e. ^2J and ^3J) with ^{13}C nuclei. The delay Δ_1, $1/(2^nJ(C,H))$, is for the low-pass J-filter and Δ_2 is set to approximately 60–80 ms.

60–80 ms), the long-range couplings $^nJ_{C,H}$ (n = 2,3) develop and the coherence is transferred to ^{13}C. The resulting 2D spectrum contains cross peaks between all protons and carbon nuclei which are not separated by more than three bonds.

In principle long-range coupling constants can be determined directly from the cross peaks which contain the active coupling, although modified sequences with better phase properties are recommended.[50] Long-range heteronuclear coupling constants are approximately of the same magnitude as homonuclear $^2J_{H,H}$ and $^3J_{H,H}$ coupling constants (1–10 Hz). Therefore, the rather small heteronuclear antiphase coupling constant $^nJ_{C,H}$ cannot be read directly because of overlapping and reciprocal cancellation of the numerous multiplet lines.

Keeler et al. have developed an eloquent procedure which allows one to determine the heteronuclear long-range coupling constants from the line shape even in such cases.[48] The multiplet of an HMBC cross peak is not purely absorptive in phase in F_2 because of the modulation through H-H couplings and through the development of the chemical shift evolution during the two delays Δ_1 and Δ_2. The multiplet includes all homonuclear couplings of the proton involved in the cross peak as well as the antiphase long-range coupling which causes the cross peak. In a homonuclear spectrum, (e.g. a 1D spectrum or a 2D RELAY or 2D TOCSY experiment) a cross peak of the same proton in the F_2 dimension has the same H–H couplings as the heteronuclear spectrum. The differences between this signal and the HMBC signal lie in the phase qualities of these couplings (here *in phase*) and the lack of the heteronuclear antiphase coupling.

To obtain the phase qualities of the heteronuclear spectrum in the ^{1}H spectrum, the 1D spectrum can be recorded with the sequence "90°(^{1}H)-(Δ_1 + Δ_2)-acquisition". However, this only applies to well-resolved signals. For overlapping signals, a TOCSY spectrum with pure phase (e.g. with the z-filter, cf. Section 2.1.1.) has to be recorded. The multiplet can then be read along the F_2 dimension, the remainder of the base line is set to zero and an IFT performed. The pseudo-FID represents the signal of this single multiplet in the time domain. The effect of the delays Δ_1 and Δ_2 can now be obtained by shifting the starting point of the FID by (Δ_1 + Δ_2) (i.e. discarding the first N data points, where $N = (\Delta_1 + \Delta_2)$/ "dwell-time"). At the end of the FID the missing points are substituted by zeros ("zero-filling"), which has been shown to produce negligible error.

The homonuclear reference multiplet which is contained in this modified FID now differs from the HMBC multiplet only by the absence of the heteronuclear antiphase coupling and the differing signal amplitude. As described in Section 2.1.3. this can be simulated by multiplication of the reference signal in the time domain with the term $\sin(\pi J_{test} t)$. The amplitude and J_{test} can now be varied by a nonlinear optimization until the deviation between the two spectra reaches a minimum, at which J_{test} should be equal to the desired coupling constant. An example of this method is shown in Figure 12.

This method has the advantage that a large number of coupling constants can be determined from one HMBC spectrum (which usually contains a large number of long-range correlations). However, the quality of the heteronuclear spectrum and especially the signal-to-noise ratio is of decisive importance for the convergence of the optimization (an elaborate analysis of errors associated with this method has appeared in the literature).[51]

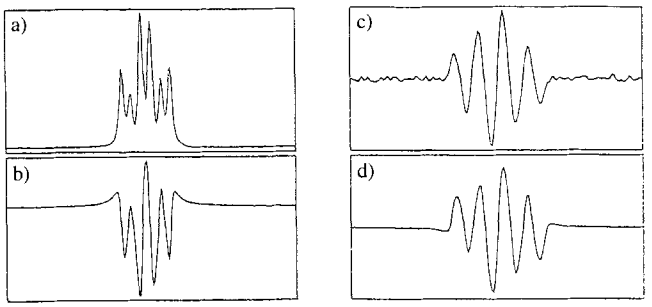

Fig. 12. Application of the Keeler-procedure for the determination of heteronuclear long-range coupling constants from an HMBC spectrum (see text). a) Reference multiplet from a z-filtered TOCSY spectrum; b) the multiplet of (a) after the phase correction of the HMBC spectrum; c) experimental multiplet from the HMBC cross peak, which differs from the multiplet in (b) by the antiphase, long-range heteronuclear coupling constant; d) the result of the simulation of the HMBC signal (c) using the reference signal (b).

2.1.5. *Inverse Fourier Transformation of In-Phase Multiplets*

Inverse FT of multiplets allows for the determination of the $^3J_{H^N,H^\alpha}$ coupling constant and is also suited for larger molecules. The method is preferably applied with NOESY spectra which have to be recorded anyway for structure determination and therefore does not increase the required measuring time.[115]

In a NOESY spectrum all cross signals of a certain proton in F_2 possess the same in-phase multiplet structure. The amide protons of amino acids in peptides (with the exception of glycine) are doublets because of the coupling to the α proton. The intraresidual (H^N,H^α) cross peak should not be used for the evaluation as it can be disturbed by scalar J coupling contributions.[52, 53] However, since the H^N signal is usually involved in a large number of NOEs to neighboring protons, another resolved signal can be selected. To determine the coupling constant $^3J_{H^N,H^\alpha}$ one uses a slice along the F_2 dimension through this signal (to increase the signal-to-noise ratio, several slices can be added, as in the DISCO procedure described above). From an IFT, a pseudo-FID corresponding to this signal is obtained (Fig. 13), which is already modulated by $\cos(\pi\ ^3J_{H^N,H^\alpha}t)$ because of the presence of the in-phase coupling.

As a first approximation the value $J^{(0)} = 1/2t_0$ for the $^3J_{H^N,H^\alpha}$ coupling constant can be estimated by using the time t_0 of the first zero crossing of the FID curve. The line width $\Gamma^{(0)}$ can be obtained from the width at half-height (naturally taking $J^{(0)}$ into consideration) (Fig. 13). Starting with these points it is possible to simulate an in-phase doublet [Eq. (2)], where t_{aq} corresponds to the experimental acquisition time; the line width is described by the decreasing exponential. The signal $S(t)$ is now submitted

$$S(t) = \cos(\pi\ ^3J_{H^N,H^\alpha}t)\,e^{-\pi\Gamma t} \quad 0 \le t \le t_{aq} \qquad (2)$$

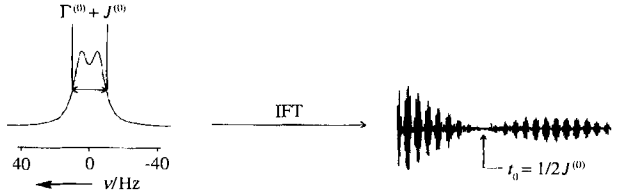

Fig. 13. The signal from a nonresolved doublet and the corresponding signal in the time domain (FID), obtained after IFT. Starting parameters for the coupling and line width, $J(0)$ and $\Gamma(0)$, can be obtained from the first null point of the FID. The exact method for the determination of the coupling constant is given in the text.

to the same procedure as the experimental signal (same filter function, zero-filling, etc.), and the deviation from the experimental FID is minimized in a nonlinear optimization with regard to $\Gamma^{(0)}$ and $J^{(0)}$.

Generally this procedure can be applied to in-phase multiplets, for example cross peaks from a (^{15}N, ^{1}H)-COSY, in which amide protons are detected. In Section 2.3.3 an alternative method, from which $^3J_{H^N,H^\alpha}$ coupling constants can be determined by signal intensities from a special (^{15}N,^{1}H)-COSY experiment, will be discussed. The advantage of the inverse Fourier transformation method is that only one spectrum is necessary, usually a NOESY spectrum. The experiment must be run in any case, for structure determination, and is relatively sensitive and needs no isotope enrichment.

2.2. The Determination of Coupling Constants with the E.COSY Principle

A large number of methods for the determination of coupling constants utilize the E.COSY principle. The name E.COSY stands for *e*xclusive *co*rrelation *s*pectroscop*y*.[10, 54, 55] It results in a simplification of the cross peak multiplet, as only the "connected transitions" are excited. The coupling can be read from the shifting of two in-phase multiplet components which are separated in the indirect dimension and therefore have no interfering influence on each other. Several procedures, which allow the measurement of homonuclear as well as heteronuclear coupling constants from signals of the E.COSY type, will be discussed in this chapter. But first the E.COSY principle, which forms the basis of all these techniques, will be described.

2.2.1. *The E.COSY Principle*

The advantage of the E.COSY experiment is a reduction of the multiplet lines in the cross peak. From this, the coupling constants can be read directly from the distance between the maximum intensity of the signal without error from line widths. This principle is illustrated in Figure 14 for a cross peak from a three-spin system, AMX, which would be observed in many common 2D experiments (e.g. COSY, TOCSY, NOESY).

In our three-spin system, the X atom is coupled to both A and M and therefore the cross peak for A,M is affected by the spin state of nucleus X. For the X nucleus in the α spin state (approximately 50% populated), we would expect the signal in Figure 14b, while for the X nucleus in the β spin state, the signal in Figure 14c would be observed. For the case of magnetization transfer from A to M, without excitation of the X nucleus, the cross peak shown in Figure 14d would be expected: the signal intensity can only be found at multiplet lines which correspond to the retention of the spin state of X ("connected transitions"), that is the left upper (α spin of X) and the lower right lines (β spin of X) in Figure 14d; the other two multiplet lines disappear. The resulting cross peak shows the typical oblique E.COSY pattern. In order to obtain such a E.COSY pattern, a mixture of spin states of X (e.g. by a 90° pulse) must be avoided.

The only requirement to reading coupling constants from an E.COSY cross peak is that the splitting in F_1 (the coupling between A and X) must be larger than the line width. The much smaller coupling constant J(M,X) can then be read from the dis-

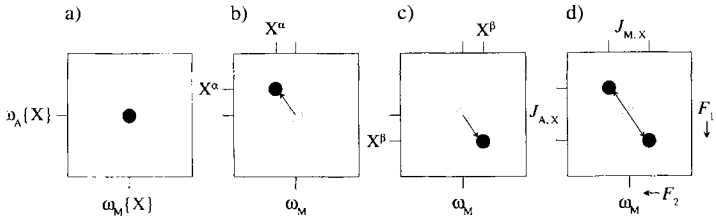

Fig. 14. The principle of the E.COSY technique. a) Schematic 2D cross peak correlating spins A and M from a system of three coupled nuclei (A, M, and X) with decoupling of spin X. b) and c) Without decoupling of X, the AM signal is shifted in both dimensions, an effect from the two different spin states (α and β) of spin X: b) X spin in the α-spin state, c) X spin in the β spin state. d) Under experimental conditions one expects a combination of spectra (b) and (c). The diagonal displacement of the signals in F_1 and F_2 contain both of the passive coupling constants J(A,X) and J(M,X).

placement in F_2 (in 2D) or F_3 (in 3D experiments), the dimension of detection which usually contains more data points and therefore higher digital resolution. The measurement can be made with the signal maxima or better yet from the mutual displacement of the coupling patterns. In addition, the direction of the displacement of the signal leads to the sign of the coupling constant.

2.2.2. *Homonuclear E.COSY Techniques*

In the homonuclear E.COSY experiment the effect outlined in the previous section is not obtained by the retention of the spin states of the passive spin, but by a suitable combination of several multiple quantum correlations. As reference [56] explains this in detail, it will not be fully developed here. The result is the same multiplet pattern as shown in Figure 14d, but all lines are additionally split in both dimensions by the active coupling, as decoupling cannot be performed in homonuclear experiments (Fig. 15). However, we would like to mention that in the case of linear combination of multiple components different transversal relaxation rates of the active in-phase and antiphase terms can influence the determination of the coupling constant.[57] In addition, longitudinal relaxation effects have been neglected in this analysis which can lead to a mixture of α and β components, which in turn leads to.[58]

A simple alternative to the E.COSY experiment is the P.E.COSY experiment (*p*rimitive E.COSY).[59] It is well known that the cross peaks in a COSY spectrum with a small flip angle of the mix pulse, $\beta' < 90°$ (β-COSY), contain strong signal components of connected transitions and that nonconnected transitions (i.e. transitions with a spin-flip of the passive nuclei) are partially suppressed. This is founded on the fact that the spin states of the passive nuclei can only be completely mixed by a 90° pulse; the influence of a very small flip angle β' on the passive spins is negligibly small [Eq. (3)].

$$\boldsymbol{I}^\alpha \xrightarrow{\beta'} \boldsymbol{I}^\alpha \cos^2\frac{\beta'}{2} + \boldsymbol{I}^\beta \sin^2\frac{\beta'}{2} \qquad (3)$$

The relation of the excitation of connected ($\boldsymbol{I}^\alpha \rightarrow \boldsymbol{I}^\alpha$) to nonconnected transitions ($\boldsymbol{I}^\alpha \rightarrow \boldsymbol{I}^\beta$) is therefore proportional to $\tan^2(\beta'/2)$. The same is true for the intensity of the corresponding multiplet lines. A problem with the β-COSY experiment is the phase difference between cross peaks and diagonal signals, which—analogous to the normal COSY spectrum—makes a simultaneous correction of both signals to absorptive signals impossible. However, the dispersive signal portions of the diagonal can easily be removed by subtracting a 2D reference spectrum with a mix pulse β' of 0° (i.e. $90° - t_1 - t_2$). This 2D reference spectrum can be obtained arithmetically from a single FID by shifting the data points in the time domain to the left by the single t_1 increments, so that the additional measurement time required corresponds to a good 1D spectrum. The P.E.COSY experiment is also more sensitive than the E.COSY experiment, since higher multiple quantum spectra (triple quantum, quadruple quantum) are not required.[10, 54, 55]

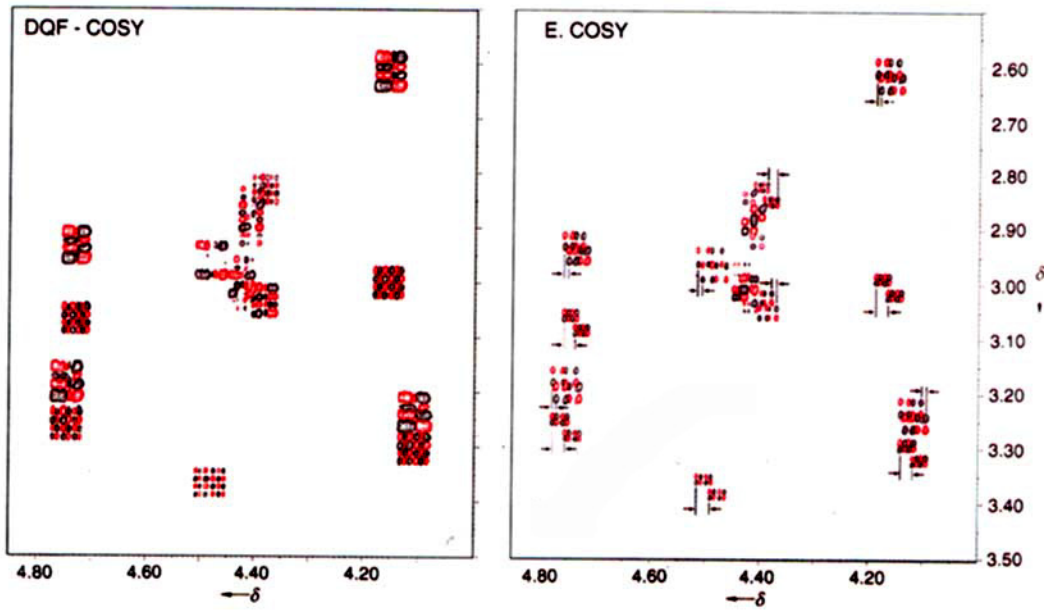

Fig. 15. A comparison of double quantum filtered COSY (left) and E.COSY (right) spectra from a cyclic hexapeptide, illustrating the H^α,H^β region. It is much easier to identifiy the multiplets in the cross peaks from the E.COSY spectrum; from the displacement of the multiplet patterns (arrows) the passive coupling constants (see Fig. 14) can be read with high accuracy.

2.2.3. *Heteronuclear E.COSY Techniques*

In heteronuclear spectroscopy multiplet cross peaks which contain only connected transitions (E.COSY pattern) can be obtained very easily. If no pulse is performed on the heteroatom (i.e. the states α and β are not mixed) each coupling of a proton with the heteroatom shows the typical

E.COSY structure. The easiest way to obtain this is by recording any homonuclear 2D experiment (e.g. H,H-TOCSY or NOESY) without any pulses on the heteronucleus; that is without heteronuclear decoupling in F_1 and F_2, and no heteronuclear pulses between F_1 and F_2. Thus an additional separation for every cross peak in two-dimensions is obtained through the coupling of the respective proton to the heteronucleus, yielding an E.COSY pattern for this coupling. Of course, this is only true for molecules with an NMR-active heteronucleus; for those nuclei in low abundance (e.g. ^{13}C and ^{15}N) the rest can be eliminated by heterofilters. For heteronuclei like ^{31}P and ^{19}F (or for samples which are enriched in NMR-active isotopes) this phenomenon can be observed effortlessly in every homonuclear 2D correlation spectra (Fig. 16).[75]

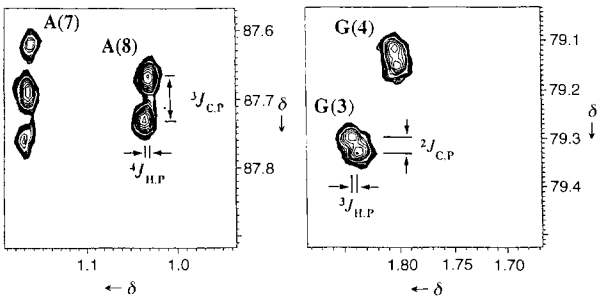

Fig. 16. $^1H,^{13}C$-HSQC spectrum from an oligonucleotide. Since the experiment was run without ^{31}P decoupling in F_1 and F_2, the coupling to the phosphorus nuclei results in the typical diagonal E.COSY cross peak pattern (see text).

Especially useful is the fact that the $^1J_{H,X}$ couplings are usually very large (^{13}C: ca. 140 Hz, ^{15}N: ca. 90 Hz), so that small coupling constants in molecules with very large line widths can easily be determined from E.COSY signals; the large ^1J couplings in the other dimension are used to separate the lines. If the NMR-active heteronucleus is in low natural abundance, the E.COSY pattern is weak and often overlapping within a normal COSY signal population. At natural abundance, the signal of E.COSY patterns is naturally very small and it is necessary to discriminate experiments which can be performed without isotopic enrichment.

Recently a large number of experiments, which in principle are all very similar, have been developed in this field. Here only a few basic experiments will be discussed. For further information we refer to Table 2, in which many experiments are summarized with respect to their field of application, measurement technique as well as advantages and disadvantages.

In principle, coupling constants with large line widths can also be determined accurately with the help of the E.COSY principle (see Sections 2.2.3.3 and 2.2.3.4). However, for heteronuclear E.COSY techniques a splitting of signals takes place, which naturally increases the probability of the overlapping of resonances. In addition, the signal intensity for E.COSY spectra is spread over two components (a doublet), which naturally leads to a loss of sensitivity by 50% in comparison to decoupled experiments (i.e. HMQC and HSQC). Again an error can arise from ignoring longitudinal relaxation which leads to a small mixture of the α and β states during the pulse sequence.

2.2.3.1. Heteronuclear ^{15}N-^1H Long-Range Coupling Constants

It was illustrated very early that in ^{15}N-enriched proteins heteronuclear $^3J_{N,H^\beta}$ and $^3J_{H^\alpha(i),N(i+1)}$ as well as $^3J_{N,H}$ coupling constants of ^{15}N spins of the side chains can be extracted from simple homonuclear scalar (RELAY or TOCSY) and dipole–dipole (NOESY or ROESY) correlated spectra.[60, 61] The coupling constant is determined from the cross peak of two protons, one of which is directly coupled to the ^{15}N spin and which is scalar coupled to the other proton. The cross peaks between the amide proton and other protons show E.COSY-like multiplet structures with the passive heteronuclear coupling constant in F_2, as no pulses are applied to the ^{15}N spins and therefore only connected transitions contribute to the signal (an analog of the HETLOC cross peak, see Fig. 17). Along the indirect dimension (F_1 in 2D spectra), the signals are split by the $^1J_{N,H}$ coupling (ca. 90 Hz) and along the direct dimension (F_2 in 2D spectra) by the smaller heteronuclear long-range coupling which is of interest. From the cross peak between the amide proton and the β-proton of the same amino acid the χ_1-dihedral angle, important for peptide and protein structures can be read (see Fig. 1). The $^3J_{H^\alpha(i)N(i+1)}$ coupling constant which depends on the ψ-dihedral angle of the peptide backbone can be determined from NOESY or ROESY spectra from the sequential (H^α_i,H^N_{i+1}) cross peak.

2.2.3.2. ω_1-Hetero-Filtered Experiments for Determination of Long-Range Coupling Constants

These methods are suited for the determination of long-range coupling constants of protons to a ^{13}C or ^{15}N nucleus in natural abundance, which carry a directly connected proton.[62–65] The pulse sequence for the HETLOC experiment is given in Figure 17.[62, 63, 180]

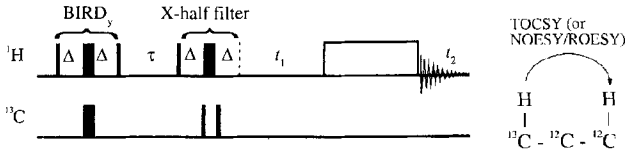

Fig. 17. Pulse sequence for a ω_1-filtered TOCSY without heteronuclear decoupling (HETLOC). The delay Δ is set to $1/(2^1J(C,H))$. In the resulting spectrum, protons directly bound to ^{13}C (frequency labeled during t_1) are correlated to other protons (frequency labeled during t_2) by scalar coupling (through chemical bonds, TOCSY) or dipole–dipole coupling (through-space, NOESY/ROESY). Since the spin states of the ^{13}C nuclei are not disturbed, the desired E.COSY cross peak pattern is produced (see text). The parameters for the BIRD pulse (i.e. relaxation delay τ and the aquisition time t_2) must be adjusted to obtain the optimal suppression of the signals of protons directly bound to ^{12}C [66]. The experiment can be easily modified to create a 3D experiment; one must simply add a ^{13}C evolution time in between the two ^{13}C-90° pulses [63].

Before the actual experiment starts, a BIRD-pulse sequence[56, 66] is used to suppress the signals of ^{12}C- or ^{14}N-coupled protons. The BIRD-pulse sequence allows one to greatly increase the pulse repetition rate, the relaxation time between two scans is reduced to approximately 1.3 T_1 from the commonly used $3T_1$, which cuts the measuring time by about one half. By using a heteronuclear ω_1-half-filter (X-half filter)[67] at the beginning of the experiment (before the t_1 delay) only protons which are directly coupled to the magnetically active heteroatom (^{13}C or ^{15}N) are selected and ^{12}CH or ^{14}NH protons are suppressed. Of course no heteronuclear decoupling can be

performed during the acquisition. The delay Δ is adjusted to the value of the heteronuclear coupling constant for the ω_1-half filter ($\Delta = 1/2(^1J_{H,C})$) resulting in in-phase magnetization at the end of these two delays, although with small phase distortions from the ^1H coupling. The following TOCSY sequence is only effective for the ^{13}C-coupled protons and transfers the magnetization through the complete spin system. In ω_1 the signals are split by the value of the $^1J_{C,H}$ coupling and in ω_2 by the value of the long-range heteronuclear coupling constant. When the proton peaks are severely overlapped the experiment can easily be expanded into a 3D-HMQC-TOCSY experiment[68] (again without decoupling). This can be accomplished simply by the addition of an evolution period during the heteronuclear half-filter. For example the approximately 200 heteronuclear, long-range coupling constants of the immunosuppressant FK506 were determined with *one* experiment.[69]

However, there are limitations of the HETLOC experiment; heteronuclear $^nJ_{H,X}$ coupling constants can only be determined for heteroatoms which have a directly bound proton. A great advantage is that many heteronuclear coupling constants can be determined for the molecule in natural abundance and with the sensitivity of an inverse detection experiment with one spectrum. In practice, a HETLOC spectrum for a sample with a concentration of about 20 mM can be obtained in approximately one day of measuring time with a high-field instrument. As an example, a HETLOC spectrum from a cyclic hexapeptide is given in Figure 18.

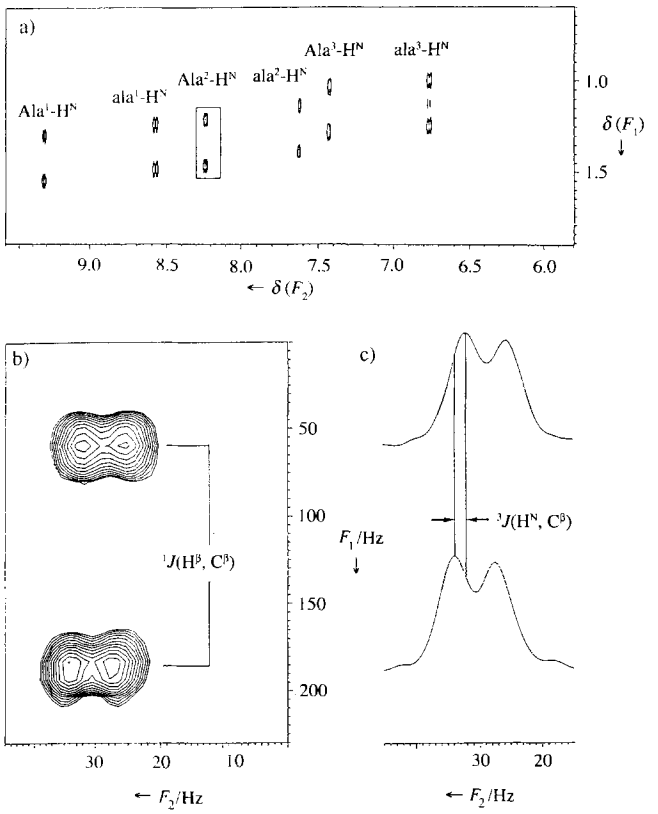

Fig. 18. HETLOC spectrum of a cyclic hexapeptide. a) The H^N,H^β region is shown. The signals are separated in F_1 by the large heteronuclear coupling constant. b) Expansion of the cross peak of Ala^2-H^N illustrating the displacement of the signal in F_2. c) From slices of the F_2 dimension through the signal the long-range heteronuclear coupling constant can be read.

2.2.3.3. Triple Resonance Experiments

Triple resonance experiments[9, 70–74] are pulse sequences which involve three different kinds of nuclei. In proteins and peptides, these are ^{13}C, ^{15}N, and ^1H. For nucleic acids ^{31}P is also of interest; for example $^3J_{C,P}$ or $^3J_{H,P}$ coupling constants can be measured.[75] As a rule, these experiments presuppose isotope enrichment of ^{13}C and often ^{15}N. For larger proteins the classification of signals is performed by triple resonance experiments, such as HNCA,[77] HN(CO)CA,[78] HCACO,[79] HNCO,[80] H(N)COCA,[81] HN(CA)H[82] to name only a few (Fig. 19). There are a large number of correlation experiments which can be modified to allow for passive couplings, producing the E.COSY-type cross peak.

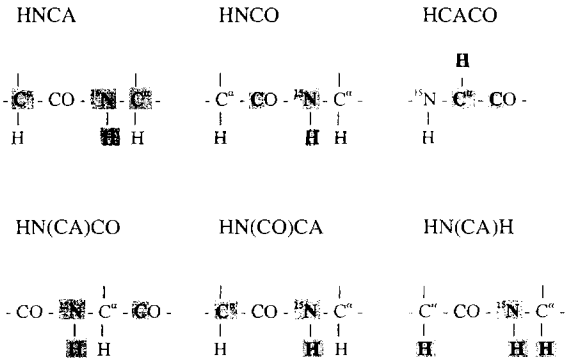

Fig. 19. Schematic representation of the more important 3D triple-resonance experiments for the assignment of the resonances of the protein backbone. The three atoms correlated in each of the three dimensions are highlighted (the HNCA and HN(CA)H produce correlations in the ^{13}C- and H^α dimension between both their own and the previous amino acid).

In the HNCA experiment amide protons, amide nitrogen nuclei, and the C^α nuclei of one residue and the preceding residue (i-1) are correlated. The H^α proton passively couples with the C^α_i, so that the option to determine the $^3J_{H^NH^\alpha}$ coupling constant presents itself.[83] An example of this will be discussed further below. But as there are a great number of other possibilities of correlation in completely enriched samples, a multitude of homo- and heteronuclear coupling constants can be determined by E.COSY techniques. Only a few of the existing experiments can be examined here, so as not to overemphasize the field of protein NMR; we refer to the references given in Table 2. Here, techniques for the determination of $^3J_{H^N,H^\alpha}$ and in the next section $^3J_{H^\alpha,H^\beta}$ will be discussed in detail for illustrative purposes.

Before the establishment of the HNCA experiment, Montelione and Wagner presented the so-called H^α-C^α-(ω_1)-N-selective-H^N-(ω_2) homonuclear RELAY experiment for the determination of the $^3J_{H^N,H^\alpha}$ coupling. The 2D experiment was first illustrated with a peptide enriched with ^{15}N. The pulse sequence is given in Figure 20.[113]

The experiment starts with a refocused INEPT pulse sequence[84] for the transfer of proton-magnetization to $^{13}C^\alpha$ nuclei. During the time of evolution a $^{13}C^\alpha$ chemical shift is developed which is decoupled from the ^{15}N nucleus, but coupled with the protons. In this way a splitting of the cross signals in the ω_1 dimension by the $^1J_{C,H}$ coupling of approximately 140 Hz is produced. The C^α magnetization is transferred to the amide nitrogen of the peptide bond by the $^1J_{C^\alpha N}$ coupling of approxi-

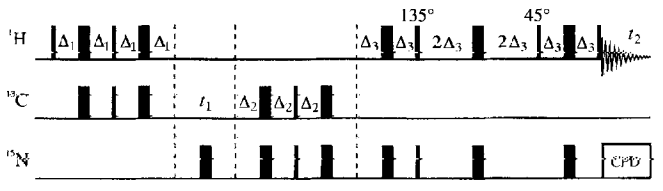

Fig. 20. Pulse sequence for a H^{α}-C^{α}-(ω_1)-N-selective-H^N-(ω_2)-heteronuclear RELAY experiment for the determination of the $^3J(H^N,H^{\alpha})$ coupling constant in peptides (see text). The delays are adjusted for the following coupling constants: $\Delta_1 = 1/(4^1J(C^{\alpha},H^{\alpha}))$, $\Delta_2 = 1/(4^1J(N,C^{\alpha}))$ and $\Delta_3 = 1/(4^1J(N,H))$.

mately 11 Hz during Δ_2. The amide nitrogen magnetization is then defocused with regard to the coupling with the amide proton and is transferred to the H^N nuclei with the help of a TANGO pulse.[85] The TANGO pulse is selective for protons which are directly coupled to ^{15}N and does not excite (change the spin state) of the α-protons. Antiphase proton-coherence is refocused and detected during t_2. The coupling constant can be read from the cross peak in the normal manner. The signal components are separated by the $^1J_{C,H}$ coupling to such an extent that the coupling constant can be determined independent of line width. The pulse sequence of Montelione and Wagner is the basis for a multitude of further experiments which are also founded on the magnetization transfer by ^1J scalar couplings.

However, for proteins with an especially high molecular weight, the pulse sequence must be modified to take into account the relaxation qualities of the molecule. An example of these methods for the HNCA-J experiment is given in Figure 21.[114, 177]

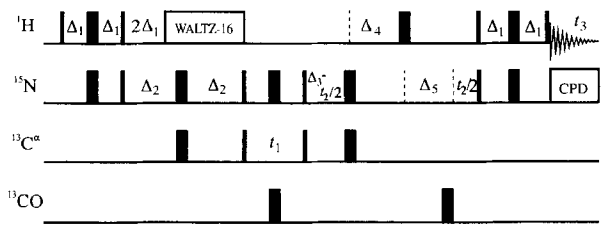

Fig. 21. Pulse sequence for the determination of the $^3J(H^N,H^{\alpha})$ coupling constant in large proteins. The delays are set to the following values: $\Delta_1 = 1/(4^1J(N,H))$, $\Delta_2 = 13$ ms, $\Delta_3 = 10$ ms, $\Delta_4 = 7.75$ ms and $\Delta_5 = 2.25$ ms.

Basically, the experiment corresponds to a constant-time 3D-HNCA experiment without proton decoupling in t_1. C^{α} spins are excited by H^N and ^{15}N and develop as antiphase magnetization with regard to ^{15}N without decoupling of the protons during t_1. After the constant-time evolution of ^{15}N in t_2 the magnetization is transferred back to the protons for detection in t_3. The ^{15}N nuclei are decoupled from the amide protons, through a switching (not mixing!) of populations of the α- and β-states with a 180° ^{1}H pulse. The E.COSY pattern is produced by the selective excitation of the protons which are coupled with ^{15}N. The spin states of the H^{α} protons must remain unperturbed by this. In this instance the effect of the last INEPT step is of importance. The ^{15}N does not strongly couple to the H^{α} nuclei during $2\Delta_1$ and therefore the last three ^{1}H pulses [$90^{\circ}_{(x)}$ - $180^{\circ}_{(x)}$ - $90^{\circ}_{(-x)}$] act as a normal 180° pulse to the α-protons along the z axis which along with the other 180° ^{1}H pulse, produces a 360° pulse, the same result after the t_1 evolution. The last portion of the sequence works similar to a 90°-BIRD pulse, selective for the amide protons, without disturbing the C^{α} protons.

2.2.3.4. HCCH-TOCSY Experiments

In a HCCH-TOCSY experiment the TOCSY transfer is applied to the ^{13}C framework. Because of this such techniques require a high enrichment in ^{13}C, which to date has been mainly limited to proteins. For very large line widths or overlapping of the H^{β} signals, the 2D E.COSY experiment cannot be used to determine the $^3J_{H^{\alpha},H^{\beta}}$ coupling and alternatives must be developed which separate the multiplet components by the large heteronuclear $^1J_{C,H}$ coupling constant along the indirect dimension. As many experiments which deal with this problem have appeared in the literature,[86-89] only one pulse sequence, for illustrative purposes, will be discussed here (Fig. 22).

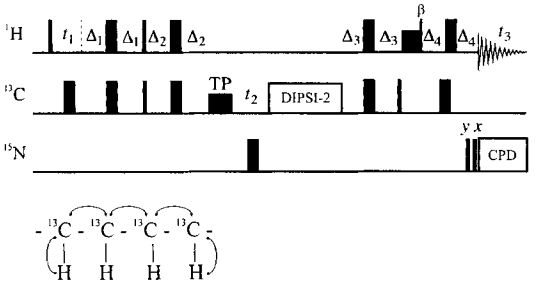

Fig. 22. Pulse sequence for a HCCH-TOCSY experiment [88] for the determination of homonuclear J(H,H) coupling constants in ^{13}C-enriched molecules. With this procedure, protons directly bound to carbon are correlated to each other by a TOCSY transfer through the ^{13}C framework. The delays are set to the following values: $\Delta_1 = 1/(4^1J(C,H))$, $\Delta_2 = 1.3$ ms, $\Delta_3 = 0.55$ ms, and $\Delta_4 = 1/(2^1J(C,H))$, $\beta \approx 35°$.

The refocused INEPT-transfer to begin the pulse sequence also contains the evolution time for the protons. During t_2 in-phase ^{13}C magnetization is developed. The TOCSY sequence is then used to transfer the magnetization to the neighboring ^{13}C nuclei. The magnetization is then transferred back to the protons for detection by reverse INEPT transfer. In comparison to analogous experiments, an advantage of this pulse sequence is that no selective pulses are necessary, and the E.COSY-pattern is obtained by a pulse with a small flip angle. A problem with the employment of selective pulses is that H^{α} nuclei must not be excited while H^{β} nuclei must be completely and uniformly excited. In practice, this cannot always be performed as the resonances of α and β protons may overlap (often the case for the amino acids threonine and serine). In addition, the signal intensities will vary with regard to the excitation profile of the selective pulse which depends on frequency. These problems can be avoided by using a pulse with a small flip angle in the reverse INEPT, especially for overlapping H^{α} and H^{β} resonances. In an (H^{α},H^{β}) cross signal the multiplet components are separated by the $^1J_{C,H}$ coupling along ω_1 and by the $^3J_{H^{\alpha},H^{\beta}}$ coupling along ω_2. An acceptable compromise between the excitation of connected and nonconnected transitions can be obtained with a flip angle β of 30°, suppressing nonconnected transitions by approximately a factor of 10 (see P.E.COSY, Section 2.2.2).

2.3. The Determination of Coupling Constants from Signal Intensities

The determination of coupling constants from signal intensities is founded on the quantification of the magnetization transfer. The precondition for this method is that the signal intensity

depends strongly on the coupling constant. The advantage is that a coupling constant in the range of only a few Hertz need not be read from the multiplet splitting, but is obtained from the signal intensity which can easily be measured.

Generally the signal intensities in most spectra are modulated in some manner by the scalar coupling, which are only in a few cases easy to interpret (e.g. COLOC, HMBC, see below). As a rule, special procedures in which the intensity is modulated by only *one* coupling and therefore easy to evaluate are necessary for the accurate measurement of couplings from signal intensities. In the following several principles will be presented with examples, in order to illustrate how intensity modulations can be evaluated: 1) simply looking at the cross signal intensities, 2) adjusting the analytical dependence of J to a series of measurements, and 3) comparison to a reference spectrum or comparing the intensities of cross peaks and diagonal signals in the same spectrum.

2.3.1. The COLOC Experiment

The COLOC experiment is an example of the determination of coupling constants directly from signal intensity. The pulse sequence is given in Figure 23.[47] The chemical shift evolution and polarization transfer is performed by shifting a pair of π pulses during the delay Δ_1 from 0 to $\Delta_1/2$. The careful optimization of both delays Δ_1 and Δ_2 is important for the suppression of direct couplings. Because of the direct detection of the heteronucleus the sensitivity of the COLOC experiment is relatively low.

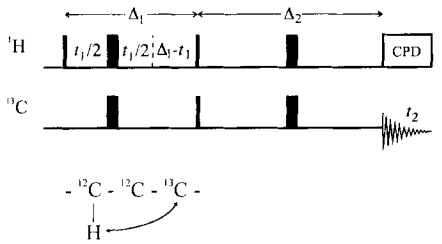

Fig. 23. Pulse sequence for the COLOC experiment for the correlation of ^1H to ^{13}C through long-range heteronuclear coupling constants. The delays Δ_1 and Δ_2 must be optimized. For peptides, values of $\Delta_1 = 25$ ms and $\Delta_2 = 30$ ms have been obtained.

The COLOC experiment was the first to use signal intensities for the determination of coupling constants.[90] For the *constant time* experiment the transfer amplitudes are easy to calculate. The general term of the transfer amplitude I_{ij} of a COLOC signal from proton i to carbon nucleus j is given in Equation 4. The letters k and l stand for passive proton nuclei, which couple with the active proton H_i and active C_j, respectively. For short delay times, $\Delta_1 \approx \Delta_2$ Equation 4 reduces to Equation 5.

As shown in Equation 4, the active coupling in question is developed with sine modulation in the constant delays Δ_1 and

$$I_{ij} = \sin(\pi J_{H_i,C_j}\Delta_1)\sin(\pi J_{H_i,C_j}\Delta_2)\prod_k \cos(\pi J_{H_i,H_k}\Delta_1)\prod_l \cdot \cos(\pi J_{H_i,C_j}\Delta_2) \quad (4)$$

$$I_{ij} \approx \sin^2(\pi J_{H_i,C_j}\Delta_2) \quad (5)$$

Δ_2, the other relevant couplings are cosine modulated. For short delays the difference in signal intensity is dominated by the sine term and therefore relative coupling constants are produced. Modulations due to homonuclear proton couplings in Δ_1 can be taken into account if the $J_{H,H}$ values are known.[90]

Often a qualitative analysis of the heteronuclear coupling constants is sufficient to obtain the stereospecific assignment of diastereotopic protons, for example, the C^β protons of amino acids in peptides. Along with the relatively easy to measure homonuclear coupling constants $^3J_{H^\alpha,H^{\beta pro-R}}$ and $^3J_{H^\alpha,H^{\beta pro-S}}$ (from an E.COSY or DISCO experiment, see Sections 2.1.2 and 2.2, respectively) the heteronuclear couplings provide an unambiguous analysis of the populations about the χ_1 side chain dihedral angle.

Of course, one can measure more than carbon heteronuclear coupling constants with the COLOC experiment. The size of ^1H-^{15}N long-range coupling constants in peptides in natural abundance can be determined, although the sensitivity is greatly reduced.[91, 92]

2.3.2. The HMBC Experiment

However, for most situations inverse detection techniques have many advantages over the methods with direct detection of the heteroatom. As already addressed in Section 2.1.4, the HMBC spectrum contains heteronuclear long-range couplings as antiphase splitting in the cross peak. If couplings for only a few selected carbon atoms are to be determined (e.g. carbonyl-carbons of a peptide) the selective HMBC is favorable to increase the resolution of the carbon dimension.[192, 193] Two illustrative pulse sequences are given in Figure 24.[93]

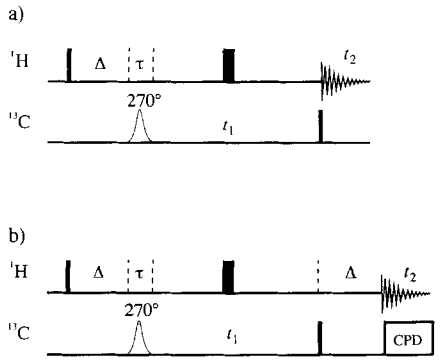

Fig. 24. Pulse sequence for heteronuclear long-range correlation with selective pulses (see the HMBC sequence, Fig. 11). a) Selective HMBC experiment for excitation of a specific region of the heteronuclei. b) Similar to (a) but with refocusing and decoupling during t_2. The delay Δ is set to 60–80 ms. τ is the length of the selective pulse. The utilization of the self-refocusing 270°-Gauss pulse has the advantage that data phase-sensitive in t_1 can be collected.

The signal intensities (transfer amplitude) for these experiments can be easily calculated with the help of the product operator formalism [Eqs. (6a) and (6b)], where H'_k stands for the

$$I = \prod_{H'_k}\cos(\pi J_{H,H'_k}(\Delta + \tau + t_1 + t_2)) \cdot \sin\left(\pi J_{C,H}\left(\Delta + \frac{\tau}{2}\right)\right)\sin(\pi J_{C,H}t_2) \quad (6a)$$

$$I = \prod_{H'_k}\cos(\pi J_{H,H'_k}(\Delta + \tau + t_1 + t_2 + \Delta))\sin\left(\pi J_{C,H}\left(\Delta + \frac{\tau}{2}\right)\right) \cdot \sin(\pi J_{C,H}\Delta)\sin(\pi J_{C,H}t_2) \quad (6b)$$

passive protons. In Equation (6a) (corresponding to the sequence in Fig. 24a) the amplitude varies very little with the coupling, constant, whereas in Equation (6b) (corresponding to the sequence in Fig. 24b) a much stronger influence of the coupling constant on the intensity is observed, as the factor $\sin(\pi J_{C,H}\Delta)$ increases the dependence of the signal amplitude on the coupling constant. Large coupling constants produce an intensive signal in both spectra, whereas small couplings with the second sequence produce a much smaller one.

2.3.3. The J-Modulated (^{15}N,^{1}H)-COSY Experiment

This experiment is used to determine the homonuclear $^{3}J_{H^N,H^\alpha}$ coupling constant. A precondition is an ^{15}N-enriched sample.[94] The desired information about the coupling constant is obtained by the temporary evolution of the proton coherence at the end of a heteronuclear correlation experiment. This procedure allows for an accurate determination of the coupling constant over a large range of J values. The coupling constant can be read from the cross peak intensities with the help of a nonlinear fitting procedure.

Recently an improved version of this method has been presented,[95] which will be discussed in the following. The pulse sequence, shown in Figure 25, is also suitable for proteins with high molecular weight.

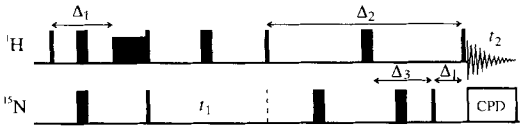

Fig. 25. Pulse sequence for a J-modulated [^{15}N,^{1}H]-COSY experiment for the determination of the $^{3}J(H^N,H^\alpha)$ coupling constants in peptides. The pulse sequence correlates ^{15}N nuclei with the directly bound amide proton. The delay Δ_1 is set to $1/(2^1J(N,H))$; Δ_2 is a variable delay, during which the $^{3}J(H^N,H^\alpha)$ coupling constant is developed; $\Delta_3 = \Delta_2 - \Delta_1 - 180°(^{15}N)$. To determine the coupling constant, a series of spectra with different Δ_2 are collected and the volume of the cross peak is fitted using Equation (7) (see Fig. 26) [93].

The experiment begins as with the related [^{15}N,^{1}H]-HSQC experiment with a spin-lock pulse for water suppression. At the beginning of the delay Δ_2 transversal heteronuclear two-spin coherence $2H_yN_y^H$ is selected, in which the coupling to H^α is developed with $\cos(\pi J\Delta_2)$. The volume of the cross peak is a function of the delay Δ_2 and is given by Equation (7), where A

$$V(\Delta_2) = A\left(\cos(\pi J\Delta_1)\cos(\pi J\Delta_2) - \frac{1}{2}\sin(\pi J\Delta_1)\sin(\pi J\Delta_2)\right) \cdot \exp\left(-\frac{\Delta_2}{T_2'}\right) \quad (7)$$

is the volume of the cross peak for $\Delta_2 = 0$, J is the $^{3}J_{H^N,H^\alpha}$ coupling constant and T_2' is the approximate transversal relaxation time. The coupling constant $^{3}J_{H^N,H^\alpha}$ is obtained by adjusting Equation (7) to the experimental dependence of the volume of the cross peaks with respect to Δ_2. An example for some amino acids from the PTS protein IIB^{Glc}[96] is shown in Figure 26.

For this method several spectra with good signal-to-noise ratio are required and therefore considerable measuring time must be invested.

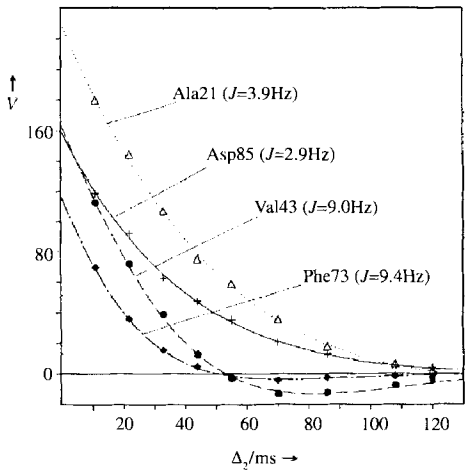

Fig. 26. Results from the fitting using Equation (7) for four amino acids (Ala21, Val43, Phe73, and Asp85) from the IIB^{Glc}-domain of the phosphotransferase transport system from *E.coli*. The volume of the cross peaks V is plotted against the length of the Δ_2 delay. The lines represent the optimal fitting from Equation (7), leading to the values of $^{3}J(H^N,H^\alpha)$ given in the Figure.

2.3.4. The HNHA Experiment

The $^{3}J_{H^N,H^\alpha}$ coupling constant in ^{15}N-enriched proteins can be determined by the HNHA experiment (Fig. 27). An advantage with regard to E.COSY techniques, which are also often used in

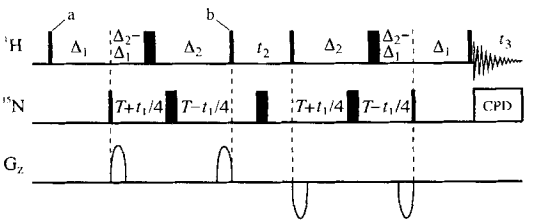

Fig. 27. Pulse sequence for the HNHA experiment. The delays Δ_1 and Δ_2 are set to values 4.5 ms and 13.05 ms, respectively. The pulse sequence is described in detail in the text.

3D NMR spectra, is that signal intensities are easier to determine than precise signal positions in multidimensional spectra with bad digital resolution. The determination of the $^{3}J_{H^N,H^\alpha}$ coupling constant is founded on the quantitative analysis of the intensity of the diagonal signal relative to the cross peak.[16] Basically, the experiment corresponds to several procedures which have already been discussed in the literature with regard to the determination of coupling constants in isotopically enriched proteins.[97-99] In addition, the intraresidual (H^N,H^α) correlation is obtained in the HNHA experiment, so that—besides the measurement of the $^{3}J_{H^N,H^\alpha}$ coupling constant—the assignment of the H^α resonances can also be obtained. The experiment is similar to the ^{15}N-edited [H^N,H^α] COSY spectrum. This sequence is therefore not very useful for large proteins, since the signal intensity is greatly reduced because of the short T_2 relaxation times.

The pulse sequence for the HNHA experiment shown in Figure 27 utilizes pulse field gradients. The gradient pulses are not essential, but they do reduce artifacts from pulse inaccuracies

and allow for a shorter phase cycle.[100] The first 90°-^{1}H pulse produces proton magnetization, which dephases during the delay Δ with respect to the $^1J_{H,N}$ coupling. The first 90°-^{15}N pulse produces zero and double quantum magnetization similar to the HMQC sequence. A ^{15}N chemical shift is developed during the simultaneous shift of the first and the third 180°-^{15}N pulse during the delays $4T$ as in constant-time experiments. Between a and b (marked in Fig. 27) in the pulse sequence the magnetization is dephased as a result of the $^3J_{H^N,H^\alpha}$ coupling. This produces the development of amide proton antiphase magnetization with regard to the H^α nucleus which is proportional to $\sin(2\pi J_{H,H}\Delta_2)$. The amide proton antiphase term is transformed to antiphase H^α magnetization by the second 90°-^{1}H pulse. After a short t_2-period it is converted back to the amide proton antiphase term with regard to the H^α magnetization. In the following period $2\Delta_2$, during which the $^3J_{H^N,H^\alpha}$ coupling is active again, the magnetization is re-phased with regard to the H^α nuclei. The last 90°-^{15}N pulse produces H^N-magnetization from the multiple quantum term which is antiphase with regard to ^{15}N and then rephases, leading to in-phase amide proton magnetization during the delay Δ_1. The detected signal is described by Equation (8), where Ω_{H^N}, Ω_N, and Ω_{H^α} are the chemical shifts

$$I = A(\cos^2(2\pi J_{H,H}\Delta_2)\cos(\Omega_N t_1)\cos(\Omega_{H^N} t_2) - \sin^2(2\pi J_{H,H}\Delta_2)\cos(\Omega_N t_1)\cos(\Omega_{H^\alpha} t_2))\exp(i\Omega_{H^N} t_3) \quad (8)$$

of amide proton, amide nitrogen, and H^α proton, respectively, and A is a constant.[*] The first term corresponds to the diagonal signal ($\Omega_{H^N}t_2$, $\Omega_{H^N}t_3$) and the second to the cross peak ($\Omega_{H^\alpha}t_2$, $\Omega_{H^N}t_3$). The value of the $^3J_{H^N,H^\alpha}$ coupling constant can now easily be determined from the intensity relation of I_{cross}/II_{diag} [Eq. (9)].

$$\frac{I_{cross}}{I_{diag}} = -\tan^2(2\pi J_{H,H}\Delta_2) \quad (9)$$

Equation 9 implies implicitly that the magnetization components which lead to the intensity of the diagonal and cross peaks relax identically during the re- and dephasing delays Δ_2. The HNHA cross peaks are the result of the antiphase, whereas diagonal signals develop from in-phase terms. Antiphase terms are known to relax faster [101–103] so that the cross peaks are less intense and the value of the measured coupling constant is too small. However, it has been shown that for proteins a simple correction of 11% (this is the estimate of the error in the measurement which arises from relaxation effects) can be used to account for this.[16]

2.3.5. {^{15}N} *Spin Echo Differences CT-HSQC*

The experiments for the determination of coupling constants from J-correlated spectra which were discussed so far dealt with either coupling constants between two protons or a proton and a heteronucleus. Here, an experiment will be discussed which is suited for the determination of ^{15}N-^{13}C coupling constants;[104] other couplings between heteronuclei can be measured analogously, for example, ^{13}C-^{13}C and ^{13}C-^{31}P. Of course, the determination of the ^{15}N-^{13}C coupling constant requires a doubly enriched sample. So far there has been little discussion of $^3J_{N,C}$ couplings in the literature[105] and therefore further study in this area is of great interest.

This method[104] allows for the determination of a multitude of ^{15}N-^{13}C couplings with doubly enriched proteins. In combination with $^3J_{C,C}$ couplings, which can measured by using similar methods,[97] the $^3J_{N,C}$ coupling constants of amide nitrogen to γ-methyl-carbon atoms can be used for the characterization of the χ_1 angle of valine, isoleucine, and threonine. As a rule, coupling constants between two heteroatoms are smaller than coupling constants involving protons and therefore cannot be resolved. Procedures which utilize the quantification of the coherence transfer are especially suited and are to be preferred to other techniques.

The pulse sequence in Figure 28 is basically a 2D difference experiment.[104] If the 180°-^{15}N pulse is performed in position A, the experiment corresponds to a normal constant-time

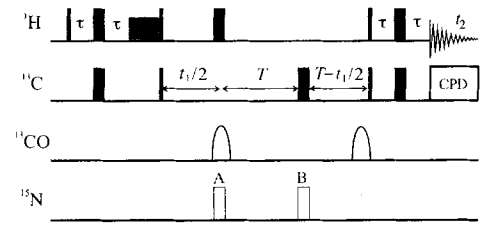

Fig. 28. Pulse sequence for the constant-time-HSQC experiment, which correlates the protons with the directly bound ^{13}C nuclei. The 180° nitrogen pulse is switched between position A and B for the two experiments. The delays τ and T are set to 1.7 ms and 28.6 ms, respectively. The second selective ^{13}CO pulse is to compensate for the Bloch–Siegert effect of the non-carbonyl carbon atoms and the resulting phase error.

HSQC experiment decoupled from ^{13}CO and ^{15}N in t_1 (signal intensity S_a). The delay 2T which corresponds to the constant-time evolution should be adjusted to $1/(^1J_{C,C})$ in order to exclude effects of ^{13}C-^{13}C couplings. In a second experiment the 180°-^{15}N pulse is performed in position B. Due to this the ^{15}N-^{13}C coupling is active during the whole period 2T. The signal intensity is decreased by the factor $\cos(2\pi J_{N,C}T)$ (signal intensity S_b). The ^{15}N-^{13}C coupling constant is the direct result of the relative signal intensities [Eq. (10)].

$$\frac{S_a - S_b}{S_a} = 1 - \cos(2\pi J_{C,N}T) = 2\sin^2(\pi J_{C,N}T) \quad (10)$$

As in other experiments of this kind sources of error derive mainly from relaxation effects. In addition, the percentage of ^{15}N-enrichment and the efficiency of the 180°-^{15}N inversion pulse are decisive for the signal intensity. The authors state that these sources of error are taken into account by scaling the measured coupling constants with the factor 1.075.

[*] In the Equations the same letters are sometimes used for constants and variables in an attempt to be consistent with the literature, they do not necessarily refer to the same quantities.

3. Coupling Constants and Computer Simulations for the Determination of Molecular Structure

The utilization of NMR data for the calculation of the three-dimensional structure of molecules is carried out by computer simulations. For these calculations, distances from NOESY and ROESY spectra are certainly important.[106, 107] Recently, it has become possible to use coupling constants in computer structural refinement,[17, 18] which has increased the quality of the structures as well as allowed for study of the dynamics and flexibility of these biomolecular systems. In this Section we detail the utilization of coupling constants in the computational refinement of protein/peptide structures. Before we can address this point, a few basic aspects about the computational methods themselves are discussed.

3.1. Computational Methods

The computational methods used in the refinement of structures from NMR data, can be broken down into two general categories: molecular mechanics/dynamics (MM or MD) [108–112] and distance geometry (DG) calculations.[113–116] Of course, there is a great variety of different computational approaches, many which utilize a combination of the two listed here, but for our purposes this general division will suffice. A discussion of the precise differences and technical details of the separate procedures could constitute a review alone.

By MM and MD we refer to the utilization of a force field to describe the molecule and produce an estimate of the potential energy of the current conformation. Many different approaches are then used in an attempt to try to minimize the potential energy of this function. The standard force field contains a term for distortion of bond lengths, bond angles, and dihedral angles plus nonbonded terms for Coulombic interactions and Lennard-Jones description of the attraction/repulsion of atoms. There are many different functional forms of the force field,[117–122] varying greatly in the detail in which the molecule is described (i.e. polarization). The greater the detail, the more intense the calculation and longer computational time required. Different recipes to increase the conformational searching to find the global minimum have been described. Many involve varying the weights of the various terms in the force field or scaling of the temperature during molecular dynamics simulations during different stages of the simulation.

The application of experimental restraints in the molecular mechanics type of calculations is achieved by simply adding an additional term, a so-called penalty function. As was mentioned above, NOEs and distance restraints are the most often used constraints; coupling constants were considered to be too difficult to interpret to be used as restraints. The penalty function minimizes the differences between the calculated value and that measured experimentally. This can be illustrated for distance restraints from NOEs simply by Equation (11), where K_{NOE} is

$$\text{energy violation} = \frac{1}{2} \cdot K_{NOE}(R_{exp} - R_{calc})^2 \qquad (11)$$

the force constant, R_{exp} the experimentally measured distance, and R_{calc} the current distance in the computer refinement. The force constant can be adjusted to vary the relative weights of the experimental restraints with respect to the remainder of the force field.

The other general approach, distance geometry calculations, utilizes a description of the molecule based solely on distances.[113] Bond lengths, bond angles, and torsions are converted into ranges of allowed distances. Distances, which satisfy these ranges, are chosen randomly to create a distance matrix. The diagonalization of this matrix, or often a metric matrix, then produces Cartesian coordinates. The procedure of choosing distances can be repeated many times, to better sample conformational space, producing many structures fulfilling the distance matrix.

The application of distance restraints into distance geometry is quite straightforward: the experimental distances are compared with the distances generated from the covalent structure; if the experimental distances are tighter, they are used in place of those from the consideration of the covalent geometry. It is important to note that chirality is not maintained with the description of the molecule solely with distances. Both enantiomers are equally probable. Chirality is maintained by inclusion of an additional penalty term applied after the generation of the Cartesian coordinates.[115]

3.2. Conformation and Coupling Constants

Similar to the NOE which provides information of the distance between the two nuclei, the coupling constant is dependent on structure. The coupling constant provides information about the dihedral angle subtended by the coupled atoms. The equation most often used is that proposed by Karplus [Eq. (12)].[5, 6]

$$^3J = A\cos^2\theta + B\cos\theta + C \qquad (12)$$

The equation was developed from simple valance bond electron calculations, and the coefficients were adjusted with structure parameters, for example from X-ray structure analyses.[123–125] The equation holds for almost all coupling constants, only the coefficients, A, B, and C are adjusted. Even if the coefficients have been determined, the multiple answers possible from Equation (12) (up to four answers can be obtained, see Fig. 29) remains a problem.

The problems with Equation 12 have limited the use of coupling constants as conformational restraints. The standard use of coupling constants was as a secondary check; after the development of a conformation from NOE data, temperature coefficients, or chemical shifts, the dihedral angles would be used to calculate the coupling constants and the agreement with the experimental values examined. The agreement was almost always found to be good, because of the range of values, up to four dihedral angles, that are produced by Equation (12). One method to address the wide range of allowed values is the measurement of additional coupling constants.[126, 127] Using this approach, only the dihedral angles that are in agreement with all of the couplings are retained. This usually allows for some of the solutions (from Equation 12) to be removed from further con-

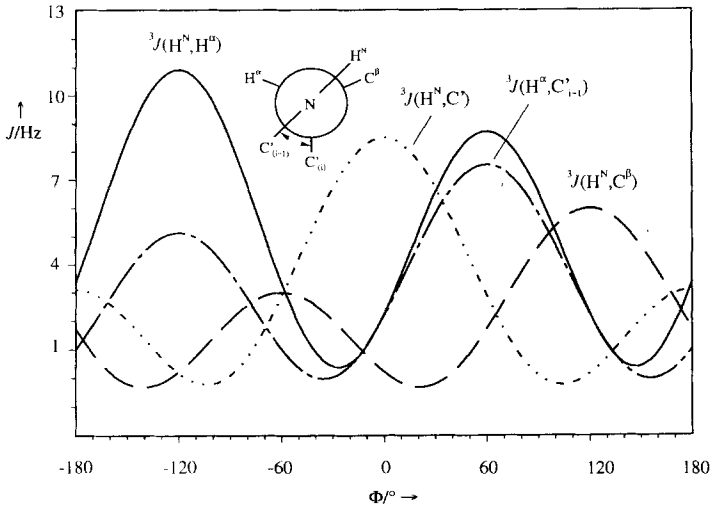

Fig. 29. The Karplus curve for four coupling constants about the ϕ dihedral angle of an L-amino acid. Because of the form of the curve, there are four dihedral angles per coupling constant. Utilizing a combination of all four coupling constants, it is usually possible to eliminate three of the possible dihedral angles.

sideration. However, the coupling constants are frequently only used to confirm an existing structure, and not to determine a conformation.

3.3. Restraints on Dihedral Angles

The first use of coupling constants in refinement calculations was to assume a range of acceptable dihedral angles from Equation (12) and then restrain the torsion to these values. This method is often referred to as dihedral angle restraining. The information from the couplings is used in the refinement, not after the fact. Of course, the problem is how to employ conformational restraints that are consistent with the multiple answers from Equation (12).

One approach to this problem is to utilize only extreme coupling constants.[128-130] For the $^3J_{H^N,H^\alpha}$ coupling constant, values greater than 8.0 Hz or smaller than 6.5 Hz are considered extreme. Couplings between these arbitrary values are considered consistent with conformational averaging and therefore not utilized. For a coupling of 8.0 Hz, the $^3J_{H^N,H^\alpha}$ curve shown in Figure 29 yields four possible dihedral angles. The two answers with positive ϕ dihedral angles are often ignored, which can be very problematic indeed. Ignoring the positive ϕ dihedral angles, a $^3J_{H^N,H^\alpha}$ coupling constant of 8.0 Hz would indicate two minima centered around $-120°$. Typical ranges of acceptable values would be $-140°$ to $-100°$ for $^3J_{H^N,H^\alpha} > 9.0$ Hz, $-160°$ to $-80°$ for 9.0 Hz $> {}^3J_{H^N,H^\alpha} > 8.0$ Hz, and $-160°$ to $-40°$ for $^3J_{H^N,H^\alpha} < 6.0$ Hz.

For each of these couplings a penalty function is applied and added to the energy function or force field that is utilized to refine the conformation. The penalty function can take many different forms. One robust approach uses the calculation of a chiral volume, calculated from the triple product of the three vectors from any of the four atoms defining the dihedral angle.[131] A target chiral volume, CH_{target}, consistent for the dihedral angle, is then calculated and used in a simple penalty function similar to that for NOEs [Eq. (13)],

$$V_{chiral} = \frac{1}{2} K_{CH} (CH_{target} - CH_{theo})^2 \quad (13)$$

where K_{CH} is an adjustable force constant and CH_{theo} is the theoretical chiral volume calculated from the present dihedral angle. Equation (13) is then minimized, along with the remainder of the penalty function, to ensure that the selected dihedral angle adopts a conformation consistent with the experimental value. This method has found widespread use in distance geometry calculations in which chiral volumes are used to maintain the stereochemistry at chirality centers, which is not possible with distances alone.

Another approach utilizes a penalty function identical to that used for dihedral angles in standard molecular dynamics or mechanics programs. For values larger than 8.0 Hz a minimum at $-120°$ is assumed, while for small coupling constants a minimum centered about -80 or $-60°$ is used. The penalty function defined in Equation (14), where K_{DH} is a scaling constant,

$$V = K_{DH} (1 + \cos(\theta - \delta)) \quad (14)$$

θ the dihedral angle, and δ a phase shift, has been shown to be useful for the refinement of conformation using molecular dynamics.[128] Depending on the coupling constant the energy minimum can be adjusted by variation of the phase shift. The K_{DH} can be adjusted to allow for a small range of values centered about the minimum (e.g. for a K_{DH} of 6.8 kJ mol^{-1}, the allowed range of the dihedral angle at 300 K would be $\pm 11°$).

The use of dihedral angle restraints assumes that some of the solutions to Equation (12) are not likely. It is often assumed that positive ϕ values are not possible, and therefore these solutions are ignored. This was done since, up till recently, there have been very few amino acids in protein structures with positive ϕ torsion angles. Recently, as more high-resolution protein structures have been determined, there have been numerous reports of amino acids, not only glycines, with positive ϕ dihedral angles.[132-134] For cyclic or otherwise constrained peptides, it is not safe to assume that the general Ramachandran energy profile will be applicable and one must consider the possibility of positive ϕ values.[135]

3.4. Direct Use of Coupling Constants

A more direct application of coupling constants in the structural refinement calculations was introduced by Kim and Prestegard.[17] The penalty function proposed [Eq. (15)] is similar to that utilized for NOE distance restraints [see Eq. (11)], where K_J is a force constant to weigh each coupling individually, J_{exp} is the experimental coupling constant, and J_{theo} is the theoretical coupling calculated using Equation (12). The difference between the experimental value and that calculated from Equation (12) is minimized during the refinement calculation. This

$$V_J = \frac{1}{2} K_J (J_{exp} - J_{theo})^2 \quad (15)$$

approach allows for all of the coupling constants to be utilized in the refinement calculations without any approximations of which ranges of dihedral angles are appropriate. In addition, multiple couplings about the same dihedral angle can be easily utilized.[137]

Equation (15) has been applied in the conformational analysis of many different peptides and proteins in molecular mechanics and dynamics calculations.[118, 119, 136] In simulations of small cyclic peptides the sole use of coupling constants has produced structures almost identical to those developed from NOE data. However, for a larger cyclic undecapeptide peptide, cyclosporin A, the sole use of coupling constants failed to produce the structure derived from NOE data.[137] There were significant differences in the backbone conformations from the application of the two different experimental restraints. The penalty-energy function for three different coupling constants for the ϕ dihedral angle of D-Ala^8 in cyclosporin A is given in Figure 30. The global minimum of the sum of the coupling constants is given at $+80°$.[138] A similar dihedral angle was obtained for the structure calculated by using only NOE restraints.

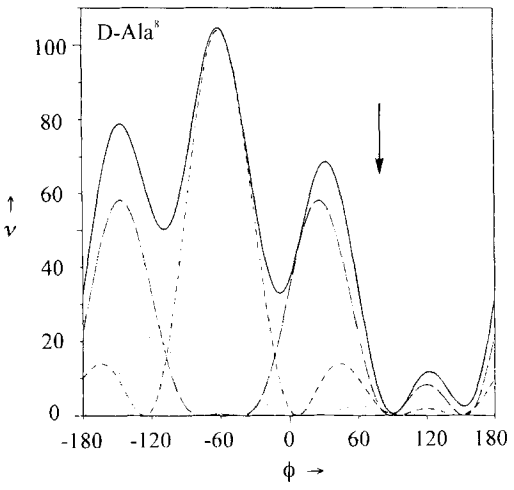

Fig. 30. The potential energy V [kJ mol^{-1}] penalty function for the coupling constants as a function of the ϕ dihedral angle of the amino acid D-Ala^8 in cyclosporin A. The "energy" is calculated from Equations (12) and (15) with a force constant, K_J, of 1.0 kJ mol^{-1} Hz^{-2}. The coefficients for Equation (12) must be known for each individual coupling. The penalty for the $^3J(H^N,H^\alpha)$ (- · -), $^3J(H^N,H^\beta)$ (···), $^3J(C'(i-1),H^\alpha(i))$ (– – –), and the sum of all of the couplings (——) are shown. The arrow indicates the ϕ dihedral angle observed from the structure calculated by using only NOEs.

The populations of the side chain conformations were identical from both calculations. The reason why no structure can be determined for cyclosporin A solely on the basis of coupling constants is because, firstly, seven of the eleven residues are N-methylated and thus only four ϕ angles can be determined from the $^3J_{H^N,H^\alpha}$ coupling constants, and secondly, the ψ dihedral angle is generally difficult to define with J values. Because of the limited number of coupling constants available, many conformations fulfilled the coupling constant restraints (multiple minima) and there was no convergence. It is important to note that the NOE structure satisfied the coupling constant restraints.

One question with the utilization of different coupling constants as conformational restraints, is the appropriate weighting of the various couplings. The experimental error in J varies greatly for the different types of coupling constants. As a general rule, homonuclear coupling constants can be measured with far greater accuracy than heteronuclear couplings. In addition, a great deal of effort must be invested in the development of the A, B, and C coefficients of Equation (12), which to date has only been carried out for the $^3J_{H^N,H^\alpha}$ coupling constant. In general the vicinial heteronuclear coupling constants are greatly influenced by substitution effects and therefore studies to develop standard coefficients for Equation 12 as has been achieved for $^3J_{H,H}$ are much more difficult.[139] The studies that have appeared to date in this area are based on purely quantum mechanical calculations or very few experimental data.

3.5. Identification of Dynamics

One of the most interesting aspects of the use of Equation (12), is the identification of conformational dynamics taking place fast on the NMR time scale.[140, 141] In situations where conformational averaging is taking place, the NOEs are averaged as a function of the sixth power of the distance R between the two participating protons (e.g. R^{-6}). On the other hand, coupling constants are averaged as a function of the cosine series of the dihedral angle subtended by the coupled atoms (i.e. $\cos^2\theta$ and $\cos\theta$). Therefore the NOE restraints will produce a different conformation from that consistent with the coupling constants. This is a clear indication that the molecule is undergoing averaging fast on the NMR time scale. The differences between the "NOE structure" and the structure from coupling constants comes from the different averaging; (R^{-6}) for NOEs and $\cos^2\theta$ and $\cos\theta$ for the coupling constants. It is important to differentiate this finding, with that discussed in the previous Section for cyclosporin A, which can be simply defined as a multiple minima problem (i.e. with the sole application of the coupling constants there exists numerous energy minima, so that the NOE conformation is not found, even though it is one of the minima).

The consideration of dynamic aspects is extremely important in the development of conformations using NMR data, particularly for smaller systems such as peptides or many natural products. Under conformational averaging, the distances calculated from the NOEs are consistent with the average structure, a structure that may not exist in solution or be even physically possible.[142] Only with the use of these two restraints which average differently is it possible to unambiguously identify such averaging. The results of the simultaneous application of coupling constant and NOE restraints to analyze a situation like this was reported recently.[22] Fast conformational averaging can also be identified when one has more than one coupling constant about the same dihedral angle, which cannot be fulfilled by one value. Here it is important to recall that the associated error in the heteronuclear coupling constants is larger, and thus one may wish to give the homonuclear couplings more weight (e.g. four $J_{H,H}$ values describe the angle YCH_2-CH_2X).

3.6. Time-Dependent Restraints

As stated in the previous section, the presence of conformational mobility would have a great influence on the NMR observables (NOEs, coupling constants, chemical shifts) and therefore on the restraints developed from these experimental parameters measurements (distances, dihedral angles), which are used for the simulation calculations. One approach to handle this situation is to apply the restraints as time averages.[143, 144] This method was first utilized for NOE restraints and recently in the use of Equation (11).[145, 146] Rather than comparing the instantaneous value of the coupling constant (or distance) to the experimentally measured coupling constant (or NOE), the time-averaged value, averaged over a short time span, is utilized. The theoretical coupling constant can be calculated by using Equation (16), where the brackets denote an

$$J_{\text{theo}} = A\langle\cos^2\theta\rangle + B\langle\cos\theta\rangle + C \qquad (16)$$

average over a specific period of time, which is usually kept rather small (10–40 ps) so that sufficient periods can be run to allow for a better statistical evaluation of the data. The method has been shown to correctly reproduce molecular dynamics that were not observed with application of more traditional constant-time restraints. As an example for the application of time-dependent restraints, results from two simulations of a cyclic tripeptide, *cyclo*(L-Pro^1-L-Pro^2-D-Pro^3-), are given in Figure 31.

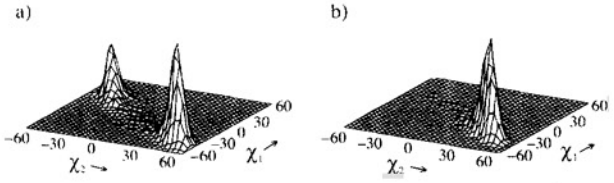

Fig. 31. Relative populations of the dihedral angles χ_1 and χ_2 of L-Pro^2 in *cyclo*(-L-Pro^1-L-Pro^2-D-Pro^3). a) Results from a 1 ns simulation, calculated with time-dependent restraints. After 400 ps both of the conformations are clearly observed with significant populations. b) Results from a 500 ps simulation with constant restraints, which produces only one of the conformations, and therefore fails to reproduce the experimental data.

We can conclude from the discrepancy of the vicinial coupling constants[147, 148] that Pro^1 and to some extent Pro^2 are undergoing fast dynamics which is in agreement with relaxation time measurements[149] and the results of an X-ray structure.[150] If the measured coupling constants are used as constant restraints then, for example, the ring of Pro^2 is drawn into one, single conformation which does not reproduce the experimentally obtained coupling constant. If the calculation is carried out with time-dependent restraints one finds two minima and excellent agreement with the measured J values. The results from these simulations are shown in Figure 31.

3.7. The Ensemble Method

Whenever an experimental measurement is carried out, the observable is an average, this can be considered a time-average over the length of the measurement or as an ensemble average, over a large (infinitely large) number of molecules. For example, the average distance from the ensemble of molecules must fulfill the experimental distance derived from NOEs.[151] Of course if the system is ergodic, the results—time-averaged and ensemble-averaged—must be the same. Recently, ensemble averaging of coupling constants has been incorporated into a refinement procedure to be used after distance geometry calculations.[22, 152] It is standard to repeat distance geometry calculations a large number of times, producing a larger number of structures. The ensemble approach then utilizes these structures to calculate an ensemble average. This ensemble average is then used to compare with the experimental values [Eq. (17)], where the sum is

$$J_{\text{theo}} = \frac{1}{N}\Sigma J_{\text{N}} \qquad (17)$$

run over the number of structures in the ensemble N. This theoretical coupling constant from Equation (17) is then utilized in the calculation of the error by using Equation (15). There can be a great variety of coupling constants, but if the average over the complete ensemble is fulfilled, the penalty function is zero and no forces are applied.

The consideration of dynamics or molecular motion is no more obvious than with the rotation about side chains. It is clear that for coupling constants involving side chains, that the observable is an average. Because of this the use of the side chain homonuclear coupling constants $^3J_{\text{H}^\alpha,\text{H}^\beta}$ for conformational information has often been limited to "extreme" couplings (i.e. $^3J_{\text{H}^\alpha,\text{H}^\beta}$ smaller than 4.0 Hz or larger than 10 Hz). However, with the measurement of numerous coupling constants about the side chain torsion and with the application of the restraint as an average, such information can be safely used in structure refinement calculations.

3.8. Assignments of the Signals of Diastereotopic Protons

The correct assignment of the signals of diastereotopic protons greatly increases the quality of structures simulated from distance restraint calculations, since the use of pseudoatoms or large modifications of the NOE-derived distances (to allow for both *pro-R* and *pro-S* protons) are not required.[153] The assignment of β-methylene protons of amino acids such as phenylalanine can be obtained from the homonuclear $^3J_{\text{H}^\alpha,\text{H}^\beta}$ along with the heteronuclear $^3J_{\text{C}',\text{H}^\beta}$ or $^3J_{\text{N},\text{H}^\beta}$. In the case of a large number of local NOEs, it is sometimes possible to make the assignments of the diastereotopic protons without the heteronuclear coupling constants, using only the homonuclear coupling constants.

One calculation procedure to facilitate the diastereotopic assignment is floating chiralities.[154–156] Floating chirality requires the removal of the energy term that is present in the force field which maintains the stereoposition of the two β-methylene protons. With this term removed, the protons can switch relative stereopositions (*pro-R* and *pro-S*) during the calculation. The adoption of the chirality is driven solely by the NOE restraints. This method originally illustrated in distance geometry calculations,[154] has been shown to work very well for proteins where the number of NOEs are often sufficient to obtain an unambiguous assignment. With peptides, there are usually not

enough NOEs to develop the diastereotopic assignment. We have recently examined the possibility of using both experimental parameters—NOEs and coupling constants—and allowing the chiralities to float. Application of this approach was successful for five out of six β-methylene groups of a substance P analog recently studied.[157] One cautionary note with the use of floating chiralities should be given. The method will produce an answer, no matter what the extent of the experimental restraints. For underdetermined systems there is a high probability of finding a local minimum. The number of restraints gives no insight into the confidence of the assignment. Also important is the nature of the restraints, a few restraints from different angles or orientations will be of more use than more NOEs from one direction. The method that we employ is a graphical representation of the NOEs to examine the confidence in the diastereotopic assignment.

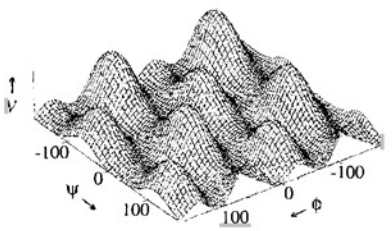
3.9. Conformational Restraints from Other Coupling Constants

Above we have concentrated on the application of vicinal coupling constants, which have been traditionally the most informative, and therefore, there is more data within the literature to develop conformational parameters. However, with the large number of proteins that have been isotopically enriched, the number of interesting couplings besides the three-bond couplings has greatly increased. It is therefore foreseeable that conformational information could be obtained from two-bond or even one-bond coupling constants. One example is the $^1J_{C,H}$ coupling constant in glycosides which varies by up to 10 Hz for the axial and equatorial protons, allowing for the determination of the anomeric configuration.[158, 159] For peptides and proteins, Egli and von Philipsborn reported many years ago that the one-bond coupling between the α-carbon and the α-proton, $^1J_{C^\alpha,H^\alpha}$, is dependent on both the ϕ and ψ backbone dihedral angles.[160] The relationship for an L-amino acid is given in Equation (18). The $^1J_{C^\alpha,H^\alpha}$ coupling constant is a function of

$$^1J = A + B\cos^2(\phi - 30^\circ) + C\cos^2(\psi - 30^\circ) \quad (18)$$

both of the backbone dihedral angles, ϕ and ψ, and can be used to develop a penalty-energy profile similar to that shown in Figure 30; however, now the dependence on two dihedral angles is illustrated (Fig. 32).

The coefficients A, B, and C for Equation 18 have been recently determined (136.4, 13.7, and -5.2, respectively), from a series of cyclic alanine-containing peptides. This expression was recently introduced into molecular dynamics program to add a conformational restraint to the ψ dihedral angle, and then use of the ^1J coupling to reduce the allowed ranges of the ψ dihedral has been shown to be useful in the examination of peptide conformation. From examination of a few proteins, a modified version of Equation (18) for the ^1J coupling has been proposed;[162] however, the conformational minima are very similar.



dral angles of a peptide backbone for a $^1J(C^\alpha,H^\alpha)$ coupling constant of 143.2 Hz. The penalty energy is calculated from Equations (15) and (18) with a force constant, K_J, of 1.0 kJ mol^{-1} Hz^{-2}.

Recent studies have illustrated some interesting correlations between conformation and coupling constants greater than ^3J. For example, the $^4J_{H^N(i),H^\alpha(i-1)}$ coupling constant is usually between -0.5 and 0.5 Hz and therefore would seem of little use. However, with a ψ dihedral angle of $+120^\circ$ and the ϕ of the next residue of $+60^\circ$, this coupling adopts values between -0.8 and -2.6 Hz.[163]

4. Conclusions

We have summarized the most important methods for the measurement of homo- and heteronuclear coupling constants for biomolecules in natural abundance, as well as for those systems isotopically enriched in ^{15}N and ^{13}C. In such a review article, all of the techniques which have appeared in the literature cannot be discussed, although we have attempted to give a more comprehensive listing in Tables 1–3. This should serve as a useful guide for the methods that have been developed and give the spectroscopist a place to begin in the literature. In addition, the use of coupling constants in computer simulations, many of which have recently been developed, has been highlighted. It is a matter of concern of this article to stress the necessity of the combined usage of distances *and* dihedral angles which is especially important when dealing with the structure of small molecules since dynamic phenomena have to be recognized and interpreted carefully.

Small molecules confront the scientist with the additional difficulty that the number of available NOEs is not sufficient for a reliable structure analysis. This is due to the fact that the ratio of surface to the inner core is much larger than in globular structures (e.g. proteins). Therefore, the structure calculations require the additional conformational information of coupling constants. The same situation, a small number of NOEs, is often observed for surface-exposed regions and active sites of many proteins. For the analysis of nucleic acids where the NOEs are often difficult to interpret, coupling constants can be very informative.

In closing, we would like to say a few words about the structure of molecules and their representation in the literature. Most methods employed today for structure analysis use MD calculations (at least to refine the results). The structure coordinates are averaged over the time profile of the simulation and presented in *one* figure. The averaging causes distorted distances and angles and therefore the structure is usually partially energy minimized. As all molecules are flexible and undergoing dynamics such a representation is not 100% accurate (i.e. it does not represent the "real" conformation). This fact must always be kept in mind when dealing with structures derived from NMR data (or any experimental data).

It is usual to begin with the simple assumption that the molecule adopts a single conformation. When all of the experimental data is reproduced by the results from the structure calculations,

this presents one and only one possible model of the conformation. The number and quality of the experimental data and the force field determine if further solutions exist (keywords: local minimum and under-determined structure). If the experimental parameters do not confirm the experiment—even if the trivial case of falsely classified or quantitatively wrong values (which in practice requires very careful scrutiny) is excluded internal dynamics must be taken into consideration. For this, extensive MD calculations, in addition to time-dependent or ensemble methods for application of experimental restraints, are suitable.

We would like to thank the Deutsche Forschungsgemeinschaft and the Fonds des Chemischen Industrie for the many years of support. Over the years, a large number of coworkers have produced significant contributions for the determination of coupling constants and their evaluation, of which only a few can be mentioned: U. Anders, J. Balbach, W. Bermel, S. Golic Grdadolnik, C. Griesinger, T. Huber, H. Oschkinat, P. Schmieder, and S. Seip. Numerous insights came from cooperation and discussion with colleagues of which three deserve special mention: R. R. Ernst (ETH, Zurich), R. Freeman (Oxford), and W. F. van Gunsteren (ETH, Zurich). We want to thank: S. Golic Grdadolnik (Figs. 29, 32), P. Schmieder (Figs. 16, 18), and T. Huber (Fig. 31) for supplying figures. Finally we want to thank M. Bachelin for his careful proof reading as well as helpful remarks.

Thermotropic Liquid Crystals Formed by Intermolecular Hydrogen Bonding Interactions

Constantinos M. Paleos* and Dimitris Tsiourvas

The role of hydrogen bonding in the formation or stabilization of liquid crystalline phases has only recently been appreciated. Following the first, well-established examples of liquid crystal formation from the dimerization of aromatic carboxylic acids, through hydrogen bonding, several classes of compounds have recently been synthesized, the liquid crystalline behavior of which is also dependent on intermolecular hydrogen bonds between similar or dissimilar molecules. In this review the main classes of compounds exhibiting liquid crystallinity due to hydrogen bonding are presented to show the diversity of organic compounds that can be used as building elements in liquid crystals. The molecules are either of the rigid-rod anisotropic or amphiphilic types such as molecules appropriately functionalized with pyridyl and carboxyl groups, whose interaction leads to the formation of liquid crystals; amphiphilic carbohydrates and amphiphilic and bolaamphiphilic compounds with multiple hydroxyl groups whose dimerization or association is indispensable for the formation of liquid crystals; and certain amphiphilic carboxylic acids with monomeric or polymeric mesogens and amphiphilic-type compounds bearing different moieties, whose interaction may lead to the formation of mesomorphic compounds. Associated with the macroscopic display of liquid crystalline phases is the supramolecular structure, and therefore rather extended discussion of these structures are included in this review.

Keywords: hydrogen bonds · liquid crystals · supramolecular chemistry

1. Introduction

Intermolecular hydrogen bonds have been considered of crucial importance in inducing aggregation in nature. The most well-known example of hydrogen bonding in the biological world is the interaction of complementary nucleobases stabilizing the double helical structure of nucleic acids. However, in liquid crystals, whose formation is attributed to intermolecular interactions, the role of hydrogen bonding has not been greatly appreciated, in particular during the early years of research in this area, and only a limited number of publications and reviews[1–6] deal with the subject. This development is probably related to the fact that simple compounds such as phenols and amines, which form hydrogen bonds, are not generally mesomorphic. The investigation of the synthesis and characterization of hydrogen-bonded liquid crystals was thus somewhat delayed.

The first compounds found to exhibit liquid crystalline behavior due to hydrogen bond formation were carboxylic acids.[1–2] These compounds dimerize through intermolecular hydrogen bonds leading to a lengthening of the rigid-rod moiety, which in turn induces liquid crystallinity. Among the carboxylic acids that form liquid crystalline phases are *trans-p*-methoxy- and *trans-p*-ethoxycinnamic acids[1, 7] and their higher alkoxy derivatives,[8] as well as *p-n*-alkoxybenzoic acids.[1, 9] Aliphatic carboxylic acids do not generally exhibit mesomorphic character. However 2,4-nonadienoic acid is liquid crystalline[10] due to the presence of the double bonds, which because of their polarizabilities increase the intermolecular attraction between the molecules. Another interesting case of liquid crystallinity exhibited by an aliphatic carboxylic acid is that of 2-hydroxy-1,2,3-nonadecanetricarboxylic acid reported in 1919.[11] The segregation of the aliphatic lipophilic moiety from the hydrophilic carboxyl groups and the hydroxyl group, coupled with their ability to form multiple hydrogen bonds, explains the liquid crystalline behavior. This is in line with the now-accepted views on the formation of liquid crystals from analogous compounds, as will be discussed further below.

The two components of the acceptor–donor complex may or may not be mesomorphic. In both cases, however, and primarily for nonmesomorphic molecules, hydrogen bonding is responsible for the formation of liquid crystalline phases. As will be examined further below, this mode of liquid crystal formation can be extended to polymers with structures modified by hydrogen bonds.

Hydrogen bonding has also been employed for the formation of liquid crystals derived from amphiphilic mesogens[6] consisting of two distinct and segregated segments, one hydrophobic

and one hydrophilic. Here, the hydrophilic moiety is a group that can form one or more hydrogen bonds leading to the formation of thermotropic liquid crystals (in analogy to ionic or nonionic amphiphiles). As with typical amphiphiles, in hydrogen-bonded amphiphiles segregation occurs between the polar groups primarily hydroxyl or carboxyl groups—and the lipophilic segments. This is the driving force for the formation of lamellar or discotic structures. Among the classes of compounds that have been found to form thermotropic liquid crystals and molecular organizates in solution are certain carbohydrate amphiphiles, some polyhydroxy compounds, and long-chain alkyl derivatives of iminodiacetic acid. In addition, a novel class of amphiphilic liquid crystalline materials now under development is prepared by molecular recognition, through the formation of multiple hydrogen bonds between amphiphiles bearing complementary groups. From this introductory discussion it is apparent that hydrogen bonding either extends the rigid-rod structure of the mesogens resulting in stabilization of the liquid crystalline phases, or it positively affects the segregation of the polar and the lipophilic groups inducing the formation of liquid crystals.

2. Liquid Crystalline Behavior of Anisotropic, Hydrogen-Bonded, Rigid-Rod Molecules

2.1. Hydrogen-Bonded Liquid Crystals from Monomeric Mesogens

Hydrogen-bonded systems composed of different components, for example molecules bearing pyridyl or bipyridyl moieties and carboxylic acid molecules, have been used to prepare new liquid crystals or stabilize already existing liquid crystalline materials. This type of interaction is shown schematically in Figure 1 and can be described in the terminology of structural chemistry as a molecular self-complementary system.[12]

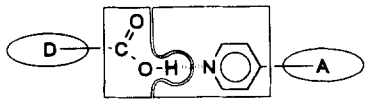

Fig. 1. Schematic representation of the interaction of pyridyl and carboxyl groups (from ref. [12]).

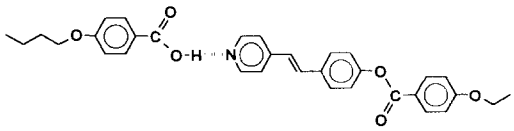
Liquid crystalline complex **1** was formed by the intermolecular interaction of 4-butoxybenzoic acid (nematic range 147–160 °C) with *trans*-4-[(4-ethoxybenzoyl)oxy]-4′-stilbazole (nematic range 165–213 °C).[13] Complex **1** exhibits a smectic phase as evidenced by its focal conic texture (range



1

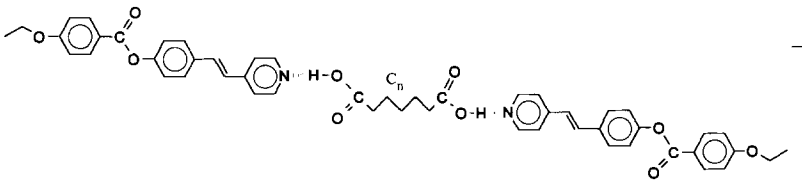
136–160 °C), which was not exhibited by either of the individual components. However, this transition was not apparent in DSC studies, and the observed smectic texture has not not been characterized. The subsequent nematic phase appeared in the region 160–238 °C. The stabilization of the mesophase of the 1:1 complex **1** was attributed to the formation of a new and elongated mesogen through intermolecular hydrogen bonding which allows **1** to behave as a one-component, liquid crystalline compound. The formation of the complex was supported by FTIR measurements, which show that the spectrum of the 4-butoxy benzoic acid dimer was replaced by that of complex **1**. The primarily adopted method for the preparation of complex **1** and analogous liquid crystalline compounds is the slow evapo-

Constantinos M. Paleos was born in 1941 in Chios, Greece, and studied chemistry from 1960 to 1964 at the Universities of Salonica and Athens, where he obtained his undergraduate degree in chemistry. He received his Ph.D. at Drexel University in Philadelphia, USA, under the supervision of Dr. M. M. Labes for studies on reactivity in liquid crystalline media. In 1973, after three years with Standard Oil (Illinois) and Motor Oil (Athens), he joined the Institute of Physical Chemistry at the National Center for Scientific Research "Demokritos" in Athens, where he has been Director since 1994. From 1991 to 1992 he was visiting professor at the University of Strasbourg. His main research interests include the formation and characterization of novel liquid crystals resulting from molecular recognition of complementary molecules, and the development of organized molecular assemblies such as micelles, vesicles, and liquid crystals.

Dimitris Tsiourvas was born in 1962 in Larisa, Greece, and completed his undergraduate studies in chemical engineering at the National Technical University of Athens. He obtained his Ph.D. at "Demokritos" in 1992 under the direction of Dr. C. M. Paleos for research on liquid crystals formed from polymeric mesogens. He is currently employed by the Research and Development Department of ARGO SA and collaborates with the Institute of Physical Chemistry at Demokritos. His research focuses on the synthetic and physicochemical aspects of supramolecular organization and molecular recognition.

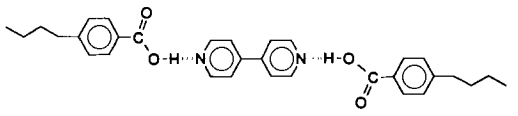
ration of an equimolar solution of the components in pyridine. In this way the hydrogen bonds of 4-butoxybenzoic acid dimer were broken.

In similar fashion mesogens **2** were formed by hydrogen bond formation between a nonmesogenic dicarboxylic acid with $n = 5-9$ and mesogenic *trans*-4-[(ethoxybenzoyl)oxy]-4′-stilbazole.[14] These compounds form twin-type liquid crystalline complexes[14] and exhibit both smectic and nematic phases. These complexes display an effect dependent on the number of C atoms (odd–even effect) similar to that reported for twin-type liquid crystals formed through covalent bonding between a mesogen and a flexible spacer.[15]

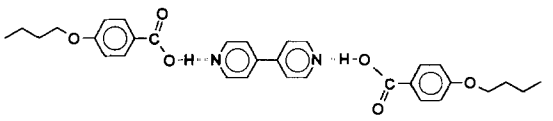


2

Liquid crystalline complexes were formed by treating 4-alkoxybenzoic acids ($n = 1-8$, 10) or alkylbenzoic acids ($n = 4$, 5, 8) with 4,4′-bipyridine[16] or *trans*-1,2-bis(4-pyridyl)ethylene.[16, 17] For instance, liquid crystals **3** and **4** formed by hydrogen bond formation between 4,4′-bipyridine and 4-butyl- or 4-butoxybenzoic acid in a molar ratio of 1:2. Sharp phase transitions and homogeneous mesophases were observed. Complex **3** exhibits only a smectic phase that it is not observed for either single component, while complex **4** shows both smectic and nematic phases.



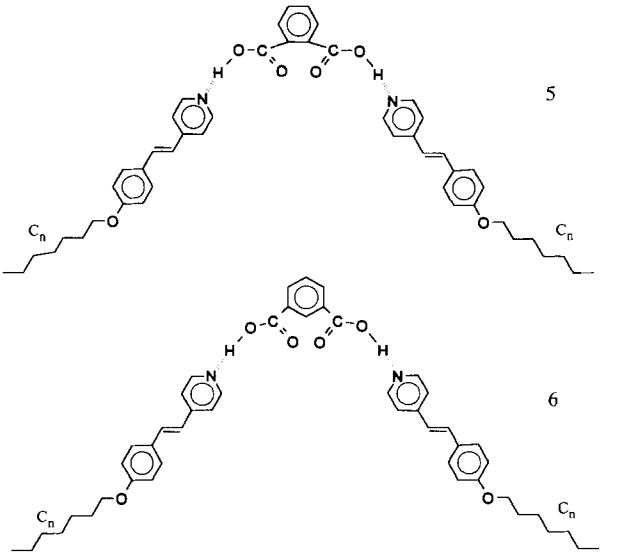
3



4

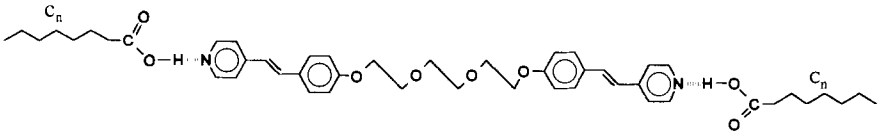
The interaction of phthalic or isophthalic acid with *trans*-4-alkoxy-4′-stilbazole ($n = 7$, 8, and 10) led to complexes **5** and **6** with bent structures.[12] The complexes exhibit liquid crystalline behavior even though they are not linear and the mesogenic groups form an angle. It is interesting to note that compounds consisting of covalently bonded, nonlinear structural units do not generally exhibit liquid crystallinity.[12]

In analogous fashion, the interaction of two stilbazole units linked by a triethyleneglycol spacer, in other words a nonmesogenic compound, with fatty and aromatic acids yielded liquid crystalline compounds **7** and **8**, respectively.[18] Monotropic smectic B phases were observed for complexes with carboxylic

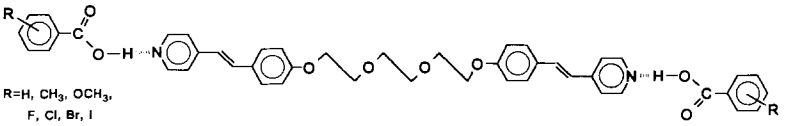


5

6



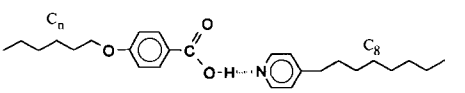
7



8

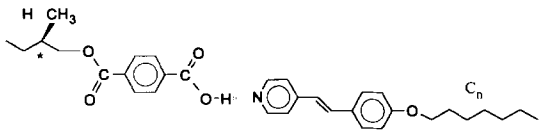
acids ranging from nonanoic up to tetradecanoic acids. Enantiomeric nematic and in some cases monotropic smectic A phases were obtained with 4-methyl-, 4-methoxy-, and 4-halobenzoic acids as donors. The stability of the induced mesophases decreased with 3- and 2-substituted benzoic acids, and with aliphatic dicarboxylic acid donors liquid crystalline phases were not observed.

Liquid crystals of the general formula **9** with a mesomorphic range near room temperature formed by complex formation between 4-alkoxybenzoic acids ($n = 6-8$, 10, 12) and 4-octyl pyridine. Thus, the simple hydrogen-bonded complex that results from two nonmesogenic aromatic compounds is sufficient to induce a nematic phase below 50 °C. Nematic phases are broadened by mixing several 1:1 complexes within this homologous series.



9

Ferroelectric liquid crystals like **10** have also been prepared by hydrogen bond formation between the mono-2(methylbutyl)



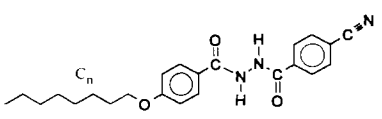
10

ester of terephthalic acid and 4-alkoxy-4'-stilbazoles with a smectic B phase ($n = 1-10$, 12, 14, 16).[20] Depending upon the chain length of the components in the complexes, blue phases, chiral nematic (N*) phases, and chiral smectic C (S_c^*) phases were obtained.

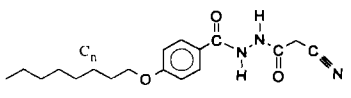
In analogous experiments Kresse et al.[21] investigated liquid crystalline materials obtained from selected monocarboxylic or dicarboxylic acids and alkylpyridine derivatives or bipyridine. One of the conclusions of this study is that the length of the pyridine component is important for inducing stability in the liquid crystalline phase of the complex, at least at the low temperatures at which the (pyridine)N $\cdots$ H–O bond is not broken.

It is therefore apparent that by simply mixing compounds functionalized by carboxyl and pyridyl groups in the bulk or in solution a wealth of liquid crystalline materials are formed with broad mesomorphic ranges. These complexes have been investigated mainly by thermal, optical, and FTIR spectroscopic studies.[22]

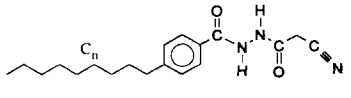
Early examples of complexes not bearing a central pyridyl–carboxyl unit that self-organize through multiple hydrogen bonds are the diacylhydrazines **11** ($n = 5-7$), **12** ($n = 5-9$), and **13** ($n = 6-9$), which were synthesized by Schubert et al.[23a] These compounds exhibit relatively broad smectic liquid crystalline phases. Models of their supramolecular structures were not presented by the authors. Another class of compounds, the chiral carbonylbis(amino acid esters),[23b] which bear a urea moiety, was investigated as early as 1973 and found to exhibit smectic mesophases. It was suggested that formation of hydrogen bonds between the urea moieties would yield supramolecular structures of parallel molecular layers, thus explaining the appearance of smectic liquid crystalline phases. These mesogens and analogous compounds resulting from the simple functionalization of urea warrant further investigation for the development of new hydrogen-bonded liquid crystals.



11

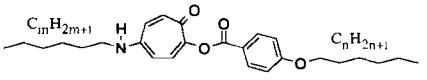


12

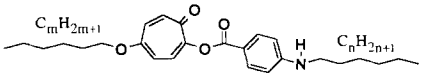


13

The previously mentioned mesogenic diacylhydrazines are not the only examples of compounds that self-assemble through hydrogen bond formation and exhibit liquid crystalline properties. It has been reported[24] that hydrogen bonding enhances the possibility of the exhibition of smectic C phase in troponoid-based liquid crystals **14** ($m = 6$, 8, 11, 12, 14, 18 and $n = 1$, 4, 12) and **15** ($m = 12$, 14, 18 and $n = 8$, 10, 12, 18). Considering intermolecular hydrogen bonding, two arrangements may be envisaged for these compounds in the liquid crystalline phase: the folded and extended structures shown in Figure 2. The extended structure explains the appearance of the smectic C phase, since the molecules are tilted with respect to the layer plane. It should be noted that only molecules with long alkyl chains exhibit the smectic C phase; those with short chains are nonmesomorphic, since hydrogen bonding raises the melting point above the mesophase–isotropic transition.



14



15

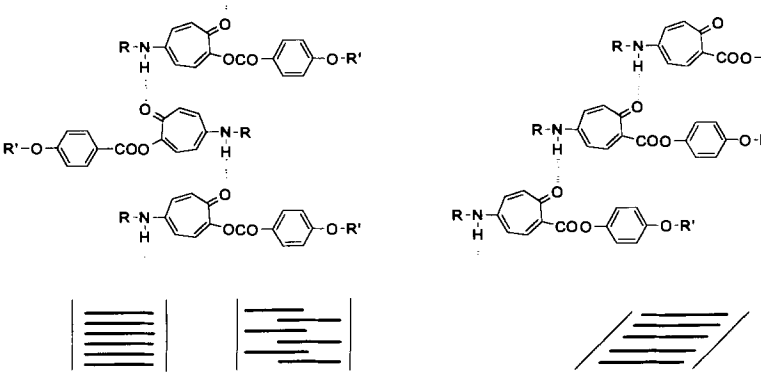


Fig. 2. Molecular arrangements for compound **14**: folded (left) and extended structure (right) (from ref. [24]).

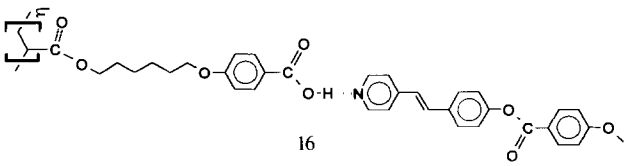
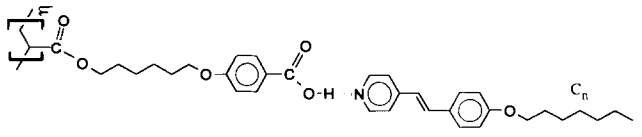
2.2. Hydrogen-Bonded Liquid Crystals Formed from Polymeric Mesogens

Liquid crystalline phases in polymers can be stabilized or induced by interaction of carboxyl and pyridyl moieties. Liquid crystalline polymers bearing a carboxyl in the side chain were mixed with 4-*trans*-stilbazole derivatives bearing a pyridyl group, and the effect on their mesomorphic properties was investigated. In this way polymer **16** was formed by the interaction



16



17

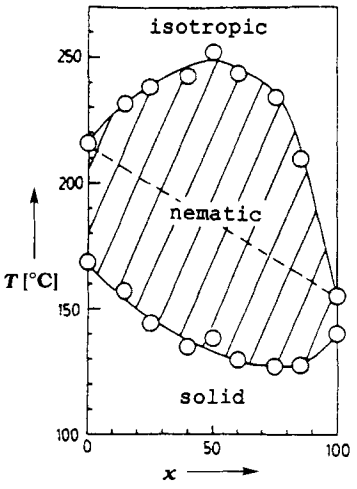


Fig. 3. Phase diagram of the binary mixture of the components forming polymer **16**, i.e. a poly(acrylic acid) and a *trans*-stilbazole ester derivative (from ref. [25]). x = mole ratio.

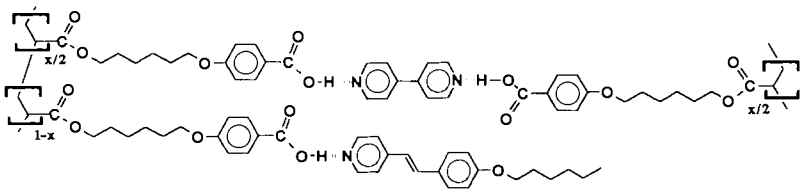
of a poly(acrylic acid) derivative with a *trans*-stilbazole ester.[25] Both components exhibit mesomorphic behavior: the polymer has a mesomorphic range between 140 and 155 °C and *trans*-stilbazole derivative between 168 and 216 °C. These two components are miscible over the whole range of composition, and the binary mixture exhibits a broad mesomorphic range (Fig. 3). This extension of the temperature range of liquid crystallinity again results from the formation of an extended mesogenic unit through hydrogen bond formation. Furthermore, a similar polymer was complexed with various *trans*-4-alkoxy-4′-stilbazoles having a linear alkyl chain spacer ($\eta = 1-8$ and 10) to afford compounds **17**.[26] Thermally stable smectic A phases were formed, and the isotropization and melting temperatures depend on the number of carbon atoms in the terminal alkoxy group (odd–even effect). Analogous monomeric 1:1 complexes were also prepared which, as expected, show lower transition temperatures than the polymeric complexes.

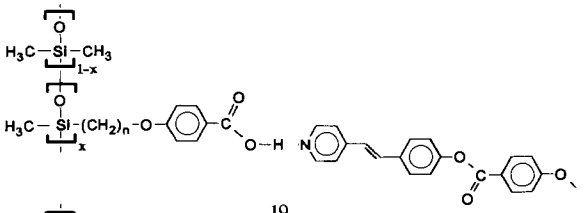
Combining the same poly(acrylic acid) derivative with the bifunctional hydrogen bond acceptor 4,4′-bipyridine and also with the monofunctional acceptor *trans*-4-hexyloxy-4′-stilbazole yielded the cross-linked polymer **18** in which two polymer



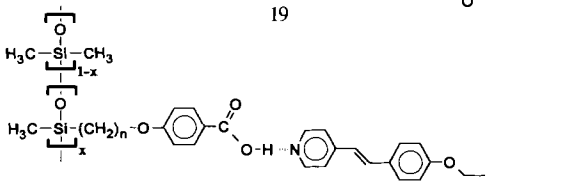
18

chains are bound.[27] As the proportion of the bifunctional acceptor increased, the glass transition also increases and the melting temperature decreases. The 1:1 complexes show mesomorphic character for the whole composition range of hydrogen bond acceptors. The isotropization temperature is roughly 200 °C for all these complexes. Reversible (noncovalent) cross-linking is assumed, since the smectic–isotropic transitions are reversible. On heating to the isotropic phase, some of the hydrogen bonds between the carboxyl group and the bipyridyl group are broken. On cooling from the isotropic melt, some of the hydrogen bonds are reformed, affording the smectic phase again. It should be noted that for covalently bonded and highly cross-linked polymers, molecular orientations are preserved in the solid phase and mesomorphic character is not observed.[26]

Similarly, polysiloxanes, specifically poly(methylsiloxanes) and poly(methyl-*co*-dimethylsiloxanes) with a benzoic acid moiety in their side chain, which themselves exhibit liquid crystalline properties due to dimerization, form hydrogen bonds with the mesogenic *trans*-4-[(4-methoxybenzoyl)oxy]-4′-stilbazole and the nonmesogenic *trans*-4-ethoxy-4′-stilbazole, affording polymers **19** and **20**, respectively, with $x = 5, 8, 10$.[28] Stilbazoles are



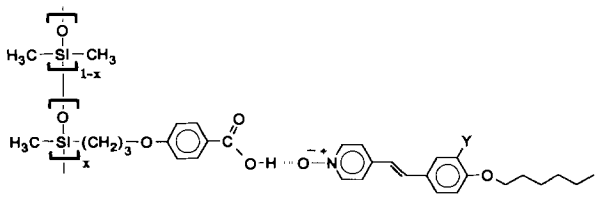
19



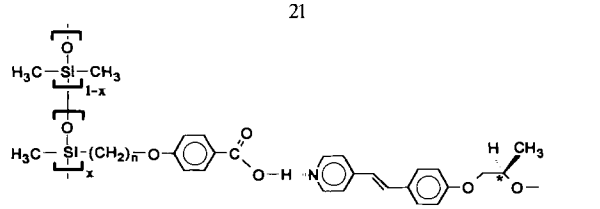
20

used so frequently as hydrogen bond acceptors because of the high enthalpy value for the formation of complexes between carboxyl and pyridine groups.[29] In this case it has also been established that formation of a liquid crystalline complex of a side-chain polymer does not require that either of the hydrogen bonding components exhibit liquid crystallinity. In addition, these polymers are completely miscible over the whole composition range and the liquid crystalline phase has excellent thermal stability. X-ray diffraction studies on nonoriented samples show smectic C or A phases for the various hydrogen-bonded complexes.

Polymers with potential practical applications were prepared by combining polymeric donors with acceptors bearing appropriate functionalities. Thus polysiloxane donors bearing a pendant propyloxybenzoic acid group were mixed with stilbazole-*N*-oxide as an acceptor leading to the formation of the polymers **21** (**21a**: $x = 1.00$, Y = H; **21b**: $x = 1.00$, Y = F; **21c**: $x = 0.43$, Y = H; **21d**: $x = 0.43$, Y = F).[30] These polymers exhibit



21

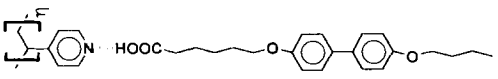


22

smectic A or smectic C phases above their glass-transition temperature, and since none of the components of the complexes exhibit liquid crystalline behavior, the observed phases reflect the formation of mesogenic moieties by hydrogen bonding. The strong dipole along the molecular axis is expected to result in liquid crystalline materials with strong positive dielectric anisotropy, which is a prerequisite for certain electrooptic applications.

In studies of analogous polysiloxanes ferroelectricity was induced when polysiloxanes bearing a pendant *p*-alkoxybenzoic acid group were complexed with the optically active (*S*)-(−)-*trans*-4-(2-methoxypropyloxy)-4′-stilbazole forming polymers **22** ($n = 5$, $x = 0.29$; $n = 5$, $x = 0.43$; $n = 8$, $x = 0.29$; $n = 8$, $x = 0.43$).[31] X-ray diffraction data of annealed unoriented samples showed an intense ring, sometimes accompanied by its second-order reflection which, together with the spontaneous polarization of the polymers, point to the formation of a smectic C phase composed of two overlapping hydrogen-bonded moieties. In **22** the $S_A \rightarrow S_C$ phase transition was proved by optical microscopy but not by DSC measurements.

In a recent study the interaction of 4-polyvinylpyridine with a mesogenic biphenyl derivative bearing a carboxyl group at one end gave polymer **23**. The monotropic liquid crystalline phase

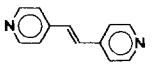


23

observed for the mesogenic compound alone disappears on mixing, and the mesophases of the resulting complexes are dependent on the ratio of interacting components and exhibited thermal stability.[32]

A reaction analogous to polycondensation may occur when dicarboxylic acid **24a** is mixed with bipyridines **24b–d**, which contain two pyridyl groups. All three complexes form enantiotropic nematic mesophases, while their starting components do not have liquid crystalline properties.[33] In complexes **24a**/**24b** and **24a**/**24d** the nematic–isotropic transition exhibits only a small hysteresis, while this is quite large, about 25 °C, for complex **24a**/**24c**. In addition polymer **24a**/**24b** exhibits smectic A phase, as evidenced by the focal conic fan-type texture in polarized light microscopy.

24a



24b

24c

24d

To conclude the discussion on monomeric and polymeric liquid crystals resulting from the interaction of pyridyl and carboxyl groups, we will briefly describe a model of these systems.[34] The mesogen complexes are termed "living systems", since their bonding properties are determined by subtle interactions. Because of the weak hydrogen bonding interactions the complexes form, separate, and recombine at the melt temperature. In the models presented for a "living" low molecular weight nematic and a "living" liquid crystalline polymer, nematic effects induce hydrogen bonding between the components, resulting in discontinuous jumps in concentration variables at the nematic–isotropic transition.

3. Hydrogen-Bonded Liquid Crystalline Compounds Derived from Amphiphilic Mesogens

3.1. Liquid Crystalline Behavior of Amphiphilic Carbohydrates

The structural versatility of carbohydrate moieties provides the basis for the synthesis of a great variety of amphiphilic carbohydrates. The first example of an amphiphilic liquid crystalline carbohydrate was a β-hexadecyl-D-glucoside prepared by E. Fischer et al.[35] more than eighty years ago. This compound showed an "anomalous" melting behavior which could not be explained at the time. Two years later Salway[36] synthesized ceryl-β-D-glucopyranosides which had similar melting behavior. No mention was made of liquid crystallinity at that time; it was thought that two modifications had been obtained. The subject of carbohydrate liquid crystals was neglected for many years. In one paper, which appeared in 1938, Noller et al.[37] interpreted the "double melting" of the amphiphilic glucoside prepared by Fischer as resulting from liquid crystalline behavior. Extensive synthetic work on alkyl carbohydrates, including amphiphilic derivatives, was performed by Hori[38] in the late 1950s. Research on liquid crystalline carbohydrates intensified in the 1980s, and interest in this area continues to increase. The subject has been reviewed by Jeffrey et al.[39, 40] and van Doren et al.[41]

Carbohydrate liquid crystals are formed by the functionalization of carbohydrate moieties with one or more long aliphatic chains. Considering the wealth of carbohydrate moieties and the nature and number of aliphatic chains, it is not surprising that numerous, diverse liquid crystals have already been synthesized.[42–61] We do not intend to describe the mesomorphic properties of the known carbohydrate liquid crystals in detail; rather we will focus on supramolecular models that rationalize the macroscopic appearance of liquid crystalline phases.

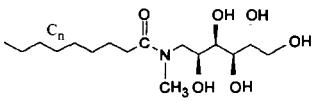
From a survey of the literature it can be seen that carbohydrate amphiphiles with one lipophilic chain form smectic phases, while carbohydrates with more than one lipophilic chain typically form columnar mesophases based on the formation of hydrogen-bonded multimers.

3.1.1. Smectic Phases Resulting from Amphiphilic Carbohydrates

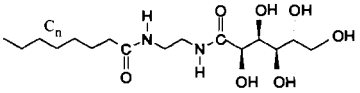
The *n*-alkyl-β-D-glucopyranosides reported by Goodby[42] exhibit smectic A liquid crystalline phases. A bilayer structure was postulated in which the carbohydrate moieties overlap each

other and are held together in the middle through extensive hydrogen bonding, while the alkyl chains are located in the exterior of the supramolecular structure. At about the same time Marcus and Finn[43] performed miscibility experiments for identifying the phases of *n*-decyl-β-glucopyranoside. They found that its smectic phase is thermodynamically identical to the lyotropic lamellar phase exhibited by a 20% solution of sodium bis-2-ethylhexylsulfosuccinate (Aerosol OT). In analogous manner it was found[44] that liquid crystalline phases of *n*-alkylgluconamides are miscible with those of *n*-alkyl-β-D-glucopyranosides, forming phases classified as smectic A (S_A) and tentatively as smectic A_d (S_{Ad}), in which an interdigitated bilayer structure is formed. The *d*-spacing in these phases should be equal to twice the length of the aliphatic chain plus the length of the carbohydrate moiety. It should be pointed out that in the smectic phase the molecules are in a dynamic state; the lipophilic chains are relatively flexible and the hydrogen bonds in the polar cores often break and reform as the molecules undergo reorientational motion. In the same period, however, Baeyens-Volant et al.[45] proposed a monolayer smectic phase based on the determination of the length of the *d*-spacing.

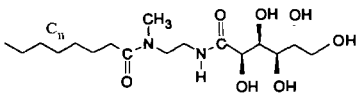
Smectic phases were also reported for the amphiphilic derivatives of 1-*O*-alkyl derivatives of 2,5-anhydrohexitols,[46] some of which are liquid crystals even at room temperature. Also, for a variety of acyclic carbohydrates, for example 1-deoxy-1-(*N*-methylalkanamido)-D-glucitols **25** ($n = 5-11$) and the closely related series of *N*-(2-(alkanamido)ethyl)-D-gluconamides **26** ($n = 5, 7, 9$) and *N*-(2-(*N*-methylalkanamido)ethyl)-D-gluconamides **27** ($n = 5, 7, 9$), it was shown[47] that they exhibit smectic A_d phases due to the interdigitated bilayer ordering of the supramolecular structures. It should also be mentioned that smectic A mesophases were observed for 1-*O*-alkyl-D-glucitols[48] originating from alkyl D-glucopyranosides and for carbohydrates incorporating calamitic mesogens.[49] For the latter compounds the introduction of the calamitic mesogenic units greatly increases the potential number of carbohydrate liquid crystalline phases and allows greater control of the thermal properties. In addition, several α- and β-glucosides were prepared,[50] and the liquid crystalline properties of mono-, di-, and trisaccharides were compared. Smectic A phases were obtained in all cases.



25

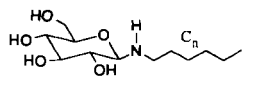


26

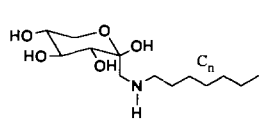


27

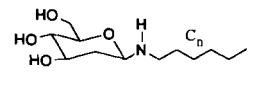
In a comparative paper[41] the liquid crystalline behavior of six homologous series of D-glucose and 2-deoxy-D-glucose derivatives with an amino-linked alkyl chain was investigated. All these compounds with diverse structures, **28**–**33** ($n = 7-16$), exhibit smectic A_d phases (i.e. partially overlapping structures). In all cases the *d*-spacing corresponds to $l < d < 2l$, where l is the length of the fully extended molecule and d is the calculated layer thickness.



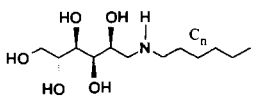
28



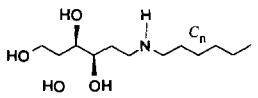
29



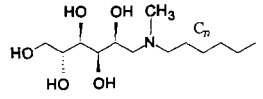
30



31



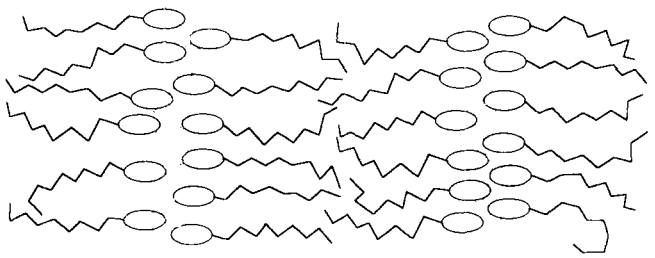
32



33

A_d phases are well-established for amphiphilic carbohydrates with one aliphatic chain. However, the originally proposed model for the arrangement of molecules within the layers (Model I in Fig. 4)[40, 51] has been questioned. In this model the car-

Model I



Model II

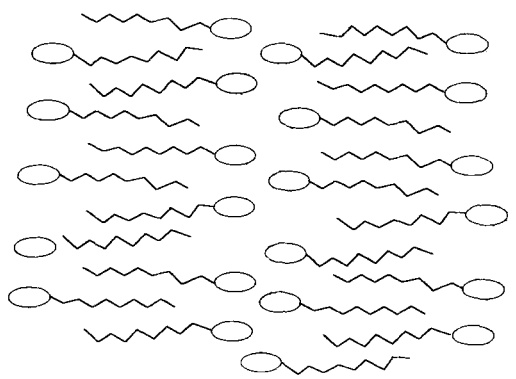


Fig. 4. Models I and II for carbohydrate mesogens.

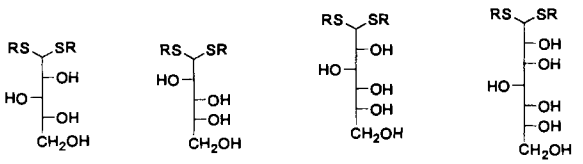
bohydrate moieties constitute the core held together in a dynamic hydrogen bonding network, and the aliphatic chains are in the exterior of the supramolecular structure. A new model, Model II (Fig. 4), was proposed by Jeffrey[52] and further supported by van Doren and Wingert.[51] Contrary to Model I, the alkyl chains constitute the core of the smectic bilayer and the carbohydrate moieties are located on the outside. This latter model is identical, with the exception of the exclusion of water, with the lamellar lyotropic phase (L_α) and consistent with experimental data. It also explains the thermal behavior and the influence of minor structural changes in the carbohydrate moiety.[40,41] Model II corresponds to the view that carbohydrate moieties are more sensitive to the increase of thermal energy than are van der Waals forces between interdigitating alkyl chains.[40]

3.1.2. Discotic Columnar Phases from Amphiphilic Carbohydrates

Dithioacetals having two aliphatic chains were investigated[53–55] almost simultaneously by three research groups. In these studies a smectic A_d[53] and a smectic B[54] phase were identified initially. Shortly thereafter a hexagonal columnar structure[56] was assigned to these Y-shaped molecules based on X-ray diffraction data showing three sharp peaks.[56] Dithioacetals with two chains R **34**–**37** (R = C_8 unit for **34**, **35**, **37** and R = C_7–C_9 unit for **36**), although different in stereochemistry,



34 35 36 37

form only one type of hydrogen-bonded disk-shaped structure through multimer formation. The supramolecular structure in Figure 5, which may rationalize these findings, was proposed by Jeffrey and Wingert.[40] The terminal hydroxyl group is essential for the formation of the columnar hexagonal mesophase, since the 6-deoxy carbohydrate dithioacetals were shown not to be mesomorphic.[56]

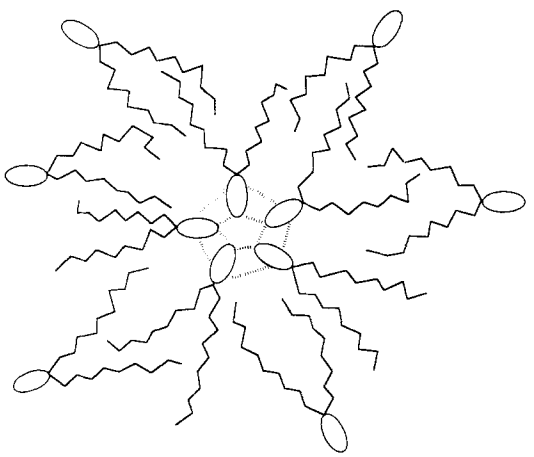


Fig. 5. Schematic representation of the molecular arrangement for the formation of a hexagonal columnar mesophase.

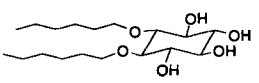
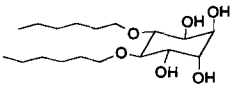
Similarly, 6,6-dialkyl-D-galactopyranoses with two alkyl chains also form columnar supramolecular structures due to the formation of multimers held together by hydrogen bonds. The miscibility of 6,6-di-*C*-*n*-octyl-α/β-D-galactopyranose with *S*,*S*-dioctyl-D-*arabino*-dithioacetal, which has a hexagonal-columnar structure,[57] verifies the formation of columnar phases.

Inositol(1,2,3,4,5,6-hexahydroxycyclohexane) mono-, di-, tri-, tetra-, and pentaethers allow detailed studies to be performed on the relationship between the type of substitution in the cyclohexane ring and the liquid crystalline character. The type of mesomorphism formed depends on the number and stereochemical arrangement of the hydroxyl groups, the length of alkyloxy chains, and also on their positions on the six-membered ring. Among the most important findings on the liquid crystalline behavior of inositol ethers[58] are that axial groups in these compounds weaken the mesophase since molecular symmetry does not favor the formation of mesophases, and that the transformation from hexagonal columnar to the smectic phase shown for compounds **38** and **39** is due to the stereochemical effect of two vicinal hydroxyl groups.



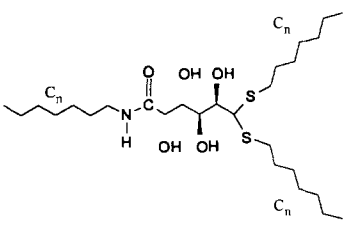
38

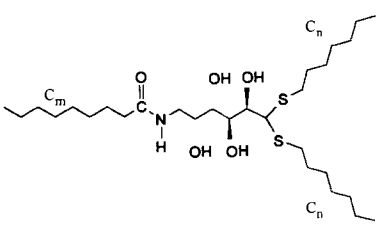


39

Further detailed studies were performed on a homologous series of cellobiose octaalkanoates[59] with alkyl chain lengths C_n ranging from $n = 7$ to $n = 14$. All the compounds form enantiotropic discotic columnar phases in which the columns are formed by the regular stacking of the cellobiose moieties in a two-dimensional lattice. The types of phases formed depend on the homologue and on the temperature. Thus homologues with $n = 9$–14 form hexagonal ordered columnar (D_{ho}) phases, whereas the member with $n = 7$ forms a rectangular ordered columnar (D_{ro}) phase. The carbohydrate with $n = 8$ forms the D_{ho} phase at higher temperatures and the D_{ro} phase at lower temperatures.

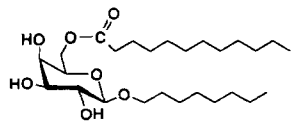
Besides the intensively investigated substituted dithioacetal carbohydrates,[53–56] several new related compounds[60] were prepared (**40**: $n = 8$; **41**: $n = 12$; **42**, $n = 12$, $m = 15$). Carbohydrates **40** and **41** exhibit enantiomeric hexagonal columnar disordered phases, as identified by polarization microscopy and X-ray diffraction. Compound **42** forms monotropic phases, the first of which has been identified as a hexagonal columnar dis-



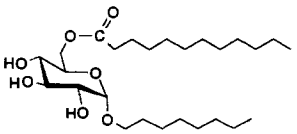


ordered (D_{hd}) phase at 91 °C, while the second as a rectangular columnar disordered (D_{rd}) phase at 70 °C. The columnar phases observed for these acyclic trialkylated compounds are surprising and in contrast to the previously mentioned dialkylated derivatives which form hexagonal columnar phases; in the former, multimers cannot form. It is suggested that the columns of **40** and **41** are constructed from single molecules stacked without preferred orientation. This arrangement is supported by strong hydrogen bording interactions and by the segregation of the hydrophilic and lipophilic moieties.

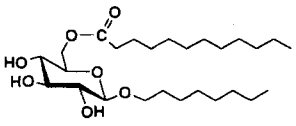
The synthesis of alkyl-6-*O*-acyl-glycopyranosides **43**–**46** by a chemoenzymatic procedure led to the development of new supramolecular model[61] for the observed liquid crystalline properties. The β-glycosides **43** and **44** form columnar discotic mesophases with clearing points above 80 °C, while the α-glycosides **45** and **46**, which presumably form discotic phases, show



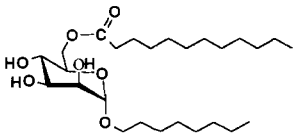
43



45



44



46

clearing points below 20 °C. Detailed textures have not been assigned for these two latter compounds. The proposed model shown in Figure 6 indicates that the driving force for the formation of these mesophases is the tendency of the hydrophilic and lipophilic moieties to segregate. In this way the surface between these stacked units constitutes a cylindrical jacket. Along this bent plane the amphiphilic carbohydrates can move in two dimensions and rotate along the longitudinal axis. Since carbohydrates **43** and **44** have equatorial-bound aglycons, the alkyl groups enclose a smaller angle than that in carbohydrates **45** and **46**, which bear an axial aglycon. It is concluded that **43** and **44** are favorably packed within the mesophase and have a higher freedom of movement and consequently higher entropy (an acute triangle rotates faster than an obtuse one). From these results and those previously mentioned, the postulated model of multimers for the formation of columnar phases, which was developed for dialkyl thiols,[56] cannot be generalized. But we can say with certainty that the supramolecular structures of amphiphilic carbohydrates remain a challenge and that further structural elaborations are expected.

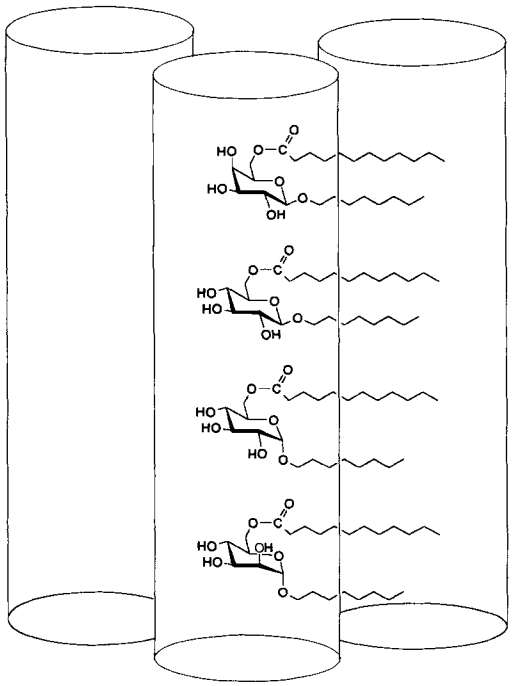


Fig. 6. A model for the formation of discotic mesophases for certain alkyl-6-*O*-acylglycopyranosides (from ref. [61]).

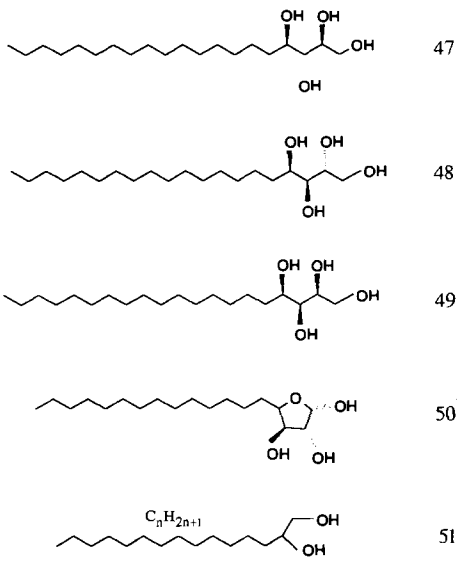
3.2. Liquid Crystalline Behavior of Amphiphilic and Bolaampiphilic Polyols

The crucial factors for the formation of liquid crystals from amphiphiles containing multiple hydroxyl groups are the tendency of the hydroxyl groups to form a dynamic network of cooperative hydrogen bonds and also their location at the ends of lipophilic chains. Diols and polyols with one polar head,[62] as well as bolaamphiphilic polyols,[63] exhibit thermotropic liquid crystalline behavior. Examples of such polyhydroxy amphiphiles with one polar head are compounds **47**–**50**. Compound **51** ($n = 5$) exhibits monotropic mesophase[64] that is stabilized by the addition of water. These polyols are structurally related to carbohydrate liquid crystals and can be regarded as the simplest members of this large class of amphiphilic mesogens.



47

48

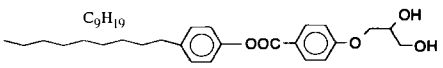
49

50

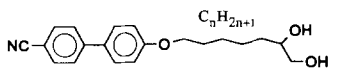
51

Recently, it has been found that the liquid crystalline phases of these compounds can be modified and stabilized by the introduction of rigid-rod moieties. For instance the introduction of

a 1,2-diol unit at the end of the *n*-alkoxy group of a nonamphiphilic phenyl benzoate affords compound **52**, which exhibits a smectic phase rather than the nematic phase exhibited by the starting material.[65] In addition, the introduction of a diol moiety to the known, liquid crystalline 4-alkoxy-4′-cyanobiphenyl results in compounds of the general formula **53** ($n = 1, 2, 4, 6, 8, 9$). The latter compounds have enhanced thermal stability but



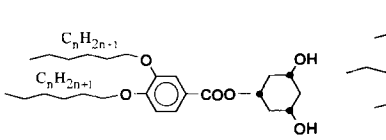
52



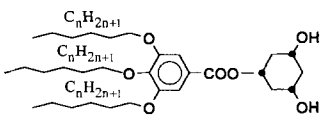
53

do not induce the formation of smectic phases. Since these compounds are amphiphilic, their mesogenic properties are affected by the addition of water, which stabilizes the mesophase and induces the formation of smectic phases. One explanation for this behavior is that water molecules penetrate the network of hydrogen bonds of the diol head groups, strengthening their interactions and therefore hindering the parallel movement of single molecules. It is therefore clear that by affecting hydrogen bonds it is possible to specifically control the molecular arrangement of amphiphilic molecules.

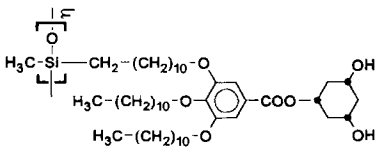
In connection with the above polyhydroxy compounds, 1,3-cyclohexanediols **54** ($n = 6, 8, 9, 10, 12, 14$) and **55** ($n = 4-14$), which are linked through an ester group to a benzene ring with two and three alkoxy chains, respectively, have been synthesized. Following detailed characterization studies,[66-71] including X-ray diffraction, it was concluded that the molecules aggregate even in the isotropic phase. In the mesophase they pack in a hexagonal array giving a phase with a structure similar to that of a columnar discotic phase. The mesogen is not a disklike unit, but six molecules assembled through hydrogen bonding to give the hexagonal structure.



54



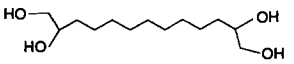
55



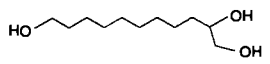
56

In addition to these monomeric diols a polymeric counterpart was synthesized by employing a hydrosilylation reaction analogous to that for polysiloxane preparation.[71] Polymer **56** was obtained bearing the 1,3-cyclohexanediol moiety. As was the case with analogous monomeric compounds, hydrogen bonding between the diols is responsible for the formation of a liquid crystalline phase, the texture of which needs further investigation.[71]

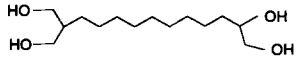
The liquid crystalline phases of these polyhydroxy derivatives can be stabilized by coupling two amphiphilic diols through their hydrophobic subunits ($n \geq 5$), affording the bolaamphiphilic compounds **57**–**62**.[63] Among these compounds the unsymmetrical tetraol **58** has the greatest mesophase diversity. Thus, when **58** is cooled from the isotropic melt, a fanlike texture



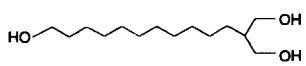
57



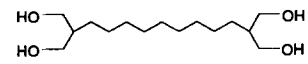
60



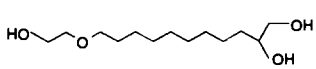
58



61



59

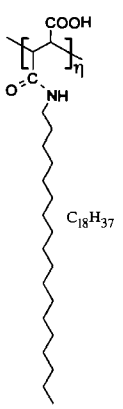


62

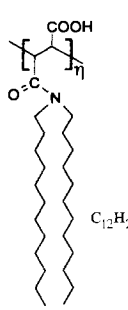
typical of lamella α-phases is obtained, which can be very easily oriented homoetropically by shearing. The hydroxyl groups, like those of amphiphilic diols, should be coupled through a dynamic network of cooperative hydrogen bonds, which are separated by the polymethylene chains, forming an L_α phase. On further cooling down to 75 °C, the texture changes and viscosity increases probably due to transition to a more highly ordered mesophase with rigid parallel polymethylene chains, that is, an L_β phase. At 43 °C another transformation occurs which cannot be studied in detail since crystallization starts. The liquid crystalline phases of polyols can again be modified by the addition of water. Specifically, the water-saturated mesophases of compounds with long aliphatic chains are stabilized, while those with shorter polymethylene chains are destabilized.

3.3. Liquid Crystalline Behavior of Monomeric and Polymeric Carboxylic Acid Amphiphiles

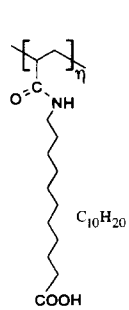
As previously established[11] and discussed in the introduction, liquid crystalline behavior is displayed not only by aromatic acids; certain amphiphilic-type acids also exhibit mesomorphic character. Thus polymers **63**–**65**, prepared by the reaction of poly(maleic anhydride)[72,73] or poly(acryloyl chloride)[74] with long-chain primary (**63**) and secondary amines (**64**) or ω-aminoundecanoic acid (**65**), exhibit liquid crystalline properties. In analogy with the dimers formed by aromatic acids, for example cinnamic



63



64



65

acid derivatives, the liquid crystalline character of **63**–**65** was attributed to the formation of supramolecular structures resulting from the association of the carboxylic groups of the polymers through hydrogen bonding.[72–74] The observed smectic phases were attributed to the lamellar structure formed by lipophilic and hydrophilic layers. These, in turn, arise owing to segregation of the aliphatic chains from the facing hydrogen-bonded carboxyl groups, which form eight-membered rings, as shown schematically for these polymers in Figure 7 (structures A and B). However, in addition to structures A and B one can envisage structures in which the adjacent carboxyl groups are linked through hydrogen bonds in a zig-zag fashion (Fig. 7, structures C and D). FTIR spectroscopy[74] and X-ray diffraction studies[75] reveal that these two supramolecular arrangements coexist in the solid and liquid crystalline phase and that the sample temperature determines which structure predominates.

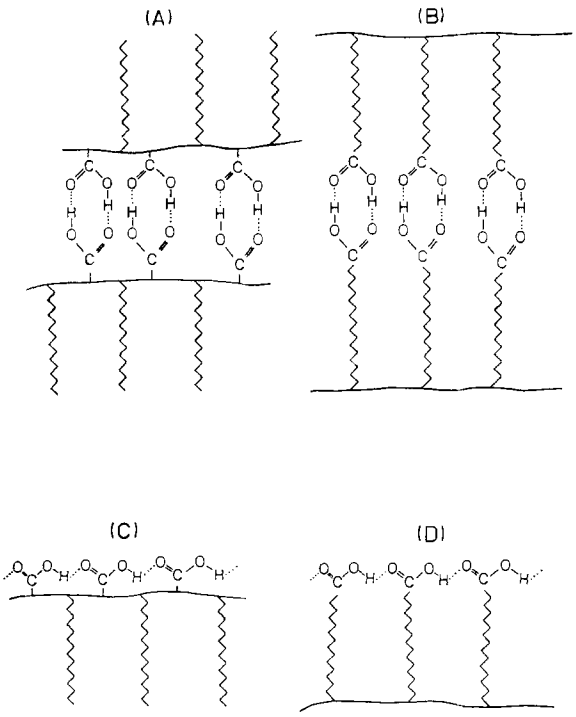


Fig. 7. Schematic representation of the dimerization of polymers **63**–**65**.

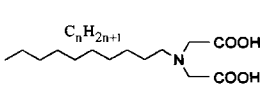
Derivatives of iminodiacetic acids with long aliphatic chains, **66** ($n = 12, 14, 16, 18$), exhibits a smectic phase in analogy with ionic amphiphilic compounds.[76, 77] Taking into consideration the zwitterionic character[78] of iminodiacetic acids, the presence of proton donors and acceptors that could lead to multiple hydrogen bonds between the two acid molecules, and the nonmiscibility of the alkyl chains, one can envisage for these acids a lamellar structure in the liquid crystalline phase. It should be noted that in the crystalline phase the hydroxyl group does not act as an acceptor, since carbonyl and carboxyl are better acceptors than hydroxyl groups.[78] Because the Bragg *d*-spacings[77] are shorter than the dimensions estimated by molecular modeling, we assume that either the aliphatic chains overlap or the molecules are tilted within the layers.



66

3.4. Liquid Crystalline Character of Amphiphiles Bearing Complementary Functional Groups

The formation of liquid crystalline phases through dimerization of certain carboxylic acids can be considered as the starting point for the formation of mesophases by hydrogen bonding between dissimilar molecules bearing complementary functional groups. A very well-known example is the interaction of nucleobases in nucleic acids.

The first reported examples of compounds that could, in principle, form liquid crystals were 2,6-diaminopyridines and uracil derivatives with long aliphatic chains.[79] In fact these compounds with complementary moieties for hydrogen bonding formed both crystalline and liquid crystalline phases. Three hydrogen bonds form between the interacting heterocyclic bases (Fig. 8, bottom). In this case the bases together with the hydrogen bonding system constitute the "polar segment" which is segregated from their lipophilic moiety. The supramolecular structure of the complex is shown in Figure 8 (top). In general, the complexes can be prepared either by allowing the interaction of the complementary bases in organic solvents, usually chloroform, by melt crystallization, or even by solid mixing. For the complex shown in Figure 8 the heterocyclic bases were dissolved in chloroform.

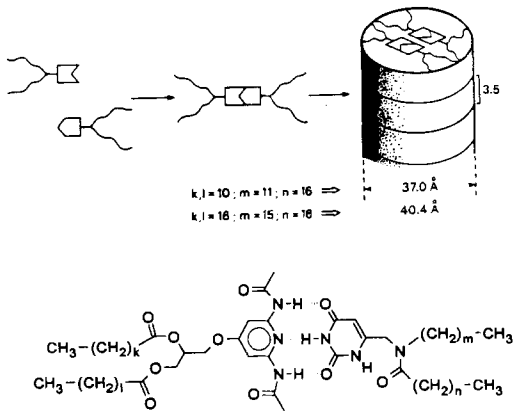


Fig. 8. Formation of a complex through hydrogen bonding (bottom) and a schematic representation of the columnar mesomorphic (top) structure (from ref. [4]).

A series of compounds was prepared by Lehn et al.[79] by modifying the length of the alkyl chain while maintaining the same basic core. The pure compounds show solid polymorphism but none of them exhibits a mesomorphic phase. All of the 1:1 mixtures of these bases that were investigated[79] showed crystalline polymorphism and five of them having long aliphatic chains exhibited a metastable mesomorphic phase. There is no direct evidence for the formation of the complex in the mesomorphic phase. The fact, however, that an analogous complex with three hydrogen bonds was found both in the solid state and in solution[79] is a convincing argument that the structure main-

tained in the melt may be the one responsible for the formation of the liquid crystalline phase. In X-ray diffraction studies of the mixtures with the chain lengths specified in Figure 8, mesophases of the columnar hexagonal type were identified. The columns have diameters of 37 and 40.4 Å and are formed by a stack of disks, each of which contains two supermolecules side by side, with a contact distance of 3.5 Å between successive disks (Fig. 8). Thus the molecular information coded by recognition between the two amphiphiles is amplified and expressed macroscopically in the formation of a liquid crystalline phase.

The interaction of a molecule having at least two functional groups with a molecule having corresponding complementary functional groups can lead, in principle, to the formation of polymeric structures. Such a bifunctional system is shown schematically in Figure 9.

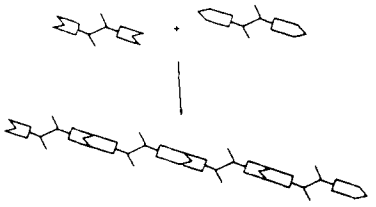

Fig. 9. Schematic representation of the interaction of two compounds each bearing two complementary recognition groups.

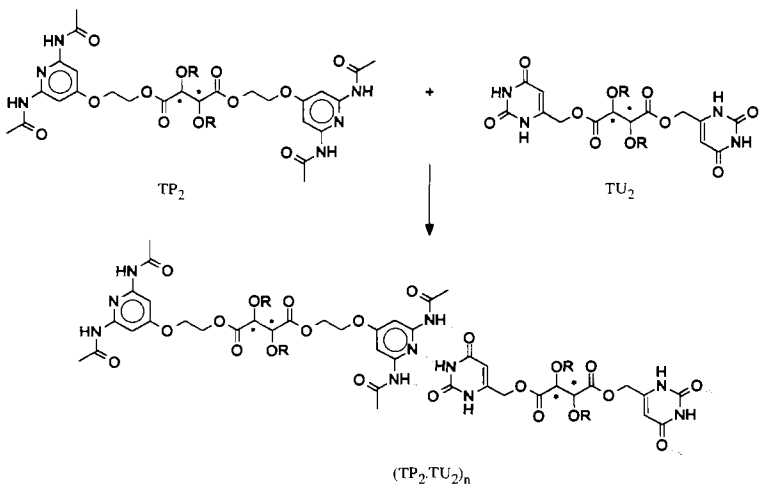
Compounds with two complementary groups were prepared[80] and their complexes characterized as far as their liquid crystalline character is concerned. Specifically, uracil (U) and 2,6-diacylaminopyridine (P) were introduced in tartaric acid (T), and the compounds were allowed to interact, forming complementary pairs with three hydrogen bonds (Scheme 1). Since tartaric acid has chiral centers, it is also possible to study their effect on the properties of the materials.

The components LP_2, LU_2, DP_2, MP_2, and MU_2 were prepared from uracil or pyridine components and L(+)-, D(−)-, and *meso*-(M) tartaric acid and can associate through their heterocyclic moieties.[80] In fact, 1:1 mixtures of the complementary pairs (LP_2 + LU_2) and (MP_2 + MU_2) gave complexes that differed from their components both in the bulk and in solution, as established by NMR and circular dichroism spectra of (LP_2 + LU_2).

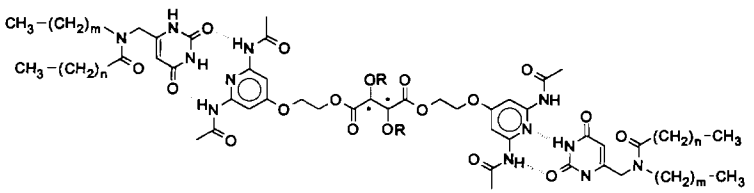


Scheme 1.

The thermal transitions of the individual components and of 1:1 mixtures were studied by DSC and polarizing microscopy. The pure compounds are polymorphic solids, whereas 1:1 mixtures exhibit liquid crystalline behavior from below room temperature to above 200 °C. The optical textures were different for LL and MM mixtures, as the mixtures (LU_2 + LP_2) and (MU_2 + MP_2) showed.[4]

The X-ray patterns of LL, DL, and MM mixtures reveal hexagonal columnar liquid crystalline phases. Details of the X-ray diffraction studies on the supramolecular structures affording these liquid crystals were reported by Lehn et al.[80] More recently, electron microscopy studies[4] were used to further explore the structure of these materials. It was shown that as the concentration of equimolar solutions of LP_2 and LU_2 increases, a progressive assembly of supramolecular entities occurs up to very large species. Initially small nuclei are formed, which grow into filaments, and finally associate laterally to give treelike species, strings, and fibers.[4] The materials formed are helical as a result of the chirality of the subunits.

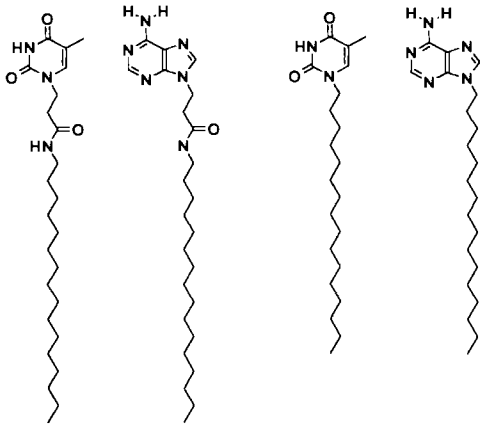
Mesophases were also obtained by the interaction of a component containing two recognition sites and a second component containing one recognition site in a 1:2 molar ratio. This is the case when two uracil components combine with the complementary LP_2 component to form the supermolecule shown in Scheme 2, having a columnar structure of rectangular section.[4]



Scheme 2.

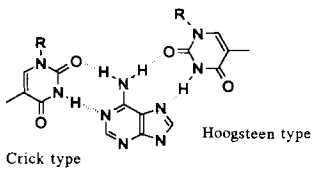
To mimic the interaction of complementary nucleobases in nucleic acids, adenine and thymine nucleobases were functionalized with long aliphatic chains, transforming these bases to amphiphilic-type compounds. Since it is known that recognition in nonbiological systems is significantly enhanced by solvents that do not form hydrogen bonds,[81–85] the amphiphilic nucleobases were mixed in chloroform or in the melt. It is of interest to note that in aqueous media vertical stacking predominates.[85] The alkylated derivatives of adenine and thymine **67**–**70** (n = 16) were prepared.[86, 87] The obvious question was whether the amphiphilic-type nucleobases exhibit liquid crystalline behavior alone or as complementary complexes. The aliphatic chains were introduced at 1- and 9-positions of thymine and adenine, respectively, in other words, at sites remote from the functionalities involved in the recognition process. This strategy must be followed in all cases when molecular recognition is required to occur.

Since the amino group in adenine has two hydrogens available for hydrogen bonding, it may in principle recognize two molecules of thymine. This is the



67 68 69 70

reason why adenine–thymine complexes with molar ratios of 1:1 and 1:2 could be prepared.[86, 87] The types of hydrogen bonds formed in these complexes, Watson–Crick and Hoogsteen interactions, are shown in Scheme 3. The amide group of the derivatives **67** and **68** may affect their organizational characteristics since it is capable of forming hydrogen bonds.



Scheme 3. Watson–Crick and Hoogsteen hydrogen bonds in adenine–thymine complexes.

The results of detailed optical and DSC studies as well as X-ray diffraction analyses of these novel nucleobases can be summarized as follows: Pure adenine and thymine derivatives and their binary mixtures have an organized arrangement in the solid state at low temperatures and form the lamellar structures typical for amphiphilic compounds. X-ray diffraction studies show that this ordering is maintained up to the isotropic phase. The optical textures indicate the formation of metastable mesomorphic phases which seems to contradict the X-ray results. Thus, these mesomorphic phases may be interpreted as transient monotropic phases, occurring on cooling from the isotropic melt and not stable enough to be detected by X-ray diffraction. We may attribute the absence of stable mesomorphic phases to the structure and shape of the molecules and their complexes, which cannot properly be accommodated in the type of supramolecular structure that affords liquid crystalline phases. Further investigations are needed to determine the order of the amphiphiles in stable liquid crystalline phases and also to assess the role of amphiphilicity and molecular recognition in the formation of novel liquid crystals.

The mesomorphic properties of diamides of alkyl-substituted 1,3-diaminobenzenes, initially prepared by Matsunaga et al.,[88] were reinvestigated in detail by Malthête et al.[89] together with some analogous compounds. The presence of methyl groups at appropriate positions on the benzene ring is crucial for the formation of the mesomorphic phases. In the example shown in Figure 10 it may be assumed that a methyl group close to an amide (4-position) or between two amide groups (2-position) turns at least one amide group out of the plane of the benzene ring. This should favor self-association and formation of supramolecular structures leading to mesomorphic phases.

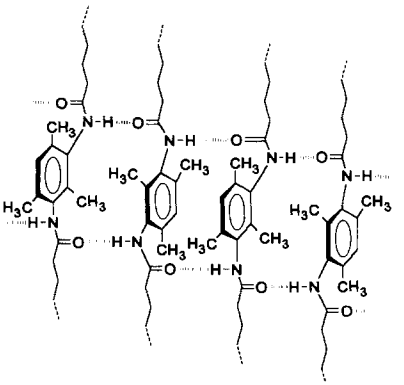


Fig. 10. Schematic representation of the potential supramolecular structure of a hydrogen-bonded associated diamide (from ref. [89]).

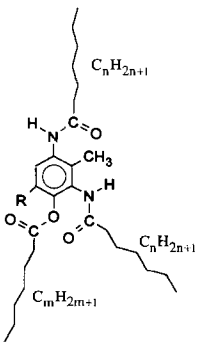
In an analogous manner, hydrogen bonding explains the "unconventional nematic phases" exhibited by the homologous series of benzdiamides—*N,N'*-dialkanoyl-2,5-dimethyl-4-alkanoyloxy-1,3-benzdiamines **71a** (R = CH_3; $n = m = 8-11, 13, 15$) and 2-methyl-5-isopropyl- **71b** (R = *i*Pr; $n = 8-11, 13, 15$ and $m = 4-15$) and 2-methyl-5-*tert*-butyl-4-alkanoyloxy-1,3-benzdiamines **71c** (R = *t*Bu; $n = m = 10, 11, 13, 15$). These results are included in the latest work[90] of Matsunaga et al.

The liquid crystalline character of 3,4,5-tris(alkoxybenzamides) can be interpreted by assuming a supramolecular structure analogous to that of the alkylated diamides previously discussed.[89] Based on optical textures only, Beginn and Lattermann[91] deduced a columnar or stacklike structure and proposed a dimeric structure (Fig. 11). It was also proposed that since the amide groups are tilted against the plane of the aromatic rings, not only intradimer but also interdimer hydrogen bonding is exercised, stabilizing the columnar structure. The existence of interdimer hydrogen bonds was supported by infrared spectroscopy and also by substitution of the benzene ring, which results in loss of mesomorphism. Apparently steric hindrance suppresses interdimeric hydrogen binding.



71

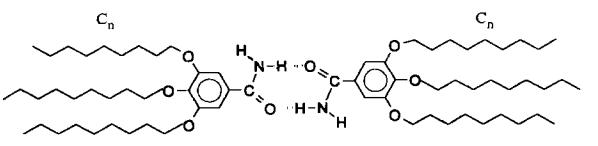


Fig. 11. Hydrogen-bonded dimers of trisalkylated primary benzamides.

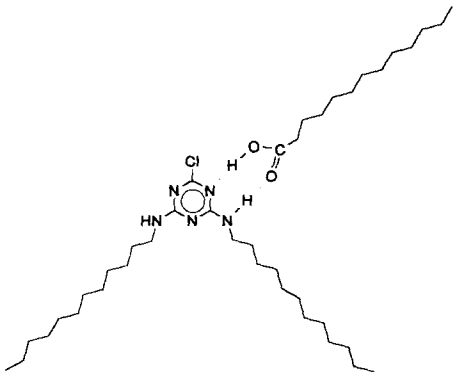
In preliminary experiments[92] the mesomorphic character of some 2,4,6-trichloro-1,3,5-triazine derivatives with long alkyl chains was investigated. These molecules, which contain in their core a typical unit for molecular recognition, N=C–NH,[93] were mixed in the melt with molecules bearing a complementary

moiety. In a typical experiment, lauric acid was combined in the melt with a disubstituted triazine derivative, affording the structure shown in the Scheme 4. In DSC and optical studies of the complex a mesomorphic texture was found which was not characterized further.



Scheme 4.

The examples described were the first attempts at preparing liquid crystalline phases through molecular recognition of dissimilar molecules. Further study is required on the structure of interacting components in order to lead to stable and diverse liquid crystalline phases. Thus, in addition to having the proper geometry and being complementary, the interacting components must also benefit from cooperativity[94] or secondary electrostatic interactions, as invoked by Jorgensen et al.[95, 96] According to a model proposed by Jorgensen, the most stable supramolecular structure is obtained when all or at least most of the donors are located in one of the interacting molecules, while the acceptors are on the other. The preparation of liquid crystals stabilized by secondary interactions is thus of current interest.

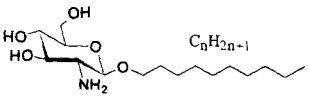
4. Summary and Outlook

The results presented in this review clearly demonstrate that hydrogen bonding is of significant importance in the formation of liquid crystalline phases and the stabilization of existing mesophases of both rigid-rod and amphiphilic molecules. In future work hydrogen bonding must be put on a more quantitative basis, taking into consideration not only the typical interaction of donor–acceptor pairs but also secondary electrostatic interactions. The development of the structural features of the recognition moieties for a more effective binding of supramolecular assemblies will be certainly the main objective of future work in the domain of hydrogen-bonded liquid crystals. These exploratory studies may very well trigger interest in identifying and synthesizing new building-block molecules with the prescribed hydrogen bonding properties, whose supramolecular assemblies may lead to novel liquid crystalline materials.

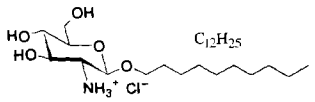
5. Addendum

A number of new studies on compounds displaying liquid crystalline phases induced by hydrogen bonding have appeared since this review was accepted for publication in September 1994. Most of this new work refers to amphiphilic polyhydroxy liquid crystalline compounds[97–100] including carbohydrates.[97–99] But there has also been research activity focusing on the formation of liquid crystalline complexes incorporating pyridyl or bipyridyl moieties.[101, 102] Some examples of these types of liquid crystals are discussed below.

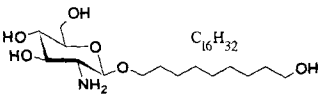
Liquid crystalline amphiphilic carbohydrates[97] based on glucosamine and 6-amino-6-deoxyhexopyranoses have been prepared. In previously synthesized aminocarbohydrates[41] the secondary amino group was placed in the bridge between the hydrophilic and hydrophobic segment, while in the new glucosamines a primary amino group is located in the hydrophilic section of carbohydrates. In addition to the simple alkyl glucosamines **72** ($n = 8$, 10, 12, 14, and 18) and its hydrochloride salt **73** ($n = 12$), which exhibit smectic phases, the hydroxyl derivative **74** ($n = 16$) also shows smectic behavior. The amides of 6-amino-6-deoxygalactose **75** ($R = SO_2C_{16}H_{33}$, $COC_{17}H_{35}$)



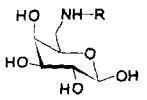
72



73



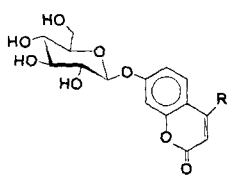
74



75

with only one alkyl group connected at the amino group form smectic S_A phases. The clearing temperatures are higher than those of the alkyl glucosides, and the sulfonamide derivative has a higher clearing temperature than the carbonamide because of differing polarities.[97] A particularly interesting feature of aminocarbohydrates is their ability to form intra- and intermolecular salts with organic acids, giving a multiplicity of liquid crystalline materials. Thus, depending on the organic acid used, smectic, discotic, or cubic phases can be prepared. The liquid crystalline properties of aminocarbohydrates are summarized as follows: *N*-Alkylglucosamines show S_A phases with lower clearing points than those of alkyl glucosides; high clearing points are induced when the amino group is located at the bridge position between the hydrophilic and the hydrophobic segments.

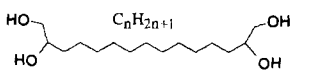
A quite recent paper extends the work on amphiphilic carbohydrates to the preparation and characterization of nonamphiphilic carbohydrate liquid crystals.[98] Thus, a coumarin moiety was incorporated in the carbohydrate and compounds **76** ($R = C_7H_{13}$, C_9H_{19}, and $C_{13}H_{27}$) were prepared. The rigid and relatively flat coumarin unit is flanked by the hydrophilic carbohydrate head group and a lipophilic tail. Although the structures of these carbohydrates are not typical for compounds exhibiting mesomorphic character, two of these compounds form liquid crystalline phases. Thus, the heptyl derivative is not liquid crystalline, while nonyl



76

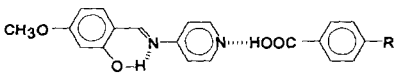
and tridecyl derivatives exhibit a smectic S_A liquid crystalline phase.

Studies on bolamphiphillic tetraols have been continued by a detailed investigation of the homologous series of 1,2,ψ,ω,*n*-alkanetetraols **77** (n = 5–18, 20).[99] The compounds that bear a rather long polymethylene chain exhibit a lamellar α phase and a mesophase at low temperatures, whereas the derivatives with short chains exhibit only a low-temperature mesophase. Characterization by X-ray diffraction showed the low-temperature phase to be an L_x phase. On the basis of the experimental d values and the estimated tilt angle of 28°, a model was proposed (Fig. 12). It is assumed that the primary hydroxyl groups interact through hydrogen bonding with the secondary hydroxyl groups of the neighboring molecule. In this way the tilt angle of about 30° can be rationalized. This low-temperature mesophase is highly ordered and viscous. Its layer thickness decreases at the transition to the high-temperature phase. This transition is accompanied by a high enthalpy change and gives rise to a mesophase in which the methylene chains are liquidlike, as is also the case with the L_α phase of lyotropic systems. The melting of the aliphatic chains should be accompanied by a reorganization of the hydrogen bonds, which would also contribute to the high transition enthalpy. With respect to the high transition enthalpy between the two mesophases and the high viscosity, the low-temperature phase may be considered to have a solidlike character although the X-ray patterns are very similar to those of the low-temperature mesophases of the amphiphilic diol compounds.[100]



77

In studies of complexes bearing pyridyl or bipyridyl moieties as acceptors two classes of compounds were investigated. The nonmesomorphic *N*-(*p*-methoxy-*o*-hydroxybenzylidene)-*p*-aminopyridine[101] was combined with *p*-alkoxybenzoic acids affording complexes **78** (n = 1–5, 10, 12). The anil moiety is protected from hydrolysis by the *ortho*-hydroxyl group. Complexes originating from methoxy-, ethoxy-, propoxy-, butoxy-, and pentyloxybenzoic acids afforded complexes with nematic liquid crystalline phases, while the complexes of decyloxy- and dodecyloxybenzoic acid with the same anil exhibit smectic and nematic phases.



78

In this context 4,4′-bipyridine was combined for the first time with phenols rather than with acids to yield complexes **79** and **80**.[102] Neither of the interacting components exhibit liquid crystalline character; for the formation of their complexes a stoichiometric ratio of 2:1 (phenol:bipyridine) was employed.

79

80

Long alkyl or alkoxy chains are needed to obtain liquid crystalline character. Thus, for complexes **79** smectic phases were observed only for the members having an alkoxy chain longer than C_9. In complexes **80** the members with an alkyl chain shorter than C_7 do not show liquid crystalline behavior. Thus derivatives with short alkyl and alkoxy chains do not form a nematic phase.

Two at One Blow: The New Chemical Elements 110 and 111

Günter Herrmann*

Nothing significant has happened at the very end of the periodic table for about a decade, since a research group around Peter Armbruster, Sigurd Hofmann, and Gottfried Münzenberg produced and identified the three then heaviest chemical elements—element 107 in February 1981, 109 in August 1982, and 108 in March 1984—at the heavy-ion accelerator UNILAC of the Gesellschaft für Schwerionenforschung (GSI) in Darmstadt (Germany). Rather, scepticism about progress beyond this limit seemed to be appropriate. "Their synthesis [of the heaviest nuclei] is strongly hindered—much more than was initially anticipated. It is this hindrance rather than the decreasing nuclear stability which seems to presently limit the extent of the periodic table: even heavier elements should be able to exist, but no way has yet been found to produce them" is pointed out in 1988 in a report[2] in this journal. Nuclear properties are the key when the limit of the periodic table is approached. The electron shell does not play a role here, but it is decisive, of course, if we ask where the heaviest elements are located in the periodic table and whether its systematics continues consistently up to this point.

Now, the same research group has again created a great stir in a very eventful beam time late in 1994: On November 9 at 16:39 h, the group discovered element 110 in form of an atomic nucleus of mass number 269.[3] On November 23 at 20:07 h a second isotope of element 110 with mass number 271 was detected.[4, 5] Rapidly thereafter, on December 8 at 05:49, element 111 followed with mass number 272.[6] Four nuclei of $^{269}110$ were observed, nine of $^{271}110$, and three of $^{272}111$.[5] Each of these new nuclei fed a long decay chain of well known α-emitters with a total of 68 registered α-particles.[4] Lifetimes and decay energies of the chain links present a very characteristic fingerprint which cannot appear accidentally. Furthermore, the information on the formation and decay of the heaviest atomic nuclei fuels the hope for still heavier elements: The "superheavy" elements around element 114, in discussion for three decades, appear now to be within reach.

The group's strategy for synthesis and detection was basically the same as for the elements 107 to 109 (for more details see the review articles[1, 2]). The heaviest elements are created by fusion of two atomic nuclei. One of them, the target nucleus at rest, is lead-208 (proton number $Z = 82$) or bismuth-209 ($Z = 83$), the two heaviest stable nuclei in nature. The other, the projectile nucleus, adds exactly the number of protons required to make the sought element. To induce a nuclear reaction, projectile and target nucleus have to be brought into contact; the repulsive electrostatic force between the two nuclei has to be overcome. The projectile, therefore, is accelerated in the UNILAC to about ten per cent of the velocity of light. To build element 110 from lead and element 111 from bismuth, nickel ($Z = 28$) is needed as the projectile. Used are its rare neutron-rich isotopes 62 or 64 (not the most abundant ones 58 or 60) to provide, at least to some extent, the neutron excess typical for very heavy nuclei.

Written as nuclear chemical reactions, the fusion processes leading to the new elements are given by Equations (1)–(3). After fusion of the two reaction partners the resulting compound nucleus is more or less heated, because the kinetic energy of the projectile, necessary to get the nuclei in contact, is not completely consumed in the nuclear reaction but remains as residual excitation energy. The hot nucleus cools down by evaporation of neutrons leaving the element unchanged but reducing the mass number accordingly. In the three synthetic reactions (1)–(3) of the new elements a single neutron (n) is sufficient for cooling. This is a peculiarity of nuclear fusions starting with lead or bismuth nuclei; they proceed without excessive excitation of the compound system.

$$^{62}_{28}\mathrm{Ni} + ^{208}_{82}\mathrm{Pb} \longrightarrow ^{269}110 + 1\,^{1}_{0}\mathrm{n} \quad (1)$$

$$^{64}_{28}\mathrm{Ni} + ^{208}_{82}\mathrm{Pb} \longrightarrow ^{271}110 + 1\,^{1}_{0}\mathrm{n} \quad (2)$$

$$^{64}_{28}\mathrm{Ni} + ^{209}_{83}\mathrm{Bi} \longrightarrow ^{272}111 + 1\,^{1}_{0}\mathrm{n} \quad (3)$$

Because of that, such reactions—first proposed 1974 by Yuri Oganessian from the Joint Institute for Nuclear Research in Dubna (Russia)—are considered the most promising for the synthesis of new elements. That they are so mild has to do with the closure of nuclear shells in lead and bismuth; such nuclei are strongly bound—deep frozen, so to speak—as are the nickel projectiles. One could aptly call such reactions "cold fusion" if this term did not recall the recent notorious flop of cold fusion of deuterium nuclei. The shell structure of atomic nuclei is a quantum mechanical phenomenon, quite analogous to the shell structure of the electron cloud and has the same stabilizing effect.

The realization of such fusion reactions are as difficult as their formulations on paper appear easy, because quite different processes predominate by far. In such heavy nuclei the repulsive force between the protons becomes competitive with the attractive nuclear force between the nucleons. Hence, the two touching nuclei may separate again before a reaction has started at all,

or when fusion is still incomplete. If the reaction proceeds to yield a (hot) compound nucleus, it most likely breaks into two fragments rather than surviving as the desired nuleus after neutron evaporation. Fusion could be promoted by increasing the projectile energy, but the compound nucleus would get even hotter and more susceptible to nuclear fission; thus, nothing would be gained.

Just how delicate the situation is can be illustrated by a few numbers. The probability for a collision between projectile and target nucleus is approximately given by their geometric cross section. This is about 10^{-24} cm^2 or 1 barn, to introduce a unit popular in nuclear research. According to the results of the Darmstadt SHIP group—called after their principal instrument *S*eparator for *H*eavy *I*on Reaction *P*roducts—the production cross sections decrease from 10^{-32} cm^2 for element 104 to 10^{-35} cm^2 for element 109, that is, to only 10 picobarn. In more illustrative terms: Only one single collision between projectile and target among 10^{11} yields element 109. Extrapolated to still heavier elements, this trend predicts figures around one picobarn for element 111, equivalent to a square millimeter in an area of a square kilometer. This level seemed to be inaccessible a decade ago even to the SHIP group. All technical resources seemed to be exhausted, and laws of nature are inviolable anyway.

But then the SHIP group succeeded in approaching the picobarn cross section level by many small improvements of their facilities.[3] At this level one would expect to observe, on average, one nucleus every six days at the UNILAC, provided the projectile energy is optimized, namely to one percent. Fusion reactions depend very sensitively on the bombarding energy. The SHIP group has studied this effect thoroughly in the synthesis of the elements 104 and 108 in order to chose the right energies in attacking the new elements.

However, the potential now available did not have to be fully exploited in the synthesis of elements 110 and 111. The two nuclei ^{269}110 and ^{272}111 are produced with cross sections of about 3 picobarn,[3, 6] and for ^{271}110 even 15 picobarn were measured[5] multiples of what had been anticipated.

But how can a few atoms of a new element be found and identified unambiguously in the profusion of uninteresting nuclei? The sorting process takes place within a few microseconds during the flight of positively charged ions through SHIP, an 11 m long recoil spectrometer. It consists of the rotating target, the actual separator—equipped with magnetic lenses and crossed electric and magnetic fields—and the detector. Fed in the instrument are all kinds of reaction products that recoil out of the target during collisions of the pulsed projectile beam with nuclei in the target foil. But the strong projectile beam also passes through the target in nearly unattenuated intensity, because most projectiles do not undergo nuclear reactions. To catch the very few, very heavy reaction products, the direction and velocity of the flying atoms are utilized: fusion products are collimated in forward direction whereas products of other reactions are more likely to escape sidewards, and fusion products move more slowly than projectiles. Only nuclei with the right direction and velocity pass through this extremly efficient filter to reach the detector.

The identification of the very rare nuclei is based on their emission of α-particles, helium nuclei with nuclear charge 2 and mass number 4. Auspicious are events with high α-particle energy, because towards the end of the periodic table this energy should increase from element to element. The presence of a new element is proven conclusively by its α-decay into a whole chain of known atomic nuclei. The α-decay of the new element yields a known nucleus, lighter by two protons and four nucleons, which is recognized by its lifetime and α-energy, and feeds a known decay chain linked together again by α-transitions.

This principle of genetic linking of new with known nuclei is ingeniously realized in SHIP in a semiconductor detector, 80 mm wide and 35 mm high, which is mechanically and electronically divided into 3700 tiny individual detectors of 0.8 mm^2 area. If an atom passing SHIP hits the detector, an electric signal is produced indicating the time and location of the event. All subsequent events at the same location are recorded: what kind of decay occurs at what time, and what energy is released. Thus, the fate of the original nucleus is followed, step by step, by the lifetimes and α-energies of its descendants.

Figure 1 shows three decay chains of the new elements. When element 110 was observed for the first time, this individual nucleus ^{269}110 decayed 393 μs after its implantation, by emitting an α-particle of 11.13 MeV energy, into a nucleus that proved to be the known ^{265}108 by its 10.57 MeV α-particle emission after

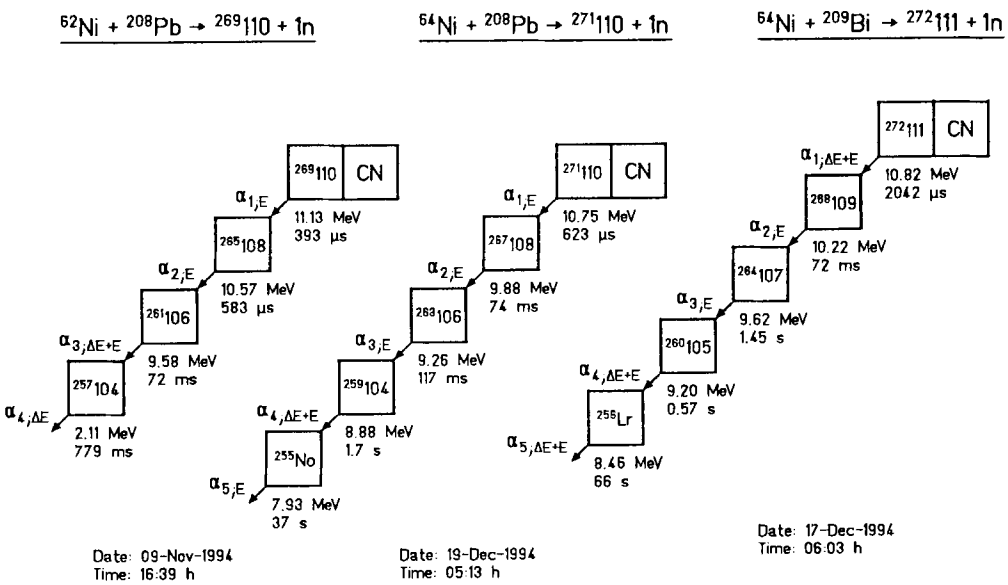

Fig. 1. Three decay chains characteristic of the elements 110 and 111 [5]. The top line gives the synthesis reactions. CN represents the compound nucleus produced by fusion of projectile and target nuclei; on its left is indicated the nucleus formed by evaporation of one neutron. This nucleus is the starting point for the decay chain. For each chain link i the measured α-particle energy α_i is given and, below, the observed individual lifetime (E and ΔE refer to details of the energy measurement). The bottom line indicates when that nucleus of the new element hit the detector.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1714 $ 10.00+.25/0

583 μs lifetime. Also for the following decay chain originating in ^{265}108, lifetimes—or, deduced from that, half-lives—and α-particle energies of all chain members agreed with known data. Therefore, the new α-emitter right at the beginning of the whole decay series had to be assigned to the nucleus ^{269}110. In the same way ^{271}110 was identified. In the case of element 111 the first two decay products, ^{268}109 and ^{264}107, were not yet known, but since three long decay chains were observed terminating at well-known isotopes of the elements 105 or 103, the initial nucleus had to be attributed to ^{272}111.

The decay data of the new elements are summarized in Table 1 as average values of all observed nuclei. The α-particle energies can be reproduced very precisely even with very few events; half-lives and production cross sections fluctuate more due to the statistical nature of radioactive processes. In the case of ^{271}110, one of the nine observed nuclei was identified to be a nuclear isomer of longer lifetime.[6]

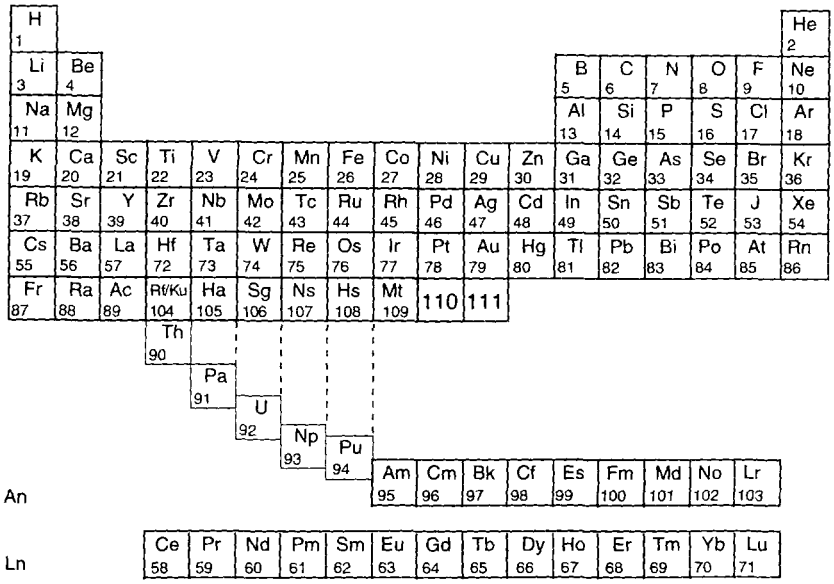

Fig. 2. The periodic table of the elements today. In this somewhat unusual presentation, the actinide elements (An) are arranged above the lanthanides (Ln) in a form that emphasizes similarities of the first actinides with subgroup elements. For the heaviest elements the names and symbols preferred by heavy-element researchers are used.

Table 1. Nuclear properties of the new elements and production cross sections x, from results of the SHIP group at the UNILAC heavy-ion accelerator [3–6].

Element	Mass number	Half-life [ms]	α-Particle energy [MeV]	x [picobarn]
110	269	0.17	11.112	3.5
	271	1.1	10.738 10.681	15
	271m [a]	56	10.709	
111	272	1.5	10.820	3.5

[a] Isomeric nucleus.

That the method of genetic linkage can be performed to such perfection with very few nuclei was demonstrated when the SHIP group repeated in this latest beam time the fusion of iron-58 ($Z = 26$) with lead-208 to form element 108 with mass number 265. Now, with 79 observed nuclei, what had been found before with only three nuclei when element 108 was discovered was confirmed.

Evidence for the synthesis of element 110 was also presented at recent conferences by two other research groups. Albert Ghiorso[7] reported in Juni 1994 on a single event observed at the Lawrence Berkeley Laboratory during fusion experiments of cobalt-59 ($Z = 27$) with bismuth-209, which may be assigned to mass number 267. However, the decay chain is rather incomplete and cannot be interpreted without making assumptions. The experiment cannot be repeated in Berkeley because the SuperHILAC heavy-ion accelerator is shut down, and the recoil separator has been dismantled. Also apparently incomplete is the single event described by Yuri Lazarev[8] in April 1995, found in Dubna in the "hot" fusion of sulfur-34 ($Z = 16$) with plutonium-244 ($Z = 94$), which may lead to mass number 273. In contrast to these events, the SHIP researchers present their assignments of element 110 as unambigous, and justifiably so.[3]

Figure 2 shows where the new elements should be located in the periodic table: 110 below platinum, 111 below gold, if after completion of the actinide series the table is continued with element 104 in the 4th subgroup and is simply carried on to the right. The chemical behavior[9] of the first two elements following the actinides, the elements 104 and 105, indeed characterizes them as part of the subgroups 4 and 5. Studies of the chemistry of heaviest elements have not yet progressed beyond element 105, hahnium, since short half-lives and extremely low production rates lead to a very unusual situation: When a new atom appears, the preceding one has already decayed, and chemical experiments have, thus, to be carried out with single atoms. Apart from the technical problems, the question arises whether studies with single atoms are representative for determining macroscopic properties. According to theoretical studies this is indeed the case for certain classes of experiments.

The chemistry of element 105, hahnium, is investigated on its isotope 262 (half-life 34 s) produced by fusion of oxygen-18 ($Z = 8$) with berkelium-249 ($Z = 97$). The production rate is so low that a hahnium decay is observed, statistically distributed, only in one out of ten experiments. What is needed under these circumstances are fully automated, miniaturized techniques; automation is required to perform thousands of experiments, miniaturization to minimize losses by radioactive decay. Nevertheless, several properties of the first two transactinide elements are already well characterized; consequently they can be compared with those of the homologous elements, for example, the species occurring in aqueous solutions or in gas phases.[9] In general, the elements 104 and 105 exhibit the expected oxidation states IV and V, respectively. In detail, they often follow more their "pseudohomologues" at the beginning of the actinide series. Element 105 behaves more like protactinium (Pa), than niobium (Nb), and scarcely like tantalum (Ta), its immediate neighbor. This could be due to rearrangements of the electron clouds caused by the relativistic mass increase of the very fast moving inner electrons. It is challenging to ask how this trend will continue at element 106 whose chemistry is not known at

all; it will soon be attacked by chemists studying the heaviest elements.

When reporting new elements one can hardly ignore the recent discussion of the names of the heaviest elements. Since controversies about the priority for some of the discoveries led to much confusion, the International Union of Pure and Applied Chemistry (IUPAC) and the corresponding Union of Physics (IUPAP) charged a working group to follow the history of all transfermium elements, that is, elements beyond 100. The group has summarized the evaluations[10] in form of discovery profiles which clearly show that several cases are quite complex and priorities should be shared. For the elements 107 to 109, however, the priority of the SHIP group is undisputed. Hence, in a celebration[11] at GSI on September 7, 1992, element 107 was named nielsbohrium (Ns), element 108 hassium (HS), and element 109 meitnerium (Mt), honoring the physicists Niels Bohr and Lise Meitner and after the state of Hessen where GSI is located. After the evaluation by the IUPAC–IUPAP working group, which did not propose names, the research groups involved apparently agreed to a large extent on names that had been established some time and are also used in this report; really in dispute remained only element 104.

Unfortunately the IUPAC Commission on Nomenclature of Inorganic Chemistry presented a rather different list of names[12] for ratification by the IUPAC Council. The proposals of the SHIP group are adopted for element 109, meitnerium; for 107 bohrium (Bh) is proposed, and for 108 hahnium, so far in use for element 105. No argument is given why element 108 should not be named after a geographic term linked to the discovery—as is the case for many natural and artificial elements—although in the same paper this tradition is followed with the name dubnium for element 104. A single sentence merely points out that naming the neighboring elements 108 and 109 after Otto Hahn and Lise Meitner is proposed as a recognition of their decisive role in the discovery of nuclear fission.[12] It might appear appealing to see these two scientists who cooperated over decades immortalized side by side in the periodic table, but the idea of moving the chemist Otto Hahn away from element 105 is nevertheless disappointing. We are already sure that the chemistry of hahnium can be studied; whether this will ever be possible for element 108 is a very open question. The other deviating proposals[12] are: dubnium instead of rutherfordium for element 104, joliotium instead of hahnium for 105, and rutherfordium instead of seaborgium for 106.

On behalf of the SHIP group, Peter Armbruster protested against this violation of the traditional right of the discoverers to choose the name for a new element.[13] Obviously the IUPAC has also violated its own rules[14] (Bylaw B2.11) that recommendations of such consequence should be considered provisional when first published, and the comments invited. Now the IUPAC seems to wish to revert to these rules.[15] Thus, the severe criticism would appear to have succeeded, and whoever already adopted the "new" names seem to have been a bit overzealous.

What about the future? How stable are nuclei beyond element 111 and how can they be made? First of all, this is a question of the shell structure of atomic nuclei; from element 108 onwards nuclei exist merely because they are held together by nuclear shells.

The strength of shell energies in kown nuclei is deduced from nuclear masses or α-decay energies, which amounts to the same thing. These experimental shell energies are input data for nuclear-model calculations used to extrapolate the shell energy of still unknown nuclei. Figure 3 shows the results of recent

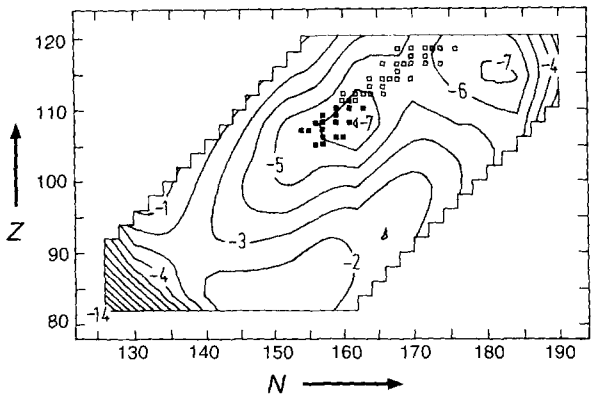

Fig. 3. Shell energies of heaviest nuclei calculated for nuclear models [16], plotted versus proton number Z and neutron number N. Contour lines connect nuclei of equal shell energy (in MeV). The more negative this energy, the more stabilized the nucleus. Three minima for nuclei with closed proton and neutron shells can be seen: in the left lower corner the steep minimum at lead-208 ($Z = 82$, $N = 126$), in the center a flat minimum at $Z = 108$ and $N = 162$, and at the upper right end a shallow minimum at $Z = 114$ and $N = 182$. Filled squares indicate the heaviest known nuclei; empty squares are compound nuclei that can be reached, in principle, by fusion of lead-208 with the appropriate projectile [5].

calculations,[16] which take into account complicated nuclear shapes. At the lower left corner this landscape of shell energy opens with a deep valley (−14.3 MeV) around lead-208. The belt of known nuclei (not indicated) then follows a steep ascent up to a saddle (− 3 MeV) at the uranium nuclei with $Z = 92$, $N \approx 146$. A gentle descent leads to a plateau oriented northeastwards with a rather flat valley (−7.2 MeV) around element 108 at neutron number 162. Here we find the heaviest known nuclei, as can be seen in Figure 3. Then the plateau continues towards the east, in the direction of more neutron-rich nuclei, and after crossing a rarely visible saddle enters another shallow valley (again −7.2 MeV) around element 114 with neutron number 182. According to another recent calculation[17] the deepest point in this valley is expected somewhat further to the west, at element 115 and 179 neutrons.

The prediction of spherical superheavy nuclei with 114 protons has kept nuclear theorists and experimentalists busy for three decades, but these nuclei were considered to form an island well separated from the mainland by the sea of instability. Now, after new nuclei have been found and nuclear models and extrapolations improved, the landscape has changed completely: The sea has gone, replaced by a broad ridge of shell-stabilized nuclei that are not spherical but look like elongated cylinders with rounded edges. Such more complicated shapes were not considered in those earlier days.

What implications do the shell energies have for the half-lives? This can be quite well estimated, but the picture is somewhat complicated by the fact that two decay modes—α-particle emission and spontaneous fission—play a role and follow different trends. In summary, α-decay with half-lives between a microsecond and a second is predicted for most of the nuclei that

can be produced with stable projectiles and accessible targets. Spontaneous fission does not yet predominate. Thus, seen in the light of nuclear stability, the limit of the periodic table is not yet in sight. This limit will finally be reached when nuclei do not hold together at all but immediately break into two fragments.

The process that produce heavy nuclei remain more difficult to judge. They are not yet well understood, and what is known about fusion reactions in lighter systems cannot be applied. Thus, one relies upon empirical extrapolations; the 15 picobarn production cross section of the nucleus ^{271}110 opens exciting perspectives, of course. The cross section extrapolated for element 112 is about three picobarn, that for element 113 and element 114 one picobarn,[5] if zinc-70 ($Z = 30$) or germanium-76 ($Z = 32$) are fused with lead or bismuth– all within reach of the SHIP group. However, the center of stability, the mountain lake around element 114, cannot be reached from lead-208. As shown in Figure 3, the channel of accessible nuclei goes past to the west. Other strategies would also not lead to success, because no combination of accessible projectile and target nuclei would provide enough neutrons. Nevertheless, it seems not to be utopian to step onto the broad western beach. If the landscape would appear there as predicted, one would also catch a glimpse of that glorious lake.

Catalytic Asymmetric Carbonyl–Ene Reactions

David J. Berrisford* and Carsten Bolm*

As one of the fundamental bond-forming reactions, the carbonyl–ene reaction between an aldehyde and an alkene bearing an allylic hydrogen attracts considerable attention[1] from the synthetic community. Given the versatile chemistry of the resulting homoallylic alcohols, both the intra- and intermolecular versions of asymmetric carbonyl–ene reactions are valuable processes.[2] Within the field of catalysis[3] the continuing improvements in the efficiency of chiral Lewis acids and the development of novel ene chemistry occur in concert. We wish to highlight a number of these developments.

A recent publication by Carreira et al.[4] documents further advances in this already topical area. The authors describe a titanium-catalyzed asymmetric carbonyl–ene reaction of the commodity chemical 2-methoxypropene ($ 49.30 L^{-1}/Janssen) with aldehydes (Scheme 1). When a catalyst prepared in situ

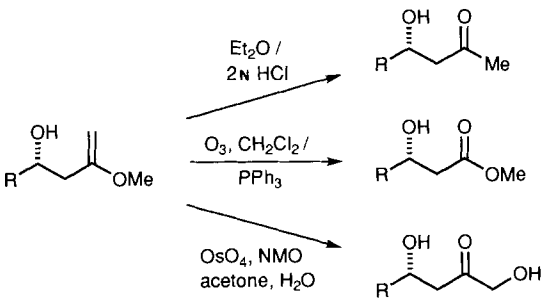
from the tridentate ligand (*R*)-**1** and $Ti(OiPr)_4$ in a 2:1 ratio is used, the yields and enantioselectivities of the new process are generally high (Table 1). The most encouraging results, up to 98% *ee*, are obtained with α,β-ynals. Thus, this reaction offers an alternative catalytic method for the synthesis of propargylic alcohols. The reaction with benzaldehyde proceeds with only modest selectivity, 66% *ee*, which is unusual for asymmetric addition processes. The only α-branched aldehyde reported to undergo addition, cyclohexanecarboxaldehyde, affords a product with 75% *ee*.

Table 1. Yields and enantiomeric excesses of the Ti-catalyzed asymmetric carbonyl–ene reaction [5] (see Scheme 1).

Aldehyde	Yield [%] [a]	*ee* [%] [a]
$Ph(CH_2)_3-C\equiv C-CHO$	99	98
$TBSOCH_2-C\equiv C-CHO$	85	93
$Ph-C\equiv C-CHO$	99	91
$Ph(CH_2)_2CHO$	98	90
PhCHO	83	66
$C_6H_{11}CHO$	79	75

[a] The corresponding β-hydroxy ketones, which were obtained by treatment of the reaction mixture with Et_2O/2N HCl, were isolated and analyzed.

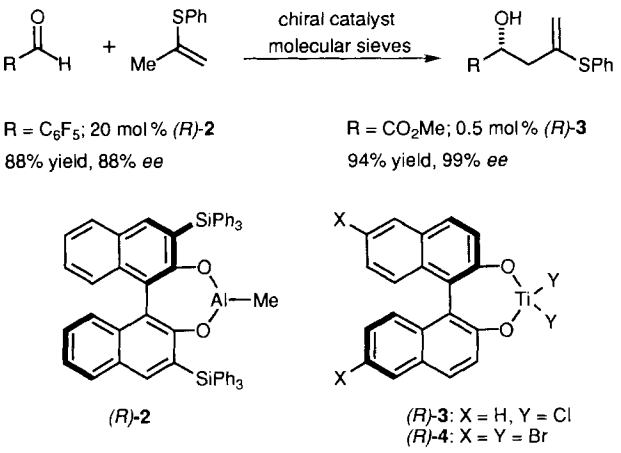
The vinyl ethers obtained from asymmetric ene reactions are valuable precursors for synthetically important optically active compounds (Scheme 2). Acid hydrolysis affords the corresponding methyl ketones, thus providing an alternative to asymmetric methyl ketone aldol additions.[5, 6] Oxidative cleavage of the enol ethers with ozone affords the corresponding β-hydroxy esters, and osmium-catalyzed dihydroxylation with *N*-morpholine-*N*-oxide (NMO) gives ketodiols.



Scheme 2.

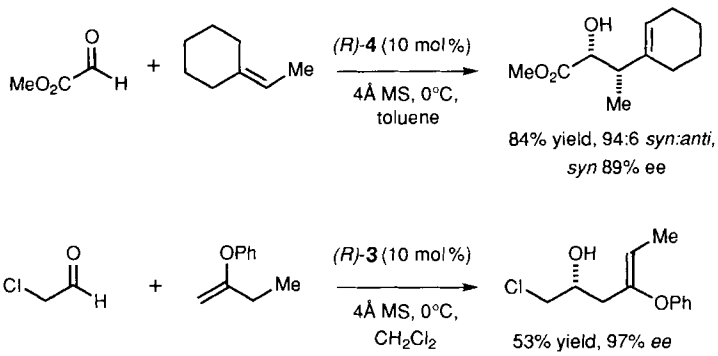
The recent work by Carreira et al. is an extension of earlier studies[5] in which a titanium(IV) catalyst prepared in situ from the tridentate ligand (*R*)-**1** and $Ti(OiPr)_4$ was used to achieve Mukaiyama aldol additions with high enantioselectivities. The chiral ligand used in both the ene and aldol chemistry is prepared from 3-bromo-5-*tert*-butylsalicylaldehyde and 2-amino-2′-hydroxy-1,1′-binaphthol. This enantiomerically pure amino alcohol is obtained from the convenient oxidative coupling procedure[7] of Smrčina et al. We expect further applications of this valuable chiral biaryl ligand.

Usually intermolecular ene reactions of simple aldehydes with otherwise inactivated 1,1-disubstituted alkenes require stoichiometric amounts of powerful Lewis acids.[1] Therefore, asymmetric variants using milder Lewis acids as catalysts have been restricted to especially reactive aldehydes in intermolecular processes or to intramolecular reactions. For example, Yamamoto et al. used the aluminum-based chiral Lewis acid (*R*)-**2** in catalyzed asymmetric carbonyl–ene reactions (Scheme 3).[8] However, the choice of enophile is limited to highly electron-deficient aromatic aldehydes such as pentafluorobenzaldehyde and chloral. Both simple 2,2-disubstituted alkenes and vinyl sulfides undergo enantioselective reaction with a maximum *ee* of 88% even with catalytic quantities (20 mol%) of the Lewis acid.



Scheme 3.

The asymmetric carbonyl–ene reaction has also been developed further by Mikami et al.[1b, c] The reaction of glyoxylate enophiles with the readily available Lewis acids $[TiX_2BINOL]$[9] (X = Cl, Br), for example (*R*)-**3** (Scheme 3), gives outstanding enantioselectivities. Many of the earlier developments have been thoroughly reviewed.[1] However, a number of important recent advances are worth highlighting.[10–15] Extremely low catalyst loadings (0.5 mol%) can be used with vinyl sulfides and selenides in the glyoxylate–ene reaction.[10] Changing the Lewis acid to (*R*)-**4** enables certain trisubstituted alkenes to be used with excellent enantio- and diastereocontrol.[11] Vinyl ethers, which are more reactive than their thioether counterparts, undergo ene reactions with high enantioselectivities when (*R*)-**3** is employed as catalyst.[12] Thus, addition of 2-phenoxybutene to chloroacetaldehyde in the presence of 10 mol% of (*R*)-**3** gives the corresponding ene product in 53% yield with 97% *ee* (Scheme 4).[12] Under these Lewis acidic conditions phenoxy

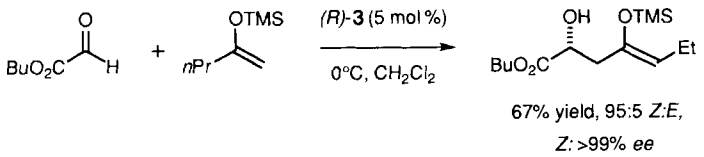


Scheme 4. MS = molecular sieves.

ethers are more stable than the corresponding hexyl and methyl ethers.

Owing to the impressive levels of stereocontrol achieved with this method, a number of concise syntheses[1] of important bioactive targets can be devised. Recent studies by the Mikami group focus on two fragments of the immunosuppressant rapamycin[13] and the prostacyclin analogue isocarbacylin; the latter application is notable for using a formaldehyde–ene reaction.[14]

An ene mechanism is also implicated in the asymmetric "aldol" additions of ketene silyl acetals of thioesters to aldehydes[15] and of silyl enol ethers to glyoxylate esters (Scheme 5).[16] The lack of accompanying silyl transfer is in contrast to other asymmetric Mukaiyama-type aldol reactions.[17]



Scheme 5.

The new methods developed by Carreira, Mikami, and others widen the scope of asymmetric catalytic ene reactions. Studies on new catalysts[18] often provide the necessary mechanistic insights from which further developments in reaction protocol ensue. With a high degree of confidence we can predict that discoveries of even more practical chiral Lewis acid catalysts, displaying wider substrate tolerance and requiring lower catalyst loadings, will continue apace.

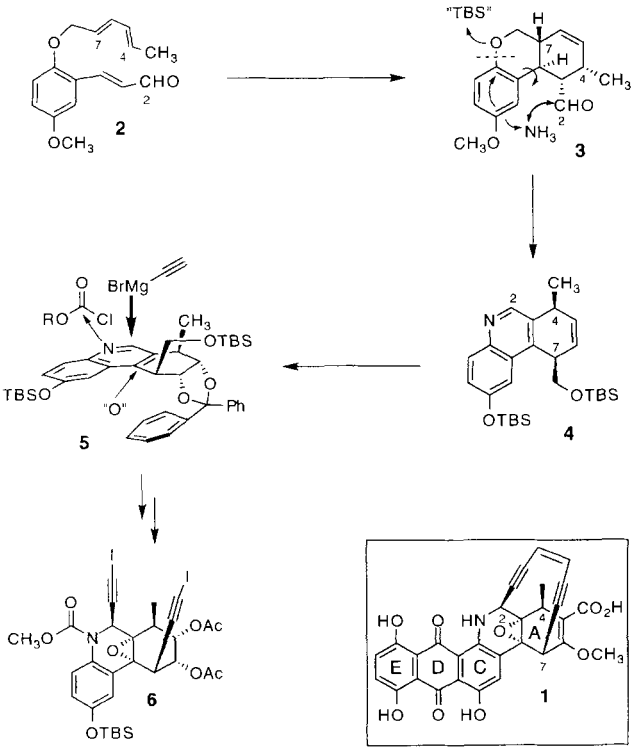
Total Synthesis of (±)-Dynemicin A**

Matthew D. Shair,* Tae-young Yoon, and Samuel J. Danishefsky

Dynemicin A (**1**) (Scheme 1), a metabolite isolated from *Micromonospora chersina*, which has DNA cleaving capacity and demonstrated in vitro antitumor properties, has elicited a great deal of excitement among chemists.[1] While it is not likely to be developed as a drug (owing to issues of abundance, formulatability, and biological specificity), the interest in dynemicin is sustained by its fascinating structure. Questions as to the mechanism of its bioactivation,[2] the search for simpler analogues that retain the central motif of dynemicin,[3] and the need to catalog modalities of recognition of the drug by DNA targets, continue to engender research.[4]



Scheme 1. Synthesis of diiodoalkyne **6**. TBS = *tert*-butyldimethylsilyl.

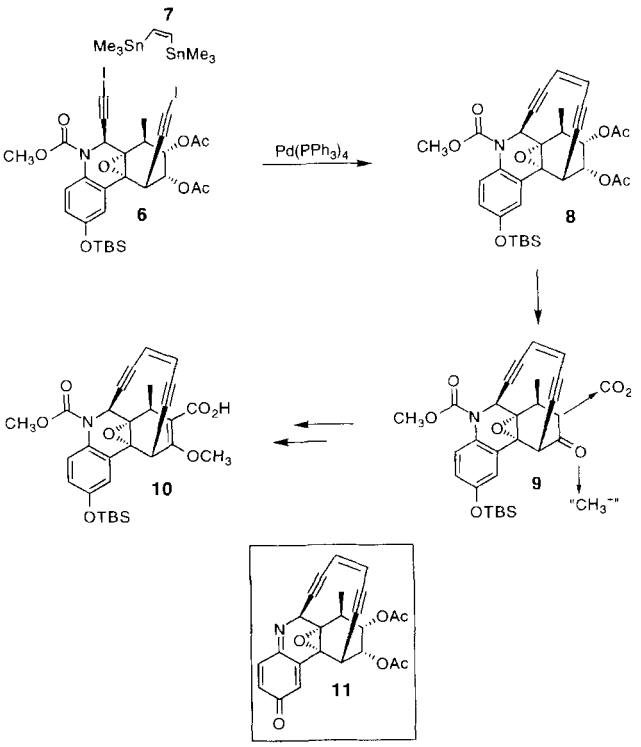
[**] This work was supported by the National Institutes of Health (grant CA 28824) and by the Memorial Sloan-Kettering Cancer Center (predoctoral fellowship to M. D. S.). We thank Dr. I. J. Kim for the preparation of bromoarene **17**, and Dr. Dolatrai M. Vyas of Bristol-Myers Squibb Pharmaceutical Research Institute for supplying an authetic sample of dynemicin A.

No less challenging is the issue of total synthesis. Major progress in this domain was registered by Schreiber et al., who first demonstrated methods for constructing truncated versions of dynemicin, lacking the anthraquinone sector.[5a] Eventually, these studies culminated in a striking synthesis of protected versions of dynemicin.[5b] Even in the face of these large accomplishments, the novelty of the dynemicin molecule continued to elicit new conjectures at the level of synthesis. The goal of preparing dynemicin in its full and exquisite structural detail continued to be worthy of attention.

Our own efforts were initially directed toward exploring some fresh departures which might eventually accomplish such a total synthesis. We demonstrated that an intramolecular Diels–Alder reaction could be used to dictate the *cis* stereochemical relationship of C-4 and C-7 (dynemicin numbering) (see **2** → **3** → **4**, Scheme 1) in pre-dynemicin structures.[6] We learned how to functionalize the C5–C6 double bond, not only for developmental purposes regarding the synthesis, but also for implementing the required stereochemical disposition of C-2 and C-7 (see **4** → **5** → **6**, Scheme 1).[6, 7] A rather new reaction type, the palladium-mediated cross-coupling reaction of a diiodoalkyne with a (*Z*)-distannylethene (see **6** + **7** → **8**, Scheme 2) was implemented to assemble the enediyne linkage.[7] In due course, we learned how to fashion the β-ketoacid enol ether moiety at C-5 and C-6 (see **8** → **9** → **10**).[7]

The time was at hand to deal with installation of the CDE trihydroxyanthraquinone ensemble. Toward this end, we reported a method for synthesizing a quinone imine of the type **11** (Scheme 2).[3a] This quinone imine linkage readily undergoes

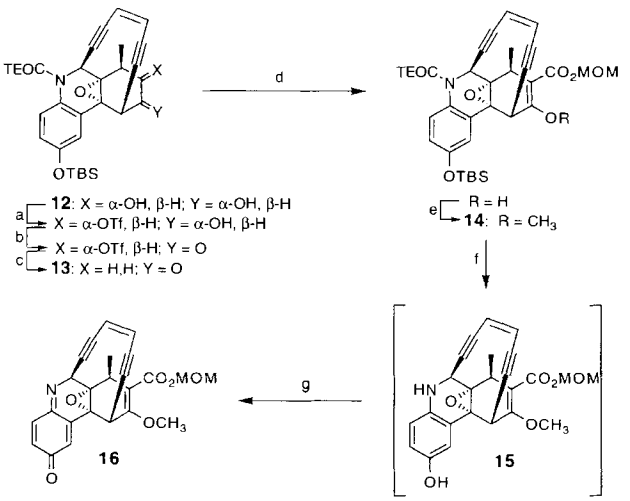


Scheme 2. Synthesis of enediyne **10**.

cycloaddition reactions of pertinence to the construction of the anthraquinone segment.

Concurrently with our own work, although through totally different premises, Myers and associates disclosed the synthesis of a closely related quinone imine[8] and also demonstrated its amenability to cycloaddition with dienes of relevance to the "DE problem."[9] Indeed, in a striking accomplishment, the Caltech workers announced the first total synthesis of dynemicin A by Diels–Alder reaction of a quinone imine with a suitable isobenzofuran. This cycloaddition was followed by eventual oxidative development of the DE system and unveiling of the C5–C6 functionality.[9]

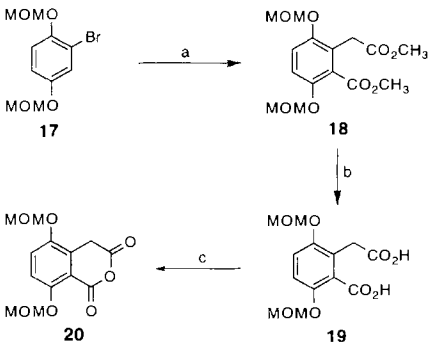
We describe here the culmination of our own efforts leading to a total synthesis of dynemicin A (**1**). We report the application of a rather different annulation strategy for the conversion of quinone imine **16** (Scheme 3) to dynemicin A. The construction of the anthraquinone follows a concise route and should be applicable to the synthesis of congeners of dynemicin or other classes of anthracycline-based antitumor agents.



Scheme 3. Synthesis of quinone imine **16**. a) 1.8 equiv Tf_2O, 40 equiv C_5H_5N, CH_2Cl_2, −20 °C, 1 h (95%); b) 3.0 equiv Dess–Martin periodinane, CH_2Cl_2, 25 °C, 2 h (91%); c) 7.0 equiv $CrCl_2$, THF, 25 °C, 2 h (75%); d) 5.5 equiv $MgBr_2$, 30.0 equiv Et_3N, CO_2, CH_3CN, 25 °C, 2.5 h, then 7.0 equiv MOMCl, 50.0 equiv iPr_2NEt, THF, 25 °C, 5 min (60%); e) excess CH_2N_2, MeOH, 0 °C, 1 h (70%); f) 5.0 equiv TBAF, THF, 0 °C, 3.5 h; g) 5.0 equiv $PhI(OAc)_2$, 0 °C, 0.5 h (60%). TEOC = trimethylsilylethoxycarbonyl, TBAF = tetra-*n*-butylammonium fluoride.

The synthesis started with compound **12**[3a] (Scheme 3) which was converted to ketone **13** and thence to **14**, in which C-5 and C-6 have been suitably functionalized.[7] Simultaneous removal of the two blocking groups TEOC and TBS generated the highly labile, uncharacterized tetrahydroquinolinol derivative **15**, which was immediately oxidized to provide **16**.[10]

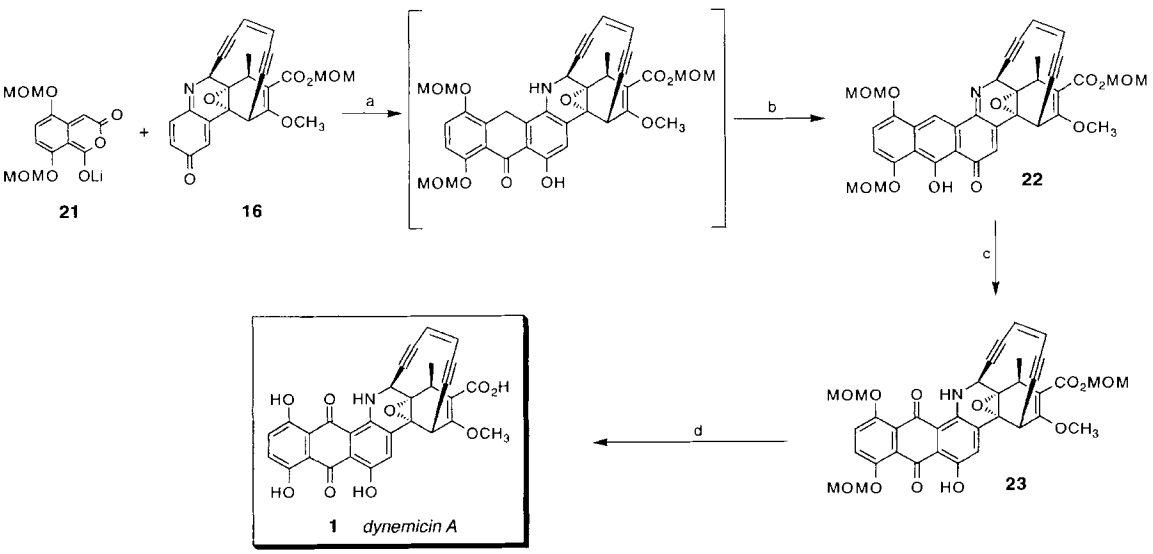
The synthesis of the protected homophthalic anhydride **20**, which would deliver the DE segment of dynemicin A, is denoted in Scheme 4.[11] Doubly MOM-protected bromoarene **17** was



Scheme 4. Synthesis of homophthalic anhydride **20**. a) 1.2 equiv $CH_2(CO_2CH_3)_2$, 2.4 equiv LiTMP, THF, −78 °C, 30 min (71%); b) 20 equiv KOH, H_2O, MeOH, reflux, 3 h (91%); c) TMSC≡COEt, CH_2Cl_2, 25 °C, 2 h (100%). LiTMP = lithium tetramethylpiperidide.

condensed with the lithium salt of dimethylmalonate and lithium tetramethylpiperidide (LiTMP) at low temperature. The homophthalic ester **18** formed immediately, presumably arising from the addition of lithium dimethylmalonate to the benzyne followed by intramolecular carboxylation of the resulting aryl anion.[12] Saponification of the diester **18** led to the formation of dicarboxylic acid **19**, which was dehydrated with ethyl trimethylsilylethynyl ether to provide the desired anhydride **20** in high yield.[13]

After much experimentation, we developed a workable annulation sequence (Scheme 5).[11] Treatment of **16** with the anion



Scheme 5. Anthraquinone annulation sequence and deprotection of **23** to provide dynemicin A (**1**). a) 5.0 equiv 2,5-bis(methoxymethyl)-homophthalic anhydride, 4.8 equiv LHMDS, 0 °C, 1 h; b) 7.0 equiv $PhI(OCOCF_3)_2$, THF, 0 °C, 5 min; c) air, high concentration, 25 °C, daylight, THF, 24 h; d) 15 equiv $MgBr_2$, Et_2O, 0–25 °C, 36 h (15% yield over 4 steps). LHMDS = lithium 1,1,1,3,3,3-hexamethyldisilazane.

21, derived from doubly MOM-protected homophthalic anhydride **20**, followed by oxidation with phenyliodondium bis(trifluoroacetate) resulted in a substance which we provisionally formulate as **22**.[14] The proposal advanced in Scheme 5 for the progression from **16** to **22** should be implemented in a formal rather than a chronological context. When a highly concentrated solution of **22** in THF was exposed to the action of oxygen and daylight, a violet-red product presumed to be the protected goal structure **23** was obtained.[15] Deprotection of **23** afforded dynemicin A (**1**). The ^{1}H NMR spectrum and TLC properties of the synthetic material matched those of an authentic sample. The relative configuration at C-4 had been independently verified by crystallography at an earlier stage.[6] The comparisons with the severely limited authentic material available, the nature of the steps, and the inherent properties of our final product, fully establish that (±)-dynemicin A (**1**) had been synthesized. Studies directed to higher yielding anthraquinone annulation protocols are underway. Also, with increased quantities of dynemicin now available to us by synthesis, investigations of some of the bioorganic issues identified above have already been initiated.

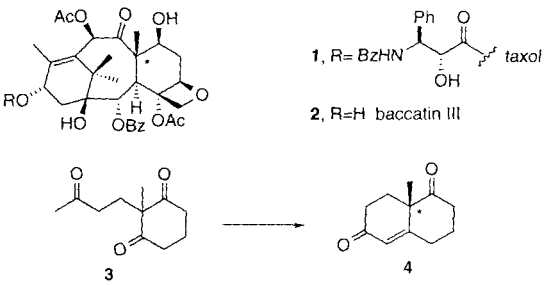
[14] The direct product of the cycloaddition between **16** and **21** prior to oxidation may also exist as the anthracenol rather than the anthrone as depicted. In addition, the C ring may have not undergone aromatization. However, the spectroscopic properties observed for the product following in situ oxidation would fit **22**.

[15] For the conversion of anthracenols to anthraquinones in the presence of ground-state oxygen and light, see: D. W. Cameron, P. E. Schultz, *J. Chem. Soc. C.* **1967**, 2121; P. L. Julian, W. Cole, G. Diemer, *J. Am. Chem. Soc.* **1945**, *67*, 1721.

A Total Synthesis of Taxol**

John J. Masters,* J. T. Link, Lawrence B. Snyder, Wendy B. Young, and Samuel J. Danishefsky

Taxol (**1**) is a clinically useful antitumor agent. First approved for the treatment of ovarian cancer, it is currently being evaluated for efficacy against a broader range of tumors.[1] The combination of the beneficial chemotherapeutic effects of taxol, its limited availability from phytochemical sources, and its novel, multifunctional structure has stimulated a great deal of interest among organic chemists.[2] The accessibility of taxol (**1**) was improved by the development of several efficient acylation sequences commencing with baccatin III (**2**, Scheme 1).[3] Since this compound is reasonably available from renewable plant sources, it is improbable that total synthesis will ever impact the availability of **2**. Thus, questions pertaining to strategy, reaction development, and access to certain classes of analogs rather than a solution of the taxol "supply problem" fuel interest in these targets.



Scheme 1.

Indeed, the challenge associated with assembling baccatin III (**2**) in the laboratory has brought forth a myriad of fascinating ideas. Most of the published works have centered on issues relating to the elaboration of the ABC ring system. Fewer have provided sound prospects for appropriate functional group development. In early 1994, Nicolaou et al. and Holton et al. reported the first and only total syntheses of baccatin III and taxol in virtually concurrent disclosures.[4, 5] The steep barrier that separates a comprehensive solution (total synthesis) from advances of a more local nature had been surmounted. Here, we report our total synthesis of baccatin III (**2**) and thence, by well-known steps, of taxol (**1**) itself.[3]

Since our synthesis also requires a multistep sequence, it does not constitute a plausible alternative to phytochemical routes to **2**. However, the synthesis described herein has the merit of not relying upon resolutions, synthetic relays, or on difficultly accessible starting materials for entering the "chiral pool". In fact, in our program, all asymmetric induction ultimately accrues from

(*S*)-Wieland Miescher ketone **4**, which, in turn, arises from the catalytically induced enantioselective aldol condensation of the prochiral trione **3** (Scheme 1).[6] Another distinguishing element of our synthesis is an early introduction of the oxetane moiety by displacement of a leaving group at C-5 with a hydroxymethyl nucleophile stationed at C-4 (Scheme 2).[7] This protocol, which we first demonstrated on a fully functionalized C ring,[8] found application at late stages in each of the first two total syntheses. Early emplacement of the oxetane seemed to offer the advantage of enhancing the convergency of the total synthesis.

As described earlier with racemic material, **4** was converted to ketone **5** by classical, high-yielding steps.[9] A significant improvement in the conversion of **5** to the previously described **6** was achieved as shown in Scheme 2.[10] Compound **6** was then converted to the oxetane **7** and thence to the ketone **8** by known methods.[7] The B ring of the latter was cleaved in an easily conducted, high-yielding sequence to produce aldehyde acetal **9**.[11]

In related efforts to assemble a baccatin–cholesterol hybrid, the dienyl iodide **10** was prepared and lithiated to provide **11** (Scheme 3).[11a] In that simpler setting, the equivalence of **11** and the hypothetical **12** had been demonstrated. However, it was unclear that joining **10** (via **11**) and **9** would be feasible in the presence of the labile oxetane. After much effort, an efficient coupling leading to **13** was accomplished under the conditions shown.

The strategy of connecting suitably functionalized A and C fragments (in this case A and CD) to build 1,2-constrained

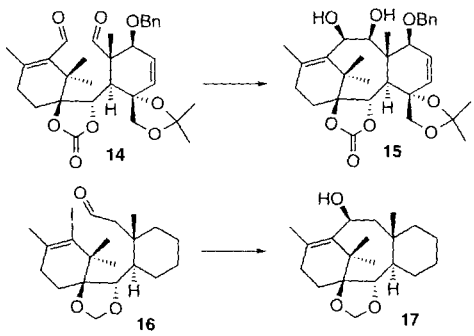
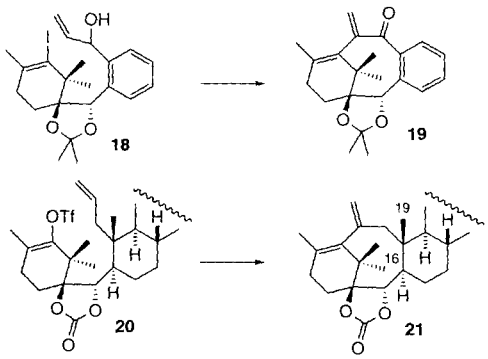
seco-B structures en route to closure of the B ring, had been implicit in our earliest publications in the taxol area.[12] Clearly the idea was central to the Nicolaou total synthesis (see Scheme 4, **14** → **15**), in which the C9–C10 bond was closed through a pinacol construction.[5] In our work, we studied possible C10–C11 closures of highly functionalized substrates. This



Scheme 4.

possibility was being investigated concurrently by Kishi and associates who pursued, broadly speaking, a Barbier-type bond formation (specifically focusing on Ni^{II}/Cr^{II}-induced closures of a C-10 aldehyde and a C-11 vinyl nucleophile; see **16** → **17**).[13] While we could reach intermediates that were substrates for this and analogous Barbier reactions, we were never able to achieve such a closure in syntheses of either the baccatin–cholesterol hybrid or baccatin itself.

We had also investigated the possibility of closing the C10–C11 bond through an intramolecular Heck reaction.[14] The first indications of feasibility were recorded in the construction of an aryl taxane (see Scheme 5, **18** → **19**).[11c] A more convinc-



Scheme 5.

ing demonstration was achieved in the conversion of **20** to **21**. Here, ring formation succeeded despite the emerging abutment of the methyl groups at C-16 and C-19.[11a] The question remaining was whether this chemistry could be conducted with highly functionalized baccatin III precursors containing the oxetane ring.

After considerable experimentation, advances toward our goal were achieved (Scheme 6). Directed epoxidation of **13** was accomplished,[15] as was subsequent reduction to **22**. Particularly challenging, in the highly hindered and marginally stable setting of **22**, was the efficient protection of the C-1 and C-2 hydroxyl groups. This too was realized (see compound **23** and

its subsequent conversion to ketone **24**). Given the dense array of functional groups in **24**, its conversion to vinyl triflate **25** was gratifying. Cleavage of the dimethylacetal linkage was conducted and elongation afforded **26**. The critical reaction was now at hand. The Heck ring closure was achieved on a highly functionalized substrate (**26** → **27**).

In reaching **27** we had deliberately relied on a robust *tert*-butyldimethylsilyl (TBS) protecting group at C-7. Preliminary studies revealed that the silyl ether could not be readily removed when the functionality in the core tetracyclic structure became more complex.[16] Accordingly, **27** was converted to the triethylsilyl (TES) ether **28** (Scheme 7). In related work on the

[3c].

construction of a baccatin III–steroid hybrid we showed how to accomplish the unexpectedly difficult conversion of the diene unit to the required functionality.[17] In the present case, the reaction sequence was initiated with epoxidation leading to **29**. The status of the oxygen substituent at C-4 was changed from benzyl ether to acetate (**29** → **30**). Phenylation of **30**, following valuable precedent, afforded benzoate **31**.[4, 5, 18] The *exo*-methylene group was cleaved to provide **32** as indicated. Deoxygenation of the oxirane was accomplished with samarium diiodide in the presence of acetic anhydride.[19] Oxidation at C-9, followed by an α-ketol interchange and acetylation provided **33**.[4] From here, allylic oxidation followed by reduction afforded 7-triethylsilyl baccatin III (**34**)[5] and thence, following deprotection, to baccatin III (**2**) itself.[20] Also, for the sake of the record, we repeated the Ojima protocol for the introduction of the side chain, thus completing the total synthesis of taxol (**1**).[3c]

These studies, featuring a remarkable intramolecular Heck reaction (**26** → **27**) to establish the core tetracyclic system, have demonstrated new and, perhaps, unsuspected capacity to carry the oxetane through complex maneuvers. As such, this chemistry is likely to be influential in accomplishing totally synthetic ventures to simpler taxol analogs.

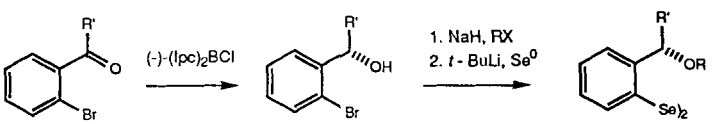
Asymmetric Reaction of Arylalkenes with Diselenides**

Thomas Wirth*

Reactions for the functionalization of non-activated C=C double bonds are an integral part in the repertoire of the synthetic chemist; however there are not many stereoselective variants of these reactions.[1, 2] Stoichiometric addition reactions of chiral reagents can be used advantageously for asymmetric synthesis, especially since some of these adducts can also be further functionalized. Functionalizations of non-activated alkenes with selenium compounds, in particular, offer attractive possibilities. However, so far only a few asymmetric variants of these reactions are known since the chiral precursors can only be prepared by multistep syntheses with low overall yields.[3, 4]

In the following new and readily accessible chiral diselenides will be described, which show interesting stereoselectivities on addition to alkenes. After activating the diselenides by conversion into selenium cations, the alkenes are added in the presence of a nucleophile, and subsequently the addition products can be isolated in good yields. The selenium compounds obtained in this way are suitable for further reactions.[5] Since they are potential radical precursors, the whole palette of radical reactions is available. Deprotonation of the selenides in the α-position to the selenium and oxidative elimination offer possibilities for further functionalizations.

The diselenides (*S*,*S*)-**2** are synthesized from the chiral alcohols (*S*)-**1**,[6] which are obtained by reduction of the ketones with (−)-*B*-chlorodiisopinocampheylborane [(Ipc)$_2$BCl] in enantiomeric excesses of 93–96%.[7] The ketones are accessible by Grignard reaction from 2-bromobenzaldehyde and the subsequent oxidation with chromium(VI) oxide.[8] After alkylation of **1** (only if the desired product is **2**, R ≠ H) the resulting product is lithiated and worked up oxidatively after the addition of elemental selenium. The chiral diselenides **2** are isolated in overall yields of 50–60%.



A (*S*)-**1** (*S*,*S*)-**2**

The diselenides **2** were initially treated with bromine to yield the bromides, which were subsequently allow to react with silver triflate to give the more reactive triflates. Coordination of the oxygen of the OR group to the selenium cation leads to the formation of a heterocycle in a fixed conformation; on addition of the alkene the chirality is transferred to the newly formed asymmetric centers. This is confirmed by analysis of the addition products **3**. For the diselenides **2a**–**2d** (R′ = Me, Table 1) the ability of the oxygen to coordinate to selenium is influenced by the size of the substituents R: the larger the substituent R the weaker the coordination of oxygen to selenium and therefore the weaker the inducing effect on the newly formed stereocenter. Thus, compound **2a** with R = H shows the highest diastereoselectivity on addition to styrene. A further indication of the coordinative effect is revealed by the ^{77}Se NMR shifts of the diselenides: the signal of the diselenide **2a** at δ = 446 is shifted

Table 1. Reaction of (*S*,*S*)-diselenides with styrene to give the addition products **3**.

Diselenide	R	R′	^{77}Se NMR [a]	*T* [°C]	Yield **3** [%]	*de* [b] **3** [%]
2a	H	Me	446	−78	70	77

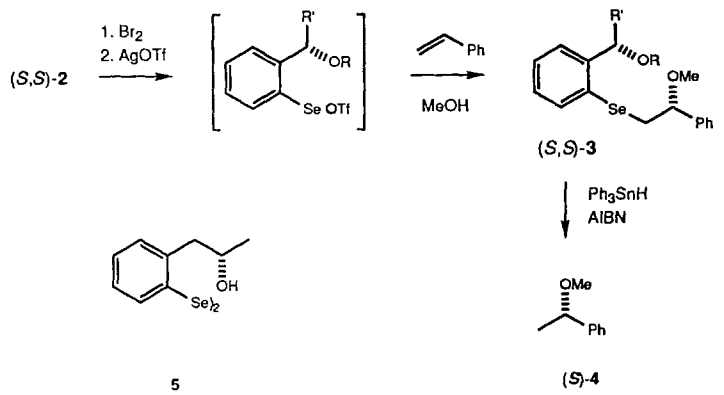
by approximately 30 ppm to lower field in contrast to that of **2d** ($\delta = 414$). The diastereomeric ratios of the addition products **3** were determined by ^1H and ^{13}C NMR spectroscopy as well as by GC analysis[7] of the cleavage products **4**.[9] In a separate synthesis of (*S*)-**4**[10] it could be shown that the *S*-configurated center in **2** induces an *S*-configuration of a new asymmetric center in **3**, thus the main diastereomer of the addition products **3** is (*S*,*S*)-configurated. The diastereoselectivity of the addition reaction is improved if the reaction temperature of $-78\,^\circ C$ is lowered to $-100\,^\circ C$.



Unprotected hydroxy groups (R = H) thus appear to coordinate the intermediate selenium cations well. An ethoxymethoxy substituent in **2e** which, in principle, contains two oxygen atoms capable of coordinating to selenium causes no increase in the diastereoselectivity in the addition reaction. The position of the hydroxy group in the side chain in the diselenide **5** is varied, and the coordination no longer leads to the formation of a five-membered ring but a six-membered ring. Because of the evidently greater flexibility of the conformation, the diastereomeric excess decreases on the addition to styrene to approximately 4:1 (60% *de*).

In contrast, if the steric demand of R' in the diselenides **2** with R = H is altered, a better side selectivity than in **2a** is achieved for **2f** with R' = Et and **2g** with R = *n*Pr for the addition to styrene; the diastereomeric ratio increases up to 16:1 (88% *de*, Table 2). For **2h** with R = *t*Bu this ratio decreases to about 2:1 (35% *de*). This effect is presumably based on the steric strain of the five-membered ring, which is formed by coordination of the oxygen atom to selenium.

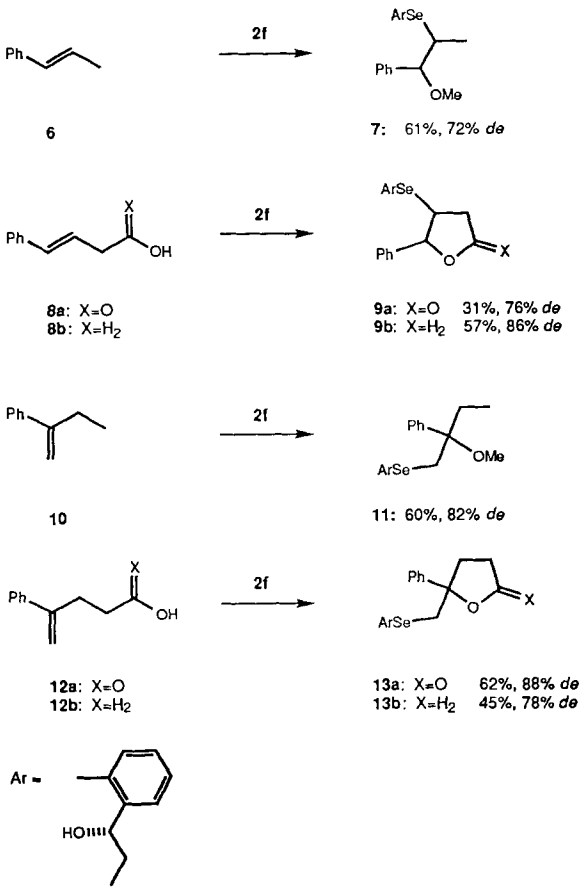
Table 2. Reaction of (*S*,*S*)-diselenides with styrene to give the addition products **3**. $T = -100\,^\circ C$.

Di-selenide	R	R'	^{77}Se NMR [a]	Yield **3** [%]	*de* [b] **3** [%]
2a	H	Me	446	67	83
2f	H	Et	456	53	88
2g	H	*n*Pr	456	54	87
2h [c]	H	*t*Bu	[d]	33	35

[a] and [b] See Table 1. [c] Compound **2h** was employed as a racemate [11]. [d] Not determined.

Other arylalkenes were also treated successfully with **2f**: **2f** reacts with (*E*)-1-phenyl-prop-1-ene **6** to give the addition product **7** in 61% yield and 72% *de*; with 2-phenyl-but-1-ene **10** the compound **11** was formed in 60% yield and 82% *de*.

An intramolecular trapping of the selenonium compounds formed by addition of the electrophilic selenium species is also possible. Thus, the carboxylic acids **8a**[12] and **12a**[13] react to give the lactones **9a** and **13a**, respectively; the alcohols[14] **8b** and **12b** yield the substituted tetrahydrofurans **9b** and **13b**, respectively. The intramolecular addition of the nucleophile is preferred; even on addition of six equivalents of methanol, the alkenes **8** and **12** do not form selenium-containing products with methoxy groups. As the products **11** and **13** show, quaternary carbon centers with good asymmetric induction can be formed by the title reaction. Alkenes without aryl groups sometimes yield mixtures of regioisomers with lower diastereoselectivities.



New chiral diselenides have been presented that are readily accessible in a few steps. In the addition to arylalkenes, diastereoselectivities up to 88% were achieved. The chiral diselenides open up new routes to asymmetric syntheses through further functionalization of the addition products. The use of other nucleophiles in the addition reactions as well as the synthesis of diselenides with different coordinating heteroatoms are currently under investigation.

Experimental Procedure

Synthesis of the diselenides **2**: 1-(2-bromophenyl)alcohol **1** [or 1-(2-bromophenyl) ether **1**, OR instead of OH] (10 mmol) was placed in dry THF (100 mL) under argon at $-78\,^\circ C$ and treated slowly with *t*BuLi (30 mmol). After the mixture had been stirred for 30 min at $0\,^\circ C$, selenium (1.18 g, 15 mmol; gray) was added. The mixture was stirred for an additional 3 h at $20\,^\circ C$, then 1 N HCl (100 mL) was added. The resulting mixture was extracted three times with *tert*-butylmethyl ether, and the combined organic phases were dried with $MgSO_4$. After subsequent addition of KOH (100 mg), the solvent was removed under vacuum. Purification by column chromatography on silica (pentane: *tert*-butylmethyl ether 2:1) afforded the dise-

lenides **2** in 50–80% yields as yellow oils. Selected spectroscopic data for **2f**: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.82$ (t, $J = 7.0$ Hz, 6H), 1.65 (dq, $J = 7.0$, 7.0 Hz, 4H), 2.28 (s, 2H), 4.76 (t, $J = 7.0$ Hz, 2 H), 7.19 (dd, $J = 7.5$, 7.5 Hz, 2H), 7.33 (dd, $J = 7.5$, 7.5 Hz, 2H), 7.45 (d, $J = 7.5$ Hz, 2H), 7.75 (d, $J = 7.5$ Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 10.3$, 31.3, 74.7, 126.4, 128.3, 129.1, 130.0, 135.3, 146.5; ^{77}Se NMR (76 MHz, $CDCl_3$): $\delta = 456.1$; $[\alpha]_D^{20} = +262.0$ ($c = 1$, $CHCl_3$); correct elemental analysis for $C_{18}H_{22}O_2Se_2$.

Addition of the diselenides **2** to styrene: **2** (0.1 mmol) was placed in dry diethyl ether (4 mL) under argon at -78 °C and bromine (0.11 mmol, 0.11 mL of a 1 M solution in CCl_4) was added. After 10 min silver triflate (72 mg, 0.28 mmol) in methanol (0.1 mL) was added and the mixture was stirred for 20 min at -78 °C. The reaction solution was cooled to -100 °C and treated with styrene (0.4 mmol, 0.046 mL). After the mixture had been stirred for 2 h, *sym.*-collidine (0.3 mmol, 0.04 mL) was added, and the resultant mixture was heated to 20 °C and washed with 7% aqueous citric acid solution (5 mL). The organic phase was dried with $MgSO_4$, and after removal of the solvent under vacuum, the addition product **3** was purified by column chromatography on silica (pentane: *tert*-butylmethyl ether 3:1). Selected spectroscopic data for **3f**: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.98$ (t, $J = 7.4$ Hz, 3H), 1.79 (quin, $J = 7.4$ Hz, 2H), 2.41 (s, 1H), 3.10–3.30 (m, 2H), 3.24 (s, 3H), 4.36 (dd, $J = 8.5$, 5 Hz, 1H), 5.04 (m, 1H), 7.13–7.51 (m, 9H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 10.4$, 31.2, 36.2, 57.0, 74.7, 83.0, 126.4, 126.7, 127.6, 128.0, 128.2, 128.6, 129.7, 133.7, 140.8, 146.0; correct elemental analysis for $C_{18}H_{22}O_2Se$.

New Fluorescent Model Compounds for the Study of Photoinduced Electron Transfer: The Influence of a Molecular Electric Field in the Excited State**

A. Prasanna de Silva,* H. Q. Nimal Gunaratne, Jean-Louis Habib-Jiwan, Colin P. McCoy, Terence E. Rice, and Jean-Philippe Soumillion

The elucidation of the structure and some functions of the bacterial photosynthetic reaction center (PRC)[1] has inspired chemists to develop synthetic supramolecular systems[2] and models[3] to mimic and understand some of these natural features. One of the most intriguing features of the photosynthetic reaction center is that photoinduced electron transfer (PET) occurs preferentially along one of two nearly identical paths. Here we describe two simple systems, **1** and **2**, which display remarkably different PET behavior because of the presence of different PET paths. We infer that PET in **1** and **2** is directed by the electrical properties of the excited state itself: in other words, PET is self-regulated.[4]

We and others have shown how PET can be exploited for the design of fluorescent sensors for many analytes according to the fluorophore–spacer–receptor format.[5] While some of the factors that control PET have been uncovered in recent years,[6] the influence of regiochemistry is unknown. Regioisomers **1** and **2**[7] were designed as fluorescent PET pH sensors[8] with very different electron transfer paths; all other factors were kept as constant as possible. We report here that the influence of regiochemistry on PET is very large.

The fluorescence of compound **1a** is strongly enhanced upon protonation (Fig. 1), as required of a fluorescent PET pH sensor based on an aliphatic amine receptor.[5] PET occurs from the unprotonated amine[9] to the fluorophore and causes fluorescence quenching. The PET process stops when the amine is protonated, resulting in recovery of fluorescence. In complete contrast, regioisomer **2a**, in which the spacer–receptor unit is linked to the fluorophore through the imide, shows only a small reduction in fluorescence upon protonation (Fig. 1). This can be attributed to fluorescence quenching in the protonated, in-

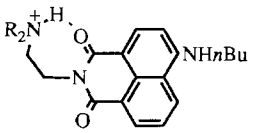
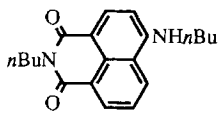
tramolecularly hydrogen-bonded structure **3**.[10] The fluorescence of the fluorophore unit is intrinsically pH-independent, as evidenced by the behavior of **4** (Fig. 1). Other parameters that



3



4

reflect the contrasting regiochemistry of compounds **1** and **2** are listed in Table 1.

The remarkably different fluorescence behavior can be easily rationalized according to Figure 2. The 4-aminonaphthalimide fluorophore in compounds **1** and **2** is a "push–pull" π electron system with the 4-amino group as donor and the naphthalimide as acceptor. This leads to strong internal charge transfer (ICT) in the lowest excited singlet state and considerable dipole character (positive pole at the 4-amino terminus).[11] The dipole moment of the excited state of the model fluorophore **4** is 11 D according to our measurements of solvent effects on its fluorescence and absorption spectra.[12] A large dipole moment in an excited state gives rise to a strong photogenerated electric field. Such a molecular electric field can, depending on its sign and magnitude, inhibit or accelerate a transiting electron in **2** or **1**, respectively.[13, 14] Thus the fluorescence quenching PET process is observed only if the electron leaving the unprotonated amine donor can enter the space of the 4-aminonaphthalimide fluorophore across the 4-position in **1** with its attractive electric field (Fig. 2). The corresponding PET path in **2** is just as feasible thermodynamically but requires the electron to enter the fluorophore across the imide moiety with its repulsive electric field and is not observed. We note that the PET process, which proceeds in opposite directions in **1** and **2** with respect to the orientation of the fluorophore, is strongly controlled by the excited state itself without the intervention of any outside agent. This self-regulation of PET is unprecedented and an important addition

[a] All the compounds (**1a–c**, **2a–c**, and **4**) were characterized by the full set of molecular spectroscopic techniques. **4** is a known compound and has been photophysically characterized [7a]. Electronic spectra (absorption and emission) were measured with 10^{-5} M solutions in aerated methanol:water (1:4, v/v), except in the studies of solvent effects; the same conditions were also used for phase modulation fluorometry. The possibility of naphthalimide ring hydrolysis was considered, but this did not occur under our conditions (pH range 4–12). pH-Dependent fluorescence measurements were carried out with excitation at isosbestic wavelengths λ_{Isos}. [b] These values were obtained by analyzing the pH dependence of the absorbance A at appropriate wavelengths with the equation $\lg[(A_{max}-A)/(A-A_{min})] = \mp$ pH $\pm$ pK_a [18]. Either set of signs on the right hand side of this equation can be valid, depending on the analytical wavelength chosen. Isosbestic points λ_{Isos} were observed for **1a–c**. [c] Obtained from fluorescence spectra which were corrected for wavelength dependence of response of the photon detection system by using quinine bisulfate [19]. [d] Rhodamine B ($\Phi_F = 0.65$ in EtOH [20]) was employed as a secondary standard. Comparison of corrected spectra was necessary since the spectrum of the secondary standard has a different shape than those of **1a–c**, **2a–c**, and **4**. [e] Factor for fluorescence enhancement induced by protons: FE = Φ_F(acid)/Φ_F(base). [f] These values are obtained by analyzing the pH dependence of fluorescence quantum yield Φ_F with the equation $\lg[(\Phi_{F,max}-\Phi_F)/(\Phi_F-\Phi_{F,min})]$ = pH – pK'_a [5a]. [g] The τ_F values in basic solution (pH 12) are 0.2 and 4.2 ns for **1a** and **4**, respectively. [h] Obtained from the following relations (J. B. Birks, *Photophysics of Aromatic Molecules*, Wiley, New York, **1970**) in acidic and basic solution: for **4**: $\Phi_F = k_F/(k_F + k_D)$ and $\tau_F = (k_F + k_D)^{-1}$; for **1a–c** with the extra PET deactivation channel, $\Phi_F = k_F/(k_F + k_D + k_{PET})$ and $\tau_F = (k_F + k_D + k_{PET})^{-1}$; for **2a–c** with the extra internal hydrogen bonding (IHB) deactivation channel, $\Phi_F = k_F/(k_F + k_D + k_{IHB})$ and $\tau_F = (k_F + k_D + k_{IHB})^{-1}$. k_F is the fluorescence rate constant; k_D is the rate constant for all the other deexcitations except PET and IHB. PET processes occur only in basic solution and IHB processes only in acidic. [i] No clear isosbestic point due to the negligible spectral shift upon protonation. [j] Cannot be determined by this method due to the small spectral shift upon protonation. [k] Cannnot be determined with this method. [l] There is no evidence for the presence of this term, and it was therefore ignored during the kinetic analysis. [m] An upper limit can be calculated as the difference of the k_D values of **2** and **4**, e.g. 0.05×10^9 s^{-1} for **2a**. Even this estimate is too high, since this can include contributions from other deexcitation processes such as those arising from solvation and/or aggregation. [n] These values refer to acidic solution. In basic solution, a value of 0.18×10^9 s^{-1} (the corresponding k_D value for model **4**) is assumed. [o] There is an additional shorter-lived component (1.0 ns) in this instance.

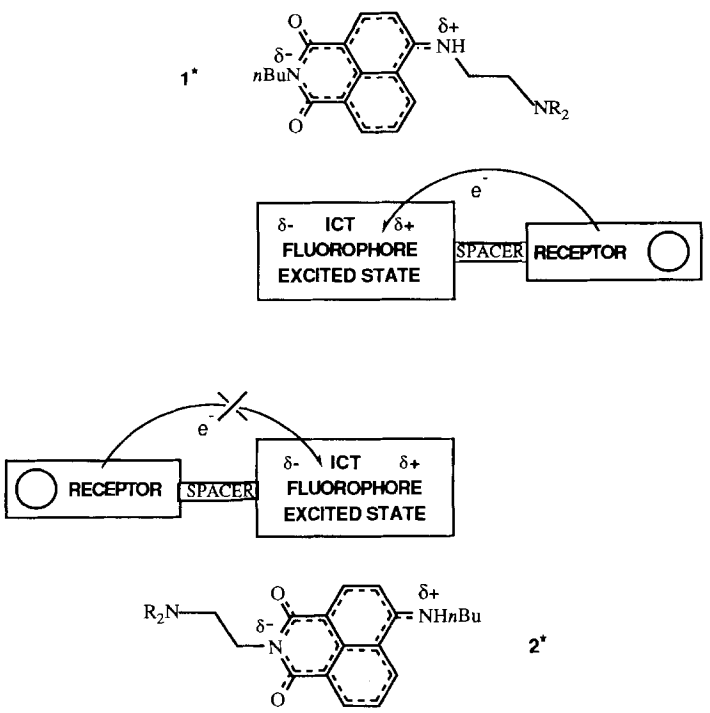

Fig. 2. Schematic representation of electron transfer to an ICT excited state of a fluorophore from an intramolecular but "external" electron donor (which is also a proton receptor) in two regioisomers. Structures of the excited states **1*** and **2*** are also shown alongside. The scheme does not distinguish between through-space or through-bond electron transfer.

to the growing number of molecular processes regulated by self-organization.[15]

Large solvent effects on fluorescence quantum yields (Φ_F) and lifetimes (τ_F) (obtained from phase modulation fluorometry[16]) are found for **1a** (Table 1) because its PET process is accelerated in polar solvents.[17] The corresponding effects are very small for the regioisomer **2a**, since PET processes are suppressed as discussed above. Model fluorophore **4**, which lacks an external aliphatic amine as electron donor, does not undergo PET processes, and solvent effects are minor.

Table 1 also gives detailed rate constants which are calculated from Φ_F and τ_F data as described in the footnotes. We estimate the PET rate in **2** to be less than $0.05 \times 10^9\ s^{-1}$, which is the difference in the k_D values (see in footnote h of Table 1) of **2** and the model fluorophore **4**, which lacks an "external" aliphatic amino group. Since k_{PET} values ranging from $1.3 \times 10^9\ s^{-1}$ to $3.3 \times 10^9\ s^{-1}$ are found for **1a–c**, we can deduce that the self-regulation of electron transfer by the ICT excited state of the 4-aminonaphthalimide fluorophore allows the discrimination between the two directions by a factor of at least 26–66.

In conclusion, the examination of the effects of pH and solvent on absorption and fluorescence behavior of **1** and **2** shows that the excited state dipole of the 4-aminonaphthalimide fluorophore can lower the kinetic barrier to electron transfer in **1** but not in **2**, since the two compounds have opposite configurations in terms of the placement of the "external" aliphatic amino group with respect to the fluorophore.

[4] With sensors **1** and **2** we were interested in demonstrating some degree of analogy with the PRC from a functional, rather than structural, viewpoint. We used two regioisomeric sensors, each of which has only one PET pathway, such that the arguments for self-regulation could be developed with maximum clarity. Two PET pathways are possible for one sensor molecule when two distinguishable dialkylaminoethyl groups are attached to the imide nitrogen and the 4-amino group of the 1,8-naphthalimide nucleus. Then the analogy with the PRC becomes apparent even in structural terms. While sensors **1** and **2** do not display symmetry breaking during PET, we note that symmetry breaking within the PRC assumes that the effects of the protein matrix and the carotenoid can be neglected. See refs. [1c,3]. We thank the referees for initiating these comments.

[7] The sensors were prepared in two stages. The derivatization of 4-chloronaphthalic anhydride with an amine to yield the corresponding 4-chloronaphthalimide is much faster than the subsequent nucleophilic aromatic substitution of the 4-chloro group by an amino moiety. Proper choice of *N,N*-dialkyl-*N*-(2-aminoethyl)amine or 1-butylamine as the reactant in the second step allows the synthesis of **1** and **2**. Synthetic procedures were adapted from a) M. S. Alexiou, V. Tychopoulos, S. Ghorbanian, J. H. P. Tyman, R. G. Brown, P. I. Brittain, *J. Chem. Soc. Perkin Trans. 2* **1990**, 837; b) Q. Xuhong, Z. Zhenghua, C. Kongchang, *Dyes Pigm.* **1989**, *11*, 13.

[8] Protons were studied in the first instance. Other guests can be studied by changing the receptor since the fluorescent PET sensor principle is quite general [5].

[9] For the unprotonated forms of both **1a** and **2a** the PET process from the aliphatic amine to the 4-aminonaphthalimide fluorophore across the dimethylene spacer has near-zero ΔG_{PET} according to the equation $\Delta G_{PET} = -E_{ox,\,fluorophore} + E_{ox,\,receptor} + \Delta G_{ion\ pair}$ [5a,b]. The oxidation potential E_{ox} of the fluorophore is 1.09 and that of the receptor 1.19 or 1.00 V (versus SCE, acetonitrile solvent; with **4** and triethylamine as models). The data for triethylamine are from H. Siegerman in *Techniques of Electroorganic Synthesis, Part II* (Ed.: N. L. Weinberg), Wiley, New York, **1975**, p. 667; C. K. Mann, K. K. Barnes, *Electrochemical Reactions in Nonaqueous Solvents*, Dekker, New York, **1970**. The attractive energy $\Delta G_{ion\ pair}$ between the radical ion pair (which is the product of the PET process) is assumed to be −0.1 V (Z. R. Grabowski, J. Dobkowski, *Pure Appl. Chem.* **1983**, *55*, 245).

[10] A. Pardo, E. Martin, J. M. L. Poyato, J. J. Camacho, M. F. Brana, J. M. Castellano, *J. Photochem. Photobiol. A Chem.* **1987**, *41*, 69, propose **3** as an explanation of the shift in fluorescence wavelength but not with regard to quenching. The presence of hydrogen bond donors near the negative pole of ICT excited states is known to result in fluorescence quenching (M. D. P. de Costa, A. P. de Silva, S. T. Pathirana, *Can. J. Chem.* **1987**, *69*, 1416). A recent report on a system closely related to **2** shows pH-independent fluorescence (D. Yuan, R. G. Brown, *J. Chem. Res. (M)* **1994**, 2346).

[12] Our measurements of solvent effects on fluorescence and absorption spectra of **4** can be analyzed with the equations $1/\lambda_{abs} = [-2\mu_0(\mu_1-\mu_0)/hca^3]\{[(\varepsilon-1)/(2\varepsilon+1)]-[(n^2-1)/(2n^2+1)]\}$ + const. and $1/\lambda_{flu} = [-2\mu_1(\mu_1-\mu_0)/hca^3]\{[(\varepsilon-1)/(2\varepsilon+1)]-[(n^2-1)/(2n^2+1)]\}$ + const.' (J. B. Birks, *Photophysics of Aromatic Molecules*, Wiley, New York, **1970**). In these equations μ_0 and μ_1 are the dipole moments of the ground and excited states, respectively, ε the solvent dielectric constant, n the refractive index, h Planck's constant, c the velocity of light, and a the Onsager cavity radius (taken to be 3.3 Å for **4**). [14] When the thermodynamic driving force for PET is calculated by the usual Weller-type thermodynamic cycle with redox potentials, ion pairing energy, and singlet energy [9], there is no opportunity to allow for the effect of the photogenerated internal electric field. This appears to be due to the fact that the internal field is only generated after photon absorption. Thus the effect of the internal field can be viewed as being largely kinetic. We are grateful to a referee for catalyzing this discussion.

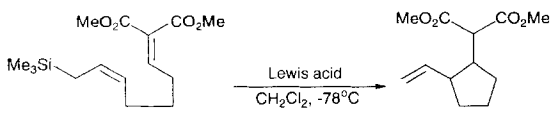
Intramolecular Allylsilane Addition to Chiral Alkylidene-1,3-dicarbonyl Compounds for the Synthesis of Enantiomerically Pure *trans*-1,2-Disubstituted Cyclopentanes and Cyclohexanes**

Lutz F. Tietze* and Christian Schünke

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

The cyclization of compounds containing an allylsilane and a carbonyl group provides a simple and elegant synthesis of five- and six-membered ring compounds.[1] In an analogous way, α,β-unsaturated ketones and aldehydes can also be converted in a type of intramolecular Sakurai reaction.[2] The simple and induced diastereoselectivities of these transformations are, however, often unsatisfactory.[3] For instance, in particular the stereoselective construction of enantiomerically pure 1,2-*trans*-disubstituted cyclopentanes has not yet been achieved successfully with this method. Such compounds are, however, of great interest for natural product synthesis.[4]

Recently we showed that racemic 1,2-*trans*-disubstituted cyclopentanes and cyclohexanes can be obtained in very good simple diastereoselectivity through intramolecular allylsilane addition from alkylidene malonates (for example, **2** from **1**); the best results were obtained with trimethylsilyl trifluoromethanesulfonate (TMSOTf) as promoter.[5]



1 **2**

TMSOTf : *trans* : *cis* = 99.6 : 0.4 ; 97 % yield

Here we describe the synthesis of enantiomerically pure *trans*-1,2-disubstituted cyclopentanes and cyclohexanes with three stereogenic centers on using the chiral malonic acid derivatives **5b–d**, which were transformed by Knoevenagel condensation with aldehydes **6** and **7** into the alkylidene-1,3-dicarbonyl compounds **8b–d** and **9d** required for the cyclization. The chiral malonic acid derivatives **5b–d** were synthesized by acylation of the oxazolidinones **4b–d**[6] with malonic acid methyl ester chloride (**3**) in the presence of 4-dimethylaminopyridine (DMAP) and triethylamine in 60–64% yield. The achiral oxazolidinone **4a** was also converted into **5a** in 90% yield. With the acid chloride **3** the conventional procedure of acylation with deprotonated oxazolidinones[7] did not lead to the products **5**, probably because in this case the primary step is a deprotonation of the malonyl chloride **3**.

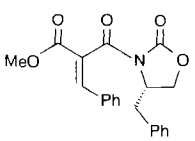
7 : $n = 2$

8 : $n = 1$
9 : $n = 2$

10 : $n = 1$
11 : $n = 2$

4, 5, 8 - 11 : **a**, R = H; **b**, R = *i*Pr; **c**, R = *t*Bu; **d**, R = Bn

The Knoevenagel condensation of **5a–d** with the aldehyde **6**, which is easily accessible from 2-trimethylsilylmethylcyclohexanone by a photochemical Norrish type I cleavage,[8] gave, in the presence of piperidine and acetic acid virtually exclusively the (*E*) isomers **8a–d** ($E:Z > 95:5$) in yields of 54–75%. The configuration of the newly formed double bond in **8a–d** was determined by NOESY measurements on **8d** as well as by comparison with **14**, which was obtained as the major product ($E:Z > 95:5$) on condensation of **5d** and benzaldehyde and characterized by X-ray crystal structure analysis.[9]



14

For the conversion of **8a–d** the Lewis acids Me_2AlCl, $EtAlCl_2$, $ZrCl_4$, $AlCl_3$, $TiCl_4$, and $SnCl_4$, as well as TMSOTf (1.0 equiv in each case) were used as promoters. During the cyclization of **8a–d** three new stereogenic centers apart from those in the auxiliary were constructed. Eight enantiomerically pure diastereomers can therefore be formed. On conversion of the achiral compound **8a**, four diastereomers are expected as

racemic mixtures. In contrast to the reaction of **1**, the use of TMSOTf in the conversion of **8d** led exclusively to the protodesilylated product. On the other hand, with the Lewis acids the cyclization was successful (Table 1).

Table 1. Lewis acid initiated allylsilane cyclization of **8a–d** to form **10a–d** and **9d** to form **11d**.

Substrate No.	R	Lewis-acid	Yield [%]	Major product	Product ratio [a]
8a	H	$SnCl_4$	80	**10a**	86/14
8b	*i*Pr	$SnCl_4$	57	**10b**	3/10/82/3/2
8c	*t*Bu	$SnCl_4$	65	**10c**	4/79/14/1/1/1
8d	Bn	$SnCl_4$	80	**10d**	95/5 [a, b]
9d	Bn	$SnCl_4$	80	**11d**	>96/4
8a	H	Me_2AlCl	92	**10a**	24/71/1/4
8b	*i*Pr	Me_2AlCl	61	**10b**	12/15/54/2/12/5

8d	Bn	$AlCl_3$	75	**10d**	86/1/11/2
8d	Bn	$TiCl_4$	61	**10d**	15/65/5/15

[a] Analytical capillary gas chromatography of the crude product. [b] ^{13}C NMR spectroscopy of the crude product. [c] Protodesilylation.

The high induced diastereoselectivity in the cyclization of **8d** and **9d** is surprising, because this is a 1,5-induction. Recently, however, we detected even a 1,6-induction with a very good simple and induced diastereoselectivity in hetero-Diels–Alder reactions.[13] Interestingly, in the hetero-Diels–Alder reaction the only auxiliary that gave good selectivities was the oxazolidinone derived from *tert*-leucine, whereas in the allylsilane cyclization of **8c** the oxazolidinone containing a *tert*-butyl group gave the worst results. At the moment it is not clear whether the particularly good results of the cyclization of **8d** with a benzyl group at the oxazolidinone can be attributed to π-stacking.[14]

We assume in the reaction of **8d** and **9d** that a reactive metal chelate complex like **15d** is first formed and that subsequently a *Si* side attack of the allylsilane moiety on the alkylidene-1,3-dicarbonyl unit forming the enolate **16d** takes place. Surprisingly,
