
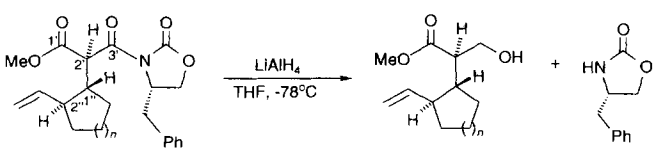
15d **16d**

The best results were obtained with $SnCl_4$ and the substrate **8d** containing the auxiliary which was derived from (*S*)-phenylalanine. Two products in a 95:5 ratio were formed in an 80% yield. The major product was **10d**, which could be obtained pure by recrystallization from ether/petroleum ether; the by-product is thought to be 2′-*epi*-**10d**. This was confirmed by the results of the conversion of the achiral substrate **8a** with $SnCl_4$, which also yielded two products, however, in an 86:14 ratio. Since the results of the cyclization of **1**[5] suggest a *trans* arrangement of the substituents on the pentane ring, the products must be the two C-2′-epimers **10a** and 2′-*epi*-**10a**.

To construct a cyclohexane derivative, **5d** was transformed selectively with (*Z*)-**7** into (2′*E*,5″*Z*)-**9d**,[10] which on reaction with $SnCl_4$ gave almost exclusively the 1,2-*trans*-disubstituted cyclohexane **11d** beside a very small amount of 2′-*epi*-**11d** (>96:4) in 80% yield. Recrystallization from ether/petroleum ether furnished pure **11d**. The configuration of the two major products **10d** and **11d** of the cyclization of **8d** and **9d**, respectively, was proved by X-ray crystal structure analyses.[11]

The chiral auxiliaries in **10d** and **11d** were removed simply by the usual methods.[12] Thus, the reduction of **10d** with $LiAlH_4$ in THF at −78 °C, for example, gave the enantiomerically pure cyclopentane derivative **12** with retention of configuration at all stereogenic centers in 77% yield; in addition **4d** could be recovered by chromatography. Similarly, **11d** was transformed into the cyclohexane derivative **13**.



10d : *n* = 1 **12** : *n* = 1 **4d**

11d : *n* = 2 **13** : *n* = 2

even the protonation to form the stereogenic center C-2′ is highly stereoselective. To test whether thermodynamic or kinetic control is operative here, we stirred **10d** and 2′-*epi*-**10d** under the reaction conditions for several days; in neither case did we observe isomerization. It must therefore be assumed that the stereogenic center C-2′ is formed under kinetic control. The possibilities suggested by this work for stereoselective protonation of enolates that are derived from **5b–d** are under investigation.[16]

Experimental Procedure

To a solution of **8a–d** or **9d** in dichloromethane (20 mL) under argon at −78 °C was added the Lewis acid (1 equiv). After two days of stirring under argon at −78 °C, the reaction was terminated by addition of a saturated aqueous solution of $NaHCO_3$ or of 2N HCl.

10d: ^1H NMR (300 MHz, $CDCl_3$): δ = 1.37 (m_c, 2H, 3″-H_2), 1.58 (m_c, 2H, 4″-H_2), 1.81 (m_c, 2H, 5″-H_2), 2.39 (m_c, 2H, 1″-H, 2″-H), 2.63 (dd, *J* = 13.5, 10.0 Hz, 1H, benzyl-CH), 3.26 (dd, *J* = 13.5, 3.0 Hz, 1H, benzyl-CH), 3.58 (s, 3H, OMe), 4.06 (dd, *J* = 9.0, 3.0 Hz, 1H, 5-H), 4.12 (dd, *J* = 9.0, 7.5 Hz, 1H, 5-H), 4.59 (d, *J* = 7.5 Hz, 1H, 2′-H), 4.65 (m_c, 1H, 4-H), 4.86 (dd, *J* = 10.0, 2.0 Hz, 1H, 2‴-H_{cis}), 4.88 (dd, *J* = 17.5, 2.0 Hz, 1H, 2‴-H_{trans}), 5.62 (ddd, *J* = 17.5, 10.0, 8.0 Hz, 1H, 1‴-H), 7.10–7.28 (m, 5H, phenyl-H). M.p. 119 °C (ether/petroleum ether), $[\alpha]_D^{20} = +48°$ (*c* = 0.6, $CHCl_3$). In the ^1H NMR spectrum of 2′-*epi*-**10d** the signal for the 2′-H appears as a doublet at δ = 4.71 with *J* = 6.0 Hz and for the methoxy group as a singlet at δ = 3.77.

11d: ^1H NMR (500 MHz, $CDCl_3$): δ = 1.18–1.29 (m, 2H, 3″-H_2), 1.32–1.42 (m, 1H, 4″-H*), 1.54 (m_c, 1H, 5″-H*), 1.69–1.82 (m, 3H, 4″-H*, 5″-H*, 6″-H*), 1.91 (m_c, 1H, 6″-H*), 2.02 (m_c, 1H, 1″-H), 2.30 (m_c, 1H, 2″), 2.60 (dd, *J* = 13.0, 10.0 Hz, 1H, benzyl-CH), 3.42 (dd, *J* = 13.0, 3.0 Hz, 1H, benzyl-CH), 3.70 (s, 3H, OMe), 4.12 (dd, *J* = 8.5, 3.0 Hz, 1H, 5-H), 4.18 (dd, *J* = 10.0, 8.5 Hz, 1H, 5-H), 4.70–4.77 (m_c, 1H, 4-H), 4.76 (d, *J* = 5.0 Hz, 1H, 2′-H), 4.95 (dd, *J* = 15.5, 2.0 Hz, 1H, 2‴-H_{trans}), 4.96 (dd, *J* = 10.0, 2.0 Hz, 1H, 2‴-H_{cis}), 5.65 (ddd, *J* = 15.5, 11.0, 10.0 Hz, 1H, 1‴-H), 7.22–7.36 (m, 5H, phenyl-H). M.p. 139 °C (ether/petroleum ether), $[\alpha]_D^{20} = +48°$ (*c* = 0.4, $CHCl_3$).

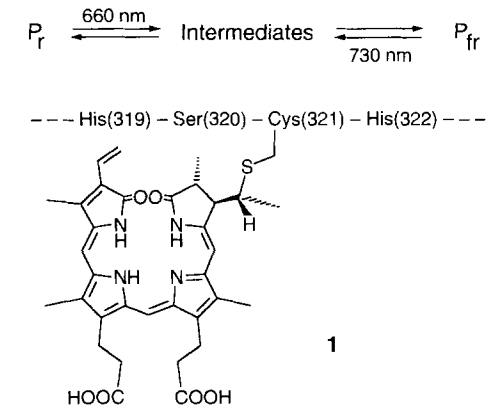
A Phycocyanobilin Seryliminoester as a New Model for the Chromophore–Protein Interaction in Phytochrome**

Ronald Micura and Karl Grubmayr*

Dedicated to Professor Albert Eschenmoser on the occasion of his 70th birthday

Phytochrome is the photoreceptor of photomorphogenesis in higher plants.[1] It exists in two forms (Pr = phytochrome red, Pfr = phytochrome far red) which differ in their absorption spectra (660 and 730 nm, respectively) and can be interconverted photochemically. Structurally, phytochrome Pr **1** is a biliprotein. It can be transformed into the physiologically active Pfr form by photoisomerization[2] and a sequence of dark reactions.[3] These dark reactions are well characterized by spectroscopy, but the structures of the intermediates involved, and that of the Pfr form itself, are largely unknown.[4]



1

Here we report on a new phytochrome model based on model compound **2**,[5, 6] whose chromophore is derived from that of the structurally related phycocyanobilin, and whose dipeptide component corresponds to the Ser(320)-Cys(321) structural component of the Pr form. The most important aspect of this model is the covalent linkage of the chromophore and the hydroxyl group of the serine to give iminoester **3**. This reaction represents a possible form of chromophore–protein interaction that has not yet been considered, and which has characteristic effects on reactivity and light absorption.

The synthesis of **3** from **2** (Scheme 1; Table 1) was carried out in a one-pot reaction and was designed on the basis of the synthesis and reactivity of oxoniaporphinato-[7] and oxoniachlorinatometal complexes.[8] The crucial change in the chromophore structure, tautomerization of the ring-A lactam into its lactim form, occurs in the first step with formation of the zinc chelate **I**. The subsequent O-acetylation serves merely to activate this chelate chemically, leading to the kinetically favored cyclization to the oxoniachlorinatozinc acetate **II** and allowing regioselective attack of the serine hydroxyl group on ring A. Decomplexation takes place during workup with aqueous sodium hydrogen carbonate.

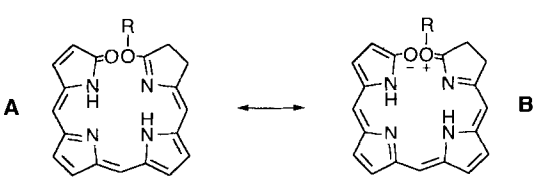
Table 1. Selected NMR spectroscopic data for compounds **2** and **3**.

2: ^{1}H NMR (360 MHz, $CDCl_3$, 25 °C, TMS): δ = 6.65 (s, 1H; H-(C10)), 5.97 (s, 1H; H-(C15)), 5.56 (s br., 1H; H-(C5)), 4.30 (ddd, ^3J(H,H) = 8.1 Hz, ^3J(H,H) = 3.9 Hz, ^3J(H,H) = 3.0 Hz, 1H; H$^\alpha$-Ser), 3.82 (dd, ^2J(H,H) = 11.0 Hz, ^3J(H,H) = 3.0 Hz, 1H; H(1)$^\beta$-Ser), 3.49 (dd, ^2J(H,H) = 11.0 Hz, ^3J(H,H) = 3.9 Hz, 1H; H(2)$^\beta$-Ser); ^{13}C NMR (90 MHz, $CDCl_3$, 25 °C, TMS): δ = 178.50 (C1), 112.38 (C10), 96.80 (C15), 92.55 (C5), 62.89 (C$^\beta$-Ser)

3: ^{1}H NMR (360 MHz, $CDCl_3$, 25 °C, TMS): δ = 11.85 (br., 1H; NH ring B), 9.98 (s, 1H; NH ring D), 6.81 (s, 1H; H-(C10)), 6.06 (d, ^2J(H,H) = 11.5 Hz, ^3J(H,H) = 0 Hz, 1H; H(1)$^\beta$-Ser), 5.90 (s, 1H; H-(C15)), 5.76 (d, ^4J(H,H) = 0.5 Hz, 1H; H-(C5)), 4.15 (dd, ^3J(H,H) = 6.9 Hz, ^3J(H,H) = 3.5 Hz, ^3J(H,H) = 0 Hz, 1H; H$^\alpha$-Ser), 3.69–3.65 (m, 1H; H(2)$^\beta$-Ser); ^{13}C NMR (90 MHz, $CDCl_3$, 25 °C, TMS): δ = 182.23 (C1), 116.65 (C10), 101.63 (C5), 97.66 (C15), 68.17 (C$^\beta$Ser)

The conversion of **2** to **3** is associated with a conspicuous color change from reddish blue to turquoise. The bathochromic shift is about 75 nm (Fig. 1, bottom) and may be explained by a donor–acceptor reversal on transformation of the ring-A lactam (N → C=O) into a lactim ether (N=C←O). In contrast to **2**, in **3** the conjugative donor–acceptor stabilization covers the entire chromophore and extends from the ring-A lactim oxygen to the ring-D lactam oxygen atom. The partial structures **A** and **B** therefore suffice for a qualitative description of electronic excitation. The porphyrin-like geometry of the chromophore leads in **A** to a short distance between the lactim ether and the



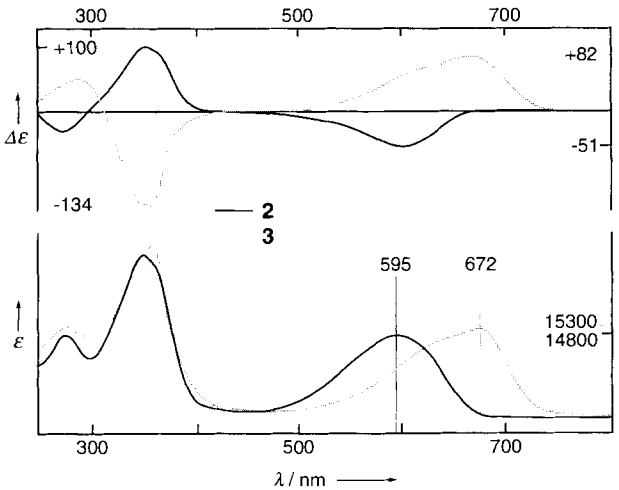


Fig. 1. CD spectra (top) and UV/Vis spectra (bottom) of **2** and **3** in $CHCl_3$ (ca. 3×10^{-5} M).

lactam and in **B** to a small (O^+/O^-) separation; the development of the electric dipole transition is therefore favored. Other experimental data also agree with this geometry: the (4*Z*,10*Z*,15*Z*,5*syn*,9*syn*,14*syn*) configuration of the chromophore can be deduced from the presence of characteristic cross peaks in the H,H-NOESY spectra;[9] the corresponding *P*-helix can be deduced from the sign alternation of the Cotton effects at 354 and 667 nm (Fig. 1, top).[10]

In view of the photochromism of phytochrome, the assumption of a seryl–ring-A iminoester allows a first experimentally supported approach to understanding the analogous chromophore–protein interaction. The model not only correctly reflects the changes in the absorption spectrum but also the possibility of the reverse reaction, which is compulsory for biological regulatory systems: hydrolysis of iminoester **3** to lactam **2** proceeds under acid catalysis within a few minutes.

A Ser(320) iminoester would be assigned a role in the reaction scheme of phytochrome as an intermediate close to the Pfr form, on the basis of its absorption properties and its chemical potential. In principle nothing speaks against the assumption that the iminoester structural element is retained even in the Pfr form itself, because **3**, like **2**, is photoisomerizable at the double bond exocyclic to ring D. This would therefore afford the photoreversibility required of a useful phytochrome model.

Calculation of the Thermodynamic Properties of Polycyclic Aromatic Hydrocarbons by an Incremental Procedure**

Karen Nass, Dieter Lenoir,* and Antonius Kettrup

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

Uniform substances are characterized by both their thermodynamic and their molecular properties.[1] After the triumphs of quantum chemistry,[2] it has been possible in the past decade to calculate the inherent molecular properties of compounds in the gas phase.[3] Certain thermodynamic properties of substances, like the melting and boiling point, the vapor pressure, and the corresponding energy values of the phase transitions, are ensemble properties of molecules and thus not accessible with these methods.[4] Apart from group theoretical procedures, several empirical methods are used for the prediction of these properties.[5] The vapor pressure and the enthalpy of sublimation of synthetic compounds (xenobiotics) are important properties relevant for the environment,[6] and a relationship between structure and these thermodynamic quantities can be used in model calculations for otherwise unknown values.

We studied the group of polycyclic aromatic hydrocarbons and found a general relationship between structure and vapor pressure, and between structure and enthalpy of sublimation. The results are based on the data from thirty polycyclic aromatic hydrocarbons containing five- and six-membered rings that are found in the environment.

The vapor pressure of several substances are known, but the quoted values vary mostly by an order of magnitude. We further developed the gas saturation method of vapor pressure determination and measured the vapor pressures and enthalpies of sublimation of the selected compounds.[9] This method can be used to measure vapor pressue over a wide range as well as in mixtures. The results of the experiments are collated in Table 1. In all cases the temperature range of between 40 and 180 °C lay well below the critical temperature for each substance. The logarithm of the value of the measured vapor pressure was plotted against the reciprocal temperature. For a linear relation this corresponds to the intergration of the Clausius–Clapeyron equation in which the temperature dependence of the enthalpy can be neglected if the measurements are made well below the critical temperature. The enthalpy of the relevant phase transition was determined from the slope of the lines.

Table 1. Vapor pressure and enthalpy of sublimation for 30 polycyclic aromatic hydrocarbons measured in the temperature range 40–180 °C in 5 °C steps; the average of three experimental values were determined at each temperature step.

	Substance	$p\,(25\,^{\circ}C)_{extrapolated}$ [Pa]	$\Delta_{sub}H_m$ [kJ mol^{-1}]

25	benzo[a]pyrene	5.30×10^{-8}	122.5
26	benzo[e]pyrene	7.89×10^{-7}	117.9
27	perylene	5.54×10^{-7}	123.2
28	benzo[g,h,i]perylene	1.01×10^{-8}	129.9
29	9,10-diphenylanthracene	1.88×10^{-8}	137.5
30	coronene	3.56×10^{-10}	143.2

The magnitude of the vapor pressure and the enthalpy of sublimation of these compounds can be derived from the structure. If naphthalene or fluorene is the reference compound, each higher homologue can be developed through the following structural features:[10]

Structural feature 1: linear *ortho* annelation
Structural feature 2: angular *ortho* annelation
Structural feature 3: angular *peri* annelation
Structural feature 4: phenyl group substitution

Each annelation step contributes a fixed increment to the magnitude of the vapor pressure and enthalpy of sublimation. The vapor pressure p at 25 °C and the enthalpy of sublimation $\Delta_{sub}H_m$ of the homologous series of polycyclic aromatic hydrocarbons can be described by Equations (a) and (b).

$$p(25\,^{\circ}C) = A\,X_1^{n_1}\,X_2^{n_2}\,X_3^{n_3}\,X_4^{n_4} \quad (a)$$

$$\Delta_{sub}H_m = B + n_1Y_1 + n_2Y_2 + n_3Y_3 + n_4Y_4 \quad (b)$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1735 $ 10.00+.25/0

In the Equations (a) and (b), n_1, n_2, n_3, and n_4 are the number of structural features 1, 2, 3, and 4; $A = 10.86$ Pa, $B = 71.7$ kJ mol^{-1} for the reference substance naphthalene; $A = 1.1 \times 10^{-1}$ Pa, $B = 84.9$ kJ mol^{-1} for the reference substance fluorene; and X_m and Y_m are constants having the values shown in Table 2.

Table 2. Values of the constants from Equations (a) and (b).

m	X_m	Y_m [kJ mol^{-1}]
1	1.29×10^{-4}	27.7
2	1.81×10^{-3}	17.7
3	2.22×10^{-2}	10.2
4	3.50×10^{-3}	18.3

The method of calculation will be demonstrated for the example of coronene (Fig. 1). The vapor pressure p at 25 °C for coronene is given as 3.58×10^{-8} and 2.01×10^{-10} Pa;[7] the published enthalpy of sublimation is 112.05 and 138.02 kJ mol^{-1}. The calculation according to Equations (a) and (b) yield a vapor pressure value of 3.4×10^{-10} Pa and an enthalpy of sublimation of 140.2 kJ mol^{-1}.

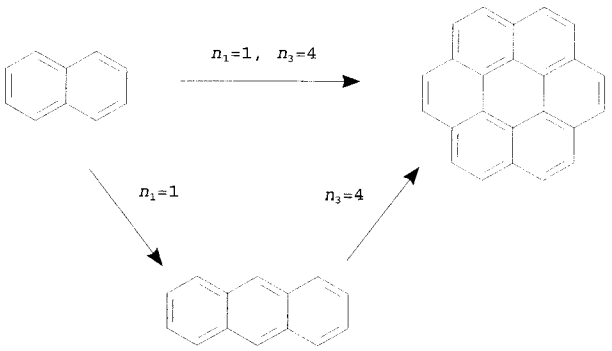

Fig. 1. Representation of the method of calculation of the vapor pressure and the enthalpy of sublimation of coronene with naphthalene as reference on the basis of Equations (a) and (b).

The results show that within a class of substances a relationship between structure and vapor pressure, and structure and enthalpy of sublimation exists.[11] To our knowledge no relationship could previously be derived for these thermodynamic parameters. The relations (a) and (b) have the mathematical form of a linear free energy relationship (LFER) somewhat like the Hammett or Hammett–Taft equation.[12] Additive relations have been derived by Benson for certain molecular properties.[13]

Thus we have shown that a relationship exists between the ensemble property of molecules and the structural elements. Through the relation between vapor pressure or enthalpy of sublimation and other thermodynamic parameters like melting and boiling points, a general derivation of thermodynamic parameters is possible.

Experimental Procedure

The measurements were performed with the VPA 434 instrument of the company Netzsch-Gerätebau, based on the gas saturation method [9a], in which a stream of inert gas flows over the sample. The saturated stream of gas is passed over an adsorption segment and after a predetermined time diverted into a gas chromatograph while heating the segment to release adsorbed substances. In this way a quantitative determination is possible. All the substances under investigation were commercially available compounds with a purity of 99.9% or greater.

The overall error of the method includes the error in calibration and the in the temperature measurement. If this error is taken into account for the linear regression of the vapor pressure curve according to $y = a + bx$, an error of $\pm 0.5\%$ is inherent in the constant a and $\pm 1\%$ in the constant b. The error in the extrapolation of the vapor pressure to 25 °C and in the calculation of the enthalpy of sublimation thus depend on the values a and b and are therefore different for each substance. Use of this error calculation with the reference substance anthracene gives a maximum error of about 36% for the extrapolated vapor pressure and about 1% for the enthalpy of sublimation. In contrast, the studies on the reproducibility for 15 measurements of anthracene yielded a standard deviation of 2.5%. The vapor pressure of anthracene therefore is 1.21×10^{-3} Pa $\pm 7.4\%$ with a statistical reliability of 99%, while the enthalpy of sublimation is 99.8 kJ mol^{-1} $\pm 1.2\%$.

The First Olefin-Substituted Peroxomolybdenum Complex: Insight into a New Mechanism for the Molybdenum-Catalyzed Epoxidation of Olefins**

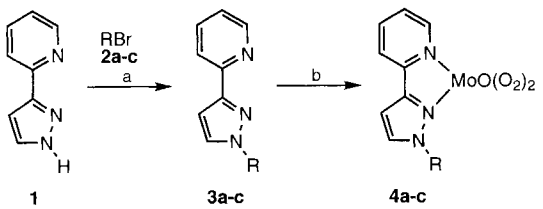
Werner R. Thiel,* and Thomas Priermeier

Dedicated to Professor Henri Brunner on the occcasion of his 60th birthday

Molybdenum complexes of type $(L-L)MoO(O_2)_2$ (L–L) = chelate ligand), with seven-fold coordination, are employed as catalysts for the epoxidation of olefins.[2] Whether these complexes function as the actual catalytic species in this commercially important reaction or as catalyst precursors is one of the central problems of the still controversial reaction mechanism.[3] Associated with this are questions as to the origin of the transferred oxygen atom, the regeneration of the catalyst, and the influence of the solvent and oxidizing agent on the rate of the reaction.

For some time our studies have focused on the design of ligands for the adaptation of known catalysts for new solvent systems. For the peroxomolybdenum complexes $(L-L)MoO(O_2)_2$, which are only sparingly soluble in most common solvents, we have succeeded, through substitution of 2-(pyrazol-3-yl)pyridine (**1**) with long-chain alkyl groups, in raising their solubility dramatically such that we may epoxidize olefins in hydrocarbon solvents.[1,4] Moreover, spectroscopic investigations into the reaction mechanism are now made possible with these soluble complexes. Indications that seven-coordinate peroxomolybdenum complexes should not epoxidize olefins in stoichiometric reactions[5] led us to the synthesis of olefin-substituted derivatives of **1**.

The synthesis of the ligands **3** was accomplished through nucleophilic substitution of bromoolefins **2** with **1**. The conversions of allyl bromide (**2a**) and 4-bromo-but-1-ene (**2b**) afforded 2-(1-allyl-pyrazol-3-yl)pyridine (**3a**) and 2-(1-but-3-enyl-pyrazol-3-yl)pyridine (**3b**), respectively, in virtually quantitative yield. Reaction of a methanolic solution of the ligand with a solution of molybdic acid in 30% H_2O_2 gave rise to the chelate complexes **4a** and **4b** (Scheme 1).



Scheme 1. a) THF, NaH, **2a–c**, 12 h, RT (**3a**: 87%, **3b**: 85%, **3c**: 55%); b) **3a–c** in MeOH, H_2MoO_4 in H_2O_2 /**4a**: 95%, **4b**: 95%, **4c**: 87%); **a**: R = $CH_2CH{=}CH_2$, **b**: R = $CH_2CH_2CH{=}CH_2$, **c**: R = cyclooct-1-enylmethyl.

Owing to their short-chain substituents, **4a** and **4b** are, however, only poorly soluble in organic solvents and are thus unsuitable for detailed spectroscopic investigations. We nevertheless succeeded in obtaining single crystals of **4a** (see Fig. 1). To increase the solubility of the molybdenum complexes **4**, we chose a methylcyclooctenyl moiety instead of a long-chain substituent, since cyclooctene is a standard substrate for investigations on olefin epoxidation (high reactivity, low tendency towards epoxide opening). The allylic precursor 1-(bromomethyl)cyclooct-1-ene (**2c**) is obtained by a five-step synthesis starting from cyclooctene.[6] The synthesis of the chelate ligand 2-[1-(cyclooct-1-ylmethyl)-pyrazol-3-yl)pyridine (**3c**) and complex **4c** proceeds analogously to that of **3a,b**/**4a,b** (Scheme 1).

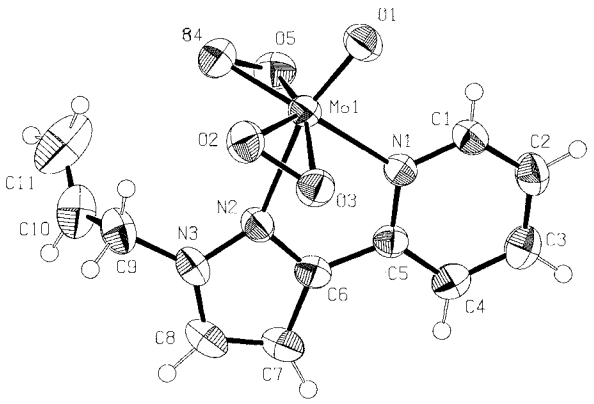


Fig. 1. Crystal structure of **4a** [7]. Selected distances [pm] and bond angles [°]: Mo-O1 167.2(1), Mo-O2 192.4(1), Mo-O3 196.3(1), Mo-O4 191.8(2), Mo-O5 194.5(1), Mo-N1 222.1(2), Mo-N2 239.1(2), O2-O3 146.8(2), O4-O5 146.9(2); N1-Mo-O1 92.37(7), N2-Mo-O1 162.72(7), N2-Mo-N1 70.49(6).

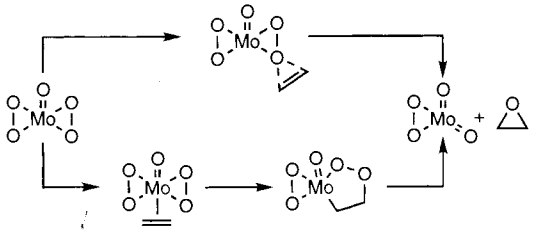
Complexes **4** exist as a mixture of two isomers. Whereas the oxo ligand adopts one of the two axial positions in the pentagonal-bipyramidal ligand sphere of the seven-coordinate Mo atom, the remaining axial position may be occupied by either the pyridine or the pyrazole ring of the ligand.[4] The single-crystal structure determination[7] of an arbitrarily selected crystal of **4a** shows the isomer with the pyrazole ring in the axial position (Fig. 1). As with all other previously known molecular structures of this type,[4,8] the Mo–N2 distance ($Mo-N_{ax}$: 239.1(2) pm) is distinctly longer than the Mo–N1 distance ($Mo-N_{eq}$: 222.1(2) pm), which may be attributed to the *trans* influence of O1. The angle N2-Mo-O1 (162.72(7)°) likewise corresponds to values found for other structures. An intra- or intermolecular interaction of the olefinic side chain at N3 with one of the oxygen ligands at molybdenum or with the central atom is not observed, even in the solid state.

The complexes **4a–c** are stable in solution as well as in the solid state. This indicates that transfer (intra- or intermolecular) of an oxygen atom from a peroxo ligand to the CC double bond does not occur for this type of complex or is otherwise very slow. This step is, however, the central element of the reaction mechanism for the olefin epoxidation discussed in the literature (Scheme 2).[3] As is shown by NMR investigations with the highly soluble compound **4c**, the cyclooctenyl ring is epoxidized only in the presence of *tert*-butyl hydroperoxide (Fig. 2).



Scheme 2. Previously accepted mechanisms for the Mo-catalyzed epoxidation of olefins [3].

[**] Metal-Catalyzed Oxidations, Part 3. We thank Professor W. A. Herrmann and the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Peroxidchemie") for support of our work. Part 2: ref. [1].

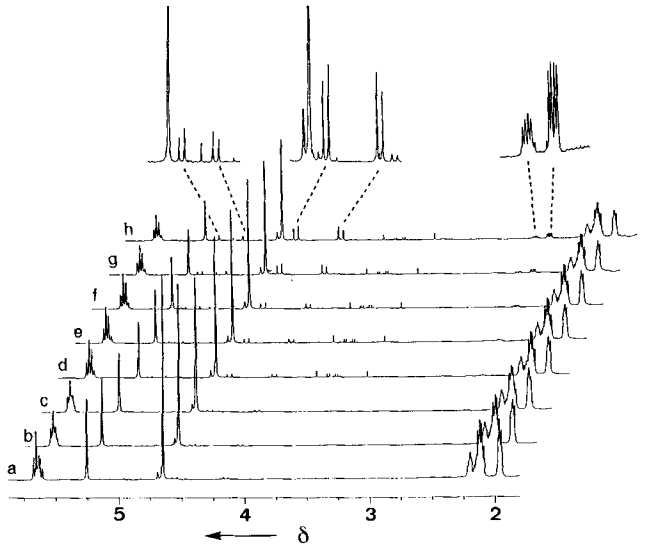

Fig. 2. Reaction of **4c** with *t*BuOOH (NMR experiment): a) **4c** in $CDCl_3$, b) after 15 min, c) after 1 h, d) after addition of 4.3 equiv of *t*BuOOH, e) 30 min after addition, f) 1 h after addition, g) 2 h after addition, h) 3 h after addition; the signals of the aromatic protons and a part of the cyclooctenyl protons are omitted.

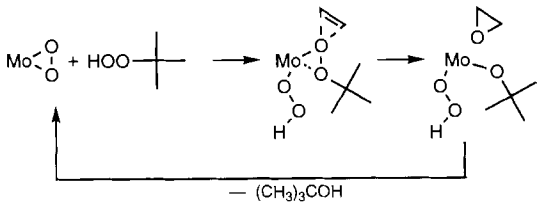
The progress of the reaction is evident by the emergence of six new signals in the ^{1}H NMR spectrum. Whereas the spectrum of the starting compound (two isomers) displays two signals for both the $N-CH_2$ group ($\delta = 5.24$ and 4.63, $2 \times s$) and the olefinic proton of the cyclooctenyl ring ($\delta = 5.64$ and 5.63, $2 \times t$, $^3J_{HH} = 8.0$ Hz), the epoxidized product (likewise two isomers) shows a more complex spectrum for these protons. Two new chiral centers are introduced into the molecule through the epoxidation. As a consequence, the protons of the $N-CH_2$ groups are no longer equivalent, and two doublets are observed for each isomer ($\delta = 5.15$, 4.92, $^2J_{HH} = 15.3$ Hz; $\delta = 4.52$, 4.16, $^2J_{HH} = 14.9$ Hz). Similarly, the signals for the protons at the epoxide C atom are split into doublets of doublets, because the protons of the neighboring CH_2 group are no longer equivalent ($\delta = 2.61$, $^3J_{HH} = 10.1$ Hz, $^3J_{HH} = 4.6$ Hz; $\delta = 2.50$, $^3J_{HH} = 10.1$ Hz, $^3J_{HH} = 4.4$ Hz).

These observations are consistent with catalytic epoxidations with alkyl-substituted peroxomolybdenum complexes and *tert*-butyl hydroperoxide as oxidant:[4] In the absence of the oxidant no reaction takes place; the olefin reacts rapidly only upon addition of TBHP. No decomposition of the catalyst is found within the limits of the accuracy of our monitoring. From these studies it may be inferred that for the complexes investigated here, the oxygen atom transferred to the olefin in the epoxidation derives not from a peroxo ligand, but from the *tert*-butyl hydroperoxide. The molybdenum complex thus activates the oxidizing agent. This activation may proceed in analogous fashion to the mechanism postulated for the epoxidation of allylic alcohols with titanium alkoxides (Sharpless epoxidation) (Scheme 3),[9a] which at the same time provides a simple explanation for the regeneration of the catalyst.

This step was also suggested by Sharpless et al. for the molybdenum-catalyzed epoxidations,[9b] but was not, however, verified further. The η^2-coordination of hydroperoxides to Lewis acidic centers has been established structurally for vanadium complexes.[10] The resulting oxenoid character of the hydroperoxide has been calculated for model systems.[11] The activation of hydroperoxide with regard to reaction with nucleophiles is demonstrated preparatively by the reaction of Li(η^2-OOR) with organolithium, -magnesium, and -copper compounds.[11a]



Scheme 3. Mechanism for the Mo-catalyzed epoxidation of olefins (formulated analogously to the postulated mechanism for the Ti-catalyzed epoxidation of allylic alcohols; cf. ref. [9]).

Through the synthesis of olefin-substituted peroxomolybdenum complexes we have succeeded in obtaining the first indications of a new reaction mechanism for olefin epoxidation with peroxo complexes. Further investigations are planned, specifically on the influence of the ligand on the activity and selectivity of the catalyst. In addition to this, the ligands introduced here should prove suitable for the synthesis of polymer-supported catalyst systems.

Design of Novel, Nonpeptidic Thrombin Inhibitors and Structure of a Thrombin–Inhibitor Complex**

Ulrike Obst, Volker Gramlich, François Diederich,* Lutz Weber,* and David W. Banner

Dedicated to Professor Albert Eschenmoser on the occasion of his 70th birthday

In the context of our work on host–guest interactions, we have developed receptors for various substrates.[1] The availability of high resolution X-ray structures of enzymes now allows the reverse process of rational design of inhibitors with the aid of molecular modeling. To this end, instead of using the enzyme's substrate as model, a small molecule, complementary to the active site with respect to hydrogen bonding as well as ionic and dispersive interactions, should be designed *de novo*.

Enzymes that are best suited for the rational design approach are those with rigid, well-defined binding pockets in the active site. Thrombin, a trypsin-like serine protease[2] with a central role in the blood coagulation process,[3] meets these requirements. The natural substrate for thrombin is fibrinogen, which is dissolved in the blood plasma. The enzyme selectively cleaves the peptide bond next to an arginine residue to form fibrin, which can polymerize. Thrombin is also the main activator of platelet aggregation. A selective inhibition of thrombin has potential therapeutic application in thrombotic diseases.

A number of X-ray structures of thrombin–inhibitor complexes were available,[4] which allowed the study of the important interactions crucial for inhibition. The active site of thrombin features three binding pockets (see Fig. 1). The bottom of the recognition pocket S1 contains Asp189 for interactions with guanidinium or ammonium groups of arginine or lysine residues. The large hydrophobic pocket (D-pocket, signifying a pocket "distal" to the catalytic site[4b]) is preferentially occupied by arene rings, which can undergo CH···π arene–arene interactions with the indole unit of Trp215. Fibrinogen, the natural substrate for thrombin, places the benzyl group of a phenylalanine residue in this pocket. An additional smaller hydrophobic pocket is positioned close to the catalytic site ("proximal": P-pocket[4b]). In the thrombin–fibrinogen complex this pocket is occupied by a valine residue. It was our goal to develop a nonpeptidic cyclic template to which three side chains could be attached in order to reach each of the three binding pockets (hydrophobic side chains for the P and D pockets, and an aromatic unit with a basic group for the recognition pocket S1 of the enzyme). The template should be rigid to avoid hydrophobic collapse of the side chains[6] and to avoid the loss of conformational degrees of freedom on complexation to the enzyme. In addition, the template should contain a hydrogen-bond acceptor (for example, a carbonyl group) to form a hydrogen bond to the amide NH of Gly216, a feature present in all known thrombin–inhibitor complexes. The synthesis should be simple and short and allow variation of the side chains. With such a synthesis, affinity and selectivity can be subsequently optimized through combinatorial solid-phase synthesis. The design of the target molecule was undertaken with the programs Insight II and Discover;[7] the force field used was the CVFF. A result of the modeling was molecule **1** (see Fig. 1). It has no structural similarity to either the natural thrombin substrate, fibrinogen, or other known synthetic thrombin inhibitors. This molecule has a series of potential interactions with the enzyme (Fig. 1): 1) a salt bridge between the amidinium group of the inhibitor and the carboxylate of Asp189 in the recognition pocket S1 of the enzyme, 2) two hydrogen bonds of the NH of Gly216 and the OH of Tyr60A to the carbonyl groups of the succinimide residue, 3) edge-to-face interactions between the indole ring of Trp215 and the benzyl group of the inhibitor in the D-pocket of the enzyme, where the benzyl group experiences additional benefits from the neighboring hydrophobic residues Ile174 and Leu99 (not shown in Fig. 1), and 4) contacts between two methyl groups of the inhibitor and the hydrophobic P-pocket of thrombin.

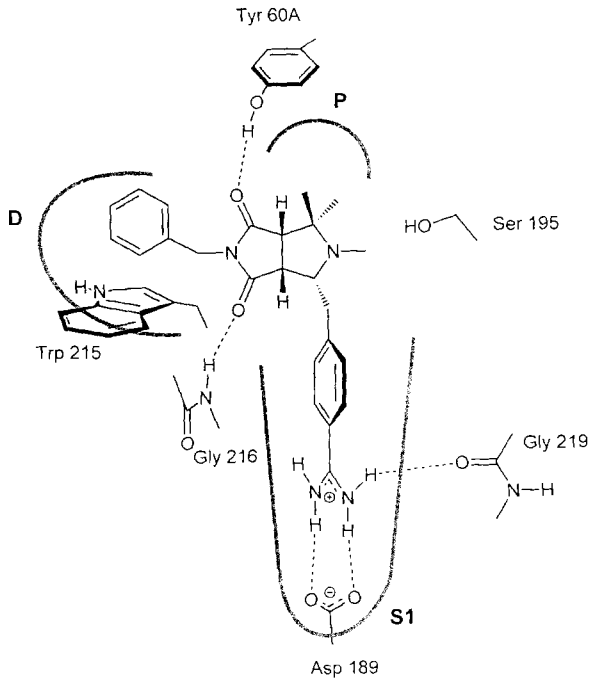

Fig. 1. Schematic representation of inhibitor **1** energy-minimized in the active site of thrombin.

The synthesis of **1** (Scheme 1) began with a 1,3-dipolar cycloaddition in a three component reaction. An azomethine ylide was generated in situ from 4-bromophenylalanine (**2**) and acetone (**3**) with decarboxylation and treated with *N*-benzylmaleimide (**4**). The pyrrolidine nitrogen atom of the cycloadduct (**5**) was methylated (→ **6**), and the bromo substituent converted into a cyano group. The conversion of the nitrile **7** into amidine **1** was achieved with a Pinner reaction.[10]

In the preparation of the bicyclic templates, it is also possible to make shorter basic benzamidinium "needles"[4c] lacking the methylene group, by using 4-cyanobenzaldehyde in the 1,3-dipolar cycloaddition (Scheme 2). Compounds **11a–m** are more easily prepared than the analogous cycloadduct **5**. In addition, their synthesis allows a larger structural variation of the "upper" side chains, a significant feature with respect to the planned

combinatorial synthesis. The structure of the major diastereomer formed in the cycloaddition was determined by X-ray crystallography of nitrile **12b**. The product was formed from an *anti*-ylide through an *endo* transition state[11] and was shown to have a different conformation in the crystal[12] (Fig. 2) than is required for the binding of the final product **14b** to thrombin. In the structure of **12b** an intramolecular CH···π arene–arene interaction and a different conformation of the pyrrolidine ring can be observed. At any rate, the structure of **12b** in the crystal does not provide information about the conformation of amidine **14b** either in solution or in the active site of thrombin.

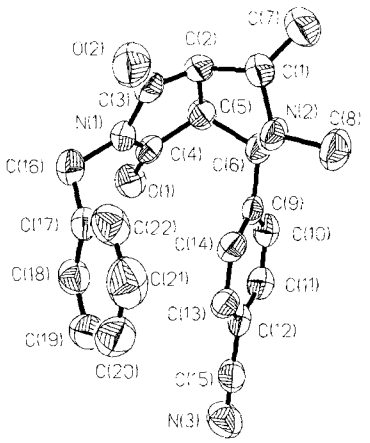

Fig. 2. Crystal structure of **12b**.

The originally proposed compound **1** was found to have a K_i value for thrombin of 18 μM as a racemic mixture[14] (for comparison: benzamidine has a K_i value of 300 μM[4c]). Compounds **14a–m**, lacking the CH_2 group in the benzamidinium needle, were significantly more active (Table 1). These compounds are conformationally more restricted than **1** because of the rigid framework and the attachment of the needle, and are therefore excellent candidates on which to study structure–activity relationships. These compounds can all be expected to follow the same binding mode.

Table 1. Activities of the thrombin inhibitors **14a–m** and selectivities with respect to complexation to trypsin.

Compd.	R^1	R^2	R^3	K_i [μM]	Selectivity [a]

On the pyrrolidine nitrogen on the right in the depicted structural formula, three structural modifications were evaluated. The compounds with a methylated nitrogen atom (**14b,e,h**) showed increased activity relative to the unmethylated ones (**14a,d,g**), whereas a dramatic reduction of activity was observed with acetylated compounds (**14c,f**). A possible explanation is that acetylation leads to a conformational change in the bicyclic template. Another possibility is that the pyrrolidine is preferentially bound in the protonated state: with acetylation

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1740 $ 10.00+.25/0

protonation is no longer possible. The highest thrombin affinities (lowest K_i values) were achieved with the addition of a five-membered ring on the right side of the molecule (**14i–k**). A six membered ring led to a reduction in affinity (**14l**), probably because this large hydrophobic moiety displaces a water molecule close to the catalytic group Ser195. A thiazolidine ring (**14m**) is probably also too big. The activity is less influenced by the substituents on the succinimide nitrogen atom for the "aryl binding pocket" (D-pocket). Butyl, benzyl, and cyclohexylmethyl substituents give rise to no large variations. The highest activity was achieved with a benzodioxol-5-ylmethyl (= piperonyl) substituent (**14j**, $K_i = 90$ nM).

The binding mode of the currently most active compound **14j** was revealed by X-ray crystallography[15] of its complex with thrombin. The inhibitor was bound in the active site of thrombin in the predicted fashion (Figs. 3 and 4). As expected, based on the rigidity of the molecule and the molecular modeling, only the (3a*S*,4*R*,8a*S*,8b*R*) enantiomer of the racemic mixture was found in the crystal structure. The benzamidinium side chain binds well in the recognition pocket S1 of the enzyme. Hydrogen bonds are formed to the carboxylate group of Asp189, to the carbonyl group of Gly219, and to a water molecule present at the bottom of the pocket. One carbonyl group of the inhibitor acts as a hydrogen bond acceptor for the NH of Gly216, whereas the other is located in the enzyme's P-pocket. The move of this carbonyl group from aqueous solution to the small hydrophobic P-pocket of thrombin must cost desolvation energy. This energy is not required for the binding of the inhibitor to trypsin, because it lacks the loop which in thrombin forms the P-pocket. This could explain why this class of inhibitors is only slightly more selective (up to 20-fold) for thrombin than for trypsin. Another hydrogen bond is formed between Tyr60A and an oxygen of the piperonyl group. The aromatic portion of the piperonyl group is located in the D-pocket of the enzyme and is involved in the expected CH $\cdots\pi$ interaction with Trp215.

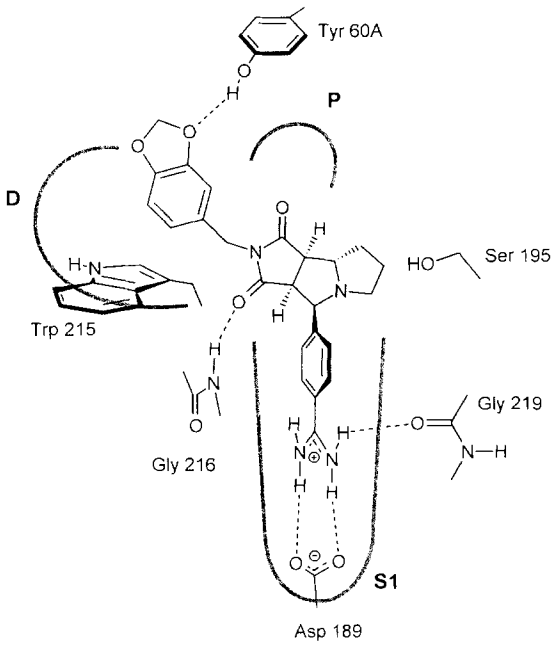

Fig. 3. Schematic representation of the interactions of **14j** with thrombin according to the crystal structure.

This inhibitor is still not optimal, especially with respect to its selectivity. Nevertheless, our results show that with a rational approach it is possible to develop new lead structures for enzyme inhibition in a relatively short time.

The synthetic strategy with 1,3-dipolar cycloaddition provides a large potential for structural variation. Most α-amino acids and several carbonyl compounds are feasible reagents to generate the azomethine ylides.[11] Most electron-poor olefins or acetylenes are conceivable dipolarophiles. Investigations involving the 1,3-dipolar cycloaddition with azomethine ylides on a solid phase are in progress. We hope that these combinatorial methods on a resin will lead to thrombin inhibitors with improved activity, selectivity, and good pharmacological properties.

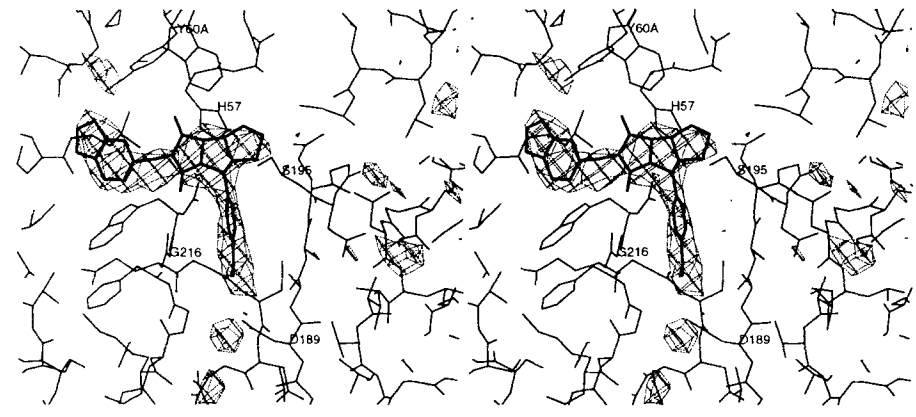

Fig. 4. Stereorepresentation of the difference electron densities of **14j** (dashed lines), thrombin (thin lines), and a model of the inhibitor (thick lines) [15]. The very small peaks represent water molecules or small changes of the protein compared to the (unrefined) model. Comparative calculations showed that the electron densities of the carbonyl groups must be weak at this resolution due to truncation of the Fourier series.

Experimental Procedure

11j: A mixture of proline (1.15 g, 10 mmol), 4-cyanobenzaldehyde (1.31 g, 10 mmol), and *N*-piperonylmaleimide (2.31 g, 10 mmol) was heated in DMF (10 mL) for 5 h at 80 °C. The solvent was removed under high vacuum, and the residue purified chromatographically on silica gel (hexane/AcOEt/NEt_3 49.5:49.5:1). Yield 37%; colorless needles (recrystallized from methanol), m.p. 176–179 °C.

14j: Dry HCl was passed through a solution of **11j** (831 mg, 2 mmol) in dry $CHCl_3$/CH_3OH 5:1 (6 mL) at 0 °C for 10 min. The reaction mixture was kept for two days at 4 °C. After addition of Et_2O a precipitate was formed, which was dried and mixed with a $NaHCO_3$ solution (5%, 8 mL) and $CHCl_3$ (20 mL). After a quick extraction the aqueous layer was again extracted twice with $CHCl_3$. The organic phase was dried over Na_2SO_4, and the solvent was distilled off. The residue was dissolved in MeOH (7 mL) and NH_4Cl (150 mg) in H_2O (1.5 mL) was added. The mixture was stirred at 65 °C for 3.5 h. After cooling, the solvent was distilled off, and the residue was separated chromatographically (RP18 silica gel, gradient from H_2O to MeOH). Yield 40%; colorless powder, m.p. 177–181 °C; IR (KBr): $\tilde{\nu} = 1701$ (C=O), 1678 (C=N) cm^{-1}; ^1H NMR (250 MHz, $(CD_3)_2SO$): $\delta = 1.68$ (m, 2H), 1.98 (m, 2H), 2.45 (m, 1H), 2.77 (m, 1H), 3.47 (d, $J = 7.8$ Hz, 1H), 3.56 (m, 1H), 3.76 (t, $J = 8.3$ Hz, 1H), 4.22 (d, $J = 8.5$ Hz, 1H), 4.33 (s, 2H), 6.02 (s, 2H), 6.67, 6.88 (AB, $J = 7.8$ Hz, 2H), 6.70 (s, 1H), 7.44, 7.71 (AB, $J = 8.2$ Hz, 4H), 9.08 (s, 2H), 9.38 (s, 2H); ^{13}C NMR (62.5 MHz, $(CD_3)_2SO$): $\delta = 23.0$, 29.0, 41.2, 48.6, 50.3, 67.4, 67.5, 101.0, 108.1, 108.2, 121.2, 126.5, 127.5, 128.7, 129.7, 145.6, 146.6, 147.2, 165.4, 175.4, 178.1; ESI(electrospray)-MS: *m/z* 433.4 ($[M + H]^+$, 100); satisfactory anal. for C, H, N, Cl.

[14] The activity of the thrombin inhibitors was determined according to R. Lottenberg, J. A. Hall, J. W. Fenton, G. M. Jackson, *Thromb. Res.* **1982**, *28*, 313 (chromogenic substrate S-2238).

[15] The data (75% complete to a resolution of 3.16 Å) were measured and worked up as described in [4b,c]. For calculation of the difference electron densities (Fig. 4) the coordinates for protein and water molecules of human thrombin were used (refined to a resolution of 2.6 Å, see Fig. 4 in ref. [4c]). Despite the modest quality of the data the binding mode of the inhibitor could be clearly identified. After refinement of protein and inhibitor the crystallographic R value was 12.9% for 7043 reflections with $F > \sigma$ with acceptable geometry (standard deviation for the bond lengths 0.012 Å and for the bond angles 2.0°). The atoms of the inhibitor have an average B value of 50 Å^2, significantly higher then the atoms of the protein. Either not all inhibitor sites are occupied or the inhibitor is present in several similar conformations. We have recently confirmed this result at higher resolution (1.9 Å) in a different crystal type (C2); details of this better defined structure will be published elsewhere.

σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation**

François Hutschka, Alain Dedieu,* and Walter Leitner

The homogeneous catalytic hydrogenation of carbon dioxide into formic acid has been the subject of recent experimental studies,[1-3] and hydridorhodium(I) complexes have been shown to be very efficient catalysts.[1, 2] It is generally believed that the catalytic cycle starts with the CO_2 insertion into the metal–hydrogen bond, a process that is well understood, experimentally and theoretically.[4, 5] The subsequent steps are more speculative. A sequence involving Rh^I and Rh^{III} intermediates was put forward in the two most recent examples. In these either $[Rh(nbd)(PMe_2Ph)_3]BF_4$ (nbd = norbornadiene)[2] or $[\{Rh(cod)(\mu\text{-}H)\}_4]$ and $[\{Rh(cod)(\mu\text{-}Cl)\}_2]$ (cod = 1,5-cyclooctadiene) in the presence of the bidendate phosphane ligand $Ph_2P(CH_2)_4PPh_2$ were used as the hydrogenation catalyst.[1a, 1d] In the former case the catalytically active species is believed to be the cationic dihydridorhodium(III) complex $[Rh(PMe_2Ph)_3(H)_2(solvent)]^+$, and insertion of CO_2 has been shown to yield a hydridoformatorhodium(III) complex. Reductive elimination of formic acid and subsequent oxidative addition of H_2 are assumed to regenerate the dihydridorhodium(III) cation. In the second, much more efficient system, the neutral species $[\{Ph_2P(CH_2)_4PPh_2\}Rh(H)]$ is believed to carry the catalytic cycle by insertion of CO_2. H_2 would then oxidatively add to the formatorhodium(I) intermediate and reductive elimination of formic acid from a dihydridorhodium(III) intermediate would lead back to the rhodium(I) compound (path A in Scheme 1). In the course of our theoretical studies of CO_2 coordination and reactivity,[6] we have started to investigate these catalytic processes.[7] The purpose of this preliminary communcation is to propose on the basis of our calculations an alternative mechanism (summarized in path B in Scheme 1) in which the rhodium center retains the formal oxidation state I throughout the reaction. Change of oxidation state is avoided by a σ metathesis reaction between the H_2 molecule and the formate complex.

Ab initio MO/MP2 calculations were carried out on the *cis*-$[HRh(PH_3)_2] + H_2 + CO_2$ model system using the Gaussian 92 program system.[8] Geometries were optimized by the gradient technique at the MP2 level, with the LANL1DZ basis set.[8, 9] Single-point MP2 energy values, to be discussed here, were obtained with an all electron basis set and with polarization functions on the active hydrogen atoms and on the carbon and oxygen atoms of CO_2.[13] We have checked that the use of the LANL1DZ basis set was appropriate for the geometry opti-

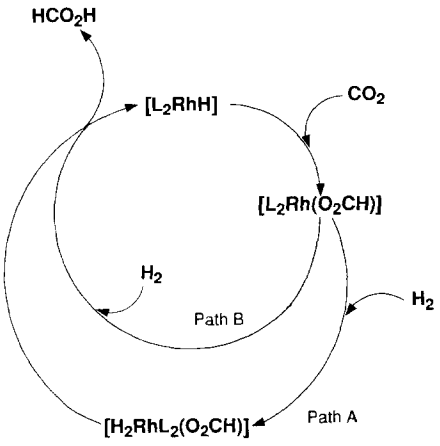
[+] New address:
Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

[**] This work was partly supported by a French–German PROCOPE contract (no. 94132). Calculations were carried out on the IBM RS 6000 workstations of our laboratory and of the Institut du Developpement et de Ressources en Informatique Scientifique (IDRIS, Orsay), and on the DEC 3000/600S workstations of the Centre Universitaire Régional de Ressources Informatiques (CURRI, Strasbourg). We thank the staff of these two centers for their cooperation. We are also grateful to Dr. L. Padel and Mrs. Fersing for their help and technical assistance.



Scheme 1. L = phosphane.

mization by performing, for some key structures, additional geometry determinations with the all electron basis set (with and without polarization functions). Similarly the validity of the conclusions reached at the MP2 level was assessed by carrying out a few calculations at the QCISD(T) level.[7a]

The optimized geometries of the various intermediates and transition states of path B (Scheme 1) are sketched in Figure 1 together with the corresponding relative energies.[16] The first

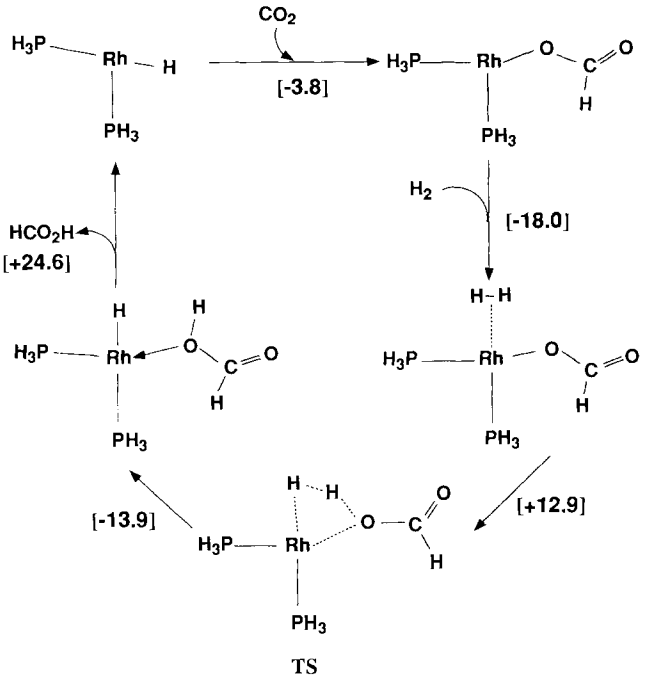


Fig. 1. Structures of various intermediates and transition states (TS) of path B in Scheme 1 (relative energies in kcal mol^{-1}).

step, which is common to paths A and B (Scheme 1), is the insertion of CO_2 into the Rh–H bond of $[HRh(PH_3)_2]$. The corresponding transition state is shown in Figure 2a with the most important geometrical parameters. This CO_2 insertion is a relatively easy process: an initially formed association complex between CO_2 and $[HRh(PH_3)_2]$[7] rearranges with a calculated energy barrier of only 4.2 kcal mol^{-1}. The overall reaction leading to the η^1-formate complex in Figure 1 is exothermic

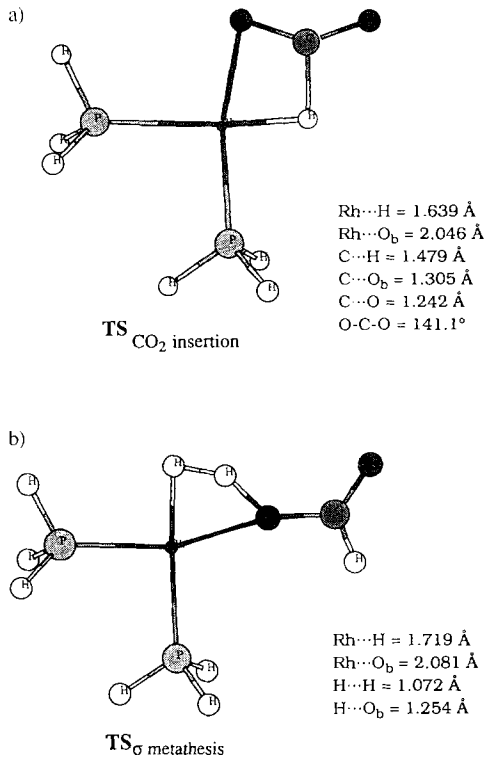

Fig. 2. a) Optimized structure of the transition state (TS) for the CO_2 insertion into the Rh–H bond of $[HRh(PH_3)_2]$. b) Optimized structure of the transition state for the $2\sigma + 2\sigma$ metathesis reaction between H_2 and $[Rh(PH_3)_2(\eta^1\text{-}O_2CH)]$.

(3.8 kcal mol^{-1}).[17, 19] The geometry of the transition state (Fig. 2a) is rather similar to the one found by Sakaki and Musahi[5e] for the insertion of CO_2 into the Rh–H bond of $[HRh(PH_3)_3]$. Only the Rh–O distance is much shorter in our case owing to the propensity of the oxygen atom to fill the vacant fourth coordination site of rhodium.

The path B is characterized by a transition state corresponding to a $2\sigma + 2\sigma$ metathesis reaction (Fig. 2b).[20] This transition state is bracketed by two intermediates. The first one is an association complex between H_2 and $[Rh(PH_3)_2(O_2CH)]$ that may be characterized as a dihydrogen complex: The Rh–H distances are 1.940 and 1.932 Å and the H–H bond length is 0.764 Å (i.e. only slightly elongated from that in H_2 (computed value 0.738 Å)). This complex is more stable than $H_2 + [Rh(PH_3)_2(O_2CH)]$ by 18.0 kcal mol^{-1}. An energy barrier of 12.9 kcal mol^{-1} must be overcome to go through the transition state of the σ metathesis reaction from this intermediate. After the transition state the formic acid remains bound to the rhodium atom, its hydroxy oxygen atom occupying the fourth coordination site. The calculated Rh–O bond length is 2.140 Å, in contrast to 1.889 Å in the three-coordinate formate complex. The dative-type interaction between rhodium and oxygen accounts for the relatively high energy requirement (+ 24.6 kcal mol^{-1}) for the complete dissociation into HCO_2H and $[HRh(PH_3)_2]$.

The most salient feature of the pathway B, however, is that none of the steps lead to large energy changes. In particular the energy barrier for the $2\sigma + 2\sigma$ metathesis reaction is rather low, and the corresponding step is not the most energy demanding in the complete cycle. We interpret this as an additional indication of the possibility of such reactions. The low energy barrier is due, as shown by previous theoretical studies,[22] to the involvement of the $d_{x^2-y^2}$ orbital of rhodium in the σ bond which is broken and in the σ bond which is formed.

According to our calculations, the dissociation of the HCO_2H molecule from the $[HRh(PH_3)_2]$ complex requires the largest energy change; but the energy requirement may be less important in solution. Moreover since CO_2 forms a preassociation complex with $[HRh(PH_3)_2]$, the substitution of HCO_2H by CO_2 in the catalytic cycle could follow an associative mechanism that might be less energy demanding than the dissociative one.

In comparison with path B, greater variations are observed for the individual steps of path A. The oxidative addition of H_2, which leads to an isomer with a geometrical arrangement favorable for the subsequent reductive elimination of HCO_2H, is computed to be exothermic by 32.6 kcal mol^{-1}. It is therefore not surprising that the reductive elimination to yield the separated HCO_2H and $[HRh(PH_3)_2]$ systems is in turn endothermic by 38.3 kcal mol^{-1}.[23] The energy barrier for the elimination of formic acid is also rather large, 23.8 kcal mol^{-1}. (The transition state lies at lower energy than the separated products of the reaction. However, as we have already mentioned the HCO_2H and $[HRh(PH_3)_2]$ can form an association complex; the association complex obtained in this case lies 4.4 kcal mol^{-1} lower in energy than the transition state.[24])

It is therefore clear from these calculations that the path B represents an alternative to the more traditional path A.[25] There are some precedents for invoking pathways that do not use reduction/reoxidation sequences.[26] For example, a σ bond metathesis pathway has also been considered, both experimentally[27] and theoretically[28] as an alternative in metal-catalyzed hydroboration reactions. We have already mentioned the importance of the involvement of a d orbital in allowing the [2 + 2] process[22] which otherwise would be forbidden according to the Woodward–Hoffmann rules. Another important factor for driving the σ metathesis reaction is the strength of the O–H bond formed during the process. One might object that our finding will apply only to the neutral hydridobis(phosphane)rhodium complex and not to the $[H_2Rh(PMe_2Ph)_3(solvent)]^+$ cation, which has been proposed as the active species for the formation of formic acid from H_2 and CO_2 catalyzed by $[Rh(nbd)(PMe_2Ph)_3]BF_4$.[2] But we can make use of the isolobal analogy between the T-shaped d^8-$[ML_3]$ and the square-pyramidal d^6-$[ML_5]$ complexes,[29] and consider now a σ metathesis reaction that would take place between H_2 and the five-coordinate d^6 complex cation $[HRh(PMe_2Ph)_3(O_2CH)]^+$ (after dissociation of the solvent). There would be no need to invoke reductive elimination of formic acid and subsequent oxidative addition of H_2— the rhodium atom would remain in the oxidation state III throughout the whole catalytic cycle. We are currently investigating this possibility.

[9] This basis set, of valence double zeta quality, is derived from the Dunning and Hay basis [10] for the first row atoms and from the Huzinaga basis [11a] for the hydrogen atom. For rhodium and phosphorus an effective core potential (up to the 4p electrons of Rh) [12] was used and the valence electrons were described by double zeta basis sets [12].

[13] For Rh a (15,10,8) ⟨6,4,4⟩ basis [14] was used. The phosphorus, carbon, and oxygen atoms were described by the standard (11,7) and (9,5) basis sets of Huzinaga [11b] contracted into ⟨4,3⟩ and ⟨3,2⟩. The hydrogen atoms were described by a (4)⟨2⟩ basis set [11a]. These basis sets were supplemented by polarization functions for the C (exponent 0.63), O (exponent 1.33), and the H atoms (exponent 0.8) actively participating in the catalytic process (i.e. the hydrogen atoms originating from H_2 and the hydride of the $[HRh(PH_3)_2]$ system).

[14] The original (15,9,8) basis set [15] was modified by the addition of a p function of exponent 0.15.

[15] A. Veillard, A. Dedieu, *Theor. Chim Acta* **1984**, *65*, 215.

[16] Zero-point energies are not taken into account. The corresponding total energies (in Hartree) are: H_2 −1.1553, CO_2 −188.0083, $[HRh(PH_3)_2]$ −5360.8454, $[Rh(PH_3)_2(\eta^1\text{-}O_2CH)]$ −5548.8597, $[H_2\cdots Rh(PH_3)_2(\eta^1\text{-}O_2CH)]$ −5550.0437, TS(σ metathesis), −5550.0231, $[HRh(PH_3)_2(HCO_2H)]$, −5550.0452, HCO_2H, −189.1606.

[17] These values have been computed on the singlet potential energy surface. One might argue that the ground state of the *cis*-$[HRh(PH_3)_2]$ system is a triplet, by analogy with what has been found for *trans*-$[RhCl(PH_3)_2]$ [18]. In our case however the singlet state is found to be, after a MP2 optimization of both the singlet state and triplet state structures, lower than the triplet state by 16.6 kcal mol^{-1} [7]. For the three-coordinate formate complex the energy difference is less important but still in favor of the singlet state by 2.2 kcal mol^{-1}.

[18] N. Koga, K. Morokuma, *J. Phys. Chem.* **1990**, *94*, 5454.

[19] Of course, the η^2 isomer is more stable (by 27.2 kcal mol^{-1}) than the η^1 isomer. But in accordance with Tsai and Nicholas [2], one can reasonably expect that because of this high stability the η^2 species is an unproductive shunt in the catalytic cycle.

[20] The transition state was characterized by an imaginary frequency of 1511*i* cm^{-1} with an eigenvector corresponding to the σ metathesis reaction. A second imaginary frequency was obtained in the frequency analysis, but with a very low value of 43*i* cm^{-1}. This residual frequency corresponds to the departure from C_s symmetry. However the very low value indicates that the C_s restriction is not a severe one and that upon a very slight move from the C_s symmetry this frequency would disappear, thus leaving only one imaginary frequency. A similar situation has been reported in the determination of the four-center transition state corresponding to the addition of the methane C–H bond across the metal nitrogen double bond of $[H_2Zr{=}NH]$ [21].

[21] T. R. Cundari, *J. Am. Chem. Soc.* **1992**, *114*, 10557.

[22] a) M. L. Steigerwald, W. A. Goddard III, *J. Am. Chem. Soc.* **1984**, *106*, 308; b) T. H. Upton, A. K. Rappé, *ibid.* **1985**, *107*, 1206; c) C. A. Jolly, D. S. Marynick, *ibid.* **1989**, *111*, 7968.

[23] The endothermicity is of course much greater if one starts from a η^2-formate $[H_2Rh^{III}(PH_3)_2(\eta^2\text{-}O_2CH)]$ complex which is again found more stable than the η^1 complex by 12.6 kcal mol^{-1}. This six-coordinate η^2 complex might in turn result from the oxidative addition of H_2 to the four-coordinate $[Rh^I(PH_3)_2(\eta^2\text{-}O_2CH)]$ complex [19]. Thus, taken together, these features probably rule out the η^2 formate complex of either Rh^I or Rh^{III} as *productive* intermediates in the catalytic cycle.

[24] After the transition state of the reductive elimination initially an association complex forms between HCO_2H and $[HRh(PH_3)_2]$ with the hydrogen atom bound to the rhodium atom, and with the formate plane perpendicular to the $[HRh(PH_3)_2]$ plane. This intermediate is more stable than the transition state by 4.4 kcal mol^{-1}. It can then easily rearrange to yield the square-planar

[HRh(PH$_3$)$_2$(HCO$_2$H)] intermediate which has been characterized in path B and which lies a further 5.7 kcal mol^{-1} lower in energy [7a].
[25] A similar conclusion has been obtained for the formation of the *cis* isomer of the formic acid [7a].

Designed Assemblies in Open Framework Materials Synthesis: An Interrupted Sodalite and An Expanded Sodalite**

Pingyun Feng, Xianhui Bu, and Galen D. Stucky*

A number of new framework materials based on zinc–oxygen and phosphorus–oxygen tetrahedra have recently been characterized,[1, 2] some of which are structural analogs of natural zeolites.[2] These include zeolite X and hydro-sodalite[3] whose structures were established by Rietveld refinement of X-ray powder data. The synthesis of solids with zinc phosphate open frameworks can be carried out from $-20\,^{\circ}C$ (zeolite X) to 200 °C.[2] This composition also pushes the limits with respect to the ionic radii of the tetrahedrally surrounded atoms (T atoms) of materials with open frameworks; Zn^{2+} (0.60 Å) is the largest for a pure (TO_2^{n+}, $T'O_2^{m-}$) phase zeolite and P^{5+} (0.17 Å) is one of the smallest ions.[4]

One important aspect in the synthesis of framework materials is the mechanism by which the inorganic framework is assembled by the templating molecule. The piperazine molecule has a number of features which can be used for such a study. The recent studies on the trioxane-templated silica sodalite[5] suggest that the molecular dimension of the similarly sized piperazine molecule is ideal for organization of four-ring units into a cage configuration. The directed hydrogen bonding should also impose at least one symmetry operation of the molecule on the framework, that is, the crystallographic site symmetry should be a subgroup of the molecular point group symmetry. This is distinct from dynamic templating in which the inorganic condensation is around a spatially averaged distribution of the organic molecules.

In this study, we were interested in those cases in which the symmetry of host frameworks is determined by nonframework template ordering.[6] A complication occurs for sodalite structures when the templating molecules are not only ordered but also have a charge less than +3, as required to balance the charge of a sodalite cage with (T^{3+}/T^{4+}) or (T^{2+}/T^{5+}) composition. We describe here two mechanisms by which the negative charge of the framework is lowered to match that of guest molecules while preserving the sodalite type cage linking: cage interruption and expansion as discovered in two newly synthesized zincophosphates. The cage interruption mechanism involves the removal of a tetrahedrally coordinated atom from the sodalite cage which reduces the negative charge from -3 to -1 per cage. The cage expansion mechanism involves the insertion of tetrahedral atom groups into the sodalite cage, which reduces the cage charge from -3 to -2 per cage. In both cases, the symmetry of template molecules (inversion center and twofold axis of piperazine molecule, respectively) plays a structure-directing role in the formation of the new cage assemblies.

Crystals of ZnPO/PPZ$^+$ (zincophosphate with a monoprotonated piperazine) were grown by "nonaqueous" synthesis from a mixture of $Zn(NO_3)_2 \cdot 6\,H_2O$, H_3PO_4, ethylene glycol, and piperazine. The molar ratio of the corresponding precursor oxides (ZnO and P_2O_5), piperazine, and ethylene glycol was 1.0:0.96:0.91:25. The gel was stirred at room temperature for about 30 minutes. The mixture was heated at 170 °C for four days in a teflon-coated steel autoclave. The product was recovered by filtration and washed with deionized water. Clear needlelike crystals of typical dimensions $0.3 \times 0.1 \times 0.1$ mm^3 were obtained, which were suitable for an X-ray structure analysis (Fig. 1a).

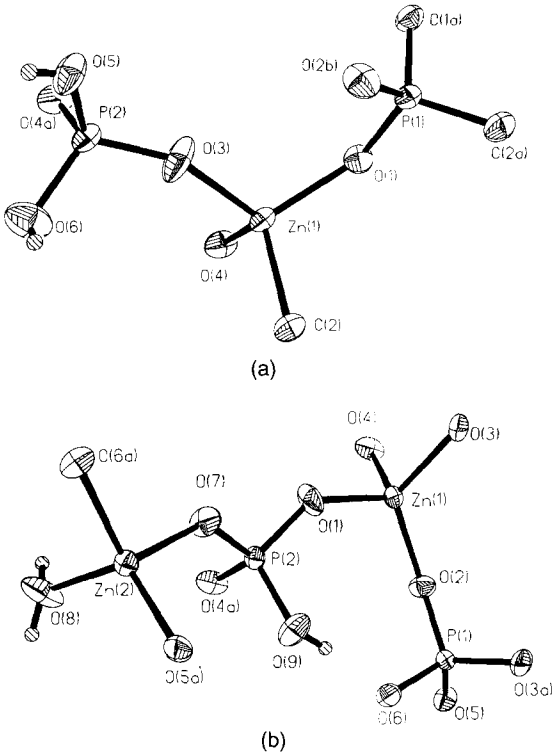

Fig. 1. Crystal structures of a) ZnPO/PPZ$^+$ and b) ZnPO/PPZ^{2+}: ORTEP views of zinc and phosphorus tetrahedra. Atom labels having "a" and "b" refer to symmetry generated atoms.

Crystals of ZnPO/PPZ^{2+} (zincophosphate with a diprotonated piperazine) were grown from a mixture of $Zn(NO_3)_2 \cdot 6\,H_2O$, H_3PO_4, H_2O, and piperazine. The molar ratio of the corresponding precursor oxides (ZnO and P_2O_5), piperazine, and water was 1.0:0.95:0.89:85. A white gel was formed at an approximate pH of 3 after stirring the mixture for about 15 minutes. The mixture was heated at 170 °C for four days in a teflon-coated steel autoclave. The product was recovered by filtration and washed with deionized water. Clear platelike crystals of typical dimensions $0.20 \times 0.17 \times 0.03$ mm^3 were obtained, which were suitable for an X-ray structure analysis (Fig. 1b).

$ZnPO/PPZ^+$ has an interrupted sodalite-type structure which is obtained by removal of a T atom (Zn^{2+} in this case) from sites related by one of the three twofold axes through opposing four-rings of the normal sodalite cage structure (Fig. 2a and 3a). One piperazine molecule per cage, whether mono- or diprotonated, is unable to provide the three positive charges which are needed to balance the negatively charged framework of an uninterrupted zincophosphate sodalite structure. The charge compensation is achieved instead by removal of one lower charged T atom (Zn^{2+}) for every six T atoms, and the addition of four protons, which form hydroxyl groups with oxygen atoms for a net charge gain of +2 per cage. The remaining −1 charge on the cage is balanced by one monoprotonated piperazine molecule located at the center of the cage.

$ZnPO/PPZ^{2+}$ has an expanded sodalite structure with eight eight-rings instead of six-rings (Figs. 2c and 3b). The structural relationship between the expanded sodalite and the normal sodalite is described below. Starting with a normal zincophosphate sodalite[3] cage ($[Zn_{12}P_{12}O_{48}]^{12-}$), oriented such that there are four four-rings on the equatorial plane, one four-ring above and one four-ring below (Fig. 2b), a hypothetical expanded structure can be derived by rotation of the top and bottom four-rings by 90° followed by insertion of four $ZnO(H_2O)_2$ units and four $PO(OH)_2^+$ units into eight T-O-T connections between the four equatorial four-rings and two four-rings above and below. This gives a stoichiometry of $[Zn_{12}P_{12}O_{48}]^{12-}$ $[Zn_4P_4O_8(H_2O)_8(OH)_8]^{4+}$ which is identical to the observed one, but with two water molecules coordinated to each of the four inserted zinc atoms and two OH groups coordinated to each of the inserted four P atoms. In the actual structure (Fig. 2c) one of the two water molecules on each zinc and one of the two OH groups on each phosphorus in the above hypothetical structure are distributed onto zinc and phosphorus atoms across the eight-rings. This gives rise to the sodalite-type cage linkage with elongated cages sharing single four-rings or single eight-rings (Fig. 3b). The reduction of the negative charge from −3 for a normal sodalite cage to −2 for an expanded cage is achieved with the introduction of one $PO(OH)_2^+$ unit per cage.

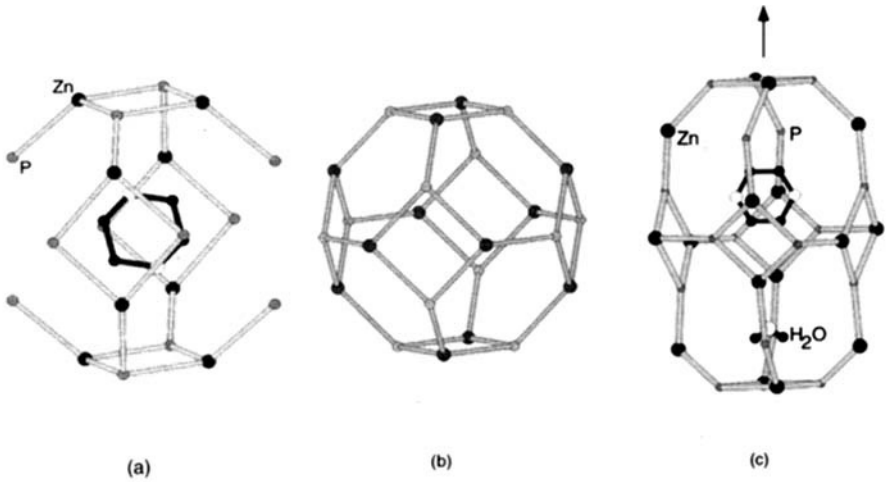

Fig. 2. a) The interrupted sodalite cage with the template molecule located on the inversion center at the cage center; b) the normal aluminosilicate sodalite cage; c) the expanded sodalite cage with the piperazinium dication and water molecule on the twofold axis.

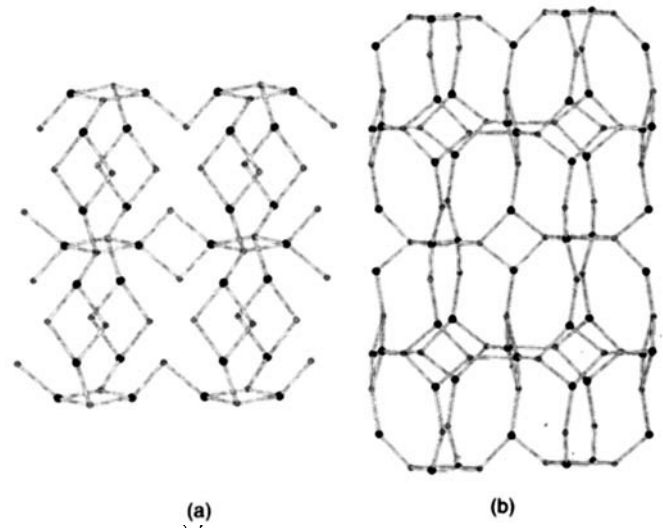

Fig. 3. Illustration of the framework structure and sodalite-type cage linkage. a) Four interrupted sodalite cages sharing single four-rings; there are no six-rings due to the T atom removal; b) four expanded sodalite cages sharing single four-rings.

The unit cell volume of $ZnPO/PPZ^+$ is 1403.8(7) Å^3 which is slightly more than twice the cell volume of 688.01(3) Å^3 for the normal zincophosphate sodalite.[3] This is consistent with four interrupted cages per unit cell. The volume increase per cage over the normal sodalite is only 2.0% which suggests that the dimension of the template molecule is ideally suited for such a four-ring assembly. In contrast, the volume increase per cage is as large as 53.7% for $ZnPO/PPZ^{2+}$ due to the cage elongation. This extra space inside the cage is occupied by ordered nonframework water molecules.

Both the interrupted and expanded sodalite cages have a point group symmetry lower than that of a regular sodalite cage. The interrupted cage is built around the inversion center on which the template molecule is located, while a twofold axis runs through the expanded cage on which both the piperazinium dications and water molecules are located. Since the carbon and nitrogen atoms in the chair conformation of the piperazine molecule have a point symmetry of $2/m$ with three individual symmetry elements (i, 2, m), the template molecule therefore imposes its individual symmetry constraint onto both types of framework structures. In the expanded cage, the symmetry match is achieved between the framework and two different template molecules, piperazine and water.

In both structures, the symmetry information of the template molecule is passed onto the framework mainly through guest–framework hydrogen bonding as illustrated in Figure 4. In $ZnPO/PPZ^+$, the extra proton in the piperazinium monocation is statistically distributed on two nitrogen sites. Each template nitrogen atom forms at least one N–H···O bond to one of four four-rings and may have another N–H···O bond depending on whether the extra proton is located on it (Fig. 4a). This observation is in contrast with the results with trioxane silica sodalite in which the guest–framework hydrogen bonding may only involve the weak C–H···O interactions due to the lack of OH groups and the trioxane molecule is orientationally disordered to preserve the cubic symmetry of the sodalite cage.[5]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1746 $ 10.00+.25/0

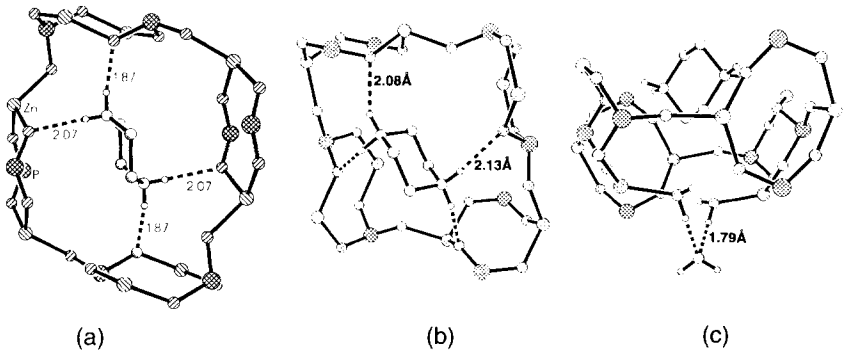

Fig. 4. Guest-framework hydrogen bonding. a) $ZnPO/PPZ^{+}$, monoprotonated piperazinium shown as di-protonated due to its statistical distribution on the two sites; b) $ZnPO/PPZ^{2+}$, top view of the four equatorial four-rings showing host-guest hydrogen bonds between piperazine NH_2 groups and framework oxygen atoms; c) $ZnPO/PPZ^{2+}$, side view of the four equatorial four-rings showing host guest hydrogen bonds between extra-framework H_2O and H_2O on Zn tetrahedra in the lower portion of the cage.

In $ZnPO/PPZ^{2+}$, one bridging oxygen atom from each of the four equatorial four-rings forms the N–H···O type bonding to each of the hydrogen atoms on NH_2 groups of piperazine molecules (Fig. 4b and 4c). All four participating oxygen atoms are on the same side of the four four-ring cluster due to the symmetry constraint imposed by a twofold axis. This is different from $ZnPO/PPZ^{+}$ where four participating oxygen atoms are divided on the two sides of the cluster formed from four four-rings, an arrangement consistent with the center of inversion. The hydrogen bonding between $Zn(H_2O)$ groups and extra-framework H_2O molecules gives OH_4 tetrahedra (Fig. 4c).

As shown in Figure 4, the molecular dimension of the piperazine molecule and the 90°/180° distribution of hydrogen atoms on the two nitrogen atoms make piperazine a perfect molecule for the organization of four four-ring units. In $ZnPO/PPZ^{+}$, these four four-rings units share single four-rings to form layers that are interconnected into the three-dimensional sodalite type framework by bridging bidentate -O-P(OH)$_2$-O- groups (Fig. 3a). Similar layers are also found in $ZnPO/PPZ^{2+}$ (Fig. 3b).

Both structures contain interruptions between tetrahedrally surrounded atoms. Due to the charge difference of the piperazine molecules in the two structures as well as the inclusion of a water molecule in the expanded structure, the style of interruption is different, leading to two unique novel cages assemblies. However, they are similar to each other in that the cages are interlinked in a manner analogous to that of sodalite. The interruption of the framework structure is one of the key structural features for several zincophosphates[7] as well as aluminophosphates.[8] In the cases discussed herein it helps to reduce the negative charge on the framework.

The symmetry matching between the inorganic host and template molecules are not limited to purely tetrahedral zincophosphate systems as described above. Recently, we discovered a new piperazine-templated vanadium(IV) phosphate (space group: *Cm*) in which the symmetry of the tetrahedral–octahedral framework is determined by the mirror symmetry of the template molecule.[9] In this structure both two-centered and three-centered hydrogen bonds are used to direct the assembly of the vanadium(IV) phosphate into an extended array.

In conclusion, we have demonstrated that all three individual symmetry elements of a piperazine molecule can direct framework formation and that partial zeolite-like cage structures can be synthesized by using a template design strategy. The results are important for the elucidation of the synthesis mechanism of sodalite-based zeolite materials in general and indicate that in future it may be possible to derive a strategy for the design of new framework structures as well as modification of existing types utilizing template symmetry, charge matching, and directed hydrogen bonding between guest and host. This strategy should apply to both interrupted and noninterrupted zeolitic systems since the directed hydrogen bonds described above are between the bridging framework oxygen atoms and piperazine molecules.

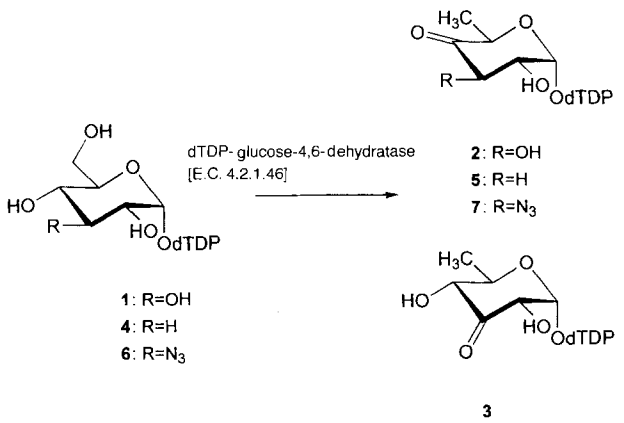
Synthesis of dTDP-6-Deoxy-4-ketoglucose and Analogues with Native and Recombinant dTDP-Glucose-4,6-dehydratase**

Andreas Stein, Maria-Regina Kula, Lothar Elling,* Stefan Verseck, and Werner Klaffke*

Activated ketoglucose derivatives play a key role in the biosynthesis of deoxygenated oligo- and polysaccharides, because they represent the branching points in many biosynthetic pathways leading to 2,6- and 3,6-dideoxy- and -aminodeoxysugars, and branched deoxysugars. Although the gene clusters for the biosynthesis of deoxysugars in bacteria have been localized and the corresponding enzymes should now be available, the insufficient availability of the intermediates and the lack of effective analytical methods still hampers detailed investigations.[1-3] Solving these problems is necessary before the chemoenzymatic synthesis of deoxyoligosaccharides is as successful as that of N-glycosidically bound glycans.

In one of the activating pathways in bacteria leading to deoxyoligosaccharides, dTDP-D-glucose **1** (dTDP = thymidine-5′-diphosphate) is converted into dTDP-L-rhamnose via the corresponding 6-deoxy-4-keto intermediate **2**, which in turn is synthesized by dTDP-D-glucose-4,6-dehydratase [EC 4.2.1.46] (Scheme 1). This enzyme from different sources has been used for the synthesis of labeled substrates.[4, 5] The recent enzymatic synthesis of dTDP-6-deoxy-4-ketoglucose **2** marks progress in this area.[6] During the preparation of this manuscript, a paper by Lindqvist et al.[7] appeared which describes the biosynthesis of CDP-D-abequose (CDP-3,6-dideoxy-D-galactose; CDP = cytidine-5′-diphosphate) and the analytical separation of the activated sugars involved.



Scheme 1.

We describe here the synthesis and the first NMR spectroscopic characterization of dTDP-6-deoxy-α-D-*xylo*-hexopyran-4-ulose (**2**) in pure form as well as the enzymatic conversion of structurally related, nonnatural dTDP-glucose analogues into the corresponding 6-deoxysugars. We also present an ion-pair HPLC method for the analytical and preparative separation of dTDP-activated hexoses.

We first used the native enzyme in the crude extract of *Escherichia coli* B for deoxygenation.[8] In addition to dTDP-D-glucose (**1**), its 3-deoxy- and 3-azido-3-deoxy derivatives **4** and **6**, respectively, were incubated to demonstrate the range of application of the preparative method. The synthesis of the 4-ulose **2** was monitored by TLC. Surprisingly, the ^{1}H NMR spectrum recorded after the reaction mixture had been worked up by passage through a basic ion exchange column and subsequent desalting showed two products not identical to **1**. Detailed analysis revealed the products to be a 3:2 mixture of **2** and **3**. The analogues **4** (K_m = 200 μM, v_{max} = 130 μmol h^{-1} mg^{-1}) and **6** (K_m = 350 μM, v_{max} = 90 μmol h^{-1} mg^{-1}) were identified as substrates in the enzyme assay;[9] however, they show only 1/5 and 1/10, respectively, of the natural selectivity (v_{max}/K_m) of **1** (K_m = 80 μM, v_{max} = 260 μmol h^{-1} mg^{-1}). In the reactions of **4** and **6** the formation of a more unpolar product after roughly 1 d at 37 °C was detected by TLC; after 3 d the reaction was complete. Since compounds **5** and **7** are much more prone to hydrolysis than **2**, the workup had to be conducted quickly at + 4 °C and with lower concentrations of LiCl. The dideoxyhexo-4-ulose **5** was obtained as white foam (20 mg) in 41% yield and was characterized by NMR spectroscopy. As expected, dTDP-3-azido-3,6-dideoxyhexo-4-ulose (**7**) was also obtained in the form of a colorless foam (23 mg, 24% yield from a 166 μmol-scale reaction).

In the course of our work we developed an HPLC method based on the reversed-phase ion-pair chromatography described by Aw et al.,[10] which allows the highly selective separation of dTDP-activated hexoses and can be scaled up for preparative-scale batches. (In preparative HPLC ca. 5 mg of the crude product is loaded on the column, whereas loads of roughly 0.01 mg are typically applied in analytical separations.) Furthermore for the synthesis of **2** the wild-type enzyme was exchanged for recombinant dTDP-glucose-4,6-dehydratase from *Salmonella typhimurium* LT2 which was overexpressed in *E. coli* BL21. With the higher specific enzyme activity the effect of contaminating activities can be nearly excluded. Figure 1 shows the chro-

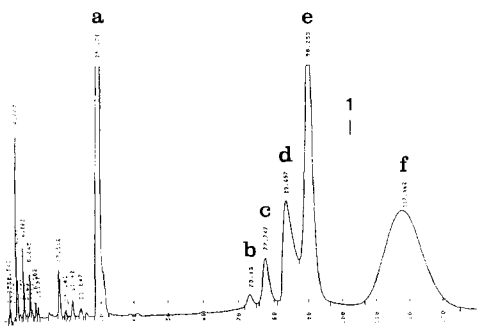


Fig. 1. Chromatogram of an analytical HPLC separation of a) dTMP, b, c) contaminants from commercial dTDPG, d) dTDP, e) dTDPG, and f) dTDP-6-deoxy-D-xylo-4-hexulose. The retention time of dTDP-L-rhamnose, which was added in other separations to demonstrate selectivity, is marked with a 1.

Sinnwell and Dr. C. Schulze (Universität Hamburg) for recording the NMR and ESI spectra, respectively. dTDP = thymidine-5′-diphosphate.

matogram of the analytical separation of a mixture consisting of dTDP-glucose, the resulting 6-deoxy-4-ulose **2**, two contaminants present in the commercial starting material, and dTMP and dTDP.

In general the instability of product **2** leads to problems.[6, 11] We found that **2** partially decomposed with formation of dTMP and dTDP during storage in salt and buffer solutions at + 4 °C and −20 °C, respectively, and on lyophilization from volatile buffers and uncompletely desalted solutions, as well as on precipitation with organic solvents. Ulose **2** was isolated after preparative HPLC with an overall yield of 70%. The product can be stored at −20 °C for at least four months. Spectroscopic characterization of compound **2** as a 1:5 mixture of the keto and hydrate forms proved it to be a pure compound.

Table 1. Selected physical data of compounds **2**, **5**, and **7**.

2: ^{1}H NMR (400 MHz, D_2O): δ = 1.13 (d, 3H, 6″-H), 1.84 (d, 3H, CH_3), 2.24–1.32 (m, 2H, 2a′-H, 2b′-H), 3.53 (ddd, 2″-H), 3.69 (d, 3″-H), 4.01 (q, 5″-H), 4.07–4.11 (m, 3H, 4′-H, 5a′-H, 5b′-H), 4.53 (m, 3′-H), 5.46 (dd, 1″-H), 6.25 (dd, 1′-H), 7.65 (d, 6-H); $J_{1',2'}$ = 3.6, $^3J_{1',P}$ = 7.0, $^4J_{2',P}$ = 3.1, $J_{2',3'}$ = 10.2, $J_{5'',6''}$ = 6.5 Hz; ^{13}C NMR (100.7 MHz, D_2O): δ = 11.7 (C-6″), 12.1 (CH_3), 39.0 (C-2′), 65.9 (C-5′), 70.0 (C-5″), 71.1 (C-2″), 71.4 (C-3′), 73.6 (C-3″), 85.4 (C-1′), 85.8 (C-4′), 94.1 (C-4″, hydrated), 95.8 (C-1″), 112.2 (C-5), 137.7 (C-6), 152.2 (C-2), 167.0 (C-4); $^2J_{C-1',P}$ = 8.6, $^3J_{C-5',P}$ = 5.7 Hz; ESI-MS (negative mode, + 3 kV): *m/z*: 562.7 [M^- − Na]; keto form: ^{13}C NMR (100.7 MHz, [D$_6$]DMSO): δ = 206.4 (C″-4); ESI-MS (negative mode, + 3 kV): *m/z*: 545 [M^- − Na].

5: ^{1}H NMR (400 MHz, D_2O): δ = 1.09 (d, 3H, 6″-H), 1.84 (s, 3H, CH_3), 2.25–2.47 (≈dd and dd, 2H, 3a″-H and 3b″-H), 3.74 (m, 2″-H), 4.02 (q, 5″-H), 5.38 (dd, 1″-H); $J_{1'',2''}$ = 3.1, $^3J_{1'',P}$ = 6.5, $J_{2'',3a''}$ = 5.5, $J_{2'',3b''}$ = 11.6, $^2J_{3a'',3b''}$ = 12.6, $J_{5'',6''}$ = 6.6 Hz; ^{13}C NMR (100.7 MHz, D_2O): δ = 11.6 (CH_3), 12.2 (C″-6), 32.4 (C″-3), 69.1 (d, C″-2), 69.8 (C″-5), 93.2 (C″-4, hydrated), 95.7 (d, C″-1); $^2J_{C-1',P}$ = 6.4, $^3J_{C-2',P}$ = 8.5 Hz; ^{13}C NMR (100.7 MHz, [D$_6$]DMSO): δ = 203.1 (C″-4, not hydrated).

7: ^{1}H NMR (400 MHz, D_2O): δ = 1.21 (d, 3H, H″-6), 1.84 (s, 3H, CH_3), 3.40 (m, 2H, H″-2, H″-3), 4.21 (q, H″-5), 5.43 (dd, H″-1); $J_{1'',2''}$ = 3.8, $^3J_{1'',P}$ = 7.0, $J_{5'',6''}$ = 6.4 Hz; ^{13}C NMR (100.7 MHz, D_2O): δ = 13.3 (CH_3), 13.6 (C″-6), 60.2 (C″-3), 82.3 (d, C″-2), 94.1 (C″-4, hydrated), 95.7 (d, C″-1); $^2J_{1'',2''}$ = 6.4, $^3J_{C-2',P}$ = 8.1 Hz; ^{13}C NMR (100.7 MHz, [D$_6$]DMSO): δ = 201.4 (C″-4, not hydrated).

To the best of our knowledge, these experiments describe the first NMR spectroscopic characterization of the dehydratase-catalyzed synthesis of the deoxy intermediate **2**. The successful conversion of nonnatural dTDP-3-deoxy-α-D-*ribo*- and -3-azido-α-D-*xylo*-hexopyranoses **4** and **6**, respectively, open a new enzymatic route to artificial nucleoside diphosphate activated glycosyl donors in which easily available crude extracts are used. The HPLC method described should enable the first complete characterization of the dTDP-L-rhamnose biosynthesis in one step. In addition, preparative amounts of **2** and related compounds can now be isolated.

Experimental Procedure

2, **5**, and **7**: The disodium salt of dTDP-glucose **1** (50 mg, 82 μmol) or its 3-deoxy derivatives **4** and **6** (available by ion exchange from the chemically synthesized dilithium salts [12,13]) was dissolved in 5 mL of Tris/HCl buffer pH 7.5 (50 mM, 0.5 mM DTT). The dehydratase was added (0.083 U; 1 U = 1 μmol min^{-1}; 1.45 mL crude extract from *E. coli* B [8]), the reaction flask filled with 10 mL of distilled water, and the solution incubated at 37 °C with constant shaking. After 2 d the reaction was complete according to TLC (2-propanol/ethanol/water = 5:3:2, 5% HOAc, 2% triethylamine; product R_F = 0.4, starting material **1** R_F = 0.3, dTMP R_F = 0.5, dTDP R_f = 0.2). The enzyme reaction was stopped by heating for 30 s in boiling water; the reaction mixture was lyophilized to a volume of 3 mL and separated on a Sephadex G-10 column (2 × 160 cm; 1 mL min^{-1}). The fractions containing the nucleotide sugars were collected, purified by ion exchange chromatography (Dowex 1 × 2, Cl$^-$ form, 5 × 18 cm, 800 mL linear gradient 0–0.8 M LiCl), and concentrated. Desalting on Sephadex G-10 and subsequent lyophilization gave the dilithium salts of the products as white foams. Yield of **2** and **3** (ca. 3:2 according to ^{1}H NMR): 26 mg (54%); yield of **5**: 20 mg (41%); yield of **7**: 23 mg (24%).

2: The disodium salt of dTDP-glucose (41 mg, 60 μmol; Sigma) was dissolved in 2 mL of Tris/HCl buffer pH 7.5 (50 mM) in a 2 mL Eppendorf flask. 1 U of recombinant dTDP-D-glucose-4,6-dehydratase (65 μL crude extract, 9.5 mg mL^{-1} protein) was added, and the reaction mixture was incubated at 37 °C. After complete conversion (ca. 2 h) the reaction mixture was incubated for 2 min at 95 °C, centrifuged for 2 min at 12400 × *g*, and filtered through a 0.45 μm membrane. The separation was performed by preparative HPLC (Hypersil ODS-10 μ, 2 × 25 cm, Macherey Nagel, Düren (Germany), 0.04 M NH_4CO_3 solution (pH 3), 0.0038% (v/v) octylamine, 1% (v/v) methanol, isocratic elution, flow rate 20 mL min^{-1}, detection at 260 nm). The fractions containing the product were collected, diluted with doubly distilled water, and pumped with 250 mL min^{-1} onto a membrane anion-exchange module (KN107Q, Sartorius, Göttingen (Germany)). The salts of the HPLC solvent were removed with a 5 mM NaCl solution, and **2** was eluted with 150 mM NaCl solution. The product solution was concentrated to 10 mL under vacuum at 30 °C and subsequently desalted on a Sephadex G-10 column (2.6 × 93 cm, flow rate 1 mL min^{-1}). After lyophilization the disodium salt of the product was obtained as fluffy white solid. Yield: 24 mg (70%). Even traces of **3** were not detectable in this batch.

Estramycins: A New Diyl Precursor Family Derived from Estradiol**

Jing Wang and Pierre J. De Clercq*

The recent discovery of a new class of anticancer antibiotics from a bacterial source, presently consisting of neocarzinostatin, the esperamycin and calicheamycin families, dynemicin, kedarcidin, and C-1027, which exert their biological activity through DNA cleavage, opens new perspectives in cancer chemotherapy.[1] DNA cleavage is effected by diradicals that are generated from cyclic polyunsaturated core structures upon suitable activation. Quite recently diyl-based DNA cleaving agents have been reported in which the core of the diradical precursor is tethered to known minor groove DNA binding agents or DNA intercalators.[2] Also, a new family of artificial enediynes (taxamycins) has been described in which the unsatu-

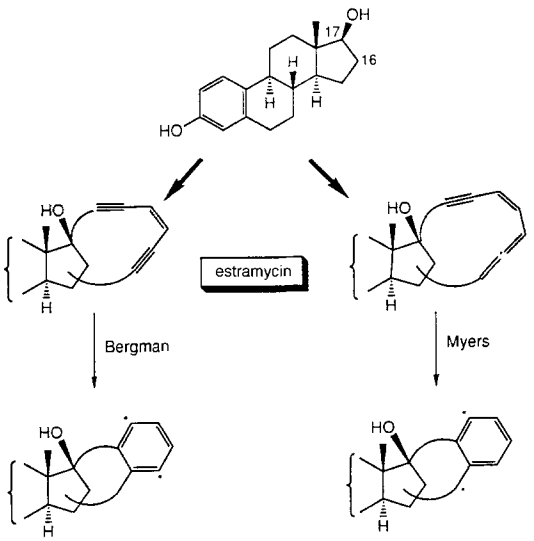
[**] This work was supported by the National Fund for Scientific Research.

rated core is intimately embedded within a structure with known antitumor activity, like taxol.[3] In the same context we aimed to study the chemotherapeutic potential of estramycins, derivatives in which the diradical precursor core is incorporated into estradiol. It is indeed known that the chemotherapeutic activity of cytostatics against hormone-responsive tumors can be enhanced by linking them to hormones.[4] Since human mammary cancers are usually rich in estrogen receptor, estrogens, and estradiol in particular, are potential vectors to transfer cytotoxic agents into the nuclei of receptor rich cells.[5] As shown in Scheme 1 potential candidates include cyclic enediynes and enyne–allenes that would generate the diradical intermediates through Bergman and Myers cyclization processes, respectively.[6, 7]



Scheme 1. Possible routes from estramycins to diradicals.

Obviously, in designing such hybrid molecules both the binding affinity of the modified estradiol for the estrogen receptor and the reactivity of the unsaturated system should be taken into account. The knowledge of the various structural features that are necessary for the activity of estradiol is crucial to the design of a successful candidate. The structure **1** (see Scheme 2) was proposed based on the following:[8] 1) Both the phenolic C3-hydroxy and β-oriented C17-hydroxy groups are intimately involved in the recognition process. 2) An α-oriented ethynyl group at C17 enhances the binding affinity. 3) Estradiol derivatives α-substituted at C16 bind well to the estrogen receptor.[9]

For the design of an appropriate enediyne core one can apply, at least in the first instance, the critical distance (*cd*) criterium introduced by Nicolaou.[10] The distance between the terminal alkyne atoms of the enediyne is taken as a measure of its ease of cyclization; the crucial turning point from stability to spontaneous cyclization lies between 331 and 320 pm. Depending on ring size candidates **1** possess varying *cd*s (Scheme 2);[11] only the ten-membered ring derivative (**1**, $n = 2$) is of potential use. From the low distance of 305 pm that is found in the lowest energy conformation of this compound one may expect the derivative to be rather unstable. Consequently, in the design of a synthesis, the enediyne core should be realized at a very late stage.[12] We now further describe the synthesis of a few derivatives of **1** and their cyclization behavior.

After protection of estrone as the *tert*-butyldimethylsilyl (TBDMS) ether,[13] the required stereoselective introduction of

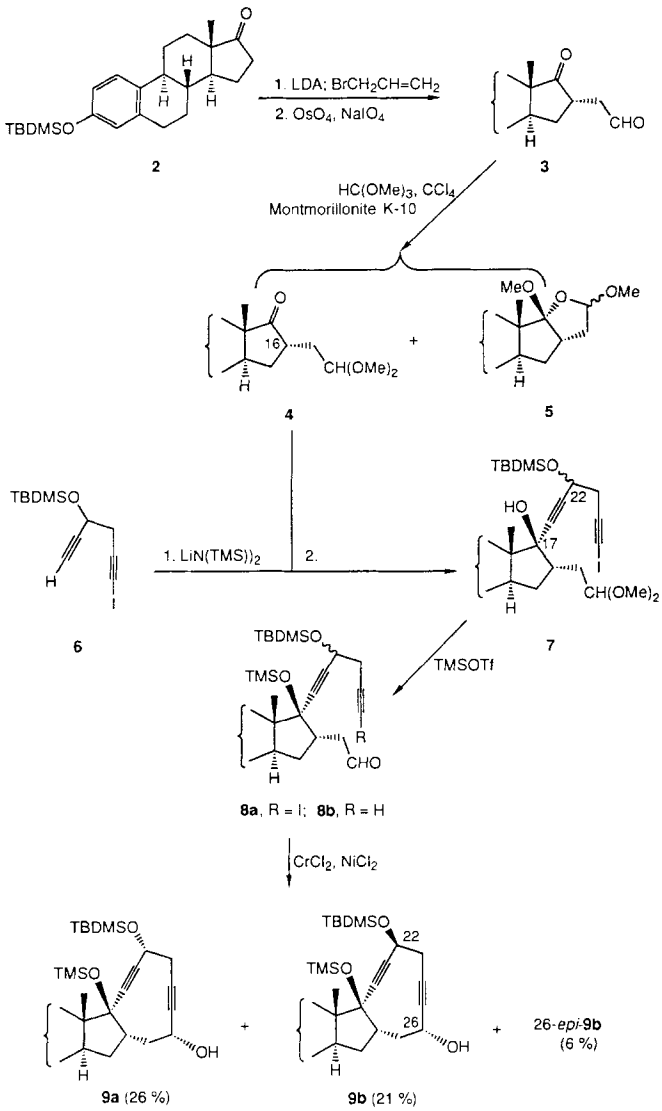
3	361

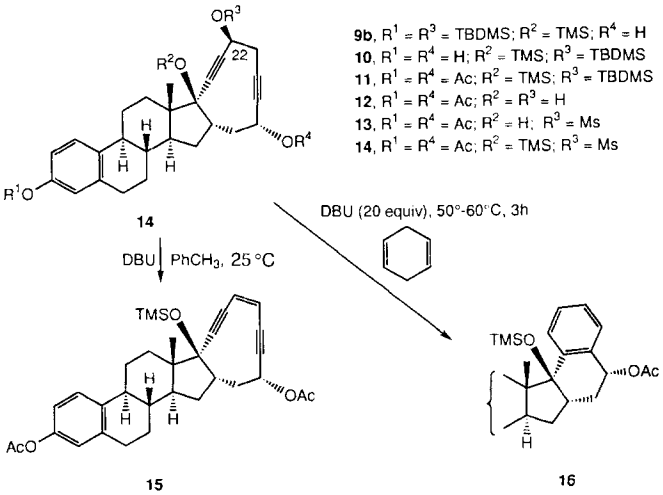
Scheme 2. Calculated *cd* values in estramycin **1**.

a 2,2-dimethoxyethyl side chain in α position at C16, as in **4**, was accomplished as follows (Scheme 3): 1) Ketone **2** was enolized (0.95 equiv. of lithium diisopropylamide (LDA), THF), and subsequently treated with 3-bromo-1-propene to form the corresponding 16α-(2-propenyl) derivative (83% yield).[13, 14] 2) Oxidative cleavage of the double bond with osmium tetroxide/sodium periodate gave the aldehyde **3** (71% yield). 3) Selective protection of the aldehyde with trimethyl orthoformate in tetrachloromethane, catalyzed by Montmorillonite K-10 clay, resulted in a mixture of desired **4** (57% yield) besides the cyclic mixed double acetal **5** as a mixture of two isomers (30% yield).[15] The stereochemistry at C16 predicted on steric grounds was further corroborated by ^{1}H NMR NOE difference spectroscopy: irradiation of the angular methyl group led to an increase of the signal of the H atom on C16.

Quite recently the intramolecular version of Nozaki's chromium(II)/nickel(II) salt mediated coupling of haloalkynes with aldehydes has been applied successfully in the synthesis of enediyne ring systems.[16, 17] The method is especially useful when dealing with enolizable aldehydes as in our case. The required cyclization precursor **8** was obtained by reaction of **4** with the alkynyl anion obtained from **6**,[18] which led to **7** as an approximate 1:1 mixture of diastereomers at C22 in 67% yield, and subsequent protection of the hydroxy group at C17 with trimethylsilyl trifluoromethanesulfonate (TMSOTf) and 2,6-lutidine in dichloromethane. Simultaneously the aldehyde function was deprotected (86% yield of **8a**, but contaminated with about 30% of deiodinated **8b**, which could not be separated at this stage).[19] The β-hydroxy configuration at C17 (shown in Scheme 3) was assigned on the basis of literature precedents and of the magnitude of the ^{1}H NMR shift of the resonance for the angular methyl group that is observed for **7** in pyridine relative to that in chloroform ($\Delta(\delta_{CDCl_3} - \delta_{C_5D_5N}) = -0.22$).[20, 21] The



Scheme 3. The synthesis of the ten-membered ring estradiol derivative **9**. TMSOTf = trimethylsilyl trifluormethanesulfonate.



Scheme 4. Synthesis and cycloaromatization of estramycins **15**. Ms = methanesulfonyl.

crucial intramolecular cyclization of the iodoalkyne–aldehyde **8a** succeeded in the presence of seven equivalents of chromium(II) chloride and 10 mol% of nickel(II) chloride in THF at room temperature. The ring-closed alcohol was obtained in 54% yield (based on the 80% iodide content of the starting material) and consisted of a mixture of three out of the four possible diastereomers, which could be separated by careful chromatography: **9a** (26%), **9b** (21%), and 26-*epi*-**9b** as a minor component (6%). The relative stereochemistry at positions 22 and 26 was assigned on the following basis: the stereochemistry at C26 in **9b** follows from the elucidation by ^{1}H NMR spectroscopy of a later intermediate (**16**); comparison of the calculated vicinal coupling constants for H22[11] with the experimental values, (for **9a**: calcd. 5.3/2.7 Hz, exp. 5.4/5.4 Hz; for **9b**: calcd 9.0/6.9 Hz, exp. 8.4/6.7 Hz)[22] and for 26-*epi*-**9b** (8.2/6.7 Hz); oxidation of 26-*epi*-**9b** with Dess–Martin periodinane leads to an alkynone that is identical with the one obtained from **9b**, but different from that obtained from **9a**.

The conversion of **9** into a precursor for cycloaromatization further requires the elimination of the C22-oxy function in a selective manner.[12] Scheme 4 depicts the laborious sequence by which this was accomplished for **9b**. Selective deprotection of the phenolsilyl ether (81% yield) followed by acetylation of **10** afforded diacetate **11** (95% yield). After further desilylation with hydrofluoric acid in acetonitrile to **12** (95% yield), the free C22-hydroxy group was converted into the corresponding methanesulfonate **13** (86% yield). The elimination of the methanesulfonate was first attempted on the unprotected 17-oxy derivative **13**.[23] Treatment with ten equivalents of 1,8-diazabicyclo[5.4.0]undec-5-ene (DBU) at room temperature proved difficult. Even after six hours most of the starting methanesulfonate was still present. When the reaction was followed by ^{1}H NMR spectroscopy (25 °C, [D_2]dichloromethane), an isolated AB system (δ = 6.01, 5.93, J = 9.4 Hz; integration indicated less than 10% of the starting material) as expected for the two hydrogen atoms of a (*Z*)-enediyne system was observed but gradually disappeared, presumably through Bergman cyclization.

At several stages during the synthesis we found that C17-alkynylated derivatives were rather unstable when they possessed a free C17-hydroxy group. The same procedure was therefore also studied on derivative **14**, in which the C17-hydroxy group is protected as the trimethylsilyl ether (90% yield with TMSOTf and 2,6-lutidine, CH_2Cl_2, −78 °C, 45 min). Upon treatment of **14** with DBU in toluene at room temperature for 1 h the expected enediyne **15** could be isolated in about 50% yield after fast workup and chromatography as well as 31% of starting methanesulfonate. The rate of its disappearance, presumably through Bergman cyclization, was estimated by means of ^{1}H NMR spectroscopy ([D]chloroform, 25 °C) at $t_{1/2}$ = 108 min (25 °C). When methanesulfonate **14** was treated with 20 equivalents of DBU in the presence of 1,4-cyclohexadiene (50 °–60 °C, 3 h), the expected cycloaromatized acetate **16** was isolated in 33% yield. The assignment of the configuration at C26 was based on comparison with calculated vicinal coupling constant values for H26,[11] (3.2/3.0 Hz for **16**; 11.1/4.3 Hz for 26-*epi*-**16**);[24] the experimental values are 3.0/3.0 Hz.

Although the estramycin derivative that has been synthesized and shown to cycloaromatize still possesses a protected C17-hydroxy group, we have shown that a 10-membered ring derivative of this type, in particular with a *cis*-ring fusion, does cycloaromatize at a rate useful for possible chemothera-

peutic use. We are convinced that this knowledge will be crucial in the development of more sophisticated estramycin derivatives.

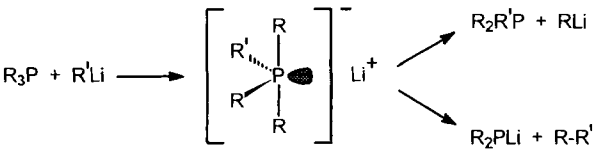
Substituent-Controlled Reactions of Iminophosphoranes with Methyllithium**

Alexander Steiner and Dietmar Stalke*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

Phosphorus ylides $R_3P{=}CR_2$ and phosphine oxides $R_3P{=}O$ can react with nucleophiles via hypervalent intermediates. These intermediates might be regarded as electronically similar to the valence-expanded $[PX_4]^-$ ions.[1, 2] The Wittig reaction, in which an intermediately formed oxaphosphetane resulting from the reaction of a phosphorus ylide and a carbonyl compound decomposes to give phosphine oxide and the related olefin, has been well studied.[3] Another example of the above-mentioned reactions is that of a pyridyl-substituted phosphine oxide with organometallic bases.[4] Aryl- and heteroaryl-substituted tertiary phosphanes can react to give either substituent-exchange[5] (Scheme 1, top) or substituent-coupling[6] products (Scheme 1, bottom).



Scheme 1.

In our ongoing studies of the influence of pyridyl substituents at phosphorus,[7] we were interested in the reaction of organolithium compounds with iminophosphoranes $R_3P{=}NR'$, which can be regarded as unsaturated $P^V{-}N$ compounds and hence as N analogues of phosphorus ylides and phosphine oxides.[8]

Both $Py_3P{=}NSiMe_3$ (**1**) (Py = 2-pyridyl) and the isoelectronic phenyl derivative $Ph_3P{=}NSiMe_3$ (**2**) were treated with methyllithium, and the structures of the resulting lithium compounds were determined. Compound **1** can readily be made by the Staudinger reaction of tri(2-pyridyl)phosphane and trimethylsilylazide [Eq. (a)].

$$Py_3P + Me_3SiN_3 \xrightarrow[-N_2]{160\,^\circ C/12\,h} \underset{\mathbf{1}}{Py_3P{=}NSiMe_3} \qquad \text{(a)}$$

Compound **1** reacts spontaneously with methyllithium in diethyl ether even at $-78\,^\circ C$, during which the solution changes from colorless to dark green. Golden brown needles can be grown from the reaction mixture on storing the flask at $0\,^\circ C$ for two days.

The results of the single-crystal X-ray structure analysis[9] are shown in Figure 1. The iminophosphorane **1** is converted into the lithium phosphine amide **3** during which the oxidation state of the central phosphorus atom decreases from V to III. The coordination sphere of the lithium ion is saturated by the substituent-coupling product 2,2′-bipyridyl obtained in this reaction. Scheme 2 shows one plausible reaction mechanism.

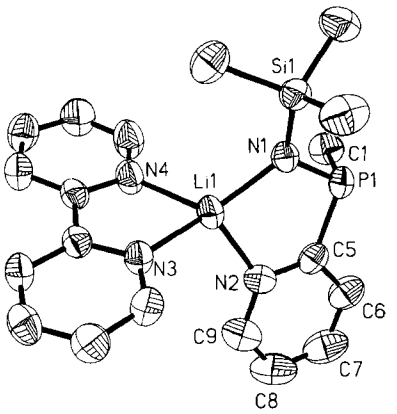

Fig. 1. Molecular structure of **3** in the crystal. Selected bond lengths [pm] and angles [°]: P1–N1 163.4(3), N1–Si1 167.5(3), P1–C1 183.8(4), P1–C5 184.9(4), C5–N2 134.7(4), Li1–N1 195.1(6), Li1–N2 203.3(6), Li1–N3 209.5(6), Li1–N4 207.0(7); N1–P1–C5 102.8(2), P1–N1–Si1 123.1(2), N1–Li1–N2 91.7(2), N3–Li1–N4 78.6(2).

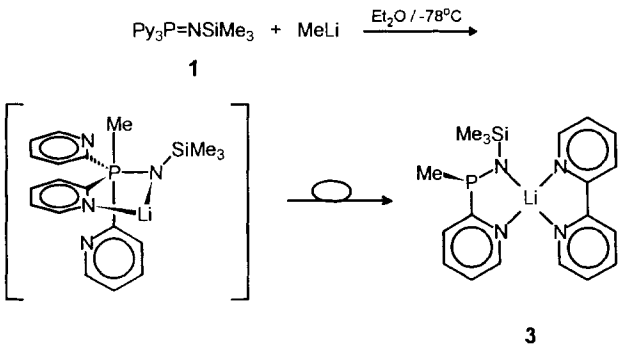

Scheme 2.

Methyllithium initially adds to the P=N bond in such a way that the methanide anion binds to the phosphorus atom and the lithium ion is coordinated by the peripheral nitrogen atoms. The hypervalent species subsequently rearranges through substituent coupling of two pyridyl groups to form the 2,2′-bipyridyl adduct **3**. Alternatively, a reaction mechanism analogous to that suggested by Wittig et al. for their phosphorane syntheses[10] is also plausible [Eq. (b)].

$$Py_3P{=}NSiMe_3 + MeLi \longrightarrow [Py_2(Me)P{=}NSiMe_3 + PyLi] \longrightarrow MeP(Py)(Me_3SiN)LiPy_2 \quad (b)$$

The P–N distance of 163.4(3) pm in **3** is remarkably short for a P–N single bond; the standard value is 170 pm.[11] In comparison the P=N bond length in iminophosphanes varies from 147 to 162 pm.[12] The P–N bond (167.2 pm) in the lithium phosphine amide $[Li(PhNPPh_2)(OEt)_2]_2$, which exhibits Li–N as well as Li–P contacts, was also considered to be relatively short.[13] A conceivable delocalization of the negative charge in the P–N unit of phosphine amide and iminophosphoranide resonance structures, which would explain the short P–N distance, however, could not be confirmed on the basis of the results of theoretical calculations on the $[H_2PNH]^-$ ion.[14] According to these calculations the negative charge is almost entirely localized at the nitrogen atom.

Li1 resides in a distorted tetrahedral environment, coordinated to its four neighboring atoms. The Li–N distance to the negatively charged N1 atom of 195.1(6) pm is 5 pm shorter than that in the $[Li(PhNPPh_2)(OEt)_2]_2$ dimer. The Li–N contacts to the neutral 2,2′-bipyridyl donor molecule (Li1–N3 209.5(6), Li1–N4 207.0(7) pm) are slightly longer than those to the pyridyl substituent of the anion (Li1–N2 203.3(6) pm).

When the phenyl-substituted iminophosphorane **2** is treated with methyllithium in diethyl ether in an analogous way to **1**, the reaction mixture only turned pale yellow at −78 °C. After the reaction mixture had been allowed to warm to room temperature, no spontaneous reaction was observed. Only after constant stirring for three days is the formation of a colorless precipitate apparent. Colorless single crystals were grown from the filtrate in two days at 3 °C. According to NMR spectroscopic studies the composition of the colorless precipitate and the single crystals growing from the solution is identical.

The single-crystal X-ray structure analysis[9] (Fig. 2) shows that, in contrast to the reaction of **1** with methyllithium, this

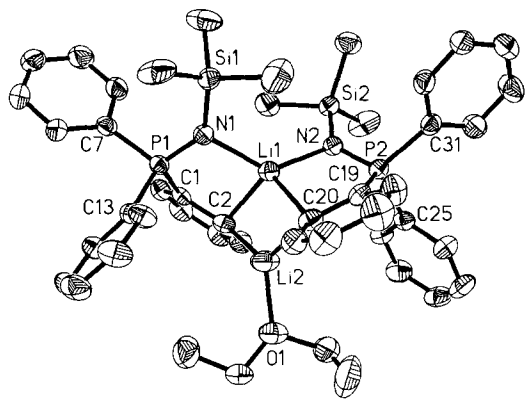

Fig. 2. Molecular structure of **4** in the crystal. Selected bond lengths [pm] and angles [°]: P1–N1 156.2(2), P1–N2 156.2(3), P1–C1 180.2(2), P1–C7 181.9(3), P1–C13 181.6(2), P1–C19 180.4(3), P1–C25 181.3(3), P1–C31 181.6(3), N1–Si1 170.1(2), N2–Si2 170.8(2), Li1–N1 203.7(5), Li1–N2 202.7(4), Li1–C2 213.8(6), Li1–C20 226.3(5), Li2–C2 213.8(6), Li2–C20 212.0(6), Li2–O1 189.7(5); P1–N1–Si1 135.2(1), P2–N2–Si2 133.5(1), C1–C2–C3 113.0(2), C19–C20–C21 113.0(2), N1–Li1–N2 132.2(2), C2–Li1–C20 107.7(2), C2–Li2–C20 121.2(2).

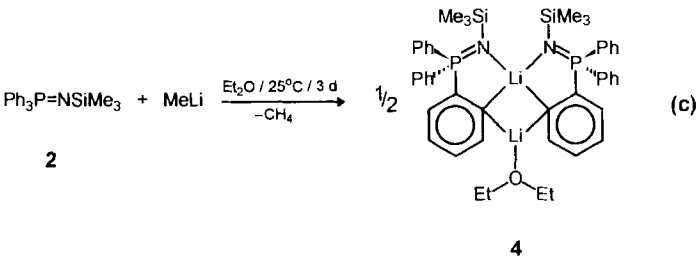
reaction does not involve nucleophilic attack at the phosphorus atom but deprotonation at the *ortho* position of one phenyl substituent leading to the dimeric organolithium complex **4** [Eq. (c)].



(c)

In the solid state **4** consists of two $Ph_3P{=}NSiMe_3$ units each deprotonated at the *ortho* position of one phenyl ring. The iminophosphorane units chelate through these *ortho*-carbon atoms and the N donor centers with a single central lithium ion (Li1; Fig. 2). A second lithium ion (Li2; Fig. 2) is coordinated to the two *ortho* ring carbon atoms and the oxygen atom of a diethyl ether molecule. Compound **4** adopts almost local C_2 symmetry.

Li1 resides in a tetrahedrally distorted environment, Li2 in an almost trigonally planar one. The Li1–C distances (C2–Li1 226.3, C20–Li1 233.1 pm) are on average 20 pm longer than the Li2–C distances (C2–Li2 213.8, C20–Li2 212.0 pm). The latter are comparable to the Li–C distances in the monomeric phenyllithium complex [PhLi·PMDETA] (PMDETA = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine).[15] In the oligomeric aggregates $[PhLi \cdot TMEDA]_2$ (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) and $[PhLi \cdot OEt_2]_4$, the related distances[16] are almost identical to the Li1–C distances in **4**. The lithium–nitrogen distances (N1–Li1 203.7(5), N2–Li1 202.7(4) pm) are comparable to the related distances in monomeric $(THF)_2Li(NSiMe_3)_2PPh_2$.[17] The Li2–O1 distance of 189.7(5) pm is within the range found for lithium ether adducts.[18] The coordination behavior of the phosphazene-substituted aryl anion in **4** is closely related to that of other bidentate monoanionic C,N-chelate ligands.[19] The phosphazene unit acts as an N-donating side arm. Preliminary results show that both lithium atoms can be replaced in a transmetalation reaction by E^{II} (E = Sn,Pb). In the solid-state structures of these compounds, the heavy p-block metal cations are coordinated in a bidentate way to both the *ortho*-carbon atoms and the two nitrogen atoms of the chelating phosphazene units.[20] Furthermore, **4** can be oxidatively coupled in the *ortho*-C positions to give the iminodiphosphorane **5**.[20] This appears to be particularly interesting in light of oligomeric phosphazenes as potential polymeric materials.

$Ph_2P(NSiMe_3)-(C_6H_4)-(C_6H_4)(NSiMe_3)PPh_2$ **5**

The ^{7}Li NMR spectrum of **4** at room temperature shows only one signal at $\delta = 3.0$ (standard: LiCl ext.). However, upon cooling the signal broadens, and beyond the coalescence point two signals can be resolved at $\delta = 3.4$ and 2.2.

The P=N bond (156.2(2) pm) in **4** is only 2 pm longer than that in the structure of the starting material **2**.[21] The P=N stretching vibration in the IR spectrum of **4** appears at $\tilde{\nu} = 1184\ cm^{-1}$. In comparison to the corresponding vibration for **2**, this is red-shifted by $120\ cm^{-1}$ as a result of the N–Li coordination.[22] The P–C bond lengths do not differ significantly (180.2(2)–181.9(3) pm).

The different reaction behavior of **1** and **2** can be attributed to the inductive effects of the substituents at the phosphorus atom. The pyridyl substituents in **1** are electron-withdrawing and facilitate the nucleophilic attack at the phosphorus atom, while the triphenyl-substituted phosphorus atom in **2** remains inert under the same conditions. Furthermore, the N donor functions of the pyridyl substituents can coordinate the lithium ion in the periphery of the molecule. This enables the attack of the methanide ion at the electrophilic P center of the molecule. Under the same conditions no nucleophilic attack at the phosphorus atom of **2** occurs, not even at 25 °C. The phenyl substituents lower the nucleophilicity of the central phosphorus atom and they themselves react as CH-acidic components with methyllithium.

The reaction of iminophosphoranes with organolithium bases controlled by pyridyl substituents opens new synthetic routes in phosphorus–nitrogen chemistry, and further interesting reactions can be expected in the near future. Because the phosphorus atom in **3** is a chiral center, diastereomeric products can be assumed when the related chiral organometallic compounds are used in syntheses. Currently we are investigating such reactions with phosphorus ylides.

Experimental Procedure

All manipulations were performed under an inert atmosphere of dry nitrogen with Schlenk techniques or in an argon glove box. Diethyl ether was dried over Na/K alloy and distilled prior to use.

1: Tri(2-pyridyl)phosphane (7.5 g, 28.0 mmol) was added to trimethylsilylazide (3.6 g, 31.0 mmol 1.1 eq), and the reaction mixture was heated to 160 °C for 12 h. At an oil bath temperature of 230 °C the dirty brown crude product was distilled off at reduced pressure (10^{-2} Torr). The resulting colorless oil solidified after addition of *n*-pentane (30 mL). This solid was washed twice with *n*-pentane (30 mL) and dried under high vacuum. Yield: 9.2 g (93%). M.p. 77 °C. IR (Nujol, KBr): $\tilde{\nu}\ [cm^{-1}] = 1574, 1424, 1295, 1234, 989, 863, 831, 746, 731, 538$. ^{1}H NMR ($CDCl_3$, 25 °C, TMS): $\delta = -0.76$ (d, $^4J(H,P) = 0.4$ Hz, 9H, $SiMe_3$), 7.26 (dddd, $^3J(H,[4]H) = 7.7$ Hz, $^3J(H,[6]H) = 4.8$ Hz, $^5J(H,P) = 2.5$ Hz, $^4J(H,[3]H) = 1.3$ Hz, 3H, [5]H), 7.72 (dddd, $^3J(H,[3]H) = 7.8$ Hz, $^3J(H,[5]H) = 7.7$ Hz, $^4J(H,P) = 3.9$ Hz, $^4J(H,[6]H) = 1.8$ Hz, 3H, [4]H), 8.05 (dddd, $^3J(H,[4]H) = 7.8$ Hz, $^3J(H,P) = 6.0$ Hz, $^4J(H,[5]H) = 1.3$ Hz, $^5J(H,[6]H) = 1.0$ Hz, 3H, [3]H), 8.68 (dddd, $^3J(H,[5]H) = 4.8$ Hz, $^4J(H,[4]H) = 1.8$ Hz, $^5J(H,[3]H) = 1.0$ Hz, $^4J(H,P) = 0.5$ Hz, 3H, [6]H). ^{13}C NMR ($CDCl_3$, 25 °C, TMS): $\delta = 3.4$ (d, $^3J(C,P) = 3.5$ Hz, $SiMe_3$), 124.5 (d, $^3J(C,P) = 3.2$ Hz, C[5]), 128.3 (d, $^2J(C,P) = 21.4$ Hz, C[3]), 135.6 (d, $^4J(C,P) = 9.4$ Hz, C[4]), 149.8 (d, $^3J(C,P) = 19.2$ Hz, C[6]), 158.0 (d, $^1J(C,P) = 131.1$ Hz, C[2]). ^{29}Si NMR ($CDCl_3$, 25 °C, TMS): $\delta = -8.0$ (d, $^2J(Si,P) = 15.8$ Hz). ^{31}P NMR ($CDCl_3$, 25 °C, H_3PO_4 / 85%): $\delta = -6.9$. MS(EI) $m/z = 337$ ($M^+ - Me$, 100%).

3: To a solution of **1** (1.0 g, 3.0 mmol) in diethyl ether (20 mL) methyllithium (3.0 mmol, 1.9 mL of a 1.6 M solution in diethyl ether) was added dropwise over 30 min at −78 °C. Subsequently the dark green reaction mixture was stirred for 3 d at 25 °C. After storage for 2 d at 0 °C golden brown needles were obtained. Yield: 0.7 g (64%). M.p. 134 °C. IR (Nujol, KBr): $\tilde{\nu}\ [cm^{-1}] = 1584, 1458, 1415, 1229, 1060, 823, 755, 498$. ^{1}H NMR ($C_6D_6$, 25 °C, TMS): $\delta = 0.45$ (s, 9H, $SiMe_3$), 1.88 (d, $^2J(H,P) = 4.3$ Hz, 3H, PMe, 6.3–8.5 (m, 12H, Py). ^{7}Li NMR (C_6D_6, 25 °C, LiCl): $\delta = 4.2$. ^{13}C NMR (C_6D_6, 25 °C, TMS): $\delta = 5.06$ (s, $SiMe_3$), 29.1 (d, $^1J(C,P) = 39.1$ Hz, PMe), 117–187 (m, Py). ^{29}Si NMR (C_6D_6, 25 °C, TMS): $\delta = -10.1$ (d, $^2J(Si,P) = 36.3$ Hz). ^{31}P NMR (C_6D_6, 25 °C, H_3PO_4/85%): $\delta = 52.5$. MS(EI) $m/z = 375$ (M^+, 32%), 79 ($[PyH]^+$, 100%).

4: To a solution of **2** (7.0 g, 20 mmol) in diethyl ether (100 mL) methyllithium (20 mmol, 12.5 mL of a 1.6 M solution) in diethyl ether was added dropwise at 25 °C. Within 3 d of stirring the formation of a colorless precipitate was observed. This was filtered and after storage of the filtrate at room temperature for 2 d colorless crystals were obtained. Spectroscopic data for the crystals and the precipitate were identical. Yield: 4.4 g (56%). M.p. 131 °C (decomp.). IR (Nujol, KBr): $\tilde{\nu}\ [cm^{-1}] = 1435, 1184, 1107, 859, 830, 725, 714, 659, 534$. ^{1}H NMR ($C_6D_6$, 25 °C, TMS): $\delta = -0.01$ (s, 18H, $SiMe_3$), 0.38 (t, $^3J(H,H) = 7.0$ Hz, 6H, Et_2O), 2.66 (q, $^3J(H,H) = 7.0$ Hz, 4H, Et_2O), 7.1–8.3 (m, 28H, Ph). ^{7}Li NMR (C_6D_6, 25 °C, LiCl): $\delta = 3.1$. ^{13}C NMR (C_6D_6, 25 °C, TMS: $\delta = 4.1$ (d, $^3J(C,P) = 3.8$ Hz, $SiMe_3$), 14.6 (s, Et_2O), 65.3 (s, Et_2O), 120–195 (m, Ph). ^{29}Si NMR (C_6D_6, 25 °C, TMS): $\delta = -5.2$ (d, $^2J(Si,P) = 4.7$ Hz). ^{31}P NMR (C_6D_6, 25 °C, H_3PO_4 / 85%): $\delta = 19.8$. MS(EI) $m/z = 334$ ($[Ph_3P{=}NSiMe_2]^+$, 100%).

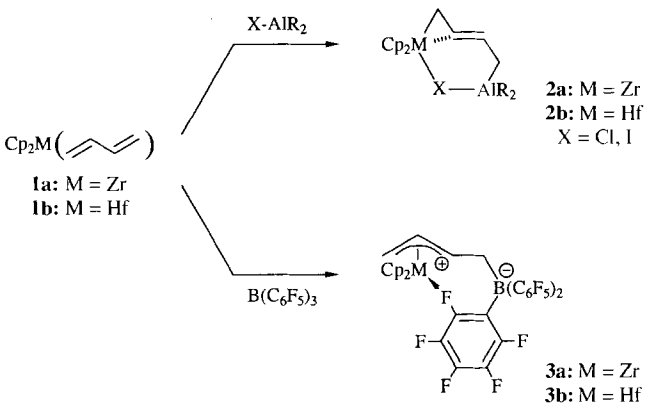
Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)borane—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts**

Bodo Temme, Gerhard Erker,* Jörn Karl, Heinrich Luftmann, Roland Fröhlich, and Sirpa Kotila

Homogeneous Ziegler-type catalysts based of bent metallocenes of the Group 4 metals have become enormously important in recent years.[1] They will probably develop into the next generation of Ziegler catalyst systems for industrial α-olefin polymer production.[2] Activation of the metallocene is mostly achieved by treatment with a very large excess of methylalumoxane.[3] New ways of activation for such CC-coupling catalysts employing only stoichiometric amounts of reagents are being developed to extend their use to other synthetic fields besides α-olefin polymerization. These methods are particularly attractive when they lead to well-characterized active catalysts or their direct precursors. Some progress has been achieved in this respect by using $[\{Cp_2ZrR^+\}\{BR_4^-\}]$-type ion pairs and related systems that are converted into active homogeneous Ziegler catalysts upon exposure to reactive α-olefins.[4] We have now found a very simple way to prepare metallocene–borate–betaine systems[5] in which the cationic and anionic parts are combined into a neutral molecule in such a way that the catalytic reactivity of the essential alkylmetallocene cation is retained. These novel organometallic compounds constitute neutral, covalently bonded molecules that rapidly polymerize α-olefins without further activation.

We have recently shown that (butadiene)zirconocene (**1a**) adds aluminum compounds $XAlR_2$ to form the heterodimetallacyclic complexes **2a**. These exhibit dynamic properties that



have been shown to originate from a reversible opening (with low activation barrier) of the Al–X bond.[6] To activate such complexes as metallocene–betaine catalysts for olefin polymerization, cleavage of the Zr–X linkage has to be facilitated by suitable molecular design. We have achieved this by introducing a more weakly coordinating bridging ligand between the main group metal and the zirconium center, and by increasing the electronic stabilization of the negative end of the potential betaine dipole.

Treatment of (butadiene)zirconocene (**1a**)[7] with tris(pentafluorophenyl)borane in toluene (−78 °C to room temperature) gives the 1:1 addition product (**3a**). It was isolated in 85% yield. The isolated material can be dissolved in tetrahydrofuran and characterized by spectroscopy and subsequent reactions in this solvent. Although complex **3a** can also be handled conveniently in toluene or benzene, it must be freshly prepared in these aromatic solvents since, once precipitated, the zirconium–boron complex **3a** is only slightly soluble in noncoordinating solvents. Single crystals of **3a** for the X-ray crystal structure analysis were obtained from toluene. A distorted π-allyl moiety is coordinated to the bent metallocene unit (Zr–C1 2.339(5), Zr–C2 2.494(6), Zr–C3 2.710(5), C1–C2 1.414(9), C2–C3 1.342(8) Å, angle C1-C2-C3 123.5(6)°; Fig. 1). The $B(C_6F_5)_3$ group is bonded to C4 (C3–C4 1.521(8), C4–B 1.633(9) Å). A characteristic feature of the structure of **3a** is the weak coordination of an *ortho*-fluoro substituent (F42) to the zirconium atom (Zr–F42 2.423(3), C42–F42 1.402(6) Å, angle C42-F42-Zr 140.0(3)°). The free coordination site of the zirconium–boron-betaine **3a** is occupied by this zirconium–fluorine interaction[4a, 5c] to give a stable metallacyclic complex.

From a comparison with the complexes **2a**, we assign complex **3a** a dimetallacyclic structure containing a distorted (π-allyl)metallocene unit in solution [^{13}C NMR spectrum in [D_8]toluene: δ = 52.7, 123.8, 131.1, 28.5 (C1–C4)]. Complex **3a** is chiral and thus exhibits two resonances for the diastereotopic Cp ligands (^{1}H NMR spectrum: δ = 5.32 and 5.28 in [D_6]benzene), as well as fast exchange on the NMR time scale

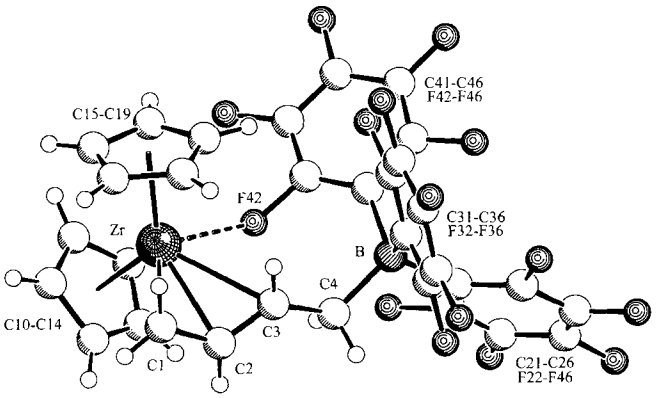

Fig. 1. Molecular structure of **3a** in the crystal.

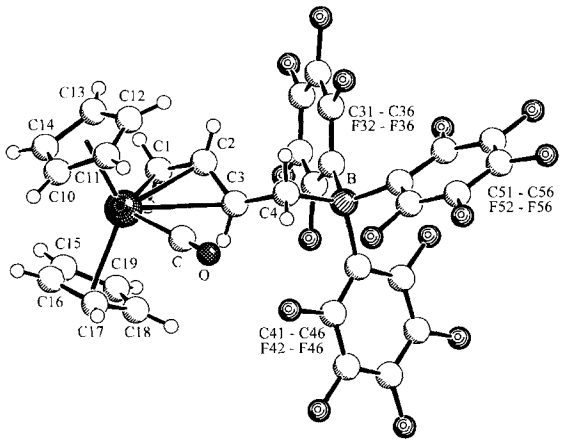

Fig. 2. Molecular structure of **5**; selected bond lengths [Å] and angles [°]: 2.246(7) (Hf–C), 1.109(8) (C–O), 2.396(5) (Hf–C1), 2.514(5) (Hf–C2), 2.742(5) (Hf–C3), 1.399(8) (C1–C2), 1.369(8) (C2–C3), 1.497(7) (C3–C4), 1.675(8) (C4–B), 176.2(6) (Hf-C-O).

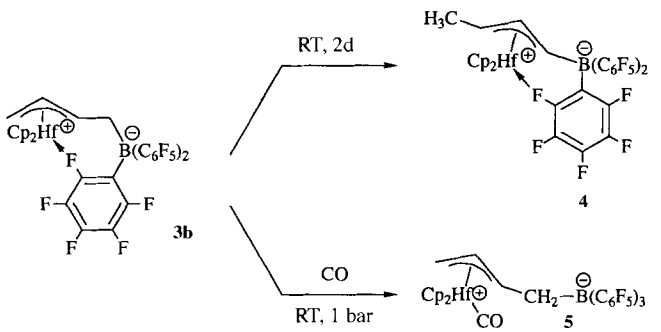
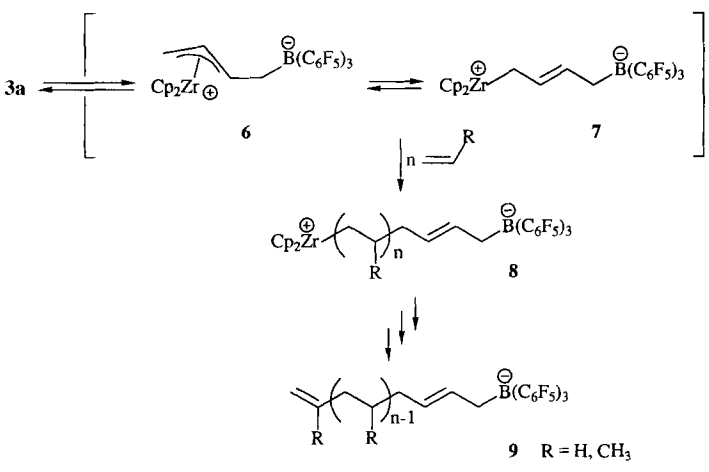
of the 1-H_{syn}/H_{anti} and 4-H/H′ protons at high temperature ($\Delta G^{\ddagger}_{enant.} \approx 17.2 \pm 0.5$ kcal mol^{-1} at 350 K).[8] Also the ^{19}F NMR spectrum of **3a** indicates dynamic behavior. Only in an oversaturated [D_8]toluene solution at 187 K are the signals of the ^{19}F NMR spectrum of **3a** resolved (external reference $CFCl_3$): three *para*-fluorine ($\delta = -158.5$, -159.2 and -160.9) and six *meta*-fluorine resonances ($\delta = -163.6$, -164.7 (three overlapping signals), -165.1, -165.3) in addition to six clearly separated *ortho*-fluorine signals, five of which appear in the usual range ($\delta = -126.4$, -130.6, -131.8, -134.0 and -137.5) are observed, whereas one signal is found at much more negative δ values (-213.2). This indicates that a single *ortho*-fluorine substituent of the $B(C_6F_5)_3$ unit coordinates to zirconium in solution, too.[5e] In [D_8]tetrahydrofuran the dynamics of **3** are still rapid on the NMR time scale at even much lower temperatures. The activation barrier of the formal allyl inversion process was estimated from the dynamic ^{1}H NMR spectra at 600 MHz in this solvent to be $\Delta G^{\ddagger}_{enant.}$(207 K) $\approx 10.0 \pm 0.5$ kcal mol^{-1}. In this solvent the ^{13}C NMR chemical shifts of the μ-C_4H_6 ligand [$\delta = 46.8$, 114.2, 147.1, 35.0 (C1–C4)] are so different from those in [D_8]toluene (see above) that we assume the presence of a THF-coordinated species.

Upon standing at room temperature for two days in [D_8]toluene solution the corresponding hafnium/boron complex **3b** quantitatively rearranges to the isomeric betaine complex **4**.[9] In the coordinating solvent THF this hydrogen migration reaction was not observed.[10] Treatment of **3b** with carbon monoxide yields the d^0-configurated (π-allyl)carbonylhafnium complex **5**, which was characterized by X-ray diffraction (Fig. 2).[11]



All these features of the zirconium complex **3a** (and its hafnium analogue **3b**) indicate that the C_6F_5 bridge is easily opened to generate a very reactive (μ-C_4H_6)M/B–betaine system. Consequently, introduction of ethylene to the Zr/B system **3a** resulted in rapid formation of polyethylene (the activity *a* is about 135 g polyethylene per mmol [Zr] per hour at 20 °C in dilute toluene solution). Complex **3a** also catalyzes the polymerization of propene. In toluene solution at 50 °C polypropylene formed with an activity of about 28 g polymer per mmol [Zr] per hour. As expected, the polymerization reaction catalyzed by **3a** is more efficient in liquid propene. A polymerization experiment employing 100 mg (0.36 mmol) of (butadiene)zirconocene and 186 mg (0.36 mmol) $B(C_6F_5)_3$ (to generate **3a** in situ) in 10 L of liquid propene at 70 °C (30 bar, 1 h) yielded about 800 g of polypropylene (*a* about 2.2 kg of polymer per mmol [Zr] per hour).[12] Both polymers have characteristics typical of polyethylene (m.p. 126 °C) and polypropylene (atactic, rather low molecular weight) formed at homogeneous Ziegler-type catalysts containing the parent bis(cyclopentadienyl)zirconium unit.[1–3]

In view of the typical chemical properties of **3a** (and **3b**, see above) one must assume that the fluoride bridge is very easily opened under the polymerization conditions. This may result in the generation of a betaine species (**6** or **7**) containing a very electrophilic zirconium center that can readily coordinate and insert α-olefins.[13] Experimental evidence for such a reaction path for betaines derived from **3a** was obtained from a laser desorption ionization MS experiment (LDI) [14] that could monitor even small quantities of anionic polymers originating



from some initial phases of the polymerization process in the presence of the "MS-silent" neutral polypropylene.

In a typical series of experiments propene was polymerized at ambient pressure in toluene at + 40 °C with **3a**. The reactions were stopped after short polymerization times (about 10 min). The solvent was removed, and an aliquot of the residue dissolved in tetrahydrofuran and treated with tetrabutylammonium bromide. The sample was introduced into the mass spectrometer, where the solvent evaporated. Laser desorption from targets treated in this manner gave time of flight mass spectra of the anions; a typical example is depicted in Figure 3. Aside from

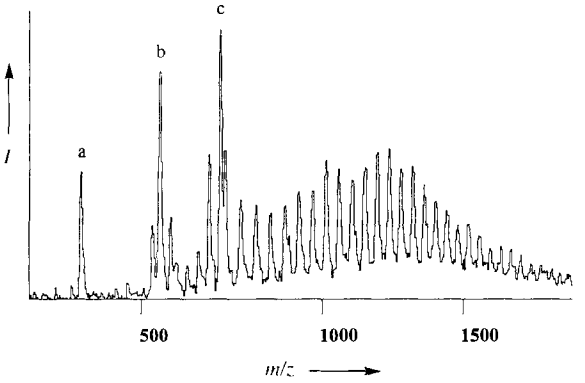


Fig. 3. LDI-TOF mass spectrum of the anions **9** (the features a–c originate from $B(C_6F_5)_3$-derived secondary products).

a few discrete features (for example, $[(C_6F_5)_3BOH]^-$ at $m/z = 529$), a broad molecular weight distribution of the anions of the general composition of $[H_2C=C(CH_3)-(propene)_{n-1}(butadiene)B(C_6F_5)_3]^-$ (**9**) are registered (for example, $m/z = 1280$ for $n = 17$). The example shown in Figure 3 contains a distribution of oligomeric anions ranging from about $n = 5$ to 27 with a broad maximum around propene insertion values of $n \approx 16-18$. This analysis shows that upon propene polymerization at the catalyst **3a**, anionic polymers containing borate groups are obtained with the typical molecular weight distribution of such a consecutive insertion process. The borate groups are probably incorporated in the initial phases of the catalytic process from **6** and **7**. Our experiment has indicated that in the reaction starting from **3a** and α-olefins, polymer modified catalyst systems are formed. This is very interesting since a covalently bound α-olefin polymer is, by the nature of its favored secondary structure, probably able to increasingly protect the active section of the catalyst system during the course of the polymerization process. The catalytic process starting from **3a** could, therefore, open new ways toward a dynamic stabilization of active catalysts that is achieved by the catalysis itself and is even enhanced as it proceeds.

The Preparation of Salts of $[Pd_2(\mu\text{-}Se_2N_2)Cl_6]^{2-}$, the First Adducts of Diselenium Dinitride**

Paul F. Kelly* and Alexandra M. Z. Slawin

The continued interest in sulfur–nitrogen chemistry is prompted by the diverse range of species involved and the remarkable, and often unique, properties they exhibit.[1] Recent years have witnessed the gradual development of an important extention to this area, in the form of the synthesis of selenium analogues of many sulfur–nitrogen compounds.[2] Although this may appear to be a relatively trivial chemical alteration, in practice the preparation of such species is fraught with difficulties, not least of which is the severely explosive nature of the most obvious starting material, Se_4N_4. Despite these hurdles, there have now been reports of the preparation of a number of noncoordinated compounds, including $(Se_3N_2)^{2+}$ and Se_4N_2, as well as complexes of a variety of Se–N ligands.[3–5]

The reactions leading to these compounds serve to highlight the likelihood that the chemistry of Se–N compounds in fact mirrors that of S–N compounds to a far greater extent than was previously thought. One area in which the latter conclusion has so far proved untrue, however, is in the preparation of Se_2N_2 and $(SeN)_x$; here we present the first conclusive evidence of the existence of the former species, in the form of a palladium adduct.

Reaction of a suspension of Se_4N_4 in CH_2Cl_2 with the salt **1**, which has a Pd^{II} dimer as the anion, in a sealed tube at 100 °C

$[PPh_4]_2[Pd_2Cl_6]$ **1**

yields a dark solution from which orange crystals may be grown by slow diffusion of ether. X-ray crystallography reveals this product to be the salt **2a** (Fig. 1).[6] The planar anion in **2a**

$[PPh_4]_2[Pd_2(Se_2N_2)Cl_6]$ **2a**

(maximum deviation from mean plane is shown by Cl2, 0.02 Å) contains the first known example of a bidentate, neutral Se_2N_2 ligand. The latter exhibits an average Se–N bond length of 1.79 Å, which is essentially identical to that in Se_4N_4.[7] In contrast, the average bond length in the sulfur analogue of **2a** (1.65 Å) is markedly longer than that in S_4N_4 (1.62 Å) although equal to that in free S_2N_2.[8]

These bond lengths in **2a** are not equivalent, reflecting a slight degree of asymmetry exhibited by the molecule as a whole. This asymmetry may be traced back to the different N1-Pd-Cl angles at each palladium atom; for Cl1 this angle is 85.6° compared to the tighter 83.6° for Cl3. (The fact that both chlorines show a substantial deformation in towards the Se_2N_2 unit mirrors an effect noted many times for S_2N_2 adducts.[9]) Thus it appears that the slightly different degree of interaction between Cl1–Se1* and Cl3–Se1 produces a concomitant difference in the N1–Se1* and N1–Se1 distances. A view of the packing arrangements in the structure of **2a** reveals a Cl3–Cl3* interaction of about 3.5 Å between neighboring anions (Fig. 2), which is probably the ultimate source of the asymmetry in the anion; Cl3

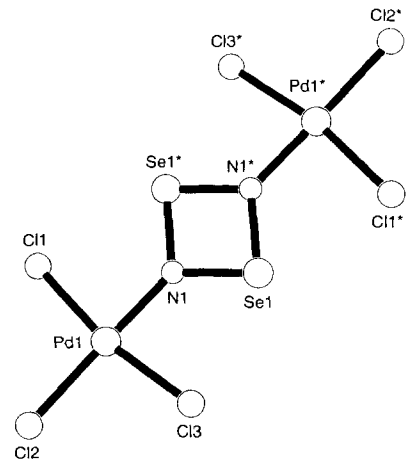

Fig. 1. X-ray structure of the $[Pd_2(Se_2N_2)Cl_6]^{2-}$ anion in **2a**. Selected distances [Å] and angles [°]: Pd1-Cl2 2.286(1), Pd1-Cl3 2.289(2), Pd1-Cl1 2.310(2), Pd1-N1 1.946(4), N1-Se1 1.779(4), N1-Se1* 1.804(5), N1-Pd1-Cl3 83.6(1), N1-Pd1-Cl1 85.6(1), Pd1-N1-Se1 130.6(3), Pd1-N1-Se1* 130.8(2), Se1*-N1-Se1 98.6(2), N1-Se1-N1* 81.4(2).

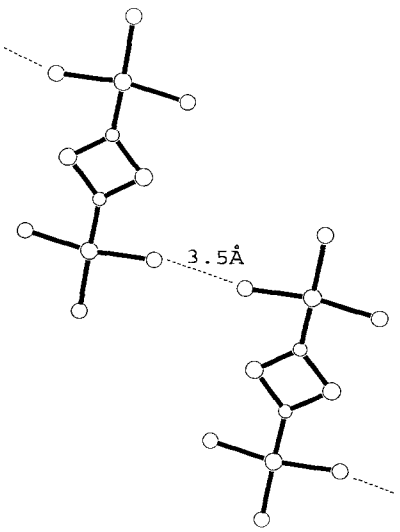

Fig. 2. The close approach of anions in the crystal packing of **2a**.

is presumably "repelled" by Cl3* into a closer approach to the nearest selenium atom. These effects at Pd1 are mirrored at Pd1*, reflecting the center of symmetry of the molecule as a whole.

The reaction gives **2a** in reasonable yield (ca. 20%) and, interestingly, this appears to be the only crystallizable product. In contrast, the analogous reaction of S_4N_4 with **1** generates a variety of species, including the S_2N_2 adduct **3** (which is

$[Pd_2(S_2N_2)Cl_6]^{2-}$ **3**

isostructural with the anion in **2a**) as well as $[Pd_2(S_3N_2)Cl_4]^{2-}$ and $[Pd(S_2N_2H)Cl_2]^-$, both of which crystallize readily.[8, 10] This implies that a different reaction mechanism applies in the two cases. We have previously suggested that for S_4N_4 this involves the initial formation of a Pd^{II}–S_4N_4 adduct, $[Pd(S_4N_4)Cl_3]^-$, which can then either react with more **1** to give **3**, or undergo a redox process leading to an unstable Pd^{IV} complex of tridentate $[S_4N_4]^{2-}$. The latter in turn decomposes to the two other isolated compounds. In the case of Se_4N_4 it may be that the latter redox process is not favorable and hence only the

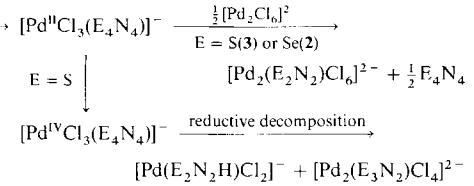
Se_2N_2 adduct is ever formed (Scheme 1). On this point, it is noteworthy that reactions that are known to generate complexes of $[S_4N_4]^{2-}$ give entirely different products with Se_4N_4.[5]



Scheme 1. Possible mechanisms for the reaction of E_4N_4 (E = S or Se) with $[Pd_2Cl_6]^{2-}$.

The reaction can be extended to $[Pd_2Cl_6]$ salts with different cations than that in **1**. Thus $[n\mathrm{Bu}_4\mathrm{N}]_2[Pd_2Cl_6]$ reacts in similar conditions to give **2b**. In this case the product may be isolated

$[n\mathrm{Bu}_4\mathrm{N}]_2[Pd_2(Se_2N_2)Cl_6]$ **2b**

as well-formed needles by cooling a CH_2Cl_2 solution for roughly 12 h. (A common feature of both salts is their surprisingly low solubility, which has caused problems in the measurement of their ^{77}Se NMR spectra.) As in the preparation of **2a**, IR spectroscopy shows the insoluble residue from the reaction to be mostly Se_4N_4.

The yield of **2b** prepared in this way (33%) is significantly higher than that of **2a**. Interestingly, when a 1:1 molar ratio of Se_4N_4 and the palladium salt are used, the yield (based upon Pd) actually increases to 53%. This is clearly a more efficient reaction; the observation fits with the mechanism in Scheme 1 insofar as the existence of only one reaction route for Se_4N_4 would allow a reaction with an overall stoichiometry of 1:1 to proceed efficiently. (For S_4N_4 the presence of the two competing routes, one of which does not result in S_4N_4 being liberated, would require a higher ratio, and we have previously shown that even at a 2:1 ratio very little S_4N_4 is left at the end of the reaction.) It is not clear, however, why the presence of an excess of Se_4N_4 should result in lower yields of **2b**.

The IR spectrum (KBr disc, Perkin-Elmer 2000R spectrometer) of **2b** is more informative than that of **2a** due to the presence of fewer strong cation vibrations. In addition to a metal–halogen stretch at 334 cm^{-1} a band at 777 cm^{-1} is observed. This is a ν(Se–N) stretch analogous to the ν(S–N) stretch seen at 877 cm^{-1} in **3**; a comparable frequency difference is observed between the bands of S_4N_4 (927, 700, 548 cm^{-1}) and Se_4N_4 (788, 570, 425 cm^{-1}).[7] In contrast to the spectrum of **3**, in which both the S–N and Pd–Cl stretches are of similar intensity, in **2b** the Se–N band is the markedly weaker of the two. A further band is seen in **3**, at 436 cm^{-1}; no analogous vibration appears in the spectrum of **2b**, although it may well be obscured by the Pd–Cl stretch.

Despite the obvious dangers associated with their preparation, it does appear that once formed, **2a** and **2b** are quite stable. This clearly bodes well for the chances of preparing free Se_2N_2, possibly by means of elimination from the adduct (as has been noted for S_2N_2 from adducts with $AlCl_3$ for example),[11] and hence $(SeN)_x$. This route may actually prove to be the best hope of making the aforementioned polymer, which has so far eluded preparation (mainly because of the involatility of Se_4N_4 and its consequent inability to mirror the vapor-phase cleavage of S_4N_4 to S_2N_2)[12].

Experimental Procedure

The salts containing the $[Pd_2Cl_6]$ anions and Se_4N_4 were prepared as reported previously. **Extreme caution** was taken with the latter since it is **severely explosive** [10,13].

2a: Solid Se_4N_4 (150 mg, 0.4 mmol) was added to a solution of **1** (222 mg, 0.2 mmol) in CH_2Cl_2 (50 mL) in a thick-walled reaction tube fitted with a Youngs greaseless joint. The mixture was stirred at room temperature under a nitrogen atmosphere. More CH_2Cl_2 was added to just below the seal of the joint, which was then closed. The tube was immersed in a preheated oil bath at 100 °C. After ca. 1 h with continuous stirring the mixture consisted of a dark solution with dark colored suspension. After cooling, the solution was filtered through celite in air and reduced in volume to 2 mL. Layering with ether followed by slow diffusion yielded a large crop of well-formed dark orange crystals of **2a**. Yield 48 mg (20%).

2b: This salt was prepared in similar manner to **2a** by the reaction of Se_4N_4 (100 mg, 0.27 mmol) with $[n\mathrm{Bu}_4\mathrm{N}]_2[Pd_2Cl_6]$ (122 mg, 0.14 mmol) in CH_2Cl_2 at 100 °C for 1.5 h. The resulting mixture was filtered and the volume reduced to ca. 10 mL in vacuo. At this point the solution was heated to redissolve any solid and then cooled at −20 °C overnight. The mass of orange needles that formed were separated from the mother liquor and redissolved in CH_2Cl_2 (50 mL). This solution was filtered through celite and the solvent then removed leaving an orange solid. Yield 44 mg; a further small amount of impure crystals was obtained by evaporation of the mother liquor; recrystallization gave a further 4 mg of pure product. Total yield 48 mg, 33% based upon Pd.

The reaction between $[n\mathrm{Bu}_4\mathrm{N}]_2[Pd_2Cl_6]$ and Se_4N_4 in a molar ratio of 1:1 was performed exactly as above, using half the amount of Se_4N_4 (50 mg, 0.135 mmol). Final yield of **2b** 78 mg (53% based upon Pd).

Rhodium-Catalyzed Hydroformylation of Internal Alkynes to α,β-Unsaturated Aldehydes**

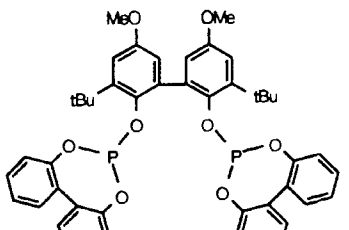
John R. Johnson, Gregory D. Cuny, and Stephen L. Buchwald*

The hydroformylation of alkenes has been widely studied and is an important industrial process.[1] The hydroformylation of alkynes has received relatively scant attention. The first reported alkyne hydroformylations with cobalt and rhodium catalysts resulted in the formation of saturated aldehydes.[2, 3] These can arise by hydrogenation of an initially formed unsaturated aldehyde intermediate, as observed with internal alkynes.[3, 4] Alternatively they may be produced by the hydroformylation of an alkene formed by alkyne hydrogenation, as observed with terminal alkynes.[3, 5]

Few examples of the selective hydroformylation of alkynes to yield unsaturated aldehydes have been reported. Conjugated enynes undergo hydroformylation with a rhodium catalyst to give formylbutadienes in low yields.[6] In addition, diphenylacetylene can be converted into 2,3-diphenylpropenal under hydroformylation conditions (approximately 30 atm CO/H_2, 80 °C) in low to moderate yield.[6a, e] However, attempts to generalize the reaction to include other alkynes have had minimal success.[6c] β-Alkynylamines were found to undergo rhodium-catalyzed hydroformylation to give substituted pyrroles.[7] These reactions are believed to proceed through α,β-unsaturated aldehyde intermediates.

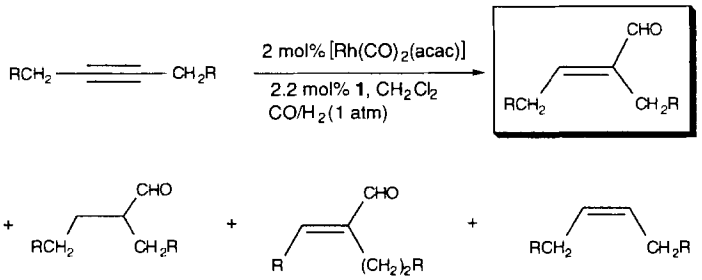
Related carbonylation reactions of alkynes have also been reported. Hydrocarboxylation and hydrocarboalkoxylation of alkynes to give (*E*)-alkenoic acids[8] or (*E*)-alkenoate esters,[9] respectively, have been achieved with palladium catalysts. In addition, rhodium catalysts silylformylate alkynes in the presence of a trialkylsilane and CO to yield β-silyl-2-enals.[10] A high degree of regiocontrol has been obtained with terminal alkynes; disubstituted alkynes are silylformylated with moderate selectivity.[10]

A catalyst capable of the stereoselective hydroformylation of alkynes to provide the conjugated aldehyde, without producing significant amounts of either the corresponding saturated aldehyde or noncarbonylated alkene, would be useful as a method for the stereoselective synthesis of trisubstituted olefins.[11] Herein, we report our initial results utilizing the catalyst system formed from $[Rh(CO)_2(acac)]$ (acac = acetylacetonate) and **1** to effect the selective hydroformylation of alkynes to α,β-unsaturated aldehydes under mild reaction conditions.



1

We recently reported that the catalyst system **1**/$[Rh(CO)_2(acac)]$ regioselectively hydroformylates α-olefin substrates that contain a variety of functional groups.[12] The reaction conditions that we employed for the hydroformylation of alkenes led to extensive hydrogenation of the enal product before conversion of the alkyne was complete. Further studies revealed that overreduction of the conjugated olefin could be suppressed if the reaction pressure was decreased to approximately 1 atm. In the presence of 2 mol% of $[Rh(CO)_2(acac)]$, 2.1 mol% of **1**, and synthesis gas (1:1 CO/H_2 mixture, 1 atm) in CH_2Cl_2 as solvent, symmetric alkynes were converted at room temperature into α,β-unsaturated aldehydes without significant formation of the saturated aldehydes (Scheme 1, Table 1). The stereochemistry



Scheme 1.

of the hydroformylation products was determined by NOE experiments to arise from the net *cis* addition of the formyl group and hydrogen.[13] The aldehyde products were obtained in good yield after Kugelrohr distillation or chromatography on silica gel.

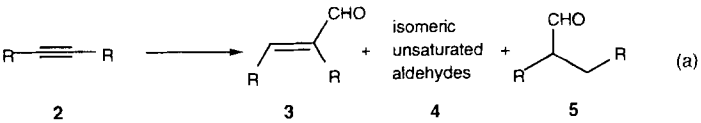


Table 1. Hydroformylation of the symmetric alkynes **2** according to Equation (a).

No.	R	Product distribution [a]		
		3	**4**	**5**
1	C_2H_5	63 (92)	(4)	(1)
2	C_3H_7	85 (96)	–	(2)
3	C_4H_9	90 (97)	(2)	(1)
4 [b]	C_5H_{11}	83 (92)	(1)	(4)
5 [c]	Ph	56 (67)	–	3 (3)
6 [d]	$CH_3OC_6H_4$	84 (86)	–	–

[a] Yield of isolated product, followed by relative percent of crude products in parentheses (uncorrected for GC response factors; numbers do not always total 100%, because small quantities of unidentified products are present). [b] 4 mol% catalyst and 4.4 mol% **1**. [c] 29% (*Z*)-stilbene formed (GC). [d] 14% (*Z*)-olefin formed (GC).

Careful monitoring of the hydroformylation of 4-octyne indicates that the saturated aldehyde can arise from the hydrogenation of the desired unsaturated aldehyde. If the reactions are allowed to continue under the standard reaction conditions for an extended period of time after complete consumption of the substrate, the saturated aldehyde increases in quantity as the amount of enal decreases and can be obtained as the major product. Diaryl-substituted alkynes, however, exhibit different behavior. In the most clear-cut case, diphenylacetylene (Table 1, Entry 5) is hydrogenated to *cis*-stilbene at a rate competitive with hydroformylation to 2,3-diphenyl-2-propenal. Upon complete consumption of the starting material, the ratio of enal to alkene was typically 3:1.[14] Allowing the reaction to continue

results in conversion of *cis*-stilbene into 2,3-diphenylpropanal by hydroformylation and to *trans*-stilbene by isomerization. Other diaryl-substituted alkynes such as di(*p*-methoxyphenyl)-acetylene (Table 1, Entry 6) are hydrogenated to a lesser extent and correspondingly higher yields of the enal are realized.

After the development of suitable reaction conditions for the hydroformylation of symmetrical alkynes, a study of the regioselectivity of the hydroformylation of unsymmetrical alkyne substrates was undertaken (Table 2). Both steric and electronic factors appear to play a role. For example, hydroformylation of 4,4-dimethyl-2-pentyne (Table 2, Entry 5) gave approximately a 5:1 ratio of enal products, in which the major regioisomer arose from the intermediacy of the less hindered vinylrhodium isomer. In contrast, hydroformylation of 1-phenyl-1-propyne (Table 2, Entry 1) gave a 2.5:1 mixture of 2-phenyl-2-butenal and 2-methyl-3-phenyl-2-propenal; the major product stems from the

2 [b]	Ph		64 (69)	(18)	(5)
3	Ph	*t*Bu	46 (74)	(14)	
4 [b]	Me	nC_5H_{11}	83 [c]		(2)
5 [d]	Me	*t*Bu	56 (67)	(13)	(11)

[a] See footnote [a] of Table 1. [b] 3 mol% $[Rh(CO)_2(acac)]$ and 3.3 mol% **1**. [c] Yield of isolated products from the purified mixture containing the α,β-unsaturated aldehyde regioisomers in a 1.3:1 ratio. [d] 4 mol% $[Rh(CO)_2(acac)]$ and 4.4 mol% **1**.

more hindered alkylrhodium isomer.[15] This example also demonstrates that competitive hydrogenation does not occur to a significant extent when at least one alkyne substituent is an alkyl group. Hydroformylation of 2-octyne led to approximately a 1:1 mixture of 2-methyl-2-octenal and 2-pentyl-2-butenal, which points to little differentiation between the methyl and the *n*-pentyl group.

In conclusion, we have shown that the catalyst system generated from $[Rh(CO)_2(acac)]$ and **1** is the first selective, reasonably general catalyst for the hydroformylation of internal alkynes to α,β-unsaturated aldehydes. With further research to optimize the regioselectivity with unsymmetrical alkyne substrates, this method should prove useful for the stereoselective synthesis of trisubstituted olefins.

$(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$: Compounds with Discrete (M_6N) Octahedra and $[Ga_5]$ Clusters**

Gerhard Cordier, Matthias Ludwig, Dagmar Stahl, Peter C. Schmidt, and Rüdiger Kniep*

The majority of intermetallic ternary compounds comprising an alkaline earth metal, an earth metal, and an element of Group 15 are electrovalent and contain complex anions (e.g. $Ca_3[AlSb_3]$[1]). Also nitrogen, as the lightest element of the Group 15 elements, participates as a ligand in the formation of covalent anionic structures (e.g. $Sr_3[Al_2N_4]$[2]). At the same time, however, the nitrido nitrogen tends to occupy—as isolated (ionic) species—the centers of coordination polyhedra formed exclusively by alkaline earth metal cations. Such structural elements with an overall positive charge form (M_6N) octahedra (M = alkaline earth metal cations) as found recently in a series of nitride compounds: Isolated (M_6N) octahedra exist in the crystal structure of $Na_{16}Ba_6N$;[3] the crystal structure of $NaBa_3N$[4] contains one-dimensional columns (Ba_3N) of face-sharing (Ba_6N) octahedra. Layer structures result by edge-sharing $((Ca_3N)_2[GaN_3]$[5]) or corner-sharing $((Ca_4N)[In_2]$[6]) of (Ca_6N) octahedra. Three-dimensional frameworks are generated by condensation of (Ca_6N) octahedra through common corners $((Ca_3N)[Au]$[7]) or common corners and edges $(Ca_{18.5}Ga_8N_7$[8]).

Cationic partial structures in nitrido compounds with alkaline earth metals can thus be varied in terms of size and volume over a wide range. This is surely one of the reasons why rather uncommon anions such as trigonal-planar $[GaN_3]^{6-}$ units ($(Ca_3N)_2[GaN_3]$[5]), helical $^1_\infty[NiN_{2/2}]$ polyanions ($Ba_2\{(Ba_6N)[NiN]_6\}$[9]), and auride ions ($(Ca_3N)[Au]$[7]) can be stabilized in the solid state.

With a view to gaining further insight into this situation, we decided to investigate the formation of compounds in the ternary systems alkaline earth metal – gallium – nitrogen. These systems are particularly attractive because of the well-known tendency of gallium to form homonuclear bonds, for example, tetrahedral Ga_4 clusters ($Ca_{18.5}Ga_8N_7$[8]), planar zigzag chains ($Ca_5[Ga_2N_4]$[10]), or even layers of tetragonal pyramids (Ca[GaN][11]). We report here the first ternary phases with the higher homologues of calcium. The isotypic compounds $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$ contain isolated octahedral cations $(M_6N)^{9+}$ and trigonal-bipyramidal anions $[Ga_5]^{7-}$. The ionic isles $(M_6N)^{9+}$ together with the homonuclear clusters $[Ga_5]^{7-}$ form the motif of a rock-salt structure.

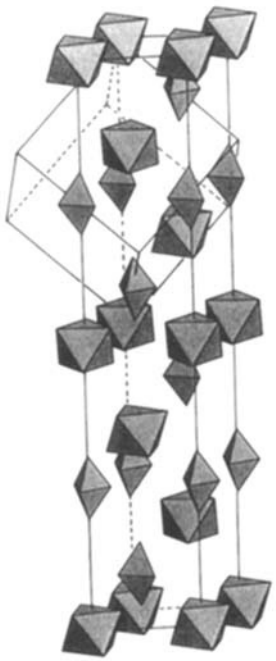

Fig. 1. Crystal structure of $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$: Hexagonal and pseudocubic unit cell. Octahedra: $(Sr_6N)^{9+}$, trigonal bipyramids: $[Ga_5]^{7-}$.

For the preparation of $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$, the metals were initially added together and heated to about 1000 °C and then subsequently treated with nitrogen.[12] The crystal structure of the isotypic phases[13] is shown in Figure 1. The Sr–N (Ba–N) distances in the isolated octahedra (M_6N) are 260.3(1) (273.4(1) pm). Comparable Ba–N distances were observed in the subnitrides $NaBa_3N$ (273 pm; strings of face-sharing (NBa_6) octahedra[4]) and $Na_{16}Ba_6N$ (283 pm; isolated (NBa_6) octahedra[3]). The (M_6N) octahedra in the crystal structures of $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$ are arranged in the form of a cubic closest packing, with Ga_5 clusters (trigonal bipyramids) occupying the octahedral holes. The Ga–Ga distances of 272.5(3) and 273.6(3) pm for the strontium compound and 272.5(3) and 272.5(3) pm for the barium compound correspond to the bond lengths in elemental gallium (271 pm[14]). The trigonal axes of the Ga_5 bipyramids are aligned parallel to the c axis. A pseudo-cubic cell is outlined in Figure 1.

The Sr–Ga distances (328.7(2)–349.4(1) pm) and the Ba–Ga distances (346.4(2)–367.1(3) pm) are comparable to those found in the intermetallic phases Sr_8Ga_7[15] (325–359 pm), Ba_8Ga_7[15] (340–368 pm), and Ba_5Ga_6[16] (332–359 pm). The shortest Sr–Sr and Ba–Ba distances (octahedral edges) (362.8(2) pm and 378.6(2) pm, respectively) are clearly shorter than the bond lengths in the elements (425 pm and 434 pm, respectively[17]).

According to the results of the crystal structure determination, the bonding in $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$ can be described by the following simple picture: the nitride ions (N^{3-}) octahedrally surrounded by six alkaline earth metal ions (M^{2+}) form positively charged units $(M_6N)^{9+}$, whose charge is compensated at least partly by the negatively charged Ga_5 clusters. If the Ga_5 cluster is considered as a Zintl anion, there are two three-coordinate (axial) Ga atoms ($\triangleq Ga^{2-}$) and three four-coordinate (equatorial) Ga atoms ($\triangleq Ga^{-}$), resulting in a total charge of $[Ga_5]^{7-}$. According to Wade, the homonuclear 22-electron system can be described as a *closo* cluster $[Ga_5]^{7-}$ with $2n + 2 = 12$ electrons in the skeleton. This situation is similar to that already known for the isoelectronic species $[Sn_5]^{2-}$[18], $[Bi_5]^{3+}$,[18] and $[Tl_5]^{7-}$.[19] For the title compounds this results in the formula $\{(M_6N)^{9+}[Ga_5]^{7-} \cdot 2e^-\}$, as a simple model of the chemical bonding; the charge is balanced by two electrons in metallic states.

For a more detailed characterization of the chemical bonding, band structure calculations for the strontium compound were carried out according to the standard ASW[20] technique (ASW = augmented spherical wave). From the total density of states ($N(E)$), metallic character ($N(E_F) \neq 0$) can be derived, as shown in Figure 2. The partial density of states of Sr (Fig. 2)

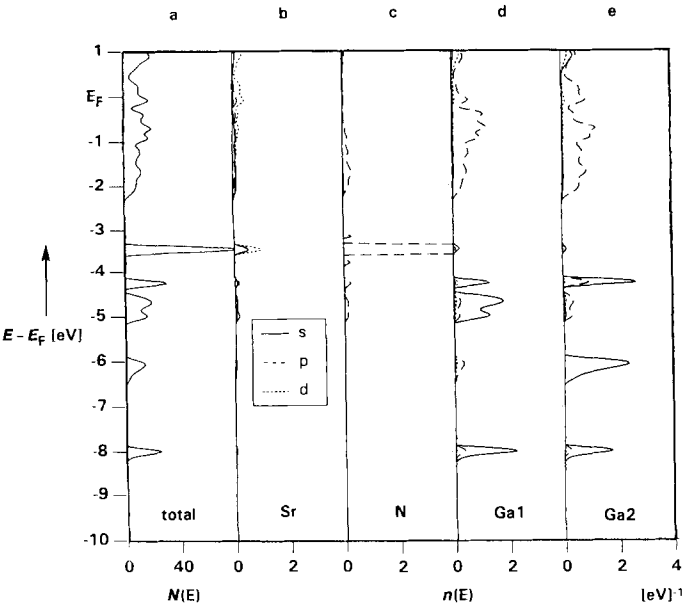

Fig. 2. Density of states (total (a) and partial (b–e)) of $(Sr_6N)[Ga_5]$ vs. energy [eV] of the valence states (calculation by ASW technique).

shows only scattering contributions below the Fermi energy corresponding to an Sr^{2+} ion.[21] The partial density of states of the nitrogen atoms exhibits a large 2p-like contribution at -3 eV. The integral of these states yields six electrons per N atom, therefore indicating that a N^{3-} species results (the 2s states of nitrogen are not shown in Fig. 2). The 2p states of the nitride ions overlap at approximately -3 eV with the scattering contributions of strontium (Sr^{2+}) and thus reflect the cationic $(Sr_6N)^{9+}$ units derived from the crystal structure determination. All further states below the minimum at -0.35 eV can be assigned to the partial density of states of the Ga atoms (Fig. 2, d and e). The integral of these states below -0.35 eV results in 22 electrons per formula unit and thus corresponds to the anionic cluster $[Ga_5]^{7-}$ already discussed. The states of two conduction electrons remain from the minimum at -0.35 eV up to the Fermi energy. The band structure of the p-like states of gallium in the range -2 eV up to E_F shows a dispersion, which is possibly consistent with a delocalization of these states over the $[Ga_5]^{7-}$ clusters and slightly over the Sr atoms. Crystal orbital

overlap population (COOP) analyses[22] of these states indicate delocalized bonds within the homonuclear clusters and only weak overlap between gallium and strontium. A direct bond between the $[Ga_5]^{7-}$ clusters can be ruled out because of the large distances ($d(Ga\cdots Ga \geq 493$ pm).

In recent work Hoffmann and Liu[23] discussed the question of whether the intermetallic phase Ba_5Ga_6[16] might not actually be a hydride "$Ba_5Ga_6H_2$". Therefore with respect to the compounds presented here, the formula "$(M_6N)[Ga_5][H_2]$" comes into contention. However, experimental indications of a hydride are certainly not evident. Suitable regions for the uptake of hydrogen would be available in the appropriate number with the relatively large trigonal-prismatic holes formed along [001] from the corners of the isolated (Sr_6N) octahedra. ($Sr\cdots Sr > 372$ pm; tetrahedral holes of the closest (Sr_6N) packing). To evaluate the possibility whether these tetrahedral holes are occupied by hydrogen atoms, we have estimated the enthalpy of formation $\Delta H(\Delta H = E((Sr_6N)[Ga_5][H_2]) - E((Sr_6N)[Ga_5]) - E[H_2])$ by calculating the total ASW energy E of the compounds $(Sr_6N)[Ga_5][H_2]$ and $(Sr_6N)[Ga_5]$ and taking the energy $E(H_2)$ of the H_2 molecule from the literature.[24, 25] These calculations gave a value of ΔH of -0.03 eV per unit cell. Since, in general an ASW calculation[26] overestimates the bonding energy, we conclude that ΔH_{exp} lies above -0.03 eV and that a reaction with hydrogen should be endothermic.

[12] Preparation of $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$: Sr and Ga (molar ratio 8:1; total weight 5 g) were heated in a sintered corundum crucible under an argon atmosphere to 1100 °C, cooled to room temperature, ground in inert gas atmosphere, and finally allowed to react with nitrogen at 1050 °C in a corundum crucible (stationary nitrogen atmosphere, 1 atm) and cooled to room temperature within 10 h. The barium compound was obtained by heating Ba and Ga (molar ratio 5:1) to 1000 °C in a corundum crucible, followed by reaction of the powdered product with nitrogen at 1100 °C. After a reaction period of 30 min, the melt was quickly cooled by removing the reaction tube from the oven. According to X-ray powder investigations, both compounds, are the main crystalline products, other phases obtained in addition have not been identified. Single crystals have a dark metallic luster and are brittle.

Solid-Phase Synthesis of Vinylogous Sulfonyl Peptides**

Cesare Gennari,* H. Peter Nestler, Barbara Salom, and W. Clark Still

The construction of synthetic combinatorial libraries with a focus on the incorporation of pharmacophore units is currently of great interest.[1] Combinatorial libraries on solid supports have helped elucidate subtle biasing of intermolecular interactions and have opened the way to new lead structures for drugs. Among the most interesting structures for clinical and biological purposes are peptides along with their analogues and isosteres.[2] Phosphoryl peptides (phosphonamidates and phosphonates) are intensively studied analogues and have been recognized as transition state mimics of peptide hydrolysis.[1b, 3] Although sulfonamides feature the same tetrahedral structure of the amide group as their phosphorus counterparts, their potential has not yet been investigated as thoroughly. Nevertheless, sulfonamides might also be interesting pharmacophores for protease inhibition.[4] Furthermore the stronger polarization of the sulfonamide bond compared to the regular peptide bond favors the formation of hydrogen bonds and leads to a more distinct preorganization of the sulfonyl peptides, which makes them interesting objects for studies of noncovalent molecular interactions.[5, 6]

Because the problem of determining the structures of the compounds in combinatorial libraries has been solved by encoding procedures,[7] the greatest current challenge is the development of techniques for organic synthesis on solid supports. In

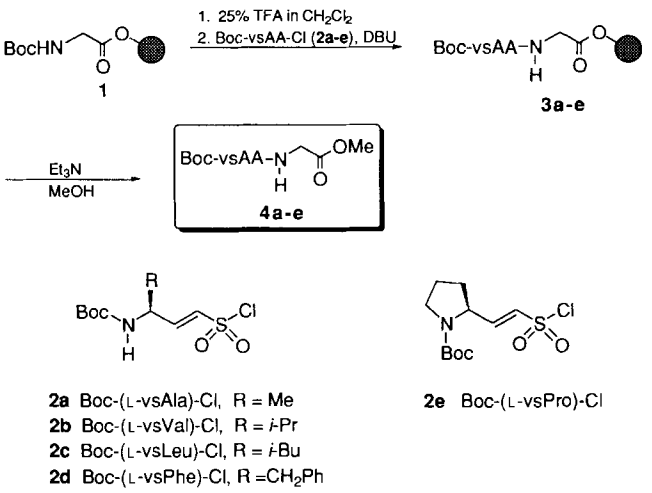
this communication we report a method for the solid-phase synthesis of vinylogous sulfonyl peptides that is compatible with peptide synthesis using Boc chemistry (Boc = *tert*-butoxycarbonyl). This method enables the construction of combinatorial libraries containing vinylogous sulfonyl peptides and thus represents an important advance in the development of synthetic combinatorial libraries—the incorporation of pharmacophore units within natural and unnatural oligomers.[1] The first solution synthesis of vinylogous sulfonyl peptides, which is based on the same strategy, was described recently.[5] Five glycine-derived sulfonyl peptides **3a–e** were prepared starting from Boc-glycine PEG-resin **1**[8] (PEG = poly(ethylene glycol)) and the sulfonyl chlorides **2a–e** (Boc-vsAA-Cl).[9] We cleaved the coupling products from the resin by methanolysis and obtained the sulfonyl peptide methyl esters **4a–e** in good yields (Scheme 1).



Scheme 1. Sulfonyl monopeptides synthesized on a solid support. See text for abbreviations.

Our synthesis of the sulfonyl peptides follows an adapted Boc-protection strategy. The Boc group was removed by treating the resin with 25% TFA (TFA = trifluoroacetic acid) in CH_2Cl_2 for 30 min, and the resulting ammonium salts were neutralized by washing with 2.5% DBU (DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene) in CH_2Cl_2 three times. After one equivalent of the sulfonyl chloride **2** was added, DBU was added in small portions at a rate of about 1.5 equivalents per hour until no more sulfonyl chloride was present in solution. The resin was washed five times with CH_2Cl_2, and the coupling was repeated three times to achieve complete conversion of the amines on the support. Finally, any unreacted amino groups were capped by treatment with acetic anhydride.

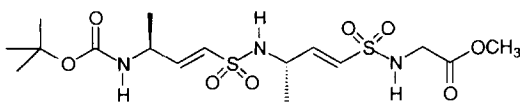
The sulfonyl peptides were cleaved by treatment of the resin with 10% Et_3N in MeOH to yield the corresponding methyl esters **4a–e** in 60–70% yield after purification by preparative TLC. The degree of conversion was determined from the ratio of the intensities of the ^1H NMR signals of the Boc group of the sulfonyl peptide ($\delta \approx 1.45$) and the acetyl group of acetyl glycine methyl ester ($\delta \approx 2.06$) in the crude cleavage mixture. After the four coupling cycles described above the conversion was greater than 95%. The acetyl glycine methyl ester used in these studies was prepared in 67% yield by deprotection of resin **1**, acetylation with acetic anhydride, methanolysis, and TLC purification.

In our studies of the synthesis of the vinylogous sulfonyl peptides in solution we found that excess DBU leads to decomposition of the sulfonyl chlorides, but also that DBU crucial to the coupling.[5] Nevertheless, we tried several methods for catalysis of the the solid-phase coupling. The addition of one or more equivalents of DBU at the beginning of the coupling favored the decomposition of the sulfonyl chloride over the coupling to the resin. When, in analogy to the protocol for the solution synthesis, we added several equivalents of sulfonyl chloride stepwise in one coupling cycle without removing the soluble byproducts and with stepwise neutralization with DBU, only partial conversion of the amino groups was achieved; the products of the sulfonyl chloride decomposition apparently prevented completion of the coupling reaction. This phenomenon was also observed when we used slightly impure sulfonyl chlorides: although all of the sulfonyl chloride was consumed, the amino group had not reacted. The replacement of DBU by 2,6-lutidine, *N*-methylimidazole, or triethylamine was not successful either. Although 2,6-lutidine gave good coupling yields for the reaction of Boc-vsAla-Cl **2a** with glycyl-polystyrene resin, the attempt to synthesize the sulfonyl dipeptide Boc-(L-vsAla)-(L-vsAla)-Gly-OMe **5** resulted in a complex mixture of products. Our studies also revealed that the PEG-resin is much more suitable for the synthesis of the sulfonyl peptides than the regular polystyrene support often used in solid-phase peptide synthesis.[8]

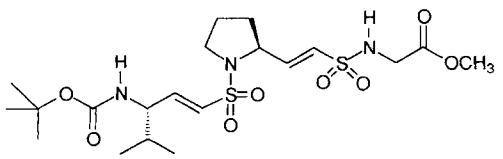
During our studies we encountered an unexpected problem in monitoring the coupling reaction. Neither the traditional Kaiser ninhydrin test[10] nor the use of bromophenol blue as a simple acid–base indicator[11] were suitable to test for the presence of free amines on the support. The coupling reaction apparently yields small amounts of amino compounds that evoke positive amine assays even after virtually complete conversion of the amines. Nevertheless we found bromophenol blue very helpful for the in situ monitoring of the consumption of the sulfonyl chlorides during the addition of DBU. As long as DBU is not in excess, the solution is yellow, and on neutralization the solution turns green. After a while a further color change to blue indicates the complete consumption of sulfonyl chloride, thus offering a convenient way for monitoring the coupling of vinylogous sulfonyl peptides during the synthesis of a combinatorial library.

After having established the conditions for the synthesis of the monopeptides, we prepared two sulfonyl dipeptides to show the applicability of the method described here for the synthesis of oligomers (Scheme 2).

Both products were obtained in satisfactory yield (57% for **5**, 52% for **6**). The synthesis of **5** proved that the coupling on the solid support occurs, like its solution counterpart, without loss of stereochemical integrity; only one diastereomer of **5** could be detected in the crude cleavage product. In the synthesis of **6** we were especially interested in the special properties of the secondary amine of proline. We could show that this amino group



Boc-(L-vsAla)-(L-vsAla)-Gly-OMe **5**



Boc-(L-vsVal)-(L-vsPro)-Gly-OMe **6**

Scheme 2. Sulfonyl dipeptides synthesized on a solid support.

does not affect the coupling with sulfonyl chlorides. Neither the reactivity on solid support nor in solution was distinctively altered compared to those of primary amino functionalities of other amino acids.

This method for coupling vinylogous sulfonyl peptides on solid supports should allow the incorporation of these peptide analogues into combinatorial libraries. Currently we are exploring the scope and limitations of this method as well as expanding the monomer basis set to include functionalized side chains (e.g. vs-Ser, vs-Gln, vs-Lys). In addition we are engaged in constructing receptors composed of vinylogous sulfonyl peptides and screening them for their affinity towards combinatorial libraries of peptides.[6]

Experimental Procedure

6: 600 mg of Boc-Gly-OPEG-resin **1** was deprotected by treatment with 10 mL of 25% TFA in CH_2Cl_2 for 30 min. After the resin was washed with CH_2Cl_2 (5 × 10 mL), the TFA salt was neutralized by washing the resin with 2.5% DBU in CH_2Cl_2 (3 × 10 mL). Excess DBU was removed by washing with CH_2Cl_2 (3 × 10 mL). Three drops of a solution of 1% bromophenol blue in dimethylacetamide (DMA) were added to monitor the reaction. The resin was then subjected to four coupling cycles. Each coupling cycle consisted of the addition of 2 mg of 4-dimethylaminopyridine (DMAP) and 40 mg of **2e** in 5 mL of CH_2Cl_2 followed by the addition of 0.4 mL of 2.5% DBU in CH_2Cl_2 every 10 min, until the reaction mixture was basic (intense blue color of bromophenol blue). (For the first cycle a total of 2 equiv DBU was necessary, but the amount of DBU had to be increased in every cycle (up to 4 equiv).) The reaction mixture was agitated for another 30 min and then washed with CH_2Cl_2 (5 × 10 mL). After the last coupling cycle the resin was treated for 1 h with 0.5 mL of Ac_2O in 10 mL of CH_2Cl_2 and washed with CH_2Cl_2 (5 × 10 mL), DMF (3 × 10 mL), and CH_2Cl_2 (3 × 10 mL) to yield **3e**. 300 mg of the resin was washed with MeOH (5 × 10 mL) and transferred into a 10 mL round-bottom flask equipped with a magnetic stirrer and treated overnight with 5 mL of 10% Et_3N in anhydrous MeOH. The suspension was filtered, and the filtrate concentrated under reduced pressure. According to the ^1H NMR spectrum, the crude residue contained less than 5% acetyl glycine methyl ester. Purification by preparative TLC (silica gel, hexanes/ethyl acetate 1:1) yielded 18 mg (75%) of **4e**. ^1H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.44 (9H, s), 1.78 (1H, m), 1.88 (2H, m), 2.10 (1H, m), 3.35–3.47 (2H, m), 3.78 (3H, s), 3.82 (2H, s), 4.45 (1H, br. s), 4.96 (1H, br. s), 6.21 (1H, d, ^3J(H,H) = 15.0 Hz), 6.65 (1H, dd, ^3J(H,H) = 15.0, ^3J(H,H) = 5.7 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$): δ = 23.546 (CH_2), 28.354 (CH_3), 30.912 (CH_2), 43.844 (NCH_2), 46.513 (CH_2N), 52.550 (OCH_3), 57.012 (CHN), 127.443 (=CH), 145.714 (=CH), 158.848 (C=O), 169.638 (C=O). High-resolution MS calcd. for $C_{14}H_{25}N_2O_6S$ (M + H): m/z: 349.1433; found: 349.1441. The remaining resin **3e** was deprotected and reacted with **2b** (21 mg in each cycle) as described above. Acetylation and release from the resin according to the aforementioned protocol yielded **6** in ca. 90% purity (^1H NMR). Purification by preparative TLC (silica gel, hexanes/ethyl acetate 2:1) yielded 18 mg (52%) of **6**. ^1H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.95 (3H, d, ^3J(H,H) = 6.7 Hz), 0.96 (3H, d, ^3J(H,H) = 6.7 Hz), 1.44 (9H, s), 1.75–2.00 (4H, m), 2.00–2.20 (1H, m), 3.25–3.50 (2H, m), 3.76 (3H, s), 3.87 (2H, d, ^3J(H,H) = 5.5 Hz), 4.13 (1H, m), 4.28 (1H, m), 4.75 (1H, d, ^3J(H,H) = 8.2 Hz), 5.44 (1H, t, ^3J(H,H) = 5.5 Hz), 6.27 (1H, d, ^3J(H,H) = 15.1 Hz), 6.46 (1H, d, ^3J(H,H) = 15.0 Hz), 6.65 (2H, dd, ^3J(H,H) = 15.0, ^3J(H,H) = 5.5 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$): δ = 18.178 (CH_3), 18.769 (CH_3), 23.927 (CH_3), 28.173 (CH_3), 31.549 (CH), 31.858 (CH_2), 43.835 (NCH_2), 48.712 (NCH_2), 52.579 (OCH_3), 56.695 (CHN), 59.157 (CHN), 124.999 (=CH), 128.911 (=CH), 144.349 (=CH), 145.616 (=CH). High-resolution MS calcd. for $C_{20}H_{36}N_3O_8S$ (M + H): m/z 510.1944; found: 510.1956. The data are in agreement with the data obtained from material that was synthesized in solution.

Synthetic Receptors Based on Vinylogous Sulfonyl Peptides**

Cesare Gennari, H. Peter Nestler,* Barbara Salom, and W. Clark Still

For a long time noncovalent intermolecular interactions have been a prime topic of interest in drug research and design. Understanding the nature of these interactions and using this knowledge for the rational prediction of receptor agonists or antagonists is one of the most intriguing tasks in supramolecular chemistry. The interaction of oligopeptides and proteins with peptides is the basis for most biochemical functions, and encoded combinatorial chemistry libraries offer an efficient means of gathering empirical information about these interactions.[1] We describe here the binding of tweezerlike molecular receptors based on vinylogous sulfonyl peptides[2] to an encoded combinatorial tripeptide library. We show that these receptors bind oligopeptides with low binding strength but high selectivity, and that the binding strength and selectivity are just as good as that of analogous receptors built with natural α-amino acids. We also

show that the binding selectivity of sulfonyl peptide based receptors differs from their peptide counterparts.

Among the peptide bond analogues, sulfonyl peptides have not received as much attention as the phosphoryl peptides (phosphonamidates and phosphonates).[3] Since the amide group in sulfonamides has a tetrahedral structure, which is recognized as a mimic of the amide hydrolysis transition state, these compounds may be potential pharmacophores for the inhibition of proteases.[4] The sulfonamide group is also more polar and more acidic than the regular peptide bond, which may lead to stronger intra- and intermolecular hydrogen bonds. Indeed, the group from Milan reported earlier that vinylogous sulfonyl peptides tend to adopt well-defined conformations.[2a] This conformational bias could aid in the preorganization of selective receptors.

First, we wanted to know if simple vinylogous sulfonyl peptides show significant binding to peptides. Several arbitrarily chosen sulfonyl peptides (**1a–c**) were derivatized with a red dye (Disperse Red 1 = DR = **4**) using glutaric acid as a linker (Fig. 1). The red-dyed sulfonyl peptides **2a–c** thus obtained

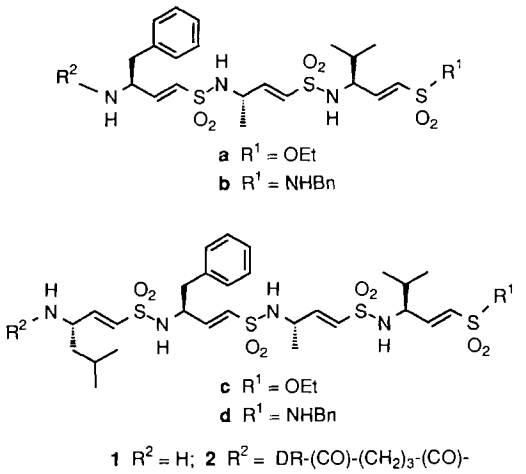

Fig. 1. Vinylogous sulfonyl peptides used in these studies. Bn = benzyl.

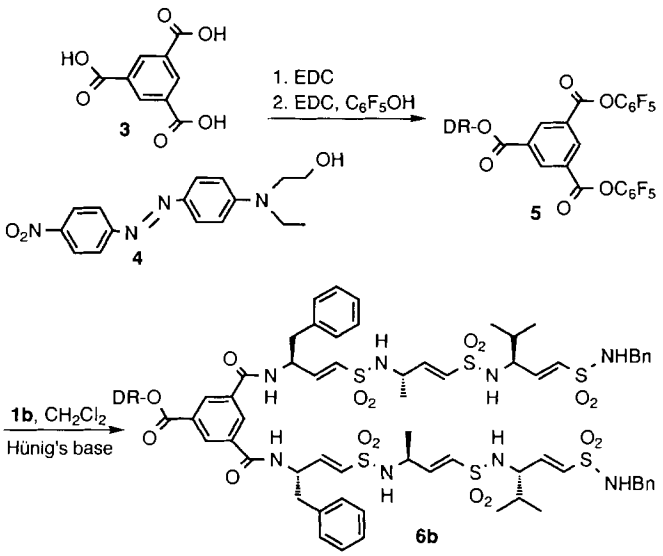
were screened for binding against an encoded combinatorial library of 50625 acylated tripeptides R-(C=O)-AA_3-AA_2-AA_1-NH-$(CH_2)_5$-(C=O)NHCH_2-polystyrene that was described earlier (R and AA_n are specified in Fig. 2).[5] Interestingly none of the three dyed sulfonyl peptides **2a–c** showed detectable binding to any of the tripeptide library members at sulfonyl peptide concentrations as high as 500 μM. As with regular peptides, higher molecular mass and a more preformed spatial structure seem to be required for significant binding.

Tweezerlike, two-armed molecules have been used previously to create receptors for simple biopolymers.[6] We therefore looked for a convenient linker that would allow the facile attachment of two sulfonyl peptide arms and also provide an anchor point for the dye molecule.

We chose 1,3,5-benzenetricarboxylic acid (trimesic acid, **3**) as the linker and used it in the three-step synthesis of the two-armed receptors **6a–d**. Tricarboxylic acid 3 was converted into the monoester by treatment with Disperse Red 1 (DR = **4**), and the two remaining carboxyls were esterified using pentafluorophenol (Scheme 1). The resulting bispentafluorophenyl ester **5** was then coupled with two equivalents of the corresponding sulfonyl peptides **1a–d** to afford the colored receptors **6a–d** in good yields (75–85%) (e.g. **6b** in Scheme 1).



Scheme 1. Synthesis of vinylogous sulfonyl peptide based receptor **6b**. EDC = 1-(3-Dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, DR = Disperse Red 1 (= **4**), Hünig's base = diisopropylethylamine.

Receptors **6a–d** were screened against the aforementioned tripeptide library following the standard protocol.[7] The procedure included the following steps: 24 h equilibration of the receptor solution in chloroform with the bead-supported tripeptide library, separation of the red-stained beads, and decoding of the information on the beads by photolytic release of the molecular tags followed by EC-GC (electron capture gas chromatographic) analysis.[7]

While receptor **6d** did not significantly bind to any of the tripeptides in the library at receptor concentrations as high as 500 μM,[8] receptors **6a–c** showed sequence-selective peptide binding at concentrations of about 200 μM. Such concentrations suggest binding constants for **6a–c** and the library tripeptides in chloroform on the order of 10^2–10^3. Of the three receptors, **6b** showed the highest selectivity, and its properties are discussed below.

At a receptor concentration of 160 μM, **6b** bound approximately 250 peptide sequences out of a total of 50625 in the library.[9] **6b** shows a distinct single residue selectivity for D-Pro at position AA_3 (41% of the decoded beads), for D-Asn/D-Gln at position AA_2 (47% of the decoded beads), and for L-Gln at position AA_1 (76% of the decoded beads). Thus the highest residue selectivity was found at AA_1, while the nature of the N-terminal acyl group was almost completely ignored (Fig. 2). Statistical analysis of the sequence data[10] revealed an even more interesting feature: **6b** has strong sequence selectivity for the tripeptide (D-Pro)-(D-Gln)-(L-Gln) (found in 18% of the decoded beads, statistically expected in 0.03%[11a]) and for (L-Pro)-(D-Val)-(D-Pro) (found in 5% of the decoded beads, statistically expected in 0.03%[11a]). The high occurrence of the former sequence is not surprising, given the high frequency of the single residues (41% D-Pro at position AA_3, 47% D-Gln at position AA_2, and 76% L-Gln at position AA_1, see above). On the other hand, the high occurrence of the second sequence is quite remarkable, given the low frequency of the single residues (16% L-Pro at position AA_3, 10% D-Val at position AA_2, and 10% D-Pro at position AA_1). This implies that recognition of this second sequence must result from synergistic multiresidue interactions within the tripeptide.

We next asked what the binding properties of the corresponding peptidic receptor would be. Would it bind tripeptides under

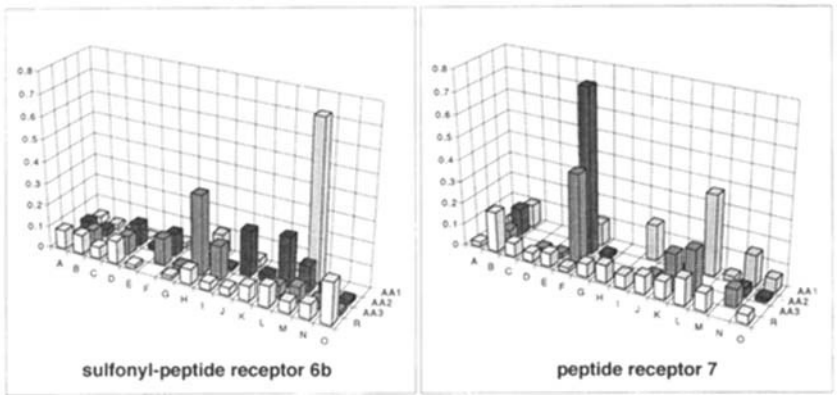

Fig. 2. Frequencies of different residues in the tripeptide library R-(C=O)-AA_3-AA_2-AA_1-NH-$(CH_2)_5CONHCH_2$-polystyrene binding **6b** and **7**. Codes for R: A = methyl, B = ethyl, C = isopropyl, D = *tert*-butyl, E = neopentyl, F = CF_3, G = isobutyl, H = methoxymethyl, I = cyclopropyl, J = cyclobutyl, K = cyclopentyl, L = acetoxymethyl, M = phenyl, N = $N(CH_3)_2$, O = morpholino; codes for AA_n: A = Gly, B = D-Ala, C = L-Ala, D = D-Ser(O*t*Bu), E = L-Ser(O*t*Bu), F = D-Val, G = L-Val, H = D-Pro, I = L-Pro, J = D-Asn(β-trityl), K = L-Asn(β-trityl), L = D-Gln(γ-trityl), M = L-Gln(γ-trityl), N = D-Lys(ε-Boc), O = L-Lys(ε-Boc).

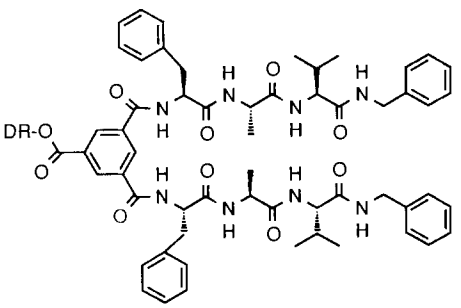
similar conditions? If so, would a different selectivity profile be obtained than that of **6b**?

The synthesis of peptide receptor **7** followed the outline shown in Scheme 1. Interestingly, while sulfonyl peptide receptor **6b** is readily soluble in chloroform, the peptide receptor dissolves only sparingly, which already pointed to strong intermolecular peptide interactions.



7

The binding properties of **7** in chloroform were determined as described for **6b**. At a concentration of 130 μM, **7** bound approximately 270 sequences out of a total of 50625 in the library.[9] The recognition ability of **7** for specific tripeptides was as distinct as that of **6b**. Like its sulfonyl counterpart, **7** neglects the terminal acylating group but is selective for the amino acid residues. In particular, **7** recognizes D-Val at positions AA_3 (37% of the decoded beads) and AA_2 (78% of the decoded beads), and D-Gln at position AA_1 (33% of the decoded beads) (Fig. 2). Thus not only does receptor **7** bind different amino acids than **6b** does, but its selectivity is greatest at a different site, namely AA_2. The tripeptide sequence derived from the most selectively bound residues, (D-Val)-(D-Val)-(D-Gln), occurs with high frequency as expected (found in 11% of the decoded beads, statistically expected in 0.03%[11a]). The most striking finding was the extraordinary sequence selectivity of **7** for a different tripeptide: (D-Gln)-(D-Val)-(L-Pro) (found in 24% of the decoded beads, statistically expected in 0.03%[11a]). Interestingly, L-Pro in position AA_1 occurred exclusively in this sequence. Furthermore the receptor recognizes the (D-Ala)-(D-Ala) dipeptide sequence (found in 5% of the decoded beads, statistically expected in 0.4%[11b]) in the position AA_3/AA_2.

We describe here nonmacrocyclic, tweezerlike molecules having significant binding selectivities for certain oligopeptides. Although the receptors studied here do not provide the large binding strengths reported recently for more rigid receptors,[5, 12] they have significant specificity in the recognition of tripeptides. Furthermore, these results and others recently described[6b–d] show that molecules having a simple motif consisting of a central linker and two oligomeric arms can act as remarkably selective receptors. The results support the idea that extensive rigidity of receptors is not necessary for selective binding.

In summary, we have shown that two-armed receptors based on sulfonyl peptides and regular peptides bind oligopeptides in chloroform with comparable binding constants (low) and selectivity (high). Not surprisingly, the particular binding properties are different for the two families. As the receptors described here are readily preparable linear molecules, they may serve as prototypes for combinatorial libraries of tweezerlike, vinylogous sulfonyl peptide based receptors, which can be screened to find specific binders of given substrates.

Experimental Procedure

6b: Sulfonyl tripeptide **1b** (7 mg) was dissolved in 2 mL of CH_2Cl_2. 0.5 mL of trifluoroacetic acid was added, and the resulting mixture was stirred for 30 min. The volatiles were removed at reduced pressure, and the residue was dried in vacuo for 2 h and then dissolved in 1 mL of CH_2Cl_2. After 20 μL of diisopropylethylamine and 3.5 mg of bispentafluorophenyl ester **5** were added, the mixture was stirred for 2 d at room temperature. The reaction mixture was purified by flash chromatography on 20 g of silica gel ($CHCl_3$/MeOH 95/5) and size exclusion chromatography on 30 g of LH20 ($CHCl_3$) to yield 5 mg (70%) of **6b**. ^{1}H NMR (400 MHz, [D_8]DMF, 25 C, TMS): δ = 0.94 (12H, d, J(H,H) = 6.8 Hz), 1.26 (3H, t, J(H,H) = 7.0 Hz), 1.32 (6H, d, J(H,H) = 7.0 Hz), 1.92 (2H, m), 3.19 (4H, m), 3.71 (2H, q, J(H,H) = 6.9 Hz), 3.85 (2H, m), 4.00 (2H, t, J(H,H) = 6.6 Hz), 4.06 (2H, m), 4.18 (4H, d, J(H,H) = 6.3 Hz), 4.63 (2H, m), 5.17 (2H, m), 6.58 6.70 (10H, m), 6.87 (2H, dd, J(H,H) = 15.1, J(H,H) = 5.6 Hz), 7.11 (2H, d, J(H,H) = 9.2 Hz), 7.18–7.41 (20H, m), 7.54 (2H, d, J(H,H) = 7.6 Hz), 7.59 (2H, d, J(H,H) = 8.4 Hz), 7.65 (2H, t, J(H,H) = 6.4 Hz), 7.94 (2H, d, J(H,H) = 9.3 Hz), 8.01 (2H, d, J(H,H) = 9.1 Hz), 8.42 (2H, m, J(H,H) = 9.1 Hz), 8.67 (2H, d, J(H,H) = 1.8 Hz), 8.71 (1H, s), 9.20 (2H, d, J(H,H) = 8.2 Hz). High-resolution MS calcd. for $C_{90}H_{95}N_{12}O_{18}S_6$ (M + H): m/z 1691.5210; found: 1691.5240.

Peptide binding assay of receptor **6b**: The general screening procedure is described in ref. [5a]. The red-dyed receptor **6b** (initial concentration ca. 250 μM) in $CHCl_3$ solution was equilibrated with the acylated tripeptide library for 24 h on a wrist-action shaker; the final concentration of the receptor in solution was found to be 160 μM. Assuming that at least 10% of the peptides on the deep red-stained beads are bound by the receptor (i.e. ≥ 10% saturated), the minimum binding constant (K_a) for the assay is estimated to be 694 ($\Delta G = -15.9$ kJ mol^{-1}). 66 of the most intensely colored beads were selected and decoded, and 58 unique four-residue sequences were found. Statistical analysis of the number of duplicate sequences found indicated that ca. 250 unique four-residue sequences are tightly bound out of the total pool of 50625 acylated tripeptides under the conditions of our assay [10].

7: Boc-(L-Phe)-(L-Ala)-(L-Val)-NHBn (120 mg) was dissolved in 7.5 mL of CH_2Cl_2, 2.5 mL of trifluoroacetic acid was added, and the mixture was stirred for 1 h. The volatiles were removed at reduced pressure, and the residue was washed with diethyl ether (2 × 10 mL) and then dried in vacuo for 4 h. The residue was dissolved in 10 mL of CH_2Cl_2, and 100 μL of diisopropylethylamine was added. After the addition of 84 mg of bispentafluorophenyl ester **5**, the mixture was stirred for 3 d at room temperature. During this time a red precipitate formed. The reaction mixture was filtered through 50 g of silica gel ($CHCl_3$/MeOH 95/5), and fractions containing only **7** (TLC analysis) were further purified by size exclusion chromatography on 30 g of LH20 ($CHCl_3$) to yield 12 mg (9%) of **7**. ^{1}H NMR (400 MHz, [D_8]DMF, 25 C, TMS): δ = 0.90 (12H, m), 1.25 (3H, t, J(H,H) = 6.9 Hz), 1.34 (6H, d, J(H,H) = 7.2 Hz), 2.13 (2H, m), 3.16 (2H, m), 3.32 (2H, dd, J(H,H) = 13.6, J(H,H) = 3.6 Hz), 3.61 (2H, q, J(H,H) = 6.9 Hz), 3.99 (2H, t, J(H,H) = 5.7 Hz),

4.31 (2H, t, J(H,H) = 6.6 Hz), 4.34 (4H, d, J(H,H) = 6.0 Hz), 4.51 (2H, t, J(H,H) = 7.2 Hz), 4.63 (2H, m), 4.94 (2H, m), 7.08 (2H, d, J(H,H) = 9.1 Hz), 7.14 (2H, d, J(H,H) = 7.4 Hz), 7.17–7.30 (14H, m), 7.41 (4H, m), 7.86 (2H, d, J(H,H) = 8.8 Hz), 7.92 (2H, d, J(H,H) = 9.1 Hz), 8.01 (2H, d, J(H,H) = 7.6 Hz), 8.43 (4H, m), 8.62 (2H, s), 8.68 (2H, d, J(H,H) = 7.2 Hz), 8.75 (1H, d, J(H,H) = 6.2 Hz), 9.27 (2H, d, J(H,H) = 8.3 Hz). High-resolution MS calcd. for $C_{73}H_{82}N_{12}O_{12}Na$ (M + Na): m/z 1341.6070, found: 1341.6050.

Peptide binding assay of receptor **7**: Receptor **7** was assayed as described above for **6b**. The final concentration of the receptor was 130 μM, and the minimum binding constant (K_a) is estimated to be 855 ($\Delta G = -16.5$ kJ mol^{-1}). 54 beads were decoded, yielding 49 unique sequences. Replicate analysis [10] indicated that under these conditions, 269 unique sequences are bound.

Miller, R.J.D. (ed.)

Surface Electron Transfer Processes

1995. XII, 368 pages
with 137 figures and 3 tables.
Hardcover. DM 128.00.
ISBN 1-56081-036-X
(VCH, New York)

This book gives an extensive theoretical treatment of its theme. The emphasis is on electronic coupling of molecular potentials to conducting band states. The essential role of surface electron transfer in catalysis, electrochemistry, photo imaging, and virtually all charge transfer solid state devices make this process one of the most important single chemical events.

Sandifer, J. R.

Ion-Transfer Kinetics

1995. X, 142 pages with
38 figures and 16 tables.
Hardcover. DM 165.00.
ISBN 1-56081-508-6
(VCH, New York)

In six concise, well-referenced chapters, this book covers the essentials of ion-transfer principles and applications, including computer simulation techniques for ion-transfer kinetics models.

It is addressed to chemists in academia and industry, to physical chemists and to chemical engineers.

A Whole New Ball Game

The Most Beautiful Molecule. An Adventure in Chemistry. By *H. Aldersey-Williams*. Aurum Press, London, 1994. 340 pp., hardcover £ 18.95.—ISBN 1-85410-302-2

Fullerene—die Bucky-Balls erobern die Chemie. By *J. Dettmann*. Birkhäuser, Basel, 1994. 248 pp., hardcover DM 59.80.—ISBN 3-7643-2947-5

In *The Most Beautiful Molecule—An Adventure in Chemistry* H. Aldersey-Williams has set out to convey the fascination and elegance of modern chemistry to a wide readership, using the history of the fullerenes for illustration. He has therefore been careful to avoid too much scientific jargon. The account contains a wealth of historical detail which the author has meticulously researched by personal interviews, and only a few examples are mentioned here.

The author describes in great detail and in chronological order all the events that led up to the discovery of the fullerenes. The experiments and the participants are described so vividly as to give the reader the feeling of having been present at the time. Where there is a possibility that difficulties of understanding might arise, these are avoided very effectively by including explanatory sections (e.g. on spectroscopic methods).

Readers will certainly also be interested in the analysis of the article by Kroto, Heath, O'Brien, Curl, and Smalley (*Nature* **1985**, *318*, 162). That publication, which reported the first "proof" of the existence of C_{60}, is examined in detail sentence by sentence. This chapter will undoubtedly provide new food for thought, not only for the authors of the paper but for everyone who publishes research results.

Equally good is the detailed description of the events at a conference. Here again the reader is held engrossed by the author's lucid and yet gripping style.

The author succeeds in the ambitious aims mentioned above, and at the same time shows through the fullerenes story how science works. Furthermore, he has managed to reveal the apparently unromantic world of chemistry in a more favorable light than recently. Thus, it is one of those rare books which hold the attention of the reader who is interested in science to the extent that he or she cannot put it down until it is finished. It is a fantastic book which occupies a high position in the literature of chemistry. The only complaint is that up to now there is only an English version.

In *Fullerene—die Bucky-Balls erobern die Chemie* Joachim Dettmann states at the outset that his aim is to show, through the example of the fullerenes, the fundamental importance of chemical research for developing future applications and new technologies, and at the same time to convey the beauty of nature at the molecular level. He brings to this task a clear and readily understandable style of writing, so that non-scientists as well as scientists will benefit from reading the book.

A preface by Wolfgang Krätschmer is followed by an eight-page introduction giving a short and succinct history of the fullerenes. In the following two chapters (100 pages altogether) the author gives an excellent and comprehensive overview of the element carbon, including the different forms in which it occurs, their structures, and methods of preparing them, and of clusters (definition, properties, preparation, magic numbers, applications). Armed with this considerable body of sound knowledge, the reader is then led into the fascinating world of the fullerenes. First the complete "fullerene story" is recounted in a chapter of 28 pages. This is followed by a 48-page chapter which takes the reader aside for a thorough discussion of symmetry. The historical origins of the concept of symmetry, the different symmetry elements, topology, and point groups are all explained clearly and in great detail. These principles, including especially Euler's theory of polyhedrons, are then applied to the case of the fullerenes.

The book is completed by a brief discussion of microarchitectures resembling the fullerenes, a chapter on the chemistry of the fullerenes (a mere 18 pages), and a summing-up which also considers the future of fullerenes. In this the author has sensibly resisted the temptation to overstate the future potential for applications of fullerenes. He takes the view that, as the field is still very new, it is too early to make firm predictions about future applications of fullerenes. The only thing that seems certain, according to Dettmann, is that the future micro-robots of nanotechnology should find that the bucky-ball is the ultimate "pill" to be kicked.

The book offers a good introduction to the chemistry of carbon. However, the title does not clearly reflect the contents, as the chemistry of the fullerenes is treated only very superficially and incompletely. In view of this a more appropriate title would be something like "Carbon Modifications—Carbon and Bucky-Balls".

Chemische Kabinettstücke. By *H. W. Roesky* and *K. Möckel*. VCH Verlagsgesellschaft, Weinheim, 1994. 314 pp., hardcover DM 68.00.—ISBN 3-527-29220-9

Even at the end of the 20th century, experiments still form the cornerstone of chemistry, and particular credit is due to H. W. Roesky and K. Möckel for taking appropriate account of this by writing "Chemische Kabinettstücke", a book that is hard to put down once one has started to enjoy

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

the excellent experimental "firework display" which the authors present in just over 300 pages. This volume, which can only be described as a success in both presentation and content, carries the reader back to the pre-video era of the great experimental lectures, and its descriptions convey the strange, almost magical fascination that the present reviewers experienced as students in Münster when those great masters of the experiment Wilhelm Klemm, Fritz Micheel, Harald Schäfer, and Claus Brendel were "on-stage".

One hundred and twenty-four experiments are described and presented with great care and in great detail. Apart from clear instructions on the experimental setup and procedure, each section includes a list of chemicals and apparatus, a short explanation of the principles, and tips on safety and waste disposal as well as literature references; these are complemented by historical, anecdotal, and even lyrical comments. This fresh approach, the strength of the book, prevents an austere "cookbook" atmosphere from developing. The descriptions of the experiments are extremely precise and complete, and are prepared with great didactic skill; they deal with subject matter which reflects the past, present, and future of chemistry and which in part represents a distillate of the authors' long experience in teaching and research. The many color plates that illustrate, and at the same time elucidate, the experiments do much to reinforce the positive impression made by the book. The majority of the experiments (almost 90%) deal with optical and color effects, while about 7% appeal to the ear, and the remainder to the senses of taste or smell.

This brilliantly structured experimental concept is unique on the German book market. The authors are not afraid to grapple with the manifold modern developments in chemistry (experiments dealing with fractals, superconductors, and crown ethers will not be looked for in vain!), and their book is not just a compendium of spectacular experimental descriptions. A perusal of the literature references does, however, make it difficult for the reviewers to stifle a little sigh of regret: was the transfer of experimental chemistry to the New World really so successful that new experiments today come almost entirely from there? (poor didacticians!). If one fault can be found with the book, then perhaps it is the "literary quotations" that accompany the experiments and sometimes appear too artificial, and of course the criticism that these do not stem from the authors' own pen.

This book sets standards and will become a "must" for all those whose job it is to organize experimental lectures, to be responsible for a "magic show" or a Christmas demonstration, or who as secondary school teachers are looking for suggestions for experiments to extend their own repertoire. The highly readable "Kabinettstücke" presented by the all-rounders Roesky and Möckel achieve flagship status in the field of experimental literature and do a great honor to the chemists' guild. The book will provide pleasure and delight for nonscientists and scientists alike and could make history by serving as the screenplay for the first video published by VCH.

Hans Georg von Schnering, Dietmar Raschke
Max-Planck-Institut für Festkörperforschung, Stuttgart (Germany)

Photochemical Key Steps in Organic Synthesis—An Experimental Coursebook. Edited by *J. Mattay* and *A. Griesbeck*. VCH Verlagsgesellschaft, Weinheim, 1994. 350 pp., paperback DM 68.00/$ 40.00.—ISBN 3-527-29214-4

The field of photochemistry has grown dramatically over the past 20 years, unveiling many exciting applications to organic synthesis, physical organic chemistry, and organometallic chemistry. However, most advanced texts of organic chemistry do not sufficiently cover the breadth of photochemical reactions, nor do they introduce important industrial applications in fields such as polymer chemistry. Furthermore, photochemical reactions have infrequently been introduced into experimental courses for students. Professors Mattey and Griesbeck have developed an experimental coursebook consisting of several multistep syntheses, each highlighting one or more photochemical key reactions. In all, this book is a compilation of nearly 100 synthetic sequences contributed by 50 or so experts in the field of organic photochemistry. Most of the experimental procedures involve multiple steps leading up to the photochemical reaction, and so this book contains a total of about 300 actual synthetic reactions. Opening each chapter, a brief (approximately 3-page) introduction provides a commentary for the reactions presented and some discussion of the mechanisms involved. In addition, a general introduction discusses the experimental considerations that are particularly important to carrying out photochemical reactions.

One of the most valuable characteristics of this book is the breadth of coverage, which includes nearly all important types of photochemical reactions. Many of the specific reactions chosen for this series are especially interesting and display the power of photochemistry for the construction of complex and strained molecules which would be available by no other means. This makes the book an especially valuable resource for graduate students and researchers in organic synthesis. The organization is excellent and contains many examples of each specific class of photochemical reactions. Furthermore, many of the most current and exciting areas of research in organometallic chemistry, asymmetric synthesis, and photolithography have representative experiments. For the reaction types covered, optimum experimental conditions (including light filters, solvents, and possible sensitizers) are detailed quite thoroughly, representing the valuable experience of the contributors.

For supervisors of laboratory courses, this experimental coursebook would provide the opportunity to introduce photochemistry early in the training of young chemists. However, there are several nontrivial reasons why photochemical experiments present difficulties in laboratory courses—most notably, the expense of the equipment and the specific hazards unique to using photochemical equipment. From the standpoint of safety, the most appropriate photochemical reactions in this coursebook for use in a laboratory course involve: a) 5 g scale or less; b) relatively non-flammable solvents; c) convenient photolysis times (preferably not unattended for long periods). In addition, reactions employing a Rayonet® photochemical reactor are perhaps more convenient for a laboratory course than reactions involving the medium-pressure mercury lamps. There are many excellent experiments in this coursebook that could be performed conveniently and within these considerations. These include the syntheses of dehydrovaline, Ibuprofen, and *trans*-bicyclo[5.3.1]undecanone, the single crystal photolysis of an ethenylanthracene compound, and the synthesis and photolithography of poly(4-ethenyl-5-methylthiadiazole).

In contrast, however, many of the others are truly research-level experiments requiring highly specialized equipment or the handling of sensitive intermediates. Some experiments employ photochemical conditions involving such forcing or potentially dangerous conditions as to make them highly inappropriate for an under-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1770 $ 10.00+.25/0

graduate laboratory course. For example, one reaction involves photolysis of 2.5 L of an *ether* solution with a 450 W Hanovia immersion lamp for 20 h. Another reaction involves the photolysis of 125 g of vinyl acetylene with a 500 W immersion lamp for 9 days. Not all experiments in this text provide the expected photolysis time, and almost none of the experiments has any specific notes pertaining to safety. It appears in some cases that the experimental procedures are identical to those appearing in the original literature, and neither the contributor nor the editors have investigated modifications in scale or procedure which would make them appropriate for a laboratory course.

The introduction to this book (10 pages) describes several important considerations for photochemical reactions and how these conditions are studied for optimization of a specific reaction. In addition, a brief section describes the hazards of using photochemical equipment. Although this section is very helpful and interesting, the beginner would benefit from a much expanded section including pictures of photochemical set-ups, operating instructions, and safety concerns. In addition, if each chapter were introduced with a more comprehensive presentation of the mechanisms and applications of the reactions in question, the result would be a much more powerful learning tool.

In conclusion, Mattay and Griesbeck have accumulated a collection of procedures from many of the leaders in the field of synthetic organic photochemistry which will be a valuable resource for researchers in the field of organic chemistry. The wealth of reaction sequences covers nearly all aspects of this field and is excellently organized. However, the use of this resource as an experimental course book would demand a good deal of responsibility and planning on the parts of the instructor and student, to assure that the experiments can be reproduced accurately and safely in a laboratory course setting.

Cambridge, MA (USA)

Radical Chemistry. (Ellis Horwood Series in Organic Chemistry.) By *M. J. Perkins*. Ellis Horwood, New York, 1994. 182 pp., paperback $ 18.00.– ISBN 0-13-320920-2

Although M. J. Perkins' *Radical Chemistry* is a book of less than 200 pages, it covers in a very thorough way the most important aspects of the subject. A short introduction, mainly concerned with the history of radical chemistry, is followed by Chapter 2 dealing with the kinetics of free radical reactions and introducing the most important concepts: chain initiation, unimolecular and bimolecular radical reactions, radical-induced fragmentations, radical rearrangements, and radical–radical and radical–molecule reactions. Chapter 3 contains a more detailed treatment of chain initiation, methods for generating radicals, and radical–radical reactions, with particular emphasis on free radicals and radical pairs in solvent cages. In Chapter 4 the author discusses reactivity and selectivity in radical reactions, beginning with the bromination or chlorination of alkanes, then with regard to radical additions to double bonds. Next the three main factors influencing selectivity, namely stereoelectronic effects (e.g. in cyclizations forming five-membered rings), polar effects, and steric effects (in stable radicals), are discussed in separate sections. This chapter ends with a discussion of intra- and intermolecular competing reactions and the competition between addition and abstraction, illustrated by the bromination of cyclohexene using *N*-bromosuccinimide.

It is not until Chapter 5 that methods for detecting radicals and determining their structures are discussed (ESR spectroscopy, hyperfine splittings, σ- and π-radicals, spin trapping, etc.). The chapter ends with an introduction to ENDOR and CIDNP spectroscopies.

Chapter 6 is devoted to the role of radicals in organic synthesis. Under the heading of chain reactions the author first describes transformations of functional groups: NBS bromination reactions, the Toray process, the Hoffmann–Löffler–Freytag reaction, and reactions using Barton esters. Under carbon–carbon bond-forming reactions the tin hydride method, used especially for cyclizations forming five-membered rings, is given prominence. The chapter ends with radical reactions not involving the chain mechanism, such as the free radical oxidation of phenols to quinones. Chapter 7 is concerned with stereochemical aspects, including a discussion of intramolecular asymmetric induction for various reactions of prochiral radical centers. Chapter 8, which deals briefly with radical ions and electron transfer reactions, deserves special praise. Chapter 9 is entitled "Some Special Topics", and discusses some other important aspects of radical reactions, including FMO theory, an introduction to the SOMO concept, nucleophilic and electrophilic radicals, radical kinetics and thermodynamics, capto-dative substituent effects, autoxidation (e.g. of unsaturated lipids), and antioxidants. Lastly Chapter 10, "Radicals in Biology", is an introduction to this most topical area of radical chemistry. The author begins by discussing the role of the hydroxy radical and the mode of action of Vitamin E, followed by enzymatic reactions. The chapter ends with the Bergman cyclization of ene-diynes.

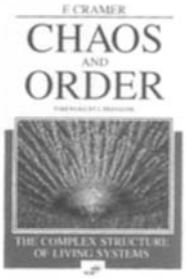
An appendix contains a list of some absolute rate constants for elementary free radical reactions. The book ends with a selected bibliography for further reading and a set of exercises, in which references to the original papers are provided to help the reader.

Altogether this book gives an excellent overview of radical chemistry, and very few aspects are neglected (although I found nothing on radical clocks nor on the stabilities of radicals). The organization of the contents is not always ideal—for example, NBS bromination is mentioned in three different places. Also in Chapter 5 on the structure of radicals and their detection, the relationship between reactivity and selectivity on the one hand (Ch. 4) and synthetic aspects on the other hand (Ch. 6) is not treated as well as it might be. However, the book is a good introduction to and general survey of free radical chemistry and is reasonably priced.

Ulrich Lüning
Institut für Organische Chemie
der Universität Kiel (Germany)

Chaos and Order. The Complex Structure of Living Systems. By *F. Cramer*. VCH Verlagsgesellschaft, Weinheim, 1993. 250 pp., hardcover DM 48.00.—ISBN 3-527-29067-2/1-56081-812-3

This book is a work of art. Like all truly inspiring scientific books it has the virtue of brevity and is also a piece of literature, on a par with classics such as G. H. Hardy's *A Mathematician's Apology* or Peter Medawar's *The Limits of Science*. In his foreword Professor Prigogine writes that *Chaos and Order* is "first and foremost an excellent introduction to the main problems of molecular biology [seen in the] context of the progress that has recently been achieved in the theory of non-linear



systems far from equilibrium". But it is much more than this, for Professor Cramer easily straddles the gap between the two cultures, in a virtuoso display of cross-references and interconnections. Taking his own research as a starting point he aims at the general picture, deftly crossing the boundaries between scientific disciplines and artistic fields. Poems by Hölderlin and paintings by Kandinsky are used to make a point about the delicate transition between order and chaos. He is right to use this approach, for it is at the fuzzy borders where different disciplines meet that innovation thrives. The book is also a very personal work (Professor Cramer even confesses his reluctance to part with it), and thus more universal in its appeal.

In *Chaos and Order* some fundamental questions are asked—what is life? how do ideas arise in our brain? what does evolution mean?—but the author is careful to separate the methods of science and philosophy. As he puts it, "scientific research cannot yield moral values and cannot teach us the meaning of life". Only children ask "why?" and only the selfish start their enquiries with "what for?"; the scientist's business is to answer the "how?" According to Goethe, what cannot be investigated is better left to contemplation. But Professor Cramer does not eschew ethical matters, stating very forcefully that "gene therapy is a violation of the personal rights of future human beings". He also does not shy away from denouncing the dangers of a capitalistic exploitation of publicly funded research with its potential for the prostitution of science. These matters are all the more important because, as he persuasively argues in the last chapter, intellectual evolution has now overtaken biological evolution. We do not develop any more organs; we invent domestic appliances instead. Information is passed from generation to generation not only through genes but also through libraries, data banks, social traditions, etc.

It is only fitting that a book about structure should itself be highly structured. Each chapter starts with a partly fictitious dialogue and ends with a poem (authors ranging from Yeats to Chemistry Nobel Prize winner Roald Hoffmann). The dialogues are constructed around an assortment of scientists (Einstein, Pauli, Darwin, the 18th century Göttingen physicist Lichtenberg, etc.), writers (Kleist, Goethe), philosophers (Socrates and Wittgenstein) and various fictional characters (Shakespeare's Hamlet or Bottom and Carroll's Alice, the latter because scientific nonsense can be very meaningful). *Chaos and Order* can thus be read on several levels—as a collection of dialogues intended to show that difficult problems are neither new nor difficult to discuss, as an anthology of poetry (in the author's words "poetic language is often capable of describing truths in a more valid, concise and enduring form", which is not unlike mathematics) or as a masterly essay on the complex structure of living systems.

Nonlinear systems with feedback coupling and a strong dependence on the initial conditions have the potential for chaotic behavior. Inevitably Professor Cramer invokes Wallace Stevens's poem *Connoisseur of Chaos*, which proclaims that a violent order and a great disorder are one and the same thing. One of the book's most impressive sections shows that esthetic harmony can be found at the irrational boundary separating order from disorder. The evidence that the famed golden section is somehow related to this transition strikes us as a true coup de théatre. The whole book, even the more difficult sections, is a pleasure to read, and is admirably illustrated with examples and illuminating parallels. Thus a tree can be looked upon as an upside-down bolt of lightning which propagates very slowly, and the phenomenon of the sudden boiling of superheated water is not all that different from a stock market crash (both are cusp catastrophes).

I was expecting the book to start—like some modern-day Genesis—with chaos, but Professor Cramer devotes the first chapter to life, seen as a dynamic system between order and decay. It is a process governed by entropy, the "arrow of time" (Eddington). This is the "leitmotiv" of the book. Once taken apart, living systems die and cannot be reassembled; in other words, the whole of life is always greater than the sum of its parts. As far as life is concerned, the Cartesian method should thus be applied with caution. All living matter is made from the same building blocks: for instance, there are more than 10000 different proteins in the human organism, but they are made from only twenty aminoacids! A sort of atomistic model seems to prevail, and the various ways of combining the structural units make for a tremendous information capability. It is clear why life is too complex to have been left to chance. The molecules of life and cells have developed recognition mechanisms of the lock and key type; these can be rather selective and sophisticated, given the complex geometry of molecular surfaces. No wonder some of the fundamental problems in biology are topological (and fractal)!

Much of the book is involved with self-organization and evolution. Along with heaviness (mass), self-organization is a basic property of matter. Eigen's theory of hypercycles (a mathematical formulation of all possible evolution systems) is imaginatively presented. Professor Cramer insists that, like quantum mechanics, Eigen's formulation is not an explanation but a description, but surely with the loss of visualization ("anschaulichkeit") that was brought about by modern physics, mathematical description became the equivalent of meaning. Then there is the question of complexity of highly-organized systems which can be quantified (a reincarnation of Boltzmann's equation for the entropy). The occurrence of bifurcation or fulguration points in the evolutionary schemes confers a kind of history on the process, and the systems become adaptable, even intelligent. In the old order of Newtonian systems, forever following their predictable paths, aging was inconceivable. If equilibrium is abandoned and bifurcations are possible, the future of the systems cannot be predicted, and Leibnitz's famous assertion "Natura non facit saltus" no longer holds. Instead of following determinism, the player has to learn the rules of the game. Predictability has ceased to be a criterion for scientific truth. But, as Professor Cramer explains in another context, growing old brings wisdom and freedom; ambitions are no longer necessary. There is a moral to this book, too.

Group Theory in Chemistry and Spectroscopy. A Simple Guide to Advanced Usage. By *B. S. Tsukerblat*. Academic Press, London, 1994, 430 pp., hardcover £ 40.00.—ISBN 0-12-702285-6

The fundamentals of symmetry methods and their applications to chemistry and spectroscopy are already well covered by many excellent textbooks and monographs. In the book reviewed here B. S. Tsukerblat aims to give an account of the principles and applications of the theory of finite groups, illustrated by detailed discussion of simple examples, and to enable the reader to solve practical problems using these methods. The main fields of application covered are the symmetry aspects of the ligand field theory, including spin–orbit interaction, and of molecular

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/1616-1772 $ 10.00+.25/0

orbital theory, selection rules, vibrational spectroscopy, electron spin resonance spectroscopy (an area that has hitherto seldom been treated from this standpoint), and exchange interaction in coordination compounds.

The choice of topics and the methods used are well suited to serve the author's aims. If more care had been taken in writing the book it might have successfully filled a large gap that exists in the present range of student textbooks on chemistry and spectroscopy. There is an unusually high incidence of printing errors, mistakes, and incorrect statements, and the fact that about 15% of the literature citations refer to publications in Russian must be a serious obstacle to readers of a book in English. It should at least have been possible to refer the reader to translations, or to English-language books covering similar ground.

The book begins with three introductory chapters dealing with symmetry operations, point groups, and their representations, which according to the preface "might well be assimilated at a pre-university level". Here we already find numerous printing errors, such as those in Table 2.3 listing the 32 crystal point groups, and in the scheme showing their sub-groups (Table 2.5), examples of poor choice of words or ambiguous phrases, such as "reflection within a plane" (p. 7), and ill-chosen examples; thus, the chair form of cyclohexane is used to illustrate a body with S_6 symmetry (Fig. 2.12), whereas there is no mention of it as an example of a body with the higher symmetry D_{3d}. Many of the statements are simply wrong; some examples are: "C_{2v} has three classes" (p. 33) this should be four; on page 29 it is stated that for odd values of n the operation S_n is "not a new symmetry operation", despite the fact that the groups C_{nh} are not introduced until later; on page 42 we read "all planar molecules possessing a C_n axis belong to D_{nh}" the last symbol should be C_{nh}. Errors such as these are confusing to the novice. Equally annoying are the occasional inconsistencies; for example, in Equation (3.88) a symmetry operation is applied to the variables of a function rather than, as previously defined in Equation (3.57), to the function itself. Also the setting up of character tables is not quite so simple as is implied in Section 3.6; the quadratic equations used here have some redundant solutions.

Some important topics of representation theory, such as the classification of energy eigenfunctions, the direct product of representations, Clebsch–Gordan coefficients, the Wigner–Eckart theorem, projection operators, and the basis functions of irreducible representations are treated in connection with the ligand field theory (Chapters 4–6). The solution to the problem of classifying energy eigenfunctions in terms of irreducible representations is "proved" on page 99, despite the fact that the concept of irreducibility must be introduced as a postulate or via the definition of "accidental degeneracy". Even some statements that are given special prominence by being enclosed in a "box" are badly formulated. For example, in restricting a group to a subgroup, an irreducible representation does not necessarily give a reducible one (p. 101). Clebsch–Gordan coefficients are introduced by means of tables (pp. 135, 232), but the discussion does not include a brief explanation of how they are calculated, which would make the tables understandable. These important topics, the results of which are needed frequently in later parts of the book, deserved to be treated in a separate chapter. The description of the ligand field theory is not very satisfactory. On many aspects, such as the calculation of energy level splittings, the relationships are not properly explained, and the reader must be content with mere literature references. Even some minor aspects are not discussed thoroughly enough, for example the effect of configuration mixing on the energy terms of a d^2 ion (p. 148).

In Chapter 7 on directed valences, the orbitals given for a trigonal-bipyramidal structure such as that of PF_5 include not only the correct hybrid orbitals of the sp^3d and spd^3 types but also some incorrect ones, including sp^3 (p. 186). In Chapter 8 it is explained how molecular orbitals are classified according to group theory; here the author even manages to make mistakes in calculating the π-MOs of benzene (p. 207).

Selection rules can be expressed in the form of conditions applied to the integrands of the corresponding transition matrix elements. However, in Chapter 9 on optical transitions, it is disturbing to find that the descriptions of "necessary" and "sufficient" conditions ("only if" and "if", respectively) are often used incorrectly (pp. 225, 238). Furthermore, through the uncritical use of the formalism of representational theory, the Laporte rule forbidding pure d–d dipole transitions is wrongly described as a "supplementary restriction" in the case of systems without an inversion center (p. 235). On the other hand, the discussion of two-photon transitions in terms of symmetry in Section 9.5 is very useful, especially as this is unlikely to be found in other books on the subject.

Chapter 10 is devoted to double groups. Chapter 11 then builds on that discussion by treating the spin–orbit interaction. Chapters 12 and 13, dealing respectively with the symmetry aspects of ESR spectroscopy and with exchange interaction in coordination compounds, are the best ones in the book, after one has corrected a few errors in the signs and terms of some of the formulas. In particular, the author constructs effective Hamiltonian operators for a paramagnetic ion in ligand fields of different symmetries, and those for describing electric field effects in ESR spectroscopy, which is especially interesting. The use of group theory for the classification of exchange multiplets in polynuclear complexes and of systems with ions in different valence states is also explained, with many examples. The main text ends with Chapter 14, dealing with normal vibrations and the Jahn–Teller effect, and with vibrational coupling in mixed-valence systems.

The appendix contains the matrices of the irreducible representations for various important point groups, the associated basis functions in the form of symmetry-adapted linear combinations of harmonic functions, the decomposition of product representations into their components, and symmetry-adapted Hamiltonian operators for special ESR problems. It would also have been useful here to include answers to the exercise problems.

The work is not, as claimed in the preface, a handbook on the subject. Unfortunately it contains too many errors, far more than have been mentioned here, and too often the author fails to explain the relationships correctly. It cannot be recommended for beginners, except for gaining a general impression of the extent to which group theory and representation theory can be successfully applied to problems of chemistry and spectroscopy. On the other hand, the more advanced reader who is prepared to tolerate the errors in the book will find in it many interesting examples and problems that are not treated in other books on the subject.

Novel Porphyrinoids for Chemistry and Medicine by Biomimetic Syntheses

Burchard Franck* and Ansgar Nonn

In 1926 Hans Fischer and Bruno Walach synthesized the first porphyrins.[1] Currently more than 1400 new articles concerning the synthesis and uses of porphyrins are published every year.[2] However, the strong interest in these compounds indicated by this is in sharp contrast to their restricted availability. This is reflected in the current price of up to 500 DM for 5 mg of the most important porphyrins used in research and other applications (see Scheme 3).

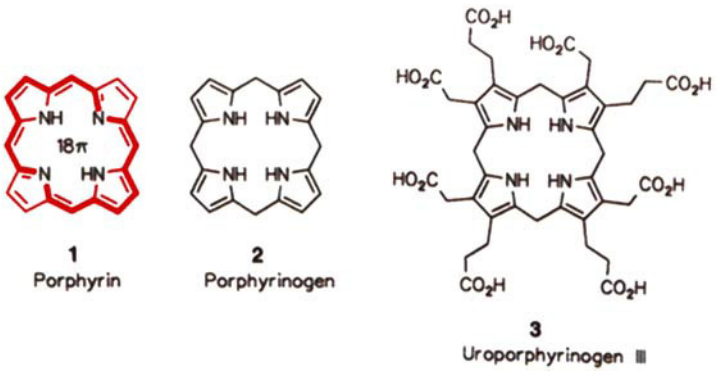
Biomimetic syntheses offer possibilities for an improved approach to porphyrins. By following the example set by nature it is also possible to obtain novel porphyrinoids which are different from naturally occurring porphyrins. This is exemplified by *N*,*N'*-bridged porphyrinogens, which have cage structures, inverted porphyrinoids (N atoms in the outer periphery) and, in particular, porphyrins with expanded systems. Among the family of expanded porphyrins are superarenes with up to 34 π electrons. Their pronounced aromaticity is indicated by ^{1}H NMR spectra, bond length equivalence, planar structures, and electrophilic substitution. With their strong absorption bands, the strongest of which have ε values of > 1 000 000, a value which exceeds the absorption intensity of all other organic pigments observed until now, and their ability to act as efficient photosensitizers, the expanded porphyrins open interesting perspectives in the fields of photochemistry and photomedicine.

Keywords: aromaticity · biomimetic syntheses · dyes · porphyrins · tumor therapy

1. Introduction

Porphyrins are important for all organisms.[3, 4] They are indispensible because of their function as complexing ligands for catalytically active metals. This relates not only to metabolism, but also to the provision of energy in living creatures and photosynthesis in the plant kingdom. The deep red porphyrin **1** contains an annulene-type cyclic conjugated 18 π-electron system. Addition of six hydrogen atoms leads to the colorless and highly reactive porphyrinogen **2**. The porphyrinogens are air sensitive and are readily reoxidized to the porphyrins.

Due to the large number of natural products and synthetic products derived from the porphyrin system, it has proved appropriate to group these products under the heading *porphyrinoids* (cf. steroids, alkaloids). This approach can today be further justified for the naturally occuring porphyrins, porphyrinogens, chlorins, and corrins not only formally but also biogenetically, since, according to current knowledge, all four groups of compounds are derived from a common precursor, uroporphyrinogen III (**3**) (Scheme 1).[5–7]



1 Porphyrin **2** Porphyrinogen **3** Uroporphyrinogen III

Scheme 1.

In order to satisfy the requirements of living organisms, nature has developed the bioproduction of porphyrinoids, the extent of which can be estimated. Let us begin with the porphyrinoid vitamin B_{12}, deficiency of which causes pernicious anemia. Humans have a daily requirement of only 0.001 mg vitamin B_{12}, an extremely tiny amount, corresponding to a total annual requirement for the earth's population of approximately 2000 kg. Heme, the red blood pigment necessary for respiration, is produced to the extent of 500 000 tonnes per year by the world's population, an amount corresponding to 25 000 full railway wagons.[8, 9] Thus, one can estimate that the total production of heme by all breathing organisms is of the order of 10 million tonnes. Even more extensive is the estimated annual production of 10^9 tonnes[10, 11] of chlorophyll by plants.

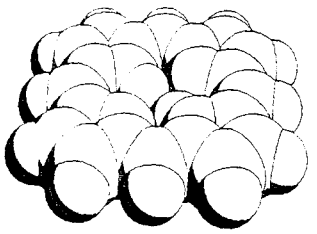

Fig. 1. MOPLO representation [12] of the unsubstituted porphyrin framework.

Aside from the bioproduction of porphyrinoids, their chemical synthesis is of growing importance. Increasingly, the porphyrin system is characterized by a multitude of reactions, properties, and transformations, which, given their compact structure (Fig. 1), at first sight appears to be surprising. In the last 27 years *Chemical Abstracts* has registered more than 20000 publications relating to porphyrins of various structures.[2] In this time the annual number of publications has risen from 234 (1967) to 1414 (1994). In addition, numerous structurally related porphyrinoids containing ring systems different from that in **1** must also be taken into consideration. A selection of applications of porphyrinoids in chemistry and medicine is given in Scheme 2.

Chemistry	Medicine
complexes	diagnosis of porphyria
light conversion	cytochrome oxidase models
autoxidation catalysis	phototoxicity
aromaticity	tumor therapy
UV/Vis/NIR sensors	virus eradication

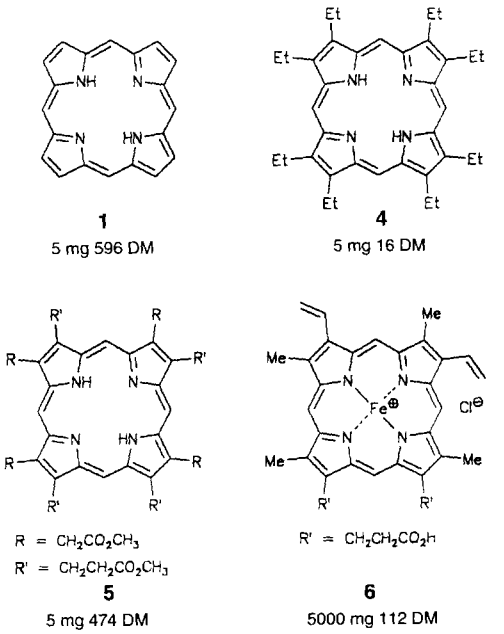
Scheme 2. Applications and research uses of porphyrins.

With regard to the areas mentioned in Scheme 2, the following goals can be set: 1) The development of more efficient processes for the synthesis of porphyrinoids. 2) Research into access to and structural limitations of novel porphyrinoids. 3) The synthesis of tailor-made porphyrinoids for investigations into aromaticity, electron spectroscopy, and photomedicinal applications. The results of research into these three areas form the content of the following discussion.

2. Do Synthetic Porphyrinoids Have To Be More Expensive Than Gold?

Despite the promising developments made with porphyrinoids in chemistry and medicine, this area of research suffers from a severe handicap: Access to the majority of the required porphyrinoids demands cumbersome, multistep syntheses with very low overall yields.

In order to illustrate the availability of porphyrins, the current commercial prices of four important examples (**1**,**4**–**6**) are shown (Scheme 3).[13] Although the simple porphyrin **1** is one of



Scheme 3. Commercial prices for porphyrin (**1**), octaethylporphyrin (**4**), uroporphyrin-III octamethyl ester (**5**) and hemin **6** [13] (5 g of gold cost ca. 90 DM [19]).

Burchard Franck, born in 1926 in Hamburg, studied chemistry at the Universities of Hamburg and Göttingen. After his Diplomarbeit on digitalis glycosides with R. Tschesche in Hamburg he received his doctorate under the supervision of H. Brockmann in Göttingen in 1952 for work on antibiotics from streptomycetes. In 1959 he was awarded his habilitation for organic chemistry at the University of Göttingen. In 1963 he accepted a call to the University of Kiel and since 1968 he has been Professor of Organic Chemistry at the University of Münster. He has been a Guest-Professor in the USA, Norway, Switzerland, China, and India. Among the awards he has received for his research are the Richard-Kuhn-Medaille der Gesellschaft Deutscher Chemiker and the Adolf-Windaus-Medaille der Universität Göttingen. His recent research work has focussed on mycotoxins, biosynthesis and biomimetic syntheses, isotopic labeling, novel porphyrins, superaromaticity, and phototherapy.

B. Franck

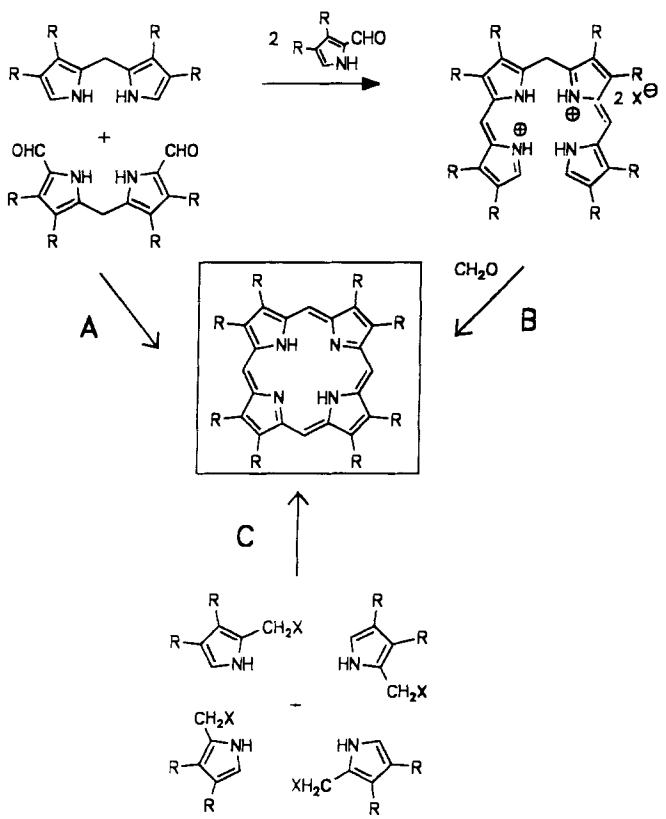
A. Nonn

Ansgar Nonn, born in 1962 in Bad Honnef, studied chemistry from 1984 to 1989 at the Universities of Cologne and Münster. He received his doctorate in 1991 under the supervision of B. Franck for work on selective porphyrin syntheses by conformational control of the cyclization. From 1991 to 1992 he carried out post-doctoral reseach with K. P. C. Vollhardt in Berkeley, USA, on the cyclization of N-heterocycles with cobalt complexes. In 1992 he joined the Bayer AG and carried out fundamental research. Since 1993 he has been a project leader in diagnostics development at Bayer AG in Uerdingen.

the most important naturally occuring aromatic systems, it cannot be easily synthesized. Accordingly, it is very expensive (Scheme 3). Octaethylporphyrin (**4**)[14, 15] is an intensively used synthetic porphyrin due to its similarity to the natural porphyrins and its much lower price. Uroporphyrin-III octamethyl ester (**5**) is a derivative of uroporphyrinogen III (**3**), which is the common biosynthetic precursor to all porphyrins and cyclic tetrapyrroles in the biosphere.[5–7] Thus, according to what has previously been stated, the annual natural production of **3** is more than 1 billion tonnes. Its price is nevertheless very high (Scheme 3), because, for practical purposes, it cannot be isolated from natural sources and its chemical synthesis requires numerous steps.[16, 17] In contrast, hemin **6** is available in abundance[18] as a porphyrin raw material from slaughterhouse blood.

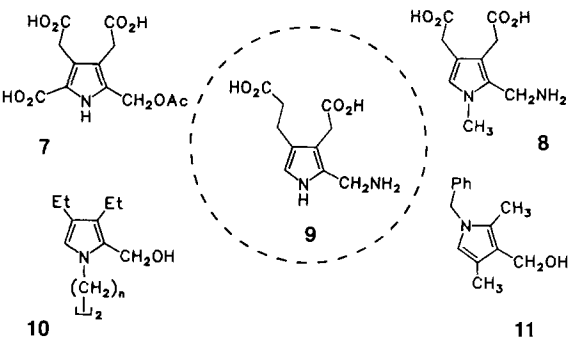
A chemist who considers embarking on the synthesis of porphyrins is well advised to learn from nature and concentrate on porphyrins bearing substituents in all eight pyrrole β positions. Cyclizations leading to porphyrins lacking these substituents, of which porphyrin **1** is an extreme example, suffer from the drawbacks of low cyclization yield, as well as instability and poor solubility of the product unless the C–H bridges between the pyrrole nuclei carry stabilizing groups.

The three most commonly used synthetic routes to β-substituted porphyrinoids are summarized in Scheme 4. These are the optimized dipyrrylmethane method **A** of Hans Fischer,[21] as modified by McDonald et al.,[20] the biladiene process **B**,[22] and the ring-forming cyclization of four monopyrroles (**C**) which resembles the biosynthesis of porphyrins.[23] All three methods are based on the tendency of open-chain tetrapyrrole intermediates to cyclize in an astonishingly selective manner.[24, 25] The biomimetic route has proved to be the most powerful of the three methods, not only from the point of view of the yields attained but also because of the lower number of steps required and the variety of products which can be synthesized using this method.[23, 26–29]



Scheme 4. Three synthetic routes to porphyrins.

Nature provides a model of biomimetic synthesis of porphyrins with the biosynthesis of the essential cyclic tetrapyrroles from the monopyrrole porphobilinogen **9** (Scheme 5).[5, 6] As

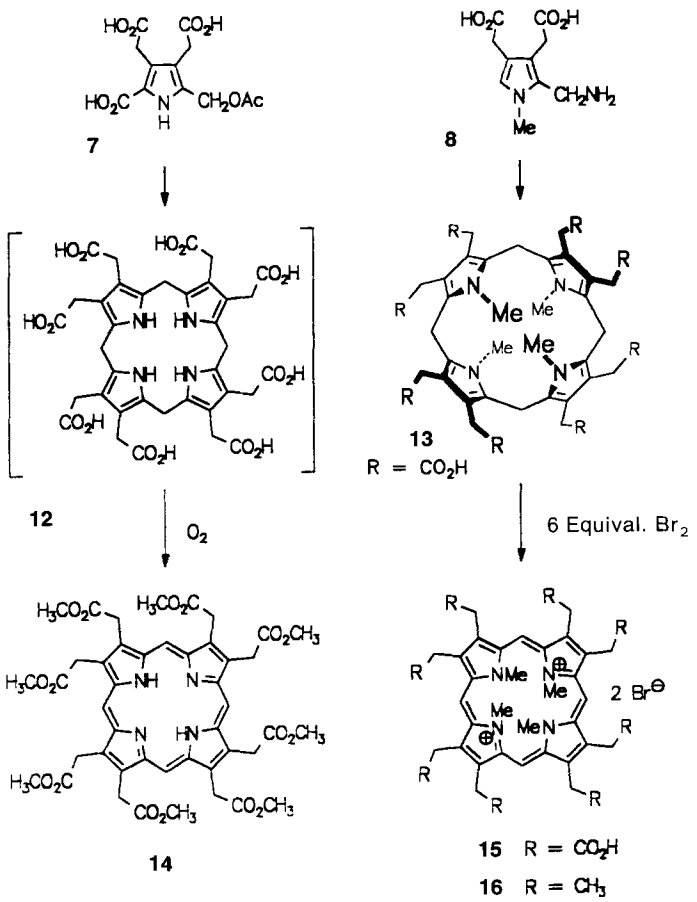


Scheme 5. Pyrroles for biomimetic synthesis.

first demonstrated by Cookson and Rimington,[23] **9** can be converted under conditions of acid catalysis to uroporphyrinogens and further to uroporphyrins, as represented by path **C** in Scheme 4. In order to explore the potential and the limitations of biomimetic syntheses of porphyrins from pyrrole precursors, we synthesized a series of derivatives of **9** (Scheme 5) and investigated their reactivity towards condensation under acid catalysis. The results obtained exceeded all expectations. Despite considerable structural variations in the monopyrroles **7**, **8**, **10**, and **11** (Scheme 5), in comparison with the biosynthetic starting material **9**, the condensations proceeded in high yields.

3. A Variety of Porphyrins through Biomimetic Synthesis: Reasonably Priced, *N*-substituted, *N,N'*-Bridged, and Inverted Porphyrinoids

Due to the presence of different side chains in the β-positions of porphobilinogen **9**, its acid-catalyzed cyclocondensation yields a mixture of isomeric uroporphyrins. Thus, the porphobilinogen derivative **7**, which contains two identical acetic acid side chains, is better suited as a reactant for biomimetic synthesis.[27] Additionally, the amino group of **9** is replaced in **7** by the better leaving group *O*-acetyl and the other α-position is reversibly protected by a carboxyl group. The cyclocondensation of **7** proceeds to give the porphyrinogen octaacetic acid **12** in high yield (Scheme 6). This can undergo autoxidation and is isolated after oxidative workup as the octamethyl ester **14**. Compound **14** differs from the expensive uroporphyrin-III derivative **5** (see Scheme 3) only by the replacement of propionic acid side chains by acetic acid units and has thus proved itself to be an



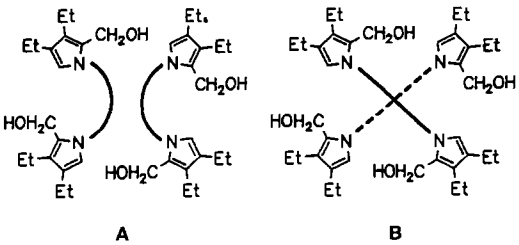
Scheme 6. Biomimetic syntheses of [18]porphyrins.

easily accessible, useful model compound for biological investigations.

The fact that exhaustive *N*-methylation of porphyrins had been shown not to be possible[30, 31] led to the assumption that *N*,*N*′,*N*″,*N*‴-tetramethylporphyrins are not capable of existence. Thus, the possibility of biomimetic condensation of the *N*-methylnorporphobilinogen **8** to the *N*,*N*′,*N*″,*N*‴-tetramethylporphyrinogen **13** seemed rather remote. We could, nevertheless, show that the acid-catalyzed condensation of **8** delivered the crystalline *N*,*N*′,*N*″,*N*‴-tetramethyporphyrinogen **13** in a yield of 17%.[26] This represents a particularly convincing example of the capability of the biomimetic principle in the synthesis of porphyrins. According to its crystal structure,[32] **13** has a structure unusual for porphyrinogens, in which the neighboring pyrrole rings are highly twisted relative to each other. This does not, however, lead to instability, but rather to high resistance towards oxidation.

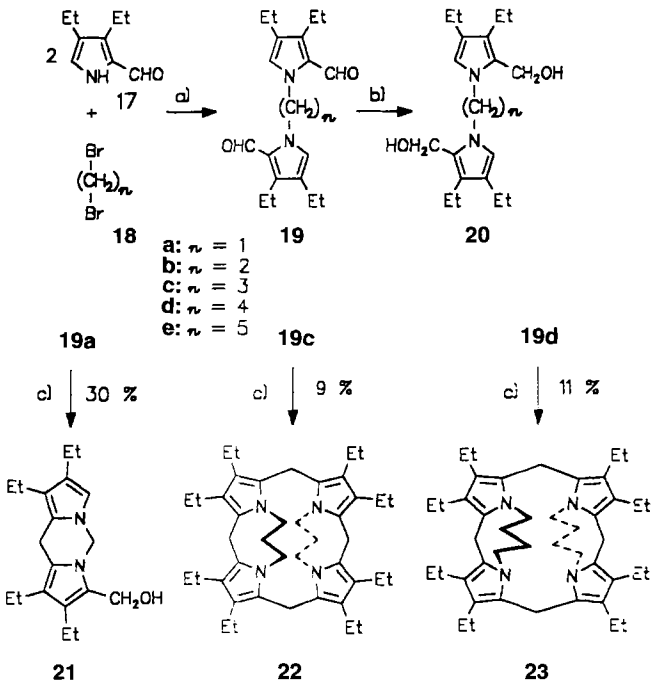
In order to convert **13**, the first autoxidation-resistant porphyrinogen, to the corresponding bis-quaternary *N*,*N*′,*N*″,*N*‴-tetramethylporphyrin **15**, one requires very powerful oxidants such as elemental bromine or cerium(IV) ammonium nitrate.[6, 33] Although **15** cannot have a completely planar structure, the ^{1}H NMR spectrum of the octamethyl ester displays a significant diamagnetic ring current effect which resembles that of Sondheimers [18]annulene **33** (see Scheme 12).[34] Thus, the resonance signals of the methine protons are strongly shifted to low field, appearing at $\delta = 10.40$, while the NCH_3 protons resonate at $\delta = -4.31$.[6] These values were confirmed by the synthesis of a similar octaethyl-*N*,*N*′,*N*″,*N*‴-tetramethylporphyrinogen (**13**, R = CH_3 instead of CO_2H)[35, 36] and also the synthesis and crystal structure of the corresponding porphyrin **16** by Vogel et al.[36]

Encouraged by these findings we took in hand the synthesis and biomimetic condensation of *N*,*N*′-bridged dipyrrole precursors.[28] Since in the *N*,*N*′,*N*″,*N*‴-tetramethylporphyrinogen **13**, the diametrically opposing *N*-methyl groups project out of the same side of the molecular plane, it could be possible to bridge the two nitrogens with an alkylene chain of the appropriate length. To this end the two principle possibilities **A** (parallel *N*,*N*′-bridges) and **B** (crossed *N*,*N*′-bridges) shown in Scheme 7 can be considered. In both cases cyclization would lead to novel polycyclic tetraaza systems.



Scheme 7. Two product types potentially accessible by the acid-catalyzed condensation of *N*,*N*′-α,ω-alkylenedipyrroles.

The synthesis of the required *N*,*N*′-α,ω-alkylenedipyrroles **19a–e** was successfully carried out by condensation of the potassium salt of the diethylpyrrolecarbaldehyde **17** with the α,ω-alkylene dibromides **18a–e** (Scheme 8).[28] The di(pyrrole-



Scheme 8. Synthesis of *N*,*N*′-α,ω-alkylenedipyrroles **19a–e** and the conversion of **19a**, **19c**, and **19d** into the bridged polycycles **21–23** by reduction and biomimetic cyclization [28,37]. a) KOH/DMSO, 20 °C; b) $NaBH_4$/MeOH, 20 °C; c) TosOH/MeOH/AcOH, −60 °C.

carbaldehydes) **19a–e** thus obtained are vinylogous amides and are thus stable compounds capable of being stored. Before further reaction they were activated by reduction with $NaBH_4$ to the diols **20a–e** and used in situ. The yields of **21–23** obtained by the acid-catalyzed condensation over one or four steps display a marked dependency not only on the chain length of the alkylene moiety but also on the transannular interactions within the heteropolycycles formed during the reaction (Scheme 8).

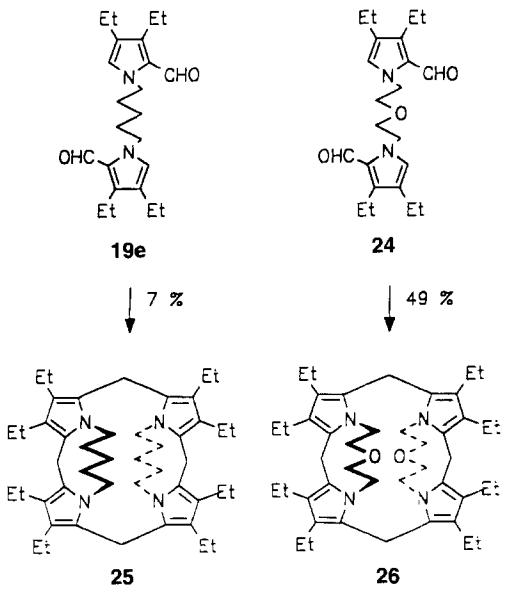
While the *N*,*N*′-methylenedipyrrole **19a** undergoes exclusively intramolecular condensation to give the novel dipyrrolo-1,3-piperazine **21**, the ethylenedipyrrole **19b** reacts to give undefined intermolecular polycondensates. The desired intra-/intermolecular condensation leading to *N*,*N*′-bridged [18]porphyrinogens only succeeds with the higher *N*,*N*′-α,ω-alkylenedipyrroles, starting from the 1,3-propanediylpyrrole **19c**. This is to be expected from inspection of molecular models.

Compounds **19c** and **19d** condense intra-/intermolecularly to the [18]porphyrinogens **22** and **23**, respectively. Both of these structures contain two novel heterotricyclic ring systems which can be classified as dipyrrolo-1,5-diazocane and dipyrrolo-1,5-diazonane, respectively. According to the following evidence, it can be concluded that both pairs of neighboring N atoms are connected by parallel bridges (cf. **A** in Scheme 7) rather than the alternative arrangement with crossed *N*,*N*′-bridges (**B** in Scheme 7): 1) In the conversion of **19c**, it was possible to isolate a dipyrrolo-1,5-diazocane (half molecule) which is an intermediate in the synthesis of the parallel-bridged **22**.[28] 2) The ^1H NMR spectrum of **22** displays two triplets for the ethyl-CH_3 groups, which shows that the molecule is not C_4 symmetrical, and thus is not a [18]porphyrinogen with crossed *N*,*N*′-bridges (cf. **B** in Scheme 7).

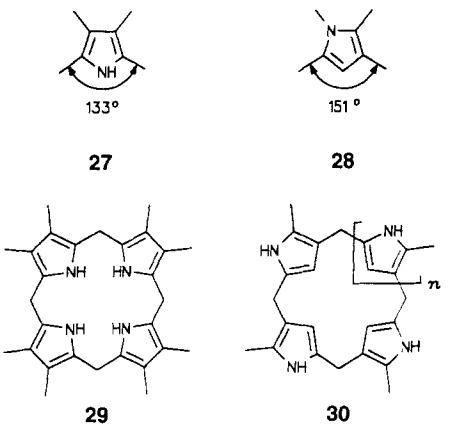
The yields of porphyrinogens **22** and **23** (Scheme 8), based on the pyrrolecarbaldehydes, are remarkably high, taking into account the multistep nature of the reaction sequence. Due to Prelog strain in medium ring systems lower yields are expected for **25**, unless the transannular interactions are reduced by substitution of CH_2 with oxygen atoms. This effect is clearly seen in the acid-catalyzed condensation of the bipyrroles **19e** and **24** (Scheme 9). While the yield of **25** is only 7%, due to Prelog strain in the dipyrrolo-1,5-diazecane ring system, the exchange of CH_2 for O in the *N*,*N*′-bridge, which leads to the dipyrrole **24**, causes the yield of **26** to jump significantly to 49%.

Similarly to the *N*,*N*′,*N*″,*N*‴-tetramethyl[18]porphyrinogen **13**, the N,N′-bridged porphyrinogens **22**, **23** and **25**, **26** are stable towards oxidation. As would be expected from their three-dimensional cage structure, **22** and **26** are incapable of dehydrogenation to [18]porphyrins even under energetic conditions, this behavior being in contrast to that of **13**. The octaethyl *N*,*N*′,*N*″,*N*‴-di(3-oxapentylene)-porphyrinogen **26** deserves consideration as a potential ligand for metal complexes because of its spherical center which contains six donor atoms.[37]

The question of whether porphyrinogens with inverted pyrrole units could be obtained by biomimetic condensation (Scheme 10) was of interest for a variety of reasons. Such invertoporphyrinogens like **30**,[38] whose nitrogen atoms are located on the periphery rather than in the center of the molecule, should provide much revealing information regarding, for example, the electronic structure, the complex formation, and the conformational control of the cyclocondensation.



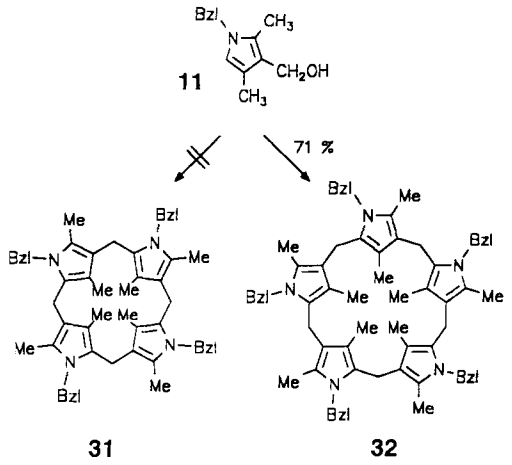
Scheme 9. Biomimetic condensation of α,ω-pentanediyldipyrrole **19e** and 3-oxa-α,ω-pentanediyldipyrrole **24** to the doubly *N*,*N*′-bridged [18]porphyrinogens **25** and **26**, respectively. (For reaction conditions see Scheme 8) [28].



Scheme 10. Comparative bond angles for the formation of porphyrinogens **29** and invertoporphyrinogens **30**.

It had to be considered for such a cyclocondensation, that the inverted pyrrole units take up a larger proportion of the sum of the internal angles of the porphyrinogen product than the non-inverted units (Scheme 10). Thus, for the normal porphyrinogen **29**, the relevant angle, that between the α-substituents of the pyrrole unit **27**, is 133°,[39] whereas the angle between the macrocycle-forming substituents for the invertoporphyrinogen **30** is 151°. Thus, each inverted pyrrole nucleus should either cause an increase in size of the macrocycle formed or lead to increased ring strain. Accordingly, one would expect that acid-catalyzed condensation would lead to a cyclic pentapyrrole.

The initially considered isomer of porphobilinogen **9** (Scheme 5), as well as a range of similar monopyrroles, proved to be unsuitable for the biomimetic synthesis of invertoporphyrinogens. Success in the acid-catalyzed condensation was achieved by using the *N*-benzylpyrrole **11**, in which the large, space-filling benzyl groups favor the ring closure[29] along the lines of the conformational helix effect (Scheme 11).[24]



Scheme 11. Biomimetic synthesis of the invertopentaphyrinogen **32** [29].

Compound **11** gave the colorless cyclic pentapyrrole **32** in 71 % yield. The pyrrole homolog of porphyrin was named pentaphyrin by Gossauer et al.[40] Following this system we have named **32** invertopentaphyrinogen.[29]

The cyclic tetrapyrrole **31** (invertoporphyrinogen) corresponding to **32**, which, due to bond angle considerations (see Scheme 10), should display substantial ring strain, could not be detected in the condensation. The pentapyrrole **32** is characterized by its high resistance to oxidation. While normal porphyrinogens are very sensitive towards oxidation and the *N*,*N*′,*N*″,*N*‴-tetramethylporphyrinogen **13** can be dehydrogenated to the corresponding deep red porphyrin **15**, albeit under more forcing conditions, such a reaction does not take place with the invertopentaphyrinogen **32**. A possible explanation for this resistance to oxidation[29] is the fact that aromatization of **32** would require a destabilizing accumulation of charge on quaternary centers.

Recently, Furuta et al.[41a] and Chmilewski et al.[41b] succeeded in demonstrating that, in the non-biomimetic synthesis of porphyrins from pyrrole and arylaldehydes (Rothemund synthesis[41c]), the major products (tetraphenylporphyrins) are accompanied by smaller amounts of isomeric monoinvertoporphyrins. This interesting observation indicates that the formation of normal porphyrins is preferred to monoinvertoporphyrins in the equilibrium-controlled acid-catalyzed condensation of simple pyrroles. This is in agreement with the conclusions which can be drawn from bond angle considerations.

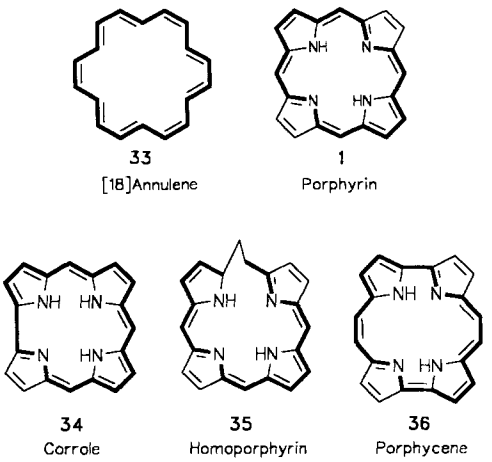
4. Routes to Novel Superarenes

The subtitle of a monograph by Lloyd[42] (cover design, Fig. 2) poses the question which has perplexed chemists since Kekulé, almost as much as Shakespeare's Hamlet was troubled by his famous existential contemplation.[43] Thanks to the pioneering work of Sondheimer[34] we know that the [18]annulene displayed in the upper right part of the cover, with its cyclic conjugated 18-π-electron system, can be considered to be a hexavinylogous benzene.

The aromaticity of **33** (Scheme 12) is indicated by the following experimental evidence: The π-electron count of the [18]annulene obeys E. Hückel's $(4n + 2)$ rule,[44] the crystal structure analysis[45] yields a planar structure with bond length equivalence, and finally, the ^{1}H NMR spectrum of **33** indicates a pronounced diatropic ring current. As with **33**, the porphyrin **1** contains a cyclic conjugated 18-π electron system, which can be designated a diazaannulene. Three further azaannulene systems related to the porphyrins are the corrole **34**,[46] the homoporphyrin **35**,[47] and the porphycene **36**.[48]

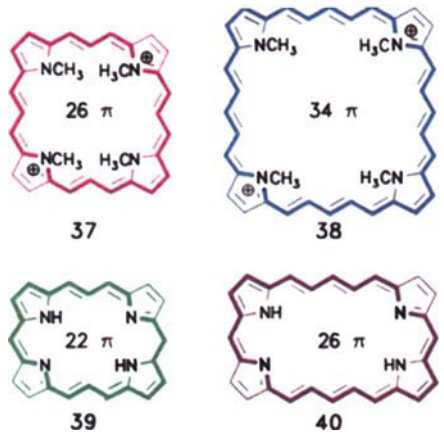


Scheme 12. 18π-electron systems.

4.1. Biomimetic Synthesis of [26]- and [34]Porphyrins

We had hoped that it might be possible to prepare vinylogous porphyrins using the biomimetic approach and related processes. Indeed it was possible to synthesize the four vinylogous porphyrin systems with 22π- (**39**), 26π-(**37**,**40**), and 34π-electron perimeters (**38**) shown in Scheme 13. We have proposed a system of nomenclature for such compounds[49, 50] in analogy to that used for the annulenes. Thus, vinylogous porphyrins are represented by a prefix in square brackets corresponding to the number of π electrons in their conjugated perimeter. Accordingly, the systems **37**–**40** in Scheme 13 would be designated [22]-, [26]-, and [34]porphyrins. Furthermore, it is sensible to extend this system to the precursors of these porphyrins. In this way one can use the names [22]-, [26]-, and [34]porphyrinogens.

The experimental[34] and theoretical[51] results from annulene chemistry represent the first hurdles standing in the way of a synthesis of vinylogous porphyrins. It has been shown that for annulenes, the resonance energies of annulenes up to [22]annulene allow the stabilization of a planar, aromatic conformation, whereas higher annulenes behave more like conjugated olefins. The experimental and theoretical studies of this subject are in good agreement. The situation regarding porphyrinoids appears to be more favorable. From the finding that simple [18]porphyrins are more chemically stable than



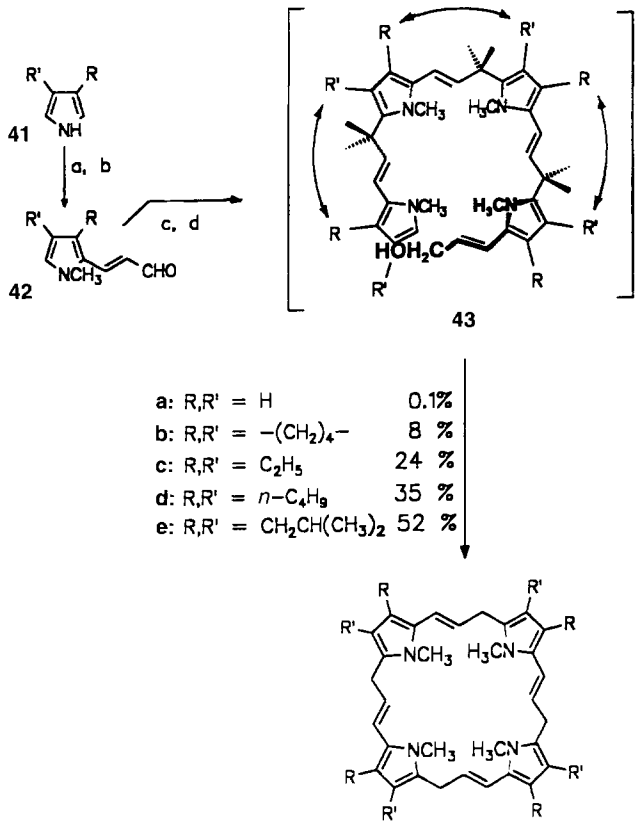
Scheme 13. Four vinylogous porphyrins with 22π-, 26π-, and 34π-electron systems.

[18]annulenes, one can presume that the rigid pyrrole units of the system can provide conformational stability, without adverse affect on the annulenoid conjugation.

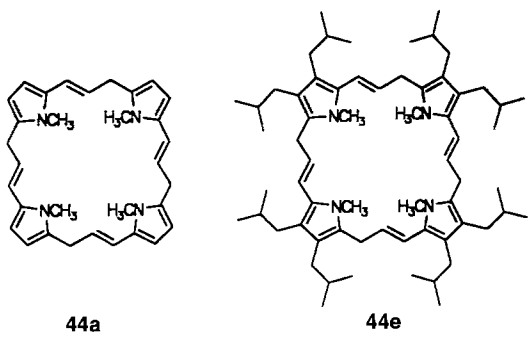
All four porphyrinoids shown in Scheme 13 are characterized by previously unknown extremes in properties related to aromaticity and light absorption. Very high diatropic ring current effects in their ^{1}H NMR spectra justify the name superarenes. Their Soret band molar extinction coefficients of $\varepsilon > 10^6$ exceed the highest previously known, found in pigments.

Following the ring closure principle of porphyrin biosynthesis, pyrrolylpropenals of type **42** (Scheme 14) were considered as starting materials for the synthesis of vinylogous porphyrinogens.[24c, 49] They differ from the biosynthetic precursor of porphyrin, porphobilinogen **9** (see Scheme 5), by the replacement of the β-position side chains by alkyl groups and the replacement of the aminomethylene group by a propenal unit. Additionally, it was found to be necessary, for reasons of stability, to replace the NH hydrogen atom with a methyl group. In order to obtain information about conformational influences on the ring closure reaction, pyrrole units with increasing steric congestion at their β-positions were chosen.

The pyrrolylpropenals **42a–e** were obtained in high yields by vinylogous Vilsmeier formylation[52, 53] in two steps from the monopyrroles **41a–e**.[24c, 49] Finally, reduction of the aldehyde group and acid-catalyzed condensation of the so-formed reactive pyrrolylpropenols in situ yielded the [26]porphyrinogens **44a–e** (Scheme 14). A significant correlation between the yields of the ring closure and the spatial requirements of the β-substituents can be detected. As in the biomimetic synthesis of normal [18]porphyrins,[24] this effect can be explained by a preferred helical conformation in the transition state of the cyclization of the intermediate tetrapyrrole **43** being favored by interactions between the β-substituents of neighboring pyrrole units. When one considers the structures of **44a** and **44e** (Scheme 15) it appears at first sight astonishing that the isobutyl groups which project far out from **44e** do not hamper the ring closure, but rather, in comparison to **44a**, significantly favor it.

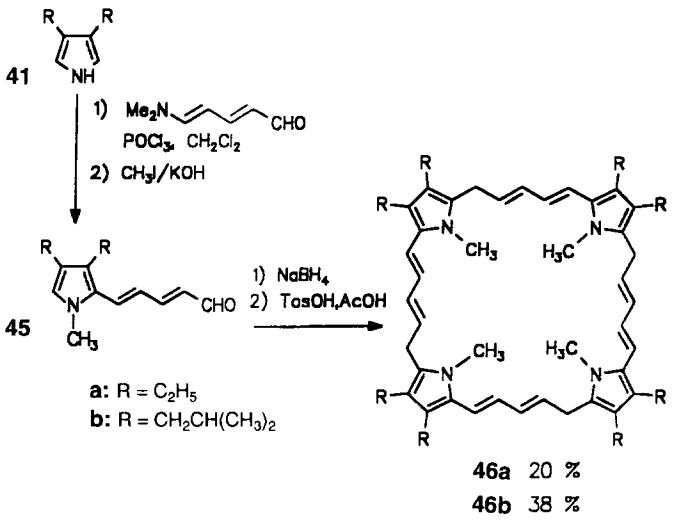


Scheme 14. Biomimetic synthesis of the [26]porphyrinogens **44a–e** [24c,49]. Reaction conditions: a) dimethylaminoacrolein ($Me_2NCH{=}CH{-}CHO$)/$POCl_3$; b) KOH/DMSO, CH_3I; c) $NaBH_4$/MeOH; d) TosOH/AcOH.



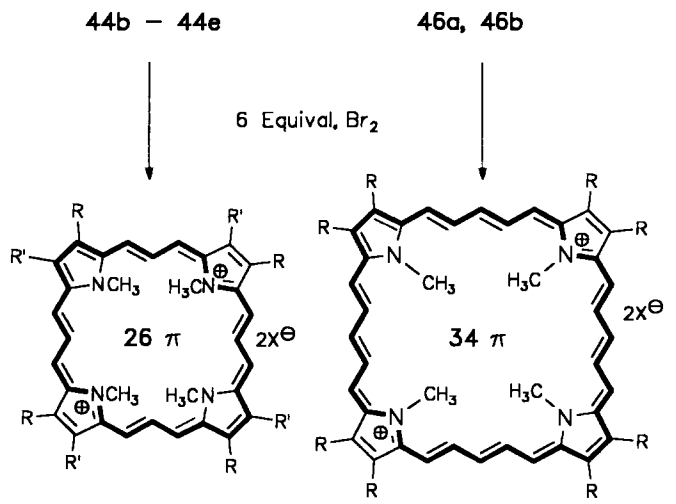
Scheme 15. Structures of **44a** and **44b**.

The question that arises next is whether the helical effect[24c] can also play an effective part in the biomimetic cyclotetramerization of monopyrroles carrying pentadienyl side chains. Such condensations should lead to octavinylogous porphyrinogens and [34]porphyrins. The starting materials **45a,b** were obtained in a similar manner to the aldehydes **42a–e** by the bis-vinylogous Vilsmeier formylation of the dialkylpyrroles **41c,e** (Scheme 14) with dimethylaminopentadienal (Scheme 16). Subsequently, the NH was methylated, the aldehyde function reduced, and the resulting, highly reactive pyrrolylpentadienol then underwent the acid-catalyzed cyclization in situ. An especially mild workup delivered the [34]porphyrinogens **46a** and **46b**.[53, 54] The yield of porphyrinogen **46b** with its sterically demanding isobutyl groups is almost twice as high as that of the octaethylporphyrinogen **46a** and indicates that, in this case too, the helical effect[24] is active in providing effective conformational control.



Scheme 16. Biomimetic synthesis of the [34]porphyrinogens **46a** and **46b** [53, 54].

The four [26]porphyrinogens **44b–e** and also the two [34]porphyrinogens **46a** and **46b** can be dehydrogenated with exactly six equivalents of bromine in the presence of polymeric base to give the deeply colored and aromatic porphyrins **47a–d**, **48a**, and **48b**, respectively (Scheme 17).[24c, 53, 54] The smooth



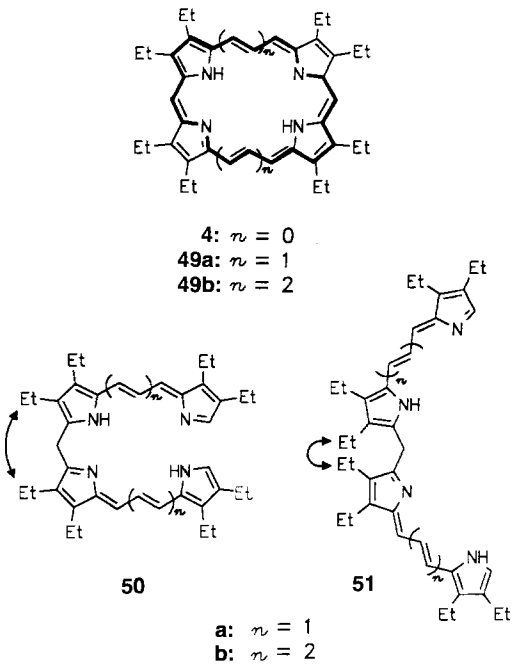
47a R,R' = $-(CH_2)_4-$ 24 %
47b R,R' = C_2H_5 41 %
47c R,R' = n-C_4H_9 39 %
47d R,R' = $CH_2CH(CH_3)_2$ 34 %
48a R = C_2H_5 12.6 %
48b R = $CH_2CH(CH_3)_2$ 13.0 %

Scheme 17. Dehydrogenation of the tetra- and octavinylogous porphyrinogens to the [26]porphyrins **47** and the [34]porphyrins **48**.

progress of this dehydrogenation of cyclic polyenes each with four reactive allyl groups would be almost inexplicable were it not for the aromatic stabilization of the reaction products. The good yields obtained in the dehydrogenation reactions proved to be essentially independent of the steric demands of the β-substituents (Scheme 17).

4.2. Synthesis of [22]- and [26]Porphyrins with the Biladiene Process

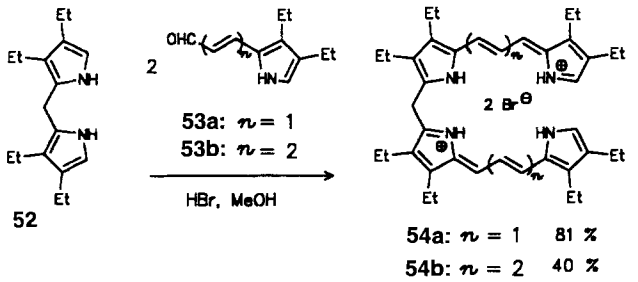
Because of the already mentioned extensive applications of Hans Fischer's octaethyl[18]porphyrin (**4**),[14] particular interest is being shown in its di- and tetravinylogues, the [22]porphyrin **49a** and the [26]porphyrin **49b**, respectively (Scheme 18). While the synthesis developed for **4** is based on the condensation of monopyrroles, a vinylogous version of the biladiene process could be applied to the synthesis of the "rectangular" C_2-symmetric porphyrins **49a,b**.[22] This would require that the vinylogous biladiene, formed as an intermediate, is capable of adopting the necessary hairpin conformations **50a** or **50b**, respectively (Scheme 18). As previously discussed for the biomimetic synthesis of "square" C_4-symmetric porphyrins, helical effects[24] of the β-substituents should favor the required conformation **50** over the linear form **51**. A further prerequisite is that the biladiene, with its vinylogous amidine structure, must possess sufficient stability.



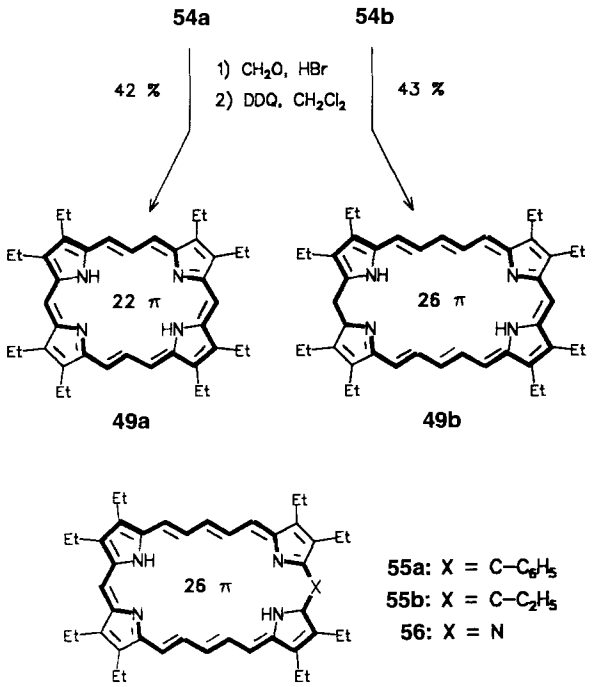
Scheme 18. The octaethyl[18]porphyrin **4** of Hans Fischer [14] together with its di- and tetravinylogues **49a** and **49b**, respectively, and the possible conformations **50** and **51** of the biladiene precursor.

The pyrrolylacroleins **53a** and **53b** are key building blocks in the synthesis of the bisvinylogous biladiene **54a** and the tetravinylogous biladiene **54b**, respectively.[24c, 53] Their condensation with the dipyrrolylmethane **52**, a porphyrin building block described by Paine and Woodward,[55] provided the highly colored vinylogous biladienes **54a** and **54b** in surprisingly high yields (Scheme 19).[50, 56]

The highly crystalline, aromatic porphyrinoids **49a** and **49b** can be obtained by the acid-catalyzed condensation of **54a** and **54b** with formaldehyde, followed by the dehydrogenation of the initially formed hydroporphyrinoids with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (Scheme 20).[56] Similarly, the



Scheme 19. Synthesis of the di- and tetravinylogous biladienes **54a** and **54b**, respectively [50, 56].



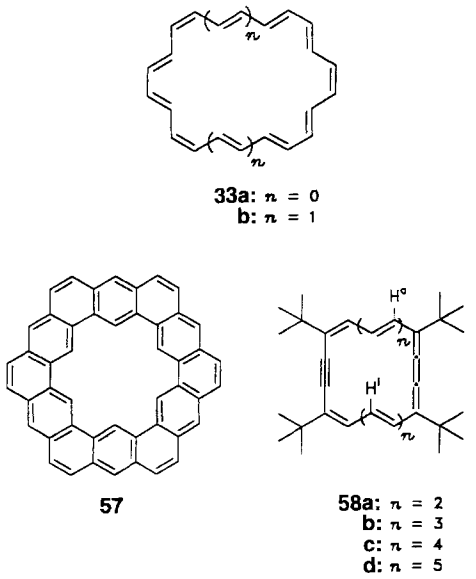
Scheme 20. Acid-catalyzed condensation of the vinylogous biladienes **54a** and **54b** to give [22]- and [26]porphyrins [50, 56].

phenyl- and ethyl-substituted [26]porphyrins **55a** and **55b** were prepared by condensation of the tetravinylogous biladiene **54b** with benzaldehyde and propionaldehyde, respectively. Condensation of **54b** with ammonia gave the aza[26]porphyrin **56**.[50]

5. The Fascination of Superaromaticity

Sondheimers synthesis of the [18]annulene **33a**[34] (Scheme 21) has had far-reaching implications for organic chemistry. For example, 40 years after the Hückel rule for benzenoid arenes[44] was postulated, this synthesis provided confirmation of the validity of this rule for systems up to and including the hexavinylogue of benzene **33a**. Furthermore, as previously mentioned, the annulenes proved the power and capabilities of HMO calculations as a method for predicting the stability of unknown molecules.[51]

These findings have stimulated intensive efforts to obtain access to higher aromatics by constraining the conformational



Scheme 21. [18]- and [22]annulenes **33a** and **33b**, respectively [34], as well as kekuléne **57** [57] and dehydroannulene **58** [58].

flexibility of annulenes. Two studies proved to be particularly informative: The synthesis of the kekuléne **57** by Staab et al.[57] and of the didehydroannulene **58** by Nagakawa et al.[58] (Scheme 21). In the case of kekuléne **57** the [18]annulene is embedded in a wreath of twelve benzene rings. This allows a direct comparison of the resonance stabilization of the benzene sextet with that of the conjugated 18π- and 30π-perimeters (inner and outer rings in **57**). As can be seen from the ^{1}H NMR spectra, **57** is a system composed of annelated benzenoid π-sextets, in which annulenoid conjugation plays no part.[57]

In the cases of the dehydroannulenes **58a–d** the alkyne and allene units provide the conjugated perimeter with steric rigidity and resonance stabilization. The ^{1}H NMR signals of the inner (H^i) and outer (H^a) protons at the conjugated perimeter indicate a correspondingly larger ring current effect than that displayed by annulenes of the same π-electron count (Table 1). The $\Delta\delta$ values ($\delta(H^a) - \delta(H^i)$), which serve as a measure of the size of the ring current effect, become smaller, starting from [18]didehydroannulene **58a**, as the molecule becomes less rigid.[58]

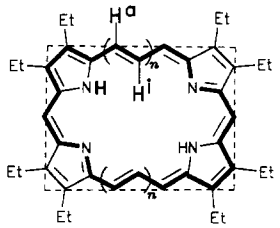
Table 1. ^{1}H NMR data for the didehydroannulenes **58a–d** [58] (see Scheme 21). δ values of the inner (H^i) and outer (H^a) protons at the conjugated perimeter, and the differences $\Delta\delta = \delta(H^a) - \delta(H^i)$.

Didehydroannulene	$\delta(H^i)$	$\delta(H^a)$	$\Delta\delta$
58a (18π)	−3.42	9.87	13.29
58b (22π)	−0.83	9.16	9.99
58c (26π)	1.95	8.23	6.28
58d (30π)	3.5	7.5	4.0

An unequivocal indication of the aromaticity of higher annulene derivatives should include, in addition to the ring current effects in the ^{1}H NMR spectrum, the proof of a planar structure with bond length equivalence in the conjugated perimeter, and the ability of the perimeter to undergo electrophilic substitution. Therefore, with regard to theoretical utility, it is desirable that

the measures taken to ensure a stable planar structure allow the molecule to remain structurally as close as possible to the annulenes. These requirements are essentially fulfilled in the case of the [22]- and [26]porphyrins **49a** and **49b**, respectively (see Scheme 20).[50, 56]

The ^{1}H NMR data for Hans Fischer's octaethyl[18]porphyrin (**4**) are summarized in Table 2 along with those of the octaethyl[22]porphyrin **49a** and the octaethyl[26]porphyrin **49b**. As is already known, the diatropic ring current effect of the normal [18]porphyrin **4**, with a $\Delta\delta$ value of 13.92, is comparable



4: $n = 0$
49a: $n = 1$
49b: $n = 2$

Table 2. ^{1}H NMR data for the vinylogous porphyrinoids. δ values of the inner protons (H^i, NH) and outer protons (H^a, NH) at the conjugated perimeter, the difference $\Delta\delta = \delta(H^a) - \delta(H^i)$, and the areas S of the rings in Å^2.

Porphyrinoid	$\delta(H^i)$	$\delta(H^a)$	δ(NH)	$\Delta\delta$	S
4 [18]	–	10.18	−3.74	13.92	50
49a [22]	−9.54	12.78	−6.61	20.2	68
49b [26]	−9.79	14.35	−5.77	24.1	84

to that of the [18]didehydroannulene **58a** (Table 1). It must be kept in mind, however, that, in the case of **4**, the δ values of the NH protons were used, replacing those of the absent inner CH protons. For the [22]porpyhrin **49a** and the [26]porphyrin **49b** the $\Delta\delta$ values increase steadily from 20.2 to 24.1. In contrast to the situation in the corresponding didehydroannulene series (Table 1), the criterion of ring current indicates no reduction in aromaticity due in some way to conformational flexibility.

The rigidity of the three porphyrinoids **4**, **49a**, and **49b** leads to an almost linear correlation between the magnitude of the ring current effect, expressed by the $\Delta\delta$ values, and the area of the ring, defined as the area within the dotted line in the formulas of the compounds above Table 2. Thus the ring areas S of **4**, **49a**, and **49b** expressed in Table 2 are approximately proportional to the $\Delta\delta$ values of the ring current effect. This relationship corresponds to that developed by Haddon[60] between the resonance stabilization (RE), the ring current (RC), and the area (S) of carbocyclic aromatic ring systems [Eq.(a)].

$$RE = \pi^2 RC/3S \qquad (a)$$

As already discovered in 1973 with the determination of the crystal structure of the octaethyl[18]porphyrin **4**,[59a] porphyrins with ethyl groups in the β-positions of the pyrrole units tend to crystallize readily as single crystals. This was confirmed in the cases of the vinylogous porphyrins **49**. Crystal structures of the bistrifluoroacetates of the [22]porphyrin **49a** and the [26]porphyrin **49b** indicated molecules with bonds of equivalent length of 136.6–138.8 pm and 137.1–139.6 pm in their respective perimeters (Figs. 3 and 4). The ring systems are almost

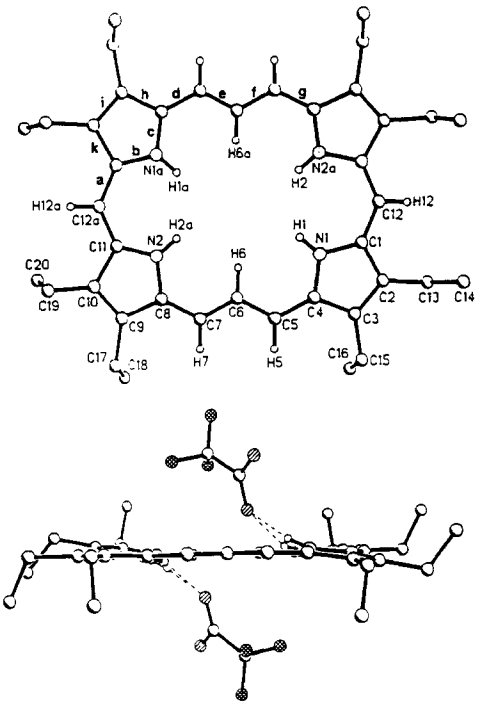


Fig. 3. Crystal structure of the bistrifluoroacetate of octaethyl[22]porphyrin **49a**; top: viewed perpendicular to the crystal plane, bottom: side view [56].

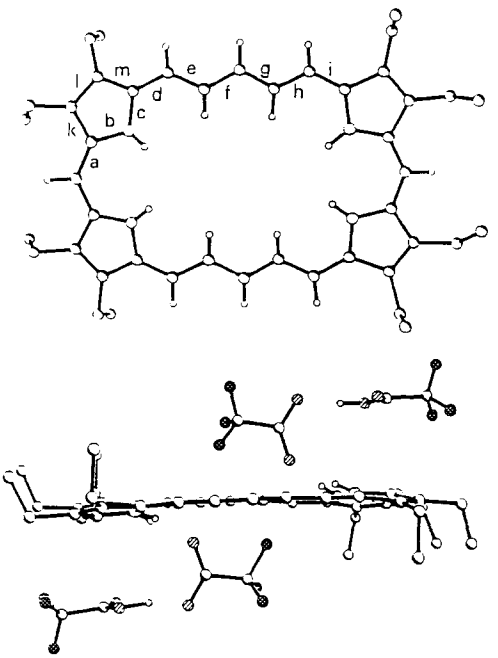

Fig. 4. Crystal structure of the bistrifluoroacetate of octaethyl[26]porphyrin **49b**; top: viewed perpendicular to the crystal plane, bottom: side view [50].

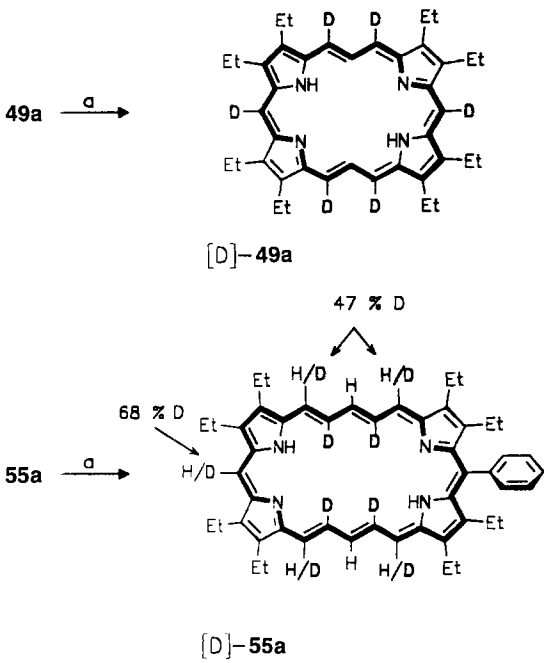
planar with maximum deviation from the central plane of 19 pm.[50, 56] The crystal structure data thus obtained for bond length equivalence and planarity for the [22]porphyrin **49a** and the [26]porphyrin **49b** agree completely with those measured by Lauher et al.[59a] and by Cetinkaya et al.[59b] for the [18]porphyrin **4**.

The vinylogous [22]- and [26]porphyrins **49a** and **49b**, respectively, offered the first opportunity to extend the investigation of

aromaticity in cyclic conjugated superarenes to the study of electrophilic substitution. The most suitable candidate for this purpose appeared to be electrophilic deuteration, for which steric considerations are minimal, and the results can be conveniently interpreted by NMR spectroscopy. Both porphyrins were treated with D_2SO_4/D_2O under identical conditions,[61] and the extent of deuteration was subsequently measured by mass spectrometry and the position and level of deuterium substitution determined by NMR spectroscopy. Significant differences in the behavior of the two porphyrins were seen (Scheme 22).

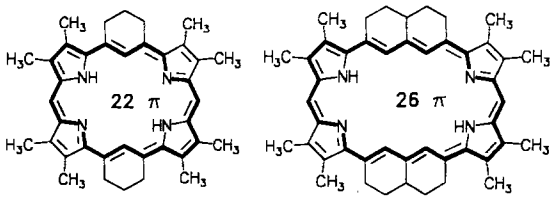


Scheme 22. Deuteration of octaethyl[22]porphyrin **49a** and 14-phenyl octaethyl-[26]porphyrin **55a**. Reaction conditions: a) $D_2SO_4/D_2O = 10:1$, 120 h, 20 °C.

In the case of the [22]porphyrin **49a**, the outer perimeter protons were almost quantitatively substituted with deuterium, with the formation of the hexadeuterio[22]porphyrin [D]-**49a**. Both inner protons proved to be inert towards electrophilic deuteration. One must assume that the NH groups undergo a D/H exchange on aqueous workup. The [26]porphyrin **49b** which is more acid sensitive than **49a**, was replaced by its phenyl derivative **55a**. Analysis of its deuteration product [D]-**55a** indicated that complete electrophilic substitution of the four inner CH protons by deuterium had taken place.

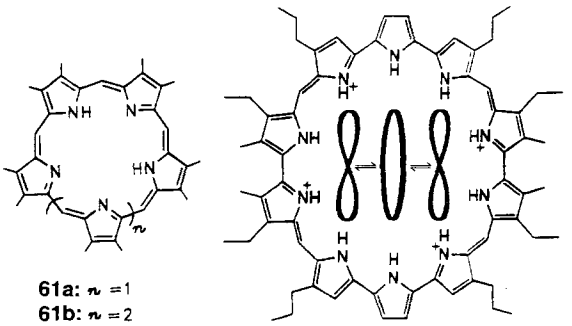
The preferred exchange of the inner protons in **55a** (→ [D]-**55a**) should be attributed to the activating effect of the phenyl substituent, rather than to the larger space inside the ring. The phenyl group proved to be an effective donor under the conditions of deuteration, compared to the more electronegative, protonated 22π-electron system. Correspondingly, the 12-phenyl[22]porphyrin underwent complete deuteration of its inner protons under the same conditions.[56b] The deuteration experiments with the [22]- and [26]porphyrins provide convincing chemical evidence for the aromaticity of these compounds. They also stimulate further interesting questions about the reactivity and regioreactivity of these novel, easily accessible[62,63] superarenes.

Conformationally stabilized diazaannulenes can similarly be represented by the [22]platyrin **59** and the [26]platyrin **60** of LeGoff et al.[64,65] (Scheme 23). These 22-π- and 26π-electron systems, prepared by a conceptually different synthetic route, can be considered to be aromatic according to the ^{1}H NMR ring current effect. Thus, **59** has a $\Delta\delta$ value of 20.6 and the less stable **60** a value of 26.0, similar to the $\Delta\delta$ values found for the [22]- and [26]porphyrins **49** (Table 2).



Scheme 23. Platyrins with aromatic 22π- and 26π-electron systems [64,65].

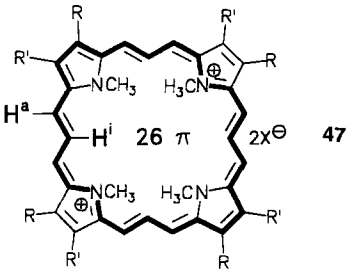
An interesting class of expanded porphyrins are the pyrrole-homologous systems, two groups of which are represented in Scheme 24. Penta- and hexaphyrins **61a** and **61b**, respectively, were described by Gossauer et al.[40] Pyrrologous macrocycles



Scheme 24. Pyrrole-homologous porphyrins: penta- and hexaphyrin **61a** and **61b**, respectively [65]; and turcasarin **62** [66].

with up to ten pyrrole units, such as the turcasarin **62** which is turquoise in solution, were achieved by Sessler et al.[66] by the insertion of di- and tripyrrole units. As was anticipated from the consideration of the angles in the perimeters (see Scheme 10), the additional pyrrole units give rise to increasing deviation from the planar structure. This leads finally, as with the cyclic decapyrrole **62**, to the formation of twisted conformations with exciting stereochemistry (Scheme 24).

The octaethyl[26]porphyrin salts **47a–d** also display pronounced aromaticity according to the ^{1}H NMR ring current effect (Table 3).[24c,49] The resonance signals of their perimeter protons are almost completely independent of the nature of the peripheral alkyl groups and lie at $\delta = -11.45$ to -11.68 for the inner protons (H^i) and at $\delta = 8.98-9.10$ for the outer protons (H^a). This gives a $\Delta\delta$ value of 25.0–25.3, which agrees very well with the values for the [26]porphyrin **49b** (Table 2) and for the [26]platyrin **60**.[64,65]



47

Table 3. ^{1}H NMR data for the salts of octaalkyl[26]porphyrins. δ values of the inner protons (H^i, CH_3N) and outer protons (H^a) at the conjugated perimeter, and the difference $\Delta\delta = \delta(H^a) - \delta(H^i)$ in $CDCl_3$.

[26]Porphyrin	$\delta(H^i)$	$\delta(H^a)$	$\delta(H_3CN)$	$\Delta\delta$
47a: R, R' = $-(CH_2)_4-$ [a]	−11.68	13.52	−9.10	25.2
47b: R, R' = C_2H_5 [a]	−11.64	13.67	−9.09	25.3
47c: R, R' = *n*-C_4H_9 [b]	−11.54	13.61	−8.98	25.2
47d: R, R' = $CH_2CH(CH_3)_2$ [b]	−11.45	13.58	−9.01	25.0

[a] Measured as the bistrifluoroacetate. [b] Measured as the dibromide.

Initial attempts to measure the diatropic ring current effect of the octaethyl[34]porphyrin salts **48a,b** from their ^{1}H NMR spectra were frustrated by the occurrence of an unexpected problem. The signals at very high field and at very low field displayed no spin splitting. It was initially presumed that this could be attributed to interconversion of conformers, as is the case with the annulenes. Therefore measurements were performed at −60 °C and at 50 °C. However, no improvements were seen. It was found that the inner (H^i) and outer protons (H^a) gave the expected splitting patterns (Fig. 5) only at extremely high dilution (0.1 mg mL^{-1}) in [D_6]DMSO.

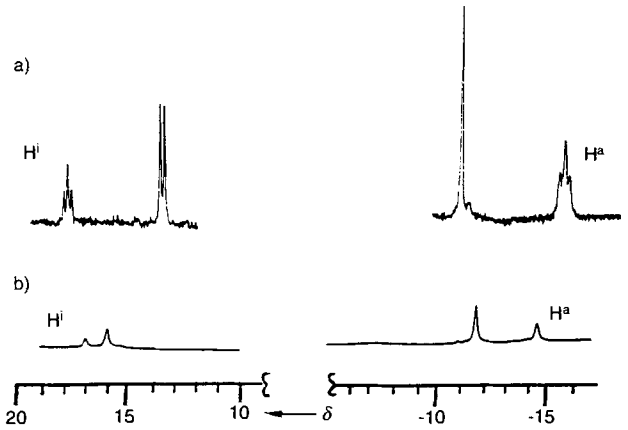


Fig. 5. ^{1}H NMR spectrum of the octaethyl[34]porphyrin **48a** in [D_6]DMSO [53]. Concentrations: a) 0.1 g L^{-1}; b) 3.0 g L^{-1}.

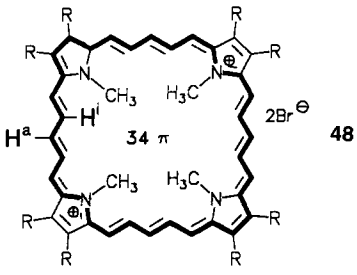
The eight H^i protons of the octaethyl[34]porphyrins **48a** and **48b**, which lie in identical positions on the inside of the C_5 bridges, display triplets at $\delta = -14.13$ and -14.23 in their ^{1}H NMR spectra (Table 4). The singlets of the CH_3N protons resonate at slightly lower field, namely $\delta = -11.30$ and -11.16, because of their somewhat larger distance from the perimeter. The twelve outer protons (H^a) on the C_5 bridges of the perimeter display two signals at $\delta = 17.18$ and at 17.04, of which the signal at lower field is derived from the protons in the center of the



48

Table 4. ^{1}H NMR data for the octaalkyl[34]porphyrin dibromides **48a, b**. δ values of the inner protons (H^i, CH_3N) and outer protons (H^a) at the conjugated perimeter, and the difference $\Delta\delta = \delta(H^a) - \delta(H^i)$ in [D_6]DMSO.

[34]Porphyrin	$\delta(H^i)$	$\delta(H^a)$	$\delta(H_3CN)$	$\Delta\delta$
48a: R = C_2H_5	−14.23	17.18	−11.30	31.4
48b: R = $CH_2CH(CH_3)_2$	−14.13	17.04	−11.16	31.2

bridges. The resulting $\Delta\delta$ value is thus greater than $\Delta\delta = 31$. Thus, the ring current effects of the [34]porphyrins **48a,b** are higher than those measured for all of the previously described arenes. Such a large span between high and low field signals in a ^{1}H NMR spectrum has only previously been observed for organometallic compounds. It is remarkable that the pyrrole units at the corners of the molecule can stabilize a planar conformation over bridges as long as C_5 and thus allow the [34]porphyrins to display aromaticity.

The fact that the spin splittings in the ^{1}H NMR spectra of the [34]porphyrins are only resolved at extremely high dilution can be considered as being due to strong associative behavior in solution. This behavior, which is also recognizable in the crystal structures of the porphyrins, might not only be due to the ring size of the octavinylogous [34]porphyrins, but may also be strengthened by the possible intercalation of anions. In contrast to the [18]porphyrins, the inner space of the octavinylogues would be well suited for this purpose, as is shown by the space-filling models in Figure 6.

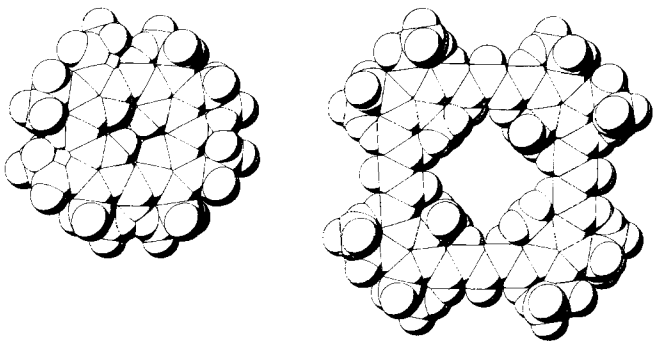


Fig. 6. Space-filling representations of the octaethyl[18]porphyrin **4** (left) and the *N,N',N'',N'''*-tetramethyl octaethyl[34]porphyrin dibromide **48a** (right) [12].

6. High Intensity Pigments with Future Perspectives

Chlorophylls cause the formation of huge amounts of biomass using energy absorbed from sunlight. In comparison with this, the light absorption of the other porphyrinoids plays a relatively minor role. Some porphyrins do have, however,

pathological or medicinally useful effects. Examples include their role as photosensitizers in porphyria[67, 68] or in photodynamic tumor therapy (PDT).[69, 70]

The new vinylogous porphyrinoids are of current interest as pigments because they display the following properties: 1) Extremely high intensity of absorption with values of the molar extinction coefficient ε as high as 1 100 000; 2) a linear relationship between the number of π-electrons and the wavelength of the most intense absorption band (Soret band); 3) high light stability, and 4) activity as photosensitizers.

The pigments, which are characterized by high extinction coefficients, could allow dyeing techniques with small amounts of substance. Up until now, the most industrially important pigments have molar extinction coefficients ε ranging from 20 000 (indigo) up to 220 000 (copper phthalocyanin).[71] The ε values of the vinylogous porphyrinoids are fifty times higher than those of indigo and three to four times higher than those of the phthalocyanins (Table 5). This fact, if supported by other useful pigment properties, may lead to interesting opportunities.

Porphyrinoid	Soret band		Longest wavelength band	
	λ_{max}	ε	λ_{max}	ε
[18]isohematoporphyrin **64**[a]	399	130 000	621	2 570
[22]porphyrin(1.3.1.3) **49a**[b]	460	1 120 000	691	7 960
[26]porphyrin(1.5.1.5) **49b**[b]	512	694 000	694	40 600
[26]porphyrin(3.3.3.3) **47b**[a]	547	909 600	783	28 000
[34]porphyrin(5.5.5.5) **48a**[c]	663	370 000	997	24 000

[a] $CHCl_3$. [b] CH_2Cl_2 + 1% TFA. [c] MeOH.

One of the prerequisites for narrow, intense absorption bands with high ε values and small half widths is a substantially symmetrical structure. Thus, the unprotonated [22]porphyrin **49a** displays a less intense Soret band ($\lambda_{max} = 463$, $\varepsilon = 419\,000$), when measured without the addition of trifluoroacetic acid (TFA) (Table 5).

The crystal structures of the bistrifluoroacetate salts of the [22]porphyrin **49a** and the [26]porphyrin **49b** (Figs. 3 and 4, respectively) indicate an almost complete bond length equivalence in the aromatic perimeter. An independent confirmation of this finding is provided for the vinylogous porphyrins from their absorption spectra. It can be seen that, as for the cyanin pigments—for the vinylogous C_4 symmetric 18π-, 26π-, and 34π-porphyrinoids—there exists a linear relationship between λ_{max} and the number of π-electrons in the aromatic perimeter (Fig. 7). According to this, the vinylogous porphyrins have fully delocalized π-electron systems comparable to those of the cyanins.[72] Because of the formal similarity, the term "Babuschka porphyrins" (in analogy with the Russian dolls in which a small doll fits inside a larger doll which fits inside an even larger doll, known as Babuschka dolls in German) is proposed for the C_4-symmetric vinylogous porphyrinoids.

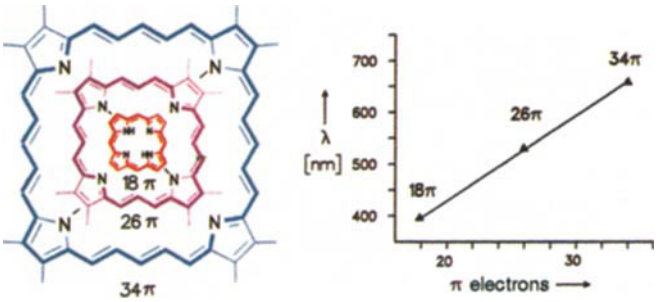

Fig. 7. Left: [18]-, [26]-, and [34]porphyrins in the colors of their solutions in CH_2Cl_2 (simplified formulas). Right: Relationship between λ_{max} (Soret band) and the number of π-electrons in the aromatic perimeter for the porphyrinoids **64**, **47b**, and **48a** with 18π-, 26-, and 34π-electron systems, respectively.

7. Tailor-Made Porphyrinoids for Photomedicine

As physiologically acceptable, effective photosensitizers, which differ only slightly from the body's own blood pigment heme, the porphyrinoids find two important applications in the field of photomedicine. These are photodynamic tumor therapy (PDT)[69, 70] and photodynamic destruction of viruses (PDV)[73] in transfusion blood. In connection with the necessity of reliably preventing viral or parasitic infections arising from blood transfusions, the second technique is of topical significance.

Thus, at the Baylor Research Institute in Dallas, it was found that viruses and other parasites in transfusion blood can be destroyed by adding a trace of a suitable photosensitizer to the blood and then irradiating it with visible light.[73] This technique is based on the fact that the photosensitizer causes the formation of singlet oxygen, which kills the virus, without causing any significant damage to the essential blood cells. Figure 8[74] shows AIDS viruses which, after multiplication within a cell, penetrate the membrane and enter into the blood stream and are, at this point, particularly exposed to attack by singlet oxygen. At present, thanks to various other techniques, particularly heat treatment of transfusion blood, the risk of infection can be substantially reduced, but not completely excluded.

In photodynamic therapy (PDT), after uptake of the photosensitizer, the tumor is irradiated with visible laser light of a suitable wavelength. This leads to inhibition and destruction of

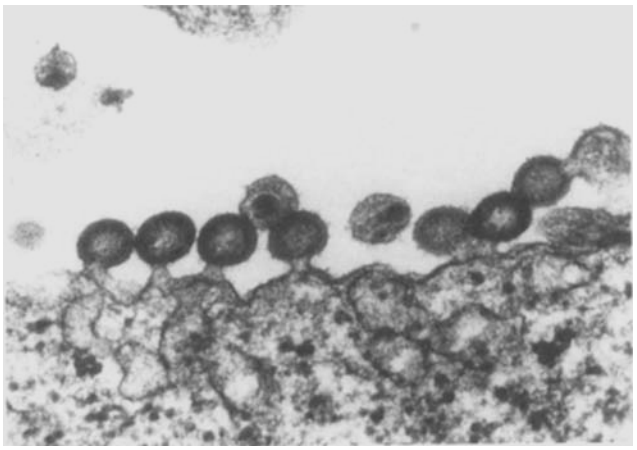

Fig. 8. Electron microscopic picture of budding AIDS viruses [74] (reprinted with kind permission of the Dana-Farber Cancer Institute, Division of Human Retrovirology, Boston, MA, USA).

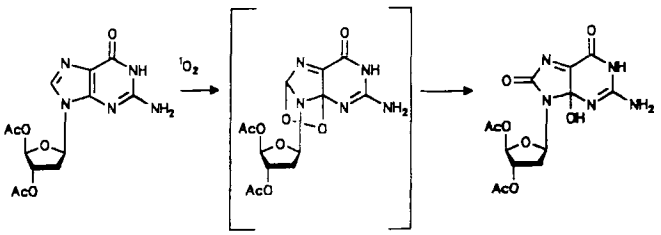
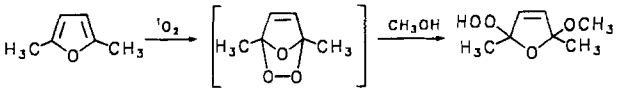
the tumor, an effect which has already been demonstrated in several thousand clinical applications.[69] Because of the success achieved up to now, and the much milder nature of the treatment in comparison to the treatment of cancer by X-ray irradiation, this area is the subject of intensive development in a worldwide collaboration between medicine and chemistry.[69, 70, 73, 75]

To explain the mechanism of action of photosensitisers in tumor therapy and in the destruction of viruses in transfusion blood, it has been assumed that the singlet oxygen which is formed on irradiation in the presence of light and oxygen, reacts with nucleosides. From this, the rapidly proliferating tumor cells are more strongly affected than the healthy tissue. Cadet et al.[76] have described oxidative transformation of deoxyguanosine acetate by singlet oxygen in a relevant model study (Scheme 25).



Scheme 25. Reaction of deoxyguanosine acetate with singlet oxygen [76].

In order to compare the photosensitizer activity of the vinylogous porphyrins, their ability to form singlet oxygen under the conditions encountered in photodynamic therapy was chemically determined (Scheme 26). The trapping reaction with 2,5-dimethylfuran and the subsequent iodometric titration of the hydroperoxide formed after the methanolysis, was chosen for this purpose.[79–81] This indicated that the divinylogous [22]porphyrin **49a** performs almost as efficiently as Rose Bengal, and exceeds the [18]porphyrin system, for example **4**, which has been predominantly used in photomedicine until now. In the case of the [34]porphyrin **48a**, the relatively low energy of the

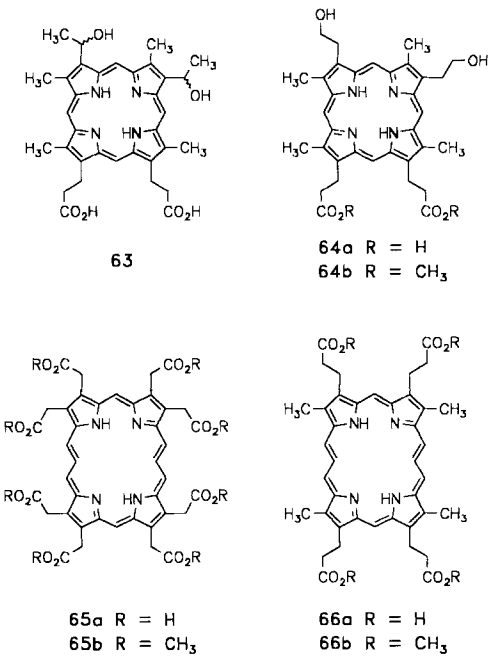


Scheme 26. Formation of $^1O_2$ by various photosensitizers under standard conditions [79–81]. Photosensitizers used (yield %): octaethyl[18]porphyrin **4** (22); octaethyl[22]porphyrin **49a** (40); octaethyl[26]porphyrin **49b** (12); octaethyl[34]porphyrin **48a** (0); Bengal Rose (44); blank (0).

higher wavelength fluorescence emission ($\lambda_{max} = 1310$ nm)[82] is not sufficient for $^1O_2$ formation.

An ideal photosensitizer for photomedicinal applications should fulfill the following criteria:[70] 1) be readily available and chemically stable; 2) be a good photosensitizer; 3) its absorption of light should differ from that of the blood pigment heme; 4) have minimal dark toxicity; 5) be pharmacokinetically innocuous; 6) be rapidly eliminated from the organism after phototherapy.

The most widely used photosensitizers have been hitherto derivatives of the hematoporphyrin **63** (Scheme 27), which have



Scheme 27. Hematoporphyrin (**63**), isohematoporphyrin (**64a**) [77], [22]porphyrin-octaacetic acid (**65a**) [78a]and [22]coproporphyrin II (**66a**) [78b] and esters.

been named Photofrin.[69] They fulfill the majority of the above-mentioned criteria. The hematoporphyrin **63** is somewhat chemically unstable due to its allylic secondary hydroxy group, which leads to mixtures of derivatives. This problem can be overcome by the use of the more stable isohematoporphyrin **64**.[77] Of greater significance is the improvement in the penetration depth of the laser light used for the photosensitization. Due to the similarity of the chromophore of hematoporphyrin **63** to that of the natural blood pigment heme, present in large excess, part of the laser light is lost during phototherapy. A remedy to this problem is offered by photosensitizers which, as in the case of the vinylogous porphyrins **65a** and **66a**, are structurally similar to the hematoporphyrin **63**, but absorb light at longer wavelengths (Scheme 27). Compound **66a**[78b] is a divinylogue of the

naturally occuring coproporphyrin II. It has a more intense UV/Vis absorption which is shifted to longer wavelengths than the blood pigments, and thus appears to be a candidate for selective photoactivation (Fig. 9).

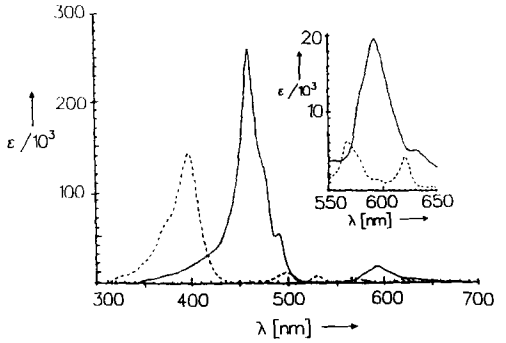


Fig. 9. UV/Vis spectra of [22]coproporphyrin II ester (**66b**) (– – –) [78b] and isohematoporphyrin (**64b**) (——) [77] in CH_2Cl_2. Because of the instability of hematoporphyrin (**63**), the spectrum of **64b**, which has the same chromophore, is shown for comparison.

Due to the short half life and therefore limited range of action of $^1O_2$,[82] the photosensitizer can only display its effect inside the viral or tumor cells. Therefore, a decisive factor for the photomedicinal application of porphyrinoids is, apart from their photosensitizing ability, their polarity. In order to investigate this, the ability to inhibit tumors in a leukemia cell line was studied for two derivatives of the isohematoporphyrin **64b** and **67**[77b] as well as for a [22]porphyrin **65b**[78a] and a [26]porphyrin **47b**[24c] (Table 6).[83] This showed that the tumor inhibitory activity of the nonpolar isohematoporphyrin dimethyl ester **64b** significantly exceeded that of the isohematoporphyrin digalactoside **67**. The nonpolar [22]porphyrin octaacetic acid octamethyl ester **65b** has similar activity to **64**, while the polar, bisquaternary [26]porphyrin **47b** has a lower activity which corresponds roughly to that of **67**.

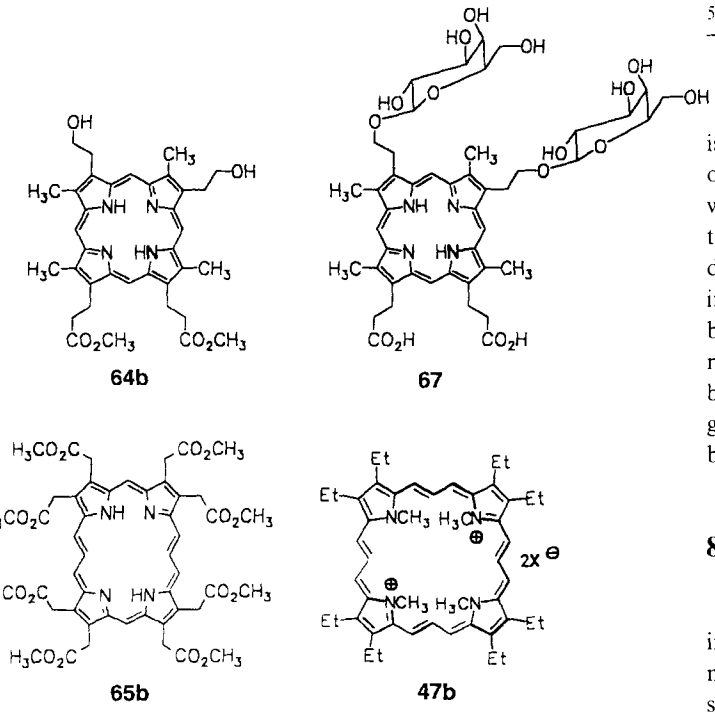

Table 6. Inhibition of tumors by the four porphyrinoids **64b**, **65b**, **67**, and **47b** of different polarity against leukemia cell lines [83]. Colony building after laser irradiation (93.6 J cm^{-2}) as a percentage of the initial value.

Concentration [%] [μg mL^{-1}]	Colony formation **64b** [77b]	**67** [77b]	**65b** [78a]	**47b** [24c]
2.5	32	78	48	62
5	12	49	29	48
7.5	8	39	1	30
10	0	10	0	15

The isohematoporphyrin dimethyl ester **64b** proved itself to be just as well suited for the photodynamic destruction of viruses in blood. Table 7 shows the destruction of Herpes simplex virus (HSV) using **64b** and 458 nm laser light. A concentration of 1 μg mL^{-1} (corresponding to 0.5 mg in a transfusion blood unit of 500 mL) is sufficient to kill 99.996% of the virus. Under the same conditions the blood leukocytes are hardly affected.

Table 7. Phototoxicity of the isohematoporphyrin dimethyl ester **64b** against Herpes simplex virus (HSV) and against blood leukocytes with laser light of 458 nm [83].

Concentration [μg mL^{-1}]	Destruction of HSV dark	laser	Surviving leukocytes dark	laser
0	–	18000000		
1	1500000	750	58	43
2.5	1500000	500	42	28
5	1400000	250	36	22

In the flow cells of a test apparatus (Fig. 10) the film thickness is so low that the absorption of laser light by blood pigments is of no importance.[73b, 83] By using the vinylogous porphyrins which absorb light at longer wavelengths, it would be possible to photodynamically sterilize blood in thicker films, potentially directly in the transfusion units. This would not only be of use in the reduction of infection from AIDS and hepatitis viruses, but also from malaria parasites. Taking into consideration the risk of infection which is always present in the use of transfusion blood and other infusion liquids, the development of safer, more generally applicable, and cheaper processes of sterilization is becoming more and more important.

8. Summary and Outlook

The results gained with the porphyrins have reinforced the importance of understanding the biosynthesis of a group of natural products, the knowledge of which opens the door to a series of novel methods and insights. In particular this holds true for the development of biomimetic syntheses, as was shown first of all in the pioneering work by Robinson and Schöpf for the alkaloids,[84, 85] then Johnson[86] for the steroids, and Rimington et al.[23] for the porphyrins. Through this approach possibilities for efficient syntheses have been realized, which allow an alternative route to active substances, generally preferable to their isolation from biological material. In the case of the porphyrins, the biomimetic principle has provided a remarkable versatility and flexibility, which has allowed access to viny-

logously expanded, *N*,*N*′,*N*″,*N*‴-tetrasubstituted, *N*,*N*′-bridged, and inverted (*N* atoms in the periphery) porphyrins.

While we are still in the early stages, the new porphyrinoids have already displayed properties which are of great promise in the fields of chemistry and medicine. If one looks for a reason for the unusually broad variability encountered in biomimetic porphyrin synthesis, one is forced to suppose that this has to do with the very early prebiotic formation of porphyrins.[87] The evolution of organisms required a versatile system with strong formation tendency, which could satisfy the demand for ligands for the essential elements Mg, Fe, Co, Ni, and V.

Our work was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG (Ludwigshafen). B. F. would, in particular, like to thank all the co-authors of the cited work, carried out in Münster. The readiness of numerous colleagues (refs. [15, 18, 25, 32, 36, 40, 46, 60, 68, 69, 72, 73, 75, 79, 82, 83]) to contribute much valuable advice or to collaborate was decisive for the success of the interdisciplinary research.

Molecular Imprinting in Cross-Linked Materials with the Aid of Molecular Templates—A Way towards Artificial Antibodies

Günter Wulff*

Can binding sites be produced in organic or inorganic polymers—similar to those in antibodies—which are able to recognize molecules and which may have catalytic action? In this article we review a method, analogous to a mechanism of antibody formation proposed earlier, by which in the presence of interacting monomers a cross-linked polymer is formed around a molecule that acts as a template. After removal of the template, an imprint containing functional groups capable of chemical interaction remains in the polymer. The shape of the imprint and the arrangement of the functional groups are complementary to the structure of the template. If chiral templates are used, the success of the imprinting process can be assessed by the ability of the polymer to resolve the racemate of the template molecule. Thorough optimization of the process has led to chromatographic separation factors of $\alpha = 4-8$, and to base line separations. There is also great interest in the surface imprinting of solid materials and monolayers. In all cases, the structure of the polymeric matrix in the imprinted materials and the function of the binding groups are of crucial importance. The mechanisms of imprinting and molecular recognition of substrates are by now well understood. A large number of potential applications for this class materials are being intensively developed, for example in the chromatographic resolution of racemates, and as artificial antibodies, chemosensors, and selective catalysts. The use of similarly produced materials as enzyme models is also of great interest.

Keywords: catalysis · enantiomeric resolution · imprinting · molecular recognition · polymers

1. Introduction

In nature, molecular recognition plays a decisive role in biological activity, for example, in receptors, enzymes, and antibodies. The chemist, too, has discovered how to develop more and more selective recognition systems. Extremely high selectivity is obtained if, as in nature, a cavity exists that has a shape to match that of the substance to be embedded in it and binding sites in a definite spatial arrangement. To form the cavity, low molecular weight ring or cage systems[1] such as crown ethers,[2] cryptates,[3] cyclodextrins,[4] cyclophanes,[5] or concave molecules[6] are usually used. The additional incorporation of catalytically active groups that can lead to enzymelike catalysts is of particular interest. Using a conceptually simpler process, similar cavities can now be created in synthetic polymers. In a technique analogous to what was formerly thought to be the mechanism of formation of antibodies,[7] cross-linked polymers are formed around a molecule that acts as a template, and this template is then removed. An imprint containing reactive groups with binding capability remains behind in the polymer.[8] This process differs from the usual template effect[9] in which a template is used to bring low molecular weight reactants into an arrangement that favors the formation of a particular low molecular weight (usually cyclic) product. It also differs from true template polymerization,[10] in which monomers are bound to a polymer that acts as a template to give defined linear polymers. In contrast to this, during the imprinting process the newly formed polymer is cross-linked, so that the three-dimensional structure formed remains unchanged after removal of the template.

The imprinting of organic polymers was first reported by our research group in 1972.[8, 11, 12] The early part of the work necessitated tedious optimization experiments. However, the process is now established and is used in many research groups. The promising areas of development include chromatography, catalysis research, biosensor technology, and the production of artificial antibodies that offer a broad range of potential practical uses. Numerous patents in the field testify to this claim.

Many papers review the subject of molecular imprinting. In addition to comprehensive review articles,[13] there are many shorter articles[14–21] and articles dealing with specific aspects such as chromatography[22–24] and binding groups.[25–27]

2. The Concept of Imprinting

To obtain highly specific binding sites of a definite shape containing functional groups in a predetermined orientation,[8, 11, 12] we bound the functional groups in a polymerizable form to a suitable template molecule (see Fig. 1a). This monomer (Fig. 1b) was then copolymerized under conditions

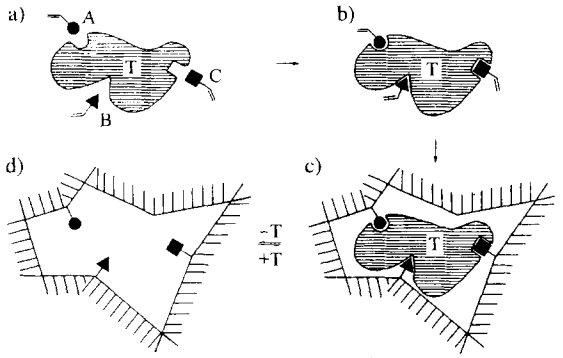

Fig. 1. Schematic representation of the imprinting of specific cavities in a cross-linked polymer by a template (T) with three different binding groups.

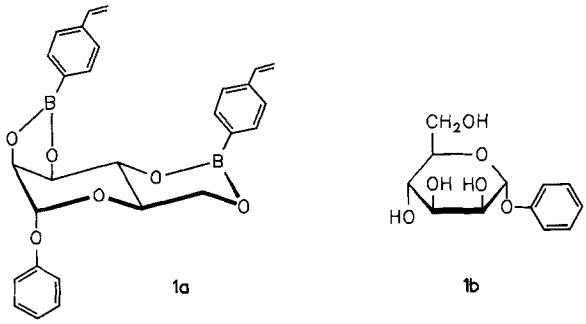
that led to the formation of highly cross-linked polymers with chains in a fixed arrangement (c). After removal of the template, polymers with well-defined cavities (d) were obtained, whose structure and arrangement of functional groups were predetermined by the chemical nature of the template. The functional groups in these cavities are located at various points in the polymer chain, and are held in a definite mutual orientation simply by the cross-linking. In this case, the stereochemical information is not carried by a low molecular weight part of the molecule. Instead, the entire arrangement of the polymer chains (topochemistry) is responsible for the stereochemical structure. This is reminiscent of the structure of the active centers of enzymes; we have therefore termed these polymers enzyme-analogous. The relationship of the template to the imprinted cavity corresponds to the key/lock principle proposed by Emil Fischer for enzyme catalysis around 100 years ago.[28] The imprinting process has a certain analogy to the attempts of F. H. Dickey to imprint silica gel by precipitation in the presence of template molecules (see Section 3.2.2).[29, 30]

The polymerization of the template monomer **1a** is an example of the imprinting method. Extensive optimization work was carried out on the methodology with this system.[31–42] The template is phenyl-α-D-mannopyranoside (**1b**) to which two molecules of 4-vinylphenylboronic acid are bound by esterification with two OH groups of the sugar. Boronic acid was chosen



as the binding group (binding site) as this undergoes a rapid and reversible reaction with diols. The monomer **1a** is subjected to radical copolymerization with large amounts of a cross-linking agent such as ethylene dimethacrylate in the presence of an inert solvent (which acts as a porogen to give a porous structure). This yields macroporous polymers with a large inner surface area and a permanent pore structure. Up to 95% of the templates can be split off again from polymers of this type by treatment with water or methanol (Fig. 2).

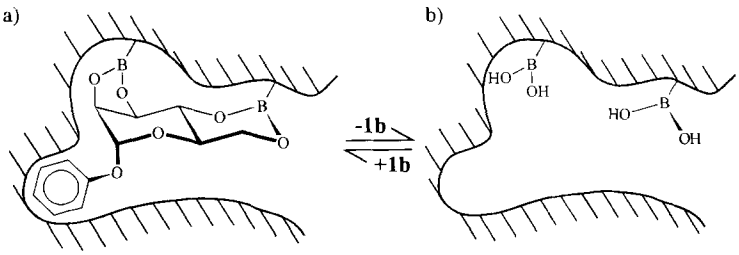


Fig. 2. Schematic representation of a cavity a) obtained by polymerization of **1a**. The template **1b** can be removed with water or methanol to give b). Addition of **1b** causes the cavity to be reoccupied, giving a) again. In this case, the binding of the template is by covalent bonds [13, 34].

Günter Wulff was born in 1935 in Hamburg where he began his chemistry studies. He was awarded his Ph.D. in Bonn in 1963 for a dissertation on the isolation and characterization of glycosidic natural products from plants under the supervision of R. Tschesche. His habilitation, dealing with glycoside synthesis, was completed in 1969 in Bonn. Since 1979 he has held the chair of Organic and Macromolecular Chemistry at the University of Düsseldorf. His present research interests include the synthesis of polymers with enzyme-analogous properties through imprinting with template molecules, the synthesis and investigation of optically active (main-chain chiral) vinyl polymers, and the application of renewable resources (monosacchaides and starch) for the synthesis of specialty polymers.

Since the template **1b** is optically active, the correct structure of the cavity can be verified by racemate resolution experiments. After the template has been removed, the polymer is equilibrated in a batch process with the racemate of **1b**, whereupon the enantiomer used as the template is preferentially taken up. The selectivity is expressed by the separation factor α, which is well known from chromatography (ratio between the distribution coefficients in solution and in the polymer for the D and L forms, K_D/K_L). Depending on the polymer structure and the equilibration conditions, values of α between 1.20 and 6.0 are obtained. With the highest values of α, the D-**1b** can be enriched to 60–70 % *ee* on the polymer in a batch process. With these polymers as stationary phases in HPLC, base line separations of the racemates can be achieved (see Section 6.1).

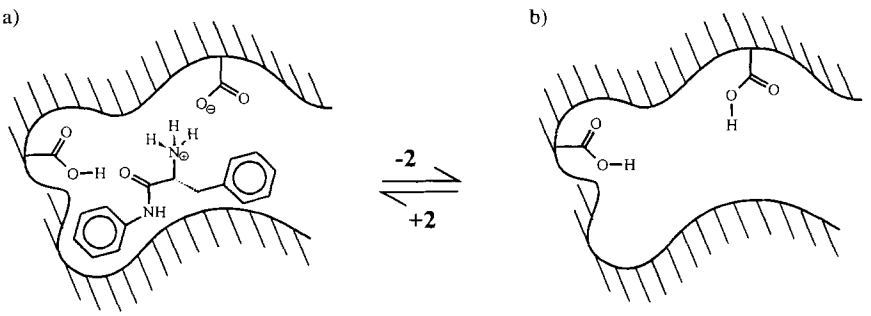

Fig. 3. Schematic representation of a cavity produced in the presence of **2**. The polymerization takes place in the presence of acrylic acid. Noncovalent electrostatic interactions and hydrogen bond formation occur [16, 43].

The extremely high selectivities for the resolution of the racemate clearly show that it is indeed possible to produce cavities with a definite structure and a precise arrangement of functional groups. Although optimization of the polymers extended their properties very considerably, only when K. Mosbach et al.[43] achieved an effective imprinting effect by using exclusively noncovalent interactions could the usefulness of the process be considerably widened. Many investigations in this direction were carried out with L-phenylalanine anilide (**2**) as template. This was polymerized with methacrylic acid as the comonomer under the polymerization conditions established for **1a**. One methacrylic acid unit forms an electrostatic bond with the template **2**, and another forms a hydrogen bond (Fig. 3).[43] The research groups of K. Mosbach and K. J. Shea extensively optimized the process, and achieved high selectivities for resolution similar to those obtained with **1b**.[43–54]

and **2**. The shape of the cavity is highly schematic, because the boundaries of the cavities are formed by polymer chains whose dimensions are actually of the same order as those of the templates; consequently, smooth surfaces are not formed.

Since then many other substances have been used as templates to produce imprinted polymers. A list of classes of substances so far used for imprinting polymers is given in Table 1.

Table 1. Classes of substances used as template molecules for imprinting polymers.

Class of substance	Reference
sugars and sugar derivatives	[18, 23, 31, 32, 34, 35, 37, 39–42, 55, 56]
diols, polyols	[8, 57]
hydroxycarboxylic acids	[8, 58–63]
amino acid derivatives	[16, 21, 43, 44, 54, 64–75]
peptides	[76]
proteins	[26, 77]
nucleosides and nucleotides	[78–80]
purine derivatives	[78, 81]
steroids	[72, 73, 82]
basic drugs	[47, 83, 84]
acidic drugs	[85]
dialdehydes	[86]
diketones	[87–90]
dicarboxylic acids	[71–91]
disulfides	[92]
dyes	[93, 94]
coenzyme analogs	[95–97]
basic condensed aromatics	[74, 98]
bisimidazoles	[26, 99, 100]
phosphonate esters	[101, 104a]
pesticides	[104b]

3. The Structure of the Polymeric Matrix

3.1. Imprinted Cavities in Synthetic Polymers

The structure of the matrix is crucial in the imprinting process. As the specific structure of the cavity is not determined by low molecular weight molecules, but by the fixed arrangement of the polymer chains, the optimization of the polymer structure is extremely important. The polymer should have the following properties:[13a]

a) *Stiffness of the polymer structure* enables the cavities to retain their shape even after removal of the template, thus giving high selectivity.
b) *High flexibility* of the polymer structure works against the above, but is essential for the kinetics, to give rapid equilibration with the substrate to be embedded.
c) *Good accessibility* of as many cavities as possible in the highly cross-linked polymer can be achieved by forming a particular polymer morphology.
d) *Mechanical stability* of the polymer particles is of great importance for many applications, for example, for use in an HPLC column at high pressure or as a catalyst in a stirred reactor.
(e) *Thermal stability* of the polymers enables them to be used at higher temperatures, at which the kinetics are considerably more favorable.

From the beginning, macroporous structures have been used almost exclusively for imprinted polymers. Macroporous polymers are obtained if polymerization of the monomers is carried out with a relatively high content of cross-linking agent (5–90%) in the presence of inert solvents (also known as porogens). During the polymerization, phase separation takes place, and, after removal of the porogen and drying, a permanent pore structure remains. The pores can change size on subsequent swelling, but usually remain present.[105] The relatively large inner surface area (50–600 $m^2 g^{-1}$) and large pores (about 10–60 nm) ensure that the specific microcavities formed by the imprinting process (about 0.5–1.5 nm in diameter) are readily accessible, and smaller molecules can diffuse freely inside the pores. If high levels of cross-linking agent are used, the cavities retain their shape quite well after removal of the templates.

The polymers first produced, however, showed relatively low selectivities ($\alpha = 1.03–1.80$) for racemate resolution,[8, 31–33, 57, 61] and their thermal and mechanical stability properties were also below par. Detailed investigations into polymer optimization in our laboratory then brought great improvements. The ratio of porogen to monomer should be approximately 1:1 (mL:g). The type of porogen (solvent or precipitating agent for the polymer being formed) has a strong influence on the morphology of the polymer, but the effect on the selectivity of the cavities formed is small.[13, 39, 54] The decisive factor for high selectivity is the type and quantity of the cross-linking agent used in the production of the macroporous polymers.[34]

Figure 6 shows the selectivity of the polymers (expressed as separation factor α) for the resolution of phenyl-D,L-mannopyranoside in a batch process as a function of the type and amount of cross-linking agent. Ethylene dimethacrylate will be used as a typical example of cross-linking agent (Fig. 6a). The cross-linking agent shows no specificity below a certain concentration (about 10%). The shape of the cavities cannot be stabilized unless the matrix is adequately cross-linked. Increase in the content of cross-linking agent from 10% to 50% increases the α value from 1.0 to approximately 1.5. Increase from 50% to 70% then leads to an unexpected increase from $\alpha = 1.5$ to $\alpha = 3.0$, corre-

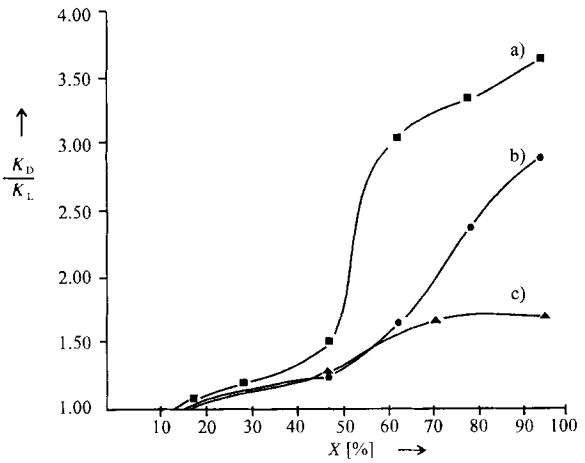

Fig. 6. Selectivity of polymers as a function of the type and amount (X) of cross-linking agent [34]. The polymers were prepared in the presence of **1a** with various proportions of the cross-linking agents ethylene dimethacrylate a), tetramethylene dimethacrylate b), and divinylbenzene c). After removal of the template **1b**, the separation factor $\alpha = K_D/K_L$ was determined for the resolution of D,L-**1b** in a batch process.

sponding to a fourfold increase in selectivity in this range. At present we cannot correlate this sudden increase with a structural change in the polymer matrix. Further increase in the content of cross-linking agent to 95% causes a further increase in selectivity to $\alpha = 3.7$ under these conditions. An even higher selectivity (up to $\alpha = 6.0$) is obtained by reducing the ratio of racemate to polymer and by equilibration at a higher temperature.

If divinylbenzene is used as the cross-linking agent (Fig. 6c), the increase in selectivity at higher content of cross-linking agent is considerably smaller. This cross-linking agent might be increasing the stiffness of the polymer network severely, thereby decreasing the accessibility of the cavities significantly, as shown by the smaller percentage of templates that can be removed. Pure *ortho*-, *meta*-, or *para*-divinylbenzene cross-linking agents behave similarly in this respect.[39] Tetramethylene dimethylacrylate is apparently too flexible as cross-linking agent to give sufficient stabilization of the cavities (Fig. 6b). Thus, a compromise must be found between an inflexible arrangement of the polymer chains to give high selectivity and an appropriate degree of flexibility, which is necessary for good accessibility of the cavities and rapid attainment of binding equilibrium.

Many other cross-linking agents, some synthesized for the first time, have been investigated in the same way.[39] However, it became apparent that ethylene dimethacrylate is not only the cheapest cross-linking agent and easy to purify, but also the most suitable for the imprinting process. Even new, optically active cross-linking agents[39, 106] did not give better selectivity for resolution. The thermal and mechanical stability of materials incorporating higher proportions of ethylene dimethacrylate is very good. Chromatographic columns based on this material did not lose their selectivity even at 80 °C and 6–10 MPa during periods of constant use over many months.[23, 37] For information on good thermal stability, see also Ref. [54]. Polymers cross-linked with divinylbenzene are subject to significant loss of selectivity on prolonged use at 70 °C.[33] Because of the superior properties of imprinted polymers produced with ethylene dimethacrylate, most research groups today use these for work on imprinting.[43, 46, 51, 53, 54, 81, 83, 84, 100, 107–109]

The cavities in polymers of this kind are quite well accessible. If the template is fixed with readily hydrolyzable or noncovalent bonds, over 90% of the templates incorporated in the polymer can be removed again. The remaining templates are located in the interior of the highly cross-linked parts of the macroporous polymer and are not accessible for reactions. Of the empty cavities, about 80–90% can be reoccupied on subsequent equilibration with an excess of template molecules. If the templates are bound by noncovalent interactions, this figure is only 10–15%.[48, 52, 54] (For a thorough discussion refer to Ref. [54].) Almost 90% of the cavities from which the noncovalently bound templates were removed cannot therefore be reoccupied; this leads to a significantly lower capacity. Evidently, after removal of the templates, relaxation of strain and swelling of the matrix cause some of the cavities to change their shape to such an extent that it is no longer possible for substances to be taken up. If the templates are bound covalently, the polar binding groups are located only in the cavity, which swells preferentially and therefore can absorb substances well. In the case of noncovalent binding, three quarters of the binding groups are situated outside the cavity.

The accessibility of the cavities depends not only on the type of cross-linking, but also essentially on the porosity and the inner surface area. The porosity in the dry state has been determined by Hg-porosimetry,[57] BET measurements (determination of the adsorption isotherms of N_2 at low temperatures), and electron microscopy.[33, 54] The porosity in the swollen state is even more important during separations. This was determined by inverse gel permeation chromatography,[33] which shows that in optimized polymers the average pore diameter is 10–30 nm, and the fraction of small pores that hinder diffusion is relatively small. The inner surface area of the polymers is about 300–600 $m^2 g^{-1}$ (determined by BET).

Interpenetrating networks should be especially favorable for imprinting. Here, the stabilizing effect of a very stiff cross-linked polymer combined with a more flexible polymer is utilized. For example, a very rigid, wide-pore polymer of styrene and divinylbenzene is first prepared. This polymer, swollen in an inert solvent containing dissolved template monomer and ethylene dimethacrylate, is then polymerized a second time. The resulting polymers are very stable and show good selectivity, although the percentage of templates that can be removed is somewhat lower.[13a, 39] In another useful technique, monodisperse microparticles are produced by a two-stage swelling/polymerization process[110] in the presence of templates.[111]

If the template is attached to the polymer matrix by bonds that are difficult to break (ester, amide, acetal), these must be cleaved by hydrolysis under vigorous conditions. As this can also cleave ethylene dimethacrylate units, the less effective divinylbenzene must be used as the cross-linking agent.[8, 63, 66, 82a] Shea et al. found that in such a case diisopropenylbenzene was a significantly better cross-linking agent.[88–90]

Extensive polymer optimization and characterization work on macroporous imprinted polymers has been carried out recently in the research group of K. J. Shea.[54, 89, 90] The properties of diffusion and reactivity in the cavities were investigated by fluorescence measurements on dansyl derivatives.[89] Also, ^{13}C CP/MAS NMR and FTIR spectroscopic investigations gave important results.[90] During the polymerization, not all the double bonds of the template monomers react; consequently, some templates are bound through only one binding group instead of two.[32, 54] On removal of the template, the unpolymerized binding group is then also split off.[32] In the cross-linking agent 6–9% of the double bonds also remain unchanged.[54] This proportion can be reduced by subsequent heating, and the polymer structure is thereby considerably improved[54] (see also Refs. [32, 55, 59]). This effect is especially marked if a photopolymerization is initially carried out at low temperature.[54]

3.2. Imprinted Cavities on and in Inorganic Carriers

3.2.1. Organic Polymer Layers on Inorganic Carriers

Thin layers (5–10 nm) of macroporous polymers that have a structure very similar to that described in the previous Section can be produced on the surface of wide-pore silica gels. For this, methacrylate groups are bound covalently to the surface of the silica gel, for example by reaction with 3-(trimethoxysilyl)propyl methacrylate. The surface is then coated with a monomer mix-

ture typical for the imprinting process and polymerized by radical initiation. In this way, highly selective adsorbents consisting of nonswellable particles with the desired particle size are obtained. These products are especially suitable for the chromatographic resolution of racemates.[35, 36, 112, 113]

3.2.2. Imprinted Silica Gels

As already mentioned in the introduction, F. H. Dickey prepared imprinted adsorbents for the first time. Developing the key/lock principle of Emil Fischer,[28] Linus Pauling recognized the great importance of shape selectivity for the action of enzymes and antibodies.[114] He recommended to his doctoral candidate Dickey that he prepare substrate-selective adsorbents.[29, 30] Dickey precipitated silica gel in the presence of dyes (methyl orange and homologues). After drying, the dyes were washed out, and the silica gels obtained showed an increased affinity for the template dye. During the formation of the rigid silica gel matrix around the template molecule, silanol groups are apparently so arranged that interactions with the template can occur.

After these initial investigations, silica gels of this type were also imprinted with optically active templates and used for racemate resolution.[115] The separation of pesticides and other substances was investigated with these silica gels as well.[116] However, as the separations were not particularly good and the selectivity disappeared readily,[117] the direction was not pursued further.

An interesting application in another direction has been reported recently.[118] The compound $CH_3-Si(OCH_3)_3$ was hydrolyzed in the presence of various amphiphiles that form double layers in the form of vesicles, lamellae, tubes, helixes, etc. After removal of the amphiphiles acting as templates, special microstructures were obtained in the silica gel.

3.2.3. Imprinted Inorganic Layers on Solid Materials

In a further development of the Dickey process, layers of cross-linked polysiloxanes were produced in the presence of template molecules on previously prepared silica gel particles in order to utilize their particle structure. Polycondensation was carried out in the presence of functional silanes containing binding groups in order to obtain additional and well-defined interactions between the template molecule and the monomer mixture to give increased affinity and selectivity in the final adsorbent.[23, 119–121] This process employs similar interactions to those used to produce imprinted polymers, except that instead of polymerizable double bonds there are polycondensable silane groups attached to the binding groups. Noncovalent interactions were used during imprinting with dyes,[119] and covalent boronate interactions with glycoproteins,[113a, 119] NAD-dimers,[121] and sugars.[23, 120] Overall, however, this methodology seems to have no advantage over imprinting in polymers.

With a view to subsequent applications as catalysts, Morihara et al.[122, 123] used a somewhat different method of modifying the surface of silica gel (described by him as the "footprint" method, see Section 6.5.).

3.2.4. Surface Modification of Solid Materials

In the typical imprinting of polymers or silica gels, the selectivity of the products so obtained depends on the shape of the cavity and the arrangement of the functional groups within it. We asked ourselves whether the distance between two binding groups on a surface could also lead to substrate selectivity.[86] To test this, bisazomethines were condensed on the surface of wide-pore silica gels. The most promising substances for the condensation were of the type $RSi(CH_3)(OCH_3)_2$.[124] The free silanol groups on the surface were then blocked by hexamethyldisilazane to prevent nonspecific adsorption. After removing the template, two amino groups were left behind at a definite distance apart (Fig. 7). To obtain good selectivity, the number of

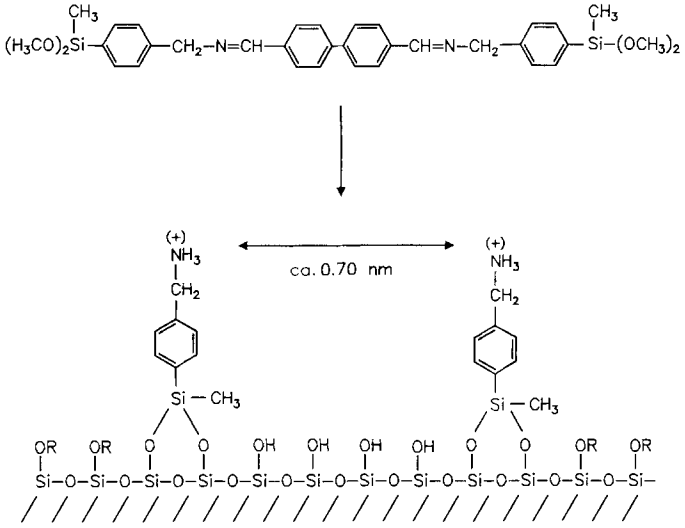

Fig. 7. Preparation of a silica gel with two amino groups on the surface a definite distance apart. The distance between the groups (about 0.70 nm) is fixed by using a biphenyl-4,4'-dialdehyde as the template [86, 124].

condensed templates must not be too high, as otherwise, after removal of the templates and subsequent equilibration with dialdehydes, bonding through adjacent amino groups that did not originally form a pair takes place. If dialdehydes in which the aldehyde groups are at various distances apart are exposed to silica gels so modified, the dialdehyde that was used to carry out the imprinting is bound preferentially.[86] Dicarboxylic acids with different distances between the carboxyl groups can also be very effectively separated on these silica gels by HPLC (Table 2),[124] because the terephthalic acid with the correct distance between the carboxyl groups (0.70 nm) is retarded the most, and those acids in which the distance is greater or smaller are less strongly retarded. Remarkably high α values can be obtained in this way. If an aldehyde is used as the binding group and a diamine as the template, diamines should also be separable after removal of the diamine and oxidation of the aldehyde to carboxyl groups.[125] In a similar way, trios of amino groups in a definite arrangement can be placed on the surface of SiO_2.[126] If the remaining silanol groups are blocked with space-filling silanes (for example, phenyldimethylmethoxysilane) after condensation of the template, contours of the size of the templates are obtained after removal of the template on the surface where the

functional groups are located (Fig. 8).[86] Long-chain aliphatic silanes can also be used for blocking for this purpose.[127]

An interesting method of modifying surfaces by self-assembling systems was used by J. Sagiv.[128] Mixed monolayers of trichloro-*n*-octadecylsilane and a dye modified with a detergent as the template were adsorbed on glass and chemically bound as siloxanes. The modified dye molecule that was not covalently bound could then be dissolved out. This left holes within the stable network of chemisorbed and polycondensed silane molecules. Such layers showed preferential adsorption of the template used (Fig. 9). However, the kinetics of the sorption–desorption process are unfavorable, as the mass transfer must take place through a channel formed by the dense arrangement

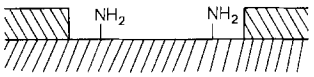

Fig. 8. Schematic representation of the surface of a silica gel with two amino groups at a definite distance apart and the contour of the original template [86].

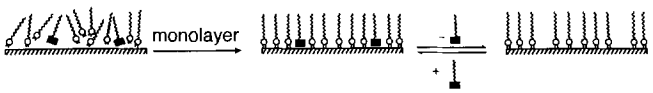

Fig. 9. Schematic representation of the production of mixed monolayers with template molecules on glass. Components that are only physisorbed can be removed [128].

of long alkyl chains in the monolayer. Molecules similar to the template can also be adsorbed in the cavities. Here, it is important that amphiphilic groups should be present in the molecule.[129] This readsorption was investigated mainly electrochemically,[130] by surface-enhanced resonance Raman spectroscopy,[129] and by ellipsometry.[131] Solid carriers included glass, tin dioxide, and gold. Tin dioxide and gold, in particular, could be used as substrates in sensors.[132]

For use in sensors, templates with different properties from those of the rest of the monolayer (for example, insulator–semiconductors) were cocondensed onto the solid carrier. If the alkyl chains are very much longer than the templates, they again form specific channels through which only certain substances penetrate to emit a signal (Fig. 10).[133, 134] Surface imprints on monolayers and vesicles are described in Section 4.4, and on microparticles in Section 4.5.

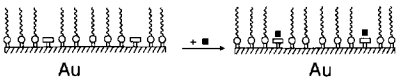

Fig. 10. Schematic representation of the production of mixed monolayers with a chemically bound template molecule. Certain substances (■) can penetrate to the template and cause a signal to be emitted [133, 134].

3.3. Imprinting in Biopolymers (Bioimprinting)

3.3.1. In Proteins

M. H. Keyes et al.[135] have thoroughly investigated the problem of converting proteins by an imprinting process into semisynthetic enzymes. These can sometimes have similar efficiency to that of natural enzymes, but have other defined properties. First the protein is partially denatured, and then brought into contact with a modifying agent, which may, for example, be an inhibitor for the enzyme to be modeled. The protein is subsequently cross-linked, and the substance acting as a template removed. In this way products with new types of enzymatic activity were obtained, although the starting proteins had either no activity (for example, albumin, concanavalin A) or a completely different type of activity (ribonuclease, trypsin, glucose oxidase, α-amylase). The partially denatured protein is assumed to bind the template, which leads to the formation of a new active center similar to that of the enzyme to be modeled.

Another method of bioimprinting was independently investigated by the research groups of A. M. Klibanov[136] and K. Mosbach.[137a] Klibanov freeze-dried proteins dissolved in water in the presence of a large excess of added multifunctional substances, and then removed the template with organic solvents. These artificial receptors had considerable selectivity for binding the template molecules. The reason for the selectivity is the increased rigidity of the protein conformation in organic solvents. In water the selectivity is completely lost, as, in contrast to the experiments of Keyes, no covalent cross-linking was carried out. Even more interesting are the results of Mosbach et al. They precipitated, for example, α-chymotrypsin in the presence of *N*-acetyl-D-phenylalanine with 1-propanol, and then dried it. In nonaqueous solution, after removal of the templates, this modified α-chymotrypsin had good selectivity for the formation of D-phenylalanine ethyl ester, whereas an enzyme analogously treated in the absence of a template showed virtually no selectivity for this reaction. A similar bioimprinting was used for the investigation of the photochemistry of labeled chymotrypsin.[137b]

3.3.2. In Carbohydrates

S. Shinkai et al.[138] cross-linked water-soluble starch with cyanuric chloride in the presence of methylene blue. The insoluble products, after removal of the methylene blue, adsorbed methylene blue considerably better than a starch cross-linked in the absence of methylene blue. The reason was that a much greater number of accessible binding sites were present in the imprinted starch.

Recently our research group has carried out detailed investigations into the stabilization of certain helical conformations in amylose. Inclusion compounds of the amylose with selected organic complexing agents were prepared and thoroughly charac-

terized.[139, 140] Depending on the bulk of the complexing agents, six, seven, or eight glucose units are obtained per turn in the amylose helix. If this complex is intramolecularly cross-linked with epichlorohydrin, or intra- and intermolecularly with cyanuric chloride, soluble or insoluble (respectively) cross-linked amylose complexes are obtained. After removal of the complexing agents (the templates), these amyloses show very different selectivity for the adsorption of substances, depending on the complexing agent used as template.[140]

The cross-linking of chitosans in the presence of metal ions is described in Section 4.5.

4. The Function of the Binding Groups

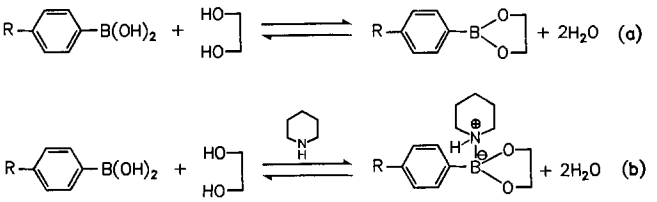
4.1. General

In the imprinting procedure, the binding groups have several functions.[13a, 22, 25, 27, 36, 54] On the one hand, the bond between the template and the binding group should be as strong as possible during the polymerization to enable the binding groups to be fixed by the template in a definite orientation on the polymer chains during cross-linking. Then the templates should be able to be removed as completely as possible. The next very important function is the interaction of the binding groups with the substrates to be bound, for example, with the compound that acted as the template. This process should be as fast and reversible as possible to enable application in chromatographic separations or catalysis. Thus, although a high activation energy is desirable for the first function, it should be as low as possible for the two other functions.

Interactions can be covalent or noncovalent. Covalent interactions have the advantage that the binding groups are precisely fixed in space during the polymerization. Covalent interactions are very suitable if a high percentage of the templates can be removed and the interactions with substrates can be strongly accelerated by catalysis. The same is true for templates fixed by bonding through metal complexes. With noncovalent interactions, a considerable excess (usually at least fourfold) of binding groups is required in the polymerization mixture so that the binding sites in the template are completely saturated at equilibrium. In this way, a considerable proportion of the binding groups are incorporated randomly. On the other hand, the template is usually very easily removed, and reversible interactions with substrates are, in principle, rapid. The structure of the template molecule determines which interactions are the most favorable in the specific case. When producing chromatographic materials for analytical purposes, noncovalent interactions are usually preferred, as the materials are more readily obtainable and an excess of binding groups apparently does not have a detrimental effect on the separations. For the construction of catalysts, the orientation of the binding groups and catalytically active groups in the cavity are of greater significance, so that covalent interactions should be more advantageous here.

4.2. Covalent Interactions

The boronic acid group is very suitable for covalent binding. Poly(vinylphenylboronic acid)s are commercially available and are used in chemoselective affinity chromatography in alkaline aqueous solution for diol-containing compounds.[141] They can also be used in a similar way for imprinting. The advantage is that relatively stable trigonal boronic acid esters are formed [Eq. (a)]. However, in aqueous alkaline solution or in the presence of certain nitrogen bases (for example, NH_3, piperidine), tetragonal boronic acid esters are formed [Eq. (b)], which equilibrate extremely rapidly with tetragonal boronic acid and diol.[22, 142] In these cases, the rate of equilibration is comparable to that for noncovalent interaction.

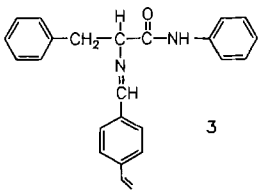


These exchange equilibria with diols are extremely rapid when the intramolecular interaction is with nitrogen bases.[22, 36, 143] A further advantage of the boronic acid group is that the B–C bond can be cleaved afterwards, and the boron acts as leaving group. In this way, other functional groups can also be introduced into the polymer.[55, 144] A large number of diols have been used as templates and polymerized as esters with 4-vinylphenylboronic acid (see, for example, **1a** and Fig. 2). Polymers have also been prepared with only one binding group present, such as those formed from glyceric acid esters[14, 58, 59, 61, 145] and propanediol.[57] These had significant ability to resolve racemates. The mandelic acid polymers prepared by A. Sarhan had remarkably good resolving power.[62, 63, 146, 147] Templates that were bound to the polymer by two boronic acid groups gave polymers with very much higher selectivity for resolution of racemates.[31–33, 35–40, 55, 56a] The optimization of the polymer structure for imprinted polymers was mainly carried out on the example of phenyl-α-D-mannopyranoside. Recently, the resolution of the racemates of free sugars (fructose, mannose, and galactose) was also possible on polymers prepared for the purpose. Thus, for the first time, sugar racemates could be resolved without first having to prepare derivatives.[41, 55, 56a]

One would think that three covalent interactions should be especially favorable for imprinting and for the subsequent molecular recognition. However, it has been shown that three boronic acid interactions,[8, 12, 57] three different covalent interactions,[35] or three or more noncovalent interactions[44, 49, 51, 148] all lead to poorer resolving powers (small number of theoretical plates N_{th}) of the polymers. Here the main factor must be the low rate of formation of polymer–substrate complexes of this type.

In the example of the boronic acids, the effect of the flexibility of the binding group on the resolving power of the polymers was also investigated.[40, 41, 145] For example, nine different polymerizable boronic acids with different degrees of mobility between the boron and the polymerizable double bond were used, with phenyl-α-D-mannopyranoside as the template.[40] As the mobility of the groups in the cavity increased, the selectivity in racemate resolution decreased.

The suitability of Schiff bases for covalent binding was also extensively investigated.[25, 64, 65, 86, 150] Schiff bases are, in principle, suitable for imprinting and subsequent binding, since the position of the equilibrium is favorable. The rate of equilibration is, however, too low for rapid chromatography.[64] By using suitable intramolecular neighboring groups, the rate of equilibration can be considerably increased.[25] With amino acids, racemic resolution in the form of anilides is especially suitable,[64] an experience which was later also confirmed with noncovalent interactions.[43] In this case, the template monomer was *N*-(4-vinylbenzylidene)-L-phenylalanine anilide (**3**) or the 5-vinylsalicylidene derivative.[64]



3

Binding with Schiff bases was successfully used either with double fixation as Schiff bases[86, 149] or in combination with other interactions.[35, 65, 150] For binding monoalcohols, both intramolecular monoesters of boronic acids (1-hydroxy-1-bora-2-oxaindene derivatives)[22, 25] and certain cyclic hemiacetals are suitable,[151] and in both cases relatively rapid equilibration takes place.

Ester groups[66, 82a, 91] and amide groups[8] are not very suitable for introducing binding groups into imprinted polymers, as only a small proportion (20%) of these can be removed. In the case of amide, the covalent bond present during polymerization can be used later in the binding of substrates as an electrostatic interaction between carboxylic acids and amino groups.[8, 11, 12, 14, 58, 59, 64]

An interesting way to combine the advantages of covalent bonding during imprinting with noncovalent interaction during equilibration was used by M. J. Whitcombe et al.[82b] They employed 4-vinylphenyl carbonate esters during imprinting. The ester is afterwards efficiently cleaved hydrolytically with loss of CO_2. The resulting binding site phenol is capable of interacting with an alcohol through hydrogen bonding.

K. J. Shea et al.[87–90] used ketals for introducing binding groups. Diketones with various distances between the keto groups were treated with polymerizable diols and after removal of the template showed considerable selectivity for the template originally used when they were reloaded with a mixture of diketones. Unlike the reloading experiments mentioned earlier, this bond formation takes place slowly, and therefore seems to be kinetically controlled, unlike the bonding reactions described so far, which are thermodynamically controlled.

An overview of covalent interactions used to date (including the interaction through metal complexes discussed in Section 4.4.) is given in Table 3.

Table 3. Covalent interactions during the imprinting process.

Polymerizable binding group	Binding site to the template	Type of bond	Reference
4-vinylphenylboronic acid	diol	boronic acid ester	[22, 142]
amines	aldehyde	Schiff base	[86, 149]
aldehydes	amine	Schiff base	[25, 35, 64, 65, 150]
diols	ketone	ketal	[87–90]
hemiacetals	alcohols	full acetal	[151]
boronaphthalide	alcohol	boronic acid ester	[22, 25]
acrylic acid	amine	amide	[8, 11, 12, 14, 58]
acrylic acid	alcohol	ester	[66, 82a, 91]
4-vinylphenyl carbonate	alcohol	ester	[82b]
cobalt chelate	amino acid	chelate complex	[68, 69]
copper chelate	imidazole	chelate complex	[26, 77, 99, 100]
alcohols	carboxylic acid	ester	[71, 91]
vinylimidazole + Co^{2+}	amino acids	chelate complex	[152]

4.3. Noncovalent Interactions

The simplest method of producing selective polymers by imprinting uses noncovalent interactions. Here, monomers that can undergo noncovalent interactions are brought together with the template molecule and the cross-linking agent to form more or less well-defined aggregates of template and monomer. These monomers ligated to the template are in rapid equilibrium with monomers in solution. To ensure that, on average, as many interactions as possible occur during the polymerization, the ratio of ligand monomer to template in the solution must be at least 4:1.[43] As in imprinting silica gels, the first templates used when imprinting polymers with noncovalent interactions were dyes, and these were cross-linked in the presence of monomers that undergo less definite interactions.[93, 94] Selectivity properties were similar to those of silica gels, namely, rather poor. Only after careful optimization by K. Mosbach et al.[43] of imprinting using noncovalent interactions could extremely good separations be performed, and in many cases these were just as good as those obtained with covalent interactions. Noncovalent interactions are considerably easier to use, and many new interacting pairs for the imprinting were found (Table 4).

The most important type of noncovalent interaction is the electrostatic one. For example, when imprinting with L-phenylalanine anilide (**2**) in the presence of methacrylic acid, the influence of this interaction on the selectivity was thoroughly inves-

Table 4. Noncovalent interactions used in the imprinting process.

tigated.[21, 43, 48, 53] The strength of the interaction depends on the pK_a values of the methacrylic acid and the amine group in the anilide **2**, on the pH of the solution, and in some circumstances on competing ions present. The interaction during imprinting takes place in a comparatively nonpolar solution (45% ethylene dimethacrylate, 50% acetonitrile, 5% **2** and methacrylic acid), whereas subsequent equilibration (chromatography) of the polymer (from which the templates have been removed) with the racemate of the template is carried out in an aqueous solution with variable pH and foreign ion concentration or a solution containing acetic acid.

However, an electrostatic interaction alone leads to relatively low selectivity,[157] so that another interaction must be present. Remarkably, a polymerizable acid and base can simultaneously interact with a template by electrostatic bonding. For this to occur, the template carboxyl group must be more acidic than methacrylic acid to enable it to react preferentially with the added base.[67]

A useful second interaction is hydrogen-bond formation, for example, as it occurs between the methacrylic acid OH group and an amide oxygen atom. Under these conditions, very selective cavities with α values for racemate resolution of 3–8 are obtained. However, if hydrogen bonds are the only interaction during imprinting and in subsequent interaction, the α values for the racemate resolution are only 1.1–2.5.[107] Examples of the influence of the binding sites are provided by templates **2**,[54] **4**,[157] **5**,[47] and **6**,[44] which were polymerized under comparable conditions in the presence of methacrylic acid or acrylic acid (Fig. 11). The capacity for resolving the racemate of the template becomes considerably less if only one interaction is possible (**4** and **5**).

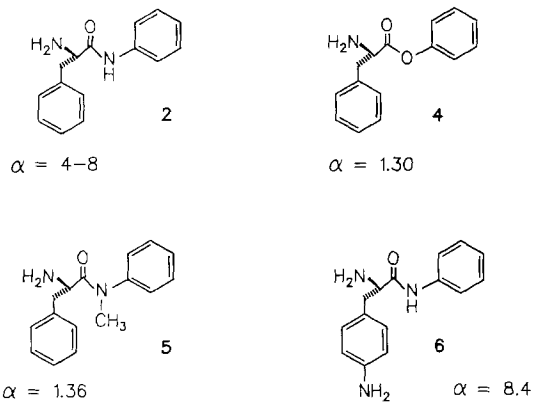

Fig. 11. Separation factors α for the resolution of the racemates of **2**, **4**, **5**, and **6**. The separation factors α were determined for polymers produced under comparable conditions with the appropriate templates.

With noncovalent interactions, it is beneficial to carry out the polymerizations at a low temperature, as these conditions favor the association equilibrium.[46, 49, 50, 54]

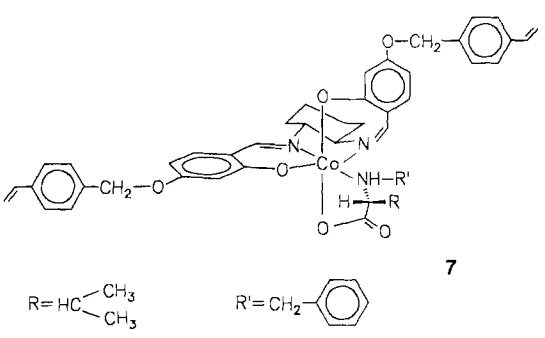
Interesting separations with noncovalent interactions have also been carried out on nucleotides and nucleosides. S. A. Piletski et al. used 2′-deoxyadenosine[156] and adenosine triphosphate (ATP)[79] for imprinting based on hydrogen bond formation and electrostatic interactions. The selectivity for the molecule of the template was considerably increased: ADP and ATP, for instance, could be separated considerably better than by chromatography on nonimprinted polymers. High selectivities of imprinted polymers with binding constants of $K_a = 76000\,M^{-1}$ were recently obtained by K. J. Shea et al.[78] They used 9-ethyladenine as the template and methacrylic acid as the binding group. The selectivity of the binding is considerably higher or similar to that of low molecular weight receptors that were prepared in multistep syntheses.[158]

New binding groups for noncovalent binding must also be developed. Ideally, they must undergo a stoichiometric reaction with the template (for example, in the ratio 1:1 or 2:1) during polymerization. This way, no excess of binding groups will be distributed unspecifically within the polymer after polymerization and after removing the template. This is especially important for the formation of catalysts. The percentage of reoccupation for noncovalent binding might then also be significantly improved, which will at the same time increase the capacity for preparative separations. In subsequent equilibrations, adaptation of the medium (nature of solvent, pH, addition of adventitious compounds) will allow the position of the equilibrium to be varied in the desired way.

Noncovalent interactions have also been used in combination with covalent interactions. Thus, electrostatic,[14, 59, 86] charge-transfer,[14, 61] and hydrophobic interactions[60, 61] could be combined with covalent interactions. The resulting polymers sometimes had considerably higher selectivities than those of polymers with a simple covalent bond to the template.

4.4. Binding by Interaction through Metal Complexes

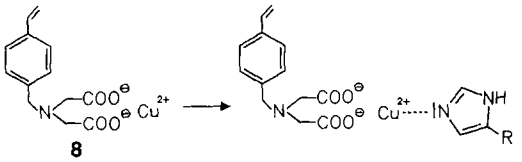
A very promising type of binding during polymerization and later in the final polymer can be achieved by coordinative bonds to metals. This type of bond is analogous to that used in ligand exchange chromatography.[159] The advantage of this kind of bond is that its strength can be controlled by experimental conditions. Definite interactions occur during the polymerization, and an excess of binding groups is not necessary. The subsequent binding of the substrate to the polymer is so rapid that in many cases even rapid chromatography is possible. This method was first used for imprinting by Y. Fujii et al.[68, 69] They obtained a remarkably high selectivity in the optical resolution of *N*-benzyl-D,L-valine using a chiral Schiff base ligand of (*1R*,*2R*)-1,2-diaminocyclohexane and 4-(4-vinylbenzyloxy)salicylaldehyde to which amino acids could be bound through a Co^{2+} cation (see **7**). The exceptionally high separation factor for the race-



mate resolution of the template molecule was found to be $\alpha = 682$. The enantiomeric excess *ee* was 95.5% in the batch process.

More detailed investigations showed that most of the separating ability was due to the cavity effect.[69] The observed selectivity is greater than that of many enzymes. Unfortunately, the mass transfer rate in the case of the Co^{2+} complex is very slow in the chromatographic separation, so that practical separations are very difficult.[160]

Recently, F. H. Arnold, P. K. Dhal et al. investigated the bonding of imidazole-containing compounds with Cu^{2+} complexes like **8** in great detail [Eq. (c)].[26, 77, 99, 100] Model experi-



8 (c)

ments were first carried out in which bisimidazoles with various distances between the imidazole groups were used as templates to position polymerizable iminodiacetate groups in the polymer.[99, 100] These experiments were aimed at developing an effective recognition for proteins that depends on the correct spatial arrangement of a few binding sites on a polymer. Polymerizable monolayers or vesicles were used. Surface imprinting with a protein then oriented the Cu^{2+} binding sites in a definite arrangement (corresponding to the imidazole units in the protein), and these were in turn fixed by polymerization (Fig. 12).[26, 77] No more detailed results are yet available on the potential of surface imprinting by proteins.

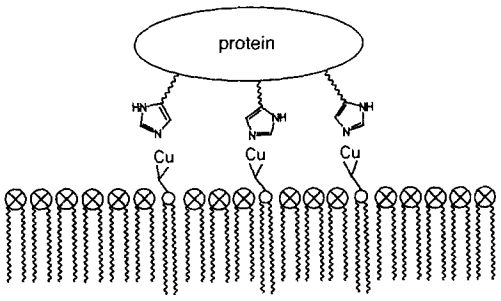


Fig. 12. Schematic representation of a monolayer with copper iminodiacetate groups that are brought into a definite arrangement by interaction with imidazole groups of a protein. The arrangement in the monolayer is then fixed by polymerization (see text) [26, 77].

4.5. Ion-Selective Imprinted Polymers

Metal cations can also serve as templates for imprinting cross-linked polymers. Suitable ligand groups are brought into contact with the cations to form a complex. This is then converted into a cross-linked polymer. After removal of the template (the cation), the adsorption of the cation used as template by such polymers is strongly enhanced and in many cases is also considerably more selective. The selectivity depends on various factors:

1. the specificity of the interaction of the ligand with the cation
2. the coordination geometry and coordination number of the cations
3. the charge on the cation and
4. to some extent, the size of the cation.

Table 5. Examples of ion-selective imprinted polymers.

Imprinting method [a]	Functional polymer/monomer	Imprinting cations	Cross-linking agent	Ref.

[a] For the description of the methods see text. [b] EDMA = ethylene dimethacrylate

The polymers can be prepared in various ways (see Table 5):

a) From linear polymers. Linear polymers with groups that can bind to a metal (for example, poly(4-vinylpyridine)) are treated with certain metal cations in solution and allowed to equilibrate for some time. Metal–polymer complexes are formed in which the conformation of the polymer chains is optimized, and many coordinations are possible. These complexes are then cross-linked to stabilize the optimum polymer conformation, and the metal is leached out. This method was used, independently of each other, by V. A. Kabanov, A. A. Efendiev et al.[164, 165] and H. Nishide, E. Tsuchida et al.[161, 176] The Russian research group found considerably increased adsorption, while the Japanese group also established for the first time an increased selectivity for the imprinting cation. The method was subsequently developed very extensively (see Table 5).

b) Polymerization of a mixture of monomers containing complexing groups. In the presence of certain metal cations, intermediate complexes are formed and polymerized with cross-linking. The method is very simple, but the selectivities are relatively poor.

c) Preparation of definite polymerizable complexes of metal cations as pure substances. Using this somewhat more laborious method, the type of complex can be precisely determined, and the polymerization proceeds under strictly controlled conditions. It is also important that the complex should not dissociate during the polymerization. This can be influenced by, for example, the choice of polymerization medium.

W. Kuchen et al.[108, 177] were the first to show that very selective ion exchangers could be prepared with the aid of certain metallic complexes of methacrylic acid and 4-vinylpyridine (Table 6). Unusually high selectivities with the imprinting technique were observed when mixtures of cations were equilibrated. Relative to a reference polymer with the same binding groups but without imprinting, Cu^{2+} was taken up 10–60 times as selectively. With a smaller degree of cross-linking, the selectivity decreases but the capacity remains high.[173]

Table 6. Selectivity of a Cu^{2+}-imprinted resin for the separation of cationic pairs on loading with mixtures of two cations [108], together with that of a blank resin (not imprinted) for comparison.

Metal ions	α [a]	α_{blank} [b]	α' [c]
Cu^{2+}/Zn^{2+}	58	4.2	14
Cu^{2+}/Cd^{2+}	136	3.3	41
Cu^{2+}/Pb^{2+}	28	0.46	62

[a] $\alpha = K_1/K_2$ = selectivity coefficient. [b] α_{blank} = selectivity coefficient for blank resin. [c] $\alpha' = \alpha/\alpha_{blank}$

d) M. Takagi et al.'s method.[175, 178] Selective chelate resins can also be prepared by a new method of surface imprinting. Emulsion polymerization with methacrylic acid as one of the comonomers is used to produce microparticles ($d = 0.4$–$0.7\ \mu m$). The particles are afterwards swollen by a cross-linking agent, and the carboxyl groups become concentrated at the surface by the action of NaOH. They are then oriented specifically by complexation with Cu^{2+}, Co^{2+}, or Ni^{2+} ions, and this arrangement is fixed by a further cross-linking step (Fig. 13). Considerable selectivity for the imprinted cation is observed. Thus, at low Cu^{2+} concentrations, the polymer imprinted with Cu^{2+} takes up 10^3 times as much Cu^{2+} as the nonimprinted polymer.

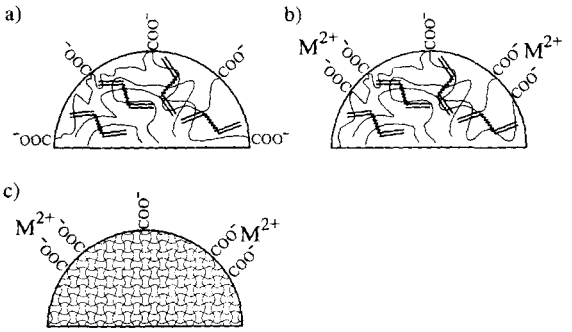

Fig. 13. Surface imprinting in the preparation of ion-selective polymers [178]. Micro-particles containing carboxyl groups are treated with NaOH and swollen with divinylbenzene (a). The carboxyl groups are positioned in a definite manner with the aid of cations (b), and are then cross-linked, for example, by using radiation from ^{60}Co (c).

5. The Imprinting Mechanism

The substance used as the template is, in general, embedded preferentially in the imprinted cavities. By using a pure enantiomer as the template, very effective racemate resolutions could be achieved with these imprinted polymers. In these cases the cavity must thus have an asymmetric structure. The question arises as to the origin of the asymmetry. It was established quite early that the asymmetry is not caused by optically active templates remaining in the polymer.[13a, 32, 43, 58] The possibility that the linear parts of the polyvinyl chains were responsible for the asymmetry was considered after monomer residues bound to a chiral template molecule were found to give optically active vinyl polymers in an asymmetric cyclocopolymerization.[179] However, monomers with a structure like **1a** do not tend to undergo such asymmetric cyclocopolymerization.[180] One must therefore conclude that it is not the configuration, but a fixed asymmetric conformation of the polymer chains that is responsible for the asymmetry.

Surprisingly, the asymmetry of the cavities can also be determined by direct measurement of their optical rotation as well as by their ability to resolve racemates.[18, 42] To measure the optical rotation, the insoluble polymer is suspended in a solvent that has exactly the same refractive index as that of the polymer. This technique has already been used with other insoluble substances.[181a] Whereas monomer **1a** has a molar optical rotation of $[M]_D^{20} = -448.9°$, after incorporation into a polymer the molar optical rotation is $[M]_D^{20} = -61.7°$. After removal of the template, the polymer has a molar optical rotation of $[M]_D^{20} = +110.0°$. This figure is not due to low molecular weight chiral compounds, but is caused by the asymmetric conformations of the polymer chains that form the chiral cavities. Thus, direct measurements on the highly cross-linked polymer are possible. If templates are again in contact with the polymer from which the templates have been removed, it first shows a

high positive molar rotation of $[M]_D^{20} \approx +200°$, which slowly (or rapidly at higher temperatures) changes to the original molar rotation of the polymer ($[M]_D^{20} = -61.7°$). As shown by parallel calorimetric measurements, the template is first bound through one boronic acid only (one-point binding), and this then changes to the stable two-point binding (Fig. 14).

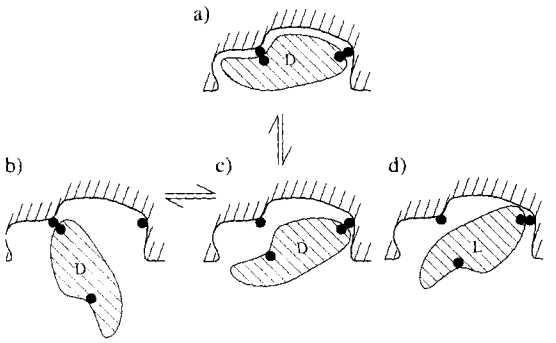

Fig. 14. Schematic representation of two-point binding (a), unproductive one-point binding (b), a productive one-point binding (c), and a one-point binding of the "wrong" enantiomer (d).

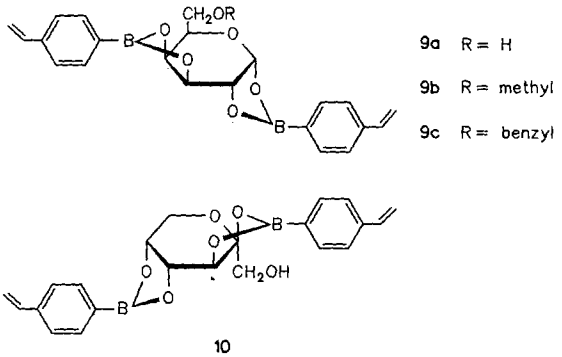
An important question is: to what extent can imprinted polymers also bind substances other than the template. For example, are racemates of other substances resolvable? In the first experiments on glyceric acid esters with a certain ester as template, imprinted polymers were shown to resolve a whole series of racemates even when the alcohol group in the racemate is varied (methyl, ethyl, benzyl, or 4-nitrophenyl).[61] Aromatic amino acids were shown to behave similarly. Here, the aromatic group in the racemates can vary. A racemate resolution is possible provided that the rest of the structure remains the same.[45] However, if the arrangement of functional groups is the same, the size and shape of the rest of the molecule are important factors for the separability, as shown, for example, in various bisketals.[88]

To determine to what extent the arrangement of the binding groups in the cavity, rather than its shape, affects the resolving power, we polymerized a series of similar monomers with various arrangements of the functional groups or with different spatial properties.[18, 23, 55, 56a] For example, imprinted polymers were prepared in the usual way with template monomers **1a**, **9a–c**, and **10**. After removal of the template, the resolving power was determined for various sugar racemates (Table 7). All polymers were able, as expected, to resolve racemates of



9a R = H
9b R = methyl
9c R = benzyl

10

Table 7. Selectivity of various polymers for racemate resolution [55, 56a].

Template monomer	Racemate	α
1a	phenyl-α-D,L-mannoside	5.0
1a	D,L-mannose	1.60
1a	D,L-fructose	1.34
9a	D,L-galactose	1.38
9c	D,L-galactose	1.58
10	D,L-fructose	1.63
10	D,L-galactose	0.85 (1.17) [a]
9a	D,L-fructose	0.80 (1.25) [a]
9b	D,L-fructose	0.71 (1.41) [a]

[a] To give a better comparison of the selectivities, reciprocal values are given in parentheses (K_L/K_D).

their own template; consequently sugars can now be directly resolved chromatographically even without the need for derivatization.[41]

D,L-Mannose can be resolved on a polymer that has been imprinted with phenyl-α-D-mannopyranoside (entry 2, Table 7). This shows that even racemates with significantly smaller spatial requirements than the template can be resolved. The same is true for the resolution of D,L-galactose on a polymer imprinted with 6-*O*-benzyl-D-galactose (entry 5, Table 7). In these cases, the template and racemate have the same arrangement of functional groups. However, with the exception of D,L-fructose, it was not possible to resolve other sugar racemates on a polymer imprinted with **1b**. The cross-equilibration of polymers that had been imprinted with D-galactose (P-**9a**) or D-fructose (P-**10**) is interesting. Whereas on equilibration with its own racemate, the template is bound preferentially, the polymer imprinted with D-fructose preferentially binds L-galactose, and the polymer imprinted with D-galactose preferentially binds L-fructose out of the racemic mixture. This inverse selectivity on cross-equilibration can be explained if one considers models of the preferred conformations of the molecules.[55] As an example, Figure 15 shows the structures of β-L-fructopyranose and α-D-galactopyranose, which are both preferentially bound by polymer P-**9a**. Both compounds have the same arrangement of hydroxyl groups that react with the boronic acids (in black). Only the hydroxymethyl groups (crosshatched) are at different positions in the molecule, which causes significantly different shapes for the molecules.

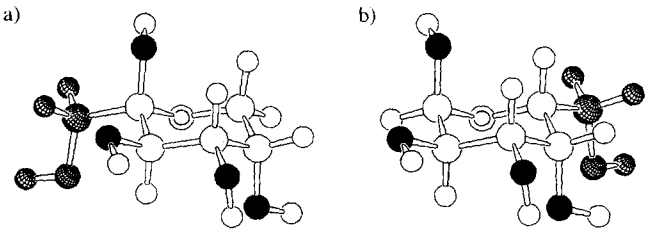


Fig. 15. Ball-and-stick model of the preferred conformations of β-L-fructopyranose (a) and α-D-galactopyranose (b). The OH groups that react with the boronic acid are represented in black. The hydroxymethylene groups which influence the shape are hatched.

Similar considerations apply to β-L-galactopyranose and α-D-fructopyranose and are also valid for phenyl-α-D-mannopyranoside and β-D-fructopyranose.[55] From these results it follows

that the arrangement of the functional groups in the cavity is the decisive factor for the selectivity, while the shape of the cavity is somewhat less important. Classes of substances with the same arrangement of interacting groups therefore have a group selectivity.

In the synthesis of catalytically active polymers, the possibility of introducing functional groups in a definite arrangement is of great importance. However, this is only possible with interactions through covalent or metal-complex bonds, or stoichiometric noncovalent interaction.

A substrate must be embedded in a specific cavity in the correct orientation so that the interactions correspond with the binding groups and the substrate fits with its shape into the cavity. With most template monomers there are two binding groups which, although often chemically identical, produce in the imprinted cavity nonidentical binding sites to the template or substrate (see Fig. 14).[36] Initial one-point binding can be productive (as in Fig. 14c) and lead to the correct two-point binding (a) on further reaction. If a "wrong" one-point bond is formed (unproductively as shown in (b)), a second bond is no longer possible. One of the two productive one-point bonds can only be made after breaking this unproductive bond. Also it can be seen that although the "wrong" (L) enantiomer (or other isomer, diastereomer, etc.) can easily form one bond (for example, (d)), this is unproductive, because a second bond cannot be formed because of the nonfitting geometry of the molecule. The correct two-point bond (as in (a)) has a significantly higher binding constant than the one-point bond. However, as shown by chromatographic investigations, it is formed much more slowly.[23, 35-37]

As already mentioned in connection with optical rotation measurements in the solid state, the formation of the two-point bond can be much accelerated at higher temperatures. Also, in the experiments of K. J. Shea et al., a considerable proportion of one-point bonds were found.[88, 90] No systematic investigations into one- and two-point noncovalent binding have been made, but similar relationships to those observed with covalent binding would be expected.

If the template is removed from the cavity, an interaction of the solvent with the binding groups occurs. The considerable volume increase of the polymer (up to 100%) that results, and especially of the cavities, facilitates embedding of the templates into the expanded cavities. Surprisingly, on binding of the original template, the volume of the cavity decreases again, approximately to the former volume.[14, 59] As the selectivity is fully maintained, the cavity must have kept its shape (memory effect). This phenomenon resembles to some degree the "induced fit" effect known from enzymology.[181b] On equilibration of the polymer with the substrate, and also during chromatography, a rapid equilibrium is established between the free and occupied cavities; consequently a rapid pulsation in the volumes of the cavities must take place. It is not known how the solvent leaves the cavity during embedding of the substrate, or whether it can penetrate the polymer matrix as it does in the case of enzymes. It is to be expected that this type of "induced fit" plays no role in noncovalent bonding.[54]

At increased temperatures the selectivity of the imprinted polymers increases considerably. This is partly because the more selective two-point binding takes place considerably more rapidly at higher temperatures. Also, swelling makes accessible more cavities (binding sites) that have particularly high selectivity and that cannot be occupied at room temperature. This leads to the unusual effect that at higher temperatures even more substance is adsorbed and the retention increases.[37] This fact makes a detailed investigation of the thermodynamics and kinetics of the binding process difficult.

In this connection it must be mentioned that, as with polyclonal antibodies, the individual cavities have varying degrees of selectivity. The selectivity distribution was determined in a multisite model where association constants for each newly occupied binding site were calculated.[31] This showed that a certain proportion of the cavities have relatively low selectivity (changes due to shrinkage or swelling, position on the surface), while the others have a distribution of selectivities around an average figure that can give very high selectivities.[31] When comparing the selectivity of different polymers, the degree of embedding during equilibration or during chromatography is of crucial importance. Figure 17b illustrates this in the case of chromatography.[54]

6. Applications of Imprinted Materials

6.1. Chromatography

Imprinted materials can be used as stationary phases in chromatography, especially for the resolution of racemates. Although the selectivity was good, strong peak broadening in the chromatographic process at first made it impossible to get complete separation, for example, of the racemate of the template **1b**.[22, 32, 33] When significantly more selective adsorbents and improved chromatographic processes coupled with higher temperatures became available, we were able for the first time in 1986 to perform a complete racemate resolution with $R_s = 2.1$.[38] Later, we achieved resolutions of $R_s = 4.3$ by using gradient elution (see Fig. 16a).[41] (The quality of a chromatographic separation is expressed by the resolution R_s, which is mainly governed by the separation factor α of the substance pair and the number of theoretical plates of the column. Satisfactory separations are obtained with $R_s \geq 1$.)

With noncovalent interactions, for example using polymers imprinted with **2**, it was thought that a separation would have been much easier to achieve. However, these systems were found to be very complicated in chromatographic practice. Strong interactions with the medium occurred, and the mass transfer was also very slow. In 1988 K. Mosbach et al. obtained a complete resolution of D,L-**2**, with $R_s = 1.2$,[43] and B. Sellergren and K. J. Shea achieved considerable improvement five years later after very careful optimization work.[53] Protonation of the substrate could be achieved in an aqueous buffer system of pH = 4, in which the carboxyl groups inside the cavities were partially deprotonated, and those outside the cavities were not deprotonated at all. This gave selective binding by an ion exchange mechanism only inside the cavities. Kinetics were good, and could be further improved by use of a heat-treated polymer[54] to give a resolution of $R_s = 2.2$ (see Fig. 16b).

Remarkably, in these separations the more strongly retarded enantiomer (corresponding to the template molecule) gives

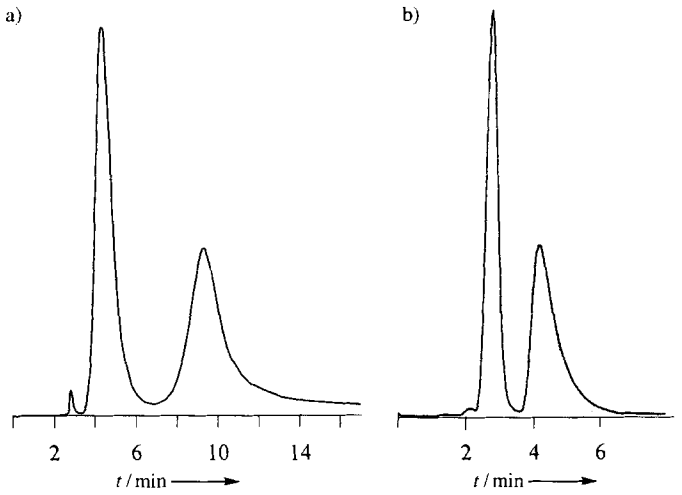

Fig. 16. Chromatographic resolutions of D,L-**1b** on a polymer imprinted with **1a** (a, elution with a solent gradient at 90 °C [41]) and D,L-**2** on a polymer imprinted with L-**2** (b, separation by isocratic elution at 80 °C [53]).

much more pronounced peak broadening if a solvent gradient is not used during chromatography. The number of theoretical plates for this compound is at most half that of the less strongly retarded compound. The reason must be essentially the two-point binding of the template molecule and the one-point binding of the other enantiomer. The difference also shows itself in the temperature dependence of the number of theoretical plates for the two enantiomers. Whereas the template molecule shows hardly any temperature dependence because of the increased two-point bonding with slow binding rates at higher temperatures, the number of theoretical plates for the second enantiomer increases rapidly, as expected (see Fig. 17a).[38] The effect of concentration on retention is also very different for the two enantiomers (see Fig. 17b).[54] The "wrong" enantiomer does not show much effect, whereas the retention in the case of the template molecule is greatly increased at lower concentrations at which only the most selective cavities are occupied by the template molecule. The selectivity therefore increases sharply.[31] Preparative separations are also possible. For example, 30 mg of the racemate of **1b** were effectively resolved by 20 g of polymer.[23]

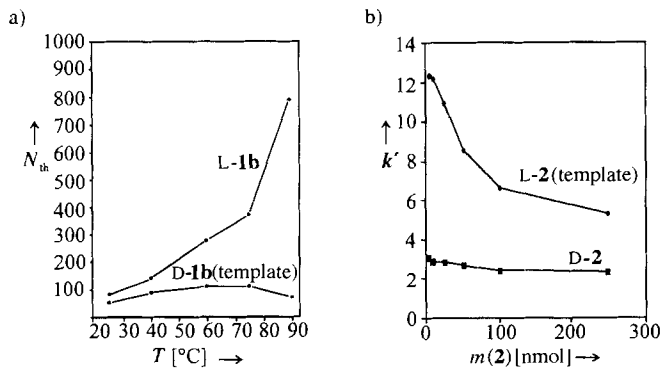

Fig. 17. Differences in the effect of temperature on number of theoretical plates and of the amount chromatographed on the retention for template molecules and their enantiomers. a) Temperature dependence of the number of theoretical plate (N_{th}) in the resolution of D-**1b** and L-**1b** on a polymer imprinted with D-**1b**. b) Dependence of the capacity factors k' on amount treated in the resolution of L-**2** and D-**2** on a polymer imprinted with L-**2**.

Many of the imprinted polymers listed in Table 1 are also used for chromatographic separations. The resolution of drugs is especially interesting, as here it is worthwhile synthesizing a suitable polymer especially for racemic resolution when such a substance is produced. Racemate resolutions of β-blockers,[83] anti-inflammatory agents,[85] and group separations of pentamidines[153a] have been described.

A method originally developed by Svec and Fréchet[182] should also be very suitable for such purposes. Here, a microparticulate polymer is produced directly inside a column. With this process, imprinted polymers can be prepared which have cavities suitable for separations.[153b, 183a] In another approach the direct preparation of imprinted microparticles for chromatography has recently been described.[110] Electrophoretic separations in capillaries filled with imprinted polymers are also of interest.[153c] Extremely high theoretical plate numbers can be obtained in this way, although selectivity in this process still leaves something to be desired. Another possibility is utilizing imprinted polymers as the basis of TLC stationary phases.[183b]

6.2. Imprinted Polymers for Radioimmunoassay

Mosbach et al. used imprinted polymers in place of antibodies for the determination of drugs in a radioimmunoassay.[81, 84] They imprinted polymers with theophylline, diazepam,[81] and morphine,[84] and for theophylline, for example, good linearity was achieved in the range between 14 and 224 μM. The cross-reactions that occur with drugs of similar structure were the same as those of antibodies. In contrast to the determinations with antibodies that are monoclonal, problems arose due to the different binding powers of the individual cavities ("polyclonal"). On further optimization of the process, an effective alternative both to the very laborious isolation of antibodies from animals and to producing them in bacteria was obtained.

6.3. Membranes and Sensors

Imprinted polymer membranes or polymer surfaces could be used as the basis of chemosensors. These are considerably more stable than biosensors and therefore have a longer lifetime. In principle, layers selective for many substances can be prepared by molecular imprinting. In practice, the preparation of effective and selective sensors is still beset with considerable difficulties. One problem is the development of a suitable detection system.

I. Tabushi et al. were the first to prepare sensors purely by surface imprinting.[132] They used Sagiv's method[128] and bound octadecylsilyl monolayers, together with inert template hosts (*n*-hexadecane, 2-cholesteryl-3,6-dioxadecylcarbonate, or decyladamantane-1-carboxylate) covalently to tin dioxide or silicon dioxide layers. After extraction of the hosts, vitamin K_1, K_2, and E, as well as cholesterol and adamantane have been detected by strong electrochemical signals.

Silicon wafers with SiO_2 coatings function similarly.[184a] The templates (nucleotides, nucleosides, and amino acids) were applied to the coatings, and the free silanol groups were then

treated with trimethylchlorosilane or octadecyltrichlorosilane. The same method was used on the surface of glass electrodes.

As already mentioned, the template molecules can also remain in the inert monolayer, thus forming molecular defect sites of definite size and binding power. Only certain molecules can then cause an electrochemical signal, which can lead to considerably increased ion selectivity.[133]

S. A. Piletsky et al.[71-73, 104b, 184b] have also investigated the development of sensors based on imprinted polymers. They prepared imprinted polymers in the form of free-standing[71] membranes or membranes supported on glass frits.[72, 73, 104b] The polymers were prepared from monomeric (2-diethylaminoethyl)methacrylate and ethylene dimethacrylate, and were imprinted with adenosine monophosphate, amino acids, cholesterol, or artrazine by noncovalent interactions. Electrodialysis showed that these membranes were selectively permeable. Also, considerable selectivity for racemates was obtained.[72, 73] The mechanism of these remarkable separations does not yet seem to be fully explained.

In a recent paper on sensors for sialic acid, fluorescence was used for the first time for detection.[184b] In another experiment a membrane was imprinted with tryptophan, and this compound could be selectively transported through it, but the capacity for selective transport was destroyed by photoisomerization of the polymer.[75] Sensors were also prepared by polymerization of an imprinted polymer layer on a silicon wafer with a thin coating of SiO_2.[185a] This very refined design gives a product with selectivity for various amino acids. Differences in embedding of the substances on the polymer coating are measured by the capacitive resistance.

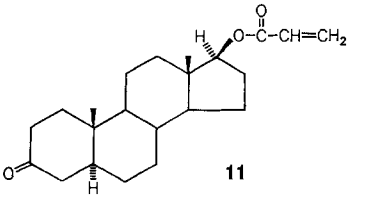
An interesting new route for the construction of sensors was found by D. C. Sherrington et al.[185b] They succeeded in synthesizing imprinted macroporous polymers as completely transparent monoliths. The template molecules bound to the polymer (for example, Michler's ketone) are irradiated with polarized light, and the molecules lying in the direction of excitation react with the polymer matrix. After removal of the unchanged template molecules the anisotropic polymer contains empty cavities that not only preferentially bind the templates, but orient them in a particular direction. The polymers therefore show a pronounced dichroism in UV light, which enables nonselective binding to be distinguished.

6.4. Selective Reactions in Imprinted Cavities

An important reason for producing cavities with a definite shape and a predetermined arrangement of functional groups is the desire to produce highly selective catalysts and enzyme models. Stereoselective and regioselective reactions in these cavities, which are then termed microreactors, constitute a step in this direction. The cavity is first imprinted with the end product of the reaction, and a precursor is then embedded into the cavity so that a reaction can convert it into the product. The first experiments were carried out by the research groups of K. J. Shea[71] and D. C. Neckers[91], who performed cycloadditions to obtain cyclopropanedicarboxylic and cyclobutanedicarboxylic acids. The latter compounds were obtained with remarkable regio- and diastereoselectivity.[91] Y. N. Belokon et al.[70, 96, 186] established that on removal of a proton from a template still located in a cavity, the carbanion formed maintains its original configuration (unlike its behavior in solution), and therefore reacts under retention.

The first asymmetric syntheses in the chiral cavity were achieved in our research group.[13, 65, 150] A cavity was made with an L-DOPA methyl ester. After removal of the template, glycine was embedded in the cavity, deprotonated, and alkylated. So far, the highest enantiomeric excesses (36% *ee*) on using imprinted polymers have been with the amino acids formed in this way. This excess is purely a result of the shape of the asymmetric cavity.

In some very remarkable experiments, S. E. Byström et al.[82a] were recently able to demonstrate high regio- and stereoselectivity in reactions inside the imprinted cavity. The steroid **11** was copolymerized as the template monomer, and removed by reduction. The hydroxyl group in the polymer newly formed from the carboxyl group was converted into an active hydride by $LiAlH_4$. On this polymer, androstan-3,17-dione was reduced exclusively in position 17 to the alcohol, whereas in solution or with a polymer with statistically distributed hydride groups it is reduced exclusively in position 3. Figure 18 shows that the reduction in the cavity is only favored at position 17. A considerable stereochemical preference (ratio of α- to β-OH groups formed) was observed, as well.



11

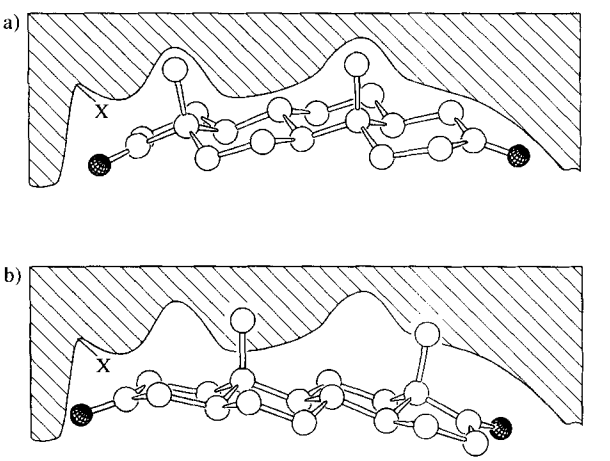


Fig. 18. Schematic representation of the embedding of androstan-3,17-dione in a cavity produced by imprinting with **11** (X = CH_2OH or $CH_2OAlH_3^-$ [82a]: Embedding when the 17-keto group (a) and the 3-keto group (b) is in close proximity to the X group. Poor fitting is obtained in (b).

6.5. Catalysis with Imprinted Polymers and Silica Gels

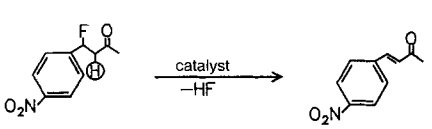
The imprinting of polymers is immediately recognized as a method for producing catalysts, especially those which function similarly to enzymes.[8, 14] It is possible to produce a cavity with a shape similar to that of the active center of enzymes. In addition, it is necessary to incorporate binding sites for substrates as

well as catalytically active groups in an optimal mutual spatial orientation. This should be possible with suitable template monomers. In these cases, as with enzymes, Michaelis–Menten kinetics are probable, and the catalytic activity should depend on k_{cat}/K_m, where k_{cat} is the rate constant of the catalyzed reaction, and K_m is a binding constant which describes the affinity of the substrate to the catalyst (enzyme). It is important that the binding to the catalyst takes place in a definite (productive) orientation, as otherwise no reaction would occur (unproductive orientation).

In addition it should be possible to use transition state analogs as templates, so producing effective catalysts similar to the catalytically active antibodies.[187] The advantage of these synthetic catalysts lies in their ease of production and stability. However, in contrast to monoclonal antibodies, the active centers are variously structured, more closely resembling polyclonal antibodies.

The first investigations into catalysis were carried out by A. A. Efendiev, V. A. Kabanov et al.[188] Cobalt complexes of linear polymers were equilibrated with, for example, ethylbenzene, the starting material of the reaction to be catalyzed, and the polymer was then cross-linked. Such polymers had two to three times the catalytic activity for the oxidation than catalysts that were not imprinted. The activity was somewhat better if imprinting was carried out with the reaction's product, α-phenylethyl hydroperoxide.

A retroracemization with an imprinted polymer containing 4-vinylpyridine units was carried out by A. Sarhan.[63] Pyridoxal-containing imprinted polymers gave some acceleration of the proton exchange in amino acid derivatives,[97] and imprinted polymers produced with vinylimidazole resulted in an increased esterolytic activity towards the template molecules.[152] However, in all cases, the template effect was very limited. This is also true of attempts to imprint polymers with phosphonic esters that function as transition state analogs for ester hydrolysis.[101–104a] Very similar phosphonic esters have been used as antigens in the preparation of antibodies, and antibodies of this type in some cases showed much increased catalytic activity for the ester hydrolysis.[187] In the imprinted polymers, acceleration by only a factor of 2 was observed,[101–103] but with a large excess of vinylimidazole the acceleration factor was 6.8.[104a] More significant catalytic acceleration was obtained by Shea et al.[109] They used benzylmalonic acid as the template to position polymerizable amines in a definite arrangement in the cavity. After removal of the template, this polymer catalyzed the dehydrofluorination of 4-fluoro-4-(*para*-nitrophenyl)butanone by a factor of 8.6 compared with the corresponding reaction in solution [Eq. (d)]. Although the



(d)

corresponding catalysis with antibodies was more effective,[189a] turnover, Michaelis–Menten kinetics, and competitive inhibition are observed. Even stronger accelerations (25-fold) were obtained during decarboxylations of 3-carboxybenzisoxazoles. In this case two amino groups were introduced a suitable distance apart in the cavity by means of a polymerizable di-Schiff base.[189b] Apparently, a cavity analogous to a transition state is not sufficient for the catalysis, and the additional cooperative effects of catalytically active groups are necessary.

Prior to some of the investigations described above, the research group of K. Morihara was working very intensively on the preparation of catalysts on the surface of silica gel. In a process described as "footprint catalysis", commercial silica gel is treated with Al^{3+} ions. Incorporation of Al^{3+} in the silicate matrix by isomorphous substitution of silicate by aluminate causes the formation of surface Lewis acid groups. The surface is then loaded with template molecules that contain Lewis base groups (the method is described in detail in Refs. [192, 196]). After aging and drying, surface cavities with Lewis acids (Al^{3+}) in a definite arrangement are formed by regrouping (Fig. 19).

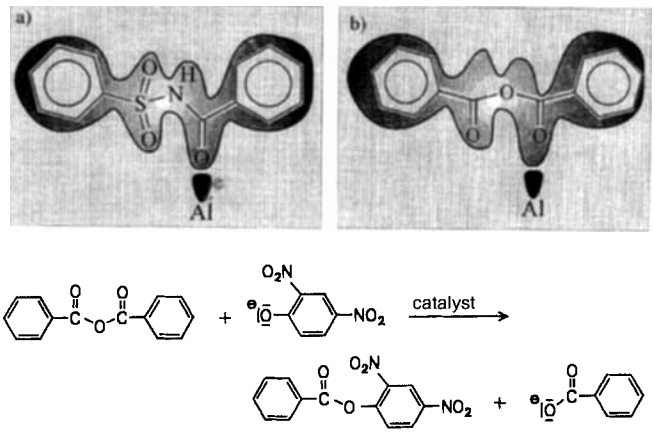


Fig. 19. Schematic representation of footprint catalysis [192, 194]. a) Imprinting with **12** on the surface and orientation of an Al^{3+} Lewis acid in the vicinity of a Lewis base. b) Embedding of the substrate benzoic acid anhydride for the reaction with 2,4-dinitrophenolate.

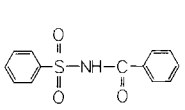
After removal of the templates, the suitability of the compounds as catalysts was investigated, for example, for the esterification of 2,4-dinitrophenolate with anhydrides. An example is given in Table 8,[192, 194] which shows that on imprinting with a template molecule analogous to the substrate, the binding ability of the substrate corresponding to Michaelis–Menten kinetics is much increased, but k_{cat} becomes smaller. Overall, k_{cat}/K_m increases by a factor of 2–8 over that of control catalysts without imprinting.[191, 193–105] However, if an imprinting molecule analogous to the transition state and containing tetrahedral phosphorus is used (**13**),[192] the binding power is increased, along with a large increase in k_{cat}. Increases of k_{cat}/K_m by a factor of 22 are possible

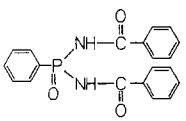
Table 8. Kinetic parameters for the catalyzed esterification of 2,4-dinitrophenolate with benzoic anhydride [192, 194].

Catalyst imprinted with	$10^4 \times K_m$ [a] [L mol^{-1}]	$10^{-2} \times k_{cat}$ [b] [L^{-1} mol s^{-1}]	$10^{-5} \times k_{cat}/K_m$ [L^{-2} mol^2 s^{-1}]
12	3.36	4.04	12.02 (3.19) [c]
13	4.06	33.36	82.23 (21.81) [c]
Control (no imprinting)	18.0	6.79	3.77

[a] K_m = Michaelis constant. [b] k_{cat} = Rate constant of the catalyzed reaction. [c] Factor for a corresponding catalyst not imprinted in parentheses.



12



13

in this way. In many cases, high substrate specificity is found.[122, 190, 194] If an optically active template is used for imprinting,[123, 193, 195, 198, 200] these catalysts cause enantiomers to react at different rates (kinetic racemic resolution). The enantiomer used for imprinting reacts two to four times more rapidly than the other.[123, 193, 195, 198] Extensive investigations into competitive inhibition and into productive and nonproductive binding[194, 195, 198] in catalysis have contributed greatly to the understanding of the process. Important applications are to be expected in the future. It is even speculated that "prebiotic enzymes" may have been produced in similar ways and may have played a part in the origin of life.[197]

Maier et al. produced a transesterification catalyst by imprinting with a phosphonate ester in silica gel.[201] The catalyst contains cavities with phosphoric acid centers acting as Lewis acid, and showed high substrate selectivity. On transesterification of ethyl phenylacetate, the octyl ester was formed eight to ten times more rapidly than the phenylethyl ester.

7. Future Prospects

The generation of imprints in polymers and other materials including surfaces has now reached a high degree of sophistication. The applications of these materials are becoming more and more interesting. As described in Section 6, such materials could find application in the near future as artificial antibodies, chemosensors, and catalysts. Application in the chromatographic resolution of racemates is especially likely. The following problems are in the forefront of investigation today:

1. When high molecular weight biopolymers such as proteins, glycoproteins etc. have to be used as templates, special methods must be used. Surface imprinting is likely to be a useful solution here.[19, 26, 77, 119, 202, 203] The further development of monolayers and vesicles[77] seems to be especially promising.
2. To enable a wider range of substrates to be used for imprinting, a broader array of binding groups must be developed, which are specific for interaction with particular functional groups.
3. In spite of considerable improvement of the mass transfer in imprinted polymers, the attainment of equilibrium in the embedding of the substrate in cavities with two-point bonding needs to be accelerated.
4. It would be very useful if the selectivity differences between individual cavities ("polyclonality") could be further minimized.
5. For preparative chromatography, the capacity of the columns must be further increased. In this context, if noncovalent interactions are used for the imprinting, it is important to increase significantly the proportion of cavities that can be refilled.
6. An important simplification of the chromatographic process would be achieved if compounds could be directly separated without first forming derivatives.
7. When imprinted polymers are used as chemosensors, extremely sensitive methods are required for the detection of substances bound to the imprinted membrane.

Special thanks are due to my co-workers who have been involved with me in research on this topic and who, through their commitment and their ideas, have contributed a significant share of these results. We have received financial support over a long period, and especially in the difficult initial phase, from the Deutsche Forschungsgemeinschaft, whom we thank in particular. Also, support from the Fonds der Chemischen Industrie has helped us considerably. I thank the following colleagues for providing me with unpublished results: S. E. Byström, Stockholm; P. K. Dhal, Cambridge; A. A. Efendiev, Baku; Y. Fujii, Ibaraki; W. Kuchen, Düsseldorf; K. Morihara, Nara; S. A. Piletsky, Kiev; B. Sellergren, Mainz; K. J. Shea, Irvine; D. C. Sherrington, Glasgow; M. J. Whitecombe, Reading. I also thank Dr. M. Aust, Düsseldorf, for drawing some of the diagrams and for the computer graphics in Figures 4 and 5, and Dr. A. Kraft, Düsseldorf, for assistance in the preparation of the English manuscript.

CHIRALITY '95 JERUSALEM

7th International Symposium on Chiral Discrimination (ISCD 7)

Jerusalem, Israel, November 12-16, 1995

Plenary Speakers

David Avnir, *Hebrew University of Jerusalem, Jerusalem, Israel*
Samuel J. Danishefsky, *Columbia University, New York, USA*
Ben L. Feringa, *University of Groningen, Groningen, The Netherlands*
Joseph Gal, *University of Colorado, Denver, Colorado, USA*
Ryoji Noyori, *University of Nagoya, Nagoya, Japan*
Frank Volker Schurig, *University of Tubingen, Tubingen, Germany*
J. Fraser Stoddart, *University of Birmingham, Birmingham, UK*
Sidney Topiol, *Sandoz Research Institute, New Jersey, USA*
David M. Walba, *University of Colorado at Boulder, Colorado, USA*
Chi-Huey Wong, *Scripps Research Institute, La Jolla, California, USA*

The Scientific Program will Highlight Advances in the Following Topics:

- Stereospecific analytical methodology
- Stereocontrol in organic synthesis
- Chiral recognition
- Chirality in pharmacodynamics, drug-action, and therapeutics
- Stereochemical aspects of drug metabolism, and pharmacokinetics
- Chirality and the future of drug design
- Regulatory aspects and intellectual property issues
- Molecular chirality
- Quantitative evaluation of chirality
- Electronic materials and chirality
- Chirality in Archeology

For further information please contact the Symposium Secretariat:
ORTRA Ltd., 2 Kaufman Street, P.O. Box 50432, Tel Aviv 61500, Israel FAX: 972-3-5174433

Catalytic Ring-Closing Metathesis: A New, Powerful Technique for Carbon–Carbon Coupling in Organic Synthesis

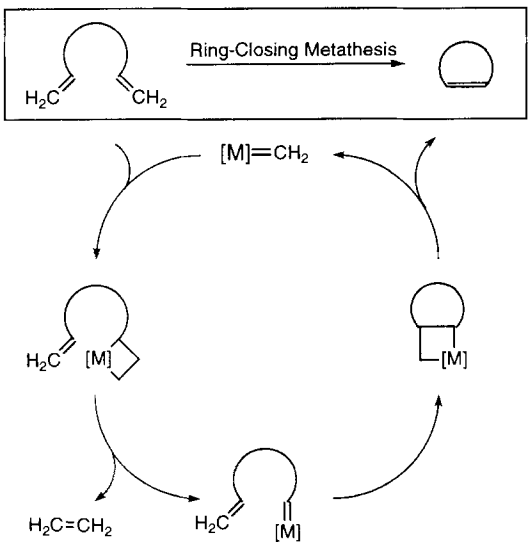
Hans-Günther Schmalz*

Introduction

Owing to the rapidly growing human population and the consequent increasing demand for the products of organic synthesis, the development of highly efficient and selective synthetic methods is one of the most urgent tasks for chemical science. In this connection, transition metal mediated reactions and, in particular, catalytic C–C bond forming processes have a great and still relatively unexplored potential.[1]

From the point of view of organic synthesis, olefin metathesis, that is, the metal-catalyzed exchange of the alkylidene groups of two olefins, is a highly interesting process.[2] This general reaction, which was previously used almost exclusively in polymer chemistry and above all for ring-opening metathesis polymerization (ROMP),[3] was recently proven to be of value in many cases for the preparation of low molecular weight compounds, in particular for cyclization reactions like that in Scheme 1.[4]

The alkylidene complexes $[M]=CH_2$ are proposed to be the catalytically active species, and the reactions are thought to proceed according to the mechanism outlined in Scheme 1 (via metallacyclobutane intermediates). If terminal 1,(ω – 1)-dienes



Scheme 1. The mechanism of cyclizations by olefin metathesis.

[*] Prof. Dr. H.-G. Schmalz

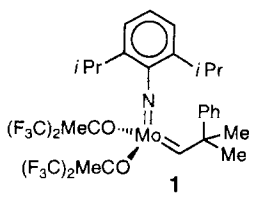
Strasse des 17. Juni 135, D-10623 Berlin (Germany)
Telefax: Int. code + (30) 314-22429

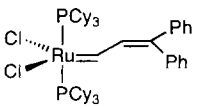
are employed as substrates, ethylene is formed as the only stoichiometric by-product. Therefore, these reactions may certainly be classified as being "atom economic".[5]

Cyclization Reactions by Olefin Metathesis

Early reports[6] including a paper by D. Villemin[6a] from 1980 on the preparation of an Exaltolid precursor by WCl_6/Me_4Sn-catalyzed metathesis cyclization went mostly unnoticed. Only when well-defined and highly active catalysts that also tolerate functional groups were discovered at the beginning of the 1990s, did research on ring-closing metathesis chemistry take off. In 1992 two key papers from the research group of R. H. Grubbs[7] appeared, which marked the beginning of intensive and still continuing research activity in this field. Initially, the molybdenum complex **1** developed by R. R. Schrock[8] was employed in most cases, but in the meantime, the easily accessible and much less air-sensitive ruthenium complex **2**

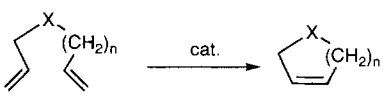


1



2

(Cy = cyclohexyl)[9] enjoys at least the same popularity. With these catalysts the construction of cyclopentene and cyclohexene derivatives[10–12] as well as five-, six-, and seven-membered (even highly functionalized) heterocycles can be achieved usually in excellent yield (Scheme 2).[7,13–15]



Scheme 2. Synthesis of heterocycles by olefin metathesis. cat = **1** or **2**.

In many cases, ring-closing methathesis reactions proceed with remarkable high efficiency, as exemplified by the examples shown in Scheme 3. Thus, (optically active) methylcyclopentene **4**, which is of interest as a monomer for the production of main chain chiral polymers using ROMP and very difficult to obtain by other techniques, can be prepared easily from β-citronellene

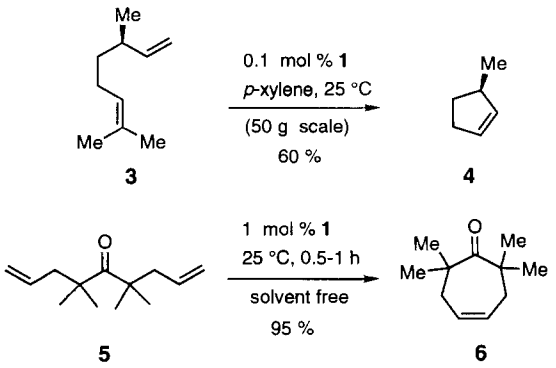
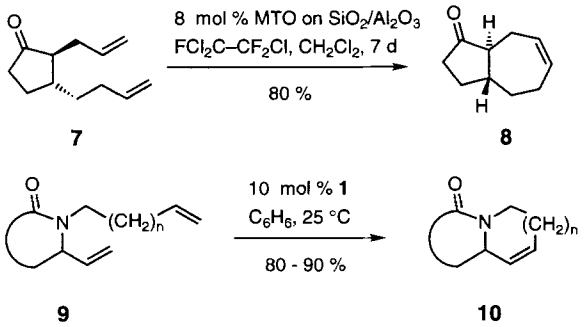


Scheme 3.

(**3**) by the action of minute amounts of catalyst **1**.[12] Another striking example is the solvent-free cyclization of diene **5** to give cycloheptenone **6**.[16] In this case, the conformational preorganization of the substrate is crucial, since the methyl-free analogue of **5** polymerizes under the same conditions—a good example of the Thorpe–Ingold effect.

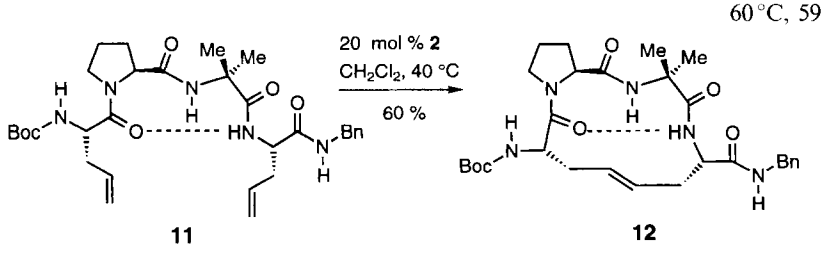
Metathesis can also be used for the construction of condensed ring systems as demonstrated by the transformations shown in Scheme 4. For the synthesis of partially hydrogenated azulenes (e.g. **7** → **8**),[17] methyltrioxorhenium (MTO)[18] was employed.



Scheme 4. Synthesis of condensed ring systems by olefin metathesis.

However, this catalyst seems to be less active than **1** or **2** and also exhibits a somewhat lower tolerance towards functional groups. The synthesis of condensed nitrogen heterocycles (**9** → **10**) was achieved using **1**.[19] This opens up a new entry to the frameworks of a number of biological active alkaloids.

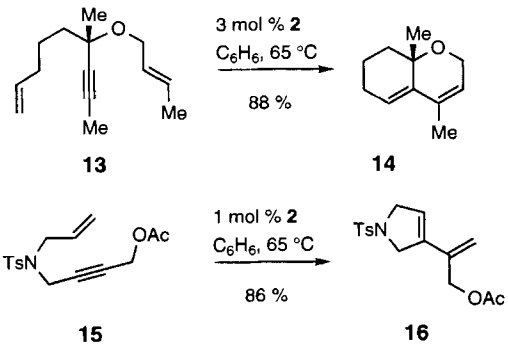
Even eight-membered rings may be closed by metathesis, but only when they are not too strained and when the substrate is structurally preorganized to a certain degree.[20] S. J. Miller and R. H. Grubbs recently reported the synthesis of cyclic peptides, demonstrating the high tolerance of the Ru catalyst **2** towards NH groups.[20b] Especially remarkable is the transformation displayed in Scheme 5, in which the conformationally preformed substrate **11** smoothly metathesizes to give the 14-membered macrocycle **12** (with β-turn-type structure).



Scheme 5.

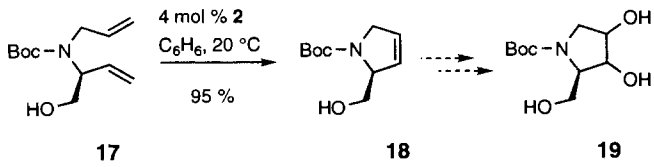
Metathesis of Enynes and Dienynes

At this point it is mentioned only briefly that metathesis chemistry can be extended with great success to conversions of enynes and dienynes.[21, 22] Thus, for example, substrate **13** reacts in excellent yield (and in a mechanistically straightforward manner) to afford the bicyclic product **14**,[21] while the enyne **15** gives the conjugated diene **16**.[22a]

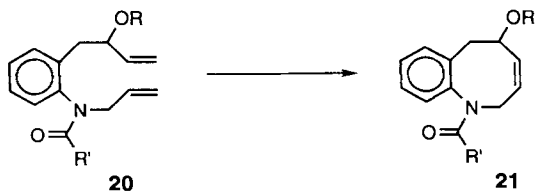


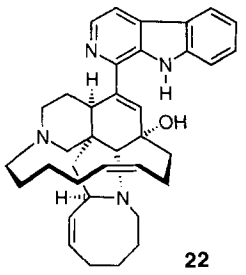
Synthetic Applications

Considering the great success of the methodological studies, it is not surprising that ring-closing metathesis was promptly applied to the synthesis of specific target molecules. For instance, C. M. Huwe and S. Blechert[23] used catalyst **2** for the cyclization of diene **17** to give the dehydroprolinol derivative **18**, which is an ideal precursor for pharmacologically interesting azasugars of type **19**.



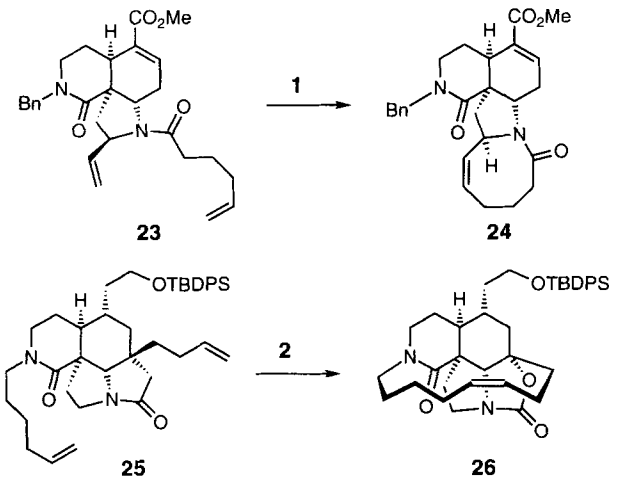
In the course of model studies directed towards the synthesis of the antitumor antibiotic FR-900482, the cyclization of dienes of type **20** to give azabenzocyclooctadienes **21** was accomplished independently by two research groups. S. F. Martin et al.[24] employed the Mo catalyst **1** (15 mol % **1**, benzene, 50 °C, 77 %), whereas R. H. Grubbs and co-workers accomplished the desired reaction with the aid of the Ru catalyst **2** (10 mol % **2**, benzene, 60 °C, 59 %).





22

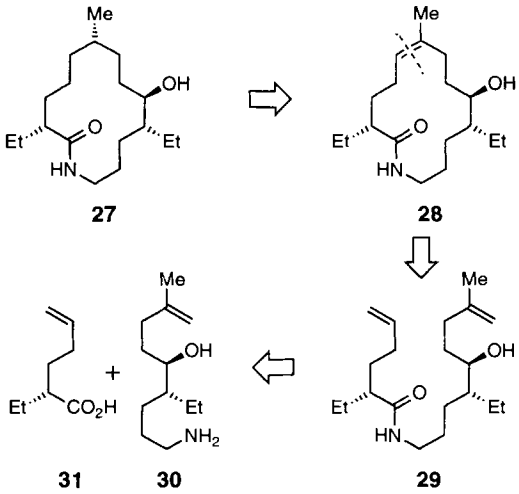
The metathesis cyclization reaction has also proven itself in connection with the planned total syntheses of manzamine A (**22**), a highly interesting antitumor alkaloid with an unusual structure, which presents a particular challenge for synthetic chemists. S. F. Martin et al.[25] used a metathesis reaction for the construction of the eight-membered ring (**23** → **24**), and U. K. Pandit and co-workers[26] demonstrated that even the macrocyclic ring can be closed by this method (Ru catalysis) (**25** → **26**, TBDPS = tBuPr$_2$Si). At this point, the power of metathesis chemistry for solving difficult synthetic problems becomes evident.



23 **24** **25** **26**

Total Synthesis of the Fluvirucin B_1 Aglycon

Recently A. H. Hoveyda and co-workers[27] described a remarkable total synthesis of the fluvirucin B_1 aglycon (**27**) in which a metathesis cyclization is employed for the formation of a 12-membered ring. Fluvirucin B_1 (also known as Sch 38516) is a naturally occurring macrolactam glycoside with interesting antifungal and antiviral properties. Retrosynthetically, Hoveyda et al. traced the target molecule back to an open-chain amide of type **29** (Scheme 6), which is cyclized in the key metathesis

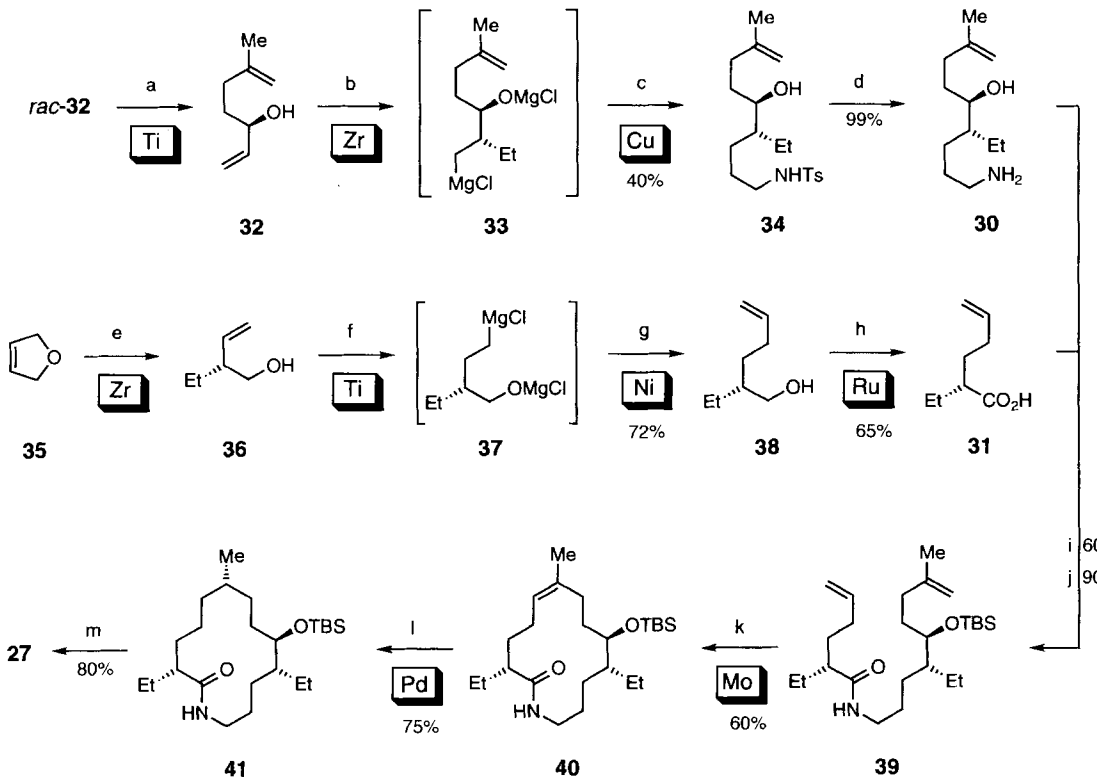


27 **28** **31** **30** **29**

Scheme 6. Strategy of the fluvirucin synthesis by A. H. Hoveyda et al. in a retrosynthetic representation.

step to give **28**. Compared to alternative synthetic strategies, in which the macrolactam ring is closed by formation of the amide bond, the cyclization precursor **29** is accessible here in a simple and convergent manner by coupling the amide **30** with the carboxylic acid **31**.

The fascinating feature of the Hoveyda synthesis is not only its clear strategic conception but the extended sequences of transition metal catalyzed reactions involved (Scheme 7). A Sharpless-type Ti-catalyzed kinetic resolution provides the optically active starting material **32**, which is regio- and diastereoselectively further converted by Zr-catalyzed carbomagnesation.[28] The resulting Grignard intermediate **33** is then



32 **33** **34** **30** **35** **36** **37** **38** **31** **41** **40** **39**

Scheme 7. Synthesis of the fluvirucin by A. H. Hoveyda et al. The element symbols in boxes indicate transition metal catalyzed transformations. For the reaction conditions for steps a–m see ref. [27].

coupled with *N*-tosyl aziridine under Cu catalysis (→ **34**). The preparation of the second fragment, the carboxylic acid **31**, starts with an enantioselective carbomagnesation[28] of **35**. The homoallylic alcohol **36** thus obtained is then homologized to **38** by Ti-catalyzed hydromagnesation (→ **37**) and Ni-catalyzed cross-coupling. Finally, **38** is oxidized to **31** in a Ru-catalyzed reaction.

After the two components **30** and **31** are coupled (→ **39**) the crucial metathesis cyclization using the Mo catalyst **1** furnishes alkene **40** with almost complete *Z*-selectivity. Considering the general problem of constructing 12-membered rings, the obtained yield of 60% is remarkably high. The synthesis is completed by (completely diastereoselective) catalytic hydrogenation of **40** (→ **41**) and desilylation.

All in all, Hoveyda et al. needed little more than ten synthetic steps, including five transition metal catalyzed C–C couplings and four other metal-catalyzed transformations. The synthesis is short, highly selective, and should be flexible enough to allow the preparation of a wide variety of fluvirucin analogues. Only a few protecting groups are needed because simple (nonactivated) double bonds, which are stable under all sorts of reaction conditions, serve as functional anchor groups for the crucial C–C bond forming reactions.

Conclusion

There is no question that transition metal mediated processes in general and catalytic C–C bond forming reactions in particular will be of increasing importance in organic synthesis. The catalytic ring-closing metathesis discussed here is only one of several new interesting methods. In some respect, the Hoveyda synthesis of the fluvirucin B_1 aglycon (see Scheme 7) can be regarded as a prototype of a new generation of total syntheses in which the multifariousness of metal-catalyzed reactions is consequently and successfully utilized. Though some of the yields achieved leave much to be desired, this synthesis emphasizes the potential of transition metal catalysis for the synthesis of challenging target molecules in a wealth of selective transformations. Yet, this masterpiece in catalytic synthetic organometallic chemistry would not have been possible without work from the laboratories of R. H. Grubbs and R. R. Schrock, who paved the way for almost all of the ring-closing metathesis reactions mentioned above.[29]

Distorted Sandwich Compounds: [1]Ferrocenophanes and [2]Ruthenocenophanes**

Max Herberhold*

Strained cyclic compounds are potential monomers for ring-opening polymerization, and strained metallocenophanes have consequently attracted interest as precursors for polymers containing transition metals such as Fe or Ru in the cage of sandwich units that are incorporated into the macromolecule.[1] The propensity towards polymerization depends on the ring strain, as may be seen for the sila[*n*]ferrocenophanes[2] fc[$(SiMe_2)_n$] with $n = 1$ (**1**) and $n = 2$ (**2**). Whereas **1** polymerizes in the melt above 130 °C to give silaferrocenylene polymers,[3] **2** requires temperatures above 350 °C to undergo ring-opening polymerization.[2, 3] Nevertheless, it is easy to oxidize fc[$(SiMe_2)_2$] **2** to 1,3-bis(dimethylsila)-2-oxa-[3]ferrocenophane fc[$(SiMe_2)_2O$] which, like fc[$(SiMe_2)_3$] **3**, is strain-free and therefore not prone to polymerization.[4]

The ring strain in [1]ferrocenophanes, which contain just a single bridging atom as a link between the two cyclopentadienyl ligands, is conveniently described by the tilt angle α of the rings and the deformation angle δ at the metal between the midpoints of the rings. (Fig. 1, cf. ref. [3]). The tilt angle α increases as the size (i.e. the covalent radius) of the bridging element E decreases, for example in the series **4**–**6**. To date [1]ferrocenophanes containing elements of the second row of the periodic table (E = B, C, N, O) as bridges have not been synthesized. The smallest bridging element possible appears to be sulfur, and the new thia[1]ferrocenophane fc[S] **6**, prepared by Ian Manners and co-workers,[5] holds the present world record for the largest tilt angle in [1]ferrocenophanes with $\alpha = 31.05(10)°$. The conformation of the two cyclopentadienyl rings in **1** and **4**–**6** is almost exactly eclipsed.

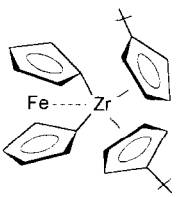
δ = 156.9(1)°
β = 28.8; 29.1°
θ = 89.03(9)°

As expected, the ring strain is reduced when the bridging atom is a heavier homologue, as for example in diphenylgerma-[1]ferrocenophane fc[$GePh_2$] ($\alpha = 16.6$, $\delta = 170$, $\beta = 32.5$, and $\theta = 90.6°$)[6b] and in the substituted phenylarsa[1]ferrocenophane fc'[AsPh] (fc' = $(C_5H_4)Fe(C_5H_3R)$, R = $CHMeNMe_2$; α = 22.9, $\delta = 162.5$, $\beta = 32.8$, and $\theta = 87.90(7)$).[7] Apparently only a single metalla[1]ferrocenophane has been structurally characterized: fc[$Zr(C_5H_4tBu)_2$] **7** ($\alpha = 6.0$, $\delta = 177.27(8)°$);[8] the metal–metal separation, d(Fe–Zr) = 296.21(5) pm, might indicate a weak bonding interaction.



fc[$Zr(C_5H_4tBu)_2$]

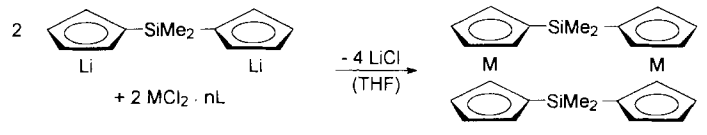
[**] Abbreviations: Cp = η^5-cyclopentadienyl, η^5-C_5H_5; Fc = 1-ferrocenyl, CpFe(C_5H_4)-; fc = 1,1'-ferrocenediyl, Fe(C_5H_4)$_2$; rc = 1,1'-ruthenocenediyl, Ru(C_5H_4)$_2$; thf = tetrahydrofuran ligand, dmso = dimethylsulfoxide ligand.

ly.[10,11] As the intramolecular ring–ring distance in the parent metallocenes MCp_2 **8a–c** expands on going from ferrocene to ruthenocene and osmocene, the distortion in the corresponding [1]- and [2]metallocenophanes must similarly increase. This might explain why dimethyldichlorosilane Me_2SiCl_2 reacts with 1,1′-dilithioferrocene $fcLi_2$ to give fc[$SiMe_2$] **1**,[12] while the corresponding reaction with 1,1′-dilithioruthenocene $rcLi_2$ leads preferentially to oligomers and polymers. The binuclear bis(dimethylsila)[1.1]metallocenophanes **9a,b** were prepared by a different route [Eq. (a)];[13] it is conceivable that small amounts of the strained mononuclear monomers fc[$SiMe_2$] **1** and rc[$SiMe_2$][9] are formed under these conditions as well.



(M = Fe ; nL = 2thf ;
M = Ru ; nL = 4dmso)

9a : fc($SiMe_2$)$_2$fc[13]
9b : rc($SiMe_2$)$_2$rc[13]

(a)

In all cases (**2**, **10**–**12**) where analogous [2]ferrocenophanes and [2]ruthenocenophanes have been structurally characterized, the ruthenium complex is always the more strained.[13] As expected, an almost linear correlation exists between the distortion angles α and δ in [1]- and [2]metallocenophanes.

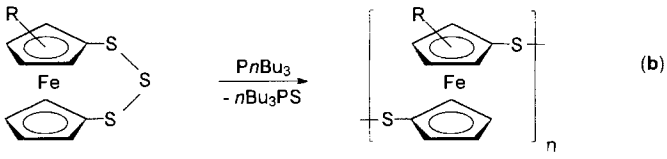
The ring-opening polymerization of the highly strained monomer fc[S] **6** is expected to lead to poly(ferrocenylene sulfide) $[fcS]_n$. A yellow product of this composition was obtained earlier from the reaction of 1,1′-diiodoferrocene fcI_2 with the copper salt of 1,1′-dimercaptoferrocene $fc(SCu)_2$ in boiling pyridine;[17] it is insoluble in all common solvents. The presence of substituents on the rings is apparently necessary to obtain tractable sulfur-bridged ferrocene polymers, which might be new materials with special properties due to the regularly arranged Fe centers.

A modified ring-opening polymerization leading to poly(ferrocenylene disulfide) $[fcS_2]_n$ **14** (R = H) was discovered by T. B. Rauchfuss and co-workers [Eq. (b)].[19–22] Starting from the unstrained 1,2,3-trithia[3]ferrocenophanes **13**, abstraction of the central sulfur atom using $PnBu_3$ generates one-dimensional



(b)

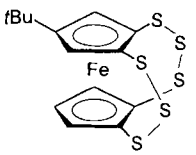
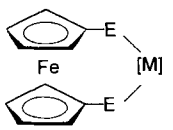
(R = H, *n*Bu, *t*Bu)

macromolecules **14**; again substituents on the rings are required to obtain soluble products. When 4-*t*ert-butyl-1,1′,2,2′-bis(1,2,3-trithia[3])ferrocenophane (**15**) is used as the monomer, giant three-dimensional networks containing disulfide bridges can be obtained.[21]

In spite of the synthetic achievements in the chemistry of distorted sandwich compounds, some questions still remain open. Thus, points of discussion are the disturbed intramolecular interactions between



15



16

E = S, Se, Te
[M] = metal complex fragment

iron and the cyclopentadienyl rings or the possible contacts of iron to the bridge elements. An attractive synthetic target for the near future will be the preparation of polymeric materials with different metals, either from metalla[1]ferrocenophanes[8,23] or from [3]ferrocenophanes **16**, which contain transition metal complex fragments in the bridge system (cf. ref. [24]).

Renew your inorganic chemistry lab course!
This book offers detailed descriptions of more than 60 experiments ranging from undergraduate to graduate level, covering organometallic, main group, solid state and coordination chemistry. Almost all reaction types, laboratory techniques and classes of compounds which constitute current curricula are exemplarily represented.

Experiments have been contributed from university teachers all over Europe. Each experiment has been thoroughly tested. Special safety instructions are always provided, hazardous substances have been substituted by less harmful ones wherever possible. Products are characterized by modern spectroscopic techniques. Also included are excercises, questions and hints to further reading. The experiments illustrate modern research directions: many compounds have only very recently been described in key journals – here you learn how to prepare them in your lab course.

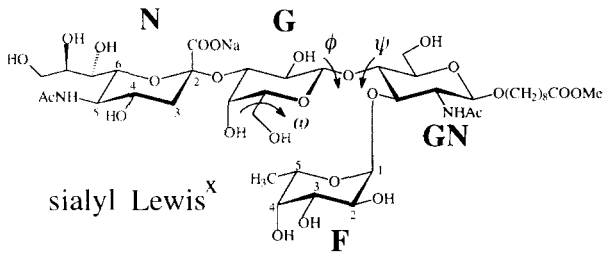
Determination of the Bioactive Conformation of the Carbohydrate Ligand in the E-Selectin/ Sialyl Lewis^x Complex**

Karoline Scheffler, Beat Ernst, Andreas Katopodis, John L. Magnani, Wey Tong Wang, Rüdiger Weisemann, and Thomas Peters*

The expression of E-selectin receptors on the surface of endothelial cells stimulated by cytokines is one of the first steps in inflammatory processes.[1, 2] E-selectin is a membrane-resident glycoprotein belonging to the selectin family (E-selectin, L-selectin, P-selectin) which specifically binds the sialyl Lewis^x antigen present on neutrophilic granulocytes. To understand the recognition and binding processes at the molecular level, the three-dimensional (3D) structure of the complex formed between E-selectin and sialyl Lewis^x must be analyzed. In this connection a considerable advance was marked by the elucidation of the crystal structure of E-selectin.[3] Unequivocal experimental data for the determination of the conformation of the ligand sialyl Lewis^x in the E-selectin complex have been lacking until now. Although two recent publications[4, 5] described transfer NOE experiments[6] for the conformational analysis of complexed sialyl Lewis^x, different conformations for the bound ligand were given and the orientation of the fucose residue in the complex was not even mentioned.

We now describe transfer NOE experiments on the E-selectin/ sialyl Lewis^x complex. The tetrasaccharide sialyl Lewis^x was prepared synthetically;[7] the E-selectin used is a recombinant chimera of E-selectin and human IgG, in which the lectin, the EGF, and six CR domains of the E-selectin replace the antigen binding sites in IgG.[8] NOESY spectra were recorded with different mixing times to determine the transfer NOEs.[9] In order to suppress the interfering proton resonance signals of the E-selectin and thus enable the quantitative evaluation of the spectra, a spinlock filter[10] was used. For comparison purposes NOESY experiments were performed on pure E-selectin and free sialyl Lewis^x.[11] The assignments of the proton resonance signals were carried out using available data.[12]

Comparison of the NOESY spectra of E-selectin and free sialyl Lewis^x shows that no interfering superposition of proton signals from the glycan portion of E-selectin occurs with those of the tetrasaccharide. As reported in previous publications,[12] small negative NOEs are observed for free sialyl Lewis^x (Fig. 1a). Interglycosidic NOEs occur which correspond with known NOEs; however, no interglycosidic NOE is observed



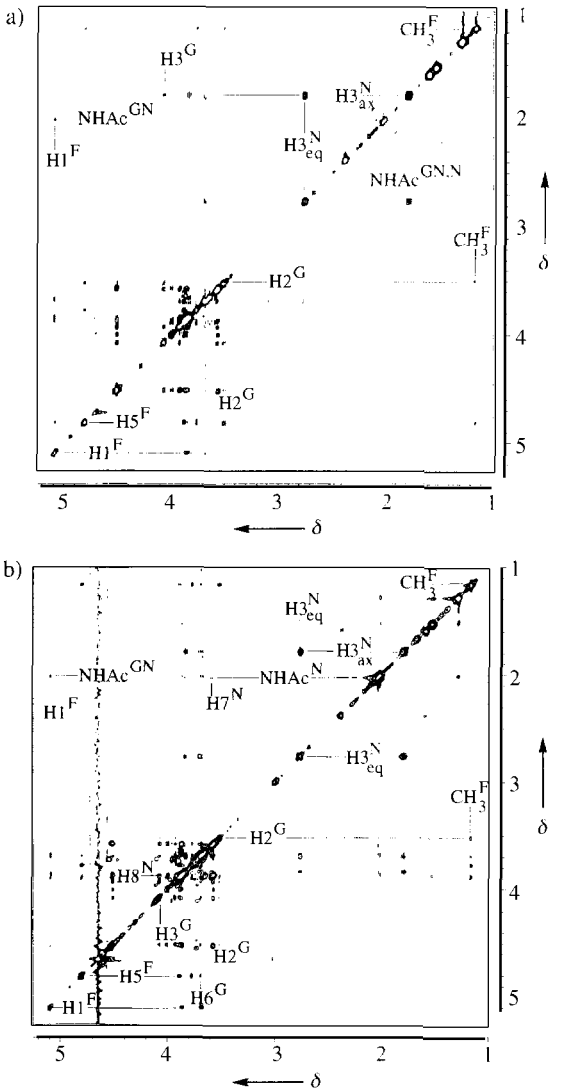


Fig. 1. 2D NOESY spectra [9, 11] of free sialyl Lewis^x (a) and sialyl Lewis^x complexed with E-selectin (b). Spectrum a was recorded with a mixing time of 900 ms without a spinlock filter, spectrum b with a mixing time of 150 ms and a spinlock filter.

between $H8^N$ and $H3^G$ as was found in ROESY experiments.[13] The corresponding effect was also observed with sialyl-$\alpha(2 \rightarrow 3)$-*N*-acetyllactosamine.[12a] The reason for these differing results is that the correlation time τ_c of the tetrasaccharide leads to a value $\omega\tau_c$ (ω = spectrometer frequency, 600 MHz) of approximately 1. In this region the intensities of the NOEs are extremely sensitive to even small changes in the local mobility of individual parts of the molecule. This is clearly shown in the C9 chain at the reducing end of sialyl Lewis^x for which no, or even very weak positive, NOEs are observed. Similarly the glycerol side chain of the *N*-acetylneuraminic acid residue may show a local correlation time τ that deviates from the global correlation time τ_c, such that NOEs in this side chain, for example NOE $H8^N/H3^G$, are no longer detectable. Taking into consideration the experiments carried out by other research groups[12a, 13] it appears that, in general, the sialyl Lewis^x tetrasaccharide exists in solution as an equilibrium of several conformations,[13] which to a large extent are characterized by the orientation of the *N*-acetylneuraminic acid residue. The ^{1}H NMR data for the tetrasaccharide are summarized in Table 1.

Table 1. ^{1}H NMR chemical shifts (δ values) for the tetrasaccharide sialyl Lewis^x in D_2O at 303 K and 600 MHz. Reference signal: δ(HDO) = 4.722.

Even with a mixing time of 25 ms, transfer NOEs occur for the complex. Since complete transfer NOE curves were obtained by recording NOESY spectra at different mixing times,[9] spin diffusion effects can be excluded from the following discussion of the NOEs. The intensities of the transfer NOEs and the position of the maxima in the transfer NOE curves clearly indicate that the observed effects are indeed transfer NOEs. Transfer NOEs between E-selectin and sialyl Lewis^x protons could not be observed at the selected protein:ligand ratio.[9] The following discussion concerns only the NOESY spectrum recorded with a mixing time of 150 ms (Fig. 1b). A precise analysis of the transfer NOE data and other NMR experiments in particular with consideration of exchange equilibria and the involvement of the amino acid protons[14] in the binding pocket of E-selectin will be published elsewhere. For comparison the corresponding section from the 2D NOESY spectrum of free sialyl Lewis^x is shown in Figure 1a. Sections of the corresponding 1D NOESY spectra relevant to the discussion of the most important effects are collected in Figure 2.

The interglycosidic transfer NOEs between the *N*-acetylneuraminic acid and galactose protons differ considerably from the corresponding NOEs in free sialyl Lewis^x (Figs. 1 and 2). The most obvious difference is the absence of a transfer NOE between $H3^N_{ax}$ and $H3^G$. However, a clear transfer NOE between $H8^N$ and $H3^G$ is observed (Figs. 2b and 2c). A weak transfer NOE is observed between the methyl group of the *N*-acetyl function attached to $C5^N$ and $H7^N$ within the *N*-acetyl-

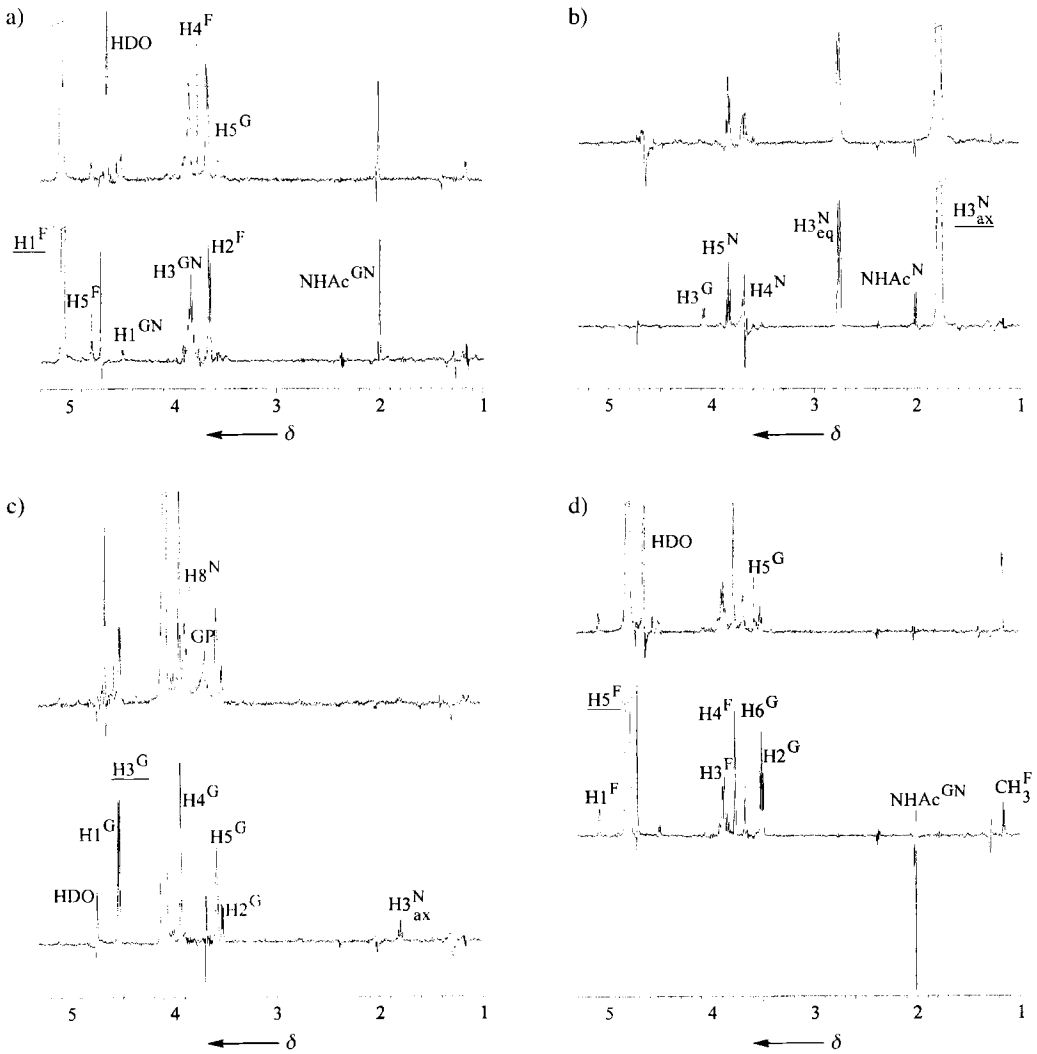

Fig. 2. 1D representations of the NOESY spectra from Figure 1, obtained by the addition of traces of F1. The lower traces are taken from the NOESY spectrum of free sialyl Lewis^x (cf. Fig. 1a); the upper traces correspond to complexed sialyl Lewis^x (cf. Fig. 1b). a) $\delta = H1^F$; b) $\delta = H3^N_{ax}$; c) $\delta = H3^G$; d) $\delta = H5^F$. The signal labeled GP arises from E-selectin. This can be shown by comparison with NOESY spectra of free E-selectin (not shown).

neuraminic acid residue. This supports the preferred *gg* (*gg* = *gauche,gauche*) orientation at the $C6^N$–$C7^N$ bond. With regard to the orientation at the $C7^N$–$C8^N$ bond, analysis of the vicinal homo- and heteronuclear coupling constants and the determination of the ^{13}C spin-lattice relaxation times have shown that in aqueous solution the hydroxyl groups attached to the $C7^N$–$C8^N$ bond[12a, 15] are oriented exclusively *trans* and that a conformational equilibrium is observed only for the hydroxymethyl group on C9. Hence, the glycerol side chain of the *N*-acetylneuraminic acid is thought to assume an orientation like that described in ref. [12a].

The transfer NOEs observed between galactose and *N*-acetylglucosamine correspond to the NOEs in the free tetrasaccharide (Fig. 1). The interglycosidic transfer NOEs originating from fucose, on the other hand, differ considerably from the corresponding NOEs in the free tetrasaccharide. Only an extremely weak transfer NOE is observed between $H5^F$ and $H2^G$ (Fig. 2d). Similarly there is a slightly weaker transfer NOE between the methyl group of the *N*-acetyl function on $C2^{GN}$ and $H1^F$ (Fig. 2a). A very weak transfer NOE between $H1^F$ and $H5^G$ or $H5^{GN}$, which is marked in Figure 2a, most likely arises by spin diffusion (based on consideration of the NOE buildup curves). The intensity of the transfer NOE between CH_3-6^F and $H2^G$, on the other hand, resembles that of the corresponding NOE in the free tetrasaccharide (Fig. 1). A transfer NOE is also detected between $H5^F$ and $H6^G$, which in sialyl Lewis^x lies at the detection limit (Fig. 2d).

For further evaluation the transfer NOEs were integrated;[16] the intensities of the intraglycosidic transfer NOEs between $H3^N_{ax}$ and $H3^N_{eq}$ were used as calibration values. The relative NOEs were converted into distance restrictions (Table 2) by

Table 2. Experimentally determined interglycosidic transfer NOEs from the NOESY spectrum (Fig. 1b) used for distance restrictions. (The NOEs for the NOESY spectrum (Fig. 1a) of the free tetrasaccharide are also given for comparison.) For the determination of the distance restrictions, r_a (lower limit) and r_b (upper limit), calibration was carried out with a known intraglycosidic distance, $H1^F$–$H2^F$ = 2.3 Å according to the "Isolated Spin Pair Approximation" (ISPA) [16]. For the determination of the NOEs a relatively large error of ±40% was used. The values of the distance restrictions r_a and r_b were then obtained from the distances calculated from the NOEs by means of ISPA and the estimated errors.

	NOE [%] complex (free)	r_a [Å]	r_b [Å]
$H1^F$-$H3^{GN}$	−37 (−8)	2.3	2.6
$H1^F$-NAc^{GN}	−9 (−1)	2.8	3.3
$H5^F$-$H2^G$	−8 (−15)	2.9	3.4
$H5^F$-$H6^G$	−12 (−1)	2.7	3.1
CH_3^F-$H2^G$	−20 (−4)	2.5	2.9
$H1^G$-$H4^{GN}$	−45 (−20)	2.2	2.5
$H3^G$-$H8^N$	−37 (0)	2.3	2.6
$H3^N_{ax}$-$H3^G$	0 (−4)	4.0	
$H3^N_{eq}$-$H3^G$	0 (0)	4.0	

application of the ISPA approximation,[17] and these in turn were used to find the conformation of bound sialyl Lewis^x. For this a 10^6-step Metropolis Monte Carlo (MMC) simulation[18] with a temperature parameter of 2000 K was performed which completely encompassed the conformational space available to sialyl Lewis^x.[19] From the 457309 conformations obtained, 29 structures were selected which fulfilled all the distance restrictions. The conformations thus found populate only a very restricted region of the conformational space and thus yield the conformation of bound sialyl Lewis^x (Fig. 3).

From their experiments Cooke et al. derived a conformation in which the *N*-acetylneuraminic acid has an orientation similar

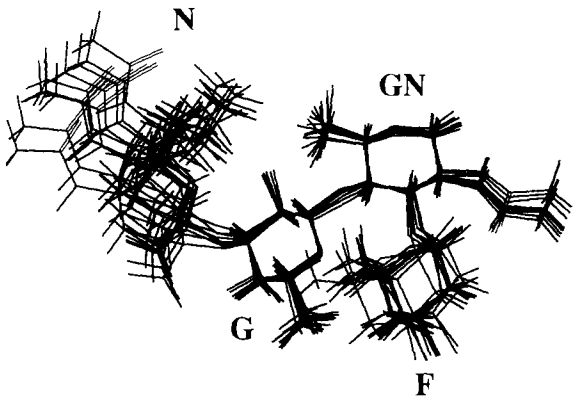

Fig. 3. Representation of the conformation of sialyl Lewis^x in the bound state. Ten of the 29 conformations obtained are shown. The following average values were obtained for the dihedral angles at the glycosidic bond (cf. Table 2): $\phi_{N\ G} = -76° +/- 10°$, $\psi_{N-G} = 6° +/- 10°$, $\phi_{G\ GN} = 39° +/- 10°$, $\psi_{G\ GN} = 12° +/- 6°$, $\phi_{F\ GN} = 38° +/- 7°$, $\psi_{F\ GN} = 26° +/- 6°$.

to that described here. However, they neither observed nor discussed a transfer NOE between $H8^N$ and $H3^G$, which is an essential distance restriction for deriving the bound conformation. The authors therefore used already published force field calculations[11b] and molecular dynamics (MD) simulations[13] to be able to suggest a possible conformation for the bound ligand. The use of the exclusion principle—only the missing NOE $H3^G$/$H3^N_{ax}$ is enlisted for an upper distance restriction—favors the conformation C suggested by Ichikawa et al.[11b] Transfer NOEs between the fucose and the *N*-acetylglucosamine unit were not discussed, and as a result the fucose residue in sialyl Lewis^x is assigned the orientation present in aqueous solution. In the recent publication of Hensley et al.[5] a "transfer NOE" between $H3^N_{ax}$ and $H3^G$ was found which, it is claimed, shows that the conformation in the bound state is identical with the conformation of sialyl Lewis^x in solution. It is not clear, however, which solution conformation is meant. Probably conformations A or B suggested by Ichikawa are implied.[11b] This cannot be reconciled with the results of Cooke et al.[4] nor can it be correlated with our results. Possibly the "transfer NOE" observed by these authors[5] may be explained by the use of a large excess of ligand and the presence of unbound sialyl Lewis^x.

Our experiments enable the determination of the conformation of bound sialyl Lewis^x on the basis of MMC simulations at 2000 K. The high temperature parameter was chosen in order to encompass, as fully as possible, the sterically available conformational space. It should be emphasized that the orientations of both the *N*-acetylneuraminic acid and the fucose residue in bound ligands lead to transfer NOEs that differ considerably from those for free sialyl Lewis^x (Figs. 1 and 2).

The most important conclusions are that E-selectin complexes exclusively a conformation of sialyl Lewis^x from the conformational mixture in aqueous solution in which the neuraminic acid shows an orientation corresponding approximately to conformation A of Rutherford et al.[13] or conformation C of Ichikawa et al.[11b] and in which fucose differs in its orientation from that preferred in aqueous solution (cf. Fig. 3). From more precise evaluation of the transfer NOE data it is possible to derive possible conclusions as to the flexibility of the $\alpha(1 \rightarrow 3)$-glycosidic bond between the fucose and the *N*-acetylglucosamine residue. These results are used at present as a basis for the modeling of potent inhibitors for E-selectin receptors.

[8] The ectodomains of human E-selectin were combined by means of the polymerase chain reaction (PCR) with the Fc region of human IgG1, and subcloned in the expression vector pcDNAI/neo (Invitrogen). Following transfection of CHO-K1 cells (ATCC CCL-61) and selection with G418 (Gibco), a stable cell line was obtained which secreted ca. 25 $\mu g\,mL^{-1}$ recombinant E-selectin/hIgG. For the production of larger amounts this cell line was cultivated in a hollow fiber bioreactor (1.1 m^2, 50 mL, Cellco) in Opti. MEM culture medium (Gibco) supplemented with 2% fetal calf serum and 200 mL^{-1} gentamycin. The supernatant of conditioned cells was first purified by affinity chromatography on protein A/agarose (Sigma). The protein fraction obtained by elution with 20 mM glycine–HCl, pH 3.0, was neutralized and chromatographed directly on an anti-human-E-selectin affinity column (2 mg monoclonal antibody 7A9 per mL affigel). Specifically bound E-selectin/IgG was eluted with 5 M urea in buffered salt solution and finally dialyzed against Dubeccos PBS solution (PBS = phosphate buffered saline). The protein thus obtained showed, in SDS (sodium decyl sulfate) polyacrylamide gel electrophoresis under reducing conditions, a single band at ca. 140 kD. For NMR analysis ca. 6 mg E-selectin/hIgG was dialyzed against 50 mM perdeuterated imidazol (Sigma), 1 mM $CaCl_2$, pH 7.4, in D_2O and concentrated by means of Centricon YM-50 (Amicon) to a final volume of 0.5 mL.
[9] a) All NMR experiments were performed in the Institut für Biophysikalische Chemie der Universität Frankfurt on a Bruker DMX600 spectrometer. We wish to thank Prof. Dr. H. Rüterjans for the the opportunity to make the measurements. b) For the NMR experiments on the complex an E-selectin(IgG chimera)/tetrasaccharide ratio of 1:15 was chosen. The concentration of sialyl Lewis^x was 0.81 mM, that of E-selectin(IgG chimera) 54 μM. [D_4]Imidazole (30 mM) was used as buffer. In addition the solution contained NaCl (50 mM) and $CaCl_2$ (1 mM). The pH was 7.4. Spinlock filtered NOESY spectra [10] with mixing times τ_m of 25, 50, 75, 100, 125, 150, 175, and 200 ms were recorded at 600 MHz and 310 K. The relaxation time was 1.85 s. The spectral width was 3000 Hz (5 ppm) in all cases. 512 Increments in τ_1 were recorded. For each increment 32 transients were acquired each with 2K data points. After zero-filling and multiplication with squared cos functions in τ_1 and τ_2, a 2K × 1K data matrix was obtained by 2D Fourier transformation.
[10] T. Scherf, J. Anglister, *Biophys. J.* **1993**, *64*, 754–761.
[11] NOESY spectra of free E-selectin(IgG chimera) and sialyl Lewis^x tetrasaccharide were recorded as described in ref. [9] with the following changes. For free E-selectin mixing times τ_m of 50, 100, 150, 200, and 400 ms (with spinlock filter) were used; for free sialyl Lewis^x mixing times of 200, 300, 500, 600, 800, and 900 ms (without spinlock filter) were used. For free sialyl Lewis^x a measurement temperature of 303 K was chosen.

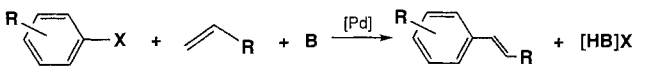
[19] The MMC simulations for sialyl Lewis^x were carried out with a temperature parameter of 2000 K and 1×10^6 macrosteps. The maximum step size was 20° (ϕ, ψ) and 25° (ω). The dihedral angles were defined as follows: ϕ = H1-C1-O1-Cx (for NeuNAc: C1-C2-O2-Cx), ψ = C1-O1-Cx-Hx (for NeuNAc: C2-O2-Cx-Hx), and ω = O5-C5-C6-O6 (for NeuNAc corresponding designations are used to indicate the orientation of the side chain). The acceptance ratio was 46%. The choice of a high temperature parameter ensured that all sterically possible conformations were considered. The evaluation of the MMC data and the extraction of the conformations that satisfied the experimentally determined distance restrictions (see Table 2) were performed with Fortran and MATLAB programs. All calculations were performed on a Silicon Graphics Indy II workstation.

Palladacycles as Structurally Defined Catalysts for the Heck Olefination of Chloro- and Bromoarenes**

Wolfgang A. Herrmann,* Christoph Brossmer, Karl Öfele, Claus-Peter Reisinger, Thomas Priermeier, Matthias Beller, and Hartmut Fischer

Dedicated to Professor Henri Brunner on the occasion of his 60th birthday

The Heck reaction has developed into a standard method of organic synthesis since its discovery in 1971.[1, 2] With it, styrene derivatives, amongst others, can be prepared as vinylic C–C coupling products in one step from iodo- and bromoarenes. Because the reaction is both regio- and stereoselective, it is often used in heterocycle and natural product chemistry.[3] The Heck reaction is also beginning to make headway in polymer chemistry.[4] However, attempts to submit the cheap chloroarenes to the Heck olefination were not an unqualified success.[5] We have found new, structurally defined, easy-to-handle palladium complexes, that surpass all previously known catalysts of the Heck reaction as regards stability and lifetime. They also enable the activation of chloroarenes.



X = Br, I
[Pd] = $Pd(CH_3CO_2)_2/P(C_6H_5)_3$
B = Base, e.g. $N(C_2H_5)_3$, K_2CO_3, $Na(CH_3CO_2)$

[**] Coordination Chemistry and Mechanisms of Metal-Catalyzed C–C Coupling Reactions, Part 5. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. Part 4: Ref. [7a].

In kinetic studies we discovered that the standard catalysts used virtually exclusively till now—comprising 1 mol% $Pd(OAc)_2$ and 2–6 mol% of a triaryl phosphane—are rapidly deactivated (Fig. 1) as a result of cleavage of the PC bond at the stage of the arylpalladium(II) halide at temperatures above 120 °C.[6, 7] This also causes the Pd deposits reported in the literature, because the constant PC cleavage depletes the system of (catalyst-stabilizing) phosphane. As is thoroughly confirmed, this degradation thwarted the application of these catalysts with technically particularly interesting chloroarenes, as well as deactivated bromoarenes.[6, 7]

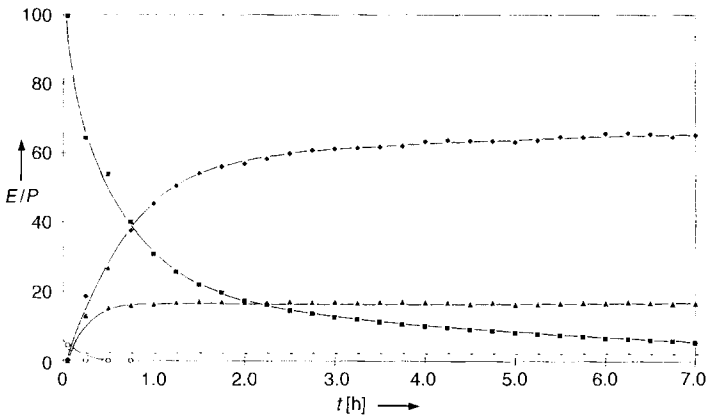

Fig. 1. Diagram of the concentration (C in mol%) vs. reaction time (t) of the Heck olefination of 4-bromoanisole (■) with n-butyl acrylate at 140 °C to form n-butyl 4-methoxycinnamate (●); catalyst $Pd(OAc)_2 + 4P(C_6H_5)_3$ (Pd/P = 1/4); for details see [7b]. The rapid cleavage of the PC bond is evident in the formation of n-butyl E-cinnamate (▲), which correlates with the degradation of the ligand $P(C_6H_5)$ (○). For this reason by-products containing the aryl groups of the particular phosphane are formed. In addition triphenylphosphane oxide forms (---).

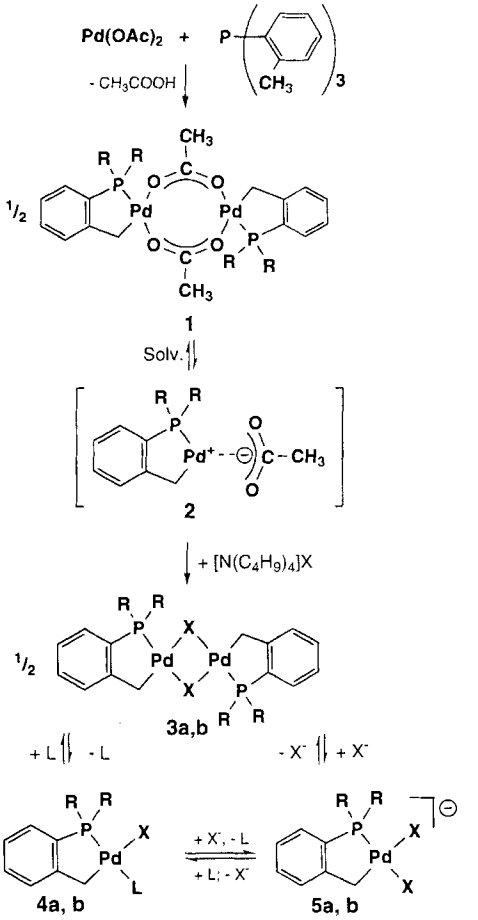

Scheme 1. Ac = CH_3CO_2; R = o-tolyl; L = DMSO, DMF, CH_3CN, $P(C_6H_5)_3$, pyridine; **a**, X = Cl; **b**, X = Br. **3b′**: as **3b**, but R = mesityl; **4b′**: L = DMF.

Treatment of palladium(II) acetate with tris(o-tolyl)phosphane in toluene affords the cyclometalation product **1** (R = o-tolyl) in 93% yield according to Scheme 1. The crystal packing and molecular structure of **1** are shown in Figure 2.[8] The approximately C_2-symmetric, dinuclear molecule has two acetate bridges which brings the two metal centers to within 311.5 pm, a nonbonding distance. In solution the cyclopalladated five-membered moieties are preserved, but the more weakly bound acetate ligands enter into monomer/dimer equilibria in which the solvent molecules are involved (^{31}P and ^1H NMR studies). The substituents R are variable (for example, o-xylyl, C_6H_5, iC_4H_9, cC_6H_{11}); tris(mesityl)phosphane also yields a palladacycle analogous to **1**.

The palladacycles **1** and **3a,b** are thermally about 100 °C more stable than conventional adducts like **6** and **7**. According to

$[Pd\{P(C_6H_5)_3\}_2(OAc)_2]$ **6**

$[Pd_2\{P(C_6H_5)_3\}_2(\mu\text{-}OAc)_2(OAc)_2]$ **7**

TG/MS studies, **1** and **3a,b** decompose only above 250 °C. Cyclometalated Pd^{II}–phosphane complexes like **1** have proven to be the most active catalysts for the Heck reaction of arenes. Figure 3 shows that for the system 4-bromoanisole/n-butyl acrylate the isolated catalyst **1**, is more active and productive than a conventional "in situ catalyst", produced from equimolar amounts of $Pd(OAc)_2$ and $P(o\text{-tol})_3$ and thus having the identical Pd/P ratio (Table 1).

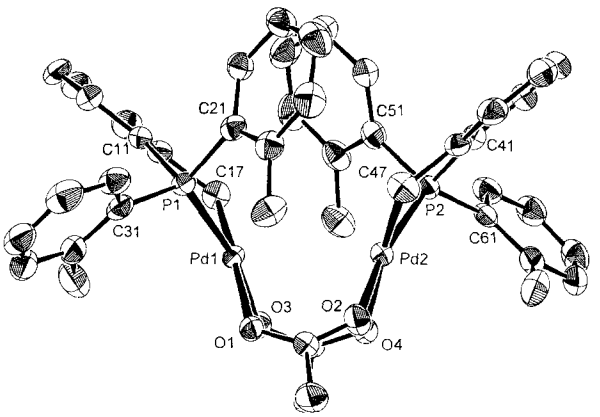

Fig. 2. PLATON representation of the crystal structure of the cyclometalation product **1** (single-crystal X-ray analysis) [8]. The thermal ellipsoids correspond to 50% probability; only one of the two independent molecules in the asymmetric unit is depicted. CH_2Cl_2 found in the unit cell is not shown. Selected distances [pm] and angles [°]: Pd1-C17 202.1(5), Pd1-O1 214.7(3), Pd1-O3 211.1(3), Pd1-P1 221.6(1), Pd2-C47 203.5(5), Pd2-P2 221.3(1), C16-C17 150.6(7); P1-Pd1-C17 82.3(2), O3-Pd1-O1 87.9(1), O1-Pd1-C17 175.8(2).

The new catalysts have the following advantages:

1) Palladium deposits, notorious in Heck reactions and formed because of the higher temperatures (usually 100–140 °C), are observed either not at all, or only in trace amounts (after longer reaction times of more than 25 h). This alone explains

Table 1. Heck olefinations of haloarenes with palladacycles as catalysts. Compound **3b′** is the same as **3b**, but with R = mesityl instead of *o*-tolyl. Reaction conditions: 50(100) mmol haloarene, 70(140) mmol *n*-butyl acrylate, 55(110) mmol sodium acetate (dry), 50(100) mL dimethylacetamide, 1 g(2 g) diethyleneglycol di-*n*-butyl ether (GC standard).

[a] Determined by GC, based on haloarene. [b] TON = turnover number [mol product per mol catalyst].

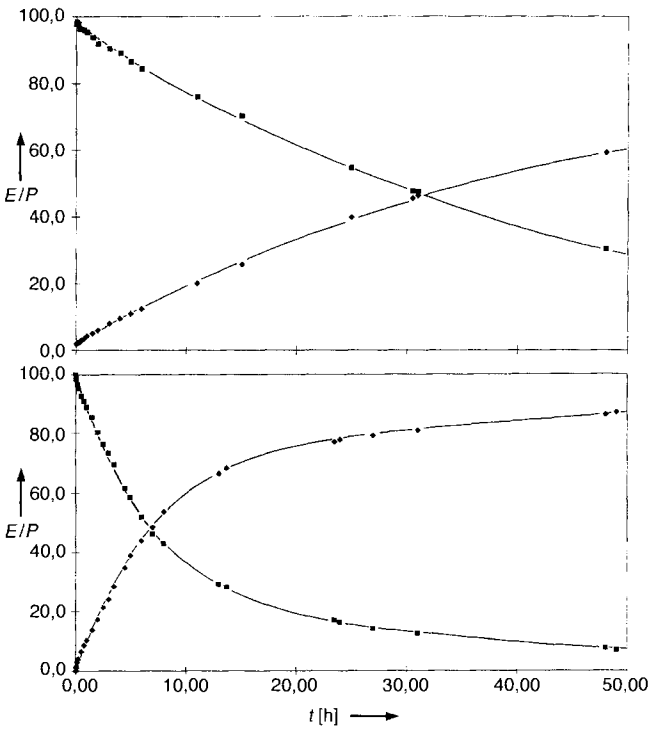

Fig. 3. Diagram of concentration (*C* in mol%) vs. reaction time (*t*) for the Heck olefination of 4-bromoanisole (deactivated bromoarene) with *n*-butyl acrylate at 140 °C; for reaction conditions see Table 1. The decrease in the concentration of the starting material 4-bromoanisole (■) and the increase in the concentration of the product *n*-butyl (*E*)-4-methoxycinnamate (◆) are shown. Top: In situ catalyst $Pd(OAc)_2$/P(*o*-Tol)$_3$ with Pd/P = 1/1 (1 mol% Pd); bottom: palladacycle **1** as catalyst (1 mol% Pd).

the increased lifetimes (long-term stability), because in no form is elemental palladium a reasonably active Heck catalyst.[9]

2) Relative to the catalyst systems $Pd(OAc)_2$ + *n* phosphane (*n* = 2–6) in common practice, they offer a saving of several phosphane equivalents.
3) The turnover numbers (TON) with bromoarenes (for example, 4-bromobenzaldehyde) reach values of 200000 [mol product per mol **1**], and the catalytic turnover frequencies (TOF) lie in the range 5000–50000 [mol product per mol **1** per hour] (Table 1).
4) Palladacycles like **1** can be used as catalysts *without* addition of phosphane: Whereas a major proportion of palladium precipitates from the $Pd(OAc)_2$/P(*o*-tolyl)$_3$ (Pd/P = 1:1) system as the element at 140 °C, **1** is stable at this temperature for days without added phosphane. Unusually small concentrations of catalyst (about 5×10^{-3} mol%) are sufficient for Heck coupling of activated bromoarenes, while up to now 0.5–5 mol% were required.
5) PC bond cleavage is insignificant at the commonest reaction temperatures around 130 °C, with the result that no yield-reducing by-products are formed.
6) Many variants of the effective structural principle of metallacyclic stabilization are possible. Compounds of this type catalyze, for instance, the Suzuki coupling of aryl boronic acids.[10]

The acetate-bridged palladacycle **1** becomes catalytically active at about 80 °C. Significant mechanistic aspects are that in Heck olefinations the bromoarenes undergo an acetate/bromide exchange at the beginning of the reaction. With increasing conversion *x*, the anionic complex **5b** is formed towards the end as a result of increasing Br^- concentration (Fig. 4). After the reaction the bromine-bridged derivative **3b**, which crystallizes well, can be isolated from the cold reaction mixture. Instead of **1**, **3b** can also be used as catalyst (cf. Scheme 1).

Interestingly, in reactions with **1** as catalyst, chloroarenes give rise to palladium deposits above 120 °C. However, the addition of special salts, in particular alkali metal salts and tetrabutylammonium bromide, leads to a substantial stabilization of the catalyst. As a result of the higher temperatures thus achievable (130–140 °C), the conversion increases. In the Heck coupling with 4-chlorobenzaldehyde, 80% butyl (*E*)-4-formylcinnamate was obtained at a TON of 600–800. By-products were not detected (no cleavage of the P–C bond). The salt effect is due to

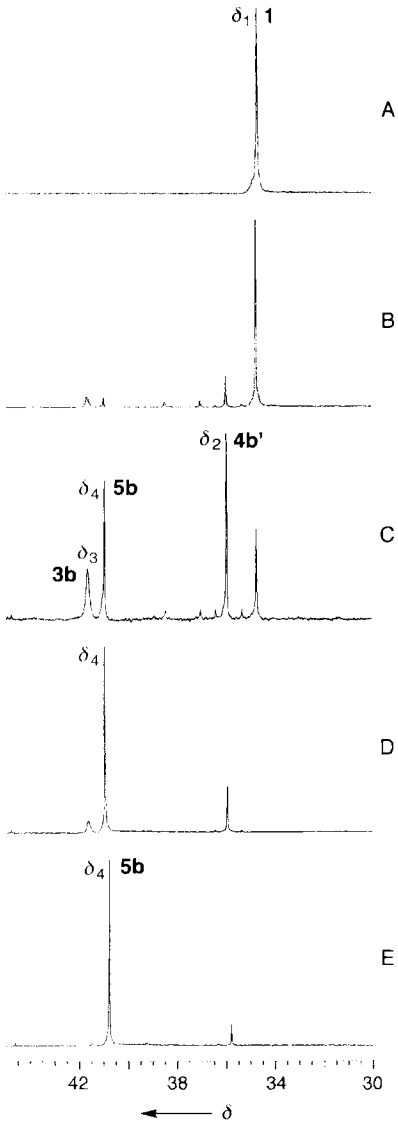

Fig. 4. $^{31}P\{^1H\}$ NMR investigation (−40 °C, [D$_7$]DMF, 161.85 MHz) on the Heck olefination of 4-bromobenzaldehyde with *n*-butyl acrylate in [D$_7$]DMF; T = 80 °C, **1** as catalyst. A: At the start (conversion x = 0), B: after 10 min (x = 2%), C: after 1 h (x = 5%), D: after 1.5 h (x = 8%), E: after 5 h (x = 10–12%). For formulas see Scheme 1.

the action of bromide ions and appears to be a concept that can be extended to optimize the new catalyst generation further.

The accelerating effect of *o*-tolyl groups in the Heck coupling has till now been explained by the steric effect of *ortho* substitution,[11a] and palladacycles were excluded as active species.[11b] This interpretation has now finally been refuted. In fact, the PC chelate structures, described here for the first time, actually compete sucessfully with the conventional electron-rich P ligands.[5a, b]

Our results suggest that, contrary to the existing textbook opinion,[12] no uniform mechanism forms the basis of the Heck reaction. Whereas the earlier assumption was that the phosphane ligands reduce the Pd^{II} salts to Pd^0 complexes at which the actual activation of the bromoarenes begins with oxidative addition,[2, 5e, 11, 12] no evidence points to a reduction of **1** and the active species derived from it under the conditions of the Heck reaction. A $Pd^{II} \rightarrow Pd^{IV}$ step also seems possible.[13] It is conspicuous that the new catalysts react with bromoarenes only when the olefin is present.

The extension of the new catalyst principle to other metallacycles (for example, rhodium) and to other carbon–carbon and carbon–heteratom coupling reactions is in progress.[14]

Experimental Procedure

1) *trans*-Di(μ-acetato)-bis[*o*-(di-*o*-tolylphosphino)benzyl]dipalladium(II) (**1**): $Pd(OAc)_2$ (4.50 g, 20.0 mmol) was dissolved in toluene (500 mL). The red-brown solution was treated with tris(*o*-tolyl)phosphane (8.00 g, 26.3 mmol). The solution, which rapidly bleached to light orange, was heated to 50 °C for 3 min and then cooled to 25 °C. The solution was reduced under vacuum to a quarter of its volume. After addition of *n*-hexane (500 mL), the precipitate was filtered off and dried under vacuum. Yield 8.80 g (93%), yellow solid. Crystallization from toluene/*n*-hexane or dichloromethane/*n*-hexane and filtration of the solution over Celite affords analytically pure, crystalline **1**.

2) Catalyst solution: **1** (5×10^{-4}–0.5 mmol) was dissolved in *N*,*N*-dimethylacetamide (DMA). The catalyst solution was degassed and purged with argon several times before use.

3) Catalytic procedure: The haloarene (50 mmol), dry sodium acetate (4.51 g, 55 mmol), and diethyleneglycol di-*n*-butyl ether (1.00 g) were placed in a 100 mL three-necked flask fitted with a septum, interior thermometer, and a condensor (with mercury check valve). After repeated degassing under oil-pump vacuum and purging with argon, *n*-butyl acrylate (10 mL, 70 mmol) was injected through the septum. The batch was heated to 100 °C. When the temperature was reached, a freshly prepared solution of **1** (see above) was injected, and the reaction mixture heated to the final reaction temperature. The course of the reaction was monitored by removing 500 μL samples after 1, 3, 6, and 24 hours, washing them with 5% HCl solution, and extracting them with 3.5 mL dichloromethane. The organic phases were transferred to GC sample bottles and analysed by gas chromatography (GC/FID, GC–MS, GC–IR–MS). The reaction is worked up by addition of water and extraction of the organic phases with CH_2Cl_2 or ether. After drying ($MgSO_4$) and removal of the solvent (CH_2Cl_2, Et_2O, DMA), the products are purified by distillation or recrystallization.

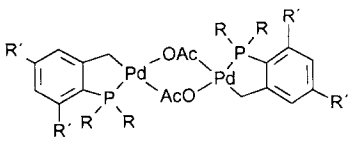
Palladacycles as Efficient Catalysts for Aryl Coupling Reactions**

Matthias Beller,* Hartmut Fischer, Wolfgang A. Herrmann, Karl Öfele, and Christoph Brossmer

In recent years a large number of palladium-mediated syntheses for complex synthetic building blocks and also for structurally simple industrially important intermediate products have been found and further developed.[1] Commercially available palladium compounds in the presence of different ligands were often used as catalysts. However, the quality of the used catalysts[2] is generally not sufficient for industrial demands. "Real" catalytic reactions of palladium complexes in the field of C–C couplings with turnover numbers (TON) larger than 10000 were described only in exceptional cases. Just recently, with the palladacycles **1** a new structure principle was discovered for Heck reactions, which allows TON > 100000.[3]



1a, b

a, R = o-tolyl, R' = T H
b, R = mesityl, R' = CH_3

As a result of the increasing importance of unsymmetrically substituted biaryl derivatives, for example as drug intermediates,[4] we were interested in the transferability of the catalytic properties of the complexes **1a, b** to the cross coupling between aryl halides and arylboronic acids.[5] We show here that palladacycles **1** catalyze this type of reaction known as Suzuki coupling with an unusual efficiency.

[**] Coordination Chemistry and Mechanisms of Metal-Catalyzed C–C Coupling Reactions, Part 6. The authors thank Mrs. Susanne Klein for her support with the experimental work. - Part 5: Ref. [3]

When 4-bromoacetophenone **2a** is treated with phenylboronic acid **3** under conditions analogous to the Heck olefination (solvent: dimethylacetamide; 1.1 molar equivalents sodium acetate as base),[3] only low turnovers (< 40%) were observed to give the desired 4-acetylbiphenyl **4a**, even after 24 h at temperatures > 130 °C and in the presence of 0.1 mol% **1a**. However, under different reaction conditions (see Table 1)[6] this product forms in over 90% yield. Turnover numbers up to 75000 with good yields (75%) were achieved with only 0.001 mol% **1a** as catalyst. Thus, the palladacycles are the most active catalysts which are known for aryl couplings catalyzed by organometallic compounds. In contrast to traditional Suzuki reactions, which were carried out with triphenylphosphanepalladium complexes $[Pd(PR_3)_n]$,[7] we did not observe any aryl scrambling at the catalyst or the associated unselective aryl transfer of the phosphane to side products.[7a, 8] Only biphenyl was detected as a minor side product in the crude solutions (< 5%, GC). A comparison of the reaction of several bromoarenes with phenylboronic acid makes it clear that the reactions occur in a similar way regardless of the substitution pattern of the arene. Thus under standard conditions (Table 1) TON of 65000–74000 were obtained both for 4-bromoacetophenone **2a** and for 4-bromoanisole **2d** (yields > 65%).

[a] mol% catalyst related to used haloarenes.

From this it follows that the oxidative insertion of the catalyst species into the aryl–halogen bond is not the rate-determining step in contrast to the situation in the Heck reaction.[3] With regard to the reaction mechanism we did not find any indication of an intermediate reduction to an active palladium(0) intermediate. Associated coupling products between the benzylic carbon atom of the ligand and the phenyl or aryl group could not be isolated. Thus Pd^{II}/Pd^{IV} intermediates have to be considered as essential intermediates in the catalysis.[9]

For the conversion of **2e** to **4e**, a catalyst system prepared in situ from 0.01 mol% palladium acetate and 0.01 mol% tri-*o*-tolylphosphane was used. In this case the yield (38%) was significantly lower than that from the direct use of **1a** (83%). Fur-

thermore, after only a short time at 130 °C palladium deposition was observed. Since under standard conditions a 50% excess of phenylboronic acid **3** was used, the reaction of **2a** to **4a** was carried out with a 1 molar equivalent (with respect to the aryl halide) of phenylboronic acid. It was shown that the yield (69%) was only marginally less than that obtained from reaction 2 in Table 1 (74%).

Since the application of the less reactive chloroarenes was particularly desirably from an industrial point of view, we investigated the reaction of 4-chloroacetophenone **2f** with phenylboronic acid **3** (reaction 8 and 9). Surprisingly, this reaction which was carried out in *o*-xylene with 2 molar equivalents of potassium carbonate as base is likewise directly catalyzed with 0.1 mol% **1a**. The desired product 4-acetylbiphenyl **4a** is isolated in 82% yield! Even when the amount of catalyst used is reduced by a power of ten, 21% of **4a** is still isolated, the corresponding turnover number is 2100. Such excellent activations of chloroarenes to aryl coupling are possible for the first time with palladacycles: as expected the comparable reaction with 0.1 mol% palladium acetate and 0.1 mol% triphenylphosphane under otherwise analogous conditions does not yield[5a, e] the desired product (< 1% **4a**).

Our investigations show that the use of palladacycles of type **1** is by no means limited to the Heck reaction.[3] On the contrary, this is a new general type of catalyst, which with regard to its efficiency exceeds all previously described catalyst systems for aryl couplings[5, 10] and which because of its single site character should allow for a rational further development. The evaluation of additional catalysis potential as well as the extension of the chloroarene activation with these new catalyst systems are in progress.[11]

Experimental Procedure

Aryl halide **2** (100 mmol), phenylboronic acid **3** (150 mmol), and potassium carbonate (200 mmol) were heated for 16 h at 130 °C with 0.01 mmol **1a** in *o*-xylene (200 mL). Subsequently the cooled reaction mixture was extracted twice with H_2O (100 mL) and the organic phase was separated. The solvent was removed under vacuum and the crude product was purified by chromatography on silica gel or by recrystallization.

Carbenoid or Lithium Complex of a Carbanion? Synthesis and Structure of $(Me_3Si)_2C{=}P(aryl){=}C(Cl)Li(thf)_3$ and LiCl Elimination To Give the Phosphirene**

Edgar Niecke,* Petra Becker, Martin Nieger, Dietmar Stalke, and Wolfgang W. Schoeller

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

The unusual reactivity of carbenoids towards both electrophiles and nucleophiles has made them important for organic synthesis up to the present day.[1] Their unusual bonding, which was substantiated experimentally by the elucidation of a structure of an alkylidenecarbenoid,[2] has been the subject of numerous theoretical studies.[3] Of particular interest is the integration of the carbenoid center in a pπ-electron system[4] and thus the possibility of an intramolecular rearrangement (Fritsch–Buttenberg–Wiechell rearrangement[5]). Phosphanylcarbenoids also undergo a rearrangement of this kind;[6] these compounds are of increasing interest as synthetic building blocks in organophosphorus chemistry.[7]

In the context of our work on anions containing a P–C pπ-bond,[8] we have been interested in ylene(phosphoranylidene)carbenoids, in which the "carbenoid" center as a component of a delocalized four-electron–three-center pπ-system appears to be capable of reacting in numerous ways.[9] We report here on the synthesis and X-ray structure analysis of a methylene(phosphoranylidene)carbenoid, which forms a phosphirene with the elimination of LiCl and ring closure.

The bis(methylene)phosphorane **2**, prepared by the treatment of aryl[bis(trimethylsilyl)methylene]phosphane (**1**)[10] with trichloromethyllithium,[11] reacts with n-butyllithium in THF at −80 °C to give the two carbenoids **3a**,**b** (**3a**:**3b** = 1:6), which

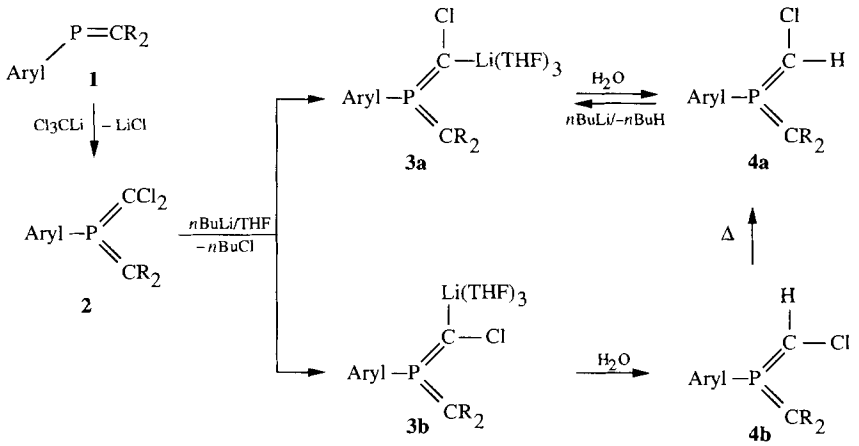

Scheme 1. Aryl = 2,4,6-tBu$_3$C$_6$H$_2$; R = SiMe$_3$.

were characterized by their low-temperature NMR spectra (Scheme 1). Quenching the reaction solution with water at $-50\,^{\circ}C$ affords the two bis(methylene)phosphoranes **4a,b** (in the ratio 1:6); above $0\,^{\circ}C$ **4b** rearranges into the thermodynamically more stable form **4a**. This product can be isolated in the form of pale yellow single crystals. The H/Li exchange in **4a** (n-butyllithium/THF, $-80\,^{\circ}C$) leads selectively to the carbenoid **3a** only, single crystals of which suitable for X-ray structure analysis can be obtained at $-60\,^{\circ}C$.

Figure 1 shows the molecular structure[12] of bis(methylene)-phosphorane **4a**. Like in all known bis(methylene)phosphoranes the phosphorus atom is trigonal-planar coordinated.

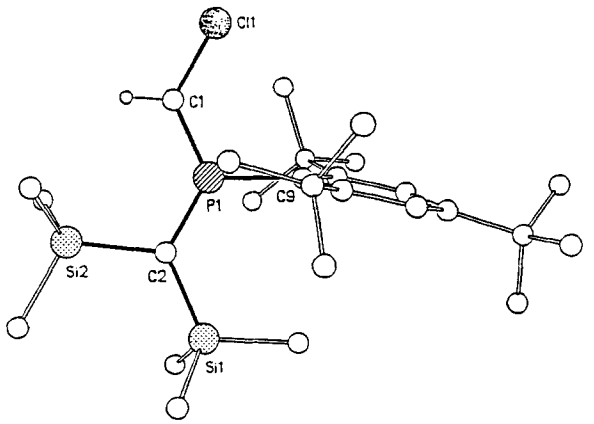

Fig. 1. Molecular structure of **4a** in the crystal. Selected bond lengths [pm] and angles [°]: P1-C1 164.5(7), P1-C2 165.6(6), P1-C9 181.6(5), C1-Cl1 171.2(8), C2-Si1 185.7(6), C2-Si2 188.6(5); C1-P1-C2 125.2(4), C1-P1-C9 115.1(3), C2-P1-C9 119.6(3), P1-C1-Cl1 123.4(5), P1-C2-Si1 126.5(3), P1-C2-Si2 113.3(3), Si1-C2-Si2 119.8(3).

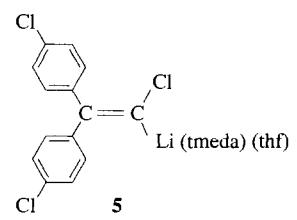
The hydrogen atom is in *endo* position, which, in agreement with the isomerization **4b** → **4a**, shows **4a** to be the energetically more favored form. In this conformation the twisting of the two methylene carbon units, as observed for bis(methylene)phosphoranes with sterically demanding substituents,[13] is avoided. Steric conditions are also responsible for the almost ideal orthogonal alignment of the aryl group with regard to the PC_2 unit. The bond angle at the phosphorus center (C1-P1-C2 125.2(4)°) and the lengths of the bonds to the sp^2 hybridized carbon centers (P1–C9 181.6(5), P1–C1 164.5(7), P1–C2 165.6(6) pm) correspond to those of comparably substituted compounds.[13]

The structural changes during the metal substitution of **4a** to give **3a** are shown in Figure 2.[12] As in **4a** the geometry of the central PC_3 framework in **3a** is determined by the formation of a delocalized π-electron system extending over three centers; the atoms $Si_2CP(C)CCl(Li)$ lie in the same plane ($\sigma = 0.054$ Å). The large P1-C1-Li1 angle (155.7(5)°) is unusual; this angle is mainly compensated by a compression of the Cl1-C1-Li1 angle to 94.8(4)° (and from P1-C1-Cl1 to 109.4(3)°). This is accompanied with a significantly longer C1–Cl1 distance (181.6(6) pm) than that in **4a** (171.2(8) pm). However, the approach of the Li atom to the Cl atom (296(1) pm) caused by this structure is not sufficient for a binding interaction between these atoms.[14] The angle deformations at the "carbenoid" center here exceed that in the alkylidenecarbenoid **5** (C-C-Li 137, Cl-C-Li 109°). The comparatively longer C–Li (219.3 pm) and shorter C–Cl distances (**3a**: 181.6; **5**: C–Li 214.4, C–Cl 185.5 pm[2]) indicate a stronger nucleophilic character of **3a**.[15] In contrast, the effects of the structural changes in the bis(ylene) unit in comparison to **4a** are small. For a similar central bond angle (C-P-C 124.7(3)°) only a small increase of the two P–C bond lengths (167.1(6), 167.5(5) pm) is observed. Noteworthy is the relatively short C–Si(*exo*) distance (182.0(6) vs. 185.7(6) pm in **4a**), which indicates a hyperconjugative charge stabilization in **3a**.[16] The lithium atom attains the coordination number four by solvatation with three THF molecules. The observed distortion of the pyramidal LiO_3 geometry (O-Li-O: 97, 99, 111°) and the different C-Li-O bond angles (106, 108, 135°) should be attributed to steric effects. The Li–O distances (196–202 pm) are not unusual. An inter-



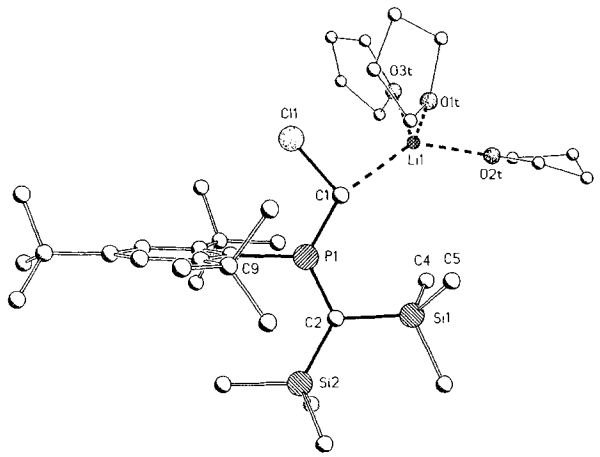


Fig. 2. Molecular structure of **3a** in the crystal. Selected bond lengths [pm] and angles [°]: P1-C1 167.1(6), P1-C2 167.5(5), P1-C9 181.7(5), C1-Cl1 181.6(6), C1-Li1 219.3(12), C2-Si1 186.8(6), C2-Si2 182.0(6), Li1-O1t 196.3(13), Li1-O2t 200.9(12), Li-O3t 201.6(12); C1-P1-C2 124.7(3), C1-P1-C9 118.1(3), C2-P1-C9 117.1(3), P1-C1-Li1 155.7(5), P1-C1-Cl1 109.4(3), Cl1-C1-Li1 94.8(4), P1-C2-Si1 113.6(3), P1-C2-Si2 126.9(3), Si1-C2-Si2 119.0(3), O1t-Li1-O2t 96.8(5), O1t-Li1-O3t 111.0(6), O2t-Li1-O3t 99.3(5), C1-Li1-O1t 105.9(6), C1-Li1-O2t 134.7(6), C1-Li1-O3t 107.9(5).

molecular Li···Cl interaction cannot be deduced from the observed packing of the molecules in the crystal lattice.

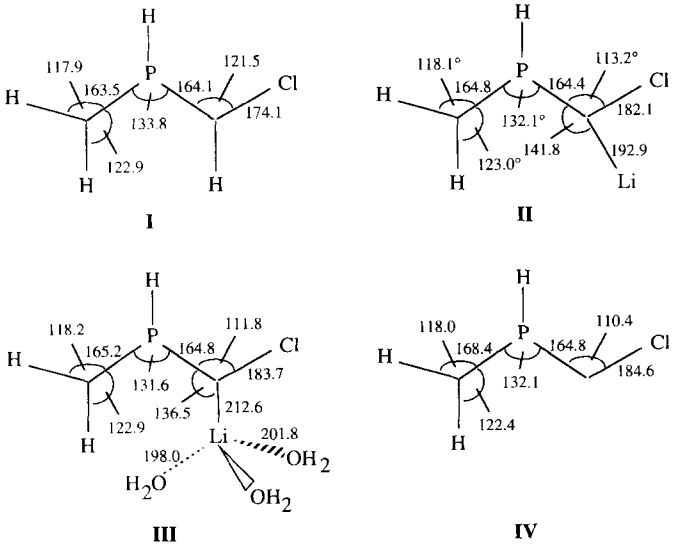
From the structures of **3a** and **4a** as well as the results of multinuclear NMR measurements (Table 1) it follows that **3b** and **4b** are the corresponding stereoisomers with an *endo*-chlorine atom; additional solvent molecules (THF) should be coordinated to the lithium atom also in **3b**. The ^{31}P and ^{13}C NMR data of the protonated compounds **4** are typical for this class of compounds.[13, 17] The different chemical environment of the

Table 1. Relevant chemical shifts δ and coupling constants J of **3** and **4**.

	$\delta^{31}P$ ($^2J_{PH/PLi}$)	$\delta^{13}C$ ($^1J_{CP}$)	
		P=C(Li/H)Cl	P=C(SiMe$_3$)$_2$
3a	164 (br., <5 Hz)	147.3 (93 Hz)	40.0 (18.3 Hz)
4a	147 (33.8 Hz)	79.5 (137 Hz)	50.3 (48.5 Hz)
3b	146 (19 Hz)	139.7 (96 Hz)	49.7 (10 Hz)
4b	134 (35.3 Hz)	77.7 (139.5 Hz)	50.0 (42 Hz)

carbon atoms in the "allyl anion system"[18] leads to an asymmetric charge distribution; the silyl groups are more capable of stabilizing the negative charge. The high field position of the corresponding ^{13}C NMR signal correlates with a significantly smaller value for the coupling constant J_{CP}. As expected, changes in the ^{13}C chemical shifts in the metal substitution to **3** are evident with a strong deshielding of the neighboring ^{13}C nucleus ($\Delta\delta$ = 67.8 **3a/4a** and 62.0 **3b/4b**, respectively). A comparable change in chemical shift on metalation is documented for halogen lithium vinylidenecarbenoids (e.g. H(Cl)C=C(H)Cl/H(Cl)C=C(Li)Cl: $\Delta\delta$ = 68[19]). There is an apparent decrease of the coupling constants J_{PC} in the conversion of **4** to **3**, which indicates a weakening of the P=C bond in the allyl system. Surprisingly, the different stereochemistry of the hydrogen atoms in **4** is not apparent from the value of $^2J_{HP}$, whereas the well-resolved ^{31}P-^7Li coupling constant (19 Hz) in **3b**, in contrast to that of **3a**, (for comparable line width, $\nu_{1/2}$ = 5 Hz) is possibly attributed to differences in the bonding at the carbenoid center.[20]

Quantum chemical ab initio calculations[21] on the model compounds **I**, **II**, **IV**, and **III** (for the modeling of solvation effect[24]) gave the following trends (Scheme 2). The formal

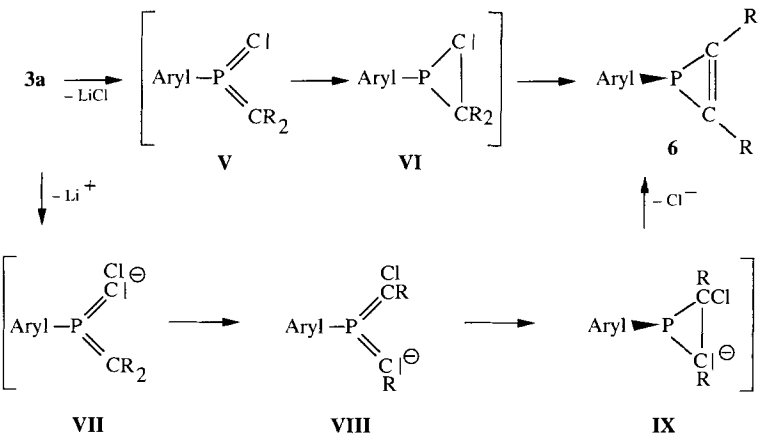


Scheme 2. Optimized geometries of the model compounds **I**–**IV**.

replacement of H by Li (**I** → **II**) leads to a significant reduction of the P-C-Cl angle (Δ 8.3°) which is accompanied by a considerable increase in the length of the P–Cl bond (Δ 8.0 pm). The C–Li distance in **II** (192.9 pm) indicates a relatively "strong" bond between these two atoms. The influence of solvation (**II** → **III**) as expected is apparent in a considerable extension of the C–Li bond (Δ 19.8 pm). The associated structural changes in the P-C-Cl angle and the r(P–Cl) bond are comparatively small, and in the series **II** → **III** → **IV** a slight compression of the angle is accompanied by a small bond extension. Population analysis implies the formal "kinship" of the solvate **III** with the free carbanion **IV**; some of the excess charge is stabilized by the allyl system.[25]

However, the carbenoid character of the remarkably stable "carbenoid" **3a** is apparent in the LiCl elimination, which in solution occurs above −10 °C and leads to the λ^3-phosphirene **6**, whose constitution is confirmed by the NMR data typical for this type of compound[26] ($\delta(^{31}P) = -184$; $\delta(^{13}C) = 159.4$, $^1J_{C,P} = 71.4$ Hz).

Model calculations[27] on the postulated neutral intermediates **V** ($H_2C{=}P(H){=}C$, $^1A'$ state)[28] and **VI** ($HP\dot{C}H_2\dot{C}$, ^1A state) deriving from an LiCl elimination however gave very high energy structures for them (**V**: 111; **VI**: 48 kcal mol^{-1}; relative to the



λ^3-phosphirene $HP(CH)_2$). This finding therefore makes a two-step elimination with the integration of a carbanionic intermediate **VII** as primary step of the reaction seem more likely. In a subsequent 1,3-silyl group shift the "carbanion" **VII** should rearrange to give the more stable isomer **VIII**, which by ring closure forms the phosphirane anion **IX**. The subsequent chloride elimination affords the phosphirene **6**.[29]

Experimental Procedure

2: A solution of CH_3Cl (0.47 g, 4 mmol) in THF (40 mL) and ether (10 mL) was treated with *n*BuLi (4.4 mmol, in *n*-hexane (c = 1.6 mol L^{-1})) at −100 °C. This was stirred for 1 h and then added dropwise to a solution of **1** (1.51 g, 3.5 mmol) in ether (10 mL). After the solution was allowed to warm to 25 °C, the volatiles were removed under vacuum, the residue was taken up in pentane, and the insoluble material (LiCl) was separated by filtration. Compound **2** crystallized from the concentrated filtrate at 25 °C. Yield: 78%; m.p. 140–142 °C. NMR (without aryl group): $^{31}P\{^1H\}$ NMR (ext.): δ = 127 (s); ^1H NMR (C_6D_6): δ = 0.6 (s, $SiMe_3$), 0.11 (s, $SiMe_3$); ^{13}C NMR (C_6D_6): δ = 90.0 (d, ^1J(C,P) = 156 Hz, $PCCl_2$), 54.5 (d, ^1J(C,P) = 48.5 Hz, $PC(SiMe_3)_2$), 4.8 (d, ^4J(C,P) = 4.7 Hz, $PCSiC_3$), 4.3 (d, ^4J(C,P) = 4.8 Hz, $PC(SiC_3)$); MS (70 eV) m/z (%): 516 (11) [M^+], 73 (100) [$SiMe_3$].

4a [**3b**, **4b**]: **2** (0.15 mg, 0.3 mmol) was dissolved in THF (3 mL), and then metalated with *n*BuLi (0.2 mL, 0.33 mmol, in hexane (c = 1.6 mol L^{-1})) at −78 °C in 10 min under constant stirring. The deep red reaction solution was subsequently quenched with H_2O (0.005 mL, 0.3 mmol) at −78 °C. After the solution was allowed to warm to 25 °C the solvent was removed under vacuum, the residue was taken up in a little pentane, and the solution was filtered through Celite. Compound

4a crystallized as yellow crystals from the yellow solution after 2 d at + 2 °C. Yield: 97%; m.p. 129–131 °C. NMR (25 °C; without aryl group): ^{31}P NMR (ext.): $\delta = 147$ (d, ^2J(P,H) = 33.8 Hz, PCHCl); ^{1}H NMR (C_6D_6): $\delta = 4.9$ (d, ^2J(H,P) = 34 Hz, PCHCl), 0.47 (s, $SiMe_3$), 0.07 (s, $SiMe_3$); ^{13}C NMR (C_6D_6): $\delta = 79.5$ (d, ^1J(C,P) = 137.1 Hz, PCHCl), 50.3 (d, ^1J(C,P) = 48.5 Hz, $PC(SiMe_3)_2$), 3.8 (d, ^4J(C,P) = 4.6 Hz, $PCSiC_3$), 1.9 (d, ^4J(C,P) = 5.7 Hz, $PC(SiC_3)$); MS (70 eV) *m/z* (%): 482 (6) [M^+], 73 (100) [$SiMe_3$].

The NMR spectroscopic characterization of the deep red reaction solution at −60 °C shows the preferred formation (> 85%) of the carbenoid **3b** (by product **3a**, < 15%). NMR (THF, −60 °C; without aryl group): ^{31}P{^{1}H} NMR (ext.): $\delta = 146$ (q, ^2J(P,Li) = 19 Hz; ^{13}C NMR ([D_8]THF): $\delta = 139.7$ (d, ^1J(C,P) = 96.1 Hz, PCLiCl), 49.7 (d, ^1J(C,P) = 10 Hz, $PC(SiMe_3)_2$), 6.1 (s, $PCSiC_3$), 4.6 (s, $PC(SiC_3)$).

The NMR spectroscopic characterization of **4b** was undertaken from the reaction solution of **3a** (**3b**) quenched with water at −20 °C. As a result of the isomerization **4b** → **4a** only occuring above 0 °C, there was a high excess of **4b** (< 85%). NMR data, without aryl group: ^{31}P NMR (ext.): $\delta = 134$ (d, ^2J(P,H) = 35.3 Hz, PCHCl); ^{1}H ([D_8]THF): $\delta = 4.2$ (d, ^2J(H,P) = 35 Hz, PCHCl), 0.35 (s, $SiMe_3$), 0.26 (s, $SiMe_3$); ^{13}C NMR ([D_8]THF): $\delta = 77.7$ (d, J(C,P) = 139.6 Hz, PCClH), 50.0 (d, J(C,P) = 42 Hz, $PC(SiMe_3)_2$), 4.8 (br, $PC(SiC_3)$), 3.6 (br, $PC(SiC_3)$).

3a and **5**: **4a** (0.14 mg, 0.3 mmol) was dissolved in THF (3 mL). The reaction solution was deprotonated at −78 °C with *n*BuLi (0.2 mL, 0.33 mmol in hexane (c = 1.6 mol L^{-1})) under constant stirring. Yellow crystals suitable for X-ray structure analysis were obtained from the deep red reaction solution after 4 months at −78 °C. **3a**: NMR (THF; −60 °C; without aryl group): ^{31}P{^{1}H} NMR (ext.): $\delta = 164$ (br); ^{13}C NMR ([D_8]THF): $\delta = 147.3$ (d, ^1J(C,P) = 93 Hz, PCClLi), 40.0 (d, ^1J(C,P) = 18.3 Hz, $PC(SiMe_3)_2$), 4.6 (s, $PCSiC_3$), 4.0 (s, $PC(SiC_3)$).

If, after the reaction mixture was allowed to warm to room temperature, the solvent was removed under vacuum, the residue was taken up in pentane, and the insoluble material (LiCl) was separated by filtration over Celite, **5** was obtained as a yellow-brown oil. **5**: Yield: 91%, b.p. 90–92 °C/10^{-2} Torr. NMR (25 °C; without aryl group): ^{31}P{^{1}H} NMR (ext.) $\delta = -184$(s); ^{1}H NMR (C_6D_6): $\delta = 0.23$ (s, $SiMe_3$), 0.20 (s, $SiMe_3$); ^{13}C NMR (C_6D_6): $\delta = 159.4$ (d, 71.4 Hz, $PCSiMe_3$), 0.07 (s, $PC(SiC_3)$); MS (70 eV) *m/z* (%): 446 (6) [M^+], 73 (100) [$SiMe_3$].

[27] Relative energies for **V** and **VI** at the RHF/6 + 31G* level plus MP4SDTQ(cf) plus zero-point vibrational energy correction.

[28] The methylenephosphorane carbene, $H_2C{=}P(H){=}C$, has a triplet ground state (^{3}A″), which is energetically more favorable by 25.7 kcal mol^{-1} than the singlet ground state (^{1}A′). ^{3}A″ (^{1}A′) : C–P = 1.710 (1.702), $C(H_2)P = 1.714$ Å, ∢ C-P-C = 129.0 (141.9), ∢ H_{endo}-C-P = 120.2 (122.0), ∢ H_{exo}-C-P = 121.0 (118.6). The energy separation between the singlet and triplet state ($\langle S^2 \rangle$ = 2009) was determined from the energy difference between a MP4SDTQ(fc)/6-31 + G*//(U)RHF/ 6-31 + G* (^{1}A′) and a (P)UMP4SDTQ(fc)/6-31 + G*//(U)RHF/6-31 + G* (^{3}A″) calculation. For the triplet state, this corresponds to a spin projection according to the formalism of Schlegel (H. B. Schlegel, *J. Chem. Phys.* **1986**, *84*, 4530). According to vibrational analysis (harmonic approximation, R(U)HF/6-31 + G* level) both the singlet and the triplet state have C_s symmetry.

Ylidediyl Halophosphane Oligomers, $(Ph_3PCPX)_n$—A Structurally Diverse Class of Compounds**

Hans-Peter Schrödel, Georg Jochem, Alfred Schmidpeter,* and Heinrich Nöth

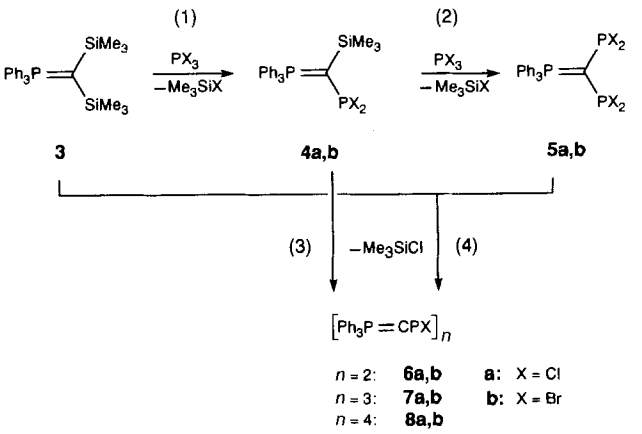
Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

Triphenylphosphonium ylidyl substituents $Ph_3P{=}CR-$,[1-4] exert a stronger +M effect than the corresponding isolobal amino groups and, for example, lead to spontaneous dissociation of halophosphanes.[1, 2] In the same way, the ylidediyl unit $Ph_3P{=}C{=}$, which is isolobal to an imino group, is expected to form halophosphaalkenes **1** (X = Cl, Br); upon dissociation, **1** would yield the triphenylphosphoniophosphaethyne ion **2**.[5]

$$\underset{\mathbf{1}}{Ph_3\bar{P}-C{=}PX} \cdot \rightarrow Ph_3P{=}C{=}PX \rightleftharpoons \underset{\mathbf{2}}{Ph_3\overset{+}{P}-C{\equiv}P\,X^-}$$

The attempted synthesis of **1** actually affords its oligomers $(Ph_3PCPX)_n$, (n = 2, 3, 4). They are related to cyclophosphazanes,[6] $(RNPX)_n$, by a formal RN/Ph_3PC exchange,[7] and consequently, similar symmetrical ring structures are predicted. However, such an analogous structure is only encountered for n = 2, whereas partial dissociation leads to structures of lower symmetry for n = 3, 4.

Treatment of bis(trimethylsilyl)ylide **3** with phosphorus trichloride or phosphorus tribromide affords the dihalophosphanyl ylides **4** and **5** (Scheme 1).[2] The mixed trimethylsilyl- and dihalophosphanyl-substituted ylides **4** (route 1) are isolable; in solution, however, self-condensation (route 3) takes place to afford the oligomers **6**–**8**. Similarly, the condensation of bis(dihalophosphanyl)ylide **5** with bis(trimethylsilyl)ylide **3** (route 4) yields oligomers **6** and **7**.



Scheme 1.

Which of these oligomers forms predominantly is frequently determined by only small changes in the reaction conditions. The choice of starting materials, solvent (benzene or pyridine), concentration, and temperature are all factors that influence the product distribution. Most often, the synthesis can be directed in such a way that *one* oligomer becomes the main product. If a mixture of oligomers is obtained, the components can be separated by their different solubilities. All oligomers have been characterized in detail by NMR spectroscopy, which yields unambiguous structure assignments. Furthermore, the dimers **6** and tetramers **8** crystallize well enough for their molecular structures to be determined by X-ray diffraction analyses of single-crystals of **6a**, **8a**, and **8b**. Unfortunately, trimers **7** could so far only be isolated as microcrystalline powders precluding their structure determination in the solid state. As expected for a structure containing a four-membered ring, the $^{31}P\{^1H\}$ NMR spectra of dimers **6** reveal an A_2B_2 spin system (Table 1). The

Table 1. $^{31}P\{^1H\}$ NMR spectra of the dimers **6** and the cations **9** and **10** derived from them (in CD_2Cl_2); coupling constants J in Hz; ν_0 = 109.379 MHz.

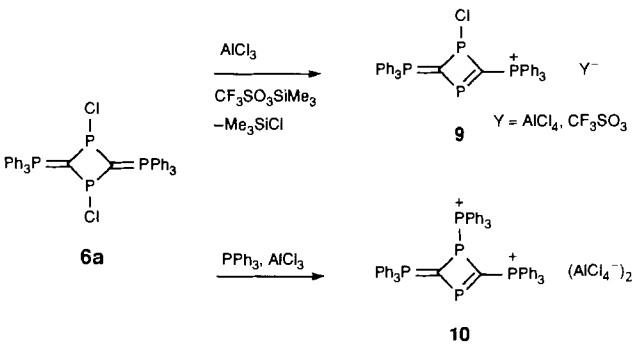
[+] X-ray structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dipl.-Chem. M. Schmidt for the structural determination of **8a**.

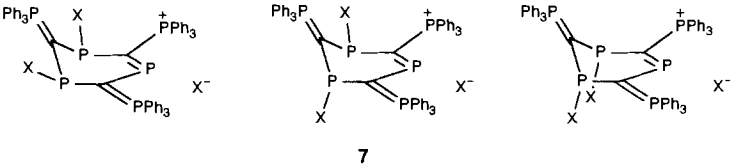
manner (angle sum 357.7° and 359.9°, respectively) despite the small interior angle of 95° and the resulting distortion of their trigonal symmetry.[10] The filled p_z orbitals of the carbon atoms and the P–Cl bonds are virtually eclipsed. This arrangement favors charge transfer to the antibonding orbitals of the P–Cl bond[11] and therefore leads to the unusual elongation of this bond to more than 220 pm (PCl_3: 204 pm). The P–Cl bond in **6a** is thus not only longer than that in another *cis* structured compound, the cyclodiphosphazane $(-t\mathrm{BuN}-\mathrm{PCl}-)_2$ (211 pm[12]), which at the time it was determined was the longest known, but also surpasses any other previously reported P^{III}–Cl distance.[2, 13]

Treatment of **6a** with aluminum trichloride or trimethylsilyl trifluoromethanesulfonate causes one P–Cl bond to dissociate; in the presence of triphenylphosphane a dication is formed (Table 1, Scheme 2).



Scheme 2.

^{31}P NMR spectra of trimers **7a, b** recorded at room-temperature show an $[AB]_3$ spin system and are thus indicative of a structure with a symmetrical six-membered ring. The signal for the trivalent phosphorus in **7a** is broad, and the coalescence temperature is approximately −10 °C; in **7b** the same signal broadens upon cooling and splits into two at approximately −60 °C. Below these temperatures the signal in **7a** splits into a low-field resonance and a high-field resonance that is twice as intense, while the signal in **7b** gives rise to one low-field and two high-field resonances of equal intensity (Table 2). The signal at $\delta = 311$ is without doubt attributable to a two-coordinate phosphenium-type phosphorus atom, providing evidence for an ionic structure. The signals at $\delta = 61$ to 68 are assigned to a halogen-substituted phosphorus in a pyramidal coordination environment. In addition, a broad, averaged signal (**7a**: $\delta \approx 180$, **7b**: $\delta \approx 190$) close to the original position and with approximately one-third of the initial intensity is discernible in the low-temperature spectra. Upon further cooling the sample these signals become even broader; however, complete coalescence is not achieved at the lowest temperature of −95 °C. The nonequivalency of the two pyramidally coordinated ring phosphorus atoms in **7b** can tentatively be explained by their different conformations: While all other ring atoms are coplanar,[14] the carbon atom opposite the two-coordinate phosphorus atom is expected to be bent out-of-plane,[15] and hence substituents on its two neighboring ring phosphorus atoms can assume either axial or equatorial positions (Scheme 3).[16]



Scheme 3.

In solution the three nonequivalent Ph_3PCPX moieties in **7** rapidly alter their identity by exchange of ionic and covalently bound halogen. At any given temperature this exchange process occurs more rapidly for bromide-containing **7b** than for chloride-containing **7a**. Replacing the bromide in **7b** with tosylate (by reaction of **7b** with silver tosylate) slows the exchange process to allow the observation, even at room temperature, of separate signals for each of the three phosphorus ring atoms (Fig. 2).

Table 2. $^{31}P\{^1H\}$ NMR data of the trimers **7** (in CD_2Cl_2); coupling constants J in Hz; $\nu_0 = 109.379$ MHz. P-5 indicates the site of the dissociating phosphorus–halogen bond in the 1,3,5-trihalo-2,4,6-triphosphoranediyl-1,3,5-triphosphinanes **7a,b**.

	7a [a] 20 °C	**7a** [b] −85 °C	**7b** [a] 20 °C	**7b** −95 °C	**7b** [c] 20 °C
δ(P-1)	168.5 [d]	61.6 [d]	194.2	61.0 [d]	58.9 [d]
δ(P-3)				68.2 [d]	66.8 [d]
δ(P-5)		311.8 [d]		311.4 [d]	330.6 [d]
δ(2-PPh_3)	28.3	32.1	27.8	28.6 [e]	29.4 [e]
δ(4,6-PPh_3)		29.6			
^2J(P-1, 2-PPh_3)	152.6 [f]	170.9	151.1 [f]		
^2J(P-1/P-5, 6-PPh_3)		143.4 [g]			

[a] Both P-1,3,5 and 2,4,6-PPh_3 are dynamically equivalent, with the result that an $[AB]_3$ spin system is observed; its A and B signals approximate a 1:2:1 triplet. [b] The part of the spectrum showing splitting on cooling. Both P-1,3 and 4,6-PPh_3 atoms are equivalent and give an $[AB]_2CD$ spin system. [c] With $TosO^-$ instead of Br^- as counterion. [d] Broad signal because of exchange processes; coupling cannot be deduced. [e] Overlapping signals of 2- ,4-, and 6-PPh_3; couplings cannot be deduced. [f] Actually $N/2$ [23]; the value can be considered as $^2J_{PP}$ with sufficient approximation, since $^4J_{PP}$ is very small in comparison. [g] Average of the two similar $^2J_{PP}$ couplings; the two $^4J_{PP}$ couplings are very small in comparison.

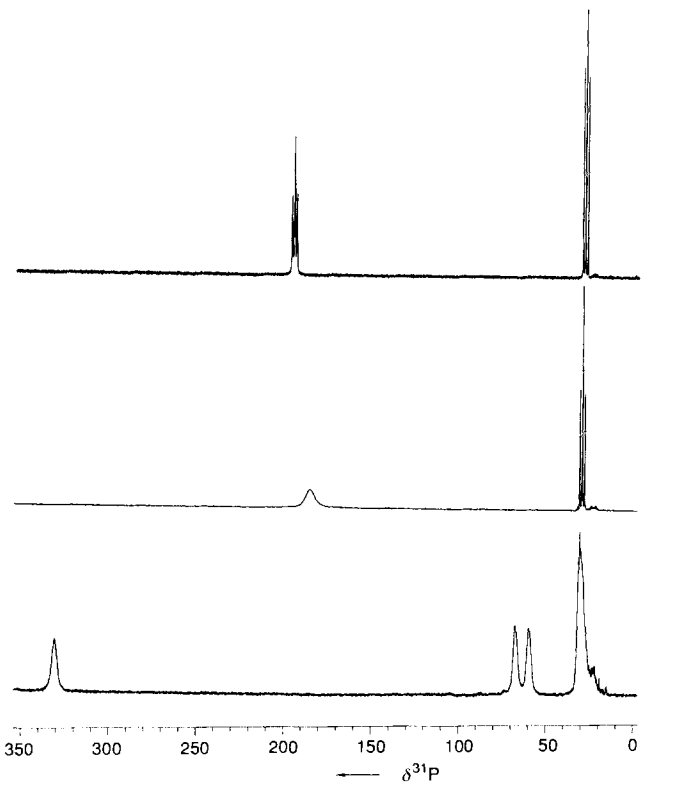


Fig. 2. ^{31}P NMR spectra of **7b** in CD_2Cl_2 at room temperature before (top) and after addition of 1 (center) and 2.5 (bottom) equivalents of silver tosylate.

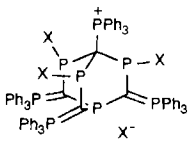
An eight-membered ring structure is commonly assumed for cyclotetraphosphazanes[6] The presence of this structural element in the permethyl derivative[17] and in several other related compounds[18] has been confirmed by X-ray structure analysis. However, the tetramers **8** do not follow the same building principle. Like the trimers **7**, tetramers **8** are ionic compounds that, however, do not undergo rapid halogen exchange. Their $^{31}P\{^{1}H\}$ spectra reveal an $[AC]_3BD$ spin system (Table 3), and no resonances attributable to a phosphenium-type phosphorus

Table 3. $^{31}P\{^{1}H\}$ NMR data of the tetramers **8** (in CD_2Cl_2); coupling constants J in Hz; $\nu_0 = 109.379$ MHz.

	8a	**8b**
δ_A(PX)	215.4	248.5
δ_B(4-PPh_3)	37.3	35.8
δ_C(2,6,8-PPh_3)	25.3	23.3
δ_D(P-1)	−88.2	−85.0
$J_{AB}(^2J_{PP})$	94.0	90.0
$J_{BC}(^4J_{PP})$	7.6	7.7
$J_{CD}(^2J_{PP})$	138.1	128.2

are present. Instead, the phosphorus affected by dissociation gives rise to a ^{31}P NMR resonance (δ_D) at strikingly high field, whereas the NMR resonance (δ_A) for the three undissociated PX units is observed at unusually low field. The symmetry of the spin system of **8** is in accord with a barrelane structure. This conclusion was confirmed for the solid state as well by an X-ray structure analysis for **8a**·4.5 pyridine and the preliminary results for **8b**. The observation of the crystallographic space group $R\bar{3}$ for **8a** requires the presence of a threefold rotational axis (Fig. 3). As observed for **6a**, the P–Cl bonds and the p_z orbital of the ylidic carbon atoms (dihedral angle Cl1-P1-C2-P3 = 90.5°) are virtually eclipsed, and the bond length of 235 pm makes these P–Cl bonds even longer than those of **6a** and by far the longest known to date. The small P1–C2 distance of 171 pm, which is of the same magnitude as the P–C distance reported for a phosphaalkene (161–171 pm[19]), is in accord with the strong negative hyperconjugation, and the consequently relatively large bond length of 174 pm for P3–C2, which corresponds to the P–C distance in acylylides.[10] The pyridine molecules and chloride ions assume vacant positions in the cation lattice (Fig. 4).



8

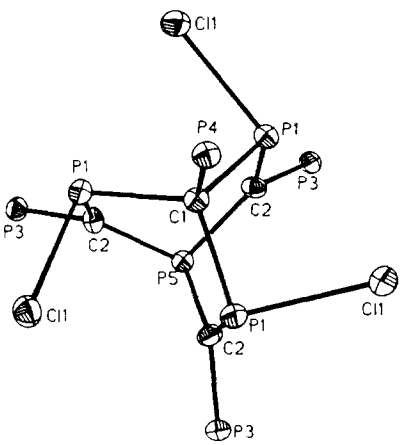


Fig. 3. Crystal structure of **8a** (thermal ellipsoids with 25% probability). For each of the four Ph_3P groups, only the phosphorus atom P3,4 is shown. Significant bond lengths [pm] and angles [°]: P1-Cl1 235.3(2), P1-C1 190.8(3), P1-C2 171.1(5), P4-C1 189.5(8), P3-C2 174.0(5), P5-C2 181.6(5); C1-P1-C2 101.3(3), Cl1-P1-C1 93.97(8), Cl1-P1-C2 109.7(2), C2-P5-C2 100.1(2), P1-C1-P4 108.4(2), P1-C1-P1 110.5(2), P1-C2-P3 117.8(3), P1-C2-P5 124.0(3), P3-C2-P5 118.1(3).

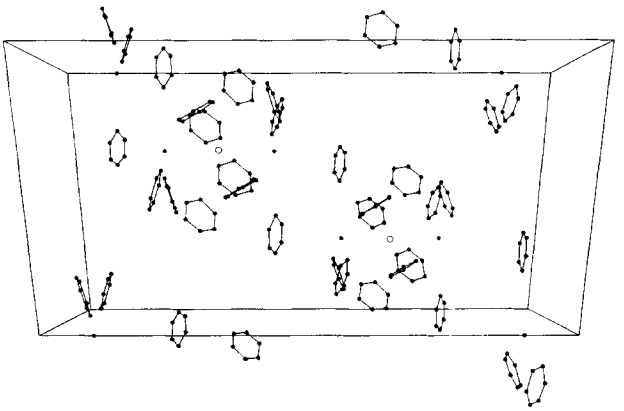

Fig. 4. Unit cell of **8a**·4.5 pyridine. View along the a axis. The packing of the six cations (not shown) leaves three vacancies about the inversion center (indicated by o). Each is filled by two chloride anions and pyridine molecules in twelve orientations with an occupancy factor of 0.75; that is, nine molecules.

The structures reported here for the oligomers of **1** forms a parrallel to the structures of the compounds obtained by cyclooligomerization of *tert*-butylphosphaethyne within the coordination sphere of transition metals. This leads, for example, to complexes of 1,3-diphosphets,[20] 1,3,5-triphosphinine,[21, 22] and 1,3,5,7-tetraphosphabarrelene.[20] An extension of this analogy seems feasible.

Experimental Procedure

6a: At room temperature, PCl_3 (1.44 mL, 11.1 mmol) was added dropwise to a well-stirred solution of **3** (4.66 g, 11.1 mmol) in benzene (150 mL). The initially yellow solution turned colorless and, upon standing, honey-yellow. Light-yellow crystals of **6a** formed after approximately 10 d. Yield: 2.51 g (67%), m.p. (decomp.) 200 °C.

6b: At room temperature, a solution of **3** (2.96 g, 7.05 mmol) in benzene (15 mL) was added dropwise to a stirred mixture of **5b** (4.62 g, 7.05 mmol) in benzene (150 mL). The suspension turned orange. After 10 d the reaction mixture was concentrated to one-half its original volume, and the yellow precipitate of **6b** was collected on a glass frit. Yield: 4.89 g (90%).

7a: A solution of **4a** (3.21 g, 7.14 mmol) in pyridine (10 mL) was stirred for 10 h at 50 °C. The resulting deep-red solution was concentrated and filtered; upon addition of benzene/pentane (30 mL, 1:1 by volume), **7a** precipitated as an orange-red crystalline powder. Yield: 1.78 g (75%). Compound **7a** crystallized from benzene with one mol of solvent.

7b and **8b**: PBr_3 (1.71 g, 6.33 mmol) was added by syringe to a warm (55 °C) solution of **3** (2.66 g, 6.33 mmol) in a mixture of benzene (7 mL) and pyridine (3 mL). The solution color changed from orange to red, and after 10 h a yellow precipitate had formed which ^{31}P NMR spectroscopy showed to be a 10:1 mixture of **7b** and **8b**. This mixture was dissolved in benzene/dichloromethane (1:1 by volume), and pentane was added until the solution began to turn cloudy. Within 12 h, **8b** precipitated in the form of yellow crystals, which were collected by filtration. On evaporating the filtrate to dryness, **7b**·1.5 pyridine was left as a yellow powder, which was recrystallized from pyridine.

8a: A stirred suspension of **3** (846 mg, 2.01 mmol) in pyridine (6 mL) was heated to 60 °C and PCl_3 (276 mg, 2.01 mmol) was added with a syringe. Within 15 min the solution turned red, and stirring was discontinued. The solution was then allowed to stand for 5–10 h at 60 °C during which time large, yellow crystals of **8a**·4.5 pyridine formed. Yield: 481 mg (43%); m.p.(decomp.) 124 °C.

[7] In general, coordination of a phosphane to a carbon atom renders the latter isolobal to an imino group or a chalcogen atom. As such the carbon atom becomes a suitable building block for the formation of saturated rings. The first such heterocycles, that is, four-membered rings consisting of two R_3PC and two $SiMe_2$ moieties have been reported by H. Schmidbaur, W. Malisch, *Chem. Ber.* **1970**, *103*, 9–103, and isosteric four-membered rings consisting of Ph_3PC and PPh_2^+ moieties by R. Appel, F. Knoll, H.-D. Wihler, *Angew. Chem.* **1977**, *89*, 415–416; *Angew. Chem. Int. Ed. Engl.* **1977**, *16*, 402–403. For compounds in which Ph_3PC and CO are combined to rings, see H. J. Bestmann, T. G. Fürst, A. Schier, *ibid.* **1993**, *105*, 1783–1784, 1784–1788 and **1993**, *32*, 1746–1747, 1747–1751. For cyclic compounds of the isoelectronic cationic unit $(Me_2N)_3PP^+$ with $PNMe_2$ and CH_2, see A. Schmidpeter, S. Lochschmidt, *ibid.* **1986**, *98*, 271–273, and **1986**, *25*, 253–254.

Carbene Complex Functionalized Sugars**

Karl Heinz Dötz,* Wolfgang Straub, Richard Ehlenz, Klaus Peseke, and Roland Meisel

Electrophilic Fischer-type carbene complexes are of interest in stereoselective organic synthesis as building blocks for metal- and ligand-centered cycloadditions,[1a–c] as ketene equivalents,[1c] and as enolate analogues for aldol and Michael reactions.[1d] In C–C bond forming reactions the transition metal may serve as a template,[2] and, moreover, the analogy between the carbonyl metal fragment and the oxygen atom in carbonyl compounds,[3a] as described by the isolobal relationship,[3b] is exploited. The stereochemical information available in carbohydrates with their wealth of chiral centers[4] has been employed in organometallic coordination chemistry only in rare cases. Whereas the capacity of sugars to serve as O-coordinated, optically active ligands for chiral induction is convincingly documented for titanium-mediated C–C bond forming reactions,[5] examples of C-metalated carbohydrates are limited for the most part to lithium and tin derivatives. Transition metals have been used in isolated cases for C-glycosidation;[6a–d] however, glycosyl complexes are known only for manganese,[6c,d] cobalt,[6e] and iron.[6f] We set out to transfer the synthetic potential of carbene complexes to carbohydrates[7] and report here on the conversion of the exposed C-1 atom of a sugar into a metal-coordinated carbene center.

We used a synthetic approach complementary to the Fischer route and constructed the metal–carbene function by addition of a metal nucleophile to an acid chloride followed by O-alkylation.[8a] Suitable metal nucleophiles are available by reduction of binary carbonyl metal compounds with graphite–potassium[8b] or sodium. We chose 2,3,4,5,6-penta-*O*-acetyl-D-galactonic acid chloride (**1**) to serve as the electrophilic sugar component; it can be prepared from D-galactose by electrochemical oxidation[9] followed by acidic acetylation and chlorination,[10]

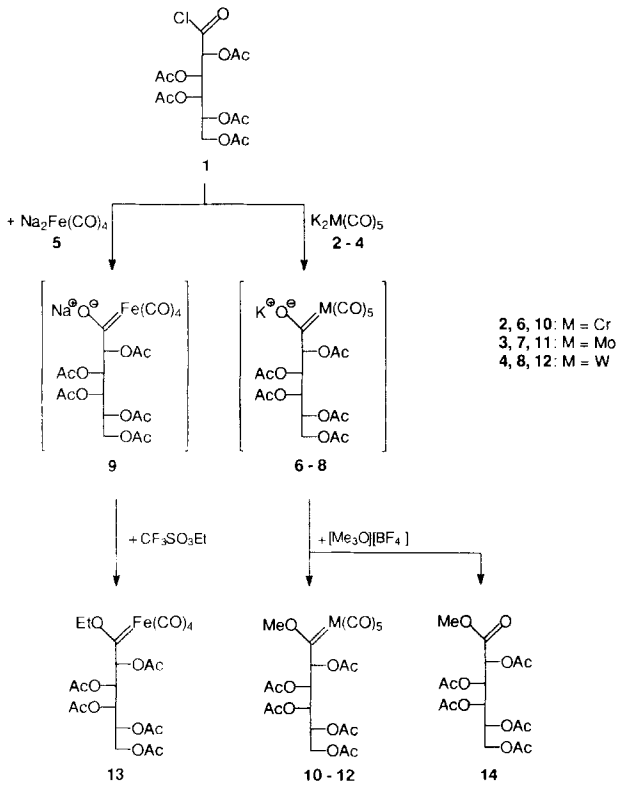
[**] Organotransition Metal Modified Sugars, Part 1. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie.

and its protecting groups are stable to carbonyl metalates **2**–**5**. Under mild conditions these reagents rather attack the acid chloride function to give the acylmetalates **6**–**9**, which react with strong alkylating agents to afford the C-1-metalated sugar derivatives **10**–**13** (Scheme 1). In the alkylation of ferrate **9** the acylmetalate function competes with the iron center for the electrophile. Collman-type ketone formation can be suppressed by the presence of HMPA and the use of ethyl trifluoromethanesulfonate,[11] but the yields of carbene complex **13** are lower than those of the pentacarbonyl analogues **10**–**12**. The carbene complexes are thermally stable in the solid state and easy to handle; nevertheless, chromatographic purification should be conducted at lower temperatures to preclude decomposition.



Scheme 1. Synthesis of sugar-carbene complexes **10**–**13**.

The NMR spectra (Table 1) show compounds **10**–**13** to be typical Fischer carbene complexes with a pronounced electrophilic C-1 atom; its ^{13}C NMR signal, for example for the chromium complex **10** ($\delta = 355.0$), is shifted distinctly downfield in comparison to that of the analogous D-galactose ester **14** ($\delta = 167.3$). The acceptor character of the metal–carbene function is also evident at the adjacent C–H fragment (**10**: ^{13}C NMR: $\delta = 84.5$; ^1H NMR: $\delta = 5.41$; **14**: ^{13}C NMR: $\delta = 69.0$; ^1H NMR: $\delta = 5.00$). The chemical shifts of the hydrogen atoms on the C3–C6 chain and their vicinial H,H coupling constants are very similar in the carbene complexes **10**–**13** and in ester **14**. This indicates that the incorporation of the metal–carbene function into the sugar framework does not impose any significant changes in the configuration and conformation.

Table 1. Characteristic ^{13}C NMR data for compounds **10**–**14** (100 MHz, $CDCl_3$, δ values). See Experimental Procedure for full charactization of **10**.

Compound	C-1	C-2	Yield [a]
10	355.0	84.5	64%
11	346.2	84.4	44%
12	328.2	86.0	42%
13	327.6	84.9	28%
14	167.3	69.0	–

[a] Yields of **10**–**13** based on **1**.

Based on the spectroscopic properties of complexes **10**–**13**, it can be expected that the electrophilicity of the carbene carbon atom and the acidity of the neighboring C–H function can be used for further controlled modification of the sugar framework.

Experimental Procedure

All experiments were conducted under argon with strict exclusion of air and moisture.

10: A suspension of **2** was prepared from potassium (0.45 g, 11.51 mmol), graphite (1.10 g, 92 mmol) and hexacarbonylchromium (1.18 g, 5.4 mmol) in 100 mL of THF. This suspension was cooled to −60 °C and a solution of **1** (2.16 mmol, 5.10 mmol) in 20 mL of THF was added dropwise. The reaction mixture was stirred a further 30 min, the solvent removed under vacuum, and the residue taken up in 120 mL of dichloromethane. This solution was cooled to −30 °C, trimethyloxonium tetrafluoroborate (0.73 g, 5.00 mmol) added, and the resulting solution stirred 5 h at 0–5 °C. To ensure complete alkylation another portion of trimethyloxonium tetrafluoroborate (0.44 g, 3.00 mmol) was added. After a further 5 h the crude product was absorbed onto silica gel (−60 °C), the solvent removed under vacuum, and the residue chromatographed (SiO_2, −15 °C, ether/petroleum ether/dichloromethane (1/1/1)) to give a fraction from which 1.93 g (64%) of **10** was isolated as an orange solid. A subsequent fraction yielded 0.21 g (10%) of methyl ester **14**. **10**: R_f (SiO_2, ether/petroleum ether, dichloromethane(1/1/1)): 0.70. M.p. 113–115 °C. FT-IR (KBr): ν(CO) [cm^{-1}] = 2071 (m), 1994 (m), 1959 (s), 1943 (vs), 1755 (s). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 5.46$ (d, $J_{3,4} = 10.2$ Hz, H-3), 5.41 (bs, H-2), 5.26–5.34 (m, 2H, H-4, H-5), 4.82 (s, 3H, OCH_3), 4.30 (dd, $J_{6,6'} = 11.6$ Hz, $J_{5,6} = 4.5$ Hz, H-6), 3.72 (dd, $J_{6,6'} = 11.6$ Hz, $J_{5,6'} = 8.3$ Hz, H-6'), 2.31, 2.11, 2.04, 2.01, 1.99 (jeweils s, 3H, $OCOCH_3$). ^{13}C-NMR (100 MHz, $CDCl_3$): $\delta = 355.0$ (C=Cr), 223.0 (*trans*-CO), 215.5 (*cis*-CO), 170.5, 170.3, 170.1, 169.8, 169.3 ($OCOCH_3$), 84.5 (C-2), 68.9 (C-3), 68.0 (C-4), 67.7 (OCH_3), 67.5 (C-5), 62.4 (C-6), 20.9, 20.6, 20.6, 20.6, 20.5 ($OCOCH_3$). MS (FAB, mNBA (*m*-nitrobenzyl alcohol): m/z = 596 (12%, M^+), 456 (4%, $M^+ - 5\,CO$), 405 (12%, $M^+ - Cr(CO)_5$), 230 (100%, $M^+ - Cr(CO)_5 - Ac_2O - CH_2OAc$).

Compounds **11** and **12** were synthesized in an analogous fashion. **11**: yellow solid. M.p. 115–117 °C. MS (FAB, mNBA): m/z = 642 (14%, M^+). **12**: red solid. M.p. 130–132 °C. MS (FAB, mNBA): m/z = 728 (10%, M^+).

13: A suspension of anhydrous **5**·1.5 dioxane [12] was prepared from pentacarbonyliron (0.72, 5.4 mmol) dissolved in 5 mL of 1,4-dioxane, sodium (0.24 g, 10.7 mmol), and benzophenone (0.22 g, 1.2 mmol). This suspension was cooled to −60 °C and a solution of **1** (2.29 g, 5.4 mmol) in 15 mL of THF was added dropwise over 30 min. After 3 h the resulting red solution was concentrated to dryness under vacuum (oil pump) and the resulting reddish brown residue was taken up in 15 mL of diethyl ether and 2.5 mL of HMPA. This solution was cooled to −70 °C, a solution of ethyl trifluoromethanesulfonate (1.05 mL, 8.1 mmol) was added over 5 min, and the resulting solution was stirred for 16 h. The reaction mixture was absorbed onto silica gel and chromatographed (SiO_2, 0 °C, diethyl ether/petroleum ether/dichloromethane (1/1/1)) to provide 0.90 g (1.5 mmol, 28%) of **13** as a red solid (m.p. 91–93 °C).

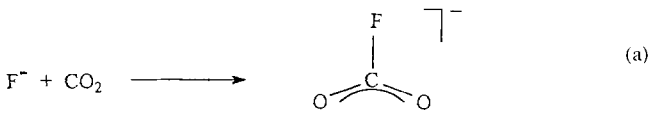
Fluorocarbonate, $[FCO_2]^-$: Preparation and Structure**

Xiongzhi Zhang, Udo Gross, and Konrad Seppelt*

Fluorocarbonate (fluoroformate), $[FCO_2]^-$, should be a stable anion, because it is isoelectronic with nitrate. The only reports about it are of matrix reactions of CO_2 or COF_2 with vaporized and matrix-deposited CsF and Tl_2O in argon to form $[FCO_2]^-$,[1, 2] as well as an ion-cyclotron resonance experiment of the reaction of F^- with CO_2 in the gas phase.[3] The postulated reaction under pressure of CO_2 with CsF in CH_3CN could not be confirmed.[4, 5] According to calculations, the conjugate acid to the base $[FCO_2]^-$, fluoroformic acid, should be metastable with respect to decomposition into CO_2 and HF;[6] this, however, says nothing about intermolecular decomposition. Very recently a photoelectron spectrum of $[FCO_2]^-$, generated by reaction of F^- with CO_2 in a molecular beam, was recorded.[7]

Supplementary to earlier data,[5] we showed that neither crystalline CsF nor AgF underwent a significant increase in mass, even after long contact times with liquid CO_2 under pressure at room temperature. NOF also does not react. In contrast, CO_2 reacts spontaneously with anhydrous quaternary ammonium fluorides like tetramethylammonium fluoride,[8] neopentyl(trimethyl)ammonium fluoride, and 1,1,3,3,5,5-hexamethylpiperidinium fluoride (pip^+F^-)[9] both without solvent or dissolved in CH_2F_2 and CF_3CHFCF_3, which are particularly suitable solvents for piperidinium fluoride. $[FCO_2]^-$ salts are obtained as colorless, almost insoluble solids [Eq. (a) gives the reaction equation for the synthesis of the anion]. Because of the extremely poor solubility in nearly all conceivable solvents, the growth of single crystals has not yet been achieved, and structural analysis has had to be done by other methods.



(a)

Besides the complete elemental analysis of $pip^+CO_2F^-$, the ^{13}C MAS NMR signal of $[(CH_3)_4N][FCO_2]$ is an almost unambiguous indication of the presence of the $[FCO_2]^-$ ion (Fig. 1), because it shows a $J_{C,F}$ coupling of 292 Hz. The splitting is independent of the NMR frequency (100.55 or 75.41 Hz), but disappears in a $\{^{19}F\}^{13}C$ decoupling experiment.

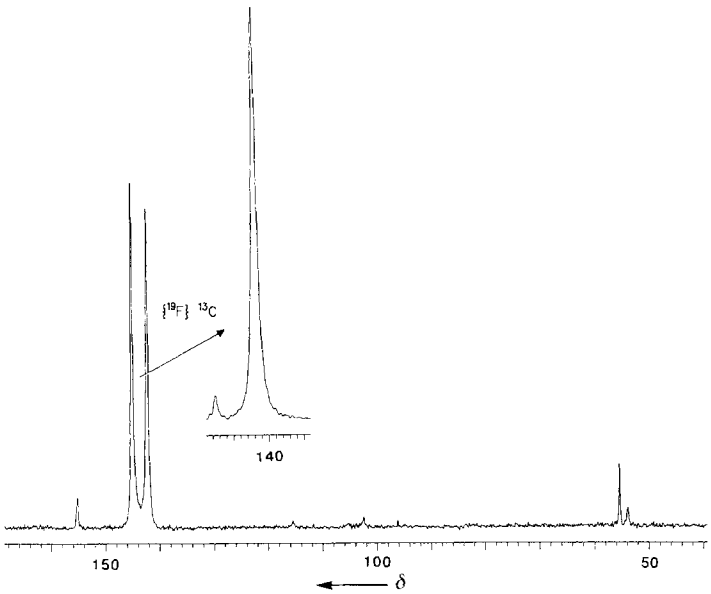


Fig. 1. $\{^1H\}^{13}C$ solid-state MAS NMR spectrum of $[(CH_3)_4][F^{13}CO_2]$, prepared from $[(CH_3)_4]F$ and $^{13}CO_2$. $B_0 = 100.557$ MHz, 5000 Hz angular velocity. $^1J(^{19}F,^{13}C) = 280.8$ Hz. The signal at $\delta = 55.39$ is attributable to the CH_3 groups with natural abundance of ^{13}C, that at $\delta = 155.21$ to a CO_3H^- impurity. Inset: $\{^{19}F\}^{13}C$ MAS NMR spectrum.

In freshly prepared solutions of $[FCO_2]^-$ in purest CH_3CN[10] a singlet is observed in the ^{19}F NMR spectrum. Depending on the fluoride content of the sample, this signal appears between $\delta = -65$ and $+18$, which suggests an exchange between F^- ions and $[FCO_2]^-$; the chemical shift of the fluoride ion in CH_3CN is $\delta = -71$. In the ^{13}C NMR spectrum of $[F^{13}CO_2]^-$ in CH_3CN a singlet appears at $\delta = 134.4$; the anticipated doublet splitting is not observed because of the exchange processes mentioned above.

The presence of moisture leads spontaneously to the formation of hydrogen carbonate,[11] hydrogen fluoride, and gaseous CO_2. Protic solvents, for example alcohols, cleave the CF bond immediately with evolution of CO_2 and the solvation of fluoride.

Indications about the structure of $[FCO_2]^-$ can be found in the IR (Fig. 2) and Raman spectra. Four of the six bands anticipated for a C_{2v} spectrum are definitely present; two further bands are weak as expected and are partly hidden by the intense bands of νCF and $\delta_s CO_2$ (Table 1). The Raman spectrum is dominated by cation bands, which have been well described;[8] the Raman emissions of the anion with its strongly polar bonds are very weak. Striking features among the stretching bands are the large difference between $\nu_{as}CO_2$ (1798 cm^{-1}) and $\nu_s CO_2$ (1275 cm^{-1}) and the low value for νCF (570 cm^{-1}). Qualitatively these observations can be explained by a very large O-C-O angle and a very weak C–F bond. To elucidate this problem we

Raman ($[F^{13}CO_2]^-$)	1750sh	1259m			569w	
MP2 ($[F^{12}CO_2]^-$)	1804(100)	1362(25)	760(2.5)	701(28)	483(20)	523(1.3)
MP3 ($[F^{12}CO_2]^-$)	1771	1262	788	763	574	551

calculated the structure with ab initio methods (Table 2). Even with small basis sets our calculations establish that $[FCO_2]^-$ is a stable anion, and the C_{2v} structure is apparently the global minimum on the potential hypersurface. The calculations indeed indicate (see Table 2) a large O-C-O angle of 136–138° and a strikingly long C–F bond (144–150 pm).[12] These results agree with those that were recently published.[7]

Table 2. Bond lengths and angles of the C_{2v} structure of $[FCO_2]^-$ (calculated) and NO_2F (calculated and experimental).

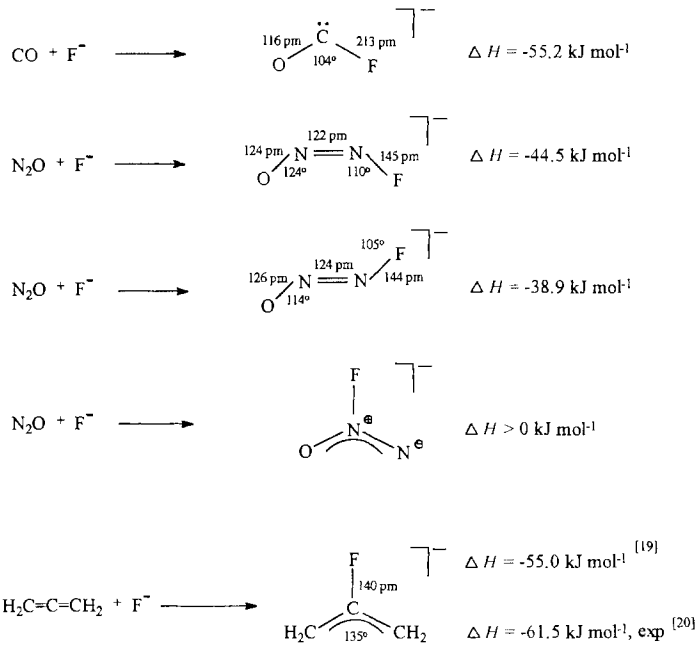
$[FCO_2]^-$	MP2	MP3	NO_2F	MP2	MP3	exp. [13]
C-F [pm]	150.5	144.6	N-F	153.6	141.2	146.7(15)
C-O [pm]	122.5	122.0	N-O	117.9	117.4	118.0(5)
O-C-O [°]	137.9	136.2	O-N-O	137.9	134.5	136.0(15)

The vibrational bands determined by ab initio calculations are in accord with experimental results after scaling. The intensities of the IR bands are correctly predicted as well. The weakness of the C–F bond in $[FCO_2]^-$ is also reflected in the strikingly small affinity of CO_2 for the F^- ion. This was determined to be $-132.6\ kJ\ mol^{-1}$ in the gas state[3] by ion-cyclotron resonance spectroscopy and calculated by us to be $-110.7\ kJ\ mol^{-1}$. For comparison, NO_2F, whose structure in the gas state has been reliably analyzed by microwave spectroscopy, was also calculated.[13] The results show that in particular the N–F bond length (like the C–F bond length) depends markedly on the basis set and on the approximations for electron correlation. Nevertheless, very long C–F or N–F bonds and a large O-C-O or O-N-O angle are always predicted. These are indeed found experimentally[13] in the case of NO_2F.

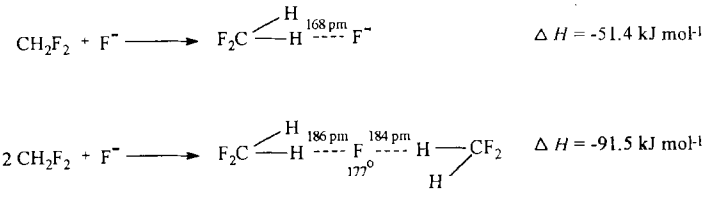
In one limit $[FCO_2]^-$ can be considered as a F^- ion solvated by CO_2, and it also behaves as such. After prolonged periods in CH_3CN a basic attack on the solvent takes place with formation of $[NC\ C(CO_2)_2H]^-$[14] and HF_2^-. $[FCO_2]^-$ therefore belongs to the fluoride oxides like NO_2F, NOF, NOF_3, and $[COF_3]^-$,[15, 16] which show pronounced negative hyperconjugation. The radical FCO_2, however, which has one electron less and which plays a role in the atmospheric chemistry of F–Cl compounds, apparently has a more normal structure: C–F 130–140 pm, C–O 121–127 pm, O-C-O ≈ 120°.[7, 17] The special features of the $[FCO_2]^-$ ion also become evident when it is compared with $[HCO_2]^-$, which has an O-C-O angle of 125.5° and C–O bond lengths of 125.6 pm.[18]

We have no evidence yet for the $[CO_2F_2]^{2-}$ ion, whose existence has already been postulated[2, 4] but questioned.[6] Products with the correct analytical composition have vibrational spectra that indicate a mixture of $[FCO_2]^-$ and F^-. Ab initio calculations for $[CO_2F_2]^{2-}$ with several basis sets yield no minimum on the potential hypersurface.

Molecules related to CO_2 like N_2O and $H_2C{=}C{=}CH_2$, and also CO, do not react with pip^+F^-. Apparently the fluoride affinities of these molecules are already so small that they no longer exceed that of the solvent or the cation. Our calculations gave the values depicted in Scheme 1 for the equilibrium structures and fluoride affinities. The small fluoride affinities compete with those of the solvent or the cation, for example, CH_2F_2 (see Scheme 2). Since the fluoride affinity of a CH_2F_2 molecule is the same size as that of CO, N_2O, and $H_2C{=}C{=}CH_2$, it is not surprising that in condensed phase no reaction takes place, especially as in this case a crystal structure study showed that a F^- ion is solvated by up to five CH_2F_2 molecules.[9] To force the reaction of CO, N_2O, and $CH_2C{=}C{=}CH_2$ with F^- a still less acidic solvent *and* cation is needed, because according to the crystal structure analysis, cation and CH_2F_2 associate almost as



Scheme 1.



Scheme 2.

strongly with F^-.[7] The fluoride affinity of CO_2 in the presently known systems with "naked" fluoride ions appears to be the approximate lower limit for a reaction.

[20] The fluoride ion affinity of $[H_2C{=}C{=}CH_2]^-$ was calculated to be 15 kcal mol^{-1} by using the acidity of $CH_3CF{=}CH_2$ measured by ion-cyclotron resonance spectroscopy [3].

$[Ni_3(alkyne)_4]$—The First Homoleptic Alkyne–Metal Oligomer (Alkyne: 2,5,5-Trimethylhex-3-yn-2-ol)**

Dirk Walther,* Thomas Klettke, and Helmar Görls

Compounds that consist solely of a combination of a d^{10} metal(0) center and an alkyne should be able to form a "homologous series" of composition $[M_n(alkyne)_{n+1}]$, in which each alkyne connects two metal centers and the ends of the chain of metal atoms are coordinated to terminally bound alkynes.

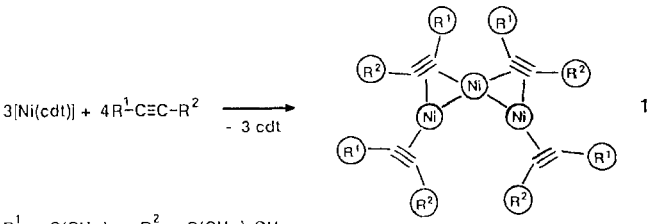
Dr. H. Görls
Max-Planck-Gruppe CO_2-Chemie an der Universität Jena (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247, Heidelberg), the Max-Planck-Gesellschaft (Arbeitsgruppe CO_2-Chemie), and the Fonds der Chemischen Industrie.

Oligomeric examples of these homoleptic compounds are of interest on account of their bonding relationships,[1] and also because of the possibility of simulating interactions of alkynes on metal surfaces. Catalytic properties and reactions of the chain ends might be of some practical significance, and may also be exploited for the construction of multimetal systems with different metals.

Until now, there has been no proof of the existence of such series. Apart from monomers,[2, 3] only $[Pt_2L_3]$ has been isolated and investigated by NMR spectroscopy,[4] but the solid-state structure is not known. The complex $[Fe_2L_4]$ (L: bis(trimethylsilyl)acetylene) is more electron-rich, as the d^8 system contains iron(0) centers.[5] The concept of utilizing peripheral hydrogen-bonding as a means of stabilizing homoleptic alkyne–Ni compounds[3] also proved successful in the synthesis of the first homoleptic alkyne–metal trimer.

Upon reaction of 2,5,5-trimethylhex-3-yn-2-ol with [Ni(cdt)] (cdt: cyclododeca-1,5,9-triene) in pentane, the red, crystalline air-sensitive compound $[Ni_3(alkyne)_4]$ **1** may be isolated, even when the reactants are introduced in a molar ratio of 2:1. Complex **1** dissolves well in THF, is reasonably soluble in ether and pentane, and is stable in the solid state at room temperature.



1

$R^1 = C(CH_3)_3$; $R^2 = C(CH_3)_2OH$

According to the crystal structure analysis,[6] the nickel(0) centers form a bent three-membered chain with a Ni-Ni-Ni angle of approximately 118° and an average Ni–Ni distance of 2.56 Å (Fig. 1). The terminal Ni centers each bind one bridging and one terminal alkyne ligand, whereas the central Ni atom is surrounded by two bridging alkynes.

Thus, **1** is held together by metal–metal bonds as well as twelve Ni–C bonds. The Ni–C bonds display normal bond lengths (1.88–1.97 Å). The groups R^1 and R^2 exert an influence only on the Ni–C bond lengths of the bridging alkynes: shorter bonds are formed between the terminal Ni centers and the C atoms bearing R^2 substituents, whereas this is reversed for Ni2. As expected, the C≡C bond lengths of the terminally bound alkynes are shorter than those of the bridging alkynes (average lengths 1.25 and 1.32 Å, respectively). Agostic interactions between the

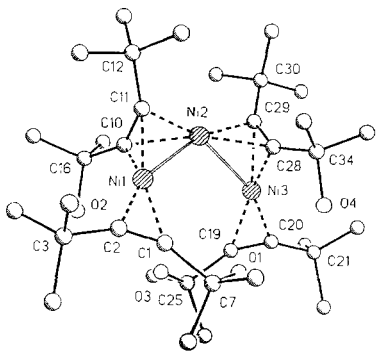


Fig. 1. Crystal structure of **1**. Selected distances [Å] and angles [°]: Ni1-Ni2 2.5468(6), Ni2-Ni3 2.5682(6), Ni1-C1 1.889(3), Ni1-C2 1.879(3), Ni1-C10 1.887(3), Ni1-C11 1.958(3), Ni2-C10 1.975(3), Ni2-C11 1.917(3), Ni2-C28 1.965(3), Ni2-C29 1.927(3), Ni3-C19 1.883(4), Ni3-C20 1.892(4), Ni3-C28 1.889(3), Ni3-C29 1.941(3), C1-C2 1.250(5), C10-C11 1.320(4), C19-C20 1.259(5), C28-C29 1.323(5); Ni1-Ni2-Ni3 118.03(2), C1-C2-C3 153.4(4), C2-C1-C7 152.7(3), C10-C11-C12 146.0(3), C11-C10-C16 146.3(3), C19-C20-C21 155.1(4), C20-C19-C25 153.1(4), C28-C29-C30 147.1(3), C29-C28-C34 146.8(3).

H atoms of the methyl groups and the metal atoms are not observed. Finally, the tolerance of the Ni_3 chain towards the peripheral OH groups is noteworthy.

The OH groups form three intramolecular and two intermolecular hydrogen bonds, such that the trimeric units are joined into a polymeric "rope" (Fig. 2). Since only a slight difference in energy is anticipated for the individual members of the hypothetical series $[M_n(alkyne)_{n+1}]$, these additional possibilities for stabilization might be crucial for the synthesis.

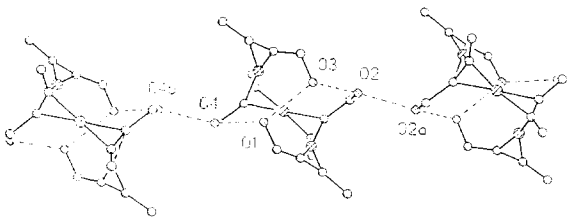

Fig. 2. Hydrogen bonding system in **1**. For clarity the methyl groups are omitted. Selected distances [Å]: O1-O3 2.842(4), O1-O4 2.751(4), O2-O3 2.780(4), O2-O2a 2.862(4), O4-O4b 2.817(4); symmetry transformation for a: $-x, 1-y, -z$; and for b: $1-x, 2-y, 1-z$.

As expected, in the IR spectrum of **1**, only two bands for C≡C stretching vibrations occur in the region for coordinated triple bonds, at 1638 and 1887 cm^{-1} (bridging and terminal alkynes, respectively).

In the 400 MHz ^{13}C NMR spectrum of **1** ([D$_8$]THF, −15 °C), the four signals of the coordinated bridging and terminal C≡C groups may be identified between $\delta = 147.1$ and 130.5. The signals for $C(CH_3)_2OH$ occur at $\delta = 69.0$ and 69.9. The highest field signals are those of $C(CH_3)_3$ at $\delta = 31.4$ and 31.5. A further eight signals in the region $\delta = 32.0-34.8$ are assigned to the methyl groups. The ^1H NMR spectrum ([D$_8$]THF, −15 °C) shows, as expected, only signals in the methyl group region and for the two OH groups. A more extensive evaluation of the spectrum is made difficult by the considerable overlap of the signals, such that it is not possible to identify which methyl signals are doubled.

Complex **1** reacts in the presence of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda) to form the dinuclear complex **2**, which may be isolated as red crystals. The two nickel

$[(tmeda)Ni_2(alkyne)_2]$ **2**

centers in **2** are connected by a bridging alkyne and a Ni–Ni bond, as demonstrated by a crystal structure analysis.[7] The second alkyne is terminally bound to one of the nickel centers, whereas at the other nickel center the tmeda functions as a chelate ligand. Thus, **2** has a structure analogous to that of the dinuclear complex $[(tmeda)Ni_2L_2]$ [L = 2,5-dimethylhex-3-yn-2,5-diol (tetramethylbutynediol)], which we reported previously.[3]

Complex **1** catalyzes the cyclooligomerization of prop-2-yn-1-ol; the selectivity is very solvent- and temperature-dependent. At 114 °C and without additional solvent, 95% cyclooctatetraene and 5% benzene derivatives are formed, according to NMR spectroscopic evidence.[8] Of the cyclotetramers, the symmetrical cycloocta-1,3,5,7-tetraene-1,3,5,7-tetramethanol predominates (70%); in addition, roughly 30% of the isomeric 1,3,5,8-tetramethanol is formed.

At −25 °C in THF, the oligoselectivity is far lower: a molar ratio of cyclooctatetraene:benzene derivatives of 63:37 was determined by NMR spectroscopy. We attribute this difference to a partial blocking of the coordination sites at the central Ni atom by alkyne ligands at −25 °C, which favors the cyclotrimerization. At 114 °C, on the other hand, the cyclotetramerization proceeds at "naked" nickel center and is reflected in the higher selectivity.[8]

Experimental Procedure

All transformations were carried out under argon.

1: Ni(cdt) (1.8 mmol) and 2,5,5-trimethylhex-3-yn-2-ol (3.6 mmol) were allowed to react together in *n*-pentane (10 mL) at −40 °C. After the reaction mixture was warmed to room temperature and filtered, dimethoxyethane (2 mL) was added. After 5 h the mixture was cooled to −78 °C and the precipitate recrystallized from *n*-pentane. Burgundy microcrystals, yield ca. 30%. Ni 23.72 (calc. 23.67)%. Single crystals from ether (with 0.5 mol ether). IR(Nujol): $\tilde{\nu} = 1887$ (C≡C), 1638 (C≡C), 3246 cm^{-1} (OH). ^1H-NMR ([D$_8$]THF, −15 °C, 400 MHz): $\delta = 1.21$, 1.26, 1.33, 1.38, 1.46, 1.50, 1.66 (CH_3), 5.65, 6.62 (OH). ^{13}C-NMR ([D$_8$]THF, −15 °C, 400 MHz): $\delta = 31.4$, 31.5 ($C(CH_3)_3$), 32.0, 32.2, 32.4, 32.6, 33.6, 33.9, 34.4, 34.8 (CH_3), 69.0, 69.9 ($C(CH_3)_2OH$), 130.5, 136.6, 142.5, 147.1 (C≡).

2: Ni(cdt) (1.4 mmol) and 2,5,5-trimethylhex-3-yn-2-ol (1.7 mmol) were allowed to react together in *n*-pentane (10 mL) at −60 °C. After warming to room temperature and filtration, the mixture was cooled to −40 °C and tmeda (23 mmol) added. Warming to 20 °C during 2 h and concentration of the solution to 4 mL led, at 0 °C, to **2**. Black-red crystals, yield 47%. Ni 22.78 (calc. 22.83)%. IR (Nujol): $\tilde{\nu} = 1839$ (C≡C), 1587 (C≡C), 3429 cm^{-1} (OH); crystal structure determination: ref. [7].

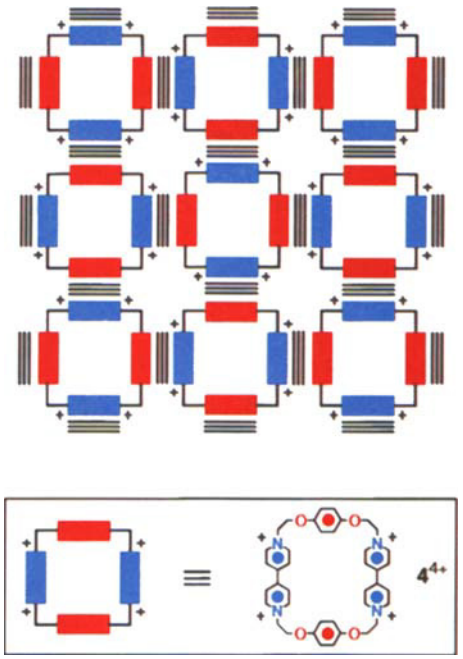
Molecular Mosaics Formed by a Square Cyclophane and Its Inclusion Complex with Ferrocene**

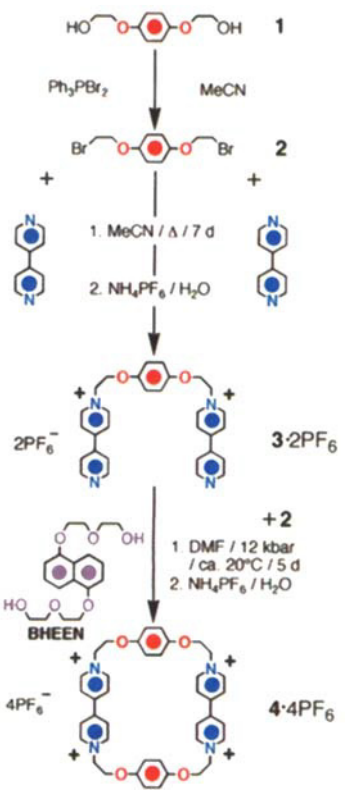
Peter R. Ashton, Christian G. Claessens, Wayne Hayes, Stephan Menzer, J. Fraser Stoddart,* Andrew J. P. White, and David J. Williams

Self-assembly processes have been employed[1] successfully to create with precision molecular assemblies and supramolecular arrays previously unattainable by conventional chemistry. One-, two-, and three-dimensional solid-state arrays and networks incorporating hydrogen bonds,[2] metal–ligand interactions,[3] and π–π stacks as recognition motifs[4] have all been designed rationally and to some extent, realized.[5] There is a feeling growing in the scientific community that the range of novel molecular and supramolecular architectures being developed at present will lead ultimately to the emergence of a new generation of materials.[6] In order to exploit the novel properties already being exhibited[7] by some of these architectures, a more fundamental understanding of the molecular recognition phenomena that give rise to these properties is required. With all these features and criteria in mind, we have designed a self-complementary cyclophane **4**·4PF_6, which can express itself simultaneously as both an *exo* and an *endo* receptor (Scheme 1). The incorporation of two hydroquinone rings and two bipyridinium units in diametrically opposite positions creating a boxlike shape gives 4^{4+} the potential to form a highly structured two-dimensional array of stacked π-donor/π-acceptor systems after a mosaiclike fashion, while retaining the ability to bind either π-electron rich or π-electron deficient substrates. Here, we report (i) the synthesis of the cyclophane **4**·4PF_6, (ii) its ability to form a 1:1 adduct with the organometallic sandwich compound ferrocene (Fc) in solution, as evidenced by UV and ^{1}H NMR spectroscopic studies, and (iii) the X-ray crystallographic characterization of both the molecular and supramolecular structures of the free (**4**·4PF_6) and complexed (**4**/Fc·4PF_6) cyclophane, respectively.



Scheme 1. Schematic representation of the expected solid-state structure of cation 4^{4+} in a crystalline salt.

The tetracationic cyclophane 4^{4+} was prepared as a PF_6 salt by the route shown in Scheme 2. The dibromide **2** was obtained by bromination[8] of the diol **1** with PPh_3Br_2 in MeCN. Portionwise addition of **2** over seven days to a tenfold excess of bipyridine in MeCN afforded, after counterion exchange, **3**·2PF_6.[9, 10] Reaction of **3**·2PF_6 with the dibromide **2** in DMF using 1,5-bis[(2-hydroxyethoxy)ethoxy]naphthalene (BHEEN) as a template afforded, after counterion exchange, the desired salt **4**·4PF_6 in 12% yield.



Scheme 2. Template-directed synthesis of the square tetracationic cyclophane 4^{4+}.

The X-ray structural analysis[10, 11] of **4**·4PF_6 reveals that the cyclophane has an open geometry with C_2 symmetry and with the two $CH_2OC_6H_4OCH_2$ units having a *syn* relationship of their OCH_2 groups (Fig. 1). The profile of the molecule is almost square with distances between the corner NCH_2 carbon atoms of 9.88 Å and 9.94 Å for the sides incorporating the bipyridinium units and the hydroquinone rings, respectively.[12] The vectors joining these four carbon atoms form a parallelogram[13] with angles of 88 and 92°. There is a retention of near coplanarity of the oxybismethylene units with the hydroquinone ring. There are marked twists (20°) about the central C–C bonds of the two bipyridinium units and a small amount of bowing, with the two NCH_2 bonds in both instances subtending angles of 11°. Whereas the planes of the bipyridinium units are essentially orthogonal to the mean plane of the cyclophane, the planes of the hydroquinone rings are appreciably inclined (by 59°). A study of the packing of the tetracation 4^{4+} shows that the expected two-dimensional π-donor/π-acceptor mosaic is present in the solid state (Fig. 1). Adjacent cyclophanes within any two-dimensional sheet are slightly stepped (Fig. 1b), whilst still retaining a proximal relationship between one of the pyridinium rings in one tetracation and a hydroquinone ring in the next and vice versa. The centroid–centroid separation between these rings in adjacent cyclophanes is 4.0 Å and the planes

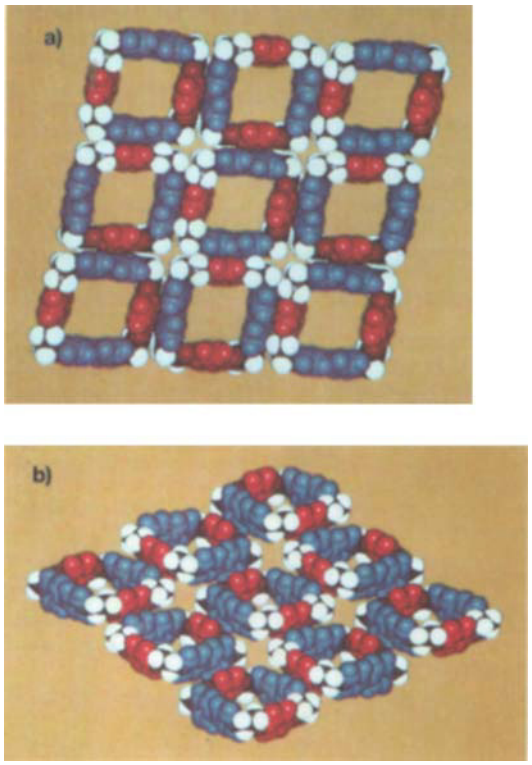

Fig. 1. a) Front view and b) side view in perspective of the packing of $\mathbf{4}^{4+}$ in the solid state (space-filling representations).

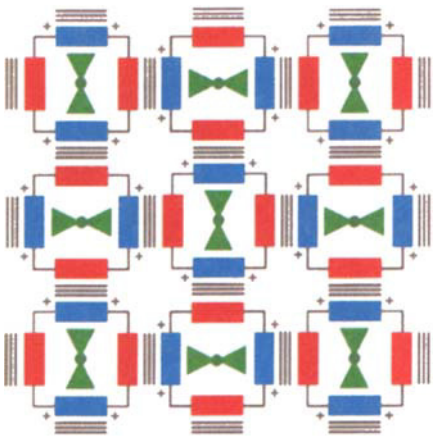
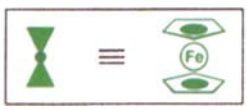
of the rings are inclined by 22°. Although adjacent sheets are separated by layers of disordered PF_6^- ions and MeCN molecules, the tetracations are in register and form channels that extend through the crystal (Fig. 2).[14]

Mixing equimolar amounts of $\mathbf{4}\cdot 4PF_6$ and ferrocene (Fc) in MeCN produces a bright green solution, which we associate with the formation of a 1:1 adduct $\mathbf{4}/Fc\cdot 4PF_6$ in the form of an inclusion complex that also displays a charge transfer (CT) interaction.[15] A UV spectrophotometric titration, using the CT band centered on 602 nm, yields an association constant K_a of $44 \pm 3\ dm^3\,mol^{-1}$ for the 1:1 adduct $\mathbf{4}/Fc\cdot 4PF_6$ in MeCN at 25°C. This K_a value corresponds to a free energy of adduct formation of $-2.2\ kcal\,mol^{-1}$. In the ^1H NMR spectrum of $\mathbf{4}/Fc\cdot 4PF_6$ (5.5×10^{-3} M in CD_3CN) significant upfield shifts are observed for the resonances of the cyclopentadienyl ring protons of Fc ($\Delta\delta = -0.29$) and also for the bipyridinium β-protons of $\mathbf{4}^{4+}$ ($\Delta\delta = -0.08$), indicating that the ferrocene molecule resides within the tetracationic cyclophane with its cyclopentadienyl rings oriented parallel to the plane of the two bipyridinium units in the tetracation. Consequently, it was anticipated that inclusion of ferrocene in this manner should permit the retention (Scheme 3) of the mosaiclike array proposed (Scheme 1) and observed (Fig. 1) in the solid state for $\mathbf{4}\cdot 4PF_6$.





Scheme 3. Schematic representation of the anticipated structure of the 1:1 adduct $\mathbf{4}/Fc^{4+}$ in a crystalline salt.

The X-ray crystallographic analysis[10, 16] of $\mathbf{4}/Fc\cdot 4PF_6$ reveals a C_i-symmetric adduct in which the iron atom of the ferrocene molecule is located on a crystallographic symmetry center and the cyclopentadienyl rings are sandwiched between the faces of the two bipyridinium units (Fig. 3). The structure of the cyclophane is very similar to that of $\mathbf{4}\cdot 4PF_6$; the *syn* arrangement of the $CH_2OC_6H_4OCH_2$ groups is retained and the distances between the corner NCH_2 carbon atoms are 9.83 and 9.95 Å with associated angles of 88 and 92° (as before!).[17] The

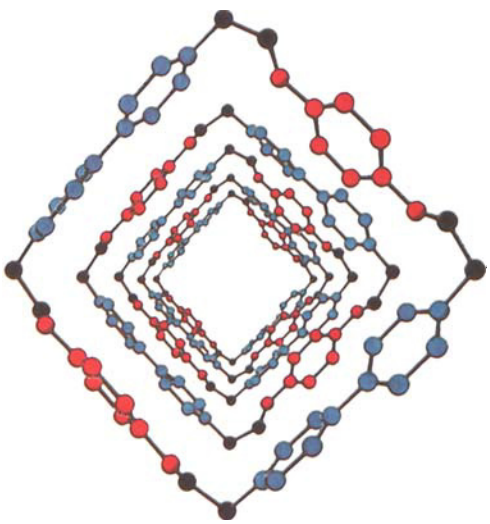


Fig. 2. View down a channel of $\mathbf{4}^{4+}$ ions in the solid state (ball-and-stick representation).

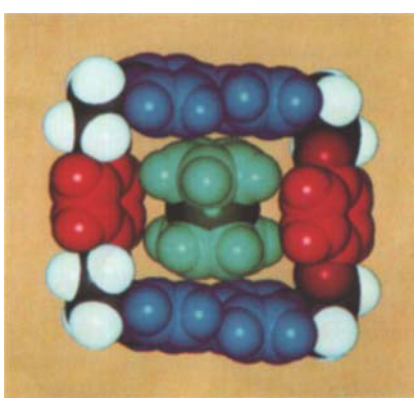

Fig. 3. Space-filling representation of $\mathbf{4}/Fc^{4+}$ in the X-ray structure of $\mathbf{4}/Fc\cdot 4PF_6$.

torsional twists within the bipyridinium units are 19° and these units are bowed by 7°. The planes of the bipyridinium units are again essentially orthogonal with respect to the mean plane of the cyclophane, but the inclination of the hydroquinone rings is increased by 5° to 54°. The bipyridinium/bipyridinium and hydroquinone/hydroquinone centroid–centroid separations are 10.1 and 10.2 Å, respectively. The distance from the center of the C–C bond of the bipyridinium unit and the centroid of the adjacent cyclopentadienyl ring of the ferrocene is 3.4 Å, and the vector linking these two centroids is inclined by 88° to the cyclopentadienyl ring plane. The packing of the 1:1 adducts (Fig. 4) is virtually identical to that of the free cyclophane

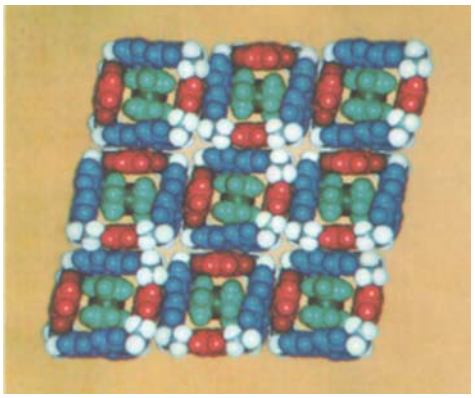

Fig. 4. View of the packing of the 1:1 adduct $\mathbf{4}/Fc^{4+}$ in the solid state (space-filling representation).

(Fig. 1a). A slightly stepped two-dimensional mosaic is observed with improved π–π stacking between the hydroquinone ring of one molecule and one of the pyridinium rings of the bipyridinium unit in an adjacent molecule. The pyridinium/hydroquinone ring centroid separations are reduced to 3.8 Å and their planes are much closer to parallel, with an inclination of only 6° (cf. 22° in $\mathbf{4}\cdot 4PF_6$). The packing of the sheets is again virtually identical to that observed for the free cyclophane; adjacent sheets are approximately in register and form partially filled channels that extend in the crystallographic *a* direction. The distance between the sheets is 9.8 Å and the interstices are occupied by MeCN and H_2O molecules and by the PF_6^- ions.

The self-assembly of $\mathbf{4}\cdot 4PF_6$ is possible as a result of sufficient information in the form of molecular recognition elements being programmed into its constituent molecular components. The information present in the symmmetrical cyclophane facilitates the efficient self-organization of a regular repeating two-dimensional supramolecular array in the solid state. The symmetrically oriented molecular recognition elements of the cyclophane $\mathbf{4}\cdot 4PF_6$ have also allowed the directionally specific inclusion of ferrocene within its cavity to form the 1:1 adduct $\mathbf{4}/Fc\cdot 4PF_6$. The ability of both $\mathbf{4}\cdot 4PF_6$ and $\mathbf{4}/Fc\cdot 4PF_6$ to generate supramolecular order on the nanometer scale in the crystalline state marks a significant development in the fields of both crystal engineering[5] and supramolecular chemistry.[6] Furthermore, it is believed that, in the solution state, the inclusion of organometallic species[18] within cyclophanes of this type, featuring π–π stacking molecular recognition motifs, will open up novel routes to new mechanically interlocked molecular systems.[19] Also, as further fascinating examples of second-sphere coordination,[20] they could find application in the design of artificial enzymes[21]—or indeed they might ultimately play a significant role in the construction[22] of functioning nanoscale devices.[23]

Experimental Procedure

$\mathbf{3}\cdot 2PF_6$: During seven days, **2** (1.05 g, 3.2 mmol) was added portionwise three times a day (50 mg per portion) to a refluxing solution of 4,4′-bipyridine (5.05 g, 32.4 mmol) in dry MeCN (100 mL) under nitrogen. The reaction mixture was maintained under reflux for a further 48 h before it was allowed to cool down to room temperature. The greenish brown precipitate was filtered, dissolved in a mixture of acetone and water, and purified by column chromatography [SiO_2; MeOH/2N aqueous $NH_4Cl/MeNO_2$ (7:2:1)] to yield, after counterion exchange, $\mathbf{3}\cdot 2PF_6$ as a yellow solid (1.3 g, 50%, m.p. >250 °C); FABMS: *m/z*: 621 ($[M - PF_6]^+$); ^1H NMR (300 MHz, CD_3COCD_3): $\delta = 4.65$ (t, 4H), 5.32 (t, 4H), 6.92 (s, 4H), 7.99 (d, 4H), 8.72 (d, 4H), 8.87 (d, 4H), 9.42 (d, 4H); ^{13}C NMR (75.5 MHz, CD_3CN): $\delta = 61.7, 67.5, 116.8, 123.2, 127.0, 142.1, 146.6, 152.2, 153.6, 155.7$. Single crystals suitable for X-ray crystallography were grown from aqueous acetone.

$\mathbf{4}\cdot 4PF_6$: A solution of **2** (32.4 mg, 0.1 mmol), $\mathbf{3}\cdot 2PF_6$ (76.6 mg, 0.1 mmol), and BHEEN (100.9 mg, 0.3 mmol) in dry DMF (10 mL) was transferred to a high-pressure reaction Teflon tube and compressed (12 kbar) at room temperature for 5 d. The precipitate that resulted on addition of Et_2O (150 mL) was filtered off and purified by column chromatography [SiO_2; MeOH/2N aqueous $NH_4Cl/MeNO_2$ (7:2:1)] to yield, after counterion exchange, $\mathbf{4}\cdot 4PF_6$ as a deep yellow solid (15 mg, 12%, m.p. >260 °C, FABMS: *m/z*: 1075 ($[M - PF_6]^+$); ^1H NMR (300 MHz, CD_3CN): δ: = 4.31 (t, 8H), 4.98 (t, 8H), 6.71 (s, 8H), 8.36 (d, 8H), 8.94 (d, 8H); ^{13}C NMR (75.5 MHz, CD_3CN): δ: = 62.3, 67.5, 116.3, 127.6, 147.3, 150.8, 153.5. Single crystals suitable for X-ray crystallography were grown by vapor diffusion of iPr_2O into a solution of $\mathbf{4}\cdot 4PF_6$ in MeCN.

$\mathbf{4}/Fc\cdot 4PF_6$ (5.5×10^{-3} M): ^1H NMR (300 MHz, CD_3CN): $\delta = 3.87$ (s, 10H), 4.31 (t, 8H), 4.96 (t, 8H), 6.74 (s, 8H), 8.28 (d, 8H), 8.89 (d, 8H). Single crystals suitable for X-ray crystallography were grown by vapor diffusion of iPr_2O into a 1:1 solution of $\mathbf{4}\cdot 4PF_6$ and ferrocene in MeCN.

Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules**

Peter R. Ashton, Paul J. Campbell, Ewan J. T. Chrystal, Peter T. Glink, Stephan Menzer, Douglas Philp, Neil Spencer, J. Fraser Stoddart,* Peter A. Tasker, and David J. Williams

Since Pedersen's discovery[1] that crown ethers form complexes with organic as well as metal cations, numerous investigations[2] of the binding of NH_4^+ and RNH_3^+ ammonium ions to macrocyclic polyethers have been reported. Almost without exception, the mode of binding (Fig. 1a) is face-to-face in character and usually 1:1 in its stoichiometry,[3] though occasionally, in closely related situations, 2:1 complexes occur.[4] By contrast, reports describing[5] the complexation of dialkylammonium ions ($R_2NH_2^+$) by crown ethers are relatively sparse. These investigations were limited almost entirely to complexes formed with medium-ring macrocycles, for example 1,7-dimethyl-1,7-diaza[12]crown-4, in which a face-to-face arrangement is inevitable and the ammonium center forms hydrogen bonds with the heteroatoms of the macrocycle.[6] In principle, increasing the size of the ring should enable the complete insertion (Fig. 1b) of an $R_2NH_2^+$ ion into and through the macro-ring center. The formation of such pseudorotaxanes[7] would be the prelude to the construction of a whole new family of interlocked molecules,[8] such as rotaxanes (Fig. 1c) and catenanes (Fig. 1d). Here, we report our first two examples of pseudorotaxanes formed between $R_2NH_2^+$ ions and dibenzo[24]crown-8 (**DB24C8**)[9] fully characterized by computational, crystallographic, and spectroscopic methods.

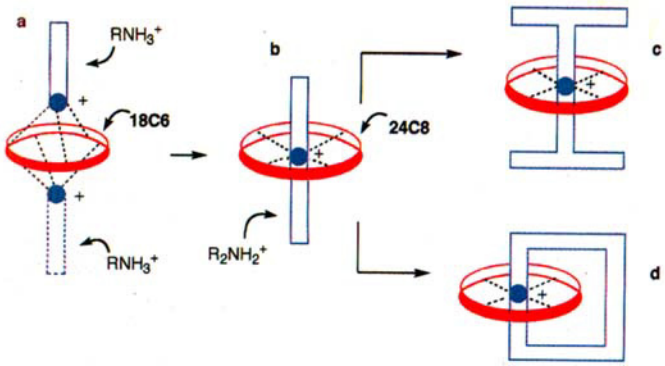

Fig. 1. Schematic representation of a) the face-to-face mode of binding RNH_3^+ to derivatives of [18]crown-6 (**18C6**) and how, in the case of $R_2NH_2^+$ and even larger macrocyclic polyethers such as **24C8**, one might expect a 1:1 complex of pseudorotaxane type (b) to form. Such a 1:1 complex can be envisioned to lead to a [2]rotaxane (c) and a [2]catenane (d).

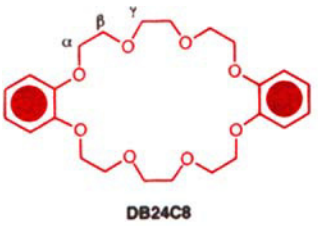
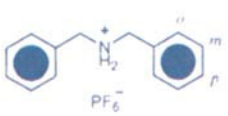
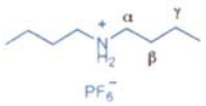
Computer modeling of the 1:1 complex in which the di-*n*-butylammonium ion is threaded through the center of the **DB24C8** ring in both vacuum[10] and solution[11] produced several low-energy assemblies with pseudorotaxane-like geometries. Encouraged by these calculations, we proceeded to



DB24C8



1-H·PF$_6$



2-H·PF$_6$

investigate the ability of **DB24C8** to form complexes in solution with dibenzylammonium (**1**-H·PF$_6$) and di-*n*-butylammonium (**2**-H·PF$_6$) hexafluorophosphates. Although these salts are quite soluble in MeOH, Me_2CO, MeCN, and Me_2SO, they are virtually insoluble in $CHCl_3$ and CH_2Cl_2. The first indication that **1**-H·PF$_6$ and **2**-H·PF$_6$ form 1:1 complexes with **DB24C8** was the observation of the ready solubilization of both these salts in $CHCl_3$ and CH_2Cl_2 solutions on addition of the crown ether. The ^{1}H NMR spectrum (Fig. 2) of a 1:1 mixture of **DB24C8**

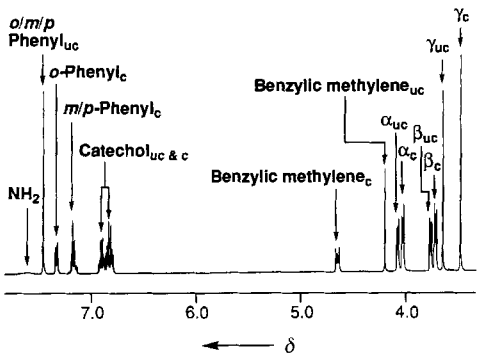


Fig. 2. The ^{1}H NMR spectrum recorded at 400 MHz in CD_3CN of an equimolar mixture of **DB24C8** and **1**-H·PF$_6$ at 20 °C. The concentrations of both the crown ether and the salt are 1.0×10^{-2} M. Three sets of resonances are evident in this spectrum: for the uncomplexed crown ether (**uc**), and uncomplexed salt (**uc**), and for the 1:1 complex between **DB24C8** and **1**-H·PF$_6$ (**c**).

and **1**-H·PF$_6$ in CD_3CN shows three sets of resonances for 1) free **DB24C8**, 2) free **1**-H·PF$_6$, and 3) the 1:1 complex[12] between the crown ether and the dibenzylammonium ion. The presence of both free and complexed species in equilibrium implies that the rates of complexation and decomplexation are both slow on the ^{1}H NMR time scale at room temperature—an observation that is not too surprising since space-filling models indicate that a phenyl ring has some difficulty threading its way through the cavity of **DB24C8**. By contrast, the ^{1}H NMR spectrum[13] of a 1:1 mixure of **DB24C8** and **2**-H·PF$_6$ shows a time-averaged set of signals consistent with the much decreased bulk of the *n*-butyl groups in **2**-H$^+$ relative to the benzyl groups in **1**-H$^+$. The much more rapid rates of complexation and decomplexation, implied by the time-averaging for association and dissociation of [**DB24C8**·**2**-H]PF$_6$, are also consistent with a pseudorotaxane-like structure for the 1:1 complex[12] in solution, given the substantial shifts observed[13] in the resonances of the butyl protons.

Crystals[14] of both 1:1 complexes were analyzed by mass spectrometry (FABMS).[15] Both [**DB24C8**·**1**-H]PF$_6$ and [**DB24C8**·**2**-H]PF$_6$ displayed very strong peaks, at *m*/*z* 646 for the [**DB24C8**·**1**-H]$^+$ ion and at *m*/*z* 578 for the [**DB24C8**·**2**-H]$^+$ ion. Indeed, the peak for the [**DB24C8**·**1**-H]$^+$ ion is by far the most abundant in the mass spectrum, an observation commensurate with a very strong 1:1 complex. Elemental microanalyses of the crystalline complexes confirmed their 1:1 stoichiometries. The solid-state structures of these 1:1 complexes were established by X-ray crystallography on suitable single crystals.[14]

[**DB24C8**·**1**-H]PF$_6$ crystallizes[16] with two crystallographically independent 1:1 complexes, **A** and **B** (Fig. 3), in the asymmetric unit. In both complexes, the **1**-H$^+$ ion is threaded

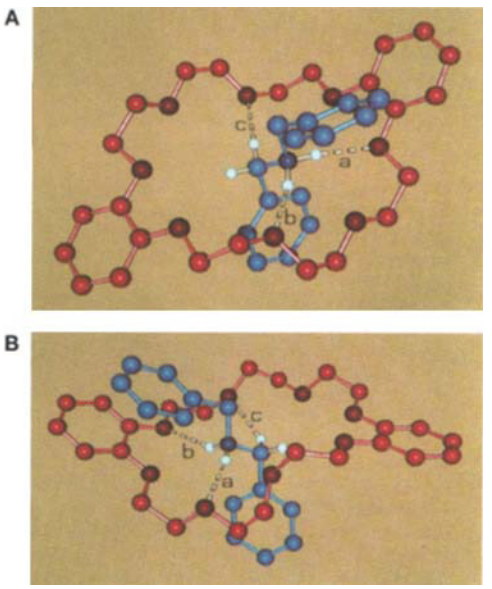

Fig. 3. The superstructures of the 1:1 complexes **A** and **B** of [**DB24C8**·**1**-H]$^+$ in the solid state. In **A**, the hydrogen bonds have the following distances and angles a) [N···O] 3.12 Å, [H···O] 2.24 Å, [N–H···O] 167°; b) [N···O] 2.85 Å, [H···O] 1.99 Å, [N–H···O] 159°; c) [C···O] 3.16 Å, [H···O] 2.21 Å, [C–H···O] 174°. In **B**, the hydrogen bonds have the following distances and angles a) [N···O] 2.99 Å, [H···O] 2.14 Å, [N–H···O] 157°; b) [N···O] 3.12 Å, [H···O] 2.28 Å, [N–H···O] 155°; c) [C···O] 3.27 Å, [H···O] 2.45 Å, [C–H···O] 143°.

through the center of the **DB24C8** macrocycle, which adopts an extended all-*gauche* (O-C-C-O) conformation. The structures of the two independent cations differ, as does the nature of the threading through the macrocyclic polyethers. The cation in **A** has a "gull-wing" conformation in which the planes of the aromatic rings are approximately orthogonal to the C–CH_2–NH_2^+–CH_2–C backbone. In **B**, one of the phenyl rings is inclined by roughly 52° to the backbone while the other one is essentially orthogonal. In both complexes, the NH_2^+ center and one of the adjacent CH_2 groups lie more or less within the plane of their polyether macrocycles. Also, in **A** and **B**, *both* NH_2^+ hydrogen atoms and *one* CH_2 hydrogen atom are directed toward polyether oxygen atoms which lie within *H*-bonding distances. However, the oxygen atoms involved in these hydrogen bonds are different in **A** and **B**, demonstrating that alterna-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3417-1866 $ 10.00+.25/0

tive three-point binding geometries can be accommodated within these 1:1 complexes. In **B**, there is an additional $\pi-\pi$ stacking interaction between one of the phenyl groups in the cation and one of the catechol rings in the crown ether (mean plane separation, 3.48 Å, centroid–centroid separation, 3.79 Å, angle formed by the ring planes, 11°). The macrocyclic components of **A** and **B** pack (Fig. 4) to form channels that extend in the crystallographic c direction with the cations threaded in such a manner as to suggest the potential for the formation of polyrotaxanes. The centrally located phenyl groups are aligned parallel to each other, with a mean interplanar separation of 3.50 Å and a centroid–centroid distance of 3.73 Å. The distance between adjacent NH_2^+ centers in the stack are 9.3 and 9.7 Å.

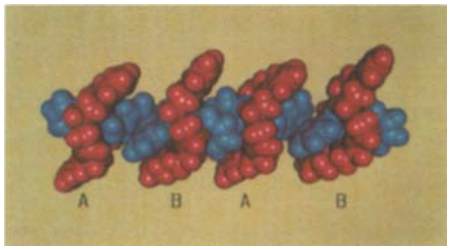

Fig. 4. Part of one of the continuous cation-threaded channels present in the crystals of [**DB24C8**·**1**-H]PF_6. The sequence of complexes from left to right is **ABAB**.

The X-ray crystal structure[16] of [**DB24C8**·**2**-H]PF_6 reveals (Fig. 5) that the macrocyclic polyether adopts an extended all-*gauche* (O-C-C-O) conformation very similar to that in [**DB24C8**·**1**-H]PF_6. The **2**-H^+ ion is threaded through the center of the **DB24C8** and bound by means of one [C–H···O] and two [N–H···O] hydrogen bonds. Although there are no dominant intercomplex interactions, the packing of the complexes suggests the possibility for polyrotaxane formation.

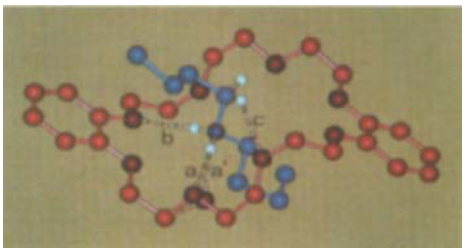

Fig. 5. The superstructure of the 1:1 complex [**DB24C8**·**2**-H]$^+$ in the solid state. The hydrogen bonds have the following distances and angles a) [N···O] 3.09 Å, [H···O] 2.20 Å, [N–H···O] 175°; a') [N···O'] 2.90 Å, [H···O'] 2.04 Å, [N–H···O'] 161°; b) [N···O] 3.25 Å, [H···O] 2.35 Å, [N–H···O] 172°; c) [C···O] 3.23 Å, [H···O] 2.48 Å, [C–H···O] 134°.

In the ^{1}H NMR spectra of an equimolar mixture of **1**-H^+ and **DB24C8** in a number of different solvents, signals for the complexed and uncomplexed species are observed (see Fig. 2). Since absolute concentrations can be determined readily from the relative abundances of the three species at equilibrium when the initial concentrations of both **1**-H^+ and **DB24C8** are known, single point determination[17] of the association constants (K_a) and derived free energies of complexation (ΔG°) are possible. The values of K_a at 25 °C are given in Table 1 for a range of common NMR solvents. A clear trend is observed: an increase in K_a values corresponds to the decrease in the Gutmann donor numbers[18] of the solvents. For instance, $CDCl_3$, a very weak hydrogen bond acceptor, gives the highest K_a value (Table 1, Entry 5), whereas, in CD_3SOCD_3, no complex formation could be observed (Entry 1).

Table 1. Effect of solvent on the association constants K_a for the 1:1 complex formed between of **DB24C8** and **1**-H·PF_6 at 25 °C.

Entry	Solvent	ε [a]	n_G [a]	K_a [M^{-1}] [b]	ΔG° [kcal mol^{-1}]
1	CD_3SOCD_3	46.5	29.8	0	-
2	CD_3COCD_3	20.6	17.0	360	−3.5
3	CD_3CN	35.9	14.1	420	−3.6
4	$CDCl_3$/CD_3CN (1:1)	–	–	1700	−4.4
5	$CDCl_3$	4.81	4.0	27000	−6.0

[a] Values of the solvent dielectric constants ε and the Gutmann donor numbers n_G were obtained from ref. [18]. [b] Association constants K_a were obtained from single-point measurements of the concentrations of the complexed and uncomplexed species in the relevant ^{1}H NMR spectra at 25 °C and using the expression $K_a = \frac{[\mathbf{DB24C8}\cdot\mathbf{1}\text{-}H]^+}{[\mathbf{DB24C8}][\mathbf{1}\text{-}H^+]}$. [c] The free energies of complexation ΔG° were calculated from the K_a values by applying the equation $\Delta G^\circ = -RT\ln K_a$.

By contrast, the time-averaged ^{1}H NMR signals associated with complexation between **DB24C8** and **2**-H^+ ions in various solvents requires the calculation of the K_a values by dilution or titration methods.[19] In $CDCl_3$, dilution from 5×10^{-2} to 5×10^{-4} M resulted in only negligible shifts for all of the resonances of the host and guest species.[20] This result reflects the low solubility of the salt **2**-H·PF_6 in $CDCl_3$ in the absence of **DB24C8** and the resulting very high K_a value of $>10^4\,M^{-1}$. In CD_3CN, in which **2**-H·PF_6 is readily soluble, dilution over the same range of concentrations resulted in significant shifts ($\Delta\delta$) of the four butyl proton resonances of between 25 and 55 Hz. Plots of $\Delta\delta$ against $(\Delta\delta/c)^{1/2}$ for different probe protons gave straight lines,[21] the slopes of which yielded K_a values of consistently around $70\,M^{-1}$. Use of the titration method,[19] in which the ratio of **DB24C8** was varied with respect to **2**-H·PF_6 in CD_3CN, gave a value of approximately $50\,M^{-1}$ for K_a. These K_a values for [**DB24C8**·**2**-H]PF_6 complexation are somewhat lower than the value (Table 1, Entry 3) of K_a for the [**DB24C8**·**1**-H]PF_6 complex in CD_3CN. This observation reflects the greater flexibility—and hence lower preorganization—of the **2**-H^+ ion compared with the more rigid **1**-H^+ ion. A mixture of **DB24C8** and **2**-H·PF_6 in a 2:1 molar ratio was dissolved in CD_2Cl_2 and investigated by variable-temperature ^{1}H NMR spectroscopy. At + 30 °C, the spectrum obtained displays a time-averaged set of resonances for both the host and guest species (Fig. 6a). At −27 °C, the signals associated with the α- and γ-OCH_2 protons in the crown ether exist as two sets of equally intense resonances arising from complexed and uncomplexed **DB24C8** molecules (Fig. 6b). The coalescence temperatures were found to be −3 °C for the α-OCH_2 protons ($\Delta\delta$ = 24 Hz at −27 °C) and −7 °C for the γ-OCH_2 protons ($\Delta\delta$ = 20 Hz at −27 °C). From these parameters, the activation barrier ($\Delta G_c^{\ddagger}$) for the exchange of the di-*n*-butylammonium ion from one crown ether molecule to another was calculated to be roughly 13.5 kcal mol^{-1}.

We have demonstrated that an extremely simple recognition motif—the binding of dialkylammonium salts with suitably sized crown ethers—can result in the self-assembly of pseudorotaxanes. The roots of this supramolecular phenomenon lie in 1) *hydrogen bonding interactions* involving charged and/or activated donors and neutral acceptors, 2) *electrostatic pole–dipole interactions* between onium centers and precisely positioned ligating atoms, as well as, in some instances, 3) *dispersive interactions*, including stabilizing $\pi-\pi$ and/or CH–π interactions. The extension of this exciting and potentially rewarding line of in-

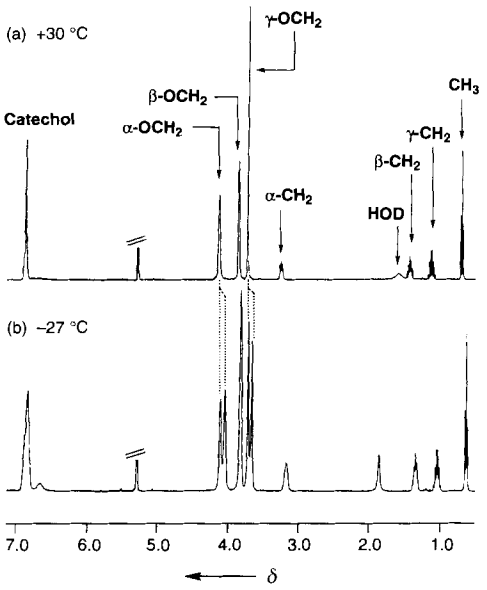

Fig. 6. The ^{1}H NMR spectrum recorded at 400 MHz in CD_2Cl_2 of a solution of **DB24C8** and **2**-H·PF_6 in a 2:1 molar ratio at a) + 30 °C and b) −27 °C. The spectrum recorded at higher temperature (a) shows a time-averaged set of signals for both **DB24C8** and **2**-H$^+$. In the spectrum recorded at lower temperature (b), signals associated with one equivalent of complexed and one equivalent of uncomplexed **DB24C8** are evident for the α-OCH_2 and γ-OCH_2 protons. The concentrations of the crown ether and the salt are 2.4×10^{-2} M and 1.2×10^{-2} M, respectively.

quiry into the elaboration of a new range of interlocked molecular compounds, specifically catenanes and rotaxanes as indicated conceptually in Figure 1, is now the subject of detailed study in our research laboratories.[2,3] It is remarkable to reflect on the fact that in the intervening three decades since Pedersen[1] first reported the complexation of (substituted) ammonium salts by crown ethers, no publications have appeared to our knowledge in which dialkylammonium ions have been shown to thread through macrocyclic polyethers.

Experimental Procedure

General procedure for the synthesis of $[R_2NH_2]PF_6$ salts: 2 M HCl (250 mL) was added to R_2NH (ca. 25 mmol) and the solution stirred for 4 h. Water was removed under vacuum and the residue dissolved in H_2O (100 mL). Saturated aqueous NH_4PF_6 was added until no further precipitation occurred. The white solid was filtered off and dried.

1-H·PF_6: Yield 91%; m.p. 205–208 °C; Analysis: found: C 48.72, H 4.53, N 4.28%; calcd for $C_{14}H_{16}NPF_6$: C 48.98, H 4.66, N 4.08%; MS (FAB): *m/z*: 198 [*M* − PF_6]$^+$; ^{1}H NMR (300 MHz, CD_3SOCD_3): δ = 4.20 (s, 4H, CH_2), 7.39–7.53 (m, 10H, aromatic protons), 9.19 (br s, 2H, NH_2); ^{13}C NMR (75 MHz, CD_3SOCD_3): δ = 50.3 (CH_2), 128.8, 129.1, 130.0, 131.9 (*ipso*-C).

2-H·PF_6: Yield 92%; m.p. 187–188 °C; Analysis: found: C 35.03, H 7.39, N 5.11%; calcd for $C_8H_{20}NPF_6$: C 34.91, H 7.27, N 5.09%; MS (CI): *m/z* 130 [*M* − PF_6]$^+$; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.97 (t, *J* = 7.5 Hz, 6H, CH_3), 1.36–1.48 (m, 4H, γ-CH_2), 1.74–1.85 (m, 4H, β-CH_2), 2.96–3.05 (m, 4H, α-CH_2), 7.65 (br s, 2H, NH_2); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 13.5 (CH_3), 19.9 (γ-CH_2), 27.6 (β-CH_2), 47.6 (α-CH_2).

[7] The name "rotaxane" is derived from the Latin words *rota* meaning wheel and *axis* meaning axle (G. Schill, *Catenanes, Rotaxanes, and Knots*, Academic Press, New York, **1971**). In the chemical sense, this type of molecule contains a linear component (the axle) encircled by a macrocyclic component (the wheel). In order to prevent the wheel from slipping off the axle, the linear component must be terminated at both ends by large blocking groups or stoppers. The addition of the prefix pseudo to the term rotaxane indicates that in a "pseudorotaxane" the wheels are free to dissociate from the axle in the same way as ligands may in a more conventional type of complex. The molecular components of a pseudorotaxane are held together only by their mutual noncovalent bonding interactions. See P. R. Ashton, D. Philp, N. Spencer, J. F. Stoddart, *J. Chem. Soc. Chem. Commun.* **1991**, 1677–1679.

[10] Calculations were performed on a Silicon Graphics 4B/35 workstation using the CVFF forcefield as implemented in the Insight II/Discover package (Version 2·3.0, Biosym Technologies, San Diego, 1993).

[11] Calculations were performed on a Silicon Graphics Crimson Elan Workstation using the MM3* forcefield, a modified version of the original MM3 forcefield (N. L. Allinger, M. Rahman, J.-H. Lii, *J. Am. Chem. Soc.* **1990**, *112*, 8293–8307) and the GB/SA solvent model (W. C. Still, A. Tempczyk, R. C. Hawley, T. Hendrickson, *J. Am. Chem. Soc.* **1990**, *112*, 6127–6129) for $CHCl_3$ as implemented by Macromodel V3.5X (F. Mohamadi, N. G. J. Richards, W. C. Guida, R. Liskamp, C. Canfield, G. Chang, T. Hendrickson, W. C. Still, *J. Comput. Chem.* **1990**, *11*, 440–467; Version 3.5X, Columbia University, 1992). Initial input structures were minimized using the Polak–Ribiere Conjugate Gradient method to a gradient of < 0.1 kJ mol^{-1} Å^{-1}. Conformational searching was performed using the Monte Carlo (MC) method. Global minima were located by 1000-step MC simulations, and the structures generated by the conformational search were minimized to a gradient of < 0.01 kJ mol^{-1} Å^{-1} using the Full-Matrix Newton–Raphson (FMNR) method. Two starting geometries were used. The same set of minimum-energy structures emerged in both cases.

[12] An NOE experiment was also undertaken in which each of the resonances associated with the protons in the 1:1 complex formed between **DB24C8** and **1**-H·PF_6 in $CDCl_3$ was irradiated in turn. The signals of the *o*-phenyl and benzylic methylene protons of the **1**-H$^+$ ion in the complex were enhanced upon irradiation of the β- and γ-OCH_2 protons of the complexed **DB24C8**, but only the signal for the *o*-phenyl protons was enhanced upon irradiation of the α-OCH_2 resonance. Conversely, irradiation of the *o*- and *m*/*p*-phenyl resonances of the complexed **1**-H$^+$ ion resulted in enhancement of all three OCH_2 signals, but irradiation of the benzylic methylene resonance of the complexed **1**-H$^+$ ion enhanced only the β- and γ-signals of the complexed **DB24C8**. Irradiation of the NH_2 signal produced small enhancements in all three **DB24C8** OCH_2 resonances. Irradiation of the signals for the aromatic protons in **DB24C8** had a negligible effect on the resonances of the bound **1**-H$^+$ ion. These NOE experiments are consistent with a 1:1 complex having a pseudorotaxane structure in solution.

[13] The Δδ values for the α-CH_2, β-CH_2, γ-CH_2, and Me protons from ^{1}H NMR spectra recorded on **2**-H·PF_6 and [**DB24C8** · **2**-H]PF_6 at 300 MHz in $CDCl_3$ are + 0.19, − 0.30, − 0.25, and − 0.23, respectively.

[14] Both 1:1 complexes were crystallized by liquid diffusion of *n*-hexane into a $CHCl_3$ solution of an equimolar mixture of the dialkylammonium salt (**1**-H·PF_6 or **2**-H·PF_6) and **DB24C8**.

[15] FAB mass spectra were recorded with a Kratos MS80RF mass spectrometer (accelerating voltage 4 kV; resolution 1000) coupled to a DS90 data system with an off-line Sun Workstation for data processing. The atom gun was an adapted saddle field source (Ion Tech Limited) operating at 7 keV with a tube current of roughly 2 mA. Krypton was used to provide a primary beam of atoms, and samples of the complexes were dissolved in a small volume (ca. 1–2 μL) of *m*-nitrobenzyl alcohol and loaded on to a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 10 s per decade.

[16] X-ray data for [**DB24C8**·**1**-H]PF_6·0.5H_2O: triclinic, space group $P\bar{1}$, $a = 14.430(3)$, $b = 15.788(4)$, $c = 18.536(5)$ Å, $\alpha = 73.30(2)$, $\beta = 75.79(2)$, $\gamma = 84.10(2)°$, $V = 3939(2)$ Å^3, $Z = 4$, $\mu(Cu_{K\alpha}) = 1.32$ mm^{-1}, $\rho_{calc} = 1.35$ g cm^{-3}, Siemens P4/PC diffractometer, graphite-monochromated $Cu_{K\alpha}$ radiation. The structure was solved using direct methods, and anisotropic refinement gave

$R = 0.063$, $R_w = 0.068$ for 6629 independent observed reflections for $[|F_o| > 4\sigma(F_o|)$, $2\theta < 110^\circ]$. X-ray data for **[DB24C8·2-H]PF$_6$**: monoclinic, space group Ia (body-centered cell chosen because C-face-centered cell has $\beta = 124^\circ$), $a = 18.597(4)$, $b = 10.362(3)$, $c = 20.265(3)$ Å, $\beta = 105.48(2)^\circ$, $V = 3763(2)$ Å^3, $Z = 4$, $\mu(Cu_{K\alpha}) = 1.30$ mm^{-1}, $\rho_{calc} = 1.28$ g cm^{-3}. Siemens P4/PC diffractometer, graphite-monochromated $Cu_{K\alpha}$ radiation. The structure was solved using direct methods, and anisotropic refinement gave $R_1 = 0.063$, $\omega R_2 = 0.169$ for 2747 independent observed reflections with $[|F_o| > 4\sigma(|F_o|)$, $2\theta < 125^\circ]$. Further details of the X-ray crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EW (UK).

[17] For an alternative type of single-point analysis for the determination of K_a values, see J. C. Adrian, Jr., C. S. Wilcox, *J. Am. Chem. Soc.* **1991**, *113*, 678–680.

[18] The Gutmann donor number provides a semiquantitative measurement of the ability of the solvent to donate its electrons into noncovalent bonds. See a) V. Gutmann, E. Wychera, *Inorg. Nucl. Chem. Lett.* **1966**, *2*, 257–260; b) C. Reichardt, *Solvents and Solvent Effects in Organic Chemistry*, 2nd ed., VCH, Weinheim, **1988**.

[19] C. S. Wilcox in *Frontiers of Supramolecular Organic Chemistry and Photochemistry* (Eds.: H.-J. Schneider, H. Durr), VCH, Weinheim, **1991**, pp. 123–143.

[20] The determination of K_a values by either titration or by Job's method of continuous variation cannot be undertaken in $CDCl_3$ because these techniques both require at some stage that the concentration of the ammonium salt be in excess relative to that of the crown ether. This situation cannot be achieved in practice on account of the low solubility of **1**-H·PF$_6$ in the absence of a molar equivalent of **DB24C8**.

[21] In the case of the dilution experiment, the values of K_a and $\Delta\delta_{max}$ were obtained after linearization of the binding data according to Equation (a), where $\Delta\delta_{max}$ corresponds to the value of the complexation-induced chemical shift, $\Delta\delta_o$ is the observed difference in chemical shift between the complex and free species for a probe proton of either host or guest, and c is the concentration of an equimolar solution of host and guest.

$$\Delta\delta_o = \Delta\delta_{max} - (\Delta\delta_o \Delta\delta_{max}/cK_a)^{1/2} \quad (a)$$

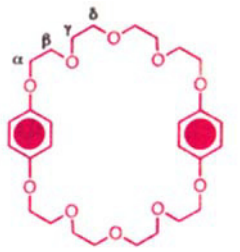
[22] The Eyring equation was employed to calculate $\Delta G_c^{\ddagger}$ values at the coalescence temperatures T_c, at which the rate constants k_c can be calculated (I. O Sutherland, *Annu. Rep. NMR Spectrosc.* **1971**, *4*, 71–235) from the approximate expression, $k_c = \pi(\Delta\nu)/(2)^{1/2}$, where $\Delta\nu$ is the chemical shift difference (in Hertz) between the coalescing signals in the absence of exchange.

[23] **Note added in proof** (August 18, 1995): After this paper had been submitted, Busch et al. (A. G. Kolchinski, D. H. Busch, N. W. Alcock, *J. Chem. Soc. Chem. Commun.* **1995**, 1289–1291) reported the synthesis of a [2]rotaxane composed of a dumbell, which incorporates a secondary dialkylammonium center, and a **DB24C8** bead. The [2]rotaxane was self-assembled by acylation of a primary amine—in a molecule also containing a secondary amino center—in the presence of the macrocycle.

Doubly Encircled and Double-Stranded Pseudorotaxanes**

Peter R. Ashton, Ewan J. T. Chrystal, Peter T. Glink, Stephan Menzer, Cesare Schiavo, J. Fraser Stoddart,* Peter A. Tasker, and David J. Williams

In the preceeding communication,[1] we described the formation of pseudorotaxanes from $R_2NH_2^+$ ions (R = $PhCH_2$ in **1**-H·PF$_6$ and R = *n*Bu in **2**-H·PF$_6$) and dibenzo[24]crown-8 (**DB24C8**) both in the solution and solid states. Subsequently, in our evaluation of the propensities of other crown ethers to bind with $R_2NH_2^+$ ions, we discovered that **1**-H·PF$_6$ forms a complex with bis-*para*-phenylene[34]crown-10 (**BPP34C10**)[2] in which two dibenzylammonium ions are threaded simultaneously through the macrocyclic polyether. Here, we describe (i) the X-ray crystal structure of this 1:2 complex, [**BPP34C10**·(**1**-H)$_2$][PF$_6$]$_2$, a "double-stranded pseudorotaxane", and also those of the solid-state superstructures that self-assemble spontaneously from solutions of α,α′-bis(benzylammonium)-*para*-xylene bis(hexafluorophosphate) (**3**-H$_2$·2PF$_6$) and (ii) **BPP34C10** and also (iii) **DB24C8**; these latter structures are intriguing examples of a double-stranded and a doubly encircled 2:2 complex and a doubly encircled 2:1 complex, respectively. Evidence that the 1:2 and 2:1 complexes ("a double-stranded pseudorotaxane" and "a doubly encircled pseudorotaxane", respectively) also exist with the same stoichiometries in solution is provided by ^{1}H NMR spectroscopy.



BPP34C10

3-H$_2$·2PF$_6$

The complex formed between **BPP34C10** and **1**-H·PF$_6$ crystallized with a 1:2 stoichiometry when an equimolar mixture of the two components was dissolved in acetone and the solution layered with *n*-pentane. The resulting single crystals were analyzed[3] by X-ray crystallography (Fig. 1). The **BPP34C10** component has the expected[2] open centrosymmetric structure; its hydroquinone rings are aligned parallel to each other with a centroid–centroid separation of 6.99 Å. Pairs of **1**-H$^+$ ions are threaded symmetrically through the macrocyclic ring. The conformation of the C-CH_2-NH_2^+-CH_2-C backbone departs from the all-*anti* geometry adopted by the **1**-H$^+$ ion in [**DB24C8**·**1**-H][PF$_6$] in its solid-state superstructure.[1] The NH_2^+ hydrogen atoms of each cationic center are directed toward polyether oxygen atoms at either end of the macrocycle. However, the 1:2 complex does not have additional stabilization through any significant [C–H···O] hydrogen bonds. Secondary stabilization is achieved by edge-to-face interactions[4] between one of the phenyl rings in each cation and the hydroquinone rings of the crown ether. The centroid–centroid distances for these pairs of symmetrically related interactions are 5.06 Å, and in each case the approach of one of the

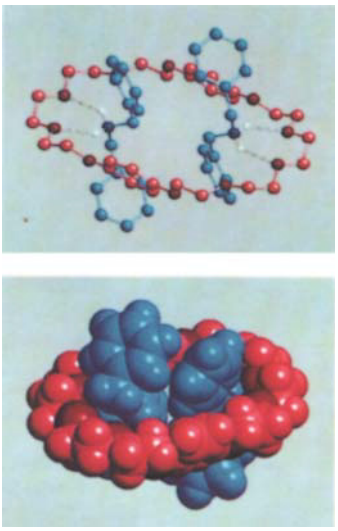


Fig. 1. Top: Ball-and-stick representation of [**BPP34C10**·(**1**-H)$_2$]$^{2+}$ in the solid state. The **BPP34C10** component is depicted in red and the $(PhCH_2)_2NH_2^+$ cations in blue. The [N–H···O] hydrogen bonds have the following distances and angles [N···O] 2.83, 2.82 Å; [H···O] 2.10, 2.06; [N–H···O] 137, 141°. Bottom: Space-filling representation of the complex.

ortho hydrogen atoms of the hydroquinone ring to the phenyl ring center is almost linear (171°; H···ring centroid distance, 2.73 Å). The distance between the two NH_2^+ centers in the complex is 8.4 Å. The **BPP34C10** rings are arranged to form channels (Fig. 2) that extend in the crystallographic *c* direction, again conjuring up the prospect of the formation of polyrotaxanes.[5] The distance between the closer NH_2^+ centers within the stack is 6.9 Å.

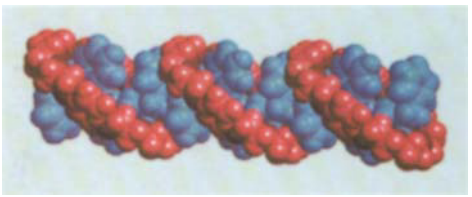

Fig. 2. Space-filling representation showing the pseudopolyrotaxane stacking motif in the crystals of $[\mathbf{BPP34C10}\cdot(\mathbf{1}\text{-}H)_2]^{2+}$.

Single crystals suitable for X-ray analysis were also obtained when an equimolar mixture of **BPP34C10** and $\mathbf{3}\text{-}H_2\cdot 2PF_6$ was dissolved in acetone and the solution layered with *n*-pentane. The X-ray crystal structure showed the complex to have 2:2 stoichiometry (Fig. 3).[3] In this superstructure, both dications

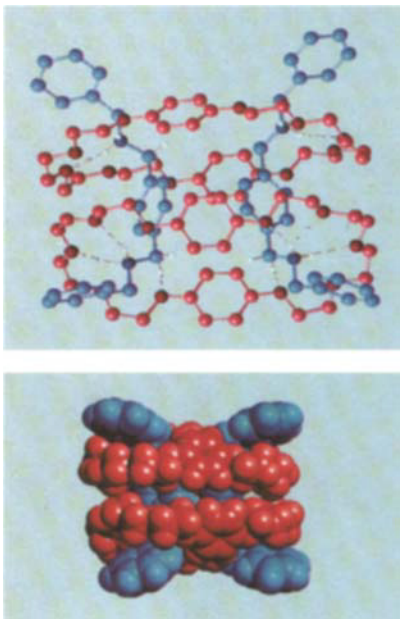

Fig. 3. Top: Ball-and-stick representation of $[(\mathbf{BPP34C10})_2\cdot(\mathbf{3}\text{-}H_2)_2]^{4+}$ in the solid state. The **BPP34C10** components are depicted in red and the $[(PhCH_2NH_2^+CH_2)_2C_6H_4]$ dications in blue. The [N–H···O] hydrogen bonds have the following distances and angles [N···O] 2.85–3.10, [H···O] 2.02–2.27 Å, and [N–H···O] 127–168°. The [C–H···O] hydrogen bonds have the following distances and angles [C···O] 3.25–3.43, [H···O] 2.32–2.48 Å, and [C–H···O] 158–167°. Bottom: Space-filling representation of the complex.

are threaded through two **BPP34C10** macrocycles positioned immediately adjacent to each other, producing an extended torus (Fig. 4). This double-stranded, doubly encircled superstructure is stabilized by a series of nine [N–H···O] and three [C–H···O] hydrogen bonds between the NH_2^+ centers and benzylic CH_2 groups of the dicationic threads and oxygen atoms of the encircled macrocyclic polyethers, respectively. The con-

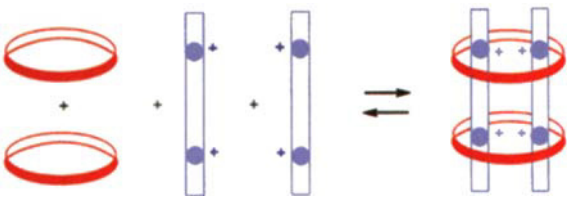

Fig. 4. Schematic representation of the formation of the 2:2 complex between two **BPP34C10** macrocycles (red) and two $[\mathbf{3}\text{-}H_2]^{2+}$ ions (blue).

formations of the two **BPP34C10** macrocycles are similar, with centroid–centroid distances between the hydroquinone rings in the upper and lower macrocycles of 7.18 and 7.00 Å, respectively. However, unlike the parallel alignments of these matching rings in $[\mathbf{BPP34C10}\cdot(\mathbf{1}\text{-}H)_2][PF_6]_2$, here they are inclined by 30° and 26°, respectively. In common with the 1:2 complex, the 2:2 complex packs with pairs of tori oriented in tubelike arrays; the enthreaded dications in each complex are aligned with respect to each other along the crystallographic *b* direction. When the crown ether is changed from **BPP34C10** to **DB24C8**, a 2:1 complex[3, 6] results in which the $[\mathbf{3}\text{-}H_2]^{2+}$ dication is threaded through the centers of two **DB24C8** macrocycles (Fig. 5). The

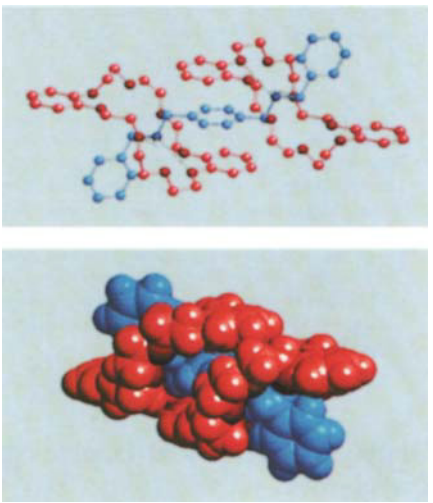

Fig. 5. Top: Ball-and-stick representation of $[(\mathbf{DB24C8})_2\cdot\mathbf{3}\text{-}H_2]^{2+}$ in the solid state. The **DB24C8** macrocycles are depicted in red and the $[(PhCH_2NH_2^+CH_2)_2C_6H_4]$ dication in blue. The [N–H···O] hydrogen bonds have the following distances and angles [N···O] 3.10, 3.05, 3.00 Å; [H···O] 2.25, 2.39, 2.33 Å; [N–H···O] 155, 133, 131°. The [C–H···O] hydrogen bonds have the following distances and angles [C···O] 3.24 Å; [H···O] 2.30 Å; [C–H···O] 163°. Bottom: Space-filling representation of the complex.

complex is centrosymmetric with respect to the central *para*-xylyl unit of the dication. Once again, the complex is stabilized by a combination of [N–H···O] and [C–H···O] hydrogen bonds. In addition, there are π–π stacking interactions between the almost parallel, aligned catechol and *para*-xylyl units within the superstructure (these rings are inclined by ca. 5° and have centroid–centroid separations of 3.65 Å). In this complex, there is an absence of any pronounced channel formation within the crystals.

Both $\mathbf{1}\text{-}H\cdot PF_6$ and $\mathbf{3}\text{-}H_2\cdot 2PF_6$ have very low solubilities[7] in CD_2Cl_2. On the addition of **BPP34C10**, the solubility of $\mathbf{1}\text{-}H\cdot PF_6$ increases significantly (ca. tenfold). The ^1H NMR spectrum of a saturated solution of $\mathbf{1}\text{-}H\cdot PF_6$ in CD_2Cl_2 in the presence of **BPP34C10** exhibits signals[8] that integrate for the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3417-1870 $ 10.00+.25/0

expected stoichiometry associated with the 1:2 complex [**BPP34C10**·(**1**-H)$_2$][PF$_6$]$_2$. By contrast, in the case of **3**-H$_2$·2PF$_6$, when **BPP34C10** is added to a saturated solution of the salt in CD_2Cl_2/CD_3CN (4:1, v/v), an approximately 1:1 ratio[9] of salt to crown ether is observed by integration. It was also noted that **3**-H$_2$·2PF$_6$ does not dissolve in $CDCl_3$, even in the presence of a large excess of **DB24C8**. However, when the spectrum of a 10:1 mixture of **DB24C8** and **3**-H$_2$·2PF$_6$ in $CDCl_3/CD_3CN$ (1:1, v/v) was recorded, only signals for the expected 2:1 complex[10] and the excess of **DB24C8** were observed under conditions of slow exchange on the ^{1}H NMR time scale. The stoichiometry of the complex was established by direct integration of the signals associated with its **DB24C8** and [**3**-H$_2$]$^{2+}$ components.

When positive-ion FAB mass spectrometry[11] was used to characterize these complexes, peaks for $[M - PF_6]^+$ ions were observed at *m/z* 1077 and 1360 for [**BPP34C10**·(**1**-H)$_2$][PF$_6$]$_2$ and [(**DB24C8**)$_2$·**3**-H$_2$][PF$_6$]$_2$, confirming the respective 1:2 and 2:1 stoichiometries of these species. The 2:2 complex formed between **3**-H$_2$·2PF$_6$ and **BPP34C10** in the solid state (Fig. 3) was not observed by positive-ion FABMS. However, a peak with *m/z* 999, corresponding to a species with 1:1 stoichiometry that has lost one counterion, is observed.

The ease with which both the monocationic (**1**-H$^+$) and dicationic ([**3**-H$_2$]$^{2+}$) species containing NH_2^+ recognition sites self-assemble with crown ether receptors such as **DB24C8** and **BPP34C10** to give highly ordered superstructures in solution, as well as in the solid state, could herald some new and fascinating developments in macromolecular science as a result of a productive marriage[12] between macrocyclic and supramolecular chemistry.

Experimental Procedure

3-H$_2$·2PF$_6$: A solution of benzylamine (5.14 g, 0.048 mol) and terephthaldehyde (3.26 g, 0.024 mol) was heated under reflux with stirring in a Dean–Stark apparatus for 10 h. After the reaction mixture was cooled down to room temperature, the solvent was evaporated off under vacuum to give the 1,4-bis(benzyliminomethyl)benzene as a brown solid [^{1}H NMR ($CDCl_3$): δ = 4.84 (s, 4H), 7.18–7.47 (m, 10H), 7.82 (s, 4H), 8.41 (s, 2H)] which was dissolved in MeOH (50 mL). $NaBH_4$ (3.80 g, 0.10 mol) was added in small portions to the reaction mixture which was heated under reflux with stirring for 8 h. It was then allowed to cool down to room temperature and concentrated HCl was added (pH < 2). After evaporation of the solvent, the residue was suspended in H_2O (30 mL) and extracted with CH_2Cl_2 (4 × 30 mL). The combined extracts were washed with 5% aqueous $NaHCO_3$ (2 × 60 mL), H_2O (50 mL), and then dried ($MgSO_4$). Removal of the solvent under vacuum afforded 1,4-bis(benzylaminomethyl)benzene (4.00 g) as a colorless solid [^{1}H NMR ($CDCl_3$): δ = 3.80 (s, 4H), 3.81 (s, 4H), 7.15–7.45 (m, 14H)] of which 2.00 g (0.006 mol) was dissolved in MeOH (30 mL). Concentrated HCl was added (pH < 2) and the reaction mixture was stirred for a further hour. Evaporation of the solvent afforded a colorless solid which was suspended in acetone (30 mL). An aqueous solution of NH_4PF_6 was added until dissolution occurred. Evaporation of acetone afforded colorless crystals of **3**-H$_2$·2PF$_6$, which were isolated, washed with H_2O, and air-dried (3.50 g, 90%, m.p. 238 °C with decomp.). Positive-ion FABMS: *m/z* 463 $[M - PF_6]^+$; ^{1}H NMR (CD_3CN): δ = 4.24 (s, 4H), 4.25 (s, 4H), 7.45–7.51 (m, 10H), 7.52 (s, 4H); ^{13}C NMR (CD_3CN): δ = 51.6, 52.4, 129.9, 130.6, 131.0, 131.2, 131.6, 132.9.

The structure was solved by direct methods and the anisotropic refinement gave R = 0.084, Rw = 0.093 for 3237 independent observed reflections with [$|F_o| > 4\sigma(|F_o|)$, $2\theta < 125°$]. Crystal data for [(**BPP34C10**)$_2$·(**3**-H$_2$)$_2$][PF$_6$]$_4$: monoclinic, space group $P2_1/n$, a = 18.101(4), b = 28.232(6), c = 27.525(6) Å, β = 99.71(3)°, V = 13865(5) Å^3, Z = 4, ρ_{calc} = 1.17 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 12 cm^{-1}, Siemens P4/RA diffractometer, graphite-monochromated $Cu_{K\alpha}$ radiation. The structure was solved by direct methods and anisotropic refinement gave R_1 = 0.154, wR_2 = 0.398 for 6773 independent observed reflections with [$|F_o| > 4\sigma(|F_o|)$, $2\theta < 110°$]. Crystal data for [(**DB24C8**)$_2$·**3**-H$_2$][PF$_6$]$_2$: monoclinic, space group $P2_1/c$, a = 11.538(3), b = 29.293(7), c = 10.820(3) Å, β = 91.39(2)°; V = 3656(2) Å^3, Z = 2, ρ_{calc} = 1.37 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 14 cm^{-1}, Siemens P4/PC diffractometer, graphite-monochromated $Cu_{K\alpha}$ radiation. The structure was solved by direct methods and refined anisotropically (based on F^2) to give R_1 = 0.087, wR_2 = 0.202 for 2516 independent observed reflections with [$|F_o| < 4\sigma(|F_o|)$, $2\theta < 114°$]. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EW (UK).

Sci.* **1994**, *19*, 843–945; c) H. W. Gibson, S. Lui, P. Lecavalier, C. Wu, Y. X. Shen, *J. Am. Chem. Soc.* **1995**, *117*, 852–874.

[6] The 2:1 complex was crystallized by vapor diffusion of diisopropyl ether into an acetonitrile solution of the bisammonium salt **3**-H$_2$·2PF$_6$ and **DB24C8** (1:2 stoichiometry).

[7] The solubility of **1**-H·PF$_6$ is roughly 8 mg in 10 mL of CD_2Cl_2, while **3**-H$_2$·2PF$_6$ is virtually insoluble in this solvent.

[8] The $\Delta\delta$ values (with reference to the uncomplexed crown ether) for the C_6H_4, α-CH_2, β-CH_2, γ-CH_2, and δ-CH_2 protons in **BPP34C10** deduced from the ^{1}H NMR spectrum of [**BPP34C10**·(**1**-H)$_2$][PF$_6$]$_2$ recorded in CD_2Cl_2 are +0.18, −0.03, −0.12, −0.31, and −0.43, respectively.

[9] For an equimolar mixture of **BPP34C10** and **3**-H$_2$·2PF$_6$ in CD_2Cl_2/CD_3CN (3:1, v/v), $\Delta\delta$ values (with reference to the free salt) of −0.34 and −0.11, respectively, are observed in the ^{1}H NMR spectrum for the aromatic and benzylic methylene protons associated with the bridging *para*-xylyl group in the [**3**-H$_2$]$^{2+}$ dication.

[10] The $\Delta\delta$ values (with reference to the uncomplexed crown ether and the free salt) for different protons obtained from the ^{1}H NMR spectrum of this sample recorded in $CDCl_3/CD_3CN$ (1:1, v/v) range a) from −0.05 to −0.19 for protons in **DB24C8** and b) from −0.67 to +0.35 for protons in **3**-H$_2$·2PF$_6$.

[11] FABMS were recorded on a Kratos MS80RF mass spectrometer (accelerating voltage 3 kV, resolution 1000) coupled to a DS data system and off-line Sun Workstation for processing the raw data. The atom gun was an adapted saddle field source (Ion Tech Limited) that operated at ca. 8 keV and with a tube current of ca. 2 mA. Krypton was used to provide a primary beam of atoms and the samples were dissolved in a small volume of 3-nitrobenzyl alcohol which had previously been coated on to a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

[12] The double-stranded inclusion complexes that are formed when γ-cyclodextrin threads simultaneously on to two poly(ethylene glycol) chains is one of the very few examples in the literature of this particular form of supermolecule involving a macrocycle. See A. Harada, J. Li, M. Kamachi, *Nature*, **1994**, *370*, 126–128. The formation of molecular nanotube aggregates of β- and γ-cyclodextrins has been reported. See G. Li, L. B. McGown, *Science* **1994**, *264*, 249–251.

$(C_5Me_5)TiF_2$—A Versatile Building Block for Generating Large Soluble Dimetallic Aggregates**

Feng-Quan Liu, Dietmar Stalke, and Herbert W. Roesky*

Dedicated to Professor Herbert Schumann on the occasion of his 60th birthday

In 1826 Berzelius observed the formation of heteropolyanions in the reaction of molybdate with phosphate and arsenate; however, it is only in the last two decades that this field of research has received tremendous attention in theory and practice.[1] Organometallic complexes of polyoxoanions were investigated for example by Day, Klemperer, and Finke.[2]

Neutral metal clusters containing up to 146 metal atoms have been structurally investigated.[3] However, the only characterized examples of systems of this size have contained one kind of metal atom. We are not aware that any organometallic fluorides have been used for dimetallic cluster formation up to now. Recently, we described the preparation and structure of $[Cp^*_6Ti_6Na_7F_{19}]$ ($Cp^* = C_5Me_5$).[4] Here we report on the preparation and structural characterization of the two large dimetallic clusters **1** and **2**, which were formed in the reaction

$[Cp^*_{12}Ti_{14}Na_{18}F_{48}(thf)_6]$ **1** $[(Cp^*TiF_2)_6CaF_2(thf)_2]$ **2**

of $[Cp^*TiF_3]$[5, 6] with the corresponding alkali and alkaline earth metal as a reducing agent in THF (THF = tetrahydrofuran) in the presence of mercury.

From the filtered reaction mixture of **1**, green, oxygen- and moisture-sensitive single crystals were obtained by recrystallization from THF/hexane. Surprisingly, no NaF precipitated during the reaction. DMPE (DMPE = 1,2-bis(dimethylphosphino)ethane) was added during the reduction to stabilize the low oxidation state of the titanium center. As expected, no DMPE is present in the final product because of the better donor properties of the fluoro ligands in this system.

The structure of this cluster was determined by single-crystal X-ray analysis[7] at low temperature. Twelve Cp^*TiF_2 groups almost completely enclose two TiF_3 and eighteen NaF molecules (Fig. 1).

The central inorganic $[(TiF_3)_2(NaF)_{18}]$ unit is covered with a hydrocarbon layer consisting of twelve Cp^*TiF_2 units and six sodium-coordinated thf molecules. This provides—although poor—solubility of the aggregate in hydrocarbon solvents. The average $Ti-Cp^*_{(centroid)}$ distance (202 pm; range from 199 to 204 pm) is in accordance with literature values;[11] the same is true for the average Na–O(thf) distance of 235 pm (range from 226 to 242 pm).[12]

The kidney-shaped inorganic core consists of 14 Ti^{III}, 18 Na, and 48 F atoms. Twelve of the 14 Ti atoms are approximately square-based pyramidal coordinated; four F atoms form the base of the pyramid and the Cp* ligand centroid adopts the apical position. The Ti–F bonds can be divided into a set of long and short distances. The two shorter Ti–F bonds (198 pm; range from 195 to 202 pm) are in accordance with the distances

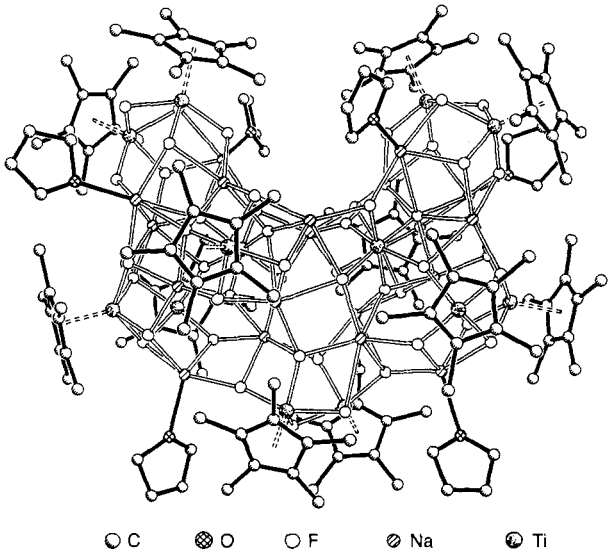

Fig. 1. The solid state structure of **1**. For clarity the nine uncoordinated THF solvent molecules are not depicted. Average bond lengths [pm] and (range): $Cp^*_{(centroid)}-Ti$ 202 (199–204), short Ti–F 198 (195(1)–202(1)), long Ti–F 205 (202(1)–210(1)), Na–F 232 (215(1)–291(2)).

in TiF_3.[13] The longer distances (205 pm; range from 202 to 210 pm) are found in the coordination to adjacent F atoms which are shared by two Ti atoms. Two of the fourteen Ti atoms are distorted octahedral coordinated by six F atoms at an average distance of 197 pm (range from 194 to 206 pm).

The eighteen Na atoms of the molecule are coordinated in four different ways: two are five-coordinate, surrounded by four F atoms and one thf molecule, four are six-coordinate surrounded by five F atoms and one thf molecule, four are five-coordinate and eight are six-coordinate surrounded exclusively by F atoms. The average Na–F distances of the four different coordination polyhedra are 226, 242, 226, and 232 pm, respectively. The average of the 96 independent distances of 232 pm is consistent with the corresponding distances in NaF.[14] The remaining nine THF molecules are not coordinated to any metal; they occupy vacant lattice sites. As a result of the paramagnetic properties and relatively poor solubility of compound **1** at low temperature, we were unable to confirm the structure in solution by NMR spectroscopy or by cryoscopic molecular weight determination. However, the presence of even larger aggregates (100–1000 Å) in solution is assumed because of the Tyndall effect of the solution (Fig. 2).

Fig. 2. The Tyndall effect of a sodium-reduced solution of $[Cp^*TiF_3]$ in THF.

The second example of the formation of a large aggregate with Cp^*TiF_2 units is the first soluble CaF_2 complex $[(Cp^*TiF_2)_6CaF_2(thf)_2]$ (**2**). Calcium difluoride is prepared in situ by adding a solution of Cp^*TiF_3 to a suspension of calcium metal in the presence of mercury at 0 °C. The reaction mixture was filtered and pale green crystals were obtained at 0 °C. Also, under these conditions the Ti^{IV} centers were reduced to Ti^{III} centers. The result of the crystal structure determination[7] of **2** is shown in Figure 3. The center between two $[Cp^*_3Ti_3F_7(thf)]$ moieties is a single Ca atom. Like in the solid-state structure of CaF_2,[15] the Ca atom is coordinated to eight F atoms but in a rather distorted way. Four Ca–F bonds are long (average 253 pm), while the other four are much shorter (average 226 pm). Hence the central unit can be described as two penetrating distorted tetrahedrons.

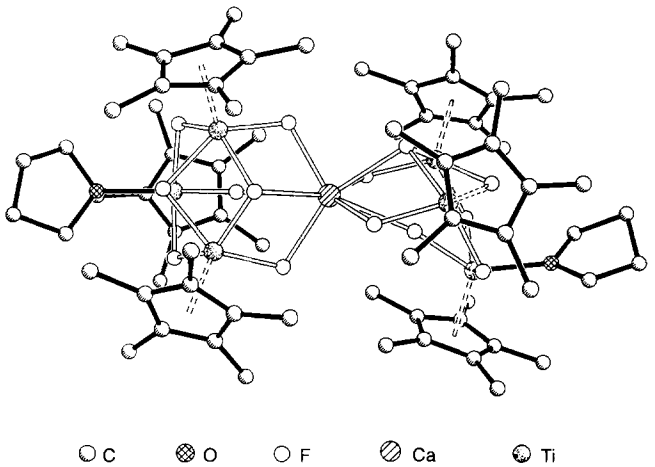

Fig. 3. The solid state structure of **2**. For clarity, the four uncoordinated THF solvent molecules are not depicted. Average bond lengths [pm] and (range): $Cp^*_{(centroid)}$ Ti 204 (201–206), Ti–F 206 (198.4(2)–213.3(2)), long Ca–F 253 (266.3(2) 244.6(2)), short Ca–F 226 (225.2(2)–227.2(2)).

Although the structural features from CaF_2 are not maintained in the structure of **2**, the average value of the Ca–F bond is in accordance with that in fluorite.[15a] To our knowledge there is only one other highly aggregated complex akin to **2**, however, it contains Ti^{IV} centers. In $[M\{Ti_2(OR)_9\}_2]$ (M = Ca, Ba), eight Ti^{IV}-bound oxygen atoms are coordinated in a similar way to the central calcium or barium atom.[16]

Unlike in **1** there are no different sets of Ti–F distances in **2**; on average (206 pm), they are even longer than the long Ti–F distances in **1**. Also the average $Ti-Cp^*_{(centroid)}$ distance (204 pm) is 2 pm longer than that in **1**. In **2** the titanium ligand distances are not influenced by the different coordination of the Ti atoms. While four Ti atoms are coordinated by four F atoms and one Cp* ligand, two are only coordinated by three F atoms and one Cp* ligand. The remaining four THF molecules are not coordinated to any metal center but occupy vacant lattice sites.

Although CaF_2 has broad applications in chemistry, up to now it was not available to organometallic chemistry because of its poor solubility in common organic solvents.[17] With the Cp^*TiF_2 building block, it now seems possible to establish a new field of chemistry at the borders of solid state and organometallic chemistry. While the dimetallic inorganic core of compounds **1** and **2** resembles that in many solid phases with respect to its structural parameters, solubility of the cluster in common organic solvents is provided by wrapping that core with the Cp^*TiF_2 unit. The generation of solids in solution and their encapsulation by organometallic moieties might have a broad application. CaF_2, which was already known from work by Agricola[18] in 1529, now seems to be accessible to well-established organometallic techniques.

Experimental Procedure

All reactions must be carried out under careful exclusion of water and oxygen.

1: A solution of $[Cp^*TiF_3]$ (0.72 g, 3.0 mmol) and DMPE (0.9 mL) in THF (40 mL) was added dropwise to a suspension of sodium metal (0.07 g, 3.0 mmol, 12 g Hg) in THF (20 mL) at 0 °C. The mixture was stirred for 12 h at room temperature during which time the solution changed from orange to green. The solution was filtered and the solvent was concentrated to 30 mL and cooled to 0 °C. Under these conditions X-ray suitable green crystals were obtained after 4 d and more crystalline material was obtained by concentrating the solution to 15 mL. The solvent-free green product was obtained at 25 °C/10^{-2} Torr after 12 h. It decomposed at 221 °C. Correct elemental analyses. IR (Nujol): 1494w, 1290m, 1054s, 934m, 719s, 492s, 403s cm^{-1}.

2: A solution of $[Cp^*TiF_3]$ (0.72 g, 3.0 mmol) in THF (40 mL) was added dropwise to Ca/Hg alloy (0.06 g, 1.5 mmol Ca in 30 g mercury) in THF (25 mL) at room temperature. The mixture was stirred for 12 h at this temperature during which time the solution changed from orange to green. The reaction mixture was subsequently filtered and the solvent was removed in vacuum. The residue was recrystallized from THF/hexane (30 mL/30 mL) which yielded 0.47 g of **2** (62%). M.p. 268 °C (decomp.). Correct elemental analyses from the solvent-free compound (10^{-2} Torr, 25 °C, 12 h). IR (Nujol) : 1496w, 1342m, 1260m, 1165m, 1074s, 874s, 477s, 394s cm^{-1}.

Platination Pathways for Reactions of Cisplatin with GG Single-Stranded and Double-Stranded Decanucleotides**

Kevin J. Barnham, Susan J. Berners-Price, Tom A. Frenkiel, Urban Frey, and Peter J. Sadler*

The anticancer drug cisplatin, *cis*-$[PtCl_2(NH_3)_2]$, disrupts cellular replication and transcription by the formation of Pt-DNA adducts, largely guanine–guanine (GG) and adenine–guanine (AG) intrastrand cross-links.[1, 2] Therefore it is important to understand the mechanisms of DNA platination and the perturbations of DNA structure which these adducts cause. The rate-determining step in GG platination is believed to be hydrolysis of cisplatin, followed by monofunctional binding to N7 of either the 3′- or 5′-G, and finally macrocyclic ring closure to give the bifunctional GG adduct. However, direct detection of aquated cisplatin during the course of DNA reactions has proved to be difficult. None was seen by Bancroft et al.[3] by ^{195}Pt NMR spectroscopy, even with enriched ^{195}Pt and high concentrations of DNA oligomers (ca. 14–32 mM). These workers were able to detect monofunctional adducts and determine the rate of ring closure by independent studies of reactions of the aqua-chloro complex with DNA. In an alternative approach, Chottard et al.[4, 5] have recently determined the rates of attack of "diaqua cisplatin" (Cl replaced by H_2O) on GG oligonucleotides and rates of ring closure using an HPLC trapping method. We report here that the major species in the pathways of platination of both single- and double-stranded GG oligonucleotides by ^{15}N-cisplatin can all be detected simultaneously by $[^1H,^{15}N]$ NMR spectroscopy. We have determined directly, for the first time, the lifetime of the aqua-chloro intermediate present at only micromolar concentrations, and investigated differences in the platination pathways for single- and double-stranded DNA. Both ^1H and ^{15}N NMR resonance signals are sensitive to cisplatin-induced helix melting. The method will be generally applicable to a wide range of DNA substrates and platinum ammine and amine complexes, and promises to provide new insights into the factors which influence Pt-DNA recognition.

We have studied platination of the deoxydecanucleotide **I** and its duplex with **II** (**I** + **II** = **III**) using ^{15}N-labeled cisplatin, *cis*-$[PtCl_2(^{15}NH_3)_2]$ (**1**) to allow the selective detection of ^1H and ^{15}N NMR resonances of Pt-NH_3 groups by the use of $^1H\{^{15}N\}$ inverse detection methods.[6] This, combined with the use of sequences incorporating pulsed-field gradients,[7] enabled detection of intermediates present at only micromolar concentrations, and also peaks whose chemical shifts lie very close to the resonance signal of the H_2O protons.

	1	2	3	4	5	6	7	8	9	10	
5′-d(	A	C	A	T	**G**	**G**	T	A	C	A)	**I**
3′-d(	T	G	T	A	C	C	A	T	G	T)	**II**
	20	19	18	17	16	15	14	13	12	11	

Duplex from **I** + **II** = **III**

The reaction between **1** and single-stranded DNA **I** (ca. 1:1 mol ratio, 1.3 mM, 10 mM sodium phosphate pH 7.1, 90% H_2O/10% D_2O, 310 K), was followed by recording a series of ^{15}N-edited ^1H NMR spectra. Assignments of peaks for products and intermediates were aided by ^{15}N chemical shifts from 2D $[^1H,^{15}N]$ spectra. These are diagnostic of the ligand (X) *trans* to the ammine group of the platinum complex: For X = O $\delta = -95$ to -75; for X = N or Cl $\delta = -70$ to -50.[8]

Within the first few minutes, resonances 2a (^{15}N *trans* to Cl) and 2b (^{15}N *trans* to O) assignable to the hydrolysis product *cis*-$[PtCl(H_2O/OH)(NH_3)_2]^+$ (**2**) were detected (Fig. 1).[9] These attained their maximum intensities after about 40 min and then gradually decreased in intensity. They were no longer visible (i.e. accounted for <1% of total Pt-NH_3) after 5 h. The hydrolysis product **2** was clearly detectable by this method even at concentrations of about 10 μM.

The pair of peaks for compound **3** (3a: $\delta = 4.45/-65.8$ and 3b: $\delta = 4.11/-68.7$) also became visible within the first 30 min (Fig. 1). They reached a maximum intensity after about 4.5 h, and then gradually decreased in intensity. Their $^1H/^{15}N$ shifts are similar to those of the monosubstituted 5′-guanosine monophosphate (GMP) complex[10] *cis*-$[PtCl(GMP\text{-}N7)(NH_3)_2]^+$,[6, 11] and therefore a reasonable assignment is to a monofunctional N7-G adduct in which Pt is bound to either the 3′- or 5′-G of the oligonucleotide **I** (G(5) or G(6), respectively).

Shortly after this, peaks for another intermediate species **4** (4a: $\delta = 4.40/-65.9$, 4b: overlapped with the signal 3b and with a ^{195}Pt satellite of the signal 1) became visible (Fig. 1). In view of their similar ^1H and ^{15}N NMR shifts and their similar time dependences, intermediates **3** and **4** can be assigned to be the monofunctional N7-G(5) and N7-G(6) adducts *cis*-$[PtCl(\mathbf{I}\text{-}N7\text{-}G)(NH_3)_2]$. Both **3** and **4** can undergo ring closure to form the bifunctional GG chelate complex *cis*-$[Pt(\mathbf{I}\text{-}N7\text{-}G(5),N7\text{-}G(6))(NH_3)_2]$ (**5**). Peaks assignable to **5** (5a: $\delta = 4.55/-68.4$, 5b: $\delta = 4.62/-66.6$) were first observed after 90 min and continued

[**] This work was supported by the Medical Research Council, Australian NH&MRC (R. Douglas Wright Award to S. J. B.-P.), The British Council, Association for International Cancer Research, and EC HCM (CHRX-CT92-0016) and COST (D1-0002-92) programs, the members of which we also thank for stimulating discussions.

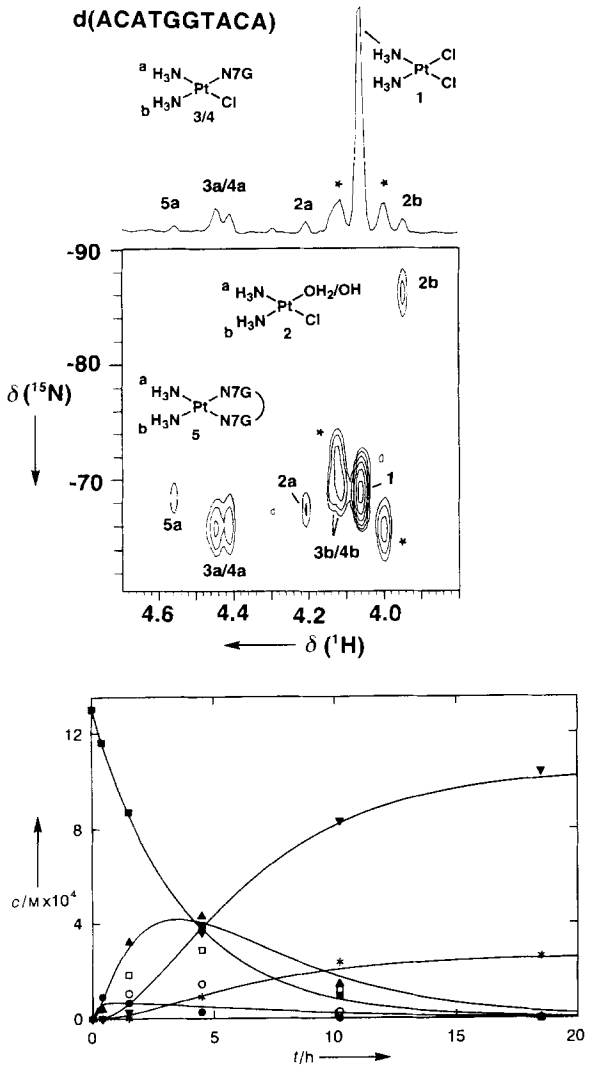

Fig. 1. Platination of single-stranded d(ACATGGTACA) (**I**) with *cis*-$[PtCl_2(^{15}NH_3)_2]$ **1** at 310 K. Top: Typical 500 MHz 2D [^{1}H,^{15}N] HSQC spectrum after 1.5 h reaction time, 310 K, acquired in 21 min, showing peaks assigned to NH_3 in the structures **1**–**5**. Peak 5b (NH_3 *trans* to N7-G6/5) is obscured by suppression of the H_2O peak (low frequency filter, Varian software), but is revealed in a ^{15}N-coupled spectrum at $\delta = 4.62/-66.6$. A broad peak for other adducts (**6**) appears after 4 h (see text). Bottom: Plot of relative concentrations of species **1**–**6** (based on Pt-NH_3 peak integrals) versus time. Cisplatin [**1**] (■), aqua-chloro intermediate [**2**] (●), monofunctional Pt-G intermediates [**3**] or [**4**] (□ and ○), sum of **3** + **4** (▲), GG chelate [**5**] (▼), and [**6**] (unassigned) (*). The curves are the computer best fits for the rate constants given in Scheme 1 (where errors represent one standard deviation).

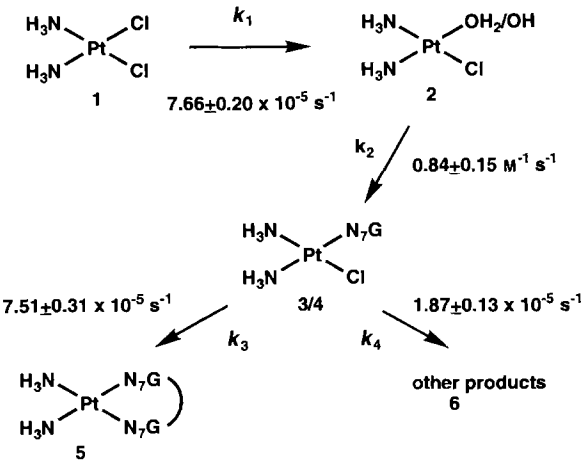
to increase in intensity until the reaction was complete (ca. 20 h). It is notable that peak 5b is very close to the H_2O peak, and previously we have observed such large low-field shifts only for Pt-NH groups strongly H-bonded to terminal 5′-phosphates in nucleotide complexes of Pt^{II} ammines and amines.[11, 12]

At reaction times less than 4 h, no other Pt-NH_3 resonances were detected. However, after this time, a new broad Pt-NH_3 resonance signal became visible with a ^{1}H/^{15}N cross-peak at about $\delta = 4.52/-65.1$. The time-dependent increase in concentration of the species (**6**) associated with this peak is shown in Figure 1 bottom. By comparison of peak integrals, **6** accounts for about 20% of the total Pt-NH_3 species present at equilibrium, the bifunctional adduct **5** accounting for the remaining 80%. Since the signal for **6** was not seen during reactions of **1** with duplex DNA (vide infra), it can be assigned to interstrand cross-linked complexes involving for example N1-G (not accessible in duplexes).

Kinetic analysis of the data as a series of consecutive first- and second-order processes gave rise to the rate constants in Scheme 1.[13] The half-life for the first aquation step of **1** (2.51 h) is close to the values reported previously for cisplatin



Scheme 1.

hydrolysis,[14] and to that determined by Bancroft et al.[3] for the disappearance of cisplatin during reactions with double-stranded chicken erythrocyte DNA by ^{195}Pt NMR spectroscopy (1.9 h) under similar conditions, and the half-life for the aqua intermediate of only 0.14 h is close to their estimated value of 0.1 h.[3] One of the N7-G monofunctional intermediates is present during the reaction in a greater proportion than the other (ratio ca. 2:1). This may be the 5′-G (G(5)) adduct **3** since Gonnet et al.[4] have shown that 3′-G monofunctional adducts formed from *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ undergo ring closure reactions about ten times faster than 5′-G monofunctional adducts. In our experiments the half-life for the conversion of monofunctional into bifunctional adducts was 2.6 h, similar to that reported for single-stranded chicken erythrocyte DNA[3] (2.1 h), and consistent with aquation controlling this step too.

The platinated duplex *cis*-[Pt(**III**-N7-G(5),N7-G(6))$(NH_3)_2$] **7** was formed by the addition of 1 mol equivalent of the complementary strand **II** to the equilibrium solution containing platinated **I**. The ^{15}N-edited ^{1}H NMR spectrum contained two sharp peaks at $\delta = 4.48$ and 4.26 (283 K), assignable to the Pt-NH_3 protons of the bifunctional adduct **7**, together with a very broad unresolved resonance at about $\delta = 4.6$ from other Pt-NH_3 species. Platinated duplex was formed also by direct reaction of cisplatin **1** with the preformed duplex **III**[15] (at 293 K to ensure that the DNA was double-stranded). The reaction was slow (in agreement with hydrolysis being the rate-limiting step) with only about 60% of the cisplatin reacting in the first 24 h, during which time peaks assignable to **2**, N7-G(5) and N7-G(6) monofunctional adducts, and at least one other intermediate were observed, as well as peaks for the products **7** and **8** described below. A kinetic analysis has not yet been attempted.

Figure 2 shows the ^{15}N-edited ^{1}H NMR spectrum after complete reaction of the duplex **III** with 1 mol equivalent cisplatin **1**. The chemical shifts and temperature dependences of the pair of peaks for the bifunctional adduct **7** are identical to those observed for the product formed on addition of **II** to the platinated single strand **I** (data not shown). Between 298 and 303 K, peaks

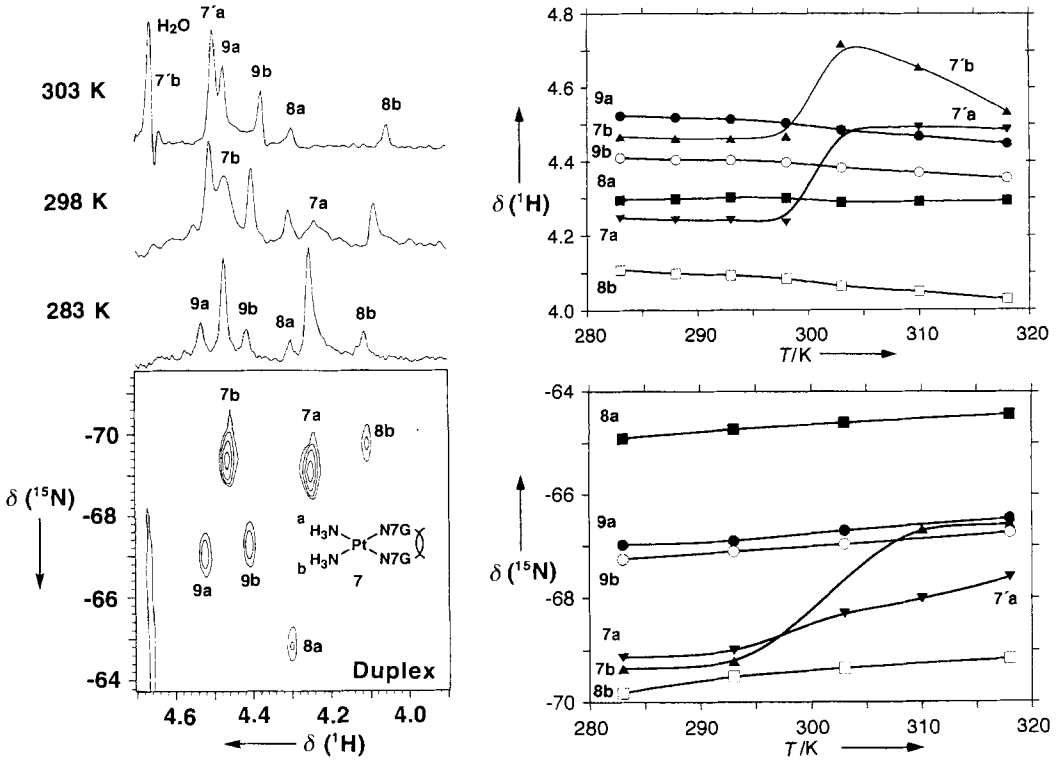


Fig. 2. Effect of temperature on the ^1H and ^{15}N NMR shifts of the platinated duplex formed by complete reaction (5 d, ca. 297 K) of 1 mol equivalent *cis*-$[PtCl_2(^{15}NH_3)_2]$ with d(ACATGGTACA)-d(TGTACCATGT) (**III**). Left: 600 MHz 2D $[^1H,^{15}N]$ HSQC spectrum at 283 K, showing peaks for *cis*-[Pt(**III**-N7-G(5),N7-G(6))$(NH_3)_2$] (**7**), and species **8** and **9** (unassigned, see text). 1D $^1H\{^{15}N\}$-edited NMR spectra for Pt-NH_3 resonances at various temperatures are also shown. Right: Temperature dependence of the ^1H and ^{15}N NMR shifts of platinated duplex. Between 298 and 303 K the peaks for **7** gradually disappear, and at >303 K two new peaks (7′a and 7′b) appear with shifts similar to those of the single-stranded GG chelate (species **5**). As for the platinated single strand, peak 7′b is obscured by the H_2O peak (but revealed in ^{15}N-coupled spectrum). Note the behavior of this peak at high temperature.

for **7** disappear, and at >303 K two new peaks (7′a and 7′b) appear with shifts similar to those assigned to the GG-platinated single strand (species **5**). This (reversible) temperature-dependent behavior can be attributed to melting of the platinated duplex with a T_m value of about 300 K,[16] an approximate 10 K lowering from the value for the unplatinated duplex, as expected.[17]

Two other stable adducts (**8** and **9**, Fig. 2) were produced by reaction of cisplatin **1** with duplex **III**. As these were not observed in spectra of the duplex formed by addition of **II** to the platinated single strand **I**, and were not sensitive to duplex melting (Fig. 2 right), they are likely to arise from Pt binding to the two G residues (G(12) and G(19)) near the terminii of the complementary strand **II**. For **9**, the ^{15}N chemical shifts of the two Pt-NH_3 groups are similar, whereas for **8** they are significantly different (Fig. 2). Their shifts, although very different, lie in the range expected for Pt-NH_3 *trans* to either N or Cl but it is not possible to distinguish between monofunctional and bifunctional adducts on this basis alone, and interstrand cross-links cannot be ruled out.

The large low-field shift of one of the Pt-NH_3 resonances (5 b) of the platinated single-strand GG adduct **5** is intriguing. Such a shift was not observed for the GG platinated duplex **7** until it melted (signal 7′b). The loss of this low-field shift at high temperature (Fig. 2 right), suggests that a GG platinated single-strand lesion has secondary structure which is destroyed on heating. This could have important functional consequences for platinated DNA. Whether this secondary structure involves a looped-back structure similar to that proposed[18] for *cis*-$[Pt(NH_3)_2\{$d-TCTCGGTCTC)-N7(5),N7(6)$\}]$, or a close interaction with the terminal bases giving rise to a ring-current shift, or hydrogen bonding to Pt-NH_3,[11] requires further investigation.

In summary, $[^1H,^{15}N]$-NMR spectroscopy can be used to study the mechanisms of DNA platination reactions at low concentration, and the major intermediates can all be detected. Aquated cisplatin had a half-life of only 8 min at 310 K in reactions of cisplatin with a single-stranded GG deoxydecanucleotide. One monofunctional Pt-N7-G intermediate dominated (by ca. 2:1) over the other, consistent with either preferential 3′- or 5′-G attack on GG and/or preferential chelate ring closure. Further experiments with the aqua-chloro complex should address this problem in a complementary manner to the reported HPLC experiments.[4] As expected, both the initial attack by cisplatin and the rate of ring closure appear to be determined by the Pt–Cl hydrolysis rate. The NH_3 resonances are very sensitive to melting of the platinated duplex and suggest that platinated lesions on single strands possess secondary structure. The method should be applicable to a wide range of oligonucleotides and lead to an improved understanding of the preferential attack by Pt on selected DNA sequences, which, in turn, will be invaluable in the drug design process.

Experimental Procedure

cis-$[PtCl_2(^{15}NH_3)_2]$ (**1**) was synthesized as described previously [19] and recrystallized from aqueous KCl. $^1H\{^{15}N\}$ NMR spectra were recorded on either a Varian UNITYplus-500 or a UNITY-600 spectrometer fitted with pulsed field gradient modules. ^1H spectra were referenced to TSP (TSP = $(Me_3Si(CD_2)_2CO_2Na)$, and ^{15}N spectra to 1.5 M NH_4Cl in 1 M HCl (external). Both 1D ^{15}N-edited ^1H NMR spectra and 2D $[^1H,^{15}N]$ HSQC spectra (optimized for $^1J(N,H) = 72$ Hz) were recorded by using the sequence of Stonehouse et al. [7]. In this sequence coherence selection and suppression of the ^1H_2O signal is achieved by the use of gradient pulses and the water magnetization is returned to its equilibrium position (z axis) before the start of data acquisition. The ^{15}N-spins were decoupled by irradiating with the GARP-1 sequence at field strength of 1 KHz during the acquisition time.

[13] The appropriate differential equations were integrated numerically and rate constants determined by a non-linear optimization procedure. The errors quoted represent one standard deviation. To simplify the kinetic treatment, it was assumed that each monofunctional intermediate (**3** or **4**) gives rise to the same products (**5** and **6**). To achieve a good fit for complex **2**, it was necessary to assume that a small excess (20%) of strand **I** over **1** was present in the reaction solution; about 20% of **I** appeared to be unreacted at equilibrium. We were able to exclude a model in which each intermediate gives rise to only one product (e.g., **3** gives **5**, and **4** gives **6**) since this did not fit the data. A more elaborate kinetic analysis will require a more detailed assessment of the errors in measurement of concentrations from peak intensities (problems of overlap and nearness to the solvent peak) and identification of unknown products.
[14] S. E. Miller, D. A. House, *Inorg. Chim. Acta* **1989**, *161*, 131–137.
[15] By mixing **I** and **II** in an equimolar ratio (1.5 mM; 10 mM phosphate buffer, pH 6.82). Seven of the ten imino proton resonances were observed at 278 K: four in the downfield region ($\delta = 13.4$ to 13.6, A–T base pairs) and three in the G–C region ($\delta = 12.5$ to 12.7), consistent with end-fraying so that the imino resonances of the terminal A–T base-pairs and either the C(9)–G(12) or C(2)–G(19) base pairs are in rapid exchange with solvent. One G–C resonance and one A–T resonance began to undergo exchange-broadening at 293 K and were in rapid exchange with solvent by 303 K, slightly below the exchange temperature of the remaining G–C and A–T resonances (303–310 K).
[16] The ^{1}H NMR spectrum of **III**-Pt (formed either from direct platination of **III**, or addition of **II** to **I**-Pt) supports the assignment of **7** as *cis*-[Pt(**III**-N7-G(5), N7-G(6))$(NH_3)_2$] and also melting of the platinated duplex at ca. 300 K. A sharp peak at $\delta = 8.62$ at 283 K began to broaden at 293 K, and by 303 K had disappeared. Above ca. 313 K a new broad signal appeared at $\delta = 8.96$ which sharpened at 328 K. This chemical shift is similar to a broad resonance at $\delta = 8.98$ for **I**-Pt at 310 K assignable to one of the G H8 protons of the bifunctional adduct **5**, and similar to the reported behavior of single- and double-stranded GG chelates of d-TCTGGTCTC: J. H. J. den Hartog, C. Altona, J. H. van Boom, G. A. van der Marel, C. A. G. Hasnoot, J. Reedijk, *J. Biomol. Struct. Dyn.* **1985**, *2*, 1137.
[17] C. J. van Garderen, H. van den Elst, J. H. van Boom, J. Reedijk, *J. Am. Chem. Soc.* **1989**, *111*, 4123–4125. Lowerings of 9–27° are typical.

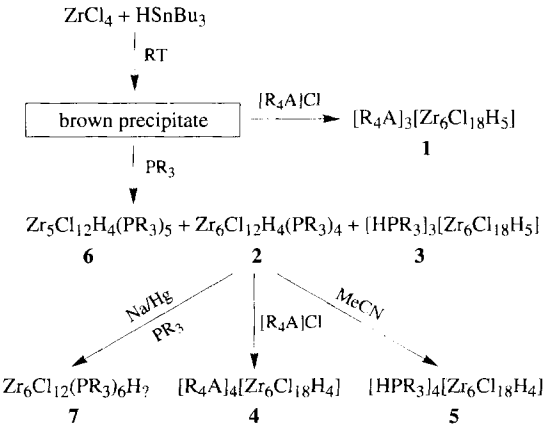
The $[Zr_6X_{18}H_5]^{3-}$ Ions with X = Cl, Br, and Related Species**

Linfeng Chen, F. Albert Cotton,* and William A. Wojtczak

Our work with low-valent zirconium cluster compounds began in 1988 with the accidental preparation and characterization of the compound $[Zr_6Cl_{12}(PMe_2Ph)_6]$.[1] It was clear that this molecule contained no atom or atoms within the Zr_6 octahedron with the possible exception of hydrogen, thus differentiating it from the many $Zr_6X_{12}Z$ type compounds, where Z is an atom such as B, C, N, or even larger atoms, at the center of the Zr_6 octahedron.[2] The first result of an effort to find an efficient and reproducible synthetic method for the $[Zr_6Cl_{12}(PR_3)_6]$ species was the preparation of a class of slightly less reduced compounds, $[Zr_6Cl_{14}(PR_3)_4]$,[3] in which, again, it was clear that no other atoms except possibly hydrogen could be present in or on the cluster. In none of these structures was there any X-ray evidence for the presence of hydrogen atoms and until recently NMR results were inconclusive. It has also been shown[4] that further reduction of $[Zr_6Cl_{14}(PMe_2Ph)_4]$ by Na/Hg in presence of PMe_2Ph affords the long-sought improved route to $[Zr_6Cl_{12}(PMe_2Ph)_6]$.

We wish to report here additional synthetic results in this area. As shown in Scheme 1, we now have routes to products containing the $[Zr_6Cl_{18}H_n]^{x-}$ ions ($x = 3,4$). Moreover, we have



Scheme 1. For **1**–**5** the number of hydrogen atoms shown is that obtained by ^{1}H NMR spectroscopic measurements. For **6** the number (4) is that previously found by X-ray crystallography. For **7** even the presence of H atoms remains uncertain.

been able to establish conclusively by ^{1}H NMR spectroscopy that there are hydrogen atoms present in these anions such that their actual formulas are $[Zr_6Cl_{18}H_5]^{3-}$ and $[Zr_6Cl_{18}H_4]^{4-}$. Again, by ^{1}H NMR spectroscopy, we find that the previously reported $[Zr_6Cl_{14}(PMe_3)_4]$ is actually $[Zr_6Cl_{14}H_4(PMe_3)_4]$. These results have been obtained by employing scrupulously pure, crystalline samples and integrating the cluster hydrogen atom signals against the ^{1}H signals from the cations or the PMe_3 ligands, as appropriate. Results for three representative compounds are shown in Figure 1 and tabulated in Table 1.

The structural characterization of the compounds containing the new $[Zr_6X_{18}H_n]^{x-}$ ions ($x = 3,4$) was first carried out without attempting to obtain evidence concerning the presence or location of hydrogen atoms. A list of the compounds so charac-

[a] At 20 °C. [b] At −60 °C. [c] At −100 °C.

The dimensions of the $[Zr_6Cl_{18}H_5]^{3-}$ and $[Zr_6Cl_{18}H_4]^{4-}$ ions are practically identical. The mean Zr–Zr distances (followed by the ranges) are 3.411 (3.393–3.438) Å and 3.366 (3.356–3.371) Å for the 3– and 4– ions, respectively. There appears to be a small but real contraction; not only do the mean values differ by 0.045 Å, but the ranges do not overlap. As for Zr–Cl_b distances, there is also a significant difference, but now the mean value for the 4– species (2.542 Å) is greater than that for the 3– species (2.484 Å), and again the ranges do not overlap. As for Zr–Cl_t distances, they are indistinguishable for the two classes of anion.

It has previously been reported[5] that in the compound $[Zr_5Cl_{12}H_4(PMe_3)_5]$ the hydrogen atoms could be found and refined by using X-ray diffraction data. Here, of course, there was no reason to expect that the hydrogen atoms would be distributed fractionally over more than one equivalent site and thus the chance of seeing and refining them at full occupancy was optimal. In view of the NMR results suggesting the presence of four or five hydrogen atoms in the $[Zr_6Cl_{18}H_n]^{x-}$ species ($x = 3,4$) and four hydrogen atoms in the $[Zr_6Cl_{15}H_4(PMe_3)_4]$ compound, we were guardedly hopeful that by employing the powerful new computational tools available in the SHELXL-93 program package,[6] we might be able to locate hydrogen atoms in at least some of these cases, despite the fact that individual sites might have only about 50% occupancy. We can now report four instances in which this has been successfully done.

As shown in Table 2, for the $[Zr_6Cl_{18}H_5]^{3-}$ ions in compounds **1a**–**c** and also in the $[Zr_6Br_{18}H_5]^{3-}$ ion in compound **1d**, hydrogen atoms have been found and refined, at partial occupancy, in or very near the centers of all triangular faces of the Zr_6 octahedra. The structure of one such anion is shown in Figure 2. The average occupancy number for all the faces is 5/8, but since the faces are, in general, not crystallographically equivalent, the occupation numbers need not be equal and do, in fact, vary about this mean value, in the range 0.50–0.80.

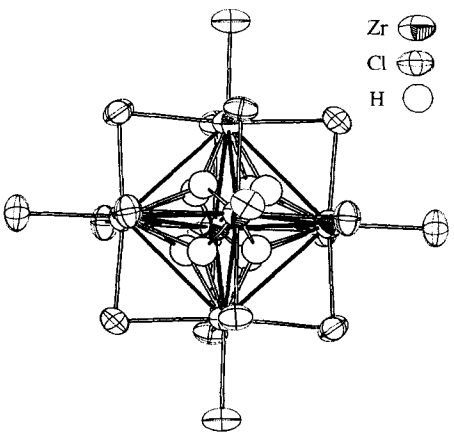

Fig. 2. ORTEP drawing of one of the two independent molecules in the unit cell for compound **1a**.

There is, as expected, a high degree of correlation between the occupancy numbers and the thermal displacement parameters. When the mean occupancy number was changed in any of the four cases from that corresponding to a total of five, to four or six hydrogen atoms, the thermal displacement parameters became *very* unrealistic.

The results presented are highly reminiscent of the classic $Th_6Br_{15}D_7$ structure of Simon et al.,[7, 8] where seven D atoms are disordered on the eight faces of the Th_6 octahedron, lying just slightly (0.22 Å) outside. They are also consistent with the results previously reported for $[Zr_5Cl_{12}H_4(PMe_3)_5]$, wherein it may be imagined that if the octahedron were completed by adding a zirconium atom, there would be four H atoms just over the centers of four alternating faces.

Experimental Procedure

All manipulations were carried out under an argon atmosphere using standard vacuum-line and Schlenk techniques. The solvents were freshly distilled under nitrogen from the appropriate drying reagents. Phosphonium and ammonium salts were dried in vacuum at 180 °C. Other reactants were used as received from the suppliers. **1**–**7**: ZrX_4 (X = Cl: 0.466 g, 2.0 mmol; X = Br: 0.822 g, 2.0 mmol) was reduced with Bu_3SnH (1.05 mL, 4.0 mmol) in benzene or toluene (20 mL) for 36 h. The resulting red-brown precipitate (dark blue for X = Br) was washed with two portions of freshly distilled toluene or benzene (each 10 mL) to remove excess Bu_3SnH. Addition of $R_4A^+X^-$ in CH_3CN or CH_2Cl_2 afforded **1** in about 30% yield. Approximately 50% of starting material was unreacted and isolated as $[R_4A]_2[ZrX_6]$. Addition of PR_3 to the red-brown precipitate yielded a purple solution of compound **6** and a purple precipitate. Compounds **2** were isolated in about 15% yield by dissolving the purple precipitate in CH_2Cl_2 and layering with hexane. When phosphanes with a higher number of carbon atoms (i.e., PBu_3, $P(tBu)_2Ph$) were used, the only isolable products from crystallization were compounds **3** in about 15% yield. Compounds **2** were converted into compounds **4** by treating with $[R_4A]^+Cl^-$ in over 90% yield. Compounds **2** were also converted gradually into compounds **5** in MeCN solution at room temperature over a period of 30 days in about 50% yield. When compounds **2** were further reduced with Na/Hg in the presence of PR_3 compounds **7** were formed in yields of about 20%.

^1H NMR measurements were made at 200 MHz on a Varian XL-200 spectrometer. Hydride signals were detected at $\delta = -3.07$ for $[Zr_6Cl_{18}H_5]^{3-}$ and at $\delta = -5.19$ for $[Zr_6Cl_{18}H_4]^{4-}$ in CH_3CN. X-ray data were collected on an Enraf-Nonius CAD-4 diffractometer or Enraf-Nonius FR590 area detector. Full reports on the structures will be published elsewhere at a later time.

New Tellurometalates of Gallium and Indium: $K[K([18]crown\text{-}6)]_2[GaTe_3] \cdot 2CH_3CN$ and $[(NEt_4)_5][In_3Te_7] \cdot 0.5Et_2O$**

Chang-Woo Park, Robert J. Salm, and James A. Ibers*

The number of known tellurometalates has increased rapidly in the past few years through the use of the traditional techniques of nonaqueous solution chemistry as well as the nontraditional techniques of cathodic dissolution of electrodes composed of metal telluride alloys,[1–6] solvent extraction of metal telluride phases,[7, 8] and solventothermal sealed-tube reactions.[9–18] Among these nontraditional techniques, the first two have been especially effective for the synthesis of main group tellurometalates. The cathodic dissolution technique is based on the constant discharge of tellurometalate anions into the cathodic cell from the metal telluride electrode by application of a steadily increasing potential at room temperature; once sufficient concentration has been achieved, crystallization may occur in that chamber. The solvent extraction technique involves the high-temperature fusion of an alkali metal with the desired elements for the tellurometalate, followed by extraction with polar solvents such as ethylenediamine.

We have developed another synthetic route for the preparation of tellurometalates, namely a chemical reduction method in which binary metal tellurides are reduced in liquid NH_3 by K in the presence of an encapsulating ligand.[19] Through the use of a chemical reducing agent, such as K, the potential remains constant and is lower than is usual for cathodic dissolution experiments. Through the use of liquid NH_3 as the solvent, the reductions occur at much lower temperatures than are commonly used in the solvent extraction method or in redox reactions in organic solvents, for example in the preparation of $[Ba(en)_4]_2[As_4Te_6]$ in refluxing ethylenediamine (en).[20] For this chemical reduction method to work an alkali-metal sequestering agent is necessary, since encapsulation of the cation helps to prevent tight-ion pairing that otherwise would cause reversion of the compounds formed to insoluble materials.[8, 21] The features of lower reduction potential and lower temperature in this chemical reduction method may enable the preparation of tellurometalates that are not accessible by other techniques. We illustrate that here with the synthesis and structural characterization of two new tellurometalates **1** and **2**.

$K[K([18]crown\text{-}6)]_2[GaTe_3] \cdot 2CH_3CN$ **1**

$[(NEt_4)_5][In_3Te_7] \cdot 0.5Et_2O$ **2**

Compound **1** was obtained as yellow plates from the chemical reduction of Ga_2Te_3. Its crystal structure includes two $[K([18]crown\text{-}6)]^+$ ions, one K^+ ion, and two CH_3CN solvent molecules per $[GaTe_3]^{3-}$ ion. The $[GaTe_3]^{3-}$ ion, which has a crystallographically imposed mirror plane through atoms Ga and Te(1), consists of a trigonal planar arrangement of Te atoms about a central Ga atom (Fig. 1). The Ga–Te distances are 2.495(3) and 2.513(2) Å, the Te-Ga-Te angles are 114.76(11) and 122.38(6)°, and the Ga atom lies 0.10 Å above the plane of the three Te atoms. These small distortions from strict trigonal planar geometry may be a result of the differing environments of the Te atoms. For example, the K^+ ion, K(4), is 3.429(1) Å from Te(1) and 3.797(1) Å from Te(2). The Ga–Te distances in $[GaTe_3]^{3-}$ are similar to those reported for $[PPh_4][GaTe_2(en)_2]$ (2.509(1) Å),[6] but are signifi-cantly shorter than those in the intermetallic compounds GaTe (average, 2.665(2) Å),[22] Ga_2Te_5 (2.641(1) Å),[22] and $K_6Ga_2Te_6$ (2.591 and 2.680 Å).[23] Among the combinations of Group 13 (M) and Group 16 (Q) elements there are number of isolated $[MQ_3]^{3-}$ ions found in compounds prepared by high-temperature solid-state methods (for example, the $[BSe_3]^{3-}$ ion in

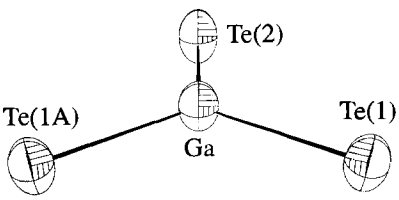

Fig. 1. Structure of the $[GaTe_3]^{3-}$ ion in **1**. Thermal ellipsoids are shown at 50% probability. Relevant distances [Å] and angles [°]: Ga–Te(1) 2.513(2), Ga–Te(2) 2.495(3); Te(1)-Ga-Te(2) 122.38(6); Te(1)-Ga-Te(1A) 114.76(11). The anion has a crystallographically imposed mirror plane through atoms Ga and Te(1).

Tl_3BSe_3[24]), but the $[GaTe_3]^{3-}$ ion appears to be the first to be prepared at low temperatures by a solution method.

Compound **2** was obtained as orange needles from the chemical reduction of In_2Te_3. The $[In_3Te_7]^{5-}$ ion, which has no known analogues, consists of an $[In_3Te_4]^{+}$ cuboidal framework (where one corner is missing) with one Te^{2-} ligand on each of the three In^{3+} centers (Fig. 2). This structure may be described as three edge-sharing "$InTe_4$" tetrahedra; each tetrahedron shares an edge with each of the other two tetrahedra. The In–$Te_{terminal}$ distances range from 2.685(2) to 2.692(2) Å; the In–(μ_2-Te) distances range from 2.802(2) to 2.824(2) Å; the In–(μ_3-Te) distances range from 2.881(2) to 2.907(2) Å. All of the "$InTe_4$" tetrahedra are distorted and have Te-In-Te angles between 94.16(5) and 120.56(7)°. This lengthening of the In–Te bonds with increasing coordination number of the Te atom is also seen in related systems. For example, the "$InTe_4$" tetrahedral moiety is contained in Na_5InTe_4,[25] in which the In–$Te_{terminal}$ distances range from 2.758(2) to 2.811(2) Å and the Te-In-Te angles are all nearly tetrahedral. The In–(μ_2-Te) bond lengths in $[NBu_4]_2[In_2Te_4]$[26] and in $Na_5In_2Te_6$[25] range from 2.786(2) to 2.814(2) Å and from 2.818(5) to 2.836(5) Å, respectively. The "In_4Te_4" cubane core is found in $[Cp(CO)_3Mo]_4In_4Te_4$;[27] in this compound the In-(μ_3-Te) distances range from 2.839(1) to 2.989(1) Å.

Experimental Procedure

Ga_2Te_3 and In_2Te_3 were prepared by the fusion of stoichiometric amounts of the constituent elements under an inert atmosphere and were finely ground before use.

1: NH_3 (ca. 60 mL) was condensed into a flask that contained [18]crown-6 (528 mg, 2.0 mmol) and K (80 mg, 2.0 mmol) at liquid N_2 temperature and the resultant blue solution was stirred for 30 min at −78 °C. Ga_2Te_3 (522 mg, 1 mmol) was then added to the flask and the resultant mixture was stirred for 2 days to provide a light brown solution. The NH_3 was allowed to evaporate at room temperature and CH_3CN (30 mL) was added to the residual material. The resultant solution was then filtered. Et_2O (80 mL) was layered on top of the filtrate to afford yellow plates of **1** (110 mg, yield 10% based on Te) after 5 days.

X-ray structural analysis: $C_{28}H_{54}GaK_3N_2O_{12}Te_3$; crystal dimensions, 0.04 × 0.16 × 0.23 mm; monoclinic, $C2/m$; a = 24.469(5), b = 14.073(3), c = 12.875(3) Å, β = 97.47(3)°, V = 4369(2) Å^3; T = 113 K; Z = 4; ρ_{calc} = 1.784 g cm^{-3}; Enraf-Nonius CAD4 diffractometer; $2\theta_{max}$ = 120.6°; $Cu_{K\alpha}$; $\lambda(K\alpha_1)$ = 1.540562 Å; ω–2θ scan mode; 11538 reflections measured, 3342 independent reflections all of which were included in the refinement; data corrected for Lorentz-polarization effects and for absorption (analytical method), μ = 192 cm^{-1}, min./max. trans. = 0.065/0.446; solution by direct methods [28], refinement on F^2 by full-matrix least-squares [29], 228 parameters, anisotropic refinement of non-hydrogen atoms, H atoms placed in calculated positions before final cycle of refinement; one CH_3CN solvent molecule is disordered; use was made of the SQUEEZE subroutine [30] of the PLATON software package [31] to account for its electron density; R_1 = 0.080; wR_2 = 0.177; residual electron density = 1.03 e Å^{-3}.

2: NH_3 (ca. 60 mL) was condensed into a flask that contained [2.2.2]cryptand (753 mg, 2 mmol) and K (80 mg, 2.0 mmol) at liquid N_2 temperature and the resultant blue solution was stirred for 30 min at −78 °C. In_2Te_3 powder (613 mg, 1.0 mmol) was then added to the flask and the resultant mixture was stirred for 2 days to provide a red-brown solution. The NH_3 was allowed to evaporate at room temperature and CH_3CN (15 mL) was added to the residual material. The resultant solution was then filtered and NEt_4Br (473 mg, 2.5 mmol) in CH_3CN (15 mL) was added to the filtrate. Et_2O (90 mL) was layered on top of the solution to yield orange needles of **2** (180 mg, yield 22% based on Te).

X-ray structural analysis: $C_{42}H_{105}In_3N_5O_{0.5}Te_7$, 0.58 × 0.12 × 0.049 mm; monoclinic, $P2_1/n$, a = 12.419(6), b = 23.005(9), c = 24.171(10) Å, β = 104.210(14)°, V = 6694(5) Å^3; T = 113 K; Z = 4, ρ_{calc} = 1.911 g cm^{-3}; Picker diffractometer; $2\theta_{max}$ = 49.5°; $Mo_{K\alpha}$; $\lambda(K\alpha_1)$ = 0.7093 Å; θ-2θ mode; 13584 reflections measured, 11544 independent reflections of which 11540 were included in the refinement; data corrected for Lorentz-polarization effects and for absorption (analytical method), μ = 40.4 cm^{-1}, min./max. trans. = 0.604/0.779; solution by direct methods [28], refinement on F^2 by full-matrix least-squares [29], 244 parameters, 21 restraints, anisotropic refinement of In and Te atoms, isotropic refinement of other non-hydrogen atoms; R_1 = 0.083, wR_2 = 0.180, residual electron density = 2.27 e Å^{-3}. Of the five independent NEt_4^+ ions only N(1)Et_4^+ is well defined; for this cation hydrogen atoms were included at calculated positions. The N atoms and the four α-C atoms of the other four cations were modeled as rigid tetrahedra with N–C bond lengths of 1.50 Å and C-N-C angles of 109.45°; β-C atoms, when located, were restrained so that αC–βC bond lengths were 1.50(3) Å. The number of β-C atoms found for the N(n)Et_4^+ ions are: n = 2, four, but two disordered over two sites; n = 3, four; n = 4, none; n = 5, three. Some of the resultant displacement parameters are unreasonably large, probably because the model of isotropically vibrating rigid groups is inadequate. An Et_2O solvent of crystallization is disordered about the origin. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Center, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

A New Quantitative Description of the Distance Dependence of Through-Space $^{19}F,^{19}F$ Spin–Spin Coupling**

Ludger Ernst* and Kerstin Ibrom

When NMR-active atomic nuclei approach each other at distances equal to or less than the sum of their van der Waals radii, their scalar spin–spin coupling can be transmitted through space.[1–3] This has been well proved experimentally for interactions between ^{19}F nuclei.[4] The efficiency of through-space spin–spin coupling is strongly dependent upon the distance between the interacting nuclei, and several attempts have been made to formulate a quantitative relationship between the magnitude of the $^{19}F,^{19}F$ through-space coupling, J_{FF}, and the nonbonding distance, d_{FF}, between the fluorine nuclei.[5–7] In this communication we demonstrate that the correlations derived previously do not reproduce the experimental facts very well. From a series of tailored difluorocyclophanes, in which we varied the F–F distance systematically, we have derived a d_{FF}/J_{FF} correlation that describes the distance dependence very much better. This correlation will be useful for structural investigations of multiply fluorinated molecules in solution.

We observed the first through-space F,F coupling (J_{FF} = 42.1 Hz) in a difluorocyclophane in **1**,[4j] a *syn*-dithia[3.3]metacyclophane, in which the aromatic rings are tilted such

	R^1	R^2
1	H	H
2	*t*Bu	*t*Bu
6	*t*Bu	H

	R^1	R^2	R^3
3	H	H	SMe
4	H	H	H
5	*t*Bu	*t*Bu	H
7	*t*Bu	H	H

that the F–C bonds point towards each other and the F–F distance amounts to 278.1 pm according to molecular mechanics computations.[8] A decrease of the distance had been achieved, on the one hand, by introducing two *tert*-butyl groups *para* to the fluorine atoms (**2**: d_{FF} = 259.7 pm). By their mutual repulsion these *tert*-butyl groups force the fluorine substituents into closer contact. Shortening the cyclophane bridges, on the other hand, diminished the F–F distance even more efficiently (**3**, **4**: d_{FF} = 251.7 and 248.1 pm, respectively). By means of these structural changes, J_{FF} had been increased to 99.3 Hz (Table 1). In order to increase the attainable range of F–F distances towards smaller values, we have now prepared the *syn*-di-*tert*-butyl[2.2]metacyclophane **5**, in which substituents are introduced and the bridges are shortened as well. The synthesis of **5** was analogous to that of **4**:[9] Stevens rearrangement of the *S*,*S*′-dimethylbissulfonium salt of **2** and subsequent removal of the methylthio groups with Raney nickel/H_2. We omitted, however, the complexation of the starting material with $Cr(CO)_3$, which proceeds with very low yield and, in the synthesis of **4**, had been meant to prevent *syn*–*anti* isomerization.[9] The *anti* isomer of **5**, which amounted to only one-third in spite of the bulky substituents, could be separated by chromatography (see Experimental Procedure). Expectedly, the desired *syn* isomer **5** displayed the largest F,F coupling constant, 110.1 Hz, because the related F–F distance, computed with MM2, is the shortest in the series (241.9 pm). The data of **6**[10] and **7**[11] show that J_{FF} is not increased by a single *tert*-butyl substituent.

Table 1. Nonbonding F–F distances d_{FF} as computed by MM2 and experimental coupling constants J_{FF} in **1**–**10**.

Cmpd.	d_{FF} [pm]	J_{FF} [Hz]	Cmpd.	d_{FF} [pm]	J_{FF} [Hz]
1	278.1	42.1	**6**	273.3	40.6
2	259.7	60.5	**7**	248.5	97.6
3	251.7	89.3	**8**	299.8	13.7
4	248.1	99.3	**9**	318.0	7.2
5	241.9	110.1	**10**	301.7	1.9

In paracyclophanes **8** and **9**[12] the best planes through the aromatic rings lie parallel to each other. Therefore, the F–F distances are larger than in the corresponding metacyclophanes and the J_{FF} values are smaller. The overall range of F–F distances in **1**–**9** extends from 318 to 242 pm and the respective F,F coupling constants lie between 7 and 110 Hz (Table 1). The relatively large number of data points permits the derivation of a function that describes the correlation between d_{FF} and J_{FF} within the range of distances covered [Eq. (a)]. Figure 1 gives a comparison of this function (curve c) with the previous d_{FF}/J_{FF} relationships.

9	CH_2SCH_2

$$J_{FF} = 275000\ e^{-0.03211 d_{FF}} \qquad (a)$$

Clearly, through-space coupling does not come into effect only at $d_{FF} = 2r_{vdW}(F) = 270$ pm, but already amounts to more than 40 Hz at this distance. Thus, as pointed out before,[4j, 6] not only are the values obtained from semiempirical calculations by Buckingham et al.[5] (curve a) distinctly too small (by a factor ≥ 10), but the empirical correlation suggested instead by Hilton and Sutcliffe[6] (curve b) also yields coupling constants that, in the range of smaller distances, are only half as large as the values we observed; this can be traced back to these authors' unrealis-

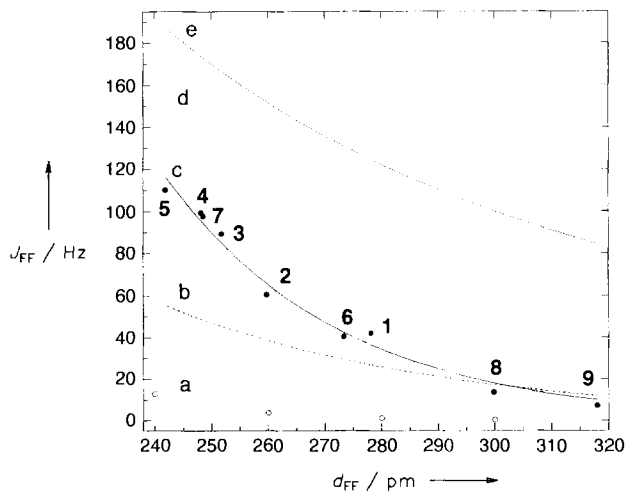

Fig. 1. Postulated dependencies of the through-space F,F coupling constant J_{FF} [Hz] upon the nonbonding distance d_{FF} [pm]. a) Values according to ref. [5]; b) $J_{FF} = 6800\ \exp(-0.0199 d_{FF})$ [6]; c) J_{FF} according to Equation (a) and appropriate experimental data (data points are labeled with the compound numbers); d) $J_{FF} = |-431\ \exp(-1.6\times10^{-5}\ d_{FF}^2) + 1.2|$ [7b]; e) $J_{FF} = 2.6\times10^9\ d_{FF}^{-3} + 3.6$ [7a].

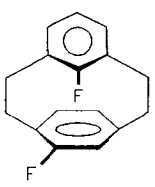
tic assumptions of the molecular geometries.[6] In contrast, both functions suggested by Russian authors[7] (curves d and e) for a given distance substantially overestimate the magnitude of J_{FF}. The main reason for this should lie in the debatable method by which the authors tried to extract the through-space component from $^4J_{FF}$ in fluorinated allyl cations. Their prediction of nonbonding F–F distances by semiempirical MO calculations is not unproblematic either.[13]

For some of our compounds the F–F distances in the solid state are known from X-ray structural analyses.[4j, 14, 15] These distances can be used to derive a function similar to Equation (a), yet it is not as good because it is based on fewer data points and d_{FF} is restricted to the range of 245 to 275 pm. Moreover, in some cases, several molecules with different F–F distances are present in the asymmetric unit, which indicates that d_{FF} is influenced by packing forces in the solid state. We therefore suppose that the structures calculated with MM2 are better suited to describe the geometries in solution.

We tested the usefulness of the new d_{FF}/J_{FF} correlation with 1,8-difluoro-4-methylnaphthalene, which has a calculated d_{FF} of 258.7 pm and a J_{FF} of 65.6 Hz. Equation (a) predicts J_{FF} to be 67.9 Hz, whereas the correlations from the literature give J_{FF} values of 39.5,[6] 153.8,[7a] and 146.5 Hz,[7b] respectively. Thus, our equation gives by far the best prediction.

Finally, we have observed a very small J_{FF} value of 1.9 Hz in the [2.2]metaparacyclophane **10**,[16] although d_{FF} in this compound is calculated to be 301.7 pm, only slightly larger than in **8** (299.8 pm) where J_{FF} is 13.7 Hz. Since the F–C bonds in **10** form a substantially larger angle than those in the other molecules studied, the small coupling constant could be a first indication that the magnitude of the through-space coupling is influenced not only by the distance d_{FF} but also by the relative spatial orientation of the interacting parts of the molecules. This has hardly been considered in the previous discussions.[20]



10

Experimental Procedure

5: Cyclophane **2** was methylated with $(MeO)_2CH^+ BF_4^-$ according to ref. [17], but the carbenium salt was added at the boiling temperature of dichloromethane instead of at −78 °C. Of the resulting dimethylbissulfonium salt (m.p. 186–188 °C, quantitative yield), 1.73 g (2.77 mmol) was subjected to an S-analogous Stevens rearrangement according to ref. [18], with a reaction time of 2 h. From the mixture of isomeric 1,9-/1,10-bis(methylthio)[2.2]metacyclophane derivatives obtained (brown oil, 1.03 g, 83%), 346 mg of the *anti*-(1*RS*,9*SR*) isomer could be precipitated by adding petroleum ether to a CH_2Cl_2 solution. Roughly 7 g of Raney nickel W7 was added to 688 mg (1.53 mmol) of the remaining isomers in 250 mL of ethanol and the mixture was hydrogenated for 5 h at 60–65 °C with 1 bar of H_2. The catalyst was filtered off and the solvent removed. After filtration over silica gel with CH_2Cl_2, 223 mg (41%) of **5** and 131 mg (24%) of its *anti* isomer were obtained by thin layer chromatography (silica gel, CH_2Cl_2/petroleum ether 1:3). **5**: m.p. 146–148 °C; *anti* isomer of **5** [19]: m.p. 214–215 °C. NMR data: see Table 2. All new compounds gave correct C,H,S analyses or high-resolution mass spectra. The NMR spectra were assigned by H,H- and C,H-COSY, C,H-COLOC, and NOE measurements.

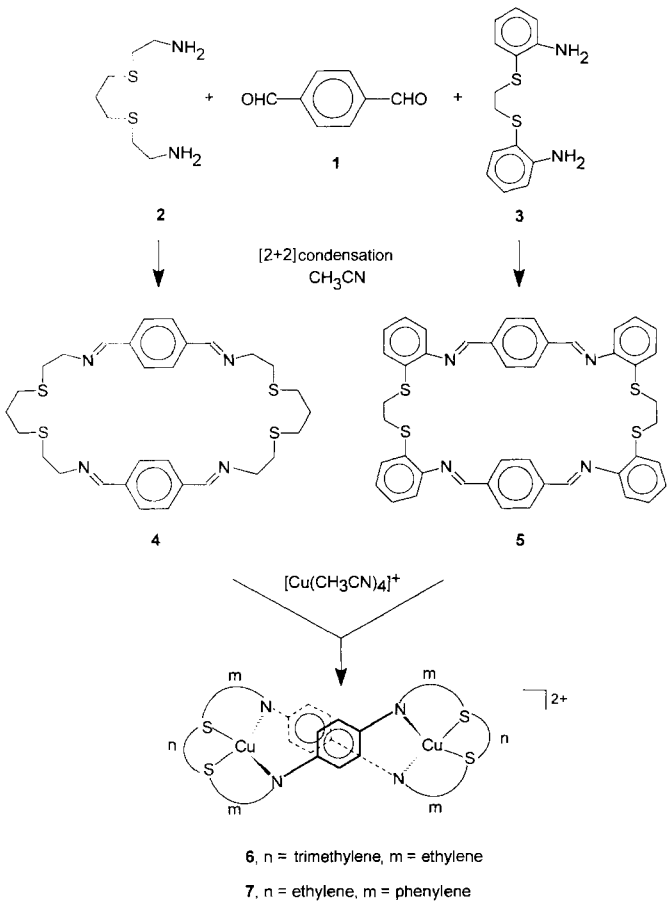
[20] **Note added in proof** (August 2, 1995): Recently we learned about two additional papers that treat the distance dependence of through-space F,F couplings: a) C. Schumann, F. Cavagna, *J. Magn. Reson.* **1975**, *18*, 172–184; b) F. Cavagna, C. Schumann, *ibid.* **1976**, *22*, 333–344. The F–F distances assumed there are based upon model considerations and are presumably too small because the data points (e.g. J_{FF} = 35.4 Hz at d_{FF} = 247 pm and 45.5 Hz at 220 pm) lie even distinctly below curve b in Figure 1. Due to the unusual nomenclature employed ("non-bond couplings") these papers had not been found in a CAS Online search.

Double Helical Dinuclear Copper(I) Complexes of Macrocyclic Bis(dithiadiimine) Ligands**

Peter Comba,* Andreas Fath, Trevor W. Hambley, and David T. Richens*

A [2 + 2] condensation reaction[1] was used to prepare 32- and 34-membered macrocyclic Schiff base type ligands with $(N_2S_2)_2$ donor sets (Scheme 1). Both imines and thiaethers favor soft metal centers and thus stabilize the +1 oxidation state of copper, which has a preference for tetrahedral coordination geometry. Because of our interest in the comparison of solid-state and solution structures of transition metal compounds,[2] the structural and spectroscopic properties of compounds **6** and **7** were of particular interest. In this communication we describe the syntheses of the ligands **4** and **5** and of their dicopper(I) complexes **6** and **7**, as well as their structural, spectroscopic, and electrochemical properties.



6, n = trimethylene, m = ethylene

7, n = ethylene, m = phenylene

[**] This project was supported by the DFG, the DAAD, the Australian Research Council and the British Council (ARC Project 484).

The addition of stoichiometric amounts of terephthalaldehyde (**1**) to solutions (CH_3CN) of 3,7-dithia-1,9-diaminononane (**2**) and 1,2-bis(1-aminothiophenyl)ethane (**3**) affords the ligands **4** and **5**, respectively, as white (yellow) solids in good yields (60–70%). The analytical data (elemental analyses, FAB^+-MS, IR, ^1H and ^{13}C NMR spectra) are compatible with symmetrical macrocycles containing four Schiff base units each. The ^1H and ^{13}C NMR spectra, in particular, demonstrate that the ligands **4** and **5** are highly symmetrical. Addition of $[Cu(CH_3CN)_4]ClO_4$ to **4** and **5** in CH_3CN/CH_2Cl_2 (1:1) produces yellow-orange or red solutions, respectively, from which orange or red-brown air-stable crystals, suitable for X-ray diffraction, were isolated after slow evaporation of the solvents.

The structural analyses of **6** and **7** (Figs. 1 and 2)[4, 5] reveal that the basic structural properties of the two dicopper(I) com-

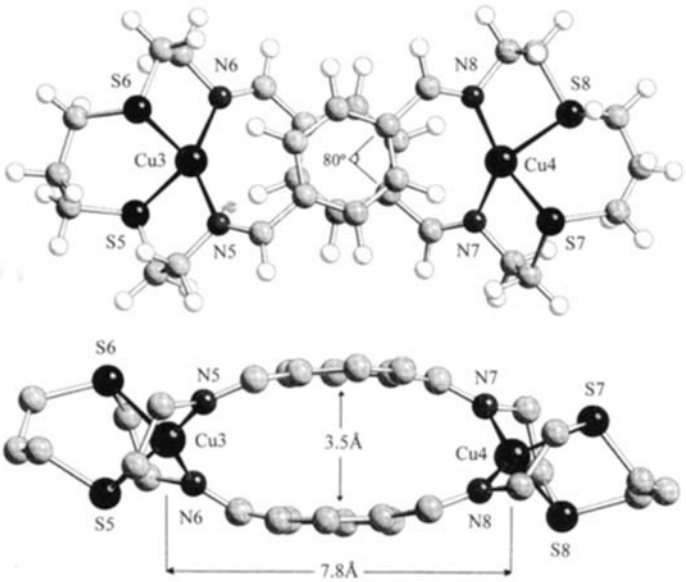

Fig. 1. Crystal structure of **6**-$(ClO_4)_2 \cdot H_2O$ (molecule A) (SCHAKAL plots [3]). pounds are rather similar. The main features are the following: a) The two N_2S_2 donor sets are each tetrahedrally coordinated to the Cu^I centers; b) the two bridging *para*-substituted phenyl rings are parallel, about 3.5 Å apart, indicative of a stabilization by π-stacking; c) the dihedral angles between the bridging phenyl rings are about 80°, resulting in a double helical arrangement (figure-of-eight loop) of the ligand backbone. The molecules **6** and **7** shown in Figures 1 and 2 have Λ configurations (both compounds crystallize as racemates; there are two crystallographically independent molecules in the asymmetric unit of **6**). The distance between the two copper(I) centers is about 7.8 Å in both compounds.

Helical metal complexes have recently attracted much attention, and aspects related to the topology and intrinsic chirality of helicates, and their relevance to biological systems and supramolecular chemistry, as well as to material sciences, have been extensively reviewed.[8] Many of the reported systems are based on open-chain ligands with polypyridine or phenanthroline donors[8, 9] but macrocyclic systems and ligands with other donor sets have also been studied.[10] The helicates reported so

far include double and triple helical systems. Preorganization of the ligands, self-assembly, and chiral self-organization have also been observed and studied.[8–10] The simplicity of the figure-of-eight loop resulting from the copper(I)-induced folding of **4** and **5** is an interesting new motif in this area.

The following questions arise: a) are the helical structures of the dicopper(I) species preserved in solution and b) are the metal-free ligands preorganized, that is, do they have helical structures or the open macrocyclic structures shown in Scheme 1. As in other systems[9, 10] these questions were addressed by ^{1}H NMR spectroscopy. The methylene protons of the metal-free ligand **5** are chemically equivalent (singlet at $\delta = 2.68$). In the dicopper(I) complex **7** these protons are diastereotopic and appear as a single AX system with a geminal coupling of 10.5 Hz and a chemical shift difference of $\Delta\delta = 1.5$. These observations imply that the dicopper(I) complex **7** is chiral in solution and kinetically inert on the NMR time scale, while the corresponding metal-free ligand **5** has an open macrocyclic structure (see Scheme 1). Preliminary model calculations[11] of the dicopper(I) complex **7** with δ conformations of the chelate rings (as in the crystal structure, see Figure 2; Λ helix of the complex) lead to a structure that is in good agreement with that observed in the solid state. The axial methylene protons are about 3.5 Å from the phenyl rings of the five-membered chelate rings separated by a methylene group (see arrow in Figure 2). In addition, complex **7** with λ conformations of the five-membered chelate rings (Λ configuration of the complex) has been refined by molecular mechanics.[11] In this configuration the complex is at least 6 kJ mol^{-1} more stable, and the axial methylene protons are separated from the phenyl rings of the neighboring chelate rings by about 3.4 Å. We interpret the chemical shift difference of the AX system of the methylene protons of $\Delta\delta = 1.5$ to be due to the ring current. The symmetry of the dicopper(I) complex and the small difference in proton to phenyl ring distance of the two conformers resulting from our preliminary calculations does not allow the assignment of the spectrum to one of the two possible conformers.

There are two possible effects contributing to the stabilization of the helical arrangement of the macrocyclic rings, namely, the preference of copper(I) for tetrahedral coordination geometry and π stacking of the phenyl rings. The solution structures of the free ligand **5** and the dicopper(I) complex **7**, deduced from ^{1}H NMR spectroscopy, indicate that stabilization by π stacking alone is not sufficient to induce helicity. Future structural studies, supported by molecular modeling studies, of metal complexes with a series of ligands with the basic structure of **4** and **5** coordinated to copper(I) and other metal centers might help to quantify the stabilization by π stacking. An important fact emerging from the arrangement of the bridging *para*-substituted phenyl rings, induced by the tetrahedral coordination geometry, is that an enforced helical arrangement of a metal-free ligand of the type discussed here would lead to tetrahedral preorganization of the ligating atoms and thus selectively stabilize metal centers with a preference for tetrahedral coordination.

Electrochemical properties of **6** have been studied by cyclic voltammetry in CH_3CN.[14] The voltammogram indicates that, due to the Cu–Cu separation of about 7.8 Å, both Cu^I centers behave largely independently. The oxidation from Cu^I to Cu^{II} at a potential of $E_{1/2} = 1.34$ V (vs NHE) is independent of the scan rate (0.1–2 Vs^{-1}). The E_p value of 55 mV indicates the presence of a reversible electron process. The stabilization of Cu^I by a tetrahedral arrangement of thioether and imine donors is demonstrated by the highly positive redox potential.

Experimental Procedure

The diaminodithiaalkanes **2** and **3** were prepared as described in [15]. The dialdehyde **1** is commercially available.

For the syntheses of the macrocyclic ligands **4** [5], the dialdehyde **1** (4.2 g, 31.5 mmol, dissolved in 500 mL CH_3CN) was added slowly (24 h) to a stirred solution of **2** (6.2 g, 31.5 mmol) [**3** (7.7 g, 31.5 mmol)] dissolved in 800 mL CH_3CN. The isolated white [yellowish] solids were recrystallized twice from CH_3CN/CH_2Cl_2 (1:1). **4**: Yield: 5.6 g (9.7 mmol, 62%); correct C,H,N,S analysis; MS (FAB$^+$, NOBA): *m/z* 585 (M^+, 30%); ^{1}H NMR (200.1 MHz, $CDCl_3$): $\delta = 8.27$ (s, 4H, NCH), 7.74 (s, 8H, Ar-H), 3.79 (t, 8H, $^3J = 6.5$ Hz, NCH_2) 2.82 (t, 8H, $^3J = 6.9$ Hz, NCH_2CH_2) 2.62 (t, 8H, $^3J = 7.1$ Hz, $CH_2CH_2CH_2$), 1.85 (p, 4H, $^3J = 7.2$ Hz, $CH_2CH_2CH_2$); ^{13}C NMR (50.3 MHz, $CDCl_3$): $\delta = 161.56$ (NCH), 137.95 (Ar-*C*-CHN), 128.42 (*o*-Ar-C), 61.87 (NCH_2), 32.82 (NCH_2CH_2), 31.22 ($CH_2CH_2CH_2$), 29.37 ($CH_2CH_2CH_2$); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1639(s), (C=N)s. [**5**: Yield: 7.9 g (10 mmol, 68%); correct C,H,N,S analysis; ^{1}H NMR (200.1 MHz, C_6D_6): $\delta = 7.82$ (s, 4H, NCH), 7.30 (s, 8H, *p*-Ar-H), 2.68(s, 8H, SCH_2), 6.25–7.90 (m, 16H, *m*-Ar-H); ^{13}C NMR (50.3 MHz, C_6D_6): $\delta = 159.52$ (NCH), 149.82 (Ar-*C*-NC), 137.87 (Ar-C-S), 135.77 (Ar-*C*-CN), 129.95, 129.84 (S-*m*-Ar-C, N-*m*-Ar-C), 129.24 (C-*o*-Ar-C), 116.43 (S-*o*-Ar-C), 114.37 (N-*o*-Ar-C), 33.50 (CH_2); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1616(s), (C=N)s.

Complex **6** [7] was synthesized under an Ar atmosphere in dry and degassed solvents. An excess of freshly prepared $[Cu(CH_3CN)_4]ClO_4$ in CH_3CN [16] was added slowly to a stirred solution of **4** (200 mg, 0.34 mmol) [**5** (200 mg, 0.27 mmol)] in 200 mL CH_3CN/CH_2Cl_2 (1:1). The yellow-orange [red] solution was filtered after 1 h and reduced to 50 mL by evaporation of the solvent under reduced pressure to afford yellow-orange [red-brown] solids. Excess $[Cu(CH_3CN)_4]ClO_4$ that precipitated with the dinuclear species was oxidized with air and removed with CH_3CN. **6**: Yield: 134 mg (0.15 mmol, 43%); correct C,H,N,S analysis. ^{1}H NMR (200.1 MHz, CD_3CN): $\delta = 8.67$ (s, 4H, NCH), 7.48 (s, 8H, Ar-H), 4.04–4.22 (m, 8H, NCH_2), 2.92–3.38 (m, 16H, $NCH_2CH_2 + CH_2CH_2CH_2$) 2.18–2.25 (m, 4H, $CH_2CH_2CH_2$); ^{13}C NMR (50.3 MHz, CD_3CN): $\delta = 166.64$ (NCH), 138.10 (Ar-*C*-NC), 129.07 (*o*-Ar-C), 61.01 (NCH_2), 36.17 (NCH_2CH_2), 32.91 ($CH_2CH_2CH_2$), 26.14 ($CH_2CH_2CH_2$); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1619(s), (C=N)s, 1093 (br. s), (Cl–O)s. [**7**: Yield: 140 mg (0.13 mmol, 47%); correct C,H,N,S analysis. ^{1}H NMR (200.1 MHz, CD_3CN): $\delta = 9.05$ (s, 4H, NCH), 8.23 (s, 8H, *m*-Ar-H), 7.95 (d, 4H, $^3J = 6.0$ Hz, N-*o*-Ar-H) 7.54–7.65 (m, 12H, Ar-H + S-*o*-Ar-H), 3.96 (d, 4H, $^2J_{AX} = 10.5$ Hz, SCH_2) 2.47 (d, 4H, $^2J_{AX} = 10.5$ Hz, SCH_2), $\Delta\nu = 298.9$ Hz; ^{13}C NMR (50.3 MHz, CD_3CN): $\delta = 165.60$ (NCH), 152.36 (Ar-*C*-NC), 140.98 (Ar-C-S), 135.42 (Ar-*C*-CN), 132.51 (S-*o*-Ar-C), 131.54 (*m*-Ar-H), 128.08 (C-*o*-Ar-C), 122.34 (N-*o*-Ar-C), 38.25 (CH_2); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1593(s), (C=N)s, 1088 (br. s), (Cl–O)s.

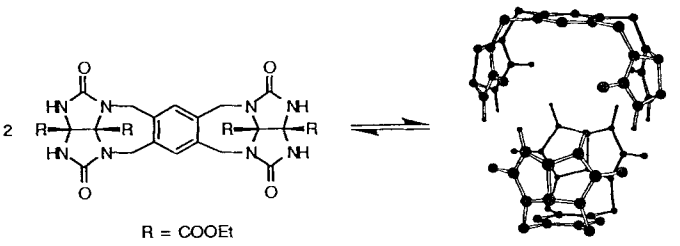
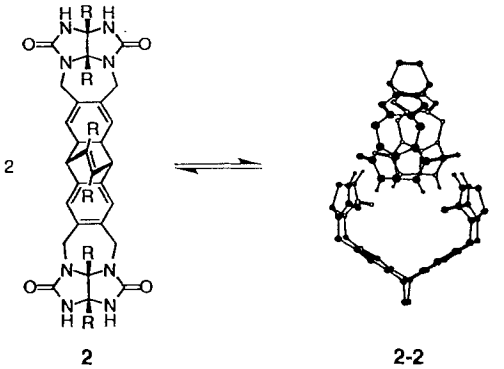
Pseudo-Spherical Host Molecules: Synthesis, Dimerization, and Nucleation Effects**

Carlos Valdés, Urs P. Spitz, Stefan W. Kubik, and Julius Rebek, Jr.*

We recently synthesized structure **1** and gave evidence for its self-assembly into **1**–**1**, a pseudo-spherical dimer.[1] The internal cavity of the dimerization acts as a host for small guests of complementary shape and volume.[2]



By replacing the benzene spacer in **1** with a bridged anthracene unit, an extended structure **2** is generated that maintains the self-complementarity required for dimerization (Scheme 1). The synthesis and characterization of **2** is outlined here, along with the unexpected formation of a recombinant (or hybrid) structure in solutions of **1** and **2**. The effects of guest nucleation on the assembly processes, as determined through NMR measurements, are also described.



Scheme 1. MM2-minimized structure of the homodimer **2**–**2**. Hydrogen atoms and the glycouril ester groups have been omitted for clarity.

The core of monomer **2** (Scheme 2) was made through tandem benzyne additions to furan as described earlier by Hart.[3] The reaction of tetrabromobenzene (**3**) with BuLi in the presence of excess disubstituted furan **4** gave mixtures of two isomeric endoxides *syn*- and *anti*-**5** in 30% (R = Bn) or 65% (R = TBDMS) combined yield. Tetrasubstituted anthracene **6**

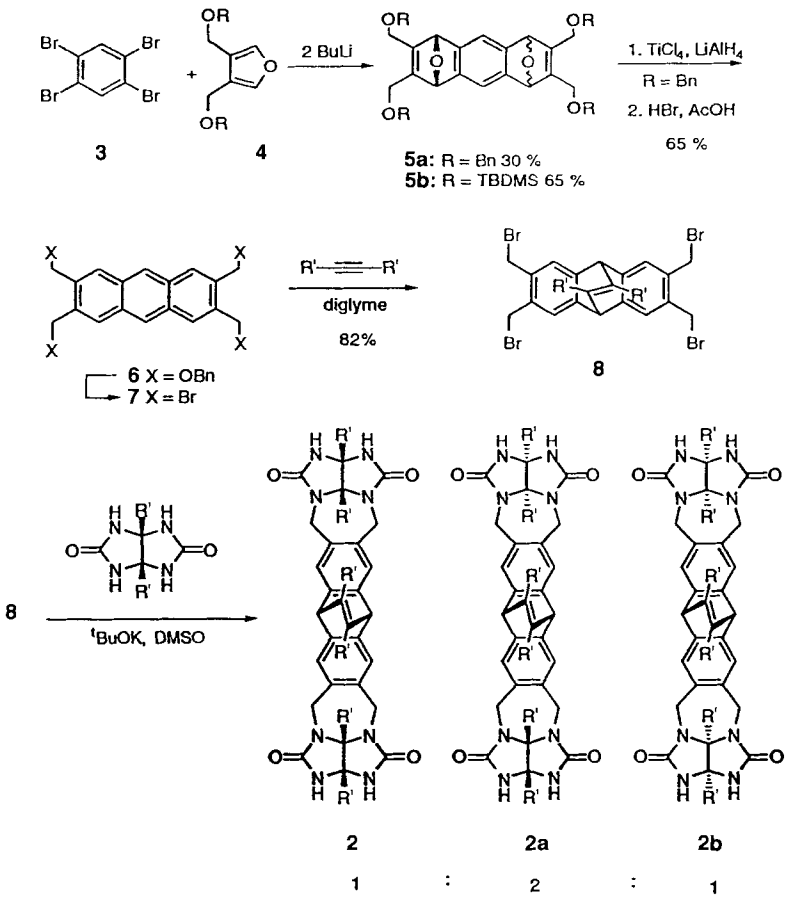
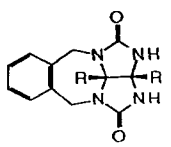
S. to the Swiss National Science Foundation for a postdoctoral fellowship, and S. W. K. to the Deutscher Akademischer Austauschdienst for a NATO postdoctoral fellowship.



Scheme 2. Synthesis of **2**. TBDMS = $tBuMe_2Si$, R' = CO_2Et.

was obtained from **5a** by reduction[4] of the *syn/anti* mixture with Ti^0. Treatment of the tetrabenzyl ether **6** with HBr/AcOH solution in $CHCl_3$ yielded the tetrabromide **7** in 65% yield. The Diels–Alder reaction of anthracene **7** with diethyl acetylenedicarboxylate proceeded well in hot diglyme to give the desired ethenoanthracene tetrabromide **8**. Reaction of **8** with an excess of the soluble glycoluril **9**[2b] in DMSO produced a mixture of the three possible isomers of **2**[5] in the expected statistical ratio (1:2:1). Target compound **2** (12% yield), the only isomer soluble in nonpolar organic solvents, was separated from the mixture by extraction with $CHCl_3$ and was further purified by flash chromatography.

Spectroscopic studies in $CDCl_3$ indicate a fully dimerized structure (**2**–**2**) in solution. The chemical shift of the NH protons in the ^1H NMR spectrum of **2** appear downfield at $\delta = 8.45$; the IR spectrum in $CHCl_3$ shows a broad absorption band at 3229 cm^{-1}. These values are very similar to those for **1**,[6] and do not change as a function of concentration. In contrast, reference compound **10**[7] shows concentration-dependent NMR signals for the NH protons (between $\delta = 6.17$ at 35 mM and $\delta = 5.45$ at 1.5 mM) and a sharp absorption band at 3442 cm^{-1} in its FTIR spectra of **2**. The dimeric arrangement proposed allows formation of the maximum number of hydrogen bonds and accounts for the spectroscopic features.



10, R = CO_2Et

Encapsulation behavior was also observed by NMR spectroscopy. When a solution of **1**–**1** in $CDCl_3$ (a guest too large to fit comfortably in **1**–**1**) was titrated with CD_2Cl_2, the appearance and growth of a new, broad NH signal at $\delta = 8.5$ was observed. This new signal represents the dimer **1**–**1** containing CD_2Cl_2 in its cavity. The shift upfield relative to "empty"[8] **1**–**1** ($\delta_{1-1} = 9.13$) is attributed to the elongation and weakening of the hydrogen bonds upon encapsulation of the guest. The signal for the empty dimer disappears completely as the concentration of CD_2Cl_2 in $CDCl_3$ reaches 20%. *Direct observation of the guest inside the cavity* of **1**–**1** is possible with ^{13}C NMR and ^{13}C-labeled samples. Addition of 10% $^{13}CH_2Cl_2$ to a solution of **1** in $CDCl_3$ results in a new signal in the ^{13}C NMR spectrum at 0 °C (Fig. 1), shifted by $\Delta\delta = 2$ upfield from free $^{13}CH_2Cl_2$.[9] Its intensity, relative to that of the ^{13}C NMR signals of the host **1**–**1** (marked with Δ), suggested that the majority of hosts contained labeled guests, and confirmed the earlier ^1H NMR assignments of signals for "full" and "empty" **1**–**1**.

In encapsulation experiments with the dimer **1**–**1**, the spectra invariably showed two sets of ^1H NMR signals, which correspond to slow exchange between the empty host and the filled host.[1, 2] However, this is not the case with **2**. Presumably, a dynamic solvent exchange, fast on the NMR time scale, takes place even at low temperatures. The openings on both sides of the dimer (Scheme 1) appear large enough for guest molecules to enter and escape the cavity without affecting many of the host's hydrogen bonds. Nonetheless, tiration experiments support encapsulation phenomena. For example, a solution of **2** in $CDCl_2CDCl_2$ (a poor guest for **2**–**2**, as its size appears too big) was titrated with $CDCl_3$ (an ideally sized guest for **2**–**2**). The resonance for the NH signal gradually shifted downfield from $\delta = 7.75$ and stabilized at $\delta = 8.25$ after 20% $CDCl_3$ had been added. As $CDCl_3$ replaces $CDCl_2CDCl_2$ inside the cavity, the host's hydrogen bonds shorten, which causes the downfield shift of its NH signals.

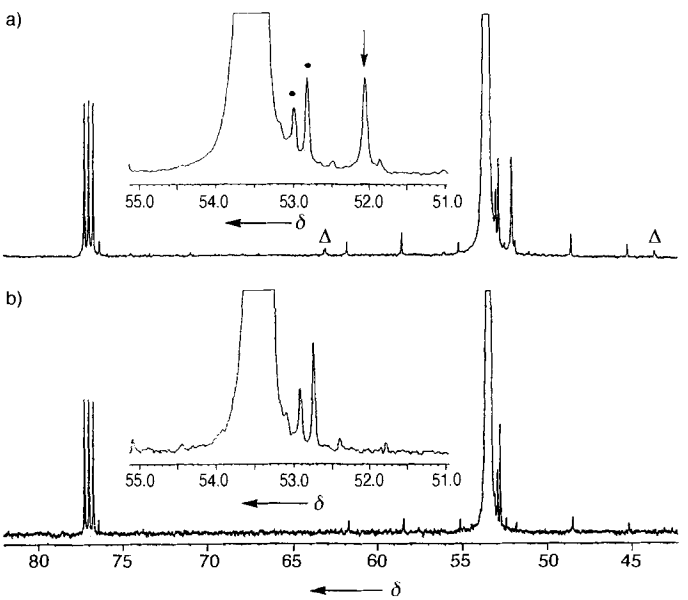


Fig. 1. a) ^{13}C NMR spectrum of **1**–**1** in a solution that contains 10% $^{13}CH_2Cl_2$. The arrow indicates the signal of encapsulated $^{13}CH_2Cl_2$, and the dots those of impurities. b) ^{13}C NMR spectrum of solvent reference.

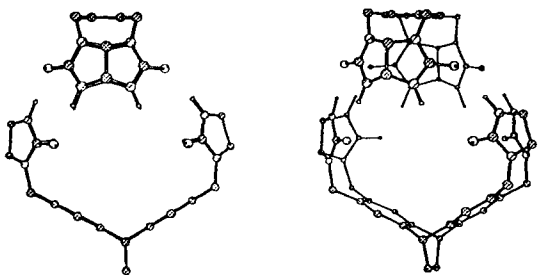
Structures **1** and **2** are self-complementary but they are also mutually well suited. The hybrid aggregate (**1**–**2**) of **1** and **2** is shown in Scheme 3. The calculated structure of the pear shaped **1**–**2** adducts suggests the formation of only six "strong" hydrogen bonds. The two additional bonds are significantly longer.



Scheme 3. Two views of MM2-minimized hybrid dimer **1**–**2**. Some hydrogen atoms and the ester groups have been omitted for clarity.

In the experiment **1**–**1** and **2**–**2** were shown to be capable of recombination to form hybrid species. Specifically, the ^{1}H NMR spectrum of an equimolar mixture of **1** and **2** in $CDCl_3$ showed signals corresponding to three different species. Besides the signals of the two homodimers **1**–**1** and **2**–**2**, a third set of signals, which we assigned to the "heterodimer" **1**–**2**, was present. This assignment was supported by NOE experiments: at $-40\,^{\circ}C$ a strong NOE was observed in the heterodimer's spectrum on irradiation of the NH protons of either of its half shells, **1** and **2**. The disproportionation constants K and the thermodynamic values for the hybrid formation were determined by ^{1}H NMR spectroscopy. In $CDCl_3$ K is 11.6 at 298 K (titrations of **1** with **2** and vice versa gave the same value). The enthalpy for heterodimerization in $CDCl_3$ was measured to be -3 kcal mol^{-1} and the entropy -5 cal K^{-1} mol^{-1}.

What is the driving force for the recombination, particularly if hydrogen bonding is better in **1**–**1** than in **1**–**2**? Nucleation by guest species is the likely answer. The distribution of the hydrogen-bonded pairs at equilibrium is influenced by the presence of suitable guests. Though all three pairs are capable of accommodating guest molecules, the cavity size of each varies. For instance, the dimer **1**–**1** readily encapsulates CH_2Cl_2 but not $CHCl_3$. Only the bridged anthracene dimer **2**–**2** appears large enough to encapsulate $CHCl_2CHCl_2$, but both **2**–**2** and the heterodimer **1**–**2** are large enough to accommodate $CHCl_3$ or even $CHBr_3$.

These surmises are borne out by the data of Table 1: in $CHCl_3$ (or even more so in $CHBr_3$) the formation of the hybrid ball **1**–**2** is favored, but very little heterodimer **1**–**2** is formed in CD_2Cl_2 or $CDCl_2CDCl_2$. These results suggest that a species is favored if its cavity can be well-filled.

Table 1. Equilibrium constants for the disproportionation (recombination) of **1**–**1** and **2**–**2** in solvents of increasing size.

Solvent	CD_2Cl_2	$CDCl_3$	$CDBr_3$	$CDCl_2CDCl_2$
$K^{298} = \frac{[1\text{–}2]^2}{[1\text{–}1][2\text{–}2]}$	no **1**–**2**	11.6	42	traces of **1**–**2**

Further evidence for these nucleation effects was provided by titration experiments and will be reported elsewhere. In the meantime, the surprisingly stable heterodimer found here augurs well for the formation of new hybrids from other self-assembly processes.[10]

Synthesis and Structure of a Free Germacyclopentadienide Ion: $[Li([12]crown\text{-}4)_2][C_4Me_4GeSi(SiMe_3)_3]$**

William P. Freeman, T. Don Tilley,* Frederick P. Arnold, Arnold L. Rheingold, and Peter K. Gantzel

Numerous investigations have focused on characterization of the electronic structures for sila- and germacyclopentadienides.[1–6] Theoretical studies generally have concluded that the silacyclopentadienide ion $(HSiC_4H_4)^-$ would have some delocalization,[2] and recent high-level ab initio calculations suggest that it would have about half the aromatic stabilization energy of $C_5H_5^-$, despite possessing pyramidal silicon.[3] NMR parameters for the lithium and sodium derivatives of $(Ph_4C_4SiBu)^-$ in THF suggest some delocalization of negative charge in the ring.[4] Germacyclopentadienide ions have also been generated in solution,[5] and an analysis of NMR parameters for $(C_4Me_4GePh)^-$ was consistent with substantial localization of negative charge on germanium.[6] Given the level of interest in possible aromatic character for these anions, we have

sought to establish the structures for uncomplexed sila- and germacyclopentadienide ions. Here we report the synthesis of an isolated germacyclopentadienide ion, $[C_4Me_4GeSi(SiMe_3)_3]^-$ as the alkali metal salt, and its crystal structure.

For comparative purposes, the molecular structure of $C_4Me_4Ge(H)Si(SiMe_3)_3$ (**1**) was determined (Fig. 1).[7] The planar C_4Ge ring contains inequivalent C–C distances that reflect isolated single (1.504(4) Å) and double (1.342(3), 1.343(3) Å) bonds. The Ge–Si distance of 2.387(1) Å is only slightly longer than the comparable distance in $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$ (2.357(2) Å),[8] and the angle between the C_4Ge plane and the Ge–Si bond is 131.0°.

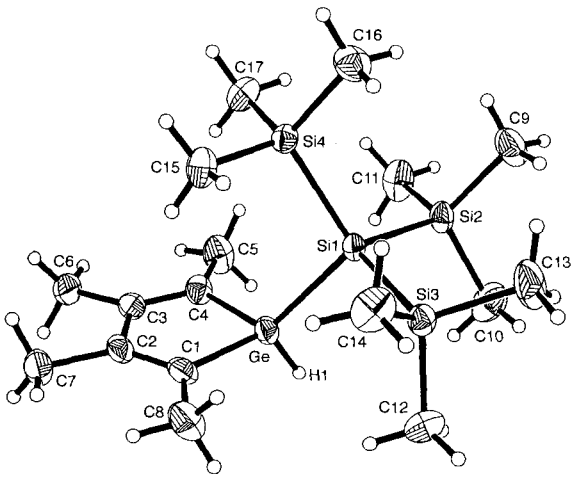

Fig. 1. Molecular structure of **1**. Selected interatomic distances [Å] and angles [°]: Ge–Si1 2.387(1), Ge–C1 1.944(3), Ge–C4 1.948(3), Ge–H1 1.43(2), C1–C2 1.342(3), C2–C3 1.504(4), C3–C4 1.343(3), C4–C5 1.502(4), C1–C8 1.510(4), C2–C7 1.510(4), C3–C6 1.513(3); Si1-Ge-C1 116.3(1), Si1-Ge-C4 119.6(1), Si1-Ge-H1 110(1), C1-Ge-C4 89.7(1), Ge-C1-C2 107.6(2), Ge-C1-C8 125.9(2), Ge-C4-C3 107.6(2), Ge-C4-C5 126.3(2).

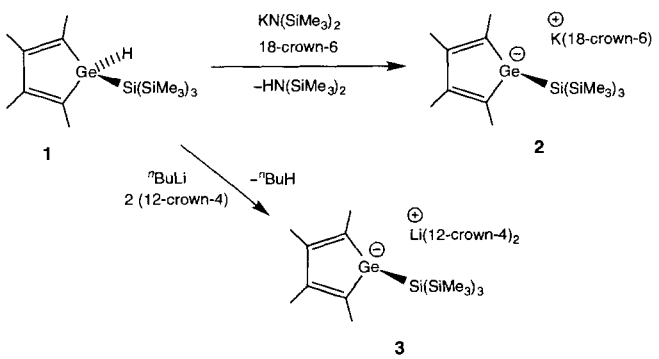
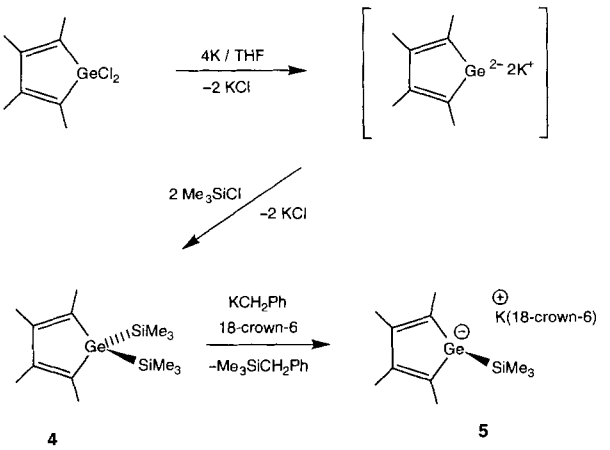
Deprotonation of **1** in the presence of a crown ether produces the alkali metal germacyclopentadienides **2** and **3**, which were isolated as crystalline solids. The NMR parameters for these compounds suggest that the anions have identical structures. The ^{13}C NMR shifts for the ring carbons ($\delta(C_\alpha) = 137$, $\delta(C_\beta) = 157$) are somewhat downfield-shifted relative to analogous resonances for **1** ($\delta(C_\alpha) = 132.89$, $\delta(C_\beta) = 146.45$)[8] and $Li(Me_4C_4GePh)$ ($\delta(C_\alpha) = 138.7$, $\delta(C_\beta) = 151.5$).[6]



The germacyclopentadienide **5** was obtained by a different route (Scheme 1) involving silylation of the $[Me_4C_4Ge]^{2-}$ dianion, followed by heterolytic cleavage of the Ge–Si bond of **4** with benzylpotassium. Compound **5** appears to possess a structure analogous to that for **2** and **3** ($\delta(^{13}C)$ of the ring carbons: $C_\alpha = 136.72$, $C_\beta = 158.56$), involving free germacyclopentadienide ions which do not interact strongly with the cations.



Scheme 1.

X-ray quality crystals of **3** were obtained by slow, vapor diffusion of pentane into a solution of the compound in diethyl ether. The structure contains well-separated cations and anions, and Figure 2 provides a view of the free anion.[9] A pyramidalization

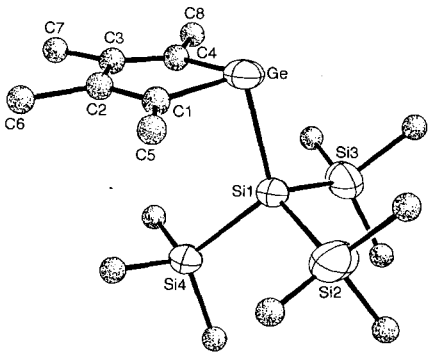


Fig. 2. Molecular structure of the anion in **3**. Selected interatomic distances [Å] and angles [°]: Ge–Si1 2.446(9), Ge–C1 2.01(3), Ge–C4 1.96(3), C1–C2 1.36(6), C2–C3 1.46(6), C3–C4 1.35(5), C4–C8 1.49(4), C1–C5 1.33(5), C2–C6 1.51(4), C3–C7 1.52(6); Si1-Ge-C1 98.0(9), Si1-Ge-C4 96.7(8), C1-Ge-C4 86(2), Ge-C1-C2 107(3), Ge-C1-C5 132(3), Ge-C4-C3 111(2), Ge-C4-C8 125(2).

at the germanium center is clear, as evidenced by the angle between the C_4Ge plane and the Ge–Si bond of only 100.1°. Furthermore, the carbon portion of the ring has considerable diene character, as indicated by the C1–C2, C2–C3, and C3–C4 bond lengths of 1.36(6), 1.46(6), and 1.35(5) Å, respectively. The Ge–Si(1) distance of 2.446(9) Å is about 0.06 Å longer than the Ge–Si distance in **1**. These data therefore suggest that $[Me_4C_4GeSi(SiMe_3)_3]^-$ gains very little stabilization by π-delocalization of the negative charge.

We have performed calculations on $(C_4H_4ESiH_3)^-$ ions at the RHF level of theory,[10] with an interest in examining the structural trends to be expected for Group 14 derivatives. The results for three structural parameters are given in Table 1: the (C-E-C plane)–(E–Si bond) angle at E (α), and the two independent C–C bond lengths (C_s symmetry) in the ring. As expected, the cyclopentadienide ion (E = C) is flat ($\alpha = 177.3°$), and the angle bends sharply as this group is descended and the bonding orbitals for E develop more p-character. This is accompanied by

Table 1. Selected calculated geometric parameters for $(H_4C_4ESiH_3)^-$ ions.

E	C	Si	Ge [a]	Sn
α [ ]	177.3	104.5	99.7 (100.1)	94.7
$d(EC_1\text{-}C_2) = d(C_3\text{-}C_4E)$ [Å]	1.408	1.367	1.361 (1.36)	1.358
$d(C_2\text{-}C_3)$ [Å]	1.428	1.477	1.484 (1.46)	1.493

[a] Experimental values in parentheses.

increased localization of the π system in the ring. The agreement between the calculated and experimental values for E = Ge is excellent. Note that the silacyclopentadienide ion is also expected to have a pyramidal, non-aromatic structure. Löwdin charges for the ring atoms are given in Table 2. The trend in the charge at E clearly parallels the Pauling electronegativities, and expected polarities for the E–C bonds. Charge differences as a function of E diminish rapidly at C1 and all but vanish at C2. For $(C_4H_4GeSiH_3)^-$, the homodesmotic aromatic stabilization energy (ASE, 5.3 kcal mol^{-1}) and the Julg parameter[13] (A, 0.532) indicate less aromaticity than is expected for $(C_4H_4SiH)^-$ (ASE = 13.8 kcal mol^{-1}; A = 0.926, based on the ab initio calculations of Schleyer et al.[3, 14]).

Table 2. Löwdin charges for ring atoms in $(H_4C_4ESiH_3)^-$ ions.

Atom	E = C	Si	Ge	Sn
E	−0.50	0.06	−0.03	0.14
C1 = C4	−0.36	−0.51	−0.48	−0.52
C2 = C3	−0.37	−0.33	−0.33	−0.33
electronegativity [a]	2.55	1.90	2.01	1.96

[a] Electronegativities are modified Pauling values from W. L. Jolly, *Modern Inorganic Chemistry*, McGraw-Hill, New York, **1984**.

The results reported here clearly characterize the title germacyclopentadienide ion as a non-aromatic ring with a pyramidal germanium center. It is interesting to compare this structure with that of $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$,[8] which contains the same germacyclopentadienide ring bonded to ruthenium. In the latter case, the ring appears to be highly delocalized, as indicated by (for example) the summation of bond angles at Ge (358.1°) and the equivalent C–C distances of 1.42 Å. Interestingly, then, coordination of a transition metal fragment induces considerable π-delocalization and apparent aromatic character for the germacyclopentadienide ring. Coordination of the analogous silacyclopentadienide ring $[Me_4C_4Si\text{–}Si(SiMe_3)_3]^-$ to $[(\eta^5\text{-}C_5Me_5)Ru]$ also leads to a delocalized ring,[15] and interestingly, Goldfuss and Schleyer have recently predicted that coordination of Li^+ would induce considerable π-delocalization in $(C_4H_4SiH)^-$.[3b]

Experimental Procedure

2: Toluene (50 mL) was added to a Schlenk flask containing **1** [8] (0.20 g, 0.47 mmol), [18]crown-6 (0.12 g, 0.47 mmol), and $KN(SiMe_3)_2$ (0.094 g, 0.47 mmol). After stirring the reaction mixture for 30 min at room temperature, the solution was reduced in volume to about 10 mL and then cooled to −40 °C to produce yellow crystals of **2** in 45% yield. Anal. calcd for $C_{29}H_{63}GeKO_6Si_4$: C 47.59, H 8.68; found: C 47.44, H 8.57. ^{1}H NMR (300 MHz): δ = 0.59 (s, 27 H, $SiMe_3$), 2.22, 2.62 (s, 6 H, CMe), 3.09 (s, 24 H, [18]crown-6). $^{13}C\{^1H\}$ NMR (75.5 MHz): δ = 3.98 ($SiMe_3$), 15.96, 20.46 (*CMe*), 69.91 ([18]crown-6), 137.13, 157.06 (*C*Me); $^{29}Si\{^1H\}$ NMR (59.63 MHz, DEPT): δ = −125.03 (s, *Si*$SiMe_3$), −8.22 (s, $SiMe_3$).

3: To a mixture of **1** (0.26 g, 0.60 mmol) and [12]crown-4 (0.22 g, 1.20 mmol) in diethyl ether (25 mL) was added *n*BuLi (0.395 mL, 0.632 mmol of a 1.6 M solution in hexanes) dropwise over 1 min, and the resulting yellow solution was stirred for 30 min. Slow diffusion of pentane into this solution via vapor transport provided X-ray quality crystals in 42% yield. Anal. calcd for $C_{33}H_{71}GeLiO_8Si_4$: C 50.30, H 9.10; found: C 50.22, H 9.10. ^{1}H NMR (300 MHz): δ = 0.62 (s, 27 H, $SiMe_3$), 2.26, 2.69 (s, 6 H, CMe), 3.18 (s, 32 H, [12]crown-4); $^{13}C\{^1H\}$ NMR (100.6 MHz, THF/[D$_6$]benzene): δ = 3.77 ($SiMe_3$), 15.59, 20.30 (*CMe*), 69.19 ([12]crown-4), 136.95, 157.03 (*C*Me); $^{29}Si\{^1H\}$ NMR (59.63 MHz, INEPT): δ = −125.57 (s, *Si*$SiMe_3$), −8.43 (s, $SiMe_3$).

4: THF (250 mL) was added to a flask containing $C_4Me_4GeCl_2$ [16] (2.28 g, 9.06 mmol) and finely divided potassium chunks (1.45 g, 37.14 mmol) at room temperature, and the reaction mixture was stirred for 4 days. To the resulting deep red solution was added Me_3SiCl (4.71 mL, 37.14 mmol) dropwise. After stirring for 5 min, the volatiles were removed by vacuum transfer and the resulting residue was extracted with pentane (3 × 40 mL). The pentane extracts were concentrated and cooled (−40 °C) to give the product as an oil at room temperature in 60% yield. Anal. calcd for $C_{14}H_{30}GeSi_2$: C 51.39, H 9.26; found: C 50.40, H 8.98. ^{1}H NMR (300 MHz): δ = 0.22 (s, 18 H, $SiMe_3$), 1.86, 2.11 (s, 6 H, CMe); $^{13}C\{^1H\}$ NMR (100.6 MHz): δ = 0.51 ($SiMe_3$), 14.71, 17.53 (*CMe*), 134.86, 145.67 (*C*Me); $^{29}Si\{^1H\}$ NMR (59.63 MHz, INEPT): δ = −7.55 (s, $SiMe_3$).

5: To KCH_2Ph (0.138 g, 1.01 mmol) and [18]crown-6 (0.247 g, 0.935 mmol) was added **4** (0.329 g, 1.01 mmol) in toluene (100 mL), and the resulting solution was stirred for 30 min. Removal of volatiles and addition of diethyl ether (25 mL) produced a red solution. Slow vapor diffusion of pentane into this solution over 3 days gave the product in 45% yield. Anal. calcd for $C_{23}H_{45}GeKO_6Si$: C 49.55, H 8.15; found: C 49.55, H 8.01. ^{1}H NMR (400 MHz): δ = 0.54 (s, 9 H, $SiMe_3$), 2.26, 2.67 (s, 6 H, CMe), 3.19 (s, 24 H, [18]crown-6); $^{13}C\{^1H\}$ NMR (100.6 MHz): δ = 2.49 ($SiMe_3$), 15.86, 20.06 (*CMe*), 70.07 ([18]crown-6), 136.72, 158.56 (*C*Me); $^{29}Si\{^1H\}$ NMR (59.63 MHz, INEPT): δ = −3.86 (s, $SiMe_3$).

[9] X-ray structure analysis of **3**: $C_{33}H_{71}GeLiO_8Si_4$, M_r = 787.8, monoclinic, $P2_1/n$, a = 17.73(3), b = 14.871(10), c = 18.83(2) Å, β = 111.60(3)°, V = 4617(9) Å^3, Z = 4; ρ_{calcd} = 1.133 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 8.06 cm^{-1}, T = 296 K; 4916 independent reflections with 4° ≤ 2θ ≤ 35° were collected (Siemens P4), of which 2327 with F_0 greater than 5$\sigma(F_0)$ were used in refinement. $R(F)$ = 0.1263, $R_w(F)$ = 0.1684, GOF = 2.68. All specimens that were screened showed extremely broad diffraction that did not sharpen or intensify significantly at 220 K. The diffuseness of diffraction likely arises from the considerable disorder seen in the cationic complex, $[Li([12]crown\text{-}4)_2]^+$, the high thermal activity of the tris(trimethylsilyl)silyl group, and the low lattice energy resulting from the extreme isolation of cationic charge. Observed diffraction data was found only to 2θ = 35°. Full profile data collection was performed at 2° min^{-1} and a learned profile routine was applied to improve the accuracy of the measurement of weak reflections. The C–Si bond distances were constrained to a distance of 1.82 Å [7b].

[10] Calculations were performed with the GAMESS [11] package on an SGI Indigo-2 computer, at the RHF level of theory, and employed the SBKJ CEP-31 basis set, supplemented by d-polarization and shared exponent (s = p) diffuse functions on all heavy atoms. C_s symmetry was employed. Geometries were confirmed to be minima by vibrational analyses. It may be noted that Mopac-6

calculations with either the AM1 or PM3 parameters of Stewart [12] failed to predict a folding of the dihedral angle at Ge, also the calculations for E = Si, Ge, and Sn indicate slight non-planarity for the C_4E rings, such that the E atom is displaced in the direction away from the SiH_3 group by folding along the C_1–C_4 vector (fold angles: Si, 6.3°; Ge, 6.0°; Sn, 4.5°). Thus, α is defined as the angle between the C_1-E-C_4 plane and the E–Si bond.

$C_4S_6^{2-}$: A Bridging Bis(dithiolato) Ligand for the Preparation of Semiconducting Inorganic Polymers**

Lisa F. Szczepura, Collin P. Galloway, Yifan Zheng, Pengdi Han, Arnold L. Rheingold, Scott R. Wilson, and Thomas B. Rauchfuss*

Difunctional ligands are key to the preparation of coordination polymers.[1, 2] Especially relevant to the design of new electronic materials are those ligands that promote strong electronic coupling between pairs of metal atoms, as is optimally effected by ligands with delocalized π-electron systems. To confer stability to the intermetallic linkage, it is further desirable that the ligands engage the metals through binding sites that are both anionic and chelating. We report a new inorganic ligand that incorporates these design features and forms inorganic polymers with a delocalized π-electron system.

We have recently reported[3] the preparation of the dithiocarbonate C_3S_7O in two steps from the Steimecke anion $[Zn(C_3S_5)_2]^{2-}$.[4] Since dithiocarbonates are susceptible to alkaline hydrolysis, this C-S-O heterocycle represents a potential precursor to novel dithio chelates. With this in mind we treated a methanolic suspension of C_3S_7O with two equivalents of NaOMe, causing the yellow solid to dissolve to give a brown-purple solution. Treatment of the reaction solution with NEt_4Br and fractional crystallization from $MeCN/Et_2O$ gave $(NEt_4)_2C_4S_6$ in 59% yield as dark blue, air-sensitive crystals [Eq. (a)]. The mechanism of this transformation has not been

investigated; however, it is obvious that it involves condensation of a pair of C_2S_x units. We observed the formation of elemental sulfur as a by-product.

The ^{13}C NMR spectrum of $(NEt_4)_2C_4S_6$ shows resonances at $\delta = 217, 189$, and 143 in an approximate ratio of 1:2:1. Solutions of $(NEt_4)_2C_4S_6$ display a rich optical spectrum including low-energy bands at $\tilde{\nu} \approx 10000\ cm^{-1}$ and a band at higher energy showing a distinct solvatochromic effect ($\tilde{\nu}$(MeCN) = 29400 cm^{-1}, $\tilde{\nu}$(MeOH) = 31100 cm^{-1})[5] (Fig. 1). These data indicate that $C_4S_6^{2-}$ is highly polarizable with a small HOMO–LUMO gap. Single-crystal X-ray diffraction[6] showed that

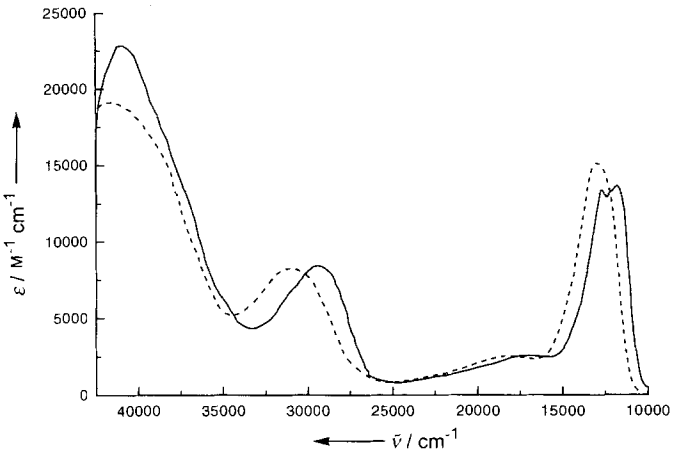

Fig. 1. Optical spectra of $(NEt_4)_2C_4S_6$ in MeCN (solid line) and MeOH (dashed line).

$C_4S_6^{2-}$ is planar with crystallographically imposed C_{2v} symmetry (Fig. 2). This is the largest anionic carbon sulfide structurally characterized.[7] The anion is disordered over two orientations within a rectangular framework defined by the four terminal sulfur atoms. The planarity and short C–S distances indicate extensive delocalization of the π system. The differing C1–S1 and C3–S3 distances suggest that the anion could be described as a 1,1-alkenedithiolate fused to a 1,2-dithione.[8]

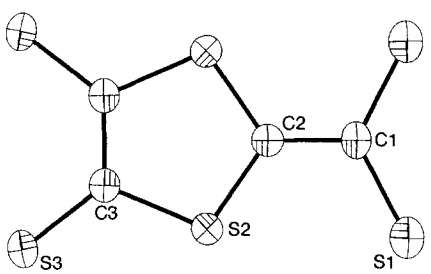

Fig. 2. Molecular structure of the dianion in $(NEt_4)_2C_4S_6$. Important bond lengths [Å] and angles [°]: S1-C1 1.745(2), S2-C2 1.700(2), S2-C3 1.742(3), S3-C3 1.638(3), C1-C2 1.402(6), C3-C3e' 1.424(5); S1-C1-S1' 126.0(2), S3-C3-C3' 127.95(10).

Vast numbers of complexes are known for 1,2- and 1,1-dithiolates[9] but the combination of the two ligand types as in $C_4S_6^{2-}$ is unique to this work. It was therefore of interest to test the ability of this bis(dithiolate) to serve as a bridging ligand. Qualitative tests showed that solutions of $C_4S_6^{2-}$ react in acetonitrile with many simple metal salts to give black insoluble solids. Starting with $[Ni(H_2O)_6]Cl_2$ we were able to prepare solids that undergo ion exchange with additional $[Ni(H_2O)_6]^{2+}$

to give a product of approximate composition $[NiC_4S_6]$. The microanalytical data fit well for $(NBu_4)_2[Ni_{45}(C_4S_6)_{46}]$, an inorganic polymer terminated by $C_4S_6^{2-}$ units. Based on the composition, diamagnetism, and semiconducting properties of this material (see below), we propose that it is a one-dimensional polymer consisting of a ribbonlike strand of edge-shared square-planar complexes [Eq. (b)].

$$Ni^{2+} + C_4S_6^{2-} \longrightarrow \left[\text{S}_2\text{C}_2\text{S}_2\text{Ni}\right]_n \qquad \text{(b)}$$

In related experiments, solutions of $C_4S_6^{2-}$ in acetonitrile were found to react with $[Cu(MeCN)_4]BF_4$ to afford black diamagnetic solids analyzing as $(NEt_4)_2[Cu_{60}(C_4S_6)_{31}]$. The IR spectra of these inorganic polymers are very simple and dominated by a single intense absorption assigned to ν_{CS} (1196 cm^{-1} for the Ni polymer, 1172 cm^{-1} for the Cu polymer). Compressed pellets of $[Cu_2C_4S_6]$ and $[NiC_4S_6]$ exhibit four-point conductivities (294 K) of 0.1 and 0.9 $S\,cm^{-1}$, respectively. In both cases the temperature dependence of the conductivities indicate that these are semiconductors. It is unusual for simple coordination polymers to exhibit such conductivities.[10]

To elucidate the structures of these semiconducting polymers we investigated bimetallic complexes of $C_4S_6^{2-}$. This proved to be quite challenging, as again most experiments produced insoluble products. The reaction with $[(p\text{-cymene})RuCl_2]_2$ (*p*-cymene = 4-isopropyltoluene) proved successful and afforded the purple compound $[(p\text{-cymene})_2Ru_2Cl_2(C_4S_6)]$ [Eq. (c)].

$$[(p\text{-cymene})_2Ru_2Cl_4] + C_4S_6^{2-} \longrightarrow [(p\text{-cymene})_2Ru_2Cl_2(C_4S_6)] + 2\ Cl^- \qquad \text{(c)}$$

A crystallographic study of the Ru_2 complex[11] established the structure shown in Figure 3. This unsymmetrical structure is maintained in solution, since both ^1H and ^{13}C NMR analyses indicate that the cymene groups are nonequivalent but that both

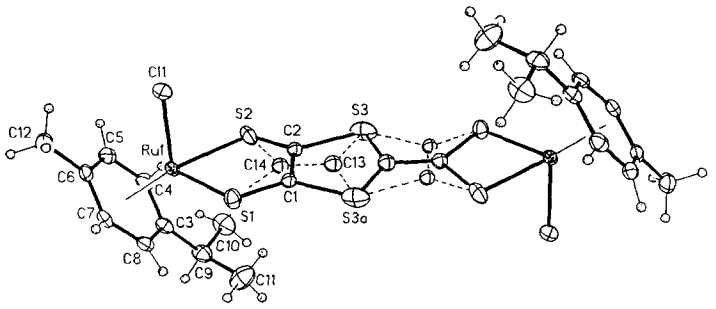

Fig. 3. Molecular structure of $[(p\text{-cymene})_2Ru_2Cl_2(C_4S_6)]$ showing the end-to-end disorder about a crystallographic inversion center. Carbon atoms C1, C2, C3, and C4 were refined isotropically at half occupancy; the remaining non-hydrogen atoms are shown with 40% probability ellipsoids.

are bisected by a symmetry plane. This diruthenium complex provides a well-defined model for a subunit of $[NiC_4S_6]$. The means by which the C_4S_6 unit bridges more than two metals, as is assumed to occur in $[Cu_2C_4S_6]$, must await further study.

Since $C_4S_6^{2-}$ is itself electroactive (it can be reduced), it should be possible to dope the new inorganic polymers reported in this paper to enhance their electrical conductivity.

Experimental Procedure

All preparative operations were conducted under purified nitrogen. C_3S_7O was prepared from "C_3S_7" [3] synthesized from the reaction of $(NBu_4)_2[Zn(C_3S_5)_2]$ [4] with purified S_2Cl_2. Electrical conductivity measurements (AC technique) were performed on pellets (ca. 0.08 g) pressed at roughly 2250 $kg\,cm^{-2}$, and the contacts were made with silver paint.

$(NEt_4)_2C_4S_6$: A fresh solution of NaOMe in 13 mL of MeOH, prepared from 0.083 g of Na, was added to 0.5 g of C_3S_7O. After stirring for 2 d, the solution was combined with NEt_4Br and concentrated to dryness. This material was extracted into MeCN, filtered to remove NaBr, and crystallized by addition of Et_2O to give 0.27 g (59% yield) of the dark blue, air-sensitive crystals. Anal. calcd for $C_{20}H_{40}N_2S_6$ (found): C 47.95 (47.65), H 8.05 (8.09), N 5.59 (5.66). IR (KBr): $\tilde{\nu} = 1173\ cm^{-1}$. UV-Vis (MeCN): λ [nm] (ε [$M^{-1}cm^{-1}$]) 240 (25000), 340 (8500), 800 (14000), 856 (13000).

The NBu_4^+ salt was obtained similarly and used in all subsequent reactions.

$[NiC_4S_6]$: Equimolar methanol solutions of $(NBu_4)_2C_4S_6$ (0.328 g) and $[Ni(H_2O)_6]Cl_2$ (0.132 g) in MeOH were added simultaneously to a flask containing 40 mL MeOH. A black solid precipitated immediately. This solid was collected, washed with MeOH, ground, and resuspended in a solution of $[Ni(H_2O)_6]Cl_2$ (1.42 g) in MeOH for 8 h. The solid was collected and dried under vacuum at 94 °C. Yield 86%. Anal. calcd for $(NBu_4)_2[Ni_{45}(C_4S_6)_{46}]$ (found): C 18.29 (18.48), H 0.51 (0.47), N 0.20 (0.23), Ni 18.62 (17.32). IR (KBr): $\tilde{\nu} = 1196\ cm^{-1}$ (vs).

$[Cu_2C_4S_6]$: Solutions of $[Cu(MeCN)_4]BF_4$ (0.254 g) and $(NBu_4)_2C_4S_6$ (0.290 g) in acetonitrile were combined to give a black precipitate, which was washed with solvent and dried under vacuum at 85 °C. Yield 87%. Anal. calcd for $(NBu_4)_2[Cu_{60}(C_4S_6)_{31}]$ (found): C 15.94 (15.84), H 0.62 (0.37), N 0.24 (0.30), Cu 32.45 (31.80). IR (KBr): $\tilde{\nu} = 1172\ cm^{-1}$ (vs).

$[(p\text{-Cymene})_2Ru_2Cl_2C_4S_6]$: Equimolar solutions of $(NBu_4)_2C_4S_6$ (0.20 g) and $[(p\text{-cymene})RuCl_2]_2$ (0.18 g) in CH_2Cl_2 were combined. After 4 h, the reaction solution was concentrated and diluted with MeCN to precipitate the purple product. Yield: 46%. Single crystals were obtained from CH_2Cl_2/MeCN. Anal. calcd for $C_{24}H_{28}Cl_2Ru_2S_6$ (found): C 36.88 (36.63), H 3.59 (3.69), Cl 9.09 (10.90), Ru 25.85 (24.43), S 24.58 (23.73). IR (KBr): $\tilde{\nu} = 1308, 1252\ cm^{-1}$ (vs). ^1H NMR ($CDCl_3$): $\delta = 1.22$ (d, 6H), 1.27 (d, 6H), 2.24 (s, 3H), 2.28 (s, 3H), 2.80 (m, 2H), 5.37 (d, 2H), 5.41 (d, 2H), 5.52 (d, 2H), 5.61 (d, 2H). ^{13}C NMR ($CDCl_3$): $\delta = 17.5$, 18.4, 21.4, 21.8, 30.2, 31.1, 84.1, 84.4, 84.8, 85.3, 101.8, 102.7, 104.9, 105.4, 154.0, 186.0, 210.6.

Synthesis of New Sworski-Type Dehydroannulenes: 3,4-Benz-1,2,5,6,8,9,12,13-octadehydro[14]-annulenes**

Yoshiyuki Kuwatani* and Ikuo Ueda

Recently, highly unsaturated conjugated compounds have attracted considerable attention as possible precursors of two- and three-dimensional carbon networks.[1] Two-dimensional carbon networks should have a rigid and planar cyclic conjugated system as a unit structure. Some compounds for these systems can be designed by insertion of two sp-hybridized carbons into appropriate C–C bonds in benzene, as shown by T. J. Sworski.[2] We had been interested in these dehydroannulenes[3] and reported the the synthesis of the dodecadehydro[18]-annulene derivative (**1**).[4]

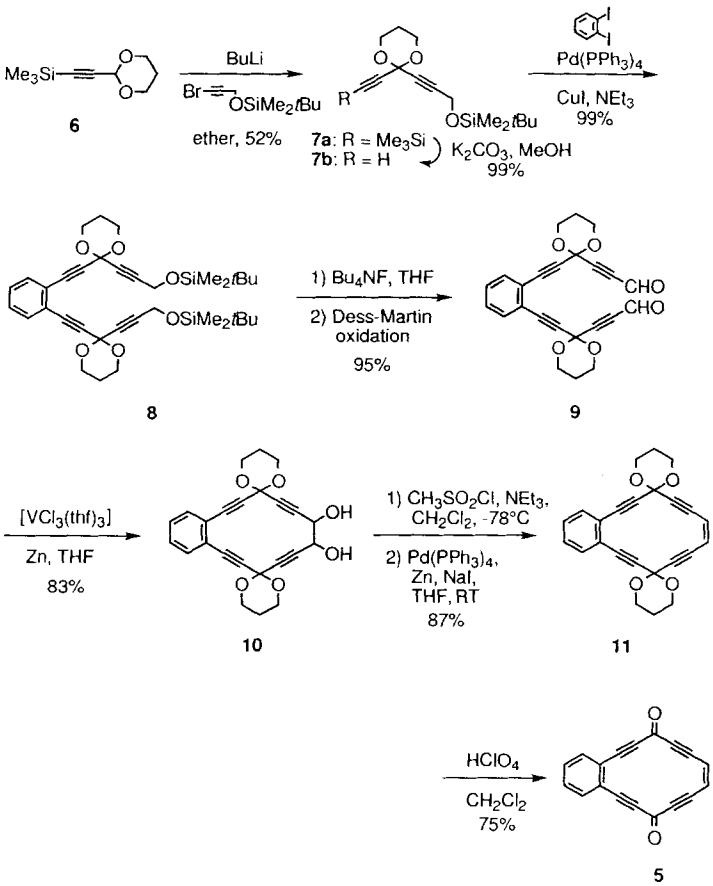
Octadehydro[14]annulene (**2**), which is classified as a Sworskii-type dehydroannulene, is represented by two equivalent canonical structures and should show properties of an aromatic $(4n + 2)$ π-electron system. Therefore it is an interesting candidate for a unit structure of two-dimensional carbon networks. Furthermore, the dehydroannulene **2** can give rise to an anthracene tetraradical **3** through the Bergman reaction, which plays important role in some antitumor antibiotics.[5] In this paper, we describe the synthesis of the benzannelated dehydroannulenes **4** and their physical properties.

Since the selective synthesis of (*Z*)-[3]cumulenes is very difficult, we decided to construct the 14-membered ring prior to introduction of cumulative double bonds. The annulenedione **5** was chosen as a synthetic intermediate and prepared from **6** as shown in Scheme 1. Trimethylsilylethynyl-1,3-dioxane (**6**) was

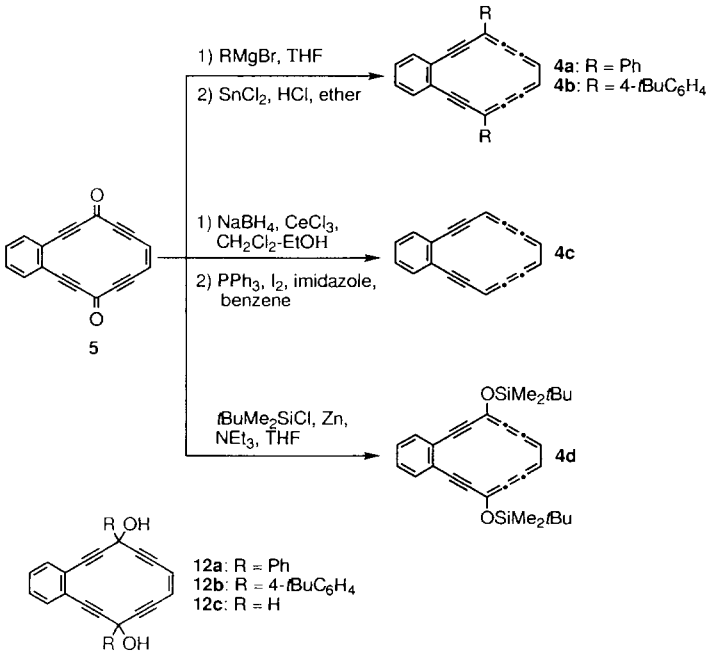


Scheme 1. Preparation of annulenedione **5** from **6**.

lithiated by *n*-butyllithium in ether[6] and then reacted with 1-bromo-3-(*tert*-butyldimethyl)silyloxy-1-propyne[7] to give the diyne **7a** in 52% yield. After removal of the trimethylsilyl group of **7a** by treatment with K_2CO_3 in methanol, the terminal alkyne **7b** was coupled with *ortho*-diiodobenzene in the presence of a palladium(0) complex and CuI to afford tetrayne **8** in quantitative yield.[8] The bis(silyloxy)tetrayne **8** was deprotected with tetrabutylammonium fluoride, and the resulting diol was oxidized to the dialdehyde **9** with Dess–Martin periodinane[9] in 95% yield. Cyclization of **9** was achieved in 83% yield by the modified Pedersen method—a pinacol coupling reaction using a low-valent vanadium complex generated from $[VCl_3(thf)_3]$ and zinc dust.[10] The pinacol **10** obtained as a mixture of two diastereoisomers was reduced to the cyclic enediyne derivative

11 via the corresponding dimesylate in 87% yield. This procedure provides a new and effective method for the construction of cyclic enediyne systems.[11, 12] The diacetal **11** was hydrolyzed by perchloric acid in dichloromethane to give the annulenedione **5** in 75% yield (see Table 1).

The transformation of **5** to the dehydroannulenes **4** was achieved by three different methods depending on the substituents (Scheme 2). The aryl-substituted derivatives **4a** and **4b** were synthesized via diols **12a** and **12b** prepared from **5** and the



Scheme 2. Synthesis of dehydroannulenes **4** from **5**.

appropriate Grignard reagent. The Grignard reaction of **5** with PhMgBr gave the diol **12a** as a mixture of diastereomers, which was reduced by $SnCl_2$ and gaseous HCl in ether[13] to afford the diphenyl-substituted dehydroannulene **4a** in 21% yield. The bis(4-*tert*-butylphenyl)-substituted derivative **4b** was also obtained by the same method in 27% yield.[14] The unsubstituted dehydroannulene **4c** was synthesized by reduction of **5** with a hydride under Luche's conditions[15] and dehydroxylation of the resultant diol (**12c**) by treatment with PPh_3, I_2, and imidazole in benzene. The direct reduction of **5** to the bis(silyloxy) derivative **4d** was achieved under electron-transfer conditions.[16] The reaction of **5** with zinc powder in the presence of *tert*-butyldimethylchlorosilane and triethylamine gave **4d**.[17]

The two diaryl-substituted derivatives **4a** and **4b** were obtained as moderately stable violet needles, but the other derivatives, **4c** and **4d**, could be obtained only in dilute, red solution. These two compounds polymerized readily in concentrated solution. Dehydroannulenes **4** show characteristic properties of arenes (Table 1). In their ^1H NMR spectra, all the signals are observed at very low field indicating the existence of a diatropic ring current, the most common criterion for aromaticity. For example, the signals of H-10 and H-11 on the 14-membered ring in **4a**, **4b**, **4c**, and **4d** are observed at $\delta = 8.18$, 8.13, 8.23, and 7.80, respectively. These signals are about 2 ppm downfield from the corresponding signal of **11**, which is observed at $\delta = 6.04$. The number of signals in the ^{13}C NMR spectra of **4** corresponds to half the number of carbon atoms, which reflects the symmetry of the compounds (C_{2v}) and is in good agreement

Table 1. Selected physical data of compounds **4**, **5**, and **11**. *J* in Hz.

4a: Deep violet needles (CH_2Cl_2/hexane), m.p. >120 °C (decomp.); MS (FAB): *m/z* 376 (M^+); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 9.03-8.96$ (2H, AA'm), 8.78 (4H, d, $J = 7.3$), 8.18 (2H, s), 8.13–8.06 (2H, BB'm), 7.67 (4H, t, $J = 7.3$), 7.49 (2H, t, $J = 7.3$); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 138.4$ (s), 132.2 (s), 131.9 (d), 130.5 (s), 129.2 (d), 129.1 (d), 128.4 (d), 127.1 (d), 121.6 (s), 111.7 (d), 104.8 (s), 103.9 (s), 100.6 (s); UV/Vis ($CHCl_3$): λ_{max} [nm] (log ε) = 295 sh (4.45), 306 (4.56), 340 sh (4.67), 353 (4.97), 393 (3.55), 535 sh (4.40), 572 (4.80); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1908 (cumulene).

4b: Deep violet needles (CH_2Cl_2/ethanol), m.p. >120 °C (decomp.); MS (FAB): *m/z* 488 (M^+); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 8.98-8.94$ (2H, AA'm), 8.64 (4H, d, $J = 8.3$), 8.13 (2H, s), 8.09–8.05 (2H, BB'm), 7.70 (4H, d, $J = 7.3$), 1.46 (18H, s); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 152.6$ (s), 135.9 (s), 131.8 (d), 131.6 (s), 129.9 (s), 128.2 (d), 126.9 (d), 126.2 (d), 121.5 (s), 111.2 (d), 104.5 (s), 103.5 (s), 100.6 (s), 35.0 (s), 31.3 (q); UV/Vis ($CHCl_3$): λ_{max} [nm] (log ε) = 295 sh (4.45), 306 (4.52), 340 sh (4.58), 356 (4.89), 397 (3.69), 542 sh (4.38), 581 (4.78); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1914 (cumulene).

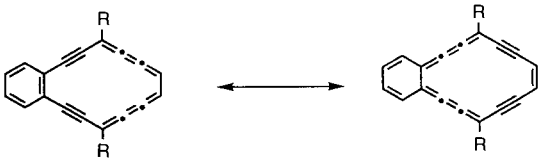
4c: ^1H NMR (270 MHz, $CDCl_3$): $\delta = 8.95-8.92$ (2H, AA'm), 8.23 (2H, dd, $J = 4.0, 1.5$), 8.15–8.11 (2H, BB'm), 8.03 (2H, dd, $J = 4.0, 1.5$); UV/Vis ($CHCl_3$): λ_{max} [nm] = 275 sh, 296 sh, 312 sh, 328, 440, 452, 481, 530, 554.

4d: ^1H NMR (270 MHz, $CDCl_3$): $\delta = 8.87-8.82$ (2H, AA'm), 8.03–7.99 (2H, BB'm), 7.80 (2H, s), 1.18 (18H, s), 0.62 (12H, s); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 131.2$ (s), 130.7 (d), 126.9 (s), 126.4 (d), 119.0 (s), 116.6 (s), 102.2 (d), 100.6 (s), 98.2 (s), 25.9 (q), 18.7 (s), 3.8 (q); UV/Vis ($CHCl_3$): λ_{max} [nm] = 296, 321 sh, 340, 480 sh, 504, 556.

5: Pale yellow needles (CH_2Cl_2/acetone), m.p. >130 °C (decomp.); MS (EI): *m/z* (rel. int. [%]) 254 (M^+, 45), 226 ($M^+ - CO$, 45), 198 ($M^+ - 2CO$, 100); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 7.68-7.65$ (2H, AA'm), 7.52–7.49 (2H, BB'm), 6.32 (2H, s); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 159.6$ (s), 135.3 (d), 131.7 (d), 126.6 (d), 96.7 (s), 93.0 (s), 88.7 (s), 85.6 (s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2210 (C≡C), 1605, 1580 (C=O).

11: Colorless needles (CH_2Cl_2/hexane), m.p. >180 °C (decomp.); MS (EI): *m/z* 370 (M^+); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 7.56-7.52$ (2H, AA'm), 7.35–7.30 (2H, BB'm), 6.04 (2H, s), 4.19 (t, 8H), 1.95–1.71 (m, 4H); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 133.0$ (d), 128.9 (d), 124.0 (s), 120.9 (d), 91.8 (s), 87.84 (s), 87.78 (s), 82.3 (s), 81.2 (s), 60.6 (t), 24.7 (t); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2255, 2230 (C≡C).

with the ^1H NMR spectra. Nine signals corresponding to the benzannulene skeleton are observed in the ^{13}C NMR spectra of **4a**, **4b**, and **4d** between $\delta = 132$ and $\delta = 98$. No signals were observed in the typical area for acetylenic carbons (e.g., $\delta = 88$ to 81 in **11**) or cumulenic sp-hybridized carbons (e.g., $\delta = 156$ in 1,4-diphenylbutatriene). This observation suggests that **4** is represented well by the hybrid resonance structures although they are nonequivalent (Scheme 3).



Scheme 3. Resonance structures of **4**.

In conclusion, the novel dehydroannulenes **4** were synthesized by means of the new strategy for the construction of cyclic enediynes. These compounds showed considerable aromaticity in spite of only nominal stability.

A Gold(I) [2]Catenane**

D. Michael P. Mingos,* John Yau, Stephan Menzer, and David J. Williams

Recently we have described the charcterization of some linear gold(I) complexes with nitrogen donor ligands,[1-3] which are very labile and therefore provide excellent precursors for the development of the coordination and organometallic chemistry of gold. When $[Au(NH_3)_2]^+$ [2] is treated with PhC≡CH the colorless crystalline compound **1** is obtained in excellent yield

$[(H_3N)Au(C{\equiv}CPh)]$ **1**

and has been characterized by elemental analyses and IR spectroscopy. When the reaction is repeated with tBuC≡CH the resultant compound is yellow and the elemental analysis suggests that the ammonia is no longer coordinated to the gold and that it is best formulated as $[Au(C{\equiv}Ct\text{Bu})]_n$. Coates and Parkin[4] have reported an identical compound and proposed that it is probably polymeric and have tentatively suggested the tetrameric structure shown in Scheme 1.

Single crystals of $[Au(C{\equiv}Ct\text{Bu})]_n$ can be obtained from EtOH from the above-mentioned synthesis, starting from $[Au(NH_3)_2]^+$. The yellow color of the crystals is unusual for linear gold(I) ethynyl compounds, the compound also has ν(C=C) stretching modes at 2002, 1983, and 1964 cm^{-1} suggesting three inequivalent triple bond environments.

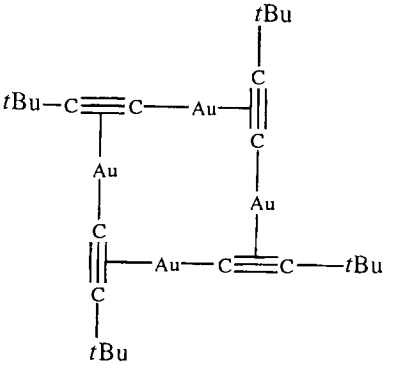

Scheme 1. Possible structure of a [Au(C≡CtBu)] oligomer.

The single-crystal X-ray crystallographic analysis of the oligomer[5] has demonstrated that it actually has a novel catenane structure based on two interlocked rings each containing six gold atoms and thus has the formula $[\{Au(C{\equiv}Ct\text{Bu})\}_6]_2$ (**2**) (Fig. 1). A crystallographically imposed C_2 axis passes through

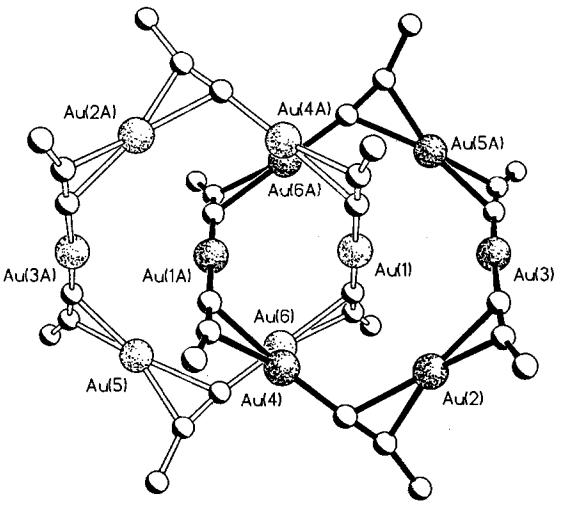

Fig. 1. Molecular structure of [2]catenane-$[\{Au(C{\equiv}Ct\text{Bu})\}_6]_2$. For reasons of clarity the methyl groups have been excluded. The crystallograhic C_2 axis is perpendicular to the page and passes through the mid-point of Au(1)–Au(1A).

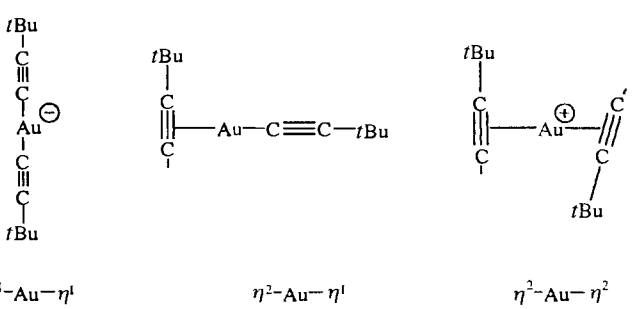
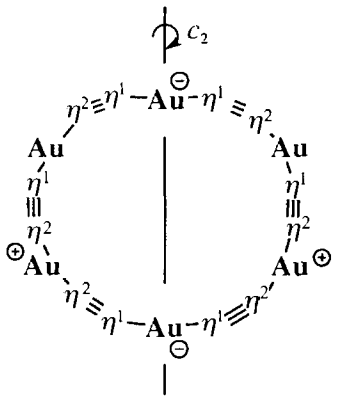
the midpoint of the Au(1)–Au(1A) vector. The ethynyl ligands in **2** adopt both η^1 and η^2 coordination modes, a feature which has been noted previously in Group 11 ethynyl complexes.[6] Each ring of (**2**) contains pairs of gold(I) atoms with the different ligand arrangements and formal charges (Scheme 2) because



Scheme 2.



Scheme 3.

some of the ethynyl ligands in [Au(C≡C*t*Bu)] have migrated in the oligomerization process. The arrangement of these coordination modes around the ring is shown in Scheme 3.

Within each ring the gold atoms form an almost regular hexagon (Au–Au contacts between 3.304(2)–3.361(2) Å) and define a plane (maximum deviation 0.1 Å). The two interlocking rings make a dihedral angle of 64.5° and inter-ring gold–gold contacts lie in the range between 3.215(2)–3.351(2) Å, leading to a symmetrical [2]catenane structure. The individual rings have approximately C_2 symmetry as a result of the ethynyl ligand bonding modes described above, and if one ignores the ligands the central Au_{12} core has approximately D_2 symmetry.

The η^2-η^2 coordination mode, not previously observed in gold(I) chemistry, results in the ethynyl ligands being mutually perpendicular in a manner similar to that reported previously for $[Pt^0(ethyne)_2]$ complexes.[7] The utilization of orthogonal C≡C π orbitals is also evident in the η^1-η^1 and η^2-η^1 coordination centers, (see Fig. 1).

The gold–gold distances within the rings and between the rings are significantly longer than those in the bulk metal (2.88 Å) but are nonetheless in the range where weak "aurophilic"[8] interactions may occur. The narrow range of the Au–Au contacts and the symmetrical nature of the structure suggests that the "aurophilic" interactions may contribute significantly to the self-assembly of the catenane.

The manner in which the basic [Au(C≡C*t*Bu)] fragments rearrange their coordination environments in solution and self-assemble in order to realize the observed solid-state structure remains a mystery. IR studies on the [2]catenane in solution have indicated that the three ν(C≡C) bands observed in the solid are also observed in solution (IR (CCl_4): ν(C≡C) 2003, 1985, 1965 cm^{-1}) suggesting that the ring structure is maintained in solution. Two ^1H resonances for the *t*Bu groups in the ratio of 2:1 in the ^1H NMR spectrum at room temperature (see experimental) are also consistant with the C_2 symmetry of the individual rings.

The observation of such an interesting catenane structure based on such simple homoleptic organometallic complex is really most unexpected and novel. Previous examples of [2]catenane complexes have the metal atoms involved in much more complex polyaromatic nitrogen ligand systems[9] and in some cases two different metal ions.[10] We are currently investigating similar compounds in order to establish the extent to which the "aurophilicity" of the gold atoms is contributing to the spontaneous formation of the [2]catenane.

Experimental Procedure

1: PhC≡CH (0.025 mL, 0.228 mmol) was added dropwise to $[Au(NH_3)_2]BF_4$ (0.065 g, 0.204 mmol) dissolved in pre-dried, degassed acetonitrile (10 mL). The colorless solution was allowed to stir for 1 h, after about 10 minutes a white microcrystalline solid separated, which was eventually collected by filtration, washed with acetonitrile (3 × 5 mL), and dried under reduced pressure. Yield 94%; elemental analysis for C_8H_8AuN; found: C 30.0, H 2.4, N 4.4; calcd: C 30.5, H 2.6, N 4.5; IR(KBr): ν(NH) bands at 3318 and 3239 cm^{-1}, ν(CH) at 3078, 3050, and 3030 cm^{-1} and ν(C≡C) at 2112 cm^{-1}.

2: *t*BuC≡CH (0.06 mL, 0.487 mmol) was added dropwise to $[Au(NH_3)_2]BF_4$ (0.10 g, 0.487 mmol) dissolved in pre-dried, degassed acetonitrile (10 mL). After about 30 min a pale yellow solution was observed, the solution was then allowed to stir for a further 30 min, after which time the volume was concentrated under reduced pressure to give a dark yellow precipitate. This was filtered, dissolved in a minimum volume of hot EtOH and left in a refrigerator at about 4°C, to give pale yellow cubes after about 2 days. Yield 65%; elemental analysis for $[(C_6H_9Au)_6]_2$; found: C 25.6, H 2.4; calcd: C 25.9, H 3.2; IR(KBr): ν(CH) bands at 2966, 2945, 2922, 2895, and 2864 cm^{-1} and ν(C≡C) at 2002, 1983 and 1964 cm^{-1}; ^1H NMR (270 MHz, C_6D_6, 25 °C, TMS): δ = 1.2 (S, 36H; 4*t*Bu), 0.5 (s, 18H; 2*t*Bu).

Novel Networks of Unusually Coordinated Silver(I) Cations: The Wafer-Like Structure of $[Ag(pyz)_2][Ag_2(pyz)_5](PF_6)_3 \cdot 2G$ and the Simple Cubic Frame of $[Ag(pyz)_3](SbF_6)$**

Lucia Carlucci, Gianfranco Ciani,* Davide M. Proserpio, and Angelo Sironi

The crystal engineering of two- (2D) and three-dimensional (3D) coordination polymers is of great current interest,[1–3] both for the theoretical aspects related to the topologies of novel networks, and for their potential physicochemical properties, such as electrical conductivity,[4] magnetism,[5] and applications in host–guest chemistry,[1, 6] and catalysis.[7] In the supramolecular chemistry of hydrogen-bonded organic molecules,[8] coordination polymers offer a higher potential because of the variety of coordination modes and the peculiarities of the metallic cen-

ters. We are currently investigating the self-assembly of silver(I) cations and bidentate N–N′-donor ligands and have already reported interesting 2D and 3D networks including the fourfold interpenetrating super-diamond structures of the complexes $[Ag(N-N')_2]X$ (N–N′ = 4,4′-bipyridyl, $X^- = CF_3SO_3^-$; N–N′ = 4-cyanopyridine, $X^- = BF_4^-$),[9] and the threefold interpenetrating 3D 3-connected frame of $[Ag_2(pyz)_3](BF_4)_2$ (pyz = pyrazine),[10] topologically related to the prototypal structure of α-$ThSi_2$.

In this paper we describe two novel Ag^I polymeric species, which contain only the linear bidentate pyz ligand as bridge: a 2D wafer-like polymer **1a**, consisting of alternating layers of different nature and composition, and containing guest solvent molecules (G) between the sheets, and a 3D polymer **2** with cubic symmetry, related to the structure of α-polonium.

$[Ag(pyz)_2][Ag_2(pyz)_5](PF_6)_3 \cdot 2G$ $[Ag(pyz)_3](SbF_6)$

1a, G = CH_2Cl_2 **2**

1b, G = $CHCl_3$

1c, G = CCl_4

These types of frameworks are unprecedented in the chemistry of coordination polymers based on molecular rods (cationic polymers), and are particularly exceptional because of the unusual coordination modes adopted by the silver ions (see below).

Compound **1** is obtained on layering a solution of $AgPF_6$ in ethanol on a solution of pyz (between 2:1 to 3:1 molar ratio of pyrazine to Ag^I salt) in the appropriate chlorinated solvent. Platelike crystals, rather unstable when removed from the mother liquor, are recovered in the three cases, the most suitable ones for a single-crystal X-ray analysis being those from CH_2Cl_2 (**1a**).[11] Variable amounts of needle-shaped crystals of the linear polymer $[Ag(pyz)](PF_6)$ (**3**) are also obtained; their nature was also established by a single-crystal X-ray analysis.[12]

The structure of **1a** (Fig. 1) consists of stacks of two different 2D layers alternating along the direction of the tetragonal *c* axis. The first one (layer I) comprises cubes of silver ions, the edges of which are formed by the pyz ligands; four faces are shared to give an infinite 2D tessellation (see Fig. 2). Each cubic unit [equatorial and axial Ag···Ag edges 7.548(2) and 7.645(3) Å, respectively] is centered by a PF_6^- anion. The metal ions, lying

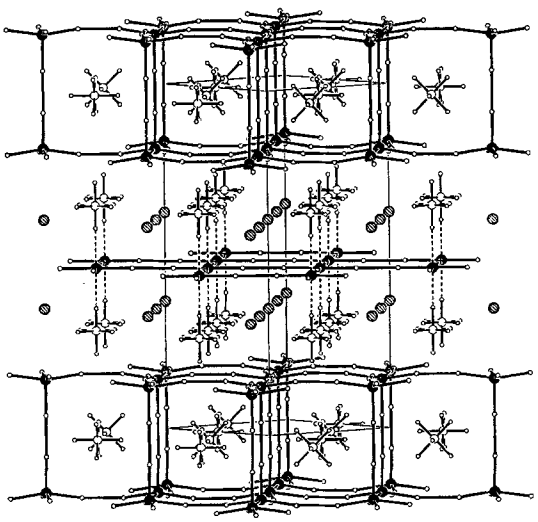

Fig. 1. The crystal packing of **1a** (SCHAKAL representation), viewed approximately down [110]. The pyz ligands are represented as rods connecting the nitrogen atoms. Solid, open, and cross-hatched spheres indicate Ag, P, and the guest molecules G, respectively.

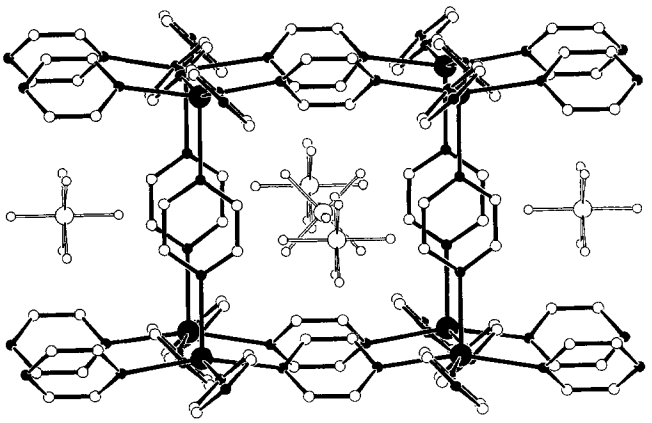

Fig. 2. The structure of layer I of **1a**. Only one model for the axially disordered pyz ligand is shown.

on fourfold axes, are five-coordinate in a square-pyramidal environment [out-of-plane displacement of Ag equal to 0.367(9) Å, N_{ax}-Ag-N_{eq} 98.6(2)° and N_{eq}-Ag-N_{eq} 162.8(4)°], with four Ag–N_{eq} bonds of 2.454(9) Å and one Ag–N_{ax} bond of 2.44(2) Å. The four equatorial pyz ligand display a propeller-like disposition and are not in line with the metal ions [Ag–N···N 166.9(2)°].

The second type of layer (layer II) is an infinite flat grid of square meshes of Ag^I ions linked by pyz ligands [Ag···Ag contact of 7.548(2) Å]. The silver ions, lying on *mmm* special positions, are in a square-planar environment, with two Ag–N bonds of 2.32(2) Å and two of 2.45(2) Å. However, they also present two long contacts [2.685(11) Å] with the fluorine atoms of two axially disposed anions (Fig. 3); taking into account

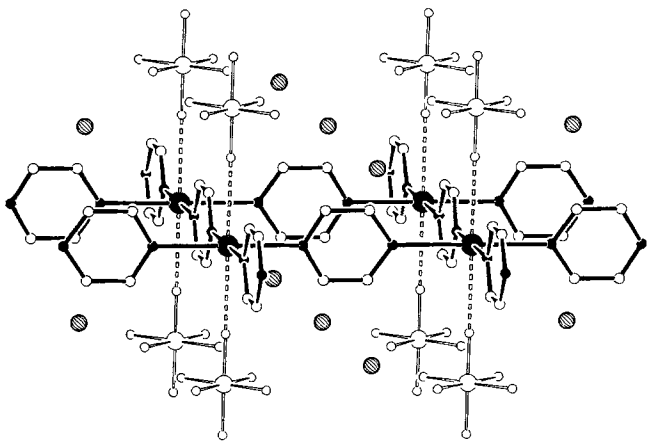

Fig. 3. The structure of layer II of **1a** (SCHAKAL representation). The axially disposed, disordered PF_6^- anions are shown in the positions with the highest occupancy factor.

these weak interactions the Ag^+ coordination can be described as a tetragonally distorted octahedron (4 + 2). The layers of this type, of composition $[Ag(pyz)_2](PF_6)_2$, are therefore negatively charged, whereas the others of composition $[Ag_2(pyz)_5](PF_6)$, are positively charged. The wafer-like structure of **1a** derives from the assembly of these layers with an *ABAB* sequence. Stacking occurs in such a manner that the metal ions of one layer are in the centers of the squares of the adjacent layers. Between each pair of layers there are cavities (approximately 100 $Å^3$) that can contain CH_2Cl_2 as guest solvent molecules.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3417-1896 $ 10.00+.25/0

The analogous products containing the other solvent molecules (**1b** and **1c**) are isomorphous with **1a** and exhibit cell parameters[13] that increase with an increasing number of chlorine atoms in the guest (about 1.7% of the cell volume in each step).

The simultaneous presence of different extended structural motifs in the same compound is quite rare in coordination polymers; another example is the polyselenide K_2PdSe_{10},[14] which consists of two interpenetrating diamondoid sublattices of different nature.

On performing the same reactions above described with $AgSbF_6$, compound **2** is obtained as beautiful multifaced crystals, irrespective of the chlorinated solvent used.

The unit cell of **2** is shown in Figure 4. It consists of a simple cubic framework of silver ions, lying on special positions having 222 symmetry, octahedrally bound to six pyz ligands, with Ag–N bond lengths between 2.481(7) and 2.519(8) Å. All the

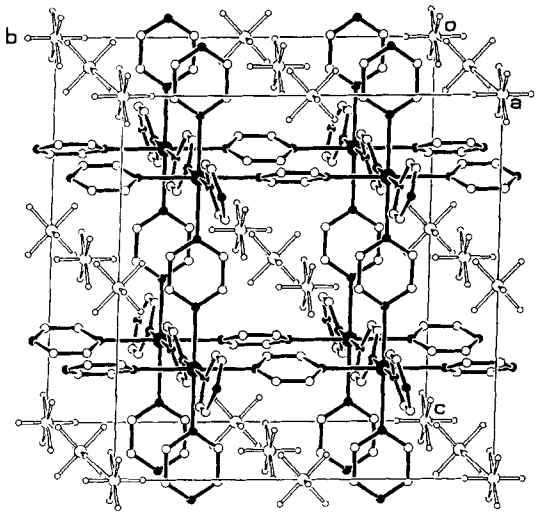

Fig. 4. The unit cell of **2** (SCHAKAL representation). The disordered SbF_6^- anions are represented in the positions with the highest occupancy factor, and a little reduced for clarity.

cubes (average Ag···Ag edge of 7.761 Å) are similar to the cubic cells of layer I of **1a** (Fig. 2) and are similarly centered by the anions. Along the linear pyz-Ag-pyz-Ag chains developing in the directions of the three crystal axes the pyz ligands are alternately rotated in opposite directions, with different rotation angles [16.5(5)°, 18.3(4)° and 2.9(7)° along *a*, *b*, and *c*, respectively].

The 6-connected framework of **2** is topologically related to the structure of α-polonium or, better, to that of ReO_3; other well-known examples are compounds like Prussian blue. It is of interest as fundamental structural types, since it represents the first cationic frame linked by molecular rods only and consisting of a single network, different from some other known interpenetrating α-polonium type frames, like the two recently reported cyano-bridged polymers $Rb[Cd(Ag(CN)_2)_3]$[16] and $[Cd(pyz)(Ag_2(CN)_3)(Ag(CN)_2)]$.[17]

The networks of **1a** and **2** are particularly surprising and unpredictable in the presence of metal centers like Ag^I, which usually adopt linear, trigonal, or tetrahedral coordination geometries.[18] It is worth mentioning that, in contrast, the known polymeric complexes of some M^{2+} octahedral cations with pyz exhibit a maximum of four M–pyz (equatorial) bonds, resulting in 2D flat sheets of squares, the other two (axial) coordination sites being involved in interactions with the counterions.[5, 19] The very existence of **2** suggests the possibility of obtaining similar 3D frames with divalent metal cations and suitable dianions, and work is in progress. However, the self-assembly of these polymers is highly influenced by factors such as the solvent system and the steric requirements of the counterion. $AgPF_6$ in H_2O/EtOH gives $[Ag(pyz)_2](PF_6)$, composed of 2D, markedly undulated sheets of squares,[20] and $AgBF_4$ in EtOH affords, inter alia, $[Ag(pyz)_3](BF_4)$, with a composition analogous to that of **2** but forming a 1D zigzag polymer of tetrahedral silver ions bearing two monodentate pyz molecules.[10] Indeed, this high structural versatility of Ag^I can be a problem for the design of new solids, but it also offers the opportunity to discover unprecedented polymeric motifs potentially extendible to other transition metal systems.

Experimental Procedure

Compound **1a**: A solution of $AgPF_6$ (0.104 g, 0.410 mmol) in EtOH (3 mL) was layered on a solution of pyz (0.103 g, 1.290 mmol) in CH_2Cl_2 (3 mL). After a few days a crystalline precipitate was recovered, which was filtered and washed with EtOH. The product slowly decomposes in air. After some needle-shaped crystals of $[Ag(pyz)](PF_6)$ (**3**) had been hand-picked, it was submitted to elemental analysis. Yield 57%. Anal. calcd. for $C_{30}H_{32}Ag_3Cl_4F_{18}N_{14}P_3$: C 25.66, H 2.28, N 13.97; found C 25.02, H 2.02, N 13.57. IR (Nujol): ν(pyz) = 1417(s), 1047(m), $\nu(PF_6^-)$ = 843(s) cm^{-1}.

Compound **2**: A solution of $AgSbF_6$ (0.230 g, 0.670 mmol) in EtOH (4 mL) was layered on a solution of pyz (0.161 g, 2.010 mmol) in CH_2Cl_2 (3 mL). After two days a crystalline precipitate was obtained, which was filtered and washed with EtOH. The product is stable in air. Yield 88%. Anal. calcd. for $C_{12}H_{12}AgF_6N_6Sb$: C 24.68, H 2.07, N 14.39; found C 24.47, H 1.98, N 14.20. IR in Nujol: ν(pyz) = 1411(s), 1031(s), $\nu(SbF_6^-)$ = 650(s) cm^{-1}.

[11] A single crystal of **1a** was mounted under a coating of cyanoacrylic glue, to prevent decomposition, on an Enraf–Nonius CAD-4 diffractometer. Crystal data: tetragonal, *P4/mbm* (no. 127), $a = b = 10.675(3)$, $c = 23.290(2)$ Å, $V = 2654.0(11)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.863$ Mg m^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). The data collection was performed at 293 K, by the ω-scan method, within the limits $3 < \theta < 26°$. The structure was solved by direct methods (SIR92) and refined by full-matrix least-squares methods (SHELX93). The pyz ligands linking the double layers to give cubes lie on fourfold axes and therefore exhibit a statistical disorder of the carbon atoms, which form two half-rings rotated by 90° about the *c* axis (only one model is shown in Fig. 2). The equatorial fluorine atoms of the PF_6^- anions axially bound to the layers of squares are disordered (two models with population 0.58 and 0.42; only the dominant model is depicted). The solvated CH_2Cl_2 molecules are also disordered: the two chlorine atoms lie on a fourfold axis, and the CH_2 groups are statistically distributed. $R = 0.0751$ for 799 independent significant [$F_0 > 3\sigma(F_0)$] absorption corrected data. Anisotropic thermal factors were assigned to all the non-hydrogen atoms [21].

[12] Crystal data for **3**: tetragonal, *I4/mcm* (no. 140), $a = b = 8.026(2)$, $c = 14.203(6)$ Å, $V = 914.9(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.417$ Mgm^{-3}. Final $R = 0.0621$ for 190 significant $[F_0 > 2\sigma(F_0)]$ absorption corrected data. The structure consists of strictly linear polymers propagating in the direction of the tetragonal axis and exhibiting pyz ligands alternately rotated by 90°, with Ag–N bonds of 2.168(14) Å [21].

[13] Compound **1b**: $a = b = 10.725(6)$, $c = 23.481(6)$ Å, $V = 2700.9$ Å^3. Compound **1c**: $a = b = 10.794(3)$, $c = 23.566(15)$ Å, $V = 2745.7$ Å^3.

A One-Step Synthesis of Squalene from Farnesol under Prebiotic Conditions**

Martin Keller, Doris Hafenbradl, Karl O. Stetter, Gérard Teller, Yoichi Nakatani, and Guy Ourisson*

We have recently recognized that a large number of terpenoids play the same role in all living organisms: forming or stabilizing membranes.[1] Among these terpenoids, squalene (**1**) is apparently present in the cells of all living organisms. It serves in particular as the precursor of membrane reinforcers: cholesterol in eucaryotes through its epoxide[2] and hopanoids in many bacteria by direct cyclization.[3] But squalene is also present in archea species in uncyclized form which apparently serves as a spacer between the lipid chains.[4] We describe now its formation under hypothetical, but plausible prebiotic conditions, namely those postulated by Wächtershäuser to have been operative in a "pyrite-driven" chemoautotrophic world.[5]

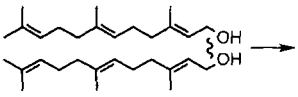
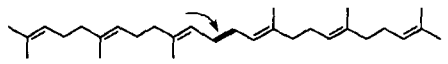
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Centre National de la Recherche Scientifique, and the Université Louis Pasteur as part of the "Supermolecules" Program (ULP/Research Development Corporation of Japan).

The complex biosynthesis of squalene has been studied in remarkable detail.[6] It starts with the formation of the sesquiterpene alcohol farnesol (**2**), the pyrophosphate of which forms the presqualene alcohol pyrophosphate, which in turn is



2



1

finally reduced to squalene by an NADPH reductase after a series of steps. We have noted that farnesol, along with its lower and higher homologues, could be derived by very simple nonenzymatic reactions of type (a) from simple C_4 and C_1 or C_5

$$-C^+ + C{=}C \longrightarrow -C-C-C^+ \qquad \text{(a)}$$

precursors.[7] We have also shown that aqueous solutions of the sodium salts of the phosphate esters of farnesol and its higher and lower homologues (di-[8] and even monopolyterpenyl phosphates[9]) spontaneously form vesicles that can be considered as models of the most primitive cell membranes. However, no reaction is known, nor have any been postulated, by which farnesol or its pyrophosphate can be transformed into squalene under potentially prebiotic conditions, and the complexity of the present biosynthetic pathway can hardly be compatible with its early operation.

Stoichiometrically, the doubling of farnesol or of its pyrophosphate is a reductive coupling,[10] which is analogous to several standard chemical reactions, for example the classical Wurtz coupling of alkyl halides, in which the reducing agent is a metal like sodium, or the van Tamelen–McMurry couplings of allylic alcohols, which rely on low-valent titanium (obtained from a mixture of a dichlorotitanium(IV) dialkoxide and molten potassium[11] or from titanium trichloride and lithium aluminum hydride[12]). While both methods give squalene from farnesol in appreciable yields (30–40%), these reducing conditions can of course in no way be considered as prebiotic.

We now show that this doubling can be achieved, albeit in low yield, by the direct reduction of farnesol to squalene with the system (b), which was advocated by Wächtershäuser as a prim-

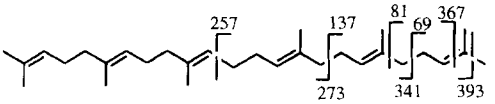
$$H_2S + FeS \longrightarrow FeS_2 + 2[H^+] \qquad \text{(b)}$$

itive reducing system and provided a basis for his unified theory of the chemoautotrophic origin of the constituents of life.[5]

We used conditions described earlier to reduce various organic substrates.[13] All experiments were carried out under fastidiously anaerobic conditions. Farnesol was heated at 100 °C for six days in the presence or absence of FeS and H_2S. The reaction mixture then showed the glistening appearance characteristic of anaerobic pyrite formation. Analysis of a chloroform extract by thin-layer chromatography and gas chromatography showed that farnesol had disappeared and new products had been formed in significant amounts when both FeS and H_2S were present. In the absence of FeS, none of these new products were observed; however, in the presence of FeS alone, which was partially hydrolyzed to H_2S under these conditions, the new products were observed but in smaller amounts. The products were analyzed by GCMS. All the experiments yielded a series of

peaks with retention times very similar to that of squalene and all with a mass peak at m/z 410. The peak having exactly the same retention time as squalene gave a mass spectrum entirely identical to that of an authentic sample.

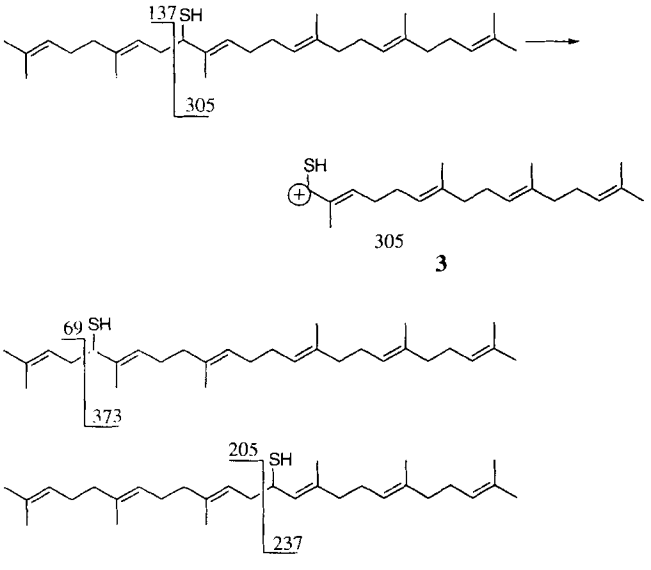
The eight major fragmentations can be interpreted as indicated in Scheme 1, with incidental H transfers. Squalene was isolated in about 0.2% yield. The other GC peaks with m/z 410 gave



Scheme 1. Main fragments in the mass spectrum of squalene.

similar mass spectra and may be double-bond isomers, in which one or more of the double bonds in squalene are *cis*-configurated; these products were not studied further.

Squalene was accompanied by four products with longer retention times, all characterized by a molecular peak at m/z 442, corresponding to $C_{30}H_{50}$ (410) + S (32). (The expected isotopic satellite corresponding to the ^{34}S analogue was observed at m/z 444.) The very remarkable similarity of the mass spectra of these products and the presence of most of the fragments observed in the mass spectrum of squalene itself suggest that they are probably close derivatives of squalene, probably squalenethiols. The high intensity of the new fragment at m/z 305 (with an isotopic satellite at m/z 307), which is absent in the mass spectrum of squalene, completely excludes structures based on difarnesyl sulfide and suggests that this cleavage corresponds to the formation of the highly stabilized allylic sulfanylcarbenium ion **3** (Scheme 2). Major peaks at m/z 237 (+239), and at 373 (+375) are attributed to isomeric squalenethiols. The



Scheme 2. Fragmentation of squalenethiols yielding allylic sulfanylcarbenium ions.

various isomers may again be double-bond isomers. These monothio derivatives are accompanied by smaller amounts of doubly sulfur-substituted squalenes (M_r (476) = squalene + S + H_2S, isotopic satellites at m/z 478 and 480).

To better evaluate the yield of the reductive coupling, we attempted to simplify the reaction mixture by desulfurizing the various thio derivatives with Raney nickel. This was not successful, because it was difficult to recover products from the nickel reagent, and some partial hydrogenation was observed. We have therefore treated the crude reaction mixture first with Raney nickel at 80 °C, which led to desulfurization and partial hydrogenation, and then completed the hydrogenation by treatment under an atmosphere of hydrogen with platinum (from platinum oxide). Only about one-fourth of the product could be recovered from this sequence. This was chromatographed and analyzed by GCMS. No farnesol remained; the mixture was mostly (90%) C_{15} products of its cyclization or isomerization. A family of C_{30} peaks were observed, the most intense of which had a retention time and a mass spectrum entirely identical with those of squalene. It was isolated in about 2% yield from farnesol.

The formation of squalene in such a low yield can of course not be construed as evidence in support of Wächterhäuser's conditions in the prebiotic formation of this hydrocarbon. We must, however, note that farnesol itself could be produced under general acidic conditions in the homogeneous or heterogeneous phase by three successive condensations of isopentenyl units, which in turn could possibly originate from isobutene and formaldehyde.[1, 5] The intermediates might be, like in the biosynthetic processes, polyprenyl phosphates. If squalene was ever produced, even in a low yield, in a system containing vesicles of polyterpenoid phosphates like those we have described, these would necessarily extract it specifically within their lipidic layer, as a most lipophilic component.[4] This would be one example of stepwise build-up of complexity in simple vesicles.[1]

Experimental Procedure

All reactions were carried out under argon. The solutions were prepared from doubly distilled water through which argon had been bubbled for 2 h. Amorphous FeS was prepared in an anaerobic chamber by adding a solution of $Na_2S \cdot 9H_2S$ to 0.6 M Fe_2SO_4, filtering the precipitate, washing it with water, and drying it under N_2:H_2 (95:5). Hydrogen sulfide was prepared by adding 50% H_2SO_4 to $Na_2S \cdot 9H_2S$ in an evacuated serum bottle. Serum bottles (120 mL) were charged with 10 mL of water, 100 mmol of farnesol, and then with 2 mmol of FeS in the anaerobic chamber. They were closed with a "Viton" diaphragm (Ochs), filled to 200 KPa with argon, and subsequently charged with H_2S (2 mmol). The pH was adjusted to 7.5. All incubations were carried out at 100 °C in a rotatory shaker (100 rpm) for 6 d. The reaction mixture was centrifuged and the supernatant extracted with chloroform. GCMS spectra were recorded with a Fisons MD800 quadrupole instrument from 50 to 500 Da. The gas chromatograph had a direct injector and a JW DB5 column (30 m, internal diameter 0.32 mm, 0.1 mm film). The samples were injected as a solution in acetone or dichloromethane.

The yields are based on farnesol. In the absence of FeS, no squalene and no squalenethiols were detected. In the presence of only FeS, we obtained 0.2 mmol of squalene, 1.7 mmol of squalenemonothiols, and 0.02 mmol of squalenedithiols. When both FeS and H_2S were used, we obtained 0.2 mmol of squalene, 3.0 mmol of squalenemonothiols, and 0.5 mmol of squalenedithiols.

Radical Cation [4 + 2] Cycloadditions with 2-Vinylindoles**

Christoph F. Gürtler, Siegfried Blechert,* and Eberhard Steckhan

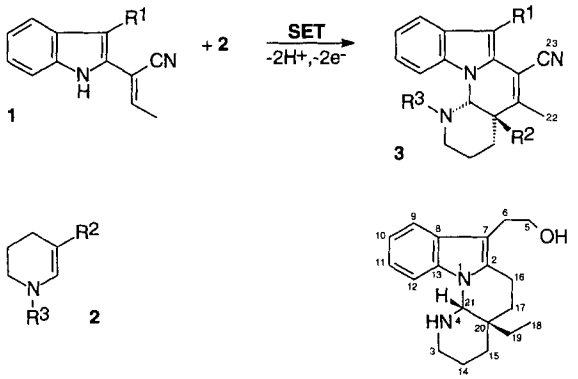
Numerous organic reactions can be traced back to electron transfer (ET) processes, which are among the most important elementary reactions in chemistry.[1] In addition to intensified mechanistic/theoretical investigations[2, 4] of ET reactions in all areas of chemistry, there is increasing interest in the preparative potential of these reactions.[3, 4]

Neutral Diels–Alder reactions that proceed slowly or not at all can in certain cases be accelerated by transforming either the diene or the dienophile into its radical cation by single electron transfer (SET). The electron-deficient radical cation reacts with the electron-rich component to form a cycloadduct radical cation, which in the catalytic case can undergo back electron transfer with the starting material. Cycloadducts of a higher oxidation state can be formed by one-electron oxidation of the product radical cation and subsequent deprotonation.

The versatility of 2-vinylindoles especially in natural product synthesis has been demonstrated[5] several times. A wide range of 2-vinylindoles are accessible[6] by a process developed by our group. Until now these Diels–Alder reactions could only be performed with electron-poor dienophiles.[7]

2-Vinylindoles react with electron-rich dienophiles in high-yielding, electron transfer induced Diels–Alder reactions under mild reaction conditions by photoelectron transfer catalysis or electrochemical initiation. We reported earlier on the reaction of 2-vinylindoles **1** with cyclohexadienes and styrene.[8] Similar reactions with enamidoesters[9] lead directly to heteroaromatic compounds by an elimination process.

Here we report the application of this type of reaction to relatively electron-rich heterosubstituted dienophiles. In contrast to known reactions of vinylindoles with carbocyclic dienes and styrenes, neither formation of carbazole derivatives nor aromatization is observed in reactions with either the 1,4,5,6-tetrahydroyridines **2** (Scheme 1) or with β-aminomethacrylates like **7** or -nitriles like **5**. Instead the preparatively interesting tetracycles **3** (indolo[1,2-*a*]-1,8-naphthyridine) result which have



Scheme 1. SET = single electron transfer.

the pyrrocoline skeleton of alkaloids (e.g. goniomitine (**4**)) (Table 1). Ring closure is effected by the indole nitrogen, which allows the electron transfer induced [*a*]annelation of the dienophiles to the indole nucleus. It is, thus, an electron transfer induced hetero [4 + 2] cycloaddition proceeding via an electrochemically generated vinylindole radical cation.

Table 1. Results of the ET-induced [4 + 2] cyclization of 2-vinylindoles **1** (diene) with 1,4,5,6-tetrahydropyridines **2** and with acceptor-substituted enamines having different steric demands (**5** and **7**) (dienophiles).

Diene	R^1	Dienophile	R^2	R^3	Product	Yield [%] [a]
1a	Me	**2a**	CN	H	**3a**	68
1b	$EtOCH_2CH_2$	**2a**	CN	H	**3b**	53

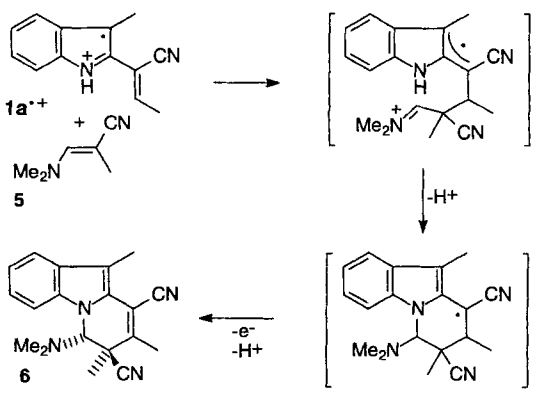
1a	Me	**2c**	COOMe	Me	**3d**	62
1a	Me	**5**			**6**	50
1a	Me	**7**			**8**	53

[a] Based on 80% conversion; see Experimental Procedure.

By potentiostatically controlled electrolysis[10] at a potential allowing only for one-electron oxidation of the vinylindole, it was acertained that only the radical cation of the diene component is formed initially.

β-Substituted enamines that do not have radical-stabilizing substituents such as cyano or methoxycarbonyl groups do not react even if they have an appropriate oxidation potential. We, therefore, assume that the stabilization of a radical intermediate is of prime importance (Scheme 2). The oxidation potentials of



Scheme 2. Proposed mechanism for the ET-induced [4 + 2] cyclization illustrated by the reaction $\mathbf{1a}^{\bullet+} + \mathbf{5} \rightarrow \mathbf{6}$.

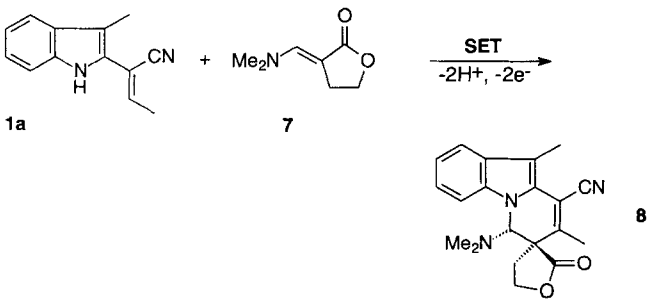
[**] This work was supported by the Volkswagen-Stiftung (I/69415) and the Fonds der Chemischen Industrie. We would like to thank Mr. P. Pritschow for recording the NMR spectra.

the dienophiles employed in this reaction are about 100 to 200 mV higher than those of the dienes. The requirement that the oxidation potentials of the two components should not differ by more than 500 mV is thus fulfilled.[11] A rather small difference of the oxidation potentials usually has a positive effect on the reaction rates.

Based on our experience with 2-vinylindoles, we propose the mechanism outlined in Scheme 2. We assume that the first step is an addition of the enamine to the electrochemically formed vinylogous iminium radical cation, followed by cyclization via the electrophilic iminium cation. Deprotonation and subsequent electron transfer terminate the reaction. Thus **6** is formed as the exclusive product in good yield.

A nonconcerted mechanism is consistent with earlier mechanistic investigations on radical cation Diels–Alder reactions.[12] At the stage of the initially formed radical cation addition product, rotation about the C–C single bond and formation of *cis*/*trans* diastereomers should generally be possible, in particular when the dienophile is bulky. If ring closure is much faster than rotation, a uniform product is to be expected. In case of acrylonitrile **5** and the sterically demanding enaminolactone **7**, (*E*)-configurated olefins lead most remarkably to *trans* products **6** and **8** exclusively (Table 1).



1a **7** **8**

The reaction described here extends the application of ET-induced Diels–Alder reaction with 2-vinylindoles as the diene component in a preparatively interesting way. It enables the rapid construction of alkaloid skeletons in high to very high yield. The mechanism and further application, especially towards the synthesis of indole alkaloids, are topics of current investigations.

Experimental Procedure

General procedure for ET-induced reactions: 1 mmol diene **1** and 0.7 mmol dienophile were dissolved in 50 mL of acetonitrile (+ 0.1 M $LiClO_4$). The solution was degassed in an electrolysis cell (undivided) and subsequently subjected to a potentiostatically controlled electrolysis at a working potential of 490 mV vs a $Ag/AgNO_3$ reference electrode. Electrolysis was performed until about 80% conversion was reached (working electrode: graphite, auxiliary electrode: graphite). For workup the solvent was removed and the residue was treated with water and extracted several times with dichloromethane. The product was purified by column chromatography (*tert*-butyl methyl ether/petroleum ether 1:3) or by HPLC (Nucleosil RP-18, water/methanol 7:3). All new compounds were characterized unequivocally by spectroscopy. 2D-NMR techniques (COLOC) and NOE experiments were used for structure determination. Selected spectroscopic data e.g. for **3c**: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.56 (d, 1H, J = 7.5 Hz, H-9), 7.36 (d, 1H, J = 7.5 Hz, H-12), 7.24 (dd, 1H, J = 7.5, 7.5 Hz, H-11), 7.12 (dd, 1H, J = 7.5, 7.5 Hz, H-10), 5.52 (s, 1H, H-21), 3.58 (s, 3H, $COOCH_3$), 3.08 (ddd, 1H, J = 3.5, 4.5, 13.0 Hz, H-3eq) 2.88 (ddd, 1H, J = 4.0, 8.0, 13.0 Hz, H-3ax), 2.52 (m, 1H, H-15eq), 2.48 (s, 3H, H-6), 2.42 (s, 3H, H-22), 2.02 (ddd, 1H, J = 4.0, 8.0, 13.0 Hz, H-15ax), 1.72 (dddd, 1H, J = 3.5, 4.0, 4.0, 14.0 Hz, H-14eq), 1.32 (m, 1H, H-14ax). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 172.4 (C-19), 146.2 (C-17), 135.6 (C-13), 130.0 (C-8), 124.2 (C-7), 124.1 (C-11), 120.4 (C-10), 119.7 (C-9), 116.1 (C-23), 111.9 (C-2), 108.7 (C-12), 106.1 (C-16), 67.6 (C-21), 53.0 (C-24), 52.5 (C-20), 44.6 (C-3), 31.3 (C-15), 22.9 (C-14), 19.3 (C-22), 8.7 (C-6). C calc.: 71.62%, found: 71.40%; H calc.: 6.31%, found: 6.40%.

New Dimensions to Familiar Themes

Two Dimensional NMR Spectroscopy. Applications for Chemists and Biochemists. 2nd Edition. Edited by *W. R. Croasmun* and *R. M. K. Carlson*. VCH Publishers, New York, 1994. 958 pp., hardcover DM 199.00.—ISBN 1-56081-664-3

Compared with the first edition of this work (published in 1987), this new edition has not only been extended and updated to take account of the latest state of development in NMR methods, it must actually be regarded for the most part as a newly written book. I therefore commend it even to readers who already have the first edition. Most of the authors have recognized that two-dimensional and multidimensional NMR techniques have undergone further radical changes during the 1990s, and that new examples were needed, especially of reverse heteronuclear experiments, to emphasize the enormous advances that these new methods have brought to the already available strategies for structure determination.

In Chapter 1 the already well-proven introduction by G. A. Gray to multidimensional NMR spectroscopy of solutions has been extended to include reverse heteronuclear correlation experiments, spin-locking pulses, and pulsed field gradients. Gray's introduction is intended for chemists who are already familiar with traditional NMR methods. Nevertheless, these readers are likely to have difficulties with Chapters 2–4, which constitute the heart of the book. W. E. Hull's chapter on experimental aspects of two-dimensional NMR spectroscopy has been completely reorganized and enlarged to 357 pages. This and the new chapters by C. Griesinger and coauthors on proton-detected heteronuclear and multidimensional NMR spectroscopy, and by H. R. Kalbitzer on computer-aided analysis of multidimensional NMR spectra, together make up over half the book. However, these chapters are definitely for practising NMR spectroscopists! Even they will be impressed by the wealth of information, and will perhaps be surprised that they have missed so much that has occurred in the last few years.

W. E. Hull describes all the technical aspects: shim systems, locks, mechanical vibration effects, probe-heads, amplitude and phase modulation of r.f. pulses for selective excitation, suppression of solvent peaks, gradient echo spectroscopy. This is followed by an explanation of the fundamental principles of 2D NMR spectroscopy and of all the important homonuclear and directly-detected heteronuclear experiments. The description and comparison of the different acquisition methods for phase-sensitive experiments deserves a special mention. The author also makes an effort to avoid using software nomenclature that is specific to individual instrument manufacturers, and altogether this Chapter 2 is a very welcome contribution. I doubt if there exists any other treatment that is so detailed and comprehensive.

In Chapter 3 Griesinger and his coauthors round off their account by describing the latest highlights: proton-detected heteronuclear spectroscopy and the 3D NMR techniques. Their introduction to the product operator formalism seems rather too condensed, and this can be better understood by reading the original publications. In contrast the reverse methods (HMQC, HMBC, HSQC, double-INEPT) and their modifications for correlation experiments with improved sensitivity, constant time experiments, and spectral editing are described in great detail; product operators are used to describe the state of the spin system at critical points in the pulse sequences. The authors compare the effectiveness of phase cycles and pulsed field gradients for suppressing the signals of solvents and of protons attached to ^{12}C atoms. 3D NMR methods help to overcome problems of assignment and enable one to measure "J-values for homonuclear and heteronuclear couplings with improved accuracy.

Chapters 5–11 describe applications of many of the NMR techniques introduced earlier to special structural problems, with particular emphasis on the considerable increase in sensitivity obtained with the reverse procedures. Regrettably, however, there are no examples of the use of pulsed field gradients that would have illustrated the saving in time or the reduction of noise in the t_1 channel. These seven chapters will probably be sufficiently understood by chemists and biochemists working in the relevant areas, and should provide these readers with an excellent introduction to the capabilities and limitations of NMR spectroscopy. In a completely rewritten Chapter 5 H. Kessler and S. Seip describe the conformational analysis of peptides, now in a more general context and no longer concentrating solely on cyclosporin A. Some very nice examples of the use of DEPT-HMQC sequences are included. However, there is some lack of coordination between this chapter and the following one by H. J. Dyson and P. E. Wright on protein structure calculations based on NMR constraints; for example, the two chapters use completely different nomenclature systems to describe the NOE effect. There is an interesting discussion about the maximum size of a protein molecule whose structure can be determined by NMR spectroscopy (stated here as 30000 u); it is concluded that the limitation is due to the increased correlation time for molecular reorientation rather than to the severe overlapping of the resonances. Next there are chapters on the structural analysis of nucleic acids (I. Goljer and P. H. Bolton), oligo- and polysaccharides (J. Dabrowski), and steroids (W. R. Croasmun and R. M. K. Carlson), all well worth reading. In Chapter 10 P. L. Rinaldi discusses applications to structural problems in organic syntheses, giving as examples an organometallic compound, a Diels–Alder product, and a polymer, and considers the merits of different NMR strategies. He also describes triple resonance experiments whereby one can selectively detect the signals of ^1H or ^{13}C nuclei adjacent to a suitable isotopically labeled site (containing ^2H, for ex-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ample) or to a third NMR-active nucleus (e.g. ^{19}F, ^{31}P, or a suitable metal nuclide). In Chapter 11 G. E. Martin and R. C. Crouch describe examples in which the structures of natural products and compounds of pharmaceutical importance have been determined. These authors indicate that by using a microprobe head it may be possible to further reduce the amount of sample needed for an NMR analysis. They show examples of reverse 2D NMR spectra obtained with 10 μg samples in reasonable measurement times.

Lastly there is a glossary explaining nearly 300 of the acronyms that are so beloved by NMR spectroscopists. This book can be thoroughly recommended.

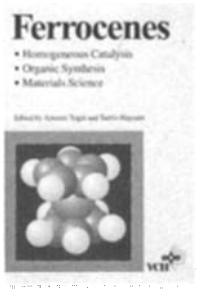
Ferrocenes. Homogeneous Catalysis. Organic Synthesis. Materials Science. Edited by *A. Togni* and *T. Hayashi*. VCH Verlagsgesellschaft, Weinheim, 1995. 540 pp., hardcover DM 248.00, $ 145.00.—ISBN 3-527-29048-6

M. Rosenblum's book *Chemistry of Iron Group Metallocenes* was published in 1965. Now, just 30 years later, we again have a new book on the same subject area, *Ferrocenes*, edited by A. Togni and T. Hayashi. In this monograph the editors have set out to cover the most important areas of research in which ferrocenes play a major role, and to extend and update the material in the ten volumes of the Gmelin Handbook devoted to ferrocenes, and in the annual reviews of ferrocenes research in the *Journal of Organometallic Chemistry*.



The book is divided into three parts: I. Homogeneous Catalysis, II. Organic Synthesis—Selected Aspects, and III. Materials Science. Chapter 1 of Part I (K.-S. Gan and T. S. A. Hor) describes the coordination chemistry and catalytic properties of 1,1′-bis(diphenylphosphano)ferrocene, and in the second chapter T. Hayashi continues this theme by describing the use of chiral ferrocenylphosphanes for asymmetric catalysis. Hayashi sets out clearly and concisely the reasons why chiral ferrocenylphosphanes are so important as catalysts and inductors in organic synthesis: the ferrocenylmethyl group of the side-chain contains suitable functional groups, the planar chirality of the 1,2-substituted ferrocene cannot racemize, both mono- and diphosphines can be prepared from the same chiral source, and lastly the characteristic orange-red color of the ferrocene derivative facilitates chromatographic work-up. Part I ends with a chapter on "Enantioselective Addition of Dialkylzinc to Aldehydes Catalyzed by Chiral Ferrocenyl Aminoalcohols" (Y. Butsugan, S. Araki, and M. Watanabe). Part II again begins with a report on chiral ferrocenes (Ch. 4, G. Wagner and R. Herrmann). However, it was not clear to me why this excellent contribution was not included in Part I, where synthetic aspects had already become an important part of the discussions.

In Chapter 5, "Ferrocene Compounds Containing Heteroelements" (M. Herberhold), the inorganic chemist's heart will certainly beat a little faster on discovering with pleasure that it contains all those compounds that would otherwise require laborious searching through the Gmelin volumes or recent original papers. It is especially commendable that this and several other chapters include some "Notes added in proof", bringing the book as up-to-date as possible by including references to publications appearing up to about August 1994. The resulting total number of references is around 2000, greatly easing the task of finding one's way into the primary literature.

However, in Chapter 6, "Macrocycles and Cryptands Containing the Ferrocene Unit" (C. D. Hall), the reader will suffer some disappointment, as this chapter compares poorly with the rest of the book. First one notices that the layout of the formula schemes is inconsistent, varying from page to page in size, quality, and line thickness. On two successive pages a σ-donor bond between sulfur and a metal ion is represented variously by a dashed line, a full line, and an arrowed line. Elsewhere ferrocene is shown as an iron atom between two cyclopentadienyl rings (represented by cpd) with no connection at all. On closer inspection one notices that about 50% of the structural formulas in this chapter are identical with the diagrams in a recent review article by P. D. Beer (*Adv. Inorg. Chem.* **1992**, *39*, 79–157). This becomes painfully obvious when small errors in symbols or in reproduction in Beer's review reappear at exactly the same positions in this chapter. But worse still, a detailed reading reveals that this copying is not confined to the formula diagrams, as some passages of text seem to have been reproduced from the above-mentioned article with only minor changes, and without acknowledging the source. For example, this is clearly seen in Section 6.4.2, which has only been very slightly altered and contains the same literature references in exactly the same sequence.

But these serious criticisms of Chapter 6 must not be allowed to give the impression that the style is typical of the book as a whole. On the contrary, the other authors' contributions are flawless and are convincingly presented. Chapter 7 (P. Zanello) gives a thorough account of the electrochemistry and structural characteristics of ferrocenes, and includes an extensive tabulation of redox potentials. Part III of the book, with the highly topical title "Materials Science", describes the many different aspects of ferrocenes as materials, ranging from charge-transfer complexes and magnetic materials (Ch. 8, A. Togni) through liquid crystalline compounds (Ch. 9, R. Deschenaux and J. W. Goodby) to organometallic polymers (Ch. 10, K. E. Gonsalves and X. Chen). These three chapters are especially enjoyable to read, as they afford a glimpse beyond the world of synthetic chemistry. After reading *Ferrocenes* it seems well justified to regard ferrocene as the organometallic counterpart of benzene in organic chemistry; this viewpoint helps one to understand why the range of topics treated in this book is so broad. On the other hand, this wide-ranging character might be seen by some readers as a disadvantage, because the ferrocene chemist, for whom this book with its wide coverage would be of greatest interest, does not really exist as such, and the individual chapters are more orientated towards the specialist. Nevertheless, this is a good book, and for that reason especially it is unfortunate that the high price is likely to restrict its effective market mainly to libraries and the above mentioned specialist.

The Chemistry of the Fullerenes. By *A. Hirsch*. Thieme, Stuttgart, 1994. 203 pp., paperback DM 80.00.—ISBN 3-13-136801-2

About ten years after the discovery of the fullerenes, and five years after they became available on a preparative scale, this book by A. Hirsch now gives us for the first time a well-written survey of the rapidly evolving chemistry of this new

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1995 0570-0833/95/3417-1904 $ 10.00+.25/0

allotropic (and molecular) form of carbon. The book covers the most important published work up to about the beginning of 1994, lucidly summarizing the results in nine chapters.

The first chapter gives a brief outline of the discovery of the fullerenes. The author describes the methods for preparing and isolating some important fullerenes and a few of their endohedral derivatives, and briefly discusses their structure and spectroscopic properties. Chapter 2 is concerned with reduced forms of fullerene-C_{60}, which are of special interest because of the extraordinary solid-state (superconducting) properties of alkali metal fullerides. Chapter 3 deals with nucleophilic addition of carbanions, amines, and hydroxide ions to fullerenes-C_{60} and -C_{70}. Special attention is given here to the important problems of regioselectivity, the initial step in additions to C_{70}, and multiple additions to the highly symmetrical C_{60}. Chapter 4 is devoted to the important organic cycloaddition chemistry of C_{60}, with a lucid treatment of [4 + 2]-, [3 + 2]-, [2 + 2]-, and [2 + 1]-cycloaddition reactions and the resulting products, as well as the possibilities for further functionalization of these fullerene derivatives. Chapter 5 is concerned with the hydrogenation of C_{60} and C_{70}. The available data on the many structural variations of constitutionally isomeric hydrogenation products and on their relative stabilities are systematically reviewed and are discussed from a theoretical standpoint. Chapter 6 discusses single and multiple additions of organic and organometallic free radicals to C_{60}, and the free radical-initiated formation of dimers and polymers. Chapter 7 deals with complexes formed by fullerenes with transition metals. Single and multiple additions of this kind can show considerable selectivity, and structural factors influencing this are briefly discussed. Chapter 8 discusses the complex oxygenation and oxidation chemistry of C_{60} and C_{70}, as well as reactions with halogens and other electrophiles. A separate section in this chapter is devoted to the pioneering work on the functionalization of fullerenes using osmium tetroxide. In the final chapter the author summarizes the general features of the reactive properties of C_{60} and C_{70}, and considers likely future developments in the chemistry of fullerenes (e.g. multiple addition products with controlled constitution, heterofullerenes, endohedral fullerenes).

This easily readable book gives an excellent insight into the still very rapidly developing chemistry of the fullerenes. It is mainly intended for chemists and materials scientists in academic and industrial laboratories, and provides a good coverage of the original literature, including much that is still novel and speculative. It is a highly valuable source of information both for those already working in the fullerenes area and for newcomers. I recommend everyone who wishes to learn about the current state of knowledge in fullerenes chemistry to buy this book.

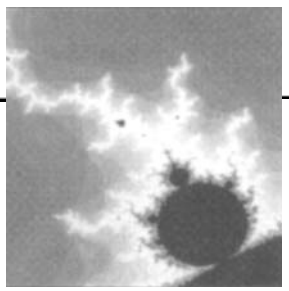
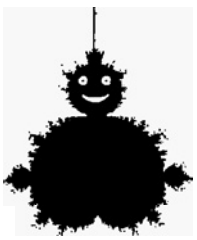
Chaos & Complexity
Discovering the Surprising Patterns of Science and Technology



1993. XXII, 593 pages with 257 figures, 2 in color
Hardcover. DM 148.-/öS 1154.-/sFr 140.-.
ISBN 3-527-29039-7 (VCH, Weinheim)
Softcover. DM 78.-/öS 608.-/sFr 75.-.
ISBN 3-527-29007-9 (VCH, Weinheim)



The surprising patterns of chaos and complexity are to be found in many areas of nature and science, examples ranging from cabbages to coastlines.

Quite often, those who could benefit most from an understanding of the principles behind chaos and complexity are denied access to the power and wonders of the field by the mathematical and unnecessarily convoluted way the topic is usually presented.

This book makes these sometimes complicated wonders accessible to students and professionals alike. Amusing tales and cartoons are used to explain the concepts and demonstrate the fascinating applications of this powerful technique.

Chemistry of Inositol Lipid Mediated Cellular Signaling**

Barry V. L. Potter* and Dethard Lampe

It is now slightly more than a decade since Michael Berridge and his collaborators reported in *Nature* "... micromolar concentrations of Ins(1,4,5)P_3 (1D-*myo*-inositol 1,4,5-trisphosphate) release Ca^{2+} from a non-mitochondrial intracellular Ca^{2+} store in pancreatic acinar cells. Our results strongly suggest that this is the same Ca^{2+} store that is released by acetylcholine". This observation ushered in a new era in the field of signal transduction with the discovery of a small-molecule second messenger linking the spatially separated events of cell surface receptor activation and intracellular Ca^{2+} mobilization. This event, which has spawned what is now one of the most active fields of current biology, also stimulated a renaissance in inositol and inositol phosphate chemistry. The synthesis of inositol polyphosphates presents a number of problems: the regiospecific protection of inositol and the optical resolution of the resulting precursors, the phosphorylation of the polyol, removal of all phosphate protecting groups without phosphate migration, and finally the purification of the water-soluble target polyanion. With the solution of these problems over the last few years it is now possible to look beyond the synthesis of naturally occurring inositol polyphosphates, whose number has been steadily increasing, to the design of chemically modified inositol phosphate analogues with the prospect of developing enzyme inhibitors, rationally modified receptor ligands and antagonists, and perhaps, through pharmacological intervention in signal transduction pathways, even the therapeutical agents of the future.

Keywords: inositol phosphates · second messengers · signal transduction

1. Transmembrane Signaling

The cells in multicellular organisms must communicate with each other in order to work together. They convey signals by using substances such as hormones and neurotransmitters (Fig. 1). Lipophilic hormones such as steroids, for example, can pass through the lipid bilayer of cell membranes and bind to their target receptors within the cell. Many chemical messengers, however, are too hydrophilic to cross membranes. In order to deliver their message they have to bind to specific receptors on the outside of the cell membrane and activate mechanisms that transmit the signal into the cell, a process known as transmembrane signaling or signal transduction. Several different classes of receptors are involved in signal transduction. If the receptor is linked to an ion channel, the opening of this channel can trigger the influx or efflux of ions into or out of the cell. A change of ion concentration in the cytosol will then activate cellular enzymes, evoking an ultimate response to the stimulatory cell surface ligand. Another class of receptor is the receptor tyrosine kinase, which is intrinsically an enzyme. It is embedded in the cell membrane and has binding sites able to recognize

[**] Abbreviations used in this review: All = allyl, Bn = benzyl, Bz = benzoyl, Cb = (*R*)-1-phenylethylcarbamoyl, Cbz = benzyloxycarbonyl, Gro = glycero, MEM = methoxyethoxymethyl, MOM = methoxymethyl, Ms = methylsulfonyl, Piv = pivaloyl, PMB = *p*-methoxybenzyl, Prop = prop-1-enyl, Ptd = phosphatidyl, Tf = trifluoromethanesulfonyl, TBDMS = *tert*-butyldimethylsilyl. All references to inositol refer to the *myo* isomer unless otherwise specified. Inositol phosphates are abbreviated Ins, Ins$P$, InsP_2, InsP_3, InsP_4, InsP_5, and InsP_6 (inositol, inositol mono-, bis-, tris-, tetrakis-, pentakis-, and hexakisphosphate, respectively), with positioning of phosphate groups, as indicated in parentheses. Deoxyfluoro analogues are identified by a prefix consisting of a number indicating the position at which the fluorine substitution has taken place and the letter F, e.g. 2-F-Ins(1,4,5)P_3 = 2-deoxy-2-fluoro-inositol 1,4,5-trisphosphate. Phosphorothioate analogues are similarly identified by a suffix including the letter S, e.g. Ins(1,4,5)P_3-5S = inositol 1,4-bisphosphate 5-phosphorothioate.

agonists on the outer surface, and an active site on the inner surface of the membrane. Binding of agonists activates the enzyme and leads to the phosphorylation of tyrosine residues on target proteins within the cell. This signal transduction mechanism is used by many growth factors and hormones including insulin.[1] Recently, the role of specific protein–protein interactions in mediating the flow of information from receptor tyrosine kinases to *ras* proteins was elucidated.[2]

Many water-soluble hormones make use of a signal transduction system whereby the receptor is coupled to the production of an internal signaling molecule via an intracellular effector. After the hormone binds to its receptor protein on the cell surface, a membrane-bound GTP-binding protein (G-protein),[3–5] which is associated with the receptor, is activated. The family of G-proteins includes several members which regulate different intracellular pathways. G-proteins are composed of three subunits designated α, β, and γ in order of decreasing mass. On activation, guanosine diphosphate (GDP) bound to the α subunit is replaced by guanosine triphosphate (GTP), causing the $\beta\gamma$ subunit to dissociate from the activated α-GTP subunit. The free subunits can now stimulate or inhibit other membrane-bound enzymes acting as amplifiers (e.g. K^+ channels, Ca^{2+} channels, adenylate cyclase (AC), guanylate cyclase (GC), PtdIns(4,5)P_2-specific phospholipase C (PtdIns-PLC)), which in turn generate so-called second messengers on the cytosolic side of the cellular membrane. The intrinsic GTPase activity of the α subunit then hydrolyzes GTP to GDP, the α-GDP subunit recombines with the $\beta\gamma$ subunit, and the G-protein returns to its basal state.

1.1. Second Messengers

Second messengers identified so far include adenosine 3′,5′-cyclic monophosphate (cAMP), guanosine 3′,5′-cyclic monophosphate (cGMP), diacylglycerol (DAG), Ins(1,4,5)P_3, and of course Ca^{2+} ions. Considerable current interest is also focused upon phosphatidylinositol 3,4,5-trisphosphate as a potential second messenger (see Section 2). Recent studies suggest that cyclic adenosine diphosphate ribose (cADP-ribose), a metabolite of NAD^+, may also have Ca^{2+}-mobilizing second messenger properties,[6–8] and the sphingolipid metabolite sphingosine 1-phosphate has been implicated as a potential second messenger in signal transduction pathways activated by certain mitogens.[9]

1.2. The Role of Ca^{2+} in Signal Transduction

The first indication that calcium ions play a role in the regulation of cellular events was an observation by Ringer in 1883.[10] On examining muscle tissue, he found that he could not induce contraction when he replaced the tap water in his medium with distilled water. The missing component was found to be Ca^{2+}.

Today, it is known that a large number of different cellular processes are controlled by protein phosphorylation induced by changes in intracellular Ca^{2+} concentration, and the mobilization of Ca^{2+} has been found to be the primary function of many

B. V. L. Potter

D. Lampe

Barry Potter was born in Brighton (UK) in 1953. He studied chemistry at the University of Oxford as an Exhibitioner of Worcester College, graduating with first-class honors and winning the Part II Thesis Prize in Organic Chemistry. He completed his doctorate in bioorganic chemistry in 1981 in Oxford under Professor Gordon Lowe with research on enzyme-catalyzed phosphoryl transfer reactions using chiral [^{16}O,^{17}O,^{18}O]phosphate esters. During that time he was a Graduate Scholar and subsequently Junior Research Fellow of Wolfson College. After postdoctoral research in nucleic acid chemistry and molecular biology as a European Exchange Fellow of the Royal Society with Professor Fritz Eckstein at the Max-Planck-Institut für Experimentelle Medizin in Göttingen, he accepted the post of Lecturer in Biological Chemistry at the University of Leicester in 1984 and was awarded a Lister Institute Research Fellowship in 1987. In 1990 he moved to the Chair of Medicinal Chemistry in the School of Pharmacy and Pharmacology, University of Bath, where he is Lister Institute Research Professor. He received his DSc from Oxford University in 1993. His fields of research activity lie in biological and medicinal chemistry, in particular enzyme mechanisms and nucleic acid and phosphorus chemistry. Special interests are the chemistry of second messengers and the synthesis of receptor ligands and enzyme inhibitors.

Dethard Lampe was born in Delmenhorst (Germany) in 1963. He studied chemistry at the Universities of Hamburg and Göttingen, where he obtained his diploma in clinical biochemistry in 1989 under Professor H.-D. Söling. In the same year he joined the research group of Dr. B. V. L. Potter in Leicester on a Wellcome Trust Prize Studentship. He moved to the School of Pharmacy and Pharmacology at the University of Bath in 1990 and completed his PhD on the synthesis of novel inositol phosphate analogues in 1993. He continued research in Bath in the area of inositol polyphosphates as a Wellcome Trust Prize Fellow. At the beginning of 1995 he moved to the Instituto de Química Orgánica General, CSIC (Prof. M. Martín-Lomas) in Madrid, where he is involved in the synthesis of biologically active oligosaccharides.

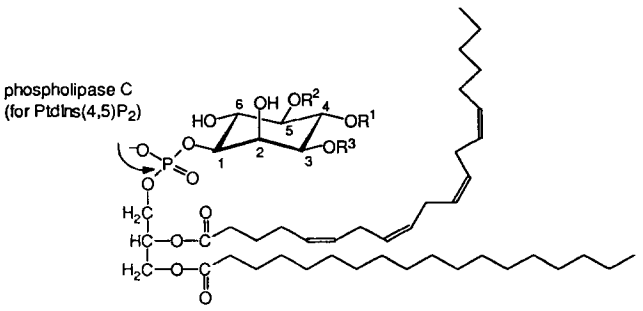
agonists. The cytosolic Ca^{2+} concentration can be regulated by two different mechanisms:

1. Many agonists operate by inducing a change in the potential difference across the membrane. This causes voltage-sensitive Ca^{2+} channels in the cell membrane to open. As most Ca^{2+} within the cell is bound to membranes or proteins, the intracellular level of free Ca^{2+} is low. Therefore there is a large gradient in favor of influx of ions into the cell and the cytosolic Ca^{2+} concentration is increased.

2. Other agonists mobilize sequestered Ca^{2+} from intracellular stores so that the Ca^{2+} concentration in the cytosol is increased and Ca^{2+}-dependent enzymes are activated. The cellular response effected depends on the type of cell targeted as well as the nature of the agonist.

2. Inositol 1,4,5-Trisphosphate: A Second Messenger

In 1850 Scherer isolated an optically inactive isomer of cyclohexanehexol from muscle, which he designated "Inosit".[11] Just over a century after this discovery and a few years prior to the discovery of the now well-established second messenger 3',5'-cyclic AMP by Rall and Sutherland,[12, 13] Lowell and Mabel Hokin demonstrated that acetylcholine stimulates the turnover of inositol-containing phospholipids in pancreas and brain cortex slices.[14] Folch had discovered the inositol-containing phospholipids in brain some ten years earlier.[15] Later work showed that the phospholipid effect described by the Hokins was observable in a number of other systems exposed to agonist stimulation, and this suggested a role for these lipids in stimulus–response coupling. In the late 1950s new analytical techniques facilitated the separation of the inositol-containing phospholipids into phosphatidylinositol (PtdIns), phosphatidylinositol-4-phosphate [PtdIns(4)*P*], and phosphatidylinositol-4,5-bisphosphate [PtdIns(4,5)P_2][16] (Fig. 2), and the chemical structures of these species were soon established by Ballou et al.[17] Despite this progress, little headway was made in understanding the physiological significance of the stimulated turnover of inositol-containing phospholipids in subsequent years, primarily since too much attention was given to the major phospholipid, PtdIns.



PtdIns: $R^1 = R^2 = R^3 = H$;
PtdIns(4)*P*: $R^1 = PO_3^{2-}$, $R^2 = R^3 = H$;
PtdIns(4,5)P_2: $R^1 = R^2 = PO_3^{2-}$, $R^3 = H$;
PtdIns(3)*P*: $R^1 = R^2 = H$, $R^3 = PO_3^{2-}$
PtdIns(3,4)P_2: $R^1 = R^3 = PO_3^{2-}$, $R^2 = H$;
PtdIns(3,4,5)P_3: $R^1 = R^2 = R^3 = PO_3^{2-}$

Fig. 2. Location of phospholipase C attack on inositol phospholipids.

A key breakthrough, however, came in 1975 when Michell[18] realized the connection between agonist-stimulated phospholipid turnover and the increased intracellular Ca^{2+} levels, which had already been in focus with regard to regulation of a variety of cellular functions. Despite this, there was no obvious contender for a chemical link between these events. Finally, at the end of 1983, Berridge and his co-workers in Cambridge, UK, and Frankfurt am Main, Germany,[19] identified the missing second messenger in the form of a *myo*-inositol polyphosphate generated from the minor phospholipid PtdIns(4,5)P_2 with the statement: "micromolar concentrations of Ins(1,4,5)P_3 (1D-*myo*-inositol 1,4,5-trisphosphate) release Ca^{2+} from a non-mitochondrial intracellular Ca^{2+} store in pancreatic acinar cells. Our results strongly suggest that this is the same Ca^{2+} store that is released by acetylcholine".

These discoveries opened up a whole new chapter in signal transduction and since then, progress in this field has been dramatic, as evidenced by the comment of Hokin:[20] "the phosphoinositide field is currently the number one field in biochemistry in the number of citations (excluding molecular biology)". Activity was still further stimulated by the mapping out of a highly complex metabolic pathway for inositol phosphates,[21, 22] including the involvement of higher inositol phosphates such as InsP_6 and even the pyrophosphate-containing InsP_7 and InsP_8.[23] Still more intriguing is the characterization of the new inositol-containing phospholipids PtdIns(3)*P*, PtdIns(3,4)P_2, and PtdIns(3,4,5)P_3 (Fig. 2) formed after the stimulation of a 3'-kinase in cells by growth factors.[24] The latter phospholipid, in particular, may be a second messenger in its own right. This whole area is under considerable scrutiny and appears to be a completely new branch of polyphosphoinositide-mediated signal transduction. Additionally, it was discovered that the cell nucleus appears to have its own autonomous phosphoinositide signaling machinery.[25, 26] Some of these newer aspects of the polyphosphoinositide signaling pathway have been reviewed.[27] Although a discrete molecule has yet to be structurally identified, much excitement has been generated recently by the discovery of a Ca^{2+} influx factor (CIF).[28, 29] CIF appears to be a diffusable messenger that is released from activated intracellular compartments in stimulated cells and stimulates Ca^{2+} influx across the plasma membrane.[30, 31] Also, attention is drawn to recent reports showing that the affinity of the *Penicillium brevicompactum* metabolites adenophostin A and B for the Ins(1,4,5)P_3 receptor is higher than that of Ins(1,4,5)P_3 itself[32–34] (Fig. 3).

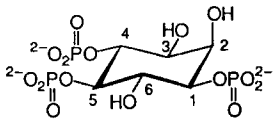


Fig. 3. The second messenger D-*myo*-inositol 1,4,5-trisphosphate.

While most of the rapid progress of the last ten years has been focused on biological aspects, it is clear that current and future efforts are, and will be directed towards pharmacological intervention in the phosphoinositide signaling system. First syntheses of Ins(1,4,5)P_3 were reported in 1986–1987, and these have been followed by significant synthetic progress to the extent that essentially all of the problems inherent to inositol phosphate

synthesis have now been overcome. The complex nature of inositol phosphate metabolism, however, which is still being uncovered, is providing new targets for synthesis with regularity. Moreover, receptors that bind second messengers, enzymes that metabolize them, and the generative pathways responsible for their formation are naturally seen as potential targets for rational drug design.[35-37] Thus, the focus of synthetic activity is now moving towards structurally modified inositol phosphates with novel biological properties.

This review focuses primarily on recent chemical progress in this area. Although attempts will be made to place the essential biological background in context, a completely comprehensive coverage of the biology of the past ten years is well beyond the scope of this article and the reader is referred to the many existing reviews[22, 38-47] and books[48-52] currently available on this topic. Several reviews and books on more recent aspects of the synthesis of inositol phosphates have also appeared.[53-56] For information on synthetic approaches prior to this, the reader is referred to two other major works.[57, 58]

3. Stereochemistry and Nomenclature of Inositol Derivatives

3.1. Stereochemistry and Nomenclature

After Scherer's discovery of "Inosit",[11] the suffix -ol was added, and when other isomers were discovered or synthesized they were also named "inositols". There are nine possible isomeric inositols, including one enantiomeric pair,[59] with the prefixes *scyllo*-, *myo*-, *neo*-, *epi*-, *cis*-, *muco*-, *allo*-, D-*chiro*-(+)-, and L-*chiro*-(−)- (Fig. 4). The large number of inositols and their derivatives has caused difficult problems of nomenclature, not all of which have been fully resolved. The publication of the "1967 IUPAC Tentative Rules for Cyclitols"[60] has gone a considerable way towards standardization, but difficulties still exist. Some aspects of these rules are outlined in the treatment of *myo*-inositol in the following section. Proposals were made that the system of stereospecific numbering should be adopted for inositol derivatives,[61] but these have not yet found widespread acceptance. A note on recent attempts to simplify nomenclature and abbreviations has appeared.[62] For a simplified discussion of this topic, the reader is referred to an excellent review.[63]

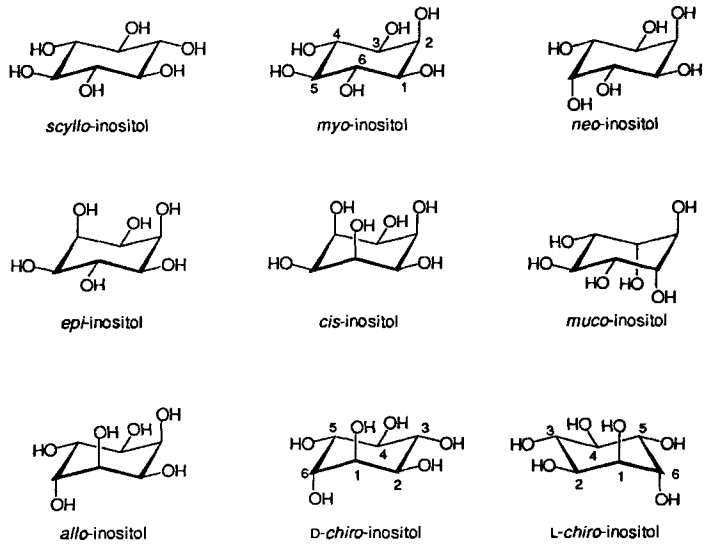

Fig. 4. The nine inositol isomers.

3.2. *myo*-Inositol

myo-Inositol is a *meso*-cyclohexane hexol, or cyclitol, and consequently possesses a plane of symmetry with five equatorial hydroxyl groups and one axial hydroxyl group. The carbon bearing the axial hydroxyl is designated C-2 and the other ring carbons can be numbered from C-1 to C-6 starting from a C-1 atom on either side of C-2 and proceeding around the ring in a clockwise or anticlockwise fashion. According to convention, an anticlockwise numbering in an asymmetrically substituted inositol leads to a configurational D prefix, and a clockwise numbering gives a substituted inositol with an L prefix. The choice of prefix is normally determined by giving preference to that which results in the lowest numbering of substituents. Thus, in *myo*-inositol the symmetry plane is through C-2 and C-5.

The substitution of one of the symmetry-related pairs of carbon atoms C-1, C-3 and C-4, C-6 gives rise to D and L enantiomers. Substitution of C-2 and/or C-5 clearly gives a *meso* product and a prefix is inappropriate. In Figure 5 the enantiomers of Ins(1,4)P_2 are shown. D-Ins(1,4)P_2 is an Ins(1,4,5)P_3 metabolite formed by phosphatase action, and L-Ins(1,4)P_2 is its synthetic enantiomer. The numberings shown were chosen since the alternatives, namely L-Ins(3,6)P_2 and D-Ins(3,6)P_2, have higher position numbers for the substituents. However, problems can arise when the IUPAC rules are adhered to strictly; in particular, when a metabolic pathway is traversed, confusing changes in nomenclature can occur. For example, D-*myo*-inositol-3,4-bisphosphate (name according to the IUPAC convention: L-*myo*-inositol-1,6-bisphosphate) is metabolized by phosphatases to the monophosphate L-*myo*-inositol-1-phosphate although the nonconventional name D-*myo*-inositol-3-phosphate allows more immediate appreciation of this fact. An IUPAC recommendation allowing all biologically relevant compounds to be denoted as D derivatives has now been proposed.[64] This convention, where possible, is adopted in this review.

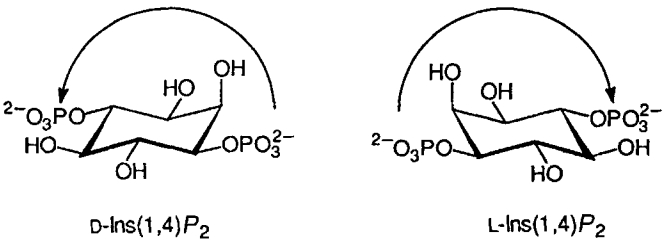

Fig. 5. The enantiomers of *myo*-inositol 1,4-bisphosphate.

4. Biosynthesis and Metabolism of *myo*-Inositol Phosphates

4.1. Biosynthesis of *myo*-Inositol

In humans the greater part of *myo*-inositol intake is from plants and only a small fraction is biosynthesized. De novo synthesis is, however, possible in both plants and animals by the isomerization of D-glucose 6-phosphate catalyzed by L-*myo*-inositol 1-phosphate synthase (D-*myo*-inositol 3-phosphate synthase). This enzyme was purified to homogeneity from yeast,[65] mammalian testis,[66,67] and brain.[68] The biosynthetic pathway has been reviewed[69,70] and stereochemical aspects have been discussed.[63] Surprisingly, the D-glucose-6-phosphate analogue D-glucose-6-phosphorothioate is not a substrate for L-*myo*-inositol-1-phosphate synthetase.[71]

myo-Inositol is then generated by the action of inositol monophosphatase on L-*myo*-inositol-1-phosphate. The monophosphatase is a key enzyme in the phosphatidylinositol cycle since it hydrolyzes both isomers of Ins(1)*P*; the L isomer arises by the above pathway and the D isomer by the hydrolysis of phosphatidylinositol phospholipids. It was shown that this single enzyme also dephosphorylates D- and L-Ins(4)*P* and in vitro Ins(5)*P*.[72] *myo*-Inositol monophosphatase was purified from brain[73-75] and an X-ray crystal structure of this enzyme has now been published.[76]

This enzyme is also of great current interest on account of its sensitivity to inhibition by lithium ions. It was observed in 1971 that levels of free *myo*-inositol decreased significantly in the brains of Li^+-treated rats.[77] Currently, links between the known therapeutic effects of lithium in the treatment of manic depression and its inhibition of *myo*-inositol 1-phosphatase are being actively sought. Since the brain does not have access to dietary *myo*-inositol, which cannot cross the blood–brain barrier, the de novo biosynthetic pathway via D-glucose 6-phosphate must be in effect. If the final stage in this pathway, the dephosphorylation of L-Ins(1)*P*, is blocked by lithium ions, the brain is unable to replenish its stores of phosphatidylinositol lipids, and the messenger system based on these lipids (see Section 4.2), which is used by neurotransmitters in cell signaling to alter electrical activity, is unable to operate. This is thought to be particularly important in hyperactive cells, as may also be the case in some forms of mania.[78,79] These important aspects have been reviewed.[80-82]

The inhibition of inositol-1-phosphatase by Li^+ ions[83] is unusual in that it is uncompetitive. Li^+ is thought to inhibit the second step of the dephosphorylation reaction, namely the breakdown of a phosphorylenzyme intermediate, possibly by coordination to an attacking water molecule at the active site, thus reducing its nucleophilicity.[83,84] It is clear that a better understanding of the molecular mechanism of Li^+ inhibition together with the crystal structure of the enzyme and the extensive medicinal chemistry which has now been carried out will go a long way towards assisting the rational design of mimics with potential antimanic properties. Several potent, albeit competitive, enzyme inhibitors have now been synthesized (see Section 9).

4.2. The Phosphatidylinositol Cycle

Inositol-containing phosphatides (Fig. 2) comprise less than 10% of the total phospholipid in animal cells. PtdIns is the most abundant (over 90%) and is primarily located in the endoplasmic reticulum (ER). The polyphosphoinositides PtdIns(4)*P* and PtdIns(4,5)P_2 are, together with a small proportion of PtdIns, located in the inner leaflet of the plasma membrane.

PtdIns isolated from plants has a different structure than that from animal sources. (The development of plant phosphoinositide signaling is beyond the scope of this article, but has been reviewed recently.[85]) In plants the *sn*-2 glycerol carbon is linked to the C_{18} fatty acid linoleic acid (18:2) and the *sn*-1 position is linked to fatty acids of the (16:0), (18:0), or (18:2) form. In contrast, in animals arachidonic acid (20:4) at C-2 and stearic acid (18:0) at C-1 predominate. PtdIns is phosphorylated by a specific kinase (PtdIns 4-kinase) to give the 4-phosphate PtdIns(4)*P*, which in turn is phosphorylated by another kinase (PtdIns*P* 5-kinase) to generate the key lipid PtdIns(4,5)P_2. On the other hand, specific phosphomonoesterases can dephosphorylate PtdIns(4)*P* and PtdIns(4,5)P_2.[86] Upon receptor activation the associated G-protein activates a membrane-bound phosphodiesterase (or phosphoinositidase), phospholipase C,[87] which cleaves PtdIns(4,5)P_2 into two second messengers, D-*myo*-inositol 1,4,5 trisphosphate (Fig. 3) and 1,2-di-*O*-acylglycerol (DAG), which together form a bifurcating signaling pathway. The hydrophilic Ins(1,4,5)P_3 diffuses into the cytosol and activates the receptor of a Ca^{2+} channel on the ER, resulting in the release of Ca^{2+} from an internal store (see Section 5).

The other product of this signaling pathway, DAG, was demonstrated to activate protein kinase C (PKC) by Nishizuka et al.[88,89] PKC was identified as the long-sought "receptor" for the tumor-promoting phorbol esters.[90] PKC was originally thought to be a single entity, but it is now clear that a large family of such protein kinase C isozymes exists.[91-93] DAG is hydrophobic, remains in the plane of the membrane, and can be metabolized by two major pathways involving a kinase or a lipase. In the first case the fatty acid moieties are conserved and DAG is phosphorylated to phosphatidic acid, which then combines with cytidine 5′-monophosphate (CMP) to form CMP-phosphatidate, which in turn can be coupled to a molecule of inositol to reform PtdIns. This reaction is catalyzed by the enzyme PtdIns synthetase. In the second case the DAG is hydrolyzed by a lipase to give a monoacylglycerol with the release of the eicosanoid precursor arachidonic acid,[94] used in prostaglandin synthesis. Structural aspects of the DAG limb of the signaling pathway have been studied by using DAG analogues,[95,96] and the structural requirements for PKC activation by lipids have been reviewed.[97]

Aside from the well-established phosphatidylinositol lipids discussed above, whose signaling involvement is now clear, a major new area has emerged recently due to the discovery of three phospholipids bearing a phosphate group at the D-3 position of the inositol ring. These lipids are PtdIns(3)*P*, PtdIns(3,4)P_2, and PtdIns(3,4,5)P_3 (Fig. 2). While their source has been the subject of some debate,[98] it is now accepted that direct phosphorylation of PtdIns(4,5)P_2 by a 3-kinase (PtdIns-3K)[99] is the main route of formation of PtdIns(3,4,5)P_3 in stimulated

cells. PtdIns(3)P and PtdIns(3,4)P_2 are derived from the parent PtdIns(3,4,5)P_3 by phosphatase action.[24, 100] The 3-phosphorylated lipids, unlike PtdIns(4,5)P_2, are not substrates for phospholipase C and thus cannot give rise to inositol phosphates as signaling molecules.[101] PtdIns-3K activation is intrinsic to mitogenic signaling by growth factor receptor tyrosine kinases[102] and has been implicated in signaling by many receptor and non-receptor protein tyrosine kinases.[103, 104] A distinctive second messenger role for PtdIns(3,4,5)P_3 is not yet apparent and the hunt is on for an intracellular effector. It may be possible that, like PtdIns(4,5)P_2,[105] PtdIns(3,4,5)P_3 interacts with the cytoskeleton.

4.3. Metabolism of *myo*-Inositol 1,4,5-Trisphosphate

Once released inside the cell, a second messenger must be efficiently deactivated in order to terminate its action and return the cell to a basal state in preparation for a new stimulus. Additionally, metabolites of the second messenger may well have physiological activities within the cell. These aspects have come under close scrutiny for Ins(1,4,5)P_3 in the past few years, and it has become clear that its metabolism to free inositol, which is then recycled into lipid synthesis, is quite complex, generating many inositol phosphates which are often difficult to separate. Only very basic features of this aspect of the PtdIns cycle will be discussed here. For more details the reader should consult the extensive reviews available.[21, 22, 106] The important features of Ins(1,4,5)P_3 metabolism are detailed in Figure 6.

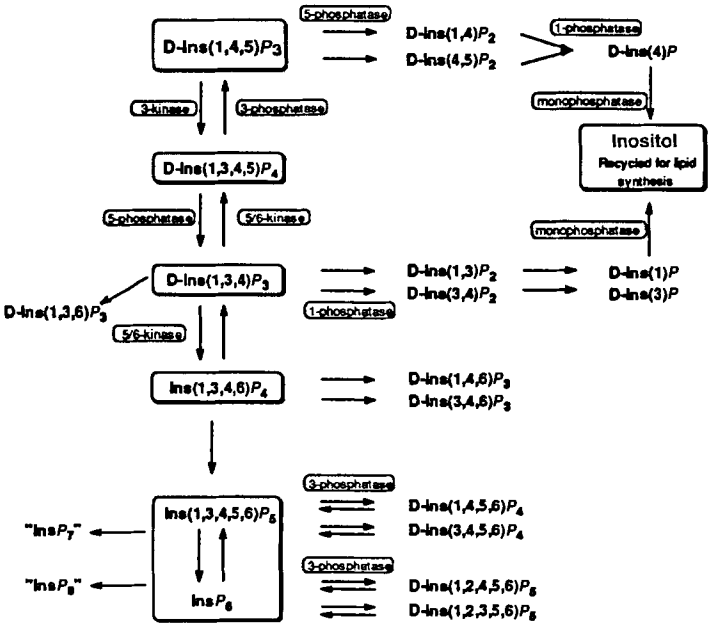

Fig. 6. Metabolism of inositol phosphates.

The PLC-mediated cleavage of PtdIns(4,5)P_2 is complicated by the fact that Ins(1,4,5)P_3 is not the sole hydrophilic product. Attack by H_2O on the phosphodiester linkage of PtdIns(4,5)P_2 gives Ins(1,4,5)P_3 and DAG, but cleavage may also be accomplished by attack of the 2-hydroxyl group at phosphorus, to yield inositol 1,2-cyclic-4,5-trisphosphate [Ins(1:2-cyclic 4,5)P_3], for example in thrombin-stimulated platelets.[107] Initial reports led to the suggestion that Ins(1:2-cyclic 4,5)P_3 is a second messenger in its own right,[108] but it proved impossible to confirm some of the earlier results.[109] The long half-life of Ins(1:2-cyclic,4,5)P_3 in parotid cells is also not compatible with a physiological function in Ca^{2+} release,[110] and its low concentration in some stimulated cells argues against an important messenger role for this compound.[111] There is no reason at present to assume that the production of Ins(1:2-cyclic 4,5)P_3 is anything other than an unavoidable and nonfunctional consequence of the mechanism of action of phospholipase C.[112]

The role of Ins(1,4,5)P_3 as a second messenger is now well established. Two major routes of metabolism have been discovered. It was known for some time that Ins(1,4,5)P_3 is metabolized by the action of a 5-phosphatase; this was first demonstrated in erythrocytes[113] and subsequently in many other cells.[21] There appear to be multiple types of this enzyme and both soluble, cytosolic forms and particulate, membrane-bound forms exist. Human platelet cytosol, for example, contains two 5-phosphatases, designated type I and type II, and the particulate type I 5-phosphatase from human placental membranes has recently been purified and characterized.[114] Since the product of the action of 5-phosphatase, Ins(1,4)P_2, has no known physiological role in this signaling pathway (there have, however, been reports that Ins(1,4)P_2 acts as an activator of DNA polymerase α[115] and 6-phosphofructo-1-kinase[116]), it seems clear that this enzyme acts merely to terminate the Ca^{2+} mobilization signal. Ins(1,4)P_2 is metabolized to Ins(4)P and subsequently converted to inositol, which reenters the cycle.

In 1985 the higher polyphosphate Ins(1,3,4,5)P_4 was discovered[117] closely followed by the 3-kinase enzyme,[118] which has been purified,[119, 120] sequenced, and cloned,[121, 122] adding a further complication to the metabolic pathway and initiating speculations about the possible function of this molecule. Despite fierce debate, no unambiguous role for this molecule has yet been elucidated. Readers are referred to recent reports on the topic.[123–126] Considerable controversy has been raised by the suggestion that Ins(1,3,4,5)P_4 acts as a second messenger in its own right and may be responsible for mediating the entry of extracellular Ca^{2+} through plasma membrane ion channels.[127] No end to this debate is yet in sight.

Whatever the function of Ins(1,3,4,5)P_4, it appears to be metabolized by the same 5-phosphatase as Ins(1,4,5)P_3. However, the situation is complicated by the existence of both soluble and particulate forms of the enzyme and more than one subtype of the former.[128] The particulate and type I soluble enzymes cleave both substrates and Ins(1,3,4,5)P_4 is a better substrate, but the type II enzyme has a very poor affinity for the tetrakisphosphate.[21, 128, 129] The product, Ins(1,3,4)P_3, has also been proposed to have a physiological function on the basis of a report that it is a moderately potent mobilizer of intracellular Ca^{2+}.[130] However, this was not confirmed[131] and there is no further evidence for a physiological role for this compound. The metabolism of Ins(1,3,4)P_3 is tissue-dependent. The products, Ins(1,3)P_2 and/or Ins(3,4)P_2, are subsequently converted into the monophosphates Ins(1)P and Ins(3)P, respectively, and these are ultimately dephosphorylated to inositol by inositol monophosphatase.

Studies on the action of Ins(1,3,4,5)P_4 have been complicated by the observation that in many tissues it can be converted to Ins(1,4,5)P_3 by a 3-phosphatase.[132, 133] It is now thought that InsP_5 and InsP_6 are the physiological substrates of this enzyme since these compounds are attacked with much higher affinity than Ins(1,3,4,5)P_4.[134] Ins(1,3,4,5)P_4 3-phosphatase was purified from hepatocytes[134] where it is compartmentalized inside the ER.[135]

Other metabolic pathways have also emerged. It is now apparent that Ins(1,3,4)P_3 can be phosphorylated by a 5/6-kinase to Ins(1,3,4,6)P_4,[136, 137] which has a weak, but distinct, Ca^{2+}-mobilizing activity.[138, 139] The 5/6-kinase will also convert Ins(1,3,4)P_3 to Ins(1,3,4,5)P_4. In animal cells Ins(1,3,4,5)P_4 is phosphorylated by 5/6-kinase to Ins(1,3,4,5,6)P_5, which is metabolized to three compounds, InsP_6 (phytic acid) and the normally inseparable enantiomeric pair Ins(3,4,5,6)P_4 and Ins(1,4,5,6)P_4. Ins(1,4,5)P_3 5/6-kinase was purified from liver with an InsP_6-linked affinity column.[140]

Such higher inositol polyphosphates have long been known to be present in plants and in avian erythrocytes[57, 70] where they function to provide phosphate storage and to modulate the oxygen affinity of hemoglobin. Their presence in mammalian cells, however, together with observations indicating that these compounds may provide intracellular and extracellular signals in brain[141, 142] indicate an interesting future for this area,[143] although it seems unlikely that these higher polyphosphates are directly involved in signal transduction. A physiological role for InsP_6 as an inhibitor of iron-catalyzed hydroxyl radical formation was suggested.[144] InsP_6 is, surprisingly, not the limit for phosphorylation, and evidence has been put forward for the existence of the pyrophosphate-containing higher polyphosphates InsP_7 and InsP_8,[23] which as yet have not been securely structurally characterized. These compounds apparently occur naturally in the slime mould *Dictyostelium*, but inositol polyphosphate pyrophosphates can also be generated by lyophilization of an inositol polyphosphate in the presence of a phosphoryl donor.[23] It seems certain that more surprises are in store.

To aid in the investigation of inositol polyphosphate metabolism in various tissues two major instrumental analytical methods were developed: one involves anion exchange HPLC[145] with on-line enzymatic hydrolysis of the phosphates, using a post-column reactor containing immobilized alkaline phosphatase, and molybdate detection of inorganic phosphate.[146] The other method relies on a metal-dye detection system not requiring dephosphorylation, in which trivalent transition metal ions are bound with high affinity to the dye 4-(2-pyridylazo)resorcinol and inositol phosphate polyanions.[147] This method permits picomolar-range detection of inositol phosphates.

Several NMR studies on inositol phosphates were also reported. Multinuclear NMR spectra were measured to confirm the structures and conformations of Ins(1,4,5)P_3,[148, 149] Ins(1,3,4,5)P_4,[149, 150] Ins(1,4,5,6)P_4,[151] InsP_6,[152] and a variety of lower inositol phosphates.[149] The data on phytic acid indicate that the conformation of this molecule varies with its degree of protonation. At high pH the molecule assumes a conformation having one axial and five equatorial phosphate groups, whereas between pH 2 and 5 it adopts a conformation with one equatorial and five axial phosphate groups, which is stabilized by intramolecular hydrogen bonding.

5. The Inositol 1,4,5-Trisphosphate Receptor

The inositol 1,4,5-trisphosphate receptor (InsP_3R) is now recognized to be a ligand-gated ion channel, activated by the binding of Ins(1,4,5)P_3 and gating Ca^{2+} (Fig. 7). In the last five years much information has accrued concerning the molecular structure of the InsP_3R, its distribution in tissues and in the cell, and its regulation.[153–158] In brain, Ins(1,4,5)P_3 receptors are highly expressed in cerebellar Purkinje cells, the hippocampus, striatum, and cerebral cortex. Peripherally, they were identified

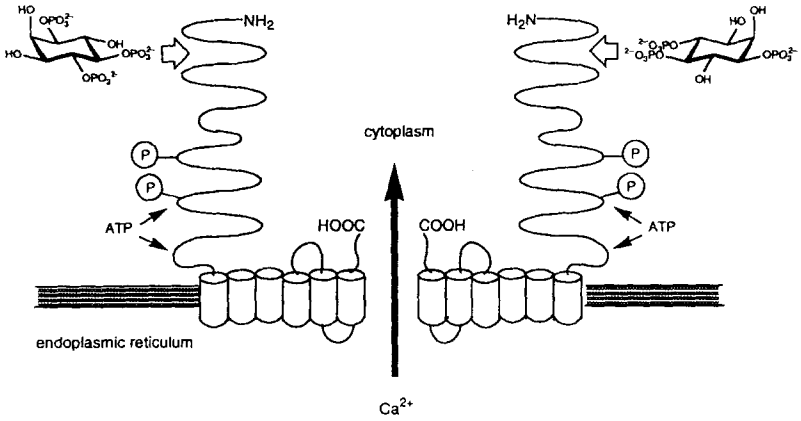

Fig. 7. Schematic representation of the Ins(1,4,5)P_3 receptor (cross section).

in the smooth muscle of arteries, uterus, and oviducts, as well as in the contractile smooth muscle of the intestine and esophagus. In Purkinje cells electron microscopy showed that the receptor is mainly associated with the smooth ER, but it is also present in the rough ER and outer nuclear membrane.

InsP_3R was purified in 1988 as two immunologically identical polypeptides: an Ins(1,4,5)P_3-binding protein[159] and the Purkinje cell enriched protein P_{400}.[160] Since then, cloning of the receptor cDNA from mouse,[161, 162] rat,[163, 164] *Drosophila*,[165] and human[164] has shown that the general structure of the receptor, first deduced from mouse cDNA, appears to be highly conserved. The receptor protein binds Ins(1,4,5)P_3 and activates Ca^{2+} channels, and reconstitution into lipid vesicles allowed the demonstration of Ins(1,4,5)P_3-gated Ca^{2+} transport.[166] The receptor is a homotetramer, as demonstrated by electron microscopy[167, 168] and cross-linking experiments.[168] Each subunit binds one molecule of Ins(1,4,5)P_3, as revealed by examination of deletion mutants,[169, 170] and InsP_3R apparently binds four molecules of Ins(1,4,5)P_3 in a noncooperative fashion;[159] however, contradictory finding have also been reported.[171]

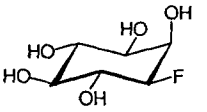
There is no homology between the primary sequence of InsP_3R and Ca^{2+} channels on the plasma membrane,[161, 172]

but a significant partial homology does exist with the ryanodine receptor of skeletal and cardiac muscle sarcoplasmic reticulum.[161, 173, 174] InsP_3R has a transmembrane domain close to the C-terminus with long N-terminal and short C-terminal portions projecting into the cytoplasm. Examination of the hydropathy profile of the highly conserved amino acid sequence suggests that the transmembrane domain has six[165] or eight[169] membrane-spanning regions. The large N-terminal region incorporates some 650 amino acid residues, which are highly conserved between species[161, 169, 170] and thought to contain the critical sequence that forms the three-dimensional Ins(1,4,5)P_3 binding site,[169, 170] since deletion of sequences within this region abolished Ins(1,4,5)P_3 binding activity. This region is enriched in positively charged arginine and lysine residues, which may have a role in binding the phosphate groups of Ins(1,4,5)P_3. A peptide labeled by an Ins(1,4,5)P_3 photoaffinity ligand has been isolated whose sequence matches that of the N-terminal 20% of InsP_3R.[175] Binding of Ins(1,4,5)P_3 must stimulate a large conformational change in the receptor, which spans almost 1400 amino acid residues from the extreme N-terminal Ins(1,4,5)P_3 binding site to the extreme C-terminal putative Ca^{2+} channel site.[153] The coupling region between the Ins(1,4,5)P_3 binding site and the Ca^{2+} channel contains sites that modulate the effect of Ins(1,4,5)P_3 on channel opening. Two serine residues present in this region can be phosphorylated by cAMP-dependent protein kinase,[153, 161, 176] which results in uncoupling Ins(1,4,5)P_3 binding from the opening of the Ca^{2+} channel in the cerebellar receptor. The receptor also binds equimolar amounts of ATP,[168] and ATP at low concentrations has a potentiating effect upon Ins(1,4,5)P_3-stimulated Ca^{2+} release. Ca^{2+} itself can also modulate channel opening, but by an unknown mechanism.[177]

InsP_3R is known to exhibit significant heterogeneity as a result of alternative mRNA splicing, giving receptors that differ in the coupling region and perhaps in the ligand binding domain. The original cerebellar receptor is now termed Type 1. New types of receptors encoded by separate genes were also reported.[164, 178] While Type 2 InsP_3R shares a significant homology with the Type 1 receptor, it has a higher affinity for Ins(1,4,5)P_3 and is 48 amino acids shorter.[164] A Type 3 InsP_3R was characterized from rats[179] and recently from humans[180] which has 63 and 64% identity with the Type 1 and 2 receptors, respectively. It is expressed in kidney, in the gastrointestinal tract, and in brain and binds Ins(1,3,4,5)P_4 and InsP_6 as well as Ins(1,4,5)P_3. A partial sequence for the C-terminal domain of a Type 4 receptor was reported.[156, 164] It is possible that the InsP_3Rs identified so far may only be the first examples of a larger family of receptors. If such receptors differ in their ligand binding affinities and specificity, they may offer an exciting prospect for the selective targeting of drugs.

6. Synthesis and Activity of Inositol Analogues

Inositol is taken up by many cells[181–183] and is incorporated into PtdIns by the enzyme PtdIns synthetase. The incorporation of synthetic analogues into phosphatidylinositol lipids offers an attractive route for pharmacological intervention in the signaling pathway. Since a large number of growth stimuli are now known to stimulate inositol lipid hydrolysis,[184] the presentation of fraudulent phospholipid species to the cell, especially those which cannot be further phosphorylated, could inhibit phospholipase C or reduce the availablity of PtdIns(4,5)P_2, thus affecting cell proliferation inter alia. A particular advantage of this route is that problems intrinsic to the introduction of highly charged phosphate-containing compounds into the cell are avoided. Fluorinated inositol analogues have proved to be particularly attractive in this respect.



1

Fig. 8. 1-Deoxy-1-fluoro-*myo*-inositol (**1**).

Kozikowski et al. prepared 1D-1-deoxy-1-fluoro-*myo*-inositol (**1**) (Fig. 8) from 1D-3-*O*-methyl-*chiro*-inositol in five steps, including fluorination with diethylaminosulfur trifluoride (DAST), via the 1,2:5,6-di-*O*-isopropylidene derivative. Direct regioselective fluorination of 1D-3-*O*-methyl-*chiro*-inositol with DAST followed by demethylation gave 1D-1,5-dideoxy-1,5-difluoro-*neo*-inositol.[185] The same group had earlier reported a ten-step synthesis of both enantiomers of 1-deoxy-1-fluoro-*myo*-inositol[186] by DAST fluorination at the 2-position of a suitably protected *myo*-inositol derivative and the optical resolution of the resulting fluoro-*scyllo*-inositol intermediate. Recovery of the *myo*-inositol configuration by Swern oxidation of the 1-hydroxyl group followed by stereospecific reduction of the keto function with L-selectride, gave, after deprotection of the respective enantiomeric intermediates, 1D- and 1L-1-deoxy-1-fluoro-*myo*-inositol.

The synthesis of 1D- and 1L-1-deoxy-1-fluoro-*myo*-inositol was also reported by Offer et al.[187, 188] Here, the problems of recovering the *myo*-inositol configuration and optical resolution were efficiently addressed in a single step by displacing a tosylate group of a fluorinated *scyllo*-inositol intermediate with (*S*)-(−)-cesium camphanate. The resulting diastereoisomers were separated and deprotected to produce the D- and L-1-fluoro analogues of *myo*-inositol. The respective 2-^{3}H-labeled analogues were prepared by an exchange of the tritium radiolabel from [2-^{3}H]-*myo*-inositol catalyzed by inositol dehydrogenase.[189]

1-Deoxy-1-fluoro-*scyllo*-inositol (**2**) (Fig. 9), the first fluorinated analogue of inositol,[190] was obtained from 1-*O*-benzoyl-3,4,5,6-tetra-*O*-benzyl-*myo*-inositol by treatment with DAST at elevated temperature and deblocking of the protected fluorinated *scyllo*-inositol intermediate. The preparation of **2** was subsequently described by another group.[191] Lowe and McPhee[192] reported the synthesis of **2** and 2-deoxy-2-fluoro-*myo*-inositol (**3**) together with their 2-^{3}H-labeled derivatives **4** and **5**. Fluorination of 1,3,4,5,6-penta-*O*-benzyl-*myo*-inositol with DAST proceeded with inversion at the 2-position to give the fluorinated *scyllo*-inositol, which was debenzylated with dry HBr to af-

ford **2**. In order to prepare **3**, the configuration at C-2 was inverted by triflation followed by displacement of the triflate moiety with sodium trifluoroacetate. Ester hydrolysis, reaction of the product with DAST, and deprotection produced **3**. Oxidation of 1,3,4,5,6-penta-*O*-benzyl-*myo*-inositol with Jones' reagent and reduction of the resulting inosose with $[^3H]NaBH_4$ gave predominantly the tritiated *scyllo*-inositol and some 1,3,4,5,6-penta-*O*-benzyl-2-[^{3}H]-*myo*-inositol. Treatment with DAST and deprotection as before gave **4** and **5**.[192] A synthesis of **3** and **5** reported by another group[189] followed a route similar to the one outlined above.

2-Deoxy-2,2-difluoro-*myo*-inositol (**6**) was prepared by oxidizing 1-*O*-allyl-3,6-di-*O*-benzyl-4,5-*O*-isopropylidene-*myo*-inositol to the corresponding 2-inosose, which was fluorinated with DAST to give the *gem*-difluoro derivative. Deprotection was carried out first by removal of the allyl and isopropylidene groups and subsequent hydrogenolysis.[191] Yang et al. used 1-*O*-benzoyl-3,4,5,6-tetra-*O*-benzyl-2-oxiranyl-*myo*-inositol to prepare 2-deoxy-2_{ax}-fluoro-2_{eq}-hydroxymethyl-*myo*-inositol (**7**)[193] and 2-deoxy-2-*C*-fluoromethyl-*myo*-inositol (**8**).[194]

The synthesis of the 2-mercapto [sulfanyl (IUPAC)] analogue **9** of *myo*-inositol was described:[195] Selective iodination of the 2-position of racemic 1,4,5,6-tetra-*O*-benzyl-*myo*-inositol using triphenylphosphine/imidazole/iodine proceeded with inversion of configuration. The free 3-hydroxyl group was silylated and the equatorial iodine displaced with sodium benzylsulfide, thus reestablishing the *myo*-inositol configuration. Fluoride-induced desilylation, debenzylation, acetylation of the crude product, purification, and methanolysis gave the thio analogue **9**.

Kozikowski et al. reported the synthesis of a number of enantiomerically pure inositol analogues modified at the 3-position (**18**–**25**, Fig. 10).[196–200] A two-step synthesis of 1D-3-deoxy-3-fluoro-*myo*-inositol (**18**) was possible by direct fluorination of L-quebrachitol (1L-2-*O*-methyl-*chiro*-inositol, **10**) with DAST,

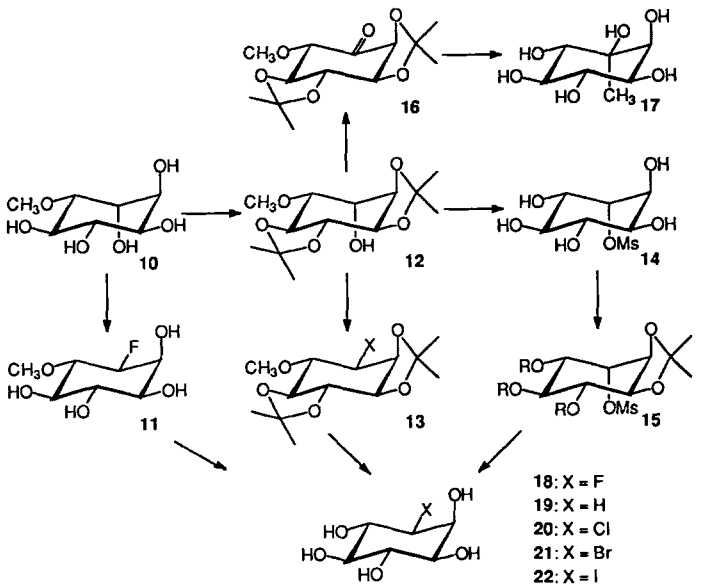

Fig. 10. C-3-modified D-*myo*-inositols from L-quebrachitol (**10**) (Kozikowski et al.).

resulting in selective reaction at the 1-position with inversion to give the *myo*-inositol configuration in **11**. Demethylation gave **18**.[196] D-3-Deoxy-*myo*-inositol (**19**) was prepared from L-3,4:5,6-di-*O*-isopropylidene-2-*O*-methyl-*chiro*-inositol (**12**) by treatment with 1,1′-thiocarbonyldiimidazole, tributyltin hydride, and finally boron tribromide.[198] Intermediate **12** was also employed in the preparation of the D-3-halogeno analogues **20**–**22**. The free hydroxyl group of this intermediate was displaced with inversion of configuration by activation with triphenylphosphine and employing CCl_4, Br_2, or I_2 as electrophilic sources of halogen. Deprotection of **13** (X = Cl, Br, or I) with boron tribromide furnished the corresponding D-3-halogenoinositols.[197] Compounds **23**–**25** were prepared by employing mesylate **15**, obtained from **12** via **14**.[198] Introduction of the azido group with inversion of configuration was achieved by displacing the mesylate in **15** (R = ethoxyethyl) with sodium azide/hexamethylphosphoramide (HMPA). Acid hydrolysis furnished D-3-azido-3-deoxy-*myo*-inositol (**23**), which could be converted into D-3-amino-3-deoxy-*myo*-inositol hydrochloride (**24**) by catalytic reduction in dilute HCl. The 3-mercaptoinositol **25** was obtained by reaction of **15** (R = Ac) with $(CH_3)_2NC(S)SNa$/HMPA, followed by reduction with $LiAlH_4$, and removal of the protecting groups. Oxidation of the hydroxyl group in **12** and treatment of the resulting ketone **16** with MeMgBr resulted in an axial attack to give the protected 3-*C*-methyl derivative, which was deblocked as described previously to yield **17**.[197]

The growth inhibitory properties of these inositol analogues on wild-type NIH 3T3 cells and v-*sis*-transformed cells were examined. v-*sis*-Transformed cells exhibit an increased PtdIns 3′-kinase activity and can therefore be expected to be more sensitive towards inhibitors of the PtdIns 3′-kinase signaling pathway than the nontransformed cells. Initial experiments[185] showed that D-3-deoxy-3-fluoro-*myo*-inositol (**18**) is a potent and selective inhibitor of cell growth, although the potency was decreased by about an order of magnitude in the presence of *myo*-inositol in the growth medium. The fluoro analogue was also found to act as a potent competitive inhibitor of [^{3}H]-*myo*-inositol uptake, suggesting that the compound is incorporated into inositol phospholipids. In further studies[197,198] on a number of C-3-modified D-*myo*-inositol analogues, D-3-azido-*myo*-inositol (**23**) was found to be highly potent (IC_{50} = 0.04 mM) and selective for v-*sis*-transformed cells (more than 1200-fold over the wild-type) in inositol-free medium. Addition of *myo*-inositol, however, caused a considerable decrease in the inhibitory properties of this compound, whereas the inhibition of growth by D-3-amino-3-deoxy-*myo*-inositol (**24**) was only moderately affected. Also investigated were D-3-deoxy-3-methylene-, -3-(hydroxymethyl)-, -3-(iodomethyl)-, and -3-phosphonomethyl-*myo*-inositol as well as the dimethyl ester of the latter compound; none of these analogues displayed any significant inhibitory activity.[199]

Both D- and L-4-deoxy-4-fluoro-*myo*-inositol were obtained from DL-1,3,4,5-tetra-*O*-benzyl-*myo*-inositol by selective tosylation of the 6-OH group, fluorination at C-2 with DAST (giving the *scyllo* derivative), and treatment with (*S*)-(−)-cesium camphanate (reestablishing the *myo*-inositol configuration by inversion at C-6 which becomes the new 2-position). The resulting mixture of two diastereoisomers could be separated by HPLC or

partial crystallization. Deprotection afforded D- and L-4-deoxy-4-fluoro-*myo*-inositol.[189] Whereas a ^{3}H-radiolabel could be introduced into the 2-position of the L isomer by employing inositol dehydrogenase and [^{3}H]-*myo*-inositol, the D isomer was not a substrate for this enzyme. The radiolabeled D analogue was prepared by oxidizing D-1,3,5,6-tetra-*O*-benzyl-4-deoxy-4-fluoro-*myo*-inositol, reducing the resulting 2-inosose with [^{3}H]$NaBH_4$, and removing the protecting groups. Syntheses of racemic 4-deoxy-, 4-deoxy-4-fluoro-, and 4-deoxy-4-methyl-*myo*-inositol employing a precursor obtained from benzene by microbial oxidation were also reported.[201]

6-*O*-Benzyl-1,2:3,4-di-*O*-cyclohexylidene-*myo*-inositol was employed in the preparation of 5-deoxy-5-fluoro-*myo*-inositol (**26**) (Fig. 11) by two different groups. DAST fluorination gave

Fig. 11. C-5-modified inositol analogues.

the product resulting from inversion of configuration and as well as minor amounts of that resulting from retention; the latter was deprotected to **26**.[202] This low-yield method was subsequently improved upon by inversion of configuration at the 5-position prior to DAST fluorination.[187, 188, 203] Thus, tosylation[187, 188] or triflation[203] of the 5-hydroxyl group followed by nucleophilic displacement with cesium propionate afforded the *neo*-inositol derivative. After saponification, fluorination with DAST reestablished the *myo*-inositol configuration and deprotection furnished **26**.

Deuteriation studies revealed that the equatorial H-2 proton of **26** is the one most rapidly exchanged.[203] Incubation of **26** with inositol dehydrogenase and [2-^{3}H]-*myo*-inositol led to an exchange of the radiolabel, which was again incorporated at the 2-position of the fluorinated analogue.[189] The 5-deoxy-5,5-difluoro analogue **27**[203] was prepared from the oxo derivative of 1,4,6-tri-*O*-benzyl-2,3-*O*-cyclohexylidene-*neo*-inositol, an intermediate in the synthesis of **26**.

Apart from the synthesis of **26** and **27** and *myo*-inositol analogues deoxygenated at positions 1, 4, and 5, Baker et al. also reported the preparation of further 5-deoxyhalogeno-*myo*- (**28**, **29**) and epimeric *neo*-inositols (**30**–**32**),[202] as well as racemic 4-deoxy-4-fluoro-*myo*-inositol. DAST fluorinations generally proceed with inversion of configuration,[204] but surprisingly, fluorination of the intermediate 3-*O*-benzyl-1,2:5,6-di-*O*-cyclohexylidene-*myo*-inositol gave predominantly the product of retention of configuration. This was rationalized as being due to steric hindrance to the backside attack of fluoride ion on the intermediate adduct with DAST.[202]

These inositol analogues were then evaluated as substrates and inhibitors of PtdIns synthetase,[205] as were a number of C-3-modified D-*myo*-inositols.[206] The enzyme showed very stringent requirements for the cyclitol substrate. All compounds examined were less effective substrates than *myo*-inositol. 5-Deoxy-5-fluoro-*myo*-inositol (**26**), the best analogue found in these studies, was incorporated into the cellular phospholipid at a rate equal to 26% of that of *myo*-inositol. Analogue **26** was further phosphorylated to give the corresponding 5-fluoro-PtdIns(4)*P* derivative but, not surprisingly, no lipid bisphosphate was detected. Other 5-deoxy-5-halogeno derivatives were very poor or inactive substrates. The 5-deoxy analogue **33**, however, was found to be well recognized. In the series of C-3-modified derivatives tested, D-3-amino- (**24**), D-3-fluoro- (**18**), and D-3-deoxy-*myo*-inositol (**19**) as well as the 3-oxo analogue were substrates for PtdIns synthetase,[206] albeit $\geq 90\%$ less well tolerated than the natural substrate. The general conclusion derived from these observations appears to be that substrate activity diminishes with increased steric bulk of the substituent. In the inhibition assay, the rank order of analogues was similar to their effectiveness as substrates, with the exception of 5-deoxy-5,5-difluoro-*myo*-inositol (**27**) which was not a substrate for PtdIns synthase but an effective inhibitor of the enzyme.

In another study[207] the inhibition of incorporation of [^{3}H]Ins into PtdIns by inositol analogues modified at the 1-, 2-, 3-, 4-, or 5-position was investigated. 1-Deoxy-1-fluoro-*scyllo*-inositol (**2**) and 5-*O*-methyl-*myo*-inositol (**34**) were found to be the most effective competitive inhibitors of both PtdIns synthase and a nucleotide-independent PtdIns/Ins exchange enzyme, whilst a number of other analogues also displayed significant inhibitory effects mainly on the exchange activity. Both [1-^{3}H]-1-deoxy-1-fluoro-*scyllo*-inositol (**4**) and [2-^{3}H]-2-deoxy-2-fluoro-*myo*-inositol (**5**) are very poor substrates for the two enzymes. However, once **5** was incorporated into the phospholipid, the corresponding analogues of PtdIns(4)*P* and PtdIns(4,5)P_2 could be detected.

Offer et al. investigated the uptake of ^{3}H-labeled monodeoxyfluoro-*myo*-inositols[189] into thymocytes and their incorporation into the phospholipid.[208] Only D-3-F-Ins **18**, 5-F-Ins **26** and to a lesser extent D-6-F-Ins showed activity as substrates for PtdIns synthase, and only **18** was both taken up actively into the cells and incorporated into the phospholipid. However, it was concluded that because of the overall selectivity for *myo*-inositol both by the uptake mechanism and by PtdIns synthase, monodeoxyfluoro analogues, unless made cell permeable, were unlikely to be of any use as inhibitors of PtdIns(4,5)P_2 formation or breakdown in intact cells.

Deoxy inositols were the subject of a report demonstrating chemoenzymatic methods for the synthesis of selectively protected derivatives of 3-deoxy-*epi*-inositol and 1-deoxy-*scyllo*-inositol, taking advantage of the preference of *Candida cylindracea* lipase for (*R*)-configurated esters.[209]

7. Synthesis of Specific *myo*-Inositol Phosphates

Recognition of Ins(1,4,5)P_3 as a second messenger has stimulated renewed interest in the chemistry of inositol phosphates. Many inositol phosphates had already been synthesized before this recent revival, and this earlier work has been discussed.[57, 58] In spite of this, some of the older procedures used were not entirely satisfactory. This was especially true for the phosphorylation of polyols, where the presence of vicinal diols

makes simultaneous polyphosphorylation difficult and encourages the formation of cyclic five-membered phosphates (for exceptions see ref.[210]). Nevertheless, Ins(4,5)P_2 was originally synthesized in 1961.[211] More recent work is covered in a new book.[56]

7.1. General Synthetic Considerations

Five distinct problems are intrinsic to inositol polyphosphate synthesis (Fig. 12): 1. Suitably protected derivatives must be prepared to facilitate later incorporation of phosphate groups at selected positions. 2. Since the D enantiomer of Ins(1,4,5)P_3 is

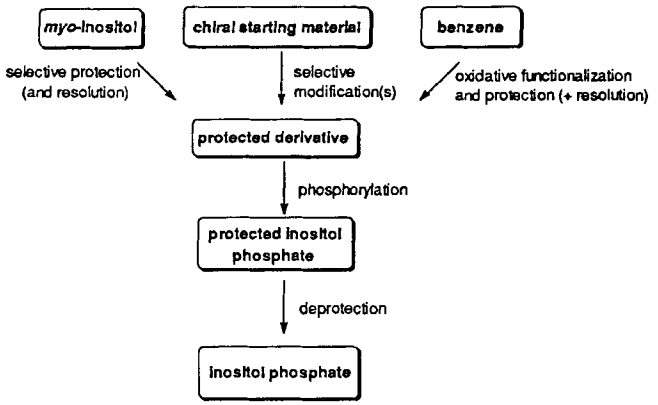

Fig. 12. Steps in the synthesis of inositol phosphates.

the natural messenger, such derivatives must be optically resolved. 3. An efficient phosphorylation strategy is required, which overcomes the difficulties associated with cyclic phosphate formation. 4. The phosphorylated intermediate must be deprotected under conditions that preclude any migration of phosphate groups onto neighboring hydroxyls. 5. The anionic polyphosphate must be efficiently purified and separated from minor potentially regioisomeric impurities, which might possess activity.

7.1.1. *Protecting Group Chemistry*

Protection strategies for the synthesis of inositol polyphosphates already have a long historical development,[57, 58] but several new approaches have been described.[212–218] The subject has been discussed in two review articles.[53, 54] The most popular temporary and permanent hydroxyl protecting groups are acetyl, benzoyl, benzyl, *p*-methoxybenzyl, allyl, isopropylidene, cyclohexylidene, and orthoformate. This will become apparent from examination of individual syntheses.

7.1.2. *Synthesis of Optically Active Compounds*

If benzene or the *meso* compound *myo*-inositol are used as starting material in the synthesis of inositol phosphates, optical resolution is required to separate D and L isomers of the inositol phosphate precursors. Most optical resolutions in the synthesis of inositol phosphates rely on the conversion of racemic inositol derivatives into a pair of diastereoisomers, which is then separated by crystallization or chromatography. Until recently, the procedures of Shvets,[219, 220] employing orthoesters of D-mannose **35** (Fig. 13), were the only methods available. Recent work, however, has highlighted the advantages of several other resolving agents such as (*S*)-(+)-*O*-acetylmandelic acid (**36**), (*R*)-(+)-camphor dimethyl acetal (**37**) and its (*S*) isomer, L-menthyl chloroformate (**38**), L-menthyloxyacetylchloride (**39**), and (*R*)-(+)-1-phenylethyl isocyanate (**40**). Optical resolution by formation of camphanates seems to be the most generally useful method available at the present time, and both (*S*)-(−)-camphanic acid chloride (**41**) and its (*R*)-(+) isomer have been employed to obtain optically active inositol derivatives. Chiral HPLC columns were used to resolve intermediates in syntheses of Ins(1,3,4)P_3[221] and Ins(1,3,4,5)P_4.[222]

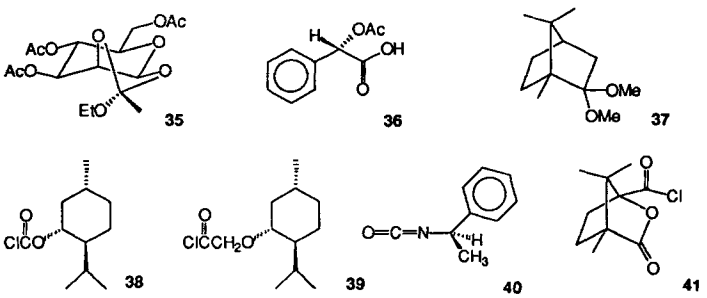

Fig. 13. Agents employed in inositol phosphate synthesis for optical resolution.

In a number of studies, enzymes such as esterases, lipases, and proteases were examined for their ability to hydrolyze enantio- and regioselectively racemic or *meso* carboxylic esters of *myo*-inositol,[223–226] 3-deoxy-*epi*-inositol and 1-deoxy-*scyllo*-inositol.[209] A new method is enzyme-catalyzed selective esterification, which was applied to resolve racemic 1,2:5,6- and 1,2:3,4-di-*O*-cyclohexylidene-*myo*-inositol,[227, 228] and to obtain enantiomerically pure D-1-*O*-butyryl-4,6-di-*O*-benzoyl-*myo*-inositol.[229]

The problem of optical resolution can be avoided altogether by employing chiral starting materials, for example naturally occurring compounds such as L-quebrachitol (**10**), D-3-*O*-methyl-*chiro*-inositol (**42**), (−)-quinic acid (**43**), D-glucurono-6,3-lactone (**44**), and galactinol (**45**) (Fig. 14). The Ferrier reac-

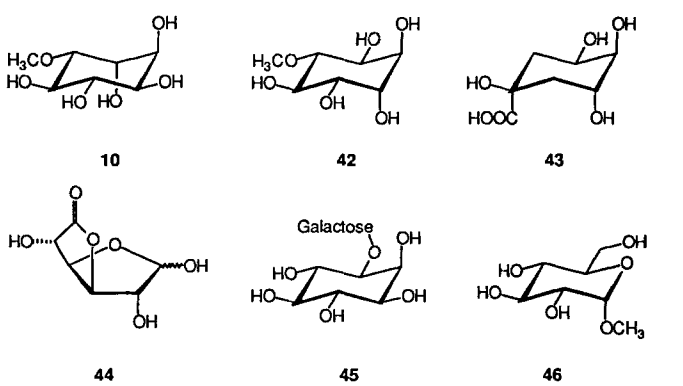

Fig. 14. Chiral starting materials for the synthesis of inositol phosphates.

tion[230] has been used to generate *myo*-inositol derivatives from D-galactose,[231] D-glucose,[232–234] and in a biomimetic approach from methyl α-D-glucopyranoside (**46**).[235, 236] A samarium diiodide promoted reductive carbocyclization of an intermediate derived from D-mannitol was employed to gain access to enantiomerically pure *myo*-inositol derivatives.[237]

7.1.3. Phosphorylating Agents

Phosphorylation of free hydroxyl groups in suitably protected inositol is performed primarily by two methods: a) employing a P^V reagent in which the phosphorus atom is already at the correct oxidation level, and b) phosphitylating the hydroxyl group with a P^{III} reagent and then oxidizing the resulting phosphite ester to give the protected phosphate ester (Fig. 15).

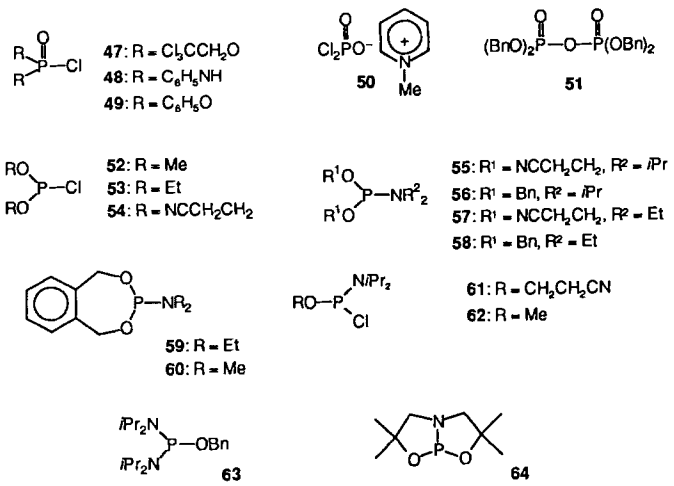

Fig. 15. Phosphorylating and phosphitylating reagents.

The advantages of P^V reagents for phosphorylation are the relative stability of reagent and products. However, problems have been encountered because of the low reactivity of the secondary hydroxyl groups of inositols; the phosphorylation of vicinal diols has proved to be especially difficult. The intermediate phosphate triesters formed upon phosphorylation of the first free hydroxyl group are prone to attack by the neighboring second hydroxyl group. The bulkiness of most P^V reagents may prevent a second reagent molecule from gaining access to the phosphorylation site after monosubstitution of the diol has taken place. Cyclization reactions are therefore able to compete successfully with substitution at the second hydroxyl group, affording five-membered cyclic phosphates rather than the desired bisphosphates.

Phosphorus(v) oxychloride was first used as a phosphorylating reagent in 1857[238] and more recently in a stepwise phosphorylation of the vicinal 4,5-diol in *myo*-inositol derivatives with two P^V reagents.[239] Phosphorylation with bis(2,2,2-trichloroethyl)phosphorochloridate (**47**) only gave a mixture of the 4- and 5-monophosphorylated inositols but not the bisphosphate presumably due to steric hindrance. When $POCl_3$ was used, however, this mixture could be converted into the mixed 4,5-bisphosphate triesters. Phosphorochloridate **47** was also applied in the preparation of Ins(1,4,5)P_3 and its 5-phosphorothioate analogue.[240–242] Dianilidophosphorochloridate (**48**) was used in the first reported synthesis of D-Ins(1,4,5)P_3;[243] however, this phosphorylation method and the removal of the protecting groups with isoamyl nitrite in pyridine/acetic acid/acetic anhydride was unsatisfactory. Diphenyl phosphorochloridate (**49**) was employed in many phosphate ester preparations, including an early synthesis of Ins(2)P[244] and the synthesis of L-Ins(1)P.[245]

Phosphorodichloridates can react with two different partners, thus forming a phosphate bridge between these moieties. As phosphodiester links are common features of many natural compounds (e.g. oligonucleotides and phospholipids), a number of phosphorodichloridates were developed for the synthesis of these substances. *N*-Methylpyridinium phosphorodichloridate (**50**) was employed in the synthesis of Ins(1:2-cyclic)P.[246]

Polyphosphates and mixed anhydrides are widely used although they react nonspecifically and often lead to the formation of cyclic phosphates or other side products. Phosphoric acid, potassium hydrogen phosphate, and pyrophosphoric acid were all employed in syntheses of carbohydrate phosphates; the latter was also used to phosphorylate *epi*- and *muco*-inositols.[247]

Tetrabenzyl pyrophosphate (TBPP, **51**)[248] is a commercially available crystalline solid formed by condensation of two equivalents of dibenzyl phosphate with dicyclohexylcarbodiimide (DCC). It is the only P^V reagent that has been employed successfully in inositol phosphate chemistry for the phosphorylation of vicinal diols.[249–251] For efficient phosphorylation with TBPP, it is necessary to convert the free hydroxyl groups into alkoxides. The strongly basic conditions can cause problems with some compounds and lead to decomposition.

P^{III} reagents are more reactive than most P^V reagents. Good results were obtained by phosphitylation with P^{III} reagents and subsequent oxidation in cases where P^V reagents failed to give the desired products, for example phosphorylation of vicinal diol precursors to Ins(1,4,5)P_3. The formation of undesired cyclic phosphodiesters is avoided. One further advantage of the P^{III} approach is that the phosphite triesters can be sulfoxidized by elemental sulfur in pyridine[252] or by phenacetyl disulfide,[253] thereby also making available phosphorothioates, which were shown to be useful nonhydrolyzable analogues of nucleotides[254] and inositol phosphates (see Section 8.4).

Although phosphorochloridites are unstable towards moisture, they have found widespread use in inositol phosphate synthesis. Dimethoxychlorophosphine (**52**) was employed in preparations of Ins(1,4,5)P_3, Ins(1,3,4,5)P_4, and Ins(1,4,5,6)P_4,[255] diethoxychlorophosphine (**53**) for Ins(1,2,4,5)P_4,[256] and di(2-cyanoethoxy)chlorophosphine (**54**) for Ins(1,3,4)P_3.[257]

The more stable phosphoramidites are used under catalytic activation by a weak acid (1*H*-tetrazole). Compounds **55**–**57** are examples of these reagents. The use of di(benzyloxy)-(diethylamino)phosphine (**58**) was considered to be less advantageous than **56**, since the latter can be easily purified by column chromatography.[258]

3-Diethylamino-2,4,3-benzodioxaphosphepane (**59**),[259] prepared by the reaction of hexaethylphosphorus triamide with 1,2-bis(hydroxymethyl)benzene, and the related dimethylamino

compound **60** are increasingly applied in preparations of inositol phosphates. 2-Cyanoethoxy(diisopropylamino)chlorophosphane (**61**) and the corresponding methoxy derivative **62** have also been extensively used, the former inter alia in syntheses of Ins(1,4,5)P_3 and Ins(4,5)P_2.[260-262] The phosphoramidites initially obtained are usually converted into phosphite triesters prior to oxidation. As bifunctional P^{III} reagents, **61** and **62** are also suitable for the preparation of phosphorothioate analogues of inositol phospholipids.[263-265] The same is true of **63**, which was employed by van Boom et al. in syntheses of a PtdIns(4,5)P_2 analogue[266] and an inositol-containing mycobacterial phospholipid.[267] Finally, the less conventional aminobicyclophosphane **64** was employed in the synthesis of inositol monophosphates.[268]

The efficiency of different methods for the oxidation of phosphite triesters was studied;[269] in inositol phosphate chemistry this transformation is usually effected with *tert*-butyl hydroperoxide (*t*BuOOH) or *m*-chloroperoxybenzoic acid (*m*-CPBA).

7.1.4. Deprotection and Purification

In order to avoid migration of protected phosphate esters to adjacent free hydroxyl groups it is essential to deblock the phosphate groups prior to the alcohols. When benzyl groups are used for protection of both hydroxyls and phosphates, deprotection in one step is possible, since the benzylphosphate esters are cleaved much more rapidly.[270] Purification after the protecting groups are removed with sodium/liquid ammonia usually involves anion-exchange chromatography. It may be possible, however, to obtain the final compound without further purification by catalytic hydrogenolysis.

7.2. Inositol Monophosphates

Four possible *myo*-inositol monophosphates exist: the symmetrical 2- and 5-phosphates and the two enantiomeric pairs inositol 4(6)-phosphate and 1(3)-phosphate. Many syntheses of racemic and optically active *myo*- and other inositol monophosphates have been published prior to and after the demonstration that the hydrolysis of brain phosphoinositides gives D-Ins(1)*P*.[271, 272] Such earlier synthetic work has been reviewed.[53, 57]

The D[273, 274] and L enantiomers[273] of Ins(1)*P* were prepared from 1L-quebrachitol (**10**) via 1L-3,4:5,6-di-*O*-cyclohexylidene-2-*O*-methyl-*chiro*-inositol. For the synthesis of D-Ins(1)*P*, this compound was oxidized to the inosose which was stereoselectively reduced to give D-1,2:5,6-di-*O*-cyclohexylidene-4-*O*-methyl-*myo*-inositol. In a six-step sequence, this intermediate was converted into the 1-silyl pentabenzoate. Desilylation, phosphorylation, and successive deblocking gave D-Ins(1)*P*. In addition, L-Ins(1)*P* [= D-Ins(3)*P*] was obtained from **12** via the 1-tosylate. An elegant route to D-Ins(1)*P*[275, 276] involved resolution of inositol by formation of the *myo*-inositol-D-camphor 2,3-acetal and selective phosphorylation of the 1-OH group with dibenzyl phosphorochloridate. L-Ins(1)*P* was accessible by using the L-camphor dimethyl acetal.[276] Optically active Ins(1)*P* was also synthesized from 1,2,4,5,6-penta-*O*-benzyl-*myo*-inositol [resolved as the (*R*)(−)-camphanate][270] and the corresponding pentaacetate (resolved as the acid oxalate),[277] which was also used in the synthesis of racemic Ins(1)*P*.[278] DL-Ins(1)*P* could be resolved on a chiral GC column after persilylation.[279]

Ins(2)*P* was first synthesized by taking advantage of the highly selective oxidation of *myo*-inositol to *scyllo*-inosose by *Acetobacter suboxydans*.[244] A more recent approach relied upon selective dibenzylation of the 4- and 6-OH groups of *myo*-inositol orthoformate and phosphorylation of the free 2-OH groups with TBPP.[280]

Synthesis of Ins(4)*P* was possible by selective benzoylation of the 3-OH group of 1,2:4,5-di-*O*-cyclohexylidene-*myo*-inositol, phosphorylation of the remaining free hydroxyl group, and deprotection.[211, 220] The corresponding 3-*O*-benzyl derivative was also used to produce racemic and, after resolution via its camphanate, optically active Ins(4)*P*.[270] A short synthesis of DL-Ins(4)*P* by chelation-controlled selective phosphorylation of the monoanion of *myo*-inositol orthoformate[281] with TBPP was reported.[280, 282] Reaction of 1,2-*O*-cyclohexylidene-*myo*-inositol with 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane gave selectively the 3,4-disiloxanylidene-inositol, which was benzoylated at the 6-position. Whereas reaction with TBPP resulted in phosphorylation at the 6-position due to benzoate migration and gave racemic Ins(4)*P* after deblocking, phosphitylation with PCl_3 and benzyl alcohol, followed by oxidation and deprotection furnished Ins(5)*P*.[283] The latter was first prepared from 2-amino-2-deoxy-*neo*-inositol,[211] which was obtained by hydrolysis of hygromycin A.

D-Ins(1,2-cyclic)*P* was synthesized from D-3,4,5,6-tetra-*O*-benzyl-*myo*-inositol by reaction with **50**.[246] Direct phosphorylation of inositol with bicycloaminophosphane **64** followed by oxidation of the resulting bicyclophosphorane, which has a five-coordinate P atom, and acid hydrolysis gave mixtures of Ins(1)*P*, Ins(2)*P*, and Ins(1,2-cyclic)*P* separable by HPLC.[268]

7.3. Inositol Bisphosphates

The synthesis of racemic inositol 1,4-, 1,6-, and 4,5-bisphosphates by phosphorylation of di-*O*-cyclohexylidene-inositols biscyclohexylidene acetals with phosphorochloridate was described as early as 1961.[211] Enantiomerically pure bisphosphates were prepared by employing the optically active diacetals obtained by resolution with orthoesters of D-mannose.[284]

Ins(1,3)P_2 was synthesized by regioselective phosphorylation of 2,4,6-tri-*O*-benzyl-*myo*-inositol using chlorophosphate **49**.[270, 280] The 1,3-bisphosphorylated product was crystallized from the mixture of 1,3- and 1,5-bisphosphorylated products. Deprotection with lithium in liquid ammonia gave Ins(1,3)P_2. Racemic Ins(1,4)P_2 was prepared by phosphitylation of 1,2:4,5-di-*O*-isopropylidene-*myo*-inositol with chlorophosphine **61**, conversion of the product into a bisphosphite ester, oxidation, and deprotection.[285] As an alternative to the resolution of 1,2:4,5-di-*O*-cyclohexylidene-*myo*-inositol via orthoacetates,[286] formation of chromatographically separable dicamphanates gives access to the enantiomers of Ins(1,4)P_2.[251] A short route to D-Ins(1,4)P_2 from *myo*-inositol D-camphor 2,3-acetal was reported.[276, 287] D-Ins(1,4)P_2 was also obtained semisynthetically by periodate treatment of deacylated phos-

phoinositides.[288] The two enantiomers of Ins(1,5)P_2[289] were synthesized from D- and L-1,2,4,6-tetra-*O*-benzyl-*myo*-inositol and **57**. Resolution of the tetrabenzyl compounds obtained by selective benzylation of 2,4,6-tri-*O*-benzyl-*myo*-inositol was possible via the mono-(−)-camphanates. DL-Ins(4,5)P_2 was prepared from 1,2,3,4-tetra-*O*-benzyl-*myo*-inositol by a P^{III} approach.[262, 290] Conduritol B derivatives obtained from benzene have also been used.[291]

7.4. Inositol Trisphosphates

7.4.1. *Inositol 1,4,5-Trisphosphate*

Not surprisingly, most attention has been focused upon the synthesis of Ins(1,4,5)P_3, which is still by far the most important inositol phosphate biologically. The first synthesis of D-Ins(1,4,5)P_3 was reported by Ozaki et al. in 1986 (Fig. 16).[243]

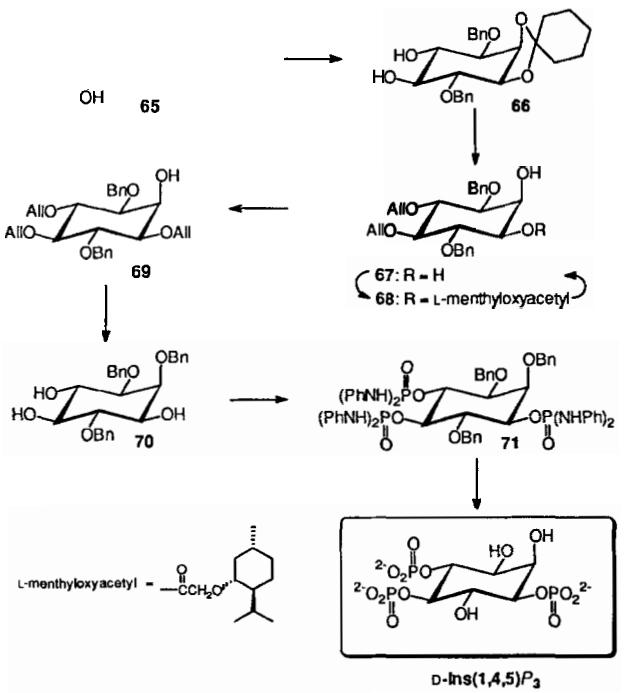

Fig. 16. The first synthesis of D-Ins(1,4,5)P_3 (Ozaki et al.)

DL-1,2:4,5-Di-*O*-cyclohexylidene-*myo*-inositol (**65**) was benzylated and the *trans*-4,5-acetal selectively removed to afford **66**. Allylation and acid hydrolysis of the remaining *cis*-acetal gave the 1,2-diol **67**, which was resolved by conversion into the diastereomeric esters **68**. Regioselective allylation of D-**67** gave **69**, which was benzylated and deallylated to yield **70**. Phosphorylation with **48** provided **71**, and deblocking of phosphate and hydroxyl groups with isoamyl nitrite and H_2/5% Pd–C, respectively, gave D-Ins(1,4,5)P_3. The use of TBPP **51** or phosphoramidite **59** allowed significant improvements to this synthesis.[292]

Racemic Ins(1,4,5)P_3 was subsequently synthesized[260, 261] by modified routes to triol **70**[213, 214] and by employing a P^{III} approach (Fig. 17). Thus, **72** was dibenzylated and the acetals

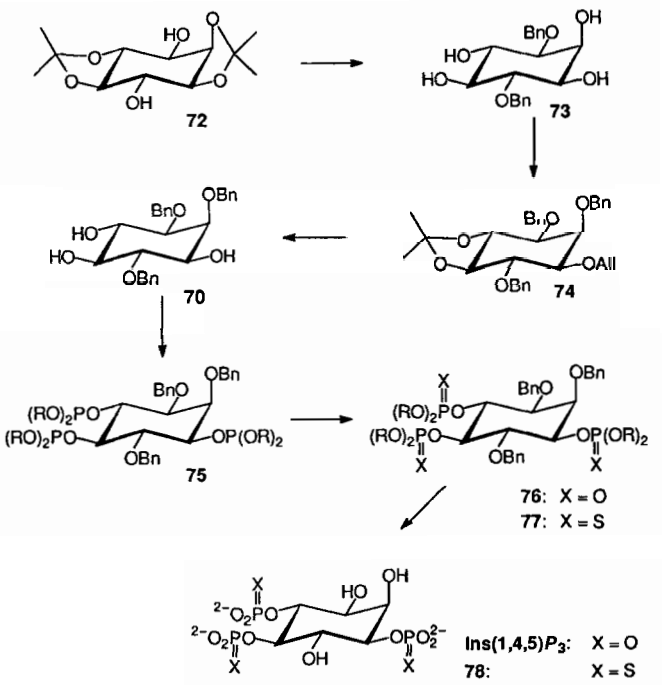

Fig. 17. Syntheses of Ins(1,4,5)P_3 and Ins(1,4,5)PS_3 by a P^{III} approach (Cooke et al.) R = CH_2CH_2CN.

removed to give **73**. Conversion to the fully protected derivative **74** required tin-mediated allylation of the 1-OH group, formation of the 4,5-acetal, and benzylation of the 2-OH group. Isomerization of the allyl group in **74** and hydrolysis of acid-labile protecting groups furnished triol **70**, which was phosphitylated with **61**, converted into **75**, and oxidized to **76**. All protecting groups were removed in one step by reaction with sodium in liquid ammonia to give DL-Ins(1,4,5)P_3. When resolved D-[214] and L-1,2,4-tri-*O*-benzyl-*myo*-inositol were employed, L-Ins(1,4,5)P_3[261] and D-Ins(1,4,5)P_3[293] were obtained, respectively.

D- and L-Ins(1,4,5)P_3 were also prepared from **79** (Fig. 18) by phosphorylation with **48** to give **80**, removal of the ketal, and resolution of the resulting intermediate via **81**. The 1-hydroxyl

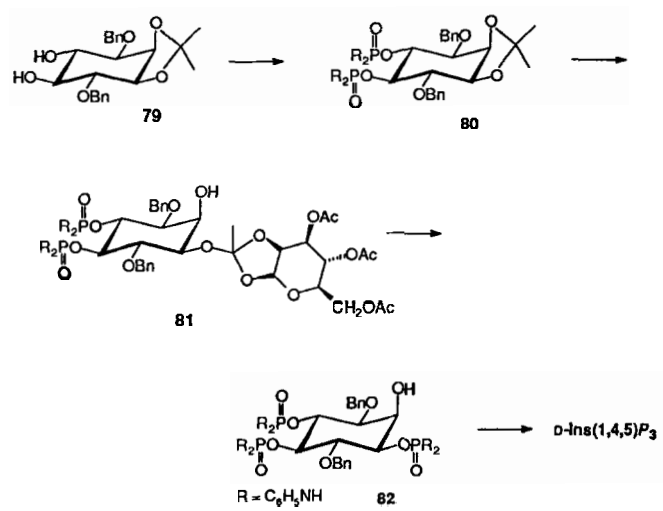

Fig. 18. Synthesis of D-Ins(1,4,5)P_3 utilizing mannose-orthoester resolution (Shvets et al.)

groups of the enantiomeric 1,2-diols obtained were then selectively phosphorylated with **48** to give **82**. Successive removal of *N*-phenyl- and benzyl protecting groups yielded the respective enantiomers of Ins(1,4,5)P_3.[294] Other phosphorylating methods are now preferred.[295]

Cyclopentylidene acetal **84** (from **83**, Fig. 19) was employed in a different approach in which silylation of the 1- and 4-hydroxyl groups afforded **85** and reaction with 2,7-dibromo-9-phenyl-9-xanthenyl chloride gave triol **86** after desilylation.

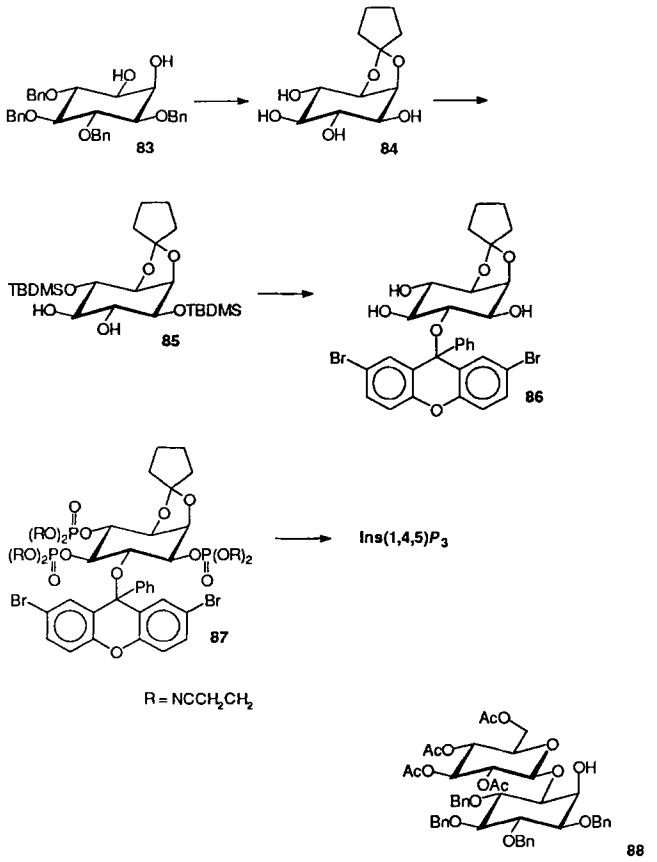

Fig. 19. Synthesis of D-Ins(1,4,5)P_3 employing the xanthenyl protecting group (Reese and Ward).

Phosphitylation with phosphine **57**, oxidation, and deblocking gave DL-Ins(1,4,5)P_3.[296] This route was also used to prepare D-Ins(1,4,5)P_3[296] by resolving diol **83** as its glucopyranosyl derivative **88**.[286]

Diastereoisomeric camphanate derivatives of 2,3:4,5-di-*O*-cyclohexylidene-6-*O*-benzyl-*myo*-inositol, synthesized by selective benzylation of the corresponding racemic 1,6-diol,[216] were used to prepare D- and L-6-*O*-benzyl-2,3-*O*-cyclohexylidene-*myo*-inositol. Phosphorylation of the tripotassium salts of these intermediates using TBPP **51**[249, 270, 280] followed by deprotection gave the enantiomers of Ins(1,4,5)P_3.[251, 297]

A short synthesis of racemic Ins(1,4,5)P_3 from 3,6-di-*O*-benzoyl-*myo*-inositol was reported.[255] Partial phosphitylation with chlorophosphite **52**, acetylation of the 2-OH group, and oxidation gave predominantly the 1,4,5-tris(dimethyl phosphate). Demethylation and saponification afforded Ins(1,4,5)P_3.

Phosphine **56** was proposed for the synthesis of inositol phosphates[258] and used to prepare DL-Ins(1,4,5)P_3 from triol **70**. The intermediate phosphite esters were oxidized with *m*-CPBA.

D-Ins(1,4,5)P_3 was synthesized from 3,6-di-*O*-allyl-1,2-*O*-cyclohexylidene-*myo*-inositol. The 4-OH group was benzylated and the 5-OH group allylated to give 3,5,6-tri-*O*-allyl-4-*O*-benzyl-1,2-*O*-cyclohexylidene-*myo*-inositol. Hydrolysis of the 1,2-ketal, optical resolution via monomenthyloxyacetyl derivatives, removal of the chiral auxiliary, dibenzylation, and deallylation produced enantiomerically pure **70**. Treatment with phosphine **58** and *t*BuOOH followed by hydrogenolysis gave D-Ins(1,4,5)P_3.[298]

Ins(1,4,5)P_3 was also synthesized by using a mixed P^{III}/P^{V} approach.[240, 242] Phosphorylation of 2,3,6-tri-*O*-benzyl-4,5-*O*-isopropylidene-*myo*-inositol[213] with **47**, removal of the ketal, and phosphorylation of the exposed vicinal diol gave a mixture of the 1,4- and 1,5-bisphosphates. The former crystallized from the reaction mixture and was phosphitylated with chlorophosphine **61**, and the resulting phosphoramidite was converted into the phosphate triester.[260] Deprotection afforded Ins(1,4,5)P_3.

3,6-Di-*O*-benzyl-4,5-bis(dibenzylphosphoryl)-*myo*-inositol was employed in an approach to D-Ins(1,4,5)P_3.[246] The enantiomers were resolved either as the 1-*O*-monomenthyloxyacetyl derivatives or with a chiral HPLC column. Regioselective silylation of the equatorial hydroxyl group, benzoylation of the 2-hydroxyl group, and desilylation exposed the 1-hydroxyl group which was phosphitylated with PCl_3/benzyl alcohol. Oxidation, hydrogenolysis, and alkaline treatment gave D-Ins(1,4,5)P_3.

D-Ins(1,4,5)P_3 was also synthesized by using enantiomerically pure 1,2:5,6-di-*O*-cyclohexylidene-*myo*-inositol,[224, 226] obtained either via the diastereomeric di(L-menthyloxyacetate) esters or by conversion into the diacetate or dibutyrate followed by regio- and enantiospecific enzymatic deacylation.

The use of 2-(*tert*-butyldimethylsilyloxy)phenylacetyl chloride for the selective protection of the 1-OH group of 2,3-*O*-cyclohexylidene-*myo*-inositol was the key step in another synthesis of enantiomerically pure Ins(1,4,5)P_3.[299] Treatment of the resulting mixture of diastereomeric esters with 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane gave the 4,5-*O*-silyl derivatives. Methoxymethylation of the free 6-OH group, chromatographic separation of the fully protected diastereoisomers, and removal of acyl and silyl groups of the individual isomers followed by phosphorylation with **56**/*m*-CPBA, and hydrogenolysis gave D- and L-Ins(1,4,5)P_3, respectively.

Regioselective 1-*O*-acylation of inositol was effected by perborylation, transmetalation with bis(acetylacetonato)-di-*n*-butyltin, and treatment of the dibutyltin intermediate with (−)-menthyl chloroformate.[300] Separation of the diastereoisomers by crystallization and treatment of the D isomer with 2,2-dimethoxypropane gave D-1-*O*-menthyloxycarbonyl-2,3:4,5-di-*O*-isopropylidene-*myo*-inositol. Benzylation of the 6-OH group, cleavage of the ester, and selective removal of the 4,5-acetal afforded, after phosphorylation and hydrogenolysis, D-Ins(1,4,5)P_3.

An elegant short route to D-Ins(1,4,5)P_3 was devised,[287] employing 2,3-*O*-(D-1,7,7-trimethyl[2.2.1]bicyclohept-2-ylidene)-*myo*-inositol (**89**) (Fig. 20),[301] prepared from inositol and D-camphor dimethyl acetal by way of a precipitation-driven

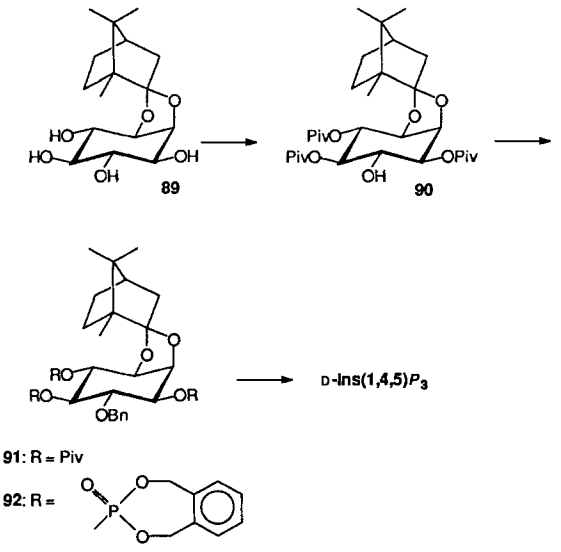

Fig. 20. Short route to D-Ins(1,4,5)P_3 via camphor acetal **90** (Salamonczyk and Pietrusiewicz).

equilibrium reaction.[275] Reaction of **89** with five equivalents of pivaloyl chloride afforded **90**, which was benzylated to provide **91**. After removal of the pivaloyl esters, phosphorylation with phosphepane **60**, and oxidation, **92** was obtained, which was deblocked to give D-Ins(1,4,5)P_3.

A conceptually different approach was developed by Ley et al.,[201, 302] who took advantage of the observation that microbiological oxidation of benzene by *Pseudomonas putida* affords *cis*-1,2-dihydroxycyclohexa-3,5-diene (**93**) (Fig. 21a).[303] The

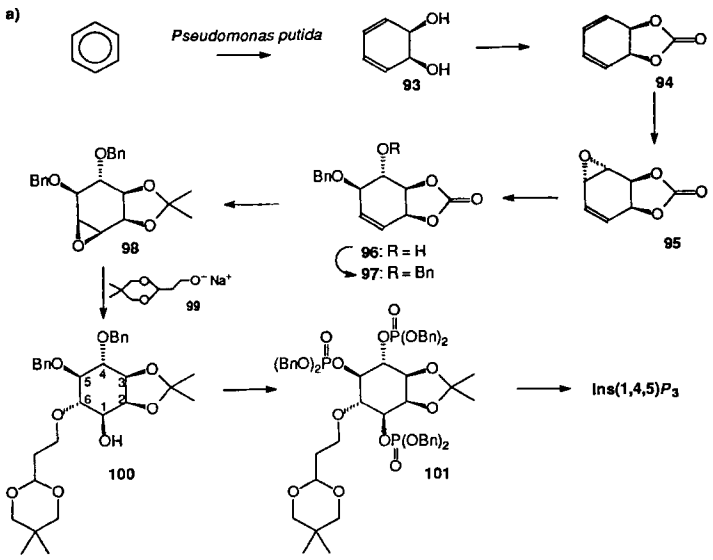

Fig. 21. Approach to D-Ins(1,4,5)P_3 employing microbial oxidation of benzene (Ley et al.): a) synthesis of Ins(1,4,5)P_3, b) reaction of intermediate **95** giving diastereomers separable by HPLC.

cyclic carbonate **94** derived from this diol was stereoselectively oxidized to the α-epoxide **95**. Regioselective ring opening of **95** with benzyl alcohol gave **96** and benzylation of the free hydroxyl group afforded **97**. Hydrolysis of the 1,2-carbonate, epoxidation of the double bond, and reprotection of the *cis*-1,2-diol as an isopropylidene acetal gave **98**. The β-epoxide was opened with **99** to give the protected inositol **100**. Debenzylation and phosphorylation with TBPP afforded **101**, which was deprotected to give racemic Ins(1,4,5)P_3, D- and L-Ins(1,4,5)P_3[201] were obtained by opening epoxide **95** with (*R*)-(+)-*sec*-phenethyl alcohol, giving diastereoisomers **102a** and **102b**, which were separable by HPLC (Fig. 21b).

Benzene was also used as starting material in a synthesis of racemic Ins(1,4,5)P_3 (Fig. 22).[291] *trans*-1,2-Dihydroxycyclo-

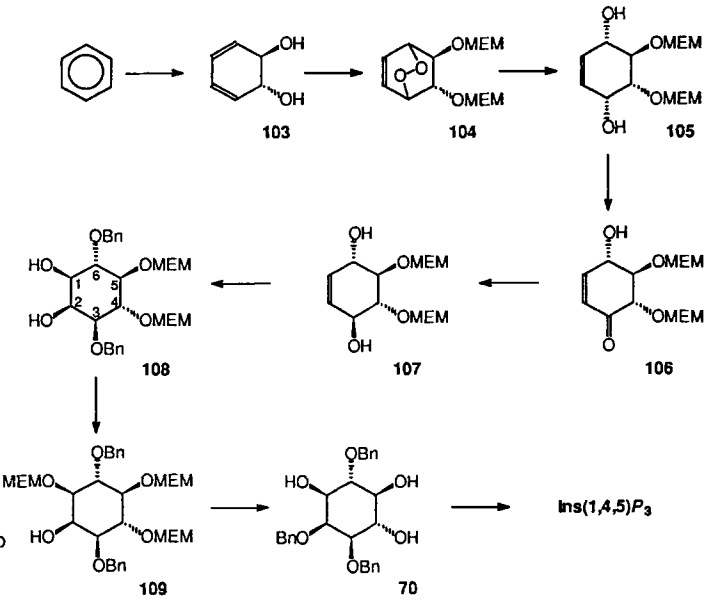

Fig. 22. Access to Ins(1,4,5)P_3 from benzene via conduritol B derivative **107** and with photooxidation of **103** as a key reaction (Carless and Busia).

hexa-3,5-diene (**103**) was prepared in 40% overall yield by Birch reduction, bromination, *trans*-hydroxylation, acetylation, and dehydrobromination. Protection of the hydroxyl groups as methoxyethoxymethyl (MEM) ethers and [4 + 2] addition of singlet oxygen furnished endoperoxide **104**, which was reduced stereospecifically to **105**.[304] Inversion at C-1 by an oxidation–reduction sequence gave the conduritol B derivative **107**. Benzylation of **107** and *cis*-hydroxylation of the double bond afforded **108**, which was regioselectively methoxyethoxymethylated to give **109**. Benzylation and removal of the MEM groups furnished **70**, and, after phosphorylation with TBPP and hydrogenolysis, Ins(1,4,5)P_3.

Falck and Yadagiri used (−)-quinic acid (**43**) to prepare D-Ins(1,4,5)P_3 (Fig. 23).[305] A four-step conversion gave ester **10**. Sequential protection of the 1-hydroxyl group as a β-(trimethylsilyl)ethoxymethyl (SEM) ether, reduction of the ester, and selenylation of the resulting primary alcohol furnished **111**. Stereoselective [2,3] sigmatropic rearrangement of the allylic selenoxide derived from **111** and benzylation generated **112** as a single stereoisomer. Transformation to silyl enol ether

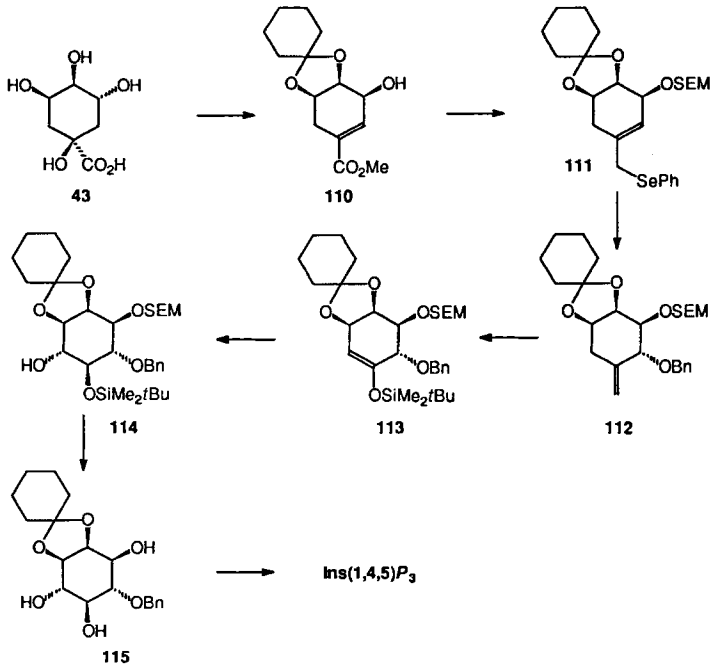

Fig. 23. Enantiospecific synthesis of D-Ins(1,4,5)P_3 from (−)-quinic acid (**43**) (Falck and Yadagiri).

113 by ozonolysis and treatment with TBDMS triflate proceeded with nearly complete regiospecificity. Hydroboration of the enol ether followed by oxidation furnished alcohol **114**, which on desilylation gave **115**. TBPP phosphorylation and hydrogenolysis afforded D-Ins(1,4,5)P_3.

Tegge and Ballou employed D- and L-*chiro*-inositol, derived by demethylation of 1D-3-*O*-methyl-*chiro*-inositol (**42**) and L-quebrachitol (**10**), respectively, to obtain both enantiomers of Ins(1,4,5)P_3 (Fig. 24).[306] Formation of the *cis,cis*-dicyclohexylidene acetal **116** (from D-*chiro*-inositol), benzylation, hydrolysis, and benzoylation gave mainly **117**. Inversion of the configuration at C-1 via the triflate afforded **118**, which was debenzylated to give **119** and then converted into D-Ins(1,4,5)P_3 by employing phosphine **56**. The L isomer was synthesized similarly from L-*chiro*-inositol.

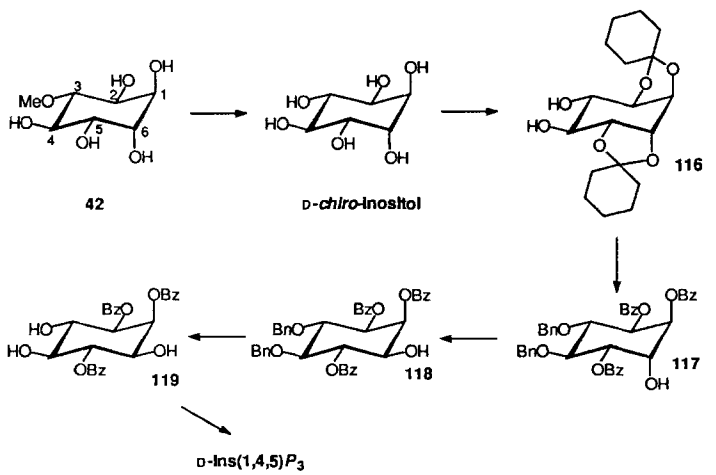

Fig. 24. Synthesis of D-Ins(1,4,5)P_3 from 1D-3-*O*-methyl-*chiro*-inositol (**42**) (Tegge and Ballou).

Other preparations of optically active[307, 308] Ins(1,4,5)P_3 were also published, including the synthesis of ^{3}H-labeled D- and L-Ins(1,4,5)P_3 by reduction of a protected inosose with [^{3}H]NaBH$_4$.[309]

7.4.2. Other Inositol Trisphosphates

D-Ins(1:2-cyclic 4,5)P_3 was synthesized by treatment of D-3,6-di-*O*-benzyl-4,5-bis(dibenzylphospho)-*myo*-inositol with **50**,[246] and (in low yield) from D-Ins(1,4,5)P_3 by using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide.[310] In the latter reaction the product was isolated by HPLC and was shown to be converted to Ins(1,4,5)P_3 by treatment with acid.

Racemic Ins(2,4,5)P_3 was prepared from 4,5-di-*O*-allyl-3,6-di-*O*-benzyl-*myo*-inositol, which was selectively benzylated at the 1-position, deallylated, and phosphorylated with TBPP.[250, 251] DL- Ins(2,4,5)P_3 was also obtained from benzene via conduritol B derivatives.[291] The synthesis of a fully protected, phosphorylated, and enantiomerically pure precursor of D-Ins(2,4,5)P_3 was reported, but the final deprotection step was not achieved.[311] The same authors did, however, prepare D-Ins(2,4,5)P_3 by phosphorylation of 3,6-di-*O*-benzyl-1,2-*O*-cyclohexylidene-*myo*-inositol with TBPP, removal of the acetals, and resolution via the diastereomeric 1-menthyloxyacetates. The equatorial hydroxyl group was regiospecifically silylated and the 2-hydroxyl group was phosphorylated by treatment with PCl_3/benzyl alcohol followed by *t*BuOOH oxidation.[246] Both D- and L-Ins(2,4,5)P_3 were prepared from L- and D-1,3,4-tri-*O*-benzoyl-*myo*-inositol, respectively,[312] which were generated in turn from D- and L-*chiro*-inositol.[306]

Ins(1,3,4)P_3 was synthesized from 2,4,5-tri-*O*-benzyl-*myo*-inositol, prepared from the corresponding 1,2:4,5-di-*O*-cyclohexylidene acetal. Phosphitylation with chlorophosphine **54**, followed by oxidation and deprotection gave racemic Ins(1,3,4)P_3,[257] which was also prepared from the same precursor by using TBPP **51**[250, 251] and phosphine **56**.[258] D-Ins(1,3,4)P_3 was prepared by resolution of 5,6-di-*O*-benzyl-3,4-di-*O*-*p*-methoxybenzyl-*myo*-inositol using a chiral HPLC column or via the diastereomeric 1-menthyloxyacetates.[221] Optically active 1,2:5,6-di-*O*-cyclohexylidene-*myo*-inositol, obtained either by an enzymatic process or by conversion into the di(L-menthylcarbonates),[224] was used in another synthesis of D-Ins(1,3,4)P_3 via D-2,5,6-tri-*O*-benzyl-*myo*-inositol.[225, 226] Finally, Boehm and Prestwich synthesized both enantiomers of Ins(1,3,4)P_3 as well as radiolabeled [1-^{3}H]-Ins(1,3,4)P_3.[313] 2,4,5-Tri-*O*-benzyl-inositol was converted to the isopropylidene ketal and resolved by means of diastereoisomeric (−)-camphanates. Saponification and oxidation of the alcohol gave the 1-inosose, which was reduced with [^{3}H]NaBH$_4$ to give the alcohol with the equatorial OH group as the major product. Phosphorylation using TBPP followed by deprotection furnished D-[1-^{3}H]-Ins(1,3,4)P_3. Despite the availability of Ins(1,3,4)P_3, there has been some doubt about its Ca^{2+}-mobilizing activity. An unambiguous synthesis of the enantiomers of this compound has now been published.[314]

A synthesis of Ins(1,4,6)P_3[315] relied upon diallylation of 1,2:4,5-di-*O*-isopropylidene-*myo*-inositol, removal of the *trans*-ketal, and tin-mediated *p*-methoxybenzylation of the 4,5-diol, which gave mainly the desired 6-alkylated derivative. Benzyla-

tion of the 5-OH group, acid hydrolysis of the *cis*-ketal, benzylation of the 1- and 2-OH groups, isomerization of the allyl ethers, and removal of the resulting prop-1-enyl as well as the *p*-methoxybenzyl groups gave the 1,4,6-triol, which was phosphorylated with **56**/*t*BuOOH. Ins(1,4,6)P_3 was also prepared by another research group both as a racemate and in optically active form.[316]

7.5. Inositol Tetrakisphosphates

7.5.1. Inositol 1,3,4,5-Tetrakisphosphate

Ins(1,3,4,5)P_4 was first synthesized in racemic form from the symmetrical inositol orthoformate **120** (Fig. 25). Chelation-controlled monoallylation of **120** gave **121**, which was benzylated to give **122**. The allyl and orthoformate groups were removed to furnish tetrol **123**, which was phosphorylated with TBPP to give **124** and Ins(1,3,4,5)P_4 after catalytic hydrogenation.[282] A similar route was adopted by another group[250] except that the benzyloxymethyl group was used instead of the allyl group for initial hydroxyl protection and a combined report has appeared.[280] 2,6-Di-*O*-benzyl-*myo*-inositol (**123**) was also used for two P^{III} approaches to Ins(1,3,4,5)P_4, employing either **60**[317] or **56**[258] as phosphitylating agents.

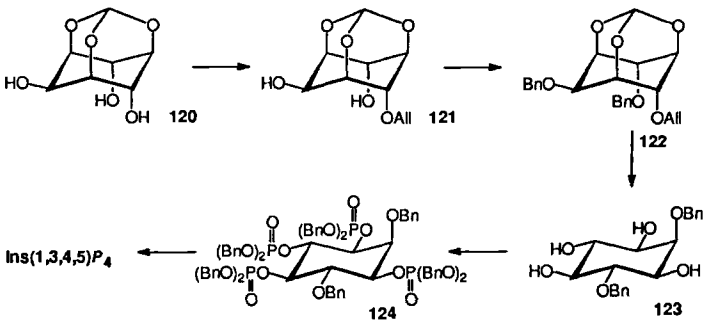

Fig. 25. Synthesis of Ins(1,3,4,5)P_4 by chelation-controlled monoallylation of *myo*-inositol orthoformate (Billington et al.).

Orthoformate ester protection of *myo*-inositol was also a key step in a synthesis by Vasella et al., which led to both enantiomers of Ins(1,3,4,5)P_4 (Fig. 26).[223] Benzylation of the silylated orthoester **125**[281] gave the racemic monobenzyl compound **126**, which was reacted with (*R*)-(+)-1-phenylethyl isocyanate to give diastereoisomeric carbamate derivatives, which could be separated as **127a** and **b** after removal of the silyl group. Subsequent benzylation of each diastereoisomer followed by removal of the carbamate and orthoformate groups gave the enantiomers of **123**, which were phosphorylated with **56**/*m*-CPBA and hydrogenolyzed to give D- and L-Ins(1,3,4,5)P_4. The enantiomeric dibenzylinositols **123** could also be derived by enantioselective monodeacylation of the symmetrical dibutyrate **128** formed by acylation and desilylation of **125**. Thus, treatment of **128** with porcine liver esterase (PLE) gave monobutyrate **129** in >95% enantiomeric excess. Dibenzylation, deacylation, and removal of the orthoester gave the precursor (L-**123**) for L-Ins(1,3,4,5)P_4. The D isomer was eventually obtained from **129** by a protection–deprotection sequence

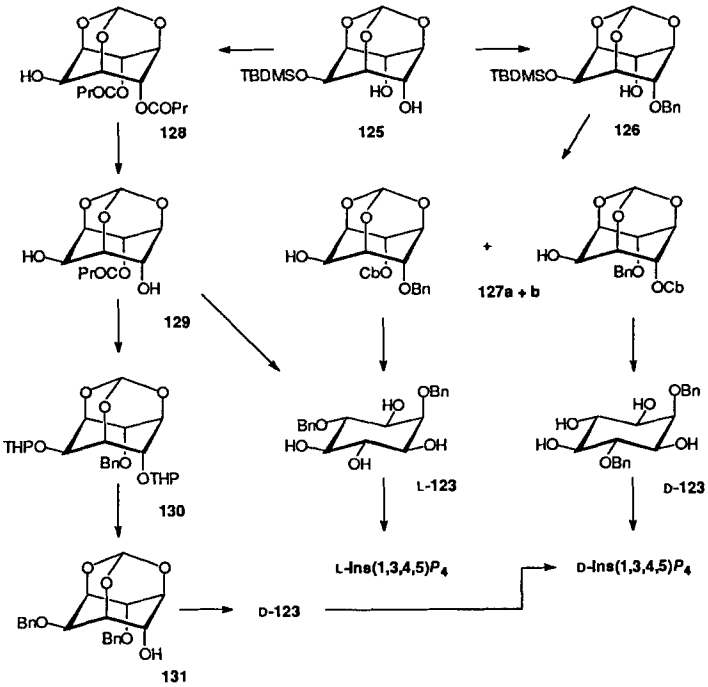

Fig. 26. Chemoenzymatic route to the enantiomers of Ins(1,3,4,5)P_4 (Vasella et al.).

via **130** and **131**. Surprisingly, L-Ins(1,3,4,5)P_4 is a higher affinity ligand than D-Ins(1,3,4,5)P_4 at Ins(1,3,4,5)P_4 binding sites in pig cerebellum, and this difference in affinity is greater than that between L-Ins(1,4,5)P_3 and D-Ins(1,4,5)P_3 at the Ins(1,4,5)P_3 receptor.[318]

Meek et al.[255] employed a base-catalyzed isomerization of the 1-benzoyl group in the readily available *myo*-inositol 1,4-dibenzoate to give inter alia the 2,4-dibenzoate. Phosphitylation with chlorophosphane **52**, oxidation, demethylation, and alkaline hydrolysis gave racemic Ins(1,3,4,5)P_4.

D-Ins(1,3,4,5)P_4 was synthesized by resolution of 3,4,5-tri-*O*-benzoyl-6-*O*-benzyl-*myo*-inositol, prepared from the 1,2:4,5-di-*O*-cyclohexylidene ketal by selective benzoylation of the 3-OH group, benzylation of the 6-OH group, removal of the *trans*-ketal, benzoylation of the 4- and 5-OH groups, and finally hydrolysis of the *cis*-1,2-ketal. Resolution by means of the monomenthyloxyacetyl derivatives and benzylation of the desired diastereoisomer followed by deacylation afforded D-**123**, which was phosphorylated with TBPP and deblocked to give D-Ins(1,3,4,5)P_4.[319] D-Ins(1,3,4,5)P_4 was also prepared from 1,4,5-tri-*O*-allyl-6-*O*-benzyl-*myo*-inositol, which was resolved via its monomenthyloxyacetyl derivative. Chemoselective tin-mediated allylation of the equatorial hydroxyl group, followed by benzylation of the 2-hydroxyl group and deallylation gave tetrol **123**, which was phosphitylated with phosphine **58**.[298] D-1,2:5,6-Di-*O*-cyclohexylidene-*myo*-inositol, obtained by chemoenzymatic means, served a starting material for another synthesis of D-Ins(1,3,4,5)P_4 via D-**123**.[225, 226]

A short route devised by Ozaki et al.[222] involved selective benzoylation of inositol. The 1,3,4,5-tetrabenzoate was isolated as major product in 34% yield. Benzylation with benzyl trichloroacetimidate and debenzoylation afforded the 2,6-protected inositol, which was phosphitylated with phosphoramidite **59**. Resolution of the tetrabenzoate by means of chiral column

chromatography gave access to enantiomerically pure Ins(1,3,4,5)P_4. The same group described the enantioselective acylation of inositol derivatives using tartaric acid monoester.[320] Thus, 1,3,5-tri-*O*-benzoyl-*myo*-inositol, obtained from direct benzoylation of inositol, was transformed enantioselectively into the 4-tartrate and the 2- and 6-OH groups were protected as silyl ethers. Separation of the fully protected diastereoisomers followed by deacylation with ethylmagnesium bromide, phosphorylation, and hydrogenolysis afforded D-Ins(1,3,4,5)P_4.[308]

7.5.2. *Other Inositol Tetrakisphosphates*

Racemic Ins(1,4,5,6)P_4 was synthesized from the 1,2-*O*-isopropylidene ketal of *myo*-inositol by phosphitylation with **52** followed by hydrogen peroxide oxidation. Demethylation was accomplished with bromotrimethylsilane, since HBr in acetic acid led to premature hydrolysis of the ketal and phosphate migration.[255] DL-Ins(1,4,5,6)P_4 was also prepared by phosphitylation of the corresponding 1,2-ketal with chlorophosphine **61**.[321] D-Ins(1,4,5,6)P_4 was obtained by resolution via the *O*-camphanylidene-*myo*-inositol *cis*-monoacetals.[276]

Ins(1,3,4,6)P_4 was prepared by treating inositol with 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane, which gave the symmetrical 1,6:3,4-*O*-bis(disiloxanylidene) regioselectively. Benzoylation and removal of the siloxanes with HF produced the 2,5-dibenzoate, which was phosphitylated with phosphoramidite **59**.[283]

DL-Ins(1,2,4,5)P_4 was previously synthesized by benzoylation of 1,2:4,5-di-*O*-cyclohexylidene-*myo*-inositol, hydrolysis of the ketal, phosphorylation with **52**/hydrogen peroxide, and stepwise deblocking.[255] A similar strategy in a more recent synthesis employed the isopropylidene ketal and **53** as phosphitylating agent.[256] Conduritol B derivatives obtained from benzene were also used to prepare Ins(1,2,4,5)P_4,[291] and L-quebrachitol served as starting material in a synthesis of L-*chiro*-Ins(1,2,3,5)P_4.[322]

8. Inositol Phosphate Analogues

Now that the second messenger properties of Ins(1,4,5)P_3 are well established, attention has turned to the synthesis of inositol phosphate analogues, which are hoped to have novel biological properties. There is currently considerable interest in the concept of pharmacological intervention in cellular signaling pathways. If suitable cell-permeable receptor antagonists and enzyme inhibitors can be synthesized, some of these compounds may have potential therapeutic value.

8.1. Deoxy Analogues

The racemic 2- and 6-deoxy analogues of Ins(1)*P* were synthesized in the search for inhibitors of inositol monophosphatase[323] (see Section 9). D-2-Deoxy-Ins(1)*P* was prepared by employing D-3,4,5,6-tetra-*O*-benzyl-*myo*-inositol, which was transformed into the 1-tetrahydropyranyl (THP) ether and deoxygenated at C-2 by the Barton–McCombie method. Cleavage of the THP ether, phosphorylation, and hydrogenolysis furnished D-2-deoxy-Ins(1)*P*.[276]

By using 4,5-di-*O*-benzoyl-3,6-di-*O*-benzyl-1,2-*O*-cyclohexylidene-*myo*-inositol, DL-2-deoxy-Ins(1,4,5)P_3 was prepared.[324] Hydrolysis of the ketal was followed by tin-mediated monomethoxymethylation of the 1-hydroxyl group. Deoxygenation at C-2 was accomplished by first oxidizing the hydroxyl group to give the inosose, which was then converted into the tosyl hydrazone and reduced. The resulting hydrazine was removed with sodium acetate. Cleavage of MOM and benzoyl protecting groups gave the 1,4,5-triol, which was phosphorylated with TBPP and deblocked.

Both D-3-deoxy-Ins(1,4,5)P_3 and D-3-deoxy-Ins(1,5,6)P_3[325, 326] were prepared from D-3-deoxy-*myo*-inositol (viburnitol), which was obtained from *O*-diisopropylidene-L-quebrachitol, by Barton deoxygenation of the free hydroxyl group, and removal of all protecting groups with boron tribromide. On treatment with 2-methoxypropene/acid, viburnitol gave a mixture of the 1,2:4,5- and the 1,2:5,6-di-*O*-isopropylidene derivatives. After benzylation, removal of the *trans*-ketals, and benzoylation, the two regioisomers could be separated by chromatography. Cleavage of the ketal of 4,5-di-*O*-benzoyl-6-*O*-benzyl-3-deoxy-1,2-*O*-isopropylidene-*myo*-inositol followed by benzoylation of the 1-hydroxyl group, protection of the axial hydroxyl group as its ethoxyethyl ether, and removal of the benzoate esters furnished the 1,4,5-triol, which was treated with TBPP and deblocked to give D-3-deoxy-Ins(1,4,5)P_3. D-3-Deoxy-Ins(1,5,6)P_3 was prepared analogously from the other regioisomer.

DL-6-Deoxy-Ins(1,4,5)P_3 **133** (Fig. 27) was synthesized by utilizing precursors derived from benzene by microbial oxidation.[201, 327] The key step was the selective ring opening of the

Fig. 27. Synthesis of C-6-modified Ins(1,4,5)P_3 analogues via epoxide **99** (Ley et al.).

intermediate epoxide **98** with $LiAlH_4$, giving predominantly the 6-deoxy-*myo*-inositol derivative **132**. D-6-Deoxy-Ins(1,4,5)P_3 was prepared from D-galactose by the Ferrier reaction. Interactions of this inositol phosphate with the Ins(1,4,5)P_3 receptor and metabolic enzymes were studied,[231] although details of the synthesis remain to be published.

Syntheses of 1D-2,3-dideoxy- and 1D-2,3,6-trideoxy-Ins(1,4,5)P_3 from 1D-1,4,5-tri-*O*-benzoyl-6-*O*-benzyl-3-deoxy-*myo*-inositol, an intermediate in the preparation of D-3-deoxy-Ins(1,4,5)P_3, were described.[326] Earlier, racemic 2,3,6-trideoxy-Ins(1,4,5)P_3 (= DL-cyclohexane 1,2,4-trisphosphate) had been synthesed by another group.[328]

8.2. Fluorinated Analogues of Inositol Phosphates

2-F-*scyllo*-Ins(1,4,5)P_3 and 2,2-F_2-Ins(1,4,5)P_3 were both synthesized from 1-*O*-allyl-3,6-di-*O*-benzyl-4,5-*O*-isopropylidene-*myo*-inositol. Treatment with DAST resulted in monofluorination at the 2-position with inversion of configuration, and the *gem*-difluoro derivative was obtained after oxidation to the 2-inososse. Deblocking of the 1-, 4-, and 5-OH groups, phosphorylation with TBPP, and hydrogenolysis gave 2-F-*scyllo*-Ins(1,4,5)P_3 and 2,2-F_2-Ins(1,4,5)P_3, respectively.[329] Syntheses of these compounds by a similar approach have also been published.[191, 330] The enantiomers of 3,6-di-*O*-benzyl-2-deoxy-2,2-difluoro-4,5-isopropylidene-*myo*-inositol were resolved by separation of the camphanates, thus giving access to D- and L-2,2-F_2-Ins(1,4,5)P_3.[191, 331, 332]

The protected *scyllo*-inositol **140** was used to prepare 2-F-Ins(1,4,5)P_3 **146** (Fig. 28).[333] Isomerization of the allyl group

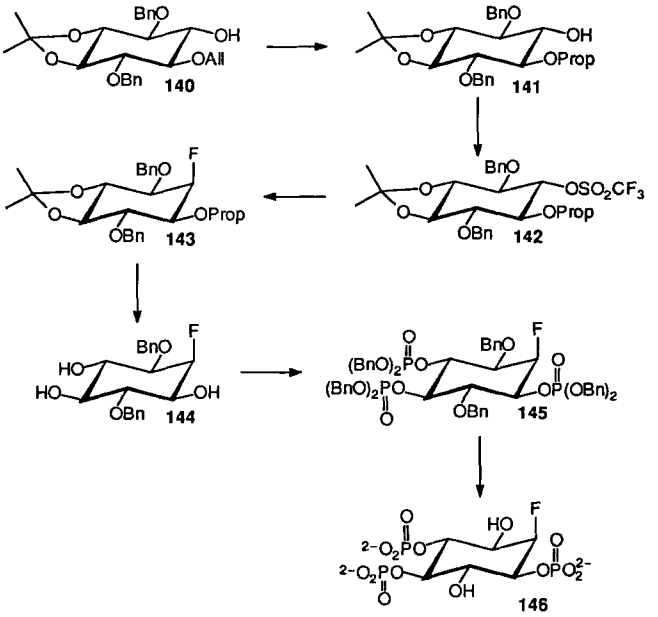

Fig. 28. Synthesis of 2-F-Ins(1,4,5)P_3 **146** (Lampe and Potter).

of **140** gave the prop-1-enyl derivative **141**, whose free 2-hydroxyl group was triflated giving **142**. Displacement of the sulfonate with tetrabutylammonium fluoride furnished the fluoroinositol **143**. Removal of acid-labile protecting groups followed by treatment of the resulting triol **144** with **56**/*t*BuOOH gave **145** and, after deprotection, **146**. An earlier attempt to synthesize 2-F-Ins(1,4,5)P_3 from **140** using DAST failed because the reaction unexpectedly proceeded with retention of configuration.[329]

Treatment of D-3-deoxy-3-fluoro-*myo*-inositol (**18**) (obtained from L-quebrachitol as above) with 2-methoxypropene/camphorsulfonic acid (cat.) produced a mixture of the 1,2:5,6- and the desired 1,2:4,5-di-*O*-isopropylidene acetal **147** (Fig. 29). The latter was benzylated to **148**, and cleavage of the *trans*-acetal followed by benzoylation gave **149**. Hydrolysis of the remaining acetal, selective benzoylation of the equatorial hydroxyl group, and protection of the free axial hydroxyl group as its

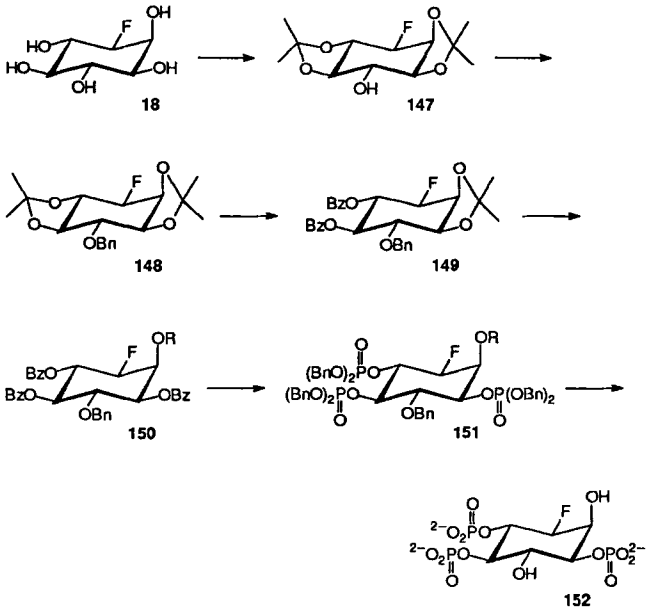

Fig. 29. Synthesis of optically active 3-F-Ins(1,4,5)P_3 **152** (Kozikowski et al.).

ethoxyethyl derivative afforded **150**. Removal of the benzoate groups and phosphorylation with TBPP gave **151**, which was deblocked stepwise to yield D-3-F-Ins(1,4,5)P_3 **152**.[334] The synthesis of D-3-*C*-(trifluoromethyl)-Ins(1,4,5)P_3 was recently described by the same group.[322]

Racemic 6-F-Ins(1,4,5)P_3 **135** was accessible from benzene by microbial oxidation via epoxide **98** (Fig. 27).[201, 327] Ring opening with $LiAlH_4$ gave mainly **134**. Debenzylation, phosphorylation with TBPP, and deprotection with trimethylsilyl bromide gave **135**.

1,3,4-Tri-*O*-allyl-5,6-di-*O*-benzyl-*myo*-inositol was employed in syntheses of 2-F-*scyllo*-Ins(1,3,4)P_3 and 2,2-F_2-Ins-(1,3,4)P_3.[313] Reaction with DAST proceeded with inversion of configuration introducing an equatorial fluoro substituent. Deallylation, TBPP phosphorylation, and hydrogenolysis afforded 2-F-*scyllo*-Ins(1,3,4)P_3. The difluoro derivative was obtained similarly by fluorination of the 2-inosose. Synthesis of the *myo*-inositol derivative was also attempted by inverting the configuration at C-2 prior to fluorination; however, the fluorinated *myo*-inositol intermediate could not be selectively deallylated.[313]

8.3. Ring-Modified Inositol Phosphate Analogues

The versatile benzene-derived epoxide **98** (Fig. 27) was employed in syntheses of racemic 6-deoxy-6-methyl-Ins(1,4,5)P_3 **137** and 6-*O*-methyl-Ins(1,4,5)P_3 **139**.[201, 302, 327] Whereas ring opening with methanolic sodium methoxide afforded mainly **136**, the precursor for **137**, reaction of **98** with lithium dimethyl(cyano)copper(I) gave **138**, which can be used to prepare **139**. DL-6-*O*-Methyl-Ins(1,4,5)P_3 was also prepared and evaluated by another group.[328]

An Ins(1,4,5)P_3 analogue with an equatorial 2-hydroxyl group, DL-*scyllo*-Ins(1,2,4)P_3, was prepared from 1-*O*-allyl-3,6-di-*O*-benzyl-4,5-*O*-isopropylidene-*myo*-inositol[333] by trifla-

tion of the 2-hydroxyl group followed by displacement of the triflate moiety with cesium acetate.

Syntheses of *chiro*-Ins(2,3,5)P_3 **159**, an Ins(1,4,5)P_3 analogue with inverted configuration at C-3, were reported by two groups. Racemic **159** (Fig. 30) was prepared from the conduri-

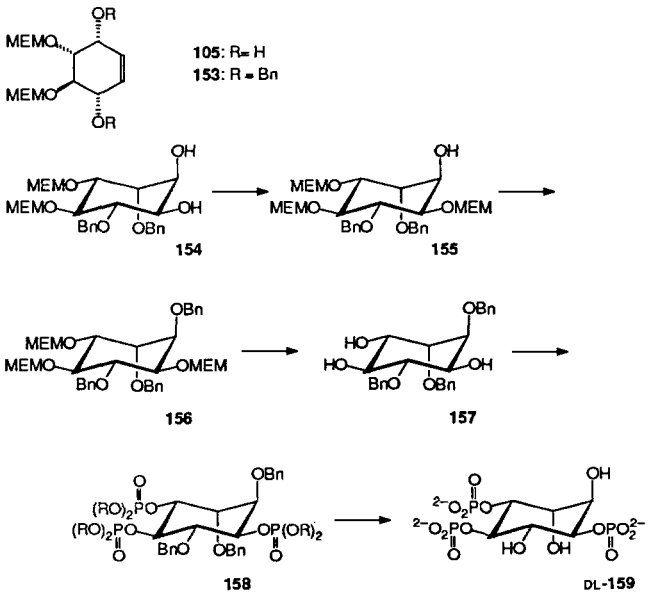

Fig. 30. Photooxidation approach to DL-*chiro*-inositol-2,3,5-trisphosphate (**159**) (Carless and Busia).

tol F derivative **105** (obtained from benzene, see Fig. 22), which was benzylated to **153** and *cis*-hydroxylated to give the *chiro*-inositol derivative **154**. Selective protection of the equatorial hydroxyl group as its methoxymethyl ether (**155**) followed by benzylation gave the fully protected **156**. Acidic hydrolysis furnished **157**, which was phosphorylated with TBPP to give **158**, and hydrogenolysis gave DL-**159**.[304] L-*chiro*-Ins(2,3,5)P_3[335, 336] was synthesized from L-*chiro*-inositol (Fig. 31). A selective tin-mediated benzylation yielded the key intermediate **160** as the major product. Perbenzoylation and cleavage of the benzyl ethers furnished **161**, which was phosphitylated with either chlorophosphine **53** or phosphine **55**. Oxidation gave **162**, which was deblocked to yield **159**. The corresponding thiophosphate **164** was prepared by sulfoxidation of the trisphosphite ester of **161** to give **163** followed by deprotection. Phosphitylation of intermediate **160** and (sulf)oxidation of the resulting trisphosphite ester gave **165** and **166**, respectively, which were deblocked to afford L-*chiro*-Ins(1,4,6)P_3 **167** and its trisphosphorothioate analogue L-*chiro*-Ins(1,4,6)PS_3 **168**.[337]

Carless and Busia[271] reported the synthesis of DL-6-F-*chiro*-Ins(2,3,5)P_3 employing the *cis*-1,4-diol **105** (see Fig. 21). Benzylation and *cis*-hydroxylation gave 1,4-di-*O*-benzyl-2,3-di-*O*-methoxymethyl-*chiro*-inositol. Selective methoxymethylation of the equatorial hydroxyl group and DAST fluorination (which proceeded with retention of configuration) furnished the fully protected fluorinated *chiro*-inositol. Hydrolysis of MOM ethers, TBPP phosphorylation, and hydrogenolysis gave DL-6-F-*chiro*-Ins(2,3,5)P_3.

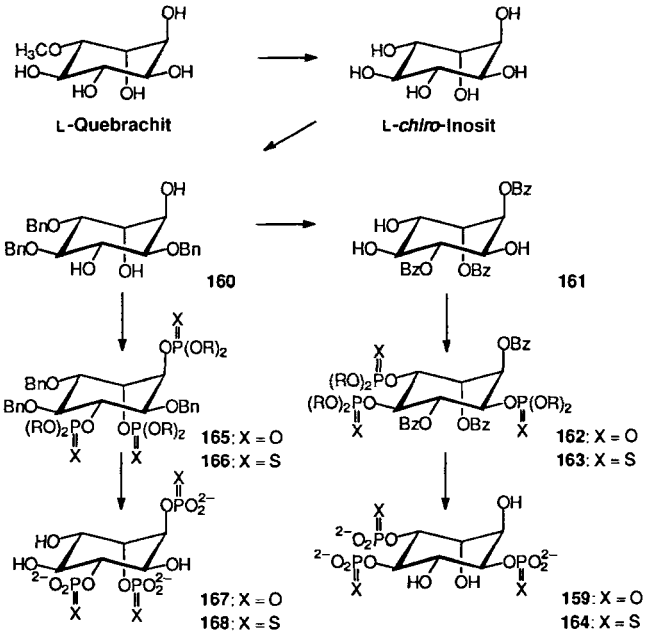

Fig. 31. Synthesis of L-*chiro*-Ins(1,4,6)P_3 **167**, L-*chiro*-Ins(2,3,5)P_3 **159**, and their trisphosphorothioate analogues from L-quebrachitol (Liu and Potter).

Other C-3-modified analogues reported include D-3-chloro-, D-3-bromo-, and D-3-O-methyl-Ins(1,4,5)P_3.[338] Recently, the first synthesis of an amino analogue of Ins(1,4,5)P_3, D-3-amino-3-deoxy-Ins(1,4,5)P_3, was published.[339]

8.4. Phosphorothioates

Phosphorothioate analogues of nucleotides have proved to be invaluable in studies in mechanistic enzymology and molecular biology[340] and in examining the stereochemistry of enzymatic phosphoryl transfer reactions,[254, 341] and phosphorothioate analogues of the established second messengers cAMP and cGMP have been available for some time. Indeed, it should be noted that phosphorothioate substitution has generated the only known competitive cAMP antagonists from the manhundreds of cAMP analogues, (R_P)-adenosine cyclic-3',5'-monophosphorothioate and the corresponding phosphorodithioate. The applicability of these analogues to the inositol phosphate field stems from their resistance to phosphatase-catalyzed degradation.[285] Already inositol phosphorothioates are emerging as the first partial agonists at the Ins(1,4,5)P_3 receptor (see Section 11.1). Synthesis of phosphorothioate analogues also provides an excellent method to introduce ^{35}S radiolabels. Since sulfoxidation is usually the final synthetic step before deprotection and can be effected with elementary sulfur, the handling of radioactive material can be kept to a minimum. Thus, D-[^{35}S]Ins(1,4,5)PS_3 was synthesized and used for enzyme[342] and receptor binding studies,[343] in which it was found to label two different sites, the Ins(1,4,5)P_3 receptor and possibly a different conformation of the receptor. Furthermore, since sulfur is a better nucleophile than oxygen, the selective attachment of reporter groups such as fluorescent labels to phosphorothioates in the presence of phosphates is possible.[344]

8.4.1. Phosphorothioate Analogues of Inositol Mono- and Bisphosphates

DL-*myo*-Inositol 1-phosphorothioate [Ins(1)*P*S] was initially obtained by treatment of inositol 1,2,4,5,6-pentaacetate with thiophosphoryl chloride followed by ester hydrolysis.[278] A synthesis of racemic as well as enantiomerically pure Ins(1)*P*S[71, 345] relied upon phosphitylation of the corresponding penta-*O*-benzylinositol (which could be resolved via camphanates) with phosphoramidite **61** and sulfoxidation. L-Ins(1)*P*S was also prepared by another group.[346]

Direct thiophosphorylation of, for example, DL-1,4,5,6-tetra-*O*-acetyl-*myo*-inositol with thiophosphoryl chloride afforded a 1:1 mixture of the *endo* and *exo* diastereoisomers of the protected 1,2-cyclic-phosphorothioates, which was separated by reverse-phase flash chromatography. Deacylation and precipitation with potassium chloride produced *endo*- and *exo*-DL-*myo*-inositol 1:2-cyclic-phosphorothioate.[347] A different approach relied upon the monophosphitylation of 1,4,5,6-tetra-*O*-benzyl-*myo*-inositol at either the 1- or 2-position using **61**, followed by cyclization of the phosphoramidites to the *exo*- and *endo*-methoxyphosphites using tetrazole. Sulfoxidation gave a mixture of the respective protected diastereoisomeric phosphorothioates which were separated by chromatography and deblocked.[263] Ins(1,4)PS_2[285] and Ins(4,5)PS_2[262] were obtained from DL-1,2:4,5-di-*O*-isopropylidene- and 1,2,3,4-tetra-*O*-benzyl-*myo*-inositol, respectively.

8.4.2. Phosphorothioate Analogues of Inositol Trisphosphates

myo-Inositol 1,4,5-trisphosphorothioate [Ins(1,4,5)PS_3, **78**] (Fig. 17)[348] was the first Ins(1,4,5)P_3 analogue reported and has proved to be a valuable tool in the elucidation of the biochemical role of Ins(1,4,5)P_3 (see Section 12). Ins(1,4,5)PS_3 was prepared from triol **70**, which was converted into the trisphosphoramidite by reaction with chlorophosphine **55** and then into trisphosphite **75** on reaction with tetrazole and 2-cyanoethanol. Sulfoxidation to **77** and deprotection produced the trisphosphorothioate **78**. A second synthesis[253] also employing triol **70** involved phosphitylation with **56** to give the intermediate trisphosphite triester. Sulfurization with phenacetyl disulfide produced the phosphorothioate which was deblocked to provide Ins(1,4,5)PS_3.

2,3,6-Tri-*O*-benzyl-4,5-*O*-isopropylidene-*myo*-inositol was used in syntheses of both the 5-phosphorothioate and the 4,5-bisphosphorothioate analogues of Ins(1,4,5)P_3, Ins(1,4,5)P_3-5S,[240, 242] and Ins(1,4,5)P_3-4,5S_2. Treatment of this intermediate with phosphorochloridate **47** resulted in phosphorylation of the 1-OH group. After removal of the ketal, phosphorylation with **47** afforded a mixture of the 1,4- and 1,5-bisphosphate triesters, from which the 1,4-bisphosphate triester crystallized. Phosphitylation of the free 5-hydroxyl group using chlorophosphine **61**, sulfoxidation, and deblocking gave Ins(1,4,5)P_3-5S. Alternatively, the 4,5-diol obtained after acetal hydrolysis could be phosphitylated with **55** or **56**, sulfoxidized, and deblocked to give Ins(1,4,5)P_3-4,5S_2. The 4,5-bisphosphorothioate was used in the synthesis of the 4,5-cyclic pyrophosphate, obtained by desulfurization with *N*-bromosuccinimide (NBS).[349] Phosphitylation of a fully benzyl-protected inositol 1,4-bisphosphate with a free 5-hydroxyl group with phosphine **56** followed by reaction with phenacetyl disulfide featured in another synthesis of Ins(1,4,5)P_3-5S.[253]

Ins(1,4,5)P_3-1S was synthesized from 1-*O*-allyl-2,3,6-tri-*O*-benzyl-*myo*-inositol by isomerization of the allyl group to give the corresponding prop-1-enyl derivative, which was then 4,5-bisphosphorylated by using P^{III} chemistry. Removal of the prop-1-enyl ether and phosphitylation of the 1-hydroxyl group followed by sulfoxidation and deprotections gave Ins(1,4,5)P_3-1S.[350] Ins(1,4,5)P_3-1S, which was used in the preparation of an Ins(1,4,5)P_3 analogue carrying a fluorescent reporter group, was obtained in optically active form by employing 1D-1-*O*-allyl-2,3,6-tri-*O*-benzyl-*myo*-inositol.[344] DL-Ins(1,4,5)P_3-1S was also prepared by using **56** as the phosphitylating reagent and phenacetyl disulfide to effect sulfoxidation.[253]

Other reported trisphosphorothioates include D-6-deoxy-Ins(1,4,5)PS_3 and L-*chiro*-Ins(2,3,5)PS_3[351, 352] as well as Ins(1,3,5)PS_3, L-Ins(1,4,5)PS_3, and L-*chiro*-Ins(1,4,6)PS_3.[353]

A different approach to the preparation of phosphorothioate analogues of Ins(1,4,5)P_3 was adopted by thiophosphorylating PtdIns and PtdIns(4)*P* using kinases in human erythrocyte ghosts and ATPγS.[354] This method can naturally be adapted to prepare the highly desirable ^{35}S radiolabeled compounds. Thus, incubation of [^{35}S]γATP with erythrocyte ghosts produced ^{35}S-labeled PtdIns(4,5)P_2 analogues, with the ^{35}S label in both the 4- and 5-positions or only in the 5-position. Activation of phospholipase C with Ca^{2+} cleaved this modified lipid to give a mixture of inositol 1,4-bisphosphate-5-[^{35}S]phosphorothioate and inositol 1-phosphate 4,5-[^{35}S]bisphosphorothioate, which was shown to be resistant to 5-phosphatase.

8.4.3. Phosphorothioate Analogues of Inositol Tetrakisphosphates

Ins(1,3,4,5)P_4-5S was obtained by phosphitylation of 2,6-di-*O*-benzyl-1,3,4-tris[(dibenzoxy)phospho]-*myo*-inositol with **56** and in situ sulfurization to produce the fully protected Ins(1,3,4,5)P_4-5S analogue. Debenzylation yielded the 5-phosphorothioate derivative.[253]

Ins(1,3,4,5)P_4-3S **176** was prepared from **169** (Fig. 32). Hydrolysis of the ketals and tin-mediated *para*-methoxybenzylation of the 1-OH group gave **170**, which was converted into **171** by simultaneous protection of the 4- and 5-OH groups as the isopropylidene ketal and benzylation of the 2-OH groups. Removal of acid-labile protecting groups and isomerization of the allyl ether gave **172**, and phosphorylation gave the 1,4,5-trisphosphate triester **173**. Hydrolysis of the prop-1-enyl ether furnished **174**. Thiophosphorylation of the free 3-hydroxyl group gave **175** and deblocking in sodium/liquid ammonia afforded Ins(1,3,4,5)P_4-3S **176**,[355] a potent inhibitor of Ins(1,3,4,5)P_4 3-phosphatase.[356] The synthesis of enantiomerically pure D-Ins(1,3,4,5)P_4-3S from L-quebrachitol was also reported.[357]

8.5. Phosphonate Analogues

The monoammonium salt of benzylphosphonic acid was employed in the synthesis of inositol 1,4,5-tris(hydrogenphosphonate). Thus, phosphonylation of **70** with the salt of the activated acid, followed by debenzylation of the product with

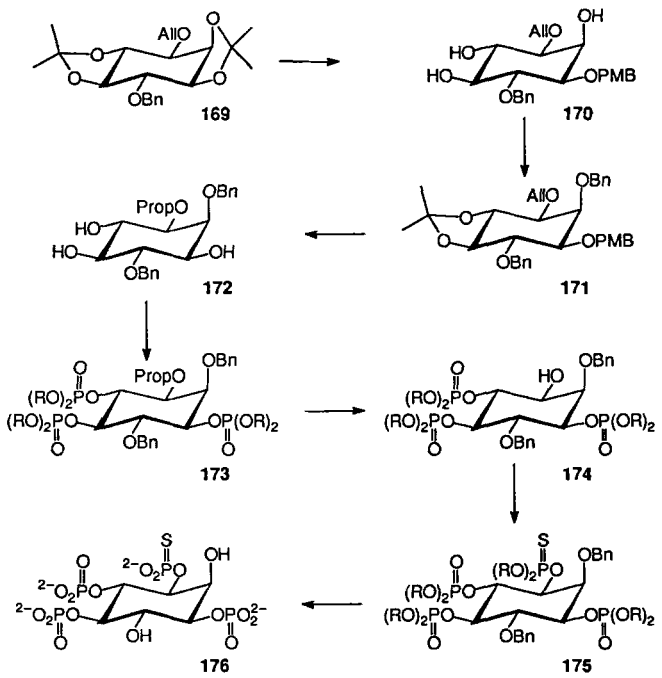

Fig. 32. Synthesis of Ins(1,3,4,5)P_4-3S **176** (Liu and Potter).

base provided the racemic 1,4,5-tris(hydrogenphosphonate).[358]

The 5-methylenephosphonate analogue of Ins(1,4,5)P_3, **180**, was also prepared (Fig. 33).[359] Compound **112**, an intermediate in the synthesis of Ins(1,4,5)P_3 from (−)-quinic acid (see Fig. 23), was desilylated, and kinetically controlled addition of

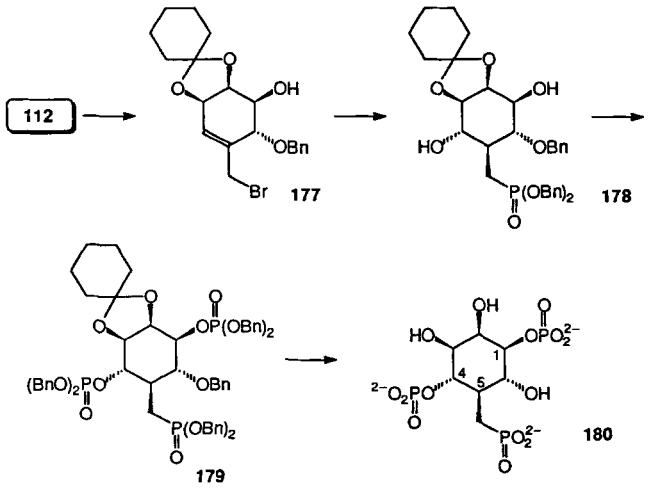

Fig. 33. Synthesis of the 5-methylenephosphonate analogue of Ins(1,4,5)P_3 from quinic acid (Falck et al.).

phenylselenyl bromide to the exocyclic alkene gave predominantly the anti-Markovnikov adduct. Oxidative elimination furnished the allylic bromide **177**, which was converted into **178** by Michaelis–Becker phosphorylation, hydroboration, and oxidative workup. Phosphorylation of the 1- and 4-hydroxyl groups gave **179**, which was deprotected to **180**.

Also synthesized were the 5-methylphosphonate analogues and the 5-(difluoromethyl)phosphonate analogues of Ins(1,4,5)P_3

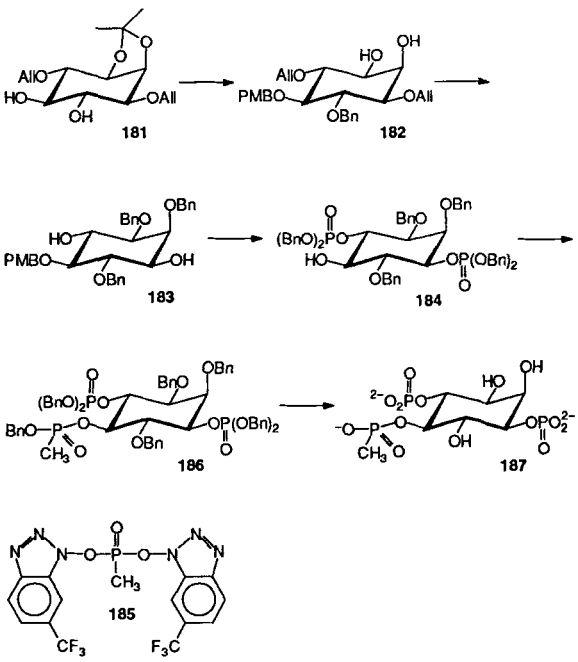

Fig. 34. Preparation of the 5-methylphosphonate analogue of Ins(1,4,5)P_3 employing phosphonylating agent **185** (van Boom et al.).

(Fig. 34) and Ins(1,3,4,5)P_4, by employing the new bifunctional phosphonylating agents bis[6-(trifluoromethyl)benzotriazol-1-yl]methylphosphonate (**185**) and (difluoromethyl)phosphonic di(1,2,4-triazolide), respectively.[360, 361] Thus, regioselective benzylation of **181** gave the 6-benzyl ether as the main product. Protection of the free 5-hydroxyl group by *p*-methoxybenzylation and removal of the *cis*-ketal furnished **182**, which was benzylated and deallylated to give **183**. Phosphorylation of the 1- and 4-OH groups with **56** and acidic removal of the *p*-methoxybenzyl group gave **184**, which was phosphonylated with **185**/benzyl alcohol. Hydrogenolysis of **186** gave the 5-methylphosphonate analogue **187**. Syntheses of racemic 3-methylphosphonate analogues of Ins(3,4)P_2 and Ins(1,3,4)P_3 were also described.[362] Additionally, phosphonylating agent **185** was used in syntheses of the methylphosphonate analogue of D-Ins(1)P[363] and DL-*myo*-inositol 1-*O*-methylphosphonate 4,5-bisphosphate.[364]

Syntheses of racemic *myo*-inositol 5-methylphosphonate, -4,5-bis(methylphosphonate), and -1,4,5-tris(methylphosphonate) were accomplished via the corresponding phosphinates.[365, 366]

8.6. "Caged" Analogues

The photochemically induced release of an active molecule of physiological interest such as ATP, GTP, second messengers, or even ions from an inactive precursor has considerable potential for studies in cellular physiology, especially kinetic aspects, since diffusional delay of agents into tissues is often a limitation. Inactive precursors which on irradiation yield, for example, a free second messenger are known as "caged" compounds[367, 368] and can be used for time-resolved measurements. Esterification of the three phosphate monoester groups

of Ins(1,4,5)P_3 with 1(2-nitrophenyl)diazoethane[369] yielded caged inositol 1,4,5-trisphosphate[370] as a mixture of singly and multiply caged compounds. The singly caged material was resolved into P-1, P-4, and P-5 isomers **188**, **189**, and **190**, respectively, by HPLC (Fig. 35). All three compounds released

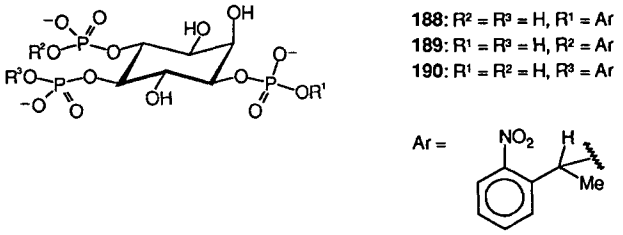

Fig. 35. Regioisomers of caged Ins(1,4,5)P_3 (Trentham et al.).

Ins(1,4,5)P_3 on irradiation. **188** is a potent releaser of Ca^{2+} and a substrate for 5-phosphatase. By contrast, **189** and **190** are inactive in Ca^{2+} release and resistant to 5-phosphatase, and **190** is a 3-kinase inhibitor. Analogues **189** and **190** were used to investigate the role of Ins(1,4,5)P_3 in excitation–contraction coupling in muscle.[371, 372] The results indicate an essential role for this compound in pharmacomechanical coupling in smooth but not striated muscle. Studies in stomatal guard cells have shown that the reversible inactivation of K^+ channels follows the photolysis of caged Ins(1,4,5)P_3 **190**.[373]

8.7. Photoaffinity Analogues and Affinity Matrices

To aid studies on localization and purification of Ins(1,4,5)P_3 receptors, it is desirable to synthesize photoaffinity analogues of Ins(1,4,5)P_3. Initially, the preparation of an arylazide derivative of Ins(1,4,5)P_3 was reported.[374] Thus, Ins(1,4,5)P_3 was coupled to *p*-azidobenzoic acid by using *N,N'*-carbonyldiimidazole. Unfortunately, the site of location of the *p*-azidobenzoic acid moiety was not determined, although hydroxyl group substitution was presumed, and a mixture was used. However, an irreversible inhibition of Ins(1,4,5)P_3-induced Ca^{2+} release in saponin-permeabilized photoirradiated macrophages was observed, which could be prevented by the presence of a large excess of Ins(1,4,5)P_3. This photoaffinity label was shown to label three proteins in macrophages.[375]

Acylation of the 2-OH group of Ins(1,4,5)P_3 yielded analogues[376] that were immobilized on Sepharose for the preparation of affinity matrices.[377] 2-*O*-*p*-Aminobenzoyl-Ins(1,4,5)P_3 was utilized in the synthesis of the photoaffinity probe **191** (Fig. 36) carrying a biotin moiety as a nonradioactive marker. This compound was successfully used to label the Ins(1,4,5)P_3 5-phosphatase of erythrocyte ghosts.[378] The same research group recently reported the preparation of affinity columns employing 2-substituted Ins(1,3,4,5)P_4 and Ins(1,3,4,5,6)P_5 analogues and their application in the isolation of Ins(1,3,4,5)P_4-binding proteins.[379]

(±)-(1*R*,3*R*,4R)-*trans*-*N*-(2-Aminoethyl)-3,4-bis(phosphonyloxy)cyclohexane-1-carboxamide was used for the preparation of an affinity matrix and a photolabel,[380] but the utility of these derivatives remains to be established. However, 6-*O*-substituted

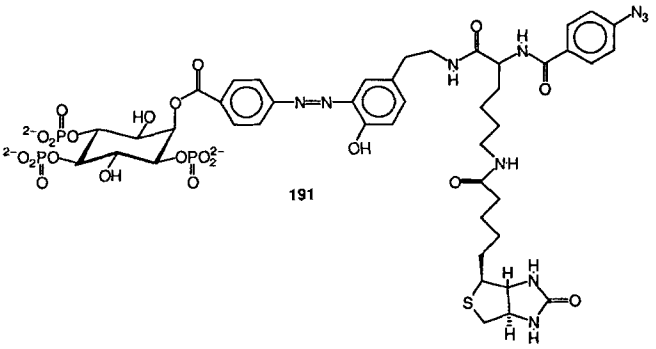

Fig. 36. Biotinylated C-2-modified Ins(1,4,5)P_3 (Ozaki et al.).

D-Ins(1,4,5)P_3 analogues were successfully applied in the production and purification of antibodies against Ins(1,4,5)P_3, by allowing the preparation of Ins(1,4,5)P_3-based immunogens and an affinity matrix.[381]

"Tetherable" derivatives of Ins(1,4,5)P_3,[382] Ins(1,3,4,5)P_4,[383] and InsP_6[384] with an ω-aminoalkyl group at P-1 were employed in the preparation of affinity matrices for the purification of binding proteins[382, 385] and [^{125}I]-labeled photoaffinity analogues.[175, 386, 387] Thus, [^{125}I](azidosalicyl)aminopropyl-Ins(1,4,5)P_3 **194** (Fig. 37) was used to identify the major

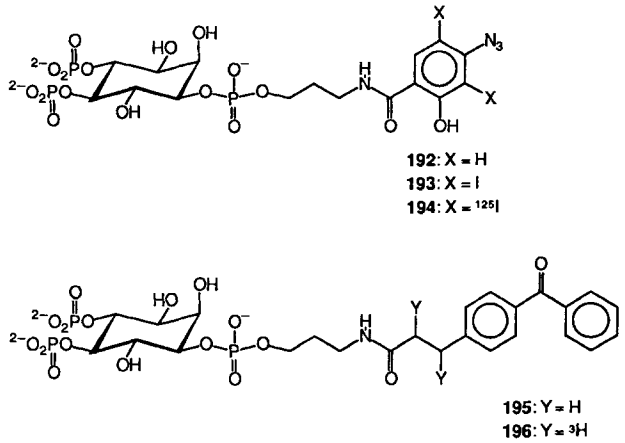

Fig. 37. Photoaffinity labeling by modification of the 1-position of Ins(1,4,5)P_3 (Prestwich et al.).

Ins(1,4,5)P_3-binding protein in olfactory cilia.[387] With the help of the new photoaffinity label [^{3}H](benzoyldihydrocinnamyl)-aminopropyl-Ins(1,4,5)P_3 **196**, which was incorporated into the rat cerebellar receptor at a substantially higher level than **194**, it was possible to purifiy and sequence a peptide matching specific sequences in the N-terminal portion of the Ins(1,4,5)P_3 receptor,[175] an area suggested to contain the Ins(1,4,5)P_3 recognition site. An InsP_6 receptor isolated by these means was subsequently identified as the clathrin assembly protein AP-2.[388] Syntheses of tetherable Ins(1,3,4)P_3 and Ins(2,4,5)P_3 derivatives and their application in the preparation of bioaffinity matrices were also described.[389]

Tethered D-Ins(1,3,4,5)P_4[235, 236] was prepared in a biomimetic synthesis involving Ferrier rearrangement of a suitably protected D-glucose derivative (Fig. 38). Thus, the primary hydroxyl group in **46** was tritylated, the secondary alcohols were

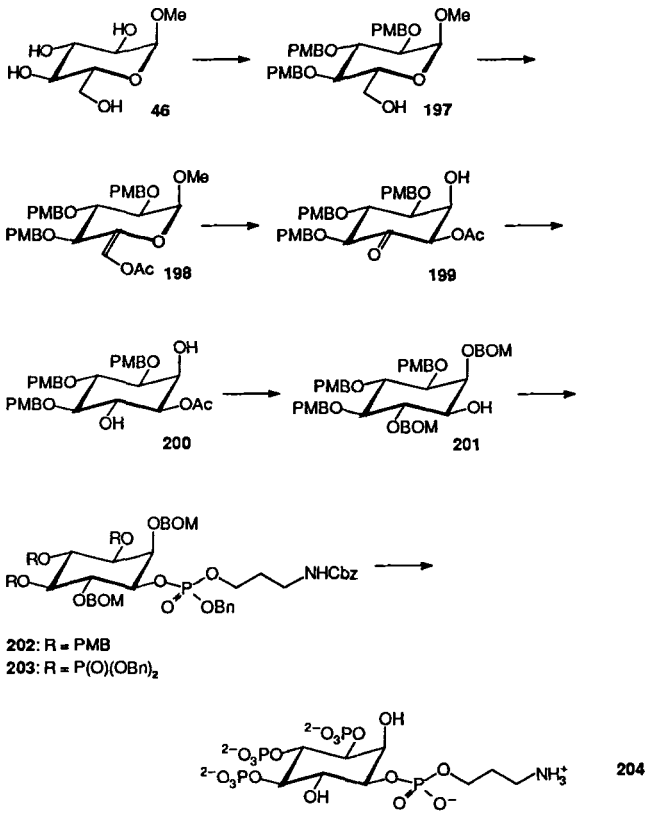

Fig. 38. Biomimetic synthesis of a precursor to an Ins(1,3,4,5)P_4 affinity label (Estevez and Prestwich).

p-methoxybenzylated, and the trityl group removed to produce **197**. Swern oxidation and treatment of the resulting aldehyde with acetic anhydride and base gave the (*Z*)-enol acetate **198**, which after Ferrier rearrangement furnished inosose **199**. Stereoselective reduction of the keto function with sodium triacetoxyborohydride gave the inositol derivative **200**. The 6- and 2-hydroxyl groups were then protected stepwise as their benzyloxymethyl ethers to minimize acetyl migration. Basic methanolysis gave **201**, and condensation with benzyloxy-{[3-(*N*-carbobenzyloxyamino)propyl]oxy}(diisopropylamino)-phosphane/tetrazole followed by oxidation provided **202**. Cleavage of the PMB ethers and phosphorylation gave **203**, hydrogenolysis of which afforded the P-1-tethered D-Ins(1,3,4,5)P_4 **204**, used to synthesize an ^{125}I-labeled affinity probe analogous to **192**.

8.8. Lipophilic Analogues

Cell-permeable inositol phosphate analogues would obviously find considerable applications. To this end the synthesis of racemic 2,3,6-tributyryl-Ins(1,4,5)P_3 was addressed[390] by phosphorylation of 1,2,4-tri-*O*-butyryl-*myo*-inositol with dianilidophosphorochloridate followed by removal of the phosphate protecting groups. The utility of this molecule, however, remains to be established.

Masking the negative charges of anionic biomolecules is another strategy that has already been successfully employed in the synthesis of a lipophilic cAMP analogue.[391] Here, the phosphate groups were esterified with acetoxymethyl bromide. Acetoxymethyl esters are rapidly cleaved intracellularly, releasing the second messenger. A preliminary report on the synthesis of membrane-permeable Ins(1,4,5)P_3 and Ins(1,3,4,5)P_4 analogues has been published.[392]

8.9. Miscellaneous

A number of C-1-modified Ins(1,4,5)P_3 analogues were prepared by chemical modification of the deacylated lipid 1-(*sn*-glycero-3-phospho)-D-*myo*-inositol-4,5-bisphosphate.[393] Syntheses of racemic sulfonamide, sulfate, and carboxymethyl analogues,[366, 394] an enantiomerically pure hexadeoxy-1,4,5-tris(methylenesulfonic acid) analogue of Ins(1,4,5)P_3,[395] and the 3-methylenecarboxylate analogue of Ins(1,3,4,5)P_4[396] were also described.

9. Inhibitors of Inositol Monophosphatase

Efforts towards the synthesis of inositol monophosphatase inhibitors by the Merck, Sharpe and Dohme group[323, 397–404] have shown encouraging results. A number of active compounds have been prepared (Fig. 39), although they are not

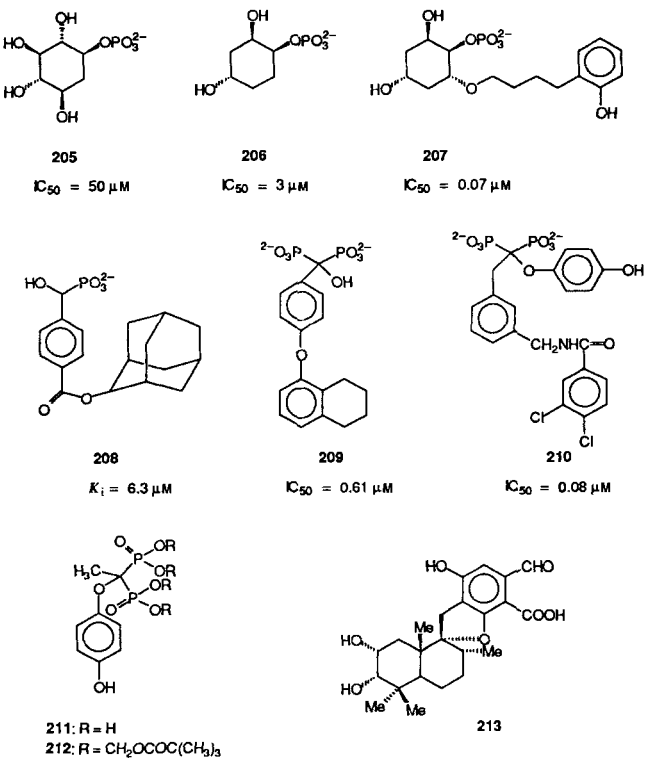

Fig. 39. Inositol monophosphatase inhibitors.

uncompetitive inhibitors like lithium. It was found that the hydroxyl groups in the 2- and 6-positions play very different roles in the hydrolysis of Ins(1)*P* by inositol monophosphatase. The 2-hydroxyl group is important for substrate recognition by the enzyme (2-deoxy-Ins(1)*P* is only a weak substrate), whereas the 6-hydroxyl group is involved in the mechanism of phosphate hydrolysis (6-deoxy derivatives like **205** have inhibitory proper-

ties). The first approach to inhibitors was based on this observation, and by a "hydroxyl group deletion" strategy, D-3,5,6-trideoxy-Ins(1)*P* **206** was synthesized and found to be a potent inhibitor,[397] indicating that the 3- and 5-hydroxyl groups are not necessary for enzyme recognition.

Inositol monophosphatase is known to be very unspecific, and the enzyme is capable of hydrolyzing 2′-nucleotides including adenosine-2′-monophosphate (2′-AMP)[74] as well as inositol monophosphates. When the molecular structures of 2′-AMP and D-3,5,6-tri-deoxy-Ins(1)*P* **206** were superimposed, it was concluded that substituents in the 6-position (the purine heterocycle in 2′-AMP) would be tolerated by the enzyme. This led to the synthesis of 6-substituted 3,5-dideoxy-Ins(1)*P* derivatives, amongst them **207**, the most potent monophosphatase inhibitor reported to date.[398]

However, phosphate esters are biologically labile and tend to have short half-lives due to hydrolysis by nonspecific phosphatases. Therefore, attempts to improve the stability of the inhibitor by replacement of the phosphate ester with an isosteric, but stable, monophosphonate group have been made. Since *myo*-inositol 1-methylenephosphonate did not show any inhibitory properties, the search for inhibitors was based on hydroxymethylene phosphonate, which had been identified as a weak inhibitor. In a series of analogues, the adamantyl ester **208** was the most potent inhibitor with a K_i value of 6.3 μM. Further studies on hydroxymethylene bisphosphonic acid derivatives[400, 403, 404] showed that compounds unrelated to the enzyme substrate like the tetralin derivative **209** can also be very potent monophosphatase inhibitors. The 3-(3,4-dichlorobenzamido)benzyl derivative **210** is the most potent, nonhydrolyzable inhibitor of inositol monophosphatase reported to date.[402] The observation that the potent bisphosphonate **211**[403] was only poorly taken up into cells led to the development of prodrug **212** with reduced polarity.[404] Synthetic efforts of the research group at Merck, Sharpe and Dohme have now been extended towards derivatives and analogues of adenosine-2′-monophosphate,[405] and molecular modeling, kinetic, and mutagenesis studies[406] are being employed to further elucidate the enzyme mechanism. Attention should be drawn to a report on the noncompetitive inhibition of inositol monophosphatase by the fungal metabolite K-76 monocarboxylic acid **213**.[407]

10. Structure–Activity Studies on Ins(1,4,5)P_3 Analogues

This section will address the consequences of structural modifications to Ins(1,4,5)P_3 on its interactions with the three binding proteins—the Ins(1,4,5)P_3 receptor and the two metabolic enzymes 5-phosphatase and 3-kinase.

10.1. Structural Requirements for Ca^{2+} Release

The Ins(1,4,5)P_3 receptor shows considerable stereo- and regiospecifity in its structural requirements for Ins(1,4,5)P_3 analogues in order to effect Ca^{2+} release. However, of the three key binding proteins Ins(1,4,5)P_3 3-kinase appears to be the most specific in its recognition of Ins(1,4,5)P_3; Ins(1,4,5)P_3 5-phosphatase is much less specific. The specificity of the Ins(1,4,5)P_3 receptor lies apparently between these two extremes.

The stereospecifity of the receptor is apparent since L-Ins(1,4,5)P_3, [= D-Ins(3,5,6)P_3] is unable to mobilize Ca^{2+}.[131, 408] The binding of this synthetic enantiomer to the receptor is roughly 2000 times weaker than that of natural D-Ins(1,4,5)P_3.[328, 409] Likewise, the enantiomers of 2-deoxy-2,2-difluoro-Ins(1,4,5)P_3 display very different agonist properties.[331, 332] D-2,2-F_2-Ins(1,4,5)P_3 was found to be a full agonist, slightly less potent than Ins(1,4,5)P_3, whereas the L isomer is only a very poor agonist.

Ins(1:2,4,5)P_3, Ins(4,5)P_2, and GroPtdIns(4,5)P_2 were shown to be 13–15 times,[109, 410] 650 times,[411] and 3–10 times[109, 393] more weakly bound than Ins(1,4,5)P_3, respectively; however, most other natural inositol phosphates including Ins(1)*P*, Ins(1:2)*P*, Ins(1,4)P_2,[19] Ins(1,3,4)P_3,[131, 328] Ins(1,3,4,5,6)P_5,[138, 412] and InsP_6 (phytic acid)[131] are ineffective as agonists at the Ins(1,4,5)P_3 receptor. Although the precise role of Ins(1,3,4,5)P_4 is still controversial, it was shown to mobilize Ca^{2+},[138] probably however via the Ins(1,4,5)P_3 receptor.[413] Ins(1,4,6)P_3 was surprisingly found to be a full agonist at the Ins(1,4,5)P_3 receptor.[315, 414] D-Ins(1,3,6)P_3 [= L-Ins(1,3,4)P_3], obtained by an unambiguous route, was shown to have Ca^{2+}-mobilizing activity in *Limulus* photoreceptors,[314] and this finding along with other data[414] helped to resolve a long-standing confusion.

The Ca^{2+}-releasing ability of a number of semisynthetic 1-substituted Ins(1,4,5)P_3 analogues[393] showed that large groups can be introduced at this position without major loss of activity. Similar results were obtained when these compounds were tested as inhibitors of aldolase A, an enzyme found to be a potent isomer-selective binder of inositol polyphosphates.[415] Similarly, the 1-*O*-(3-aminopropyl) ester of Ins(1,4,5)P_3 and a derived photoaffinity analogue[382] were able to effect Ca^{2+} release; the binding of both compounds was roughly eight times weaker than that of Ins(1,4,5)P_3. The binding of these derivatives by the receptor was equally good, and the photoaffinity derivatives were successfully used to label Ins(1,4,5)P_3 binding sites.[175] The 1-phosphorothioate analogue of Ins(1,4,5)P_3 as well as fluorescently labeled Ins(1,4,5)P_3-1S were also found to be potent Ca^{2+}-mobilizing agonists.[344]

The introduction of large groups is also tolerated at the axial 2-position and does not affect the ability of the analogue to act as a full agonist at the Ins(1,4,5)P_3 receptor.[410] Deoxygenation resulted in only a slight loss of activity,[410] and inversion of the configuration of the hydroxyl-bearing carbon [*scyllo*-Ins(1,2,4)P_3[333]] gave a highly potent full agonist.[416] DL-2-F-Ins(1,4,5)P_3[333] had the same potency as Ins(1,4,5)P_3 in mobilizing sequestered Ca^{2+} ions. Comparison with 2-F-*scyllo*-Ins(1,4,5)P_3 and 2,2-F_2-Ins(1,4,5)P_3 (which are also full agonists at the Ins(1,4,5)P_3 receptor)[330, 417] shows that the greater structural similarity of 2-F-Ins(1,4,5)P_3 to Ins(1,4,5)P_3 is reflected in its biological activity. The assumption that the 2-hydroxyl group of Ins(1,4,5)P_3 may interact with the receptor by acting as a hydrogen bond acceptor rather than a donor[330, 417] thus appears to be strengthened: the fluoro substituent of 2-F-Ins(1,4,5)P_3 can no longer donate a hydrogen bond, but the ana-

logue is still as potent as Ins(1,4,5)P_3. DL-Ins(1,2,4,5)P_4 was pharmacologically evaluated and found to be the most potent inositol tetrakisphosphate described to date.[256]

D-3-Deoxy-Ins(1,4,5)P_3,[325] D-3-F-Ins(1,4,5)P_3,[334] and D-3-*C*-(trifluoromethyl)-Ins(1,4,5)P_3[322] all mobilized Ca^{2+} as full agonists. The potency of these compounds is similar to that of Ins(1,4,5)P_3. Analogues with substituents at C-3 of increasing steric bulk (3-chloro, 3-bromo, and 3-*O*-methyl) were found to display decreasing activity with respect to receptor binding and Ca^{2+} release.[200, 338] L-*chiro*-Ins(2,3,5)P_3,[335, 336] an Ins(1,4,5)P_3 analogue with an axial rather than equatorial 3-hydroxyl group, is a potent agonist for the mobilization of sequestered Ca^{2+} with an EC_{50} only 5 to 10 times higher than that of Ins(1,4,5)P_3.[335, 417] The pharmacological properties of DL-6-F-*chiro*-Ins(2,3,5)P_3[271] are not yet available. Ins(1,3,4,5)P_4, the product of 3-kinase action on Ins(1,4,5)P_3, was shown to inhibit the binding of [^{3}H]Ins(1,4,5)P_3 to cerebellar membranes. The receptor affinity of this tetrakisphosphate is, however, about 60-fold lower than that of Ins(1,4,5)P_3,[418] and a similar decrease in potency was observed in Ca^{2+} release.[328] By analogy, an axial phosphate group at the 3-position is likewise not well tolerated.[322] These results show that the 3-hydroxyl group surprisingly plays a relatively insignificant role in receptor binding and Ca^{2+} release. Substituents at this position with increased steric demand (like an additional phosphate group), however, reduce receptor binding properties considerably. It has therefore been proposed that phosphorylation to Ins(1,3,4,5)P_4 may be the major regulatory mechanism for Ins(1,4,5)P_3 receptor binding.[417] Interestingly, a recently published study on D-3-amino-3-deoxy-Ins(1,4,5)P_3 appears to indicate that this compound is a pH-dependent partial agonist.[339]

Since the early work of Berridge and Irvine[419] the 4,5-bisphosphate motif has been thought to be crucial for Ca^{2+}-mobilizing activity. The phosphate group at C-4 appears to be essential for recognition by the Ins(1,4,5)P_3 receptor: all inositol phosphates lacking this moiety are inactive (for exceptions see ref. [420]). Ins(1,4,5)P_3-4,5S_2 is a potent Ca^{2+}-mobilizing agonist, suggesting that at least phosphorothioate substitution at C-4 is well tolerated.[349] However, no Ins(1,4,5)P_3 analogues selectively modified at the 4-position have yet been studied, and this is a clear area for future synthetic activity.

Ins(1,4,5)P_3-5S[241, 242] was found to bind with high affinity to the Ins(1,4,5)P_3 receptor and as a full agonist for mobilization of sequestered Ca^{2+} is only about seven times less potent than Ins(1,4,5)P_3. Similar to the trisphosphorothioate Ins(1,4,5)PS_3, Ins(1,4,5)P_3-5S is not dephosphorylated by the 5-phosphatase and is therefore able to produce a sustained release of Ca^{2+}. Only preliminary evaluations were carried out on the 5-methylenephosphonate analogue **180**, but these initial studies showed that this compound releases Ca^{2+} from bovine adrenal gland microsomes in a sustained fashion similar to other nonhydrolyzable analogues of Ins(1,4,5)P_3.[359] 5-Methylphosphonate **187** was reported to antagonize Ins(1,4,5)P_3-stimulated Ca^{2+} release in a pH-dependent manner, and to act as a competitive inhibitor of [^{3}H]Ins(1,4,5)P_3 binding to bovine adrenocortical microsomes.[360, 361] Full biological data for this compound and the 5-difluoromethylphosphonate analogue, which is also supposed to act as a weak antagonist,[360, 361] are awaited with interest, as these would be the first small-molecule antagonists of Ins(1,4,5)P_3 action. If these results can be confirmed, then clearly the phosphate group at C-5 is crucial for the activity of Ins(1,4,5)P_3.

D-6-Deoxy-Ins(1,4,5)P_3 was found to be a full agonist for Ca^{2+} release in permeabilized SH-SY5Y human neuroblastoma cells and is roughly 70 times less potent than Ins(1,4,5)P_3.[231] Other C-6-modified Ins(1,4,5)P_3 analogues were synthesized, including the fluoro, methyl, and methoxy derivatives.[201, 302, 327, 421] The biological properties of these compounds have not been reported to date except those of DL-6-*O*-methyl-Ins(1,4,5)P_3. This derivative was found to mobilize Ca^{2+} with an EC_{50} value over 200 times higher than that of Ins(1,4,5)P_3,[328] a result similar to those obtained for other 6-*O*-substituted analogues.[381] DL-Ins(1,4,5,6)P_4 exhibited no Ca^{2+}-releasing activity and did not appear to influence the Ins(1,4,5)P_3-mediated Ca^{2+} release at concentrations of up to 10 μM.[138] Clearly, the 6-OH group plays a significant role in receptor binding or fixing the conformation of the 5-phosphate group by hydrogen bonding. Substitution of this hydroxyl group by both uncharged and charged groups effectively abolishes activity. There is a clear need to examine the potency of 6-F-Ins(1,4,5)P_3, which remains as yet unevaluated.

The unnatural inositol phosphates Ins(2)P,[422] Ins(2,4)P_2, Ins(1,2,6)P_3,[423] Ins(1,3,5)P_3,[328] and 3-deoxy-Ins(1,5,6)-P_3[325] are all, like inositol, unable to release Ca^{2+}. Ins(1:2-cyclic 4,5)P_3 was initially reported as being equipotent to Ins(1,4,5)P_3,[130, 424] and there were speculations that this cyclic inositol phosphate may be a second messenger in its own right.[424] Further studies,[109] however, showed that Ins(1:2-cyclic 4,5)P_3 is only a weak agonist more than an order of magnitude less potent than Ins(1,4,5)P_3. Ins(2,4,5)P_3 was found to effect Ca^{2+} release and is 12–68 times less potent than Ins(1,4,5)P_3.[109, 328, 410, 411, 425] Tegge et al.[312, 425] obtained the same EC_{50} value [roughly 30 times higher than that of Ins(1,4,5)P_3] for D-Ins(2,4,5)P_3 and for D-*chiro*-Ins(1,3,4)P_3, an analogue of Ins(2,4,5)P_3 with an axial 1-hydroxyl group. It thus appears that the difference between the two compounds, an equatorial rather than an axial hydroxyl group at C-1, is insignificant with respect to Ca^{2+}-mobilizing activity. The L enantiomers of both compounds were much less active than the D isomers and roughly 800 to 960 times less active than Ins(1,4,5)P_3.[312, 425] D-3-Azido-3-deoxy-Ins(2,4,5)P_3 was considerably less potent than Ins(1,4,5)P_3 in Ca^{2+} release studies;[426] its affinity for binding to the receptor is reduced by a factor of 2000. The compound was found to mobilize 21% of sequestered Ca^{2+} at a concentration of 100 μM, whereas Ins(1,4,5)P_3 released 53% at 10 μM. The binding affinity of D-2,3-dideoxy-Ins(1,4,5)P_3 to bovine adrenal cortices was only six times lower than that of Ins(1,4,5)P_3, and its potency in effecting Ca^{2+} release was reduced by a factor of 3.5. In sharp contrast, additional deletion of the 6-hydroxyl group resulted in a further 100-fold reduction in binding affinity, and D-2,3,6-trideoxy-Ins(1,4,5)P_3 was also a very poor receptor agonist with an EC_{50} value more than 200 times higher than Ins(1,4,5)P_3.[326] This confirmed results of an earlier study in which the trideoxy analogue, albeit in racemic form, had been shown to effect Ca^{2+} release from permeabilized smooth muscle cells

with an EC_{50} value some 130 times higher than that of Ins(1,4,5)P_3.[328]

Benzene 1,2,4-trisphosphate was found to block the binding of Ins(1,4,5)P_3 to adrenal cortex microsomes competitively with an IC_{50} value of 34 μM. The affinity for the receptor is about 10000 less than that of Ins(1,4,5)P_3, and no Ca^{2+} release could be induced.[427] Benzene 1,2,4-tris(methylenephosphonate) was likewise inactive in binding and Ca^{2+} release assays, as were (1*R*,2*R*,4*R*)-cyclohexane 1,2,4-trismethylenephosphate, -tris(methylenephosphonate), -tris(methylenesulfonate), and the (4*S*) isomer of the latter.[428] Racemic trissulfate, trissulfonamide, triscarboxymethyl, and trismethylphosphonate analogues of Ins(1,4,5)P_3 did not show any biological activity;[365,366] neither did the 4,5-dimethylenephosphonate analogue of DL-Ins(4,5)P_2.[429] Inositol-1-phosphate-4,5-pyrophosphate[349] and an enantiomerically pure hexadeoxy-1,4,5-tris(methylenesulfonic acid) analogue of Ins(1,4,5)P_3[395] were also found to be inactive.

A report by Schultz et al.[420] that *cis,cis*-cyclohexane 1,3,5-trisphosphate and related analogues with a 1,5-bisphosphate arrangement are able to effect Ca^{2+} release from isolated vacuoles of *Neurospora crassa* should be treated with caution, because Ins(1,3,5)P_3 was shown not to act as an agonist in bovine aortic smooth muscle cells.[328] If these results were to be confirmed, it would imply that the vacuolar receptor of *Neurospora crassa* is different from mammalian receptors, which seems remarkable since Ins(1,4,5)P_3 receptors in different species have to date been found to be highly similar. It seems possible that Ca^{2+} contamination of the synthetic compound may be responsible for this effect.

These results suggest that the vicinal 4,5-bisphosphate moiety is essential for receptor recognition and that the presence of an additional phosphate group at C-1 greatly enhances Ca^{2+}-mobilizing properties. The fact that Ins(2,4,5)P_3 is also a full and relatively potent agonist may possibly be explained by an interaction of the axial 2-phosphate with the receptor site normally occupied by the equatorial 1-phosphate of Ins(1,4,5)P_3. Clearly, however, analogues can be synthesized with bulky substituents at the 2-hydroxyl and the 1-phosphate groups, suggesting that this area is probably relatively open to solvent. It remains to be seen which substituents can be tolerated at the 3-position, but the low activity of Ins(1,3,4,5)P_4 makes it unlikely that this is an attractive site for chemical modification (Fig. 40).

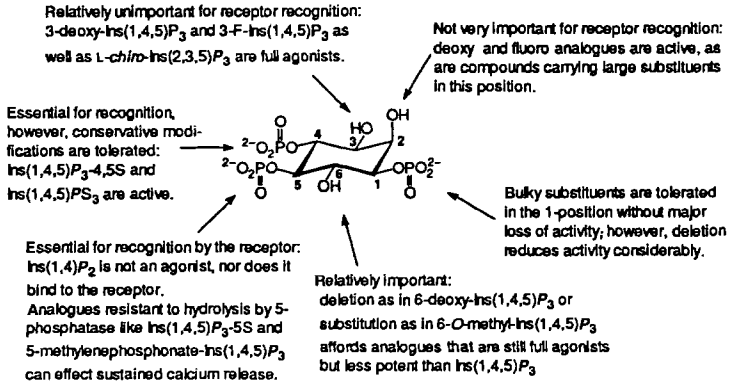

Fig. 40. Structure–activity relationships for the Ins(1,4,5)P_3 receptor.

10.2. Structure–Recognition Studies on Ins(1,4,5)*P*3 3-Kinase

The specifity of 3-kinase is in many respects greater than that of the Ins(1,4,5)P_3 receptor itself;[46] Ins(1,4,5)P_3 and Ins(1,3,4,5)P_4 are the only natural inositol polyphosphates known to be recognized with high affinity.[328]

Removal of the 1-phosphate group greatly decreases affinity for the 3-kinase: Ins(4,5)P_2 and Ins(2,4,5)P_3 are both very poor substrates for this enzyme,[328,430] and Ins(1:2 cyclic 4,5)P_3 is not phosphorylated.[431] The 1-phosphate group therefore appears to be essential for substrate recognition, which is in agreement with the observation that whilst both Ins(1,4,5)P_3-5S[241,432] and Ins(1,4,5)P_3-4,5S_2[433] are substrates for 3-kinase, an additional phosphorothioate substitution at C-1 is not tolerated: Ins(1,4,5)PS_3 is not a substrate.[434,435]

DL-2-Deoxy-Ins(1,4,5)P_3 effectively inhibits phosphorylation of [^{3}H]Ins(1,4,5)P_3 by 3-kinase;[410] the apparent K_i value is close to that of Ins(1,4,5)P_3. Other analogues carrying bulky substituents at C-2 were also recognized well by the enzyme. However, no data indicating whether these analogues act as substrates or inhibitors were given. Both DL-2-F-*scyllo*-Ins(1,4,5)P_3 and DL-2,2-F_2-Ins(1,4,5)P_3 appeared to be substrates for 3-kinase.[330] After resolution of the racemic *gem*-difluoride, however, the substrate properties of D- and L-2,2-F_2-Ins(1,4,5)P_3 were found to be quite different. Whereas the D isomer is a substrate for 3-kinase, the L isomer is a potent inhibitor of this enzyme.[332] The reason for this inhibitory activity is not yet known; however, L-2,2-F_2-Ins(1,4,5)P_3 represents a novel lead in the design of further effective inhibitors for the pharmacological intervention in the polyphosphoinositide pathway and has the advantage that it does not mobilize intracellular Ca^{2+}. 2-F-Ins(1,4,5)P_3 is also a good substrate for 3-kinase,[416] acting as a potent competitive inhibitor of the phosphorylation of [^{3}H]Ins(1,4,5)P_3 by this enzyme (apparent K_i = 3.0 μM; for comparison: 2-F-*scyllo*-Ins(1,4,5)P_3 and 2,2-F_2-Ins(1,4,5)P_3 have K_i values of 8.8 and 11.0 μM, respectively).

As can be expected with C-3-modified Ins(1,4,5)P_3 analogues, both D-3-F-Ins(1,4,5)P_3[325,334] and L-*chiro*-Ins(2,3,5)P_3,[335,336] a D-Ins(1,4,5)P_3 analogue with inverted configuration at C-3, are resistant to phosphorylation by the 3-kinase, and they are potent inhibitors of this enzyme.[436] Ins(1,3,4,5)P_4, the product of Ins(1,4,5)P_3 phosphorylation by 3-kinase, is a weak inhibitor (IC_{50} = 90 μM). However, based upon the IC_{50} data it seems unlikely that sufficient Ins(1,3,4,5)P_4 can accumulate to affect the rate of Ins(1,4,5)P_3 phosphorylation significantly, suggesting that it plays no role in any "feedback" mechanism.[328] Phosphorylation of the 3-OH group results in effective exclusion from the Ins(1,4,5)P_3 receptor, and this could be a regulatory mechanism to modulate Ins(1,4,5)P_3 binding.[417] Similarly, Ins(1,3,4,5)P_4-5S was reported to be a competitive inhibitor of 3-kinase.[253]

No compounds with selective modifications at the 4-position have been pharmacologically evaluated to date. However, the affinity of Ins(1,4,5)P_3-4,5S_2 for 3-kinase was ten times less than that of Ins(1,4,5)P_3-5S,[433] indicating that the 4-phosphate group is important for substrate recognition.

Unlike Ins(1,4,5)PS_3, DL-Ins(1,4,5)P_3-5S is a substrate for 3-kinase.[253, 432] but phosphorylation of this compound was much slower than that of the natural substrate. The 5-methylenephosphonate analogue of Ins(1,4,5)P_3, reported to elicit a sustained release of Ca^{2+},[360, 361] is presumably therefore not a substrate for 3-kinase, although full biological details on this compound remain to be published. It appears that only conservative modifications are tolerated in this position.

6-Deoxy-Ins(1,4,5)P_3 is one of the few compounds that is recognized by the highly selective 3-kinase.[231] The kinetics of its metabolism indicate that it is a substrate for this enzyme, and the phosphorylation of Ins(1,4,5)P_3 is inhibited competitively by 6-deoxy-Ins(1,4,5)P_3. It appears that hydroxyl group deletion remote from the site of action of the 3-kinase has no major effect on the binding properties of the substrate. In contrast to the 6-deoxy analogue, DL-6-methoxy-Ins(1,4,5)P_3 showed a marked drop in affinity (by roughly a factor of 120) for 3-kinase.[328] Since the hydrogen bonding potential at the 6-position is removed in both analogues, it seems possible that the increased steric bulk at the 6-position of DL-6-methoxy-Ins(1,4,5)P_3 is the cause for the low affinity of this analogue. Once again it would be useful to evaluate 6-fluoro-Ins(1,4,5)P_3 in this context.

DL-Cyclohexane 1,2,4-trisphosphate is only a weak inhibitor of [^{3}H]Ins(1,4,5)P_3 phosphorylation (IC_{50} = 327 μM).[328] Surprisingly, benzene 1,2,4-trisphosphate was relatively well recognized by 3-kinase (IC_{50} = 6.1 μM) with an affinity about ten times less than that of Ins(1,4,5)P_3.[427] D-2,3-Dideoxy- and D-2,3,6-trideoxy-Ins(1,4,5)P_3 displayed K_i values of 19 and 36 μM, respectively, whereas various other multiply deoxygenated analogs did not show any interaction[428] (Fig. 41). Interestingly, 3-kinase is also inhibited by adriamycin.[437]

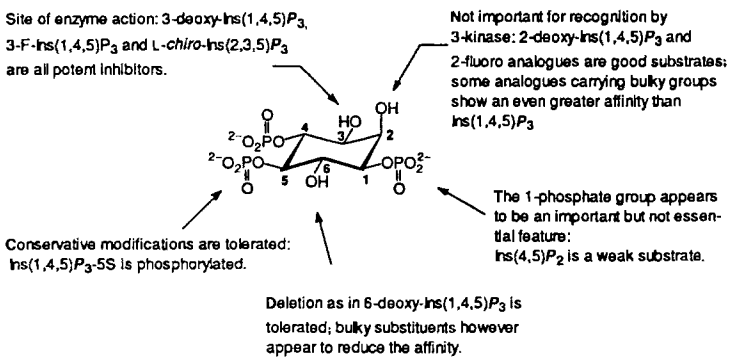

Fig. 41. Structure activity relationships for Ins(1,4,5)P_3 3-kinase.

10.3. Structure–Recognition Studies on Ins(1,4,5)P_3-5-Phosphatase

In contrast to the Ins(1,4,5)P_3 receptor and the 3-kinase, Ins(1,4,5)P_3 5-phosphatase seems to be relatively nonspecific. However, while many analogues bind to the phosphatase, only a few appear to be substrates.

The 1-phosphate group is an important feature in substrate recognition by 5-phosphatase, since Ins(4,5)P_2 is a very poor substrate.[433]

A number of racemic Ins(1,4,5)P_3 analogues modified at the 2-hydroxyl group were examined for their ability to interact with erythrocyte ghost and brain cytosol 5-phosphatase.[410] It was found that all compounds are competitive inhibitors of the enzyme and substrates for 5-phosphatase, although the extent of hydrolysis varied. Surprisingly, 2-deoxy-Ins(1,4,5)P_3 and most of the other C-2-modified analogues showed an even greater affinity for 5-phosphatase than Ins(1,4,5)P_3. 2-F-*scyllo*-Ins(1,4,5)P_3 was found to be recognized but is a weaker substrate than Ins(1,4,5)P_3.[330] The 5-phosphatase substrate properties of D- and L-2,2-F_2-Ins(1,4,5)P_3 are quite different. Whereas D-2,2-F_2-Ins(1,4,5)P_3 is a good substrate, the L enantiomer is a potent inhibitor of the enzyme.[332] Since 5-phosphatase is known to be specific for the D isomer of Ins(1,4,5)P_3, and analogues of the L enantiomer are usually not recognized very well by this enzyme [cf. L-Ins(1,4,5)P_3[438]], this result is surprising. However, there were reports of 2-substituted analogues that also display 5-phosphatase resistance,[439] and surprisingly, the L isomer of 2-aminobenzoyl-Ins(1,4,5)P_3 was found to be a potent inhibitor. Interactions of DL-2-F-Ins(1,4,5)P_3 with 5-phosphatase were also studied, and this derivative was found to be a moderately potent competitive inhibitor of this enzyme. It may be tentatively assumed that by analogy with the difluoro analogue 2,2-F_2-Ins(1,4,5)P_3, the inhibitory effect of DL-2-F-Ins(1,4,5)P_3 is due to the presence of L-2-F-Ins(1,4,5)P_3 in the racemic mixture, whereas the D isomer, like D-2,2-F_2-Ins(1,4,5)P_3, is probably a substrate for this enzyme. Thus, it may be concluded that the 2-hydroxyl group is involved in substrate recognition by Ins(1,4,5)P_3 5-phosphatase, although it does not appear to be an essential feature.

3-Deoxy-Ins(1,4,5)P_3 is a good substrate, binding with a slightly higher affinity than Ins(1,4,5)P_3 itself,[433] and 3-F-Ins(1,4,5)P_3 is also a substrate for erythrocyte 5-phosphatase.[436] In contrast, L-*chiro*-Ins(2,3,5)P_3, which can be visualized as Ins(1,4,5)P_3 with inverted configuration at C-3, was found to be a potent inhibitor.[335, 336, 436] This is surprising, since the hydroxyl group at C-3 in this molecule is remote from the site of attack of the enzyme. Two possible explanations for this phenomenon were given: The conformation of L-*chiro*-Ins(2,3,5)P_3 in solution and/or bound to 5-phosphatase may be sufficiently different from that of Ins(1,4,5)P_3 that although the analogue binds to the enzyme in a similar mode as Ins(1,4,5)P_3, the catalytic mechanism of the enzyme is interrupted. Alternatively, the inhibition may be the result of nonproductive binding of the inverted substrate L-*chiro*-Ins(2,3,5)P_3 in a rotated fashion. In this arrangement the analogue would mimic three elements of Ins(1,4,5)P_3 correctly, namely the ring pucker, the crucial vicinal 4,5-bisphosphate moiety (as the 2,3-bisphosphate pair), and the 3-hydroxyl group (as the 4-hydroxyl group). The 5-phosphate group of L-*chiro*-Ins(2,3,5)P_3 in this arrangement mimics an equatorial 2-phosphate group of an Ins(1,4,5)P_3 analogue, and such a phosphate could presumably still bind reasonably well to the hydrophilic pocket of the enzyme, which usually interacts with the equatorial 1-phosphate group of Ins(1,4,5)P_3. In this inverted binding mode the axial 1-hydroxyl group of L-*chiro*-Ins(2,3,5)P_3 now mimics the axial 6-hydroxyl group of an Ins(1,4,5)P_3 analogue. As discussed below, the equatorial 6-hydroxyl group of Ins(1,4,5)P_3 may play an important role in the mechanism of 5-phosphatase-catalyzed hydrolysis, and the inhibitory proper-

ties of L-*chiro*-Ins(2,3,5)P_3 may possibly be ascribed to the pseudo-axial 6-hydroxyl group in the inverted binding conformation.

Phosphorothioate substitution at the 5-position creates a potent inhibitor of Ins(1,4,5)P_3-5-phosphatase, Ins(1,4,5)P_3-5S.[241, 242] The 5-methylenephosphonate analogue of D-Ins(1,4,5)P_3 is another long-lived agonist of Ca^{2+} mobilization.[359] The sustained release of Ca^{2+} by this compound indicates that it is not dephosphorylated and thus deactivated by the 5-phosphatase. Full data have yet to be published, and details on interactions of the 5-methylphosphonate and 5-difluoromethylphosphonate analogues of Ins(1,4,5)P_3[360, 361] are also awaited with interest.

D-6-Deoxy-Ins(1,4,5)P_3[231] inhibited the dephosphorylation of [^{32}P]Ins(1,4,5)P_3 by erythrocyte 5-phosphatase and is a moderately potent inhibitor of this enzyme. The nonselectivity of this enzyme is underlined by the moderate reduction in affinity of D-6-deoxy-Ins(1,4,5)P_3 (ca. twofold) and DL-6-methoxy-Ins(1,4,5)P_3 (ca. fourfold) for the aortic smooth muscle 5-phosphatase[328] relative to the natural substrate. The resistance of these two analogues to dephosphorylation confirms that the minimal structural requirements for substrate hydrolysis by the 5-phosphatase include the vicinal 4,5-bisphosphate moiety and a free 6-hydroxyl group. It is possible that the function of the 6-hydroxyl group of Ins(1,4,5)P_3 is similar to the role that the 6-hydroxyl group of Ins(1)P plays in the dephosphorylation of this compound by inositol monophosphatase; in other words, the absence of this group has no significant effect on binding, but its presence is essential for the enzyme to act on the substrate.

Whereas Ins(2,4,5)P_3[410] and Ins(1:2-cyclic 4,5)P_3[310] are substrates for the 5-phosphatase, DL-Ins(1,4,5)PS_3 is resistant to degradation by this enzyme.[440] DL-Cyclohexane 1,2,4-trisphosphate is a weak competitive inhibitor (K_i = 124 mM), and no inorganic phosphate release due to hydrolysis by the enzyme was detected.[328] Benzene 1,2,4-trisphosphate[427] and (1*R*,2*R*,4*S*)-cyclohexane 1,2,4-tris(methylenesulfonate)[428] were found to inhibit the degradation of [^{3}H]Ins(1,4,5)P_3 by 5-phosphatase surprisingly well, indicating that even radical structural alterations can be tolerated by the enzyme. The trisphosphorothioates L-Ins(1,4,5)PS_3, Ins(1,3,5)PS_3, and L-*chiro*-Ins(1,4,6)PS_3 were found to be 5-phosphatase inhibitors of the highest potency with submicromolar K_i values of 0.50, 0.43, and 0.3 μM, respectively.[353] The latter two compounds do not interact with 3-kinase, nor do they mobilize Ca^{2+}.[441, 442] These analogues are therefore ideal tools for the selective inhibition of 5-phosphatase (Fig. 42).

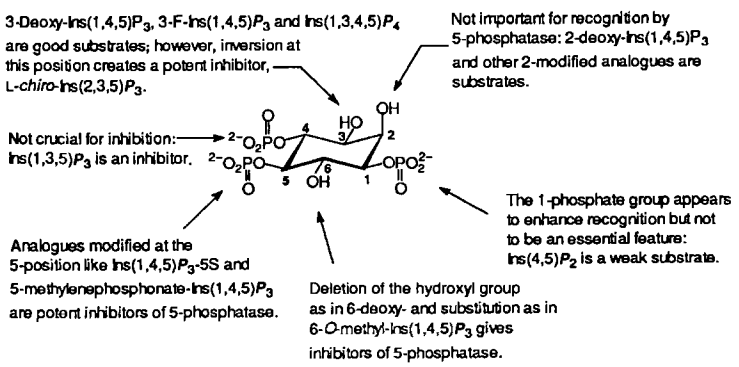

Fig. 42. Structure–activity relationships for Ins(1,4,5)P_3 5-phosphatase.

11. Ins(1,4,5)P_3 Partial Agonists and Antagonists

Only a small number of chemical agents are available for intervention in the phosphatidylinositol signaling pathway, which is underlined by the lack of a simple small-molecule Ins(1,4,5)P_3 antagonist. To aid the design of such an antagonist, extensive structure–activity studies are required. In the rational search for an agent having high affinity for the receptor yet not releasing Ca^{2+}, it is necessary to dissect the structural features of Ins(1,4,5)P_3 that determine binding affinity from those that trigger opening of the Ca^{2+} ion channel. Many naturally occurring and synthetic inositol phosphates display lower binding affinity than Ins(1,4,5)P_3 for the receptor, which can be correlated with correspondingly lower Ca^{2+}-releasing ability. However, no compound lacking a D-vicinal 4,5-bisphosphate grouping has yet been found to release Ca^{2+}. Modifications at this locus may be the way to design a small molecule that can directly affect channel opening, providing that high binding affinity can be maintained in such an analogue.

11.1. Partial Agonists at the Ins(1,4,5)P_3 Receptor

A number of partial agonists at the Ins(1,4,5)P_3 receptor have been identified: Ins(1,3,4,6)P_4 was found to have moderate affinity for the receptor and to give a maximal Ca^{2+} release only some 80% of that of mobilized by Ins(1,4,5)P_3. If the maximally effective Ca^{2+}-releasing concentration of Ins(1,3,4,6)P_4 is administered together with Ins(1,4,5)P_3, the EC_{50} value of the latter is increased.[138] This has led to the conclusion that the Ca^{2+} released is not only from the same intracellular store, but it also strongly indicates that Ins(1,3,4,6)P_4 and Ins(1,4,5)P_3 compete for the same receptor site.[138, 139] As Ins(1,3,4,6)P_4 does not nominally possess the vicinal 4,5-bisphosphate moiety normally required for agonist activity, it is not obvious why this tetrakisphosphate should release Ca^{2+}. However, two alternative binding conformations of Ins(1,3,4,6)P_4 to the Ins(1,4,5)P_3 receptor can be visualized, in which a number of important recognition features are mimicked, including the 4,5-bisphosphate unit and the 1-phosphate group. It may be that one or both of these binding conformations are the cause of the partial agonist behavior exhibited by Ins(1,3,4,6)P_4. Chemical modification of Ins(1,3,4,6)P_4 may provide a solution to this.

Weaker partial agonist behavior was found for 6-deoxy-Ins(1,4,5)PS_3 and L-*chiro*-Ins(2,3,5)PS_3.[351, 352] They were able to mobilize only 42 and 34% of the Ins(1,4,5)P_3-sensitive Ca^{2+} pool, respectively. As weak partial agonists they can be used to antagonize Ins(1,4,5)P_3-induced Ca^{2+} release, albeit at relatively high concentrations. It should be noted that both compounds are C-3- or C-6-modified analogues of Ins(1,4,5)P_3, respectively, in addition to carrying phosphorothioate groups rather than phosphates in the 1-, 4-, and 5-positions. As the weakest partial agonists, these compounds and L-*chiro*-Ins(2,3,5)PS_3 in particular represent key leads in the hunt for a small-molecule Ins(1,4,5)P_3 receptor antagonist. Partial agonist properties were also demonstrated for *scyllo*-Ins(1,2,4,5)PS_4.[416]

11.2. Ins(1,4,5)P_3 Receptor Antagonists

At present, none of the Ins(1,4,5)P_3 analogues synthesized has shown any antagonistic properties apart from the 5-methylphosphonate analogue of Ins(1,4,5)P_3[360,361] and L-*chiro*-Ins(2,3,5)PS_3.[433] The latter, however, has significant intrinsic activity. The only molecules that have been clearly demonstrated to potently inhibit Ins(1,4,5)P_3-receptor binding are heparin[443-449] and decavanadate;[19,450-452] neither of them, however, shows specifity for the Ins(1,4,5)P_3 receptor,[418,453] and they are therefore of only limited use as pharmacological tools.

11.2.1. Heparin

Heparin is a polysulfated polysaccharide with a molecular weight between 6000 and 20000, depending on origin and preparation. Initial indications that heparin could interact with Ins(1,4,5)P_3 binding sites came from the observation that the cerebellar site first described by Worley et al.[454] is sensitive to heparin.[443] Indeed, subsequently the protein representing this site was significantly purified using heparin-agarose affinity chromatography.[159] Heparin was also found to inhibit Ins(1,4,5)P_3-induced Ca^{2+} release in hepatocytes,[447] pancreatic β-cells,[448] and rat liver microsomes.[449] The potent antagonism of Ins(1,4,5)P_3-activated Ca^{2+} release by heparin was demonstrated to be both competitive and reversible, with an affinity of heparin for the binding site of roughly 3 nM.[444] It was also found that the heparin fragment TV84558-51 (average $M_r = 5100$) is as potent as heparin itself in inhibiting [^{3}H]Ins(1,4,5)P_3 binding, whereas smaller heparin fragments and less sulfated or unsulfated glycosaminoglycans (chondroitin sulfate and hyaluronic acid) did not affect binding.[443] This is also the case for O- and N-desulfated, N-reacetylated heparin; N-desulfated heparin showed a decreased inhibitory activity at the Ins(1,4,5)P_3 receptor but not at the Ins(1,3,4,5)P_4 binding site, whilst pentosan polyphosphate is another potent but nonelective inhibitor at both Ins(1,4,5)P_3 and Ins(1,3,4,5)P_4 binding sites.[418] In contrast to the inhibitory effects of heparin and related substances observed in many animal and plant tissues, Ins(1,4,5)P_3-induced Ca^{2+} mobilization in fungi is heparin-insensitive.[455] Heparin also inhibits Ins(1,4,5)P_3 3-kinase activity (but not that of Ins(1,4,5)P_3 5-phosphatase),[445] the specific binding of Ins(1,3,4,5)P_4 to cerebellar membranes,[418] and the ability of Ins(1,3,4,5)P_4 to release Ca^{2+} from cerebellar microsomes.[412]

It seems likely that the negatively charged sulfate groups of heparin interact with the hydrophilic pockets in the receptor binding site that usually accommodate the phosphate groups of Ins(1,4,5)P_3. However, it is interesting to note here that *myo*-inositol-1,4,5-trissulfate, in spite of carrying sulfate groups in the positions that are occupied by the phosphate groups in Ins(1,4,5)P_3, does not seem to have any antagonistic properties.[366] Although fragments of lower molecular weight have been investigated with some success,[456] their effectiveness is still an order of magnitude away from that of a true Ins(1,4,5)P_3 analogue. Clearly, a closer study of the heparin-receptor interaction is essential in the search for structural features that can be incorporated into a small-molecule antagonist.

11.2.2. Decavanadate

Different vanadates were examined for their ability to inhibit Ins(1,4,5)P_3-receptor binding and Ca^{2+} release. It was found that decavanadate ($V_{10}O_{28}^{6-}$ at pH 7)[457] inhibits Ins(1,4,5)P_3-induced Ca^{2+} mobilization in permeabilized rat insulinoma and PC12 cells (IC_{50} 5 μM)[310] and SH-SY5Y cells (K_i = 1.2 μM),[451] and inhibits the binding of [^{3}H]Ins(1,4,5)P_3 to its receptor in cerebellar and adrenal cortex membranes.[451] Orthovanadate and oligovanadate on the other hand do not inhibit Ins(1,4,5)P_3-receptor binding,[450] possibly because they are unable to bridge the multiple Ins(1,4,5)P_3 binding sites suggested by Meyer et al.[458] Decavanadate also suppresses Ins(1,3,4,5)P_4-induced Ca^{2+} release from permeabilized SH-SY5Y cells and inhibits Ins(1,4,5)P_3 5-phosphatase, 3-kinase, and Ins(1,3,4,5)P_4 5-phosphatase.[451]

Although decavanadate is a potent and competitive antagonist at the Ins(1,4,5)P_3 receptor, the fact that its specifity is low will most likely prevent it from becoming a useful tool to investigate the second messenger role of Ins(1,4,5)P_3. However, molecular modeling studies based upon decavanadate, and indeed heparin, may provide important leads.

12. Applications of Inositol Phosphate Analogues

Apart from caged and photoaffinity analogues of Ins(1,4,5)P_3 with obvious applications, Ins(1,4,5)PS_3 has proved to be the most versatile Ins(1,4,5)P_3 analogue synthesized to date. Ins(1,4,5)P_3 receptors recognize Ins(1,4,5)PS_3 with high affinity in brain[409,440] and liver.[459] The analogue, a full intracellular Ca^{2+}-releasing agonist, is only three to four times less potent than Ins(1,4,5)P_3 in a number of cells, including *Xenopus* oocytes,[408,460] permeabilized Swiss 3T3 cells,[131,408] GH_3 cells,[131] hepatocytes,[435] pancreatic[461-463] and parotid[464] acinar cells, skeletal muscle triads,[465] mouse lacrimal cells,[466] and SH-SY5Y neuroblastoma cells.[46] Ins(1,4,5)PS_3 is resistant to dephosphorylation by 5-phosphatase[435,440] and can produce a sustained cellular Ca^{2+} transient.[46,435] Ins(1,4,5)PS_3 was the first competitive inhibitor of 5-phosphatase reported,[432,438] but is not bound by 3-kinase and does not compete with Ins(1,4,5)P_3 for this enzyme.[432,435] Ins(1,4,5)PS_3, which is resistant to all known routes of Ins(1,4,5)P_3 metabolism, is now commercially available, and is finding an increasing number of biological applications, as illustrated here.

The possibility of synergistic interactions between Ins(1,4,5)P_3 and its metabolite, Ins(1,3,4,5)P_4, in promoting Ca^{2+} entry at the plasma membrane has been the subject of considerable recent debate.[123,124,126] When a Ca^{2+}-activated K^+ current in singly internally perfused mouse lacrimal acinar cells was monitored by using a patch-clamp technique for whole-cell current recording, addition of Ins(1,4,5)PS_3 alone gave rise to a single transient response, independent of external Ca^{2+} and typical of Ins(1,4,5)P_3. In the presence of Ins(1,3,4,5)P_4, however, this analogue gave a sustained response dependent upon external Ca^{2+}. The transient response of Ins(1,4,5)P_3 is therefore presumed not to be a consequence of rapid metabolism, and Ins(1,3,4,5)P_4 does not act by protecting Ins(1,4,5)P_3 against dephosphorylation by 5-phosphatase, for which it is also a substrate.[466]

Intracellular Ca^{2+} oscillations are often observed in cells stimulated by extracellular agonists coupled to polyphosphoinositide hydrolysis, and the role and generative mechanisms of such oscillations have been the subject of significant recent interest and controversy.[47,467] Models of the processes underlying these oscillations have been developed.[467,468] Singly perfused mouse pancreatic acinar cells treated with Ins(1,4,5)PS_3 [or Ins(1,4,5)P_3], applied through a patch pipette, were found to evoke repetitive pulses of Ca^{2+}-activated Cl^- current, similar in amplitude and frequency to the response to acetylcholine, acting through muscarinic receptors. Pulsatile Ca^{2+} release is possible, therefore, even at a constant level of the analogue, and presumably therefore also of Ins(1,4,5)P_3, which is an argument against a receptor-controlled oscillator in the generation of local maxima in Ca^{2+} concentration, and a role for the periodic phosphorylation or degradation of Ins(1,4,5)P_3.[462] Different types of cytosolic Ca^{2+} fluctuation patterns, mimicking those produced by the natural agonist, can be generated by Ins(1,4,5)PS_3 depending on its concentration.[463] Low Ins(1,4,5)PS_3 concentrations evoke repetitive local maxima in the Ca^{2+} concentration, whereas at relatively high concentrations repetitive Ca^{2+} waves are produced.

When invertebrate microvillar photoreceptors are exposed to light, Ca^{2+} release from the ER is effected by the intermediacy of Ins(1,4,5)P_3 acting through an Ins(1,4,5)P_3 receptor. In ventral photoreceptors of the horseshoe crab *Limulus* Ins(1,4,5)PS_3 was used to investigate mechanisms that terminate Ins(1,4,5)P_3-induced Ca^{2+} mobilization. The action of Ins(1,4,5)P_3 in these cells is stereospecific for the D enantiomer and the second messenger is normally rapidly deactivated by metabolism. In the *Limulus* photoreceptor, Ins(1,4,5)PS_3 generates sustained repetitive oscillation of Ca^{2+}-dependent membrane potential which persists for tens of minutes.[469] Oscillations of membrane potential[408] and Ca^{2+}-dependent Cl^- current[460] can be generated by microinjection of Ins(1,4,5)PS_3 into *Xenopus* oocytes. Such oscillations are not sustained here, however, indicating that factors other than metabolism are important in terminating the response. Ins(1,4,5)PS_3-evoked membrane potential oscillations differ from those generated by Ins(1,4,5)P_3, and resemble more those of Ins(2,4,5)P_3. The reason for this is not clear, but different mechanisms for setting up Ca^{2+} oscillations may be possible.[126] Oscillations in Ca^{2+}-dependent Cl^- current induced by Ins(1,4,5)PS_3 appear to resemble those induced by Ins(1,3,4,5)P_4 rather than Ins(1,4,5)P_3.[470]

The free intracellular Ca^{2+} concentration increased in a localized cellular area through the action of stimulus-induced elevation of Ins(1,4,5)P_3 can give rise to actively propagated Ca^{2+} waves, which extend this signal to other parts of this cell. Ins(1,4,5)PS_3 was employed to investigate the propagation of Ca^{2+} waves through the cytoplasm of *Xenopus* oocytes.[471] Ins(1,4,5)PS_3-stimulated Ca^{2+} waves were found to be very similar to those induced by stimulation of acetylcholine receptors and probably therefore result from the same intracellular mechanisms. However, since Ins(1,4,5)PS_3 cannot be hydrolyzed and is not readily metabolized by *Xenopus* oocytes,[460] it can be inferred that such Ca^{2+} waves do not require fluctuations in Ins(1,4,5)P_3 levels and may be derived by a mechanism dependent upon Ca^{2+} stimulation of Ins(1,4,5)P_3-induced Ca^{2+} release.

When receptor activation in *Xenopus* oocytes is followed, complex spatial and temporal patterns of Ca^{2+} release in the form of regenerative circular and spiral waves can be observed. Such spiral waves could be generated by injection of the nonmetabolizable Ins(1,4,5)PS_3 and were indistinguishable from receptor-induced Ca^{2+} patterns.[472] Stimulation of Ca^{2+} release by such a compound, however, did not result in gross alteration of the Ca^{2+} release pathway. This and other similar behavior suggested that the metabolism of Ins(1,4,5)P_3 is not responsible for the cessation of Ca^{2+} activity. Clearly the Ins(1,4,5)P_3 concentration remains relatively constant during the period of regenerative wave stimulation. Regenerative activity is probably due to the cyclical nature of stimulation and inhibition of the Ins(1,4,5)P_3 receptor channel as governed by cytoplasmic Ca^{2+} concentrations. Ins(1,4,5)PS_3 has also been employed to study the influence of Ca^{2+} influx on Ca^{2+} waves induced by microinjection of the analogue. Receptor-activated Ca^{2+} influx was found to modulate the frequency and velocity of Ins(1,4,5)P_3-dependent Ca^{2+} waves in *Xenopus* oocytes.[473]

Microinjection of cGMP into unfertilized sea urchin eggs elicits its activation by stimulating a rise in the intracellular free Ca^{2+} concentration by means of an unknown mechanism. This Ca^{2+} release and activation are prevented in eggs in which the Ins(1,4,5)P_3-sensitive Ca^{2+} stores were emptied by prior injection of Ins(1,4,5)P_3. Indeed, injection of Ins(1,4,5)PS_3 into sea urchin eggs caused a Ca^{2+} transient of similar magnitude and duration to that elicited by Ins(1,4,5)P_3. However, subsequent injections of Ins(1,4,5)PS_3 resulted in only small subsequent repetitive Ca^{2+} transients in contrast to the much larger ones elicited by Ins(1,4,5)P_3. This is because, as a result of the nonhydrolyzable nature of Ins(1,4,5)PS_3, the resting Ca^{2+} level is relatively greater in Ins(1,4,5)PS_3-injected eggs. Thus, the Ca^{2+} store can be progressively depleted by successive injections of Ins(1,4,5)PS_3.[474]

Ins(1,4,5)PS_3 was exploited to help distinguish functionally between Ins(1,4,5)P_3-sensitive and -insensitive nonmitochondrial MgATP-dependent Ca^{2+} pools in rat pancreatic acinar cells.[461] The Ins(1,4,5)P_3-sensitive Ca^{2+} pool was kept empty by Ins(1,4,5)PS_3 and Ca^{2+} reuptake occurred into the Ins-(1,4,5)P_3-insensitive pool.

Ins(1,4,5)PS_3 and the related monophosphorothioate analogue Ins(1,4,5)P_3-5S are potent 5-phosphatase inhibitors[432,438] and have been employed to inhibit Ins(1,4,5)P_3 breakdown in electrically permeabilized SH-SY5Y human neuroblastoma cells.[475] Inhibition of 5-phosphatase-mediated metabolism of exogenously added 5[^{32}P]Ins(1,4,5)P_3 was about ten times greater than that of cell-membrane-derived [^{3}H]Ins(1,4,5)P_3, indicating the possibility of Ins(1,4,5)P_3 compartmentation, in other words that homogenous mixing of exogenously added and endogenously generated Ins(1,4,5)P_3 does not occur. Ins(1,4,5)P_3-5S is a substrate for Ins(1,4,5)P_3 3-kinase and inhibits the phosphorylation of [^{3}H]Ins(1,4,5)P_3 by this enzyme.[432]

Intracellular Ca^{2+} release can be "quantized", where the size of the Ins(1,4,5)P_3-sensitive Ca^{2+} pool is apparently dependent upon the concentration of Ins(1,4,5)P_3.[124] Ins(1,4,5)PS_3 has been employed in the investigation of quantal Ca^{2+} release in permeabilized hepatocytes.[476] The failure of submaximal con-

centrations of Ins(1,4,5)P_3 or Ins(1,4,5)PS_3 to empty the Ca^{2+} store completely was not due to stimulus deactivation or to receptor desensitization. Use of the metabolically stable Ins(1,4,5)PS_3 allowed Ca^{2+} efflux experiments to be performed at a high cell density, at which metabolic degradation of Ins(1,4,5)P_3 would normally have posed significant problems.

Ins(1,4,5)P_3 activates a novel voltage-dependent K^+ conductance in rat CA1 hippocampal pyramidal cells.[477] When injected into these cells, Ins(1,4,5)PS_3 inhibited action potential firing. The metabolic stability of Ins(1,4,5)PS_3 was crucial for these observations. Ins(1,4,5)P_3 itself did not elicit this conductance, presumably because of its rapid enzymatic metabolism. Thus, importantly, the use of Ins(1,4,5)PS_3 may uncover activities of Ins(1,4,5)P_3 that may not be observable experimentally with the natural messenger because of rapid metabolism or the slow diffusion of exogenously added agonist.

In rabbit skeletal muscle triads, Ins(1,4,5)PS_3 released up to 20% of an actively loaded Ca^{2+} pool, although activation of ryanodine receptor Ca^{2+} channels was zero or minimal,[465] raising the possibility that the Ca^{2+}-mobilizing activity may be mediated by other channels or mechanisms. Evidence was provided for two types of intracellular Ca^{2+}-sensitive channels displaying fast activation kinetics, namely Ins(1,4,5)P_3-sensitive and Ca^{2+}-sensitive channels. The kinetics of Ca^{2+} release by Ins(1,4,5)PS_3 in rabbit skeletal muscle SR were surprisingly fast (20–150 ms, depending upon agonist concentration), indicating that Ins(1,4,5)P_3 receptors of skeletal muscle may be kinetically competent to signal the raid elevation of cytosolic Ca^{2+} that preceeds muscle contraction.[478]

A role for Ins(1,4,5)P_3 in red blood cells has yet to be established, although the turnover of polyphosphoinositides is well known. In permeabilized human red blood cells Ins(1,4,5)P_3 evokes transient release of Ca^{2+}, disorganization of the spectrin network, and reversible shape changes, as measured by immunofluorescence.[479] However, Ins(1,4,5)PS_3 evokes sustained release of Ca^{2+} and irreversible shape changes and disorganization of the spectrin network. The polyphosphoinositide signaling pathway evidently plays an important role in the shape maintenance of red blood cells.

13. Syntheses of Inositol Lipids and Analogues

Much of the earlier work on the synthesis of phosphatidylinositol lipids and their analogues has been covered in a review.[480] The synthesis of four stereoisomers of dipalmitoyl phosphatidylinositol to probe the substrate stereospecificity of PtdIns 4-kinase was reported.[481,482] The PtdIns(4,5)P_2 phospholipid analogue 1-*O*-(1,2-di-*O*-palmitoyl-*sn*-glycero-3-phospho)-D-Ins(4,5)P_2 was synthesized using a P^{III} approach.[266] (The preparation of the di-*O*-stearoyl phospholipid had been described previously by a Russian group,[219,483,484] and the work of this group in this area has been reviewed.[480,485]) A synthesis of optically active 1-*O*-(1,2-di-*O*-stearoyl-*sn*-glycero-3-phospho)-D-Ins(3,4,5)P_3 from (−)-quinic acid[486] has been complemented by a short synthesis of this PtdIns(3,4,5)P_3 analogue in racemic form.[487]

The first synthesis of a fluoro analogue of an inositol lipid was described as early as 1982.[190] 2-Deoxy-2-fluoro-1-phosphatidyl-*scyllo*-inositol was obtained by condensation of 2-fluoro-2-deoxy-3,4,5,6-tetra-*O*-benzyl-*scyllo*-inositol with the sodium salt of dipalmitoyl-L-α-phosphatidic acid, followed by hydrogenolysis. More recently, preparations of D-3-deoxy-3-fluoro-1-phosphatidyl-*myo*-inositol and the respective 3-chloro derivative were reported.[488–490] The former PtdIns analogue displayed cytostatic properties, inhibiting cell growth of NIH 3T3 cells at concentrations on the order of 100 μM.

The synthesis of 2-deoxy-PtdIns was described.[491] Racemic 3,4,5,6-tetra-*O*-benzyl-*myo*-inositol was selectively acetylated at the 1-hydroxyl group. Deoxygenation was effected employing the Robins' variation of the Barton–McCombie sequence: thionocarbonate formation and radical reduction. Saponification and optical resolution of the resulting alcohol via its camphanates afforded D-3,4,5,6-tetra-*O*-benzyl-2-deoxy-*myo*-inositol, which was phosphitylated with the novel coupling agent bis(diisopropylamino)(2-trimethylsilylethoxy)phosphine. Reaction with dipalmitoylglycerol and oxidation of the phosphite triester gave the protected deoxy-PtdIns analogue as a mixture of diastereoisomers at phosphorus. Stepwise deblocking then gave 2-deoxy-PtdIns, which was used to study the specificity of phospholipase C (PLC).

Syntheses of the PtdIns analogue 1,2-dipalmitoyl-*sn*-glycero-3-thiophospho-*myo*-inositol (DPPsI) were reported by two groups.[263–265] In the first synthesis,[263,264] 1D-2,3:5,6-di-*O*-cyclohexylidene-4-*O*-methoxymethyl-*myo*-inositol was phosphitylated with methoxy(diisopropylamino)chlorophosphine (**61**) and then converted directly to the protected 1,2-dipalmitoyl-*sn*-glycero-3-thiophospho-*myo*-inositol by reaction with 1,2-dipalmitoyl-*sn*-glycerol and sulfoxidation. Deprotection with acid and demethylation with trimethylamine afforded (R_P + S_P)-DPPsI as a mixture of diastereoisomers, which was used to examine the stereochemical mechanism by which PtdIns-specific PLCs cleave their substrates. In the second approach,[265] 1,2-dipalmitoyl-*sn*-glycerol was reacted with **61** to produce the phosphoramidite, which was then condensed with 1D-2,3,4,5,6-penta-*O*-benzyl-*myo*-inositol. Sulfoxidation afforded a mixture of the phosphorothioate diastereoisomers separable by chromatography. Deprotection produced the individual diastereoisomers of 1,2-dipalmitoyl-*sn*-glycero-3-thiophospho-1-*myo*-inositol. The synthesis of a number of PtdIns analogues with thiophosphoester bonds designed to inhibit PtdIns-PLC was also reported.[492]

Phosphonylating agent **185** was employed in syntheses of optically active phosphonate analogues of PtdIns and PtdIns(4)P[493] as well as in the preparation of the diastereomeric uncharged methylphosphonate analogues of PtdIns.[363] The phosphonate analogue of PtdIns has proved to be a potent antiinflammatory and analgesic agent.[494] Phosphonate derivatives of PtdIns with a single alkyl chain in place of the diacylglycerol moiety were also described,[495] as were isosteric methylenephosphonate and isopolar difluoromethylenephosphonate analogues of PtdIns containing short-chain ethers rather than lengthy acyl chains on the *sn*-1 and *sn*-2 oxygens of the glycerol unit to improve the water solubility of these compounds.[496]

14. Glycosyl-Phosphatidylinositol Anchors

Many proteins are bound to biological membranes. Whereas integral membrane proteins have one or more hydrophobic domains and are embedded to a great extent in the lipid bilayer, other proteins are covalently attached to lipids which serve as anchors to the cell membrane. It has been shown that many of these latter proteins are linked to the membrane by phosphatidylinositol anchors attached to the C-terminal amino acid of the protein through an intervening glycan structure [glycosylphosphatidylinositol (GPI) anchor].[497-500] More than 30 different cell surface proteins with a GPI anchor have been identified (for the biosynthesis of GPI anchors see ref. [501]), including hydrolytic enzymes (e.g. alkaline phosphatase and acetylcholinesterase[502]), mammalian antigens (e.g. Thy-1[503]), and cell adhesion proteins. The generic structure of GPI anchors is PtdIns-glucosamine-mannose$_3$-phosphoethanolamine-protein; however, modifications of the core mannosyl residues by additional side chains are common and other variations (e.g. in the fatty acid composition of PtdIns) have also been observed.

The discovery of GPI anchors has attracted the interest of bioorganic chemists, and efforts to synthesize the GPI anchor of the variant surface glycoprotein (VSG) of the parasitic protozoan *Trypanosoma brucei*[504] (Fig. 43) have been successful.[505, 506] The survival of African trypanosomes depends on the integrity of their cell-surface coat, which is formed by VSGs arranging into tightly packed monolayers and which protects the parasite from lytic factors of the host serum. By expressing different VSGs at different times the parasite is able to evade the host's immune response. This antigenic variation makes it difficult for the immune system to supply the appropriate antibodies at the right time, and it also renders drugs against specific VSGs ineffectual. Inhibition of the biosynthesis of the VSG GPI anchor, however, or drugs targeting specific features of this GPI anchor, could prove successful. This explains the interest this particular GPI anchor has attracted. Whereas the backbone structure of the VSG GPI anchor is similar to that of other GPI anchors, the α-galactose side chain of the VSG GPI anchor seems to be parasite-specific. Thus the design of drugs aiming at this side chain may prove successful.

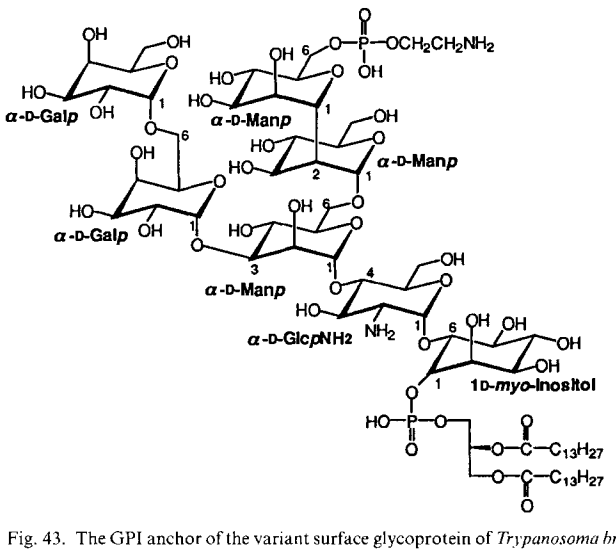

Fig. 43. The GPI anchor of the variant surface glycoprotein of *Trypanosoma brucei*.

Some metabolic fragments of the protein–GPI complex formed by the combined actions of specific endogeneous proteases and a glycosyl-phosphatidylinositol-specific phospholipase C (GPI-PLC) were found to display certain biochemical properties previously associated with crude preparations of putative insulin mediators (PIMs). (This GPI-PLC is distinct from the PtdIns-PLC, which hydrolyzes PtdIns, PtdIns(4)P and PtdIns(4,5)P_2 and is located on the inner membrane rather than the cell surface.) PIMs are phosphorylated inositol-glycans generated after insulin stimulation of the cell surface receptor and can mimic some biochemical properties of insulin in vitro.[500, 507, 508] However, it is as yet still premature to regard inositol phosphate glycans as second messengers of insulin action. Several groups directed their attention towards the preparation of PIMs[234, 509-512] and related GPIs. Syntheses of fragments of mycobacterial inositol phospholipids were also reported.[267, 513]

15. Summary and Outlook

The first evidence of a second messenger role for Ins(1,4,5)P_3[19, 419] catapulted the study of polyphosphoinositide metabolism and its effects from the position of a relatively modest backwater to one of the most active fields at the forefront of modern biology. The resulting upsurge in interest in cyclitol and inositol phosphate chemistry shows no current signs of subsiding. Indeed, it is likely that a significant proportion of future progress in inositol phosphate biology will be underpinned by the current interest in inositol phosphate chemistry. Continuing development of synthetic inositol phosphate analogues with novel biological properties can be envisaged, including receptor antagonists, caged compounds, cell-penetrating compounds, affinity, photoaffinity, and spin-labeled inositol phosphate analogues, fluorescent probes, and inositol phosphates linked to affinity columns for the purification of receptors and enzymes. The prospect of a whole new signaling pathway based upon PtdIns(3,4,5)P_3 opening up, the anticipation of the structural characterization of the as yet elusive "Ca^{2+}-influx factor", and the advent of novel potent Ins(1,4,5)P_3 receptor ligands unrelated to Ins(1,4,5)P_3 such as adenophostins (Fig. 44) together with the real possibility of devising drugs of the future by pharmacological intervention in signaling transduction pathways means that interdisciplinary collaborations by chemists with cell biologists, biochemists, and pharmacologists will be crucial to meet these new challenges and apply the results.

C–H and C–C Bond Activation by Bare Transition-Metal Oxide Cations in the Gas Phase

Detlef Schröder and Helmut Schwarz*

Dedicated to Michael Henchman and Rudolf Zahradnik

Over the last decade the gas-phase chemistry of bare transition-metal oxide cations MO^+ has received considerable attention. This interest is primarily due to the particular role of metal oxides in the oxidation of organic compounds in a variety of chemical and biochemical transformations. At a molecular level the simplest model system for these processes deals with reactions of bare metal-oxide ions in the gas phase. Due to the high oxophilicities of the early transition metals, their monoxide cations MO^+ do not mediate O-atom transfer to any organic compounds at all. In contrast, monoxide cations of late transition metals can oxygenate a variety of hydrocarbons, and the most reactive ions, MnO^+, FeO^+, NiO^+, OsO^+, and PtO^+, even activate methane. Insight into the reaction mechanisms of these oxidation processes can be obtained by analysis of reaction kinetics, isotope effects, product distributions etc., and for the reactions of MO^+ with alkanes the initial C–H bond activation by MO^+ is often rate-determining. Interestingly, the high reactivity of some MO^+ ions is not always associated with a decrease in regioselectivity; for example, FeO^+ ions induce regiospecific γ-C–H bond activation of dialkylketones in the gas phase. The situation for the epoxidation of olefins in the gas phase turns out to be even more complex than for condensed-phase analogues. This is primarily because the metal ion that mediates O-atom transfer to the olefin also catalyzes the isomerization of the epoxides formed, to afford the energetically more stable aldehydes or ketones. Aromatic compounds can also be hydroxylated by MO^+ ions, and particularly the oxidation of benzene by bare FeO^+ ions in the gas phase reveals striking parallels to the metabolism of arenes. Furthermore, the storing capabilities of ion cyclotron resonance mass spectrometers even permit the design of catalytic processes in which a single metal ion converts more than one substrate molecule into an oxygenated product in a sequence of strictly bimolecular reactions. The most outstanding examples are the Pt^+-mediated oxidation of methane by molecular oxygen and the Co^+-mediated hydroxylation of benzene by N_2O as oxidant. Finally, the key features of the gas-phase reactions are compared with observations in condensed-phase systems in which metal oxides are anticipated as central intermediates. The result of this comparison is promising in the sense that, in general, the understanding of transition-metal-mediated oxidations in the gas phase may lead to a more uniform description of these processes at a molecular level. Ultimately, it is hoped that gas-phase studies will serve as one of the building blocks in the evolution of tailor-made catalysts.

The selective activation of carbon–hydrogen bonds of alkanes constitutes the search for the chemists' Holy Grail.
Sir Derek Barton, 1990

1. Introduction

Transition-metal-mediated oxidation of organic compounds is of fundamental importance in various branches of chemistry, biology, and chemical engineering. In general, three basic areas can be distinguished: 1) Heterogeneous catalysis for the conversion of hydrocarbons into more valuable products by use of economical oxidants such as peroxides, oxygen, or even air. Numerous methods are applied in large scale processes, for example, the conversion[1] and coupling[2] of methane, or the olefin epoxidation on silver contacts.[3] 2) Homogeneous catalysis for similar purposes as well as for small-scale synthetic applications, for example, the Wacker process,[4, 5] the oxidation of cyclohexane,[5] or many preparative procedures, as for example the enantioselective Katsuki–Sharpless epoxidation.[6] 3) Biochemical transformations that involve one or several transition metals in the enzymes' reaction centers. For example, metal-containing enzymes are essential for oxygen transportation, storage, and activation in living organisms.[7] In this context the iron-centered cytochromes, the methane monooxygenases and related systems are of particular relevance.[8]

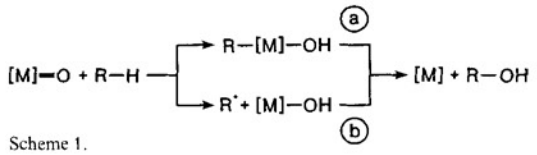
Although in view of the tremendous variety of metals, ligands, and oxidants many mechanistic routes may exist, it has been repeatedly conjectured that a large number of these otherwise different systems involve transition-metal oxides [M]=O as the catalytically active species;[9] here, [M] refers to a ligated mono- or oligonuclear transition-metal compound or even a metal atom embedded in the surface of a solid catalyst. Therefore, considerable interest focused on the synthesis, characterization, and reactivity studies of these species and their appropriate model compounds in the condensed phase.[10] One of the most fundamental processes mediated by [M]=O deals with the hydroxylation of organic compounds, and a simplified mechanism for C–H bond activation of a hydrocarbon RH by a metal-oxide fragment is depicted in Scheme 1. The initial (and



Scheme 1.

frequently rate-determining) step commences with the activation of an R–H bond resulting in the formation of an inserted species R–[M]–OH or a pair of cage-trapped radicals R˙ and [M]˙–OH. Subsequent product formation can proceed by reductive elimination (path ⓐ) or an OH-rebound process[11] (path ⓑ); the latter is sometimes described in terms of a radical recombination. Both pathways yield the oxygenated hydrocarbon ROH and reduced [M]. Alternatively, if R has a second α-H atom, water elimination can give rise to carbene intermediates $[M]=CR^1R^2$ which, subsequently, can be converted into the corresponding carbonyl compound by an appropriate O-atom donor.[12] For catalytic applications the oxidant should also be capable of reoxidizing [M] to the active species [M]=O. Frequently O_2, H_2O_2, and hydroperoxides are used for this purpose.

The ultimate goal is to unravel the mechanistic features of transition-metal-catalyzed oxidation at a molecular level. One of the simplest and most straightforward approaches to tackle this problem deals with reactivity studies of ionic transition-metal oxides in the gas phase by mass-spectrometric methods.[13] Here, any contribution of ligand effects, counterions, solvents etc. can be rigorously excluded. In addition, by studying ligated metal fragments, the sequential effects of ligands L on the reactivity may be evaluated. Consequently, this approach allows an evaluation of whether the catalytic activity of L[M]=O represents an intrinsic property of the corresponding molecule in a certain oxidation state, or if the reactivity is governed by the ligands, solvation phenomena, surface properties, cooperative effects etc. of the "real life" catalysts. As a prerequisite for the evaluation and the proper understanding of mass-spectrometric experiments, it is important to note that due to the net coulombic charge of the ions as well as the absence of counter ions and solvation, these coordinatively unsaturated ("naked") species will, in general, be much more reactive than their condensed-phase analogues.[14] Thus, the gas-phase studies to be described here will, in principal, *never* account for the precise mechanisms, energetics, and kinetics operating for applied catalysis. Yet, the gas-phase experiments are not meaningless, for they provide an efficient means to obtain insight into reactivity patterns, the role of ligands, the chemo- and regioselectivities, and the intermediates operative at molecular level. In fortunate cases predictions may be possible for those condensed-phase systems that are suggested to involve "free" metal-oxide species. In general, the studies of isolated molecules under well-defined conditions may be viewed as one of the key features stones in the evolution of paradigms aimed at a more comprehensive understanding of elementary steps, knowledge of which is mandatory for the design of tailor-made catalysts.

In this review we will describe the current status of knowledge of the reactivity of bare transition-metal-oxide ions towards various classes of organic compounds. We shall focus on the chemistry of mononuclear, cationic transition-metal monoxides, MO^+, since hitherto most of the reactivity studies deal with these species. However, where appropriate some representative

Helmut Schwarz, born in 1943, spent four years as a chemical technician before reading chemistry at the Technische Universität Berlin (TUB), where he obtained his Ph.D under the supervision of F. Bohlmann in 1972 and his habilitation in 1974. Since 1978 he has been associated with the TUB as a Professor of Chemistry and has resisted all temptation to leave Berlin for good. He held visiting appointments in Cambridge, Lausanne, Jerusalem and Haifa, and Canberra. Among his several awards are the Otto-Klung, Otto-Bayer, and Leibniz Prizes, and the Max-Planck Research Award, which he received jointly with C. Lifshitz. In 1992 the Hebrew University of Jerusalem conferred an honorary doctorate on him and in 1994 the J. J. Thomson Gold Medal. H. Schwarz is a fellow of the Lepoldina (Halle), the Academy of Sciences at Erfurt and at Berlin-Brandenburg, and an Overseas Fellow of the Churchill College Cambridge. His current interests, besides the topic of this review, focus on the generation and characterization of elusive molecules of interstellar and atmospheric importance.

Detlef Schröder, born in 1963, began to study chemistry at the TUB in 1983. In 1988 he joined the group H. Schwarz and completed his Ph. D. on the topic of ligand effects in organometallic gas-phase chemistry in 1992. He is author of more than sixty papers and recipient of the Klaus-Koch Award of the TUB and the Schering Prize (1993). His prime interests are in the field of gas-phase ion chemistry of organometallic compounds, with special emphasis on C–H and C–C activation, oxidation, and the reactive intermediates, as well as reaction mechanisms, isotope effects, and mass spectrometry.

examples of reactions of anionic, neutral, and high-valent transition-metal oxides will be included.

The review begins with a brief description of the experimental methods used for gas-phase reactivity studies. Then, the formation, thermochemistry, and bonding of MO^+ ions are discussed, followed by chapters that deal with reactions of metal-oxide ions with alkanes, olefins, arenes, and monofunctionalized hydrocarbons. A comparison of reactivity patterns, isotope effects, and regioselectivities of MO^+ ions with some representative condensed-phase analogues will be presented in terms of simplified mechanistic schemes. In an extra section, the design of catalytic processes in the gas phase is described, and the implications for the condensed phase are discussed. Finally, an outlook is given on the possible development of this field in the near future. To limit the size of the article, we will refrain from describing experimental and theoretical findings in detail, as these are available in the original references.

2. Experimental Procedure and Theoretical Methods

This section serves as a brief survey of the experimental methods that are used to examine the reactivity of metal-monoxide cations as well as high-valent transition-metal-oxide cations in the gas phase; to illustrate the techniques we refer to the oxidation of methane by FeO^+ as an example. Similar techniques have been applied for reactivity studies of the corresponding anionic[15] and neutral[16] transition-metal oxides.

Most of the experimental studies have been performed by ion cyclotron resonance (ICR) mass spectrometry or its modern variant, Fourier transform (FT)ICR.[17] Here, MO^+ ions are trapped in the magnetic field of an ion cyclotron setup and mass-selected by specifically modulated radio-frequency pulses. Reactivity studies are performed by leaking in neutral reactants and monitoring the time dependencies of the MO^+ and product-ion signal intensities (for example, $FeO^+ + CH_4 \rightarrow Fe^+ + CH_3OH$); neutral products cannot be detected by (FT)ICR. Provided the MO^+ species are properly thermalized,[18] the reactions can be considered to take place at thermal energies (300 K) at which only exothermic or almost thermoneutral processes can occur.[14, 19] consequently, the observation of a particular ion/molecule reaction can be used to bracket thermodynamic thresholds for reactant and product channels.[20] Furthermore, the time dependencies of the ion signals can be analyzed in terms of pseudo-first-order kinetics, and the corresponding rate constants k_R (in general determined with an experimental error of $\pm 25\%$)[21] can be compared to the capture rates k_C as derived from collision theory.[22] The efficiency, defined as $\phi = k_R/k_C$, is a measure of the reactivity of a given MO^+ ion towards a neutral molecule, and the magnitude of ϕ is a measure of the importance of thermodynamic or kinetic restrictions that are associated with the process of interest. Furthermore, isotopically labeled substrates permit the evaluation of kinetic isotope effects (KIEs)[23] on the rate constants k_R and product branching ratios.[24] These, in turn, provide insight into the reaction mechanism, reveal the rate-determining step (RDS), and may uncover structural and energetical features of reaction intermediates. In addition, other techniques such as ligand-exchange reactions[13, 25] and collision-induced dissociation experiments[26] permit the elucidation of the structures of the ionic reaction products. In spite of this richness, (FT)ICR mass spectrometry often does not provide a complete picture of the reaction mechanisms for the oxidation of organic compounds RH by MO^+ cations. This is mostly due to 1) the instability of the rovibrationally highly excited eneounter complexes $[RH \cdot MO^+]^*$ formed in the absence of stabilizing collision partners and 2) the high exothermicities of the oxidation reactions: Consequently, in (FT)ICR often only the final ionic products, but no reaction intermediates or neutral species, are detected.

Fortunately, tandem mass spectrometry[27] with multi-sector-field instruments constitutes a complementary approach and can be used to generate and characterize possible reaction intermediates of the process of interest. In these experiments structural isomers of the proposed intermediates are generated by chemical ionization (CI) of appropriate precursor molecules. For example,[28] intermediates of the elemental composition $[Fe,C,H_4,O]^+$, which are believed to be involved in the formation of methanol from FeO^+ and methane, can be generated by CI, starting from different precursor mixtures: 1) $Fe(CO)_5$, N_2O, and CH_4 yield the encounter complex of the reactants, $(CH_4)FeO^+$; 2) $Fe(CO)_5$ and CH_3SO_3H give rise to the inserted species H_3C-Fe^+-OH; 3) $Fe(CO)_5$, c-C_3H_6, and H_2O lead to the carbene complex $H_2C=Fe^+-OH_2$; and finally, 4) $Fe(CO)_5$ and CH_3OH form the product complex $(CH_3OH)Fe^+$. The structures of the so-formed isomeric ions as well as interconversion processes between various isomers can be probed by means of collisional activation (CA) of mass-selected ion beams and related techniques.[27] Most recently, neutralization–reionization mass spectrometry (NRMS)[29] was added to the repertoire and successfully applied to examine transition-metal-mediated oxidation reactions. For details of the slightly more complex NRMS setup, we refer to the original sources; however, it should be pointed out that this technique permits insight into the structures of not only the ionic, but also of *neutral* products being formed in the course of an oxidation process.

Most of the experiments that address the thermochemistry[20] of transition-metal oxides as well as a few reactivity studies have been performed with another sophisticated mass-spectrometric method, the guided ion beam (GIB)[30] technique. In this type of experiment mass-selected ions of interest are made to collide at well-defined collision energies with either an unreactive neutral, for example a rare gas, or a reactive substrate that has a potential-energy hypersurface related to that of the molecule of interest. For example, the experimental threshold for the formation of Fe^+ by colliding translationally excited FeO^+ with xenon can be converted into the bond dissociation energy (BDE) of the Fe^+–O bond; similarly, the appearance of an endothermic ion/molecule reaction can be related to thermodynamic and kinetic barriers, for example, $Fe^+ + CH_3OH \rightarrow FeO^+ + CH_4$. Because of its well-defined energy scale, this technique is an excellent tool for the evaluation of the thermodynamics of ionic and neutral molecules; furthermore, GIB has been applied for state-specific reactivity studies of transition-metal fragments.[31] Exothermic ion/molecule reactions can also be studied by means of GIB experiments; however, their quantification in terms of reaction energetics is not as straightforward as for endothermic processes. In addition, flow-tube measurements,[32] ion-trap mass spectrometry,[33] and flame-ionization methods[34] have been used to examine metal-oxide ions in the gas phase.

In a more general sense, these complementary experimental methods probe different parts of a potential-energy hypersurface of an MO^+/RH system, as depicted in Figure 1 for an exothermic hydroxylation process. The (FT)ICR method establishes whether an exothermic ion/molecule reaction of thermalized MO^+ ions with the substrate RH occurs, and sheds light on

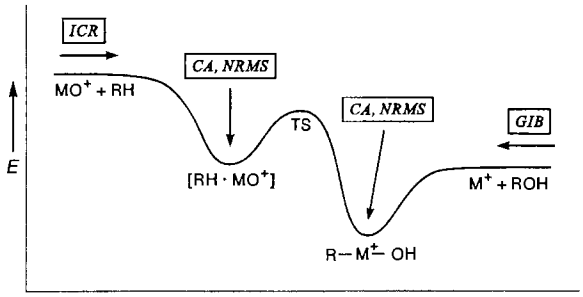


Fig. 1. Exothermic hydroxylation of RH with MO^+. The x axis represents the reaction coordinate. TS = transition structure.

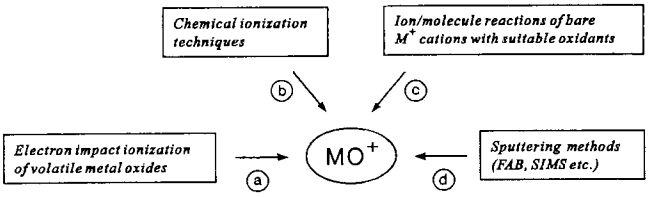
the kinetics and isotope effects. Collisional activation of ions generated by chemical ionization in a sector instrument permit insight into connectivity, stability, and interconversion processes of the reaction intermediates. Furthermore, NRMS can be used to derive the structure(s) of the neutral oxidation products being formed. Finally, the GIB technique is particularly valuable for probing the endothermic (reverse) reactions to establish thermodynamic and kinetic thresholds for the reaction of interest as well as reaction dynamics.

In principle, the currently available experimental methods permit reactivity studies of almost all metal-oxide cations and anions with a large variety of substrates. However, in practice these experiments are sometimes limited by the problems associated with the generation of the corresponding metal-oxide ions in reasonable quantities. Furthermore, in many laboratories the lack of isotopic labeling facilities hampers the unambiguous interpretation of data with respect to intermediates and reaction mechanisms.

Finally, enormous progress in the last decade has been brought about by theoretical methods. Besides conventional high-level molecular orbital calculations,[35] the recent density functional theory (DFT)[36] approach gained particular relevance because of its economical use of computer time.[37] Although transition-metal complexes often have a vast number of energetically closely spaced electronic states, computational methods now permit relatively reliable predictions of the energetics and structures of many of these species, at least for small systems.[38] These computational results represent a versatile and complementary extension of the experimental methods and permit an interpretation with respect to minima on the potential-energy hypersurface, that is, possible reaction intermediates. More importantly, even the salient features of the corresponding transition structures (TS) connecting the minima can be probed. Thus, geometries, activation barriers, and harmonic vibrational frequencies are available and can be used to refine the analysis of experimental data. In fact, the successful interplay of theoretical and experimental studies gives hope that reaction pathways will be reliably mapped out and mechanisms for transition-metal-mediated oxidations will be understood.[39]

3. Formation, Energetics, and Bonding Features of Metal-Oxide Ions

Transition-metal oxides can be generated by a variety of mass spectrometric means starting from different precursors (Scheme 2). Of course, for reactivity studies, the method of choice is determined by both the particular experimental setup and the absolute yields associated with making the metal-oxide ion of interest.



Scheme 2.

Electron impact ionization (method ⓐ) has been applied to generate metal-oxide ions from volatile precursors, for example, CuO_n^+ from anhydrous copper(II) nitrate ($n = 1, 2$),[40] OsO_n^+ from osmium(VIII) tetraoxide ($n = 1-4$),[41] and the high-valent organometal-oxide cation radical $CH_3ReO_3^+$ from the corresponding neutral compound.[42] Chemical ionization of mixtures of organometallic compounds with appropriate oxidants (method ⓑ) has been applied for various metals, for example, FeO^+ from $Fe(CO)_5$ and N_2O,[28] and FeO_n^- from $Fe(CO)_5$ and O_2 ($n = 1-4$).[43] For most of the reactivity studies metal-oxide ions have been generated by ion/molecule reactions of bare metal ions M^+ with O-atom donors such as molecular oxygen, oxirane, dinitrogen oxide, or ozone (method ⓒ).[44] These methods are of particular relevance, since they occur under well-defined conditions, and thus the formation of electronically excited ions can be more or less excluded. Almost all MO^+ ions can be generated from the corresponding metal salts by sputtering methods (ⓓ) such as secondary ion mass spectrometry (SIMS) or fast atom bombardment mass spectrometry (FAB-MS);[45] however, the absolute ion currents obtained for MO^+ by the latter methods as well as the experimental setups themselves often hamper further reactivity studies.

In addition, thermoionization in flames[34] has been used for the generation of MO^+; however, the experimental conditions do not always allow their reactivity with organic substrates to be probed. Unfortunately, only a few MO^+ ions have so far been examined by photoionization methods. Among these studies, those of Dyke et al. should be pointed out.[46] Photoionization experiments are highly desirable, because they may allow the assignment of electronic ground states, the investigation of state-specific reactivities, and also the spectroscopic characterization of reactants, intermediates, and products.

The evaluation of the thermodynamics of MO^+ began in the 1960s with the evolution of Knudsen cell mass spectrometry.[47] Nowadays, most of these early data have been refined by more sophisticated techniques; in particular, the accurate GIB studies by Armentrout et al. brought about significant progress.[48] Figure 2 displays the bond dissociation energies (BDEs) of the MO^+ cations of the first-row transition metals. In accordance

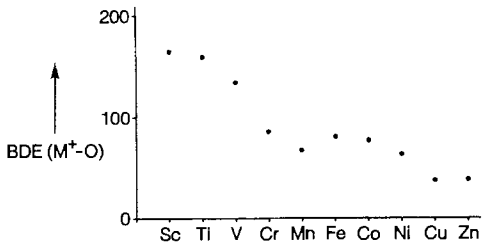


Fig. 2. Bond dissociation energies (BDE in kcal mol^{-1}) of the first-row transition-metal monoxide ions MO^+ (Data taken from Ref. [48]).

with the well-known high oxophilicities of the early transition metals (Sc, Ti, and V), the corresponding BDEs (M^+–O) are fairly high (Table 1) and exceed that of many other atoms and molecules. For example, bare Sc^+ is capable of abstracting an oxygen atom from carbonyl compounds to yield ScO^+ and the corresponding alkenes as neutral products.[49] For Group 6–10 transition metals (Cr–Ni) the values for BDE (M^+–O) are moderate and vary between 63 and 86 kcal mol^{-1}, whereas for Cu and Zn the BDEs amount to less than 40 kcal mol^{-1}. In general, these trends are in line with the bond dissociation energies of other transition-metal cations, for example, BDE(M^+–H) or BDE(M^+–CH_3).[50] Due to the higher oxidation state in MO^+, most of the BDEs of the corresponding neutral transition-metal oxides exceed that of the cations by 10–20 kcal mol^{-1},[51] as is apparent from the increase of the ionization energies (IEs) for the metal oxides relative to the bare metal atoms (Table 2). For second- and third-row transition-metal oxides a comprehensive set of data is not yet available, and the reported figures are less precise than those determined by GIB experiments, as demonstrated by the error bars in Table 1. Nevertheless, the general trend parallels the features observed for the first-row transition-metal series (high BDEs for the early and lower ones for the late transition metals). Within a group of the periodic table, the BDEs seem to increase for heavier elements; however, the precise orderings are determined by an interplay of electronic ground states, orbital-overlap factors, and relativistic effects.[52, 53]

For the first-row transition-metal series Carter and Goddard III predicted the electronic ground states and analyzed the binding situations of the MO^+ cations on the basis of valence-bond (VB) theory.[54] While organic chemists are perhaps more familiar with describing bonding properties in terms of the equivalent molecular orbital (MO) picture, both theories cover the basic features of the bonding in metal-oxide cations, they account for most of the thermodynamics, and also allow a prediction of symmetries and multiplicities of the electronic ground states.[39, 55] Figure 3 shows the occupancy of the valence molecular orbitals for three representative examples, ScO^+, FeO^+, and ZnO^+. In the low-spin ground state of ScO^+ ($^1\Sigma^+$) all bonding valence orbitals, 1σ, 2σ, and 1π, are doubly occupied, while the remaining orbitals are empty, thus giving rise to a low-spin ground state ($^1\Sigma^-$) and a high BDE (164 kcal mol^{-1}). This description also accounts well for the high oxophilicities of the other early transition metals. In contrast, in the high-spin ground state of FeO^+ ($^6\Sigma^+$), besides the doubly occupied bonding orbitals, all five 1δ, 2π, and the 3σ orbitals are singly occupied, and consequently, BDE (Fe^+–O) is moderate (81 kcal mol^{-1}). Finally, in ZnO^+ ($^2\Pi$), with the exception of one antibonding orbital, all orbitals are doubly occupied, resulting in a fairly low BDE (38 kcal mol^{-1}). As a rule of thumb,[54] the bonding in the oxides from ScO^+ through

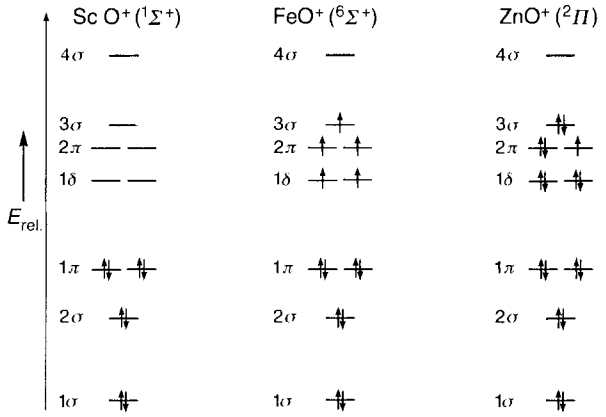

Fig. 3. Schematic molecular orbital diagram for the representative first-row transition-metal-monoxide cations ScO^+, FeO^+, and ZnO^+ (only the valence orbitals are depicted; for a discussion, see Ref. [39]).

CrO^+ can be viewed as analogous to carbon monoxide, whereas for those from FeO^+ through CuO^+ the bonding resembles that of triplet dioxygen.[39, 54] This simple analogy of the MO^+ ground states to CO and O_2 is of particular relevance for the interpretation of the observed reactivity patterns, as will be demonstrated later.

Recently the pictorial description of the bonding in MO^+ has been evaluated quantitatively by means of ab initio molecular orbital calculations (Table 3),[39, 55] which predict CO-like bonding for the low-spin ground states of the early transition-metal oxides from ScO^+ through CrO^+ and O_2-like bonding from FeO^+ to CuO^+. MnO^+ occupies an intermediate position.

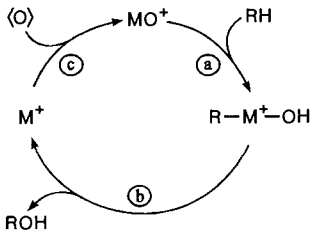
[a] According to ab initio calculations using a density functional theory approach [39, 55]. [b] For nomenclature of the orbitals, see Fig. 2.

In accordance with this picture, FeO^+, CoO^+, NiO^+, and CuO^+ exhibit high-spin ground states rather than their perfect-pairing, low-spin electromers, analogous to the singlet/triplet splitting in dioxygen. These assignments of the electronic ground states agree well with the predictions by Carter and Goddard III,[54] although some differences in the occupancy of the 1δ and 3σ orbitals exist. These differences are because, in the electronic ground states of MO^+, the metal atom participates in its s^1d^n configuration. In addition, these results reveal that the description of a metal oxide in terms of a double bond between the metal and oxygen atoms, for example, [M]=O, is somewhat misleading; however, for the sake of simplicity we keep using this description.[56]

Unfortunately, not much effort has yet been expended to characterize metal-oxide ions spectroscopically. However, the electronic ground state assignments derived from these few experimental studies are in good agreement with the theoretical predictions: TiO^+ ($^2\Delta$) and TiO^+ ($^2\Sigma^+$) with an experimentally measured excitation energy ($\Delta E_{exp.}$) of 1.5 eV;[57] VO^+ ($^3\Sigma^-$) and VO^+ ($^3\Delta$) with $\Delta E_{exp.} = 1.2$ eV;[58] CrO^+ ($^4\Sigma^+$),[59] FeO^+ ($^4\Delta$),[60] ZrO^+ ($^2\Sigma^+$),[61] and HfO^+ ($^2\Sigma^+$).[61]

From a chemical point of view, we can expect catalytic activity for those metals for which on one hand BDE (M^+-O) is sufficiently low but BDE (M^+-H) and/or BDE (M^+-CH_3)[50] are high enough to render the initial activation reaction (step ⓐ in Scheme 3) exothermic. On the other hand, BDE (M^+-O) must be high enough to permit the reoxidation of the reduced metal to the corresponding oxide by a suitable O-atom donor by reaction ⓒ.

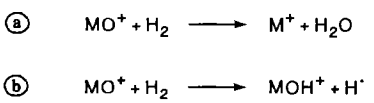


Scheme 3.

Furthermore, the ionization energy (IE) of the metal oxide (Table 2) should not exceed that of the organic substrate RH. A high IE of MO would give rise to an electron-transfer process from the substrate to the MO^+ ion, to yield the corresponding organic cation radicals, which are expected to lead to less specific product formation in subsequent reactions. Different reactivities have been predicted for different electronic states of the MO^+ cations. The high-spin metal-oxide ions, for example FeO^+ ($^6\Sigma^+$), should preferentially involve atom- or group-abstraction reactions as well as electron-transfer processes, whereas the low-spin states, for example, FeO^+ ($^4\Delta$), should also permit more complex reactions, such as multibond rearrangements or hydride transfers.[39] This enhanced reactivity of the low-spin states in synchronous C–H bond activation can be attributed to the fact that these states have both high-lying doubly occupied as well as low-lying unoccupied molecular orbitals that can interact with the σ^* and σ orbitals of the R–H bond to be broken.[62] In metal-oxide cations with high-spin ground states, such favorable HOMO/LUMO interactions are not possible. However, as outlined below, for transition-metal compounds this simple picture is complicated by the ease of curve crossing mediated by spin–orbit coupling between states of different multiplicities and symmetries. Indeed, the facile interconversion of various electronic states is quite probably the most crucial issue for the particular reactivity of transition-metal compounds.

4. Reactions of Metal-Oxide Cations with Hydrocarbons

Before we address reactions of MO^+ cations with organic substrates, it is worthwhile to discuss briefly the simplest system, the reaction of MO^+ with dihydrogen to yield M^+ and H_2O as products. The particular simplicity of this reaction renders it an attractive model system for experimentalists and theoreticians. First, most of the thermochemical data of reactants and products are well established, and for the few missing species one can derive reasonable estimates from literature, and thermochemical thresholds for reactions ⓐ and ⓑ can be evaluated (Scheme 4). Second, the reaction of MO^+ with H_2 (or HD



Scheme 4.

and D_2) can be measured in almost all experimental setups without serious difficulties. Finally, this four-atom system is small enough to allow high-level calculations with reasonable accuracy and reliability.

For the early transition-metal oxide cations from ScO^+ through VO^+ and also for ZrO^+ and NbO^+ neither reaction ⓐ nor ⓑ can proceed at room temperature on simple thermodynamic grounds (Table 4).[62, 63] However, both reactions occur

Table 4. Efficiencies ϕ [%], product branching ratios [%], and reaction exothermicities ΔH_r (kcal mol^{-1}) associated with the formation of M^+ and H_2O in the reactions of MO^+ with molecular hydrogen [a, b].

MO^+	ϕ	$MOH^+ + H^\cdot$	$M^+ + H_2O$	ΔH_r

FeO^+	1 [c]		100	−36
CoO^+	0.1 [c]		100	−41
NiO^+	0.2		100	−54
OsO^+	0.5		100	−17

[a] H-atom abstraction reactions are observed for a number of other MO^+ ions when these are subjected to translational excitation [63]. [b] The data are extracted from Refs. [18, 41, 62, 64, 66, 70, 80]; for further details, see text and the original sources. [c] Note the somewhat lower efficiencies measured by Armentrout et al. [65].

at the thermochemical thresholds when the MO^+ cations (M = Sc, Ti, V) are subjected to translational excitation, which indicates the absence of significant kinetic barriers for reactions ⓐ and ⓑ for these systems.[62] In contrast, from CrO^+ through ZnO^+ the formation of water (reaction ⓐ) is quite exothermic, and for MnO^+, CuO^+, and ZnO^+ the H-atom abstraction ⓑ is also energetically feasible. Despite a favorable thermochemistry, CrO^+, CoO^+, and NiO^+ hardly react with molecular hydrogen (or even not at all), and for FeO^+ the reaction rate k_R is surprisingly slow and occurs only once in every hundred collisions.[18, 64] More recently, the value of the thermal rate constant for the reaction of FeO^+ with H_2 came under criticism;[65] however, the general features of the reaction were confirmed. Only the reaction of MnO^+ with H_2 is efficient, leading to both $MnOH^+$ (75%) and Mn^+ (25%) as ionic products.[66] Unfortunately, CuO^+ and ZnO^+ have not yet been studied experimentally, because they could not be generated in reasonable quantities. In addition, slow occurrence of reaction ⓐ was observed for OsO^+, the third-row homologue of FeO^+.[41]

The high efficiency observed for MnO^+ can be easily rationalized by a mechanism involving initial exergonic abstraction of a hydrogen atom to give a loosely bound complex $[H\cdots MnOH^+]$; this rovibrationally excited intermediate may either rearrange to form a second O–H bond followed by reductive elimination of water, reaction ⓐ, or the complex may lose an H atom, reaction ⓑ.[66] A more detailed analysis reveals[66] that the hallmark of the MnO^+/H_2 system (and also for other MnO^+/RH couples) is a nearly barrier-free[67] H-atom abstraction. The reaction is therefore primarily driven by the intrinsic thermodynamics of the system, instead of by the lowering of an activation barrier associated with H–H bond activation. As far as metal-catalyzed oxidation processes are concerned, the inefficiency of the exothermic reaction ⓐ for the other MO^+ cations is much more telling: the low rate constants for these processes imply the existence of considerable kinetic barriers associated with H–H bond activation. Recently, independent studies from Armentrout's[65] and our laboratories[18, 39] have shown that the barrier associated with water formation by reaction ⓐ originates not only from a tight, four-centered transition state en route to the products, but also from a curve crossing between the high-spin to the low-spin potential-energy hypersurfaces of FeO^+ and H_2.

Some of the salient features of the FeO^+/H_2 system are given in the simplified potential-energy hypersurface depicted in Figure 4. The reaction of FeO^+ ($^6\Sigma^+$) with H_2 to yield Fe^+ (^6D) and water has been examined by high-level ab initio calculations in

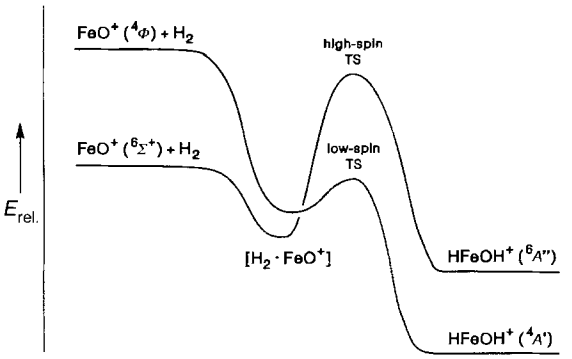

Fig. 4. Reaction of FeO^+ ions with H_2. TS = transition structure.

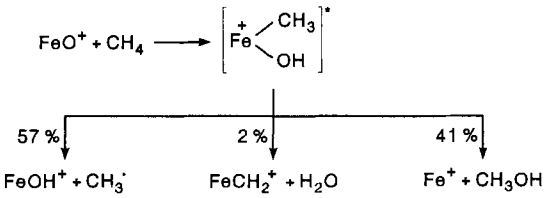
which DFT and MO approaches were combined.[39] According to these computations the corresponding transition structure (TS) on the high-spin entrance channel is too high in energy to account for the reactivity observed at thermal energies. In contrast, the TS on the low-spin surface, which is derived from an excited quartet state of FeO^+ ($^4\Phi$ or $^4\Delta$), is relatively low in energy. Consequently, at thermal energies reaction ⓐ has to involve a curve crossing mediated by spin–orbit coupling from the sextet to the quartet surface for M = Fe. These arguments agree well with the absence of a significant intermolecular kinetic isotope effect for the activation of H_2, HD, and D_2, respectively.[18] Furthermore, a qualitative analysis indicates that the lower activation barrier associated with the low-spin surface reveals a general phenomenon for H–H and C–H bond activation by late transition-metal-oxide ions, since only in the low-spin states can bond formation and breaking occur synchronously. Consequently, the very small efficiencies of the reactions of the late transition-metal oxide cations MO^+ (M = Cr, Fe, Co, and Ni) with H_2 do not reflect unfavorable thermochemistry; rather, they are controlled by reaction barriers and the ease of curve crossing from the high-spin ground state of MO^+ to the low-spin surface; it is the latter that leads to product formation.

4.1. Reactions of MO^+ Ions with Alkanes

Hydroxylation of nonactivated C–H bonds is a central issue in contemporary chemistry. Recently the efficient conversion of methane into methanol has been listed as one of the ten chal-

lenges for catalysis.[68] Furthermore, the activation of C–H bonds of higher saturated hydrocarbons is of economic interest—for example, the oxidation of cyclohexane to cyclohexanone.[5] In this section we will review the current status and the scope of reactions of alkanes in the gas phase with transition-metal oxide cations.



Scheme 5.

4.1.1. Methane

The efficiencies ϕ and the product branching ratios for the reactions of methane with the MO^+ cations studied so far are collated in Table 5. If one takes into account that the larger polarizability of methane (relative to that of H_2) increases the efficiency of an ion/molecule reaction, the trends for the first-row transition-metal oxides are similar to those already discussed for the activation of H_2. For example, MnO^+ reacts in a fast process by facile hydrogen-atom abstraction to yield exclusively $MnOH^+$.[66] In contrast, FeO^+ reacts somewhat less efficiently; however, most interestingly methanol is also formed as neutral product.[28, 39, 69] Not unexpectedly, the early transition-metal oxides ScO^+, and TiO^+ do not react at all, and the activation of methane by VO^+ and CoO^+ hardly occurs.[44, 62, 65, 70] The only exception deals with NiO^+ which reacts much faster with methane and other alkanes than with H_2.[71]

Table 5. Efficiencies ϕ [%] and product branching ratios [%] for the reactions of MO^+ with methane [a, b].

MO^+	ϕ	$MOH^+ + CH_3^\cdot$	$MCH_2^+ + H_2O$	$M^+ + CH_3OH$
MnO^+	40	100		<1
FeO^+	20 [c]	57	2	41
CoO^+	0.5 [c]			100
NiO^+	20			100
PtO^+	100		75	25

[a] The data are extracted from Refs. [66, 69–71, 75]; for further details, see text and the original sources. [b] OsO^+ also reacts efficiently with methane [41]; however, the only product corresponds to dehydrogenation rather than oxidation (see text). [c] Note the somewhat lower efficiencies measured by Armentrout et al. [65].

Again, it is the reaction of FeO^+ that has attracted particular interest.[28] Here, reductive elimination of methanol corresponds to a formal O-atom transfer from the metal oxide to methane, and this process can be viewed as a model for alkane hydroxylation. Experimental and theoretical analysis of this reaction revealed that it commences with activation of the C–H bond of methane to yield the iron(III) insertion compound H_3C-Fe^+-OH (Scheme 5).[28, 39] This rovibrationally excited species is the key intermediate which subsequently decomposes to the products, $FeOH^+ + CH_3^\cdot$, $FeCH_2^+ + H_2O$, and $Fe^+ + CH_3OH$. As mentioned in Section 2, chemical ionization of appropriate precursor molecules, isotopic labeling studies, and collisional activation (CA) mass spectrometry were applied to characterize structural isomers formed en route to the products.[28] The essential CA data and the respective precursors are collected in Table 6. The isomer (Table 6, line 1) corresponds to the encounter complex of the reactants, $(CH_4)FeO^+$, as evident from the signal indicative of the structure of FeO^+. The key intermediate of methane hydroxylation, H_3C-Fe^+-OH, is generated independently from methanesulfonic acid and $Fe(CO)_5$ and is characterized by competitive losses of $CH_3^\cdot$ and $HO^\cdot$, which in turn yield $FeOH^+$ and $FeCH_3^+$. The ratio of both fragment ions is in line with the larger BDE for Fe^+-OH (79 kcal mol^{-1}) than for Fe^+-CH_3 (59 kcal mol^{-1}).[20, 72] The carbene complex $H_2C=Fe^+(OH_2)$ undergoes a characteristic loss of water, which accounts for the $FeCH_2^+$ product ion observed in the reaction of FeO^+ with methane at thermal energies. Finally, the CA mass spectrum of the product complex $(CH_3OH)Fe^+$ is dominated by an intense loss of the intact methanol ligand to yield Fe^+. Like the reaction of FeO^+ with H_2, hydroxylation of methane also most likely involves curve crossing from the high-spin to the low-spin surface of the metal oxide as crucial step. As mentioned above, the larger efficiency of the methane oxidation ($\phi = 0.2$) than that of H_2 ($\phi = 0.01$) can be accounted for by the larger polarizability of methane, which increases the lifetime of the encounter complex and lowers the energy demand of the more polarized four-center transition structure in the case of methane.[39, 74]

Methane activation has also been reported for the third-row transition-metal oxides OsO^+ and PtO^+. Interestingly, these third-row transition metal oxides exhibit quite another reactivity than their first-row congeners. For example, PtO^+ reacts with methane at the collisional limit ($\phi = 1$) to yield the carbene complex $PtCH_2^+$ and water as predominant products,[75] whereas the isoelectronic NiO^+ reacts five times more slowly and gives rise to Ni^+ and methanol only.[71] Similarly, while FeO^+ oxygenates methane, its third-row congener OsO^+ ($\phi = 0.6$)[41] exclusively dehydrogenates methane to yield a complex of composition $[Os,C,H_2,O]^+$. Secondary reactions indicate that this product ion has the oxo–osmium carbene structure $O=Os^+=CH_2$ rather than that of a formaldehyde complex,

Table 6. Characteristic fragments (ion intensities in % relative to the base peak) in the CA mass spectra of $[Fe,C,H_4,O]^+$ isomers generated by chemical ionization of various organic precursors with $Fe(CO)_5$ [a, b].

Precursors	Ion Structure	$Fe(OH_2)^+$	$FeOH^+$	FeO^+	$FeCH_3^+$	$FeCH_2^+$	Fe^+
CH_4/N_2O	$(CH_4)FeO^+$	1	20	100	1	15	50
CH_3SO_3H	CH_3-Fe^+-OH		100	4	9	4	
c-C_3H_6/H_2O	$CH_2=Fe^+-OH_2$	25	6			100	15
CH_3OH	$(CH_3OH)Fe^+$		50	2			100

[a] For the sake of clarity intensities smaller than 1% are omitted. [b] Data from Ref. [28].

that is, $(CH_2O)Os^+$. This agrees with the observation that methane is also dehydrogenated by bare Os^+ itself to yield $H_2C{=}Os^+$.[41, 76] Apparently the oxygen atom is not actively involved in methane activation by OsO^+. The different reactivity of third-row MO^+ ions relative to their first-row analogues can partly be traced back to thermodynamic grounds, which originate from the significantly increased $M^+{=}CH_2$ bond strengths for third-row transition metals.[77]

4.1.2. Higher Alkanes

In general, higher alkanes react much more efficiently with MO^+ than methane does (Table 7). This is not primarily due to the increase in polarizability; rather, a new reaction channel

Table 7. Efficiencies ϕ [%] for the reactions of MO^+ with alkanes [a].

MO^+	CH_4	C_2H_6	C_3H_8	n-C_4H_{10}
ScO^+	<0.01	<0.01		
TiO^+	<0.01	<0.01		
VO^+	<0.01	<0.01	[b]	[b]
CrO^+	<0.01	100	100	100
MnO^+	40	100	100	100

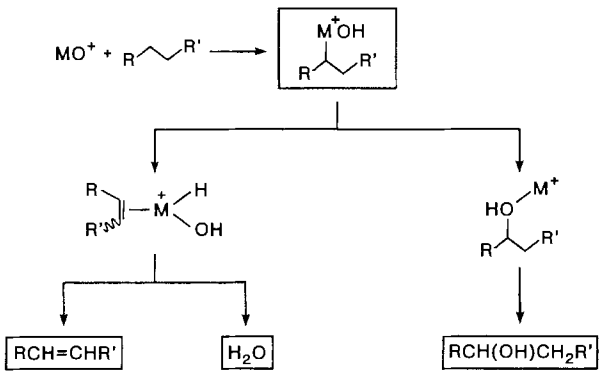
CoO^+	0.5	50	50	100
NiO^+	20	100	100	100
OsO^+	60	[c]	[c]	[c]
PtO^+	100	[c]	[c]	[c]

[a] The data are extracted from Refs. [41, 62, 64, 66, 69–71, 75, 78]; for further details, see text and the original sources. [b] In Ref. [78] the occurrence of dehydrogenation was reported; however, kinetic data were not examined. [c] In Refs. [41] and [75] no efficiencies were given; however, these reactions are likely to occur with $\phi \approx 1$.

opens for these alkanes, namely, β-hydrogen transfer to the metal center after initial C–H bond activation (Scheme 6). Since β-hydrogen transfer is by far the most facile reaction of organometallic compounds and is often associated with low activation barriers, the major products of the reactions of MO^+ with higher homologues of methane reflect losses of molecular hydrogen, water, alkanes, alkenes, and alkanols. Because these processes are not limited to transition-metal-oxide species, and β-hydrogen transfer also follows initial hydroxylation, we restrict ourselves to the discussion of a few representative and some exceptional studies.



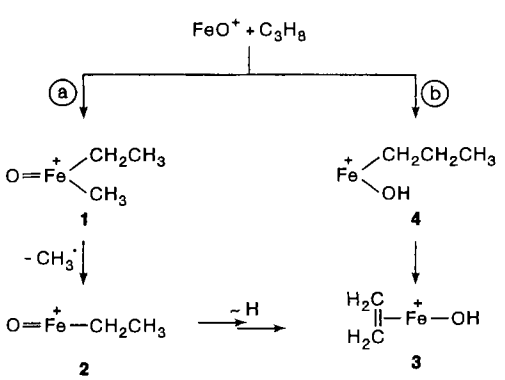
Scheme 6.

As expected, the oxides of the early transition metals are, in general, much less reactive towards alkanes than the bare metal cations. For example, V^+ dehydrogenates propane quite rapidly, whereas VO^+ is completely unreactive.[78] Similarly, the bare V^+ cation induces oligomerization of butanes, whereas VO^+ does not. Thus, for the highly oxophilic early transition metals the oxide ligand decreases the reactivity relative to that of bare M^+, and this effect can be ascribed to the high BDEs of these metal oxides. As a consequence, the early transition-metal oxides are not good catalyst for the oxidation of alkanes, since their high BDEs do not allow transfer of the oxide ligand to the substrate. Moreover, bare Sc^+ ion even deoxygenates methanol to yield ScO^+ and methane, precisely the reverse of the desired hydroxylation process (Scheme 7).[79]

$$Sc^+ + CH_3OH \rightleftharpoons ScO^+ + CH_4$$

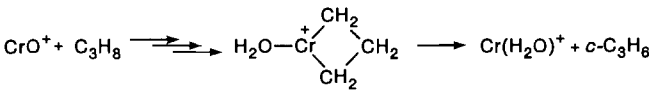
Scheme 7.

In contrast, for many other transition metals the presence of an oxygen ligand dramatically enhances the reactivity towards hydrocarbons.[80] For example, at thermal energies none of the first-row M^+ ions reacts with methane, but MnO^+ through NiO^+ do. Similarly, none of the M^+ ions (M = Cr–Ni) activate ethane at thermal energies, but all the corresponding MO^+ ions lead to C–H bond activation and subsequent losses of ethanol, ethene, or water.[64, 66, 71, 80] The ease of these reactions can also be ascribed to the moderate strength of the M^+–O bonds, rendering initial C–H bond activation probable. Subsequent β-hydrogen transfer is expected to be associated with small activation barriers,[81] and the reaction rates approach the collision limit ($\phi = 1$). Once more, a typical example is the reaction of FeO^+ with alkanes (Scheme 6; M = Fe):[80] Ethane (R = R′ = H) is rapidly oxidized to ethene (20%), water (70%), and ethanol (10%) as neutral products. Similarly, propene (10%), water (50%), and propanol (20%) are formed when FeO^+ reacts with propane. In addition, a new product (20%) originates from the loss of a methyl radical in the FeO^+/C_3H_8 system to yield a species of composition $[Fe,C_2,H_5,O]^+$; this ion is most likely an ethene/$FeOH^+$ complex (**3**) rather than an iron(II) ethoxide cation ($Fe(OC_2H_5)^+$). Freiser et al.[80] explained the formation of **3** by a mechanism (Scheme 8, path ⓐ) which involves an initial insertion of the iron center into a C–C bond to form **1**; subsequent $CH_3^{\bullet}$ loss to give **2**, followed by two consecutive hydrogen rearrangements, will lead to the product structure (**1** → **2** → **3**). However, as outlined above, the initial step in the reactions of MO^+ with alkanes is most likely O–H bond formation, thus generating the key intermediate **4**, which



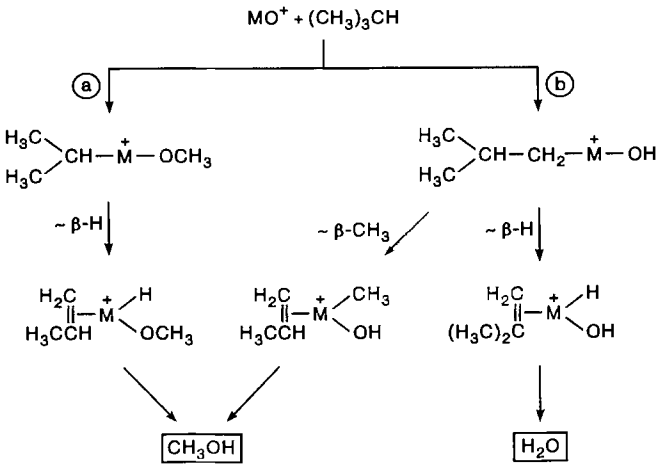
Scheme 8.

upon facile β-C–C bond cleavage dissociates to **3**. Path ⓑ of Scheme 8 is also expected to be energetically favored over the generation of the formally high-valent iron(v) compound **1**. This mechanism is further supported by the observation of a sizable $CH_3^{\bullet}$ loss from the 1-propanol/Fe^+ complex upon collisional activation.[82] Moreover, losses of alkyl radicals are also prominent in the reactions of MnO^+ with alkanes, and, as shown above, initial C–H bond activation is the hallmark in the gas-phase chemistry of MnO^+.[66] Because of the high exothermicity of the oxidation of RH by MO^+, alkanes larger than propane also give rise to consecutive, facile losses of H_2O and H_2, thus leading to alkadiene complexes: for example, $MO^+ + n\text{-}C_4H_{10} \rightarrow M(C_4H_6)^+ + H_2O + H_2$ (M = Mn, Fe, Co, Ni). In addition, if the IE of R$^{\bullet}$ is small enough, initial C–H bond activation of RH by CoO^+ is completed by single-electron transfer from R$^{\bullet}$ to the $CoOH^+$ unit, resulting in the production of a carbocation R^+ and neutral CoOH: for example, $CoO^+ + n\text{-}C_4H_{10} \rightarrow C_4H_9^+ + CoOH$.[70] Interestingly, for CrO^+ yet another mechanism is operative. In their comprehensive study Kang and Beauchamp[64] demonstrated by using labeled substrates that water loss from propane and CrO^+ includes the conventional 1,2-elimination and, in addition, a formal 1,3-dehydrogenation to yield cyclopropane was proposed (Scheme 9).



Scheme 9.

Similar mechanisms were reported for the reactions of MO^+ with branched alkanes. The product distribution can be explained if one takes into account the larger tendency for C–C bond activation in branched molecules concomitant with a decreased formation of alkadiene/M^+ complexes (Scheme 10).[13] For *iso*-butane, rather than C–C bond activation (path ⓐ), the initial step for these alkanes is more likely to be C–H bond activation, followed by either β-H or β-alkyl transfer or rearrangement of the carbon skeleton (path ⓑ). As for the larger linear alkanes, selectivity decreases with the size



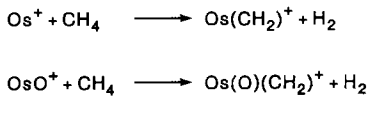
Scheme 10.

of branched alkanes. For example, FeO^+ reacts with *neo*-hexane to yield no less than ten products.[80]

In only two cases has clear evidence for initial C–C bond activation by MO^+ been reported, and both deal with small ring compounds (cyclopropane and cyclobutane).[64, 80] For example, in the reaction of FeO^+ with cyclopropane[83] the carbene complex $FeCH_2^+$ constitutes a major product ion, and its formation can easily be explained by C–C bond activation to yield a metallacyclic intermediate.[85] Here, C–C bond activation can be ascribed to the particular bonding in the three-membered ring, which results in stronger C–H bonds and weaker C–C bonds than in acyclic systems or less-strained rings.[86]

The diversity of competing C–H bond activation of primary and secondary positions, potential radical losses, carbocation formation, and consecutive processes gives rise to quite complex product mixtures for larger alkanes. Thus, the activation of alkanes by late transition-metal-oxide cations is facile, but it lacks chemo- and regioselectivity. Similar mechanisms to those for reactions of the corresponding atomic M^+ ions (M = Cr–Ni) with alkanes and alkanols are operative,[87] but the large exothermicities of the primary oxidation processes (for example, water formation) enforce subsequent fragmentations. For example, though $Fe(C_6H_6)^+$ is the sole product ion in the reaction of FeO^+ with cyclohexane, Fe^+ also transforms cyclohexane and cyclohexanol to the intermediate dehydrogenation products $Fe(c\text{-}C_6H_{10})^+$ and $Fe(c\text{-}C_6H_8)^+$ respectively.[80]

At the end of this section, two experiments in which gas-phase reactions of alkanes with high-valent transition-metal oxides were examined should be mentioned briefly. In their comprehensive study of the OsO_n^+ chemistry ($n = 0$–4), Irikura and Beauchamp[41] demonstrated that not only OsO^+ but also OsO_2^+ ions react efficiently with hydrogen, methane, and larger alkanes. In particular, the reaction of OsO_2^+ with methane (Scheme 11) is noteworthy in that it may be viewed as a model for the catalytic conversion of methane into formaldehyde. Interestingly, the higher valent OsO_3^+ was found to be much less reactive than OsO_n^+ ($n = 0$–2); for example, OsO_3^+ does not react at all with methane, whereas OsO^+ and OsO_2^+ are quite efficient ($\phi = 0.6$ and 0.5, respectively). OsO_4^+ also reacts with methane ($\phi = 0.7$), but the sole product corresponds to a hydrogen abstraction to yield the protonated species $Os(O)_3OH^+$ (actually a typical reaction for a cation radical such as OsO_4^+). Similar behavior was found for the higher alkanes, and OsO_3^+ turned out to be the least reactive species of all OsO_n^+ ($n = 0$–4) ions.



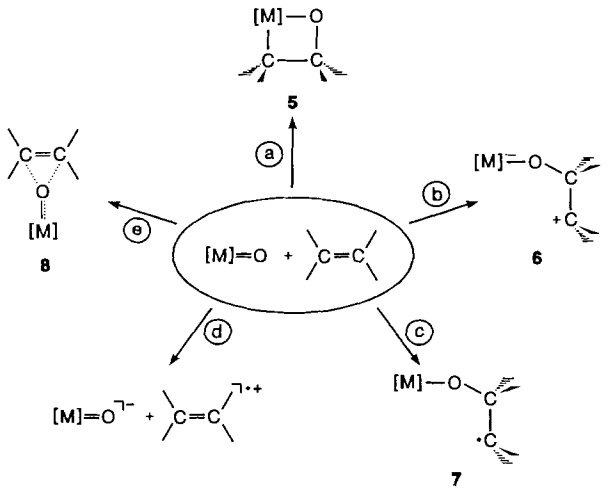
Scheme 11.

Another study addressed the reactions of the formal iron(IV) compound $OFeOH^+$ with small alkanes.[88] In this unusual oxidation state of iron, the metal oxide is somewhat less reactive than its formal iron(III) analogue FeO^+. For example, $OFeOH^+$ oxidizes methane ($\phi = 0.1$) half as fast as FeO^+ ions. Perhaps more important is the observation that the complex of $OFeOH^+$ with CH_4 does not yield any open-shell neutral species as products, whereas $CH_3^{\bullet}$ loss amounts to 57% in the reaction of FeO^+

These examples demonstrate that high-valent transition-metal oxides are indeed accessible in the gas phase and need not necessarily be stabilized by a highly coordinating ligand environment. In addition, high-valent species are expected to exhibit distinct reactivities and selectivities towards alkanes and similar substrates, which render these cationic oxides attractive candidates for further studies.[89, 90]

4.2. Reactions of MO^+ with Alkenes

From the point of view of applications, by far the most important oxidation reaction of alkenes is O-atom transfer from an oxidant to yield the epoxides.[91] Numerous preparative methods as well as large-scale industrial processes deal with this important topic. In fact, nowadays many sophisticated methods for the epoxidation of a large variety of alkenes are available, including regio- and stereospecific epoxidation (and also dihydroxylation) of alkenes.[91b–c, 92] Reaction mechanisms differ for classical methods (for example, employing peracids) and transition-metal-catalyzed epoxidations.[91a] In the latter reactions metal-oxide species are often involved; however, a huge number of mechanistic routes prevail in the condensed phase. At least five different pathways can be distinguished for the rate-determining step of epoxidation processes mediated by [M]=O (Scheme 12):[93] 1) In a more or less concerted [2+2] cycloaddition a metallaoxacyclobutane (**5**) is formed as central



Scheme 12.

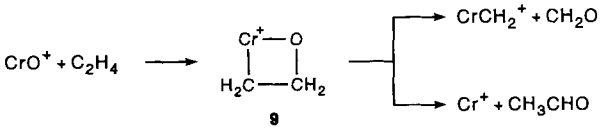
intermediate (path ⓐ); 2) stepwise bond breaking and formation, having either an ionic (**6**) or radical nature (**7**), take place (paths ⓑ and ⓒ); 3) initial single-electron transfer from the alkene to the metal oxide (path ⓓ) is followed by subsequent transformation of the alkene cation radical; 4) direct O-atom transfer from the metal to the alkene proceeds through a multicentered structure (**8**, path ⓔ). Obviously, depending on the mechanistic details not only the stereochemical outcome of the epoxidation may vary, but also characteristic side-products are likely to be formed in nonconcerted pathways. In the condensed phase, the elucidation of the mechanism(s) of epoxidations was studied in detail with H/D kinetic isotope effects and isotope exchange processes,[94] to probe regio- and stereochemical features,[95] and analysis of the side-products[95b, c] to identify the reaction intermediates.[96]

Previously, gas-phase studies focused on the characterization of the reaction intermediates and determination of the rate-determining step(s) of olefin epoxidation, and one may rightly raise the question whether the models developed are suitable to improve the understanding of the condensed-phase analogues.

4.2.1. Ethene

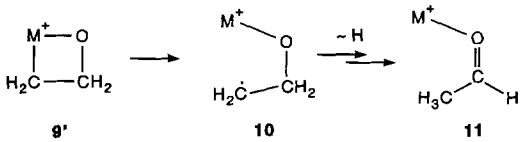
A number of gas-phase studies have addressed the epoxidation of ethene by MO^+ ions or the reverse reaction of M^+ with oxirane.[97–101] According to thermochemistry, oxidation of ethene to its epoxide can only occur if $BDE(M^+-O) \leqq 85\ kcal\,mol^{-1}$.[20] Consequently, the oxophilic early transition-metals need not be considered further. In fact, Sharpless epoxidation, which is one of the most powerful tools in contemporary organic oxidation chemistry, does not involve [Ti]=O species as intermediates.[6b, c] In the gas phase, TiO^+ only undergoes adduct formation with ethene to yield $(C_2H_4)_3TiO^+$ as final product, whereas naked Ti^+ is capable of inducing polymerization of ethene.[97]

For CrO^+ ($BDE = 86\ kcal\,mol^{-1}$), the formation of oxirane is almost thermoneutral, and may thus occur in a thermal ion/molecule reaction. Indeed, Kang and Beauchamp reported rapid O-atom transfer from CrO^+ to ethene to yield Cr^+ and a compound of composition $[C_2,H_4,O]$.[98] However, comparative studies of the reverse reaction of Cr^+ with oxirane and with acetaldehyde revealed that not oxirane, but rather, the energetically more stable acetaldehyde is formed as the neutral product in the reaction of CrO^+ with ethene. Although these authors did not suggest a reaction mechanism, they provided evidence for the formation of the metallacycle **9** as central intermediate (Scheme 13). This assignment was based on the occurrence of a



Scheme 13.

metathesis-like ring-opening of **9** to yield formaldehyde and $CrCH_2^+$ as products. In fact, the reaction of CrO^+ with C_2H_4 demonstrates the central problem in studying olefin oxidation in the gas phase: While the initial addition of MO^+ to the C–C double bond quite likely leads to the metallacycle **9**, this intermediate does not necessarily undergo a one-step reductive elimination to generate the epoxide. Unfortunately, the transition-metal ion that mediates O-atom transfer to the olefins preferably catalyzes the isomerization of the so-formed epoxides to the corresponding carbonyl compounds (Scheme 14). Thus, instead of providing a conceptually simple model system aimed at improving the understanding of the condensed phase analogues, in the gas phase the situation is even more complicated because of subsequent M^+-mediated intramolecular H-migration (**10** → **11**). In other words, the reactivity of naked MO^+ ions



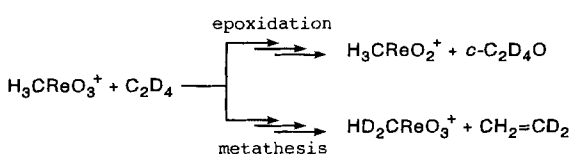
Scheme 14.

is simply too high to permit selective gas-phase epoxidation of olefins.

Similarly, the late transition-metal oxides MnO^+, FeO^+, CoO^+, and NiO^+ rapidly oxidize ethene, and most likely acetaldehyde rather than oxirane is formed as neutral product.[99-104] This interpretation was further supported by Armentrout et al. who studied the reverse reactions, that is, oxirane with M^+ (M = Fe, Co, Ni, Cu), by means of GIB mass spectrometry.[100, 101] On the basis of the experimental findings the formation of acetaldehyde was attributed to the bonding in **9'**, for which homolytic ring opening to **10** and subsequent H transfer to yield the aldehyde complex **11** are expected to be facile (Scheme 14). However, this picture needs further investigation; in particular, a detailed description of the rearrangement **10** → **11** and the overall mechanism is not yet available. Furthermore, the current experimental findings cannot exclude the formation of the enol form of acetaldehyde (that is, vinylalcohol) as a reaction product or at least a role as for it as an intermediate en route to the products.

A formal O-atom transfer to ethene has also been reported for OsO^+.[41] Here, the high BDE of the Os^+–O bond (100 kcal mol^{-1}) precludes oxirane formation, and again, acetaldehyde is most likely generated as the neutral product. As in the reaction of OsO^+ with alkanes (see above), dehydrogenation of ethene to yield $[Os,C_2,H_2,O]^+$ competes with its oxidation, indicating that for Os^+ the oxygen atom can also serve simply as a spectator ligand. Interestingly, the high-valent dioxide OsO_2^+ reacts much more slowly than OsO^+ with ethene to yield exclusively a compound of composition $[Os,H_2,O_2]^+$ and acetylene. Furthermore, the higher oxides OsO_3^+, OsO_4^+, and also the organometal oxide $(CH_3)_4OsO^+$ do not epoxidize ethene at all.[41, 105]

As far as other high-valent transition-metal oxides are concerned, CrO_2Cl^+, $CH_3ReO_3^+$, and CeO_2^+ have been shown to bring about stoichiometric O-atom transfer with ethene.[42, 107, 108] Whereas the formal Cr^{VI} compound CrO_2Cl^+ as well as the lanthanide dioxide CeO_2^+ presumably lead to acetaldehyde, collisional activation studies of the $[C_2H_4/CH_3ReO_3^+]$ system and related ions revealed that for this rhenium-based organometal oxide, formation of oxirane is indeed observed and competes with olefin metathesis (Scheme 15).[42] Interestingly, the competition of olefin epoxidation and metathesis parallels the chemistry of CH_3ReO_3 in the condensed phase, where it was demonstrated that this organometal oxide catalyzes both reactions.[109]

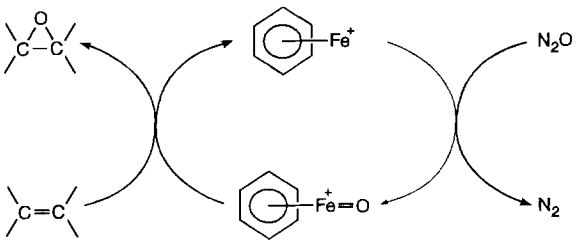


Scheme 15.

4.2.2. *Ligand Effects*

As outlined in the previous paragraph, the rapid isomerization of the desired product, that is, of the epoxides to the energetically more stable carbonyl compounds, constitutes a severe problem in the gas-phase olefin oxidation. Thus, instead of representing a conceptually simple model system for elucidating mechanistic aspects of epoxidation processes, the consecutive rearrangements render the gas-phase experiments even more complicated than their condensed-phase analogues. Since this isomerization usually does not affect epoxidation in condensed-phase chemistry, this pitfall might be overcome by sequential addition of appropriate ligands to the reactive MO^+ center.[110] The approach may moderate the reactivity of MO^+ and 1) permit a stabilization of reaction intermediates and 2) suppress the subsequent isomerization processes. Such a ligand effect is already illustrated in the epoxidation of ethene with $CH_3ReO_3^+$, as described above (Scheme 15).[42] Unfortunately, the high reactivity of MO^+ towards a variety of substrates that may serve as ligands renders this concept quite difficult to realize. For example, the attempt to mediate the reactivity of FeO^+ by adding a hexafluorobenzene ligand failed:[111] even hexafluorobenzene is rapidly oxidized by FeO^+ through C–F bond activation. The generation of $(C_6F_6)FeO^+$ and further reactivity studies with this system were thus precluded.[84] Yet another problem was encountered by Irikura and Beauchamp, who tried to add an oxide ligand to a metalloporphyrin ion in order to mimic cytochrome chemistry directly.[112] The porphyrin system seems to be too large to permit rapid reactions of the metal center with various O-atom donors to produce oxide species, and none of the (porphyrin)FeO_x^+ species ($x = 1, 2$) were observed. The intermediacy of (porphyrin)$FeO^{+/-}$ ions has been reported for NO_2 as an oxidant and (porphyrin)$Fe^{+/-}$; unfortunately, further reactivity studies were precluded on experimental grounds.[113] Furthermore, the reactivity of an metalloporphyrin–oxide species might be too low to be monitored in the time window of gas-phase experiments. Obviously, the direct translation of results of condensed-phase systems to gas-phase studies and vice versa is not a very promising prospect. In this context, a study which describes consecutive formal O-atom transfers from oxirane to $(c\text{-}C_5H_5)Fe^+$ to yield $(c\text{-}C_5H_5)FeO^+$ and $(c\text{-}C_5H_5)FeO_2^+$ is relevant.[114] These reactions demonstrate that the additional cyclopentadienyl ligand influences not only the reactivity, but also the thermochemistry of the formal metal-oxide species, since on thermochemical grounds the reverse reaction of ethene epoxidation is unlikely to occur. However, neither mechanistic insight nor energetic details were given in this study;[114] in particular, these experiments lack a thorough thermalization of precursor ions as well as a definitive characterization of the reaction products.

Most recently, the idea of mediating a gas-phase epoxidation by ligand effects has been realized:[115] The ligated metal oxide $(C_6H_6)FeO^+$, generated by treating $(C_6H_6)Fe^+$ with N_2O, serves as an excellent gas-phase oxidant for alkenes (Scheme 16). Although bare FeO^+ itself is capable of oxidizing benzene,[116] the integrity of the $(C_6H_6)FeO^+$ formed in this way was established by collisional activation studies and the occurrence of a clean, degenerate ligand exchange with C_6D_6 to yield $(C_6D_6)FeO^+$. As expected, the presence of the additional



Scheme 16.

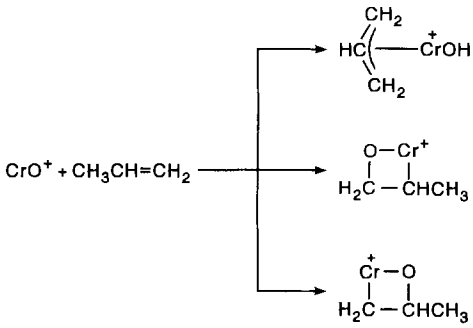
benzene ligand both decreases and modifies the reactivity of $(C_6H_6)FeO^+$ dramatically relative to that of bare FeO^+; for example, $(C_6H_6)FeO^+$ does not react at all with alkanes such as methane or even *iso*-butane. However, recent results of ion/molecule reactions of $(C_6H_6)FeO^+$ with various alkenes indicate that this ligated metal oxide brings about O-atom transfer to yield the neutral epoxides; rearrangement to the carbonyl compound is indeed prevented.[115] Thus, addition of suitable ligands to the reactive metal-oxide center can enhance the selectivity at the expense of reactivity, and systematic studies on tuning chemical reactivity by suitable ligands are under way in our laboratory.

4.2.3. Higher Alkenes

In the epoxidation of alkenes larger than ethene the competing activation of allylic C–H bonds is a serious problem. For example, while oxirane is produced in large amounts by oxidation of ethene with molecular oxygen on silver contacts,[3] the related oxidation of propene often leads to allyl alcohol or other products.[117]

As far as gas-phase experiments are concerned, allylic C–H bond activation and the problems associated with epoxidation of ethene by MO^+ are expected to bring about a vast complexity in the reactions of MO^+ with higher alkenes. Consequently, detailed mechanistic studies of gas-phase oxidation of alkenes larger than ethene have not yet been conducted. This is particularly regrettable, since only with alkenes larger than ethene can the intriguing aspects of the regio- and stereospecificity of gas-phase epoxidations in competition with C–H and C–C bond activation be explored. As discussed in the previous section, it will be mandatory to modify the reactivity of MO^+ by adding suitable ligands to the metal in order to tackle this important topic successfully.

Not surprisingly, all MO^+ ions which oxidize ethene also react rapidly with higher alkenes to yield a variety of products. The complexity of these processes leads us only to refer to the quite comprehensive study on gas-phase epoxidation by Kang and Beauchamp.[98] In their study of the reactions of CrO^+ with alkenes it was demonstrated that indeed allylic C–H bond activation competes with olefin epoxidation (Scheme 17). Furthermore, consecutive isomerization of the intermediates to carbonyl compounds was also observed. Despite this isomerization, CrO^+ was found to exhibit a significant selectivity in its reactions with olefins. For example, the product distributions for 1- and *cis*-2-butene were clearly distinguishable, demonstrating that allylic C–H bond activation does not lead to a complete loss of positional integrity of the carbon–carbon double bond



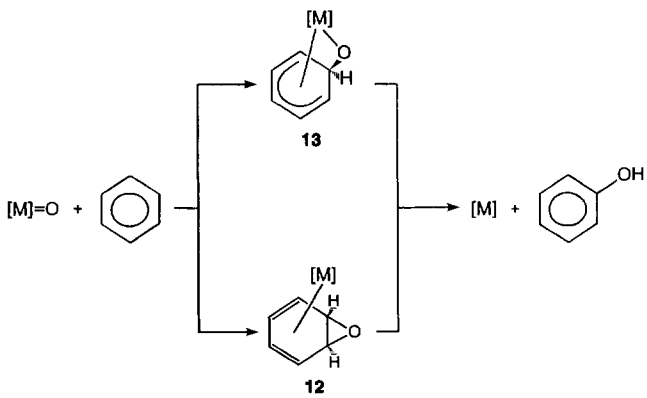
Scheme 17.

within the butene skeleton. We note in passing that this observation, which appears to be trivial, constitutes one of the rare examples in which the butene isomers have been differentiated by mass-spectrometric means. Unfortunately, these authors did not report the reactions of CrO^+ with the *cis*- and *trans*-stereoisomers of 2-butene.

Finally, other unsaturated hydrocarbons such as dienes[84] and acetylenes[44a] are also efficiently oxidized by cationic late transition-metal oxides in the gas phase; for example, FeO^+ reacts with C_2H_2 to yield an approximate 1:1 ratio of $FeCH_2^+$ and Fe^+ as ionic products, accompanied by CO and C_2H_2O formation; the latter neutral species is most probably a ketene.

4.3. Reactions of MO^+ with Arenes

Hydroxylation of arenes is a process of industrial relevance. It is also the most important pathway in the metabolization of aromatic compounds. In common with other oxidations, several mechanistic pathways for arene hydroxylation have been suggested.[8a] As far as processes in which metal oxides play a central role are concerned, the arene–oxide path has received considerable attention.[118] Here, O-atom transfer from an appropriate donor, depicted as [M]=O, leads to an arene oxide (**12**), which subsequently undergoes rearrangement ("NIH" shift)[119] to the corresponding phenol (Scheme 18). However, the arene-oxide path came under criticism, and alternative mechanisms involving σ-complexes (for example, **13**) or electron-transfer reactions were suggested.[120]



Scheme 18.

Although the conjectured reaction mechanisms are highly dependent on substrate and oxidant,[121] gas-phase studies may open up a new view on aromatic hydroxylation processes. Previously, detailed mechanistic gas-phase studies have only been reported for the reactions of FeO^+ with arenes. Therefore, in the following discussion we will primarily address iron oxide, which is also believed to play a central role in the cytochrome P-450 mediated metabolization of arenes.[8a]

4.3.1. Benzene

In a recent study the ion/molecule reactions of benzene with the first-row transition-metal oxides ScO^+–NiO^+ have been examined (Table 8).[122] Early and late transition-metal oxides can by and large be classified as for C–H bond activation of alkanes: The early transition-metal oxides ScO^+, TiO^+, and VO^+ do not hydroxylate benzene, but undergo adduct formation exclusively. As found for alkanes, MnO^+ is highly reactive ($\phi = 1$) and acts as a potent H-atom abstraction reagent, as evidenced by the formation of $MnOH^+$ with concomitant loss of a neutral phenyl radical among other products. CrO^+, CoO^+ and NiO^+ also react efficiently (all, $\phi = 1$) to yield the bare metal cations and neutral C_6H_6O as major products; for these reactions no mechanistic studies have yet been conducted.

Table 8. Efficiencies ϕ [%] and product ion branching ratios [%] in the reactions of MO^+ with benzene [a].

MO^+	ϕ	$(C_6H_6)MO^+$ [b]	$M(C_6H_4)^+$	$M(C_5H_6)^+$	$M(OH)^+$	M^+
ScO^+	15	100				
TiO^+	30	100				
VO^+	95	100				
CrO^+	100					100
MnO^+	100		18		15	67
FeO^+	100		5	37 [c]		56
CoO^+	100			30		70
NiO^+	100					100

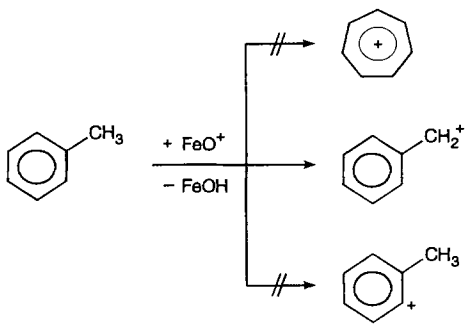
[a] Data taken from Refs. [116] and [122]. [b] The entry corresponds to the formation of the adduct complexes. [c] In addition, the so-formed $Fe(C_5H_6)^+$ undergoes consecutive $H^\cdot$ loss (2%) to yield $Fe(C_5H_5)^+$.

Mechanistic aspects of the benzene hydroxylation by bare MO^+ ions have been studied in quite some detail for FeO^+.[116, 123] In particular, the combination of isotopic labeling studies with ion/molecule reactions under ICR conditions, and collisional activation experiments in a sector field instrument provided significant insight into the reaction intermediates and the potential-energy hypersurface of the species $[Fe,C_6,H_6,O]^+$. NRMS was used to the structure of neutral C_6H_6O and unequivocally established that a C–O bond was present in the FeO^+/C_6H_6 system.[116a] Further experiments strongly favored the phenol structure.[116b] The results indicate that besides the *arene–oxide path*, an alternative mechanistic route must exist, which most probably involves formation of the σ-complex **13** (M = Fe^+ in Scheme 18). This conclusion was derived from comparative CA studies in which the complex of benzene oxide with Fe^+ was found to behave similar to authentic phenol/Fe^+, whereas in the reaction of FeO^+ with benzene significant amounts of the keto form, cyclohexadienone/Fe^+, were formed. Consequently, the arene–oxide path has to be questioned in bimolecular gas-phase chemistry as well. Interestingly, these studies also revealed that bare Fe^+ does not significantly affect the barrier for the interconversion of the keto and enol forms of phenol; however, isomerization of cyclohexadienone/Fe^+ to phenol/Fe^+ was achieved in the presence of a single water molecule added to the ligand sphere of the metal.[116b]

3.2. Alkylbenzenes

In the previous section it has been demonstrated that FeO^+ ions are capable of hydroxylating benzene with a reaction rate near the collisional limit, while the reaction with methane is less efficient. Consequently, it is intriguing to probe the chemistry of FeO^+ ions with toluene; in addition to the kinetic aspect, the site of the activation (benzylic or aromatic C–H bond) or possible competition between the two are points of interest.[124]

In spite of the high reactivity of FeO^+, the reaction of FeO^+ with toluene is highly selective and favors C–H bond activation at the benzylic position. The predominant products of the reaction of FeO^+ with toluene are a benzyl cation and neutral FeOH (Scheme 19).[125] Three aspects of this ion/molecule reaction

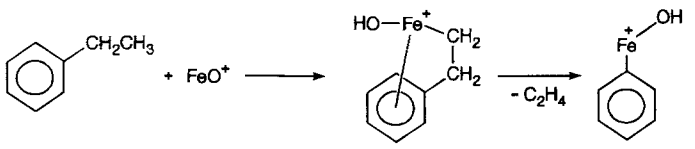


Scheme 19.

deserve mention: 1) Although the IEs of FeO and $C_6H_5CH_3$ are very similar,[20] electron transfer to yield the toluene cation radical hardly competes with oxidation. Since electron-transfer processes are assumed to take place very rapidly in such large molecules, its absence in the $C_6H_5CH_3/FeO^+$ system underlines the high intrinsic chemical reactivity of the iron oxide cation. 2) MS/MS studies establish that the $C_7H_7^+$ cation formed from FeO^+ and $C_6H_5CH_3$ exhibits exclusively the benzylium structure, rather than that of the energetically more stable tropylium ion.[126] Thus, the iron does not induce the interconversion of the two isomers. Further, the labeling studies reveal that activation of the aromatic C–H bonds does not take place. 3) As demonstrated by the preferential benzylic C–H bond activation, the high reactivity of FeO^+ is not necessarily accompanied by a decrease of selectivity.

We currently cannot decide whether the reaction mechanism for the formation of $C_6H_5CH_2^+$ involves a direct hydride anion transfer from the benzylic position to FeO^+ or whether it involves stepwise single-electron and H-atom transfers, or vice versa. Obviously, further studies with donor- and acceptor-substituted toluenes are indicated to probe this subtle question.

Not surprisingly, FeO^+ also reacts efficiently with the higher alkylbenzenes, for example, ethyl-, propyl-, *n*-butyl, and *n*-pentylbenzene.[127] Again, isotopic labeling studies demonstrate that activation of aromatic C–H bonds does not take place. With respect to site-selectivity, these reactions turn out to be more complicated in the sense that C–H as well as C–C bond activation of benzylic positions compete with activation of remote groups. For example, one pathway in the reaction of FeO^+ with ethylbenzene involves C–H bond activation in the β-position, thus, initiating C–C bond activation and subsequent loss of ethene (Scheme 20).[116b, 127]



Scheme 20.

4.4. Comparison with the Condensed Phase

A major issue in the evaluation of gas-phase experiments concerns their relevance for condensed-phase analogues. Since iron–oxide species play a central role in metalloporphyrin chemistry[8, 9] as well as in artificial systems (for example, the *Gif* mixtures)[12] and in view of the fact that FeO^+ has been studied quite comprehensively in the gas phase, we restrict the comparison to the iron system. As mentioned in the introduction, gas-phase experiments refer to reactions of isolated, and often almost entirely unligated molecules, bearing a real coulombic charge (no counterions) in a highly diluted atmosphere under strictly bimolecular conditions. Therefore, the characteristic features of an ion/molecule reaction are a priori different from a formally related reaction in solution. Furthermore, the binding in an unligated transition-metal oxide like FeO^+ is completely different nature to that of an iron–oxide species embedded in a large ligand like a porphyrin skeleton.[128] Besides the electronic differences in structure, the steric requirements may have an influence as well. For example, for bare FeO^+ it is easy to form an additional covalent bond to another atom, whereas the planar ligand environment in a porphyrinatoiron oxide renders the formation of an additional covalent bond on the same site as the oxygen atom much more difficult, if not impossible. Consequently, products as well as their distributions can vary substantially between the gas and the condensed phase. And yet, a comparison of mechanistic features is both interesting and promising, as it may provide insight into the role of reaction intermediates, the rate-determining steps, and, in particular, H/D kinetic isotope effects, prevailing under otherwise quite different conditions.

In the gas phase, the H/D kinetic isotope effects associated with hydroxylation of alkanes by FeO^+ are quite large; for example, $k_H/k_D = 4.6$ has been observed for FeO^+ and methane.[69] Similarly, aliphatic C–H bond activation by iron porphyrins and related systems display effects within this range or even larger.[129] Also, initial C–H bond activation is the rate-determining step in both cases. Furthermore, in the gas phase the H/D kinetic isotope effects (both inter- and intramolecular) associated with hydroxylation of benzene by FeO^+ are close to unity, that is, $k_H/k_D = 1.00 \pm 0.03$ for C_6H_6, C_6D_6, and $C_6H_3D_3$.[116a] This finding parallels that in condensed-phase systems, in which negligible kinetic isotope effects were reported for the hydroxylation of arenes by a variety of [M]=O-based oxidants.[8a, 130] The absence of an H/D kinetic isotope effect for both the gas-phase and the solution chemistry in these systems was attributed to the formation of either an arene oxide or a σ-complex in the rate-determining step. Likewise, the studies reveal that in both cases the arene-oxide path cannot be the only reaction mechanism responsible for product formation (see Section 4.3.2). For toluene, yet another mechanism is operative. In the condensed phase the H/D kinetic isotope effects associated with benzylic C–H bond activation vary from moderate to quite large, depending on the nature of the oxidant.[131] In the gas phase the reaction of FeO^+ with toluene is also associated with a primary kinetic isotope effect ($k_H/k_D = 1.8$);[125] however, its magnitude is substantially smaller than in the condensed phase. This relatively low value can be attributed to the high exothermicity for the formation of a benzyl cation and neutral FeOH (-24 kcal mol^{-1}), which diminishes the role of differing C–H and C–D bond energies in the transition structures, and k_H/k_D decreases. Alternatively, the small KIE may point to a reaction mechanism in which in the rate-determining step, stretching of the benzylic C–H bond is negligible (for example, an electron-transfer process). Finally, in the reaction of FeO^+ with labeled ethylbenzenes,[127] a distinct influence of the isotopic labeling on the product distribution has been reported, which indicates the existence of isotopically sensitive branching ("metabolic switching"), which has been observed earlier in hydroxylation of α-labeled ethylbenzene by cytochrome P-450.[132]

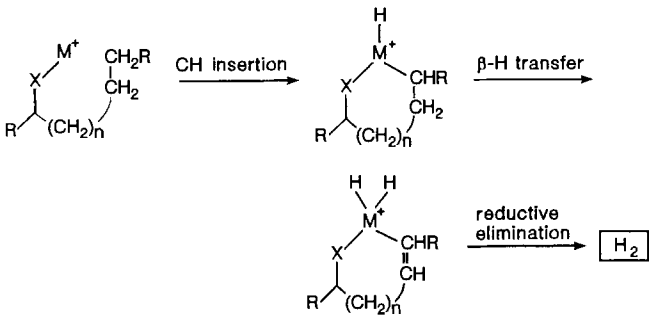
In spite of these pleasing similarities, we emphasize once more that beause of the principal differences of gas- and condensed-phase systems, any overinterpretation of the findings should be avoided. In fact, in some cases such as the reactions of bare MO^+ ions with alkenes, the current knowledge of the gas-phase process is even much worse than that of the condensed-phase analogues. Thus, instead of providing solutions to mechanistic problems that are not addressable in large-scale epoxidations, the situation for even the simplest system, namely MO^+/C_2H_4, turns out to be quite complex at the molecular level.

However, as demonstrated above in the hydroxylation of hydrocarbons, some analogies between the two media are obvious, and the gas-phase data may complement if not guide further research. In particular, the size of the systems under study renders them promising candidates for more sophisticated theoretical approaches. Finally, we should like to address one of the most promising processes in contemporary oxidation research, the Gif Systems introduced by Barton et al.[12] These rather complex mixtures bring about the transformation of hydrocarbons to ketones without formation of alcohols as intermediates.[133] Unfortunately, none of the gas-phase systems studied so far provided any evidence for the occurrence of these or related processes. Most likely, this failure is because for the transformation of a methylene group into R_2CH_2 into the corresponding ketone R_2CO, formally two O-atom equivalents are mandatory to yield water as an energetically stable oxidation product. Thus, the cationic metal monoxides will, on fundamental grounds, not be capable of satisfying the stoichiometry of this oxidation.

5. Reactions of MO^+ with Other Substrates

This chapter deals primarily with the reactions of monofunctionalized alkanes RX[87] with MO^+ ions. Due to its polar character any functional group will preferentially bind the charged metal center ("docking"). Therefore, in an ion/molecule reaction of an MO^+ ion with a functionalized alkane, the ion will initially coordinate to the heteroatom moiety[134] rather than directly activate C–H or C–C bonds as for pure hydrocarbons. Consequently the regioselectivity of C–H bond activation of the alkane backbone by coordinated MO^+ ions will be subject to additional conformational constraints, which, in turn, may determine the product formation.

For bare transition-metal cations M^+, coordination of the metal cation definitely leads to highly selective C–H and C–C bond activation remote from the functional group, and regioselective derivatization of nonactivated bonds in flexible alkyl chains thus becomes feasible. In analogy to Breslow's terminology[135] this process has been referred to as remote functionalization of nonactivated C–H and C–H bonds in the gas phase; Scheme 21 illustrates this mechanism for a metal-induced dehydrogenation.[136]



Scheme 21.

As shown in Section 4, late transition-metal oxide cations are very reactive towards alkanes, and for larger alkanes hardly any regiospecificity is observed, since all C–H bonds are more or less equivalent. Thus, it is an intriguing question, whether coordination of a reactive MO^+ species to a functional group will introduce any specificity or if the intrinsically high reactivity of the MO^+ ions will preclude selective processes. In fact, the former prospect is quite attractive, since nowadays only few procedures are known which allow regio- or even stereospecific hydroxylation of C–H bonds embedded in simple alkyl chains or rings.[137] Unfortunately, the gas-phase experiments performed so far are limited almost exclusively to reactions of FeO^+ with only a few substrates.

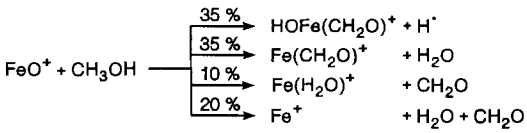
5.1. [C,H,O] Compounds

Oxygen-containing organic compounds are particularly suited for probing the regioselectivity in the gas-phase reactions of R–X with MO^+ on the following grounds: 1) Numerous gas-phase studies have shown that O-functionalities are among the weakest ligands for metal cations;[13, 87, 138] consequently, the intrinsic reactivity of MO^+ may override the stabilization from initial coordination to the functional group. On the other hand, remote functionalization of O-compounds by bare metal ions M^+ has been shown to exhibit high regio- and even stereoselectivity.[139] Therefore, O-compounds can be expected to serve as versatile probes for regioselectivity, when competition with nonselective processes within the hydrocarbon backbone is feasible. 2) Oxygen compounds, such as alcohols, ketones, or carbonic acids, are easily oxidized in the α-position. Thus, the competition between hydroxylation of activated and nonactivated C–H bonds can be examined. 3) Finally, oxygen compounds fulfill another requirement of mass spectrometric studies: Due to the high electronegativity of oxygen, hydride abstraction by MO^+ to yield neutral MOH and the corresponding organic cations is less favorable than for other heteroatom-containing substrates. Hence, the thermodynamic driving force for charge transfer from the metal to the functional group is small for [C,H,O] compounds and will not interfer reactivity studies.

5.1.1. *Alcohols*[84, 140]

A large variety of oxidants are capable of converting primary and secondary alcohols into the corresponding carbonyl compounds, for example, ketones, aldehydes, or even acids in the condensed phase. In these processes the activated C–H bond next to the hydroxyl moiety is involved.[141]

Indeed, if FeO^+ undergoes a reaction with methanol, formation of formaldehyde or its organometallic complexes by C–H bond activation is observed (Scheme 22). Similarly, FeO^+ oxidizes ethanol, 1-propanol, and 2-propanol to the corresponding

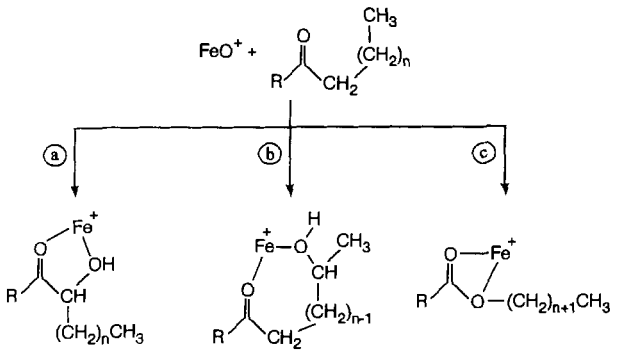


Scheme 22.

aldehydes, ketones, and their Fe^+ complexes. Interestingly, these substrates also exhibit formal transfer of a hydroxide anion to the metal center to yield the corresponding carbocations and neutral OFeOH.[84, 88] For larger alcohols, such as 1-pentanol, oxidation to the aldehyde and OH^- transfer become less important, and new reaction pathways open up with FeO^+. Among these, products arising from C–H and C–C bond activation remote from the functional group are observed.

5.1.2. *Ketones*

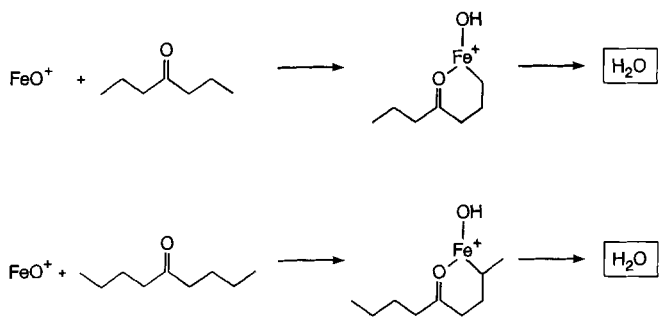
From a chemical point of view three different types of initial bond activations can be envisaged when a ketone is allowed to react with a reactive transition-metal-oxide cation such as FeO^+ (Scheme 23): 1) Hydroxylation of an activated C–H bond in the α-position leading to α-hydroxyketone/Fe^+ complexes and subsequent fragmentations (path ⓐ). 2) C–H bond activation of other positions in terms of remote functionalization (path ⓑ). 3) O-atom insertion into the C–C bond next to the keto group, giving rise to the corresponding ester/Fe^+ complexes (path ⓒ).



Scheme 23.

Surprisingly, in the reaction of the simplest ketone, namely acetone, α-C–C bond cleavage dominates and leads to subsequent loss of CH_3^+ and—most likely—formation of a cationic iron(II) acetate, $H_3CCOOFe^+$ (path ©).[142, 143] Since for almost all alkanes studied so far, C–H bond activation by FeO^+ was found to predominate, its apparent suppression in the acetone/FeO^+ system implies a substantial influence of the coordinating carbonyl group. Most probably, the complexation renders the C–H bonds of acetone less accessible for the metal oxide, and thus, for geometric reasons, C–C bond activation prevails.

Larger ketones exhibit a significantly different reactivity towards FeO^+ cations. The symmetrical ketones 4-heptanone and 5-nonanone have been shown to undergo regiospecific functionalization of nonactivated C–H bonds in the alkyl side chains when treated with FeO^+ (Scheme 24).[144] The supposition that geometric reasons influence the chemoselectivity of FeO^+ in the reaction with acetone (that is, C–C rather than C–H bond activation) is further supported by these findings. Moreover, the regioselective C–H bond activation of remote positions (namely the γ- and δ-C–H bonds) further emphasizes that the high reactivity of FeO^+ is not necessarily associated with a loss of specificity. We note in passing that the selectivity for the oxidative dehydrogenation of ketones by FeO^+ in the gas phase resembles the one observed in the derivatization of carbonyl compounds mediated by cytochrome P-450.[145]



Scheme 24.

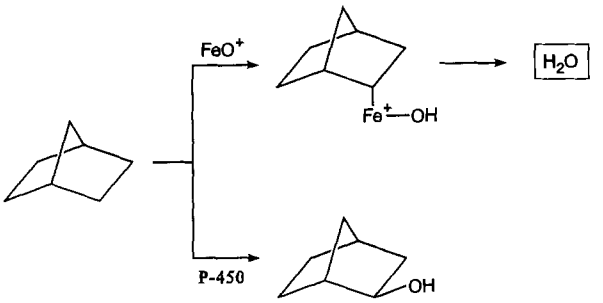
5.1.3. *Other [C,H,O] compounds*

Previously only a few other oxygen-containing organic substrates have been treated with MO^+ ions. Most of these studies did not explicitly address the reactions of MO^+ but rather reported them as secondary processes or side reactions, often in a quite different context.[41, 79a, 146] However, one example is of interest for fundamental reasons and should therefore be discussed here:[84] When acetaldehyde is treated with FeO^+, among other products, the pairs $FeOH^+/CH_3CO^\bullet$ (35%) and $CH_3CO^+/FeOH$ (15%) are formed. Since these product channels differ only in the location of the positive charge, it is somewhat surprising in view of the relative magnitudes of the ionization energies of $CH_3CO^\bullet$ (IE = 7.0 eV) and FeOH (IE = 7.9 eV) that less CH_3CO^+ is generated than $FeOH^+$. Either electron transfer from the initially charged iron center to the acetyl moiety must be hampered by a significant kinetic barrier, or that instead of $CH_3CO^\bullet$ the isomeric $^\bullet CH_2CHO$ radical must accompany $FeOH^+$ formation. Both possibilities are quite intriguing, and the results clearly indicate the need for further studies to probe the intrinsic reactivity of FeO^+ and other metal oxides towards aldehydes.

5.2. Miscellaneous Substrates

Experimental studies of the reactions of bare MO^+ with various substrates have been reported in the literature. However, these efforts did not always investigate the mechanistic features of MO^+ chemistry; rather, they dealt with side reactions.[147] Specific studies that deal with oxidation processes were performed for MO^+ when it was treated with hexafluorobenzene, pyridine and other nitrogen-containing heterocycles, aliphatic amines, and nitriles.[90, 111, 114, 148, 149] In general, the products observed correlate with the reactions of hydrocarbons and oxygen-containing compounds if one takes into account the additional effects of the heteroatom(s) present in the substrates. Furthermore, the differences in relative reactivities of the various metal-oxide cations are also noteworthy for these substrates. For example, the reactive metal oxides MnO^+ and FeO^+ are capable of oxygenating such a robust substrate as hexafluorobenzene,[66, 111] whereas in the reaction of pyridine with the early transition-metal-oxide cation NbO^+ only loss of HCN, rather than oxidation processes are observed. Moreover, loss of HCN from pyridine is also affected by the bare Nb^+ ion itself.[90]

The only two reactions of MO^+ (M = Fe) which should be discussed in this section involve the polycyclic hydrocarbons norbornane and adamantane.[140, 150] These alkanes serve as probes for regio- and stereoselectivity as well. The ion/molecule reactions of FeO^+ with norbornane and adamantane give rise to a variety of products, and the selectivities associated with the C–H and C–C bond activations were derived from extensive labeling experiments. Moreover, the carbon skeletons of both substrates are broken up in the reaction with FeO^+; for example, both precursors yield $Fe(C_6H_6)^+$ among other products.[151] Without going into detail, two points should be mentioned here: 1) C–H bond activation of norbornane by FeO^+ proceeds at the 2-position preferentially, with an *endo*-site selectivity (Scheme 25). This contrasts with the preferential *exo*-selectivity reported for hydroxylation of norbornane by cytochrome P-450.[152] 2) In the C–H bond activation of adamantane by FeO^+ to yield $C_{10}H_{15}^+$ and neutral FeOH, only a methyne group is involved, and this process is associated with an H/D kinetic isotope effect of $k_H/k_D = 2.7$. The reactivity of



Scheme 25.

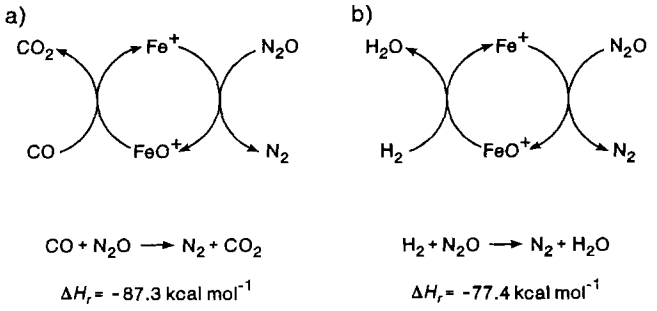
FeO^+ in the gas phase parallels the selectivities found for P-450-mediated oxidation of adamantane in the condensed phase,[129e] whereas in the *Gif* systems preferential attack at a methylene group takes place.[153]

6. Catalytic Oxidations in the Gas Phase

The storage capability of (FT)ICR mass spectrometry permits the examination of catalytic processes occurring in the gas phase.[154] In this context, catalysis is defined as a sequence of reactions in which *one* charged species converts more than one substrate molecule into a product. Since ion/molecule reactions in the low-pressure regime of (FT)ICR mass spectrometry can only proceed if they are exergonic (or more or less thermoneutral), the catalytic cycle must be designed so that each individual bimolecular step of the whole sequence must fulfill the condition of $\Delta G \leq 0$. Moreover, the bimolecular nature of the reactions permits modeling of the complete catalytic cycle in terms of a set of differential equations which, in turn, allows a determination of the reaction kinetics, the turnover number, and cooperative effects.

6.1. Earlier Studies and the "Perfect" Catalytic Cycle

The first gas-phase catalysis was described by Kappes and Staley, who reported that Fe^+ ions mediate the catalytic combustion of carbon monoxide to carbon dioxide with N_2O as oxidant.[44a] The reaction sequence is quite simple and commences with the oxidation of Fe^+ to FeO^+ by N_2O. Fe^+ is regenerated in the second step in which CO is converted into CO_2 (Scheme 26a). However, no further details concerning reaction kinetics and the turnover number were reported. Other authors proposed catalytic cycles for methane activation and olefin epoxidation in the gas phase, but did not examine them in great detail.[41, 102]



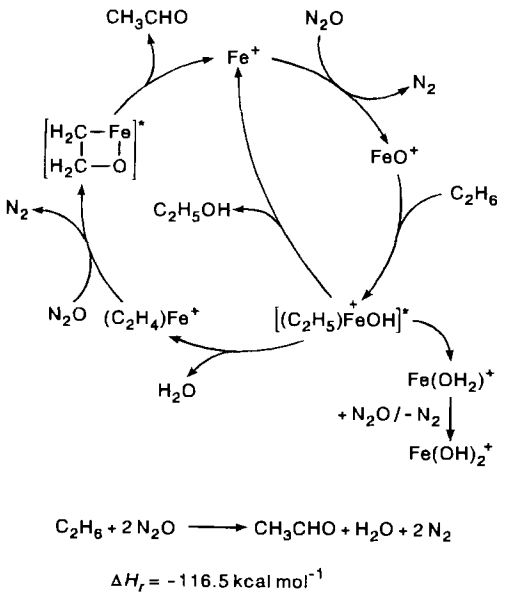
Scheme 26.

A example well-suited for a catalytic gas-phase reaction is, again, the simplest system, that is, the Fe^+-mediated oxidation of H_2 to H_2O with N_2O as an oxidant.[18] As outlined above, Fe^+ reacts with N_2O to yield FeO^+ and N_2, and in the second step Fe^+ is recovered in the reaction of FeO^+ with H_2; water is formed in the reaction. Thus, when N_2O and H_2 are leaked into an (FT)ICR mass spectrometer, the Fe^+ ions are capable of catalyzing the reaction $N_2O + H_2 \rightarrow N_2 + H_2O$, which itself does not occur at room temperature in the absence of a catalyst (Scheme 26b). Furthermore, the "catalyst" is inert towards reactants and products in that the oxidant N_2O does not react with the oxidized form FeO^+, nor does the substrate H_2 react with the reduced form Fe^+. If background contaminants as well as trapping losses from the cyclotron setup are neglected,[17] the catalytic cycle depicted in Scheme 26b proceeds with an infinite turnover number; in practice, however, side reactions with background hydrocarbons and water limit the turnover number to about 100. Of course, this process has no practical importance, since combustion of hydrogen does not need to be performed catalytically; rather, the strong exothermicity permits an efficient chain reaction to occur. In addition, it is obvious that catalysis in an (FT)ICR mass spectrometer cannot be used for real applications, since the ion concentrations are extremely low (about 10^{-15} mol L^{-1}). However, these studies are more than "l'art pour l'art" exercises, since intrinsic properties of the reactive center of a catalyst can be evaluated at a molecular level. In fact, the principles uncovered for the isolated system may hold true to some extent for applied catalysis, for example, an [M]=O species on the surface of a heterogeneous catalyst.

6.2. Catalytic Oxidation of Alkanes

The principles outlined above for the Fe^+-catalyzed oxidation of H_2 by N_2O can also be applied to mediate the oxidation of methane.[69] However, the formation of $FeOH^+$ is substantial, and this ion is unreactive towards methane on thermochemical grounds;[155] consequently, first-principle considerations limit the turnover number to 1.6. However, in a more general view, the release of a methyl radical in the course of $FeOH^+$ formation can also be seen as a model for methane oxidation or coupling processes[1, 2] by recombination of $CH_3^{\bullet}$ with other radicals, for example, $CH_3^{\bullet}$ or $HO^{\bullet}$. Of course, these bimolecular reactions of neutral species are precluded in the low-pressure regime of the (FT)ICR instrument, and the radicals are simply pumped away.

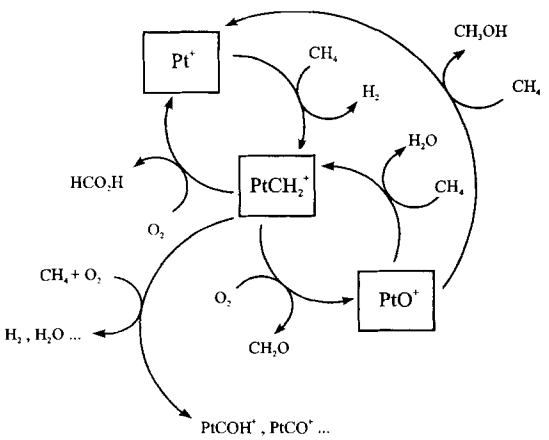
The same concept has also been applied to the ethane/N_2O/Fe^+ system.[156] The overall sequence of reactions can be described as an Fe^+-catalyzed oxidation of ethane to yield ethanol and acetaldehyde as major products with a turnover number of about 2.5 (Scheme 27). Here, the sink in the catalytic cycle is caused by the irreversible formation of $Fe(OH)_2^+$ as a side product. The nonreactivity of $Fe(OH)_2^+$ towards ethane emphasizes the essential function of the metal-oxide moiety in FeO^+, rather than the formal oxidation state iron(III). Moreover, as $Fe(OH)_2^+$ can be described as hydrated FeO^+, the reactive spe-



Scheme 27.

cies might be regenerated by loss of water. Actually, this finding illustrates, to some extent, an analogy to applied catalytic processes in which desorption of the product, in this case, loss of the water ligand, is often rate-limiting. In practice, dehydration is achieved by performing the oxidation at elevated temperatures. Irion et al.[154a–d] mimicked the effect of temperature in gas-phase catalytic processes by kinetically exciting the unreactive product complexes of a catalytic cycle in order to regenerate the active species.

Most recently, a turnover number of about 6.0 was found for the Pt^+-mediated oxidation of methane.[75] In this example it is particularly interesting that molecular oxygen can be used as the oxidant. The overall reaction sequence is somewhat more complicated (Scheme 28), since not only PtO^+, but also bare Pt^+ itself and the intermediate $PtCH_2^+$ activate methane. The sink in the catalytic cycle is a result of minor consecutive reactions of $PtCH_2^+$ with methane. Furthermore, the reactions reveal a general problem also encountered in the applied catalysis: On one hand increasing the excess of oxygen in its mixture with methane minimizes the side reactions, and thus increases the turnover, but on the other hand, this procedure will decrease the overall

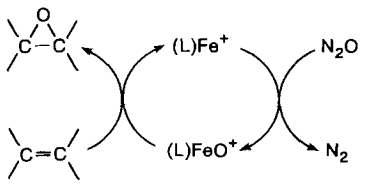


Scheme 28.

rate of methane oxidation. In addition, the product distribution reveals that in the gas phase, as in the condensed phase, oxidation of methane is associated with overoxidation to yield formic acid and eventually CO_2. Obviously, we are a long way from finding the ideal "methane → methanol" conversion catalyst.

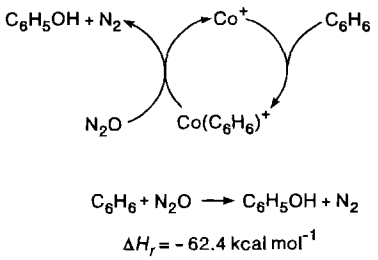
6.3. Catalytic Oxidation of Other Hydrocarbons

Upon increasing the size of the substrate the reactions often become less selective than those of methane or ethane. A drop in the turnover numbers can therefore be expected. Not many examples of gas-phase catalysis have been examined yet. In all reactions reported so far for other substrates, Fe^+ catalyzes the oxidation of acetylene[44a] and ethene[102, 157] with N_2O as oxygen source. As described above for olefin epoxidation by MO^+ the highest selectivity and also the largest turnover number can be achieved for ligated metal oxides rather than the bare MO^+ species. For example, $Fe(L)^+$ ions (L = benzene, pyridine, naphthalene) catalyze the epoxidation of ethene, propene, *iso*-butene, and cyclohexene by N_2O as oxidant with turnover numbers up to 6 (Scheme 29).[158]



Scheme 29.

Recently Co^+-catalyzed oxidation of benzene, most probably to phenol, has been reported.[122] This process is particularly interesting in the sense that it mimics heterogeneous catalysis (Scheme 30): In the first step benzene coordinates to bare Co^+ to afford the corresponding $(C_6H_6)Co^+$ complex. Subsequently, the oxidant N_2O also coordinates to the complex, and the reaction yields neutral C_6H_6O and regenerates the catalytically active Co^+. Here, the cobalt–oxygen species just serves as an intermediate en route to product formation. Moreover, the reaction exothermicity leads to dissociation of the product complex $((C_6H_6O)Co^+)$; consequently product formation does not represent a sink for the overall cycle. The turnover number for the Co^+-catalyzed hydroxylation of benzene is therefore quite high for a gas-phase process (about 18).



Scheme 30.

7. Conclusions

Gas-phase reactions of bare transition-metal-oxide ions represent the simplest model systems for oxidation processes that involve metal-oxide species [M]=O. In particular, these systems are ideally suited for a combination of state-of-the-art experimental and theoretical approaches. As demonstrated above, the oxides of the late transition-metal cations undergo O-atom

transfer to alkanes, alkenes, arenes, as well as functionalized alkanes. In fact, hardly any substrates exist that are not oxidized by highly reactive species such as MnO^+ and FeO^+. As far as the reaction mechanisms are concerned, C–H bond activation by MO^+ proceeds either by direct H-atom abstraction (provided this process is thermochemically feasible) or by a multicentered transition structure as well as curve crossing—mediated by spin–orbit coupling—between the high-spin and low-spin surfaces of the intermediates.[55a]

Despite the high reactivity of FeO^+, it is rather selective with respect to the site of C–H bond activation. Furthermore, gas-phase reactions of FeO^+ with various substrates reveal interesting parallels to related processes occurring in the condensed phase, which involve metal oxides as central intermediates. In particular, selectivities and kinetic isotope effects of the gas-phase reactions are often similar to those observed in solution chemistry, and to the reactions of cytochrome P-450 in particular. These results are promising in the sense that the elementary steps of C–H bond activation may be elucidated. Within this context, further experiments with specifically designed substrates are indicated, for example, ring-substituted toluenes or cyclopropyl derivatives which may serve as a probe for radicaloid intermediates.[159] Furthermore, additional significant information might be obtained by using other experimental approaches, as for example the powerful analysis of kinetic energy release distributions and related techniques.[160]

However, the example of epoxidation reactions demonstrates that the translation of gas-phase results to well-known condensed-phase analogues is not at all straightforward. Indeed, for olefin oxidation the situation in the gas phase turns out to be more complicated than in solution. Here, the neglect of ligand effects is critical, and these effects deserve to be studied much more carefully in the future. Actually, recent results of ligated FeO^+ cations that mediate selective epoxidation reactions already indicate a potential route towards higher selectivity and are likely to stimulate further research. Similarly, the design of catalytic variants for gas-phase processes might bring about a more detailed understanding of the principles of catalysis, as demonstrated for the few examples given in Section 6.

In addition, the activation of molecular oxygen for oxidation processes represents an attractive prospect that should be addressed in the future. Preliminary gas-phase experiments[161] demonstrate that olefin/Fe^+ complexes are efficiently oxidized by O_2, whereas other olefin/M^+ complexes (M = Na, Mg, Sc–Mn, Co–Zn, Ru–Pd, and Os–Pt)[84, 161, 162] do not promote olefin oxidation. Interestingly, the exceptional reactivity of the cationic iron complexes in the gas phase parallels the relevance of iron for transportation, storage, and activation of molecular oxygen in the condensed phase, and in biochemistry in particular.[7] Obviously, continuing experimental and theoretical studies on the reactions of dioxygen and transition-metal dioxygen complexes are indicated.[89, 163, 164] In addition, gas-phase reactions of organometallics with other O-atom donors, for example, peroxides, need to be considered.

Last but not least, the impetus of theoretical methods will improve significantly our understanding of oxidation reactions mediated by transition metals. In particular, theoretical approaches can shed light on reaction dynamics and the role of the various electronic states in these processes.

In conclusion, gas-phase studies of bare and ligated transition-metal-oxide ions provide valuable insight into the elementary steps of oxidation processes. However, when gas-phase data are compared to data from the condensed phase, the fundamental differences of both approaches must always be considered. Thus, despite the considerable progress witnessed in the chemistry of transition-metal-oxide species in the condensed as well as the gas phase, continuous efforts are needed to unify these fields and to bring about a more uniform understanding of oxidation catalysis at a molecular level to account for the experimentally observed effects.[165] Ultimately, it is hoped that the combination of theoretical and experimental gas-phase studies and its cautious comparison with results from applied processes may help to realize the design of tailor-made catalysts.

The generous and continuous financial support of our work by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Volkswagen-Stiftung, and the Freunde der Technischen Universität Berlin is gratefully acknowledged. We are indebted to our co-workers for helpful discussions and additional information, in particular to Dr. Jan Hrušák, Matthew F. Ryan PhD, Dr. Detlef Stöckigt, Dr. Hansjürgen Becker, Dipl.-Chem. Andreas Fiedler, Dipl.-Chem. Christoph Heinemann, Dipl.-Chem. Josef Schwarz, and Dipl.-Chem. Ralf Wesendrup. Likewise, we thank Professors Peter B. Armentrout, Diethard K. Böhme, Wolfgang A. Herrmann, Nico M. M. Nibbering, Tom Ziegler, and Dr. K. K. Irikura for sending preprints and communicating unpublished results. We also appreciate enlightening discussions on theoretical aspects with Professors Wolfram Koch, Keiji Morokuma, Sason Shaik, and Per E. M. Siegbahn. H. S. is grateful to the Alexander-von-Humboldt Foundation for support (Max-Planck Research Award). In particular, he appreciates the hospitality of Professor Leo Radom and the Research School of Chemistry at the Australian National University for a Visiting Fellowship, which made possible his stay in Canberra where part of this review was completed.

[72] Experimental values for BDE (Fe^+–OH) range from 73 to 87 kcal mol^{-1} [73]. Due to this uncertainty it is not clear whether its formation from FeO^+ and H_2 is endothermic or not; therefore, we refer to the "standard" value of 79 kcal mol^{-1} given in Ref. [20b]; for discussions, see Refs. [65a] and [73d] as well as P. B. Armentrout, D. E. Clemmer in Ref. [50b], p. 321.

Terminal E_1 Ligands from Elements of Group 15**

Manfred Scheer*

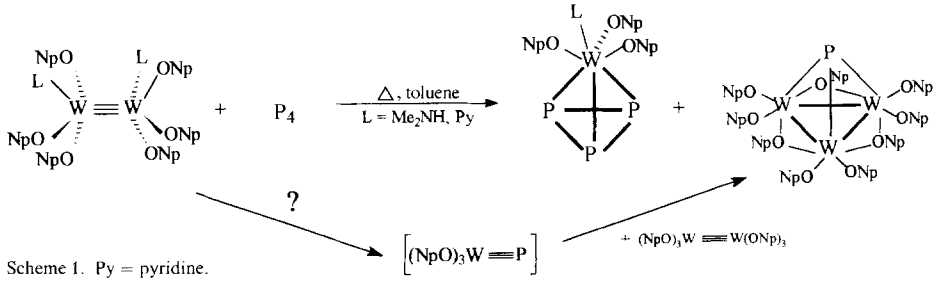
In recent years interest in complexes containing multiple bonds between transition metal and main group elements has risen sharply.[1] This field is dominated by compounds with terminal ligands from elements of the first row of the periodic table with M=E units (e.g. E = CR_2, NR, O) or M≡E (E = CR, N). The synthesis of complexes with ligands of higher homologues of the main group elements was first achieved at the beginning of the nineties. Thus, Parkin et al. succeeded in synthesizing the first complexes with terminal tellurido ligands.[2]

For complexes containing ligands from elements of group 15 the situation is as follows: Coordination compounds with terminal nitrogen ligands have been known for some time.[3, 4] Examples include the square-pyramidal complexes of type $[MNCl_4]^-$ (M = Mo, W, Re, Ru, Os),[5] which have a very short metal–nitrogen bond. The Lewis base properties of the nitrido ligands are expressed above all in the addition to Lewis acids such as BF_3, and in their tendency towards intermolecular association.[3, 6] For the heavier elements of group 15 there have been, up to now, no examples of this type of coordination, whilst numerous other coordination polyhedra with E_1 ligands are known.[7] Only recently has there been a breakthrough in the successful synthesis of isolable phosphido complexes,[***] and the following discussion traces their development from objects of speculation to manipulable compounds.

Ziegler et al., who were working on the reactivity of trinuclear clusters capped by As, postulated $[Cp(CO)_2M{\equiv}As]$ (M = Mo, W) as intermediates during the co-photolysis of $[\{CpM(CO)_2\}_3(\mu_3\text{-As})]$ with $[CpM'(CO)_2]$ (M' = Co, Rh)[8a, b] or with $[Fe_2(CO)_9]$ and $[Fe(CO)_5]$.[8c] The transformation of the trinuclear cluster into species of the types $[Cp(CO)_2M{\equiv}As]$ and $[\{CpM(CO)_2\}_2]$ ($M{\equiv}M$) can be deduced from the nature of the reaction products.

Rheingold et al. recently reported a gas-phase reaction of Sb_2^- species, generated by laser evaporation of antimony metal, with carbonyl complexes in an ion-cyclotron spectrometer (FT-ICR).[9] Under these conditions the formation of the anionic complexes $[(CO)_nM{\equiv}Sb]^-$ (n = 4, M = Cr, Mo, W; n = 3, M = Fe) could be observed. Ab-initio-MP2 calculations on the Mo complex indicated a square-pyramidal structure (C_{4v} symmetry) with a Mo≡Sb bond length of 2.55 Å.

In 1987 Chisholm et al. found that during the reaction of $[W_2(ONp)_6(HNMe_2)_2]$ (Np = neopentyl) with P_4 a complex with a P_1 and a complex with a P_3 ligand are formed (Scheme 1).[10] Here it was proposed that a phosphido complex



Scheme 1. Py = pyridine.

of type $[(NpO)_3W{\equiv}P]$ could be an intermediate in this reaction. This reacts further with the dimeric W^{III} alkoxide to give a trinuclear cluster with a capping phosphorus ligand. This assumption is supported by the fact that the reaction of $[W_2(O\mathit{t}Bu)_6]$ with alkynes generates alkylidynetungsten complexes[11] and that $[(RO)_3W{\equiv}CR']$ adds to $[(RO)_3W{\equiv}W(OR)_3]$ to form $[W_3(\mu_3\text{-}CR')(OR)_9]$.[12]

A phosphido complex intermediate is also suggested by Becker et al.,[13] for the reaction of $[W_2(O\mathit{t}Bu)_6]$ with the phosphaalkyne $\mathit{t}BuC{\equiv}P$. A reaction pathway as shown in Scheme 2 is proposed.[14] This is based on the identification of **3** with a WC_2P four-membered ring and on data from ^{31}P NMR spectroscopy which indicates the existence of a possible product **4**. Accordingly, there should be a metathesis reaction between the phosphaalkyne $\mathit{t}BuC{\equiv}P$ and the tungsten complex $[W_2(O\mathit{t}Bu)_6]$ to afford alkylidyne compound **1** and the phosphido complex **2**. Subsequent rapid reactions produce intermediates with four-membered rings which stabilize themselves by a 1,3-migration of an alkoxy group to the give the final products **3** and **4**.

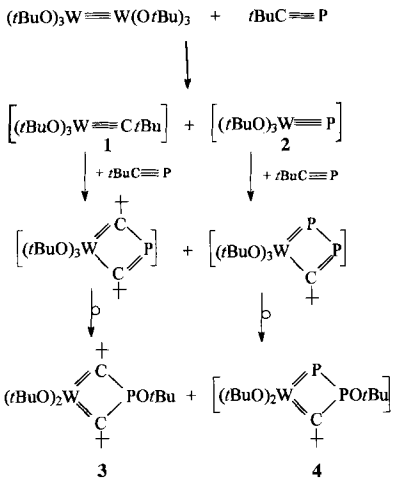
[**] My thanks go to Dr. M. Häser (University of Karlsruhe) for the very valuable discussions which contributed to the development of this work.

[***] The term phosphido ligand for the P^{3-} ligand complies with the IUPAC guidelines (and analogously: arsenido-, antimonido- and bismutido ligand). Hitherto this name has been used incorrectly for the R_2P ligand. This name should be given to $[L_nM{\equiv}P]$, in analogy to the nitrido complex, in preference to terms such as metallaphosphaalkyne or phosphinidyne complex. The latter is derived from the isolobal relationship of the P ligand with the CR fragment.



Scheme 2. Postulated course of the reaction between $[W_2(OtBu)_6]$ and $tBu{\equiv}P$.

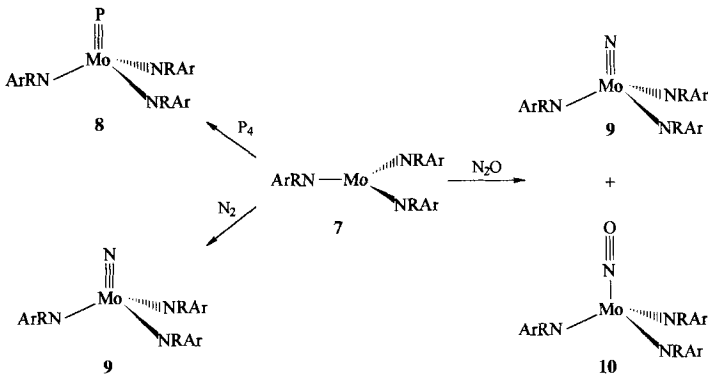
In recent years we have developed a concept for the elucidation of the transformation pathway of the P_4 tetrahedron in the coordination sphere of transition metal complexes.[15] By addition of simple carbonyl complexes such as $[Cr(CO)_5(thf)]$ to the appropriate reaction solutions containing P_4 it is possible to stabilize intermediates through the coordination of the lone pairs on the phosphorus atoms to the carbonyl complex. If the reaction given in Scheme 2 is carried out in the presence of pentacarbonyl complexes, the alkylidyne complex **1** and the product **5** are obtained.[16] However, a subsequent reaction with $tBuC{\equiv}P$ followed by 1,3-migration of the alkoxy ligand to form the compounds **3** and **6**, with four-membered rings, cannot be completely prevented. Since the reaction mixture could not be separated by column chromatography, only the enrichment of **5a,b** by fractional crystallization was achieved. The ^{31}P NMR chemical shifts at $\delta = 595.4$ (**5a**) and 544.6 (**5b**), the large $^1J(^{183}W,^{31}P)$ coupling constants of 535.8 Hz (**5a**) and 554 Hz (**5b**), and the appearance of a second coupling in the case of the $[W(CO)_5]$-substituted product **5b** of $J = 163$ Hz together with the ratio of signal integrals proves the existence of the compounds.

$[(tBuO)_3W{\equiv}P \rightarrow M(CO)_5]$ (M = Cr, W) **5a,b**

$[(tBuO)_2W\{(CtBu)P(M(CO)_5)P(OtBu)\}]$ (M = Cr or W) **6a,b**

The first isolated and structurally characterized complexes containing metal–phosphorus triple bonds were obtained by the groups of Cummins[17] and Schrock,[18] and marked a breakthrough in this field.

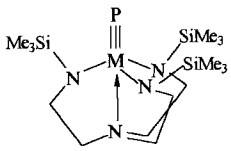
The phosphido complex **8** can be obtained from the reaction of the molybdenum(III) complex **7** with P_4 (Scheme 3).[17] The molybdenum starting material **7** is planar, probably without any $N \rightarrow Mo$ $p\pi$-$d\pi$ bonds. The three unpaired electrons are localized on the Mo atom.[19] This complex is extremely reactive and can cleave N–N bonds in N_2O[19] and even in N_2[20] under very mild conditions (Scheme 3). In the former case the nitrido complex **9** and the nitrosyl complex **10** are obtained. In the latter reaction, with N_2, a η^1-N_2 coordinated intermediate is proposed, onto which a second molecule of the starting material can coordinate to form a $(\mu,\eta^1$-$N_2)$ complex. Subsequent cleavage of



Scheme 3. $R = C(CD_3)_2CH_3$; $Ar = 3,5\text{-}C_6H_3Me_2$.

the N–N bond generates the nitrido complex **9**. Investigations on the reactivity of the molybdenum starting complex are in their infancy, so that further very interesting results can be expected.

Schrock et al. used the N_3N ligand ($N_3N = (Me_3SiNCH_2CH_2)_3N$) for the synthesis of the phosphido complexes **11a,b**. This figand promotes the formation of a multiple bond (between the transition metal and the ligand) *trans* to the intramolecular N donor. Thus, the phosphinidene complex **12** is obtained from the reaction of $[(N_3N)TaCl_2]$ with LiPHR.[21] Treatment of $[(N_3N)SnBu]$ with $[(tBuO)_3Mo{\equiv}N]$ leads to the nitrido complex **13**.[22] Therefore, the chloro complexes $[(N_3N)MCl]$ (M = Mo, W) are predestined as starting materials for a M–E triple bond system. They react with MeLi to give the corresponding methyl derivatives; under mild thermal conditions (80 °C), $[(N_3N)WCH_3]$ loses H_2 to form the alkylidyne complex **14**.[23] Using the same principle of synthesis (halogeno complex and LiPHPh) the phosphido complexes **11a,b** are now accessible. The reaction pathway is not completely understood; however, the phenylphosphanido complexes **15a,b** should be precursors of **11a,b**.



11a: M = Mo
11b: M = W

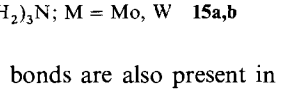
$[(N_3N)Ta{=}PR]$, $N_3N = (Me_3SiNCH_2CH_2)_3N$; R = Ph, Cy, *t*Bu **12**

$[(N_3N)Mo{\equiv}N]$, $N_3N = (MeNCH_2CH_2)_3N$ **13**

$[(N_3N)W{\equiv}CH]$, $N_3N = (Me_3SiNCH_2CH_2)_3N$ **14**

$[(N_3N)M{-}PPhH]$, $N_3N = (Me_3SiNCH_2CH_2)_3N$; M = Mo, W **15a,b**

Formal metal–phosphorus triple bonds are also present in phosphinidene complexes with an almost linear MPR arrangement (Scheme 4, type **A**). The p orbitals of phosphorus can form π bonds with the d orbitals of the metal. A comparison of the metal–phosphorus bond lengths in **12** (2.145(7) Å),[21] **16** (2.169(1) Å), and **11b** (2.162(4) Å) justifies this view. The bond lenghts are almost



A **B**

Scheme 4. Coordination modes of phosphinidene complexes.

identical in two tungsten compounds (**11b** and **16**). On the other hand, the observed coupling constants $^1J(^{183}W,^{31}P)$ of **11b** (138 Hz) and **16** (649 Hz) seem to contradict themselves, and even for **5a,b** values of 535 and 554 Hz are found.[16] In the bent phosphinidene complex **17b**,[25] in which there is only a

$[CO(Me_3P)_2Cl_2W{\equiv}PAr']$, Ar' = 2,4,6-$tBu_3C_6H_2$ **16**

$[Cp_2M{=}PAr']$, Ar' = 2,4,6-tBu$_3$C$_6$H$_2$; M = Mo, W **17a,b**

double bond present (Scheme 4, type **B**; cf. structure of **17a**) the value of $^1J(^{183}W,^{31}P)$ amounts to 153.5 Hz.[26] It seems sensible to attribute the small coupling constants of **11b** to the high oxidation state of the metal center (tungsten(VI)). However, the W^{II} complex $[CpW(CO)_2(SnMe_3)PR_3]$ (R = OMe) shows, for example, a coupling of 493.6 Hz, whilst smaller values have been found for W^0 complexes.[27a] There is also the consideration that the Fermi-contact term, which is essentially determined by the s-character of the bonding orbital, is not the sole controlling factor for the resulting coupling constants, but coupling contributions which are transmitted through the π-electron system (spin dipole contribution or the paramagnetic orbital contribution) must be taken more effectively into account.[27b] It is noteworthy that there is always a relatively large coupling constant $^1J(^{183}W,^{31}P)$ when the phosphido ligand is coordinated in a linear fashion to a second bonding partner, for example an aryl group as in **16** or a pentacarbonyl-metal complex fragment as in **5**. Indeed, the comparative analysis of the electronic structures of uncoordinated and coordinated phosphido ligand complexes shows that with approximately constant π-bonding contributions, the phosphorus-3s orbital contribution to a W–P bond increases by about 30% whilst at the same time the phosphorus-3p σ-contribution decreases.[28] There must certainly be a connection between the enormous increase of $^1J(^{183}W,^{31}P)$ in linear coordination of phosphorus in the experimentally investigated complexes **5** and **15**.

Summary: The synthesis of the first stable complexes with terminal phosphido ligands is of fundamental importance and will lend the field of coordination chemistry considerable impetus. The synthesis of analogous complexes with ligands of the heavier homologues have now moved within reach. Both synthetic pathways should give access to, for example, the corresponding arsenido complexes. Moreover, we can now set about answering fundamental questions on the properties of P_1 ligands both experimentally and theoretically.

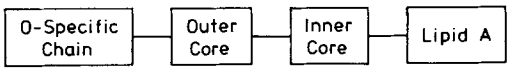
Endotoxin Antagonists: Possible Candidates for the Treatment of Gram-Negative Sepsis**

Otto Holst*

The endotoxins [lipopolysaccharides (LPS)] of Gram-negative bacteria are amphiphilic macromolecules located in the outer membrane of the cell wall.[1, 2] LPS are essential for bacterial survival; they augment the rigidity of the cell wall and protect bacteria from bile acids, gut enzymes, and defense mechanisms of the host, and from antibiotics. In higher animals and humans, however, endotoxins exhibit a variety of pathophysiological effects. Even in minor amounts they may invoke a sepsis which, accompanied by hypotension and multiple organ failure, leads to septic shock that is the major cause of death in intensive care units worldwide. Moreover, LPS are antigens and thus involved in the process of recognition of bacteria and the host's defense. The biological activities of LPS and their clinical relevance are main impulses for tremendous international research on the structure and function of LPS and possible approaches to sepsis therapy.

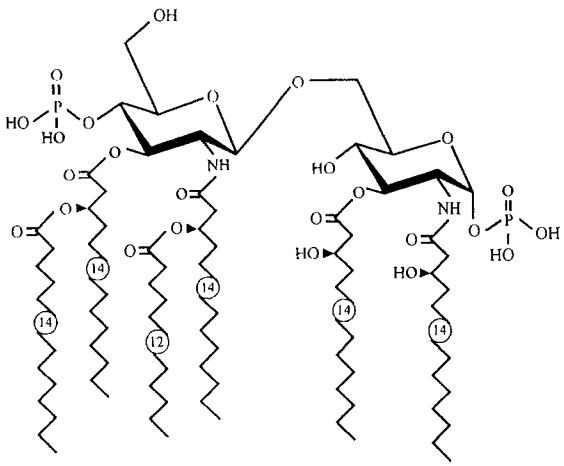
LPS of all Gram-negative bacteria share a common architecture (Scheme 1).[2] They consist of a lipidic portion, the lipid A,[3] which anchors the molecule in the outer membrane



Scheme 1. General structure of bacterial LPS.

and which is linked to a more or less complex carbohydrate chain. In various bacterial families (e.g. *Enterobacteriaceae, Vibrionaceae*) this is an oligosaccharide unit with up to 15 monosaccharides (the core region), which is substituted with a polysaccharide of repeating units (the O-antigen, S-form LPS).[4] A second type of LPS, which was first identified in mutants carrying a defect in the gene cluster responsible for O-antigen biosynthesis (*rfb*), consists only of lipid A and the core region (R-form LPS). Later, this type of LPS was also found in bacteria without known genetic defects, for example, in *Bordetella pertussis* (whooping cough) and *Neisseria gonorrhoeae* (gonorrhea).

During infection, LPS are liberated from bacteria, for example after cell death. These LPS react with various serum components, a prominent member of which is the "lipopolysaccharide binding protein" (LBP). LPS complex with LBP and may then be bound to a receptor (CD14) of macrophages, which through a not yet elucidated signal transduction pathway are stimulated to synthesize and release distinct mediator substances such as tumor necrosis factor-α (TNF-α) and the interleukins (Il) 1, 6, and 8.[5] Overproduction of mediators results in the pathophysiological effects of endotoxins. The initialization of this cascade does not require a complete LPS molecule. As postulated in the 1950s and verified in the 1980s[6, 7] in various biological experiments using natural isolates and synthetic *Escherichia coli* lipid A (Scheme 2), lipid A represents the toxic principle of LPS.



Scheme 2. Structure of lipid A from *E. coli*. The circled numbers refer to the length of the carbon chain.

Today, the mortality rate of Gram-negative sepsis is still as high as 60%, owing to an increasing distribution of antibiotic-resistent bacteria in hospitals. Additionally, LPS are liberated from bacteria by antibiotics. New strategies to avoid or treat Gram-negative sepsis could affect different stages of the endotoxin cascade: the LPS, the interaction of LPS with serum components/cell receptors, or the production and secretion of mediators. Besides efforts to obtain cross-reactive and -protective antibodies in particular against lipid A, an inhibitor of the TNF-α synthesis was identified which protects mice against the lethal effects of endotoxin. One monoclonal antibody (HA-1A) was applied clinically; however, its distribution has been stopped in the meantime, since it proved to be a failure.

In my opinion recent investigations concerning the effects of nontoxic endotoxin antagonists are also very important. These are structural analogues of lipid A, some of which are shown in Scheme 3. One example is tetraacyl lipid A (**A**) (precursor Ia), a precursor in lipid A biosynthesis which has also been synthesized chemically (Compound 406).[8, 9] As shown by different research groups, precursor Ia inhibits the LPS-induced specific mRNA production for monokines in human macrophages. Comparison of investigations using different structural analogues revealed that the effectiveness of these disaccharide an-

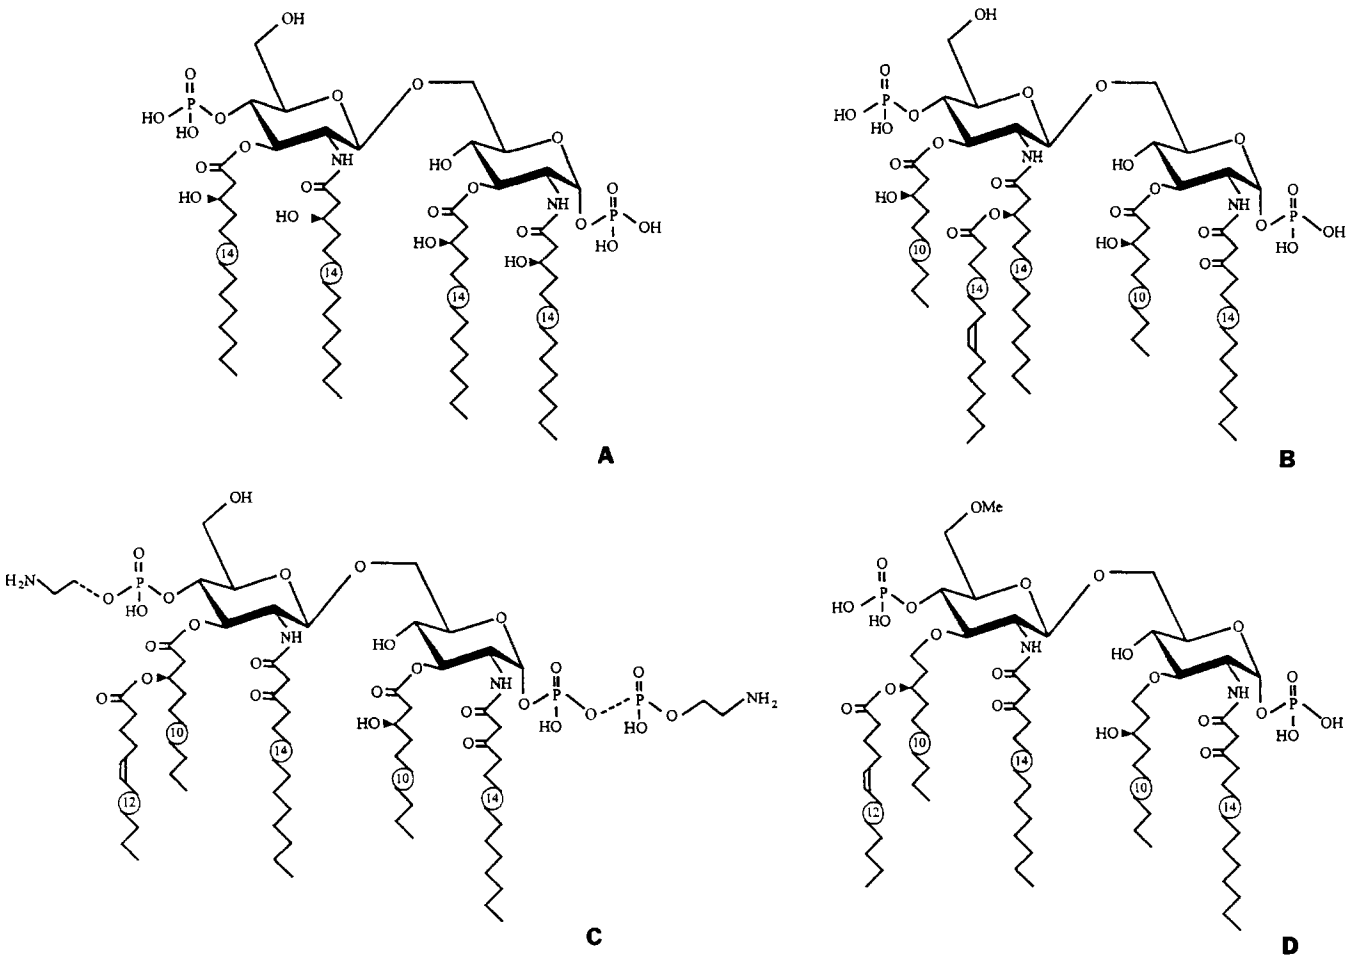
[**] I thank Dr. U. Zähringer for help in preparing the schemes and Professor H. Brade for critical reading of the manuscript.



Scheme 3. Structures of precursor Ia (**A**), lipid A from *R. sphaeroides* (**B**), lipid A from *R. capsulatus* (**C**), and E5531 (**D**).

tagonists depends on their acylation and phosphorylation pattern. Tetraacylated and bisphosphorylated precursor Ia is one of the most effective inhibitors known to date. In macrophages and monocytes, the mechanism of the inhibition is based on competitive binding of the antagonist to CD14. However, since precursor Ia exhibits agonistic activities in vitro and in vivo in mice (but not in humans), it is not possible to test this substance in a murine sepsis model.

Other antagonists are the nontoxic lipid A of *Rhodobacter sphaeroides* (**B**) and *R. capsulatus* (**C**) (Scheme 3).[10–15] The lipid A of *R. sphaeroides* (**B**) was also chemically synthesized.[16] A spectroscopic analysis identified differences with the structure of the natural isolate, most likely in the fatty acids. The authors thus suggested that the published structure of the isolated lipid A is not correct. However, the discrepancy has not yet been finally clarified. Recently, the synthesis of a structural analogue (E5531, **D** in Scheme 3) of the lipid A from *R. capsulatus* was described along with a broad characterization of its toxic and antagonistic properties.[17] Since the chemically synthesized *R. capsulatus* lipid A (**C**) appeared to be unstable during storage (hydrolytic cleavage of the acyl groups at C-3 and C-3′ of the glucosamine disaccharide) and, thus, did not fulfill an important prerequisite of a drug, it was necessary to synthesize a stable derivative thereof. This was possible by introducing ether substituents at positions C-3 and C-3′. Just as fascinating as the chemical synthesis are the results of the biological in vitro and in vivo experiments using E5531 (**D**). First of all, the LPS-induced monokine production in human monocytes and whole blood was inhibited by E5531. Notably, and in contrast to precursor Ia (**A**), E5531 (**D**) did not show any agonistic activity in either human or murine cells. Therefore, murine in vivo models could be established. It was shown that the LPS-induced increase in the TNF-α concentration in plasma and the 100% mortality rate of the animals could be negated by coinjection of E5531 (**D**). Even more important is the establishment of a murine infection model, in which the animals can be protected from experimental *E. coli* peritonitis by combined injection of E5531 and a β-lactam antibiotic. This was not possible by injection of either E5531 or the antibiotic alone, and in the latter case it was found that the antibiotic killed the bacteria but also liberated higher amounts of LPS. This infection model seems to represent important processes of human sepsis and may thus be an essential instrument in future in vivo investigations. Owing to its favorable biological properties, E5531 (**D**) has already been tested in a clinical phase I study; it did not show agonistic activity and decreased dose-dependant endotoxic LPS-effects, for example the amount of released cytokines.

The results obtained to date indicate that nontoxic structural analogues of lipid A such as precursor Ia and E5531 are potent endotoxin antagonists in vitro and, partially, also in vivo. Most

promising is E5531, a compound that may lead to an important progress in the treatment of Gram-negative sepsis.

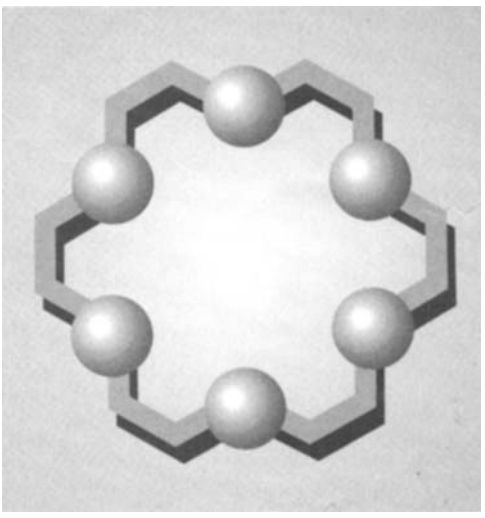
Third, Revised and Enlarged Edition

E. V. Dehmlow / S. S. Dehmlow

Phase Transfer Catalysis



1993. XIII, 499 pages with 49 tables.
Hardcover. DM 198,00.
ISBN 3-527-28408-7

Phase Transfer Catalysis has matured and so has this book. Certain PTC-variants have become standard techniques in the lab, and PTC may be on the brink of large-scale use.
This new edition describes important new developments in PTC.
Furthermore, it has been extensively updated and offers a comprehensive list of very recent references.

New material has been added on

- solid/liquid PTC
- enantioselective reactions
- metal-organic reactions
- reduction and oxidation reactions
- elimination and substitution reactions.

The Metallic Bond—Dead or Alive? A Comment and a Reply

Comment by Leland C. Allen* and Jeremy K. Burdett*

In a recent 'Highlight' J. C. Schön discussed[1] a point of view put forward by ourselves[2, 3] that the term 'Metallic Bond' should be dropped from the chemical vernacular. Although Dr. Schön gives a useful summary of the thrust of our work, his conclusions are the opposite to ours—the metallic bond is alive and well, he believes, as a distinct entity on a par with the ionic, van der Waals, and covalent bonds which chemists use to categorize compounds. There are some other points that support our view, which are worth stating here. We will show once again that 'metallic bonds' are a subset of that large group of bonds we loosely call 'covalent'.

1) To estimate the strength of ionic interactions, one would use an interatomic potential of the form $-e^2/r + A/r^6$, where the electrostatic interaction is balanced by a repulsive term. This approach has been used for years to estimate the cohesive energies of ionic materials. To estimate the strength of van der Waals interactions we would use a potential of the form of $-B/r^6 + C/r^{12}$, the age-old Lennard–Jones 6–12 potential. To estimate the strength of covalent bonding we would try to evaluate the integral $\int \phi_1 H^{\text{eff}} \phi_2 d\tau$, or use empirical expressions to access these overlap terms. But what do we use to estimate the strength of 'metallic bonding'? What is the special electronic characteristic that distinguishes it from the other three types? In fact, we use the same considerations as for covalent bonding. Tight-binding theory used in the solid state, for metals as well as insulators, is just like the Hückel theory of the organic chemist.[4] The use of the terms 'ionic', 'covalent', and van der Waals, are of course frequently imprecise, but in a perfectly accurate electronic structure calculation, all of these considerations are included. Importantly no special theory is included for the 'metallic' bond.

2) Energy differences between the bcc, fcc, and hcp crystal structures of the transition elements[5, 6] as a function of electron count may readily be calculated, and thus the most stable structure identified. Excellent agreement with the observed structures is found. These particular calculations[5, 6] used tight-binding theory—as we pointed out in (1), the solid state analog of molecular orbital theory. No special 'metallic bonding' was used to get these results—just orbital overlap considerations. Thus the crystal structures, and indeed their cohesive energies, are determined by d-band covalency. The Hume–Rothery electron compounds, often very complex crystal structures that are found for metallic alloys with between 11 and 12 valence electrons per atom are also completely accessible[7] using this solid-state equivalent of Hückel theory. Again no special 'metallic bonding' needs to be implied.

3) Pauling[8] regarded metals as really no different from large molecules where there are not enough electrons to form electron pair bonds between all close atomic contacts. He used the concept of resonance to get over this problem, just as he used resonance to view the electronic structure of the π manifold of benzene. His Resonating Valence Bond model certainly has an appeal, and has recently found new uses in the physics community. Thus, as pointed out in our paper,[2] and hardly a new observation, there are strong similarities between the electronic descriptions of metallic solids and molecules with delocalized electrons such as benzene.

4) Important in this regard too are aspects of the van Arkel–Ketelaar diagram.[3] The electronic underpinnings of the scheme come from 'covalent' arguments. Particularly interesting, is the reduction of a three variable scheme (the original triangle itself, with 'ionic', 'covalent' and 'metallic' bonding variables) to a two variable scheme,[3] essentially 'ionic' and 'covalent' indices.

In view of these comments, which surely put the electronic structures of metals within the same electronic framework as the 'covalent' bond, our argument stands, that the 'metallic bond' as a separate term with equal weight to the other three traditional schemes should be abandoned. Certainly it does not have a mathematical framework distinct from the other three categories as shown in (1) above. However, if one wishes to use the term to describe that subset of 'covalent' systems, which are metals then one should be aware of the discussion above.

Reply by J. Christian Schön*

It appears to me that L. C. Allen and J. K. Burdett are not really far away from the point of view I have presented in the Highlight.[1] It seems that we would agree that the proper way to deal with solids from the theoretical point of view is the use of quantum mechanics, preferably on the level of ab initio calculations. Clearly, on this level one would not make a distinction between different types of bonding; only after having done the calculation, one could try to classify the electronic structure according to some criteria, by which one would *define* what should constitute a covalent, metallic, or ionic bond.

If one leaves the level of ab initio calculations, one becomes concerned with the calculation of band structures for some effective potential seen by the electrons. As I have pointed out in the Highlight, there are a number of techniques to perform such a calculation. The most popular ones derive from expansions of the wave function in Bloch functions of either the plane-wave or the atomic/molecular orbital type (nearly-free-electron theory or tight-binding approach). Both sets are complete systems of eigenfunctions (at least, if one includes ionized states with the atomic arbitals), and a proper diagonalization of the Hamiltonian matrix within either set should lead to the same spectrum of energies, that is, to the same band structure. Note that, in principle, all pairs of eigenfunctions must be used in evaluating the matrix elements of the Hamiltonian (unless they vanish by some symmetry considerations); it is, in general, not sufficient to restrict oneself, for example, to atomic/molecular orbitals belonging to neighboring sites.

The authors now point out in (1) and (2) that in many systems good results are found with the tight-binding theory. I agree; the only surprise is the great success of the band approximation. From this they conclude that tight-binding theory should be the language of choice for discussing the electronic structure of solids. So far, this is a matter of personal choice, and I do not object. However, I disagree if tight-binding theory is now to be set equivalent with the theory of covalent bonding—a much more local concept than the full tight-binding theory necessary to correctly describe the solid within the band approximation—and all the historic associations and visualizations of, for example, directed bonds that go along with this term.

Results as good as those obtained with the tight-binding method can be achieved with sufficiently large plane-wave expansions. I think Allen and Burdett would agree that one should not use the latter fact to claim that, since all substances can basically be viewed as more or less perturbed free-electron systems, they should be considered as "metals". Such a claim would lead us to describe covalent or ionic insulators as "metals" with an energy gap. To conclude, once we treat the solid on a high enough quantum mechanical level, the distinction among the different chemical concepts of bonding is no longer very meaningful. As an example, consider the Group 4 elements C (diamond) through Pb. Their electronic structure can be calculated with either plane-waves or atomic orbitals, and exhibit the closing of the energy gap in the band structure for Pb. But if one tried a classification with regard to the bonding situation, one would clearly ascribe "directed" covalent bonds to carbon in the diamond structure and "undirected" metallic bonds to lead in the fcc-structure.

Finally, judging by the feel of the arguments presented in (1), it appears that the authors would always like to associate with the term "bond" some two-body interaction, either in the form of an effective potential or an overlap integral. But already for the π-manifold mentioned in (3) or the "three-center, one-electron-pair bonds" such a view is rather problematic. One might perhaps argue that the "bonds" in the benzene molecule are still between (nearest) neighbors, and that the π-electrons just "strengthen" these bonds. But if that were allowed, then one could also treat the metallic bond as, for example, a van der Waals bond cleverly strengthened by the energetic advantage gained by letting the valence electrons become delocalized over the whole crystal. Of course, it is difficult to write down a simple heuristic variant of, for example, the Lennard-Jones potential suitable for a two-body description of the cohesive energy of a metal, but the same problem applies to the covalent picture, where because of the directionality of the bonds at least three-body terms are necessary for a proper effective potential.

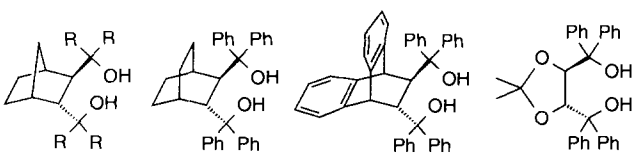
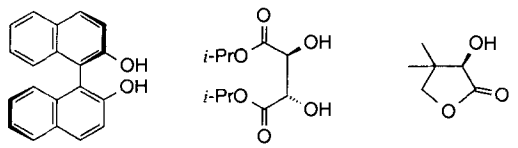
Chiral Titanium Alkoxides as Catalysts for the Enantioselective Reduction of Ketones with Boranes

Guido Giffels, Claus Dreisbach, Udo Kragl, Michael Weigerding, Herbert Waldmann, and Christian Wandrey*

Asymmetric catalysis has gained much significance during the last 15 years.[1] In this area, chiral titanium alkoxides have proven to be very versatile tools and have been employed successfully in enantioselective epoxidations of allyl alcohols,[2] asymmetric Diels–Alder and ene reactions, syntheses of cyanohydrins, aldol reactions,[3] and addition reactions of diethylzinc to aldehydes.[4] We recently introduced the use of the bicyclic diols **1** and **3** as ligands in the latter reaction type.[5] Currently we are interested in to what extent the enantioselective titanate-catalyzed hydride transfer can be applied to keto-carbonyl substrates.

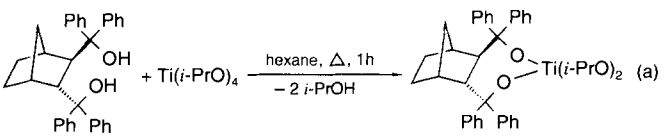


1: R = Ph **2**: R = 2-Naphthyl **3** **4** **5**



6 **7** **8**

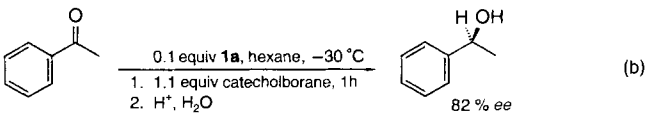
Catalytic reductions with boron-containing Lewis acids have been thoroughly investigated,[6, 7] titanium(IV) alkoxide-catalyzed reductions, on the other hand, are unknown.[8] We have now been able to show that reductions of this kind are feasible and result in good enantiomeric excesses when boranes are used as the reducing agents. Several chiral diols, including **1**–**7** and (D)-pantolactone (**8**), were employed as the Ti ligands. The best results were accomplished with the TADDOL-analogous ligands **1**–**4**, in particular with **1** and **3**, as well as with TADDOL **5**.[9] The corresponding titanium alkoxides **1a**–**8a** were prepared in situ from 1.15 equivalents of the ligand and 1.0 equivalents of titanium tetraisopropoxide in *n*-hexane by azeotropic removal of isopropyl alcohol [Eq. (a)]. The reducing agents used



1 **1a** (a)

include the adducts borane-tetrahydrofuran (1 M in THF), borane-dimethylsulfide, and 1,3,2-benzodioxaborole (catecholborane).

Initially, we investigated the reduction of acetophenone to 1-phenylethanol [Eq. (b)]. The results are summarized in Table 1. The best results were obtained with **1** or **3** as the ligand,



82 % *ee* (b)

[a] BH_3-THF (1 M). [b] Reducing agent BH_3-SMe_2. [c] 2.5 mol%. [d] Control experiment without titanium tetraisopropoxide.

catecholborane as the reducing agent, and *n*-hexane as the solvent. The enantioselectivities obtained in these transformations did not decrease even with catalyst concentrations as low as 2.5 mol%.

An excess of titanium tetraisopropoxide with respect to the ligand decreases the observed enantiomeric excess. This can be explained by the fact that the achiral alkoxide catalyzes the reduction in the same way as the chelate complex. We assume that the borate ester of phenylethanol is formed as the reduction

product. Therefore, it is not necessary to use an excess of titanium tetraisopropoxide to regenerate the chiral alkoxide in the catalytic cycle as in the addition of diethylzinc to aldehydes.[10] Without a catalyst, hardly any reduction takes place; however, when using 0.1 equivalents of **1a** (with respect to the ketone) and 1.1 equivalents of catecholborane, numerous ketones can be reduced quantitatively with moderate to good enantioselectivities within 1 h as shown in Table 2.

Table 2. Results of the reduction of various ketones with 0.1 equiv of **1a** as the catalyst and 1.1 equiv of catecholborane after a reaction time of 1 h.

A reduction of the titanate in the presence of catecholborane does not occur. Furthermore, there is no evidence that low-valent titanium species are involved in the transformation. Upon the addition of BH_3-THF to a solution of **1a** in *n*-hexane, the colorless reaction solution turns pale violet after a reaction time of more than half an hour, which indicates the presence of titanium(III). However, in the presence of a ketone, this color change does not take place. On the other hand, adding an excess of BH_3-SMe_2 results in the formation of a titanium precipitate.

To rule out the possibility that the asymmetric induction is based on an interaction between the borane and any excess ligand, we performed control experiments in which we used the ligand in the absence of titanium tetraisopropoxide. In these experiments, the reduction was significantly slower and produced only racemic product (see Table 1).

At present, we can only speculate about the mechanism of the reaction. The steric model introduced by Seebach et al.[11] for the titanate-catalyzed addition of diethylzinc to benzaldehyde cannot be applied to the system titanium-acetophenone-catecholborane, since it does not adequately explain the observed product configurations. When employing catecholborane and BH_3-THF, an attack of the nucleophile to the *re*-face of the carbonyl group can be observed, as is the case for example in the reduction of ketones with AlH_x-TADDOLates[10] or in the addition of primary Grignard reagents to ketones in the presence of Mg-TADDOLate.[12] Surprisingly, the enantioselectivity is reversed when using BH_3-SMe_2 (see Table 1). Similar to Grignard additions, the reaction exhibits a strong solvent dependence.[12]

The reaction introduced herein constitutes the first example of the asymmetric reduction of ketones with readily available achiral boranes in which chiral titanates are used as catalysts. The variety of available ligands offers the possibility for further optimization of the enantiomeric excesses obtained in these reactions.

Experimental Procedure

Preparation of the titanium alkoxides: **1** (320 mg, 0.69 mmol) or a corresponding amount of one of the other chiral ligands **2**–**8** in *n*-hexane (250 mL) in an inert gas atmosphere was treated with titanium tetraisopropoxide (175 μL, 0.6 mmol), and the reaction mixture was heated to reflux for 1–2 h. Thereafter, about 25 mL of the solvent was removed by distillation. To this catalyst solution were added consecutively at −30 °C acetophenone (700 μL, 6 mmol) and catecholborane (700 μL, 6.6 mmol). After 1 h (conversion >95% according to GC), 1 M HCl (50 mL) was added and the mixture was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were washed with 1 M NaOH (3 × 50 mL), dried over sodium sulfate, and the solvent was removed by distillation. Chromatography on silica gel (eluent: dichloromethane) afforded (*S*)-1-phenylethanol (560 mg, 78%) in a purity of >99% and with 82% *ee* according to GC on a permethylated β-cyclodextrin phase. $[\alpha]_D^{25} = -38.5$ (*c* = 1 in toluene).

Diastereoselective Cathodic Cyclization of 1-(4- and 1-(3-Oxoalkyl)pyridinium Salts to Quinolizidine and Indolizidine Derivatives**

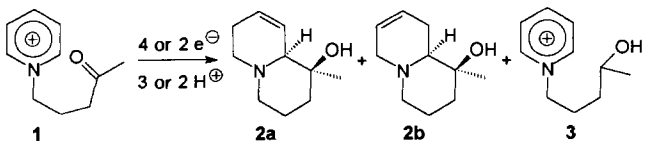
Rüdiger Gorny, Hans J. Schäfer,* and Roland Fröhlich

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 70th birthday

The umpolung of reactivity by electron transfer has developed into a powerful synthetic principle for cyclizations. In this process, in acyclic molecules with two functional groups of the same reactivity, one of these groups has its reactivity reversed by oxidation or reduction, thereby initiating intramolecular C–C bond formation. The electrode has proven to be a useful reagent for this, as documented by numerous cyclizations at both the anode[1] and the cathode.[2]

Acetone and pyridine can be coupled cathodically in acidic electrolytes to form tetrahydropyridyl alkyl alcohols.[3–5] We report here on an intramolecular version of this C–C bond formation, which opens up a facile route to heterobicyclic systems. We chose oxoalkylpyridinium halides as starting materials, which are readily available by nucleophilic substitution of halogen ketones with pyridine and in which the arene is additionally activated for the reduction by the quaternization of nitrogen.

Compound **1** was obtained in 68% yield from pyridine and 5-chloropentan-2-one.[6] The potential-controlled electrolysis of **1** in a divided cell at −1.37 V (relative to the saturated calomel electrode) in 10% aqueous H_2SO_4 gave, after current consumption of 18 F mol^{-1}, 12% **2a,b** in a 1.3:1.0 ratio and 28% **3**;[7] at the same time a strong evolution of hydrogen was observed. An electrolysis with a current consumption of 4 F mol^{-1} gave 9% yield of **2a,b** (**a**:**b** = 1.3:1.0).



The yield of **2** can be increased by reducing the competing reduction of protons. A decrease of the H^+ concentration to 5% did not improve the yield; at pH 7 **2** was not formed at all. However, if the electrolysis was carried out at a constant current the yield of **2** was improved to 30% by reducing the current density ($\bar{i}$ = 4.2 mA cm^{-2}). A further increase in yield of **2** to 58% was possible by doubling the amount of charge. Under these conditions the best yield was obtained with a 0.2 M solution of **1**; higher (0.4 M **1**: 44% **2**) or lower concentrations of **1** (0.1 M **1**: 50% **2**) led to decreases in the yield. The most favorable sulfuric acid concentration is 10%; in 5% H_2SO_4 the yield drops slightly, in 20% H_2SO_4 more strongly. The temperature only slightly influenced the yield in the range of 3 to 40 °C. In every case the ratio of **2a**:**2b** remained 1.3:1.0. A more or less pronounced passivation takes place when the mercury cathode is replaced with a graphite, glassy carbon, or lead cathode. On the lead cathode, if the electrolysis is repeatedly interrupted and the cathode surface is polished a 38% yield of **2** was obtained. The more pronounced passivation on graphite or glassy carbon cannot be alleviated in this way: **1** was not transformed on these cathodes.

The structure of **2a,b** was determined by NMR spectroscopy and in the case of **2a** confirmed by X-ray analysis (Fig. 1a). The ^{1}H NMR signals of the olefinic protons at δ = 5.7 and 5.8 are only consistent with **2a** and **2b** among the conceivable double-bond isomers. The quinolizidines **2a** and **2b** were converted by catalytic hydrogenation (H_2/Pd/C) to the known (1*S**, 9a*S**)-1-methylquinolizidin-1-ol (**4**)[9] in 92% yield (not shown).

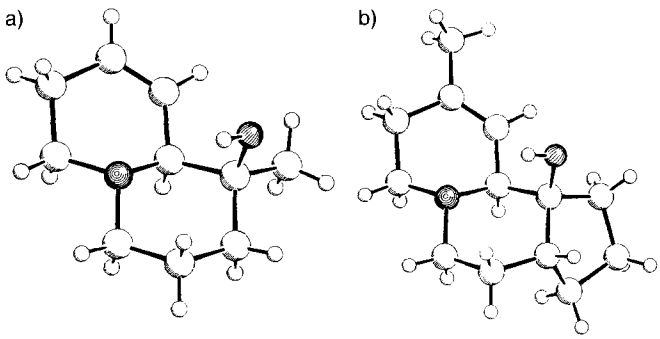


Fig. 1. a) Structure of **2a** and b) of **29a** in the crystal [8].

[+] X-ray structure analyses.

[**] Electroorganic Syntheses, Part 61. This work was supported by the Fonds der Chemischen Industrie with a doctoral grant to R. G. and from the Graduiertenkolleg "Hochreaktive Mehrfachbindungssysteme". Part 60, B. Klotz-Berendes, H. J. Schäfer, M. Grehl, R. Fröhlich, *Angew. Chem.* **1995**, *107*, 218–220; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 189–191.

Measurements with differential pulse polarography at pH values from 1–4 and extrapolation of the values to 10% sulfuric acid indicate that the pyridinium group and the carbonyl group are reduced at −1.43 V and −1.37 V, respectively. The relative positions of these potentials, the structures of the products, and postulated course[10] of the cathodic coupling of acetone with pyridine support the mechanism outlined in Scheme 1.

The protonated carbonyl group is reduced to the radical, which adds to the pyridinium ring. According to AM1-calculations the nitrogen in the radical cation **5** has a negative partial charge, thus the cyclization from conformation **5a** is favored possibly through a hydrogen bond, whereas cyclization from conformation **5b** is sterically hindered because of the interaction between the methyl group and the pyridinium ring. Compound **6** is formed from **5a** and has the (1*S**, 9a*S**) configuration; **6** is then protonated to form the immonium ions **7a** and **7b**, whose 2e reduction leads to **2b** and **2a**, respectively.

In order to demonstrate the utility of this reductive cyclization, substituents were placed on the pyridinium ring and the size of the annulated ring was varied. Thus, the pyridinium salts **8**–**12** were prepared from the corresponding pyridines and 5-chloropentan-2-one in 33–63% yield and subsequently cyclized under the optimal conditions for **2** to give the quinolizidines **13**–**17** (Table 1).

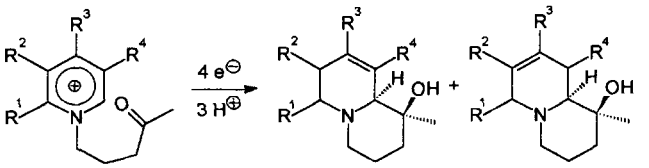

Table 1. Reductive cyclization of the 1-(4-oxopentyl)pyridinium chloride **1** and **8**–**12** to the quinolizidines **2** and **13**–**17**, respectively [a].

Entry	Pyridinium salt	R^1	R^2	R^3	R^4	Product	Yield [%]
1	**1**	H	H	H	H	**2**	58
2	**8**	CH_3	H	H	H	**13**	40
3	**9**	H	CH_3	H	H	**14**	45
4	**10**	H	H	CH_3	H	**15**	59
5	**11**	H	H	*t*Bu	H	**16**	62
6	**12**	CH_3	H	H	*n*Bu	**17**	41

[a] Conditions: Charge used: 8 F mol^{-1}, current density: 4.2 mA cm^{-2}, 10% sulfuric acid, 0.2 M pyridinium salt solution, 20 °C.

The structures of **13**–**17** were determined by ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry and in the case of **16a** confirmed by X-ray structure analysis.[8] Owing to the alkyl substituents, several diastereomers were formed in the reduction of **8**, **9**, and **12**. Six diastereomers were obtained from **9** in the ratio 2.4:1.5:1.2:1.0:3.6:3.6 (according to gas chromatography); however, these could not be separated by liquid chromatography. The unsubstituted carbon C-6 of the pyridinium ring in **8** couples preferentially; products of the coupling at the substituted C-2 were only identified in trace amounts. Double-bond isomers and C-2 epimers from the coupling at C-6 were obtained from **12**. The yields for the cyclizations of the 4-substituted pyridinium chlorides **10** and **11** are comparable with those for the unsubstituted **1**. The yields of the cyclizations of **8**, **9**, and **12** are slightly lower, possibly because of steric interaction with the substituents on the pyridinium ring.

The reductive cyclization of **18** and **19** should lead to the indolizidine skeleton. Compounds **18** and **19** were prepared in 80 and 88% yield, respectively, by the alkylation of pyridine and 4-*tert*-butylpyridine, respectively, with 2-(2-bromoethyl)-2-methyl-1,3-dioxolane. Their cathodic reduction under the optimized conditions for **2** gave in each case only one double-bond isomer of the indolizidines **20** and **21**, respectively (Table 2).

The structures of **20** and **21** were determined by comparison of their spectroscopic data with those of **2a** and **16a** and in the case of **20** additionally confirmed by an X-ray structure analysis.[8]

While the yield of the cyclization to the five-membered ring is hardly reduced in comparison to that of **2**, as expected this is not the case for the annulation of the seven-membered ring. Compounds **24a,b** (14%) and **25a,b** (16%) were obtained together with the acyclic alcohols **26** (16%) and **27** (16%) from **22** and **23** (prepared from the reaction of 6-bromohexan-2-one with pyridine and 4-*tert*-butylpyridine, respectively, in 83% and 87% yield), respectively, using the optimized conditions for **2** (Table 2).

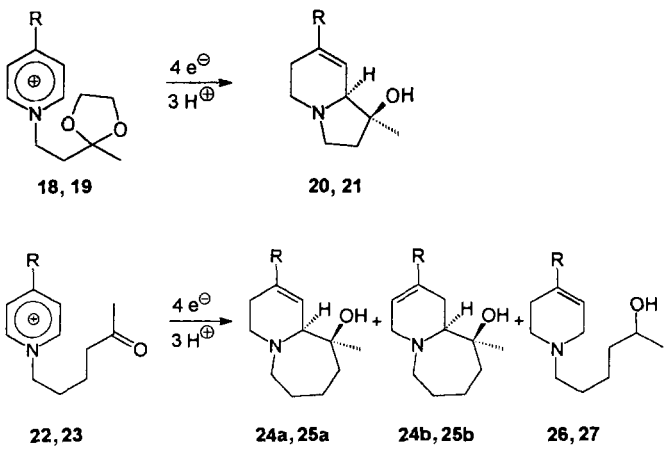

Table 2. Reductive cyclization of the 1-[2-(2-methyl-1,3-dioxolan-2-yl)ethyl]pyridinium bromides **18** and **19** to the indolizidines **20** and **21**, respectively, and 1-(5-oxohexyl)pyridinium bromides **22** and **23** to the pyridoazepines **24** and **25**, respectively, as well as the alcohols **26** and **27**, respectively. For conditions see Table 1.

Entry	Pyridinium salt	R	Products	yield [%]		yield [%]
1	**18**	H	**20**	55		
2	**19**	*t*Bu	**21**	58		
3	**22**	H	**24a, b**	14	**26**	16
4	**23**	*t*Bu	**25a, b**	16	**27**	16

A tricyclic quinolizidine is also readily available in only three steps from **28**. The pyridinium bromide **28** was prepared by alkylation of γ-picoline with 2-(2-bromoethyl)cyclopentanone in 83% yield. The cathodic cyclization of this compound gave **29a,b** in 46% yield in the ratio >20:1. The structure of **29a** was determined spectroscopically and confirmed by an X-ray structure analysis (Fig. 1b).[8]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3418-2008 $ 10.00+.25/0

In this case a double-bond isomer was formed regioselectively, and at the same time three stereogenic centers were formed diastereoselectively. The preferential formation of the (3a*R**,9a*S**,9b*S**) diastereoisomer in this case can be explained by the smaller steric interaction between the 2-H of the pyridinium ring and the *exo*-orientated angular H atom of the side chain.

Quinolizidine and indolizidine derivatives are diastereoselectively accessible in only two or three steps in a simple reaction in which the key step is the new cathodic cyclization described here.

Experimental Procedure

28: 4-Methylpyridine (2.79 g, 30 mmol) and 2-(2-bromoethyl)cyclopentanone [11] (3.82 g, 20 mmol) were heated to 120 °C for 20 min. After cooling to room temperature the reaction mixture was treated with ether (80 mL), stirred for 10 min and then the ether was decanted off. This procedure was repeated twice with ether (with 50 mL). The residue was then dissolved in methanol (5 mL) with gentle warming, treated with ether (80 mL) and stirred for 5 min before the supernatant was decanted off. After the final wash with ether (50 mL) and subsequent decanting, the residue was filtered through a short column filled with silica using methanol as eluant. After removal of the methanol under vacuum, 4.82 g (17 mmol, 83%) **28** remained. ^{1}H NMR (CD_3OD): δ = 1.61–2.00 (m, 2H, NCH_2CH_2), 2.03–2.45 (m, 7H, cyclopentanone-H), 2.73 (s, 3H, CH_3), 4.65–4.86 ((partially covered by CH_3OH) NCH_2), 7.99 (d, ^3J = 6.5 Hz, 2H, NCHC*H*), 8.91 (d, ^3J = 6.5 Hz, 2H, NCH). ^{13}C NMR (CD_3OD): δ = 21.9 (t, NCH_2CH_2), 22.3 (q, CH_3), 30.9 (t, $OCCH_2CH_2$), 32.8 (t, $OCCHCH_2$), 38.8 (t, $OCCH_2$), 47.3 (d, OCCH), 60.7 (t, NCH_2), 130.3 (d, NCHCH), 145.3 (d, NCH), 161.7 (s, CCH_3), 222.0 (s, CO).

29: **28** (2.84 g, 10.0 mmol) was dissolved in 10% sulfuric acid (50 mL) and electrolyzed in a divided beaker type cell with a mercury pool cathode (19 cm^2) and a platinum anode (1 cm^2), a current density of 4.2 mA cm^{-2} (related to the cathode), at a temperature of 20 °C, until the consumption of 8.2 F mol^{-1}. The catholyte was made basic by addition of solid sodium carbonate and shaken with dichloromethane. After drying the organic phase with magnesium sulfate, it was concentrated and the solution filtered through silica with diethyl ether as eluant to give 0.95 g (4.6 mmol, 46%) **29a,b**. ^{1}H NMR ($CDCl_3$): δ = 1.44–2.03 (m, 10H), 1.68 (s, CH_3), 2.23–2.36 (m, 3H, 7-H_{ax}, 8-H_{ax}, 5-H_{ax}), 2.51–2.58 (m, 2H, 5-H_{eq} and 10a-H), 2.61 (s, 1H, OH), 2.71–2.81 (m, 1H, 7-H_{eq}), 5.35 (s, 1H, 10-H). ^{13}C NMR ($CDCl_3$): δ = 19.4 (t, C-2), 23.3 (q, CH_3), 23.5 (t, C-4), 26.1 (t, C-3), 30.4 (t, C-1), 33.5 (t, C-8), 43.8 (d, C-3a), 51.3 (t, C-5), 52.5 (t, C-7), 63.2 (d, C-10a), 78.5 (s, C-10b), 118.5 (d, C-10), 135.8 (s, C-9).

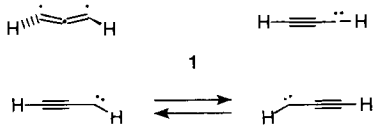
Automerizations and Isomerizations in Propynylidene (HCCCH), Propadienylidene (H_2CCC), and Cyclopropenylidene (c-C_3H_2)**

Randal A. Seburg and Robert J. McMahon*

The structure and rearrangements of triplet propynylidene (**1**, propargylene) and its derivatives remain topics of current interest.[1–8] Despite considerable experimental and theoretical effort spanning 35 years, a detailed understanding of the structure of **1** emerged only recently. Experimental[1] and theoretical[2] investigations implicate a C_2-symmetric, 1,3-diradical-like structure for **1**, rather than the linear structure concluded from early experiments[3] or the bent C_s structure predicted by other theoretical studies[4, 5] (Scheme 1). Our ^{13}C-labeling studies not



Scheme 1. Currently accepted and previously proposed structures for triplet propynylidene (**1**).

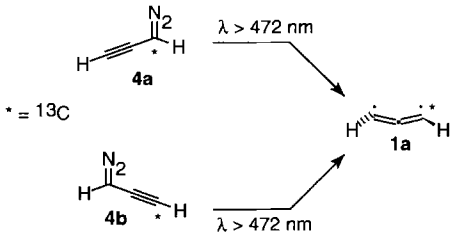
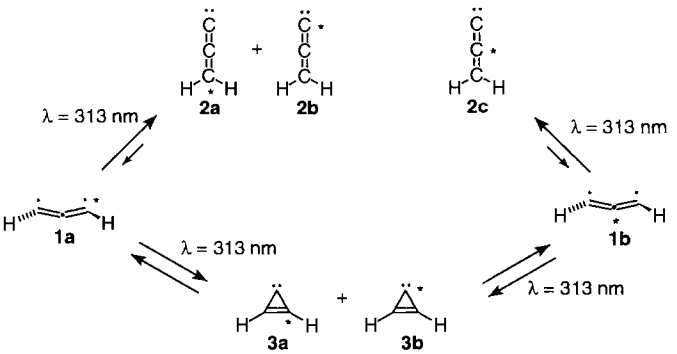
only establish the structure of propynylidene (**1**),[1] but also provide a probe of the photochemical rearrangements on the C_3H_2 energy surface.[4a] The presence of the ^{13}C label breaks the symmetry of the system, thereby revealing a manifold of rearrangement pathways that was not evident in previous investigations. We describe here the rearrangements leading to scrambling of the ^{13}C label in isomeric C_3H_2 carbenes. The automerization of propadienylidene (**2**) can be rationalized by a mechanism involving cyclopropyne as an intermediate or transition state. Although Maier et al. recently reported evidence for a silacyclopropyne intermediate on the C_2SiH_2 energy surface,[6] our studies provide no direct spectroscopic evidence for the corresponding cyclopropyne intermediate on the C_3H_2 energy surface.

Photolysis ($\lambda > 472$ nm) of either [1-^{13}C]diazopropyne (**4a**) or [3-^{13}C]diazopropyne (**4b**), isolated in an argon matrix at 8 K, yields exclusively [1-^{13}C]propynylidene (**1a**).[1] Subsequent irradiation of **1a** at $\lambda > 237$ nm for 15.4 h results in the decrease of **1a** and the appearance of IR signals due to [2-^{13}C]propynylidene (**1b**), three ^{13}C-isotopomers of propadienylidene (**2a–c**), and two ^{13}C-isotopomers of cyclopropenylidene (**3a, b**) (Scheme 2). The photoproducts show complete scrambling of the ^{13}C label.[9] Table 1 contains both experimental and computed vibrational frequencies and intensities of the seven ^{13}C-labeled species. Assignment of the bands was made by comparison with the experimental IR spectra of unlabeled **1**, **2**, and **3**,[4a]





Scheme 2. Proposed mechanism for automerization of **1a** upon irradiation with $\lambda = 313$ nm.

by comparison with the calculated IR spectra of the ^{13}C-isotopomers of **1**, **2**, and **3**,[10] and by comparison with the known photochemical behavior of the unlabeled C_3H_2 isomers.[4a] Ab initio calculations at the QCISD/6-31G* level of theory yield an IR spectrum that agrees best with the spectrum of unlabeled **1** obtained experimentally;[2a] we therefore used this method to compute the IR spectra of **1a** and **1b**. The RHF/6-31G* level of theory, which reliably reproduces the IR spectra of the unlabeled singlets **2** and **3**, was used to calculate the IR spectra of **2a–c** and **3a, b**. When a matrix containing only **1a** is warmed to 37 K neither thermal automerization to **1b** nor rearrangement to any of the ^{13}C-propadienylidenes or ^{13}C-cyclopropenylidenes is observed.

Irradiation ($\lambda = 313$ nm) of a matrix containing only propynylidene **1a** leads to scrambling of the ^{13}C label in the various photoproducts. The scrambling process was monitored by IR spectroscopy. Automerization of **1a** to **1b** is evident after only 0.4 h; the absorption of **1b** grows quickly to a maximum at 3.0 h, after which its intensity decreases (Fig. 1). Propynylidenes **1a** and **1b** reach a 2:1 ratio (statistical distribution) after about 10 h. Cyclopropenylidenes **3a** and **3b** appear immediately in a 2:1 ratio (statistical distribution) and maintain the same relative

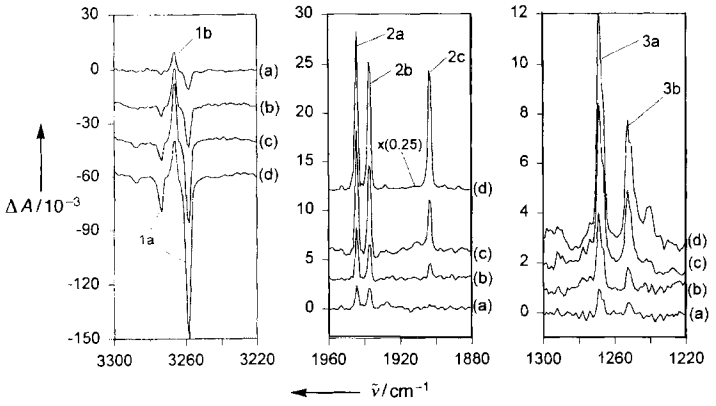

Fig. 1. IR difference spectra obtained upon photolysis (λ = 313 nm) of **1a** in an argon matrix at 8 K, showing generation of **1b**, **2a–c**, and **3a**, **b**. Irradiation time: a) 0.4, b) 1.2, c) 3.0, and d) 24.5 h. The spectra (b) through (d) are offset to facilitate viewing.

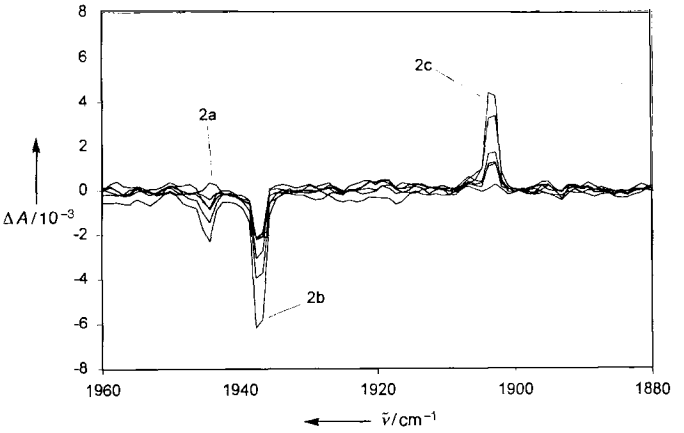

Fig. 2. IR difference spectra obtained upon irradiation (λ > 444 nm) of an argon matrix containing **1a**, **b**, **2a–c**, and **3a**, **b** (see text), illustrating automerization of **2b** and **2c**. Irradiation time: 20, 40, 50, 80, 180, and 240 min.

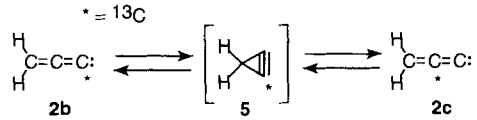
intensity ratio as their intensities grow during the photolysis. Their growth slows as the photolysis continues. Propadienylidenes **2a** and **2b** are also produced immediately in a 1:1 ratio and grow at the same rate. Appearance of center-labeled **2c** lags well behind **2a** and **2b**. Even after 24.5 h of irradiation, the intensity of the **2c** band at 1903 cm^{-1} has reached only about 70% of its photoequilibrium magnitude (see Table 1). Thus, photolysis of triplet propynylidene **1a** affords statistical label distribution in **3** at the earliest detection times and statistical label distribution in **1** within 10 h, yet incomplete label distribution in **2** after 76 h.

The time evolution of the photolysis (λ = 313 nm) provides information regarding the mechanism of the label scrambling, for which we suggest the mechanism shown in Scheme 2. Photolysis of triplet propynylidene **1a** affords cyclopropenylidenes **3a** and **3b** in a ratio of roughly 2:1. A hydrogen shift must accompany the formation of **3b**, although we do not know whether migration precedes or follows cyclization. Simple ring closure of **1a** followed by rapid 1,2-hydrogen shifts in the nascent **3a** accounts for statistical distribution of the ^{13}C label in **3**.[11] Once **3b** is formed, a sequence of two reversible photoequilibria serve to scramble the label rapidly into propynylidene **1b** and then slowly from **1b** into propadienylidene **2c**.[4a, b] Conversion of **1** to **2** must occur by a photochemical 1,3-hydrogen shift, since only **2a** and **2b** are formed initially from photolysis of **1a**. The third isotopomer **2c** appears only after a significant amount of **1b** is present, consistent with the proposed mechanistic scheme. Conversion of **1** to **2** is slow relative to interconversion of **1** and **3**, for **1b** appears quickly relative to **2c**, and **1a** and **1b** reach their equilibrium intensity ratio after roughly 10 h whereas the proportion of **2c** is still increasing relative to **2a** and **2b** after 76 h. In order to account for the continued growth of **2c** at long irradiation times, we postulate that **2** must return to **1** during irradiation at λ = 313 nm. This process must be very slow, since statistical distribution of the label in **2** is not reached even after 76 h.

Using different irradiation conditions, we obtain evidence for a distinct label-scrambling mechanism in ^{13}C labeled propadienylidenes **2**. At short irradiation times (8.3 h), photolysis (λ = 313 nm) of a matrix containing only **1a** produces **1**, **2**, and **3** with incomplete scrambling of the ^{13}C label in **2** (vide infra). The concentration of **2c** is only 60% of that of **2b**. Broadband irradiation (λ > 444 nm, up to 4 h) results in rapid conversion of **2b** to **2c** with virtually no change in the concentration of **2a** (Fig. 2). Control experiments impose important constraints on possible mechanisms for this automerization process. First, triplet propynylidenes **1a** and **1b** are stable to these irradiation conditions and are therefore not possible intermediates in the transformation of **2b** to **2c**. Second, the conversion of cyclopropenylidenes **3a**, **b** to propadienylidenes **2a–c** is extremely slow under these irradiation conditions. Reversible photoequilibration of **2** and **3** cannot account for the rapid changes observed for **2b** and **2c**, nor can it account for the substantial difference in disappearance rates between **2a** and **2b**. Thus, we conclude that the automerization of **2b** to **2c** does not proceed via **1** or **3** and suggest that **2b** and **2c** interconvert through a cyclopropyne (**5**) intermediate or transition state (Scheme 3). In



Scheme 3. Proposed mechanism for automerization of **2b** and **2c** upon irradiation with λ > 444 nm.

our experiments, no IR bands were observed that could be attributed to **5**. Theory indicates that singlet cyclopropyne is not a discrete energy minimum but a transition state approximately 40 kcal mol^{-1} higher in energy than propadienylidene (**2**).[5c, 7] The atomic motion in the vibrational mode of cyclopropyne characterized by an imaginary frequency corresponds to ring opening to **2**.[7] A second mechanism that accounts for automerization of **2b** to **2c** involves photochemical cleavage of **2b** to yield methylene and C_2 followed by rapid recombination at either end of the C_2 fragment. This process is analogous to the known fragmentation/recombination reactions that occur upon photolysis of diazomethane or ketene in low-temperature matrices.[12] It seems unlikely to us that fragmentation of **2b** would occur upon irradiation with visible light (photon energy $\leq$64 kcal mol^{-1}).

In summary, our experiments reveal two distinct photochemical processes leading to scrambling of a ^{13}C label in C_3H_2 isomers. UV photolysis (λ = 313 nm) scrambles the label during the photoisomerization of **1** to **3** (Scheme 2). Broadband visible irradiation (λ > 444 nm) scrambles the label in **2** by means of an automerization reaction (Scheme 3). Both mechanisms proceed under the conditions of broadband UV photolysis (λ > 237 nm) to produce rapid, statistical distribution of the ^{13}C label.

Experimental Procedure

[1-^{13}C]- and [3-^{13}C]diazopropyne (**4a** and **4b**, respectively) were prepared by pyrolysis of the corresponding tosylhydrazone salts. Experimental details of the syntheses of the tosylhydrazones are described in ref. [1]. The apparatus and techniques for matrix-isolation spectroscopy have been described elsewhere [13].

[9] ESR spectroscopy provides further evidence for automerization of **1a** to **1b**. A matrix containing **1a** (Ar, 15 K, $|D/hc| = 0.641\ cm^{-1}$, $|E/hc| = 0.00130\ cm^{-1}$, hyperfine coupling constant $A_X = A_Y = 38$ G) [1] was irradiated ($\lambda > 237$ nm, 19 h; then $\lambda > 200$ nm, 7 h) to effect complete scrambling of the ^{13}C label. The signal of a second ^{13}C-propynylidene (**1b**) with the ^{13}C-hyperfine coupling constant $A_X = A_Y = 24$ G appears. Simulation [1] of the hyperfine splitting in the X_2Y_2 region of the ESR spectrum satisfactorily reproduces the experimental spectrum only when a 2:1 mixture of **1a** and **1b** is assumed.

Synthesis of Chiral γ,δ-Unsaturated Amino Acids by Asymmetric Ester Enolate Claisen Rearrangement**

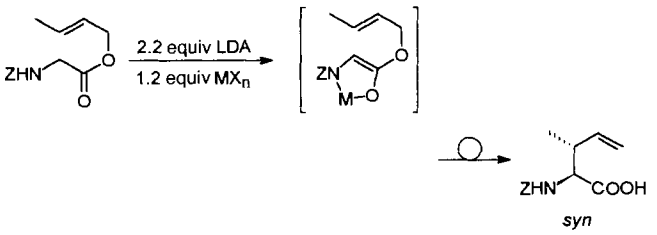
Uli Kazmaier* and Achim Krebs

The synthesis of γ,δ-unsaturated amino acids has received more attention in recent years, since some of these amino acids,[1] which also occur in nature, showed distinct antibiotic activity and could be applied as enzyme inhibitors.[2] From a point of view of the synthesis, these unsaturated amino acids are likewise of great interest, since more complex compounds may be generated readily by functionalization of the double bond.[3] Besides electrophilic and nucleophilic allylations,[4] sigmatropic rearrangements are extremely well suited for the stereoselective introduction of unsaturated side chains.[5]

As early as 1975, Steglich et al. reported the thermal Claisen rearrangement of the allylic esters of *N*-(benzoyl)-α-amino acids under dehydrating conditions via an intermediate 5-allyloxazole.[6] Owing to the highly diastereoselective course of the [3,3] sigmatropic rearrangement, brought about by a highly ordered transition state, this elegant method has found plenty of applications, especially in the synthesis of α-alkylated amino acids.[7] Bartlett et al. published their investigations on the Ireland–Claisen rearrangement[8] of allylic esters of amino acids in 1982.[9] By employing esters of chiral allylic alcohols in this rearrangement, optically active amino acids were generated under transfer of chirality. The rearrangement of chiral allylic amides gave similarly good results.[10]

Although great advances have been made in the field of asymmetric catalysis in recent years, no catalytic asymmetric version of the [3,3] sigmatropic rearrangement has been found to date. Yamamoto et al. reported for the first time a Lewis acid catalyzed asymmetric Claisen rearrangement of allylvinyl ethers by employing chiral aluminum complexes.[11] Shortly thereafter Corey et al. described an interesting asymmetric boron enolate version of the Claisen rearrangement.[12]

We recently published a new version of the ester enolate Claisen rearrangement which occurs via chelate-bridged ester enolates (Scheme 1).[13] As a result of the enolate geometry



Scheme 1. Chelate-bridged ester enolate Claisen rearrangement. Z = benzyloxycarbonyl, LDA = lithium diisopropylamide.

fixed by chelation, the rearrangement proceeds with high diastereoselectivity; the chairlike transition state is clearly preferred. This rearrangement can be applied to acyclic and cyclic allylic esters[14] and even to peptides.[15] Thus unsaturated side

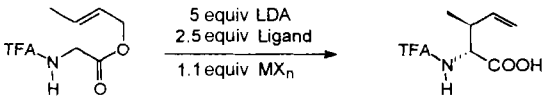
chains can be introduced into peptides at a later stage. In addition to the greater reactivity of the chelate enolates in comparison with the corresponding silylketene acetals, and the fixed enolate geometry, the chelate enolate Claisen rearrangement we investigated has the advantage that it enables the possibility of coordination of chiral ligands to the chelating metal.

We report herein the first asymmetric ester enolate Claisen rearrangement of chelate-bridged enolates in the presence of chiral bidentate ligands. As a standard reaction to investigate the influence of the metal salts and ligands used, we chose the rearrangement of *N*-(trifluoroacetyl) glycine crotyl ester (Scheme 2).[1,6] Some of the results are listed in Table 1.



Scheme 2. Rearrangement of *N*-(trifluoroacetyl) glycine crotyl ester.

Table 1. Rearrangement of *N*-(trifluoroacetyl) glycine crotyl ester in the presence of different ligands and metal salts MX_n (see Scheme 2).

quinine	$MgCl_2$	98	91	69	(2*R*,3*S*)
quinine	$CaCl_2$	73	96	65	(2*R*,3*S*)
quinine	$Al(OiPr)_3$	70	98	86	(2*R*,3*S*)

[a] Ratio determined by GLC (Chira-Si-(L)-Val). [b] Configuration determined after catalytic hydrogenation by correlation with the naturally occurring stereoisomers of isoleucine.

Thus a multitude of metal salts could be employed for the asymmetric version of the chelate enolate Claisen rearrangement; the best results were achieved by using $Al(OiPr)_3$. The selectivity and yield were significantly lower with $ClTi(OiPr)_3$ and $Ti(OiPr)_4$; the lower yield is attributed to partial transesterification reactions. Among the bidentate ligands, amino alcohols have proven to be particularly suitable, whereas diols and diamines gave no significant induction. By far the best results with regard to diastereoselectivity and enantioselectivity were achieved by using the cinchona alkaloids. Rearrangements in the presence of quinine gave the corresponding γ,δ-unsaturated amino acids in very high yields and large enantiomeric excesses. The highest enantioselectivity was found when two to three equivalents of quinine were employed. Therefore the rearrangement of a range of allylic esters under these conditions was investigated (Scheme 3, Table 2). Application of lithium hexamethyldisilazide (LHMDS) as base again led to a considerable increase in the yields.

In all cases, the observed diastereoselectivity (98% *ds*) was clearly higher than in rearrangements without addition of ligand.[1,3] The same is true with regard to the the yields. Quinine

presumably coordinates as a bidentate ligand to the aluminum, thus leading to the liberation of 2-propanol. No induction could be observed after blocking the alcoholic moiety of quinine by acylation or alkylation. In the presence of *O*-methylquinine, the same yield and diastereoselectivity were found as in the case without ligand addition, therefore strongly indicating an absence of coordination.

The enantiomeric excess was found to lie in the range 80–90% *ee* in all cases. The introduction of sterically demanding moieties onto the allylic esters evidently raises the enantiomeric excess (see Table 2). The rearrangement in the presence of quinine gave the unnaturally configured (2*R*) amino acids. The corresponding (2*S*) derivatives were generated analogously, by using quininidine as inducing ligand. The yields and the selectivities were comparable to those achieved with quinine. Simple recrystallization with 1-phenylethyl amine afforded the optically pure amino acids.

The major advantages of this method over the classsical procedure are that the reaction is extremely simple to carry out and that the possibility exists to regenerate the chiral auxiliary. Thus, for example, the quinine employed could be recovered to more than 90% by simple extraction, especially when used on a larger scale.

Experimental Procedure

General procedure for rearrangements: LHMDS solution was prepared by adding *n*-butyllithium (1.6 mL of a 1.55 M solution in hexane, 2.5 mmol) at −20 °C under argon to hexamethyldisilazane (470 mg, 2.9 mmol) in dry THF (1.5 mL) and stirring for 20 min. The glycine ester (0.5 mmol), $Al(OiPr)_3$ (0.55 mmol), and the ligand (1.25 mmol) were dissolved under argon in dry THF, cooled to −78 °C, and the freshly prepared LHMDS solution was added slowly. The reaction mixture was allowed to warm to room temperature over 12 h. After dilution with ether (50 mL), the reaction mixture was hydrolyzed by addition of aqueous $KHSO_4$ solution (25 mL, 1 M). The organic layer was washed again with $KHSO_4$ solution (1 M), before the reaction product was extracted with saturated aqueous $NaHCO_3$ solution (3 × 25 mL). The basic solution was subsequently acidified by careful addition of solid $KHSO_4$ to pH 1 and extracted with ether (3 × 25 mL). The combined ethereal extracts were dried with Na_2SO_4 and the solvent was evaporated under reduced pressure. For the determination of the enantiomeric and diastereomeric ratios of the product, the residue was treated with diazomethane in ethereal solution. Subsequent chromatography on silica gel gave the corresponding methyl esters.

Synthesis of Hexagonally Packed Mesoporous TiO_2 by a Modified Sol–Gel Method**

David M. Antonelli and Jackie Y. Ying*

In 1992 researchers at Mobil first demonstrated[1, 2] that hexagonally packed, mesoporous silicate and aluminosilicate materials (MCM-41) with uniformly sized pores and surface areas approaching 1400 $m^2 g^{-1}$ could be synthesized by an micelle-assisted crystallization of the inorganic phase[3, 4] Since then there have been many unsuccessful attempts to extend this methodology to the synthesis of related transition metal oxide structures.[5, 6] Such materials would be very attractive as adsorbents and in a wide variety of catalytic processes, because the large and uniform pore sizes should lead to fast diffusion to the active sites during catalysis, even for large molecules. Most attempts aimed at synthesizing these structures have led to lamellar phases in which the surfactant and metal oxide phases are layered. Few purely transition metal based hexagonal phases have been reported.[5] However, these tungsten and antimony systems are thermally unstable and their structures collapse readily upon surfactant removal during calcination such that mesoporous hexagonal oxide phases cannot be attained. Until recently,[7, 8] the only reported example of a hexagonally packed, mesoporous material containing a transition metal is one in which a small percentage of TiO_2 has been incorporated into a silica structure.[9] Herein we report the first synthesis of a thermally stable titanium-based hexagonally packed, transition metal oxide molecular sieve (Ti-TMS1), which has been accomplished through a novel modified sol–gel process involving titanium isopropoxide bis-acetylacetonate and alkylphosphate surfactants.

Previous work demonstrated that basic hydrolysis of $Si(OEt)_4$ in the presence of 0.3–0.6 mol equivalents of alkyl(trimethyl)-ammonium bromide surfactants led to MCM-41 structures.[10] Other work showed that 1 mol% Ti could be incorporated into these structures by addition of titanium isopropoxide.[9, 11] We postulated that it would also be possible to use metal alkoxides in the presence of the appropriate surfactant to synthesize hexagonal mesoporous phases comprising purely transition metal oxides. Initial attempts at hydrolysis of titanium isopropoxide in the presence of alkyl(trimethyl)ammonium bromide surfactants at pH 8–10 produced only the TiO_2 anatase phase after calcination. Similarly, hydrolysis at lower pH with alkyl(trimethyl)ammonium bromide surfactants, or anionic sulfate, carboxylate, and phosphate surfactants gave either anatase or amorphous titania. It is known that 1 mol equivalent of acetylacetone is required in the hydrolysis of zirconium alkoxides in order to obtain stable gels.[12] In the absence of acetylacetone, gel formation was disfavored due to the rapid precipitation of oxide–alkoxide aggregates. When we employed titanium acetylacetonate tris-isopropoxide as a precursor, the desired hexagonally packed titanium oxide mesostructures (Ti-TMS1) were obtained with phosphate surfactants (10 wt%) at pH 3–6 after two days of aging at 80 °C. This strategy was successful with surfactants with phosphate head groups, but not with cationic surfactant or other anionic surfactants we tried, such as those with carboxylate or sulfate head groups.

The powder X-ray diffraction (XRD) pattern (Fig. 1a) for isolated as-synthesized Ti-TMS1 made with 0.5–1 mol equivalents of potassium tetradecylphosphate gives the expected (100)

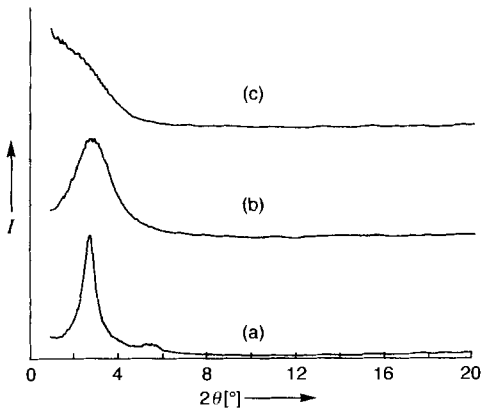

Fig. 1. XRD patterns of three samples of Ti-TMS1 prepared with tetradecylphosphate-to-titanium ratios of a) 1:1, b) 1:3, and c) 1:9. All samples were synthesized at pH = 4 with an acetylacetone-to-metal ratio of 1:1 after five days aging at 80 °C. The most distinct hexagonal crystalline pattern was associated with the sample prepared with 1:1 surfactant-to-metal ratio and had a *d* spacing for the (100) reflection at 36 Å. The (110) and (200) peaks are not clearly resolved. *I* = intensity in arbitrary units.

peak at a d spacing of 36 Å. No amorphous or layered phases were observed in this material. The low-intensity (110), (200), and (210) peaks became more distinct when the sample was aged for longer periods. The material isolated after only one day aging at room temperature gives a diffraction pattern in which the (100) peak is broad and the smaller peaks are not clearly distinguished. This phenomenon has been observed before in MCM-41 materials and has been attributed to either disordered packing of the individual tubes in the mesostructure[9] or very small crystallite size.

Samples of Ti-TMS1 calcined to 350 °C in air for 4 h (heating rate 1 K min^{-1}) have narrow pore size distributions as determined by N_2 adsorption (Fig. 2) and BET (BET = Brunauer-Emmett-Teller) surface areas of approximately 200 m^2 g^{-1}. This is the first example of a non-alumina or non-silica based hexagonally packed mesoporous material retaining its pore structure after surfactant removal by calcination. Although the surface area is only one-third that expected on the basis of MCM-41, taking into account the difference in molecular mass between silica and titania, we feel this process can be optimized to yield greater surface areas. When calcination is conducted in pure O_2 a light-off occurs at about 180 °C resulting in a greater degree of pore collapse as evidenced by a reduction of the BET surface area to about 100 m^2 g^{-1}. IR spectroscopic studies of the calcined material revealed a strong band at 1087 cm^{-1} indicative of the phosphate ion. This result suggests that phosphate is still present in the calcined structure. The XRD pattern of this material (Fig. 3) indicated that the diffraction intensity has diminished and the (110) and (200) reflections are no longer distinctive due to reduced crystalline domain sizes in the calcined mesostructure. Transmission electron microscopy (TEM) illustrated that there was still considerable retention of the hexagonal pore structure (Fig. 4) for the Ti-TMS1 sample calcined under O_2 at 500 °C, demonstrating the thermal stability of this material even after calcination. The domain size for hexagonally packed structures is about 100 nm. We are currently investigating the optimization of the surfactant removal step to yield materials with higher surface areas.

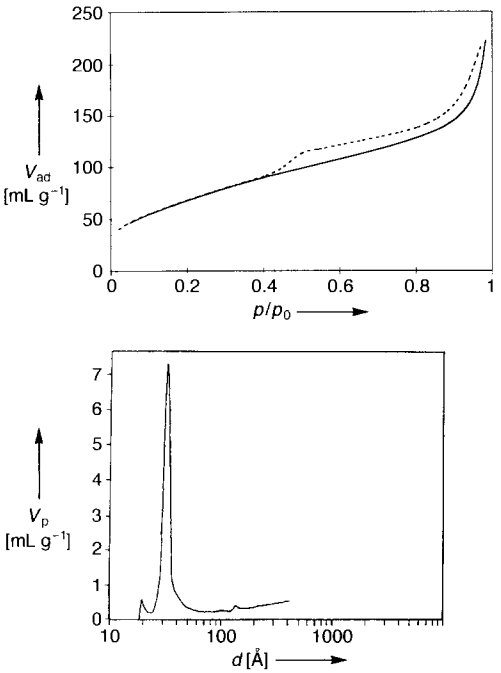

Fig. 2. Top: Nitrogen adsorption (—) desorption (- - -) isotherm for Ti-TMS1 synthesized from tetradecylphosphate after surfactant removal at 350 °C in air for four hours. The sharp decline in the desorption curve is indicative of mesoporosity, while the hysteresis between the two curves demonstrates that there is a diffusion bottleneck, possibly caused by pore damage. V_{ad} = volume adsorbed. p/p_0 = relative pressure. Bottom: BJH (BJH = Barrett-Joyner-Halenda method) desorption pore size distribution of the same sample with sharp peak at 32 Å illustrating the narrow pore size distribution and mesoporous nature of Ti-TMS1. V_p = pore volume. d = pore diameter.

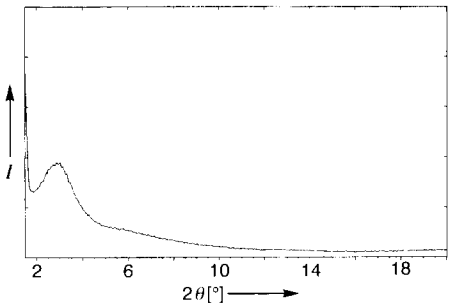

Fig. 3. XRD pattern for a sample of Ti-TMS1 synthesized from tetradecylphosphate at a surfactant:Ti ratio of 1:2 with one equivalent of acetylacetone at pH = 5 after surfactant removal at 350 °C in air for four hours. There is a considerable reduction in the intensity and sharpness of this pattern as compared to the as-synthesized sample. This is consistent with the results of nitrogen adsorption and TEM studies which reveal that there is partial loss of structure and reduction in crystalline domain size on calcination. The d spacing of the (100) reflection is centered at 34 Å as compared to 35 Å in the as-synthesized material, indicative of a small degree of pore shrinkage on thermal treatment. I = intensity in arbitrary units.

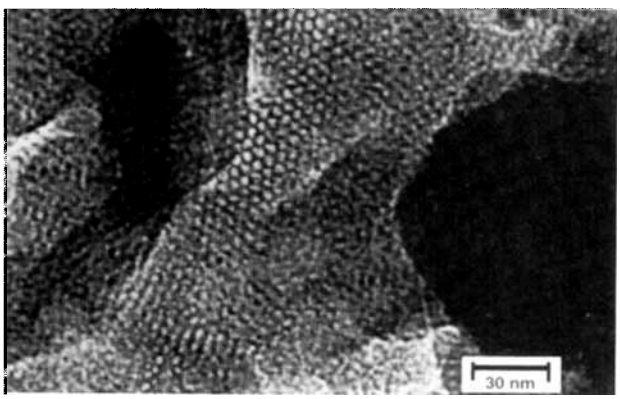

Fig. 4. TEM image of Ti-TMS1 prepared from tetradecylphosphate and calcined at 500 °C under O_2 for ten hours showing the retained 32 Å pores ordered in a hexagonal array.

A series of 120 experiments were conducted to determine the optimal pH, molar ratio of surfactant, and molar ratio of acetylacetone in the synthesis of Ti-TMS1. The pH was varied in integer steps from 2–6, the acetylacetone-to-Ti ratio was varied from 0–3 in integer steps, and the surfactant-to-Ti ratio was studied at levels of 1:9, 1:6, 1:4, 1:3, 1:2, and 1:1. In all cases, one parameter was changed while the other two were held constant. The aging temperature and time were always held at 80 °C and five days, respectively. The weight percent of surfactant used was 7–10% depending on the pH. This slight variation was necessary because the surfactant is less soluble at lower pH and higher ionic strength. In the appropriate weight percent and pH ranges, liquid crystal micelle formation for phosphates of chain length greater than 10 carbon atoms is favored.[13, 14] The quality of the materials was assessed by XRD which elucidates the presence and crystallinity of the hexagonal phase in the

as-synthesized material. The parameters that seemed most critical were the acetylacetone concentration and the surfactant-to-Ti ratio. The effect of the pH was not dramatic in the precursor compositions which favor the formation of mesostructures. The optimum surfactant-to-Ti ratio under all conditions examined was 1:1. Figure 1 shows the XRD patterns obtained for as-prepared samples synthesized with tetradecylphosphate-to-Ti ratios of 1:1, 1:3, 1:9 at pH = 4 after five days aging at 80 °C. Hexagonal structures with poorly defined XRD patterns were obtained for surfactant-to-Ti ratios of 1:2–1:4, while the materials were largely amorphous at a ratio of 1:6. At 1:9 the surfactant effect was so small that only anatase was observed at all pH and acetylacetone concentrations.

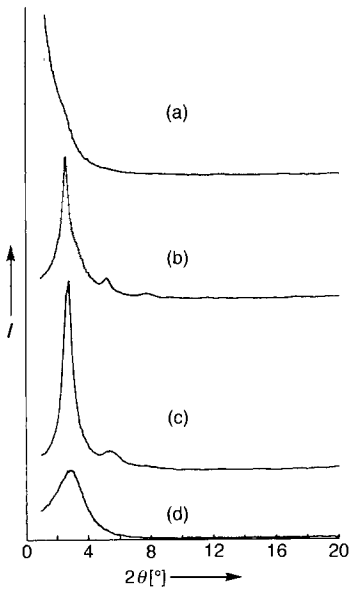

Fig. 5. XRD patterns of samples of Ti-TMS1 prepared from tetradecylphosphate at pH = 4 with a surfactant-to-Ti ratio of 1:1 at acetylacetone-to-Ti ratios of a) 0:1, b) 1:1, c) 2:1, and d) 3:1 illustrating that the optimal amount of acetylacetone is 1–2 equivalents. The (100) reflection for samples b) and c) appear at 36 Å as expected. I = intensity in arbitrary units.

The optimal molar ratio of acetylacetone to Ti was established at 1:1 as shown in Figure 5. In the absence of acetylacetone only amorphous materials or anatase were formed in all surfactant-to-Ti ratios and pH ranges. With one equivalent of acetylacetone, the results were the best at a pH of 4–6, while at two equivalents the results were best at a pH of 2–3, with precipitation time required increasing from less than five minutes to over one day. This is not unexpected since the effect of the acetylacetone is to slow down the hydrolysis. The chelating six-membered metallo-acetylacetonate ring is kinetically quite stable to hydrolysis in the absence of acid.[8] Thus, lower pH was required to promote the hydrolysis when two equivalents of acetylacetone per mol Ti were used. Since the phosphate surfactant becomes less soluble at a pH of less than 3, it is better to use a higher pH with only one equivalent of acetylacetone. In excess of three equivalents of acetylacetone, no precipitation occurred at all. This may be due to the formation of a hydrolytically inert cationic octahedral tris(acetylacetonate) complex.

The alteration of pH had little effect on the system in acetylacetone and surfactant concentration domains where Ti-TMS1 formation was favored. The main effect seemed to be one of acceleration or deceleration of the hydrolysis process. At very low pH however, there was a tapering off of the product crystallinity which may be due to protonation of the phosphate head group, reducing the strength of the interaction between the organic micellar phase and the inorganic phase. At pH values lower than 1, alkylphosphates exist almost exclusively as the dihydrogen phosphates.[13, 14] This would be expected to disfavor Ti-TMS1 formation, and in fact it does. Also, at higher basic pH where the Ti layer was expected to develop a negative charge and interact more strongly with OH^- ions than with the surfactant, no mesoporous structures were obtained. In summary, these experiments revealed that the best conditions for Ti-TMS1 synthesis were a molar ratio of surfactant-to-Ti of 1:1, a molar ratio of acetylacetone-to-Ti of 1:1, and a pH of 4–6.

In order to determine the ideal surfactant head group for the synthesis of Ti-TMS1, a series of studies were conducted with C_{14} hydrocarbons functionalized at the 1-position with trimethylammonium, sulfate, carboxylate, phosphate, amine, and acetylacetone. Two general approaches were used. The first was to dissolve the monopotassium salt of the anionic surfactant or the bromide salt of the tetradecyl(trimethyl)ammonium cation in water at a concentration above the critical micelle concentration (cmc) for that particular system followed by adjustment of the pH and addition of the Ti precursor. This room-temperature route was not applicable to the amine and acetylacetone surfactants because of the very low pK_b of the deprotonated form. The second approach involved first mixing the protic form of the anionic or neutral surfactant in ethanol with the titanium alkoxide precursor followed by hydrolysis with water of a preadjusted pH at −78 °C. This low-temperature approach was not used for tetradecylammonium bromide since it has no conjugate acid. Metal alkoxides react quickly with a wide variety of donor ligands. Thus, we would expect the precursor molecules formed in this step to have a structure in which the head group is chemically bonded to the titanium alkoxide fragment. In general, the strength of the resulting metal–ligand interaction decreases as follows: acetylacetonate > carboxylate > phosphate > sulfate. Amine ligands are difficult to place on this scale since they can form amino, amido, and imido complexes, the stability of which is largely dependent on the metal center and ancillary ligands. In all cases the surfactant-to-Ti ratio was held at 1:1. After aging at room or higher temperatures, the crystallinity of the materials was characterized by XRD (Fig. 6).

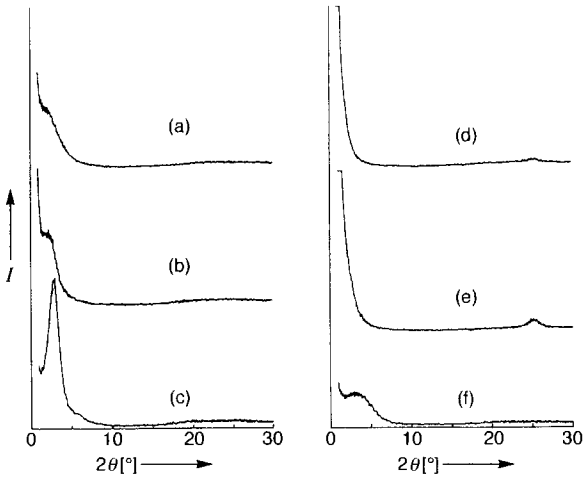

Fig. 6. XRD patterns of samples of Ti-TMS1 prepared with a surfactant chain length of 14 carbon atoms at pH = 4, 1:1 surfactant-to-Ti ratio, 1:1 acetylacetone-to-Ti ratio, and aged at room temperature for 24 h: a) Amino, b) carboxylate, c) acetylacetonate, d) sulfate, e) trimethylammonium bromide, and f) phosphate are employed as the surfactant head groups. I = intensity in arbitrary units.

Systems involving trimethyl(tetradecyl)ammonium bromide and sodium sulfate gave no mesoporous materials at pH values ranging from 2–9 under both the room-temperature and low-temperature routes. By the room-temperature route, the carboxylate system gave anatase at basic pH, but could not be extended to acidic pH because the surfactant was not very soluble under those conditions. However, by using the low-temperature route, low-crystallinity hexagonal materials were isolated after aging at room temperature for pH 4–7. Further aging at

80 °C led to phase separation and isolation of amorphous materials. The acetylacetonate-functionalized surfactant (3-tetradecyl-2,5-pentanedione) worked the best in the series studied with the low-temperature route, producing materials with broadened hexagonal patterns after one day aging at room temperature. Further heating led to the leaching away of the insoluble surfactant as a separate phase on top of the water layer. Potassium hydrogen tetradecylphosphate works almost as well as tetradecyl acetylacetone in the low-temperature preparation, but vastly surpasses the latter during the aging process. While acetylacetone is a much better ligand to the Ti ion than phosphate, the fact that the phosphate surfactant is soluble at pH 2–12 makes it possible to age these materials without phase separation induced surfactant loss from the liquid crystal phase. The materials produced by the low-temperature route are identical to those obtained by using the room-temperature route as long as KCl is added to the mixture after warming the former to room temperature. The quality of the materials obtained by the low-temperature route without any further aging follows the trend of the head group's donor abilities listed above: acetylacetonate > carboxylate > phosphate. Further aging, however, favors the phosphate system, presumably because of the solubility of the free surfactant in the supernatant. Under the conditions described the amine surfactants gave materials with weak hexagonal patterns which collapsed on aging at 80 °C.

The effects of aging temperatures and ionic strength of the medium were also investigated. In general, temperatures higher than 120 °C led to degradation of the as-synthesized material, possibly indicating low hydrothermal stability. The absence of KCl in the aging medium was found to yield poorly crystalline materials, while the presence of more than three equivalents of KCl led to formation of layered phases. For example, treatment of a 10 wt% solution of dodecyl phosphoric acid with titanium bis(acetylacetonate)isopropoxide gave only poorly crystalline materials after three days of aging at 80 °C without KCl.

In summary, the best synthesis conditions for Ti-TMS1 involve either: a) the prior addition of tetradecylphosphate to titanium acetylacetonate tris-isopropoxide, followed by hydrolysis at −78 °C and subsequent aging to 80 °C at pH 4–6 at a 1:1 surfactant-to-Ti ratio in the presence of 1 equivalent of KCl, or b) the addition of titanium acetylacetonate tris-isopropoxide to a 10 wt% solution of the monopotassium salt of the surfactant at pH 4–6 followed by aging at 80 °C for several days.

In this study we have prepared the first hexagonally packed mesoporous materials based on early transition metal oxides. The synthesis of this novel system proceeds by a modified sol–gel method. This approach should be extendable to a wide range of mesoporous and microporous materials well beyond the typical aluminosilicate based compositions. We have also reported the first examples of hexagonal mesoporous materials based on transition metal oxides which retain their pore structure on removal of surfactant by calcination. These new materials should have applications in a variety of areas, including catalysis, molecular adsorption, nonlinear optics, and thermal or acoustic insulation.

Experimental Procedure

X-ray powder diffraction data were recorded on either a Siemens D-5000 θ-θ diffractometer using Cu_{K_α} radiation and a scintillation detector at 2.2 kW or a Rigaku RU-300 θ-2θ with a rotating anode using Cu_{K_α} radiation at 10 kW. High-resolution transmission electron microscopy (TEM) images and electron diffraction patterns were obtained on a JEOL 2010 transmission electron microscope operated at 200 kV. Samples were prepared by sonication in isopropyl alcohol and suspension on carbon-coated copper grids. Nitrogen adsorption data were collected on a Micromeritics ASAP 2000 Sorption Analyzer.

In a typical preparation, tetradecylphosphate (3.75 g, 8.8 mmol) was dissolved in water (25 mL) with KOH (0.49 g, 8.8 mmol) and the pH adjusted to 5.0 with 12.5 M HCl. In a separate beaker, titanium isopropoxide (5.0 g, 8.8 mmol) was treated with acetylacetone (0.9 mL, 8.8 mmol). The solution immediately turned yellow and heat was liberated. This solution was cooled and then added to the surfactant solution with vigorous stirring. The thick yellow meringue was then aged at ambient temperature for two hours and then at 80 °C for five days. The resulting fawn powder was then collected by filtration, washed with water (3 × 100 mL) and subsequently dried in an oven at 120 °C overnight. Calcination at 350 °C in air yielded a mesoporous sample of Ti-TMS1 with 196 $m^2 g^{-1}$ surface area and a pore size of 32 Å as determined by nitrogen adsorption.

A Facile Access to $1\lambda^5,3\lambda^5$-Benzodiphospholes

Hans Jürgen Bestmann,* Helmut Paul Oechsner, Lothar Kisielowski, Claudia Egerer-Sieber, and Frank Hampel

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

Diphosphaheterocycles that contain a pentacoordinate and a tetracoordinate phosphorus atom as part of their PCP unit have not previously been reported. We have discovered a facile route to the first compound of this type, namely the 1,1,1,3,3-pentaphenyl-$1\lambda^5,3\lambda^5$-benzodiphospholes (**10**).

When hexaphenylcarbodiphosphorane **1**[1] is treated with halides **2**, the cationic 1,3-diphosphaallyl salts **3**[2] form. The same type of compound can be obtained if alkynyl phosphonium salts **4** are treated with phosphonium ylides **5** (except for $R^2 = R^3 = H$). The reactions probably take place via a cycloaddition intermediate, which opens to **7**.[3]

Reaction of **3** or **7** with sodium hexamethyldisilazanide (**8**) in benzene or pyridine gives 1,1,1,3,3-pentaphenyl-1λ^5,3λ^5-benzodiphospholes (**10**). The heterocyclic ring system consists of a pentacoordinated and a tetracoordinated phosphorus atom in 1, 3 juxtaposition. The carbon atom of the ligand between the two phosphorus atoms, has ylidic character.

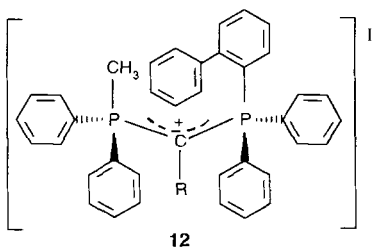
10 11



12

Apparently an ortho proton is removed from one of the six phenyl rings of **3** or **7**.[4] The resulting zwitterion **9** undergoes ring closure to create a new C–P bond (→ 10). Thus, a trigonal bipyramid is formed with a pentacoordinate phosphorus atom at its center. The rules governing attack and departure of ligands in reactions involving the mutual interconversion of tetra- and pentacoordinate phosphorus[5] predict that the incoming ligand should be located in the apical site. Pseudo rotation of the five-membered ring in a,e position should be strongly hindered, since the ylidic ligand, which serves as an electron donor, prefers an equatorial position.[6] A crystal structure analysis of **10a** (R = CH_3) was performed[7] (Fig. 1).

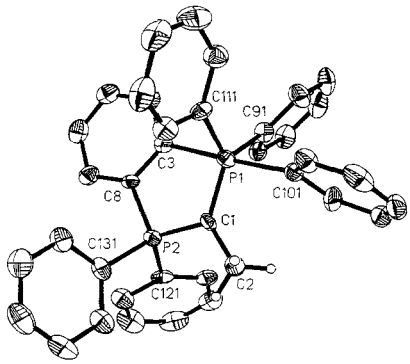


Fig. 1. Crystal structure of **10a** (R = CH_3) with selected bond lengths [pm] and bond angles [°]: C1-C2 150.9(9), C1-P1 176.2(6), C1-P2 171.7(6), P1-C3 198.8(7), P1-C111 185.1(6), P1-C91 188.6(7), P1-C101 197.7(7), C3-C8 138.5(9), P2-C8 180.0(6), P2-C131 182.1(7), P2-C121 182.5(7); P1-C1-P2 116.9(4), C1-P1-C101 90.9(3), C1-P1-C91 124.6(3), C1-P1-C111 120.3(3), C1-P1-C3 90.8(3), C91-P1-C101 88.6(3), C91-P1-C111 115.0(3), C3-P1-C111 87.2(3), C2-C1-P1 128.4(5), C2-C1-P2 89.6(3), C1-P2-C8 103.4(3), C1-P2-C131 114.6(3), C1-P2-C121 114.6(3), C8-P2-C131 110.7(3), C121-P2-C131 104.6(3), P1-C3-C8 119.9(5), P2-C8-C3 109.0(5), C3-P1-C101 178.0(3) [7].

A nearly ideal trigonal bipyramid can be detected in the molecule. As expected, the newly formed C–P bond is located in an apical position and forms part of the five-membered ring. The ylidic C atom is situated in an equatorial position.

The P1–C1 bond (1.76 Å) is considerably shorter than the two equatorial C–P bonds (1.85 and 1.88 Å). However, it is longer than the C1–P2 bond (1.72 Å). The five-membered ring is perpendicular to the equatorial plane and is distorted, as expected, but nearly flat. C2 lies in the plane of the five-membered ring (angle sum about C1 357.8°). It can be assumed that the ylidic electron pair is as π-donor perpendicular to this plane and therefore lies in the equatorial plane. This is in accord with molecular orbital calculations for the pentavalent phosphorus by R. Hoffmann et al.[6] The ^{31}P NMR spectrum shows a doublet at $\delta = -80$ to -81 for the pentacoordinate P atom of compound **10** derived from **3** and another doublet at $\delta = 10.0$ to 11.5 for the tetracoordinate P atom. The coupling constant ^2J(P,P) is 93 Hz. For **10** obtained from **7** the analogous values are $\delta = -81 - -83$ and $\delta = 3.5 - 5.5$. In these cases the coupling constants ^2J(P,P) are 94–102 Hz. Between −60 °C and +40 °C the ^{31}P NMR spectra are not temperature-dependent. In the ^{1}H NMR spectrum of **10a** the CH_3 moiety gives rise to a doublet at $\delta = 1.1$ (^2J(P,H) = 12 and 16 Hz). The signal of the C atom of the same CH_3 group is again a doublet in the ^{13}C NMR spectrum at $\delta = 12.4$ (determined from ^{31}P–^{13}C satellites). The resonance of the quaternary C atom could not be observed. Table 1 gives an overview of some of the 1λ^5,3λ^5-benzodiphospholes **10** synthesized in our group.

If **10** is heated in refluxing benzene (5 days) or toluene (8 hours), compound **11** is obtained by migration of a phenyl ring and formation of a biphenyl moiety at the ylidic P atom. The new substrate now contains a tricoordinate and tetracoordinate phosphorus atom. The latter is part of an ylide moiety.[8] Structure **11a** (R = CH_3) was confirmed by X-ray analysis.[9]

We assume that the phosphorane–phosphane rearrangement[10] follows an a,a cheletropic reaction mechanism. At the

[a] Decomposition. [b] δ values. σ indicates the number of bonds.

trigonal bipyramid of **10** a diaxial bond is broken, while simultaneously the *o*-biphenyl system is formed. According to R. Hoffmann[16] thermal cheletropic reactions at the pentavalent phosphorous atom that involve e,e and a,a bond breakage are allowed, while those with a,e bond cleavage are forbidden. Since we were unable to detect any biphenyl by a thermal treatment of **10**, ring strain and steric congestion at the five-membered ring in **10** might be the determining factor that steers the rearrangement exclusively into the a,a path. However, alternative mechanisms cannot be excluded. Investigations of the rearrangement by ESR spectroscopy gave no evidence for radicals.

The ^{31}P NMR spectra of the compounds **11** show two doublets with chemical shifts between $\delta = +2$ and -6 for P^{III} and $\delta = +20$ and $+27$ for P^{IV}. The geminal coupling constants ^2J(P,P) lie between 175 and 200 Hz (Table 2).

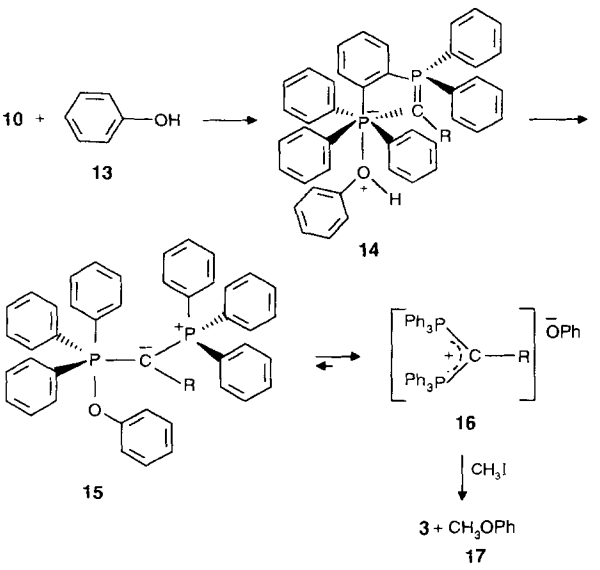
[a] δ values. σ indicates the number of bonds.

If a suspension of compound **10** is stirred in benzene with excess of phenol or cresol for approximately 6 days, an oil is obtained. On addition of iodomethane the cationic 1,3-diphosphaallyl salts of **3** (X = I) are recovered. Furthermore, anisol **17** is obtained; the oil is therefore assigned the structure **16**. On carrying out the reaction with hexadeuterophenol, deuterium is introduced in the *ortho* position of a phenol ring, as can be proven by FD-MS and NMR experiments (^{1}H,^{13}C coupling).

Treatment of **10** with HCl leads to a number of products that have not yet been identified. However, **3** could not be detected among them (^{31}P NMR). If **10** is treated with iodomethane, a small amount of the cationic diphosphaallyl iodide **12a** (R = CH_3) can be isolated after stirring for several days. Compound **12** also can be obtained by treatment of **11a** with iodomethane.[11] We cannot therefore conclude that formation of **16** from **10** and **13** occurs by primary elimination of a phenylic anion from the apical position. We rather tend to the view that a hexacoordinated species **14**[12] is formed, which then ring-opens with formation of a phenylic anion. This anion accepts the phenolic proton to afford **15**, which transforms into **16**.[13] On treatment of **16** with iodomethane, **3** (X = I) and anisole **17** are obtained.



Experimental Procedure

Synthesis of **10**: **8** (510 mg, 2.8 mmol) and **3** or **7** (2.0 mmol) were dissolved in dry pyridine (8 mL). After stirring for six days with exclusion of light the product was filtered off, rinsed with 2 portions each of dry pyridine (5 mL) and dry petroleum ether (5 mL), and dried under high vacuum for 24 h at room temperature.

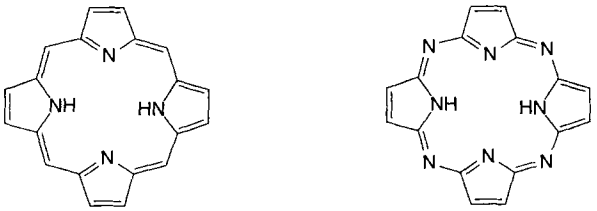
Octathioporphyrazine Crown Ethers: An Octanuclear Ag^I Complex with Coordination in the *meso* Pocket**

John W. Sibert, Steven J. Lange, Charlotte L. Stern, A. G. M. Barrett,* and Brian M. Hoffman*

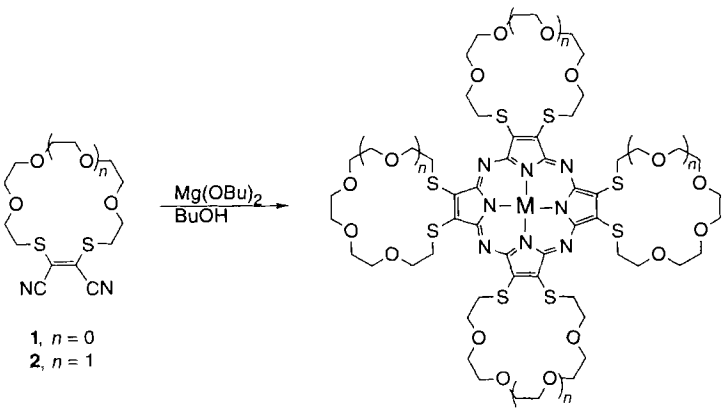
Porphyrazines (tetraazaporphyrins) and porphyrins are related by the isoelectronic replacement of the *meso* CH unit in the latter with the *meso* N atom in the former (Scheme 1).[1] This



Scheme 1.

replacement influences the binding of a metal ion in the central cavity.[2] However, it has not been widely recognized that the *meso* N atoms' lone-pair electrons, which are in the plane of the macrocycle and directed away from it, potentially can coordinate to additional metal ions at the macrocycle's periphery. We recently reported the first structurally characterized example displaying this behavior, a peripherally metalated porphyrazine where each *meso* N atom of porphyrazineoctathiolate acts together with its two nearby peripheral S atoms to function as a tridentate "*meso*-pocket" ligand that binds a dialkyltin molecule.[3] Because the metal-binding capabilities of the thiolato sulfur atoms are strong, it was by no means clear that coordination by the *meso* N atom made a major contribution to the binding. This is now shown to be the case for the remarkable peripheral ligation of eight silver(I) ions by an octakis(alkylthio)-tetraazaporphyrin containing four crown ether units, in which both crown ether and *meso*-pocket coordination is exhibited.[4]

We[5] and others[6] have reported on the synthesis and coordination chemistry of crown ether derivatives ("oxa-crowned" derivatives) of dithiomaleonitrile (for example, **1** and **2** in Scheme 2). The mix of soft sulfur and hard oxygen donor atoms



Scheme 2. Synthesis of the porphyrazine crown ethers **3**–**10**.

renders these crown ethers particularly well suited for the ligation of heavy metal ions; endocyclic complexes of $HgCl_2$,[5a] and Ag^I,[5b] and exocyclic complexes of PdX_2 (X = Cl, Br),[6a] are known. In addition to being ligands themselves, **1** and **2** are the direct precursors to oxa-crowned octakis(alkylthio)tetraazaporphyrins.[4, 7]

The oxa-crowned porphyrazines were synthesized by the Mg^{II} template cyclization of the appropriate crowned derivative of dithiomaleonitrile as described (Scheme 2).[8] Consistent with the work of Linstead and co-workers for the synthesis of octamethyltetraazaporphyrin,[9] we obtain the highest yields for the preparation of the Mg^{II} porphyrazines **3** and **7** (about 35%) using butanol as the reaction medium. van Nostrum et al. reported yields of 20–22% for a similar synthesis of **3** and **7** in propanol.[7] Treatment of the Mg-porphyrazines with trifluoroacetic acid provided the metal-free porphyrazines **4** and **8**. Subsequent reaction with $Ni(OAc)_2$ or $Cu(OAc)_2$ in chlorobenzene/DMF (5/1) quantitatively produced the corresponding centrally metalated porphyrazines (**5**, **9** and **6**, **10**; see Table 1 for the characterization).

Preliminary studies of the binding of Ag^I, $HgCl_2$, $CdCl_2$, and Pb^{II} to the periphery of **5** dissolved in chloroform/methanol (3/1) solutions employed UV/Vis spectroscopy. Reactions with $HgCl_2$ and $CdCl_2$ caused the precipitation of compounds that could not be sufficiently purified. No evidence for complexation with Pb^{II} was observed. However, the addition of a large excess of $AgBF_4$ led to significant color changes, from blue to greenish-blue, that could be monitored.[10] The spectrum of the parent compound **5** has strong π–π^* absorptions at 326 and 672 nm and an n–π^* transition at 485 nm that involves the peripheral S atoms.[11] The color change upon addition of Ag^I ions corre-

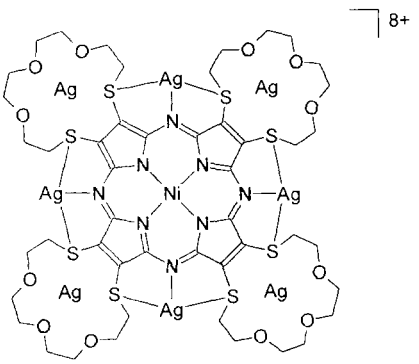
[a] Theoretical values are given in parentheses. [b] Compounds **4**–**6**, **8**–**10** in chloroform, [**11**·8 BF_4] in methanol. [c] The chemical shifts of the internal NH protons for **4** and **8** are $\delta = -2.31$ and -2.18, respectively. [d] Analysis of the monohydrate. [e] The analytical and crystallographic data for the two crystalline forms of [**11**·8 BF_4] are consistent with ten Ag^I ions, of which eight are directly coordinated to the porphyrazine, and four water molecules per molecule.

sponded to the disappearance of the transition at 485 nm and sharpening (but not shifts) in the $\pi-\pi^*$ transitions.

The absence of the $n-\pi^*$ transition indicates that the Ag^I ions coordinate to the peripheral S donor atoms. The small changes in the $\pi-\pi^*$ transitions are unlike those observed for the *meso*-coordinated tin adduct of porphyrazineoctathiolate. In the latter case the Soret band is shifted out of the visible region of the spectrum, presumably as a result of the stabilization of the a_{1u} molecular orbital through coordination to the *meso* N atoms. *Thus, in solution* **5** *appears to coordinate* Ag^I *ions through the crown moieties alone without participation of the meso* N atoms.

Slow evaporation in the dark of a chloroform/methanol solution containing **5** and an excess of $AgBF_4$ produced complex **11**



11

as blue crystals with a red reflex in two distinct morphologies (needles and cubes). The analysis of both types of crystals indicates more than eight Ag^I ions per porphyrazine. Importantly, when only eight or fewer equivalents of $AgBF_4$ were added to **5**, no crystalline product was obtained.

X-ray diffraction studies on [**11**·8 BF_4][12, 13] yield the first structural characterization of a crowned porphyrinic macrocycle incorporating metal ions in the crowns. They disclose a far more interesting situation than inferred from the behavior in solution: a crystal having the needle morphology[12] has not four, but eight Ag^I ions coordinated to the periphery of the porphyrazine (Fig. 1).[14] Four Ag^I ions are coordinated in an endocyclic fashion by the crown moieties, consistent with the

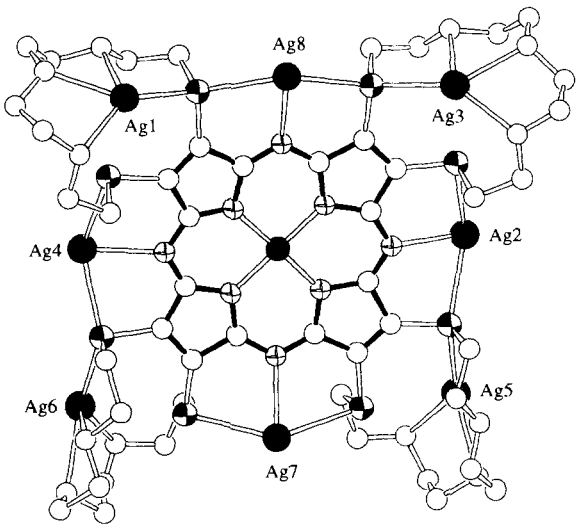


Fig. 1. X-ray structure of the porphyrazine cation **11** with all other atoms of the complex [**11**·8 BF_4] removed for clarity.

inferences based on optical spectra of solutions. However, four additional Ag^I ions occupy the *meso* pockets and undergo tridentate, S-N-S coordination by the peripheral thioether S and the *meso* N atoms (the coordination sphere of these Ag^I ions is completed by O atoms from solvent). The lack of evidence for *meso* coordination in solution suggests a preference for the ligation of Ag^I by the crown moieties of **5**.

As shown in Figure 2a, each of the four Ag^I ions in the crown subunit is coordinated by one S atom (average distance 2.55(1) Å; range 2.50(1)–2.60(1) Å), and all three macrocyclic O atoms (average distance 2.52(3) Å; range 2.39(3)–2.69(3) Å). In addition there is a weaker interaction with the remaining S donor atom (average 2.98(1) Å; range 2.95(1)–3.04(1) Å). The Ag–S and Ag–O bond lengths are typical and similar to those in the related Ag^I complexes of macrocycles **1**, **2**,[15b] and 1,4-dithia-7,10,13-trioxacyclopentadecane.[15] Each of the four Ag^I ions in the *meso* pockets is coordinated unsymmetrically by the two S donor atoms (Fig. 2b). The short Ag_{meso}–S bond lengths average 2.69(1) Å (range 2.65(1)–2.74(1) Å), whereas the long Ag_{meso}–S bond lengths average 2.81(1) Å (range 2.71(1)–

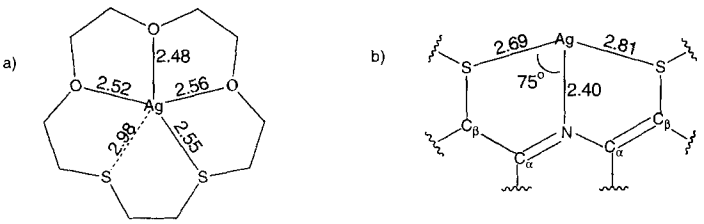

Fig. 2. Coordination geometry about Ag^{I} ions in the crown ether units (a) and in the *meso* pockets (b) of the porphyrazine cation **11**. The average bond lengths are given in angstroms.

2.88(1) Å). The Ag–N_{meso} bonds are slightly longer (average 2.40(3) Å; range 2.37(3)–2.43(3) Å), though similar to those reported for Ag–N(pyridine) bonds.[16]

The ability of S-appended porphyrazines to coordinate metal ions in two distinct binding sites is due to the flexibility of the C_{β}–S bond. This flexibility can be gauged by examining the "bite" distance between the two S atoms on each pyrrole unit. In the tin-capped porphyrazine octathiolate, a purely *meso*-coordinated complex, the S···S distance is 3.74 Å. This distance decreases to 3.25 Å in the nickel-capped porphyrazine octathiolate, a complex exhibiting the classic bidentate "dithiolene" coordination of a Ni^{II} ion by both S atoms on each pyrrole ring.[17] An intermediate value for the S···S separation might be expected for **11**, because it contains both types of bonding in the same molecule, and such is the case. The average S···S distance in **11** is 3.58 Å (range 3.57–3.60 Å), comparable to that in an octathiomethylporphyrazine (S···S = 3.53 Å) with no peripherally coordinated metal ions.[3b]

As first seen with the tin-capped porphyrazine octathiolate, heteroatoms at the β positions of the pyrrole ring can function together with the *meso* N atom to form a tridentate binding pocket that readily accepts metal ions. This is now found to be true in both thiolate- and thioether-appended porphyrazines, thus establishing that porphyrazines should not be viewed simply as modified porphyrins, but as a discrete class of molecules with its own unique properties. We anticipate that a rich chemistry with *meso*-pocket coordination will grow from the study of functionalized porphyrazines.

Experimental Procedure

4: A suspension of magnesium turnings (30 mg; 1.23 mmol) in butanol (8–10 mL) was heated at reflux for 24 hours with iodine as an initiator. To the resulting magnesium butoxide suspension was added solid **1** (1.0 g; 3.3 mmol). The solution rapidly turned yellow, then green and, after several minutes, settled at a deep blue color. The reaction was kept at reflux under a nitrogen atmosphere for 18 h. The butanol was then removed under reduced pressure, and the residue taken up in chloroform and filtered. The filtrate was passed through a silica column (5% CH_3OH in $CHCl_3$ as eluent) to afford the Mg-porphyrazine **3**, which was used without further purification. Compound **3** was dissolved in neat trifluoroacetic acid (10 mL) and stirred at room temperature for 1 h. The solution was poured over ice and neutralized with ammonium hydroxide. The resulting precipitate was filtered and washed with water and methanol. Column chromatography on silica (3% CH_3OH in $CHCl_3$) produced pure **4** as a blue solid: yield 35–40% (based on **1**). Porphyrazine **8** was prepared from crown ether **2** by an identical procedure.

5 (M = Ni) and **6** (M = Cu): The 21*H*,23*H*-porphyrazine **4** (150 mg) and a large excess of $M(OAc)_2$ (M = Ni or Cu) were added to a mixture of chlorobenzene/DMF (5/1; 10 mL). The reaction was heated to 100 °C under a nitrogen atmosphere and stirred for 18 h. The solvent was then removed under reduced pressure, and the solid residue washed with methanol and filtered. The product was isolated in nearly quantitative yield following column chromatography on silica (3% CH_3OH in $CHCl_3$). Porphyrazines **9** and **10** were prepared from **8** by an identical procedure.

11: To a solution (chloroform/methanol 3/1, 50 mL) of **5** (40 mg) was added $AgBF_4$ (> 10 equiv). The color of the solution immediately changed from blue to greenish-blue. Slow evaporation of the solvent in the dark produced **11** as blue crystals with a red sheen.

[12] Crystal data: triclinic, space group $P\bar{1}$ (no. 2), $a = 15.377(8)$, $b = 17.685(6)$, $c = 19.002(7)$ Å, $\alpha = 104.94(3)$, $\beta = 95.57(4)$, $\gamma = 99.71(4)°$, $V = 4867(8)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.161$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 4.20$ cm^{-1}. A blue, platelike crystal ($0.48 \times 0.14 \times 0.02$ mm) was mounted on an Enraf-Nonius CAD-4 diffractometer with graphite monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). Data collection at $T = -120$ °C, ω–θ scan, $2\theta_{max} = 45.9°$, 14110 measured reflections, 13512 unique ($R_{int} = 0.065$), of which 6424 with $I > 3\sigma(I)$ were used in all calculations. An analytical absorption correction was applied which resulted in transmission factors ranging from 0.74 to 0.96. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXS-86) and refined by the full-matrix least-squares technique (Texsan 5.0). The Ag, Ni, S, and O atoms were refined anisotropically; the remaining atoms were refined isotropically. The residual electron density was not completely modeled. The positions of the porphyrazine atoms and the peripheral coordination of eight silver ions are unambiguous. The highest peak in the final difference Fourier map was 2.90 e Å^{-3}. At final convergence, $R = \sum||F_o| - |F_c||/\sum|F_o| = 0.109$, $R_w = [(\sum w(|F_o| - |F_c|)^2/\sum wF_o^2)]^{1/2} = 0.136$ for 632 parameters. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK) on quoting the full journal citation.
[13] Crystals having cubic morphology have also been isolated. Crystal data: cubic, $a = b = c = 30.200(5)$ Å.
[14] Additional Ag^{I} ions, not bonded to the porphyrazine, are cocrystallized in the lattice.

Routes to Dendritic Networks: Bis-Dendrimers by Coupling of Cascade Macromolecules through Metal Centers**

George R. Newkome,* Ralf Güther, Charles N. Moorefield, Francesca Cardullo, Luis Echegoyen, Eduardo Pérez-Cordero, and Heinrich Luftmann

The chemistry of cascade molecules (or dendrimers)[1] has allowed the construction of macromolecular assemblies possessing vast numbers of precisely juxtaposed nuclei by the iterative connection of multifunctional building blocks. A notable feature of the dendritic method is the ability to control spatial or topological relationships between similar and dissimilar macromolecular subunits incorporated into a branched polymeric framework. Consequently, this controlled synthesis of branched (or linear) macroassemblies has potential in such areas of supramolecular chemistry as molecular devices[2] and molecular information processing.[3] Thus, the potential creation of precisely ordered dendritic "superclusters" or "networks"[4] has provided the impetus for the investigation of definite dendritic conjointment. Reports of contructing cascade molecules by connecting preconstructed dendrimers as macroassembly subunits include the random, nonspecific linking of "starburst dendrimers" to yield "starburst polymers"[5] and the highly branched poly(arylamide) polymers.[6] Specific connectivity is noted in the connection of dendritic wedges with both ends of polyethylene glycol or polyethylene oxide producing polyethereal copolymers,[7] in the trapping of living polystyrene to afford linear - globular ABA copolymers,[8] and in the attachment of dendrimers to a polyfunctional core.[9, 10, 11]

We now report the ruthenium-mediated assembly of a novel series of well-defined cascade macroassemblies[12] possessing maximal $1 \rightarrow 3$ branching multiplicity at a carbon atom. The use of a ruthenium(II) metal center (**<Ru>**)[13] allowed the formation of stable complexes between the discrete terpyridine receptor units attached to different cascade macromolecules. Since the proof of the structure of specific organic networks is often difficult, the use of metal spacers will help to establish the network patterns. The electrochemical results presented here for the complexes, when compared to those of several model systems, clearly establish the presence of the **<Ru>** center bound to two O-substituted terpyridine ligands. These results, coupled with the other spectroscopic evidence and the synthetic strategy utilized, confirm the presence of the bis-dendrimers. Used in this fashion, electrochemical results become useful tools for rapid assessment of the structure of nanoscopic complex formation.

Escamilla for their time preparing the computer graphics.

The second-tier, metal-cascade molecule **9 < Ru** (Scheme 1) was prepared in the following manner: 4'-chloro-2,2':6'2''-terpyridine[14] (**3**) and 1-hydroxydodecanoic acid (**1**) were converted with KOH in DMSO into the terpyridinecarboxylic acid **4**. Peptide-type coupling of **4** with amine **6** under standard conditions[15] led to triester **7a**, which was readily hydrolyzed to the corresponding polyacid **7b**. Repetition of the amide coupling gave the well-defined nonaester **9**. Treatment of **7a** and **9** with $RuCl_3 \cdot 3H_2O$ generated the desired Ru-containing cascades (**7a<Ru** and **9<Ru**), as microcrystalline, paramagnetic, orange-brown complexes. Because of their paramagnetic nature, definitive NMR spectra could not be obtained, but elemental analysis and MALDI-TOF mass spectra support the desired structures. The series of receptor cascades was similarly synthesized by utilizing a shorter connecting moiety, for example 1-hydroxybutyric acid monosodium salt (**2**), and treating it with **3** to afford the terpyridinecarboxylic acid **5** as the core precursor. Subsequent repetitive amidation and hydrolysis procedures, as described above, gave the first, second, third, and fourth generation receptor cascades **8**, **10**, **11**, and **12**, respectively (Schemes 1 and 2). ^1H and ^{13}C NMR spectra and correct ele-

mental analysis of the higher generations **11** and **12** support the structure of the cascade molecules. MALDI-TOF mass spectra[16] of the second generation **10a** gave the correct molecular peak ($[M + H^+]$ *m/z* 1758; $[M + Na^+]$ *m/z* 1780). In the mass spectra of the third and the fourth generation **11a** and **12**, fragmentation was observed. The spectrum of **11a** showed several fragmentation peaks in addition to a broad peak near the expected molecular peak. Only fragmentation peaks (from 6500 to

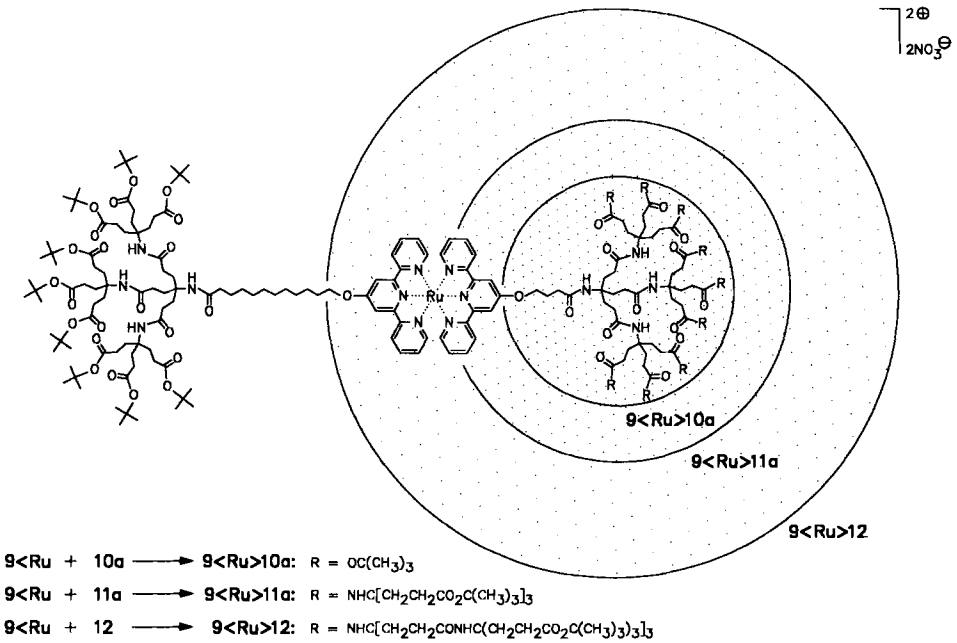
11200 amu) were observed in the spectra of **12**; however, the observed chemical and spectral properties as well as other analytical data confirm the desired structure.

The complementary metallo-donor and receptor cascade macromolecules were readily connected by a single Ru^{II} center. This coupling was performed in MeOH with 4-ethylmorpholine[17] as the reducing agent, and, in each case, afforded the resultant red, crystalline bis-dendrimer complex with the general formula (***X*<Ru>*Y***;[18] Scheme 3). Five different Ru complexes were synthesized with either **7a<Ru>** or **9<Ru>** and receptors **8a**, **10a**, **11a**, and **12**. Evidence for complexation was provided by NMR and UV spectroscopy, elemental analysis, and electrochemistry data. The ^{13}C NMR spectra proved the most useful for structure verification; for example, the NMR spectrum of complex **9<Ru>10a** combines the characteristic signals of both cascade parts at $\delta = 27.91$ ($C(CH_3)_3$), 57.47, 57.65 (C-quat.), 69.11, 70.37 (CH_2Otpy), 80.46 ($C(CH_3)_3$) 172.83 ($CO_2C(CH_3)_3$), as well as the significant doubling of all the terpyridine signals, due the dissymmetry of the two terpyridine moieties. The characterization of complex **9<Ru>12** was, however, difficult with NMR techniques because of the presence of the 90 *tert*-butyl groups, which masked the signals of the internal terpyridine unit. The UV spectra were consistent with complex formation: the electronic spectra of all ***X*<Ru>*Y*** complexes in MeCN showed exactly the same characteristic MLCT transitions in the visible region at 486 nm. The absorption maximum at 394 nm for **9<Ru>** is also distinctive. The MALDI-TOF mass spectrum of **9<Ru>10a** gave the correct mass with the highest intensity for the $[M + Na^+]$ peak. In the mass spectra of **9<Ru>11a**, a small parent peak at the correct mass can be observed, as well as several fragmentation peaks (around 2200 for the metal-donor cascade part and from 3400 to 5100 for the receptor cascade part). The Ru complexes appear to be unstable under the conditions used for MALDI-TOF spectrometry.

The Ru–terpyridine redox-active centers of these bis-dendritic complexes are readily probed with electrochemical techniques.[19] Both terpyridine-based cathodic cyclic voltammetry (CV) as well as Ru-based anodic CV are presented in Figure 1. These results were obtained with a glassy carbon working electrode for 1 mM solutions of the complex in acetonitrile containing 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$) as supporting electrolyte.

Figure 1a depicts the cyclic voltammogram of the simplest member (**7a<Ru>8a**) of this bis-dendrimer family. Both the cationic and anionic scans yield electrochemically and chemically reversible processes. The two electron transfer steps in the cathodic scan correspond to the two terpyridine ligands. The Ru^{2+}/Ru^{3+} couple seen on the anodic scan is also chemically reversible, as evidenced by the i_C/i_A ratio, and electrochemically quasi-reversible with $\Delta E_{pp} =$ 76 mV (Table 1). The complex **7a<Ru>8a** thus displays the expected electrochemistry. There is a slight splitting of the anodic wave corresponding to the second cathodic process, which is not currently well understood but ascribed to an electrode surface effect.



Scheme 3. Synthesis of the bis-dendritic metal complexes. 4-Ethylmorpholine, EtOH, 1.5 h at reflux. Yields: **9<Ru>10a**: 65%; **9<Ru>11a**: 61%; **9<Ru>12**: 63%.

Although the steric hindrance around the redox active centers increases in going from **7a<Ru>8a** to **9<Ru>10a** (Fig. 1b), hardly any difference is observed in the corresponding cathodic electrochemistry (Table 1). However, the Ru^{2+}/Ru^{3+} couple exhibits a larger ΔE_{pp}, indicative of slower electron transfer than for **7a<Ru>8a**. Nevertheless, the overall difference in electrochemical behavior between these 1:1- and 2:2-tier complexes is negligible.

In going from the **9<Ru>10a** (2:2 tier) to **9<Ru>11a** (2:3 tier) the redox couples remain electrochemically and chemically reversible except for the first cathodic couple (Fig. 1c). Thus,

[a] F_c/F_c^+ as internal standard. [b] a)–e): see Fig. 1. Numbers in parentheses refer to the number of generations in the components of the cascade molecule. [c] Inflection point. [d] Very poorly defined.

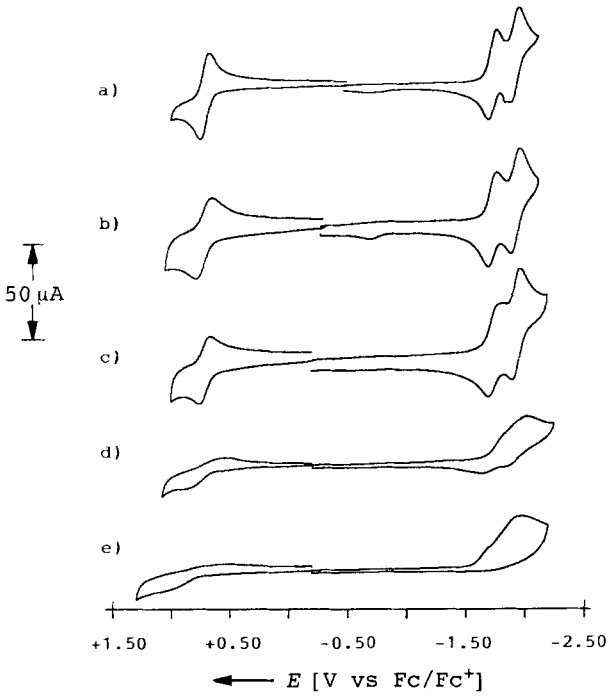

Fig. 1. Cyclic voltammograms of a) **7a<Ru>8a**; b) **9<Ru>10a**; c) **9<Ru>11a**; d) **7a<Ru>12**; and e) **9<Ru>12**. Numbers in parentheses indicate the ratio of the number of tiers in the two dendrimer components. All voltammograms were obtained from MeCN/100 mM TBAPF$_6$ at a scan rate of 100 mV s^{-1}, with a glassy-carbon working electrode, a Pt counter electrode, and a Ag wire pseudo-reference electrode. The potential is referred to the internally added ferrocene/ferrocenium (Fc/Fc^+) couple.

even though the steric hindrance has increased considerably at this stage, there is still a high degree of permeability for electron transfer to and from the redox centers. However, for the first time electrochemical irreversibility is detected for this first cathodic couple, with a $\Delta E_{pp} = 117$ mV. The second cathodic process remains electrochemically quasi-reversible and chemically reversible.

Drastic irreversible behavior first becomes evident for the more sterically congested 1:4-tiered complex **7a<Ru>12** (Fig. 1d). All redox couples exhibit electrochemically irreversible behavior and, more importantly, for the first time in the series there is evidence of chemical irreversibility. This is clear from the small currents upon scan reversal, both for cathodic as well as anodic waves. The wave exhibiting the largest ΔE_{pp} is the Ru^{2+}/Ru^{3+} couple, at 360 mV. Interestingly, the $E_{1/2}$ values for the three couples remain essentially constant relative to those of the 1:1-, 2:2-, and 2:3-tiered complexes (Table 1). This is in contrast to the recent report by Diederich et al.[20] on potential shifts for zinc porphyrin dendrimers upon successive generation buildup. These authors also observed increased chemical irreversibility as the steric hindrance increased, although they did not mention this explicitly in their work. Since the intervening chemical groups in their systems are nearly the same as those reported here, it is interesting to note this difference in the electrochemical behavior as the dendrimer generation increases; potential shifts could also possibly reflect the difference in counterion penetration in the various dendrimer generations.

Completely irreversible behavior is clearly seen (Fig. 1e) for **9<Ru>12** (2:4). Since it was difficult to measure peak potentials for any of the processes upon scan reversal, no ΔE_{pp} values are reported in Table 1. Note that the peak potential of the

oxidation of the Ru^{2+} center is much more positive than that of the other complexes, but the peak reduction potentials remain remarkably constant. However, what is clear is that the electrochemical processes are chemically irreversible, showing almost no perceptible return upon scan reversals. There is only a hint of a return cathodic wave for Ru^{3+}/Ru^{2+} at + 0.532 V, but none could be detected upon anodic reversal after reduction of the terpyridines.

The reason for the observed chemically irreversible voltammetric responses is currently not well understood. It is possible to speculate that, due to the increased steric hindrance for **9**<**Ru**>**12**, either reduction or oxidation leads to sufficient destabilization. These redox processes occur in the vicinity of the metal center and could result in decomposition of the complex. Such a redox-driven "unlocking" of a complex could form the basis for a reversible formation–decomposition mechanism. This possibility, as well as the full characterization of the redox products, are currently under intense investigation.

In summary, this construction concept allows the synthesis of specific polymacrocascade networks, as well as the incorporation of metal receptor units on or at a precise depth inside the macromolecule, to be controlled. We confirmed earlier that it is possible to encapsulate relevant molecules[21] randomly within a lipophilic region or to bind them covalently at a specific locus in the interior of cascades.[22] We now demonstrate the application of directed complex formation to generate the first stages in the construction of dendritic networks through metal-centered connectivity.

[19] Cyclic voltammograms at 20 °C were recorded on a BAS-100-W electrochemical apparatus from Bioanalytical Systems, Inc. A conventional three-electrode configuration was used with a 3 mm diameter glassy-carbon disk as the working electrode, a platinium counter electrode, and a silver wire pseudo-reference electrode. Electrochemical grade $TBAPF_6$ was recrystallized twice from pure EtOH and pulverized. HPLC grade MeCN was dried over P_4O_{10}, and the vapor transferred directly into the electrochemical cell after three freeze-pump-thaw degassing cycles at 10^{-5}–10^{-6} mm Hg. In general, a 0.5 mL sample solution containing 1 mM metal complex and 100 mM $TBAPF_6$ was prepared by drying the solid reagents directly in the electrochemical cell at 10^{-5}–10^{-6} mm Hg and then transferring the solvent directly into it through the vacuum line.

Stereoselective Syntheses of Retro-Isomers of *N*-Glucoasparagine**

Oliver Frey, Matthias Hoffmann, and Horst Kessler*

Dedicated to Professor Dr. Richard R. Schmidt on the occasion of his 65th birthday

The extension of the structural diversity of peptides is important for the discovery of new lead structures in drug design. For this purpose carbohydrate moieties can be linked to peptides, because they can modulate the biological activity, increase the bioavailability, and improve the solubility of the compounds.[1]

If the sugars are bound, by the natural O-glycosidic linkage, to a serine residue (**1**), or by a N-glycosidic bond to the amide nitrogen of asparagine (**2**), one obtains glycopeptides having a glycosidic bond that is unstable towards base,[2] acid,[3] or enzymes.[4] A more stable linkage between the carbohydrate moiety and the peptide backbone results from a carbon–carbon bond (C-glycoside **3**). Up to now there have been only a few examples of C-glycosylated amino acids in which either the O or N atom is replaced by an isosteric methylene group[5] or the oxygen atom is omitted.[6]

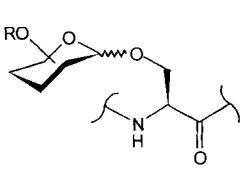
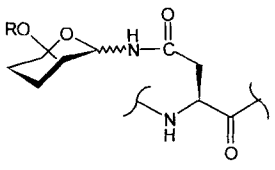
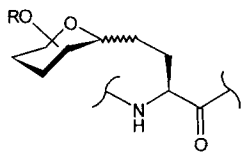
We report now a simple and stereoselective access to the glucoheptonamides **4** and **5**, in which the amide group between the sugar and amino acid is inverted relative to that of the natural N-glycosides (retroamide) to give a pyranose linked by a C-glycosidic bond to the amino acid. Though there are some examples of glucoheptonamides in the literature,[7] none has a retroamide bond between a carbohydrate moiety and an amino acid.



1



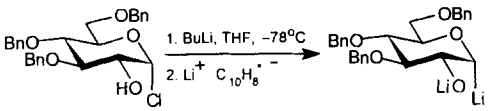
2



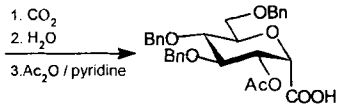
3

To synthesize the desired compounds **4** and **5**, it was necessary to prepare the corresponding sugar acids derived from D-glucose and an amino acid derivative containing an amino function in the β position. The α-configurated acid is particularly interesting, because there is only a single report of an α-heptonic acid,[7b] whereas the β-configurated acids are well known.[8]

The required acid **6** was prepared according to a procedure already described by us:[9] The chlorohydrin **7** was deprotonated with *n*-butyllithium and treated with lithium naphthalenide to give the dianion **8**, which was then trapped by carbon dioxide. The acid was purified by flash chromatography, and then acetylated to give **6** to avoid side reactions during the coupling step to the amide. With this procedure the α-heptonic acid **6** could be isolated in 57% overall yield, starting from **7**.



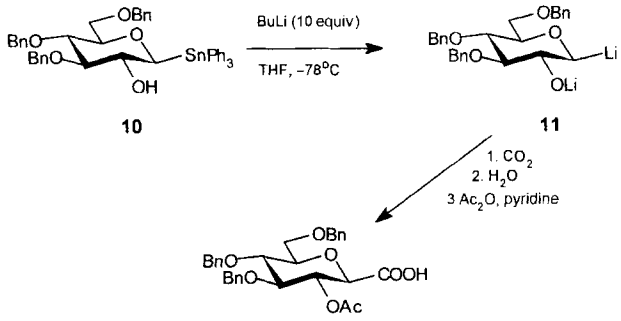
7 **8**



6

The β-heptonic acid **9** was also synthesized according to a procedure that we developed for the stereoselective synthesis of β-C-glycosides:[9b, 10] The readily accessible triphenyltin compound **10**[9] was deprotonated with an excess of *n*-butyllithium and transmetalated to **11**. This dianion was trapped by carbon dioxide, and purified and acetylated in analogy to **6**. The β-heptonic acid **9** could be isolated in 82% overall yield starting from **10**.

The β-aminoalanine derivative **12**, required for the coupling with the sugar acids **6** and **9**, was synthesized according to a procedure of Ranganathan et al., starting from the methyl ester



10 **11** **9**

of Cbz-protected asparagine, and using iodobis(trifluoroacetoxy)benzene.[11] Compound **12** was isolated as trifluoroacetate salt and used in subsequent reactions without purification.

The acid and amino components was first coupled by synthesizing a mixed anhydride of the sugar acid, which was then treated with the amine **12** in analogy to a procedure of Bemiller et al.[12] In the case of the α-heptonic acid **6**, the coupling product **4** was isolated after purification by chromatography in 82% yield. The β-heptonic acid **9** was coupled only in 55% yield by this method to give compound **5**.

An improved procedure was then developed in which the coupling was performed with the classical peptide coupling reagents *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU)[13] and 1-hydroxybenzotriazol (HOBt) in the presence of 2 equivalents of diisopropylethylamine (DIEA) in *N*-methylpyrrolidone (NMP) as solvent. Compound **4** was isolated in 88% by this method, and **5** was now prepared in 70% yield.

The α and β configuration at the anomeric centers of the pyranoses were deduced from the coupling constants between H^1 and H^2 in the ^{1}H NMR spectra, which were found to be 3.2 Hz for compound **4** and 9.2 Hz for compound **5** (Table 1).

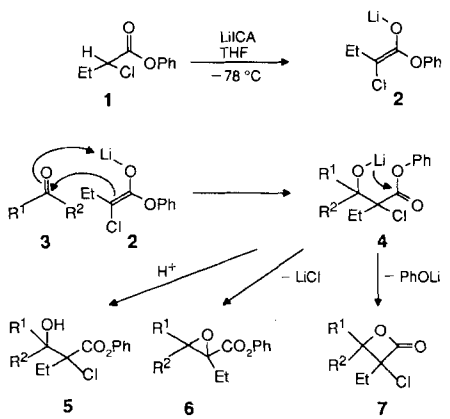
Unexpected Course of the Darzens Reaction of Phenyl Esters of α-Chlorocarboxylic Acids with Carbonyl Compounds—A Novel One-Step Synthesis of α-Chloro-β-lactones**

Christine Wedler, Annamarie Kunath, and Hans Schick*

The Darzens reaction, the classical procedure for the preparation of glycidic esters by condensation of aldehydes or ketones with α-halocarboxylic esters in the presence of a base, has been known for more than 100 years[1, 2] and thoroughly exploited for the synthesis of a large variety of α-halo-β-hydroxy esters and α,β-epoxy esters. By hydrolysis and decarboxylation of the epoxy esters, aldehydes[3] and ketones[4] have been prepared. In most cases methyl, ethyl, isopropyl, and *tert*-butyl esters of α-chlorocarboxylic acids have been used as starting material.[2] To our knowledge the phenyl esters have never been employed in a Darzens reaction. A simple and broadly applicable one-step synthesis of α-chloro-β-lactones, which we report here, has therefore been overlooked until now.

Recently our group found that indium[5] as well as lithium[6] enolates derived from phenyl esters of α-branched or straight-chain carboxylic acids react with ketones to form α,α,β,β-tetrasubstituted or α,β,β-trisubstituted β-lactones in good yields. The question arose whether, instead of the phenyl ester of α-branched carboxylic acids, the phenyl esters of α-halocarboxylic acids could be used for the synthesis of β-lactones with two substituents in α-position, one of them an alkyl group, the other a halogen atom. The success of this idea should depend on whether lithium phenoxide is eliminated more easily than lithium halide from the anticipated intermediate **4**.



Scheme 1. Formation of α-chloro-β-lactones **7** by reaction of the carbonyl compounds **3** with the lithium phenyl ester enolate **2**. (The meaning of R^1 and R^2 is given in Table 1).

In order to decide this question, phenyl 2-chlorobutanoate (**1**) was deprotonated with lithium *N*-cyclohexyl-*N*-isopropylamide (LiICA) in THF at −78 °C to give the ester enolate **2**, which was treated with cyclohexanone **3a**. After workup the α-chloro-β-lactone **7a** was isolated in 80% yield (Table 1, entry 1). This

[a] All compounds were characterized by ^1H and ^{13}C NMR spectra. Correct elemental analysis for C, H, and Cl. [b] The mixture of *syn* and *anti* compound could not be separated by flash chromatography on silica gel. [c] *syn*/*anti*: 2/3. [d] The mixture of *syn* and *anti* compound was separated by flash chromatography on silica gel. [e] *syn*/*anti*: 1/1. [f] *syn*/*anti*: 2/1.

experiment revealed that the elimination of lithium phenoxide is the only observed reaction of the O-lithiated phenyl α-chloro-β-hydroxyalkanoate **4a**. Neither the anticipated α,β-epoxy ester **6a** nor the α-chloro-β-hydroxy ester **5a** seemed to be formed by elimination of lithium chloride from, or protonation of, the intermediate **4a**. The same course of reaction was observed when ketones **3b–f** were treated with the lithium phenyl ester enolate **2**. Again the α-chloro-β-lactones **7b–f** were obtained in acceptable yields (entries 2–6).

It was of interest for the synthesis of less substituted α-chloro-β-lactones to determine whether aldehydes could be included in this reaction. Indeed, the enolizable 3-phenylpropanal **3h** afforded the β-lactone **7h** in 40% yield (entry 8). The nonenolizable pivalaldehyde (**3g**) even gave the β-lactone **7g** in 62% yield (entry 7). However, the reaction was unsatisfactory with butanal. In this case a complicated reaction mixture was formed, from which the corresponding β-lactone could be isolated in contaminated form in only about 10% yield.

Unsymmetrically substituted carbonyl compounds such as butan-2-one (**3d**), acetophenone (**3f**), pivalaldehyde (**3g**), and 3-phenylpropanal (**3h**) yielded diastereomeric products. In all these cases mixtures of *syn* and *anti* β-lactones were obtained in a ratio between 1:1 and 1:2. The β-lactones **7f** and **7g** could be separated into the *syn* and *anti* diastereoisomers by flash chromatography. The configuration of these isomers was assigned on the basis of NOE difference spectroscopy (NOE = *n*uclear *O*verhauser *e*nhancement).

The low diastereoselectivity of the reaction of unsymmetrically substituted carbonyl compounds with the lithium ester enolate **2** (derived from phenyl α-chlorobutanoate **1**) parallels that of the normal Darzens reaction. For instance, the reaction of acetophenone[7] or benzaldehyde[8] with ethyl α-bromopropanoate provides the *syn* and *anti* diastereoisomers in a ratio of about 1:1.

Notwithstanding the outlined stereochemical problems, the described process opens a new one-step approach to many α,β,β-trisubstituted and α,β-disubstituted α-chloro-β-lactones. This class of compounds was previously available from α-chloro-β-hydroxyalkanoic acids by reaction with benzenesulfonyl chloride,[9] but only a few examples have been found in the literature. Except for **7b**[9] all α-chloro-β-lactones **7** described in this paper seem to be new compounds.

In conclusion it can be emphasized that the simple substitution of an alkyl α-chlorocarboxylate by a phenyl α-chlorocarboxylate in the Darzens reaction causes the elimination of lithium phenoxide instead of lithium chloride from the O-lithiated phenyl α-chloro-β-hydroxyalkanoate intermediate **4** and turns the classical Darzens reaction for glycidic ester synthesis into a useful α-chloro-β-lactone synthesis. To our knowledge only one observation in the literature is related to this possibility. Wemple et al. described the formation of **7a** (Me instead of Et) as a side product in the Darzens reaction of cyclohexanone with *S*-*t*-butyl 2-chloropropanethioate.[10] In this case, a competition between lithium chloride and lithium *t*-butyl sulfide elimination from the intermediate **4a** (*t*BuS instead of PhO) led to an α-chloro-β-lactone, but in a yield of only 10%.

Experimental Procedure

A solution of *n*-butyllithium in hexane (1.35 N, 4.4 mL, 6.0 mmol) was added by syringe at −10 °C within 1 min to *N*-cyclohexyl-*N*-isopropylamine (1.10 mL, 6.6 mmol) in THF (20 mL). The mixture was allowed to warm to ambient temperature over 15 min and thereafter cooled again to −78 °C. Then the phenyl α-chlorocarboxylate **1** (1.19 g, 6 mmol), dissolved in THF (5 mL), was precooled with acetone and dry ice to −70 °C in a dropping funnel equipped with a cooling jacket. This solution was slowly added over 30 min to the solution of lithium amide. During the addition the temperature was kept below −70 °C. After the mixture was stirred for additional 20 min at this temperature, a precooled solution of the carbonyl compound **3** (5 mmol) in THF (5 mL) was added over 20 min from the dropping funnel, while the temperature was again kept below −70 °C. Then the mixture was allowed to warm to 0 °C within 2 h. After addition of diethyl ether (50 mL), aqueous NaOH (1 N, 15 mL, 15 mmol), and water (50 mL), the organic phase was separated, washed with 1 N NaOH (2 × 7.5 mL) and brine (2 × 20 mL), dried over Na_2SO_4, and filtered. Removal of the solvent under reduced pressure afforded a pale yellow oil, from which the corresponding α-chloro-β-lactone **7** was isolated by flash chromatography on silica gel with hexane/ethyl acetate (10/1) as eluent.

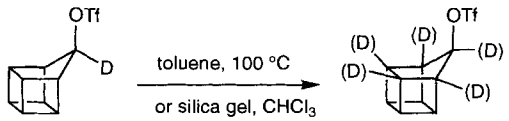
Fluxionality Induced by High Pressure: [9-D]9-Homocubyl Triflate, a Pressure-Sensing Molecule**

Urs P. Spitz and Philip E. Eaton*

1

2

The solvolysis of 9-homocubyl triflate (**1**) and similar derivatives occurs by ionization to a tight ion pair containing the σ-bridged homocubyl cation (**2**).[1, 2] Recently, and in accord with this interpretation, we reported that [9-D]9-homocubyl triflate ([9-D]-**1**) on exposure to heat or to polar solids like silica gel undergoes multiple automerizations that result in scrambling of the deuterium label over five positions of the homocubyl skeleton [Equation (a)].[1] Starting material recovered from incomplete solvolyses of [9-D]-**1** has the label scrambled in the same way. It follows from these

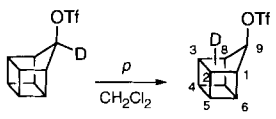


[9-D]-**1** [D]-**1** (a)

observations that only C–C bonds anti to the ionizing group undergo Wagner–Meerwein shifts. Continual automerization results in a formal rotation of a cyclopentyl cation against a cyclobutane ring. Herein we report that these automerizations occur simply upon pressurizing solutions of [9-D]9-homocubyl triflate.

Samples of labeled triflate [9-D]-**1**[1] in dichloromethane were subjected to hydrostatic pressures of about 10000 atm.[3] After various periods of time the triflate was recovered, and the label distribution was determined by proton and deuterium NMR spectroscopy. Under the conditions of high pressure, as is apparent from the data in Table 1, a nonsolvolytic, highly stereoselective scrambling process took place.[4] Exposure for several days (entry 5) led to essentially statistical distribution of the deuterium label [20% C(9), 40% C(1,8) 40% C(2,3)] over the syn face. At normal pressure under otherwise the same conditions no significant scrambling of the label occurred. Although the solution of the triflate darkened during the pressure-induced scrambling process, no significant decomposition could be detected by NMR spectroscopy. This is remarkable because at least ten automerizations, each involving the formation of the ion pair and internal return of the triflate, are necessary to spread the label evenly (±3%) over the five positions. In contrast, thermally induced scrambling of the label of [9-D]-**1**, for example in hot toluene, was accompanied by complete decomposition of the triflate well before the statistical distribution of the label could be reached.[1]

Table 1. Pressure-induced scrambling in labeled triflate [9-D]-**1** as a function of time.



[9-D]-**1** [D]-**1**

Entry	Pressure [atm]	Time [h]	D at position [a] C(9)	C(1,8)	C(2,3)
1	10000	0.25	70	30	≈0
2	10700	1.75	52	41	7
3	9400	6	46	41	13
4	10000	12	23	40	37
5	10000	72	20	40	40

[a] In % (±3%); determined by integration of ^{1}H NMR signals. The comparison with data from the ^{2}H NMR spectra was satisfactory.

Pressure has two very particular effects on chemical reactions.[5] The first, intuitively obvious, follows the ancient principle of Le Chatelier: Increasing pressure is countered by a decrease in volume. Thus, reaction rates are strongly enhanced by pressure if in the transition state molecules associate (negative volume of activation). The second important effect, electrostriction, is less obvious: The polarization induced by a charge (an ion) in a dielectric (a solvent) increases intermolecular forces. This causes the dielectric medium to pack more densely and decrease its volume. Consequently, processes involving charge separation can be promoted by pressure. We suppose that the electrostriction effect is the operating principle in the present examples. In this case, quite extraordinarily, pressure controls the relative rate with which a cyclobutane rotates relative to a cyclopentane ring. This pressure-regulated "molecular gear" is certainly unique.

[3] The apparatus (LECCO model PG-200 HPC) consisted of a steel chamber containing a pressure transmission fluid (castor oil) in which a sample holder was immersed. The system was pressurized by a hydraulically driven differential area piston. The sample was contained in Teflon tubing sealed with glass stoppers.
[4] Significant adiabatic heat is produced during pressurization and might affect the experimental results. To reduce the problem, the experiments were run with samples pre-cooled in ice water, and the pressure was raised relatively slowly.

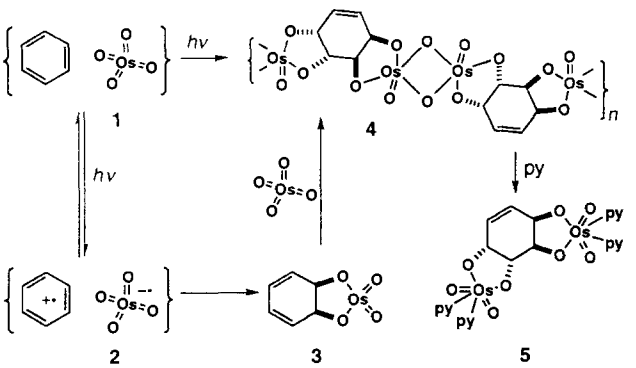
Catalytic Photoinduced Charge-Transfer Osmylation: A Novel Pathway from Arenes to Cyclitol Derivatives**

William B. Motherwell* and Alvin S. Williams

The ability of the enzymatic system present in strains of *Pseudomonas putida* to achieve stereospecific vicinal *cis* dihydroxylation[1] of benzene has spawned recent intense interest among synthetic organic chemists. The resultant *cis* diene diol and functionalized chiral derivatives have been widely used as starting materials for the syntheses of a diverse array of biologically important molecules including conduritols, inositols, prostaglandins, and carbohydrates.[2-4] It was therefore of interest to devise a simple *chemical* method for the production of these useful building blocks, particularly since the commonly encountered reagents for in vitro oxidation of arenes, such as ozone and ruthenium tetraoxide, also lead to the concomitant cleavage of the carbocyclic ring. We now present the results of a preliminary study in which we have achieved the first direct metal-catalyzed, one-pot conversion of benzene and some simple arenes to conduritol and inositol derivatives.

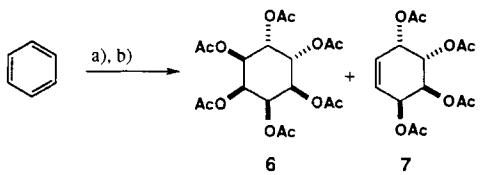
The basis for our work rests on an elegant study by Kochi and Wallis,[5] who demonstrated that actinic (UV) irradiation of the Electron Donor–Acceptor (EDA) complex[6] (**1**) formed on mixing benzene and osmium tetraoxide led, in the presence of an excess of the OsO_4 and at a frequency equal or greater than that of the absorption maxima, to a polymeric 2:1 adduct (**4** Scheme 1), which could be isolated as a monomer (**5**) by the addition of pyridine. The proposed mechanism involves photochemically induced charge transfer from the complex (**1**) to form an ion pair (**2**), which can collapse to the osmate ester of benzene diol (**3**) followed by a second thermal *anti* osmylation.



Scheme 1.

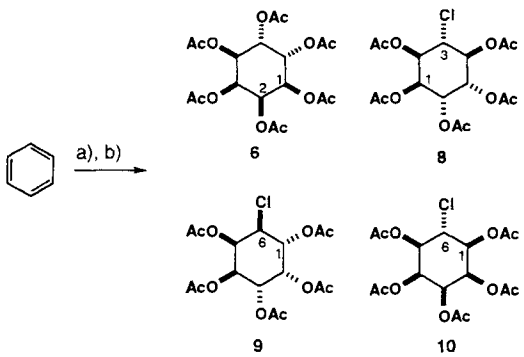
Although yields of the isolated adducts such as **5** were low even in the stoichiometric reaction, we envisaged that such a process could be made catalytic in osmium through careful selection of a suitable solvent system and oxygen atom transfer reagent. In this respect, since the heat of formation of the EDA complex between benzene and osmium tetraoxide has been estimated to be of the order of 0.5 kcal mol^{-1},[6] it was of paramount importance to avoid the use or generation of any molecule whose donor ability would give more stable OsO_4 complexes. Thus a series of simple control experiments served to indicate that *N*-methylmorpholine, pyridine, acetone, and *tert*-butanol were all fatal competitive inhibitors of the EDA complex. The use of aqueous solutions of barium chlorate[7] in a biphasic system with the arene were shown to provide suitable conditions for a catalytic photoosmylation.

In a typical early experiment, irradiation of benzene (0.65 mL) in the presence of aqueous barium chlorate (0.22 M, 75 mL) and osmium tetraoxide (25 mg; 1.3 mol%) led, after reductive workup with sodium disulfite and acetylation, to the *meso* derivative *allo*-inositol hexaacetate (**6**) in 31% yield[8] (Scheme 2). Conduritol E tetraacetate (**7**),[9] which is derived from the major but less reactive *anti*-isomer at the tetrol stage,[10] was also formed in 5% yield. This corresponds to a catalytic turnover for osmium tetraoxide of 76.



Scheme 2. a) OsO_4 (cat.), *hv*, $Ba(ClO_3)_2$ (0.22 M); b) Ac_2O, Et_3N, DMAP; **6**:**7** (6.2:1) 36%.

At a later stage, during studies using a higher chlorate concentration (1.10 M) and a reduced water:arene ratio (1:1.5) (see Experimental Procedure), we were intrigued to note that the formation of deoxychloroinositols is possible (Scheme 3). In this manner, photoosmylation of benzene (15 mL) followed by acetylation provided not only the anticipated *allo*-inositol hexaacetate on a gram scale (1.120 g) but also the deoxychloro-*chiro*- (**8**), *-neo*- (**9**) and *-epi*-inositols (**10**) (0.616 g, 2:2:1 respectively) corresponding to a catalytic turnover of 108 for osmium tetraoxide.



Scheme 3. a) OsO_4 (cat.), *hv*, $Ba(ClO_3)_2$ (1.10 M); b) Ac_2O, Et_3N, DMAP; **8**:**9**:**10** (2:2:1).

Since the formation of derivatives **8**, **9**, and **10** was indicative of competitive *trans* addition of hypochlorous acid at an early intermediate stage, it was of interest to examine the behavior of the inherently even more reactive bromate anion as the oxygen transfer reagent. Even under the original "standard" conditions that led only to vicinal dihydroxylation products with the chlorate anion, brominated derivatives were formed (Scheme 4), and even predominated over *allo*-inositol hexaacetate (**6**; 7.7%). The structure of the major diastereoisomer, isolated in 15.7% yield, was based on its ^1H and ^{13}C NMR

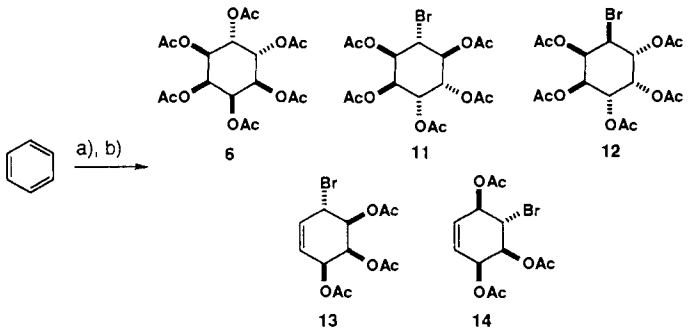
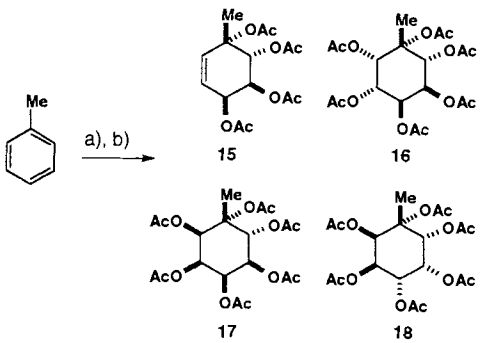


Scheme 4. a) OsO_4 (cat.), *hv*, $NaBrO_3$ (0.22 M); b) Ac_2O, AcOH; **6** 7.7%, **11**:**12** (5.1:1) 18.8%, **13**:**14** (1:5) 2.3%.

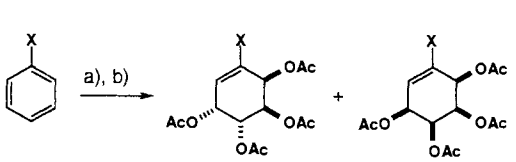
spectra and confirmed by X-ray analysis[11] to be the deoxybromo-*chiro*-inositol (**11**). Minor amounts of the deoxybromo-*neo*-inositol (**12**) (3.1%) and the bromoconduritols C (**13**) and F (**14**) (2.3% yield; **13**:**14** = 1:5) were also isolated.

A preliminary screening of some simple monosubstituted arenes gave the following results: Oxidation of the stereochemically more complex toluene (Scheme 5) was achieved in 13% overall yield (catalytic turnover 29) to the single C-methyl conduritol isomer E (**15**) and an isomeric mixture (ratio 2:1:1) of C-methyl-*allo*-inositols **16**, **17**, and **18** in a conduritol:inositol ratio of 1:5. Inspection of the relative configuration of **15** (X-ray analysis)[11] reveals it to be the precursor of the major portion of the inositol derivatives **16** and **17**, and also suggests that the initial photoosmylation step occurs at either the 1,2 or 3,4 positions. Interestingly, in contrast with the Etard oxidation,[12] which also involves metal-mediated electron transfer, only trace amounts of benzaldehyde were formed.



Scheme 5. a) OsO_4 (cat.), *hv*, $Ba(ClO_3)_2$ (0.22 M); b) Ac_2O, Et_3N, DMAP; **15** 2.2%, **16**:**17**:**18** (2:1:1) 10.8%.

As expected on the basis of their higher ionization potentials, the "catalytic" turnover of the oxidation of halogenated arenes under our initial conditions is very slow indeed (Scheme 6; combined yields: **19** 0.6%, **20** 3.4%, **21** 2.6%). Nevertheless, it is significant to note that no inositol derivatives were detected, presumably since the remaining double bond—a vinylic halide—is resistant to further osmylation on electronic grounds. In these experiments the preference for the formation of the *anti*-tetrols is much higher[13] than in the OsO_4-catalyzed vicinal dihydroxylation of the 2,3-diol produced by oxidation of bromobenzene with *Pseudomonas putida*, where the ratio of **21a**:**21b** is 1.1:1.0.[3c]



19: X=F	**19a**	4.4:1	**19b**
20: X=Cl	**20a**	5.0:1	**20b**
21: X=Br	**21a**	5.5:1	**21b**

Scheme 6. a) OsO_4 (cat.), *hv*, $Ba(ClO_3)_2$ (0.22 M); b) Ac_2O, Et_3N, DMAP; **19** 0.6%, **20** 3.4%, **21** 2.6%.

In view of the many kinetically discrete photochemical and thermal steps involving formation and oxidative hydrolysis of different regio- and stereoisomeric osmate esters during a single reaction sequence, it is not surprising that the nature and relative ratios of the products isolated are influenced by temperature, relative concentrations of reactants and reagents, and the duration of the radiation and its intensity. Although we have not yet carried out systematic optimization studies for each system, the present work indicates for the first time that the controlled catalytic vicinal dihydroxylation of benzene and simple arenes can lead to a variety of usefully functionalized inositol and conduritol derivatives without cleavage of the carbocyclic ring.

Experimental Procedure

6, **8**, **9**, **10**: To deionized water (10 mL) in a 25 mL Pyrex florentine flask fitted with a Teflon tap was added $Ba(ClO_3)_2$ (3.53 g), benzene (15 mL), and OsO_4 (25 mg, 0.1 mmol) in CCl_4 (0.25 mL). The biphasic system was stirred vigorously and irradiated with a 400 W medium-pressure Hg bulb for 43 h. The solution was then cooled to 0 °C and reduced with $Na_2S_2O_5$ (15 g), stirred for a further 2 h, and evaporated to dryness under reduced pressure. The dried salts were then powdered, treated with Et_3N (70 mL), Ac_2O (20 mL), and 4-dimethylaminopyridine (DMAP, catalytic amount), and heated (70 °C) for 3 h. The reaction mixture was cooled (0 °C), water was added (100 mL), and the mixture was filtered through a pad of Celite and extracted with ether (3 × 100 mL). The extract was washed with brine (100 mL), dried over $MgSO_4$, and concentrated at reduced pressure to give a yellow oil, which crystallized on standing. Column chromatography (SiO_2, 70% ether in petroleum spirits) gave, in order of elution, **8** and **9** as a 1:1 mixture (0.495 g, 1.21 mmol), **10** (0.121 g, 0.30 mmol), and **6** (1.120 g, 2.59 mmol). Compound **8** was separated from **9** by HPLC (SiO_2, 25% EtOAc in hexane).

6: ^1H NMR (400 MHz, $CDCl_3$, 55 °C, $CHCl_3$): δ = 2.05 (bs, 18H; 6 × CH_3), 5.30 (m, 2H; H-3, 6), 5.44 (m, 4H, H-1, 2, 4, 5); ^{13}C NMR (100 MHz): δ = 20.5–20.6 (6 × CH_3), 67.4–67.7 (6 × CH), 169.2, 169.3, 169.5 (6 × OCOMe); MS (70 eV, NH_3): *m/z*(%): 450 $[M + NH_4]^+$. Tantalum-Mediated Coupling of Methane and Carbon Dioxide in the Gas Phase**

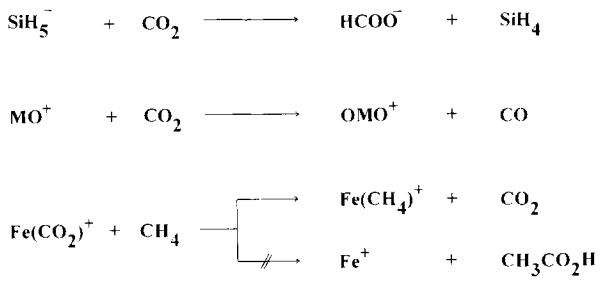
Ralf Wesendrup and Helmut Schwarz*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

Activation of carbon dioxide and its use as a C_1 building block in chemical reactions has been a challenge for chemists for decades.[1] Nature has solved the problem impressively, for example in photosynthesis. Driven by both the advances in organometallic chemistry and in the insights into the mechanisms of biochemical processes that involve reactions of CO_2, substantial progress in CO_2 activation has been made in the past years.[2] For example, quite efficient catalytic systems for the hydrogenation of CO_2 to formic acid have become available, at least on a laboratory scale.[3] However, inherent thermochemical and kinetic problems result in a partial solution at best for the ultimate goal of CO_2 chemistry, the simultaneous coupling of CO_2 with alkanes RH to yield the corresponding carboxylic acids RCO_2H. Formation of acetic acid from CH_4 and CO_2, for example, is endergonic under standard conditions and even 9 kcal mol^{-1} endothermic in the gas phase.[4] Thus, it can only be accomplished by taking advantage of solvation enthalpies in polar solutions or by complexation of the reactants and/or products to a metal center.[1] While ion–molecule reactions in the gas phase are a valuable tool for investigating the elementary steps of organometallic reactions,[5] gas-phase studies on the reactivity of CO_2 are relatively scarce, and a few examples are summarized in Scheme 1.



Scheme 1.

Anions like SiH_5^- can reduce carbon dioxide by hydride transfer to yield the formate anion HCO_2^- [Scheme 1, reaction (a)];[6] analogous results have not yet been reported for cationic systems and are not likely ever to emerge. Of course, CO_2 can be deoxygenated to carbon monoxide by "naked" metal cations or by oxo cations MO^+ [reaction (b)], provided the bond energy of the newly formed (O)M–O bond exceeds 127 kcal mol^{-1}.[7] Recently, Schwarz and Schwarz successfully isolated an $Fe(CO_2)^+$ complex and probed its reactivity towards dihydrogen and methane [reaction (c)].[8a] Unfortunately, hydrogen does not react at all, and only the slow ligand exchange of the intact CO_2 molecule for a methane molecule [reaction (c)] has been observed, but no evidence for the activation of CO_2/CH_4 to generate CH_3CO_2H has been found. Since methane itself is not activated by "bare" Fe^+ [5a, b] cations in the ground state, and the weakly bound CO_2 ligand does not significantly alter the electronic situation of the metal center,[8b, c] this negative finding is not really surprising. However, a transition metal cation that can react with both methane and carbon dioxide might also activate them simultaneously and lead to coupling. Previous experiments demonstrate that the third-row metal ions Ta^+, W^+, Os^+, Ir^+, and Pt^+ dehydrogenate methane in an exothermic reaction to form the corresponding carbene complexes MCH_2^+ as primary ionic product.[9] Only Ta^+ and W^+ form a strong enough M^+–O bond to enable an exothermic reduction of CO_2.[4] For example, when W^+ is treated with CO_2 under single-collision conditions the oxo cation WO^+ is the primary and WO_2^+ the secondary product.[9d] Although Ta^+ cations are highly reactive species that activate even inert molecules like O_2,[10a] NH_3,[10b] benzene,[10c] and SF_6,[10d] to the best of our knowledge its reactivity towards CO_2 has not yet been reported.

In this article we describe the gas-phase reactions of "bare" Ta^+ and its carbene complex $TaCH_2^+$ with CO_2, and we will demonstrate that this system can indeed couple CH_4 and CO_2. All experiments were performed with a Spectrospin CMS 47X FT-ICR mass spectrometer equipped with an external ion source.[11] Ta^+ cations were generated by laser desorption/laser ionization of pure tantalum,[12] and the ions were transferred to the analyzer cell through a system of electric potentials and lenses. Isolation of $^{181}Ta^+$ and all other isolation steps were performed with FERETS.[13] The ions were thermalized by collisions with pulsed-in nitrogen and subsequently reisolated. Background argon pressures of $2-5\times10^{-7}$ mbar was used as a collision gas for additional thermalization and collision induced dissociation (CID) experiments. The oxo cations TaO^+ and TaO_2^+ were generated by the reaction of bare Ta^+ with pulsed-in CO_2, the carbene $TaCH_2^+$ with pulsed-in CH_4, and $[TaCH_2O]^+$ by consecutive pulses of CH_4 and CO_2. Reactant gases were bled into the FT-ICR cell at constant pressure through a leak valve. The pseudo-first-order rate constants were determined from the logarithmic decay of the precursor-ion intensity with

Abbreviations: ICR = ion cyclotron resonance spectroscopy, FERETS = front-end resolution enhancement using tailored sweeps, CID = collision-induced dissociation, ADO = averaged dipole orientation.

time and corrected for reactions with background impurities. The error in the rate constants determined in this way is ±50%.

The temporal evolution and disappearance of the ions in the reaction of Ta^+ with CO_2 are plotted in Figure 1. As expected, TaO^+ is the primary ionic product and reacts further to form the dioxocation TaO_2^+. Both reactions are highly exothermic (−57 and −29 kcal mol^{-1}, respectively) and proceed at collision

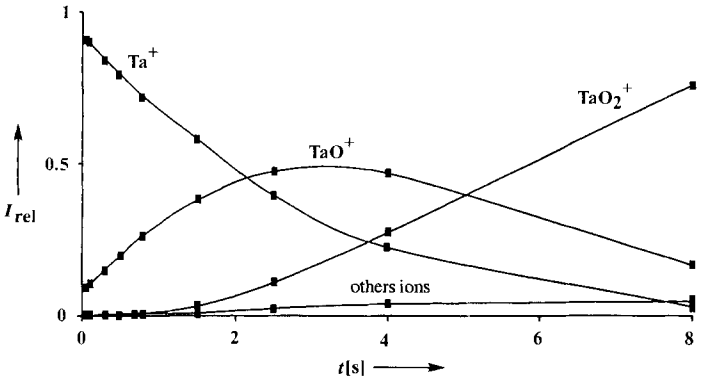

Fig. 1. Intensity vs time curves for the ions in the reaction of Ta^+ and CO_2.

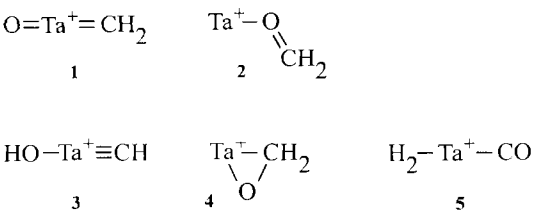
rate.[14] In contrast to many late transition metal oxides,[15] neither TaO^+ nor TaO_2^+ activate methane; this corresponds to an experimental rate constant k_r smaller than 10^{-14} cm^3 molecule^{-1} s^{-1}. We decided therefore to treat CH_4 with Ta^+ first and then to investigate the reactivity of the resulting carbene complex $TaCH_2^+$ towards CO_2.

In fact, $TaCH_2^+$, like the bare Ta^+ cation, is able to deoxygenate CO_2 rapidly ($k_r = 6.9 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}; $k_{ADO} = 6.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) to yield CO and a complex of the elemental composition $[TaCH_2O]^+$ (Fig. 2). The formulas **1**–**5** depict possible connectivities for this species. The



formation of a Ta^+–formaldehyde complex (**2**) can be excluded on thermochemical grounds, since this would require a Ta^+–(CH_2O) bond dissociation energy of more than 70 kcal mol^{-1}. The generation of a mixed dihydrogen carbonyl complex (**5**) can also be ruled out on energetic considerations. More likely, the complex contains a covalent Ta^+–carbon and a Ta^+–oxygen bond. This supposition is reinforced by CID experiments, which generate TaO^+ (44%) and Ta^+ (40%) as major products. As by-products $TaCO^+$ (10%) and TaH_2^+ (6%) are presumably generated by a collision-induced isomerization/dissociation path via intermediate **5**. Since no loss of an OH radical is observed, the hydroxo(carbyne) HO–Ta^+–CH **3** is also not likely to be formed in the reaction of $TaCH_2^+$ with CO_2. However, both the oxo(carbene) **1** and the cyclic structure **4** are in accord with the experimental data, and an unequivocal distinction cannot be made.

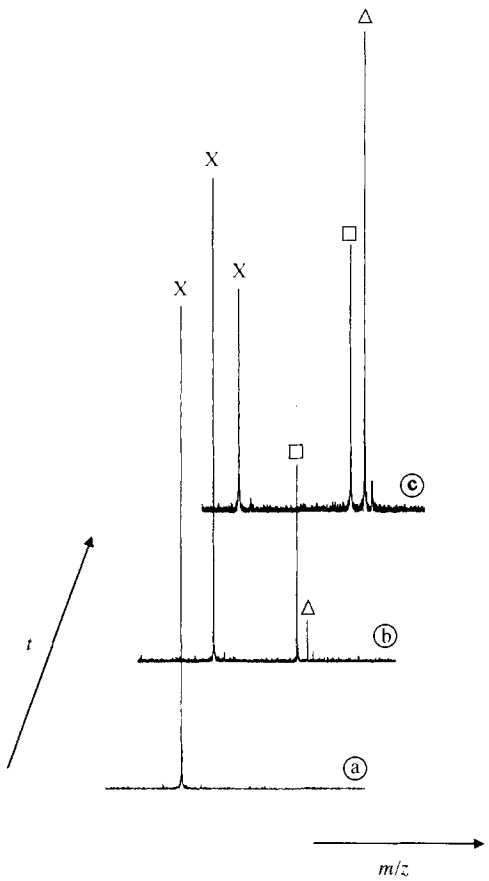


Fig. 2. Section of the mass spectra of $TaCH_2^+$ in the presence of CO_2, recorded after a) 0.3 s, b) 6 s, and c) 16 s reaction time (X: $TaCH_2^+$; □: $Ta[CH_2O]^+$; Δ: TaO_2^+).

Most interestingly, regardless of its actual connectivity, the tantalum complex $[TaCH_2O]^+$ reacts slowly ($k_r = 1.3 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}; $k_{ADO} = 6.3 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) with a further equivalent of CO_2 to yield the dioxo cation TaO_2^+ as the only ionic product (Fig. 2). The more important aspect of this reaction concerns the nature of the neutral product. Although the FT-ICR mass spectrometer does not provide direct structural information on the neutral "C_2H_2O", thermochemical data can be used to narrow down the number of possibilities. Table 1 summarizes the heats of formation for different isomers of "C_2H_2O" or dissociation products thereof. According to this data, the overall reaction $Ta^+ + CH_4 + 2CO_2 \rightarrow TaO_2^+ + H_2 + CO + C_2H_2O$ is exothermic only if genuine ketene ($\Delta H_r = -53$ kcal mol^{-1}) or hydroxyacetylene ($\Delta H_r = -16$ kcal mol^{-1}) (Scheme 2)[16] are formed. On mechanistic grounds, the formation of HC≡COH from either **1** or **4** is quite difficult. The tantalum-mediated coupling of the C_1 units

Table 1. Heats of formation for isomers of C_2H_2O and fragmentation products [a].

Species	ΔH_R [kcal mol^{-1}]
$CH_2=C=O$	−11.4
HC≡COH	25.6 [b]
oxirene	66 [c]
$CH_2 + CO$	67
$C_2HO^{\cdot} + H^{\cdot}$	94
$H_2O + C_2$	141
$CH_2O + C$	145
$HCO^{\cdot} + CH^{\cdot}$	153

$$Ta^+ + CH_4 \longrightarrow TaCH_2^+ + H_2$$

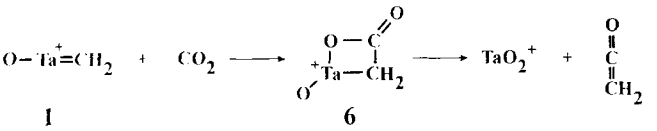
$$TaCH_2^+ + CO_2 \longrightarrow Ta(O)CH_2^+ + CO$$

$$Ta(O)CH_2^+ + CO_2 \longrightarrow TaO_2^+ + C_2H_2O$$

$$Ta^+ + CH_4 + 2\,CO_2 \longrightarrow TaO_2^+ + H_2 + CO + C_2H_2O$$

Scheme 2.

CO_2 and CH_4 and their conversion to ketene by a metathesis reaction involving **1** and **6** (Scheme 3) is more plausible. Interestingly, a related reaction has recently been discovered by Proulx and Bergman in the condensed phase.[18] They investigated the reactivity of a tantalum–carbene complex towards a CO donor and obtained a product containing a vinylidene ($C{=}CH_2$) and a TaO unit. Common to both processes is the fact that new C–C and Ta–O multiple bonds are formed at the cost of C–O and Ta–C bonds. Although the exact mechanism of the metathesis reaction is not yet known, it is quite attractive to suggest a Wittig-like process. This may involve the formation of an oxametallacyclobutanone **6**, followed by ring opening and cleavage to yield the observed products (Scheme 3). While Proulx and Bergman favor a ring fragmentation by a zwitterionic intermediate for their system, a concerted process is more appropriate for the cationic system reported here.



1 **6**

Scheme 3.

The reported sequence of reactions (Scheme 2) demonstrates for the first time that, at a molecular level, activation and coupling of CO_2 and CH_4 to form an acetic acid equivalent, most likely $CH_2{=}C{=}O$, can be achieved by a relatively simple system. Nevertheless, the reaction suffers from the drawback that Ta^+ is used in stoichiometric amounts and consumed as TaO_2^+. While the formation of strong tantalum–oxygen bonds is, on one hand, the driving force for ketene formation, on the other hand the fact that TaO_2^+ cannot be reduced to Ta^+ by any of the common reagents such as dihydrogen or alkanes limits the scope of the reaction. Obviously, the task of developing a genuine catalytic system for acetic acid synthesis, based on methane and carbon dioxide coupling, remains a challenge.

$[Pb_{18}I_{44}]^{8-}$—An Iodoplumbate with an Unusual Structure**

Harald Krautscheid* and Frieder Vielsack

The synthesis and characterization of polynuclear complexes of various compositions have been the subject of increasing interest in the past several years. These types of compounds can be regarded as a link between mononuclear complexes and the corresponding binary solids and may possibly provide insight into the molecular steps in the precipitation of the corresponding insoluble binary phase from solution. The heavier elements of Group 15 form anionic halogeno complexes with either discrete or polymeric anions with a surprising diversity of structures.[1]

In the synthesis of iodobismutate complexes, the solvent, the stoichiometric ratio $Bi^{3+}:I^-$, and the nature and size of the counterion used for crystallization control the structure of the resulting complexes. For example, salts such as $[Li(thf)_4]_4[Bi_5I_{19}]$, with isolated anions, and compounds with infinite one-dimensional anions like $(Bu_4N)[Bi_2I_7]$ or $(Et_3PhN)_2[Bi_3I_{11}]$ can be isolated and characterized by X-ray structure analysis.[2] PbI_2 is also known to form complexes with halide ions; for example $Cs_4[PbI_6]$ contains octahedral $[PbI_6]^{4-}$ ions.[3] Although the compositions of a large number of halogeno complexes of Pb^{II} are known, their structures are mainly undetermined.[4]

PbI_2 has a low solubility in polar organic solvents such as dimethylformamide, acetonitrile, and acetone, which increases upon the addition of an alkali metal iodide. Treatment of the resulting yellow solution with quaternary ammonium salts leads to the formation of ionic lead(II) complexes. According to their elemental analyses, some of these salts have the composition $(R_4N)[PbI_3]$. A single-crystal X-ray structure analysis for the $(Me_4N)[PbI_3]$ complex confirmed the composition and showed that the polymeric anion $[PbI_3]^-$ consists of an infinite chain of *trans*-face-sharing PbI_6 octahedra.[5]

We are currently investigating the possibility of synthesizing iodoplumbate complexes of different structure types and report here the structure of $(Bu_4N)_8[Pb_{18}I_{44}]$ (**1**), which is formed according to Equation (a).

$$18\,PbI_2 + 8\,NaI + 8\,Bu_4NPF_6 \xrightarrow[-8\,NaPF_6]{\text{acetone/ether}} \underset{\mathbf{1}}{(Bu_4N)_8[Pb_{18}I_{44}]} \qquad \text{(a)}$$

Compound **1** crystallizes in space group $I4/m$[6] with two formula units and 32 molecules of acetone in the unit cell.[7] According to the results of the X-ray structure analysis the anion of **1** has crystallographic $4/m$ symmetry (D_{4h}) approaching even O_h symmetry. Figure 1 shows that the outer 38 (I1, I2, I4, I5, I6, I7, I9) of a total of 44 I atoms are arranged as a v_3-octahedron (an octahedron with a threefold edge length; thus with four I atoms on each edge and ten I atoms on each face of the octahedron). Inside the v_3-I-octahedron there is a v_2-octahedron (three Pb atoms on each edge of the octahedron) consisting of 18 Pb atoms. Inside this lies a simple octahedron formed by six I atoms (I3, I8). The I structure is reminiscent of the metal framework in the cluster $[Ni_{38}Pt_6(CO)_{48}H_2]$.[8] The Pb atoms in **1** occupy the octahedral sites of the I_{44} framework. In contrast to the above-mentioned iodoplumbate $(Me_4N)[PbI_3]$,[5] the anion in **1** consists of edge-sharing PbI_6 octahedra. If the $[Pb_{18}I_{44}]^{8-}$ ion is schematically divided into shells of atoms around the unoccupied center, one finds, with increasing distance from the center, an I_6 octahedron (I3, I8), a Pb_{12} cuboctahedron (Pb2, Pb3), an I_8 cube (I4), a Pb_6 octahedron (Pb1, Pb4), a truncated octahedron formed by 24 I atoms (I2, I5, I6, I7) and, on the outside again, an I_6 octahedron (I1, I9).

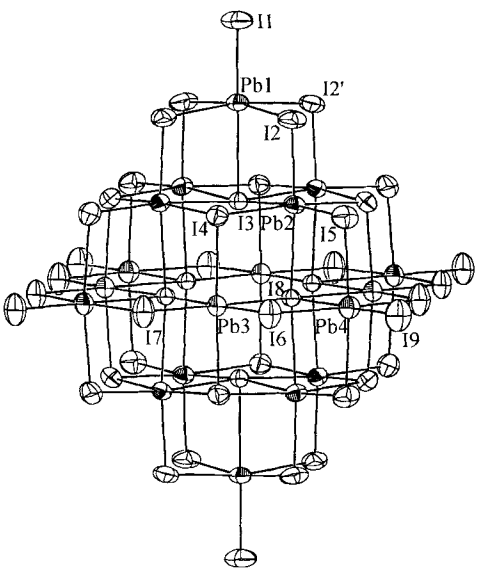

Fig. 1. ORTEP representation of the structure of the anion in **1** (ellipsoids drawn at the 50% probability level). I1, Pb1, I3 and equivalent atoms lie on the fourfold axis. The Pb atoms are marked by hatching of the ellipsoids. Important distances [pm] and angles [°]: Pb1–I1 296.8(2), Pb1–I2 324.57(9), Pb1–I3 352.50(13), Pb2–I2 303.65(9), Pb2–I3 339.19(5), Pb2–I4 323.35(8), Pb2–I5 304.53(9), Pb2–I8 339.34(5), Pb3–I4 322.64(8), Pb3–I6 304.59(11), Pb3–I7 304.46(12), Pb3–I8 337.94(10), Pb4–I5 323.46(9), Pb4–I6 324.69(13), Pb4–I8 352.21(10), Pb4–I9 295.85(12), Pb1–Pb2 474.55(7), Pb3–Pb4 471.43(8), I1–Pb1–I2 95.17(2); I1-Pb1-I3 180, I2-Pb1-I2' 89.536(3), I2-Pb1-I3 84.83(2), I2-Pb2-I3 90.48(3), I2-Pb2-I4 93.14(2), I2-Pb2-I5 95.95(2), I2-Pb2-I8 173.36(2), I3-Pb2-I5 173.56(3), I5-Pb2-I8 90.69(2).

Neglecting the vacant site in the center, $[Pb_{18}I_{44}]^{8-}$ can be described—with idealized symmetry—as an octahedral fraction of the solid-state structure of NaCl. This relationship to the structure of NaCl is reflected in the layered structure of the anion (see Fig. 1). The stacking of the Pb and I layers alternates and can be described as "A γ B α C β A" (where A, B, and C are layers of I atoms, and α, β, γ are layers of Pb atoms). The mean distance between layers formed from I atoms is 373 pm. In contrast, PbI_2 crystallizes in the CdI_2 structure type with "A γ B □, A ..." stacking; other polytype forms are observed as a consequence of variants of stacking. For the most common 2H-form, the distance between I layers for an occupied (Pb) intermediate layer γ is 373 pm, that between I layers for an unoccupied intermediate layer[9] 324 pm. The distances between the Pb atoms in **1** range from 471 to 480 pm, indicating the absence of Pb–Pb bonds. As expected, the Pb–I bond lengths (295.85(12)–352.50(13) pm) depend on the bridging mode of the I ligands: I_{term}–Pb 295.85(12), 256.8(2) pm (I1, I9); μ_2-I-Pb 303.65(9)–324.69(13) pm (I2, I5, I6, I7); μ_3-I-Pb 322.64(8)–323.35(8) pm (I4); μ_5-I-Pb 337.94(10)–352.50(13) pm (I3, I8).

The distances between the Pb atoms in PbI_2 are 456 pm. All I atoms bridge three Pb atoms each; the Pb–I bonds (323 pm) are as long as the μ_3-I-Pb distances in **1**. The μ_2-I ligands in $(Me_4N)[PbI_3]$ bridge the Pb atoms symmetrically with Pb–I distances of 322.3(1) pm; the distance between the Pb atoms is 395.8(1) pm.

The octahedral anions of **1** with edge lengths of 1364 and 1366 pm occupy the vertices and the center of the tetragonal unit cell. The equatorial plane of the octahedra formed by I9 and symmetry equivalent atoms is twisted by 13.4° around the crystallographic *c* axis with respect to the unit cell; thus the shortest distance between two anions is 715 pm (I6 to I9 of the neighboring anions).

Experimental Procedure

Synthesis of **1**: PbI_2 (0.50 g, 1.1 mmol) and NaI (0.09 g, 0.6 mmol) were dissolved in acetone (100 mL). After addition of $(Bu_4N)(PF_6)$ (0.42 g, 1.1 mmol) the solution was filtered, concentrated to 30 mL and over one week ether (20 mL) was condensed into the acetone solution. Highly refractive, yellow, octahedral crystals of **1** are formed in 45% (0.30 g) yield. Reaction of PbI_2 (0.50 g, 1.1 mmol) with NaI (0.16 g, 1.1 mmol) followed by the addtion of $(Bu_4N)(PF_6)$ (0.42 g, 1.1 mmol) led to the formation of $(Bu_4N)[PbI_3]$ [10].

Low-Temperature Tandem Enyne Allene Radical Cyclizations: Efficient Synthesis of 2,3-Dihydroindenes from Simple Enediynes**

Janet W. Grissom* and Dahai Huang

In recent years, the enediyne antitumor antibiotics[1] have received widespread attention due to their unique mechanism of DNA cleavage and unusual structures, which represent a challenging synthetic problem. Synthesis and cyclization of less complex models of enediyne,[2, 3] enyne allene,[4, 5] and enyne ketene[6] systems have also been studied. While considerable effort has been devoted to the synthetic and DNA cleaving studies of these enediynes and enyne allenes,[1-5] limited attention has been focused on trapping the intermediate diyl in further radical cyclizations.[7-10]

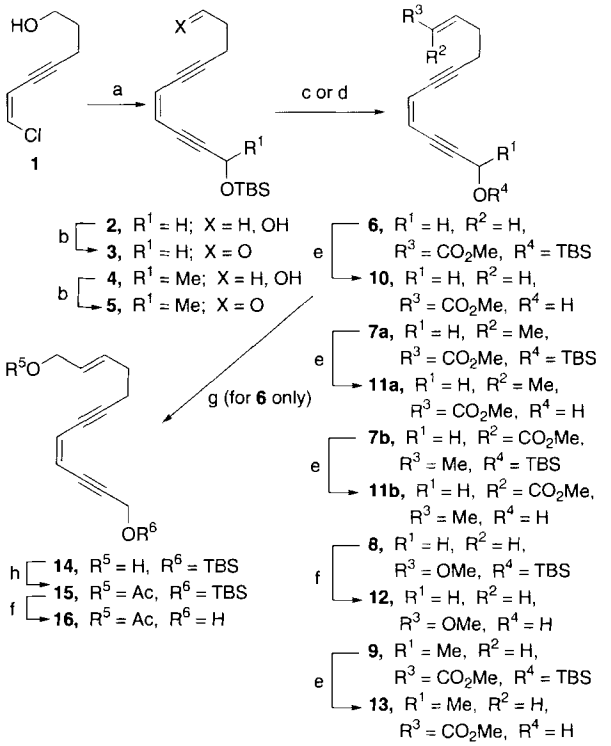
Previously, we have reported that benzindene derivatives can be synthesized in excellent yields by a tandem enediyne radical cyclization of aromatic enediynes.[8a-f] The corresponding non-aromatic enediynes also undergo a similar cyclization to provide indene derivatives;[8g] however, the yields are only moderate. Both reactions require high temperatures (ca. 170–230 °C). More recently, we have developed the tandem enyne allene radical cyclization for the preparation of 2,3-dihydrobenz[*e*]-indenes.[9] Although the reaction proceeds at low temperature (ca. 75 °C) and in excellent yield, the synthesis of the cyclization precursors requires eight to nine steps. In line with our effort to lower the reaction temperature, improve the cyclization of non-aromatic systems, and simplify the synthesis of the reaction precursors, we herein report the synthesis of 2,3-dihydroindenes by a tandem enyne allene radical cyclization that proceeds at 37 °C.

Enediynes **10**–**13** were readily synthesized in four steps from chloroenyne **1**, which can be prepared from commercially available *cis*-dichloroethylene (Scheme 1).[8g] Two consecutive Pd^0-



Scheme 1. a) 3-(*tert*-Butyldimethylsilyloxy)propyne or 3-(*tert*-butyldimethylsilyloxy)butyne (1.2 equiv), $[Pd(PPh_3)_4]$ (0.017 equiv), CuI (0.04 equiv), $nBuNH_2$ (1.7 equiv), benzene, 50 °C (85% for **2**, 79% for **4**); b) PCC, CH_2Cl_2 (75% for **3**, 77% for **5**); c) trimethyl phosphonoacetate or trimethyl (2-methyl)phosphonoacetate (1.5 equiv), LiCl (2.0 equiv), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (1.5 equiv), CH_3CN, room temperature (RT) (86% for **6**, 82% for **7a** and **7b**, $E/Z = 8:1$, 92% for **9**); d) (methoxymethyl)triphenylphosphonium chloride (2.5 equiv), *t*BuOK (2.5 equiv), THF, −78 °C (62% for **8**, $E/Z = 6:1$); e) $Et_2O \cdot BF_3$, CH_2Cl_2, RT (86% for **10**, 80% for **11a**, 82% for **11b**, 84% for **13**); f) tetrabutylammonium fluoride, THF, RT (88% for **12**, $E/Z = 6:1$, 83% for **16**); g) DIBAL, CH_2Cl_2, 0 °C (78%); h) Ac_2O, NEt_3, CH_2Cl_2 (95%). TBS = *tert*-butyldimethylsilyl.

catalyzed coupling reactions under modified Castro–Stephens conditions[11] followed by oxidation with pyridinium chlorochromate (PCC) provided aldehydes **3** and **5**.[8g] A subsequent Horner–Emmons reaction or Wittig reaction followed by desilylation afforded **10**–**13** in excellent yields. Enediyne **16** was

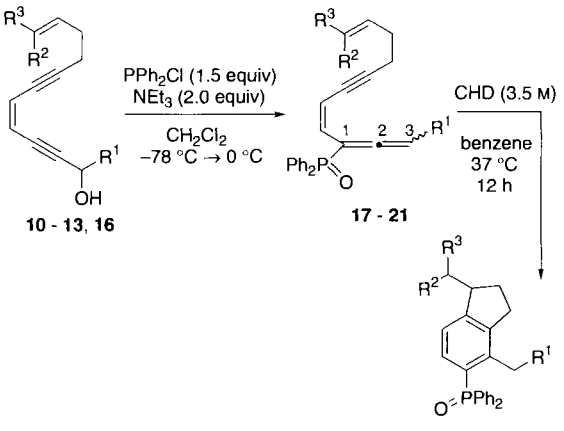
obtained by reduction of **6** with diisobutylaluminum hydride (DIBAL) followed by acetylation and desilylation.[8g]

Given the reliability of the α,β-unsaturated ester as a radical acceptor in tandem enediyne and enyne allene radical cyclizations,[8, 9] we initially decided to investigate the enyne allene **17** (Table 1). When enediyne **10** was treated with PPh_2Cl and NEt_3 in CH_2Cl_2 at −78 °C and the mixture allowed to stir at 0 °C, enyne allene **17** was formed by a [2,3] sigmatropic rearrangement.[5a, b, j] Unfortunately, **17** was isolated in poor yield (ca. 10%) since it decomposes on silica gel and alumina. Therefore the subsequent cyclization was performed without the purification of **17**. Upon mild thermolysis of the crude enyne allene **17** in anhydrous benzene at 37 °C in the presence of 1,4-cyclohexadiene (1,4-CHD, 3.5 M) for 12 h, 2,3-dihydroindene **22** was isolated in 68% overall yield from **10**. It is noteworthy that 2,3-dihydroindene **22** was produced at 37 °C in excellent yield from the tandem enyne allene radical cyclization, whereas synthesis of similar compounds via a tandem enediyne radical cyclization proceeded both at much higher temperatures (ca. 170–230 °C) and in lower yields.[8g]

Table 1. Tandem enyne allene radical cyclization.

Enediyne	Enyne allene	R^1	R^2	R^3	Product	Yield [%] [a]
10	**17**	H	H	CO_2Me	**22**	68
11a	**18a**	H	Me	CO_2Me	**23a, b** [b]	70
11b	**18b**	H	CO_2Me	Me	**23a, b** [b]	67
12 [c]	**19**	H	H	OMe	**24**	55
16	**20**	H	H	CH_2OAc	**25**	62
13	**21**	Me	H	CO_2Me	**26**	52

[a] Overall yield for two steps. [b] Isolated as a 3.5:1 mixture of diastereomers. [c] $E/Z = 6:1$.

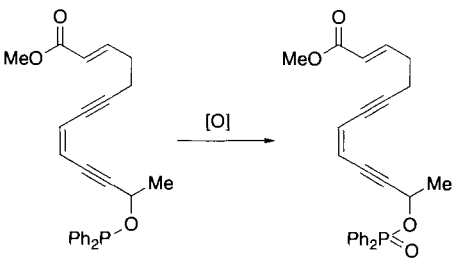


22 - 26

Encouraged by the successful tandem enyne allene radical cyclization of **17**, we thermolyzed enyne allene **18a**, which was generated from **11a** by a [2,3] sigmatropic rearrangement, at 37 °C in the presence of 1,4-CHD (3.5 M) to provide 2,3-dihydroindenes **23a** and **23b** as a 3.5:1 diastereomeric mixture in 70% overall yield from **11a**. When the same reaction sequence was applied to **11b**, 2,3-dihydroindenes **23a** and **23b** were obtained as an identical 3.5:1 diastereomeric mixture in 67% overall yield from **11b**. The fact that the diastereoselectivities observed in both reactions are identical with previous results observed in the tandem enediyne radical cyclizations and the comparable tributyltin hydride mediated radical cyclizations[8b] indicates that the current reaction likely proceeds through a radical intermediate and that the configuration of the double bond within the α,β-unsaturated ester affects neither the diastereoselectivity nor the yield of the radical cyclization.

To test our method with other radical acceptors and to determine the scope of the reaction, both vinyl ether **12** and allylic acetate **16** were subjected to the standard reaction conditions. Treatment of **12** and **16** with PPh_2Cl followed by thermolysis of the corresponding enyne allenes **19** and **20** at 37 °C in the presence of 1,4-CHD (3.5 M) produced 2,3-dihydroindenes **24** and **25** in 55% and 62% overall yields, respectively. It should be pointed out that the tandem enyne allene radical cyclization of **19** bearing a methyl vinyl ether in the side chain occurred smoothly at 37 °C, while the vinyl ether functionality in a nonaromatic enediyne similar to **12** did not survive the tandem enediyne radical cyclization at high temperatures.[8f, g]

Finally, enediyne **13** was chosen to determine how a simple alkyl substituent at the C-3 position of the resulting allene would affect the enyne allene cyclization.[4] When **13** was treated with PPh_2Cl and NEt_3 at −78 °C and the mixture allowed to stir at 0 °C, enyne allene **21** was formed as the major product along with an impurity (ca. 15% based on ^1H NMR). Subsequent thermolysis of the crude **21** at 37 °C in the presence of 1,4-CHD (3.5 M) afforded 2,3-dihydroindene **26** in 52% overall yield from **13** and 12% of a minor product, which is identical with the impurity formed in the [2,3] sigmatropic rearrangement. NMR data suggest that the minor product may be phosphonate **28**, which could arise from oxidation of the corresponding phosphinite **27**.



The mechanism of the overall transformation is outlined in Scheme 2. Enyne allene **17**, generated from a [2,3] sigmatropic rearrangement of the corresponding enediyne **10**, undergoes an enyne allene cyclization to form the biradical **29**. Subsequent 5-*exo* radical cyclization of the aryl radical within **29** followed by H· abstraction from 1,4-CHD furnish the 2,3-dihydroindene derivative **22**.

In conclusion, we have extended the tandem enyne allene radical cyclization to the preparation of 2,3-dihydroindene derivatives. The cyclization precursors can be readily synthesized from commercially available starting materials. In contrast to the tandem enediyne radical cyclization that proceeds at high temperatures (ca. 170–230 °C) and in moderate yields,[8g] the tandem enyne allene radical cyclization of nonaromatic enyne allenes occurs at physiological temperature (ca. 37 °C), and the 2,3-dihydroindenes are formed in good to excellent overall yields. Furthermore, the present method should tolerate a variety of functional groups due to the mild reaction condi-

A Series of Well-Defined Metathesis Catalysts—Synthesis of $[RuCl_2(=CHR')(PR_3)_2]$ and Its Reactions**

Peter Schwab, Marcia B. France, Joseph W. Ziller, and Robert H. Grubbs*

Over the past three years there has been considerable effort in our group to explore the metathesis activity of vinylcarbene ruthenium complexes **1** and **2** which are available from

$RuCl_2(=CH-CH=CPh_2)(PR_3)_2]$, R = Ph (**1**),[1] R = Cy (**2**)[2]

$[RuCl_2(PPh_3)_3]$ and diphenyl cyclopropene. Although these complexes exhibit both high metathesis activity and remarkable stability towards functional groups, the multistep synthesis of the carbene precursors and the low initiation rates of **1** and **2** at present limit their use. The latter phenomenon leads to relatively broad molecular weight distributions in Ring Opening Metathesis Polymerization (ROMP)[3–5] and prolonged reaction times in Ring Closing Metathesis (RCM).[6] We now report that the use of diazoalkanes[7] as an alternative carbene source provides a series of novel alkylidene ruthenium complexes $[RuCl_2(=CHR')(PR_3)_2]$ (R' = alkyl, aryl; R = Ph, Cy) in high yields and that these complexes have high initiation rates.

$[RuCl_2(PPh_3)_3]$ reacts at −78 °C in CH_2Cl_2 with alkyl and aryl diazoalkanes to form **3**–**6**, which are isolated as air-stable green solids in 80–89% yield (Scheme 1). In contrast to **1**, **3**–**6**

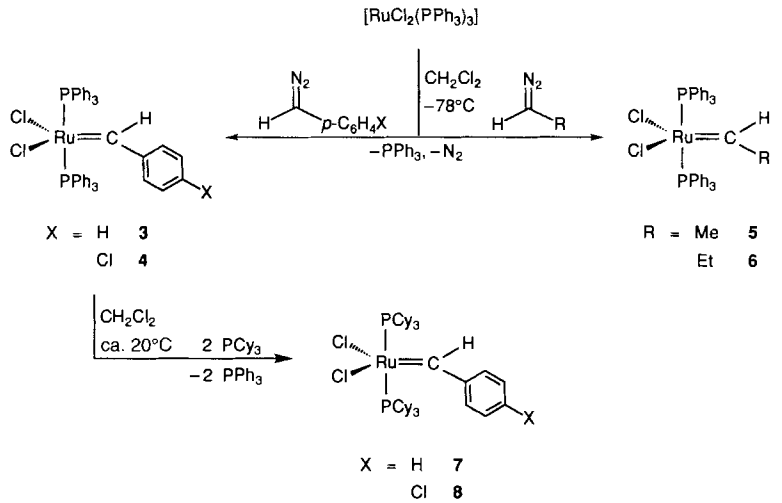

Scheme 1. Synthesis of alkylidene complexes from diazoalkanes and subsequent phosphane exchange. Cy = cyclohexyl.

Table 1. Selected spectroscopic data for compounds **3**–**13** (omitting the ^1H and ^{13}C NMR data for the phosphane ligands).

3: ^1H NMR (300 MHz, C_6D_6): $\delta = 19.56$ (t, $J(P,H) = 10.2$ Hz, Ru=CH), 7.80–7.64 and 6.99–6.66 (both m, C_6H_5); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 310.12$ (t, $J(P,C) = 11.4$ Hz, Ru=CH), 155.36 (s, *ipso*-C of C_6H_5), 130.03, 128.71 and 127.09 (all s, C_6H_5); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 30.63$ (s, PPh_3).

4: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 19.27$ (t, $J(P,H) = 9.2$ Hz, Ru=CH), 7.51–7.44 and 6.88–6.84 (both m, C_6H_4Cl); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 307.34$ (t, $J(P,C) = 10.6$ Hz, Ru=CH), 153.82 (s, *ipso*-C of C_6H_4Cl), 128.87, 128.81 and 128.07 (all s, C_6H_4Cl); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 30.47$ (s, PPh_3).

5: ^1H NMR (300 MHz, CD_2Cl_2): $\delta = 18.47$ (tq, $J(P,H) = 10.2$, $^3J(H,H) = 5.1$ Hz, Ru=CH), 2.59 (d, $^3J(H,H) = 5.1$ Hz, CH_3); ^{13}C NMR (75.5 MHz, CD_2Cl_2): $\delta = 320.65$ (t, $J(P,C) = 9.9$ Hz, Ru=CH), 49.17 (s, CH_3); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 29.99$ (s, PPh_3).

6: ^1H NMR (300 MHz, CD_2Cl_2): $\delta = 18.21$ (tt, $J(P,H) = 10.8$, $^3J(H,H) = 6.6$ Hz, Ru=CH), 3.11 (dq, $^3J(H,H) = {}^3J(H,H') = 6.6$ Hz, CH_2CH_3), 0.79 (t, $^3J(H,H) = 6.6$ Hz, CH_2CH_3); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 320.88$ (t, $J(P,C) = 10.0$ Hz, Ru=CH), 53.20 (s, CH_2CH_3), 29.74 (s, CH_2CH_3); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 30.02$ (s, PPh_3).

7: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 20.02$ (s, Ru=CH), 8.44 (d, $^3J(H,H) = 7.6$ Hz, *o*-H of C_6H_5), 7.56 (t, $^3J(H,H) = 7.6$ Hz, *p*-H of C_6H_5), 7.33 (dd, $^3J(H,H) = {}^3J(H,H') = 7.6$ Hz, *m*-H of C_6H_5); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 294.72$ (s(br.), Ru=CH), 153.17 (s, *ipso*-C of C_6H_5), 131.21, 129.49 and 129.27 (all s, C_6H_5); ^{31}P NMR (202.5 MHz, CD_2Cl_2): $\delta = 36.61$ (s, PCy_3).

8: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 19.98$ (s, Ru=CH), 8.43 (d, $^3J(H,H) = 8.7$ Hz, *o*-H of C_6H_4Cl), 7.29 (d, $^3J(H,H) = 8.7$ Hz, *m*-H of C_6H_4Cl); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 291.46$ (t, $J(P,C) = 8.0$ Hz, Ru=CH), 151.81 (s, *ipso*-C of C_6H_4Cl), 134.64, 132.56, and 129.51 (all s, C_6H_4Cl); ^{31}P NMR (202.5 MHz, CD_2Cl_2): $\delta = 36.81$ (s, PCy_3).

9: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 18.94$ (s, Ru=CH_2); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 294.71$ (t, $J(P,C) = 7.6$, $J(C,H) = 164.0$ Hz, Ru=CH_2); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 43.74$ (s, PCy_3).

10: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 19.26$ (q, $^3J(H,H) = 5.1$ Hz, Ru=CH), 2.57 (d, $^3J(H,H) = 5.1$ Hz, CH_3); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 316.32$ (t, $J(P,C) = 7.6$ Hz, Ru=CH), 49.15 (s, CH_3); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 35.54$ (s, PCy_3).

11: ^1H NMR (500 MHz, CD_2Cl_2): $\delta = 19.12$ (t, $^3J(H,H) = 5.0$ Hz, Ru=CH), 2.79 (dq, $^3J(H,H) = 5.0$, $^3J(H,H') = 7.1$ Hz, CH_2CH_3), 1.35 (t, $^3J(H,H) = 7.1$ Hz, CH_2CH_3); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 322.59$ (t, $J(P,C) = 9.3$ Hz, Ru=CH), 53.48 (s, CH_2CH_3), 29.57 (s, CH_2CH_3); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 36.39$ (s, PCy_3).

12: ^1H NMR (300 MHz, CD_2Cl_2): $\delta = 19.06$ (d, $^3J(H,H) = 10.5$ Hz, Ru=CH), 8.11 (ddd, $^3J(H,H) = 10.5$, $^3J(H,H^{cis}) = 9.3$, $^3J(H,H^{trans}) = 16.8$ Hz, CH=CH_2), 6.25 (d, $^3J(H,H) = 9.3$ Hz, H^{cis} of CH=CH_2), 6.01 (d, $^3J(H,H) = 16.8$ Hz, H^{trans} of CH=CH_2); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 296.00$ (t, $J(P,C) = 7.6$ Hz, Ru=CH), 153.61 (s, CH=CH_2), 115.93 (s, CH=CH_2); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 36.17$ (s, PCy_3).

13: ^1H NMR (300 MHz, CD_2Cl_2): $\delta = 3.63$ (s, Ru=C=CH_2); ^{13}C NMR (125.8 MHz, CD_2Cl_2): $\delta = 327.41$ (t, $J(P,C) = 17.2$ Hz, Ru=C=CH_2), 99.34 (s, Ru=C=CH_2); ^{31}P NMR (161.9 MHz, CD_2Cl_2): $\delta = 35.36$ (s, PCy_3).

decompose in solution (**3** and **4** faster than **5** and **6**) within several hours through bimolecular pathways, as shown by the formation of the corresponding disubstituted olefins R'HC=CHR' (R' = Ph, *p*-C_6H_4Cl, Me, Et). This instability is attributed to a lack of conjugation, which can be inferred from the significant downfield shift of the carbene resonances in the ^1H and ^{13}C NMR spectra [$\delta(^1H) = 17.94$ (**1**), 19.56 (**3**); $\delta(^{13}C) = 288.9$ (**1**), 310.1 (**3**)].

Complexes **3**–**6** are efficient catalysts for the living ROMP of norbornene and substituted cyclobutenes. For example, monodisperse polynorbornene (PDI = $\bar{M}_W/\bar{M}_N = 1.04$) may be prepared from reaction of **3** with 100 equivalents of norbornene in CH_2Cl_2 or C_6H_6 at room temperature (PDI = 1.25 with **1**[11]). Kinetic studies have shown that the initiation rate for **3** is about 1000 times greater than for **1** (for comparison, the ratio of initiation rate to propagation rate $k_i/k_p = 9$ for **3** compared to 6×10^{-3} for **1**[8].)

Treatment of **3** or **4** with two equivalents of tricyclohexyl phosphane results in facile phosphane exchange to give **7** or **8**, respectively, as air-stable solids in 85–90% yield (Scheme 1). In contrast to **3** and **4**, **7** and **8** are stable at 60 °C in C_6D_6 for more than 48 h. Single-crystal X-ray analysis of **8** (Fig. 1)[9] reveals

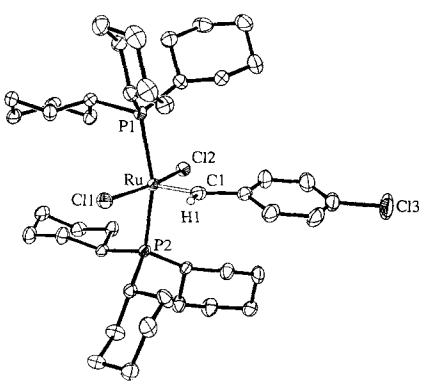

Fig. 1. Crystal structure of **8**. Selected bond distances [Å] and angles [°]: Ru–C1 1.839(3), Ru–Cl1 2.401(1), Ru–Cl2 2.395(1), Ru–P1 2.397(1), Ru–P2 2.435(1), Cl1-Ru-P1 87.2(1), P1-Ru-C1 97.5(1), P1-Ru-Cl2 91.5(1), Cl1-Ru-P2 90.8(1), C1-Ru-P2 101.2(1), Cl1-Ru-C1 88.7(1), Cl1-Ru-Cl2 167.6(1), C1-Ru-Cl2 103.7(1), P1-Ru-P2 161.1(1), Cl2-Ru-P2 86.5(1).

distorted square-pyramidal coordination with a nearly linear Cl1-Ru-Cl2 angle (167.61°). The carbene unit is perpendicular to the P1-Ru-P2-plane, and the aryl ligand is only slightly twisted out of the Cl1-Ru-Cl2-C1-plane. The Ru–C1 bond distance is shorter [1.838(3) Å] than that in **2** [1.851(21)] or in [RuCl(=C(OMe)–CH=CPh_2)(CO)($PiPr_3$)$_2$](BF_4) [1.874(3)].[10]

Besides its remarkable activity in ROMP and RCM reactions, **7** has great potential as a catalyst for metathesis of acyclic olefins (Scheme 2) and is significantly more reactive than the vinylcarbene derivative **2**.[11] Complex **7** is quantitatively converted into [$RuCl_2$(=CH_2)(PCy_3)$_2$] (**9**) by reaction with excess ethylene. To our knowledge, **9** is the *first isolable methylidene complex which is an active metathesis catalyst*. Alkylidene complexes with alkyl substituents on the carbene carbon, such as **10** and **11**, are quantitatively available on reaction of **7** with a small excess of the corresponding terminal olefin and rapid workup.

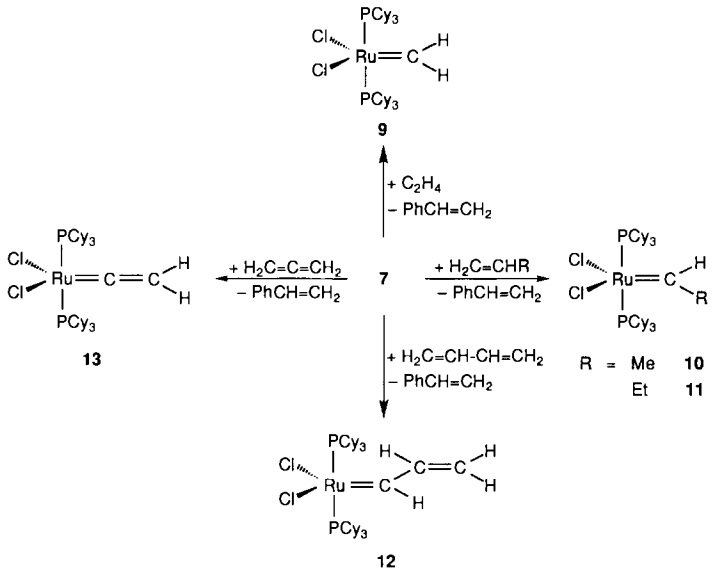

Scheme 2. Methathesis of acyclic alkenes with **7** as catalyst.

However, longer reaction times favor the formation of **9**, which is the sole product after 20 h. This suggests that alkylidene complexes (**10**, **11**) are kinetic products, and the methylidene complex **9** is the thermodynamic product. Complex **7** may be used to prepare substituted carbenes by reaction with excess conjugated and cumulated olefins: The reaction of **7** with 1,3-butadiene leads to the formation of complex **12** with an unsubstituted vinylalkylidene ligand, which cannot be synthesized by ring opening of cyclopropene.[11] In addition, reaction of **7** with excess 1,2-propadiene (allene) leads to the formation of vinylidene complex **13** in essentially quantitative yield.

These results demonstrate that diazoalkanes are excellent carbene sources for the facile synthesis of a wide range of well-defined ruthenium metathesis catalysts of the type $[RuCl_2(=CHR')(PR_3)_2]$. These complexes display greater metathesis activity than **1** and **2** because of facile initiation. The complex with R' = Ph, R = Cy (**7**) not only yields the first metathesis-active methylidene complex (**9**) in quantitative yield, but also serves as an efficient precursor to a variety of alkylidene complexes by cross metathesis. The use of functionalized alkylidenes in the preparation of telechelic polymers, as well as detailed investigations into the kinetics and mechanisms of olefin metathesis processes, are under investigation.

Experimental Procedure

3: A solution of $[RuCl_2(PPh_3)_3]$ (2.37 g, 2.47 mmol) in CH_2Cl_2 (20 mL) was treated at −78 °C with a solution (−50 °C) of phenyldiazomethane (584 mg, 4.94 mmol, 2.0 equiv) in CH_2Cl_2 (3 mL). After the cool-bath had been removed, the solution was stirred for 5 min, and the brown-green solution concentrated to about 3 mL. Upon addition of pentane (20 mL) a green solid precipitated, which was separated from the brown mother liquor, redissolved in CH_2Cl_2 (3 mL), and reprecipitated with pentane. This procedure was repeated until the mother liquor was almost colorless. After drying in vacuo, a grey-green, air-stable microcrystalline solid was recovered; yield 1.67 g (89%). C,H analysis: found: C 65.83, H 4.59%; calcd: C65.65, H 4.61%. Compounds **4**, **5**, and **6** were prepared in a similar way; yield 80–85%.

7: A solution of **3** (242 mg, 0.31 mmol) in CH_2Cl_2 (10 mL) was treated with a solution of tricyclohexylphosphane (190 mg, 0.68 mmol, 2.2 equiv) in CH_2Cl_2 (3 mL) and stirred at room temparature for 30 min. The solvent was removed in vacuo, and the residue repeatedly washed with acetone (5 mL) and dried in vacuo. A purple, air-stable microcrystalline solid was obtained; yield 209 mg (89%). C,H analysis: found: C 62.84, H 8.71%; calcd: C62.76, H 8.82%. Compound **8** was prepared analogously; yield 87%.

9: A solution of **7** (821 mg, 1.00 mmol) in CH_2Cl_2 (15 mL) was stirred under an atmosphere of ethylene for 20 min at room temperature. The solvent was removed in vacuo, and the residue repeatedly washed with acetone or pentane (5 mL) and dried thoroughly in vacuo. A red-purple, air-stable microcrystalline solid was obtained; yield 745 mg (quant.). C,H analysis: found: C 59.42, H 9.29%; calcd: C 59.50, H 9.18%. Compounds **10**–**13** were prepared similarly; yield about 95%.

Polynorbornene from **3**: A solution of norbornene (59 mg, 0.63 mmol) in CH_2Cl_2 (0.7 mL) was treated with a solution of **3** (4.9 mg, 6.25 μmol) in CH_2Cl_2 (0.3 mL). The viscous solution was stirred at room temperature for 1 h, then exposed to air, and treated with CH_2Cl_2 (2 mL) containing traces of 2,6-di-*tert*-butyl-4-methylphenol and ethyl vinyl ether. The solution was stirred for 20 min and, after filtration through a short column of silica gel, precipitated by pouring into vigorously stirred methanol. The white, tacky polymer was washed several times with methanol and dried in vacuo; yield 56 mg (95%), 90% *trans*, M_n = 34.5 kg mol^{-1}, PDI (toluene): 1.04.

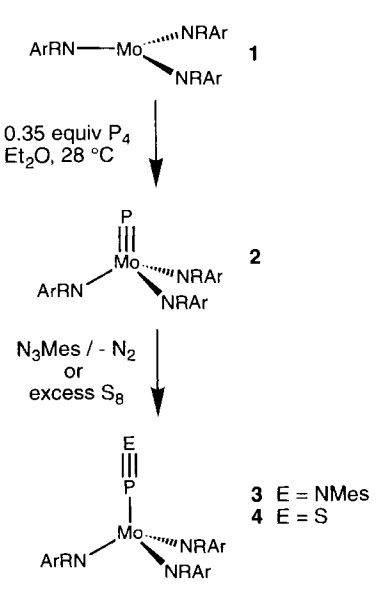
A Molybdenum–Phosphorus Triple Bond: Synthesis, Structure, and Reactivity of the Terminal Phosphido (P^{3-}) Complex $[Mo(P)(NRAr)_3]$**

Catalina E. Laplaza, William M. Davis, and Christopher C. Cummins*

In two recent reports we showed that the three-coordinate molybdenum(III) complex $[Mo(NRAr)_3]$ (**1**, R = $C(CD_3)_2CH_3$, Ar = 3,5-$C_6H_3Me_2$) is an avid nitrogen-atom acceptor; the reactions of **1** with nitrous oxide[1] and dinitrogen[2] both occur with N–N bond cleavage to give the molybdenum(VI) complex $[Mo(N)(NRAr)_3]$ having a terminal nitrido ligand. To determine whether the tendency of **1** to abstract a trivalent atom would extend to a heavier homologue, we investigated the reaction of $[Mo(NRAr)_3]$ (**1**) with white phosphorus (P_4). Accordingly, we present herein the synthesis and structure of the monomeric phosphido (P^{3-}) complex $[Mo(P)(NRAr)_3]$ (**2**), which contains a molybdenum–phosphorus triple bond. Doubly and triply bridging bonding modes for P_1 ligands in bimetallic or trimetallic systems, respectively, are well-documented,[3] but terminal P_1 ligation has not been established previously.[4]

Orange-red $[Mo(NRAr)_3]$ (**1**) is a trigonal-planar, high-spin complex isolobal[5] with a nitrogen or a phosphorus atom. Its stability as a monomeric entity derives at least in part from the considerable steric demands imposed by an array of three NRAr ligands. The monomeric nature of **1** stands in stark contrast with the stability of triply bonded dimers (M≡M) of formula $[M_2X_6]$ (M = Mo, W; X = alkyl, amide, alkoxide).[6] Addition of 0.35 equiv of solid P_4 (a 40% excess) directly to an agitated solution of **1** (0.05 M in ether) resulted in a color change to brown-green over about 45 min (Scheme 1). The deep color of the reaction mixture does not reflect the color of the isolated product, $[Mo(P)(NRAr)_3]$ (**2**), which is yellow-gold both in solution and in the crystalline state. ^1H and ^2H NMR spectra[7] of aliquots taken from the reaction mixture at times varying from 5 to 60 min did not reflect the presence of any intermediate complexes. Analytically pure **2** was obtained in good yield (ca. 79%) by recrystallization from ether at −35 °C. The phosphido (P^{3-}) ligand in **2** is substantially deshielded, exhibiting a ^{31}P NMR signal at $\delta = 1216$. ^1H, ^2H, and ^{13}C NMR spectra of diamagnetic **2** (see Experimental Procedure) are reminiscent of those for the related nitrido complex, $[Mo(N)(NRAr)_3]$.[1] Complex **2** is soluble in standard organic solvents, and is perfectly stable in an inert atmosphere at 28 °C for days in the solid state and in solution.



Scheme 1. Synthesis of **2**–**4**.

The structure of $[Mo(P)(NRAr)_3]$ (**2**, Fig. 1) was determined by single-crystal X-ray diffraction in order to verify its monomeric nature, and to corroberate the proposed terminal bonding mode of the P_1 ligand.[8] The molecule crystallizes as a discrete neutral species with its Mo–P vector on a crystallographic threefold axis. The Mo–P interatomic distance is 2.119(4) Å and is consistent with the presence of a molybdenum–phosphorus triple bond.[9] Complex **2** possesses a pseudotetrahedral $MoPN_3$ core geometry as observed previously for $[Ti(Cl)(NRAr)_3]$[10] and $[Sn(I)(NRAr)_3]$.[11] The latter molecules likewise exhibit the familiar propellor arrangement of the three NRAr ligands, with the unique axial substituent shielded by *tert*-butyl groups. In the crystal structure of **2** this feature is evidenced by an *inter*molecular Mo–P distance of 9.553(3) Å.

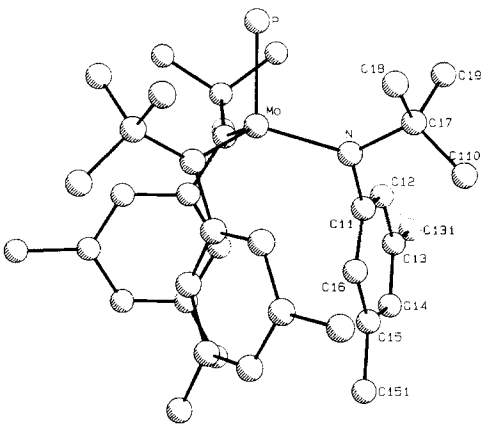


Fig. 1. PLUTO drawing of the molecular structure of **2**. Selected bond lengths [Å] and angles [°]: Mo1–P1 2.119(4), Mo1–N1 1.966(7), N1–C11 1.46(1), N1–C17 1.52(1); P1-Mo1-N1 104.8(2), N1-Mo1-N1 113.7(1), Mo1-N1-C11 111.1(5), Mo1-N1-C17 133.7(5), C11-N1-C17 114.1(6).

Derivatization of $[Mo(P)(NRAr)_3]$ was achieved by treatment with mesityl azide[12] (see Experimental Procedure for details). A process reminiscent of the Staudinger reaction,[13] the reaction proceeded (Scheme 1) with slow (ca. 22 h at 28 °C) conversion to $[Mo(PNMes)(NRAr)_3]$ (**3**). Conversion of **2** to diamagnetic, dark blue-green **3** transpired with no significant accumulation of any observable intermediates (the reaction was monitored by ^1H NMR). We attribute a ^{31}P NMR signal at $\delta = 159$ to the single phosphorus atom in **3**, a reasonable value for two-coordinate phosphorus.[3] It was anticipated for **3** that the angle at phosphorus would be nearly linear, because the molecule is isolobal with the linear nitrosyl derivatives $[Mo(NO)(NRAr)_3]$[14] and $[Cr(NO)\{N(SiMe_3)_2\}_3]$.[15] This expectation was borne out by a single-crystal X-ray diffraction study of $[Mo(PNMes)(NRAr)_3]$ (**3**, Fig. 2).[16] The $PMo(NRAr)_3$ portion of molecule **3** is largely unperturbed relative to **2**. As far as we are aware, **3** provides a unique example of a terminally complexed iminophosphenium ("monophosphadiazonium") (PNR^+) residue.[17]

A unique deep-red phosphorus monosulfide complex $[Mo(PS)(NRAr)_3]$ (**4**) was also readily obtained (Scheme 1)

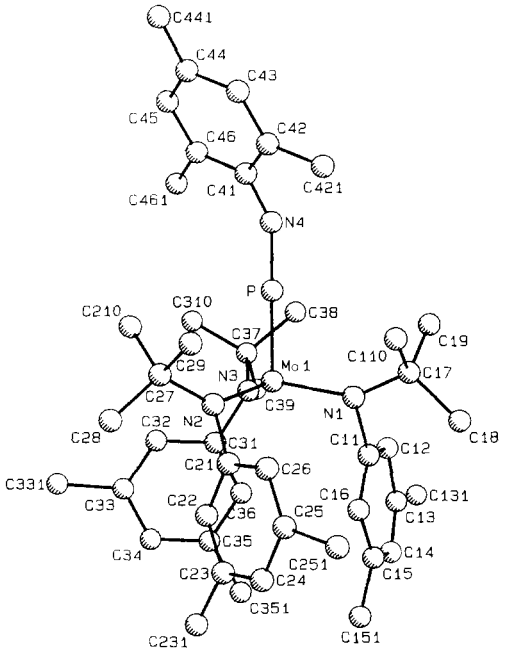

Fig. 2. PLUTO drawing of the molecular structure of **3** [15].

upon treatment of **2** with either an episulfide or excess S_8 (see Experimental Procedure for details).[18] ^{1}H, ^{2}H and ^{13}C NMR spectral data for **4** are consistent with its formulation as a monomeric entity; a ^{31}P NMR signal attributable to **4** was located at $\delta = 383$. Further characterization of **4** is in progress.

Interest in multiple bonding between transition metals and phosphorus has climaxed in recent studies of terminal phosphinidene (PR) complexes[19] (such as those summarized in Scheme 2) following the seminal preparation of $[M(PAr^*)Cp_2]$

$[W(PAr^*)(CO)(PMePh_2)_2(Cl)_2]$ [20] $[Ta(PCy)\{(Me_3SiNCH_2CH_2)_3N\}]$ [21]

$[ZrCp_2(PAr^*)(PMe_3)]$ [22] $[Ta(PPh)(OSi^tBu_3)_3]$ [23]

Scheme 2. Complexes with terminal phosphinidene (PR) ligands. Cy = cyclohexyl, $Ar^* = 2,4,6\text{-}^t Bu_3\text{-}C_6H_2$.

(M = Mo, W; $Ar^* = 2,4,6\text{-}^t Bu_3C_6H_2$) by Lappert and coworkers.[24] Prior reports of naked phosphido ligands engaged in triple bonding to a metal center have been confined to the speculation, by Chisholm and coworkers, that $[W(P)(OCH_2{}^tBu)_3]$ (not observed) was generated upon addition of P_4 to $[W_2(OCH_2{}^tBu)_6(HNMe_2)_2]$.[25] (The *cyclo*-$P_3$ complex $[W(\eta^3\text{-}P_3)(OCH_2{}^tBu)_3(HNMe_2)]$[26] and the tritungsten cluster $[W_3(\mu_3\text{-}P)(OCH_2{}^tBu)_9]$ were ultimately isolated from that reaction.) The work we report here is unique in that a robust complex containing a metal–phosphorus triple bond has been prepared by simple addition of elemental phosphorus (P_4) to a complex of known structure. In a report submitted concurrently with this one, Zanetti, Schrock, and Davis describe an alternative means for installing a terminal P_1 ligand. They report the synthesis of $[M(P)\{(Me_3SiNCH_2CH_2)_3N\}]$ (M = Mo, W) complexes in which the phosphorus atom derives from breakdown of a bound phenylphosphido (PHPh) unit.[4] Many interesting questions concerning the chemical reactivity of the terminal P_1 ligand are now open for study. $[Mo(P)(NRAr)_3]$ (**2**), as a terminal phosphido (P^{3-}) complex, joins phosphaalkynes[3] as a representative of the growing class of one-coordinate phosphorus compounds.

Experimental Procedure

All manipulations were carried out in an atmosphere of dry, oxygen-free nitrogen inside a Vacuum Atmospheres glovebox using appropriately dried and deaerated solvents. $[Mo(NRAr)_3]$ (**1**) was prepared as described previously [1].

2: White phosphorus (136 mg, 1.10 mmol, 0.35 equiv) was added in small pieces to a stirred orange-red solution of $[Mo(NRAr)_3]$ (**1**, 2.015 g, 3.13 mmol) in ether (60 mL) at 28 °C. Over 90 min the color of the reaction mixture became brown-green. The ^{2}H NMR spectrum of an aliquot taken at this time showed that **1** had been completely consumed. The reaction mixture was filtered and the filtrate was concentrated to a volume of about 30 mL. Storing the concentrated filtrate at −35 °C for several hours provided $Mo(P)(NRAr)_3$ (**2**, 1.661 g, 2.46 mmol, 78.7% yield) as a yellow crystalline solid (m.p. 221–224 °C). ^{1}H NMR (C_6D_6): δ = 6.59 (s, 3H, *para* $C_6H_3Me_3$), 5.50 (s, 6H, *ortho* $C_6H_3Me_3$), 1.97 (s, 18H, *meta* $C_6H_3Me_2$), 1.35 (s, 9H, $C(CD_3)_2CH_3$); ^{13}C NMR ($CDCl_3$): δ = 150.03 (s, *ipso* $C_6H_3Me_2$), 136.35 (q, *meta* $C_6H_3Me_2$), 129.84 (d, *ortho* $C_6H_3Me_2$), 127.15 (d, *para* $C_6H_3Me_2$), 59.93 (s, $C(CD_3)_2CH_3$), 33.40 (s, $C(CD_3)_2CH_3$), 32.80 (m, $C(CD_3)_2CH_3$), 21.23 (q, *meta* $C_6H_3Me_2$); ^{31}P NMR (C_6D_6): δ = 1216 (s). Anal. calcd for $C_{36}H_{36}D_{18}MoN_3P$: C 64.17, H 8.08, N 6.24; found: C 64.40, H 8.13, N 6.09.

3: A solution of mesityl azide (253 mg, 1.57 mmol) in ether (2 mL) was added to a stirred solution of **2** (0.400 g, 0.594 mmol) in ether (10 mL). The reaction mixture acquired a blue-green color over several (3 to 4) hours. After a total of 22 h, the reaction mixture was concentrated and cooled to −35 °C to provide [Mo(PNMes)$(NRAr)_3$] (**3**, 0.35 g, 0.43 mmol, 73%) as a dark blue-green crystalline solid (m.p. 181–183 °C). ^{1}H NMR (C_6D_6): δ = 6.95 (s, 2H, *meta* $C_6H_2Me_3$), 6.67 (s, 3H, *para* $C_6H_3Me_2$), 6.00 (br, 6H, *ortho* $C_6H_3Me_2$), 2.80 (s, 6H, *ortho* $C_6H_2Me_3$), 2.28 (s, 3H, *para* $C_6H_2Me_3$), 2.08 (s, 18H, *meta* $C_6H_3Me_2$), 1.45 (s, 9H, $C(CD_3)_2CH_3$); ^{13}C NMR ($CDCl_3$): δ = 149.79 (s, *ipso* $C_6H_3Me_2$), 136.65 (q, *meta* $C_6H_3Me_2$), 131.66 (s), 131.03 (d, *ortho* $C_6H_3Me_2$), 130.00 (s), 129.47 (s), 127.90 (d), 127.82 (d), 61.58 (s, $C(CD_3)_2CH_3$), 34.33 (q, $C(CD_3)_2CH_3$), 34.00 (m, $C(CD_3)_2CH_3$), 21.38 (q, *meta* $C_6H_3Me_2$), 20.68 (q, *para* $C_6H_2Me_3$), 20.21 (q, *ortho* $C_6H_2Me_3$)]; ^{31}P NMR (C_6D_6): δ = 159 (s). Anal. calcd for $C_{45}H_{47}D_{18}MoN_4P$: C 66.97, H 8.12, N 6.94; found: C 67.31, H 8.09, N 6.89.

4: Method a: Elemental sulfur (S_8, 575 mg, 2.24 mmol) was added to a solution of **2** (301 mg, 0.447 mmol) in ether (10 mL). The agitated reaction mixture changed color slowly, over 1.5 d, to purple-red. Consumption of **2** was complete after 43 h according to the ^{1}H NMR spectrum of an aliquot. The excess sulfur was removed by filtration, and the filtrate was cooled and concentrated to give $[Mo(PS)(NRAr)_3]$ (**4**, 197 mg, 0.279 mmol, 62%) as a dark red crystalline solid. Method b: Cyclohexene sulfide (7-thiabicyclo[4.1.0]heptane) (ca. 70 mg, 0.6 mmol, 1.1 equiv) was added dropwise to a magnetically-stirred solution of **2** (353 mg, 0.524 mmol) in ether (10 mL). A color change to purple-red was observed. After 1.5 h, the reaction mixture was filtered, and all volatile material was removed from the filtrate in vacuo. Recrystallization (ether, −35 °C) provided $[Mo(PS)(NRAr)_3]$ (**4**, 186 mg, 0.26 mmol, 50%) as a dark red crystalline solid (m.p. 175–180 °C (decomp)). ^{1}H NMR (C_6D_6): δ = 6.62 (s, 3H, *para* $C_6H_3Me_2$), 5.89 (s, 6H, *ortho* $C_6H_3Me_2$), 2.01 (s, 18H, *meta* $C_6H_3Me_2$), 1.45 (s, 9H, $C(CD_3)_2CH_3$); ^{13}C NMR ($CDCl_3$): δ = 148.37 (s, *ipso* $C_6H_3Me_2$), 136.90 (q, *meta* $C_6H_3Me_2$), 130.76 (d, *ortho* $C_6H_3Me_2$), 128.32 (d, *para* $C_6H_3Me_2$), 63.01 (s, $C(CD_3)_2CH_3$), 33.86 (q, $C(CD_3)_2CH_3$), 33.36 (m, $C(CD_3)_2CH_3$), 21.30 (q, *meta* $C_6H_3Me_2$); ^{31}P NMR (C_6D_6): δ = 383 (s). Anal. calcd for $C_{36}H_{36}D_{18}MoN_3PS$: C 61.25, H 7.71, N 5.95; found: C 61.58, H 7.61, N 5.95.

[7] We use ^{2}H NMR routinely to monitor reactions involving ^{2}H-labeled paramagnetic complexes such as [Mo(NRAr)$_3$] (**1**); see: *NMR of Paramagnetic Molecules* (Eds.: G. N. La Mar, W. D. Horrocks Jr., R. H. Holm), Academic Press, New York, **1973**.

[8] a) A suitable crystal of **2**·THF, of approximate dimensions $0.28 \times 0.24 \times 0.12$ mm, was obtained by cooling a THF solution of **2** to -35 °C. The crystal was mounted on a glass fiber in a stream of cold N_2. Data were collected at -86 °C on an Enraf-Nonius CAD-4 diffractometer with graphite monochromated $Mo_{K\alpha}$ radiation. A total of 2109 reflections were collected to a 2θ value of 45.0°. The structure was solved by direct methods. Non-hydrogen atoms were refined anisotropically except for the THF atoms; the THF molecule is disordered about a symmetry element. The final cycle of least-squares refinement was based on 1585 observed reflections ($I > 3.00\sigma(I)$) and 263 variable parameters and converged with $R = 0.058$ and $R_w = 0.062$. A final difference Fourier map showed no chemically significant features. Crystal data are $a = 11.434(1)$, $c = 18.051(3)$ Å, $V = 2043.7(5)$ Å^3, space group $P6_3$, $Z = 2$, $M_r = 719.80$, and $\rho_{calcd} = 1.169$ g cm^{-3}. b) Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

[9] The P≡P distance in gaseous P_2 is 1.895 Å: N. N. Greenwood, A. Earnshaw, *Chemistry of the Elements*, Pergamon, Oxford, **1984**. The Mo≡Mo distance in [Mo$_2$(NMe$_2$)$_6$] is 2.214 Å: M. H. Chisholm, F. A. Cotton, B. A. Frenz, W. W. Reichert, L. W. Shive, B. R. Stults, *J. Am. Chem. Soc.* **1976**, *98*, 4469. The sum of Mo and P triple bond covalent radii may therefore be taken as 2.055 Å.

[16] A crystal of **3** having approximate dimensions $0.38 \times 0.29 \times 0.12$ mm was mounted on a glass fiber in a stream of cold N_2. Data were collected at -86 °C on an Enraf-Nonius CAD-4 diffractometer with graphite monochromated $Mo_{K\alpha}$ radiation. A total of 5628 reflections were collected to a 2θ value of 54.9°. The structure was solved by direct methods. Non-hydrogen atoms were refined either anisotropically or isotropically. Aromatic rings were refined as rigid groups. Because of poor crystal quality we regard this structure as a confirmation of atom connectivity only, and offer no detailed discussion of bond lengths and angles at this time. The final cycle of least-squares refinement was based on 2943 observed reflections ($I > 3.00\sigma(I)$) and 160 variable parameters and converged with $R = 0.095$ and $R_w = 0.084$. A final difference Fourier map showed no chemically significant features. Crystal data are $a = 22.626(2)$, $b = 18.380(2)$, $c = 10.619(1)$ Å, $V = 4416(2)$ Å^3, space group $Pna2_1$, $Z = 4$, $M_r = 788.95$, and $\rho_{calcd} = 1.186$ g cm^{-3} [8b].

[17] The free "monophosphadiazonium" cation [PNAr*]$^+$ (Ar* = 2,4,6-tBu$_3$C$_6$H$_2$) has been isolated and structurally characterized as its tetrachloroaluminate salt: E. Niecke, M. Nieger, F. Reichert, *Angew. Chem.* **1988**, *100*, 1781; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 1715

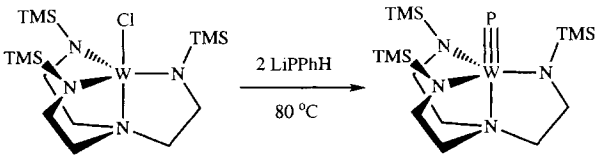
Monomeric Molybdenum and Tungsten Complexes That Contain a Metal–Phosphorus Triple Bond**

Nadia C. Zanetti, Richard R. Schrock,* and William M. Davis

Monomeric complexes of the type [(N$_3$N)Ta=PR] (N$_3$N = [(Me$_3$SiNCH$_2$CH$_2$)$_3$N]$^{3-}$; R = Ph, cyclohexyl, tBu) can be prepared by treating [(N$_3$N)TaCl$_2$] with two equivalents of LiPHR.[1] A crystal structure of [(N$_3$N)Ta=P(cyclohexyl)] showed that the Ta=P bond length is 2.145(7) Å and the Ta-P-C angle is 170(1)°, consistent with strong donation of the phosphorus lone pair to give a Ta–P pseudo triple bond. More recently we have shown that tungsten–carbon triple bonds form remarkably readily by ejection of dihydrogen from d^2 alkyl complexes of the type [(N$_3$N)W(CH$_2$R)],[2] even when β protons are present in the alkyl ligands, which suggests that the W≡C bond in this type of d^0 alkylidyne complex[3] is highly favored thermodynamically. Therefore we speculated that for both steric and electronic reasons, and because of the diagonal relationship between some C and P chemistry,[4] [(N$_3$N)W≡P], a monomeric compound containing the heretofore unknown transition metal to phosphorus triple bond,[4–7] would be a worthwhile and achievable goal. We describe here the synthesis of [(N$_3$N)W≡P] and [(N$_3$N)Mo≡P] by an unconventional route. These results should be compared with the synthesis and structure of [{3,5-Me$_2$C$_6$H$_3$)(tBu)N}$_3$Mo≡P] reported by Cummins et al. in the preceding article in this issue.[8]

The slow reaction between [(N$_3$N)WCl][2] and two equivalents of LiPPhH (toluene/tetrahydrofuran, 4/1, two days) yields yellow, crystalline, pentane-soluble, diamagnetic [(N$_3$N)W≡P] in approximately 50% yield [Eq. (a)]. An X-ray study revealed



(a)

a structure (Fig. 1) that is unremarkable for heavy metal monomeric complexes of this general type[1, 9] except for the presence of a terminal phosphorus ligand 2.162(4) Å from tungsten, a metal–P distance that is essentially the same as that in [(N$_3$N)Ta=P(cyclohexyl)].[1] The ^{31}P NMR signal of [(N$_3$N)W≡P] is found at $\delta = 1080$, but J(P,W) is only 138 Hz (Table 1). This value for J(P,W) should be compared with that of 410 Hz for the planar phosphido phosphorus in [W(CtBu)(PPhH)(PEt$_3$)$_2$Cl$_2$],[10] in which the metal also can be said to be d^0, and J(P,W) = 719 Hz in [(N$_3$N)W(PPhH)] (see below). Such a low value for J(P,W) in the W≡P bond could be indicative of a low % s character in the σ portion of the bond, if the relationship that is so well-known for C–H bonds were to hold also for W–P bonds. The IR spectrum of [(N$_3$N)W≡P]

[+] X-ray structure analysis.

[**] This work is an extension of a program supported by the National Institutes of Health (GM 31978) designed to elucidate chemistry of N$_3$N complexes relevant to the reduction of dinitrogen.

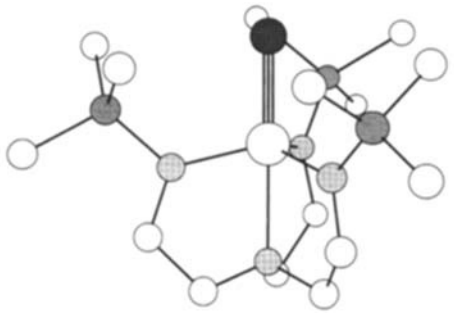

Fig. 1. A Chem 3D drawing of the structure of $[(N_3N)W{\equiv}P]$. Selected bond lengths [Å]: W–P 2.162(4), W–N_{eq} 1.975(6), W–N_{ax} 2.34(1).

Table 1. Selected NMR data for compounds with M(PPhH) and M≡P units.

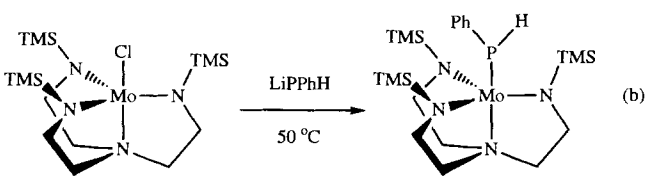
Complex	δP(J(P,W))	δH(J(H,P)·J(H,W))	δ^1H value [a]
$[(N_3N)W(PPhH)]$	91 (719)	18.68 (300,36)	3.37 (t, CH_2) 2.21 (t, CH_2) 0.33 (s, TMS)
$[(N_3N)Mo(PPhH)]$	142	12.16 (283)	3.38 (t, CH_2) 2.35 (t, CH_2) 0.28 (s, TMS)
$[(N_3N)W{\equiv}P]$	1080 (138)	–	3.52 (t, CH_2) 1.69 (t, CH_2) 0.72 (s, TMS)
$[(N_3N)Mo{\equiv}P]$	1346	–	3.36 (t, CH_2) 1.77 (t, CH_2) 0.73 (s, TMS)

[a] N_3N ligand. TMS = trimethylsilyl.

above 550 cm^{-1} is similar to that of $[(N_3N)WCl]$ except for a medium strength peak at 935 cm^{-1}, but we are cautious about ascribing this to the W≡P stretch until further studies are carried out. Since examples of M≡E (M = Mo or W) stretching frequencies include ν(Mo≡N) at 991 cm^{-1} in $[\{(MeNCH_2CH_2)_3N\}Mo{\equiv}N]$[11] and ν(W≡C) at 911 cm^{-1} in $[Cl(Me_3P)_4W{\equiv}CH]$,[12] we would expect the value for ν(W≡P) to be lower than 935 cm^{-1}.

Before the reaction shown in Equation (a) is complete a diamagnetic threefold symmetric species can be observed by NMR spectroscopy along with $[(N_3N)W{\equiv}P]$ and paramagnetic $[(N_3N)WCl]$. We propose that this intermediate is $[(N_3N)W(PPhH)]$ (Table 1) by analogy with the NMR data for the crystallographically characterized $[(N_3N)Mo(PPhH)]$ (see below). $[(N_3N)W(PPhH)]$ is diamagnetic because the lone pair on phosphorus is donated to the metal and the d_{xz}/d_{yz} orbital degeneracy thereby is split, but it still has C_3 symmetry on the NMR time scale. The NMR data for the PPhH ligand in $[(N_3N)W(PPhH)]$ should be compared with those for the PPhH ligand in $[W(CtBu)(PPhH)(PEt_3)_2Cl_2]$[10] ($\delta$P = 233, δH = 10.0, J(P,W) = 410 Hz, J(P,H) = 362 Hz, and J(H,W) = 65 Hz). Reactions between $[(N_3N)WCl]$ and *one* equivalent of LiPPhH also give mixtures that contain $[(N_3N)W{\equiv}P]$, $[(N_3N)WCl]$, and $[(N_3N)W(PPhH)]$.

The reaction between $[(N_3N)MoCl]$ and one equivalent of LiPPhH [Eq. (b)] yields an orange, crystalline diamagnetic



(b)

threefold symmetric species in more than 60% yield that has NMR parameters similar to those for $[(N_3N)W(PPhH)]$ (Table 1) and which was shown in an X-ray study (Fig. 2) to contain a planar phenylphosphido ligand in which Mo–P distance is 2.227(3) Å and the Mo-P-C and Mo-P-H angles are 129.7(2)° and 134(1)°, respectively. The distance between Mo

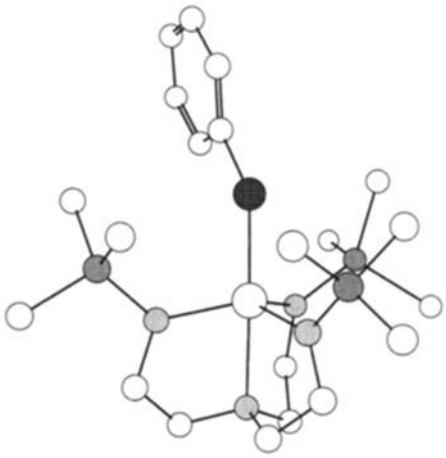


Fig. 2. A Chem 3D drawing of the structure of $[(N_3N)Mo(PPhH)]$. Selected bond lengths [Å] and angles [°]: Mo–P 2.227(3), Mo–N_{eq} 1.992(5), 2.014(5), 2.010(5), Mo–N_{ax} 2.251(5); Mo-P-C 129.7(2), Mo-P-H 134(1).

and H (3.23(1) Å) is too great to invoke any bonding interaction. These data are consistent with a Mo–P pseudo double bond being formed by using one of the two available π-type orbitals pointing toward P along the N-Mo-P (z) axis. An electron pair must be present on Mo in the remaining π-type orbital that lies approximately in the C-P-H-Mo plane. It is interesting to note that a hydrido(phosphinidene) analog of the recently characterized cyclopentylidene hydrido complex, $[(N_3N)W(C_5H_8)(H)]$,[13] is disfavored. Note also that the Mo–N_{axial} distance in $[(N_3N)Mo(PPhH)]$ is shorter (2.26 Å) than the W–N_{axial} distance in $[(N_3N)W{\equiv}P]$ (2.34 Å), consistent with a larger *trans* effect for the W–P triple bond than for the Mo–P pseudo double bond.

Addition of *two* equivalents of LiPPhH to $[(N_3N)MoCl]$ (toluene/THF, 80 °C, 12 h) or one equivalent of LiPPhH to $[(N_3N)Mo(PPhH)]$ (toluene/THF, 25 °C, 2 days) yields yellow crystalline $[(N_3N)Mo{\equiv}P]$ in about 75% yield in which the ^{31}P NMR signal is found at δ = 1346, $\Delta\delta$ = 266 further downfield than the corresponding signal in $[(N_3N)W{\equiv}P]$.

The mechanism of formation of $[(N_3N)M{\equiv}P]$ complexes is not clear at this stage. So far we know that $[(N_3N)Mo{\equiv}P]$ is not observed when a $[D_8]$toluene solution of pure $[(N_3N)Mo(PPhH)]$ is heated at temperatures up to 120 °C for up to three days, even though a solution of pure $[(N_3N)Mo{\equiv}P]$ remains unchanged after being heated to 120 °C for three days. We also have found that $[(N_3N)Mo(PPhH)]$ does not react with butyllithium in $[D_8]$toluene at 25 °C over a period of one day. Preliminary experiments suggest that the reaction between $[(N_3N)WCl]$ and two equivalents LiP(cyclohexyl)H also yields $[(N_3N)W{\equiv}P]$ in more than 50% yield.

The results reported here demonstrate that d^0 terminal phosphido complexes can be formed readily in the sterically protected C_3 environments found in $[\{(Me_3SiNCH_2CH_2)_3N\}M]$ complexes. In future studies we will attempt to elucidate the mechanism of forming terminal phosphido complexes and explore their reactivity patterns, and attempt to prepare analogous terminal arsenido complexes by similar techniques.

Experimental Procedure

All operations were performed under dinitrogen using appropriately dried and degassed solvents. NMR data are reported in [D_6]benzene at 20°C unless otherwise noted. See Table 1 for selected NMR data.

[$(N_3N)W{\equiv}P$]: A mixture of [$(N_3N)WCl$] (164 mg, 0.28 mmol) and LiPPhH (66 mg, 0.57 mmol) in a mixture of toluene (20 mL) and tetrahydrofuran (5 mL) was heated for 2 days at 80°C. The color changed from orange to deep red. The solvent was removed in vacuo and the residue was dissolved in pentane (100 mL). The mixture was filtered and the solvent was removed from the filtrate in vacuo. The resulting orange residue was recrystallized from ether at −40°C; yield 87 mg (53%). Anal. calcd (found) for $WC_{15}H_{39}N_4P$: C 31.36 (31.54), H 6.84 (6.55), N 9.75 (9.48).

[$(N_3N)Mo(PPhH)$]: A solution of [$(N_3N)MoCl$] (135 mg, 0.27 mmol) and LiPPhH (38 mg, 0.33 mmol) in a mixture of toluene (15 mL) and tetrahydrofuran (5 mL) was heated for 12 h at 50°C. The solvent was removed in vacuo and the residue was taken up in pentane (50 mL). The mixture was filtered and the solvent was removed from the filtrate in vacuo. The orange residue was recrystallized from ether at −40°C; yield 109 mg (70%).

[$(N_3N)Mo{\equiv}P$]: A solution of [$(N_3N)MoPPhH$] (60 mg) and LiPPhH (16 mg) in a mixture of toluene (20 mL) and tetrahydrofuran (5 mL) was heated to 70°C for 12 h. The color changed from orange to yellow. The solvent was removed in vacuo and the residue was dissolved in pentane (50 mL). Concentration of the pentane solution in vacuo produced a yellow crystalline solid; yield 42 mg (81%). [$(N_3N)Mo{\equiv}P$] also can be prepared directly from [$(N_3N)MoCl$] in a manner analogous to that used to prepare [$(N_3N)W{\equiv}P$]. Anal. calcd (found) for $MoC_{15}H_{39}N_4P$: C 37.02 (36.80), H 8.08 (7.85), N 11.51 (11.53).

X-ray diffraction study of [$(N_3N)W{\equiv}P$], $WC_{15}H_{39}N_4Si_3P$, $M = 574.58$. A yellow, cubic crystal ($0.280 \times 0.280 \times 0.280$ mm) was determined to possess cubic metric symmetry (25 reflections, 14.0–22.0° in 2θ): $a = 17.166(4)$ Å, $V = 5058(1)$ Å^3, $\rho_{calcd} = 1.509$ g cm^{-3}, space group $Pa\bar{3}$ (no. 205), $Z = 8$, $F(000) = 2304$, $\mu(Mo_{K\alpha}) = 48.72$ cm^{-1}. Data were collected on an Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ ($\lambda = 0.71069$ Å) radiation, at 187 K. Reflections were measured with widths of $(0.80 + 0.35 \tan\theta)°$ in ω in the ω-2θ mode at a rate of between 1.9 and 16.0° min^{-1} in ω to a $2\theta_{max}$ of 44.9°. A total of 3693 reflections were collected, of which 1239 were unique ($R_{int} = 0.08$). Lorentz-polarization, absorption (trans. factors: 0.91–1.06), and secondary extinction (0.30939×10^{-7}) corrections were applied. The structure was solved by standard Patterson and difference Fourier techniques. Full-matrix least squares converged at $R(R_w) = 0.028(0.025)$ and GOF = 1.05 using neutral atom scattering factors and anomalous dispersion terms for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions. Final cycles based upon |F| with 683 observations ($I > 3\sigma(I)$) and 74 variables gave rise to residual electron density of 0.69 e Å^{-3}. All calculations were performed with TEXSAN crystallographic package.

X-ray diffraction study of [$(N_3N)Mo(PPhH)$], $MoC_{21}H_{45}N_4Si_3P$, $M = 564.78$. An orange, prismatic crystal ($0.280 \times 0.140 \times 0.280$ mm) was determined to possess monoclinic metric symmetry (25 reflections, 20.0–30.0° in 2θ): $a = 16.32(2)$, $b = 9.82(2)$, $c = 19.55(2)$ Å, $\beta = 110.7(1)°$, $V = 2932(7)$ Å^3, $\rho_{calcd} = 1.279$ g cm^{-3}, space group $P2_1/n$ (no. 14), $Z = 4$, $F(000) = 1192$, $\mu(Mo_{K\alpha}) = 6.25$ cm^{-1}. Data were collected on a Rigaku AFC6S diffractometer, $Mo_{K\alpha}$ ($\lambda = 0.71069$ Å) radiation, at 173 K. Reflections were measured with widths of $(1.31 + 0.30 \tan\theta)°$ in ω in the ω-2θ mode at a rate of 16.0° min^{-1} in ω (8 rescans) to a $2\theta_{max}$ of 45.2°. A total of 4193 reflections were collected of which 4025 were unique ($R_{int} = 0.125$). Lorentz-polarization, absorption (trans. factors: 0.91–1.06), and secondary extinction (0.16781×10^{-7}) corrections were applied. The structure was solved by standard Patterson and difference Fourier techniques. Full-matrix least squares converged at $R(R_w) = 0.040(0.037)$ and GOF = 1.75 using neutral atom scattering factors and anomalous dispersion terms for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions. Final cycles based upon |F| with 2889 observations ($I > 3\sigma(I)$) and 272 variables gave rise to residual electron density of 0.35 e Å^{-3}. All calculations were performed with TEXSAN crystallographic package. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

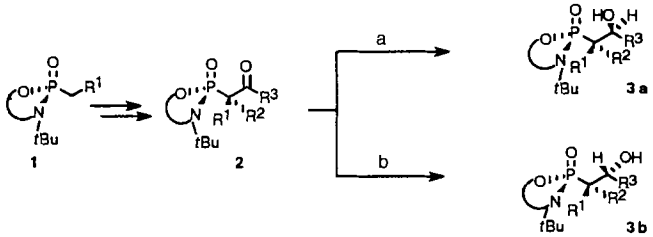
Cerium(III) Chloride Promoted Nucleophilic Addition of Organolithium Reagents to α-Alkyl-β-Ketophosphine Oxides: A New Protocol for the Synthesis of Stereochemically Defined Trisubstituted Olefins

Giuseppe Bartoli,* Enrico Marcantoni, Letizia Sambri, and Monica Tamburini

Given the importance of stereochemically defined carbon–carbon double bonds, extensive effort has been devoted over the years to their stereoselective construction.[1] Nevertheless, while efficient procedures are available for the synthesis of stereochemically defined disubstituted alkenes,[2] a general method for trisubstituted compounds is still needed. The classical Horner method offers poor stereocontrol in the formation of the key phosphine oxide intermediates with a tertiary hydroxyl group in the β-position.[2–4] An efficient access to trisubstituted olefins has been recently proposed by Denmark et al.,[4] who succeeded in adapting the Warren variant of the Horner–Wittig method[5] for the highly stereoselective construction of α-dialkyl-β-hydroxyphosphine oxide intermediates by using the chiral reagent **1** as starting material (Scheme 1). The method is



Scheme 1. Denmark synthesis of α-dialkyl-β-hydroxyphosphamidates. a) Diisobutylaluminum hydride (DIBAL), b) $CeCl_3$, $NaBH_4$, or $LiBHEt_3$ or $LiBH_sBu_3$.

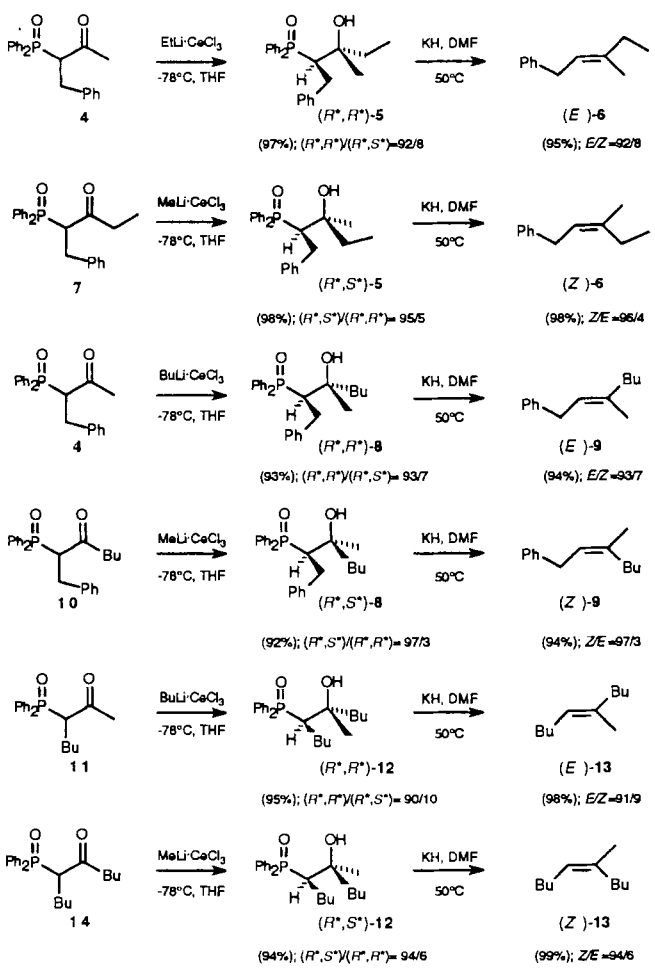
useful for the synthesis of trisubstituted alkenes in both isomeric forms with high diastereoselectivity. However, there are some problems in the key step of the Denmark sequence, the stereoselective reduction of β-ketophosphine oxides **2** to hydroxyl derivatives **3**, the precursors of the alkenes. To ensure high selectivity in all cases, it was necessary to adopt a specific reduction method (with even opposite selectivity) for each pair of diastereomers depending on the nature of R^3 group. In addition, the stereoselective conversion of β-hydroxyphosphonoamidates into the corresponding alkenes requires very drastic conditions (thermal decomposition at 105 °C in THF).

The most straightforward method for constructing Wittig intermediates with high diastereoselectivity is the stereocontrolled addition of a carbon nucleophile to the carbonyl function of a β-ketophosphine oxide with a chiral carbon center in α position.

We report now that this goal can be achieved by using $RLi \cdot CeCl_3$ complexes. As shown in Scheme 2, when racemic



Scheme 2. Synthesis of trisubstituted olefins in both isomeric forms.

β-ketophosphine oxide **4** is allowed to react with the preformed $EtLi \cdot CeCl_3$ complex,[6] (*R**,*R**)-**5**[7] (see Table 1) is obtained in high yields (97%) and with excellent diastereoselectivity[8] (92/8). β-Hydroxyphosphine oxide (*R**,*R**)-**5** is transformed directly into alkene (*E*)-**6**[9] (see Scheme 2 and Table 2) without any purification from the small amount of the corresponding diastereomer. This conversion occurs in high yield (95%) and with excellent stereoselectivity ($E/Z = 92/8$). In an analogous manner, the isomer (*Z*)-**6** can be obtained in high yield (95%) and with excellent diastereoselectivity ($Z/E = 96/4$) from **7**. The same procedure can be used to synthesize olefins (*E*)- and (*Z*)-**9** from **4** and **10**, respectively.

Equally satisfactory results were obtained when the α-alkyl substituent was not a benzyl group. In fact, we were able to convert α-butyl-β-ketophosphine oxides **11** and **14** into (*E*)- and (*Z*)-6-methyl-5-decene ((*E*)- and (*Z*)-**13**), respectively, in comparable high yields and diastereoselectivities.

The present method is characterized by the following features:

a) The procedure is useful for preparing trisubstituted alkenes with excellent diastereoselectivity and in both isomeric forms. In particular the latter goal can be achieved easily by simply exchanging the aliphatic groups on the β-ketophosphine oxide with those of the lithium-cerium complex.

Table 1. Selected ^1H NMR data of α-alkyl-β-hydroxyphosphine oxides.

(*R**,*R**)-**5**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 0.77$ (t, 3H, $J = 7.4$ Hz, CH_2CH_3), 1.35 (s, 3H, CH_3), 1.6 (q, 2H, $J = 7.4$ Hz, CH_2CH_3), 2.9–3.2 (m, 3H, CH_2Ph and CH), 4.7 (br.s, 1H, OH), 4.8 (br.s, 1H, (*R**,*S**)-**5**-OH), 6.7–7.9 (m, 15H, 3Ph)

(*R**,*S*)-**5**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 0.83$ (t, 3H, $J = 7.4$ Hz, CH_2CH_3), 1.2 (s, 3H, CH_3), 1.7 (q, 2H, $J = 7.5$ Hz, CH_2CH_3), 2.8–3.3 (m, 3H, CH_2Ph and CH), 4.7 (br.s, 1H, (*R**,*R**)-**5**-OH), 4.8 (br.s, 1H, OH), 6.7–7.9 (m, 15H, 3Ph)

(*R**,*R**)-**8**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 0.57$ (t, 3H, $J = 6.9$ Hz, $(CH_2)_3CH_3$), 0.6–1.5 (m, 6H, $(CH_2)_3CH_3$), 1.3 (s, 3H, CH_3), 2.7–3.1 (m, 3H, CH_2Ph and CH), 4.79 (br.s, 1H, (*R**,*S**)-**8**-OH), 4.82 (br.s, 1H, OH), 6.6–7.8 (m, 15H, 3Ph)

(*R**,*S**)-**8**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C: $\delta = 0.7$ (t, 3H, $J = 6.8$ Hz, $(CH_2)_3CH_3$), 0.9–1.7 (m, 6H, $(CH_2)_3CH_3$), 1.1 (s, 3H, CH_3), 2.7–3.3 (m, 3H, CH_2Ph and CH), 4.80 (br.s, 1H, OH), 4.83 (br.s, 1H, (*R**,*R**)-**8**-OH), 6.7–7.8 (m, 15H, 3Ph)

(*R**,*R**)-**12**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 0.57$ (t, 3H, $J = 6.8$ Hz, $CH_3(CH_2)_3$), 0.6–1.8 (m, 15H, $CH_3(CH_2)_3$ and $2CH_3(CH_2)_3$), 1.2 (s, 3H, CH_3), 2.3–2.45 (m, 1H, CH), 4.85 (br.s, 1H, (*R**,*S**)-**12**-OH), 4.92 (br.s, 1H, OH), 7.3–7.9 (m, 15H, 3Ph)

(*R**,*S**)-**12**: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 0.60$ (t, 3H, $J = 6.6$ Hz, $CH_3(CH_2)_3$), 0.7–1.9 (m, 12H, $2CH_3(CH_2)_3$), 0.88 (t, 3H, $J = 6.9$ Hz, $CH_3(CH_2)_3$), 1.18 (s, 3H, CH_3), 2.35–2.45 (m, 1H, CH), 4.88 (br.s, 1H, OH), 5.0 (br.s, 1H, (*R**,*R**)-**12**-OH), 7.4–7.9 (m, 15H, 3Ph)

b) The method works well when the substituents are small and similar in size (CH_3, C_2H_5), in contrast to the classical Horner approach.[2]

c) Unlike the Denmark method, the stereochemical outcome is uniform: in all cases examined, the attack of the carbon nucleophile on the β-ketophosphine oxide occurs at the side opposite to the α-alkyl substituent.[10]

d) Stereospecific decomposition of β-hydroxyphosphine oxides to give alkenes requires very mild conditions.[5b, 11]

The method described here is a new protocol for the synthesis of trisubstituted alkenes with excellent diastereoselectivity and in both isomeric forms. It relies on easily available β-ketophosphine oxides as starting materials.[12] Studies are in progress in our laboratory to rationalize the unexpected selective alkylation and to explore the potential of this reaction especially in comparison with other strategies such as that recently published[13] based on addition of organocuprates to phenylthioacetylenes.

Experimental Procedure

α-Alkyl-β-hydroxyphosphine oxides: β-Ketophosphine oxide **6** (2 mmol), prepared according to Warren's method [12c], was added dropwise to a suspension [6] of $RLi \cdot CeCl_3$ (7 mmol) in THF (15 mL) at $-78\,^{\circ}C$. The mixture was stirred at this temperature for 2 h, then quenched with 5 mL of aqueous AcOH (5%) and extracted with Et_2O. The organic layer was washed with saturated $NaHCO_3$ (20 mL) and dried (Na_2SO_4). The product was purified by flash chromatography (SiO_2, ethyl acetate/Et_2O = 1/4) [14].

Trisubstituted alkenes: Compound **8** (1.5 mmol) was dissolved in anhydrous DMF (3 mL), treated with an excess of KH, and heated at 50 °C for 30 min. The mixture was cooled, 5 mL of pentane added, and the resulting solid removed by filtration and washed with pentane. The organic mother liquor was washed with water, dried, and concentrated to dryness. The olefins obtained had purities higher than 99%.

[7] The descriptors *R**, *S** are used throughout the text and in Scheme 2 to indicate that the diastereomeric compounds are obtained as racemates.

[8] Diastereomeric ratios were determined on the basis of the relative intensity of OH signals in ^1H NMR spectrum of the reaction mixture. The configuration was assigned on the basis of the configuration of the final alkene.

[9] Ratios between (*Z*) and (*E*) alkenes were determined by GLC-GM analysis. Configuration of olefins was assigned by NOE experiments.

[10] A possible explanation of this stereochemical outcome is the formation of a six-membered intermediate, in which the Ce atom chelates the P=O and C=O groups. The nucleophile adds to the diastereotopic face of the C=O group opposite the alkyl group on the carbon atom between P=O and C=O. For an analogous situation see: J. Elliott, S. Warren, *Tetrahedron Lett.* **1986**, *27*, 649.

An Alkylperoxoiron(III) Intermediate and Its Role in the Oxidation of Aliphatic C–H Bonds**

Jinheung Kim, Edmund Larka, Elizabeth C. Wilkinson, and Lawrence Que, Jr.*

Alkylperoxoiron(III) species have been invoked in mechanisms of alkane functionalization catalyzed by nonheme iron complexes in concert with alkyl hydroperoxides.[1] These catalytic systems have attracted interest as models for methane monooxygenase[2] and other nonheme iron oxygenases.[3] Ménage et al. have recently observed the transient formation of an intermediate when **1**[4] is treated with ROOH in the presence

$[Fe_2O(bpy)_4(H_2O)_2](ClO_4)_4$ **1**

of alcohols (R'OH).[5] This species has been formulated as a mononuclear Fe(III)-OOR complex, **2**, on the basis of a) its

$[Fe(bpy)_2(OOR)(R'OH)]^{2+}$ **2**

low-spin Fe(III) EPR signal which accounts for as much as 0.8 spin per Fe, b) resonance Raman features associated with the alkylperoxo moiety, and c) the perturbation of spectral features when different alcohols are used. In this paper, we demonstrate that an analogous intermediate can also be formed from a different (μ-oxo)diiron(III) catalyst, **3**, and establish its nature

$[Fe_2O(tpa)_2(H_2O)_2](CF_3SO_3)_4$ **3**

by resonance Raman spectroscopy and electrospray ionization mass spectrometry. We further show that this intermediate is directly responsible for the cleavage of aliphatic C–H bonds required for the oxidation of alcohols by this catalytic system.

Complex **3** has been synthesized and characterized as a (μ-oxo)diiron(III) complex with terminal aqua ligands.[6] In concert with *t*BuOOH (TBHP[4]), **3** catalyzes the oxidation of cyclohexane to cyclohexanol (7 turnovers) and the oxidation of cyclohexanol to cyclohexanone (18 turnovers).[7] In the case of alcohol substrates, treatment of **3** with excess TBHP in CH_3CN at $-40\,^{\circ}C$ affords a transient blue species **4** (λ_{max} 598 nm, Fig. 1)

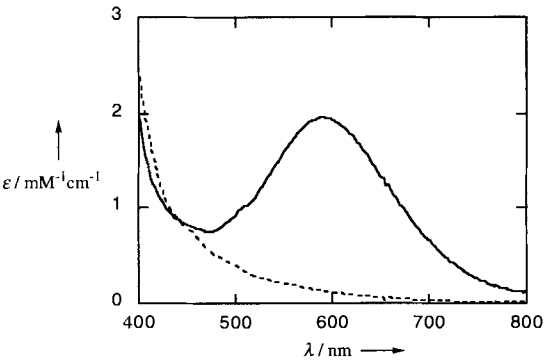

Fig. 1. Electronic spectra of **5** (----) and **4** (——) in CH_3CN for the case R'OH = cyclohexanol. Species **5** was prepared by mixing **3** (0.7 mM) and cyclohexanol (0.14 M). Species **4** was generated by adding TBHP (21 mM) to **5** at $-40\,^{\circ}C$ under argon.

with EPR and Raman properties similar to those of **2**.[5] Complex **4** exhibits an $S = 1/2$ EPR spectrum with $g = 2.19$, 2.14, and 1.98, typical of low-spin Fe(III) complexes and with a signal intensity that accounts for as much as 0.8 spin/Fe (Fig. 2). When excited at 597.8 nm, **4** exhibits resonance-enhanced Raman features at 490, 696, and 796 cm^{-1} (Fig. 3a) which are all

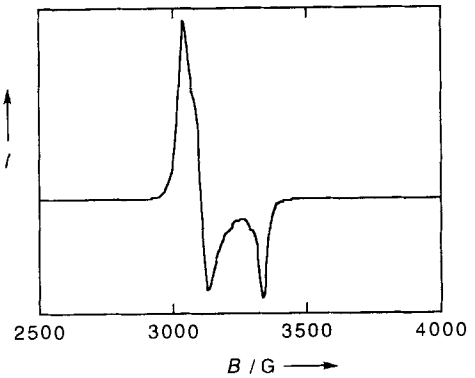

Fig. 2. EPR spectrum of **4** in CH_3CN generated by adding TBHP (21 mM) to **5** (1.4 mM, R'OH = cyclohexanol) at $-40\,^{\circ}C$ under argon. Spectrometer: 9.23 GHz, 15 μW power, modulation amplitude 10 G, temperature 20 K.

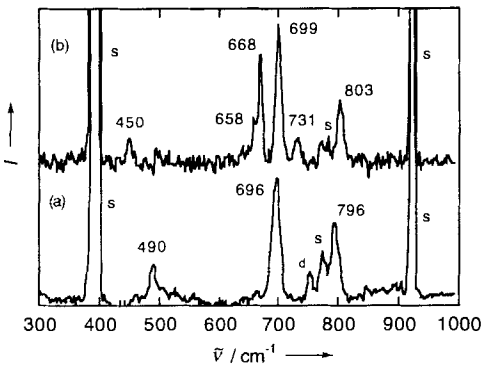

Fig. 3. Resonance Raman spectra (597.8 nm excitation, 77 K) of **4** derived from a) TBHP and b) $[D_9]$TBHP in CH_3CN. Peaks labeled s and d derive from solvent and decomposed product, respectively.

sensitive to the use of $[D_9]$TBHP[8] (Fig. 3b) but insensitive to the presence of $H_2{}^{18}O$; these observations suggest that the blue chromophore arises from an alkylperoxo-to-iron(III) charge transition and not from an iron-oxo species. Thus **4** is a mononuclear iron species with a coordinated alkylperoxo group.

Further spectroscopic studies provide new insight into the formation of the intermediate. NMR and EPR titrations show that the addition of alcohol to dinuclear **3** affords a mononuclear species **5** which is in equilibrium with its precursor. The NMR signals of **3** in the region $\delta = 5$–35 associated with the tpa pyridyl β- and γ-H's of a (μ-oxo)diiron(III) complex[9] are replaced by broader signals at $\delta = 120$, 114 (py β-H), and -18 (py γ-H), typical of a mononuclear high-spin iron(III) species; when dissolved in CD_3OD, **3** is quantitatively converted to **5**. Similarly, increasing amounts of alcohol elicit the appearance of an EPR signal at $g = 4.3$ which is characteristic of a mononuclear high-spin iron(III) center in a rhombic environment. Electrospray ionization mass spectrometry of a solution of **3** treated with 200 equiv $PhCH_2OH$ shows prominent positive and negative ion clusters at m/z 552 and 750, respectively, the observed masses and isotope patterns of which correspond to the ions $[\{Fe(tpa)(OCH_2C_6H_5)\}(ClO_4)]^+$ and $[\{Fe(tpa)(OCH_2C_6H_5)\}(ClO_4)_3]^-$ (Fig. 4a). These features respectively shift to m/z 544 and 742 when CF_3CH_2OH is used in place of $C_6H_5CH_2OH$, consistent with the decreased mass of CF_3 relative to C_6H_5. Species **5** is thus formulated as $[Fe(tpa)(OR')]^{2+}$.

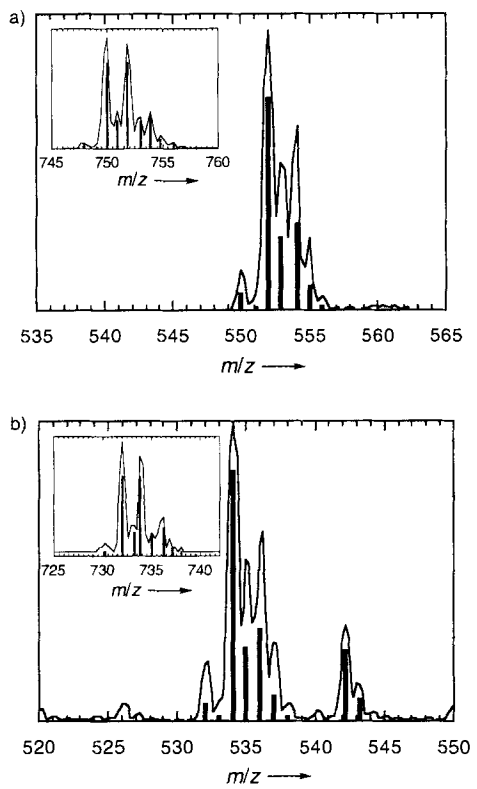

Fig. 4. Positive ion and (as insert) negative ion electrospray ionization mass spectral data. a) **3** + $PhCH_2OH$, b) **4**. Calculated isotope patterns are represented by bars under each peak cluster.

Electrospray ionization mass spectra of **4**, obtained by co-injecting solutions of **3** + alcohol and TBHP into a pre-cooled mixing chamber and channeling the output directly into the mass spectrometer, show prominent ion clusters at m/z 534 and 732, the masses and isotope patterns of which are consistent with the ions, $[\{Fe(tpa)(OO\mathit{t}Bu)\}(ClO_4)]^+$ and $[\{Fe(tpa)(OO\mathit{t}Bu)\}(ClO_4)_3]^-$, respectively (Fig. 4b). Furthermore these ion clusters shift by 62 mass units when CHP[4] is used in place of TBHP. Although these observations may suggest that **4** can be formulated as $[Fe(tpa)OOR]^{2+}$, its low-spin nature would require a six-coordinate species. The sixth ligand may be water or alcohol. The observed ions at m/z 534 and 732 would then derive from the loss of either water or benzyl alcohol from $[Fe(tpa)(OO\mathit{t}Bu)(HOR')]^{2+}$ (R' = H, benzyl) moiety. Evidence for the latter can be found in the positive ion mass spectrum of **4** which also shows a peak at m/z 542 (Fig. 4b). Its mass and isotope pattern correspond to $[Fe(tpa)(OO\mathit{t}Bu)(OCH_2Ph)]^+$ which would derive from the loss of $HClO_4$ from the parent ion $[\{Fe(tpa)(OO\mathit{t}Bu)(HOCH_2Ph)\}(ClO_4)]^+$. The coordination of the alcohol is also supported by kinetic evidence (see below).

Species **4** decomposes in a pseudo-first-order process as monitored by the disappearance of the 598 nm band, but further addition of TBHP re-generates **4**. Its rate of decomposition de-

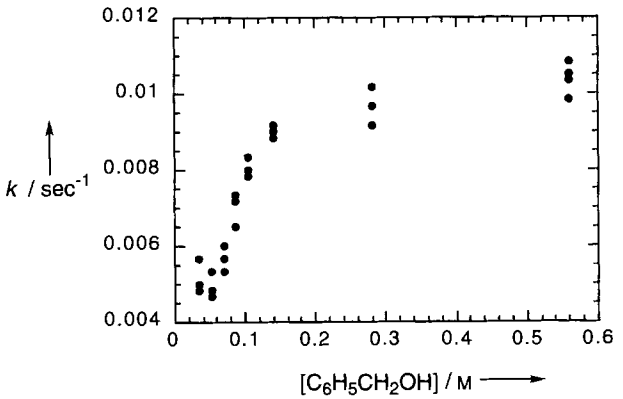

Fig. 5. Dependence of pseudo-first-order decomposition rate constants of **4** on benzyl alcohol concentration. The rates of decomposition were measured with 0.7 mM **3**, 21 mM TBHP, and 0.035–0.56 M benzyl alcohol in acetonitrile at −20 °C under argon. Each point represents one kinetic run.

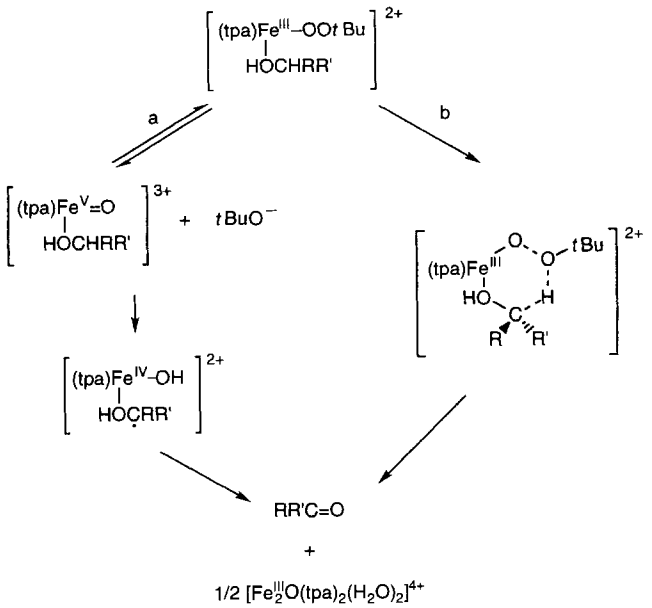
pends on the amount of alcohol present. As shown in Figure 5, the pseudo-first-order rate constant for the decomposition of **4** increases as benzyl alcohol concentration is increased but reaches a plateau at high alcohol concentrations. The observed saturation kinetics implies the binding of alcohol to the complex prior to its decomposition. Furthermore, the decomposition rate decreases significantly in the presence of 200 equiv $C_6D_5CD_2OH$ ($k_H/k_D = 4.8$), indicating that the decomposition of the peroxide intermediate is accompanied by the breaking of the benzylic C–H bond.

Scheme 1 shows two mechanisms that are consistent with the observed substrate dependence for the decomposition of **4**.



Scheme 1. Two possible mechanisms for the oxidation of alcohols by peroxides in the presence of **3**.

Pathway *a* is based on the heme precedent[10] but requires that the high-valent iron-oxo species responsible for the C–H bond attack be *reversibly* formed from **4**. That an O–O bond can be formed from a high-valent oxo species and OH^- is suggested by observations of Mascharak and Busch who have independently reported the formation of hydroperoxoiron(III) species by the reaction of iron(III) complexes with PhIO in basic media.[11] However, intermediate **4** is not formed when **5** is treated with PhIO and *t*BuO$^-$ ion. Furthermore, the addition of 100 equiv cumyl alcohol to a 1 mM solution of **4** does not result in the appearance of Raman features that can be attributed to a bound -OO-cumyl group.[12] Thus **4** is not in equilibrium with a high-valent iron-oxo species, and we consider pathway *a* unlikely.

Pathway *b*, on the other hand, involves contemporaneous O–O and C–H bond cleavage via an attractive six-membered ring transition state (Scheme 1). The direct participation of a metal-peroxo species in oxidation mechanisms has been considered in a number of studies involving nonheme systems,[2b, 3b, 13] because of the perceived difficulty of stabilizing a high-valent metal-oxo species in the absence of porphyrins. The data reported here however represents the first kinetic evidence that an alkylperoxoiron(III) species may directly cleave aliphatic C–H bonds. We cannot as yet establish whether an analogous alkylperoxoiron(III) species participates in the alkane oxidations catalyzed by **3**. Since alkanes lack the functionality to coordinate to the metal center, such a species would differ from **4** and may not have a sufficient lifewtime to be observed. Work is in progress to address this problem.

Experimental Procedure

3: A 1:1:4 ratio of $Fe(CF_3SO_3)_3 \cdot 6H_2O$, tpa·3$HClO_4$, and Et_3N was combined in CH_3OH to produce a red solution. A solid was obtained in 78% yield upon treatment with Et_2O. Recrystallization was accomplished by vapor diffusion of Et_2O into a CH_3CN solution of **3** to yield diffraction quality crystals. Anal. calcd for $C_{42}H_{40}F_{12}Fe_2N_8O_{15}S_4$: C 36.96, H 3.33, N 8.21, F 16.30; found: C 36.72, H 3.48, N 8.33, F 16.12.

Electrospray ionization mass spectra were acquired using a PE Sciex API III triple quadrupole mass spectrometer (Norwalk, CT). Samples in CH_3CN were infused into an Upchurch Scientific metal-free static mixing tee (Oak Harbor, WA) using a pair of Harvard Apparatus Model 22 syringe pumps (South Natick, MA), each delivering 20 μL min^{-1} of solution to the mixing tee. The syringes and the mixing tee were cooled with dry ice.

Kinetics: The decrease of the 598 nm band of **4** was monitored on a Hewlett-Packard 8452A diode array spectrometer fitted for low-temperature measurements with a dewar with quartz windows cooled by a Neslab Cryocool CC-100II immersion cooler.

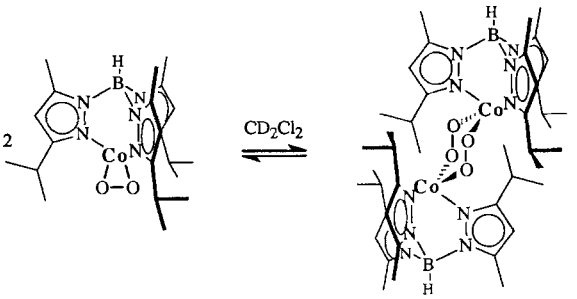
Novel Binuclear Cobalt Dioxygen Complex—A Step on the Path to Dioxygen Activation**

Olivia M. Reinaud, Glenn P. A. Yap, Arnold L. Rheingold, and Klaus H. Theopold*

The "activation" of dioxygen by complexation to transition metals is an important theme of contemporary chemical research.[1] The synthesis and characterization of novel dioxygen complexes (with O_2, O_2^-, or O_2^{2-} ligands) is thus part of the search for catalytic oxidation reactions that use air as an environmentally benign oxidant.[2] Such complexes may also serve as models for the active sites of biomolecules that facilitate transport and utilization of dioxygen in living organisms. Herein we describe the formation of a cobalt dioxygen complex containing an unprecedented structural motif. The cobalt is coordinated by sterically congested tris(pyrazolyl)borate moieties,[3] a class of ligands that have shown a propensity for stabilizing unusual binding modes in dioxygen complexes.[4]

As previously described, exposure of solid [Tp″Co(CO)] (Tp″ = hydrotris(3-isopropyl-5-methylpyrazolyl)borate) to an excess of O_2 gas yielded the dioxygen complex [Tp″Co(O_2)].[5] The spectroscopic characterization of this paramagnetic compound left little doubt that it is a close analogue of the structurally characterized complex [Tp′Co(O_2)] (Tp′ = hydrotris(3-*tert*-butyl-5-methylpyrazolyl)borate),[4b] which was the first example of a dioxygen complex with a symmetrically side-on bound superoxido ligand. However, in marked contrast to the very stable Tp′ complex, the sterically less encumbered [Tp″Co(O_2)] decomposed in solution at room temperature, producing [Tp″Co(μ-O_2)CoTp″] as a transient intermediate, and ultimately leading to hydrogen atom abstraction from the ligand. Below $-10\,^\circ$C [Tp″Co(O_2)] was stable for hours, but its variable-temperature NMR spectra revealed yet another difference between the Tp″ and the Tp′ complexes. Upon progressive cooling of a solution of the paramagnetic [Tp″Co(O_2)] complex in CD_2Cl_2, the five isotropically shifted ^{1}H NMR resonances were gradually replaced by a set of peaks in the range δ = 0–10, indicating the formation of a diamagnetic compound. These spectroscopic changes were reversible, and they were accompanied by changes in the color of the solution. At 270 K the solution appeared brown, similar to the color of [Tp′Co(O_2)]; cooling to 220 K produced a dark green solution. Similar color changes were observed in toluene, THF, and acetonitrile. Higher concentrations of [Tp″Co(O_2)] increased the fraction of the diamagnetic complex. Based on these observations we propose that a monomer–dimer equilibrium (Scheme 1) causes the spectroscopic changes.



$$K_{eq} = \frac{[[Tp''Co(O_2)]_2]}{[Tp''Co(O_2)]^2}$$

Scheme 1. Equilibrium between monomeric and dimeric forms of [Tp″Co(O_2)].

Cooling a concentrated solution of [Tp″Co(O_2)] in acetonitrile to $-30\,^\circ$C yielded green crystals of [{Tp″Co(O_2)}$_2$·2CH_3CN] suitable for a low-temperature X-ray structure determination; apparently the dimer is much less soluble in this solvent and crystallizes out selectively. The molecular structure featuring crystallographic inversion symmetry is depicted in Figure 1.[6] Each cobalt atom is bound to three nitrogen atoms of its Tp″ ligand and to two oxygen atoms; the coordination environment about the metal closely approximates an idealized square pyramid. There are two dioxygen molecules, both linking

the cobalt atoms in a *trans* μ-η^1:η^1 fashion; the resulting six-membered Co_2O_4 ring adopts a chair conformation. To our knowledge, this structural motif is unprecedented in the coordination chemistry of O_2. The O–O distance of 1.354(5) Å is intermediate between the ranges usually associated with μ-superoxido (1.24–1.32 Å) and μ-peroxido ligands (1.38–1.53 Å).[7] However, the Co–N bond lengths (average Co–N = 2.08 Å) are characteristic of a tris(pyrazolyl)borate moiety bound to Co^{II} centers. Besides, five-coordinate Co^{III} complexes are rather rare in general,[8] and we have yet to find an example of a stable Co^{III} complex containing one of these sterically demanding Tp ligands. Thus we suggest that the structural evidence is most consistent with the designation of $[\{Tp''Co(O_2)\}_2]$ as a Co^{II} superoxido complex.

Since thermochemical parameters for the interaction of O_2 with transition metals are important, we measured the temperature dependence of the monomer–dimer equilibrium described above. The relative concentrations of $[Tp''Co(O_2)]$ and $[\{Tp''Co(O_2)\}_2]$ were measured by ^1H NMR spectroscopy over the temperature range 220–260 K. The temperature dependence of the equilibrium constant in the form of a van't Hoff plot is depicted in Figure 2. The thermochemical parameters

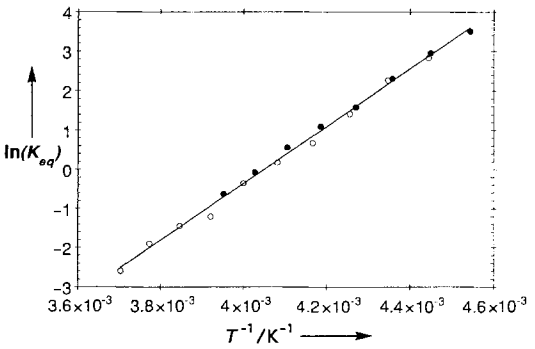

Fig. 2. Temperature dependence of the equilibrium constant K_{eq} (see Scheme 1). ○: [Co] = 0.033 M; ●: [Co] = 0.40 M in CD_2Cl_2 at 25 °C. Results of the van't Hoff analysis: $\Delta H = -14.5(5)$ kcal mol^{-1}, $\Delta S = -60(3)$ cal mol^{-1} K^{-1}.

derived therefrom are $\Delta H = -14.5(5)$ kcal mol^{-1} and $\Delta S = -60(3)$ cal mol^{-1} K^{-1}. As the conversion of the monomer into the dimer involves the opening of two strained CoO_2 rings and the formation of one six-membered ring, the reaction enthalpy provides a measure of the strain energy of roughly 7 kcal mol^{-1} per three-membered ring.

We also monitored the magnetic susceptibility of $[Tp''Co(O_2)]/[\{Tp''Co(O_2)\}_2]$ solutions at various temperatures by the Evans method.[9] At 270 K, where monomeric $[Tp''Co(O_2)]$ is the only species detectable by NMR, the effective magnetic moment μ_{eff} was 3.3(1) μ_B. This value is the same as that measured for solid $[Tp''Co(O_2)]$ at room temperature,[5] and it is consistent with two unpaired electrons ($S = 1$) resulting from strong antiferromagnetic coupling of a Co^{II} ion ($S = 3/2$) to the superoxido ligand ($S = 1/2$). When the solution was cooled, the magnetic moment decreased rapidly, concomitant with the appearance of the NMR signals of the dimer. Although we have not been able to extend these measurements to low enough temperatures to actually convert all of the cobalt complex into the dimeric form, extrapolation of the magnetic data indicates diamagnetic character for $[\{Tp''Co(O_2)\}_2]$. The narrow line widths, absence of isotropic shifts, and lack of significant temperature-dependence in the ^1H NMR spectrum of the dimer are also consistent with this notion.[10] The Co–Co distance of 3.50 Å rules out any direct interaction; instead we suggest that the diamagnetism of $[\{Tp''Co(O_2)\}_2]$ may result from strong antiferromagnetic coupling between low-spin Co^{II} ions ($S = 1/2$) and the adjacent superoxido ligands ($S = 1/2$).

Interestingly, dimeric $[\{Tp''Co(O_2)\}_2]$ is thermally less stable than monomeric $[Tp''Co(O_2)]$. Whereas the monomer is perfectly stable in the solid state at ambient temperature, green crystals of the dimer decomposed rapidly at room temperature, yielding a gas (O_2?) and a pink solid, very similar in nature to the decomposition products of $[Tp''Co(\mu\text{-}O_2)CoTp'']$. These observations suggest that $[\{Tp''Co(O_2)\}_2]$ may also be an intermediate in the solution reaction of $[Tp''Co(O_2)]$. Its formation, followed by loss of one of its two dioxygen moieties, constitutes a reasonable mechanistic pathway for the formation of $[Tp''Co(\mu\text{-}O_2)CoTp'']$, (much preferable to preequilibrium dissociation of O_2 from monomeric $[Tp''Co(O_2)]$) followed by trapping of the coordinatively unsaturated [Tp"Co] by $[Tp''Co(O_2)]$. The first proposal would also explain the surprising difference in reactivity between $[Tp''Co(O_2)]$ and its more hindered analogue $[Tp'Co(O_2)]$; a dimeric form of the latter is obviously much less accessible. Indeed, this reaction pathway may be crucial to our success in constructing a catalyst for the activation of O_2, which depends on simultaneous binding of one O_2 molecule to two metals atoms in the presence of excess O_2.

Experimental Procedure

$[Tp''Co(O_2)]$: An analytically pure sample of $[Tp''Co(CO)]$ (500 mg, 1.07 mmol) was ground into a fine powder in a dry box. The powder was transferred into a glass ampoule, which was then evacuated for 2 h to remove any trace of solvent. Upon exposure to 0.8 atm of dry O_2, the color of the solid changed rapidly from green to brown (within 1 min); the exposure was continued for 2 h. To ensure quantitative reaction, two more cycles of evacuation and exposure to O_2 were carried out. The solid thus obtained in quantitative yield was pure $[Tp''Co(O_2)]$.

$[\{Tp''Co(O_2)\}_2]$: Single crystals of $[\{Tp''Co(O_2)\}_2 \cdot 2CH_3CN]$ were obtained by cooling a solution of $[Tp''Co(O_2)]$ (50 mg) in MeCN (1 mL) to −30 °C for 2 d. The mother liquor was then pipetted out of the vial and cold oil introduced in order to coat the green crystals, and to protect them from contact with air during collection of the X-ray diffraction data. A crystal of dimensions $0.36 \times 0.38 \times 0.38$ mm was mounted on a Siemens P4 diffractometer at 222 K, and 4917 reflections were collected, of which 3033 were judged observed ($F < 4.0\sigma(F)$). The structure was solved by direct methods, using Siemens SHELXTL PLUS software.

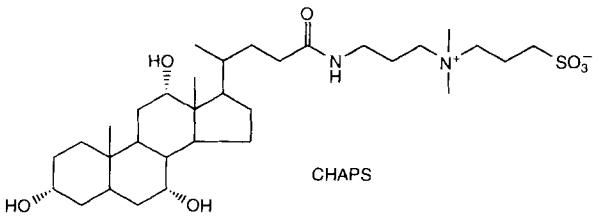
Gas-Phase Micelles

Gary Siuzdak* and Brian Bothner

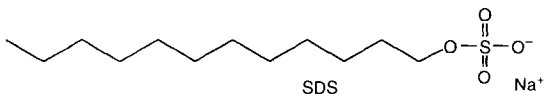
Surfactant micelles represent primitive vesicles associated with the origin of life. Their formation preceded the development of biochemical interactions, membrane assembly, and the beginning of cellular evolution. Micelles are used extensively in biochemistry to facilitate the transport of hydrophobic material and as a site for chemical reactions, thus mimicking their utility in the primordial pools. They are studied through a variety of methods, including gel permeation chromatography,[1] light scattering,[2] and interfacial tensiometry.[3,4] In this study, pneumatically assisted electrospray (ionspray) ionization (ESI) was used to transfer micelles from the condensed phase into the gas phase. Previous electrospray studies[5] on glycolipids resulted in the observation of Ca^{2+}-dependent glycolipid dimers. Evidence suggests that the origin of these dimers was, in part, due to the noncovalent disruption of glycolipid micelles. We now focus on the detection of the intact micelle.

The electrospray ionization technique (ESI) enables charged molecules to be transferred from a liquid solution to the gas phase by creating a fine spray of highly charged droplets. The sample solution is sprayed from the tip of a metal syringe maintained at approximately 5000 V. Dry gas is fed to the stream of droplets before they enter the vacuum of the mass spectrometer, which facilitates solvent evaporation. As each droplet decreases in size, the electric field density on its surface increases. The mutual repulsion between like charges on this surface becomes so great that it exceeds the forces of surface tension and results in the ion's ejection from the droplet. The ions are then directed into the mass analyzer by electrostatic lenses. This type of ionization is conducive to the formation of highly charged molecules and noncovalently bound molecular complexes.[6-9]

This study focused on CHAPS (3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate) and SDS (sodium dodecylsulfate). The surfactants sodium octylsulfate, octylamine,



CHAPS



SDS

dodecylamine, sodium taurocholate, sodium taurodeoxycholate, and cholic acid were also analyzed. Experiments were performed with an API III Perkin Elmer Sciex triple-quadrupole mass spectrometer having an upper m/z range of 2400 and capable of analyzing for positive and negative ions. An electrospray interface potential of 5.0 kV was used for sample introduction. The declustering potential was varied between 30–250 V to control the orifice collisional energy. Samples with concentrations from 0.01 to 1.00 mM were dissolved either in water or 50:50 methanol:chloroform and introduced at a rate of 3.0 $\mu L\,min^{-1}$. Both positive and negative ions were monitored in these experiments and gave analogous results, although the positive ions generally gave a greater signal intensity.

Since ESI is an evaporation process, it is important to minimize the sample concentration and thus maximize evaporization efficiency to maintain a strong ion signal. To facilitate ionization in these experiments, the concentration of surfactants (1.0 mM) was kept below the critical micelle concentration (cmc; 6–10 mM for CHAPS and 7–10 mM for SDS).[10] However, since desolvation occurs more slowly[11] than micelle formation,[12] it can readily be assumed that the critical micelle concentration is been reached prior to ion ejection, and micelles are formed. Micelle formation in the droplet is likely, since the concentration of the solute in the droplet increases by a factor of 100[11] before ion ejection.

Micelle observation by mass spectrometry may be affected by a number of factors: 1) the size of the micelle, 2) the stability of the charged micelle in the gas phase, and 3) the conditions during evaporation of the droplets (temperature and pressure fluctuations). The first factor was addressed by using a variety of large and small micelle systems. An important feature of mass spectrometers is that they measure the mass-to-charge ratio, m/z, making it possible to observe very large molecules or molecular complexes with an instrument having a relatively small m/z range if the molecules are multiply charged. Micelles typically have counterions at the head group to minimize head group repulsion, and while removal or addition of these counterions (for example, H^+, Na^+, or Cl^-) is necessary in mass analysis in order to create a charged species, this may result in the destabilization and fragmentation of the micelle. Larger micelles would require many charges in order to be observed and could be destabilized by the numerous charges. The second factor was addressed with the choice of surfactants, some of which would potentially undergo intramicellar hydrogen bonding. Micelle formation in solution is driven by an entropy gain of the solvent; therefore, it is important that the molecules forming the micelle have strong intramicellar binding to preserve structure in the gas phase. Lastly, the inability to control droplet conditions precisely (third factor) could be detrimental to micelle formation; however, performing these experiments under identical conditions minimized these fluctuations.

The surfactants CHAPS, sodium taurocholate, sodium taurodeoxycholate, and cholic acid were selected because they have relatively low aggregation numbers and contain intermolecular binding sites[13] that could potentially stabilize association into the gas phase. The electrospray ionization source allows an ion's kinetic energy to be adjusted by means of the declustering potential; declustering potentials on the order of 70 V or lower are conducive to the observation of noncovalent complexes, while greater potentials usually promote the dissociation of noncovalent complexes and even covalent bonds. All of the experiments in which micelles were observed were performed at low declustering potentials, typically at or below 50 V. Figure 1 shows the mass spectra of CHAPS at declustering potentials of 50 V and 150 V. The spectrum acquired at 50 V contains oligomers that correlate with the expected micelle aggregation number (4–14).[10] Experiments performed at a declustering potential of 150 V gave no evidence of micelle formation. Similar results were obtained for sodium taurocholate and sodium taurodeoxy-

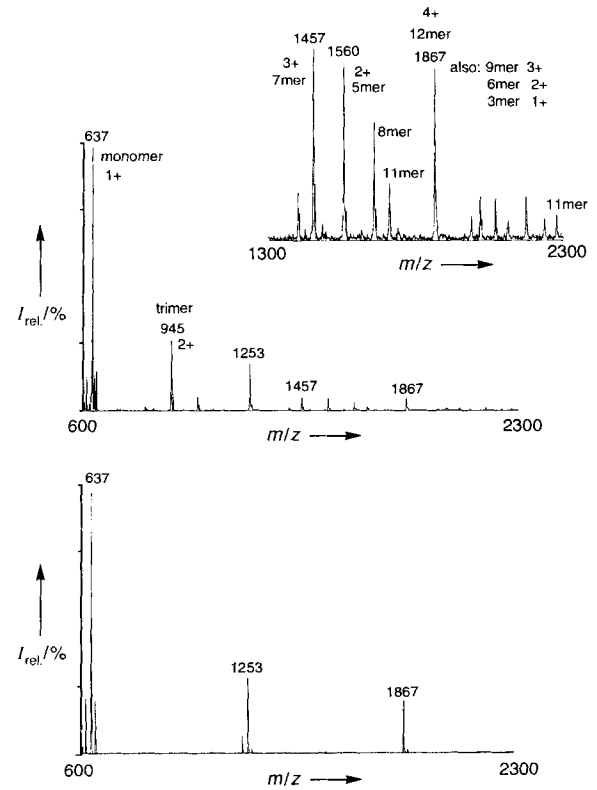

Fig. 1. Positive ion electrospray mass spectra of CHAPS micelles obtained from water at declustering potentials of 50 (a) and 150 V (b). At 50 V the micelles (as Na^+ adducts) vary in size and charge; for example, the ion m/z 1457 represents the $[(CHAPS)_7 + 3Na]^{3+}$. At 150 V only the singly charged monomer, dimer, and trimer were observed. Charge states were based on isotope distribution, cation addition, and MS/MS data.

cholate; however, cholic acid produced no evidence of micelle formation. From these results it is concluded that the zwitterionic nature of CHAPS, sodium taurodeoxycholate, and sodium taurocholate, and the hydrogen bonding interactions between their monomers may have facilitated the observation of gas phase micelles by stabilizing the charged (micelle) structure. Typically, CHAPS, sodium taurodeoxycholate, and sodium taurocholate produced micelles containing at least three charges.

The measured charge states were based on isotope patterns, cation addition, and MS/MS data. The spacing between isotope lines provides a means of determining charge state (Fig. 2); the

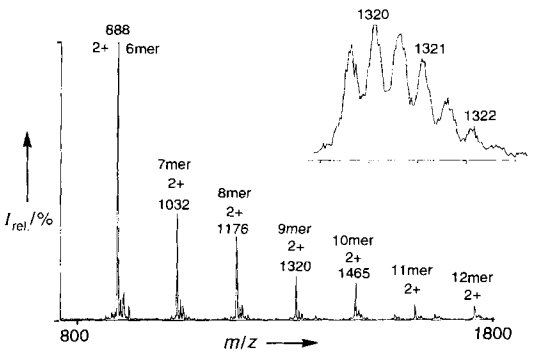

Fig. 2. Aggregates $[(SDS)_n + 2Na]^{2+}$ ($n = 6-12$) observed by positive ion electrospray mass analysis. Charge states determination can be based on spacing of the isotopes; for example, ^{13}C isotopes spaced 1.0 mass unit apart correspond to the 1 + charge state, those 0.5 mass units apart to the 2 + charge state, etc. This spectrum demonstrates the uniform stepwise addition typical of salt aggregates and nonspecific molecular aggregations.

resolving power of the quadrupole instrumentation allowed the determination of up to the 3 + charge state. Cation addition also served to identify the charge states (Fig. 3). The spacing between the cation adducts provided the same information as the isotope pattern without the need for high resolving power.

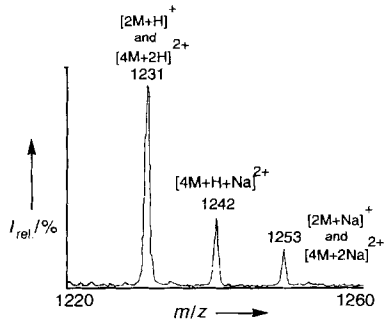

Fig. 3. Mass spectrum of CHAPS obtained at a declustering potential of 75 V. Cation addition is another way of determining an ion's charge state, analogous to examining the isotope distribution. The formation of cation adducts at half the mass of the ion is indicative of a 2 + charge state, at one third the mass of the ion of a 3 + charge state, and so on.

Cation addition was also used to test the effect different cation adducts may have on observing micelle formation. Here, Na was replaced with other alkali metals, Li, K, and Cs; however, no other significant changes were observed in the charge states or ion intensitites with the different cations. MS/MS data provided information about the charge states, since fragment ions were indicative of the minimum aggregation number.

SDS and other alkyl surfactants were also analyzed. In order to observe SDS micelles (aggregation number of 62)[10] with this instrumentation, they would require a positive or negative charge of at least 7. However, the mass spectrum of SDS shows no association that could correlate with micelle formation (Fig. 2), but is more consistent with spectra obtained from salt aggregates.[14] The same experiments were performed on structurally related surfactants, including sodium octyl sulfate, octylamine, and dodecylamine and gave results similar to those observed for SDS. No micelles were observed with these systems regardless of their size. The inability to observe micelles may be associated with significant head group repulsion on the highly charged micelles, as only charges of less than or equal to 2 + were observed for the aggregates. It was theorized that attempts to observe micelles with relatively high aggregation numbers may be difficult due to their instability when highly charged. Furthermore, the relatively weak van der Waal interactions of these molecules may be insufficient to stabilize micelles for transfer to the gas phase.

Tandem mass analysis was used along with the declustering potential to identify the micelle ions further. Tandem mass analysis through collision-induced dissociation (CID or MS/MS) is used to effect fragmentation. An ion of interest is selected with the mass analyzer and introduced into a collision cell, where, typically, argon is used as collision gas. The selected ion will collide with an inert gas molecule to give fragment ions, which are recorded with a second analyzer. Tandem mass spectrometry experiments were performed on the cholic acid derivatives at two different declustering potentials (50 V and 150 V) again to establish micelle formation at the low declustering potentials and a minimal aggregation number for the observed ions. The fragmentation data of the cholic acid derivatives under low declustering potentials (50 V) produced fragment ions (hep-

tamer, decamer, and undecamer) consistent with a dodecamer precursor ion. Figure 4 also illustrates the fragmentation of CHAPS at a declustering potential of 150 V to form only the monomer and dimer, fragments that are more consistent with the trimer precursor ion.

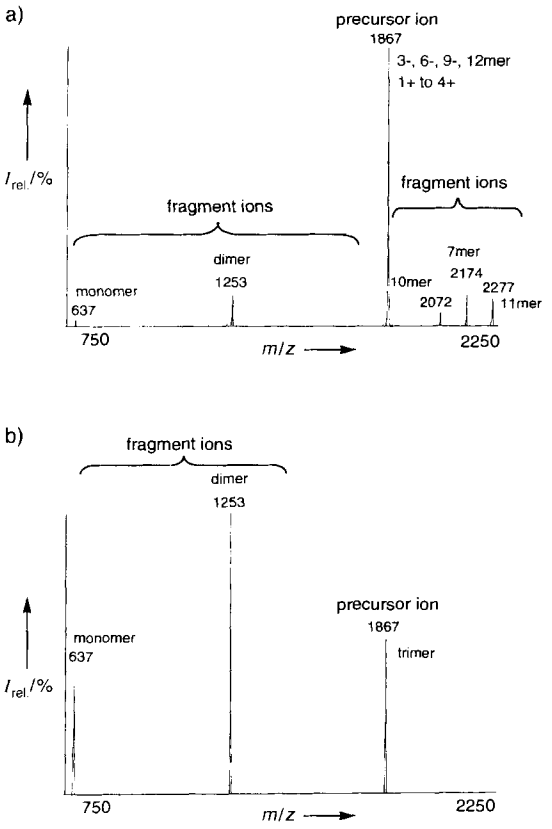

Fig. 4. Positive ion electrospray MS/MS analysis of the ion, m/z 1867, at declustering potentials of 50 V (a) and 150 V (b). The data at 50 V are consistent with the following structures: $[(CHAPS)_{12} + 4Na]^{4+}$, $[(CHAPS)_9 + 3Na]^{3+}$, $[(CHAPS)_6 + 2Na]^{2+}$, and $[(CHAPS)_3 + Na]^{1+}$. The data at 150 V are consistent with $[(CHAPS)_3 + Na]^{1+}$.

SDS and CHAPS were also evaluated in methanol:chloroform (50:50), a solvent system that is conducive to reverse micelle formation. Under these conditions the ion distribution for SDS closely resembled that under aqueous conditions, which further suggested that the clusters observed for these compounds were the result of nonspecific aggregation. However, CHAPS in methanol:chloroform (50:50) produced significantly different results in terms of ion distribution and relative ion intensity than those obtained in aqueous solution. This change could be attributed to the structural difference between reverse micelle and micelle formation.

Additional evidence of micelle formation in the gas phase was obtained from experiments monitoring the critical micelle concentration (cmc). The cmc is defined as the surfactant concentration above which micelles are formed.[10] The cmc's of CHAPS, taurocholate, and taurodeoxycholate are 6–10 mM, 3–11 mM, and 1–4 mM, respectively. The cholesterol-like surfactants were especially ideal for this study, because their similar structures are likely to produce similar evaporation conditions. In these experiments, the concentration of each surfactant was increased from a concentration of 0.01 mM in 0.01 mM increments, and the onset of micelle formation determined by the observation of the heptamer in the 2+ and 3+ charge states. The heptamer was chosen because it is consistent with the aggregation number of all three surfactants, and its signal does not overlap with that of any other oligomer ions in the 1+, 2+, or 3+ charge states.

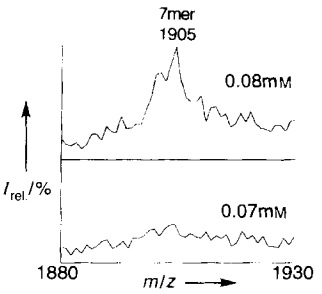

Fig. 5. Onset of micelle formation for taurocholate, monitored with the signal of the heptamer $[(TC)_7 + 2Na]^{2+}$ at 0.08 mM (top) and 0.07 mM (bottom).

The cmc for CHAPS, taurocholate (TC), and taurodeoxycholate (TDC) was found to be 0.06 mM, 0.08 mM, and 0.02 mM, respectively (Fig. 5, Table 1). Assuming evaporation increased the droplet surfactant concentration by a factor of approximately 100,[11] the results correlate with the absolute cmc values and are also consistent with respect to the relative cmc's of the surfactants. These experiments were also performed on SDS, cmc 7–10 mM, where SDS produced significant aggregation only at concentrations greater than 0.20 mM. The aggregation was deemed to be significant if the signal-to-noise ratio of the heptamer was greater than 2. The relatively high concentrations needed to observe aggregation of SDS is further evidence of the nonspecific nature of its aggregation, while the absolute and relative cmc correlations between the steroid surfactants further suggest that micelles were formed.

Table 1. A comparison of critical micelle concentrations (cmc) determined in solution and obtained with ESI for the surfactants CHAPS, TC, TDC, and SDS.

Surfactant	CHAPS	TC	TDC	SDS
cmc (solution) [mM]	6–10	3–11	1–4	7–10
cmc (ESI) [mM]	0.06	0.08	0.02	0.20
c [mM] [a]	6	8	2	20

[a] Estimated concentration of surfactant upon ion ejection.

The "soft" ionization/vaporization process of electrospray has allowed the transfer of micelles into the gas phase and thus the ability to analyze micelles by mass spectrometry. CHAPS, sodium taurodeoxycholate, and sodium taurocholate have provided useful models, probably because they form relatively small micelles and stable, multiply charged complexes.[15]

Incorporation of Membrane Proteins in Solid-Supported Lipid Layers

Renate Naumann,* Alfred Jonczyk, Ralf Kopp, Jan van Esch, Helmut Ringsdorf, Wolfgang Knoll, and Peter Gräber

Solid-supported lipid layers[1] are able to incorporate membrane proteins only if an aqueous layer separates the lipid layer from the substrate. This can be achieved by transferring lipids to hydrophilic surfaces either by Langmuir–Blodgett techniques[2] or by the fusion of liposomes.[3] Alternatively such layers can be formed by self-assembly if the lipid is attached to the substrate by a hydrophilic spacer group. For example, disulfide-functionalized amphiphilic copolymers (hydroxymethacrylates) form lipid layers on gold substrates separated by a swellable aqueous layer.[4, 5] The same holds for thiolipids having hydrophilic oxyethylene spacers of defined length, which were reported to form lipid mono- and bilayers[6] capable of incorporating intrinsic membrane proteins such as the $5HT_3$ receptor from calf brain.[7] Lipid layers having peptide spacers were first prepared on polymer beads. Bacteriorhodopsin incorporated in these layers was shown to operate as a proton pump.[8] Lipid layers on gold with peptide spacers will be described in the present paper.

In analogy to previous work[8] the relatively hydrophobic pentamer of alanine **1** (Fig. 1) was first functionalized with terminal sulfur groups followed by the more hydrophilic peptide **2**. These peptides have a tendency to form helical structures,[9] particularly when they are attached to gold substrates through sulfur groups and organize themselves by self-assembly.[10] Once the peptide **2** was covalently linked to the substrate, the free terminal COOH group was activated in situ and coupled to a lipid, for example DMPE (dimyristoylphosphatidyl ethanolamine), through the NH_2 group. A thiolipid monolayer with peptide spacer **3** is thus formed by further self-assembly. The formation of this layer was followed by electrochemical techniques such as cyclic voltammetry (CV) und impedance spectroscopy (IS) as well as by surface plasmon resonance spectroscopy (SPR). Table 1 shows the decrease in capacitance and the increase in layer thickness indicated by CV and SPR due to the formation of the lipid mono- and bilayers. The capacitance of perfect lipid monolayers determined by CV was reported to be as low as 0.5 $\mu F\ cm^{-2}$.[6, 7] The comparatively high capacitance found in our case indicates a lower degree of perfection. This conclusion is also supported by the fact that the layer thickness is much less than the calculated length of the molecule (Fig. 1), which can be explained by the incomplete coupling of the peptide in situ.

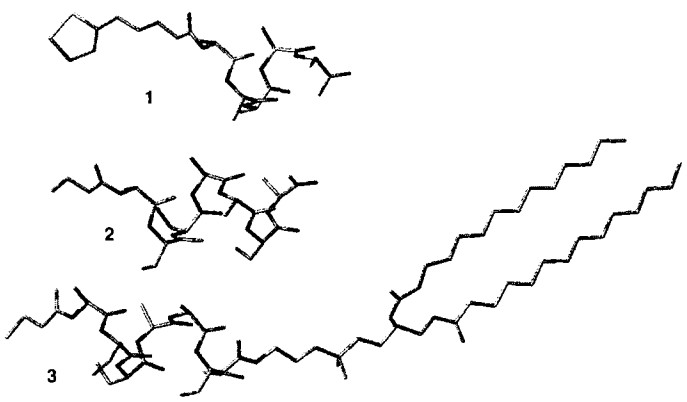

Fig. 1. Structures of peptides **1** and **2** as well as the thiolipid **3** with peptide spacer. Maximum lengths: **1**: 18.2 Å, **2**: 15.9 Å, **3**: 42.1 Å.

Table 1. Capacitance (measured by CV [6]) and layer thickness (measured by SPR and calculated using an effective refractive index of 1.5) of the films.

	Capacitance/$\mu F\ cm^{-2}$	layerthickness/nm
bare gold	18	–
lipid monolayer	2–3	2
lipid bilayer, no protein	1–2	4
lipid bilayer with ATPase	1–2	8.5

The thickness of these imperfect monolayers increases when they are exposed to a suspension of liposomes (Fig. 2). This increase does not occur below the transition temperature of the lipid and also when the peptide layer alone comes into contact with the liposomes (not shown). The shift in the resonance angle in SPR due to the formation of the mono- and bilayer with and without incorporated ATPase is shown in Figure 3. The layer thickness given in Table 1 is calculated from these shifts based on an effective refractive index of 1.5. In view of the theoretical thickness of 5 nm for a perfect lipid bilayer, the thickness of 4 nm is compatible with the formation of an imperfect bilayer. The thickness increases to 8.5 nm when the monolayer is exposed to liposomes with incorporated ATPase. Compared to the lateral extension of ATPase, which is also 8.5 nm,[11] and since a single orientation of the protein is possible only owing to the large F_0 part, this is a strong indication for the formation of a bilayer with incorporated ATPase. Figure 4 reflects the relative proportions.

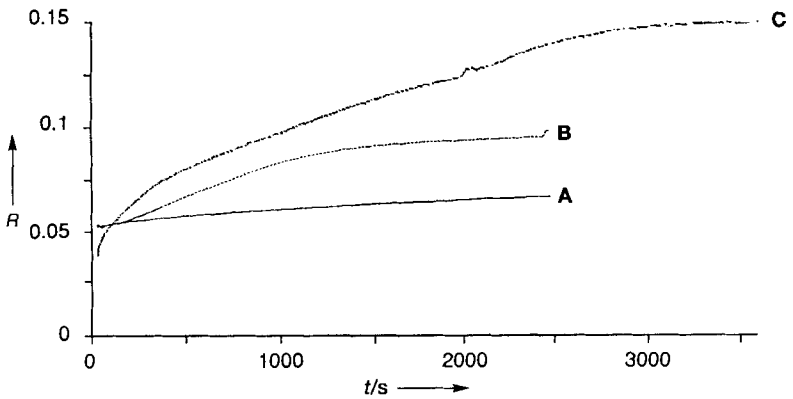

Fig. 2. Reflectivity R (arbitrary units) of the lipid monolayer as a function of time exposed to a suspension of liposomes without ATPase, at 20 °C (curve A) and 30 °C (curve B), and with incorporated ATPase at 30 °C (curve C).

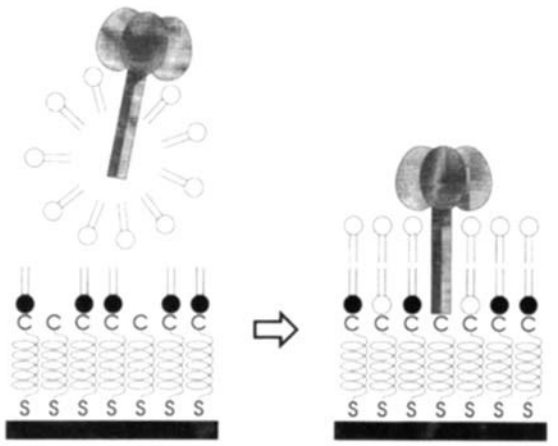

Fig. 4. Schematic representation of the fusion of liposomes with the lipid monolayer and formation of the lipid double layer with incorporation of ATPase.

Further indications of the incorporation of ATPase into the lipid layers are obtained by electrochemical techniques. ATPases CF_0F_1 from chloroplasts and EF_0F_1 from *E. coli*[13] catalyze the translocation of protons across the lipid membrane by hydrolysis of adenosine triphosphate (ATP). This process is possible only with an intact lipid layer and results in a pH gradient of pH 7–8 on the outside and pH 4 on the inside of the lipid.[12] Protons transported to the inside can be detected by the current when they are discharged at the gold surface. This discharge occurs only at relatively high negative potentials. To avoid damage to the lipid layers, fast pulse techniques such as square wave voltammetry (SWV) and chronoamperometry (CA) were employed. The SWV of a lipid layer with incorporated ATPase EF_0F_1 shows a peak at -0.7 V (Fig. 5), which increases in height as a function of the concentration of ATP. This indicates an increase in proton activity on the inside of the lipid layer to pH 4, while the pH of the solution remains the same, pH 7.4. A similar result was obtained for ATPase CF_0F_1 from chloroplasts (not shown). Figure 6 shows the decline of the

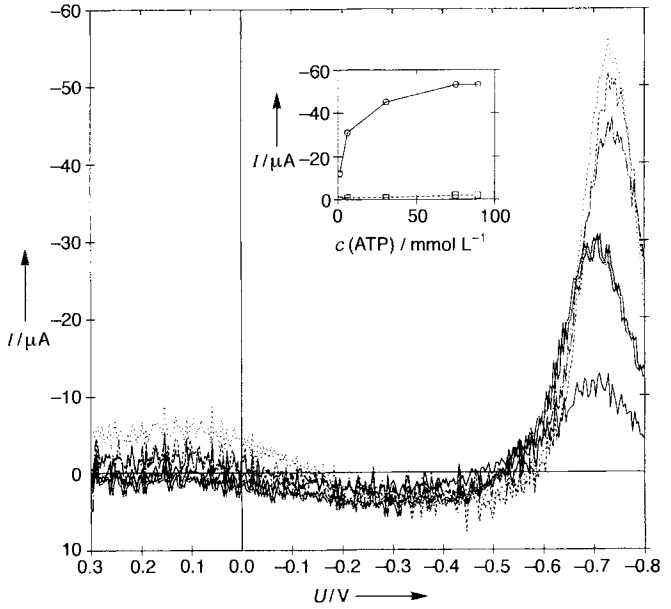

Fig. 5. Square wave voltammogram (corrected for the blank curve) of a lipid double layer with incorporated EF_0F_1 in the presence of 1 (—), 6 (═), 30 (—·—), 75 (- - - -), and 89 mmol L^{-1} ATP (····). Insert: Peak height as function of the concentration of ATP without (- - - -) and with EF_0F_1 (—).

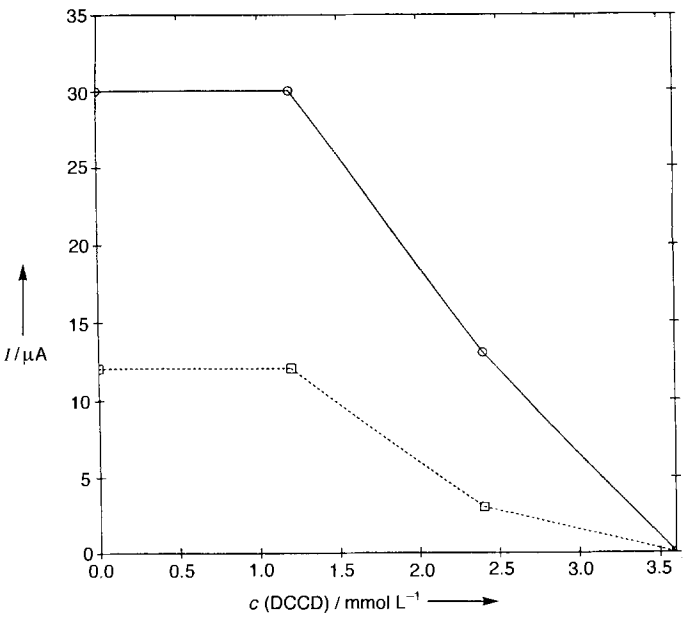

Fig. 6. Peak height in SWV of a lipid double layer with incorporated EF_0F_1 in the presence of constant concentrations of 1 (- - - -) and 6 mmol L^{-1} ATP (—), as a function of the concentration of DCCD.

SWV peak at -0.7 V caused by a specific inhibitor of ATPase, dicyclohexylcarbodiimide (DCCD).[14]

SWV measurements are designed to show only a static picture of proton translocation. Chronoamperometry, on the other hand, can be expected to yield information on the kinetics of the enzyme. In these measurements a current is recorded as a function of time while a potential pulse is applied to the electrode. The result is shown in Figure 7 for a lipid bilayer incorporating EF_0F_1 in the presence of increasing concentrations of ATP. In chronoamperometric measurements a double potential pulse technique is applied; that means the first pulse is applied at $+0.2$ V followed by a second at -0.7 V. The positive pulse is

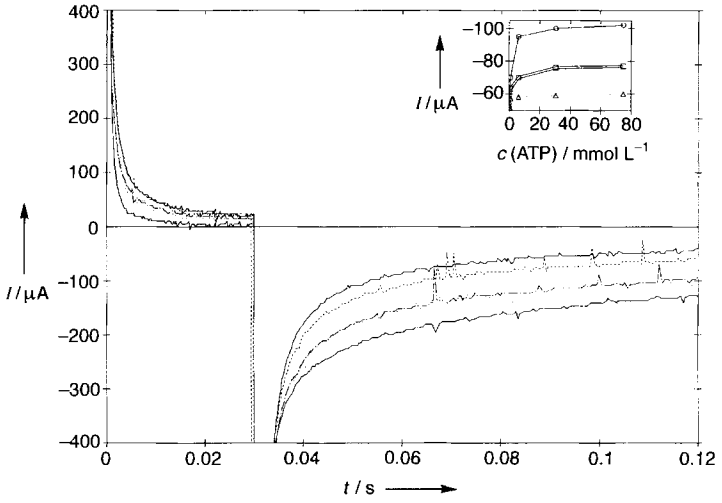

Fig. 7. Chronoamperometric measurements of the lipid double layer with incorporated EF_0F_1 as a function of the concentration of ATP (1–90 mmol L^{-1}). Insert: Stationary current as function of ATP concentration without ATPase (- - - -), with CF_0F_1 (═), and with EF_0F_1 (—).

conducive to the activation of the enzyme,[15] whereas the negative pulse causes discharge of protons. During this latter process, a decrease in the capacitive current is first observed. This is followed by a stationary cathodic current, indicating the activity of protons, which shows saturation behavior with respect to the concentration of ATP (insert, Fig 7). This stationary current is about two orders of magnitude higher than the current calculated from the kinetics of ATPases EF_0F_1 from *E. coli*[13] and CF_0F_1 from chloroplasts[12] (Table 2). Relative enzyme kinetics, however, are reasonably well reflected. Hence the activity of the enzymes appears to be preserved. This is possible only if the enzymes are properly arranged in space and above all if a lipid layer separates the inner aqueous layer from the outer solution. Only under these conditions is a pH gradient conceivable as long as the pH of the solution remains unchanged. Nonspecific adsorption of the enzyme is, therefore, highly unlikely. The relatively high current in the CA experiment could be due to an acceleration of proton translocation in the electric field. This will be investigated in further studies. The results so far are taken as a first indication that the enzymes in the lipid layer have comparable similar activities to those in liposomes, and that protein denaturation is apparently prevented by the peptide spacer.

Table 2. Stationary current I due to the discharge of protons at the gold electrode, compared to the current calculated from the amount of protons translocated by the enzymes.

Enzyme	$I/\mu A\,cm^{-2}$ calculated[a]	experimental
EF_0F_1	0.7	90
CF_0F_1	0.07–0.14	10

[a] From $G = 1.1 \times 10^{10}$ (enzymes per surface area, calculated from the concentration of enzymes in the liposomes and assuming a perfect lipid layer); activity: 100 ATP s^{-1} (EF0F1) und 10–20 ATP s^{-1} (CF0F1), at $4H^+$/ATP.

Experimental Procedure

Preparation of peptides: **1** and **2** were obtained by solid-phase peptide synthesis in a continuous flow synthesizer [16] using Fmoc (9-fluorenyl-methoxycarbonyl) strategy [17] with acid-labile protection of the side chain on an acid-labile Wang resin. The synthesis was monitored continuously by UV spectroscopy at 310 nm. After removal of the Fmoc groups the peptide was coupled with tritylmercaptopropionic acid. The peptide and side chain protecting groups were cleaved with TFA (trifluoroacetic acid). Purification was achieved by gel filtration and HPLC. The purity and identity of the peptide was determined by FAB-MS (fast atom bombardment mass spectroscopy), HPLC and capillary electrophoresis.

Gold (0.94 cm^2) was deposited onto clean glass slides by electrothermal evaporation over a sublayer of 30 nm of chromium at 300 °C and a pressure of 10^{-5} to 10^{-6} mbar using a Leybold-Heraeus L 650 vapor deposition apparatus. The thickness of the gold layer was 400 nm.

Preparation of the lipid monolayers: After the glass substrates were cleaned in a solution of 1 g of potassium bichromate in 100 mL of sulfuric acid (98%), they were incubated in a solution of the peptide in TFA (1 mg mL^{-1}) for 96 h. The substrates were then rinsed with TFA, dimethyl formamide (DMF), and dichloromethane (CH_2Cl_2). The terminal COOH groups of the peptide were activated with 20 μL mL^{-1} diisopropyl carbodiimide (DICD) and coupled in a solution of 1 mg mL^{-1} dimyristoyl phosphatidyl ethanolamine (DMPE) in a mixture of DMF, CH_2Cl_2, and LiCl (20:40:0.4). After addition of 10 μL mL^{-1} *N*-ethyl diisopropylamine, the substrates were incubated for a further 96 h. Activation and coupling were repeated using a fresh coupling mixture. The substrates were then rinsed with DMF and CH_2Cl_2 and dried in a stream of nitrogen.

Preparation of the lipid double layer: Liposomes were prepared from phophatidylcholine and phosphatidic acid (1:20). The ATPases CF_0F_1 and EF_0F_1 were incorporated into these liposomes by using biobeads [18]. Substrates with the lipid monolayers were incubated in suspensions of these liposomes at 30 °C; concentrations of the lipid and the protein were 1.4 mg mL^{-1} and 30 μg mL^{-1} of CF_0CF_1 and EF_0F_1, respectively.

CV, SWV, and CA measurements were carried out at 30 °C in a buffer solution of K_2SO_4 (0.1 mol L^{-1}), tricine (0.0005 mol L^{-1}), Na_2HPO_4 (0.0005 mol L^{-1}), and $MgSO_4$ (0.0002 mol L^{-1}) at pH 7.4, in a cell equipped with a silver rod as counter electrode and an Ag/AgCl (sat. KCl) reference electrode, and with an Autolab instrument (ECO Chemie) using GPES3 software. ATP was added from a stock solution of adenosine-5′-triphosphoric acid disodium salt (0.25 mol L^{-1} adjusted with NaOH to pH 7.4). Potential scan rate and range of potentials used in CV were 0.1 Vs^{-1} and 0.3 to −0.2 V, respectively. Frequency and range of potentials in SWV were 80 Hz and 0.3 to −0.8 V. Potential pulses applied in CA were 0.2 and −0.7 V. Duration of potential pulses was 0.07 s and duration of current sampling was 0.00011 s.

SPRS study was carried out in Kretschmann configuration [19] with a HeNe Laser (λ = 633 nm).

Ammunition against Chemical Scaremongers

The Consumer's Good Chemical Guide. A Jargon-free Guide to the Chemicals of Everyday Life. By *J. Emsley*. W. H. Freeman, New York, 1994. XI, 347 pp., hardcover $ 24.95.—ISBN 0-7167-4505-4

For those concerned with the current epidemic of chemophobia and anti-science attitudes rampant in today's society—and that should include all of us—this book, which received the 1995 Rhône-Poulenc Science Book Prize, brings good news. Its author, John Emsley, recipient of the 1993 Glaxo Award for Science Writing, spent a quarter-century lecturing at the University of London and is now Science Writer in Residence at London's Imperial College of Science, Technology and Medicine. In this successful attempt to counter the "bad press" created for chemistry by scare-of-the-week stories, he deals with timely issues frequently in the news by systematically exposing misinformation disseminated by irresponsible media about chemicals with which we daily come in contact. In accessible, nontechnical language he presents up-to-date information on natural and artificial sweeteners, cholesterol, fats, fiber, painkillers, PVC, plastics, dioxins, nitrates, and carbon dioxide and the greenhouse effect. In separate chapters he shows how perfume chemists are trying to make the world a better place and simultaneously saving wildlife and how alcohol can not only improve the quality of life but may also prolong it. Some chemicals about which the public is worried, such as CFCs, lead, or radon are not included for the simple reason that they actually *are* dangerous (the book's title refers to good chemicals that are only generally *assumed* to be bad).

In contrast to the prevalent practice of accusing a given chemical of causing a disease or illness on the basis of alarming but unsound statistics, Emsley lucidly explains the chemistry involved and then shows that it is inconsistent with the accusations being made against the chemical. Intending his guide primarily for nonscientists, he eschews chemical formulas in the text but provides structural formulas and additional technical data on 193 substances (designated in the text by boldface type) from acesulfam to yohimbine in a 54-page cross-referenced alphabetical appendix. The information is not limited to the present-day controversial aspects of chemicals, such as their effects on life on earth and on the environment, but much fascinating and valuable background material, historical as well as anecdotal, is provided. For example, Emsley traces the evolution of perfumery from biblical times, discloses the fragrances in Chanel No. 5, discusses what makes a molecule taste sweet, reveals how to avoid a hangover, and shares with the reader the classical basis for successful dieting as well as "the boring diet that's guaranteed to work" according to the laws of chemistry. At the end of each chapter he summarizes his conclusions, and he is not afraid to take a stand, as, for example, when he declares, "As far as our animal friends are concerned we should continue to research the dioxins, but as far as humans are concerned the dioxin scare is over" (p. 203). A 10-page bibliography lists books and articles, divided according to each of the book's ten chapters and subdivided into general and specialist reading, as well as the sources that Emsley consulted in writing the book. A 17-page (2 columns per page) index facilitates location of topics.

This handy volume provides readers (with or without a scientific background) with unexpected, surprising, and reassuring answers that expose the misinformation and disinformation that surround many of the controversial chemicals that we all encounter today and that impinge on our lives. As such, it will be of interest not only to the public at large but also to instructors of chemistry, biology, environmental science, and risk assessment courses. Emsley promises a second volume in which he will deal with additional chemicals that have given rise to alarm such as phosphates, MSG, preservatives, chlorine, nicotine, methanol, and the HFCs and others that have led to unrealistic hopes of improved health, such as vitamin C and calcium.

Practical Surface Analysis. A2, Vol. 1. Auger and X-Ray Photoelectron Spectroscopy. 2nd Edition. Edited by *D. Briggs* and *M. P. Seah*. Wiley, Chichester/Salle & Sauerländer, Aarau, 1994. 649 pp., paperback £ 49.95.—ISBN 0-471-9540-7

The first edition of this work, published in 1983 with a distinctive cover that gave it its common name "the blue book", soon became established as an indispensable handbook for the practitioner in the field of applied Auger spectroscopy (AES) and X-ray photoelectron spectroscopy (XPS). In 1990 it was followed by a second edition ("the red book"), enlarged and improved in many respects, and this has now also become available in a paperback version.

The declared aim of the editors is to provide a practical aid, within a single book, for users of AES and XPS, the two most important methods of electron spectroscopy, especially with beginners in mind. The ground covered ranges from introducing the theoretical basis of the methods to describing the most important areas of application. The contributions make up a well coordinated whole, which is undoubtedly an important reason why this has become *the* standard book, not just for beginners but for many surface analysts.

The book consists of ten chapters, of which the first five are devoted to the basic principles of AES and XPS, whereas Chapters 6 to 10 concentrate on the most important areas of application. Chapter 1 introduces general aspects of the analysis of surfaces and thin films by irradiation with electrons, ions, or photons. Chap-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ter 2, "Instrumentation", is of particular interest for newcomers to surface analysis, familiarizing them with the most important components of ultra-high vacuum systems and of electron spectrometers. Chapter 3 describes the characteristic features of Auger and photoelectron spectra, and explains in a clearly understandable way how such spectra are interpreted and what information they contain. Chapters 4 and 5 are concerned with depth profile analysis and with the methods used to establish quantitative scales of concentration and depth. All the most important theoretical relationships are given here, as well as practical methods for obtaining quantitative data, and the problems of depth profiling by ion sputtering are also treated. These two chapters are among the best in the book.

The following chapters describe important areas of application of AES and XPS, and this naturally involves reviewing the current state of progress in research and techniques. Some representative examples of applications in specialized fields are described. In the course of this the authors devote particular attention to experimental problems that must be overcome, such as surface charging, effects of radiation damage, and limitations on lateral and depth resolution, as well as some important complementary methods of analysis. Thus the editors' aim of providing an introduction to the various areas of application and also giving a broad survey is achieved in nearly every case. Chapter 6 deals with "Applications of AES in Microelectronics" and Chapter 7 with "AES in Metallurgy". The latter chapter begins with an interesting introduction and a discussion of ways of studying segregation, then deals in detail with theoretical aspects, thermodynamic processes, and the kinetics of segregation. In contrast to these two rather weak chapters, Chapter 8 contains an excellent account of the applications of electron spectroscopy in heterogeneous catalysis research, including a very good discussion of the experimental problems and possible sources of error. XPS studies of catalyst support materials, platinum metal catalysts, zeolites, and desulfuration methods are discussed in detail. Electron energy loss spectroscopy (EELS) is also included as an important complementary technique. Chapter 9 is devoted to "XPS in Polymer Technology"; in particular it contains very useful sections on bond energies and functional groups. Lastly, Chapter 10 describes the use of electrochemical measurements as an important complementary method in corrosion research, with detailed discussions of surface roughness and radiation effects. The book ends with nine appendices which cover physical aspects and experimental results of importance in electron spectroscopy. Appendices 5–9 contain useful and up-to-date tables of energies, sensitivity factors, and line positions.

To summarize, this book is a must for all analysts working in the field of Auger and photoelectron spectroscopy, and the availability of a paperback version now makes buying one's own copy easier from the standpoint of cost.

Crystal Structure Analysis for Chemists and Biologists. By *J. P. Glusker, M. Lewis,* and *M. Rossi.* VCH Publishers, New York, 1994. 854 pp., hardcover $ 69.95, DM 120.00.—ISBN 0-89573-273-4

After many years during which chemical crystallography experienced a dearth of good or outstanding new monographs or textbooks, there has recently been a marked increase in the choice of material. Notwithstanding this welcome improvement, it is an exciting development when a further addition appears under the authorship of such a doyen of the discipline as Jenny Glusker, in collaboration with M. Lewis and M. Rossi. After a long wait since the first announcement, we at last have before us a work of 854 pages. As stated in the title, the book aims to make crystal structure analysis more easily accessible to chemists and biologists. In fact, the first sentence of the introduction narrows down the anticipated readership still further to those chemists and biochemists who, although not actually using the method themselves, need to be able to understand the results. On first picking up this bulky and comprehensive work, which does not merely deal with the applications but includes a careful and thorough treatment of the basic principles, one is almost inclined to say that it is not ideally suitable for the readership indicated, although that in no way detracts from the excellence of this book in covering nearly every facet of the subject that the title implies.

However, to discuss matters in their proper order: the book consists of 18 chapters covering the subject of chemical crystallography. About half the chapters are concerned mainly with the method itself, including the physical and mathematical fundamentals. The rest of the book concentrates on the results that it can give, and on their interpretation in terms of structure and the related chemistry and biochemistry. However, the boundary between theory and applications is a very fluid one, which is one reason why one can never become bored while reading the book. Another pleasing feature is that the authors avoid imposing too rigid a distinction between "small" and "large" molecules. In the examples discussed there is a strong emphasis on molecules and macromolecules related to biological systems, which comes as no surprise in view of the authors' backgrounds.

Each chapter ends with a brief résumé in which the main points covered are summarized with a paragraph for each, followed by a glossary of the most important terms and a comprehensive bibliography. For each of the publications cited the title is given in the original language, together with a translation of any title that is not in English. Altogether the book contains 102 (!) summary paragraphs, 435 (!!) glossary terms, and 1834 (!!!) literature references. The introduction alone contains 14 references. Even these rather dry statistics provide impressive evidence that the authors have not shirked their task, and the quality of the final result fully justifies the book's claims in every respect.

The manner in which the method and its applications are explained and discussed is very far from dry. Even the chapters devoted to the method itself impress one by the way in which applications are described for illustration, while ensuring that this does not detract from the thoroughness of the treatment. Historical aspects (some of which are little known) are also interwoven with the discussion, so that one often becomes really absorbed in the story. For example, where else would one discover that the first correct proposal for the structure of diborane appeared in an article by W. Dilthey in 1921 with the title "Über die Konstitution des Wassers" (*Z. Angew. Chem.* **1921**, *34*, 596)? Incidentally, this example also illustrates the point that by no means all the structures discussed relate to biological systems. In addition to boron and boranes, inorganic chemists will be pleased to find such ancient topics as the various tin modifications and blue (copper) vitriol, or may enjoy a glimpse at fullerenes.

The treatment of fundamentals begins with the structure and symmetry of crystals, then goes on to their physical properties, diffraction by crystals, superposition of waves, Fourier syntheses, measurement of structural amplitudes, the solution of the phase problem, electron density syntheses, and structure refinement. Al-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3418-2060 $ 10.00+.25/0

though this arrangement of the subject matter largely follows the conventional pattern, the style of treatment is different in many respects from that in other books, with resulting benefits. The exceptionally clear way in which the subject is developed is no less than one expects from these authors. Although lengthy mathematical derivations are not completely absent, they are often avoided in favor of a more effective pictorial presentation. Where mathematical derivations do occur, they are enclosed in boxes separated from the main text, a device which again greatly improves the readability of the book. Despite this, the discussion is never simplified where that would be inappropriate, nor is the required depth of treatment ever sacrificed. The discussion is illustrated throughout by many examples (both old and new), and together with the carefully prepared figures, many of which are in stereoscopic form, these further serve to bring out the essentials in great clarity. The many tables and summaries also make the book a valuable reference source. The clear definitions and explanations of terms, which are provided in the text and in the glossary, are especially commendable.

In the part of the book devoted to applications the treatment is very different from that in other related texts (and is much better). The strong emphasis on biological aspects in the many examples of crystal structures has already been mentioned. Some of the topics to which considerable space is given are: molecular conformation (including its importance in biological macromolecules), chirality and absolute structure, structure comparisons including the use of data banks, receptors and molecular recognition, and stereochemical aspects of chemical reactions in crystals (although the latter topic appears under the rather misleading heading "Structure–Activity Results"). The authors have not neglected such highly topical (and difficult) areas as atomic and molecular scattering phenomena, molecular dynamics of polypeptides, and packing in molecular crystals. Atomic coordinates and their interpretation also receive careful treatment.

Although the book contains some practical advice and discusses the experimental aspects of crystal structure analysis, it is definitely not intended as a handbook for the practitioner. It does not even go into the details of crystallographic computer programs. In fact that would not be very desirable, as it would not fit in well with the character of the book in its present form. Moreover, a wide choice of other textbooks of a more practical kind is already available. On the other hand, one regrets that there is no discussion of the many different kinds of errors that can arise in crystal structure analysis and interpretation (and which regrettably occur increasingly often). In omitting this aspect the authors have missed a good opportunity to review the now extensive literature on "incorrect crystal structure analyses", to point out the most important kinds of errors that are likely to occur, and to persuade the reader to give some thought to this very important subject.

However, that is a very minor shortcoming in this thoroughly excellent book, and in no way detracts from the wide recognition that it deserves. The style of presentation, the construction of the book, and the treatment of the examples mark this out as a typical "Glusker". At almost every point one is aware that a lifetime's experience in both research and teaching have been distilled into the text. It can be confidently predicted that this book will remain one of the standard works in chemical crystallography for some years to come.

The Conquest of Taxol

Kyriacos C. Nicolaou* and Rodney K. Guy

Much has been written about taxol, one of the newest weapons against cancer, and its producer, the Pacific Yew tree (*Taxus brevifolia*).[1] In this article, the authors give a frank and behind-the-scenes account of their encounter with this well-known molecule, which they and their collaborators faced as a synthetic target.[2–6] Once again total synthesis is found to offer excellent opportunities for developing new synthetic strategies and novel reactions. The team of chemists who took up this challenge emerged with valuable experience and confidence in their skills.

Keywords: natural products · taxol · total syntheses

1. Introduction

Rarely has a molecule received as much media attention as taxol (**1**, Fig. 1) has in recent years. Taxol and its producer, the Pacific Yew, earned their positions of public prominence after a long association between the yew and humans. By 1991 taxol was a "celebrity molecule", hailed as a miracle drug against cancer but in desperately short supply.[7, 8a] The media frenzy surrounding taxol focused daily attention on issues of life and death for cancer patients who desperately needed the drug, on the yew tree whose exclusive taxol-producing ability meant sure death for the tree, and on a rare owl species whose natural habitat was being destroyed systematically by the logging of the same forests that harbor the yew. The ethical and pragmatical dilemma that accompanied the discovery of taxol was fiercely argued by doctors, environmentalists, and politicians. The solution, they all agreed, was to find an alternative source of taxol. Chemists and biologists were challenged to find a solution. Today taxol is obtained semisynthetically from baccatin III, which is isolated from the needles of the European Yew, *Taxus baccata*.[8b]

Some chemists had been interested in the compound much earlier. Never before, however, had the urgency been so great. Anticipation of approval by the Food and Drug Administration (FDA) spurred on the 30 or so research groups around the world working on the total synthesis of taxol. It was at this juncture that we began to consider taking up the challenge of taxol's synthesis. Although we were attracted by the molecule's intricate structure, our initial feelings were mixed because we knew that we would be one of the last groups to enter the already heated race towards synthetic taxol, a race that had begun for some research groups shortly after the molecule's discovery in 1971.

1

Before we describe our exciting journey, we should go back and trace the path of the yew tree and taxol through human history. The story of the yew is as old as the history of Western civilization itself.[9] Almost three millennia ago, Homer related the earliest tale of its use for bow-making in the Iliad. Alexander Pope translates:

Atrides, watchful of th' unwary foe,
Pierc'd with his Lance the Hand that grasp'd the Bow,
And nail'd it to the Eugh.

The yew has maintained its preeminence as the wood of choice for making bows to the present time. The Greeks, the Romans, and the English all appreciated its superiority and used the wood in their eras. Yew bows have figured prominently and decisively in wars over the years. For example, it was an arrow from a yew bow that killed King Harold the Saxon at the Battle

of Hastings in 1066 A. D., helping to turn the tide in favor of William the Conqueror.

A clue of the yew's cytotoxic properties comes from its long history as a producer of poison. In one of his books Julius Caesar recorded the death of Cativolcus, a chieftain of a Gaelic tribe, who committed suicide after his defeat at the hands of the Roman legions by drinking tea made from the bark of the yew. In fact, the Latin name for the Yew's genus, *Taxus*, probably has its origin in one or both of the Greek words *toxo*, for bow, and *toxikon*, for poison. It seems quite appropriate that a tree that has long represented death to man would provide one of the most potent weapons in our battle against cancer.

One of the seven major species of yews, *Taxus brevifolia*, commonly known as the Pacific Yew, grows in the oldest forests of the Pacific Northwest of North America.[9, 10] Long ago, Native Americans such as the Quinalt, the Tualitan, and the Nez Percé tribes recognized its unique qualities and used its bark as a disinfectant, an abortifacient, and even as a medicine for healing skin cancer. They also valued its wood, like the Europeans and the Asians did the wood of related yews, for bow-making and carving. It was in these forests, in 1962, that botanist Arthur Barclay encountered the Pacific Yew and collected its bark for chemical and biological studies. Little did he know that this particular sample would prove different from the others and would eventually catch the worldwide attention of scientists, doctors, politicians, environmentalists, and journalists.

The yew samples found their way, through the National Institutes of Health (NIH), to chemical, biological, and crystallographic laboratories, where eventually the structure of a compound active against leukemia cells was determined. Named taxol by its discoverers (Wani, Taylor, Wall, Coggen, and McPhail), this novel molecule was first described in the *Journal of the American Chemical Society* in 1971.[11] Despite its early promise and novel molecular architecture, taxol was not pursued further for several reasons. Scarcity, insolubility, and lack of knowledge regarding its mechanism of action were all responsible for this unfortunate delay. However, in 1979 this situation changed dramatically when S. Horwitz and her colleagues discovered that taxol acts by catalyzing tubulin polymerization and by stabilizing microtubules, essential fibers of the cytoskeleton.[12] The initial lethargy turned quickly into a campaign to rapidly develop the drug. By the time we started addressing a total synthesis, taxol was close to receiving approval by the FDA for clinical use against ovarian cancer.[13]

2. Embarking on the Taxol Project: The First Proposal to NIH

2.1. The Synthetic Efforts[*]

In 1991, Erik Sorensen, Chris Claiborne, and Kip Guy, three graduate students in my laboratories at the University of California at San Diego (E. S.) and Scripps (C. C., K. G.), were in search of Ph.D. projects. Intrigued by taxol's beautiful structure and therapeutic potential, they came to me with an interest in pursuing its total synthesis. Impressed by their courage and vision, and also attracted by the challenge, I immediately told them of my intentions of assembling a team to tackle the problem: they were the first to join. In the fall of 1991, we started to give serious thought as to how taxol could be put together in the laboratory. One of our most difficult problems was finding a route that did not merely duplicate the large body of chemistry already in the literature.

By February 1, 1992, we dispatched our first proposal requesting funding from the NIH for the total synthesis of taxol. Central to this proposal were: a) a convergent strategy (Fig. 2), b) the utilization of two metal-assisted C–C bond forming reactions to construct the eight-membered ring of taxol (Fig. 3, ring

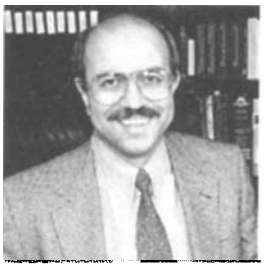
K. C. Nicolaou was born in Cyprus and received his Ph.D. degree from the University of London under F. Sondheimer and P. Garratt. After postdoctoral work at Columbia University with T. Katz and at Harvard University with E. J. Corey, in 1976 he joined the faculty at the University of Pennsylvania, where he was promoted to Rhodes-Thompson Professor of Chemistry. In 1989 he accepted joint appointments as Professor of Chemistry at the University of California San Diego and as Darlene Shiley Professor of Chemistry and Chairman of the Department of Chemistry at The Scripps Research Institute. His awards include a Guggenheim Fellowship, a Humboldt Senior American Scientist Award, the American Chemical Society Award for Creative Work in Synthetic Organic Chemistry, and the Dr. Paul Janssen Prize for Creativity in Organic Synthesis. He has received honorary degrees from the Universities of Pennsylvania, London, and Athens. Nicolaou's research interests focus on chemical synthesis, molecular design and recognition, and the biological function of molecules. He is the author of 330 publications, 45 patents, and two books. A new textbook by Nicolaou, "Classics in Total Synthesis" (coauthor: E. J. Sorensen), will be published this year by VCH.



K. C. Nicolaou

R. K. Guy

Rodney "Kip" Guy was born in 1968 in Fort Rucker, Alabama (USA), and obtained his bachelor's degree from Reed College. He worked until the fall of 1991 at the Synthetic Development Laboratory of IBM's Almaden Research Center in San Jose, California. He then joined the Nicolaou group at the Scripps Research Institute as a doctoral student and has been working on the taxol project. He has received graduate fellowships from both the Office of Naval Research and the American Chemical Society Division of Organic Chemistry. His scientific interests include the synthesis of natural products and their use to probe cellular processes.

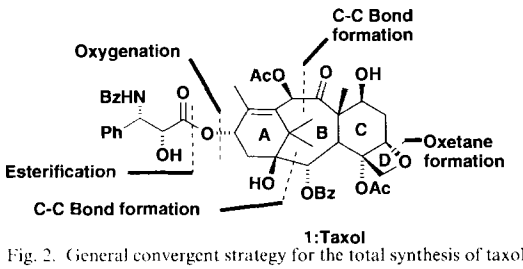


Fig. 2. General convergent strategy for the total synthesis of taxol (October 1991).

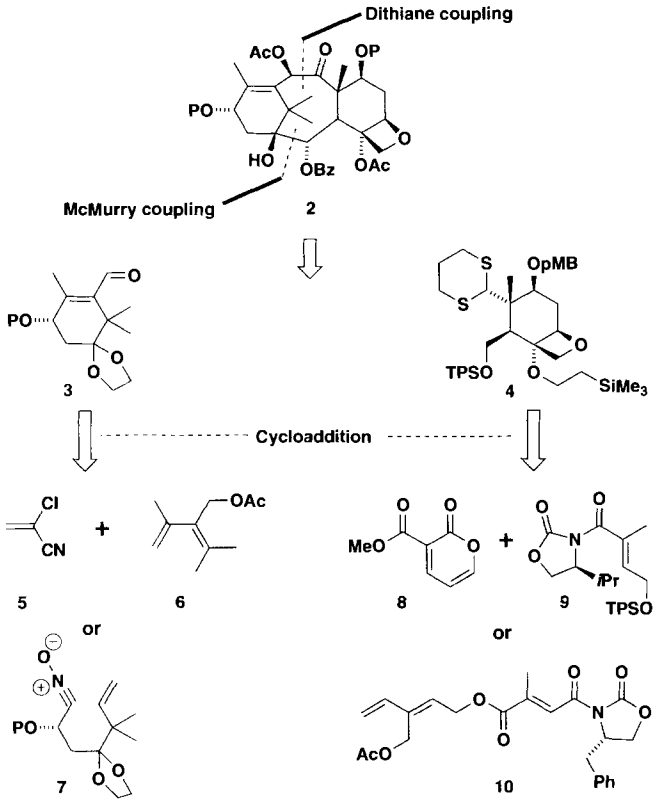

Fig. 3. The first plan for the convergent synthesis of taxol (January 1992).

B), c) the exploitation of Diels–Alder reactions to construct both rings A and C, and d) an alternative model study involving an oxy-Cope-based strategy to gain entry into the ABC tricyclic framework of taxol (Fig. 4). Despite our expectations, however, the study section found our first proposal unconvincing and sent us a depressing message, a score of 1.65 (39th percentile) [best possible evaluation: 1 (lowest percentile); worst possible evaluation: 5 (highest percentile)]. The squad was not deterred, and with stronger determination we wasted no time in preparing and submitting a new proprosal to NIH.

2.2. The Diels–Alder Approach to Ring A

In the meantime we had started our first assault on taxol. Our first goal was to explore the Diels–Alder chemistry outlined in Figure 3 for the construction of rings A and C. Erik, Chris, and C.-H. (Jack) Hwang, a research associate, concentrated on ring A, while research associates Jin-Jun Liu, Wei-Min Dai, and Jack, and graduate student Kip Guy focused on ring C. The designed route to ring A worked smoothly (Fig. 5), delivering a variety of related compounds of potential use in the total synthesis of taxol (e.g. **19**–**21**). Due to the success of this Diels–

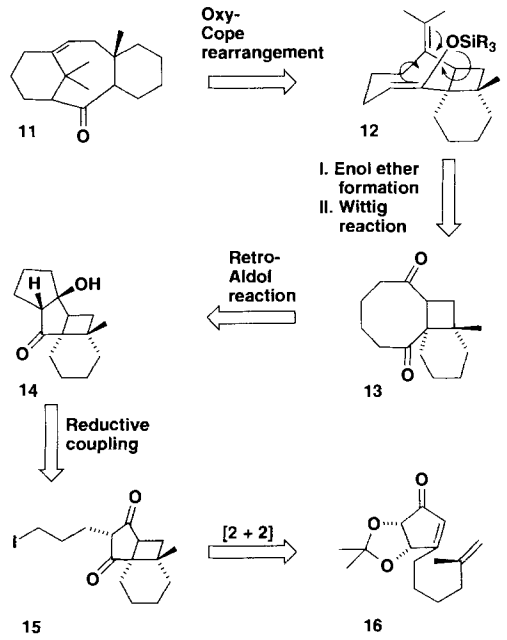

Fig. 4. An oxy-Cope strategy proposed as a model study (January 1992).

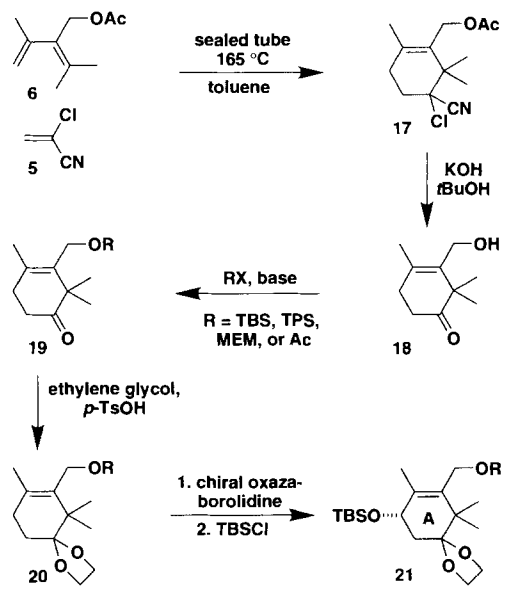

Fig. 5. The synthesis of the A ring unit proceeds as planned (Spring 1992).

Alder route, the alternative, intramolecular nitrile oxide/olefin cycloaddition approach (see Fig. 3) was never attempted. Because of the importance of this work to our taxol project and the fierce competition, we immediately dispatched a communication the synthesis of the A ring.[14] Parenthetically, this early report was rejected by *Angewandte Chemie*.

2.3. The Diels–Alder Approach to Ring C

In contrast to our experience with ring A, the initial attempts toward ring C met with frustrating failures (Fig. 6). While 2-methoxycarbonylpyrone **8** failed to react with chiral dienophile **9**, fusion of **8** with **22** proceeded in excellent yield in refluxing benzene. On examination of the product, however, we realized,

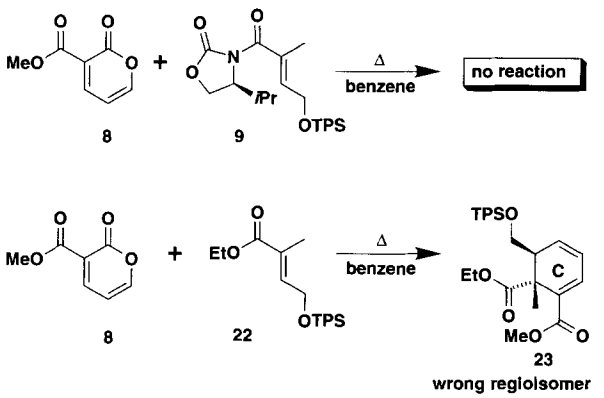

Fig. 6. Failed initial attempts to form taxol's C ring through Diels–Alder reactions (December 1991).

much to our disappointment, that the reaction furnished exclusively the undesired regioisomer **23**. In light of these discouraging results, we continued to search for new ideas.

One morning soon thereafter in my office I opened the latest issue of *Synthesis* and immediately noticed a paper by Koichi Narasaka et al. from the University of Tokyo.[15] I first turned to the paper because of my long-standing friendship with Koichi going back to the 1970s, when we were together at Harvard in the laboratories of E. J. Corey. The relevance of their work to our problem was unmistakable! As seen in Figure 7, the

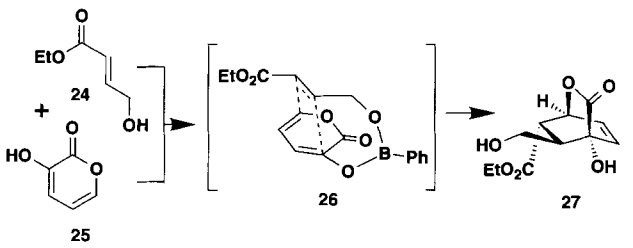

Fig. 7. A particularly propitious precendent from the group of Narasaka.

Narasaka reaction cleverly utilizes a boronate as a template for the assembly of a diene and a dienophile in a specific orientation, thus leading to the specific Diels–Alder regioisomer required for our taxol strategy! Only a methyl group was missing; a simple rearrangement would then provide ring C for our purposes.

Within days, the resistance of ring C to the Diels–Alder approach was broken and a beachhead was established by the application of Narasaka's brilliant boron-tethering device (Fig. 8). This facile process allowed the construction of the highly functionalized ring C in compound **31** in short order. Not only did the Diels–Alder reaction proceed in excellent yield with the requisite regioselectivity, but the desired skeletal rearrangement took place spontaneously under the reaction conditions (**30** → **31**), presumably because of the strain introduced by the extra methyl group. Intermediate **31** was quickly converted into a number of more advanced compounds, some of which are shown in Figure 9. Included among these compounds was the CD ring system **36**, in which taxol's oxetane ring is already installed. Due to the competitive nature of the taxol field, we sent a preliminary communication on this work along with the manuscript on our approach to ring A (vide supra)[16] to the

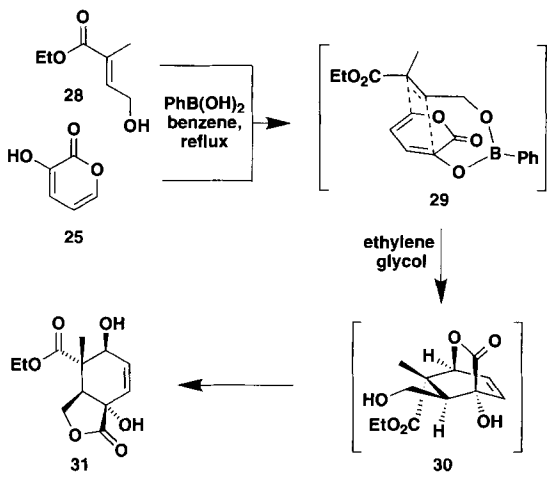

Fig. 8. Application of Narasaka's chemistry leads to an unexpected but advantageous rearrangement (December 1991).

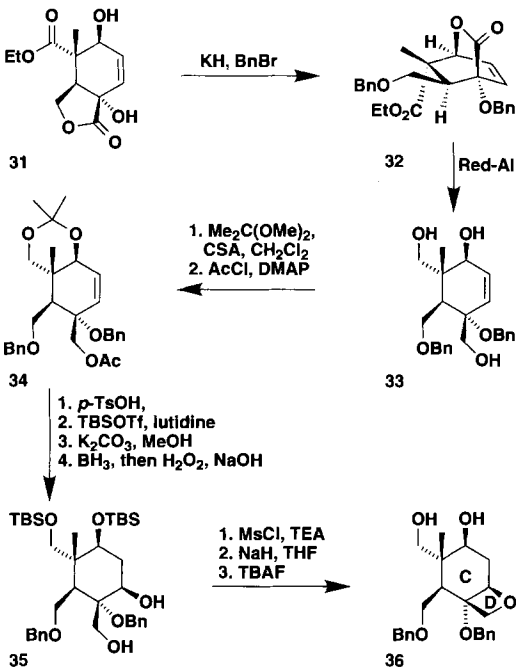

Fig. 9. The original synthesis of the CD ring system in taxol from the paper in *J. Chem. Soc. Chem. Commun.* (Spring 1992).

Journal of the Chemical Society, Chemical Communications. The anxiety one always feels on completion of a piece of work is amazing: it seems that the whole world is working on the same idea and that a "scoop" is imminent! More often than not, of course, one is mistaken, but the feeling cannot be avoided.

2.4. Initial Attempts to Couple "Top First, Bottom Second" Fail

With the two requisite fragments for taxol readily available, our attention turned next to their coupling. Given such functionalized intermediates as **37** and **38** (Fig. 10), one might surmise that final success would be just around the corner. Much to the surprise of the inexperienced (and there were some on the team at the time!), this would not be the case. Our first approach

was to attempt coupling of the two fragments at the "top" and then cyclize at the "bottom" to construct the eight-membered ring. As indicated in Figure 10, aldehyde **38** did not react either

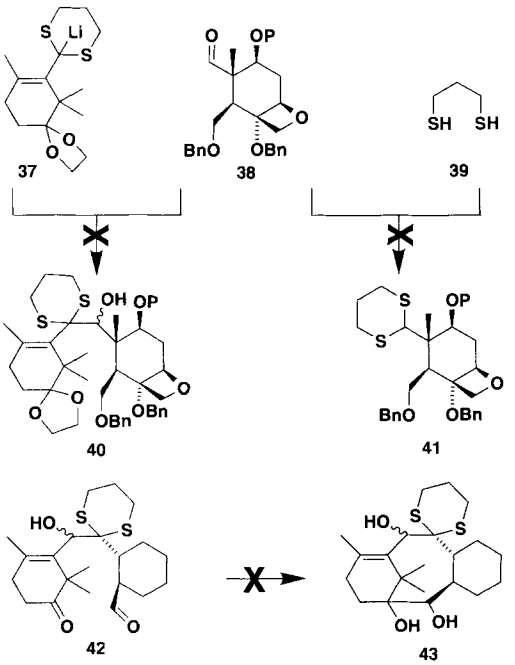

Fig. 10. Attempts to couple "top first, bottom second" fail (Spring 1992).

with lithiodithiane **37** to afford coupling product **40**, or with 1,3-propanedithiol (**39**) to give the expected dithiane **41**. At the same time a model study allowed the preparation of compound **42**, but its intramolecular McMurry coupling to yield compound **43** failed. Attributing these failures to severe steric hindrance within the systems, we decided to reverse the strategy and attempt coupling on the "bottom" first and then cyclizing on the "top" to construct ring B. The previous work by Pattenden[17] and Kende[18] gave us confidence in the McMurry reaction for closing the B ring. Therefore, we concentrated on the ways and means for coupling of the two fragments at the bottom.

2.5. A Crucial Observation and an Important Insight Point the Way

It was at this time that Erik Sorensen made a crucial observation. While attempting to benzylate hydroxy ketone **18** (Fig. 11) under standard basic conditions, he found that double C-alkylation adjacent to the carbonyl group occurred to afford compound **44**. This observation revealed how readily a second double bond is introduced in compound **18** in order to relieve transannular strain. Although useless for the benzylation of the hydroxyl group in **18**, this reaction pointed the way to intermediates such as **45** for our next generation of attempts at coupling fragments A and C. We first tested an enol triflate in a Stille-type coupling with an acid chloride (Fig. 12). Although this sequence worked quite well to give model compound **49**, more realistic intermediates were poor substrates. A new alternative was sought in haste.

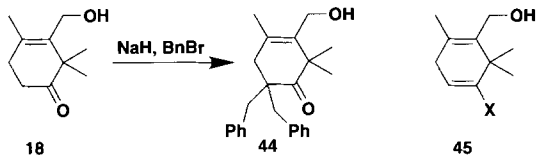

Fig. 11. Unusual preference for C-alkylation indicates that an additional double bond is advantageous for the A ring (June 1992).

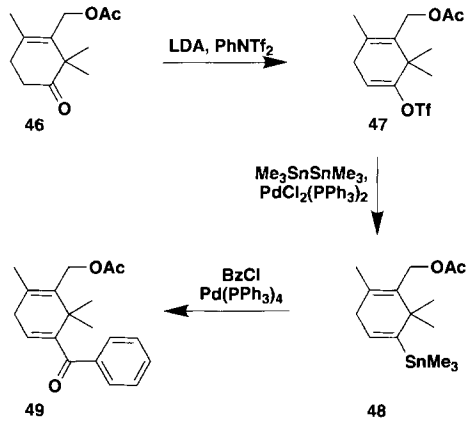

Fig. 12. Utilizing Stille chemistry to take advantage of the propensity for enolization works well in simple models but proves impractical with complex substrates (Summer 1992).

2.6. A Model Study for Exploring the Territory Ahead

The next insight came from Zhen Yang, who insisted on the Shapiro reaction as a means to connect rings A and C, despite the misgivings of several of his teammates and the lack of much precedent for such chemistry in complicated systems. The Shapiro approach was tried first with the model systems shown in Figure 13. The results were spectacular: coupling

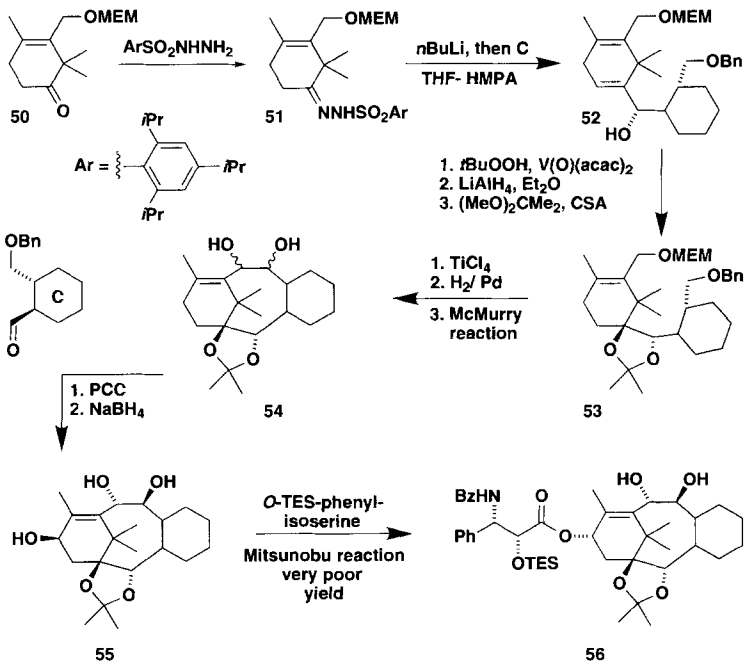

Fig. 13. The first successful closure of the B ring: validation of the Shapiro–McMurry approach (Summer–Fall 1992).

product **52** could be obtained in yields of over 80%. Furthermore, the prospects of stereochemical control in the actual synthesis of taxol added to the excitement of this discovery. This first model study carried out by Zhen, Erik, and Masahisa Nakada (visiting professor from the University of Tokyo) led to the successful synthesis of taxoid **56** (Fig. 13), thus exploring the territory ahead. The main findings of this exercise were that the Shapiro ("bottom first") and McMurry ("top second") reactions were viable options for constructing the desired ABC taxoid skeleton, and that unfortunately the acetonide functionality could not be removed at the final stages of the synthesis without destroying the molecule.[19] To find solutions for the remaining problems, yet another model study was designed and pursued.

2.7. A Second Model Study to Gather More Information of What Lies Ahead

The new model study, spearheaded by Chris, involved substituting a benzenoid framework for the CD ring system of taxol and utilized a cyclic carbonate to fix the 1,2-diol moiety in a highly preorganized conformation for the McMurry reaction (Fig. 14). The ready availability of the benzenoid CD equivalent, the stereoselectivity of the Shapiro coupling, and the high-yielding McMurry coupling observed in this study all contributed to the rapid and efficient synthesis of the benzenoid taxoid system **63**.[20] An important step in this synthesis was the efficient and regiospecific opening of the carbonate ring in **61**, which furnished the desired benzoate **62**. This reaction was originally developed in the ongoing retrosynthetic studies involving natural taxoids (see Section 2.9).

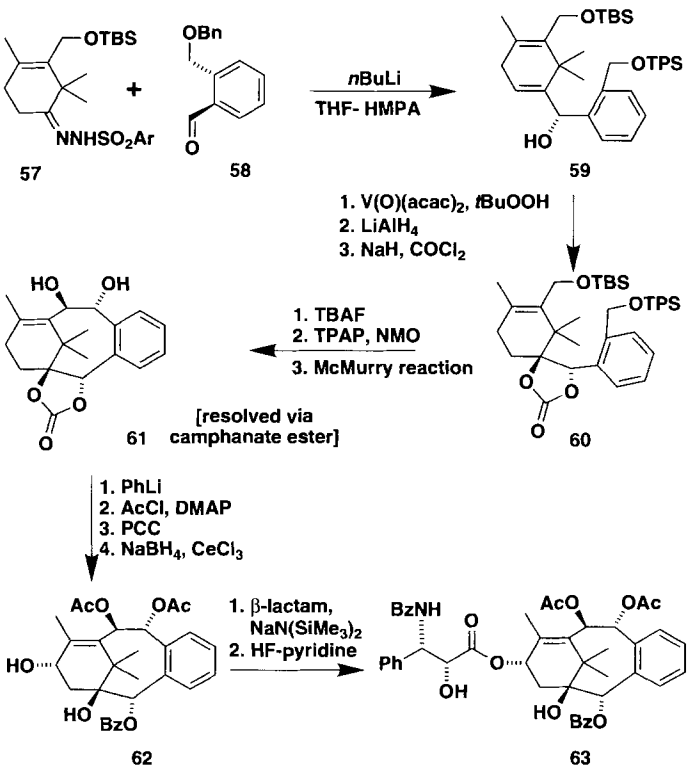

Fig. 14. A second model system helps establish the anticipated conclusion of the total synthesis (Summer - Fall 1992).

2.8. The Second Proposal to NIH

In the meantime a second research proposal had been assembled and submitted to NIH by October 1, 1992. This version described both model studies (Figs. 13 and 14), with considerable progress along the way, and a complete plan to finish the total synthesis of taxol. Additionally, the preparation of a series of designed taxoids was proposed. It was not long, however, before we learned that our revised proposal had the same fate as the first one: A score in the 37th percentile sent us back to the drawing board, and we scrambled for funding from other sources in order to maintain our momentum. A third proposal was prepared over the ensuing few months and sent back to NIH as our drive towards the target continued unabated.

As we entered 1993, the race for taxol was becoming quite heated. Rumors of imminent announcements of taxol's synthesis came and went without confirmation. Progress in our laboratory seemed rather slow; each problem that was solved gave way to another.

2.9. The Retrosynthetic Studies

It was decided at a relatively early stage that degradation studies with taxol would play a crucial role in answering questions about the final stages of the synthesis. There was a problem, however: the supply of taxol. No company would give us any taxol for our studies, despite repeated requests. We bought a small amount at an outrageous price, but that was not enough and unless we were prepared to risk bankruptcy something had to be done! It was finally through the generosity of Dr. Ezio Bombardelli of the Indena company, that we were given several grams of 10-deacetyl baccatin III (**64**, Fig. 15). Research associate Philippe Nantermet and Kip Guy, who were later joined by visiting scientist Hiroaki Ueno, probed taxol's chemistry systematically. Since a 13-deoxy-1,2-carbonate intermediate such as **68** (Fig. 15) was a projected key intermediate in our total synthesis of taxol, this compound became a target in our retrosynthetic studies. Thus, 10-deacetyl baccatin III (**64**) was converted into compound **65** by silylation and acetylation and then subjected to a variety of transformations (Fig. 15). After considerable experimentation, a sequence leading from **65** to **68** was established, and most importantly, the reverse path taking **68** back to **65** was worked out via compounds **67**, **66**, and **70**. Such exercises of securing a projected synthetic intermediate in advance from a natural product and converting it back into target compound are of considerable value in total synthesis. In this instance, these studies, along with the previously known conversion of **65** to taxol, allowed us to define, with complete confidence, compound **68** as an advanced intermediate for our total synthesis. At this stage, we knew that only six completely secured steps separated intermediate **68** and taxol.[21] Armed with this information, we pushed ahead in the synthetic direction to reach **68** from our ring A and ring C intermediates.

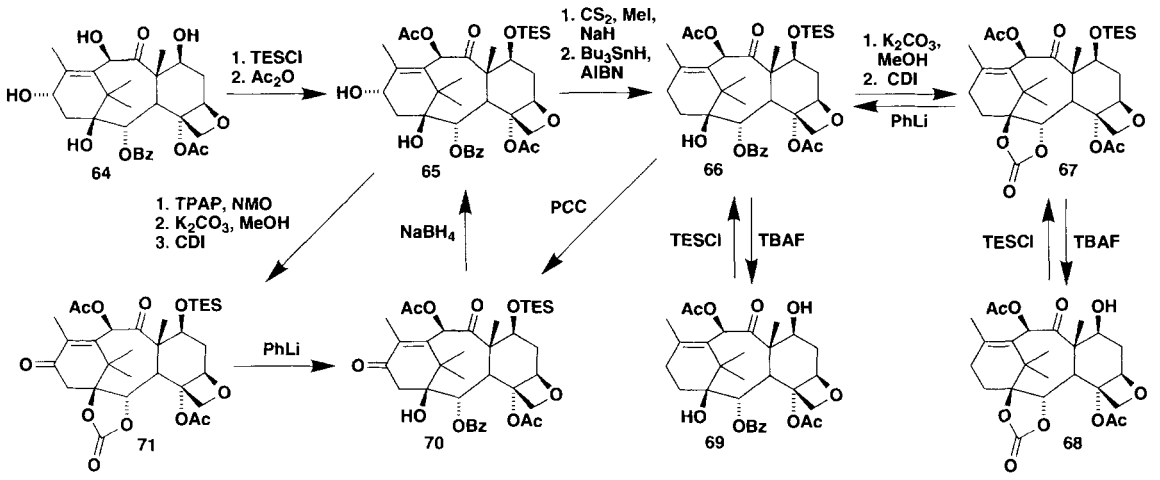

Fig. 15. Degradation studies facilitate planning of the final stages of the total synthesis (Summer 1992 to Summer 1993).

Achieving this goal still required walking a tightrope. A particularly important development was the application of a regioselective opening of the carbonate moiety to introduce the C2 benzoate system of taxol.

2.10. The Initial Attempts to Construct the Eight-Membered Ring of Taxol

Our initial efforts to construct an ABC taxoid system are summarized in Figure 16. The Shapiro coupling of fragments **72** and **57** proceeded in high yield, furnishing product **73** as a single diastereoisomer. Early attempts to generate the aldehyde function in **73**, however, gave mixed acetal **74**, which resisted further useful manipulation. We then turned our attention to the seven-membered ring carbonate **75** as a potential candidate for further advance. This compound proved elusive, however, as attempts to construct it by reaction of the diol with phosgene led to the tetrahydrofuran system **76** instead. Apparently, compound **77**, a presumed intermediate in this reaction, undergoes an internal attack by the C2 hydroxyl group at the primary carbon causing expulsion of CO_2 and HCl to afford **76**. The next attempt was directed towards the γ-lactone dialdehyde **79**, a potential McMurry substrate for the desired ring closure. The preparation of **79** proceeded according to plan, but unfortunately, all efforts to obtain **80** by the McMurry reaction failed, producing only diol **81**. At this point it became clear that this particular synthetic design did not favor the required ring closure and that a new tactic had to be adopted.

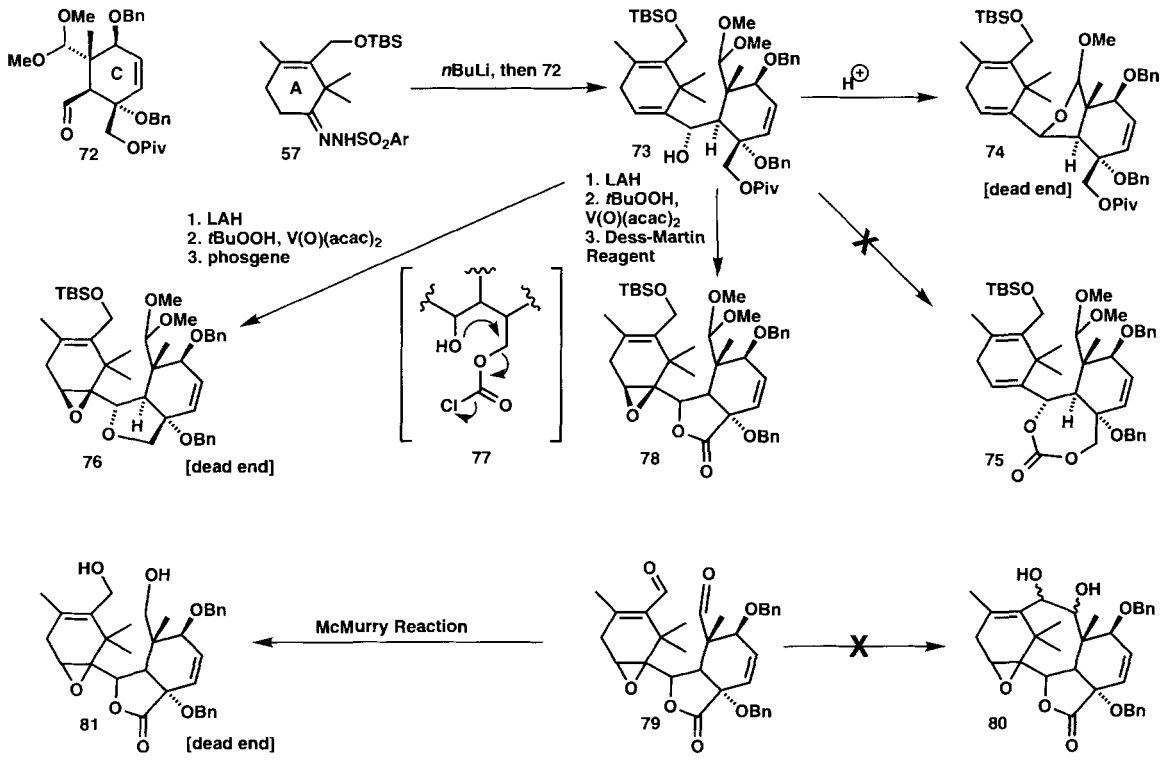

Fig. 16. Initial attempts to construct the eight-membered B ring of taxol fail (Fall 1992).

2.11. The Final Shapiro Elaboration and Preorganization of the Cyclization Precursor

The important results of the carbonate opening from the retrosynthetic studies (see Section 2.9) could not have come in a more timely fashion. We used that information to define a more specific strategy. According to this new plan, hydrazone **57** (ring A) and aldehyde **86** (ring C, Fig. 17) were paired as the Shapiro-coupling partners. The double bond in the resulting intermediate (**87**, Fig. 18) would serve in construction of the oxetane ring. Due to the sensitivity of the oxetane system, its construction was postponed until after the fabrication of the ABC skeleton.

The Shapiro coupling of **86** with **57** proceeded remarkably well (Fig. 18) both in terms of efficiency (80% yield) and stereoselectivity (a single isomer formed, whose configuration was later confirmed by X-ray crystallography). Figure 19 provides graphically a mechanistic rational for the observed stereoselectivity in this reaction. After many missteps along the way dialdehyde **92** was finally reached.

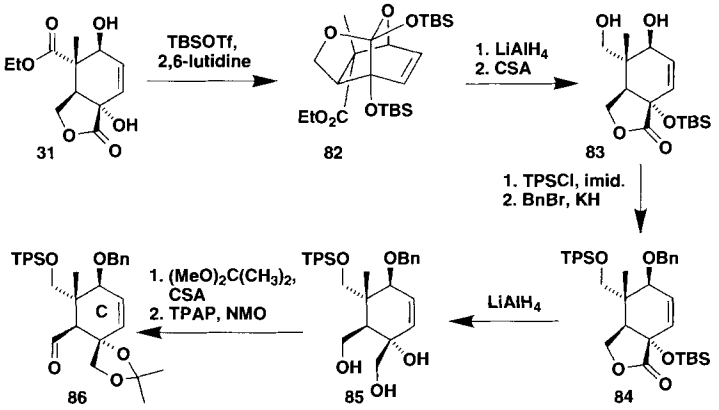

Fig. 17. Construction of the fully functionalized and protected C ring fragment aldehyde **86** (Spring 1993).

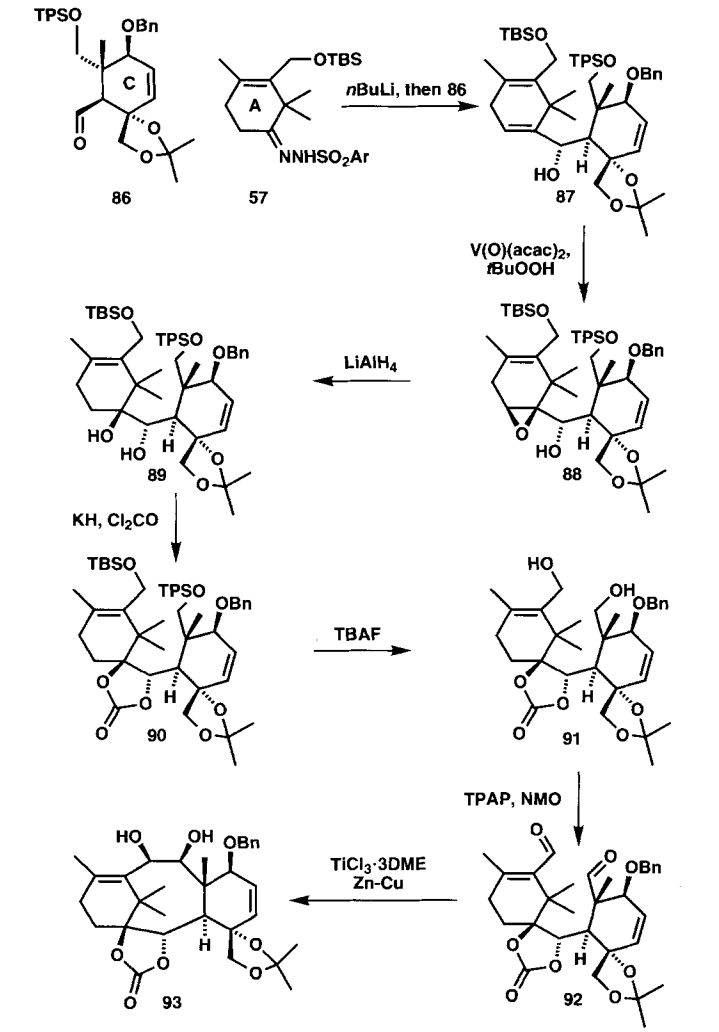

Fig. 18. Construction of compound **92** for the decisive McMurry reaction and formation of taxol's eight-membered ring (Spring–Summer 1993).

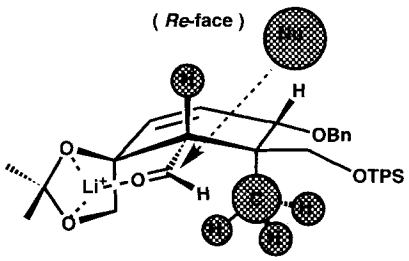

Fig. 19. A mechanistic rationale for the observed stereoselectivity of the Shapiro reaction. The Li^+ ion complexes the acetonide and aldehyde oxygen atoms, fixing the carbonyl group. The nucleophile attacks from the more accessible face, opposite the methyl group.

2.12. The McMurry Cyclization to Form the ABC Taxoid Skeleton

We then faced one of the most daunting problems of the entire campaign: the closure of taxol's B ring. With optimum preorganization, dialdehyde **92** seemed to be the best precursor we had synthesized thus far. Zhen Yang was chosen as the pointman to attempt the crucial McMurry cyclization—and it worked! The cyclized diol **93** (structure secured by spectroscopic and X-ray crystallographic analysis) was obtained, albeit in modest yield. The desired product **93** was accompanied by compounds **94**–**96** (Fig. 20). Despite many attempts by Chris and Zhen to improve the yield of **93** from this reaction, we could not prevail in the

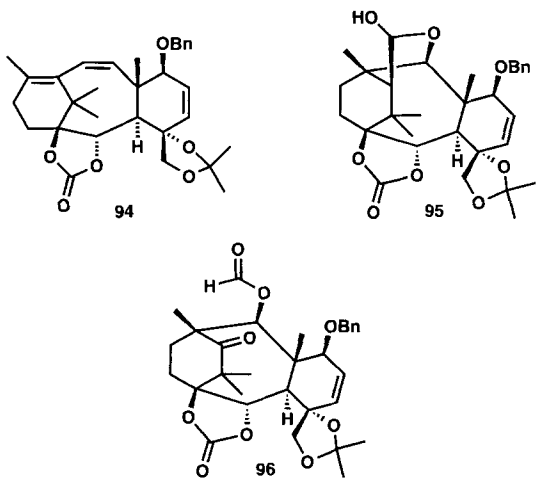

Fig. 20. The undesired side products of the McMurry reaction of **92** (see Fig. 18).

short time that we suspected we had. A major dilemma arose at this juncture. Should we continue to search for improvements of this cyclization method or should we abandon it to search for a new, more efficient procedure? Finally, Zhen Yang volunteered to become the "McMurry machine." But even this idea had its drawbacks, since the McMurry cyclization could not be scaled up to more than a few tens of milligrams without loss in efficiency. Nevertheless, Dr. Yang was able to provide a constant supply of diol **93** for the rest of the team, whose task was now to advance it further along the projected pathway to taxol.

At this stage, we chose a classical resolution to separate the two enantiomers of **93** for the production of natural taxol. Figure 21 illustrates this resolution, which relied on chromatographic separation of the diastereomeric camphanate esters **97a** and **97b**. Luckily, one of the diastereoisomers, the wrong one as it turned out, crystallized nicely, and X-ray crystallographic analysis revealed its absolute stereochemistry (**97b**, see ORTEP drawing, Fig. 21). This development enabled us to push forward to the next stage with the desired isomer, **93a**.

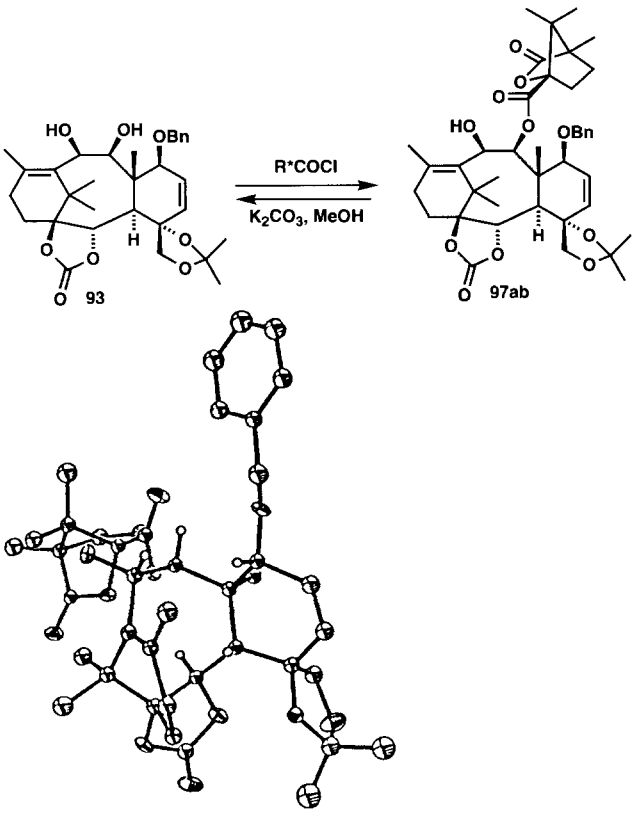

Fig. 21. Top: Resolution of the diol (±)-**93** via its camphanic esters provides (+)-**93** (Fall 1993). R*COCl = (1*S*)-camphanic anhydride. Bottom: X-ray structure of **97b**.

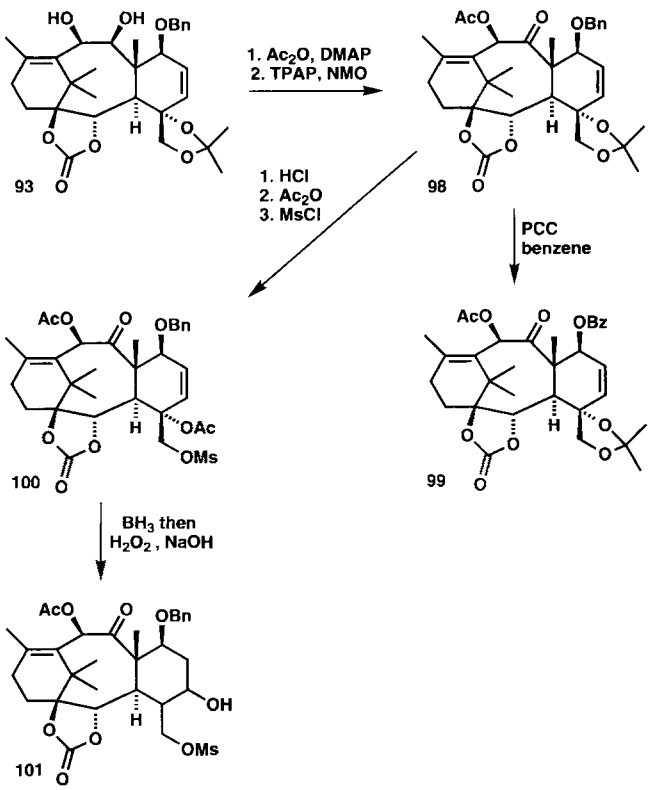
2.13. The Third NIH Proposal

In June 1993, while in the "heat of the battle" during final stages of the synthesis, we submitted the third version of our proposal to NIH. This latest revision included over ten alternative approaches to the eight-membered ring of taxol and a series of designed taxol mimics. Ironically, the announcement of the proposal's acceptance and eventual funding would come after we had completed the total synthesis of taxol. The positive response from NIH came hastily by fax on Saturday morning, February 19, 1994, providing us with a deep sense of the meaning of the expression "better late than never!"

2.14. The Fortunate Configurational Adjustments at C9 and C10

Since we had the enantiomerically pure diol **93**, the next objective was to settle the issue of the regio- and stereochemical arrangements in the C9–C10 region of the molecule. To our pleasant surprise, monoacetylation of **93** (Fig. 22) proceeded well, as did the ensuing NMO–TPAP oxidation of the remain-



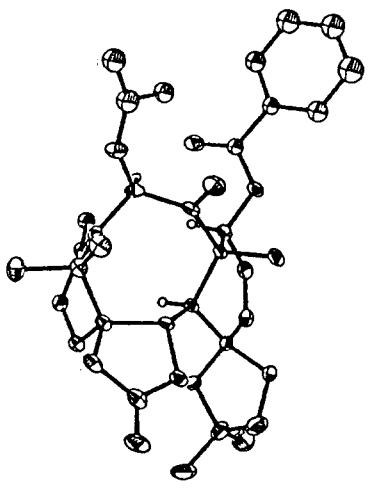


Fig. 22. Top: Attempts at hydroboration and allylic oxidation fail (Fall 1993). Bottom: X-ray structure of **99**.

ing free hydroxyl group. The regio- and stereochemical outcome of this sequence was the subject of much debate. NMR data pointed to the desired structure **98** but did not provide overwhelming evidence. Considering the X-ray crystallographic analysis of the camphanate ester **97b** mentioned above, we thought the regiochemistry of **98** odd, since it required acetylation at the other hydroxyl group, and this was not fully accepted at first by everyone on the team. Why should camphenyl chloride and acetic anhydride lead to opposite regiochemical outcomes in these esterifications? Soon thereafter, an unequivocal confirmation of the structure of **98** was obtained, largely through serendipity. Oxidation of **98** with PCC, aiming at oxidation at C13, gave unexpectedly the crystalline benzoate ester **99**, whose X-ray crystallographic analysis (Fig. 22 bottom) proved beyond doubt both the regio- and stereochemistry of the C9 acetate. This news was received with relief with regards to the C9–C10 region of the molecule, but also with chagrin since it implied that the protecting group at C7 must be replaced with one that would withstand an allylic oxidation. Could it be that the allylic alcohol at C10 is considerably more reactive than that at C9, but much less accommodating of a sterically demanding group such as the camphanate ester? Molecular models reveal only slight steric differences between the two positions.

2.15. Preparing for the Oxetane Ring: Introduction of the C5 Oxygen Atom

At this juncture we began to address the introduction of the hydroxyl group at C5. We placed hydroboration at the top of our list as a potential means of bringing in the required oxygen atom. The prospect of the two hydroxyls at C4 and C20 acting as directing groups was considered to be an advantage of such a substrate. Therefore, the acetonide group was removed from the substrate **98** to furnish the corresponding diol (Fig. 22). However, all our attempts to hydroborate this diol and a number of its derivatives met with a serious side reaction: cleavage of the allylic C–O bond leading to C4-deoxy systems as illustrated by the transformation of **100** to **101** (Fig. 22).

Faced with this new and serious problem, and putting aside for the moment the issue of the configuration of the carbon atom bearing the hydroxyl group, we decided to attempt the hydroboration reaction on acetonide **98**, hoping to avoid the undesired C–O bond cleavage. Much to our surprise, the reaction worked quite well, giving rise to a major isomer whose configuration became the subject of a major argument (Fig. 23). The orientation of the newly installed hydroxyl group at C5 in compound **102** was not easily deduced by NMR spectroscopy, but chemical correlation with authentic material, derived from natural compound by a degradation sequence (Fig. 24), showed this compound to be the α isomer.[3]

2.16. Installation of the Oxetane Ring

The next task in the drive towards taxol was the installation of the oxetane ring. Considering the work of P. Potier with naturally derived materials in which he and his collaborators at Gif-sur-Yvette formed an oxetane from a triol similar to **102**

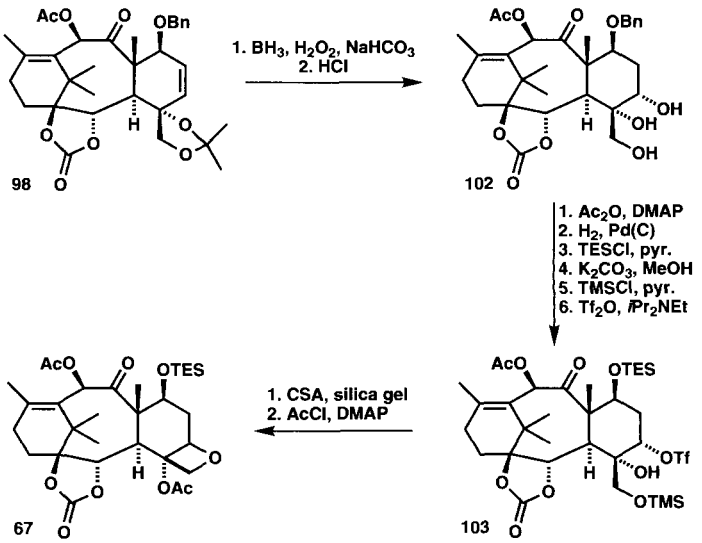

Fig. 23. Construction of the oxetane system and arrival at the desired tetracyclic intermediate **67** (Fall–Winter 1993).

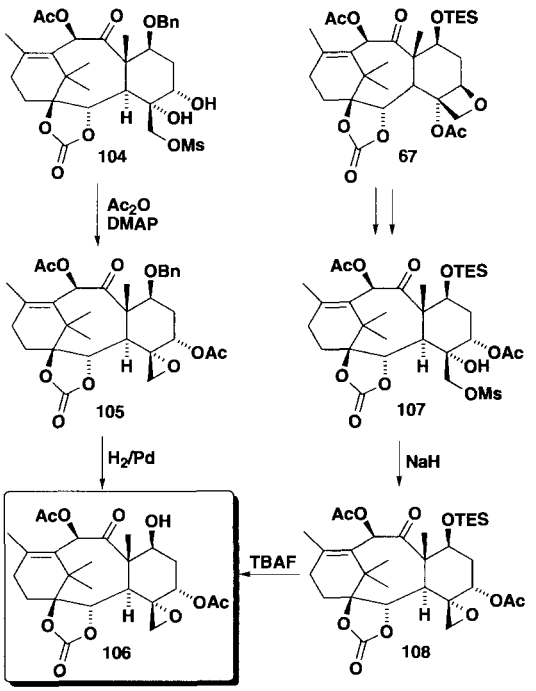

Fig. 24. Proof of the configuration at C5 by comparison of the degradation product **106** obtained from **67** with the derivative of **104** (Winter 1993).

(Fig. 23), we expected to solve this problem within a matter of days. But it took the team more than two months! First, and unforgivably so, we had missed Potier's important paper in *Tetrahedron*;[22] as a result this reference is missing from our review on the chemistry and biology of taxol, which was published in January 1994 in *Angewandte Chemie*.[1] Second, protection of the tetraol system in ring C presented a serious challenge. The problem was finally solved by utilizing the triflate group at C5 and displacing it intramolecularly with the hydroxyl nucleophile group at C20 by an S_N2-type reaction, a tactic used by Danishefsky et al. in a model system[*] (Fig. 23).[23] Application

[*] See footnote on p. 2089.

of Potier's mesylate protocol, which eventually came to our attention, worked even better. The final bulwark of taxol's fortress fell on January 19, 1994. Compound **67** matched an authentic sample by all the usual criteria, and as outlined in Figure 25, was carried through to taxol. The total synthesis of

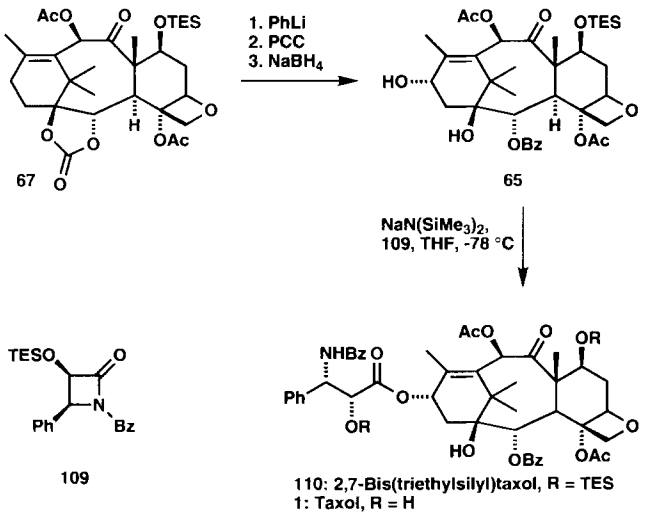

Fig. 25. Final stages of the total synthesis of taxol (January, February 1994).

taxol was reported in *Nature*, on February 17, 1994, shortly after the *Science* had designated taxol as a runner-up "Molecule of 1993".[24] Our publication appeared almost at the same time as another taxol total synthesis by the research group headed by Holton.[25, 26] Both syntheses met with highest acclaim.[27–29] Those early days of 1994 were quite dramatic and worth sharing here.

3. The Conquest

3.1. The Exhilarating Triumphant Moments

It was 11:00 pm on Wednesday, January 19, 1994, when the phone rang. Georgette, my wife, woke me up saying, "There's a man with an accent on the phone for you." Reluctant and very sleepy, I picked up the phone and said, "Hello?" It was Hiroaki Ueno asking me to come to the lab immediately because he wanted to talk to me. "What is it?" I said, "Can we talk tomorrow?" My thoughts started to turn to some bad accident in the lab. "No," he said, "You have to come now. It is very important, we have some news." To press me to come, Hiroaki put Jin-Jun on the line, who also insisted that I come to the lab, by saying, "We have the compound—we made taxol!" "I'll be there in five minutes," I said slamming the phone down and jumping out of bed. I put on my jogging suit and ran out the door to the car, saying to Georgette, "I have to go. They say they have some good news they finished taxol. I'll be back soon." In five minutes I was in my office looking at the spectra. The NMR spectra of synthetic and authentic intermediate **67** were identical. The synthetic and retrosynthetic sequences had been bridged! Only five already secured steps remained; our goal was only a matter of days if not hours from completion! Satisfied with what I saw, I left saying, "I'll see you tomorrow morning to discuss whatever we have to do to polish the work and write up the paper."

The next morning, I was in my office early pacing back and forth until everyone on the project arrived. Hiroaki was still in the lab when I arrived, having spent all night and morning bringing up material for a repeat of the final stages. Jin-Jun and Philippe were both away interviewing for jobs. The rest of the team, consisting of visiting professor Elias Couladouros from the University of Athens, research associates Johanne Renaud, K. Paulvannan, anad Zhen Yang, and graduate students Kip Guy, Chris Claiborne, and Erik Sorensen arrived shortly, and we decided that they would press around-the-clock until all intermediates leading to taxol were finally characterized and the final sequence was repeated; I was to immediately start working on preparing the manuscript. By the afternoon of Friday, January 21, 1994, the manuscript on the total synthesis of taxol was dispatched to *Nature*. Our paper was accepted, after peer review, on Monday, January 31, 1994, and scheduled to be published on Thursday, February 17, 1994.

3.2. The Competition

This story would not be complete without paying tribute to those researchers whose work in the area of taxol chemistry made the field so rich, exciting, and fruitful. In Europe, the groups of Potier, Greene, Pattenden, Commerçon, Blechert, Fetizon, and Jenkins contributed admirably to this area. In Japan, the work of Kuwajima, Kitagawa, Yamada, Ohtsuka, Takahashi, and Mukaiyama is nothing less than brilliant. In the USA, Wender, Trost, Danishefsky, Kende, Paquette, Swindell, Shea, Ojima, and Holton enriched considerably the field and provided much excitement and drama over the last two decades or so. A number of other groups have also touched upon various aspects of taxol's chemistry and biology.[1]

Particularly striking were the two papers from Holton's group at Florida State University. They not only describe the total synthesis of taxol itself, but also that of its enantiomer. One has to admire the courage of this group, who apparently risked all the glory of publishing first, by waiting to complete both syntheses before submitting their papers.[*]

4. Conclusion

The conquest of taxol as a synthetic target was both intense and exciting. Driven by the desire to succeed, the team of ten in the Nicolaou group (Fig. 26) proved themselves second to none and rose to the challenge. This was a magnificent opportunity for all of us to develop some new strategies in total synthesis and to discover chemistry leading to the synthesis of taxol and a series of designed analogues. This team came out of this project very proud of their success but also very tough, experienced, and ready to attack any challenge in synthesis placed in front of

Cytomimetic Organic Chemistry: Early Developments

Fredric M. Menger* and Kurt D. Gabrielson

This article describes how chemical and physical stimuli cause a simple system, the giant vesicle, to undergo a variety of "cytomimetic" transformations such as fusion, fission, endocytosis, budding, aggregation, birthing, and foraging. For example, when a giant vesicle, which happens to have a smaller vesicle inside it, is exposed to octyl glucoside, the smaller vesicle can pass through the outer membrane into the external medium ("birthing"). The resulting injury to the membrane of the host vesicle heals immediately. Addition of cholic acid, on the other hand, induces a feeding frenzy in which a vesicle grows rapidly as it consumes its smaller neighbors. After the food is gone, the giant vesicle then self-destructs (a case of "birth, growth, and death"). Such lifelike morphological changes were obtained by using commercially available chemicals; thus these processes should be assigned to organic chemistry, and not to biology or even biochemistry. Experimental details (e.g. the preparation and observation of the vesicles) are included in this review in hopes of helping others enter this undeveloped field.

Keywords: cytomimetic organic chemistry · microscopy · supramolecular chemistry vesicles

1. Introduction

The ancient Greeks believed that conversion of an unorganized universe ("chaos") into an organized one (the "cosmos") was the work of their dieties. Today, organization (especially in complex biological systems such as the cell) seems almost as puzzling as it did centuries ago. In mysterious ways, molecules organize themselves into elaborate assemblies to produce a phenomenon called "life". Since living systems presumably obey the fundamental laws of chemistry, biological behavior must, by default, originate from its collective and holistic nature. Biology is, in effect, organized organic chemistry. The question then becomes: Are the properties of organized organic molecules predictable from the familiar properties of individual molecules? Or in other words: Are organic "systems" simple extrapolations of single-molecule chemistry? We have already argued negatively to these questions.[1] To learn about organized assemblies, and ultimately about biology, one must forsake single-molecule organic chemistry and confront the assemblies themselves despite the difficulties, complications, and uncertainties that will undoubtedly ensue.

Consider the role of the π-meson in chemistry. Since π-mesons are components of all nuclei including that of carbon, organic chemistry necessarily embodies them. A decarboxylation, for example, entails a loss of π-mesons. Why then are chemists completely indifferent to these elementary particles? The answer is that chemists operate at a level of complexity and organization where particle physics is of absolutely no consequence. Three related quotes reinforce this general point. W. H. Thorpe: "The behavior of large and complex aggregates of elementary particles is not to be understood as a simple extrapolation of the properties of a few particles. Rather, at each level of complexity entirely new properties appear". P. W. Anderson: "At each level of organization, types of behavior open up which are entirely new and basically unpredictable from a...detailed analysis of the entities which make up the...higher level systems." And A. R. Peacocke: "Higher levels of complexity are distinguished by some genuinely new features and activities, and these require distinctive theories, language, and concepts to describe them". It is the philosophy embraced in these quotes that motivated the work that will be described in the following pages.

Vesicles, also called liposomes, are spherical structures composed of a closed lipid shell surrounding an aqueous interior (Fig. 1). Under certain conditions, lipids can self-assemble into giant vesicles the size of living cells.[2] As will be detailed later, giant vesicles engage in many cell-like activities such as aggregation, budding, fusion, and fission.[3] We refer to this behavior as "cytomimetic" chemistry.[4] Although we are hesitant to introduce such new jargon, the descriptor cytomimetic for the striking morphological changes (visible under a light microscope) seems appropriate enough. And, to paraphrase J. S. Mill, "Hardly any thoughts

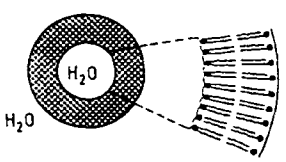

Fig. 1. Schematic representation of a unilamellar vesicle composed of a single bilayer of lipid molecules.

Telefax: Int. code + (404)727-6586

ever make their way among mankind, even in the minds of their inventors, until aptly selected words nail them down and hold them fast".

We are hardly the first to become fascinated by cytomimetic chemistry. Over sixty years ago, in a brilliant piece of work, Crile et al.[5] combined the ether-soluble fraction of brain tissue (i.e. the lipids) with the water-soluble fraction (i.e. the proteins and nucleic acids).[6] Within minutes remarkable structures, called "autosynthetic cells", formed in the water. Each contained a microscopically visible central organelle resembling a nucleus. The structures grew slowly, multiplied by budding or direct division, and occasionally moved like an amoeba. They even exhibited a high rate of oxygen consumption. Although the findings have been confirmed independently,[7, 8] they have been largely ignored. We are currently resurrecting this work (the desire to do so being irresistible!), but the present article will deal only with much simpler systems composed of material that is not of direct biological origin.

It is necessary to stress the preliminary nature of what is about to unfold. Work began just two years ago in a small office made over to house a microscope. The plan was to watch the response of giant vesicles as they were exposed to chemicals, heat, touch, and various other irritations. At this early stage of research, we hoped more for a slow accumulation of information than for instant illuminative insights. J. F. Wilford described the situation succinctly: "Science proceeds first by open exploration, the time of initial discoveries. Then follows reconnaissance, gathering evidence on a broad front, pursuing leads to the far corners of the problem, and generating preliminary hypotheses. Finally, if warranted by the results of the exploration and reconnaissance, there comes the time for detailed studies and the testing of more informed hypotheses". By all counts, we are in the "open exploration" phase. Yet even so, the results to date have been sufficiently intriguing that their publication, in hopes that others join the enterprise, appears justified.

Since this article is intended for a broad range of nonexperts, an attempt has been made to avoid a technical, dehydrated style of writing. This was easy to do because "when we begin the study of any science, we are in a situation, respecting that science, similar to that of children" (A. Lavoisier). Indeed, many were the times when we gazed with a child's wonder at the dynamics of our giant vesicles.

2. A Brief History of Giant Vesicles

A. Einstein said "A hundred times every day, I remind myself that my inner and outer life are based on the labors of other men, living and dead, and that I must exert myself to give in the same measure as I have received." We too owe a debt to others who, before us, investigated giant vesicles and related systems. In 1911 Otto Lehmann wrote a book entitled "Die Flüssigen Kristalle" ("Fluid Crystals") in which he published optical micrographs of long tubules projecting from the edges of hydrated phospholipid films.[12] He also observed vesicle structures that he called "kunstliche Zellen" ("artificial cells"). As we shall see, Lehmann's tubules were important to our own research carried out eight decades later. D. Hammarskjold once asked, "Why this desire in all of us that, after we have disappeared, the thoughts of the living shall now and again dwell upon our name?" Otto Lehmann certainly had, at least in our laboratory, his wish fulfilled.

For all practical purposes, Lehmann's system lay dormant until the mid-1960s when it was revitalized by Alec Bangham. (Vesicles, in fact, were once referred to as "bangosomes"). Bangham was among the first to appreciate fully what now seems to be a rather obvious fact: Vesicles separate an interior volume from the external solvent by means of a semipermeable barrier (i.e. the lipid bilayer).[9] Substances placed within vesicles can, therefore, be protected (at least temporarily) from the surrounding bulk medium. This, plus the ability to target vesicles to specific biological sites, has stimulated considerable commercial interest. Since prospective uses of vesicles in pharmacology, medicine, cosmetics, diagnostics etc. are discussed elsewhere,[10] little more will be written about them here. Suffice it to state that the mundane lipid is a particularly interesting and useful substance not because of its molecular structure per se but because of its aggregated form. Organized lipid assemblies are, accordingly, ubiguitous in Nature. Even "our souls may reside in fat" (E. Chargaff).

The bulk of vesicle research has employed so-called small unilamellar vesicles (SUVs) or large unilamellar vesicles (LUVs).[11] Both are submicroscopic structures (about 30–50 nm and 100–200 nm in diameter, respectively). A typical SUV preparation is carried out as follows:[12] Lecithin or some other phospholipid (20 mg in 200 μL $CHCl_3$) is placed in a 4-dram vial

Fredric M. Menger was born, raised, and educated in the Northern temperate zone. His fondness for quotes, evident in the text, prompts one from the late rock star Frank Zappa: "I write because I am personally amused at what I do". Realizing that his professorial desk is a dangerous place from which to view the world, he travels extensively to far-flung places, often carrying his blues harmonica with him.

Kurt D. Gabrielson carried out most of the experiments described in this article. He has a BS from Rhode Island College, and he recently received his Ph.D. from Emory. He is now working for the Georgia Pacific Corporation.

F. M. Menger

K. D. Gabrielson

and the solvent evaporated with a stream of nitrogen. The resulting lipid film is then dried under reduced pressure, mixed with 2.0 mL buffer, and sonicated (probe or bath) for up to 15 min at a temperature exceeding the phase-transition temperature of the lipid (70 °C being sufficient for most lipids). Dynamic light scattering can be used to determine the size distribution of the resulting SUVs. LUVs are commonly prepared by rapidly injecting an alcoholic solution of the lipid into buffer.[13] Alternatively, an ether solution of the lipid is slowly injected into a warm aqueous phase where the ether evaporates, and the lipid assembles into large vesicles.[14]

Three disadvantages of SUV and LUV systems are worthy of note. a) Generally, SUVs and LUVs display a rather broad size distribution. This can present a problem if the various sizes within a population do not have identical properties (permeability, spectra etc.). b) SUVs and LUVs, being of small diameter, possess a high curvature compared to the much flatter cellular membranes. Curvature perturbs lipid packing and affects, therefore, the membrane behavior. c) Since one cannot visualize SUVs and LUVs under a light microscope, much information about them is necessarily difficult to obtain. It is not easy, for example, to differentiate SUV fusion from SUV aggregation. Undulation of membrane bilayers is almost impossible to monitor. And SUV/LUV systems do not lend themselves to the studies of injury and healing processes within the membrane. For all these reasons, we decided to switch to so-called giant vesicles that can be directly visualized under the light microscope.

At one time, when we were deeply immersed in SUV/LUV research,[15] we invoked the three famous questions of Kant: What can I know? What ought I do? What may I hope? With regard to the first question, we felt that there were important processes (e.g. membrane injury and healing as mentioned above) that could *not* be properly defined by using SUV/LUV systems. Therefore, in response to the question of what ought to be done, we thought it advisable to shift to giant vesicles. What may be hoped by doing this? That, of course, is a main theme of this paper.

Before proceeding, it might be useful to discuss an important parameter: vesicle size. Table 1 gives, in various units, the diameters of different types of vesicles and biological objects.

Table 1. Diameters of various chemical and biological entities.

	Å	nm	μm	mm
micelle	50	5		
SUV	300-500	30-50		
LUV	1000-2000	100-200	0.1-0.2	
rabies virus	1300	130	0.13	
typhoid bacillus	7000	700	0.70	
red blood cell	7×10^4	7×10^3	7	0.007
amoeba	10×10^5	10×10^4	100	0.10
giant vesicle	0.5 20×10^5	$0.5-20\times10^4$	5-200	0.01 0.20

Since giant vesicles equal or exceed cellular dimensions, they are microscopically visible. Although giant vesicle preparations are usually polydisperse (multisized), this takes on far less significance compared to SUV/LUV systems because, as will be shown, we select and operate on only one giant vesicle at a time. And the size of this vesicle is always known. Since this article is intended to be, in part, a primer on giant vesicles, it is worthwhile to summarize the methods that have been reported for their preparation.

2.1. Drying-Rehydration Method[16]

Phospholipid (1-3 mg) is dissolved in 1 mL $CHCl_3$/MeOH (10:1) in a 5 mL-round-bottom flask. The solvent is then removed by rotary evaporation (keeping the flask as horizontal as possible to maximize the film area). About 5 mL deionized water (or aqueous solution with less than 1 mM salt) is added carefully so as not to disturb the lipid film, and the flask is placed in warm water (70 °C) for 1 hour during which the hydrated film separates from the walls of the flask (Fig. 2). On continued

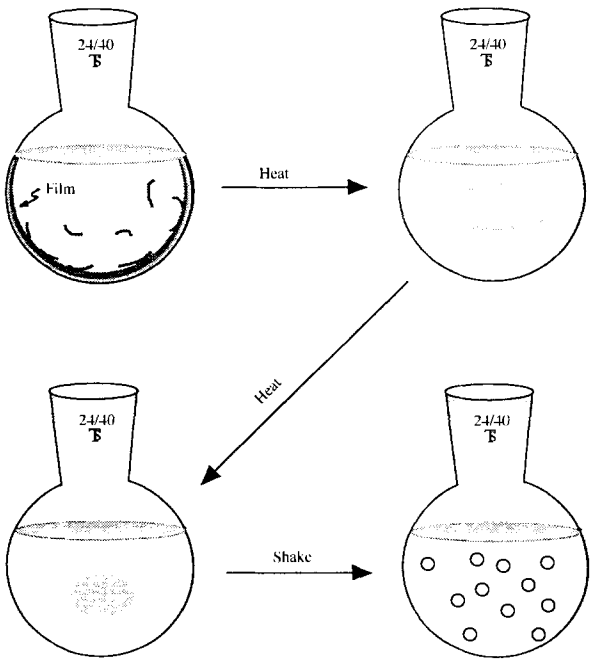

Fig. 2. The drying-rehydration method for making giant vesicles. Phospholipids are often hydrated at 70 °C, whereas 50 °C is sufficient for didodecyldimethylammonium bromide (DDAB).

heating (4 hours to 2 days), the lipid forms a single globule, perhaps 1 cm in diameter, that resembles a translucent sea-creature suspended in water. The flask is removed from the bath and shaken for only a few seconds (no more!) while it is still warm. This causes the globule to disintegrate into a polydisperse collection of giant vesicles suspended in a nearly clear solution. The vesicle size distribution depends upon the incubation time as well as the duration and vigor of the shaking step. Modifications of this procedure are described in the literature.[17]

2.2. Dialysis Method[18]

In this approach, 1-*O*-methylglucoside (200 mg) plus lipid (10 mg) in 400 μL methanol are dialyzed against pH = 7.4 buffer for two days. Giant vesicles are formed under conditions

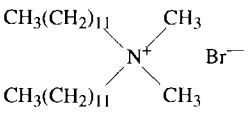
where their internal contents are continuously hyperosmotic. Diameters range from 10–100 μm. It is claimed that the vesicles are mainly unilamellar (a single bilayer) as opposed to multilamellar (several bilayers in an onionlike configuration). Sodium trichloroacetate can also be used to achieve an osmotic gradient across the bilayer.[19] The dialysis method has an advantage over drying-rehydration in that it can be used with high salt concentrations. On the other hand, possible contamination by the "indifferent solute" is an ever-present concern.

2.3. Freeze-Thaw Method[20]

Giant vesicles are produced from SUV systems, generated in water by sonication, when the latter are repeatedly frozen in liquid nitrogen and then thawed. This method is advertized as being particularly suitable for lipid systems containing proteins because drying-rehydration and dialysis could conceivably denature the proteins.

2.4. Solid Hydration

From our point of view, it was especially important to minimize formation of multilamellar (onionlike) vesicles owing to their complexity. Vesicle fusion, for example, becomes difficult to interpret when multiple layers of varying curvature collectively get into the act. In our hands, all three of the above methods (especially dialysis and freeze-thaw) gave significant populations of multilamellar vesicles with both phospholipids and synthetic surfactants. We discovered, however, a fourth method that gives >90% unilamellar vesicles with a synthetic lipid, didodecyldimethylammonium bromide (DDAB).[4]



DDAB

In this method, DDAB (0.1–0.2 mg) was placed within a rubber washer (14 mm i.d.) cemented onto a glass slide. The powder was then immersed in 450 μL water and allowed to hydrate. (The amounts of DDAB and water are important; too much DDAB gives multilamellar vesicles; too little DDAB results in only a few vesicles by light microscopy). Hydration begins instantly as seen by wormlike tubules (myelin figures) forming at the surface of the solid particles (Fig. 3). After about five minutes, one observes many grapelike clusters some of which transform into 5–10 μm vesicles. Remaining clusters develop (via a poorly understood fusion process requiring about two hours) into giant unilamellar vesicles. These were easily distinguishable, by phase-contrast microscopy, from the small population of the more opaque multilamellar vesicles. Giant unilamellar vesicles will henceforth be symbolized by GUVs.

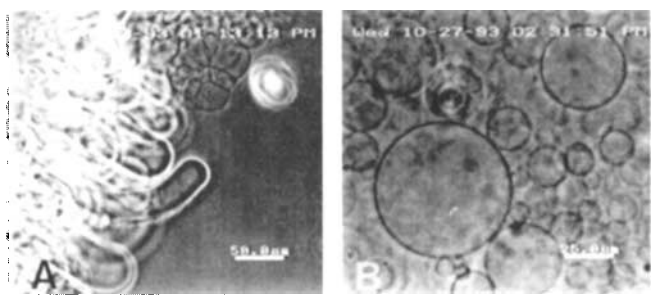


Fig. 3. Hydration of powdered DDAB as observed by phase-contrast microscopy. A: Initial formation of tubules. B: Subsequent formation of giant unilamellar vesicles (GUVs).

The preceding recipe works well for DDAB but not so well for phospholipids. In our experience, the conditions for making GUVs must be worked out individually for each particular lipid and temperature. Since DDAB gave such excellent preparations (even in the presence of additives such as cholesterol), and since the preparations displayed such a variety of cell-like morphological changes, we used DDAB exclusively for our initial studies. There is no reason in principle, however, why our experimental approach cannot be extended to all sorts of lipids, natural and synthetic alike.

Giant unilamellar vesicles, prepared by hydrating solid-state DDAB, are stable for two–three days after which they tend to aggregate. Note that GUVs do not lie in a global energy minimum despite their seemingly spontaneous formation.[21] The global energy minimum is in fact occupied by flat bilayer sheets; energy input is required to impose curvature upon such sheets. Convection currents and vibrations (usually unnoticed) suffice to achieve the mild curvature in GUVs (while, as mentioned, sonication generates high-curvature SUVs). Since GUVs, tubules, and many of their structural variations are all relatively flat, and thus of similar energy, a rich array of interconvertible morphology is possible.

Before continuing, the reader can rightly expect answers to some basic questions, the most important of which is: How do we know that our GUVs are indeed unilamellar (i.e. endowed with only a single lipid bilayer)? This is far from a trivial question as evidenced by the fact that we initially mistook multilamellar vesicles for unilamellar structures. The confusion arose from three sources: a) Literature reports on giant vesicles assume, often without sufficient supporting data, a unilamellar assembly. Initially, we did likewise. b) As mentioned above, unilamellar vesicles are far more desirable than multilamellar vesicles. We should have kept in mind the quote of H. J. Van Till: "The purpose of empirical research is to discover what the physical world is really like, not to verify its conformity to our preferences". c) Finally, as chemists we were novices with the light microscope. The unilamellar issue could not be resolved until we had become experienced in its use.

Vesicles turned out to be invisible by ordinary bright field microscopy because the refractive indices of the vesicle and aqueous medium are too similar. We thus called upon phase-contrast microscopy which is particularly useful in such cases. In phase-contrast microscopy, a hollow cone of light passes through the sample, and in this manner one achieves a variation in brightness across boundaries even when the difference between refractive indices is small. Phase-contrast illumination is easily produced with an inexpensive metal ring that is slipped into the microscope's condenser. Further details of phase-contrast optics can be found elsewhere.[22]

Figure 4 shows phase-contrast photomicrographs of giant DDAB vesicles (ca. 90 μm in diameter at 400× magnification). Although the vesicles are spherical, they appear flat because the microscope's depth of field (1.5 μm with a 40× objective lens)

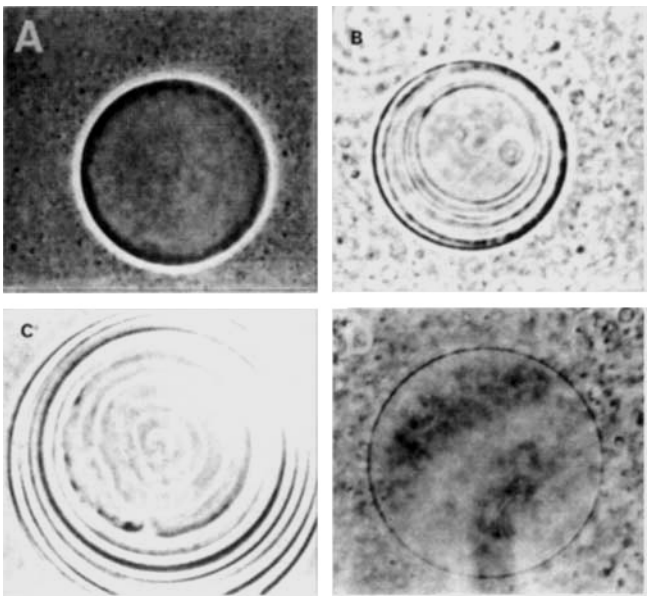

Fig. 4. Phase-contrast photomicrographs of a multilamellar giant vesicle (A), an oligolamellar giant vesicle (B and C), and a unilamellar giant vesicle (D).

is much less than the vesicle diameter. Phase-contrast microscopy can "see" only a narrow slice of lipid at the equator; attempts to focus above or below the equator produce only a blur. A typical multilamellar vesicle is given in Figure 4A. It is readily identified as such by an opacity and texture that differ from the medium surrounding the vesicle. The vesicles in Figures 4B and 4C are also multilamellar, but the layers can actually be resolved because they are, in this case, less densely packed. Finally, Figure 4D shows a giant unilamellar vesicle, the type that is most desirable for membrane research.

A lipid bilayer, being only about 40 Å thick, is obviously impossible to see by light microscopy. Thus, the dark ring in Figure 4D is an optical effect; in no way does it portray the actual membrane thickness. Similarly, light microscopy cannot differentiate between a membrane composed of a single bilayer (a true GUV) and a membrane composed of a few bilayers. Although the distinction makes little difference from the point of view of our experiments, we believe that true unilamellar vesicles are indeed formed for the following reasons: a) When GUVs are chemically or physically destroyed, the ring disappears as a unit, leaving no visible inner ring. (In contrast, multilamellar vesicles are often seen to "peel off" their layers one by one). b) Published cryoelectron micrographs on vesicles similar to those in Figure 4D suggest the presence of a single-layered configuration.[23] c) So-called bilayer lipid membranes (BLMs), in which a 60–100 Å film spans a 1 mm hole in a Teflon plate,[24] prove that one or two bilayers are capable of maintaining structural integrity over macroscopic distances.

3. The Literature

When the plan of studying giant vesicles was first initiated, we knew little about how to prepare, observe, and manipulate them. "Between the idea and reality stands the shadow" (T. S. Elliot). Past work of others helped illuminate the "shadow". Among the rather limited literature on giant vesicles, a few articles stand out as having been particularly relevant to our work. These will now be reviewed briefly.

Mueller et al.[25] published early experiments on giant vesicles prepared (by the dehydration-rehydration method) from brain lipids, egg lechithin, and synthetic phospholipids. A number of points are of interest: a) The vesicles can be made in distilled water and in solutions of non-electrolytes but not in salt solutions where the lipids precipitate. b) After growing in size for several days, the vesicles are stable for weeks. c) Vesicles can be fractionated according to size by centrifugation in specially designed tubes. Apparently, the giant vesicles can survive 40000 g for 30 min (our DDAB vesicles being too fragile to tolerate such abuse). d) Vesicles made in distilled water seem to be under osmotic stress (of unknown origin) because physically rupturing them causes interior contents to be rapidly expelled. e) Finally, and this is important, the micrographs of Mueller et al. were obtained by dark-field microscopy. This technique (which, like phase-contrast, uses a special attachment in the condenser) portrays the vesicles as a ring of light in an otherwise dark field (Fig. 5). In our experience, such a ring of light is seen primarily with multilamellar vesicles. One should resist the temptation to assume that a single shell in dark-field microscopy necessarily signifies a unilamellar structure.

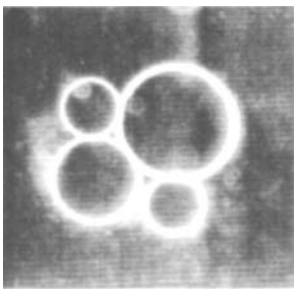

Fig. 5. Dark-field photomicrograph of giant multilamellar vesicles.

Zimmerman et al.[26] observed by light microscopy an electric-field-induced fusion of giant vesicles prepared from a 1:1 mixture of a cationic lipid and cholesterol. Application of an alternating electric field (200 Vcm^{-1}, 100 kHz) first caused the vesicles to move into direct contact with each other (Fig. 6). The fusion process, requiring about one second, was initiated by turning off the AC field and subjecting the sample to a 3–9 $kVcm^{-1}$ field pulse of 20–50 μs duration. The electric breakdown of the membrane creates, it is postulated, large numbers of aligned pores in the contact zone (Fig. 6). Reorganization of lipid then bridges the

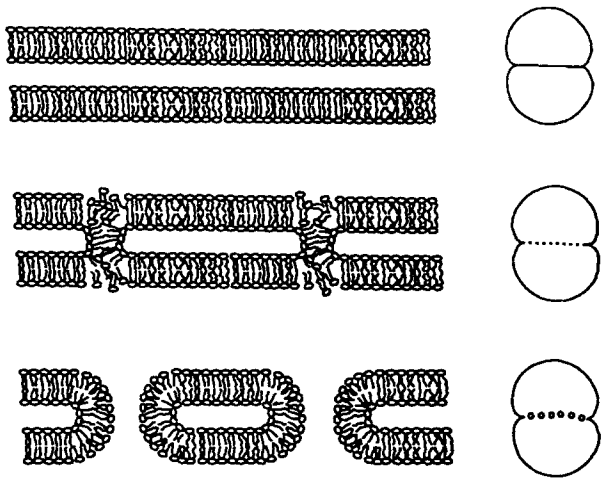

Fig. 6. Fusion induced by an electric field as adapted from ref. [26].

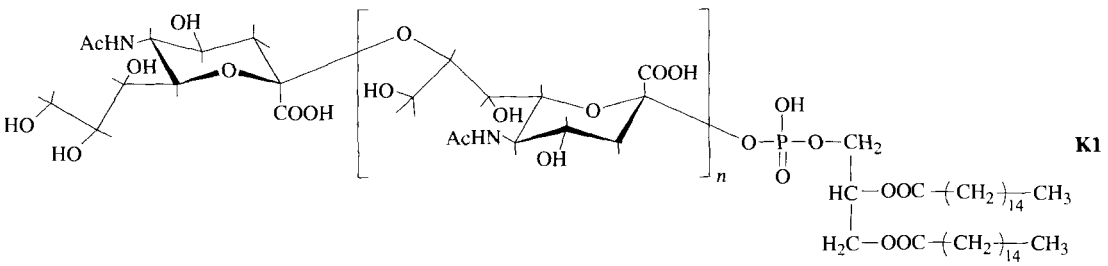
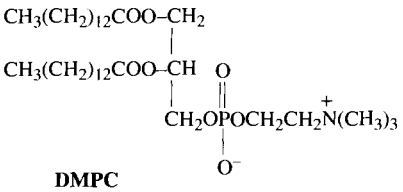


K1

two giant vesicles while simultaneously creating microscopically invisible SUVs that become trapped within the new vesicle.

The research group of H. Ringsdorf[27] injected a polysaccharide, isolated from *E. coli* and called K1, into a giant vesicle preparation. It was found that K1 inserts itself into the vesicle bilayer (presumably by means of K1's lipid moiety). Proof for binding of K1 to the vesicle was obtained by adding a fluorescent-labeled anti-K1 antibody to the preparation. Fluorescent microscopy showed giant vesicles with brightly fluorescent peripheries, clearly indicating that the antibody had concentrated itself at the external membrane surface. In the absence of K1, the antibody fluorescence remained distributed uniformly throughout the aqueous medium.

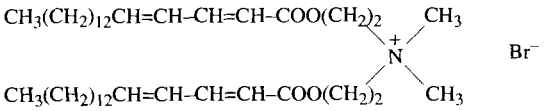


DMPC

It should be mentioned that the above work is only one of several beautiful experiments described in reference [27]. The 1988 review (which also discusses endocytosis, hole formation, vesicle domains, and polymerization processes) is "must" reading for anyone entering the field of giant vesicles. We ourselves owe it a special debt.

Among the diverse membrane papers of E. Sackmann, one finds a few devoted to the giant vesicle. Four experiments in particular will be mentioned here:

Experiment 1:[28] Giant vesicles were prepared from the quaternary ammonium lipid **1**, which has a phase-transition temperature of 42 °C. (A phase-transition temperature is the point at



1

which a lipid transforms from a highly ordered gel state to a more disorganized liquid crystalline state). The normally spherical vesicle took on a discoid shape at 42 °C (Fig. 7). When the temperature was raised to 42.5 °C, the form of the vesicle changed to a "bowling pin", while at 41.5 °C the vesicle invaginated to a crescent. This extreme sensitivity of morphology to temperature was not observed in our experiments with the related DDAB vesicles. Membrane morphology obviously depends upon lipid structure in ways that are not yet understood.

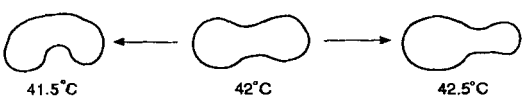


Fig. 7. Shape transformations in a giant vesicle composed of a synthetic lipid as the temperature is raised and lowered 0.5 °C above and below the phase-transition temperature of 42 °C [28].

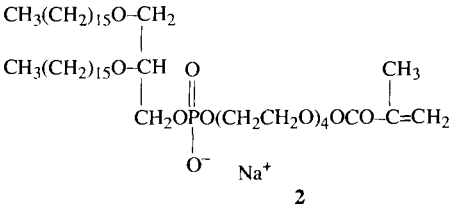
Experiment 2:[29] Giant vesicles were prepared from a 4:1 mixture of dimyristoylphosphatidylcholine (DMPC) and a polymerizable phospholipid **2**. When polymerization was induced by UV irradiation, the vesicles were seen to invaginate



2

(a photochemically-induced endocytosis, Fig. 8). The explanation given for the phenomenon rests on two assumptions: a) Polymerizable lipid is of slightly higher concentration in the outer leaflet of the membrane bilayer than in the inner leaflet

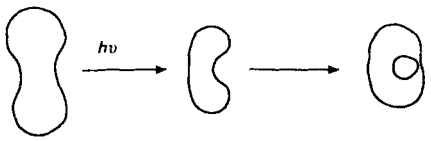


Fig. 8. A photochemically induced "endocytosis" with a giant vesicle composed of a 4:1 mixture of dimyristoyphosphatidylcholine (DMPC) and a polymerizable phospholipid [29].

(the former possessing slightly more room for the bulky headgroup). b) Polymerization decreases the area per molecule. If both factors are operative, polymerization will shrink the outer leaflet more than the inner one, and the composite bilayer will, therefore, distort inwardly. Svetina and Zeks,[30] in a classic article, were the first to propose that alterations in bilayer curvature arise because the two-component leaflets of a bilayer expand and contract independently from one another. We will have occasion to call upon this concept later on.

Experiment 3:[29] A vesicle composed of pure DMPC was shown to go from a spherical shape to an invaginated state and then to a two-vesicle form (Fig. 9) when the coverglass, resting

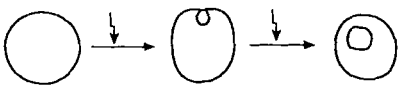

Fig. 9. Effect on a DMPC giant vesicle when the coverglass is lightly tapped [29].

on the sample, was lightly tapped. It was correctly argued that this experiment demonstrates the metastability of vesicle morphologies. One important question was not addressed however: Is the shape transformation (in this case triggered by mechanical agitation) seen frequently or is it a rare occurrence? We pose this question because in our experience many bizarre morphological events occur only infrequently, so that publishing their pictures without some statement as to their "probability" can be misleading.

The study of the physically induced vesicle transition is instructive for another reason. Vesicle preparations in experiment 3 were examined as thin films placed between a slide and a coverglass. We have avoided handling samples in this manner for two reasons: a) It is desirable to minimize vesicle/glass interactions especially those that might crush vesicles between two glass surfaces (recall that GUVs can have diameters of 0.2 mm or larger; see Table 1). b) We planned to manipulate our vesicles (i.e. move them about, inject into them etc.) much the way cytologists handle living cells. This precludes the use of a coverglass. Since uncovered thin films evaporate quickly, we invariably used a thick aqueous sample placed within the confines of a circular "wall" (details to be given later). A more sophisticated setup that accomplishes the same thing is given elsewhere.[31]

Experiment 4:[31] Shape transformations of DMCP GUVs in ion-free water were studied as a function of temperature (Fig. 10). The morphologies portrayed in Figure 10 occurred in

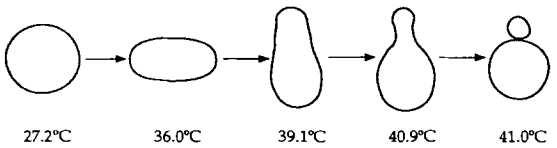

Fig. 10. Shape transformations of a DMPC GUV in ion-free water as a function of temperature [31].

35 out of 98 vesicles when "lateral stress" (of uncertain definition) was exerted upon the vesicles prior to heating. The GUVs changed from spherical (27.2 °C) to an ellipsoid (36.0 °C) to various pear-shapes (37.5–40.9 °C). All these morphologies were stable and reversible. A further temperature increase of 0.1 °C to 41.0 °C destabilized the pear-shape and created what appears to be an attached "bud" on the verge of becoming a separate daughter vesicle. Even more exotic transformations were observed but will not be detailed here. Suffice it to say that the shape transitions are qualitatively explainable in terms of the Svetina–Zeks model[30] in which the two component leaflets of the bilayers have slightly different thermal expansivities.

A degree of caution is necessary whenever vesicle morphologies are studied. It must never be forgotten that phase-contrast microscopy detects only a thin band around the equator of the vesicle. Consequently, it is possible to confuse a "sphere-to-pear" transition with a 90° rotation of a pear-shaped vesicle (Fig. 11). Similarly, a 90° rotation could be mistaken for a transition from an invaginated vesicle to a "vesicle inside a vesicle" (Fig. 11). Such ambiguity can be resolved by demonstrating the reversibility of the transition; it is unlikely that 90° rotations coordinate themselves with medium conditions as the latter switch back and forth between two states.

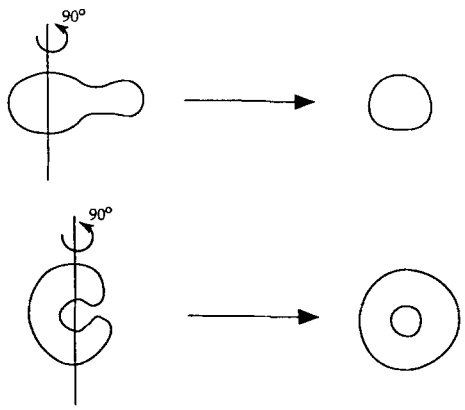

Fig. 11. Apparent shape changes in phase-contrast microscopy that arise from rotations rather than from true morphological changes.

The ingenious studies of giant vesicles by Evans and Needham[17, 32] can serve as a fitting conclusion to this historical section (which is by no means intended to be an all-inclusive review). Evans and Needham aspirated a 20 μm GUV with a 5 μm micropipet under a suction pressure of 0.03 atm or less. This caused the vesicle to be partially drawn into the pipet (Fig. 12) with a concomitant increase in the membrane area (as measured indirectly from the membrane projection length inside the pipet). Two types of experiments were performed: a) The suction pressure was increased at constant temperature. b) The temperature was increased at a fixed suction pressure. These experiments provided two thermoelastic coefficients: the compressibility modulus K and the thermal expansivity α. A few specific results, cited below, illustrate the power of the method.

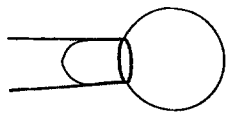

Fig. 12. Aspiration of a 20 μm GUV into a 5 μm pipet under a suction pressure of 0.03 atm or less [32].

When a GUV is cooled at constant pressure from above to below the phase-transition temperature, the membrane contracts abruptly by about 20%. In addition, the compressibility modulus increases dramatically. For example, the K value for DMPC (with a transition temperature of 24 °C) increases from 150 dyn cm^{-1} at 29 °C to 855 dyn cm^{-1} at 8 °C. Adding equimolar amounts of cholesterol to the DMPC at 29 °C increases the K value from 150 dyn cm^{-1} to 685 dyn cm^{-1} even though the membrane remains fluidlike (i.e. in its liquid-crystalline phase). Cholesterol apparently forms a tight complex with DMPC that greatly reduces the bilayer compressibility relative to a bilayer of pure DMPC above its transition temperature. Evans and Needham were also able to detect the presence of a "rippled membrane phase" from an unusually short projection length in the mircopipet at low tensions. A ripple phase has a corrugated structure with the lipid chains lying perpendicular to the overall membrane plane.

As is evident from the references cited thus far, the great majority of the giant vesicle work has appeared in the biochemical and biophysical literature. Chemists, especially organic chemists such as ourselves, have paid comparatively little attention to giant vesicles. In attempting now to publicize the topic to the chemical community, we face a severe communications problem, a problem stemming in part from the fact that giant

vesicle research is a composite of chemistry and biology. Whereas chemistry contributes its simple and defineable experimental conditions (composition, concentration, etc.), biology contributes a particular brand of data reporting (photography). As a result of the latter, chemists are (at least for the moment) denied the graphs, tables, equations, and spectra they love so well. Nonetheless, we ask that chemists resist exclaiming "This is not chemistry!" What else but chemistry could it be when, for example, a giant vesicle, prepared from a compound purchased from a chemical supplier, divides in two after being exposed to a synthetic surfactant? Eventually, of course, we will yield to reductionism and discuss our "chemical systems"[1] on more molecular terms. But before this can be accomplished, the fundamental behavioral modes of our membrane models must first be observed and recorded. Occasionally, explanations will be set forth here at the molecular level, but the reader will likely find them rather primitive. Remember, however, that we are at an early stage of understanding and that, at the moment, many problems in vesicle chemistry are, as J. Wiesner would say, "just too complicated for rational, logical solutions. They admit of insights, not solutions".

4. The Light Microscope

"The ladder of natural systems consists of elementary particles, atoms, molecules, macromolecules, cell parts, cells, organs, organisms, populations, and ecosystems" (R. Wesson). In the main, elemental particles have been the province of physicists; molecules the province of chemists; macromolecules the province of biochemists; and cells the province of cytologists. This division of labor is becoming increasingly obscure. Inevitably, as a particular level of science matures, the adventurous seek out the next higher level of complexity. Those who do so are of the same temperament as Thomas Lincoln who once remarked to his son (Abe) that people should move their homes as soon as they can see the smoke from their neighbor's chimney. Chemistry provides as good an example as any of this relentless move up the complexity scale. Thus, one hears more and more at chemistry conferences about DNA, antibodies, and receptor sites. The present paper recommends that chemists take a two-step jump from molecules to cell parts. A recommendation is hardly necessary because chemists have already applied their familiar methods (NMR, ESR, kinetics etc.) to membrane systems. What is unusual, however, is the suggestion that chemists befriend that old workhorse of the cytologist, the light microscope.

Those who have a mere passing interest in the subject of cytomimetic chemistry will wish to skip this section on light microscopy and move directly to the subsequent results section. But those who might be tempted to actually enter the field should read the following brief remarks on the light microscope. The light microscope has, in recent times, been upstaged by other techniques, but "it is not widely known outside the biological community that a renaissance and a revolution in light microscopy are now underway".[33]

Our laboratory is equipped with two instruments: A Leitz Laborlux S standard light microscope and a Nikon Diaphot-TMD inverted light microscope. The latter style, possessing the lens assembly below the stage and illumination above it, allows for easier micromanipulation of the vesicles (discussed later) and for less interference problems when water condenses on the coverslips at reduced temperatures.

Both microscopes are fitted with 10× ocular lenses. The objective lenses have four recommended features: a) They are specifically manufactured and sold for phase-contrast work. b) They are flat-field or PLANO to reduce the curvature of the field and thus bring into focus both the central portion and periphery of the image. c) They are achromatic which means they are corrected for one wavelength (yellow-green) with respect to spherical aberrations. Owing to this feature, a green filter is always placed in the path of illuminating light source. d) They are long working-distance lenses as required for our thick vesicle samples. The four features, specified when purchasing the lenses, are not recommended for high-quality bright-field, cross-polarizing, or fluorescence microscopy.

The microscope condensers, which focus the light onto the sample, are universal in the sense that they can handle many forms of light microscopy. Since their iris is always wide open in phase-contrast microscopy, the condensers are never touched once they are initially centered and focused.

Each objective lens is associated with a numerical aperture (NA) at the time of its manufacture. Our NAs vary from 0.25 to 0.55. Two important parameters, the resolution and depth-of-field, depend upon the NA value. Resolution can be defined as the smallest distance between two points that can be distinguished. According to the Rayleigh equation,[34] the greater the NA, the better the resolution. Note that objects smaller than the resolution can be detected but not in any detail. Resolutions of our various objective lenses vary from 0.52 μm to 0.87 μm.

Depth-of-field can be regarded as the distance from the nearest image plane to the farthest image plane that remains in acceptable focus. Depth-of-field can play a role, for example, in the study of a small vesicle departing from the inside of a larger one. As the depth-of-field diminishes, it becomes increasingly unlikely that the small and large vesicle will reside in the same image plane and thus both be in focus. Although a large NA enhances resolution, it decreases the depth-of-field, thereby making focusing more troublesome. For example, NA = 0.25 and DF = 8.5 μm; NA = 0.55 and DF = 1.5 μm. Working with light microscopes teaches the principle of compromise.

The light microscope can be used with an array of optional peripheral equipment (Fig. 13). Special mention should be made of a solid-state camera that is inserted into a microscope port made for that purpose. The camera's signal is sent to an Argus 10 image processor that digitally enhances images to give greater contrast. It also provides a "zooming" capability so that a 400× magnification becomes an 800× or 1600× magnification. The block diagram in Figure 13 also includes a VCR for making video tapes in real time, a monitor for viewing images on a screen, and a printer for making "stills". One should not be intimidated by the apparent complexity of Figure 13. All components are commercially available, attached quickly to the system, and easy to use.[35] Simple refocusing and stage repositioning are the main skills necessary to track "unidentified swimming objects".[36]

One of the major advantages of GUVs over their submicroscopic cousins is that they can be micromanipulated just like

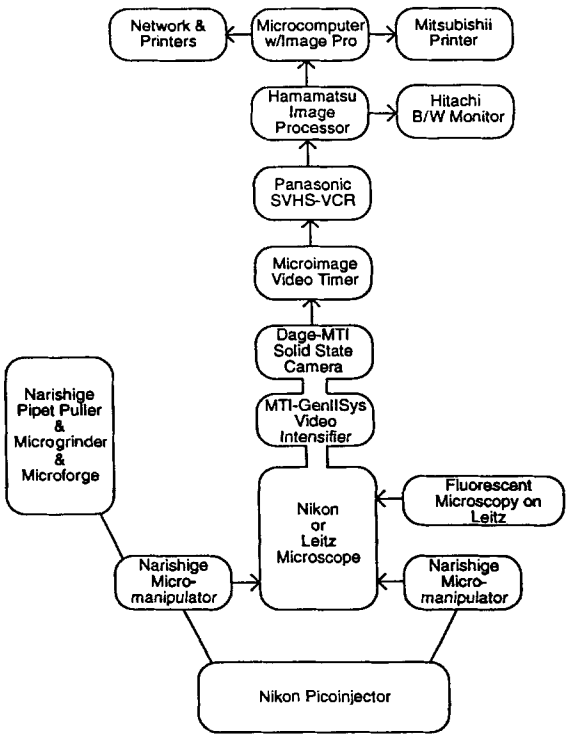

Fig. 13. Block diagram of video microscope setup and peripheral equipment used in our work. Many GUV experiments can, however, be carried out with a simple microscope equipped with a phase-contrast attachment and a Polaroid camera.

cells. Micropipets as small as 1000 Å in diameter can be made with a commercially available "pipet puller". A vertical glass capillary, weighted at the bottom end with suspended metal blocks, is threaded through an electric coil at the top end. When the switch is turned on, the hot coil melts the capillary section within it, the weights come crashing down, and the capillary is pulled into a narrow-diameter pipet. The pipet can be further fashioned with a microgrinding wheel or with a so-called microforge. The latter allows one to polish the end of the pipet or to bend it into any desired shape.

Micropipets were useful to us primarily for holding vesicles in place and for injecting into them. Holding pipets have large smooth ends that can latch onto a GUV when a slight suction is applied. Injection pipets are much smaller in diameter than the vesicles and are ground to a sharp point. Administration of both suction through an empty pipet and pressure on a filled pipet was carried out with a "picoinjector" hooked to a tank of nitrogen. A picoinjector can supply orders of magnitude less liquid than the nanoliter volume of a typical GUV.

Micropipets were directed toward a desired point in the microscope's image with the aid of a micromanipulator. This device, fixed to the microscope's stage, has a "joy-stick" that provides extremely small movements to the end of an attached pipet. All the micromanipulation techniques described here are commonplace in cytology.

Mention has already been made of sample preparation by the DDAB hydration method (see Section 2.4). The hydration took place within a rubber washer (14 mm i.d.) cemented onto a glass slide. Sufficient sample (0.45 mL) was used to fill the washer and to minimize the amount of air between the sample and the coverglass resting upon the washer. Coverglasses reduced evaporation and surface vibrations of the sample. Of course, when micromanipulation was desired, a coverglass was not possible. A simple homemade thermostated stage was installed when temperature control was necessary.

This concludes the background information pertinent to the subject of cytomimetic chemistry. Individual tastes and needs will dictate whether too much or too little detail has been provided. Either way, the time has arrived to inspect actual photomicrographs and view first-hand the intricacies of membrane behavior. Most of the photomicrographs in the next section have not been published previously.

5. Experimental Results

Our experimental results have been categorized below into various cytomimetic processes (aggregation, fusion, fission, etc.). Each process is portrayed by a series of still photographs selected from video films produced by the microscope setup. Admitedly, viewing the still photographs is like looking at a Mickey Mouse film one frame at a time. Fortunately, however, vesicle behavior can in fact be reasonably well described with still photographs as long as they span a suitable time period. This is not to say that nothing has been sacrificed by the unavoidable shift from a dynamic to a semistatic representation. No still photograph can, for example, elicit the delight of seeing, in real time, an entire vesicle fusion or fission. And no still photograph is likely to instill a sense of wonder of the type that once caused a visiting scientist to exclaim: "How do you make those cells do that?" Those "cells", we then revealed to the visitor, had been made from a compound purchased from Eastman Chemicals; and they do what they do because of simple chemical and physical stimuli.

5.1. Hydration

We have already described how hydration of lipid films leads to the production of giant vesicles (see Fig. 2). In our hands, this method led mainly to multilamellar vesicles (which is one reason why the solid-state hydration, pictured in Figure 3, was developed). It turns out that giant multilamellar vesicles, prepared by the drying-rehydration method, also tend to form unilamellar vesicles if allowed to sit around and hydrate for several days. This hydration process was examined under the microscope (Fig. 14).

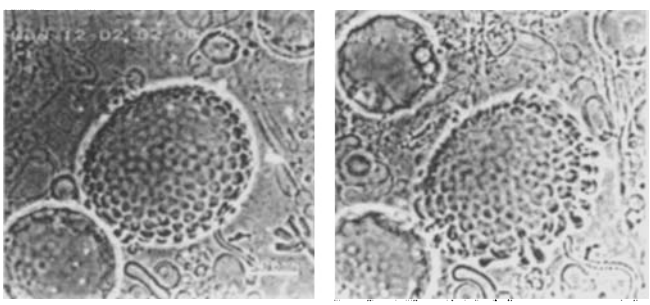

Fig. 14. Phase-contrast photomicrographs of a giant multilamellar vesicle hydrating to give, eventually, small unilamellar vesicles. Left: after 2.5 h. Right: after 4.5 h. Scale-bar in the bottom-right of photographs = 100 μm.

Multilamellar vesicles are seen first to "blister" at their outer shells. These blisters then grow into tubules that project radially from the vesicles' outer surface. Ultimately, the tubules break off to become unilamellar vesicles. Thus, one-by-one the layers of the multilamellar vesicles are eroded into GUVs. The apparent instability of multilamellar vesicles relative to their unilamellar counterparts may stem, in part, from electrostatic repulsion between the concentric DDAB layers within the onionlike configuration.

5.2. Aggregation

A. Einstein once wrote, "The only apparatus necessary for observing Brownian motion is the microscope, and it need not even be a particularly good one". Similarly, a simple microscope is all that is required to visualize vesicle aggregation. One merely adds low levels of Na_2SO_4 (1.0mM) to a sample containing widely spaced giant vesicles. Over the course of several minutes, the vesicles will assemble into clumps (Fig. 15). Note that this experiment, carried out early on in our research, used dark-field microscopy rather than the phase-contrast microscopy that we now prefer.

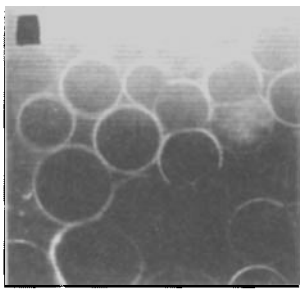

Fig. 15. Dark-field photomicrographs of sulfate-induced aggregation of giant vesicles. Prior to addition of sulfate, there were only three vesicles in the microscopic field.

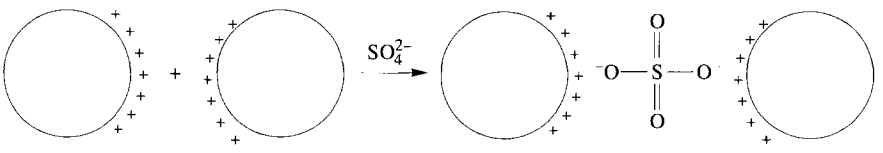
The aggregation process is viewed as an electrostatic neutralization of the long-range double layer repulsion among the vesicles.[37] Dianionic sulfate can, apparently, serve as a far more effective "adhesive" than can the bromide counterion of DDAB (Scheme 1).



Scheme 1.

No sulfate-induced fusion was seen with the GUVs although this has been reported with vesicles only 80 nm in diameter.[38] Small vesicles have a high curvature and might be expected to show a greater propensity to fuse than the GUVs. One is reminded of the so-called "Ostwald ripening" in which large colloidal droplets grow at the expense of small ones.[39] Interfacial tension within the small droplets drives the coalescence. The absence of fusion with the sulfate-treated GUVs suggests that sulfate is unable to bring the vesicles sufficiently close together to overcome the "hydration repulsion" as would be necessary for fusion. Hydration repulsion reflects the need to desolvate headgroups prior to phase instability in the membrane.[40]

5.3. Fusion

If it were not for barriers to membrane fusion, humans would, like slime mold, exist as multinucleated masses of protoplasm. And if it were not for mechanisms that trigger fusion, many important biological events (infection, fertilization, conjugation etc.) would not be possible. Little wonder that fusion is a recurrent theme in treatises on membrane behavior. Unfortunately, a footnote number is the only homage we can give to the immensely fertile literature on membrane fusion.[41] Space restrictions force this embarassingly rapid trek through the subject of fusion in which the focus lies entirely on our own cursory experiments.

5.3.1. Physical Constraint

Two giant vesicles can be forced into intimate contact with the aid of holding pipets under slight suction (Fig. 16). Note that in the left photograph, the lefthand vesicle becomes distorted by the pressure from its neighbor. Moreover, when the vesicles are separated, the lefthand vesicle in the right photograph is pulled, however slightly, into an oval shape. The shape then restores itself instantly into a sphere. Despite the obvious close proximity of the vesicles, no fusion occurs for periods up to an hour. Fusion can be induced chemically (as we shall see next) but not physically.

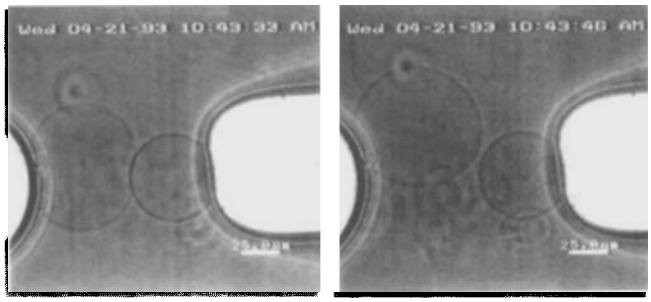


Fig.16. A failed attempt at physically inducing fusion in two DDAB giant vesicles. The vesicles were manipulated by means of holding pipets under slight suction. In the left photograph, the vesicles have just been pulled apart, an action that caused slight distortion in the lefthand vesicle.

5.3.2. Acetate-Induced Fusion

A remarkable sequence of events was observed when 100 μL of 0.25 M NaOAc was added, in tiny portions without stirring, to a sample of giant multilamellar vesicles (0.45 mL of 9×10^{-4} M DDAB; drying-rehydration method). First, the vesicles began immediately to disintegrate. In the course of 20 minutes, the vesicles deteriorated into structureless masses that eroded into submicroscopic material to give, finally, an absolutely clear microscopic field. (This vesicle disappearance was anticipated because didodecyldimethylammonium acetate is a highly water-soluble compound that does not form giant vesicles). But a peculiar thing happened when the samples were kept at or below

the DDAB phase-transition temperature of 17 °C. Small "globules" reappeared and began to speckle the microscopic field. The term globule is used because the structures were too opaque to be multilamellar vesicles. Whatever their exact morphology, the DDAB globules fused at a prodigious rate. Figure 17 shows

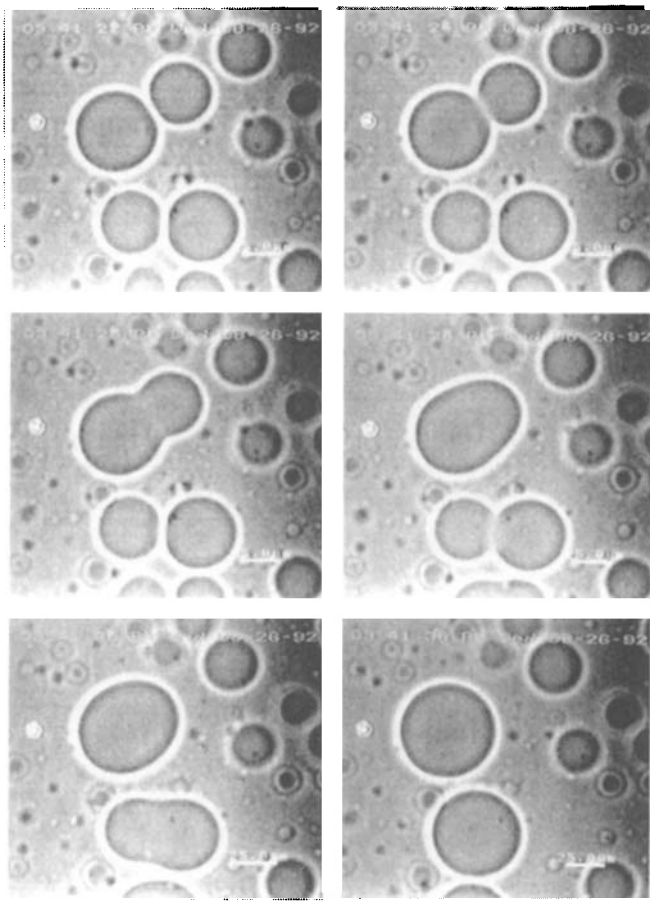

Fig. 17. Phase-contrast micrographs of an acetate-induced fusion taking place over a few seconds. Scale-bar = 25 μm.

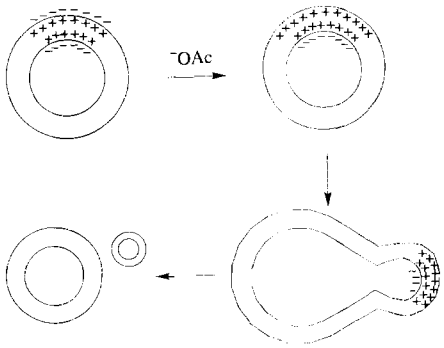
a sequence in which two globules, after having resided side-by-side for many minutes, suddenly fused over the course of a few seconds. The fusion was reproducible in several experiments.

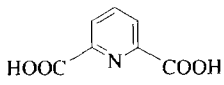
One cannot attribute the vesicle disappearance solely to osmotic stress since the effect was salt-dependent (being caused by acetate, fluoride, and hydroxide but not chloride). Two notions, however satisfactorily explain our observations: a) Strongly hydrated anions, such as acetate, bind relatively loosely to cationic surfaces.[42] b) According to the Svetina–Zeks model,[30] the coupled leaflets in a bilayer can act independently. Thus, when excess acetate is added externally to the DDAB vesicles, acetate exchanges with bromide to produce an outer leaflet that is more highly dissociated from its counterions. Owing to the resulting headgroup headgroup repulsion, the outer leaflet expands relative to the inner one. Such asymmetry would be expected to increase curvature[43] and, therefore, promote the expulsion of small vesicles and the eventual disappearance of microscopically visible structures (Scheme 2).



Scheme 2.

5.3.3. DPA-Induced Fusion

Engberts et al.[44] have reported that the dianion of dipicolinic acid (DPA) causes 3000 Å DDAB vesicles to fuse into vesicles 2–3 μm in diameter. The behavior of DPA is reminiscent of the well-known fusogenic effect of the Ca^{2+} ion on negatively charged vesicles.[45] Owing to the affinity of Ca^{2+} ions for anionic lipid, the Ca^{2+} ion enforces a vesicle/Ca^{2+}/vesicle association. The resulting surface dehydration and vesicle proximity trigger a fusion.



DPA

DPA (25 μL of 5 mM; pH adjusted to 7.0 with NaOH) was added to a vesicle preparation obtained by solid-state hydration. Scattered among the resulting GUVs were globules of undefined morphology that underwent rapid DPA-induced fusion (Fig. 18). The GUVs, on the other hand, converted from rigid spheres into floppy irregular enclosures (Fig. 19). Picolinic acid, with only one carboxylate, had no such effect.

We can only conjecture on the molecular basis for the loss of structural rigidity in the GUV membranes. One possibility is

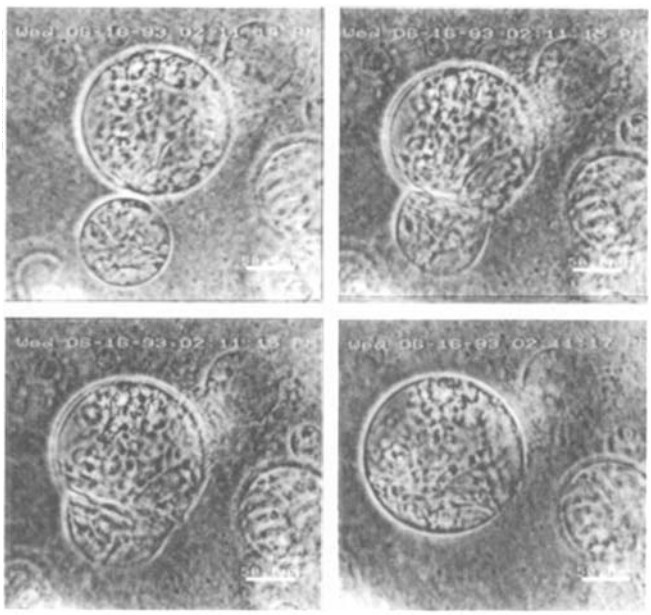


Fig. 18. Phase-contrast micrographs of a DPA-induced fusion of DDAB vesicles of unknown structure. Scale-bar = 50.0 μm. Process took place in less than four seconds.

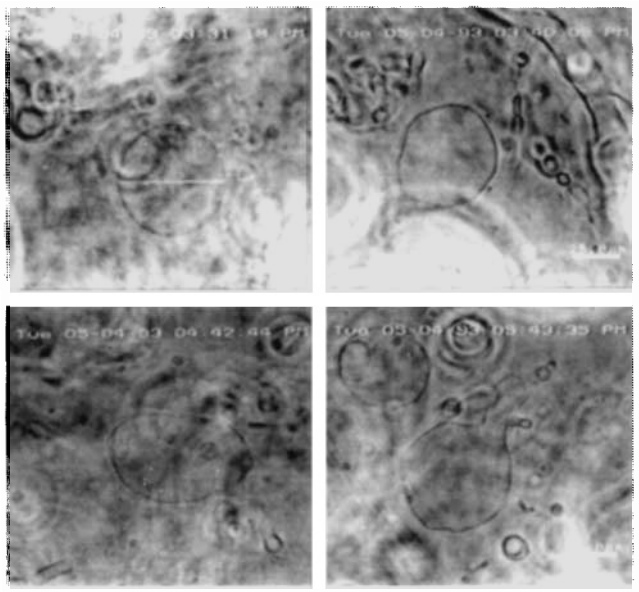

Fig. 19. Effect of DPA on DDAB GUVs. Top left to top right: 10 min. Top right to bottom left: 1 h. Bottom left to bottom right: 1 h.

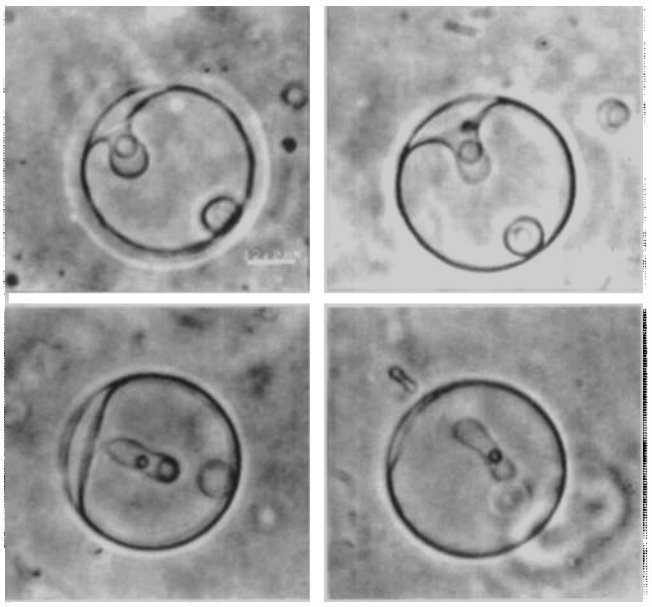

Fig. 20. Giant unilamellar vesicle undergoing a DPA-induced endocytosis over the course of about 30 min. Process was seen repeatedly but with only the occasional vesicle.

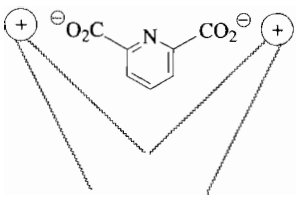


Scheme 3.

that the DPA incorporates itself into the headgroup region and spreads the lipid molecules apart (Scheme 3). Since the lipid packing is thereby loosened, distortions from the usual spherical shape become feasible. A second possibility relates to the fact, often observed in our work, that the GUVs seem to be under osmotic tension (i.e. internal pressure that inflates the vesicles). The source of the tension in the absence of any added salt is not yet understood. In any event, the DPA may render the vesicles permeable to water and small molecules, thus allowing pressures to equilibriate and vesicles to deflate.

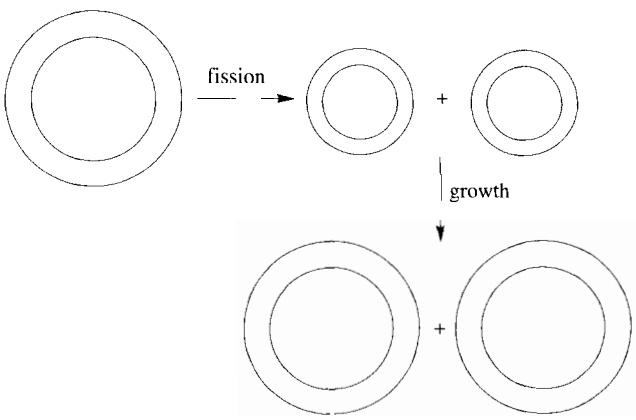
5.4. Endocytosis

In many experiments with DPA, we saw an occasional GUV undergoing a process remarkably similar to cellular endocytosis (Fig. 20). A giant vesicle begins to engulf a smaller vesicle, and after about 30 minutes the smaller vesicle is completely "eaten". No doubt the DPA promotes the endocytosis by enhancing the membrane flexibility. One wonders what sort of endocytosis-stimulating substances are produced by an amoeba when it senses an edible morsel in its vicinity. Or how a virus manages to persuade a host cell to allow it to enter.

By now it should be obvious that a pattern is developing. We are enumerating wonderful morphological changes in a simple nonbiological membrane. But the readers are not being supplied with the molecular basis of these changes except at the most rudimentary level. There should never be an apology for the lack of detail when an area of science opens up and the investigation has only touched the surface. The pleasure of discovery in science derives not only from an incisive analysis but from the formulation of a problem which, according to A. Einstein, is "often more important than the solution". New observations leading to unanswered questions, unsolved puzzles, fresh possibilities, and untried experiments – that is what this paper is all about. In essence, we have taken the advice of R. Hoffmann: "Row a boat into that tall mysterious grass just because you have heard a strange bird call there". In our case, the "mysterious grass into which we rowed" is the world of chemical microscopy, and the "strange bird calling us" is the giant vesicle with all its amazing transformations.

5.5. Fission

Fission was of particular interest to us because the combination of fission, growth, and fission again is equivalent to self-replication, a long-range goal of ours (Scheme 4). As will be shown, fission has indeed been achieved but not the "one-vesicle-into-two-equal-vesicles" as would be ideal for a self-replicating process.



Scheme 4

5.5.1. Mechanical Agitation

Figure 21 represents an attempt to inject a sharp micropipet into a vesicle being held by a holding pipet under slight suction. This was an early experiment, and at the time we did not realize that the giant vesicle was multilamellar. In any event, the injecting pipet (being controlled by a micromanipulator fixed to the

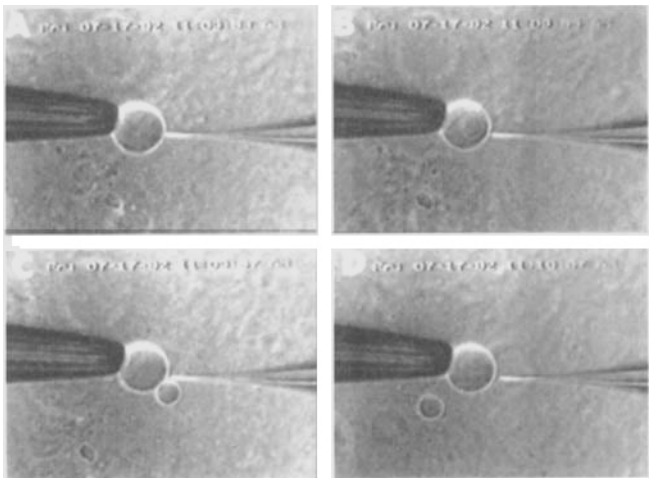


Fig. 21. Thigmatropic fission in which prodding of a multilamellar vesicle causes the formation and release of a smaller vesicle. The parent vesicle is held in place by a holding pipet, while a sharp pipet, controlled by a micromanipulator, prods the vesicle surface.

microscope stage) experienced great difficulty in penetrating the vesicle. Eventually, the prodding caused a new smaller vesicle to form. We surmise that the outermost bilayer of the multilamellar vesicle had been physically damaged by the pipet. Lipid molecules in the injured bilayer then had an opportunity to reorganize themselves into an independent unilamellar vesicle where bilayer–bilayer repulsion was not a factor.

Occasionally, one encounters an oligolamellar vesicle in which the concentric bilayers are sufficiently well-spaced that they are visible individually. Figure 22 shows the layer-by-layer

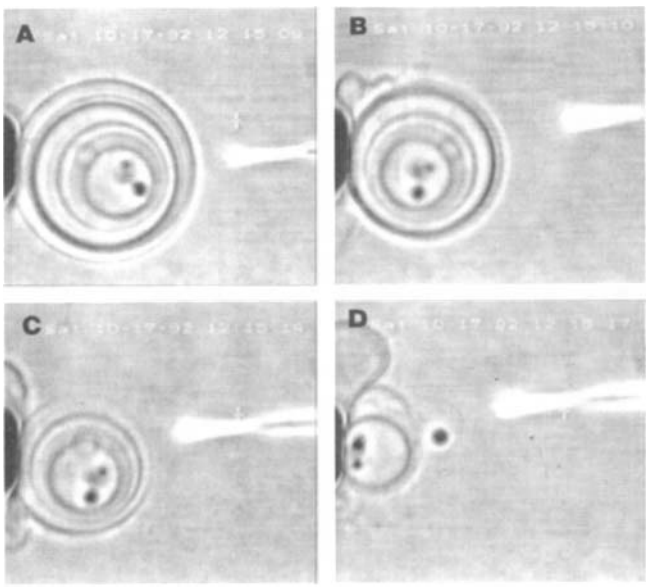

Fig. 22. Individual layers of an oligolamellar giant vesicle being ruptured by a sharp pipet, causing the vesicle to become smaller and smaller.

destruction of an oligolamellar vesicle when agitated by a sharp pipet. The vesicle becomes smaller and smaller as the layers are shed.

5.5.2. Dilution

When giant multilamellar vesicles are prepared by hydration of a lipid film (a method that, as mentioned, was supplanted by our solid-state hydration), the vesicles remain unchanged for at least a day unless the sample is diluted four- to twentyfold with water. Dilution stimulates the ejection of 5–30 μm GUVs from the multilamellar vesicles until the latter have entirely disappeared (Fig. 23). As small GUVs depart, their inner contents are

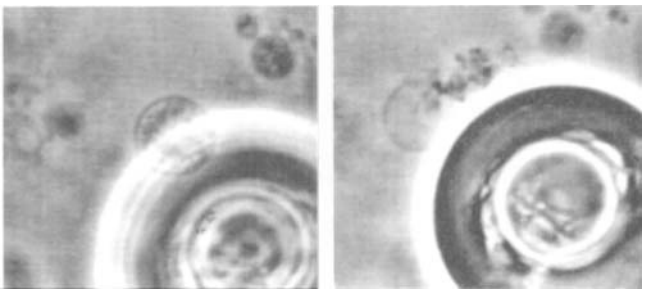

Fig. 23. Ejection of a small unilamellar vesicle from a multilamellar vesicle induced by dilution. Note how the particulate matter inside the unilamellar vesicle is expelled through a defect created at the contact point of the two vesicles. The two photographs are spaced three seconds apart. Less than five seconds later, the daughter vesicles had moved away from the parent and healed the defect.

rapidly expelled from the hole where the GUV and multilamellar vesicle had been momentarily attached. (The hole then heals immediately to give an intact GUV). Expulsion of the internal contents of the GUV is a further indication of the internal stress that seems to characterize GUV systems.[46]

Why does dilution with water induce fission? Osmotic stress does not seem to supply an answer because the vesicles, prepared in ion-free water, were also diluted with ion-free water. It seems, instead, that there is a delicate balance between vesicle–vesicle repulsion and bilayer–bilayer repulsion. When a sample is diluted, the vesicle–vesicle repulsion is diminished, but the bilayer–bilayer repulsion within the multilamellar vesicles remains unaffected. Consequently, GUV formation becomes thermodynamically favored. Small energy differences between different morphologies are key to giant vesicle behavior.

5.6. Birthing[4]

The interactions between surfactants and GUVs attracted our attention owing to the widespread use of surfactants in solubilizing biomembrane components.[47] M. N. Jones[48] proposed that surfactants bind to phosopholipid membranes by means of hydrophobic forces. When saturation levels are reached, the bilayer begins to expel mixed micelles composed of lipid plus surfactant. Ueno and Akechi,[49] who observed 200-nm vesicles by freeze fracture electron microscopy, found that octyl glucoside transforms a vesicle into a cluster of 20–30-nm spheres (resembling a raspberry). These tiny particles depart one-by-one

from the surface to become, soon thereafter, solubilized in the water as mixed micelles. We know of no example in which vesicle destruction by a surfactant has been observed by light microscopy.

Adding 25 μL of 5 mM octyl glucoside to a standard GUV preparation (20–21 °C), giving a surfactant concentration well below its critical micelle concentration of 25 mM, caused minimal vesicle destruction in the first hour. The most striking observation was a "birthing process" involving the occasional GUV that possessed a smaller vesicle within it. Under the influence of octyl glucoside, the entrapped vesicle can force its way through the bilayer wall of the parent vesicle (Fig. 24). A gap is created

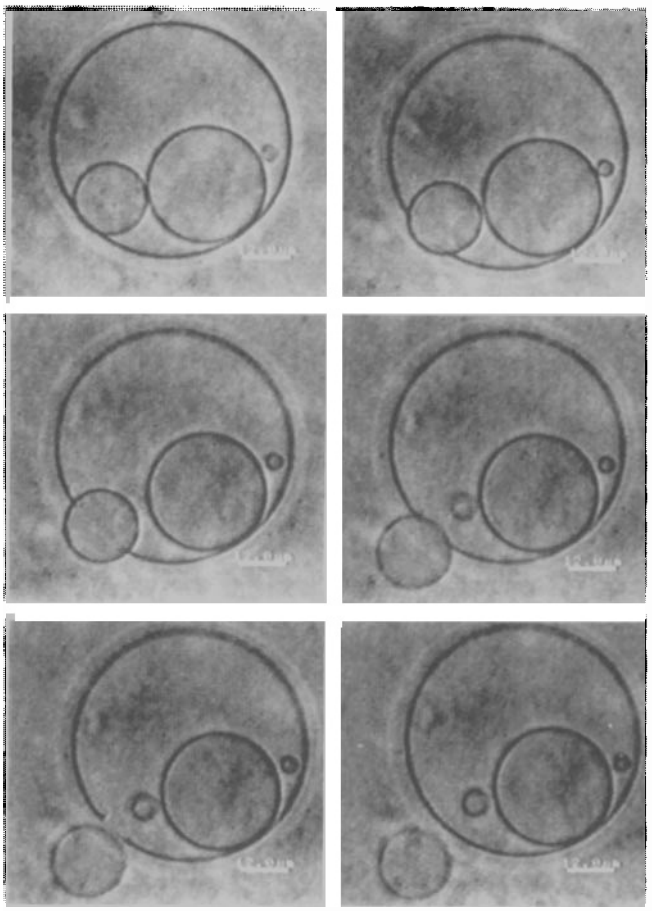

Fig. 24. "Birthing" of a vesicle induced by octyl glucoside (phase-contrast microscopy on giant unilamellar vesicles; scale-bar = 12.0 μm). Note how the hole in the parent vesicle (bottom left) heals itself instantly. The process takes about twelve seconds from start to finish.

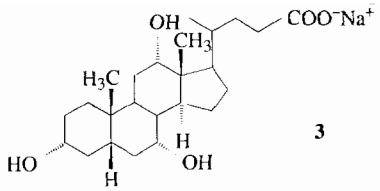
in the parent vesicle that heals instantly (bottom photographs). The sequence of events was observed repeatedly with every preparation. Light microscopy can obviously capture dynamic events that are difficult to detect by the more commonly used electron microscope. Moreover, artifacts from drying, metal coating, etc., a problem in electron microscopy, are avoided.

Combining the results from both light microscopy and electron microscopy,[49] we surmise that octyl glucoside weakens the cohesion among the organized DDAB molecules, perhaps by the formation of weakly associated spherical particles. The membrane subunits are able to temporarily separate from one another and, thereby, allow the passage of an entrapped vesicle. Evidence for this model came from experiments using higher octyl glucoside concentrations (10–25 mM) that rapidly destroy the GUVs. During the process, 0.1–1.0-μm particles are seen to speckle the vesicle surface (not shown). These particles (which appear from bright-field microscopy to be either solid or multilamellar lipid) break away while, simultaneously, the diameter of the GUV diminishes at a rate dependent on the octyl glucoside concentration.

5.7. Foraging[4]

The dramatic effect of octyl glucoside on the giant vesicles led us to investigate a natural surfactant, sodium cholate **3**. The cholate **3** is a member of the bile salt family of steroids used to solubilize fatty material in the gut. Addition of cholate (50 μL of 5 mM) to GUV preparations induced a rapid fusion process among the vesicles. As seen in Figure 25, the GUV in the upper right hand corner consumes the smaller vesicles in the grapelike cluster beside it.



3

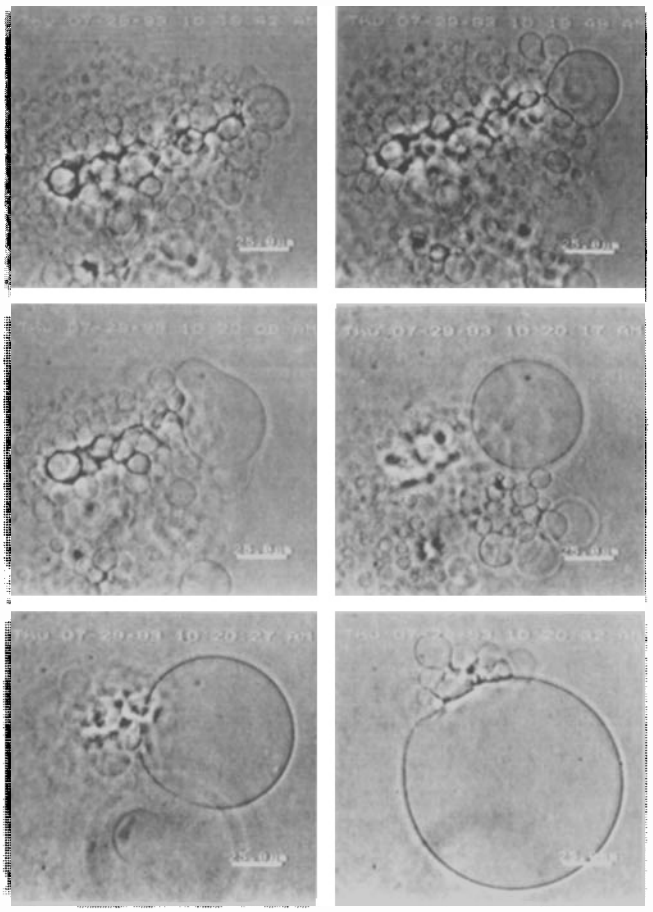


Fig. 25. Sodium cholate-induced foraging of a DDAB giant unilamellar vesicle. The vesicle in the upper right corner grows as it consumes its smaller nighbors. The entire process takes less than a minute.

The foraging vesicle grows in diameter with each small vesicle that is consumed. When small vesicles no longer exist in proximity of the foraging vesicle, an unexpected and previously unreported event occurs: The large vesicle disintegrates by a sequential ejection of lipid molecules (Fig. 26), a process that takes

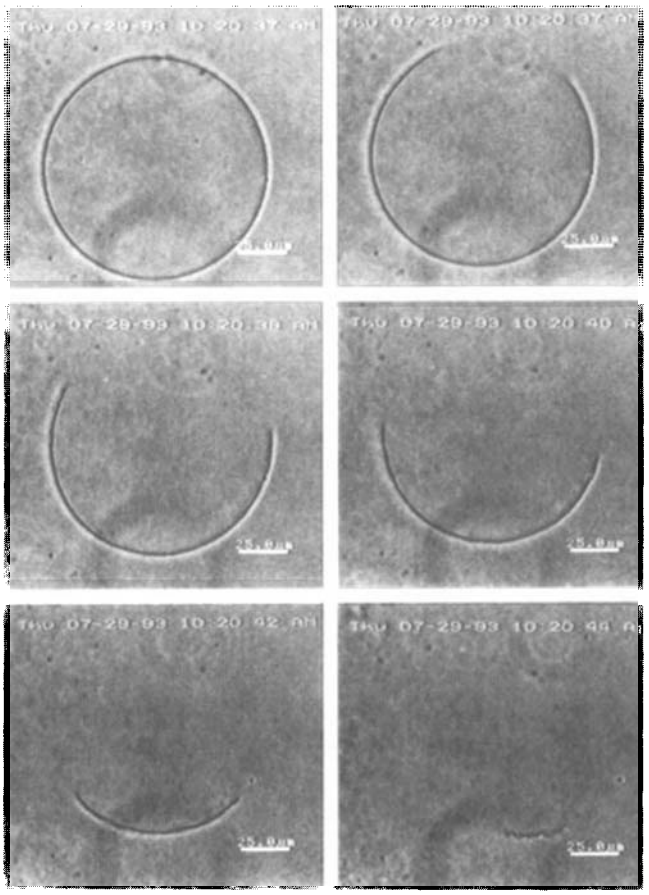

Fig. 26. Decay of giant unilamellar vesicle immediately following the foraging seen in Fig. 25. Entire dissolution of the membrane takes six seconds.

only a few seconds. It is as if a defect in the GUV created an edge of exposed lipid molecules. Lipid molecules are then continuously solubilized from this defect by the cholic acid until the vesicle bilayer disappears. Remarkably, the original spherical shape is retained throughout the process. The products of the membrane dissolution are submicroscopic and may well be the mixed micelles postulated by others.[48, 49] At higher concentrations, crystals of DDAB/cholate eventually fall out of solution. It should be noted that another steroid, cholesterol, has no such effect on the GUVs. In fact, 30% cholesterol incorporated into the DDAB bilayer actually stabilizes the vesicles.

5.8. Injection

Injection into giant vesicles has been a high-priority objective of ours since the very beginning. If a pipet could be inserted into a vesicle (the way cytologists routinely do with living cells), a host of experiments fall into place. For example, biological macromolecules, such as enzymes and DNA, could be examined within the confines of a giant vesicle. Or various volumes of water might be injected into a vesicle to test the bilayer's resilience to internal pressure. Or a perturbing solute might be introduced to determine how its effects on the interior and exterior leaflets of the bilayer compare.

Injection was not an easy thing to achieve. In the case of multilamellar vesicles, attempts to inject led to shedding of the bilayers (see Figs. 21 and 22). Most unilamellar vesicles, on the other hand, burst when prodded with a micropipet. We finally succeeded, however, with GUVs that are ≥ 200 μm in diameter containing 5% cholesterol. Such vesicles are pliable, and they resist bursting. A good example is shown in Figure 27. It is

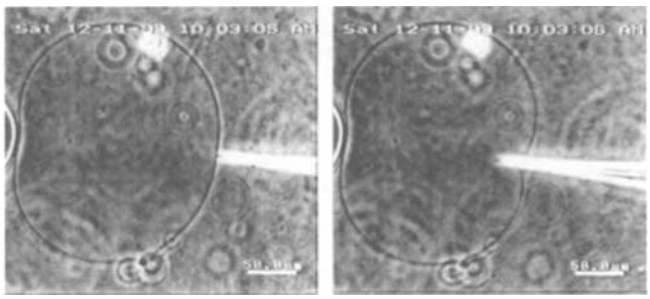

Fig. 27. Insertion of a micropipet into a giant unilamellar vesicle. The vesicle is composed of DDAB and cholesterol (95:5). Scale-bar = 50 μm.

believed that the pipet has actually penetrated the bilayer because the vesicle becomes distorted in the experiment and because both the tip of the pipet and the vesicle are in focus. A further indication of pipet entry into the vesicle interior is given in Figure 28. A bright particle within the vesicle is removed by the suction applied through the pipet. Note also the easy deformability of the vesicle as well as its ability to heal the wound created by the pipet.

5.9. Final Remarks

We finish, appropriately enough, with a quote from Albert Szent-Gyorgi in his "Personal Reminiscences":

"In my hunt for the secret of life, I started research in histology. Unsatisfied by the information that cellular morphology could give me about life, I turned to physiology. Finding physiology too complex, I took up pharmacology. Still finding the situation too complicated, I turned to bacteriology. But bacteria were even too complex, so I descended to the molecular level, studying chemistry and physical chemistry . After twenty years' work, I was led to conclude that to understand life we have to descend to the electronic level, and to the world of wave mechanics. But electrons are just electrons, and have no life at all. Evidently on the way I lost life; it had run out between my fingers."

The above words should not be regarded as a call for biologically oriented chemists to abandon their craft. Quite the contrary, their efforts should be intensified. But this should be done while bearing in mind that the living cell has an organizational complexity totally absent in the reaction flask. Future emphasis must, therefore, be away from "single-molecule chemistry" and

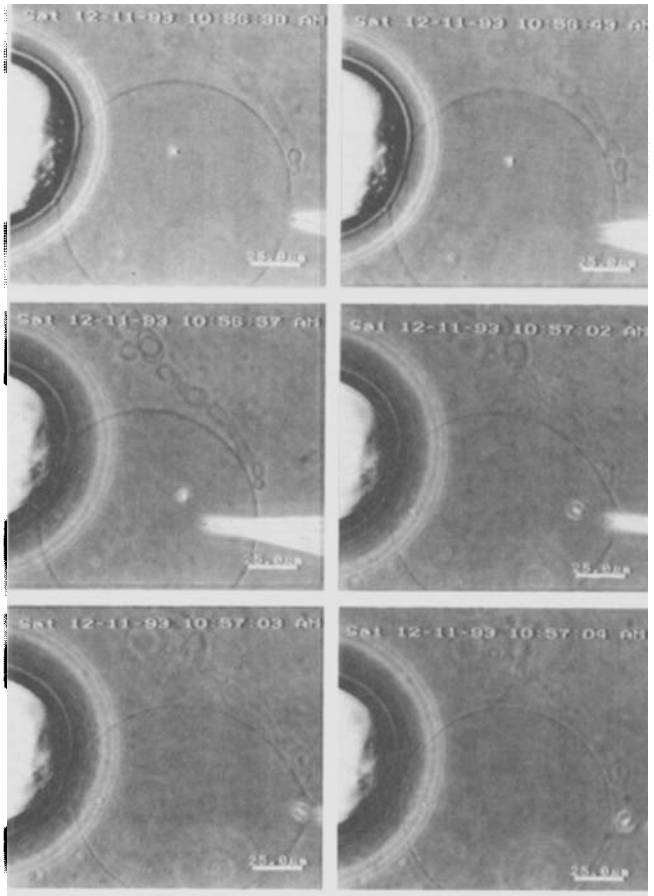

Fig. 28. Withdrawal of a particle (bright spot) from the interior of a giant unilamellar vesicle (DDAB + cholesterol 95:5) using an inserted micropipet under slight suction.

towards molecular assemblies. Because an organized group of molecules behaves differently from a molecule operating as a single entity, there is a need to define the differences. It is with this philosophy that our research group has worked over the past two decades;[1] and it is with this philosophy that "cytomimetic organic chemistry" was conceived.

It was a novelist, Tim O'Brien, who wrote the following words: "The thing about a story is that you dream it as you tell it, hoping that others might dream along with you, and in this way memory and imagination and language combine to make spirits in the head". Perhaps this is also the best that scientists can hope for: to create spirits in the mind.[50, 51]

Work was supported by the National Institutes of Health. The article is dedicated to— and, to some extent, written for—those special students whose days are controlled, measured, and defined by the pursuit of science.

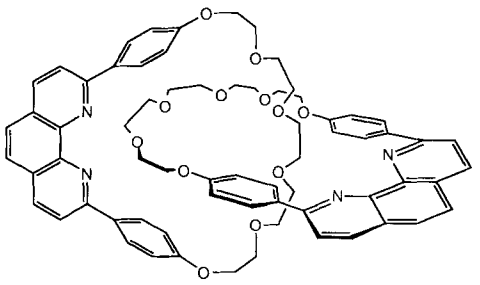
Gold in Chains: Self-Assembly of a Gold(I) Catenane

Andreas Grohmann*

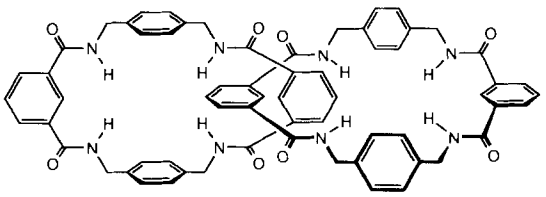
Catenane is the generic name for molecular assemblies consisting of interlocking rings that are arranged like the links of a chain (catena is Latin for chain).[1] Such compounds are characterized by the absence of any covalent bonds holding the rings together; instead, catenanes are systems with a "mechanical bond" between molecular subunits, and for this reason they have long intrigued chemists. The possibility of preparing linked-ring molecules was probably suggested as early as the beginning of this century by Willstätter, but it was not until the 1960s that catenanes and related species such as rotaxanes (that is, "threaded" macrocycles) and molecular knots became the subject of scientific inquiry.[2, 3]

In the beginning,[4] catenane chemistry involved herculean synthetic effort and was considered to be a highly specialized and somewhat esoteric area of science. It came to be seen in a different light, however, when DNA, the archetype of biomolecules, was shown to adopt catenated and knotted topologies in certain cases.[5] At the same time, the increasing appreciation of the importance of noncovalent bonding interactions (for example, van der Waals, charge–transfer interactions, and hydrogen bonding) in chemistry at large led to the conceptualization of a "chemistry beyond the molecule", namely supramolecular chemistry, which has been defined as the chemistry of molecular assemblies and of the intermolecular bond.[6] From these developments, the study of catenanes and related compounds gained new impetus, in particular with a view to creating materials with novel properties,[7] for example new types of polymer[2] and molecular-scale devices.[8]

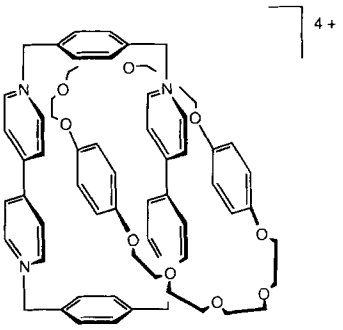
Over the last fifteen years, template synthesis and the application of self-assembly have enabled chemists to synthesize a variety of catenated structures:[9] "Metal ion templating" allows the positioning of building blocks before ring closure in the synthesis of catenands (that is, catenanes with ligand properties, such as **1**),[10] while "organic templating" through hydrogen bonds and π–π interactions is instrumental in the preparation of **2**, the newest addition to the family of lactam catenanes.[11] The similarly facile synthesis of linked-ring molecules such as **3** relies on the preformation by self-assembly of a threaded crown ether macrocycle. While π-donor–acceptor interactions keep the two components locked in place, the open-chain bis(bipyridinium) ion may be formed into the second ring.[12]



1



2



3

Whereas various types of wholly "organic" molecular chains are thus accessible, catenanes in which metal ions are incorporated into the macrocycles have remained a rarity.[13] The first such example was described in 1993 by Bickelhaupt and coworkers, who observed the formation of **4** from two preformed rings in an equilibrium that involves Mg–C bond dissociation, threading of the crown ether ring by an open-chain magnesium–organic intermediate, and reformation of the metal–carbon bond.[14] A variation on this theme was reported in 1994 by the group of Ogura and Fujita, who draw a parallel between their synthesis and the trick of interlinking "magic

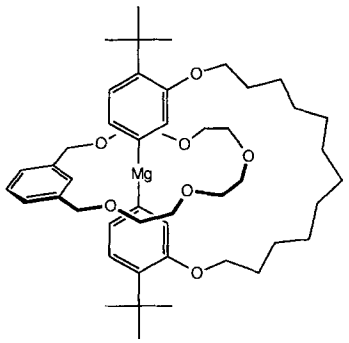
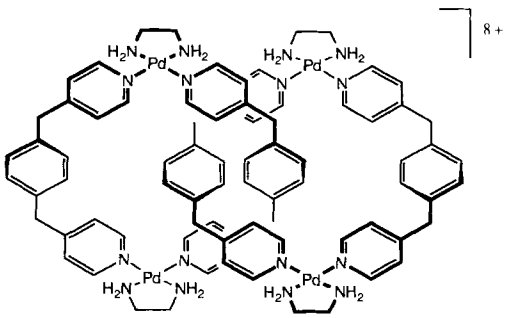
rings".[15] Again, two preformed molecular rings are in equilibrium with a [2]catenane (**5**), and while the mechanism by which the two rings interlock has not yet been established, it is likely that two metal centers on different rings exchange ligands twice, with concomitant twisting of the rings around each other.[7]

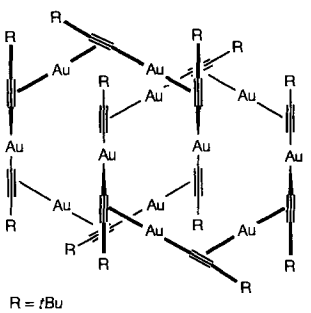


4



5

The most recent addition to the class of metal-containing catenanes comes from the laboratory of D. M. P. Mingos and coworkers, who describe the synthesis by self-assembly of a [2]catenane of monovalent gold (**6**).[16] It may be obtained from the reaction of $[Au(NH_3)_2]BF_4$ with *t*BuC≡CH in acetonitrile in a yield of 65%, and its solid-state structure is characterized by two interlocking cyclic [Au(C≡C*t*Bu)] hexamers. This compound, which is only the second example of an organometallic catenane, is highly unusual also against the backdrop of organogold chemistry.[17] With regard to other homoleptic alkynyl gold(I) species,[18] it is noteworthy that all the possible coordination modes of two alkynyl ligands about a gold(I) center (η^1-Au-η^1, η^1-Au-η^2, η^2-Au-η^2) are realized in **6**; the η^2-Au-η^2 arrangement of ligands is without precedent. While compounds of general formula $[Au(C{\equiv}CR)]_n$ (R = Ph, *t*Bu) were first obtained by a different route some 30 years ago, their polymeric nature has hampered structural characterization ever since. On the basis of a series of molecular weight determinations, Coates and Parkin[19] suggested a cyclic tetrameric structure for the *tert*-butyl derivative in which each gold atom is coordinated by two alkynyl residues in η^1-Au-η^2 fashion, but conclusive structural evidence has so far been lacking. It thus seems that the degree of association of monomers in $[Au(C{\equiv}Ct\text{Bu})]_n$ (n = 4, 6) depends on the reaction conditions, the influence of which requires further study.



6

The most striking aspect about the formation of **6** is the apparent ease with which the [Au(C≡C*t*Bu)] units rearrange in solution and self-assemble in order to realize the observed catenane topology in the solid state. While there is evidence for the presence of $[Au(C{\equiv}Ct\text{Bu})]_6$ rings in solution, it is not yet clear whether separate rings and catenated species are in equilibrium. In this regard, it is interesting to note that the rearrangement necessary for the construction of **6** involves processes of ligand dissociation and association that are similar to the transmetalation reactions postulated in the formation of **5**.

In the solid state, the structure of **6** is characterized by close intra- and interring Au···Au contacts in a range between 3.2–3.5 Å, indicating a significant degree of attraction between the metal centers.[20] It is well known that aurophilic interactions of this kind, which are due to relativistic effects,[21] often have a decisive influence on the solid-state structures of gold compounds as well as on the course of reactions, the stability of main group element centered gold cluster cations being an example in point.[22] In the case of gold(I), the energy of the Au···Au interaction has been estimated to be of the order of 29–33 kJ mol^{-1} and thus of a magnitude comparable to the energy involved in hydrogen bonding.[23] Given the pivotal role that other types of noncovalent bonding interactions play in the self-assembly of supramolecular entities, it is reasonable to assume that the formation of **6** is due to secondary Au···Au bonding, which induces the rearrangement of the [Au(C≡C*t*Bu)] fragments and their subsequent formation into interlocking rings.

With a first synthesized gold catenane, the tantalizing vision of a gold rotaxane now appears on the horizon, and it will be interesting to see whether aurophilic interactions can be harnessed eventually to realize even more intricate ("knotted") molecular superstructures.

From *cyclo*-Te_8 to Te_x^{n-} Sheets: Are Nonclassical Polytellurides More Classical than We Thought?

Mercouri G. Kanatzidis*

The structural diversity of the allotropic forms of the chalcogenide elements diminishes when we move from sulfur to selenium and tellurium, and polymeric tellurium is the only stable form of this element known to date. The recent discovery of the *cyclo*-octatellurium ring Te_8 in the solid-state structure of Cs_3Te_{22} by Sheldrick and Wachhold[1] is an important landmark in polychalcogenide chemistry. Te_8, the stability of which has been debated by chemists for a long time, completes the chalcogen series S_8, Se_8, and Te_8; although, it must be noted that Te_8 is not a true allotrope, since it coexists with other components in Cs_3Te_{22}. The Te_8 molecule has the expected puckered ring structure (Fig. 1). It acts as a crown ether to a Cs^+ ion, which is presumably a major contributory factor to its stability in this compound. The ring seems to have been templated by the alkali metal ion, and this has broader implications for the role of the counterion effect in polychalcogenide and monochalcogenide chemistry in general. This role has not been properly appreciated in the past, but the accumulation of structural data seems to reveal a powerful influence of the counterion on the formation and structures of products, which in most cases shadows electronic factors. Given the great allotropy of sulfur and the abundance of rings such as S_6, S_7 etc., is it possible to template other Te_x rings ($x \neq 8$) by using, for example, Rb or K ions? Such expectations may no longer seem unrealistic. Another equally interesting component in the structure of Cs_3Te_{22} is the unusual $[Te_6]_n^{3n-}$ unit, which forms perfectly flat layers that sandwich the Te_8 molecules.

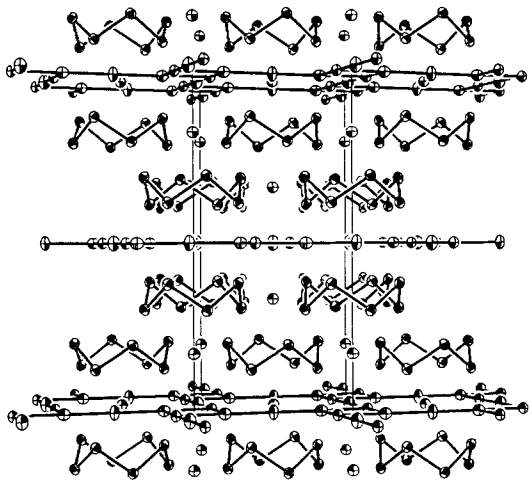

Fig. 1. Solid-state structure of Cs_3Te_{22}.

[**] Financial support from the National Science Foundation DMR-9202428 and the Office of Naval Research (contract no. N00014-94-1-0935) for the authors research program are gratefully acknowledged.

The timing of the discovery of new Te structural features is not accidental, since it comes in a period in which polychalcogenide chemistry, especially that of the heavier members, is experiencing unprecedented development in laboratories around the world. The fascination of chemists with the chalcogen group arises for many reasons, not the least of which is the ability of the elements in this series to catenate and form intriguing polyanions and polycations.

The most unusual behavior ("nonclassical") among the chalcogens is undoubtedly displayed by tellurium, the most "classical" by sulfur. By "nonclassical" is meant the violation of the octet rule. Although violation of the octet rule is not at all unusual in main group compounds, most polysulfides, polyselenides and a few polytellurides do follow this rule. That tellurium chains associate even if they carry negative charge, and the ability of Te to form T-shaped three-coordinate centers or linear two-coordinate centers, set the behavior of tellurium distinctly apart from that of sulfur and selenium. This behavior can be considered as "nonclassical" (see Fig. 2). The structures of

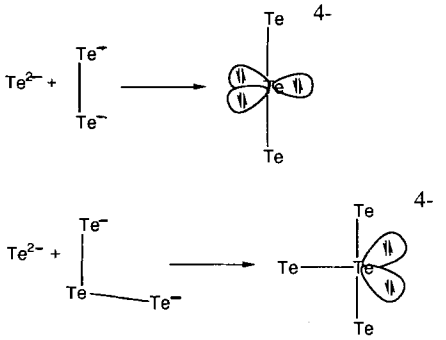

Fig. 2. The structures of Te_3^{4-} and Te_4^{4-} species formed by the association of two different Te_x^{2-} units. The stereochemically active lone pairs of electrons around the central Te atoms are shown. For the lighter polychalcogenides, such $\{Q_x^{2-} \cdot Q_y^{2-}\}$ (Q = chalcogen) interactions would normally be repulsive.

$\{Te_x^{2-} \cdot Te_y^{2-}\}$ adducts are consistent with VSEPR theory. The compounds $NaTe_3$,[2] $CsTe_4$,[3] Li_2Te_6,[2] Rb_2Te_5,[4] and Cs_2Te_5,[5] and $RbTe_6$[6] gave some of the early indications of the extraordinary structural behavior of tellurium. The $\{Te_x^{2-} \cdot Te_y^{2-}\}$ interactions are also found in coordination compounds such as $[NbTe_{10}]^{3-}$,[7] $[MTe_7]^{2-}$ (M = Zn, Hg),[8] and $[AuTe_7]^{3-}$,[9] $[Cu_3Te_{12}]^{9-}$,[10] and $(Et_4N)_2Te_{12}$.[11]

The normal polychalcogenide chains (Q_x or Q_x^{2-}) are characterized by Q-Q-Q angles and Q-Q-Q-Q dihedral angles of $105 \pm 5°$ and $100 \pm 5°$, respectively, which are responsible for the observed helical and cyclic structures of these species, including the structures of Te_8 and polymeric Te_x. These structures would now have to be considered classical. The special structural features of the polytellurides, that is Te-Te-Te angles of 90° or 180° and Te-Te-Te-Te dihedral angles of 0° or 180°, permit additional molecular structures. Thus not only helical chains and puckered rings, but also novel kinked chains, linear chains, branched, and spirocyclic chains (both finite and infinite), as well as puckered layers and strictly planar networks can be formed. For example, the polytellurides shown in Figure 3 have no analogues in sulfur or selenium chemistry. Occasionally, polyselenides have shown some of the same structural features but not nearly to the same extent as the polytellurides.

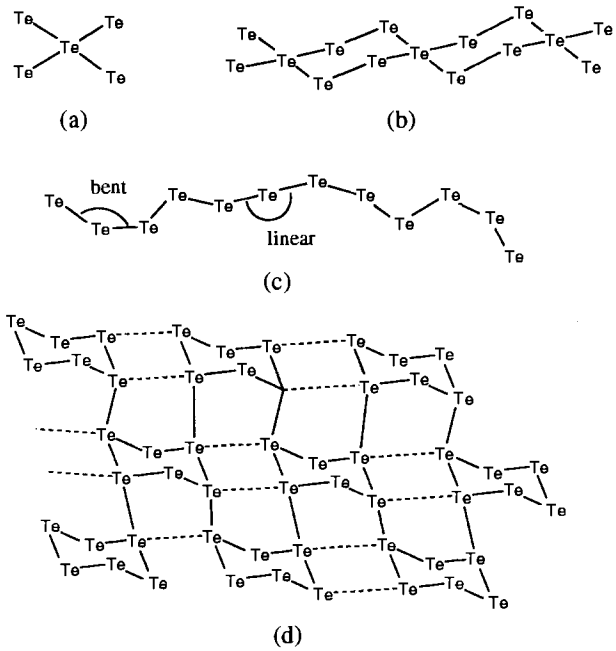

Fig. 3. Some examples of polytelluride anions with unique molecular structures: a) the Te_3^{2-} ion in Ga_2Te_3, b) the Te_5^{2-} spirocyclic chain in Rb_2Te_5, c) the Te_6^{2-} infinite chain in Li_2Te_6, and d) the puckered layer of $[Te_6]^-$ in $RbTe_6$. Undoubtedly, the counterion is paramount in controlling the form of the $\{Te_x^{2-} \cdot Te_y^{2-}\}$ interactions.

In Cs_3Te_{22} beautiful tetragonally symmetric, perfectly planar, $[Te_6]_n^{3n-}$ layers act as hosts for the Te_8 molecules. Such discoveries underscore the potential of polytellurides to teach us a great deal about the fundamental chemistry of chalcogenide elements. Although the properties of the $[Te_6]_n^{3n-}$ layers are not known yet, it would appear that they might be metallic. Topologically, these layers derive from planar 4^4 nets, in which 2/5 of the nodes (Te atoms) are removed. Such a 4^4 net has recently been discovered in $KBa_2[Ag_3Te_3][Te_3]$,[12] in which a strictly planar $[Te_3]_n^{2n-}$ square-net is sandwiched between two K/Ba layers. The relationship between these two structures is shown in Figure 4. The perfect square net of $[Te_3]_n^{2n-}$ is subject to electronically driven distortions which give rise to an incommensurate charge density wave (CDW). This leads to a metal-to-insulator transition. It would be very interesting to see if such phenomena are observed in the $[Te_6]_n^{3n-}$ layer as well. For example, the systems may be prone to distortion towards discrete Te_4^{2-} units. The puckered layer found in $RbTe_6$ (see Fig. 2d) is characterized by short and long bonds which suggest a strong localization of the bonding electrons and the presence of a band gap. The absence of any distortions in the $[Te_6]_n^{3n-}$ layer would make it the first one with completely delocalized electrons. The fact that the anionic polytelluride layers are electron-rich suggests that they may allow for a limited variation (fractional removal or addition of electrons) in the number of electrons, by redox chemistry, and therefore, modification if not control of their electronic properties. A more extensive change in the number of electrons would violate the Zintl–Klemm rules according to which another structure should be obtained. Undoubtedly, either way novel materials should result with semiconducting, metallic, and even magnetic

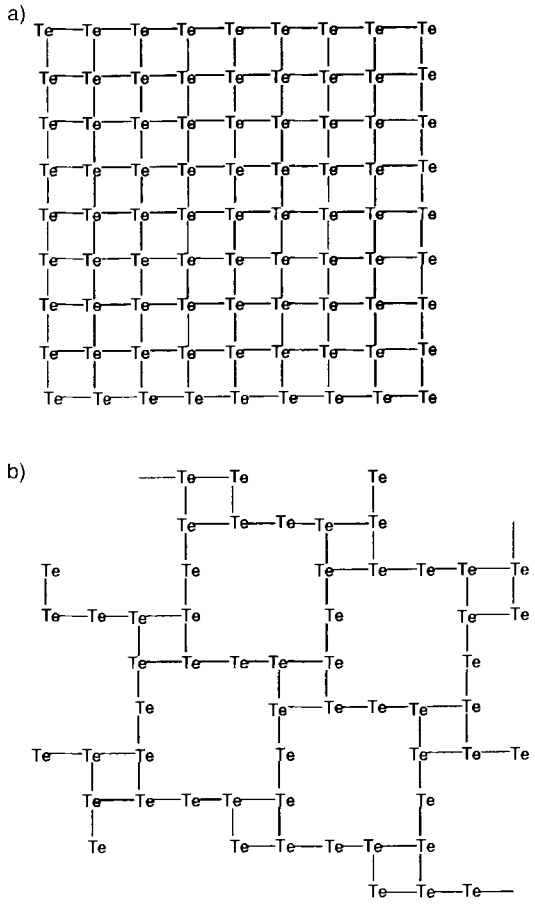

Fig. 4. The structural relationship between the $[Te_3]_n^{2n-}$ (a) and $[Te_6]_n^{3n-}$ (b) planar nets. The network in Fig. 4b can be derived from the network in Fig. 4a if 2/5 of the nodes (Te atoms) are removed.

properties that may exhibit interesting transitions to CDW and superconducting behavior.

The presence of well-separated polytelluride layers in the compounds mentioned above implies that it might be possible to obtain related compounds with more than one type of layer as part of a homologous family or other sheet-structure types. The pursuit of compounds of the type $A_xB_yTe_n$ (A = alkali metal; B = alkaline earth metal) is now justified because they may also contain nonclassical $[Te_x]^{n-}$ layers with varying electron count.

As every researcher active in this area knows, the synthetic and structural chemistry of polychalcogenides is characterized by a lack of predictability of both product composition and structure. While the results obtained can be rationalized, predictability depends on whether we understand the thermodynamics of crystallization and anion–cation packing in the solid state. However, little theoretical work has been carried out in this area. Thus, most of the exciting results have relied on a certain degree of serendipity, and the discovery of Te_8 seems to be no exception. All these highlight the paramount importance of *exploratory synthesis* in advancing inorganic chemistry, particularly in areas in which a deeper understanding of the mechanisms and thermodynamics is needed. This is also true for many areas of solid-state chemistry, and is in stark contrast to the procedure in organic chemistry in which the planned synthesis of compounds has been possible for a long time. In the coordination chemistry of main group elements and solid-state chemistry, imagination, creativity, and a lot of luck are still the prime tools of the trade. Zintl and Klemm would be proud to see how far the field of polychalcogenides has come since the 1920s and 1930s. The future of polychalcogenide chemistry seems indeed bright!

Condensed $RuSn_6$ Octahedra in $Ru_3Sn_{15}O_{14}$**

Werner Reichelt,* Tilo Söhnel, Otto Rademacher, Heinrich Oppermann, Arndt Simon,* Jürgen Köhler, and Hansjürgen Mattausch

The SnO_2/RuO_2 system is of interest with regard to the electronic properties of dimension stable anodes (DSA).[1] Detailed studies of the ternary system Ru/Sn/O[2] led to the discovery of new oxygen-poor phases. From the compound described as "$RuSn_5O_4$" by phase analysis, red translucent crystals can be obtained in a tin melt.[3] The X-ray structure analysis[4] of these crystals gave the composition $Ru_3Sn_{15}O_{14} \triangleq RuSn_5O_{4.67}$, in good agreement with the composition $RuSn_{4.95}O_{4.2}$ determined previously by systematic investigations of the phase equilibria and electron beam microanalysis of single crystals.[5] Due to the M:O ratio of greater than 1 for the compound, an unusual structure was expected. Indeed, the $Ru_3Sn_{15}O_{14}$ structure is remarkable for several reasons.

The projection of the monoclinic unit cell parallel to [010] (Fig. 1) shows characteristic triple chains of corner-sharing $RuSn_6$ octahedra. They run in the direction of the projection [010] and are surrounded from all sides by O atoms, which link the strands partially together. Each strand has the composition $Ru_3Sn_{14}O_{14}$. A polyhedral representation of the arrangement of the Sn atoms in the strand is given in Figure 2. In addition the

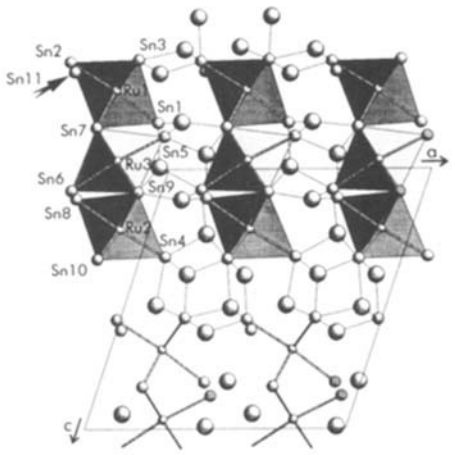

Fig. 1. Projection of the unit cell of $Ru_3Sn_{15}O_{14}$ parallel to [010]. The Ru, Sn, and O atoms are drawn with spheres of increasing size, and the $RuSn_6$ octahedra are highlighted in the top part of the figure. The Sn atom (Sn11) which does not belong to a $RuSn_6$ octahedron is marked with an arrow. Heterododecane units of Sn and O atoms can be seen between the cluster strands.

structure contains a further Sn atom (Sn 11) marked with an arrow in Figure 1, which does not belong to the assembly of the strand. This Sn atom leads to the loss of the symmetry centers (*Cm* instead of *C2/m*), whereas the variation of all other atom positions from the higher symmetry is small. Thus, there are two equivalent positions for the specially positioned Sn atom which are linked through a pseudo inversion center in the center of the strand. According to X-ray crystallographic findings[4] only one position is occupied (Fig. 1). Bond length–bond strength considerations[6, 7] show that the bonding around the occupied and the empty position are completely equivalent, which is manifested in the uniform bond order sums near 2 for the participating O atoms. The discrete Sn atom is also divalent. The corresponding analysis of the Sn–O bonds for the Sn atoms in the strand showed that all the terminal atoms likewise are divalent (type 1: Sn 1,2,3,4,5,6,8,10), whereas the atoms that function as linking elements in the strand (type 2: Sn 7,9) have bond order sums of almost 1.[8] The difference results directly from the coordination of the Sn atoms: eight atoms of the type 1 form the apices of SnO_4 pyramids such as in SnO, two atoms form the apices of trigonal SnO_3 pyramids. The apices of the pyramids each point towards the Ru atoms. The (four) atoms of type 2 are coordinated in a distorted tetrahedral fashion by two O and two Ru atoms. The most striking structural feature in $Ru_3Sn_{15}O_{14}$ are the corner-linked $RuSn_6$ octahedra. The Ru–Sn distances lie in the range between 251 and 262 pm and the Sn–Sn distances between 333 and 380 pm. $RuSn_6$ octahedra are also found in the intermetallic phase Ru_2Sn_3.[11] Here the Ru–Sn distances are (2×) 282 and (4×) 259 pm. The $RuSn_6$ octahedron is also known from the "inorganometallic complex" $[Ru(SnCl_3)_6]^{4-}$.[12]

The linkage scheme given in Figure 2 is closely related to the topology of the perovskite structure. In the latter, corner-sharing TiO_6 octahedra are arranged parallel. In the $GdFeO_3$ variant[13] the octahedra are tilted towards one another. Those in the strand found in $Ru_3Sn_{15}O_{14}$ correspond to a one-dimensional section of this structure. However, the tilting of the octahedra in the strand is so extreme that faces and edges of neighboring octahedra span almost regular tetrahedra, which in turn are linked together through a face, edge, and two corners. Thus, the sequence of the Sn atoms parallel to (001) corresponds to the section from a hexagonal close packing arrangement.

The above comparison with the perovskite structure is a rough simplification, in that in $Ru_3Sn_{15}O_{14}$ metal-centered metal octahedra are linked to one another. Systems of con-

densed clusters with such units, among others those with Ru as interstitial atom, are known for the electropositive rare earth metals, however only in terms of the motif of the edge linkage.[14, 15] A diverse range of corner-sharing systems of metal octahedra occur in metal-rich oxoniobates.[16] In contrast to $Ru_3Sn_{15}O_{14}$, here strong homonuclear metal–metal bonds are present, and the octahedra are empty. Indeed, the strand found in the latter compound corresponds to a one-dimensional section from the layers of octrahedra in $Ba_2Nb_5O_9$ with a tilting of the octahedra by about 30°. Interestingly, the special direction of this section in the metal-rich oxoniobates could so far not be detected despite a directed search.

The band structure calculation on the basis of the extended Hückel method[17, 18] shows $Ru_3Sn_{15}O_{14}$ to be a semiconductor (Fig. 3a), in agreement with the transparency of the compound. The COOP analysis reveals that, as expected, no Sn–Sn bonds but exclusively strong Sn–O and Ru–Sn bonds are present.

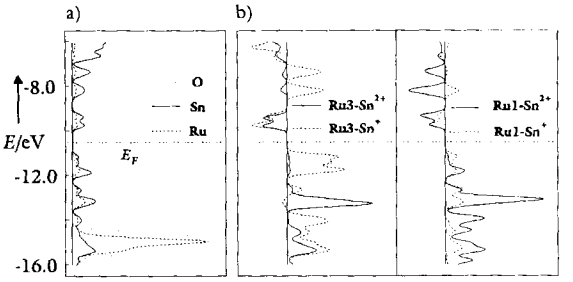

Fig. 3. a) Projected density of states for $Ru_3Sn_{15}O_{14}$. b) COOP curves for Ru3 Sn and Ru1–Sn interactions in the $RuSn_6$ octahedra (to the right bonding). Ru1 and Ru2 atoms center the peripheral octahedra. Ru3 atoms the central $RuSn_6$ octahedra. The COOP curves for Sn atoms of the same oxidation state are very similar within a $RuSn_6$ octahedron and therefore are each represented as a sum in the figure.

The corresponding analysis of the Ru–Sn interactions shows very similar bonding for the peripheral Ru1 and Ru2 atoms, however, considerably different bonding for the central Ru3 atom (Fig. 3b). The difference may at first be surprising due to the geometrically very similar coordination of the Ru atoms by Sn atoms; however, it is simply the result of the already stressed chemical dissimilarity of the Sn atoms. Up to the Fermi edge E_F only bonding Ru–Sn states are occupied. The upper edge of the valence band is dominated by Ru–Sn^{1+} interactions, and, since the central Ru3 atom is surrounded by four Sn atoms of this type, the electronic structure directly below the Fermi edge is particularly dominated by the states of this atom.

By using a simple approach, a picture of the distribution of valence electrons can be developed, which explains the electronic localization. Starting from the oxidation state II for all Sn atoms of the type 1 and the discrete Sn atom, an ionic limit $(Ru_3Sn_{8/2})^{6+}(Sn^{2+})_{10}Sn^{2+}(O^{2-})_{14}$ is reached. With the oxidation state I for the Sn atoms of the type 2 a possible charge distribution follows according to $(RuSn_{4/2})^{2+}(RuSn_{2/2})_2^{2+}$ with a formally zero valent central Ru atom and monovalent peripheral Ru atoms. The distribution is plausible since the Sn atoms of the type 2 (3-electron donors) together with four and two atoms, respectively, of the type 1 (2-electron donors) lead to the 18-electron configuration for all Ru atoms: $\overset{0}{Ru}\overset{1+}{Sn_4}\overset{2+}{Sn_2}$ with $8e + 4\times 1/2\times 3e + 2\times 1\times 2e = 18e$ (central octahedron), $\overset{1+}{Ru}\overset{1+}{Sn_2}\overset{2+}{Sn_4}$ with $7e + 2\times 1/2\times 3e + 4\times 1\times 2e = 18e$ (peripheral octahedra); the linking $\overset{1+}{Sn}$ (3e) counts half and the terminal $\overset{2+}{Sn}$ (2e) is fully included in the count. Thus $Ru_3Sn_{15}O_{14}$ forms a solid-state analogue of a hypothetical (polymeric) carbonyl–nitrosyl complex $[Ru_3(NO)_4(CO)_{10}]^{2-}$.

The "Submetalate" $Ba_{17}Al_3O_7$: The First Member of a New Class of Compounds**

Caroline Röhr* and Rita George

Recent investigations on metal-rich ternary oxides and nitrides have shown that these can have structural features, like those which occur in Rb/Cs suboxides, also with barium as an electropositive bonding partner. These structural features are namely units comprising face-linked oxygen-centered octahedra in a metallic matrix.[1] In the ternary sodium–barium subnitrides $NaBa_3N$[2] and Na_5Ba_3N,[3] octahedral chains ($^1_\infty[NBa_{6/2}]$) are present like those that occur in Cs_3O;[4] in the crystal structures of the isotypic series $Ba_{21}M_2O_5$ (M = In, Tl, Si, Ge),[5,6] $[O_5Ba_{18}]$ clusters consisting of five $[OBa_6]$ octahedra linked through four common faces were observed. The clusters in the above-mentioned compounds are separated by further metal atoms (Na, M, and Ba, respectively), comparable for example with the $[O_3Cs_{11}]$ units in Cs_7O.[7]

The synthesis of metallic, shining, brittle, extremely air-sensitive crystals of $Ba_{17}Al_3O_7$ (**1**) is achieved by the reduction of Al_2O_3 in barium-rich melts. Two crystallographically different Al and three crystallographically different O positions are found in the crystal structure (tetragonal, space group $P4_2/ncm$).[8] The Al1 atoms are tetrahedrally surrounded by oxide ions. Two tetrahedra each are linked through a common corner (O3) to give dialuminate ions $[Al_2O_7]^{8-}$ (Fig. 1a). The terminal oxygen

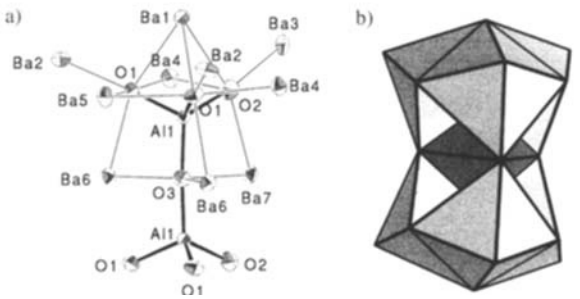

Fig. 1. The $[O_3(Al_2Ba_{17})]$ cluster with an internal dialuminate ion $[Al_2O_7]^{8-}$. a) ORTEP representation, b) polyhedral representation.

atoms of this anion (O1 and O2) are each centers of distorted octahedra comprising the Al1 atom and five Ba atoms. Three of these $[O(AlBa_5)]$ octahedra are linked through three common faces in such a way that the Al1–Ba1 edge is common to all three octahedra resulting in a $[O_3(AlBa_{10})]$ assembly. Thus, topologically, the linkage of the octahedra corresponds to those of the $[OCs_6]$ octahedra in the Cs suboxides (e.g. $Cs_{11}O_3$[9]). The bridging oxygen atom of the dialuminate ion is trigonal bipyramidally coordinated by three barium (Ba6 and Ba7) and two Al1 atoms. Two $[O_3(AlBa_{10})]$ clusters (light shading in Fig. 1b) are linked through common edges of the $[O(Al_2Ba_3)]$ trigonal bipyramids around O3 (dark) in such a way that clusters with the formula $[O_7(Al_2Ba_{17})]$ are formed. These subaluminate clusters are completely separated in the unit cell. The Al2 atoms are positioned in the region between the clusters, and these atoms achieve a distorted tetragonal antiprismatic coordination, surrounded by Ba atoms (Fig. 2). Clusters and coordination polyhedra about Al2 are corner-linked and form vertical [001] layers (Fig. 3).

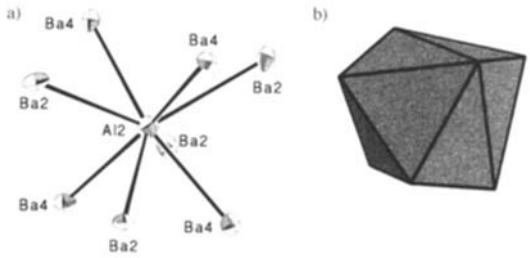

Fig. 2. The coordination polyhedron of the Al2 atom in the crystal structure of $Ba_{17}Al_3O_7$. a) ORTEP representation, b) polyhedral representation.

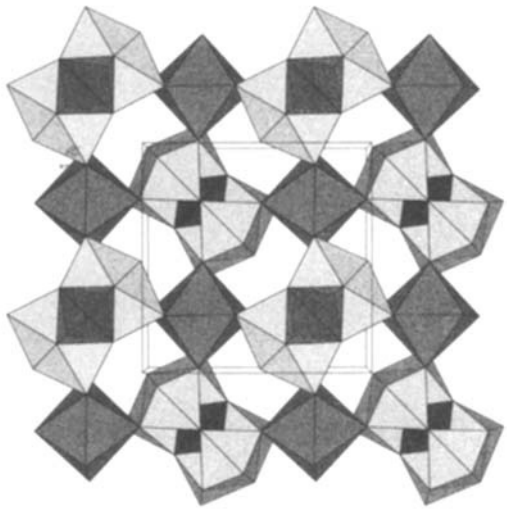

Fig. 3. View along [001] onto the layer of corner-linked $[O_7(Al_2Ba_{17})]$ clusters and distorted square antiprisms $[Al2Ba_8]$ ($z = 0$ to 1/2) in $Ba_{17}Al_3O_7$.

The Al–O distances (190.1–195.8 pm) in the dialuminate ion are significantly longer than the mean value of 176 pm found for aluminates. This result is not surprising considering the face linkage of the $[O(AlBa_5)]$ octahedra: like in the Rb/Cs suboxides with the same topology, the oxygen atoms in $Ba_{17}Al_3O_7$ (**1**) are shifted away from the centers of octahedra and the common octahedra faces; in good agreement with the findings in binary suboxides in this case are the longer Al–O bonds and the O–Ba distances which vary considerably (see below). Accordingly, the Al–O distance in the bridge—in contrast to the situation in the Si–O bonds of the disilicates—is shorter than the terminal Al–O bonds. The O-Al1-O angles deviate by up to 5° from the ideal tetrahedral angle; the angles to the bridging oxygen atom (111.9° and 114.5°, respectively) are larger and those between the terminal oxygen atoms are smaller (105.4° and 107.2°, respectively) than the ideal tetrahedral angle. The linear coordination of O^{2-} by Al^{3+} (for O3) is also found in the crystal structure of $BaAl_2O_4$.[10]

The O–Ba distances of the terminal oxygen atoms of the $[Al_2O_7]$ group vary from 252.2 (to "external" atoms Ba2/Ba3) to 299.1 pm and thus fluctuate—corresponding to the shift of O^{2-} from the octahedra centers—about the value in real salts (e.g. BaO: 275 pm). Similarly short O–Ba distances are known in the suboxides $Ba_{21}M_2O_5$.[6] The O–Ba distances of the bridging O3 atoms, which form the centers of trigonal bipyramids

[**] We thank Prof. Dr. R. Kniep and Dr. habil. B. Eisenmann for their generous support and many stimulating discussions. This work was supported by the Dr.-Otto-Röhm-Gedächtnis-Stiftung.

$[O(Al_2Ba_3)]$, are of the same order of magnitude (265.3 and 273.9 pm). The Ba–Ba distances in the clusters are 372.1–444.7 pm and thus lie in the range of distances in salts (e.g. BaO: 389 pm). In contrast, the distances between the clusters (apart from Ba1–Ba4 with 406.6 pm) are greater than 443.7 pm and thus lie in the range typical for metals (Ba–Ba in the metal: 436 pm; metallic radius: 224 pm[11]). The same is true for the Ba–Al2 distances, which with values of 347.7–381.5 pm (for CN 8 for Al to Ba) are comparable to the atomic distances in the intermetallic phases Ba_4Al_5[12] and Ba_3Al_5[13] (352–370 pm).

The first dialuminate ion described to date occurs in $Ba_{17}Al_3O_7$ (**1**). However, the Al–O distances, as a result of the face linkage of the $[O(AlBa_5)]$ octahedra, are significantly longer than in comparable electrovalent[*] aluminates; thus, a description as $[Al_2O_7]^{8-}$ can be considered as a resonance formula.

Like the oxide ions in the suboxides, these dialuminate ions in **1** form the centers of clusters ($[[O_7(Al_2Ba_{17})]]$); thus the compound can be described as a "subaluminate" in analogy to the suboxides. The comparability is evident from the bond lengths and coordination numbers: *within* the clusters the conditions are typically ionic and *between* the clusters they are typically metallic. The direct structural analogy to the clusters comprising oxygen-centered face-sharing octahedra, characteristic for the suboxides, however, requires the inclusion of the Al centers of the complex anion in the octahedra, thus one may refer to heteroclusters. The relationship of $Ba_{17}Al_3O_7$ (**1**) to the suboxides is particularly apparent, since elements of the $[O_7(Al_2Ba_{17})]$ cluster are topologically identical with the $[O_3Cs_{11}]$ cluster in the Cs suboxides.

The possibility of including "metallic" M (M = element of group 13 and 14) into the regions between the subclusters in metal-rich oxides is already known for the series of isotypic compounds $Ba_{21}M_2O_5$ (M = In, Tl, Si, Ge).[6] As in this series, the metallic state of M in **1** is also revealed by the distances and coordination numbers characteristic for metals.

Thus, $Ba_{17}Al_3O_7$ (**1**) is the first compound that contains both cationic (within the clusters) and metallic aluminum (between the clusters). In analogy to the suboxides, this compound can be regarded as the first member of a new class of compounds, namely the submetalates.

Experimental Procedure

$Ba_{17}Al_3O_7$ (**1**) was formed by the reduction of dried powders of Al_2O_3 (Merck, analytical grade) and ZnO (Merck, analytical grade) with elemental barium (Degussa, 99.5%) with Ba:ZnO:Al_2O_3 ratios of 15:1:1. The samples were heated to 1020 K in dried corundum crucibles under argon, tempered for 5 h, and then cooled down again at a rate of 150 K h^{-1}. Compound **1** crystallized in a barium matrix together with $Ba_{21}Zn_2O_5$ ($Ba_{21}Si_2O_5$ type [6]) and BaZn in the form of brittle, xenomorphic crystals with a metallic shine, which decomposed in moist air within a few seconds. It is still unclear whether the ZnO acts as a mineralizer in the synthesis, however, it can be replaced by other transition metal oxides such as NiO. The synthesis of phase-pure **1** has so far not been achieved. The EDX analysis of the measured crystal confirms within the limits of error of the method the composition determined from X-ray investigations (results for the measured crystal (in wt%, theoretical values in parentheses): Ba 84.7(85.0), Al 15.3(15.0)). For the crystal structure analysis selected crystals were sealed in X-ray capillaries under Na-dried paraffin oil.

Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks**

Peter Murer and Dieter Seebach*

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

In our work on the synthesis of chiral dendrimers[1] we have thus far used –with one exception[2]—only chiral central units and achiral branches[2–5] (cf. ref. [6]). We report here on the synthesis and properties of dendrimers of the zero to third generation[7] containing, without exception, chiral building blocks in both the central unit and the branches.

The method was outlined in our earlier work,[2, 5] and follows the convergent route first adopted by Fréchet et al.[8] For both, double and triple branching, (*R*)-3-hydroxybutanoic acid was used as the starting material. It was benzylated[9] for the double branching (see **1**) and hydroxybenzylated[10] for the triple branching, where two epimers **2** and **3** became available. For the peripheral building blocks, the OH groups of the branched diols and triols were etherified with MeI. The *tert*-butyldiphenylsilyl (TBDPS) protective groups in **1**–**3** (R = Me) were removed to construct the branches and a benzylic bromide was prepared, which was then used for the etherification of the OH groups of the corresponding diol or triol. Reaction of this branch bromide with the triols **4a** and **4b**[4] yielded dendrimers **5**–**7** with unextended and **8**–**11** with elongated central units, respectively (Scheme 1).

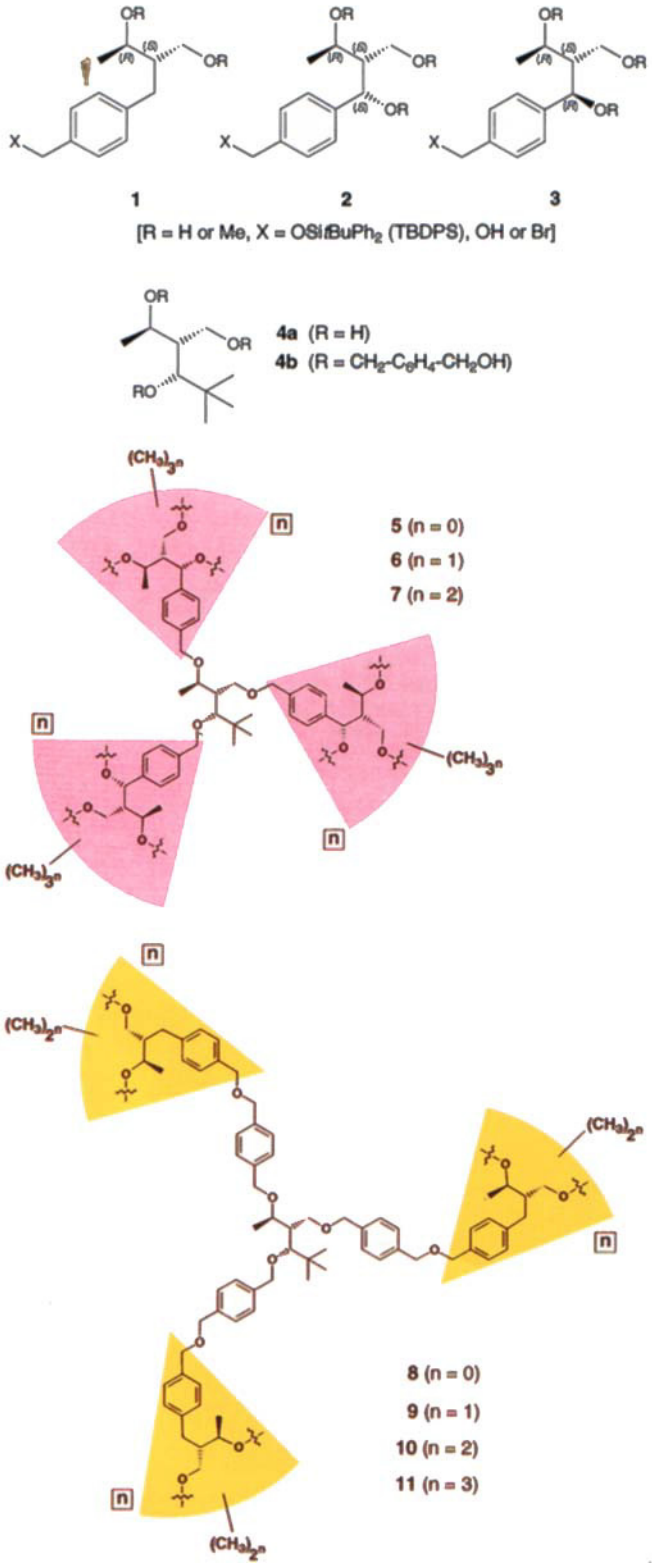
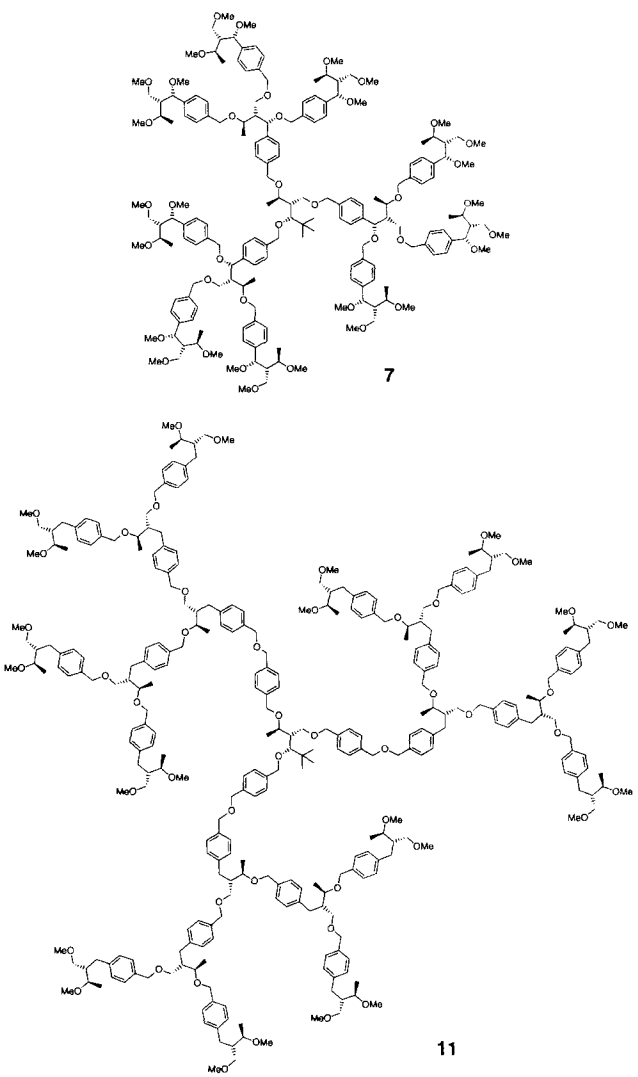
[**] Part of the proposed dissertation by P. Murer.



Scheme 1. Building blocks **1**–**4** for the construction of the dendrimers **5**–**11**; general formulae of the triply branched dendrimers **5**–**7** with unextended central units and the doubly branched dendrimers **8**–**11** with elongated central units.

As expected with an increasing number of generations, a higher degree of branching and the absence of an extension at the central unit, the coupling of three branches with triols of type **4** became increasingly more difficult.[11] Scheme 2 shows the largest molecules with triple or double branching which we have been able to prepare up to now; they are **7** (2nd generation, unextended central unit, 39 stereogenic centers) and **11** (3rd generation, extended central unit, 45 centers, 3.5×10^{13} possible stereoisomers, molecular weight 4911 Da). All branch building blocks and final dendrimers were fully characterized (IR, ^{1}H NMR, ^{13}C NMR, UV, CD, mass spectrometry, osmometry, and elemental analysis).

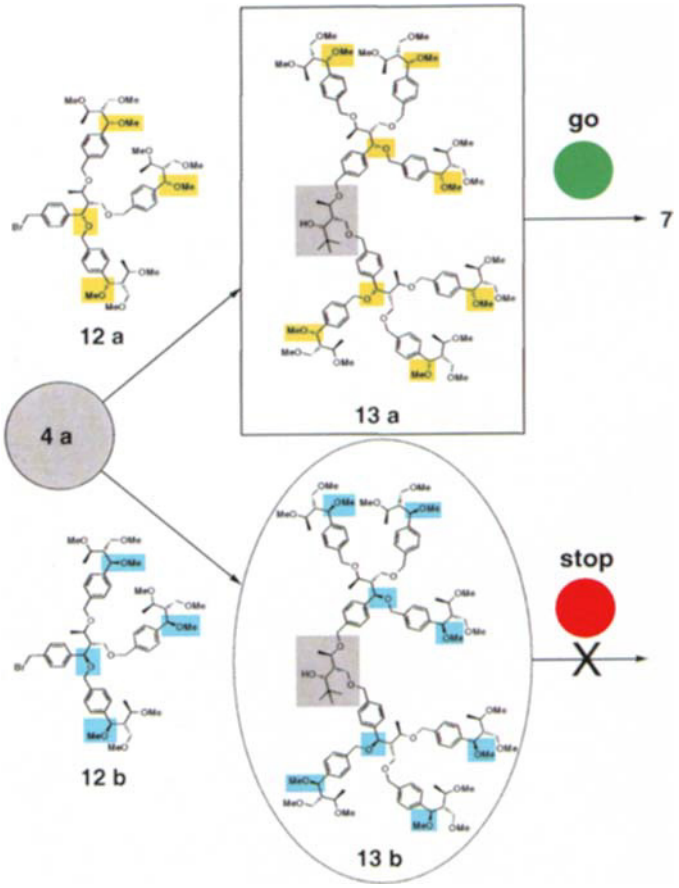


Scheme 2. The triply branched second generation dendrimer **7** with an unextended central unit and the doubly branched third generation dendrimer **11** with an elongated central unit.

In the synthesis of the most compact dendrimer **7**, we stumbled upon a spectacular case of diastereoselectivity (Scheme 3): when a branch bromide **12a** with (*S*)-configuration at the four benzylic stereogenic centers was used, the reaction proceeds smoothly to give the desired dendrimer **7** (51 % yield); if, on the other hand, the corresponding (*R*)-configured bromide **12b** was used, the reaction stopped at the doubly coupled product **13b** (88 % yield).[12]

At room temperature the dendrimers are very viscous, honey-like (**6**, **9**–**11**) or glassy (**7**, **13b**) substances, some of which retain solvent tenaciously (to obtain an analytically pure sample of **11**, it had to be kept at 80 °C/0.02 Torr for several days). These dendrimers are very soluble in moderately polar solvents such as CH_2Cl_2, $CHCl_3$, and Et_2O.[13]

The signal for the central hydrogen appears at $\delta = 2.46$ in the ^{1}H NMR spectrum of **7**. On the other hand, for **5** and **6**, for the analogues with elongated central units and for all doubly



Scheme 3. Preparation of dendrimer **7** from the central unit **4a** and the branch bromide **12a** via **13a**. The attempted formation of a diastereoisomer of **7** by coupling with the branch bromide **12b** led to **13b** which carried only two branches and which did not react further.

branched dendrimers it appears at $\delta = 2.30$. The MALDI-TOF mass spectrum of **11** recorded in the linear mode is shown in Figure 1.

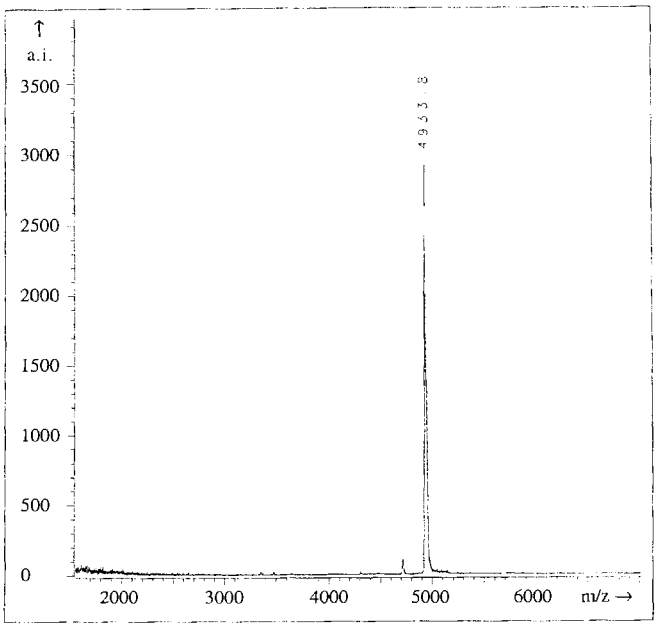


Fig. 1. MALDI-TOF mass spectrum of **11**. Recording conditions: linear mode, acceleration energy: 20.0 kV, N_2 laser (337 nm), α-cyano-4-hydroxycinnamic acid matrix, Bruker REFLEX. The peak at 4934 corresponds to $[M^+ + Na]$.

The chiroptical properties of the dendrimers presented here are informative. In the triply branched dendrimers, a reversal of the sense of rotation is observed on going from the first to the second generation (**6**: $[\alpha]_D = -38$; **7**: $[\alpha]_D = +12$). In the doubly branched dendrimers, this occurs on going from the second to the third generation (**10**: $[\alpha]_D = +4$; **11**: $[\alpha]_D = -5$). The CD spectra of the doubly branched compounds **8**–**11** in the region 220 to 270 nm are shown in Figure 2. As can be seen, the nature

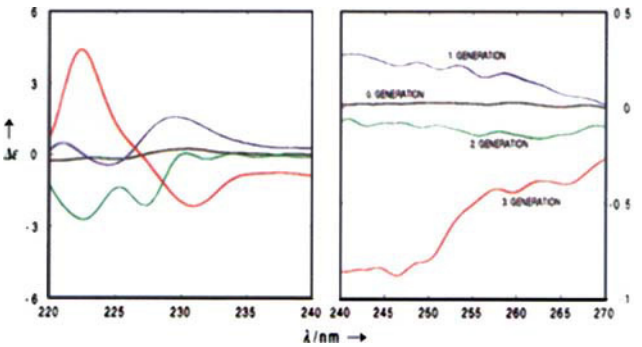

Fig. 2. CD spectra of the dendrimers **8**–**11** (10^{-3} to 10^{-4} M in CH_3CN, JASCO-J-710 spectrometer). Black: **8**, blue: **9**, green: **10**, red: **11**. The region of the spectrum usually used for the application of the benzene-sector and chirality rules [14] is shown on the right. The λ_{max} values for the long wavelength benzene absorption in the UV spectra of **8**–**11** alternate and lie at 261, 255, 263, and 254 nm, respectively.

of the curves changes from generation to generation; particularly large differences appear in moving from the second (**10**) to the third (**11**) generation. This may be an indication of conformationally chiral substructures in the dendrimer branches.

We are currently preparing larger quantities of chiral dendrimers to enable us to test their chemical behavior, for example, as additives to solvents for enantioselective reactions.

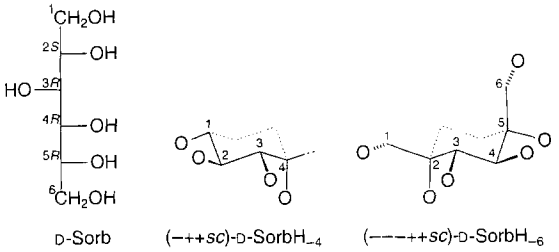

Scheme 1. D-Sorbitol (D-Sorb) in the Fischer projection (left), as a fourfold (center), and as a sixfold deprotonated ligand (right) in **1**; the additional dotted lines completing C_4 fragments leading to six-membered rings helps to provide a three-dimensional impression; charges have been omitted.

A Hexadecanuclear Polyolatometalate of Copper(II) Ions and Multideprotonated D-Sorbitol**

Peter Klüfers* and Jörg Schuhmacher

Polyols can be multideprotonated in aqueous alkali solutions of copper(II) salts to furnish polyolatocuprates; ligands with three or more functional groups, such as anions of glycerol or sugar alcohols, can be used as building blocks for the formation of oligo- or polymeric metalates.[1] For the synthesis of multinuclear alkoxo clusters, which for instance, could be interesting as low-dimensional magnetic materials, chiral hexitols seem to be the best ligands to choose: They are readily available, and the numerous potential sites for bonding to the metal atom are fixed in a pattern of low symmetry, and thus a complex molecular architecture can be deliberately imposed upon the end products.

Metal complexes of chiral hexitols have probably been known for a long time. Much attention has been paid to the compound arising from iron(III) ions and D-sorbitol in aqueous alkali solutions; the structure is not known, although a multinuclear framework is conceivable.[2] We report here on the crystallization and structural elucidation[3] of the D-sorbitol–copper(II) compound **1**, which is obtained on concentrating aqueous solutions of the composition LiOH:$Cu(OH)_2$:D-sorbitol in the molar ratio of 1:2:1 in the form of monoclinic, blue crystals of the same stoichiometry. In **1** (D-Sorb = D-sorbitol) half of the

$Li_8[Cu_{16}(D\text{-}SorbH_{-6})_4(D\text{-}Sorb1,2,3,4H_{-4})_4]\cdot ca.\ 46H_2O$ **1**

D-sorbitol ligands are completely deprotonated η^6,μ_5-hexaanions (Scheme 1), which form regardless of the protolytic equilibria and the competing aqua, hydroxo, and oxo ligands of the aqueous system. The other half of the D-sorbitol ligands are present as μ_3-tetraanions, in which four neighboring hydroxy groups have been deprotonated (H at O-1 to O-4 using the same numbering as for glucose, cf. Scheme 1). The eight polyolate ions are the sole ligands in this, therefore homoleptic, hexadecanuclear cuprate. To our knowledge there are no examples known of nonpolymeric copper(II) complexes with a greater number of metal atoms. It appears that such a multinuclear structure is necessary in order to achieve the largest possible number of metal–ligand contacts for a hexadentate, but C_1 symmetric ligand (cf. the simple structure of the coordination polymer from copper(II) ions and the anion of dulcitol, an isomeric hexitol of C_i symmetry[1b]).

The hexadecacuprate ion is toroidal with an oval cross-section and has approximate D_2 symmetry (Fig. 1).[3] It resembles the multinuclear polyolato metal structures obtained with cyclodextrin ligands. In contrast to compound **1**, the shape of the torus in $Pb_{16}(\gamma\text{-}CDH_{-16})_2$[4] is predetermined by the ligands. Common to both compounds is the fact that they do not need to be synthesized in metal-rich solutions; they can also be ob-

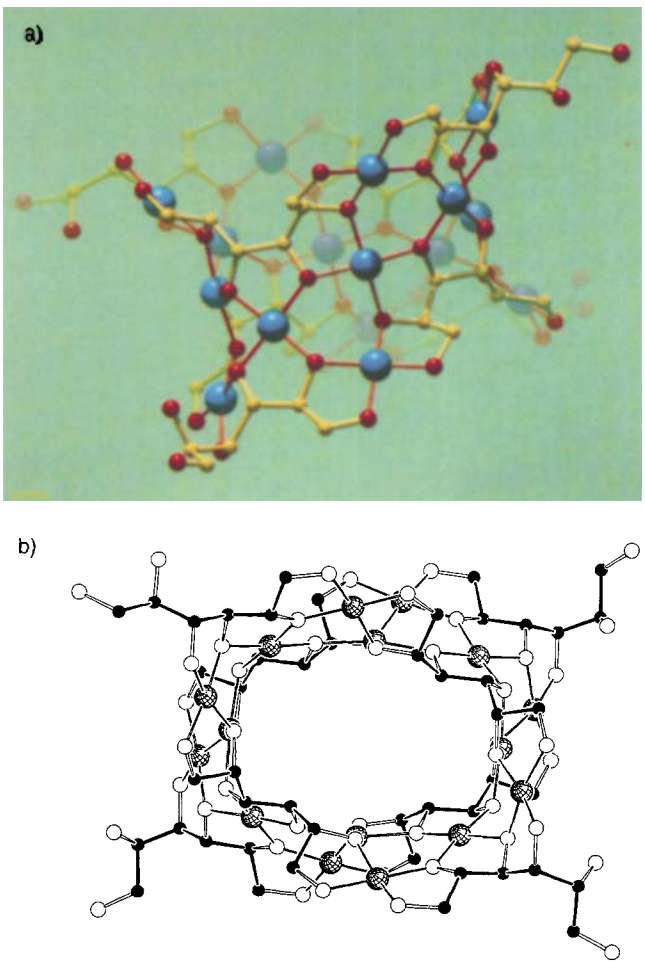

Fig. 1. Two views of the toroidal hexadecacuprate ion in **1**. a) Side view of the area of least curvature (blue: Cu, red: O, yellow: C). b) Oval cross-section (large circles: Cu, small circles: C (shaded), O (unshaded).
