The X-ray crystal structure of the *Escherichia coli* photolyase allows a deeper understanding of one of the most unusual processes in nature, the use of sunlight for the efficient repair of DNA.[4] The single events involved are the specific recognition of a photodamaged DNA region, possibly through the flipped-out conformation of the damaged bases, and the subsequent cleavage of the pyrimidine dimers employing energy and electron transfers steps. The mechanism of this repair reaction is comparable only with that of photosynthesis, where light-harvesting chromophores situated around an active center funnel their excitation energy to a specific chromophore, the "special pair". This special pair transfers a single electron to a special acceptor chromophore as the first event in an electron transfer cascade.[6] It is remarkable that a very similar reaction sequence is used in the photoreactivation process to maintain the genome, a problem presumably as old as life. The exciting finding that the peptide sequences of bacterial photolyases and the newly found blue photoreceptors, which are essential for the early

development of plants, show strong homologies fuels widespread speculation. Perhaps energy and electron transfer steps are not only used to convert sunlight into chemical energy (photosynthesis) and to protect organisms from the deleterious effects of far-UV light (photoreactivation), but are also involved in the induction of an early development signal in green plants (photoreceptors) by a yet unknown mechanism.[4, 14]

Reactions of Neopentyl 2,2,2,-Trifluoroethanesulfonate (Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose

Comment by Herbert P. Jennissen*

In their paper[1] the authors confirm our general findings on agarose beads[2] that certain tresylates exhibit hitherto unexpected reactions without SO scission: a) the tresyl sulfur remains in the reaction product, b) fluoride is the main leaving group, and c) alkaline hydrolysis generates an acidic product. At the time of our work we had no possibility of stringently analyzing our solid-phase reaction products, and consequently, the proposed structures of the products under the assumption that S–C scission takes place (sulfates, sulfamates, and thiosulfates)[2] were of preliminary nature and other alternatives were discussed.[3]

In their interesting paper[1] King and Gill show that neopentyl tresylate reacts with butylamine, diethylamine, and phenylmethanethiol yielding amides, fluoromonosulfides, and a ketene dithioacetal. However, we feel that it has not been proved that these reactions (especially for thiols) can be generalized and assumed to be identical in all respects in a homogeneous phase as well as a heterogeneous phase system.

In independent work[3,4] we have done structural studies of tresyl agarose, tresyl silica, and the coupling products obtained with the nucleophiles butyl amine and butane thiol. Solid phase CP/MAS ^{13}C NMR and IR spectra (DRIFTS) of butyl-*NS*-agarose (coupling of butylamine with tresyl agarose) in conjunction with GC-MS analysis of the liquid phase obtained by alkaline hydrolysis of tresyl agarose led to the conclusion of a β-sulfonyl amide bond structure without S–C scission[4] in agreement with the structure of King and Gill. Besides butyl amide, a small amount of β-sulfonyl carboxylic acid was also detected, which from our elemental and ^{14}C-tracer analysis[2] was estimated to be no more than 5–10% (side reaction). β-Sulfonyl carboxylic acid (acetic acid-*S*-agarose) could also be identified as the above-mentioned acidic product[2] of alkaline hydrolysis.

In contrast, our CP/MAS ^{13}C NMR spectra of the butane thiol coupling products (butyl-*SS*-agarose, butyl-*SS*-silica) a) failed to turn up any signals resulting from an ethylenic group or of the α- and β-sulfonyl carbon atoms as suggested by King and Gill. In addition b) it is difficult to follow the conclusions of King and Gill, who explain our quantitative data as a result of 50% acid (due to hydrolysis of tresyl agarose) and 50% dithio derivative, since this is at variance to their own statement: "With three equivalents of the thiol the product was mainly **7** (i.e. dithio derivative, 80% yield)". Since under our coupling conditions[2] we had a large excess of thiol over immobilized tresyl groups, the main reaction product should have been the dithio derivative for which the molar ratio *sulfur in product* to *sulfur in tresyl agarose* is 3.0 (for 100% yield) or 2.4 (for 80% yield). A small calculation based on our elemental analysis and ^{14}C-tracer studies,[2] however, gives for this molar ratio $2.04 \pm 0.10(6)$ (instead of 2.4–3.0). The molar ratio of *^{14}C-butyl residue in product* to *sulfur in tresyl agarose* is $1.14 \pm 0.22(6)$ instead of 2.0. If a 50% yield (in spite of thiol excess) is accepted, a correspondingly strong signal for carboxyl groups should have been observed in our ^{13}C NMR spectra in agreement with the postulated 50% *carboxyl groups* per *sulfur in tresyl agarose*. However, only small signals (in butyl-*SS*-agarose) or no signals (in butyl-*SS*-silica) from carboxyl groups were observed, indicating a minor reaction. These two main discrepancies either indicate a different reaction sequence[2,3] or possibly a mixture of reaction products in the case of thiol coupling in heterogeneous phase.

Reply by James F. King* and Manjinder Singh Gill

We are pleased to learn that Professor Jennissen accepts two-thirds of our structural revisions. For the third species, butyl-*SS*-agarose, it would appear that the matter is not yet settled. In view of the fact that seven species, $ROSO_2CH_2COOH$, $ROSO_2CH{=}CF(SR')$ (two stereoisomers), $ROSO_2CH{=}C(SR')_2$, $ROSO_2CH_2C(SR')_3$, $ROSO_2CH_2CO{-}SR$, and RSR', have been identified as products in our model reactions, it would not be surprising if the butyl-*SS*-agarose were to prove to be structurally complex, as we have already suggested in the final sentence of our footnote 9. The lack of strong signals pointing to particular structural features in butyl-*SS*-agarose could arise either because a) butyl-*SS*-agarose is structurally complex, and (or) b) CP/MAS ^{13}C NMR spectra of polymers do not always show clear signals for all carbons. Further experimentation is clearly required.

A Novel Method for the Synthesis of Isocyanates Under Mild Conditions**

Hans-Joachim Knölker,* Tobias Braxmeier, and Georg Schlechtingen

Isocyanates are important commercial precursors for the synthesis of polyurethanes and polyureas. Moreover, they are frequently used as intermediates in the synthesis of biologically active compounds.[1] The most widely utilized method for the synthesis of isocyanates, the phosgenation of amines, uses highly toxic phosgene as a reagent and therefore involves environmental and safety problems. Alternative methods, such as the thermolysis of carbamates (urethanes), very often require rather drastic reaction conditions.[1] We now describe a procedure that converts alkyl- and arylamines into isocyanates in high yields by reaction with activated carbonates (for example, di-*tert*-butyl dicarbonate) in the presence of a catalytic amount of a nucleophilic nitrogen base at room temperature.[2]

Di-*tert*-butyl dicarbonate, $(Boc)_2O$, is a widely used protecting group reagent in peptide synthesis.[3] We have discovered that the reaction of substituted anilines with $(Boc)_2O$ in the presence of a stoichiometric amount of 4-dimethylaminopyridine (DMAP)[4] in an inert solvent (acetonitrile, dichloromethane, ethyl acetate, tetrahydrofuran, toluene) at room temperature leads to aryl isocyanates within 10 min in almost quantitative yields (Table 1).

With this strategy 2,6-disubstituted arylamines can be converted almost quantitatively into aryl isocyanates (see synthesis of **2a–d**). The application of the method is particularly straightforward when performed in acetonitrile followed by an acidic workup with sulfuric acid (see Table 1 and Experimental Section). When starting with 2-monosubstituted, 2,4-disubstituted, or 2,3,4-trisubstituted arylamines, the yields of the aryl isocyanates range between 40 and 90% (**2e–k**). In order to obtain 2,6-unsubstituted aryl isocyanates, such as **2l**, in moderate yields, the products have to be isolated by column chromatography on silica gel at −30 to −45 °C. The lower yields obtained with sterically less hindered arylamines arise from reaction of the isocyanates with the simultaneously formed *tert*-butanol affording an *N*-Boc derivative (urethane) and from product loss during workup.

When the arenediamines 2,4,6-trimethylbenzene-1,3-diamine and 2,2′,6,6′-tetramethyl-4,4′-methylenediphenylamine were treated under the same reaction conditions with 1.4 equivalents of $(Boc)_2O$ and 1.0 equivalent of DMAP per amino group in acetonitrile at room temperature (method A, workup with sulfuric acid), 2,4,6-trimethylbenzene-1,3-diisocyanate (**3**) and 2,2′,6,6′-tetramethyl-4,4′-methylenediphenyl isocyanate (**4**) were obtained in 84% and 93% yield, respectively. Arenediyl diisocyanates play a very important role as monomers for the industrial synthesis of polyurethanes and polyureas.[5]

separated from the *tert*-butanol formed simultaneously. Consequently, its yield is reduced. In contrast, higher branched alkyl isocyanates, like **6**, can be isolated in quantitative yields.

Some time ago Steglich et al. recognized early on the high efficiency of 4-dimethylaminopyridine (DMAP) as a catalyst in acylation reactions.[4] The reactive intermediates of these acylation reactions are *N*-acylpyridinium ions. Upon reaction of acetic anhydride with DMAP it could be proven that 1-acetyl-4-dimethylaminopyridinium acetate is spontaneously formed in equilibrium.[4] Based on spectroscopic studies and additional experiments, we postulate the reaction mechanism depicted in Scheme 1 for the novel isocyanate synthesis. The reaction mixture initially forms an equilibrium between the two starting reagents, DMAP and $(Boc)_2O$, and 1-*tert*-butoxycarbonyl-4-dimethylaminopyridinium-*tert*-butyl carbonate (**7**). Nucleophilic attack of the amine at the *tert*-butoxycarbonyl group of the pyridinium system **7** presumably leads to the tetrahedral intermediate **8**, which is converted into **9** by a transprotonation. In principle, the regeneration of the carbonyl group could also occur by loss of the pyridinium species (pathway B), which would provide *tert*-butanol, carbon dioxide DMAP, and urethane **10** (*N*-Boc derivative of the amine). However, the products we found indicate that intermediate **9** decomposes into *tert*-butanol and **11** (pathway A). Deprotonation of **11** by *tert*-butyl carbonate affords intermediate **12**. The rapid and irreversible decarboxylation of the resulting *tert*-butyl monoester of carbonic acid, which generates *tert*-butanol, shifts the equilibrium towards the intermediate **12**. Finally, loss of the pyridinium leaving group in **12** provides the isocyanate along with regenerated DMAP.

All spectroscopic and experimental results support the mechanism depicted in Scheme 1. 1-*tert*-Butoxycarbonyl-4-dimethylaminopyridinium-*tert*-butyl carbonate (**7**) is the key reagent in this novel isocyanate synthesis. Wakselman et al. described the corresponding chloride[6] and tetrafluoroborate[7] as reagents for the transfer of the Boc group in aqueous medium. Comparison of the ^{1}H NMR and ^{13}C NMR spectra of the tetrafluoroborate prepared as described by Wakselman et al. and of potassium *tert*-butyl carbonate[8] with the spectra of the equilibrium mixture of $(Boc)_2O$ with DMAP (1.1:1) in $[D_3]$acetonitrile proved unequivocally the existence of intermediate **7** in solution. The ^{1}H NMR and ^{13}C NMR spectra also revealed that DMAP and **7** exist in a ratio of 1:1.4 in this equilibrium mixture at room temperature. In agreement with Ragnarsson et al.,[9] we did not find any evidence for the formation of the [Boc-OCO-DMAP]$^+$ adduct postulated by Kemp and Curran.[10] In contrast to this report, the reagent mixture is stable for 1 h in anhydrous acetonitrile and decomposes only slowly to *tert*-butanol, isobutene, carbon dioxide, and di-*tert*-butyl carbonate.

Our mechanistic studies also emphasize the key role of intermediates analogous to **7** in the DMAP-catalyzed reaction of dialkyl dicarbonates and carboxylic acids, which was recently reported for the preparation of esters.[11] Control experiments showed that the reaction of the above-mentioned tetrafluoroborate with mesitylamine (**1a**) in acetonitrile does not give isocyanate **2a**. This shows the necessity of a counteranion that can function as an efficient base. Addition of potassium *tert*-butyl carbonate to this solution leads to immediate formation of *tert*-butanol, carbon dioxide, DMAP, and mesityl isocyanate, which can subsequently be isolated in more than 90% yield. Two equivalents of *tert*-butanol (detection and quantification by ^{1}H NMR) as well as one equivalent of carbon dioxide (gas-phase IR spectroscopy, quantification by gas volumetric analysis) are formed in the DMAP-mediated isocyanation of amines. The reaction of an arylamine with $(Boc)_2O$ in the absence of a nucleophilic nitrogen base exclusively affords the *N*-Boc derivative (urethane), as well established in protecting group chemistry. The urethane is not an intermediate of the isocyanate synthesis described here, since it does not undergo a reaction with either $(Boc)_2O$ or DMAP alone. The reaction of the urethane with $(Boc)_2O$ in the presence of DMAP, however, results in a nucleophilic reaction with **7** in which the *N*,*N*-bis-Boc derivative is formed.[12] The synthesis of *N*,*N*-bis-Boc derivatives can be explained by the formation of the [Boc-DMAP]$^+$ cation resulting from the activation of $(Boc)_2O$ by DMAP (Scheme 1).

The regeneration of DMAP as postulated in the mechanism outlined in Scheme 1 suggests the use of this component in catalytic amounts. This assumption was extensively investigated in the synthesis of mesityl isocyanate (**2a**) (Table 2). When employing low concentrations of DMAP, we isolated increasing amounts of the by-product *N*,*N*′-dimesitylurea (**14**) (see Table 2), arising from the reaction of the isocyanate with mesitylamine.[13] Nevertheless, the isocyanate was obtained in 92% yield when using 1 mol% of DMAP as the catalyst. With 0.1 mol% of DMAP, the reaction is incomplete after 10 min as a result of the low catalyst concentration. The yields, however, increased with increasing reaction times. 4-Pyrrolidinopyridine (PPY), which was used as an acylation catalyst by Steglich et al.,[4] was found to be another efficient catalyst for the isocyanation reaction described here. In contrast to the situation for acylation reactions, PPY did not prove to be a superior catalyst

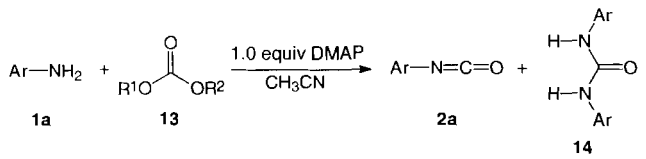
[b] Formation of *N*,*N*′-dimesitylurea (**14**) as a by-product (see Table 3). [c] Incomplete reaction. [d] Formation of *tert*-butyl-*N*-mesityl carbamate (**10**) (R = mesityl) as a by-product.

for this transformation. Along with isocyanate **2a**, urethane **10** (which most likely arises from the direct, uncatalyzed reaction of mesitylamine with $(Boc)_2O$) and urea **14**, which is a secondary product of isocyanate **2a**, were found when less nucleophilic pyridine bases such as 4-methoxypyridine (4-MeOPy), pyridine itself, or triethylamine were used.

For ecological reasons it seemed particularly important to achieve the isocyanation of amines with C1 building blocks that, unlike $(Boc)_2O$, can be synthesized without the use of phosgene. In fact, other activated carbonates can be used for the isocyanation of amines in the presence of DMAP (Table 3). However,



1a **13** **2a** **14**

Ar = Mesityl

Table 3. DMAP-mediated synthesis of mesityl isocyanate (**2a**) from mesitylamine (**1a**) with the activated carbonates **13** as the C1 building blocks. **13a** = $(Boc)_2O$.

13	R^1	R^2	T [°C]	t	**2a** Yield [%]	**14** Yield [%]
a	*t*BuOCO	*t*Bu	25	10 min	96	0

d	4-$NO_2C_6H_4$	4-$NO_2C_6H_4$	82	18 h	9	86

due to its extreme reactivity, $(Boc)_2O$ (**13a**) provides the highest yields in a very rapid reaction. As an alternative to $(Boc)_2O$, we first synthesized *tert*-butoxycarbonyl pivalate (**13b**), which is readily available by successive transformation of *tert*-butanol with potassium and carbon dioxide followed by an in situ acylation with pivaloyl chloride. The reaction of **13b** with mesitylamine (**1a**) in the presence of DMAP provided isocyanate **2a** in 17% yield, along with 64% of urea **14**. In this context it is important to note that the urea is formed exclusively from the isocyanate under these reaction conditions and not from the corresponding urethane. The reaction of the mesitylamine-*N*-Boc derivative **10** (R = mesityl) in the presence of an equimolar amount of mesitylamine and DMAP afforded only 0.9% of *N*,*N*′-dimesitylurea (**14**) after 14 d in acetonitrile at 82 °C. Consequently, the urethane formed by the direct transformation of $(Boc)_2O$ with mesitylamine (**1a**) does not provide an isocyanate-free way to urea **14**. Thus, the isolation of larger amounts of urea gives direct evidence for the intermediate isocyanate as shown in the pathway outlined above. While dimethyl carbonate, di-*tert*-butyl carbonate, and ethylene carbonate did not react, the reaction of diphenyl carbonate (**13c**) with mesitylamine and DMAP in acetonitrile under reflux yielded urea **14** in a moderate 29% yield after 15 d. Under these reaction conditions, complete conversion of the isocyanate into the respective urea derivative is not unexpected. Because of the milder reaction conditions, when bis(4-nitrophenyl) carbonate (**13d**) is used, isocyanate **2a** could be isolated along with the secondary product **14**. The combined yield of 95% at 82 °C indicates that the DMAP-catalyzed reaction pathway involving the isocyanate is virtually the exclusive route in this case.

In conclusion, the DMAP-catalyzed reaction with activated carbonates as C1 building blocks constitutes a convenient laboratory method for the phosgene-free isocyanation of amines. The application of this method in the synthesis of symmetrical and unsymmetrical ureas as well as of heterocycles is currently under investigation.

Experimental Procedure

All reactions were performed in anhydrous solvents.

General procedure for the synthesis of alkyl and aryl isocyanates with stoichiometric amounts of DMAP: A solution of di-*tert*-butyl dicarbonate (1.4 equivalents) in acetonitrile was treated successively with a solution of 4-dimethylaminopyridine (1.0 equiv) in acetonitrile and a solution of the arylamine (1.0 equiv) in acetonitrile. The resulting mixture was stirred for 10 min at room temperature (dichloromethane was used as the solvent for workup according method B). Workup, method A: The reaction mixture was treated with sulfuric acid (7 equiv) as a 40% solution in acetonitrile ($\rho = 1.03\ g\,cm^{-3}$), and was stirred for 2 min. The mixture was then extracted three times with hexane. The combined hexane layers were dried over magnesium sulfate, and the solvent was removed in vacuo. Workup, method B: The solvent (dichloromethane) was completely removed, and the residue is extracted several times with small amounts of eluent (for example, hexane/ethyl acetate 4/1). The resulting suspension was subjected to silica gel chromatography at −30 °C to −45 °C.

Synthesis of mesityl isocyanate (**2a**) with a catalytic amount of DMAP: A solution of di-*tert*-butyl dicarbonate (619 mg, 2.84 mmol) in acetonitrile (2 mL) was treated successively with a solution of 4-dimethylaminopyridine (33 mg, 0.27 mmol) in acetonitrile (2 mL) and a solution of **1a** (365 mg, 2.7 mmol) in acetonitrile (2 mL). The reaction mixture was vigorously stirred for 10 min. After the addition of concentrated sulfuric acid in acetonitrile (40% solution, $\rho = 1.03\ g\,cm^{-3}$, 0.47 mL), the resulting mixture was stirred for 5 min. Water (0.47 mL) was then added, and the mixture was stirred for an additional 5 min. The reaction mixture was then poured into an equal amount of water, the solution was extracted three times with hexane, and the combined hexane layers were dried over magnesium sulfate. Removal of the solvent in vacuo afforded **2a** (420 mg, 97%) as colorless crystals, m.p. 42 °C; IR (KBr): $\tilde{\nu} = 2281$ (NCO), 1592, 1509 cm^{-1}; ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): $\delta = 135.06$ (C), 132.68 (2C), 128.73 (2CH), 128.54 (C), 124.24 (NCO), 20.79 (CH_3), 18.62 ($2CH_3$); analysis for $C_{10}H_{11}NO$: calcd C 74.51, H 6.88, N 8.69; found C 74.38, H 6.79, N 8.71.

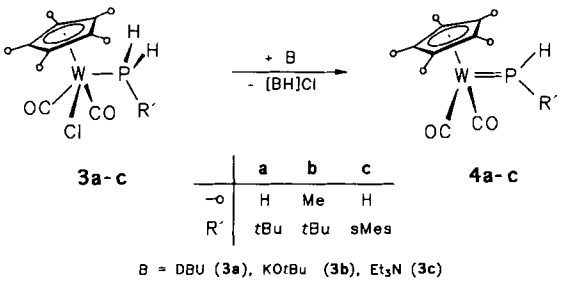
P–H-Functionalized Phosphenium Complexes $[C_5R_5(OC)_2W{=}P(H)R']$ (R′ = *t*Bu, sMes): Synthesis, Isomerization, and Transformation into Hydrido Complexes Containing a *t*BuP(H)OH Ligand**

Wolfgang Malisch,* Ulrich-Andreas Hirth, Klaus Grün, Martin Schmeusser, Oliver Fey, and Udo Weis

Dedicated to Professor Hubert Schmidbaur on the occasion of his 60th birthday

The metal–phosphorus double bond in phosphenium complexes of the type $[Cp(OC)_2M{=}PR_2]$ (M = Mo, W) is employed increasingly in cycloaddition reactions,[1] which represent a first step towards the application of these compounds in the synthesis of organophosphorus compounds mediated by metal complexes. However, in the compounds known to date, bulky organo or heteroatom substituents on the phosphorus, which stabilize the double bond, limit the addition activity of the M=P unit quite considerably.[1] In this context promising candidates are hydrogen-substituted M=P units with an sp^2-hybridized phosphorus atom, which can be regarded as phosphorus analogues of primary carbene complexes.[2a, b] These units display increased potential for cycloaddition, but the possibility of isomerizations by hydrogen migration must also be taken into account.[2c] Furthermore, the possibility of exchange and insertion reactions involving the highly reactive P–H bond must be considered.[3]

The existence of these R(H)P=M complexes, which have been postulated repeatedly as intermediates in reactions of P–H-functionalized phosphido-osmium complexes,[4] has, to date, only been confirmed by the compound $[(Et_3P)_2(Me_3CC)Cl_2W{=}P(H)Ph]$ obtained by Schrock from a complex reaction.[5] The reason for the difficulty in isolating these compounds is the high reactivity of the insufficiently shielded M=P unit, which spontaneously dimerizes, as proved in the case of $[C_5R_5(OC)_2W{=}P(H)Mes]$ (R = H, Me) with the formation of phosphinidene complexes $[C_5R_5(OC)_2W{=}PMes\{W(PH_2Mes)(CO)_2C_5R_5\}]$.[6]



(a)

We have now been able to demonstrate that P–H-functionalized phosphenium complexes $[C_5R_5(OC)_2W{=}P(H)R']$ are accessible providing that the phosphorus carries a *tert*-butyl or a supermesityl (sMes) group. The synthesis is achieved by the dehydrochlorination of the complexes **3a–c**[7] obtained thermally from $[C_5R_5(OC)_3WCl]$ (**1**) and the primary phosphanes $R'PH_2$ (R′ = *t*Bu, sMes) **2** by reaction with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (**3a**, −78 °C), potassium *tert*-butyl alcoholate (**3b**, −10 °C), or triethylamine (**3c**, 25 °C) in toluene [Eq. (a)].

Whilst the supermesitylphosphenium complex **4c** can be isolated as a pale violet, air-stable crystalline powder, the *tert*-butyl-substituted compounds **4a** and **4b** only exist in toluene at −60 and 0 °C, respectively, for about three hours (spectroscopic data see Table 1). Compounds **4a–c** can be characterized unambiguously by the low-field shifts of the ^{31}P NMR resonance typical for W=P complexes (δ = 285.5 (**4a**), 275.1 (**4b**), 211.8 (**4c**)) and by the large $^1J(W,P)$ coupling (571.6 (**4a**), 575.5 (**4b**), 604.0 (**4c**) Hz).[8] At room temperature **4a,b** undergo rapid de-

Table 1. Selected spectroscopic data of the complexes **4a–c**, **5–8**, **9a,b**, and **10a,b**.

4a/4b: ^{31}P NMR (162 MHz, [D$_8$]toluene, −60 °C): δ = 285.5/275.6 (s, $^1J(W,P)$ = 571.6/575.5 Hz)

5: ^1H NMR (90 MHz, [D$_1$]chloroform): δ = 4.45 (d, $^1J(P,H)$ = 354.2 Hz, 1H, HP), −12.6 (d, $^2J(P,H)$ = 26 Hz, 1H, μ-H); ^{31}P NMR (36 MHz, [D$_1$]chloroform): δ = 276.6 (s, $^1J(W,P)$ = 221.8 Hz)

4c: ^1H NMR (200 MHz, [D$_6$]benzene): δ = 12.80 (d, $^1J(P,H)$ = 379.0 Hz, 1H, HP), 7.44 (d, $^4J(P,H)$ = 2.0 Hz, 2H, *m*-H), 5.08 (d, $^3J(P,H)$ = 0.3 Hz, 5H, H_5C_5), 1.37 (d, $^5J(P,H)$ = 0.7 Hz, 18H, *o*-$(H_3C)_3C$), 1.15 (s, 9H, *p*-$(H_3C)_3C$); ^{31}P NMR (162 MHz, [D$_6$]benzene): δ = 211.8 (s, $^1J(W,P)$ = 604.0 Hz); IR (pentane): $\tilde{\nu}$ = 1953 (vs), 1881 (s) (CO), 2299 (w) (PH) cm^{-1}

6/7: ^{31}P NMR (162 MHz, [D$_6$]benzene): δ = 201.8/262.8 (s, $^1J(W,P)$ = 711.6/617.8 Hz)

8: ^1H NMR (200 MHz, [D$_8$]toluene): δ = 7.04 (s, 1H, *m*-H), 6.92 (s, 1H, *m*-H), 5.24 (s, 5H, H_5C_5), 1.50 (s, 9H, *p*-$(H_3C)_3C$), 1.08 (s, 18H, *o*-$(H_3C)_3C$), −10.03 (d, $^2J(P,H)$ = 110.5 Hz, 1H, HW); ^{31}P NMR (162 MHz, [D$_6$]benzene): δ = 819.9 (s, $^1J(W,P)$ = 123.1 Hz); IR (benzene): $\tilde{\nu}$ = 1939 (vs), 1862 (s) (CO) cm^{-1}

9a/9b: ^{31}P NMR (162 MHz, [D$_6$]benzene): δ = −59.9/−9.4 (s, $^1J(W,P)$ = 64.5/71.5, $^2J(P,P)$ = 30.1/32.8 Hz), −12.9/−17.1 (s, $^1J(W,P)$ = 250.6/269.4 Hz, $^2J(P,P)$ = 30.1/32.8 Hz)

10a/10b: ^1H NMR (400 MHz, [D$_8$]toluene): δ = 7.32/7.23 (dd, $^1J(P,H)$ = 363.8/351.1, $^3J(H,H)$ = 2.7/3.4 Hz, 1H, HP), 1.23/2.67 (br.s/d, $^2J(P,H)$ = 8.8 Hz, 1H, HO), −8.49/−7.80 (dd, $^2J(P,H)$ = 88.3/79.6, $^3J(H,H)$ = 2.7/3.4 Hz, 1H, HW); ^{31}P NMR (162 MHz, [D$_8$]toluene): δ = 133.1/143.6 (s, $^1J(W,P)$ = 281.3/279.9 Hz).

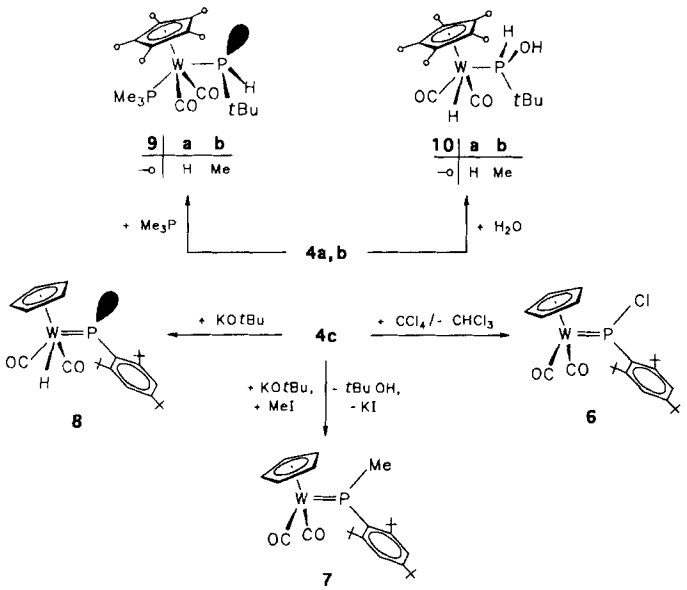
[**] Phosphenium Complexes, Part 27. This work was funded by SFB 347 ("Selektive Reaktionen Metall-aktivierter Moleküle"). Part 26: W. Malisch, K. Grün, N. Gunzelmann, S. Möller, R. Lankat, J. Reising, M. Neumayer, O. Fey in *Selective Reactions of Metal-Activated Molecules* (Eds.: H. Werner, J. Sundermeyer), Vieweg, Braunschweig, **1995**, pp. 183–190. sMes = supermesityl = 2,4,6-tBu$_3$C$_6$H$_2$.

composition in solution. In the case of **4a** this leads to the binuclear complex **5**, which is the product of the formal addition of the 16-electron complex fragment "$[Cp(OC)_2WH]$" to the W=P unit.

$[(\mu_2\text{-H})(\mu_2\text{-}t\text{BuHP})\{W(CO)_2Cp\}_2]$ **5**

Due to the greatly reduced reactivity of the M=P bond, **4c** preferentially undergoes reactions involving the P–H function (Scheme 1). Complex **4c** reacts with carbon tetrachloride by H/Cl exchange at the phosphorus atom to afford the extremely thermally stable PCl complex **6**.



Scheme 1.

The reaction of **4c** with an equimolar amount of potassium *tert*-butyl alcoholate and excess methyl iodide in tetrahydrofuran yields the P-methylated phosphenium complex **7**. In the presence of the deprotonation reagent KO*t*Bu, isomerization of **4c** is evident by the change in color of the solution from violet to turquoise, during which a H atom migrates from the phosphorus center to the metal center, producing the phosphinidene complex **8**. This process is similar to the α-H abstraction in electron-rich Schrock carbene complexes[2a] and provides an explanation for the ready formation of phosphinidene–tantalum complexes.[9] Compound **8**, the first terminal phosphinidene complex with a functionalized metal center, is stable in solution up to 60 °C; however, it converts back into **4c** on attempted isolation. The structure of **8** was determined from a comparison of its ^{31}P NMR data [$\delta(^{31}P)$: 819.9 ($^1J(W,P) = 123.1$ Hz)] with those of the structurally characterized, bent phosphinidene complex $[Cp_2W{=}P(sMes)]$ [$\delta(^{31}P)$: 661.6 ($^1J(W,P) = 153.5$ Hz)].[10] The ^1H NMR resonance of the hydrido ligand at $\delta = -10.03$ splits into a doublet with an unusually large $^2J(P,H)$ coupling of 110.5 Hz.

The addition capacity of the M=P double bonds in complexes **4a,b**, which do not exhibit an analogous isomerization, exceed that of all the phosphenium complexes known to date (Scheme 1). Treatment of **4a** and **4b** with trimethylphosphane leads to the corresponding secondary metallophosphanes **9a** and **9b**. In tetrahydrofuran **4a** and **4b** react spontaneously with an excess of water at −78 and −10 °C, respectively, to yield the 1,2-addition products **10a** and **10b**. These contain complex-stabilized *t*Bu(H)P(OH), the tautomer of primary *tert*-butylphosphane oxide unknown in the free state.[11] As proven for **10a**,[12] the structure is characterized by the sterically determined *anti* arrangement of the *tert*-butyl ligand to the cyclopentadienyl unit (Z-W-P-C9 = 168°, Z = center of the cyclopentadienyl ring) and its eclipsed position relative to one of the two carbonyl groups (Fig. 1). The formation of intermolecular hydrogen bonds between the oxygen atom of the carbonyl group and the hydrogen atom of the hydroxyl group [d(O3–H31) = 1.13(3), d(O2–O3) = 2.820 Å[13]] leads to dimers with a puckered twelve-membered ring in the crystal.

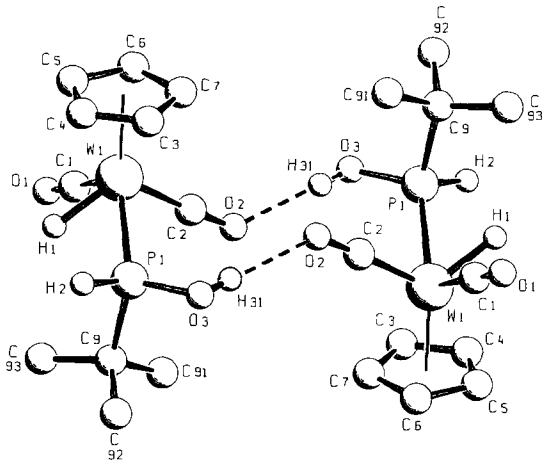


Fig. 1. Crystal structure of **10a**. All the hydrogen atoms except for H1, H2, and H31 have been omitted for the sake of clarity. Selected distances [Å], bond and dihedral angles [°]: W1-P1 2.371(1), W1-H1 1.65(5), P1-O3 1.642(5), P1-H2 1.40(5), O3-H31 1.13(3), O2-O3 2.820; C2-W1-C1 79.2(2), O3-P1-W1 116.7(2). O3-P1-H2 109.2(5), P1-O3-H31 113(7), Z-W-P-C9 167.9.

Experiments demonstrating the cycloaddition behavior of the P–H-functionalized phosphenium complexes presented here and subsequent reactions of the cycloadducts involving the P–H function will be reported in due course.

Experimental Procedure

All manipulations were performed in the absence of air and moisture.

4a/**4b**/**5**: A solution of **3a** (123 mg, 0.29 mmol)/**3b** (155 mg, 0.31 mmol) in toluene (10 mL) was treated at −78 °C/−10 °C with DBU (43 mg, 0.29 mmol)/KO*t*Bu (35 mg, 0.31 mmol) and stirred. This gave a violet solution of **4a** and **4b**, respectively, which was stable at −60 °C/0 °C for about 3 h. Workup of **4a** by column chromatography (column 8 × 1.5 cm, Al_2O_3, activity grade III, neutral, tetrahydrofuran, yellow zone) produced **5**. Yield: 49 mg (25%), orange-red crystalline powder, m.p. 166 °C (decomp.).

4c: A stirred solution of **3c** (80 mg, 0.13 mmol) in benzene (0.5 mL) was treated with triethylamine (79 mg, 0.78 mmol) at about 25 °C. After the mixture had been stirred for a further 10 min, it was centrifuged to remove the $(Et_3NH)Cl$ formed. The clear, violet solution was evaporated to dryness in vacuum. The residue, **4c**, was treated with pentane (2 mL) and dried in vacuum. Yield: 52 mg (69%), pale violet crystalline powder, m.p. 108 °C.

6: A solution of **4c** (85 mg, 0.15 mmol) in benzene (5 mL) was treated with carbon tetrachloride (22 mg, 0.15 mmol) and stirred for 22 h at about 25 °C. Yield: 86 mg (96%), red-violet crystalline powder, m.p. 120 °C.

7/**8**: A solution of **4c** (85 mg, 0.15 mmol) in tetrahydrofuran (10 mL) was treated with KO*t*Bu (19 mg, 0.15 mmol) at 0 °C; the color of the solution immediately changed from violet to turquoise indicating the spontaneous formation of **8**. After addition of methyl iodide (114 mg, 0.80 mmol), the mixture was stirred for 5 min at about 25 °C and then worked up by column chromatography (column 10 × 1.5 cm, Al_2O_3, activity grade IV, neutral, pentane). Yield: 69 mg (79%), violet crystalline powder, m.p. 135 °C (decomp.).

9a/**9b**: A solution of **3a** (168 mg, 0.39 mmol)/**3b** (240 mg, 0.48 mmol) and trimethylphosphane (30 mg, 0.39 mmol)/(37 mg, 0.48 mmol) in toluene (10 mL)

was treated at about 25 °C with DBU (59 mg, 0.39 mmol)/KO*t*Bu(57 mg, 0.48 mmol). After workup by column chromatography (column 10 × 2 cm, Al_2O_3, activity grade IV, neutral, diethyl ether) **9a**/**9b** was isolated from the light yellow fraction. Yield: 154 mg (84%)/182 mg (70%), lemon yellow crystalline powder/pale yellow crystalline powder, m.p. 126 °C/111 °C.

10a/**10b**: To a solution of **3a** (416 mg, 0.97 mmol)/**3b** (240 mg, 0.48 mmol) in tetrahydrofuran (20 mL) and H_2O (1 mL) was added DBU (147 mg, 0.97 mmol)/KO*t*Bu (54 mg, 0.48 mmol) at −78 °C/0 °C. After workup by column chromatography (column 15 × 2 cm, Al_2O_3, activity grade IV, neutral, toluene, tetrahydrofuran) **10a**/**10b** was isolated. Yield: 288 mg (72%)/100 mg (43%), pale yellow/light yellow crystalline powder, m.p. 97 °C/102 °C.

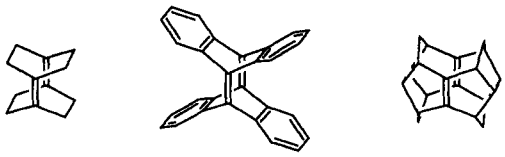
[12] Crystal structure analysis of **10a** ($C_{11}H_{17}O_3PW$): $M = 412.08$; yellow crystal (0.3 × 0.3 × 0.4 mm); triclinic; space group $P\bar{1}$ (no. 2); $a = 8.04(1)$, $b = 8.38(8)$, $c = 10.60(5)$ Å, $\alpha = 99.60(7)$, $\beta = 99.22(9)$, $\gamma = 103.72(7)°$, $V = 669.9(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.043$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 87.31$ cm^{-1}; CAD4 Enraf-Nonius diffractometer (graphite monochromator, $Mo_{K\alpha}$), 1784 independent reflections ($2\theta_{max} = 44°$), of which 1604 with $I > 2\sigma(I)$ used for the structure solution with SHELXS-86 (direct methods) and refinement with SHELXL93 (179 parameters), absorption correction ψ scan (EAC in SDP), correction for decompositional decay in SDP (15.9%). The hydrogen atoms H1–H7 could be localized and were refined isotropically, the *tert*-butyl group and H31 were calculated from ideal geometry, fixed and included in the calculation of the structural factor. R = 0.019, Rw = 0.052, $w = 2.0672/[\sigma^2(F) + 0.000134F^2)$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-404302.

[13] The values were calculated with the program SCHAKAL 92.

Oxidative Transformations of a Pyrimidalized 1,5-Diene**

Gerald Dyker,* Jutta Körning, Peter G. Jones, and Peter Bubenitschek

In pyramidalized alkenes[1] the olefinic carbon atoms do not lie in the plane of the three atoms to which they are bonded. The deviation from the ideal geometry for CC double bonds may be remarkable. The pyramidalized 1,5-dienes **1**[2] and **2**[3] and the cage compound **3**[4] are of special interest: not only do they display the typical enhanced reactivity of pyramidalized alkenes, but they may also undergo other reactions due to the transannular interactions of the parallel-oriented π-orbitals. The shortest transannular distance in **2** is only 242 pm with a pyramidalization angle Φ of 35°;[1b, 3] this structure makes transannular addition reactions possible.[3c]



1 **2** **3**

For the synthesis of the pyramidalized diene **7** the recently described dienophilic character of the annelated pentalene **4** was exploited.[5] The Diels–Alder reaction with 9,10-dibromoanthracene (**5**) yielded the benzeno-bridged [4.3.3]propellane **6**, which is already suitably functionalized for conversion into the pyramidalized diene **7**. Monolithiation of **6** should lead to a 1,4-elimination of lithium bromide and cleavage of the strained central CC single bond of the propellane skeleton. The reagent of choice is the sterically hindered triphenylmethyllithium, and **7** was isolated in 79% yield in the form of colorless crystals (Scheme 1).[6] *n*-Butyllithium is not suitable as a lithiating agent in this case since it can add to diene **7**. Zinc dust in DMF at 150 °C, which are suitable conditions for the synthesis of **3** from the corresponding dibromide,[7] was less successful here because of the competing double dehalogenation.

In the X-ray structure analysis confirming the structure of **7** unusual structural features are evident (Fig. 1).[8] The length of the double bonds, 134 pm, is in the normal range, but in the side view (Fig. 1 right) distinct pyramidalization is apparent. The pyramidalization angle Φ on the benzeno-bridged side is 34.9° and corresponds to the value determined in the related compound **2**. On the naphthaleno-bridged side the pyramidalization angle Φ is 16.5°. The distances between the symmetrically positioned carbon atoms are 247.1 and 265.9 pm.

Whereas **1** is converted spontaneously by oxygen into its diepoxide,[2] diene **7**, in the dark, is kinetically stable towards oxygen. However, in sunlight a solution of **7** in $CDCl_3$ was completely oxidized within a few hours. The main products were

Scheme 1. Syntheses of **6** and **7**; a) 220 °C, 3 h, yield 78%; b) triphenylmethyllithium, THF, room temperature, 4 h, yield 79%.

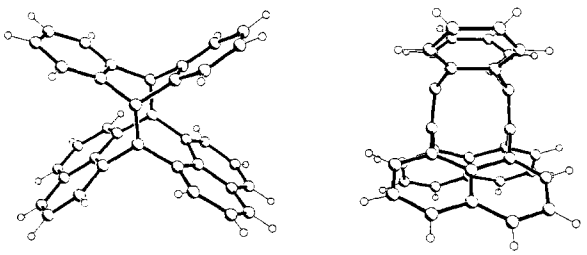

Fig. 1. Two views of the molecular structure of **7** in the crystal (arbitrary radii) [8].

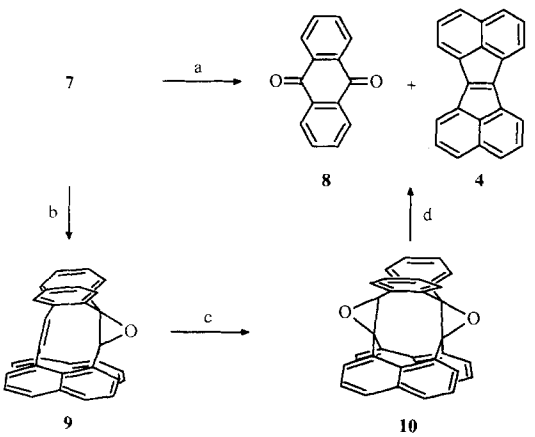
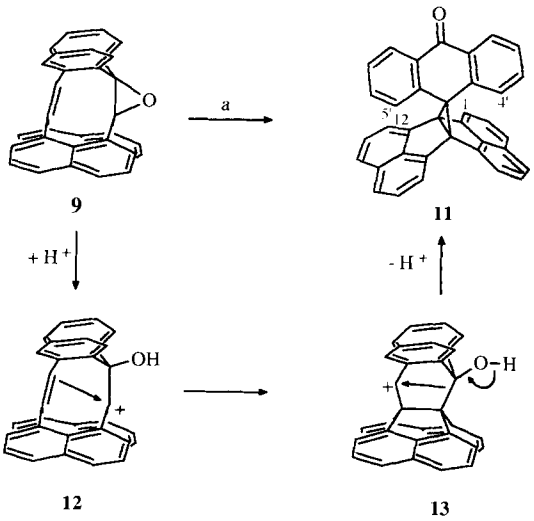
identified by ^{1}H NMR spectroscopy as the annelated pentalene **4** and anthraquinone (**8**); the most likely oxidizing agent is singlet oxygen. In a reaction with rubrene endoperoxide[9] as a thermal source of singlet oxygen (xylene, 136 °C, 6 h) the fragmentation products **4** and **8** were also detected. The diepoxide **10** is not considered to be the reactive intermediate since solutions of **10** in $CDCl_3$ are stable even in sunlight. Only when heated in naphthalene at 285 °C for two hours (glass ampule) does **10** decompose almost completely into **4** and **8** (Scheme 2).



9 10

Scheme 2. Oxidative transformations of **7**: a) sunlight, aerial oxygen, $CDCl_3$; b) acetone/CH_2Cl_2/H_2O, $NaHCO_3$, oxone ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$, conditions for the formation of dimethyldioxirane in situ), 15 °C, 40 min, yield 55%; c) 0.05 M dimethyldioxirane in acetone, room temperature, 16 h, yield 80%; d) naphthalene, 285 °C, 2 h, glass ampule.

Diepoxide **10** was prepared by stepwise oxidation of **7** with dimethyldioxirane.[10] Monoepoxide **9** was isolated as an intermediate. In contrast to diepoxide **10**, which was purified without any problems by column chromatography on either silica gel or neutral alumina, the monoepoxide proved to be extremely labile on both of these stationary phases. A quantitative rearrangement of **9** giving the spiroannelated [3.3.1]propellane **11** occurred both when silica gel was loaded with a solution of **9** in dichloromethane at 40 °C, and when a toluene solution of **9** was passed through neutral alumina. We assume that the first reaction step is an acid-induced ring opening of the epoxide to give the carbenium ion **12**. Transannular ring closure provides the reactive intermediate **13**, and the cationotropic shift of an alkyl group leads finally to the formation of the cyclopropyl ring in **11** (Scheme 3).[11] According to semiempirical calculations (AM1), this process results in a gain of approximately 13 kcal mol^{-1}.



Scheme 3. Rearrangement of **9**; a) silica gel, 50 °C or neutral alumina/toluene, room temperature, yield 96%.

The X-ray structure analysis of **11** shows that the anthrone partial structure is present in a definite boat conformation due to the steric interactions of the hydrogen atoms H4′/H5′ in the "*peri*" positions of the naphthalene unit (Fig. 2). In contrast, the most stable conformer of spiro[anthracene-9,10′-cyclopropan]-10-one is planar.[12] The observation of six signals for different CH groups in the naphthalene unit in the NMR spectra of **11** agrees with this result (see Table 1). Apparently, inversion of the anthrone unit is not possible on the NMR time scale on steric grounds.[13] The H4′/H5′ doublet is shifted anisotropically to high field ($\delta = 6.34$).

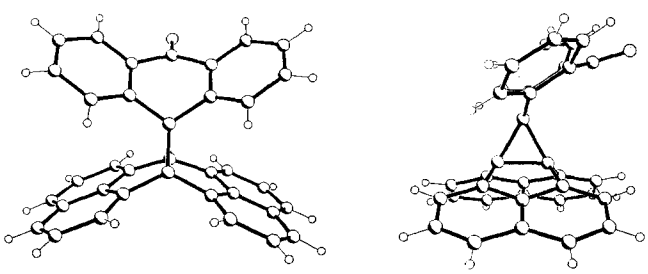


Fig. 2. Two views of the molecular structure of **11** in the crystal (arbitrary radii) [8].

We will continue to investigate dibromoanthracene **5** as a building block for the synthesis of alkenes with unusual structures and reactivities.

Experimental Procedure

6: A mixture of **4** (276 mg, 1.00 mmol) and **5** (1.01 g, 3.00 mmol) was ground to homogeneity, then allowed to react under nitrogen in a sealed ampule for 3 h at 220–225 °C (the melting point must be reached; at 200 °C no reaction takes place). Unreacted **5** was removed by sublimation at 220 °C/0.1 Torr, and the residue was purified by column chromatography (toluene/silica gel) and crystallization from $CHCl_3$. Yield: 477 mg (78%) **6**.

7: A solution of triphenylmethane (5.80 g, 19.0 mmol) in 50 mL of THF was treated at 0 °C with 7 mL of 15% *n*-butyllithium/*n*-hexane. After 2 h of stirring, a solution of **6** (986 mg, 1.60 mmol) in 100 mL of THF was added. Stirring was continued for a further 4 h at room temperature, and the mixture was then hydrolyzed with 5 mL of ethanol and 100 mL of water. After extraction with Et_2O (3 × 150 mL), the organic phase was adsorptively filtered through silica gel and the solvent removed by distillation. The crude product was digested with 400 mL of pentane, and the residue was dissolved in ethanol, adsorptively filtered through silica gel, and fractionally crystallized from ethanol. Yield: 572 mg (79%) **7**.

Soluble Aluminosilicates with Frameworks of Minerals**

Mavis L. Montero, Andreas Voigt, Markus Teichert, Isabel Usón, and Herbert W. Roesky*

Dedicated to Professor Edwin Hengge on the occasion of his 65th birthday

In the last century the American philosopher Ralph Waldo Emerson wrote that "it is a long way from granite to the oyster".[1, 2] An important component of granite is an aluminosilcate; the Al-O-Si fragment found therein is the most important unit of many natural and synthetic zeolites. Compounds of this type are used as ion-exchangers, acid-base catalysts, or as supports for metal catalysts.[3, 4]

We have been interested in the synthesis of aluminosilicates with different frameworks for a long time.[5, 6] We recently reported the details of a structural unit present in the mineral gismondine.[5] A large number of rocks and minerals comprise

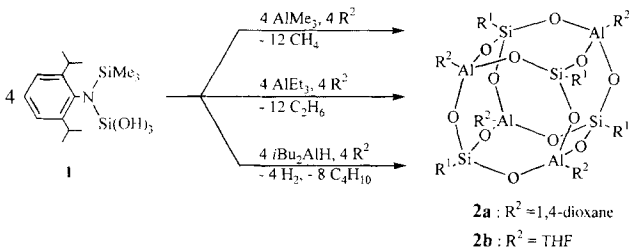
alkali metal aluminosilicates. Among these are the feldspars, which often have a silicon–aluminum ratio close to one. Examples include the natural zeolites cancrinite ($Na_6Al_6Si_6O_{24}\cdot CaCO_3\cdot 2H_2O$) and sodalite ($Na_8Al_6Si_6O_{24}(OH)_2\cdot 2H_2O$) which are both used industrially.[7] Synthetic compounds belonging to this class are zeolites of the Linde type A (LTA) with the ideal composition $Na_{12}Al_{12}Si_{12}O_{48}\cdot 27H_2O$.[7] A characteristic structural feature of LTA is the cubic $Al_4Si_4O_{12}$ unit. We report here on the synthesis of $Al_4Si_4O_{12}$ and $Na_4Al_4Si_4O_{12}$ compounds that are soluble in organic solvents.

Molecular aluminosiloxanes, which function as model substances for zeolites, are known.[5, 6, 8–12] Feher et al. synthesized an aluminosilsesquioxane by the "corner-capping" reaction of $(cyclo\text{-}C_6H_{11})_7Si_7O_9(OH)_3$ with $AlMe_3$.[12] Aluminosiloxanes could also be synthesized from aqueous tetramethylammonium silicate and tetramethylammonium aluminate solutions.[8] In 1987 Smolin et al. described the compound $[(CH_3)_4N]_4[Si_4Al_4O_{12}(OH)_8]$.[9] Disadvantages of these reactions include the low flexibility with respect to the products that can be synthesized and the often uncontrollable course of the reaction.

We have previously synthesized various heterosiloxanes by using kinetically stable silanetriols.[5, 6, 13, 14] The silanetriols enable the synthesis of compounds with different skeletons. We report here on the reaction of the stable silanetriol **1** with alkylaluminum compounds. Elimination of alkane or hydrogen leads to **2a** and **2b**, respectively (Scheme 1). The reaction course

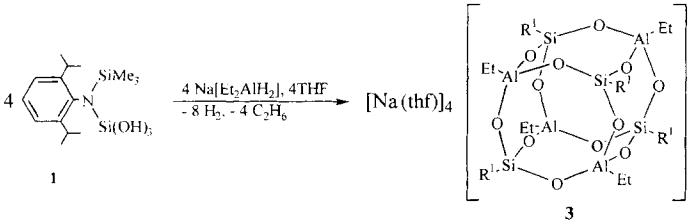


Scheme 1. Synthesis of **2a** and **2b**. $R^1 = (2,6\text{-}iPr_2C_6H_3)(SiMe_3)N$, R^2 = 1,4-dioxane or THF.

can be followed by monitoring the amounts of gas collected. The reaction is complete within about 2 min. The addition of a donor solvent, such as THF or 1,4-dioxane, is necessary to saturate the fourth coordination site on the aluminum atoms.

In contrast to this reaction, an organic group remains bound to aluminum when **1** is allowed to react with $Na[Et_2AlH_2]$ to form **3** (Scheme 2). Compound **3** is the first sodium aluminosilicate that is soluble in common organic solvents (diethyl ether, THF, toluene).

The structures of **2a** (Fig. 1), **2b**, and **3** (Fig. 2) comprise a cubic-shaped $Al_4Si_4O_{12}$ core built up of two eight-membered $Al_2Si_2O_4$ rings connected to each other by four oxygen



Scheme 2. Synthesis of **3**. $R^1 = (2,6\text{-}iPr_2C_6H_3)(SiMe_3)N$.

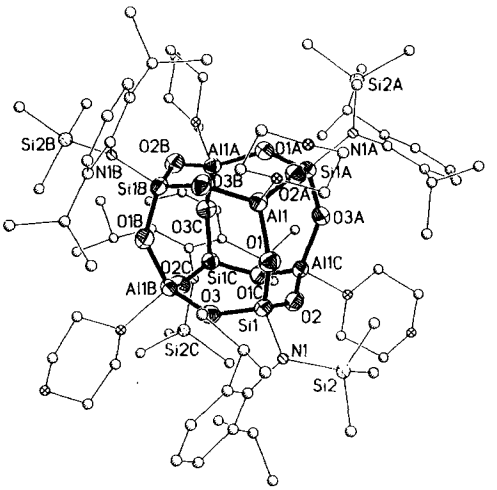


Fig. 1. Structure of **2a** in the crystal. Selected distances [pm] and angles [°]: Al1–O1 170.8 (3), Al1–O2 170.6 (3), Al1–O3 170.6 (3), Al1–O4 188.0 (3), Si1–O1 161.2 (3), Si1–O2 161.0 (3), Si1–O3 160.9 (3), Si1–N1 173.8 (3), O2–Al1–O1 113.9 (1), O2–Al1–O3 115.3 (1), O3–Al1–O1 117.6 (1), O3–Si1–O2 111.2 (2), O3–Si1–O1 109.8 (2), O2–Si1–O1 109.1 (2).

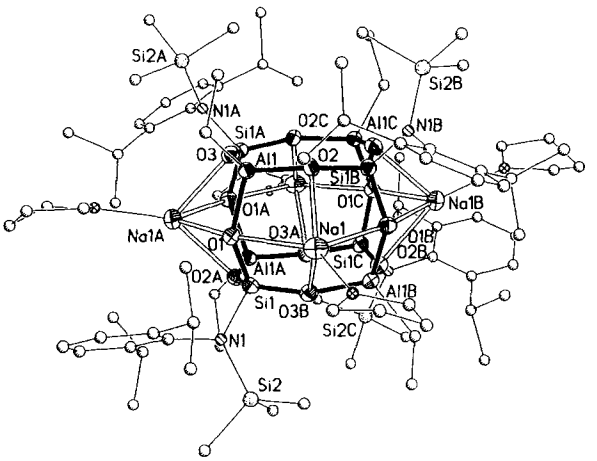

Fig. 2. Structure of **3** in the crystal. Selected distances [pm] and angles [°]: Al1–O1 178.4 (4), Al1–O2 175.4 (4), Al1–O3 175.3 (4), Al1–C1 196.0 (6), Si1–O1 162.8 (4), Si1–O2 160.3 (4), Si1–O3 161.1 (4), Si1–N1 174.0 (5), O3–Al1–O2 116.0 (2), O3–Al1–O1 104.5 (2), O2–Al1–O1 103.9 (2), O2–Si1–O3 112.9 (2), O2–Si1–O1 107.2 (2), O3–Si1–O1 110.1 (2).

atoms.[15] The same structural unit is also found in the zeolite of the Linde type A. The $Al_2Si_2O_4$ rings are in a chair–chair conformation. In **3**, four of the faces of the cube are capped by a sodium atom. The two remaining faces of the cube which have no contact with the sodium atoms are almost planar (7 pm deviation).[16] The coordination at the aluminum centers in **2a** is distorted tetrahedral; the bond angles range from 101.0(1)° to 117.6(1)°. The endocyclic Al–O bonds in **2a** are on average 171 pm long. As expected, the exocyclic Al–O bonds to the coordinated 1,4-dioxane are longer (188.0(3) pm). The silicon atoms of the core have almost ideal tetrahedral coordination; the bond angles range from 107.6(2)° to 111.2(2)°. The average Si–O bond length is 161 pm. The body diagonal of the Si_4Al_4 core in **2a** is about 540 pm, and the cubic-shaped core in **2b** is similar to that in **2a**. Owing to disorder in the core, a more detailed discussion of its structural parameters will be avoided. The coordination around the aluminum centers in **3** is distorted tetrahedral; the bond angles range from 103.9(2)° to 116.0(2)°. As expected, the endocyclic Al–O bonds (average 176 pm) are

longer than those in **2a** as a result of coordination to the fourth anionic ligand. The silicon atoms of the core also have distorted tetrahedral coordination (106.3(2)° to 112.9(2)°). The average Si–O bond length is 161 pm, and all experimentally determined Si–O bond lengths correspond well with those in aluminosilicates (ca. 160–161 pm).[17] Good agreement of the Al–O bond lengths with those in aluminosilicates (ca. 174–176 pm)[17] is only found for **3**. The sodium atoms in **3** are coordinated to the oxygen atoms of the cage through two shorter (240.5(4) and 241.5(4) pm) and two longer (257.4(4) and 267.1(4) pm) distances. The length of the bond between the Na atom and the oxygen of the coordinated THF molecule is 228.5(5) pm. Similar square-pyramidal environments for the Na atoms are found in the sodium zeolite A (Na–O distances of ca. 232–293 pm).[18, 19]

The syntheses of **2a** and **2b** show that cubane-like aluminosiloxanes can be obtained readily by choosing suitable reaction conditions. A large number of natural and synthetic zeolites have alkali metal counterions in addition to the anionic aluminosilicate framework. Earlier attempts to build an anionic lattice did not lead to the desired products.[12] Thus, reactions of $MOSiMe_3$ (M = alkali metal) with aluminosiloxanes resulted in the degradation of the aluminosiloxane framework. The reaction method leading to **3** seems to be suitable for a broad range of products of varying compositions. It remains to be seen, how many related, soluble compounds with Al-O-Si units can be synthesized. Products such as **3** could serve as precursors for novel solid-state syntheses under mild conditions.

Experimental Procedure

General procedure for **2a** and **2b**: A suspension of **1** (1.63 g, 5.00 mmol) in *n*-hexane (30 mL) and 1,4-dioxane or THF (5 mL) was treated with the aluminum compound (5.00 mmol) in *n*-hexane at room temperature. After about 2 min three equivalents of gas had been formed. The solution was concentrated to half its volume in vacuum. A white, microcrystalline solid was obtained at −21 °C (yield: 60–70%). Single crystals were obtained at 0 °C from *n*-hexane/1,4-dioxane and *n*-hexane/THF (10:1), respectively. **2a**: M.p. 127 °C; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = -0.05$(s, 9H, $Si(CH_3)_3$), 1.18 (d, 6H, $CH(CH_3)_2$), 1.26 (d, 6H, $CH(CH_3)_2$), 2.92 (m, 2H, $CH(CH_3)_2$), 3.53 (m, 4H, 1,4-dioxane), 3.60 (m, 4H, 1,4-dioxane), 6.92 (m, 3H, H_{arom}); ^{29}Si NMR (50 MHz, C_6D_6, TMS): $\delta = -80.3$ (SiO_3), 2.0 ($Si(CH_3)_3$); IR (KBr, nujol): $\tilde{\nu}$ = 1383, 1249, 1053, 958, 910, 804, 685, 543 cm^{-1}; MS (EI, *m/z* (%)): 1389 (10) $[C_{59}H_{101}Al_4N_4O_{12}Si_8]^+$, 162 (100) $[C_{12}H_{18}]^+$; correct elemental analysis. **2b**: M.p. > 200 °C (decomp.); ^{1}H NMR (250 MHz, C_6D_6, TMS): $\delta = 0.32$ (s, 9H, $Si(CH_3)_3$), 1.25 (m, 4H, THF), 1.35 (d, 6H, $CH(CH_3)_2$), 1.41 (d, 6H, $CH(CH_3)_2$), 3.45 (m, 4H, THF), 4.00 (m, 2H, $CH(CH_3)_2$), 7.02 (m, 3H, H_{arom}); ^{29}Si NMR (50 MHz, C_6D_6, TMS): $\delta = -75.0$ (SiO_3), 1.2 ($Si(CH_3)_3$); IR (KBr, nujol): $\tilde{\nu}$ = 1440, 1360, 1247, 1077, 943, 837, 544, 491 cm^{-1}; MS (EI, *m/z* (%)): 1069 (20) $[C_{45}H_{61}Al_4N_4O_{12}Si_4]^+$, 162 (100) $[C_{12}H_{18}]^+$; correct elemental analysis.

3: A solution of **1** (0.98 g, 3.00 mmol) in toluene (30 mL) was slowly added to a solution of $Na[Et_2AlH_2]$ (0.33 g, 3.00 mmol) in toluene/THF (15 mL/0.5 mL) at 0 °C. The solution was allowed to warm to room temperature and was then heated at reflux for 2 h. Afterwards, it was concentrated to half its volume in vacuum. Compound **3** was obtained as a white, microcrystalline solid at −21 °C (yield: 0.5 g, 35%). Single crystals were obtained at room temperature from toluene/THF (10:1). M.p. > 200 °C (decomp) ^{1}H NMR (250 MHz, [D$_8$]THF, TMS): $\delta = -0.32$ (m, 2H, CH_2CH_3), −0.10 (m, 3H, CH_2CH_3), 0.08 (s, 9H, $Si(CH_3)_3$), 1.21 (d, 12H, $CH(CH_3)_2$), 1.82 (m, 4H, THF), 3.00 (m, 2H, $CH(CH_3)_2$), 3.65 (m, 4H, THF), 7.13 (m, 3H, H_{arom}); ^{29}Si NMR (50 MHz, [D$_8$]THF, TMS): $\delta = -112$ (SiO_3), −1 ($Si(CH_3)_3$);); IR (KBr, nujol): $\tilde{\nu}$ = 1250, 1046, 936, 840, 767, 643, 547, 490 cm^{-1}; MS (EI, *m/z* (%)): 1479 (20) $[C_{61}H_{103}Al_4N_4Na_4O_{12}Si_4]^+$, 162 (100) $[C_{12}H_{18}]^+$; correct elemental analysis.

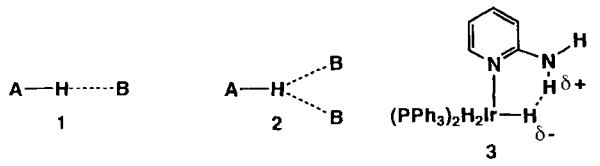
An Unconventional Intermolecular Three-Center N–H···H_2Re Hydrogen Bond in Crystalline $[ReH_5(PPh_3)_3]\cdot$indole$\cdot C_6H_6$

Jeremy Wessel, Jesse C. Lee, Jr., Eduardo Peris, Glenn P. A. Yap, Jeffrey B. Fortin, John S. Ricci, Gjergji Sini, Alberto Albinati,* Thomas F. Koetzle,* Odile Eisenstein,* Arnold L. Rheingold,* and Robert H. Crabtree*

In the hope of introducing ideas from molecular recognition into transition metal complexation and catalysis, we have been studying hydrogen bonding[1] in metal complexes. H-bonding is common between a weak acid A–H and one or two weak bases B, to give a 2-center (**1**) or three-center H-bond (**2**). In a number of recent cases,[2] for example **3**,[2a] intramolecular H-bonds of



an unconventional kind have been discovered in which the weak base component is a metal hydride. Structural and spectroscopic data[2] suggest H···H distances of about 1.7–1.9 Å and H-bond strengths of 3–6 kcal mol^{-1}. If the Ir–H bond in **3** is replaced by Ir–X (X = F, Cl, Br, or I), conventional N–H···X H-bonds are formed, but surprisingly, these are weaker for X = Cl, Br, and I, and only marginally stronger for X = F.[3] We wanted to find out if intermolecular H-bonding was possible with a suitable H-bond donor AH, and if so, what geometry would be adopted in the absence of geometrical constraints such as those present in the chelate system **3**.

We chose indole because it is a good H-bond proton donor but does not self-associate significantly because it has no good H-bond proton acceptor site. We now find that the polyhydride $[ReH_5(PPh_3)_3]$ cocrystallizes with indole to give $[ReH_5(PPh_3)_3]\cdot C_8H_6NH\cdot C_6H_6$ (**4**) as large yellow crystals. An X-ray crystal structure clearly showed that the N–H hydrogen atom of indole is close to two of the rhenium hydrides, forming a three-center H-bond of type **2**. A subsequent neutron diffraction study (Fig. 1) confirmed this result, and both studies located the hydrogens in positions similar to those found[4] for free $[ReH_5(PMePh_2)_3]$ by neutron diffraction.

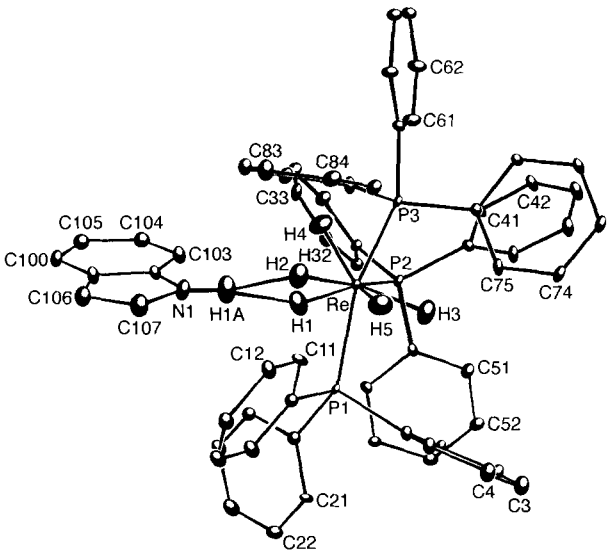


Fig. 1. The ORTEP diagram of the neutron diffraction structure (20 K) of **4** with ellipsoids drawn at 50% probability. The metric parameters of the N–H···H_2Re unit are given in Figure 2. Selected distances [Å] and angles [°]: Re–P1, 2.396(3); Re–P2, 2.387(4); Re–P3, 2.376(3); P1-Re-P2, 110.0(1); P2-Re-P3, 105.6(1); P1-Re-P3, 133.9(1); Re–H1, 1.683(6); Re–H2, 1.683(5); Re–H3, 1.686(5); Re–H4, 1.683(6); Re–H5, 1.681(6); H1-Re-H2, 79.2(3).

A similar compound $[ReH_5(Cyttp)]$ (Cyttp = $[Cy_2P(CH_2)_3]_2PPh$) can be protonated with $HSbF_6\cdot C_6H_6$ to give $[ReH_6(Cyttp)]SbF_6$.[5] In our case, $[ReH_5(PPh_3)_3]$ cocrystallizes with a much weaker acid, indole, to give crystals in which the $L_3H_3ReH_2\cdots H-NC_8H_6$ interaction is strong enough to hold the two components together in the crystal without complete proton transfer. A molecule of benzene was also found, but apart from the $ReH_2\cdots H-N$ interaction, there are no other close contacts in the structure.

The unusually precise neutron diffraction study[6] shows that the two short H···H distances in **4** are very asymmetric (H1A···H1, 2.212(9) Å; H1A···H2, 1.734(8) Å), the shorter being similar to the distances found[2] (1.7–1.9 Å) in the intramolecular N–H···H–M examples. Nonbonding H···H contacts are normally about twice the van der Waals radius[1] of H, or 2.4 Å; all other NH···HRe distances found here are greater than 2.6 Å. The finding that the NH proton lies at a distance of only 0.066(7) Å from the plane defined by N1, H1, and H2 fulfills the usual criteria[1c] for three-center H-bonding (**2**). The N–H bond points towards the closer metal hydride, H2 (N-H-H2 = 163.1(6), N-H-H1 = 130.9(5)°), which implies that the dominant interaction is with Re–H2 (Fig. 2). H2 is unique in that it is the only hydrogen in the structure occupying a B-site

[**] This work was supported by the NSF, the CNRS (URA 506) and Fellowships from the NSF and W. R. Grace & Co. to J. W. The neutron study was carried out at the High Flux Beam Reactor at Brookhaven National Laboratory under contract DE-AC02-76CH00016 with the US Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences.

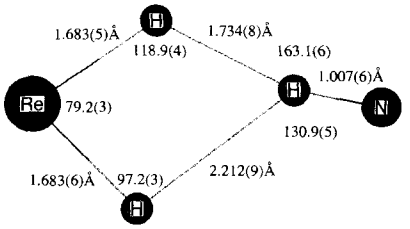

Fig. 2. The detailed structure of the $NH\cdots H_2Re$ unit from the neutron diffraction results.

of a dodecahedron (Fig. 3), and so is sterically the least hindered.

In order to eliminate the possibility that nonspecific crystal packing forces are responsible for the structure, we attempted to grow crystals using indene, which is isosteric with indole but lacking the NH bond. If the $N-H\cdots H$ interaction were not important for holding the supramolecule together, indene ought to cocrystallize just as well as indole. However, only small crystals could be grown under conditions identical to those used for **4** but substituting indene for indole, and these contain only $[ReH_5(PPh_3)_3]$ and no indene (from NMR and IR evidence). This suggests that the $N-H\cdots H$ interaction is indeed important in holding the assembly together and that the very short $H\cdots H$ distance is a result of the H-bonding. Weak aromatic stacking interactions between PPh_3 and indole may well also contribute to the stabilization of the supramolecular assembly, however.

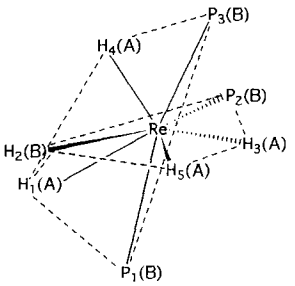

Fig. 3. The dodecahedral coordination geometry in the same molecular orientation as Figure 1 showing A and B sites and the two orthogonal BAAB trapezoids (dotted).

The IR spectrum (KBr pellet) shows a shift in the N–H band from 3437 cm^{-1} in free indole to 3242 cm^{-1} in crystals of **4**. According to the Iogansen equation,[7] which relates the bond strength to the shift in IR frequency, the H-bond strength in this case is 4.3 kcal mol^{-1}, close to the values (3–6 kcal mol^{-1}) determined for intramolecular $M-H\cdots H-N$ interactions.[2]

Figure 2 shows the structural details of the $ReH_2\cdots HN$ interaction. The $N-H\cdots H$ angles are comparable to those seen[1] in standard three-center H-bonds, but the $Re-H\cdots HN$ angles (97.2(3) and 118.9(4)°) are strongly bent. A nonlinear $M-H\cdots HN$ arrangement was already apparent[2a] in **3** ($Ir-H\cdots H = 132°$) and related species[2b] but could have been a result of the constraints of chelation. Now we see that in an unconstrained system like **4**, a strongly nonlinear $ReH\cdots HN$ arrangement is still preferred. This may be because an electrophile tends to attack a σ bond in a side-on manner.[8] In this view, **4** can be considered to represent the earliest stages of protonation of the Re–H2 hydride to give an H_2 complex, which would be bound side-on. This picture suggests other types of σ bonds should show H-bonding behavior; indeed, we have now found similar intramolecular $B-H\cdots H-N$ interactions, with bent $B-H\cdots H-N$ angles, in a number of amine–boranes.[9]

Theoretical work confirms that the interaction is attractive. The model compound $[ReH_5(PH_3)_3]\cdot NH_3$ was studied by ECP ab initio calculations with functional density theory.[10] Free ReH_5L_3 was first optimized and found to be in close agreement with the neutron structure.[4] It was then frozen, and NH_3 was placed in the vicinity of H1 and H2. Geometrical optimization, on a very flat potential surface, of the relative positions of the two molecules gives a structure similar to that of **4**. In particular, a three-center H-bond is preferred over the two- or four-center types, and the asymmetry of the experimental structure is reproduced ($H\cdots H$ distances: 1.92 Å (H2) and 2.48 Å (H1)). The interaction energy of 8 kcal mol^{-1} is in reasonable agreement with experiment (4.3 kcal mol^{-1}). In the theoretical study, the N–H is slightly closer to P1 than is found in **4**; steric effects may be responsible. As is well known,[11] the lone pair in a d^2 dodecahedral complex is perpendicular to both trapezoidal planes. Although in this complex it is not far from H2, it does not point towards the NH bond and so is unlikely to contribute much to the stabilization of the hydrogen bond. This emphasizes the electron donor power of the MH bond, which is also apparent in the ready formation of H_2 complexes by protonation of metal hydrides (even in competition with protonation at the metal),[8] in the ability of M–H in such complexes as $[Cp_2Zr(H)_2(CO)]$[12] to engage in back donation, and in the $M-H/H_2$ "cis effect".[13]

Our studies show that the presence of indole as crystallizing agent for $[ReH_5(PPh_3)_3]$ allows rapid formation of much larger (ca. 5 mm^3) crystals than in its absence, but that the structure of the complex is not significantly altered by H-bonding. Indole may be a useful agent whenever a compound that is a potential H-bond acceptor fails to crystallize satisfactorily for crystallographic or other single-crystal studies; it complements the Ph_3PO agent suggested by Etter[14] for compounds having H-bond donor groups.

Experimental Procedure

The general synthetic and spectroscopic methods were previously described [2a]. Pentahydrido(tristriphenylphosphane)Re^V·indole: A 0.8 mL aliquot of a filtered solution of the complex [15] $[ReH_5(PPh_3)_3]$ (1.1 g, 1.1 mmol) in benzene (10 mL) was added to a test tube containing indole (50 mg, 0.4 mmol). Hexanes were added to form a supernatant layer, and the sample tube refrigerated at 5 °C. After 1 day, large yellow crystals formed (18 mg, 21%).

[6] a) Neutron diffraction structure of **4** ($M_r = 1173.3$), triclinic, space group $P\bar{1}$; $T = 20$ K; $a = 13.037(3)$, $b = 13.410(4)$, $c = 19.221(5)$ Å, $\alpha = 91.67(2)$, $\beta = 107.79(2)$, $\gamma = 119.02(2)°$, $V = 2733(1)$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.425$ g cm^{-3}, crystal dimensions $3.4 \times 1.9 \times 0.72$ mm^3; $2\theta_{max}$ 91°; $\mu = 1.952$ cm^{-1}; $\lambda_{neutrons} = 1.0462$ Å; scan mode $\omega:2\theta$, 12394 independent reflections observed, all of which were used for refinement; conventional $R(F)$, $[R > 3\sigma(F)] = 0.052$. Measurements carried out at the Brookhaven High Flux Beam Reactor. The crystal was sealed in an Al can under He, mounted in a DISPLEX refrigerator, and placed on the diffractometer. A hemisphere of reciprocal space was sampled, to a limit of $\sin\theta/\lambda = 0.67$ Å^{-1}. The $\omega/2\theta$ step-scan profiles were reduced to integrated intensities, assuming the first and last tenth of each scan to be background. Lorentz factors and absorption corrections (range $e^{-\mu t} = 0.702$–0.865), calculated by means of an analytical procedure [6b], were applied. The crystal was approximated by seven boundary planes, as follows: (010), (001), ($\bar{1}11$), ($\bar{1}1\bar{1}$), ($1\bar{1}2$), ($1\bar{1}0$). Initial coordinates for all atoms were taken from the

X-ray results. Refinements were carried out by a least-squares procedure [6c], minimizing $\Sigma w(F_o^2 - k^2F_c^2)^2$ using all independent data. Weights were assigned as $w = \sigma^{-2}$, where $\sigma^2 = (\sigma_{exp}^2 + (0.015)F_o^2)^2$. The structure model included adjustable positional and anisotropic thermal parameters for all 136 atoms, a scale factor k, and a parameter for an isotropic-type I extinction correction with Lorentzian mosaic spread [6c]. The maximum extinction correction was 10%, for the ($\bar{1}23$) reflection. Neutron scattering lengths were taken from a recent compilation by Sears [6b]: $b_C = 0.66484$, $b_H = -0.3741$, $b_N = 0.936$, $b_P = 0.513$, $b_{Re} = 0.920$ (all $\times 10^{-12}$ cm). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation. b) J. Hydrothermal Synthesis of a Novel Se_{12} Ring in $[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2[Se_{12}]]$**

Richard A. Stevens, Casey C. Raymond, and Peter K. Dorhout*

Since their discovery,[1] the $[Mo_3S_{13}]^{2-}$ core clusters have spurred researchers on to further study. Electron-poor, trinuclear molybdenum chalcogenides, sulfides in particular, have aroused considerable interest because of their hydrodesulfurization activity.[2] New ventures into trinuclear molybdenum polychalcogenide chemistry have yielded several new "polymeric" materials: $[Mo_9Se_{40}]^{8-}$, $[Mo_3Se_{18}]^{2-}$, $[Mo_{12}Se_{56}]^{12-}$, $[Mo_3S_{15}]^{2-}$, and $[Mo_6Se_{27}]^{6-}$.[3,4] In this paper we report the formation of a novel puckered Se_{12} ring, stabilized by $[Mo_3S_{13}]^{2-}$ clusters through interchalcogen interactions. This new form of selenium fits into the Q_n sequence (Q = chalcogen) of homoatomic sulfur ring structures, S_8, S_{10}, S_{12}, ... S_{20}.[5]

Large ring systems of polyselenides and polytellurides have been examined as parts of metal complexes.[6,7] For example, it has been known that selenium and tellurium ions can form complex rings since the isolation of an Se_8^{2+} ring in $[Se_8][AlCl_4]_2$.[8] Kanatzidis has found isolated Se_{11}^{2-} rings in $(Ph_4P)_2[Se_{11}]$. These rings comprise two Se_5^{2-} ions and one Se^{2+} ion and link to form a cluster of corner-sharing "cyclohexane-like" rings of selenium.[9] Very recently, Sheldrick reported that the structure of Cs_3Te_{22} contains a two-dimensional 4^4 network of tellurium Te_6^{3-} ions as well as discrete Te_8 rings.[7]

The synthesis of the above-mentioned polychalcogenides has been achieved through moderate temperature reactions of the elements with oxidizing agents[8]—in the case of polyselenide ions with a mild oxidant[9]—or through methanothermal reactions with the elements.[10] We have had some success in preparing large polysulfide clusters by hydrothermal reactions,[4,11] and we used this synthetic route to prepare the title compound **1**.

$[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2[Se_{12}]]$ **1**

The hydrothermal reaction of $(NH_4)_2MoS_4$ with A_2S_x (A = Na, K; $x = 2-6$) generally resulted in the formation of a new phase of $(NH_4)_2[Mo_3S_{13}]$.[11] Replacing the polysulfide salt with A_2Se_x (A = Na, K; $x = 2-4$) yielded primarily selenium metal, molybdenum metal, and some soluble polychalcogenides. By preparing a new heteropolychalcogenide salt, $Na_2S_3Se_3$,[12] whose redox potential lies between the polysulfide and polyselenide,[13,14] we were able to tune the chemistry of the redox reaction and isolate compound **1**.

The solid-state structure of **1** is shown in Figures 1 and 2.[15,16] Double layers (AB packing) of trinuclear molybdenum

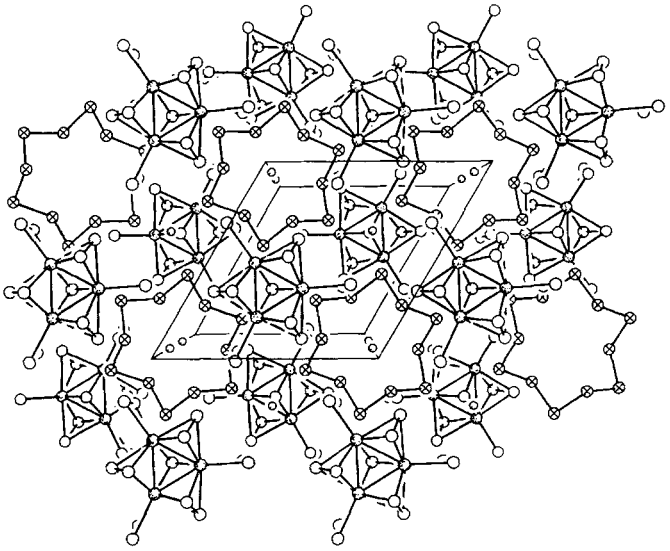

Fig. 1. Crystal structure of **1** viewed along the c axis [15]. Only half the cell is shown for clarity. ○: N atoms, ◍: Mo atoms, ○: S atoms, ⊗: Se atoms. The Se–Se bonds within the Se_{12} ring are nearly all identical: 2.335(2) and 2.327(2) Å. The internal Se-Se-Se ring angles are consistent with those found for Se_8 and Te_n [7], alternating between 105.14(4) and 102.94(7)°. Instead of $[Mo_3S_{11.72}Se_{1.28}]$ the simplified structure of $[Mo_3S_{13}]$ is shown.

[**] Financial support was provided by the American Chemical Society, Petroleum Research Foundation, and the Research Corporation, Cottrell Fellowship. Additional help provided by C. M. Zelenski (EDS), S. M. Miller (X-ray diffraction), and Dr. H. Murray, Exxon Research, for providing some molybdenum starting materials.

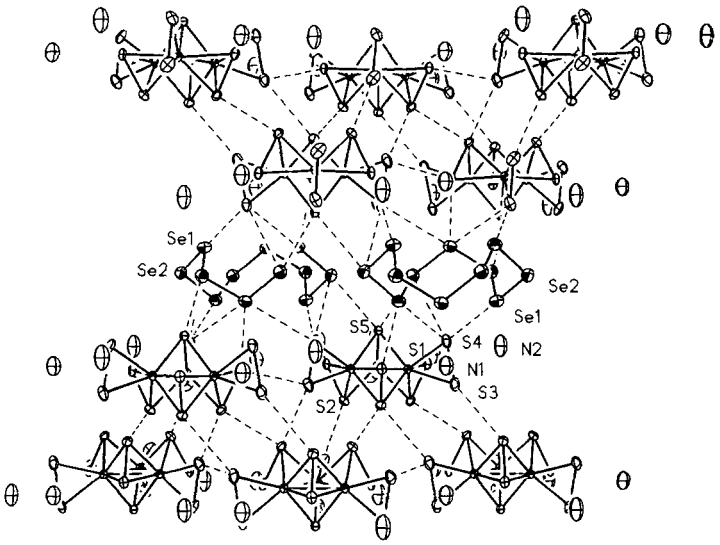

Fig. 2. Crystal structure of **1** viewed along the *a* axis and showing important Se–S intercluster interactions (dashed lines). Anisotropic thermal ellipsoids are shown: Mo and Se atoms are shaded, S and N atoms are principle axis ellipsoids. Selected chalcogen interaction distances [Å]: interactions between clusters from layer A and clusters from layer B: S2–S2, 3.207(3); S2–S3, 3.507(3); interactions between clusters within the same layer: S1–S3, 3.466(3); cluster–ring interactions: S1–Se1, 3.331(3); S4–Se1, 3.754(3) and 3.492(3); S4–Se2, 3.472(3); S5–Se2, 3.544(3). Instead of $[Mo_3S_{11.72}Se_{1.28}]$ the simplified structure of $[Mo_3S_{13}]$ is shown.

clusters of $[Mo_3S_{11.72}Se_{1.28}]^{2-}$ encircle D_{3d} rings of Se_{12}. One type of ammonium cation is located above and below the Se_{12} rings, located within the planes of the molybdenum clusters (N1, Fig. 2). A second ammonium cation (N2) is found centered on the other threefold axis in the cell, above and below the double layers. The packing forms a very intricate network of interactions between anionic clusters and neutral Se_{12} rings (Fig. 2). A summary of atomic coordinates is found in Table 1.

Table 1. Atomic coordinates. U(eq) ($Å^2 \times 10^3$), and site-occupancy factors SOF for **1**.

Se(2)	0.7372(1)	0.1506(1)	0.0030(1)	38(1)	
Se(3)	0.6579(19)	0.9417(22)	0.1905(6)	24(3)	0.214(7)
Se(4)	0.6683(29)	0.9788(34)	0.1099(9)	27(5)	0.211(7)

The neutral Se_{12} rings are reminiscent of the S_{12} allotrope of sulfur.[17] Until now, the largest known neutral selenium ring systems were only Se_8 rings[18] and heteropolychalcogenide, *n*-membered S_xSe_y rings (where $6 \le n \le 12$).[19] (Of course, gray selenium exists in the more common, "infinite" chain form.[20])

Unlike with our previous structures,[4, 11] the $[Mo_3Q_{13}]^{2-}$ portion of **1** (Q = S, Se) did not refine well. It was quite possible that both S_2^{2-} and Se_2^{2-} formed during the reaction of MoS_4^{2-} with the heteropolychalcogenide salt in aqueous solution.[14] The S3 and S4 atoms that comprise the "paddles" of the cluster were the only sulfur atoms that did not refine satisfactorily. This is consistent with the relative ease of substitution at this position of the $[Mo_3S_7]^{4+}$ core.[21] Using a correlated site-occupancy model,[22] we refined the site-occupancy factor of two related atoms (S and Se) on two different sites. The resulting refinement yielded a cluster best modeled as formula **2**.

$[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3\{\eta_2\text{-}(S_{2-x}Se_x)\}_3]^{2-}$ **2** $x = 0.425$

The reactivity of our new heteropolychalcogenide anion $S_3Se_3^{2-}$ in hydrothermal reactions has proven to be unique. Hydrothermal synthesis has yielded a new form of neutral selenium that is intimately held within a network of molybdenum polychalcogenide clusters and ammonium ions.

Experimental Procedure

The title compound **1** was prepared by combining $(NH_4)_2MoS_4$ (0.131 g, 0.5 mmol) and $Na_2S_3Se_3$ (0.381 g, 1.0 mmol) with 500 μL degassed water in an evacuated, flame-sealed, fused silica ampoule. The reaction was complete under autogenous pressure at 150 °C after 100 h. The resulting solution was filtered, and the solids washed with deionized water until the filtrate was colorless. Since diffraction lines from any other compound were absent from the powder diffraction pattern of the product solids, the yield was nearly quantitative; selenium and molybdenum powders were, however, found. Elemental analysis (EDS) for $H_{16}N_4Mo_6S_{23.44}Se_{14.56}$ [%]: calcd. Mo 22.58, S 29.48, Se 45.11; found Mo 22.53, S 29.77, Se 44.71.

From Porphyrin Isomers to Octapyrrolic "Figure Eight" Macrocycles

Emanuel Vogel,* Martin Bröring, Jürgen Fink, Daniel Rosen, Hans Schmickler, Johann Lex, Kyle W. K. Chan, Yun-Dong Wu,* Dietmar A. Plattner, Maja Nendel, and Kendall N. Houk*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

The synthesis of porphycene **2**[1] marks the beginning of a promising new direction of research in porphyrin chemistry: the investigation of porphyrin isomers.[2] The formally simple construction principle of **2** involved the reorganization of the structural elements of porphyrin **1**—four pyrrole and four methine units—while maintaining the N_4 coordination site. This principle also led to the assembly of no less than six additional structural isomers, which contain one or two (as in **2**) (*Z*)-configured C···CH···CH···C units (arene fragments).

The structural isomers of [18]porphyrin-(1.1.1.1) resulting from this operation are depicted in order of increasing energy in Figure 1.[3] Presumably, there are even more candidates than shown, since the structural isomers of **1** might also occur as (*E*) forms due to the presence of the C=CH–CH=C group(s). While the existence of an (*E*) form of **2** can be safely excluded because of geometrical constraints, (*E*) forms are conceivable in the cases of the other isomers **3**–**8**. It should be noted that nonplanar isomers, regardless of their configuration (*E* or *Z*), may adopt chiral conformations, thus offering the possibility of separation of enantiomers.

For the synthesis of the porphyrin isomers **3**–**8**, it is useful to know their energies relative to that of **1**. These energies, calculated by the UHF/PM3 and BLYP/6-31G**//3-21G methods,[4] are given in Figure 1 (in kcal mol^{-1}) for the most stable NH tautomer. In each case, this particular tautomer has a diagonal

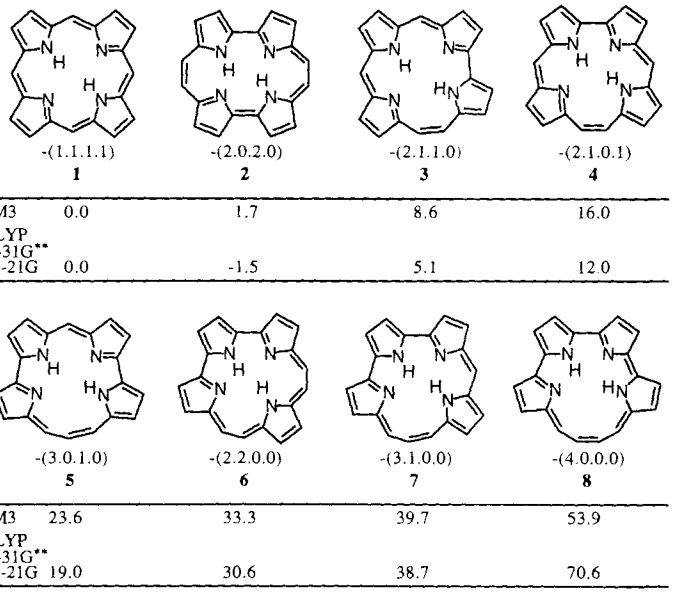

Fig. 1. Porphyrin and its isomers with an N_4 coordination site: [18]porphyrin-(*n.m.p.q*) (**1**–**8**). Data below the structural formulas: values of the relative energies (in kcal mol^{-1}) calculated by PM3 and BLYP/6-31G**//3-21G.

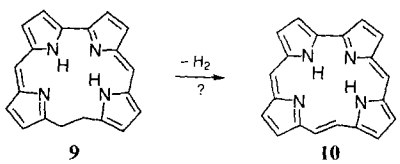
("trans") arrangement of the imino protons as shown in the formulas.[5] It is interesting to find that the stability of porphycene compares favorably with that of porphyrin; depending on the computational method employed, either **1** or **2** is predicted to be the more stable isomer. Evidently, the slightly strained porphycene is stabilized by the presence of strong NH ··· N hydrogen bonds. [18]Porphyrin-(2.1.1.0) (**3**, hemiporphycene) and [18]porphyrin-(2.1.0.1) (**4**, corrphycene) are predicted to be only moderately higher in energy. This prognosis is in accord with the observation that the hemiporphycenes[6] and corrphycenes[7] that have been synthesized recently have properties similar to porphyrins. The energies of the porphyrin isomers **6**–**8** relative to those of **1**–**5** increase so drastically that it is doubtful whether these species will be stable molecules.

These considerations turned our interests to (*E*)-corrphycene (**10**, Scheme 1). Inspection of the Briegleb–Stuart model indicat-



Scheme 1. The 3,4-diethyl substituents of the pyrrole rings are omitted for clarity.

ed that **10** is nearly unstrained but rigid, having the formal double bond in an orthogonal arrangement with respect to the tetrapyrrolic π system. Semiempirical UHF/PM3 calculations predict a similar geometry for **10** and an energy 8 kcal mol^{-1} above that of the (*Z*)-isomer **4**.[8] Consequently, **10** is likely to be a chiral, C_2 symmetric, and nonaromatic porphyrinoid. Porphyrinoid **10** can possibly be synthesized by dehydrogenation of dihydrocorrphycene **9**. According to models, the dihydro compound **9** has a conformation similar to that of **10** with the CH_2CH_2 group in a position conducive to the generation of an (*E*) double bond.

This synthetic strategy fell short of the original goal, since compound **9** never materialized. However, the search was success-

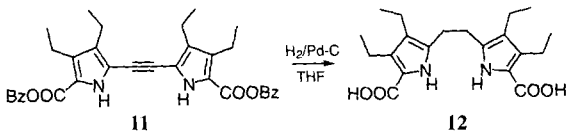
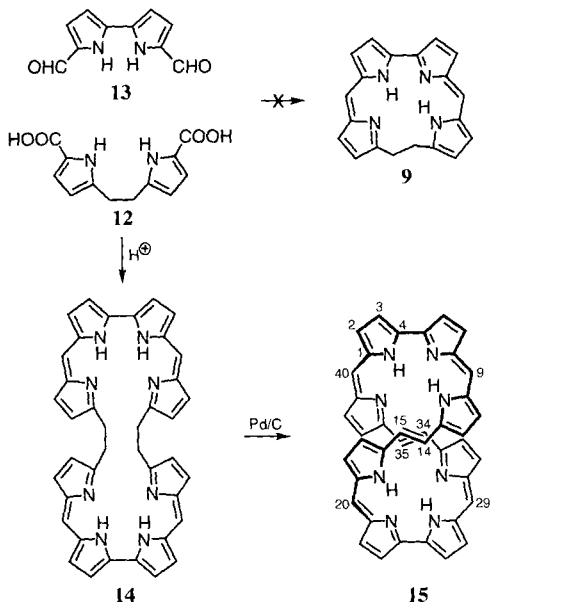
ful in other respects in that it led to the serendipitous discovery of octapyrrolic "figure eight" macrocycles. These new substances are potential ligands for dinuclear metal complexes.[9]

Octaethyldihydrocorrphycene **9**, the key intermediate in the planned route to (*E*)-corrphycene **10**, was expected to be readily prepared by a MacDonald condensation[10] of the bipyrrole dialdehyde **13** with the dipyrrylethane dicarboxylic acid **12**



11 **12**

(Scheme 2). The previously unknown dicarboxylic acid **12** was obtained as a thermally labile compound by catalytic hydrogenation of the acetylenic dibenzyl ester **11**[11] (see Scheme 2, Table 1) with 10% palladium on carbon in tetrahydrofuran and in the presence of triethylamine (room temperature, 40 h). Because the acid decarboxylates rapidly in the solid state to form 1,2-dipyrrylethane (which then polymerizes readily), no attempts at isolation were undertaken. The MacDonald condensation was



Scheme 2. Synthesis of the octapyrrolic macrocycle **15**. The 3,4-diethyl substituents of the pyrrole rings are omitted for clarity.

therefore carried out by the addition of dialdehyde **13** to a solution of hydrogenated **11**, followed by the dropwise addition of this mixture to a solution of methanol and 70% perchloric acid (30/1). To complete the reaction, the mixture was stirred for three hours, and then aqueous ammonia solution was added until the solution turned alkaline (color change from green to violet). Conventional workup afforded the crude product, which was chromatographed on aluminum oxide (activity II–III, hexane/toluene 2/1). From the brown-reddish main fraction a pure compound was isolated: black-violet crystals (needles) from dichloromethane/hexane (1/1); decomposition above 240 °C; yield 30%. Surprisingly, this compound turned out to be not the expected dihydrocorrphycene **9**, but the tetrahydrooctaphyrin-(2.1.0.1.2.1.0.1)[12] **14** (a formal dimer of **9**), resulting from the condensation of two molecules each of **12** and **13** (Scheme 2).

Initially, the ^{1}H NMR spectrum of **14** (300 MHz, $CDCl_3$, 217 K) was interpreted in terms of the presence of dihydrocorrphycene **9**, due to an absorption pattern compatible with the chiral, rigid, and C_2 symmetric structure expected for compound **9**. The following signals were observed: one singlet (*meso* protons), one AA'BB' system (CH_2CH_2 protons), four ABX_3 systems (ethyl groups with diastereotopic CH_2 protons), and a broad singlet (NH protons). On raising the temperature to 378 K ([D_8]toluene), the only significant change in the spectrum is the broadening and finally the disappearance of the NH signal. Complementary to the ^{1}H NMR spectrum, the ^{13}C NMR spectrum shows 18 signals. A reassignment of the spectra to compound **14**

Table 1. Selected physical data of the compounds **11**, **14**, **15**, and **19**. ^{1}H NMR: 300 MHz; ^{13}C NMR: 75.5 MHz; IR: CsI; UV/Vis: CH_2Cl_2.

became inevitable when the FAB mass spectrum (FAB = fast atom bombardment) indicated a molecular mass double that of **9** (*m/z* 1072, 62%). The new interpretation is consistent with the data if one assumes that **14**—as is the case for its derivative **15**, for which it was demonstrated by X-ray structure analysis—exhibits a figure-eight conformation. Chirality and the C_2 symmetry axis corresponding to the hypothetical **9** are maintained. In view of the small changes in the ^{1}H NMR spectrum upon varying the temperature (except for the NH protons), and particularly in view of the unchanged diastereotopic behavior of the ethyl-CH_2 protons, **14** must be a relatively rigid molecule.

Attempts to oxidize **14** with DDQ did not lead to a well defined product. However, upon heating, the compound (apart from experiencing some decomposition) is dehydrogenated to form the fully conjugated octaphyrin **15** with two (*E*)-configured double bonds. The thermal dehydrogenation of **14** by 10% palladium on carbon in toluene at reflux (48 h) takes place essentially without side reactions. Chromatographic filtration of the dehydrogenation product on aluminum oxide (activity II–III, hexane/toluene 1/1) and recrystallization from dichloromethane/hexane (1/1) gives **15** as bright golden, thin plates (solutions of **15** are deep blue); decomposition above 310 °C; yield 85%.

The ^{1}H NMR spectrum (300 MHz, $CDCl_3$, 217 K) reflects the transition from **14** to **15** by the replacement of the AA′BB′ system of the CH_2CH_2 protons with a singlet in the olefinic region ($\delta = 7.19$) for the four protons of the two (*E*) double bonds.[13] Thus, it appears that octaphyrin **15** adopts a figure-eight conformation as well. Special electronic effects that might have resulted from the cyclic conjugated π system (the main conjugation path has 36 [4*n*] π electrons; aromaticity is therefore excluded) have not been observed with **15**. Further, the data of the UV/Vis spectrum are not consistent with the presence of a porphyrinoid molecule. The diastereotopicity of the ethyl-CH_2 protons is maintained in the high temperature ^{1}H NMR spectrum (378 K) of **15**, thus indicating an inversion barrier larger than 20 kcal mol^{-1}. This suggests that the resolution of **15** into stable enantiomers should be possible. The same is true for the precursor **14**.

Upon treatment of **15** with 10% hydrochloric acid in dichloromethane, the tetrakis(hydrochloride) is formed, accompanied by small quantities of the bis(hydrochloride) **15a**. Treating it with perchloric acid, on the other hand, yields the tetrakis(hydroperchlorate) **15b** exclusively. In contrast to the free base **15**, its salts **15a** and **15b** could be analyzed by single crystal X-ray diffraction methods (Fig. 2).[14] Although both X-ray analyses need further refinement, it can be concluded unequivocally that the doubly protonated macrocycle **15a** (with chloride as counterion) forms a figure-eight loop with approximate D_2 symmetry. The same type of conformation applies to the tetraprotonated **15b**, even though in this case the incorporation of two more counterions stretches the skeleton like an accordion. Studies of whether **14** and **15** are able to form dinuclear complexes are currently under way.

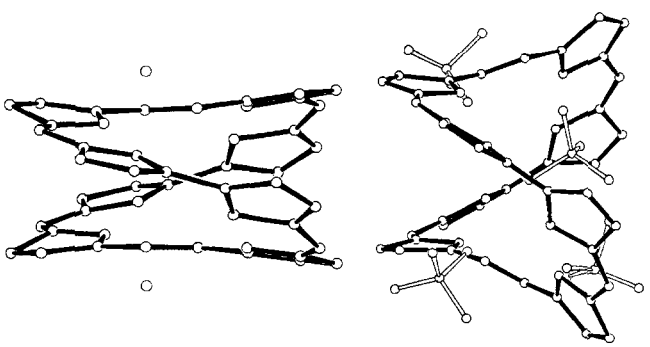

Fig. 2. Structures of the bis(hydrochloride) **15a** and tetrakis(hydroperchlorate) **15b** of **15** in the crystal (side views of **15a** (left) and **15b** (right); the ethyl substituents are omitted for clarity).

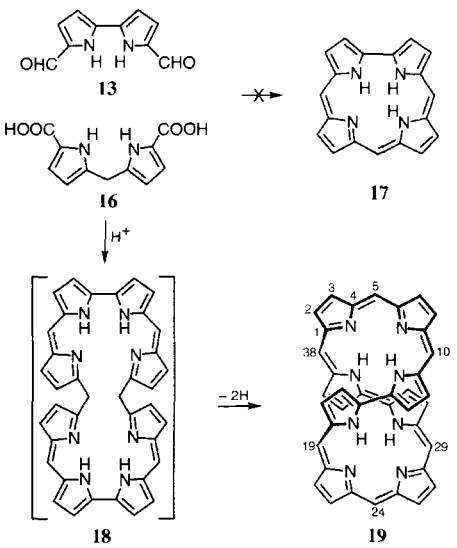
The thought that **14** and **15** might represent an entire class of octapyrrolic macrocycles prompted us to replace the dipyrrylethane by the dipyrrylmethane dicarboxylic acid **16** in the synthetic scheme of **14**. Initially we had thought that a MacDonald condensation of **13** with **16** would provide an improved access to corroles **17**.[15] As it turned out, the formation of the octapyrrolic macrocycle predominates over the formation of the cyclic tetrapyrrole in a condensation experiment performed as follows: dialdehyde **13** (300 mg, 1 mmol) and dicarboxylic acid **16** (346 mg, 1 mmol), dissolved in tetrahydrofuran (250 mL), are added dropwise under stirring to a solution of methanol (400 mL) and 70% perchloric acid (20 mL) at room temperature. After the addition is completed, the solution is allowed to stand for 30 minutes without stirring, and then concentrated aqueous ammonia solution is added until the reaction turns alkaline. The diethyl ether extract is worked up conventionally. Chromatography on aluminum oxide (activity II–III, hexane/toluene 2/1) provides a green fraction; after evaporation of the solvent and crystallization from dichloromethane/hexane the macrocycle **19**, an octaphyrin-(1.1.1.0.1.1.1.0), is obtained as red-golden cubes with a metallic luster; decomposition above 275 °C; yield 72 mg (10%) (see Scheme 3).



Scheme 3. Synthesis of the octapyrrolic macrocycle **19**. The 3,4-diethyl substituents of the pyrrole rings are omitted for clarity.

The ^{1}H NMR spectrum of **19** (300 MHz, [D_8]toluene, 298 K, thiophenol as radical trapping agent) consists of two singlets (*meso* protons), four ABX_3 systems (ethyl groups with diastereotopic CH_2 protons), and one more singlet (NH protons), indicating that the compound is chiral and D_2 symmetric. The position of the *meso* proton signals at relatively high field ($\delta = 5.88$ and 6.42) indicates that **19** is not aromatic, although the compound has a 34 π electron main conjugation path. As for the NH tautomerism in **19**, inverse ^{1}H–^{13}C long range experiments show that the major tautomer is the one depicted with the NH protons on both bipyrrole units. Similar to **14** and **15**, compound **19** is restricted in its conformational flexibility, and its enantiomers might be separable since the diastereotopicity of the ethyl-CH_2 protons encountered in the ^{1}H NMR spectrum is maintained over the entire temperature range studied (193 K to 378 K).

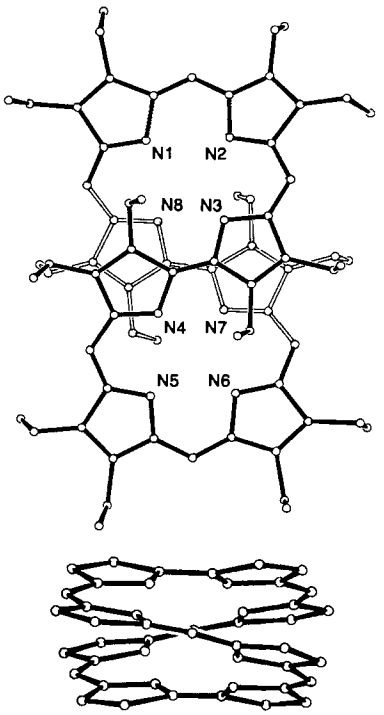


Fig. 3. Structure of the octapyrrolic macrocycle **19** in the crystal (top: top view; bottom: side view, with the ethyl groups omitted).

The X-ray crystal structure of **19** as free base[14] (Fig. 3) does not yet provide the accuracy necessary to assign molecular parameters for bond lengths, but it shows unequivocally that the figure-eight conformation of the molecule in solution is also present in the solid state.

The formation of the dehydrogenation product **19** in the course of the MacDonald condensation of **13** with **16** is surprising, since the fully conjugated tautomer of **18** with six imino protons would be anticipated to be the final product of the reaction. Because **19** is not aromatic, aromatization is ruled out as the driving force in the facile formation of **19** from **18**; the dehydrogenation of **18** (or its tautomer) is probably due to a decrease of conformational strain upon conversion to **19**.

A precedent for the synthesis of the figure-eight octaphyrins **14**, **15**, and **19** is found in the preparation of the blue-violet pigment turcasarin with ten pyrrole rings by J. L. Sessler et al.;[16] these discoveries will give new impetus to research on polypyrrolic macrocycles, molecules that show promise as versatile complexing agents (dinuclear and host–guest complexes).[17]

These latest developments notwithstanding, (*E*)-corrphycene **10** remains a synthetic goal worth pursuing. The hypothetical **10** is of particular significance, since, in conjunction with its (*Z*) isomer **4**, it demonstrates the close relationship existing between porphyrin and annulene chemistry. Most likely, the isomeric pair (*Z*)- and (*E*)-corrphycene parallels the known isomeric pair *syn*- and *anti*-bismethano[14]annulene[18] in representing a prime example of a geometrically induced loss of aromaticity in a cyclic conjugated $(4m + 2)$ π electron system.

Aukauloo, R. Guilard, *New J. Chem.* **1994**, *18*, 1205. The knowledge of the properties of the octapyrrolic macrocycle **15** made it possible to show that **15** is also produced, albeit in very small quantities (less than 1%), during the synthesis of octaethylcorrphycene (experiments together with S. Pracht).

[8] An entirely different geometry for **10** (likewise a *trans*-tautomer) was subsequently obtained by calculations by the BLYP/6-31G**//3-21G method. Here, the result is a nonplanar, bowl-like structure in which the (*E*) double bond of the (CHCH) bridge is only slightly bent out of the mean plane of the adjacent pyrrole rings. The increase in energy with respect to (*Z*)-corrphycene **4** is found to be 16.1 kcal mol^{-1} (as compared to 8 kcal mol^{-1} by the UHF/PM3 method).

[11] The synthesis of the dibenzylic ester **11** was inspired by that of bis(3,4-diethyl-5-formyl-2-pyrryl)ethyne: N. Jux, P. Koch, H. Schmickler, J. Lex, E. Vogel, *Angew. Chem.* **1990**, *102*, 1429; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 1385; D. O. Mártire, N. Jux, P. F. Aramendía, R. M. Negri, J. Lex, S. E. Braslavsky, K. Schaffner, E. Vogel, *J. Am. Chem. Soc.* **1992**, *114*, 9969.

[12] This name is proposed following Franck's porphyrin nomenclature; see: M. Gosmann, B. Franck, *Angew. Chem.* **1986**, *98*, 1107; *Angew. Chem. Int. Ed. Engl.* **1986**, *25*, 1100.

[13] The (*E*) configuration of the double bond can be deduced from the ^{1}H NMR spectrum (^{13}C satellites): the coupling constant ^3J (H14, H15) is 15.3 Hz, typical for an olefinic *trans* coupling constant.

[14] Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å). The structure was solved by direct methods and refined with F^2 by using all observed reflections (heavy atoms with anisotropic temperature factors, H atoms have not yet been included); $wR2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$. Programs used: MolEN (Enraf-Nonius) for the structure determination and SHELXL-93 (G. M. Sheldrick, University of Göttingen, **1993**) for the refinement. The calculations were performed at the Regional Computational Center of the University of Cologne. Further details of the X-ray structure analysis can be requested from the Director of Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ, on quoting the full journal citation. Preliminary X-ray structural data of **15a**: $C_{72}H_{94}N_8Cl_2$, crystallized from acetone; monoclinic, space group $C2/c$, $a = 14.065(3)$, $b = 26.425(8)$, $c = 19.783(5)$ Å, $\beta = 100.60(2)°$, $Z = 4$, $\rho_{calcd} = 1.050$ g cm^{-3}, $\mu_{Mo} = 1.33$ cm^{-1}; 4229 reflections measured; 1251 reflections observed ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 22°$; $R1 = 0.12$, $wR2 = 0.25$. Preliminary X-ray data of **15b**: $C_{72}H_{96}N_8Cl_4O_{16}$, crystallized from dichloromethane/hexane (1/1); monoclinic, space group $P2_1/c$, $a = 28.004(8)$, $b = 10.138(4)$, $c = 28.014(9)$ Å, $\beta = 104.57(2)°$, $Z = 4$, $\rho_{calcd} = 1.27$ g cm^{-3}, $\mu_{Mo} = 2.22$ cm^{-1}; 6975 reflections measured; 2209 reflections observed ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 21°$; $R1 = 0.13$, $wR2 = 0.24$. Preliminary X-ray data of **19**: $C_{70}H_{90}N_8$, crystallized from dichloromethane/hexane (1/1); triclinic, space group $P\bar{1}$, $a = 13.258(3)$, $b = 14.410(3)$, $c = 19.150(5)$ Å, $\alpha = 68.15(2)°$, $\beta = 84.97(2)°$, $\gamma = 66.67(2)°$, $Z = 2$, $\rho_{calcd} = 1.114$ g cm^{-3}, $\mu_{Mo} = 0.65$ cm^{-1}; 4487 reflections measured; 2525 reflections observed ($F_o^2 > 2\sigma F_o^2$); $\theta_{max} = 20°$; $R1 = 0.070$, $wR2 = 0.153$.

[15] The MacDonald condensation of 5,5'-diformyl-2,2'-bipyrroles with 5,5'-dicarboxy-2,2'-dipyrrylmethanes was reported to afford mainly linear hexapyrroles (M. Conlon, A. W. Johnson, W. R. Overend, D. Rajapaksa, C. M. Elson, *J. Chem. Soc. Perkin 1* **1973**, 2281), but for various reasons it seemed expedient to us to study the reaction again.

[16] J. L. Sessler, S. J. Weghorn, V. Lynch, M. R. Johnson, *Angew. Chem.* **1994**, *106*, 1572; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1509. In the case of the decapyrrolic turcasarin a figure-eight conformation is assumed, based on an X-ray crystallographic analysis of the tetrakis(hydrochloride) derivative.

[17] In the helicene and cyclophane field, molecules with a figure-eight topology are well-known; see B. Thulin, O. Wennerström, *Acta Chem. Scand., Ser. B* **1976**, *30*, 688; R. Schenk, K. Müllen, O. Wennerström, *Tetrahedron Lett.* **1990**, *31*, 7367.

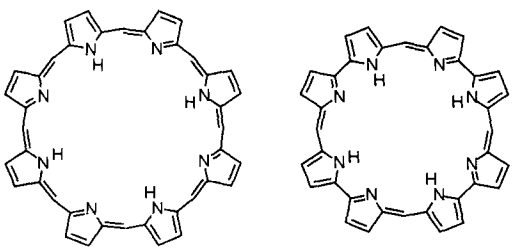
Octaphyrin-(1.0.1.0.1.0.1.0)

Martin Bröring, Jörg Jendrny, Lars Zander, Hans Schmickler, Johann Lex, Yun-Dong Wu,* Maja Nendel, Jiangang Chen, Dietmar A. Plattner, Kendall N. Houk,* and Emanuel Vogel*

Dedicated to Professor Wolfgang R. Roth on the occasion of his 65th birthday

Polypyrrolic macrocycles with eight or more pyrrole units arouse interest as potential ligands for dinuclear metal complexes[1] and from various other points of view. The first representative of these macrocycles—turcasarin with ten pyrrole rings—was described recently by J. L. Sessler[2] in the course of work in the "expanded porphyrins"[3,4] area. Shortly thereafter, during an attempt—so far unsuccessful—to synthesize the porphyrin isomer (*E*)-corrphycene,[5] we discovered that a number of cyclooctapyrroles differing in structural type can be obtained relatively easily by MacDonald condensation reactions of appropriate dipyrrolic building blocks. Evidently, cyclooctapyrroles tend to form if the ring closure to cyclotetrapyrroles is hindered for mechanistic or conformational reasons. The cyclooctapyrroles known so far have a common geometrical feature – a chiral figure-eight topology with restricted conformational flexibility. Consequently, these molecules are potentially resolvable into enantiomers.[6]

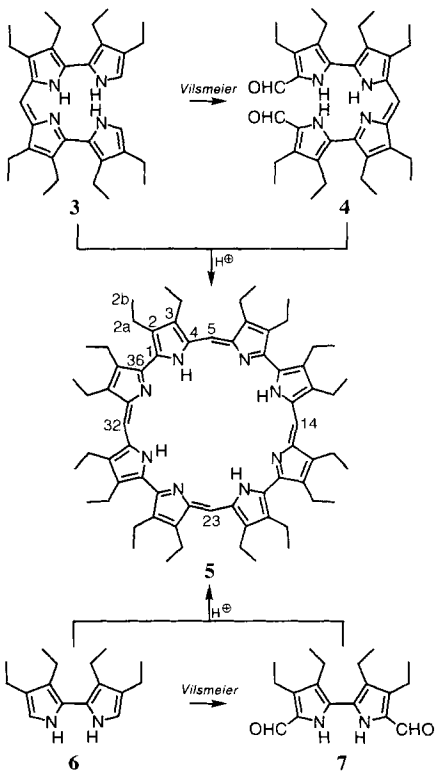
The highly symmetric cyclooctapyrroles **1** and **2**, octaphyrin-(1.1.1.1.1.1.1.1) and octaphyrin-(1.0.1.0.1.0.1.0),[7] shown in planar representations, are particularly attractive targets among



1 **2**

this class of compounds. Octaphyrin **1** is a homologue of porphyrin,[8] although it does not conform to the latter in its π electron structure.[9] Octaphyrin **2** derives from porphyrin by replacing the four pyrrole rings with four bipyrrole units. While **1** remains a synthetic challenge, **2** has now been prepared by two routes described here.

The simplest concept to approach octaphyrin-(1.0.1.0.1.0.1.0) is inspired by the Rothemund synthesis[10] of tetra-*meso*-substituted porphyrins, namely, the condensation of tetraalkyl-substituted bipyrroles (unsubstituted in the α and α′ positions) with aromatic aldehydes under acidic oxidizing conditions. This reaction, explored by J. L. Sessler et al. several years ago,[11] unexpectedly affords the hexapyrrolic "expanded porphyrin" rosarin [hexaphyrin-(1.0.1.0.1.0)] in high yield, rather than the octapyrrolic cyclic condensation product. Rosarin readily gives a tris(hydrochloride) with aqueous hydrochloric acid and was characterized as such by X-ray diffraction and NMR methods. Linear tetrapyrrole **3** and the α,ω-dialdehyde **4**, prepared by a Vilsmeier reaction of **3**, are both intermediates in our synthesis of isocorroles.[12] The availability of these intermediates invited the condensation of the two tetrapyrroles as an alternative synthetic route to octaphyrin-(1.0.1.0.1.0.1.0). When **3** and **4** are treated with trifluoroacetic acid in dichloromethane at room temperature, the octapyrrolic homologue **5** of rosarin is formed as the only well-defined product. Subsequently, it was found that **5** is obtained more expeditiously if two equivalents each of bipyrrole **6** and of bipyrrole dialdehyde **7**[13] are condensed with acid catalysis (see Experimental Procedure). In both cases, the chromatographically purified **5** is obtained after crystallization from dichloromethane/methanol as dark green rhombohedra with a metallic luster (yield 11% in the first case, 7% in the second).



The ^{1}H NMR spectrum (300 MHz, $CDCl_3$, Al_2O_3 to remove traces of water) of **5** only consists of a singlet ($\delta = 6.57$, *meso* protons), a broad singlet ($\delta = 13.30$, NH protons), and two ABX_3 systems (ethyl groups with diastereotopic CH_2 protons). With [D_8]toluene as solvent no significant changes occur in the NMR spectrum in the temperature range between −100 °C and 100 °C. These NMR observations might best be explained by the two following scenarios, both of which are consistent with the constant diastereotopicity of the CH_2 protons: 1) Octaphyrin **5** exists in an achiral tub conformation resembling cycloocta-

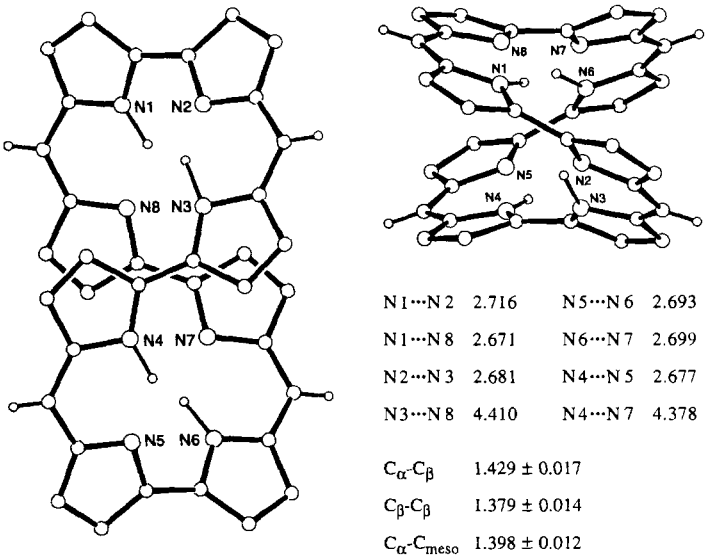
tetraene and does not invert on the NMR time scale. 2) **5** consists of two enantiomeric figure-eight conformers that are interconverting rapidly via a tub conformation.

To answer the question whether the molecule **5** is static (excluding the NH tautomerism) or dynamic, a force field conformational analysis was performed. Based upon this study, scenario 2 is most probable, and the barrier to racemization is too low to allow separation of enantiomers. Additionally, the study shows that the conformational change is coupled to NH tautomerism.[14]

In accordance with the presence of four basic nitrogen atoms, **5** is protonated by 70% perchloric acid in dichloromethane to form its tetrakis(hydroperchlorate). Since this perchlorate has the same splitting pattern in the ^{1}H NMR spectrum as **5**, it is improbable that salt formation has a profound effect on the conformation of the product.

The X-ray analysis of the free base **5** shows the figure-eight conformation in the solid state (Fig. 1).[15] As can be seen from



N1···N2	2.716	N5···N6	2.693
N1···N8	2.671	N6···N7	2.699

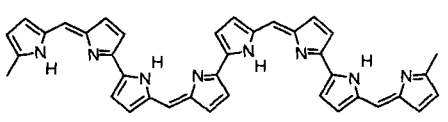
C_α-C_{meso}	1.398 ± 0.012

Fig. 1. Structure of octaphyrin **5** in the crystal (left: top view, right: side view). N···N contact distances and selected bond lengths are given in Å. Ethyl groups are omitted for clarity.

the structural parameters, **5** consists of four almost planar dipyrrin (pyrromethene) subunits (torsional angles between 1 and 10°) that maintain their individuality to a certain degree.[16] The conformation of the molecule arises mainly because the pyrrole rings of the bipyrrole units are rotated about their linking bond (the torsional angles are in the range of 43 to 52°). It was possible to assign the four imino hydrogen atoms to distinct nitrogen atoms. Evidently, as a result of the figure-eight conformation, the hydrogen atoms are located on N1, N3, N4, and N6 (Fig. 1) and not as shown in the drawing of **5**.

Octaphyrin **5**, made up of four dipyrrin units, is a remarkably stable yet chemically versatile compound. One is therefore tempted to "extrapolate" from **5** to the hitherto elusive polymers derived from the monobasic monomeric dipyrrin, specifically to the intriguing linear polypyrrole **8** and its helical variant.



8

Experimental Procedure

5: 3,3',4,4'-Tetraethyl-5,5'-diformyl-2,2'-bipyrrole (**7**; 900 mg, 3 mmol) and 3,3',4,4'-tetraethyl-2,2'-bipyrrole (**6**; 732 mg, 3 mmol) dissolved in tetrahydrofuran (300 mL) are added dropwise to a solution of methanol (300 mL) and 70% perchloric acid (15 mL), followed by stirring at room temperature for 24 h. The solution is made basic with dilute sodium hydroxide, worked up by extraction into dichloromethane, and chromatographed on aluminum oxide (activity grade II–III according to Brockmann, column 10 × 2 cm) with hexane/toluene (2/1). Octaphyrin **5** is isolated as the only nonpolymeric product and was obtained after crystallization from dichloromethane/methanol (5/1) as dark green rhombohedric crystals with a metallic sheen; m.p. >300 C; yield 84 mg (7%). Selected physical data: ^{1}H NMR (300 MHz, $CDCl_3$, Al_2O_3): δ = 13.30 (br. s, 4H; NH), 6.57 (s, 4H; H-5,14,23,32), 2.57 (ABX_3 system, AB part, 16H; H-3a,3a',7a,7a',12a,12a',16a,16a',21a,21a', 25a,25a',30a,30a',34a,34a'), 2.57 (ABX_3 system, A part, 8H; H-2a,8a,11a, 17a,20a,26a,29a,35a), 2.45 (ABX_3 system, B part, 8H; H-2a',8a',11a',17a', 20a',26a',29a',35a'), 1.22 (ABX_3 system, X_3 part, 24H; H-3b,7b,12b,16b,21b, 25b,30b,34b), 1.13 (ABX_3 system, X_3 part, 24H; H-2b,8b,11b,17b,20b,26b, 29b,35b); ^{13}C NMR (75.5 MHz, $CDCl_3$, Al_2O_3): δ = 147.49, 140.40, 139.73, 132.12, 115.17, 18.32, 17.82, 17.33, 15.73; IR (CsI): $\tilde{\nu}$ = 3196, 2961, 2928, 2869, 1589, 1464, 1388, 1301, 1278, 1207, 1185, 1110, 1056, 1009, 950, 867, 764 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 361 (28500), 548 nm (104000); MS (FAB): *m/z* (%): 1018 (98) [$(M+2H)^+$], 1017 (100) [$(M+H)^+$], 1016 (78) [M^+].

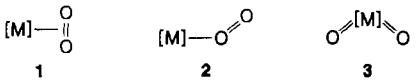
Coordination of Dioxygen in Three Representative Transition Metal Cations: FeO_2^+, CrO_2^+, and $[CH_3Re(O_2)_2O]^+$**

Detlef Schröder, Andreas Fiedler, Wolfgang A. Herrmann, and Helmut Schwarz*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

The activation of molecular oxygen for selective oxidations is important in numerous synthetic, industrial, and biological processes.[1] The transition metal mediated oxidation of hydrocarbons deserves special interest,[2] and here the use of dioxygen as the oxidant is chemically attractive. Activation of a dioxygen molecule by a mononuclear transition metal complex may involve three modes of coordination of the two oxygen atoms to "bare" or ligated metals [M] (Scheme 1):[3] 1) [M] may coordinate O_2 to yield the side-on complex **1**, which can also be described as a metal peroxide; 2) end-on coordination of O_2 to [M] leads to the linear or bent complex **2**, which may also be viewed as a metal superoxide; 3) if a high oxidation state is energetically possible for [M], cleavage of the O–O bond leads to the linear or bent metal dioxide **3**.



Scheme 1.

Gas-phase experiments reveal fundamental principles of binding for organometallic species, and reactivity studies can be used to evaluate the intrinsic properties of transition metals, thus uncovering the reaction mechanisms at a molecular level. In a few cases the information obtained has direct implications for applied chemistry.[4, 5] We describe here three prototypes of cationic $[M,O_2]^+$ systems in which the different types of bonding, as depicted in Scheme 1, are probed by experimental and theoretical methods. We have deliberately chosen iron and chromium compounds and a high-valent rhenium compound, since these metals are important in numerous oxidation processes.[1, 2, 6, 7] For the sake of brevity, we will focus on the structures of types **1**–**3** and will not discuss mechanistic or thermodynamic details of the oxidation reactions observed experimentally.[5]

Recently,[8] it was demonstrated that among the first-row transition metal cations only Fe^+ can mediate the coupled activation of molecular oxygen and that of C–H/C–C bonds in the ion/molecule reactions of $M(C_2H_4)^+$ complexes (M = Sc–Zn) with O_2. The cationic olefin complexes of Ru–Pd and Os–Pt are also unreactive in this respect.[9] As a possible explanation for the unique behavior of the iron system we proposed[10] a facile interconversion of structures **1** and **3** for [M] = Fe^+. As shown in Figure 1, the potential energy surface of $[Fe,O_2]^+$ does indeed permit the spin- and symmetry-allowed isomerization **1** ⇌ **3**, and the barrier associated with this process amounts to only a few kcal mol^{-1}. Consequently, one should expect that $[Fe,O_2]^+$ will react either as a dioxygen complex **1** or as the corresponding dioxide **3** in ion/molecule reactions. This is indeed observed experimentally (Scheme 2): Whereas $^{18}O_2$ and ethene simply replace the dioxygen ligand in $[Fe,O_2]^+$, propane reacts by hydride and methanide transfer to yield the corresponding carbocations and neutral OFeOH and $OFeOCH_3$, respectively. The fact that oxidation of the olefin does not occur when $[Fe,O_2]^+$ reacts with ethene but is observed[8] in the ion/molecule reaction of $Fe(C_2H_4)^+$ with O_2 can be attributed to

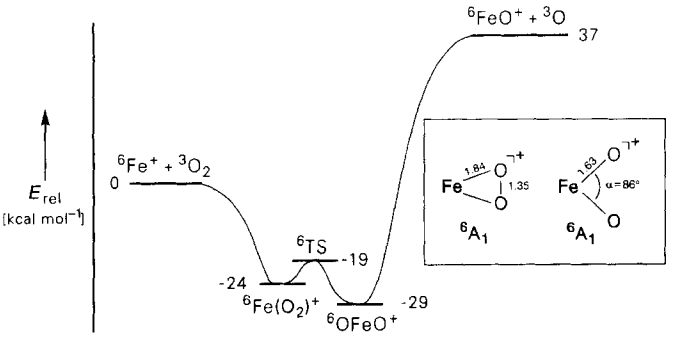


Fig. 1. Calculated sextet potential energy surface for $[Fe,O_2]^+$ ($^6A_1$); the exit channel leading to $FeO^+(^6\Sigma^+) + O(^3P)$ was taken from refs. [11, 13]. The inset shows the geometries of the minima (bond lengths in Å and angles in degrees). TS = transition structure.

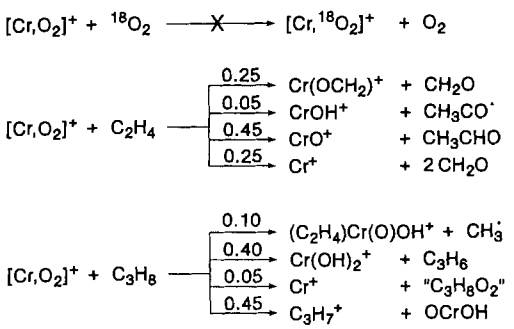
thermochemical properties. Since the bond dissociation energy $BDE(Fe^+-C_2H_4) = 34.5\ kcal\,mol^{-1}$[11] exceeds $BDE\ (Fe^+-O_2) \approx 25\ kcal\,mol^{-1}$, the energy gained in the association of C_2H_4 with $Fe(O_2)^+$ is great enough that the exothermicity leads to a rapid loss of the more weakly bound oxygen ligand prior to any C–H/C–C bond activation.

High-valent chromium compounds are widely applied as powerful oxidants in organic synthesis;[6] thus, it is not surprising that the $[Cr,O_2]^+$ cation generated by electron ionization of chromyl chloride CrO_2Cl_2 oxidizes ethene as well as propane (Scheme 3) through activation of both C–H and C–C bonds.[12] The absence of any isotope exchange of the $[Cr,O_2]^+$

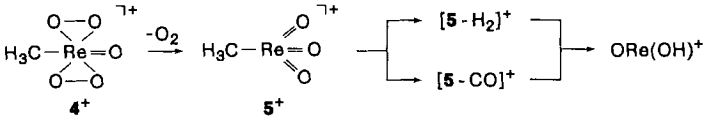


Scheme 3.

cation with $^{18}O_2$ supports the assignment of the chromium(V) dioxide cation with a connectivity like that in **3**. In line with this interpretation, computations reveal that the potential energy surface (PES) of the $[Cr,O_2]^+$ system differs greatly from that of $[Fe,O_2]^+$. For example, for the former, the global minimum corresponds to the low-spin chromium dioxide cation $Cr(O)_2^+(^2B_2)$. The calculated stability of $34\ kcal\,mol^{-1}$ for its dissociation into ground state $Cr^+(^6S)$ and $O_2\ (^3\Sigma_g^-)$ is in agreement with the literature value of $28 \pm 10\ kcal\,mol^{-1}$.[13] This dissociation, however, is spin-forbidden and an allowed, yet more energy-demanding pathway leads to the formation of singlet oxygen (Fig. 2). Nevertheless, spin-orbit coupling may render dissociation into the ground states possible by curve crossing. These calculated features of the PES explain why the $[Cr,O_2]^+$ cation generated from CrO_2Cl_2 is not capable of undergoing isotopic exchange with $^{18}O_2$ and instead acts as an oxidant in its reactions with C_2H_4 and C_3H_8 (Scheme 3). As far as the dioxygen complexes of Cr^+ are concerned, the lowest energy isomer $Cr(O_2)^+(^6B_2)$ is derived from the sextet surface and exhibits the (linear) end-on structure **2**; furthermore, the $BDE(Cr^+-O_2)$ amounts to only $10\ kcal\,mol^{-1}$, whereas that for bent $Fe^+-(O)_2$ is $24\ kcal\,mol^{-1}$. Both the thermochemical and the structural effects can be attributed to the spherical $3d^5$ configuration of the $Cr^+(^6S)$ ground state, since the large loss in exchange energy accompanying spin-pairing and the small radial extension of the d orbitals disfavor covalent bonding with oxygen.

In 1993[14] the aqua complex of $[CH_3Re(O_2)_2O]$ (**4**) was isolated and recognized as the active intermediate in the rhenium-catalyzed[15] epoxidation of olefins by H_2O_2. Our mass spectrometric experiments indicate that the cation 4^+ is also accessible. Further, no evidence was obtained for the occurrence of H/D or $^{16}O/^{18}O$ exchange in **4** in reactions with D_2O and $^{18}O_2$, thus indicating that the methyl as well as the peroxy groups in **4** remain intact upon ionization. With respect to the chemical reactivity towards hydrocarbons, the relatively high ionization energy (IE) of **4** (ca. 10.2 eV)[16] implies that electron-transfer chemistry dominates the ion/molecule reactions of 4^+ with electron-rich organic substrates. Indeed, with propene (IE = 9.7 eV)[13] rapid electron transfer from the alkene to 4^+ takes place to yield $C_3H_6^{+\cdot}$ and neutral **4**. In contrast, ethene (IE = 10.5 eV)[13] is hardly oxidized by 4^+. Furthermore, the fact that neither propene nor ethene can replace a dioxygen unit in 4^+ lends further support to the existence of intact peroxy units in 4^+, since for loosely coordinated dioxygen displacement by an alkene is expected. Interestingly, oxygen transfer of an atom from 4^+ to C_2H_4 and C_3H_6 does not take place in the gas phase.

Of interest in the rhenium case is the unimolecular dissociation of metastable 4^+. Loss of molecular oxygen yields the methyltrioxorhenium(VII) cation 5^+ (Scheme 4, Fig. 3). This process is accompanied by a kinetic energy release[17] of roughly 80 meV, pointing to the existence of a barrier for the reverse reaction, that is, addition of O_2 to 5^+. Subsequently, 5^+ undergoes unimolecular fragmentations of H_2 and CO ($\Delta m = 30$), as reported earlier for authentic 5^+.[18] Note that the large intensities of the signals for the consecutive dissociations point to a significant internal energy content in metastable 5^+, when it is



Scheme 4.

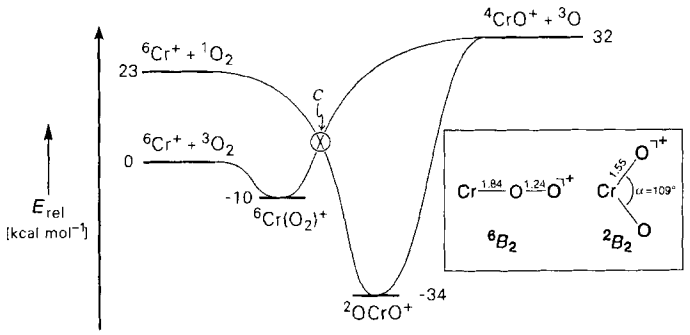


Fig. 2. Calculated potential energy surface for $[Cr,O_2]^+$; the exit channels leading to $CrO^+(^4\Sigma^+) + O(^3P)$ and $Cr^+(^6S) + O_2(^1\Delta_g)$ were taken from refs. [11, 13]. The inset shows the geometries of the minima (bond lengths in Å and angles in degrees). The encircled area is tentative and the point *C* denotes where curve crossing may occur.

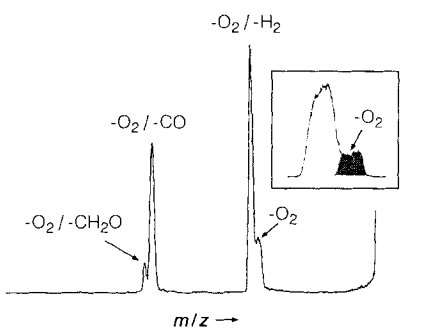

Fig. 3. Metastable-ion mass spectrum of $[CH_3Re(O_2)_2O]^+$ formed by electron ionization of neutral **4**. The inset shows the peak shape of the signals for O_2 and O_2/H_2 losses on an enlarged scale. The shaded area indicates the peak broadening due kinetic energy release; the inset was obtained by monitoring the unimolecular decay in the field-free region after B(2) by scanning E(2).

formed by unimolecular dissociation of $\mathbf{4}^+$. This result points to the existence of a substantial activation barrier for the process $\mathbf{4}^+ \rightarrow \mathbf{5}^+ + O_2$. In addition, for the $^{18}O_2$ complex of methyltrioxorhenium cation, $[CH_3ReO_3(^{18}O_2)]^+$ ($\mathbf{6}^+$), unimolecular loss of the coordinated $^{18}O_2$ is observed exclusively; this implies that the formation of $[CH_3Re(O_2)_2O]^+$ is not reversible. The existence of an activation barrier for dioxygen loss from **4** is essential (Fig. 4). Apparently, the additional ligands in **5** induce a significant barrier for the rearrangement of an incoming O_2 ligand. With respect to the condensed phase, these observations suggest that high-valent **4** is kinetically stable towards loss of dioxygen, since spin conservation would require the formation of singlet oxygen as both **4** and **5** have singlet ground states.

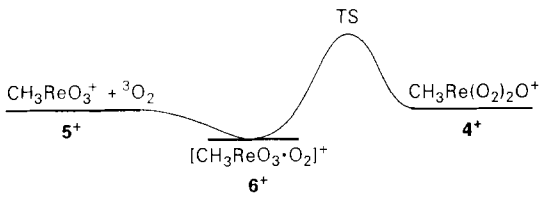

Fig. 4. Qualitative potential energy surface for the dissociation of $[CH_3Re(O_2)_2O]^+$ ($\mathbf{4}^+$) into $CH_3ReO_3^+$ (**5**) and O_2.

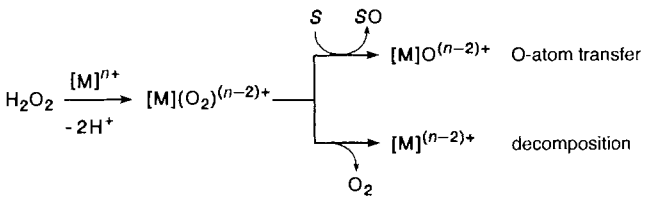
Finally, we would like to compare the present findings to the behavior of the transition metals chromium, iron, and rhenium towards hydrogen peroxide in the condensed phase. In general, two different reactivity patterns of a metal towards H_2O_2 are conceivable (Scheme 5): 1) The metal is oxidized to a high-



Scheme 5.

valent metaloxo species or it forms a peroxo complex, which can transfer an oxygen atom to an appropriate substrate *S*. 2) The metal may decompose hydrogen peroxide to yield dioxygen. Although the present gas-phase data cannot be compared directly to behavior in the condensed phase, the results parallel the observation that iron compounds, in general, catalyze the decomposition of H_2O_2 and can also serve as catalysts for the activation of dioxygen.[4, 5] In contrast, high-valent chromium and rhenium compounds may well mediate O-atom transfer rather than decompose peroxides. The particular role of the (formal) oxidation state of the metal in O_2 activation and H_2O_2 decomposition is the subject of ongoing studies.

Experimental Procedure

Most of the experiments were performed with a VG ZAB/HF/AMD 604 mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sectors), which has been described elsewhere [19]. Ionization of the precursors or appropriate mixtures (i.e. $Fe(CO)_5/O_2$, CrO_2Cl_2, $CH_3Re(O_2)_2O \cdot H_2O$, $CH_3ReO_3/^{18}O_2$) was achieved in either an electron or a chemical ionization source, and the ions of interest, having 8 keV kinetic energy, were mass-selected using B(1)E(1) at a resolution of $m/\Delta m \approx 3000$. Unimolecular dissociations were monitored in the field-free region preceding B(2) and recorded by scanning this sector. Additional experiments were performed with a Spectrospin CMS 47X Fourier Transform ion cyclotron resonance (FTICR) mass spectrometer, which has been described previously [20]. In brief, ions were generated by electron ionization (12–100 eV electron energy) in the external ion source and transferred to the analyzer cell, which is located within a superconducting magnet (max. field strength 7.05 Tesla). For ion/molecule reactions the ions of interest were mass-selected using the FERETS technique [21]; in the case of $[CH_3Re(O_2)_2O^+]$, the mixture of ^{185}Re and ^{187}Re isotopes of $\mathbf{4}^+$ was mass-selected. In order to afford ion thermalization, argon and methane were pulsed in several times (ca. 200 collisions each) and pumped out; quenching with methane is essential for thermalization.

Although the vapor pressure of $\mathbf{4} \cdot H_2O$ is fairly high, the compound is somewhat difficult to handle and several precautions should be taken to prevent spontaneous decomposition in the inlet system of the mass spectrometer; full details will be described in a forthcoming paper [16]. Briefly, for the experiments using the tandem mass spectrometer, $\mathbf{4} \cdot H_2O$ was introduced through the solid probe; this procedure allows relatively constant ion currents for 3–7 min. The ion gauge and the vacuum protection system were switched off while **4** was present. As a consequence of these experimental conditions, the determination of the kinetic energy release (KER) for O_2 loss from $\mathbf{4}^+$ is less accurate than that by more standard experiments; however, within the context of this study the existence of a KER as such is of interest. Because the FTICR instrument has a different inlet system, the experimental difficulties are less severe. Here, a glass tube containing $\mathbf{4} \cdot H_2O$ was immersed into a water bath at ca. 15 °C and connected to the ion source.

The computational study of $[Cr,O_2]^+$ was performed in the same way as in our previous study of $[Fe,O_2]^+$, which is described in more detail in refs. [10, 22]; complete details of these calculations as well as the experimental characterization of other isomers will be published elsewhere [23]. In brief, geometries were optimized using the local density functional approach (LSD/DZP) of the DGAUSS 2.3 program [24]. Subsequently, the energies of the low-lying states in all spatial and spin symmetries were evaluated at the CASPT2D level of theory using the MOLCAS-2 package [25]. The results reported here were obtained with a (14s9p4d3f)/[5s4p3d2f] basis set for oxygen and a (21s15p10d6f4g)/[8s7p6d4f2g] basis set for chromium [26].

In the case of the $Cr(O_2)^+$ complex, geometry reoptimization of the bending mode at the CASPT2D level of theory reveals the linear structure to be a minimum, while this species exhibits an imaginary frequency in the LSD/DZP approach.

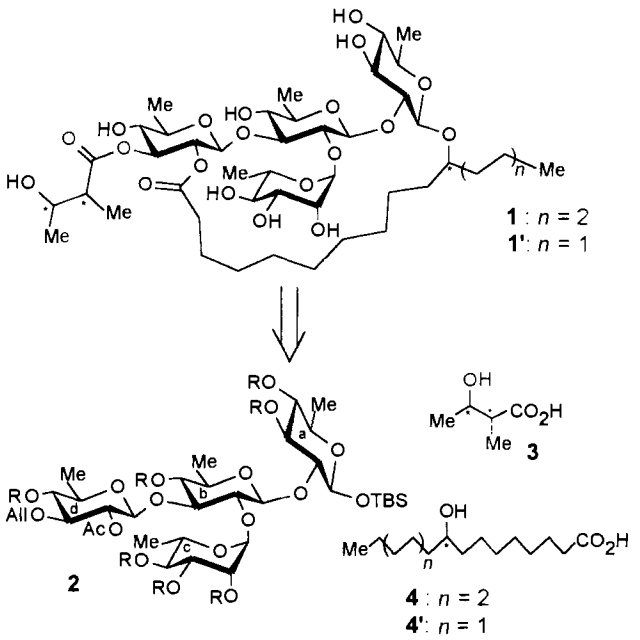

Scheme 1. Retrosynthesis of calonyctin A (**1**).

The Macrolidic Glycolipid Calonyctin A, a Plant Growth Regulator: Synthesis, Structural Assignment, and Conformational Analysis in Micellar Solution**

Zi-Hua Jiang, Armin Geyer, and Richard R. Schmidt*

Calonyctin A, extracted from *Calonyction aculeatum* L. House (moonlight flower), exhibits a strongly promoting effect on the growth and yield of various crops like peanuts, beans, and wheat.[1, 2] Calonyctin A consists of a mixture of the homologous 22-membered macrocycles **1** and **1'** (Scheme 1), which are assembled from the tetrasaccharide D-Quiβ(1-3)[L-Rhaα(1-2)]-D-Quiβ(1-2)D-Qui and the aglycons 3-hydroxy-2-methylbutyric acid (nilic acid, **3**) and 11-hydroxyhexadecanoic acid (jalapinolic acid, **4**) or 11-hydroxytetradecanoic acid (**4'**), respectively. The configurations of **3**, **4**, and **4'** have not been assigned. In addition, it was assumed that only the D isomer of quinovose (D-Qui) occurs in **1**, since it is the most common quinose isomer in nature.[1] Starting from the previously described tetrasaccharide intermediate **2**,[3] which has four orthogonal protecting groups in appropriate positions (*tert*-butyldimethylsilyl (TBS) at 1a, acetyl (Ac) at 2d, allyl (All) at 3d, and benzyl (Bn) at all other hydroxyl groups), we have now synthesized the unique macrolide calonyctin A (**1**) and determined its structure.[4] In addition, we performed a detailed conformational analysis of this 22-membered macrocyclic oligosaccharide in micellar solution. NMR methods (NOESY) were employed to derive proton–proton distances, and these were used in computer simulations of the glycolipid.[5] Based on these results, calonyctin A exhibits a well-defined conformation in the micellar environment. Rotational degrees of freedom of the tetrasaccharide moiety are reduced by the macrocyclic ring structure.

Assembled from one L-rhamnose and three D-quinovose units, the TBS-protected tetrasaccharide **2**[3] was desilylated with tetrabutylammonium fluoride (TBAF) in THF. Subsequent treatment with trichloroacetonitrile in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as base furnished trichloroacetimidate **5**, as a tetraosyl donor [^{1}H NMR: $\delta = 5.72$ (d, $J_{1a,2a} = 7.6$ Hz; 1a-H), 4.98 (dd, $J_{1d,2d} = 8.1$ Hz, $J_{2d,3d} = 9.5$ Hz; 2d-H)] (Scheme 2). 11-Hydroxyhexadecanoic acid (**4**), which was needed as an acceptor for the synthesis of **1**, was prepared as the racemic ethyl ester **7** from **6** according to a known procedure.[1] Racemic **7** was used in the glycoside synthesis; by adding $BF_3 \cdot OEt_2$ as catalyst in CH_2Cl_2 at $-8\,^\circ C$, we obtained a 1:1 mixture of two diastereomeric β-glycosides in 80% yield. The product mixture was treated with KOH in $MeOH/H_2O$ and purified by chromatography (SiO_2, petroleum ether/ethyl acetate 2.5:1 then 2:1) to provide the 2d-*O*-deprotected acids (*S*)-**8** [^{1}H NMR: $\delta = 4.24$ (d, $J_{1a,2a} = 7.1$ Hz; 1a-H); $[\alpha]_D^{20} = -2.5$ ($c = 1.0$ in $CHCl_3$)] and (*R*)-**8** [^{1}H NMR: $\delta = 4.27$ (d, $J_{1a,2a} = 7.5$ Hz; 1a-H); $[\alpha]_D^{20} = 2.0$ ($c = 1.0$ in $CHCl_3$)]. Hydrogenolytic debenzylation and total hydrolysis of (*S*)-**8** in 1 M H_2SO_4 at 100 °C gave 11-hydroxyhexadecanoic acid (*S*)-**4** in 60% yield. The (*S*) configuration was assigned by comparing optical rotations with literature data [$[\alpha]_D^{20} = 0.6$ ($c = 2.3$ in $CHCl_3$); ref. [7]: $[\alpha]_D^{20} = 0.7$ ($c = 0.9$ in $CHCl_3$)]. Since (*S*)-**4** was found previously as a component of structurally related, open-chain resin glycosides,[8] we performed the ring closure to give the 22-membered lactone with compound (*S*)-**8**. We employed a redox condensation with 2-pyridyl disulfide and triphenylphosphane, which was first described by Corey et al.[9] The intermediate 2-pyridylthioester was refluxed in toluene (4×10^{-4} M) to form macrolide (*S*)-**9** in 80% yield [^{1}H NMR: $\delta = 5.53$ (dd, $J_{1d,2d} = 8.2$ Hz, $J_{2d,3d} = 9.8$ Hz; 2d-H), 3.60 (dd, $J_{2d,3d} = 9.8$ Hz, $J_{3d,4d} = 9.1$ Hz; 3d-H); $[\alpha]_D^{20} = -4.2$ ($c = 1.0$ in $CHCl_3$)].

The allyl protecting group of quinovose d in (*S*)-**9** was isomerized with Wilkinson's catalyst[10] and then removed by addition of $HgO/HgCl_2$ in acetone/water giving (*S*)-**10** [^{1}H NMR: $\delta = 5.21$ ($J_{1d,2d} = 8.1$ Hz, $J_{2d,3d} = 9.8$ Hz; 2d-H); $[\alpha]_D^{20} = -9.1$

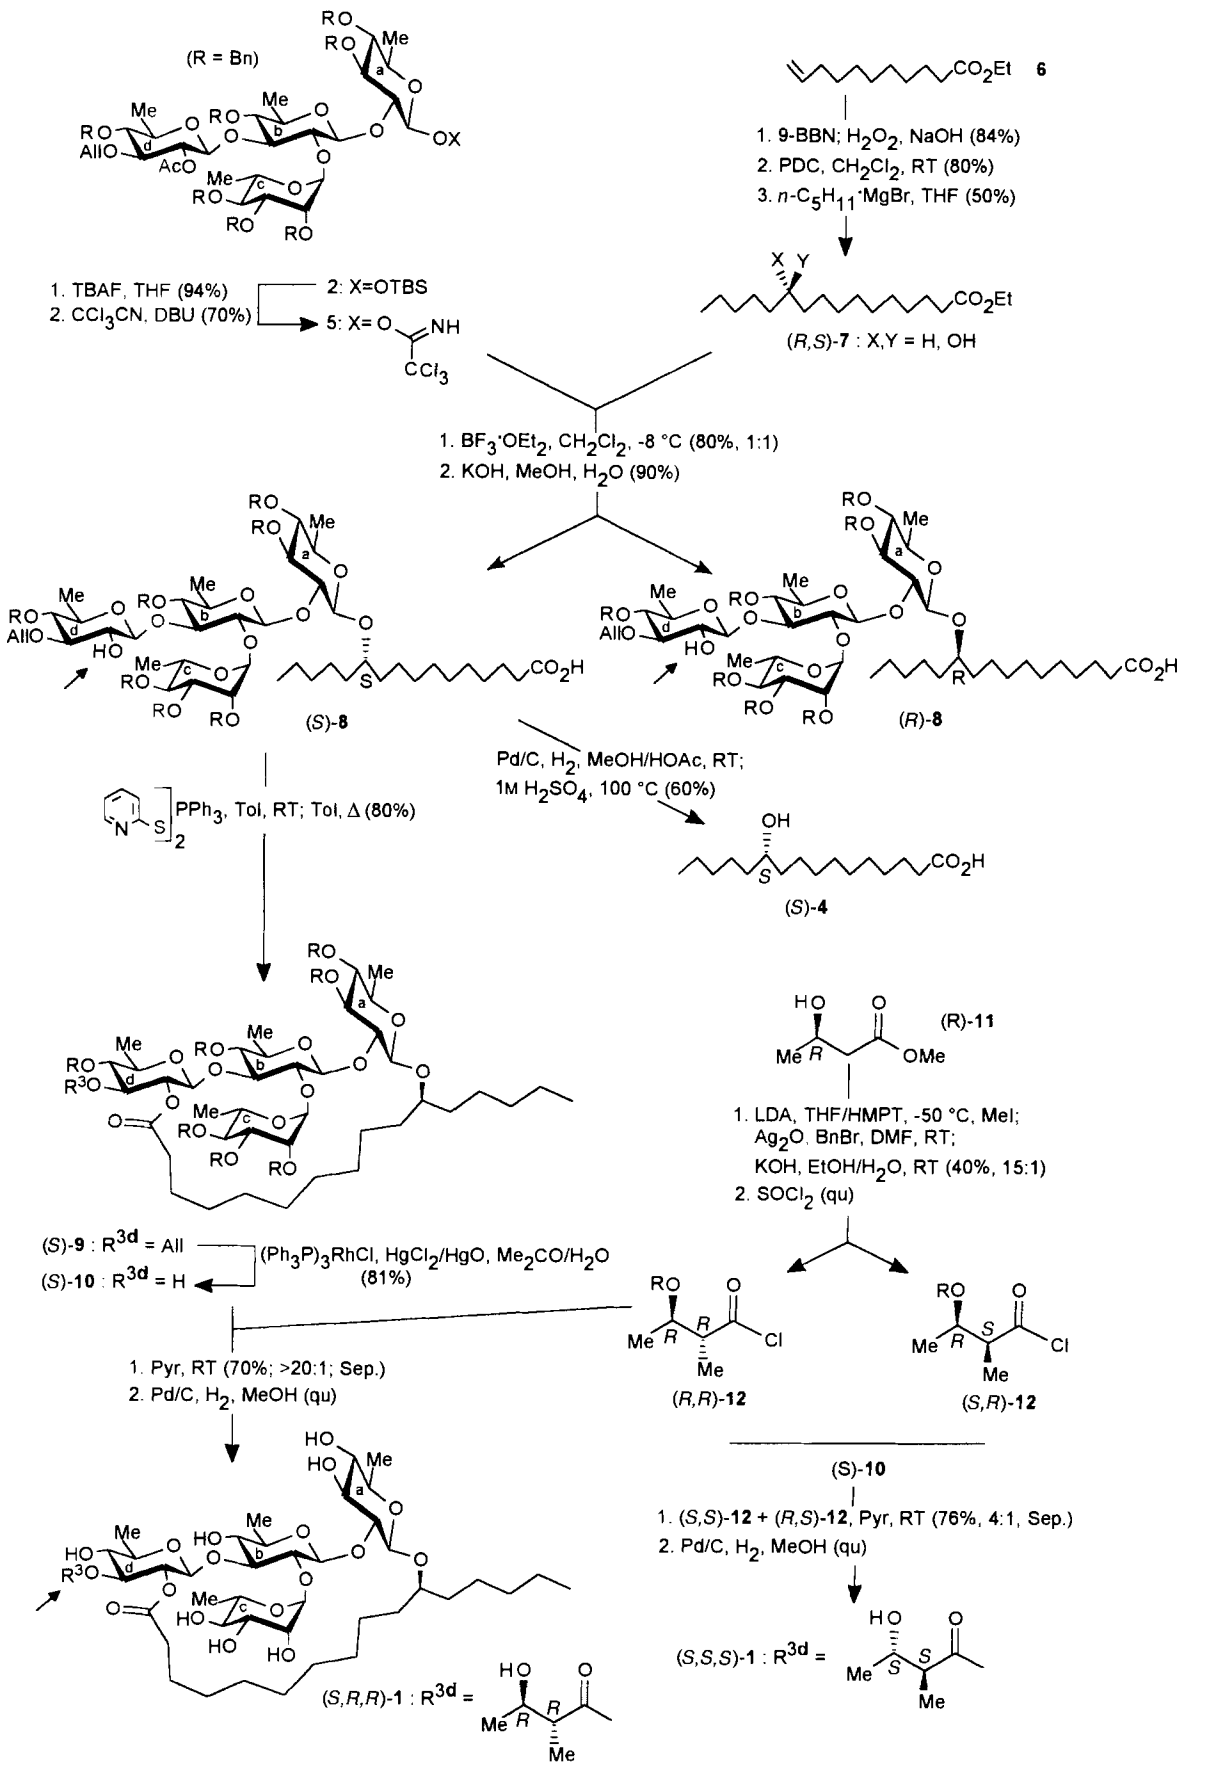

Scheme 2. Synthesis of calonyctin A (**1**). 9-BBN = 9-borabicyclo[3.3.1]nonane, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene, HMPT = hexamethylphosphoric triamide, LDA = lithium diisopropylamide, qu = quantitative, RT = room temperature, Sep. = separation, TBAF = tetrabutylammonium fluoride, TBS = *tert*-butyldimethylsilyl, Tol = toluene.

($c = 2.0$ in $CHCl_3$)]. Stereoselective synthesis of **12** was achieved by α-methylation of chiral β-hydroxyesters according to Fratér et al.[11] The commercially available methyl ester of 3-hydroxybutyric acid (*R*)-**11** was deprotonated at −50 °C and C-methylated. Subsequent O-benzylation with benzyl bromide/Ag_2O and saponification of the ester resulted in a 15:1 mixture of (*R,R*)- and (*S,R*)-3-hydroxy-2-methylbutyric acids. Further treatment with thionyl chloride gave the acid chlorides (*R,R*)-**12** and (*S,R*)-**12**. A 15:1 mixture of acid chlorides (*S,S*)-**12** and (*R,S*)-**12** was synthesized in an analogous way starting from (*S*)-**11**. 3-Hydroxy-2-methylbutyric acid is found in the (*R,R*) configuration in other natural substances,[12] therefore we concentrated on this compound. The reaction of (*S*)-**10** in pyridine with an excess of the 15:1 mixture of (*R,R*)-**12** and (*S,R*)-**12** (ca. 5 equiv) gave nearly exclusively the (*S,R,R*) diastereomer [(*S,R,R*)/(*S,S,R*) ≥ 20:1] in 70% yield as a result of diastereodifferentiation. Hydrogenolytic debenzylation in MeOH gave quantitatively the (*S,R,R*) diastereomer of **1**. In the same way, (*S*)-**10** was reacted with (*S,S*)-/(*R,S*)-**12**; diastereodifferentiation resulted in a 4:1 mixture of the (*S,S,S*) and the (*S,R,S*) diastereomers. (*S,S,S*)-**1** was obtained after chromatographic separation and hydrogenolytic debenzylation. Comparison of optical rotations [(*S,R,R*)-**1**: $[\alpha]_D^{20} = -55.0$ ($c = 1.0$ in EtOH); (*S,S,S*)-**1**: $[\alpha]_D^{20} = -51.2$ ($c = 1.0$ in EtOH)] and NMR data (Table 1) of these two compounds with those of isolated material [$[\alpha]_D^{20} = -55.0$ ($c = 1.0$ in EtOH)[11]] proved that calonyctin A and (*S,R,R*)-**1** are identical.[13] Intermediate compounds **5**, (*S*)-**8**, (*R*)-**8**, (*S*)-**9**, and (*S*)-**10** were structurally characterized by NMR (^1H, ^{13}C) and FAB-MS data. The ^1H and ^{13}C NMR signals of calonyctin A were fully assigned in [D_5]pyridine; a section of the HMBC spectrum[14] is shown in Figure 1.

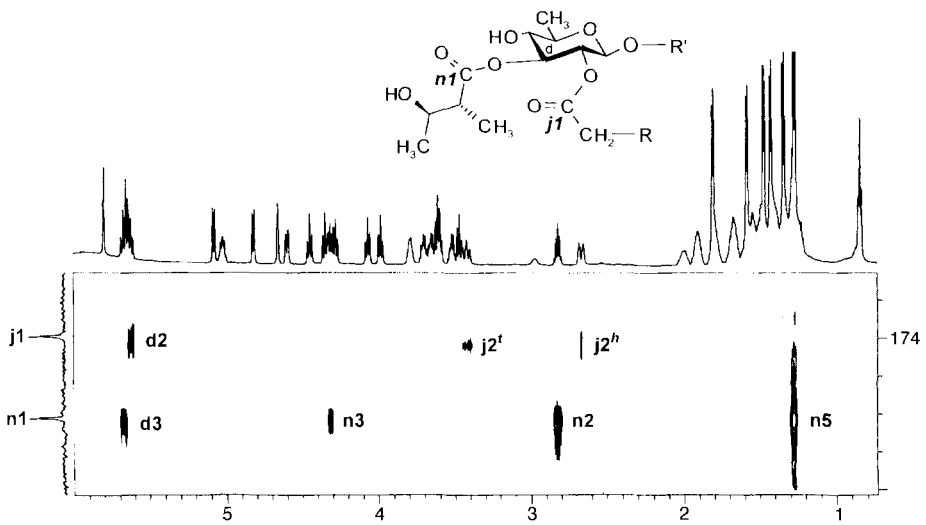

Fig. 1. Section from the low-pass filtered HMBC NMR spectrum of calonyctin A (1) (600 MHz, 300 K, [D_5]pyridine, linear prediction in F1). Proper connection of the aglycons is proven by the cross signals between the carbonyl carbons of jalapinolic acid (j1) and nilic acid (n1), and between the protons d2 and d3 of the carbohydrate chain.

Table 1. ^1H and ^{13}C chemical shifts [δ values] of the nilic acid aglycon of isolated calonyctin A and the synthetic analogues (*S,R,R*)-**1** and (*S,S,S*)-**1** in [D_5]pyridine. *Significant chemical shift differences were not observed for the other aglycons.*

Compounds **1** are amphiphilic substances; calonyctin A, which is nearly insoluble in water, is readily dissolved in a micellar solution of [D_{25}]sodium dodecylsulfate (SDS) in water (3 mg (*S,R,R*)-**1**, 46 mg [D_{25}]SDS in 0.5 mL D_2O). The glycolipid inserts into the SDS micelles, as indicated by clear increase in the intensity of the cross signals in the NOESY spectrum,[15] which was recorded with a mixing time of 150 ms at a ^1H resonance frequency of 600 MHz (Fig. 2). For such short mixing times the volume integrals of the NOE cross signals can be correlated to proton–proton distances (two-spin approximation). Cross signals of a geminal proton pair of the aglycon jalapinolic acid were calibrated at 178 pm. Proton–proton distances from Tables 2 and 3 were calculated according to the r^{-6} dependence of the NOE.[16] The clear signal separation allowed the quantification of 59 proton–proton distances, a remarkably high number for a tetrasaccharide. For both quinovose units b and d we could assign all ten possible proton–proton NOEs for each monosaccharide (intraglycosidic NOEs, Table 2). Quinovoses b and d exhibit $^4C_1$ conformation (^1H NMR: $J_{b1,b2} = 7.8$ Hz; $J_{d1,d2} = 7.9$ Hz[17]), and we could check the quality of the NOE data at these two hexoses. The average deviation of the NOE data from that of an idealized $^4C_1$ quinovose is less than 10% (Table 2). This is also true for the $^1C_4$ conformation of rhamnose c. Too little experimental data could be extracted for quinovose a due to signal overlap. The coupling constant $J_{Ha1,Ha2}$ of only 7.2 Hz indicates that quinovose a is distorted from $^4C_1$ conformation. An enhanced flexibility for this hexose is also found in computer simulations (vide infra).

The force field MM+ of the *HyperChem* program package was employed for the computer simulations of calonyctin A.[18] Binding parameters for the glycosidic bonds were adapted to experimental data.[19] Two intraglycosidic NOEs per hexose,

Table 2. Proton–proton distances [pm] for β-quinovose in $^4C_1$ conformation and α-rhamnose in $^1C_4$ conformation; average values from 50 ps of MD simulation without NOE distance restraints. Interproton distances for rings a–d were derived from a NOESY spectrum of (*S,R,R*)-**1** (Fig. 2). Due to signal overlap only three NOEs could be used for Qui a; the good quality of the interproton distances in rings b–d obtained from the NOE data is apparent. In all three cases the average deviation Δ is less than 10%.

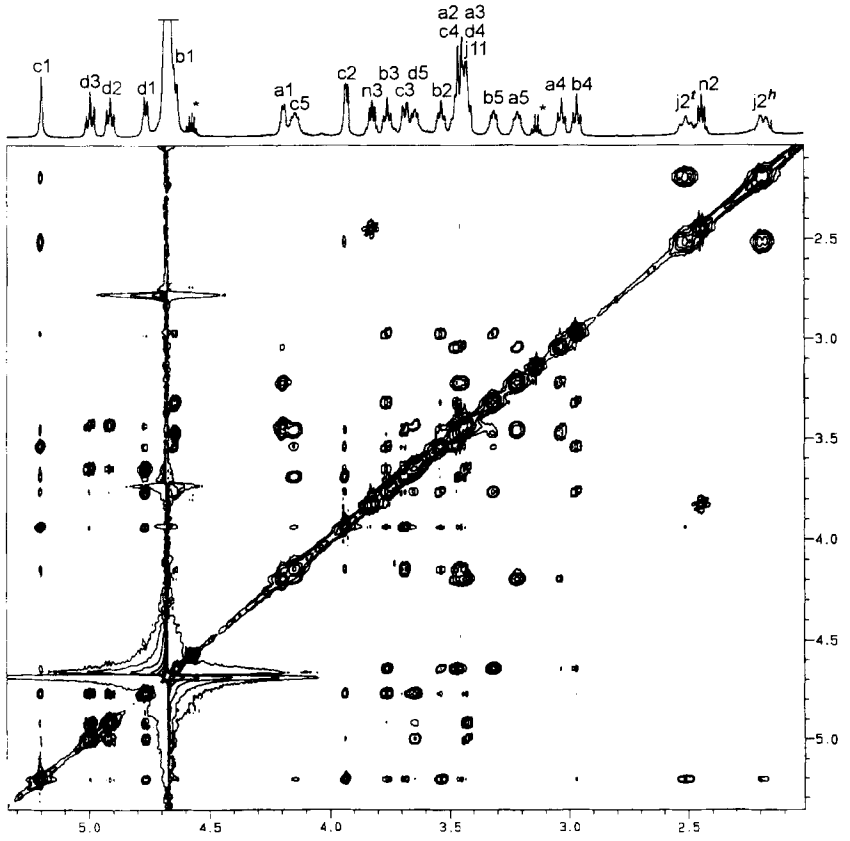

Fig. 2. Section from the NOESY spectrum of calonyctin A (**1**) (600 MHz, 300 K, 98.4% $[D_{25}]$SDS; micelle signals are marked with stars). The insertion of the glycolipid into the surface of the micelles slows down molecular tumbling and leads to intense NOE buildup rates in the NOESY spectrum.

four NOEs between quinovose c and jalapinolic acid, and 26 interglycosidic NOEs (total 38) served as experimental distance restraints in a molecular dynamics (MD) simulation. NOE distances were implemented as penalty terms in the computer simulation; a force constant of 7 kcal mol^{-1} Å^{-2} was used for the pseudo-potentials. Two starting structures converged after 50 ps of MD at 1000 K. During the following 75 ps at 300 K, 150 structures were stored; the average NOE violation is again less than 10% (Table 3). The ten superimposed structures shown in Figure 4 were determined in steps of 5 ps. A last simulation over 50 ps without NOE restraints shows no significant differences to the NOE structures. Thus, the structures in Figures 3 and 4 represent an energetic minimum in the physical force field independent of the experimental data.[20]

The glycosidic angles ϕ and ψ are within the expected ranges;[21] enhanced flexibility in the region of quinovose a is reflected by a wider fluctuation of glycosidic angles about their average values (Table 4).

The macrolide ring leads to a stabilization of the solution conformation of calonyctin A. Interproton distances determined in the biomimetic environment of SDS micelles are fulfilled by a single conformation of **1** recorded during the MD simulation. Apparently the amphiphilic glycolipid inserts its two hydrophobic fatty acid chains into the micelles. The tetrasaccharide moiety is aligned along the surface of the pseudo-membrane, and the hydroxyl groups form a network of hydrogen bonds with the polar head groups of the SDS membrane. Calonyctin A is clearly distinguished from other glycolipids, which have their carbohydrate chains oriented perpen-

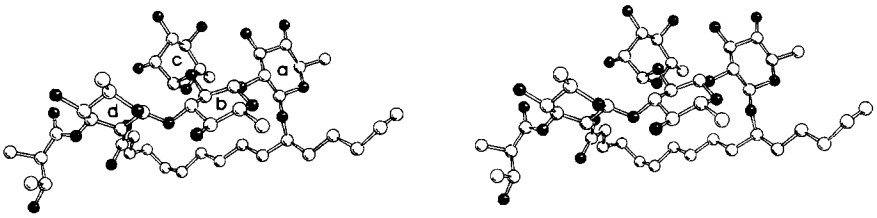

Fig. 3. Stereoplot of calonyctin A (**1**) (C: white, O: black). The glycolipid is shown after 75 ps of MD simulation at 300 K with NOE distance restraints.

Table 3. 26 Interproton distances [pm] in the four monosaccharide units of (*S,R,R*)-**1** in SDS micelles. The four distances between d and the geminal pair of protons in jalapinolic acid that is not diastereotopically assigned (numbering according to Fig. 1) were extended by 50 pm. The columns labeled MD contain the averaged distances from the MD simulation over 75 ps at 300 K. *l* and *h* denote the low-field or high-field signal in the ^{1}H NMR spectrum.

dicular to the membrane surface; glycosphingolipids, for example, extend far into the periplasmic space.[22]

Reduction of the rotational degrees of freedom by ring formation is a well-known principle in nature and frequently found in peptides and macrolides; as a result their selectivity in ion or receptor binding and stability against enzymatic digestion is enhanced. Calonyctin A is the first cyclic plant glycolipid whose structure has been proved by total synthesis and whose configuration and conformation have been analyzed in detail. The development of new drugs derived from oligosaccharides can profit from studies of native glycolipids along this line.

Synthesis of Novel Tetrathiafulvalene-Based [3]Pseudocatenanes by Self-Assembly; Prevention of *trans/cis* Isomerization**

Zhan-Ting Li, Paul C. Stein, Niels Svenstrup, Kirsten H. Lund, and Jan Becher*

Dedicated to Professor Richard Neidlein on occasion of his 65th birthday

Catenanes, molecules consisting of interlocked rings, were prepared initially by the statistical threading method or by the Möbius strip approach, and the yields were usually very low.[1] During the past decade the applications of metal templating[2] and noncovalent interactions[3] have made such molecules preparatively accessible; the second strategy was developed by Stoddart et al. and has been utilized by other groups to synthesize different types of catenanes.[4]

Our studies on the synthesis of tetrathiafulvalene(TTF)-containing macrocyclic systems using the readily available 1,3-dithiole-2-thione-4,5-dithiolate[5–7] recently resulted in the development of a convenient method for their construction.[8] It is known that TTF forms a strong 1:1 electron-transfer complex with the π-electron-accepting, tetracationic cyclophane cyclobis(paraquat-*p*-phenylene),[9] and a molecular shuttle incorporating a TTF unit as an electron donor has also been reported.[10] We were therefore interested in exploring the possibility of synthesizing TTF-based catenanes by self-assembly. We expected that novel types of catenanes could be constructed,[11] because the TTF moiety is, in principle, tetravalent, while most building blocks hitherto used to construct macrocyclic and hence catenane systems, for example hydroquinone, phenylene-1,4-diamine, benzidine, and bipyridine, are divalent. In this report we describe the efficient preparation of two TTF-based bismacrocyclic compounds and subsequently the synthesis of a novel type of [3]pseudocatenanes by self-assembly. These new pseudocatenanes were characterized by electrospray mass spectrometry, NMR spectroscopy, and elemental analysis.

Biscycles **4** and **7** were chosen as the electron donors, because CPK models indicated that the triethylene glycol chains (albeit in a strained conformation) would lead to a separation between the TTF unit and hydroquinone or hydroanthroquinone units of approximately 7 Å. This distance had been identified as being optimal for the complexation of paraquat, because π–π charge-transfer stabilization is most effective when the interacting rings are 3.5 Å apart.[3a] The difference in the sizes and electrondonating abilities of the hydroquinone and hydroanthraquinone units might have a significant influence on the self-assembly and hence the structures and properties of the products. The synthesis of **4** from **1**[12] and **2**[13] by two-step macrocyclizations under high-dilution conditions in *N*,*N*-dimethylformamide (DMF) is shown in Scheme 1.[14] In a similar way, **7** was prepared from **1** and **5**[15] (Scheme 1).

Catenanes **10**·4PF$_6$, **11**·4PF$_6$, and **12**·4PF$_6$ self-assembled on treatment of the dication **8**·2PF$_6$[17] and 1,4-bis(bromomethyl)benzene (**9**) with an excess of **4** in DMF at room temperature and under atmospheric pressure (Scheme 2). Cate-

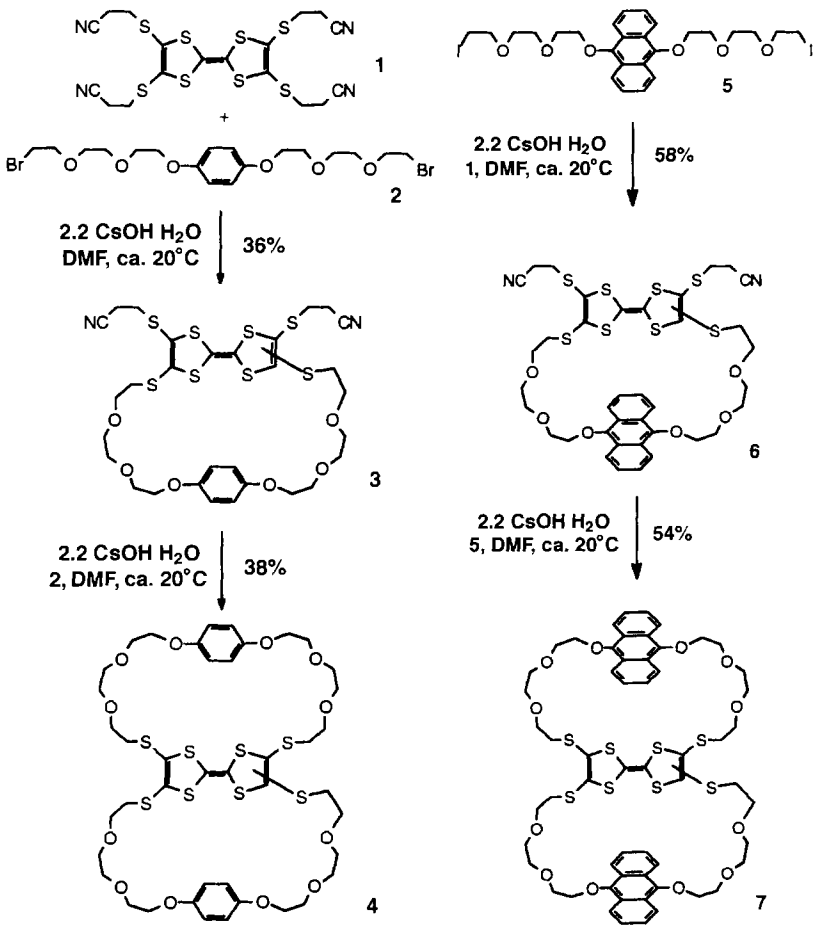
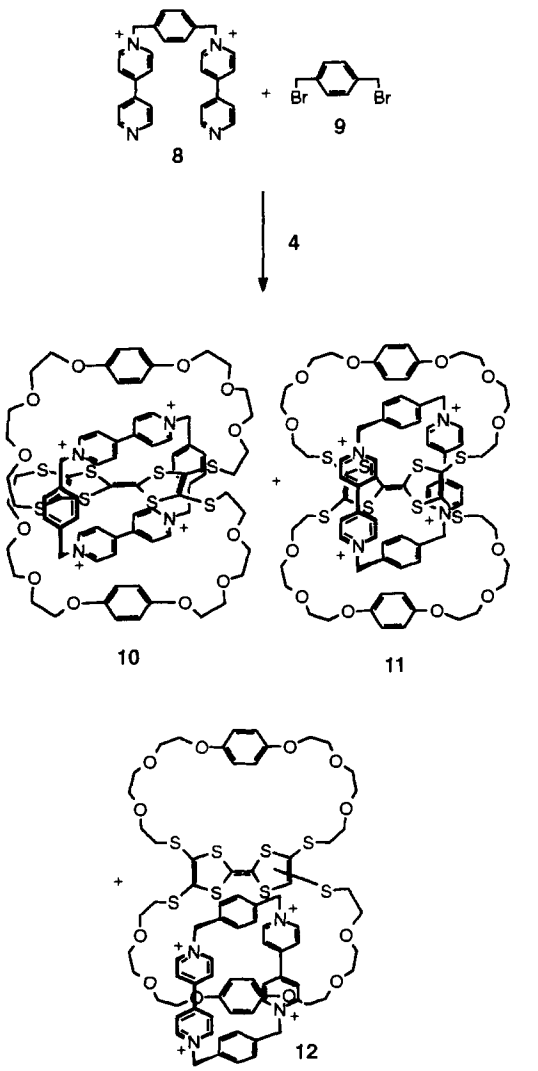
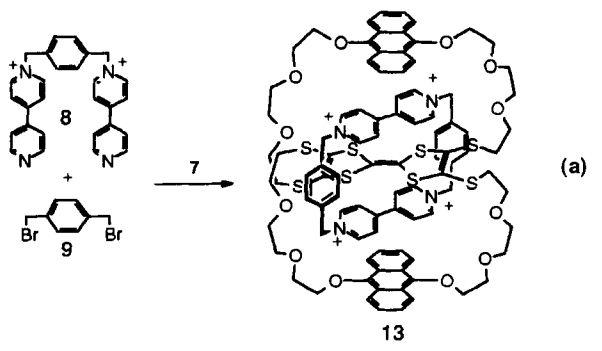


Scheme 1. The synthesis of **3**, **4**, **6**, and **7** under high-dilution conditions; **3**, **4**, **6**, and **7** are mixtures of *trans*/*cis* isomers [16].



Scheme 2. Synthesis of [3]pseudocatenanes **10**·4PF$_6$, **11**·4PF$_6$, and **12**·4PF$_6$ by self-assembly. For details see the Experimental Procedure.

nanes **10**·4PF$_6$, **11**·4PF$_6$, and **12**·4PF$_6$ (a mixture of *trans* and *cis* isomers according to the ^{1}H NMR spectrum) were obtained in yields of 15, 10, and 4%, respectively. However, under similar conditions, the reaction of **7**, **8**·2PF$_6$, and **9** gave only one product, catenane **13**·4PF$_6$, in 4% yield [Eq.(a)]. We attribute



the low yield to the greater steric demand of the anthracene units. No catenane with *cis* structure like that of **11**·4PF$_6$ was detected. As expected, a product with a structure similar to that of **12**·4PF$_6$ was not produced because the anthracene units is too large to be encircled by the cyclobis(paraquat)-*p*-phenylene macrocycle. When this reaction was conducted under high pressure (10 kbar), **13**·4PF$_6$ was produced in 27% yield. We refer to these compounds as [3]pseudocatenanes because **4** and **7** consist of two macrocyclic units and one central TTF group.

All the catenanes were characterized by electrospray mass spectrometry.[18] It is worth noting that, in addition to other peaks, all the catenanes gave the ion peaks corresponding to the loss of four PF_6^- ions from three catenane species: *m*/*z* 1437 for **10**·4PF$_6$, **11**·4PF$_6$, and **12**·4PF$_6$, and *m*/*z* 1587 for **13**·4PF$_6$.[19]

The configurations of **10**·4PF$_6$, **11**·4PF$_6$, and **13**·4PF$_6$ were determined by ^{1}H NMR, ^{13}C NMR, DQ-COSY, and NOESY spectra.[20] The ^{1}H NMR spectra of **10**·4PF$_6$ and **11**·4PF$_6$ at room temperature are shown in Figure 1. Although the protons of the hydroquinone units of **10**·4PF$_6$ give rise to only a single signal (probably because of rapid rotation around the glycol chains), both the α- and the β-protons of the bipyridinium rings give rise to two signals with the same integrative strength (Fig. 1A). This proves that **10**·4PF$_6$ is D_2-symmetric and has a *trans* configuration. In contrast **11**·4PF$_6$ gives two simple doublets at $\delta = 8.95$ and 7.82, corresponding to the α- and β-protons of the bipyridinium rings and reflecting its D_{2h} symmetry and *cis* configuration (Fig. 1B). The α- and β-protons of the bipyridinium rings of **13**·4PF$_6$ are also each split into two signals, indicating its *trans* configuration and D_2 symmetry. The

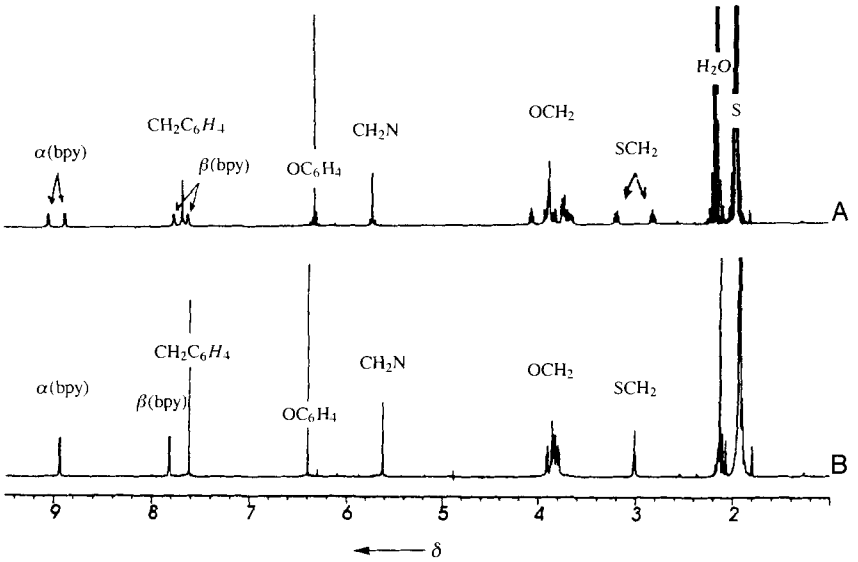


Fig. 1. 500 MHz ^{1}H NMR spectra of **10**·4PF$_6$ (A) and **11**·4PF$_6$ (B) in CD_3CN at room temperature.

resonances attributed to the polyether moieties are nonequivalent for **10**·4PF$_6$ and **13**·4PF$_6$ but equivalent for **11**·4PF$_6$. This proves that **10**·4PF$_6$ and **13**·4PF$_6$ exhibit a *trans* and **11**·4PF$_6$ a *cis* configuration. The symmetry of the polyether moiety in **11**·4PF$_6$ indicates that the polyether chains lie in the plane of the TTF unit. The ^{1}H NMR spectrum of **11**·4PF$_6$ is independent of temperature between -35 and 75 °C, whereas the signals of the aromatic protons of **10**·4PF$_6$ and **13**·4PF$_6$ show a strong temperature dependence. NOESY (chemical exchange) spectra prove that this temperature dependence is due to thermally activated exchange between sites on the aromatic rings. It seems that the rotational barrier is higher in **13**·4PF$_6$. The fact that the ^{1}H NMR spectrum of **11**·4PF$_6$ is temperature independent, and especially the fact that the observed scalar couplings between the protons of the polyether moiety are temperature independent, show that all motions of the polyether chains of **11**·4PF$_6$ are frozen out on the NMR time scale. The pyridine and hydroquinone or hydroanthraquinone rings are highly mobile in the *trans* compounds, **10**·4PF$_6$ and **13**·4PF$_6$. This indicates that the polyether moieties are configurated such that there is room enough for these ring systems to rotate around their axes. The hydroquinone rings of the *cis* compound **11**·4PF$_6$ do not show any sign of such motion. The only way to explain this result is that the position of the benzene rings of the tetracationic macrocycle stabilizes the hydroquinone rings by $\pi-\pi$ stacking. Such stacking is not possible in a *trans* configuration.

The redox behavior of the bicycles **4** and **7** and all the catenanes was investigated by cyclic voltammetry (CV) and their half-wave potentials are listed in Table 1. For **4** and **7** the first two redox waves result from the oxidation to the monocation and the dication of the TTF units, while the third redox waves are attributed to the oxidation of the hydroquinone and hydroanthraquinone units, respectively. All three oxidation steps of **7** are at significantly lower potentials than those of **4** because of the stronger electron-donating ability of the hydroanthraquinone units and their greater interactions with the TTF unit. The values of **10**·4PF$_6$ and **11**·4PF$_6$ show no significant difference, indicating that the change in configuration does not greatly affect the redox process. The first two oxidation steps of **12**·4PF$_6$, that is, the oxidation of the TTF unit to the mono- and dication, are very similar to those of **4** and apparently unaffected by the bipyridium macrocycle. This indicates that the interaction between the TTF unit and the bipyridium units in **12**·4PF$_6$ is weaker than in **10**·4PF$_6$ and in **11**·4PF$_6$. For pseudocatenane **13**·4PF$_6$ the last three waves correspond to the three processes described above; in addition a very low-energy redox process occurs as the first wave. We speculate that this process results from the intermolecular stacking interaction between two hydroanthraquinone units. UV/Vis spectra in acetonitrile reveal the charge-transfer absorption bands of **10**·4PF$_6$, **11**·4PF$_6$, **12**·4PF$_6$, and **13**·4PF$_6$ centered at 785 ($\varepsilon = 3100$), 807 (2900), 770 (900), and 773 nm (4200 $M^{-1}cm^{-1}$), respectively.

Table 1. Half wave-potentials [V] for the oxidation by cyclic voltammetry, determined in MeCN; electrolyte Bu_4NPF_6; electrolyte 100 mVs^{-1}, vs. Ag/AgCl [a].

[a] Reversible redox process unless noted otherwise. [b] Determined in CH_2Cl_2.

Addition of trifluoroacetic acid (0.1 M) to the solution of **10**·4PF$_6$ or **11**·4PF$_6$ in acetonitrile did not lead to any change that could be detected by TLC, indicating that *trans*/*cis* isomerization did not take place. This was also the case for **13**·4PF$_6$. These surprising observations seem to indicate that once the tetracationic macrocycle is interlocked around the TTF unit, it will efficiently prevent the protonation and hence isomerization of the TTF unit.[21] This observation may be important for the future use of TTF-derived macrocycles in supramolecular chemistry.[22]

Stoddart et al. originally developed the idea of using donor–acceptor interactions in the synthesis of catenanes. The template-directed synthetic strategy described here for inclusion of a TTF unit within catenanes is the first stage in the synthesis of a series of more elaborate and complex TTF-based catenanes. Replacing the hydroquinone and hydroanthraquinone units with other electron-rich systems such as hydronaphthoquinone and incorporating multiple TTF units into the macrocyclic polyether groups should lead to the construction of new types of catenanes.

Experimental Procedure

3: Under an atmosphere of nitrogen, **1** (1.09 g, 2.0 mmol) was stirred in DMF (40 mL). A solution of cesium hydroxide monohydrate (0.74 g, 4.4 mmol) in methanol (10 mL) was added dropwise with stirring within 10 min, and the resulting solution was stirred for 1 h. Then this solution and a solution of **2** (1.0 g, 2.0 mmol) in DMF (50 mL) were added simultaneously with a perfusor pump to 100 mL of DMF over 10 h at room temperature with stirring under high-dilution conditions. Stirring was continued for another 2 h and the reaction mixture concentrated in vacuo. The residue was then partly dissolved in dichloromethane (200 mL). The solution was washed with water (3 × 50 mL), dried ($MgSO_4$), and concentrated in vacuo to afford an oily residue, which was purified by column chromatography on silica gel using CH_2Cl_2/EtOAc (5:1) as an eluent. Compound **3** was obtained as an orange oil (0.56 g, 36%). ^{1}H NMR ($CDCl_3$): $\delta = 2.69$ (m, 4H), 3.04 (m, 8 H), 3.69 (m, 12H), 3.81 (m, 4H), 4.10 (m, 4H), 6.85 and 6.88 (s, 4H); EI-MS: *m/z* (%): 778 (4), 776 (11) [M^+], 537 (5), 436 (27), 404 (71), 172 (65), 54 (100), 32 (94); Anal. calcd. for $C_{30}H_{36}N_2O_6S_8$: C 46.36, H 4.68, N 3.61; found: C 46.12, H 4.49, N, 3.77.

4: Reaction of **3** and **2** in a similar way afforded **4** in 38% yield as an orange oil. ^{1}H NMR ($CDCl_3$): δ = 2.95 (m, 8H), 3.60 (m, 24H), 3.80 (s, 8H), 4.10 (m, 8H), 6.84 and 6.88 (s, 8H); EI-MS: m/z (%): 1008 (18) [M^+], 883 (10), 518 (28), 414 (40), 76 (100), 45 (77); Anal. calcd. for $C_{42}H_{56}O_{12}S_8$: C 49.97, H 5.60; found: C 49.89, H 5.72.

6: Orange oil, prepared from **1** and **5** in 58% yield according to a procedure similar to that used for the synthesis of **3**. ^{1}H NMR ($CDCl_3$): δ = 2.39 (t, 2H), 2.68 (t, 2H), 2.81 (t, 2H), 3.01 (t, 2H), 3.09 (m, 4H), 3.72–3.90 (m, 12H), 3.97 (m, 4H), 4.36 (m, 4H), 7.38 (m, 2H), 7.51 (m, 2H), 8.45 (m, 4H); EI-MS: m/z (%): 876 (8) [M^+], 208 (87), 76 (100); Anal. calcd. for $C_{38}H_{40}N_2O_6S_8$: C 52.02, H 4.61, N 3.19; found: C 52.14, H 4.60, N 3.40.

7: Orange oily solid, prepared from **5** and 6 in 54% yield. ^{1}H NMR ($CDCl_3$): δ = 2.84 (m, 4H), 2.92 (m, 4H), 3.05 (m, 8H), 3.75 (m, 24H), 3.97 (m, 8H), 4.34 (m, 8H), 7.39 (m, 4H), 7.49 (m, 4H), 8.39 (m, 8H); PD-MS: m/z: 1209.4 [M^+]. The compound was unstable and therefore used directly in the next step.

10·4PF_6, **11**·4PF_6, and **12**·4PF_6: A solution of **4** (200 mg, 0.2 mmol), **8**·2PF_6 (71 mg, 0.1 mmol), and **9** (29 mg, 1.1 mmol) in dry DMF (15 mL) was stirred under nitrogen at room temperature and under atmospheric pressure for 10 d. The solvent was then removed in vacuo and CH_2Cl_2 (20 mL) added. The resulting green solid was removed by filtration and washed with CH_2Cl_2 (2 × 10 mL). The organic phases were combined and concentrated in vacuo, giving 160 mg (80%) of starting material **4**. The solid residue was purified using column chromatography (silica gel) with MeOH/2 M aqueous NH_4Cl solution/$MeNO_2$ (7:2:1) as the eluent. Two blue fractions and one brown fraction were eluted from the column. The first fraction afforded a blue solid, which was partially dissolved in MeOH, filtered, and dried again. The residue was then dissolved in a minimum amount of water (about 8 mL), and a saturated aqueous NH_4PF_6 solution was added until precipitation was complete. The solid product was removed by filtration (Celite), washed with water, dried under vacuum, and then extracted with MeCN. After the solvent was removed under vacuum, 32 mg (15%) of **10**·4PF_6 was obtained as a dark blue solid. M.p. 220 °C (decomp); ^{1}H NMR (CD_3CN): δ = 2.80 (m, 4H; SCH_2), 3.21 (m, 4H; SCH_2), 3.71–4.12 (m, 40H; OCH_2), 5.66 (s, 8H; NCH_2), 6.32 (s, 8H; OC_6H_4), 7.63 (d, 4H; β-CH), 7.68 (s, 8H; $C_6H_4CH_2$), 7.80 (d, 4H; β-CH), 8.82 (d, 4H; α-CH), 9.01 (d, 4H; α-CH); ES-MS: m/z: 1437 [$(3M-4PF_6)^{4+}$], 1261 [$(2M-3PF_6)^{3+}$], 1008 [4^+], 909 [$(M-2PF_6)^{2+}$], 558 [$(M-3PF_6)^{3+}$], 382 [$(M-4PF_6)^{4+}$]; Anal. calcd. for $C_{78}H_{88}N_4O_{12}F_{24}P_4S_8 \cdot 2H_2O$: C 43.66, H 4.33, N 2.61; found: C 43.74, H 4.51, N 3.05.

Similarly, **11**·4PF_6 (21 mg, 10%) and **12**·4PF_6 (8 mg, 4%) were obtained after workup. **11**·4PF_6: Dark blue solid; m.p. 185 °C (decomp); ^{1}H NMR (CD_3CN): δ = 3.01 (t, 8H; SCH_2), 3.77–3.92 (m, 40H; OCH_2), 5.62 (s, 8H; NCH_2), 6.41 (s, 8H; OC_6H_4), 7.63 (s, 8H; $C_6H_4CH_2$), 7.82 (s, 8H; β-CH), 8.95 (s, 4H; α-CH); ES-MS: m/z: 1964 [$(M-PF_6)^+$], 1437 [$(3M-4PF_6)^{4+}$], 1261 [$(2M-3PF_6)^{3+}$], 909 [$(M-2PF_6)^{2+}$], 558 [$(M-3PF_6)^{3+}$], 382 [$(M-4PF_6)^{4+}$]; Anal. calcd. for $C_{78}H_{88}N_4O_{12}F_{24}P_4S_8 \cdot 2H_2O$: C 43.66, H 4.33, N 2.61; found: C 43.88, H 4.19, N 2.67.

12·4PF_6: Brown solid; m.p. 200 °C (decomp); ES-MS: m/z: 1964 [$(M-PF_6)^+$], 1437 [$(3M-4PF_6)^{4+}$], 1261 [$(2M-3PF_6)^{3+}$], 909 [$(M-2PF_6)^{2+}$], 558 [$(M-3PF_6)^{3+}$], 382 [$(M-4PF_6)^{4+}$]; Anal. calcd. for $C_{78}H_{88}N_4O_{12}F_{24}P_4S_8 \cdot H_2O$: C 44.03, H 4.27, N 2.63; found: C 44.42, H 4.52, N 2.73; Because **12**·4PF_6 is a mixture of *trans* and *cis* isomers, it is difficult to assign its ^{1}H NMR spectrum.

13·4PF_6: A solution of **7** (360 mg, 0.2 mmol), **8**·2PF_6 (71 mg, 0.1 mmol), and **9** (32 mg, 1.2 mmol) in dry DMF (40 mL) was stirred in the dark at room temperature and under atmospheric pressure for three weeks. The solvent was then removed under high vacuum without heating and CH_2Cl_2 (30 mL) added. The solid material was removed by filtration and washed with CH_2Cl_2 (2 × 20 mL). The organic phases were combined and, after concentration, gave 330 mg (92%) of starting material **7**. The solid residue was subjected to column chromatography. After workup, 9 mg (4%) of **13**·4PF_6 was obtained as a dark blue solid. **13**·4PF_6 was also obtained in 27% yield from a reaction conducted under ultrahigh pressure (10 kbar) at room temperature over 3 d. M.p. 250 °C (decomp); ^{1}H NMR (CD_3CN): δ = 2.70 (m, 4H; SCH_2), 3.13 (m, 4H; SCH_2), 3.55 (m, 8H; OCH_2), 4.04 (s, 8H; OCH_2), 4.13 (m, 4H; OCH_2), 3.82 (m, 16H; OCH_2), 4.47 (m, 4H; OCH_2), 5.59 (dd, 8H; NCH_2), 6.95 (d, 4H; 1-CH(anth)), 7.32 (d, 4H; 4-CH(anth)), 7.35 (t, 4H; 2-CH(anth)), 7.50 (t, 4H; 3-CH(anth)), 7.60 (s, 8H; $C_6H_4CH_2$), 7.86 (d, 4H; β-CH), 8.13 (d, 4H; β-CH), 8.50 (dd, 4H; α-CH), 8.87 (dd, 4H; α-CH); ES-MS: m/z: 1587 [$(3M-4PF_6)^{4+}$], 1395 [$(2M-3PF_6)^{3+}$], 1009 [$(M-2PF_6)^{2+}$], 625 [$(M-3PF_6)^{3+}$], 432 [$(M-4PF_6)^{4+}$]; Anal. calcd. for $C_{94}H_{96}N_4O_{12}F_{24}P_4S_8$: C 48.87, H 4.20, N 2.43; found: C 49.00, H 3.99, N 2.27.

[14] TTF-containing macrocyclic compounds have been prepared in most cases using a coupling reaction with trialkyl phosphites from the corresponding thiones (see ref.[6]). There are only few reports to date describing the synthesis of TTF-derived macrocyclic systems starting directly from TTF-containing precursors (see ref.[8]).

[16] The isomers could not be separated because they slowly interconverted in solution in the presence of trace amounts of acid; this was detected by thin layer chromatography (TLC). The first step (yielding **3** and **6**) did not afford 2,3-deprotected products (TLC indicated that no other important products formed except insoluble linear oligomers), although tetrathiafulvalene-2,3,6,7-tetrathiolate was produced quantitatively by treatment with eight equivalents of cesium hydroxide (see ref.[12]).

[18] All spectra were recorded with a Kratos MS50TC instrument operating at 4.7 kV accelerating voltage and fitted with an electrospray ion source.
[19] This type of fragmentation pattern has apparently not been observed before; however, ion peaks corresponding to the loss of three PF_6^- ions from a catenane dimer have been reported, see: P. R. Ashton, C. L. Brown, J. R. Chapman, R. T. Gallagher, J. F. Stoddart, *Tetrahedron Lett.* **1992**, *33*, 7771.

[20] NMR spectra were recorded on a Bruker 250 or a Varian unity 500 spectrometer. The temperature was maintained at 25 °C. ^{1}H, ^{13}C, DQ-COSY, and NOESY spectra were recorded using standard pulse sequences. All chemical shifts are referenced to TMS.

[21] Unsymmetric TTF compounds usually isomerize easily, catalyzed by trace amounts of acid. Two methods have been reported to be able to control the configurational interversion of TTF-based macrocyclic systems. The first utilizes the difference in ring strain between the *trans* and *cis* configurations, see ref.[5] and also F. Bertho-Thoraval, A. Robert, A. Souizi, K. Boubekeur, P. Batail, *J. Chem. Soc. Chem. Commun.* **1991**, 843. In the second approach, one-electron oxidation of [12]- and [14]tetrathiafulvalenophanes was employed to control their *trans/cis* isomerization, see K. Boubekeur, C. Lenoir, P. Batail, R. Carlier, A. Tallec, M.-P. Le Paillard, D. Lorcy, A. Robert, *Angew. Chem.* **1994**, *106*, 1448; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1379. However, in all these cases the planarity of the neutral TTF subunits was prevented by the short chains linking the opposite ends of the TTF groups. We found that the macrocyclic system incorporating a nonplanar TTF unit and a hydroquinone unit did not give catenanes by self-assembly in the presence of **8**·2PF$_6$ and **9** (Z.-T. Li, J. Becher, unpublished results).

[22] We have not yet studied the possibility of photochemical isomerization of these catenanes.

Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals**

Johan A. Martens,* Wim Souverijns, Wim Verrelst, Rudy Parton, Gilbert F. Froment, and Pierre A. Jacobs

It is generally assumed that the confinement of active sites within micropores is the key to the success of zeolites in a variety of petrochemical processes.[1-4] Although, it has been suggested that active sites present in interrupted cavities and pore mouths at the external surface of zeolite crystals are not merely responsible for selectivity loss, but are able to perform a significantly different catalytic chemistry,[5] the necessity to invoke the active participation of the external surface is still a matter of debate.[6-8] In order to rationalize detailed product distributions of the skeletal isomers produced by isomerization of long-chain *n*-alkanes and alkylcycloalkanes on ZSM-22 zeolite, selective pore mouth catalysis has to be invoked. An array of adjacent pore openings serves as a template for the branching; the spacing of the holes in the crystal surface determines the position of the chain branchings in the hydrocarbon skeletons.

Pore mouth catalysis occurs with bulky substrate molecules that cannot penetrate zeolite micropores and when intracrystalline counter diffusion of reactants and products within the zeolite is slow compared to the rate of the chemical reaction. The latter is typically the case in tubular pore zeolites in which the diameters of the pore openings approach those of the substrate molecules.[9]

To probe external surface catalysis, long-chain *n*-alkanes were allowed to react over ZSM-22 zeolite. The framework of ZSM-22 has parallel, uniform tubular pores with the smallest pore openings (0.55 × 0.45 nm) known for tubular pore zeolites.[10] As the pores run through the crystals in the [001] direction, arrays of pore mouths are available at crystal terminating [001] faces. ZSM-22 was synthesized according to an established recipe[11] and calcined to remove organic compounds. Then an ion exchange with ammonium ions (tenfold excess with respect to the ion exchange capacity) followed by impregnation in aqueous solution with $[Pt(NH_3)_4]^{2+}$ ions was carried out. The subsequent calcination and reduction in a hydrogen atmosphere at 673 K afforded the catalyst with 0.5 wt% of dispersed platinum metal. Scanning electron microscopy showed bundles of crystal needles of 1–2 × 0.1–0.5 μm. An ultrastable (US)-Y zeolite (USY:Si/Al ratio 4.0, prepared from NaY by ion exchange with ammonium ions, followed by steaming, and acid leaching) was included in the study as a reference large-pore zeolite catalyst. This catalyst was activated in the same way as ZSM-22. The reaction products were analyzed with high-resolution gas chromatography (GC) and GC/MS techniques (CPSil5 column with 150000 theoretical plates, length: 100 m).

The yields of specific product fractions from the isomerization of heptadecane over ZSM-22 and USY are plotted as a function of the reaction temperature in Figure 1. The isomeriza-

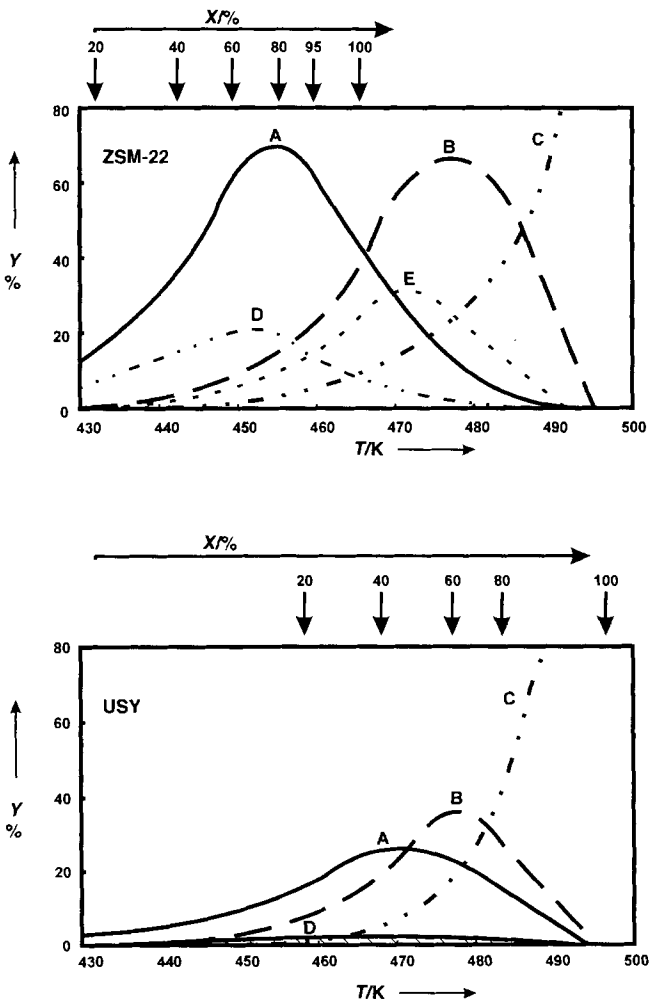

Fig. 1. Product yield (Y) of the heptadecane isomerization on ZSM-22 (top) and USY (bottom) zeolites. The conversion of heptadecane (X) is increased by increasing reaction temperature at constant space time. Monobranched products: curve A, multibranched products: curve B, cracked products: curve C, 2-methylhexadecane: curve D, sum of 2,7-, 2,8-, 2,9-, 2,10-, and 2,11-dimethylpentadecanes: curve E. Reaction conditions: H_2 pressure, 150 kPa; $C_{17}H_{34}$ pressure, 0.5 kPa; space time (W/F_0), 3.7 kg h mol^{-1}. (W is the catalyst weight and F_0 the molar flow rate at the reactor entrance.)

tion to monobranched and multibranched compounds as well as hydrocracking of *n*-heptadecane are consecutive reaction steps on both zeolites. The reactivity of hydrocarbons increases with their degree of branching.[12] In the catalysis with USY the areas below the curves for monobranching, multibranching, and hydrocracking overlap considerably. For ZSM-22, the curve maxima of the consecutive steps are much better separated, and the maximum yields of monobranched and multibranched isomers are significantly higher.

On ZSM-22, monobranching of *n*-heptadecane results in the formation of methyl-branched isomers, and particularly of 2-methylhexadecane, while 4-, 5-, 6-, 7-, and 8-methylhexadecane formation is strongly suppressed (Fig. 2). In contrast for USY,

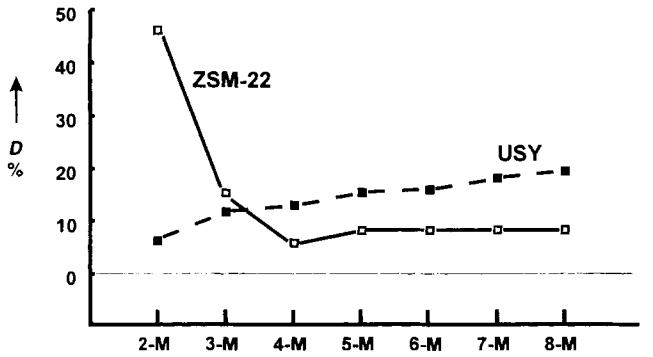

Fig. 2. Distribution (*D*) of methylhexadecane positional isomers at 15% conversion of heptadecane (for reaction conditions see legend to Fig. 1).

methyl branching at central positions in the chain is favored (Fig. 2). The isomerization of decane[11, 13] and dodecane[14] over ZSM-22 zeolites—like in the analogous reaction of heptadecane—was found to result in selective 2-methyl branching. The selectivity with which terminally branched alkane chains can be prepared on ZSM-22 has been ascribed to a pore mouth catalysis mechanism; isoalkanes with the longest possible linear chain are favored.[13]

Multibranching of monobranched isoheptadecanes proceeds only after almost complete conversion of the linear isomer (curve A in Fig. 1). Heptadecane can form 219 possible dibranched and 1171 tribranched isomers. The gas chromatographic analysis of the reaction products obtained on USY (Fig. 3 right) shows two envelopes of overlapping peaks that can be attributed to large numbers of di- and tribranched isoheptadecanes. The gas chromatogram of the compounds formed on ZSM-22, showed only signals for dibranched isoheptadecanes (Fig. 3 left, region B). Of the possible dimethyl-branched isomers, only five are obtained in significant quantities, namely 2,7-, 2,8-, 2,9-, 2,10-, and 2,11-dimethylpentadecane. These products contribute significantly to the overall yield of the multibranched isomers (curve E in Fig. 1). The formation of these specific isomers cannot be attributed to shape-selective reactions inside the uniform tubular micropores of ZSM-22. However, this behavior is readily rationalized when selective catalysis occurs at the [001] planes of the external crystal surface of the zeolite. When 2-methylhexadecane, the preferred monobranched isomer, is stretched across an external [001] crystal face such that the methyl group is pinned in one pore mouth, dibranching appears to occur when a neighboring pore mouth and its active site are in reach. The thickness of the pore wall, that is, the distance between two neighboring pore mouths, thus appears to determine the second branching position (Fig. 4).

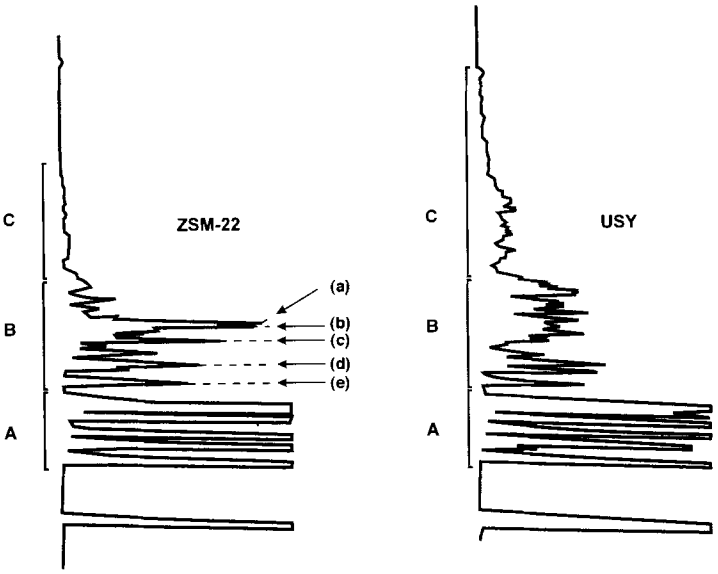

Fig. 3. Gas chromatogram of monobranched (A), dibranched (B), and tribranched (C) isoheptadecane isomers [(a) 2,9-, (b) 2,10-, (c) 2,8-, (d) 2,7-, (e) 2,11-dimethylpentadecane] obtained with ZSM-22 (left) and USY (right) (column: CP-Sil5CB, 60 m (Chrompack), film thickness: 1.31 μm, internal diameter 0.32 mm, 150000 theoretical plates).

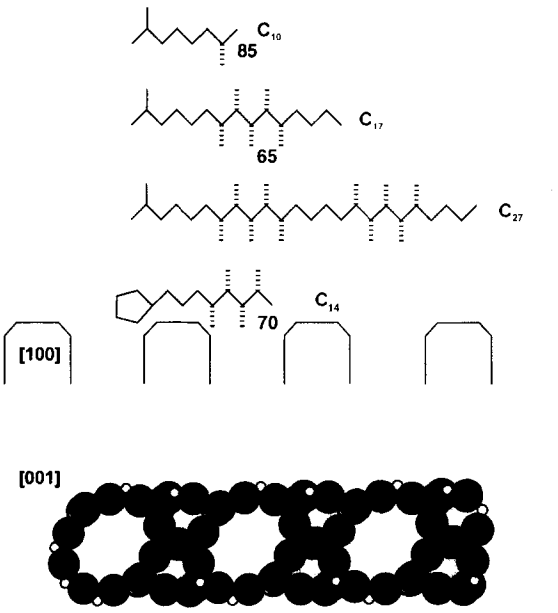

Fig. 4. Observed (for n-$C_{10}H_{22}$, n-$C_{17}H_{36}$, and 1-cyclopentylnonane) maximum product selectivities (%) of multi-methyl-branching of *n*-alkanes and *n*-alkylcycloalkanes by a selective lock-and-key mechanism at the [001] crystal faces of ZSM-22. For details see text.

The preferred isomers can maximize their van der Waals interactions with the zeolite surface; the two methyl substituents each penetrate neighboring pore mouths, and the hydrocarbon chain stretches across the framework oxygen atoms of the zeolite pore wall lying between them. The model also rationalizes why heptadecane forms virtually no tribranched isomers with ZSM-22 as catalyst: the hydrocarbon chain is too short to reach a third neighboring pore mouth (Fig. 4). Only with icosane (n-$C_{20}H_{42}$) or longer hydrocarbons are trimethyl-branched isomers accessible in large quantities. The high yield of 2,7-

dimethyloctane in the isomerization of *n*-decane on ZSM-22,[11] which was interpreted as methyl branching at both hydrocarbon chain ends,[11, 13] is another example of the same kind of selective catalysis at the external surface of the zeolite. This can be considered as a form of lock-and-key model in which the alkane (key) needs to fit in the pore opening of the catalyst (lock) (Fig. 4). The isomerization of *n*-dodecane on ZSM-22[14] in which 2,4-, 2,5-, 2,6-, 2,7-, 2,8-, 2,9-, 3,7-, and 3,8-dimethyldecane are formed in 6.0, 9.0, 8.8, 11.8, 26.6, 29.8, 1.8, and 3.1% yield, respectively, can now also be rationalized. This corresponds to the distribution required by the proposed lock-and-key model of selective branching at the [001] planes of the crystal surface.

The fate of 1-cyclopentylnonane on the ZSM-22 catalyst further supports the concept of shape-selective catalysis at the zeolite pore mouths (Fig. 4), as side-chain branching occurs preferentially at C atom positions remote from the ring. At 10% conversion more than 70% of the methyl-branched 1-cyclopentyloctanes have the methyl branching at positions 5-, 6-, or 7- in the alkyl chain. In these products and in the preferred dimethyl-branched isoheptadecanes, a minimum number of three or four methylene groups separates the respective tertiary carbon atoms (Fig. 4).

The proposed lock-and-key model for *n*-alkane isomerization seems to be valid for other 10-ring zeolites and long-chain alkanes as well. Waxes (n-$C_{26}H_{54}$ to n-$C_{34}H_{70}$) isomerized on a SAPO-11 catalyst were found to be multi-methyl-branched, with an average of three methyl branches per molecule.[15] Based on the proposed model and considering that the thickness of the pore wall for SAPO-11 and ZSM-22 materials is similar,[10b] it can be speculated that the waxes are branched at the carbon atoms C_2, C_7–C_{11}, C_{16}–C_{20}. For alkanes with more than 28 carbon atoms, an additional branching might be generated at positions C_{25}–C_{29}.

The present study demonstrates that external surfaces of zeolite crystals have to be considered as potential shape-selective environments. In particular, in view of the variety of available zeolite structure types, tailored multibranching of hydrocarbon skeletons should now be possible.

Photochromism Dependent on Crystal Packing: Photoinduced and Thermal Proton-Transfer Processes in Single Crystals of 6-(2,4-Dinitrobenzyl)-2,2′-Bipyridine**

Yoav Eichen, Jean-Marie Lehn,* Michael Scherl, Dietrich Haarer, Jean Fischer, André DeCian, Anne Corval, and Hans Peter Trommsdorff

Thermo- and photoinduced inter- and intramolecular transformations provide means to control the physical properties of solid phases[1] such as polymeric films, glasses, and crystals. The development of such tunable materials is a key step for the design of new applications in optical data processing and storage[2] such as optical memories and all-optical processors. Proton-transfer (PT) and proton-mediated electron-transfer (PMET) processes are of particular interest, as they present a number of unique properties: a) they are in most cases reversible and can be used for many cycles; b) PT does not necessarily induce large structural changes and therefore can take place in the solid state, amorphous and crystalline, even at low temperatures; c) PT processes are in general electronically well shielded, and the coulombic interactions far from the reactive site need not be considered; d) the lifetimes of proton-transferred states range from the picosecond regime to seconds, hours, and even days at low temperatures.

A variety of molecular and supramolecular structures have been shown to undergo photo-, thermo-, and piezoinduced PT processes.[3–6] PT has been found to be strongly dependent on the topography of the reaction center. Thus, the differences in the PT properties of the polymorphs of salicylidene anilides were attributed to the variations in the free volume offered by the crystal packing.[5]

One of the most interesting solid-state photoactive PT processes is the photoinduced PT (PIPT) taking place in 2-(2,4-dinitrobenzyl)pyridine crystals (α-DNBP, **1**). Although the photochromism of **1**, was reported as early as 1925,[7] only little is known about this process in solid matrices and about the correlation between the structure (molecular and crystalline) and its PT properties. The phototautomerization of **1** to its "NH" tautomer **1a** may, in principle, proceed directly or via its metastable "OH" tautomer. Scheme 1 shows the proposed mechanism for the reaction in the crystalline state.[8] None of the other 2,4-dinitrobenzyl derivatives prepared to date was reported to be photochromic in the solid state.[9]

In order to prepare new PT systems exhibiting longer lifetimes for the proton-transferred tautomers and to understand the

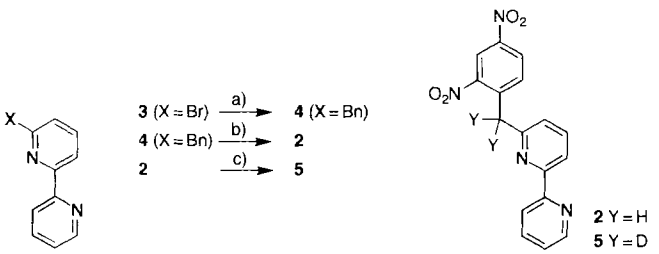
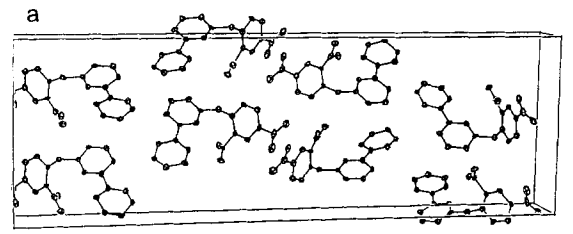
structure-PT dynamics relationship better, 6-(2,4-dinitrobenzyl)-2,2′-bipyridine (**2**) has been synthesized according to Scheme 2. After eluting **2** from the chromatographic column, two different forms of colorless crystals, **2I** and **2II**, are obtained. The intermolecular arrangements in the unit cells of **2I** (monoclinic) and **2II** (orthorhombic) are shown in Figure 1.[10]



Scheme 2. a) BnZnBr, $[(Ph_3P)_4Pd]$, 50 °C, 2 h, 95%; b) HNO_3, H_2SO_4, 25 °C, 3 h, 75%; c) EtOD, Et_3N (cat.), 40 °C, 7 d, 92–95% D.



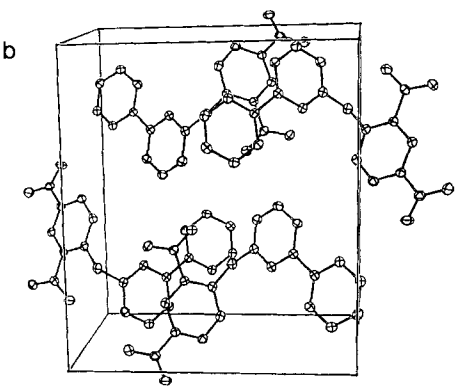


Fig. 1. a) Crystallographic unit cell of the photochromic phase **2I**; b) crystallographic unit cell of the nonphotochromic phase **2II**.

Table 1 presents some important intra- and intermolecular parameters; the numbering scheme is shown in Figure 2. In both crystals one benzylic proton is close to one oxygen atom of the *o*-nitrophenyl moiety; $d_{N-O\cdots H-C}$ is 2.4093 ± 0.0027 for **2I** and 2.3792 ± 0.0017 for **2II**. In the two polymorphs, the molecules of **2** are π-stacked, forming infinite chains.

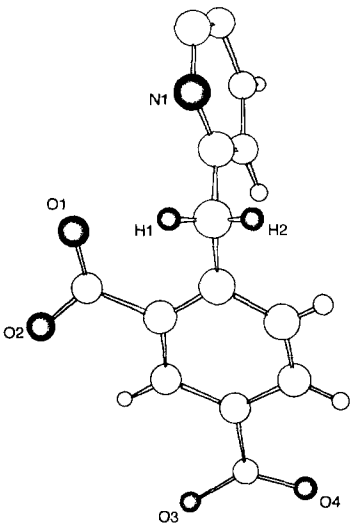

Fig. 2. Atomic numbering scheme for **2**.

Table 1. Selected intermolecular and intramolecular distances for **2** [Å] [a].

Pair of atoms	**2I** [b]	**2I** [b]	**2II**
N1-H1	2.936(6)	2.873(6)	>3
N1-H2	>3	>3	2.724(2)
O1-H1	2.409(3)	2.306(3)	2.379(2)
O1-H2	>3	>3	>3
N1-O1	3.155(6)	3.193(6)	4.004(6)
N1-H1′	>3	>3	>3
O2-H2′	2.363(3)	2.492(3)	2.406(2)
N3-H1′	>3	>3	2.850(2)
N3-H2′	>3	>3	2.830(2)

[a] For numbering see Fig. 2. [b] The values refer to the two different molecules in the **2I** phase.

Although structurally similar, **2I** was photochromic, whereas **2II** did not change its color upon illumination (the crystal did not show any photochromic properties between 330 and 800 nm at 4–300 K). Figure 3 shows the absorption spectrum of irradiated **2I**. The similarities in the intramolecular coordinates

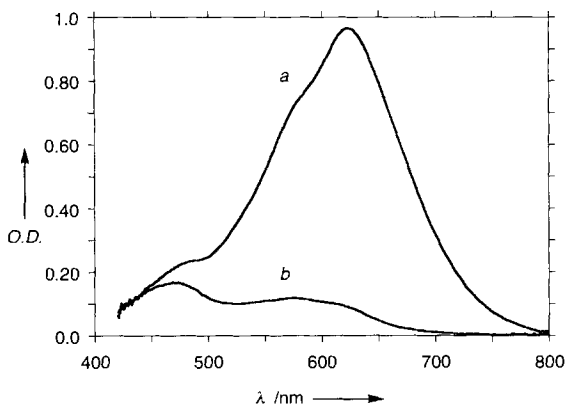

Fig. 3. Absorption spectra of **2I** that was partially converted into the "NH" form; the spectra were obtained with polarized light: a) 0°, b) 90°.

around the reaction center (the dinitrobenzyl group) and the negligible difference in the crystal density ($\rho_{2I} = 1.467\ g cm^{-3}$ and $\rho_{2II} = 1.460\ g cm^{-3}$) seems to rule out the possibility that the difference in reactivity originates from the differences in the crystal free volume, as was suggested for salicylidene anilides.[5] One would expect to observe at least the first PT step, the conversion of **2** from the "CH" form into the "OH" form, in **2I** and **2II**, as the O···H distances associated with this process are virtually the same. The differences in reactivity must therefore have another cause associated with the intermolecular arrangement of molecules of **2** in the different crystals.

In the photochromic crystal (**2I**) the molecules present π-stacking ($d_{center-center} = 3.77$ Å; $\alpha = 13.28°$) between the bipyridine rings in which one 2-pyridine ring interacts with its neighbors' 2′-pyridine ring, (Fig. 4a). This leaves the 2,4-dinitrobenzyl chromophore relatively isolated and with no close inter-ring contacts ($d_{center-center} > 5$ Å). On the other hand, in the nonphotochromic crystal (**2II**) the 2,4-dinitrobenzyl chromophore of one molecule is tightly sandwiched between a 2-pyridine and a 2′-pyridine ring of two adjacent molecules ($d^1_{center-center} = 3.79$ Å; $\alpha = 7.36°$; $d^2_{center-center} = 3.73$ Å; $\alpha = 5.56°$) (Fig. 4b). In this arrangement, deactivation pathways other then PT could be envisaged because of stronger electronic coupling between the excited chromophore and the π-systems of neighboring molecules.

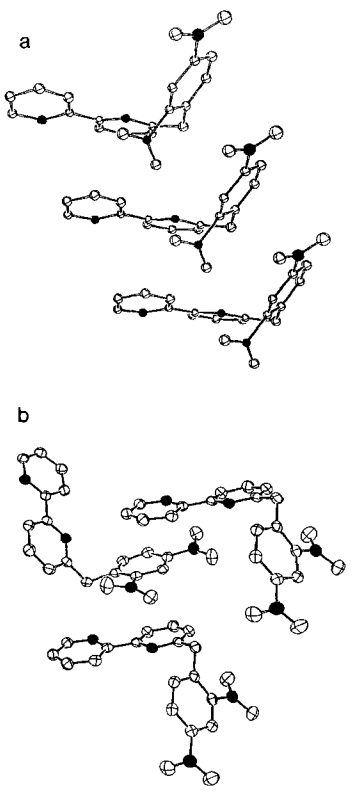

Fig. 4. Intermolecular arrangement of the molecules of **2** in the crystals of **2I** (a) and **2II** (b).

Unlike in salicylidene anilides, deuteration of **2** to give **5** (Scheme 2) resulted in a remarkably strong isotope effect on the photocoloration and the rate of thermal decoloration. This effect emphasizes that a PT is involved in the rate-determining steps of both processes. The blue color of irradiated **2I** and **5I**, attributed to their "NH" forms,[11a] fades slowly in the dark, and the molecules revert to the thermodynamically stable "CH" form. This thermal back reaction leads to a monoexponential decay of the "NH" form in both crystals.[11b] Figure 5 shows the temperature dependence of the "NH" to "CH" transformation for **2** and **5** relative to that of **1**. Each of the crystals shows a typical Arrhenius behavior indicating a uniform thermally activated process. The lifetime of the "NH" tautomer is significantly longer at all temperatures for **5I** than for **2I** and **1**, in spite of the insignificant difference in the activation barrier. For instance, the lifetimes of **5I**, **2I**, and **1** at 330 K are 17800 s, 3200 s, and 440 s, respectively. Extrapolating to room temperature (298 K) the "NH" lifetimes are expected to be 595000 s, 97200 s, and 15500 s (that is, 6.9 days, 27 h, and 4.3 h) for **5I**, **2I**, and **1**, respectively. The deuterated **5I** showed

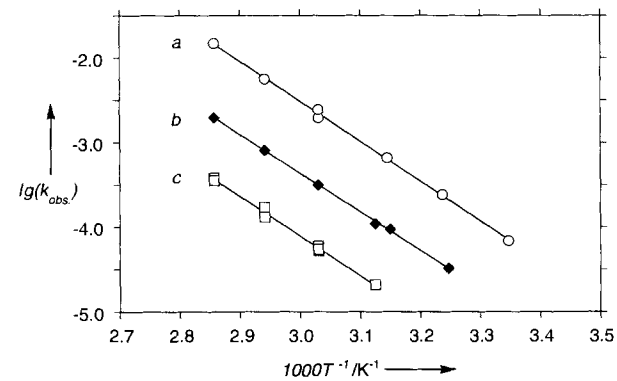

Fig. 5. Arrhenius plots for the "NH"-to-"CH" thermal backconversion: a) **1**; b) **2** in the **2I** phase; c) **5** in the **5I** phase.

a barrier of $90.0 \pm 2.9\ KJ mol^{-1}$ for the "NH" thermal decay to "CH" as compared to $87.5 \pm 0.8\ KJ mol^{-1}$ and $90.4 \pm 1.7\ KJ mol^{-1}$ for **2I** and **1** crystals, respectively.

In addition, deuteration had a marked effect on the formation ratio of the polymorphs. All crystallization conditions tried gave **5II** as the major product with variable minute amounts of **5I**, whereas for **2** the **2I** phase dominated under the same crystallization conditions.[11c] The strong influence of hydrogen/deuterium exchange at the benzylic position on the ratio of polymorph formation may indicate that intermolecular N–O···H–C interactions contribute to the crystal packing.

Other dinitrobenzyl derivatives are currently being prepared and studied to further elucidate the origins of the photocoloration process as well as the correlation between the molecular and crystal structure and PT dynamics. The control of these PIPT processes in the solid state may have promising prospects for the development of materials for optical data processing and storage.

Experimental Procedure

4: A suspension of zinc dust (1.1 g, 17 mmol) in dry THF, under argon, was activated with 0.1 mL HCl solution in dry 1,4-dioxan (4 M, Aldrich). When hydrogen evolution ceased, benzyl bromide (1.1 mL, 4.4 mmol) was added dropwise over 15 minutes. The solution was stirred at 20 °C for another 1 hour, and then filtered. A solution of 6-bromo-2,2′-bipyridine [12] (**3**, 1 g, 4.25 mmol) and $[(Ph_3P)_4Pd]$ (0.2 mmol) in THF (15 mL) was added to the benzyl zinc bromide solution. The mixture was stirred for 2 h at 50 °C, the solvent then removed under reduced pressure, and the product extracted into an acidic aqueous solution. The product was re-extracted after basification of the aqueous solution with dichloromethane. Chromatography (alumina; eluent 2% ethyl acetate in hexane, $R_f = 0.7$) afforded 0.98 g (95%) of pure **4**, m.p. (ether) 61–62 °C. Elemental analysis: calcd for $C_{17}H_{14}N_2$: C 82.90, H 5.73, N 11.37; found: C 83.06, H 5.78, N 11.19. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 4.25$ (s, 3H), 7.11 (d, 1H), 7.36–721 (m, 5H), 7.70 (t, 1H), 7.81 (dt, 1H), 8.22 (d, 1H), 8.46 (d, 1H), 8.67 (dd, 1H).

2: **4** (0.9 g, 3.6 mmol) was dissolved in 97% cold sulfuric acid (11 mL). The solution temperature was set to −10 °C; then nitric acid (1.5 mL, 100%) was added drop by drop while stirring vigorously. The solution was stirred for another 3 h at room temperature, then poured on ice, neutralized with NH_4OH, and extracted with three portions of dichloromethane (100 mL each). The combined organic layers were concentrated under reduced pressure and chromatographed (alumina; eluent ether/hexane 1/1, $R_f = 0.7$) yielding 0.9 g (75%) of **2**. Recrystallization from ether/hexane gave **2I** (m.p. 110–110.5 °C), whereas from ethanol **2II** (m.p. 118–118.5 °C) was obtained. Elemental analysis: calcd for $C_{17}H_{12}N_4O_4$: C 60.71, H 3.60, N 16.66; found: C 60.81, H 3.60, N 16.50. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 4.69$ (s, 2H), 7.30 (d, 1H), 7.82–763 (m, 4H), 8.11 (d, 1H), 8.28 (d, 1H), 8.41 (dd, 1H), 8.64 (d, 1H), 8.86 (d, 1H).

5: **2** (0.5 g, 1.5 mmol) was dissolved in dry THF (5 mL) under argon. To this solution were added two drops of dry triethylamine and 10 mL of [D$_1$]ethanol. The solution was heated at 40 °C for one week, and the solvent was subsequently removed under reduced pressure. The white crystals that separated from solution were filtered and dried. NMR characterization showed 92–95% deuteration, exclusively at the benzylic position.

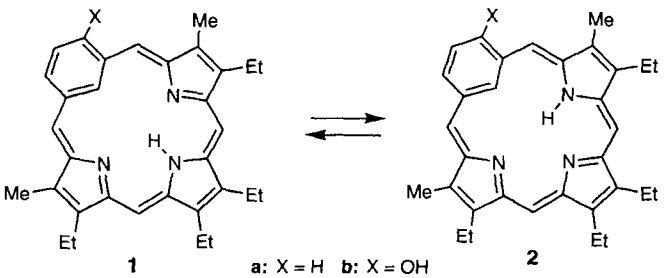
Oxybenziporphyrin, a Fully Aromatic Semiquinone Porphyrin Analog with Pathways for 18π-Electron Delocalization**

Timothy D. Lash*

Investigations into the synthesis of novel conjugated macrocycles related to the porphyrins have intensified in recent years, in part because these compounds are potentially useful in numerous, seemingly unrelated areas such as the development of novel materials (molecular wires, shape-selective catalysts, etc.)[1] and photodynamic therapy.[2] A number of approaches have been taken to modify the porphyrin chromophore, including the synthesis of structural variants (inverted porphyrins,[3] porphyrin linkage isomers[4]), expanded porphyrins,[5] heterocyclic analogs (macrocycles containing furan, thiophene, and other heterocyclic subunits),[6] and highly conjugated porphyrins bearing fused aromatic subunits.[7]

In a recent paper by Berlin and Breitmaier,[8] the synthesis of a benzene containing porphyrin analog **1a** (benziporphyrin) by the acid-catalyzed condensation of a tripyrrane dicarboxylic acid with isophthalaldehyde was reported. Although this system might exist as a fully aromatic macrocycle, aromatization would only be possible at the expense of losing the conjugative pathway of the benzene subunit and the associated resonance stabilization energy. Perhaps not surprisingly, this system did not exhibit aromatic properties as a whole, and the ^{1}H NMR data suggested that benziporphyrin existed as a mixture of two nonequivalent tautomers **1a** and **2a** (Scheme 1). Although this



Scheme 1. Structures for the two nonequivalent tautomers for benziporphyrin.

is an intriguing system, fully aromatic structures related to benziporphyrin would be of far greater intrinsic interest. The reasoning that a suitably placed hydroxyl substituent, as in structures **1b** and **2b**, would allow access to the related keto tautomers **3** (Scheme 2), structures that should be able to support porphyrin-like aromatic 18π-electron pathways, led to the successful synthesis of this remarkable new system, termed oxybenziporphyrin, disclosed here.

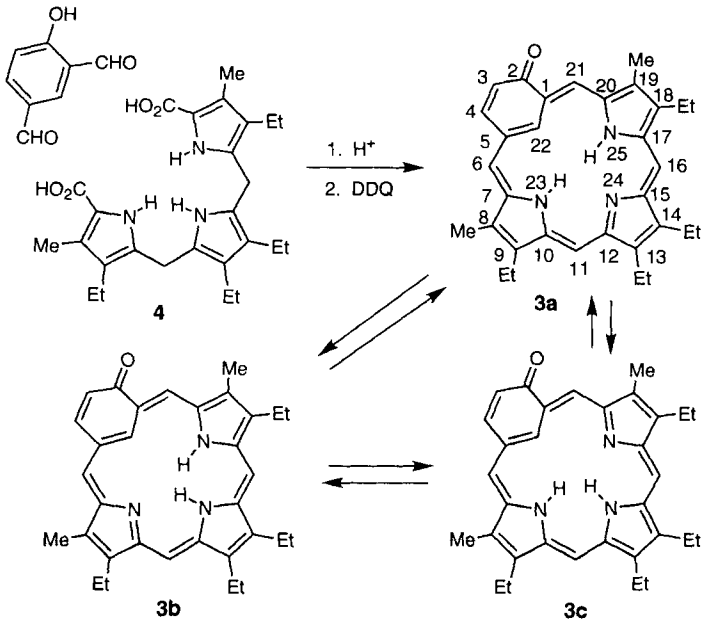

Scheme 2. Synthesis of oxybenziporphyrin **3**.

Tripyrrane dicarboxylic acid (**4**)[9] was decarboxylated with trifluoroacetic acid, diluted with dichloromethane, and condensed with 5-formylsalicylaldehyde (Scheme 2). After 2 h the mixture was neutralized with triethylamine and oxidized with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) for a further 1 h. Chromatography of the reaction mixture on alumina yielded a green band, which was collected and recrystallized from chloroform/methanol to give the required porphyrin analog as lustrous purple crystals in 35% yield. The conjugated macrocycle gave deep green solutions in chloroform and dichloromethane.

The structure of oxybenziporphyrin was confirmed by using a variety of spectroscopic techniques. IR spectra showed an intense band at 1624 cm^{-1} that was consistent with the presence of a cross-conjugated carbonyl unit. Electronic spectra were also consistent with a porphyrinoid system, showing an intense Soret band at 426 nm with a molar extinction coefficient of over 1.6×10^5 $dm^3 mol^{-1} cm^{-1}$ and a series of smaller absorptions in the visible region (Fig. 1). The ^1H NMR spectrum of **3** confirmed the presence of a macrocyclic ring current, showing the signal attributable to the bridge methine protons downfield at $\delta = 8.8-10.3$ (Fig. 2). The internal CH group of the semiquinone subunit was extensively shielded, giving rise to a doublet coupled to the *meta* proton ($^4J_{H,H} = 2$ Hz) at $\delta = -7.2$, and the signal of the two NH protons appeared as a broad resonance near $\delta = -4$. As expected, the protons at positions 3 and 4 yielded a doublet ($\delta = 7.35$) and a doublet of doublets ($\delta = 8.49$), respectively, and their relative chemical shifts were in accord with an α,β-unsaturated ketone subunit. Several aromatic tautomers for **3** are possible (structures **3a–c**, Scheme 2), although the NMR data is consistent with a single structure at room temperature, probably due to rapid equilibration between these different species. The ^{13}C NMR spectrum of **3** was in complete agreement with the assigned structure: the chemical shift for the carbonyl unit was fairly typical ($\delta = 188$), and all 22 of the ring carbons for this asymmetrical macrocycle were observable as separate resonances. The 70 eV electron-impact mass spectrum for **3** (Fig. 3) revealed a very strong molecular ion, as expected for a stable aromatic system, and showed only a small amount of benzylic fragmentation ($M^+ - 15$).

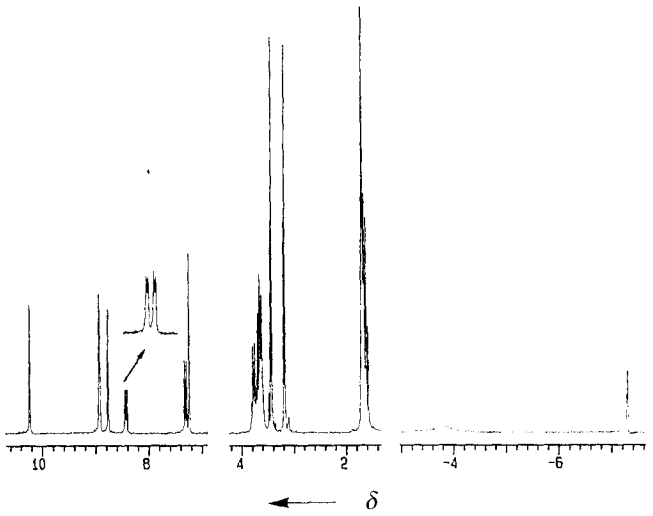

Fig. 2. 300 MHz ^1H NMR NMR spectrum of oxybenziporphyrin **3** in $CDCl_3$.

This study demonstrates a new approach to the synthesis of modified porphyrin-like chromophores, and application of this strategy should allow access to a number of other related aromatic systems including pyridine-containing macrocycles[10, 11] and expanded porphyrin systems. These possibilities are currently under investigation.

Experimental Procedure

Oxybenziporphyrin **3**: Tripyrranedicarboxylic acid (**4**) (200 mg) was stirred with trifluoroacetic acid (2 mL) under an atmosphere of nitrogen for 10 min. Dichloromethane (38 mL) was added, followed immediately by 5-formylsalicylaldehyde (66 mg), and the mixture was stirred under nitrogen for a further 2 h. The mixture was neutralized by the dropwise addition of triethylamine, DDQ (102 mg) was added, and the resulting solution was stirred for an additional 1 h. The mixture was washed with water and chromatographed on alumina (Grade 3) by eluting first with dichloromethane and then with chloroform. A deep green fraction was collected and recrystallized from chloroform/methanol to give the porphyrin analog (73 mg; 35%) as bright purple microneedles. Selected physical and spectroscopic data for **3**: m.p. 261–262 °C (decomp.); UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 426 (5.05), 452 (4.89), 507 (3.62), 547 (3.93), 588 (4.39), 635 (3.89), 698 nm (3.70); IR (KBr): $\tilde{\nu}$ = 3030, 2961, 2929, 2867, 1624, 1593, 1560, 1553, 1522, 1498, 1464, 1450, 1420, 1376, 1364, 1348, 1315, 1272, 1252, 1226, 1187, 1162, 1154, 1116, 1095, 1057, 1015, 976, 949, 876, 851, 828, 805, 768, 739, 681, 660, 620, 591, 560, 546, 517, 472 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$): δ = −7.17 (1H, d, J = 2 Hz, 22H), −3.8 (2H, br, 2 × NH), 1.61–1.73 (12H, 4 overlapping triplets, 4 × CH_2CH_3), 3.29 (3H, s), 3.65 (3H, s) (8,19-CH_3), 3.62-3.81 (8H, 4 overlapping quartets, 4 × CH_2CH_3), 7.35 (1H, d, J = 9 Hz, 3-H), 8.49 (1H, dd, ^3J = 9 Hz, ^4J = 2 Hz, 4-H), 8.85 (1H, s), 8.98 (1H, s), 8.99 (1H, s) (6,11,16-H), 10.29 (1H, s, 21-H); ^{13}C NMR ($CDCl_3$): δ = 11.39, 11.85, 17.08, 17.17, 18.25, 18.32, 19.31, 19.41, 19.74, 93.29, 94.92, 105.66, 111.07, 112.27, 121.35, 126.08, 130.15, 131.61, 134.14, 135.31, 136.28, 137.12, 137.90, 138.07, 140.07, 144.54, 145.07, 147.09, 154.64, 156.17, 187.94; MS (70 eV): *m/z* (%): 477 (100) [M^+], 462 (19) [$M^+ - CH_3$]; HR-MS: calculated for $C_{32}H_{35}N_3O$: *m/z* 477.2782; found: 477.2774. A Dinuclear (μ-Carboxylato)manganese(II) Complex Derived from a Macrocyclic Ligand: A Structural Model for Active Sites in Natural Systems**

Harry Adams, Neil A. Bailey, Noele Debaecker, David E. Fenton,* Wakako Kanda, Jean-Marc Latour,* Hisashi Okawa, and Hiroshi Sakiyama

Active sites containing two manganese atoms have been implicated recently in a growing number of proteins with various redox or hydrolytic functions; representative examples are the catalases (H_2O_2 disproportionation),[1] arginase (L-arginine hydrolysis),[2] and the xylose isomerases (isomerization of β-hydroxyaldehydes to β-oxoalcohols such as glucose to fructose).[3]

D-Xylose isomerase catalyzes the isomerization of the aldose xylose to the ketose xylulose as the second step in the utilization of D-(+)-xylose as a food source by bacteria.[3a] Two metals (Mg^{II}, Mn^{II}, or Co^{II}) are required at the active site.[3b] The general features of this metal-containing active site are clearly shown in the structure of the D-xylose isomerase from *Arthrobacterr* strain B3728 (Fig. 1).[3d] One manganese atom is

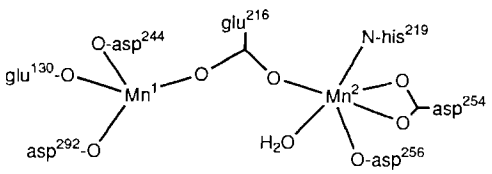

Fig. 1. The metal-containing binding site of D-xylose isomerase from *Arthrobacterr* strain B3728.

octahedrally coordinated and the second is four-coordinate; this second manganese atoms has two vacant sites that can be occupied by water molecules or by the incoming substrate. The manganese atoms are linked by a single bridging glutamate residue.

Two other structures have been solved for D-xylose isomerases. The metal-containing binding site in the enzyme from *Actinoplanes missouriensi*, with Mg^{II}, Co^{II}, or Mn^{II} as the metal, is very similar to that shown in Figure 1.[3e] The dinuclear site in D-xylose isomerase from *Streptomyces rubiginosus* also has a single glutamato bridge, this time between two manganese atoms separated by 4.9 Å.[3f] The two manganese atoms are both six-coordinate: Mn^1 binds to Glu217, Glu181, Asp245, Asp282, and two water molecules, whereas Mn^2 binds to Glu217, Asp255, Asp257, His220 (twice), and one water molecule.

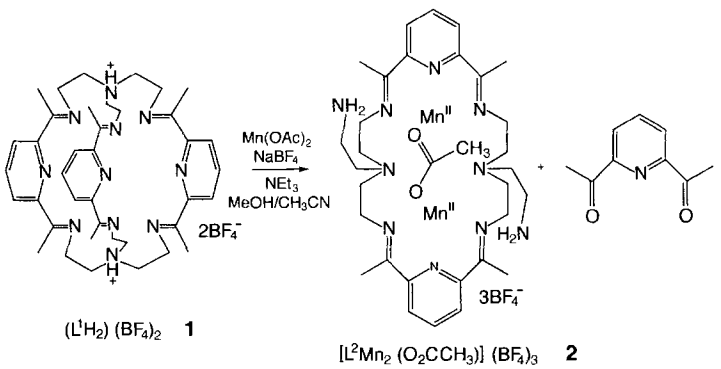
A common feature of these sites is the single bridging glutamate residue; to our knowledge this mode of single carboxylato bridging has not previously been simulated in model studies. Herein we report the isolation and characterization of a dinuclear manganese(II) complex containing only a single carboxylato bridge. This complex can be viewed, through its structural and physicochemical parameters, as providing a model for the occurrence of such a species at the metal-containing site in D-xylose isomerase.

Reaction of the diprotonated Schiff base cryptate $(L^1H_2)(BF_4)_2$ (**1**)[4] with manganese(II) acetate in methanol/acetonitrile (1:1), to which sodium tetrafluoroborate and triethylamine have been added, leads to complex **2**.[9] Recrystallization from acetonitrile/ethanol gives orange crystals of $2 \cdot CH_3CN \cdot 0.5CH_3CH_2OH$.



$(L^1H_2)(BF_4)_2$ **1**

$[L^2Mn_2(O_2CCH_3)](BF_4)_3$ **2**

The X-ray crystal structure (Fig. 2) confirms that a single ring-opening of the Schiff base cryptand has occurred to yield a carboxylato-bridged dinuclear manganese(II) complex of the bibracchial tetraimine Schiff base macrocycle L^2.[6] The macrocyclic trication accommodates two manganese(II) atoms, each of which is coordinated to five nitrogen atoms—three from a pyridine dicarbimine head unit, one from a tertiary amino group, and one from the pendant aminoethane residue. The two manganese atoms are thus located at opposite ends of the 24-membered macrocycle which has a semiopen, concertina-like conformation. The metal–metal separation of 4.82 Å may be compared with that of 4.9 Å found in the D-xylose isomerase from *Streptomyces rubiginosus*.[3f] The metal atoms in **2** are singly bridged in an unusual *syn-anti* manner by an acetato ligand. This is a relatively rare bridging bonding mode for the anion and leads to a greater metal–metal distance than that in other carboxylato-bridged dimetallic centers. This was previously noted in two structures containing dinuclear Mn^{II} centers bridged by two *syn-anti* carboxylates, $[Mn_2(OAc)_2(bpy)_4](ClO_4)_2$[7] and $[Mn_2(OAc)_2(bpen)_2](ClO_4)_2$ (bpen = *N,N'*-dimethyl-*N,N'*-bis(2-pyridylmethyl)ethane-1,2-diamine).[8] The metal separations in these two complexes are 4.58 and 4.29 Å respectively. More generally, dinuclear acetato-bridged species have been synthesized in which a single M-O-M bridge is also present.[9] This leads to a *syn-syn* bridging mode for the acetato ligand and a metal separation of roughly 3.5 Å. The absence of the one-atom bridge appears to lift any steric constraints imposing a *syn-syn* bridge and allows the achievement of the sterically less demanding *syn-anti* configuration. The Mn–Mn separation of 4.82 Å in **2** may also be contrasted with that of 5.6 Å found in a dinuclear Mn^{III} complex derived from salen and bearing a single bridging carboxylate anion.[10]

Figure 3 illustrates the dependence of the molar magnetic susceptibility of complex **2** with $1/T$ at two extreme fields (0.5 and 5 Tesla).[11] The curves follow linear Curie behavior only at temperatures above 10 K, which indicates the presence of a

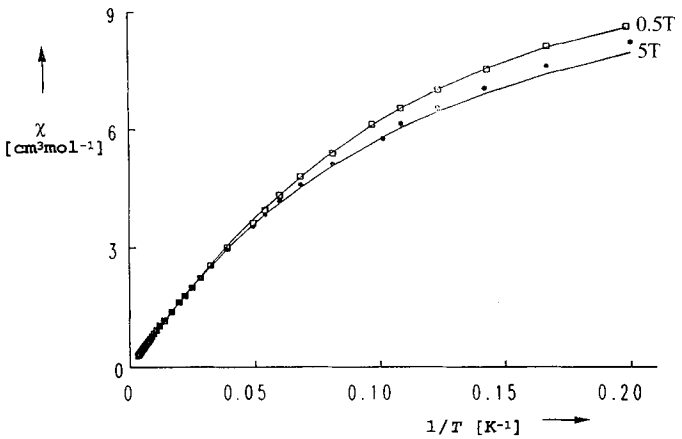


Fig. 3. Dependence of the magnetic susceptibility of **2** on the inverse temperature at two extreme field strengths; the solid lines correspond to calculated values.

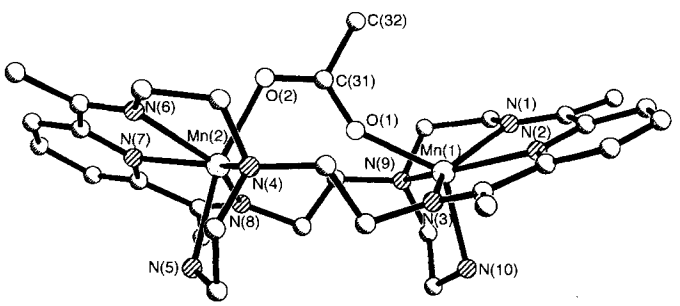

Fig. 2. The crystal structure of the cation in **2**. Selected bond lengths [Å]: Mn(1)-Mn(2) 4.82, Mn(1)-O(1) 2.10, Mn(1)-N(1) 2.29, Mn(1)-N(2) 2.26, Mn(1)-N(3) 2.35, Mn(1)-N(9) 2.47, Mn(1)-N(10) 2.54, Mn(2)-O(2) 2.16, Mn(2)-N(4) 2.40, Mn(2)-N(5) 2.28, Mn(2)-N(6) 2.30, Mn(2)-N(7) 2.28, Mn(2)-N(8) 2.36. Selected bond angles [°]: Mn(1)-O(1)-C(31) 145.7, Mn(2)-O(2)-C(31) 116.2, O(1)-C(31)-O(2) 122.1, O(2)-C(31)-C(32) 117.5, O(1)-C(31)-C(32) 120.3.

small exchange interaction. A slight field dependence at low temperature is evident, which points to the occurrence of some zero-field effects, albeit small. This behavior is clearly consistent with the simultaneous occurrence of a small exchange interaction and a small zero-field effect. These data were fitted with a Hamiltonian operator,[12] taking into account both the exchange coupling (J) and the anisotropic Zeeman interaction (zero-field splitting parameters D and E) of two identical ions of spin 5/2. The solid lines in the figures correspond to the theoretical values obtained with the following best fit parameters: $g_x = 2.07$, $g_y = 1.96$, $g_z = 2.02$, $J = -0.37\ cm^{-1}$. Approximations of comparable quality were obtained with $-0.1\ cm^{-1} < D < 0.1\ cm^{-1}$, and $E \neq 0$. Therefore while the exchange integral J is determined with good accuracy, the zero-field splittings cannot be estimated properly. This is not too astonishing since D values estimated through EPR experiments amount to a few hundredths of wavenumbers. Attention is drawn to the weakness of the antiferromagnetic exchange interaction mediated by the single bridging acetate group.

Figure 4 shows two EPR spectra of **2**. The spectrum measured at 4 K in a toluene/acetonitrile glass[13] consists of a broad line centered at $g = 1.96$ flanked by several features both at lower and higher fields. As described by Khangulov et al.,[14] such

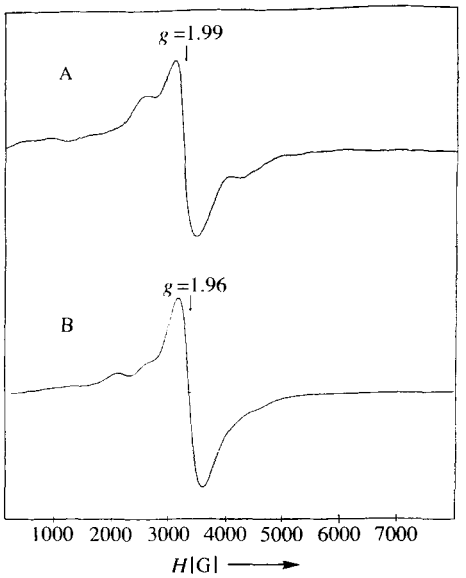

Fig. 4. X-Band EPR spectra of **2** in the solid state (A) and in a toluene/acetonitrile (1:1) glass (B) at 4 K. Operating conditions: microwave power 0.5 mW, modulation amplitude 1 G, gain 5000 (A) and 2000 (B), time constant 0.128 s.

spectra are very common for weakly coupled manganese(II) derivatives and correspond to the superposition of spectra of the various excited spin states ($s = 1-5$) of the manganese(II) pair modulated by a Boltzmann distribution. In the case of dimanganoproteins and complexes with exchange interactions of several wavenumbers, only the first excited state dominates with some contribution from the second. In the present case, however, owing to the very small exchange coupling ($J = -0.37\ cm^{-1}$), the situation is more complicated since more states are likely to be contributing, as shown by their respective populations p ($s = 0$, $p = 0.3989$; $s = 1$, $p = 0.3057$; $s = 2$, $p = 0.1795$; $s = 3$, $p = 0.0808$; $s = 4$, $p = 0.0278$; $s = 5$, $p = 0.0073$). Nevertheless, contributions from the first and second excited states can be clearly identified in the spectrum. It is noteworthy that the solution-state spectrum (Fig. 4B) is quite similar to that of the polycrystalline sample (Fig. 4A). This finding is a strong indication that the complex retains the acetato bridge in solution. It is therefore concluded that complex **2** can be viewed as a structural model for the metal-containing active site in D-xylose isomerase.

[5] Microanalytical data: calcd for $2 \cdot CH_3CN \cdot 0.5CH_3CH_2OH$: C 40.41, H 5.33, N 14.81%; found: C 40.49, H 5.36, N 14.83%. The fast atom bombardment mass spectrum has a peak of highest mass at m/z 889, which corresponds to $[L^2Mn_2(O_2CCH_3)(BF_4)_2]^+$, indicating that a ring-opening has occurred; there are further peaks at m/z 821 $[L^2Mn_2(O_2CCH_3)(BF_4)F]^+$, 802 $[L^2Mn_2(O_2CCH_3)(BF_4)]^+$, and 734 $[L^2Mn_2(O_2CCH_3)F)]^+$. No peaks are observed that can be assigned to a species retaining the intact Schiff base cryptand.

[6] Crystal structure data for $2 \cdot CH_3CN \cdot 0.5CH_3CH_2OH$ (empirical formula: $C_{35}H_{55}B_3F_{12}Mn_2N_{11}O_{2.5}$; $M = 1040.2$, orange blocks from acetonitrile/ethanol; crystal dimensions $0.60 \times 0.40 \times 0.2$ mm): monoclinic, $a = 11.883(14)$, $b = 15.731(8)$, $c = 26.148(13)$ Å, $\beta = 101.90(7)^\circ$, $V = 4783(7)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.455\ g\,cm^{-3}$, space group $P2_1/n$ (a nonstandard setting of $P2_1/c$ (C_{2h}^5, No.14), $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), $\mu(Mo_{K\alpha}) = 0.620\ mm^{-1}$, $F(000) = 2140$. Reflections were collected in the range $3.5 < 2\theta < 45$ on a Nicolet R3 diffractometer by the ω-scan method. The 3601 independent reflections (of 6649 measured) for which $|F|/\sigma(|F|) > 3.0$ were corrected for Lorentz and polarization effects, and for absorption (minimum and maximum transmission coefficients 0.568, 0.622). The structure was solved by direct methods and refined by blocked cascade least squares methods. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final $R = 0.0817$ ($Rw = 0.0795$, 580 parameters, mean and maximum δ/σ 0.004, 0.039), with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density -0.49 and $0.62\ e\,Å^{-3}$. The weighting scheme $w^{-1} = \sigma^2(F) + 0.00156F^2$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL/PC [15] as implemented on the Viglen 486dx computer. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB2 1EZ (UK), on quoting the full journal citation.

[11] Multifield saturation magnetization data were collected on crystals of the complex using a Quantum Design MPMS squid magnetometer. Measurements were performed in the 5–300 K temperature range at six field strengths (0.5, 1, 2, 3, 4, 5 Tesla). The magnetization of the sample holder (kel F bucket) was measured at the same temperatures and field strengths and subtracted from the sample measurements. The diamagnetic correction was estimated from Pascals constants.

[12] The Hamiltonian operator is given in Equation (a) and $\mathcal{H}_{iz}$ is defined in Equation (b). J is the isotropic exchange interaction and D and E are the axial

$$\mathcal{H} = -2JS_1S_2 + \sum_{i=1,2}[D(S_{iz}^2 - 2) + E_i(S_{ix}^2 - S_{iy}^2)] + \mathcal{H}_{iz} \quad \text{(a)}$$

$$\mathcal{H}_{iz} = \mu_B(g_xH_xS_{ix} + g_yH_yS_{iy} + g_zH_zS_{iz}) \quad \text{(b)}$$

and rhombic parameters of the zero-field splitting tensors. In agreement with the structural data, the two metal sites are assumed to be identical. The usual hypothesis is made that for each ion the zero-field splitting and g tensors can be diagonalized simultaneously.

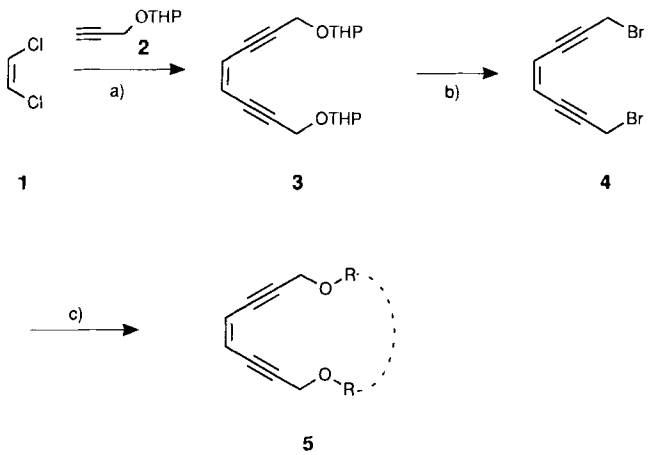
[13] EPR spectra were measured in the range 4–20 K on a Varian E9 spectrometer operating at 9.2 GHz equipped with an Oxford cryostat.

Activation of Macrocyclic Biaryl-Enediynes by Metal Ion Coordination**

Burkhard König,* Helli Hollnagel, Birte Ahrens, and Peter G. Jones

Aromatic diradicals have been identified as the active species in several natural products with antitumor activity. The cytotoxic action is explained as being caused by hydrogen abstraction from DNA by the radical, leading to strand cleavage and cell death.[1] The reactive intermediates are formed by the cyclization of enediynes or enynallenes to arene diradicals. Pharmaceutical applications of these highly cytotoxic compounds depend on a selective trigger mechanism for radical formation. Several mechanisms have been investigated for triggering the activation of designed or natural prodrugs, including bioreduction and activation by light, bases, metal ions, or nucleophiles.[2] Conformational changes in the prodrug that increase the strain of the unsaturated cycle or lower the energy of the transition state for the cyclization can cause activation at the molecular level.[3] We describe here the synthesis of functionalized macrocyclic enediynes and the modulation of their chemical reactivity by metal ion coordination.

Compound **4** is a versatile building block in the synthesis of functionalized acyclic and cyclic enediynes by nucleophilic displacement of the bromine substituents. The basicity of the nucleophile is important in this process. Strong bases induce the formation of unstable enynallenes by propargyl–allene tautomerization.[4] The (*Z*) configuration of **4** favors the formation of cyclic compounds with suitable bisnucleophiles. High-dilution conditions are therefore not necessary to obtain the cyclic enediynes **5a–d** (Scheme 1, Table 1, Table 2). Palladium-catalyzed coupling[5] of (*Z*)-1,2-dichloroethene (**1**) with **2**, followed by OTHP/bromine[6] exchange (THP = tetrahydropyranyl) with PPh_3/Br_2 provides **4** in multigram quantities.



Scheme 1. Synthesis of the macrocyclic enediynes **5a–d**. a) 2 mol% $[Pd(PPh_3)_4]$, 15 mol% CuI, $nBuNH_2$, benzene, 12 h room temperature, 75%; b) PPh_3, Br_2, dichloromethane, 6 h room temperature, 77%; c) dimethylsulfoxide, ROH, KOH (for **5d**: K_2CO_3), room temperature, 8 h.

[a] ^1H NMR: 400 MHz, $CDCl_3$, TMS; ^{13}C NMR: 100 MHz, $CDCl_3$; the multiplicity of the ^{13}C NMR signals was determined by DEPT experiments and denoted as (+) for CH_3 and CH groups, (−) for CH_2 groups, and C_q for quarternary carbons.

Figure 1 shows the X-ray structure[7] of the 16-membered macrocyclic enediyne ester **5a**. The phenyl rings subtend an interplanar angle of 68°, while the carbon atoms of the enediyne moiety are almost coplanar (mean deviation 2.5 pm). Enantiomeric conformers of the molecule, which displays crystallographic twofold symmetry, are packed alternatingly in the crystal lattice.

The thermal stability of the cyclic enediynes **5a–d** was investigated by differential scanning calorimetry (DSC).[8] The DSC

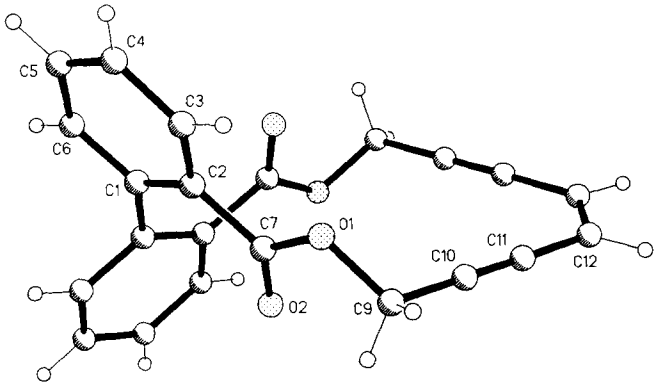

Fig. 1. X-ray crystal structure of **5a**. Selected bond lengths [pm] and angles [°]: C12-C12A 133.5(3), C10-C11 119.2(2), C1-C1A 149.6(2), C10-C10A 432.1(3), C11-C11A 294.2(3); C10-C11-C12 178.1(2), C12A-C12-C11 124.36(8), interplanar angle of the biaryl unit 68 .

trace of **5a** (Fig. 2) clearly indicates an exothermic, irreversible reaction at 445 K.[9] The 2,2′-bipyridine macrocycle **5c** shows an exothermic reaction at approximately 510 K.[9] The coordination of the 2,2′-bipyridine moiety by transition metal ions[10]

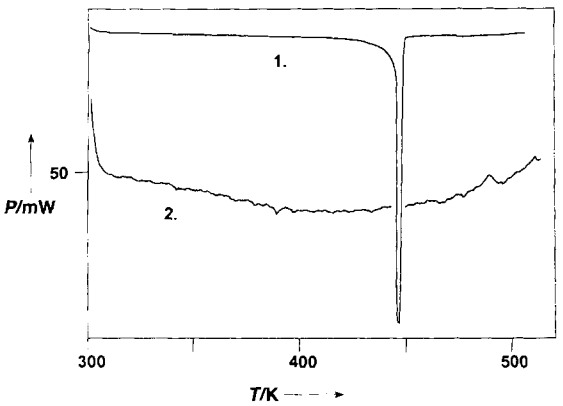

Fig. 2. DSC analysis of **5a**. The power input P (endothermic process) is plotted against the temperature T. Scan rate 10 K min^{-1}; 1. first heating cycle; 2. second heating cycle.

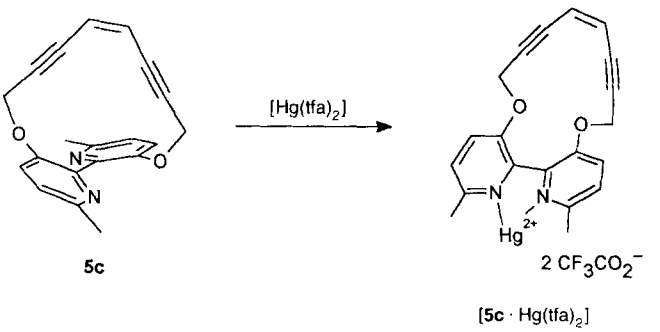
alters the conformation of the macrocycle. Without metal ion coordination, the less strained *transoid* orientation of the 2,2′-bipyridine should be favored, according to force field calculations (Scheme 2).[11] When $[Hg(tfa)_2]$ (tfa = O_2CCF_3) is added to a suspension of **5c** in methanol, a clear solution is formed instantaneously and significant changes in the ^{1}H NMR spectra indicate metal coordination. The preserved symmetry of the



Scheme 2. Coordination of **5c** by $[Hg(CF_3CO_2)_2]$.

compound suggests that both nitrogen atoms are coordinated symmetrically. However, the metal ion must induce a change in the conformation of the 2,2′-bipyridine unit to a predominantly *cisoid* orientation for complex formation. In this conformation the macrocyclic enediyne is more strained,[11] which is reflected in a decrease of the cyclization temperature to 418 K as shown by DSC.[9] When a suitable 2,2′-bipyridine binding site for strong coordination of a metal is not available, the cyclization temperature is not affected by addition of $[Hg(tfa)_2]$. In DSC analyses mixtures of **5a** and $[Hg(tfa)_2]$ show the exothermic reaction at the same temperature as pure **5a**.[12]

In contrast to the results discussed here, a rigid conformation can stabilize an enediyne moiety against thermally induced cyclization. No exothermic reaction is observed when the compound **5d** is heated to 530 K.

Although elevated temperatures are still necessary to trigger the cyclization of the macrocycles **5a–d**, their reactivity can be significantly altered by noncovalent interactions that influence their conformation. The use of even more strained bicyclic enediynes[13] might lead to the development of compounds that can be selectively triggered by a chemical signal at room temperature.

Experimental Procedure

General procedure for the reaction of **4** with nucleophiles: Macrocycle **4** (262 mg, 1.0 mmol) was dissolved in 2 mL of DMSO and added to a solution of 2.0 mmol of the nucleophile (or 1.0 mmol of the bisnucleophile) and 4 mmol of KOH in 30 mL of DMSO at room temperature. The reaction mixture was stirred for 6 h, poured into 100 mL of saturated aqueous NH_4Cl, and extracted with dichloromethane. The organic phase was dried over $MgSO_4$ and concentrated in vacuo; the products were purified by column chromatography on silica gel.

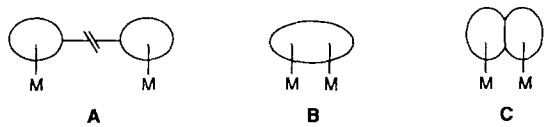
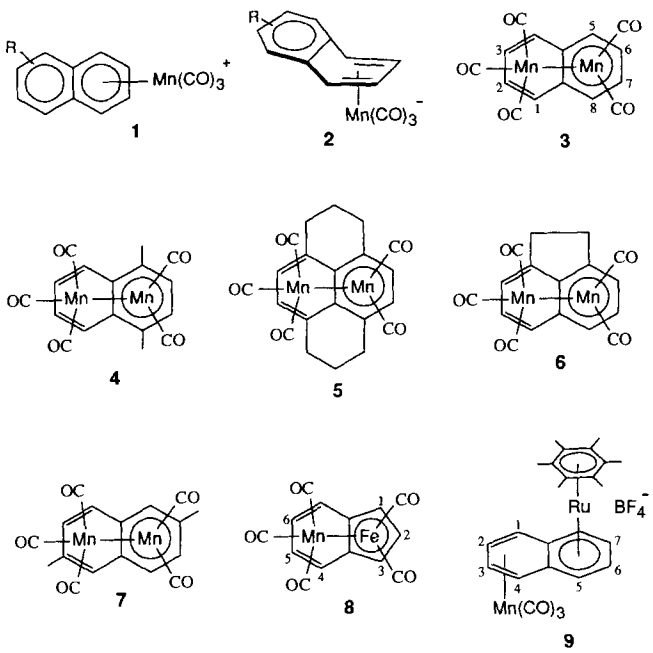
Synthesis and Structure of Bimetallic η^4,η^6-Naphthalene Complexes Containing a Mn–Mn Moiety Bonded in a *syn*-Facial Manner: A General Route to Homo- and Heteronuclear Bimetallic Complexes of Polyarenes**

Shouheng Sun, Conor A. Dullaghan, Gene B. Carpenter, Anne L. Rieger, Philip H. Rieger, and Dwight A. Sweigart*

Bimetallic organometallic complexes have long been investigated in order to probe the effect of electron delocalization and metal–metal interactions on physical properties such as charge transfer, conductivity, and nonlinear optical behavior. Equally interesting has been the chemical application of bimetallic systems to stoichiometric and catalytic reactions. There are three common types of bimetallic complexes. In type **A** complexes the metals are coordinated to separate π-hydrocarbon rings, which are attached directly to each other or are separated by a spacer.[1] The metals may have a *syn*-facial or *anti*-facial arrangement; in the former case there is sometimes a direct metal–metal interaction, whereas in the latter any such interaction is necessarily indirect through the ligand system. In type **B** complexes two metals are bound (*syn* or *anti*) to the same π-hydrocarbon ring,[2] and in type **C** systems the metals are bound to adjacent fused rings. Examples of type **C** systems include complexes with pentalene, azulene, indenyl, and naphthalene-type ligands;[3–6] most of the known examples contain indenyl ligands.[4] By comparison, bimetallic complexes with naphthalene-type ligands are rare and those known[5] have the metals in an *anti*-facial conformation.[7] In this paper we outline a general synthetic route to homo- and heteronuclear bimetallic naphthalene complexes that usually, but not always, yields products with a *syn*-facial arrangement of metal atoms and a metal–metal bond. Furthermore, it is demonstrated that the procedure can be extended to fused ring systems other than naphthalenes.



We recently reported[8] that $[Mn(\eta^6\text{-polyarene})(CO)_3]^+$ complexes such as **1** function as efficient manganese tricarbonyl transfer (MTT) reagents by rapidly and cleanly transferring the $[Mn(CO)_3]^+$ moiety to other arenes upon warming in dichloromethane. The facility of the MTT reaction was shown to correlate with the ease of $\eta^6 \rightarrow \eta^4$ ring slippage in **1**, which accompanies associative nucleophilic attack at the metal. In a similar vein, we find that two-electron chemical or electrochemical reduction of **1** (R = H, 1,4-Me_2, 2,6-Me_2) reversibly generates the anionic 18-electron η^4-diene complex **2**.[9, 10] The diene complex **2** with R = H was previously prepared by an alternative route and structurally characterized.[11] However, when only one equivalent of reducing agent (cobaltocene) is present, complexes **1** react not to give the η^4-diene complex, but rather the novel deeply colored ("black") bimetallic species shown in structures **3**–**7**. That the compounds **3**–**5** contain two *syn*-facial metal atoms was confirmed by single-crystal X-ray structure analyses. Figure 1 shows the structure of **3**; details of the structures of **4** and **5** will be published separately.[12] When the naphthalene ligand in **1** is the relatively rigid hexahydropyrene or acenaphthene, it was found that the bimetallic products **5** and **6**, respectively, are formed in good yield even when excess cobaltocene is used. It is likely that this is due to a structurally imposed barrier that inhibits slippage to the η^4-diene complex, which is a conclusion supported by electrochemical experiments.[9]



Complex **3** has a Mn–Mn bond length of 2.9231(7) Å, a value close to that in $[Mn_2(CO)_{10}]$.[13] The dihedral angle between

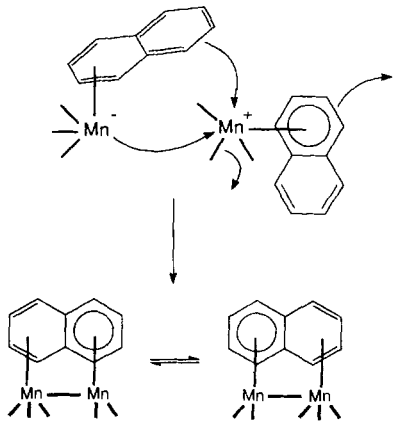
Fig. 1. Crystal structures of complexes **3**, **8**, and **9** (BF_4^- ion omitted for clarity). Selected bond lengths [Å] for **3**: Mn(1)-Mn(2) 2.9231(7), Mn(2)-C(1) 2.240(3), Mn(2)-C(2) 2.143(3), Mn(2)-C(3) 2.147(3), Mn(2)-C(4) 2.246(3), Mn(1)-C(5) 2.164(3), Mn(1)-C(6) 2.119(4), Mn(1)-C(7) 2.116(3), Mn(1)-C(8) 2.164(3), Mn(1)-C(9) 2.168(3), Mn(1)-C(10) 2.154(3); for **8**: Mn-Fe 2.8270(7), Mn-C(4) 2.267(3), Mn-C(5) 2.145(3), Mn-C(6) 2.150(3), Mn-C(7) 2.268(3), Fe-C(1) 2.085(3), Fe-C(2) 2.077(4), Fe-C(3) 2.103(4), Fe-C(8) 2.106(3), Fe-C(9) 2.117(3); for **9**: Mn-C(1) 2.183(6), Mn-C(2) 2.081(6), Mn-C(3) 2.104(6), Mn-C(4) 2.226(6), Ru-C(5) 2.230(6), Ru-C(6) 2.167(6), Ru-C(7) 2.179(6), Ru-C(8) 2.214(6), Ru-C(9) 2.412(5), Ru-C(10) 2.452(5).

planes C1-C2-C3-C4 and C1-C9-C10-C4 is 16.6°, which is considerably less than the values found in **2**[11] and other[14] monometallic η^4-naphthalene-type complexes. The obvious reason for this difference is the presence of the second metal, which is simultaneously η^6-bonded to the second naphthalene ring and bonded to the other metal atom. As far as we are aware, **3** is the first example of a bimetallic η^4,η^6-naphthalene complex with *syn*-facially bound metal atoms.

The pure dimanganese complexes **3**–**7** are moderately stable as solids and in solution. The IR spectra are simple and give no evidence for bridging CO ligands in solution. The ^{1}H NMR spectra between ambient temperature and −80 °C indicate that the environments of the manganese atoms in **3** and **5**–**7** are identical on the NMR timescale. For example, the four protons $H^{2,3}$ and $H^{6,7}$ in **3** give a single resonance as do the two methyl groups in **7**, suggesting very rapid $\eta^4,\eta^6 \rightarrow \eta^6,\eta^4$ interconversion (Scheme 1). This transformation probably occurs through an



Scheme 1. Possible mechanism for the formation of *syn*-facial bimetallic complexes of naphthalenes.

intermediate with a bridging CO ligand. Voltammetric oxidation of **3**–**7** in CH_2Cl_2/TBAPF$_6$ (TBA = tetra-*n*-butylammonium) occurs as a one-electron, partially chemically reversible process (scan rate: 0.5 Vs^{-1}) at $E_{1/2} = 0.45$ V relative to ferrocene ($E_{1/2} = 0.50$ V). The intense color of **3**–**7** and the rather low redox potential suggests that the HOMO is essentially Mn–Mn σ-bonding. This was confirmed by measuring the ESR spectrum of $\mathbf{5}^+$ at 110 K in CH_2Cl_2/1,2-$C_2H_4Cl_2$. The spectrum consists of a broad envelope with eight resolved features at lower and higher fields; these are the outer members of the 1:2:3:4:5:6:5:4:3:2:1 multiplet expected for two *equivalent* ^{55}Mn nuclei ($I = 5/2$) and correspond to $g_1 = 2.067$, $A_1^{Mn} = 57.0 \times 10^{-4}$ cm^{-1}. The other two g components are approximately 2.0 and 2.1, but these have much smaller manganese couplings. Assuming that each Mn atom contributes a 3d orbital to the SOMO, the dipolar contribution to the coupling matrix is $A_{\parallel} = (4/7)P\rho^d$ where $P = 205 \times 10^{-4}$ cm^{-1}.[15] Since the two missing hyperfine components are small, $\langle A \rangle \approx A_{\parallel}/3$ and $\rho^d \approx 0.3$, and hence we may conclude that the HOMO is largely metal-based.

The mechanism of formation of **3**–**7** when a reducing agent is added to **1** probably involves initial formation of some η^4-diene anion **2**, which attacks remaining cation **1**. Scheme 1 shows a plausible pathway (for R = H), and in accordance with this, the addition of a solution of the η^4-diene to a separate solution of **1** (R = H) gave the bimetallic complex **3**. This scheme suggests that heteronuclear bimetallic complexes may be formed by the reaction of **1** with appropriate metal complexes that possess ambident nucleophilic behavior. In this manner, complex **8** was prepared from the reduction of a mixture of [Fe(indenyl)$(CO)_3$]$^+$ and **1**. Figure 1 shows the structure of **8**, which is a bimetallic complex with η^4,η^5-bonding. The dihedral angle between planes C4-C5-C6-C7 and C4-C9-C8-C7 is 18.1°, and the Mn–Fe bond length is 2.8270(7) Å. In a related experiment, the reaction of the nucleophilic complex [(η^4-naphthalene)-Ru(C_6Me_6)] with **1** (R = H) was found to give the bimetallic complex **9**, which is prevented for steric reasons from forming a Ru–Mn bond (Fig. 1). In this case the C1-C2-C3-C4 plane is folded about the C1-C9-C10-C4 plane by 22.9°.

In conclusion, we have shown that the ability of **1** to function as a facile manganese tricarbonyl transfer reagent provides a general synthetic route to homo- and heteronuclear bimetallic complexes of fused ring systems which, in the absence of steric constraints, adopt a *syn*-facial structure. Herein we have described homocyclic fused ring systems; preliminary results with the η^6-manganese tricarbonyl complexes of the fused ring hete-

rocycles *N*-methylindole and benzothiophene indicate that cobaltocene reduction also leads to bimetallic complexes in these cases.[16] The usefulness of the new bimetallic complexes in promoting/catalyzing chemical reactions is currently under investigation.

Experimental Procedure

3–**7**: Cobaltocene (0.2 mmol) was added to the appropriate manganese complex **1** (0.2 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred under N_2 for 15 min and then chromatographed rapidly through a short column of deactivated neutral alumina with CH_2Cl_2 as the eluent. After solvent removal, the dark solid was washed with pentane and dried. Analytical and spectroscopic data showed the product to be pure. **3**: yield 40%; m. p. 74 °C; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 2008(s), 1941(s), 1885(w); ^1H NMR (CD_2Cl_2): δ = 5.27 ($H^{2,3,6,7}$), 4.05 ($H^{1,4,5,8}$). **4**: yield 55%; m. p. 88 °C; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 2004(s), 1937(s), 1875(w); ^1H NMR (CD_2Cl_2): δ = 5.43 ($H^{2,3}$), 5.20 ($H^{6,7}$), 4.06 ($H^{1,4}$), 1.77 (Me). **5**: yield 60%; m. p. 128 °C; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 1996(s), 1935(s), 1869(w); ^1H NMR (CD_2Cl_2): δ = 5.18 ($H^{2,3,6,7}$), 1.80–2.55 (H^{9-14}). **6**: yield 43%; m. p. 112 °C; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 2002(s), 1935(s), 1877(w); ^1H NMR (CD_2Cl_2): δ = 3.93 ($H^{2,3,6,7}$), 3.40 ($H^{1,8}$), 2.60–2.90 ($H^{9,10}$). **7**: yield 31%; m. p. 90 °C; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 2004(s), 1935(s), 1877(w); ^1H NMR (CD_2Cl_2): δ = 5.24 ($H^{3,7}$), 3.95 ($H^{1,4,5,8}$), 2.26 (Me). Complexes **3** and **7** were also synthesized by an alternative method: cobaltocene (0.2 mmol) and **1** (0.1 mmol, R = H) were combined in CH_2Cl_2 (10 mL) and stirred under N_2 for 10 min. To this solution of the anion **2** (R = H), the cationic complex **1** (0.1 mol, R = H or 2,6-Me_2) was added. After stirring for 20 min, the reaction mixture was chromatographed as above. High-quality single crystals of **3**–**7** were readily grown by pentane diffusion into a solution of the respective compound CH_2Cl_2 at −20 °C.

8: Cobaltocene (0.42 mmol) was added to a mixture of [Mn(1-methylnaphthalene)$(CO)_3$]BF_4 (0.21 mmol) and [Fe(indenyl)$(CO)_3$]BF_4 (0.21 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred under N_2 for 10 min, during which CO evolution was evident. Workup was as described above for **3**–**7**. Yield 72%; IR (CH_2Cl_2): ν_{CO} [cm^{-1}] = 2018(s), 1956(s, br); ^1H NMR (CD_2Cl_2): δ = 5.49 (dd, $H^{4,7}$), 5.09 (t, H^2), 4.34 (dd, $H^{5,6}$), 4.12 (d, $H^{1,3}$). X-ray quality crystals of **8** were grown by slow evaporation of a hexane solution at −20 °C.

9: Cobaltocene (0.2 mmol) was added to [(naphthalene)Ru(C_6Me_6)]$(BF_4)_2$ [1f,17] (0.1 mmol) in CH_2Cl_2 (10 mL) and the mixture stirred under N_2 for 1 h. Complex **1** (0.1 mmol, R = H) was then added and the stirring continued for 3 h. After most of the solvent had been removed, purification was effected by chromatography on deactivated neutral alumina by first eluting with CH_2Cl_2 to remove any neutral Mn–Mn complex and then CH_2Cl_2/acetone (2:1) to elute the product. Solvent removal gave **9** as a dark red solid. Yield 51%; IR (KCl): ν_{CO} [cm^{-1}] = 1985(s), 1920(s), 1886(s); ^1H NMR (CD_2Cl_2): δ = 5.90 ($H^{6,7}$), 5.74 ($H^{5,8}$), 3.47 ($H^{2,3}$), 3.14 ($H^{1,4}$), 2.16 (Me). Diffusion of diethyl ether into a solution of **9** in acetone at −20 °C afforded crystals suitable for X-ray diffraction.

Commensurate Freezing of *n*-Alkanes in Silicalite**

Willy J. M. van Well, Jillus P. Wolthuizen, Berend Smit, Jan H. C. van Hooff, and Rutger A. van Santen*

Computer simulations recently suggested the occurrence of a kind of phase transition in the adsorption of *n*-alkanes in zeolites.[1] The described transition occurs as commensurate freezing of certain *n*-alkanes into the zigzag channels of silicalite. It was shown that *n*-alkanes that just fit in the zigzag channels, *n*-hexane and *n*-heptane, have to be first commensurately frozen in these channels before loadings higher than approximately half the maximum loading can be reached. Due to the additional loss of entropy, an increased pressure is needed to freeze the molecules into the channels. This increase in pressure is reflected as a step in the adsorption isotherms. The transition is also found in the adsorption isotherms of *n*-hexane and *n*-heptane in silicalite measured experimentally.[2-4] In agreement with the additional loss of entropy, the occurrence of the step in the adsorption isotherms of *n*-hexane shows a temperature dependence.[2, 3, 5] We have studied the behavior of *n*-alkanes as adsorbates in silicalite by temperature programmed desorption (TPD) and herein we discuss the results obtained; furthermore *n*-alkanes that have been predicted to show commensurate freezing behavior are compared with those that do not.

The synthesis of the silicalite sample was described in reference [6]. The elemental analysis revealed a Si/Al ratio greater than 4000 and a Si/Na ratio of 529. According to X-ray diffraction, the as-synthesized sample was highly crystalline. Calcination was performed in situ in a Setaram TG-DSC 111 apparatus (in which the adsorption and desorption measurements were also performed) in a mixture of helium and air (5% O_2) at 943 K for 1 h. The liquid sorbates, ranging from *n*-pentane to *n*-decane, were obtained from Janssen Chimica (Geel, Belgium). The purity of these sorbates was 99% or higher; *n*-butane 3.5 (purity 99.95%) was obtained from Hoek Loos (Schiedam, The Netherlands).

Adsorption into silicalite was achieved at room temperature by mixing the gaseous sorbate (*n*-butane) or a helium flow saturated with the vapor of the liquid sorbate in a pure helium flow of approximately 1.8 L h^{-1}. The rate of both the *n*-butane flow and the helium flow saturated with sorbate was about 0.6 L h^{-1}. Therefore, adsorption is achieved at a relative adsorbate pressure in the helium flow of at most 0.25. Saturation was reached within a few minutes for *n*-butane, while adsorption over 24 hours was needed to saturate the sample with *n*-decane. The obtained maximum loadings of the different sorbates and the micropore volumes calculated from these maximum loadings are given in Table 1. All loadings agree very well with the maximum loadings reported in literature, indicating that the crystallinity of the sample we studied was very good. However, the loadings reported by Flanigen,[7] 1.9 mmol g^{-1} for *n*-butane and 1.5 mmol g^{-1} for *n*-hexane, were not reached.

Table 1. Maximum loadings of the *n*-alkanes on silicalite, and the micropore volume of silicalite calculated from these loadings. The micropore volume is calculated by using the density of the *n*-alkane at 20 °C relative to water at 4 °C. uc = unit cell.

n-Alkane	Maximum loading [molecule uc^{-1}]	Maximum loading [mmol g^{-1}]	Micropore volume [mL g^{-1}]
n-butane	9.3	1.8	0.16
n-pentane	8.7	1.5	0.17
n-hexane	8.1	1.4	0.18
n-heptane	7.3	1.3	0.18
n-octane	5.4	0.93	0.15
n-nonane	5.1	0.89	0.16
n-decane	5.1	0.87	0.17

Temperature programmed desorptions were performed at a heating rate of 5 K min^{-1} to a temperature of 723 K in a helium flow of 1.8 L h^{-1}. The temperature program was started immediately after the flow with sorbate was switched off. A blank run of the clean sample was subtracted from all TPD curves to correct for the temperature effect on the mass. All curves were measured on the same sample of activated silicalite with a mass of 10.39 mg.

A schematic drawing of silicalite (an all-silica zeolite) is given in Figure 1. As can be seen, it has a three-dimensional pore system consisting of intersecting straight and zigzag channels.

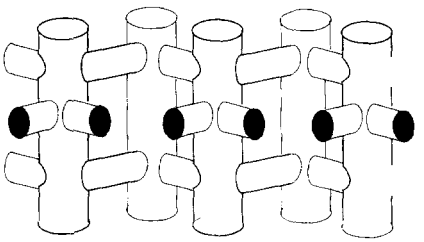

Fig. 1. Pore structure of silicalite.

In Figure 2, the TPD curves of the *n*-alkanes ranging from *n*-butane to *n*-decane are given. The differential mass loss (dm/dT) curves of *n*-pentane, *n*-hexane, *n*-heptane, and *n*-octane are

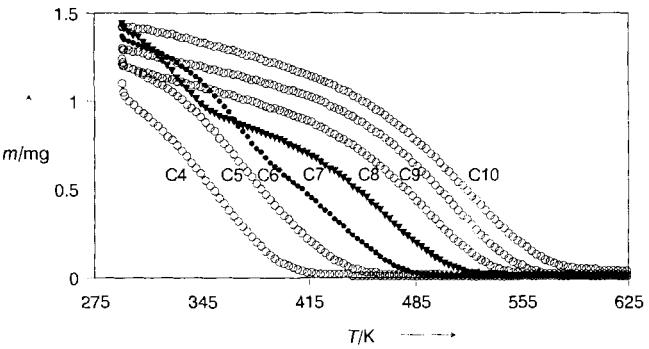

Fig. 2. Temperature programmed desorption curves of *n*-alkanes from silicalite; 10.39 mg silicalite; heating rate 5 K min^{-1}.

shown in Figure 3. For the sake of clarity in Figure 3, the differential mass curves are separated from each other. The curves of *n*-butane, *n*-nonane, and *n*-decane are similar to the curves of *n*-pentane and *n*-octane. Also for the sake of clarity, these curves are not displayed. The temperatures at which the maximum

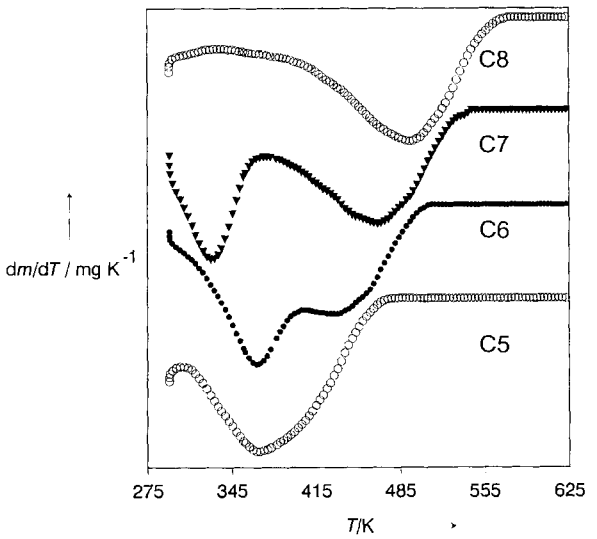

Fig. 3. Differential mass loss, dm/dT, during the TPD. The curves are separated from each other for the sake of clarity.

mass loss of the different sorbates occurred are given in Table 2. The reported results were verified by measurements on a different silicalite sample using a different heating rate (7 K min^{-1}).

Table 2. Temperatures at which the mass loss of the *n*-alkanes is at a maximum.

n-Alkane	*T* [K] of maximum mass loss	*T* [K] of maximum mass loss
n-butane	–	355
n-pentane	–	369
n-hexane	367	429
n-heptane	329	467
n-octane	–	493
n-nonane	–	512
n-decane	–	520

While *n*-butane, *n*-pentane, *n*-octane, *n*-nonane, and *n*-decane show a single desorption step, *n*-hexane and especially *n*-heptane show a two-step desorption profile. The second desorption peak of *n*-hexane and *n*-heptane, and the desorption peaks of the other *n*-alkanes occur at increasing temperatures in accordance with their increasing chain length. The first desorption peak of *n*-hexane and *n*-heptane occurs, however, at lower temperature than expected on the basis of the chain length of these two *n*-alkanes. Furthermore, it is remarkable that the first desorption step of *n*-heptane takes place at a lower temperature than that of *n*-hexane.

The results show that at high loadings some of the adsorbed *n*-hexane and *n*-heptane molecules desorb more easily from silicalite than the other *n*-alkanes. Since the first desorption step of *n*-heptane takes place before that of *n*-hexane, this first mass loss should be determined by entropic effects rather than by energetic effects. This means that the low temperature at which the first desorption peak occurs should be caused by a relative high gain in entropy upon desorption compared to the other *n*-alkanes. The relative high gain in entropy upon desorption can only be the result of a low entropy value, a constrained position of the adsorbed *n*-hexane and *n*-heptane molecules at high loadings.

The two-step desorption profile of *n*-hexane and *n*-heptane gives evidence for commensurate freezing of these two *n*-alkanes in silicalite. The commensurate freezing of some of the molecules in the zigzag channels at high loadings results in a particularly low entropy value for these molecules. Consequently, the desorption of these *n*-hexane and *n*-heptane molecules will result in a relative high gain in entropy causing the first desorption peak to occur at relatively low temperatures. Partial desorption then allows a rearrangement of the adsorbed *n*-hexane and *n*-heptane molecules, resulting in an ordering similar to the ordering of the other *n*-alkanes with a normal entropy value. The similarity in ordering is reflected in the second desorption peak of *n*-hexane and *n*-heptane and the desorption peak of the other *n*-alkanes. These peaks occur at temperatures that are in accordance with the chain length of the *n*-alkane. The occurrence of a rearrangement during the desorption of *n*-hexane and *n*-heptane is consistent with the earlier interpretation of Richards and Rees[8] of a two-step desorption of *n*-hexane from silicalite. The observation of a single-step desorption of the other *n*-alkanes agrees with the computational results, which indicated the absence of commensurate freezing for these molecules.

Furthermore, it can be concluded that the *n*-heptane molecules are much more constrained in the zigzag channels than the *n*-hexane molecules. This is indicated by the lower temperature of desorption, compared to that of *n*-hexane, at which the first *n*-heptane desorption peak occurs. The last result is supported by the simulated[1] and measured[2–5] adsorption isotherms of *n*-hexane and *n*-heptane. These show that the step in the adsorption isotherm of *n*-heptane is more pronounced than the step in the adsorption isotherm of *n*-hexane.

The temperature programmed desorption of *n*-alkanes from silicalite has provided evidence for the existence of a kind of phase transition during the filling of silicalite. Moreover, in agreement with the results from computer simulations, the occurrence of this transition is a subtle function of the *n*-alkane length and only occurs for molecules that just fit into the zigzag channels.

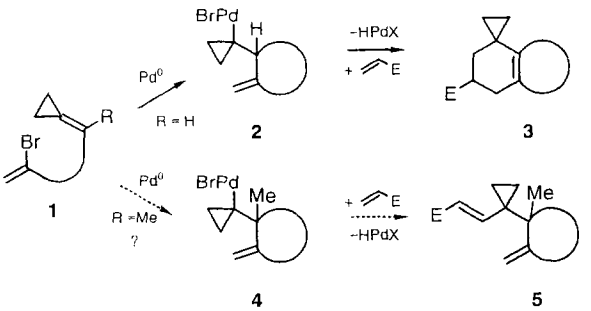
Unprecedented Intra- and Intermolecular Palladium-Catalyzed Coupling Reactions with Methylenecyclopropane-Type Tetrasubstituted Alkenes**

Stefan Bräse and Armin de Meijere*

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

In trying to elucidate the scope and limitations of a recently developed domino sequence consisting of an intramolecular Heck reaction and a subsequent intermolecular Diels–Alder reaction,[1] we have successfully used 2-bromo-1,6-dienes of type **1** with methylenecyclopropane end groups. Compounds **1** with R = H react in the usual way to give vicinal exodimethylenecycloalkanes, which cycloadd dienophiles like methyl acrylate to yield products of type **3** (Scheme 1).[1b] A different situation arises for **1** with R = Me, because the intermediate cyclopropylpalladium bromide **4** would probably be reluctant to undergo β-hydride elimination (to give a cyclopropene) and might prefer to couple with the methyl acrylate.



Scheme 1. E = CO_2Me.

To test this hypothesis, the bromodiene **8a**[2] was treated with methyl acrylate under the previously described conditions[1a] ($Pd(OAc)_2$, PPh_3, Ag_2CO_3). However, no coupling product of type **5** was observed; instead the reaction took a totally different course. Under typical Heck conditions ($Pd(OAc)_2$, PPh_3, NEt_3)[3] (A in Scheme 2) a new product was formed in 72% yield and identified as the cross-conjugated triene **9a**.[4] The homologous 2-bromo-1,7-diene **8b** reacted in the same way to give the seven-membered ring analogue **9b** in 53% yield. However, the corresponding 2-bromo-1,5-diene did not yield any cyclization product but underwent a Cope rearrangement even at 60 °C (in the absence of palladium).[5] Under the conditions of the Trost cycloisomerization reaction[6] (B in Scheme 2), the 1,6- and 1,7-enynes **10a** and **10b** gave the dendralenes[7] **9a** and **9b** in 78 and 100% yield, respectively. In the presence of iodobenzene under Heck conditions the enyne **10a** gave the phenyl-substituted (*Z*)-dendralene **6a** (45%) together with the phenyl-substituted enyne **7a** (42%).

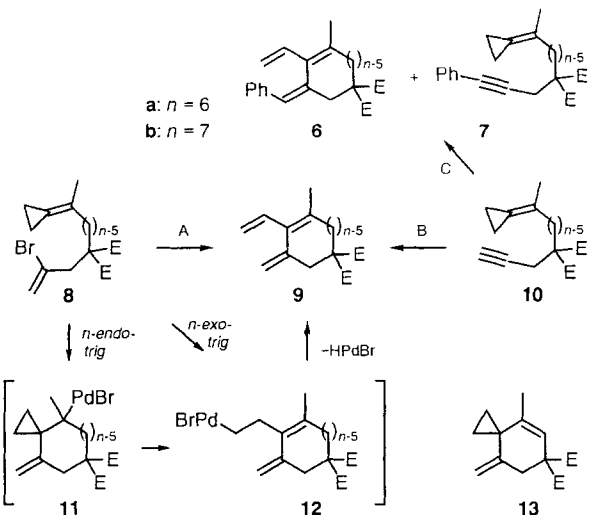
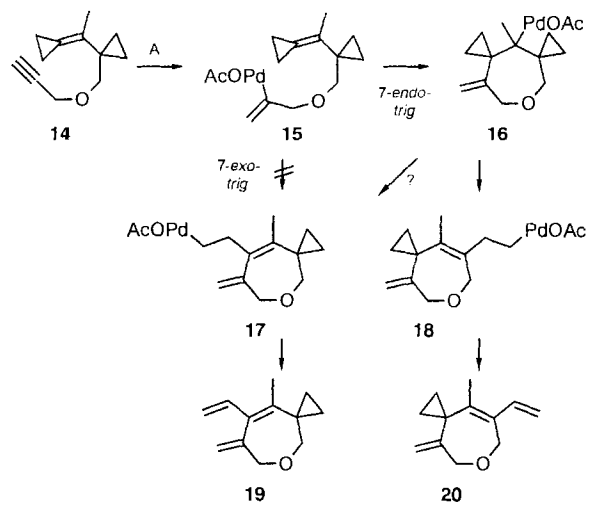
[**] Cyclopropyl Building Blocks for Organic Synthesis, Part 32. This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie as well as by BASF, Bayer, Degussa, Hoechst, and Hüls AG (chemicals). S. B. is grateful to the Fonds der Chemischen Industrie for a graduate fellowship. Part 31: ref. [17e]. Part 30: ref. [17f].



Scheme 2. A) $Pd(OAc)_2$, PPh_3, NEt_3, DMF, 100 °C, 12 h; B) $[Pd_2(dba)_3] \cdot CHCl_3$, $P(o\text{Tol})_3$, HOAc, PhH, 20 °C, 12 h; C) PhI, $Pd(OAc)_2$, PPh_3, NEt_3, DMF, 100 °C, 12 h; E = CO_2Me, CO_2Et.

This strikingly facile formation of cross-conjugated trienes **9** is also interesting mechanically. This type of product might result from the attack of an intermediate σ-alkenylpalladium species like **15** on the tetrasubstituted double bond of the strained methylenecyclopropane moiety[8] to yield the neopentyl-type σ-alkylpalladium intermediate **11** in an *n-endo-trig* cyclization.[9] A cyclopropylcarbinyl → homoallyl type rearrangement[10] would lead to **12** and subsequent β-hydride elimination would then yield **9** (Scheme 2). Alternatively, an *n-exo-trig* cyclization of the first intermediate with attack across the cyclopropyl σ-bond[1] could lead directly to **12**. A careful check of the reaction mixture from **8a** disclosed formation of the 8-methylenespiro[2.5]oct-4-ene derivative **13** as a by-product (22% yield), which must have been formed from intermediate **11a** rather than **12a** by direct β-hydride elimination. To further test this mechanism, the model enyne **14**[2] with an additional cyclopropyl group was subjected to cycloisomerization conditions B (Scheme 3). The fact that only product **20** (45% yield) was isolated along with a trace of dimeric intermolecular coupling product of two molecules of **14** (9%)[12] proved that no direct 7-*exo-trig*[9c] ring closure to intermediate **17** had oc-



Scheme 3. A) $[Pd_2(dba)_3] \cdot CHCl_3$, $P(o\text{Tol})_3$, HOAc, PhH, 20 °C, 12 h.

curred, as that would have led to the dendralene **19**. It is not fully understood, however, why the intermediate **16** selectively opened one spirocyclopropane group to give **18** and not the other one to give **17**.

Dendralenes of type **9** ought to be useful intermediates for organic synthesis as they are good candidates for subsequent domino Diels–Alder reactions,[13] which can lead to complex skeletons in remarkably few steps. The scope of this new route to cross-conjugated systems can be substantially extended by applying the palladium-mediated sequential addition–rearrangement–elimination in an intermolecular fashion using bicyclopropylidene (**22**)[14] as an acceptor alkene. Thus in the intermolecular coupling of **22** and iodobenzene under Heck conditions the expected product **21** was obtained in 57% yield but tends to polymerize in neat form. When treated with various dienophiles, **21** gave the spiro[2.5]octenes **25** regioselectively in moderate to good yields (Table 1). The chiral, nonracemic *N*-acryloylcamphorsultame **24c**[15] gave a single diastereomer of the spirooctene **25c** ($dr > 20:1$). The reaction sequence can even be conducted as a one-pot operation. When a mixture of bicyclopropylidene (**22**), iodobenzene, and one of the dienophiles **24a–c** was subjected to Heck conditions (A in Scheme 4), the spiro[2.5]octenes **25a–c** could be isolated in good yields (61–65%); even with methyl acrylate **24a** only traces of methyl cinnamate resulting from direct coupling with iodobenzene were formed. This indicates that bicyclopropylidene (**22**), although it is a tetrasubstituted alkene, is more reactive (ca. 10 times) than an acrylate in the intermolecular Heck reaction.[16]

Table 1. A domino-type cascade of an intermolecular coupling of bicyclopropylidene (**22**) with aryl and alkenyl halides/sulfonates and Diels–Alder reaction(s).

Substrate	Dienophile	R^1	R^2	Product	Yield [a] [%]
PhI	**24a**	H	CO_2Me	**25a**	61 [b]
PhI	**24b**	CO_2Me	CO_2Me	**25b**	55 [c]
PhI	**24c**	H	COR* [d]	**25c**	49 [b]
C_6H_9ONf [e]	**24b**	CO_2Me	CO_2Me	**28b**/**29b**	41 [c]

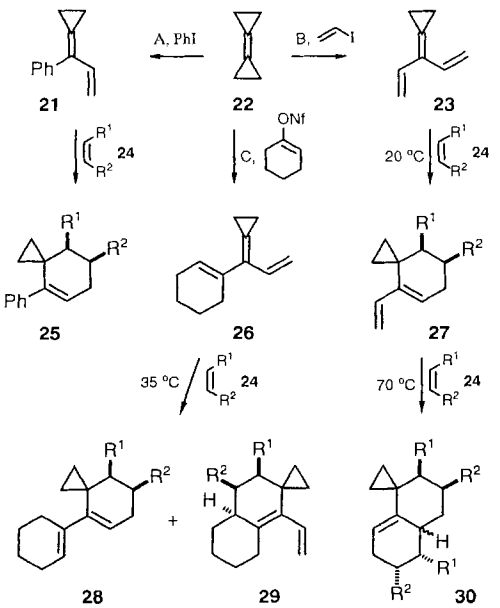
C_2H_3I	**24c**	H	COR* [d]	**27c**	35 [c]

[a] Isolated material. [b] One pot, one step. [c] One pot, two steps. [d] *N*-acryloyl-(*S*)-camphorsultame. [e] 1-Cyclohexenyl nonafluorobutanesulfonate. [f] Vinyl iodide. [g] Mixture of two regioisomers each consisting of four diastereomers. [h] Mixture of four diastereomers.



Scheme 4. A) $Pd(OAc)_2$, PPh_3, NEt_3, DMF, 80 °C, 4 h; B) $Pd(OAc)_2$, PPh_3, NEt_3, DMF, 75 °C, 20 h; C) $[Pd(PPh_3)_4]$, MeCN, 75 °C, 4 h; ONf = $OSO_2nC_4F_9$; for further details see Table 1.

Under appropriate conditions (C in Scheme 4), cyclohexenyl nonaflate reacted with **22** to give the expected dendralene **26** in 41% yield. The Diels–Alder reaction of **26** with dimethyl maleate at 35 °C led to both possible monoadducts **28** and **29** in a ratio of 2:1 (79% total yield based on **26**). It is remarkable that the more highly substituted diene moiety in **26** reacts at roughly the same rate as the other one. Vinyl iodide and bicyclopropylidene (**22**) gave the rather sensitive, novel dendralene **23** in 43% yield. When one of the dienophiles **24a–c** was added to the reaction mixture prior to workup, the monoadducts **27a–c** were isolated at ambient temperature. Heating a mixture of **22**, vinyl iodide, and one of the dienophiles **24a**, **b** in the presence of the palladium catalyst, resulted in bisadducts **30a**, **b** directly.

In conclusion, methylenecyclopropanes are not only favorable reaction partners in intramolecular [3 + 2] cycloadditions,[17a–c] Pauson–Khand,[17d, e] and Diels–Alder reactions,[17e, f] but also in cascade reactions consisting of a Heck-type coupling and subsequent Diels–Alder cycloaddition.

A Functionalized Polyoxometalate Bearing a Ferrocenylimido Ligand: Preparation and Structure of $[(FcN)Mo_6O_{18}]^{2-}$**

Joseph L. Stark, Victor G. Young, Jr., and Eric A. Maatta*

Charge-transfer interactions involving polyoxometalate anions[1] as acceptors form the basis of an intensifying research area with relevancy and applications in fields ranging from photocatalytic reactions of organic substrates[2] to the preparations of new types of magnetic[3] and electrically conducting[4] materials. Currently, polyoxometalate-based donor–acceptor systems are restricted to existence either in the solid state only[5] or in those solutions wherein the donor constitutes a significant fraction of the solvent.[6] It is therefore highly desirable to provide a means of enforcing and controlling the donor–acceptor interactions that occur in solution. Here we report on the preparation and structure of the ferrocenylimidohexamolybdate complex **1** (isolated as the tetrabutylammonium salt), which features the covalent attachment of an oxidizable donor to a reducible polyoxometalate acceptor system.

$[Bu_4N]_2[(FcN)Mo_6O_{18}]$
$[Bu_4N]_2$-**1**

Reaction of $[Bu_4N]_2[Mo_6O_{19}]$ with ferrocenyl isocyanate in pyridine (Scheme 1) affords a purple solution from which crystalline $[Bu_4N]_2$-**1** is obtained in 19% yield after workup and recrystallization. To our knowledge, **1** is the first example of a ferrocenylimido complex; since isocyanates are often employed as imido delivery reagents in metatheses with oxo–metal functions,[7] we expect that this methodology will be applicable to the preparations of various ferrocenylimido complexes $[FcN{\equiv}ML_n]$.

Cyclic voltammetry studies of $[Bu_4N]_2$-**1** (CH_3CN; 298 K; Pt electrode; $[Bu_4N][PF_6]$ supporting electrolyte; 100 mVs^{-1}) in the range +1.0 V to −1.5 V (vs. Ag/Ag^+) reveal a one-electron oxidation wave at 0.226 V ($\Delta E_p = 0.060$ V) and a one-electron reduction wave at −0.951 V ($\Delta E_p = 0.162$ V); under these conditions, the electrochemical couple of added ferrocene was observed at $E_{1/2} = 0.119$ V, and that of the $[Mo_6O_{19}]^{2-}$ ion at $E_{1/2} = -0.706$ V. These two processes for **1** are attributed to oxidation of the ferrocenyl $[Fe]^{2+}$ center and reduction of the $[(FcN)Mo_6O_{18}]^{2-}$ cluster,[8] respectively. Extending the scan to more negative potentials reveals a second, irreversible wave ($E_{pc} = -2.168$ V), and upon reversing the sweep a new reversible wave is observed at −0.248 V. The species and events responsible for this apparent EC process are not yet understood.

The structure[9] of the anionic cluster **1** is shown in Figure 1. The ferrocenylimido ligand is bound in a terminal position at

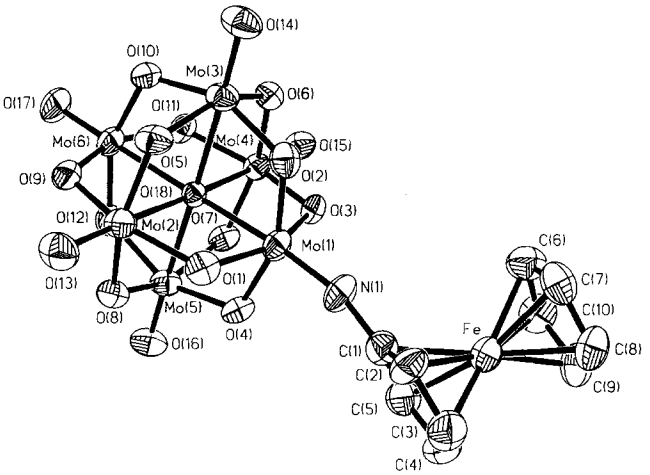

Fig. 1. Crystal structure of **1** (ORTEP drawing). Selected bond lengths [Å] and angle [°]: Mo(1)-N(1) 1.720(7), Mo(2)-O(13) 1.681(6), Mo(3)-O(14) 1.688(6), Mo(4)-O(15) 1.695(6), Mo(5)-O(16) 1.692(6), Mo(6)-O(17) 1.673(6), Mo(1)-O(18) 2.213(5), Mo(2)-O(18) 2.350(5), Mo(3)-O(18) 2.343(5), Mo(4)-O(18) 2.325(5), Mo(5)-O(18) 2.317(5), Mo(6)-O(18) 2.360(5); Mo(1)-N(1)-C(1) 164.8(7).

[**] Organoimido Ligands with Remote Functionality, Part 2. We thank the National Science Foundation and the NSF-EPSCoR "KAN-SYN" program for supporting this work. Part 1: P. L. Hill, G. P. A. Yap, A. L. Rheingold, E. A. Maatta, *J. Chem. Soc. Chem. Commun.* **1995**, 737. FcN = $(\eta^5\text{-}C_5H_5)Fe\text{-}(\mu\text{-}\eta^5\text{:}\sigma\text{-}C_5H_4N)$.

the hexamolybdate and its metrical parameters (Mo(1)–N(1) = 1.720(7) Å; Mo(1)-N(1)-C(1) = 164.8(7)°) are consistent with the presence of a formal Mo≡NFc triple bond. As in other imidohexametalate structures, the bond between the imido-bearing Mo(1) atom and the central O(18) atom (2.213(5) Å) is substantially shorter than the remaining Mo–O(18) interactions, which range from 2.317(5)–2.360(5) Å. The cyclopentadienyl rings within the ferrocenylimido ligand deviate by only about 4.4° from an ideal eclipsed conformation. The Fe–Mo(1) distance is 4.78 Å.

Within the lattice of $[Bu_4N]_2$-**1**, $[(FcN)Mo_6O_{18}]^{2-}$ ions are organized into pairs displaying close intercluster approaches between cyclopentadienyl hydrogen atoms and μ_2-oxygen atoms (Fig. 2). The closest H···O separations observed are for

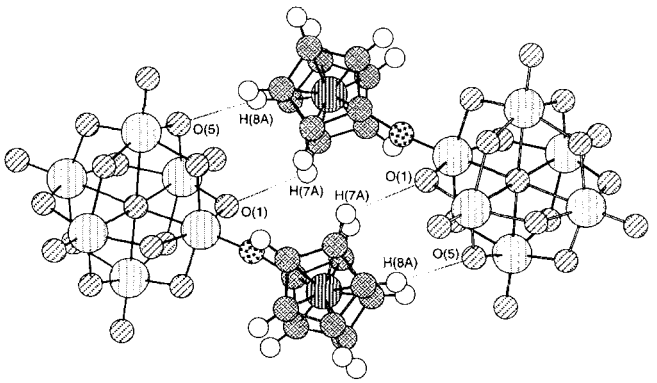

Fig. 2. Pairing of the anions **1** in the lattice of $[Bu_4N]_2$-**1**. Highlighted distances [Å]: H(8A)-O(5) 2.37, H(7A)-O(1) 2.62.

H(8A)–O(5) at 2.37 Å and for H(7A)–O(1) at 2.62 Å. These distances are similar to those observed between the methyl hydrogen atoms of the cationic ferrocene derivative $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CH_2N(CH_3)_3)]^+$ and oxygen atoms of $[Mo_6O_{19}]^{2-}$ (2.56–2.60 Å) in a recently reported 2:1 charge-transfer salt.[10] The "dimerization" observed for the anions **1** in the solid state is undoubtedly facilitated by the superior electron donation provided by the organoimido ligand,[8] which renders the μ_2-oxygen sites of **1** more basic than those in the $[Mo_6O_{19}]^{2-}$ ion.

The electronic spectrum of **1** is unique among all other monoimidohexamolybdates (Table 1). Apart from the transition at 337 nm, which is common to the systems shown in Table 1, the spectrum of **1** also contains a strong, broad absorption centered at 536 nm ($\varepsilon = 1500$). Based on its intensity, this band cannot be a d-d transition[12] within the ferrocenyl component of **1**, and we assign this feature as arising from an intramolecular charge transfer from the $\{Fe^{2+}\}$ center to the $\{(NMo_6O_{18})^{2-}\}$ cluster; the position of this band in **1** is similar to that observed in the (solid-state) diffuse reflectance spectrum

Table 1. Electronic spectra of $[Mo_6O_{18}(NR)]^{2-}$ systems (recorded in CH_3CN as $[Bu_4N]^+$ salts).

Complex	λ_{max} [nm]	ε [$M^{-1}cm^{-1}$]
$[Mo_6O_{18}(NBu)]^{2-}$ [a]	329	6.0×10^3
$[Mo_6O_{18}(NCy)]^{2-}$ [a]	325	7.0×10^3
$[Mo_6O_{18}(NPh)]^{2-}$ [b]	342	2.0×10^4
$[Mo_6O_{18}(NAr)]^{2-}$ [a, c]	351	1.9×10^4
$[Mo_6O_{18}(NFc)]^{2-}$ [d]	337	1.0×10^4
	536	1.5×10^3

of the above-mentioned $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CH_2N(CH_3)_3)]^+$ charge-transfer salt of the $[Mo_6O_{19}]^{2-}$ ion [10] (λ_{max} = 550 nm). Studies of the photophysics and photochemistry of **1** are now underway.

In summary, we have demonstrated that a ferrocenyl donor can be bound covalently to a polyoxometalate acceptor, thereby ensuring that the integrity of the donor–acceptor system is maintained in solution. The simple methodology employed in this synthesis suggests that a variety of other donor/antenna groups may be similarly incorporated into polyoxometalates.

Experimental Procedure

Ferrocenyl isocyanate [13] (0.25 g, 1.1 mmol) and $[Bu_4N]_2[Mo_6O_{19}]$ [14] (1.50 g, 1.1 mmol) were stirred in dry pyridine (50 mL) at 25 °C for 48 h, which led to a purple solution. The solvent was evaporated under vacuum and the residue was extracted into CH_2Cl_2, filtered, taken to dryness, washed with Et_2O, and the resulting purple solid **1** was dried under vacuum (0.32 g, 19%). Analysis for $C_{42}H_{81}N_3O_{18}FeMo_6$: Calc. C 32.60, H 5.28, N 2.72; found: C 32.52, H 5.18, N 3.06. ^{1}H NMR (CD_3CN, 25 °C): δ = 4.66 (t, 2H, C_5H_4), 4.50 (s, 5H, C_5H_5), 4.22 (t, 2H, C_5H_4), 3.08 (m, 16H, N-CH_2), 1.60 (m, 16H, CH_2), 1.35 (m, 16H, CH_2), 0.96 (t, 24H, CH_3). Solvated crystals of $[Bu_4N]_2$-**1** were grown by diffusion of Et_2O vapor into a CH_3NO_2 solution of the salt at 25 °C and a suitable specimen for X-ray analysis was chosen under the mother liquor.

[9] Summary of crystal structure data for $[Bu_4N]_2$-**1**·(disordered solvent). The crystals are stable only under the mother liquor and the identity of the solvate(s) could not be established; three carbon atoms of the disordered solvate(s) located near an inversion center were refined in the structural analysis and are included in the following density and empirical formula calculations: M = 1583.62, monoclinic, $P2_1/n$, a = 17.153(4), b = 17.095(3), c = 20.510(6) Å, β = 105.043(13)°, V = 5808(3) Å^3, Z = 4, ρ_{calcd} = 1.811 g cm^{-3}, T = 173(2) K, crystal dimensions = 0.50 × 0.25 × 0.10 mm, μ = 1.563 mm^{-1}, λ = 0.71073 Å; 23202 reflections (8986 independent) were collected on a Siemens SMART system ($2\theta_{max}$ = 48.3°) of which 8984 independent reflections with $I > 2\sigma(I)$ were used in refinement. The structure was solved by direct methods and refined by full-matrix least-squares (on F^2) and difference Fourier cycles (SHELXTL V5.0). A face-indexed analytical absorption correction was applied (T_{min}/T_{max} = 0.6153). All non-hydrogen atoms (except those of the disordered solvent) were refined anisotropically. H atoms were treated as idealized isotropic contributions. Final residuals were $R1$ = 0.0662 and $wR2$ = 0.1157 for 8984 data and 651 parameters. Largest difference peak and hole = 0.914 and −0.866 e Å^{-3}. GOF (F^2) = 1.183. A $Te_2N_6Li_4$ Cage Containing the Tris(*tert*-butylimido)tellurite Dianion**

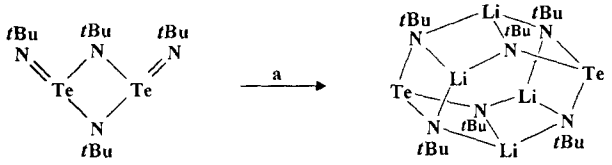
Tristram Chivers,* Xiaoliang Gao, and Masood Parvez

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

The development of tellurium–nitrogen chemistry has been impeded for many years on account of the explosive nature of simple compounds such as Te_3N_4[1, 2] and $K_2[Te(NH)_3]$.[2] Recently, however, significant progress has resulted from the discovery of Te–N reagents that are safe to handle. Many Te–N compounds exhibit structures and/or reactions that are either unique or significantly different from those of their lighter chalcogen analogues.[3] For example, the three tellurium atoms in the twelve-membered rings of $(XTeNSN)_3N$ (X = Cl, F) are connected by a μ_3-nitrido bridge,[4] the Te^{II} derivative $(Me_3Si)_2NTeN(SiMe_3)_2$ forms a monomeric cation radical upon oxidation with AsF_5,[5] the cation $Te_2S_2N_4^{2+}$ adopts a bicyclic structure,[6] and *N*,*N*′-di-*tert*-butyltellurium(IV) diimide exists as a thermally stable dimer (tBuN)Te(μ-NtBu)$_2$Te(NtBu) (**1**).[7]

A characteristic reaction of sulfur(IV) diimides RN=S=NR is the quantitative formation of sulfinimidamides [RNS(R)NR]Li on treatment with R′Li reagents;[8] the structures of these organolithium adducts have only been determined recently.[9] We report here on the reaction of the dimer **1** with phenyllithium or, preferably, tBuNHLi, which produces $[(tBuN)_3TeLi_2]_2$ (**2**) (Scheme 1). Complex **2** forms a $Te_2N_6Li_4$ cage which contains



1 **2**

Scheme 1. a) + 4 tBuNHLi, −2 tBuNH$_2$.

the first structurally characterized tris(imido)tellurite ion $Te(NR)_3^{2-}$ (R = tBu). This dianion is isoelectronic with the recently described $Sb(NR)_3^{3-}$ (R = $PhCH_2CH_2$) trianion, which, as its trilithium derivative, exists as an $Sb_2N_6Li_6$ cage.[10] The reaction of **2** with two molar equivalents of $PhPCl_2$ or $PhBCl_2$ yields the spirocyclic tellurium(IV) derivative Ph(tBuN)P(μ-NtBu)$_2$Te(μ-NtBu)$_2$P(NtBu)Ph **3** or the four-membered ring compound PhB(μ-NtBu)$_2$Te(NtBu) **4**, respectively.

[**] Financial support from the Natural Sciences and Engineering Research Council (Canada) is gratefully acknowledged.

Compound **2** was initially obtained unexpectedly in 35% yield, together with diphenyltelluride, as moisture-sensitive, colorless crystals from the reaction of **1** with phenyllithium. The dimeric structure of **2** was established by X-ray crystallography. Subsequently, it was found that **2** may be prepared in 91% yield by the treatment of **1** with four molar equivalents of tBuNHLi in toluene at −78 °C, followed by warming to room temperature.

A low-temperature X-ray structure determination confirmed the presence of a $Te_2N_6Li_4$ cage in **2** (Fig. 1).[11] All the lithium

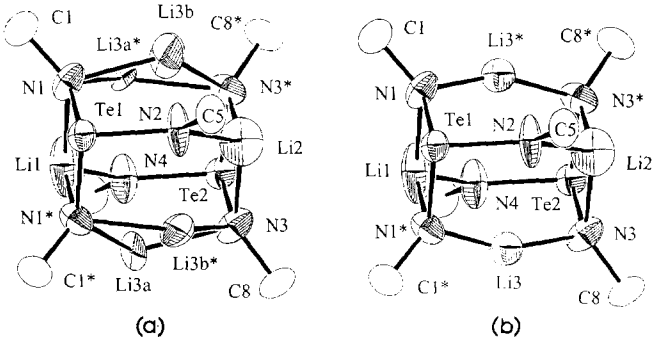

Fig. 1. Representations of the dimer **2** showing a) all lithium sites [with 50% occupancies for Li(3a) and Li(3b)] and b) an averaged structure with Li(3) and Li(3)* at the midpoint between two disordered sites. Only the α-carbon atoms of tBu groups attached to nitrogen atoms are shown for clarity. Selected bond lengths [Å] and bond angles [ ] are given in the text. Asterisks indicate atoms related by symmetry: x, 1/2−y, z.

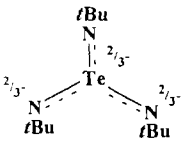
atoms are unsolvated (recrystallization from toluene). The lithium atoms Li(3) and Li(3)* each inhabit two sites with 50% occupancies. Figure 1 shows both the disordered and averaged structures of the $Te_2N_6Li_4$ cage. In the dimer $[W(NtBu)_4Li_2]_2$, which also contains a $M_2N_6Li_4$ cage, disorder involving all four lithium atoms (with 2/3 occupancies) was observed.[12] In the context of the estimated values of 2.05 and 1.83 Å for Te^{IV}–N single and double bonds, respectively,[13] the mean Te–N distance of 1.980 Å and the distorted pyramidal geometry at the tellurium centers with mean N-Te-N bond angles of 93.6° are consistent with the description of **2** as the dilithium derivative of the tris(*tert*-butylimido)tellurite $Te(NtBu)_3^{2-}$ dianion, which may be represented as the resonance hybrid **5** (the lone pair on the Te atom has been omitted).



5

As a general rule Li–N bond lengths increase as the coordination number of Li increases;[14] however, both types of lithium atoms in the $Te_2N_6Li_4$ cage of **2** are three-coordinate. The mean Li–N distances for Li(1) and Li(2) are 1.93(2) Å and 2.07(2) Å, respectively, whereas the mean Li–N distances for Li(3a) and Li(3b) are 2.08(3), 2.14(3), and 2.20(2) Å, the longest of which lies across the "waist" of the cage (see Fig. 1a and Scheme 1). Thus the dimer **2** can be viewed as a distorted hexagonal prism (cf. $[(thf)Mg(NPh)]_6$[15a] and $(RAlN(R')_6$[15b]). The Li–Li contacts of 2.25(3)–2.35(3) Å are not considered to have bonding significance.[16]

The ^{1}H NMR and ^{7}Li NMR spectra of **2** in C_7D_8 both exhibit singlets at δ = 1.34 and 5.7, respectively, throughout the temperature range 185 to 298 K. In view of the tendency of organonitrogen–lithium compounds to have different degrees of association in solution than those observed in the solid state,[16] a full understanding of the structure of **2** in solution must await more detailed NMR studies and molecular weight measurements.

The novel cage compound **2** is the first structurally characterized triimidotellurite ion $Te(NR)_3^{2-}$. The compound $K_2[Te(NH)_3]$ **6**, which presumably contains the parent

$K_2[Te(NH)_3]$ **6**

$Te(NH)_3^{2-}$ ion, was obtained many years ago in unspecified yield as colorless crystals from the remarkable reaction of diphenyltelluride with potassium amide in liquid ammonia; it was identified on the basis of analytical data alone.[2] Compound **6** is *highly explosive*, however, whereas **2** can be handled without fear of explosion and is readily soluble in organic solvents such as toluene or THF. The $Te(NtBu)_3^{2-}$ ion is formally isoelectronic with the tellurite TeO_3^{2-} ion and is a potentially versatile building block for the construction of rings (or cages) involving other main group elements, as illustrated by the following examples.

The reaction of **2** with two molar equivalents of $PhPCl_2$ in hexane at $-100\,^{\circ}C$, followed by warming slowly to room temperature, produced orange crystals of the spirocyclic compound **3** and elemental tellurium. Complex **3** was characterized by ^1H, ^{31}P, and ^{125}Te NMR spectroscopic data (see Experimental Procedure) and by an X-ray crystallographic analysis.[17] The spirocyclic structure of **3** (Fig. 2) is comparable to that determined

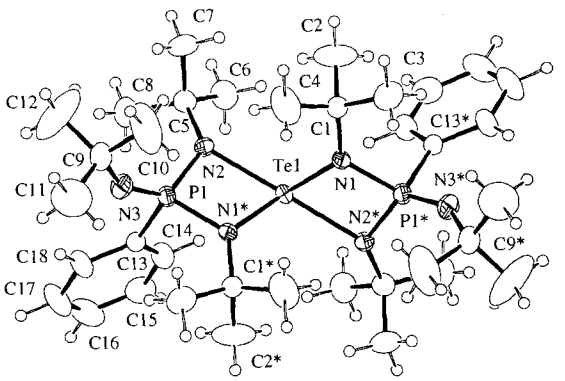


Fig. 2. Crystal structure of **3**. Selected bond lengths [Å] and bond angles [°]: Te(1)-N(1) 2.034(5), Te(1)-N(2) 2.212(5), P(1)-N(1) 1.736(5), P(1)-N(2) 1.646(5), P(1)-N(3) 1.498(6); N(1)-Te(1)-N(1)* 103.4(3), N(1)-Te(1)-N(2) 110.6(2), N(1)-Te(1)-N(2)* 68.2(2), N(2)-Te(1)-N(2)* 178.2(3), Te(1)-N(2)-P(1) 97.3(2), Te(1)-N(1)*-P(1) 101.3(3), N(1)*-P(1)-N(2) 89.7(2). Asterisks indicate atoms related by symmetry: $2-x, y, 1/2-z$.

recently for the related complex $PhB(\mu\text{-}NtBu)_2Te(\mu\text{-}NtBu)_2BPh$.[18] We note, however, that the boron complex is prepared from $TeCl_4$ and $PhB(NtBu)_2Li_2$ (1:2 molar ratio) in a straightforward metathesis reaction, whereas the formation of **3** involves a redox process with transfer of $NtBu$ groups from tellurium to phosphorus and the formation of elemental tellurium. For comparison, the reaction of **2** with two molar equivalents of $PhBCl_2$ produces the new four-membered BN_2Te ring **4** as yellow crystals in about 30% yield, together with the known cyclic tellurium(II) imide $(tBuNTe)_3$.[7] The structure of **4** was confirmed by a single-crystal X-ray analysis (Fig. 3).[19] The B–N bond lengths (1.45–1.46 Å) and the almost planar structure at the bridging nitrogens (sum of angles = 356.7°) are consistent with substantial multiple bonding.[20] The endocyclic and exocyclic Te–N bond lengths of 2.081 and 1.878 Å are identical to the values found for the tellurium diimide dimer **1**,[7] indicating single and double bonds, respectively.

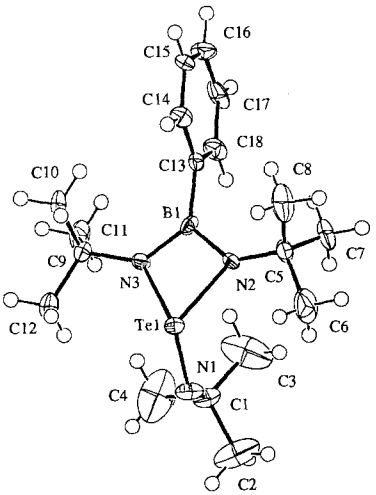

Fig. 3. Crystal structure of **4**. Selected bond lengths [Å] and bond angles [°]: B(1)–N(2) 1.46(1), B(1)–N(3) 1.45(1), Te(1)–N(1) 1.878(7), Te(1)–N(2) 2.081(7), Te(1)–N(3) 2.081(6); N(2)-B(1)-N(3) 104.1(8), B(1)-N(2)-Te(1) 93.6(6), B(1)-N(3)-Te(1) 94.1(5), N(2)-Te(1)-N(3) 67.0(3), N(1)-Te(1)-N(2) 113.0(3), N(1)-Te(1)-N(3) 111.8(3).

In view of the recently demonstrated ability of the trithiotellurite ion TeS_3^{2-} to form a variety of novel layer structures with transition metals,[21] investigations of the ligand behavior of **5** should be fruitful.

Experimental Procedure

2: A solution of $tBuNHLi$ (0.360 g, 4.49 mmol) in toluene (30 mL) was added to a stirred, orange solution of $Te_2(NtBu)_4$ (0.60 g, 1.11 mmol) in toluene (10 mL) at $-78\,^{\circ}C$. The mixture was allowed to warm to $23\,^{\circ}C$ to give an almost colorless solution. After 5 h, the volume of the solution was reduced to about 0.5 mL and the resulting colorless crystals were rinsed quickly with 5 mL of cold toluene ($-30\,^{\circ}C$). A second crop was obtained from the filtrate at $-20\,^{\circ}C$ when the volume was reduced to about 1 mL. The combined yield of **2** was 0.718 g (1.01 mmol, 91%). ^1H NMR (C_7D_8, 25 °C): $\delta = 1.34$(s); ^{125}Te NMR (C_7D_8, 25 °C, Ph_2Te): $\delta = 152.6$(s); ^7Li NMR (C_7D_8, 25 °C, 4.0 M $LiClO_4$ in D_2O): $\delta = 5.7$(s).

3: A solution of $PhPCl_2$ (0.050 g, 0.282 mmol) in hexane (10 mL) was added dropwise to a stirred, colorless solution of $[Li_2Te(NtBu)_3]_2$ (0.100 g, 0.141 mmol) in hexane (20 mL) at $-100\,^{\circ}C$ to give an orange solution. Upon warming to 23 °C, some black precipitate (elemental Te) was formed. The mixture was stirred for a further 10 h and then filtered. The volume of the orange filtrate was reduced to 3 mL and large platelets of **3** formed within a few hours. A second crop of **3** was obtained by cooling the concentrated mother liquor (ca. 0.5 mL) to $-20\,^{\circ}C$. The combined yield of **3** was 87 mg (0.113 mmol, 40%). ^1H NMR (C_6D_6, 25 °C): $\delta = 7.9$–8.1(m), 7.05–7.3 (m, 5H), 1.66 (d, $J = 1.46$ Hz, 9H), 1.60 (s, 9H), 1.35 (s, 9H); $^{31}P\{^1H\}$ NMR (C_6D_6, 25 °C, 85% H_3PO_4): $\delta = -37.9$ (s, $^2J(^{125}Te,^{31}P) = 121.5$ Hz); ^{125}Te NMR (C_6D_6, 25 °C, Ph_2Te): $\delta = -254.0$ (t, $^2J(^{125}Te,^{31}P) = 124.2$ Hz).

4: A solution of $PhBCl_2$ (0.118 g, 0.741 mmol) in pentane (5 mL) was added slowly to a solution of $[Li_2Te(NtBu)_3]_2$ (0.263 g, 0.371 mmol) in toluene (20 mL) at $-78\,^{\circ}C$. The colorless solution turned orange in 20 min. The reaction mixture was allowed to warm up to 23 °C, stirred for 2 h, and then filtered through a fine frit. Solvent was removed from the filtrate under vacuum and the residue was dissolved in diethyl ether (2 mL). This solution was cooled to $-20\,^{\circ}C$ and colorless crystals of **4** (0.092 g, 0.215 mmol, 29%) were isolated. ^1H NMR (C_6D_6, 25 °C): $\delta = 7.2$–7.6 (m, 5H), 1.70 (s, 9H), 1.11 (s, 18H); ^{11}B NMR (C_6D_6, 25 °C): $\delta = 36.0$(s) (ref. $NaBH_4$ in D_2O). Some orange crystals of $Te_3(NtBu)_3$ (identified by ^1H NMR and MS) [7] were obtained from a pentane solution of the residue after the isolation of **4**.

Satisfactory C, H, N analyses were obtained for **2**, **3**, and **4**.

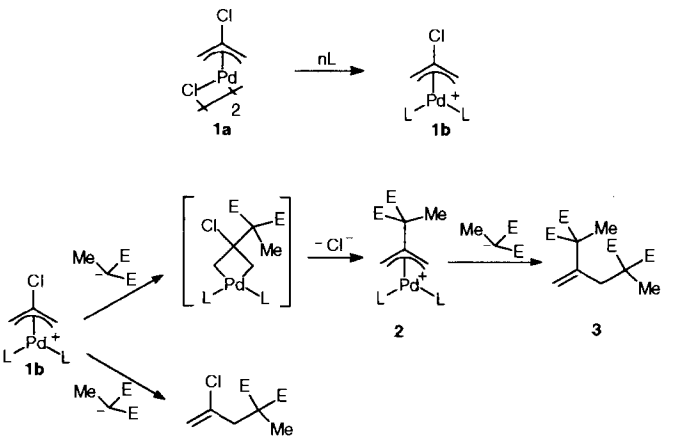
Nucleophilic Attack on (π-Allyl)palladium Complexes: Direction of the Attack to the Central or Terminal Carbon Atom by Ligand Control**

Ana M. Castaño, Attila Aranyos, Kálmán J. Szabó, and Jan-E. Bäckvall*

Nucleophilic addition to (π-allyl)palladium complexes is an important step in a number of synthetically useful palladium-catalyzed reactions,[1] for example, allylic nucleophilic substitutions,[2] allylic acetoxylation,[3] and 1,4-oxidation of conjugated dienes.[4] In all these reactions the regiochemistry observed has been attack at either terminus (C1 or C3) of the π-allyl group. However, some time ago Hegedus reported an example of attack at the central carbon (C2),[5] and since then several examples of such unusual reactivity have been reported with (π-allyl)palladium complexes.[6] Recently for a number of other (π-allyl)metal complexes attack at the central carbon has also been observed,[7, 8] sometimes in a reversible reaction.[7b, 8]

Until now it has generally been assumed that only less stabilized carbon nucleophiles (pK_a 20–30) are able to attack the central carbon in (π-allyl)palladium complexes.[5, 6] In this communication we provide evidence that also more stabilized carbon nucleophiles (pK_a 14–15), such as diethyl methylmalonate, attack at the central carbon under certain conditions. We have studied the factors governing the regiochemistry of the attack (at the central or the terminal carbon) and explain the observed regiochemistry.

The (π-allyl)palladium complex **1a**, prepared in 90% yield by reaction of 2,3-dichloropropene with 1 equiv of $PdCl_2$ in the presence of CO,[9] was used as a substrate to study the effect of the ligand and other parameters in the regiochemistry of the nucleophilic attack.[10] Complex **1a** was allowed to react with sodium diethyl methylmalonate (2.0–2.5 equiv) in THF at −78 °C in the presence of different ligands (2–6 equiv) and left to warm up overnight to room temperature. Two products, the doubly alkylated product **3** and the monoalkylated product **4**, were obtained (Scheme 1, Table 1).



Scheme 1. Reaction of complex **1** with sodium diethyl methylmalonate. E = CO_2Et.

Table 1. Product distribution in the reaction of sodium diethyl methylmalonate with a series of allyl complexes **1** containing different ligands L [a].

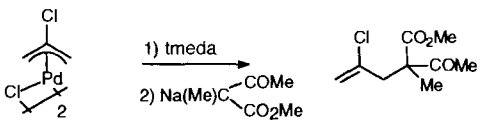
Entry	L (equiv)	**3**:**4** [b]
1	PPh_3 (4) [c]	<2:>98
2	PBu_3 (4)	13:87
3	$P(OPh)_3$ (6)	<1:>99
4	dppf (2) [c]	<1:>99
5	dppe (2) [c]	25:75
6	dppe (4.5) [c]	23:77
7	dppb (2) [c]	10:90
8	bpy (2) [d]	>99:<1
9	tmeda (2) [d]	>99:<1

[a] Unless otherwise stated, the ligand was added to a solution of **1** in THF at −78 °C, followed by addition of sodium diethyl methylmalonate in THF. The reaction was allowed to warm to room temperature overnight. Conversion of **1** to products **3** and/or **4** was >95%. Abbreviations: dppf = 1,1′-bis(diphenylphosphino)ferrocene; dppe = 1,2-bis(diphenylphosphino)ethane; dppb = 1,4-bis(diphenylphosphino)butane; bpy = 2,2′-bipyridine; tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine. [b] Ratio determined by ^{1}H NMR spectroscopy. [c] After adding the ligand, the cold bath was removed for a few minutes to facilitate the ligand exchange. [d] Variable amounts of diethyl (allyl)methylmalonate and diethyl 2-(2-propenyl)methylmalonate were also obtained.

Compound **3** is formed in a multistep process: addition of the nucleophile to the central carbon of the (π-allyl)palladium complex followed by elimination of Cl^- gives the substituted (π-allyl)palladium complex **2**, which subsequently undergoes a second nucleophilic attack at the terminal carbon atom.[11] Compound **4** is formed in a one-step attack by the nucleophile at the terminal carbon atom.

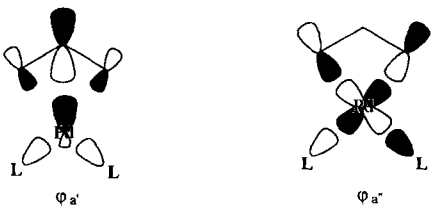
The ratio between products **3** and **4** is strongly dependent on the choice of the ligand (Table 1). π-Acceptor phosphorus ligands favor terminal attack, whereas strong σ-donor nitrogen ligands favor C2 attack. Thus, the use of triphenylphosphane as ligand afforded **4** highly selectively (>98%), indicating terminal attack by the nucleophile (entry 1). With the more electron-donating tributylphosphane some C2 attack took place, the ratio of **3** to **4** being 13:87 (entry 2). Interestingly, the bidentate phosphane ligand dppe gave significant amounts of C2 attack (entries 5 and 6). With bipyridine and tmeda as ligand only product **3** from initial C2 attack was observed (entries 8–9).

Reaction of **1a** with an even more stabilized carbon nucleophile, sodium methyl methylacetoacetate, afforded product **5** by terminal attack even if tmeda was used as a ligand [Eq. (a)].



1a **5**

To gain further insight into the mechanism of this reaction, ab initio[12] calculations at the Hartree–Fock level as well as at the second and fourth order Møller–Plesset perturbation theory[13] were performed on (π-allyl)palladium complex **6**, which contains simple phosphorus and nitrogen ligands. Previous theoretical studies on C2 attack by nucleophiles on (π-allyl)palladium complexes have employed Extended Hückel MO (EHMO) calculations.[7b,14] From results one of the studies,[14] frontier orbital controlled nucleophilic attack at the central carbon atom was considered unlikely, whereas in the other study[7b] it was argued to be a possible pathway. Our calculations on **6** show that: 1) The orbital energies of the two lowest unoccupied MOs, $\varphi_{a'}$ and $\varphi_{a''}$, (Fig. 1) are rather similar and vary for different ligands.[15] 2) With NH_3 as ligand $\varphi_{a'}$ is the LUMO and approximately 0.4 eV below $\varphi_{a''}$. 3) With PH_3 as ligand the order is reversed, and $\varphi_{a''}$ has the lowest energy, although the energy difference between the two orbitals is small (<0.2 eV) and perhaps not significant.



$\varphi_{a'}$ $\varphi_{a''}$

Fig. 1. Possible LUMOs in Pd(π-allyl) complexes.

There are two possible explanations for the ligand effects observed (Table 1): 1) There is a balance between charge controlled and orbital controlled reactions. 2) The reaction is frontier orbital controlled for all ligands, but the LUMO is different for different ligands ($\varphi_{a'}$ or $\varphi_{a''}$). According to the first explanation, an electron-accepting ligand such as triphenylphosphane would create significant carbenium ion character at the allyl moiety. The complex can be best described as an allyl cation coordinated to Pd^0, and therefore the positive charge in the allyl group is located more on the terminal carbon atoms. As a result, charge controlled attack at the terminal carbon would be favored. On the other hand, with more strongly electron-donating ligands such as tmeda, the positive charge will be smaller and frontier orbital control will become more important. When $\varphi_{a'}$, where the MO coefficient is large at the C2 carbon, is the LUMO, attack at this carbon will predominate. The fact that the methyl methylacetoacetate anion [Eq. (a)], which is more stabilized than the dialkyl methylmalonate anion, gives terminal attack in a reaction with the allylpalladium complex containing tmeda as ligand is consistent with the first explanation. The energy of the nucleophile orbital (HOMO) will be significantly lower in this case and therefore the rate of the frontier orbital controlled pathway, which is inversely dependent on the difference $E_{LUMO}-E_{HOMO}$, would decrease.[16]

On the other hand, if the reaction is completely governed by frontier orbital control (as in the second explanation) the terminal attack on allylic complexes with PPh_3 and $P(OPh)_3$ as ligands would be explained by a change of LUMO from $\varphi_{a'}$ to $\varphi_{a''}$ on changing from the strong σ-donor ligands to the π-acceptor phosphorus ligands. This is in agreement with the calculations. However, the reason for terminal attack by sodium methyl methylacetoacetate on **1** with tmeda as ligand [Eq. (a)] is not obvious with this explanation, but may be rationalized by repulsive HOMO(nucleophile)–HOMO(allyl) interactions as suggested by Musco et al.[7b]

Recently, Murai et al.[7c] showed that the nucleophile sodium diethyl methylmalonate attacks the C2 carbon atom of a (π-allyl)platinum intermediate corresponding to **1**. The (π-allyl)-platinum species was generated from 2-chloro-2-propenyl-acetate and $[Pt(CH_2{=}CH_2)(PPh_3)_2]$ in a catalytic reaction that afforded **3** as final product.

In summary, we have demonstrated for the first time that nucleophilic attack by a dialkyl malonate anion (a more stabilized carbon nucleophile) takes place at the central carbon atom of a (π-allyl)palladium complex. The regiochemistry of the reac-

tion is controlled by proper choice of ligand on the metal. The effect of temperature, chelation, and other reaction parameters are under investigation.

[10] Recently, Murai et al. generated homologous (π-allyl)palladium and -platinum complexes in situ in catalytic reactions from 2-chloro-2-propenylacetates to study the site of nucleophilic attack [7c].

[11] Complex **1** is indeed highly reactive and reacts even at −78 °C with stabilized carbon nucleophiles.

[12] a) The program GAUSSIAN 92 was employed. For hydrogens the primitive (4s) [12b] basis was used contracted to [2s]. For carbon, nitrogen, and chlorine atoms the (9s,5p) basis of Huzinaga [12b] was used, augmented with one d-function and contracted to [3s,2p,1d]; the chlorine core was replaced by an effective core potential (ECP) [12c]. For palladium a relativistic ECP according to Hay and Wadt [12d] was used. The 4s and 4p orbitals are described by a single zeta contraction, the valence 5s and 5p orbitals by a double zeta basis, and the 4d orbital by a triple zeta basis including one diffuse d-function. b) S. Huzinaga, *J. Chem. Phys.* **1965**, *42*, 1293; c) P. J. Hay, W. R. Wadt, *ibid.* **1985**, *82*, 270; d) P. J. Hay, W. R. Wadt, *ibid.* **1985**, *82*, 299.

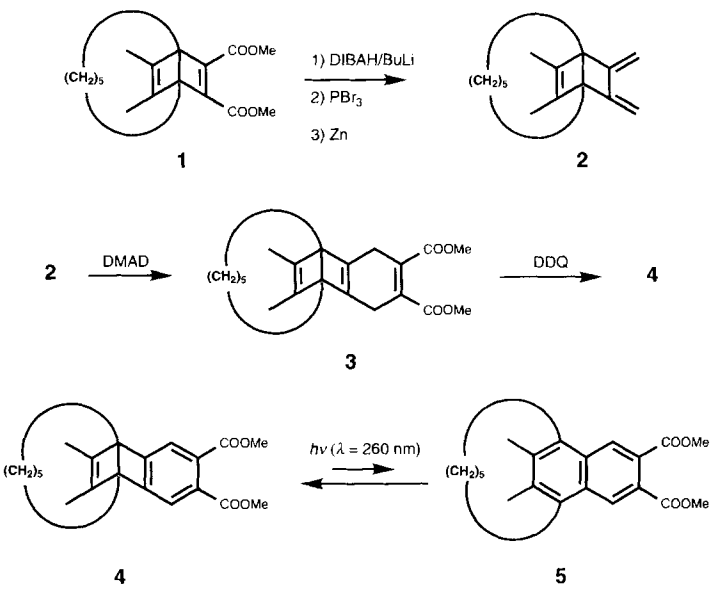
6,7-Bis(methoxycarbonyl)-2,3-dimethyl-[5](1,4)naphthalenophane, the First Benzoannelated [5]Paracyclophane

Daniël S. van Es, Franciscus J. J. de Kanter, Willem H. de Wolf, and Friedrich Bickelhaupt*

The chemistry of small strained cyclophanes keeps fascinating chemists, both because of the remarkable physical and chemical properties of these compounds and because of the challenge posed by their synthesis.[1] In 1985, we reported the first synthesis of [5]paracyclophane, which was at that time the smallest known [*n*]paracyclophane.[2] In contrast to its next higher homologue [6]paracyclophane,[3] [5]paracyclophane is not stable at room temperature; it could only be stored in dilute solution at low temperatures.[2] Introduction of substituents at the benzene ring slightly increased the thermal stability.[4] Therefore, a further increase in stability could be expected on annelation of an additional benzene ring, especially since Tobe and co-workers had shown that [6](1,4)naphthalenophane is more stable than [6]paracyclophane.[5] Here we report the synthesis and characterization of a derivative of [5](1,4)naphthalenophane, which is the smallest known [*n*](1,4)naphthalenophane and the first benzoannelated [5]paracyclophane.

The Dewar benzene **1**[4b] was converted by known methods,[6, 7] as indicated in Scheme 1, via the corresponding diol



Scheme 1. Synthesis of **5** from **1**. DIBAH = Diisobutylaluminum hydride.

(step 1) and dibromide (step 2) to the triene **2** (step 3). In a Diels–Alder reaction with dimethyl acetylenedicarboxylate (DMAD), **2** yielded the adduct **3**, which in turn was oxidized with dichlorodicyanobenzoquinone (DDQ) to give **4**. After preparative thin layer chromatography, **4** was obtained in low yield, but pure.

Initial attempts to aromatize **4** photochemically to the naphthalenophane **5** with a white light source resulted in the forma-

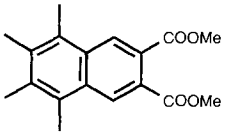
Telefax. Int. code + (20)4447488

tion of polymer only. By excitation with monochromatic light ($\lambda = 260$ nm) at low temperatures (248 K), we were able to obtain **5** in 35% yield in a photodynamic equilibrium with **4**.[8] Even after 280 hours of irradiation in [D$_8$]THF, the sample showed no degradation; in contrast, on irradiation at wavelengths longer than 350 nm, **5** underwent photoreversion to **4**. It should be pointed out that the yield of **5**, 35%, is the highest one recorded so far in the photochemical aromatization of any Dewar isomer of a small cyclophane.

The comparison of the ^{1}H NMR spectrum (400 MHz, [D$_8$]THF, 210 K) of **5** with that of the unstrained reference compound **6**[9] reveals that the aromatic protons of **5** (major isomer: $\delta(^1H\{5,8\}) = 8.29$; minor isomer: $\delta(^1H\{5,8\}) = 8.26$) show the shift typical for a naphthalene derivative (cf. **6**: $\delta = 8.43$; **4**: $\delta = 7.41$). Some of the methylene signals ($\delta = -0.37$, 2H, homobenzylic; $\delta = -0.61$, 1H, central methylene group) are characteristic for a substituted [5]paracyclophane;[4] these bridge protons are found in the shielding cone of the aromatic ring. It is remarkable that the shielding in **5** is stronger than that in monocyclic [5]paracyclophanes (homobenzylic: $\delta = 0.22$,[2] 0.33,[4b] central: $\delta = 0.01$,[2] -0.55,[4b]). This effect may be attributed to the increased ring current of a naphthalene system compared to that of a benzene ring.



6

The fluorescence excitation spectrum of **5** shows a red shift for the first electronic transition in **5** ($\lambda = 390$ nm) of about 40 nm compared to that of the unstrained model **6**.[9] Thus, this shift is significantly smaller than those reported for monocyclic [5]paracyclophanes (70–90 nm[2, 4b]).

Like other unsymmetrically substituted [5]paracyclophanes, **5** occurs as an equilibrating mixture of two conformational isomers **5′** and **5″**. However, in contrast to other [5]paracyclophanes, one conformer strongly dominates in a ratio of 95:5, as

5′ **5″**

indicated by the arene signals at 210 K. Despite extensive NOE experiments, we have not been able to assign the conformations, as most signals of the minor conformer are obscured by those of the major one and of **4**.

The barrier for the conformational change of the pentamethylene bridge (**5′**⇌**5″**) was determined from variable temperature ^{1}H NMR measurements (206–244 K). Usually, this barrier decreases with decreasing strain in the molecular skeleton; thus, Tobe and co-workers found in the [6]paracyclophane series that the ring flip barrier does indeed decrease slightly with an increasing number of annelated rings.[5] However, the parameters of **5** ($\Delta H^{\neq} = 11.3 \pm 1.2$ kcal mol^{-1}, $\Delta S^{\neq} = -15.1 \pm 5.1$ cal K^{-1} mol^{-1}) are nearly identical to those of its monocyclic analogue.[4b]

Of all [5]paracyclophanes, **5** is the most stable one known to date. In the 2:1 mixture of **4** and **5**, **5** slowly decomposed at 298 K leading to the formation of a white insoluble polymer (half-life >80 h); for monocyclic [5]paracyclophanes, half-lives of 12[10] to 22 hours[4a] have been determined. In contrast, the chemical reactivity of **5** is still very high. The bright yellow solution of the 2:1 mixture of **4** and **5** mentioned above decolorized immediately on exposure to air; in the NMR spectrum the signals of **5** disappeared (formation of a white insoluble polymer), whereas those of **4** remained unchanged.

The synthesis of **5**, the first derivative of [5]paracyclophane with sufficient thermal stability, will form the basis of investigations of the chemical behavior of this class of highly strained aromatic compounds.

Experimental Procedure

2: The products of the first three steps of Scheme 1 were prepared by using known methods [6,7]; details of the syntheses are available on request from the authors. The yield of **2** as a transparent oil was about 0.18 g (0.90 mmol, ca. 82%); because of its sensitivity, it was only characterized by NMR spectroscopy and was directly used in the next reaction step. ^{1}H NMR (200.1 MHz, $CDCl_3$, 298 K): $\delta =$ 5.16 (br. s, 2H), 4.76 (br. s, 2H), 1.8–1.2 (m, 10H), 1.55 (s, 6H); ^{13}C NMR (50.32 MHz, $CDCl_3$, 298 K): $\delta = 153.1$ (s), 143.0 (s), 101.3 (t), 62.0 (s), 33.0 (t, central bridge-CH_2), 28.5 (t), 26.5 (t), 10.1 (q).

3: The bright yellow reaction mixture from **2** (0.14 g, 0.70 mmol) and four equivalents of DMAD (0.40 g) in benzene (20 mL) were stirred for 4 h at 80 °C. Then the benzene was removed at room temperature under reduced pressure, and the excess DMAD was removed under high vacuum. The residue was chromatographed (Kieselgel 60, pentane/ether 50/50)) to give a colorless oil **3** (0.22 g, 0.63 mmol, 90%). ^{1}H NMR (200.1 MHz, $CDCl_3$, 298 K): $\delta = 3.57$ (s, 6H), 3.04 (m, 2H), 2.99 (m, 2H), 1.67 (m, 4H), 1.60 (s, 6H), 1.52 (m, 6H); ^{13}C NMR (50.32 MHz, $CDCl_3$, 298 K): $\delta = 168.9$ (s), 144.5 (s), 143.0 (s), 134.0 (s), 63.6 (s), 52.0 (q), 33.4 (t, central bridge-CH_2), 28.1 (t), 27.2 (t), 26.3 (t), 11.4 (q).

4: To **3** (0.22 g, 0.63 mmol) in benzene (25 mL) was added 1.1 equivalents of DDQ. This mixture was stirred at 80 °C for 3 h, and then poured into ice-water and extracted with diethyl ether (three times). The combined organic phases were washed with water (four times), brine, and dried over $MgSO_4$. After the solvent was removed under reduced pressure, a brown oil remained containing largely **4**. Purification was finally achieved by preparative thin layer chromatography (Al_2O_3 on glass, pentane/ethyl acetate 90/10). Due to losses during attempted purification, meaningful yields could not be determined. **4** (colorless oil): ^{1}H NMR (200.1 MHz, $CDCl_3$, 298K): $\delta = 7.41$ (s, 2H), 3.87 (s, 6H), 2.04 (m, 4H), 1.56 (s, 6H), 1.47 (m, 6H); ^{13}C NMR (50.32 MHz, $CDCl_3$, 298K): $\delta = 168.8$ (s), 155.4 (s), 143.7 (s), 130.3 (s), 121.6 (d, J(C,H) = 164 Hz), 64.9 (s), 52.3 (q, J(C,H) = 147 Hz), 33.1 (t, J(C,H) = 121 Hz, central bridge-CH_2), 28.3 (t, J(C,H) = 125 Hz), 26.3 (t, J(C,H) = 125 Hz), 11.1 (q, J(C,H) = 126 Hz); high resolution MS: $C_{21}H_{24}O_4$ (M^+) calcd.: m/z 340.1674, observed 340.1677 ± 0.0005; fluorescence excitation/emission spectroscopy (THF, 298 K, Perkin Elmer LS-50); excitation spectrum: $\lambda_{em} = 430$, $\lambda_{max} = 260$, 325 nm; emission spectrum: $\lambda_{exc} = 260$ nm, $\lambda_{max} = 392$ nm.

5: A solution of **4** in [D$_8$]THF was filled into a quartz NMR tube, degassed by means of five freeze-pump-thaw cycles, and sealed in vacuo. The tube was irradiated at −25 °C with a Xenon-arc lamp (450 W) fitted with a monochromator set at 260 nm. After about 60 h of irradiation, a photodynamic equilibrium had been reached at 35% of **5** (^{1}H NMR). Major isomer (the signals of the minor isomer are largely obscured by other signals, with the exception of the arene signal at $\delta = 8.26$): ^{1}H NMR (400.1 MHz, [D$_8$]THF, 210 K): $\delta = 8.29$ (s, 2H), 3.85 (s, 6H, OMe), 3.22 (dd, ^2J(H,H) = 12.7 ± 0.3 Hz, ^3J(H,H) = 4.9 Hz, 2H, Ar-CHH), 2.63 (ddd, ^2J(H,H) = 12.4 ± 0.3 Hz, ^3J(H,H) = ^3J(H,H) = 5.2 Hz, 2H, Ar-CH*H*), 2.41 (s, 6H, Ar*Me*), 1.50 (m [11]), 1.20 (m [11]), −0.37 (m, 2H), −0.61 (ddd, ^2J(H,H) = 16.2 Hz, ^3J(H,H) = ^3J(H,H) = 7.3 Hz, 1H); ^{13}C NMR (100 MHz, [D$_8$]THF, 210 K): $\delta = 168.9$ (s), 143.8 (s), 140.4 (s), 137.7 (s), 128.8 (s), 125.7 (d), 53.0 (q), 36.8 (t), 34.9 (t), 20.3 (t), 19.3 (q); fluorescence excitation spectroscopy (THF, 298 K, Perkin Elmer LS-50): $\lambda_{em} = 500$ nm, $\lambda_{max} = 260$ nm, 330 nm, 390 nm.

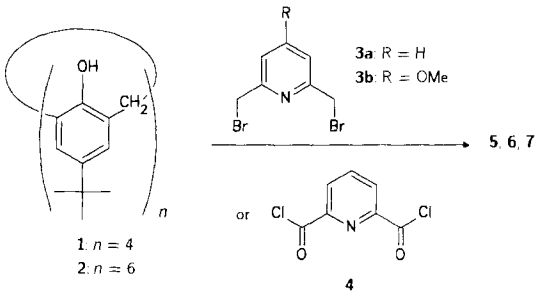
Concave Reagents Based on Calixarenes**

Haymo Ross and Ulrich Lüning*

The high (stereo)selectivity of an enzyme is mainly caused by the concave environment of the active site. In comparison, reagents with simpler structures behave unselectively. According to the concept of concave reagents, the selectivity of standard reagents can be altered by placing them in a concave environment.[1, 2] Like a light bulb in a lamp shade, the functional group of the concave reagent is built into a bimacrocycle. Various synthetic pathways are used to prepare concave pyridines, phenanthrolines, benzoic acids, and thiolacetates.[2] The unit with the functional group, for example a pyridine ring,[1–3] is either first cyclized to give a monomacrocycle and then bridged to form a bimacrocycle, or it is converted directly into a bimacrocycle in a one-pot reaction. Often high-dilution conditions are necessary.

Our goal was to use a new strategy for the synthesis of concave reagents: An easily accessible macrocycle was to be bridged with a building block that contained the functional group. Calixarenes[4] are well suited for this purpose because they are easily accessible and can be bridged regioselectively. Examples for the bridging of *p-tert*-butylcalix[4]arene (**1**) have been known for quite some time,[5] and the bridging of the larger *p-tert*-butylcalix[6]arene (**2**) was reported recently.[6] Usually the bridges are either flexible aliphatic chains or polyether chains, or they are rigid units with geometries adjusted to the calixarenes **1** or **2**.[6–8] Acidic or basic functional groups in the bridges are the exception: an alkali metal complexing calix[4]arene containing a 2,6-dianisylpyridine bridge has been synthesized.[9] But it is not a concave base because its pyridine nitrogen atom is more accessible from the outside than from within the calixarene cavity.

Our attempts to bridge *p-tert*-butylcalix[4]arene with 2,6-bis(bromomethyl)pyridine (**3a**) led to a [2 + 2] cyclization product,

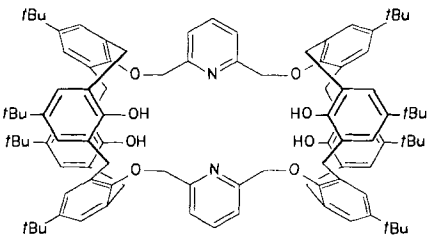


1: n = 4
2: n = 6

4

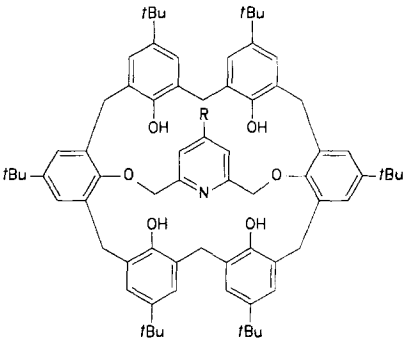
Scheme 1.

the biscalix[4]arene **5**. It is also not a concave base because the pyridine nitrogen atoms do not point exclusively into the calixarene cavity; they are also accessible from the sides.



5

[1 + 1] Bridging with 2,6-bis(bromomethyl)pyridine (**3a**) and its methoxy derivative **3b** was successful when carried out with the larger *p-tert*-butylcalix[6]arene (**2**). The reactions of **2** and compounds **3** in the presence of an excess of potassium *tert*-butoxide gave the new concave bases **6** in initial yields of 36% (**6a**)



6a R = H
6b R = OMe

[**] Concave Reagents, Part 16. We thank Mrs. G. Kohlmeyer-Yilmaz for carrying out the NMR titrations. Part 15: U. Lüning, M. Müller, M. Gelbert, K. Peters, H. G. von Schnering, M. Keller, *Chem. Ber.* **1994**, *127*, 2297–2306.

and 32% (**6b**) after several hours of stirring in THF at room temperature without high dilution. Better yields (55% and 51%, respectively) were obtained when the reaction was carried out in THF/DMF (9:1) at reflux with sodium hydride as base.

The ^{1}H NMR spectrum of **6a** indicates that it is an A,D-bridged[10] C_{2v}-symmetric calixarene. Since two conformers with this symmetry are conceivable, a NOESY spectrum was recorded to determine the conformation. The interactions H_a/H_d, H_b/H_d, H_c/H_f, and especially H_a/H_b show that all the phenyl rings of the calixarene are oriented *syn* (Fig. 1). The

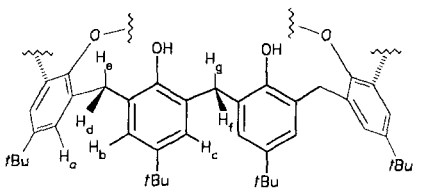

Fig. 1. Partial structure of **6a** to explain the NOE interactions.

differences in the chemical shifts ($\Delta\delta = 0.86$ and 0.61) of the AB doublets belonging to the methylene groups of the calixarene provide further support for the all-*syn* conformation.[11] The calixarene cavity is bridged by the pyridine moiety. The *tert*-butyl groups are located at the open side of the cavity; the nitrogen atom points into the cavity. Because the ^{1}H NMR data of **6b** are similar to those of **6a**, a concave geometry can also be assumed for **6b**.

In addition to the bromides **3a** and **3b**, pyridine-2,6-dicarboxylic acid dichloride (**4**) was also used to bridge *p-tert*-butylcalix[6]arene (Scheme 1). A solution of **2**, **4**, and potassium *tert*-butoxide was stirred for several days at room temperature to give the A,C-bridged calix[6]arene **7** in 24% yield. The yield could not be increased by altering the reaction conditions as was possible for **6a** and **6b**. To our knowledge, **7** is the first example of an A,C-bridged calix[6]arene obtained directly from **2**.[12] An A,D-bridged calix[6]arene could not be isolated after reaction with the dichloride **4**, and likewise no A,C-bridged calix[6]arene was obtained using the dibromides **3a** or **3b**. The low flexibility of **4** together with a change in reaction mechanism when the acid chloride **4** is used instead of an alkyl bromide **3** seems to be the reason for the difference in regioselectivity of the bridging process.

The addition of 4-nitrophenol to a solution of **6a** in [D$_1$]chloroform leads to shifts in the ^{1}H NMR signals, which can be explained by inclusion of the phenol in the cavity of **6a**. The singlet arising from the *tert*-butyl hydrogen atoms (54 H) at $\delta = 1.23$ splits into two singlets with a ratio of 2:1 at $\delta = 1.15$ and 1.23. This and shifts of the pyridine signals are in accordance with formation of a hydrogen bond. An association constant K_{ass} of 12 M^{-1} was determined by NMR titration ($CDCl_3$, 300 MHz, 25 °C) (Table 1). The more acidic, but bulkier 2-chloro-4-nitrophenol is bound less strongly, the phenols 2,6-dimethyl-4-nitrophenol and 2,4-dinitrophenol, which are even bulkier but have considerable differences in acidity, are not bound detectably. An excess of the latter two phenols leads to no significant changes in the ^{1}H NMR spectrum. The association constants can therefore only be estimated (< 1 M^{-1}); the exact values cannot be determined.

For comparison, the association of the nonconcave 2,6-dimethylpyridine with the phenols mentioned above was also investigated by NMR spectroscopy. The difference in the association constants of 2,6-dimethylpyridine with 4-nitrophenol and

Table 1. Association constants determined by NMR titration ($CDCl_3$, 300 MHz, 25 °C).

Phenol	K_{ass} [M^{-1}] with **6a**	K_{ass} [M^{-1}] with 2,6-dimethylpyridine
4-$NO_2C_6H_4OH$	12	13
2-Cl-4-$NO_2C_6H_3OH$	6	(2) [a]
2,4-$(NO_2)_2C_6H_3OH$	[b]	(3) [a]
2,6-$(CH_3)_2$-4-$NO_2C_6H_2OH$	[b]	5

[a] Larger shifts in the signals than in the other cases, probably due to partial protonation of 2,6-dimethylpyridine. [b] $K_{ass} < 1$; a more accurate value cannot be determined owing to the small shifts in the signals.

with 2,6-dimethyl-4-nitrophenol is smaller than in the case of **6a**. The association constants determined by titration of 2,6-dimethylpyridine with 2-chloro-4-nitrophenol and 2,4-dinitrophenol, however, cannot be compared with the others, because the detectable signal shifts are much larger ($\Delta\delta_{max}$ ca. 1.0 instead of 0.2) and indicate partial protonation of the 2,6-dimethylpyridine.

The differing behavior of **6a** with phenols with varying steric demand indicates that substrate specificity in base-catalyzed reactions may be possible. Calixarene **6a** was already used successfully as a catalyst in the base-catalyzed addition of alcohols to diphenylketene. To eliminate the influences of phenolic and therefore acidic hydroxyl groups of the calixarenes, investigations are now being carried out with tetra-*O*-alkyl derivatives of **6a** and **6b**.

Experimental Procedure

5: Under nitrogen, the *p-tert*-butylcalix[4]arene–toluene complex (**1** · toluene) [13b] (1.550 g, 2.092 mmol) was suspended with potassium carbonate (580.0 mg, 4.197 mmol) in 360 mL of acetonitrile. After addition of [18]crown-6 (27.6 mg, 0.104 mmol), the mixture was stirred for 30 min at 70 °C. Then a solution of **3a** (554.2 mg, 2.092 mmol) in 240 mL of acetonitrile was added dropwise over a period of 24 h, and the mixture was stirred for another 2 h at 70 °C. After evaporation of the solvents in vacuo, the residue was dissolved in 200 mL of dichloromethane. The solution was washed (60 mL of water, 60 mL of 1 N hydrochloric acid, 60 mL of water) and dried over magnesium sulfate. Column chromatography (silica gel 0.06–0.20 mm, dichloromethane) gave **5** in 52% yield as a colorless solid, m.p. > 350 °C (decomp). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.08$ (s, 36 H, $C(CH_3)$), 1.28 (s, 36 H, $C(CH_3)_3$), 1.56 (br. s, < 6 H, H_2O), 3.37 (d, $J = 13.1$ Hz, 8 H, Ar-CH_2-Ar), 4.49 (d, $J = 13.1$ Hz, 8 H, Ar-CH_2-Ar), 5.16 (s, 8 H, -CH_2O-), 6.96 (s, 8 H, Ar*H*), 7.05 (s, 8 H, Ar*H*), 7.35 (t, $J = 7.9$ Hz, 2 H, 4-Py*H*), 7.97 (s, 4 H, O*H*), 8.33 (d, $J = 7.9$ Hz, 4 H, 3,5-Py*H*); IR (KBr): $\tilde{\nu} = 3406$ cm^{-1} (OH); MS (70 eV): *m/z* (%): 1502 (100, M^+); elemental analysis: $C_{102}H_{122}N_2O_8 \cdot 2H_2O$ (1504.09 + 36.02): calcd C 79.55, H 8.25, N 1.82; found C 79.84, H 8.02, N 1.80.

6a: Compound **2** [13a] (973 mg, 1.00 mmol) was added to a suspension of sodium hydride (250 mg, ca. 6.25 mmol; the dispersion in mineral oil (60%) was washed several times with *n*-pentane prior to use) in 100 mL of THF/DMF (9:1) under nitrogen. After 15 min of stirring at room temperature the mixture was heated at reflux. A solution of **3a** (318 mg, 1.20 mmol) in 30 mL of THF/DMF (9:1) was added dropwise, then the mixture was refluxed for another 15 h. After cooling, 5 mL of methanol and 40 mL of 0.1 N hydrochloric acid were added, and the mixture was extracted with 75 mL of chloroform. The aqueous layer was removed and the combined organic phases were dried with magnesium sulfate. Column chromatography (silica gel 0.06–0.20 mm, dichloromethane) of the crude product gave **6a** in 55% yield as a colorless solid, m.p. 215–219 °C (decomp). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.23$ (s, 54 H, $C(CH_3)_3$), 1.61 (br. s, < 3 H, H_2O), 3.28 (d, $J = 14.4$ Hz, 2 H, Ar-CH_2-Ar), 3.57 (d, $J = 14.3$ Hz, 4 H, Ar-CH_2-Ar), 4.14 (d, $J = 14.4$ Hz, 2 H, Ar-CH_2-Ar), 4.18 (d, $J = 14.3$ Hz, 4 H, Ar-CH_2-Ar), 5.07 (s, 4 H, -CH_2-O-), 6.96 (d, $J = 2.4$ Hz, 4 H, Ar*H*), 7.09 (d, $J = 2.4$ Hz, 4 H, Ar*H*), 7.19 (s, 4 H, Ar*H*), 7.34 (d, $J = 7.7$ Hz, 2 H, 3,5-Py*H*), 7.71 (t, $J = 7.7$ Hz, 1 H, 4-Py*H*), 7.81 (s, 4 H, O*H*); IR (KBr): $\tilde{\nu} = 3344$ cm^{-1} (OH); MS (EI, 70 eV): *m/z* (%): 1075 (100, M^+); elemental analysis: $C_{73}H_{89}NO_6 \cdot H_2O$ (1076.51 + 18.01): calcd C 80.10, H 8.37, N 1.27; found C 79.93, H 8.20, N 1.21.

6b was obtained analogously: m.p. 284–288 °C (decomp); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.22$ (s, 18 H, $C(CH_3)_3$), 1.23 (s, 36 H, $C(CH_3)_3$), 1.64 (< 6 H, H_2O), 3.29 (d, $J = 14.6$ Hz, 2 H, CH_2), 3.58 (d, $J = 14.2$ Hz, 4 H, CH_2), 3.86 (s, 3 H, CH_3), 4.12 (d, $J = 14.6$ Hz, 2 H, CH_2), 4.14 (d, $J = 14.2$ Hz, 4 H, CH_2), 4.97 (s, 4 H, -O-CH_2-), 6.87 (s, 2 H, Py*H*), 6.94 (d, $J = 2.5$ Hz, 4 H, Ar*H*), 7.09 (d, $J = 2.5$ Hz, 4 H, Ar*H*), 7.19 (s, 4 H, Ar*H*), 7.80 (s, 4 H, O*H*); IR (KBr): $\tilde{\nu} = 3384$ cm^{-1} (OH); MS

(EI, 70 eV): m/z (%): 1105.8 (100, M^+); elemental analysis: $C_{74}H_{91}NO_7 \cdot 0.5H_2O$ (1106.54 + 9.01): calcd C 79.67, H 8.31, N 1.26; found C 79.79, H 8.27, N 1.31.

7: Under nitrogen, **2** [13a] (973 mg, 1.00 mmol) and potassium *tert*-butoxide (741 mg, 6.60 mmol) were stirred for 20 min in 100 mL of THF. Then a solution of **4** (245 mg, 1.20 mmol) in 20 mL of THF was added dropwise. The mixture was stirred for 48 h at room temperature. The reaction was quenched by adding 10 mL of 1 N hydrochloric acid. After evaporation of the solvents in vacuo, the residue was dissolved in 150 mL of dichloromethane. The solution was washed with 60 mL of 1 N hydrochloric acid and twice with 50 mL of water, and was dried over magnesium sulfate. Column chromatography (silica gel 0.06–0.20 mm, dichloromethane) gave **7** in 24% yield as a colorless solid, m.p. 280–284 °C (decomp). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.05 (s, 9H, $C(CH_3)_3$), 1.18 (s, 9H, $C(CH_3)_3$), 1.24 (s, 18H, $C(CH_3)_3$), 1.27 (s, 18H, $C(CH_3)_3$), 1.92 (s, ca. 6H, H_2O), 3.34 (d, J = 13.9 Hz, 2H, CH_2), 3.37 (d, J = 16.4 Hz, 2H, CH_2), 3.48 (d, J = 14.0 Hz, 2H, CH_2), 3.75 (d, J = 16.2 Hz, 2H, CH_2), 3.89 (d, J = 13.9 Hz, 2H, CH_2), 4.49 (d, J = 13.9 Hz, 2H, CH_2), 5.22 (s, 1H, OH), 6.68 (d, J = 2.4 Hz, 2H, Ar*H*), 6.77 (s, 2H, Ar*H*), 7.02 (d, J = 2.5 Hz, 2H, Ar*H*), 7.06 (s, 2H, Ar*H*), 7.18 (d, J = 2.4 Hz, 2H, Ar*H*), 7.41 (d, J = 2.4 Hz, 2H, Ar*H*), 7.81 (s, 2H, O*H*), 8.22 (t, J = 7.8 Hz, 1H, 4-Py*H*), 8.56 (d, J = 7.8 Hz, 2H, 3,5-Py*H*), 8.89 (s, 1H, O*H*); IR (KBr): $\tilde{\nu}$ = 3342 cm^{-1} (OH), 1750 (C=O); MS (EI, 70 eV): m/z (%): = 1103.6 (100, M^+); elemental analysis: $C_{73}H_{85}NO_8 \cdot 3H_2O$ (1104.48 + 54.03): calcd C 75.68, H 7.92, N 1.21; found C 75.38, H 7.61, N 1.19.

Synthesis and Structure of the Three-Dimensional Coordination Polymers $[(Me_3Sn)_4M(CN)_8]$ (M = Mo, W)**

J. Lu, W. T. A. Harrison, and A. J. Jacobson*

Three-dimensional polymers formed by coordination between inorganic units and organic or organometallic ligands have been closely studied.[1–5] These materials can form porous structures with channels that are potentially tunable by changing the building unit sizes or functional groups. A large number of compounds with three-dimensional structures formed by connecting metal cyanide anions with organotin cations $(R_3Sn)^{3+}$ have been synthesized and studied in some detail;[1] however, limited structural information is available. The metal ions in these three-dimensional polymers are either octahedrally coordinated (e.g. $[M(CN)_6]^{3-}$, M = Co, Fe, Ru, Os; $[M(CN)_6]^{4-}$, M = Fe, Ru, Os)[1] or tetrahedrally coordinated (e.g. $[Cu(CN)_4]^{3-}$).[3] A previous attempt to use the $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$ anions to form single crystals of the title compounds was apparently not successful.[2]

The structure of the building unit $[M(CN)_8]^{4-}$ can be either dodecahedral (e.g. $K_4[Mo(CN)_8]$) or square antiprismatic (e.g. $H_4[W(CN)_8]$) depending on the counterion.[6] Either geometry can lead to the formation of three-dimensional structures that differ considerably from those obtained with octahedrally or tetrahedrally coordinated metal cyanide ions. We report here on the synthesis, structure, and preliminary characterization of the coordination polymers **1**-*n*THF and **2**-*n*THF. The compounds **1** and **2** are formed in a straightforward way by the reaction given in Equation (a).

$$K_4M(CN)_8 + 4Me_3SnCl \xrightarrow{H_2O/THF} [(Me_3Sn)_4M(CN)_8] \quad \text{(a)}$$
1, M = Mo
2, M = W

Polymers of the type $[(R_3E)_nM(CN)_{2n}]$ (E = Sn or Pb) with n = 4 have been proposed previously but synthesis attempts led to the formation of layered compounds, for example, $[(Me_3Sn)_2MoO_4]$, presumably due to molybdenum oxidation in air.[2] When the reactions were carried out in sealed tubes, **1** and **2** formed without difficulty. In a comparison experiment carried out in an open tube, colorless crystals were formed that were shown by single-crystal X-ray diffraction to have the same unit cell as $[(Me_3Sn)_2MoO_4]$.

Infrared C–N stretches in compound **1** (2143 (s), 2105 (w, sh) cm^{-1}) and **2** (2141 (s), 2105 (w, sh) cm^{-1}) are blue shifted from those of $K_4[Mo(CN)_8]$ (2102 (s), 2125 (s) cm^{-1}) and $K_4[W(CN)_8]$ (2096 (s), 2127(s) cm^{-1}). Small weak shoulders are also observed at $\approx$2105 cm^{-1} in both **1** and **2**. Metal cyanide–organotin compounds typically show this behavior.[1] The Me_3Sn group is a Lewis acid and is unable to π back-bond and consequently the C–N stretching frequency increases on coordination.[7]

The structures of **1** and **2** were determined by single-crystal X-ray diffraction.[8] The compounds **1** and **2** are isostructural and have similar cell dimensions. Elemental analysis results in-

dicated that the disordered interstitial solvent molecules are THF.[9] In the structures of **1** and **2**, every $M(CN)_8$ group is connected through Me_3Sn bridges to eight $M(CN)_8$ groups which form the corners of a body-centered tetragonal unit cell (Fig. 1). The $M(CN)_8^{4-}$ unit rearranges from the dodecahedral structure of the starting $K_4M(CN)_8$ compounds[10] to square

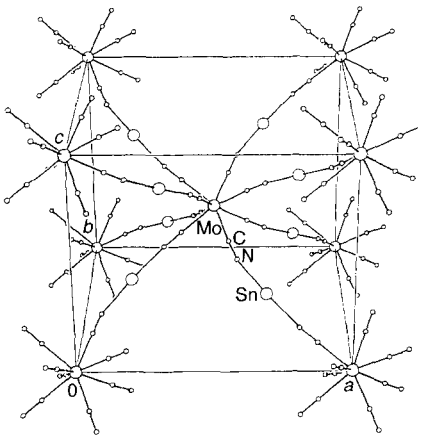

Fig. 1. A view of the unit cell of **1**. The methyl groups are omitted for clarity.

antiprismatic geometry in the final products. The M–C and C–N bond lengths remain the same within experimental error. The N–Sn distances (2.335(5) Å and 2.32(1) Å for **1** and **2**, respectively) are comparable to those in similar compounds such as $[(Me_3Sn)_3Co(CN)_6]$[1] (av. 2.32 Å) and $[(nBu_4N)(Et_3Sn)_2Cu(CN)_4]$[3] (av. 2.33 Å). The local coordinations of the $Mo(CN)_8$ and Me_3Sn units are shown in Figure 2.

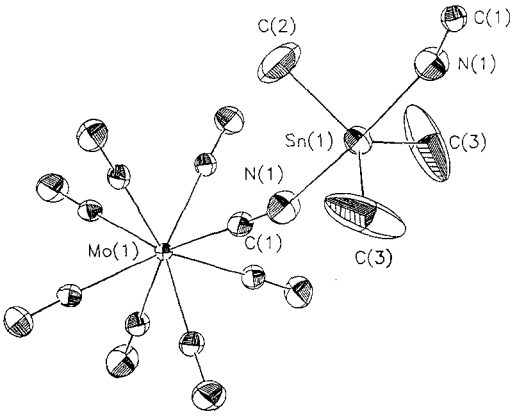

Fig. 2. ORTEP drawing of the local coordination environments of the molybdenum and tin atoms in **1**.

Compounds **1** and **2** crystallize in the chiral space group *I*422. Every Sn-$M(CN)_8$ unit is equivalent and has the same chirality. When one looks down the fourfold axis (Fig. 3 top), the tin atoms appear in pairs, with two tin atoms in each pair closer to each other in the projection. The top molybdenum to tin vectors rotate to the right to overlap with the corresponding vectors at the bottom of the projection. Thus, the chirality of the local arrangement around the molybdenum or tungsten atoms in **1** and **2** can be described as right-handed.

The structures of **1** and **2** can be compared with other compounds of this general type, $[(R_3E)_nM(CN)_{2n}]$ (E = Sn, Pb), where the metal coordination is tetrahedral ($n = 2$) or octahedral ($n = 3$). The structure of polymeric compound with $n = 2$,

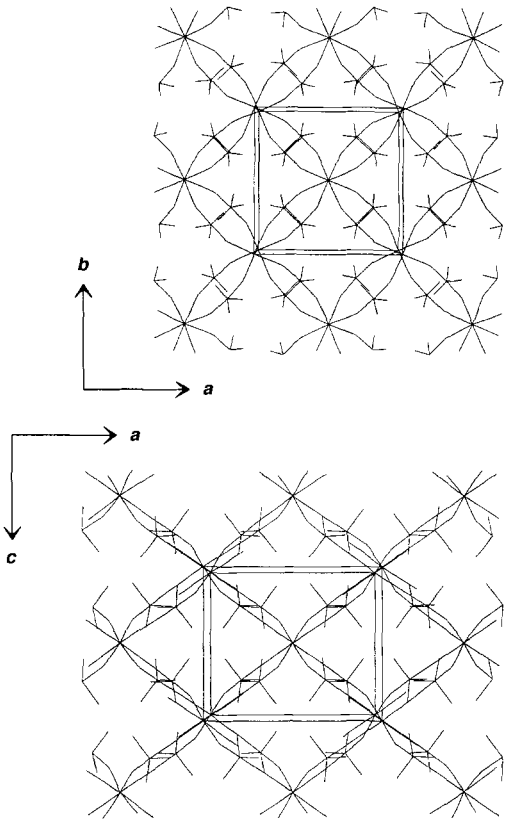

Fig. 3. Views of the structure of **1** along the crystallographic *c* axis (top) and along the crystallographic *b* axis (bottom).

$[(nBu_4N)(Et_3Sn)_2Cu(CN)_4]$, has a distorted diamond-type network but with a more compact lattice than the ideal diamondoid framework.[3] The compounds with $n = 3$, $[(Me_3E)_3Co(CN)_6]$ (E = Sn, Pb), have three-dimensional structures with cavities smaller than the ideal "super-Prussian-blue" structure and do not include guest molecules.[1] In both cases the networks condense by bending the E-N-C angles away from 180°. The minimum values of the E-N-C angle in the above-mentioned structures range from 125° to 149.3°. Similarly, the C-N-Sn angles in **1** and **2** (163.7(5)° and 166.0(9)°, respectively) also deviate from 180° but are closer to the ideal value. The views of the structure along the principal crystallographic axes (Fig. 3) show the channels in the network. A space-filling model shows that the methyl groups block the channels along the *a* and *b* axes, but along the *c* axis an open channel of about 2.8×2.8 Å^2 remains. If we regard the methyl groups as not rigidly fixed, the maximum size of the channel along *c* is about 6.0×6.0 Å^2 and the size of channels along *a* and *b* is about 7.1×5.2 Å^2. The channels are occupied by disordered THF solvent molecules.

Unlike the networks formed by porphyrin building blocks,[4] the framework is retained upon removing some of the solvent molecules. Thermogravimetric analysis of **1** showed a slow weight loss below 200 °C as the temperature was increased. The residues from heating samples of either **1** or **2** to 185 °C for 2 h retained the same structure as shown by X-ray powder diffraction. At temperatures above 225 °C, the rate of weight loss increased and a powder pattern for a tungsten sample heated to 250 °C indicated decomposition and loss of the original structure. No reabsorption of THF or absorption of *n*-hexane or dichloromethane was observed at room temperature by samples that had been outgassed at 185 °C indicating that even at this temperature some surface decomposition must occur.

Experimental Procedure

$K_4[Mo(CN)_8]$ (0.496 g, 1 mmol) or $K_4[W(CN)_8]$ (0.584 g, 1 mmol) was dissolved in distilled water (10 mL) and was placed in a 30 mL screw-capped culture tube. A 5 mL mixture of 1:1 water/THF was carefully layered onto this solution as a protection layer and 5 mL of a 1.0 M THF solution of Me_3SnCl was layered on the very top. The tube was left undisturbed and capped. Slow diffusion of Me_3SnCl into $K_4[M(CN)_8]$ (M = Mo, W) solutions resulted in the formation of yellow block-shaped crystals at the interface in about a week. When interdiffusion was allowed to procede to completion and the product washed and dried, yields of 0.8816 g of the molybdenum compound **1** (92% based on formula $[(Me_3Sn)_4Mo(CN)_8]$) or 1.0273 g of the tungsten compound **2** (98% based on formula $[(Me_3Sn)_4W(CN)_8]$) were obtained. The powder X-ray patterns of the bulk solids were the same as patterns simulated by using the single-crystal structure data. The products are insoluble in most common solvents and indefinitely stable in air.

Te_8^{4+}: A Cubic Polycation in the Structure of $Te_8(VOCl_4)_2$

Johannes Beck* and Gunter Bock

Tellurium does not exhibit the allotropic diversity of the lighter homologues sulfur and selenium; under normal conditions, only one stable modification of tellurium is known. However, very recent discoveries have shown the existence of neutral, eight-membered tellurium rings in the polytelluride Cs_3Te_{22}.[1] In comparision to this structural paucity, polyanionic[2] and polycationic[3] forms of tellurium abound and exhibit an unusually rich and varied structural chemistry.

Polycations of tellurium can be obtained either through selective oxidation of the element itself, or through Lewis acid base reactions of suitable halide ion acceptors with the subhalides of tellurium. To date, the ions Te_4^{2+},[4] Te_6^{2+},[5] Te_6^{4+},[6] $[Te_7^{2+}]_n$,[7] and Te_8^{2+}[8] have been characterized. The halides and halide oxides of the elements in group 7, that is niobium and tantalum, have proven to be suitable Lewis acids; the weak basic character of anions obtained from these compounds suffices to stabilize the polycations of tellurium as for example in $Te_4^{2+}(Nb_2OCl_{10}^{2-})$,[9] $Te_4^{2+}(TaCl_6^-)_2$,[10] and $Te_7^{2+}(NbOX_4^-)(X^-)$ (X = Cl, Br).[11] We have extended these reactions to include the chloride oxide of pentavalent vanadium. The reaction of elemental tellurium with $VOCl_3$ in a temperature gradient of 190 to 170 °C leads to **1**, in the form of black, rodlike crystals.

$Te_8(VOCl_4)_2$ **1**

An X-ray structure analysis[12] shows that **1** contains one-dimensional polymeric $VOCl_4^{2-}$ chains and strands of Te_8^{4+} ions. The $VOCl_4^{2-}$ chains lie along a 4_1 screw axis and the cationic chains along a $\bar{4}$ inversion axis. The chains of cations and anions in the structure are arranged in the sense of a tetragonal rod-packing. Figure 1 shows the unit cell of **1**; the structure of the Te_8^{4+} polycations and a section of the polymeric $VOCl_4^{2-}$ chain are depicted in Figure 2. The $VOCl_4^{2-}$ chains contain square-pyramidal $VOCl_4$ units, which show an approximate C_{4v} symmetry and are linked together through shared oxygen atoms to give linear chains. The $VOCl_4$ units are eclipsed, similar to the

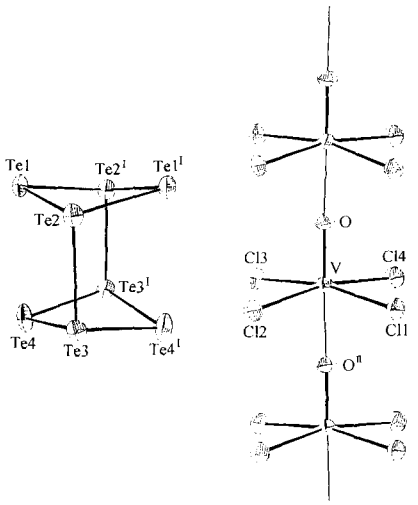

Fig. 2. The Te_8^{2+} polycation and a section of the polymeric $VOCl_4^{2-}$ chain in the structure of **1** (thermal ellipsoids drawn at the 70% probability level). Symmetry operations: I $= -x+1, -y+1/2, z$; II $= y+3/4, -x+3/4, z-1/4$; selected bond lengths [pm] and angles [°]: Te(1)–Te(2) 278.5(1), Te(1)–Te(2^{I}) 276.2(1), Te(2)–Te(3) 301.0(1), Te(3)–Te(4) 274.8(1), Te(3)–Te(4^{I}) 274.3(1); Te(2)-Te(1)-Te(2^{I}) 87.51(2), Te(1)-Te(2)-Te(1^{I}) 89.91(2), Te(1)-Te(2)-Te(3) 99.18(2), Te(3)-Te(4)-Te(3^{I}) 88.48(2), Te(4)-Te(3)-Te(4^{I}) 88.84(2), Te(2)-Te(3)-Te(4) 98.16(2); V-O 161.8(4), V-O^{II} 205.1(4), V-Cl(1) 239.9(2), V-Cl(2) 238.2(2), V-Cl(3) 238.1(2), V-Cl(4) 239.4(2); O-V-O^{II} 178.3(2), O-V-Cl 95.0(2) to 96.5(2).

situation found in the structure of $WOCl_4$.[13] The short V=O distance (162 pm) indicates the presence of a double bond, the long V···O^{II} distance (205 pm) a weak, coordinative bond. The V–Cl bond lengths differ only slightly; they lie between 238 and 240 pm. That the vanadium center in **1** is present in the + IV oxidation state was confirmed by a magnetic measurement, which delivered the paramagnetism expected from one unpaired electron per vanadium ion. The reciprocal susceptibility is a nearly linear function of the temperature between 76 and 295 K. The Curie–Weiss constant is + 5 K and the magnetic moment is 1.84 μ_B. Thus, **1** contains a polymeric $^{1}_{\infty}[VOCl_4^{2-}]$ dianion. This is confirmed by comparing the bond lengths in **1** with those in $[(C_6H_5)_4As][VOCl_4]$,[14] which contains a monomeric, square-pyramidal $VOCl_4^{-}$ anion with ideal C_{4v} symmetry; the vanadium is present in the + V oxidation state. The V=O bond length of 155 pm and the V–Cl distance of 226 pm are, as expected, considerably shorter than those for the polymeric $^{1}_{\infty}[VOCl_4^{2-}]$ ion of **1**.

The Te_8^{4+} ions in **1**, which deviate only slightly from cubic symmetry, are built up from two Te_4 rings that are linked together through two slightly elongated (301 pm) Te–Te bonds. The Te–Te distances (between 274 and 279 pm) in the four-membered rings lie in the range of Te–Te single bonds; the distances Te1–Te4 and Te1^{I}–Te4^{I} are 385 pm and lie on the upper limit of significant interactions. The four three-bonded, ψ-tetrahedrally coordinated Te atoms that connect the two four-membered rings each have a formal positive charge according to the Zintl–Klemm[15] concept.

The Te1 and Te1^{I} atoms are 359 pm apart as are the Te2 and Te2^{I} atoms in neighboring Te_8^{4+} ions. Single Te_8^{4+} ions are thus paired through weak interactions along the strand. These additional Te–Te interactions compensate the lengthening of the two bonds bridging the two four-memberd rings contained in a single Te_8^{4+} unit. A similar lengthening of the transannular bonds to 299 pm is observed in the bicyclic Te_8^{2+} ions found in **2**.[8] Further Te atoms become partially bonded to three centers

$Te_8(WCl_6)_2$ **2**

through the pairwise association of ions in the strands in **1** and through association into undulating chains in **2**, thus allowing the positive charge to be delocalized over several atoms in the polycations.

The typical chalcogen–halogen contacts in compounds containing chalcogen polycations and halogenometalate anions are also present in **1**. In fact, because of the high charge density present in Te_8^{4+} ions, an uncommonly large number of cation–anion interactions are found in **1**. Up to a limit of 370 pm, thus, a distance which lies well below the sum of the van der Waals radii of Te and Cl (400 pm),[16] 24 such contacts are found in the structure of **1**; however, only 14 such contacts are present in structure **2**.

The structure of this new Te_8^{4+} ion in **1** can be derived from already known structures of metals, or from structures of tellurium polycations (Fig. 3). The distorted cubic form of the Te_8^{4+} ion suggests that it is derived from the α-Po structure. If the

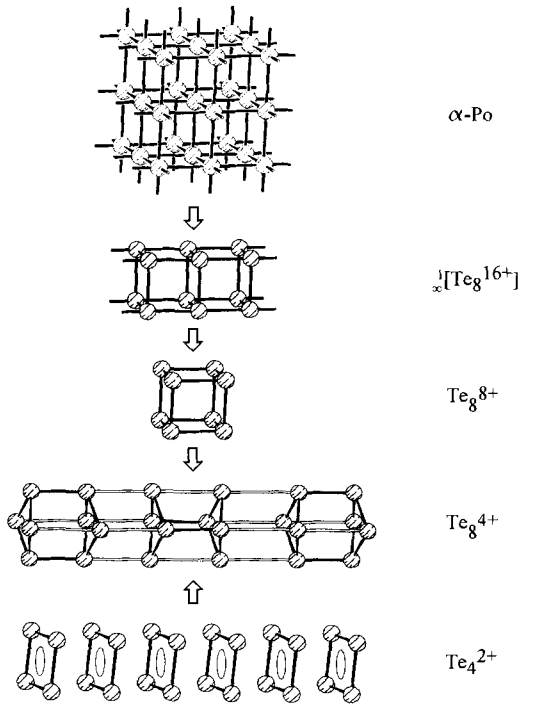

Fig. 3. The structure of the Te_8^{2+} polycation can be derived from the α-Po structure. Through systematic decreases in the number of bonds formed to Te, the Te_8^{4+} ion can be obtained via the hypothetical intermediate species $^{1}_{\infty}[Te_8^{16+}]$ and Te_8^{8+}. An alternative derivation assumes a stack of equidistant Te_4^{2+} ions, which are paired together in the sense of a Peierls distortion.

connectivity of the Te atoms in the three-dimensional network were to be decreased from six to four by removal of electrons, a hypothetical, one-dimensional polymeric $^{1}_{\infty}[Te^{16+}]$ ion would result in which each Te atom is four-bonded and carries a + 2 charge. The structure of this hypothetical polycation shows a considerable similarity to the strandlike structure of the Te_8^{4+} ions in **1**. The next step would then be to break Te–Te bonds by the introduction of pairs of electrons; thus leading to the as yet unknown monomeric Te_8^{8+} ion. This cubic ion is built up of eight three-bonded Te atoms, each carrying a single positive charge. If two opposite edges of the Te_8 cube are then stretched by addition of two pairs of electrons, the number of bonds per Te atom in the cube is further decreased and the Te_8^{4+} ion results, in which only four Te atoms are three-bonded. However, if the Te_8^{4+} ion is considered to be constructed of two four-membered

Te rings linked through two Te–Te bonds, an alternative possibility for the derivation of its structure exists. Pairing, in the sense of a Peierls distortion, occurs in strands of Te_4^{2+} ions arranged parallel and equidistant. The delocalized double bond character in the Te_4^{2+} ions is lost through the formation of inter-ion bonds, resulting in $(Te_4^{2+})_2$ pairs with localized bonding. Associated with this is the increase in the bond lengths in the four-membered rings from 267 pm in Te_4^{2+} to 274 pm in Te_8^{4+} and the loss of planarity. However, as yet, dimerization of Te_4^{2+} ions has not been observed.

Discrete Te_4^{2+} ions are found in conjunction with a multitude of counterions, however, not with one-dimensional polyanions. Undoubtedly, the formation of Te_8^{4+} ions is favored by the rigid framework provided by the polymeric $^1_\infty[VOCl_4^{2-}]$ counterion.

Experimental Procedure

A 15 cm-long glass ampoule with a diameter of 1.5 cm was freed from adsorbed moisture by heating in vacuo. The ampoule was then flushed with argon and filled with Te (0.65 g, 5.1 mmol). $VOCl_3$ (0.2 mL) was then added with a syringe. The ampoule was then cooled with liquid nitrogen, evacuated, and sealed, and subsequently heated for five hours at 200 °C in a horizontal tube furnace. During this heating process, green $VOCl_2$ powder and black crystals of Te_3Cl_2 were formed. These products were then melted together at 270 °C, and the ampoule was again placed in a horizontal position and a temperature gradient of 170 to 190 °C was applied. The melt was located at the warmer end of the temperature gradient. After a week, black, tetragonal, rodlike crystals of **1** were deposited at the cooler end of the ampoule. The yield was approximately 70%.

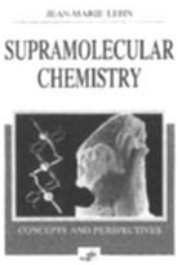
Chemistry Beyond the Molecule

Supramolecular Chemistry. Concepts and Perspectives. By *J.-M. Lehn*. VCH Verlagsgesellschaft, Weinheim, 1995. 271 pp., hardcover DM 128.00.—ISBN 3-527-29312-4; softcover DM 58.00.—ISBN 3-527-29311-6

The embryonic science of supramolecular chemistry existed before Jean-Marie Lehn, but he has given the field its name, an intellectual focus, and a vision for the future. Supramolecular chemistry is "chemistry beyond the molecule", and its goal is to gain control over the intermolecular noncovalent bond. It is, therefore, concerned with the organization and properties of ensembles of molecules held together by weak interactions rather than with the individual molecules themselves. Host-guest complexes, self-assembled objects, and spatially organized films can all be conjured out of small building blocks by the careful exploitation of hydrogen bonds, metal-ligand binding, $\pi-\pi$ interactions, and hydrophobic effects, and the resulting ensembles have potential as catalysts, sensors, or new materials. In one sense, of course, there is nothing new in all this: as Lehn himself points out early in this book, Werner's complexes have been known for a hundred years, and the hydrogen-bonded acetic acid dimer for over fifty. But the bringing together of such disparate elements to form an emerging, coherent discipline that crosses conventional boundaries is relatively new and is partly a result of Lehn's passionate advocacy over many years.



This book is an attempt to summarize Lehn's concepts of supramolecular chemistry. It is based on two sets of lectures; most of the discussion is centered around his own group's enormous contributions. The attraction of this personal approach is that enthusiasm and immediacy leap off the page as the author guides us through twenty years of his research. Starting with the recognition of simple metal ions by macrocycles, we move through chapters on anion recognition, receptors with multiple sites, supramolcular reactivity and catalysis, transport, devices, and self-assembly. Each chapter brings a new species into his "molecular bestiary" including coronands, spherands, and cryptophanes. There is also a whole new vocabulary of categories and topics: here are endoreceptors, nanostructures, semiophores, and chemionics in all their glory. At this stage in their development, many of these words may feel like unnecessary jargon, and some will undoubtedly wither into obscurity, but many of them will come to be essential as they provide the linguistic key for communicating the ideas they represent.

This is an excellent guide to the supramolecular efforts of Lehn and over 200 coworkers, bringing together hundreds of papers that are scattered through the literature of several disciplines. This approach, however, does not make an ideal text for teaching purposes. It assumes too much fundamental knowledge of kinetics, thermodynamics, intermolecular interaction, and synthesis to provide the basis for a satisfying teaching course except at a very high level. There is still room for a real textbook of supramolecular chemistry.

A final feature of the personal approach is that it enables Lehn to bring in connections with literature and sculpture, placing chemistry in a wider, philosophical context. He ends with an inspirational call to chemistry to invent, and above all, to *create*. The joy of chemistry in general, and of supramolecular chemistry in particular, is that we are not limited to the repertoire of reactions and receptors that Nature has provided or the natural products that have evolved over the millenia: we can create our own. And each of us can create a unique structure: whereas in most fields scientists are competing to clone the same receptor, solve the same equation, or make the same natural product, those of us in the supramolecular community can cooperate, each building block from each laboratory contributing its own unique features and personality. It is this combination of cooperativity, art, and science that makes supramolecular chemistry such fun, and it is a feeling that Jean-Marie Lehn has captured so well in this book.

Container Molecules and Their Guests. By *D. J. Cram* and *J. M. Cram*. (Series: Monographs in Supramolecular Chemistry, Vol. 4). Royal Society of Chemistry, Cambridge, 1994. 223 pp., hardcover £ 49.50.—ISBN 0-85186-972-6

In this monograph devoted to supramolecular chemistry the authors review a subject that originates mainly from their own research into host-guest complexation chemistry, and include closely related results from other groups. The ten chapters of the book present topics covering the twenty-five year period from 1970, with a particular emphasis on the authors' work from 1987. As defined by D. J. Cram in his preface, this review is "essentially a chronicle of the more successful parts of the journey [his] research group took into the wilderness of complexation phenomena". It is indeed a fascinating and impressive presentation of a masterpiece of supramolecular chemistry. The design of synthetic molecular receptors is one of the main challenges facing organic chemists in the field of supramolecular chemistry. This book will familiarize the reader with new classes of molecular containers, i.e. new molecules large enough to trap and encapsulate ionic or neutral guests to form a supramolecular complex. There is a thorough dis-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

cussion of the methods for achieving synthesis and structural recognition in complexation. The dependence of binding power on structure is discussed at length, as it depends on many factors including size and stereoelectronic complementarities, topology of the host, solvation effects, the nature and the number of binding sites, and preorganization of the partners involved.

In Chapter 1 the authors define the terms "host" and "guest", and the concept of host–guest complexation, terms which form the basis of the design of container molecules. The first section is concerned with fundamentals, namely the molecular receptors based on crown ether structures. Because of the importance of structural recognition in complexation, the authors discuss crystal structure and molecular modeling, including examination of CPK molecular models, as the necessary tools of the supramolecular chemist ("the crystal structures and molecular modeling connection").

Chapter 2 deals with synthesis, complexation, and molecular structures of spherands and their relatives. Spherands and hemispherands provide a series of preorganized hosts whose complexing properties are the basis of the principles of complementarity and preorganization, which respectively govern structural recognition and binding power. The wide-ranging importance of chiral recognition is emphasized by devoting a separate chapter to this topic. Chapter 3 provides a survey of the results in this field, extending from 2,2′-disubstituted-1,1′-binaphthyl corands as resolving agents for primary amine salts to the concepts of a "resolving machine" and chiral catalysis; this chapter is highly recommended for chirophiles. Chapter 4 ("Partial Enzyme Mimics") discusses the use of binaphthyl corands and preorganized hosts as organic catalysts. The authors describe their approach and results for a transacylase mimic based on their synthetic hosts. The different factors that influence the catalytic reaction are examined, and in this context the authors report on the effect of preorganization and on the design of more elaborate host molecules that could stabilize transition states. The introduction of cyclic urea units has been a further step in the design of such molecular receptors, and they have been applied in the approach to a serine protease mimic.

Chapters 5 and 6 introduce the reader to the concept of container molecules through the chemistry of *cavitands*. These are rigid hollow organic hosts containing an interior cavity large enough to form complexes (*caviplexes*) with organic guests. The tetraresorcinol cyclic oligomer is the building block of this widely developed chemistry. It forms the basis of the numerous molecular receptors that were obtained by substituting the phenol groups with bridging units leading to cavitands (bowl-shaped receptors described in Chapter 5) and other vases, kites, and velcrands (Chapter 6). All these molecular vessels have specific complexing properties that are related to their molecular size and the nature of the substituents that allow the formation of enforced cavities. These chapters are devoted to the synthesis, solid state structures, and formation of complexes.

The last four chapters are concerned with the most recent molecular containers, the *carcerands*, and their complexed forms, the *carceplexes*. Over a hundred pages are devoted to the molecular design and architecture of these structures. This new family of synthetic hosts is actually the most sophisticated one. It arose from the logical approach of the Cram group to the design of preorganized molecular systems with highly efficient complexing properties. The carcerands are essentially closed surface molecular spheres whose guest molecules are permanently encapsulated during synthesis to form carceplexes. The question regarding the properties of the inner part of the molecule has been examined, and a new phase of matter was proposed on the basis of the special status of the imprisoned guest. The authors report on the movements and the particular reactivity of the encapsulated guests. *Hemicarcerands* containing portals large enough for encapsulated guests to escape from their host are described. Complexation–decomplexation processes in these systems are temperature-dependent, and have been studied mainly by NMR spectroscopy.

The book is readily understandable and the numerous three-dimensional structures of molecules presented throughout the ten chapters make reading them even more enjoyable and instructive. This is not only a highly recommended reference book on container molecules, it is also an important contribution to modern organic chemistry which any chemist, even a newcomer to the field, would be well advised to own. As you leaf through this book, you will be impressed and fascinated by the beauty and the importance of the work and ideas that were developed by the Cram group. This monograph is recommended to all who are concerned with synthesis and applications of supermolecules, as well as advanced students and academic and industrial chemists interested in the progress of the chemical sciences.

Kirk/Othmer Encyclopedia of Chemical Technology. 4th Edition. Series editor: *J. I. Kroschwitz*. Vols. 3–10. Wiley, Chichester, 1992–1994. 1050–1316 pp., hardcover, 195.00 £ per volume.—ISBN 0-471-52671-1, -52672-X, -52673-8, -52674-6, -52675-4, -52676-2, -52677-0, -52678-9

Since the first two volumes of the 4th Edition were reviewed a further eight have been published. Thus the publishers have kept to the timetable that was originally announced.

The numbers of individual contributions contained in Volumes 3–10 range from 21 in Volume 10 to 38 in Volume 4. In accordance with the usual practice followed in Kirk–Othmer, the volumes present the various articles in alphabetical order and describe products and classes of compounds (from antibiotics to fire retardants) together with the relevant manufacturing processes, basic chemical engineering operations (distillation, filtration, drying, etc.), analytical and measurement methods, computer-based techniques (CAD, expert systems, chemometrics, etc.), and other topic areas concerned with industrial production, such as availability of raw materials, energy management, and criteria for economic evaluation.

The choice of articles to be included has taken into account the most important advances in science and technology. Thus, for example, there are new chapters on biotechnology, biosensors, and carbon fibers. Topics that have declined in importance, such as benzidine, crotonaldehyde, and cork, are no longer covered by separate articles.

The marked upsurge in the importance of environmental protection since the third edition is reflected in the inclusion of a separate chapter on "Environmental Impact". Environmental and safety aspects are also treated in detail in the articles on the relevant types of substances (e.g. dyes). There are also separate articles on important environmental protection methods (e.g. combustion technology).

In general the articles are well written and clearly understandable. Attention is drawn to new developments in manufac-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0044-8249/95/10722-2564 $ 10.00+.25/0

turing processes (e.g. the synthesis of ethylene from methane by oxidative coupling), to new product types (e.g. fullerenes), and to relevant developments in basic science and technology (e.g. the use of pervaporation as a separation method for the removal of alcohol from whisky).

The literature references and the data that are included are up-to-date. The few exceptions to this, for example in the chapter on "Azine Dyes" which includes no references later than 1987, and in that on energy management where the data on energy consumption by industry in the USA extend only up to 1988, only emphasize the general rule.

The illustrations (reaction schemes, diagrams, etc.) are clear and well presented. Where necessary for clarity, use has been made of three-dimensional illustrations (e.g. in descriptions of apparatus) or of color (e.g. in the chapter on color photography). In contrast to the previous two volumes, the use of abbreviations has been reduced to a sensible level, and those used are fully explained.

To summarize, after looking through the first ten volumes it is clear that the fourth edition of Kirk-Othmer is again a work of reference of world class, providing expert and comprehensive coverage of the field of chemical technology. Libraries concerned with science and technology are recommended to buy it.

Inorganic Experiments. Edited by *J. D. Woollins*. VCH Verlagsgesellschaft, Weinheim, 1994. 286 pp., hardcover DM 148.00.—ISBN 3-527-29235-7

The editor of this book, J. D. Woollins, has succeeded in enlisting no less than 71 authors from throughout the world as contributors. The result is a collection of 64 laboratory recipes for preparations to be carried out in inorganic chemistry student practical sessions. The experiments are grouped into three categories, described as "introductory" (16), "intermediate" (23), and "advanced" (25). This classification is intended as a guide both to the learning content and to the need for specialized apparatus. Most of the descriptions follow a set pattern, consisting of a short introduction, sometimes with an explanation of the teaching objective, a paragraph (highlighted) on safety precautions and health risks, the actual experimental procedure, and relevant literature references. Some of the experiments are valuable new material in works of this kind, for example those on the preparations of siloxane polymers, of arsenium cations, and of liquid-crystalline metal complexes, and the magnetic studies on exchange coupling in bimetallic paramagnetic complexes. Highly topical experiments such as these cannot be found in standard works on preparative inorganic chemistry, such as *Brauers Handbuch* or *Inorganic Syntheses*. On the other hand, some other experiments are "old friends", such as the preparations of Fremy's salt, ferrocene, and potassium peroxochromate. In his preface the editor explains that he deliberately avoided trying to introduce a uniform style, so as not to lose the lessons that can be drawn from comparing the procedures in the various laboratories. Nevertheless, the book would have benefited from the imposition of a small degree of uniformity and editorial tidying-up. One occasionally encounters local peculiarities that are incomprehensible, as when a glass beaker is cleaned by using a "policeman", when "methylated spirits" is used as a solvent, and where one is continually instructed to proceed "carefully" or "cautiously" without a more specific explanation of what this means. The concentration of aqueous ammonia is specified in three different ways (in %, in vol, and as 0.880, the latter being presumably the density). Some of the experiments described could only be performed in a small number of laboratories, such as the preparation of metal carbonyls by reductive carbonylation in an autoclave under CO at high pressure. Some could not be carried out at all—for example, where one is instructed to condense 1.73 g of a gas from a pressurized vessel into a solution maintained in a frozen state by liquid nitrogen, without explaining how such a precise dosage is to be achieved. Some of the experiments lack safety recommendations, while for others there are no literature references.

However, the descriptions of most of the experiments are good. The introductions explaining the learning points, the exercise problems, and the notes on identification of the products (mainly by spectroscopy) are useful. Undoubtedly one of the book's particular strengths is the topicality of many of the experiments in the "advanced" part, many of which are very attractive for use in advanced practical sessions. The book is of interest to all college and university teachers and assistants responsible for practical classes in inorganic chemistry. Those interested in discovering what is being done in other laboratories, or who can benefit from a little gold-mine of ideas for new practical exercises, should certainly buy this book. However, many of the procedures need to be thoroughly checked before introducing them into one's course.

Palladium-Catalyzed Reactions of Propargylic Compounds in Organic Synthesis

Jiro Tsuji* and Tadakatsu Mandai

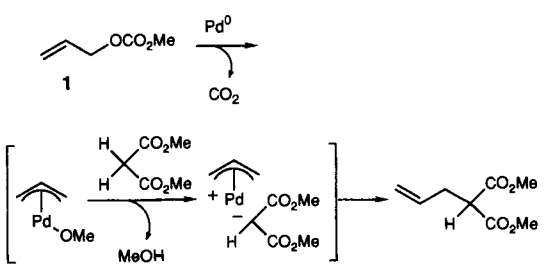
Palladium was used in organic synthesis for long time only as a heterogeneous catalyst for hydrogenating unsaturated compounds. But in recent years palladium compounds have found broad application as homogeneous catalysts. In the last decade, homogeneous catalysis relying on transition metal complexes has led to innovations in organic synthesis. Complexes of various transition metals are now used for organic synthesis, and each metal has its own characteristic features. Palladium complexes are the most versatile and used extensively in organic synthesis, particularly for carbon–carbon bond formation. Palladium-catalyzed reactions can be classified into several groups based on their substrates: organic halides, allylic compounds, conjugated dienes, alkenes, and alkynes. Propargylic compounds undergo a variety of palladium-catalyzed transformations and make up one important class of these reactions. It is well known that copper and silver salts promote or catalyze several reactions of propargylic compounds. However, palladium compounds, particularly Pd^0 complexes, show catalytic activities entirely different from those of silver and copper salts. Advances in the research on the palladium-catalyzed reactions of propargylic compounds in the last decade have made the scope of the reactions clear. The ready availability of numerous propargylic alcohols and their esters by the reaction of terminal alkynes with carbonyl compounds clearly enhances the synthetic utility of their reactions. Palladium complexes, in particular palladium phosphane complexes, are soluble in organic solvents and behave as active catalysts under homogeneous conditions.

Keywords: alkynes · carbonylations homogeneous catalysis · palladium compounds · propargylic compounds

1. Introduction

Many useful synthetic reactions catalyzed by homogeneous palladium catalysts are classified based on substrates.[1] As one important class of substrates, propargylic compounds undergo several types of transformations promoted by palladium catalysts. Propargylic compounds (2-alkynyl compounds) are derivatives of alkynes; however, palladium-catalyzed reactions of propargylic compounds, particularly their esters and halides, are clearly different mechanistically from those of simple alkynes except in a few cases. Therefore the palladium-catalyzed reactions of propargylic compounds should be treated independently of those of simple alkynes. Copper and silver-catalyzed and -promoted reactions of propargylic compounds are known,[2] but they differ distinctly from the palladium-catalyzed reactions.

Since the discovery of carbon–carbon bond formation by the reaction of π-allylpalladium complexes with carbon nucleophiles such as malonates and β-keto esters,[3] the chemistry of π-allylpalladium complexes has been studied extensively. Catalytic reactions, in particular, attract the attention of synthetic organic chemists, and many useful synthetic reactions based on π-allylpalladium compounds have been discovered.[4] Later, allylic carbonates were found to be more reactive sources of allyl ligands than allylic acetates, which were used under basic conditions; the former undergo several transformations under mild and neutral conditions not possible with corresponding acetates.[5] As an example, the reaction of allyl methyl carbonate (**1**) with malonate is outlined in Scheme 1. The key steps in the palladium-catalyzed reaction of allylic carbonates are the facile decarboxylation and the subsequent in situ generation of a methoxide ion, which acts as a base and abstracts a proton from



Scheme 1. Palladium-catalyzed allylation of malonate via a π-allylpalladium complex.

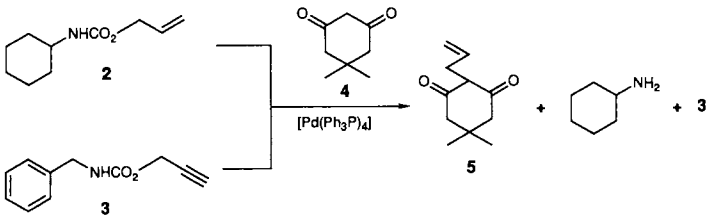
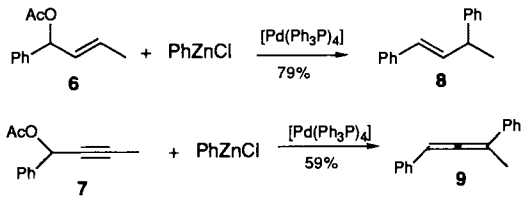
malonate. Thus the allylation of malonate can be carried out under neutral conditions without any added base. Carbonate is also the best leaving group in the palladium-catalyzed reactions of propargylic compounds.

In contrast to the extensive studies conducted on the palladium-catalyzed reactions of allylic compounds, studies on the analogous reactions of propargylic compounds were initiated much later and were less extensive. One reason is that propargylic compounds are less reactive toward palladium catalysts than allylic compounds. For example, the reaction of a mixture of allyl carbamate **2** and propargyl carbamate **3** with 5,5-dimethyl-1,3-cyclohexanedione (dimedone) (**4**) gave only the allylated product **5**. Propargyl carbamate **3** was recovered, showing that an allyl carbamate is more reactive than a propargyl carbamate (Scheme 2).[6]



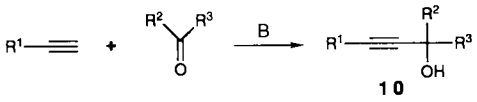
Scheme 2. Competition reaction between an allyl and a propargyl carbamate.

Allylic acetates also react smoothly with dimethyl malonate, whereas the reaction of malonate with the corresponding propargylic acetates does not occur under the same conditions. On the other hand, both allylic acetate **6** and propargylic acetate **7** react with phenylzinc chloride to afford **8** and **9** with comparable rates.[7]



Another reason for the limited interest in the Pd-catalyzed reactions of propargylic compounds may be the instability of the reaction products. Allene derivatives are formed from propargylic compounds in many cases, and these highly unsaturated products frequently undergo further, sometimes complex Pd-catalyzed transformations. Thus the reaction conditions and isolation methods for the reactions of propargylic compounds must be chosen much more carefully than for the analogous reactions of allylic compounds.

In the last ten years, the scope of the palladium-catalyzed reactions of propargylic compounds has been defined through careful studies. Therefore it seems timely to summarize the behavior of propargylic compounds in the presence of palladium catalysts under various conditions. This review is intended to give an overview of the palladium-catalyzed reactions of propargylic compounds and their synthetic applications. Since propargylic alcohols **10** are easily prepared by the reaction of terminal alkynes with carbonyl compounds (Scheme 3), the palladium-catalyzed transformation of various propargylic compounds has high synthetic value.



Scheme 3. R^1, R^2, R^3 = alkyl, aryl. B = base.

2. Classification of Catalytic Reactions Based on Mechanistic Considerations

Pd^0 complexes are active catalysts in most cases. The Pd^0-catalyzed reactions of propargylic compounds can be understood by the following mechanistic considerations. The first step of the catalytic reaction is the oxidative addition of a propargylic com-

Jiro Tsuji was born in 1927 in Shiga, Japan. He received his B.S. from Kyoto University, and his Ph.D. from Columbia University in 1960 for his work with G. Stork on natural product synthesis. After returning to Japan, he worked at Basic Research Laboratories, Toray Industries Inc., and moved in 1974 to the Tokyo Institute of Technology as a professor. In 1988 he moved to the Okayama University of Science, where he is now a professor. His major research interests include the development of new synthetic reactions catalyzed by transition metal complexes, particularly palladium complexes, and application of these new catalytic reactions to the total synthesis of natural products. His awards include the Japan Chemical Society award, the Synthetic Society of Japan award, and the Silver Medal with Purple Ribbon from the Japanese government.

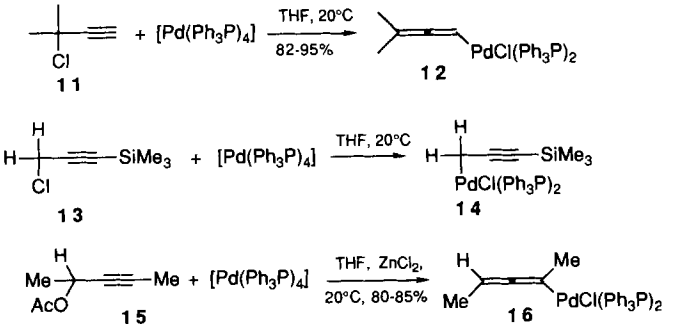
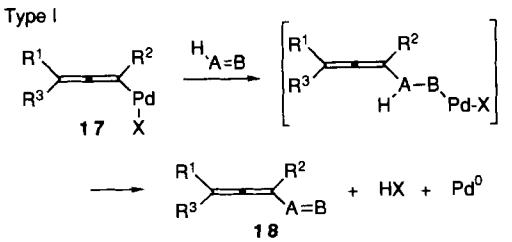
T. Mandai

Tadakatsu Mandai was born in 1951 and received his doctorate in 1979 from the Tokyo Institute of Technology for research with J. Tsuji. In 1979 he joined the Okayama University of Science as an assistant professor, and in 1995 he was promoted to full professor. His major research interest is synthetic organic chemistry using sulfur compounds and palladium-catalyzed reactions; these synthetic methods are also applied to natural product synthesis. He received the Japan Chemical Society Award for Young Chemists in 1985.

pound to the Pd^0 species to form an intermediate complex.[8] In this step Pd^0 is oxidized to Pd^{II}. The intermediate Pd^{II} complex undergoes further reactions with other reactants. The stoichiometric reactions of propargylic chlorides **11** and **13** with tetrakis(triphenylphosphane)palladium $[Pd(Ph_3P)_4]$ were studied; the σ-allenylpalladium complex **12** and the propargylpalladium complex **14** were isolated as yellow powders.[9] The allenylpalladium chloride **12** is formed by the S_N2'-type displacement of the chlorine by Pd^0. Compound **14**, generated by direct oxidative addition, forms when a bulky group such as trimethylsilyl or *tert*-butyl is attached to the alkyne terminus. Propargylic acetate **15** is unreactive, but it can be converted to the allenylpalladium chloride **16** by reaction with $[Pd(Ph_3P)_4]$ in the presence of zinc chloride or lithium chloride. It is reasonable to expect that Pd^0-catalyzed reactions of propargylic compounds proceed via either intermediate **12** or **14**, which seem to be in equilibrium.



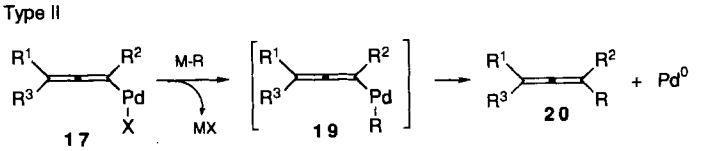
The known Pd^0-catalyzed reactions of propargylic compounds can be classified into four types (I, II, III, and IV) based on their mechanisms. The intermediate complex **17** can undergo three types of transformations depending on the reactants. Reactions of type I proceed by insertion of unsaturated bonds into the σ bond between palladium and the sp^2 carbon in **17** (Scheme 4).



Scheme 4. Insertion reaction to allenylpalladium complexes **17**; R^1, R^2, R^3 = alkyl, aryl.

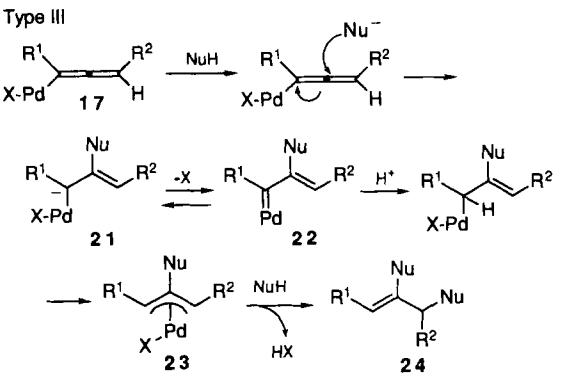
The reactivity of this σ bond is similar to that of the σ bond formed by the oxidative addition of alkenyl halides to Pd^0 in the Heck reaction. Therefore, intermediate **17** is expected to undergo reactions similar to those observed under the Heck conditions. Alkenes and carbon monoxide are known to insert into the palladium–carbon σ bond, and allene derivatives **18** result.

Reactions of type II proceed by transmetalation of complex **17**. Hard carbon nucleophiles MR (M = main group metals) such as Grignard reagents and metal hydrides MH undergo transmetalation with **17** to generate **19**. Subsequent reductive elimination gives the allene derivative **20** as the final product (Scheme 5).



Scheme 5. Transmetalation of allenylpalladium complexes **17**; R^1, R^2, R^3 = alkyl, aryl.

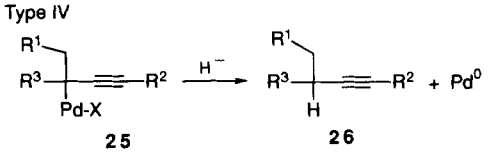
In reactions of type III a nucleophile attacks at the central sp carbon of the allenyl system of complex **17**. Reactions of soft carbon nucleophiles derived from compounds with activated methylene groups, for example β-keto esters and malonates, as well as oxygen nucleophiles, belong to this type. The attack of the nucleophile generates intermediate **21**, which can be considered equivalent to the palladium–carbene complex **22**. Intermediate **21** abstracts a proton from the activated methylene group and the π-allylpalladium complex **23** is formed, which, as expected, undergoes further reaction with a nucleophile to give alkene **24** (Scheme 6).



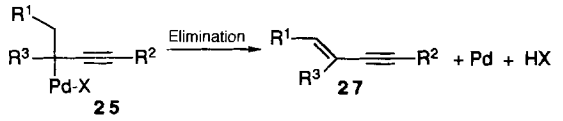
Scheme 6. Reaction of soft carbon nucleophiles with allenylpalladium complexes **17**; R^1, R^2 = alkyl, aryl.

Most of the known Pd^0-catalyzed reactions of propargylic compounds can be explained by the formation of allenylpalladium intermediates like **12** and are of types I, II, or III.

Two reactions are known, however, that are of type IV. They proceed via propargylpalladium complexes like **25**. Direct displacement of palladium in **25** with hydride to form alkynes **26** is one possibility (Scheme 7). Elimination of a Pd–H species from **25** to form enyne **27** is another (Scheme 8).



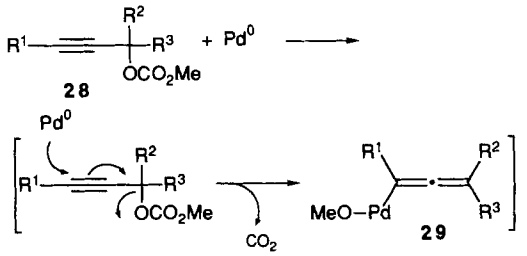
Scheme 7. Hydrogenolysis of propargylpalladium intermediates **25** to form alkynes **26**; R^1, R^2, R^3 = alkyl, aryl.



Scheme 8. Formation of enynes by elimination from propargylpalladium complexes **25**; R^1, R^2, R^3 = alkyl, aryl.

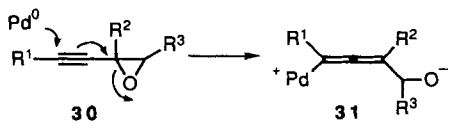
The selection of reaction conditions is crucial for the palladium-catalyzed reactions of propargylic compounds. The most essential factor is choosing the appropriate phosphane ligand (particularly monodentate and bidentate phosphanes) for a given reaction.

A number of propargylic derivatives can be used for the palladium-catalyzed reactions, but they have different reactivities. Propargylic halides are used with or without palladium catalysts in the presence of bases. Although propargylic alcohols are most easily available, they are less reactive substrates; however, their esters such as acetates, carbonates, and phosphates are reactive. Propargylic acetates are used in the presence of bases, but they are less reactive than the corresponding carbonates. Propargylic carbonates like **28** are highly reactive and undergo various palladium-catalyzed reactions smoothly, especially under neutral conditions, as observed with allylic carbonates.[5] In the facile irreversible oxidative addition of a propargylic carbonate carbon dioxide is evolved and an allenylpalladium methoxide such as **29** results (Scheme 9). The reaction can be carried out under



Scheme 9. Formation of an allenylpalladium methoxide **29** from a propargyl carbonate **28**; R^1, R^2, R^3 = alkyl, aryl.

neutral conditions because methoxide is generated. Therefore in most of the extensive studies on propargylic compounds propargylic carbonates were used as convenient substrates. Alkynyloxiranes **30** also undergo facile reactions with Pd^0 catalysts under neutral conditions via alkoxypalladium complexes **31** (Scheme 10).



Scheme 10. Formation of allenylpalladium complex **31** from alkynyloxirane **30**; R^1, R^2, R^3 = alkyl, aryl.

In the next sections we will discuss the Pd^0-catalyzed reactions of propargylic compounds based on the above-mentioned classification. But first the syntheses of suitable Pd^0 catalysts need comment. The commercially available Pd^0 complexes $[Pd(Ph_3P)_4]$ and $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone) or $[Pd(dba)_2]$ are used directly. In addition, some Pd^{II} salts can be used as precursors of Pd^0 species. $Pd(OAc)_2$ is used in many cases, because $Pd(OAc)_2$ is easily reduced to Pd^0 in situ with reducing agents such as CO,[10] alcohols, alkenes, and even aqueous KOH.[11] In the most convenient preparations Pd^0 species are generated by the reaction of $Pd(OAc)_2$ with phosphanes; Ph_3P is known to reduce $Pd(OAc)_2$ slowly.[12, 13] The reduction proceeds rapidly when $Pd(OAc)_2$ is mixed with nBu_3P in solution to form a very active Pd^0 catalyst and phosphane oxide **32**.[14]

$$Pd(OAc)_2 + n\text{-}Bu_3P \xrightarrow{H_2O} Pd^0 + n\text{-}Bu_3PO + AcOH$$

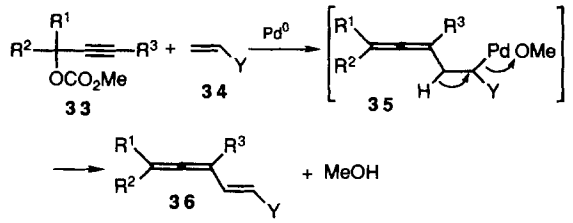
3. Type I Reactions: Insertion into the Pd–C_{sp^2} Bond

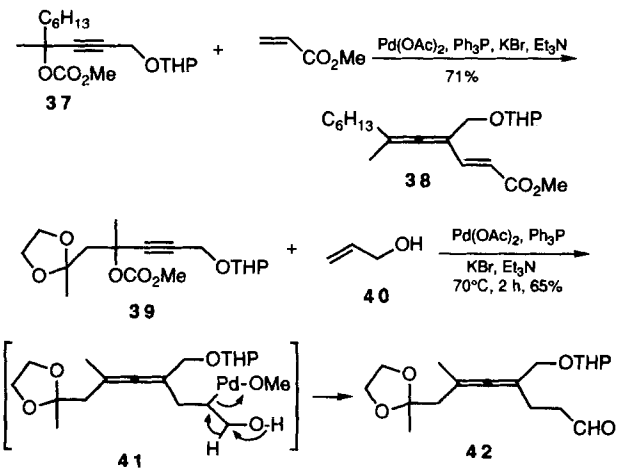
3.1. Reaction of Alkenes: Formation of 1,2,4-Trienes

The reaction of propargylic carbonates **33** with alkenes **34** provides a good synthetic approach to 1,2,4-trienes **36**. Smooth insertion of alkene **34** into the allenylpalladium bond generates **35**, and subsequent elimination of a β-hydrogen atom affords the 1,2,4-triene **36** (Scheme 11).[15] The reaction proceeds



Scheme 11. Preparation of 1,2,4-alkatrienes **36**; R^1, R^2, R^3 = alkyl, aryl.

smoothly in dimethylformamide (DMF) at 70 °C with $Pd(OAc)_2/Ph_3P$ as the catalyst. The addition of potassium bromide and triethylamine is important. The reaction of methyl acrylate with **37** afforded 2,4,5-trienoate **38** in good yield. The reaction of allyl alcohol (**40**) as an olefin component with **39** gave the allenyl aldehyde **42** by the elimination of a β-hydrogen atom from the O-substituted carbon atom of intermediate **41** (Scheme 12).

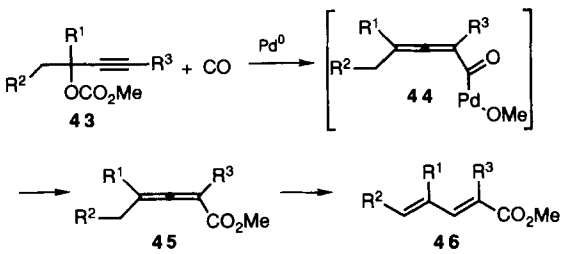


Scheme 12. Formation of triene **38** from **37** and methyl acrylate, and of aldehyde **42** from propargyl carbonate **39** and allyl alcohol (**40**).

3.2. Carbonylation

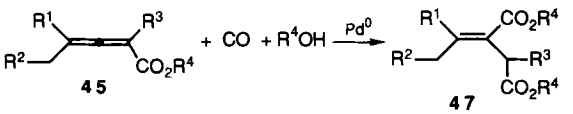
3.2.1. Reaction Features

Carbon monoxide also reacts with complex **17** by insertion. Propargylic compounds undergo facile palladium-catalyzed mono- and dicarbonylations, depending on reaction conditions.[16] The palladium-catalyzed carbonylation of propargylic compounds was first reported in 1966. In this first study the carbonylation of propargylic alcohols was carried out under fairly severe conditions to afford mainly dicarbonylation products.[17, 18] Later it was found that facile monocarbonylation proceeds under milder conditions when propargylic carbonates are used.[19] The mono- and dicarbonylations in an alcohol solvent can be explained by the following mechanism. In the first step, insertion of carbon monoxide into the allenylpalladium intermediate generates the acylpalladium complex **44**, which reacts with the alcohol to give the 2,3-dienoate **45**. Under certain conditions, **45** isomerizes to the 2,4-dienoate **46** (Scheme 13).



Scheme 13. Monocarbonylation of propargylic carbonates to give 2,3-dienoates; R^1, R^2, R^3 = alkyl, aryl.

Carbonylation of propargylic carbonates under mild conditions stops at this stage. Under high CO pressure or when the substrate has an activating group (e.g. $R^3 = CO_2R$), further attack of carbon monoxide at the central sp carbon of the allenyl intermediate **45** takes place to give the diester **47** (Scheme 14).

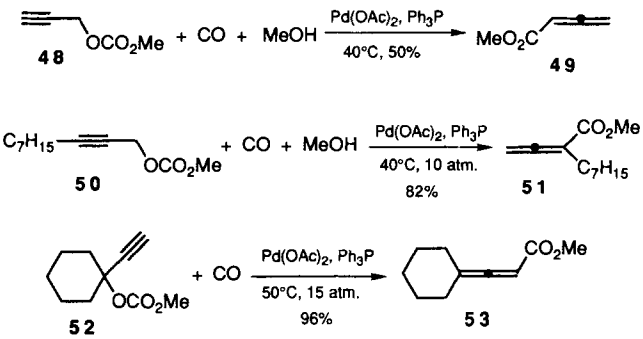


Scheme 14. Further carbonylation of 2,3-dienoates; R^1, R^2, R^3 = alkyl, aryl; R^4 = alkyl.

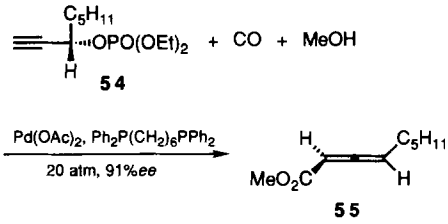
In the next sections the mono- and dicarbonylations of propargylic carbonates, alcohols, and halides will be treated. Then the extension of the carbonylation reactions to various derivatives of propargylic carbonates to yield cyclic compounds will be discussed.

3.2.2. Preparation of 2,3-Dienoates and Their Derivatives by Monocarbonylation

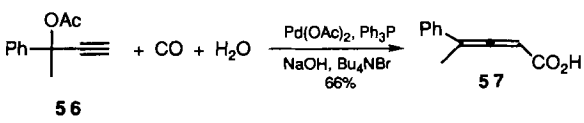
Similar to the facile decarboxylation–carbonylation of allylic carbonates to afford 3-alkenoates,[20] smooth decarboxylation–carbonylation of propargylic carbonates **43** occurs in alcohol solvents to afford 2,3-dienoates **45** under mild neutral conditions. The reaction offers a new preparative method for 2,3-dienoates **45**.[19] In this carbonylation, carbon monoxide is introduced at the γ position of propargylic carbonates. The reaction proceeds at 50 °C under 1–10 atm of carbon monoxide. The yield of 2,3-butadienoate **49**, the simplest 2,3-dienoate, from methyl propargyl carbonate (**48**) is somewhat low, because **49** is very reactive. In some cases, a mixture of 2,3- and 2,4-dienoates (**45** and **46**) is obtained. When the reaction is conducted in ether instead of in methanol and for a longer time, 2,4-dienoates **46** are formed by isomerization of 2,3-dienoates **45**. The facile carbonylation of propargylic carbonates shows that, as in the reaction of allylic carbonates, carbonate is an excellent leaving group under mild and neutral conditions. The terminal allenic ester **51** is prepared in good yield from **50**. The tertiary propargylic carbonate **52** with a terminal triple bond is very reactive and gives a high yield of the allenic ester **53**.



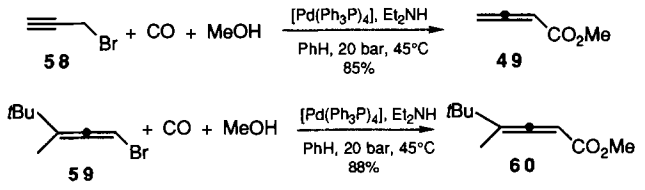
Carbonylation of propargylic acetates and phosphates proceeds in the presence of bases under somewhat more severe conditions (100 °C, 50 atm). Carbonylation of the optically active propargylic phosphate **54** gave the optically active 2,3-dienoate **55** with retention of configuration. The use of biden-



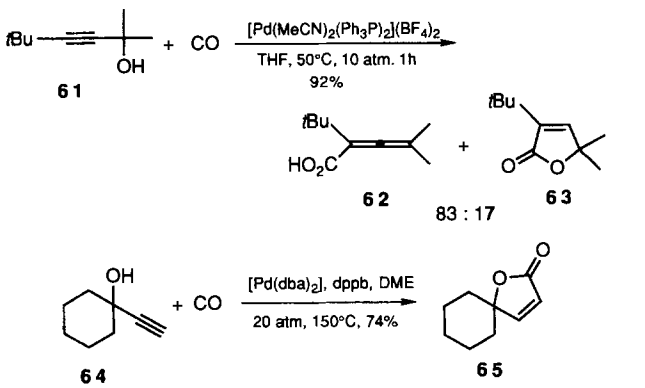
tate ligands such as 1,3-bis(diphenylphosphino)propane (dppp) and 1,6-bis(diphenylphosphino)hexane is important for complete chirality transfer.[21] Carbonylation of propargylic acetate **56** under mild conditions (1 atm, 55 °C) in a two-phase system of aqueous sodium hydroxide and 4-methyl-2-pentanone in the presence or absence of tetrabutylammonium bromide gave 2,3-pentadienoic acid **57**.[22] Carbonylation of propargyl bromide (**58**) in methanol in the presence of either



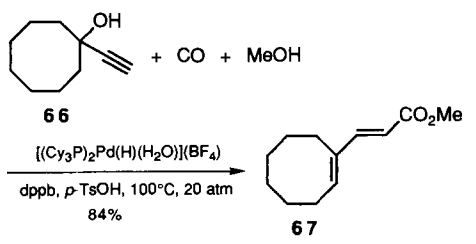
triethylamine or diethylamine under high pressure (20 bar) at 45 °C afforded methyl 2,3-butadienoate (**49**) in 85% yield.[23] 1-Bromo-3-*tert*-butyl-1,2-butadiene (**59**) was converted into 4-*tert*-butyl-2,3-pentadienoate (**60**) via an analogous allenylpalladium intermediate under similar conditions.



Propargylic alcohols are less reactive than their esters, and their carbonylation requires more severe conditions. Carbonylation of the tertiary propargylic alcohol **61** in THF using a cationic palladium complex as a catalyst gave the 2,3-dienoic acid **62** and the 2(5*H*)-furanone **63** in high yields in a ratio of 83:17 in one hour; **62** is easily converted into furanone **63** by treatment with *p*-toluenesulfonic acid.[24] Similarly, the carbonylation of the tertiary propargylic alcohol **64** at high pressure and temperature (20 atm, 150 °C) in dimethoxyethane (DME) under neutral conditions and with dppb as a ligand afforded the 2(5*H*)-furanone **65**. But a different mechanism not

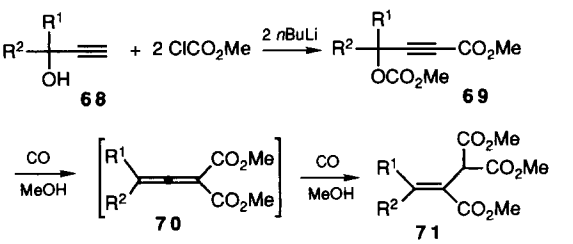


involving cleavage of the C–O bond in **64** was proposed for the formation of this furanone.[25] The 2,4-dienoate **67** was obtained when a cationic aqua(hydrido) complex and dppb were used for the carbonylation of 1-ethynylcyclooctanol (**66**); the presence of *p*-toluenesulfonic acid is essential for this reaction. Formation of **67** may be explained by the acid-catalyzed isomerization of the 2,3-dienoate formed initially.[26]



3.2.3. *Preparation of Triesters by Dicarbonylation*

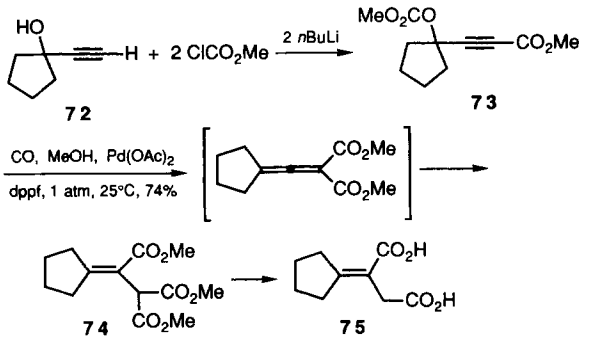
Selective monocarbonylation takes place when the carbonylation is carried out under mild conditions, as described in Section 3.2.2. But dicarbonylation dominates when the triple bond of the propargylic carbonate bears an ester group. In the carbonylation of the 1-substituted 3-methoxycarbonyl-2-propynyl methyl carbonate **69**, vicinal dicarbonylation rather than the monocarbonylation occurs to afford triester **71**. This shows that the ester group has a strong activating effect (Scheme 15).[27]



Scheme 15. Preparation of triesters **71** from propargylic alcohols by dicarbonylation; R^1, R^2 = alkyl, aryl.

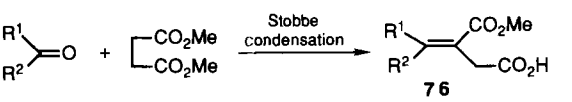
The dicarbonylation proceeds at room temperature, and it is not possible to stop the reaction after the monocarbonylation forming **70**. Bidentate ligands such as dppp and 1,1′-bis(diphenylphosphino)ferrocene (dppf) are the most effective for the dicarbonylation. Triphenylphosphane is not a suitable ligand.

The carbonylation of tertiary carbonate **73** proceeds at room temperature under 1 atm of carbon monoxide to yield **74** (Scheme 16). But secondary carbonates are less reactive and



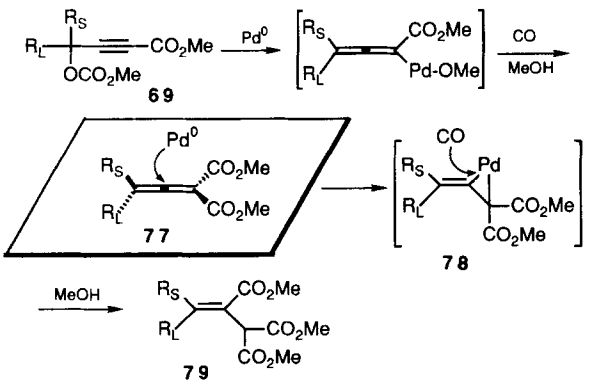
Scheme 16. Preparation of alkylidenesuccinic acid **75** from propargylic alcohol **72**.

their reaction proceeds only under 5 atm of carbon monoxide. Exclusive formation of (*E*) double bonds in the triesters **71** is observed. Acetylenic esters **69** and **73** can be prepared easily in one step by the treatment of propargylic alcohols **68** and **72** with two equivalents of *n*-butyllithium and reaction with two equivalents of methyl chloroformate. The dicarboxylic acid **75** (alkylidenesuccinic acid), obtained by hydrolysis and decarboxylation of triester **74**, resembles product **76** of the Stobbe condensation (Scheme 17).[28]



Scheme 17. R^1, R^2 = alkyl, aryl.

One possible mechanism is the following: The geminal allenyl diester **77**, which is not isolable, is expected to be susceptible to Michael-type addition of L_nPd^0 species to the allenyl sp carbon yielding palladacyclopropane **78**. Insertion of carbon monoxide and methanolysis affords the triester **79** (Scheme 18). The con-



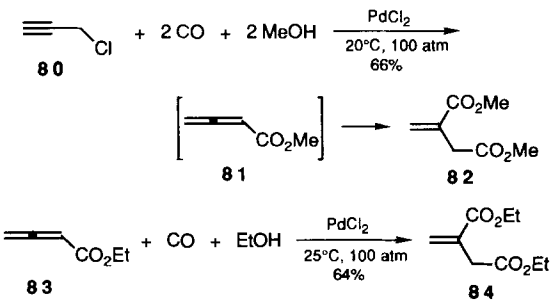
Scheme 18. Mechanism of stereoselective dicarbonylation; $R_L > R_S$; R = alkyl, aryl; L = large, S = small.

figuration of the double bond in product **79** is exclusively (*E*). The high stereoselectivity can be rationalized by assuming that the nucleophilic attack of the Pd^0 species to the allenyl sp carbon in **77** occurs from the less hindered side having the smaller alkyl substituent (R_S). Needless to say, in allene **77** the two ester groups and the substituents R_L and R_S are perpendicular.

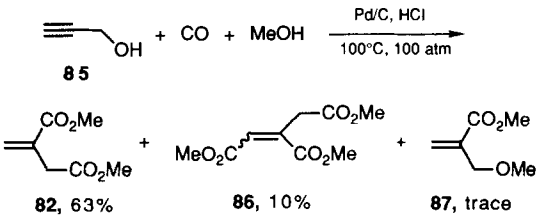
3.2.4. Dicarbonylation of Propargylic Chlorides and Alcohols

Dicarbonylation occurs mainly when the carbonylation of propargylic halides and alcohols is carried out under high CO pressure. The carbonylation of propargyl bromide (**58**) at 20 bar affords 2,3-butadienoate (**49**) as described in Section 3.2.2. In contrast, carbonylation of propargyl chloride (**80**) in methanol at room temperature under high pressure (100 atm) catalyzed by $PdCl_2$ or Pd/charcoal affords methyl itaconate (**82**). The primary product seems to be 2,3-butadienoate (**81**≡**49**), which is carbonylated further.[17, 18] As supporting evidence, diethyl itaconate (**84**) is produced in 64% yield by the carbonylation of ethyl 2,3-butadienoate (**83**) at room temperature under high pressure.

Propargylic alcohols are less reactive than their esters, and their carbonylation requires somewhat severe conditions (100 °C, 100 atm).[17, 18] The carbonylation products under

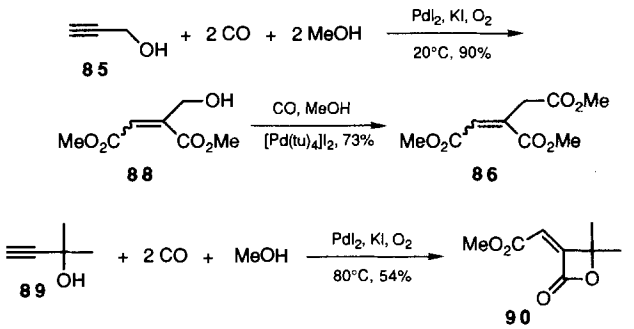


these conditions are different from those obtained by the carbonylation of the corresponding carbonates under milder conditions. Carbonylation of propargyl alcohol (**85**) in methanol without a phosphane ligand proceeds in the presence of hydrochloric acid to afford methyl itaconate (**82**) as a main product and methyl aconitate (**86**) as a minor product. In addition, a small amount of methyl 2-methoxymethacrylate (**87**) is formed. $PdCl_2$ and Pd/charcoal are active catalysts.[18]



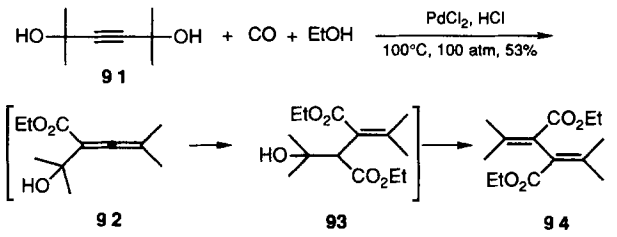
The formation of these products can be understood by assuming that two reaction pathways are possible for the carbonylation of propargyl alcohol under high pressure. One is the Pd^0-catalyzed carbonylation and the other is the Pd^{II}-catalyzed oxidative carbonylation. 2,3-Butadienoate **83** is a primary product of the Pd^0-catalyzed carbonylation, but further attack of carbon monoxide at the central sp carbon of **83** under high CO pressure yields itaconate **84** as the dicarbonylation product.

The formation of aconitate **86** is explained by the oxidative dicarbonylation of a triple bond with a Pd^{II} species, followed by Pd^0-catalyzed allylic carbonylation. As supporting evidence, methyl aconitate (**86**) was obtained selectively in 65% overall yield by the palladium-catalyzed two-step carbonylation of propargyl alcohol (**85**). The first step is the oxidative dicarbonylation of the triple bond using PdI_2 under oxygen atmosphere to give hydroxymethylfumarate (**88**). In the second step the allylic alcohol moiety of **88** is carbonylated further to give aconitate **86**. β-Lactone **90** was obtained when 2-methyl-3-butyn-2-ol (**89**) was carbonylated under similar conditions (Scheme 19).[29] It is known that fumarate and maleate are obtained by the oxidative dicarbonylation of acetylene using $PdCl_2$.[30]

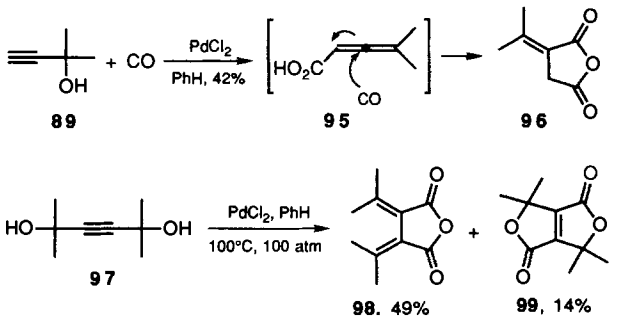


Scheme 19. tu = thiourea.

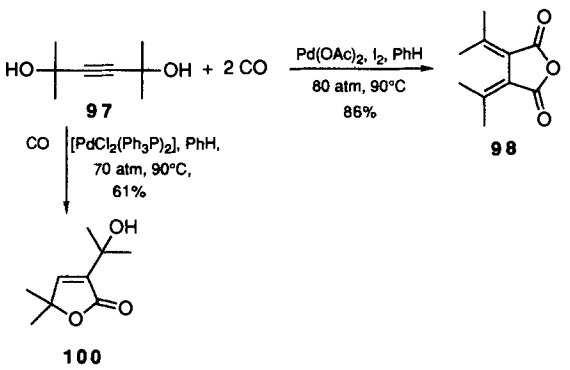
Carbonylation of 2,5-dimethyl-3-hexyne-2,5-diol (**91**) in ethanol containing hydrochloric acid (5%) affords diethyl diisopropylidenesuccinate (**94**). The reaction is explained by the Pd^0-catalyzed dicarbonylation to give **93**, and subsequent elimination of water to give **94**.[18]



Dicarbonylations in aprotic solvents yield acid anhydrides and in some cases lactones by the Pd^0-catalyzed carbonylation and Pd^{II}-catalyzed oxidative carbonylation. Teraconic anhydride (**96**) is obtained by the Pd^0-catalyzed dicarbonylation of 2-methyl-3-butyn-2-ol (**89**) via **95** in benzene. Similarly, fulgide **98** (a derivative of dimethylenesuccinic anhydride) was obtained in 49% yield by the Pd^0-catalyzed dicarbonylation of 2,5-dimethyl-3-hexyne-2,5-diol (**97**≡**91**) in benzene; bis(1-hydroxy-1-methylethyl)fumaric acid dilactone (**99**) was obtained as a

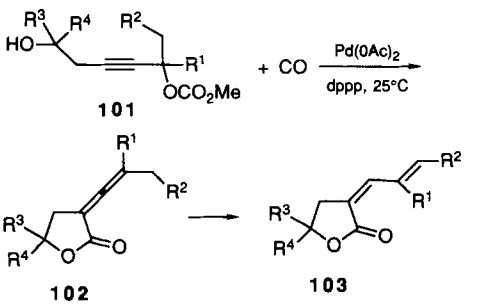


by-product (14%). This dilactone is a product of the oxidative dicarbonylation and bislactonization.[18] The fulgide-forming reaction was improved by using $Pd(OAc)_2$ as the catalyst with iodine ($Pd:I_2 = 1:1$) instead of hydrochloric acid. When [$PdCl_2(Ph_3P)_2$] was used as the catalyst, furanone **100** was obtained in 61% yield by monocarbonylation.[31] Fulgides are photochromic substances and this straightforward synthesis is useful.



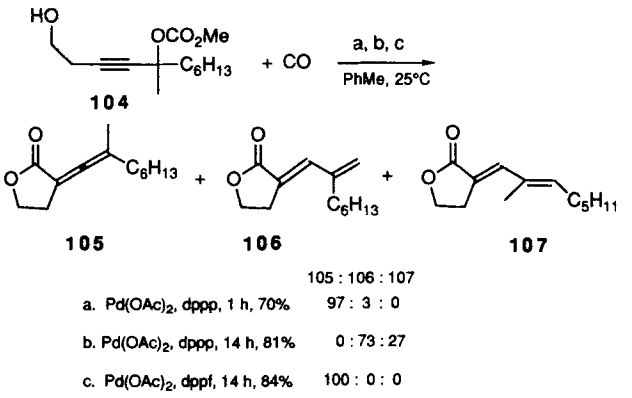
3.2.5. *Preparation of α-Alkenylidene-γ-lactones*

α-Alkenylidene-γ-lactones **102** are prepared in good yields by carbonylation of 5-hydroxy-2-alkynyl methyl carbonates **101** under mild conditions (Scheme 20).[32] The reaction proceeds at room temperature under 1–10 atm CO. Ph_3P is not a suitable



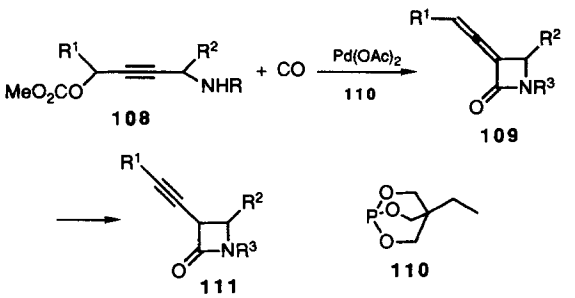
Scheme 20. Formation of α-alkenylidene-γ-lactones **102**; R^1, R^2, R^3, R^4 = alkyl, aryl.

ligand; bidentate ligands, particularly dppp and dppf, are the best ligands. Although α-alkenylidene-γ-lactone **102** is the main product, it isomerizes to form 1,3-diene **103** depending on the substrate, reaction time, and ligand. The isomerization is complete when dppp is used as a ligand or when a longer reaction time is chosen. No isomerization to give a triple bond was observed. As a typical example, carbonylation of **104** afforded products **105**–**107**, whose ratios depend on the reaction conditions.



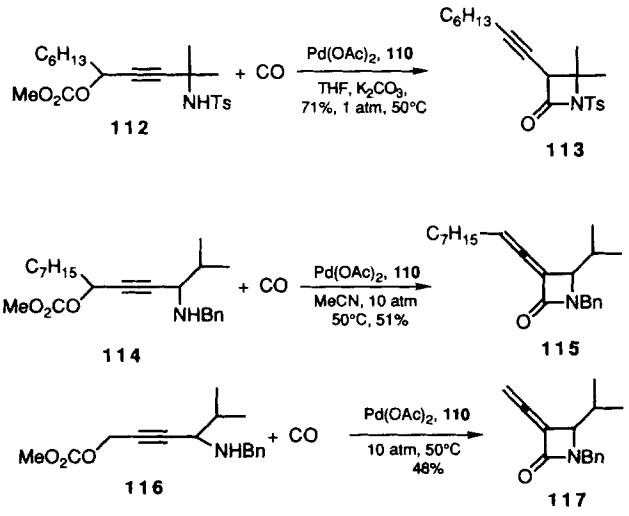
3.2.6. *Preparation of α-Alkenylidene-β-lactams*

In addition to alcohols, other nucleophiles can be used to trap the acylpalladium intermediates. Carbonylation in the presence of amines yields amides. α-Alkenylidene-β-lactams **109** are prepared by the carbonylation of 4-benzylamino-2-alkynyl methyl carbonates **108** (Scheme 21).[33] Selection of the ligand is crucial for the smooth formation of β-lactams. The best results are obtained with the cyclic phosphite 4-ethyl-2,6,7-trioxa-1-phos-



Scheme 21. Preparation of α-alkenylidene-β-lactams **109**; R^1, R^2, R^3 = alkyl, aryl.

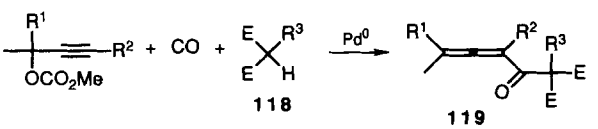
phabicyclo[2.2.2]octane (**110**); triphenylphosphane and bidentate phosphanes give rather poor results. Another important factor is the selection of a protecting group for the amino function. Free amines cannot be used for the carbonylation. When the amino group is protected by benzylation, the reaction proceeds under neutral conditions and α-alkenylidene-β-lactams **109** are obtained. The carbonylation of *p*-tosylated amines must be carried out in the presence of potassium carbonate as a base, without which the yield is low. Under these conditions, the alkenylidenelactam isomerizes to the α-alkynyl-β-lactam **111**. For example, the α-alkynyl-β-lactam **113** is obtained as the sole product of the carbonylation of the *p*-tosyl amide **112**. In contrast, carbonylation of the benzylamine **114** affords the α-alkenylidene-β-lactam **115**. The carbonylation is carried out in THF or acetonitrile as the solvent at 50 °C under 1 – 10 atm CO. R^1 and R^2 in **108** can be any alkyl group. When R^1 = H, as in **116**, the α-vinylidene-β-lactam **117** is obtained.



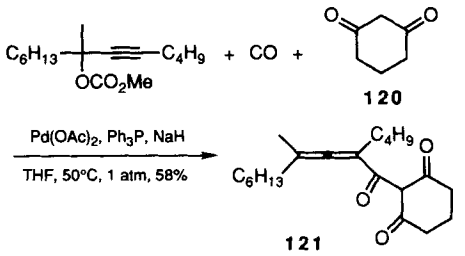
The α-alkenylidene-β-lactams **109** are known inhibitors of β-lactamases. Although several derivatives have been prepared by other methods,[34] the palladium-catalyzed carbonylation seems to offer the most convenient synthetic method for this type of β-lactam.

3.2.7. *Carbonylation in the Presence of Compounds with Activated Methylene and Methyne Groups*

Acylpalladium complexes, the intermediates in palladium-catalyzed carbonylations, can be trapped by nucleophiles other than alcohols. Compound **118**, which has an activated methylene group, can be used for trapping the acylpalladium complex (Scheme 22). Allenyl ketone **119** is formed by carbonylation in the presence of malonate, β-keto ester, or a β-diketone and a strong base; the methyl ester is not formed, showing that the carbanion formed from **118** by reaction with NaH is more reactive toward the acylpalladium intermediate than methoxide ion.[35] The triketone **121** is obtained by the reaction with cyclohexane-1,3-dione (**120**). The carbonylation proceeds under atmospheric pressure at 50 °C; triphenylphosphane is a suitable ligand.

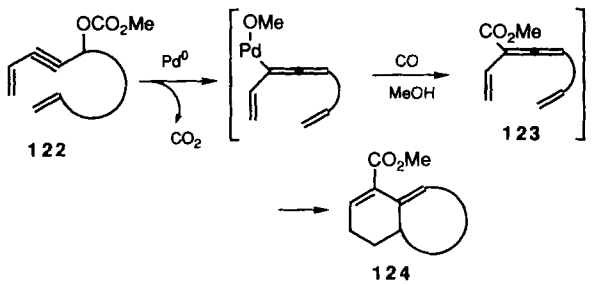


Scheme 22. Preparation of allenyl ketones **119** by reaction with compounds having activated methylene groups; E = electron-withdrawing group; R^1, R^2, R^3 = alkyl, aryl.



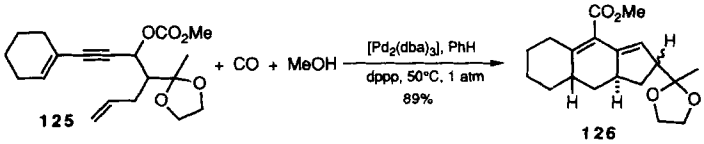
3.2.8. *Tandem Carbonylation and Diels–Alder Reaction*

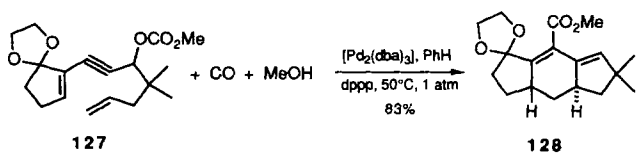
The allenyl unit in conjugation with an ester group, which is formed by the carbonylation of propargylic carbonates, is highly reactive and reacts further when other double bonds are present in the molecule. As one example, the dienyne carbonate **122** undergoes smooth carbonylation, followed by intramolecular Diels–Alder reaction under mild conditions (Scheme 23).



Scheme 23. Tandem carbonylation and Diels–Alder reaction.

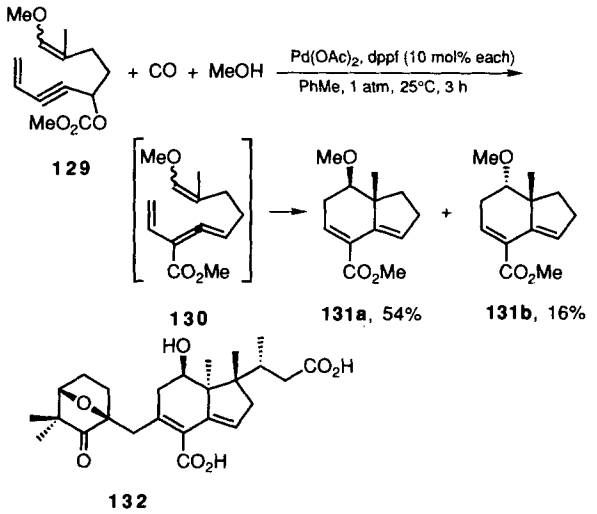
The reaction proceeds smoothly in benzene at 50 °C under 1 atm CO and does not stop after formation of the allenyl ester **123**. The cyclized product **124** formed by an intramolecular Diels–Alder reaction is isolated in good yields (Scheme 23);[36] dppp is the most suitable ligand. This uncatalyzed intramolecular





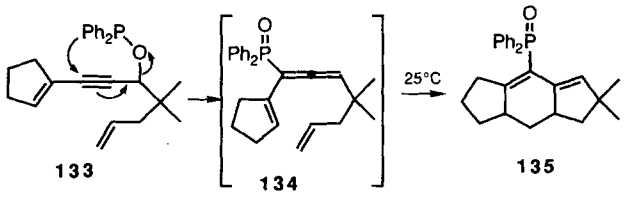
Diels–Alder reaction proceeds under surprisingly mild conditions, showing that the allenyl system is very reactive. Tricyclic compounds **126** and **128** are obtained in high yields by the carbonylation of **125** and **127**, respectively, at 50 °C under 1 atm.

The reaction proceeds even at room temperature when the dienophile has an electron-donating group. Carbonylation of the propargylic carbonate **129** at room temperature under 1 atm affords the cyclized products **131a** and **131b** in 70% total yield. Thus the Diels–Alder reaction of intermediate **130**, in which the diene has an electron-withdrawing group (CO_2Me) and the dienophile has an electron-donating group (OMe), proceeds at room temperature (Scheme 24).[37] This reaction provides access to the bicyclic skeleton of glycinoeclepin (**132**).



Scheme 24. Preparation of the bicyclic skeleton of glycinoeclepin (**132**).

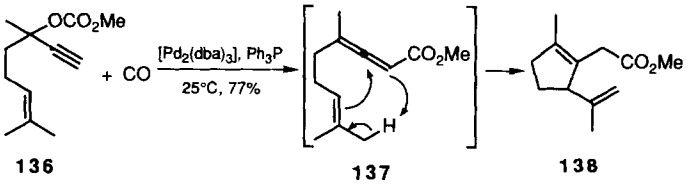
Facile intramolecular Diels–Alder reaction of the related allenyldiene **134**, generated by the C–O → C–P rearrangement of **133**, yields **135** (Scheme 25).[38]



Scheme 25. Tandem C–O → C–P rearrangement and Diels–Alder reaction affording **135**.

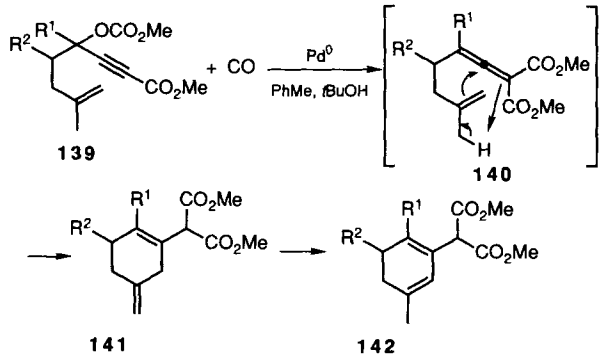
3.2.9. *Tandem Carbonylation and Ene Reaction*

The allenyl esters formed by Pd-catalyzed carbonylation undergo an intramolecular ene reaction when a double bond is located at a suitable position. The cyclopentene derivative **138** was obtained in 77% yield by the carbonylation of dehydrolinalyl methyl carbonate (**136**) (Scheme 26).[19] The allenyl ester **137** is first formed and undergoes an intramolecular ene reaction to give **138**.

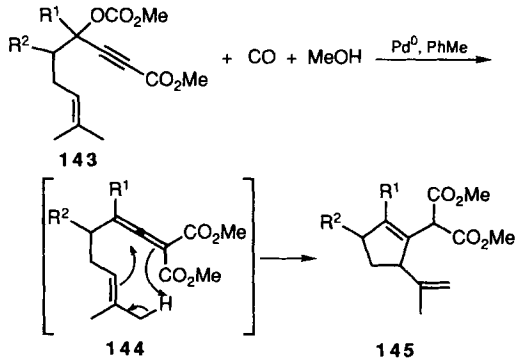


Scheme 26. Tandem carbonylation and ene reaction yielding **138**.

A particularly facile ene reaction is observed with propargyl carbonates having an ester group attached to the triple bond. The carbonylation and intramolecular ene reaction of methyl carbonates **139** and **143** afford cyclohexadiene **142** and cyclopentene **145** via the geminal allenyl diesters **140** and **144**, respectively (Schemes 27 and 28).[39] Further carbonylation of



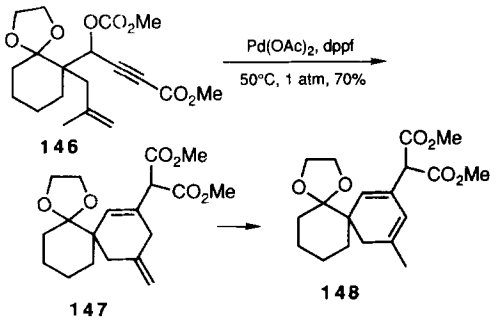
Scheme 27. Tandem carbonylation and ene reaction to give cyclohexadienes **142**; R^1, R^2 = alkyl, aryl.



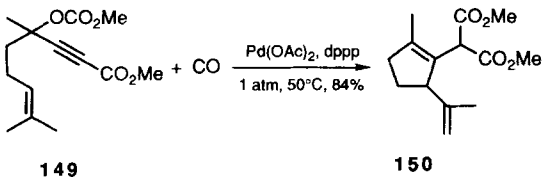
Scheme 28. Tandem carbonylation and ene reaction to form cyclopentenes **145**; R^1, R^2 = alkyl, aryl.

intermediates **140** and **144** to afford the corresponding triesters (cf. **71** in Scheme 15) does not occur. Instead, the sole reaction is the intramolecular ene reaction, which takes place smoothly at 50 °C under 1 atm CO and with $Pd(OAc)_2$/dppp or $Pd(OAc)_2$/dppf (1:2 ratio) as the catalyst.

Substrates **139** and **146**, which both bear an isopropenyl group, undergo palladium-catalyzed monocarbonylation followed by an ene reaction via intermediates like **140** to yield products containing six-membered rings. The ensuing thermodynamically controlled isomerization of the 1,4-dienes **141** and **147** affords the 1,3-cyclohexadienes **142** and **148**, respectively, in high yields (Scheme 27). In sharp contrast, carbonylation of the

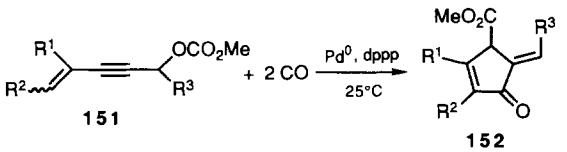


substrates **143** and **149**, which both have 2-methyl-1-propenyl groups, proceeds via intermediates like **144** and yields products **145** and **150** with five-membered rings and isopropenyl substituents (Scheme 28).



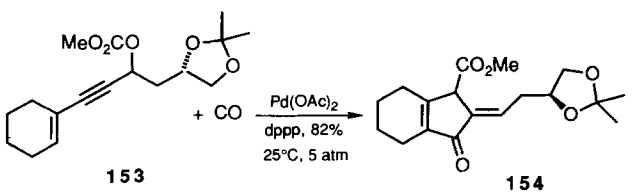
3.2.10. Preparation of Cyclopentenonecarboxylates

The tandem carbonylation and Diels–Alder reaction described in Section 3.2.8 proceeds only intramolecularly. Attempted carbonylation and intermolecular Diels–Alder reaction of conjugated 4-en-2-ynyl carbonates **151** (5 atm CO, room temperature) in the presence of various alkenes as dienophiles gave entirely different products. The 4-oxo-5-alkylidene-2-cyclopentenecarboxylates **152** are obtained unexpectedly by the incorporation of two molecules of carbon monoxide (Scheme 29). In a

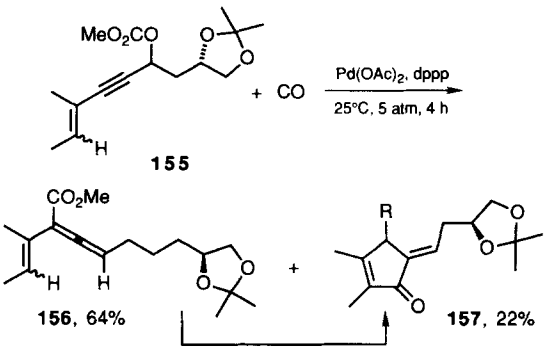


Scheme 29. One-step synthesis of cyclopentenonecarboxylates **152**; R^1, R^2, R^3 = alkyl, aryl.

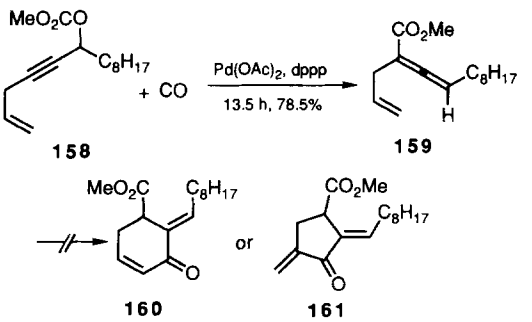
specific case, cyclopentenone **154** was obtained in 82% yield by the reaction of **153** at 25 °C under 5 atm CO.[40] Bidentate ligands such as dppp or bis(diphenylphosphino)ethane (dppe) are required; triphenylphosphane is not effective.



Results of the following experiments give important clues to the mechanism. Isolation of the expected intermediate, a trienecarboxylate ester, is not possible in most cases. As an exception, the trienecarboxylate **156** was isolated (64%) together with the cyclized product **157** (22%) from the reaction of **155** after 4 h. Intermediate **156** was converted into the cyclized product **157** on further exposure to the carbonylation conditions, showing that it is a precursor of **157**.

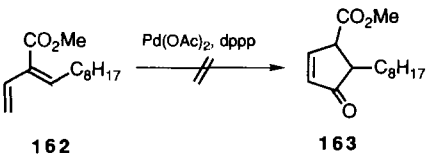


Also the carbonylation of the 1,4-enyne **158** gives only the allenecarboxylate **159**. Further carbonylation to give the cyclic ketones **160** or **161** is not observed (Scheme 30). In addition, the

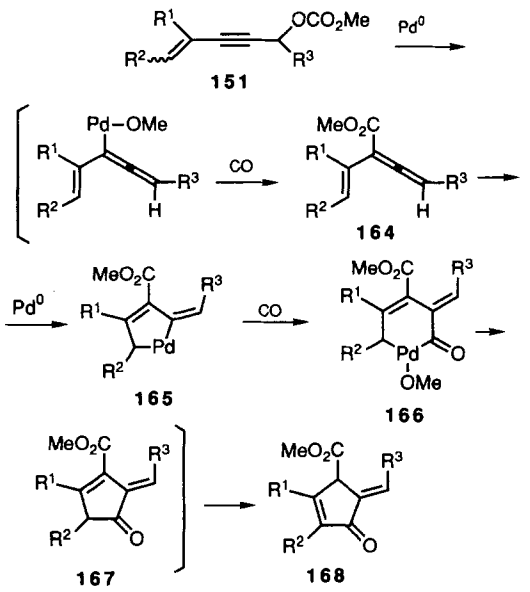


Scheme 30. Monocarbonylation of 1,4-enyne **158**.

1,3-diene ester **162** is recovered intact under the same carbonylation conditions and the cyclized product **163** is not obtained.



These results imply that the conjugated enallene ester system (1,2,4-triene-3-carboxylate) is required for incorporation of the second molecule of carbon monoxide, and the following mechanism has been proposed. Palladacyclopentene **165** is presumed to arise from **164** and is postulated as an intermediate in the formation of **168**. Insertion of CO into palladacycle **165** generates the acylpalladium complex **166**. Subsequent reductive elimination affords cyclopentenone **167**, which isomerizes to give cyclopentenone **168** as the final product (Scheme 31).

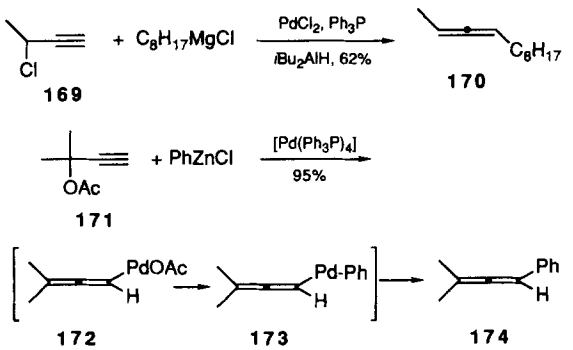


Scheme 31. Proposed mechanism for the formation of cyclopentenonecarboxylates **168**; R^1, R^2, R^3 = alkyl, aryl.

4. Type II Reactions: Transmetalations and Related Reactions

4.1. Reactions with Hard Carbon Nucleophiles

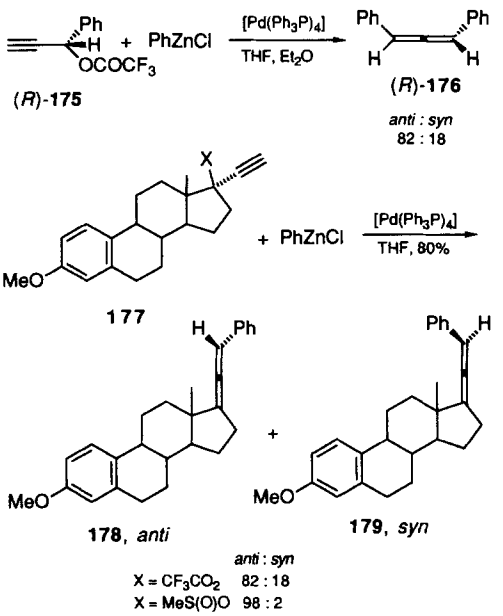
Pd^0-catalyzed reactions of propargylic compounds with hard carbon nucleophiles give different products than those with soft carbon nucleophiles. Propargylic halides, acetates, and phosphates react with hard carbon nucleophiles MR (M = main group elements such as Mg, Zn, B) to give allenyl derivatives. Octylmagnesium chloride reacts with 3-chloro-1-butyne (**169**) to give 2,3-dodecadiene (**170**).[41] Reaction of phenylzinc chloride with 3-acetoxy-3-methyl-1-butyne (**171**) affords 1-phenyl-3-methyl-1,2-butadiene (**174**) in high yield (Scheme 32).[7, 42, 43]



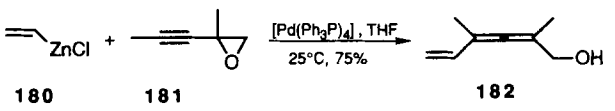
Scheme 32. Transmetalation reactions and mechanism of the reaction of phenylzinc chloride with propargyl acetate **171**.

The reaction can be explained by transmetalation of the allenylpalladium intermediate **172** with phenylzinc chloride to generate the allenyl(phenyl)palladium intermediate **173**, followed by reductive elimination to afford **174**.

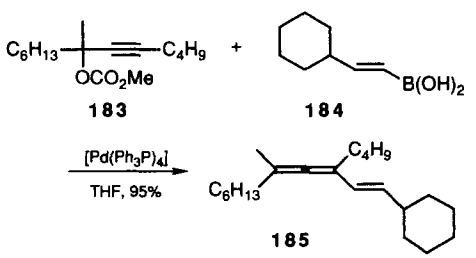
anti Stereoselectivity was observed in the reaction of (*R*)-(−)-1-phenyl-1-trifluoroacetoxy-2-propyne (**175**) with phenylzinc chloride to produce the levorotatory allene (*R*)-**176**; the ratio of *anti* vs. *syn* 1,3-substitution was approximately 82:18. Also the reaction of the 17β propargylic ester **177** with phenylzinc chloride gave mainly the *anti* product **178** with high stereoselectivity. The observed *anti* stereoselectivity is explained by assuming that formation of the allenylpalladium intermediate involves configuration inversion; the transmetalation and reductive elimination proceed with retention of configuration.[43] It is well-established that the same stereoselectivity (overall inversion) is observed in the Pd^0-catalyzed substitution reaction of allylic esters with hard carbon nucleophiles.



2-Alkynyloxiranes react smoothly with alkynyl-, alkenyl-, and arylzinc reagents. Reaction of 2-methyl-2-(1-propynyl)-oxirane (**181**) with vinylzinc chloride (**180**) yields 2,4-dimethyl-2,3,5-hexatrien-1-ol (**182**).[44]

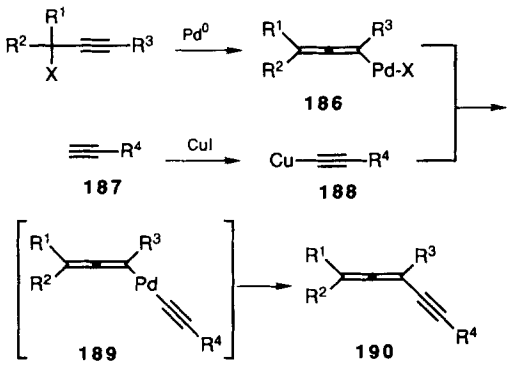


Organoboranes also react with propargylic carbonates. Usually, addition of a base is indispensable for palladium-catalyzed reactions of organoboranes with aryl, alkenyl, and allyl halides. But the reaction of organoboranes with methyl propargyl carbonates proceeds without added base, because methoxide is generated in situ from the carbonate. For example, 1,3,4-triene **185** is obtained from the reaction of alkenylborane **184** with propargylic carbonate **183** under neutral conditions.[45]



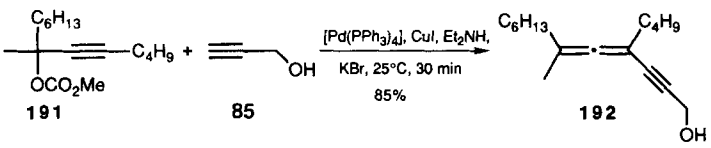
4.2. Reactions of Terminal Alkynes; Formation of 1,2-Dien-4-ynes

1,2-Dien-4-ynes **190** (allenylacetylenes) can be prepared in good yields by the palladium-catalyzed coupling of terminal alkynes **187** with propargylic compounds such as carbonates, acetates, and halides in the presence of the cocatalyst cuprous iodide (Scheme 33). Addition of cuprous iodide is not necessary



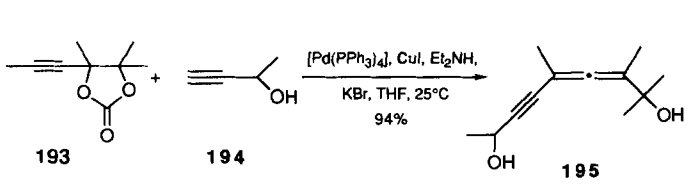
Scheme 33. Mechanism of the Pd/Cu-catalyzed coupling of propargylic compounds with terminal alkynes; X = OCO_2Me, OAc, Cl; R^1, R^2, R^3, R^4 = alkyl, aryl.

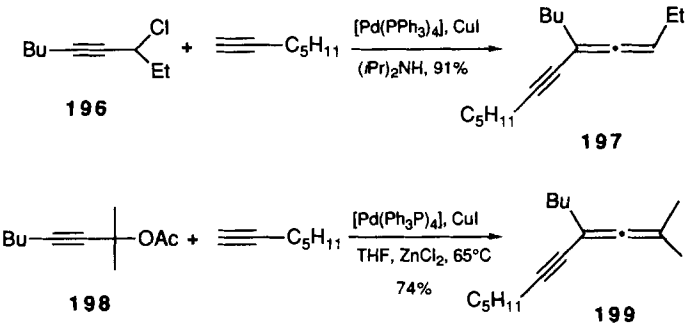
when metal acetylides are used. The Pd/Cu-catalyzed coupling of propargylic carbonates with terminal alkynes proceeds at room temperature rapidly within 30 min.[46] The addition of lithium chloride or potassium bromide and diethylamine rather than triethylamine gives better results. The allenylalkynes formed by the coupling are reactive and apparently undergo further palladium-catalyzed reactions—their yields tend to decrease for extended reaction times. Therefore the reaction must be stopped as soon as the coupling is complete. The reaction can be explained by the following mechanism (Scheme 33). Reaction of cuprous iodide with the terminal alkyne **187** affords the copper acetylide **188**, which undergoes transmetalation with **186** to form the allenyl(alkynyl)palladium intermediate **189**. Reductive elimination then gives the allenylacetylene **190**. The coupling of **191** with propargyl alcohol (**85**) gave rise to 1,2-dien-4-yne **192** at room temperature in 85% yield in 25 min.



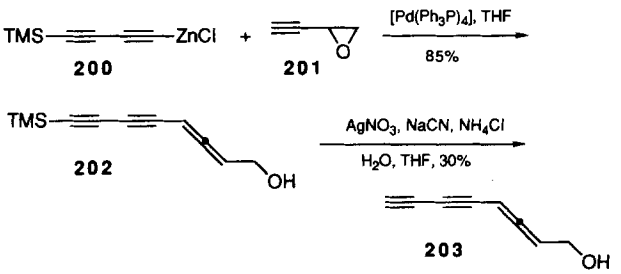
The cyclic carbonate **193** reacts with the terminal alkyne **194** under similar conditions to give the 2,3-alkadien-4-yn-1-ol derivative **195**.[47]

Propargylic chlorides also react with terminal alkynes in the presence of triethylamine or diisopropylamine. 5-Butyldodeca-3,4-dien-6-yne (**197**) was obtained in 91% yield from the reaction of 3-chloro-4-nonyne (**196**) with 1-heptyne in diisopropylamine. Coupling of the propargylic acetate **198** with 1-heptyne is possible in the presence of three equivalents of zinc chloride with or without cuprous iodide to give the 2,3-dien-5-yne **199**.[48]



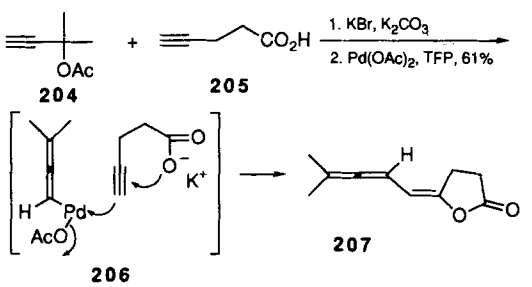


Various metal acetylides can be coupled smoothly with propargylic halides and acetates, and with 2-(1-alkynyl)oxiranes to give 2,3-dien-5-yn-1-ols.[42,44] In one synthetic application the unstable 2,3-octadiene-5,7-diyn-1-ol (**203**), a fungus metabolite, was prepared by coupling 4-trimethylsilylbutadiynylzinc chloride (**200**) with 2-ethynyloxirane (**201**) to give the allenyl alcohol **202**, which was then desilylated (Scheme 34).[44]



Scheme 34. Synthesis of 2,3-octadiene-5,7-diyn-1-ol (**203**), a fungus metabolite.

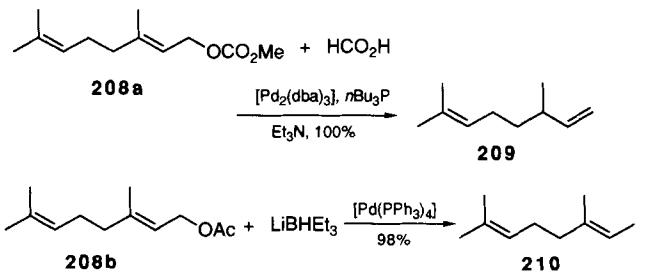
The unsaturated *exo*-enol lactone **207** was obtained by coupling the propargylic acetate **204** (≡**171**) with 4-pentynoic acid (**205**) in the presence of potassium bromide and with tri(2-furyl)phosphane (TFP) as the ligand. Oxypalladation of the triple bond of 4-pentynoic acid (**205**) with the allenylpalladium intermediate and the carboxylate (as shown in **206**) is the first step, and the subsequent reductive elimination affords lactone **207** (Scheme 35). The (*E*) double bond is formed because the oxypalladation is a *trans* addition.[49]



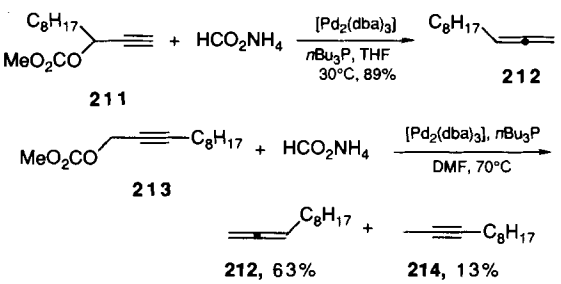
Scheme 35. Formation of the unsaturated *exo*-enol lactone **207** from 4-pentynoic acid (**205**).

4.3. Hydrogenolysis of Propargylic Compounds Having Terminal Triple Bonds with Formate and Other Hydrides to Give Allenes

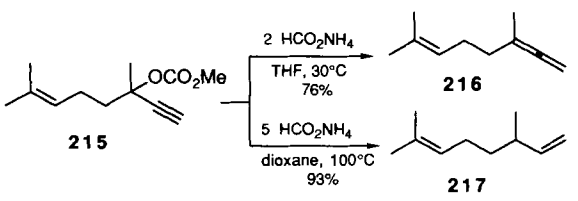
The Pd-catalyzed reaction of the terminal allylic esters geranyl carbonate (**208a**) and acetate (**208b**) with ammonium formate or triethylammonium formate affords olefin **209**, which has a terminal double bond, regioselectively.[50] Hydrogenolysis with other hydrides affords the isomeric diene **210** with two



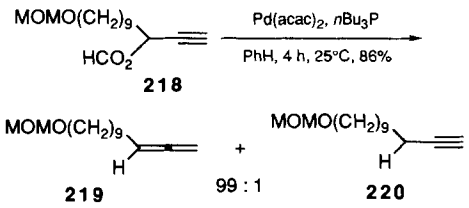
internal double bonds.[51] Formate is a special reducing agent since it gives the terminal alkene with high regioselectivity. Similarly, the facile hydrogenolysis of the terminal propargylic carbonate **211** at room temperature with ammonium formate using $[Pd_2(dba)_3]/nBu_3P$ in THF affords 1,2-undecadiene (**212**). The reaction of the isomeric carbonate **213** having an internal triple bond is slower and proceeds at 70 °C to give allene **212**.[52] In addition, alkyne **214** is formed as a by-product. Formation of



alkynes as the main product of the hydrogenolysis of propargylic esters will be discussed separately in Section 6.1, because it is a type IV reaction.[52] The selective, Pd^0-catalyzed formation of allenes by hydrogenolysis is a convenient means of preparing allenes from propargylic alcohols. Allenes are reduced further to 1-alkenes by treatment with an excess of ammonium formate at 65–100 °C. As an example, the 1-alkene **217** is obtained from **215** directly by reduction with five equivalents of ammonium formate at 100 °C in dioxane. Allene **216** is obtained by treatment of **215** with two equivalents of ammonium formate at room temperature in THF.

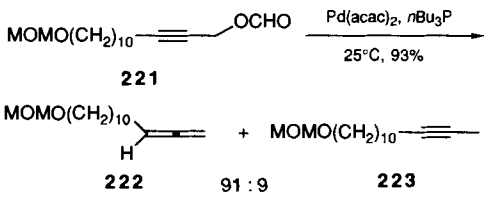


The formation of allenes from terminal propargylic esters proceeds much more cleanly when propargylic formates are used. Decarboxylation–hydrogenolysis giving allenes is then possible without ammonium formate. Allene **219** is obtained cleanly from the propargylic formate **218**; only a small amount of alkyne **220** is formed (MOM = methoxymethyl).

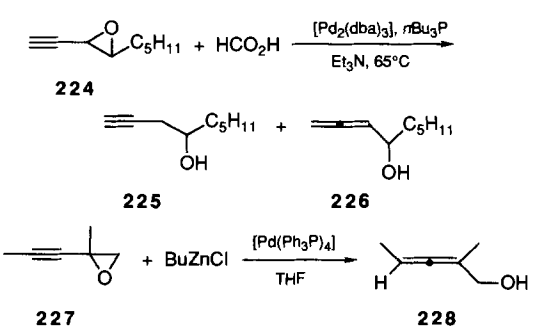


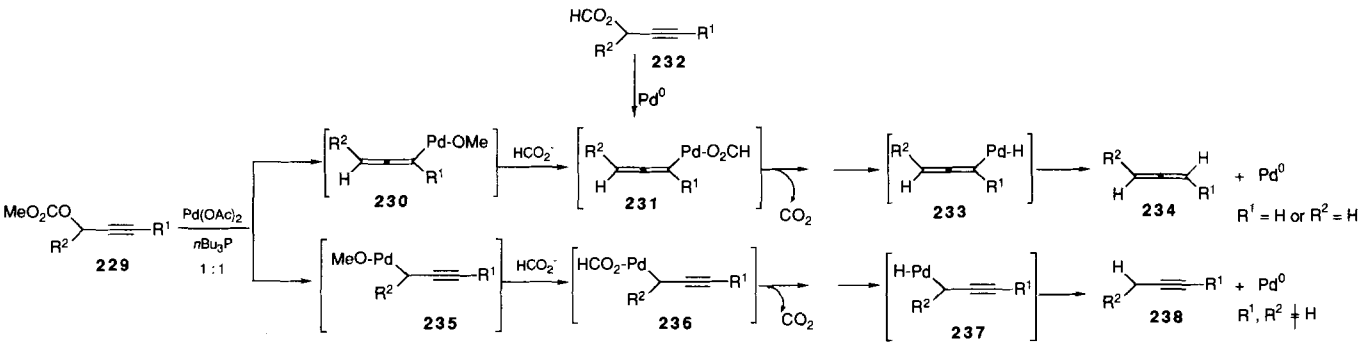
Preparation of an active Pd^0 catalyst is crucial for the clean formation of allenes. The catalyst generated in situ from $Pd(OAc)_2$ or $Pd(acac)_2$ and nBu_3P (1:1 ratio) is very active and particularly effective for this reaction.[14] The most satisfactory results with this catalyst are obtained with primary and secondary propargylic formates having terminal triple bonds. Tertiary propargylic formates cannot be prepared; in this case the corresponding carbonates are reduced by treatment with triethylammonium formate. Triethylammonium formate is more soluble than ammonium formate in organic solvents and thus gives better results. In addition, propargylic formates are superior to other esters, because the allenes produced are not reduced further to the corresponding alkenes. In particular, the reaction of terminal propargylic formates affords allenes smoothly.[53, 54]

Propargylic esters with internal triple bonds are converted into alkynes by the hydrogenolysis discussed in Section 6.1. In one exception, the primary propargylic formate **221** gives allene **222** as the main product and alkyne **223** as a minor product.



The hydrogenolysis of the 2-(1-alkynyl)oxirane **224** with triethylammonium formate is not selective. A mixture of 1-alkyn-4-ol **225** and the expected 1,2-dien-4-ol **226** was obtained in a ratio of 6:4.[52] However, the reaction of 2-(1-alkynyl)oxirane



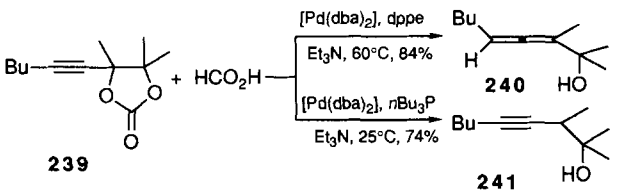


Scheme 36. Mechanism of the hydrogenolysis of propargylic esters **229** with formate.

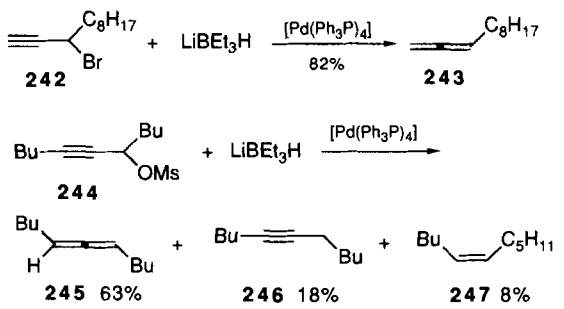
227 (≡**181**) with *n*-butylzinc chloride afforded the expected 2,3-dien-1-ol **228** as the main product.[44]

The following mechanism has been proposed for the hydrogenolysis of propargylic carbonate **229** with ammonium formate (Scheme 36). Oxidative addition yields the allenylpalladium methoxide **230**, which reacts with ammonium formate to generate the allenylpalladium formate complex **231**. This intermediate is also formed directly by oxidative addition of the corresponding propargylic formate **232**. Decarboxylation of **231** gives the allenylpalladium hydride complex **233**, which finally undergoes reductive elimination to give allene **234** and the Pd^0 catalyst. The propargylic complex **235** may also be formed, depending on the substituent, and converted into propargylic formate **236**. Alkyne **238** is obtained from the propargylpalladium hydride comple **237**, which is considered to be in equilibrium with **233**.

Hydrogenolysis of the cyclic alkynyl carbonate **239** with triethylammonium formate afforded the α-allenyl alcohol **240** when dppe was used as a ligand. On the other hand, the homopropargylic alcohol **241** was obtained with nBu$_3$P.[55]

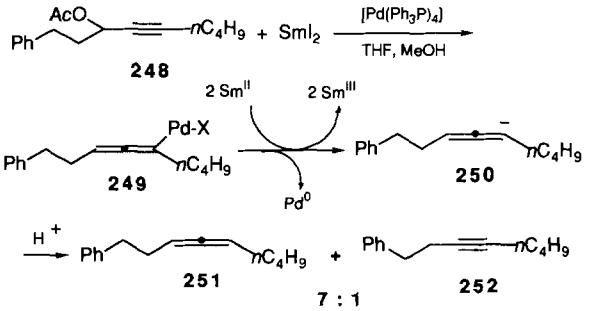


Terminal propargylic bromides, mesylates, and phosphates are hydrogenolyzed with $LiAlH_4$, $NaBH_4$, and $LiBHEt_3$, and the selectivity is dependent on the hydride species. Hydrogenolysis of the terminal propargylic bromide **242** with $LiBHEt_3$ gives allene **243** with high selectivity. Propargylic mesylates, bromides, and phosphates with internal triple bonds are converted into mixtures of allenes and alkynes with these metal hydrides. Treatment of the propargylic mesylate **244** with $LiBEt_3H$ gives allene **245** as the main product and alkyne **246** as a minor product. But a considerable amount of overreduction to alkene **247** is also observed.[56]



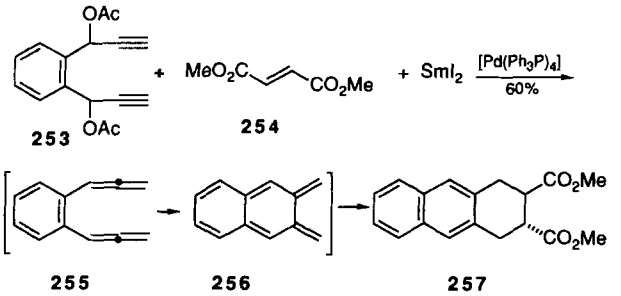
Propargylic acetates are not suitable for the hydrogenolysis with ammonium formate. At room temperature, almost no reaction of propargylic acetates with ammonium formate takes place, and a mixture of allene and 1-alkene is obtained at elevated temperatures. Thus propargylic formates and carbonates are the best substrates for the allene formation. The method offers a new and efficient preparative approach to allenes from easily available propargylic alcohols via their formates or carbonates.

Reduction of propargylic compounds with samarium diiodide is possible in the presence of palladium catalysts. Propargylic acetate **248** is converted mainly to allene **251** by the palladium-catalyzed reaction with samarium diiodide in the presence of a proton source. Propargylic phosphates react with samarium diiodide similarly.[57] In this reaction, the allenylpalladium complex **249** is reduced with bivalent samarium to give the allenyl anion **250**, which is protonated to afford the allene **251**. Alkyne **252** is formed as a by-product (Scheme 37). The reactive



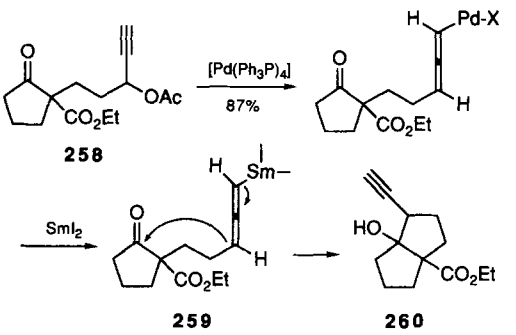
Scheme 37. Mechanism of the hydrogenolysis of propargylic acetate **248** with SmI_2.

intermediate 2,3-naphthoquinodimethane (**256**) can be generated by this reaction. Treatment of 1,2-di(1-acetoxypropynyl)benzene (**253**) with samarium diiodide affords 1,2-dipropadienylbenzene (**255**), which spontaneously cyclizes to give 2,3-naphthoquinodimethane (**256**). Then facile Diels–Alder reaction of **256** with fumarate (**254**) gives the tetrahydroanthracene derivative **257** (Scheme 38).[58] Similarly, compound



Scheme 38. Tandem hydrogenolysis of propargylic acetate **253** with SmI_2 and Diels–Alder reaction.

259, a synthetic equivalent of a propargylic anion, is generated by the reaction of propargylic acetate **258** with samarium diiodide; the anion attacks the ketone intramolecularly to give the homopropargyl cycloalkanol **260** (Scheme 39).[59a] The reaction was applied to the synthesis of the enyne A ring synthon of 1α-hydroxy vitamin D.[59b]



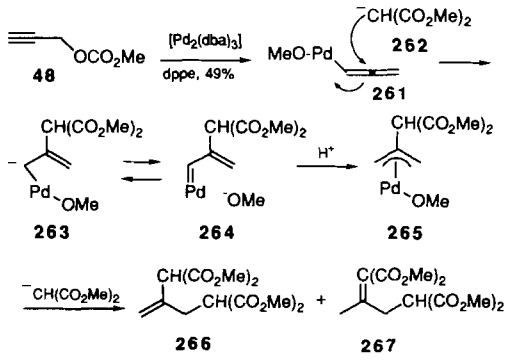
Scheme 39. Generation of intermediate **259**, a synthetic equivalent of a propargylic anion.

5. Type III Reactions: Reactions with Soft Carbon and Oxo Nucleophiles

5.1. Reactions with Soft Carbon Nucleophiles

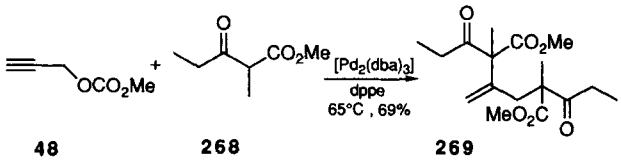
Type III reactions proceed by attack of a nucleophile at the central sp carbon of the allenylpalladium complex. In contrast to allylic esters, which undergo facile Pd^0-catalyzed reactions with soft carbon nucleophiles via π-allylpalladium intermediates, propargylic esters are less reactive. Propargylic acetates do not react with soft carbon nucleophiles. But soft carbon nucleophiles such as β-keto esters and malonates react with propargylic carbonates under neutral conditions and with dppe as the Pd ligand.[60]

2-Propynyl carbonate (**48**) reacts with two equivalents of malonate **262** or methyl α-alkylacetoacetate **268** to give the 2,3-disubstituted propenes **266**, **267**, and **269** under neutral conditions in boiling THF (Scheme 40). The carbanion **262** attacks the central sp carbon of the allenylpalladium species **261** to generate **263**, which abstracts a proton from malonate to form the π-allylpalladium intermediate **265**. Intermediate **263** can be considered equivalent to the palladium carbene complex **264**. In the last step malonate anion attacks the π-allylpalladium intermediate **265**, as expected, to give **266**. Migration of the double bond in

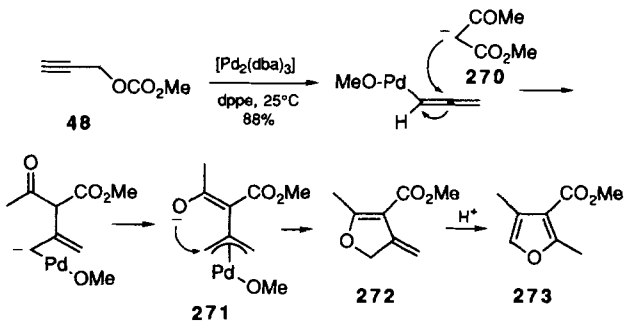


Scheme 40. Mechanism of the reaction of propargyl carbonate **48** with malonate **262**.

266 affords **267**. The reaction of α-alkylacetoacetate **268** gives **269**.[60,61] Thus the propargylic carbonate **48** has two sites for nucleophilic attack. The best ligand for the reaction is dppe; the reaction is slow when Ph_3P is used.

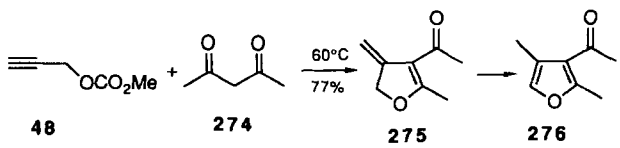


Acetoacetate **270**, bearing two activated hydrogen atoms, reacts with methyl propargyl carbonate (**48**) in a 1:1 ratio in THF under neutral conditions at room temperature to give an entirely different product. In the first step C-alkylation generates the π-allylpalladium intermediate **271** (Scheme 41). Intramolecular

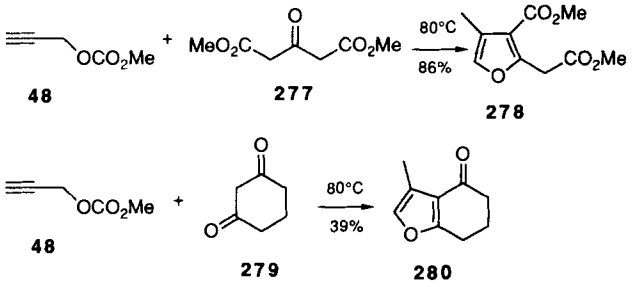


Scheme 41. Mechanism of furan formation by the Pd-catalyzed reaction of acetoacetate **270** with propargyl carbonate (**48**).

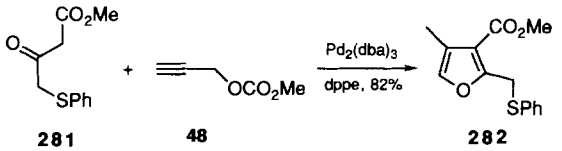
attack by the nucleophilic enolate oxygen then gives 4-(methoxycarbonyl)-5-methyl-3-methylene-2,3-dihydrofuran (**272**) in 88% yield. The methylenedihydrofuran **272** is unstable and isomerizes to the stable furan **273** quantitatively under slightly acidic conditions.[60,61] This type of C- and O-alkylation of propargylic carbonates provides a useful approach to furans. Acetylacetone (**274**) reacts analogously with **48** to give the corre-



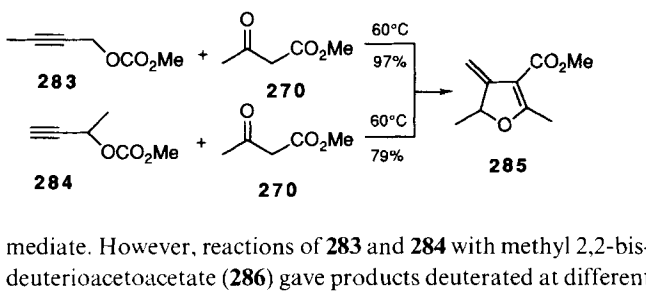
sponding dihydrofuran **275**, which isomerizes to **276**. Similarly, reactions of dimethyl 3-oxoglutarate (**277**) and 1,3-cyclohexanedione (**279**≡**120**) afford **278** and **280**, respectively, in good yields.

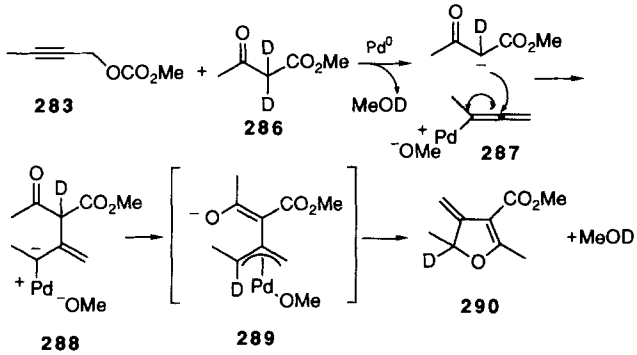


This method for the preparation of substituted furans has been applied to the synthesis of phenylthiomethyl-substituted furan **282** by the reaction of **48** with β-keto ester **281**; furan **282** was used for the syntheses of natural products such as neoliacine.[62]

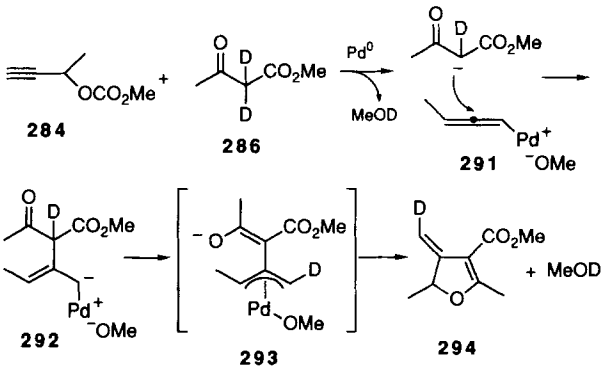


To study the mechanism of the furan formation, the reactions of methyl acetoacetate (**270**) with the isomeric 2-butynyl methyl carbonate (**283**) and 1-methylpropynyl methyl carbonate (**284**) were examined. Both give the product **285**, indicating that the furan formation from **283** and **284** proceeds via a common intermediate. However, reactions of **283** and **284** with methyl 2,2-bisdeuterioacetoacetate (**286**) gave products deuterated at different carbons. The 2-deuterio-3-hydrofuran **290** was obtained from **283** via **289** (Scheme 42), whereas reaction of **284** with **286** afforded furan **294** via **293** (Scheme 43). These results are explained by assuming that the attack of oxygen nucleophilic (O-allylation) occurs at the more substituted side of π-allylpalladium systems in **289** and **293**.



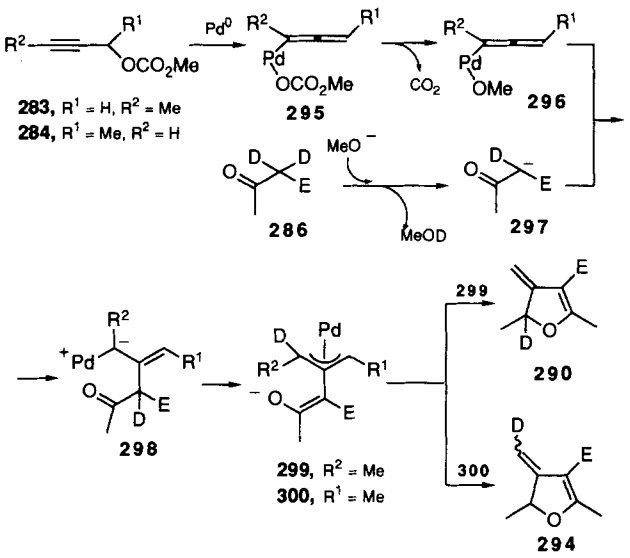


Scheme 42. Deuterium incorporation in a furan derivative formed by the reaction of deuterated acetoacetate **286** with **283**.



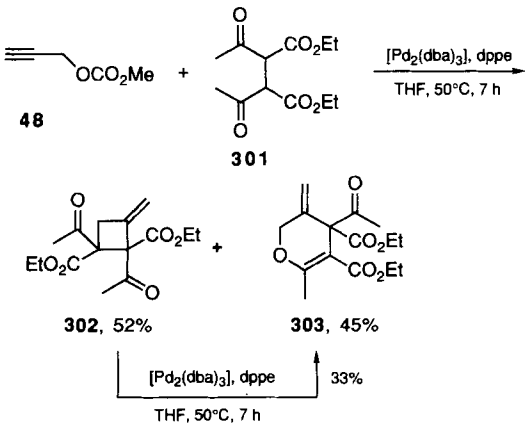
Scheme 43. Deuterium incorporation in a furan derivative formed by the reaction of deuterated acetoacetate **286** with **284**.

Formation of the labeled furans from **283** and **284** is explained by the following mechanism (Scheme 44). In the first step propargylic carbonate **283** (**284**) reacts with Pd^0 to give the allenylpalladium carbonate **295**, which is converted into the palladium methoxide complex **296**. The methoxide abstracts an acidic hydrogen (or deuterium) from acetoacetate **286** to give **297**. Then the enolate anion **297** attacks the central carbon of the allenyl moiety of **296** to generate **298**, and intramolecular deuterium transfer furnishes the π-allylpalladium complex **299** (**300**). This, intermediate undergoes intramolecular O-alkylation with the enolate oxygen to give the labeled *exo*-methylene furan **290** (**294**). The key conclusion is that the oxygen anion attacks the more substituted side of the π-allyl systems in **299** and **300**.

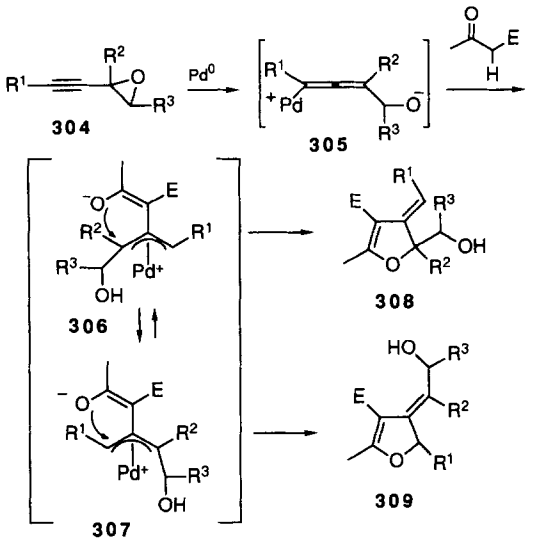


Scheme 44. Mechanism for the formation of the labeled furans **290** and **294**; E = CO_2Me.

The reaction of propargyl carbonate **48** with 2,5-hexanedione-3,4-dicarboxylate (**301**) catalyzed by $[Pd_2(dba)_3]$/dppe afforded after seven hours methylenecyclobutane **302** (double C-alkylation) and 3-methylenedihydropyran **303** (C- and O-alkylations) in 52 and 45% yield, respectively. Since cyclobutane **302** is a product of a reversible reaction, 33% of **302** could be converted into **303** by treatment with the same catalyst for seven hours.[63]



2-Alkynyloxiranes **304** undergo the palladium-catalyzed furan formation with soft nucleophiles by two cyclization paths to give either **308** or **309** as the primary product (Scheme 45). The

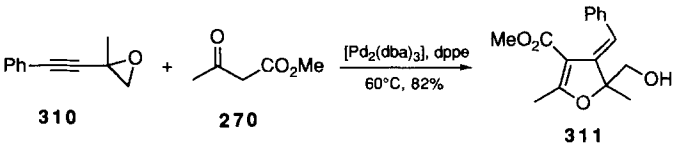


Scheme 45. Furan formation from 2-(1-alkynyl)oxiranes **304**; R^1, R^2, R^3 = alkyl, aryl.

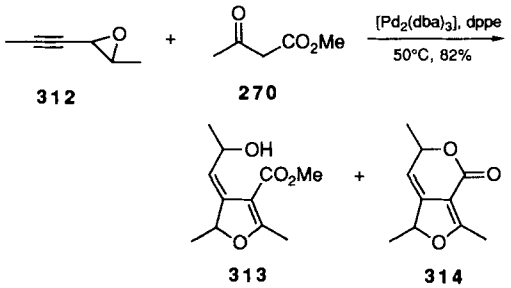
dihydrofuran undergoes further transformations depending on its substituents.[61, 64] In the first step the allenylpalladium complex **305** is generated, which is converted into the two π-allylpalladium complexes **306** and **307**, from which two products are formed. When R^2 is not H, the enolate oxygen attacks the more substituted side to give furan **308**. Formation of **311** and **318** can be explained by evoking the π-allylpalladium complex **306** as an intermediate (Scheme 46). When R^2 is H, furan **309** is obtained.

The formation of furans **314** and **321** also belongs to this class of reactions (Scheme 47). Furthermore, the final products depend on the substitutents, as shown by the following examples.

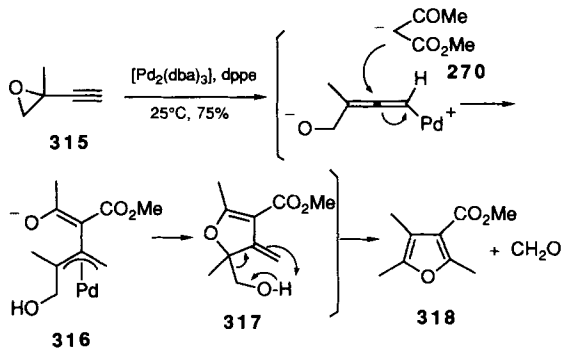
Oxirane **310** reacted with methyl acetoacetate (**270**) in the presence of $[Pd_2(dba)_3]$ and dppe in dry THF at 60 °C to give



2,3-dihydrofuran-4-carboxylate **311** in 82% yield. The *exo* double bond in **311** has (*E*) configuration, since the reaction proceeds via π-allylpalladium intermediate **306**, in which R^1 (Ph) assumes the *syn* orientation preferentially for steric reasons. In addition, the fact that the furan **313**, formed from **312** and **270**, undergoes facile lactonization to form furolactone **314**

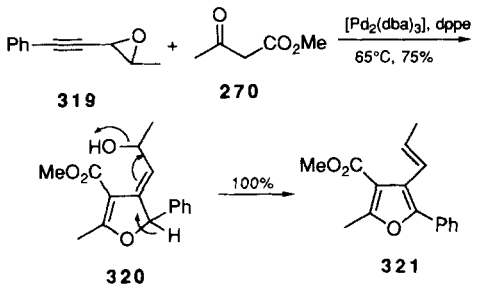


supports the (*E*) configuration of the *exo* double bond in **313**. The *exo*-methylenefuran **317**, formed from **315** via π-allylpalladium intermediate **316**, is a highly acid-sensitive compound. The dehydroxymethylation to give methyl 2,4,5-trimethylfuran-3-carboxylate (**318**) can be observed by NMR analysis in $CDCl_3$; the reaction also takes place quantitatively on treatment with acid (Scheme 46). On the other hand, benzylidenefuran **311**



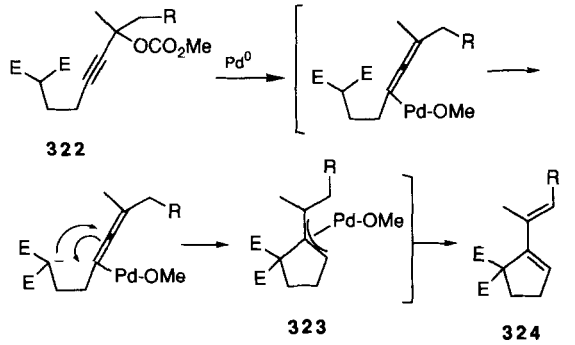
Scheme 46. Furan formation with elimination of formaldehyde.

does not undergo either dehydroxymethylation or dehydration under the same conditions. The 2-phenyldihydrofuran **320** formed from **319** undergoes facile dehydration to give **321**, rather than lactonization (Scheme 47).



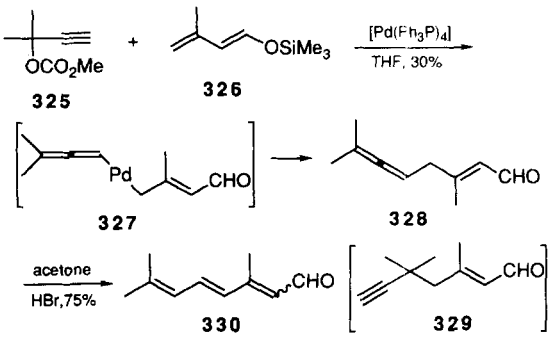
Scheme 47. Furan formation with dehydration.

In an intramolecular reaction of the malonate-type carbon nucleophile in **322**, the intermediate π-allylpalladium complex **323** undergoes β-hydride elimination to form the diene **324** (Scheme 48).[65]



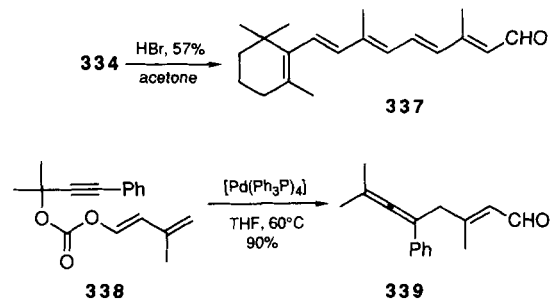
Scheme 48. Intramolecular attack of a malonate-type anion followed by elimination; E = CO_2R, R = alkyl.

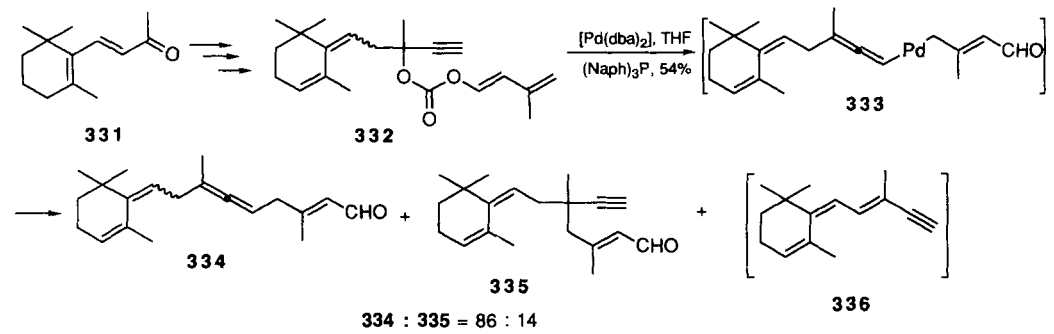
Carbon–carbon bond formation can take place by the Pd^0-catalyzed reaction of propargylic carbonates with silyl enol ethers or by rearrangement of propargylic enol carbonates as masked carbon nucleophiles. Propargylic carbonates are expected to react with silyl enol ethers via allylpalladium enolates by transmetalation. In an attempted synthesis of unsaturated isoprenoid aldehydes, the reaction of 1-trimethylsiloxyisoprene (**326**) with 1,1-dimethylpropynyl methyl carbonate (**325**) gave the α,β-unsaturated isoprenoid allenyl aldehyde **328** and the unsaturated alkynyl aldehyde **329**, although the yield was low (30%). The allenylpalladium complex **327** is an intermediate of **328**, which is converted to dehydrocitral **330** (Scheme 49).[66] It is well-established that the corresponding allylic carbonates react with silyl enol ethers by transmetalation to afford allylated carbonyl compounds in good yields.[67]



Scheme 49. Reaction of silyl enol ether **326** with propargylic carbonate **325** to give allenyl aldehyde **328**, and its conversion into triene aldehyde **330**.

α,β-Unsaturated isoprenoid allenyl aldehydes can be prepared in higher yields by rearrangement of mixed propargyl enol carbonates. Carbonate **332** was prepared from β-ionone (**331**) and allowed to undergo the palladium-catalyzed rearrangement to give the allenyl aldehyde **334** as an (*E*/*Z*) mixture and alkynyl aldehyde **335** in 54% combined yield, as well as an elimination product **336** (25%) (Scheme 50); trinaphthylphosphane was used as the ligand. The allenylpalladium complex **333** is an intermediate of the rearrangement and its reductive elimination affords **334**. Aldehyde **334** is reconjugated with hydrogen bromide, and the all-*trans* isomer of retinal (**337**) is obtained by a simple equilibration.[66] The reaction is applicable to syntheses of polyunsaturated aldehydes and ketones. The single product **339** was obtained in high yield by the palladium-catalyzed rearrangement of the propargylic enol carbonate **338**.[68] It should be added that the corresponding allyl enol carbonates undergo a similar rearrangement to give α-allyl aldehydes in high yields.[69]

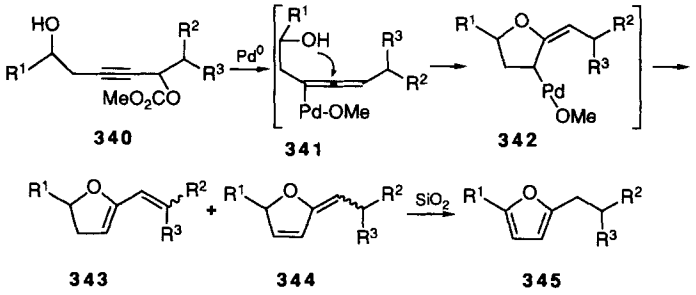




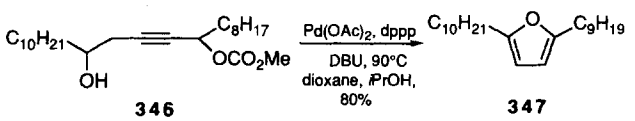
Scheme 50. Rearrangement of propargyl enol carbonate **332** to give allenyl aldehyde **334**.

5.2. Reactions with Oxo Nucleophiles

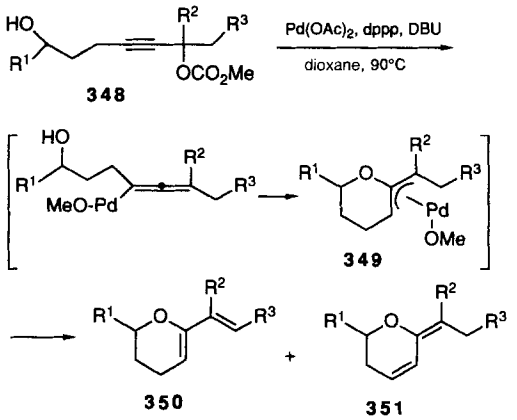
Propargylic carbonate **340** is cyclized by attack of the C-5 hydroxyl group at the central carbon of the initially formed allenyl system **341**. The intermediate σ-allylpalladium complex **342** undergoes β-hydride elimination to give the dienes **343** and **344**, which are converted into the more stable furan **345** as the final product (Scheme 51).[70] The reaction proceeds in the presence of diazabicycloundecane (DBU). The primary products **343** and **344** are isomerized easily to the furan **345** during column chromatography on silica gel. In a related example, propargylic carbonate **346** was converted into the furan **347** in



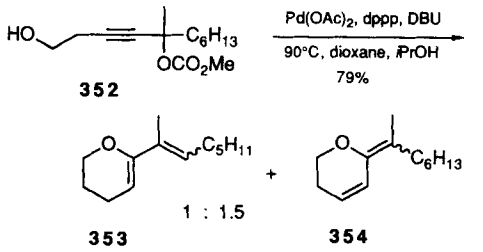
Scheme 51. Furan formation by intramolecular reaction of propargylic carbonates with OH groups; R^1, R^2, R^3 = alkyl, aryl.



80% yield in refluxing dioxane and with dppp as the ligand. Similarly, dihydropyrans **350** and **351** are formed from 6-hydroxy carbonates **348** via intermediate **349** (Scheme 52). Formation of the dihydropyrans **353** and **354** from **352** is another example.



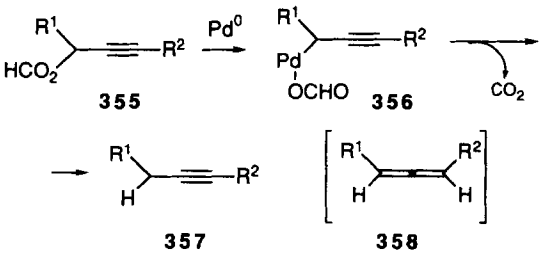
Scheme 52. Dihydropyran formation by intramolecular reaction of propargylic carbonates with OH groups; R^1, R^2, R^3 = alkyl, aryl.



6. Type IV Reactions: Reactions via Propargylpalladium Intermediates

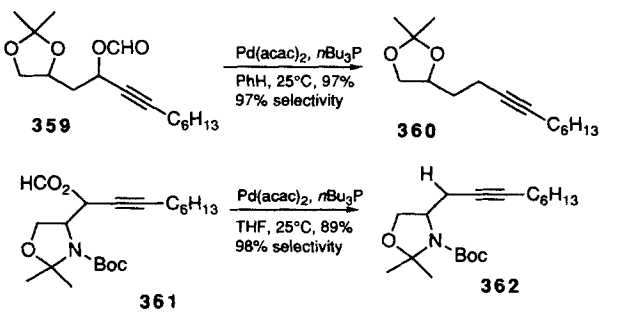
6.1. Hydrogenolysis of Propargylic Compounds Having an Internal Triple Bond with Formate and Other Hydrides

Palladium-catalyzed reactions via propargylic palladium intermediates like **356** are rather rare. One reaction that certainly proceeds via **356** is the decarboxylation–hydrogenolysis of propargylic formates **355**, which have an internal triple bond and can have various functional groups. Treatment of formate **355** with a Pd^0 catalyst in benzene or THF at room temperature gives the internal alkyne **357** almost exclusively and not allene **358** (Scheme 53).

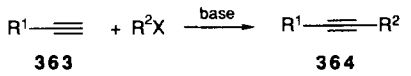


Scheme 53. Mechanism of the hydrogenolysis of propargylic formates to give alkynes; R^1, R^2 = alkyl, aryl.

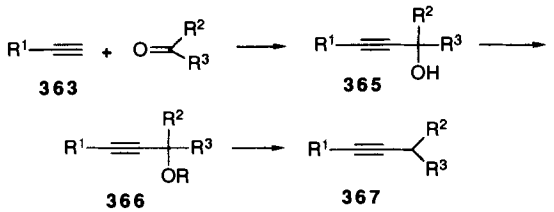
The preparation of the catalyst is crucial to this reaction. A catalyst prepared by mixing Ph_3P or dppe with $[Pd_2(dba)_3]$ does not give **357** cleanly. The best catalyst is prepared by mixing $Pd(OAc)_2$ or $Pd(acac)_2$ with nBu_3P in a ratio of 1:1.[114] With this catalyst, the internal alkynes **360** and **362** were formed in high yields and with over 97% selectivity from the functionalized propargylic formates **359** and **361**, respectively; the corresponding allenes were not formed.



This reaction is useful for selective preparation of internal alkynes, particularly those with labile functional groups. It is not always easy to prepare disubstituted alkynes **364** by simple alkylation of terminal alkynes **363**. Propargylic alcohols **365** are



prepared more easily by reaction of terminal alkynes **363** with ketones or aldehydes, and internal alkynes **367** are prepared by the hydrogenolysis of their formates or carbonates **366** (formates of primary and secondary alcohols, and carbonates of tertiary alcohols) (Scheme 54).

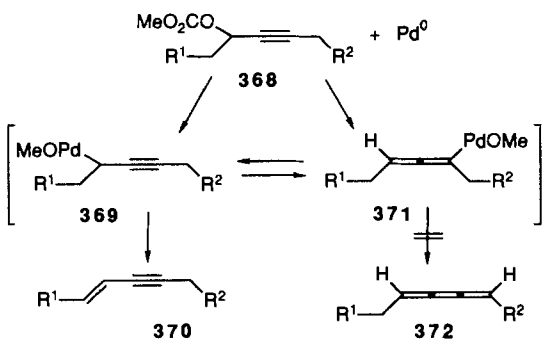


Scheme 54. Preparation of internal alkynes from terminal alkynes; R^1, R^3 = alkyl, aryl; when R^2 = H, R = CHO; when R^2 = alkyl, aryl, R = CO_2Me.

Internal propargylic halides and phosphates are reduced to internal alkynes with $LiAlH_4$, $NaBH_4$, and $LiAlEt_3H$ in the presence or absence of palladium catalysts. Selectivity is highly dependent on the hydride used.[56]

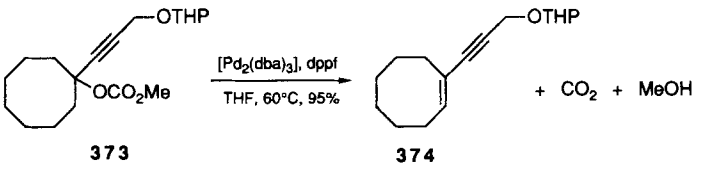
6.2. Eliminations: Formation of Conjugated Enynes

When the propargylic carbonate **368** is treated with a palladium catalyst in the absence of any other reactant, elimination of a β-hydrogen atom from the propargylpalladium intermediate **369** occurs to afford the conjugated enyne **370**. Formation of 1,2,3-triene **372** by elimination from the allenylpalladium intermediate **371** is not observed (Scheme 55).[54, 71] The elimination reaction proceeds with a variety of propargylic carbonates under mild and neutral conditions. Bidentate phosphanes, particularly dppf, are the best ligands for tertiary carbonates, and Ph_3P is used for secondary carbonates. The reaction with the tertiary

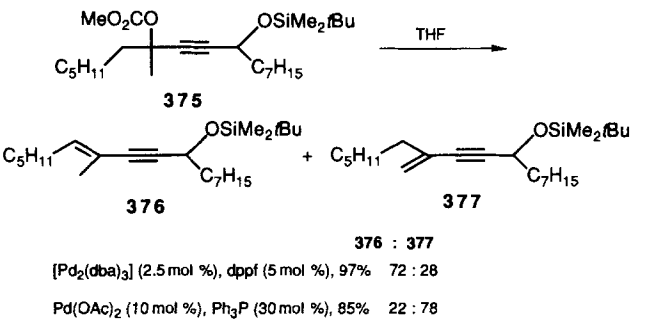


Scheme 55. Preparation of conjugated enyne **370** by elimination of propargylic carbonates; R^1, R^2 = alkyl, aryl.

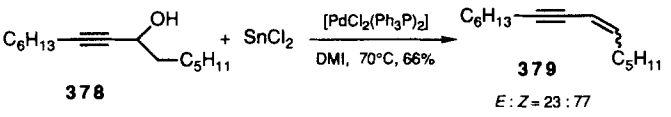
propargylic carbonate **373** derived from cyclooctanone proceeds smoothly to give the conjugated enyne **374** in good yield. The reaction is applicable to a number of other cyclic ketones



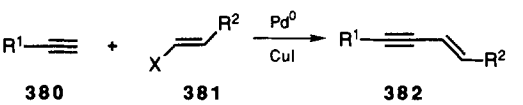
but not to cyclohexanone. The regioselectivity in the elimination of **375** is significantly affected by the catalytic species. When Ph_3P is used as the ligand, elimination from **375** gives mainly the disubstituted alkene **377**; with dppf the major product is enyne **376**.[54, 71]



In another elimination reaction the propargylic alcohol **378** is dehydrated to give the conjugated enyne **379** in 1,3-dimethylimidazolidin-2-one (DMI) at 70 °C in the presence of a palladium catalyst and a stoichiometric amount of stannous chloride.[72]



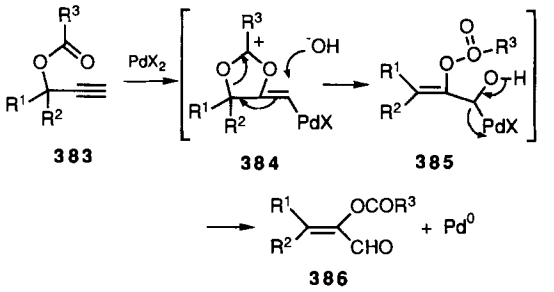
Another Pd-catalyzed reaction providing the conjugated enynes **382** is the coupling of alkenyl halides **381** with terminal alkynes **380** (≡**363**).[73] Although the method is useful, the preparation of alkenyl halides **381**, particularly those having a labile functional group, is not always easy. The present carbonate method can be carried out easily using carbonyl compounds as building blocks even in the presence of functional groups.



7. Miscellaneous Reactions

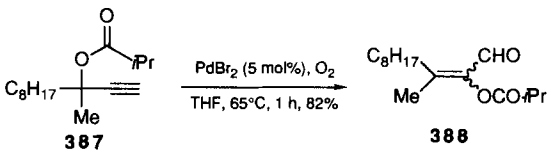
Some reactions of propargylic compounds that do not belong to the above-mentioned types are known. These reactions are surveyed in this section, although their mechanisms are not always clear.

Propargylic ester **383** undergoes an interesting oxidative rearrangement catalyzed by Pd^{II} salts under oxygen atmosphere to yield the α,β-unsaturated α-acyloxy aldehyde **386** in high yield (Scheme 56).[74] The reaction proceeds by intramolecular oxy-

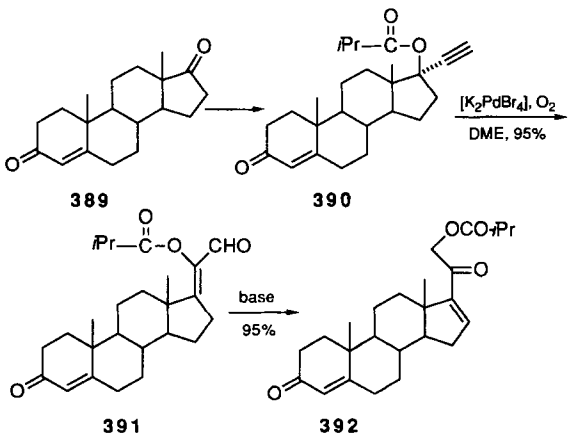


Scheme 56. Mechanism of formation of the α,β-unsaturated α-acyloxy aldehydes **386** from propargylic esters **383**; R^1, R^2, R^3 = alkyl, aryl.

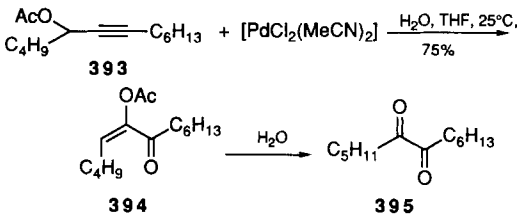
palladation of the triple bond to generate **384**, followed by an attack of hydroxide to form **385**. Elimination of Pd^0 from **385** affords **386**. Somehow Pd^0 is reoxidized to Pd^{II} with oxygen and recycled. The propargylic ester **387** is oxidized to give **388** in



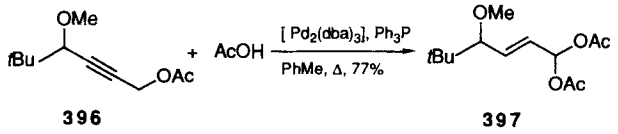
satisfactory yield by using 5 mol% of $PdBr_2$ under oxygen. This rearrangement was used to introduce the side chain in the corticosteroid **392** starting from the 17-keto steroid **389**. Preparation of propargylic ester **390** from **389** and its rearrangement gave **391** in 95% yield. The reaction proceeded with a catalytic amount of $PdBr_2$ in DME under oxygen atmosphere. Isobutyrate and benzoate gave better results than acetate for this reaction. Treatment of **391** with a base then gave **392**.[75]



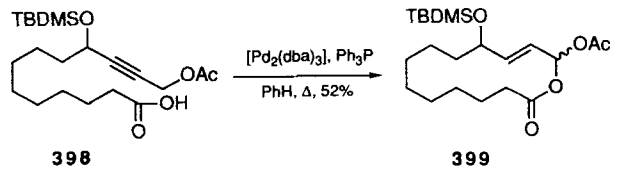
In a related reaction, oxidative conversion of the propargylic acetate **393** into the α,β-unsaturated α-acetoxyketone **394** takes place with a stoichiometric amount of $[PdCl_2(MeCN)_2]$ in aqueous THF. Hydrolysis of **394** gives rise to the α-diketone **395**.[76]



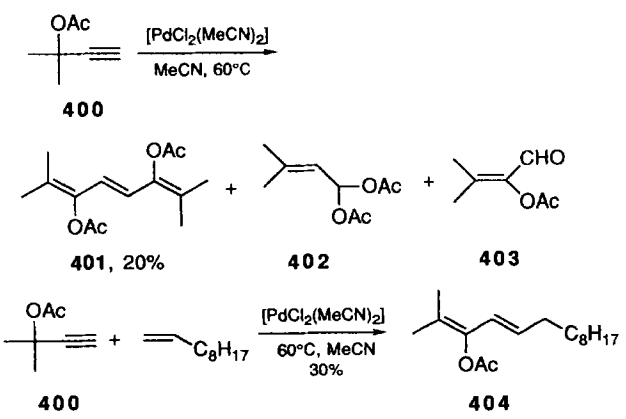
Propargylic acetates are less reactive than the corresponding carbonates toward Pd^0 and do not form allenylpalladium intermediates easily. Addition of acetic acid to the propargylic acetate **396** catalyzed by $[Pd_2(dba)_3]/Ph_3P$ affords the geminal allylic diacetate **397**. An intramolecular version of this reaction



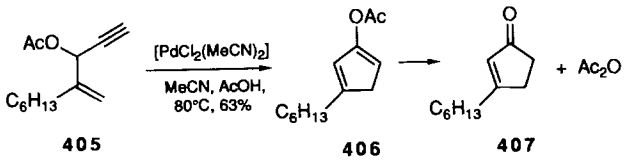
offers a good synthetic method for acetoxylactones. The 14-membered acetoxylactone **399** was obtained in refluxing benzene in 52% yield from **398**.[77]



Propargylic acetates undergo facile transformations catalyzed by Pd^{II} salts. $[PdCl_2(MeCN)_2]$ is a good catalyst for some reactions involving transposition of the acetoxy group. The reaction of 1,1-dimethyl-2-propynyl acetate (**400**≡**171**) catalyzed by $[PdCl_2(MeCN)_2]$ furnished the interesting conjugated triene **401** as a homocoupling product in 20% yield along with several other minor products such as **402** and **403**. The conjugated diene **404** was obtained in 30% yield by the cross-coupling of **400** with 1-decene. These reactions proceed via a palladium–carbene intermediate.[78]



A variant of the Nazarov cyclization of 1-ethynyl-2-propenyl acetate derivatives giving cyclopentenones is possible with a Pd^{II} salt as the catalyst. 3-Acetoxy-4-methylene-1-decyne (**405**) was converted to 3-hexyl-2-cyclopentenone (**407**) in 63% yield in the presence of one equivalent of acetic acid. Formation of the acetoxycyclopentadiene **406** as a precursor of **407** was confirmed by trapping with *N*-phenylmaleimide. A palladium–carbene complex is assumed to be the intermediate of this reaction, too.[79]



405 **406** **407**

8. Summary and Outlook

New synthetic approaches to allene derivatives have been uncovered by the palladium-catalyzed reactions of propargylic compounds. Since propargylic esters are readily available by the reaction of terminal alkynes with carbonyl compounds and subsequent esterification, applications of propargylic esters can be important in organic synthesis. A number of compounds containing interesting functional groups, which are difficult to synthesize by other means, can be prepared easily by the palladium-catalyzed reactions of propargylic compounds. Applications of the palladium-catalyzed reactions surveyed in this review have hardly been tapped. The synthesis of novel complex molecules, in particular, based on these transformations is open for further study. Because most of the products of the palladium-catalyzed reactions, including allenes, are chiral, asymmetric synthesis with these interesting compounds should be possible. But so far no studies have been reported on successful catalytic enantioselective reactions of propargylic compounds. In addition, since preparation of optically active propargylic alcohols is rather easy, chirality transfer in their palladium-catalyzed reactions is another interesting problem to be studied. Progress in this area would lead to interesting optically active compounds.

Research on the palladium-catalyzed reactions of propargylic carbonates has been carried out at both the Tokyo Institute of Technology and the Okayama University of Science. We thank our many collaborators in these two laboratories who are cited in the references.

Computer-Assisted Planning of Organic Syntheses: The Second Generation of Programs**

Wolf-Dietrich Ihlenfeldt and Johann Gasteiger*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

The planning of syntheses in organic chemistry has continuously been given more solid foundations during the last decades. Widely applicable rules have been formulated. Nearly parallel with the systematization of this field the potential for the automation of synthesis planning by the use of computers has been promulgated. However, after more than two decades of continuing efforts by a number of groups, computer-assisted synthesis planning, which relies on large libraries of synthons and transforms, has failed to establish itself firmly. This is in marked contrast to the acceptance of reaction databases. Their use has become routine within a surprisingly short time. Apparently the classical approaches to computer-assisted synthesis planning do not satisfy the needs of the preparative chemist. However, this lack of success does not yet mean the complete demise of the whole field. The conceptual shortcomings and problems of the first generation of programs are both of technical and psychological nature and need to be critically analyzed. Meanwhile, work has begun on systems of the second generation, which try to support the chemist in the synthesis laboratory with new methods in novel ways. Care is taken to mimic and support the typical planning style of the human chemist, who often on the spur of the moment switches direction in planning as well as his (sub) goals and methods. New tools that correspond better to the thinking patterns and working habits of chemists empower the user to plan syntheses of organic molecules in an interactive and innovative fashion. We feel that this field is far from dead and continue our research activities. In this article we introduce a system with a number of novel concepts and demonstrate its capabilities with some practical examples.

Keywords: computer chemistry · synthesis planning · WODCA

1. The First Generation

Amongst the most important progress in the concepts of organic chemistry during the last three decades is the systematization and categorization of organic synthesis. No chemists today finish their university education without learning the step-by-step planning of simple model syntheses with the aid of Corey's synthon concepts.[1–4] The clear and logical structure of this concept and alternative models has been a challenge for chemists and computer scientists since their development. The aim of computer-assisted design has been the implementation of these principles with computer programs to make the computer a tool in synthesis planning.[5] At the same time the laudable fact that about all relevant literature in chemistry has been abstracted in computer-readable form has motivated researchers to make this enormous treasure of experimental knowledge and experience searchable and retrievable. The ultimate goal here is to replace the traditional walk to the library in order to look for information on the feasibility of a planned reaction or synthesis step with more effective means of information retrieval, directly from the laboratory workplace.

1.1. Computer-Assisted Synthesis Planning

During the last decades two main classes of programs for organic synthesis-planning support in the broadest sense have emerged: One group comprises synthesis-planning systems based on the synthon and transform principles (or related concepts) or formal reaction generation. The second group are reaction databases, which make a large number of reactions that have already been performed in the laboratory searchable and retrievable. They inform the synthetic chemist about solutions of problems from related tasks. A third, smaller but nevertheless important class of programs predict reactions. They model chemical reactions and provide information about products and reaction conditions by interpolating within or extrapolating

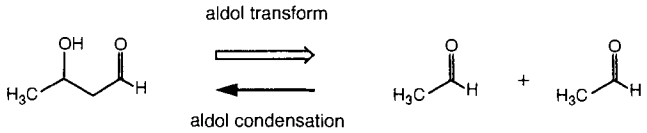
beyond a training set of known reactions. Quantum chemical computations become increasingly important for the prediction and optimization of compound properties. In the field of reaction prediction, however, they have, almost without exception, not yet been very successful for practical systems. In the following two sections we try to give a short historical overview of the history of the classical systems.

1.2. Programs for Synthesis Planning and Reaction Prediction

The development of synthesis-planning and reaction-prediction programs is closely related to progress in both reaction systematization and the mind-boggling advances in computers and peripherals. Readers of historical papers tend to be utterly surprised at how limited the core memory was and how primitive I/O devices were with which the pioneers somehow managed, and at what ingenious tricks they used to code chemical structures in this environment. The total number of programs that are in some way related to synthesis planning is estimated to exceed 50.[5] The number of systems that handle the planning of organic syntheses in a more comprehensive manner is smaller. We estimate it to be around 10.

1.2.1. The Synthon Principle

Today the synthon principle is regarded as obvious and natural. But its introduction was a major, nearly iconoclastic change of paradigm. Syntheses were no longer viewed from the aspect of potential name reactions and single steps, but as the global transformation of the skeleton and the pattern of charges and polarities, decoupled from the nature of the substituent that is the origin of the charge pattern. A central point of such an analysis is consideration of reactions used in synthesis from the opposite direction (retrosynthetically). These reverse (retro) reactions are typically called transforms. Scheme 1 shows this idea for the aldol reaction.



Scheme 1. The retrosynthetic point of view: the aldol condensation and the corresponding retrosynthetic transform.

A synthesis planned according to the textbook follows two steps:

a) The strategic bonds are defined and b) the specific transformations that connect or disconnect the strategic bonds in the desired fashion are formulated. A broken strategic bond yields (typically charged) fragments called *synthons*. They are converted by the addition or removal of atoms, ions, or chemical groups into specific molecules. These are precursors or starting materials (Scheme 2).

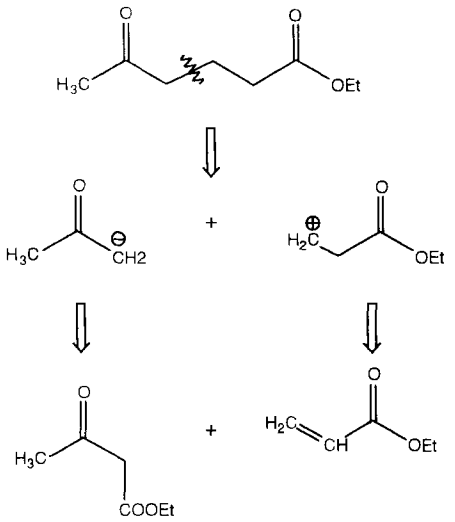
In the simplest case the reactions required are known from the literature. Other possibilities are generalizations from success-

J. Gasteiger

W.-D. Ihlenfeldt

Johann Gasteiger was born in Dachau, Germany, in 1941. After studying chemistry at the universities in Munich and Zürich, he obtained his doctorate under the supervision of Prof. Rolf Huisgen in 1971. He spent one year as postdoctoral fellow with Prof. A. Streitwieser, Jr., at the University of California in Berkeley, after which he accepted a post at the Technische Universität (TU) München and completed his habilitation there in 1979. In recognition of his contributions to computer chemistry he was awarded the 1991 Gmelin-Beilstein Medal of the GDCh. In 1994 he accepted a position as professor of Organic Chemistry at the Universität Erlangen–Nürnberg. Together with Prof. Dr. P. von Ragué Schleyer and Priv.-Doz.T. Clark he founded the Computer-Chemie-Centrum der Universität Erlangen–Nürnberg. His main research topics are the development of computer programs for synthesis planning, reaction prediction, and reactivity prediction, for the analysis and simulation of mass and infrared spectra, and for the discovery of lead structures with biological properties. The extraction of information from chemical databanks and the application of neural networks and genetic algorithms for chemical problems are further fields of interest.

Wolf-Dietrich Ihlenfeldt was born in Hamburg in 1963. He studied Chemistry in Hamburg, Heidelberg, and at the TU München, completing his doctorate with Professor Gasteiger on synthesis planning in 1991. He then worked as postdoctoral fellow at the Toyohashi University of Technology (Japan) until October 1994 on novel network-supported chemical information systems. At present he is working under commission of the Fachinformationszentrum Chemie, Berlin, on the evaluation of innovative information distribution and generation models in Chemistry. The focus of his interests is the linking of global computer networks and the dynamic, open techniques for data representation and manipulation with information data and processing specific to Chemistry, a field at the interface of Chemistry and Computer Science.



Scheme 2. Dissection of a target compound at a strategic bond yielding the (charged) synthons, followed by transformation to specific reagents.

fully applied reactions for molecules with a similar substituent pattern or even from purely formal, unprecedented bond rearrangements. This multilevel process provides some promising starting points for the development of algorithms. The simplest approach is the systematic application of reactions, described more abstractly as synthon schemes. However, because the number and variation of known reactions is enormous, some control and screening is mandatory. The selection of strategic bonds and the rating of a carefully selected subset of reactions is qualitatively much more difficult than simple, systematic structure transformation. The consecutive and parallel application of this approach results in an ever broadening scheme of steps and sequences of retroreactions. This plot is called the *synthesis tree* (Fig. 1).

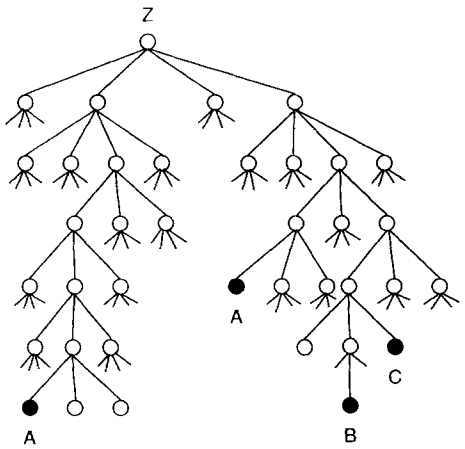


Fig. 1. A synthesis tree displayed as a sequence of retroreactions, which were obtained by systematic retrosynthetic analysis. A, B, and C are available starting materials; Z is the target molecule.

A synthesis tree easily becomes very large. Even if for each intermediate only ten alternative retroreactions are considered the tree already contains $10^3 = 1000$ reactions and precursors in the third level and after five levels more than $10^5 = 100000$ entries. All these entries have to be evaluated and compared, an immensely laborious task though a five-step synthesis is not lengthy. This example shows the problems inherent in a systematic retrosynthetic approach. An extremely careful evaluation of merit and a rigorous and early rejection of possible, but not very promising reaction sequences is mandatory. However, the price of not discovering potentially interesting syntheses has often to be paid if cuts in the synthesis tree are made too early or too deep.

1.2.2. Coding of Reactions

The classical programs for synthesis planning and reaction prediction[5] use comparatively few, simple models for the internal representation of their database. A core element is the description of the reaction center and the changes it undergoes during a reaction. This description consists of either a complete reaction including a full set of bond reordering instructions, or a set of half reactions (that is, a formal dissociation step followed by a separate recombination step), or a series of microsteps that describe single bond cuts and bond formations. Some programs store additional information such as details about interfering substituents, general considerations like an estimation of usability and synthetic merit of a reaction, or even physicochemical models of the reactivity of the bonds contained in the reaction center.

An important point is that only an isolated part of the data described in the literature is stored. The knowledge base of the classical synthesis-planning programs does not contain complete and detailed descriptions of single reactions with the relevant background information, but rather the distilled essence of many sources and practical experience. This raw information is concentrated and leads to either estimated or statistically validated parameters, depending on the specific philosophy of a system. In the more modern systems the knowledge base is kept outside the core system and can be edited and expanded; it therefore acquires some characteristics of a database. In contrast to reaction databases the raw information has been heavily processed. Every scheme, every reaction model is equivalent to the condensed essence of a normally large number of reactions taken from literature, while a plain reaction database contains isolated citations. The process of data compression and model building has not yet been reliably automated.

1.2.3. Representative Systems

LHASA,[6] the successor of OCSS[7] is generally considered to be the first synthon-based system. Its development still continues. Another important disconnection system is SECS[8] and its derivative CASP, which has been developed by a group of German and Swiss chemical companies. Some other representative examples are SYNCHEM,[9] SYNGEN,[10] SCANCHEM,[11] COMPASS,[12] SYNSUP-MB,[13] AIPHOS,[14] LILITH,[15] TRESOR,[16] and SYNTHON.[17] These classic systems either rely on a database of completely defined reactions including classical name reactions and, due to continuous literature survey, also a large number of exotic reactions, or they are based on more generally formulated synthon schemes or half-reactions.

The merit evaluation of a reaction in these programs is based on the analysis of the character of the substituents in and around

the reaction center, a scan for interfering functionality at other sites, and some general rules about usefulness. Every reaction or synthon scheme is coded manually (SYNCHEM and AIPHOS contain mechanisms for unsupervised learning from reaction databases, and for SECS add-ons are available for the same purpose[18]) and augmented with estimated parameters for the merit evaluation functions. Additional modules may allow a tighter control of the course of the program, for example, by the detection of strategic bonds by general, reaction-independent heuristics, the intentional, preferential application of reactions with large synthetic potential,[6c] or the use of global strategic concepts.[19]

A more formal approach was taken in the EROS system.[20] Reactions are coded in a way reminiscent of the mechanistic electron shifts with the curved arrows a chemist writes on paper to explain the mechanism of a reaction. With very few such shift patterns a large part of the stock of organic reactions can be covered. The central problem was then the development of methods that could decide which shift patterns to select and to which bonds in a given molecule they should be applied.

The selection of bonds to break and make during a reaction is based on quantitative estimations of electronic and energy effects on the atoms and bonds of the molecule.[20c] After performing a reaction a final merit evaluation takes place. Factors such as reaction enthalpy,[21] charge distribution,[22] inductive[23] and resonance effect,[22] as well as polarizability[24] are used. The direction of the reaction design (forward for reaction prediction, backward for synthesis planning) decides how these factors are combined to a final merit value.

Because of the strong emphasis on physicochemical rating of reactions, the further development of EROS quite naturally focused on reaction prediction. Continuous refinement of the merit evaluation procedures led to a point where it seemed no longer reasonable to treat both reaction prediction and synthesis planning in a single program system. Accordingly, these two problems are now handled by separate systems: EROS has been completely redesigned, and its use from version 6.0 onwards is essentially limited to reaction prediction.[25a] The merit evaluation functions for the different types of chemical reactions are kept separate from the core program in rule data files and can be easily modified and refined.[25b] The reaction models derived with these rules arise from careful statistical analyses[25b] or are represented by neural networks.[26] The generation of validation or reaction models for EROS 6 is demanding, but the models obtained are often very precise.[27]

For synthesis planning a radically different approach was adopted: The WODCA (*W*orkbench for the *O*rganization of *D*ata for *C*hemical *A*pplications) system combines a multitude of methods and tools that can be applied to the various problems of synthesis planning. This will be explained in detail in the following chapters.

A different approach for reaction prediction is taken by the CAMEO program.[28] Hundreds of estimated reactivity parameters cover a wide scope of reactions without relying on predefined bond rearrangement schemes. The reaction conditions and acceptable reaction classes are, however, selected by the user. The CAMEO parameters are more easily obtained than those in the EROS system (sometimes they are just estimated) but often lack fundamental statistical validation. This diminishes the reliability. Nevertheless, this system generates mostly correct predictions about major and minor products under the specified reaction conditions (but not about product ratios or kinetics) under a wide range of conditions. Classical organic chemistry is covered nearly completely, much more completely than, for example, in the EROS system, which has reaction models only for a few selected reaction classes at present.

A strong formal treatment of reactions is the basis of the Dugundji–Ugi matrix model of constitutional chemistry.[29] Building on this concept, a scheme for reaction classification was developed, which was implemented in a program designed for formal reaction generation called IGOR.[30] This program can generate a complete set of atom and bond mappings for a specific reaction scheme. A complementary program, RAIN, creates isomeric ensembles from a given molecular ensemble and can be used for the generation of structures and reactions.[31] In another operation mode, it formulates a network of reactions that connects two molecular ensembles.[31]

Both IGOR and RAIN rely exclusively on formal criteria such as allowed valence levels and number or structural characteristics of the intermediates specified by the user in their selection of structures and reaction. The advantage is that all conceivable structures and reactions are obtained, including unprecedented ones. Still, the task of selecting the reactions that can actually be carried out is left to the user, because no merit evaluation, for example, by physicochemical characteristics of structures and reactions or by comparison with known reactions or reaction types, is undertaken.[29]

Finally, one important program has characteristics difficult to assign to the program types introduced so far. CHIRON[32] is basically a system for the retrieval and analysis of molecular structures in which structures are mapped onto each other to detect common structural fragments, especially with respect to stereochemical relationships. CHIRON is no synthesis-planning or reaction-prediction system per se, and it does not implement many traditional database retrieval operations, but it is definitely useful for the discovery of starting materials with a stereochemical configuration appropriate for the target. A particular strength of CHIRON is its large, manualy compiled catalog with about 2000 compounds with well-defined stereochemical features. It does not only contain commercially available compounds, but also many from the literature, which can be synthesized in few steps from easily secured starting materials. This unique catalog can also be used by our new WODCA system as will be explained later.

1.3. Reaction Databases

Within this decade the number of accessible reaction databases has increased enormously.[33–38] While there seems to be no aggressively marketed synthesis-planning program outside the educational sector, numerous reaction-retrieval systems and reaction databases have been on offer for quite a while.

1.3.1. Principles and Availability

It was already mentioned that the information content of reaction databases is much more elementary than that of transform libraries. At the same time the raw information content is

much larger. Entries in a reaction database typically include complete literature citations with information on reaction conditions, yields, and references to the reactions of previous and subsequent steps in longer syntheses. If a clear connection between a planned reaction and a literature precedent can be established, the difficulties of the actual synthesis can be estimated rather easily. It must, however, be noted that the detection of such a connection is not always trivial. The focus of interest typically is the reaction center, that is, the atoms and bonds directly involved in the bond-rearrangement process. The presence or absence of potentially disturbing chemical groups can be established by simple substructure search. However, the automatic or manual identification of the reaction center is not unequivocally possible in every case. The bond-rearrangement process with the smallest number of discrete steps is not always the one occurring in reality. This is still an active research area, and progress is steady. Most of these systems have another criticized weakness: negative (that is, failed) reaction entries are missing.

Searches in reaction databases have become routine in many laboratories. Reaction databases are helpful only if the searcher has a rough idea of the kind of reaction required. Whereas the classical reaction-prediction and synthesis-planning programs can, at least in principle, employ their knowledge base systematically and exhaustively, the user of a reaction database must already have devised the general framework of the synthesis.

1.3.2. Reaction Database Application

The extent to which reactions are systematically abstracted from literature has increased enormously. Since the introduction of CASREACT,[34] ChemInform RX,[35] and ChemReact, a broad field is exhaustively covered and continuously updated. Classical, molecule-oriented databases such as Beilstein provide search facilities that indirectly lead to results comparable to the direct search in reaction-oriented databases.[39] Important data sets of basic reactions such as the catalogs of Theilheimer, CRDS (Chemical Reactions Documentation Service), JSM (Journal of Synthetic Methods), and from the *Organic Synthesis* book series are now also available.[40]

As far as companies with a large number of proprietary reaction data are concerned, reaction databases provide many advantages over the maintenance of transform systems. The most important benefit is that the systems operate exclusively with "hard", uninterpreted data, which can be input without any technical problems or even directly transferred from an electronic laboratory journal. In such a database every entered reaction is valuable, but for a transform or synthon record a single instance of a reaction is not sufficient. The generally accepted standpoint is that transforms that were compiled from too few instances of reactions or from too narrow an application are damaging, not beneficial, because they yield too many overrated results stemming from extrapolation beyond the area covered by the example data. Even if a carefully crafted new entry is important and beneficial in principle, it is difficult to balance the merit functions of the new entry against those of the old, especially if the team in charge comprises several chemists with divergent background and experience.

The automated extraction of transform libraries from reaction data is not yet well advanced. One of the main problems is the grouping of exemplary reactions into classes that form the basis for meaningful generalizations of reactions.[18,41] When these methods are sufficiently advanced and reliable to be able to work autonomously on large reaction databases, they should be able to automatically derive knowledge for reaction prediction and synthesis planning, which might foster the importance of reaction prediction, or maybe even the synthon/transform concept within synthesis-planning systems. In this context once again the very same problem as before arises: reactions which do *not* run as expected (negative examples) are hardly documented, either in literature or in reaction databases. The difficulties that had to be overcome before the reaction proceeded smoothly with an acceptable yield are also often lacking. This information would, however, be of prime importance to fence the area of applicability of a reaction or transform and evaluate its general usefulness. This problem also occurs during a simple reaction database query but is somewhat ameliorated by the auxiliary information attached to the retrieved entries.

The automatic classification of the contents of reaction databases or larger sets of hits from the queries on such databases will become mandatory in the long run anyway. Parallel to the increase of the number of database entries—some databases already contain more than a million reactions (for instance, CASREACT)[34]—the hit-lists grow longer. The number of answers a human chemist is willing to page through is limited. Here a hierarchical reaction classification (an additional step of computerized processing) must be inserted in order to sort the hits into a classified graph showing the hidden relationships between the reaction instances. Such a highly structured access to the voluminous factual material assists the user to perceive the gist of the database query results. Work has begun on these topics.[41]

1.4. The End of the Road for First Generation Programs

Computer-assisted synthesis planning has been met with utter scepticism, even hostility, from the majority of chemists. Now, after 25 years of development in this field by several teams of researchers not a single system has become widely accepted as a routine tool, and the generally very critical attitude toward this kind of system has been corroborated. Even those scientists who initially greeted computer-assisted synthesis planning with enthusiasm have lost their illusions. One of the major disappointments was certainly the suspension of development of the CASP system. Among all the transform-based systems CASP by far owns the largest collection of reaction types. The lack of truly convincing results gained from this monumental knowledge base, combined with the general lack of acceptance from synthetic chemists defines an endpoint in the evolution of this kind of system. This does not mean that CASP is not used anymore, but the extension of the transform database within the program framework has been recognized as too burdensome and no longer promising. The conceptual limits of this system have been reached. Attempts to generate transforms for this program automatically from reaction databases have also failed. The last large-scale project supported by a consortium of chemical com-

panies with plenty of financial funding is the Japanese AIPHOS system.[14] In the end this system also applies synthons and transforms on strategic bonds, so ultimately the same kind of problems are to be expected if innovative concepts are not integrated. Though new lines of research are being followed at the conceptual and early implementation level,[42] it is too early to comment on the possible impact of those approaches.

2. New Approaches

The success or demise of a program system is determined by the end-users, not the developers. The user statistics of the CAOS/CAMM Center[43] (Table 1) is a good reflection of the situation today, if users have complete freedom of choice among a multitude of system. The dominance of reaction databases becomes obvious from these figures alone. Furthermore, according to the author of the survey, the majority of the activations of the synthesis-planning systems are motivated by curiosity, because a significant, but not exactly known number of activations are explorations by first-time users, who do not come back again and should therefore be subtracted from the true user count. The statistics for ORAC include structure searches in the Fine Chemicals Directory (FCD), a comprehensive listing of commercially available chemicals. The majority of the CAMEO activations are thought to be pK_a evaluations, not reaction predictions. At least in tendency these numbers support the thesis that the average chemist-user does not know how to benefit from the current generation of synthesis-planning systems.

Table 1. User statistics of the CAOS/CAMM Center (January 1993–May 1993).

Program	N [a]	Program	N [a]
LHASA	ca. 25	ORAC	877
CAMEO	7	REACCS	103
CHIRON	12	SYNLIB	123
SYNGEN	8		

[a] N = number of activations.

2.1. Conceptual Problems of the Classical Systems

The numbers in Table 1 make clear that the currently available program systems are either grossly immature or are off-target, missing the needs of the synthetic chemists. The methods utilized by practicing chemists for synthesis-planning tasks vary, of course, with personal style and experience, but general trends can be formulated.

Chemists don't follow a rigid scheme when they plan syntheses. They consider individual reactions or even synthons often only at the very last stage. At the beginning of the development of a strategy larger structural fragments that might serve as building blocks for the target molecule are sought. This approach is augmented by the examination of functionality in the target structure and its distribution on the skeleton. These functionality patterns are not necessarily immediately categorized according to the synthon principle, because the arsenal of umpolung methods is now so extensive that a wrong polarity at some positions is no longer an insurmountable obstacle. Furthermore, very early in the planning procedure long-range relationships to potential starting materials and other, structurally related compounds are recognized. Only after a crude structural classification of possible intermediates and starting materials has been established are the remaining gaps filled with specific reactions or synthon schemes. During this final bridging and gap-filling procedure the precise structures of the intermediates and starting materials crystallize step by step and under continuous interplay with the modifications of the global plan. This is neither a classical bottom-up nor a top-down search, nor a simple bidirectional search, but rather a complex network consisting of the target molecule, possible starting materials, shadowy intermediates perceived as potentially useful by the chemist, and knowledge about usable reactions and available reagents. The search for synthetic pathways does not proceed in ordered small steps from one compound to the next, but rather in a random mixture of small and large jumps in both synthetic and retrosynthetic directions during which the structure of the linking intermediates and starting materials change continuously. This approach is demonstrated in Fig. 2 with the example of three published syntheses of the anti-malaria drug qinghaosu (**1**).[45a]

The first essential step during the development of a synthesis for **1** was the idea of constructing the unusual 1,2,4-trioxane

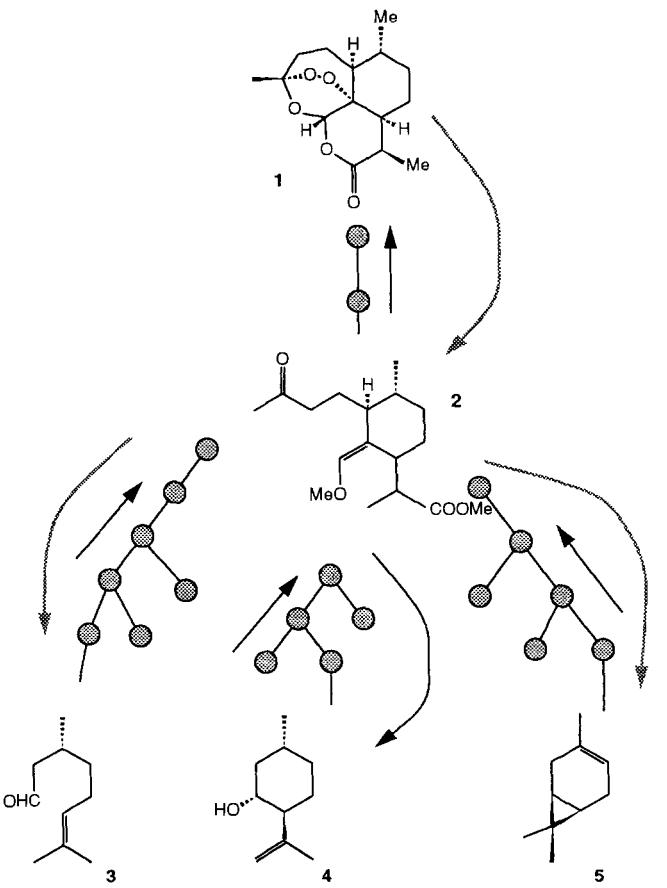

Fig. 2. Synthesis planning in reality: an array of different methods for search and planning, applied both in retrosynthetic and synthetic direction, is utilized in order to avoid tracking the entire synthesis tree. For details, see text.

ring by a photooxidation of the precursor **2**. The transformation of **2** to **1** could be accomplished with only two steps.[45b] After **2** was defined as a central intermediate and forward planning from **2** to target **1** revealed a promising route, the synthesis of **2** had to be designed. Three competing research groups looked for readily available starting materials that already contained important structural features of precursor **2**. *R*-(+)-citronellol (**3**),[45b] (−)-isopulegol (**4**),[45c] and (+)-car-3-ene (**5**)[45d] were somehow selected by the three groups. The three cited syntheses were developed in forward direction from the starting materials, always focusing on the agreed upon intermediate **2**. The combination of a retroanalysis to a central precursor, the development of a method to convert this precursor into the target, the detection of structural similarity between the precursor and readily obtainable starting materials, and the sometimes tedious pathfinding from the starting material to the central precursor was finally met with success in all three groups. None of them planned their synthesis by systematic, stepwise retrosynthetic analysis.

Another problem that is difficult to treat with the classical approaches to computer-assisted synthesis planning is the lack of a rigidly defined target structure. Especially in the pharmaceutical sector the target structure is sometimes defined as a hypothetical pharmacophore, and the precise structural definition of the synthesis target is the solution of an optimization problem tightly coupled to the synthesis-planning process. External parameters such as charge distribution and shape characteristics need to be included in the evolution of a lead structure to a specific synthesis target. The target becomes fuzzy, and an efficient synthesis yielding a compound that is functionally equivalent to a model structure, but only similar and not structurally identical to it, becomes an acceptable problem solution. This kind of problem is very difficult to treat with classical transform-based methods, because a specific target structure for systematic dissection is required.

During the fill-up step between the landmarks of a synthesis, reaction databases can be extremely useful. Full structure or substructure searches in catalogs of chemicals are very well suited to detecting specific starting materials. These mature technologies have been readily accepted by synthetic chemists. In comparison, classical synthesis-planning programs are far less useful. Systematic searches typically generate enormous synthesis trees with single-step reactions and precursors, which are extremely unwieldy and predominantly contain dead ends that an experienced chemist would have intuitively avoided. If the search is limited to short sequences, useful, but often obvious reactions are the result. Still, because of the nature of the underlying transform and synthon schemes, there is no guarantee that a precedence under comparable conditions exists. This needs to be checked by consulting a reaction database or the literature, and since the reaction sequence is short, this kind of verification can be performed directly without the aid of a synthesis-planning program. Furthermore, the nodes in the synthesis tree are completely defined compounds that are linked by completely defined reactions. Small variations in a target or subtarget require renewed program runs, or, if this variation was already generated in the original run, gives rise to an independent subtree and participates in inflating the synthesis tree to its intractable size.

2.2. New Methodology To Support Synthetic Chemists

The detection of long-range relationships and similarities between the target compound, commercially available starting materials, and potential precursors is one of the central issues of practical planning. The present systems fail to support the chemist in this essential task. A system that reveals potentially synthetically exploitable similarity between the target compound and the stock of commercially marketed compounds, which is too large for the human chemist to overview, will certainly be very helpful for synthesis design. The emphasis on *synthetically exploitable* similarity is intentional. This requirement is not very well covered by traditional similarity detection algorithms.[46]

The methods for the computation of a minimal chemical distance,[47] that is, the minimal set of bond rearrangements, subject to boundary conditions, between two molecules are valuable for the recognition of potential complex sequences of bond rearrangements. Because of the computational demands, these methods cannot yet be used for the systematic comparison of a target compound with thousands of potential starting materials. The current implementations are exclusively based on topological criteria, that is, reactivity criteria are not taken into account, and accordingly the chances for a practical implementation of a bond-rearrangement scheme is not assessed. The potential of these methods lies particularly in the recognition of rearrangement paths, and they will certainly become a tool for special cases but probably no remedy for all the various problems of recognizing similarity.

If no direct link between a target compound and a starting material can be found, mechanisms for the systematization of a synthesis study beyond the synthesis tree are needed. Manual or computer-assisted breakdown of a target compound at bonds recognized as strategic leads to central intermediates, which can be subjected to further search and planning operations such as similarity search, reaction planning, reaction prediction, and additional decomposition steps. The elements registered in such a study are no longer simple molecules but fragmentation groups, hit-lists from database queries, or reaction-prediction results. The chemist is given a set of tools that supports him in his quest and protocols the steps taken. He must be free to use any tool of his choice at any point he deems promising, so that he can switch freely between synthetic and retrosynthetic analysis. Human reasoning is superior to any synthesis-planning program if large uninteresting regions need to be excluded from a study. It does not mean that the big advantage of unbiased computation is lost. Paths not found because the chemist could not or would not perform a specific search exhaustively, should still be unlockable. If a chemist encounters troublesome areas in a study, or if some region of a study is not obvious or not resolved satisfactorily, the user can still instruct the computer to examine this problem systematically, as deeply as he chooses. The common opinion among users and experts is that the systematic application of thousands of transforms on multiple levels, which is the basic functionality of the classical systems, yields so much uninteresting data that a search for the golden needle in the haystack is not reasonable for the average user.

2.3. Structural Similarity

One of the most urgently needed methods is the detection of *synthetically exploitable similarity*. This term that has not yet been unequivocally defined. Similarity search procedures are applied with success in biological activity studies or QSAR (*Q*uantitative *S*tructure–*A*ctivity *R*elationships) models.[46] However, the similarity criteria in this kind of application are not necessarily compatible with the requirements of synthesis planning. A popular method, for example, is the counting of chemical groups and atoms in the molecules of the data set.[48] The counts of the structural elements are tied to a similarity rating, which often correlates well with physiological activity. The problem with this kind of similarity measure is the lack of sensitivity toward changes in the core skeleton and the overrating of changes in the reactive heteroatom centers. For physiological activity, often the addition or removal of a methyl group is quite irrelevant, but it can be a decisive factor for usability in a synthesis if the target is fixed, or this group influences a reaction center through reactivity or spatial effects. On the other hand the specific nature of a reactive heteroatom center is uninteresting for an intermediate in a synthesis as long as reactivity and propensity for selective attack are still maintained, and the reaction conditions can be adapted to these changes. The synthetic potential of a compound is dependent on many factors that are interrelated in complex ways specific to synthesis planning.

This rule generally applies to most similarity criteria from QSAR, and the extensive set of criteria from this field can be utilized for synthesis planning only in a very limited way. The classic substructure search methods from database applications are too inflexible. Queries become rather nonselective and inefficient if a carbon skeleton is input with the specification that all open valencies are hydrogen or any heteroatom. In addition, such search methods do not consider reactivity, for example, the influence of the environment on the reactivity of hydrogen atoms.

SST[49] is a pioneering system providing in a very elementary approach a relationship between a target compound and a catalog of starting materials. SST is not a synthesis-planning system but simply offers as query methods three degrees of abstraction for the substituents in the core carbon skeleton, which are searched on the database whose entries have been pretransformed with the same abstracting process. In our group we have developed a number of similarity definitions and methods that are specifically aimed at detection of structural similarities for synthetic problems.[50a–c] Some of these are based on extended common substructures such as ring systems and core carbon skeletons in the molecules to be compared. The majority of these methods though, rely on criteria that have been derived directly from generalized chemical reactions. It has been observed that these are the most powerful methods for synthesis-planning problems. Algorithms for these novel similarity criteria have been integrated into the WODCA system. This will be discussed in detail in the following sections of this paper.

3. The WODCA System

During the last six years the WODCA system has been developed in our group.[50] WODCA is an interactive, graphics-oriented support system for chemists working on synthetic problems. WODCA fulfills the requirements for a new generation of synthesis-planning programs outlined in the previous sections and implements novel ideas and algorithms for such systems. It serves as a test bed for the fundamental ideas and methods. As the name already intimates, the system is not only a synthesis-planning program but fulfills other purposes within our group. This paper will only describe the synthesis-planning aspects.

Among the highlights of the system are the implementation of novel similarity criteria for database queries, the use of a flexible system for the organization of studies, and the dynamic integration of modules that perform intelligent operations on and with molecules (for example, merit evaluations and the detection of strategic bonds). The application of a classical synthon- or transform-oriented knowledge base has been consistently avoided. A number of external programs can be used from within WODCA: the programs of the EROS series[20] for reaction prediction and reactivity estimation, PETRA for the computation of physicochemical properties of molecular structures,[21–24] and a number of auxiliary help and visualization applications such as structure and reaction displays, plan overviews, and a report generator. Classical database search methods such as full structure and substructure queries and some published similarity algorithms are an integral part of the system. Linking WODCA to reaction databases is one of the next goals and currently under way.

WODCA is an interactive system with strong graphics support. Figure 3 shows a typical example for the information transmitted graphically during a WODCA session. Modern window systems (here on a Sun workstation under SunView; ports to X11 and MS Windows are in progress) allow the concurrent display of the results of many analysis and search methods. This approach intentionally and specifically supports the lateral thinking of chemists who jump back and forth between different threads of thought and problem areas. In Figure 3 the results of a strategic bond determination, a query for starting materials suitable for the synthesis of the fragments obtained by cutting the bond, and the full catalog data and ordering information for one of the possible starting materials are simultaneously displayed.

This pictures also demonstrates how a user actively participates in a synthesis-planning study. He freely selects instruments from WODCA's toolbox, gets new ideas by scanning the results of the chosen search and retrieval methods, and quickly drives the study to ward those results that are most useful.

The collection of methods in WODCA are meant to supply the chemist with immediate answers to "what would happen if" questions in a continuous interactive exchange between the creativity of the experienced chemist and the speed, precision, and thoroughness of the computer. Speed of execution was an important design goal. Normally, a preliminary answer computed by a workstation should be available within seconds, and the user can always interrupt processing after only the first few answers of the full scan. The chemist is in charge of selecting the methods best suited to the task at hand. WODCA refrains from forcing the user to adhere to rigid rules concerning sequence and thoroughness of scans and operations, but rather relies on the experience and intelligence of the chemist. If the system

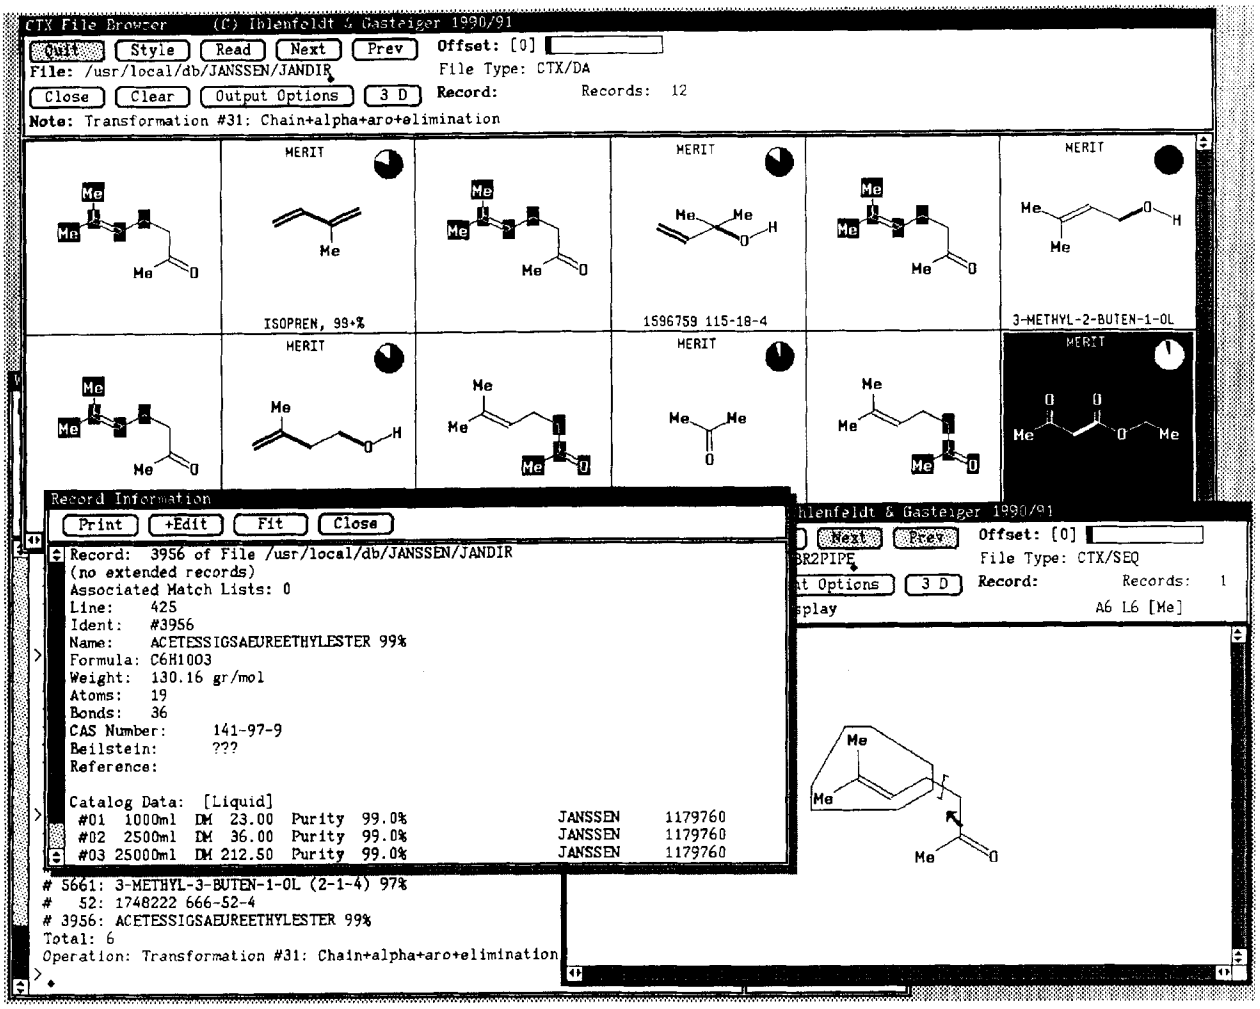

Fig. 3. Graphical user interface of WODCA: The window on the lower right-hand displays the target molecule. The strategic bond currently being worked on is marked. One of the fragments obtained from breaking this bond has been highlighted by a frame. The upper region of the screen copy shows compounds from a starting material catalog that were recognized as being related to either one of the two fragments. Left of each of the possible starting materials, is the formula of the target on which the coincidence with the embedded fragment is highlighted by black boxes. The calculated degree of structural similarity is visualized as a pie diagram in the upper right corner. The similarity criterion selected by the user (in bottom left corner: transformation no. 31: core carbon skeleton + α-hetero atoms + preserved arenes + elimination) requires correspondence of the preserved carbon skeleton and the heteroatoms of the α sphere. Arene rings must not be changed, but structural differences that can be removed by generic elimination-type reactions are allowed. The user has selected one of the proposed compounds (dark background) in order to retrieve further information from the starting material library. This auxiliary data such as name, structural formula, molar mass, CAS registry number, and pricing information is listed in the uppermost floating window.

generates proposals with which the user disagrees, a different proposal can be entered manually or the system's answer can be edited before this data is passed to another module. Examples of this kind of editing operation are automatically detected strategic bonds, where the user sometimes has a broader perspective than the system. Strategic bonds can be deleted, added, or their attribute set changed with a mouse click.

The whole arsenal of methods can be applied to any suitable object within a study, and thus the study can be expanded in any direction starting at arbitrary points. The system comprehensively records not only the results of the operations but also the selected operations themselves. These data are stored in logfiles and can be viewed immediately. Every step becomes a plan element, and the relationships between these plan elements are shown graphically. Important classes of plan elements are structures, sets of strategic bonds, fragments, results from database queries (match-lists), and results from reaction prediction. Studies can be interrupted and resumed at any time.

3.1. Core Operations of the System

The general course of actions during the study of a synthesis problem with WODCA is displayed in Figure 4. In the current program configuration three core operations can be identified:

- search for starting materials
- search for synthesis precursors
- prediction of reactions

The difference between a synthesis precursor and a starting material in this context is that a starting material is a fully specified molecule found in a catalog of chemicals while a synthesis precursor is a vaguely defined, compound, hovering somewhere between starting material and target. The gaps between these three species are bridged step by step.

The most important task in synthesis planning is the establishment of a relationship between the target and suitable starting materials. Therefore, databases with commercially marketed compounds figure prominently within the WODCA system.

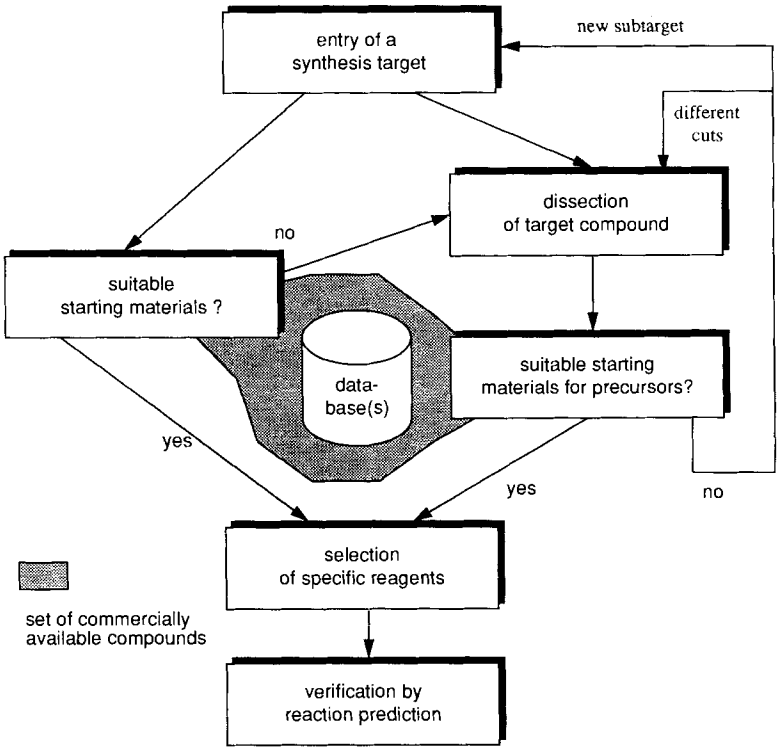

Fig. 4. Flowchart explaining the sequence of actions in a synthesis planning study with WODCA: an interplay of starting material search, determination of precursors, and verification by reaction prediction.

Many query methods (see Section 3.1.1 and Fig. 5) are provided for the retrieval of suitable starting materials for a synthesis (left-hand branch in Fig. 4). For more complex target compounds this will not be directly possible. The molecule therefore needs to be dissected into fragments at bonds perceived as strategic. These fragments are then submitted to the search for starting materials (right-hand branch of Fig. 4). The process of dissection and search for starting materials is repeated until all precursors can be linked to readily available starting materials. From the set of potential starting materials suitable reagents are selected, and with the aid of reaction prediction a verification step examines whether the reaction really proceeds in the intended direction (lower part of Fig. 4). Precursors and starting materials are entered into a planning tree, which coarsely resembles a synthesis tree but is far smaller than in a classical, retrosynthetic analysis. On the other hand, the information content and complexity (classification, history, relationships to other entries) is much higher.

3.1.1. Search for Starting Materials

One of the most important aspects of working with WODCA is the creation of relationships between a synthesis target or precursor and a starting material. A number of catalogs of chemicals are available in the system, including the lists of several manufacturers of fine chemicals, special hand-compiled catalogs, and the database of the CHIRON program.[32] Additional compound libraries can be added easily. All operations can function on any catalog, and the user is free to switch catalogs within a study.

WODCA provides classical retrieval methods such as full structure search (by a novel hashcoding procedure[51]), fragment-oriented similarity measures, and general-purpose database queries such as numerical and textual search on names and structure attributes. Additionally a number of methods were developed that focus on synthetically exploitable similarity. Two of the new methods are the following:

1. Transformation searches: A query structure is transformed by clearly defined principles, which correspond to generalized reaction types and emphasize certain structural elements. It is then compared to the similarly transformed molecules in the database. The new hashcoding algorithm[51] is applied here as well, and consequently, this type of search yields results extremely fast, typically in less than a seond.

2. Pathlength code searches: The substitution pattern and structure of the core skeleton of a pair of molecules are compared in a synthetically significant manner. Some applications are found in Sections 4.1 and 4.2. Figure 5 shows a general overview of the arsenal of methods in WODCA.

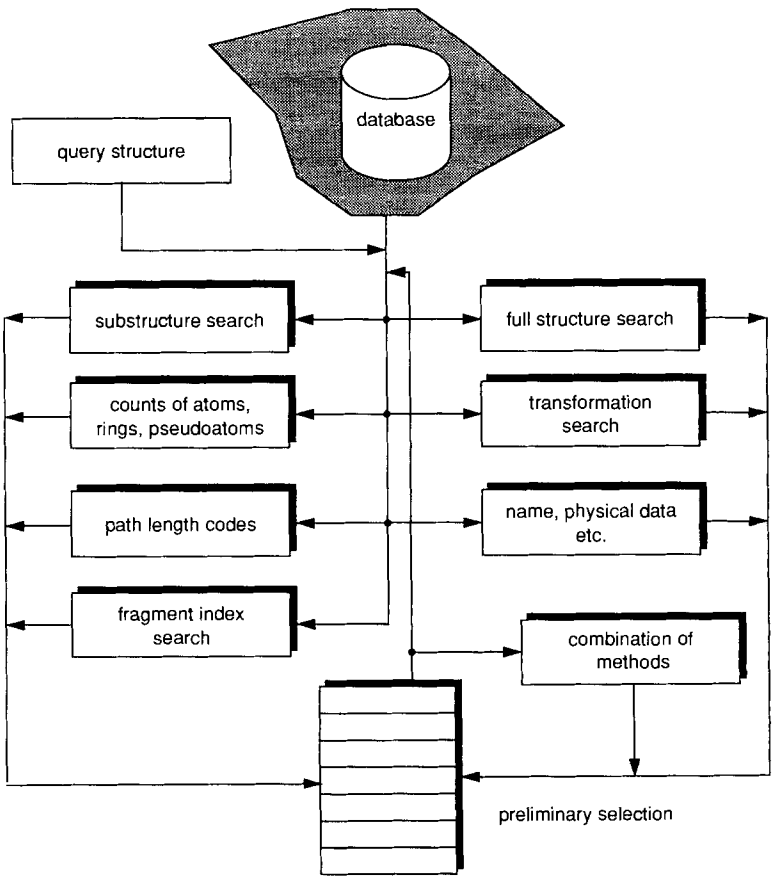

Fig. 5. Arsenal of available methods for preselection of starting materials.

Because transformation searches and pathlength code searches are extremely powerful in defining synthetically exploitable similarity, their use will be emphasized in this paper. A more detailed explanation of the transformation search principles, and examples that highlight their importance for synthesis planning have been published.[50a-c] Generally speaking, transformation searches can be classified into two groups: A class that detects similarity by important common substructures and another class that defines similarity of compounds by interconvertability through generalized reaction types such as substitution, hydrolysis, or oxidation. The boundaries between these two classes are sometimes not very sharp, because many transformations of the first class have been designed around core structure elements that remain constant during the course of reactions.

Figure 6 shows the result of a similarity search with 1,8-diazabicyclo[5.4.0]undec-7-ene (**12**) as query structure. This search

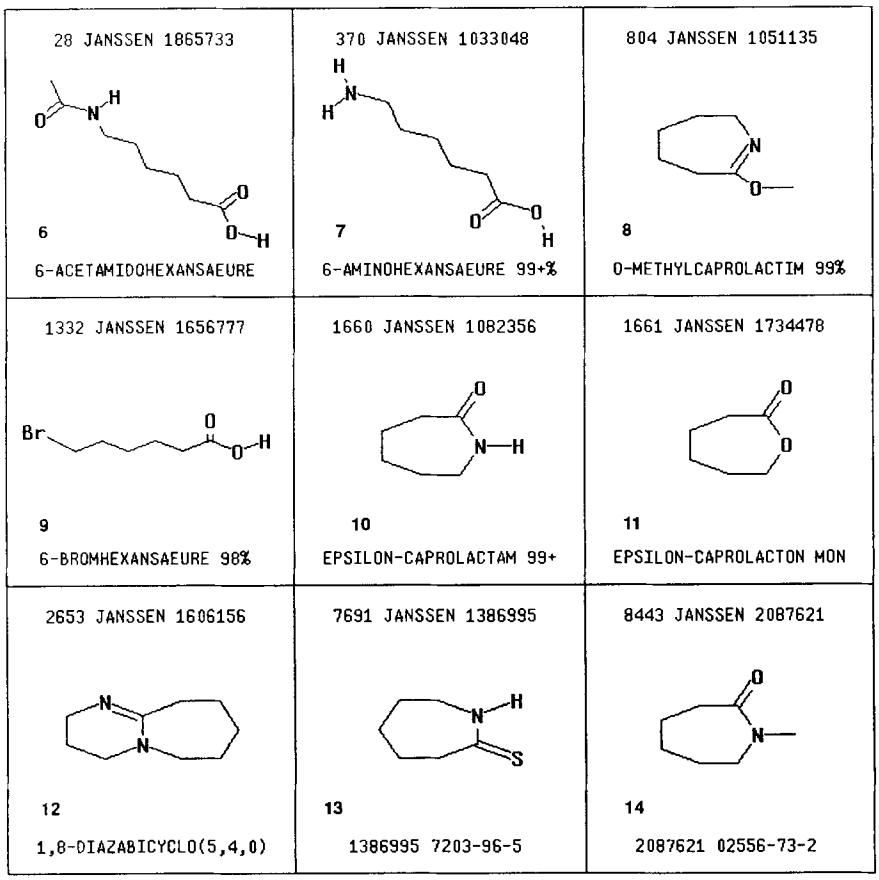

Fig. 6. Compounds similar to 1,8-diaza-bicyclo[5.4.0]undec-7-ene. They contain the same carbon skeleton and the same substitution pattern for heteroatoms.

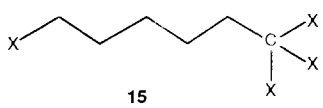
employed, as most examples in this paper, the 1988 catalog of Janssen Chimica (now Acros Organica Division), which contains 8465 compounds. Of these compounds 7849 are structurally different, that is, they are not variations in purity, quality, preparation method, or isotope labeling. Stereoisomers are different compounds by this definition.

For this example, a similarity criterion based on a common substructure was selected. Molecules are perceived as similar if they contain the same carbon skeleton with the same substitution pattern of heteroatoms. Basically, all listed compounds are reduced by this transformation to structure **15**. If, like query molecule **12**, a molecule is broken into two fragments during a transformation, the procedure continues with only the single molecule containing the largest number of carbon atoms. In the current implementation it is assumed that the largest fragment has the most interesting functionality. This simplification certainly fails in some instances but serves well as a rule of thumb in the large majority of cases.



15

Confronted with this list of compounds it is easy for chemists to recall intermediates and reactions that might lead to a successful synthesis of **12**, proceeding most favorably via ε-caprolactam (**10**). Should any doubts remain about the feasibility of the transformation of **10** to **12** (reaction with acrylonitrile and hydrogenation with ring closure), similarity searches with the smaller structural fragment, tetrahydropyrimidine, would be initiated. Possible syntheses for ε-caprolactam (**10**) are obvious from the list of structures in Figure 6: ring closure reactions with **7** or with **6** after cleavage of the protecting group, and from **9** and **11** after treatment with ammonia. The other structures (**8**, **13**, and **14**) can also be synthesized from **10**.

This example demonstrates how the results of a similarity search can inspire chemists to creatively design a synthesis with their knowledge: chemist and program form a team for the efficient solution of synthetic problems. In the next example (Fig. 7) we introduce a similarity criterion based on a generalized reaction type: here, elimination. All compounds displayed in Figure 7 can be transformed into each other by an elimination and/or addition. Note that the Saytsev rule is observed. Such queries, which are oriented along reactivity patterns, are extremely difficult to specify by normal substructure search mechanisms. Once again the task to select reagents and reaction conditions for the practical implementation is left in the first phase to the chemist (how to achieve Markovnikov or anti-Markovnikov addition?). Chemists will need verification by a search in a reaction database only in nontrivial cases, and they decide on this themselves.

Another similarity definition combines compounds that can be interconverted by substitution reactions. It is easily understood that this similarity measure is more restrictive, because from the compounds in Figure 10 this criterion recognizes only structures **16**, **17**, and **19** as related and puts them into one

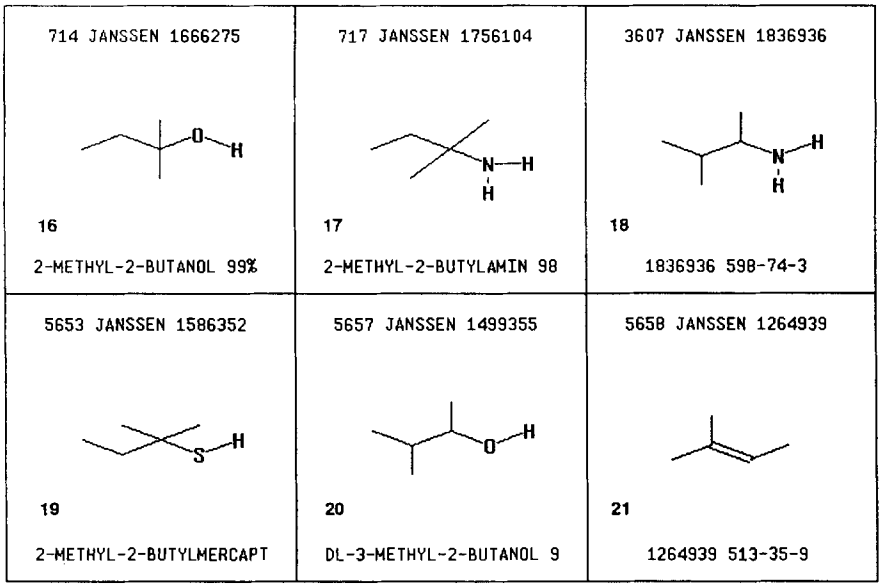


Fig. 7. Compounds detected as similar, because they can be converted by elimination into the same product.

group. Molecules **18** and **20** are put in a separate group. The direct relationship between **21** and the structures in the other two groups will be lost, together with possibility of transforming one group into the other via **21**. Some of the similarity definitions take into account the configuration of chiral centers and stereogenic bonds.

The similarity criteria that are based on structural transformations detect similarity and specify the structural changes or reaction classes that can exploit this structural identity, but do not give a quantitative measure of similarity. In order to define similarity quantitatively, another approach was taken: the computation of pathlength codes. The starting point has been an idea from Randic and Wilkins.[52] In a molecule all paths of length one (one bond or atom pair), two (a sequence of three linked atoms) etc. are counted. We have significantly extended this simple approach by including heteroatoms, rings, aromatic systems, multiple bonds, etc. Figure 8 shows the result of an example query with structure **22** and two molecules **23** and **24**

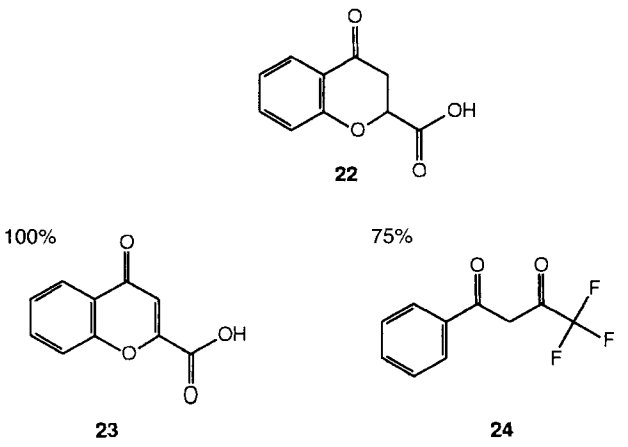

Fig. 8. A target molecule and two potential starting materials found by a pathlength code search. The similarity rating is normalized to 100%.

recognized as similar by pathlength coding. The percentage is the scaled numerical degree of similarity. Compound **23** with the highest similarity rating needs only reduction to be converted into the target structure **22**, while compound **24** requires more extensive structural modifications.

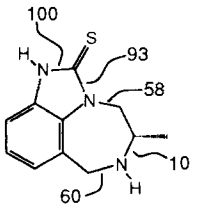
This example once again underscores the big advantage of similarity criteria defined by transformations: they often directly hint at reactions that can be employed to achieve the structural conversion. Measures based on pathlength codes detect similarity only by summing up substructural features without implicit reference to applicable reactions.

All these methods are used only for a quick preselection of candidate structures and are not expected to yield a final result. WODCA incorporates mechanisms to determine the degree of suitability of a compound as a starting material precisely and comprehensibly. One of the most powerful methods is the merit evaluation of good overlaps of starting material molecules and the target compound or intermediates. Factors like stereochemical compatibility, reactivity of the centers that need to be modified, and the possibility of selective attack on these modification sites are estimated. Accessibility and reactivity also influence the merit evaluation of the stereocenters requiring inversion, so this is not just a simple projection and count of necessary modifications. For the reactivity estimation WODCA uses the same physicochemical parameters that the EROS program series employs for reaction prediction,[20, 21, 25] where they have already proven their validity. An example for the power of these rating functions will be discussed in Section 4.3.

3.1.2. *The Search for Precursors*

Only in simple and propitious cases can a link between the target and a starting material be established directly. WODCA therefore includes mechanisms to dissect structures and subdivide the problem. To do this WODCA features functions that recognize and mark strategic bonds. Both topological and reactivity-oriented data, which are extracted from an analysis of the pattern of physicochemical properties of atoms and bonds, are procured and analyzed. This is not yet a final retrosynthetic analysis but only defines first locations for cuts. The atoms and groups that are ultimately used to generate specific precursors or reagents from the fragments (synthons) are not yet defined at this step or are present only as tendency markers (electron-withdrawing group).

Bonds between carbon atoms and heteroatoms are important locations for the dissection of a compound into smaller fragments. Strategic merit values are assigned to the bonds on the basis of the nature of the heteroatoms and their electronegativity, the resonance stabilization of charges generated after het-



25

erolytic bond cleavage, the size of the rings etc. Compound **25** is an example in which the strategic bonds together with the respective merit values have been automatically determined.

The chemical intelligence contained in the automatic functions for strategic bond detection is illustrated with the tricyclic compound **25**. C–X bonds are correctly perceived as the primary focus of interest and breakable in retrosynthetic direction. In the imidazolthione ring the bonds from the nitrogen atoms to the thione groups receive excellent ratings, while the bonds from the nitrogen atoms leading to the aromatic ring are recognized as difficult to break retrosynthetically. For the evaluation the methods take into account that these bonds can only be formed by nucleophilic aromatic substitution. These kind of reactions typically require drastic reaction conditions and hence do not possess a high degree of synthetic versatility. The ratings of the two bonds to the third nitrogen atom have different values of 10 and 60, respectively. The low value of 10 arises because this bond leads to a chiral center. Since its formation (that is, in synthetic direction) requires a stereospecific reaction, it is much more preferable to have this bond in the starting material already and to form the bond between the nitrogen atom and the benzylic carbon atom. Consequently, this preferred bond is rated much higher (60).

Of course, methods that detect strategic carbon–carbon bonds are also available. Polar reactions play an important role in the construction of carbon skeletons in organic compounds. Accordingly, during the determination of strategic bonds in a synthetic target special regard is given to the distribution and stabilization of the formal charges generated by cutting these bonds. Resonance stabilization of the charges is especially important. Both heterolytic cuts of every relevant C–C bond are examined. Detection functions also exist for the rating of radical processes. Besides local stabilization issues, general topological factors such as the distance to the center of the molecule and inclusion of the bond in a ring influence the merit evaluation.

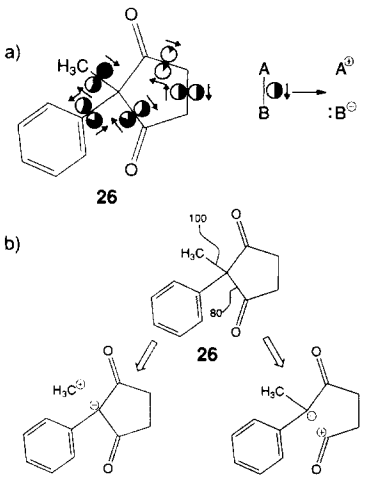


Fig. 9. a) Heterolytic cleavage of C–C bonds in 2-methyl-2-phenylcyclopentane-1,3-dione (**26**), and the amount of resonance stabilization estimated for the formal charges after bond cleavage. The arrow indicates the direction in which the electron pair from the broken bond moves. The shaded circles indicate the amount of resonance stabilization. b) Strategic bonds obtained by analysis of the resonance stabilization data in **26** and the synthons generated using this information.

Figure 9 presents the amount of resonance stabilization experienced by the formal charges generated by separate heterolytic cleavage of all C–C bonds (except those in the aromatic ring) in 2-methyl-2-phenylcyclopentane-1,3-dione (**26**). The more favorable heterolytic processes lead to cyclopentane-2,5-dion-1-ide. The detachment of the methyl cation is presumed to be more favorable than the generation of a phenyl cation. Furthermore, stabilization is expected to be relatively high for the dissection of the C1–C2 ring bond, which leads to an acyl cation and an enolate anion. Only very limited stabilization is anticipated for the other C–C ring bonds. These deliberations eventually point out and rate two strategic bonds as shown in Figure 9 b and their attached ratings. The disconnection of a phenyl cation is "penalized" by the system, so that this bond is no longer considered strategic. The target molecule can now be cut automatically at the strategic locations. The fragments are converted into precursors and can be subjected to similarity searches. The user may also add handpicked strategic bonds or exclude bonds from the automatically generated set, to steer the analysis into the desired direction. The relationship between the dissections, which can be extended across several levels, and the target compound is entered into the synthesis plan. All potential operations on the target compound can also be applied to these fragments. Thus a path that consists not of complete reactions, but of vaguely specified intermediates can be paved to the starting materials (see Fig. 4). The gaps between the stations are filled by reaction prediction (Section 3.1.3) or, in a future version, by reaction database queries until a reaction sequence is completed from starting material to target.

3.1.3. Reaction Prediction

WODCA cannot yet connect to a reaction database in order to extend plans stepwise in retrosynthetic direction with reactions from literature. Nevertheless, it is already possible to use the EROS system for reaction prediction and thus for verification of a proposed route in the forward direction. The latest version, EROS 6,[25] allows the automatic generation of reaction rules from reaction samples in a database. These rules have predictive power that extends beyond the training set. If a genuinely substantial training set is provided, and the reaction class under examination is not too erratically sensitive to peripheral influences such as temperature, ions and solvent, even absolute reaction rates and product ratios can be predicted to within a few percent.[25] Reaction simulation is always the method of choice if no strikingly similar reaction can be uncovered in literature. EROS can model the influence of substituents and generates predictions that are more reliable than those from database searches. The Diels–Alder reaction (including the hetero-Diels–Alder reaction) is an example of a reaction that can be modeled very well. The amide hydrolysis reaction showed that simulations by EROS can also predict absolute reaction rates reliably.[27] If an EROS reaction rule exists for a reaction class, it is possible to check immediately whether WODCA's fragmentation proposals or manually selected sets of strategic bonds lead to feasible syntheses. The simulation results are also added to the plan and can be analyzed later.

An example for a reaction prediction by EROS 6 initiated by WODCA is shown in Figure 10. Strategic bonds for a potential Diels–Alder reaction have been recognized automatically (small window left of center). Yet the character of the reagents is so unusual that the practical success of the reaction is doubtful. EROS predicts only one product with a scaled rating of more

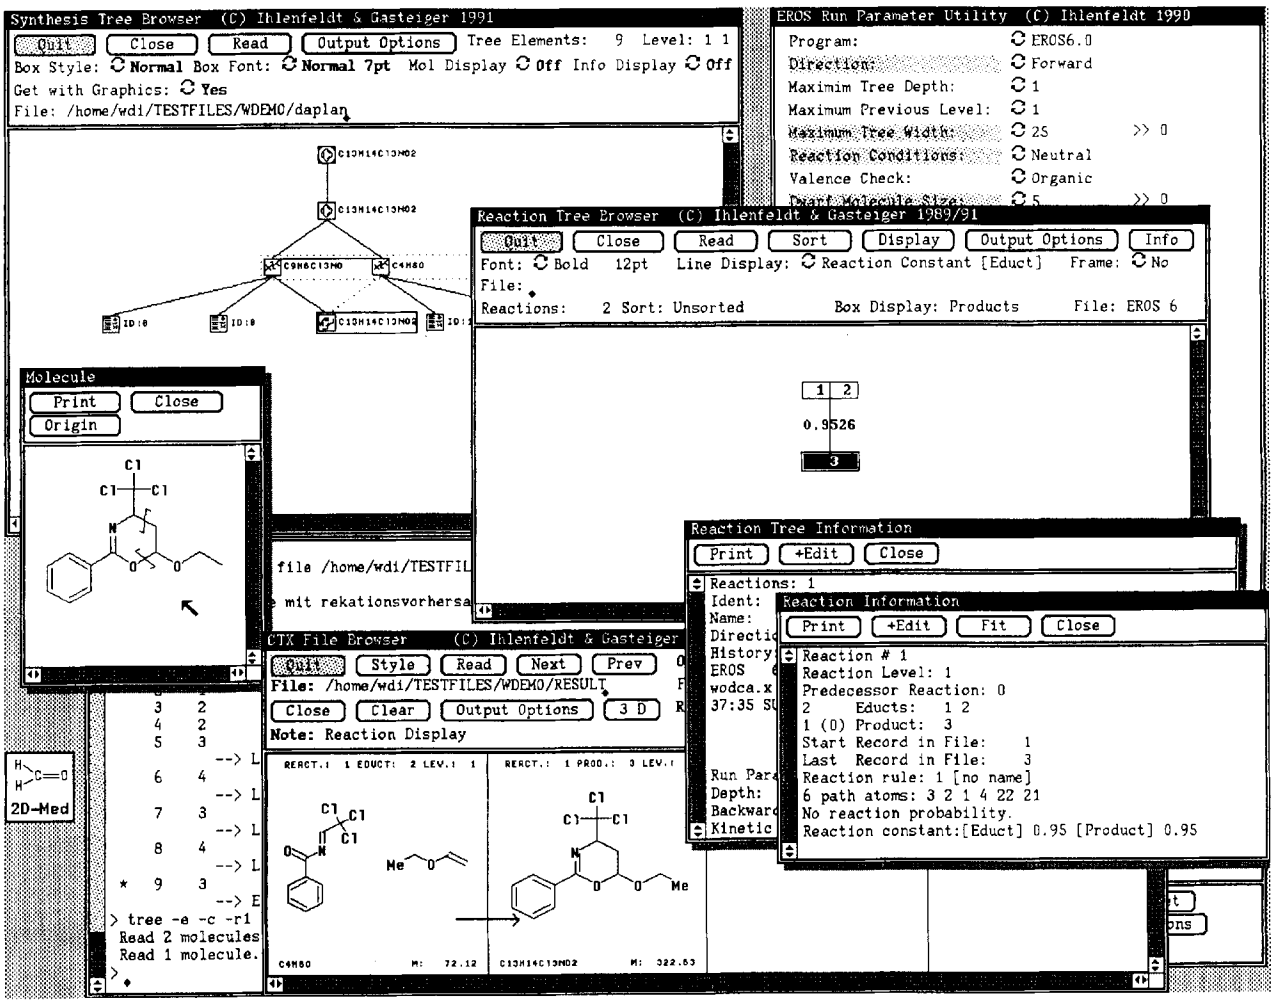

Fig. 10. Prediction of regioselectivity in a Diels–Alder reaction by the EROS program in the context of a verification of WODCA's strategic bond proposal. For a detailed explanation of the information displayed in the various windows, see text.

than 95% (central window, slightly to the right) and the required orientation (central bottom).[53] The prediction becomes part of the evolving plan (upper left).

3.2. System Design

The description as *program system* already implies that WODCA is not a single program but a set of cooperating programs. Most of the programs run in parallel and exchange data in real time. WODCA itself is the core system, which is surrounded by a shell of peripheral programs. The strict modularization has a number of advantages:

- smaller programs are more easily maintained
- memory consumption is relatively small, because the user selects only those subsystems needed for the work on a specific project
- parallel development of subsystems by teams of programmers is easier
- various tools with distinct user interfacing and interaction philosophy but providing similar functionality can be freely selected
- use of single tools is detached from the complete system for special tasks.

Peripheral programs, which run in parallel to the core system, are distinct from secondary programs, which are started from WODCA. Secondary programs are either called from within WODCA and continue to run independently or WODCA starts them and waits until they deliver their results. In contrast to the peripheral programs one cannot switch at will between them.

All functions representing the chemical intelligence of the system (merit evaluation of starting materials, search for strategic bonds, filter functions) are not hard-coded in the program but stored in external data files, which are read during the run. This mechanism can supply not only generally applicable functions but also specialized functions for specific cases, which are loaded when necessary. The user not only controls the general method suitable for a specific problem but also selects the particular variation of a method and how the results should be interpreted. Figure 11 displays the dataflow between the interactive program set. Unidirectional and bidirectional data streams are distinguished by the arrowheads attached to the channels.

To avoid waste of memory space, the WODCA system can be configurated to the task at hand. Before starting the system the user selects those tools that are necessary besides the core program. They are started together with the core program and shut

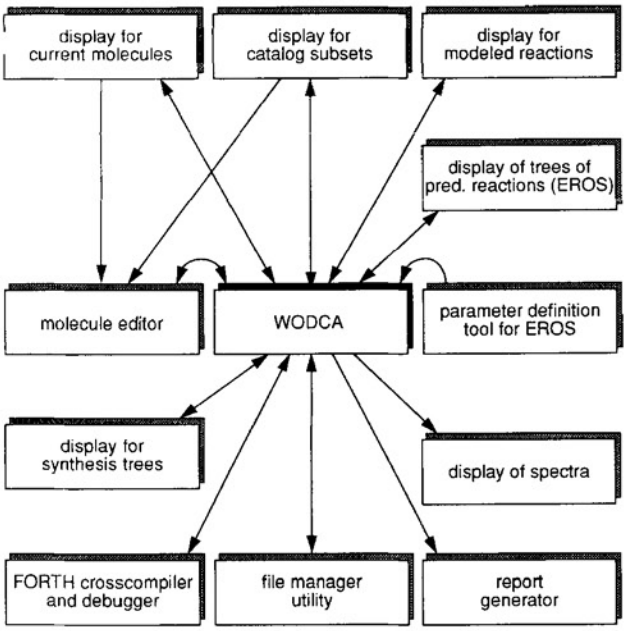

Fig. 11 Data flow in the WODCA system.

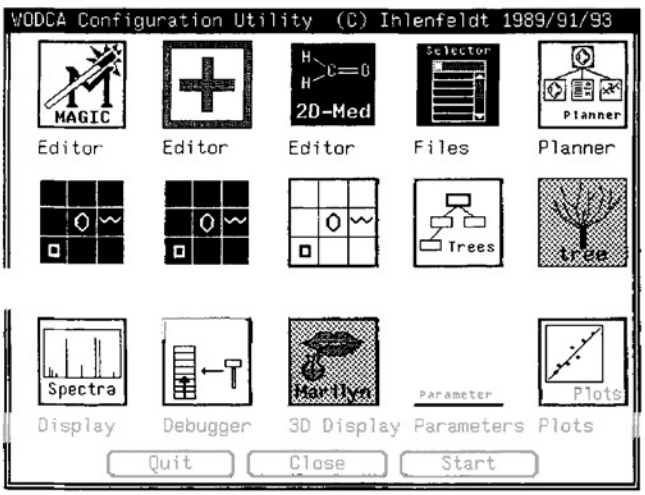
down when the core program exits. The set of programs is configured by clicking on the icon panel displayed in Figure 12. Currently, all peripheral programs to be used in a study must be chosen at start-up.

Although the system has been running in the described configuration for several years, it is a young system just emerging from development. Some efforts are still required to make the system even more user-friendly.

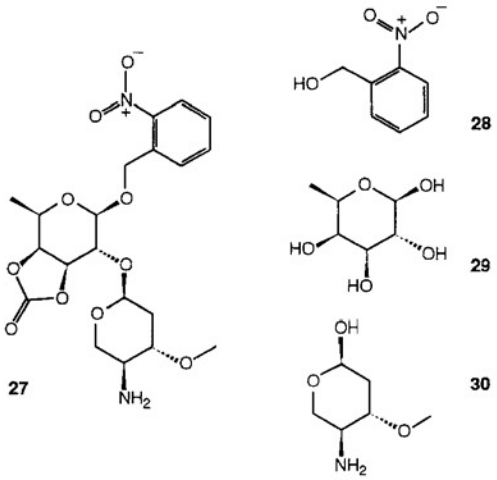


4. Examples for the Work with WODCA

The following three examples are intended to give a global and preferably untechnical overview of the practical work with WODCA. The examples have been chosen to demonstrate a large number of the basic operations of the system without undue repetition. Due to constraints in space and to maintain readability of this paper, the developed synthesis studies and plans are kept smaller than usual or incomplete. They are meant to serve as a guided tour through WODCA, not as comprehensive real-life studies.

4.1. Calicheamicin

The first example demonstrates in a general manner the setup of a plan and simple database queries to retrieve starting materials. It is somewhat limited and artificial, because the studied compound is only an intermediate in a larger synthesis and parts of the structure are protecting groups. The target compound **27** is an intermediate in a calicheamicin synthesis.[54]



Structure **27** obviously can be dissected into three larger fragments **28**, **29**, and **30**, a process also carried out fully automatically by WODCA, based on perceived strategic bonds. The small ester protecting group is considered structurally uninteresting and is therefore discarded in the first coarse partitioning step. WODCA does not yet restrict the oxygen atoms at the cuts to any precursor. They are simply duplicated on each fragment where they serve as a space-holder for arbitrary functionality. This kind of bond cleavage is distinctly different from a transform-oriented retrosynthesis. Here no assumptions are made about the reactions that will link the fragments. Only structural fragments and their relationship to the whole target are isolated for separate processing later. The closing of the gap between the generalized precursors and the target is an altogether separate task.

The synthesis target, the set of (in this case automatically selected) bonds that are the cleavage points of the fragmentation, and finally the set of molecules that are generated after cutting these strategic bonds form the first building block of the emerging plan, which is shown in Figure 13. This plan uses only a single set of strategic bonds (in this example C–X bonds), which are converted by a single method into actual fragments. In more complicated studies several alternative sets of strategic bonds may be employed, which, for example, may have been found by different methods for strategic bond detection. Each of these sets can be cut with alternative methods. Adjustable parameters for bond cutting include, but are not limited to, the

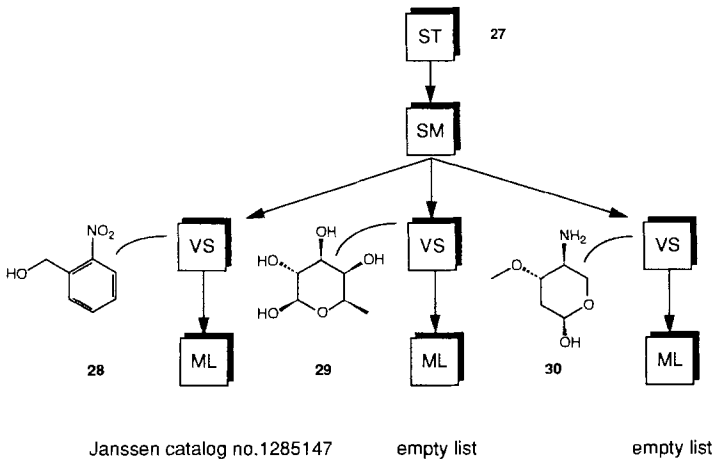


Fig. 13. First step of the synthesis plan for the calicheamicin precursor **27**. As a start a nonspecialized broad-range method is applied to determine the strategic bonds in the synthesis target (ST) automatically. This step yields the strategic molecule (SM) with attached strategic bond information. Cutting **27** at the strategic sites results in precursors **28**, **29** and **30**. Each of these compounds is submitted to a full structure search in the Janssen Chimica catalog but only 2-nitrobenzyl alcohol (**28**) is found to be directly available. The other two match lists (ML) remain empty (contain no structures).

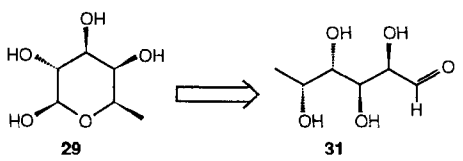
maximum number of bonds cut in parallel and sequencing hints for these cuts, types of filler atoms to saturate the open valences, or directions for the elimination of atoms or ions in order to produce an uncharged precursor. In addition, after cutting the bonds or a bond subset, another detailed evaluation of the fragments and the remaining strategic bonds that were not yet cut can be inserted, because at this level the environment of the remaining strategic bonds has changed, and new insight for the evaluation of the merit of these bonds can be gained.

In the next step an attempt is made to find the precursors as full structures in a catalog of starting materials. The largest library presently accessible to WODCA is the catalog of Janssen Chimica with nearly 8000 compounds. The full structure search can be applied automatically in parallel for all precursors. The result of the query is protocoled and inserted as a logical link to its corresponding query structure in the plan, even if an empty hit-list shows that no corresponding starting material was found. This is done in order to log all steps undertaken during a study, so that it can be reproduced and reexamined in its entirety any time later. Only *o*-nitrobenzylalkohol **28** is found with this classical search method in the compound catalog. The search in the CHIRON catalog and in an extract of the Aldrich catalog also does not yield the remaining two compounds **29** and **30**.

After relaxing the match criteria a little by the application of a similarity search with a transformation hashcoding, which preserves the central carbon skeleton, the α-heteroatoms, and, of course, the stereochemistry, but ignores differences in the substituents of the second sphere onwards and does not distinguish between open-chain and cyclic forms, D-fucose (**31**) is found in the Aldrich catalog as matching compound for **29**.



Only the third precursor, the 2′-deoxyaminosugar **30** remains without a direct link to a commerical product. This compound is not registered in open-chain or cyclic form in any of the catalogs accessible to WODCA. Searching with an even broader similarity definition is required. A search method that recognizes the substituent pattern on the core carbon skeleton, but ignores the nature of the substituent and stereochemistry, provides a list of eight structures from the CHIRON catalog (Fig. 14). The search on the 2211 entries of the CHIRON catalog took less than five seconds via pathlength codes, and the list represents those structures that exhibit a scaled similarity rating of more than 10%. The ratings are not yet a detailed merit evaluation. WODCA also provides methods for a more detailed examination of such a preselection, which will be explained in some of the examples in the next sections. Nevertheless, this first selection is surprisingly discriminating. Penta-1,4-dien-3-ol is probably not a very interesting compound, but some of the other compounds are certainly worth a second look. We refrain from disclosing a more in-depth analysis of these potential

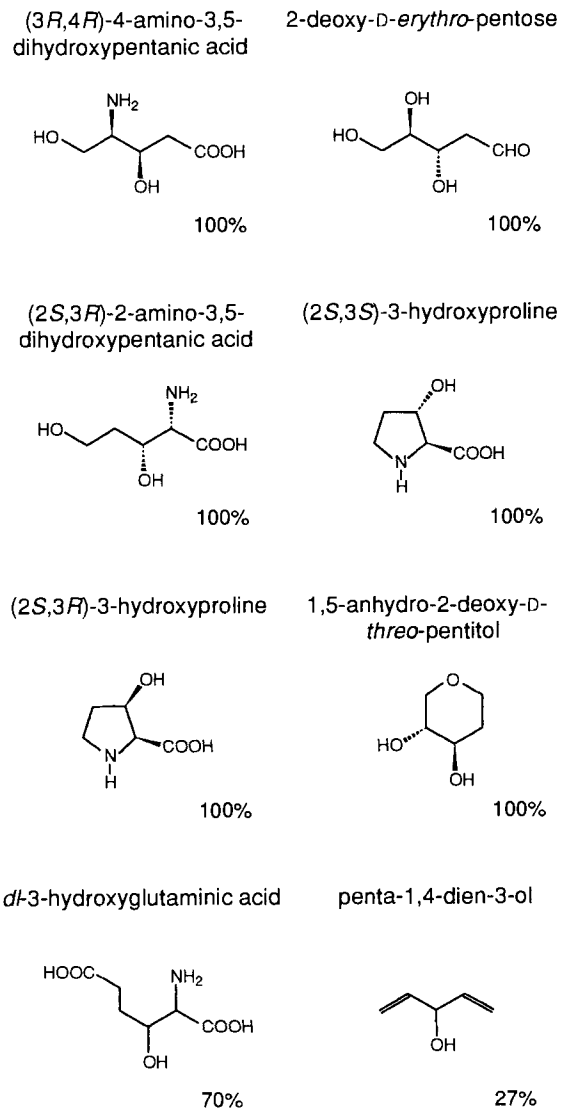


Fig. 14. Preselection of eight potential starting materials for the calicheamicin precursor **30**, selected by a pathlength code search. The percentages are the measure of similarity inherent in the search procedure; they do not include an estimate of synthetic usefulness or stereochemical factors.

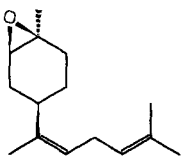
precursors and the development of a sequence of reactions to synthesize **30**, because without experimental verification it remains speculative. Finally all fragments of **27** are now associated with starting materials. The next step would be the search for specific reactions to fill the gaps in the forward direction. This part of WODCA is still under construction.

The published synthesis actually uses *o*-nitrobenzyl-alcohol (**28**) and D-fucose (**31**). The third precursor was introduced into the reaction sequence as a protected fluoride. It was prepared from the hydrochloride of L-serine methyl ester in twelve steps with an accumulated yield of 14% up to the 9th step. Maybe some of the compounds in the list might lead in fewer steps and with a higher yield to the used precursor. Unfortunately, again this paper[54] does not provide any hints on how the starting materials and reagents were selected. This is a general problem in complex syntheses: the applied reactions are often very well documented with many literature references and were probably known to the authors when they devised their synthesis. On the other hand, starting materials are regarded as self-explanatory, and no more documentation on this aspect is provided besides sometimes a catalog number of the manufacturer. This is incompatible with our notion of the importance of the methods that lead to the selection of starting materials, an operation at the very heart of synthesis planning. In our opinion they should be documented much more carefully.

4.2. Sexual Hormones of the Green Stink Bug

The complex sexual hormones of the green stink bug (bisabolenes) were synthesized first by Nicolaou et al. in 1989.[55] The pheromones of this class differ in the stereochemistry of the attachment points of the alkyl groups. In this example we treat only a single compound: (+)-α-bisabolene (**32**).



32

According to WODCA's automatic analysis, only two strategic C–C bonds are present: the double bonds. The central double bond is rated higher because of general tactical advantages (it is more central, and therefore the chances for a convergent synthesis are higher). If WODCA is allowed to proceed unguided, both possible dissections are entered into the plan (Fig. 15). The right-hand branch, which was evaluated lower by WODCA, leads to precursor **35** and a fragment with an isopropyl skeleton. It does not look very promising. The isopropyl fragment is of course available in hundreds of variations, but the larger fragment **35** cannot be connected by any substructure search or similarity transformation to a related compound in any of the catalogs available to WODCA.

For the analysis of the left-hand branch of the synthesis tree leading to precursors **33** and **34**, the CHIRON catalog is activated first in order to have the maximum choice among terpenoid structures with defined stereochemistry. A simple substructure search (a search for fragment **33** embedded in the catalog compounds), neglecting stereochemistry but with the constraint that the skeleton size of the catalog compounds must not exceed the skeleton size of the query structure by more than 25 percent and requiring at least one stereocenter with defined configuration

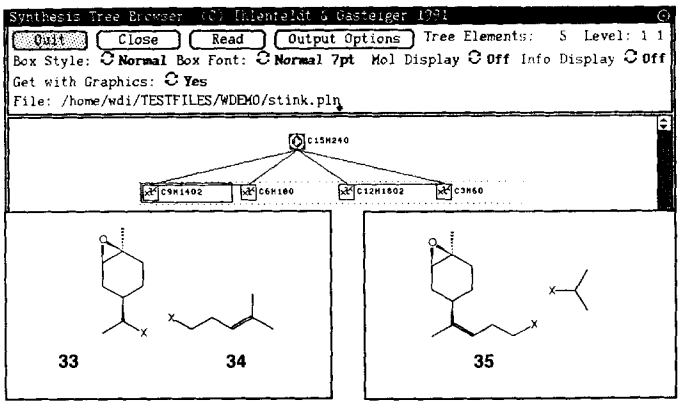


Fig. 15. First steps of the synthesis plan of (+)-α-bisabolene (**32**).

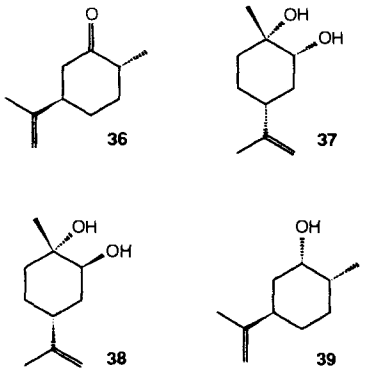
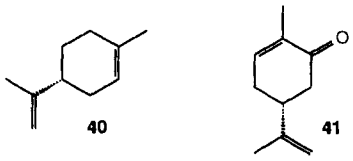
somewhere in the molecule, retrieved 24 potential precursors. Then the rating functions mentioned in the previous section are employed. All 24 candidates are superimposed on the query fragment **33**, and the complexity of the required transformations as well as the stereochemical complementarity are estimated. The candidates rated best by WODCA (**36**–**39**) cannot be ordered from a supplier because they were extracted for the CHIRON database from literature. Since the database includes the literature citations, they can be displayed with a mouse click and sent to a printer if desired. The common characteristic of these top rated structures is a defined configuration at the methyl-substituted ring atom.



On the other hand, the top-rated commercially available compounds ((*R*)-limonene **40** and (*R*)-carvone, **41**) are reactive at this position (because of a double bond), but are not yet stereochemically differentiated at this site. The stereochemical merit evaluation function attempts to estimate to what extent the proximate groups might influence the stereochemical course of a reaction. For **40** and **41**, however, the potential for induction is regarded as rather small. Consequently, these compounds received a distinctly lower score than compounds **36**–**39**.



Remarkably, all compounds selected by WODCA contain a larger carbon skeleton than the required precursor **33**. The normal size (and typically also complexity) relationship between synthesis target and precursor has been inverted, and the starting materials contain one more carbon atom (and some exhibit more structural complexity) than the synthetic product. Classical inflexible methods, which expect the starting material to be a substructure of the target compound, can overcome this com-

plication only with difficulty; the search strategy from the WODCA toolbox employed here encounters no difficulties.

In the original paper[55] racemic, epoxidized limonene was ozonized, and the resulting racemate was resolved. Epoxidized limonene was bought in the original study but is not listed in the catalogs accessible to WODCA. For commercial compounds the complete catalog information is in the database and can be viewed. It is even possible to send selected candidate records to an external report generator, which can print summary tables or completed order forms.

After finding apparently quite suitable precursors for the synthesis of **33** in carvone and limonene, the second fragment **34** needs attention. At first glance it does not look very complicated. Surprisingly, not a single compound with the same carbon skeleton and substitution pattern as **34** exists in the diverse WODCA catalogs with altogether more than 10000 structures. Clearly, the substitution-pattern-oriented pathlength codes search is again required. One of the characteristics of this method, which has already been briefly mentioned in Section 3.1.1, is the identification of structures whose carbon skeletons are very similar to, but not necessarily absolutely identical to the query structure. At the same time, whereas the substituent pattern can be varied, it should be similar. The specific type of the substituents is ignored, and true substituents and carbon–carbon double bonds are also somewhat interchangeable. Even this type of search does not yield any clearly ideal starting material. However, a closer analysis of the hits reveals some interesting relationships, which probably would have been overlooked on paging through printed catalogs. Nine structures (**42**–**50**) taken from the condensed subset of the 30 top-rated compounds extracted from the catalog in a few seconds are shown in Figure 16.

None of the listed molecules can be used immediately. Nonetheless, this selection will indeed stimulate new ideas. The

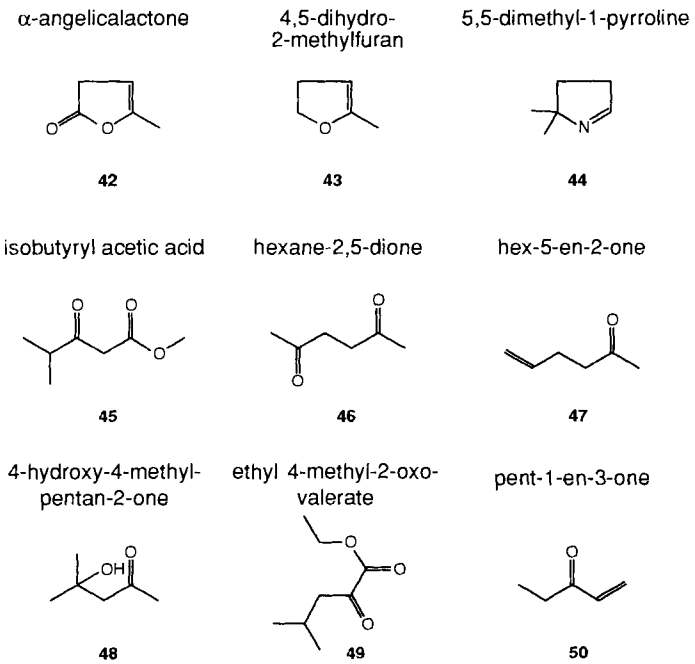


Fig. 16. Potential starting materials for the synthesis of **34**, obtained in a very broad-range search.

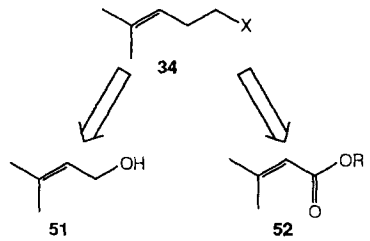
ring of the pyrroline **44** can certainly be opened, and functionality is present for the introduction of the double bond and the adjustment of the terminal group. After ring-opening, angelicalactone (**42**) and the dihydrofuran derivative (**43**) also possess functionality at the right place, but both require the introduction of a methyl group. In this case the compounds obtained high ratings because of the good fit of functionality in spite of an incomplete core carbon skeleton. Compounds such as hex-5-en-2-one (**47**) require a degradation (double bond cleavage) as well as a methylation of the skeleton in order to obtain the terminal functionality. Other candidates such as 4-hydroxy-4-methyl-pentan-2-one (**48**) have the basic structure including the central double bond, but the functionality needs to be shifted to the terminal atom. Some molecules that appear strange at first glance trigger a cascade of associations in the mind of the chemist on a more thorough examination. Of course, it is possible to dissect fragment **34** further. WODCA then finds unerringly 3-methyl-but-2-en-1-ol (**51**) and derivatives of 3,3-dimethylacrylic acid (**52**). These compounds were also perceived as similar in the original search but are placed rather low on the list sorted according to the similarity value because of the much reduced size of the carbon skeleton.

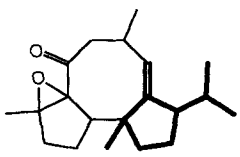


In the original synthesis[55] fragment **34** was assembled from tiny building blocks. In six steps three carbon-containing compounds (two C_1 fragments and a C_4 fragment) were attached to the limonene frame. Surely this cannot be called a convergent synthesis. If such tiny building blocks are assembled one can no longer speak of similarity and the recognizable relationship to the target molecule. It is not within the realm of WODCA during a first analysis to generate associations that lead to such tiny synthetic steps. Only if no suitable synthesis is suggested under a more global perspective is a second analysis initiated to cover the minute details of such kind of synthesis approach.

4.3. (+)-7,8-Epoxy-2-basmen-6-one

The last example is the search for starting materials for (+)-7,8-epoxy-2-basmen-6-one (**53**). This example was selected to demonstrate WODCA's ability to yield valuable starting points for synthesis planning across extreme synthesis distances.

Compound **53**, which occurs in nature in dried tobacco leaves, was prepared for the first time in 1991 by Paquette in a total synthesis. Search operations for this target with a rather complex stereochemistry were again based on the CHIRON catalog. The natural approach to such complicated compounds is to pass along as much stereochemistry as possible from starting materials. It appears the logical choice to start with a compound that already possesses one of the two five-membered rings. Consequently, the boundary con-



ditions for the first selection of starting material candidates were exactly one single five-membered ring, but no six-membered rings (in the SSSR—the *s*mallest *s*et of *s*mallest *r*ings[57]), plus at least one stereocenter with defined configuration. These filtering conditions yielded 84 candidates. Their merits were again estimated by the stereochemical fitness function of WODCA. The list, sorted according to the result of the merit evaluation, is presented to the user as a table as well as graphically with plots of the candidate structures.

It was not specified which one of the two five-membered rings should be the starting point. All of the compounds in the list were superimposed in all conceivable orientations[58] over both five-membered rings of the target and were also mapped onto the other structural regions. Especially good fits were evaluated in detail. The results are listed in Table 2 and Figure 17. The

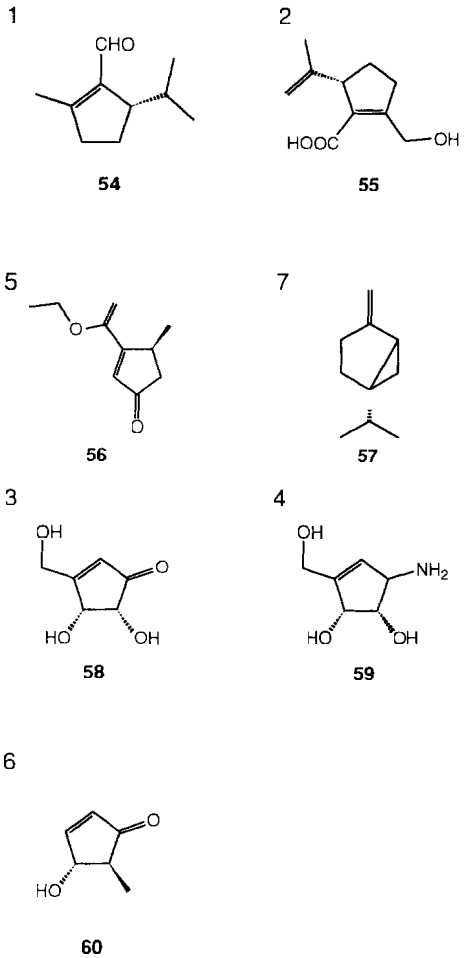


Fig. 17. Potential starting materials that include the right-hand (top two rows) and left-hand (bottom two rows) five-membered ring in (+)-7,8-epoxy-2-basmen-6-one **53**.

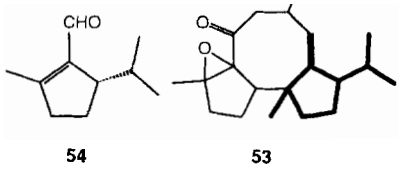
better candidates were found for the right-hand five-membered ring. Only for this ring were positive merit values for best fits computed at all. The best fit of the top-rated starting material **54** into target **53** is shown in Scheme 3.

This embedding appears to be obvious but it certainly is not the only orientation examined. The six best orientations for the top candidate, taken from several dozen mappings evaluated in detail for this compound alone, are displayed in Figure 18.

Table 2. Merit of basmenone precursors that include right-hand five-membered ring (fist four entries) and the left-hand five-membered ring (last three entries).

Rank	Merit	Compound
1	979	(5*S*)-5-isopropyl-2-methylcyclopentenecarboxaldehyde **54**
2	959	DL-2-hydroxymethyl-5-isopropenylcyclopent-1-enecarboxylic acid **55**
5	−148	ethyl (5*S*)-5-methylcyclopent-1-en-3-onecarboxylate **56**
7	−194	sabinene **57**
3	−56	(4*R*,5*R*)-4,5-dihydroxy-3-hydroxymethylcyclopent-2-enone **58**
4	−59	(3*R*,4*S*,5*R*)-3-amino-4,5-dihydroxy-1-(hydroxymethyl)-cyclopentene **59**
6	−173	(4*R*,5*S*)-*trans*-4-hydroxy-5-methylcyclopent-2-enone **60**



54 **53**

Scheme 3. Most promising starting material **54** and its fit into the target compound **53**.

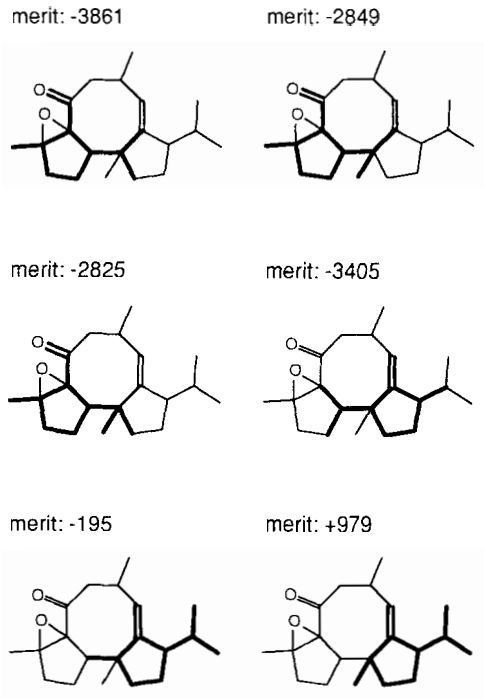


Fig. 18. Most important embeddings of **54** into the target compound **53**, together with their evaluated merits.

By comparison of the rating values and the corresponding fits it is possible to understand the factors influencing the rating procedure. Stereochemical complementarity weighted by the reactivity of the involved centers, reactivity of the connection points that need modification on the way to the target structure (compare the numbers for the embeddings on the lower right and lower left), and more general topological factors are the core elements of this algorithm. It is important to know that not only embeddings of the whole starting material, that is, of the

full carbon skeleton (of course with hydrogen atoms and heteroatoms) were computed. Dozens of alternatives where parts of the starting material carbon skeleton were no longer present in the target were examined as well. In this case (in contrast to the bisabolene example) they did not receive competitive ratings. The stereochemical complementarity of the second best candidate **55** is about as good as that of the top candidate, but more structural conversions are necessary, and thus the evaluation score is lower. The difference is rather small in this example, because the positions which need to undergo transformation in structure **55** are, in principle, quite accessible. On the other hand the enantiomer of the top candidate, which is also contained in the CHIRON database, receives a low score. Because the configuration of a difficult and rather unreactive center must be inverted, this compound does not appear in the top twenty of the 85 scanned library entries.

Some of the search compounds that included the left-hand five-membered ring of **53** provide better starting points for synthesis. The three best-rated candidates **58**–**60** of this type are depicted in Figure 17 (in the bottom two lines), and the best overlays of two of these compounds are shown in Figure 19.

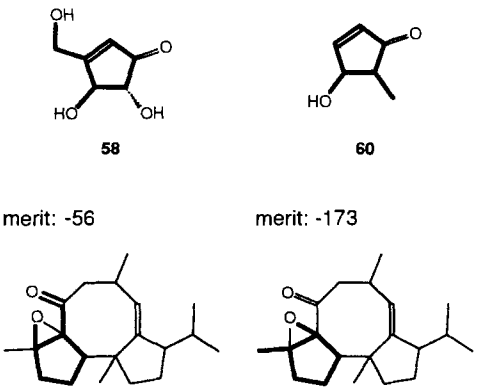

Fig. 19. Best merit values for the fit of **58** and **60** into the left-hand five-membered ring in (+)-7,8-epoxy-2-basmen-6-one (**53**).

The published synthesis[56] did in fact use (5*S*)-5-isopropyl-2-methylcyclopentenecarboxaldehyde (**54**) as starting material. WODCA's analysis is confirmed. The synthesis starting from this material required 28 or 30 steps, depending on the step counting method. Unfortunately, again no information about the way the starting material was selected was published. WODCA has proved in this example that it can perceive synthetically exploitable and convincing structural similarity over an enormous chemical distance. However, this computation cannot be executed any longer in a truly interactive manner. For the close evaluation of the 85 candidates, preselected in a few seconds, about 25 minutes of computer time were spent on a Sparc II workstation. In this time span some hundred thousand superpositions were generated and about 1000 were submitted for merit value computation. This time needs to be seen in comparison to the concentrated effort and limited thoroughness of a human chemist flipping through catalogs manually—it then seems negligible. Moreover, state-of-the-art computers used routinely nowadays for molecular modeling tasks have ten times more computing power, so that the interactive treatment even of such a complex problem is on the horizon.

5. Conclusion and Perspectives

WODCA is a prototype of a new generation of synthesis planning programs, which are oriented closer to the thought patterns of synthesis chemists. WODCA offers a broad spectrum of methods that support chemists in their self-guided search for syntheses of organic compounds. Some of the tools found to be of special importance for this task were custom developed for the field of synthesis planning and were collected, together with known search methodology, into a program. The program is now mature enough to provide ideas for real-world synthetic tasks. One can only hope that WODCA and other systems that shed the rigid synthon and transform schemes of the synthesis-planning programs of the first generation manage to achieve wide acceptance and become as common a planning tool as the library has been for hundreds of years and the reaction database has developed into during the last decade. It is too early to announce the requiem for computer-assisted synthesis planning. The design faults and shortcomings of the first generation of programs have been analyzed and understood. The second generation is now waiting for the signal to commence.

The development of the WODCA system has been made possible by a doctoral scholarship from Studienstiftung des deutschen Volkes for W.-D. Ihlenfeldt and through support from DFG project Ga 208/17-1. We express our thanks to Shell Forschung (now: Cyanamid Forschung) and in that team particularly to Prof. Dr. R. Mengel for helpful support. Prof. S. Hanessian, University of Montreal, generously provided the catalog of the CHIRON system. Janssen Chimica (now: Acros Organica Division) made their starting materials catalog available in computer-readable form. R. Fick created and ran some of the examples described in this review.

Glossary of Acronyms

AIPHOS: Artificial Intelligence for Planning and Handling Organic Synthesis
CASP: Computer Assisted Synthesis Planning
CAMEO: Computer Assisted Mechanistic Evaluation of Organic reactions
CHIRON: CHIral synthON (and name of the wisest of the centaurs)
COMPASS: COMPuter ASSisted organic synthesis
EROS: Evaluation of Reactions for Organic Synthesis
Hashcoding: A method of one-way data compression that loses information. A complex set of data is reduced to a single number, which has a high probability of being unique for the specific input data (see Ref. [51]).
IGOR: Interactive Generation of Organic Reactions
LHASA: Logics and Heuristics Applied to Synthetic Analysis
LILITH: no acronym, name of a demoness in spider shape
OCSS: Organic Chemistry Synthesis Strategies
RAIN: Reactions And Intermediates Network
SECS: Simulation and Evaluation of Chemical Synthesis
SSSR (Smallest Set of Smallest Rings): A set of elementary rings that forms the basis of all other rings (for instance, envelopes).
SST: Starting Material Strategies
SYNCHEM: SYNthetic CHEMistry
TRESOR: TRacing and Evaluation of Syntheses in Organic Reactions
WODCA: Workbench for the Organization of Data for Chemical Applications

[43] Summary of a couple of replies to a question about user experiences with synthesis-planning systems, posted on the *OSC Chemistry Mailing List* chemistry@osc.edu, July 26th, 1993. The original message that we cite originated from J. W. Boiten.

[44] One of the referees was of the opinion that this is not a valid comparison. He stated that often a reaction database query would be initiated just to check the feasibility of a reaction when a chemists does some manual planning. In our opinion this clearly is a significant symptom of a lack of acceptance of synthesis-planning programs. Ideally any plan should be developed in an integrated planning system, and the query should originate from such a system in order to verify the program's proposal.

[57] Here, in the case of sabinene, the six-membered ring is an envelope. The elementary rings are the three- and five-membered rings. Therefore the six-membered ring is allowed and passes.

[58] This statement is not absolutely correct. The exhaustive mapping of two graphs in all possible orientations is computationally too demanding. Therefore WODCA uses some heuristics in order to reduce the number of mappings in a synthetically sound manner. The maximum common substructure is only among the examined mappings if at least some part of the border region between the embedded substructure and the compared compounds contains reactive centers.

X-ray Crystal Structures of Cytochrome c Oxidases from *Paracoccus denitrificans* and Bovine Heart and Their Implications for the Molecular Mechanism of Cell Respiration

Bernhard Kadenbach*

Thirty-four years ago, two years after the first high-resolution X-ray structure analysis of a protein (myoglobin) by Kendrew, crystals of cytochrome c oxidase (COX) from bovine heart were obtained by Yonetani.[1] But all efforts to determine the three-dimensional structure of the enzyme at the atomic level failed due to the poor quality of crystals.[2] Now high-resolution (2.8 Å) X-ray crystal structures of the oxidized COX from *Paracoccus denitrificans* and from bovine heart have been published almost simultaneously by Michel and co-workers,[3] and by Yoshikawa and co-workers,[4] respectively. In the two cases, however, different approaches were used. Michel et al. obtained crystals of COX from *Paracoccus* only after forming a complex with the variable fragment of a monoclonal antibody, whereas Yoshikawa et al. obtained crystals of COX from bovine heart only after addition of the detergent decylmaltoside during crystallization.

COX, the terminal enzyme of the respiratory chain of bacteria and mitochondria from all eucaryotes, is essential for life on earth, because it is the only enzyme that reduces oxygen to water without producing reactive intermediates and conserves the released energy. After its first description in 1925 by Warburg as "Atmungsferment" and 1925 by Keilin as cytochrome aa_3, the enzyme was intensively studied, but not until recently were all the metal atoms participating in the reduction of oxygen identified. The two membrane-bound oxidases from *Paracoccus* and bovine heart are almost identical in their catalytic properties. Both transfer electrons from cytochrome c to molecular oxygen accompanied by formation of an electrochemical proton gradient across the membrane. But they differ in their number of protein subunits. COX from *Paracoccus* has four different subunits, the enzyme from bovine heart and other mammals has thirteen.[5] The three largest subunits, which are homologous to those of the bacterial enzyme, are encoded on mitochondrial DNA, the other ten on nuclear DNA.

The reports of the X-ray structures emphasize different aspects. Whereas Michel et al. describe the catalytic centers and the structures of the four bacterial subunits in detail, Yoshikawa et al. concentrate on the metal centers and postpone the much more complicated description of the thirteen protein subunits to a later publication. The structures of both enzymes confirm many structural features previously concluded from biochemical studies. All four and thirteen subunits of the two enzyme complexes have been confirmed in equimolar ratios. Also, the pathway for electrons from cytochrome c to Cu_A in subunit II, via heme *a* and heme a_3-Cu_B in subunit I, and finally to O_2 is corroborated by both structures. Concerning the general structure, the "lopsided Y" deduced from electron microscopic studies on two-dimensional crystals[6] could not be verified. Interestingly the bovine heart enzyme crystallized as a dimer, as was previously found by electron microscopic studies on "membrane sheets".[6] In contrast, the bacterial COX, which is more lipophilic owing to the absence of the subunits coded by nuclear DNA, crystallized as a monomer only after complexation with the variable fragment of a monoclonal antibody. This type of cocrystallization could be useful for the crystallization of other hydrophobic proteins.

Until recently, in addition to the two heme *a* groups, only two copper ions (Cu_A and Cu_B) have been assumed to occur in the catalytic center of COX. The finding that the Cu_A site contains two copper atoms led for the first time to speculations on the occurrence of a Cu–Cu bond in a biomolecule.[7] The X-ray structures of both enzymes, however, revealed that the two copper atoms are in a plane with and coordinated to two cysteine S atoms. This structure corresponds to the [2Fe–2S] center of iron–sulfur proteins, which instead contain inorganic sulfur. The tetrahedral coordination environments of the two copper ions, each with a charge of +1.5, are completed by a histidine and methionine, and by a histidine and a peptide carbonyl group of glutamic acid, respectively, all within subunit II. Except for the peptide carbonyl group, all other ligands had been identified correctly by site-directed mutagenesis of bacterial COX.[8] The distances between the copper atoms were determined to be 2.6 Å (*Paracoccus*) and 2.7 Å (bovine heart).

Three further metal atoms of the catalytic center of COX, two iron atoms (in heme *a* and heme a_3) and Cu_B, are located within the periplasmic (*Paracoccus*) or cytoplasmic half (bovine heart) of the membrane domain of subunit I. Subunit I contains twelve transmembrane helices (TM), representing the center of the enzyme, which is almost identical in both enzymes. In principle, the twelve TM had already been deduced correctly from hydropathy plots, but the boundaries of the transmembrane re-

gions vary. The planes of heme *a* and heme a_3 are perpendicular to the membrane plane and form an angle of 108° (*Paracoccus*) and 104° (bovine heart). The fifth and sixth ligands of heme *a* Fe are imidazole groups located at TM-II and TM-X. The latter transmembrane also contains the fifth ligand of heme a_3 Fe, again an imidazole group of a conserved histidine. These ligands have also been identified previously by site-directed mutagenesis.[9] A sixth ligand of heme a_3 Fe was not found, but it could be a delocalized water molecule not detectable by X-ray diffraction.

The heme a_3–Cu_B binuclear center binds molecular oxygen, which is reduced to water by four electrons from cytochrome c and four protons from the cytoplasm (*Paracoccus*) or matrix space (bovine heart). In COX from *Paracoccus* a heme a_3 Fe–Cu_B distance of 5.2 Å was found, and in COX from bovine heart a distance of 4.5 Å was determined. The difference could be due to crystallization of the *Paracoccus* enzyme in the presence of azide, a ligand of the binuclear center. In EXAFS measurements (EXAFS = extended X-ray absorption fine structure) with the oxidized enzyme from bovine heart and from *Paracoccus* Powers et al. found a distance of only 3.75 Å and a sulfur atom (methionine or cysteine) as bridging ligand. But this repeatedly postulated bridging ligand was not found in either of the present structures.

Cu_B is complexed by a histidine in TM VI and two histidines of the loop region between TM VII and TM VIII. These histidine ligands of Cu_B were also identified earlier by site-directed mutagenesis in bacterial COX.[9] While in the enzyme from bovine heart all three histidine ligands of Cu_B were evident, in the *Paracoccus* enzyme the electron density of the side chain of His325 was lacking. This finding, indicating multiple conformations of the imidazole group, was the starting point for the development of a mechanism for proton translocation in COX by Michel et al. (vide infra).

The arrangement of the twelve transmembrane helices of subunit I within the membrane was surprising. Four helices together form a semicircle, which forms a pore with one helix of another semicircle. Thus the pores A (of TM III–VI with TM II), B (of TM VII–X with TM VI), and C (of TM XI, XII, I, II with TM X) are formed with threefold rotational symmetry (Fig. 1). Pore A contains mainly conserved aromatic amino acids, pore B contains the binuclear center heme a_3–Cu_B, and pore C contains heme *a*; in the latter a hydrophobic hydroxyethylfarnesyl side chain seals the pore to the cytoplasm. For the reduction of

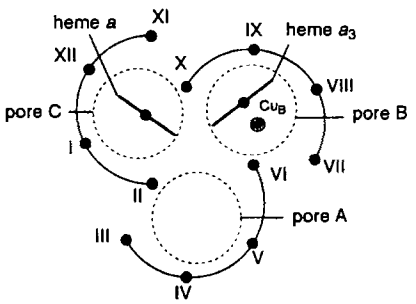

Fig. 1. Schematic representation of the transmembrane helices I–XII of subunit I in COX from *Paracoccus*. Sets of four helices are arranged together in semicircles and form pores (A, B, C) with one helix of an adjacent semicircle (taken from ref. [3] with permission).

an O_2 molecule four protons are taken up from the cytoplasmic (*Paracoccus*) or matrix space (bovine heart), while for the coupled proton translocation four further protons are transported from the cytoplasm (matrix) into the periplasmic (cytosolic) space.

Michel et al. postulate separate channels for the "chemical" and the translocated protons. The "chemical" protons could pass through pore B directly to the O_2-binding site (heme a_3–Cu_B). In fact, hydrophilic groups (Ser291, Lys354, Thr351, the hydroxyl group of heme a_3, and Tyr280) are located within this channel. This is unexpected, because normally only hydrophobic amino acids are found in transmembrane helices. The pumped protons could be translocated through the cytoplasmic half of pore A and the periplasmatic half of pore B. In the lower part of pore A hydrophilic amino acids are also found (Asp124, Thr203, Asn199, Asn113, and Asn131). Exchange of one of these amino acids by a hydrophobic one through site-directed mutagenesis resulted in inhibition of proton translocation but not of electron transport (H_2O formation)[11]. These latter results had led previously to the proposal of separate channels for "chemical" and translocated protons.

For proton pumping in COX Michel et al. developed a "histidine cycle/shuttle" mechanism, following the "histidine cycle" mechanism of Wikström et al.[12] In this mechanism His325 cycles through the imidazolate, imidazole, and imidazolium states and shuttles between two positions. Proton translocation is mainly based on protonation of the imidazole of His325 while it is bound to Cu_B, and its deprotonation in its second position as a ligand of the formyl side chain of heme a_3. This plausible mechanism, however, has not yet been proven. In their crystal structure Yoshikawa et al. found imidazole rings with the expected electron density for all three ligands of Cu_B (His240, His290, and His291) and thus obtained no indication of multiple conformations.

Michel et al. also describe subunit III, which contains seven transmembrane helices and contributes largely to the mass of the membrane-bound enzyme. It binds to subunit I at the side opposite to subunit II, but its function is unknown. Within subunit III of *Paracoccus* COX a phosphatidylcholine molecule with unknown function was found. The lipid cardiolipin, essential for the catalytic activity of COX, was not found in either the enzyme from *Paracoccus* or that from bovine heart.

In the paper of Yoshikawa et al. the position of a magnesium ion is described, which was already known as a stoichiometric COX component. It has distorted tetrahedral coordination to two ligands of subunit I (Asp369, His368), one ligand of subunit II (Glu198), and one water molecule. The conserved amino acids Asp and His were identified previously by site-directed mutagenesis in bacterial COX as ligands of manganese, which can be exchanged by magnesium.[13] The authors postulate that the magnesium center is not only important for the structure but also serves in the redox state dependent regulation of the electron transfer from Cu_A to Fe_a and from Fe_a to Fe_{a3}. In COX from bovine heart the position of a zinc ion was described, which is located in the nontransmembrane subunit Vb at the matrix side and complexed by four sulfur atoms (Cys60, Cys62, Cys82, and Cys85). The function of the zinc ion, which is absent in the bacterial enzyme, is so far unknown.

The two X-ray crystal structures are milestones on the way to understanding the structure and function of COX. Surprisingly many previous results could be corroborated; others were proven wrong. A number of unsolved questions like the mechanisms of electron transport and of proton translocation will only be solved by parallel functional studies. This holds in particular for questions on the regulation of activity, which, due to the large number of additional subunits in the mammalian COX, appears to be particularly complex.

New Evidence Concerning the Structure of Amorphous Red Phosphorus

Hans Hartl*

One of the unsolved problems of the structural chemistry of elemental phosphorus is the structure of amorphous red phosphorus, a material found on nearly every matchbox for more than 150 years. Since an X-ray structural characterization of this material has not been possible, our knowledge derives from indirect evidence, which is providing more and more precise information about the structural principles of this phosphorus modification. Two important contributions in this respect are the recently published results of Böcker and Häser[1] as well as those of Pfitzner and Freudenthaler.[2] The combination of their results with the findings of earlier investigations allows a model of the structure of amorphous red phosphorus to be established that seems to be not far from reality.[3–5]

The trivalency of phosphorus atoms with slightly varying P–P bond lengths (ca. 220 pm) and P-P-P angles ranging from 60° to 120° permits a great variety of different types of atomic connectivities. Between the three basic types—white, red, and black phosphorus—a series of further allotropic forms of phosphorus are conceivable, ranging from small phosphorus clusters to phosphorus-rich oligomers as well as one-, two-, and three-dimensional polymers. Baudler and Glinka[4] as well as von Schnering and Hönle[5] emphasized in their brillant reviews about mono- and polycyclic phosphanes and phosphorus-rich polyphosphides, respectively, the diversity of atomic frameworks of phosphorus-rich compounds with P–P bonds. They pointed out that a close relationship exists between these compounds and unsubstituted, uncharged P_n clusters.

Baudler and Glinka proposed a set of rules for the construction of larger phosphorus frameworks by aggregation and/or condensation of small subunits. One of these rules (not to be taken as reaction mechanisms!) states that a larger framework with an additional five-membered ring can be built up by a formal [2+3]cycloaddition. The fact that five-membered rings are preferred and widespread structural units in polyphosphanes, polyphosphides, and also in Hittorf's phosphorus led to the statement that among isomeric structures those with the largest number of five-membered rings are favored.[4] These and other "Baudler rules" which have been verified by already known structures were recently refined and extended by Böcker and Häser.[1, 6] Based on these rules they introduced a very helpful symbolic notation[7] and a chemical heuristic for the systematic deduction of covalent phosphorus frameworks in polycyclic phosphanes, phosphorus-rich polyphosphides, and allotropes of phosphorus (with the exception of black phosphorus). The authors did not confine themselves to deducing experimentally established structural units but also designed hypothetical phosphorus structures not yet represented by already known structures. They discussed the existence of those structures only known on paper, including macromolecular forms of elemental phosphorus, on the basis of energetic stabilities calculated by ab initio techniques (SCF/SVP level; relative equilibrium energies given in kJ mol$(P_4)^{-1}$ as compared with molecular

phosphorus P_4).[1] The quality of calculation techniques employed was tested by comparing the theoretically calculated energies, bond lengths, and bond angles with the experimentally determined values for Hittorf's phosphorus. The agreement is so convincing that one can also expect that the analogous calculations of the energies of experimentally not yet established structures which could be possible modifications of red phosphorus should also be very reliable (relative stabilities: $E_{theor.} = -61\ kJ\,mol(P_4)^{-1}$; $E_{exp.} = -62\ kJ\,mol(P_4)^{-1}$). In Hittorf's

$^{2}_{\infty}\{]P2[P8]P2[P9]\}$ **1**

phosphorus **1** (notation of Böcker and Häser[1, 7]), P_8 and P_9 clusters are connected by P_2 units through formal [2+3]cycloaddition, forming tubular strands (Fig. 1a). These tubes are

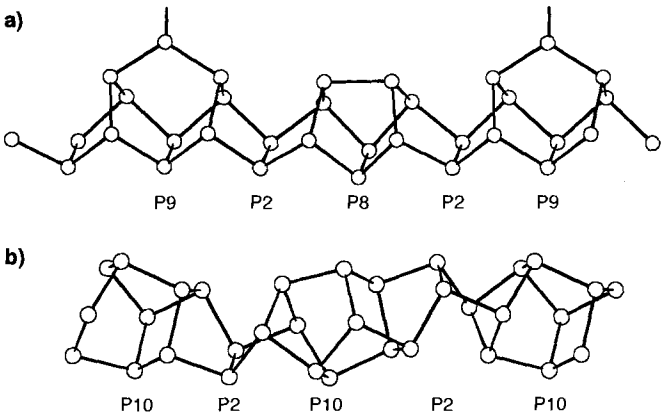

Fig. 1. Phosphorus strands $^{1}_{\infty}\{]P2[P8]P2[P9]\}$ (a) and $^{1}_{\infty}\{]P2[P10]\}$ (b). The notations P2, P8, P9, and P10 characterize phosphorus clusters (basic units) [7]. P_2 units connect P_8, P_9, and P_{10} clusters through formal [2+3]cycloaddition. Six- and predominantly five-membered rings exist in both types of chains.

oriented *perpendicular* to each other and cross-linked to the double layers of Hittorf's[3] phosphorus by the free valences of one of the phosphorus atoms of the P_9 units (according to Baudler and Glinka a formal condensation!).

Among the polymeric phosphorus structures with the highest calculated, relative stabilities are **2**, in which pairs of tubular strands of the same type as in Hittorf's phosphorus (Fig. 1a) are linked *parallel* ($E_{theor.} = -62\ kJ\,mol(P_4)^{-1}$), and **3**, in which P_{10} clusters are connected by P_2 units, once again through a formal [2+3]cycloaddition, forming polymeric helical tubes (Fig. 1b) without free valences suitable for further cross-links ($E_{theor.} = -61\ kJ\,mol(P_4)^{-1}$).

$^{1}_{\infty}\{(]P2[P8]P2[P9])_2\}$ **2**

$^{1}_{\infty}\{]P2[P10]\}$ **3**

The proposed structural unit **3** is a fascinating model for the structure of amorphous red phosphorus: calculated radial distribution functions agree very well with those derived from X-ray and neutron diffraction experiments on amorphous red phosphorus.[1, 3, 8] Furthermore, the existence of the chain **3** was established experimentally. Recently Pfitzner and Freudenthaler isolated the crystalline compound $(CuI)_3P_{12}$ in connection with attempts to synthesize new Cu^I ionic conductors.[2] Two nearly identical, crystallographically independent helical strands **3** are embedded into a matrix of CuI layers. Both chains differ mainly with respect to their Cu^I environments. The coordination of phosphorus to Cu^I apparently has no significant influence on the structure of the phosphorus framework and the P–P bond lengths. The Cu^I/I^- system builds up very flexible CuI frameworks, which serve not only as adaptable host lattices for uncharged molecules but also for anions, as long as there is an excess of Cu^I (for example $^{1}_{\infty}[P^{-}_{15}]$ in $Cu_3I_2P_{15}$[9]), and for cations with different shapes and sizes in case of excess I^-.[10, 11] The CuI host lattices in combination with Cu^I–P interactions promote the development of an ordered structure with helix **3** as a subunit, whereas unfavorable packing conditions seem to prevent the crystallization of a corresponding pure allotropic phosphorus modification. The CuI sublattice of $(CuI)_2P_3$ stabilizes chains of type **4**.[12] The structure of **4** contains not only five- and six-membered rings but also energetically unfavored four-membered rings. Accordingly, the ab initio calculations show a lower stability for this atomic arrangement than for those in structures **1**, **2**, and **3** with only five- and six-membered rings ($E_{theor.} = -48\ kJ\,mol(P_4)^{-1}$).[1]

$^{1}_{\infty}\{]P4(4)[P8]\}$ **4**

Missing steps to a definitive proof of the structure of amorphous red phosphorus are the synthesis of **3** by leaching CuI out of $(CuI)_3P_{12}$, the isolation of **3** from red phosphorus by reaction with CuI, and conclusive solid-state ^{31}P NMR spectroscopic investigations of the reaction products. If these experiments can be carried out successfully, the last sceptics should be convinced that $^{1}_{\infty}\{]P2[P10]\}$ strands are an essential component of amorphous red phosphorus.

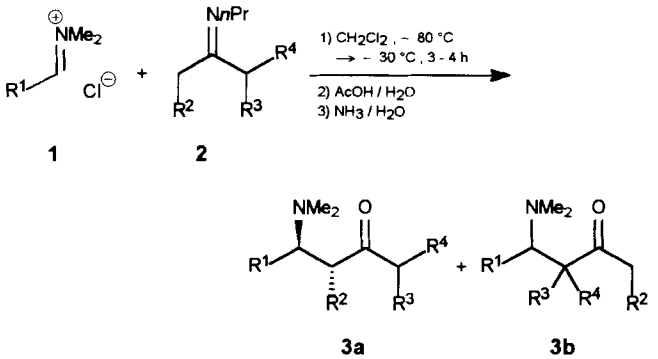
Regio- and Diastereoselective Synthesis of β-Amino Ketones by Addition of Imines to Iminium Salts**

Michael Arend and Nikolaus Risch*

β-Amino ketones (Mannich bases) and their derivatives have a wide range of applications, for example in drugs, crop protection agents, and as general synthetic building blocks.[2] However, the Mannich reaction, the classical method of synthesizing β-amino ketones is fraught with many serious disadvantages—drastic reaction conditions, formation of undesired side products, little or no stereo- or regioselectivity, etc.[2] Numerous attempts have been made to overcome these limitations owing to the importance of the products.[3] Therefore, methods of stereoselective aminomethylation[4] and aminoalkylation[1, 5] are currently active areas of research.

In addition to controlling stereoselectivity, directing regioselectivity is a central, frequently unsolved problem in modern chemistry. Many attempts have been made to improve the regioselectivity of aminomethylation[3, 6] and thus simultaneously provide a versatile method for the regioselective functionalization of ketones (generation of Michael acceptors; the amino group can also be substituted readily).[2] The most important regioselective variants of the Mannich reaction are the reactions of methylene iminium salts with ketones,[6a] enolates, and enol ethers.[6b] However, these reactions either require tedious procedures, or their applications and efficiency have only limited known scope.

In comparison, the reaction of preformed iminium salts **1**[7] with imines **2** (Scheme 1) has fundamental advantages. The starting materials can be prepared readily from economical reagents or, like the methylene iminium salt **1** (R^1 = H), are commercially available. The preliminary, laborious regioselective synthesis of enolates or enol ethers is not necessary. This is not only a simple and convenient method, it also has a wide range of applications. The Mannich bases are prepared under mild conditions and obtained generally in analytically pure form in good yields and with excellent regioselectivities. In contrast to all other approaches, our method can also be used for regioselective amino*alkyl*ation, which is highly diastereoselective as well (Table 1).



Scheme 1. Regio- and diastereoselective aminoalkylation of imines **2** with iminium salts **1**.

Table 1. Regio- and diastereoselective aminoalkylation of imines **2** with iminium salts **1**.

Entry	R^1	R^2	R^3	R^4	**3a**:**3b** [a]	Yield [%]

11	H	Ph	Me	H	≥99: ≤1	78
12	Ph	Ph	Me	H	81: 19	68

[a] The ratios of regio- and diastereoisomers were determined by ^1H and ^{13}C NMR spectroscopy. Unless specified otherwise the products are diastereomerically pure (≥ 99% *ds*). [b] Two diastereomers (*cis*/*trans* diastereomers relative to the α and α′ centers) are obtained in a ratio of 63:37. The relative configurations of the diastereomers could not yet be determined. [c] Two diastereomers are obtained in a ratio of 7:3; these are presumably *cis*/*trans* diastereomers relative to the α and α′ centers (cf. footnote [b]). The relative configurations of the diastereomers could not yet be determined. [d] If the reaction is conducted at 25 °C (2 h), regioisomeric products are obtained with a ratio (**3a**:**3b**) of ≥99: ≤1 (59% yield). [e] If the reaction is conducted at 25 °C (2 h), regioisomeric products are obtained with a ratio (**3a**:**3b**) of 73:27 (62% yield). Similar results were obtained in THF (73:27, 61%) and MeCN (74:26, 60%), and when the iminium tetrachloroaluminate salt was used instead of the chloride salt (76:24, 59%).

In analogy to the mechanisms previously proposed for reactions of imines with other electrophiles,[8] we assume that not the imines but rather the corresponding tautomeric secondary enamines react with the iminium salts. This hypothesis is supported by the finding that identical products are obtained regardless of whether the benzylidene iminium salt **1** with R^1 = Ph is treated with imines **2** (Table 1, Entries 1,2) or with the corresponding tertiary enamines (pyrrolidine derivatives).[1] Typically the reaction of iminium salts **1** (R^1 = alkyl, aryl) with enamines yields exclusively the *anti* Mannich bases.[1] For this reason and also based on NMR spectroscopic data, we have assigned the *anti* configuration to all the β-amino ketones formed in the reaction of **1** (R^1 = Ph) with **2**.

This reaction differs from related reactions, for example the alkylation of imines with Michael acceptors[8] and the aminomethylation of ketones with methylene iminium salts,[6a] in a number of respects. Whereas in these other reactions the more highly substituted α-C atom is generally attacked, in our

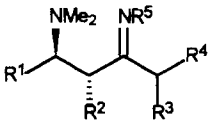
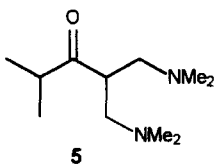
[**] Stereoselective Synthesis of Mannich Bases, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 2: ref. [1].

case the iminium salt attacks the sterically less hindered α position of the imine with high regioselectivity. Good regioselectivities are achieved even when the two α-C atoms are only marginally different (Table 1, cf. Entries 7 and 9, 8 and 10). Within the limits of our studies, the solvent, the counterion of the iminium salt, and the reaction temperature do not have a significant effect on the regio- and diastereoselectivity of the reaction (Table 1, footnotes [d] and [e]). The regioselectivity reversed, as expected, only when electronics dictate that the sterically more hindered tautomeric enamine is virtually the exclusive intermediate (Table 1, Entries 11, 12).



4

Besides these advantages the reaction of imines with iminium salts offers a list of notable prospects. The initially formed imines **4**, for example, are interesting synthetic building blocks, which may allow easy access to many valuable products (e.g. β-lactams and 1,3-diamines). Preliminary experiments also indicate that Mannich bases such as **5** can be obtained by bisaminomethylation with high regioselectivities and in good yields. Moreover, based on the excellent results achieved in the alkylation of chiral imines with Michael acceptors,[8] we expect our method to be suitable for the enantioselective synthesis of β-amino ketones.



5

Experimental Procedure

3a: The reactions were conducted in water-free apparatus under argon. A solution of imine **2** (2.5 mmol) in anhydrous CH_2Cl_2 (2.5 mL) was cooled to −80 °C. The iminium salt **1** (2.5 mmol) was added in one portion and the reaction mixture was stirred for 3–4 h, during which the temperature increased to about −30 °C. To obtain good results in every case the reaction mixture should be stored for about 15 h at this temperature in a freezer before the workup. The reaction mixture was treated with aqueous AcOH solution (2 N, 5 mL) and Et_2O (50 mL), and stirred at 25 °C for 3–4 h. Then HCl (6 N, 5 mL) was added and the mixture stirred a further 10 min. The organic phase was decanted off and the aqueous phase washed with Et_2O (2 × 50 mL). The aqueous phase was finally treated with dilute NH_3 solution (25 mL, 25% NH_3:H_2O = 1:4) with vigorous stirring and extracted with Et_2O (3 × 50 mL, 1 min each). The combined organic phases were dried over Na_2SO_4 and the solvent removed on a rotary evaporator without heating.

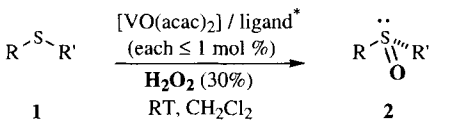
Asymmetric Sulfide Oxidation with Vanadium Catalysts and H_2O_2**

Carsten Bolm* and Frank Bienewald

The evaluation of asymmetric catalytic reactions often fails to consider practical criteria important for applications in large-scale reactions.[1] Generally, attention is focused on the enantioselectivity and not on the practicability of the reaction or the catalytic efficiency, which is measured as the turnover number per time. There are only few enantioselective catalytic reactions that meet the expectations of the users and are therefore employed in syntheses by people both outside and inside the research groups originally involved in their development.[2] We report herein a method for the asymmetric oxidation of sulfides,[3] which provides optically active sulfoxides with *ee* values up to 85%. Moreover, this method proceeds under very simple reaction conditions (room temperature, exclusion of air and humidity unnecessary) and can be performed with H_2O_2, a cheap and safe oxidizing agent, as well as with a readily accessible chiral vanadium catalyst (≤ 1 mol%) [Eq.(a)].



1 → **2** (a)

Enantioselective oxidations of aryl alkyl sulfides with vanadium complexes were reported by Fujita and co-workers as early as 1986. Using 10 mol% of the vanadium–salen catalyst **3** and cumyl hydroperoxide as the oxygen source, they obtained enantioselectivites of up to 40% *ee*.[4–6] The enantioselectivities reported by Fujita et al. are lower than those obtained when using

the modified Sharpless reagent [tartrate, $[Ti(OiPr)_4]$, H_2O, organic hydroperoxide],[7] which was introduced by Kagan et al. for the oxidation of sulfides. Nevertheless, the vanadium-catalyzed transformation has the advantage of requiring a smaller amount of the carrier of chiral information (metal and ligand).

We have now found that sulfides can be oxidized rapidly and efficiently into optically active sulfoxides (ee_{max} = 85%) by us-

ing a catalyst formed in situ from $[VO(acac)_2]$ (acac = acetylacetonate) and ligands of type **4**.[8, 9] This catalytic reaction is remarkable for the following reasons: 1) Aqueous H_2O_2 (30%, 1.1 equivalents) is the most efficient oxidizing agent. Other vanadium-catalyzed reactions have been reported, which use *tert*-butylhydroperoxide as the oxygen source. Those catalytic reactions, however, are often inhibited by the presence of water. 2) The reaction conditions are unusually simple. The oxidation maybe performed in open reaction vessels, since atmospheric oxygen and water do not affect the outcome. 3) The catalytic system is extremely efficient and catalyzes the sulfoxide formation in concentrations of 0.01 mol% of the complex. When 1 mol% of the catalyst is used, the reaction becomes very rapid and vigorous; for that reason, the oxidizing agent has to be added slowly, because an increase of the reaction temperature results in the formation of the respective sulfone. 4) The use of the very simple ligands readily available from salicylaldehydes and amino alcohols gives rise to relatively high *ee* values (Table 1). 5) The reaction is ligand-accelerated,[10] and the enantioselectivity is not or only slightly affected by the presence of achiral vanadium species (that is, excess $[VO(acac)_2]$). A ligand/vanadium ratio of 1:1 is therefore sufficient to obtain good asymmetric induction.

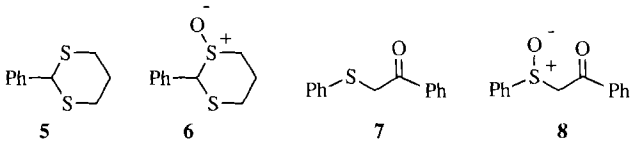
Table 1. Catalytic enantioselective oxidation of sulfides with H_2O_2 and 1 mol% of $[VO(acac)_2]$ as well as 1.5 mol% of the ligand.

No.	Ligand	Sulfide	Sulfoxide	Yield[%]	*ee*[%]	Config.[a]
1	**4a**	Ph-S-Me	**2a**	94	70	(*S*)-(−)
2	**4b**	Ph-S-Me	**2a**	73	59	(*S*)-(−)
3	**4c**	Ph-S-Me	**2a**	54	56	(*S*)-(−)
4	**4d**	Ph-S-Me	**2a**	88	50	(*S*)-(−)
5	**4a**	Ph-S-*i*Pr	**2b**	64	62	(*S*)-(−)
6	**4a**	Ph-S-*n*-$C_{10}H_{21}$	**2c**	77	53	(*S*)-(−)[b]
7	**4a**	*p*$NO_2C_6H_4$-S-Me	**2d**	55	63	(*S*)-(−)[b]
8	**4a**	*t*Bu-S-CH_2Ph	**2e**	91	65	(−)[b]
9	**4a**	**5**	**6**	77	76	(−)[b]
10	**4b**	**5**	**6**	84	85	(−)[b]
11	**4b**	**7**	**8**	65	57	(−)[b]

[a] The *ee* values were determined by HPLC on a chiral phase; the absolute configurations were obtained from optical rotations (**2a** in EtOH; **2b**, **6** in $CHCl_3$; **2c**–**e**, **8** in acetone) and by comparing the obtained data with the literature values. [b] The absolute configuration of the products was not determined unequivocally and is, in some cases, based on analogous systems.

The influence of the ligand structure on the product configuration and the obtained enantioselectivity has been thoroughly studied in the oxidation of methyl phenyl sulfide (**1a**) (Table 1). Both factors are primarily determined by the steric demand of the imino alcohol substituent and the stereoelectronic properties of the aryl substituent of the ligand. The highest enantioselectivities were obtained with ligands derived from *tert*-leucinol. The (*S*) enantiomer yielded the (*S*)-configurated product in excess. A sterically demanding substituent, such as the *tert*-butyl group, at C-6 of the aryl group generally enhanced the enantioselectivity. Ligands containing large silyl substituents or simply a hydrogen atom at the same position (**4c** and **4d**, respectively) furnished the corresponding sulfoxides with lower *ee* values. A significant improvement in the enantioselectivity was obtained with *p*-nitro-substituted ligands.

The chiral vanadium/H_2O_2 catalyst system oxidizes a variety of structurally different sulfides enantioselectively (Table 1). Aryl alkyl sulfides gave the corresponding sulfoxides in 53–70% *ee*. The best result was obtained in the case of thioacetal **5**. When ligand **4b** was used, the *trans*-sulfoxide **6** was formed exclusively in 85% *ee*, whereas the catalyst containing the nitro-substituted ligand **4a** resulted in a lower enantioselectivity (77% yield, 76% *ee*). Alkyl benzyl sulfides as well as functionalized sulfides (entries 8 and 11) can also be converted into optically active sulfoxides.



5 **6** **7** **8**

Sulfones are formed only in low quantities when using the vanadium complex described here.[11] From the reactivity difference between sulfide **1** and sulfoxide **2** it is deduced that the *ee* value of **2** does not arise from a selectivity enhancement caused by kinetic resolution of the chiral sulfoxide,[12] but is the direct result of the enantioselective oxidation.[13] This conclusion is further supported by the fact that the enantiomeric excess of **2a** does not change significantly during the reaction.

Since we did not observe chiral amplification,[14] we assume that the catalyst contains only one ligand in the configuration-determining step. ^{51}V NMR spectroscopic investigations of mixtures containing $[VO(acac)_2]$, the ligand, and H_2O_2 showed that several species of vanadium with higher oxidation states are formed. Consequently, vanadium(v) compounds such as $VOCl_3$ or V_2O_5 can also be used as catalyst precursors.[15] Attempts to replace vanadium by niobium in the oxidation of methyl phenyl sulfide (1 mol% of $NbCl_5$/**4b**, 1.1 equivalents of H_2O_2, room temperature, 20 h) resulted in the formation of the corresponding sulfoxide **2a** in a yield of 86% but in only 7% *ee*.

Investigations are currently underway to expand the scope of this reaction[16] and to determine which vanadium species[17, 18] is responsible for the obtained enantioselectivities and the reaction behavior.

Experimental Procedure

$[VO(acac)_2]$ (2.6 mg, 0.01 mmol) and the ligand (0.015 mmol) were dissolved in a test tube in dichloromethane (2 mL), and the solution was stirred for 5 min. After the additon of the sulfide (1 mmol) and the dropwise addition of 30% H_2O_2 (1.1 mmol), the mixture was stirred for 16 h at ambient temperature (approximately 200 r min^{-1}). The aqueous layer was separated off, and the solvent removed in vacuo from the remaining mixture. The crude product was purified by chromatography on silica gel and—if necessary—also by Kugelrohr distillation under high vacuum. The enantioselectivities were determined by chiral HPLC (Daicel UV detector (254 nm), flow rate 0.5 mL min^{-1}). Retention times [min]: (*R*)-**2a** 21.4, (*S*)-**2a** 26.5 (Chiralcel OD, hexane/2-propanol 9/1); (*R*)-**2b** 20.6, (*S*)-**2b** 24.7 (Chiralcel OD-H, hexane/2-propanol 96/4); (+)-**2c** (acetone) 13.5, (−)-**2c** 16.1 (Chiralcel OD-H, hexane/2-propanol 9/1); (+)-**2d** (acetone) 38.8, (−)-**2d** 44.9 (Chiralcel OJ, hexane/2-propanol 7/3); (−)-**2e** (acetone) 22.6, (+)-**2e** 31.4 (Chiralcel OD, hexane/2-propanol 9/1); (−)-**6** ($CHCl_3$) 15.0, (+)-**6** 34.5 (Chiralcel OD, hexane/2-propanol 7/3); (+)-**8** (acetone) 38.6, (−)-**8** 55.6 (Chiralcel OD, hexane/2-propanol 9/1).

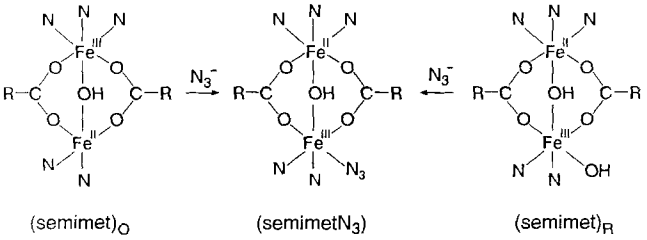
The First μ(OH)-Bridged Model Complex for the Mixed-Valent $Fe^{II}Fe^{III}$ Form of Hemerythrin**

Ursula Bossek, Helga Hummel, Thomas Weyhermüller, Eckhard Bill, and Karl Wieghardt*

There is at least one mixed-valent $Fe^{II}Fe^{III}$ form known for the iron-containing metalloproteins hemerythrin, ribonucleotide reductase, purple acid phosphatase, and methanemonooxygenase.[1] The electronic structures of the active dimetallic centers have been well characterized with spectroscopic methods (UV/Vis, ESR and, to some extent, Mössbauer spectroscopy). In the case of hemerythrin three such species have been reported; they differ in the coordination at the two iron centers (Scheme 1).[2] Recent ENDOR and ESEEM studies (ENDOR = Electron Nuclear Double Resonance, ESEEM = Electron Spin Echo Envelope Modulation) on the mixed-valent forms of hemerythrin and methanemonooxygenase have detected the presence of a bridging OH group between the Fe^{II} and Fe^{III} ions.[3]



Scheme 1. Three mixed-valent species of semimethemerythrin (semimet).

Although there are good model complexes for the completely reduced Fe^{II}_2 and oxidized Fe^{III}_2 species containing these active dimetallic centers, no mixed-valent $Fe^{II}Fe^{III}$ complexes with a bridging OH group have been reported to date. On the other hand, $Fe^{II}Fe^{III}$ complexes with a bridging phenoxy group are well known.[4] In these *redox-stable* complexes the valences are frequently localized (class I or II; even at 300 K); this causes a weak, intramolecular antiferromagnetic coupling between the high-spin Fe^{II} (d^6) ion and the high-spin Fe^{III}(d^5) ion, which results in an ESR-active $S_t = 1/2$ ground state. A probably μ-oxo bridged $Fe^{II}Fe^{III}$ complex was characterized in solution by ESR spectroscopy.[5]

We have now discovered that the reaction of 1,4,7-trimethyl-1,4,7-triazacyclononane (L) with $Fe^{II}(ClO_4)_2 \cdot 6H_2O$ and pivalic acid (piv) gives a transparent, light green solution in acetone under argon. The color quickly turns blue-violet on controlled exposure to air. When kept for a prolonged period at $-18\,^{\circ}C$ we obtained blue-violet crystals of **1**-$(ClO_4)_2$. If a solution of **1** was purged with air, or oxidized by addition of H_2O_2, we obtained an orange solution from which orange crystals of **2**-$(ClO_4)_2$ were isolated.

$[LFe^{III}(\mu\text{-}OH)(\mu\text{-}piv)_2Fe^{II}L](ClO_4)_2$ **1**-$(ClO_4)_2$

$[L_2Fe^{III}_2(\mu\text{-}O)(\mu\text{-}piv)_2](ClO_4)_2$ **2**-$(ClO_4)_2$

[**] We are grateful to the Fonds der Chemischen Industrie for support of this work.

The X-ray crystal structure analyses of **1** and **2**[6] prove the dinuclear nature of these complexes; both salts crystallize in the space group $P2_1/n$ with very similar unit cell dimensions; Figure 1 shows the structure of **1**. The corresponding Fe–X bond lengths in **1** at the two iron atoms, Fe(1) and Fe(2), differ only

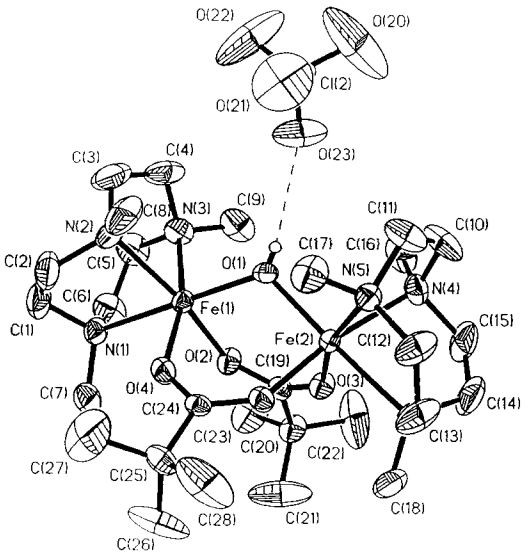

Fig. 1. Structure of **1** with one ClO_4^- counterion; the structure of **2** is very similar and is not represented. Selected distances [Å] and angles [°] (the corresponding values for **2** are given in parentheses): Fe(1)-N(1) 2.254(5) (2.269(7)), Fe(1)-N(2) 2.215(6) (2.188(9)), Fe(1)-N(3) 2.216(6) (2.204(9)), Fe(1)-O(1) 2.005(5) (1.800(5)), Fe(1)-O(2) 2.040(4) (2.025(6)), Fe(1)-O(4) 2.057(4) (2.026(6)), Fe(1)···Fe(2) 3.400(3) (3.123(2)), O(1)···O(23) 2.961(5) (4.097(7)), Fe(2)-N(4) 2.186(5) (2.177(7)), Fe(2)-N(5) 2.236(4) (2.212(7)), Fe(2)-N(6) 2.248(5) (2.281(8)), Fe(2)-O(1) 1.961(5) (1.788(6)), Fe(2)-O(3) 2.020(4) (2.033(6)), Fe(2)-O(5) 2.004(4) (2.021(6)); Fe(1)-O(1)-Fe(2) 118.1(2) (121.0(3)).

very slightly; in the cation of **2**, they are of equal length. The bent Fe^{II}-OH-Fe^{III} unit is not quite symmetrical: one $Fe-O_{hydroxo}$ distance is longer than the other. The valences of the Fe ions are almost localized in the solid state (class II according to Robin and Day): Fe(1) is Fe^{II} whilst Fe(2) is an Fe^{III} ion. One O atom of the ClO_4^- counterion forms a weak O–H···O hydrogen bond with the OH bridge of **1**; in **2** there is no such OH bridge. The structure of **2** is very similar to the analogous model complexes with a bent $Fe_2^{III}(\mu\text{-O})$ structural unit.[2]

The UV/Vis spectrum of **2** in acetonitrile exhibits a series of absorption maxima in the visible region typical for metazidohemerythrin and $Fe_2^{III}(\mu\text{-O})$ model complexes with bent Fe^{III}-O-Fe^{III} units.[2f] On the other hand, deoxyhemerythrin and its yellow model complex $[L_2Fe_2^{II}(\mu\text{-OH})(\mu\text{-ac})_2](ClO_4)\cdot H_2O$[5, 7] show d–d transitions of only very low intensity at 928 nm ($\varepsilon = 10\ L\,mol^{-1}\,cm^{-1}$) and 1100 nm (sh) ($7\ L\,mol^{-1}\,cm^{-1}$). The UV/Vis spectrum of **1** in anhydrous acetonitrile shows an intervalence band at 1350 nm ($138\ L\,mol^{-1}\,cm^{-1}$) along with a few bands of greater intensity in the visible region, which, in contrast to the μ-phenoxy-bridged $Fe^{II}Fe^{III}$ complexes, cannot be assigned to phenolate → Fe^{III} charge-transfer bands. In the spectrum of semimethemerythrin (N_3), two maxima in the NIR region were found at 910 and 1190 nm.[8] The latter was assigned to an intervalence band.

Measurements of the temperature dependence of the susceptibility[9] of solid samples of **2** showed a strong ($J = -111\ cm^{-1}$) intramolecular antiferromagnetic coupling (Fig. 2); this coupling is weaker for **1** ($J = -12.9\ cm^{-1}$). In good agreement with this, a coupling of $J \approx -15\ cm^{-1}$ was determined for

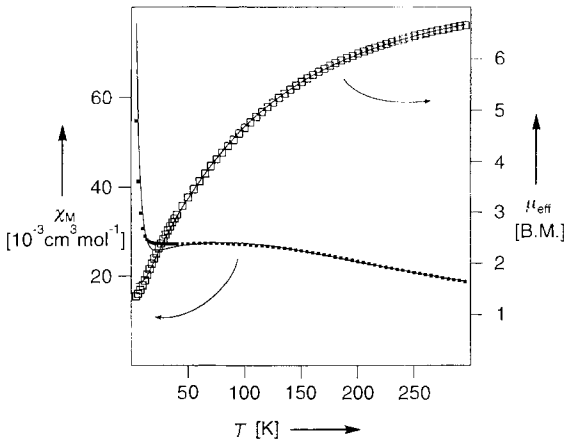

Fig. 2. Temperature dependence of the molar susceptibility and of the magnetic moment of solid **1**. The solid lines repesent the results of the fitting calculations [9].

semimethemerythrin (N_3),[10] whilst it is noticeably smaller for phenoxy-bridged complexes ($J \approx -3$ – $-7\ cm^{-1}$). Therefore, the ground state of complex **2** is diamagnetic with $S_t = 0$ and for complex **1** it is paramagnetic with $S_t = 1/2$.

The X-band ESR spectrum of the cation in **1** in acetonitrile at 10 K confirms the $S_t = 1/2$ ground state. The signal is rhombic with $g_1 = 1.95$, $g_2 = 1.52$, $g_3 = 1.43$ (from a simulation). Typically for mixed-valent forms of the metalloproteins and for all of the $Fe^{II}Fe^{III}$ model complexes known to date, g values are smaller than 2; in the spectrum of semimethemerythrin (N_3) the rhombic signal has g values of 1.92, 1.82, 1.50.[10]

The valences in **1** also appear to be essentially localized on the time scale of Mössbauer spectroscopy ($\approx 10^{-7}$ s). The zero-field spectrum at 300 K shows two quadrupole doublets of almost equal intensity with isomeric shifts relative to α-Fe at 25 °C of $\delta = 0.80(2)\ mm\,s^{-1}$ and $0.55(2)\ mm\,s^{-1}$ and corresponding quadrupole splittings of $\Delta E_Q = 1.12(1)\ mm\,s^{-1}$ and $0.68(1)\ mm\,s^{-1}$, respectively. The former is typical of a high-spin Fe^{II} ion in an octahedral environment, whilst the latter can be assigned to a high-spin Fe^{III} ion likewise in an octahedral environment. The Mössbauer spectrum of solid **2** at 4.2 K shows only one quadrupole doublet; values of $\delta = 0.48(1)\ mm\,s^{-1}$ and $\Delta E_Q = 1.54(1)\ mm\,s^{-1}$ were determined.

The natural form of hemerythrin consists of eight identical subunits, each of which contains an active diiron center (a total of 16 Fe). Wilkins et al.[1b] found that the forms of semimethemerythrin containing eight $Fe^{II}Fe^{III}$ subunits are unstable and disproportionate[10] to produce four homovalent Fe_2^{II} and four Fe_2^{III} subunits [Eq. (a)]. From the kinetic point of view, this is a first-order process.

$$[Fe^{II}Fe^{III}]_8 \longrightarrow [Fe_2^{II}]_4[Fe_2^{III}]_4 \qquad (a)$$

A striking feature is that O_2-free, blue-violet solutions of **1**-$(ClO_4)_2$ in anhydrous aceto- or butyronitrile are only stable for 10–30 min at 25 °C, they then suddenly change color to orange within 5 min. This process can be followed by spectrophotometry as a function of time (Fig. 3). At first the spectrum of **1** is observed, it remains practically unchanged for about 30 min. The final spectrum after about 50 min corresponds to pure **2**. Quantitative analysis of this spectrum shows that exactly half of the original **1** was transformed into **2**. The other half must then be present as the very pale yellow $[L_2Fe_2^{II}(\mu\text{-OH})(\mu\text{-piv})_2]^+$ ion. That this is, in fact, the case was proved by aerating the above reaction solution after the anaerobic color change; the position

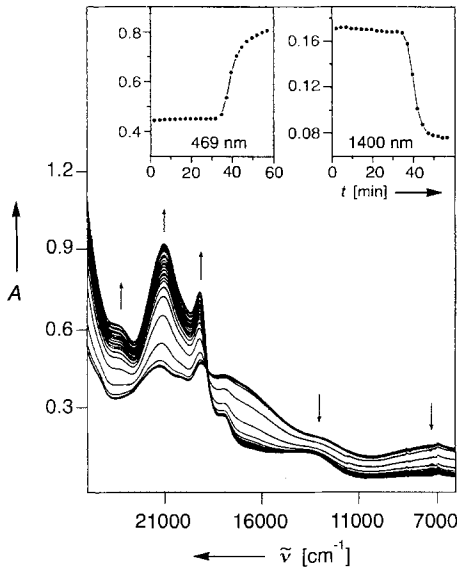

Fig. 3. Vis spectrum of **1** (1.1×10^{-3} M) in dry CH_3CN at 298 K and under Ar as a function of time (spectra were recorded every 2.5 min). The insets show the absorption at 469 nm and at 1400 nm as a function of time.

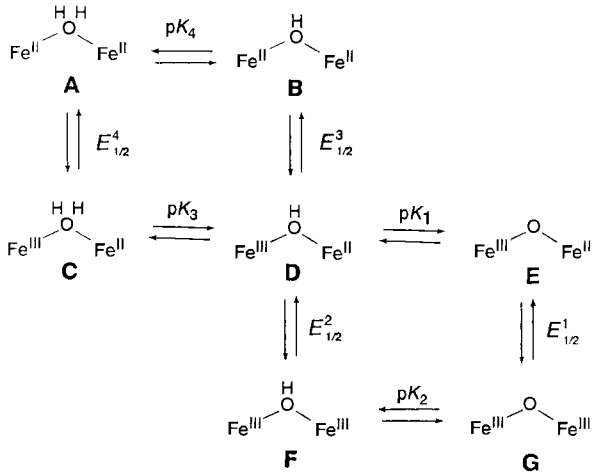
of the maxima in the spectrum did not change, but the intensity doubled. Thus anaerobic disproportionation of **1** and subsequent oxidation with O_2 yields **2** quantitatively.

The long induction period for the disproportionation of **1** under anaerobic conditions indicates that the reaction is autocatalytic. As shown in Scheme 2, **1** (**D** in Scheme 2) in solution



Scheme 2. Possible protonated and redox species of the diiron centers in hemerythrin and in the model complexes.

can be protonated on the OH-bridge to give the μ-aqua complex **C**, or it can be deprotonated to the μ-oxo form **E**.[11] There is a pH-dependent equilibrium between the complexes **C**, **D**, and **E**. The more protonated mixed-valent species is a stronger oxidizing agent than the less protonated species;[5] this results in intermolecular electron-transfer between the more or less highly protonated species as given in Equations (b)–(d).

$$\mathbf{D} + \mathbf{C} \longrightarrow \mathbf{F} + \mathbf{A} \quad \text{(b)}$$

$$\mathbf{E} + \mathbf{D} \longrightarrow \mathbf{G} + \mathbf{B} \quad \text{(c)}$$

$$\mathbf{C} + \mathbf{E} \longrightarrow \mathbf{A} + \mathbf{G} \quad \text{(d)}$$

Because both product **F** and **A** are strong acids, the protons that are thus set free during the course of the disproportionation can protonate **D**. In this way the relative concentration of **C** increases: Thus, the disproportionation is accelerated by autocatalysis. This mechanism is supported by the observation that not only the addition of acid ($HClO_4$) but also of base (triethylamine) to the CH_3CN solution of **1**-$(ClO_4)_2$ drastically shortens the period of induction. Futhermore, the orange solution containing 50% of **2** is obtained during dissolution of **1**-$(ClO_4)_2$ in protic solvents such as water, methanol, or ethanol.

Therefore, complex **1** is not only a good structural model for the mixed-valent active center in semimethemerythrin (N_3) as it has a very similar electronic structure, but it also shows similar redox reactivity. Thus, **1** is also a functional model. With complex **1**, along with $[L_2Fe^{II}_2(\mu\text{-OH})(\mu\text{-acetate})_2]^{+}$ [5, 7] and $[L_2Fe^{III}_2(\mu\text{-O})(\mu\text{-acetate})_2]^{2+}$ [5, 7], there is now a series of very good models available for all the redox states of hemerythrin. The extent to which the structural and electronic relationships in the active center of the metalloprotein is reproduced by these complexes is very gratifying.

Experimental Procedure

1-$(ClO_4)_2$: A light green solution of 1,4,7-trimethyl-1,4,7-triazacyclononane (L, 0.5 g), purged with argon, 0.4 g pivalic acid, and 1.0 g $Fe^{II}(ClO_4)_2 \cdot 6H_2O$ in 40 mL acetone at 25 °C was carefully purged with air for 5 min until the color changed to blue-violet. This solution was subsequently purged with argon until it was air-free and then stored in a sealed vessel at −18 °C for 2 d. Blue-violet crystals of **1**-$(ClO_4)_2$ were isolated in about 70% yield (0.85 g). Single crystals were obtained by slow evaporation of the reaction solution in a stream of argon. $C_{28}H_{61}Cl_2N_6O_{13}Fe_2$ (872.4 g mol^{-1}); elemental analysis: found C 38.3, H 7.3, N 9.6%; calcd. C 38.5, H 7.0, N 9.6%. UV/Vis (CH_3CN): λmax (ε) = 346 (3.0×10^3), 413(sh) (≈380), 472 (363), 496(sh) (342), 526 (404), 561 (417), ≈800(sh) (≈200), 1350 nm (138 L mol^{-1} cm^{-1}); MS(FAB): m/z = 772.3 $[M - (ClO_4)]^+$.

2-$(ClO_4)_2$: To a solution of 0.5 g L and 0.4 g pivalic acid in 40 mL acetone was added 1.0 g $Fe^{II}(ClO_4)_2 \cdot 6H_2O$. The mixture was vigorously stirred at 20 °C for 30 min in air (alternatively 30% H_2O_2 (2 mL) was added) until the solution became a transparent orange. On slow evaporation of the reaction mixture in a stream of air, orange crystals of **2**-$(ClO_4)_2$ were isolated in about 70% yield. Single crystals were obtained from a saturated acetone solution of **2**-$(ClO_4)_2$. $C_{28}H_{60}Cl_2N_6O_{13}Fe_2$ (871.4 g mol^{-1}); elemental analysis: found C 38.4, H 7.1, N 9.5%; calcd. C 38.6, H 6.9, N 9.6%. UV/Vis (CH_3CN) λ_{max} (ε) = 248 (15.9×10^3), 355 (7.7×10^3), 430(sh) (945), 475 (1406), 520 (1.1×10^3), 560(sh) (286), 729 nm (167 L mol^{-1} cm^{-1}); MS(FAB): m/z 771.2 $[M - (ClO_4)]^+$.

[9] The temperature dependence of the molar magnetic susceptibility was measured with a SQUID-magnetometer (Quantum Design) in the range 2–300 K on solid samples of **1** and **2**. After diamagnetic correction of the raw data, fitting calculations were carried out using the isotropic Heisenberg-Dirac-van Vleck model ($H = -2JS_1 \cdot S_2$). The fitting shown in Figure 2 for **1** was obtained with the following parameters: $S_1 = 5/2$, $S_2 = 2$, $J = -12.9(\pm 0.5)\ cm^{-1}$, $g_1 = 2.0$ (fixed), $g_2 = 2.16$, and zero-field splitting parameters $D_1 = D_2 = 0$ (fixed); there was also a small paramagnetic impurity with $S = 5/2$ of 0.6%. For **2** ($S_1 = S_2 = 5/2$, $g_1 = g_2 = 2.0$, $D_1 = D_2 = 0$ (fixed)), these calculations gave a coupling constant of $J = -111(\pm 3)\ cm^{-1}$.

Synthesis and Structures of Triamino- and Tetraaminosilanes**

Karsten Wraage, Antje Künzel, Mathias Noltemeyer, Hans-Georg Schmidt, and Herbert W. Roesky*

Dedicated to Professor Richard Neidlein on the occasion of his 65th birthday

In 1993 P. P. Power et al. described the first triaminosilane containing a carbon-bound organic substituent; this had the composition $RSi(NH_2)_3$ ($R = (C_6H_5)_3C_6H_2$).[1] To date further reactions of this compound have not been reported. In light of our experience with valence-isoelectronic silanetriols,[2, 3] we were interested in triamino- and tetraaminosilanes ($R_2NSi(NH_2)_3$, $ROSi(NH_2)_3$) with substituents bound through nitrogen and oxygen, respectively. These two systems have the advantage that the group containing organic substituents can be subsequently hydrolytically removed after reaction at the NH_2 groups, whereas this is not possible for the carbon-bound triaminosilanes under mild conditions.

The above-mentioned silanetriols[2, 3] show interesting reactivity. Among other applications, they can be used to make soluble zeolite precursors [4] and titanium-containing heterocubanes. We now report on the synthesis and reactivity of compounds of the form $RSi(NH_2)_3$.

The trichlorosilanes $RSiCl_3$, $R = iPr_2C_6H_3NSiMe_3$ or $R = tBu_3C_6H_2O$, react in liquid ammonia, with formation of ammonium chloride, to give **1a** and **1b**, respectively [Eq. (a)]. These compounds are very soluble in common organic solvents. Single crystals of the compounds were obtained from *n*-hexane.

$$RSiCl_3 + 6\ NH_3 \xrightarrow[-3\,NH_4Cl]{} RSi(NH_2)_3 \qquad \text{(a)}$$

1a: $R = iPr_2C_6H_3NSiMe_3$

1b: $R = tBu_3C_6H_2O$

Compound **1a** forms colorless needles that melt at 73 °C and are stable at room temperature under an inert atmosphere. The colorless crystals of **1b** melt at 170 °C. Characteristic broad singlets are observed for the amino protons in the ^1H NMR spectra ($\delta = 0.5$ (**1a**) and $\delta = 1.14$ (**1b**)). The IR spectra show three N–H bands in the region for valence vibrations (3345.4 to 3472.2 cm^{-1} (**1a**) and 3407.5 to 3502.6 cm^{-1} (**1b**)).

The Si–N bond lengths (168.7 to 172.0 pm) in **1a** and **1b** are similar to those in the known triaminosilane[1] (Figs. 1 and 2). The amino groups on silicon in **1a** and **1b** are arranged in a distorted tetrahedral manner with bond angles ranging from 101.10(12) to 123.3(3)°. In the solid state **1a** and **1b** show nitrogen–hydrogen bridges (**1a**: 241.4 pm and **1b**: 266.1 pm). In **1a** two amino groups form bridging interactions, while in **1b** only one N–H bridge forms. The latter is attributed to the more sterically demanding ligands in **1b**. In the unit cell of **1b** the molecules are rotated with respect to each other so as to maximize the distance between them. As a result, only two amino groups are capable of forming bridges.

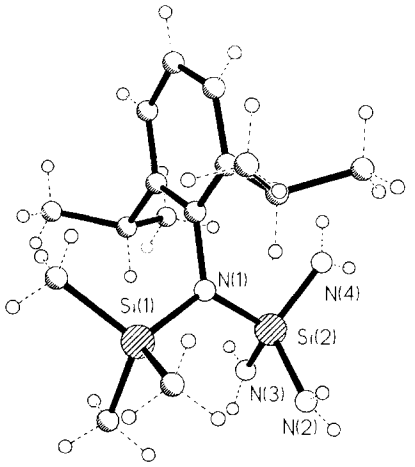

Fig. 1. Structure of **1a** in the crystal. Selected bond lengths [pm] and angles [°]: Si(2)-N(2) 171.4(2), Si(2)-N(3) 172.0(2), Si(2)-N(4) 169.3(2); N(2)-Si(2)-N(3) 101.10(12), N(4)-Si(2)-N(3) 105.80(11), N(4)-Si(2)-N(2) 121.36(12) [7].

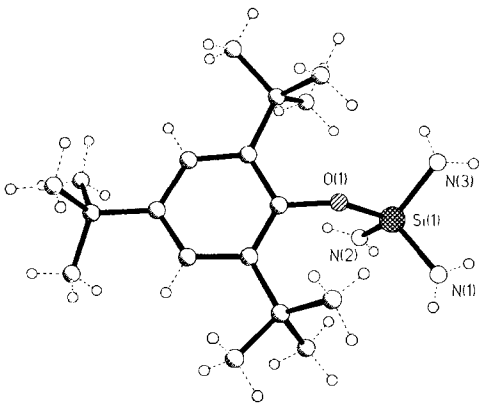

Fig. 2. Structure of **1b** in the crystal. Selected bond lengths [pm] and angles [°]: Si(1)-N(1) 168.8(6), Si(1)-N(2) 168.7(5), Si(1)-N(3) 170.3(6); N(2)-Si(1)-N(1) 108.1(3), N(2)-Si(1)-N(3) 123.3(3), N(1)-Si(1)-N(3) 100.9(3) [7].

Compound **2** is formed by the addition of a solution of **1a** to $[Cp^*TiMe_3]$[5] ($Cp^* = C_5Me_5$) in *n*-hexane at room temperature [Eq. (b)] and is soluble in common organic solvents. The ^1H NMR spectrum of **2** shows a singlet ($\delta = 0.34$) for the protons on the amino group; this signal is shifted to higher field in comparison to that for **1a** ($\Delta\delta = 0.5$).

$$\underset{\textbf{1a}}{RSi(NH_2)_3} + [Cp^*TiMe_3] \xrightarrow[-2\ MeH]{} \underset{\textbf{2}}{R{-}Si(NH)_2{-}Ti(Cp^*)(Me){-}NH} \qquad (b)$$

A comparison of the structure of **2** with **1a** shows similar Si–N bond lengths (169.8(3) to 173.9(2) pm) (Fig. 3). The Ti–N distances are 190.6 and 190.0 pm. The N(1)-Si(2)-N(2) bond angle (90.91(11)°) of the titanium-bound amino groups is about 20° smaller than that of the unbound amino groups. Compound **2** forms a distorted silicon-nitrogen-titanium heterocycle with some widely varying bond angles (N(1)-Ti(1)-N(2) 81.10(10)°, Si(2)-N(1)-Ti(1) 93.91°, Si(2)-N(2)-Ti(1) 93.89°).

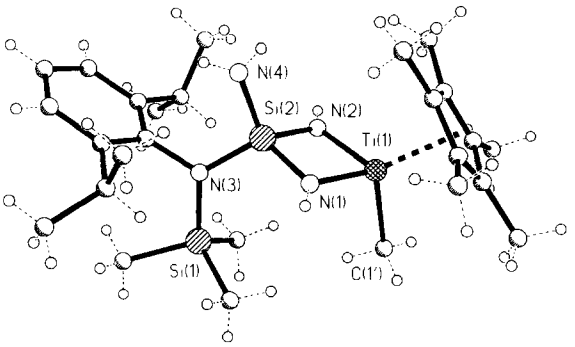

Fig. 3. Structure of **2** in the crystal. Selected bond lengths [pm] and angles [°]: Si(2)-N(1) 173.3(2), Si(2)-N(2) 173.9(2), Si(2)-N(4) 169.8(3), Ti(1)-N(1) 190.6(2), Ti(1)-N(2) 190.0(2); N(1)-Si(2)-N(2) 90.91(11), N(4)-Si(2)-N(2) 112.54(13), N(4)-Si(2)-N(1) 116.36(13), N(1)-Ti(1)-N(2) 81.10(10), Si(2)-N(1)-Ti(1) 93.91(11), Si(2)-N(2)-Ti(1) 93.89(11) [7].

Compound **3** is formed by the reaction of **1a** with Me_3SnCl (in excess) in boiling *n*-hexane [Eq. (c)]. It is soluble in common

$$\underset{\textbf{1a}}{RSi(NH_2)_3} + Me_3SnCl \xrightarrow[-HCl]{} \underset{\textbf{3}}{RSi(NH_2)_2(NHSnMe_3)} \qquad (c)$$

organic solvents and melts at 62 °C. The ^{119}Sn NMR spectrum shows a singlet ($\delta = 168.40$) for the tin atom in the $SnMe_3$ group. In addition, one N–H band disappears from the IR spectrum.

Compounds **2** and **3** show that selective substitutions of the amino groups can be achieved. Furthermore, compounds **1a** and **1b** are possible precursors for dendrimers and ceramics; they contain reactive hydrogen atoms ideal for these syntheses. The high hydrogen content favors the elimination of the organic group in the synthesis of ceramics.

Experimental Procedure

1a: $iPr_2C_6H_3NSiMe_3SiCl_3$ (1.2 g, 3.1 mmol) [2] was dissolved in liquid ammonia (25 g) at −78 °C and then heated at reflux for 4 h at −30 °C. Thereafter, the ammonia was evaporated off, the residue taken up in diethyl ether, and the ammonium chloride formed was removed by filtration. Removal of the solvent in vacuo left a colorless solid, which was recrystallized from *n*-hexane (5 mL). Yield 0.8 g (79%) **1a**. $C_{15}H_{32}N_4Si_2$ (M = 324.22 g mol^{-1}; m.p. 73 °C; ^1H NMR (200 MHz, C_6D_6, TMS): δ = 0.2 (s, 9 H, $SiMe_3$), 0.5 (s, 6 H, $Si(NH_2)_3$), 1.22 (d, ^3J(H,H) = 6.9 Hz, 6 H, $CH(CH_3)_2$), 1.25 (d, ^3J(H,H) = 6.9 Hz, 6 H, $CH(CH_3)_2$), 3.65 (sept, 2 H, $CH(CH_3)_2$), 7.05 (s, 3 H, H_{arom}); ^{29}Si NMR (49 MHz, C_6D_6, TMS): δ = 3.6 ($SiMe_3$), −41.0 ($Si(NH_2)_3$); IR (KBr, Nujol): 3345.4, 3392.4, 3472.2 cm^{-1}; MS (EI, 70 eV): 324 (M^+, 12%), 307 ($M^+ - NH_2$, 100%); correct elemental analysis [6].

1b: **1b** was prepared analogously to **1a**. Yield 1.5 g (80%) **1b**. $C_{18}H_{35}N_3OSi$ (M = 337.58 g mol^{-1}); m.p. 170 °C; ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 1.14 (bs, 6 H, NH_2), 1.30 (s, 9 H, *t*Bu), 1.49 (s, 18 H, 2 *t*Bu), 7.27 (s, 2 H, H_{arom}); ^{29}Si NMR (50 MHz, $CDCl_3$, TMS): δ = −50.05 ($Si(NH_2)_3$); IR (KBr, Nujol): 3407.5, 3481.2, 3502.6 cm^{-1}; MS (EI, 70 eV): 337 (M^+, 28%), 280 ($M^+ - t$Bu, 100%); correct elemental analysis [6].

2: A solution of **1a** (0.65 g, 2.0 mmol) in *n*-hexane (5 mL) was added dropwise at room temperature to $[Cp^*TiMe_3]$ (0.46 g, 2.0 mmol) [5] in *n*-hexane (8 mL). After the gas evolution had ceased, the solution was stirred for 1 h and then the solvent was removed in vacuo. The resulting solid was recrystallized from pentane (8 mL). Yield 0.92 g (91%) **2**. $C_{25}H_{44}N_4Si_2Ti$ (M = 522.30 g mol^{-1}); m.p. 148 °C (decomp.); ^1H NMR (200 MHz, C_6D_6, TMS): δ = 0.22 (s, 9 H, $SiMe_3$), 0.34 (s, 4 H, $Si(NH)_2NH_2$), 1.25 (m, 12 H, $CH(CH_3)_2$), 1.76 (m, 15 H, Cp^*), 2.08 (s, 3 H, $Ti\text{-}CH_3$), 3.72 (sept, 2 H, $CH(CH_3)_2$), 7.05 (m, 3 H, H_{arom}); ^{29}Si NMR (50 MHz, C_6D_6, TMS): δ = 3.22 ($SiMe_3$), −38.53 ($Si(NH)_2NH_2$); IR (KBr, Nujol): 3366.8, 3404.0, 3494.6 cm^{-1}; MS (EI, 70 eV): 505 ($M^+ - Me$, 100%); correct elemental analysis [6].

3: **1a** (2.0 g, 6.2 mmol) and Me_3SnCl (3.7 g, 18.6 mmol) were combined as solids and then heated at reflux in *n*-hexane (30 mL). Thereafter, the solution was allowed to cool to room temperature and the solvent was removed in vacuo. A colorless solid was obtained and recrystallized from *n*-hexane (10 mL). Yield 2.5 g (83%) **3**.

$C_{18}H_{40}N_4Si_2Sn$ (M = 487.43 gmol^{-1}); m.p. 62 C; ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 0.11 (s, 9 H, $SiMe_3$), 0.64 (s, 9 H, $SnMe_3$), 0.78 (s, 5 H, $Si(NH_2)_2NH$), 1.17 (d, ^3J(H,H) = 6.9 Hz, 6 H; $CH(CH_3)_2$), 1.21 (d, ^3J(H,H) = 6.9 Hz, 6 H, $CH(CH_3)_2$), 3.54 (sept, 2 H, $CH(CH_3)_2$), 7.04 (t, 3 H, H_{arom}); ^{29}Si NMR (50 MHz, $CDCl_3$, TMS): δ = 4.02 ($SiMe_3$), −40.29 ($Si(NH_2)_2NH$); ^{119}Sn NMR (93 MHz, $CDCl_3$, $SnMe_4$): δ = 168.40 ($SnMe_3$); IR (KBr, Nujol): 3413.0, 3499.4 cm^{-1}; MS (EI; 70 eV): 307 (M^+ − $SnMe_3$ − NH_2, 100%), 472 (M^+ − Me, 1.4%); correct elemental analysis [6].

Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium**

Joachim Burger, Claudia Gack, and Peter Klüfers*

The trivalent ions of the 3d metals as well as those of aluminum and its homologues form mononuclear aqua ions in aqueous solution only at low pH, but in the physiological pH range they are, to a large extent, condensed to isopolybases. The identification of low molecular weight "bioligands" that form complexes with the M^{III} ions in neutral aqueous solution, competing with the formation of networks of hydroxo and oxo bridges, is one of the basic aims of bioinorganic chemistry. A concrete example is the question of the constitution of the coordination spheres of the metals during transfer between macromolecules like transferrin and ferritin.[7a] In particular for iron(III), the investigations extend to carbohydrates, which are ubiquitous in organisms;[2a, b] because the crystallization of the target complexes is problematic,[2c] however, definite proposals for the structure are lacking. For iron(III) complexes, which have been studied by numerous methods, most structural suggestions concentrate around dinuclear hydroxo-iron cores surrounded by sugar ligands that are assumed to be up to doubly deprotonated.[2d, e, g] We now report on a series of isotypic sugar complexes of trivalent metals, that could be crystallized from weakly basic aqueous solution. The compounds $Ba_2[M^{III}_2(\beta\text{-D-Man}f\text{H}_{-5})_2]\cdot n\,H_2O$ (M = Fe (**1**), V (**2**), Cr (**3**), Al (**4**), Ga (**5**); Man$f$ = mannofuranose; $n \approx 13$) are each the first structurally characterized complex of the particular metal with a nonprotected monosaccharide.

Starting point for the study was a "barium ferri mannose" that was described by Traube, Kuhbier, and Härting in 1933 as the trihydrate $BaFeC_6H_7O_6\cdot 3\,H_2O$ with fivefold deprotonated D-mannose.[3] The compound forms from an aqueous solution of sodium hydroxide, D-mannose and iron(III) nitrate on precipitation with $BaCl_2$. This time we were successful in crystallizing Traube et al.'s mannose compound both with D-mannose and with D-fructose—as well as with D-glucose in low yield—from weakly alkaline solution (pH of the mother liquor at the end of the diffusion experiments was approximately 9) in the form of yellow rhombic prisms and in characterizing them structurally (Table 1).[4] Compound **1** contains a homoleptic sugar–iron complex as anion (Fig. 1), which despite the preparation from aqueous solution includes no hydroxo or oxo ligands. Instead all the protons of the five hydroxyl groups of mannose are split off to form a pentaanionic polyolato ligand. The polyolate is derived from the β-furanose form of the free mannose, which is insignificant in solution,[5] but is the only form with all the hydroxyl groups on one side of the ring. In the stable forms of D-mannose—the two anomeric pyranose forms with $^4C_1$ conformation—this bonding mode is just as inconceivable as with the two less favorable pyranoid anomers with $^1C_4$ conformation (Scheme 1). For all the other aldohexoses, only in one other case, the rare gulose, can there be a similar favorable arrangement of all hydroxyl groups. The isomerization to a sugar ligand with the highest possible denticity, observed here for D-fructose and D-glucose, has already been described for an oxomolybdenum(VI) complex: thus the formation of β-D-mannofuranose from the epimeric D-glucose corresponds entirely to an analogous transformation of the aldopentose D-xylose into the fourfold deprotonated β-D-lyxofuranose ligand.[6]

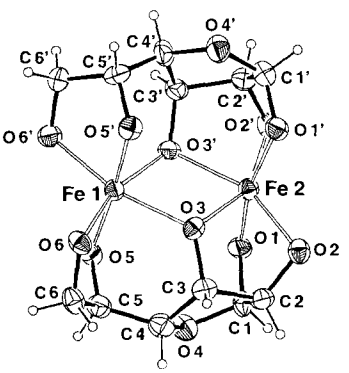

Fig. 1. The $[Fe_2(\beta\text{-D-Man}f\text{H}_{-5})_2]^{4-}$ ion in **1**; for distances and angles see Table 1. Average distances [pm] (standard deviation in the last decimal place on averaging): C O_{deprot} 141.2(15), C O_{Ring} 146.0(17), C C 154.1(22), Ba1 to the seven neighboring O 278.3(30), Ba2 to the six neighboring O 275.2(47); puckering parameters [9] of the furanose ring containing O4-C1...: Q_2 = 34.7(10) pm, ϕ_2 = 267.1(14)°, containing O4'-C1'...: Q_2 = 35.0(10) pm, ϕ_2 = 261.5(14)°.

$^4C_1$ $^1C_4$ E_2

Scheme 1. Coordination possibilities for the chair conformations of D-mannopyranose and for the E_2 envelope conformation of D-mannofuranose (without H atoms and charges).

The environments of the two iron atoms in **1** are not equivalent. Fe1 forms five- and six-membered chelates with the open-chain part of the ligand, whereas Fe2 is surrounded by two oxolanetriolato fragments in a distorted E_2 conformation; this yields the α-D-erythrofuranose partial structure, which is also present in one of the anomers of each of D-ribo- and D-lyxo-, as well as D-talo- and D-allofuranose. In the envelope conformation with C2 as flap, the O1 and O3 atoms are closest together. As is usual for polyolato complexes of other metals, in **1** the alkoxide functions are also either bound to cations (here 6+1- and 7+1-fold coordinated barium), or they are acceptors in a hydrogen-bonding system constructed from water molecules in which the donors are distributed over extended cooperative sequences, or both.

Green prisms of **2** and **3**, as well as colorless crystals of **4** and **5** were obtained analogously if instead of iron nitrate vanadium(III), chromium(III), aluminum(III), or gallium(III) salts are employed.

The structure analyses demonstrate that monosaccharides can also be multiply deprotonated in the presence of metal ions as was shown for the sugar alcohols recently with D-sorbitol.[1] The mentioned M^{III} ions are converted into small anionic complexes in weakly alkaline aqueous solution with the hexoses common in organisms.[7] Charge and binding modes of the ligand in **1**–**5** now reveal that species of a different kind than previously assumed are possible in solution.

For the imminent study of equilibria in solution it is particularly advantageous that the complexes contain central metals that can be well studied by spectroscopy (V^{III}: visible spectroscopy as described in reference [8], but without limitations by slow ligand exchange as in Cr^{III} or by weak absorption because of a spin-forbidden d–d transition as in Fe^{III}; Al and Ga: NMR spectroscopy).

dad Compounds of Niobium and Tantalum: Examples of the Structural Flexibility of dad Ligands**

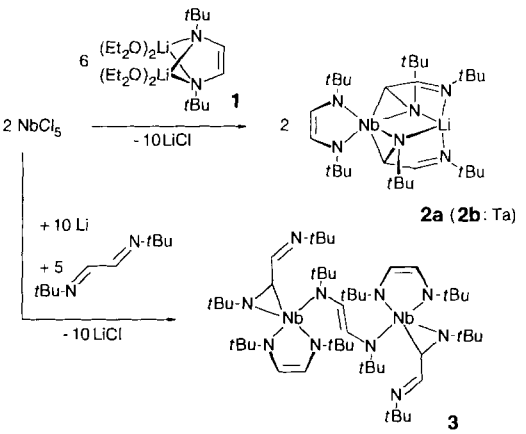
Bodo Richter, Joachim Scholz, Joachim Sieler, and Karl-Heinz Thiele*

Lately the number of structurally characterized dad complexes of the early transition metals and lanthanides has increased substantially. Because of the stability of the high oxidation states of the metal ions, the dad ligands have been reduced to the dianion (enediamide) in most of these complexes.[1] In addition, irrespective of the type of complex and the kind of coligands, the N-heterodienes are bound to the metal as chelate in all cases. This structural uniformity is surprising in the light of the electron and steric diversity of dad ligands, and is in contrast to the large range of structures of dad complexes with late transition metals.[2] Versatile applications for dad complexes of the early transition metals can be expected only if different dad–metal interactions can be realized.[3] We report here novel dad complexes of niobium and tantalum, which demonstrate that a variety of coordination types is possible for the dad ligand with the early transition metals. A particularly good example is the dinuclear niobium complex **3**, in which the dad ligands are coordinated to the metal atoms in three different ways.

In the reaction of $NbCl_5$ or $TaCl_5$ with the di-*tert*-butyl-substituted dad derivative **1** in a 1:3 molar ratio in diethyl ether, the compounds **2a** and **2b** are formed (Scheme 1) as yellow,

$[Li\{M(tBu\text{-}dad)_3\}]$ M = Nb (**2a**), Ta (**2b**)

air- and moisture-sensitive crystals. Surprisingly, they are very soluble not only in polar solvents like diethyl ether or THF, but also in *n*-pentane. This property and the lack of coordinated



Scheme 1. Synthesis of **2a**, **b** and **3**.

solvent molecules (NMR evidence) suggest that both the transition metal atom and the lithium atom are coordinatively saturated within one ligand shell formed by the three dad ligands, and that this feature masks the ionic character of these complexes. A crystal structure analysis of **2a** confirms this supposition.[4] The unit cell contains two crystallographically independent molecules; however, their interatomic distances and bond angles do not differ significantly. One of the two molecules is shown in Figure 1.

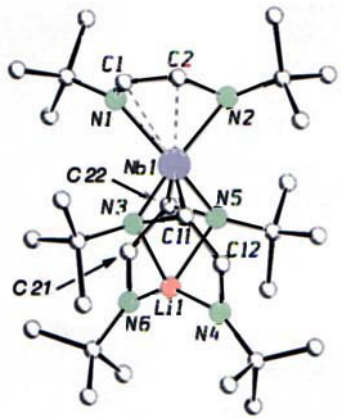


Fig. 1. Crystal structure of **2a**. The figure shows one of the two crystallographically independent molecules. Selected bond lengths [Å] and angles [°]: Nb1-N1 2.072(7), Nb1-N2 2.069(7), Nb1-N3 1.993(6), Nb1-N5 2.004(6), Nb1-C1 2.443(14), Nb1-C2 2.43(2), Nb1-C11 2.245(10), Nb1-C21 2.263(10), Nb1-Li1 2.82(2), Li1-N3 2.12(2), Li1-N4 2.07(2), Li1-N5 2.20(2), Li1-N6 1.98(2), N1-C1 1.44(2), N2-C2 1.49(2), C1-C2 1.32(2), N3-C11 1.44(1), N4-C12 1.30(1), C11-C12 1.42(1), N5-C21 1.41(1), N6-C22 1.27(1), C21-C22 1.45(1); N1-Nb1-N2 84.1(3), N3-Nb1-C11 39.1(3), N5-Nb1-C21 37.9(3), N3-Li1-N4 87.2(6), N5-Li1-N6 86.7(7), Nb1-N3-Li1 86.7(6), Nb1-N5-Li1 84.3(6); N3-C11-C12-N4 16.9(11); N5-C22-C21-N6 9.3(11); [N1-Nb1-N2][N1-C1-C2-N2] 67.2.

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. dad = 1,4-diaza-1,3-butadiene; *t*Bu-dad = *N*,*N*′-bis(*tert*-butyl)-1,4-diaza-1,3-butadiene.

The Nb atom is surrounded by three dad ligands. Only one is coordinated to the metal as *cis*-configured dad dianion and forms a folded Nb–N–C=C–N five-membered ring (envelope structure[5]). The other two dad ligands are each η^2-coordinated to the Nb atom through an N=C group. Consequently, the N=C bond lengths are substantially lengthened and are hardly distinguishable from usual N–C single-bond distances (N5–C21 1.408(12), N3–C11 1.437(12) Å.[6] Since the Nb–N and Nb–C distances resemble those of known Nb–N and Nb–C single bonds[7] (Nb1–N3 1.993(6), Nb1–C11 2.245(10), Nb1–N5 2.004(6), Nb1–C21 2.263(10) Å), the bonding in **2a** is similar to that in other azametallacyclopropane rings.[8] In addition, the two N atoms of these Nb,N,C three-membered rings act as a bridge between the Nb atom and the Li^+ ion. The remaining positions of the slightly distorted coordination tetrahedron around the Li^+ ion are occupied by the still intact imine groups of the dad ligands coordinated in an η^2 fashion to the Nb atom. In this way the lithium ion is surrounded in a stable fashion and without solvent molecules by the ligand molecules of the complex.

Temperature-independent NMR spectra, which are analogous for **2a** and **2b** to a large extent, indicate that in solution the structure of both compounds resemble that of **2a** in the solid state (Table 1). For instance, the signal for the imine hydrogen atoms of the dad ligand that coordinates as chelate to the transition metal center is, as expected, observed in the typical range for olefinic protons (**2a**: δ = 5.72, 5.69; **2b**: δ = 5.74, 5.62). In contrast, a distinct charge differentiation can be seen for the imine-H protons of the two η^2-coordinated dad ligands. Whereas the signals of the H atoms of the azametallacyclopropane rings are shifted to higher field than those of the chelating dad ligand (**2a**: δ = 3.09, 2.25; **2b**: δ = 2.77, 2.03), those of the imine groups bound to the lithium ion are shifted strongly downfield (**2a**: δ = 8.44, 8.05; **2b**: δ = 8.48, 8.14). This charge differentiation is more pronounced in the ^{13}C NMR spectra (Table 1). Thus, within these two dad ligands there is a difference in function of the C=N groups: one acts exclusively as σ donor at the lithium ion and the other exclusively as π acceptor at the transition metal center.

[a] ^1H NMR: 300 MHz ([D$_8$]THF, 25 °C); ^{13}C NMR: 75 MHz ([D$_8$]THF, 25 °C).

The dinuclear niobium complex **3** in which a dad dianion links two niobium atoms arises when $NbCl_5$, Li, and *t*Bu-dad in a 2:10:5 molar ratio are allowed to react in diethyl ether. Compound **3** crystallizes from diethyl ether as orange prisms and can be handled in air for short periods.

The crystal structure analysis of **3**[4] (Fig. 2) shows that this dinuclear niobium complex contains five dad ligands in three different bonding modes. The coordination geometry at the two niobium atoms is virtually identical. One dad ligand binds as *cis*-configured enediamide dianion to each metal center; in this way two five-membered rings folded along the N,N axis are formed. Another two dad ligands are coordinated only through one imine function in a η^2 fashion. As in **2a**, they form azametallacyclopropane rings with relatively short Nb–N and

Fig. 2. Crystal structure of **3**. Nb–C contacts[7] (Nb1–N9 1.946(3), Nb2–N3 1.943(3), Nb1–C41 2.223(3), Nb2–C11 2.217(3) Å) and N–C single bonds (N3–C11 1.424(4), N9–C41 1.433(4) Å).[6] The bonding mode of the fifth dad ligand has not previously been observed in complexes between dad and transition metals: this ligand is a *trans*-configured enediamide dianion (N1–C1–C2–N2 177.1(4)°) bridging the two Nb atoms. A similar *trans* structure in a dad ligand is present in the dinuclear Pt complex $[\{PtCl_2(PBu_3)\}_2(t\text{Bu-dad})]$.[9] In contrast to **3**, however, in this complex the only transition metal complex with a μ-η^1,η^1-dad bridge that has yet been structurally characterized, the *t*Bu-dad ligand is bound as neutral bidentate σ donor.

From the temperature-independent ^{1}H NMR spectra of **3** it may be deduced that the exceptional molecular structure persists in solution. In accord with the three coordination modes of the dad ligands, three complete sets of signals are observed, which could be unequivocally assigned on the basis of the crystal structure. So, for instance, the imine-H signals at $\delta = 6.56$ and 6.20 are attributable to the two dad ligands that form enediamide chelates as in **2a** and **2b**. The imine-H resonance of the C=N groups coordinated in an η^2 fashion to the Nb atoms is strongly shifted to higher field as expected ($\delta = 3.79$), whereas the chemical shift of the CH=N group of the noncoordinated half of the ligand hardly differs from that of the free dad ligand ($\delta = 7.08$).[10] The singlet at $\delta = 5.41$ is attributable to the imine-H atom of the μ-η^1,η^1-bound dad bridging ligand.

The unusual structures of **2a** and **3** show that although the dad ligands in these complexes are all bound as dianions to the metal centers, other types of coordination are viable than the chelate that was the exclusive structure known till now. Accordingly the steric flexibility of dad ligands is also preserved in their dianionic form, which opens the way to similar applications of dad chemistry for the early transition metals as for the late transition metals.

Experimental Procedure

2a: A solution of **1**, prepared from *t*Bu-dad (3.73 g, 22.2 mmol) and lithium (0.30 g, 44.4 mmol) in diethyl ether (50 mL) was added dropwise to a suspension of $NbCl_5$ (2.0 g, 7.40 mmol) in diethyl ether (50 mL) at -78 °C. The orange-brown reaction mixture was stirred for a further 8 h at room temperature and then filtered. After concentration and storage at -20 °C, yellow crystals separate from the filtrate. These were recrystallized from diethyl ether/*n*-pentane (10/1). Yield: 2.1 g (48%); correct C, H, N analysis.

2b: The synthesis is analogous to that of **2a**. From the reaction of $TaCl_5$ (2.6 g, 7.40 mmol) and **1** (22.2 mmol) yellow crystals of **2b** were isolated (2.8 g, 54%). Correct C, H, N analysis.

3: $NbCl_5$ (5.34 g, 19.8 mmol) and lithium (0.69 g, 99.4 mmol) was added at room temperature to a solution of *t*Bu-dad (10 g, 59.4 mmol) in diethyl ether (100 mL). The color of the reaction mixture changed immediately to red-brown. The mixture was stirred overnight, and the LiCl formed was then filtered off. From the filtrate, which was concentrated to half its volume and cooled to -20 °C, orange prisms of **3** separated. Repeated concentration and cooling yielded more of **3**. The crystals were recrystallized from a mixture of diethyl ether and *n*-pentane. Overall yield: 8.9 g (43%); correct C, H, N analysis.

Zeolite Encaged Cu(Histidine) Complexes as Mimics of Natural Cu Enzymes **

Bert M. Weckhuysen,* An A. Verberckmoes, Ina P. Vannijvel, Josephina A. Pelgrims, Philip L. Buskens, Pierre A. Jacobs, and Robert A. Schoonheydt

The most abundant, active, and selective catalysts in nature are enzymes. Their operational domain is, however, relatively narrow as far as temperature and solvent are concerned. Enzyme mimicking is the building of the active center of enzymes (or an analogy of it) into a matrix which allows a larger operational temperature domain and a broader spectrum of solvents. In the case of inorganic matrices, zeolites are the obvious choice because the pore diameters and pore geometry introduce shape selectivity in the reactions. Up to now, the active center of the enzyme has been mimicked by construction of robust, rigid, and stable transition metal ion complexes in zeolite cavities and channels.[1, 2] The most prominent examples are phthalocyanine and bipyridine complexes.[3, 4] However, these complexes can only be synthesized in situ and this procedure is time-consuming. Moreover, the turnover numbers in catalytic oxidations are relatively low.

Here, we report for the first time on the immobilization of Cu(histidine) complexes in zeolites by a simple ion exchange procedure. Amino acids, like histidine, are the key building units of natural enzymes; therefore, the obtained inorganic enzyme has an active center, very close to that of its natural enzyme counterparts. In addition, the complexes are built in by a simple ion exchange procedure. Cu^{2+} was chosen as the transition metal ion, because its complexes are stable[5] and easily characterized by electron spin resonance (ESR) and diffuse reflectance spectroscopy (DRS) in the UV/VIS/NIR region.[6] Furthermore, copper proteins play a key role in both plant and animal physiology, for example hemocyanin is the oxygen-carrying protein in the hemolymph of molluscs and arthropods; ascorbate oxidase catalyzes the oxidation of L-ascorbate and galactose oxidase, which catalyzes the oxidation of galactose and many other substrates, like aliphatic and aromatic alcohols.[7–11]

Cu(histidine) complexes are typically prepared in bidistilled water with a histidine:Cu^{2+} ratio of 5:1. By using an increasing amount of preformed $[Cu(His)_2]^+$ complex at pH 7.3 in bidistilled water[12] together with a zeolite Na-Y, we have measured the amount of released Na^+, together with the amount of Cu^{2+} taken up by the zeolite material. The results are presented in Figure 1. Although there is a considerable spread of points, the data show unambiguously that ion exchange is operative. The slope of the straight line ($7Na^+/Cu^{2+}$) indicates that besides $[Cu(His)_2]^+$, His^+ is exchanged too. Chemical analysis indeed confirms that the histidine:Cu^{2+} ratio on the solid is 6:1. Thus at the low exchange levels investigated,[13] for each $[Cu(His)_2]^+$ exchanged, four His^+ cations are co-exchanged. The fact that on the average seven Na^+ ions are released and not six is indicative for charge compensation by H^+; thus some residual acidity is expected on the solids.

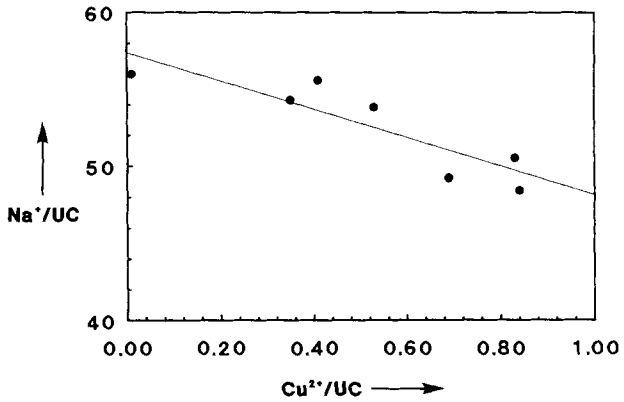

Fig. 1. The amount of released Na^+ and immobilized Cu^{2+} complex in zeolite Y for increasing concentration of Cu(histidine) complex in the ion exchange solution. UC = unit cell.

The hydrated light blue samples are characterized by an absorption band around 15600 cm^{-1} in the diffuse reflectance spectrum and a typical axially symmetric ESR spectrum with hyperfine splitting (hfs) with values for $g_\parallel$, $g_\perp$, and $A_\parallel$ of around 2.27, 2.06, and 170 G, respectively, and a seven-line superhyperfine structure (shfs) with an $A_{N\perp}$ value of 12.3 G (Fig. 2). These spectroscopic features are due to the presence of

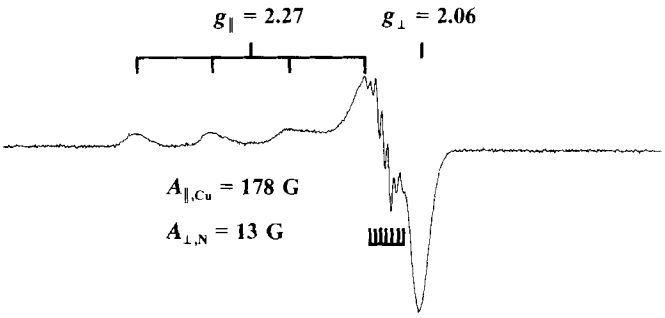

Fig. 2. ESR spectrum of a $[Cu(His)_2]^+$ complex in zeolite Y.

three nitrogen atoms ($2 \times I_N \times n_N + 1 = 7$) in the first coordination sphere of the Cu^{2+} ion. Comparable spectroscopic parameters are observed for copper proteins (e.g. galactose oxidase with an absorption at 15900 cm^{-1} and ESR parameters:[8] $g_\parallel = 2.24$; $g_\perp = 2.06$; $A_\parallel = 175$ G (hfs); $A_\perp < 0.5$ G with shfs : $A_{N\perp} = 15.1$ G) with an NNNO coordination around the Cu^{2+} ion. The intensity of the d–d absorption band in the diffuse reflectance spectrum and the amount of Cu^{2+}, as determined by quantitative ESR measurements, are given in Figure 3 for increasing Cu(histidine) loading in zeolite Y. The d–d absorption band of Cu^{2+} linearly increases with increasing Cu loading. The same holds for the intensity of the ESR signal, suggesting the presence of only one type of occluded Cu(histidine) complex. In addition, the amount of ESR-visible Cu^{2+} equals the amount determined by chemical analysis, confirming the absence of uncomplexed Cu^{2+}.

The occluded $[Cu(His)_2]^+$ can be envisaged as a complex with a Cu^{2+} center surrounded by three nitrogen atoms and one oxygen atom by ligation of two histidine molecules, one coordinating by two N ligands, the other only by one O and N atom. The fourth ligand is thus an oxygen atom of the carboxy group of histidine. A possible representation of this Cu complex is shown in Figure 4. Molecular modeling shows that the

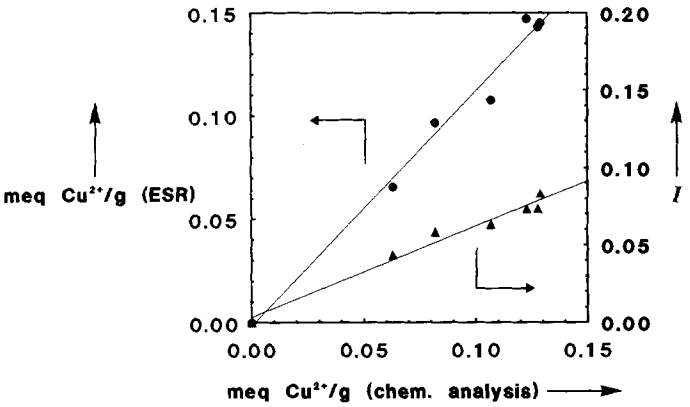

Fig. 3. Intensities of the Cu^{2+} signals in the diffuse reflectance spectrum (I) and ESR spectrum as function of the loading of the [Cu(His)] complex in zeolite Y. meq = milliequivalents.

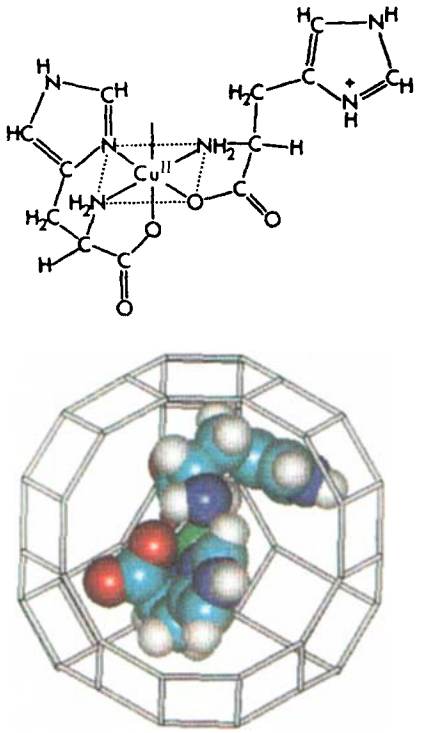

Fig. 4. Representation of $[Cu(His)_2]^+$ occluded in the supercage of zeolite Y. Top: schematic representation of the $[Cu(His)_2]^+$ complex; Bottom: space-filling molecular model, as generated by Hyperchem (light blue, carbon; black, hydrogen; green, copper; red, oxygen; dark blue, nitrogen).

$[Cu(His)_2]^+$ complex is occluded in the zeolite supercage without distortion.

Drying of the samples results in the removal of water and only a slight shift in the absorption in the diffuse reflectance spectrum (15700 cm^{-1}) and ESR parameters ($g_{\|}$, $g_{\perp}$, and $A_{\|}$ values are 2.26, 2.07, and 175 G,respectively). Furthermore, the occluded $[Cu(His)_2]^+$ complexes are thermally stable up to 100 °C. Admission of ammonia onto the sample dried at room temperature results in the formation of a $Cu(His)_2(NH_3)_x$ complex with an absorption at 16000 cm^{-1} and $g_{\|}$, $g_{\perp}$, and $A_{\|}$ values of 2.26, 2.07, and 160 G, respectively. The absence of the superhyperfine splitting in the ESR spectrum is due to a distortion of the complex. Removal of the ammonia in vacuo at 50 °C leads to the initial Cu^{2+} state and this process is totally reversible. Thus, by simple evacuation a free coordination site is produced.

The presence of such a coordination site gives catalytic potential to these materials. The oxidation of alcohols and alkenes with *tert*-butyl hydroperoxide, an environmentally friendly and cheap oxidant,[14] in the presence of $[Cu(His)_2]^+$-Y has been studied at 60 °C in batch-type reactors. The catalytic performances of $[Cu(His)_2]^+$-Y with 0.75 Cu/UC are summarized in Table 1. 1-Pentanol is oxidized to pentanoic acid with a selectivity of 100%, while the oxidation of benzyl alcohol gives both benzaldehyde and benzoic acid in a ratio of about 2:1. Similar oxidation reactions are catalyzed by galactose oxidase, which has a broad substrate specificity.[15] Excellent catalytic results were, however, obtained for the epoxidation of cyclohexene. At a turnover of 3230, the major reaction product is 1,2-cyclohexanediol. This product is formed from the hydrolysis of cyclohexenoxide, on some acid sites of zeolite Y. A minor allylic oxidation is also observed, indicative of only traces of free copper. After reaction, no free Cu ions were detected in the reaction mixture and combined DRS and ESR measurements show also that the $[Cu(His)_2]^+$ complexes were maintained inside the cages of zeolite Y. This strong encapsulation can be explained by the positive charge of the complex. Furthermore, after repeated regeneration (three times), no changes in catalytic and spectroscopic properties were observed. Thus, a new stable and selective oxidation catalyst has been designed.

Table 1. Catalytic performances of $[Cu(His)_2]$ complexes encaged in zeolite Y at 60 °C [a].

Substrate [a]	Time [h]	Conversion [%]	TON [b]	Selectivity [mol%]
1-pentanol	24	12	1425	pentanoic acid [100]
benzylalcohol	24	56	2421	benzoic acid [33], benzaldehyde [66]
cyclohexene	24	28	3230	cyclohexenoxide [9], 1,2-cyclohexanediol [89], cyclohex-2-en-1-ol [0.3] and cyclohex-2-en-1-one [1.7]

[a] 100 mmol substrate, 150 mmol *tert*-butyl hydroperoxide; no Cu leaching during reaction, as determined by AAS; no catalytic activity was observed for zeolite Y and histidine exchanged zeolite Y, while Cu/zeolite Y only decomposes the peroxide. [b] TON = turnover number.

In conclusion, we have discovered that $[Cu(His)_2]^+$ complexes can be immobilized in the cages of zeolite Y by a simple ion exchange method, which results in the formation of a typical coordination geometry frequently encountered in biological Cu proteins. The presence of a free coordination site opens the way for oxidation catalysis at relatively low temperatures in the presence of peroxides, especially olefin epoxidations and alcohol oxidations. To our knowledge, this system is the first example of immobilized transition metal ion (amino acids) complexes in zeolites. Further studies on the mechanism of the oxidations and the extension to other transition metal ions, amino acids, and inorganic oxides are in progress and should increase our understanding of these occluded complexes.

Experimental Procedure

The Cu(histidine)/Y samples were prepared starting from Na-Y from Ventron (Si:Al ratio of 2.49 and cation exchange capacity of 4.32 meq g^{-1}) after the zeolite had been put in its Na^+ form by two successive exchanges with 1 M NaCl solutions, followed by washing until free from Cl^- ions, and drying in air at room temperature overnight. The zeolites obtained were then ion exchanged with a solution of Cu(histidine) in bidistilled water at a fixed pH. After ion exchange, the samples were separated from the solution by centrifugation, washed, and dried at 60 °C overnight in air. The amounts of Na^+ and Cu^{2+} were determined by atomic absorption

spectroscopy (AAS) after dissolution of known quantities of the zeolites materials in HF/H_2SO_4. AAS measurements were performed with an Instrumentation Laboratory Inc. apparatus with a nitrous oxide/acetylene flame. Scanning electron micrographs (SEM) were obtained by using a Jeol Superprobe 733 instrument, while diffuse reflectance spectroscopy (DRS) was performed on a Varian Cary 5 UV/VIS/NIR spectrophotometer at room temperature. The diffuse reflectance spectra were recorded against a halon white reflectance standard in the range 2200–200 nm. The computer processing of the spectra consisted of the following steps: 1) subtraction of the baseline, 2) conversion to wavenumber, and 3) calculation of the Kubelka-Munk (KM) function. For ESR spectroscopy, a Bruker ESP300E spectrometer at X-band (ca. 9.5 GHz) was used. Quantitative ESR results were obtained by comparison with Cu(acetylacetonate)/KCl reference samples (spin density : 10^{16}–10^{20} $Cu^{2+}\,g^{-1}$). The molecular models were generated by the commercial software package Hyperchem™ of Autodesk.

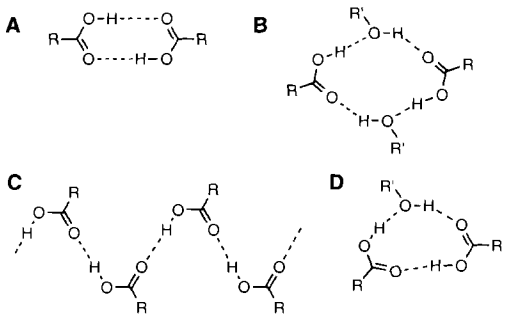
Self-Assembly of 1,3,5-Benzenetricarboxylic Acids (Trimesic Acids) and Several Analogues in the Solid State**

Sergei V. Kolotuchin, Edward E. Fenlon, Scott R. Wilson, Colin J. Loweth, and Steven C. Zimmerman*

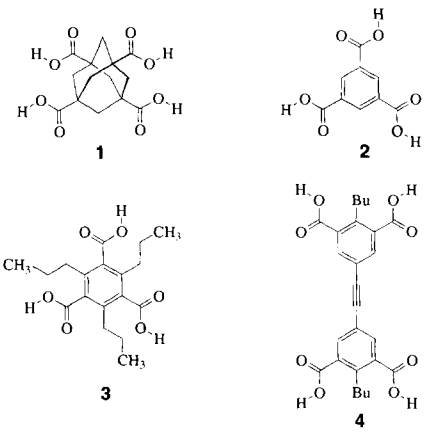
The design of organic compounds that crystallize in a predictable way remains a contemporary challenge to chemists.[1] Particular attention has recently focused on the rational design of clathrates that may be useful in separations or catalysis.[2] Hydrogen bonding can be useful in this regard[3] because it is a moderately directional intermolecular interaction that may control short-range packing. Ideally, each functional group or set of groups would form a single hydrogen bonding motif. Unfortunately, however, the complex interplay of crystal packing forces makes this less likely to occur. For example, carboxylic acids are well-known to form centrosymmetric dimers (Scheme 1, **A**), but



Scheme 1. Four hydrogen bonding motifs for carboxylic acids. **A**: symmetrical dimer, **B**: doubly bridged dimer, **C**: catemer, **D**: singly bridged dimer.

other motifs exist.[4] These alternate motifs are nonetheless rare and the reported high frequency of dimer formation suggests that carboxylic acids are attractive candidates for controlling short-range crystal packing.[1a]

Longer range packing might be controlled through compounds containing two or more such functional groups in a defined spatial arrangement. Two paradimatic examples of this approach to engineering hydrogen bonded networks are adamantanetetracarboxylic acid (**1**) and 1,3,5-benzenetricarboxylic acid (trimesic acid, **2**), which form diamondoid[5] and



hexagonal[6] networks, respectively. However, channels or cavities are not present as a result of extensive interpenentration. In the case of **2**, the "chicken-wire" networks of trimesic acid molecules are pleated and the 14 Å holes are filled by a mutual triple catenation. Herein we describe the results from three different approaches to break the interpenetration of the trimesic acid lattice to give cavity clathrates. The results bear on the issue of whether the hydrogen bonding of carboxylic acids, and by extension, related functional groups can be used to reliably control the structure of crystals.

The first approach to break interpenetration involved crystallization of trimesic acid in the presence of a guest that might pack efficiently within the 14 Å channels. Partial success using this approach was reported by Herbstein et al. in 1987.[7] How-

ever, the incorporated guests such as *n*-octane and isooctane were highly disordered, and the goal to construct long channels by aligning the chicken-wire networks was not achieved. With *n*-octane and isooctane as guest molecules, the number of stacked two-dimensional networks was only two and three, respectively.

We reasoned that a larger and less flexible guest molecule (e.g. a polycyclic aromatic compound) would produce a more ordered structure(s) which would, hopefully, retain the stacked chicken-wire networks. Of the many aromatic guests tried, pyrene readily formed a cocrystal by slow evaporation from ether/ethanol that was suitable for single-crystal X-ray diffraction (Fig. 1).[8a] The lattice was found to be monoclinic with a

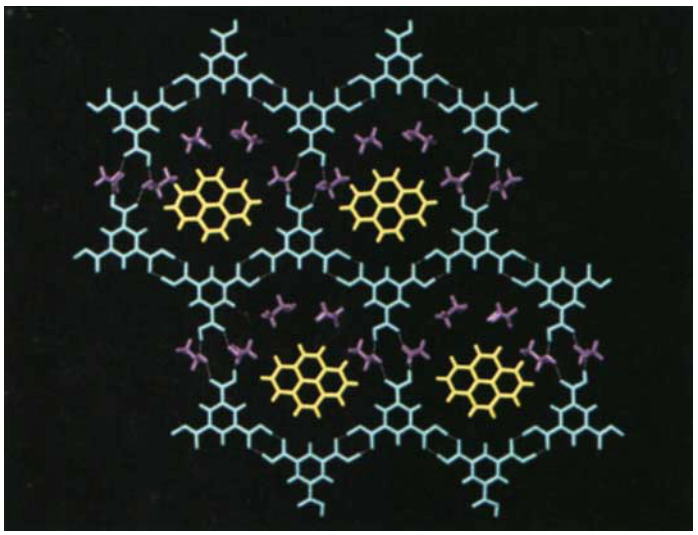

Fig. 1. Section from one layer of the crystal lattice of [2**2** · pyrene · 2 EtOH]. Light blue: **2**; yellow: pyrene; purple: EtOH.

large unit cell that contained 16 molecules of trimesic acid, 8 of pyrene, and 16 of ethanol. The structure consists of stacked layers of noninterpenetrated hydrogen bonded networks that superficially resemble the chicken-wire motif found in trimesic acid. In actuality the hydrogen bonded network is expanded. Thus, "infinite" ribbons are found wherein each trimesic acid is linked to two other trimesic acids by standard carboxylic acid dimers. The layers are formed by linking the remaining carboxylic acids with two ethanol molecules in a 12-membered hydrogen bonded ring (Scheme 1, **B**). The holes created by these "expanded" carboxylic acid dimers reside within one layer and are filled by one pyrene molecule and the ethyl groups of two ethanol molecules from an adjacent layer.

The second approach to disrupt interpenetration involved functionalizing the trimesic acid core.[9] Molecular modeling indicated that the chicken-wire networks derived from 2,4,6-tri-*n*-propyltrimesic acid (**3**) would have cylindrical holes with a diameter of approximately 6 Å. However, it remained to be seen whether the highly hindered carboxylic acids could form dimers, whether such dimers would result in hexagonal networks, and whether the layers would stack to form channels or cavities. For example, dimer formation is disfavored in 2,6-disubstituted benzoic acids.[10] The synthesis of **3** began with 1,3,5-trichlorobenzene, which was coupled with *n*-propylmagnesium bromide and [Ni(dppe)Cl_2] (dppe = ethane-1,2-diylbis(diphenylphosphane)) to give 1,3,5-tripropylbenzene in 64% yield.[11] Exhaustive bromination (62% yield) was followed by treatment with cuprous cyanide to give 2,4,6-tricyano-1,3,5-tri-*n*-propylbenzene in 80% yield. Hydrolysis to give the tricarboxylic acid occurred through the intermediacy of the triamide (80% w/w aq H_2SO_4, 155 °C), which was treated directly with sodium nitrite (95 °C) to give **3**. Compound **3** was best purified *in* the form of its trimethyl ester (CH_2N_2, 41% yield from nitrile); chromatography removed compounds containing unreacted nitrile or amide functions. The triester was converted into **3** in 64% yield by heating with a solution of hydrogen bromide in acetic acid.

Crystals of the acid were grown by slow evaporation from acetone and from aqueous ethanol, both giving the same X-ray structure (Fig. 2).[8b] All the carboxylic acid groups in the structure are nearly perpendicular to the plane of the benzene ring, yet two from each molecule form standard carboxylic acid dimers. These contacts produce an infinite ribbon similar to that found in isophthalic acid[12] and the trimesic acid inclusion complex described above. Rather than engaging in normal carboxylic acid dimers, which would produce the hexagonal networks found in trimesic acid, the third set of carboxylic acid groups form hydrogen bonded chains of type **C** (Scheme 1, Fig. 2). There is precedent for this nonstandard hydrogen bonding motif, known as the "catemer" motif, but it has been considered rare.[4] In the present structure this motif allows the third set of carboxylic acids in each stack of ribbons to be linked to those in two adjacent stacks. Close packing results with retention of the linear hydrogen bonds between the carboxylic acid groups.

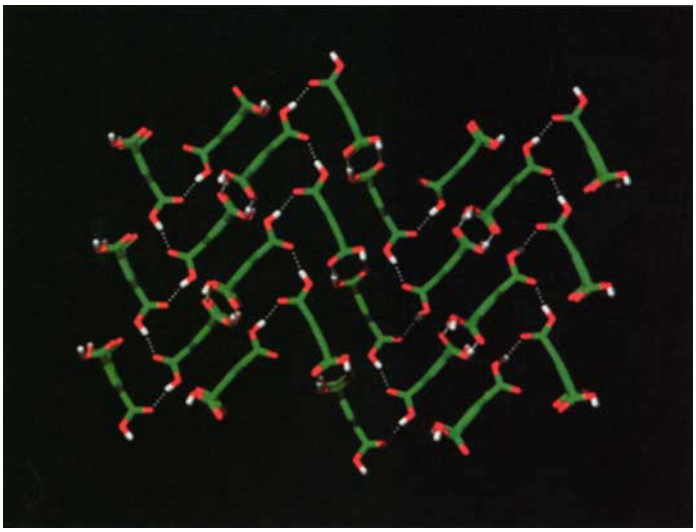

Fig. 2. View of the X-ray crystal structure of **3** along the *b* axis. The region $3a \times 2b \times 2c$ is shown. The propyl groups are removed for clarity.

The Cambridge Crystallographic Data File (CCDF, version 5.09) was searched to evaluate the number of examples containing the hydrogen bonding motifs **B**–**D** relative to those with the standard carboxylic acid dimer.[13] With the criterion that the intermolecular H···O distance in O–H···O interactions be < 2.8 Å and with an angle of > 90°,[14] 709 cases (90%) contained the standard dimer motif **A**, 31 (4%) the catemer

motif **C**, 39 (5%) the doubly bridged dimer **B**, and 9 (1%) the singly bridged dimer **D**. Although the 90% abundance of motif **A** indicates a degree of reliability, this figure is an upper limit because other packing motifs that occur were not considered. It is clear that carboxylic acid groups have a strong tendency to form centrosymmetric dimers, but several other motifs are possible.

A common feature that emerges in the structures of [2**2**·pyrene·2EtOH], **3**, and isophthalic acid[12] is the linking of benzene-1,3-dicarboxylic acid groups by carboxylic acid dimers to form ribbons. In the two structures described herein, the nonstandard carboxylic acid contacts occurred between the third carboxylic acid groups which link ribbons. This observation suggested the replacement of this putative carboxylic acid dimer by a covalent linkage that would unambigously hold the two isophthalic acid units in the desired orientation. For this reason **4** was synthesized[11] by palladium-mediated coupling of *tert*-butyl 5-bromo-2-butylbenzene-1,3-dicarboxylate and *tert*-butyl 5-ethynyl-2-butyl-benzene-1,3-dicarboxylate (30% yield) followed by deprotection with a mixture of formic and trifluoroacetic acid (90% yield).

Crystals of tetracarboxylic acid **4** were obtained by slow evaporation from tetrahydrofuran. Its structure, determined by X-ray analysis, showed the predicted hydrogen bonded network (Fig. 3),[8e] in which two layers stack with a slight offset along

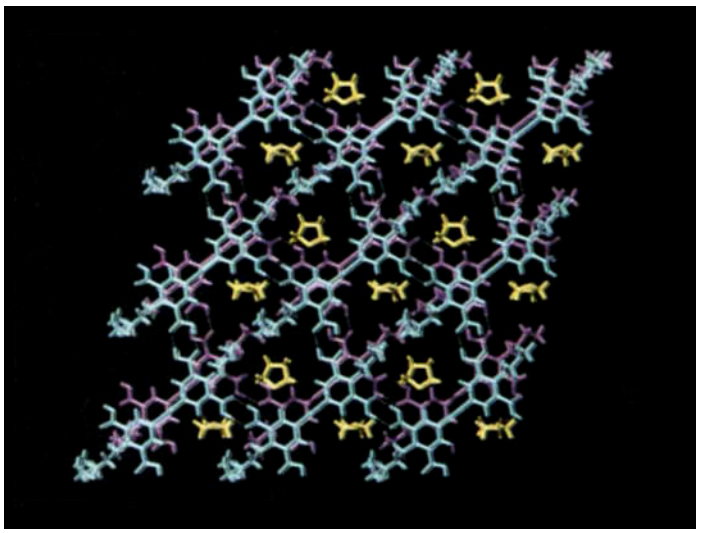

Fig. 3. View of the X-ray crystal structure of **4**·2THF along the *c* axis. The region $2a \times 2b \times 0.5c$ is shown.

the axis of the acetylene groups. Four butyl groups project into each of the resultant holes, partitioning them into two cavities, each of which is occupied by a THF molecule. The next two pairs of layers are identically stacked, but offset relative to the first pair to enclose the THF molecules in cavities. Two of the eight butyl groups of **5** in the unit cell are disordered in their methyl group positions.

The crystal packing of carboxylic acids has been studied extensively by Leiserowitz,[4] Etter,[10b] and others.[10a, 15] Our results with **2**–**4** and the CCDF searches described above indicate an even greater diversity of packing motifs for carboxylic acids, including dimers expanded by incorporation of one or two hydroxyl groups. Although there is a clear preference for formation of standard carboxylic acid dimers in the solid state, the reliability of this motif is perhaps less than previously thought. This lack of "geometrical persistence" presumably occurs because these alternative motifs allow for more favorable overall packing energies. We further suggest that nonstandard motifs are more common when the desired hydrogen bonded lattice is porous and thus in conflict with the demands of close packing. The design of **4**, which successfully crystallized as a clathrate, took into account the longer range packing preference that isophthalic acid exhibits in forming ribbons. We are currently testing the generality of this design strategy.

Synthesis and Structure of the Nanodimensional Multicyclophane "Kuratowski Cyclophane", an Achiral Molecule with Nonplanar $K_{3,3}$ Topology**

Chao-Tsen Chen, Peter Gantzel, Jay S. Siegel,* Kim K. Baldridge,* Robin B. English, and Douglas M. Ho

As chemists strive to synthesize polycyclic molecules with nanometer dimensions, problems of molecular entwinement become more prevalent,[1] and the general task of achieving topological stereocontrol arises.[2] The synthesis of molecules having the form of Möbius ladders,[3] trefoil knots,[4] and catenanes[5] exemplify topological stereocontrol in the construction of macrocycles (Fig. 1).[6] Möbius ladders belong to a family of

Fig. 1. Topologically defined synthetic targets. Möbius ladder (left), trefoil knot (middle), catenane (right).

structures with a nonplanar graph as their topological stereoelement.[7] The stereoelement of the Möbius-[3]ladder contains two sets of three points (atoms), where each point in one set is connected to every point in the other set; this element is called $K_{3,3}$.[8, 9] In general, topological stereoelements have symmetry as well as connectivity characteristics, and in the case of the Möbius-[3]ladder, the $K_{3,3}$ element is chiral. Directed construction of an achiral $K_{3,3}$ stereoelement is unrepresented in macrocyclophane synthesis.[10, 11] To address this issue, we present the molecular design, synthesis, and structure elucidation of an achiral (D_{2d}) macrocyclophane belonging to the $K_{3,3}$ nonplanar molecular graph family.

Kuratowski cyclophane **1**,[12] a polycyclic macrocyclophane, comprises a prolate spicular core of eight benzene rings (**2**) with the flanking rings connected pairwise across the equator by four 2,7-dihydroxynaphthalene units. The $K_{3,3}$ subgraph embeds on the molecular skeleton such that the vertices of the two independent three-point sets are one terminal benzene ring and the two flanking benzene rings of the opposite terphenyl crescent (Fig. 2).[13] The maximal symmetry is D_{2d} with achiral subsymmetries of C_{2v}, S_4, and C_s.

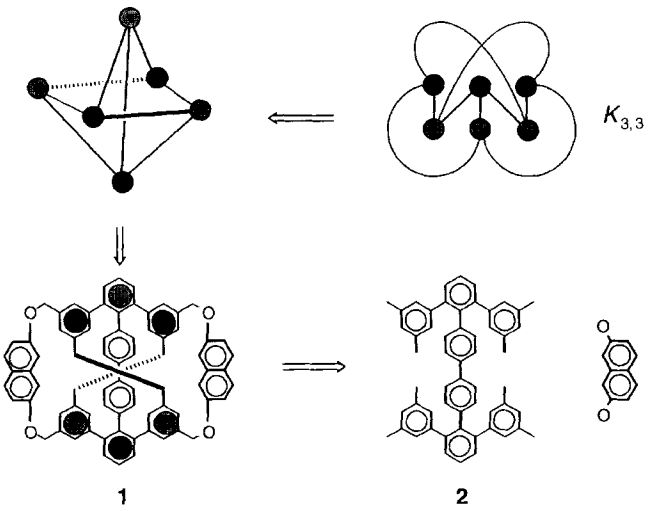

Fig. 2. Relationship between the $K_{3,3}$ graph and the structure of **1**, and dissection of **1** into its components.

The strategy for the synthesis of **1** was first to prepare the core and then perform a multifold macrocyclic ring closure to form eight bonds and four cycles in one step. The symmetric octaphenyl core could be prepared convergently from two different dissections: one divides the core into two quaterphenyl moities, whereas the other requires the capping of biphenyl with two terphenyl crescents (Fig. 3). Such *m*-terphenyl units can be

readily synthesized via benzyne intermediates by the action of an excess of an aryl Grignard reagent on 1,3-dichloro-2-iodobenzene (Hart reaction).[14]

Application of the Hart reaction of 3,5-dimethylphenylmagnesium bromide with 1,3-dichloro-2-iodobenzene followed by quenching with iodine, and alternatively trimethoxyborate, gave direct access to the terphenyl crescents **3** and **4**, respectively (Scheme 1). Ullmann coupling of **3** with 4-iodonitrobenzene followed by reduction of the nitro group with iron and Sandmeyer substitution ($NH_2 \rightarrow I$) produced quaterphenyl **5**, the sample of which was partitioned in two.[15] One part was converted to the boronic acid and then coupled with the other portion (Suzuki reaction) to yield the octamethyloctaphenyl core **2** (Table 1). Alternatively, direct Suzuki coupling of **4** with 4,4′-diiodobiphenyl gave **2** in one step. Conversion of the eight methyl groups of **2** into bromomethyl groups proceeded in four steps (oxidation with permanganate/pyridine, formation of the methyl ester, reduction with lithium aluminum hydride, and bromination with phosphorus tribromide/benzene) to give **6** in 50% overall yield (Table 1). Macrocyclization of **6** with four equivalents of 2,7-dihydroxynaphthalene formed macrocyclophanes **7** and **1**, which were separated by flash chromatography, in yields of 10 and 15%, respectively (Table 1). The two products showed the same molecular weight, and number and type of ^1H and ^{13}C NMR signals, indicating that both the D_{2h} and D_{2d} modes of cyclization occurred.

Semiempirical computations give energy-minimized structures for **7** and **1** with D_2 and S_4 symmetry, respectively.[16] The energy of **7** is 2.3 kcal mol^{-1} higher than that of **1** as gauged by the AM1 Hamiltonian. The ideal D_{2d} structure of **1** is a stationary point roughly 14 kcal mol^{-1} higher in energy than the S_4 conformation. Although the S_4 conformer is the most stable, dynamically a whole manifold of conformational minima are accessible. This dynamic behavior is responsible for the fluxional symmetry deduced from the degeneracy of the NMR signals.

Crystals of **1** and **7** were grown from benzene/hexane and subjected to X-ray diffraction analysis.[19] Diffraction data for **7** was consistent with the space group of *Pbcn* with four molecules in the unit cell. The direct-methods solution revealed **7** to be the "D_{2h}"-symmetric isomer. The data for **1** was collected assuming a $P\bar{1}$ space group with four molecules in the unit cell. A solution in line with the "D_{2d}"-symmetric isomer was proposed.[20] This solution refined to an R factor of 0.148. A disorder model using the chemically reasonable geometry from the AM1 calculations refined to a similar R factor. Neither isomer **7** nor **1** adopts its idealized symmetry in the crystal; **7** sits on a twofold axis and **1** in a C_1 general position. From the molecular geometry the structure of **1** is approximately S_4-symmetric, consistent with the calculations (Fig. 4). Each of the isomers crystallized with two benzenes of solvation per macrocyclophane included in the unit cell. In the case of **7**, the benzenes of solvation are trapped in specific clefts of the host molecule (Fig. 5) and are situated such that attractive polar/π interactions are maximized.[21] In the case of **1**, the benzenes of solvation form a herringbone channel filling the space between host molecules.[22]

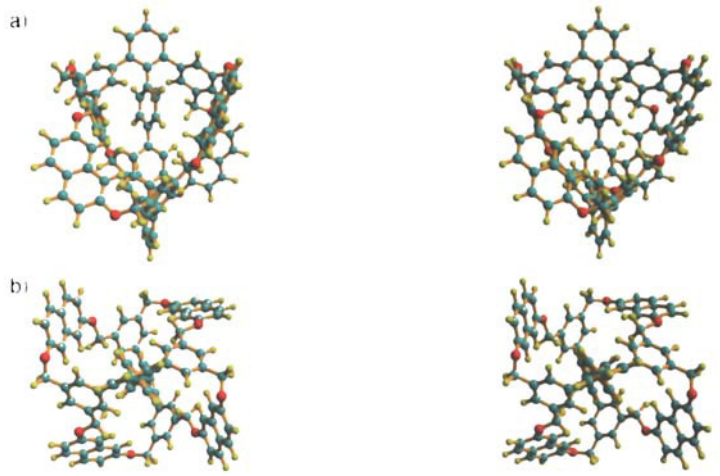

Fig. 4. Stereoview of **1** a) perpendicular to and b) down the long molecular axis (AM1 structure).

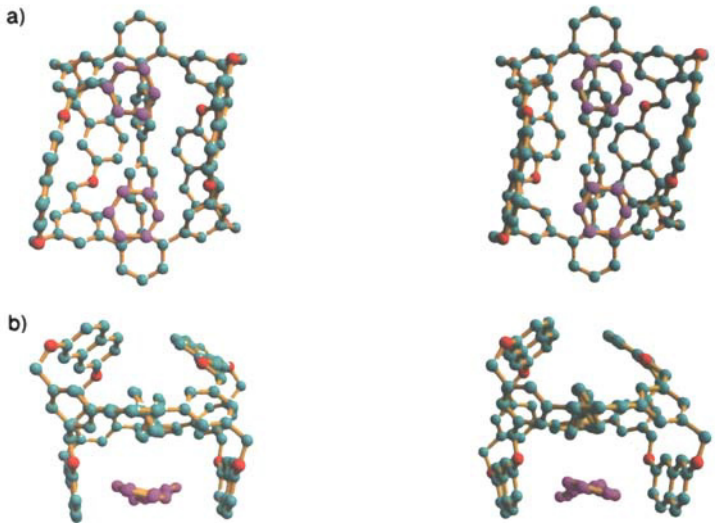

Fig. 5. Stereoview of **7** a) perpendicular to and b) down the long molecular axis (X-ray structure analysis).

The dimensions of these intricately entwined macrocyclophanes are nanometers in terms of length and kilodaltons in terms of mass, yet they can be prepared rapidly with clearly defined relative molecular masses, modeled accurately by a variety of computational algorithms, and characterized to atomic resolution by modern X-ray diffraction methods. The octaphenyl core of **1** can serve as a building block for the design of 10 kDa molecules that extend 100 Å. Thus, this study of a fundamental frontier of stereochemistry will expand to the development of molecules of novel dimensions and architectures.

[6] It is important that the reader and practitioner in the area of topological stereochemistry understand that a structure's "topology" is strongly dependent on definitions of connectivity (bonding), which in turn are dependent upon the context of the structural discussion. Indeed, in a trivial sense, crystalline sodium chloride is rich with topological networks, if each coulombic interaction is viewed as a connection. Thus, without novel structural design, chemical synthesis, and/or molecular properties as motivation, the chemical significance of such investigations loses context.

[8] Within mathematical graph theory there are two fundamental nonplanar graphs, the graph of five points maximally connected to one another (K_5) [9], and the graph of two sets of three points maximally cross connected ($K_{3,3}$). See: F. Harary, *Graph Theory*, Addison-Wesley, Reading, MS, USA, **1969**.

[9] For molecules described by K_5 graphs see a) chiral: H. E. Simmons, III, J. E. Maggio, *Tetrahedron Lett.* **1981**, *22*, 287; S. A. Benner, J. E. Maggio, H. E. Simmons, III, *J. Am. Chem. Soc.* **1981**, *103*, 1581; b) achiral: D. Kuck, A. Schuster, *Angew. Chem.* **1988**, *100*, 1222; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 1192.

[10] Liang and Mislow have surveyed structures including those of coordination compounds and iron–sulfur clusters and have found alternative achiral $K_{3,3}$ molecules, which they discuss in the context of the classification of topological molecules, see: C. Liang, K. Mislow, *J. Math. Chem.* **1994**, *15*, 245.

[11] For a discussion of the complete molecular graph and its ramifications on discussions of chemical connectivity and topology. See: K. Mislow, *Bull. Soc. Chim. Belg.* **1977**, *86*, 595.

[12] Compound **1** was named after the mathematician Casimir Kuratowski, who first proved that K_5 and $K_{3,3}$ are the fundamental nonplanar graphs and that every nonplanar graph must contain one or both of these fundamental graphs. See: C. Kuratowski, *Fund. Math.* **1930**, *15*, 271.

[13] Identifying the vertices of the graph with entire benzene nuclei, as we have in Fig. 2, yields a representation that is contractible only to $K_{3,3}$. Liang and Mislow have chosen to view our structure with specific atoms as vertices; the added cyclic paths lead to a graph connectivity that can be contracted to either K_5 or $K_{3,3}$ [10]. The possibility of graphs having both K_5 and $K_{3,3}$ subgraphs is an instructive demonstration. See: R. J. Trudeau, *Dots and Lines*, Kent State University Press, **1976**, p. 91.

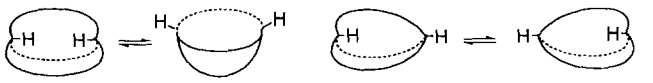
Homeomorphic Isomerism in a Peptidic Macrobicycle**

Richard S. Wareham, Jeremy D. Kilburn,*
David L. Turner, Nicholas H. Rees,
and Duncan S. Holmes

Bicyclic molecules with sp^3-hybridized carbon bridgehead atoms exhibit an unusual form of isomerism, since such molecules can exist as *in–in* (**1**), *out-out* (**2**), or *in-out* isomers (**3** and **4**) (Scheme 1).[1] In principle, isomers (atropisomers) **1** and **2** can interconvert when one of the chains slips through the center of the ring it bridges, effectively turning the molecule inside out—a process referred to as homeomorphic isomerization.[2] A similar homeomorphic isomerization is also possible for the *in–out* isomers **3** and **4**, although these two structures are degenerate unless one of the chains is appropriately labeled, since the sense of each bridgehead is simply exchanged. Although a number of possible isomers of bicyclic systems with sp^3-hybridized carbon bridgehead atoms have been prepared,[3] interconversion of such compounds by homeomorphic isomerization has rarely been reported.[4] *In–out* homeomorphic isomerism was first observed for large bicyclic polyethers,[5] based on changes in the NMR spectra of these compounds at low temperature, and more recently *in–in* to *out–out* homeomorphic isomerism of bicyclo[6.5.1]tetradecane has been described,[3c] again based on NMR studies of the equilibrium mixture.



Scheme 1. Diagrammatic representation of homeomorphic isomerization.

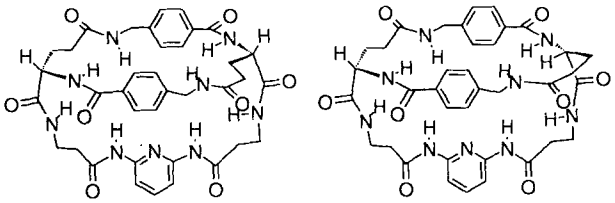
[**] We would like to thank Glaxo Research and Development and the SERC for a CASE award to R. S. W., and Dr. Graham Calder, Rowett Research Institute, Aberdeen (UK), for the amino acid analysis.

In our own work we have synthesized a series of macrobicyclic molecules, designed to serve as receptors for peptide derivatives by combining binding sites for the carboxylic acid terminus of a peptidic guest with additional amide functionalities to bind to the backbone of such a guest.[6] Thus we have reported the synthesis of the racemic C_2-symmetric (L-Glu, L-Glu) macrobicycle **5**, which was prepared along with the diastereomeric (L-Glu, D-Glu) macrobicycle **6**.[6b] Determination of the solution conformation of **5** revealed that it exists as the *out–out* isomer, with no trace of the corresponding *in–in* isomer. The diastereomeric macrobicycle **6** can be viewed as an *in–out* isomer, but homeomorphic isomerization of this compound (L-Glu-*out*,D-Glu-*in* ↔ L-Glu-*in*,D-Glu-*out*) merely leads to the mirror-image structure. In this paper we describe a related macrobicycle, which has been isolated as two distinct *in–out* atropoisomers and which, in solution in DMSO at room temperature, interconvert with a half-life of the order of several days.

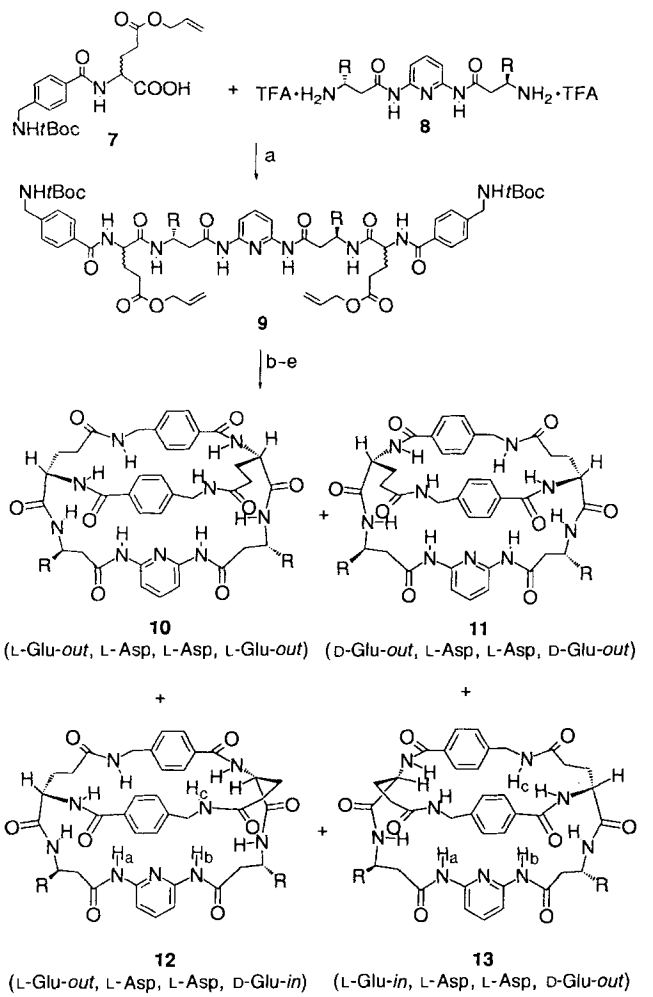


5 (L-Glu-*out*, L-Glu-*out*)

6 (L-Glu-*out*, D-Glu-*in*)

Our original studies[6b] on the solution conformation of macrobicycle **5** revealed that the amidopyridine unit is inverted and sandwiched between the aromatic units of the two other chains, in a conformation that is not predisposed to bind peptides as we had planned. In addition **5** is soluble only in polar solvents such as DMSO, which tends to preclude strong hydrogen bonding interactions in host–guest complexes. To improve the solubility of related compounds we undertook the synthesis of the closely related macrobicycle **10**, which simply required the replacement of β-alanine in the original structure **5** with the more lipophilic benzyl ester of aspartic acid. The synthesis of **10** (Scheme 2) parallels the original synthesis of **5**, and, as before, racemization of the glutamic acid centers in the course of the synthesis led to the isolation of diastereomeric macrobicycles, including the desired C_2-symmetric (L-Glu, L-Asp, L-Asp, L-Glu) macrobicycle **10** and the C_2-symmetric (D-Glu, L-Asp, L-Asp, D-Glu) macrobicycle **11**.[7]

In addition we isolated two other macrobicyclic structures, **12** and **13**, with different R_f values and whose NMR spectra (Fig. 1) indicate that they are not C_2 symmetric. On standing in a solution of DMSO at room temperature, however, both of these initially pure compounds converted over several days to a mixture of the two. Three pairs of amide proton resonances (NH_a, NH_b, and NH_c, Scheme 2) were monitored during equilibration by NMR spectra measured at 20 °C, starting from a pure sample of the minor form. The changes in the integrals of these signals over time yielded a half-life of 158 h ($k_{20} = 1.22 \times 10^{-6}$ s^{-1}) for the major component; the final ratio of isomers of 62:38 corresponds to a difference in energy of 1.16 kJ mol^{-1}. Monitoring the later stage of equilibration at 50 °C gave a half-life of 4 h ($k_{50} = 4.84 \times 10^{-5}$ s^{-1}) and an approximate activation energy of 95 kJ mol^{-1}. Subsequent amino acid analysis of the two separate compounds indicated that they were both derived from L-aspartic acid and a 50:50 mixture of



Scheme 2. Synthesis of macrobicycles **10**–**13**, R = CO_2Bn. a) PyBOP, DIPEA, DMF (57%); b) 5 mol% $[Pd(PPh_3)_4]$, 12.5 mol% Ph_3P, pyrrolidine, CH_2Cl_2 (100%); c) C_6F_5OH, DCC, THF; d) 25% TFA in CH_2Cl_2; e) syringe pump addition of bis(TFA) salt in DMF to a solution of DIPEA (6.0 equiv) in CH_3CN at 30 °C, 5 mM final concentration (30% combined yield of **10**–**13** over three steps). PyBOP = benzotriazol-1-yloxytripyrrolidinophosphonium hexafluorophosphate; DIEA = diisopropylethylamine; DCC = dicyclohexylcarbodiimide; TFA = trifluoroacetic acid.

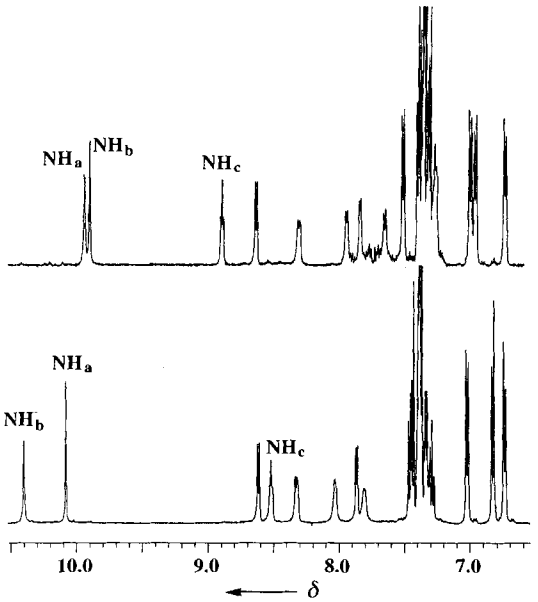


Fig. 1. 500 MHz ^1H NMR spectra of the minor (top) and major (bottom) forms of the macrobicyclic isomers **13** and **12**, respectively.

L- and D-glutamic acid.[8] Furthermore, the interproton distances across the peptide linkages (based on self-consistent distance constraints obtained from ROESY spectra of each form; vide infra) showed unequivocally that the amide bonds are all *trans* in both compounds. This rules out the possibility that the two compounds result from *cis*–*trans* configurational isomerism of one of the amide bonds. We therefore concluded that the interconversion of the two compounds is due to conformational (homeomorphic) isomerism of the two atropoisomers of the (L-Glu, L-Asp, L-Asp, D-Glu) macrobicycle, namely, the (L-Glu-*in*, L-Asp, L-Asp, D-Glu-*out*) isomer **12** and the (L-Glu-*out*, L-Asp, L-Asp, D-Glu-*in*) isomer **13**, which are distinguishable by virtue of the stereocenters in the aspartic acid residues.

Interconversion of **12** and **13** requires one of the chains to slip through the ring it bridges. To establish the most likely mechanism for this process we have determined the conformations of both **12** and **13** in DMSO solution by means of distance geometry calculations[9] with self-consistent distance constraints[10] based on the ROESY spectra. The NMR spectra of both forms were fully assigned using ROESY, TOCSY, and COSY spectra obtained at 500 MHz, as described previously.[6b] Self-consistent distance constraints were obtained from the ROESY spectra of each form by using a model with bridgehead carbons having D and L configurations but with the absolute configurations of the carbons bearing the benzyl ester substituents unspecified. Stereochemical assignment of the methylene protons in the chains with phenyl groups proved straightforward. Also, although the phenylene groups rotate rapidly in both forms, with the assumption of 180° ring flips,[6b] several crosspeaks could be assigned specifically to one side or the other of each phenylene ring. The orientation of one phenylene ring was more clearly defined than the other, indicating that it occupies a central position in the structure. The conformations obtained for the two forms (excluding the benzyl ester substituents) were well defined and almost exact mirror images, even though the limited time allowed for data acquisition (before appreciable isomerization had occurred) meant that interproton distances were defined for the minor form with an accuracy of only 0.45 nm and only 0.40 nm for the major form. The similarity between the two conformations is consistent with the similar patterns of NMR coupling constants and the observation that the chemical shifts of individual protons change by no more than 0.5 ppm between the two forms. However, the absolute configurations at the sites of benzyl ester attachment are not clear cut as a result of a lack of constraints, partially due to signal overlap. This uncertainty is not surprising in view of the small energy difference between the conformers, which implies that the ester groups are sterically unconstrained in both forms, and the absence of cross peaks to the benzyl ester methylene protons. However, the minor form (Fig. 2) fits structure **13** slightly better.

The solution conformations clearly indicate that the isomers isolated are indeed the two atropoisomers **12** and **13** of the (L-Glu, L-Asp, L-Asp, D-Glu) macrobicycle. Furthermore, whereas in the solution conformation of the *out*–*out* macrobicycle **5**[6b] the amidopyridine unit is inverted and sandwiched between the aromatic units of the two other chains, in the solution conformations of the *in*–*out* macrobicycles **12** and **13** the amidopyridine unit is folded around the outside, effectively sandwiching one of the two phenylene groups between the amidopyridine unit and the other phenylene. These conformations suggest that in a likely mechanism of isomerization the central chain, incorporating the sandwiched phenylene group, moves through the ring it bridges. The measured activation energy for interconversion (95 kJ mol^{-1}) is sufficiently high for the transition state to involve nonplanar peptide links, and ex-

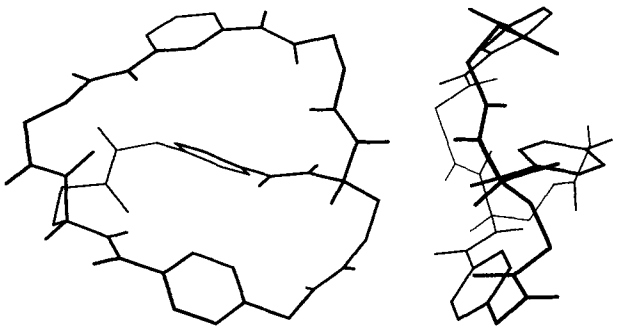

Fig. 2. Views of the solution conformation of the minor atropisomer, excluding hydrogen atoms (except NH and the two bridgehead protons) and the benzyl ester substituents. All protons were assigned except for those on the chain containing the amidopyridine unit. The distance geometry calculations included 68 upper and 60 lower limit distance constraints, none of which were violated by more than 0.5 Å. This form probably corresponds to **13** (see text).

amination of CPK models suggests that interconversion may indeed require substantial twisting of amide bonds. Examination of CPK models also indicates that the alternative mechanism, slippage of the diamidopyridine chain through the center of the structure, is sterically improbable.

In conclusion, two interconverting atropoisomers of an *in–out* bicyclic compound with sp^3-hybridized bridgehead carbon atoms have been isolated for the first time. The solution conformations of these isomers have been determined and a likely mechanism for the interconversion (homeomorphic isomerism) has been identified.

Emge, *ibid.* **1992**, *57*, 433, and references therein; c) M. Saunders, N. Krause, *J. Am. Chem. Soc.* **1990**, *112*, 1791, and references therein.

[4] Bicyclic systems with nitrogen bridgehead atoms can also exhibit *in–in*, *out–out*, or *in–out* isomers, and have been studied in detail: see R. W. Alder, E. Heilbronner, E. Honegger, A. B. McEwen, R. E. Moss, E. Olefirowicz, P. A. Petillo, R. B. Sessions, G. R. Weisman, J. M. White, Z.-Z. Yang, *J. Am. Chem. Soc.* **1993**, *115*, 6580, and references therein. However, intercoversion between the various isomeric forms can occur by inversion of the nitrogen atom, which is not homeomorphic isomerism.

[5] a) B. J. Gregory, A. H. Haines, P. Karntiang, *J. Chem. Soc. Chem. Commun.* **1977**, 918; b) A. H. Haines, P. Karntiang, *J. Chem. Soc. Perkin Trans. 1* **1979**, 2577.

[7] Close similarities between the 1D ^{1}H NMR and ROESY spectra of **5**, and of **10** and **11**, indicate that the latter two are also *out–out* isomers, and also probably have the pyridine inverted as described for **5**. No compounds that might correspond to the *in–in* isomers were isolated in these studies.

[8] Amino acid analysis was performed by complete hydrolysis of **12** and **13** and conversion of the resulting amino acids into their methyl ester *N*-pentafluoropropionyl derivatives. The D and L isomers were separated on a Chirasil-L-Val capillary column.

Synthesis and Structure of $[Li(thf)_4]_2(Ph_2P)_{10}Cd_4]$ Containing a Dianion with a Cd_4P_{10} Adamantanoid Core**

Michael A. Beswick, Paul R. Raithby, Christopher A. Russell, Alexander Steiner, Kerry L. Verhorevoort, Gregory N. Ward, and Dominic S. Wright*

In the past twenty years there has been considerable interest in "single-source" precursors, in particular those containing elements of Groups 13 and 15 in well-defined stoichiometries, for vapor-phase deposition of semiconducting thin films such as [GaAs] and [InP].[1–3] The use of such precursors has considerable advantages over more traditional two-component deposition, for example GaAs from $[GaMe_3]$ and $[AsH_3]$, because their stoichiometry is easier to control and they are easier to purify, less toxic, and less pyrophoric. In contrast, single-source materials containing mixtures of elements from Groups 12/15 and Groups 12/16 have been studied far less extensively, despite the potential applications of these materials to a number of technologically important phases such as [CdS][4] and $[Zn_3P_2]$.[5] We have recently reported the syntheses and structures of a number of molecular zinc phosphide complexes generated from metalation of secondary phosphanes R_2PH with $ZnEt_2$.[6] These complexes, containing various Zn:P ratios, are potential single-source materials for the deposition of Zn/P phases. However, possibly owing to the lack of a commercially available organometallic source of Cd and partly as a result of the lack of a general method of synthesis, very few Cd/P complexes have been investigated. The monomer $[Cd\{P(SiPh_3)_2\}_2]$[7] and the dimer $[\{(Me_3Si)_2PCd[\mu\text{-}P(SiMe_3)_2]\}_2]$[8] are prepared by deprotonating $(R_3Si)_2PH$ (R = Ph, Me) with $[Cd\{N(SiMe_3)_2\}_2]$. These complexes, along with the trimer $[\{MeCd(\mu\text{-}PtBu_2)\}_3]$, which is prepared by the ligand transfer reaction of Me_2Cd with $[Ga(PtBu_2)_3]$,[9] are among the few simple phosphido complexes that have been structurally characterized. With respect to the lack of generality of synthetic routes to these complexes, it is noteworthy that desilylation reactions of phosphide anions result in mixed-ligand (phosphide/halide) aggregates, as is observed in the synthesis of $[Cd_4Cl_4(PPh_2)_4(PnPr_3)_2]$ from the reaction of Ph_2PSiMe_3 and $CdCl_2$ in the presence of $PnPr_3$.[10]

We report here the high-yielding synthesis of complex **1** from the nucleophilic substitution reaction of $[Cd\{N(SiMe_3)_2\}_2]$ with $[LiPPh_2]$ (mol ratio 1:2) in THF (Scheme 1). The complex con-

$[Li(thf)_4]_4[(Ph_2P)_{10}Cd_4]$ **1**

tains an adamantane-like $[(Ph_2P)_{10}Cd_4]^{2-}$ anion, the first polynuclear, organometallic, anionic cadmium phosphide to be structurally characterized. The product of the reaction of $[Cd\{N(SiMe_3)_2\}_2]$ with phosphide anions appears to be dictated by the organic groups R present in the alkali metal diorganophosphide $LiPR_2$. In contrast to the synthesis of **1**, the reaction of $[Cd\{N(SiMe_3)_2\}_2]$ with $[LiP(cy)_2]$ (cy = cyclohexyl, C_6H_{11}) results in the formation of $(cy_2P)_2$ **2**[11] as a consequence of a

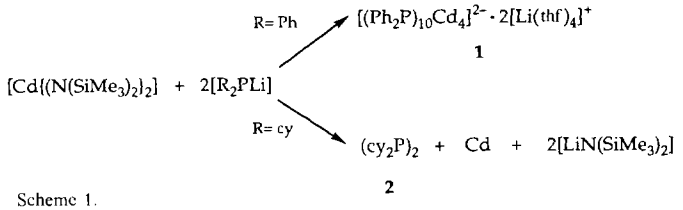

Scheme 1.

coupling reaction (see Experimental Procedure). This observation presumably reflects the relative stability of the intermediate Group 12 metal phosphide complexes initially formed and may be attributed to the lack of conjugative stabilization in the cyclohexylphosphide anion.

An X-ray crystallographic study of **1** shows that the complex is an ion-separated species (Fig. 1).[12] In addition, 5.5 molecules of THF as lattice solvent are present per asymmetric unit.

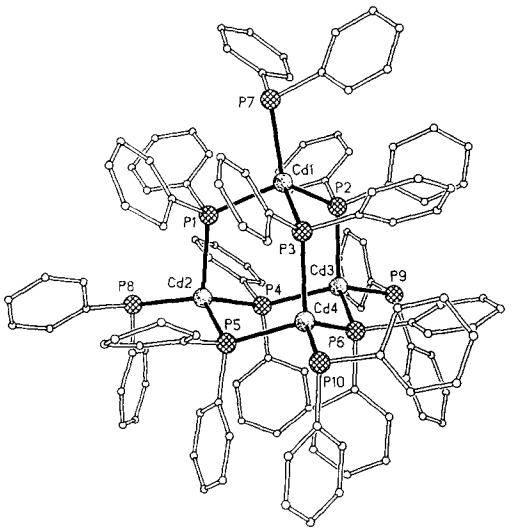

Fig. 1. Molecular structure of the dianion in **1**. Lattice-bound THF molecules and hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Cd(1)-P(1) 2.647, Cd(1)-P(2) 2.646(3), Cd(1)-P(3) 2.661(3), Cd(1)-P(7) 2.596(3), Cd(2)-P(1) 2.683(3), Cd(2)-P(4) 2.684(3), Cd(2)-P(5) 2.635(3), Cd(2)-P(8) 2.624(3), Cd(3)-P(2) 2.651(3), Cd(3)-P(4) 2.649(3), Cd(3)-P(6) 2.635(3), Cd(3)-P(9) 2.604(3), Cd(4)-P(3) 2.687(3), Cd(4)-P(5) 2.674(3), Cd(4)-P(6) 2.635(3), Cd(4)-P(10) 2.612(3); P(1)-Cd(1)-P(2) 109.07(8), P(1)-Cd(1)-P(3) 99.11(8), P(1)-Cd(1)-P(7) 106.76(9), P(2)-Cd(1)-P(3) 104.53(8), P(2)-Cd(1)-P(7) 121.40(9), P(3)-Cd(1)-P(7) 113.69(9), P(1)-Cd(2)-P(4) 101.94(8), P(1)-Cd(2)-P(5) 106.52(8), P(1)-Cd(2)-P(8) 105.20(9), P(4)-Cd(2)-P(5) 106.59(8), P(4)-Cd(2)-P(8) 107.83(9), P(5)-Cd(2)-P(8) 126.24(8), P(2)-Cd(3)-P(4) 105.71(8), P(2)-Cd(3)-P(6) 106.01(8), P(2)-Cd(3)-P(9) 106.54(9), P(4)-Cd(3)-P(6) 103.62(9), P(4)-Cd(3)-P(9) 121.54(9), P(6)-Cd(3)-P(9) 112.34(10), P(3)-Cd(4)-P(5) 104.98(8), P(3)-Cd(4)-P(6) 102.72(8), P(3)-Cd(4)-P(10) 109.43(9), P(5)-Cd(4)-P(6) 103.58(8), P(5)-Cd(4)-P(10) 110.36(9), P(6)-Cd(4)-P(10) 124.07(9), Cd(1)-P(1)-Cd(2) 119.34(10), Cd(1)-P(2)-Cd(3) 115.97(9), Cd(1)-P(3)-Cd(4) 121.62(9), Cd(2)-P(4)-Cd(3) 118.48(10), Cd(2)-P(5)-Cd(4) 116.24(9), Cd(3)-P(6)-Cd(4) 119.78(10).

The $[(Ph_2P)_{10}Cd_4]^{2-}$ ion of **1** contains a Cd_4P_6 core with the adamantanoid structural motif of three interlocking six-membered rings containing μ-PPh_2 ligands. Each cadmium center is also bonded to a terminal PPh_2 phosphido moiety. The Cd-μ-P bonds are longer than those made with the terminal phosphido ligands, (av Cd-μ-P 2.66 Å, cf. 2.54 Å in $[Cd_4Cl_4(PPh_2)_4(PnPr_3)_2]$;[10] av $Cd-P_{terminal}$ 2.63 Å). Presumably as a consequence of the steric requirements of the phenyl rings, the cadmium centers have distorted tetrahedral coordination environments (μ-P-Cd-$P_{terminal}$ angles range 105.20(9)–126.24(8)°, μ-P-Cd-μ-P angles range 99.11(8)–109.43(9)°). In contrast, the Cd-P-Cd bond angles within the cage are more uniform (range 115.97(9)–121.62(9)°).

Adamantanoid cores have also been observed in the structures of a few cadmium sulfides: $(NMe_4)_2[(\mu\text{-}SC_6H_5)_6Cd_4Br_4]$,[14] $(Et_3NH)_2[(\mu\text{-}SC_6H_5)_6Cd_4(SC_6H_5)_4]$,[15] $(NEt_4)_2[(\mu\text{-}SiPr)_6Cd_4Br_4]$,[16] and $[(\mu\text{-}SiPr)_6(CdPPh_3)_2(CdOClO_3)_2]\cdot EtOH$.[17] Although $[Cd_4Cl_4(PPh_2)_4(PnPr_3)_2]$ contains a neutral adamantanoid core, **1** contains the first structurally characterized homolyptic cadmium phosphide adamantanoid fragment. The exclusion of the halide is of importance in the anion of **1** because of its potential application as a single-source precursor for semiconducting Cd/P phases.

The ^{31}P NMR spectrum of **1** in solution exhibits a single resonance at room temperature ($\delta = -41.5$). As the temperature is decreased, splitting of the signal is observed (<213 K). The low temperature required for this resolution corresponds to the low activation energy of a process such as intramolecular interconversion of the terminal and bridging PPh_2 ligands of the anion. In addition, at lower temperatures satellites are also observed, corresponding to the $^{31}P-^{111/113}Cd$ coupling of roughly 100 Hz.

In conclusion, complex **1** is a rare example of a structurally characterized organometallic cadmium phosphide, which not only has an interesting structure but is also a potential single-source precursor for the formation of a Cd/P semiconducting phase.

Experimental Procedure

1: BuLi (3.13 mL of 1.6 M solution in hexanes, 5.0 mmol; Aldrich) was added to a solution of diphenylphosphane (0.87 mL, 5.0 mmol; Strem) in 10 mL of THF. $[Cd\{N(SiMe_3)_2\}_2]$ [18] (1.0 mL, 2.5 mmol) was added to the red solution formed. The reaction mixture was stirred at room temperature for 5 min. The resulting yellow precipitate was dissolved by the addition of a further 30 mL of THF and heated to reflux. The yellow solution was allowed to stand for 12 h at room temperature, and air-sensitive, yellow crystals of **1** formed in 70% yield (1.00 g, first batch). During isolation the lattice-bound THF was removed under vacuum (10^{-2} atm, 10 min), resulting in an amorphous yellow powder, which was used in the following analyses: decomposition to a black solid above 200 °C; ^1H NMR (+25 °C, 250 MHz, 0.2 mol L^{-3}, $[D_8]$THF): $\delta = 7.41-7.26$ (overlapping multiplets, 100 H, Ph), 3.60 (m, 32 H, THF), 1.75 (m, 32 H, THF); ^{31}P NMR (+25 °C, 101.2 MHz, 0.2 mol L^{-3}, $[D_8]$THF, referenced to 85% H_3PO_4 at $\delta = 0$): $\delta = -41.5$; Anal. calcd C 63.0, H 5.7, P 10.7; found C 62.4, H 5.7, P 10.4.

2: BuLi (3.13 mL of 1.6 M solution in hexanes, 5.0 mmol; Aldrich) was added to a solution of cy_2PH (1.1 mL, 5.0 mmol; Strem) in 10 mL of THF. $[Cd\{N(SiMe_3)_2\}_2]$ [18] (1.0 mL, 2.5 mmol) was added to the yellow solution produced and the mixture was brought to reflux for 5 min. The reaction mixture was filtered (Celite, porosity 3) to produce a yellow solution. The solution was reduced in vacuo to 7 mL and 2 mL of hexane was added. Subsequent storage for 24 h at room temperature yielded air-sensitive, colorless crystals of **2** in 35% yield (0.35 g, first batch). Physical properties of **2** are in agreement with the literature data [11, 19]. M.p. 173 °C; ^1H NMR (+25 °C, 250 MHz, 0.2 mol L^{-3}, $[D_8]$THF): $\delta = 2.04-1.22$ (overlapping multiplets, 44 H, cy); ^{31}P NMR (+25 °C, 101.2 MHz, 0.2 mol L^{-3}, $[D_8]$THF, referenced to 85% H_3PO_4 at $\delta = 0$): $\delta = -22.2$ (s); Anal. calcd C 73.0, H 11.2, P 15.7; found C 72.4, H 11.0, P 15.0.

[12] Crystal data for **1**: $C_{152}H_{164}Cd_4Li_2O_8P_{10}\cdot 5.5\,THF$, $M = 3288.58$, triclinic, space group $P\bar{1}$, $a = 17.261(6)$, $b = 17.996(6)$, $c = 29.470(13)$ Å, $\alpha = 88.89(3)$, $\beta = 89.14(2)$, $\gamma = 61.85(2)°$, $V = 8070(5)$ Å^3, $Z = 2$, $\rho_{calc} = 1.353$ Mgm^{-3}, $\lambda = 0.71073$ Å, $T = 153$ K, $\mu(Mo_{K\alpha}) = 0.679$ mm^{-1}. Data was collected on a Siemens-Stoe AED diffractometer using an oil-coated, rapidly cooled crystal of dimensions $0.4 \times 0.3 \times 0.3$ mm mounted directly from solution [13]; θ/ω method ($5° \le 2\theta \le 45°$). The data were corrected for absorption by a semiempirical method based upon Ψ-scan data with maximum and minimum transmission of 0.908 and 0.775, respectively. Of 21 897 reflections collected, 21 131 were independent. The structure was solved by direct methods (SHELXTL PLUS) and refined by full matrix least squares on F^2; $R1$ [$F > 4\sigma(F)$] and $wR2$ (all data) to 0.0729 and 0.1656, respectively (SHELXL-93, Göttingen, **1993**). All the non-hydrogen atoms in the anion of **1** were refined with anisotropic displacement parameters. One of the $[Li(thf)_4]^+$ cations and 3.5 of the 5.5 independent noncoordinated THF molecules are disordered on two positions, half of them on the inversion center. All five non-hydrogen atoms of each THF molecule in the unit cell were refined with the same isotropic parameters and distance restraints. Hydrogen atoms were set geometrically. Maximum and minimum residual electron density in the final difference map, 2.018 and -1.103 e Å^{-3}, respectively. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

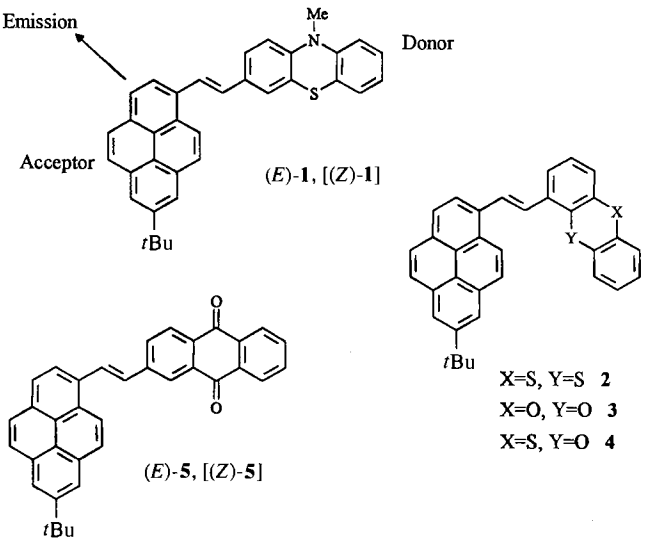
Luminescence Stimulated by Electron Transfer: Fluorescent Donor/Acceptor-Substituted Stilbenes Containing Pyrenoid and Heteroaromatic Subunits**

Andreas Knorr and Jörg Daub*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

The donor/acceptor concept has gained fundamental meaning for the chemistry and the physics of dyes because it describes both the absorption and the nonlinear optical (NLO) effects (e.g. molecular hyperpolarization) of compounds with auxochromic and antiauxochromic groups.[1] Donor and acceptor subunits not only lead to the polarization of conjugated π-electron systems, they can also participate in the exchange of electrons, resulting in the formation of radical cations and radical anions. In the broadest sense, this structural principle is responsible for the basic process of artificial and natural photosynthesis (photochemically induced charge separation)[2] and also serves as a basis for developing model compounds.[3] The energy stored in radical anion/radical cation pairs can also lead to the emission of electromagnetic radiation, a process that occurs in solution as electrochemically generated luminescence (ECL).[4] This process is at present under intensive investigation in view of the application of polymeric and oligomeric compounds in light-emitting devices.[5] We report here on specially designed donor/acceptor-substituted stilbenes. The "optoelectronic" multifunctionality of these compounds is determined by the electron transfer active donor/acceptor subunits and by the luminescent substructure. These stilbenes have been studied in detail by using electrochemical and optoelectrochemical methods to clarify the relation of electron transfer, electronic structure, and molecular structure. The long-range goal is to develop substances and materials for the conversion of electrochemical energy into photonic energy.[6]

Stilbenes **1**–**4** contain the pyrene chromophore as an acceptor group and phenothiazine, thianthrene, dibenzodioxine, or phenoxathiin building blocks as donor groups. These combined units



are expected to give rise to an adequate emission.[7] For comparison, pyrenyl vinyl anthraquinone **5** is included in the investigations.

Compounds **1**–**5** were synthesized by Wittig reactions of suitable precursors. The (*E*)/(*Z*) isomers were separated by conventional column chromatography on silica gel.[8]

Cyclic voltammetry shows that it is not the heterocyclic but rather the pyrene subunit that is responsible for the formation of the radical cations of **2**–**4** by oxidation; the radical cations are formed at a potential typical of pyrenes and the process is irreversible. The oxidation of the anthraquinone derivatives (*Z*)-**5** and (*E*)-**5** is also irreversible. In the case of the phenothiazine derivative **1**, the reversible oxidations observed are typical of phenothiazines. In compounds **1**–**4**, the electron transfer in the reduction region is determined by the pyrene substructure, as expected. On the other hand, the anthraquinone derivatives (*Z*)-**5** and (*E*)-**5** show three reversible reduction waves in the cyclic voltammogram: the first two electron transfers can be assigned to the anthraquinone and the third electron transfer to the pyrene (Table 1).

Generally, in all electrochemical processes of **1**–**5** one observes a shift of the $|E|$ values of the electron transfer processes to

[a] Half-wave potentials $E_{1/2}$ [mV] of the parent compounds: pyrene: Red. −2535, Ox. (E_{pa}) 910; *N*-methylphenothiazine: Ox. 325; 9,10-anthraquinone: Red. 1 −1320, Red. 2 −1920; thianthrene: Ox. 835; dioxine: Ox. 995; phenoxathiin: Ox. 800.

lower potentials in comparison to those of the unsubstituted electrophores. This indicates that the energy of the highest occupied molecular orbital increases and/or the energy of the lowest unoccupied molecular orbitals decreases in comparison to those of the parent structures (Table 1).

This observation is again confirmed by spectroelectrochemical studies. Reversible processes on the time scale of electrochemistry are found for the oxidation of (*E*)-**1** to its radical cation as well as for the reduction of **2**–**5** to their radical anions. In all cases both the wavelength of the absorption bands and the structure of the spectra are remarkably different from those from the spectra of the unsubstituted electrophores (Table 2). In particular, the longest wavelength absorptions of **1**–**5** are significantly red-shifted with respect to those of the unsubstituted subunits (Table 2). This indicates that the optical properties are not determined by substructures but by the whole chromophore. However, in case of (*Z*)-**5** similarities with the unsubstituted anthraquinone are apparent, indicating a localized anthraquinone/semiquinone spectrum, which can be explained by a nonplanar structure and pronounced twisting between the substructures.

Table 2. UV/Vis/NIR data of the radical ions and UV/Vis data of the neutral compounds from spectroelectrochemical experiments. Isosb. pt. = isosbestic point.

Process [a]	Neutral cmpd. λ [nm] (log ε) [b]	Radical ion λ [nm] [c]	Isosb. pt. λ [nm] [c]

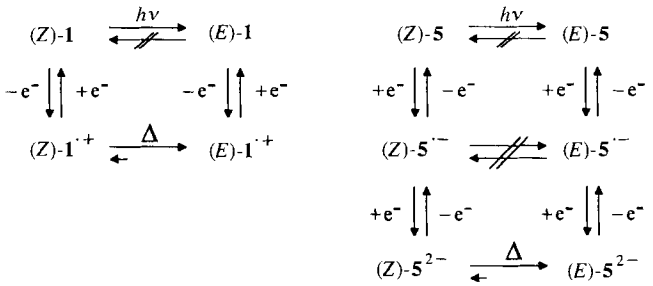
4 → **4**$^{\cdot-}$	375 (4.6), 285 (4.4), 233 (4.8)	1345	420

[a] For comparison, the data of the unsubstituted electrophores are also given: SN = *N*-methylphenothiazine, An = 9,10-anthraquinone, P = pyrene. [b] Measurements in acetonitrile; sh = shoulder; not listed in the table: (*Z*)-**1** UV/Vis: λ [nm] [log ε]: 386 (sh), 342 (4.2), 326 (sh), 274 (4.4), 267 (4.4), 242 (4.5). [c] Only the long wavelength absorptions and the isosbestic points of the radical ions are listed.

The *cis*-stilbenes (*Z*)-**1** and (*Z*)-**5** show a photochemical "one-way" isomerization:[9] irradiation of the (*Z*) compounds in solution (cyclohexane and acetonitrile) leads exclusively to the (*E*) isomers, as proven by a comparison with the spectra of the pure (*E*) isomers. In contrast, irradiation of the (*E*) isomers has no effect on the UV spectra. The spectroelectrochemical studies of these cisoid stilbenes indicate that the oxidation of (*Z*)-**1** is accompanied by a *cis*/*trans* isomerization at the stage of the radical cation. After one oxidation/reduction cycle the UV spectrum of the neutral form of (*E*)-**1** is obtained (Scheme 1). The two-step reduction/reoxidation of (*Z*)-**5** via the dianion leads to the UV spectrum of (*E*)-**5**, indicating (*Z*)/(*E*) isomerization of the dianion $\mathbf{5}^{2-}$. At the end of the spectroelectrochemical experiment, the UV absorptions of (*Z*)-**5** are found. In contrast, the radical anion of (*Z*)-**5** is configurationally stable. Thus, one can conclude that the "one-way" isomerization may be effected not only photochemically but also by both reductive and oxidative electron transfer processes.



Scheme 1. Isomerization of (*Z*)-**1** and (*Z*)-**5** during irradiation and electron transfer.

In addition to the electrochemical and spectroelectrochemical behavior of these compounds, their fluorescent properties are of interest. (Experimental optical data: Table 3; for conditions see Experimental Procedure.)

Table 3. Data from emission and ECL measurements; see also Fig. 1.

λ_{em} [nm]	Emission	Excimer [a]	ECL
(*E*)-**1**	593 [b]	620	600
2	455, 555 (sh)	550	525
3	433, 447	545	510
4	439 (sh), 456, 525 (sh)	541	523

[a] The values given are approximate. [b] Uncorrected; the corrected emission maximum is located slightly above 600 nm.

In almost all of the concentration-dependent measurements made in various solvents (cyclohexane, methylene chloride, and acetonitrile) an excimer emission could be observed in addition to the normal emission band, a phenomenon not uncommon for pyrenoid compounds.[10]

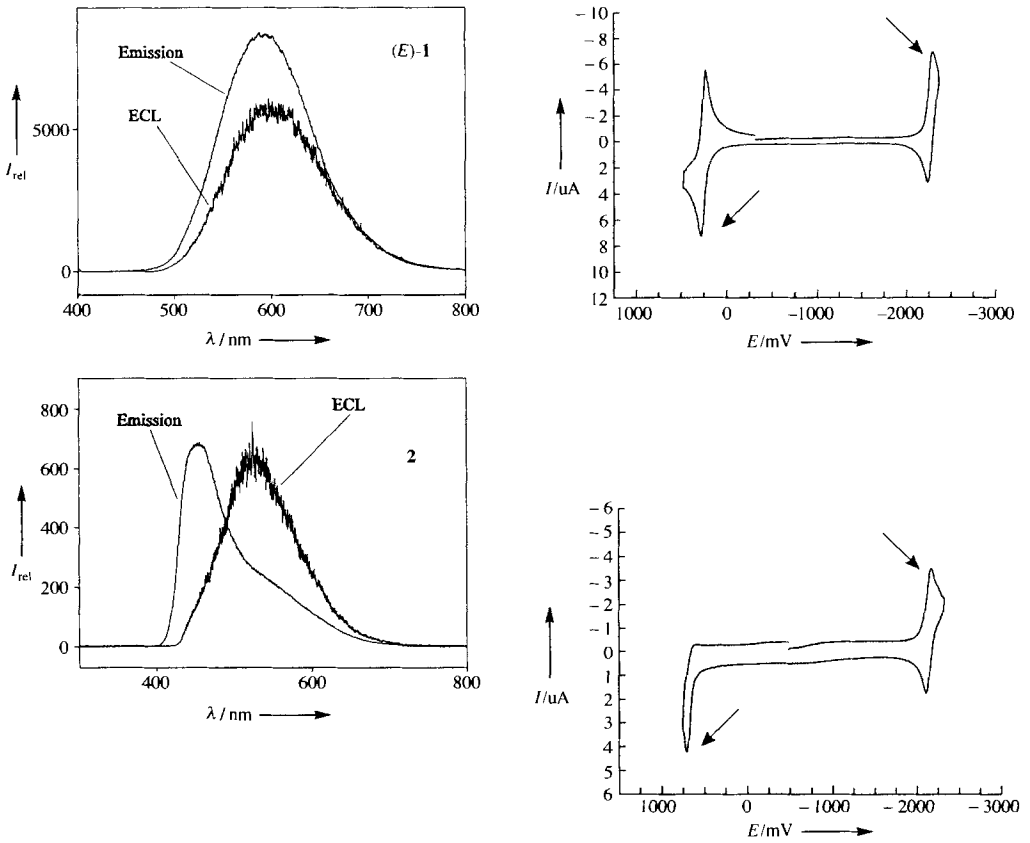


Fig. 1. Left: Comparison of the ECL and emission spectra of (*E*)-**1** and **2**; for conditions see Experimental Procedure. Right: Corresponding cyclic voltammograms with the switching potentials indicated by arrows.

It is also remarkable that in all cases except **5**, which is non-emissive in acetonitrile, the generation of radical cation/radical anion pairs electrochemically is followed by the formation of an electronically excited state and subsequent emission. However, whereas the ECL curve of (*E*)-**1** is compatible with the photoemission spectrum, this is not the case for the compounds **2**–**4**. A comparison of the electrochemical and photochemical experiments suggests that the electrochemically generated emission is essentially based on the formation of an excimer (Table 3, Fig. 1), especially since the energy brought into the system electrochemically would not be sufficient to populate directly the S_1 state of the monomeric species. Furthermore the encounter complex preceding an electron transfer is certainly structurally similar to that of an excimer.

Experimental Procedure

Cyclic voltammetry: Solvent acetonitrile; potentials in [mV] versus ferrocene (FOC); reversible half-wave potential $E_{1/2}$, anodic and cathodic peak potentials E_{pa} and E_{pc}. Experimental conditions: room temperature, scan rate: 250 mVs^{-1}, working electrode: platinum disc electrode, pseudo reference electrode: Ag/AgCl, counter electrode: platinum spiral electrode; supporting electrolyte: tetrabutylammonium hexafluorophosphate (TBAHFP).

Optical spectra: If not indicated otherwise, the emission spectra are true spectra. All measurements were carried out in acetonitrile at concentrations between 5×10^{-5} and 5×10^{-6} M, excitation wavelength: (*E*)-**1**: 398 nm; **2**–**4**: 375 nm (these excitation wavelengths were also used for recording the excimer emission). Due to low solubility only an approximate wavelength of the excimer emission can be given, since this band appears as a shoulder of the normal emission. The determination was made by means of measurements at different concentrations.

ECL: The ECL measurements were carried out with an unstirred solution ($c = 1 \times 10^{-3}$ to 1×10^{-4} M; supporting electrolyte: 0.1 M TBHFP) in an electrochemical cell specially constructed for this purpose [11]. The applied potential was switched with alternation between the oxidation and reduction potentials determined by cyclic voltammetry at time intervals of 20 ms.

Glc-PC, a New Type of Glucosidic Phospholipid**

Michael Mickeleit, Thomas Wieder, Klaus Buchner, Christoph Geilen, Johann Mulzer,* and Werner Reutter*

Dedicated to Professor Richard R. Schmidt on the occasion of his 60th birthday

Phospholipids such as phosphatidyl choline (PC) are fundamental structural components of biological membranes. In addition to their structural role, they are also important in cellular signal transduction[1] and as regulators of enzyme activity.[2] It has been known for some time that 2-*O*-alkyl and 2-*O*-acyl derivatives of 2-lysophosphatidylcholine display both cytotoxic and growth-promoting activities,[3] and this has led to the development of dermatological agents, for instance for the treatment of skin metastases.[4] Until now, it was not possible to suppress the cytotoxic effects of these compounds without decreasing their ability to inhibit cell proliferation. With the synthesis of a new type of glyceroglycophospholipid (Glc-PC **1**, Scheme 1), we have now found a solution to this problem. The starting material, (*R*)-isopropylideneglyceraldehyde (**2**),[5] was converted into the α,β-unsaturated ester **3** to better differentiate between the quasi-enantiotopic end groups. The primary advantage of this unusual "protective group" is that it minimizes steric hindrance in the later 2-glycosidation and can be removed under extremely mild conditions (ozonolysis/reduction) without the danger of a 1,3-acyl migration. After acidic hydrolysis of the acetonide ring in **3** to give the diol **4**, ester **5** was synthesized by a highly chemoselective monoacylation of the primary OH function and then converted into a mixture of anomers **7** ($\alpha:\beta = 9:1$) by treatment with glucosylfluoride **6**.[7]

Before the phosphate could be introduced as the final glycerol substituent, the olefinic unit generated early in the synthesis was oxidized to produce the aldehyde **8**, and this was reduced to the alcohol **9**. Selective reduction of **8** without endangering the stearoyl ester was achieved with zinc borohydride in ether as the reducing agent.[9] The alcohol was esterified with phosphorylchloride, and the dichloro ester was treated immediately with choline tosylate to produce the phosphocholine **10**.[10, 11]

Since the stearoyl group is labile under hydrogenolytic conditions, it was not entirely surprising that removal of the protective benzyl group presented considerable problems. After careful optimization, however, the reaction gave good yields (Scheme 1). Compound **1** was obtained in gram quantities in eight reaction steps with an overall yield of 22% (for spectroscopic data see Table 1). It should be possible to introduce many different acyl and glycosyl residues.

The biological test of cytotoxicity was performed in a serum-free cell culture system. Figure 1 B shows that Glc-PC **1** is non-

Scheme 1. toxic up to a concentration of 10 $\mu mol\,L^{-1}$ (cell viability >95%). The protected intermediate **10** (Bn-PC) showed only low toxicity even at 1000 $\mu mol\,L^{-1}$ (Fig. 1 A), and it inhibited cell proliferation only at relatively high concentrations, namely, greater than 100 $\mu mol\,L^{-1}$; this effect is probably due to unspecific cell damage (Fig. 1 A). In nontoxic concentrations, **1** inhibits the proliferation of HaCaT cells; thus, at 10 $\mu mol\,L^{-1}$ cell proliferation was inhibited by 80% (Fig. 1 B).

Since, as a group, various isoenzymes of protein kinase C (PKC) play an essential role in the control of cell proliferation,[12] we tested the effect of **1** on this enzyme. As already

Table 1. Selected physical properties and spectroscopic data of **10** and **1**.

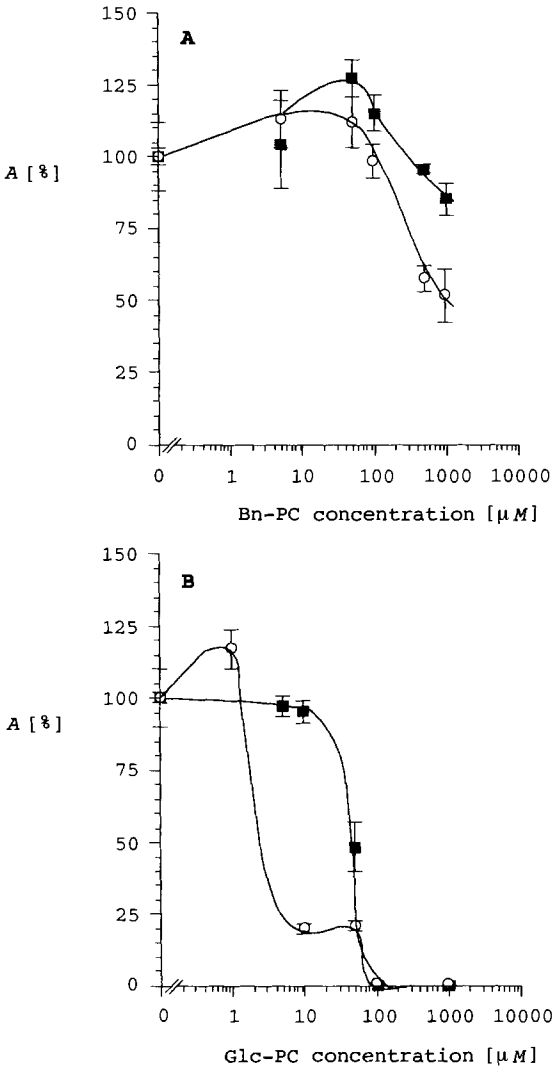

Fig. 1. Influence of **1** and **10** on the viability (■) and proliferation (○) of HaCaT cells. Confluent HaCaT cells were treated for 3 h with different concentrations of Bn-PC **10** (A) or Glc-PC **1** (B). The controls contained DMSO (A) or no further additions (B). After incubation, cell viability was determined as described in the Experimental Procedure (■). Values *A* refer to the activity [%] relative to the control experiment. HaCaT cells (20000 cells cm^{-2}) were treated for 24 h with different concentrations of **10** (A) or **1** (B). The controls contained DMSO (A) or no further additions (B). After incubation the cell count was determined by the crystal violet method (○). Values *A* refer to the activity [%] relative to the control experiment.

shown for 2-lysophosphatidylcholine,[13] the PKC activity at low concentrations of **1** was increased by up to 70%. At higher concentrations of **1** this activation decreased (Fig. 2). In contrast to 2-lysophosphatidylcholine, however, even high, toxic concentrations of **1** do not inhibit PKC activity in vitro. Compound **1** also had no effect on basal activity.[14]

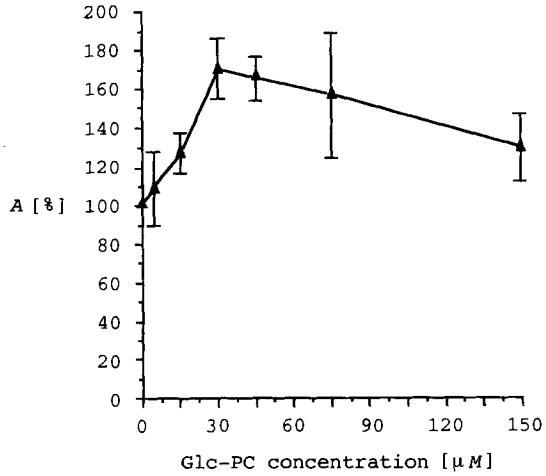

Fig. 2. Influence of **1** on the activity of protein kinase C. The activity of PKC was determined in the presence of different concentrations of Glc-PC **1** as a percentage of the activity *A* under control conditions. Up to concentrations of 100 mg L^{-1}, **1** caused an increase of PKC activity; a maximal activation of about 1.7 times the control value was observed at 20–30 mg L^{-1}. Each point is derived from the results of four to six experiments.

Compound **1** is therefore a noncytotoxic inhibitor of cell proliferation, whose inhibitory action is not mediated by protein kinase C. Further 2-glycosidic derivatives must now be synthesized to determine whether this unusual property is due to the glucoside residue.

Experimental Procedure

Cell culture: HaCaT cells [15] were maintained in liquid culture medium [16]. Confluent cells were released from the plate with 0.1% trypsin/0.02% EDTA solution, then passaged. For the duration of the experiment, the cells were kept in serum-free keratinocyte growth medium. Compound **10** was first dissolved in DMSO (85 mmol L^{-1}) then added to keratinocyte growth medium to obtain the required concentration. Compound **1** was dissolved directly in keratinocyte growth medium.

Cytotoxicity test: The cytotoxicity of **10** and **1** against HaCaT cells was determined by the trypan blue exclusion method. Confluently grown HaCaT cells were incubated for 3 h with different concentrations of the two synthesized lipids. The media were removed by aspiration, and the cells were washed with phosphate-buffered saline (PBS). Trypan blue solution (0.1% in PBS) was then added, and the blue (dead) and colorless (live) cells counted under a diavert microscope. At least 200 cells were counted for each determination. As an additional control of the cytotoxicity of **10** and **1**, the alkaline phosphatase activity of the treated HaCaT cells was determined [17].

Measurement of cell proliferation: The influence of **10** and **1** on the proliferation of HaCaT cells was determined by the crystal violet method [18]. HaCaT cells were sown at a density of about 20000 cells cm^{-2}. The cells were allowed to adhere then incubated for 24 h with different concentrations of **10** and **1**. The medium was removed by aspiration and the cells washed with PBS. Finally, cell numbers were determined after staining with 0.1% crystal violet solution [19].

Measurement of protein kinase C activity: Protein kinase C was purified from bovine brain [20]. Enzyme activity was determined in a reaction mixture (total volume 50 μL) containing 20 mM triethanolamine (pH 7.4), 4 mM magnesium acetate, 0.1 mM $CaCl_2$, 50 mM mercaptoethanol, 0.1 g L^{-1} histone III S, 50 g L^{-1} phosphatidylserine, 5 g L^{-1} diolein, and 20 mM ATP supplement with [γ-^{32}P]ATP (total radioactivity 2×10^5 cpm). Phosphatidylserine, diolein, and **1** were dissolved in methanol/chloroform (1:1). Before addition to the reaction mixture, the solvent was removed under nitrogen and the residue suspended in a suitable volume of 20 mM triethanolamine by ultrasonic treatment. The reaction was started by addition of enzyme (10–20 ng). After 2 min incubation at 30 °C, an aliquot (40 μL) of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3423-2668 $ 10.00+.25/0

the reaction mixture was transferred to a Whatman P81 filter. The filter was washed three times in 0.5% phosphoric acid, and the radioactivity determined by measurement of the Cerenkov radiation in water [21, 22].

[21] Since the substrate is histone, the measured activity is due predominantly to the "classical" isoforms of protein kinase C (α, β, γ). The test system consists of purified components only and contains no other enzymes besides PKS. A role for Glc-PC as a prodrug with respect to 2-lysophosphatidylcholine (LPC) can thus be ruled out.

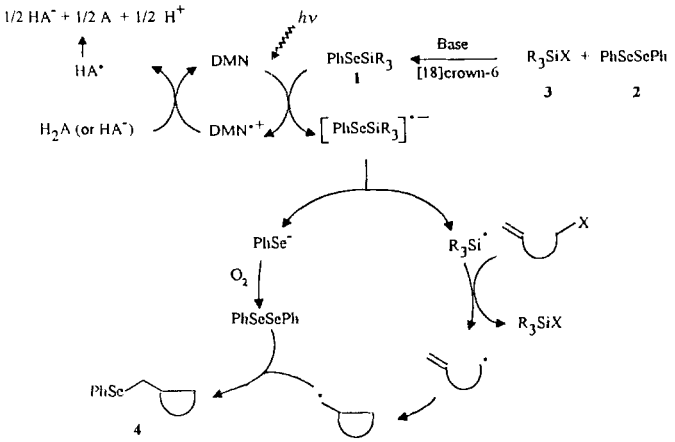
A New Dimension in Radical Chain Group Transfer Reaction by Photosensitized Electron Transfer (PET) Reductive Activation of $PhSeSiR_3$**

Ganesh Pandey* and K. S. Sesha Poleshwar Rao

Dedicated to Professor U. R. Ghatak on the occasion of his 65th birthday

Despite the drawbacks[1] associated with tin hydrides, most of the recent applications of radical reactions in organic synthesis[2] are based on the use of this reagent. While alternative approaches involving the silyl radical,[3] which is a better halophile than its tin radical counterpart,[4] have partially overcome the limitations of the tin reagent, the high cost of its precursor tris(trimethylsilyl)silane (TMSS) and the loss of functionality during the last chain propagation step has limited its popularity among organic chemists. To circumvent the known limitations of these two reagents, and the necessity for a better reagent for radical chain reactions in organic synthesis, we introduce here $PhSeSiR_3$ **1**[5, 6] ($R_3 = Ph_2tBu$), which under PET (photosensitized electron transfer) reductive reaction conditions initiates radical chain group transfer reactions (Scheme 1).



Scheme 1. Mechanism of the PET-driven reduction of **1** and the radical chain sequences. DMN = 1,5-dimethoxynaphthalene; H_2A = ascorbic acid; HA^- = ascorbate; A = dehydroascorbic acid, $PhSeSiR_3$ = $PhSeSiPh_2tBu$.

The potential of **1** to initiate the radical chain sequences shown in Scheme 1 was envisaged by considering the expected dissociation of the radical anion $\mathbf{1}^{\bullet-}$ into the silyl radical, useful for chain initiation, and PhSeSePh (**2**). The latter was formed after the oxidative dimerization of the corresponding $PhSe^-$ anion and participates in the termination step.[7] The generation of $\mathbf{1}^{\bullet-}$ was envisioned through one-electron PET reductive processes involving 1,5-dimethoxynaphthalene (DMN) as a light harvesting (> 300 nm) electron donor and ascorbic acid (H_2A) as co-reductant.[8] The thermodynamic feasibility of electron

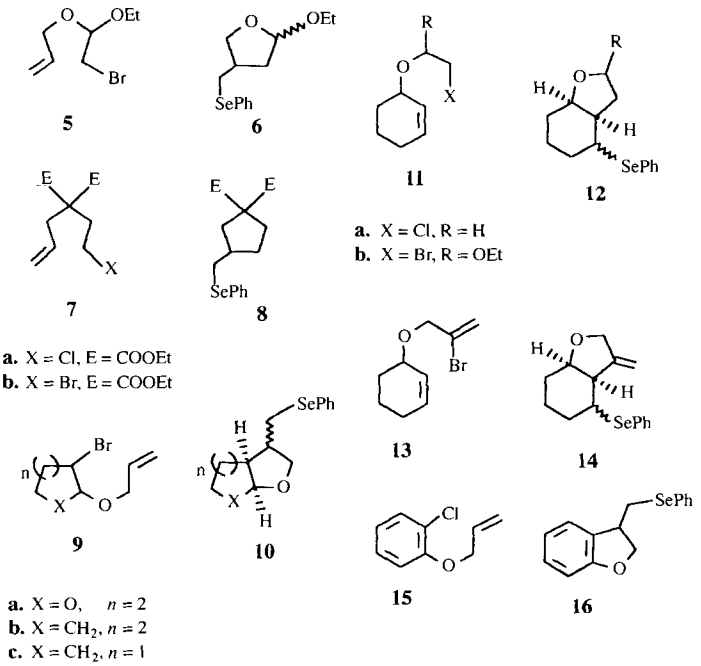
[**] This work was supported by the Department of Atomic Energy (Dr. K. S. Krishnan Fellowship to K. S. S. P. R.) and partly by the Department of Science and Technology, New Delhi. We are grateful to Dr. K. Vijay Mohan and M. P. Vinod for measuring reduction potentials of **1** and H_2A.

transfer (ET) between DMN* and **1** was established by estimating the ΔG_{et} value ($-210\ kJ\,mol^{-1}$)[13] by using the Weller equation.[9, 10] Further evidence for the ET phenomenon between DMN* and **1** was obtained by evaluating the rate constant of the diffusion-controlled ($1.09\times10^{10}\ M^{-1}s^{-1}$) fluorescence quenching ($\lambda_{exc}=300$ nm, $\lambda_{em}=344$ nm) of DMN at varying concentrations of **1**. Ground state association between **1** and DMN was ruled out since the absorption spectroscopic properties did not change. The exciplex emission was not detected either in polar or in nonpolar solvents and therefore the charge-transfer (CT) stabilized intermediate between ^{1}DMN* and **1** could be implicated to explain the observed photophysical observations. Similarly, the feasibility of ET between $DMN^{\cdot+}$ and H_2A was evaluated by estimating the Gibbs free energy change ($\Delta G_{et}=-18\ kJ\,mol^{-1}$).[12, 13] The transformation of the ascorbate ion (HA^-) to the dehydroascorbic acid (A) and a proton shown in Scheme 1 is known.[14]

Preparative photolysis (>300 nm, light absorbed by DMN only) of a mixture of DMN (0.1 mmol), **1** (0.3 mmol), and H_2A (0.3 mmol) in CH_3CN, without the removal of the dissolved oxygen, led to the rapid disappearance ($\phi_{disapp}=0.0423$)[15] of **1** and the formation of **2** and the disilane $(R_3Si)_2$. DMN remained quantitatively unchanged after the reaction. The formation of these products was rationalized by implicating heterolytic cleavage of the primary product $\mathbf{1}^{\cdot-}$ and subsequent dimerization of the resultant phenylselenyl anion and silyl radical species.

The correlation between the observed photophysical processes and the photochemical cleavage of **1** could be quantified by a double reciprocal plot (ϕ^{-1} vs. $[Q]^{-1}$) of ϕ_{disapp} and the concentration of DMN. Within the limits of experimental error this plot showed a linear relationship and gave an identical $Kq\tau$ value ($0.993\times10^{10}\ M^{-1}s^{-1}$, intercept/slope) to that obtained from fluorescence quenching measurements ($1.023\times10^{10}\ M^{-1}s^{-1}$). The limiting quantum yield ($\phi_{lim}=1$/intercept) was also estimated to be 0.034.

The efficient generation of $R_3Si^{\cdot}$ and **2** by the cleavage of $\mathbf{1}^{\cdot-}$ provided us with an unique opportunity to use **1** for radical chain initiation and group transfer reactions. These expectations were confirmed by the smooth cyclization of **5** to **6** (81% yield) by photolyzing **5** in the presence of DMN, H_2A, and **1** for 7 h. Additional reactions reveal the efficiency and generality of the method (Table 1, Scheme 2). The regio- and stereochemistry of the cyclization products (Table 1) are in accord with standard Beckwith rules.[16] Radical chain processes could be initiated with both -C-Cl (**7a**, **11a**, **15**) and -C-Br compounds; however, the rate of the reaction with -C-Br compounds was slightly higher. Photolysis under conditions where **1** absorbed light (254 nm) failed to initiate radical chain reactions; a very complicated uncharacterizable reaction mixture ensued.



Scheme 2. Formulae of the compounds given in Table 1.

The conceptually new strategy for radical chain group transfer reactions presented here circumvents the limitations of earlier methodologies. Further applications of this approach for intermolecular reactions are in progress and the results will be disclosed in a full paper.

Table 1. Radical chain group transfer reactions.

Substrate [a]	Product(s) [b, c]	*cis/trans* ratio [d]	Yield [%] [e]	*exo/endo* ratio [d]
5	**6**	16/84	81	–
7a	**8a**	–	68	95/5
7b	**8b**	–	77	94/6
9a	**10a**	73/27	87	94/6
9b	**10b**	81/19	82	95/5
9c	**10c**	82/18	77	–
11a	**12a**	77/23	72	97/3
11b	**12b**	88/12	84	–
13	**14**	–	63	–
15	**16**	–	55	–

[a] Irradiated until 70% consumption of substrates. [b] Characterized by ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry. [c] Irradiation time varies from 7–12 h. [d] Ratios measured by using ^{1}H NMR and HPLC analysis. [e] Yields not optimized: calculated based on consumption of substrates.

Experimental Procedure

A solution of **5** (0.261 g, 1.25 mmol), **1** (0.55 g, 1.4 mmol), DMN (0.094 g, 0.5 mmol), and H_2A (0.246 g, 1.4 mmol) in CH_3CN (250 mL) was irradiated, without removing dissolved oxygen from the solution, with a Pyrex-jacketed 450 W Hanovia medium-pressure mercury vapor lamp at room temperature. The progress of the reaction was monitored by HPLC analysis. After irradiation for 7 h (consumption of **5**, 70%), the photolysis was stopped and the solvent was removed under reduced pressure. The crude photolysate was chromatographed on silica gel to afford **6** (0.201 g) in 81% yield as a pale yellow liquid. DMN was recovered (99%) as such. The product **6** was characterized by ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry.

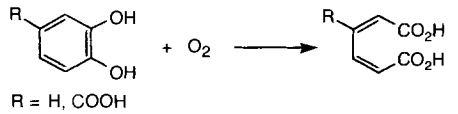
A Highly Reactive and Catalytically Active Model System for Intradiol-Cleaving Catechol Dioxygenases: Structure and Reactivity of Iron(III) Catecholate Complexes of *N,N'*- Dimethyl-2,11-diaza[3.3](2,6)pyridinophane**

Welf O. Koch and Hans-Jörg Krüger*

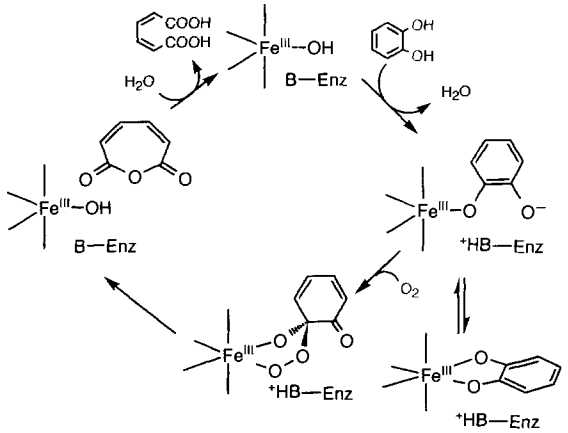
In memory of Professor Nobumasa Kitajima

Intradiol-cleaving catechol dioxygenase[1] represents a class of bacterial enzymes that catalyzes the oxidative cleavage of the *intradiol*-C–C bond of various catechol derivatives with molecular oxygen, yielding the corresponding muconic acid [Eq. (a)].



R = H, COOH (a)

In its resting state, the active site of the enzyme comprises a high-spin iron(III) ion coordinated by two histidines, two tyrosinates, and a water molecule or a hydroxide ion in a trigonal-bipyramidal geometry.[2] Probably the most unusual property of this enzyme is that the trivalent oxidation state of the iron center is retained during the entire catalytic cycle. Through the prominent work of L. Que and co-workers,[1] a mechanism was proposed which is displayed in Scheme 1. After the initial coordination of the substrate, the resulting catecholate complex reacts with the oxygen molecule to form an intermediary peroxo complex. Only now the C–C bond cleavage occurs to yield the muconic anhydride which is subsequently hydrolyzed. The unusual reactivity of an iron(III) complex with oxygen is explained by the partial transfer of electron density from the bound catecholate ligand to the metal ion, thereby furnishing the coordinated catecholate with partial semiquinone character and partially reducing the trivalent metal ion.



Scheme 1. Postulated mechanism of the intradiol-cleaving catechol dioxygenase [1].

A study[3] on biomimetic model complexes revealed that two easily accessible *cis* coordination sites are needed for coordination of the catecholate ligand and its subsequent reaction with molecular oxygen. In a series of complexes containing different tripodal ligands, it was shown that the order of reactivity of the coordinated 3,5-di-*tert*-butylcatecholate ligand (dbc^{2-})[4] in the complexes $[Fe(tpa)(dbc)]^+ > [Fe(bpg)(dbc)] > [Fe(pda)(dbc)]^- > [Fe(nta)(dbc)]^{2-}$ is correlated to the Lewis acidity of the iron(III) ion. This result was interpreted to mean that increasing the Lewis acidity of the metal ion enhances the previously mentioned partial transfer of electron density from the coordinated catecholate ligand to the metal ion. Accordingly, a correlation was observed between the reactivity and the energy of the LMCT band in the visible region of the electronic absorption spectrum as well as the chemical shifts of the ^1H NMR signals of the coordinated catecholate. Of all the complexes mentioned above, only the $[Fe(nta)(dbc)]^{2-}$ complex has been reported[3c] to catalyze the conversion of $dbcH_2$ to 3,5-di-*tert*-butyl-5-carboxymethyl-2-furanone (**1**)[5] with small amounts of 3,5-di-*tert*-butyl-1,2-benzoquinone (**2**) as by-product. However, the reaction proceeds very slowly and needs several days for completion. In addition, a borate buffer is needed to prevent the oxidation of the catechol derivative by air itself to **2**. Further, and most noteworthy, the product distribution has been questioned, since instead of the oxidative-cleavage product **1**, the *o*-quinone **2** was found to be the major product in this reaction.[6] Here we report on the synthesis of two iron(III) catecholate complexes and their reactivity with oxygen. For the first time, a highly reactive and catalytically active compound is presented that models the reactivity of intradiol-cleaving catechol dioxygenase; its use in catalytic reactions yields muconic anhydride as the main product.

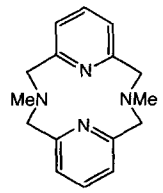
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The reaction of the tetraazamacrocyclic ligand L-N_4Me_2 with iron(III) chloride in an alcoholic solution followed by addition of catecholate anions (cat^{2-} or dbc^{2-}) results in the formation of intense purple-colored solutions of the ions **3** and **4**, respectively. Metathesis with lithium tetraphenylborate affords both compounds as microcrystalline materials in good yields. The visible regions of the electronic absorption spectra of solutions of the complexes **3** and **4** in acetonitrile are dominated by two intense LMCT bands at 501 and 734 nm and at 553 and 784 nm, respectively. The similarity of the electronic absorption spectra to those spectra of solid samples of the compounds implies that the modes of coordination of the catecholate ligands prevail also to the largest extent in solution.



L-N_4Me_2

$[(L\text{-}N_4Me_2)Fe(cat)]^+$ **3**

$[(L\text{-}N_4Me_2)Fe(dbc)]^+$ **4**

A structure determination was carried out on complex **3**.[7] A perspective view of the complex cation is shown in Figure 1.

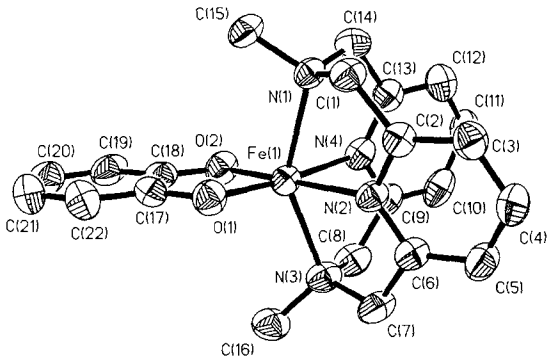


Fig. 1. Crystal structure of **3** showing thermal ellipsoids at 50% probability and the atom numbering scheme. Selected distances [Å] and angles [°]: Fe(1)-O(1) 1.903(3), Fe(1)-O(2) 1.915(3), Fe(1)-N(1) 2.222(3), Fe(1)-N(2) 2.105(3), Fe(1)-N(3) 2.223(3), Fe(1)-N(4) 2.106(3), O(1)-C(17) 1.353(5), O(2)-C(18) 1.329(5); O(1)-Fe(1)-O(2) 85.6(1), O(1)-Fe(1)-N(1) 97.7(1), O(1)-Fe(1)-N(2) 100.4(1), O(1)-Fe(1)-N(3) 107.3(1), O(1)-Fe(1)-N(4) 174.7(1), O(2)-Fe(1)-N(1) 103.7(1), O(2)-Fe(1)-N(2) 173.7(1), O(2)-Fe(1)-N(3) 99.0(1), O(2)-Fe(1)-N(4) 93.0(1), N(1)-Fe(1)-N(2) 77.4(1), N(1)-Fe(1)-N(3) 147.3(1), N(1)-Fe(1)-N(4) 77.6(1), N(2)-Fe(1)-N(3) 77.6(1), N(2)-Fe(1)-N(4) 81.1(1), N(3)-Fe(1)-N(4) 77.9(1).

Due to the small cavity of the twelve-membered macrocyclic ring, a distorted *cis* octahedral coordination geometry is found around the iron ion.[8] The ligand is folded along the N_{amine}-N_{amine} axis, and the metal ion protrudes to some extent out of the cavity as manifested by the deviation of the N_{amine}-Fe-N_{amine} angle (147.3°) from the ideal value of 180°. The Fe-N_{py} and Fe-N_{amine} distances of 2.106 and 2.223 Å, respectively, are within the range commonly observed for these bonds in high-spin iron(III) complexes with this ligand.[8] The catecholate ligand is bound to the *cis* coordination sites in the equatorial plane of the complex. As expected for a molecule with approximate C_{2v} symmetry, both Fe-O bond lengths are almost the same (deviation: 0.012 Å). The Fe-O bond length of 1.909 Å and the average C-O bond length of 1.341 ± 0.012 Å show no manifestation of a partial semiquinone character. A preliminary X-ray structure determination assigns an analogous structure to complex **4** with Fe-O bond lengths of 1.899 ± 0.012 Å and C-O bond lengths of 1.351 ± 0.003 Å. Similar Fe-O bond lengths have been observed for $[Fe(tpa)dbc]^+$ ions.[3a]

Both complexes react with oxygen as indicated by the disappearance of the purple color of the solutions. The progress of the oxygenation reaction, for example of complex **4** in acetonitrile, can be monitored by the decrease of intensity of the charge-transfer (CT) bands in the electronic absorption spectrum over time (Fig. 2). Analysis of the reaction products reveals that the coordinated dbc^{2-} ion in complex **4** is nearly quantitatively converted to the intradiol cleavage products 3,5-di-*tert*-butylmuconic anhydride (**5**) (47%) and the γ-lactone **1** (48%).[9] Preliminary kinetic evaluations of the disappearance of the lowest energy CT bands indicate pseudo-first order kinetics for the reactions of the catecholate complexes in acetonitrile solutions. The reaction velocity constants for complexes **3**[10] and **4** at room temperature were determined to be $2.77 \times 10^{-3}\ M^{-1}s^{-1}$ and $3.77 \times 10^{-1}\ M^{-1}s^{-1}$, respectively ($[O_2] = 8.1$ mM in acetonitrile,[11] pressure 1 atm). The increase of the reaction velocity by a factor of 100 for complex **4** is paralleled by a red shift of the LMCT absorption bands of the complex by 50 nm. This correlation agrees with the previously discussed dependence of the reactivity on the extent of partial transfer of electron density from the catecholate moiety to the metal ion. It is noteworthy that here, for the first time, ring opening has been demonstrated for the reaction of oxygen with coordinated catecholate,[10] the true substrate of intradiol-cleaving catechol dioxygenase, although the reaction velocity is considerably lower than that observed for the enzyme ($2.5 \times 10^5\ M^{-1}s^{-1}$).[12] The reactivity of complex **4** lies between those of the $[Fe(tpa)(dbc)]^+$ and [Fe(bpg)(dbc)] complexes. Dei and co-workers,[13] who observed no reaction for the $[Fe(cyclam)(dbc)]^+$ ion with oxygen despite the rather low energy of the LMCT band (833 nm), deduced that in addition to the two *cis* coordination sites for the catecholate, a third one is needed for the attack of the oxygen onto the metal. While the inertness towards partial substitution may be questioned for tripodal ligands,[14] from our experience

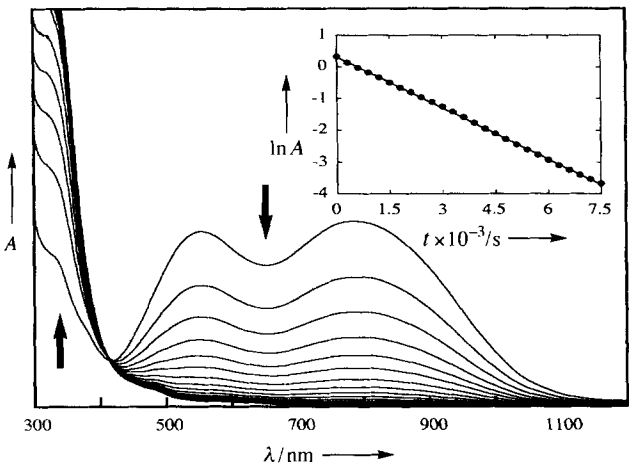

Fig. 2. Progress of the reaction of **4** with air in MeCN at room temperature as monitored by electronic absorption spectroscopy in 10 min intervals. The arrows indicate how the intensities of absorption bands change over time. Inset: plot of ln *A* vs. time *t*. *A* = absorption.

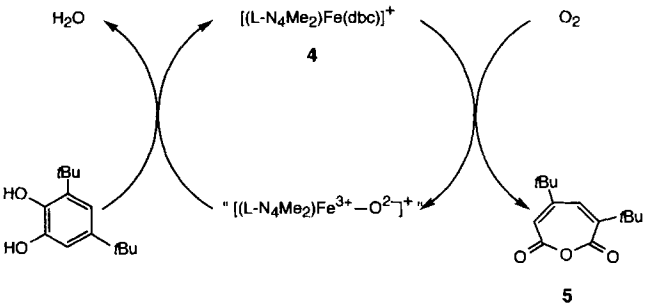
of the NMR properties of diamagnetic complexes with the L-N_4Me_2 ligand, we are quite certain that because of its pronounced rigidity, the ligand, once coordinated, remains bound through all nitrogen donor atoms to the metal ion at all times. This inertness to substitution can be extended to the iron(III) catecholate complexes under current discussion. Therefore the attack of the oxygen molecule must occur either directly onto the catecholate ligand coordinated in a bidentate fashion to the iron(III), or, an equilibrium must be inferred to exist in solution between a bi- and a monodentate coordination mode of the catecholate ligand in order that the reaction of the oxygen can take place with a five-coordinate iron intermediate.

A prerequisite for any catalytic activity is that the iron catecholate complex has to be stable in the presence of a large excess of unbound catecholate. By UV/Vis spectroscopy it was shown that even a 100fold excess of dbc^{2-} ions was not able to expel the tetraazamacrocyclic ligand from the coordination sphere of the iron(III) ion to yield the corresponding triscatecholatoferrate(III) complex. Addition of a tenfold excess of dbc^{2-} ions to a solution containing stoichiometric amounts of iron(III) perchlorate and L-N_4Me_2 in DMF, followed by the exposure of the resulting purple mixture to air resulted, in contrast to the stoichiometric reaction, in the persistence of the initial intensity of the absorption band at 780 nm for about 13 h after which the CT band disappeared. The absorption band could be recovered with its original intensity by the addition of another tenfold excess of dbc^{2-} ions and vanished again after a further 13 h of exposure to air. This finding is clear evidence that **4** is a catalyst for the oxidative cleavage of catechol.

In a typical catalytic reaction, a mixture of iron(III) perchlorate (0.1 mmol) and L-N_4Me_2 (0.1 mmol) in DMF (10 mL) was treated under anaerobic conditions with a solution of $dbcH_2$ (1 mmol) and triethylamine (0.2 mmol) in DMF (10 mL) and then exposed to an atmosphere of pure oxygen. In addition to the change of color from purple to yellow, the progress of the reaction can be monitored by ^1H NMR spectroscopy (Fig. 3). The decrease in the intensities of the NMR signals of unbound catechol (δ = 6.83, 6.76, 1.38, and 1.22) over time is accompanied by the appearance of signals corresponding to the major product muconic anhydride **5** (δ = 6.74, 6.29, 1.28, and 1.18) and the minor product *o*-benzoquinone **2** (δ = 7.08, 6.15, 1.25, and 1.23). The reaction is essentially finished after 3 h. Workup afforded 70% of **5** and 13% of **2**. Based on the NMR signals between δ = 0.97 and 1.16, the residual products are attributed to some not yet identified derivatives of **1** and, therefore, the yield of oxidative-cleavage products is even higher than 70%. In this study, the direct observation of the products' composition over time during catalytic turnovers allows the conclusion that muconic anhydride is indeed the direct product of the oxygenation reaction. The products' evolution over time definitely excludes any involvement of benzoquinone as an intermediate in the oxygenation reaction.[15] Since the amounts of the minor product **2** increase in the catalytic reaction compared to the stoichiometric reaction and, since catechol itself is susceptible to oxidation by oxygen in basic solutions, the formation of **2** is thought to be not mediated by the iron complex **4**. For the catalytic reaction, only two equivalents of a base are needed per iron(III) ion. With 1% of the iron(III) catalyst, yields of 54% of **5** and 17% of **2** were obtained after a reaction time of 30 h. In contrast to the previous study with $[Fe(nta)(dbc)]^{2-}$ ions,[3c] no borate buffer was needed to protect $dbcH_2$ from oxygen and the reaction proceeded in considerably less time. The investigation of this very efficient catalytic cycle with turnover numbers of 54 is summarized in Scheme 2.



Scheme 2. Catalytic cycle of the oxygenation with **4**.

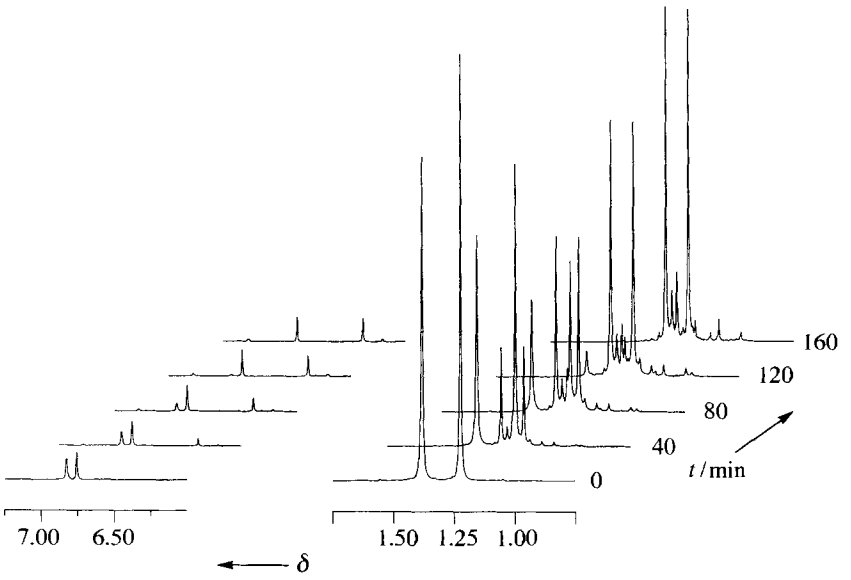


Fig. 3. Catalytic oxidation of $dbcH_2$ in $[D_7]$DMF as monitored by ^1H NMR spectroscopy (oxygen pressure 1 atm, room temperature, initial ratio of $dbcH_2$:$[D_{15}]NEt_3$:$[Fe(L\text{-}N_4Me_2)(DMF)_2]^{3+}$ = 10:2:1).

The exact identity of the putative "$[(L\text{-}N_4Me_2)Fe^{3+}\text{-}O^{2-}]^+$" intermediate is not yet known. In contrast to the $[Fe(tpa)(dbc)]^+$ complex,[3a] the products of the stoichiometric reaction of **4** with oxygen display none of the characteristic CT transitions of a μ-oxo-μ-furanoneacetato-bridged diiron(III) complex in the electronic absorption spectrum. However, the considerably less paramagnetically shifted ^1H NMR signals of the coordinated ligand and the substantial decrease of magnetic susceptibility of the products indicate formation of an antiferromagnetically coupled μ-oxo bridged diiron(III) species. The detection of the cleavage products **1** and **5** in a ratio of approximately 1:1 agrees well with reaction (b). Whether in the catalytic reaction a basic mononuclear iron(III) or a μ-oxo-bridged diiron(III) species reacts with $dbcH_2$, cannot be elucidated at the moment and therefore any preference would only be speculative.

Herein we have reported a well-defined stoichiometrically functioning and catalytically highly active biomimetic model system for the reactivity of intradiol-cleaving catechol dioxygenases. Even though the coordination environment of the iron centers in complexes **3** and **4** does not match that of the enzyme, a detailed study on the mechanistic aspects of the reaction of these complexes with oxygen promises to contribute to the elucidation of the intimate mechanism of the enzyme, where questions regarding the C–C cleavage step and the actual attack of the iron(III) catecholate complex by an oxygen molecule still remain open. These mechanistic studies and the description of the electronic properties of reactive iron(III) catecholate complexes such as **3** and **4** will be reported elsewhere.

Experimental Procedure

Preparation of [(L-N_4Me_2)Fe(dbc)](BPh_4) (**4**): Under strictly oxygen-free conditions, a solution of $FeCl_3 \cdot 6H_2O$ (135 mg, 0.5 mmol) in methanol (10 mL) was added to solution of L-N_4Me_2 (134 mg, 0.5 mmol) in methanol (20 mL). After the reaction mixture was heated shortly to reflux temperature and then allowed to cool again to room temperature, it was treated with a solution containing $dbcH_2$ (111 mg, 0.5 mmol) and triethylamine (210 μL, 1.5 mmol) in methanol (10 mL). An immediate color change from orange-yellow to purple occurred. After filtration and metathesis with 10 mL of a methanolic solution of tris(ethylenglycoldimethylether)lithium tetraphenylborate (300 mg, 0.5 mmol), the resulting crystalline purple material was isolated by filtration, washed twice with small amounts of methanol and dried in vacuo to afford 387 mg of analytically pure product (90% yield). Anal. calcd. for $C_{54}H_{60}BFeN_4O_2$: C 75.09, H 7.00, N 6.49; found: C 74.50, H 6.75, N 6.46. Absorption spectrum (acetonitrile): λ_{max} (ε_M) = 553 (2640), 784 (2780) nm.

Preparation of [(L-N_4Me_2)Fe(cat)](BPh_4) (**3**): Accordingly, in an only slightly modified procedure using 96% ethanol as solvent and catechol as ligand, [(L-N_4Me_2)Fe(cat)](BPh_4) was prepared in 81% yield as a dark blue crystalline material. Anal. calcd. for $C_{46}H_{44}BFeN_4O_2$: C 73.52, H 5.90, N 7.45; found: C 73.66, H 5.82, N 7.56. Absorption spectrum (acetonitrile): λ_{max} (ε_M) = 501 (2580), 734 (2920) nm.

Assessing Similarity and Diversity of Combinatorial Libraries by Spatial Autocorrelation Functions and Neural Networks**

Jens Sadowski, Markus Wagener, and Johann Gasteiger*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The recent availability of high throughput techniques to find new lead structures by random screening has increased the need for a continuous supply of novel compounds. One way of fulfilling this need is by preparation of chemical libraries through combinatorial chemistry:[1] The repetitive and systematic application of a synthesis principle to a number of chemical building blocks can produce large populations of different structures. Thus, a library of 20^4 = 160000 compounds can be built by systematically connecting twenty building blocks in four reaction steps. By changing some of the building blocks or the reactions used, a nearly unlimited number of different libraries can be realized. Therefore, efficient means for comparing libraries and for assessing the diversity of the compounds contained in them are needed. We present here a new approach for the analysis of chemical libraries, which is based on spatial autocorrela-

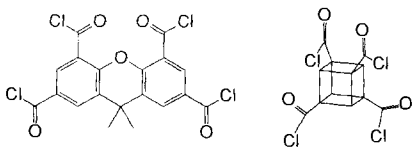
tion functions and neural networks. Using this method several chemical libraries are compared, and an estimation of their similarity and diversity is given. This analysis leads to recommendations for the proper selection of libraries for further investigations.

Recently we introduced autocorrelation vectors as 3D-QSAR descriptors that combine the spatial positions of points on a molecular surface with property values (for example, the electrostatic potential) at these points.[2] To determine this descriptor the distances between randomly chosen surface points are sorted into intervals with preset lower and upper bounds, d_l and d_u. An autocorrelation coefficient $A(d_l, d_u)$ can then be obtained from Equation (a). The variables p_i and p_j are the property

$$A(d_l, d_u) = 1/L \sum_{ij} p_i p_j \qquad (d_l \le d_{ij} < d_u) \qquad \text{(a)}$$

values at surface points i and j, respectively, and L is the total number of distances in the interval $[d_l, d_u[$. For a series of distance intervals with different lower and upper bounds, a low-dimensional vector of autocorrelation coefficients is obtained. It represents a condensed description—a fingerprint—of the distribution of the property p over the molecule. Since only distances are used in Equation (a), the 3D-structures do not need to be aligned in 3D-space. This descriptor was successfully used for modeling the biological activity of two different classes of compounds.[2] It can be determined in a way efficient enough to cope with the enormous number of compounds commonly contained in combinatorial libraries.

In order to outline the computational methods and to demonstrate their merits for handling combinatorial libraries we have chosen an example from the literature. Rebek et al. recently reported on the synthesis and screening of libraries of semirigid compounds in solution for finding potent trypsin inhibitors.[3] The libraries were obtained by combining rigid central molecules like the xanthene derivative **1** or the cubane derivative **2** with a mixture of 19 L-amino acids.[4]



1

2

Combination of **1** and the 19 building blocks theoretically yields 65 341 different structures. Due to its higher symmetry, **2** combines with the same set of building blocks to form only 11 191 compounds. The libraries obtained were screened on a trypsin assay and subsequently broken down into sublibraries. Finally a new potent lead was identified.[3b]

Compounds based on xanthene **1** should adopt a disklike shape, whereas derivatives of cubane **2** should give molecules with a more spherical shape. Thus, a 3D-descriptor for handling this type of combinatorial libraries seems to be crucial.

To prepare for the computational study, we first generated the 3D-autocorrelation descriptors for all compounds of the two libraries in five distinct steps: 1) 3D-models of the central molecules **1** or **2** and the 19 L-amino acids were obtained by the 3D-structure generator Corina.[5] 2) These fragments were fed into a structure generator that fully exploded them into 3D-structures of all possible combinations. 3) Atomic charges were calculated by fast empirical methods.[6] 4) The electrostatic potential at randomly distributed points on the van der Waals surface with a point density of 1 point per Å^2 was calculated by a classical Coulomb approach. 5) The distances between points were split into twelve equally spaced intervals between 2 and 20 Å. Autocorrelation coefficients were then calculated according to Equation (a) by using the electrostatic potential values, yielding a total of 12 autocorrelation coefficients for each molecule. For the 65 341 compounds of the xanthene library this required about 49 hours on a Sun Sparc 10/512 workstation and took about 4 MB disk space for the descriptors—rather moderate resources.

The question is now: How can one extract useful information about the nature of the xanthene and cubane libraries from this sea of numbers (65 341 × 12 descriptors for the xanthene library only)? We used a Kohonen network[7] to visualize the chemical diversity of the library compounds. The Kohonen procedure is an unsupervised learning method, which is able to project information from a high-dimensional descriptor space into a two-dimensional map retaining the topology of the information.[8] Thus, neighboring points in the descriptor space occupy neighboring neurons in the map. Figure 1 illustrates this process.

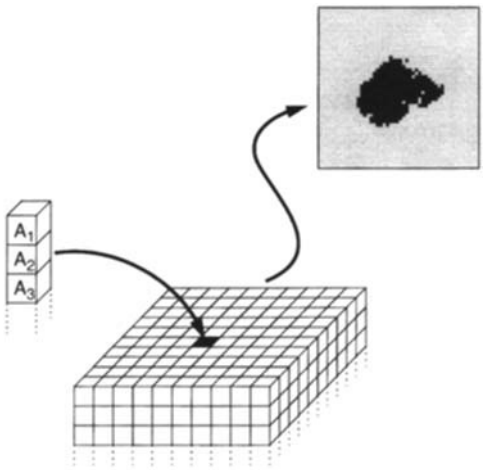


Fig. 1. Projection of the xanthene and cubane libraries onto a Kohonen map. Twelve-dimensional input vectors, $\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{12}$ are used to train the Kohonen net. After the training the neurons can be colored according to the core molecule: xanthene gray and cubane black.

The twelve-dimensional autocorrelation vectors **A** describing the xanthene and cubane library compounds obtained from the structure generator (step 2) were used to train a 50 × 50 network. This required about twelve minutes on a Sun Sparc 10/512 workstation. After training was finished each compound corresponded to one distinct neuron of the network. The core molecule of the library compounds was used to visualize the xanthene (gray) and the cubane (black) derivatives in a two-dimensional map (see Fig. 2a). The total chemical space spanned by the two libraries corresponds to the 50 × 50 map. All 2500 neurons are occupied. The cubane derivatives (black) form a discrete cluster surrounded by the compounds of the xanthene library. Only a small number of xanthene and cubane derivatives occupy the same neuron (2649 compounds or 3%). Thus, the network was able to separate the two libraries completely. The conclusion drawn from this result is that the two libraries are diverse enough that both warrant synthesis and testing, since they occupy different parts of the chemical space.

In order to show that our method can also be used to determine the similarity of libraries we defined a third, hypothetical library that was assumed to be closely related to the cubane

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3423-2675 $ 10.00+.25/0

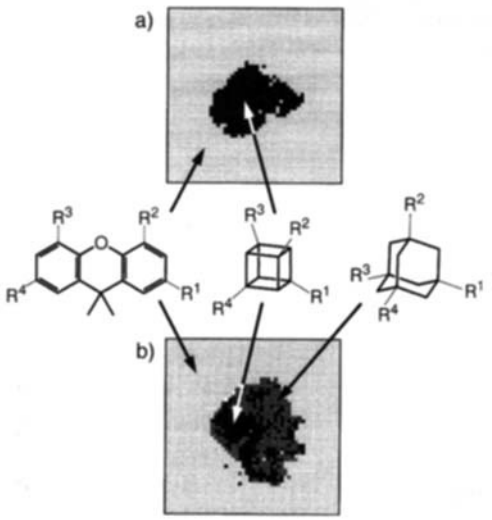

Fig. 2. a) Kohonen projection of the xanthene and the cubane libraries onto a two-dimensional map. b) Kohonen projection of all three libraries—xanthene, cubane, and adamantane—onto a two-dimensional map. In both cases the same color scheme is used: xanthene light gray, adamantane dark gray, and cubane black.

library. We chose adamantane functionalized at the four bridgehead atoms as the central building block, because the amino acids have directions comparable to those in the cubane derivatives. The same number of compounds as for the cubane library (11191) were generated. Figure 2b shows the Kohonen map trained with the data of the three libraries, where each neuron was colored according to the most frequent core molecule. Again, a sharp border between the xanthene derivatives and the other compounds is observed. However, the network was unable to distinguish between the cubane and the adamantane libraries, as they form a single cluster in Figure 2b. In this cluster 92% of the cubane and adamantane derivatives are grouped together into common neurons, making the cluster even more homogeneous than indicated by Figure 2b.

To put this visual impression onto a quantitative basis we looked for equivalent compounds in the three libraries, that is, those compounds having the same substitution pattern (for example, Ala, Gly, Leu, Pro). Their distance in the Kohonen map in the form of the median number of neurons between them should give a quantitative measure for the similarity of the libraries: xanthenes–cubanes 19 neurons; xanthenes–adamantanes 19 neurons; cubanes–adamantanes 4 neurons. Thus, the cubane and the adamantane libraries are close together and occupy almost the same part of the chemical space. They should be able to replace each other. It is therefore only worth the effort to synthesize the xanthene library and one of the other two libraries.

Rebek et al.[3] found that only the xanthene library showed significant trypsin inhibition. Thus, they decided next to deconvolute the xanthene library into sublibraries for subsequent testing. From the original set of 19 amino acids[4] cysteine was omitted. The remaining 18 amino acids were split into six groups, each containing three amino acids with similar side chains. Groups 1 and 2 contained alkyl amino acids, group 3 basic amino acids, group 4 hydroxy- and methylthio-functionalized amino acids, group 5 aromatic amino acids, and group 6 amino acids bearing a second acid or an amide function.[9] Each sublibrary was obtained by omitting the three amino acids of one group from the full set. Thus, six sublibraries built from xanthene **1** and fifteen amino acids resulting in 25425 compounds per library were obtained. The overlap between these sublibraries is rather high: Each sublibrary has 10440 compounds (41%) in common with any other sublibrary, and each compound is contained in at least two sublibraries.

For the computer analysis of this partitioning again a Kohonen map was used. First, the network was trained with the data of the 65341 compounds of the complete xanthene library. This gave a map defining the total chemical space spanned by the xanthene library. Then, the trained network was used for the subsequent visualization of the neurons occupied by single sublibraries. Figure 3 shows these maps and the numbers of unoccupied neurons.

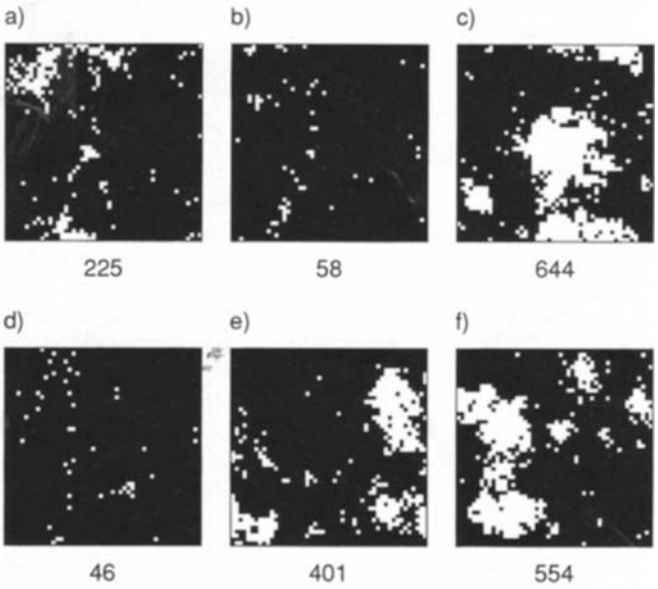

Fig. 3. Visualization of the six xanthene sublibraries in a map trained with the complete xanthene library. The number of unoccupied neurons is given below each map. In a) and b) alkyl amino acids were omitted, in c) basic amino acids, in d) the hydroxyl- and methylthio-functionalized amino acids, in e) aromatic amino acids, and in f) amino acids bearing a second acid or an amide function [9].

The visual inspection of white areas in the maps, that is, those neurons with no corresponding structures, gives an impression of how diverse the individual sublibraries are. The more unoccupied neurons there are, the smaller the diversity of the sublibrary. Despite the high redundancy in the sublibraries (vide supra), the maps show remarkable differences. Sublibraries 2 and 4 (Fig. 3b, d) fill almost the complete map. Thus, the omission of the larger alkyl amino acids (group 2) or the hydroxy- and methylthio-substituted amino acids (group 4) does not seem to result in a loss of diversity. The other sublibraries show large white areas in the maps—parts of the chemical space not covered by them. The largest number of unoccupied neurons can be found for sublibrary 3 (Fig. 3c). Therefore, the basic amino acids (group 3) omitted in this sublibrary seem to have some qualities that cannot be covered by any other building block.

In order to show which compounds were considered similar by the Kohonen network, the contents of one arbitrarily chosen single neuron of the complete xanthene map are given in Scheme 1. Four pairs of structures (**3** and **4**, **5** and **6**, **7** and **8**, **9** and **10**) differ only by one amino acid—a chemist would group them together, too. On the other hand, the similarities between these four pairs are not as evident. Only the analysis with the Kohonen network revealed their similar distribution of the electrostatic potential on the molecular surface—a finding that cannot easily be derived from the structure diagrams.

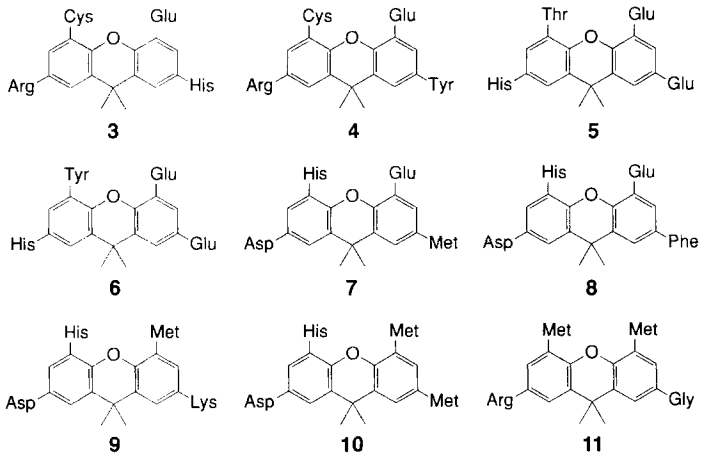

Scheme 1. Nine xanthene derivatives that were grouped together into neuron (6, 13) of the Kohonen map trained with the complete xanthene library.

It would be interesting to compare the result of this kind of similarity analysis with activity data as well. Unfortunately only for two of the xanthene library compounds[3b] is the exact activity known. We have found that 41 compounds were grouped together with the most potent trypsin inhibitor into one neuron of the Kohonen net. In our opinion, these 41 compounds would be worthwhile targets for further testing.

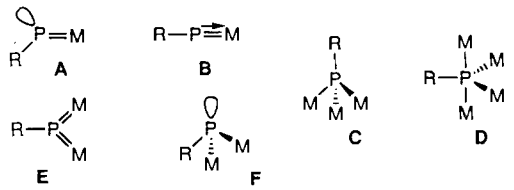
Synthesis of a Cationic 1,3-Diphospha-2,4-dipallada(II)tricyclo[1.1.1]pentane Derivative: The First Structurally Characterized Pyramidal μ_2-Phosphinidene**

Yves Canac, Antoine Baceiredo, Heinz Gornitzka, Dietmar Stalke, and Guy Bertrand*

Dedicated to Professor Herbert Roesky on the occasion of his 60th birthday

The phosphinidene fragment can give rise to six different types of complex **A**–**F**[1] (Scheme 1). Recently, a few examples of stable η^1(bent)[1a–c, 2] and η^1(linear)-phosphinidene complexes (types **A** and **B**, respectively)[3] have been reported. The μ_3- and μ_4-phosphinidenes have been extensively used as building blocks for transition metal clusters (types **C** and **D**, respectively).[1e, f] Dinuclear phosphinidene compounds of type **E** in



Scheme 1.

which an RP entity, by virtue of its two lone pairs, forms two donor bonds to two coordinatively unsaturated transition metal centers are well known.[1d–f] Since there is no lone pair left at the phosphorus center, there is no reason for pyramidalization around phosphorus and hence the three-center–four π-electron system **E** is trigonal planar. Phosphinidine complexes of type **F** can merely be considered as phosphanes with organometallic moieties on substituents, but very surprisingly only one example of a pyramidal μ_2-phosphinidene of this type has been reported and it has only been characterized by IR spectroscopy.[4] Here we report the synthesis and structure of the title compound, which features two nonplanar μ_2-phosphinidene units.

Palladium tetrakis(triphenylphosphane)[5] cleanly reacts at $-40\,^{\circ}C$ with one equivalent of diphosphacyclopropenium ion **1**[6] to yield the 1-pallada(II)-2σ^4,4σ^2-diphosphacyclobutene **2**. Very surprisingly, when a solution of complex **2** in dichloromethane was refluxed overnight in the presence of the three-membered heterocycle **1** (0.5 equiv) a new complex **3a** was formed (Scheme 2); no other species were detected by ^{31}P NMR spectroscopy. After workup, **3a** was isolated as a yellow powder (in 25% yield based on **2**; m.p. 175–176 °C).[7] Note that **3a** can also be directly obtained by heating **1** with 0.75 equivalents of the palladium(0) complex (Scheme 2). The low solubility of **3a** in nonpolar solvents was strong evidence of its ionic nature, which was confirmed by the presence of a sharp singlet for BF_4^-

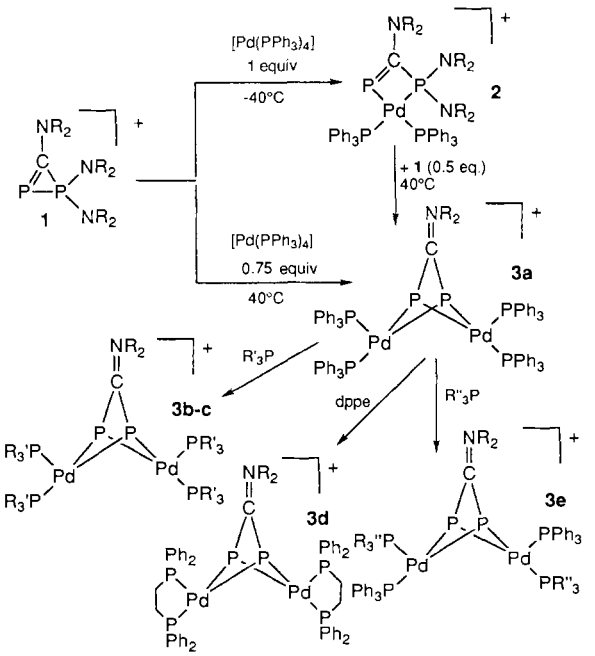
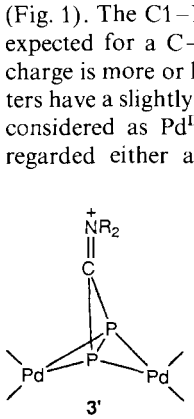


Scheme 2. R = iPr$_2$N, counterion BF_4^-. R'$_3$P = Me$_3$P (**3b**), Ph$_2$MeP (**3c**); R"$_3$P = (c-Hex)$_3$P. dppe = bis(diphenylphosphino)ethane.

at $\delta = 0$ in the ^{11}B NMR spectrum. According to ^{1}H and ^{13}C NMR spectroscopy, only one diisopropylamino group, not directly bonded to phosphorus, and four triphenylphosphane ligands were present in the molecule. The ^{31}P{^{1}H} NMR spectrum showed a triplet at $\delta = +17.7$ and a quintet at $\delta = +66.0$ (J(P,P) = 16.8 Hz), demonstrating the presence of two and four magnetically equivalent phosphorus atoms.

Since no obvious structure could be deduced from the spectroscopic data and the stoichiometry of the reaction, and since all attempts to obtain crystals of **3a** suitable for an X-ray diffraction study failed, we carried out exchange reactions with a variety of phosphanes (Scheme 2). Using trimethylphosphane, diphenylmethylphosphane, and 1,2-bis(diphenylphosphino)ethane, the four triphenylphosphane ligands of **3a** were exchanged giving **3b–d**, while with tricyclohexylphosphane only two of these ligands were replaced affording **3e**.[7] According to the spectroscopic data, the basic skeletons of complexes **3a–e** were identical; for **3e**, careful ^{13}C NMR ^{31}P coupled and decoupled experiments revealed the presence of one carbon directly bonded to two equivalent phosphorus atoms ($\delta = 234.1$, t, J(P,C) = 89.6 Hz).

The exact structure of complex **3e** (m.p. 178–180 °C) was determined by a single-crystal X-ray diffraction analysis[8] (Fig. 1). The C1–N1 bond length (1.325(10) Å) is in the range expected for a C–N double bond, implying that the positive charge is more or less localized at nitrogen. The palladium centers have a slightly distorted square-planar geometry and can be considered as Pd^{II}. At a first glance, this compound can be regarded either as a [1.1.1]propellane **3**,[9] which possesses bridgehead phosphorus atoms having an inverted tetrahedral geometry (Scheme 3), or alternatively as a tricyclo[1.1.1]pentane (asterane) **3** in which the P–P bond is broken. The P1 $\cdots$ P2 distance (2.681(3) Å) is much shorter than that observed in the 1,3-diphospha-2,4-disila-5-platinabicyclo[1.1.1]pentane (3.063 Å)[10] and related P_2B_3, P_2B_2Si, and P_2B_2Ge derivatives (2.86–3.07 Å),[11] but longer than normal P–P single bonds (2.20–2.35 Å).[12] The P1-Pd-P2 and P1-C1-P2 bond angles (69.17(8), 69.48(8), and 96.4(4)°, respectively) resemble those observed in the four-membered ring **2** (70.23 and 96.2°, respectively); however, the P1-C1-P2 bond angle is much larger than that in the three-membered ring **1** (73.9°). Therefore, complex **3** has an asterane structure with two strongly pyramidalized bridgehead phosphorus atoms (sum of angles = 254.0 and 251.7°).



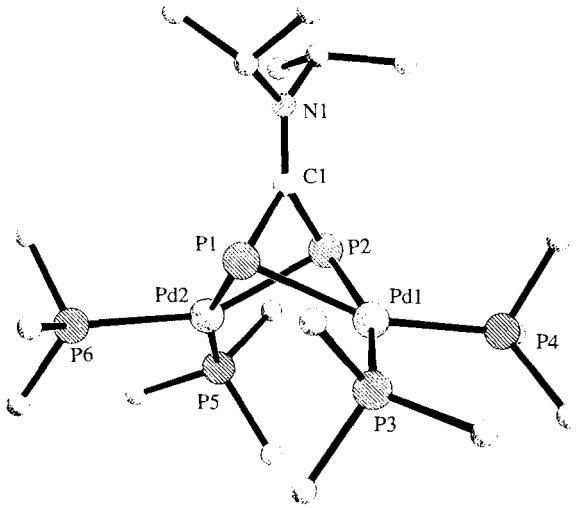


Fig. 1. Crystal structure of **3e**. For clarity only the C$_\alpha$ atoms of the cyclohexyl groups on the P3 and P5 and the C(ipso) atoms of the phenyl groups on the P4 and P6 atoms are shown. Selected bond lengths [Å] and angles [°]: Pd1-P1 2.358 (2), Pd1-P2 2.365 (2), Pd1-P3 2.394 (2), Pd1-P4 2.369 (2), Pd2-P1 2.336 (2), Pd2-P2 2.368 (2), Pd2-P5 2.392 (2), Pd2-P6 2.379 (2), P1-C1 1.794 (8), P2-C1 1.803 (4), C1-N1 1.325 (10); P1-Pd1-P2 69.17 (8), P1-Pd1-P3 90.88 (8), P3-Pd1-P4 106.77 (8), P2-Pd1-P4 93.44 (8), P1-Pd2-P2 69.48 (8), P1-Pd2-P6 91.74 (8), P5-Pd2-P6 106.68 (8), P2-Pd2-P5 94.28 (8), P1-C1-P2 96.4 (4), C1-P1-Pd1 81.6 (3), C1-P1-Pd2 84.4 (3), Pd2-P1-Pd1 88.01 (8), C1-P2-Pd1 81.3 (3), C1-P2-Pd2 83.3 (3), Pd2-P2-Pd1 87.11 (8).

Although the stoichiometry of the reaction, the cleavage of the diisopropylamino groups, and the mechanism as a whole for the reaction leading to **3a** is still obscure and deserves further study, this type of complex is unique in several respects: it features two pyramidalized μ_2-phosphinidene units, it contains metal atoms from Group 10, and can be considered as a 2,4-dimetallatricyclo[1.1.1]pentane and as an asterane possessing a trigonal carbon atom.

[7] **3a**-BF_4: To a solution of **1**-BF_4 (0.46 g, 1 mmol) in dichloromethane (5 mL) at −50 °C was added palladium tetrakis(triphenylphosphane) (0.86 g, 0.75 mmol). After stirring for 18 h at 40 °C, the solvent was removed in vacuo, and the residue was washed several times with toluene and ether to give **3a**-BF_4 as a yellow powder (25% yield); m.p. 175–176 °C; ^{31}P NMR ($CDCl_3$): $\delta = +17.7$ (t, ^2J(P,P) = 16.8 Hz, Ph_3P), +66.0 (q, ^2J(P,P) = 16.8 Hz, Pd-P-C); ^{1}H NMR ($CDCl_3$): $\delta = 1.08$ (d, ^3J(H,H) = 6.8 Hz, 12H, CH_3), 4.07 (sept., ^3J(H,H) = 6.8 Hz, 2H, CH), 7.00–7.28 (m, 60H, H_{arom}); ^{13}C NMR ($CDCl_3$): $\delta = 19.1$ (s, CH_3), 52.7 (s, CH), 127.8 (s, C_m), 129.5 (s, C_p), 132.7 (m, C_i), 133.5 (s, C_o), the signal of PCP was not observed; MS (FAB/NPOE, CH_2Cl_2): 1174 [$M^+ - Ph_3P$].

3b–**e** (as BF_4 salts): To a solution of **3a**-BF_4 in dichloromethane at room temperature was added 4 equiv of phosphane [(trimethylphosphane) (**3b**), (diphenylmethylphosphane) (**3c**), (tricyclohexylphosphane) (**3e**)], or 2 equiv of 1,2-bis(diphenylphosphino)ethane (**3d**). After 30 min at room temperature, the solvent was removed in vacuo, and the residue was washed several times with toluene and ether to eliminate the excess of phosphane. Complexes **3b**–**e** (as BF_4 salts) were obtained in near quantitative yield **3b**-BF_4: red oil; ^{31}P NMR ($CDCl_3$): $\delta = -28.0$ (t, ^2J(P,P) = 20.3 Hz, Me_3P), +65.8 (m, Pd-P-C); **3c**-BF_4: red oil; ^{31}P NMR (C_6D_6): $\delta = -1.7$ (t, ^2J(P,P) = 18.1 Hz, Ph_2PMe), +73.0 (q, ^2J(P,P) = 18.1 Hz, Pd-P-C); **3d**-BF_4: red oil; ^{31}P NMR (C_6D_6): $\delta = 31.5$ (t, ^2J(P,P) = 14.7 Hz, Ph_2PCH_2), +75.9 (m, Pd-P-C); **3e**-BF_4: orange crystals; m.p. 178–180 °C; ^{31}P NMR ($CDCl_3$): $\delta = +14.2$ (m, *c*-Hex_3P), +21.4 (m, Ph_3P), +65.1 (m, Pd-P-C).
[8] Crystal data of **3e**-BF_4: $C_{107}H_{166}BF_4NO_2P_6Pd_2$ were grown from a THF/ether solution, $M = 2064.85$, triclinic, space group $P\bar{1}$, $a = 1445.2(3)$, $b = 1655.9(3)$, $c = 2354.1(5)$ pm, $\alpha = 97.51(3)$, $\beta = 104.52(3)$, $\gamma = 95.77(3)°$; $V = 5.355(2)$ nm^3; $Z = 2$; $\rho_{calcd} = 1.281$ Mg m^{-3}, $F(000) = 2190$, $\lambda = 71.073$ pm, $T = 153$ K, $\mu(Mo_{K\alpha}) = 0.485$ mm^{-1}, data were collected on a Stoe-Siemens-AED diffractometer. Intensities of a 0.3 × 0.3 × 0.2 mm rapidly cooled crystal in an oil drop [13] were collected by the $2\theta/\omega$ method in the range of $8 \le 2\theta \le 45°$. Of a total of 14777 reflections, 14002 were independent, and after empirical absorption correction 13994 reflections were used to refine 1431 parameters. largest difference peak and hole: 0.539 and −0.548 e Å^{-3}, $R1(F > 2\sigma(F)) = 0.069$ and $wR2 = 0.169$ (all data) with $R1 = \sum||F_o| - |F_c||/\sum|F_o|$ and $wR2 = (\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2)^{0.5}$. The structure was solved with direct methods (SHELXS-92) [14] and refined by full-matrix least-squares on F^2 (SHELXL-93) [15]. A riding model was applied to refine the hydrogen atom positions. The uncoordinated disordered THF molecules were refined by applying 1-2- and 1-3-similarity restraints. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Two Diorganopotassates: Crystal Structure of $[K(C_6H_6)][K\{C(SiMe_3)_2(SiMe_2Ph)\}_2]$**

Colin Eaborn, Peter B. Hitchcock, Keith Izod, and J. David Smith*

Salts **1a**–**1c** containing the diorganolithate anion $[LiR_2]^-$, R = $C(SiMe_3)_3$ (Scheme 1), were isolated between 1983 and 1986[1] and the first dialkylsodate, **2**, was described recently.[2]

$M[Li\{C(SiMe_3)_3\}_2]$ **1a**, M = $[Li(thf)_4]$
1b, M = $[Li(tmen)_2]$
1c, M = [(pmdeta)Li(μ-Cl)Li(pmdeta)]

$[Na(tmen)_2(OEt_2)][Na\{C(SiMe_3)_3\}_2]$ **2**

$[K(C_6H_6)][K\{C(SiMe_3)_2(SiMe_2Ph)\}_2]$ **3**

$[K(OSiMe_2)_7][K\{C(SiMe_3)_2[SiMe_2(HC{=}CH_2)]\}_2]$ **4**

Scheme 1. tmen = *N*,*N*,*N*′,*N*′-Tetramethylethylenediamine, pmdeta = *N*,*N*,*N*′,*N*″-pentamethyldiethylenetriamine.

Reactions between the methyl derivatives of the heavier alkali metals[3] and $HC(SiMe_3)_3$ gave solvent-free compounds $M[C(SiMe_3)_3]$ which, in the solid state, formed chains of alternate cations M^+ and planar anions $[C(SiMe_3)_3]^-$ (M = K,[4] Rb[5]) or ion pairs separated by coordinated benzene (M = Cs).[5] The analogous compounds $M[C(SiMe_2Ph)_3]$, M = Na,[2] K,[4] Cs,[6] all crystallized as yellow solids which were rather insoluble in organic solvents. In crystals alternate anions and cations were linked by coordination between alkali metal and phenyl groups from the anion periphery.

The different structures adopted by the compounds $M[C(SiMe_3)_3]$ and $M[C(SiMe_2Ph)_3]$ suggested that it might be rewarding to synthesize the compound $K[C(SiMe_3)_2(SiMe_2Ph)]$. This was readily achieved by metalation of $HC(SiMe_3)_2(SiMe_2Ph)$ with methylpotassium, and crystals suitable for an X-ray diffraction study were obtained from benzene. The structure[7] (Fig. 1) consists of chains of alternate K^+ ions and $[C(SiMe_3)_2(SiMe_2Ph)]^-$ ions, but as there are two distinct environments for potassium it is best described as a potassium dialkylpotassate (**3**) (Scheme 1). The cation K1 lies on a twofold

axis and is bound to two phenyl groups from the neighboring anions and a molecule of benzene. Interactions between alkali metals and benzene or phenyl groups have been identified in a wide range of organometallic compounds.[8, 9] In contrast to the benzene molecule in $Cs[C(SiMe_2Ph)_3]\cdot 3C_6H_6$[5] that in **3** is held tenaciously: it is not removed by pumping under vacuum for several hours at 10^{-3} Torr. The tight bonding is reflected in the K–C(C_6H_6) bond lengths (mean 3.28(1) Å) which are comparable with the values of 3.33 to 3.43 Å in various liquid clathrates.[9c–f] The K–C(Ph) distances (3.155(4)–3.190(5) Å) are similar to those in [KCPh$_3$·thf·pmdeta].[9a] and $K_2[Ph_2CCH{=}CHCPh_2]\cdot 2Et_2O$.[9b] The second potassium ion in **3**, K2, lies at a crystallographic center of symmetry and is bound to the two central carbon atoms from adjacent $C(SiMe_3)_2(SiMe_2Ph)$ groups and, more weakly, to six methyl groups. The fact that all the K2–C distances are significantly shorter than those in $K[C(SiMe_3)_3]$ is consistent with the description of the compound as a potassium potassate. A polymeric compound $[K(thf)]_n[K\{C_3N_3Ph_2nButBu\}_2]_n$ containing substituted dihydrotriazine residues has recently been described[10] but, as far as we are aware, **3** is the first dialkylpotassate to be isolated.

Metalation of $HC(SiMe_3)_2(SiMe_2(CH{=}CH_2))$ with methylpotassium likewise gave an organopotassium derivative, and NMR data suggested that this was $K[C(SiMe_3)_2(SiMe_2(CH{=}CH_2))]$. The fine crystals obtained from methylcyclohexane/Et_2O, which were too fragile for an X-ray structure determination, were allowed to stand in the mother liquor for four weeks, during which larger crystals appeared. These were shown to consist of the potassate **4**, but because of disorder in the anion the data are not sufficiently accurate to justify a detailed discussion.[11] The cation in **4** has been reported previously;[12] as in our work it was formed by the adventitious reaction between an organometallic compound and a hydrocarbon solution containing a trace of silicone grease. Since in our experiments the Schlenk tube was at all times kept upright the grease must have dissolved as solvent distilled slowly on to the stopper and ran back into the solution.

Experimental Procedure

3: $HC(SiMe_3)_2(SiMe_2Ph)$ (5.0 g, 17 mmol) was added to a cold (−10 °C) suspension of MeK (27 mmol) in Et_2O (50 mL). The mixture was stirred for 1 h at −10 °C and then for a further 16 h during which time it was allowed to warm to room temperature. Solvent was removed under vacuum, the sticky residue was extracted into warm benzene/THF (1:1, 70 mL), the extract filtered and solvent evaporated. The solid obtained was washed with light petroleum (b. p. 40–60 °C) and recrystallized from hot benzene to give orange crystals of **3**. The compound was too air- and moisture-sensitive for satisfactory C and H analysis; ^{1}H NMR ([D$_8$]THF, chemical shifts relative to SiMe$_4$, 25 °C): $\delta = -0.11$ (s, 18H, Me_3Si), 0.12 (s, 6H, Me_2Si), 6.96 (m, 1H, *p*-H), 7.05 (m, 2H, *m*-H), 7.30 (s, 3H, C_6H_6), 7.68 (m, 2H, *o*-H); ^{13}C NMR: $\delta = 0.2$ (CSi_3), 7.3 ($SiMe_2$), 8.4 ($SiMe_3$), 125.9, 126.5, 135.1, 154.4 (Ph), 128.9 (C_6H_6); ^{29}Si NMR: $\delta = -9.6$ ($SiMe_2$), −7.5 ($SiMe_3$).

4: $HC(SiMe_3)_2(SiMe_2(CH{=}CH_2))$ (1.3 g, 5.35 mmol) was added to a suspension of KMe (6.21 mmol) in Et_2O at −10 °C. The mixture was allowed to warm slowly with stirring to room temperature. Solvent was removed, the residue extracted into benzene, and the extract was filtered and concentrated. The crystals which separated were washed with light petroleum. ^{1}H NMR (C_6D_6, 25 °C): $\delta = 0.34$ (s, 18H, Me_3Si), 0.47 (s, 6H, Me_2Si), 5.46 (dd, 1H), 5.62 (dd, 1H), and 6.64 (dd, 1H) ($H_2C{=}CH$); ^{13}C NMR: $\delta = 5.3$ (CSi_3), 5.4 (Me_2Si), 8.5 (Me_3Si), 124.2, 154.5 (C=C); ^{29}Si NMR: $\delta = -14.5$ (Me_2Si), −10.4 (Me_3Si). Fine crystals were obtained from methylcyclohexane/Et_2O. After four weeks larger crystals were formed and these were shown by X-ray diffraction to be **4**; ^{1}H NMR ([D$_8$]THF, 25 °C): $\delta = -0.06$ (s, 18H, Me_3Si), −0.01 (s, 6H, Me_2Si), 0.08 (s, 21H, Me_2SiO), 5.42 (dd, 1H), 5.54 (dd 1H), 6.42 (dd, 1H) and ($H_2C{=}CH$).

Structure-Determining C–H···O–Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil**

Peter Behrens,* Gianpietro van de Goor, and Clemens C. Freyhardt

The formation of zeolite-type solids by hydrothermal treatment of silica gels or solutions in the presence of organic molecules is currently under intensive investigation.[1] Organic molecules like amines, alkylammonium ions, or cyclic ethers are incorporated in the voids of the crystallizing framework and influence the type of structure that is formed. However, there are no clear host–guest relations in the sense of a real template effect. In accordance with this, in most of the cases the guest molecules exhibit orientational or rotational disorder at room temperature.[1] Nevertheless, there is at least some control of the reaction product, which could lead to a design of solid-state structures[2] (structure-directed synthesis of solids). The size and shape of the structure-directing molecules were recognized

as the most important parameters. These determine the size and the shape of the voids in the tetrahedral network of the host.[3] Details of the interaction between the organic guest molecules and the host framework, however, are known only in a few cases.

Currently, there is considerable interest in using organometallic complexes as components for the construction of solid inorganic compounds.[4] Metallocene complexes have been intercalated into layered sulfides[4a-c] and inserted into zeolites.[4d,e] These reactions often yield products with ill-defined stoichiometries, the structures of which are difficult to characterize. In contrast, self-assembly from solution gives stoichiometric products, often as single crystals, as presented recently by Schwarz et al.[4f] They investigated the reaction of cobaltocenium cations, hexacyanoferrate(II) anions, and trimethyltin chloride which leads to a channel-type inclusion compound with a three-dimensional framework structure.

Recently, it was shown that organometallic complexes can also act as structure-directors in the hydrothermal synthesis of zeolite-type compounds.[5-7] We[6] found that the cobaltocenium cation $[Co(C_5H_5)_2]^+$, $[CoCp_2]^+$, directs the formation of stoichiometrically well-defined clathrasils[8a] of the nonasil, the octadecasil, and the dodecasil 1H type (abbreviated as NON, AST, and DOH, respectively;[8b] the topology of the nonasil structure is shown in Fig. 1a). With increasing temperature, structures with increasingly larger cages are formed.[9] Of special interest here is the nonasil $[CoCp_2]^+F^-[SiO_2]_{22}$ **1**, prepared

$$[CoCp]^+F^-[SiO_2]_{22} \triangleq [CoCp_2]F\text{-NON} \quad \mathbf{1}$$

by the fluoride method,[10] which is the compound that crystallizes in the lowest temperature regime (between 420–440 K). The single-crystal X-ray structural analysis of this product (performed at 220 K) reveals some extraordinary features.[6]

The similarity of the shape of the largest void of the nonasil structure, the $[5^86^{12}]$ cage, and of the sandwich complex (Fig. 1b and 1c respectively), suggested that the organometallic cation occupies this void. Indeed, we found the cobaltocenium cation

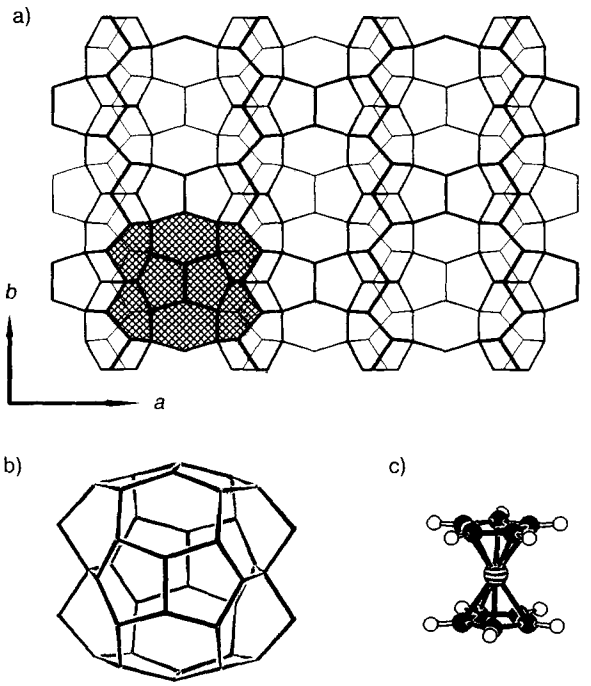

Fig. 1. a) Topology of the nonasil structure (oxygen atoms omitted); b) the $[5^86^{12}]$ cage of the nonasil structure; its shape resembles that of the cobaltocenium cation (c).

in the expected orientation in a staggered conformation which conforms to the symmetry of the inversion center in the center of the cage (at the position of the Co atom). The cation is fixed and does not show rotational disorder with regard to its fivefold axis (Fig. 2a). This result was unexpected, because sandwich complexes with unsubstituted cyclopentadienyl ligands often exhibit such disorder also in simple salts; in the case of a zeolite-type host–guest compound, where the guest species usually are disordered at room temperature, the absence of disorder is even more unexpected. A reversible phase transition, which is associated with the onset of rotation of the $[CoCp_2]^+$ ions, was observed at $T_c = 485$ K by microcalorimetry (DSC).[6]

The detailed description of the C–H···O–Si contacts as derived from the X-ray structural analysis[11] reveals the type of the unusual strong host–guest interactions which are responsible for the absence of disorder. Figures 2b and 2c depict the

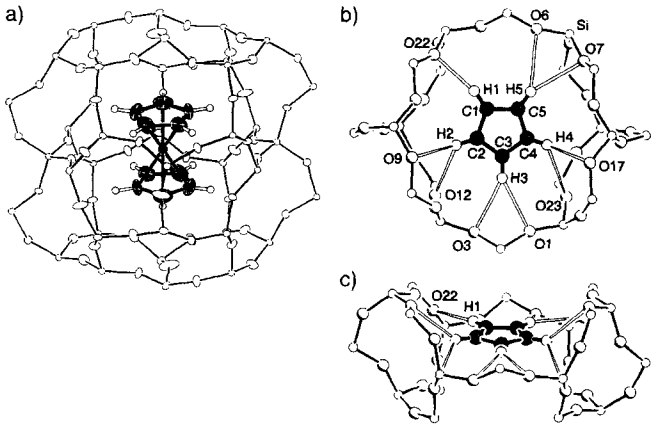

Fig. 2. Crystal structure of **1** [11]: a) ORTEP drawing of the $[5^86^{12}]$ cage containing the cobaltocenium cation; b) and c): SCHAKAL plots showing the C–H···O–Si interactions between the cobaltocenium cation and the SiO_2 framework. Important bond lengths and angles (d(H···O) in Å, d(C···O) in Å, ∢ C–H···O in °): C1–H1···O22: 2.309, 3.369, 166.7; C2–H2···O9: 2.645, 3.527, 138.5; C2–H2···O12: 2.846, 3.527, 121.1; C3–H3···O1: 2.604, 3.591, 151.6; C3–H3···O3: 2.700, 3.677, 150.3; C4–H4···O17: 2.699, 3.544, 134.8; C4–H4···O23: 2.884, 3.554, 120.4; C5–H5···O6: 2.765, 3.704, 145.3; C5–H5···O7: 2.644, 3.649, 154.5.

arrangement of a cyclopentadienyl ring with regard to the surrounding oxygen atoms of the framework (due to the inversion center at the site of the Co atom the situation is the same for the opposing five-ring of the CoCp cation). Four of the five hydrogen atoms (H2 to H5) of a Cp ring have C–H···O–Si contacts with distances in the range of d(H···O) = 2.60–2.88 Å or d(C···O) = 3.53–3.70 Å (∢ C–H···O = 120–155°); for each hydrogen atom, two framework oxygen atoms are in this distance range. The fifth hydrogen atom of a Cp ring (H1) exhibits only one C–H···O–Si contact, which, however, is considerably shorter: d(H1···O) = 2.31 Å or d(C1···O) = 3.37 Å (∢ C–H1···O = 167°).

In the last few years, it has become apparent that C–H···O interactions exist in organic crystals[13,14] and that they influence the packing of molecules in crystals,[14] disorder phenomena,[15] and thermal parameters of neighboring atoms.[16] On the basis of these results, criteria were developed with regard to the occurrence of C–H···O hydrogen bonds in organic compounds.[17,18] Steiner's criteria[18] are: d(H···O) < 2.8 Å and ∢ C–H···O > 90°.

The bifurcated C–H···O interactions of H atoms H2 to H5 are thus located on the border between van der Waals contacts[19] and hydrogen bonds. Such C–H···O–Si interactions probably occur in many porosils[8a] that contain organic guest

molecules, although only a few quantitative investigations have been carried out to date. In trioxane silica sodalite, for example, each trioxane molecule is involved in a total of eighteen C–H···O–Si interactions of this kind (d(O-H): 9 × 2.72 Å and 9 × 2.93 Å). In spite of these interactions the trioxane molecules are disordered over four equivalent sites at room temperature.[20] Therefore, we believe that also in the case of $[CoCp_2]$F-NON **1** the longer C–H···O–Si contacts alone are not sufficient to fix the $[CoCp_2]^+$ ions. In our opinion, the absence of rotational disorder is due to the short C–H1···O–Si interactions, which clearly must be classified as hydrogen bonds. Interestingly, in this context, Steiner et al.[15] have recently attributed the absence of (expected) disorder in a β-cyclodextrin complex of pentane-1,5-diol to a C–H···O hydrogen bond.

The IR spectrum of **1** exhibits a splitting of the C–H valence bands, corresponding to the different strengths of the C–H bonds which vary due to the different C–H···O–Si interactions (Fig. 3). In comparison to the C–H bands of cobaltocenium hexafluorophosphate (ν_{C-H} = 3128 cm^{-1}) and of the cobaltocenium clathrasil of the DOH type (ν_{C-H} = 3120 cm^{-1}),[21] an additional signal appears in the nonasil **1** at ν_{C-H} = 3100 cm^{-1}, which we assign to the C–H valence vibration of the H1 atom. The splitting decreases with increasing temperature, especially above T_c.[22] The IR spectrum of the DOH clathrasil shows no indications of a similarly strong C–H···O–Si interaction and, on the basis of this and the results of other investigations,[21] we assume that in this case the complex is rotationally disordered at room temperature. Since the complex cation occupies a considerably larger void in the DOH compound (430 Å^3 compared to 290 Å^3 in NON), one can assume that the extraordinarily strong interaction in nonasil **1** is due to steric reasons rather than being caused by specific properties of the $[CoCp_2]^+$ ion: The geometry of the sandwich complex fits perfectly to that of the $[5^86^{12}]$ cage of the NON framework (Figs. 1b, c, Fig. 2a), and this perfect fit may well be the driving force for the formation of the strong C–H···O–Si interactions. A further indication for this is the fact that the temperature region, in which **1** crystallizes (420–440 K), has a rather low upper limit. Evidently, above this limit, the space requirement of the complex cations in the synthesis gel increases too strongly because of their dynamical movements, and thus a structure with a larger cage is formed (AST type, volume of the largest cage: 360 Å^3).

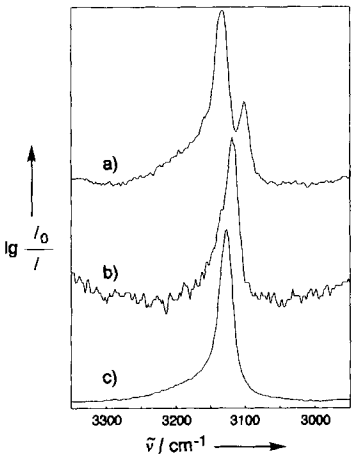

Fig. 3. IR spectra: Region of C–H valence vibrations of the cobaltocenium cation in the fluoride nonasil **1** (a), in the dodecasil 1H (b), and in the hexafluorophosphate (c).

This work provides the first direct proof of strong C–H···O–Si hydrogen bonds between a guest molecule and a zeolite-type host framework. We suppose that the C–H···O–Si interactions found in the crystal may also play a role during nucleation in the synthesis gel within the temperature regime of 420–440 K. This idea is supported by the fact that the phase transition temperature T_c, which marks the onset the rotational disorder,[6] lies well above the synthesis temperature (485 K versus 420–440 K). Our results are not only of importance with regard to the synthesis of zeolite-type phases. The proof that strong C–H···O–Si bonds are possible is of general importance for the interactions of organic or organometallic molecules with solid surfaces. Such interactions also play a role in heterogeneous catalysis and in biomineralization.

[11] The crystal structure investigation, which was performed at 220 K, has been described in ref. [6]. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-58258. For the results described here, it is of importance that the positions of all H atoms were constructed geometrically and refined fixed to the respective carbon atom (riding mode). The typical value of C–H bond lengths in arenes (0.97 Å), as obtained from X-ray diffraction analyses [12], was used for the refinement. For the calculation of interatomic $H_{guest}\cdots O_{host}$ distances, an approximate correction of the well-known systematic error of X-ray methods was applied. The lengths of the C–H bonds in the arene rings were set to the standard value of 1.08 Å [12]. Thus, the H–O distances of the C–H···O–Si contacts discussed here were not determined directly from the experiment. However, regarding the rigid geometry of the $[CoCp_2]^+$ ions, the true positions of the H atoms cannot deviate significantly from the positions used here.

[21] Using the fluoride method, $[CoCp_2]$F-DOH is formed only as a by-product at high synthesis temperatures [6]. Pure, single-phase $[CoCp_2]$OH-DOH is obtained in the classical basic hydrothermal synthesis. Rietveld refinement of X-ray powder diffraction data, refinement of a single-crystal diffraction data set (both measured at 298 K), the occurrence of a phase transition at 228 K as well as the IR spectrum shown in Figure 3 indicate that the $[CoCp_2]^+$ ions in $[CoCp_2]$OH-DOH are rotationally disordered at room temperature (B. Lindlar, G. van de Goor, A. M. Schneider, P. Behrens, J. Felsche, unpublished results).

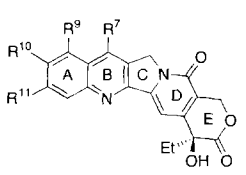
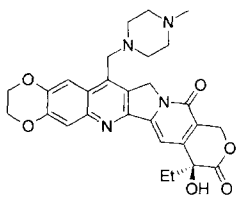
Cascade Radical Reactions of Isonitriles: A Second-Generation Synthesis of (20*S*)-Camptothecin, Topotecan, Irinotecan, and GI-147211C**

Dennis P. Curran,* Sung-Bo Ko, and Hubert Josien

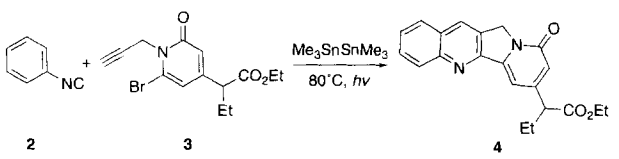
The camptothecin family of molecules has recently moved to the forefront of research in the treatment of solid tumors by chemotherapy.[1] The parent of this family, (20*S*)-camptothecin (**1a**), is highly active, and it is thought to operate by interfering with the unwinding of DNA by the enzyme topoisomerase I.[2] Camptothecin's clinical use has been limited by its insolubility, but extensive structure–activity studies have identified many analogs of camptothecin with equal or better antitumor activity and with better solubility properties.[3] Generally speaking, substitution at C7 and C9–C11 is permitted, while substitution at other positions tends to decrease or completely eliminate activity. Several analogs of camptothecin with improved solubility in water, including topotecan (**1b**),[1] irinotecan (**1c**),[1] and GI-147211C (**1d**),[4] are now in various stages of clinical trials around the world.





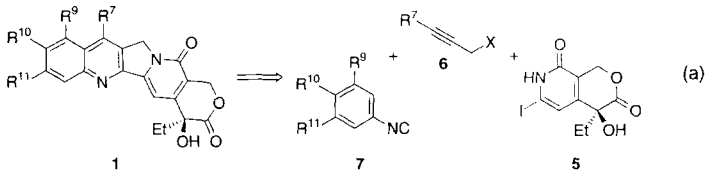
1a, camptothecin, R^7-R^{11} = H
1b, topotecan, R^7,R^{11} = H, R^9 = CH_2NMe_2, R^{10} = OH
1c, irinotecan, R^7 = Et, R^9,R^{11} = H, R^{10} = OCON
1d, GI-147211C

The synthesis of camptothecin was an active area of research about 20 years ago,[5] and the medicinal importance of this family has now rekindled interest. A number of new syntheses and significant improvements to existing syntheses have recently been reported.[6] In late 1992, we described a formal synthesis of racemic camptothecin that featured a new radical cascade reaction.[7] Reaction of phenyl isonitrile (**2**) with the readily available bromopyridone **3** provided the well-known "Danishefsky tetracycle" **4**.[8] Though very short (8 steps) and efficient, this synthesis suffered from two major problems: 1) the final products were racemic; and 2) the introduction of the E-ring lactone by hydroxymethylation of **4** occurred in poor yield, and the conditions were not tolerant of substituents on the A and B rings.[7d]



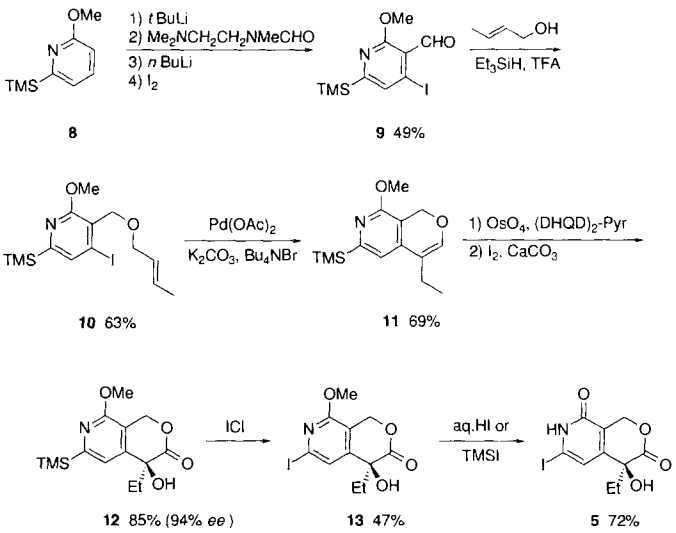
2 **3** **4**

Because the cascade radical reaction should tolerate all kinds of A- and B-ring substituents, we reformulated the synthetic plan to proceed via the key pyridone lactone **5** [Eq. (a)]. Variation of the propargyl substituent R^7 in **6** (X = I, Br) and the aryl substituents of isonitrile **7** should then allow access to camptothecin as well as known and new analogs. We now report a highly convergent second-generation synthesis of (20*S*)-camptothecin (**1a**). The synthesis is well suited to preparing A- and B-ring analogs of camptothecin, and to demonstrate this we have also synthesized GI-147211C (**1d**) and the immediate precursors of topotecan (**1b**) and irinotecan (**1c**).



1 **7** **5** (a)

The synthesis of lactone **5** is summarized in Scheme 1. Metalation of 2-bromo-6-methoxypyridine and quenching with TMSCl provided **8**. This was then converted in one step to iodoaldehyde **9** by following the procedure of Comins.[9] The E ring was then introduced by a sequence of reductive etherification[10] to form **10** and subsequent Heck reaction[11] to give enol ether **11**.[12] The Sharpless asymmetric dihydroxylation[13] of **11** followed from a model study,[14] and **12** was obtained in 85% yield and 94% *ee* after oxidation of the intermediate α-hydroxy lactol.[12] Exchange of the TMS group in **12** for iodine occurred upon exposure to ICl.[5] At about 50% conversion of **12** the reaction rate slowed dramatically. When the reaction was stopped at this point, iodide **13** was isolated in 47% yield and **12** was recovered in 45% yield. Demethylation of **13** then provided **5**.



8 **9** 49% **10** 63% **11** 69% **12** 85% (94% *ee*) **13** 47% **5** 72%

Scheme 1. Synthesis of intermediate **5**. TMS = trimethylsilyl, TFA = trifluoroacetic acid.

N-Propargylation of **5** under optimized conditions[16] with **14a** provided **15a** in 88% yield. In the key radical cascade,[17] a solution of **15a**, phenyl isonitrile (**2**), and hexamethyldistannane (1.5 equiv) in benzene was warmed to 70 °C and irradiated with

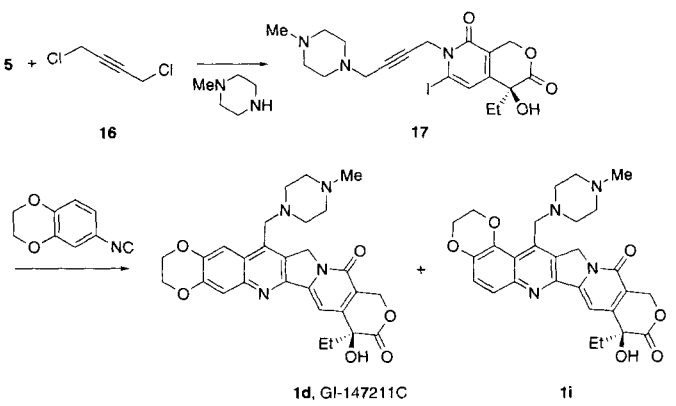
a sunlamp. Highly enantiomerically enriched (20*S*)-camptothecin (95% *ee*) crystallized from the reaction mixture and was isolated in 63% yield by simple filtration and washing with ether. Camptothecin (**1a**) could also be produced by substituting hexamethyldisilane for the distannane (52%) or by using *t*-butyl alcohol as the solvent (45%). Reaction of **15a** with *p*-methoxyphenylisonitrile provided **1e** in 51% yield, and subsequent demethylation with HBr provided 10-hydroxycamptothecin (**1f**).[18] This highly active natural product is the precursor of topotecan (**1b**).[19]

To prepare irinotecan (**1c**), lactone **5** was N-propargylated with **14b**, and the resulting product **15b** was treated with *p*-methoxyphenylisonitrile under the standard conditions. Demethylation of the product **1g** with HBr then gave 7-ethyl-10-hydroxycamptothecin (**1h**),[18] which is both a synthetic precursor of irinotecan (**1c**)[20] and the active antitumor agent produced in vivo when irinotecan is metabolized.[21]

The synthesis of GI-147211C (**1d**) starts with N-propargylation of **5** with **16** followed by addition of *N*-methylpiperazine to provide lactone **17**. Reaction of this lactone with 3,4-ethylene-



dioxyphenylisonitrile then provided an inseparable 3:2 mixture of GI-147211C (**1d**) and its regioisomer **1i** in 57% yield. This reaction illustrates a frequent regiochemical problem that occurs when *meta*-substituted isonitriles are used in radical cascade reactions.[17] A strategic solution to this problem has recently been developed and this will be reported separately.

This synthesis of camptothecin and its analogs provides a graphic demonstration of the power of cascade radical reactions. The approach is short and efficient, and it may be useful for preparing larger quantities of these compounds. Perhaps more importantly, the modular "mix-and-match" strategy [Eq. (a)] implemented in the radical cascade is ideally suited to the known structure–activity relationship of the camptothecin family. Lactone **5** is an invariant module that can be combined in as few as two steps with two variable modules—propargyl bromide **6** and aryl isonitrile **7**—to give a member of the camptothecin family. Because the radical reaction tolerates functional groups, the strategy promises to be useful in preparing a large assortment of both known and new analogs of camptothecin.

The Formal Potentials of Solid Metal Hexacyanometalates**

Fritz Scholz* and Aleš Dostal

We report here on the first formal potentials of a series of solid metal hexacyanometalates $(M^+)_nM'[M''(CN)_6]$ (M^+ = Li^+, K^+, Na^+, Rb^+, Cs^+; M' = Ag, Al, Cd, Co, Cr, Cu, Fe, Ga, In, Mn, Ni, Pb; M'' = Cr, Fe, Mn), as determined by solid-state voltammetric experiments. The experimental data can be understood both in terms of the polarizing effect (ionic potential) of the nitrogen-bonded M'^{n+} ions and also in terms of the free energy of hydration of the cations M^+, which are inserted into the channels and holes of the zeolitic structure of the solid compounds during reduction of the $[M''(CN)_6]^{m-}$ units of the solid compounds. The results of this study support the assumption that M''→C π back bonding increases as the acid–base interaction on the nitrogen end of the cyanide ions increases.

Recently, increasing attention has focused not only on electrochemical reactions with solid electrolytes,[1] but also on electrochemical reactions in which electron transfer is coupled with an ion transfer between the electrolyte solution and the solid compound. Typical examples are topotactic electrochemical reactions with ion insertion (or intercalation in the case of layer structures),[2] for instance the reactions of Prussian blue and other metal hexacyanometalates.[3–5]

If "Ox" denotes the oxidized form and "Red" the reduced form of a metal ion in the solid compound, and if M^+ is the cation inserted into the solid compound during reduction, the electrode reaction with the potential $E^\circ_{s,f}$ can be formulated according to Equation (a). Here $E^\circ_{s,f}$ is the formal potential of

$$\{Ox\}_s + e^- + M^+ \rightleftharpoons \{RedM\}_s \quad (a)$$

this electrode reaction (the subscript s indicates that the entire redox couple is confined to the solid phase). The electrode reaction can be separated into two independent equilibria [Eq. (b) (standard potential: E°_s) and Eq. (c) (equilibrium constant K)]. Equilibrium (c) is itself an electrochemical reaction because it describes the distribution of a charged particle between two phases. For equilibrium (b) we can formulate the Nernst equation in Equation (d), where E°_s is the standard

$$\{Ox\}_s + e^- \rightleftharpoons \{Red\}_s^- \quad (b)$$

$$\{RedM\}_s \rightleftharpoons \{Red\}_s^- + M^+ \quad (c)$$

$$E = E^\circ_s + RT/nF\ln(f_{Ox}/f_{Red}) + RT/nF\ln(c_{Ox}/c_{Red}) \quad (d)$$

potential of the redox system in the solid matrix. Equilibrium (c) can be described by the constant defined in Equation (e). The combination of Equations (d) and (e) yields Equation (f), where

$$K = (a_{Red}a_M)/a_{RedM} = (f_{Red}c_{Red}a_M)/(f_{RedM}c_{RedM}) \quad (e)$$

$$E = E^\circ_s + RT/nF\ln(f_{Ox}/f_{Red}) - RT/nF\ln(K/f_{Red}) + RT/nF\ln(c_{Ox}/c_{RedM}) + RT/nF\ln a_M \quad (f)$$

the first three terms can be regarded as the formal potential $E^\circ_{s,f}$ of reaction (a). Unfortunately, a separate experimental determination of E°_s and K is not possible.

Previously the determination of the formal potentials of metal hexacyanometalates was possible only when these compounds could be precipitated on metal electrodes. In some cases the metal hexacyanometalates were chemically bonded to the electrode surface or they were incorporated into graphite oil pastes.[6] Of course, these techniques do not yield the formal potentials of pure solid metal hexacyanometalates.

Recently, we introduced a new electrode technique that enables direct electrochemical measurements on pure solid materials.[7, 8] Here the solid compound is immobilized as microcrystalline particles on a suitable electrode. This technique was applied for the study of insoluble organometallic compounds[9, 10] and also for the determination of thermodynamic data of insoluble compounds.[11, 12] This technique combined with cyclic voltammetry can also be used to determine the formal potentials $E^\circ_{s,f}$ of reaction (a) of metal hexacyanometalates. The cyclic voltammograms of the hexacyanometalate ions indicate that the electrochemical reaction is diffusion controlled. At a given concentration of K^+, the formal potential is calculated as $E_f = (E_{p,a} + E_{p,c})/2$, where $E_{p,a}$ and $E_{p,c}$ are the anodic and cathodic peak potentials, respectively. The formal potential $E^\circ_{s,f}$ is determined by extrapolating the E_f values to $a_{K^+} = 1$. Activities for potassium ions in dilute solutions were calculated by the simple Debye–Hückel approximation. Table 1 shows the formal potentials of the solid metal hexacyanometalates for the insertion of potassium ions. These values are compared to the standard potentials of the hexacyanometalate ions in aqueous solution. Table 2 gives the formal potentials $E_{s,f}$ (these values refer to $c_{K^+} = 0.1$ mol L^{-1}) of some hexacyanoferrates for the insertion reaction with different alkali metal ions.

Table 1. Formal potentials $E^\circ_{s,f}$ of metal hexacyanometalates on potassium ion insertion as well as the difference ΔE between the standard potentials E°_{aq} of the hexametalate ions [a] in aqueous solution and $E^\circ_{s,f}$.

$Cr^{3+}[Mn^{2+/3+}(CN)_6]$	0.352	− 0.592

[a] The following standard potentials for the hexacyanometalate ions in aqueous solution were used: $[Fe(CN)_6]^{3/4-}$: + 0.355 V, $[Cr(CN)_6]^{3/4-}$: − 1.140 V, $[Mn(CN)_6]^{4/5-}$: − 1.050 V, $[Mn(CN)_6]^{3/4-}$: − 0.240 V (all vs. SHE) [15]. [b] The formulas M'[M''(CN)$_6$] indicate only the metal M' coordinated to nitrogen and the metal M'' coordinated to carbon. Depending on the oxidation state of M'' the charge is compensated by the alkali metal ions inserted from the solution, which are not given in the formulas. [c] The formal potentials were determined by cyclic voltammetry with a scan rate of 0.1 Vs^{-1} at 22 °C. For experimental details, see refs. [5, 8].

Table 1 indicates that hexacyanometalate (hcm) ions in the solid state are generally much stronger oxidants than in aqueous solution. If ΔG°_{aq} is the standard free energy of the electrochemical oxidation of hcm ions dissolved in water and ΔG°_s is the standard free energy of the electrochemical oxidation of the

same hcm ions when they are bonded to M′ in a solid compound, we can write Equation (g). Here, ΔG°_{it} denotes the

$$\Delta G^\circ_s = \Delta G^\circ_{aq} + \Delta G^\circ_{intr} + \Delta G^\circ_{it} \quad (g)$$

standard free energy of the ion transfer of M^+ ions, and ΔG°_{intr} is the intrinsic change in the standard free energy caused by the bonding of the nitrogen atoms of the cyanide ions to M′ instead of to water. ΔG°_{it} cannot be determined separately ($\Delta G^\circ_{it} = -RT\ln K$), because the difference between E°_{aq} and E°_s is not known. It can be supposed that ΔG°_{intr} is determined by the strengths of the bond between M′ and the nitrogen atoms of the cyanide ions. For a series of hexacyanoferrates with the same inserting cation (e.g. K^+), it was assumed that ΔG°_{it} is almost constant and $E^\circ_{s,f}$ can be correlated with the polarization power of M′. The plot of $E^\circ_{s,f}$ versus the ionic potential Φ ($\Phi = z/r_{eff}$; z = charge, r = effective radius) of the Me^I ions has a statistically significant ($p > 0.99$) correlation ($r_{corr} = 0.74$, $n = 12$) (Fig. 1a). The effective radii of the M′ ions are those of the hexacoordinated high-spin ions because the ligand field of the nitrogen-coordi nated cyanide ions is rather weak. The stronger the polarizing effect is, the weaker the σ bond between the iron atom and the cyanide ions is, which is accompanied by an increase in π back

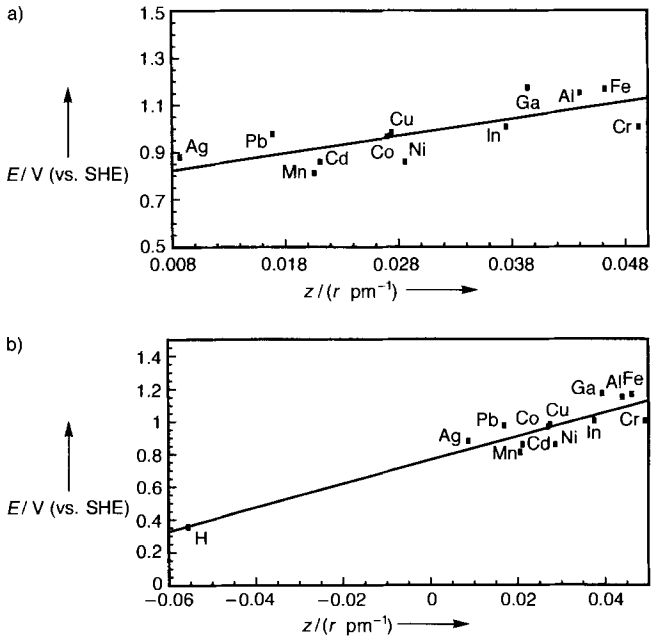

Fig. 1. a) Plot of $E^\circ_{s,f}$ of solid metal hexacyanoferrates M′[M″(CN)$_6$] versus the ratio z/r of the effective charge and radius of the metal ions M′. b) The same plot as in Fig. 1a but with the standard potential E°_{aq} of the hexacyanoferrate ions in water as well as the ratio z/r for protons.

bonding. According to Shriver[19] this leads to a decrease in the absolute energy of the fully filled t^6_{2g} orbitals (low-spin Fe^{2+} ions). This favors the +2 oxidation state of the iron centers and shifts the oxidation potentials towards more positive values. Figure 1b shows the same function as Figure 1a, but the bridging proton of a H_2O molecule is included, for which the effective radius is −18 pm (coordination number 2).[16] The corresponding ionic potential of the proton is the standard potential of the hexacyanoferrate ions in water. The inclusion of the proton in the correlation is justified because in aqueous solution the hexacyanoferrate ions are coordinated to water, in other words bound to protons, rather than to monovalent metal ions. It is very remarkable that the coordinates of the proton lie on the line of the formal potentials of solid metal hexacyanoferrates. This implies that ΔG°_{intr} is much more important for $E^\circ_{s,f}$ than ΔG°_{it} is. In fact, the plot in Figure 1b bridges the solution and solid-state chemistry of the hexacyanoferrates, which has not been shown earlier. The interpretation of the plot given in Figure 1a is strongly supported by Mössbauer spectra of these compounds, which show that the increasing polarizing effect of M′ decreases the electron density at the iron ion.[20] This is also supported by infrared data for cyanide.[19]

It is evident from Table 2 that the $E^\circ_{s,f}$ values also depend to some extent on the nature of the M^+ ions. ΔG°_{it} can be taken as the difference between ΔG°_{stab}, which is the free energy of the "solvation" of M^+ ions in the metal hexacyanometalate host lattice, and ΔG°_h, which is the free energy of hydration of M^+ ions in water. Our values in Table 2 and also those reported earlier for thin films of nickel hexacyanoferrate on nickel[18] show that the transfer of the alkali metal cations from the aqueous phase to the metal hexacyanometalate phase is generally easier the bigger the alkali metal ions are. The channel diameter of the solid hexacyanometalates is nearly constant (ca. 320 pm) for different metal M′ hexacyanometalates.[14] The diameters of the naked cations are: Li^+ 148, Na^+ 204, K^+ 276, Rb^+ 298, and Cs^+ 340 pm.[13] When the cations enter the channel, the hydration sphere is disassemblied by the orifice and the channel, and hydration is possible, if at all, only along the axis of the channel. Since the number of water molecules in the solvation sphere decreases from lithium to cesium, and hence the free energy of solvation decreases in the same way, it is much easier to transfer the higher alkali metal ions than lithium ions. Rubidium is the largest alkali metal ion that can be electrochemically inserted into the holes of the hcm. Presumably cesium ions are attached only to the surface of the solid, which explains why Cs^+ does not usually fit the general trend in potentials from Li to Rb.

Figure 2 shows a plot of the lattice constants of solid metal hexacyanometalates versus the formal potentials $E^\circ_{s,f}$ of the hexa-

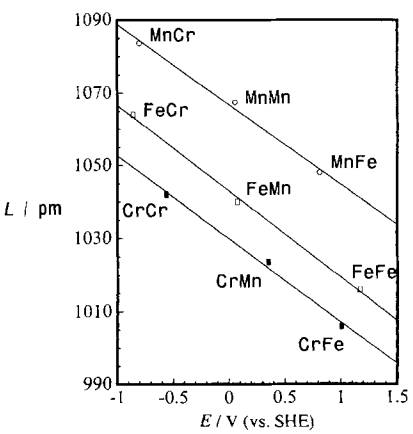

Fig. 2. Plot of the lattice constants L of solid metal hexacyanometalates M′[M″(CN)$_6$] versus the formal potentials $E^\circ_{s,f}$ of the hexacyanometalate ions [M″(CN)$_6$]. The compounds are indicated as M′M″. The lattice constants were taken from refs. [21–24].

cyanometalate ions in the solid compounds. It is very interesting that the formal potentials of the hexacyanoferrates, hexacyanochromates, and hexacyanomanganates change in the same way when they are coordinated to manganese, iron, and chromium ions. The order of formal potentials is the same for the solid compounds as it is for the hexacyanometalate ions dissolved in water (see footnote [a] of Table 1). The reason for the linear correlation in the plot in Figure 2 is the fact that the strength of π back bonding increases from chromium to iron in the hexacyanometalate ions. This is accompanied by a decrease in lattice constants and by an increase of formal potentials.

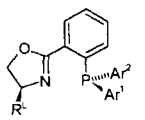
Palladium Complex Catalyzed Asymmetric Allylic Substitutions with Nitromethane: Enantioselectivities Exceeding 99.9% *ee***

Heiko Rieck and Günter Helmchen*

The reaction of allylic acetates or carbonates with stabilized, soft carbanions such as malonates is among the most important methods for C–C bond formation in asymmetric synthesis.[1] In reactions of this type the use of palladium complexes of 4,5-dihydrooxazoles **1**, chiral ligands introduced by us and others,



1

	R^L	Ar^1	Ar^2
1a	*i*Pr	Ph	Ph
1b	Ph	Ph	Ph
1c	*t*Bu	Ph	Ph
1d	(*i*BuSCH$_2$)Me$_2$C	Ph	Ph
1e	*i*Pr	1-($C_{10}H_7$)	Ph
1f	*i*Pr	Ph	1-($C_{10}H_7$)
1g	*i*Pr	1-($C_{10}H_7$)	1-($C_{10}H_7$)

gave enantioselectivities of over 98% *ee* for several cases.[2] The stereochemical course of this substitution can be generally described by a transition state in which the nucleophile attacks at the carbon atom of the allylic moiety in *trans* position relative to the phosphorus atom of the *exo* isomer (Fig. 1).[3]

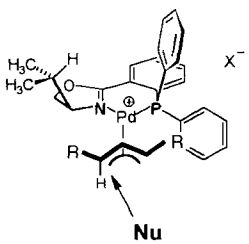


Fig. 1. Postulated transition state for the reaction of a nucleophile Nu with an allyl palladium complex of the ligand **1a**.

We have now used nitronates derived from nitromethane as nucleophiles, which were not extensively studied previously because of multiple alkylation and formation of side products. Nitronates are of interest as nucleophiles,[4] because the resultant products can be further transformed into a variety of synthetically important compounds. Despite this, reactions with chiral catalysts were studied for only one particular intramolecular reaction, which gave at best 70% *ee* with Pd complexes of classical C_2-symmetric diphosphanes.[5]

Carbonates **2a**–**2c** served as representative allylic compounds (Schemes 1 and 2). The comparatively complicated reaction mixtures were analyzed by chromatography (see Experimental Procedure). O-Alkylation of nitronates, typical for the uncatalyzed reaction, was not observed with palladium complexes of dihydrooxazoles **1** as catalysts. With analogous N,S and N,Se ligands[3] very low turnover was observed at best.

With the alkylated substrates **2a** and **2b** only monosubstitution products **3a** and **3b**, respectively, are formed in very high yield (Table 1). In case of the aryl-substituted substrate **2c** rates of the mono- and the disubstitution are similar (Table 2). The disubstitution products include diastereomers *meso*-**4**, which

9 [c]	**1a**	24	1:99	96 [d]	n.d. [e]	>99.9

[a] As in Table 1; molar ratio CH_3NO_2: **2c** = 5:1 for entries 1–8. [b] (**4** + *ent*-**4**):*meso*-**4** = 47:53. [c] Molar ratio CH_3NO_2: **2c** = 5:1. [d] Yield of **4c**. [e] n.d. = not determined.

have a pseudoasymmetric carbon atom, in addition to enantiomers **4** and *ent*-**4**. The composition of the product mixture can be controlled by adjusting the molar ratio of nitromethane and allylic compound **2**. Figure 2 demonstrates that the disubstitution product **4** can be obtained almost exclusively when a stoichiometric ratio of reactants is employed. For example, the reaction with the molar ratios **2c**:CH_3NO_2 = 2:1 and 1:100 yields mixtures of products with the ratios **3c**:**4c** = 1:99 and 94:6, respectively. Entries 6–8 of Table 2 show that when the ligand has a bulkier diarylphosphanyl group, the reactivity decreases and the monoallylation product dominates (cf. entries 3 and 8).

The enantioselectivity of the monosubstitution (see Table 1) depends on the steric situation in the complex, and is slightly higher with nitronates as the nucleophile than with malonates[2] or amines.[6] The substituent R^L in the dihydrooxazole ring of ligand **1** is particularly important for the small substrates

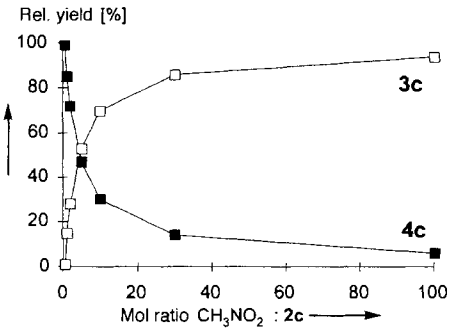

Fig. 2. Relative yields of **3c** and **4c** versus the molar ratio of nitromethane to **2c** (ligand **1a**; reaction conditions described in the Experimental Procedure).

2a and **2b**: the larger the substituent, the higher the enantioselectivity. Similarly, increasing the steric bulk of the substituent on the allyl moiety enhances the enantioselectivity. With the new ligand **1d**, easily available from penicillamine, reactions with 80% *ee* were possible with substrate **2a**, which is a distinct advance over the previous highest value of 60% *ee*.

For compounds with R = Ph, obtained from substrate **2c**, only substitution products with (*E*) configuration were formed, as anticipated; however, in the case of the alkyl-substituted compounds **2b** and **2c** (*Z*)-configurated products were obtained in up to 70% yield (Table 1). This is very surprising because reactions of these substrates with amines[6] and malonates[2] gave (*Z*) isomers in less than 5% yield. Equally interesting is the (*R*) configuration of the (*Z*) product and the possibility of controlling the (*E*)/(*Z*) ratio by adjusting the ratio of nitromethane to substrate. We assume that the (*E*,*S*) products are formed by the pathway mentioned in the introduction, but that the (*Z*) products arise by a yet unknown reaction path leading to **3a,b** with (*Z*,*R*) configuration.[7]

For substrates with R = Ph we were able to determine precisely the enantioselectivities of the mono- (**3c**) as well as the

disubstitution products (**4c**) (Table 2). Interestingly, the disubstitution products were invariably formed with higher enantiomeric purity than the monosubstitution products. When ligand **1c** was used, an enantioselectivity exceeding 99.9% *ee* was obtained. This can be rationalized by assuming that the selectivity of the substitution reaction is independent of the nucleophile. Thus, in the first step **3c** and *ent*-**3c** are formed in a ratio of roughly 100:1. In the subsequent step **4c** is formed preferentially from **3c** with approximately equal selectivity and in a configuratively analogous manner, but *ent*-**3c** leads to one of the diastereomers *meso*-**4c**; this causes a decrease of the relative amount of *ent*-**4c** and an increase of the ratio **4c**:*ent*-**4c** to a value of approximately 10000:1.[8]

When ligands with opposite configurations, **1** and *ent*-**1**, are used for the mono- and the bisallylation, the *meso* compounds *meso*-**4** are expected to be favored. These products can indeed be prepared in a controlled way, however, only as mixtures of pseudoasymmetric diastereomers, which equilibrate under the reaction conditions because of epimerization of the stereogenic center carrying the NO_2 group.[9] Thus, the reaction of nitromethane with the carbonate **2c** catalyzed by the Pd complex of the ligand **1c** first yields (+)-**3c**; its further reaction with **2c** catalyzed by the Pd complex of the ligand *ent*-**1b** affords a 1:1 mixture of the diastereomers *meso*-**4c** in 98% yield.

These results demonstrate that under appropriate conditions nitronates are well suited as nucleophiles for Pd-catalyzed allylic substitutions. Of particular general interest is the new reaction channel. Currently, further experiments are being carried out to elucidate the reaction mechanism.

Experimental Procedure

3a: Under an inert atmosphere at ca. 25 °C, $Pd_2dba_3 \cdot CHCl_3$ [10] (25.9 mg, 50 μmol with respect to Pd) and **1d** (27.5 mg, 60 μmol) were dissolved in 12 mL of dry THF to give a dark red solution. After 20 min the resulting yellow-orange solution was treated with **2a** (721 mg, 5.0 mmol) and nitromethane (6.1 g, 0.1 mol). After 4 d the solvent was removed in vacuo and the residue dissolved in ether. The solution was extracted with NH_4Cl and NaCl solution, the organic phase concentrated to dryness, and the residue purified by chromatography (50 g silica gel, *n*-hexane/ethyl acetate (20/1)). Yield of **3a**: 85%; (*E*)-**3a**:(*Z*)-**3a** = 74:26; GC: Chrompack CP Chirasil DEX CB, 75 °C, t_R[(*E*)-**3a**] = 17.4/18.4 min, t_R[(*Z*)-**3a**] = 17.2/21.3 min.

3b: In analogy to the preparation of **3a**, carbonate **2b** (172 mg, 1.0 mmol) was treated with $Pd_2dba_3 \cdot CHCl_3$ (12.8 mg, 25 μmol with respect to Pd), **1d** (14.0 mg, 30 μmol), and nitromethane (305 mg, 5.0 mmol) in 5 mL of dry THF. Yield of **3b**: 96%; (*E*)-**3b**:(*Z*)-**3b** = 59:41; GC: Macherey-Nagel FS-Lipodex E, 90 °C, t_R[(*E*)-**3b**] = 18.8/19.3 min, t_R[(*Z*)-**3b**] = 20.6/21.0 min.

3c: In analogy to the preparation of **3a**, carbonate **2c** (536 mg, 2.0 mmol) was treated with $Pd_2dba_3 \cdot CHCl_3$ (15.0 mg, 30 μmol with respect to Pd), **1a** (22.5 mg, 60 μmol), and nitromethane (12.2 g, 0.2 mol) in 10 mL of dry THF. After 16 h, 449 mg of **3c** (89%) was obtained with enantiomeric purity of 96.7% *ee* (HPLC, Daicel Chiralcel OD H, *n*-hexane/*i*PrOH (4/1)).

4c: In analogy to the preparation of **3a**, carbonate **2c** (2.0 mmol) was treated with $Pd_2dba_3 \cdot CHCl_3$ (15.0 mg, 30 μmol with respect to Pd), **1a** (22.5 mg, 60 μmol), and nitromethane (61.0 mg, 1.0 mmol) in 10 mL of dry THF (reaction time: 1 d). Yield of **4c**: 94%; enantiomeric purity of **4c**: >99.9% *ee* (HPLC, Daicel Chiralcel OD H, *n*-hexane/EtOH (250/1)). The minor enantiomer was determined precisely with the help of standard solutions.

Transition Metal Complexes as Both Host and Guest: Second-Sphere Coordination between a Pt-Azacrown Ether Host and a Pt-NH_3 Guest**

Beth R. Cameron, Sonia S. Corrent, and Stephen J. Loeb*

A transition metal complex containing hydrogen-bond donor groups on its periphery (for example M-NH_3) can act as a guest, binding to a hydrogen-bond receptor through second-sphere coordination. This phenomenon has been discussed in a review by Stoddart et al.;[1] the majority of the adducts of this type are those between crown ethers or benzocrown ethers and transition metal complexes containing aqua or ammine ligands. Alternatively, transition metal complexes with peripheral hydrogen-bond acceptor groups have recently been used as hosts to bind neutral, cationic, and anionic guests. This form of host is often referred to as a *metalloreceptor*.[2–5]

We describe herein the preparation of a new class of metalloreceptor based on covalently linking azacrown ethers to a phosphaneplatinum(II) unit, the use of ^{31}P NMR spectroscopy as a probe for measuring host–guest association constants, and the structure elucidation of the first host–guest complex in which *both* the host and guest are transition metal compounds.

The reaction of equimolar amounts of *trans*-[$PtCl_2(PEt_3)(NH_3)$] and azacrown ethers such as [12]NO_3, [15]NO_4, and [18]NO_5[6] in chloroform, results in substitution of the ammine ligand at Pt^{II} by the secondary nitrogen atom of the azacrown ether and formation of complexes of the type [$PtCl_2(PEt_3)$(azacrown)] (Scheme 1). Also, if two equivalents of *trans*-[$PtCl_2(PEt_3)(NH_3)$] are treated with one equivalent of [18]N_2O_4, a dinuclear complex [$\{PtCl_2(PEt_3)\}_2$([18]N_2O_4)], similar to the known complex[7] [$\{Rh(nbd)(NH_3)\}_2$([18]N_2O_4)], is formed with the loss of two equivalents of ammonia.

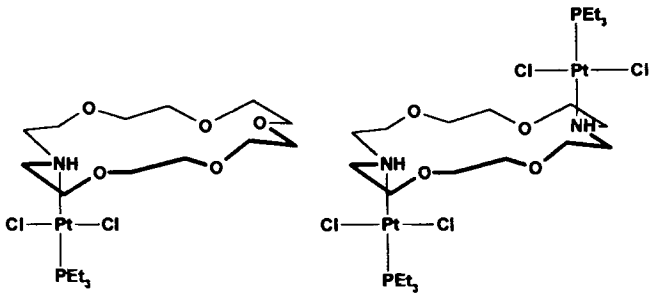

Scheme 1.

The X-ray structure analysis[8] of $[PtCl_2(PEt_3)([18]NO_5)]$ (Fig. 1) demonstrates that these complexes are square-planar species in which the P-Pt-N vector is perpendicular to the crown

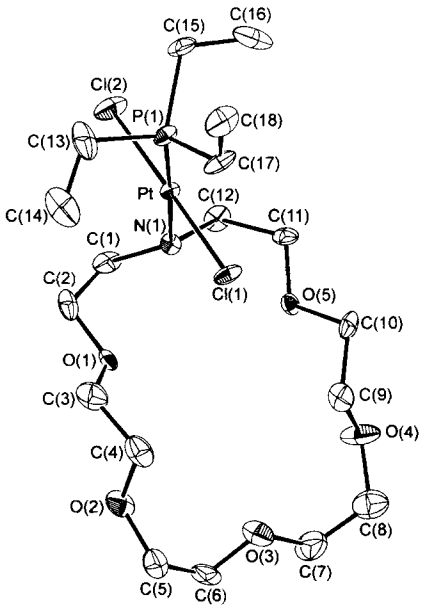

Fig. 1. Crystal structure of the host $[PtCl_2(PEt_3)([18]NO_5)]$ (ORTEP drawing). Selected distances [Å] and angles [°]: Pt–P(1) 2.231(6), Pt–Cl(1) 2.282(5), Pt–Cl(2) 2.316(6), Pt–N(1) 2.10(2); P(1)-Pt-Cl(1) 92.9(2), P(1)-Pt-Cl(2) 89.7(2), P(1)-Pt-N(1) 177.9(5), Cl(1)-Pt-Cl(2) 177.4(2), Cl(1)-Pt-N(1) 87.7(4), Cl(2)-Pt-N(1) 89.7(4).

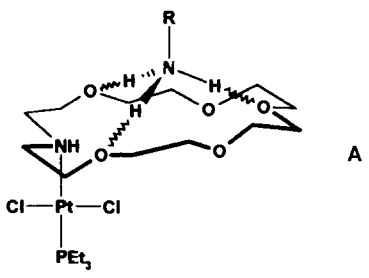
ether ring. The azacrown ether complex has alternating oxygen atoms O(1), O(3), and O(5) available for hydrogen bonding to an appropriate guest molecule such as an ammonium ion which contains a complementary, triangular array of hydrogen atoms and leads to adducts of type **A**.



A

In derivatizing these azacrown ethers with a $Pt-PEt_3$ unit, it was reasoned that the host properties of the parent azacrown ether would largely be retained, while the ability to measure binding by ^{31}P NMR spectroscopy would be introduced. Initial host–guest experiments employing $[PtCl_2(PEt_3)([18]NO_5)]$ involved binding to the cations NH_4^+, $tBuNH_3^+$ (as BPh_4^- salts) and the neutral species *trans*-$[PtCl_2(PEt_3)(NH_3)]$.[9] In the $^{31}P\{^1H\}$ NMR spectra of the host–guest complexes, only a singlet with ^{195}Pt-satellites is observed for the single ^{31}P nucleus of the host; an exception is *trans*-$[PtCl_2(PEt_3)(NH_3)]$ as a guest for which a further set of ^{31}P resonances were observed. The downfield shift of this easily detectable resonance with increasing guest concentration was used to determine association constants in $[D_6]$acetone for the supramolecular species $\{(NH_4)\cdot[PtCl_2(PEt_3)([18]NO_5)]\}^+$ ($170 \pm 28\ M^{-1}$) and $\{(tBuNH_3)\cdot[PtCl_2(PEt_3)([18]NO_5)]\}^+$ ($45 \pm 7\ M^{-1}$).[9] However, when *trans*-$[PtCl_2(PEt_3)(NH_3)]$ was employed as guest, accurate determination of a binding constant could not be made since saturation of host with guest, in $CDCl_3$, resulted in too small a change in chemical shift for a reliable analysis.

An X-ray structural analysis (Fig. 2) of the second-sphere adduct $\{[PtCl_2(PEt_3)(NH_3)]\cdot[PtCl_2(PEt_3)([18]NO_5)]\}$ verifies the nature of the hydrogen-bonding interaction inferred for the host–guest interactions described above. This adduct is the first

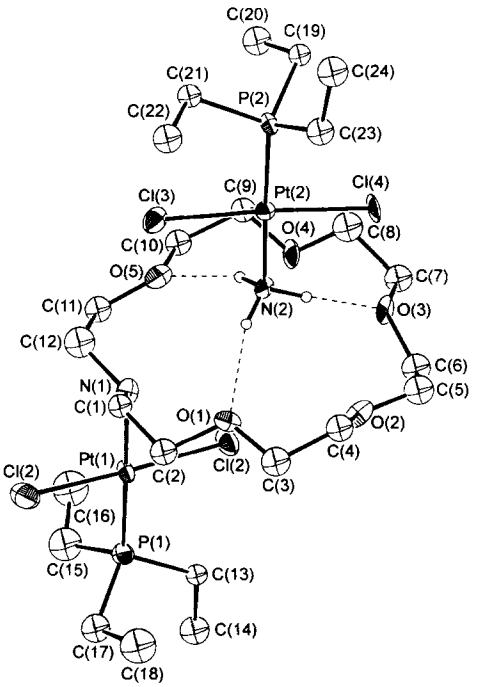


Fig. 2. Crystal structure of the supramolecular, host–guest complex $\{[PtCl_2(PEt_3)(NH_3)]\cdot[PtCl_2(PEt_3)([18]NO_5)]\}$ (ORTEP drawing). example of a host–guest complex in which *both* host and guest are transition metal compounds. The interaction of host and guest occurs through hydrogen bonding of the Pt-bound NH_3 group of the $[PtCl_2(PEt_3)(NH_3)]$ guest to alternating ether oxygen atoms on the $[PtCl_2(PEt_3)([18]NO_5)]$ host. The macrocycle adopts the familiar all-*gauche* conformation characteristic of RNH_3^+, BX_3NH_3, and $[PtCl_2(PMe_3)(NH_3)]$ binding to [18]crown-6 derivatives.[1] The guest perches over the crown ether ring on the side of the ring opposite the $Pt-PEt_3$ unit of the host. Each of the hydrogen atoms of the ammine ligand is involved in a linear hydrogen bond to alternating O atoms of the crown ether moiety: N···O distances [Å]: N(2)···O(1) 3.13(3), N(2)···O(3) 3.19(4), N(2)···O(5) 2.98(3); H···O distances [Å]:

H(N2A)···O(1) 2.21, H(N2C)·····O(3) 2.27, H(N2B)···O(5) 2.06; N-H···O angles [°]: N(2)-H(N2A)···O(1) 164, N(2)-H(N2C)···O(3) 160, N(2)-H(N2B)···O(5) 161.

Derivatization of an azacrown ether with a Pt–PEt_3 unit results in a simple crown ether type host containing a lariat ether type, peripheral appendage. The phoshorus atom of the Pt complex fragment serves as a NMR spectroscopic marker and allows a straightforward determination of host–guest association constants. The X-ray structure determination of the first host–guest complex in which *both* the host and guest are transition metal complexes provides detailed solid-state evidence for the hydrogen-bonding nature of the noncovalent interaction.

Experimental Procedure

$[PtCl_2(PEt_3)([18]NO_5)]$: *trans*-$[PtCl_2(PEt_3)(NH_3)]$ [10] (50.0 mg, 0.125 mmol) was added with stirring to a solution (1 mL) containing aza[18]crown-6 (33.0 mg, 0.125 mmol) in chloroform, and the mixture stirred for three hours. The solvent was removed to give a yellow solid which was recrystallized from chloroform and diethyl ether. Yield of yellow crystals: 73 mg (90%). ^1H NMR ([D$_6$]acetone): $\delta = 4.15$ (br. s, 2H, OCH_2), 3.74–3.52 (m, 18H, OCH_2), 3.29 (br. s, 2H, NCH_2), 2.90 (br. s, 2H, NCH_2), 1.86 (m, 6H, PCH_2), 1.17 (m, 9H CH_3). $^{31}P\{^1H\}$ NMR 3.17 (^1J(P,Pt) = 3373 Hz).

$\{[PtCl_2(PEt_3)(NH_3)]\cdot[PtCl_2(PEt_3)([18]NO_5)]\}$: A solution containing equimolar amounts of *trans*-$[PtCl_2(PEt_3)(NH_3)]$ and $[PtCl_2(PEt_3)([18]NO_5)]$ in chloroform was allowed to slowly evaporate in a fumehood. After four days, yellow crystals suitable for X-ray crystallography were isolated by filtration; yield 42%. ^1H NMR ($CDCl_3$): $\delta = 4.24$ (t, 4H, OCH_2), 3.84 (m, 4H, OCH_2), 3.73 (m, 4H, OCH_2), 3.62 (m, 4H, OCH_2), 3.34 (t, 4H, OCH_2), 2.93 (m, 4H, NCH_2), 2.73 (s, br, 1H, N H), 2.02 (s, br, 3H, NH_3), 1.83 (m, 12H, PCH_2), 1.16 (m, 18H CH_3); $^{31}P\{^1H\}$ NMR ([D$_6$]acetone) 3.36, (^1J(P,Pt) = 3376 Hz), 1.41, (^1J(P,Pt) = 3461 Hz).

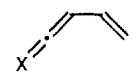
A Study on Rhodium–Vinylallene Complexes Leading to a New Reaction, Rhodium-Catalyzed Carbonylative [4 + 1]Cycloaddition

Masahiro Murakami,* Kenichiro Itami, and Yoshihiko Ito*

The coordination of unsaturated organic molecules to transition metals has been studied intensively both experimentally and theoretically; η^4 complexes of 1,3-dienes constitute an important class.[1] Conjugated dienes that are extended with a cumulated double bond, like vinylketenes (**1**, X = O), also form η^4 complexes having interesting structures and reactivities.[2] Although vinylallenes (**2**, X = CR_2) also belong to this class of cumulated diene systems, their η^4 complexes have been rare; examples have been limited to iron carbonyl complexes prepared directly from a vinylallene[3] and a phenylallene,[4] or indirectly via η^4-vinylketene complexes.[5] In the course of our studies,[6] we became interested in why η^4-vinylallene complexes are so uncommon. We report here on the synthesis of (vinylallene)rhodium(I) complexes with two different coordination modes, η^2 coordination and η^4 coordination, and a reaction proceeding via the latter type of complex, the rhodium(I)-catalyzed carbonylative [4 + 1]cycloaddition of vinylallenes. The insight into the fundamental properties of (vinylallene)rhodium(I) complexes has opened a pathway to a new catalytic carbonylation.



1 X = O
2 X = CR_2

In the first experiment vinylallene **2a**, which has no substituents at the terminal allenic carbon, was treated with $[RhCl(PPh_3)_3]$ in benzene at room temperature. In analogy to the related reaction of a simple allene,[7] **2a** displaced one PPh_3 ligand from the rhodium to afford **3** in 78% isolated yield (Scheme 1). The molecular structure, determined by an X-ray crystallographic analysis, indicates η^2 coordination at the terminal allenic π bond (Fig. 1).[8] The rhodium center has a square-planar coordination geometry, the less hindered side of the allenyl group is *trans* to the chlorine atom, and the axis of the

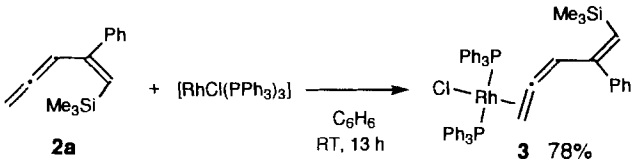

Scheme 1. Synthesis of the η^2-(vinylallene)rhodium complex **3**. RT = room temperature.

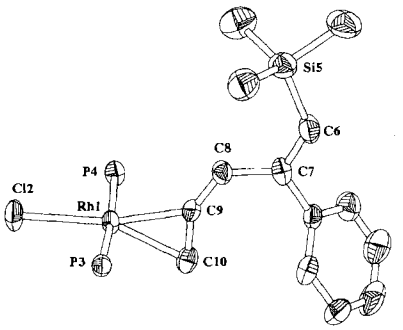

Fig. 1. Molecular structure of **3** in the crystal; the phenyl groups on the phosphorus atom and the hydrogen atoms are omitted for clarity (thermal ellipsoids at 40% probability) [8].

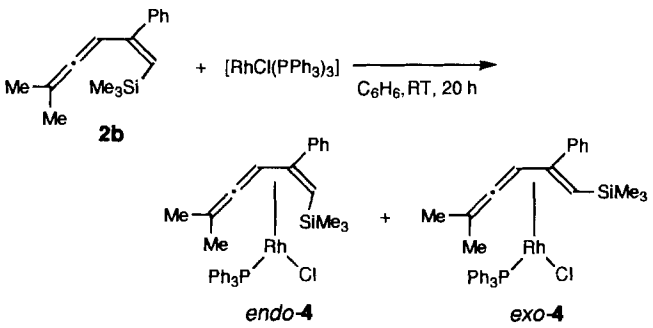
η^2-coordinated bond lies perpendicular to the RhP_2Cl plane. As a consequence of the η^2 coordination, the allenyl group is distorted from linearity (C8-C9-C10 149.6(9)°). As was observed previously,[7, 9] the distance from the rhodium atom to the central allenic carbon atom C9 (2.015(9) Å) is less than that to the terminal allenic carbon C10 (2.115(10) Å), probably reflecting the higher s character in the hybrid orbital on C9.

Next, vinylallene **2b**, which has two methyl groups at the allenic terminal, was treated with $[RhCl(PPh_3)_3]$. In marked contrast to the reaction of **2a**, two PPh_3 ligands were displaced to yield (η^4-vinylallene)rhodium(I) complex **4** as a mixture of *endo* and *exo* isomers isolated in 44 and 19% yield, respectively (Scheme 2). The structure of *endo*-**4** was determined by X-ray



Scheme 2. Synthesis of the η^4-(vinylallene)rhodium complexes *endo*-**4** and *exo*-**4**.

crystallography (Fig. 2 left).[8] The rhodium(I) atom has a distorted square-planar coordination environment. The two *cis* sites are occupied by the internal allenic π bond and the vinylic π bond; the chlorine atom is *trans* to the former π bond. The η^4-coordinated skeleton is in a cisoid, planar form. The silicon atom in *endo* position deviates from this plane, away from the metal, with a torsion angle Si4-C5-C6-C7 of 52.7°. The Rh1–C8 bond is shorter than those to the other coordinated carbon atoms, presumably due to the difference in hybridization.

The X-ray structure analysis of *exo*-**4** confirms an *exo* orientation of the trimethylsilyl group (Fig. 2 right).[8] Interestingly,

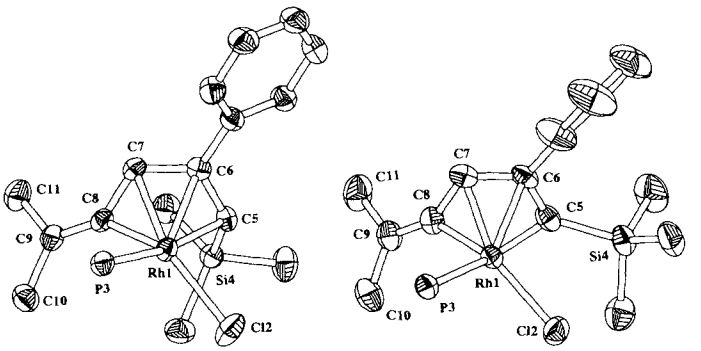


Fig. 2. Molecular structures of *endo*-**4** (left) and *exo*-**4** (right); the phenyl groups on the phosphorus atoms and the hydrogen atoms are omitted for clarity (thermal ellipsoids at 40% probability) [8].

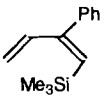
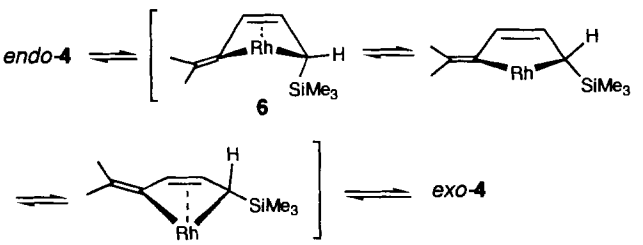
the C5–Si4 bond is approximately coplanar with the η^4-coordinated skeleton, or rather, slightly bent toward the metal center (torsion angle Si4-C5-C6-C7 170.3°).

It is instructive to compare the reactivity of butadiene **5**, which has the same substitution pattern as **2** but lacks the cumulated double bond. When **5** was treated with a stoichiometric amount of $[RhCl(PPh_3)_3]$ under conditions similar to those used for the synthesis of **4**, no ligand exchange was evident in the ^1H NMR spectrum. This result underlines the facility of vinylallenes for ligand exchange. The preferred η^4 coordination of ligand **2b** can be ascribed to spatial interactions between the allenic substituents and phosphane ligands, which would disfavor the sterically more demanding η^2 coordination of the terminal allenic π bond. Although this steric effect controlling the coordination mode of vinylallenes may be amplified in the present case with $[RhCl(PPh_3)_3]$, which has bulky phosphane ligands, it is reasonable to assume that a similar determinant operates generally in ligand substitution reactions with vinylallenes.



5

Notably, isolated *endo*-**4** in C_6D_6 underwent gradual isomerization to *exo*-**4** on standing at 70 °C ($t_{1/2}$ = 22.5 h). In contrast, *exo*-**4** did not isomerize. A plausible mechanism for this thermal *endo*–*exo* isomerization is based on the rhodacyclo-3-pentene intermediate **6** (Scheme 3).[10] Decomplexation of the double

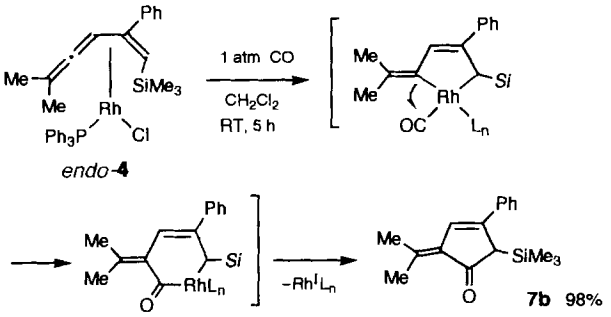


Scheme 3. The thermal flip-envelope isomerization of *endo*-**4** to give *exo*-**4**.

bond of **6** and a subsequent flip of the rhodacycle envelope lead back to the η^4 complex with *exo* orientation. It is likely that in the reaction of **2b** with $[RhCl(PPh_3)_3]$, simple ligand substitution results in the initial formation of *endo*-**4** with retention of the original orientation of the silyl group. A "flip-envelope" isomerization subsequently occurs to furnish a mixture of the two forms.

The observed isomerization of *endo*-**4** suggests considerable contribution from the rhodacyclo-3-pentene form. One impor-

tant ramification is that incorporation of carbon monoxide into the conjugated diene skeleton may be possible by coordination and insertion of carbon monoxide into the C–Rh σ bond of the rhodacyclo-3-pentene. This would result in a [4 + 1] assembly. Moreover, η^4 coordination of a vinylallene to rhodium through straightforward ligand exchange is particularly attractive because it would offer access to a catalytic cycle. Thus, we next examined the reaction of the rhodium(I) complex *endo*-**4** with carbon monoxide (Scheme 4). A solution of *endo*-**4** in



Scheme 4. [4 + 1]Cycloaddition of the η^4-(vinylallene)rhodium complex *endo*-**4** with CO.

CH_2Cl_2 was stirred at room temperature under CO at atmospheric pressure. A [4 + 1]cycloaddition reaction proceeded cleanly to furnish 2-(alkylidene)cyclopentenone **7b** in 98% yield. A plausible mechanism is shown in Scheme 4. Carbon monoxide is introduced into the coordination sphere of the metal to give a (vinylallene)(carbonyl)rhodium, which also acquires the contribution of a rhodacyclo-3-pentene resonance form in solution. Migratory insertion of the carbonyl group into the Rh–C_{sp^2} (or Rh–C_{sp^3}) σ bond of the rhodacyclo-3-pentene and the subsequent reductive elimination of Rh^I produce **7b**. In contrast, the η^2 complex **3** afforded no cycloaddition product under analogous conditions, indicating that η^4 coordination is requisite for the carbonylative [4 + 1]cycloaddition.

Our efforts were then directed at establishing a catalytic system. A free vinylallene was treated with a catalytic quantity of a variety of rhodium(I) complexes under carbon monoxide (1 atm). Whereas little activity was observed with [RhCl(PPh$_3$)$_3$], cationic rhodium complexes like [Rh(cod)(MeCN)$_2$]PF$_6$ and [Rh(cod)(dppb)]BF$_4$ (cod = cyclooctadiene, dppb = bis(diphenylphosphino)butane) were found to efficiently catalyze the carbonylative [4 + 1]cycloaddition of vinylallenes (Table 1). The corresponding 2-alkylidene-3-cyclopentenone **7** was obtained together with 2-alkylidene-4-cyclopentenone **7′** in good yield. The ratio **7′**:**7** increased as the reaction proceeded, suggesting that **7′** forms by transposition of the C^3–C^4 double bond of the primary product **7** through double-bond isomerization and/or protodesilylation. The trimethylsilyl groups of the primary products from **2b** and **2d** are located α to both the carbonyl group and the C–C double bond, and hence, these trimethylsilyl groups are extremely labile toward hydrolysis. It is likely that the trimethylsilyl group reacts with water in the reaction mixture and is cleaved as trimethylsilanol.

It is reasonable to assume that the catalytic cycle is analogous to the reaction shown in Scheme 4 followed by coordination of a new vinylallene molecule to the rhodium(I) center. Vinylallenes **2d** and **2e**, in which the allenyl group is not symmetrically substituted, gave only one stereoisomer with regards to the exocyclic C=C bond. This stereoselectivity can be accounted for by assuming face-selective η^4 coordination from the less-hindered

Table 1. Rh^I-catalyzed [4 + 1]cycloaddition of vinylallenes with CO [a]. dppe = Bis(diphenylphosphino)ethane, dppb = bis(diphenylphosphino)butane, dppp = bis(diphenylphosphino)pentane, cod = cyclooctadiene.

[a] The reaction was carried out with 2–10 mol% of the Rh^I complex under CO (1 atm) unless otherwise noted. [b] Compound numbers with a prime designate 2-(alkylidene)-4-cyclopentenone forms. [c] Yield of isolated product. [d] The reaction was carried out in an autoclave under 15 atm CO.

side of the vinylallene and subsequent specific disrotatory ring closure to give a rhodacyclo-3-pentene intermediate. In contrast to the vinylallenes listed in Table 1, which have substituents at the allenyl terminal, the vinylallene **2a** failed to undergo catalytic cycloaddition. This result can be explained in terms of the steric preference of η^4 over η^2 coordination.

Although the [4 + 1]cycloaddition is a potential method for the construction of five-membered carbocycles,[11] there have been no reports on the transition metal catalyzed carbonylation of 1,3-dienes without cumulated double bonds.[12] Two examples reported make use of bisallene[13] and 4-en-2-ynyl carbonate.[14] Indeed, similar Rh^I-catalyzed carbonylation reactions failed to proceed with 1,3-dienes like 2,3-dimethyl-1,3-butadiene, 2,3-diphenyl-1,3-butadiene, and 1,4-diphenyl-1,3-butadiene. The pronounced reactivity of vinylallenes can be ascribed to both the substantial facility for ligand exchange and

the significant contribution from a metallacyclo-3-pentene resonance form in the resultant η^4 complex. We are currently examining further utilization of the potential of vinylallenes in reactions with transition metal catalysts proceeding through η^4 complexes.

Experimental Procedure

3: To a solution of (*E*)-4-phenyl-5-(trimethylsilyl)-1,2,4-pentatriene (**2a**, 25 mg, 0.12 mmol) in benzene (3 mL) at room temperature was added $[RhCl(PPh_3)_3]$ (129 mg, 0.139 mmol). After the mixture was stirred for 13 h, the solvent was removed under vacuum. The residue was subjected to column chromatography (silica gel, CH_2Cl_2:hexane = 3:1) to afford **3** (80 mg, 78%) as a yellow powder.

4: To a solution of (*E*)-5-methyl-2-phenyl-1-(trimethylsilyl)-1,3,4-hexatriene (**2b**, 40 mg, 0.165 mmol) in benzene (4 mL) at room temperature was added $[RhCl(PPh_3)_3]$ (153 mg, 0.165 mmol). After the mixture was stirred for 20 h, the solvent was removed under vacuum. The residue was subjected to preparative thin-layer chromatography (silica gel, CH_2Cl_2:hexane = 3:1) to afford *endo*-**4** (47 mg, 44%, orange powder) and *exo*-**4** (20 mg, 19%, yellow powder).

7c, **7c'**: A mixture of $[Rh(cod)_2]PF_6$ (10.9 mg, 23.5 μmol), dppe (11.2 mg, 28.1 μmol), and **2c** (200 mg, 1.17 mmol) in toluene (2 mL) was stirred at 80 °C for 20 h under 15 atm of CO in an autoclave. After the mixture was cooled, the solvent was removed under vacuum. The residue was subjected to column chromatography (silica gel, ether:hexane = 1:10) to afford **7c** (130 mg, 56%) and **7c'** (60.0 mg, 26%) as colorless solids.

Distinguishing the Silanol Groups in the Mesoporous Molecular Sieve MCM-41**

Jiesheng Chen,* Qinghua Li, Ruren Xu, and Fengshou Xiao

The successful synthesis of M41S materials,[1,2] a new family of novel silicates with uniform mesopores, opened a vast range of applications[3–7] in catalysis, sorption, molecular recognition, electronics, and photochemistry. One of the members of this family of materials is MCM-41, which contains a hexagonal array of mesopores with a pore diameter of 20–100 Å depending on the conditions of its synthesis. It is postulated[2] that the inorganic walls around the mesopores of MCM-41 are constructed of disordered SiO_4 tetrahedral units, as is also the case for amorphous silicates. NMR studies[2,8] reveal that MCM-41 contains many silanol groups both before and after the template molecules have been removed. These silanols may act as functional groups in chemical reactions or can be utilized to attach molecules having other functional groups. Although the structure and stability of the pores are well understood, little is known about the nature of the silanol groups in MCM-41. To shed some light on this, we monitored the IR absorptions of the silanol groups in template-free MCM-41 as a function of evacuation temperature before and after silylation by chlorotrimethylsilane (CTMS) and chlorotriphenylsilane (CTPS).

Figure 1 shows the IR spectra between 4000 and 2400 cm^{-1} of template-free MCM-41 evacuated (1×10^{-3} mbar) at various temperatures. At room temperature the spectrum exhibits a broad featureless band between 3700 and 3200 cm^{-1} with the maximum at around 3525 cm^{-1}, and a less distinct shoulder absorption at about 3740 cm^{-1}. A small band (not shown in Fig. 1) is also observed at about 1685 cm^{-1}, which is due to

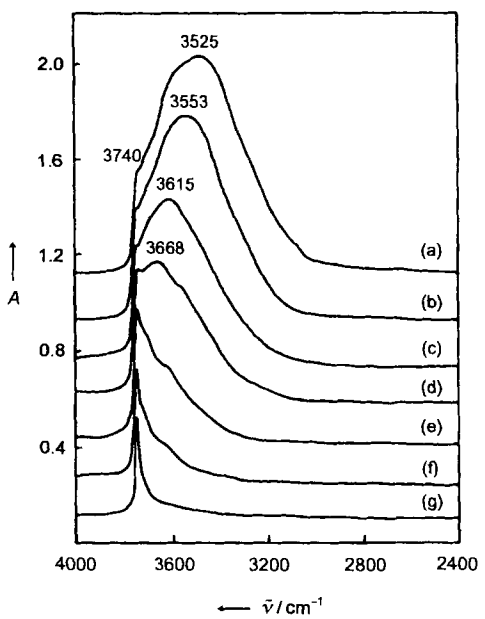

Fig. 1. IR spectra of template-free MCM-41 evacuated at a) ca. 25 °C, b) 100 °C, c) 150 °C, d) 200 °C, e) 250 °C, f) 300 °C, g) 350 °C, and h) 450 °C.

adsorbed water. Upon evacuation at 100 °C, this absorption disappears, indicating removal of the adsorbed water. At the same time the band between 3700 and 3200 cm^{-1} becomes narrower and its maximum shifts towards higher frequency to about 3553 cm^{-1}. The absorption at 3740 cm^{-1}, which was also observed[9] previously for a MCM-41 sample calcined in vacuum, is attributed to isolated silanol groups, whereas that at 3553 cm^{-1} is associated with hydrogen-bonded silanols.[10, 11] Since the internal surface area of MCM-41 is much greater than the external, it is assumed that the majority of the silanol groups are located on the internal surface. At higher temperatures the low-frequency side of the broad band disappears, indicating condensation of the H-bonded silanol groups. At 450 °C only the absorption at 3740 cm^{-1} remains and its intensity is more or less the same as that at room temperature. Apparently the isolated silanol groups in MCM-41 are much more resistant to high-temperature evacuation than the hydrogen-bonded species. It is almost impossible to distinguish between these H-bonded silanols in MCM-41 since they interact with one another to give a broad IR band.

When MCM-41 is silylated with chlorotrimethylsilane (CTMS), the IR spectra change (Fig. 2). All the spectra show a

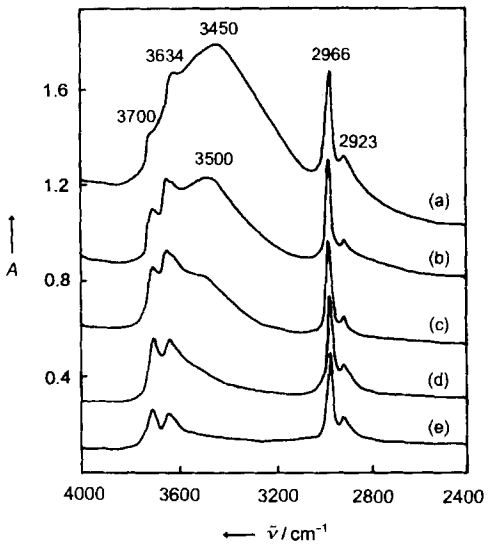

Fig. 2. IR spectra of CTMS-silylated MCM-41 evacuated at a) ca. 25 °C, b) 100 °C, c) 200 °C, d) 300 °C, and e) 450 °C.

sharp peak at 2966 cm^{-1} and a weak absorption at 2923 cm^{-1} characteristic of the trimethylsilyl groups. The absence of the band at 3740 cm^{-1} suggests that all the isolated silanol groups are highly accessible and have reacted with CTMS to form Si-O-$Si(CH_3)_3$ bonds. It has been shown[2] that silylation with CTMS results in a distinct decrease in the pore size of MCM-41, indicating that the silylation occurs inside the mesoporous channels. At room temperature a broad band with shoulders at 3700 and 3634 cm^{-1}, which are not observed for the nonsilylated sample, appears between 3600 and 3200 cm^{-1}. The absorption at 1685 cm^{-1} confirms that the sample contains adsorbed water molecules. As is the case for the nonsilylated material, when the evacuation temperature is increased, the adsorbed water molecules are removed and the broad band becomes narrower. In contrast, the two absorptions at 3700 and 3634 cm^{-1} remain even at 450 °C, although their intensities are greatly reduced.

A similar change occurs in the spectrum of the CTPS-silylated MCM-41 when the temperature is increased (Fig. 3). The small

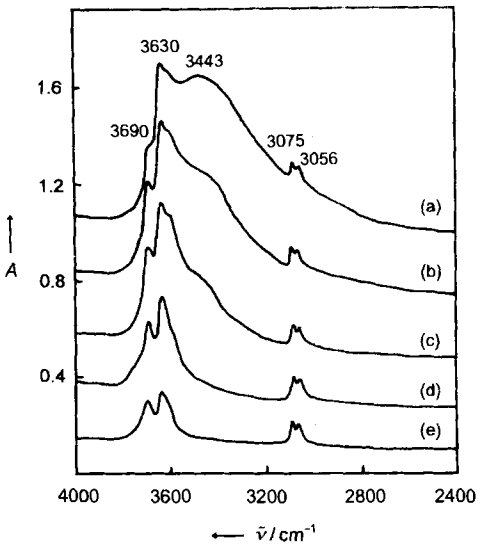

Fig. 3. IR spectra of CTPS-silylated MCM-41 evacuated at a) ca. 25 °C, b) 100 °C, c) 200 °C, d) 300 °C, and e) 450 °C.

absorption peaks at 3075 and 3056 cm^{-1} are assigned to the triphenylsilyl moieties. A peak at 3740 cm^{-1} is not evident, but when the sample is evacuated at elevated temperatures two bands at 3690 and 3630 cm^{-1} appear. The presence of triphenylsilyl moieties and the absence of isolated silanol groups strongly suggest that in spite of their bulk CTPS molecules react with the isolated hydroxyl groups present in the nonsilylated MCM-41 to form Si-O-$SiPh_3$ bonds.

By comparing the spectra for the nonsilylated and silylated MCM-41 materials, it can be concluded that there are at least four types of silanol groups in template-free MCM-41: 1) isolated silanol groups corresponding to the 3740 cm^{-1} absorption, 2) silanol groups associated with the band at 3690–3700 cm^{-1}, 3) silanol groups responsible for the 3620–3640 cm^{-1} band, and 4) silanol groups with IR absorptions at lower frequencies (3600–3450 cm^{-1}). The latter three types of silanol groups are believed to be involved in hydrogen bonding, but the strength of the hydrogen bonds differ from type to type. On the basis of the literature,[10–12] we assign the silanol groups of types 2–4 as follows (Fig. 4): Type 2 silanols are those in which the O atom forms a hydrogen bond with a H atom of an adjacent silanol. Type 3 silanols correspond to hydroxyl groups in which a H atom forms a hydrogen bond with the O atom of an adjacent silanol. Type 4 species are probably chains of hydroxyl groups[12] that contain more than one pair of mutually hydrogen-bonded OH groups.

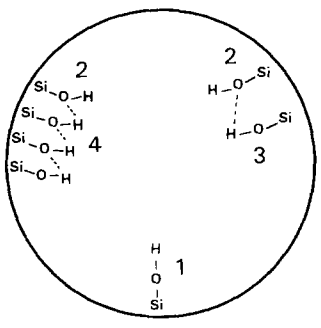

Fig. 4. Representation of the four types of silanol groups in a channel of MCM-41; for an explanation see discussion in text.

In the original nonsilylated MCM-41, interactions not only within each type of silanol group but also among all four types are evident. As a result, silanol groups of types 2–4 are not distinguishable even when a considerable amount of the OH groups have been removed by evacuation at elevated temperatures. However, when the sample is silylated, some of the hydrogen-bonded species are converted to siloxanes, which prevent

interactions. As some of the OH groups condense at elevated temperatures, the remaining species give more distinct IR signals. Moreover, these siloxane barriers impede the movement of protons on the surface of MCM-41, rendering the hydrogen-bonded silanols much more difficult to remove by evacuation than those in the nonsilylated material. This is reflected by the fact that the signals of all the H-bonded silanol groups for the nonsilylated MCM-41 disappear at 450 °C, whereas silanol groups of type 2 and 3 are still evident in the two silylated MCM-41 samples at this temperature. It seems that silylation with CTPS yields a more effective barrier than that with CTMS, probably due to the bulk of the triphenylsilyl group; the IR intensities of type 2 and type 3 OH groups in CTPS-silylated MCM-41 are distinctly stronger than those in the CTMS-silylated MCM-41 at a given temperature (cf. Figs. 2 and 3).

Experimental Procedure

The MCM-41 sample was prepared hydrothermally by following the procedure described elsewhere [2]. The silicate gel used had a molar composition of $0.35\,TMAOH:SiO_2:0.7\,CTABr:25.0\,H_2O$ (TMAOH = tetramethylammonium hydroxide, CTABr = cetyltrimethylammonium bromide as template). X-ray powder diffraction (XRD) indicated that the sample corresponded to MCM-41 with high crystallinity. The template molecules were removed by calcination at 550 °C in air for 10 h. Silylation was conducted by stirring the template-free sample, which was preheated at 100 °C to remove most of the adsorbed water, with a solution of chlorotrimethylsilane or chlorotriphenylsilane in toluene at 80 °C for 48 h. The solid was recovered by centrifuging, then washed with refluxing toluene and acetone, and dried at ambient temperature. The IR spectra were recorded on a Nicolet 5DX FTIR spectrometer. Samples were pressed into pellets (each wafer was 10 mg in weight and 12 mm in diameter) and mounted in a quartz cell with CaF_2 windows. XRD proved the wafers to be as crystalline as the unpressed powder samples. Prior to measurement, each sample was evacuated at a particular temperature for about 1 h then allowed to cool to room temperature. The resolution for the spectra was 4 cm^{-1}.

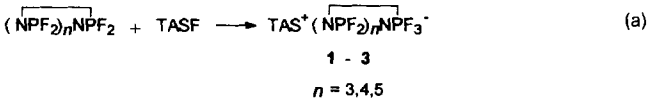
Fluorophosphazenate Ions: A Route to Complexation of Fluoride Ions**

Enno Lork, Dieter Böhler, and Rüdiger Mews*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

The incorporation of anions into molecular hosts is a very topical area of research in inorganic as well as organic chemistry.[1–3] Attempts at the complexation of fluoride ions, however, have been relatively unsuccessful so far.[4] We are endeavoring to achieve this goal by using multifunctional sulfur and phosphorus compounds. Sulfanuric fluoride (1,3,5-trifluoro-1,3,5-trioxo-1λ^6,3λ^6,5λ^6,2,4,6-trithiatriazine), $(NS(O)F)_3$[5] and the isoelectronic cyclofluorophosphazenes $(NPF_2)_n$ (n = 3–17[6]) appear to us to be ideal host molecules, and we have chosen $(Me_2N)_3S^+Me_3SiF_2^-$ (TAS-fluoride)[7] as the fluoride ion donor because of its high solubility in organic solvents. Structural investigations on $TAS^+S_3N_3O_3F_4^-$[8] show that in the anion, one of the axial fluoro substituents of the pentacoordinate sulfur center is three-coordinate[8] (1 + 2), as a result of strong, nonbonding interactions with both of the remaining two sulfur atoms. $P_3N_3F_7^-$, the phosphazenate analogue of $S_3N_3O_3F_4^-$, undergoes further reaction, even at −40 °C (with formation of $P_3N_3F_5NPF_2NPF_2NPF_5^{2-}$[9]). Nevertheless, the fluoride ion addition products of the larger rings, $(NPF_2)_n$ (n = 4–6), have proved to be isolable, as reported herein.

Salt **1** was isolated in quantitative yield as a colorless solid (m.p. 79 °C) from the reaction of TASF with $P_4N_4F_8$ in CH_3CN at −30 °C [Eq. (a)]. After removal of the volatile products and



(a)

solvent, **2** and **3** remained behind in almost analytically pure form as viscous, pale yellow residues; the melting points of both compounds lie below 0 °C.

The products were unambiguously characterized by NMR spectroscopy and X-ray crystal structure analysis (for **1** and **3**). Only one resonance was observed in both the ^{19}F and ^{31}P NMR spectra of the cyclic anions at all temperatures down to the freezing point of the solvent used (CD_3CN), indicating that all fluorine and phosphorus nuclei are magnetically equivalent due to a rapid exchange process. The observed splitting of the signals (Table 1) suggests an intramolecular exchange of fluoro substituents between each of the phosphorus centers.

The structure of the $P_4N_4F_9^-$ ion in **1** is shown in Figure 1.[10] Addition of a fluoride ion to one of the tetracoordinate phosphorus centers of $P_4N_4F_8$ leads to the transformation of the saddle conformation[11] into a boat conformation. F(1) draws closer to the other three ring-phosphorus atoms (F(1)–P(2) 275.3, F(1)–P(4) 276.5, and F(1)–P(3) 305.9 pm) as a result of

Table 1. ^{19}F and ^{31}P NMR data for the cyclophosphazenate ions (CD_3CN solution, -40 °C) [a].

Anion	$\delta^{31}P$	$\delta^{19}F$	J(P,F)
$P_3N_3F_7^-$	-5 (oct)	-46 (quar)	258
$P_4N_4F_9^-$	-17.8 (dec)	-53.43 (quin)	185.3
$P_5N_5F_{11}^-$	-23.77 (dod)	-54.7 (sex)	157.2
$P_6N_6F_{13}^-$	-21.4 (tede)	-52.9 (sep)	136

[a] quar = quartet, quin = quintet, sex = sextet, sep = septet, dec = decet, dod = dodecaplet, tede = tetradecaplet.

the large *syn*-leaning of the F(1)-P(1)-F(2) axis. These distances are considerably shorter than the sum of the van der Waals radii of P and F (325 pm); F(1) forms the apex of a heavily distorted square pyramid and may be described as tetracoordinate (1 + 3). These strong interactions explain the rapid, intramolecular fluoride exchange in solution.

$P_5N_5F_{11}^-$ could only be detected by NMR spectroscopy (Table 1). The rapid fluorine exchange in solution and the flexibility of the PN backbone[12] suggest that in the solid state one of the fluorine centers probably interacts with all five phosphorus atoms.

A side-on view of the structure of the s-shaped $P_6N_6F_{13}^-$ ion in **3** is presented in Figure 2.[13,14] All P-N (152.6(4) pm) and P-F (152.1(3) pm) bond lengths to the tetracoordinate phosphorus centers are identical within the limits of error. The bonding situation at the pentacoordinate phosphorus center is comparable to that of P(1) in $P_4N_4F_9^-$. In the $P_6N_6F_{13}^-$ ion, the atoms P(2), N(2), P(3), P(5), N(5), and P(6) form a central plane from which the atoms deviate very little (max. 7.4 pm). P(1) sits 163 pm above and P(4) 167 pm below this plane. The position of F(1) is remarkable, as it can be considered as the center of this anion. F(1) sits only 54 pm above the central plane; it is unable to come any closer due to repellent interactions to N(5) and N(2) (nonbonding distances 288.9 and 290.4 pm, respectively, sum of the van der Waals radii of N and F is 290 pm). The distances from F(1) to the phosphorus atoms P(2) (272.0 pm), P(3) (288.3 pm), P(5) (291.9 pm), and P(6) (270.4 pm) in the plane are all significantly shorter than the sum of the van der Waals

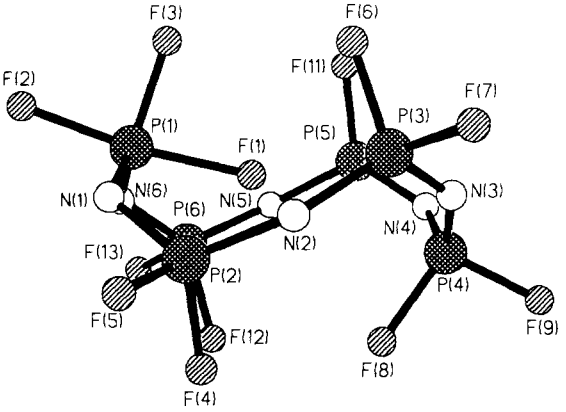

Fig. 2. Structure of the $P_6N_6F_{13}^-$ ion in the crystal. Selected bond lengths [pm] and angles [°]: P(1)-F(1) 172.1(7), P(1)-F(2) 161.9(7), P(1)-F(3) 155.6(7), P(1)-N(1) 159.5(10), P(1)-N(6) 160.8(10), N(1)-P(2) 156.3(9), N(6)-P(6) 149.3(10), P-N 152.0(11)-153.9(10), P-F 149.9(7)-154.1(9); F(1)-P(1)-F(2) 172.2(4), F(1)-P(1)-F(3) 84.6(4), F(1)-P(1)-N(1) 92.9(4), F(1)-P(1)-N(6) 91.0(4), F(2)-P(1)-N(1) 90.4(4), F(2)-P(1)-N(6) 92.9(5), F(3)-P(1)-N(1) 117.3(5), F(3)-P(1)-N(6) 117.8(4), N(1)-P(1)-N(6) 124.9(5), F(2)-P(1)-F(3) 87.7(4), P(1)-N(1)-P(2) 129.2(6), P(1)-N(6)-P(6) 131.8(7), P-N-P 142.3(8)-144.6(7), N-P-N 122.2(6)-126.3(6)

radii of P and F, and the distance from F(1) to P(4) on the other side of the ring is 294.7 pm, only marginally longer than these. The interactions of the six phosphorus atoms of the ring system results in a distorted octahedral coordination for F(1), in which the "coronate" $P_6N_6F_{12}$ ligand wraps around the central fluoride ion in three dimensions. The coordination sphere of the central fluoride ion is illustrated in Figure 3. Remarkably, none of the

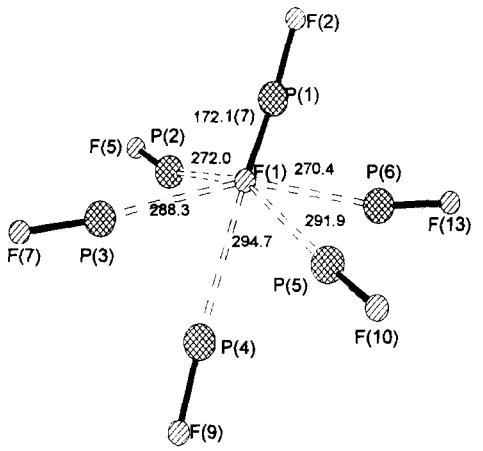

Fig. 3. Coordination of the central fluoride ion in the $P_6N_6F_{13}^-$ ion.

F···P-F angles deviate significantly from 180°. Theoretical studies should show whether this is due to purely electrostatic effects or if multicenter bonding is a more appropriate description. Besides the development of a bonding model for these intramolecular interactions, it is also of interest in the field of fluorophosphazenate ions whether higher coordination for the fluoride ion can be achieved by using larger ring systems, whether multiple fluoride ion addition is possible, and by which reaction pathways the intramolecular fluoride exchanges take place.

Experimental Procedure

1: $(NPF_2)_4$ (0.8 g, 2.66 mmol) was condensed into a λ-shaped Schlenk vessel with a Teflon valve, containing $(Me_2N)_3S^+Me_3SiF_2^-$ (0.6 g, 2.18 mmol) in CH_3CN (5 mL), at -196 °C. The vessel was placed in an ethanol bath (-35 °C) and the

reaction mixture allowed to stir at this temperature. After 15 minutes, diethyl ether (10 mL) was condensed onto the mixture, and **1** precipitated as a colorless solid. The liquid was decanted into the second arm of the Schlenk vessel, the volatiles were pumped off under dynamic vacuum at −30 °C, and the solid was then allowed to warm slowly to room temperature.

2, **3**: After addition of the ether at −35 °C a second phase was formed which was decanted into the second arm of the reaction vessel. The workup of the residue was carried out as described for **1**.

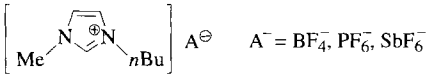
A Novel Class of Versatile Solvents for Two-Phase Catalysis: Hydrogenation, Isomerization, and Hydroformylation of Alkenes Catalyzed by Rhodium Complexes in Liquid 1,3-Dialkylimidazolium Salts**

Yves Chauvin,* Lothar Mussmann, and Hélène Olivier

The decisive advantages of homogeneous over heterogeneous catalysis with respect to activity and selectivity are well documented,[1] but the problems associated with the separation of products from the catalyst constitute major drawbacks for industrial applications. Possible solutions to this problem include "heterogenizing" a homogeneous catalyst, either by anchoring the catalyst on a support, or by using a liquid–liquid two-phase system. Aqueous/organic systems have been applied to the hydrogenation and hydroformylation of unsaturated substrates catalyzed by rhodium and ruthenium complexes.[2] Nevertheless, in spite of many advantages, the use of these systems suffers from low reaction rates, due to the poor ability of water to dissolve organic substrates. On the other hand, water is a strongly coordinating protic solvent that limits the application to ligands and catalysts that are stable in water. Nonpolar perfluorohydrocarbons have recently been proposed as a nonaqueous phase for the two-phase catalytic hydroformylation of olefins; however, to solubilize rhodium complexes in the "fluorous" phase, special fluorinated ligands have to be designed.[3]

Our new approach reported herein, involves the use of room temperature ionic liquids based on 1-*n*-butyl-3-methylimidazolium (BMI^+) salts[4] as nonaqueous solvents for Rh-catalyzed two-phase hydrogenation, isomerization, and hydroformylation of unsaturated substrates (Scheme 1). In these solvents, catalysts



Scheme 1. BMI^+ salts used.

can be "immobilized" either because of their ionic character or by using polar modified ligands. From the wide range of ionic liquids, we have selected those based on nonnucleophilic PF_6^-, SbF_6^-, BF_4^-, and $CuCl_2^-$ ions, since they are easy to prepare and handle, and are also stable in air and water.[5] As these media are known to dissolve charged species, we first applied them to the hydrogenation of pent-1-ene using the Osborn complex **1** as the cationic catalyst precursor.[6]

$[Rh(nbd)(PPh_3)_2]^+PF_6^-$ **1** (nbd = norbornadiene)

As illustrated in Table 1, remarkable solvent effects are observed. When the $BMI^+SbF_6^-$ salt was used, hydrogenation rates were nearly five times higher (Table 1, entry 2) than for the comparable homogeneous reaction in acetone (Table 1, entry 1), in spite of the expected limited solubilities of reactants in the polar phase. A plot of the product distribution as a function of time shows that there is a competitive fast isomerization of pent-1-ene. However, the formation of pent-2-ene did not significantly detract the hydrogenation rate (Fig. 1).

Table 1. Rh-catalyzed hydrogenation of pent-1-ene [a].

Entry	Solvent	Conversion [%] pent-1-ene	Yield [%] pentane	Yield [%] pent-2-ene	TOF [min^{-1}] [b]
1 [c]	acetone	99	38	61	0.55
2	$BMI^+SbF_6^-$	96	83	13	2.54
3	$BMI^+PF_6^-$	97	56	41	1.72
4	$BMI^+BF_4^-$	10	5	5	0.15
5 [d]	BMI^+Cl^-:CuCl	18	0	18 (98% *cis*)	0
6 [e]	$BMI^+PF_6^-$	99	25	74	0.73

[a] **1**: 0.05 mmol; pent-1-ene: 18.4 mmol; solvent: 4 mL; $T = 30\,^{\circ}C$; $p(H_2) = 0.1$ MPa; $t = 2$ h. [b] Turnover frequency (TOF) defined as mol(pentane) per mol(rhodium) per min. [c] Acetone: 10 mL; pent-1-ene: 9.2 mmol. [d] Molten salt prepared by reacting 1.5 equiv of CuCl with 1 equiv of BMI^+Cl^-. [e] Acetone (2 mL) added.

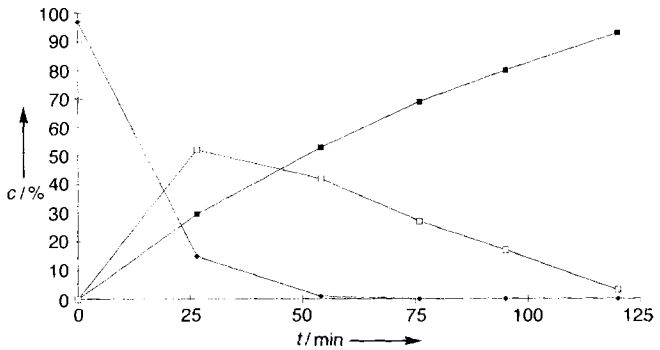

Fig. 1. A plot of the product distribution as a function of time for hydrogenation and isomerization of pent-1-ene catalyzed by **1** in the $BMI^+SbF_6^-$ salt; (•) pent-1-ene, (□) *cis*/*trans* pent-2-ene, (■) pentane.

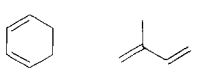
When the $BMI^+PF_6^-$ salt was used (Table 1, entry 3), lower turnover frequencies were observed. This effect is not easy to understand. On the one hand, it is well known that the nature of anion associated with cationic Rh catalysts does not affect the rate of hydrogenation.[6] On the other hand, preliminary experiments indicate that the solubility of pent-1-ene is two times higher in the SbF_6^- based salt than in the PF_6^- salt. In the case of the $BMI^+BF_4^-$ salt, which is water-miscible and which cannot be properly purified, the lower activity can be ascribed to the presence of trace amounts of the strongly coordinating chloride ion in the salt (Table 1, entry 4).

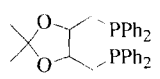
When ionic liquids prepared from BMI^+Cl^- and CuCl (1:1.5) were used only isomerization to *cis*-pent-2-ene was observed with a selectivity of 98% (Table 1, entry 5), in sharp contrast to the previous results. This demonstrates that selectivity can be strongly influenced by the nature of the anion. The addition of small amounts of a coordinating solvent (acetone, Table 1, entry 6) to the $BMI^+PF_6^-$ salt leads to a decrease of the reaction rate.



2 **3**

Conjugated diolefins such as cyclohexa-1,3-diene (**2**) and 2-methylbuta-1,3-diene (**3**) can also be hydrogenated. This is all the more interesting since diolefins are more soluble in ionic liquids than the corresponding monoalkenes (e.g. **2** is five times more soluble than cyclohexene in the $BMI^+SbF_6^-$ salt). This can improve potentially the selectivity of the hydrogenation. When complex **1** was used as the catalyst precursor in the $BMI^+SbF_6^-$ salt under the reaction conditions given in Table 1, **2** gave cyclohexene with 98% selectivity at 96% conversion. The reaction activity (TOF = 3.2 min^{-1}) was comparable to that observed in organic solvents. Substitution of the triphenylphosphane ligand in complex **1** by the chelating 1,2-bis(diphenylphosphino)ethane (dppe) ligand provides the $[Rh(nbd)dppe]PF_6$ catalyst precursor which catalyzes the hydrogenation of **3** (TOF = 3.1 min^{-1}). As in the homogeneous reaction, a mixture of 2-methylbut-1-ene (22%), 3-methylbut-1-ene (10%), and 2-methylbut-2-ene (23%) is obtained.[7]

In all these experiments, the ionic solutions containing the catalyst can be reused. Only a negligible loss of rhodium was observed (less than 0.02%; under the detection limit). In comparison to the recently described aqueous two-phase system, no formation of stable emulsions occurred.[2d]



= diop

As an extension, the chiral cationic $[Rh(cod)\{(-)\text{-diop}\}]PF_6$ (cod = cycloocta-1,3-diene) complex (0.03 mmol), dissolved in the $BMI^+SbF_6^-$ salt (4 mL), catalyzed the asymmetric hydrogenation of α-acetamidocinnamic acid (3 mmol in 8 mL of *i*PrOH) to (*S*)-phenylalanine in 64% *ee*. The product could be separated quantitatively and the recovered ionic liquid can be reused.

By analogy to homogeneous catalysis, we first supposed the existence of an equilibrium between a cationic Rh-dihydrido complex, which would be responsible for the hydrogenation, and a noncharged monohydrido complex, which would be responsible for both the hydrogenation and isomerization reactions [Eq. (a)]. Surprisingly, addition of two equivalents of the

$$[H_2Rh(PPh_3)_2(Solv.)_n]^+ \rightleftharpoons[-H^+] [HRh(PPh_3)_2(Solv.)_n] \qquad (a)$$

acid HPF_6 (60% in water) to the active Rh catalyst in the $BMI^+SbF_6^-$ salt, neither suppresses isomerization by shifting the equilibrium to the dihydrido cationic complex, nor decreases the hydrogenation activity. Direct characterization of the active species in these media is not easy. Upon activation by molecular hydrogen, the orange complex **1** gives a brown solution. Norbornane is detected in the organic phase by GC. The ^{31}P NMR spectrum of the $BMI^+SbF_6^-$ salt displays a doublet at $\delta = 40.6$ [$^1J_{Rh,P} = 103$ Hz] suggesting the formation of a symmetrical Rh-hydride.

Thus, as ionic liquids are known to stabilize preferably cationic species and do not solvate the Rh complex, we assume that the prevailing active catalyst is a cationic unsolvated Rh-dihydrido complex which has two free coordination sites (see the detrimental effect of acetone: Table 1, entry 6). To our knowledge, this is the first example of two-phase hydrogenation reactions in which an active rhodium catalyst is "immobilized" in a polar phase without special ligand design.

Two-phase pent-1-ene hydroformylation can also be achieved, as hexanals are poorly soluble in ionic liquids. Preliminary experiments using the $[Rh(CO)_2(acac)/PPh_3]$ uncharged molecular system as catalyst precursor, show high catalytic activity in the $BMI^+PF_6^-$ salt (TOF = 333 h^{-1}; Table 2, entry 2).

Table 2. Rh-catalyzed hydroformylation of pent-1-ene [a].

[c] Turnover frequency (TOF) defined as mol(converted pent-1-ene) per mol(rhodium) per hour. [d] THF (1 mL) added. [e] $p(H_2/CO\ 1/1) = 4$ MPa, 5 mL heptane, 0.2 mL H_2O, EMI^+ = 1-ethyl-3-methylimidazolium.

After removal of the organic products, the ionic phase can also be reused and gives quite similar activity. However, a small part of the active Rh catalyst is extracted into the organic phase. Thus, in contrast to the hydrogenation reactions, the uncharged $[Rh(CO)_2(acac)]$ catalyst precursor has to be immobilized in the salt by a polar ligand. For this purpose, the sodium salts of monosulfonated- (tppms) and trisulfonated- (tppts) triphenylphosphane ligands have been used. In this way, extraction of the Rh catalyst could be completely avoided. Although catalytic reaction rates are lower when the $[Rh(CO)_2(acac)]$/tppms or $[Rh(CO)_2(acac)]$/tppts systems are used in the $BMI^+PF_6^-$ or $BMI^+BF_4^-$ salts, reasonable TOF are still obtained (Table 2, entries 3 and 4).

Investigations on modified phosphites, which are not stable in an aqueous two-phase system[9], but seem to be promising ligands in these nonaqueous ionic liquids, are currently under way. In summary, this paper describes a few examples illustrating the advantages of using BMI^+ molten salts as novel solvents for two-phase Rh-catalyzed reactions. In view of the existing limitations of the present liquid–liquid systems, these nonaqueous solvents could be a potentially valuable medium for further developments of two-phase catalysis.

Experimental Procedure

Hydrogenation: **1** (0.05 mmol) dissolved in $BMI^+SbF_6^-$ molten salt (4 mL) was transferred under argon, into a 70 mL Fischer-Porter glass flask, equipped with a magnetic stirring bar. After the evacuation of argon , the hydrogen pressure was adjusted to 0.1 MPa and the catalyst was activated with stirring for 10 min. The reactor was depressurized and pent-1-ene (18.4 mmol) was injected through a septum. The hydrogen pressure was again adjusted to 0.1 MPa, and the reaction was monitored by GC (PONA, 50 m × 0.2 mm). For further experiments with the same molten salt, the remaining upper organic phase was removed, the molten salt evacuated (15–20 min, 30 °C), the reactor was flushed twice with H_2 (0.1 MPa) and pent-1-ene (18.4 mmol) was added and the reaction was started again.

Asymmetric hydrogenation: The reactions were conducted as previously described except that the starting material (α-acetamidocinnamic acid) was dissolved in *i*PrOH (5 mL). At the end of the reaction, the upper organic phase was evaporated to dryness and the product workup was carried out as described in ref. [9].

Hydroformylation: A 100 mL stainless steel autoclave, equipped with a glass lining, was charged with a mixture of $[Rh(CO)_2(acac)]$ (0.075 mmol) and 3 to 10 equivalents of the phosphorus ligand dissolved in 4 mL of the ionic liquid. The autoclave was purged with CO/H_2 (1/1) and pent-1-ene (68 mmol) with heptane (2 mL; internal standard) was added. The temperature was raised to 80 °C, the pressure (CO/H_2) was adjusted to 2 MPa, and the mixture was then stirred. The product distribution was determined by GC.

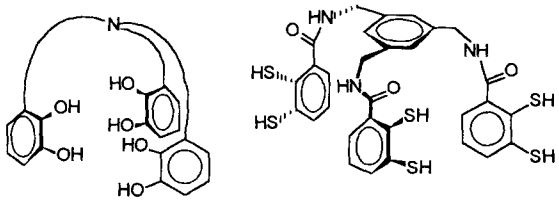
Synthesis and Coordination Chemistry of *ortho*-Functionalized Dimercaptobenzene: Building Blocks for Tripodal Hexathiol Ligands**

F. Ekkehardt Hahn* and Wolfram W. Seidel

Tripodal tricatechol ligands with six oxygen atoms of type H_6-**1**[1] have been investigated thoroughly, because they have a high affinity for various metal ions and are model substances for the siderophore enterobactin.[2] Tripodal ligands with three *ortho*-phenylenediamine groups[3] have also been described, whereas hexathiol ligands of type H_6-**2** derived from dimercaptobenzene are still unknown. Polythiol ligands that contain aliphatic[4] or aromatic thiol groups[5] as well as both thioether and thiol groups[6] as donor functions are well established, but the bridging of dimercaptobenzene units to give a poly(dithiolene) ligand has not been achieved so far. Being aware of the interesting coordination chemistry of dithiols for different oxidation states of the metal atom,[7] we expected to find in complexes with ligands of type H_6-**2** not only the stabilization of metal ions in unusual oxidation states but also—caused by the tripodal backbone—the formation of coordination polyhedra that do not form with unbridged dimercaptobenzene ligands. In this paper we report a method for the preparation of *o*-functionalized dimercaptobenzene that will allow for the first time the synthesis of tripodal tris(dithiol) ligands such as H_6-**2**, as well as initial investigations concerning the coordination chemistry of H_6-**2**.



H_6-**1** H_6-**2**

The synthesis of H_6-**2** is best achieved by the reaction of 2,3-dimercaptobenzoyl chloride with 1,3,5-tris(aminomethyl)-benzene under formation of three amide bonds, a strategy that has been proved successful for the preparation of various tripodal tri(carboxamidocatechol) ligands.[8] The starting point for our work was the synthesis of *ortho*-mercaptobenzoic acid from thiophenol, published in 1989.[9]

The reaction of *ortho*-dimercaptobenzene (**3**)[10] with three equivalents of *n*BuLi and dry CO_2 yields after hydrolysis with H_2O/HCl (Scheme 1) a mixture of the benzoic acid derivative **4a** and the terephthalic acid derivative **4b**.[11] Attempts to separate the components of this mixture were not successful. To facilitate this separation on the one hand and to make the next step to the amide possible without interference by acidic groups on the other, the thiol functions were protected by the reaction with isopropyl bromide/sodium methanolate. The resulting derivatives **5a**/**5b** could then be separated by column chromatography. This way we obtained **5a** analytically pure as crystals and confirmed its identity by X-ray crystallography (Fig. 1).[12]

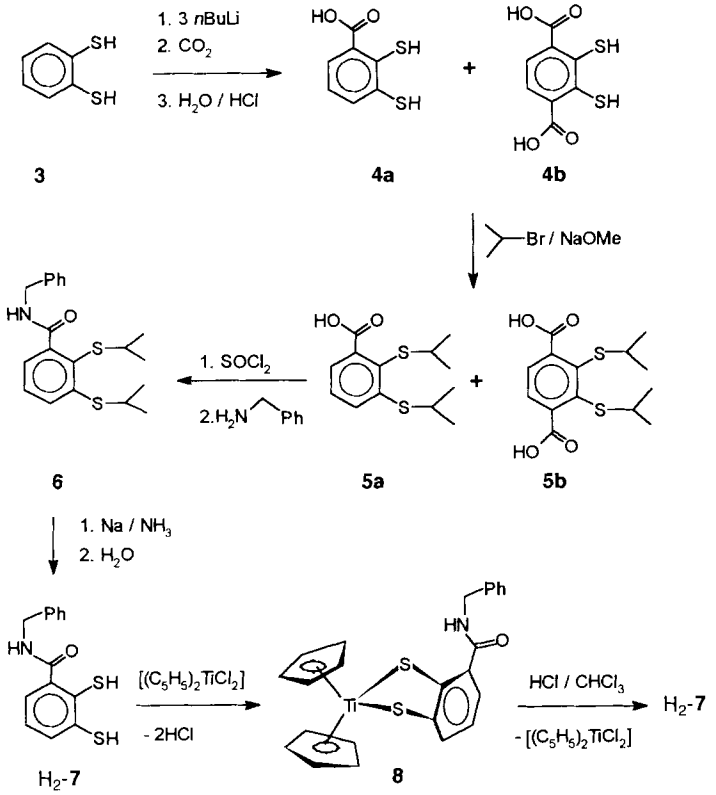

Scheme 1. Synthesis and reactions of 2,3-dimercaptobenzoic acid.

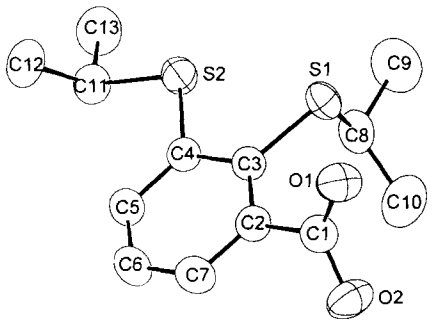

Fig. 1. ORTEP plot of **5a** in the crystal. Selected bond lengths [Å] and angles [°]: S1–C3 1.771(2), S1–C8 1.827(3), S2–C4 1.761(2), S2–C11 1.815(3), C1–C2 1.498(3), C1–O1 1.237(3), C1–O2 1.279(3); C3-S1-C8 100.2(1), C4-S2-C11 105.8(1), O1-C1-O2 123.4(2), O1-C1-C2 120.7(2), O2-C1-C2 115.9(2).

Derivative **5a** crystallizes without intermolecular oxygen–oxygen contacts shorter than 2.6 Å. Apparently the formation of intermolecular hydrogen bonds is prevented by the bulky substituents on the sulfur atoms. The $S-C_{sp^2}$ distances are, as expected, approximately 0.05 Å shorter than the $S-C_{sp^3}$ distances. The atoms of the aromatic ring form a plane that also contains the atoms S1, S2, and C1 (maximum deviation 0.08 Å for S1). The typical lengthening of the (S)C–C(S) bond in the ring observed in coordinated *ortho*-dimercaptobenzene (which can be explained by the resonance of coordinated dithiolate and dithioketone[17b–d]) was not observed in **5a**.

After treatment with $SOCl_2$, **5a** can be converted into the amide **6** by the reaction with benzylamine (Scheme 1).[11] We found that the protection groups in **6** can be removed easily by reaction with sodium in ammonia[13] (Scheme 1).[11] The formation of cyclohexadienes or side reactions at the amide group were not observed. The bidentate dithiol ligand H_2-**7** was obtained as an impure white solid.

The purification of the dithiol H_2-**7** turned out to be extremely difficult because of its facile oxidation by atmospheric oxygen. Purification by formation and controlled decomposition of a metal complex provides a simple alternative. For that purpose we treated impure H_2-**7** with $[(C_5H_5)_2TiCl_2]$ and isolated the blue-green complex $[(C_5H_5)_2Ti(7)]$ **8**.[11] Unlike H_2-**7**, this complex is air-stable and can be purified very easily by chromatography. The X-ray structure analysis confirmed the identity of **8** (Fig. 2).[12]

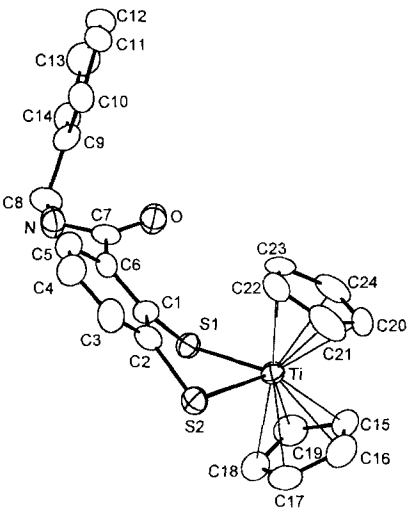

Fig. 2. ORTEP plot of **8** in the crystal. Selected bond lengths [Å] and angles [°] (Cp1 and Cp2 are the centroids of the cyclopentadienyl rings): Ti–S1 2.389(3), Ti–S2 2.418(3), Ti–Cp1 2.035, Ti–Cp2 2.073, S–C1 1.76(1), S2–C2 1.76(1); S1-Ti-Cp1 104.6, S1-Ti-Cp2 110.7, S1-Ti-S2 81.4(1), S2-Ti-Cp1 108.0, S2-Ti-Cp2 108.5, Cp1-Ti-Cp2 132.0, Ti-S1-C1 97.4(4), Ti-S2-C2 95.9(4).

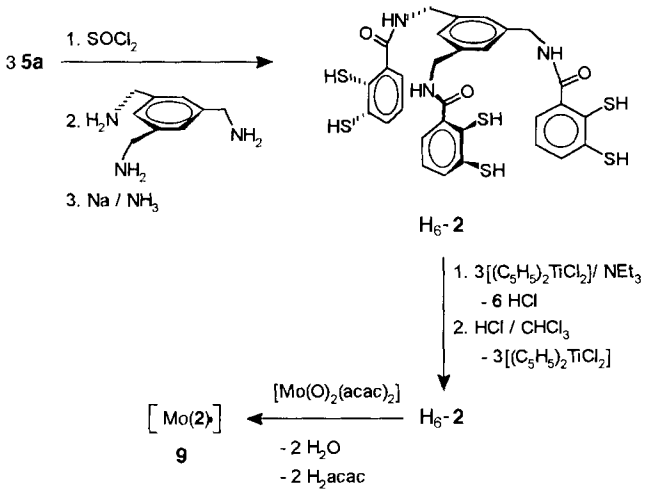
Bond lengths and bond angles of the $(C_5H_5)_2Ti(S_2C_6)$ unit in **8** differ only slightly from those in $[(C_5H_5)_2Ti(S_2C_6H_4)]$.[14] Only one Ti–S bond in **8** is slightly shorter than the corresponding bond in $[(C_5H_5)_2Ti(S_2C_6H_4)]$. The substitution of the dithiol by a bulky amide in *ortho* position has no consequences for the binding to the titanium atom. Thus it can be predicted that no steric factors hinder the coordination of poly(dithiols) bridged over amide groups in *ortho* position. Ligand **7** in complex **8** adopts the envelope conformation in which the five-membered chelate ring is folded along the S–S axis [the angle between the TiS_2 and C_6 planes is 42.7(4)°]. This folding leads to remarkably short Ti–C1 [3.14(1) Å] and Ti–C2 [3.13(1) Å] distances. Also remarkable are the large torsion angles for C5-C6-C7-N [– 45.3°] and C5-C6-C7-O [131.0°], which show clearly how the amide function is twisted out of the plane of the aromatic dithiolate system (Fig. 2).

As a consequence of the folding of the chelate ring around the S–S axis, the cyclopentadienyl ligands do not have the same environment. However, at increased temperature in solution (313 K) a flip around the S–S axis is observed,[15] which leads to the observation of only one slightly broadened signal for the cyclopentadienyl protons in the ^{1}H NMR spectrum.[11] Both conformational isomers can be observed at low temperature, which is illustrated by two signals for the cyclopentadienyl protons together with two signals for the diastereotypical benzyl protons.[11] The difference in the chemical shift for the cyclopentadienyl protons of **8** at 233 K ($\Delta\nu$ = 165 Hz) is far greater than was observed for the similarly built complex with an

unsubstituted dimercaptobenzene.[16] However, owing to the different coalescence temperatures, the estimated activation energy of 55 kJ mol^{-1} for the flip falls in the range described for $[(C_5H_5)_2Ti(S_2C_6H_4)]$ (53 kJ mol^{-1}).[16]

The recovery of pure H_2-**7** from **8** is complete within seconds by reaction with HCl in $CHCl_3$ with formation of the deep red $[(C_5H_5)_2TiCl_2]$. Syntheses and characterization of compounds **5**–**7** clearly showed that the preparation of tripodal tris(dithiol) ligands such as H_6-**2** by bridging three dimercaptobenzoic acid units through a tripodal triamine should be possible. We therefore attempted the synthesis of H_6-**2** according to Scheme 2.



Scheme 2. Synthesis and reactions of the tris(dithiol) ligand H_6-**2**.

The reaction of three equivalents of **5a** with the tripodal triamine 1,3,5-tris(aminomethyl)benzene[8e] yielded the tripodal hexathioether. The removal of the protection groups was achieved as for H_2-**7**. Through reaction with three equivalents of $[(C_5H_5)_2TiCl_2]$, the impure ligand H_6-**2** was transformed into the trinuclear complex $[\{(C_5H_5)_2Ti\}_3$(**2**)], which, in turn, was purified very easily by chromatography. Reaction of $[\{(C_5H_5)_2Ti\}_3$(**2**)] with HCl in $CHCl_3$ led to $[(C_5H_5)_2TiCl_2]$ (soluble in $CHCl_3$) and H_6-**2**, which precipitated from the chloroform solution as a white, analytically pure powder.[17] In a first experiment H_6-**2** was suspended in methanol and mixed with a colorless methanolic solution of $[Mo(O)_2(acac)_2]$. Within an hour the deep green color typical for molybdenum tris(dithiolate) complexes appeared (Scheme 2).[18] The complex [Mo(**2**)] (**9**) can be purified by chromatography on SiO_2 (eluent CH_2Cl_2/MeOH). UV/Vis and mass spectra prove the formation of a mononuclear Mo^{VI} tris(dithiolate) complex. Further investigations on the molecular structures and properties of complexes with the described tris(dithiolene) ligands are in progress.

[11] Correct elemental analyses for **5a**, **5b**, **6**, and **8**. For the synthesis of a mixture of **4a** and **4b**, compound **3** (4.0 mL, 34.8 mmol) dissolved in cyclohexane (10 mL) was added dropwise to a solution of *n*BuLi (174 mmol) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (174 mmol) in cyclohexane (90 mL). The resulting yellowish suspension was stirred for 4 days under argon at room temperature. Thereafter, CO_2 (dried over P_4O_{10}) was bubbled through the ice-cooled reaction mixture for 30 min. After hydrolysis with H_2O/HCl the mixture was extracted with diethyl ether. The product mixture **4a**/**4b** contains up to 30% of **3**. To separate the products the mixture **4a**/**4b**/**3** was added to a solution of sodium (3.2 g, 140 mmol) in methanol (100 mL). To this was added isopropyl bromide (13.2 mL, 140 mmol), and the reaction solution was heated at reflux for 24 h. After removal of the solvent the reaction mixture was hydrolyzed with water/HCl, extracted with diethyl ether, and the resulting product mixture separated chromatographically (SiO_2, diethyl ether/petroleum ether, 1/2; v/v). Yield 3.2 g (11.8 mmol, 34%) **5a** and 1.5 g (4.7 mmol, 13%) **5b**. Selected spectroscopic data for **5a**: IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1701 (s, CO); ^{1}H NMR (250 MHz, $CDCl_3$): δ = 8.00 (m, 1H; Ar-H), 7.40 (m, 2H; Ar-H), 3.40 (m, 1H; SCH), 3.35 (m, 1H; SCH), 1.42 (d, 6H; $CH(CH_3)_2$), 1.31 (d, 6H; $CH(CH_3)_2$); LRMS (70 eV): m/z = 270 ([M^+], 100%), 228 ([M^+] − C_3H_6, 9%). For **5b**: IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1704 (s, CO); ^{1}H NMR (250 MHz, $CDCl_3$): δ = 8.05 (s, 2H; Ar-H), 3.55 (sept, 2H; SCH), 1.35 (d, 12H; $CH(CH_3)_2$); LR-MS (70 eV): m/z 314 ([M^+], 76%), 229 ([M^+ − C_3H_6 − C_3H_7], 100%). For **6**: IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1637, 1538 (s, CO); ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.45–7.25 (m, 8H; Ar-H), 7.12 (t, 1H; N-H), 4.65 (d, 2H; CH_2), 3.50–3.35 (m, 2H; SCH), 1.40 (d, 6H; $CH(CH_3)_2$), 1.15 (d, 6H; $CH(CH_3)_2$); LR-MS (70 eV): m/z 359 ([M^+], 91%). For the removal of the protection groups, **6** (dissolved in THF) was added dropwise to a solution of ammonia and sodium (stoichiometric excess of Na). The reaction was complete after 30 min, and the ligand H_2-**7** was obtained after removal of the NH_3, hydrolysis with H_2O/HCl, and extraction with ether as a colorless, not yet analytically pure, oxidation-sensitive powder. The pure compound was obtained by the synthesis of **8** from H_2-**7** and $[(C_5H_5)_2TiCl_2]$ in THF in the presence of triethylamine. Complex **8** was obtained as blue-green plates in 70% yield (based on **6**). **8**: IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1664, 1499 (s, CO); ^{1}H NMR (300 MHz, $CDCl_3$, T = 313 K): δ = 7.75 (dd, 1H; Ar-H), 7.56 (dd, 1H; Ar-H), 7.51 (s, br, 1H; N-H), 7.40–7.17 (m, 6H; Ar-H), 6.06 (s, br, 10H; C_5H_5), 4.69 (d, 2H, CH_2); (T = 233 K): N-H and Ar-H signals are almost unchanged, 6.42 (s, 5H; C_5H_5), 5.87 (s, 5H; C_5H_5), 4.82 (dd, 1H; CH_2), 4.64 (dd, 1H; CH_2). The liberation of H_2-**7** from **8** takes place within a few seconds by treatment of **8** with $CHCl_3$/HCl to form $[(C_5H_5)_2TiCl_2]$. H_2-**7**: ^{1}H NMR (270 MHz, $CDCl_3$): δ = 7.45–7.23 (m, 7H; Ar-H), 7.04 (t, 1H; Ar-H), 6.35 (s, br, 1H; N-H), 5.62 (s, 1H; S-H), 4.60 (d, 2H; CH_2), 3.81 (s, 1H; S-H).

[12] Crystal structure analyses: Crystals of **8** crystallized from benzene are systematically twinned. Data sets for both individuals of one crystal were recorded. The data for the larger individual were used for the structure determination and refinement. From the two orientation matrices and the scan range 216 overlapping reflexes were identified, of which 83 were suppressed in the following least-squares refinement. Structure parameters: **5a** [**8**]: $C_{13}H_{18}O_2S_2$ [$C_{24}H_{21}ONS_2Ti$], triclinic [triclinic], space group $P\bar{1}$ [$P\bar{1}$], a = 7.952(3) [8.186(4)], b = 9.420(5) [11.417(7)], c = 10.671(4) [12.445(7)] Å, α = 105.21(4) [67.48(4)], β = 91.79 [71.35(4)], γ = 111.80(3) [85.54(4)]°, V = 708.8(13) [1016.7(12)] Å^3, Z = 2 [2], ρ_{exp} = 1.28 [1.46], ρ_{calcd} = 1.267 [1.475] g cm^{-3}, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), $\mu(Mo_{K\alpha})$ = 3.15 [6.28] cm^{-1}. 2847 [2658] symmetry-independent data measured at 20(2) [20(2)] °C in the 2θ-range [°] 4–48 [2–45]. Structure determination with direct methods, refinement of the positional parameters of all non-hydrogen atoms with anisotropic thermal parameters, hydrogen atoms on calculated positions [d(C-H) = 0.95 Å, d(N-H) = 0.87 Å] with U_H = 0.081 Å^2 (for **5a**), B_H = 1.3 $B_{eq(C)}$ (for **8**), respectively, position of the carboxylate hydrogen atom in **5a** was not determined. R = 3.88 [6.75], R_w = 3.74 [9.71] for 2087 [1630] structure factors $I \geq 2\sigma(I)$ [$F_o^2 \geq 3\sigma(F_o^2)$] and 155 [262] variables. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD-59134.

$Ta_5(S,Te)_2$: Microporous Tantalum with Chalcogen-Coated Inner Surfaces**

Thomas Degen and Bernd Harbrecht*

The structural chemistry of tantalum-rich chalcogenides is dominated by the competition between two basic building principles. On one hand, chalcogenides are known that fragmentarily contain the body-centered cubic (bcc) arrangement of the metal components. The prototype is Ta_2Se.[1] This layered structure, which is symmetry related to bcc tantalum, consists of two-dimensional bcc-Ta fragments. The remaining valences on the surfaces of each sheet are saturated with selenium. The mixed sulfide selenides, $Ta_2(S,Se)$[2] (Ta_2Se-type), $Ta_5(S,Se)_2$[4] (isostructural with $(Nb,Ta)_5S_2$[3]), and $Ta_9(S,Se)_4$,[4] the latter of which results from a chemical intergrowth of the 2:1 and 5:2 phases, form similar layered-type, bcc-related structures. Binary pendants of the metal-rich 5:2 and 9:4 phases do not seem to exist. The sulfides meet this building principle only if tantalum is partly replaced, for example by niobium. $(Nb,Ta)_nS_4$ (n = 11, 12)[5] and the quaternary sulfide telluride $(Nb,Ta)_9(S,Te)_5$[6] are typical representatives of structures resulting from a three-dimensional cross-linking of columnar bcc fragments.

On the other hand, there are tantalum-rich chalcogenides that contain centered, distorted, Ta_{13} icosahedra as a uniform structural motif. The metal icosahedra interpenetrate along a pseudo-fivefold rotation axis, thus forming pentagonal-antiprismatic chains. Ta_6S (dimorphic),[7] Ta_2S,[8] Ta_3S_2,[9] and the substitution phases of the type $M_xTa_{6-x}S$ (M = V, Cr)[10] comprise such chains. The recently characterized telluride Ta_6Te_5[11] exhibits the same feature.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Ministerium für Wissenschaft und Technologie des Landes Nordrhein-Westfalen. We thank Dr. M. Nieger for the measurement of the single-crystal data.

The surprising result that the telluride is structurally related to the tantalum-rich sulfides, but not to the tantalum-rich selenides, has led us to preparatively explore the tantalum-rich region of the system Ta-S-Te for the existence of additional phases with complex structures. As part of these investigations we uncovered two new phases, $Ta_5(S,Te)_2$ and $Ta_{61}(S,Te)_{30}$.[12] Herein we report on the 5:2 phase $Ta_5(S,Te)_2$ (**1**).[13] It has the same composition as the sulfide selenide richest in tantalum; its structure, however, is not composed of bcc fragments, but results from the meandered penetration of three chemically independent, centered, icosahedral clusters.

Coarse crystals of **1** (up to 4 mm) were prepared by reduction of an equimolar mixture of the dichalcogenides with tantalum in the presence of iodine as a transport agent at about 1800 K within one day. The reactions were performed in tantalum ampoules. The rod-shaped crystals preferentially grew fascicularly on the interior wall of the tantalum ampoule. Similar reactions performed without iodine yielded **1** as a nearly pure, microcrystalline product. The phase composition of the samples was controlled by X-ray powder diffractometry and Rietveld refinements[14] (Fig. 1). The tellurium-rich compounds additionally

Top: measured (dotted) and calculated profile; middle: calculated Bragg positions; bottom: difference between calculated and measured intensity; insert: electrical resistivity of a single crystal of $Ta_5(S,Te)_2$ as a function of the temperature; (◇ = cooling, + = heating; crystal dimensions: 2.65 × 0.15 × 0.12 mm^3, current: 1 mA, contacted with epoxy silver paste).

contained at least one more phase which has not yet been fully characterized. In samples richer in sulfur the sulfide telluride **1** forms together with Ta_6S or Ta_2S. Energy dispersive microanalyses (EDX) point to a narrow homogeneity range ($Ta_5S_{1.0(1)}Te_{1.0(1)}$). The differences between the lattice parameters[15] (< 4 pm) of phases at both stability boundaries are correspondingly small.

$Ta_5(S,Te)_2$ exhibits an unexpected microporous tantalum partial structure for such a metal-rich compound. Figure 2 shows a polyhedral representation[16] of the metal framework as a projection along the c axis. Large channels with a free width of more than 0.6 nm run through the structure that results from the interpenetration of three distinct clusters. The metal atoms of the clusters are grouped around the icosahedrally coordinated atoms Ta1, Ta4, and Ta8. As can be seen from Figure 3, only Ta4 is exclusively coordinated by tantalum atoms. The metal coordination about Ta1 corresponds to an *arachno*-Ta_{11}, that

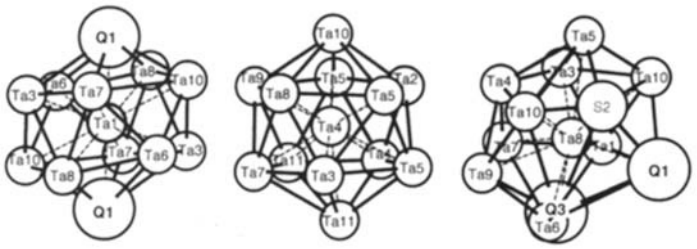

Fig. 3. Polyhedra about the three distorted icosahedrally coordinated atoms: Ta1(295.9), Ta4(290.4), and Ta8(296.8) (values in parentheses correspond to mean distances [pm] for the coordination number 12).

about Ta8 to a *hypho*-Ta_{10} icosahedral fragment. Q1 (mixed occupied site: 96% Te, 4% S) completes the Ta_{11} fragment, Q3 (34% Te, 66% S) and S2 complete the Ta_{10} fragment to give closed deltahedra. The three clusters interpenetrate to form meandered chains running along the *a* axis (Fig. 4). The specific

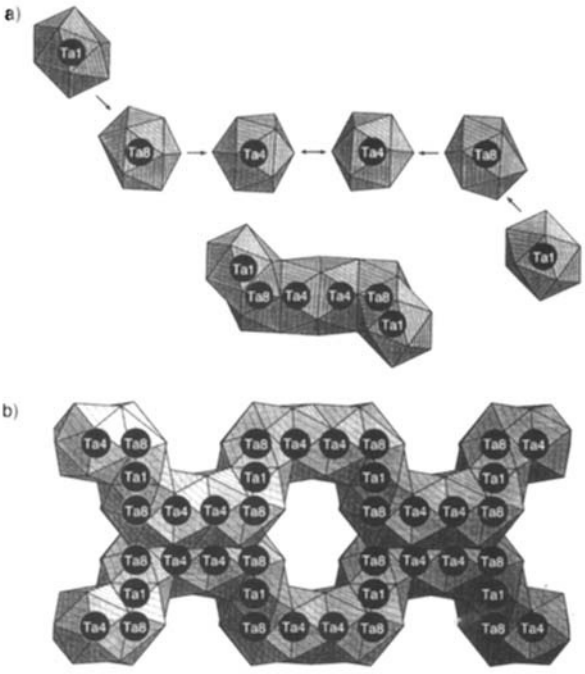

Fig. 4. a) Mutual penetration of the three icosahedral clusters around Ta1, Ta4, and Ta8 to form a meandered chain; b) linkage of two such chains depicted as a projection along the *c* axis.

mutual orientation of the chains that are three-dimensionally linked by common edges (2 × Ta5) and apices (Ta10), leads to pores which are limited by 16 icosahedral groupings in the projection plane. The chalcogen atoms contributing to the icosahedral coordinations of Ta1 and Ta8, namely Q1, Q3, and S2, are located at the pore walls. The remaining atoms S1 and Q2 (92% Te, 8% S) cover the rest of the interior metal surfaces. In accord with the surface-covering function, the chalcogen atoms are always one-sided fourfold (Q2,Q3), fivefold (Q1,S1), or sixfold (S2) surrounded by Ta. The five coordination polyhedra of seemingly arbitrary shape (Fig. 5) are more or less open frag-

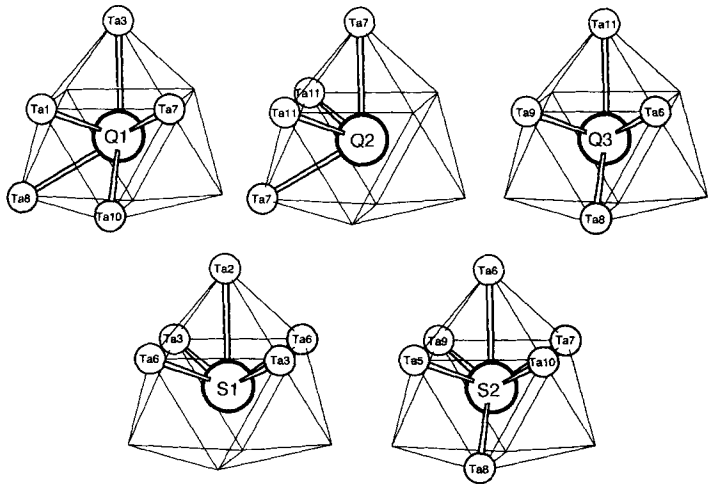

Fig. 5. Coordination polyhedra around the five distinct chalcogen atoms, Q1(294.3), Q2(291.4), Q3(270.4), S1(249.8), and S2(254.6), schematically depicted as fragments of an imaginary triangulated tetrakaidecahedron (values in parentheses represent mean Q,S–Ta distances [pm] for the respective coordination number).

ments of an imaginary QTa_9 polyhedron, a tetrakaidecahedron confined by 14 triangular planes. S1 and S2 cover the surface in areas of larger, Q1, Q2, and Q3 in areas of lesser pore curvature. Some of the neighboring chalcogen atoms are in close contact (Q1–S1 = 325.7 pm, Q1–Q3 = 332.7 pm). Q2, located in the center of the area of lower flexure, is—similar to the case of layered-type chalcogenides—sixfold surrounded by S2, Q1, and Q3. These atoms are in van the Waals contact (349.6–374.5 pm). Four further distant Q1 and Q3 centers (389.7 and 390.7 pm) are situated at the opposite pore wall. The chalcogen atoms that are segregated at the inner surface of the microporous tantalum partial structure themselves sheathe empty channel-like hollows, which potentially could serve as receptors for small metal atoms.

Ta–Ta and Ta–Q bonds contribute in different ways to the stability of $Ta_5(S,Te)_2$ **1**: in regions deviating away from the pore walls the cohesion is solely maintained by three-dimensionally extended, Ta–Ta interactions. Strong metal–metal bonds are reflected in numerous short Ta–Ta contacts (270.5–337.5 pm). The bonds between Ta and the chalcogen atoms can barely compensate the high cohesive energy of the 5d metal, upon which this complex metal partial structure is based. They afford an additional stabilization through the formation of heteronuclear bonding regions (246.7–306.2 pm) that are uncoupled from the metal cores. These bonds are confined to areas near the pore walls. Thus, the hierarchy of the bonding interactions explains why the structure of this tantalum-rich chalcogenide is not shaped by the dispersion of the minor components (S, Te) in the metal but by the spatial segregation of the metal and non-

metal components. The spatial confinement of the metallic bonding regions associated with the pores might give rise to quantum size effects for this clusterlike compound. The electrical resistivity of single crystals measured by a four-point-direct current method[17] (Fig. 1) confirms that the title compound is a metallic conductor. The resistivity lies in the mΩ cm range and is nearly two orders of magnitude larger than that of elemental tantalum. Anomalies in the temperature dependence of the resistivity—in accordance with the large hysteresis—point to a first-order phase transition.

Towards the Development of Molecular Wires: Electron Localization, Exchange, and Transfer in Alkyne-Bridged Multinuclear Complexes**

Vincent Grosshenny, Anthony Harriman,* and Raymond Ziessel*

Stepwise assembly of preformed molecular modules around a metal center provides an attractive means for constructing multicomponent arrays capable of information storage and transport.[1] To ensure fast and quantitative exchange of information within the array, the bridge must facilitate strong electronic communication between the components. This situation is realized, at least for through-bond electron transfer, when the energy level of the bridge slightly exceeds that of the reactants.[2] Thus, alkenes[3–5] and alkynes[6–9] appear to be promising bridges, and the latter is ideal for construction of rigid, rodlike arrays.[10, 11] The efficacy of alkynes for promoting long-range electronic coupling has not been explored extensively, although several systems have been studied because of their nonlinear optical properties.[12–15] Here, we describe the processes that occur upon excitation of multinuclear complexes assembled from ruthenium(II) bis(terpyridyl) subunits covalently attached to a free terpyridyl ligand by ethynediyl or butynediyl bridges.[9] If a second metal cation is included in this complex,[16, 17] a linear, photoactive array results, in which ruthenium(II) units are termini (Scheme 1) and the central cation (M) controls the photochemistry.

It is important to recall that the parent compound $[Ru^{II}(terpy)_2]^{2+}$ is a poor sensitizer at ambient temperature.[18] This is partly because a relatively low-lying metal-centered (MC) excited state promotes nonradiative deactivation of the lowest energy triplet excited state, which has metal-to-ligand charge-transfer (MLCT) character, to the ground state. Incorporation of an alkyne group into one of the terpyridyl ligands, however, decreases the energy of this MLCT triplet state, thereby minimizing the extent of its mixing with the higher energy MC state.[9] Thus, excitation into the MLCT absorption transition localized on the $[Ru^{II}(terpy)_2]^{2+}$ subunits of the Zn^{II}-containing complexes **Ru_2Zn(1)** and **Ru_2Zn(2)** in acetonitrile at 20 °C results in luminescence. The emission maxima (λ_P) of these compounds are red-shifted and the luminescence quantum yields (Φ_L) are significantly enhanced relative to the weakly emissive parent (Table 1). The triplet lifetimes (τ_T) of the trinuclear complexes, measured in deoxygenated acetonitrile, are much longer than that of $[Ru^{II}(terpy)_2]^{2+}$ (Table 1) and of other mononuclear derivatives having comparable triplet energies.[18–20] In contrast, the half-wave potentials for one-electron oxidation of the Ru^{II} center ($E^{ox}_{1/2}$) are similar to that of the parent,[21] as might be expected for derivatives with a weakly electron-withdrawing substituent.[19] Since the redox potentials for one-electron reduction of the terpyridyl ligand ($E^{red}_{1/2}$) are slightly less negative for the alkyne-substituted ligands than for the parent (Table 1), the decreased triplet energy noted for **Ru_2Zn(1)** and **Ru_2Zn(2)** might arise, in part, from an electronic effect. It is also important to note that in the complexes with the

butynediyl bridge, oxidation of the Ru^{II} center occurs at much higher potential for the Fe^{II}- and Co^{II}-containing trinuclear complexes, in which the central metal (M) has a lower oxidation potential (Table 1). This behavior is suggestive of electronic coupling between the metal centers.

The enhanced triplet lifetimes of the two Zn^{II}-containing complexes relative to that of the parent compound might arise from decoupling of the MC and MLCT excited states. To isolate this effect from any additional stabilization phenomena due to the alkyne group, luminescence studies were conducted in ethanol at 77 K. Under these conditions the emission maxima are blue-shifted and the triplet lifetimes of the parent and Zn^{II}-containing complexes increase dramatically (Table 1). At 77 K the triplet lifetimes of **$Ru_2Zn(1)$** and **$Ru_2Zn(2)$** are similar to that of the parent, despite their significantly lower triplet energy; the "energy-gap law" demands that the rates of nonradiative transitions increase with decreasing triplet energy.[22] By comparing the triplet lifetimes (τ_T) measured for **$Ru_2Zn(1)$** and **$Ru_2Zn(2)$** with those expected for a $[Ru^{II}(terpy)_2]^{2+}$ derivative having the same triplet energy (τ_O),[18–20] one can estimate the stabilizing effect of the ethynyl groups. This property is reflected by the ratio of triplet lifetimes[23] measured at 77 K and corresponds to an approximate fivefold increase in the lifetime of the triplet state. The origin of this "stabilization effect" may be vibronic and/or electronic in nature but a full quantum mechanical explanation is not yet available.

Irradiation into the MLCT absorption transition of these asymmetrical $[Ru^{II}(terpy)_2]^{2+}$ derivatives promotes a d electron from the Ru^{II} center to the alkyne-substituted terpyridyl ligand. The electron is localized on this ligand but, because of increased conjugation, it resides in an extended π^* orbital that includes the alkyne bridge and the bridging terpyridyl ligands.[9] Laser flash photolysis studies in deoxygenated acetonitrile at 20 °C indicate that, in addition to bleaching of the ground-state MLCT band ($\lambda = 497$ nm), an intense absorption band appears at longer wavelength ($\lambda \approx 640$ nm), which is not seen for the parent complex (Fig. 1a). Similar bands can be observed for the alkyne-substituted mononuclear $[Ru^{II}(terpy)_2]^{2+}$ derivatives **Ru(1)** and **Ru(2)**; the photophysical properties of these complexes are similar to those of **$Ru_2Zn(1)$** and **$Ru_2Zn(2)$** (Table 1). These absorption bands, which exhibit maxima at roughly 600 nm (**$Ru_2Zn(1)$**) and 640 nm (**$Ru_2Zn(2)$**), are likely due to the π radical anion of the alkyne-substituted terpyridyl ligands, although they are much more intense than those reported for mononuclear $[Ru^{II}(terpy)_2]^{2+}$ derivatives.[20]

The iron(II)-containing complexes **$Ru_2Fe(1)$** and **$Ru_2Fe(2)$** are nonemissive, but MLCT absorption transitions associated with $[Ru^{II}(terpy)_2]^{2+}$ ($\lambda_{max} \approx 500$ nm) and $[Fe^{II}(terpy)_2]^{2+}$ ($\lambda_{max} \approx 595$ nm) subunits are well resolved. Irradiation in acetonitrile solution into the $[Fe^{II}(terpy)_2]^{2+}$ absorption band generates the triplet state localized on the Fe^{II} unit, which has a lifetime of 2.6 ± 0.4 ns (**$Ru_2Fe(1)$**) and 3.9 ± 0.5 ns (**$Ru_2Fe(2)$**). Similarly, excitation into the $[Ru^{II}(terpy)_2]^{2+}$ absorption band leads to the triplet state of that chromophore with a lifetime of 12 ± 2 ps (**$Ru_2Fe(1)$**) and (16 ± 3) ps (**$Ru_2Fe(2)$**). This deactiva-

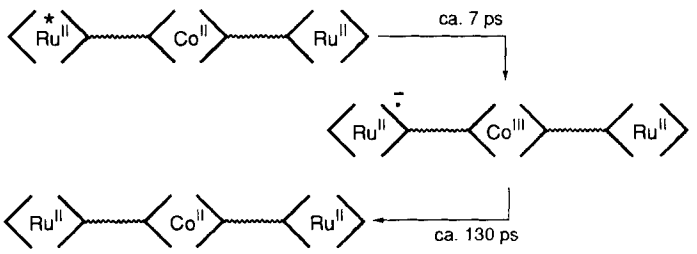
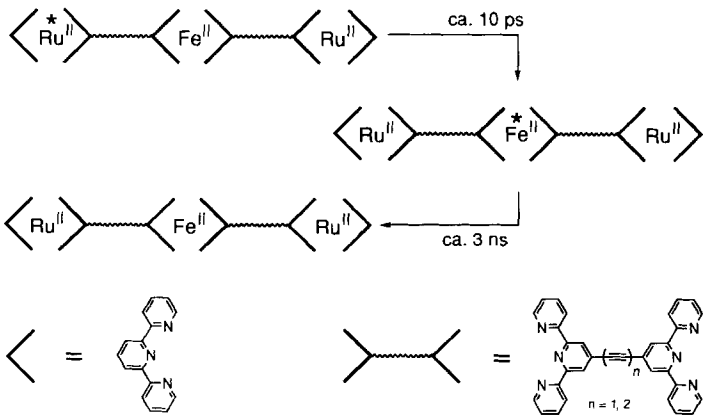
The absorbance scale is given in units of optical density divided by 1000.

tion is accompanied by bleaching of the MLCT transition associated with the $[Fe^{II}(terpy)_2]^{2+}$ subunits (Fig. 1b), the rate of which matches the rate of restoration of the ground state of the $[Ru^{II}(terpy)_2]^{2+}$ chromophore. This situation is ascribed to intramolecular energy transfer between the triplet states,[10, 18] which most probably occurs by way of electron exchange since the overlap integral for dipole-dipole transfer is rather small. Electron exchange corresponds to concerted transfer of an electron and a positive hole through orbitals localized on the alkyne bridge. Electron transfer may be facilitated by selective population of the orbitals of the bridging ligand followed by electron delocalization over an extended π^* orbital that encompasses the terpyridyl ligand and part of the alkyne bridge. Conversely, hole transfer involves d orbitals localized on each metal center. The fast rate of energy transfer, occurring over distances of 15.2 Å (**$Ru_2Fe(1)$**) and 17.7 Å (**$Ru_2Fe(2)$**) indicates that the subunits are in good electronic communication. A schematic description of the overall process in shown in Scheme 2.

Luminescence could not be detected for the Co^{II}-containing trinuclear complexes **$Ru_2Co(1)$** and **$Ru_2Co(2)$**; however, excitation at 440 nm generates the triplet state of the $[Ru^{II}(terpy)_2]^{2+}$ chromophore, which has a lifetime of 6 ± 2 ps and 8 ± 2 ps, respectively. A longer-lived transient species persisted after decay of the triplet (Fig. 1c), which was identified[24] as containing a $[Co^{III}(terpy)_2]^{3+}$ unit and the reduced form of the $[Ru^{II}(terpy)_2]^{2+}$ unit generated by intramolecular one-electron transfer ($\Delta G^0 \approx -0.37$ eV). This species has a lifetime of 125 ± 25 ps (**$Ru_2Co(1)$**) and 140 ± 20 ps (**$Ru_2Co(2)$**) before charge recombination occurs to restore the ground state ($\Delta G^0 \approx -1.75$ eV). The forward (light-induced) step involves long-range (over 15–18 Å) hole transfer from Ru^{III} to Co^{II}, occurring through HOMOs on the bridging ligand. Subsequent restoration of the ground state occurs through electron transfer from the alkyne-substituted terpyridyl π radical anion to the Co^{III} center. The rates of both forward and reverse steps are only weakly dependent on the length of the bridge, but the forward reaction is at least ten times faster than the reverse process, possibly due to the large amount of vibrational energy that must be dissipated during charge recombination. In fact, our results can be explained by assuming that the forward reaction occurs close to the apex of a Marcus-type bell-shaped curve (for the plot of rate vs energy gap), while charge recombination occurs well within the inverted region of the curve. This situation, in turn, demands that the total reorganization energy accompanying electron tranfer is in the region of about 0.5 eV. A schematic description of the overall process in shown in Scheme 3.



Scheme 3. Activation and deactivation of complexes **$Ru_2Co(1)$** and **$Ru_2Co(2)$**.



Scheme 2. Activation and deactivation of complexes **$Ru_2Fe(1)$** and **$Ru_2Fe(2)$**.

It is interesting to consider the requirements for the spacer group in such multicomponent systems and to see how well the alkyne group fares. First, the spacer must function as a molecular scaffold, providing spatial rigidity and integrity, and should inhibit incoherent migration of individual subunits. The alkyne bridge, especially in conjunction with terpyridyl ligands, acts as a rigid, photochemically inactive girder separating the metal centers by well-defined distances, which increase incrementally by roughly 2.5 Å per ethynyl group. Second, the spacer group must provide a means of directionality corresponding to vectorial transfer of information. Integration of an alkyne group into one of the terpyridyl ligands renders the complex sufficiently asymmetric that the electron in the MLCT triplet state is completely localized on the alkyne-containing ligand. This propensity for electron capture, together with subsequent delocalization of the electron over an extended π^* orbital, provides the directive for propagation of energy or electron transfer along the bridge. Third, the spacer must actively promote, not simply mediate, the transfer while inhibiting reverse processes that restore the ground state. In particular, the primary step should be quantitative so as to avoid undesired side reactions. The alkyne substituent group increases the triplet lifetime of $[Ru^{II}(terpy)_2]^{2+}$ at room temperature, thereby facilitating reactions that might not otherwise compete with nonradiative deactivation of the excited state. Intramolecular electron exchange (for **$Ru_2Fe(1)$** and **$Ru_2Fe(2)$**) and electron transfer (for **$Ru_2Co(1)$**

and $\mathbf{Ru_2Co(2)}$) proceed rapidly but the products survive for reasonably long times. These processes are quantitative and unidirectional.

The observation of fast energy and electron transfer in these systems and electron delocalization in the Zn^{II}-containing trinuclear complexes indicates efficient electronic coupling between the terminal $[Ru^{II}(terpy)_2]^{2+}$ subunit and the alkyne bridge. The rate of through-bond electron or hole transfer in these systems is only slightly attenuated. Rough estimates[10] for the attenuation factor (β) for hole tunneling ($\beta \approx 0.12 \pm 0.06$ Å^{-1}) and for electron tunneling ($\beta \approx 0.04 \pm 0.02$ Å^{-1}) are available from the kinetic results obtained with the Co^{II}-containing trinuclear complexes. Despite the large error limits, it seems probable that hole transfer is more attenuated than electron transfer, whilst the attenuation factor for triplet energy transfer[10] ($\beta \approx 0.17 \pm 0.05$ Å^{-1}) corresponds to the sum of factors derived for electron and hole transfer.[23] The energy of the bridge presumably decreases with increasing length, due to conjugation, which might offset the effect of increasing the length of the bridge. In this way, individual ethynyl groups exert a positive cooperative effect for promoting through-bond electron and/or hole transfer and form bridges having excellent potential as molecular wires.

Experimental Procedure

Photophysical measurements were made with a variety of laser excitation sources. In most cases the compounds were excited at 532 nm with a 30-ps laser pulse. The $[Fe^{II}(terpy)_2]^{2+}$ subunit in $\mathbf{Ru_2Fe(1)}$ and $\mathbf{Ru_2Fe(2)}$ was excited at 595 nm with a 0.3-ps laser pulse, while the $[Ru^{II}(terpy)_2]^{2+}$ chromophore in these compounds and in the corresponding Co^{II}-containing materials was excited at 440 nm. Redox potentials were measured by cyclic voltammetry with a silver reference electrode and tetrabutylammonium hexafluorophosphate as supporting electrolyte. All photophysical and electrochemical studies were made in acetonitrile, which had been deoxygenated by bubbling with N_2.

Synthesis: To an argon deoxygenated solution of complexes **Ru(1)** or **Ru(2)** (10 mg) in 7 mL of CH_3CN/H_2O 1/1 (for Fe), CH_3CN/CH_3OH 1/1 (for Co), or CH_3OH (for Zn) was added solid $FeSO_4 \cdot 7H_2O$, $CoCl_2 \cdot 6H_2O$, or $Zn(CH_3COO)_2 \cdot 2H_2O$ in threefold excess. Ten minutes exposure to ultrasound (35 kHz, 800 W, room temperature) resulted in marked and characteristic color changes due to metal complexation. The solution was stirred overnight at room temperature before NH_4PF_6 (5 equiv) in H_2O (10 mL) was added. Slow evaporation of the organic solvent resulted in precipitation of a dark solid. This precipitate was washed by centrifugation with water (3 × 10 mL) and diethyl ether (3 × 20 mL), dried under high vacuum, and recrystallized by slow evaporation of acetone from acetone/hexane solution to give analytically pure complexes.

Characterization of the complexes:

$Ru_2Zn(1)$: 87% yield; $R_f = 0.81$ (alumina, eluent CH_2Cl_2/MeOH (8/2)); Electrospray MS (in H_2O/CH_3CN (1/1), grammicidin as internal standard): *m/z*: 285.5 [$(M - 6PF_6)/6$, calcd 285.2], 500.6 [$(M - 4PF_6)/4$, calcd 500.3], 715.5 [$(M - 3PF_6)/3$, calcd 715.3], 1145.8 [$(M - 2PF_6)/2$, calcd 1145.5]; UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 498.2 nm (45000); Anal. calcd. for $C_{94}H_{62}F_{36}N_{18}P_6Ru_2Zn$ (M_r = 2580.968): C 43.75, H 2.42, N 9.77; found: C 43.53, H 2.28, N 9.49.

$Ru_2Zn(2)$: 77% yield; $R_f = 0.79$; Electrospray MS: *m/z*: 293.8 [$(M - 6PF_6)/6$, calcd 293.2], 512.9 [$(M - 4PF_6)/4$, calcd 512.3], 731.9 [$(M - 3PF_6)/3$, calcd 731.4], 1170.1 [$(M - 2PF_6)/2$, calcd 1169.5]; UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 496.6 nm (34300); Anal. calcd. for $C_{98}H_{62}F_{36}N_{18}P_6Ru_2Zn$ (M_r = 2629.012): C 44.77, H 2.38, N 9.59; found: C 44.49, H 2.17, N 9.36.

$Ru_2Fe(1)$: 91% yield; $R_f = 0.32$; Electrospray MS: *m/z*: 284.5 [$(M - 6PF_6)/6$, calcd 283.6], 498.3 [$(M - 4PF_6)/4$, calcd 497.9], 712.0 [$(M - 3PF_6)/3$, calcd 712.2], 1140.2 [$(M - 2PF_6)/2$, calcd 1140.7]; UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 596 (57500), 497 nm (43200); Anal. calcd. for $C_{94}H_{62}F_{36}N_{18}P_6Ru_2Fe + CH_3COCH_3$ (M_r = 2571.434 + 58.081): C 44.31, H 2.61, N 9.59; found: C 43.95, H 2.54, N 9.23.

$Ru_2Fe(2)$: 90% yield; $R_f = 0.10$; Electrospray MS: *m/z*: 292.4 [$(M - 6PF_6)/6$, calcd 291.6], 510.5 [$(M - 4PF_6)/4$, calcd 509.9], UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 596 (59300), 499 nm (48600); Anal. calcd. for $C_{98}H_{62}F_{36}N_{18}P_6Ru_2Fe + CH_3COCH_3$ (M_r = 2619.479 + 58.081): C 45.31, H 2.56, N 9.42; found: C 44.98, H 2.41, N 9.09.

$Ru_2Co(1)$: 94% yield; $R_f = 0.66$; Electrospray MS: *m/z*: 284.6 [$(M - 6PF_6)/6$, calcd 284.1], 499.1 [$(M - 4PF_6)/4$, calcd 498.6], 713.7 [$(M - 3PF_6)/3$, calcd 713.2], 1142.8 [$(M - 2PF_6)/2$, calcd 1142.3]; UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 503.4 nm (55600); Anal. calcd. for $C_{94}H_{62}F_{36}N_{18}P_6Ru_2Co$ (M_r = 2574.21): C 43.85, H 2.43, N 9.79; found: C 43.39, H 2.18, N 9.43.

$Ru_2Co(2)$: 94% yield; $R_f = 0.72$; Electrospray MS: *m/z*: 292.7 [$(M - 6PF_6)/6$, calcd 292.1], 511.3 [$(M - 4PF_6)/4$, calcd 510.7], 729.8 [$(M - 3PF_6)/3$, calcd 729.2]; UV/Vis (CH_3CN): λ_{max} (ε [$M^{-1}cm^{-1}$]) = 501.2 nm (51300); Anal. calcd. for $C_{98}H_{62}F_{36}N_{18}P_6Ru_2Co$ (M_r = 2622.565): C 44.88, H 2.38, N 9.61; found: C 44.42, H 2.07, N 9.29.

[23] A reasonably linear plot was obtained for the logarithm of the inverse of the triplet lifetime versus the triplet energy for nonalkyne-substituted $[Ru^{II}(terpy)_2]^{2+}$ complexes, in accordance with the energy-gap law. The gradient of this plot was used to estimate the expected triplet lifetime (τ_O) of a nonalkyne-substituted compound having a given triplet energy. Subsequently, the magnitude of the stabilization effect (τ_T/τ_O) was derived by comparing this extrapolated lifetime with that obtained for an alkyne-substituted compound having an identical triplet energy (τ_T).
[24] Spectral characterization was accomplished by spectroelectrochemistry for $[Co^{II/III}(terpy)_2]^{2+}$ and by one-electron pulse radiolytic reduction of **Ru(1)** and **Ru(2)**.

Butatrienes by Cumuhomologation of Propadienes

Rolf. W. Saalfrank*, Andreas Welch, and Martin Haubner

In the series of butatrienes only a few derivatives that exhibit functionality are known.[1-4] In particular, fewer than half a dozen papers have been published on formyl/acyl-[2] and acyloxy-substituted[3,4] butatrienes. Established methods for the synthesis of butatrienes[5] do not work for acyloxy-substituted butatrienes. In contrast, a strategy to generate butatrienic carboxylates by elimination from suitable substituted allenic precursors turned out to be extremely successful.[4]

Transallenation of 1,3-bis(dialkylamino)-1,3-diethoxyallenes with disubstituted malonyl chlorides yielded allene-1,1-dicarboxamides.[6-8] In addition we synthesized new *N*-phenylallenecarboxanilides starting from the reaction of 1,1-disubstituted propargylic ethers with diphenylcarbamoyl chloride and followed by reactions with sulfinyl chlorides, sulfenyl chlorides, diethoxy- and diphenylchlorophosphane, or orthoesters, and subsequent [2,3] and [3,3] sigmatropic rearrangements.[7] However, our efforts to expand this transallenation reaction to a cumuhomologation reaction failed. Thus, reaction of 1,3-bis(dialkylamino)-1,3-diethoxyallene with alkylidenemalonyl chloride yielded only the vinylacetylene isomer of the expected butatriene.[8,9]

We therefore developed a new method. Starting from alcohol **1** and potassium hypobromite we synthesized bromoalkynol **2**.[10] Reaction of **2** with the orthoesters **3** generates the bromoalkynyl vinyl ether intermediates **4**, which undergo spontaneous [3,3] sigmatropic rearrangements under the reaction conditions applied to yield bromoallenes **5**.[11] Elimination of hydrogen bromide from the allene **5a** with sodium ethanolate in ethanol gives butatriene **6**. In contrast, elimination of hydrogen bromide from the allene **5b** to give butatriene **7a** is accomplished by sodium bis(trimethylsilyl)amide, whereas **5c** is dehydrohalogenated to **7b** by use of sodium bis(trimethylsilyl)amide in combination with silver acetate. The cumuhomologation[12] reaction of the propadienes **5** to give butatrienes **6** and **7** is impressive in its simplicity and in the high yields obtained.

Experimental Procedure

5: General procedure: To a solution of bromoalkynol **2** (7.8 g, 48 mmol) in dry toluene (20 mL) were added orthoester **3** (144 mmol) and five drops of propionic acid, and the reaction mixture was heated for 3 h at 105–110 °C while the generated alcohol was removed continuously in a gentle flow of nitrogen. The solvent was removed under reduced pressure, the excess of orthoester subsequently distilled off at 65–70 C/0.5 Torr over a Vigreux column, and the residue dissolved in diethyl ether (20 mL). The organic layer was washed with hydrochloric acid (50 mL, 5%) and saturated sodium bicarbonate solution (50 mL), and then dried over magnesium sulfate. The solvent was removed under reduced pressure, and the product purified by vacuum distillation. Yields: 60–85%. **5a**: colorless liquid, b.p. 83 °C (2.5 Torr); IR (NaCl): $\tilde{\nu}$ = 1970 (C=C=C), 1740 cm^{-1} (C=O); ^1H NMR ($CDCl_3$): δ = 1.28 (t, J = 7.3 Hz, 3H, CH_3); 1.82 (s, 6H, 2 CH_3); 3.41 (s, 2H, CH_2); 4.19 (q, J = 7.3 Hz, 2H, CH_2); ^{13}C NMR ($CDCl_3$): δ = 14.16, 20.51 ($3CH_3$); 44.51 (CH_2); 61.09 (OCH_2); 81.32, 105.76 (2 =C); 169.25 (C=O); 198.74 (=C=); EI-MS (70 eV): m/z (%): 232 (41) [M^+ − H].

6: Under exclusion of air and moisture, sodium ethanolate (0.3 g, 4.5 mmol) diluted in dry ethanol (10 mL) was added to a solution of bromoallene **5a** (1.0 g, 4.3 mmol) in dry ethanol (50 mL) at − 50 °C. The colorless solution turned deep yellow. The solution was allowed to warm to 20 °C within 2 h, and the solvent removed under reduced pressure. The residue was dissolved in hexane (40 mL), and after 5 min of stirring, the solvent was removed under reduced pressure. Yield: 95–98% [13], yellow liquid; IR (NaCl): $\tilde{\nu}$ = 2040 (=C=C=), 1710 cm $^{-1}$(C=O); ^1H NMR (400 MHz, $CDCl_3$): δ = 1.30 (t, J = 7.1 Hz, 3H, CH_3), 2.07, 2.13 (s, 3H, CH_3), 4.20 (q, J = 7.1 Hz, 2H, CH_2), 5.58 (s, 1H, =CH); ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 14.29, 25.23, 25.85 ($3CH_3$), 60.66 (CH_2), 93.03 (=CH), 132.20, 154.33, 165.62, 171.52 (3 =C, C=O); EI-MS (70 eV) m/z (%): 152 (100) [M^+].

7: To a solution of bromoallene **5b** [11] (1.0 g, 4 mmol) or bromoallene **5c** [11] (1.0 g, 4 mmol) in dry acetonitrile (80 mL) under exclusion of air and moisture was added sodium bis(trimethylsilyl)amide (0.75 g, 4.1 mmol) at − 40 °C [and for **7b** additionally silver acetate (1.34 g, 8 mmol)]. The solution was allowed to warm to 20 °C within 2 h, the solvent was removed under reduced pressure, the residue was dissolved in hexane (40 mL), and after 5 min of stirring the solvent was removed under reduced pressure. **7a**: Yield: 95–98% [13], yellow liquid; IR (NaCl): $\tilde{\nu}$ = 2050 cm^{-1} (=C=C=), 1710 (C=O); ^1H NMR (400 MHz, $CDCl_3$): δ = 1.30 (t, J = 7.1 Hz, 3H, CH_3), 2.04 (s, 6H, 2 CH_3), 2.07 (s, 3H, CH_3), 4.19 (q, J = 7.1 Hz, 2H, CH_2); ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 14.20, 18.01, 24.80, 25.19 ($4CH_3$), 60.74 (CH_2), 101.79, 125.69, 153.18, 166.24, 166.71 (4 =C, C=O); EI-MS (70 eV) m/z (%): 166 (100) [M^+]. **7b**: Yield: 95–98% [13], yellow liquid; IR (NaCl): $\tilde{\nu}$ = 2060 cm $^{-1}$ (=C=C=), 1700 (C=O); ^1H NMR (400 MHz, $CDCl_3$): δ = 1.10 (t, J = 7.3 Hz, 3H, CH_3), 2.05, 2.07 (s, 3H, CH_3), 2.40 (q, J = 7.3 Hz, 2H, CH_2), 3.74 (s, 3H, OCH_3); ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 12.61, 25.08, 25.23 ($3CH_3$), 24.61 (CH_2), 52.00 (OCH_3), 108.25, 125.84, 154.91, 165.59, 166.80 (4 =C, C=O); EI-MS (70 eV) m/z (%): 166 (100) [M^+].

[13] According to the spectra the compound was pure. Chromatography or distillation led to decomposition.

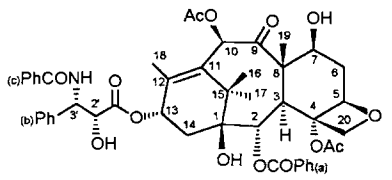
New Fluorescent Water-Soluble Taxol Derivatives**

André A. Souto, A. Ulises Acuña, José M. Andreu, Isabel Barasoain, Miguel Abal, and Francisco Amat-Guerri*

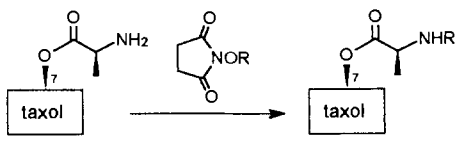
Paclitaxel (taxol, **1**), a natural diterpenoid found in the stem bark of the pacific yew *Taxus brevifolia*,[1] is one of the most promising anticancer agents for a variety of tumors,[2] due to its unique ability to inhibit cell division as well as other interphase processes by stabilizing microtubules.[3] This has stimulated an intense and detailed study in many laboratories of the chemistry and the biochemistry of this exciting antitumor agent. Reports describing the total synthesis of taxol,[4] its chemical modification and structural analysis,[5] and the search for new taxoids with improved pharmacological properties[6] have been published. The basic mechanism of the biological action of taxol is also a research topic of relevance for the development of practical therapies with this drug.[7] We have described the low-resolution solution structures of taxoid-induced microtubules,[8] the assembly of purified GDP-tubulin in the presence of taxoids, and the link between the taxoid binding and microtubule assembly reactions.[9] In the course of these investigations we realized that a fluorescent and water-soluble taxol derivative would be an enormous help, because a) it would allow the direct in vivo study of the target microtubules in tumour cell cultures by fluorescence microscopy, and b) it would provide an extremely useful tool for the study of the molecular mechanisms of taxoid-induced microtubule assembly, as well as for the discovery of other putative taxol targets and clinical diagnostic assays.

The synthesis of fluorescent taxol analogues has been attempted before but with limited success. Thus, Kingston et al.[5a] mentioned a fluorescent taxol derivative with a low-absorbance dansyl group linked through a β-alanyl amino spacer to the 7-position; the bioactivity of this compound has, however, yet to be demonstrated. Another emitting taxoid with a *meta*-amino group at the 2-benzoyl substituent, but less active than the parent drug, has also been briefly reported.[10] Somewhat related to our purpose is the synthesis of photoactivatable taxoids with an azido substituent at the 3′-benzoylamino group,[11] which are useful as photoaffinity labels in the mapping of the taxoid binding site in tubulin.

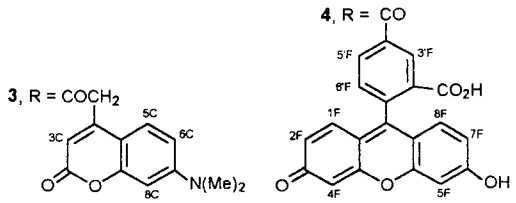
Here we report the synthesis and the characterization of two new bioactive fluorescent taxol derivatives, one of which is much more water-soluble than taxol itself, and provide an example of their use in the first direct visualization of the taxol-microtubule system in cultured cells. As it has been established that modifications at the 7-hydroxyl group do not appreciably affect the biological activity of taxol,[5b, c, 12] we selected this position for the linking of two fluorescent dyes through a spacer containing a free amino group. The synthesis of the 7-ester of taxol with L-alanine (**2**) has been previously described by Mathew et al.[13]



1



2 **3, 4**



during their search for water-soluble taxoids. Starting from taxol (**1**), this synthesis comprises three steps: 1) esterification of both the 7- and 2′-OH groups of the taxol molecule with the NH_2-protected amino acid *N*-(*tert*-butyloxycarbonyl)-L-alanine (BOC-alanine), yielding 2′,7-di(BOC-L-alanyl)taxol; 2) deprotection with formic acid of both amino groups, producing 2′,7-di(L-alanyl)taxol; and 3) selective aqueous hydrolysis of the 2′-ester group, eventually yielding 7-(L-alanyl)taxol (**2**).[14] Amino acid esters of taxol deprotected at the NH_2 group are difficult to purify, because they degrade easily through epimerization and side-chain cleavage during the workup.[13] However, we have found that the crude product **2** can readily react through the free amino group with amine-reactive fluorescent dyes such as the succinimidyl esters of 7-dimethylaminocoumarin-4-acetic acid[15] or of 4′-fluoresceincarboxylic acid, to produce the corresponding conjugates **3** and **4** in good yields. The proper selection of solvent for this reaction is crucial, particularly for compound **4**. The structure of each compound was confirmed by MS-FAB$^+$ and ^{1}H NMR spectroscopy.[16] These two fluorophors were preferred, because they show spectroscopic and photophysical

Taxol was provided by Bristol-Myers Squibb, the owner of the registered trade name. A. A. S. acknowledges a fellowship from CNPq (Brazil). We thank J. Evangelio for the HPLC analysis.

properties that are optimal for our purposes: large absorption coefficients at wavelengths well separated from the protein's intrinsic absorption and matching available laser excitation sources, as well as large emission yield and anisotropy. The synthetic method reported here is of general applicability for the introduction of fluorophors into the taxol molecule and can be used to generate a family of new fluorescent taxol derivatives.

An important limitation in the clinical use of taxol is its low solubility in water (5 μM),[17] and therefore it is not surprising that much effort is aimed at the synthesis of soluble taxol derivatives. This has been achieved by introducing polar or ionic substituents at the 2′ and/or 7-hydroxyl groups, in many cases linked through spacers.[18] In this way water solubilities as high as 0.01 M[18e–e] and, in the case of a derivative with a 7-(polyethylene glycol) chain, 0.1 M[18f] have been demonstrated, although in many cases the biological activity of these drugs, when tested in whole cells, was seriously impaired relative to that of the parent compound **1**. In the case of the fluorescent derivatives **3** and **4**, although the water solubility of the former (approximately 1 μM) is less than that of taxol, that of the bioactive fluorescein taxoid **4** is about two orders of magnitude higher (0.3 mM) than that of the natural drug.

The biochemical and cell biological properties of compound **4** are being compared with those of taxol. Interestingly, preliminary results indicate that compound **4** retains essentially the activity of the parent drug, and that it is able to induce the assembly of otherwise inactive GDP-tubulin into microtubules, a unique characteristic of active taxoids.[9] When this probe is tested in epithelial PtK2 cultured cells, the microtubule system can readily be seen under the fluorescence microscope (Fig. 1).

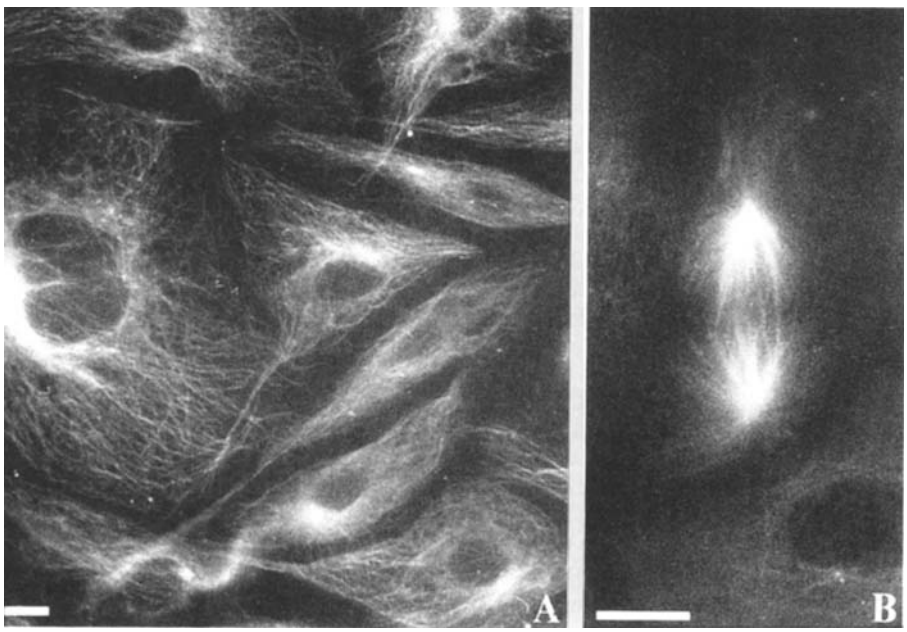

Fig. 1. Image of microtubules in epithelial PtK2 cultured cells with the fluoresceinated taxol derivative **4** [19]. A: A representative view of interphase cells. B: Enlargement of a bright mitotic spindle in a dividing cell. The bar corresponds to 10 μm.

Experimental Procedure

3: To a solution of crude 7-(L-alanyl)taxol **2** (10 mg, 10.8 mmol) and Et_3N (15 μL, 108 mmol) in dioxane (1 mL) was added another solution of succinimidyl 7-dimethylaminocoumarin-4-acetate (5.6 mg, 16.2 μmol) in dioxane (0.5 mL). After stirring for 24 h at room temperature in the dark, the solvent was removed. The crude product **3** was purified by preparative TLC (silicagel, 1:1 ethyl acetate-dichloromethane). Yield 9.5 mg (77%). M.p. 182–185 °C. HPLC purity >96% (C-4 column, 20 to 80% acetonitrile in water as eluent). FAB$^+$-MS (*m*-NBA, *m/z*: 1176.50 ($M + Na^+$), 1154.50 (MH^+, calculated for $C_{63}H_{67}N_3O_{18}$ 1153.44); UV/Vis (MeOH): λ_{max} (ε) = 376 nm (20200 $M^{-1}\,cm^{-1}$); emission (excitation at 376 nm): λ_{max} 462 nm; ^1H NMR (500 MHz, $CDCl_3$, 30 °C, TMS): δ = 8.10 (d, J = 7.3 Hz, 2H, *o*-H of Ph(a)), 7.75 (d, J = 7.3 Hz, 2H, *o*-H of Ph(c)), 7.61 (t, J = 7.5 Hz, 1H, *p*-H of Ph(a)), 7.50 (m, 6H, H-5C, *m*-H of Ph(a), *o*-H of Ph(b), *p*-H of Ph(c)), 7.41 (m, 4H, *m*-H of Ph(b), *m*-H of Ph(c)), 7.35 (t, J = 7.3 Hz, 1H, *p*-H of Ph(b)), 6.98 (d, J = 9.0 Hz, 1H, 3′-N*H*), 6.67 (d, J = 8.9 Hz, 1H, NH of Ala), 6.59 (dd, J = 2.4, 8.9 Hz, 1H, H-6C), 6.48 (d, J = 2.4 Hz, 1H, H-8C), 6.17 (t, J = 8.5 Hz, 1H, H-13), 6.12 (s, 1H, H-3C), 6.09 (s, 1H, H-10), 5.78 (dd, J = 2.4, 9.0 Hz, 1H, H-3′), 5.65 (d, J = 6.7 Hz, 1H, H-2), 5.60 (dd, J = 7.3, 10.4 Hz, 1H, H-7), 4.89 (d, J = 8.9 Hz, 1H, H-5), 4.78 (dd, J = 2.4, 5.1 Hz, 1H, H-2′), 4.68 (m, 1H, CH of Ala), 4.30 (d, J = 8.3 Hz, 1H, H-20a), 4.16 (d, J = 8.3 Hz, 1H, H-20b), 3.88 (d, J = 6.7 Hz, 1H, H-3), 3.65 (s, 2H, CH_2CONH), 3.56 (d, J = 5.1 Hz, 1H, 2′-O*H*), 3.03 (s, 6H, $N(CH_3)_2$), 2.47 (m, 1H, H-6a), 2.36 (s, 3H, 4-CH_3CO), 2.32 (m, 2H, H-14), 2.10 (s, 3H, 10-CH_3CO), 1.84 (m, 1H, H-6β), 1.79 (s, 3H, H-18), 1.76 (s, 3H, H-19), 1.73 (s, 1H, 1-O*H*), 1.19 (s, 3H, H-17), 1.13 (overlapped d, 3H, CH_3 of Ala), 1.12 (s, 3H, H-16).

4: To a solution of crude **2** (10 mg, 10.8 mmol) in DMF (1 mL) and aqueous pH 9 carbonate/bicarbonate buffer (1 mL) was added another solution of succinimidyl fluorescein-4′-carboxylate (7.7 mg, 16.2 mmol) in the same solvent mixture (1 mL). After stirring for 2 h, the solvent was removed, and the crude product **4** was purified by preparative TLC (silica gel, 1:4 ethyl acetate–dichloromethane). Yield 8.0 mg (60%). M.p. >300 °C. HPLC purity >92% (C-18 column, 20 to 80% acetonitrile in water as eluent). FAB$^+$-MS (*m*-NBA), *m/z*: 1305.50 [$M + Na^+$], 1283.50 (MH^+, calculated for $C_{71}H_{66}N_2O_{21}$ 1282.42); UV/Vis (water): λ_{max} 494 nm; (basic MeOH) λ_{max} 499 nm (ε 70000 $M^{-1}\,cm^{-1}$); emission (in water, excitation at 494 nm): λ_{max} 520 nm; ^1H NMR (500 MHz, D_2O, 40 °C, ref. H_2O at δ = 4.61): δ = 8.20 (s, 1H, H-3′F), 8.00 (d, J = 8.0 Hz, 3H, *o*-H of Ph(a), H-5′F), 7.81 (d, J = 7.9 Hz, 2H, *o*-H of Ph(c)), 7.68 (t, J = 8.0 Hz, 1H, *p*-H of Ph(a)), 7.63 (t, J = 7.9 Hz, 1H, *p*-H of Ph(c)), 7.58 (t, J = 8.0 Hz, 2H, *m*-H of Ph(a)), 7.54 (t, J = 7.9 Hz, 2H, *m*-H of Ph(c)), 7.50 (overlapped d, 2H, H-1F, H-8F), 7.49 (s, 2H, H-4F, H-5F), 7.31 (m, 1H, *p*-H of Ph(b)), 7.13 (m, 2H, *m*-H of Ph(b)), 6.69 (d, J = 8.0 Hz, 4H, H-2F, H-7F, *o*-H of Ph(b)), 6.62 (d, J = 8.4 Hz, 1H, H-6′F), 6.34 (s, 1H, H-10), 6.10 (t, J = 9.0 Hz, 1H, H-13), 5.64 (d, J = 7.7 Hz, 1H, H-2), 5.52 (m, 1H, H-7), 5.46 (d, J = 7.1 Hz, 1H, H-3′), 5.04 (m, 1H, H-5), 4.85 (d, J = 7.1 Hz, 1H, H-2′), 4.73 (q, J = 7.5 Hz, 1H, CH of Ala), 4.24 (m, 2H, H-20), 3.79 (d, J = 7.7 Hz, 1H, H-3), 2.64 (m, 1H, H-6a), 2.29 (s, 3H, 4-CH_3CO), 2.19 (s, 3H, 10-CH_3CO), 1.91 (m, 2H, H-6b, H-14a), 1.86 (s, 3H, H-19), 1.78 (s, 3H, H-18), 1.74 (m, 1H, H-14b), 1.45 (d, J = 7.5 Hz, 3H, CH_3 of Ala), 1.16 (s, 6H, H-16, H-17).

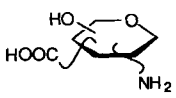
Saccharide–Peptide Hybrids as Novel Oligosaccharide Mimetics**

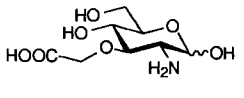
Hans Peter Wessel,* Catherine M. Mitchell, Cinta Maria Lobato, and Gérard Schmid

The important role of carbohydrates in physiological processes has been increasingly recognized in recent years. The establishment of "glycobiology" as a new area of research has evoked growing interest in carbohydrate mimetics. Examples of monosaccharide mimetics are hydroxylated piperidine derivatives, which have been investigated particularly in their role as glycosidase inhibitors.[1] Oligosaccharides have been mimicked by C-disaccharides[2] or C,C-trisaccharides[3] in which the interglycosidic oxygen atom is replaced by a methylene group. In other disaccharide analogues, pyranose rings are coupled directly,[4] through substituted methylene groups,[5] or also through more extended units.[6] We present here novel oligosaccharide mimetics consisting of peptide-linked monomers.

Carbohydrate amino acids such as muramic acid[7] are well known in nature and have also been prepared synthetically, for example to induce defined peptide conformations.[8] Carbohydrate amino acids of type **1** not only contain an intact carbohydrate epitope, but can also undergo reaction to form amide linkages. This procedure has the advantage over oligomerization through glycosidic linkages that no stereoisomers are formed; in addition, methods for the oligomerization of amino acids in solution or on solid phase are well established. The oligomerization of identical or different carbohydrate amino acids, and thus the formation of novel compound libraries, should be feasible. The approach is exemplified[9] here by the synthesis of a tetramer containing normuramic acid (**2**)[10] as a building block.



1



2

This building block is characterized by the free anomeric center, which provides the option of introducing a hydrophobic group to increase protein binding;[11] in the present example we have employed benzyl glycosides. Normuramic acid derivatives suited for oligomerization can be prepared in very good yield; reaction of the known[12] glucopyranoside **3** with a bromoacetic acid ester results in **4**, which can be deblocked to furnish the free acid **5** or, alternatively, amine **6** (Scheme 1).

Coupling to give dimers has been carried out by the diester method (Scheme 2); the known[13] benzyl glucopyranoside **7** was chosen as a terminal building block. The benzylidene protective groups were removed at the dimer level, since the cleavage from higher oligomers proved to be troublesome. The activating reagent of our choice for the highly polar acid derivative **9** was 2-chloro-4,6-dimethoxy-1,3,5-triazine (CDMT);[14] the coupling could be carried out in DMF as a solvent.

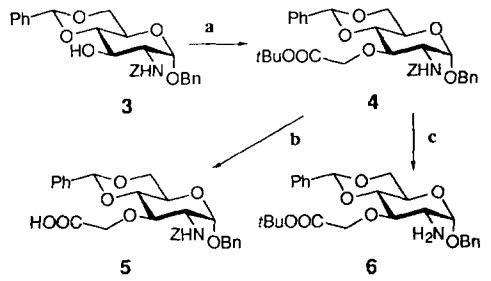
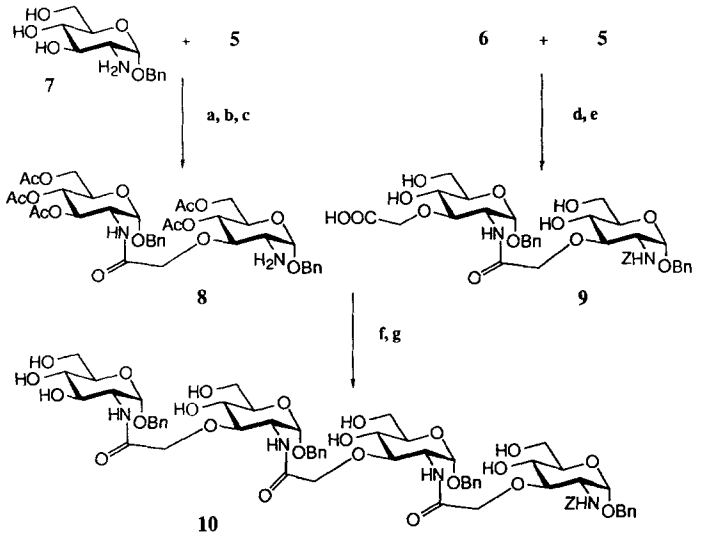


Scheme 1. a) $BrCH_2COOtBu$, KOH, dioxane, 55 °C, 2 h, 91%; b) $KOCMe_3$, THF, H_2O, 0 °C, 2 min, 95%; c) H_2, Pd/C, MeOH/THF, 20 °C, 1.5 h, 96% (Z = benzyloxycarbonyl).



Scheme 2. a) $ClCOOiBu$, NEt3, THF/MeCN, 20 °C, 12 h; Ac_2O, Py, 87%; b) AcOH 80%, 80 °C, 1.5 h; Ac_2O, Py, 20 °C, 18 h, 90%; c) H_2, Pd/C (10%), dioxane/H_2O, 20 °C, 1.5 h, 95%; d) $ClCOOiBu$, NEt_3, THF/MeCN, 20 °C, 30h, 84%; e) AcOH 80%, 80 °C, 1.5 h; 0.3 M NaOMe, dioxane/MeOH, 20 °C, 10 h, 85%; f) CDMT, *N*-methylmorpholine, DMF, 50 °C, 18h; Ac_2O, Py 40%; g) 0.3 M NaOMe, dioxane/methanol, 20 °C, 2.5 h, 81%.

This block synthesis of tetramer **10**[15] demonstrates the comparatively efficient access to a novel class of oligosaccharide mimetics comprising peptide–saccharide hybrids.

Experimental Procedure

To a suspension of **9** (771 mg) in DMF (3 mL), activated with CDMT (176 mg) in the presence of *N*-methylmorpholine (121 µL) for 1.5 h, is added a solution of **8** (789 mg) in DMF (2 mL). After stirring for 18 h at 50 °C the reaction mixture is concentrated and acetylated with Ac_2O/pyridine. The solvent is removed, and the residue chromatographed over silica gel (eluent: ethyl acetate/hexane). Pure product fractions (684 mg, 40%) are deacetylated in a mixture of methanol (6 mL) and dioxane (4 mL) containing 0.3 M sodium methanolate solution in methanol (1 mL). Neutralization with ion exchange resin (Amberlite IR120 H^+) and chromatography over silica gel (ethyl acetate/methanol/water 85/10/5) affords pure amorphous **10** (81%).

Synthesis and X-ray Structure of a Shape-Persistent Macrocyclic Amphiphile

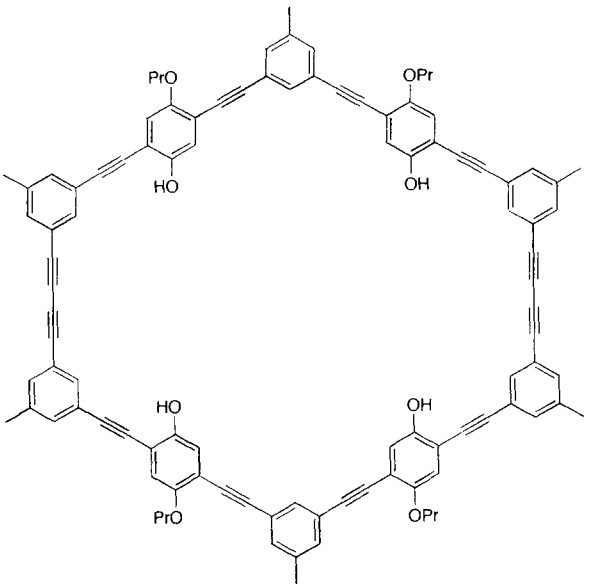
Sigurd Höger* and Volker Enkelmann

The study of shape-persistent, structurally defined macrocycles capable of binding guest molecules within their cavities has attracted a great deal of interest during the last few years.[1] For example, naturally occuring cyclodextrins and their derivatives are able to bind organic substrates through hydrophobic interactions and are also capable of catalyzing chemical reactions of certain substrates.[2] Host molecules having a hydrophobic exterior and a hydrophilic interior have also been synthesized and studied in detail as models for enzymes.[3] A great

[*] Dr. S. Höger, Dr. V. Enkelmann
Max-Planck-Institut für Polymerforschung
Ackermannweg 10, D-55128 Mainz (Germany)
Telefax: Int. code +(6131)379100

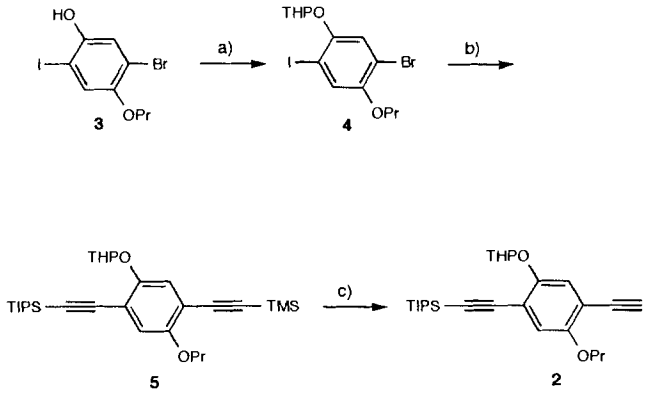
deal of effort has been directed recently towards the preparation of macrocycles with cavities having nanometer dimensions.[4] In addition to their ability to complex large guest molecules, large macrocycles may play an important role in the design of organic zeolites.[5]

Here we describe the synthesis and X-ray structure of **1**, an interesting example of a macrocyclic amphiphile, which has a shape-persistent molecular backbone and hydrophilic and hydrophobic substituents. Our research has been directed towards the synthesis of molecules of defined shape, size, and functionality,[6] in which the polarity of the interior depends on the polarity of the surrounding solvent and/or confined guest molecules.



1

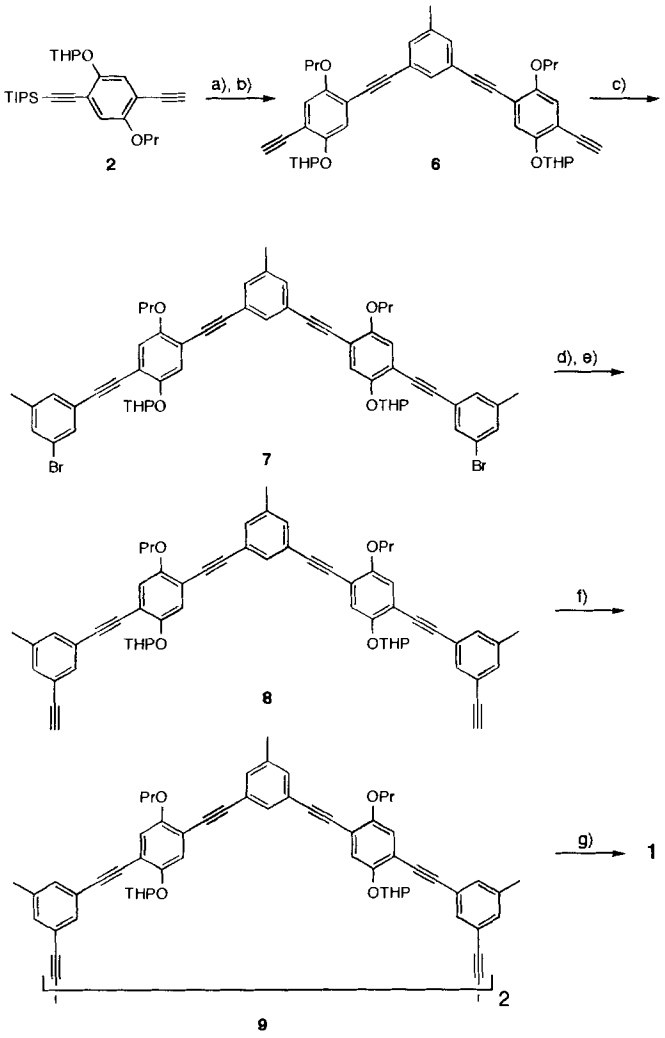
The preparation of large amounts of the macrocycle **1** described here depended on an efficient route to monoprotected diynes of type **2**. Preliminary attempts to obtain the trimethylsilyl (TMS) analogue of **2**, starting from the corresponding diyne, by deprotonation with EtMgBr and trapping of the acetylide with TMSCl led to a statistical mixture of starting material and mono- and bis-TMS-protected compounds. We were not able to separate larger amounts of these materials because of their similar R_f values. Therefore, it was necessary to find an alternative way to **2** (Scheme 1). The key steps in this approach are the selective coupling of a terminal alkyne with an aryl iodide in the presence of an aryl bromide[7] and the site-selective removal of the TMS group in the presence of the triisopropylsilyl (TIPS) group.[8]



Scheme 1. a) 3,4-Dihydro-2*H*-pyran, CH_2Cl_2, H^+, 0 °C 1 h, room temperature (RT), 1 h (90%); b) 1. 1.1 equiv TIPS-acetylene, 4 mol% $[PdCl_2(PPh_3)_2]$, 2 mol% CuI, piperidine, 55 °C, 4 d; 2. 2 equiv TMS-acetylene, 4 d (82%); c) 1 N NaOH, MeOH/THF (1/1), RT, 30 min (96%).

Phenol **3**[9] was first converted into the tetrahydro-(2*H*)-pyranyl (THP) ether **4**, which was coupled successively in a one-pot Pd-catalyzed reaction with 1.1 equivalents of TIPS-acetylene for four days at 55 °C and then two equivalents of TMS-acetylene for an additional four days at the same temperature to yield **5**. Selective removal of the TMS group was accomplished by stirring a solution of **5** in MeOH/THF (1/1) in the presence of a small amount of 1 N aqueous NaOH. This method can be used to prepare **2** in 20–30 g quantities.

Palladium-catalyzed coupling of **2** with 3,5-diiodotoluene, followed by removal of the TIPS protecting group, yielded tetrayne **6** (Scheme 2). Coupling of **6** with 3-bromo-5-iodotoluene gave the dibromide **7**. The much higher reactivity of aryl iodides over aryl bromides prevents, in this case, formation of oligomeric side products. Coupling of **7** with TMS-acetylene, followed by removal of the TMS group, generated the bisacetylene **8**. The



Scheme 2. a) 3,5-diiodotoluene, 4 mol% $[PdCl_2(PPh_3)_2]$, 2 mol% CuI, piperidine, 55 °C, 14 h; b) Bu_4NF, THF, RT, 2 h (88%); c) 3-bromo-5-iodotoluene, 4 mol% $[PdCl_2(PPh_3)_2]$, 2 mol% CuI, piperidine, 55 °C, 14 h (84%); d) TMS-acetylene, 4 mol% $[PdCl_2(PPh_3)_2]$, 2 mol% CuI, piperidine, 55 °C, 4 d; e) 1 N NaOH, MeOH/THF (1/1), RT, 3 h (70%); f) CuCl/$CuCl_2$, pyridine, RT (60–65%); g) CH_2Cl_2/MeOH (2/1), H^+, 1 d (quantitative).

THP-protected macrocycle **9** was obtained by a modified Eglington–Glaser coupling[10] of **8** under high-dilution conditions.[11] The crude product was recrystallized from CH_2Cl_2 to give **9** in 45% yield as slightly yellow crystals, which were unstable when removed from the mother liquor.[12] Acid-catalyzed deprotection of **9** produced compound **1** in nearly quantitative yield.[13] All synthetic procedures outlined can be scaled up such that this new amphiphile is available in gram quantities.

In its synthesis macrocycle **1** is formed as a slightly yellow precipitate, which darkens in the presence of air but is stable under an inert atmosphere. The compound is marginally soluble in most organic solvents but readily soluble in THF, pyridine, pyridine–water mixtures (with only limited amounts of water) at room temperature and in tetrachloroethane at elevated temperatures. Single crystals suitable for X-ray analysis were obtained by recrystallization from pyridine. Like crystals of **9**, these also decompose, although more slowly, when removed from the mother liquor due to loss of solvent. A suitable crystal was therefore embedded in Inertoil and the data collection was performed at 165 K.[14] Under these conditions the crystal was stable for several weeks and a good-quality X-ray structure of **1** was obtained (Figs. 1 and 2). The *R*-value after anisotropic refinement was 0.063.[15]

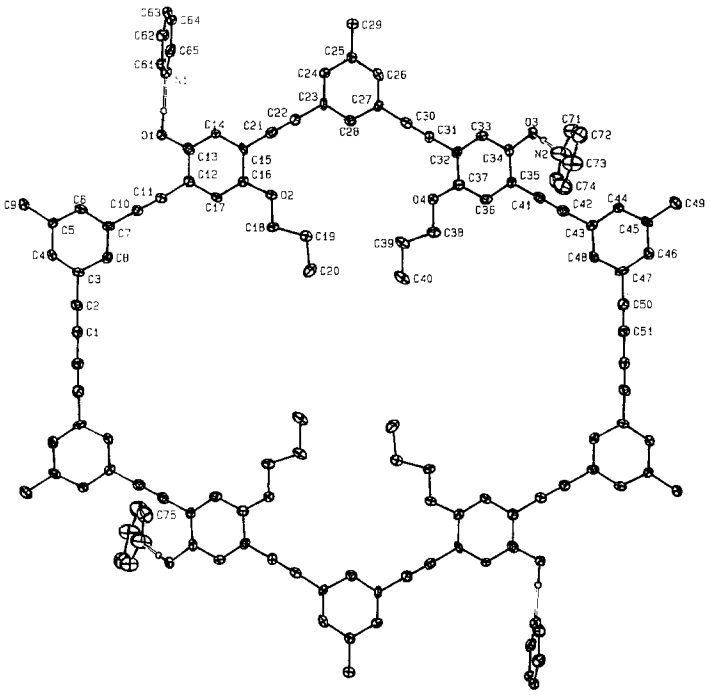


Fig. 1. Crystal structure of **1**; top view of the macrocycle. For clarity only the hydrogen bonded pyridine molecules are shown.

The nonbonding distances of C51–C51′ (2.400(1) nm) and C28–C28′ (2.009(1) nm) give an idea of the size of the interior of the macrocycle. In its crystal structure **1** has a center of symmetry. For each macrocycle eight molecules of pyridine were localized. Four of them form hydrogen bonds (distances: O3···N2: 2.85 Å, O1···N1: 2.72 Å) with the phenolic OH groups on the outside of the ring. The remaining pyridines pack within the crystal lattice without specific interactions with the macrocycle. One of them is localized at the center of symmetry, which leads to orientational disorder. In this case the N and one C atom occupy the same position with a probability of 50%. The macrocycle itself is not planar; the torsion angle around the

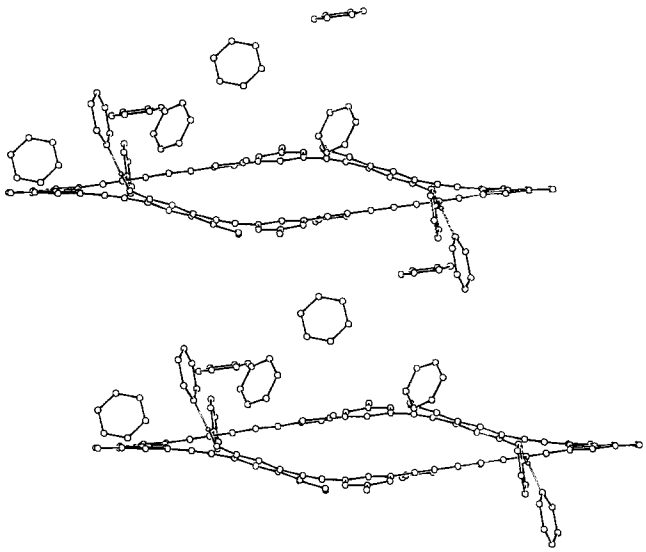

Fig. 2. Crystal structure of **1**; view perpendicular to the stacking axis.

diyne bridge is 6.7°. It is interesting to note that the deformation of the macrocycle is not symmetrical. The section ring(C3...8)/ring(C12...17)/ring(C23...28) is nearly linear, whereas the rest (C30...47) shows a strong bending (C27-C30-C31 173.3(10)°, C30-C31-C32 175.4(10)° deviate significantly from linearity). As a result of this torsion and deformation the arene units C23... C28 and C23′... C28′ are separated by a vertical distance of 3.4 Å within the macrocycle. ^{1}H NMR data at room temperature and above show that in solution the macrocycle is either symmetric or, more probable, in several, rapidly interconverting conformations. It is still unclear whether the propyloxy groups, which are coplanar with their aromatic rings in the crystal structure, prefer to be on the inside of the ring in solution.

Compound **1** is the first example of an amphiphilic shape-persistent macrocycle, in which free rotation about diphenyl acetylene units in the molecule should result in either a more hydrophilic or a more hydrophobic interior. Current studies of **1**, derivatives of **1**, and amphiphilic macrocycles of other size and structure are addressing this issue.

Structure and Magnetic Properties of a Decanuclear Oxoiron(III) Cluster: A Further Step to Understanding Iron Aggregation Processes**

Andrea Caneschi, Andrea Cornia, Antonio C. Fabretti, and Dante Gatteschi*

The hydrolysis of iron salts can be controlled by organic ligands so as to yield soluble molecular aggregates with nanometer dimensions, which can often be isolated in crystalline form and structurally characterized.[1–3] Though some work has been carried out directly in aqueous environments, the use of nonaqueous media with a low water content has led to the synthesis of an unexpected variety of polynuclear clusters.

Our group has isolated cyclic hexairon(III) complexes of general formula **1** (M = Li, Na; HL = Hdbm, Hpmdbm[5]).[1, 4]

$[MFe_6(OCH_3)_{12}L_6]^+$ **1**

These compounds are reliable structural models of OH-bridged polynuclear complexes believed to exist in aqueous solution. In the course of this study Fe_2,[4] Fe_3,[6] and Fe_4[4] complexes were also isolated. Though these complexes contain CH_3O and L ligands, they are structurally reminiscent of the infinite lattices of iron oxides and hydroxides.[6] Here we report the synthesis, crystal structure, and magnetic properties of the novel decairon(III) cluster $\mathbf{2} \cdot x CHCl_3$, which extends the previously

$[Fe_{10}O_4(OCH_3)_{16}(dbm)_6] \cdot x CHCl_3$ $\mathbf{2} \cdot x CHCl_3$

mentioned series of polynuclear compounds and has an inorganic core arising from hydrolysis.

The crystal lattice[7] of $\mathbf{2} \cdot x CHCl_3$ contains decairon clusters **2** and highly disordered chloroform molecules. The structure of **2** is shown in Figure 1. A view of the iron–oxygen core is presented in Figure 2. Cluster **2** can be formally broken down into two pentanuclear subunits related by an inversion center, which are assigned primed and unprimed atom labels in Figures 1 and 2. The iron(III) ions in each subunit are found to lie on a plane (max. deviation 0.08 Å). The intralayer Fe–Fe separations are

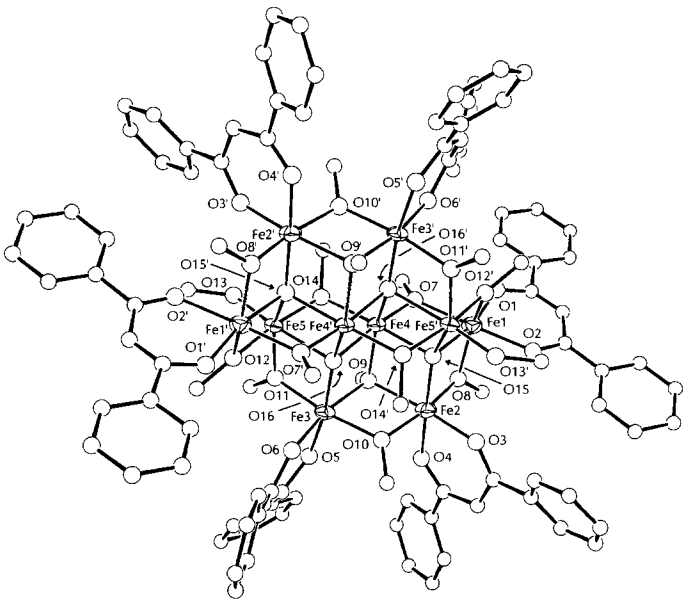

Fig. 1. Structure of **2** (ORTEP representation with atom labels). Hydrogen atoms have been omitted for clarity. An inversion center relates the primed atoms to the unprimed ones. Thermal ellipsoids for iron atoms enclose 35% probability. All the remaining atoms are represented by spheres of arbitrary radius. Relevant distances [Å] and angles [°]: O1-Fe1 2.07(3), O2-Fe1 2.06(3), O7-Fe1 2.00(3), O8-Fe1 2.05(2), O15-Fe1 2.07(3), O12'-Fe1 1.97(3), O3-Fe2 1.98(3), O4-Fe2 2.07(2), O8-Fe2 2.00(3), O9-Fe2 2.15(2), O10-Fe2 2.02(3), O15-Fe2 1.96(2), O5-Fe3 2.00(2), O6-Fe3 2.00(3), O9-Fe3 2.15(3), O10-Fe3 1.99(3), O11-Fe3 2.00(3), O16-Fe3 1.89(2), O7-Fe4 1.94(3), O9-Fe4 2.17(2), O14-Fe4 1.98(2), O15-Fe4 2.04(2), O16-Fe4 2.09(3), O16'-Fe(4) 2.00(3), O16-Fe5 2.20(3), O11-Fe5 1.97(2), O12-Fe(5) 2.05(3), O13-Fe5 1.90(3), O14-Fe5 2.03(3), O15'-Fe5 2.04(2); Fe2-O15-Fe1 99(1), Fe2-O15-Fe5' 148(1), Fe4-O15-Fe5' 99(1), Fe1-O15-Fe5' 100(1), Fe4-O15-Fe1 98(1), Fe4-O15-Fe2 103.7(9), Fe4-O16-Fe3 105(1), Fe4'-O16-Fe3 155(2), Fe4'-O16-Fe4 94(1), Fe4'-O16-Fe5 95(1), Fe3-O16-Fe5 100(1), Fe4-O16-Fe5 96(1), O12'-Fe1-O8 152(1), O16'-Fe4-O9 157(1).

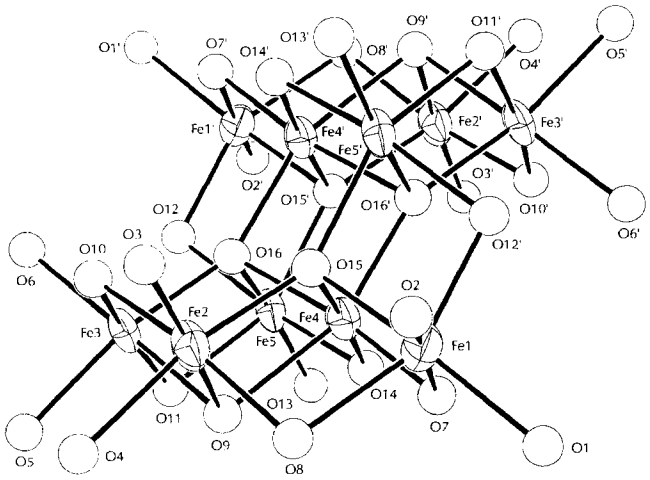

Fig. 2. ORTEP view of the iron–oxygen core of **2**. See legend to Figure 1 for details.

in the range 3.07–3.20 Å, but the shortest Fe–Fe contact occurs between metal ions belonging to different layers (Fe4–Fe4′ 2.99 Å). μ_2-OCH_3, μ_3-OCH_3, and μ_4-O ligands interconnect the iron(III) ions and are key structural elements in the architecture of the core. Notably, the iron atoms Fe4 and Fe5 are bound to CH_3O and O ligands only. The two subunits are connected through O12, O15, O16, and their symmetry equivalents. As a result, severe distortions affect the binding geometry of the μ_4-O ligands and the coordination spheres of Fe1 and Fe4.

It can be easily seen in Figure 2 that the oxygen atoms in each pentanuclear fragment form two layers on each side of the Fe_5 moiety. Planes *a* (O1, O4, O5, O7, O8, O9, O11, O13, O14) and *b* (O2, O3, O6, O10, O12, O15, O16) form a dihedral angle of 7° and are parallel to the best plane through the Fe centers (deviation 5°). The O–O separations within planes *a* and *b* average 3.0(2) and 3.1(2) Å, respectively.

The whole architecture of the iron–oxygen core can be rationalized in a straightforward manner by referring to an idealized overall cubic closest packing (ccp) of oxygen atoms (Fig. 3).[8] The O atoms belonging to planes *b* and *b*′ are thus in the same plane $b + b'$, which now comprises 14 atoms. The iron ions occupy the octahedral holes between plane $b + b'$ and planes *a* and *a*′.

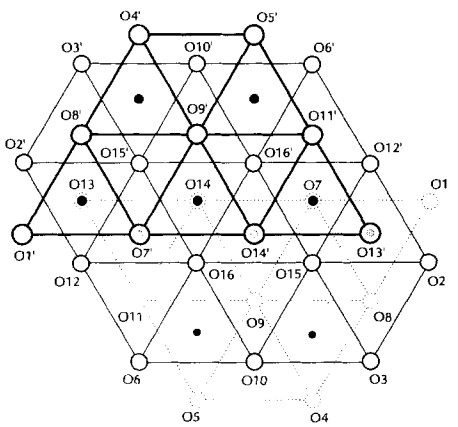

Fig. 3. The arrangement of the oxygen atoms in the core of **2**. Bold, normal, and dotted lines denote the upper (*a*′), middle ($b + b'$), and lower (*a*) layers, respectively. The iron atoms are represented by filled circles. An inversion center relates primed atoms to unprimed ones. Three iron atoms are hidden under O13′, O14′, and O7′.

Two well-defined layers of closest packed oxygen atoms have been identified in a number of alkoxoiron(III) clusters with β-diketonate ligands.[1, 4, 6] The cores of the clusters $[Fe_{17}O_4(OH)_{16}(heidi)_8(H_2O)_{12}]^{3+}$ and $[Fe_{19}O_6(OH)_{14}(heidi)_{10}(H_2O)_{12}]^{+}$,[3, 5] which assemble in water/pyridine, are characterized by an analogous double layer of closest packed oxygen atoms from hydroxo ligands. More than two layers of oxygen atoms displaying cubic closest packing similar to that in **2** are apparent in few polyiron(III) aggregates such as the octahedral clusters $[N(CH_3)_4]_2[Fe_6O(thme)_6]\cdot 4CH_3OH$ and $Na_2[Fe_6O(OCH_3)_{18}]\cdot 6CH_3OH$,[5, 9] and in two mixed-valent dodecairon clusters.[4, 10] Structurally, these compounds resemble the solid-state structures of iron oxides and hydroxides such as FeO (wüstite), and γ-FeOOH (lepidocrocite).[6] The structure of α-FeOOH (göthite) is based on a hexagonal closest packing (hcp) of oxygen atoms. Among the products arising from the methanolysis of Fe^{II}/Fe^{III} in the presence of β-diketonates, complex **2** is unique in that its core contains O ligands of hydrolytic origin.[11] The isolation and characterization of **2** can be of particular relevance to the study of iron(III) aggregation processes. The presence of two layers of metal atoms suggests that formation of **2** may be a result of water-promoted condensation of two pentanuclear clusters having the tentative formula $[Fe_5(OCH_3)_{11}(dbm)_4]$ [Eq. (a)] and the same layered CdI_2-type

$$2[Fe_5(OCH_3)_{11}(dbm)_4] + 4H_2O \longrightarrow [Fe_{10}O_4(OCH_3)_{16}(dbm)_6] + 6CH_3OH + 2Hdbm \quad (a)$$

structure found in triiron(III), tetrairon(III) and hexairon(III) species with the same ligands.

The temperature dependence of the magnetic susceptibility of **2** in an applied field of 1 T has been investigated. χ increases continuously as the temperature is lowered. χT decreases smoothly from 18.8 emu K mol^{-1} at 260 K to 9.0 emu K mol^{-1} at 60 K. Below about 60 K the decrease becomes steeper and χT reaches 1.2 emu K mol^{-1} at 2.7 K. The χT value at 260 K is substantially lower than that calculated for ten uncoupled $S = 5/2$ spins (43.8 emu K mol^{-1}, $g = 2.00$). The Curie–Weiss law is roughly followed for $T > 150$ K ($C = 33.90$ emu K mol^{-1}, $\theta = -210.5$ K). The overall magnetic behavior is therefore indicative of the presence of rather strong antiferromagnetic interactions between the $S = 5/2$ iron(III) centers, with a low value of S in the ground state, probably $S = 0$. Intercluster interactions must play a minor role, since an analysis of the crystal packing revealed no magnetically significant contact between clusters. Given the complexity of the network of possible exchange–coupling interactions, it is not possible at this stage to give any explanation of the nature of the ground state. The fact that no maximum in the susceptibility is observed seems to be indicative of spin frustration effects, in agreement with the numerous triangles present in the spin topology. Some further hints on the nature of the lowest lying spin states can be obtained from the field dependence of the magnetization at 4.2 K. In the range 0–7 T the magnetization increases continuously and almost linearly, with no tendency toward saturation at the highest fields. This points to the presence of a ladder of closely spaced spin states near the ground state, in other words, a solid-state behavior that is presumably related to the compact structure of the core.[12]

Experimental Procedure

Iron(III) chloride (1.622 g, 10 mmol) was allowed to react with Hdbm (2.243 g, 10 mmol, 1 equiv) and 4 equiv of sodium methoxide in 150 mL of methanol (distilled over Mg/I_2 shortly before use). The resulting yellow solid is soluble in organic solvents; prolonged diffusion of methanol vapors in a chloroform solution led to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3423-2717 $ 10.00+.25/0

yellow-orange block-shaped crystals in very low yield (5–10%). After removal of the lattice chloroform molecules in vacuo, the compound analyzed (C, H, Fe) satisfactorily as $[Fe_{10}O_4(OCH_3)_{16}(dbm)_6]$. The crystals are *extremely* air-sensitive; one large individual was sealed in a thin-walled capillary tube containing the mother liquor and was used for an X-ray diffraction experiment.

[7] Crystal data for **2** ($x = 1$): $Fe_{10}C_{107}H_{115}O_{32}Cl_3$, $M_r = 2577.9$, crystal size $0.2 \times 0.3 \times 0.4$ mm, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, triclinic, space group $P\bar{1}$, $a = 15.072(2)$, $b = 18.047(3)$, $c = 29.105(4)$ Å, $\alpha = 91.02(1)$, $\beta = 94.72(1)$, $\gamma = 112.77(1)°$, $Z = 2$, $V = 7264(3)$ Å^3, $T = 298$ K, $5° < 2\theta < 40°$, $\omega - 2\theta$ scan mode, $\rho_{calcd} = 1.18$ g cm^{-3}, $\mu = 10.2$ cm^{-1}, 9740 reflections collected, 9520 independent (4028 with $I > 4\sigma(I)$); Lorentz polarization but no absorption correction applied; direct methods (SHELX86); for 742 parameters $R(F_o) = 0.121$ and $R_w(F_o) = 0.128$; anisotropic thermal parameters for metal and chlorine atoms only; hydrogen atoms treated as fixed contributors in calculated positions with $B(H) = 1.2\ B(C)$. Two centrosymmetric clusters are located around inversion centers at (0, 0.5, 0.5) and (0.5, 0, 0). The metrical parameters of the two clusters show insignificant differences. The relatively high R values reflect the bad diffracting quality of the crystals and the high degree of disorder of the lattice chloroform. One disordered chloroform molecule per cluster was clearly located, but several low-intensity peaks (< 1.2 e Å^{-3}) were still present in the final ΔF map. The given formula weight and the calculated density, which is quite low for this kind of compound, must therefore be taken as lower limits. "Fast Amide Cleavage" or Reproducible, Concentration- and Time-Dependent Aggregation of Anionic and Cationic Surfactants?

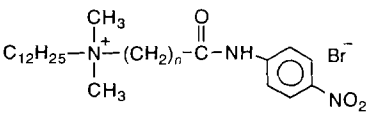
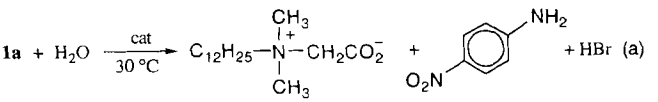
Wilmer K. Fife* and Shanghao Liu

A recent report by Menger and Fei in this journal[1] announced unprecedented, rapid hydrolysis ($t_{1/2} \approx 3$ min, pH 8, 25 °C) of the activated amide **1a**, within aggregates that contained 1.0 equivalent of hexadecanoate ion. We have reinvestigated this experiment in connection with our on-going study of synthetic, enzyme-like, acyl transfer catalysts. We find that the process reported previously as amide hydrolysis [Eq. (a)] is a time-dependent, concentration-dependent aggrega-



1a, $n = 1$
1b, $n = 3$



tion of amide substrate **1**, a cationic surfactant, with hexadecanoate ion, an anionic surfactant. Anion–cation surfactant pairs are known to form molecular aggregates such as bilayer membranes or vesicles at concentrations well below the CMC values (CMC = critical micelle concentrations) of the individual surfactants.[2–4]

Surfactant-enhanced hydrolysis of lipophilic substrates, especially *p*-nitrophenyl esters, has received much attention.[1, 5, 6] The reactivity of carboxamides, however, is widely known to be quite different from that of related *p*-nitrophenyl esters,[1, 7] so discovery of rapid hydrolysis of an amide under mild conditions commands attention.

Reinvestigation of the Menger–Fei experiment in our laboratory with **1a** (2×10^{-5} M) and hexadecanoate (1×10^{-5} and 2×10^{-5} M) gave results similar to theirs (Fig. 1 and Table 1). For example, researchers in both laboratories obtained the value 0.12 min^{-1} for k_{obs} at 1×10^{-5} M hexadecanoate and observed an approximate doubling of the values of k_{obs} and ΔA_{390} (the difference between absorbance values of the reaction mixture at 390 nm for $t = 0$ and ∞) when the hexadecanoate concentration was increased to 2×10^{-5} M. However, we found that no further increases in k_{obs} and ΔA_{390} accompany increases in concentration of both **1a** and hexadecanoate to 3×10^{-5} or 4×10^{-5} M. Additional experiments with dodecyl sulfate or hexadecane sulfonate as the anionic surfactant or replacement of **1a** with the unactivated amide **1b** as the cationic surfactant produced time-dependent increases in A_{390} similar to those described above. Menger and Fei[1] reported no "reaction" for mixtures of **1b** and hexadecanoate ion. Thus, they failed to observe the absorbance increases we repeatedly obtained at

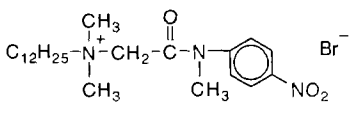
[a] The reaction medium was 2×10^{-5} M in cationic surfactant amide, and buffered at pH 8 (0.05 M in $H_2PO_4^-$/ HPO_4^{2-}). [b] $\Delta A_{390} = A_{390}(t_x) - A_{390}(t_0)$. [c] Value taken from ref. [1]. The "reaction" temperature was 25.0 °C. [d] Concentration: 3×10^{-5} M. [e] Concentration: 4×10^{-5} M.

390 nm with various anion–cation surfactant mixtures (see Table 1). We have no explanation for these differences in results. In contrast to the experiments with **1a** and **1b**, equimolar mixtures of **2**, the *N*-methyl analog of **1a**, and hexadecanoate or dodecyl sulfate give *no increase* in A_{390} over time.



2

Full spectral scans (200–800 nm) of the various surfactant mixtures at different times after mixing yielded significant results (Fig. 2). The mixture of **1a** and hexadecanoate in pH 8 buffer clearly showed a time-dependent, progressive increase in absorbance at 390 nm *and throughout the UV/VIS spectrum* (Fig. 2, scans a → d); however, λ_{max} remained at 310 nm. Addition of concentrated aqueous sodium hydroxide to make the mixture 1.0 M in hydroxide ion caused almost immediate restoration of the original base line; that is, loss of turbidity, disappearance of the absorption band at 310 nm, and appearance of a new band at 360 nm. The band at 360 nm gave way to another at 380 nm ($\varepsilon = 1.4 \times 10^4$ M^{-1}) over several hours. This latter band, (Fig. 2, scan e) is identical to that reported for

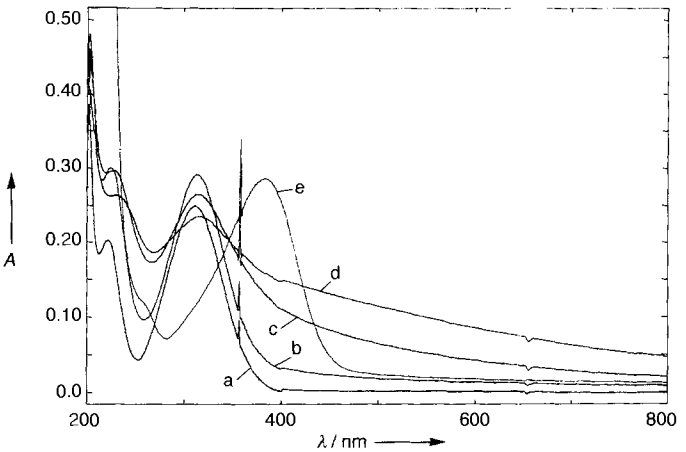


Fig. 2. Scans of A_{390} vs. wavelength [nm] for mixtures equimolar in **1a** and hexadecanoate (2×10^{-5} M) at pH 8, 30 °C in water: a) For **1a** alone; b) within 10 s, c) 3.5 min, d) 40 min after adding hexadecanoate; and e) 7 h after adding NaOH to make mixture 1.0 M in hydroxide ion. The spikes at 360 nm are instrument artifacts.

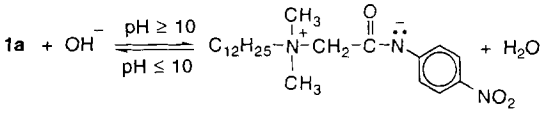
p-nitroaniline[8] and is stable over the pH range 8 to 14. When a fresh mixture of **1a** and hexadecanoate ion was quickly scanned at pH > 12, only one band at $\lambda_{max} = 354$ nm ($\varepsilon = 1.06 \times 10^4$ M^{-1}) was observed. Immediately after acidification of the mixture with hydrochloric acid to pH < 9, a spectrum identical to that in Figure 2a, was obtained. If the mixture of **1a** and hexadecanoate ion is maintained at pH > 12 for several days, its spectrum becomes identical to that in Figure 2e. These observations are consistent with rapid, reversible deprotonation–protonation of **1a** [Eq. (b)], and very slow hydrolysis of it at high



(b)

3

pH. The pK_a value of **1a** in water is 10.42 as determined by spectrometric titration of **1a** ($\lambda_{max} = 310$ nm) and its conjugate base **3** ($\lambda_{max} = 354$ nm). Similar results were obtained with **1b** whose pK_a value is 12.82 with absorption maxima at 310 nm for **1b** and 365 nm for its conjugate base. Results from analogous experiments with **2** show that it not only fails to undergo rapid hydrolysis but it also does not exhibit the acid–base chemistry of amides **1**.

An accurate explanation for the observed behavior of the anion–cation surfactant pairs is complicated by the overlapping spectral bands of *p*-nitroaniline, the expected hydrolysis product of **1a** and **1b**, and zwitterion **3**, the conjugate base of **1a**, as well as time-dependent absorbance increases of the solutions of the anion–cation surfactant pairs themselves. All of these processes, chemical and physical, are marked by increases in absorbance in the 350–400 nm region of the UV/Vis spectrum.

Enzymes remain supreme as catalysts and chemists remain unable to replace them with simple, inexpensive surfactants such as hexadecanoate. However, the present study and the earlier report of Menger and Fei[1] document for the first time the reproducible nature of *a kinetically slow* anionic–cationic surfactant aggregation process. The time and concentration dependence of the process closely resembles that of a true chemical reaction. Finally, we must point out that two rapid stages of surfactant aggregation equilibria are well-known and have received intensive study over the past 20 years.[9]

Experimental Procedure

Amides **1** were synthesized by the reaction sequence: $Br(CH_2)_nCOCl \rightarrow Br(CH_2)_nCONHPhNO_2 \rightarrow [C_{12}H_{25}N^+(CH_3)_2(CH_2)_nCONHPhNO_2]\,Br^-$. After recrystallization from EtOAc/CH_3CN **1a** had a melting point of 208–209 °C and **1b** melted at 156–157 °C. Cationic substrate **2** was obtained as a gel-like, yellow solid from *N*-methyl-*p*-nitroaniline according to the Scheme for **1** above. All compounds had ^1H and ^{13}C NMR spectra and elemental analysis consistent with given formulae. Kinetic data were obtained by following the absorbance of reaction mixtures containing surfactant components at 390 nm (Table 1). All UV/Vis data were obtained with a Hewlett-Packard Model 8450 spectrophotometer. Mixture components were added to the cuvet by pipet and shaken vigorously by hand for 2–3 s. The results were not influenced by the order of addition of mixture components.

A Strategy of "Random Glycosylation" for the Production of Oligosaccharide Libraries**

Osamu Kanie, Frank Barresi, Yili Ding, Jill Labbe, Albin Otter, L. Scott Forsberg, Beat Ernst, and Ole Hindsgaul*

The use of combinatorial chemistry for the rapid, simultaneous synthesis of individual molecules, or mixtures containing a large number of molecules, is considered one of the new frontiers in organic chemistry useful in drug discovery. Tremendous successes were achieved initially in the area of oligopeptides and oligonucleic acids and their analogs, and more recently in the area of small organic molecules.[1]

[**] This work was initiated through a Steacie Fellowship Award to OH by the Natural Sciences and Engineering Research Council of Canada and supported financially by Ciba-CANADA. We thank Ms. Y. Kanie for assistance with the HPLC separations.

Despite their potential importance[2] both for the discovery of carbohydrate-binding receptors and for the identification of new lead compounds (for example, cell-adhesion inhibitors) the generation of oligosaccharide libraries remains unexplored. This is most probably because of the serious logistical difficulties that would be encountered when currently available glycosylation and protecting-group technologies are applied to the conversion of polyvalent monosaccharide residues into useful mixtures of oligosaccharides.

We report here the first results obtained with a new strategy of "random glycosylation" for the production of oligosaccharide libraries. The objective is to produce mixtures of products (typically trisaccharides) that contain all of the possible desired oligosaccharide products and to evaluate the mixture itself in a biological assay. The random-glycosylation strategy is illustrated in Figure 1, where it is contrasted with the classical multistep synthesis[3] of a systematic series of trisaccharides. In this hypothetical example the objective is to prepare all six α-fucosylated βGal(1 → 3)βGlcNAc sequences, some of which are known blood-group antigens[2] that react with antibodies, enzymes, and receptors. The conventional multistep synthesis approach would produce the individual fucosylated trisaccharides as shown. Starting from the unprotected disaccharide acceptor **1** having six free OH-groups, at least 12–15 protecting-group manipulation steps would be required to produce individual acceptors for six independent α-fucosylation reactions. The final removal of protecting groups would require several steps for each trisaccharide, depending on the number of protecting groups used. The protecting-group manipulations would have to be different for every new disaccharide acceptor. For example, if the terminal sugar in **1** is changed from Gal to Glc, the protection schemes would get significantly longer. Chromatographic purification would have to be performed at almost every step in this approach.

In contrast, in the random-glycosylation strategy (Fig. 1) the unprotected disaccharide **1** is directly α-fucosylated with an appropriate donor at low conversion (approximately 30%) to produce predominantly trisaccharides in a single step. These would be separated from unchanged **1** and over-fucosylated tetrasac-

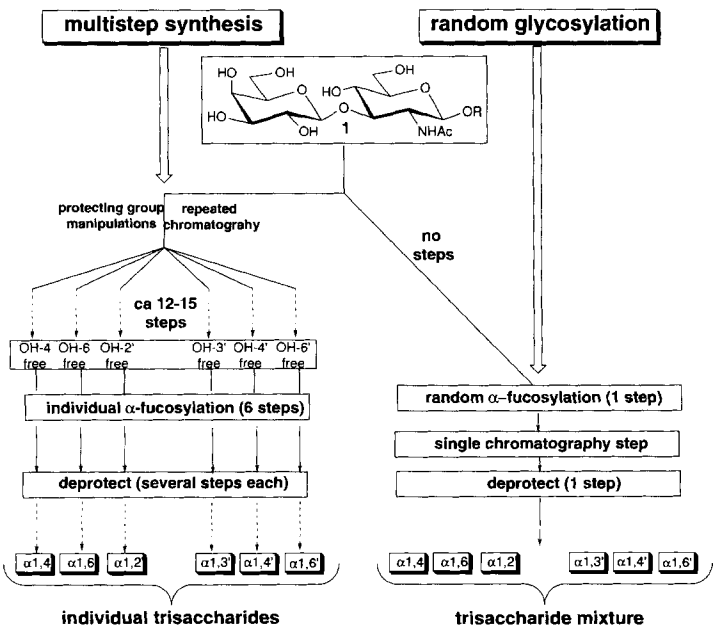

Fig. 1. The contrast between the preparation of the six possible α-fucosides that can be formed from **1** using systematic multistep synthesis and random glycosylation.

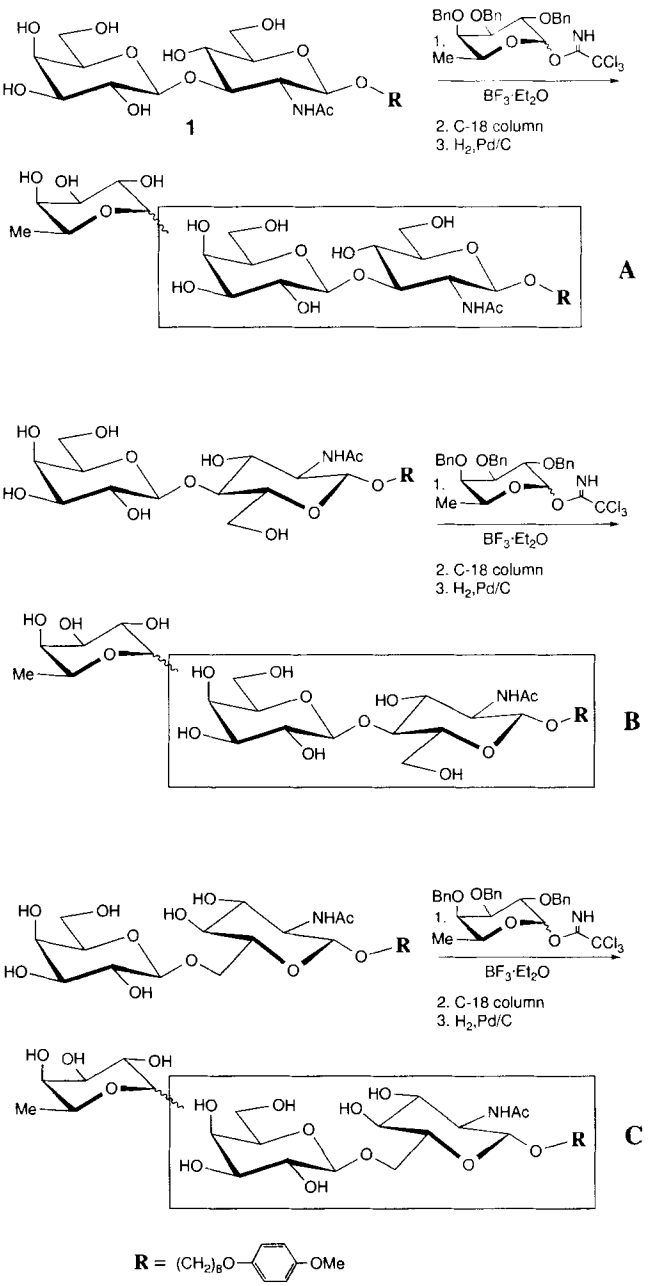
charides in one chromatographic step, and only one step would be sufficient for removal of the protecting groups, which are present only on the donor. Thus, only two chemical steps would be required to produce the same six trisaccharides as in the multistep approach, but these would be present as a mixture. If the oligosaccharide mixture produced by this method showed activity in a biological assay (for example, as an enzyme substrate or as an inhibitor of carbohydrate–protein recognition in cell adhesion), the active component would have to be identified through a classical deconvolution strategy: either through affinity or conventional chromatography followed by structural elucidation or through the systematic multistep synthesis of individual members of the mixture.

If it could be implemented, the random-glycosylation strategy could tremendously accelerate the initial phases of the search for new ligands. For this strategy to be useful, however, at least two criteria must be met: firstly, random-glycosylation reactions must produce mixtures that contain all the possible target oligosaccharides, ideally in nearly equal amounts. Secondly, for the generation of a true library rather than just a mixture of a small number of oligosaccharides, sequential, random glycosylation reactions should be feasible. In this paper, we present the first results demonstrating that the first criterion can indeed be fulfilled, since conditions for α-fucosylation were developed that proceed with near complete lack of regiospecificity.

Random glycosylation of unprotected oligosaccharides requires a polar solvent to dissolve the polyhydroxylated acceptor. DMF or DMF–acetonitrile mixtures were found to be interchangeable. Fucose residues are present only in the α-L configuration in mammalian oligosaccharides, so 2,3,4-tri-*O*-benzyl-activated fucopyranose derivatives were examined as the glycosyl donors. Fucosyl bromide, fluoride, thioglycosides, xanthates, pentenyl glycoside, phosphites, and trichloroacetimidate were evaluated with many of the commonly used activating agents.[3] Only the trichloroacetimidate method developed by Schmidt[3f] reproducibly gave clean reaction products with either BF_3-Et_2O or trimethylsilyl triflate (TMSOTf) as the promoters.

Hydrophobic 8-*p*-methoxyphenoxyoctyl glycosides[4] were used as the disaccharide acceptors for both convenience of isolation[5] and detection by UV absorption. Thus, reaction of βGal(1 → *n*)βGlcNAc-OR (*n* = 3, 4, or 6, R = $(CH_2)_8OC_6H_4pOCH_3$; Scheme 1) with tri-*O*-benzylfucopyranosyl trichloroacetimidate[4f] (2.0 equiv) in the presence of BF_3-Et_2O (0.2 equiv) in DMF (room temperature, 3 h) gave the sought-after complex mixtures in which about 30% of the starting disaccharide acceptors were fucosylated. Separation of acceptors having no benzyl groups from trisaccharides (having three benzyl groups) and tetrasaccharides (having six benzyl groups) could be conveniently accomplished with a step gradient in reverse phase chromatography.[6] Hydrogenolysis of the resulting trisaccharide fraction then gave the product mixture, which was adsorbed onto C-18 resin[5] and then washed with water to remove by-products formed by the degradation of the fucosyl donor. The trisaccharides were then eluted with methanol.

The ^1H NMR spectra of the three trisaccharide mixtures thus obtained are shown in Figure 2. The starting disaccharides contained only β-linkages, so the new doublets (J = 3–4 Hz) appearing in the region δ = 4.7–5.3 are from the 1-H atoms of the added α-fucose residue. The fast atom bombardment (FAB) mass spectra confirmed that the products were the expected trisaccharides with minor contamination by difucosylated tetrasaccharides (due to column overloading). Minor signals from these are also seen in the ^1H NMR spectra. Integration of the 1-H signals revealed that mixtures A and B contained



Scheme 1. Random fucosylation of βGal(1 → *n*)βGlcNAc-OR (*n* = 3, 4, or 6) to produce trisaccharide mixtures A, B, and C. R = $(CH_2)_8OC_6H_4pOCH_3$

about 20% of β-linked fucose, while mixture C contained nearly 5%.

Only mixture A, produced by random fucosylation of βGal(1 → 3)βGlcNAc-OR, was analyzed in detail through separation of the individual isomers by repeated chromatography[7] at both the protected and deprotected stages, followed by ^1H NMR analysis to determine the anomeric configuration of the sugar residues. Methylation analysis[8] was used for assigning the position of attachment of the new fucosyl units.[9] The distribution of the α-fucosylation on disaccharide **1** was thus shown to be 12% α(1 → 4), 22% α(1 → 6), 19% α(1 → 2′), 23% α(1 → 3′), 8% α(1 → 4′) and 16% α(1 → 6′). The statistical distribution would be 17% of each isomer. Figure 2a also shows the presence of the characteristic[10] downfield-shifted quartet ($\delta \approx 4.8$) for 5-H of fucose α-linked to 4-O of the GlcNAc

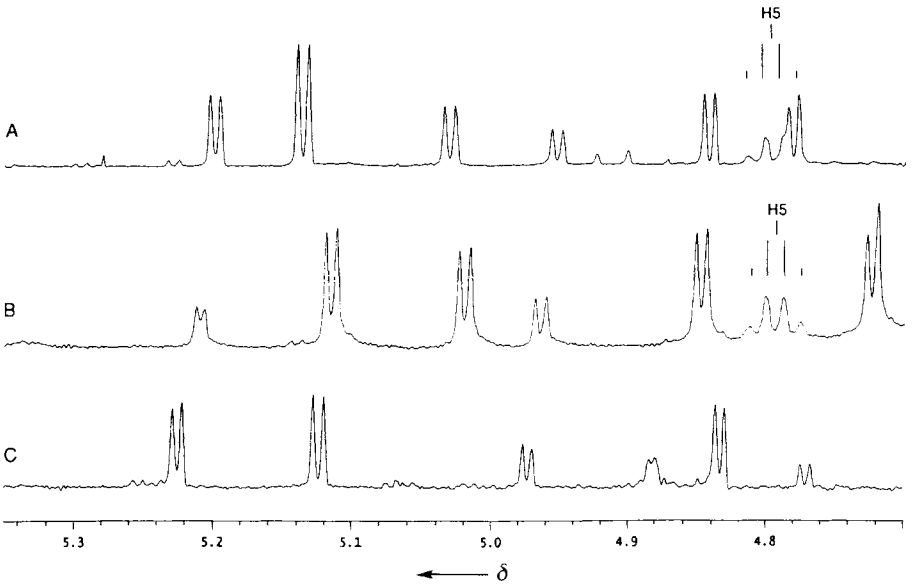


Fig. 2. ^{1}H NMR spectra (500 MHz, 45 °C, CD_3OD) of the α-anomeric region of the mixtures of trisaccharides obtained by random fucosylation of βGal(1 → 3)βGlcNAc-OR (A), βGal(1 → 4)βGlcNAc-OR (B), or βGal(1 → 6)βGlcNAc-OR (C).

residue in the Lewis^a blood group trisaccharide βGal(1 → 3)-[αFuc(1 → 4]βGlcNAc-OR that had formed as 12% of the product mixture.

Mixture B, produced by random fucosylation of βGal(1 → 4)βGlcNAc-OR and processed in the same way, gave a strikingly similar pattern in the ^{1}H NMR spectrum. The identity of the individual isomers was not established, but since only six α-fucosylated trisaccharides are possible, and six α-doublets are seen, they are all present in the mixture in comparable amount. The characteristic[10] 5-H quartet of the α-linked fucose residue in the blood-group Lewis^x structure βGal(1 → 4)-[αFuc(1 → 3)]βGlcNAc-OR is also seen near $\delta = 4.8$. Finally, the ^{1}H NMR spectrum of mixture C, produced by random fucosylation of βGal(1 → 6)βGlcNAc-OR, again confirmed the presence of all six possible α-linked fuco-trisaccharides, none of which has an unusually shifted signal for 5-H of fucose.

Chemical intuition, based on numerous literature precedents[3] demonstrating highly varying hydroxyl-group reactivities, would have predicted that the major products in the above fucosylation reactions would be those formed by glycosylation of the least hindered primary alcohols, 6-OH or 6′-OH. This was clearly not the case in any of the three examples. The greatest difference between the major and the minor α-fucoside, based on integration of the anomeric signals, is only 3:1 and all isomers are present in at least half the expected statistical amount. The mixtures produced were confirmed to contain the kinetic product distribution, since running the reactions at much lower conversion (10%) to trisaccharides, or leaving the reaction for much longer (16 h) yielded the same distribution of products. It is astonishing that all of the OH groups on the acceptor disaccharides showed such a similar reactivity. The explanation is undoubtedly complex but will include the fact that since no protecting groups are used, no added steric hindrance prevents access of the glycosyl donor to any of the OH groups. In addition, the reaction is taking place in DMF, a very polar hydrogen-bond-accepting solvent, and the reacting molecules are very likely involved in very complex arrays of inter- and intramolecular hydrogen bonds.

Further investigations on the random glycosylation of unprotected acceptor oligosaccharides are in progress to evaluate the generality of the method for the production of oligosaccharide libraries. Clearly, sugars other than fucose must be demonstrated to be capable of nonregiospecific glycosylations,[11] and methods for biasing the anomeric configurations of the newly formed linkages must also be developed, so that β-glycosides can be made to dominate if so desired. Meanwhile, even in the present primitive formulation, the random glycosylation strategy successfully generated all 18 possible αFuc(1 → *m*)-[βGal(1 → *n*)βGlcNAc] trisaccharides (*n* = 3, 4, or 6, $n \neq m$) from their unprotected disaccharide precursors[12] in the simplest and fastest manner possible.

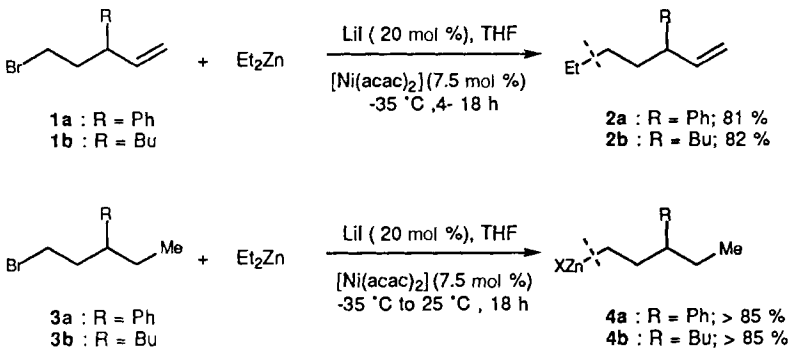
A New Nickel-Catalyzed Cross-Coupling Reaction between sp^3 Carbon Centers**

Arokiasamy Devasagayaraj, Thomas Stüdemann, and Paul Knochel*

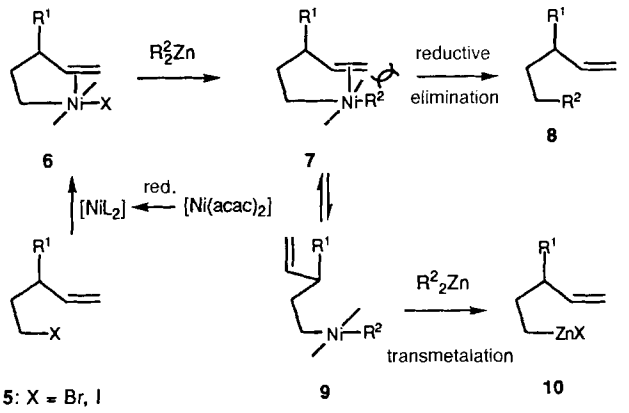
The cross-coupling between sp^3-hybridized C centers is an important method for forming carbon–carbon bonds.[1] The severe limitations of the classical Wurtz reaction led to the development of transition metal catalyzed methods. Copper(I)-catalyzed coupling reactions of organomagnesium halides and organocuprate-mediated substitutions have proven to be especially useful.[2] Yet the drawbacks of these methods such as the necessity of using organomagnesium or organolithium compounds having few functional groups[2, 3] and the need of stoichiometric amounts of copper salts for the formation of cuprates make alternative approaches still desirable. Nickel and palladium catalysts have been used with great success for cross-coupling reactions[4] between unsaturated halides and organotin reagents, but coupling between two sp^3 C centers is almost unknown.[5] Herein, we report a new nickel-catalyzed cross-coupling reaction between sp^3 C centers allowing the synthesis of polyfunctional products.

In the course of studies on radical cyclizations using Et_2Zn,[6] we observed that the unsaturated alkyl bromides **1a** and **1b** undergo a fast coupling reaction with Et_2Zn in the presence of catalytic amounts of $[Ni(acac)_2]$ (7.5 mol%) and LiI (20 mol%) in THF (−35 °C, 4 h for **1a**, 18 h for **1b**) to afford the ethylated products **2a** and **2b**, respectively (81–82% yield; Scheme 1).



Scheme 1.

This behavior was unusual[5, 6] and led us to suspect that the presence of the double bond in the alkyl iodide was responsible for the easy coupling of **1a**,**b**.[7] To test this assumption we prepared the corresponding saturated bromoalkanes **3a** and **3b** and submitted them to the same reaction conditions. No coupling reaction was observed at −35 °C, but when the reaction mixture was allowed to warm to room temperature, a nickel-catalyzed bromine–zinc exchange took place leading to the zinc reagents **4a** and **4b** in over 85% yield as shown by iodolysis experiments.[8] The absence of cross-coupling products shows clearly the importance of the double bond in the alkyl iodide for this reaction pathway. Based on the pioneering work of Yamamoto and Sustmann,[7] a reasonable mechanism was proposed (Scheme 2).



Scheme 2.

The catalytically active species $[L_2Ni^0]$, obtained by the in situ reduction of $[Ni(acac)_2]$, undergoes oxidative addition to the alkyl halide **5** producing a nickel(II) complex **6**, in which the double bond is complexed to the metal center. After ligand exchange with the dialkylzinc compound R^2_2Zn, the new complex **7** is obtained. The coordination of the double bond by nickel removes electron density from the metal and favors therefore the reductive elimination affording the coupling product **8**. However, if the alkyl group R^2 is too large or if the double bond is only weakly coordinated to nickel due to steric interactions with the carbon backbone, then dissociation may occur leading to the nickel(II) complex **9**. Dialkylnickel and -palladium complexes are known to have a low tendency for reductive elimination and prefer to undergo transmetalation with the dialkylzinc compound R^2_2Zn leading to the organozinc derivative **10**.[6a, 8] Low temperatures (−35 °C) favors the cross-coupling reaction, whereas higher temperatures, which promotes the dissociation of the double bond in **7**, lead to mixtures of the cross-coupling product **8** and halogen–zinc exchange product **10**. Also under the reaction conditions described in Scheme 1, a more bulky zinc reagent like dipentylzinc reacts with alkyl bromides leading to mixtures of products **8** and **10**. This may be explained by the steric bulk of the pentyl group in complex **7** or to the lower reactivity of an alkyl bromide in the coupling reaction.

Interestingly, replacing the $[Ni(acac)_2]$ catalyst by $[PdCl_2(CH_3CN)_2]$ or related palladium(II) complexes leads only to the bromine–zinc exchange products—an indication that nickel complexes are better catalysts for the cross-coupling reaction.

The mechanistic picture shown in Scheme 2 was very useful for improving the synthetic scope of the reaction. After much experimentation we found reaction conditions for the efficient cross-coupling of a wide range of diorganozinc compounds with primary unsaturated alkyl iodides (Schemes 3, 4 and Table 1). Thus the reaction of dialkylzinc **11**, prepared either by iodine–zinc exchange[9] or by boron–zinc exchange,[10] with an unsaturated alkyl iodide **12** bearing a double bond either in position 4 or 5 in the presence of $[Ni(acac)_2]$ (7–10 mol%) in THF/NMP

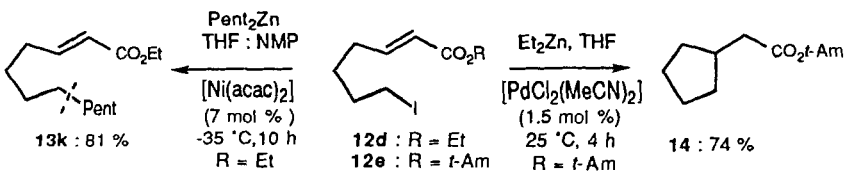
[a] Pent = pentyl, Piv = pivaloyl, TMS = trimethylsilyl. [b] Yield of analytically pure products. [c] Yield for the reaction conducted in THF in parentheses.



Scheme 4. *t*-Am = *t*-amyl = $C(CH_3)C_2H_5$, Pent = $(CH_2)_4CH_3$.

(2/1) at −35 °C provides a range of polyfunctional cross-coupling products **13** in good yields (65–90%). The use of NMP as cosolvent dramatically accelerates the reaction (3 h reaction time instead of 24 h in THF for the formation of **13a**) and improves the yields (entries 1, 3, and 4 of Table 1). The presence of an electron-withdrawing substituent like an ester group at the double bond also has a beneficial effect, since it strengthens the nickel–olefin bond (entries 5–10). The structure of the nickel-olefin complex is also important, and the alkyl iodides **12a–c** ($n = 3$) react faster than the corresponding alkyl iodide **12d**, in which the double bond is at a more remote position ($n = 4$). It is remarkable that the coupling reaction[11] proceeds at temperatures as low as −35 °C, since the related Negishi coupling reaction[4c, d, 12] of alkylzinc halides with alkenyl and aryl iodides in the presence of a palladium catalyst occurs only at or above room temperature. The difference in chemoselectivity between the nickel and palladium complexes is best shown in Scheme 5. Thus the reaction of **12d** with $Pent_2Zn$ in the presence of $[Ni(acac)_2]$ in THF/NMP (2/1) furnishes the coupling product **13k**, whereas in the presence of $[PdCl_2(CH_3CN)_2]$ as catalyst (1.5 mol%) and Et_2Zn in THF, the cyclization product **14** is obtained as sole product in 74% yield.

We have shown that the presence of a remote double bond in a primary alkyl iodide enables the first selective nickel-catalyzed cross-coupling reactions between sp^3 C centers, because the intramolecular complexation of the double bond on the nickel center favors the reductive elimination. Further studies to determine the synthetic scope of the method and other extensions of the chemistry of nickel–olefin complexes are currently underway in our laboratories.

Experimental Procedure

General procedure: Preparation of **13h** (entry 8 of Table 1): A 50 mL two-necked flask equipped with an argon inlet and a rubber septum was charged with $[Ni(acac)_2]$ (116 mg, 0.45 mmol, 7.5 mol%). After the flask was cooled to −40 °C, THF (2.5 mL), NMP (1.5 mL), and **12d** (1.69 g, 6 mmol, 1.0 equiv) were added successively by syringe. The reaction mixture was cooled to −78 °C. Then a solution of bis(5-acetoxypentyl)zinc [9] (3.88 g, 12 mmol, 2 equiv) in THF (2 mL) prepared from 5-iodopentyl acetate (6.14 g, 24 mmol) and Et_2Zn by an iodine–zinc exchange reaction was slowly added. The reaction mixture was allowed to warm up to −35 °C and was stirred for 15 h at this temperature. Excess dialkylzinc was quenched with saturated aqueous NH_4Cl solution. After the usual workup the resulting crude oil obtained after evaporation of the solvents was purified by chromatography (hexanes/ether 20/1 to 5/1) affording **13h** (1.33 g, 4.7 mmol, 78% yield) as a colorless oil.

Water-Soluble Dendritic Iron Porphyrins: Synthetic Models of Globular Heme Proteins**

Peter J. Dandliker, François Diederich,* Jean-Paul Gisselbrecht, Alain Louati, and Maurice Gross*

Current interest in dendritic polymers stems from their unique structural properties and potential utility. Through judicious choice of branched building blocks and functional group chemistry, one can precisely control their shape, dimensions, density, polarity, flexibility, and solubility.[1] Dendrimers with functional components located on the exterior surface,[2] within the dendritic branches,[3] and at the interior core[4] are of particular interest since they exploit dendritic topology to modify the physical and chemical behavior of those components, giving rise to new materials with desirable properties.[5]

Functional dendrimers could also serve as synthetic models of globular enzymes. Dendritic mimics of heme-containing proteins such as cytochrome c are particularly intriguing targets, since their study could help clarify the reasons for the large changes in redox potential of the Fe^{III}/Fe^{II} couple observed in the biological systems.[6, 7] To systematically investigate the influence of peptide-like superstructure on iron porphyrin redox potentials in a purely synthetic system, we designed and synthesized the first and second generation dendrimers **1·FeCl** and **2·FeCl**, which contain an iron porphyrin core unit, and studied their redox behavior in both CH_2Cl_2 and aqueous solution. We found that as the dendritic structure progresses from being relatively open in **1·FeCl** to densely packed in **2·FeCl**, the redox potential for the Fe^{III}/Fe^{II} couple, measured in water, becomes 420 mV more positive. We attribute this substantial potential shift to the structured hydrophobic microenvironment created by the dendritic branches around the core iron porphyrin of the higher generation.

The dendritic iron porphyrins **1·FeCl** and **2·FeCl** were synthesized from the zinc derivatives **3** and **4**, respectively.[8] Activation of the carboxylic acid end groups in **3** and **4** with *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBT) in triethyleneglycol monomethyl ether as solvent, followed by preparative gel permeation chromatography (GPC), yielded **1·Zn** and **2·Zn** in 92 and 89% yield, respectively (Schemes 1 and 2, Table 1).

Table 1. Selected physical and spectroscopic data of compounds **1·FeCl**, **2·Zn**, **2·H_2**, and **2·FeCl** [a].

1·FeCl: Viscous brown oil. FT-IR ($CHCl_3$): $\tilde{\nu}$ = 1728, 1615 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = −0.8–5.9 (br. signals, about 280 H), 13.13 (bs, 4H, β_2-H), 15.24 (bs, 4H, β_1-H); porphyrin *meso* H (2H) and aryl H (6H) not visible; UV/Vis ($CHCl_3$): λ_{max} (ε) = 375 (sh, 57500), 409 (107000), 460 (sh, 11000), 504 (13200), 572 (5500), 644 (4400); FAB-MS: *m/z* (%): 3955.2 (100, $[M-Cl]^+$, $^{12}C_{182}{}^{13}C_2H_{296}FeN_8O_{80}$ requires 3955.9).

2·Zn: Viscous red oil. FT-IR ($CHCl_3$): $\tilde{\nu}$ = 1733, 1668 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.12–1.42 (br.m, 8H, $OCH_2CH_2CH_2CH_2$), 1.71–1.83 (br.m, 8H, $OCH_2CH_2CH_2CH_2$), 2.45 (br.s, 24H, OCH_2CH_2, first generation), 2.44–2.60 (br.m, 72H, OCH_2CH_2, second generation), 3.24–3.75 (m, 660H, dendritic ether and triethyleneglycol monomethyl ether protons), 3.80 (br.s, 8H, $OCH_2CH_2CH_2$), 4.14 (br.s, 72H, $CO_2CH_2CH_2$), 6.14–6.26 (br.s, 16H, NH), 7.06 (δ, J = 7.5 Hz, 4H, *m*-aryl H), 7.69 (t, J = 7.5 Hz, 2H, *p*-aryl H), 8.94 (d, J = 3.9 Hz, 4H, β_2-H), 9.26 (d, J = 3.9 Hz, 4H, β_1-H), 10.07 (s, 2H, *meso* H); ^{13}C NMR (125 MHz, $CDCl_3$, 298 K): δ = 23.8, 31.8, 34.6, 36.8, 58.7, 59.6 (2×), 63.4, 66.5 (2×), 67.3, 68.8 (2×), 68.9, 70.2, 70.3 (2×), 71.6, 104.5, 105.1, 111.6, 120.7, 129.8, 131.0, 131.5, 148.7, 150.2, 159.5, 170.9, 171.3, 172.0; UV/Vis ($CHCl_3$): λ_{max} (ε) = 394 (sh, 34700), 415 (468000), 545 (16200); MALDI-TOF-MS (positive ion, linear mode): *m/z*: 11330 ($[M+Na]^+$, $^{12}C_{502}{}^{13}C_6H_{884}N_{20}O_{248}{}^{66}Zn$ + Na requires 11329), and fragments for loss of $C[CH_2OCH_2CH_2CO_2(CH_2CH_2O)_3CH_3]_3$.

2·H_2: Viscous dark purple oil. FT-IR ($CHCl_3$): $\tilde{\nu}$ = 1733, 1667 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = −3.13 (br.s, 2H, pyrrole NH), 1.23–1.46 (br.m, 8H, $OCH_2CH_2CH_2CH_2$), 1.68–1.85 (br.m, 8H, $OCH_2CH_2CH_2CH_2$), 2.35 (br.s, 24H, OCH_2CH_2, first generation), 2.49 (br.s, 72H, OCH_2CH_2, second generation), 3.20–3.70 (m, 660H, dendritic ether and triethyleneglycol monomethyl ether protons), 3.79 (br.s, 8H, $OCH_2CH_2CH_2CH_2$), 4.14 (br.s, 72H, $CO_2CH_2CH_2$), 6.06–6.18 (br.s, 16H, amide NH), 7.05 (d, J = 8.0 Hz, 4H, *m*-aryl H), 7.68 (t, J = 8.0 Hz, 2H, *p*-aryl H), 8.92 (d, J = 4.5 Hz, 4H, β_2-H), 9.25 (d, J = 4.5 Hz, 4H, β_1-H), 10.12 (s, 2H, *meso*-H); ^{13}C NMR (75 MHz, $CDCl_3$, 298 K): δ = 23.6, 31.8, 34.7, 37.0, 58.9, 59.7 (2×), 63.5, 66.6 (2×), 67.4, 68.9 (2×), 69.0, 70.4 (3×), 71.8, 104.1, 105.3, 111.5, 118.9, 130.5, 131.1 (2×), 144.7, 147.5, 159.5, 170.9, 171.4, 172.1; UV/Vis ($CHCl_3$): λ_{max} (ε) = 391 (sh, 67600), 410 (331000), 504 (11500), 540 (5400), 577 (5000), 630 (500); MALDI-TOF-MS (positive ion, linear mode): *m/z*: 11260 ($[M+Na]^+$, $^{12}C_{502}{}^{13}C_6H_{886}N_{20}O_{248}$ + Na requires 11265), and fragments for successive loss of $C[CH_2OCH_2CH_2CO_2(CH_2CH_2O)_3CH_3]_3$.

2·FeCl: Viscous brown oil. FT-IR ($CHCl_3$): $\tilde{\nu}$ = 1738, 1667 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$, 298 K): extremely broad spectrum with aliphatic signals between $\delta \approx$ 1.7 and 4.5, 13.22 (br.s, 4H, β_2-H), 15.25 (br.s, 4H, β_1-H); porphyrin *meso* H (2H) and aryl H (6H) not visible; UV/Vis ($CHCl_3$): λ_{max} (ε) = 375 (sh, 69200), 415 (95500), 461 (sh, 11700), 505 (10700), 551 (7100), 645 (3100); MALDI-TOF-MS (positive ion, linear mode): *m/z*: 11299 ($[M-Cl]^+$, $^{12}C_{502}{}^{13}C_6H_{884}FeN_{20}O_{248}$ requires 11296), and fragments for successive loss of $C[CH_2OCH_2CH_2CO_2(CH_2CH_2O)_3CH_3]_3$.

[a] The matrices for FAB-and MALDI-TOF-MS were 3-nitrobenzyl alcohol and 2,4,6-trihydroxyacetophenone, respectively.

Demetalation of **1·Zn** and **2·Zn** with HCl in $CHCl_3$ gave the corresponding dendritic free-base porphyrins **1·H_2** and **2·H_2** in 93 and 88% yield, respectively. The Zn–H exchange was confirmed by the appearance of ^1H NMR signals at about δ = −3.13 (pyrrole NH), the appearance of four bands in the visible absorption spectrum characteristic of metal-free porphyrin, and correct mass spectral data (Table 1). Heating **1·H_2** or **2·H_2** at reflux in THF with $FeCl_2$ followed by removal of the solvent, re-dissolution in $CHCl_3$, and extensive washing with water provided **1·FeCl** and **2·FeCl** in 85 and 80% yield, respectively. The successful introduction of the metal ion was con-

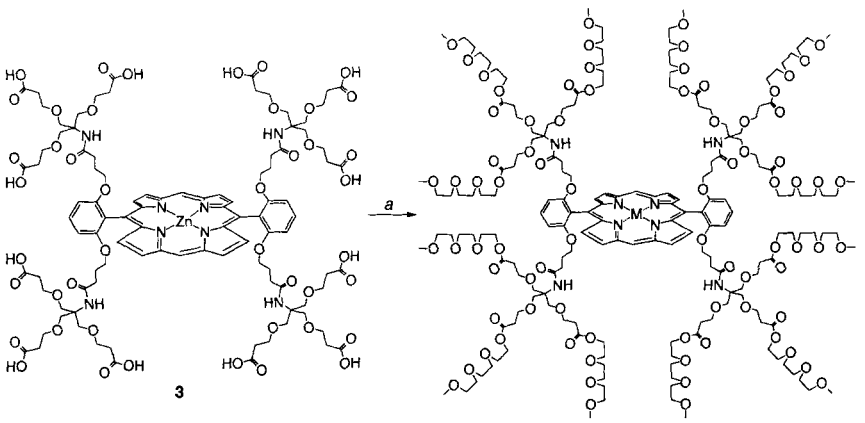
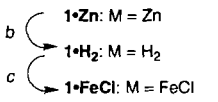
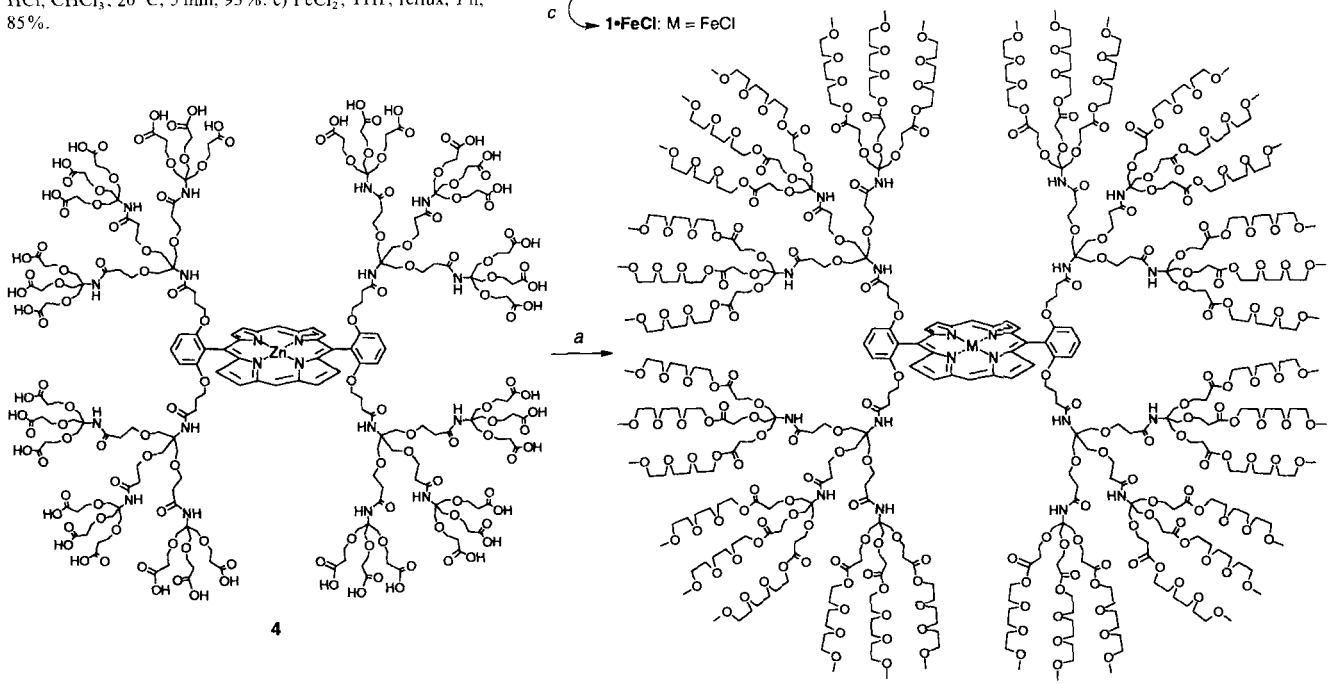
[**] This work was supported by a grant from the research council of the ETH Zürich and the U. S. Office of Naval Research.

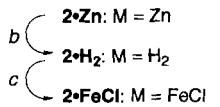


Scheme 1. Synthesis of dendritic porphyrins **1·Zn**, **1·H$_2$**, and **1·FeCl**. a) DCC, HOBT, collidine, triethyleneglycol monomethyl ether, 0 °C to 20 °C, 2 days, 92%. b) 0.4 M aq. HCl, $CHCl_3$, 20 °C, 5 min, 93%. c) $FeCl_2$, THF, reflux, 1 h, 85%.



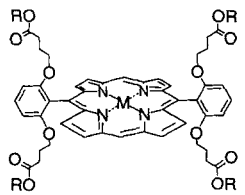
in organic solvents.[8, 10] In particular, Momenteau and co-workers synthesized bridged "basket-handle" iron porphyrins in which the bridging chains, containing ether or amide groups, were linked directly over the metalloporphyrin's π-faces.[10] The amide-containing chains sterically hindered the approach of solvent and counterions to the porphyrin and also exerted a marked through-space electrostatic effect, thus shifting the half-wave potential of the Fe^{III}/Fe^{II} couple to more positive values. Given the steric bulk of the dendritic shell and the high local density of polar amide groups near the porphyrin ring in **1·FeCl** and **2·FeCl**, we expected similar effects to operate in these systems.





Scheme 2. Synthesis of dendritic porphyrins **2·Zn**, **2·H$_2$**, and **2·FeCl**. a) DCC, HOBT, collidine, triethyleneglycol monomethyl ether, 0 °C to 20 °C, 2 days, 89%. b) 0.4 M aq. HCl, $CHCl_3$, 20 °C, 5 min, 88%. c) $FeCl_2$, THF, reflux, 1 h, 80%.

firmed by the characteristic UV/Vis spectrum for iron(III) porphyrins, ^{1}H NMR signals for the β-pyrrole protons at about $\delta = 13.2$ and 15.2, and the expected mass spectral data (Table 1). All dendritic porphyrins **1** and **2** are viscous oils that dissolve remarkably well in solvents in the polarity range between water ($E_T(30) = 63.1$) and *p*-xylene ($E_T(30) = 33.1$).[9] Control compound **6·FeCl** without dendritic branches was synthesized from the free-base porphyrin **5** in a similar manner.



5: R = H, M = H_2

6·FeCl: R = $CH_2(CH_2OCH_2)_2CH_2OCH_3$, M = FeCl

The effects of bulky superstructure on the electrochemical properties of porphyrins have been studied extensively

Cyclic voltammetry in CH_2Cl_2 (glassy carbon electrode, 0.1 M Bu_4NPF_6 as supporting electrolyte) showed irreversible waves for the Fe^{III}/Fe^{II} couple in **6·FeCl**, typical of Fe^{III} porphyrin chlorides, and consistent with equilibrated dissociation of the chloride counterion from the metal ion during electroreduction.[11] In contrast, both **1·FeCl** and **2·FeCl** showed reversible waves for the Fe^{III}/Fe^{II} couple at -10 and $+70$ mV vs. the standard calomel electrode (SCE), respectively (Table 2).

Both **6·FeCl** and **1·FeCl** showed waves for one-electron oxidation at $+1.06$ V, and waves for one-electron reduction from Fe^{II} to Fe^{I} at -1.29 and -1.27 V, respectively, typical values for iron porphyrins (Table 2). The potential difference between the oxidation at $+1.06$ V and reduction to Fe^{I} was within the normal value of 2.25 ± 0.15 V reported for other metalloporphyrin complexes.[12] Compound **2·FeCl** underwent reduction from

Table 2. Half-wave potentials of the dendritic iron porphyrins in CH_2Cl_2 [a].

Porphyrin	$E^{1/2}(Fe^{II}/Fe^{I})$	$E^{1/2}(Fe^{III}/Fe^{II})$	$E^{1/2}_{ox}$
6·FeCl	− 1.29 [b]	− 0.59 [c, d] + 0.12 [c, e]	+ 1.06 [b]
1·FeCl	− 1.27 [c]	− 0.01 [f]	+ 1.06 [b]
2·FeCl	− 1.46 [c]	+ 0.07 [f]	–

[a] Redox potentials in CH_2Cl_2 determined by cyclic voltammetry (CV): $E^{1/2}$ (approximated by $(E^a_p + E^c_p)/2$) in V vs. SCE; supporting electrolyte 0.1 M Bu_4NPF_6; glassy carbon working electrode, scan rate = 0.1 Vs^{-1}, T = 293 K. [b] Quasi-reversible transfer. [c] Irreversible transfer, peak potential from CV. [d] Cathodic peak potential. [e] Anodic peak potential. [f] Reversible transfer.

Fe^{II} to Fe^{I} at −1.46 V, that is, at a 170 mV more negative potential than the reference compound **6·FeCl**.

In order to assign the observed cyclic voltammetric signals to particular redox reactions of the core iron porphyrin, spectroelectrochemical studies were performed at a platinum grid working electrode in CH_2Cl_2 with 0.1 M Bu_4NPF_6 as supporting electrolyte. Compound **1·FeCl** exhibited well-defined isosbestic points on the first reduction step, and the absorption spectrum remained characteristic of an iron porphyrin with only small changes in the position of the Soret and Q bands. Following the second reduction step, the spectrum remained typical for the metalloporphyrin, displaying red shifts of 20 nm for the Soret band and 16 nm for the Q band. This behavior is characteristic of successive metal-centered reductions from Fe^{III} to Fe^{II} and Fe^{I} porphyrins, respectively. Compound **2·FeCl** exhibited analogous behavior, which confirmed that the first reduction step corresponded to the Fe^{III}/Fe^{II} couple. The presumed generation of an Fe^{I} species during the second reduction step at −1.46 V vs. SCE could not be monitored, since it occurred too close to the accessible cathodic potential limit of the solvent.

To compare the redox behavior of the dendritic iron porphyrins to that of heme proteins more directly, cyclic voltammetric studies in water with 0.1 M Et_4NClO_4 as the supporting electrolyte were carried out. For solubility reasons, only compounds **1·FeCl** and **2·FeCl** could be studied in aqueous solution. They both exhibited irreversible one-electron oxidation waves at the glassy carbon electrode at + 0.97 and + 1.09 V vs. SCE, respectively (Table 3). Compounds **1·FeCl** and **2·FeCl** also exhibited two reductions, the second of which was irreversible and occurred at the same potential of −1.26 V vs. SCE. In contrast, the increased density of the dendritic superstructure in **2·FeCl** relative to **1·FeCl** caused the potential of the fully reversible Fe^{III}/Fe^{II} couple of **2·FeCl** to shift from −0.23 V to + 0.19 V and thus to become 420 mV more positive.

Table 3. Half-wave potentials of the dendritic iron porphyrins in H_2O [a].

Porphyrin	$E^{1/2}(Fe^{II}/Fe^{I})$	$E^{1/2}(Fe^{III}/Fe^{II})$	$E^{1/2}_{ox}$
1·FeCl	− 1.26 [b]	− 0.23 [c]	+ 0.97 [b]
2·FeCl	− 1.26 [b]	+ 0.19 [c]	+ 1.09 [b]

[a] Redox potentials in H_2O determined by cyclic voltammetry (CV): $E^{1/2}$ (approximated by $(E^a_p + E^c_p)/2$) in V vs. SCE; supporting electrolyte 0.1 M Et_4NClO_4; glassy carbon working electrode, scan rate = 0.1 Vs^{-1}, T = 293 K. [b] Irreversible transfer, peak potential from CV. [c] Reversible transfer.

These results show that environmental polarity strongly influences the redox potential of electrochemical reactions that occur at the heme metal center. In CH_2Cl_2, the iron porphyrins in both the more open **1·FeCl** and the more densely packed **2·FeCl** experience similar microenvironments; hence similar potentials for the Fe^{III}/Fe^{II} couple are measured. In water, the relatively open dendritic branches of **1·FeCl** do not impede aqueous solvation of the iron porphyrin, whereas the densely packed dendritic superstructure of **2·FeCl** significantly reduces contact between the heme and external solvent, destabilizing the oxidized, more charged state and shifting the redox potential to a more positive value.

The remarkable potential difference between **2·FeCl** and **1·FeCl** is similar to that (about 300 mV) found between cytochrome c and a similarly ligated, more solvent-exposed cytochrome c heme octapeptide.[13] Despite resemblance in globular shape and dimensions between **2·FeCl** and cytochrome c,[14] as suggested by computer modeling, further analogies between dendritic and biological system are currently limited by the difference in axial ligation to the heme iron. Whereas the protein uses a histidine-N atom and a methionine-S atom, the nature of the axial ligands of the dendrimer in water is different but remains to be determined. By covalently inserting the natural N- and S-ligands into dendritic iron porphyrins, their model character for cytochrome c could be further extended in future work.

A New Strategy in Heterogeneous Catalysis: The Design of Cortex Catalysts

Manfred T. Reetz,* Stefan A. Quaiser, Rolf Breinbauer, and Bernd Tesche

The majority of chemical transformations in industry are catalytic processes, more than 75% of which are carried out using heterogeneous catalysts.[1] A large group of heterogeneous catalysts are the impregnation catalysts, prepared by impregnating solid supports with metal salts followed by calcination and reduction at high temperatures.[1, 2] More recently, solvated metal atoms[3] as well as certain molecular metal complexes and metal clusters have been immobilized on commercial solid metal oxides.[4] Another current approach concerns surface organometallic chemistry according to which discrete catalytically active species are anchored on solid supports.[5] Although many of these catalysts have been characterized by a variety of techniques such as transmission electron microscopy (TEM), energy dispersive X-ray analysis (EDX), and X-ray photoelectron spectroscopy (XPS),[1–6] the precise location of the metal particles or ligated metals on the support remains unclear. Generally, it is desirable to achieve metal dispersion preferably on the outer surface of the support, because this minimizes diffusion problems. This is the reason why shell catalysts, especially those of the eggshell type, are often preferred. Accordingly, mm-sized pellets are treated in special impregnation procedures during which a metal-containing outer region several hundred μm thick is formed. However, it is likely that in this macroscopically visible region the metal particles are not exclusively fixed on the outer surface in a microscopic sense, but are also distributed deep in the pores of the solid support. In order to prevent this, we have now immobilized preformed and size-selectively prepared metal clusters on solid supports. By considering pore diameter and cluster size, it is possible to design catalysts in which metal particles of a specified size are found solely on the outer surface of the support.

Recently we described an electrochemical process for the production of nanostructured transition metal clusters (e.g. Ni, Pd, Pt, Co, Rh, Ru)[7] and dimetallic clusters (e.g. Ni/Pd, Fe/Co, Fe/Ni, Pt/Sn)[8, 9] stabilized by tetraalkylammonium salts. The diameter of the particles ranges between 1 and 10 nm and can be controlled by adjusting the current density. The spherical clusters are surrounded by tetraalkylammonium salts that function as a stabilizing mantle; the visualization of this protective monomolecular layer is possible through a combination of transmission electron and scanning tunneling microscopy (TEM/STM).[10] The solubility of these stabilized clusters is dependent on the ammonium salt; thus, those with $(C_{18}H_{37})_4N^+Br^-$ are soluble in nonpolar solvents such as pentane and those with betains such as $C_{12}H_{25}$-$(CH_3)_2N^+CH_2CH_2CH_2SO_3^-$ are soluble in water.[8]

Upon stirring solutions of these preformed clusters at room temperature in the presence of solid supports such as SiO_2 or Al_2O_3 in the form of powders or pellets, immobilization occurs without any change in cluster size.[8, 11] This means that metal crystallites of a defined size and elemental composition can be specifically placed on such supports. In the case of pellets, shell catalysts[1, 2] are easily produced without the need for special preparation techniques necessary in conventional impregnation processes such as pretreatment of the solid support with certain salts, use of viscous solvents or additives, or special drying procedures. For example, impregnation of Al_2O_3 pellets (Johnson Matthey 11838) with a 0.5M THF solution of 3 nm sized (by TEM) $(C_8H_{17})_4N^+Br^-$-stabilized Pd clusters leads to rapid immobilization. Eggshell catalysts are obtained within 1–4 s, as shown by photographs of pellet cross sections (Fig. 1a, b). The

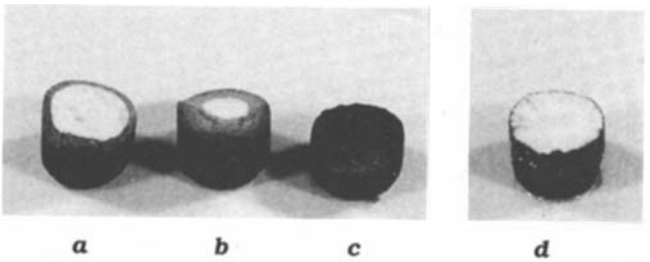

Fig. 1. Cross sections of Al_2O_3 pellets (diameter 3.2 mm). a) After penetration with a 0.5M tetrahydrofuran solution of $(C_8H_{17})_4N^+Br^-$-stabilized Pd clusters for 1 second. b) For 4 seconds. c) For 10 seconds. d) After penetration with an aqueous 0.5M solution of betain-stabilized Pd clusters for 5 h.

extent of the uniform macroscopic penetration is time-dependent; the penetration is complete after 10 s (Fig. 1c). In sharp contrast, interaction of the same pellets with a 0.5M aqueous solution of betain-stabilized Pd clusters (3 nm by TEM) affords only eggshell-type catalysts (penetration < 100 μm), even after prolonged periods of interaction. For example, gentle shaking of such a black-colored solution of the cluster with the above Al_2O_3 pellets for 5 h results in complete immobilization of the cluster (Fig. 1d). Following decantation, the water is completely colorless and contains about 70% of the original betain stabilizer. If so desired, further washing can remove up to 95% of the stabilizer.

The dramatic difference in the rate and depth of penetration in going from $(C_8H_{17})_4N^+Br^-$ to $C_{12}H_{25}$-$(CH_3)_2N^+CH_2CH_2CH_2SO_3^-$ can be explained on the basis of different degrees of interaction of the stabilizer with the support. In the case of the $(C_8H_{17})_4N^+Br^-$ stabilizer which has four lipophilic *n*-octyl chains at nitrogen, the interaction with the hydrophilic surface of Al_2O_3 is relatively weak, and rapid macroscopic penetration occurs as the cluster-containing solvent moves into the pellet. In the case of the betain-stabilized clusters, strong interaction between the polar substituents of the stabilizer and the Al_2O_3 surface lowers the rate and degree of

penetration. The use of aqueous solutions of betain-stabilized clusters is noteworthy, because such a procedure is economically and ecologically attractive. In comparison, conventional impregnation of the same Al_2O_3 pellets with a 0.5 M aqueous solution of $Pd(OAc)_2$ for one minute without special precautions results in fully penetrated pellets (characterized following calcination/reduction).

Methods for the controlled positioning of metal particles on a *microscopic* level are even more important because catalytically active components far inside small pores are not readily accessible during catalytic reactions. Furthermore, catalysts having the dispersed metals mainly on the outer surface can be expected to be more selective in industrially important reactions such as selective hydrogenation or partial oxidation because of short contact times. We have discovered that the use of the preformed ammonium-stabilized metal clusters described here allows for such a control. Indeed, the metal crystallites can be positioned precisely on the outer surface of the support without deep penetration into the pores.

For example, using a commercially available alumina (Aldrich 19997-4) with an average pore size of 5.8 nm, $(C_4H_9)_4N^+Br^-$-stabilized Pd clusters with an inner metal core diameter of 3.5 nm (by TEM) and an outer diameter of 4.9 nm (by STM) were immobilized in the usual way. Following the removal of the solvent the solid material was washed several times with ethanol to remove the stabilizer. The concentration and amount of Pd clusters were varied so that materials containing 1% and 5% palladium were obtained. Conventional TEM analyses showed that in both cases materials with particles with an average diameter of 3.5 nm are obtained, again demonstrating that undesired agglomeration does not occur. However, such conventional studies provide only limited characterization because they do not reveal where the clusters are actually located, since by nature the transmission electron micrographs are only two-dimensional projections of three-dimensional materials.[6]

To solve this analytical problem, we have applied a technique well known in biology, medicine, and materials science, but seldom used in heterogeneous catalysis, namely ultramicrotometry in combination with TEM.[12] Accordingly, particles of the two Pd-containing Al_2O_3 powders (1% and 5% metal loading) were first embedded in an epoxy resin. Slices of ultramicrotometrically cut materials were then studied by TEM. Figure 2a shows the TEM image of such a cross section. Clearly, most of the metal particles are located on the outer surface of the Al_2O_3 particles. This means that the preformed clusters have not entered the pores of the Al_2O_3 support to any significant extent (less than 10 nm penetration). In contrast, samples of a commercial Pd catalyst on Al_2O_3, prepared by conventional impregnation/calcination/reduction, have completely different morphological features. The corresponding TEM image in Figure 2b shows that in this case the metal is distributed more or less evenly throughout the three-dimensional network of the support. Evidently, impregnation of Al_2O_3 by palladium salts results in uncontrolled migration into the pores of the solid matrix before the corresponding Pd^0 particles are formed in the final reduction step. Capillary forces operating in the pores induce this type of salt penetration on a microscopic level, a process which does not occur as readily with the relatively large-sized preformed metal clusters.

Using supports such as Al_2O_3, we have applied our approach successfully to Pd clusters of different sizes (e.g., 1.4 and 4.8 nm-sized samples), to Ni clusters, and to Pt/Sn dimetallic clusters. It remains to be seen whether such morphologically well-defined materials, which we call *cortex* catalysts (to distinguish them from the usual shell catalysts), have significant advantages over heterogeneous catalysts prepared by conventional procedures. In preliminary experiments involving the hydrogenation of cyclooctene, a palladium cortex catalyst (5% Pd on Al_2O_3; see Fig. 2a) turned out to be about three times more active than a comparable commercially available industrial catalyst (5% Pd on Al_2O_3; Aldrich 37148-3).

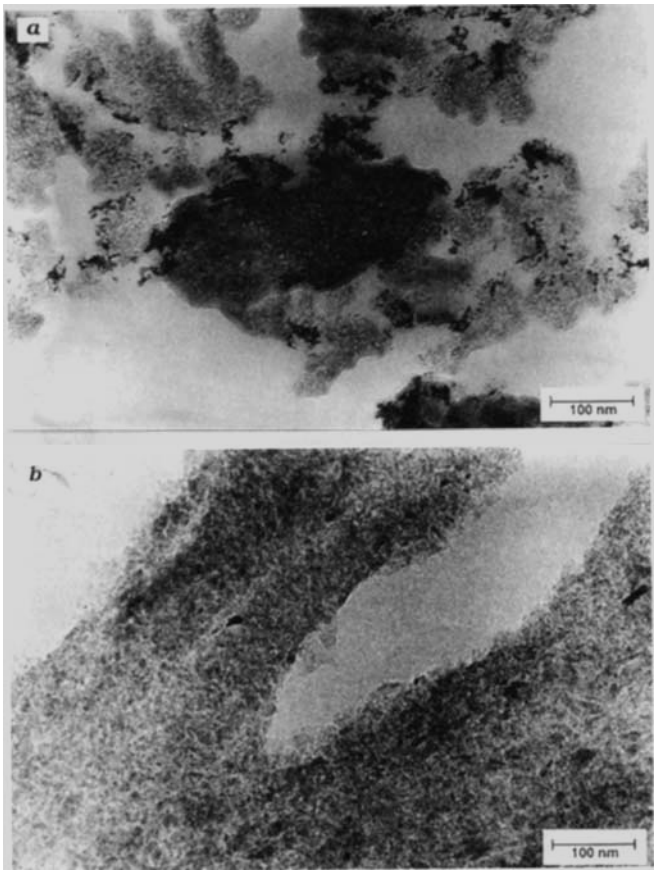

Fig. 2. TEM images of ultramicrotometrically cut alumina powders. a) After penetration with a 0.5 M solution of $(C_4H_9)_4N^+Br^-$-stabilized Pd clusters. b) Conventionally prepared impregnation catalyst (Aldrich 37148-3).

The present findings together with the fact that ammonium-stabilized homo- and dimetallic clusters are accessible in a size-selective manner and defined composition allow for the design of heterogeneous catalysts with well-defined compositional and structural features on a macroscopic and microscopic level. Due to the simplicity of the method of preparation, these cortex catalysts may be industrially viable.

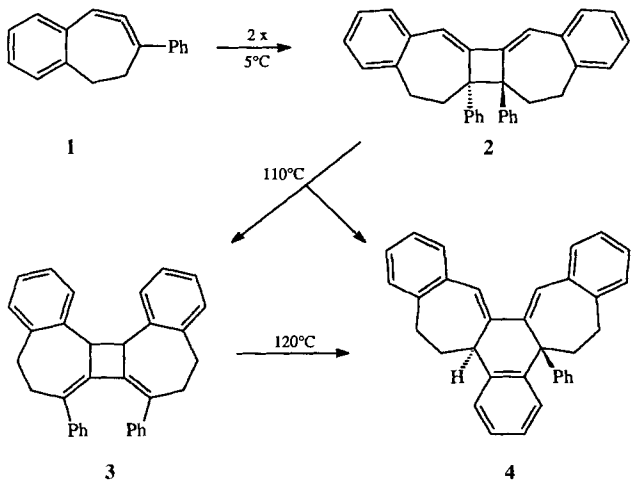
1-Phenyl-1,2-cyclooctadiene Dimerizes in an Unusual Manner**

Manfred Christl,* Marcus Rudolph, Eva-Maria Peters, Karl Peters, and Hans Georg von Schnering

As has been demonstrated recently,[1] the dimerization of the seven-membered cycloallene **1** proceeds in the usual manner[2,3] to yield the C_2 symmetric 1,2-bismethylenecyclobutane derivative **2**.[1] On thermolysis, **2** is converted into the isomers **3** (configuration unknown) and **4**. Finally, **3** rearranges to **4** as well. According to the present knowledge,[4] a tetramethyleneethane diradical has to be assumed as the intermediate for both the formation of **2** and its isomerization. En route to **4**, this diradical closes a six-membered ring by attack of one allyl radical terminus at the phenyl group of the second phenylallyl radical subunit. With the allene **6**, we have now synthesized a compound for which this elementary process is kinetically preferred, furnishing the unusual dimer **7**.

1-*tert*-Butyl-1,2-cyclooctadiene is the only eight-membered cycloallene stable at 20 °C.[5] The parent compound[6,7] and its 1-methyl derivative [2] can be observed; however, they dimerize



rather rapidly even at 20 °C to give the usual products, namely the C_2 symmetric 1,2-bismethylenecyclobutane derivatives.[6,7] These reactions were investigated in detail recently by application of the Doering–Moore–Skattebøl method for the preparation of these allenes.[7] Using this procedure, we also generated **6**; the dibromocarbene adduct **5**[8] of 1-phenylcycloheptene was treated with methyllithium in ether at −40 °C. After work up at this temperature, **6** could not be detected by low-temperature ^{13}C NMR spectroscopy. Only signals of the methylene-1,3-cyclohexadiene derivative **7** were present, which was isolated in 50–60% yield and structurally elucidated by X-ray diffraction[9] (Fig. 1).

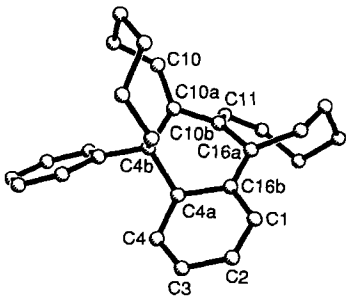


Fig. 1. Crystal structure of **7** [9]. The C4a–C4b bond is particularly long (160.9 pm), probably due to steric overcrowding. Whereas the ethene subunits C4–C3, C2–C1, and C16b–C16a are almost coplanar (torsional angles −1.8 and −178.2°), the torsional angle for C16b–C16a and C10b–C11 is −127°; however, this does not prevent a long-wavelength absorption in the UV spectrum (see Table 1). The ethene subunits are strongly twisted against each other (−51.0°) also in the 1,3-butadiene system C10-C10a-C10b-C11.

Unlike the precursor to **4**, which is analogous to **7**, compound **7** did not aromatize on heating, but rearranged to give a symmetric dimer of **6** (6 d, 20 °C, CH_2Cl_2 or 4 h, 70 °C, C_6H_6, 50%). The addition product from this dimer and tetracyanoethylene (TCNE) is symmetric as well, which is why the C_s symmetric formulas **12** and **8** have to be ascribed to this adduct and the precursor diene, respectively. The configuration of **8** was confirmed by an X-ray structure analysis[9] (Fig. 2). 1,2-Cyclononadiene does form a C_s symmetric dimer,[10]

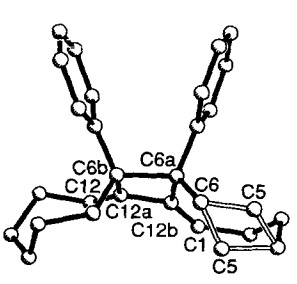

Fig. 2. Crystal structure of **8** [9]. In one of the two eight-membered rings, the second CH_2 group (C5) next to the phenyl-substituted bridgehead is disordered. As a result of severe steric overcrowding, the C6a–C6b bond is unusually long (165.0 pm) and is thus similar to the corresponding bonds in **2** [1] and another sterically highly encumbered 1,2-bismethylenecyclobutane [11]. The 1,3-butadiene system C1-C12b-C12a-C12 deviates only slightly from the planar arrangement (torsional angle −11.2°).

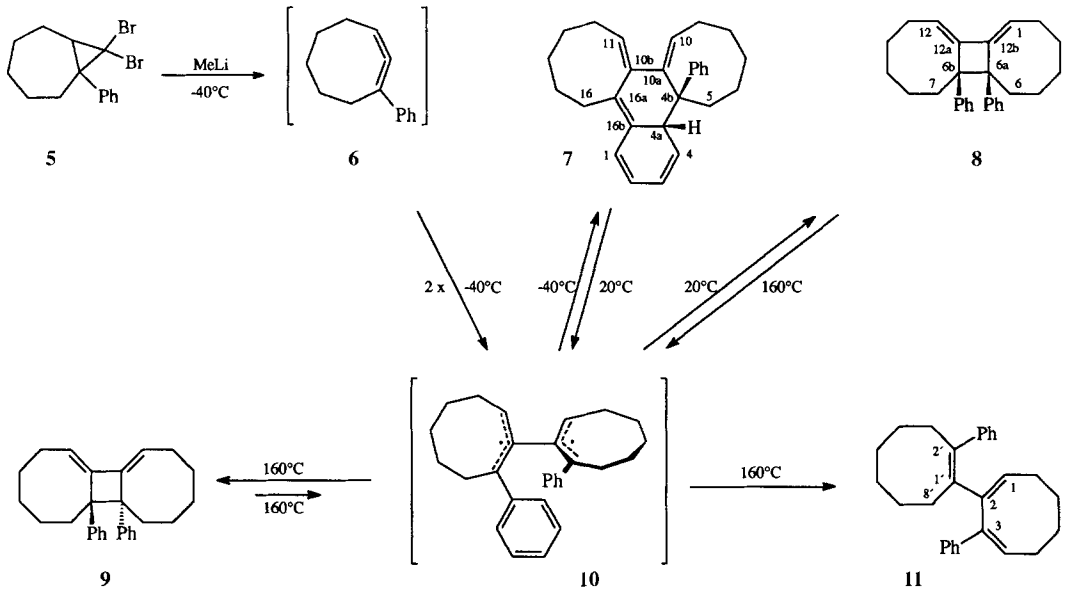
[**] Cycloallenes, Part. 10. This work was supported by the Fonds der Chemischen Industrie and by CHEMETALL GmbH. Part 9: M. Christl, M. Braun, E. Wolz, W. Wagner, *Chem. Ber.* **1994**, *127*, 1137–1142.



5 6 7 8

9 10 11

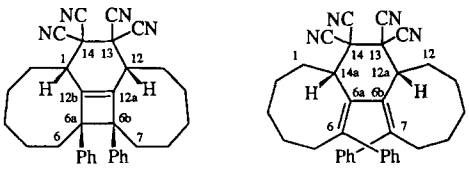
symmetric dimer,[10] however, such a product is as yet unknown from a cycloallene with an eight-membered or a smaller ring.

The bismethylenecyclobutane **8** was not the final product of the thermolysis; upon heating at 160 °C (24 h, C_6H_6), **8** was converted into the cyclooctenylcyclooctadiene **11** (90%), the structure of which was determined by NMR spectroscopic studies (2D-INADEQUATE). At intermediate stages of the thermolysis, the NMR spectra of the solution indicated further components. The most important one, as far as quantity is concerned, reached a proportion of 25% prior to the formation of larger amounts of **11** (after 4 h at 160 °C). A fraction strongly enriched in that compound could be obtained by chromatography. Based on the similarity to those of **8**, its NMR spectra support the structure of the *trans*-annulated 1,2-bismethylenecyclobutane **9**.

Although **7** is formally the product of a Diels–Alder reaction of two molecules of **6**, all the above processes should be mediated by the tetramethyleneethane diradical **10**, the formation of which has to be expected on dimerization of **6**.[4] The fast collapse of **10** to give the new six-membered ring of **7** is probably caused by the conformation of the eight-membered rings placing the reaction centers in favorable positions. This prerequisite is obviously absent in the less flexible diradical originating analogously from **1**, since it selects the closure of a six-membered ring only as the route for final stabilization.

Dimer **7** seems to be in equilibrium with **10** in solution even at 20 °C; the latter then collapses to give **8**. As shown by the relatively high concentration of **9** on thermolysis of **8**, the thermodynamic stability of **9** should resemble that of **8**. However, the kinetic barrier to formation of **9** from **10** must be much higher than that of **8**. This is astounding because the least-motion process of **10** providing a bismethylenecyclobutane (conrotation) would just furnish **9**. En route to **8**, both the allyl radical subunits of **10** would have to arrange in a common plane and then form the bond by disrotation. Possibly, instead of **10**, its diastereomer with *one* 3-phenylcyclooct-*trans*-2-en-1-yl moiety is involved, the least-motion ring closure of which would lead to **8**. Both alternatives appear to be costly in terms of the energy demand. The comparison with the route to **2** indicates that the conformation of the eight-membered rings of **10** should be the reason for the much higher barrier separating **10** from **9**. The conversion of **8** and **9** into **11** should proceed via **10** as well, in which a hydrogen atom has to be transferred from one eight-membered ring to the other. Albeit intermolecular, such disproportionations are well-known elementary reactions of radicals.

The addition of TCNE to cycloallene dimers has been employed repeatedly for the structure elucidation of such dienes.[3,7,12] As mentioned above, the reaction of **8** with TCNE (24 h, 20 °C, C_6H_6) gave rise to the tetracycle **12** (31%). Akin to



12 13

other 3,4-diphenylcyclobutenes,[13] **12** underwent opening of the four-membered ring under mild conditions (slowly at 20 °C and rapidly at 80 °C in C_6H_6). As revealed by an X-ray structure analysis (Fig. 3), formula **13** has to be ascribed to the product (28% from **8**). Hence, contrary the rules regarding the conservation of orbital symmetry, a disrotatory motion governed the isomerization. The rigid helical arrangement of the *Z*,*Z*-1,4-diphenyl-1,3-butadiene subunit is responsible for the missing symmetry of **13** indicated by the NMR spectra (Table 1).

We achieved the aromatization by treating **7** with *p*-toluenesulfonic acid (4 h, 20 °C, CH_2Cl_2, 50%). NOE measurements support structure **14** by proving the proximity of the olefinic proton (16-H) to one proton of the annulated benzene moiety (1-H).

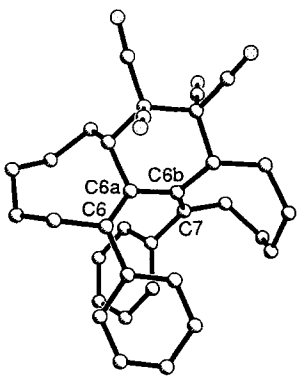


Fig. 3. Crystal structure of **13** [9]. The 1,3-butadiene system C6-C6a-C6b-C7 deviates strongly from the planar arrangement (torsional angle 74.8°), which is why the UV spectrum shows short-wavelength absorptions (see Table 1) only.

Table 1. Selected physical data of 7–**9** and **11**–**14**; ^{1}H and ^{13}C NMR spectra (600 and 151 MHz, respectively, measured in $CDCl_3$, except where stated otherwise); in so far as specified, the assignments of the NMR signals are supported by DEPT, ^{1}H,^{1}H-COSY, and 2D-INADEQUATE spectra as well as NOE measurements.

7: M.p. 113 °C (from pentane); ^{1}H NMR (250 MHz): δ = 1.15-2.00 (m; 15H), 2.21 (br. ddd, J = 15, 10, 5 Hz; 1H), 2.34-2.64 (m; 3H), 2.74 (ddt, J = 16.9, 9.5, 3.2 Hz; 1H), 3.15 (br. s; H4a), 5.19 (br. dd, J(3,4) = 9.8, J(4,4a) = 4.7 Hz; H4), 5.71 (≈ t, J = 8.9 Hz), 6.06 (dd, J = 6.9, 4.8 Hz) (H10,11), 5.77 (br. dd, J = 9.7, 5.7 Hz), 5.99 (dddd, J = 9.7, 5.7, 2.2, 0.8 Hz) (H2,3), 6.50 (dq, J = 9.6, 0.8 Hz; H1), 7.19 (*p*-H), 7.29 (*m*-H), 7.36 (*o*-H); ^{13}C NMR (63 MHz): δ = 22.4, 23.4, 23.7, 25.7, 25.8, 28.5, 28.7, 29.9, 30.4, 34.7 (C5-9,12-16), 52.5 (C4b), 53.5 (C4a), 120.7, 124.7 (C2,3), 122.5 (C1), 129.9 (C4), 123.4, 125.2 (C10,11), 125.4 (*p*-C), 127.5 (*o*-C), 127.6 (*m*-C), 129.5, 135.3, 142.8, 146.1, 148.0 (C10a,10b,16a,16b, *i*-C); UV (CH_3CN): λ_{max} (lg ε) = 357 nm (4.772).

8: M.p. 123–125 °C (from pentane); ^{1}H NMR (250 MHz): δ = 1.05–2.10 (m; 8H), 2.18 (br. dd, J = 14.0, 9.7 Hz; 1H), 2.34 (br. dd, J = 14.0, 6.7 Hz; 1H), 6.05 (dd, J(1,2) = 7.7, 6.3 Hz; H1), 6.70 (br.; 1 aromat. H), 6.78-6.98 (br.; 4 aromat. H); ^{13}C NMR (63 MHz): δ = 23.8, 26.2, 27.3, 28.8, 35.6 (C2-6), 63.1 (C6a), 118.1 (C1), 124.6 (*p*-C), 126.7, 126.9, 127.2, 129.5 (br., *o*-,*m*-C), 143.3, 143.7 (C12a, *i*-C); UV (CH_3CN): λ_{max} (lg ε) = 264 nm (4.152).

9: ^{1}H NMR (250 MHz): δ = 0.60–2.20 (m; 10H), 5.95 (dd, J(1,2) = 9.3, 7.2 Hz; H1), 7.00–7.30 (m; 4 aromat. H), 7.47 (m; 1 *o*-H); ^{13}C NMR (63 MHz): δ = 22.1, 26.1, 27.2, 28.0, 40.6 (C2-6), 61.2 (C6a), 117.8 (C1), 125.7, 126.3, 127.2, 127.9, 131.4 (*o*-,*m*-,*p*-C), 141.3, 144.2 (C12a, *i*-C).

11: Oil (glass), b.p. 250–300 °C (bath)/10 $^{-3}$ Torr; ^{1}H NMR: δ = 0.84–1.09 (m; 2H), 1.19–1.89 (m; 12H), 1.89–2.39 (m; 6H), 5.54 (dd, J = 9.2, 7.3 Hz), 5.91 (dd, J = 8.8, 7.6 Hz) (H1,4), 6.89 (m; 2 *o*-H), 6.94 (m; 2 *o*-H), 6.97–7.19 (m; 4 *m*-H, 2 *p*-H); ^{13}C NMR: δ = 23.2 (C6), 23.6 (C7), 26.7 (C5′), 26.8 (C6′), 28.1 (2 signals; C8,4′), 29.0 (C5), 30.7 (C7′), 32.7 (C8′), 35.2 (C3′), 125.5 (*p*′-C), 126.2 (*p*-C), 126.8 (*m*′-C), 127.4 (2 signals; *o*-,*m*-C), 129.0 (*o*′-C), 130.8 (C4), 132.8 (C1), 135.9 (C1′), 138.9 (C2′), 139.2 (2 signals; C2,3), 141.5 (*i*-C), 144.8 (*i*′-C); UV (CH_3CN): λ_{max} (lg ε) = 236 nm (4.313).

12: M.p. 182–183 °C (from petroleum ether/ethyl acetate); ^{1}H NMR: δ = 1.17–1.25 (m; 2H), 1.39 (m;1H), 1.71–1.85 (m; 4H), 2.03–2.12 (m; 2H), 2.75 (br. d, J ≈ 15 Hz; 1H), 3.55 (br. t, J ≈ 9 Hz; 1H), 6.75 (m; 1 *o*-H), 6.85 (m; 1 aromat. H), 6.90-6.94 (m; 2 aromat. H), 6.96 (m; 1 *o*-H); ^{13}C NMR: δ = 22.2, 22.7, 26.4, 27.7, 32.7 (C2-6), 40.7 (C1), 45.5 (C13), 66.3 (C6a), 110.5, 112.0 (2 CN), 125.9, 127.3 (2 signals), 127.6, 129.3 (*o*-,*m*-,*p*-C), 141.0, 144.7 (C12a, *i*-C).

13: M.p. 219–220 °C (from petroleum ether/ethyl acetate); ^{1}H NMR: δ = 0.41 (br.; 1H), 1.12-1.23 (m; 2H), 1.38 (m; 1H), 1.42–1.53 (m; 3H), 1.59 (m; 1H), 1.78 (br.; 1H), 1.90 (m; 1H), 1.97 (m; 1H), 2.04–2.17 (m; 3H), 2.27 (m; 1H), 2.42–2.51 (m; 2H), 2.59 (m; 1H), 2.77 (m; 1H), 3.42 (m; 1H), 3.57 (m; 1H), 3.74 (m; 1H), 6.32 (br.; 2 *o*-H), 7.08 (m; 2 *m*-H), 7.16 (m; 1 *p*-H), 7.18 (m; 2 *o*-H), 7.36-7.43 (m; 2 *m*-H, 1 *p*-H); ^{13}C NMR: δ = 23.4, 24.0, 25.9, 26.0, 26.7, 29.2, 31.6, 31.9, 35.4, 36.1 (C1-5,8-12), 46.8 (C13 or C14), 47.1 (2 signals; C12a or 14a, C14 or C13), 51.1 (C14a or C12a), 110.5, 111.1, 111.6, 112.2 (4 CN), 124.6, 129.3 (C6,7), 126.8 (*p*-C), 127.2 (*o*-C), 127.5 (*m*-C), 128.0 (*p*-C), 128.1 (*m*-C), 128.3 (*o*-C), 143.5, 144.0, 144.4, 147.2 (C6a,6b, 2 *i*-C); UV (CH_3CN): λ_{max} (lg ε) = 255 nm (4.048 sh), 236 (4.165).

14: M.p. 124–125 °C (from pentane); ^{1}H NMR (C_6D_6): δ = 1.14–1.22 (m; 2H), 1.30–1.42 (m; 6H), 1.45–1.51 (m; 2H), 1.61–1.67 (m; 2H), 1.69–1.75 (m; 2H), 2.08–2.50 (m; 4H), 2.39 (t, J = 7.0 Hz; 2H), 2.42 (m; 15-H_2), 6.24 (t, J = 8.4 Hz; 16-H), 7.06 (m; *o*-H), 7.08 (m; *p*-H), 7.14 (m; *m*-H), 7.20 (td, J(1,2)= J(2,3) = 7.6, J(2,4) = 1.3 Hz; H2), 7.24 (td, J(3,4) = 7.6, J(1,3) = 1.6 Hz; H3), 7.57 (dd; H4), 7.58 (dd; H1); ^{13}C NMR: δ = 24.3 (3 signals), 25.8, 26.6, 28.3, 30.3, 31.6 (2 signals), 38.4 (2 signals) (C5-15), 46.9 (C4b), 124.5, 124.9 (C1,4), 125.58, 125.64, 126.2 (C2,3, *p*-C), 125.8 (C16), 127.6 (*o*-C), 130.3 (*m*-C), 133.3, 138.4, 139.1, 141.0, 144.1, 147.4 (C4a,10a,10b,16a,16b, *i*-C); UV (hexane): λ_{max} (lg ε) = 270 nm (4.074).

Correct elemental analyses have been obtained from all isolated products except **11**, the empirical formula of which is supported by a high-resolution mass spectrum. Selected data of the compounds **7**–**9** and **11**–**14** are collected in Table 1.

Multidimensional Solid-State NMR and Polymers. By **K. Schmidt-Rohr, H. W. Spiess.** Academic Press, London, **1994.** 478 pp., hardcover, £ 65.00.—ISBN 0-12-626630-1

An Atlas of Fullerenes. By **P. W. Fowler, D. E. Manolopoulos.** Oxford University Press, Oxford, **1995.** 392 pp., hardcover, £ 65.00.—ISBN 0-19-855787-6

Handbook of Food Additives. Compiled by **M. and I. Ash.** Gower, Hampshire, **1995.** 1040 pp., hardcover, £ 175.00. ISBN 0-566-07592-X

Special Trends in Thermal Analysis. By **F. Paulik.** Wiley, Chichester, **1995.** 459 pp., hardcover, £ 90.00.—ISBN 0-471-95769-0

Advances in Photochemistry, Vol. 19. Edited by **D. C. Neckers, D. H. Volman, G. von Bünau.** Wiley, Chichester, **1995.** 325 pp., hardcover, £ 96.00. ISBN 0-471-04912-3

Spectra of Atoms and Molecules. By **P. F. Bernath.** Oxford University Press, Oxford, **1995.** 400 pp., hardcover, £ 37.50.—ISBN 0-19-507598-6

Advances in Mass Spectrometry, Vol. 13. Proceedings of the 13th International Mass Spectrometry Conference. Edited by **I. Cornides, G. Horváth, K. Vékey.** Wiley, Chichester, **1995.** 645 pp., hardcover, £ 120.00.—ISBN 0-471-95323-7

Chemical Principles of Synthetic Fibre Dyeing. By **S. M. Burkinshaw.** Blackie Academic, London. **1995.** 223 pp., hardcover, £ 55.00.—ISBN 0-7514-0043-3

Spectroscopy in Environmental Science. Advances in Spectroscopy, Vol. 24. Edited by **R. J. H. Clark, R. E. Hester.** Wiley, Chichester, **1995.** 462 pp., hardcover, £ 130.00.—ISBN 0-471-95370-9

Macromolecular Reactions. Peculiarities, Theory and Experimental Approaches. By **N. A. Platé, A. D. Litmanovich, O. V. Noah.** Wiley, Chichester, **1995.** 438 pp., hardcover, £ 80.00.—ISBN 0-471-94392-4

Organomagnesium Methods in Organic Synthesis. By **B. J. Wakefield.** Academic Press, London, **1995.** 249 pp., hardcover, £ 50.00.—ISBN 0-12-730945-4

Surfactant-Enhanced Subsurface Remediation: Emerging Technologies. Edited by **D. A. Sabatini, R. C. Knox, J. H. Harwell.** American Chemical Society, Washington, **1995.** 312 pp., hardcover, $ 84.95.—ISBN 0-8412-3225-3

Röntgenfluoreszenzanalytische Methoden. Grundlagen und praktische Anwendung in den Geo-, Material- und Umweltwissen-schaften. By **P. Hahn-Weinheimer, A. Hirner, K. Weber-Diefenbach.** Vieweg, Wiesbaden, **1995.** 283 pp., hardcover, DM 98.00.—ISBN 3-528-06579-6

Destillation, Absorption, Extraktion. By **E.-U. Schlünder, F. Thurner.** Vieweg, Wiesbaden, **1995.** 215 pp., paperback, DM 49.50.—ISBN 3-528-06678-4

Immunoanalysis of Agrochemicals: Emerging Technologies. ACS Symposium Series No. 586. Edited by **A. E. Karu, J. O. Nelson, R. B. Wong.** American Chemical Society, Washington. **1995.** 380 pp., hardcover, $ 99.95.—ISBN 0-8412-3149-4

Reduction of Nitrogen Oxide Emissions. ACS Symposium Series No. 587. Edited by **U. S. Ozkan, S. K. Agarwal, G. Marcelin.** American Chemical Society, Washington, **1995.** 248 pp., hardcover, $ 79.95. ISBN 0-8412-3150-8

Modern Countercurrent Chromatography. ACS Symposium Series No. 593. Edited by **W. D. Conway, R. J. Petroski.** American Chemical Society, Washington, **1995.** 248 pp., hardcover. $ 69.95.—ISBN 0-8412-3167-2

Fruit Flavors: Biogenesis, Characterization, and Authentication. ACS Symposium Series No. 596. Edited by **R. L. Rouseff, M. M. Leahy.** American Chemical Society, Washington, **1995.** 304 pp., hardcover, $ 84.95.—ISBN 0-8412-3227-X

Flow-Induced Structure in Polymers. ACS Symposium Series No. 597. Edited by **A. I. Nakatani, M. D. Dadmun.** American Chemical Society, Washington, **1995.** 378 pp., hardcover, $ 99.95.—ISBN 0-8412-3230-X

AUTHOR INDEX [*Angew. Chem. Int. Ed. Engl.* 1995, *34*]

The page numbers in square brackets refer to the German edition [*Angew. Chem.* **1995**, *107*] of Angewandte Chemie. Page numbers in round brackets indicate errata.

Zsolnai, L. 316 [354]
Zubieta, J. 223 [229]

INDEX OF AUTHORS AND REVIEWERS OF BOOKS

This index lists separately the names of Authors/Editors and Reviewers, respectively, of books reviewed in *Angew. Chem. Int. Ed. Engl.* **1995**, *34*.

Bookauthors

Albert, W. H. 243
Aldersey-Williams, H. 1769
Atherton, N. M. 1033
Atkins, P. W. 599
Baneyx, F. 697
Behr, J.-P. 2293
Bertini, I. 1036
Bogdanov, A. A. 1521
Breggin, G. R. 1250
Breggin, P. R. 1250
Briggs, D. 2059
Brown, B. R. 1249
Buback, M. 120
Buchachenko, A. L. 936
Carlson, R. M. K. 1903
Charushin, V. N. 2419
Chupakhin, O. N. 2419
Cintas, P. 121
Cram, D. J. 2563
Cram, J. M. 2563
Cramer, F. 1771
Craver, C. D. 601
Croasmun, W. R. 1903
Daintith, J. 2167
Daniel, H.-D. 359
Dettmann, J. 1769
DiTrocchio, F. 1370
Djerassi, C. 241
Emsley, J. 2059
Feltz, A. 242
Frankevitch, E. L. 936
Gjertsen, D. 2167
Glusker, J. P. 2060
González-Morega, G. 121
Gray, H. B. 1036
Griesbeck, A. 1770
Hampden-Smith, M. J. 1651
Haslam, E. 361
Hassner, A. 935
Hayashi, T. 1904
Hegedus, L. S. 1035
Hirsch, A. 1904
Ho, T.-L. 1369
Huisgen, R. 1129
Kavarnos, G. J. 495
Kennewell, P. D. 828
Klabunde, K. J. 1252
Kleinpeter, E. 1251
Knight, D. 1034
Kocienski, P. J. 1370
Kodas, T. T. 1651
Kosuge, K. 1033
Kroschwitz, J. I. 2564
Kyriacou, D. 1521
Laidler, K. J. 360
Langford, C. H. 599
Lappin, A. G. 1249
Laue, T. 935
Lehn, J.-M. 2563
Lewis, M. 2060
Lippard, S. J. 1036
Lucotte, G. 697
Lunn, G. 1037
Masseyeff, R. F. 243
Mattay, J. 1770
Mezey, P. G. 361
Mitchell, S. 2167
Möckel, K. 1769
Niemantsverdriet, J. W. 495
Nógrádi, M. 1372
Papp, R. B. 935
Patai, R. 2419
Patai, S. 1251
Pepperrell, C. 359
Perkins, M. J. 1771
Pihlaja, K. 1251
Plagens, A. 935
Pollard, B. D. 935
Porter, R. 2168
Quin, L. D. 1651
Rappoport, Z. 1251
Rhodes, G. 496
Roesky, H. W. 1769
Rossi, M. 2060
Sansone, E. B. 1037
Schmid, G. 122
Seah, M. P. 2059
Shabarova, Z. A. 1521
Shriver, D. F. 599
Splitter, J. S. 497
Staines, N. A. 243
Stoltzenberg, D. 119
Stumer, C. 935
Suppan, P. 599

Talsky, G. 1522
Taylor, J. B. 828
Taylor, L. R. 935
Thomas, E. L. 600
Togni, A. 1904
Tootill, E. 2167
Tsukerblat, B. S. 1772
Tureček, F. 497
Urban, M. U. 601
Valentine, J. S. 1036
van der Plas, H. C. 2419
van Gunsteren, W. F. 1034
Verkade, J. G. 1651
Vögele, H. P. 120
Wagnière, G. H. 827
Weiner, P. K. 1034
Whitesides, G. M. 1523
Wilkinson, A. J. 1034
Wong, C.-H. 1523
Woolins, J. D. 2565
Zollinger, H. 1653

Reviewers

Anslyn, E. V. 2293
Bach, T. 1369
Bain, C. D. 827
Beck, J. 2565
Braun, N. 935

SUBJECT INDEX [*Angew. Chem. Int. Ed. Engl.* 1995, *34*]

(A second page number to an entry indicates an erratum to the corresponding article.)

(R) = Review Article (H) = Highlight (C) = Short Communication (B) = Book Review (L) = Correspondence

Ab initio calculations
- An Ab Initio Investigation of the Rh^{I}-Catalyzed Hydroboration of C=C Bonds: Evidence for Hydrogen Migration in the Key Step (C) 115
- A P_2C_2 Four-Membered Ring with Unusual Bonding—Synthesis, Structure, and Ring Opening of a 1,3-Diphosphacyclobutane-2,4-diyl (C) 555
- Aromaticity and Antiaromaticity in Five-Membered C_4H_4X Ring Systems: "Classical" and "Magnetic" Concepts May Not Be "Orthogonal" (C) 337
- 4c/3e Radical Cations with Cage-Directed Configurations (C) 1016
- Compounds with Planar Tetracoordinate Boron Atoms: Anti van't Hoff/Le Bel Geometries without Metal Centers (C) 327
- Computational Evidence for the Existence of Cu^{III} Intermediates in Addition and Substitution Reactions with Dialkylcuprates (C) 476
- Conical Intersections and the Mechanism of Singlet Photoreactions (H) 549
- Coordination of Dioxygen in Three Representative Transition Metal Cations: FeO_2^+, CrO_2^+, and $[CH_3Re(O_2)_2O]^+$ (C) 2517
- Covalent Inorganic Azides (R) 511
- Diborylcarbenes as Reactive Intermediates in Double 1,2-Rearrangements with Low Activation Enthalpies (C) 1340
- Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State (C) 986
- Electrochemistry and Ab Initio Study of the Dimetallofullerene $La_2@C_{80}$ (C) 1094
- Electron Transfer and Polar Reactions of Cyclizable Anion Radicals: Structural Consequences of Orbital Selection Rules and Chain-Length Constraints (C) 1495
- Elusiveness of Cu^{III} Complexation; Preference for Trifluoromethyl Oxidation in the Formation of $[Cu^{I}(CF_3)_4]^-$ Salts (C) 80
- Fluorocarbonate, $[FCO_2]^-$: Preparation and Structure (C) 1858
- Formal Oxidation State versus Partial Charge—A Comment (C) 986
- Formation and Structures of New Metallo- and Metallapolysulfanes, $[MS_y]^+$ (y = 2–16) (C) 201 (1032)
- Mechanism of the Fe^+ Mediated C–C and C–H Bond Activations in Ethane from a Theoretical Viewpoint (C) 2282
- σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation (C) 1742
- N-Confused Porphyrins and Singlet Carbenes: Is There a Connection? (C) 1028
- New Evidence Concerning the Structure of Amorphous Red Phosphorus (H) 2637
- Reaction of 1,1-Dimethylsilene with Formaldehyde (C) 929
- $S(NPMe_3)_4^{2+}$: The First Structure Determination of a Dication of Hexavalent Sulfur (C) 1362
- Structure and Bonding of Transition Metal Dihydrogen Complexes $[M(CO)_5(H_2)]$ (M = Cr, Mo, W) (C) 354
- Tetraphosphatricyclo[4.2.0.$0^{2,5}$]octadienes; New Phosphaalkyne Cyclotetramers Derived from $\lambda^3\sigma^2$-Diphosphetes (C) 484
- The Cope Rearrangement Transition Structure Is Not Diradicaloid, but Is It Aromatic? (C) 334
- The First Unambiguous Characterization of a Neutral Phosphorus Ylide–Lithium Complex: Isolation, Structure, and Ab Initio Investigations of $[(PhCH_2)_2NLi{\cdot}CH_2PPh_3]_2$ (C) 478

Acepentalenes
- Dilithium Acepentalenediide: An Unusual Dimer of Contact Ion Triplets with Bowl-Shaped Dianions (C) 1492

Acetylcholine receptor
- Toxins as Tools in Neurochemistry (R) 39

Acetylene complexes
- A Li_2Ti_2-Substituted Acetylene Formed from Ethylene by Reaction with (*meso*-Octaethylporphyrinogen)titanium (C) 1092

Actinides
- First Determination of the Ionization Potential of Americium and Curium (C) 814

Activated metals
- Activated Metals in Organic Synthesis (B) 121

Acyl anions
- α-Ethoxyvinyllithium: An Unexpected Polymeric Structure—Tetrameric Subunits Linked by Li–C π Interactions (C) 1594

Acylations
- Crystal Structure of the Dimeric (4-*tert*-Butylthiazolato)(glyme)lithium: Carbene Character of a Formyl Anion Equivalent (C) 487

Acyliminium ions
- Synthesis of D-(+)-Biotin through Selective Ring Closure of *N*-Acyliminium Silyl Enol Ethers (C) 2391

Acyloin condensation
- Peripherally Substituted Cobaloximes; X-Ray Crystal Structure Analysis of σ-Hexylbis[1,8-di(*N*-morpholino)octane-4,5-dioximato]pyridinecobalt(III) (C) 2389

Adamantanoid compounds
- Synthesis and Structure of $[Li(thf)_4]_2[Ph_2P)_{10}Cd_4]$ Containing; a Dianionic with a Cd_4P_{10} Adamantanoid Core (C) 2662

Adducts
- Stable 1:1 Adducts from Iodoacetylenes and Iodide Ions: Ion Pair Strain as an Additional Driving Force? (C) 441
- The Consequences of an Electrostatic "Forced Marriage" between Two Electron-Rich Particles: Strained Ion Pairs (C) 439

Adenylate cyclases
- G Proteins and Regulation of Adenylate Cyclase (Nobel Lecture) (R) 1406

Aggregation
- $(C_5Me_5)TiF_2$—A Versatile Building Block for Generating Large Soluble Dimetallic Aggregates (C) 1872
- Structure and Magnetic Properties of a Decanuclear Oxoiron(III) Cluster: A Further Step to Understanding Iron Aggregation Processes (C) 2716

Agostic interactions
- Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center (C) 916

Aldehydes
- A Highly Stereoselective Synthesis of 1,2-*trans*-C-Glycoside via Glycosyl Samarium(III) Compounds (C) 909

Aldolases
- Disaccharide Mimetics by Enzymatic Tandem Aldol Additions (C) 1639
- (*S*)-Selective Retroaldol Reaction and (*R*)-Selective β-Elimination with an Aldolase Catalytic Antibody (C) 2285

Aldol reactions
- (*S*)-Selective Retroaldol Reaction and (*R*)-Selective β-Elimination with an Aldolase Catalytic Antibody (C) 2285
- Synthesis and Characterization of the First Mixed Alkali Metal Enolate Containing Amine Ligands: A Novel "Open-Stack" Structure and its Implications for Aldol Addition (C) 1117

Alkali metal compounds
- Alkali Metallocene Anions: Syntheses and Structures (C) 2376
- Binding of Boron and Alkali Metal Cations by a Pseudocryptand (C) 1115
- "Cation-π Interactions" Detected by Mass Spectrometry; Selective Recognition of Alkali Metal Cations by a π-Basic Molecular Cavity (C) 1364
- Discrete Crown-Shaped Te_8 Rings in Cs_3Te_{22} (C) 450
- Synthesis and Characterization of the First Mixed Alkali Metal Enolate Containing Amine Ligands: A Novel "Open-Stack" Structure and its Implications for Aldol Addition (C) 1117
- The First Unambiguous Characterization of a Neutral Phosphorus Ylide–Lithium Complex: Isolation, Structure, and Ab Initio Investigations of $[(PhCH_2)_2NLi{\cdot}CH_2PPh_3]_2$ (C) 478
- The Stabilization of the Rb^- Ion in $Na_{16}Rb_7Sb_7 = Na_{16}(RbRb_6)Sb_7$ (C) 103
- The Synthesis and Crystal Structures of $RbC(SiMe_3)_3$ and $CsC(SiMe_3)_3{\cdot}3.5C_6H_6$: A One-Dimensional Ionic Solid and an Ionic Solid with a Molecular Structure (C) 687

Alkaline earth metal compounds
- Coordination of CO to the Alkaline Earth Metallocene $[(Me_5C_5)_2Ca]$ (C) 791

Alkanes
- Commensurate Freezing of *n*-Alkanes in Silicalite (C) 2543
- Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals (C) 2528

Alkene complexes
- A New Nickel-Catalyzed Cross-Coupling Reaction between sp^3 Carbon Centers (C) 2723
- Does the Facile Inter- and Intramolecular C–H Bond Activation by Tp*–Rh Complexes Proceed via Rh^{I} or Rh^{III} Intermediates? (C) 231
- New Findings in the Electrophilic Addition of Halogens to Olefins (H) 51

- Synthesis and Structure of 1-Aza- and 1-Phospha-2-titanacyclobut-4-enes (C) 688

Alkenes
- Cerium(III) Chloride Promoted Nucleophilic Addition of Organolithium Reagents to α-Alkyl-β-Ketophosphine Oxides: A New Protocol for the Synthesis of Stereochemically Defined Trisubstituted Olefins (C) 2046
- Control of the Reactivity of Double Bonds through Their Fixed Geometrical Arrangement (H) 2225
- Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)borane—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts (C) 1755
- Rhodium-Catalyzed Hydroformylation of Internal Alkynes to α,β-Unsaturated Aldehydes (C) 1760
- Stereospecific Olefin Polymerization with Chiral Metallocene Catalysts (R) 1143 (1368)
- Synthesis, Chemical Trapping, and Dimerization of 3,7-Dimethyltricyclo-[3.3.0.0^{3,7}]oct-1(5)-ene: [2+2] Retrocycloaddition of the Cyclobutane Dimer (C) 912

Alkoxo clusters
- A Hexadecanuclear Polyolatometalate of Copper(II) Ions and Multideprotonated D-Sorbitol (C) 2119

Alkylations
- A Camouflaged Icosahedral Carborane: Dodecamethyl-1,12-dicarbo-*closo*-dodecaborane(12) and Related Compounds (C) 1332
- A New Platform for Designing Ligands for Asymmetric Induction in Allylic Alkylations (C) 2386
- Asymmetric Alkylation of Amide Enolates with Pseudoephedrine and Ephedrine as Chiral Auxiliaries—Unexpected Influence of Additives? (H) 433
- Benzopyranoisoxazolidines as Chiral Auxiliaries for Asymmetric Synthesis (C) 793
- Cerium(III) Chloride Promoted Nucleophilic Addition of Organolithium Reagents to α-Alkyl-β-Ketophosphine Oxides: A New Protocol for the Synthesis of Stereochemically Defined Trisubstituted Olefins (C) 2046
- Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution (C) 462
- The Crafts–Friedel Reaction: Aromatic Alkylation within the Complex Formed upon Addition of a Gaseous Arenium Ion to an Olefin (C) 1589

Alkyne complexes
- New Findings in the Electrophilic Addition of Halogens to Olefins (H) 51
- $[Ni_3(alkyne)_4]$—The First Homoleptic Alkyne–Metal Oligomer (Alkyne: 2,5,5-Trimethylhex-3-yn-2-ol) (C) 1860

Alkynes
- Novel "π-Boat" Cage Compounds as Potential Cryptands (C) 789
- Palladium-Catalyzed Resactions of Propargylic Compounds in Organic Synthesis (R) 2589
- Rhodium-Catalyzed Hydroformylation of Internal Alkynes to α,β-Unsaturated Aldehydes (C) 1760
- The Reactivity of 1,3-Butadiyne Moieties in the "Exploding" [*n*]Rotanes—A Crown of Thiophenes (C) 781

Alkynetrimerization
- A Rhodium-Mediated, Stepwise Trimerization of an Alkyne That Does Not Lead to a Benzene but Selectively to a Hexadienyne Derivative (C) 191

Allenes
- Transition Metal Catalyzed Dimerization of Allenyl Ketones (C) 1581

Allosterism
- Complexes from Polyazacyclophanes, Fluorescence Indicators, and Metal Cations—An Example of Allosterism through Ring Contraction (C) 321

Allotropy
- New Evidence Concerning the Structure of Amorphous Red Phosphorus (H) 2637

Allylation
- Highly Stereoselective Allylation of Benzaldehyde: Generation of a Stereochemically Defined Allylzinc Species from a π-Allylpalladium Intermediate and Diethylzinc (C) 787

Allyl complexes
- C–C Coupling Reactions as a Novel Synthetic Route to π-Allyl- and π-Butadienylrhodium Complexes (C) 1244

Allylsilanes
- Intramolecular Allylsilane Addition to Chiral Alkylidene-1,3-dicarbonyl Compounds for the Synthesis of Enantiomerically Pure *trans*-1,2-Disubstituted Cyclopentanes and Cyclohexanes (C) 1731

Altrose
- β-Cycloaltrin: A Cyclooligosaccharide Consisting of Seven α(1→4)-Linked Altropyranoses (C) 1621

Aluminum compounds
- AlMepO-α: A Novel Open-Framework Aluminum Methylphosphonate with Organo-Lined Unidimensional Channels (C) 1199
- Al,Ti Avoidance in the Microporous Titanoaluminosilicate ETAS-10 (C) 1003
- Cobalt-Containing Molecular Sieves as Catalysts for the Low Conversion Autoxidation of Pure Cyclohexane (C) 560
- Galloxane and Alumoxane Hydroxides: $[Ga_{12}tBu_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$ and $[Al_6tBu_6(\mu_3\text{-}O)_4(\mu\text{-}OH)_4]$ (C) 1201
- Soluble Aluminosilicates with Frameworks of Minerals (C) 2504
- Structure Organization of Aluminosilicate Polyanions with Surfactants: Optimization of Al Incorporation in Aluminosilicate Mesostructural Materials (C) 1499
- Synthesis and Structure of Organometallic Compounds with $(Al_2Si)_2$ and Al_3Sb_2 Frameworks (C) 919
- The "Submetalate" $Ba_{17}Al_3O_7$: The First Member of a New Class of Compounds (C) 2115

Americium
- First Determination of the Ionization Potential of Americium and Curium (C) 814

Amide hydrolysis
- "Fast Amide Cleavage" or Reproducible, Concentration- and Time-Dependent Aggregation of Anionic and Cationic Surfactants? (C) 2718

Amides
- Relationship between C(O)–N Twist Angles and ^{17}O NMR Chemical Shifts in a Series of Twisted Amides (C) 1113
- The First Unambiguous Characterization of a Neutral Phosphorus Ylide–Lithium Complex: Isolation, Structure, and Ab Initio Investigations of $[(PhCH_2)_2NLi\cdot CH_2PPh_3]_2$ (C) 478

Aminations
- Palladium-Catalyzed Amination of Aryl Halides—Catalysts on New Routes to Known Targets (H) 1316

Amino acids
- Asymmetric Pictet–Spengler Reactions Employing *N,N*-Phthaloyl Amino Acids as Chiral Auxiliary Groups (C) 2402
- Enantioselective Synthesis of β-Amino Acids: TMS-SAMP as a Chiral Ammonia Equivalent for the Aza Analogous Michael Addition to α,β-Unsaturated Esters (C) 455
- Photo Electron Transfer Induced Macrocyclization of *N*-Phthaloyl-ω-aminocarboxylic Acids (C) 474
- Probing Protein Structure and Function with an Expanded Genetic Code (R) 621
- Recent Trends in Photoaffinity Labeling (R) 1296
- Synthesis of Chiral γ,δ-Unsaturated Amino Acids by Asymmetric Ester Enolate Claisen Rearrangement (C) 2012
- The Arndt–Eistert Reaction in Peptide Chemistry: A Facile Access to Homopeptides (C) 471

Amino alcohols
- Diastereo- and Enantioselective Synthesis of 1,2-Amino Alcohols from Glycol Aldehyde Hydrazones; Asymmetric Synthesis of (*R,R*)-Statin (C) 1219

Amino aldehydes
- First Dynamic Kinetic Resolution of Racemic α-Amino Aldehydes (C) 1023

Aminoalkylations
- Regio- and Diastereoselective Synthesis of β-Amino Ketones by Addition of Imines to Iminium Salts (C) 2639

Amino compounds
- Zeolite Encaged Cu(Histidine) Complexes as a Mimic of Natural Cu Enzymes (C) 2652

Aminocyclopentadienes
- Aminocyclopentadienes, Aminoferrocenes, and Aminocobaltocenes (C) 800

Aminosugars
- Enantiospecific Syntheses of Valiolamine and Its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid (C) 1643

Amorphous inorganic materials
- Amorphous Inorganic Materials and Glasses (B) 242

Amphiphiles
- Mesogenic Properties of Amphiphilic Liquid Crystals with an Unusual Head-Group Topology (C) 1631
- Synthesis and X-ray Structure of a Shape-Persistent Macrocyclic Amphiphile (C) 2713

α-Amylase assay
- Chemoenzymatic Synthesis of a Modified Pentasaccharide as a Specific Substrate for a Sensitive Assay of α-Amylase by Fluorescence Quenching (C) 1239

Analytical methods
- Basic Principles of Thermoanalytical Techniques and Their Applications in Preparative Chemistry (R) 1171
- Instrumental Methods for Determining Elements (B) 935
- Methods of Immunological Analysis, Vols. 1–3 (B) 243
- Vibrational Spectroscopy in Supercritical Fluids: From Analysis and Hydrogen Bonding to Polymers and Synthesis (R) 1275

Anhydrides
- Highly Enantioselective Opening of Cyclic *meso*-Anhydrides to Isopropyl Hemiesters with Diisopropoxytitanium TADDOLates (C) 2395

Anilines
- Complexation of [*N,N'*-Bis(salicylidene)-ethylenediiminato]cobalt(III)$^+$ by Anilines in Dimethylformamide (C) 1086

Anion complexation
- Molecular Recognition of Anions by Zwitterionic Host Molecules in Water (C) 65

Anion–cation surfactant aggregation
- "Fast Amide Cleavage" or Reproducible, Concentration- and Time-Dependent Aggregation of Anionic and Cationic Surfactants? (C) 2718

Annulation
- Sequential Transformation of Benzothiopyrylium Salts to Diastereoselectively Annulated Benzothiopyranones (C) 647

Annulenes
- Novel Structures from Tris(benzocyclobutadieno)cyclohexatriene: Triscyclopropanation and Trisoxacyclopropanation to the First [2.1.2.1.2.1]Hexaannulanes (C) 563
- Synthesis of Belt Cyclophanes (C) 1437

Anthraquinones
- Total Synthesis of (±)-Dynemicin A (C) 1721

Antiaromaticity
- C_3-Symmetric Hexakis(trimethylsilyl)[7]-phenylene ["Tris(biphenylenocyclobutadieno)cyclohexatriene"], a Polycyclic Benzenoid Hydrocarbon with Slightly Curved Topology (C) 1478

Antibiotics
- Biosyntheses of Novel Emycins from the Mutant Strain *Streptomyces cellulosae* ssp. *griseoincarnatus* 1114-2 (C) 1617
- Efficient Total Synthesis of the Pharmacophore of the Anticancer Antibiotic CC-1065 by Zirconocene- and Palladium-Initiated Cyclizations (C) 1366
- Estramycins: A New Diyl Precursor Family Derived from Estradiol (C) 1749
- 9-Methoxystrobilurins—A Link Between Strobilurins and Oudemansins (C) 196
- Relative and Absolute Configuration of Filipin III (C) 1227
- Total Synthesis of Natural (+)-SF2315A and Determination of the Absolute Configuration (C) 2396

Antibodies
- Micron-Scale Patterning of Biological Molecules (C) 91

Antidepressants
- Talking Back to Prozac: What Doctors Aren't Telling You about Today's Most Controversial Drug (B) 1250

Antimony compounds
- Cage Expansion of $[\{(cyNLi)_3Sb\}_2]$; Synthesis and Structure of the Trimetallic Complex $[\{(cyNLi)_3Sb\}_2(t\text{BuOK})_3 \cdot x C_6H_5CH_3]$ (C) 1012
- Structure and Bonding in Organometallic Anions of Heavy Group 14 and 15 Elements (R) 1545
- Synthesis and Structure of Organometallic Compounds with $(Al_2Si)_2$ and Al_3Sb_2 Frameworks (C) 919
- The First Distibabutadiene: Synthesis and Structure of *trans*-1,4-Bis(trimethylsiloxy)-1,4-bis(2,4,6-tri-*tert*-butylphenyl)-2,3-distibabutadiene (C) 492
- The Stabilization of the Rb^- Ion in $Na_{16}Rb_7Sb_7 = Na_{16}(RbRb_6)Sb_7$ (C) 103

Antisense systems
- 1,5-Anhydrohexitol Nucleic Acids, a New Promising Antisense Construct (C) 1338 (2165)
- Phosphorothioates: β-Fragmentation versus β-Silicon Effect (C) 2406

Antitumor agents
- Efficient Total Synthesis of the Pharmacophore of the Anticancer Antibiotic CC-1065 by Zirconocene- and Palladium-Initiated Cyclizations (C) 1366
- Estramycins: A New Diyl Precursor Family Derived from Estradiol (C) 1749
- Lactendiynes: A New Class of Triggered Cyclic Enediynes (C) 2393
- Platination Pathways for Reactions of Cisplatin with GG Single-Stranded and Double-Stranded Decanucleotides (C) 1874
- Synthesis, Antitumor Activity, and Tolerability of Phospholipids with Nitrogen Homologues (C) 238

Anti van't Hoff/Le Bel geometries
- Compounds with Planar Tetracoordinate Boron Atoms: Anti van't Hoff/Le Bel Geometries without Metal Centers (C) 327

Aqua complexes
- The Nonaaquabismuth(III) Cation (C) 2416

Archaea bacteria
- On the Mechanism of Catalysis by a Metal-Free Hydrogenase from Methanogenic Archaea: Enzymatic Transformation of H_2 without a Metal and Its Analogy to the Chemistry of Alkanes in Superacidic Solution (C) 2247

Arene anions
- Self-Diffusion of Charged Polycyclic Systems and Their Parent Compounds: A PGSE NMR Study (C) 816

Arene complexes
- Additions of Carbanions to a Cationic Cyclopentadienyl(naphthalene)iron Complex (C) 2161
- Aromatic Gallium Heterocycles: Synthesis of the First Gallatabenzene (C) 1357
- Hydrocarbon Activation with Metal Halides: Catalysis of the Jacobsen Rearrangement by $(ZrCl_4)_n$ in the Presence of Aromatic Hydrocarbons (C) 1510
- Mononuclear Tris(arene)–Metal Complexes (H) 53
- Radical Additions to (η^6-Arene)-(tricarbonyl)chromium Complexes: Diastereoselective Synthesis of Hydrophenalene and Hydrobenzindene Derivatives by Samarium(II) Iodide Induced Cyclization (C) 2383
- Synthesis and Structure of Bimetallic η^4,η^6-Naphthalene Complexes Containing a Mn–Mn Moiety Bonded in a *Syn*-Facial Manner: A General Route to Homo- and Heteronuclear Bimetallic Complexes of Polyarenes (C) 2540
- [Bis{(η^5-pentamethylcyclopentadienyl)-cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands (C) 592
- $[R_3Si-\text{arene}]^+$ σ Complexes in the Gas Phase (C) 654

Arene oxidation
- Catalytic Photoinduced Charge-Transfer Osmylation: A Novel Pathway from Arenes to Cyclitol Derivatives (C) 2031

Arenes
- Diodelike Current–Voltage Curves for a Single Molecule—Tunneling Spectroscopy with Submolecular Resolution of an Alkylated, *peri*-Condensed Hexabenzocoronene (C) 1609
- First-Ever Per(onio) Substitution of Benzene: The Role of the Counterion (C) 1319
- Fullerene Model Compounds: Bowl-Shaped Aromatic Hydrocarbons and Cyclophane-Based Cage Molecules (H) 1429
- Quaterrylenebis(dicarboximides) (C) 1323
- Reactions of Neopentyl 2,2,-Trifluoroethanesulfonate (Neopentyl Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose (C) 2495
- Self-Diffusion of Charged Polycyclic Systems and Their Parent Compounds: A PGSE NMR Study (C) 816

Arndt–Eistert reactions
- The Arndt–Eistert Reaction in Peptide Chemistry: A Facile Access to Homopeptides (C) 471

Aromaticity
- Aromaticity and Antiaromaticity in Five-Membered C_4H_4X Ring Systems: "Classical" and "Magnetic" Concepts May Not Be "Orthogonal" (C) 337
- Five-Membered Aromatic and Anti-aromatic Rings with Gallium, Germanium, and Bismuth Centers: A Short March through the Periodic Table (H) 295
- Novel Porphyrinoids for Chemistry and Medicine by Biomimetic Syntheses (R) 1795
- Oxybenziporphyrin, a Fully Aromatic Semiquinone Porphyrin Analog with Pathways for 18π-Electron Delocalization (C) 2533
- Synthesis and Structure of a Free Germacyclopentadienide Ion: $[Li([12]crown-4)_2][C_4Me_4GeSi(SiMe_3)_3]$ (C) 1887
- 1,3,5,7-Tetra-*tert*-butyl-4-aza- and 1,3,5,7-Tetra-*tert*-butyl-4-phospha-*s*-indacene (C) 330

Aromatic substitutions
- Nucleophilic Aromatic Substitution of Hydrogen (B) 2419
- The Crafts–Friedel Reaction: Aromatic Alkylation within the Complex Formed upon Addition of a Gaseous Arenium Ion to an Olefin (C) 1589

Arsenic compounds
- η^5:η^2 Coordination of a *cyclo*-E_5 Ligand, E = P, As (C) 1321
- Diphosphanyl- and Diarsanyl-Substituted Carbene Homologues: Germanediyls, Stannanediyls, and Plumbanediyls with Remarkable Electronic Structures (C) 1614

Arylamines
- A Simple Catalytic Method for the Conversion of Aryl Bromides to Arylamines (C) 1348
- Palladium-Catalyzed Amination of Aryl Halides—Catalysts on New Routes to Known Targets (H) 1316

Arynes
- Single-Crystal X-Ray Structure of the Metastable Aryne Precursor Tetrafluorophenyllithium and of 1,2,3,4-Tetrafluorobenzene (C) 1517

Asteranes
- Synthesis of a Cationic 1,3-Diphospha-2,4-dipallada(II)tricyclo[1.1.1]pentane Derivative: The First Structurally Characterized Pyramidal μ_2-Phosphinidene (C) 2677

Asymmetric syntheses
- A Chiral Cyanohydrin Phosphate for Carbonyl Umpolung—Stereoselective Synthesis of Tertiary Cyanohydrins (C) 917
- Acyclic 1,4-Diastereoselectivity in γ-Substituted α-Enones: Transmission of Chiral Information through Conjugation (C) 2254
- A Highly Stereoselective Synthesis of 1,2-*trans*-C-Glycoside via Glycosyl Samarium(III) Compounds (C) 909
- A New Platform for Designing Ligands for Asymmetric Induction in Allylic Alkylations (C) 2386
- A Simple, Chirogenic, Enantioselective Synthesis of Chlorins and Isobacteriochlorins (C) 784

- Asymmetric Alkylation of Amide Enolates with Pseudoephedrine and Ephedrine as Chiral Auxiliaries—Unexpected Influence of Additives? (H) 433
- Asymmetric Allylic Substitution with Nitromethane Catalyzed by a Pd Complex: Enantioselectivities Exceeding 99.9% ee (C) 2687
- Asymmetric Pictet–Spengler Reactions Employing *N,N*-Phthaloyl Amino Acids as Chiral Auxiliary Groups (C) 2402
- Asymmetric Reaction of Arylalkenes with Diselenides (C) 1726
- Asymmetric Sulfide Oxidation with Vanadium Catalysts and H_2O_2 (C) 2640
- Asymmetric Syntheses of Stavudine (d4T) and Cordycepin by Cycloisomerization of Alkynyl Alcohols to Endocyclic Enol Ethers (C) 350
- Asymmetrization of *meso* 1,4-Enediol Ethers by Isomerization with a Chiral binap–Rh^I Catalyst (C) 2287
- Benzopyranoisoxazolidines as Chiral Auxiliaries for Asymmetric Synthesis (C) 793
- Carbenoid Transfer to Imines: A New Asymmetric Catalytic Synthesis of Aziridines (C) 676
- Catalytic Asymmetric Carbonyl–Ene Reactions (H) 1717
- Catalytic Asymmetric C–C Bond Formation: New Enolato- and Organolithium Chemistry (H) 178
- Cerium(III) Chloride Promoted Nucleophilic Addition of Organolithium Reagents to α-Alkyl-β-Ketophosphine Oxides: A New Protocol for the Synthesis of Stereochemically Defined Trisubstituted Olefins (C) 2046
- Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution (C) 462
- Chiral Titanium Alkoxides as Catalysts for the Enantioselective Reduction of Ketones with Boranes (C) 2005
- Diastereo- and Enantioselective Synthesis of 1,2-Amino Alcohols from Glycol Aldehyde Hydrazones; Asymmetric Synthesis of (*R,R*)-Statin (C) 1219
- Diastereo- and Enantioselective Synthesis of Polyfunctional Ketones with Adjacent Quaternary and Tertiary Centers by Asymmetric Carroll Rearrangement (C) 2278
- Diastereoselective Coupling of Anodically Produced Radicals Bearing Chiral Amide Groups (C) 189
- Discrimination between Enantiotopic Groups in a Diels–Alder Reaction (C) 448
- Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)-cobalt(II) Complexes (C) 2145
- Enantioselective Synthesis of β-Amino Acids: TMS-SAMP as a Chiral Ammonia Equivalent for the Aza Analogous Michael Addition to α,β-Unsaturated Esters (C) 455
- Enantiospecific Syntheses of Valiolamine and Its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid (C) 1643
- Facial Diastereoselectivity in the Paternò–Büchi Reaction of Chiral Silyl Enol Ethers (C) 2271
- First Dynamic Kinetic Resolution of Racemic α-Amino Aldehydes (C) 1023
- Generation of Enantiomerically Enriched Lithium Indenides by Means of (−)-Sparteine: Structure, Stereoselective Substitution, and Solvent Effects (C) 2158
- Highly Enantioselective Opening of Cyclic *meso*-Anhydrides to Isopropyl Hemiesters with Diisopropoxytitanium TADDOLates (C) 2395
- Intramolecular Allylsilane Addition to Chiral Alkylidene-1,3-dicarbonyl Compounds for the Synthesis of Enantiomerically Pure *trans*-1,2-Disubstituted Cyclopentanes and Cyclohexanes (C) 1731
- Ligand-Accelerated Catalysis (R) 1059
- Preparation of a Surface-Active Chiral Diphosphane and Its Use in the Hydrogenation of Prochiral Olefins (C) 1645
- Regio- and Diastereoselective Synthesis of β-Amino Ketones by Addition of Imines to Iminium Salts (C) 2639
- Stereoselective Syntheses of Peptide Derivatives with 2-Acetamido-3,4,6-tri-*O*-acetyl-1-amino-2-deoxy-β-D-glucopyranose by Four-Component Condensation (C) 1104
- Stereoselective Synthesis (B) 1372
- Strong Electronic Effects on Enantioselectivity in Rhodium-Catalyzed Hydroborations with Novel Pyrazole-Containing Ferrocenyl Ligands (C) 931
- C_2-Symmetric Cationic Copper(II) Complexes as Chiral Lewis Acids: Counterion Effects in the Enantioselective Diels–Alder Reaction** (C) 798
- Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks (C) 2116
- Synthesis and Structural Characterization of a Stereospecific Dinuclear Gallium Triple Helix: Use of the *trans*-Influence in Metal-Assisted Self-Assembly (C) 996
- Synthesis of Chiral γ,δ-Unsaturated Amino Acids by Asymmetric Ester Enolate Claisen Rearrangement (C) 2012

Atmospheric chemistry
- Sulfuric Acid, from Sulfur Trioxide and Water—A Surprisingly Complex Reaction (H) 1313

ATP
- Octacationic Cyclophanes: Binding of ATP and Other Anionic Guests in Water (C) 2147

ATPase
- Incorporation of Membrane Proteins in Solid-Supported Lipid Layers (C) 2056

Atropisomerism
- A New Application of Capillary Zone Electrophoresis: Determination of Energy Barriers of Configurationally Labile Chiral Compounds (C) 1635
- Homeomorphic Isomerism in a Peptidic Macrobicycle (C) 2660

Aurophilicity
- A Gold(I) [2]Catenane (C) 1894
- Gold in Chains: Self-Assembly of a Gold(I) Catenane (H) 2107

Autocorrelation
- Assessing Similarity and Diversity of Combinatorial Libraries by Spatial Autocorrelation Functions and Neural Networks (C) 2674

Automerizations
- Automerizations and Isomerizations in Propynylidene (HCCCH), Propadienylidene (H_2CCC), and Cyclopropenylidene (c-C_3H_2) (C) 2009
- Fluxionality Induced by High Pressure: [9-D]9-Homocubyl Triflate, a Pressure-Sensing Molecule (C) 2030

Autoxidation
- Cobalt-Containing Molecular Sieves as Catalysts for the Low Conversion Autoxidation of Pure Cyclohexane (C) 560

Aza-Claisen reaction
- Synthesis of Optically Active Nine-Membered Ring Lactams by a Zwitterionic Aza-Claisen Reaction (C) 1026

Azacyclophanes
- Complexes from Polyazacyclophanes, Fluorescence Indicators, and Metal Cations—An Example of Allosterism through Ring Contraction (C) 321

Azepines
- First Synthesis of 2*H*-Azepine (C) 1469

Azetidinones
- Lactendiynes: A New Class of Triggered Cyclic Enediynes (C) 2393

Azides
- Covalent Inorganic Azides (R) 511
- Ring Expansion of the Fullerene Core by Highly Regioselective Formation of Diazafulleroids (C) 1343

Aziridines
- Carbenoid Transfer to Imines: A New Asymmetric Catalytic Synthesis of Aziridines (C) 676

Azo compounds
- Photoswitchable Phase Separation in Hydrophobically Modified Poly(acrylamide)/Surfactant Systems (C) 88

Azolides
- Tris(dimethylamino)sulfoniumcyclopentadienide $[TAS]^+[C_5H_5]^-$ and Tris(dimethylamino)sulfoniumpyrrolide $[TAS]^+[C_4H_4N]^-$: Two Isostructural Salts with "Naked" Anions A^- and the "Inverse" Sandwich-Cations $[\{(Me_2N)_3S\}_2A]^+$ (A = $C_5H_5^-$, $C_4H_4N^-$) (C) 443

Azomethine ylides
- Design of Novel, Nonpeptidic Thrombin Inhibitors and Structure of a Thrombin–Inhibitor Complex (C) 1739

Azoninones
- Synthesis of Optically Active Nine-Membered Ring Lactams by a Zwitterionic Aza-Claisen Reaction (C) 1026

Baccatin III
- A Novel Intramolecular Heck Reaction: Synthesis of a Cholesterol–Baccatin III Hybrid (C) 452
- A Total Synthesis of Taxol (C) 1723

Barbituric acid
- Barbituric Acid/2,4,6-Triaminopyrimidine Aggregates in Water and Their Competitive Interaction with Monolayers of Barbituric Acid Lipids at the Gas–Water Interface (C) 58

Barium compounds
- The Lipophilically Wrapped Polyion Aggregate $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$, a Face-Sharing (Octahedron + Prismane) $Ba_6Li_3O_2$ Polyhedron in a Hydrocarbon Ellipsoid: Preparation, Single Crystal Structure Analysis, and Density Functional Calculations (C) 1353
- The "Submetalate" $Ba_{17}Al_3O_7$: The First Member of a New Class of Compounds (C) 2115

Benzodiphospholes
- A Facile Access to $1\lambda^5,3\lambda^5$-Benzodiphospholes (C) 2017

Biaryls
- Activation of Macrocyclic Biaryl-Enediynes by Metal Ion Coordination (C) 2538
- A New Family of Chiral Binaphthyl-Derived Cyclophane Receptors: Complexation of Pyranosides (C) 1596

Bicyclonucleotides
- Triple-Helix Formation of Oligodeoxynucleotides Containing [(3′*S*,5′*R*)-2′-Deoxy-3′,5′-ethano-β-D-ribofuranosyl]nucleosides ("Bicyclo-deoxynucleosides") (C) 694

Bicyclopentanes
- Heteroatom-Substituted Bicyclo[1.1.1]-pentanes with Two Boron Atoms as Electron-Deficient Centers (C) 657

Binuclear complexes
- Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center (C) 916

- *closo*-$[B_5H_4PPh_3\{Fe(CO)_3\}\{Ir(CO)_2PPh_3\}]$: The First Structurally Characterized *closo*-Heterobimetallaheptaborane System (C) 1641

Brain lipids
- New Brain Lipids that Induce Sleep (H) 2362

Bridging ligands
- A Li_2Ti_2-Substituted Acetylene Formed from Ethylene by Reaction with (*meso*-Octaethylporphyrinogen)titanium (C) 1092
- Oligomethylene-Bridged Vitamin B_{12} Dimers (C) 84

Bromine compounds
- Bromides of Rare Earth Metal Boride Carbides—A System of Building Blocks (C) 1633
- Synthesis, Structure, and Decay of In_4Br_7 (C) 1126

Butatrienes
- Butatrienes by Cumuhomologation of Propadienes (C) 2709

Cadmium compounds
- Self-Assembled Helicates of Zinc and Cadmium Cyanides, $[M_x(CN)_{2x+1}]^-$, $x \leq 27$ (C) 314

- Synthesis and Structure of Tetra- and Octanuclear Chelate Complexes—Exohedral Guest Exchange in Tetrahemispheraplexes (C) 993
- Synthesis and Structure of $[Li(thf)_4]_2[Ph_2P)_{10}Cd_4]$ Containing; a Dianionic with a Cd_4P_{10} Adamantanoid Core (C) 2662

Cage compounds
- Cage Expansion of $[\{(cyNLi)_3Sb\}_2]$; Synthesis and Structure of the Trimetallic Complex $[\{(cyNLi)_3Sb\}_2(tBuOK)_3 \cdot xC_6H_5CH_3]$ (C) 1012
- Crystal Structure of Dilithioacetylacetone: A Twenty-Four Vertex Li-O Cage Molecule with Limited Li–C(terminal) Bonding and Selective THF Solvation (C) 1233
- Fullerene Model Compounds: Bowl-Shaped Aromatic Hydrocarbons and Cyclophane-Based Cage Molecules (H) 1429
- Galloxane and Alumoxane Hydroxides: $[Ga_{12}tBu_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$ and $[Al_6tBu_6(\mu_3\text{-}O)_4(\mu\text{-}OH)_4]$ (C) 1201
- Modeling the Remote-Controlled Organization of Particles in a Nanodimensional Cavity: Synthesis and Properties of $(Et_3NH)_3(tBuNH_3)_2Na_2[(H_2O)_2,N_3^-\subset V_{14}O_{22}(OH)_4(PhPO_3)_8]\cdot 6\,H_2O\cdot 2$ DMF (C) 779
- Novel "π-Boat" Cage Compounds as Potential Cryptands (C) 789
- Synthesis, Chemical Trapping, and Dimerization of 3,7-Dimethyltricyclo-[3.3.0.0^{3,7}]oct-1(5)-ene: [2+2] Retrocycloaddition of the Cyclobutane Dimer (C) 912
- *meso*-Tetrakis[4-(diphenylphosphino)-phenyl]porphyrin and a Water-Soluble Octakis(phosphonium salt) Porphyrin Double-Decker with a Cage Structure. (C) 2230

Calcium compounds
- New Surprises in Metal Carbonyl Chemistry (H) 2489

Calixarenes
- Calixarenes, Macrocycles with (Almost) Unlimited Possibilities (R) 713
- "Cation-π Interactions" Detected by Mass Spectrometry; Selective Recognition of Alkali Metal Cations by a π-Basic Molecular Cavity (C) 1364
- Concave Reagents Based on Calixarenes (C) 2555
- Molecular Recognition at an Interface: Binding of Monolayer-Anchored Ferrocenyl Groups by an Amphiphilic Calixarene Host (C) 235
- Silicon-Bridged Macrocycles—Synthesis of Sila-Calixarenes (C) 661

Calonyctin A
- The Macrolidic Glycolipid Calonyctin A, a Plant Growth Regulator: Synthesis, Structural Assignment, and Conformational Analysis in Micellar Solution (C) 2520

Camptothecin
- Cascade Radical Reactions of Isonitriles: A Second-Generation Synthesis of (20*S*)-Camptothecin, Topotecan, Irinotecan, and GI-147211C (C) 2683

Capillary zone electrophoresis
- A New Application of Capillary Zone Electrophoresis: Determination of Energy Barriers of Configurationally Labile Chiral Compounds (C) 1635
- Direct On-Line Coupling of Capillary Electrophoresis and ^1H NMR Spectroscopy (H) 641

Carbene analogues
- Diphosphanyl- and Diarsanyl-Substituted Carbene Homologues: Germanediyls, Stannanediyls, and Plumbanediyls with Remarkable Electronic Structures (C) 1614

Carbene complexes
- A Series of Well-Defined Metathesis Catalysts—Synthesis of $[RuCl_2(=CHR')(PR_3)_2]$ and Its Reactions (C) 2039
- Carbene Complex Functionalized Sugars (C) 1856
- Catalytic Ring-Closing Metathesis: A New, Powerful Technique for Carbon–Carbon Coupling in Organic Synthesis (H) 1833
- Dicobalt and Diplatinum Complexes of Diborylcarbenes (C) 1111

Carbene reactions
- (*S*)-(+)- and (*R*)-(−)-1,5-Dimethyl-4-phenyl-1,5-dihydro-2*H*-pyrrol-2-ones by Carbene Ring Contraction and Decarboxylation of (2*R*,3*S*)-(−)- and (2*S*,3*R*)-(+)-6-Diazo-3,4-dimethyl-2-phenyloxazepane-5,7-diones (C) 78

Carbenes
- Automerizations and Isomerizations in Propynylidene (HCCCH), Propadienylidene (H_2CCC), and Cyclopropenylidene ($c\text{-}C_3H_2$) (C) 2009
- Crystal Structure of the Dimeric (4-*tert*-Butylthiazolato)(glyme)lithium: Carbene Character of a Formyl Anion Equivalent (C) 487
- Diborylcarbenes as Reactive Intermediates in Double 1,2-Rearrangements with Low Activation Enthalpies (C) 1340
- Metal Complexes of N-Heterocyclic Carbenes—A New Structural Principle for Catalysts in Homogeneous Catalysis (C) 2371
- N-Confused Porphyrins and Singlet Carbenes: Is There a Connection? (C) 1028
- Preparation, Structure, and Reactivity of 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene, a New Stable Carbene (C) 1021
- Reaction of 1,1-Dimethylsilene with Formaldehyde (C) 929
- Synthesis of a 2*H*-Azirine by [1+2] Cycloaddition of a Phosphinocarbene with a Nitrile and Its Ring-Expansion to a 1,2λ^5-Azaphosphete (C) 1246

Carbenoids
- Carbenoid or Lithium Complex of a Carbanion? Synthesis and Structure of $(Me_3Si)_2C{=}P(aryl){=}C(Cl)Li(thf)_3$ and LiCl Elimination To Give the Phosphirene (C) 1849
- α-Ethoxyvinyllithium: An Unexpected Polymeric Structure—Tetrameric Subunits Linked by Li–C π Interactions (C) 1594

Carbides
- Bromides of Rare Earth Metal Boride Carbides—A System of Building Blocks (C) 1633

Carbocations
- 4c/3e Radical Cations with Cage-Directed Configurations (C) 1016
- Common Origin of Enthalpic and Entropic Substituent Effects in Reactions of Benzhydryl Cations with Nucleophiles (C) 490
- Fluxionality Induced by High Pressure: [9-D]9-Homocubyl Triflate, a Pressure-Sensing Molecule (C) 2030
- My Search for Carbocations and Their Role in Chemistry (Nobel Lecture) (R) 1393
- On the Mechanism of Catalysis by a Metal-Free Hydrogenase from Methanogenic Archaea: Enzymatic Transformation of H_2 without a Metal and Its Analogy to the Chemistry of Alkanes in Superacidic Solution (C) 2247
- Reactions of Carbocations with π Nucleophiles: Polar Mechanism and No Outer Sphere Electron Transfer Processes (C) 1225
- The Coexistence of the Reactivity–Selectivity Principle and of Linear Free Energy Relationships: A Diffusion Clock for Determining Carbocation Reactivities (C) 2250

Carbocycles
- Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings (H) 2223

Carbohydrate amino acids
- Saccharide–Peptide Hybrids as Novel Oligosaccharide Mimetics (C) 2712

Carbohydrates
- A New Family of Chiral Binaphthyl-Derived Cyclophane Receptors: Complexation of Pyranosides (C) 1596
- Carbene Complex Functionalized Sugars (C) 1856
- Disaccharide Mimetics by Enzymatic Tandem Aldol Additions (C) 1639
- Enzymes in Organic Synthesis: Application to the Problems of Carbohydrate Recognition (Part 1) (R) 412
- Enzymes in Organic Synthesis: Application to the Problems of Carbohydrate Recognition (Part 2) (R) 521
- Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium (C) 2647
- Mesogenic Properties of Amphiphilic Liquid Crystals with an Unusual Head-Group Topology (C) 1631
- Palladacycles as Structurally Defined Catalysts for the Heck Olefination of Chloro- and Bromoarenes (C) 1844
- Reactions of Neopentyl 2,2,2-Trifluoroethanesulfonate (Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose (C) 1612
- Thymidine Diphospho-6-deoxy-α-D-*ribo*-3-hexulose—Synthesis of a Central Intermediate in the Biosynthesis of Di- and Trideoxysugars (C) 1328

Carbon allotropes
- Solubilized Derivatives of C_{195} and C_{260}: The First Members of a New Class of Carbon Allotropes $C_{n(60+5)}$ (C) 1466

Carbon dioxide
- Carbon Dioxide as a Raw Material: The Synthesis of Formic Acid and Its Derivatives from CO_2 (R) 2207
- Fluorocarbonate, $[FCO_2]^-$: Preparation and Structure (C) 1858
- σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation (C) 1742
- Tantalum-Mediated Coupling of Methane and Carbon Dioxide in the Gas Phase (C) 2033

Carbonylations
- Palladium-Catalyzed Resactions of Propargylic Compounds in Organic Synthesis (R) 2589
- Rhodium–Vinylallene Complexes and a New Reaction, Rhodium-Catalyzed Carbonylative [4+1]Cycloaddition (C) 2691

Carbonyl complexes
- Coordination of CO to the Alkaline Earth Metallocene $[(Me_5C_5)_2Ca]$ (C) 791

- New Surprises in Metal Carbonyl Chemistry (H) 2489

Carbonyl–ene reactions
- Catalytic Asymmetric Carbonyl–Ene Reactions (H) 1717

Carbon–carbon coupling
- Atom Economy—A Challenge for Organic Synthesis: Homogeneous Catalysis Leads the Way (R) 259
- C–C Coupling Reactions as a Novel Synthetic Route to π-Allyl- and π-Butadienylrhodium Complexes (C) 1244

Carboranes
- A Camouflaged Icosahedral Carborane: Dodecamethyl-1,12-dicarbo-*closo*-dodecaborane(12) and Related Compounds (C) 1332
- Surprising Formation of a Carborane-Substituted Digallane (C) 332

Carboximides
- Quaterrylenebis(dicarboximides) (C) 1323

Carboxylic acids
- Self-Assembly of 1,3,5-Benzenetricarboxylic Acids (Trimesic Acids) and Their Analogues in the Solid State (C) 2654

Carbyne complexes
- Aminocarbyne Complexes of Chromium in a High Oxidation State—Synthesis, Structure, and Reactivity (C) 924

Cascade reactions
- Cascade Radical Reactions of Isonitriles: A Second-Generation Synthesis of (20*S*)-Camptothecin, Topotecan, Irinotecan, and GI-147211C (C) 2683
- Sequential Transformation of Benzothiopyrylium Salts to Diastereoselectively Annulated Benzothiopyranones (C) 647
- Unprecedented Intra- and Intermolecular Palladium-Catalyzed Coupling Reactions with Methylenecyclopropane Type Tetrasubstituted Alkenes (C) 2545

Catalysis
- An Ab Initio Investigation of the Rh^I-Catalyzed Hydroboration of C=C Bonds: Evidence for Hydrogen Migration in the Key Step (C) 115
- A New Method for the Preparation of Nanostructured Metal Clusters (C) 2240
- A New Nickel-Catalyzed Cross-Coupling Reaction between sp^3 Carbon Centers (C) 2723
- A New Strategy in Heterogeneous Catalysis: The Design of Cortex Catalysts (C) 2728
- A Simple Catalytic Method for the Conversion of Aryl Bromides to Arylamines (C) 1348
- Asymmetric Allylic Substitution with Nitromethane Catalyzed by a Pd Complex: Enantioselectivities Exceeding 99.9% ee (C) 2687
- Asymmetric Sulfide Oxidation with Vanadium Catalysts and H_2O_2 (C) 2640
- Asymmetrization of *meso* 1,4-Enediol Ethers by Isomerization with a Chiral binap–Rh^I Catalyst (C) 2287
- A Tailor-Made Metallocene for the Copolymerization of Ethene with Bulky Cycloalkenes (C) 2273
- Atom Economy—A Challenge for Organic Synthesis: Homogeneous Catalysis Leads the Way (R) 259
- Catalytic Asymmetric Carbonyl–Ene Reactions (H) 1717
- Catalytic Asymmetric C–C Bond Formation: New Enolato- and Organolithium Chemistry (H) 178
- Catalytic Ring-Closing Metathesis: A New, Powerful Technique for Carbon–Carbon Coupling in Organic Synthesis (H) 1833
- Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution (C) 462
- Chiral Titanium Alkoxides as Catalysts for the Enantioselective Reduction of Ketones with Boranes (C) 2005
- Cobalt-Containing Molecular Sieves as Catalysts for the Low Conversion Autoxidation of Pure Cyclohexane (C) 560
- Commensurate Freezing of *n*-Alkanes in Silicalite (C) 2543
- Competing Pathways in the Reaction of Bis(pentafluorophenyl)borane with Bis(η^5-cyclopentadienyl)dimethylzirconium: Methane Elimination versus Methyl–Hydride Exchange and an Example of Pentacoordinate Carbon (C) 1230
- Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)-cobalt(II) Complexes (C) 2145
- Enhancement of Catalytic Activity for Hydroformylation of Methyl Acrylate by Using Biphasic and "Supported Aqueous Phase" Systems (C) 1474
- Exciting Results from the Field of Homogeneous Two-Phase Catalysis (H) 1575
- Ligand-Accelerated Catalysis (R) 1059
- Metal Complexes of N-Heterocyclic Carbenes—A New Structural Principle for Catalysts in Homogeneous Catalysis (C) 2371
- σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation (C) 1742
- Models for Bimetallic Catalysts: Multiple Oxidation States in Pt_3Re Cluster Cations (C) 346
- Molecular Imprinting in Cross-Linked Materials with the Aid of Molecular Templates—A Way towards Artificial Antibodies (R) 1812
- New Process for the Sulfonation of Phosphane Ligands for Catalysts (C) 811
- Palladacycles as Efficient Catalysts for Aryl Coupling Reactions (C) 1848
- Palladium-Catalyzed Amination of Aryl Halides—Catalysts on New Routes to Known Targets (H) 1316
- Preparation of a Surface-Active Chiral Diphosphane and Its Use in the Hydrogenation of Prochiral Olefins (C) 1645
- Rhodium-Catalyzed Hydroformylation of Internal Alkynes to α,β-Unsaturated Aldehydes (C) 1760
- Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals (C) 2528
- Stereospecific Olefin Polymerization with Chiral Metallocene Catalysts (R) 1143 (1368)
- Sulfoxide-Stabilized Giant Palladium Clusters in Catalyzed Oxidations (C) 457
- Synthetic Aspects of Metal-Catalyzed Oxidations of Amines and Related Reactions (R) 2443
- Synthetic Ribozymes and the First Deoxyribozyme (H) 1189
- The Catalytic Oxidative Coupling of Methane (R) 970
- The First Clusters with a Y-Shaped Arrangement of Ligands at Three-Coordinate Rh^I Atoms in the Solid State: $[M^1M^2\{\mu\text{-}P(C_6H_{11})_2\}(CO)_8Rh(PPh_3)]$ (M^1, M^2 = Mn, Re) (C) 1325
- The First Olefin-Substituted Peroxomolybdenum Complex: Insight into a New Mechanism for the Molybdenum-Catalyzed Epoxidation of Olefins (C) 1737
- Transition Metal Catalyzed Diboration of Vinylarenes (C) 1336
- Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings (H) 2223
- Zeolite Encaged Cu(Histidine) Complexes as a Mimic of Natural Cu Enzymes (C) 2652

Catalytic antibodies
- Antibody-Catalyzed Phosphate Triester Hydrolysis (C) 2275
- Peptide Ligases—Tools for Peptide Synthesis (H) 175
- (*S*)-Selective Retroaldol Reaction and (*R*)-Selective β-Elimination with an Aldolase Catalytic Antibody (C) 2285

Catechol
- Formation of a "*meso*-Helicate" by Self-Assembly of Three Bis(catecholate) Ligands and Two Titanium(IV) Ions (C) 2134

Catechol dioxygenases
- A Highly Reactive and Catalytically Active Model System for Intradiol-Cleaving Catechol Dioxygenases: Structure and Reactivity of Iron(III) Catecholate Complexes of *N*,*N*′-Dimethyl-2,11-diaza[3,3](2,6)pyridinophane (C) 2671

Catenanes
- A Gold(I) [2]Catenane (C) 1894
- Controlling Translational Isomerism in [2]Catenanes (C) 571
- Facile Synthesis and Solid-State Structure of a Benzylic Amide [2]Catenane (C) 1209
- Gold in Chains: Self-Assembly of a Gold(I) Catenane (H) 2107
- Kinetic Selection in the Template-Directed Self-Assembly of [2]Catenanes (C) 2378
- Structurally Diverse and Dynamically Versatile Benzylic Amide [2]Catenanes Assembled Directly from Commercially Available Precursors (C) 1212
- Synthesis of Novel Tetrathiafulvalene-(TTF)-Based [3]Pseudocatenanes by Self-Assembly; Prevention of *trans*/*cis* Isomerization (C) 2524
- $[Mn(C_{18}H_{16}N_2O_2)_3](ClO_4)_2$: A Polymeric 34- and 68-Membered Metallacyclic Network Forming a Novel Woven Polycatenated Structure (C) 574

Catenates
- Formation of the First Isomeric [2]Catenates by Self-Assembly about Two Different Metal Ions (C) 582

cyclo-C_n compounds
- Solubilized Derivatives of C_{195} and C_{260}: The First Members of a New Class of Carbon Allotropes $C_{n(60+5)}$ (C) 1466

Cell respiration
- X-ray Crystal Structures of Cytochrome c Oxidases from *Paracoccus denitrificans* and Bovine Heart and Their Implications for the Molecular Mechanism of Cell Respiration (H) 2635

Cellulose derivatives
- Topochemical Aspects of the Formation of Networks in Layered Langmuir–Blodgett (LB) Assemblies (C) 340

Cerium compounds
- Cerium(III) Chloride Promoted Nucleophilic Addition of Organolithium Reagents to α-Alkyl-β-Ketophosphine Oxides: A New Protocol for the Synthesis of Stereochemically Defined Trisubstituted Olefins (C) 2046

C-glycosides
- A Highly Stereoselective Synthesis of 1,2-*trans*-C-Glycoside via Glycosyl Samarium(III) Compounds (C) 909
- Stereoselective Syntheses of Retro-Isomers of *N*-Glucoasparagine (C) 2026

Chalcogen compounds
- From *cyclo*-Te_8 to Te_x^{n-} Sheets: Are Non-classical Polytellurides More Classical than We Thought? (H) 2109
- $(Nb,Ta)_9(S,Te)_5$, a Metal-Rich Chalcogenide with a Microporous Metal Substructure (C) 1089

Channel structures
- AlMepO-α: A Novel Open-Framework Aluminum Methylphosphonate with Organo-Lined Unidimensional Channels (C) 1199

Chaos theory
- Chaos and Order. The Complex Structure of Living Systems (B) 1771

Charge transfer complexes
- Electronic Energy Transfer in a Supramolecular Species Containing the $[Ru(bpy)_3]^{2+}$, $[Os(bpy)_3]^{2+}$, and Anthracene Chromophoric Units (C) 595

Chelate ligands
- A Novel Hexanuclear Fe^{III}-*cis*-Inositolato Complex as a Model for Fe^{III}–Polyol Interactions in Aqueous Solution (C) 2242
- Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium (C) 2647
- Metal Oxo Cation Receptors: Multimode Coordination to the Dioxoosmium(VI) Cation (C) 1359
- Stereoselective Synthesis of Chiral Zirconocenes from Doubly Substituted, Donor Functionalized Cyclopentadienes via Helical Chelate Complexes (C) 2266
- C_2-Symmetric Cationic Copper(II) Complexes as Chiral Lewis Acids: Counterion Effects in the Enantioselective Diels–Alder Reaction** (C) 798
- Synthesis and Coordination Chemistry of *ortho*-Functionalized Dimercaptobenzene: Building Blocks for Tripodal Hexathiol Ligands (C) 2700
- Synthesis and Structure of Tetra- and Octanuclear Chelate Complexes—Exohedral Guest Exchange in Tetrahemispheraplexes (C) 993
- The Formation of a Mixed Organolithium Aggregate $Li_4R_2nBu_2$ (R = 2,6-$(CH_2NMe_2)_2$-3,5-$Me_2C_6HCH_2$) during the Heteroatom-Assisted Lithiation of 1,3-Bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (C) 219

Chemicals of everyday life
- The Consumer's Good Chemical Guide. A Jargon-free Guide to the Chemicals of Everyday Life (B) 2059

Chemoenzymatic syntheses
- Chemoenzymatic Synthesis of a Modified Pentasaccharide as a Specific Substrate for a Sensitive Assay of α-Amylase by Fluorescence Quenching (C) 1239

Chiral auxiliaries
- A New Platform for Designing Ligands for Asymmetric Induction in Allylic Alkylations (C) 2386
- Asymmetric Pictet–Spengler Reactions Employing *N,N*-Phthaloyl Amino Acids as Chiral Auxiliary Groups (C) 2402
- Benzopyranoisoxazolidines as Chiral Auxiliaries for Asymmetric Synthesis (C) 793
- Carbenoid Transfer to Imines: A New Asymmetric Catalytic Synthesis of Aziridines (C) 676
- Catalytic Asymmetric Carbonyl–Ene Reactions (H) 1717
- Chiral Titanium Alkoxides as Catalysts for the Enantioselective Reduction of Ketones with Boranes (C) 2005
- Diastereoselective Coupling of Anodically Produced Radicals Bearing Chiral Amide Groups (C) 189
- Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)-cobalt(II) Complexes (C) 2145
- Enantioselective Synthesis of β-Amino Acids: TMS-SAMP as a Chiral Ammonia Equivalent for the Aza Analogous Michael Addition to α,β-Unsaturated Esters (C) 455
- First Dynamic Kinetic Resolution of Racemic α-Amino Aldehydes (C) 1023
- Generation of Enantiomerically Enriched Lithium Indenides by Means of (−)-Sparteine: Structure, Stereoselective Substitution, and Solvent Effects (C) 2158
- Preparation of a Surface-Active Chiral Diphosphane and Its Use in the Hydrogenation of Prochiral Olefins (C) 1645
- Stereoselective Syntheses of Peptide Derivatives with 2-Acetamido-3,4,6-tri-*O*-acetyl-1-amino-2-deoxy-β-D-glucopyranose by Four-Component Condensation (C) 1104
- Synthesis of Chiral γ,δ-Unsaturated Amino Acids by Asymmetric Ester Enolate Claisen Rearrangement (C) 2012

Chiral dendrimers
- Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks (C) 2116

Chiral diselenides
- Asymmetric Reaction of Arylalkenes with Diselenides (C) 1726

Chirality
- A New Application of Capillary Zone Electrophoresis: Determination of Energy Barriers of Configurationally Labile Chiral Compounds (C) 1635
- Optical Activity of Chiral Dendritic Surfaces (C) 1206
- Preparation and Detection of Enantiomerically Enriched and Configurationally Stable α-Thioalkyllithium Compounds (C) 323
- Stereoselective Synthesis of Chiral Zirconocenes from Doubly Substituted, Donor Functionalized Cyclopentadienes via Helical Chelate Complexes (C) 2266

Chirality transfer
- Synthesis of Optically Active Nine-Membered Ring Lactams by a Zwitterionic Aza-Claisen Reaction (C) 1026

Chiroptical studies
- Optical Activity of Chiral Dendritic Surfaces (C) 1206

2-Chlorocarboxylic acids
- Unexpected Course of the Darzens Reaction of Phenyl Esters of α-Chlorocarboxylic Acids with Carbonyl Compounds—A Novel One-Step Synthesis of α-Chloro-β-lactones (C) 2028

α-Chloro-β-lactones
- Unexpected Course of the Darzens Reaction of Phenyl Esters of α-Chlorocarboxylic Acids with Carbonyl Compounds—A Novel One-Step Synthesis of α-Chloro-β-lactones (C) 2028

Chromatography
- Structure Determination of Vitamin A Acetate Isomers through Coupled HPLC and ^1H NMR Spectroscopy (C) 1014
- Synthesis of dTDP-6-Deoxy-4-ketoglucose and Analogues with Native and Recombinant dTDP-Glucose-4,6-dehydratase (C) 1748
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples III: Development of a Fast Analytical Method (C) 186

Chromium compounds
- Aminocarbyne Complexes of Chromium in a High Oxidation State—Synthesis, Structure, and Reactivity (C) 924
- Radical Additions to (η^6-Arene)-(tricarbonyl)chromium Complexes: Diastereoselective Synthesis of Hydrophenalene and Hydrobenzindene Derivatives by Samarium(II) Iodide Induced Cyclization (C) 2383
- Synthesis, Structural Investigation, and Ligand Properties of Isocyanoacetonitrile (C) 914

Circular dichroism
- Optical Activity of Chiral Dendritic Surfaces (C) 1206
- Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks (C) 2116

Clathrasils
- Structure-Determining C-H · · · O-Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil (C) 2680

Clathrates
- Self-Assembly of 1,3,5-Benzenetricarboxylic Acids (Trimesic Acids) and Their Analogues in the Solid State (C) 2654
- Supramolecular Synthons in Crystal Engineering—A New Organic Synthesis (R) 2328

Clusters

- Condensed $RuSn_6$ Octahedra in $Ru_3Sn_{15}O_{14}$ (C) 2113
- Dimensional Reduction of $Re_6Se_8Cl_2$: Sheets, Chains, and Discrete Clusters Composed of Chloride-Terminated $[Re_6Q_8]^{2+}$ (Q = S, Se) Cores (C) 226
- First Steps Towards Ordered Monolayers of Ligand-Stabilized Gold Clusters (C) 1442
- Free Atoms, Clusters and Nanoscale Particles (B) 1252
- Models for Bimetallic Catalysts: Multiple Oxidation States in Pt_3Re Cluster Cations (C) 346
- $Na_2Ti_2Cl_8$: From Isolated Ti^{2+} Ions to $[Ti_3]^{6+}$ Clusters (C) 71
- New Selenolato-Bridged Clusters of Iron and Nickel; the Structures of $[Fe_{12}(SePh)_{24}]$ and $[Na_2(POPh_3)_6]$-$[Ni_{20}Se_{12}(SeMe)_{10}]$ (C) 307
- Novel Alkali Metal Phosphanide Aggregates (C) 316
- $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$: Compounds with Discrete (M_6N) Octahedra and $[Ga_5]$ Clusters (C) 1761
- Sulfoxide-Stabilized Giant Palladium Clusters in Catalyzed Oxidations (C) 457
- Supramolecular Synthons in Crystal Engineering—A New Organic Synthesis (R) 2328
- The First Clusters with a Y-Shaped Arrangement of Ligands at Three-Coordinate Rh^I Atoms in the Solid State: $[M^1M^2\{\mu\text{-}P(C_6H_{11})_2\}(CO)_8Rh(PPh_3)]$ (M^1, M^2 = Mn, Re) (C) 1325

- The $[Zr_6X_{18}H_5]^{3-}$ Ions with X = Cl, Br, and Related Species (C) 1877
- $[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]^{(25\pm5)-}$: A Water-Soluble Big Wheel with More than 700 Atoms and a Relative Molecular Mass of About 24000 (C) 2122

Cobaloxime
- Peripherally Substituted Cobaloximes; X-Ray Crystal Structure Analysis of σ-Hexylbis[1,8-di(*N*-morpholino)octane-4,5-dioximato]pyridinecobalt(III) (C) 2389

Cobalt compounds
- A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1′-Ferrocenedithiolato Complexes (C) 656
- A μ-η^6:η^6-1,3,5-Triboratabenzenebis(cyclopentadienylcobalt) Triple-Decker Complex (C) 681
- Complexation of [*N*,*N*′-Bis(salicylidene)ethylenediiminato]cobalt(III)$^+$ by Anilines in Dimethylformamide (C) 1086
- Dicobalt and Diplatinum Complexes of Diborylcarbenes (C) 1111
- Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)cobalt(II) Complexes (C) 2145
- Hydrolysis of a Phosphate Diester Doubly Coordinated to a Dinuclear Cobalt(III) Complex: A Novel Mechanism (C) 2412
- Novel Binuclear Cobalt Dioxygen Complex—A Step on the Path to Dioxygen Activation (C) 2051
- Oligomethylene-Bridged Vitamin B_{12} Dimers (C) 84
- Phosphorane Iminato Complexes of Manganese and Cobalt with Heterocubane Structure (C) 1235
- Photoinduced Valence Tautomerism in Cobalt Complexes Containing Semiquinone Anion as Ligand: Dynamics of the High-Spin $[Co^{II}(3,5\text{-dtbsq})_2]$ to Low-Spin $[Co^{III}(3,5\text{-dtbsq})(3,5\text{-dtbcat})]$ Interconversion (C) 1481
- Polymers with Complexed Cyclobutadiene Units in the Main Chain: The First Example of a Thermotropic, Liquid Crystalline Organometallic Polymer (C) 569
- Structure-Determining C-H···O-Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil (C) 2680
- [Bis{(η^5-pentamethylcyclopentadienyl)cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands (C) 592
- $_\infty^3$[$(CoCp_2)_2$⊂Fe(μ-CNSnMe$_3$NC)$_3$]: A Purely Organometallic Channel Inclusion Compound (C) 1197

Coenzymes
- Evidence for a Mechanism Involving Transient Fragmentation in Carbon Skeleton Rearrangements Dependent on Coenzyme B_{12} (C) 2398
- One-Electron Redox Reactions of CoASH Esters in Anaerobic Bacteria—A Mechanistic Proposal (C) 1502

Colloids
- Clusters and Colloids. From Theory to Applications (B) 122

Combinatorial chemistry
- A Strategy of "Random Glycosylation" for the Production of Oligosaccharide Libraries (C) 2720
- Combinatorial Synthesis and Multidimensional NMR Spectroscopy: An Approach to Understanding Protein–Ligand Interactions (R) 953
- Optimization of the Biological Activity of Combinatorial Compound Libraries by a Genetic Algorithm (C) 2280
- Radiofrequency Encoded Combinatorial Chemistry (C) 2289
- Solid-Phase Synthesis of Vinylogous Sulfonyl Peptides (C) 1763
- Synthetic Receptors Based on Vinylogous Sulfonyl Peptides (C) 1765

Complexes with arsenic ligands
- η^5:η^2 Coordination of a *cyclo*-E_5 Ligand, E = P, As (C) 1321

Complexes with boron ligands
- Synthesis and Structure of the First Transition Metal Borylene Complexes (C) 825

Complexes with carbon ligands
- A Rhodium-Mediated, Stepwise Trimerization of an Alkyne That Does Not Lead to a Benzene but Selectively to a Hexadienyne Derivative (C) 191
- Nucleophilic Addition to (π-Allyl)-palladium Complexes: Control of the Attack at the Central or Terminal Carbon Atom by Ligands (C) 2551
- Synthesis and Structure of Bimetallic η^4,η^6-Naphthalene Complexes Containing a Mn–Mn Moiety Bonded in a *Syn*-Facial Manner: A General Route to Homo- and Heteronuclear Bimetallic Complexes of Polyarenes (C) 2540
- Synthesis, Structural Investigation, and Ligand Properties of Isocyanoacctonitrile (C) 914
- $[Fe(2,4,6\text{-}tBu_3C_6H_2)_2]$, a Monomeric Diaryl Complex with Two-Coordinate Iron(II) (C) 325
- $[\{Ti(\mu\text{-}CH_3)_5(\mu\text{-}CH_2)\}\{(tmeda)Li\}_3]\cdot$ THF: An Unusual and Highly Fluxional Titanium Organometallic Compound (C) 2264

Complexes with carboxylato ligands
- Octadecanuclearity in Manganese Carboxylate Chemistry: $K_4[Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ ($phthH_2$ = phthalic acid) (C) 887

Complexes with chalcogen ligands
- Models for Bimetallic Catalysts: Multiple Oxidation States in Pt_3Re Cluster Cations (C) 346

Complexes with elements of group 15
- Terminal E_1 Ligands from Elements of Group 15 (H) 1997

Complexes with ferrocenyl ligands
- A Functionalized Polyoxometalate Bearing a Ferrocenylimido Ligand: Preparation and Structure of $[(FcN)Mo_6O_{18}]^{2-}$ (C) 2547

Complexes with hydrido ligands
- Reaction of a Vanadium(III) Amide with H_2: Isolation and Characterization of a Polynuclear Mixed-Valence Polyhydrido–Nitrido Complex (C) 822

Complexes with macrocyclic ligands
- Double Helical Dinuclear Copper(I) Complexes of Macrocyclic Bis(dithiadiimine) Ligands (C) 1883
- The First Dinuclear Low-Valent Samarium Complex with a Short Sm–Sm Contact (C) 2141

Complexes with nitrido ligands
- Reaction of a Vanadium(III) Amide with H_2: Isolation and Characterization of a Polynuclear Mixed-Valence Polyhydrido–Nitrido Complex (C) 822

Complexes with nitrogen ligands
- A Dinuclear (μ-Carboxylato)manganese(II) Complex Derived from a Macrocyclic Ligand: A Structural Model for Active Sites in Natural Systems (C) 2535
- A Model of Semimet Hemerythrin; NMR Spectroscopic Evidence of Valence Localization in Bis(μ-carboxylato)(μ-phenolato)diiron(II,III) in Solution (C) 588
- A Nickel(II) Azide Cubane Characterization of the Magnetic Exchange Interactions Mediated by a Triply Bridging Azide Group Bound End-On (C) 889
- Lanthanoid Complexes with [(dad)Li]Ligands—New Starting Materials for Organolanthanoid Chemistry (C) 673
- Metal Oxo Cation Receptors: Multimode Coordination to the Dioxoosmium(VI) Cation (C) 1359
- Molecular Recognition of Terephthalic Acid by Supramolecular Self-Assembly of an Acridine-Pendant Cyclen–Zn^{II} Complex (C) 663
- Mutually Interpenetrating Sheets and Channels in the Extended Structure of [Cu(4,4′-bpy)Cl] (C) 207
- μ-Nitridodiiron Complexes with Asymmetric $[Fe^{IV}\equiv N\text{–}Fe^{III}]^{4+}$ and Symmetric $[Fe^{IV}=N=Fe^{IV}]^{5+}$ Structural Elements (C) 669
- Novel Networks of Unusually Coordinated Silver(I) Cations: The Wafer-Like Structure of $[Ag(pyz)_2][Ag_2(pyz)_5](PF_6)_3\cdot 2G$ and the Simple Cubic Frame of $[Ag(pyz)_3](SbF_6)$ (C) 1895
- Self-Assembly of a Ferromagnetically Coupled Manganese(II) Tetramer (C) 1443
- Synthesis, Structure, and Properties of Dinuclear and Trinuclear Rack-Type Ru^{II} Complexes (C) 1122
- The pH-Dependent Synthesis and Structural Study of Dimeric and Cyclic Trimeric Complexes of 9-Methyl- or 9-Ethylhypoxanthine Nucleobases with (η^5-Pentamethylcyclopentadienyl)rhodium Aqua Complexes (C) 1514
- 2,4,6-Tri(4-pyridyl)-1,3,5-triazine as a 3-Connecting Building Block for Infinite Nets (C) 820
- [WL(NO)(O)(CH_3)]—An Unusual Nitrosyltungsten Complex (C) 1435

Complexes with oxygen ligands
- A Cyclic Hexairon(III) Complex with an Octahedrally Coordinated Sodium Ion at the Center, an Example of the [12]Metallacrown-6 Structure Type (C) 467
- A Model of Semimet Hemerythrin: NMR Spectroscopic Evidence of Valence Localization in Bis(μ-carboxylato)(μ-phenolato)diiron(II,III) in Solution (C) 588
- A New Type of Trinuclear Oxoiron(III) Cluster (C) 205
- A Nickel(II) Azide Cubane: Characterization of the Magnetic Exchange Interactions Mediated by a Triply Bridging Azide Group Bound End-On (C) 889
- A Novel Hexanuclear Fe^{III}-*cis*-Inositolato Complex as a Model for Fe^{III}–Polyol Interactions in Aqueous Solution (C) 2242
- A Stable Aquairon(III) Complex with S = 1: Structure and Spectroscopic Properties (C) 1216 (1649)
- Complexes with Polar W–W Multiple Bonds: $[W_2(OiPr)_4L(dmpe)_2]$ (L = $(H)_2$, CO) and $[W_2(O)_4(\mu\text{-}O)\{W(CO)(dmpe)_2\}_2]$ (C) 891
- Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium (C) 2647
- Formation of an Alkylperoxoiron(III) Complex during Oxidations Catalyzed by μ-Oxodiiron(III) Complexes (C) 203

- Solid-State and Solution Structures of $[\{NW(OC(CH_3)_2CF_3)_3\}_3]$ and Factors Favoring the Metathesis of C–N and N–W Triple Bonds in Reactions Involving Organic Nitriles and Ditungsten Hexaalkoxides (C) 110
- Structure and Magnetic Properties of a Decanuclear Oxoiron(III) Cluster: A Further Step to Understanding Iron Aggregation Processes (C) 2716
- $[Mn(C_{18}H_{16}N_2O_2)_3](ClO_4)_2$: A Polymeric 34- and 68-Membered Metallacyclic Network Forming a Novel Woven Polycatenated Structure (C) 574
- $[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]^{(25\pm5)-}$: A Water-Soluble Big Wheel with More than 700 Atoms and a Relative Molecular Mass of About 24000 (C) 2122
- $[WL(NO)(O)(CH_3)]$—An Unusual Nitrosyltungsten Complex (C) 1435

Complexes with phosphorus ligands
- A Molybdenum–Phosphorus Triple Bond: Synthesis, Structure, and Reactivity of the Terminal Phosphido (P^{3-}) Complex $[Mo(P)(NRAr)_3]$ (C) 2042
- A Redox-Switchable Hemilabile Ligand: Electrochemical Control of the Coordination Environment of a Rh^I Complex (C) 1624
- Complexes with Polar W–W Multiple Bonds: $[W_2(O\mathit{i}Pr)_4L(dmpe)_2]$ (L = $(H)_2$, CO) and $[W_2(O)_4(\mu\text{-}O)\{W(CO)(dmpe)_2\}_2]$ (C) 891
- $\eta^5{:}\eta^2$ Coordination of a *cyclo*-E_5 Ligand, E = P, As (C) 1321
- 2,4-Di-*tert*-butyl-1λ^3,3λ^3-diphosphinines: Targeted Synthesis at Iron(0) Centers and Oxidative Release (C) 198
- Monomeric Molybdenum and Tungsten Complexes That Contain a Metal–Phosphorus Triple Bond (C) 2044
- ^{31}P CP/MAS NMR Spectroscopy of Transition Metal Phosphane Complexes: "*J*-Recoupling" between Chemically Equivalent ^{31}P Nuclei in Polycrystalline Compounds of the Type *trans*-$[(PR_3)_2MX_2]$, M = Pd, Pt (C) 667
- P–H-Functionalized Phosphenium Complexes $[C_5R_5(OC)_2W{=}P(H)R']$ (R' = *t*Bu, sMes): Synthesis, Isomerization, and Transformation into Hydrido Complexes Containing a *t*BuP(H)OH Ligand (C) 2500
- Synthesis and Structure of $[Li(thf)_4]_2[Ph_2P)_{10}Cd_4]$ Containing; a Dianionic with a Cd_4P_{10} Adamantanoid Core (C) 2662

Complexes with P,N ligands
- Strong Electronic Effects on Enantioselectivity in Rhodium-Catalyzed Hydroborations with Novel Pyrazole-Containing Ferrocenyl Ligands (C) 931

Complexes with selenium ligands
- New Selenolato-Bridged Clusters of Iron and Nickel; the Structures of $[Fe_{12}(SePh)_{24}]$ and $[Na_2(POPh_3)_6]$-$[Ni_{20}Se_{12}(SeMe)_{10}]$ (C) 307

Complexes with semiquinone ligands
- Photoinduced Valence Tautomerism in Cobalt Complexes Containing Semiquinone Anion as Ligand: Dynamics of the High-Spin $[Co^{II}(3,5\text{-dtbsq})_2]$ to Low-Spin $[Co^{III}(3,5\text{-dtbsq})(3,5\text{-dtbcat})]$ Interconversion (C) 1481

Complexes with sulfur ligands
- A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1'-Ferrocenedithiolato Complexes (C) 656
- *Enantiomerically Pure Palladacycles Derived from β-Ketosulfoxides (C) 1351*
- $[Cp^*(Me_3P)_2Ru(\eta^2\text{-}O{=}SO_2)]PF_6$, the First Complex between a Transition Metal and Sulfur Trioxide (C) 1008

Composites
- A Molecular Composite Containing Organic and Inorganic Components—A Complex from β-Cyclodextrin and Hydrated Magnesium Chloride (C) 2381

Compound libraries
- Assessing Similarity and Diversity of Combinatorial Libraries by Spatial Autocorrelation Functions and Neural Networks (C) 2674
- Optimization of the Biological Activity of Combinatorial Compound Libraries by a Genetic Algorithm (C) 2280
- Saccharide–Peptide Hybrids as Novel Oligosaccharide Mimetics (C) 2712

Computer chemistry
- Assessing Similarity and Diversity of Combinatorial Libraries by Spatial Autocorrelation Functions and Neural Networks (C) 2674
- Computer-Assisted Planning of Organic Syntheses: The Second Generation of Programm (R) 2613

Concave reagents
- Concave Reagents Based on Calixarenes (C) 2555

Conduritols
- Catalytic Photoinduced Charge-Transfer Osmylation: A Novel Pathway from Arenes to Cyclitol Derivatives (C) 2031

Configuration determination
- Carbon–Carbon Bond Cleavage with Inversion of Configuration: Conversion of (*R*)-(+)-1-Methoxytetrafluoropropionic Acid to (*S*)-(−)-1,2,2,2-Tetrafluoroethyl Methyl Ether (C) 222

Conformation
- Activation of Macrocyclic Biaryl-Enediynes by Metal Ion Coordination (C) 2538

Conical intersection
- Conical Intersections and the Mechanism of Singlet Photoreactions (H) 549

Coordination
- Galloxane and Alumoxane Hydroxides: $[Ga_{12}t\mathrm{Bu}_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$ and $[Al_6t\mathrm{Bu}_6(\mu_3\text{-}O)_4(\mu\text{-}OH)_4]$ (C) 1201
- Octathioporphyrazine Crown Ethers: An Octanuclear Ag^I Complex with Coordination in the *meso* Pocket (C) 2020
- Rhodium–Vinylallene Complexes and a New Reaction, Rhodium-Catalyzed Carbonylative [4+1]Cycloaddition (C) 2691
- Structure and Bonding of Transition Metal Dihydrogen Complexes $[M(CO)_5(H_2)]$ (M = Cr, Mo, W) (C) 354
- The First Clusters with a Y-Shaped Arrangement of Ligands at Three-Coordinate Rh^I Atoms in the Solid State: $[M^1M^2\{\mu\text{-}P(C_6H_{11})_2\}(CO)_8Rh(PPh_3)]$ (M^1, M^2 = Mn, Re) (C) 1325
- The pH-Dependent Synthesis and Structural Study of Dimeric and Cyclic Trimeric Complexes of 9-Methyl- or 9-Ethylhypoxanthine Nucleobases with (η^5-Pentamethylcyclopentadienyl)rhodium Aqua Complexes (C) 1514
- Volatile Metal Alkoxides According to the Concept of Donor Functionalization (R) 2187

Coordination polymers
- Novel Networks of Unusually Coordinated Silver(I) Cations: The Wafer-Like Structure of $[Ag(pyz)_2][Ag_2(pyz)_5](PF_6)_3\cdot 2G$ and the Simple Cubic Frame of $[Ag(pyz)_3](SbF_6)$ (C) 1895

Cope rearrangements
- Pericyclic Reactions in Nature: Spontaneous Cope Rearrangement Inactivates Algae Pheromones (C) 1602
- The Cope Rearrangement Transition Structure Is Not Diradicaloid, but Is It Aromatic? (C) 334

Copolymerizations
- A Tailor-Made Metallocene for the Copolymerization of Ethene with Bulky Cycloalkenes (C) 2273

Copper compounds
- A Hexadecanuclear Polyolatometalate of Copper(II) Ions and Multideprotonated D-Sorbitol (C) 2119
- C_2-Symmetric Cationic Copper(II) Complexes as Chiral Lewis Acids: Counterion Effects in the Enantioselective Diels–Alder Reaction** (C) 798
- Carbenoid Transfer to Imines: A New Asymmetric Catalytic Synthesis of Aziridines (C) 676
- Computational Evidence for the Existence of Cu^{III} Intermediates in Addition and Substitution Reactions with Dialkylcuprates (C) 476
- $(CuI)_3P_{12}$: A Solid Containing a New Polymer of Phosphorus Predicted by Theory (C) 1647
- Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State (C) 986
- Double Helical Dinuclear Copper(I) Complexes of Macrocyclic Bis(dithiadiimine) Ligands (C) 1883
- Elusiveness of Cu^{III} Complexation; Preference for Trifluoromethyl Oxidation in the Formation of $[Cu^I(CF_3)_4]^-$ Salts (C) 80
- Formal Oxidation State versus Partial Charge—A Comment (C) 986
- Mutually Interpenetrating Sheets and Channels in the Extended Structure of [Cu(4,4'-bpy)Cl] (C) 207
- Novel Biological Copper Proteins through Anion Addition to the Mutant Met121Gly of *Pseudomonas aeruginosa* Azurin (C) 1622
- Rapid Hydrolysis of RNA with a Cu^{II} Complex (C) 472
- The Metallic Bond—Dead or Alive? A Comment and a Reply (C) 2003
- Zeolite Encaged Cu(Histidine) Complexes as a Mimic of Natural Cu Enzymes (C) 2652

Correspondences
- Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State (C) 986
- Formal Oxidation State versus Partial Charge—A Comment (C) 986
- Reactions of Neopentyl 2,2,-Trifluoroethanesulfonate (Neopentyl Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose (C) 2495
- The Metallic Bond—Dead or Alive? A Comment and a Reply (Comment) (C) 2003

Corrigenda 240, 826, 1032, 1368, 1649, 2165, 2561

Cosensitization
- Radical C–C Bond Formation by Photoinduced Electron Transfer Addition of α-Silyl Carbamates to Acceptor-Substituted Alkenes (C) 2137

Cracking
- Coupling of Endothermic Thermal Cracking with Exothermic Oxidative Dehydrogenation of Ethane to Ethylene Using a Diluted SrO/La_2O_3 Catalyst (C) 665

Cross-coupling
- A New Nickel-Catalyzed Cross-Coupling Reaction between sp^3 Carbon Centers (C) 2723

Crown compounds
- Controlling Translational Isomerism in [2]Catenanes (C) 571
- Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules (C) 1865
- Doubly Encircled and Double-Stranded Pseudorotaxanes (C) 1869
- Investigation of Self-Assembled Supramolecular Species in Solution by IL-ESMS, a New Mass Spectrometric Technique (C) 209
- Octathioporphyrazine Crown Ethers: An Octanuclear Ag^I Complex with Coordination in the *meso* Pocket (C) 2020
- Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$ (C) 2374
- Strong Binding of Paraquat and Polymeric Paraquat Derivatives by Basket-Shaped Hosts (C) 2132
- Synthesis of Novel Tetrathiafulvalene-(TTF)-Based [3]Pseudocatenanes by Self-Assembly; Prevention of *trans/cis* Isomerization (C) 2524
- The Reactivity of 1,3-Butadiyne Moieties in the "Exploding" [*n*]Rotanes—A Crown of Thiophenes (C) 781
- Transition Metal Complexes as Both Host and Guest: Second-Sphere Coordination between a Pt-Azacrown Ether Host and a $Pt\text{-}NH_3$ Guest (C) 2689

Cryptands
- Binding of Boron and Alkali Metal Cations by a Pseudocryptand (C) 1115

Crystal engineering
- Porous Solids by Design: $[Zn(4,4'\text{-}bpy)_2(SiF_6)]_n \cdot x$DMF, a Single Framework Octahedral Coordination Polymer with Large Square Channels (C) 2127 (2561)
- Self-Assembly of 1,3,5-Benzenetricarboxylic Acids (Trimesic Acids) and Their Analogues in the Solid State (C) 2654
- Supramolecular Inorganic Chemistry: Small Guests in Small and Large Hosts (R) 2311

Crystallization
- Homogeneous versus Heterogeneous Zeolite Nucleation (C) 73

Crystallography
- Crystallography Made Crystal Clear. A Guide for Users of Macromolecular Models (B) 496
- Crystal Structure Analysis for Chemists and Biologists (B) 2060

Cumulenes
- *para*- and *ortho*-Quinodimethanes Intermediates with Cumulative Double Bonds (C) 2367
- Butatrienes by Cumuhomologation of Propadienes (C) 2709

Cuprates
- Computational Evidence for the Existence of Cu^{III} Intermediates in Addition and Substitution Reactions with Dialkylcuprates (C) 476
- Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State (C) 986
- Elusiveness of Cu^{III} Complexation; Preference for Trifluoromethyl Oxidation in the Formation of $[Cu^I(CF_3)_4]^-$ Salts (C) 80
- Formal Oxidation State versus Partial Charge—A Comment (C) 986

Curium
- First Determination of the Ionization Potential of Americium and Curium (C) 814

Curtin-Hammett principle
- Kinetic Selection in the Template-Directed Self-Assembly of [2]Catenanes (C) 2378

CVD precursors
- Volatile Metal Alkoxides According to the Concept of Donor Functionalization (R) 2187

CVD techniques

- Preparation, Structure, and Reactivity of 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene, a New Stable Carbene (C) 1021
- Rhodium–Vinylallene Complexes and a New Reaction, Rhodium-Catalyzed Carbonylative [4+1]Cycloaddition (C) 2691
- Synthesis of a 2*H*-Azirine by [1+2] Cycloaddition of a Phosphinocarbene with a Nitrile and Its Ring-Expansion to a $1,2\lambda^5$-Azaphosphete (C) 1246
- The Dimerization of (*E*)-1,3-Diphenyl-1,3-butadiene Proceeds Suprafacially with Respect to Both Components: Evidence for a Concerted [4+2] Cycloaddition (C) 895
- Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings (H) 2223

Cycloalkynes
- Automerizations and Isomerizations in Propynylidene (HCCCH), Propadienylidene (H_2CCC), and Cyclopropenylidene ($c\text{-}C_3H_2$) (C) 2009

Cycloallenes
- 1-Phenyl-1,2-cyclooctadiene Dimerizes in an Unusual Manner (C) 2730

β-Cycloaltrin
- β-Cycloaltrin: A Cyclooligosaccharide Consisting of Seven α(1→4)-Linked Altropyranoses (C) 1621

Cycloaromatizations
- Lactendiynes: A New Class of Triggered Cyclic Enediynes (C) 2393

Cyclobutadienes
- A P_2C_2 Four-Membered Ring with Unusual Bonding—Synthesis, Structure, and Ring Opening of a 1,3-Diphosphacyclobutane-2,4-diyl (C) 555
- Polymers with Complexed Cyclobutadiene Units in the Main Chain: The First Example of a Thermotropic, Liquid Crystalline Organometallic Polymer (C) 569
- [Bis{(η^5-pentamethylcyclopentadienyl)-cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands (C) 592

Cyclobutenes
- A Remarkable Effect of Silyl Substitution on Electrocyclization of Vinylallenes (C) 1476
Cyclodehydrogenations
- A Cycloaddition–Cyclodehydrogenation Route from Stilbenoids to Extended Aromatic Hydrocarbons (C) 1583
Cyclodextrins
- A Molecular Composite Containing Organic and Inorganic Components—A Complex from β-Cyclodextrin and Hydrated Magnesium Chloride (C) 2381
- A New Application of Capillary Zone Electrophoresis: Determination of Energy Barriers of Configurationally Labile Chiral Compounds (C) 1635
- β-Cycloaltrin: A Cyclooligosaccharide Consisting of Seven α(1 → 4)-Linked Altropyranoses (C) 1621
- Molecular Recognition between Chemically Modified β-Cyclodextrin and Dec-1-ene: New Prospects for Biphasic Hydroformylation of Water-Insoluble Olefins (C) 2269
- Rapid Water Diffusion in a Cage-Type Crystal Lattice: β-Cyclodextrin Dodecahydrate (C) 1452
- Side-Chain Polyrotaxanes with a Tandem Structure Based on Cyclodextrins and a Polymethacrylate Main Chain (C) 309
Cyclohexanes
- Intramolecular Allylsilane Addition to Chiral Alkylidene-1,3-dicarbonyl Compounds for the Synthesis of Enantiomerically Pure *trans*-1,2-Disubstituted Cyclopentanes and Cyclohexanes (C) 1731
Cyclohexatriene
- X-Ray Diffraction Evidence for a Cyclohexatriene Motif in the Molecular Structure of Tris(bicyclo[2.1.1]hexeno)benzene: Bond Alternation after the Refutation of the Mills–Nixon Theory (C) 1454
Cyclooctatetraene complexes
- Cyclopentadienyl-Free Organolanthanide Chemistry (R) 2466
Cycloolefin copolymers
- A Tailor-Made Metallocene for the Copolymerization of Ethene with Bulky Cycloalkenes (C) 2273
Cyclooligomerizations
- Selective Syntheses of 1,3-Diphosphacyclobutadiene, Dewar-1,3,5-triphosphabenzene, 1,3,5-Triphosphabenzene, and 1,3,5,7-Tetraphosphabarrelene by Cyclooligomerization of Phosphaalkynes (C) 2227
Cyclopentadiene analogues
- Lanthanoid Complexes with [(dad)Li]Ligands—New Starting Materials for Organolanthanoid Chemistry (C) 673
Cyclopentadienes
- Aminocyclopentadienes, Aminoferrocenes, and Aminocobaltocenes (C) 800
- Stereoselective Synthesis of Chiral Zirconocenes from Doubly Substituted, Donor Functionalized Cyclopentadienes via Helical Chelate Complexes (C) 2266
Cyclopentadienides
- Five-Membered Aromatic and Anti-aromatic Rings with Gallium, Germanium, and Bismuth Centers: A Short March through the Periodic Table (H) 295
Cyclopentadienyl complexes
- Aggregation of Nitrido–Metal Complexes: The Example of $[(\eta^5\text{-}C_5Me_5)\text{-}Mo(N)Cl_2]$ (C) 112
- Macrobicyclic Titanium(IV) Complexes with C_3-Symmetric Synthetic Peptides (C) 1449
- Tris(dimethylamino)sulfoniumcyclopentadienide $[TAS]^+[C_5H_5]^-$ and Tris(dimethylamino)sulfoniumpyrrolide $[TAS]^+[C_4H_4N]^-$: Two Isostructural Salts with "Naked" Anions A^- and the "Inverse" Sandwich-Cations $[\{(Me_2N)_3S\}_2A]^+$ (A = $C_5H_5^-$, $C_4H_4N^-$) (C) 443
Cyclopentanes
- Intramolecular Allylsilane Addition to Chiral Alkylidene-1,3-dicarbonyl Compounds for the Synthesis of Enantiomerically Pure *trans*-1,2-Disubstituted Cyclopentanes and Cyclohexanes (C) 1731
Cyclopentenes
- A Concise Synthetic Route to Cyclopentenes by [3+2] Cycloaddition of Dipolar Trimethylenemethane to Alkynes (C) 2154
Cyclophanes
- *para*- and *ortho*-Quinodimethanes Intermediates with Cumulative Double Bonds (C) 2367
- A New Family of Chiral Binaphthyl-Derived Cyclophane Receptors: Complexation of Pyranosides (C) 1596
- A New Quantitative Description of the Distance Dependence of Through-Space $^{19}F,^{19}F$ Spin–Spin Coupling (C) 1881
- "Cation-π Interactions" Detected by Mass Spectrometry; Selective Recognition of Alkali Metal Cations by a π-Basic Molecular Cavity (C) 1364
- Fullerene Model Compounds: Bowl-Shaped Aromatic Hydrocarbons and Cyclophane-Based Cage Molecules (H) 1429
- Octacationic Cyclophanes: Binding of ATP and Other Anionic Guests in Water (C) 2147
- Synthesis and Structure of the Nanodimensional Multicyclophane "Kuratowski Cyclophane", an Achiral Molecule with Nonplanar $K_{3,3}$ Topology (C) 2657
- Synthesis of a Stable Arenesulfenic Acid Bearing a Bowl-Shaped Macrobicyclic Cyclophane Skeleton (C) 1124
- Synthesis of Belt Cyclophanes (C) 1437
- Topochemical Reaction Control in Solution (C) 685
- 6,7-Bis(methoxycarbonyl)-2,3-dimethyl [5](1,4)naphthalenophane; the First Benzoannelated [5]Paracyclophane (C) 2553
Cyclophilin
- Rational Design of Orthogonal Receptor–Ligand Combinations (C) 2129
Cyclopropanations
- Isolation and X-Ray Crystal Structure of a Palladacyclobutane: Insight into the Mechanism of Cyclopropanation (C) 100
- Novel Structures from Tris(benzocyclobutadieno)cyclohexatriene: Triscyclopropanation and Trisoxacyclopropanation to the First [2.1.2.1.2.1]Hexaannulanes (C) 563
- Reversible Template-Directed Activation of Equatorial Double Bonds of the Fullerene Framework: Regioselective Direct Synthesis, Crystal Structure, and Aromatic Properties of $T_h\text{-}C_{66}(COOEt)_{12}$ (C) 1607
Cyclopropanes
- Formation of Nitronic Acids by Ring Opening of Nitrocyclopropanes by a Concerted, Acid-Catalyzed Mechanism (C) 1091
- Unprecedented Intra- and Intermolecular Palladium-Catalyzed Coupling Reactions with Methylenecyclopropane Type Tetrasubstituted Alkenes (C) 2545
Cyclopropenylium compounds
- Stable 1:1 Adducts from Iodoacetylenes and Iodide Ions: Ion Pair Strain as an Additional Driving Force? (C) 441
- The Consequences of an Electrostatic "Forced Marriage" between Two Electron-Rich Particles: Strained Ion Pairs (C) 439
Cyclosporin
- Rational Design of Orthogonal Receptor–Ligand Combinations (C) 2129
Cyclotetramers
- Tetraphosphatricyclo[4.2.0.0^{2,5}]octadienes; New Phosphaalkyne Cyclotetramers Derived from $\lambda^3\sigma^2$-Diphosphetes (C) 484
Cystine
- X-Ray Structure of a Self-Assembled Gelating Fiber (C) 585
Cytochrome c peroxidase
- Direct Electrochemical Coupling of Components of the Biological Electron Transfer Chain to Modified Surfaces: Molecular Recognition between Cytochrome c Peroxidase and Cytochrome c (C) 2409
Cytochrome c oxidase
- The Active Sites of the Native Cytochrome-c Oxidase from Bovine Heart Mitochondria: EXAFS-Spectroscopic Characterization of a Novel Homobinuclear Copper Center (Cu_A) and of the Heterobinuclear $Fe_{a3}\text{-}Cu_B$ Center (C) 1488
- The Dinuclear Cu_A Center in Cytochrome *c* Oxidase and N_2O Reductase—A Metal–Metal Bond in Biology? (H) 771
- X-ray Crystal Structures of Cytochrome c Oxidases from *Paracoccus denitrificans* and Bovine Heart and Their Implications for the Molecular Mechanism of Cell Respiration (H) 2635
Cytomimetic chemistry
- Cytomimetic Organic Chemistry: Early Developments (R) 2091
C–H activation
- An Alkylperoxoiron(III) Intermediate and Its Role in the Oxidation of Aliphatic C–H Bonds (C) 2048
- Does the Facile Inter- and Intramolecular C–H Bond Activation by Tp*–Rh Complexes Proceed via Rh^I or Rh^{III} Intermediates? (C) 231
- Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center (C) 916

Darzens reaction
- Unexpected Course of the Darzens Reaction of Phenyl Esters of α-Chlorocarboxylic Acids with Carbonyl Compounds—A Novel One-Step Synthesis of α-Chloro-β-lactones (C) 2028
Dehydratases
- Synthesis of dTDP-6-Deoxy-4-ketoglucose and Analogues with Native and Recombinant dTDP-Glucose-4,6-dehydratase (C) 1748
Dehydroalanine
- The Role of Dehydroalanine in Catalysis by Histidine Ammonia Lyase (C) 1464
Dehydroannulenes
- Synthesis of New Sworski-Type Dehydroannulenes: 3,4-Benz-1,2,5,6,8,9,12,13-octadehydro[14]annulenes (C) 1892
Dehydrogenations
- Coupling of Endothermic Thermal Cracking with Exothermic Oxidative Dehydrogenation of Ethane to Ethylene Using a Diluted SrO/La_2O_3 Catalyst (C) 665
Dendralenes
- Unprecedented Intra- and Intermolecular Palladium-Catalyzed Coupling Reactions with Methylenecyclopropane Type Tetrasubstituted Alkenes (C) 2545

Dendrimers
- Optical Activity of Chiral Dendritic Surfaces (C) 1206
- Routes to Dendritic Networks: Bis-Dendrimers by Coupling of Cascade Macromolecules through Metal Centers (C) 2023
- Spherical Cyclophosphazene Dendrimers to the Fifth Generation (C) 578
- Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks (C) 2116
- Synthesis and Structure of a Dendritic Polysilane (C) 98
- Water-Soluble Dendritic Iron Porphyrins: Synthetic Models of Globular Heme Proteins (C) 2725

De novo design
- Design of Novel, Nonpeptidic Thrombin Inhibitors and Structure of a Thrombin–Inhibitor Complex (C) 1739

Density functional calculations
- Mechanism of the Fe^+ Mediated C–C and C–H Bond Activations in Ethane from a Theoretical Viewpoint (C) 2282
- N-Confused Porphyrins and Singlet Carbenes: Is There a Connection? (C) 1028
- Self-Assembled Helicates of Zinc and Cadmium Cyanides, $[M_x(CN)_{2x+1}]^-$, $x \leq 27$ (C) 314
- The Lipophilically Wrapped Polyion Aggregate $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$, a Face-Sharing (Octahedron + Prismane) $Ba_6Li_3O_2$ Polyhedron in a Hydrocarbon Ellipsoid: Preparation, Single Crystal Structure Analysis, and Density Functional Calculations (C) 1353

Deoxycarbohydrates
- Synthesis of dTDP-6-Deoxy-4-ketoglucose and Analogues with Native and Recombinant dTDP-Glucose-4,6-dehydratase (C) 1748

Deoxysugars
- Thymidine Diphospho-6-deoxy-α-D-*ribo*-3-hexulose Synthesis of a Central Intermediate in the Biosynthesis of Di- and Trideoxysugars (C) 1328

Dewar naphthalene
- 6,7-Bis(methoxycarbonyl)-2,3-dimethyl [5](1,4)naphthalenophane; the First Benzoannelated [5]Paracyclophane (C) 2553

Dialuminoxane
- Tetrakis[bis(trimethylsilyl)methyl]dialuminoxane with a Linear Al-O-Al Group (C) 989

Diazadiene complexes
- DAD Compounds of Niobium and Tantalum: Examples of the Structural Flexibility of DAD Ligands (C) 2649

Diazo compounds
- (*S*)-(+)- and (*R*)-(−)-1,5-Dimethyl-4-phenyl-1,5-dihydro-2*H*-pyrrol-2-ones by Carbene Ring Contraction and Decarboxylation of (2*R*,3*S*)-(−)- and (2*S*,3*R*)-(+)-6-Diazo-3,4-dimethyl-2-phenyloxazepane-5,7-diones (C) 78
- A Series of Well-Defined Metathesis Catalysts Synthesis of $[RuCl_2(=CHR')(PR_3)_2]$ and Its Reactions (C) 2039
- Diazo Chemistry I (B) 1653

Diborations
- Transition Metal Catalyzed Diboration of Vinylarenes (C) 1336

Di-*tert*-butyl dicarbonate
- Reactions of Neopentyl 2,2,-Trifluoroethanesulfonate (Neopentyl Tresylate) with Nucleophiles: A Model Study for the Coupling of Nucleophiles with Tresyl Agarose (C) 2495

Diels–Alder reactions
- A Cycloaddition–Cyclodehydrogenation Route from Stilbenoids to Extended Aromatic Hydrocarbons (C) 1583
- A Highly Symmetric Sixfold Cycloaddition Product of Fullerene C_{60} (C) 87
- An Yttrium-Based Strong Lewis Acid for the Heterogeneous Catalysis of the Diels–Alder Reaction (C) 2143
- C_2-Symmetric Cationic Copper(II) Complexes as Chiral Lewis Acids: Counterion Effects in the Enantioselective Diels–Alder Reaction** (C) 798
- Discrimination between Enantiotopic Groups in a Diels–Alder Reaction (C) 448
- First Synthesis of 2*H*-Azepine (C) 1469
- Free-Energy Profile for a Host-Accelerated Diels–Alder Reaction: The Sources of *exo* Selectivity (C) 217
- Synthesis, Chemical Trapping, and Dimerization of 3,7-Dimethyltricyclo-[3.3.0.$0^{3,7}$]oct-1(5)-ene: [2+2] Retrocycloaddition of the Cyclobutane Dimer (C) 912
- Total Synthesis of Natural (+)-SF 2315A and Determination of the Absolute Configuration (C) 2396
- Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings (H) 2223

Dienynes
- A Rhodium-Mediated, Stepwise Trimerization of an Alkyne That Does Not Lead to a Benzene but Selectively to a Hexadienyne Derivative (C) 191

Diffusion
- Rapid Water Diffusion in a Cage-Type Crystal Lattice: β-Cyclodextrin Dodecahydrate (C) 1452
- Self-Diffusion of Charged Polycyclic Systems and Their Parent Compounds: A PGSE NMR Study (C) 816

Digallanes
- Surprising Formation of a Carborane-Substituted Digallane (C) 332

Digitalis
- Digitalis Research in Berlin–Buch—Retrospective and Perspective Views (R) 282

Dihydroindenes
- Low-Temperature Tandem Enyne Allene Radical Cyclizations: Efficient Synthesis of 2,3-Dihydroindenes from Simple Enediynes (C) 2037

Dihydrooxazinones
- The Arndt–Eistert Reaction in Peptide Chemistry: A Facile Access to Homopeptides (C) 471

Dihydrooxazoles
- Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution (C) 462

Dihydroxylations
- Enantiospecific Syntheses of Valiolamine and Its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid (C) 1643
- Ligand-Accelerated Catalysis (R) 1059

Dimerizations
- 1-Phenyl-1,2-cyclooctadiene Dimerizes in an Unusual Manner (C) 2730
- Synthesis of Belt Cyclophanes (C) 1437
- The Dimerization of (*E*)-1,3-Diphenyl-1,3-butadiene Proceeds Suprafacially with Respect to Both Components: Evidence for a Concerted [4+2] Cycloaddition (C) 895

Dioxygen complexes
- Novel Binuclear Cobalt Dioxygen Complex—A Step on the Path to Dioxygen Activation (C) 2051

Diphosphaallylic cations
- A Facile Access to $1\lambda^5,3\lambda^5$-Benzodiphospholes (C) 2017

Diphosphacyclopentenes
- Synthesis of 1,2-Diphospholide Ions (C) 590

Diphosphete derivatives
- Tetraphosphatricyclo[4.2.0.$0^{2,5}$]octadienes; New Phosphaalkyne Cyclotetramers Derived from $\lambda^3\sigma^2$-Diphosphetes (C) 484

Diphospholides
- Synthesis of 1,2-Diphospholide Ions (C) 590

Diradicaloids
- Conical Intersections and the Mechanism of Singlet Photoreactions (H) 549

Diradicals
- Estramycins: A New Diyl Precursor Family Derived from Estradiol (C) 1749
- 1-Phenyl-1,2-cyclooctadiene Dimerizes in an Unusual Manner (C) 2730
- The Dimerization of (*E*)-1,3-Diphenyl-1,3-butadiene Proceeds Suprafacially with Respect to Both Components: Evidence for a Concerted [4+2] Cycloaddition (C) 895

Disaccharide mimetics
- Disaccharide Mimetics by Enzymatic Tandem Aldol Additions (C) 1639

Distannenes
- Bis(hypersilyl)tin and Bis(hypersilyl)lead, Two Electron-Rich Carbene Homologs (C) 1334

Distellenes
- Synthesis of Rodlike Distellenes (C) 1001

DNA
- 1,5-Anhydrohexitol Nucleic Acids, a New Promising Antisense Construct (C) 1338 (2165)
- Platination Pathways for Reactions of Cisplatin with GG Single-Stranded and Double-Stranded Decanucleotides (C) 1874
- Triple-Helix Formation of Oligodeoxynucleotides Containing [(3′*S*,5′*R*)-2′-Deoxy-3′,5′-ethano-β-D-ribofuranosyl]nucleosides ("Bicyclo-deoxynucleosides") (C) 694

DNA-binding molecules
- DNA–Carbohydrate Recognition: Design and Synthesis of an Eight-Base Sequence-Specific DNA-Binding Oligosaccharide (C) 576

DNA cleavage
- Carbon–Hydrogen Bonds of DNA Sugar Units as Targets for Chemical Nucleases and Drugs (R) 746
- DNA–Carbohydrate Recognition: Design and Synthesis of an Eight-Base Sequence-Specific DNA-Binding Oligosaccharide (C) 576

DNA enzymes
- Synthetic Ribozymes and the First Deoxyribozyme (H) 1189

DNA oxidation
- *N*-Hydroxypyridinethiones as Photochemical Hydroxyl Radical Sources for Oxidative DNA Damage (C) 2156
- Photosensitized Formation of 8-Hydroxy-2′-deoxyguanosine in Salmon Testes DNA by Furocoumarin Hydroperoxides: A Novel, Intercalating "Photo-Fenton" Reagent for Oxidative DNA Damage (C) 107

DNA repair
- Sunlight-Damaged DNA Repaired with Sunlight (H) 2491

Donor functionalization
- Volatile Metal Alkoxides According to the Concept of Donor Functionalization (R) 2187

Donor–acceptor systems
- A Functionalized Polyoxometalate Bearing a Ferrocenylimido Ligand: Preparation and Structure of $[(FcN)Mo_6O_{18}]^{2-}$ (C) 2547

Drugs
- A Chiral Cyanohydrin Phosphate for Carbonyl Umpolung—Stereoselective Synthesis of Tertiary Cyanohydrins (C) 917
- Digitalis Research in Berlin–Buch—Retrospective and Perspective Views (R) 282
- Disulfide-Reductase Inhibitors as Chemotherapeutic Agents: The Design of Drugs for Trypanosomiasis and Malaria (R) 141
- Endotoxin Antagonists: Possible Candidates for the Treatment of Gram-Negative Sepsis (H) 2000
- New Fluorescent Water-Soluble Taxol Derivatives (C) 2710
- Three-Dimensional Chemical Similarity Searching (B) 359

Dyes
- Bis(dicyanomethylene) and Bis(cyanoimino) Derivatives of Indigo and Thioindigo (C) 464
- Deformation of Polymethine Structures by Intermolecular Interactions (C) 690
- Novel Porphyrinoids for Chemistry and Medicine by Biomimetic Syntheses (R) 1795
- Quaterrylenebis(dicarboximides) (C) 1323

Dynemicins
- Synthesis of a Dynemicin A Analogue and Its Bergman-Type Cycloaromatization (C) 1345
- Total Synthesis of (±)-Dynemicin A (C) 1721

Electrochemistry
- A New Method for the Preparation of Nanostructured Metal Clusters (C) 2240
- A Redox-Switchable Hemilabile Ligand: Electrochemical Control of the Coordination Environment of a Rh^I Complex (C) 1624
- Diastereoselective Cathodic Cyclization of 1-(4- and 1-(3-Oxoalkyl)pyridinium Salts to Quinolizidine and Indolizidine Derivatives (C) 2007
- Electrochemical Evidence for Through-Space Orbital Interactions in Spiromethanofullerenes (C) 1591
- Electrochemical Synthesis of a Redox-Active Polymer Based on Buckminsterfullerene Epoxide (C) 194
- Electrochemistry and Ab Initio Study of the Dimetallofullerene $La_2@C_{80}$ (C) 1094
- Incorporation of Membrane Proteins in Solid-Supported Lipid Layers (C) 2056
- Modern Electroorganic Chemistry (B) 1521
- Photoswitchable Electrical Communication of Glucose Oxidase and Glutathione Reductase with Electrode Surfaces through Photoisomerizable Redox Mediators (C) 1604
- Radical Cation [4+2] Cycloadditions with 2-Vinylindoles (C) 1900
- Routes to Dendritic Networks: Bis-Dendrimers by Coupling of Cascade Macromolecules through Metal Centers (C) 2023
- Water-Soluble Dendritic Iron Porphyrins: Synthetic Models of Globular Heme Proteins (C) 2725

Electrocyclic reactions
- A Remarkable Effect of Silyl Substitution on Electrocyclization of Vinylallenes (C) 1476

Electron-deficient compounds
- Diborylcarbenes as Reactive Intermediates in Double 1,2-Rearrangements with Low Activation Enthalpies (C) 1340
- The First Mixed-Metal Borole Cluster; Stabilization of Formally 14e Pd Centers in the Re_2Pd_2 Electron-Deficient $[\{[(\eta^5\text{-}C_4H_4BPh)(CO)_3Re]Pd\}_2]$ Cluster (C) 1010

Electron diffraction
- Bis(trifluoromethyl)trioxide: First Structure of a Straight-Chain Trioxide (C) 2244
- Hexakis(trifluoromethyl)tetrazane (C) 586

Electronic energy transfer
- Electronic Energy Transfer Across Ethynyl-Bridged Ru^{II}/Os^{II} Terpyridyl Complexes (C) 1100

Electronic structure
- A P_2C_2 Four-Membered Ring with Unusual Bonding—Synthesis, Structure, and Ring Opening of a 1,3-Diphosphacyclobutane-2,4-diyl (C) 555
- A Stable Aquairon(III) Complex with $S = 1$: Structure and Spectroscopic Properties (C) 1216 (1649)
- Distinguishing Copper d^8 and d^{10} Configurations in a Highly Ionic Complex; A Nonformal Metal Oxidation State (C) 986
- Elusiveness of Cu^{III} Complexation; Preference for Trifluoromethyl Oxidation in the Formation of $[Cu^I(CF_3)_4]^-$ Salts (C) 80
- Formal Oxidation State versus Partial Charge—A Comment (C) 986
- Structure Determination from Powder X-Ray Diffraction Data of a Hydrogen-Bonded Molecular Solid with Competing Ferromagnetic and Antiferromagnetic Interactions: The 2-(3,4-Dihydroxyphenyl)-α-Nitronyl Nitroxide Radical (C) 55

Electron localization
- Hyperbolic Lone Pair Structure in $RhBi_4$ (C) 1204
- μ-Nitridodiiron Complexes with Asymmetric $[Fe^{IV}\equiv N-Fe^{III}]^{4+}$ and Symmetric $[Fe^{IV}=N=Fe^{IV}]^{5+}$ Structural Elements (C) 669
- The Stabilization of the Rb^- Ion in $Na_{16}Rb_7Sb_7 = Na_{16}(RbRb_6)Sb_7$ (C) 103

Electron polarization
- Deformation of Polymethine Structures by Intermolecular Interactions (C) 690

Electron transfer
- A New Dimension in Radical Chain Group Transfer Reaction by Photosensitized Electron Transfer (PET) Reductive Activation of $PhSeSiR_3$ (C) 2669
- Catalytic Photoinduced Charge-Transfer Osmylation: A Novel Pathway from Arenes to Cyclitol Derivatives (C) 2031
- Direct Electrochemical Coupling of Components of the Biological Electron Transfer Chain to Modified Surfaces: Molecular Recognition between Cytochrome c Peroxidase and Cytochrome c (C) 2409
- Effective Charge Separation in Intermolecular Complexes of an Electron Donor and a Doubly Branched Triad Assembly: A Model System for Environmental Effects Controlling Electron Transfer (C) 1005
- Electron Transfer and Polar Reactions of Cyclizable Anion Radicals: Structural Consequences of Orbital Selection Rules and Chain-Length Constraints (C) 1495
- Electron Transfer through DNA: Site-Specific Modification of Duplex DNA with Ruthenium Donors and Acceptors (C) 352
- Fundamentals of Photoinduced Electron Transfer (B) 495
- Luminescence Stimulated by Electron Transfer: Fluorescent Donor/Acceptor-Substituted Stilbenes Containing Pyrenoid and Heteroaromatic Subunits (C) 2664
- Model Reactions for Photosynthesis—Photoinduced Charge and Energy Transfer between Covalently Linked Porphyrin and Quinone Units (R) 849
- New Fluorescent Model Compounds for the Study of Photoinduced Electron Transfer: The Influence of a Molecular Electric Field in the Excited State (C) 1728
- Photoinduced Valence Tautomerism in Cobalt Complexes Containing Semiquinone Anion as Ligand: Dynamics of the High-Spin $[Co^{II}(3,5\text{-dtbsq})_2]$ to Low-Spin $[Co^{III}(3,5\text{-dtbsq})(3,5\text{-dtbcat})]$ Interconversion (C) 1481
- Radical Additions of Activated Haloalkanes to Alkenes Initiated by Electron Transfer from Copper in Solvent-Free Systems (C) 902
- Radical Cation [4+2] Cycloadditions with 2-Vinylindoles (C) 1900
- Reactions of Carbocations with π Nucleophiles: Polar Mechanism and No Outer Sphere Electron Transfer Processes (C) 1225
- Redox Mechanisms in Inorganic Chemistry (B) 1249
- Sunlight-Damaged DNA Repaired with Sunlight (H) 2491

Hydrogenations
- A Novel Class of Versatile Solvents for Two-Phase Catalysis: Hydrogenation, Isomerization, and Hydroformylation of Alkenes Catalyzed by Rhodium Complexes in Liquid 1,3-Dialkylimidazolium Salts (C) 2698
- Exciting Results from the Field of Homogeneous Two-Phase Catalysis (H) 1575
- σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation (C) 1742
- Preparation of a Surface-Active Chiral Diphosphane and Its Use in the Hydrogenation of Prochiral Olefins (C) 1645

Hydrogen bonds
- A Comparison of Enthalpies of Formation in Solution and Enthalpies for HPLC Retention for Hydrogen-Bonded Host–Guest Complexes (C) 2404
- A Molecular Composite Containing Organic and Inorganic Components—A Complex from β-Cyclodextrin and Hydrated Magnesium Chloride (C) 2381
- A New Family of Chiral Binaphthyl-Derived Cyclophane Receptors: Complexation of Pyranosides (C) 1596
- An Unconventional Intermolecular Three-Center N–H···H_2Re Hydrogen Bond in Crystalline $[ReH_5(PPh_3)_3]\cdot$indole·C_6H_6 (C) 2507
- A Self-Assembled Bifunctional Receptor (C) 2124
- Designed Assemblies in Open Framework Materials Synthesis: An Interrupted Sodalite and An Expanded Sodalite (C) 1745
- Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules (C) 1865
- Highly Effective Hydrogen-Bonding Receptors for Guanine Derivatives (C) 2163
- Mesogenic Properties of Amphiphilic Liquid Crystals with an Unusual Head-Group Topology (C) 1631
- Metal Oxo Cation Receptors: Multimode Coordination to the Dioxoosmium(VI) Cation (C) 1359
- Patterns in Hydrogen Bonding: Functionality and Graph Set Analysis in Crystals (R) 1555
- Porous Solids by Design: $[Zn(4,4'\text{-bpy})_2(SiF_6)]_n\cdot x$DMF, a Single Framework Octahedral Coordination Polymer with Large Square Channels (C) 2127 (2561)
- Self-Assembling Discotic Mesogens (C) 1637
- Self-Assembly of 1,3,5-Benzenetricarboxylic Acids (Trimesic Acids) and Their Analogues in the Solid State (C) 2654
- Structure-Determining C-H···O-Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil (C) 2680
- Sulfuric Acid from Sulfur Trioxide and Water—A Surprisingly Complex Reaction (H) 1313
- Supramolecular Inorganic Chemistry: Small Guests in Small and Large Hosts (R) 2311
- The Consequences of an Electrostatic "Forced Marriage" between Two Electron-Rich Particles: Strained Ion Pairs (C) 439
- The Nonaaquabismuth(III) Cation (C) 2416
- Thermotropic Liquid Crystals Formed by Intermolecular Hydrogen Bonding Interactions (R) 1696
- $[WL(NO)(O)(CH_3)]$—An Unusual Nitrosyltungsten Complex (C) 1435

Hydrolyses
- Antibody-Catalyzed Phosphate Triester Hydrolysis (C) 2275
- Hydrolysis of a Phosphate Diester Doubly Coordinated to a Dinuclear Cobalt(III) Complex: A Novel Mechanism (C) 2412

Hydroperoxides
- Nonheme Iron Centers in Oxygen Activation: Characterization of an Iron(III) Hydroperoxide Intermediate (C) 1512
- Photosensitized Formation of 8-Hydroxy-2′-deoxyguanosine in Salmon Testes DNA by Furocoumarin Hydroperoxides: A Novel, Intercalating "Photo-Fenton" Reagent for Oxidative DNA Damage (C) 107

Hydrophobic effect
- Burial of Hydrocarbon Causes Cooperative Enhancement of Electrostatic Binding (C) 1483

Hydrothermal syntheses
- Hydrothermal Synthesis of a Novel Se_{12} Ring in $[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2\cdot[Se_{12}]]$ (C) 2509
- Investigations into the Targeted Design of Solids: Hydrothermal Synthesis and Structures of One-, Two-, and Three-Dimensional Phases of the Oxovanadium–Organodiphosphonato System (C) 223

Hydroxamic acids
- Formation of Nitronic Acids by Ring Opening of Nitrocyclopropanes by a Concerted, Acid-Catalyzed Mechanism (C) 1091

Hydroxyaldehydes
- Temperature and Solvent Effect on the Nucleophilic Addition of *n*-Butyllithium to the *N*-(Trimethylsilyl)imine of (2*S*)-Lactal (C) 2150

8-Hydroxy-2′-deoxyguanosine
- Photosensitized Formation of 8-Hydroxy-2′-deoxyguanosine in Salmon Testes DNA by Furocoumarin Hydroperoxides: A Novel, Intercalating "Photo-Fenton" Reagent for Oxidative DNA Damage (C) 107

Hydroxyl radicals
- *N*-Hydroxypyridinethiones as Photochemical Hydroxyl Radical Sources for Oxidative DNA Damage (C) 2156
- Photosensitized Formation of 8-Hydroxy-2′-deoxyguanosine in Salmon Testes DNA by Furocoumarin Hydroperoxides: A Novel, Intercalating "Photo-Fenton" Reagent for Oxidative DNA Damage (C) 107

N-hydroxypyridinethione
- *N*-Hydroxypyridinethiones as Photochemical Hydroxyl Radical Sources for Oxidative DNA Damage (C) 2156

Hyperconjugation
- Heteroatom-Substituted Bicyclo[1.1.1]-pentanes with Two Boron Atoms as Electron-Deficient Centers (C) 657

Hypersilyl derivatives
- Bis(hypersilyl)tin and Bis(hypersilyl)lead, Two Electron-Rich Carbene Homologs (C) 1334

Hypervalent compounds
- Stable 1:1 Adducts from Iodoacetylenes and Iodide Ions: Ion Pair Strain as an Additional Driving Force? (C) 441

ICR spectroscopy
- The Crafts–Friedel Reaction: Aromatic Alkylation within the Complex Formed upon Addition of a Gaseous Arenium Ion to an Olefin (C) 1589

Imides
- Tetracarboxylic Bisimide–Lactam Ring Contraction: A Novel Type of Rearrangement (C) 2234

Imines
- Regio- and Diastereoselective Synthesis of β-Amino Ketones by Addition of Imines to Iminium Salts (C) 2639
- $S(NPMe_3)_4^{2+}$: The First Structure Determination of a Dication of Hexavalent Sulfur (C) 1362
- Temperature and Solvent Effect on the Nucleophilic Addition of *n*-Butyllithium to the *N*-(Trimethylsilyl)imine of (2*S*)-Lactal (C) 2150

Iminophosphoranes
- Substituent-Controlled Reactions of Iminophosphoranes with Methyllithium (C) 1752

Immobilization
- A New Strategy in Heterogeneous Catalysis: The Design of Cortex Catalysts (C) 2728
- Direct Electrochemical Coupling of Components of the Biological Electron Transfer Chain to Modified Surfaces: Molecular Recognition between Cytochrome c Peroxidase and Cytochrome c (C) 2409
- Efficient Heterogeneous Biocatalysts by Entrapment of Lipases in Hydrophobic Sol–Gel Materials (C) 301
- Micron-Scale Patterning of Biological Molecules (C) 91

Immunological analysis
- Methods of Immunological Analysis, Vols. 1–3 (B) 243

Immunophilins
- Rational Design of Orthogonal Receptor–Ligand Combinations (C) 2129

Immunosensors
- Micron-Scale Patterning of Biological Molecules (C) 91

Imprinting
- Molecular Imprinting in Cross-Linked Materials with the Aid of Molecular Templates—A Way towards Artificial Antibodies (R) 1812

Inclusion compounds
- Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules (C) 1865

- $^3_\infty[(CoCp_2)\subset Fe(\mu\text{-}CNSnMe_3NC)_3]$: A Purely Organometallic Channel Inclusion Compound (C) 1197

Indacenes
- 1,3,5,7-Tetra-*tert*-butyl-4-aza- and 1,3,5,7-Tetra-*tert*-butyl-4-phospha-*s*-indacene (C) 330

Indenes
- Generation of Enantiomerically Enriched Lithium Indenides by Means of (−)-Sparteine: Structure, Stereoselective Substitution, and Solvent Effects (C) 2158

Indigo
- Thermal Isomerization of Indigo (C) 67

Indigo derivatives
- Bis(dicyanomethylene) and Bis(cyanoimino) Derivatives of Indigo and Thioindigo (C) 464

Indium compounds
- New Tellurometalates of Gallium and Indium: $K[K([18]crown\text{-}6)]_2[GaTe_3]\cdot 2CH_3CN$ and $[(NEt_4)_5][In_3Te_7]\cdot 0.5\,Et_2O$ (C) 1879
- Synthesis, Structure, and Decay of In_4Br_7 (C) 1126

Indoles
- An Unconventional Intermolecular Three-Center $N-H\cdots H_2Re$ Hydrogen Bond in Crystalline $[ReH_5(PPh_3)_3]\cdot indole\cdot C_6H_6$ (C) 2507
- A Simple Catalytic Method for the Conversion of Aryl Bromides to Arylamines (C) 1348
- Titanium-Induced Zipper Reactions (C) 678

Indolizidines
- Diastereoselective Cathodic Cyclization of 1-(4- and 1-(3-Oxoalkyl)pyridinium Salts to Quinolizidine and Indolizidine Derivatives (C) 2007

Induced volatiles
- Jasmonic Acid and Coronatin Induce Odor Production in Plants (C) 1600

Inhalational anesthetics
- Carbon–Carbon Bond Cleavage with Inversion of Configuration: Conversion of (*R*)-(+)-1-Methoxytetrafluoropropionic Acid to (*S*)-(−)-1,2,2,2-Tetrafluoroethyl Methyl Ether (C) 222

Inorganic chemistry
- Inorganic Chemistry (B) 599
- Inorganic Experiments (B) 2565
- Redox Mechanisms in Inorganic Chemistry (B) 1249

Inositol phosphates
- Chemistry of Inositol Lipid Mediated Cellular Signaling (R) 1933

Inositols
- Catalytic Photoinduced Charge-Transfer Osmylation: A Novel Pathway from Arenes to Cyclitol Derivatives (C) 2031

Insertions
- Preparation, Structure, and Reactivity of 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene, a New Stable Carbene (C) 1021

π–π Interactions
- Novel, Blue-Transparent Frequency Doublers Based on 1,8-Di(hetero)arylnaphthalenes (C) 1485

π Interactions
- Tetrakis[bis(trimethylsilyl)methyl]dialuminoxane with a Linear Al-O-Al Group (C) 989

Intermetallic phases
- Hyperbolic Lone Pair Structure in $RhBi_4$ (C) 1204

In vitro selection
- Synthetic Ribozymes and the First Deoxyribozyme (H) 1189

Iodine compounds
- $[Pb_{18}I_{44}]^{8-}$—An Iodoplumbate with an Unusual Structure (C) 2035

Ion channels
- A Non-Peptidic Ion Channel with K^+ Selectivity (C) 693
- Toxins as Tools in Neurochemistry (R) 39

Ion chromatography
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples III: Development of a Fast Analytical Method (C) 186

Ionic liquids
- A Novel Class of Versatile Solvents for Two-Phase Catalysis: Hydrogenation, Isomerization, and Hydroformylation of Alkenes Catalyzed by Rhodium Complexes in Liquid 1,3-Dialkylimidazolium Salts (C) 2698

Ionization potentials
- First Determination of the Ionization Potential of Americium and Curium (C) 814

Ion pairs
- Deformation of Polymethine Structures by Intermolecular Interactions (C) 690
- The Consequences of an Electrostatic "Forced Marriage" between Two Electron-Rich Particles: Strained Ion Pairs (C) 439

Ion–molecule reactions
- Control of Ion–Molecule Reactions in the Gas Phase (H) 885

Iridium compounds
- A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1′-Ferrocenedithiolato Complexes (C) 656
- Direct Observation of O–H Reductive Elimination from Ir^{III} Complexes (C) 229
- *closo*-$[B_5H_4PPh_3\{Fe(CO)_3\}\{Ir(CO)_2PPh_3\}]$: The First Structurally Characterized *closo*-Heterobimetallaheptaborane System (C) 1641

Iron compounds
- A Cyclic Hexairon(III) Complex with an Octahedrally Coordinated Sodium Ion at the Center, an Example of the [12]Metallacrown-6 Structure Type (C) 467
- Additions of Carbanions to a Cationic Cyclopentadienyl(naphthalene)iron Complex (C) 2161
- A Highly Reactive and Catalytically Active Model System for Intradiol-Cleaving Catechol Dioxygenases: Structure and Reactivity of Iron(III) Catecholate Complexes of *N*,*N*′-Dimethyl-2,11-diaza[3,3](2,6)pyridinophane (C) 2671
- A Model of Semimet Hemerythrin; NMR Spectroscopic Evidence of Valence Localization in Bis(μ-carboxylato)(μ-phenolato)diiron(II,III) in Solution (C) 588
- An Alkylperoxoiron(III) Intermediate and Its Role in the Oxidation of Aliphatic C–H Bonds (C) 2048
- A New Type of Trinuclear Oxoiron(III) Cluster (C) 205
- A Novel Hexanuclear Fe^{III}-*cis*-Inositolato Complex as a Model for Fe^{III}–Polyol Interactions in Aqueous Solution (C) 2242
- A One-Step Synthesis of Squalene from Farnesol under Prebiotic Conditions (C) 1898
- A Stable Aquairon(III) Complex with $S = 1$: Structure and Spectroscopic Properties (C) 1216 (1649)
- Distorted Sandwich Compounds: [1]Ferrocenophanes and [2]Ruthenocenophanes (H) 1837
- Ferrocenes. Homogeneous Catalysis. Organic Synthesis. Materials Science (B) 1904
- Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium (C) 2647
- Formation of an Alkylperoxoiron(III) Complex during Oxidations Catalyzed by μ-Oxodiiron(III) Complexes (C) 203
- Formation of the First Isomeric [2]Catenates by Self-Assembly about Two Different Metal Ions (C) 582
- New Selenolato-Bridged Clusters of Iron and Nickel; the Structures of $[Fe_{12}(SePh)_{24}]$ and $[Na_2(POPh_3)_6][Ni_{20}Se_{12}(SeMe)_{10}]$ (C) 307
- μ-Nitridodiiron Complexes with Asymmetric $[Fe^{IV}\equiv N-Fe^{III}]^{4+}$ and Symmetric $[Fe^{IV}=N=Fe^{IV}]^{5+}$ Structural Elements (C) 669
- Structure and Magnetic Properties of a Decanuclear Oxoiron(III) Cluster: A Further Step to Understanding Iron Aggregation Processes (C) 2716
- The First μ(OH)-Bridged Model Complex for the Mixed-Valent $Fe^{II}Fe^{III}$ Form of Hemerythrin (C) 2642
- Water-Soluble Dendritic Iron Porphyrins: Synthetic Models of Globular Heme Proteins (C) 2725
- *closo*-$[B_5H_4PPh_3\{Fe(CO)_3\}\{Ir(CO)_2PPh_3\}]$: The First Structurally Characterized *closo*-Heterobimetallaheptaborane System (C) 1641
- $^3_\infty[(CoCp_2)\subset Fe(\mu\text{-}CNSnMe_3NC)_3]$: A Purely Organometallic Channel Inclusion Compound (C) 1197
- $[Fe(2,4,6\text{-}tBu_3C_6H_2)_2]$, a Monomeric Diaryl Complex with Two-Coordinate Iron(II) (C) 325

Iron–molybdenum cofactor
- On the Synthesis of the FeMo Cofactor of Nitrogenase: Gene-Controlled in Nature versus Laboratory-Produced by Man (R) 1071

Iron–sulfur cluster

- Single-Crystal X-Ray Structure of the Metastable Aryne Precursor Tetrafluorophenyllithium and of 1,2,3,4-Tetrafluorobenzene (C) 1517
- Substituent-Controlled Reactions of Iminophosphoranes with Methyllithium (C) 1752
- The Formation of a Mixed Organolithium Aggregate $Li_4R_2nBu_2$ (R = 2,6-$(CH_2NMe_2)_2$-3,5-$Me_2C_6HCH_2$) during the Heteroatom-Assisted Lithiation of 1,3-Bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (C) 219
- The Lipophilically Wrapped Polyion Aggregate $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}(OC_4H_8)_3\}$, a Face-Sharing (Octahedron + Prismane) $Ba_6Li_3O_2$ Polyhedron in a Hydrocarbon Ellipsoid: Preparation, Single Crystal Structure Analysis, and Density Functional Calculations (C) 1353

Lock and key principle
- The Lock and Key Principle. The State of the Art—100 Years on (B) 2293

Low-valent compounds
- A New Method for the Synthesis of Amphipolar Phosphorus-Containing Heterocycles (C) 557

Luminescence
- Effective Charge Separation in Intermolecular Complexes of an Electron Donor and a Doubly Branched Triad Assembly: A Model System for Environmental Effects Controlling Electron Transfer (C) 1005
- Luminescence Stimulated by Electron Transfer: Fluorescent Donor/Acceptor-Substituted Stilbenes Containing Pyrenoid and Heteroaromatic Subunits (C) 2664

McMurry reactions
- Titanium-Induced Zipper Reactions (C) 678

Macrocycles
- Activation of Macrocyclic Biaryl-Enediynes by Metal Ion Coordination (C) 2538
- A Stable Aquairon(III) Complex with $S = 1$: Structure and Spectroscopic Properties (C) 1216 (1649)
- Binding of Boron and Alkali Metal Cations by a Pseudocryptand (C) 1115
- Concave Reagents Based on Calixarenes (C) 2555
- Facile Synthesis and Solid-State Structure of a Benzylic Amide [2]Catenane (C) 1209
- From Porphyrin Isomers to Octapyrrolic "Figure Eight" Macrocycles (C) 2511
- Homeomorphic Isomerism in a Peptidic Macrobicycle (C) 2660
- Macrobicyclic Titanium(IV) Complexes with C_3-Symmetric Synthetic Peptides (C) 1449
- Octacationic Cyclophanes: Binding of ATP and Other Anionic Guests in Water (C) 2147
- Octaphyrin-(1.0.1.0.1.0.1.0) (C) 2515
- Photo Electron Transfer Induced Macrocyclization of *N*-Phthaloyl-ω-aminocarboxylic Acids (C) 474
- Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$ (C) 2374
- Silicon-Bridged Macrocycles—Synthesis of Sila-Calixarenes (C) 661
- Structurally Diverse and Dynamically Versatile Benzylic Amide [2]Catenanes Assembled Directly from Commercially Available Precursors (C) 1212
- Synthesis and Structure of the Nanodimensional Multicyclophane "Kuratowski Cyclophane", an Achiral Molecule with Nonplanar $K_{3,3}$ Topology (C) 2657
- Synthesis and X-ray Structure of a Shape-Persistent Macrocyclic Amphiphile (C) 2713
- *meso*-Tetrakis[4-(diphenylphosphino)-phenyl]porphyrin and a Water-Soluble Octakis(phosphonium salt) Porphyrin Double-Decker with a Cage Structure. (C) 2230
- The Reactivity of 1,3-Butadiyne Moieties in the "Exploding" [*n*]Rotanes—A Crown of Thiophenes (C) 781

Macrolides
- Relative and Absolute Configuration of Filipin III (C) 1227
- The Macrolidic Glycolipid Calonyctin A, a Plant Growth Regulator: Synthesis, Structural Assignment, and Conformational Analysis in Micellar Solution (C) 2520

Macromolecules
- Routes to Dendritic Networks: Bis-Dendrimers by Coupling of Cascade Macromolecules through Metal Centers (C) 2023

Magnesium compounds
- Silicon Analogues of Grignard Compounds: Synthesis and Structure of Amine-Stabilized Trimethylsilylmagnesium Halides (C) 1030

Magnetic properties
- A Cyclic Hexairon(III) Complex with an Octahedrally Coordinated Sodium Ion at the Center, an Example of the [12]Metallacrown-6 Structure Type (C) 467
- A New Type of Trinuclear Oxoiron(III) Cluster (C) 205
- A Nickel(II) Azide Cubane: Characterization of the Magnetic Exchange Interactions Mediated by a Triply Bridging Azide Group Bound End-On (C) 889
- $Na_2Ti_3Cl_8$: From Isolated Ti^{2+} Ions to $[Ti_3]^{6+}$ Clusters (C) 71
- Octadecanuclearity in Manganese Carboxylate Chemistry: $K_4[Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ ($phthH_2$ = phthalic acid) (C) 887
- Self-Assembly of a Ferromagnetically Coupled Manganese(II) Tetramer (C) 1443
- Structure and Magnetic Properties of a Decanuclear Oxoiron(III) Cluster: A Further Step to Understanding Iron Aggregation Processes (C) 2716
- Structure Determination from Powder X-Ray Diffraction Data of a Hydrogen-Bonded Molecular Solid with Competing Ferromagnetic and Antiferromagnetic Interactions: The 2-(3,4-Dihydroxyphenyl)-α-Nitronyl Nitroxide Radical (C) 55
- The First μ(OH)-Bridged Model Complex for the Mixed-Valent $Fe^{II}Fe^{III}$ Form of Hemerythrin (C) 2642
- The Two-Dimensional Network Structure and Metamagnetic Properties of the 2:1 Complex of $[Mn(3\text{-}MeOsalen)(H_2O)]ClO_4$ and $K_3[Fe(CN)_6]$ (C) 1446
- 2-[*p*-(*N*-*tert*-butyl-*N*-oxyamino)phenyl]-4,4,5,5-tetramethyl-4,5-dihydroimidazol-3-oxide-1-oxyl, a Stable Diradical with a Triplet Ground State (C) 927

Main group elements
- Synthesis and Structure of Organometallic Compounds with $(Al_2Si)_2$ and Al_3Sb_2 Frameworks (C) 919
- Te_8^{4+}: A Cubic Polycation in the Structure of $Te_8(VOCl_4)_2$ (C) 2559

Manganese compounds
- A Dinuclear (μ-Carboxylato)manganese(II) Complex Derived from a Macrocyclic Ligand: A Structural Model for Active Sites in Natural Systems (C) 2535
- Aromatic Gallium Heterocycles: Synthesis of the First Gallatabenzene (C) 1357
- Characterization of an Oxo(porphyrinato)manganese(IV) Complex by X-ray Absorption Spectroscopy (C) 343
- Octadecanuclearity in Manganese Carboxylate Chemistry: $K_4[Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ ($phthH_2$ = phthalic acid) (C) 887
- Phosphorane Iminato Complexes of Manganese and Cobalt with Heterocubane Structure (C) 1235

- Self-Assembly of a Ferromagnetically Coupled Manganese(II) Tetramer (C) 1443
- Synthesis and Structure of Bimetallic η^3,η^6-Naphthalene Complexes Containing a Mn–Mn Moiety Bonded in a *Syn*-Facial Manner: A General Route to Homo- and Heteronuclear Bimetallic Complexes of Polyarenes (C) 2540
- Synthesis and Structure of the First Transition Metal Borylene Complexes (C) 825
- The Two-Dimensional Network Structure and Metamagnetic Properties of the 2:1 Complex of $[Mn(3\text{-}MeOsalen)(H_2O)]\text{-}ClO_4$ and $K_3[Fe(CN)_6]$ (C) 1446
- $[Mn(C_{18}H_{16}N_2O_2)_3](ClO_4)_2$: A Polymeric 34- and 68-Membered Metallacyclic Network Forming a Novel Woven Polycatenated Structure (C) 574

Mannich bases
- Regio- and Diastereoselective Synthesis of β-Amino Ketones by Addition of Imines to Iminium Salts (C) 2639

Mass spectrometry
- An Alkylperoxoiron(III) Intermediate and Its Role in the Oxidation of Aliphatic C–H Bonds (C) 2048
- Applications of Mass Spectrometry to Organic Stereochemistry (B) 497
- "Cation-π Interactions" Detected by Mass Spectrometry; Selective Recognition of Alkali Metal Cations by a π-Basic Molecular Cavity (C) 1364
- $C_{59}N^+$ and $C_{69}N^+$: Isoelectronic Heteroanalogues of C_{60} and C_{70} (C) 2257
- Coordination of Dioxygen in Three Representative Transition Metal Cations: FeO_2^+, CrO_2^+, and $[CH_3Re(O_2)_2O]^+$ (C) 2517
- C–H and C–C Bond Activation by Bare Transition-Metal Oxide Cations in the Gas Phase (R) 1973
- Formation and Structures of New Metallo- and Metallapolysulfanes, $[MS_y]^+$ (y = 2–16) (C) 201 (1032)
- Gas-Phase Activation of Fluorocarbons by "Bare" and "Coordinated" Praseodymium Cations (C) 213
- Gas-Phase Micelles (C) 2053
- Investigation of Self-Assembled Supramolecular Species in Solution by IL-ESMS, a New Mass Spectrometric Technique (C) 209
- Nonheme Iron Centers in Oxygen Activation: Characterization of an Iron(III) Hydroperoxide Intermediate (C) 1512
- Synthesis and Properties of First to Third Generation Dendrimers with Doubly and Triply Branched Chiral Building Blocks (C) 2116
- Tantalum-Mediated Coupling of Methane and Carbon Dioxide in the Gas Phase (C) 2033
- The Synthesis of Tris(perfluoroalkyl)-phosphanes (C) 1241
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples II: Accelerator Mass Spectrometry (AMS) (C) 183
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples I: Laser Mass Spectrometry (C) 181
- $[R_3Si-arene]^+$ σ Complexes in the Gas Phase (C) 654

Matrix isolation
- Reaction of 1,1-Dimethylsilene with Formaldehyde (C) 929

Medicinal chemistry

Poly(ethylenimine)s
- Formation of a Hexagonal Columnar Mesophase by N-Acylated Poly(ethylenimine) (C) 795

Polyhedral nets
- Hyperbolic Lone Pair Structure in $RhBi_4$ (C) 1204

Polyiodides
- Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$ (C) 2374

Polyion aggregates
- The Lipophilically Wrapped Polyion Aggregate $\{H_{120}C_{144}O_{24}(OP)_2N^-Na_6^+\}$, a Hexameric Sodium Tetraphenyl Imidodiphosphate Containing an $[Na_6O_{12}]$ Core in a Hydrocarbon Ellipsoid (C) 1355
- The Lipophilically Wrapped Polyion Aggregate $\{[Ba_6Li_3O_2]^{11+}[^-OC(CH_3)_3]_{11}\cdot(OC_4H_8)_3\}$, a Face-Sharing (Octahedron + Prismane) $Ba_6Li_3O_2$ Polyhedron in a Hydrocarbon Ellipsoid: Preparation, Single Crystal Structure Analysis, and Density Functional Calculations (C) 1353

Polyketides
- Biosyntheses of Novel Emycins from the Mutant Strain *Streptomyces cellulosae* ssp. *griseoincarnatus* 1114-2 (C) 1617
- Combinatorial Biosynthesis—An Approach in the Near Future? (H) 881
- Novel Genetically Engineered Tetracenomycins (C) 1107

Polymacromonomers
- Lyotropic Phases Formed by "Molecular Bottlebrushes" (C) 1472

Polymerizations
- Distorted Sandwich Compounds: [1]Ferrocenophanes and [2]Ruthenocenophanes (H) 1837
- Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)borane—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts (C) 1755
- Stereospecific Olefin Polymerization with Chiral Metallocene Catalysts (R) 1143 (1368)
- Synthesis and Structure of the First Sulfur-Bridged [1]Ferrocenophane (C) 1506

Polymers
- Architectural Control in "Living" Free Radical Polymerizations: Preparation of Star and Graft Polymers (C) 1456
- $C_4S_6^{2-}$: A Bridging Bis(dithiolato) Ligand for the Preparation of Semiconducting Inorganic Polymers (C) 1890
- Design, Synthesis, and Properties of Molecule-Based Assemblies with Large Second-Order Optical Nonlinearities (R) 155
- Electrochemical Synthesis of a Redox-Active Polymer Based on Buckminsterfullerene Epoxide (C) 194
- Formation of a Hexagonal Columnar Mesophase by N-Acylated Poly(ethylenimine) (C) 795
- Lyotropic Phases Formed by "Molecular Bottlebrushes" (C) 1472
- Molecular Imprinting in Cross-Linked Materials with the Aid of Molecular Templates—A Way towards Artificial Antibodies (R) 1812
- Structure and Properties of Polymers (B) 600
- Structure – Property Relations in Polymers. Spectroscopy and Performance (B) 601

- Synthesis and Structure of the Three-Dimensional Coordination Polymers $[(Me_3Sn)_4M(CN)_8]$ (M = Mo, W) (C) 2557
- $[Mn(C_{18}H_{16}N_2O_2)_3](ClO_4)_2$: A Polymeric 34- and 68-Membered Metallacyclic Network Forming a Novel Woven Polycatenated Structure (C) 574

Poly(metallocene)s
- Synthesis and Structure of the First Sulfur-Bridged [1]Ferrocenophane (C) 1506

Polymethacrylate
- Side-Chain Polyrotaxanes with a Tandem Structure Based on Cyclodextrins and a Polymethacrylate Main Chain (C) 309

Polymethines
- Deformation of Polymethine Structures by Intermolecular Interactions (C) 690

Polymorphism
- Orthorhombic and Monoclinic 2,3,7,8-Tetramethoxythianthrene: Small Structural Difference—Large Lattice Change (C) 76

Polyolato complexes
- A Hexadecanuclear Polyolatometalate of Copper(II) Ions and Multideprotonated D-Sorbitol (C) 2119

Polyols
- A Novel Hexanuclear Fe^{III}-*cis*-Inositolato Complex as a Model for Fe^{III}–Polyol Interactions in Aqueous Solution (C) 2242
- Fivefold Deprotonated D-Mannose as Ligand in Homoleptic Dinuclear Metalates of Trivalent Iron, Vanadium, Chromium, Aluminum, and Gallium (C) 2647

Polyoxometalates
- A Functionalized Polyoxometalate Bearing a Ferrocenylimido Ligand: Preparation and Structure of $[(FcN)Mo_6O_{18}]^{2-}$ (C) 2547
- A Novel Chainlike Heteropolyanion Formed by Keggin Units: Synthesis and Structure of $(ET)_{8n}[PMnW_{11}O_{39}]_n \cdot 2nH_2O$ (C) 1460
- Hydroxylation of Alkanes with Molecular Oxygen Catalyzed by a New Ruthenium-Substituted Polyoxometalate, $[WZnRu^{III}_2(OH)(H_2O)(ZnW_9O_{34})_2]^{11-}$ (C) 1587
- Investigations into the Targeted Design of Solids: Hydrothermal Synthesis and Structures of One-, Two-, and Three-Dimensional Phases of the Oxovanadium–Organodiphosphonato System (C) 223
- Supramolecular Synthons in Crystal Engineering—A New Organic Synthesis (R) 2328
- $[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]^{(25\pm5)-}$: A Water-Soluble Big Wheel with More than 700 Atoms and a Relative Molecular Mass of About 24000 (C) 2122

Polyrotaxanes
- Side-Chain Polyrotaxanes with a Tandem Structure Based on Cyclodextrins and a Polymethacrylate Main Chain (C) 309

Polyselenides
- Hydrothermal Synthesis of a Novel Se_{12} Ring in $[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2\text{-}[Se_{12}]]$ (C) 2509

Polysilanes
- Synthesis and Structure of a Dendritic Polysilane (C) 98

Polysulfides
- Hydrothermal Synthesis of a Novel Se_{12} Ring in $[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2\text{-}[Se_{12}]]$ (C) 2509

Porous materials
- Porous Solids by Design: $[Zn(4,4'\text{-bpy})_2(SiF_6)]_n \cdot x$DMF, a Single Framework Octahedral Coordination Polymer with Large Square Channels (C) 2127 (2561)

Porphyrazines
- Octathioporphyrazine Crown Ethers: An Octanuclear Ag^I Complex with Coordination in the *meso* Pocket (C) 2020

Porphyrinoids
- Aldehyde-Appended Tetraphenylporphyrin: A New Building Block for Porphyrin Arrays (C) 900
- A Li_2Ti_2-Substituted Acetylene Formed from Ethylene by Reaction with (*meso*-Octaethylporphyrinogen)titanium (C) 1092
- Alteration of the Reactivity of a Tellurophene Within a Core-Modified Porphyrin Environment: Preparation and Oxidation of 21-Telluraporphyrin (C) 2252
- A Simple, Chirogenic, Enantioselective Synthesis of Chlorins and Isobacteriochlorins (C) 784
- Assembly and Crystal Structure of a Photoactive Array of Five Porphyrins (C) 1096
- Characterization of an Oxo(porphyrinato)manganese(IV) Complex by X-ray Absorption Spectroscopy (C) 343
- Free-Energy Profile for a Host-Accelerated Diels–Alder Reaction: The Sources of *exo* Selectivity (C) 217
- From Porphyrin Isomers to Octapyrrolic "Figure Eight" Macrocycles (C) 2511
- Model Reactions for Photosynthesis—Photoinduced Charge and Energy Transfer between Covalently Linked Porphyrin and Quinone Units (R) 849
- N-Confused Porphyrins and Singlet Carbenes: Is There a Connection? (C) 1028
- Novel Porphyrinoids for Chemistry and Medicine by Biomimetic Syntheses (R) 1795
- Octaphyrin-(1.0.1.0.1.0.1.0) (C) 2515
- Oxybenziporphyrin, a Fully Aromatic Semiquinone Porphyrin Analog with Pathways for 18π-Electron Delocalization (C) 2533
- *meso*-Tetrakis[4-(diphenylphosphino)-phenyl]porphyrin and a Water-Soluble Octakis(phosphonium salt) Porphyrin Double-Decker with a Cage Structure. (C) 2230
- Tetraphenanthro[9,10-*b*:9,10-*g*:9,10-*l*:9,10-*q*]porphyrin, a New Highly Conjugated Porphyrin System (C) 683
- The First Dinuclear Low-Valent Samarium Complex with a Short Sm–Sm Contact (C) 2141
- Water-Soluble Dendritic Iron Porphyrins: Synthetic Models of Globular Heme Proteins (C) 2725

Potassium compounds
- Cage Expansion of $[\{(cyNLi)_3Sb\}_2]$; Synthesis and Structure of the Trimetallic Complex $[\{(cyNLi)_3Sb\}_2(t\text{BuOK})_3 \cdot xC_6H_5CH_3]$ (C) 1012
- Two Diorganopotassates: Crystal Structure of $[K(C_6H_6)][K\{C(SiMe_3)_2(SiMe_2Ph)\}_2]$ (C) 2679

Prebiotic syntheses
- A One-Step Synthesis of Squalene from Farnesol under Prebiotic Conditions (C) 1898

Product selectivity
- Control of Ion–Molecule Reactions in the Gas Phase (H) 885

Proliferation inhibitors
- Glc-PC, a New Type of Glucosidic Phospholipid (C) 2667

Propadiene
- Butatrienes by Cumuhomologation of Propadienes (C) 2709

Propargylic compounds
- Palladium-Catalyzed Resactions of Propargylic Compounds in Organic Synthesis (R) 2589

Propellanes
- Oxidative Transformations of a Pyrimidalized 1,5-Diene (C) 2502

Protecting groups
- Protecting Groups (B) 1370
- Synthesis of the Palmitoylated and Farnesylated C-Terminal Lipohexapeptide of the Human N-*Ras* Protein by Employing an Enzymatically Removable Urethane Protecting Group (C) 2259

Protein dimerization
- Rational Design of Orthogonal Receptor–Ligand Combinations (C) 2129

Protein kinase C
- Glc-PC, a New Type of Glucosidic Phospholipid (C) 2667

Protein mimics
- A Model of Semimet Hemerythrin; NMR Spectroscopic Evidence of Valence Localization in Bis(μ-carboxylato)(μ-phenolato)diiron(II,III) in Solution (C) 588

Proteins
- Combinatorial Synthesis and Multidimensional NMR Spectroscopy: An Approach to Understanding Protein–Ligand Interactions (R) 953
- Crystal Structure Analysis for Chemists and Biologists (B) 2060
- Modified Triple Resonance NMR Experiments with Optimized Sensitivity for Rapidly Exchanging Protons (C) 469
- Photochemically Initiated Protein Splicing (C) 1629
- Probing Protein Structure and Function with an Expanded Genetic Code (R) 621
- Recent Trends in Photoaffinity Labeling (R) 1296

Ras proteins
- Synthesis of the Palmitoylated and Farnesylated C-Terminal Lipohexapeptide of the Human N-*Ras* Protein by Employing an Enzymatically Removable Urethane Protecting Group (C) 2259

Proton transfer
- Dependent on Photochromism Crystal Packing: Photoinduced and Thermal Proton-Transfer Processes in Single Crystals f 6-(2,4-Dinitrobenzyl)-2,2'-Bipyridine (C) 2530
- X-ray Crystal Structures of Cytochrome c Oxidases from *Paracoccus denitrificans* and Bovine Heart and Their Implications for the Molecular Mechanism of Cell Respiration (H) 2635

Prozac
- Talking Back to Prozac: What Doctors Aren't Telling You about Today's Most Controversial Drug (B) 1250

Prussian blue
- The Two-Dimensional Network Structure and Metamagnetic Properties of the 2:1 Complex of $[Mn(3\text{-MeOsalen})(H_2O)]\text{-}ClO_4$ and $K_3[Fe(CN)_6]$ (C) 1446

Pseudodimers
- Pseudo-Spherical Host Molecules: Synthesis, Dimerization, and Nucleation Effects (C) 1885

Pyramidalized alkenes
- Oxidative Transformations of a Pyrimidalized 1,5-Diene (C) 2502

Pyrenes
- Luminescence Stimulated by Electron Transfer: Fluorescent Donor/Acceptor-Substituted Stilbenes Containing Pyrenoid and Heteroaromatic Subunits (C) 2664

Quinic acid
- Enantiospecific Syntheses of Valiolamine and Its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid (C) 1643

Quinodimethanes
- *para*- and *ortho*-Quinodimethanes Intermediates with Cumulative Double Bonds (C) 2367

Quinolizines
- Diastereoselective Cathodic Cyclization of 1-(4- and 1-(3-Oxoalkyl)pyridinium Salts to Quinolizidine and Indolizidine Derivatives (C) 2007

Quinones
- Model Reactions for Photosynthesis—Photoinduced Charge and Energy Transfer between Covalently Linked Porphyrin and Quinone Units (R) 849

Radialenes
- Hexakis(trimethylsilylethynyl)[3]radialene: A Carbon-Rich Chromophore with Unusual Electronic Properties (C) 805

Radical cations
- Detection and Reactions of Radical Cations Generated by Photolysis of Aromatic Compounds with Tetranitromethane in 1,1,1,3,3,3-Hexafluoro-2-propanol at Room Temperature (C) 2268
- Radical Cation [4+2] Cycloadditions with 2-Vinylindoles (C) 1900

Radical polymerization
- Architectural Control in "Living" Free Radical Polymerizations: Preparation of Star and Graft Polymers (C) 1456

Radicals
- A New Dimension in Radical Chain Group Transfer Reaction by Photosensitized Electron Transfer (PET) Reductive Activation of $PhSeSiR_3$ (C) 2669
- A Second-Generation Synthesis of (20*S*)-Camptothecin, Topotecan, Irinotecan, and GI-147211C (C) 2683
- Diastereoselective Coupling of Anodically Produced Radicals Bearing Chiral Amide Groups (C) 189
- Low-Temperature Tandem Enyne Allene Radical Cyclizations: Efficient Synthesis of 2,3-Dihydroindenes from Simple Enediynes (C) 2037
- Radical Additions of Activated Haloalkanes to Alkenes Initiated by Electron Transfer from Copper in Solvent-Free Systems (C) 902
- Radical Chemistry (B) 1771
- Radical C–C Bond Formation by Photoinduced Electron Transfer Addition of α-Silyl Carbamates to Acceptor-Substituted Alkenes (C) 2137
- Structure Determination from Powder X-Ray Diffraction Data of a Hydrogen-Bonded Molecular Solid with Competing Ferromagnetic and Antiferromagnetic Interactions: The 2-(3,4-Dihydroxyphenyl)-α-Nitronyl Nitroxide Radical (C) 55
- The Catalytic Oxidative Coupling of Methane (R) 970
- 2-[*p*-(*N*-*tert*-butyl-*N*-oxyamino)phenyl]-4,4,5,5-tetramethyl-4,5-dihydroimidazol-3-oxide-1-oxyl, a Stable Diradical with a Triplet Ground State (C) 927

Radionuclides
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples II: Accelerator Mass Spectrometry (AMS) (C) 183
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples III: Development of a Fast Analytical Method (C) 186
- Trace Analysis of the Radionuclides ^{90}Sr and ^{89}Sr in Environmental Samples I: Laser Mass Spectrometry (C) 181

Raman spectroscopy
- Novel Biological Copper Proteins through Anion Addition to the Mutant Met121Gly of *Pseudomonas aeruginosa* Azurin (C) 1622
- Rapid Water Diffusion in a Cage-Type Crystal Lattice: β-Cyclodextrin Dodecahydrate (C) 1452
- Vibrational Spectroscopy in Supercritical Fluids: From Analysis and Hydrogen Bonding to Polymers and Synthesis (R) 1275

Reaction mechanisms

- Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)-cobalt(II) Complexes (C) 2145

Reductive elimination
- Direct Observation of O–H Reductive Elimination from Ir^{III} Complexes (C) 229

Resorcarenes
- Calixarenes, Macrocycles with (Almost) Unlimited Possibilities (R) 713

Resorcinol
- A Non-Peptidic Ion Channel with K^+ Selectivity (C) 693

Rhenium compounds
- An Unconventional Intermolecular Three-Center N–H···H_2Re Hydrogen Bond in Crystalline $[ReH_5(PPh_3)_3]\cdot$indole$\cdot C_6H_6$ (C) 2507
- Dimensional Reduction of $Re_6Se_8Cl_2$: Sheets, Chains, and Discrete Clusters Composed of Chloride-Terminated $[Re_6Q_8]^{2+}$ (Q = S, Se) Cores (C) 226
- Models for Bimetallic Catalysts: Multiple Oxidation States in Pt_3Re Cluster Cations (C) 346
- The First Mixed-Metal Borole Cluster; Stabilization of Formally 14e Pd Centers in the Re_2Pd_2 Electron-Deficient $[\{[(\eta^5\text{-}C_4H_4BPh)(CO)_3Re]Pd\}_2]$ Cluster (C) 1010
- Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center (C) 916

Rhodium compounds
- A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1′-Ferrocenedithiolato Complexes (C) 656
- An Ab Initio Investigation of the Rh^I-Catalyzed Hydroboration of C=C Bonds: Evidence for Hydrogen Migration in the Key Step (C) 115

- A Redox-Switchable Hemilabile Ligand: Electrochemical Control of the Coordination Environment of a Rh^{I} Complex (C) 1624
- A Rhodium-Mediated, Stepwise Trimerization of an Alkyne That Does Not Lead to a Benzene but Selectively to a Hexadienyne Derivative (C) 191
- Asymmetrization of *meso* 1,4-Enediol Ethers by Isomerization with a Chiral binap-Rh^{I} Catalyst (C) 2287
- Does the Facile Inter- and Intramolecular C–H Bond Activation by Tp*–Rh Complexes Proceed via Rh^{I} or Rh^{III} Intermediates? (C) 231
- Electronically Tuned *trans* Labilization Controls the Substitution Behavior of Rhodoximes (C) 2245
- Enhancement of Catalytic Activity for Hydroformylation of Methyl Acrylate by Using Biphasic and "Supported Aqueous Phase" Systems (C) 1474
- σ Metathesis as a Critical Step for the Transition Metal Catalyzed Formation of Formic Acid from CO_2 and H_2? An Ab Initio Investigation (C) 1742
- Molecular Recognition between Chemically Modified β-Cyclodextrin and Dec-1-ene: New Prospects for Biphasic Hydroformylation of Water-Insoluble Olefins (C) 2269
- Rhodium-Catalyzed Hydroformylation of Internal Alkynes to α,β-Unsaturated Aldehydes (C) 1760
- Rhodium–Vinylallene Complexes and a New Reaction, Rhodium-Catalyzed Carbonylative [4+1]Cycloaddition (C) 2691
- The First Clusters with a Y-Shaped Arrangement of Ligands at Three-Coordinate Rh^{I} Atoms in the Solid State: $[M^1M^2\{\mu\text{-}P(C_6H_{11})_2\}(CO)_8Rh(PPh_3)]$ (M^1, M^2 = Mn, Re) (C) 1325
- The pH-Dependent Synthesis and Structural Study of Dimeric and Cyclic Trimeric Complexes of 9-Methyl- or 9-Ethylhypoxanthine Nucleobases with (η^5-Pentamethylcyclopentadienyl)rhodium Aqua Complexes (C) 1514
- Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings (H) 2223

Ribozymes
- Synthetic Ribozymes and the First Deoxyribozyme (H) 1189

Ring-opening polymerization
- Synthesis and Structure of the First Sulfur-Bridged [1]Ferrocenophane (C) 1506

RNA
- 1,5-Anhydrohexitol Nucleic Acids, a New Promising Antisense Construct (C) 1338 (2165)
- The Three-Dimensional Structure of Hammerhead Ribozymes (H) 643
- Triple-Helix Formation of Oligodeoxynucleotides Containing [(3′*S*,5′*R*)-2′-Deoxy-3′,5′-ethano-β-D-ribofuranosyl]nucleosides ("Bicyclo-deoxynucleosides") (C) 694

RNA cleavage
- Rapid Hydrolysis of RNA with a Cu^{II} Complex (C) 472

RNase A
- Peptide Ligases—Tools for Peptide Synthesis (H) 175

Rotanes
- The Reactivity of 1,3-Butadiyne Moieties in the "Exploding" [*n*]Rotanes—A Crown of Thiophenes (C) 781

Rotaxanes
- Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules (C) 1865
- Doubly Encircled and Double-Stranded Pseudorotaxanes (C) 1869

Ruthenium compounds
- A Series of Well-Defined Metathesis Catalysts—Synthesis of $[RuCl_2(=CHR')(PR_3)_2]$ and Its Reactions (C) 2039
- Condensed $RuSn_6$ Octahedra in $Ru_3Sn_{15}O_{14}$ (C) 2113
- Distorted Sandwich Compounds: [1]Ferrocenophanes and [2]Ruthenocenophanes (H) 1837
- Effective Charge Separation in Intermolecular Complexes of an Electron Donor and a Doubly Branched Triad Assembly: A Model System for Environmental Effects Controlling Electron Transfer (C) 1005
- Electronic Energy Transfer Across Ethynyl-Bridged Ru^{II}/Os^{II} Terpyridyl Complexes (C) 1100
- Electron Transfer through DNA: Site-Specific Modification of Duplex DNA with Ruthenium Donors and Acceptors (C) 352
- Hydroxylation of Alkanes with Molecular Oxygen Catalyzed by a New Ruthenium-Substituted Polyoxometalate, $[WZnRu_2^{III}(OH)(H_2O)(ZnW_9O_{34})_2]^{11-}$ (C) 1587
- Routes to Dendritic Networks: Bis-Dendrimers by Coupling of Cascade Macromolecules through Metal Centers (C) 2023
- Synthesis, Structure, and Properties of Dinuclear and Trinuclear Rack-Type Ru^{II} Complexes (C) 1122
- Towards the Development of Molecular Wires: Electron Localization, Exchange, and Transfer in Alkyne-Bridged Multinuclear Complexes (C) 2705
- Unprecedented Mode of Bonding for Olefins on Bimetallic Complexes: An Agostic Interaction of a sp^2 C–H Bond with a Ruthenium Center in Addition to a π bond to a Rhenium Center (C) 916
- $[Cp^*(Me_3P)_2Ru(\eta^2\text{-}O=SO_2)]PF_6$, the First Complex between a Transition Metal and Sulfur Trioxide (C) 1008

Salen complexes
- The Two-Dimensional Network Structure and Metamagnetic Properties of the 2:1 Complex of $[Mn(3\text{-}MeOsalen)(H_2O)]ClO_4$ and $K_3[Fe(CN)_6]$ (C) 1446

Samarium compounds
- A Highly Stereoselective Synthesis of 1,2-*trans*-C-Glycoside via Glycosyl Samarium(III) Compounds (C) 909
- Radical Additions to (η^6-Arene)-(tricarbonyl)chromium Complexes: Diastereoselective Synthesis of Hydrophenalene and Hydrobenzindene Derivatives by Samarium(II) Iodide Induced Cyclization (C) 2383
- The First Dinuclear Low-Valent Samarium Complex with a Short Sm–Sm Contact (C) 2141

SAMP hydrazones
- Diastereo- and Enantioselective Synthesis of Polyfunctional Ketones with Adjacent Quaternary and Tertiary Centers by Asymmetric Carroll Rearrangement (C) 2278

Sandwich complexes
- A Co_3 Complex Containing a Bent Trimetal Chain, and Other 1,1′-Ferrocenedithiolato Complexes (C) 656
- Alkali Metallocene Anions: Syntheses and Structures (C) 2376
- Aminocyclopentadienes, Aminoferrocenes, and Aminocobaltocenes (C) 800
- A Tailor-Made Metallocene for the Copolymerization of Ethene with Bulky Cycloalkenes (C) 2273
- Competing Pathways in the Reaction of Bis(pentafluorophenyl)borane with Bis(η^5-cyclopentadienyl)dimethylzirconium: Methane Elimination versus Methyl–Hydride Exchange and an Example of Pentacoordinate Carbon (C) 1230
- η^5:η^2 Coordination of a *cyclo*-E_5 Ligand, E = P, As (C) 1321
- Coordination of CO to the Alkaline Earth Metallocene $[(Me_5C_5)_2Ca]$ (C) 791
- Distorted Sandwich Compounds: [1]Ferrocenophanes and [2]Ruthenocenophanes (H) 1837
- Ferrocenes. Homogeneous Catalysis. Organic Synthesis. Materials Science (B) 1904
- Molecular Mosaics Formed by a Square Cyclophane and Its Inclusion Complex with Ferrocene (C) 1862
- Molecular Recognition at an Interface: Binding of Monolayer-Anchored Ferrocenyl Groups by an Amphiphilic Calixarene Host (C) 235
- Organometallic Compounds for Nonlinear Optics—The Search for En-light-enment! (R) 21 (826)
- Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)borane—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts (C) 1755
- Reactions of 1,1′-Ferrocenediylbis{chloro-[(1,2,5,6-η)-1,5-cyclooctadiene]}-diplatinum with Triarylphosphane and Molecular Oxygen (C) 319
- Stereospecific Olefin Polymerization with Chiral Metallocene Catalysts (R) 1143 (1368)
- Synthesis and Structure of the Firs Sulfur-Bridged [1]Ferrocenophane (C) 1506
- Synthesis of 1,2-Diphospholide Ions (C) 590
- Tris(dimethylamino)sulfoniumcyclopentadienide $[TAS]^+[C_5H_5]^-$ and Tris(dimethylamino)sulfoniumpyrrolide $[TAS]^+[C_4H_4N]^-$: Two Isostructural Salts with "Naked" Anions A^- and the "Inverse" Sandwich-Cations $[\{(Me_2N)_3S\}_2A]^+$ (A = $C_5H_5^-$, $C_4H_4N^-$) (C) 443
- [Bis{(η^5-pentamethylcyclopentadienyl)-cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands (C) 592

Scandium compounds
- Synthesis of the First Adducts of the Dimetallofullerenes $La_2@C_{80}$ and $Sc_2@C_{84}$ by Addition of a Disilirane (C) 2139

Scanning tunneling microscopy
- Diodelike Current–Voltage Curves for a Single Molecule—Tunneling Spectroscopy with Submolecular Resolution of an Alkylated, *peri*-Condensed Hexabenzocoronene (C) 1609
- Oligothiophenes—Yet Longer? Synthesis, Characterization, and STM Images of Homologous, Isomerically Pure Oligo(alkylthiophene)s (C) 303

Schiff base complexes
- Complexation of [*N*,*N*′-Bis(salicylidene)-ethylenediiminato]cobalt(III)$^+$ by Anilines in Dimethylformamide (C) 1086

Second messengers
- Chemistry of Inositol Lipid Mediated Cellular Signaling (R) 1933

Second-sphere coordination
- Transition Metal Complexes as Both Host and Guest: Second-Sphere Coordination between a Pt-Azacrown Ether Host and a Pt-NH_3 Guest (C) 2689

Selectins
- Palladacycles as Structurally Defined Catalysts for the Heck Olefination of Chloro- and Bromoarenes (C) 1844
- Synthesis of an RGD-Sialyl-Lewis^x Glycoconjugate: A New Highly Active Ligand for P-Selectin (C) 990

Selenium compounds
- A New Dimension in Radical Chain Group Transfer Reaction by Photosensitized Electron Transfer (PET) Reductive Activation of $PhSeSiR_3$ (C) 2669
- Asymmetric Reaction of Arylalkenes with Diselenides (C) 1726
- Hydrothermal Synthesis of a Novel Se_{12} Ring in $[\{(NH_4)_2[Mo_3S_{11.72}Se_{1.28}]\}_2\text{-}[Se_{12}]]$ (C) 2509
- Synthesis and Reactions of Vinyl Isoselenocyanates (C) 1627
- The Preparation of Salts of $[Pd_2(\mu\text{-}Se_2N_2)Cl_6]^{2-}$, the First Adducts of Diselenium Dinitride (C) 1758

Self-assembly
- A Gold(I) [2]Catenane (C) 1894
- A Self-Assembled Bifunctional Receptor (C) 2124
- Controlling Translational Isomerism in [2]Catenanes (C) 571
- Design, Synthesis, and Properties of Molecule-Based Assemblies with Large Second-Order Optical Nonlinearities (R) 155
- Dialkylammonium Ion/Crown Ether Complexes: The Forerunners of a New Family of Interlocked Molecules (C) 1865
- Doubly Encircled and Double-Stranded Pseudorotaxanes (C) 1869
- Formation of a "*meso*-Helicate" by Self-Assembly of Three Bis(catecholate) Ligands and Two Titanium(IV) Ions (C) 2134
- Formation of the First Isomeric [2]Catenates by Self-Assembly about Two Different Metal Ions (C) 582
- Gold in Chains: Self-Assembly of a Gold(I) Catenane (H) 2107
- Kinetic Selection in the Template-Directed Self-Assembly of [2]Catenanes (C) 2378
- Molecular Mosaics Formed by a Square Cyclophane and Its Inclusion Complex with Ferrocene (C) 1862
- New Nonlinear Optical Materials: Expedient Topotactic Self-Assembly of Acentric Chromophoric Superlattices (C) 1497
- Patterns in Hydrogen Bonding: Functionality and Graph Set Analysis in Crystals (R) 1555
- Pseudo-Spherical Host Molecules: Synthesis, Dimerization, and Nucleation Effects (C) 1885
- Self-Assembling Discotic Mesogens (C) 1637
- Self-Assembly of a Ferromagnetically Coupled Manganese(II) Tetramer (C) 1443
- Self-Assembly of Molecular-Sized Boxes (H) 1079
- Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$ (C) 2374
- β-Sheet Peptide Architecture: Measuring the Relative Stability of Parallel vs. Antiparallel β-Sheets (C) 95
- Structurally Diverse and Dynamically Versatile Benzylic Amide [2]Catenanes Assembled Directly from Commercially Available Precursors (C) 1212
- Synthesis and Structural Characterization of a Stereospecific Dinuclear Gallium Triple Helix: Use of the *trans*-Influence in Metal-Assisted Self-Assembly (C) 996
- Synthesis and Structure of Tetra- and Octanuclear Chelate Complexes—Exohedral Guest Exchange in Tetrahemispheraplexes (C) 993
- Synthesis of Novel Tetrathiafulvalene-(TTF)-Based [3]Pseudocatenanes by Self-Assembly; Prevention of *trans/cis* Isomerization (C) 2524
- Synthesis, Structure, and Properties of Dinuclear and Trinuclear Rack-Type Ru^{II} Complexes (C) 1122
- The Structural and Thermodynamic Basis for the Formation of Self-Assembled Peptide Nanotubes (C) 93
- X-Ray Structure of a Self-Assembled Gelating Fiber (C) 585

Semiconductors
- $C_4S_6^{2-}$: A Bridging Bis(dithiolato) Ligand for the Preparation of Semiconducting Inorganic Polymers (C) 1890
- The Novel Copper Polytelluride Salts $NaBa_6Cu_3Te_{14}$ and $(K_{0.60}Ba_{0.40})Ba_6Cu_{2.58}Te_{14}$: Discrete Clusters or Extended Solids? (C) 68

Semiempirical calculations
- LaI: An Unprecedented Binary Rare Earth Metal Monohalide with a NiAs-Type Structure (C) 233
- Synthesis of a Dynemicin A Analogue and Its Bergman-Type Cycloaromatization (C) 1345
- Thermal Isomerization of Indigo (C) 67

Sensitization
- Radical C–C Bond Formation by Photoinduced Electron Transfer Addition of α-Silyl Carbamates to Acceptor-Substituted Alkenes (C) 2137

Sensors
- New Fluorescent Model Compounds for the Study of Photoinduced Electron Transfer: The Influence of a Molecular Electric Field in the Excited State (C) 1728

Shape selectivity
- Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals (C) 2528

β-Sheet structures
- β-Sheet Peptide Architecture: Measuring the Relative Stability of Parallel vs. Antiparallel β-Sheets (C) 95

Shikimic Acid
- Shikimic Acid (B) 361

Sialyl Lewis^x
- Palladacycles as Structurally Defined Catalysts for the Heck Olefination of Chloro- and Bromoarenes (C) 1844
- Synthesis of an RGD-Sialyl-Lewis^x Glycoconjugate: A New Highly Active Ligand for P-Selectin (C) 990

Sialyltransferase
- A Multienzyme System for a One-Pot Synthesis of Sialyl T-Antigen (C) 893

Signal transduction
- Chemistry of Inositol Lipid Mediated Cellular Signaling (R) 1933
- Signal Transduction: Evolution of an Idea (Nobel Lecture) (R) 1420

Silaboranes
- First Reaction of 1,2-Dimethyl-*o*-silaborane: Nucleophilic Degradation (C) 2236

Silacyclopentadienide
- Synthesis and Structure of a Free Germacyclopentadienide Ion: $[Li([12]crown\text{-}4)_2][C_4Me_4GeSi(SiMe_3)_3]$ (C) 1887

Silanetriols
- Soluble Aluminosilicates with Frameworks of Minerals (C) 2504

Silenes
- Reaction of 1,1-Dimethylsilene with Formaldehyde (C) 929

Silicon compounds
- A Framework Containing Ga-O-Ga Links: The Synthesis and Structure of Gallobicchulite $Ca_8(Ga_2SiO_6)_4(OH)_8$ (C) 2414
- Al,Ti Avoidance in the Microporous Titanoaluminosilicate ETAS-10 (C) 1003
- A New Zincosilicate Zeolite with Nine-Ring Channels (C) 63
- A Silicon Strand of More than 7 Å in Diameter in $Ba_2Eu_3Si_7$ (C) 1462
- Distinguishing the Silanol Groups in the Mesoporous Molecular Sieve MCM-41 (C) 2694
- First Reaction of 1,2-Dimethyl-*o*-silaborane: Nucleophilic Degradation (C) 2236
- Homogeneous versus Heterogeneous Zeolite Nucleation (C) 73
- New Surprises in Metal Carbonyl Chemistry (H) 2489
- Silacyclopropene: Generation by High-Vacuum Flash Pyrolysis and Matrix-Spectroscopic Identification (C) 1439
- Silicon Analogues of Grignard Compounds: Synthesis and Structure of Amine-Stabilized Trimethylsilylmagnesium Halides (C) 1030
- Silicon-Bridged Macrocycles—Synthesis of Sila-Calixarenes (C) 661
- Structure-Determining C-H $\cdots$ O-Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil (C) 2680
- Structure Organization of Aluminosilicate Polyanions with Surfactants: Optimization of Al Incorporation in Aluminosilicate Mesostructural Materials (C) 1499
- Synthesis and Structure of a Dendritic Polysilane (C) 98
- Synthesis and Structure of Organometallic Compounds with $(Al_2Si)_2$ and Al_3Sb_2 Frameworks (C) 919
- Synthesis and Structure of Triamino- and Tetraaminosilanes (C) 2645
- The Chemistry of Silylenoids: Preparation and Reactivity of (Alkoxysilyl)-lithium Compounds (C) 818
- Two Diorganopotassates: Crystal Structure of $[K(C_6H_6)][K\{C(SiMe_3)_2\text{-}(SiMe_2Ph)\}_2]$ (C) 2679

Silver compounds
- $C_{60}H_{60}$ and $C_{54}H_{48}$: Silver Ion Extraction with New Concave Hydrocarbons (C) 481
- Formation of the First Isomeric [2]Catenates by Self-Assembly about Two Different Metal Ions (C) 582
- Novel Networks of Unusually Coordinated Silver(I) Cations: The Wafer-Like Structure of $[Ag(pyz)_2][Ag_2(pyz)_5]\text{-}(PF_6)_3\cdot 2G$ and the Simple Cubic Frame of $[Ag(pyz)_3](SbF_6)$ (C) 1895
- Octathioporphyrazine Crown Ethers: An Octanuclear Ag^I Complex with Coordination in the *meso* Pocket (C) 2020

- Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$ (C) 2374

Silyl cations
- $[R_3Si-arene]^+$ σ Complexes in the Gas Phase (C) 654

Silyl effect
- A Remarkable Effect of Silyl Substitution on Electrocyclization of Vinylallenes (C) 1476

Silylenoids
- The Chemistry of Silylenoids: Preparation and Reactivity of (Alkoxysilyl)-lithium Compounds (C) 818

Silyl enol ethers
- Synthesis of D-(+)-Biotin through Selective Ring Closure of *N*-Acyliminium Silyl Enol Ethers (C) 2391

Single molecule spectroscopy
- Diodelike Current–Voltage Curves for a Single Molecule—Tunneling Spectroscopy with Submolecular Resolution of an Alkylated, *peri*-Condensed Hexabenzocoronene (C) 1609

Sodalites
- A Framework Containing Ga-O-Ga Links: The Synthesis and Structure of Gallobicchulite $Ca_8(Ga_2SiO_6)_4(OH)_8$ (C) 2414
- Designed Assemblies in Open Framework Materials Synthesis: An Interrupted Sodalite and An Expanded Sodalite (C) 1745

Sodium compounds
- $Na_2Ti_3Cl_8$: From Isolated Ti^{2+} Ions to $[Ti_3]^{6+}$ Clusters (C) 71
- The Lipophilically Wrapped Polyion Aggregate $\{H_{120}C_{144}O_{24}(OP)_2N^-Na_6^+\}$, a Hexameric Sodium Tetraphenyl Imidodiphosphate Containing an $[Na_6O_{12}]$ Core in a Hydrocarbon Ellipsoid (C) 1355

Solid-phase syntheses
- A Novel Allylic Anchor for Solid-Phase Synthesis—Synthesis of Protected and Unprotected O-Glycosylated Mucin-Type Glycopeptides (C) 803
- A Versatile Solid-Phase Synthesis of N-Linked Glycopeptides (C) 60
- Solid-Phase Syntheses of Unnatural Biopolymers Containing Repeating Urea Units (C) 907
- Solid-Phase Synthesis of Vinylogous Sulfonyl Peptides (C) 1763

Solids
- Novel Networks of Unusually Coordinated Silver(I) Cations: The Wafer-Like Structure of $[Ag(pyz)_2][Ag_2(pyz)_5](PF_6)_3 \cdot 2G$ and the Simple Cubic Frame of $[Ag(pyz)_3](SbF_6)$ (C) 1895

Solid-state chemistry
- $ATh_{12}N_6X_{29}$ (A = Li...Rb; X = Cl, Br): A New Type of Thorium Cluster with a $Th_{12}N_6$ Core (C) 567
- Chemistry of Non-Stoichiometric Compounds (B) 1033
- Dimensional Reduction of $Re_6Se_8Cl_2$: Sheets, Chains, and Discrete Clusters Composed of Chloride-Terminated $[Re_6Q_8]^{2+}$ (Q = S, Se) Cores (C) 226
- Does the Death Knell Toll for the Metallic Bond? (H) 1081
- Preparative Solid-State Chemistry with High-Power CO_2 Lasers (R) 634
- The Metallic Bond—Dead or Alive? A Comment and a Reply (Comment) (C) 2003

Solid-state electrochemistry
- The Formal Potentials of Solid Metal Hexacyanometalates (C) 2685

Solid-state structures
- A Novel Chainlike Heteropolyanion Formed by Keggin Units: Synthesis and Structure of $(ET)_{8n}[PMnW_{11}O_{39}]_n \cdot 2nH_2O$ (C) 1460
- A Silicon Strand of More than 7 Å in Diameter in $Ba_2Eu_3Si_7$ (C) 1462
- Bromides of Rare Earth Metal Boride Carbides—A System of Building Blocks (C) 1633
- Condensed $RuSn_6$ Octahedra in $Ru_3Sn_{15}O_{14}$ (C) 2113
- $CsPr_9NbBr_{15}N_6$: A New Type of Interstitially Stabilized Cluster Compound (C) 2262
- $(CuI)_3P_{12}$: A Solid Containing a New Polymer of Phosphorus Predicted by Theory (C) 1647
- Dependent on Photochromism Crystal Packing: Photoinduced and Thermal Proton-Transfer Processes in Single Crystals f 6-(2,4-Dinitrobenzyl)-2,2′-Bipyridine (C) 2530
- Designed Assemblies in Open Framework Materials Synthesis: An Interrupted Sodalite and An Expanded Sodalite (C) 1745
- Discrete Crown-Shaped Te_8 Rings in Cs_3Te_{22} (C) 450
- Investigations into the Targeted Design of Solids: Hydrothermal Synthesis and Structures of One-, Two-, and Three-Dimensional Phases of the Oxovanadium–Organodiphosphonato System (C) 223
- LaI: An Unprecedented Binary Rare Earth Metal Monohalide with a NiAs-Type Structure (C) 233
- $(Nb,Ta)_9(S,Te)_5$, a Metal-Rich Chalcogenide with a Microporous Metal Substructure (C) 1089
- Patterns in Hydrogen Bonding: Functionality and Graph Set Analysis in Crystals (R) 1555
- Rapid Water Diffusion in a Cage-Type Crystal Lattice: β-Cyclodextrin Dodecahydrate (C) 1452
- Six Interpenetrating Quartz-Like Nets in the Structure of $ZnAu_2(CN)_4$ (C) 1203
- $(Sr_6N)[Ga_5]$ and $(Ba_6N)[Ga_5]$: Compounds with Discrete (M_6N) Octahedra and $[Ga_5]$ Clusters (C) 1761
- Stable 1:1 Adducts from Iodoacetylenes and Iodide Ions: Ion Pair Strain as an Additional Driving Force? (C) 441
- Substituent-Controlled Reactions of Iminophosphoranes with Methyllithium (C) 1752
- Synthesis, Structure, and Decay of In_4Br_7 (C) 1126
- $Ta_5(S,Te)_2$: Microporous Tantalum with Chalcogen-Coated Inner Surfaces (C) 2703
- The Synthesis and Crystal Structures of $RbC(SiMe_3)_3$ and $CsC(SiMe_3)_3 \cdot 3.5C_6H_6$: A One-Dimensional Ionic Solid and an Ionic Solid with a Molecular Structure (C) 687
- 2,4,6-Tri(4-pyridyl)-1,3,5-triazine as a 3-Connecting Building Block for Infinite Nets (C) 820

Solvent effects
- The Colors of C_{60} Solutions (C) 105

Solvent-free conversions
- Radical Additions of Activated Haloalkanes to Alkenes Initiated by Electron Transfer from Copper in Solvent-Free Systems (C) 902

Sol–gel processes
- Efficient Heterogeneous Biocatalysts by Entrapment of Lipases in Hydrophobic Sol–Gel Materials (C) 301
- New Dimensions in the Sol–Gel Process (H) 1578
- Synthesis of Hexagonally-Packed Mesoporous TiO_2 by a Modified Sol–Gel Method (C) 2014

D-Sorbitol
- A Hexadecanuclear Polyolatometalate of Copper(II) Ions and Multideprotonated D-Sorbitol (C) 2119

Spectroelectrochemistry
- Hexakis(trimethylsilylethynyl)[3]radialene: A Carbon-Rich Chromophore with Unusual Electronic Properties (C) 805

Spectrophotometry
- Derivative Spectrophotometry. Low and Higher Order (B) 1522

Spectroscopy
- Spectroscopy in Catalysis. An Introduction (B) 495
- Thermal Isomerization of Indigo (C) 67

Spherands
- $C_{60}H_{60}$ and $C_{54}H_{48}$: Silver Ion Extraction with New Concave Hydrocarbons (C) 481

Sphingosines
- New Brain Lipids that Induce Sleep (H) 2362

Spin chemistry
- Chemical Generation and Reception of Radio- and Microwaves (B) 936

Spin crossover
- Photoinduced Valence Tautomerism in Cobalt Complexes Containing Semiquinone Anion as Ligand: Dynamics of the High-Spin $[Co^{II}(3,5\text{-dtbsq})_2]$ to Low-Spin $[Co^{III}(3,5\text{-dtbsq})(3,5\text{-dtbcat})]$ Interconversion (C) 1481

Splicing
- Photochemically Initiated Protein Splicing (C) 1629

Squalene
- A One-Step Synthesis of Squalene from Farnesol under Prebiotic Conditions (C) 1898

Squalestatins
- Total Syntheses of Zaragozic Acid (H) 773

Stacking interactions
- Polar Interactions between Stacked π Systems in Fluorinated 1,8-Diarylnaphthalenes: Importance of Quadrupole Moments in Molecular Recognition (C) 1019

Stannylenes
- Bis(hypersilyl)tin and Bis(hypersilyl)lead, Two Electron-Rich Carbene Homologs (C) 1334

Star polymers
- Architectural Control in "Living" Free Radical Polymerizations: Preparation of Star and Graft Polymers (C) 1456

Statins
- Diastereo- and Enantioselective Synthesis of 1,2-Amino Alcohols from Glycol Aldehyde Hydrazones; Asymmetric Synthesis of (*R*,*R*)-Statin (C) 1219

Stereochemistry

Total syntheses
- A Total Synthesis of Taxol (C) 1723
- Synthesis of D-(+)-Biotin through Selective Ring Closure of *N*-Acyliminium Silyl Enol Ethers (C) 2391
- The Conquest of Taxol (R) 2079
- Total Syntheses of Zaragozic Acid (H) 773
- Total Synthesis of (±)-Dynemicin A (C) 1721
- Total Synthesis of Natural (+)-SF 2315A and Determination of the Absolute Configuration (C) 2396

Transesterifications
- Acceleration of a Phosphate Diester Transesterification Reaction by Bis(alkylguanidinium) Receptors Containing an Appended General Base (C) 1237

Transition metals
- Carbon Dioxide as a Raw Material: The Synthesis of Formic Acid and Its Derivatives from CO_2 (R) 2207
- Carbon–Hydrogen Bonds of DNA Sugar Units as Targets for Chemical Nucleases and Drugs (R) 746
- Cluster Chemistry (B) 121
- Coordination of Dioxygen in Three Representative Transition Metal Cations: FeO_2^+, CrO_2^+, and $[CH_3Re(O_2)_2O]^+$ (C) 2517
- C–H and C–C Bond Activation by Bare Transition-Metal Oxide Cations in the Gas Phase (R) 1973
- Electronic Energy Transfer in a Supramolecular Species Containing the $[Ru(bpy)_3]^{2+}$, $[Os(bpy)_3]^{2+}$, and Anthracene Chromophoric Units (C) 595
- Transition Metals in the Synthesis of Complex Organic Molecules (B) 1035

Transition states
- Antibody-Catalyzed Phosphate Triester Hydrolysis (C) 2275
- Electron Transfer and Polar Reactions of Cyclizable Anion Radicals: Structural Consequences of Orbital Selection Rules and Chain-Length Constraints (C) 1495

Translational isomerism
- Controlling Translational Isomerism in [2]Catenanes (C) 571

Transmission electron microscopy
- A New Method for the Preparation of Nanostructured Metal Clusters (C) 2240
- Sulfoxide-Stabilized Giant Palladium Clusters in Catalyzed Oxidations (C) 457

Transuranium elements
- Two at One Blow: The New Chemical Elements 110 and 111 (H) 1713

Triaminopyrimidine aggregates
- Barbituric Acid/2,4,6-Triaminopyrimidine Aggregates in Water and Their Competitive Interaction with Monolayers of Barbituric Acid Lipids at the Gas–Water Interface (C) 58

Triazines
- 2,4,6-Tri(4-pyridyl)-1,3,5-triazine as a 3-Connecting Building Block for Infinite Nets (C) 820

Trigermanes
- Reactions of Hexa-*tert*-butylcyclotrigermane: Isolation of an Enantiomerically Pure 1,3-Diiodotrigermane (C) 1085

Trimethylenemethane
- A Concise Synthetic Route to Cyclopentenes by [3+2] Cycloaddition of Dipolar Trimethylenemethane to Alkynes (C) 2154

Trioxides
- Bis(trifluoromethyl)trioxide: First Structure of a Straight-Chain Trioxide (C) 2244

Triple-decker complexes
- A μ-η^6:η^6-1,3,5-Triboratabenzenebis(cyclopentadienylcobalt) Triple-Decker Complex (C) 681
- [Bis{(η^5-pentamethylcyclopentadienyl)cobalt}-μ-(η^4:η^4-arene)]: Synthesis, Structure, and Unusual Reactivity of a New Type of Triple-Decker with Bridging Arene Ligands (C) 592

Tripodal ligands
- Synthesis and Coordination Chemistry of *ortho*-Functionalized Dimercaptobenzene: Building Blocks for Tripodal Hexathiol Ligands (C) 2700

Tris(*tert*-butylimido)tellurite
- A $Te_2N_6Li_4$ Cage Containing the Tris(*tert*-butylimido)tellurite Dianion (C) 2549

Tris(pyrazolyl)borates
- Novel Binuclear Cobalt Dioxygen Complex—A Step on the Path to Dioxygen Activation (C) 2051

Tumor therapy
- Novel Porphyrinoids for Chemistry and Medicine by Biomimetic Syntheses (R) 1795

Tungsten compounds
- Chiral Phosphanodihydrooxazoles in Asymmetric Catalysis: Tungsten-Catalyzed Allylic Substitution (C) 462
- Complexes with Polar W–W Multiple Bonds: $[W_2(O\mathit{i}Pr)_4L(dmpe)_2]$ (L = $(H)_2$, CO) and $[W_2(O)_4(\mu\text{-}O)\{W(CO)(dmpe)_2\}_2]$ (C) 891
- Monomeric Molybdenum and Tungsten Complexes That Contain a Metal–Phosphorus Triple Bond (C) 2044
- P–H-Functionalized Phosphenium Complexes $[C_5R_5(OC)_2W{=}P(H)R']$ (R′ = *t*Bu, sMes): Synthesis, Isomerization, and Transformation into Hydrido Complexes Containing a *t*BuP(H)OH Ligand (C) 2500
- Solid-State and Solution Structures of $[\{NW(OC(CH_3)_2CF_3)_3\}_3]$ and Factors Favoring the Metathesis of C–N and N–W Triple Bonds in Reactions Involving Organic Nitriles and Ditungsten Hexaalkoxides (C) 110
- Synthesis and Structure of the Three-Dimensional Coordination Polymers $[(Me_3Sn)_4M(CN)_8]$ (M = Mo, W) (C) 2557
- Synthesis, Structural Investigation, and Ligand Properties of Isocyanoacetonitrile (C) 914
- Terminal E_1 Ligands from Elements of Group 15 (H) 1997
- *meso*-Tetrakis[4-(diphenylphosphino)-phenyl]porphyrin and a Water-Soluble Octakis(phosphonium salt) Porphyrin Double-Decker with a Cage Structure. (C) 2230
- [WL(NO)(O)(CH_3)]—An Unusual Nitrosyltungsten Complex (C) 1435

Two-phase catalysis
- A Novel Class of Versatile Solvents for Two-Phase Catalysis: Hydrogenation, Isomerization, and Hydroformylation of Alkenes Catalyzed by Rhodium Complexes in Liquid 1,3-Dialkylimidazolium Salts (C) 2698
- Exciting Results from the Field of Homogeneous Two-Phase Catalysis (H) 1575

Umpolung
- A Chiral Cyanohydrin Phosphate for Carbonyl Umpolung—Stereoselective Synthesis of Tertiary Cyanohydrins (C) 917
- Highly Stereoselective Allylation of Benzaldehyde: Generation of a Stereochemically Defined Allylzinc Species from a π-Allylpalladium Intermediate and Diethylzinc (C) 787

Uranium compounds
- New Surprises in Metal Carbonyl Chemistry (H) 2489

Uranyl phenylphosphonates
- Synthesis and X-Ray Powder Structure of a Novel Porous Uranyl Phenylphosphonate Containing Unidimensional Channels Flanked by Hydrophobic Regions (C) 1508

Urea
- Solid-Phase Syntheses of Unnatural Biopolymers Containing Repeating Urea Units (C) 907

Urocanase
- On the Mechanism of Action of Urocanase: Observation of the Enzyme-Bound NAD^+–Inhibitor Adduct by ^{13}C NMR Spectroscopy (C) 652

UV/Vis spectroscopy
- Barbituric Acid/2,4,6-Triaminopyrimidine Aggregates in Water and Their Competitive Interaction with Monolayers of Barbituric Acid Lipids at the Gas–Water Interface (C) 58
- Quaterrylenebis(dicarboximides) (C) 1323
- The Colors of C_{60} Solutions (C) 105

Vacuum traps
- Aligning and Trapping Molecules with Light (H) 2365

Valiolamine
- Enantiospecific Syntheses of Valiolamine and Its (1*R*), (2*R*), (1*R*,2*R*) Diastereomers from (−)-Quinic Acid (C) 1643

Vanadium compounds
- Asymmetric Sulfide Oxidation with Vanadium Catalysts and H_2O_2 (C) 2640
- Investigations into the Targeted Design of Solids: Hydrothermal Synthesis and Structures of One-, Two-, and Three-Dimensional Phases of the Oxovanadium–Organodiphosphonato System (C) 223
- Modeling the Remote-Controlled Organization of Particles in a Nanodimensional Cavity: Synthesis and Properties of $(Et_3NH)_3(\mathit{t}BuNH_3)_2Na_2[(H_2O)_2,N_3^-\subset V_{14}O_{22}(OH)_4(PhPO_3)_8]\cdot 6\,H_2O\cdot 2\,DMF$ (C) 779
- Reaction of a Vanadium(III) Amide with H_2: Isolation and Characterization of a Polynuclear Mixed-Valence Polyhydrido–Nitrido Complex (C) 822

Vapor pressure
- Calculation of the Thermodynamic Properties of Polycyclic Aromatic Hydrocarbons by an Incremental Procedure (C) 1735

Vesicles
- Cytomimetic Organic Chemistry: Early Developments (R) 2091
- Metal-Induced Dispersion of Lipid Aggregates: A Simple, Selective, and Sensitive Fluorescent Metal Ion Sensor (C) 905

Vinylallenes
- A Remarkable Effect of Silyl Substitution on Electrocyclization of Vinylallenes (C) 1476
- Rhodium–Vinylallene Complexes and a New Reaction, Rhodium-Catalyzed Carbonylative [4 + 1]Cycloaddition (C) 2691

Vinylidene complexes
- C–C Coupling Reactions as a Novel Synthetic Route to π-Allyl- and π-Butadienylrhodium Complexes (C) 1244

Vitamin A
- Structure Determination of Vitamin A Acetate Isomers through Coupled HPLC and ^{1}H NMR Spectroscopy (C) 1014

Vitamin B_{12}
- Oligomethylene-Bridged Vitamin B_{12} Dimers (C) 84
- Peripherally Substituted Cobaloximes; X-Ray Crystal Structure Analysis of σ-Hexylbis[1,8-di(*N*-morpholino)octane-4,5-dioximato]pyridinecobalt(III) (C) 2389
- Vitamin B_{12}: How the Problem of Its Biosynthesis Was Solved (R) 383

Voltammetry
- The Formal Potentials of Solid Metal Hexacyanometalates (C) 2685

Wacker oxidation
- Molecular Recognition between Chemically Modified β-Cyclodextrin and Dec-1-ene: New Prospects for Biphasic Hydroformylation of Water-Insoluble Olefins (C) 2269

WODCA
- Computer-Assisted Planning of Organic Syntheses: The Second Generation of Programm (R) 2613

Xenon compounds
- $XeOF_5^-$, an Anion with Pentagonal-Pyramidal Structure (C) 1586

X-ray absorption spectroscopy
- The Active Sites of the Native Cytochrome-c Oxidase from Bovine Heart Mitochondria: EXAFS-Spectroscopic Characterization of a Novel Homobinuclear Copper Center (Cu_A) and of the Heterobinuclear Fe_{a3}-Cu_B Center (C) 1488

X-ray scattering
- Lyotropic Phases Formed by "Molecular Bottlebrushes" (C) 1472

D-Xylose isomerase
- A Dinuclear (μ-Carboxylato)manganese(II) Complex Derived from a Macrocyclic Ligand: A Structural Model for Active Sites in Natural Systems (C) 2535

Ylides
- Ylidediyl Halophosphane Oligomers, $(Ph_3PCPX)_n$—A Structurally Diverse Class of Compounds (C) 1853

Yttrium compounds
- An Yttrium-Based Strong Lewis Acid for the Heterogeneous Catalysis of the Diels–Alder Reaction (C) 2143

Zaragozic acids
- Total Syntheses of Zaragozic Acid (H) 773

Zeolite analogues
- AlMepO-α: A Novel Open-Framework Aluminum Methylphosphonate with Organo-Lined Unidimensional Channels (C) 1199
- Mutually Interpenetrating Sheets and Channels in the Extended Structure of [Cu(4,4′-bpy)Cl] (C) 207

Zeolites
- Al,Ti Avoidance in the Microporous Titanoaluminosilicate ETAS-10 (C) 1003
- A New Zincosilicate Zeolite with Nine-Ring Channels (C) 63
- Cobalt-Containing Molecular Sieves as Catalysts for the Low Conversion Autoxidation of Pure Cyclohexane (C) 560
- Commensurate Freezing of *n*-Alkanes in Silicalite (C) 2543
- Designed Assemblies in Open Framework Materials Synthesis: An Interrupted Sodalite and An Expanded Sodalite (C) 1745
- Homogeneous versus Heterogeneous Zeolite Nucleation (C) 73
- Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals (C) 2528
- Soluble Aluminosilicates with Frameworks of Minerals (C) 2504
- Structure-Determining C-H · · · O-Si Hydrogen Bonds in Cobaltocenium Fluoride Nonasil (C) 2680
- Zeolite Encaged Cu(Histidine) Complexes as a Mimic of Natural Cu Enzymes (C) 2652
- $_\infty^3[(CoCp_2)\subset Fe(\mu\text{-}CNSnMe_3NC)_3]$: A Purely Organometallic Channel Inclusion Compound (C) 1197

Ziegler catalysts
- Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)borane—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts (C) 1755

Zinc compounds
- A New Nickel-Catalyzed Cross-Coupling Reaction between sp^3 Carbon Centers (C) 2723
- A New Zincosilicate Zeolite with Nine-Ring Channels (C) 63
- Highly Stereoselective Allylation of Benzaldehyde: Generation of a Stereochemically Defined Allylzinc Species from a π-Allylpalladium Intermediate and Diethylzinc (C) 787
- Molecular Recognition of Terephthalic Acid by Supramolecular Self-Assembly of an Acridine-Pendant Cyclen–Zn^{II} Complex (C) 663
- Porous Solids by Design: $[Zn(4,4'\text{-}bpy)_2(SiF_6)]_n \cdot x$DMF, a Single Framework Octahedral Coordination Polymer with Large Square Channels (C) 2127 (2561)
- Self-Assembled Helicates of Zinc and Cadmium Cyanides, $[M_x(CN)_{2x+1}]^-$, $x \leq 27$ (C) 314
- Six Interpenetrating Quartz-Like Nets in the Structure of $ZnAu_2(CN)_4$ (C) 1203

Zintl anions
- A Silicon Strand of More than 7 Å in Diameter in $Ba_2Eu_3Si_7$ (C) 1462

Zintl phases
- New Tellurometalates of Gallium and Indium: $K[K([18]crown\text{-}6)]_2[GaTe_3] \cdot 2CH_3CN$ and $[(NEt_4)_5][In_3Te_7] \cdot 0.5\,Et_2O$ (C) 1879
- The Stabilization of the Rb^- Ion in $Na_{16}Rb_7Sb_7 = Na_{16}(RbRb_6)Sb_7$ (C) 103

Zirconium compounds
- Competing Pathways in the Reaction of Bis(pentafluorophenyl)borane with Bis(η^5-cyclopentadienyl)dimethylzirconium: Methane Elimination versus Methyl–Hydride Exchange and an Example of Pentacoordinate Carbon (C) 1230
- Efficient Total Synthesis of the Pharmacophore of the Anticancer Antibiotic CC-1065 by Zirconocene- and Palladium-Initiated Cyclizations (C) 1366
- Hydrocarbon Activation with Metal Halides: Catalysis of the Jacobsen Rearrangement by $(ZrCl_4)_n$ in the Presence of Aromatic Hydrocarbons (C) 1510
- Mononuclear Tris(arene)–Metal Complexes (H) 53
- Reaction of (Butadiene)zirconocene with Tris(pentafluorophenyl)boranc—A Novel Way of Generating Methylalumoxane-Free Homogeneous Ziegler-Type Catalysts (C) 1755
- Stereoselective Synthesis of Chiral Zirconocenes from Doubly Substituted, Donor Functionalized Cyclopentadienes via Helical Chelate Complexes (C) 2266
- 1,3,5,7-Tetraphosphabarrelene: A New Cyclic Phosphaalkyne Tetramer (C) 81
- The $[Zr_6X_{18}H_5]^{3-}$ Ions with X = Cl, Br, and Related Species (C) 1877

ZSM-22
- Selective Isomerization of Hydrocarbon Chains on External Surfaces of Zeolite Crystals (C) 2528

Zwitterionic states
- Direct Spectroscopic Evidence for a Hitherto Elusive "Zwitterionic" Excited State (H) 547
