tained from ligand-rich solutions, indicating a cooperative mode of formation. For example, the addition of a twofold amount of sorbitol ($LiOH:Cu(OH)_2$:D-Sorb = 2:1:1) still leads to crystals of compound **1**.

Vertex-sharing, six-membered rings of Cu_3O_3, which are found in an isolated form in the glycerol complex **2**[1a] consti-

$Li_3[Cu_3(GlycH_{-3})_3]\cdot 6H_2O$ **2**

tute the construction motif in compound **1**. The conformations of the four completely deprotonated sorbitol molecules are more or less the same. On account of the formation of five condensed five-membered chelate rings, all the diol fragments are found in a synclinal (sc) conformation to their neighboring fragments and the sign of their torsion angles gives the sequence $---++$ (Scheme 1, right). This is the conformation with the largest possible flattening of the C_6 chain under the limiting condition that all the ligating atom positions are synclinal. Likewise, the deprotonated fragments of the tetraanionic sorbitol ligands all have the same conformation, here there is a $(-++)$ synclinal arrangement (Scheme 1, center).

It is immediately apparent from the structure that the magnetic properties will be determined by the superexchange mechanism for which there are the optimal geometric conditions. In **1**, as in all known polyolatocuprates, the central atoms have a square-planar coordination geometry. In this mode of coordination the magnetic orbital of the d^9-Cu^{II} ions is directed towards the four ligating atoms which can, in addition, effectively pass on spin polarization through Cu-O-Cu angles which are to some extent unusually obtuse.[7] The magnetic properties are therefore determined by copper units which are still spin-coupled at room temperature, but whose net spins show further interactions at low temperatures.

The magnetic moment of **1** has been measured between 2 K and room temperature in a magnetic field with a flux density of 2 T.[5] The susceptibility follows an extended Curie–Weiss relationship (Fig. 2). The value of the Curie constant C is not the

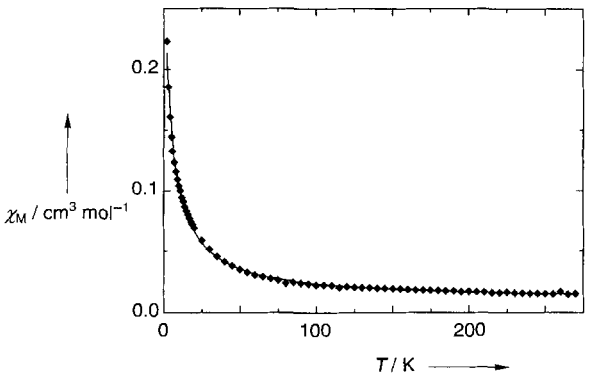

Fig. 2. Magnetic susceptibility of **1** (data points) and fitting by the Curie–Weiss law with an additive constant χ_0: $\chi = \chi_0 + C/T-\theta$ with $\chi_0 = 9.9\times10^{-3}$ cm³ mol⁻¹, $C = 1.4$ cm³ K mol⁻¹, and $\theta = -4.8$ K (solid line).

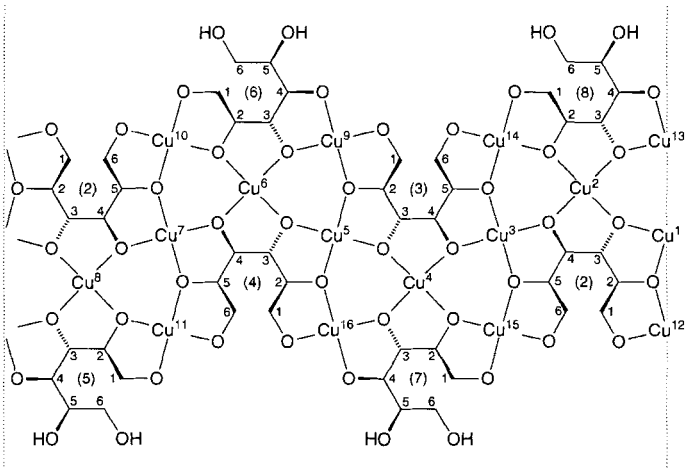
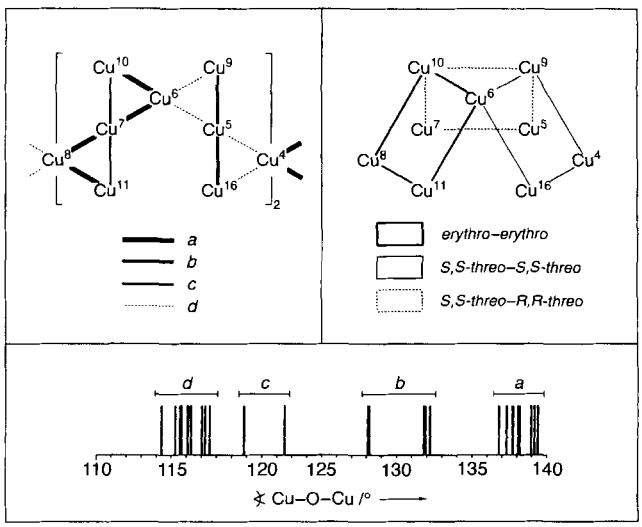
expected 16×0.374 cm³ K mol⁻¹ for 16 uncoupled $S=1/2$ spins, but a smaller value which corresponds to about 4 $S=1/2$ spins. The value of θ indicates a weak antiferromagnetic coupling of these four spins.

This behavior can be explained by the distribution of the Cu-O-Cu angles which determine the spin polarization. These angles are not all equal, as in the Cu_3-building unit in **2** with C_3 symmetry, but vary by about 25° (legends to Scheme 2 and



Scheme 2. Linkage within the anion of **1**, represented by a torus which has been cut open and flattened. C and O atoms are designated as C*mn* and O*mn*, respectively, *m* is the number for the sorbitol ligand given in parentheses, *n* follows the numbering in glucose (see Scheme 1); selected distances [pm] and angles [°]: average value Cu–O 191.9 (average standard deviation 1.2, standard deviation of the average value 2.5, smallest and largest value 187.6 and 198.8, respectively); Cu4-O33-Cu5 114.8(6), Cu8-O23-Cu1 115.2(6), Cu8-O53-Cu12 115.6(5), Cu6-O43-Cu5 116.6(6), Cu1-O13-Cu2 116.7(6), Cu16-O73-Cu4 116.9(6), Cu3-O15-Cu15 116.9(6), Cu9-O63-Cu6 117.3(5), Cu13-O83-Cu2 117.6(6), Cu11-O45-Cu7 119.2(5), Cu7-O25-Cu10 122.9(6), Cu5-O42-Cu16 128.3(6), Cu5-O32-Cu9 131.0(7), Cu3-O35-Cu14 131.2(7), Cu1-O22-Cu13 131.7(7), Cu2-O14-Cu3 136.7(7), Cu8-O52-Cu11 136.7(6), Cu4-O34-Cu3 137.2(7), Cu2-O82-Cu14 137.9(7), Cu8-O24-Cu7 138.3(6), Cu6-O62-Cu10 138.7(6), Cu4-O72-Cu15 139.2(7), Cu6-O44-Cu7 139.3(6).

Scheme 3, bottom). The smallest angles, which are approximately 115°, lie in the range expected for antiferromagnetic coupling, if they are compared to dihydroxo-bridged Cu_2 species.[7] However, it must be taken into account that each Cu_2 unit in **1** is bridged by only one O atom, so that the exchange constant J for the smaller angles could lie at around 0.[6] If it is assumed that there is a steep increase in $-J$ with the Cu-O-Cu angle, as found for the μ-hydroxocopper complexes,[7] the angle distribution as shown in Scheme 3 (bottom) also represents the hierarchy of the antiferromagnetic coupling. According to this



Scheme 3. Top left: Pathways of antiferromagnetic coupling, arranged according to Cu-O-Cu angles (*a*, *b*, *c*, *d* are defined in the bottom part of the Scheme); top right: stereochemistry of the diolato pairs (cf. Scheme 1 and the numbering of the C atoms in D-sorbitol), which bridge the long sides of the Cu_5 building blocks (highlighted by the three rectangles); bottom: frequency distribution of the Cu-O-Cu angles in **1**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3419-2120 $ 10.00+.25/0

the hexadecanuclear cluster can be divided into two groups of five copper atoms and two groups of three copper atoms, and within each group there is a strong antiferromagnetic coupling between the paramagnetic centers. Each group contributes with $S = 1/2$ towards the Curie constant as a consequence of the uneven number of copper atoms. Between the individual Cu_3 and Cu_5 groups there is only a weak antiferromagnetic coupling, this determines the observed value of θ: All the Cu-O-Cu angles between these groups are approximately equal and belong to the category with the smallest values (*d* in Scheme 3, bottom). The positive value of χ_0 indicates that the spin-coupled paramagnetic centers within the Cu_3 and/or Cu_5 groups are excited as the temperature increases, so that the susceptibility decreases more slowly as would be expected from a Curie–Weiss relationship.

The distribution of the Cu-O-Cu angles, along with the flattening of the torus shape, could also result from secondary interactions such as packing forces in the crystal. However, this is not the case here, rather the geometry of the hexadecacuprate ion reflects the linkage requirements arising from the stereochemistry of D-sorbitol. This is particularly apparent for the Cu_5 fragment. The O atoms participating in all of the Cu-O-Cu angles of category *a* (Scheme 3) are O-4 atoms from the $SorbH_{-6}$ ligands and O-2 atoms from the $SorbH_{-4}$ ligands (Scheme 2). Both sites are distinguished by the fact that they are the only ones with a (−+)-synclinal environment (Scheme 1). These correspond to the sequences eee or eae (e = equatorial, a = axial) in the chair conformation of a six-membered ring, and they give rise to an obtuse Cu-O-Cu angle. All the remaining triolato fragments bridge the copper atom pairs in a (−−) or (++) conformation (eea in the six-membered ring with *C* conformation; cf. Scheme 1), this results in a smaller angle at the bridging O atom. The Cu-O-Cu angles of category *b*, which determine the coupling in the Cu_3 fragment—here the bridging O atom is O-2 of the $SorbH_{-6}$ ligand—also belong qualitatively in this second class of the stereochemical classification, so that only the numerical values of the torsion angle along the C_6 chain reflect the further differentiation (average values for the size of the torsion angle O-C-C-O for the $SorbH_{-6}$ ligands: C1–C2 52.0(11), C2–C3 38.1(21), all the others 45.4(23)°, the standard deviation of the average value is given in parentheses).

The possibilities for a multifunctional polyol to adopt a favorable conformation for complexation are governed by the configuration. In order to explain this there are three possibilities depicted in Scheme 3 (right) of highlighting Cu_5 fragments as centered rectangles (in a D_2 torus only these three types are symmetry independent). A comparison with the left-hand side of the Scheme demonstrates the geometric relationship of the magnetically coupling Cu_3 and Cu_5 fragments. The different coupling behavior correlates with the different ligand configurations along the sides of the rectangles. A comparison with Scheme 2 shows that each of the four coordinating O atoms along the long sides of the rectangles differ with respect to the stereochemistry of the diolate function in the center. There is strong coupling within the Cu_5 rectangle which has *erythro*-configured μ-diolato fragments on both of its long sides; this is also the site of the least curvature in the torus. Spin-coupled Cu_3 units are found on both of the short sides of the flattened torus in a twofold *S,S-threo* environment, whilst there is no coupling between the Cu_3 and Cu_5 groups which have *S,S-threo-R,R-threo* configured diolate pairs.

Polyfunctional polyols should, according to these results, be suitable building blocks for self-assembling multinuclear alkoxo clusters. These complexes are thermodynamically very stable,[8] so that well-defined structures can be expected; in the case of Cu^{II} they are also kinetically labile, so that the complex frameworks also have the opportunity of undergoing self-organization. The construction of the complicated molecular architecture does not, in the case of the polyols, need a complicated synthesis of the ligand, which has an unsymmetrical shape and numerous linkage sites, because nature itself provides a wide range of such building blocks with differing stereochemistry. We are currently investigating whether the strong antiferromagnetic coupling along copper chains with uneven numbers of members can be used to construct ferrimagnets by the addition of further paramagnetic cations.[9]

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

In a previous paper we showed how, in the field of polyoxometalate chemistry, ever larger clusters with open shells can be constructed from small fragments.[1] Using the reaction system with which the giant cluster anions **1**, as well as **2** and **3**[1] (for which the conditions were adapted slightly) were synthesized, we have now succeeded in isolating the substantially larger, mixed-valent (type III; Mo^{V}/Mo^{VI}), diamagnetic compound **4** with a molar mass of about 30000 g mol^{-1}, and to grow

$[Mo_{57}V_6(NO)_6O_{180}(OH)_3(H_2O)_{18}]^{21-}$ **1**

$[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$ **2**

$[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ **3**

The approximately ring-shaped anion of **4** (Fig. 1) consists of 140 MoO_6 octahedra and 14 pentagonal bipyramids of the type $\{Mo(NO)O_6\}$. It can be described as a tetradecamer with approximate D_{7d} symmetry[4] (Fig. 2, top). Each of the fourteen subunits has a pentagonal-bipyramidal $\{Mo(NO)O_6\}$ center about which seven other MoO_6 octahedra are grouped by corner- and edge-sharing to form an $\{Mo_8\}$ fragment. The fragments arranged above and below the equatorial plane of the cluster anion are linked to each other by the oxygen atoms in this plane and the total of 14 equatorial Mo centers (Fig. 3, top), in accordance with the details given below.

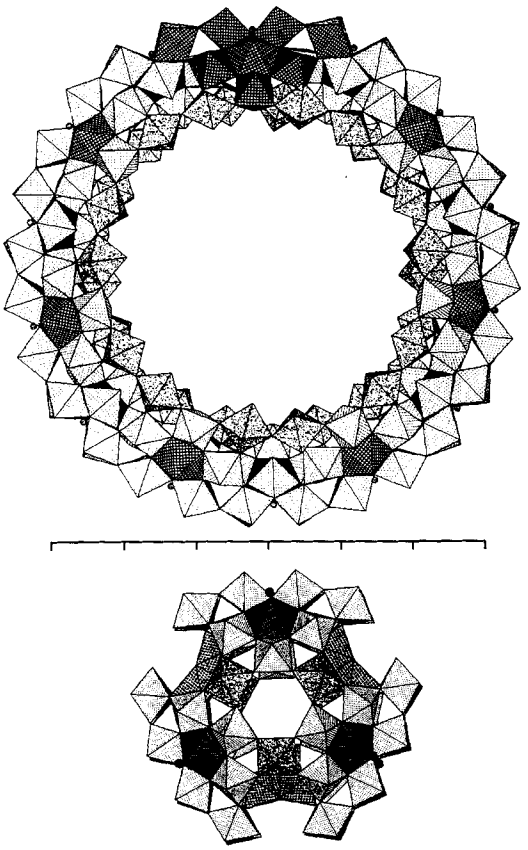

Fig. 2. Polyhedral representation of the cluster anion of **4** (top: view parallel to the approximate C_7 axis) and of **1** (or **2**) (bottom: view roughly parallel to the C_3 axis). In the top section, one example of the $\{Mo_8\}$ subunits constructed from seven MoO_6 octahedra and the central, pentagonal-bipyramidal $\{Mo(NO)O_6\}$ group has been highlighted by checkered shading. The other polyhedra, with the exception of the pentagonal bipyramids, which are also checkered, and the linking $\{MoO_2(H_2O)(\mu_2\text{-}O)MoO_2(H_2O)\}$ units, which are irregularly dotted, are shaded with regular dots. In the bottom section the polyhedra of $\{MoO_8\}$ units (or $\{MoO_7\}$ units)—that is, those with the central Mo(NO) groups—are represented as in the top section, but no $\{Mo_8\}$ unit is highlighted by special shading. In addition the $\{Mo^{V}(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo^{V}\}^{9+}$ fragments are indicated by crosses and the $\{V^{IV}O(H_2O)\}^{2+}$ (or $\{Fe^{III}(H_2O)_2\}^{3+}$) units by irregularly dotted shading (cf. ref. [1]). The distance between two graduations of the scale is 5 Å.

Corresponding, equivalent $\{Mo_8\}$ building blocks also occur in the anions **1** and **2**, which, however, have D_{3h} symmetry. The fundamental difference between the two structural types is that in **1** and **2** the $\{Mo_8\}$ fragments lie directly on top of each other and are transformed into each other by reflection across the equatorial mirror plane (Fig. 3, bottom), whereas in **4** they are twisted relative to each other about the approximate C_7 (S_{14}) axis by an angle of 360/14° (Fig. 3, top).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3419-2122 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 19

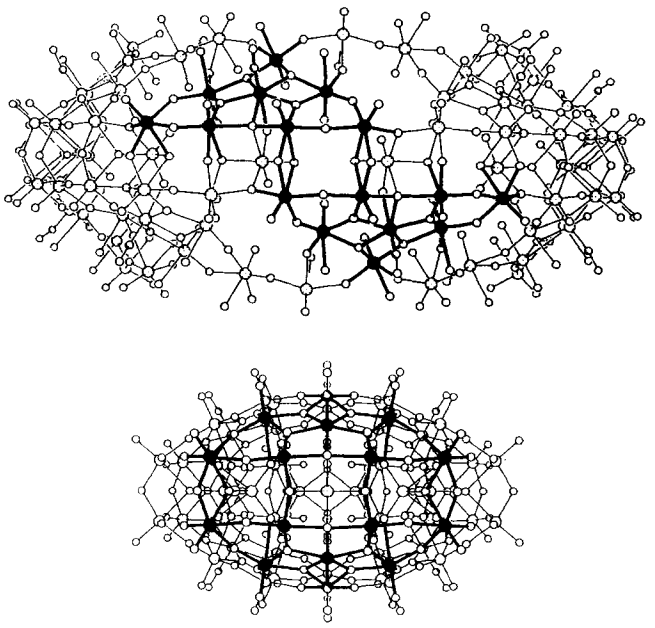

Fig. 3. Ball-and-stick model of the cluster anion of **4** (top: view parallel to an approximate C_2 axis and perpendicular to the view shown in Fig. 2, top; for reasons of clarity only the "half anion" has been drawn) and of **1** (or **2**) (bottom: view parallel to a C_2 axis and perpendicular to the view shown in Fig. 2, bottom). The $\{Mo_8\}$ units are in boldface in each case.

In **1** and **2** the pentagonal bipyramids of each unit are linked to each other through *one* additional Mo atom lying in the equatorial plane (Fig. 3, bottom), and therefore "discrete" $\{Mo_{17}\}$ fragments ($2 \times 8 + 1$) are formed. These are present as *transferrable ligands*, "isolated" from each other and linked solely through the cationic $\{V^{IV}O(H_2O)\}^{2+}$ or $\{Fe^{III}(H_2O)_2\}^{3+}$ and $\{Mo^{V}(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo^{V}\}^{9+}$ groups, respectively (Fig. 2, bottom).

In contrast, in **4** the shift of the $\{Mo_8\}$ units relative to each other (described above) means that in each case *two* equatorial Mo atoms are required to link two $\{Mo_8\}$ fragments (Fig. 3, top). Neighboring $\{Mo_8\}$ fragments above and below the equatorial plane are directly linked together through a μ_3-O atom, too (Fig. 2, top). The smaller curvature of the cluster ion relative to **1** and **2** correlates with the finding that in the region of the cavity there is enough space for a further linkage of the $\{Mo_8\}$ units through *two* Mo centers (or one $\{MoO_2(H_2O)(\mu_2\text{-}O)MoO_2(H_2O)\}$ unit) instead of only *one* V^{IV} or *one* Fe^{III} center as in **1** and **2**, respectively (Fig. 2, top). In this context the presence of two 42-membered rings containing alternating molybdenum and oxygen atoms, which give access to the cavity, is remarkable (Fig. 1).

The cavity itself, which, like a car tire, is broader at the equator, measures about 20 Å in diameter at its narrowest point, and thus corresponds fairly closely to the outer diameter of the cluster anions **1** and **2** (Fig. 2). A plausible hypothesis is therefore that the fragments in the solution that are also involved in the construction of **1**, **2**, and **3** induce the formation of the spherical cluster shell of **4**.

A further characteristic of the structure of the anion **4** is the exceptionally large number of protons resulting from the high degree of reduction. A careful analysis of the bond valence sums reveals 28 singly and 70 doubly protonated oxygen atoms. Singly protonated are the 28 equivalent μ_3-O atoms situated in the equatorial plane (Fig. 3, top) and linking two $\{Mo_8\}$ units as well as another Mo atom that also lies in this plane. Of the doubly protonated O atoms (the terminal H_2O ligands), 42 are coordinated to the Mo atoms that participate in the construction of the two 42-membered rings (one H_2O ligand per Mo atom). In these rings the H_2O ligands are arranged both above and below the ring's plane, and an alternating (*trans*) orientation between two adjacent centers is favored. The remaining 28 H_2O ligands are coordinated to the 28 equivalent metal centers in octahedral environments, which are in the immediate vicinity of the ring polyhedra. On considering all available data (degree of reduction and number of cations), further protonation is very unlikely.

Whereas the structure of the cluster ion could now be determined unequivocally, it will probably never be possible to ascertain the exact number of NH_4^+ ions because of disorder in the cationic lattice and the problematic nature of the analysis (about 2% nitrogen and an extremely high content of water of crystallization, which, moreover, decreases even at room temperature as a result of facile weathering).

A remarkable feature is that despite its large molar mass, **4** dissolves extremely well in water and on exclusion of air can be recovered from the solution without decomposition. The relatively high solubility can be attributed to the large surface area resulting from the tirelike form and the large number of H_2O and OH^- ligands (causing a large enthalpy of hydration). This also is manifest in the exceptionally large number of H_2O molecules in the crystal structure, with the result that even in the crystal the anions appear to be "swimming in water".

Interesting perspectives for further research are offered by the unusual potential and properties of the anion: the inclusion of substrates and their transformation within a host system that has mesoscopic dimensions, an extremely large surface area, and the electron-storage capability. Furthermore, the anion of **4** has a magnitude and surface area that places it on the border of the colloidal state, and yet it can still be included in a crystal lattice.

Experimental Procedure

A mixture of $Na_2MoO_4 \cdot 2H_2O$ (7.46 g, 30.8 mmol), NH_4VO_3 (1.19 g, 10.2 mmol), $NH_2OH \cdot HCl$ (12.83 g, 184.6 mmol), HCl (3.5%, 9.5 mL), and water (200 mL) was stirred for 1–2 min and then heated at 65–70 °C without stirring in a 300 mL, narrow-necked Erlenmeyer flask (covered with a watch glass) for 20 h. The resulting precipitate contained blue-black, rhombic crystals of **4**, suitable for X-ray structure analysis, but also water-insoluble, greenish crystals of a not yet more closely identified compound [5]. After separation from the hot reaction solution by filtration, the dark green filtrate was diluted with 100 mL hot water (70 °C), cooled to 20 °C, and allowed to stand to crystallize in a 300 mL, narrow-necked Erlenmeyer flask covered with a watch glass. Compound **4**, which precipitated within 2–3 days, was filtered off under exclusion of air and dried under inert atmosphere over $CaCl_2$. Yield: 0.3 g (5% based on Mo). (As a consequence of the differing solubility in H_2O, **4** can be separated from the greenish compound.)

[1] a) A. Müller, W. Plass, E. Krickemeyer, S. Dillinger, H. Bögge, A. Armatage, A. Proust, C. Beugholt, U. Bergmann, *Angew. Chem.* **1994**, *106*, 897; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 849; b) A. Müller, E. Krickemeyer, S. Dillinger, H. Bögge, W. Plass, A. Proust, L. Dloczik, C. Menke, J. Meyer, R. Rohlfing, *Z. Anorg. Allg. Chem.* **1994**, *620*, 599. The underlying principle is to generate highly negatively charged fragments in the reaction mixture (for example, by substitution of $\{MoO\}^{4+}$ by $\{MoNO\}^{3+}$ or Mo^{VI} by V^{IV}, as well as by reduction), which are stabilized by a high energy of hydration . This hampers the formation and crystallization of compounds with typical solid-state structures by further condensation—that is, by the operation of translation symmetry—and molecular growth processes can take place in the solution.

[2] **4**: space group $C2/m$; $a = 4790.2(8)$, $b = 4760.2(8)$, $c = 2100.2(3)$ pm, $\beta = 110.26(1)°$, $V = 44926(12) \times 10^6$ pm^3, ($\mu = 21.9$ cm^{-1}); $Z = 2$, Solution with direct methods, $R = 0.098$ for 16431 independent reflections ($F_0 > 4\sigma(F_0)$);

Siemens R3m/V diffractometer Mo_{K_α} radiation, graphite monochromator. Because of their air sensitivity, the blue-black, rhombic crystals were mounted in silicon oil when removed from the mother liquor, and the measurement was performed at −85 °C. Since the cationic lattice is partly disordered, it is not possible to distinguish between H_2O and NH_4^+ centers. The overall number of both of these groups found in lattice positions is about 320 per formula unit; however, it must be assumed that some of those units are so disordered that they are not detectable by difference Fourier syntheses. Thus, for instance, no relevant lattice positions could be localized in the vicinity of the center of the cavity of the cluster. Results of model calculations revealed that a further 50–70 positions that should be occupied by H_2O units are present. Elemental analyses, redox titrations, and the determination of the NH_4^+ content by the Kjeldahl method yielded the quoted formula. As a result of the quite characteristic bond valence sums, the positions of protonation could be unequivocally located. The calculated values lie between 0.15 and 0.45 for the 70 doubly protonated and between 1.1 and 1.3 for the 28 singly protonated oxygen atoms. This corresponds to what we expected from our experience with numerous other relevant cluster anions. Furthermore, significantly lowered bond valence sums (average 5.66) for 70 Mo atoms without H_2O ligands, which lie in the equatorial plane or above and below it on the periphery of the tire-shaped anion, show that the 4d electrons (and likewise the "Mo^V" centers without consideration of the $\{Mo(NO)\}^{3+}$ units) are predominantly localized here. This correlates with the degree of reduction corresponding to the molecular formula, which was also determined by manganometric redox titration (see ref. [1]). (Calculation of bond valence sums according to I. D. Brown in *Structure and Bonding in Crystals, Vol. II* (Eds.: M. O'Keefe, A. Navrotsky), Academic Press, New York, **1981**, p. 1.) Part of the $\{Mo(O_{br})_3(O_{term})_2(H_2O)\}$ and the $\{Mo(O_{br})_4(O_{term})(H_2O)\}$ octahedra (br = bridging, term = terminal) is disordered in such a way that the *trans* O_{term} and H_2O ligands exchange their positions (in each case unequivocally recognized in the individual octahedra through two Mo positions with apparent "distances" between 0.7 and 0.8 Å). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-59058.

[3] Characterization of **4**: some characteristic IR bands (KBr disc prepared under argon): $\tilde{\nu}$ [cm^{-1}] = 1610 (m, br, $\delta(H_2O)$ and $\nu(NO)$), 1407 (m, $\delta_{as}(NH_4^+)$), 967 (m), 905 (m, $\nu(Mo{=}O)$), 812 (sh), 740 (s), 636 (s), 551 (s). Characteristic resonance Raman bands (solid/λ_e = 1064 nm): $\tilde{\nu}$ [cm^{-1}] = 806 (s, A_1), 536 (s), 462 (s), 326 (s), 221 (s). Vis/NIR (in H_2O): λ [nm] (ε_M [10^5 $L\,mol^{-1}\,cm^{-1}$]) = 750 (1.7, IVCT), 1080 (1.3, IVCT).

[4] The conditions required for the occurrence of D_{7d} symmetry were approximately fulfilled only for the Mo atoms. Deviations are observed mainly for the O_{term} and H_2O ligands of the $\{MoO_2(H_2O)(\mu_2\text{-}O)MoO_2(H_2O)\}$ units that are not transformed into each other by reflection across the dihedral planes.

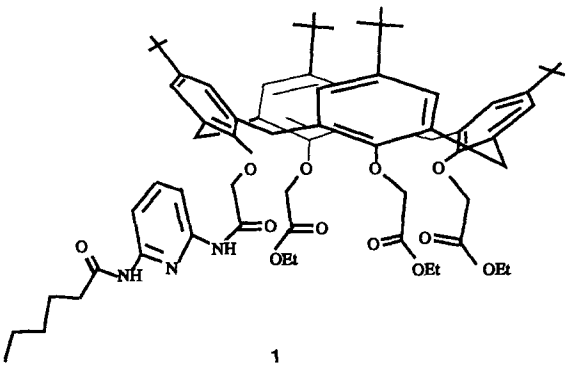
[5] The exciting process of nucleus formation in the case of ionic crystals with "giant ions" will, after thorough examination, be reported elsewhere. The relevant stochastic process in the present case leads not only to (large) crystals but also to a noncrystalline part or to material with a different degree of crystallization, the powder diagram of which corresponds to the envelope of that calculated from single crystal data. The Raman, IR, and UV/Vis/NIR spectra, and the analyses, are identical for the crystalline and noncrystalline parts.

A Self-Assembled Bifunctional Receptor

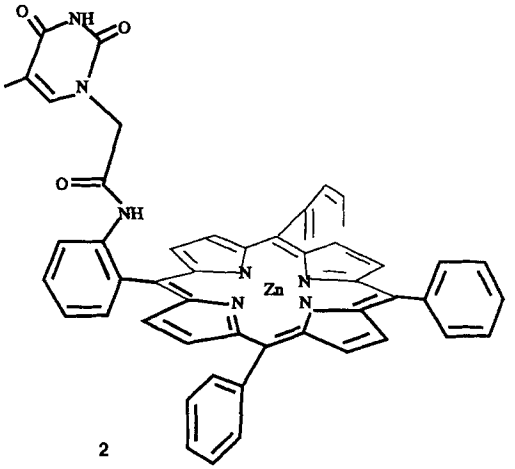
Dmitry M. Rudkevich,* Alexander N. Shivanyuk, Zbigniew Brzozka, Willem Verboom, and David N. Reinhoudt*

Molecular self-assembly is an important part of life processes and biological systems.[1] It results in a wide variety of complex structures such as double-stranded DNA, viral protein coatings, lipid membranes, and globular proteins. Self-assembling processes have also found applications in the design of nanostructures such as inorganic clusters, tubes and channels, monolayers, and hydrogen-bonded networks. The functions of such assemblies can be extrapolated from molecular properties.[2, 3] Recently, Sessler et al. reported photoinduced energy transfer in noncovalently linked photosynthetic systems.[4] Molecular recognition by encapsulation of small guest molecules in cavities assembled through noncovalent interactions has been achieved.[5] Self-assembled nanotubes constructed from cyclic peptide subunits can transport glucose across lipid bilayers.[6]

Previously we have described bifunctional receptors having in the same molecule covalently connected cation and anion binding sites.[7] In this communication we describe the molecular recognition of ionic species by a bifunctional receptor system, in which a cation and an anion binding site are positioned in close proximity by means of self-assembly. Such a system is able to bind simultaneously both cationic and anionic guest species. The strategy applied is based on the assembly of known receptors through hydrogen bonding. The cation receptor calix[4]arene **1**, which contains one amide and three ester groups,



1



2

complexes alkali metal cations with a high selectivity for Na^+.[8] This calixarene was prepared in 78% yield from the corresponding triester monocarboxylic acid chloride[9] and 2-amino-6-(hexanamido)pyridine. The anion receptor porphyrin **2** was obtained in 49% overall yield by reaction of thymine with the appropriate bromoacetamidoporphyrin[10] in DMSO in the presence of K_2CO_3 as a base, followed by metalation with $Zn(OAc)_2 \cdot 2H_2O$. The Zn center in porphyrin **2** is expected[11] to bind anions in aprotic solution. For the assembly through hydrogen bonding, compounds **1** and **2** are functionalized with complementary diamidopyridine and thymine units, respectively.[12, 13]

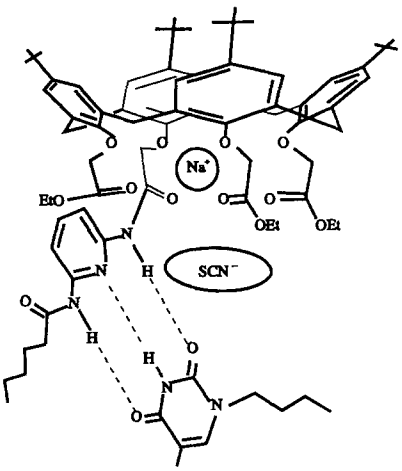
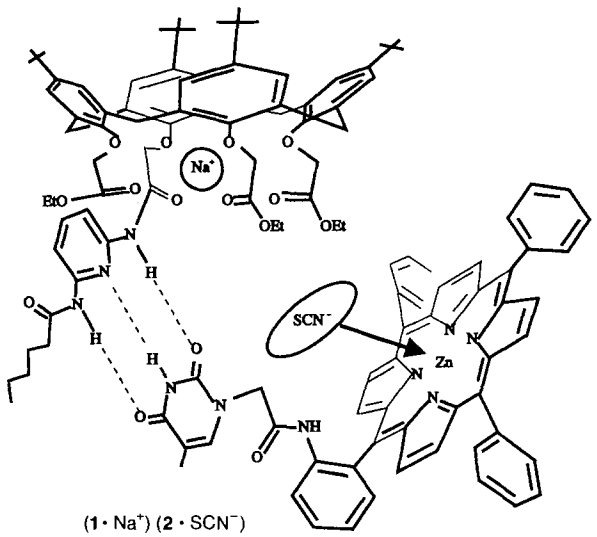
Calix[4]arene **1** strongly complexes Na^+ in $CDCl_3$, $[D_3]$MeCN, and $[D_8]$toluene solutions; from dilution experiments in $[D_3]$MeCN with $NaNO_3$ an association constant (K_{ass}) of $5.0 \times 10^4\ mol^{-1}$ was found. Calixarene **1** could be converted easily to the corresponding lipophilic complexes $(\mathbf{1}\cdot Na^+)ClO_4^-$, $(\mathbf{1}\cdot Na^+)I^-$, and $(\mathbf{1}\cdot Na^+)SCN^-$ by stirring a CH_2Cl_2 solution of **1** with saturated aqueous solutions of the appropriate sodium salts for three to five hours. With the more hydrophilic salts NaF and NaH_2PO_4 no complexes could be obtained.

Surprisingly, the diamidopyridine fragment in free **1** does not form hydrogen-bonded aggregates with complementary molecules such as *N*-butylthymine. In the ^1H NMR spectra no characteristic shifts[12] of C(O)NH signals were observed upon addition of *N*-butylthymine to $CDCl_3$, $[D_3]$MeCN, or $[D_8]$toluene solutions of **1**. The diamidopyridine moiety in **1** is apparently involved in intramolecular hydrogen bonding with the ethyl carboxylate groups, because the C(O)NH signals of **1** are shifted roughly $\Delta\delta = 0.3$ and 0.8 downfield in comparison with those of the $(\mathbf{1}\cdot Na^+)ClO_4^-$ complex in $CDCl_3$ and $[D_3]$MeCN, respectively. The Na^+ complexes of **1**, in which the carbonyls from the ester groups and the amide group are coordinated to the cation, do form hydrogen bonds with complementary molecules as indicated by the downfield shifts for the diamidopyridine C(O)NH protons of approximately $\Delta\delta = 0.5$–0.6 in $CDCl_3$, $[D_3]$MeCN, and $[D_8]$toluene upon addition of *N*-butylthymine to a solution of the $(\mathbf{1}\cdot Na^+)ClO_4^-$ complex. From dilution experiments in $[D_8]$toluene K_{ass} values of $1.5 \times 10^3\ mol^{-1}$ ($-\Delta G = 17.8\ kJ\,mol^{-1}$) and $1.7 \times 10^3\ mol^{-1}$ ($-\Delta G = 18.1\ kJ\,mol^{-1}$) were calculated for $(\mathbf{1}\cdot Na^+)ClO_4^-$ and $(\mathbf{1}\cdot Na^+)SCN^-$, respectively.[14, 15] This provides an interesting possibility of "switching on" the hydrogen bonding ability of **1** by complexation with Na^+ ions.[16] It means that anion receptor **2** can in principle be assembled with $(\mathbf{1}\cdot Na^+)ClO_4^-$ or $(\mathbf{1}\cdot Na^+)SCN^-$ complexes through a diamidopyridine–thymine interaction. UV/Vis experiments with porphyrin **2** show that it complexes I^- and SCN^- ions (introduced as tetrabutylammonium salts) in apolar solvents (CH_2Cl_2 and toluene). A bathochromic shift of the Soret band of 8–10 nm was found upon addition of $Bu_4N^+I^-$ and $Bu_4N^+SCN^-$ to a toluene solution of **2**, which is in agreement with the data published for simple tetraphenylporphyrins.[11] This binding is not strong; from dilution experiments a K_{ass} value of roughly $10\ mol^{-1}$ ($-\Delta G = 5.6\ kJ\,mol^{-1}$) was calculated for both I^- and SCN^- ions in toluene. No indication for complexation of the ClO_4^- ion was observed. Addition of *free* calix[4]arene **1** to a toluene solution of porphyrin **2** did not change the anion binding properties of **2**; K_{ass} values of roughly $10\ mol^{-1}$ for the complexation of I^- and SCN^- ions were found. Interactions between the hydrogen bonding sites of **1** and **2** were not observed in the ^1H NMR spectra upon mixing.

The final assembly experiment was carried out between $(\mathbf{1}\cdot Na^+)SCN^-$ and **2**.[17] Addition of porphyrin **2** to a $[D_8]$toluene solution of $(\mathbf{1}\cdot Na^+)SCN^-$ resulted in a pronounced thymine–diamidopyridine interaction. From the ^1H NMR chemical shifts of the C(O)NH signals a K_{ass} value of $2.8 \times 10^4\ mol^{-1}$ ($-\Delta G = 24.9\ kJ\,mol^{-1}$) for $(\mathbf{1}\cdot Na^+)(\mathbf{2}\cdot SCN^-)$ was calculated. This is significantly higher than those of the interactions in $(\mathbf{1}\cdot Na^+)\cdot$*N*-butylthymine$\cdot SCN^-$ and $Bu_4N^+(\mathbf{2}\cdot SCN^-)$ separately. A Job plot confirmed the 1:1 stoichiometry of the complex (Fig. 1).[18, 19] The $(\mathbf{1}\cdot Na^+)(\mathbf{2}\cdot SCN^-)$ assembly in toluene was also confirmed by UV/Vis spectroscopy; the Soret band displayed a bathochromic shift of 8 nm thus reflecting the Zn–SCN^- interaction (Fig. 2). From these experiments a K_{ass} value of $2.5 \times 10^4\ mol^{-1}$ was calculated, indicating strong anion binding.



$(\mathbf{1}\cdot Na^+)\cdot$Thymine$\cdot SCN^-$



$(\mathbf{1}\cdot Na^+)\,(\mathbf{2}\cdot SCN^-)$

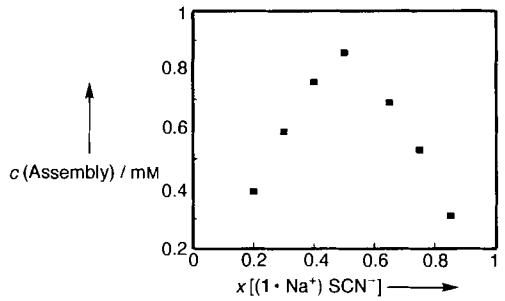


Fig. 1. Titration of 1 mmol of $(\mathbf{1}\cdot Na^+)SCN^-$ with 1 mmol of **2** in $[D_8]$toluene with formation of the assembly $(\mathbf{1}\cdot Na^+)(\mathbf{2}\cdot SCN^-)$ (Job plot).

These results prove the formation of the *noncovalently* organized bifunctional receptor system $(\mathbf{1}\cdot Na^+)(\mathbf{2}\cdot SCN^-)$ (Fig. 3).[20] The Na^+ ion is complexed by calixarene **1**, the SCN^- ion coordinates to the Zn-porphyrin **2**, and these cation and anion receptors are connected through hydrogen-bonded aggregation. The (significant) enhancement of the hydrogen bonding as well as the anion complexation points to a *coopera-*

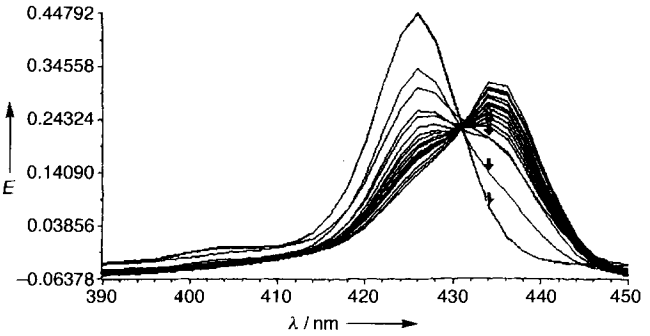

Fig. 2. Complexation of $(1\cdot Na^+)SCN^-$ with **2** in toluene. The assembly was monitored by UV/Vis spectroscopy between 390 and 450 nm (E = extinction). [**2**] = 1×10^{-3} mM; the concentration of $(1\cdot Na^+)SCN^-$ ranges from 5×10^{-4} to 1×10^{-1} mM.

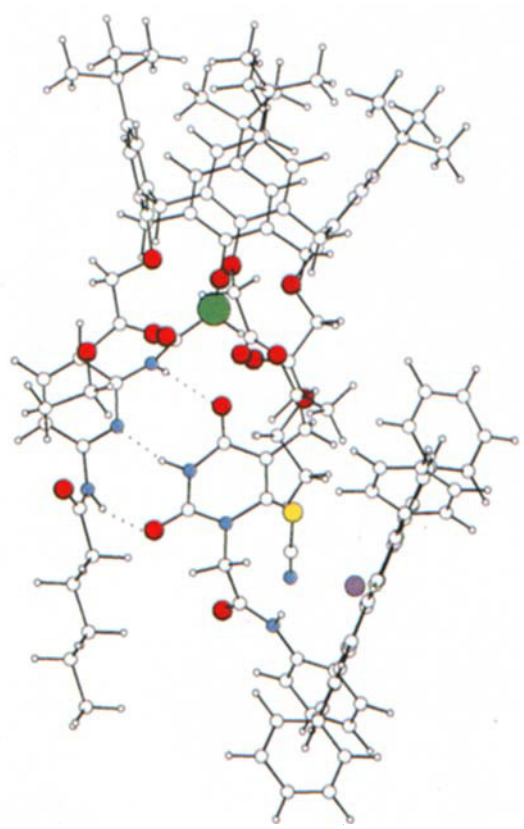

Fig. 3. Energy-minimized structure of the assembly $(1\cdot Na^+)(2\cdot SCN^-)$. Na = green, Zn = violet, S = yellow, O = red, N = blue, C,H = white.

tion of the individual interactions between calix[4]arene **1**, Zn-porphyrin **2**, and the Na^+ and SCN^- ions. The positions of all four components in the complex are fixed in solution by specific ion–dipole interactions and hydrogen bonding. The assembly can be "switched on" by complexation of the Na^+ ion with receptor **1**, and "switched off" by addition of MeOH, which is able to destroy hydrogen bonds.

[13] Selected data for **1**: M.p. 88–89 °C (MeCN); ^{1}H NMR ([D$_8$]toluene): δ = 9.61, 8.61 (2 br s, 2H, NH), 8.25, 8.12 (2 d, ^3J(H,H) = 8.0 Hz, 2H, diamidopyridine), 7.19 (t, ^3J(H,H) = 8.0 Hz, 1H, diamidopyridine), 6.92, 6.82, 6.69 (3 s, 8H, arom.), 5.12, 4.78 (2 d, ^3J(H,H) = 14.0 Hz, 4H, $CH_2C(O)$), 4.98, 4.72, 3.17, 3.10 (4 d, ^3J(H,H) = 13.0 Hz, 8H, CH_2-calix), 4.78, 4.53 (2 s, 4H, $CH_2C(O)$), 4.9–4.5 (m, 6H, OCH_2), 2.45 (t, ^3J(H,H) = 7.5 Hz, 2H, $CH_2C(O)N$), 1.85–1.75, 1.4–1.3 (2 m, 6H, CH_2), 1.15 (s, 18H, *t*Bu), 1.09, 1.03 (2 s, 18H, *t*Bu), 0.91 (t, ^3J(H,H) = 7.2 Hz, 9H, CH_3), 0.80 (t, ^3J(H,H) = 7.5 Hz, 3H, CH_3); FAB-MS (NBA matrix): *m/z*: 1154.4 (M^+, calcd 1154.5). Selected data for **2**: M.p. 253–255 °C; UV/Vis (toluene): λ_{max} = 426 nm; ^{1}H NMR ([D$_8$]toluene): δ = 9.06 (d, ^3J(H,H) = 8.0 Hz, 1H, arom.), 8.98 (s, 4H, porphyrin), 8.88, 8.67 (2 d, ^3J(H,H) = 4.8 Hz, 4H, porphyrin), 8.3–8.0 (m, 8H, arom.), 7.80 (d, ^3J(H,H) = 8.0 Hz, 1H, arom.), 7.6–7.4 (m, 10H, arom. + NH), 7.09 (t, ^3J(H,H) = 7.2 Hz, 1H, arom.), 5.30 (s, 1H, thymine), 2.70 (s, 2H, $NCH_2C(O)$), 2.01 (s, 3H, CH_3); FAB-MS (NBA matrix): *m/z*: 859.1 (M^+, calcd 859.3). NBA = nitrobenzyl alcohol.

[14] All K_{ass} values were obtained at 293 K using a constant concentration of the $(1\cdot Na^+)$ complex of 1.00 mM and a varying concentration of a guest of 0.25–5.00 mM. The values were calculated by nonlinear regression according to the procedure described in: J. A. A. de Boer, D. N. Reinhoudt, S. Harkema, G. J. van Hummel, F. de Jong, *J. Am. Chem. Soc.* **1982**, *104*, 4073–4076. The estimated error is 5%.

[15] The complex $(1\cdot Na^+)I^-$ appeared to be very light-sensitive and decomposed upon titration.

[16] A similar phenomenon has recently been reported, see: H. Murakami, S. Shinkai, *J. Chem. Soc. Chem. Commun.* **1993**, 1533–1535.

[17] Porphyrin **2** complexes F^- ions (as the tetrabutylammonium salt) very strongly; a K_{ass} value of 2.3×10^4 mol^{-1} in toluene was calculated. Since the complex $(1\cdot Na^+)F^-$ could not be obtained, a toluene solution of the complex $(1\cdot Na^+)(2\cdot ClO_4^-)$ was titrated (UV/Vis, ^{1}H NMR) with $Bu_4N^+F^-$. Despite the very strong interaction ($K_{ass} \approx 3.0\times10^4$ mol^{-1}) initially detected, fast precipitation of NaF from the toluene solution followed, which prevented further assembly.

[18] K. A. Connors, *Binding Constants*, Wiley, New York, **1987**, p. 24.

[19] ^{1}H NMR spectrum of $(1\cdot Na^+)/(2\cdot SCN^-)\cdot$([D$_8$]toluene): δ = 10.29, 10.18 (2 br s, 2H, NH), 8.99 (s, 4H, porphyrin), 8.95, 8.26 (2 d, ^3J(H,H) = 8.0 Hz, 2H, arom.), 8.83 (q, ^3J(H,H) = 4.8 Hz, 4H, porphyrin), 8.50 (d, ^3J(H,H) = 8.0 Hz, 2H, arom.), 8.2–8.0, 7.8–7.5 (2 m, 18H, arom. + NH), 7.38 (t, ^3J(H,H) = 8.0 Hz, 1H, arom.), 7.25, 7.17 (2 s, 8H, arom.), 5.60 (s, 1H, thymine), 4.60, 4.22 (2 s, 4H, $CH_2C(O)$), 4.55, 4.49, 3.30, 3.25 (4 d, ^3J(H,H) = 13.0 Hz, 8H, CH_2-calix), 4.38, 4.11 (2 d, ^3J(H,H) = 14.0 Hz, 4H, $CH_2C(O)$), 4.0–3.8 (m, 6H, OCH_2), 3.28 (s, 2H, $NCH_2C(O)$), 2.53 (t, ^3J(H,H) = 7.5 Hz, 2H, $CH_2C(O)N$), 2.01 (s, 3H, CH_3), 1.85–1.75, 1.4–1.1 (2 m, 6H, CH_2), 1.21 (s, 36H, *t*Bu), 1.03, 1.00 (2 t, ^3J(H,H) = 7.2 Hz, ^3J(H,H) = 7.5 Hz, 6H, CH_3), 0.80 (t, ^3J(H,H) = 7.2 Hz, 6H, CH_3).

[20] The proposed structures were additionally confirmed by molecular mechanics calculations performed with Quanta/CHARMm Version 3.3. Energy minimizations (conjugate gradient) were carried out (Steepest Descents followed by Adopted Based Newton Raphson) until the root mean square of the gradient was less than 0.01 kcal mol^{-1} Å^{-1}.

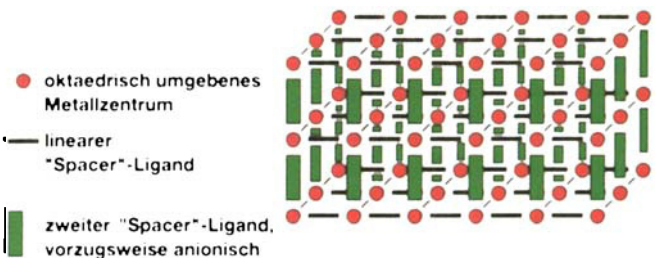
Porous Solids by Design: $[Zn(4,4'\text{-bpy})_2(SiF_6)]_n \cdot x\,DMF$, a Single Framework Octahedral Coordination Polymer with Large Square Channels**

S. Subramanian* and Michael J. Zaworotko*

The concept of crystal engineering[1] has in recent years provided numerous examples of rationally designed one- (1D), two- (2D), and three-dimensional (3D) polymeric structures. Of particular potential interest to inclusion chemistry are 2D and 3D coordination polymers which, in principle at least, can be designed to have very specific pore size and type. In such a context, there already exist examples of 2D square[2] and hexagonal/honeycomb[3] grids generated from metal ions in square-planar or trigonal environments, respectively, coordinated to linear bifunctional ligands such as 4,4'-bipyridine or pyrazines. Furthermore, 3D diamondoid coordination polymers based upon tetrahedral or S_4 coordination environments have been generated by either coordinate covalent bonds or hydrogen bonding.[4] However, given the ubiquity of octahedral metal environments, it is somewhat surprising that simple 3D octahedral polymers[5] remain largely unexplored. Indeed, to our knowledge μ-cyano polymers such as $Fe^{III}_4[Fe^{II}(CN)_6]_3$, Prussian Blue,[6] the poorly characterized $[Cd(CN)_2(quinoxaline)]_n$,[7] and triply interpenetrated $[Cd(pyrazine)\{Ag_2(CN)_3\}\{Ag(CN)_2\}]$[8] represent the only examples of such structures.[9a] Recently a coordination polymer from silver ions and pyrazine was synthesized and structurally characterized.[9b] In this contribution we detail a potentially general strategy for generation of such polymers.

Scheme 1 illustrates how cross-linking of cationic square grids with suitable linear bifunctional anionic ligands could in principle afford neutral octahedral polymers with porosity controlled by the length, volume, and chemical type of the spacer ligands. Compound **1** polymerizes to afford square grids with sides of length 11.43 Å.[2] Unfortunately, unlike $[Cd(4,4'\text{-bpy})_2](NO_3)_2$, which eschews interpenetration,[2] the large cavity in **1** is self-included with hexafluorosilicate ions, which are bound through hydrogen bonds to water molecules, and a second independent $[Zn(4,4'\text{-bpy})_2]$ square grid. It occurred to us that the anhydrous form of **1** could be expected to fit the hypothetical network proposed in Scheme 1 since SiF_6^{2-} ions are capable of acting as a linear bridge between transition metal moieties such as $[Co(N\text{-vinylimidazole})_4]^{2+}$[10] and $[Cu(5\text{-phenylpyrazole})_4]^{2+}$.[11] We therefore synthesized the anhydrous form of **1**, namely **2**, and herein report its remarkable crystal structure.



Scheme 1. Schematic illustration of how a three-dimensional coordination polymer might be generated by cross-linking of square grids.

$[Zn(4,4'\text{-bpy})_2(H_2O)_2]SiF_6$ **1**

$[Zn(4,4'\text{-bpy})_2]SiF_6$ **2**

The compound $\mathbf{2} \cdot x\,DMF$ crystallizes in the tetragonal space group $P4/mmm$ with $Z = 1$ and therefore sits around a crystallographic $4/mmm$ position.[12] This alone is quite a remarkable feature since the space group symmetry manifests the maximum D_{4h} point group symmetry that can be sustained by an MX_4Y_2 species. The space group symmetry and cell dimensions are therefore entirely rational or indeed predictable based upon the chemical composition of **2**. However, an even more remarkable feature of **2** is that it eschews interpenetration[13] and therefore, as Figure 1 reveals, large square channels are generated parallel

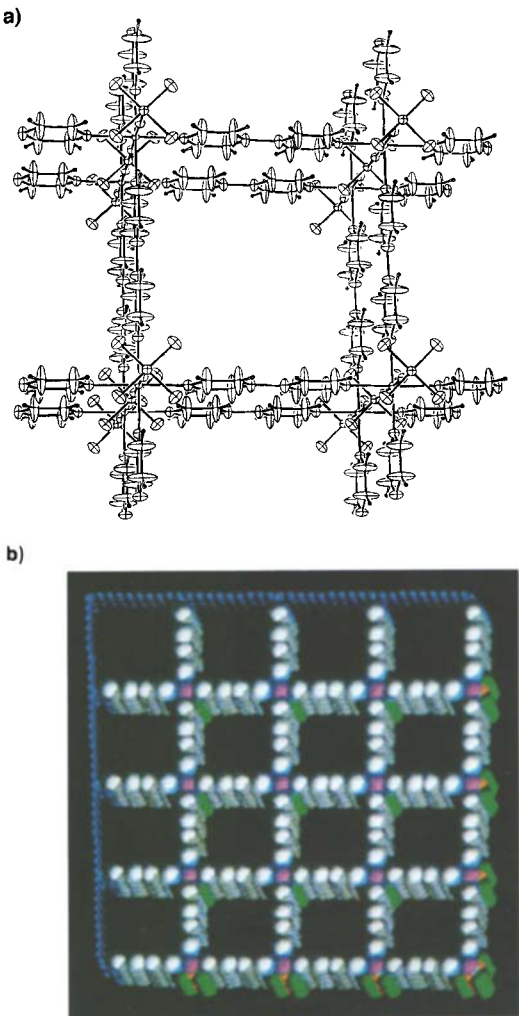


Fig. 1. ORTEP (a) and space-filling (b) views of the *ab* plane in **2**. The square channels have the same dimensions as the unit cell (11.396 × 11.396 Å) and therefore measure about 16 Å diagonally. The effective cross-sectional area is given by subtracting the van der Waals radius of an aromatic ring (ca. 1.7 Å) from each face of the channel, thereby affording a void that should hold molecules with a cross-sectional area of about 8 × 8 Å.

to the crystallographic c axis. As would be anticipated, these channels have essentially the same dimensions as those seen in the interpenetrated dihydrate, 11.3959(11) × 11.3959(11) Å, and the effective size of their pores (8 × 8 Å) compares well with the pore sizes of large zeolites.[14] The volume of the channels is about 50% of the total volume.[15] The μ-SiF_6^{2-} ions form perfectly linear bridges, and the Zn–F distances of 2.082(10) Å, are shorter than the M–F distances encountered in previous studies concerning μ-SiF_6^{2-} units.[10, 11] The Zn–N distances (2.157(8) Å) are also within the expected range. That there is no interpenetration in **2** can possibly be attributed to the orientation of the 4,4′-bipyridine ligands (Fig. 2). These ligands are

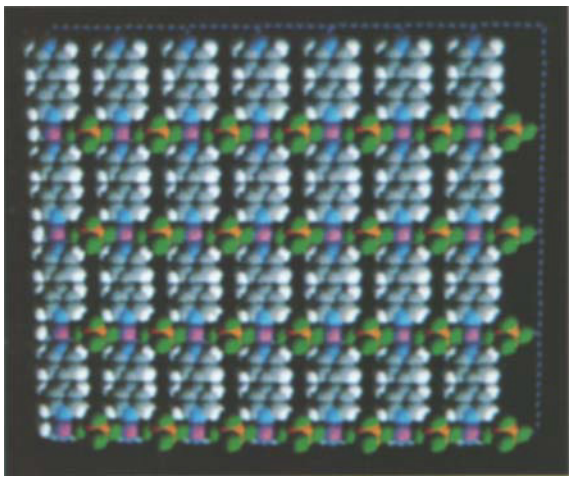

Fig. 2. A view of the *ac* plane in **2**. The 4,4′-bipyridine moieties are aligned with the *ac* plane and therefore preclude porosity or interpenetration in this direction. The α-C-H moieties of the 4,4′-bipyridine ligands are hydrogen-bonded to the fluorine atoms of the SiF_6^{2-} ions.

disposed such that the pyridine moieties are almost coplanar with each other[16] and the crystallographic *ac* and *bc* planes, respectively. The former is quite unusual since such a conformation for 4,4′-bipyridine is sterically disfavored, and the latter is important since it precludes porosity and interpenetration along either the crystallographic *a* or *b* directions. We attribute this conformation and orientation to the existence of C-H···F hydrogen bonds between α-C-H hydrogen atoms and fluorine atoms of the SiF_6^{2-} ions.[17]

Although **2** does not compare to other zeolitic solids in terms of stability in aqueous environments or potential catalytic activity, we consider the following features of this study to be particularly salient: 1) Compound **2** represents, to our knowledge, the first example of a neutral octahedral coordination polymer and, therefore, there are no counterions occupying the microchannels.[18] 2) Compound **2** is inherently modular and all three components are in principle interchangeable. 3) The dimensions of the channels are precisely what one would expect based upon the geometric features of the three components. 4) The channels in **2** are hydrophobic. 5) The space group of **2** can be regarded as a direct manifestation of the point group symmetry (i.e. the structure of **2** can be regarded as having been "crystal engineered" even from the perspective of space group symmetry). We consider **2** to be the prototype of a potentially wide range of porous octahedral structures and are actively investigating the generality of this class of solid and its ability to incorporate medium-sized hydrophobic molecules of cross-sectional area consistent with the dimensions observed in **2**.

Experimental Procedure

2: $[Zn(OH_2)_6]SiF_6$ (0.31 g, 1.0 mmol) was suspended in 1,4-dioxane (25 mL) and benzene (25 mL), and the mixture was heated to reflux in a Dean–Stark apparatus to azeotropically remove the water. The powder of $ZnSiF_6$ thus formed was dissolved by adding DMF (25 mL) to the above mixture. Most of the benzene and 1,4-dioxane were removed by rotoevaporation at this point. The mixture was cooled and a solution of 4,4′-bipyridine (0.31 g, 2.0 mmol) in 1,4-dioxane (10 mL) was added. The solution was heated to reflux for 30 min. The resulting pale gold/yellow solution was cooled and allowed to stand at room temperature for 12 h. This afforded colorless crystals of **2** (0.48 g). Crystals appear to lose solvent and crystallinity within minutes if left to stand exposed to a solvent-free atmosphere and dissolve readily in water. IR (nujol mull): $\tilde{\nu}$ = 2985, 2872 (bpy C-H); 1668 (DMF C=O); 1609, 1457, 1379, 1236, 1086, 833, 770, 635 cm^{-1}.

[12] X-ray structure of **2**·*x*DMF: $C_{20}H_{16}F_6N_4SiZn \cdot x$DMF, colorless cubes (0.30 × 0.30 × 0.40 mm), tetragonal, space group *P4/mmm*, with a = 11.3959(11), c = 7.6775(9) Å, V = 997.05(15) Å^3, Z = 1, ρ = 0.87 Mg m^{-3} (octahedral polymer only) or 1.27 Mg m^{-3} (including disordered solvent). Data were collected on an Enraf-Nonius CAD-4 diffractometer with $Mo_{K\alpha}$ radiation (λ = 0.71073 Å). Non-hydrogen atoms of the coordination polymer were refined with anisotropic thermal parameters. The solvent molecules were observed to be disordered in a manner that could not be readily resolved. Solvent atoms were therefore treated as carbon atoms and refined with fixed isotropic thermal parameters and variable site occupancy. Values of R = 0.063 and R_w = 0.061 were obtained for 426 out of 569 reflections with $I > 2.5\sigma(I)$ and 48 parameters. Hydrogen atoms of the 4,4′-bipyridine moieties were placed in calculated positions with d_{C-H} = 1.00 Å. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ (UK) on quoting the full journal citation.

[13] Self-inclusion by interpenetration invariably occurs when cavities would be larger than 50% of the volume in 3D or 2D frameworks. For example, in diamondoid systems up to sevenfold interpenetration has been observed: K. Sinzger, S. Hunig, M. Jopp, D. Bauer, W. Bietsch, J. U. von Schutz, H. C. Wolf, R. K. Kremer, T. Metzenthin, R. Bau, S. I. Khan, A. Lindbaum, C. L. Lengauer, E. Tillmanns, *J. Am. Chem. Soc.* **1993**, *115*, 7696.

[15] The density of **2** in the absence of solvent is just 0.87 Mgm^{-3} compared to 1.856 Mgm^{-3} in the corresponding dihydrate **1**. The density was not determined experimentally because of the tendency of the crystals to lose solvent rapidly.
[16] As noted by a reviewer and revealed by Figure 1a, there is considerable distortion of the thermal ellipsoids associated with carbon atoms 2,3,5,6,2',3',5' and 6' of the 4,4'-bipyridine ligands. This observation is consistent with slight twisting of the the pyridine moieties and either static or dynamic disorder between two orientations.
[17] C-H···F and C···F contacts, 2.342 and 3.429(9) Å, respectively, are well within ranges expected for significant C-H···F interactions: L. Shimoni, H. L. Carrell, J. P. Glusker, M. M. Coombs, *J. Am. Chem. Soc.* **1994**, *116*, 8162.
[18] Compounds with comparable or larger pores have recently been reported but either cations (T. J. McCarthy, T. A. Tanzer, M. G. Kanatzidis, *J. Am. Chem. Soc.* **1995**, *117*, 1294) or anions are necessarily present in the pores (B. F. Abrahams, B. F. Hoskins, D. M. Michall, R. Robson, *Nature*, **1994**, *369*, 727).

Rational Design of Orthogonal Receptor–Ligand Combinations**

Peter J. Belshaw, Joseph G. Schoepfer, Karen-Qianye Liu, Kim L. Morrison, and Stuart L. Schreiber*

Signal transduction in cells occurs primarily by two mechanisms, one involving allostery and the other involving proximity.[1] The role of ligand-induced allosteric change in proteins has been appreciated for many years, and has led to the synthesis of numerous molecules that either promote or inhibit the allosteric change required to transduce information in cells. More recently, cell biological studies have illuminated the role of regulated protein dimerization or oligomerization as a means of information transfer. Such an event can promote a proximal relationship between an enzyme and its substrate or a receptor and its ligand, thereby facilitating a molecular interaction leading to a signaling event. Examples include the dimerization of growth factor receptors,[2] oligomerization of antigen receptors,[3] and dimerization of transcription factors.[4] These insights have created new opportunities for chemists to synthesize molecules with two protein-binding surfaces and thereby to induce protein association. Such chemical inducers of dimerization (CIDs) have the potential to activate many cellular processes, including ones of biological and medical significance. We recently described a method to inducibly control the association of proteins in cells.[5, 6] This was accomplished through the expression of chimeric proteins in mammalian cells, consisting of a dimerization domain fused to a protein or protein domain of interest. By treating these cells with a synthetic, cell-permeable CID that binds to the dimerization domain, self-association of the protein occurs and a signal is transmitted (Fig. 1).

Although in theory many receptor–ligand systems can be used, the immunophilins FKBP12 and cyclophilin A (CyP) and their ligands FK506 and cyclosporin A (CsA) were selected for this purpose. The ligands are cell permeable and can be modified

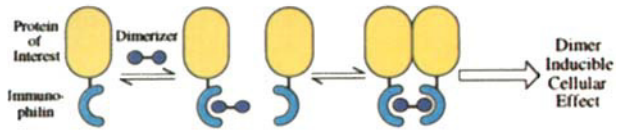

Fig. 1. Regulated intracellular dimerization with cell-permeable synthetic ligands named CIDs.

synthetically in a rational way to remove their intrinsic immunosuppressive and toxic properties. This requires modifying the calcineurin-binding (but not the immunophilin-binding) domain of these naturally occurring CIDs. FKBP12 and CyP bind their ligands with high affinity (K_d = 0.5 nM and 5 nM, respectively), are monomeric, have no discernible effect when expressed in cells, and their small size (12 kDa and 18 kDa, respectively) facilitates the incorporation of their cDNA into expression vectors. A shortcoming is that the natural immunophilins are expressed at high levels in many cells and can therefore diminish the potency of CID ligands toward immunophilin fusion proteins by forming nonproductive receptor–ligand complexes (Fig. 2a). The resulting loss in specificity is expected to be especially troublesome in whole organisms, where cells expressing the fusion proteins may be relatively few in number, thus magnifying the buffering effect of natural immunophilins.

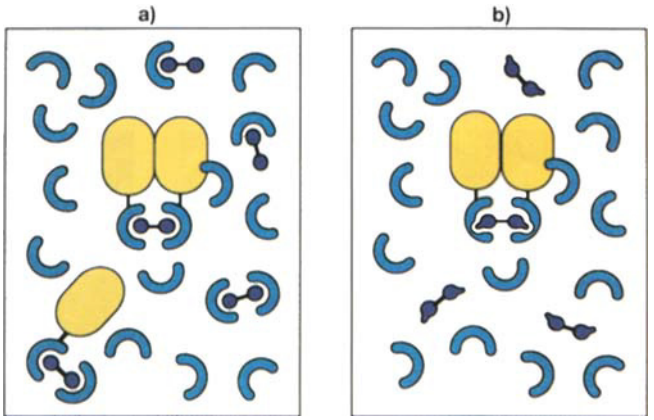

Fig. 2. Improved receptor–ligand pairs for the regulated intracellular protein association with synthetic ligands a) Possible protein associations occurring in cells expressing wild-type immunophilins as dimerization domains. b) Protein associations predicted to occur in cells by using modified CIDs and immunophilins with compensatory mutations.

To solve this problem we envisioned the creation of new receptor–ligand pairs with interacting surfaces that ensure a high degree of specificity. Immunophilin ligands were designed to contain substituents that clash sterically with amino acid sidechains in the immunophilin receptor, thereby abolishing their interaction with endogenous immunophilins. Compensatory mutations in the receptor were sought that would remove the offending interaction, thereby creating a unique receptor that would be used as a dimerization domain (Fig. 2b). Herein, we report the implementation of this strategy using CyP-CsA as a test system. In addition to providing an effective solution to the specific research problem outlined above, we propose that the creation of new receptor–ligand pairs in this manner will result in new experimental systems for testing our understanding of molecular recognition involving protein receptors.

The high-resolution X-ray structure of the CyP-CsA complex[7, 8] served as the starting point for the design of modified ligands. The primary hydrophobic interaction between CyP and CsA involves the sidechain of MeVal11 of CsA and a deep pocket on the receptor that is lined with the hydrophobic residues Phe60, Met61, Ala101, Phe113, and Leu122 (Fig. 3A). Several CsAs with modifications at residue 11 have been synthesized previously.[9] Binding assays showed that an increase in the size of the MeVal11 sidechain abrogated binding to CyP (MeIle11, Me-allo-Ile11), and conversely that compounds with smaller sidechains (MeAla11) still bind with substantial affinity. Our approach would lead to an increase in buried hydrophobic surface, and as hydrophobic interactions can provide a significant contribution to the free energy of binding,[10] this pocket was selected for modification.

For simplicity, the first target selected was MeIle11CsA. A hypothetical model of MeIle11CsA bound to CyP (Fig. 3B) suggests there should be a steric clash between the strategic methyl group of the modified ligand and the phenyl ring of Phe113 of the receptor. Removal of this ring (Phe113 to Ala) should relieve the steric clash (Fig. 3C), yet it should also create a considerable volume of unoccupied space. To minimize these voids and maximize binding energy, two secondary mutations were designed wherein nearby sidechains were increased in size. A Ser99 to Thr mutation (Fig. 3D) adds an extra methylene group and a Cys115 to Met mutation (Fig. 3E) adds two methylenes. Computer models were generated with MacroModel 4.0 by performing Monte Carlo substructure minimizations with all torsions specified for the sidechains of residues MeIle11, Phe60, Met61, Met115, and Thr99. All other atoms within 6 Å of these atoms were considered but were assigned a 100 kJ Å^{-1} movement penalty. These calculations indicated that the conformer required for efficient packing was the one least frequently observed for threonine residues in protein X-ray structures.[11] These modeling studies also predicted that the two secondary mutants could simultaneously assume their preferred conformations, thus the triple mutant was also investigated (Fig. 3F). These mutant proteins were prepared by PCR mutagenesis using the megaprimer method[12] and verified by sequencing.

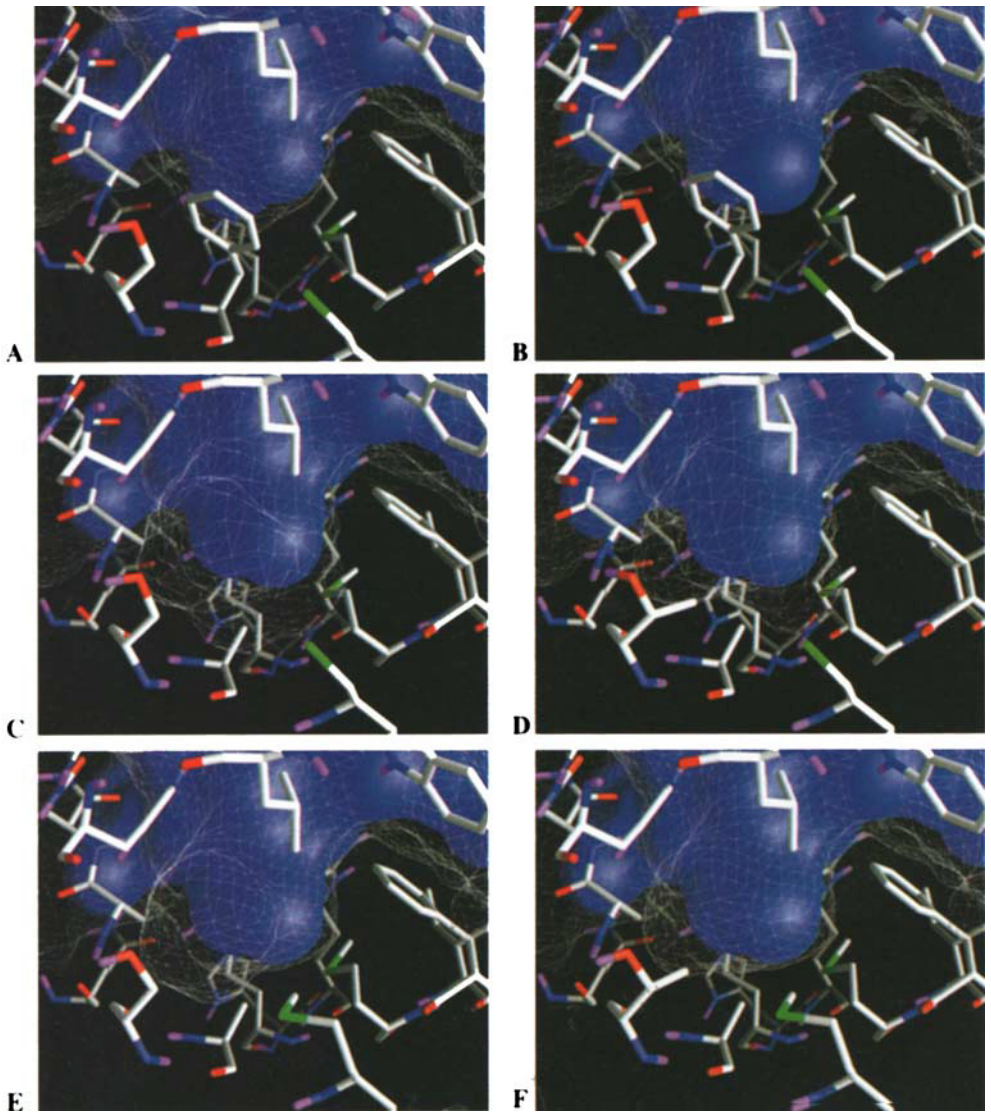

Fig. 3. Graphical representation of the binding interfaces between Cyp and CsA and variants. The solid blue surface and white mesh represent the solvent-accessible surfaces of CsA and Cyp, respectively (nonpolar hydrogens omitted). The contact sidechains of Cyp are represented as tubular bonds and viewed from the inside of the protein; the lowest protrusion of solid blue corresponds to the sidechain of residue 11 of CsA. A) Cyp-CsA crystal structure. B) Hypothetical model of Cyp-MeIle11CsA complex. C) Cyp(F113A)-MeIle11CsA complex. D) Cyp(S99T, F113A)-MeIle11CsA complex. E) Cyp(F113A, C115M)-MeIle11CsA complex. F) Cyp(S99T, F113A, C115M)-MeIle11CsA complex. Graphical representations were created by using GRASP [23].

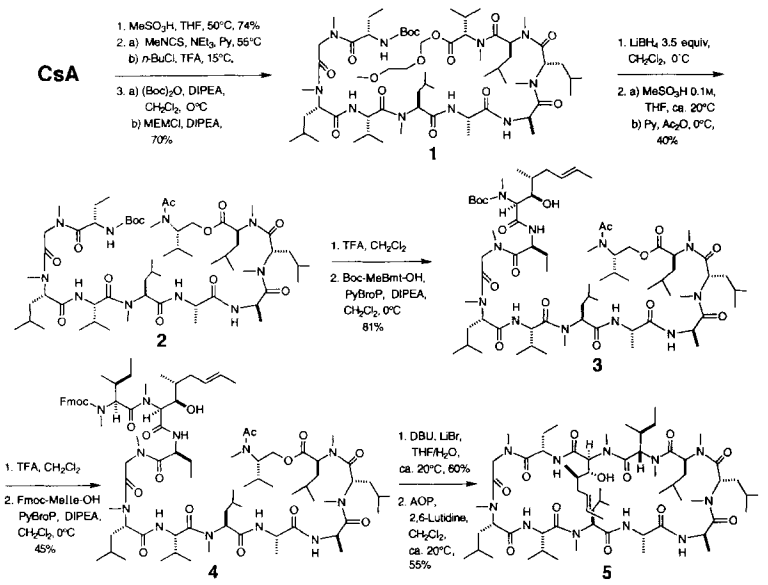
Our synthetic route begins with the readily available CsA, and produces a common intermediate for the synthesis of compounds with modifications at residues 1 and 11 (Scheme 1). This plan is particularly attractive since position 1 is the site we have used previously to prepare dimeric versions of CsA, named (CsA)2.[13] Thus, by using modified amino acids at positions 1 and 11, we should be able to simplify the synthesis of CIDs with greater specificity than (CsA)2. CsA was ring-opened and degraded by first converting it to iso-CsA[14] and then subjecting the resulting amine to a modified Edman degradation sequence.[15] This procedure excises the MeBmt amino acid, producing a linear peptide that was protected at its amino- and carboxy-termini. The selection of the MEM ester was essential for the subsequent reduction,[16] as all other combinations of common esters and reducing agents failed. Following reduction, another acid-catalyzed N to O shift and an N-acylation produced the target intermediate from which CsAs with modifications at residues 1 and/or 11 are accessible. Two cycles of deprotection and coupling

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3419-2130 $ 10.00+.25/0



Scheme 1. Semi-synthesis of MeIle11CsA from CsA. For details see Experimental Procedure.

yielded a linear, protected undecapeptide that was deprotected and cyclized to give MeIle11CsA. This unprecedented cyclization between residues 10 and 11 proceeds with good yield and no detectable racemization. The choice of coupling agent and base proved to be critical for efficient cyclization.[17]

CyP experiences an approximate twofold enhancement in fluorescence upon binding CsA. This effect provides a convenient assay for the determination of K_d values.[18–20] Using this fluorescence assay, the binding constants for MeIle11CsA and CsA with the wild-type and mutant CyP proteins were determined and are shown in Table 1. The data show that the extra methyl group of MeIle11CsA dramatically decreases binding to CyP.

Table 1. Binding constants K_d [nM] of CsA-based ligands for wild-type and mutant CyPs.

Protein	MeIle11CsA	CsA
hCyP(wild-type)	> 3000 [a]	5 ± 1
hCyP(F113A)	53 ± 9	55 ± 15
hCyP(F113A, C115M)	75 ± 13	19 ± 7
hCyP(S99T, F113A)	2 ± 0.5	5 ± 1
hCyP(S99T, F113A, C115M)	4 ± 1	7 ± 1

[a] This value represents the lowest possible value, as precise determination is hindered by the solubility of the ligand.

Mutation of Phe113 to Ala has an even more dramatic effect, restoring the binding affinity to within an order of magnitude of the wild-type receptor. The double mutant CyP(S99T, F113A) binds MeIle11CsA with an affinity of 2 nM. Thus, by adding a substituent to CsA and by creating a binding pocket for it on its receptor using site-directed mutagenesis, a new receptor–ligand pair results that binds with two- to threefold greater affinity than the wild-type system. The other double mutant, CyP(F113A, C115M), has less affinity for MeIle11CsA than the F113A single mutant, indicating that this mutation is slightly destabilizing. This appears to be due to an interfering contact between the terminal methyl of M115 and the terminal methyl of the MeIle11 sidechain. Models show that this interaction is slightly closer than any other contact in the binding pocket, although we cannot rule out a disturbance of the local structure due to the Met. Interestingly, the triple mutant CyP(S99T, F113A, C115M) binds MeIle11CsA more poorly than the double mutant CyP(S99T, F113A), and the free energy difference between these two mutants is approximately the same as the difference between CyP(F113A) and CyP(F113A, C115M). This indicates that the destabilizing effect of the C115M mutation is independent of the S99T mutation. All of the mutants show good binding to CsA with affinity generally increasing as the predicted void volume decreases.

We have successfully generated new high affinity receptor–ligand pairs through structure-guided rational design. By selecting other residues with large, hydrophobic, conformationally constrained sidechains as replacements for MeIle11 and by judicious introduction of point mutations, we may be able to extract even greater free energy gains from the hydrophobic effect. In addition to this goal, we intend to synthesize dimeric versions of these new ligands in order to induce the dimerization of target proteins in vivo, thereby assessing the effect of endogenous immunophilins in these types of experiments. The generation of "bumps" and compensatory "holes" provides a controlled system for studying molecular recognition involving protein receptors. Through the iterative interplay of synthesis, molecular and structural biology, and calorimetry and/or other physical methods, the contribution of specific molecular interactions to the free energy of binding can be assessed.

Experimental Procedure

Fluorescence measurements were made on a Hitachi F2000 fluorescence spectrometer following a 10 min incubation with ligand at 20 °C. Excitation was at 280 nm, 10 nm bandwidth and 33/100 filter. Emissions were scanned at 300–400 nm, 10 nm bandwidth. Proteins were diluted to 3 mL in Tris-buffered saline pH 7.4 at about 100 nM (for $K_d > 10$ nM) or 200–500 nM (for $K_d < 10$ nM). Small aliquots of ligand in 50% ethanol were added between successive measurements such that the total volume added was < 1.5%.

An equation relating the observed fluorescence change (ΔF_{obs}), the total fluorescence change at saturation (ΔF_{sat}), the protein concentration (E_o), the ligand concentration (I_o), and the K_d can be derived from consideration of tight binding kinetics and the assumption that $F_{obs} = (EI)F_{sat}/E_o$ [Eq. (a)].

$$\Delta F_{obs} = [(E_o + I_o + K_d) - \{(E_o + I_o + K_d)^2 - 4(E_o)(I_o)\}^{1/2}]\,(\Delta F_{sat})/2) \qquad (a)$$

The fluorescence change at 338 nm (after adjustment for fluorescence of the ligand solution alone) was plotted vs the concentration of the ligand. The data for each determination of K_d (≥ 14 measurements) were fitted to Equation (a) with Kaleidagraph 3.0. All fits have $r > 0.99$.

Physical data for all compounds are in accord with the expected structures and are available upon request from the authors.

1: To a solution of IsoCsA [14] (2.886 g, 2.401 mmol) in pyridine, (144 mL) triethylamine (7.2 mL) and methyl isothiocyanate (7.2 mL) were added. The solution was heated under nitrogen at 50 °C for 30 min. More triethylamine (2.9 mL) and methyl isothiocyanate (2.9 mL) were added and the reaction mixture was heated for an additional 30 min. Following evaporation at room temperature (RT), the residue was dissolved in chorobutane/trifluoroacetic acid (TFA) (9/1), stirred at 10 °C for 1 h, evaporated, and the residue was precipitated three times from EtOAc/hexane to give the crude precursor of **1**. To this crude product (2.4 g) in dichloromethane (DCM) (100 mL) was added *tert*-butyoxycarbonyl (Boc) anhydride (654 mg, 3.0 mmol) and diisopropylethylamine (DIPEA) (1.4 mL, 8.00 mmol). After 4h at RT, MEMCl (570 μL, 5 mmol) was added and the mixture was stirred overnight. The solution was diluted with DCM (200 mL), washed with sodium bisulfate (1 M), water, sodium bicarbonate (sat.), water, and brine (50 mL each). The organic layer was dried (Na_2SO_4), filtered, and evaporated. The residue was chromatographed (silica gel, DCM/MeOH (98/2, 95/5) to afford **1** (1.933 g, 66 % from IsoCsA).

2: To a solution of **1** (975 mg, 0.795 mmol) in DCM (10 mL), 1 mL of 2 M lithium borohydride in THF was added dropwise at 0 °C. The reaction mixture was stirred overnight at room temperature and an additional 0.5 mL of lithium borohydride solution was added. After 24 h the reaction mixture was cooled to 0 °C and

quenched with a solution of citric acid. The mixture was diluted with DCM (100 mL) and washed with sodium bicarbonate (sat.), water, and brine (25 mL each). The organic layer was dried (Na_2SO_4), evaporated, and the residue was dissolved in DCM/MeOH (98/2) and filtered through a plug of silica gel. Evaporation gave the crude precursor of **2** (773 mg). To this crude product (746 mg) in dry THF (40 mL) was added methanesulfonic acid (300 μL). After stirring the mixture at RT for 72 h under nitrogen, pyridine (400 μL), DIPEA (1.5 mL), and acetic anhydride were added at 0 °C. After 2 h the solution was diluted with DCM (100 mL), washed with sodium bisulfate (1 M), water, sodium bicarbonate (sat.), water, and brine (25 mL each). The organic layer was dried (Na_2SO_4), filtered, evaporated, and chromatographed (silica gel, DCM/MeOH (98/2)) to afford **2** (360 mg, 40 % based on **1**).

3: To **2** (60 mg, 0.051 mmol) in DCM (1 mL), TFA (0.5 mL) was added dropwise and stirred for 1 h at 0 °C. The reaction mixture was diluted with DCM (50 mL) and washed three times with sodium bicarbonate (sat.) then water and brine (10 mL each). The organic layer was dried (Na_2SO_4), evaporated, and redissolved in DCM (0.5 mL). Boc-(2*S*,3*R*,4*R*,6*E*)-3-hydoxy-4-methyl-2-(methylamino)-6-octenoic acid (Boc-MeBmt)[21] (18.7 mg, 0.062 mmol), bromotripyrrolidinophosphonium hexafluorophosphate (PyBroP)[22] (27 mg, 0.060 mmol) and DIPEA (27 μL) were added at 0 °C under nitrogen. After 2 h at 0 °C the reaction was allowed to warm to RT, diluted with DCM (50 mL), washed with sodium bisulfate (1 M), water, sodium bicarbonate (sat.), water, and brine (20 mL each). The organic layer was dried (Na_2SO_4), filtered, evaporated and chromatographed (flash silica gel, EtOAc/acetone (9/1)) to give **3** (56 mg, 81 %).

4: To **3** (27 mg, 0.022 mmol) in DCM (1 mL), TFA (0.5 mL) was added dropwise and stirred for 1 h at 0 °C, diluted with DCM (50 mL) and washed three times with with sodium bicarbonate (sat.), water and brine (10 mL each). The organic layer was dried (Na_2SO_4), filtered and evaporated. To the residue in DCM (30 μL), Fmoc-N-MeIle (12 mg, 0.032 mmol), PyBroP (14 mg, 0.032 mmol) and DIPEA (15 μL) were added and the mixture was stirred for 6 h at 0 °C and 30 min at RT. Fmoc-N-MeIle (5 mg, 0.013 mmol), PyBroP (5 mg, 0.011 mmol) were added again at 0 °C and allowed to warm to RT overnight. The mixture was diluted with DCM (50 mL), washed with sodium bisulfate (1 M), water, sodium bicarbonate (sat.), water, brine (20 mL each). The organic layer was dried (Na_2SO_4), filtered, evaporated, and chromatographed (silica gel, EtOAc/acetone 9:1) to afford **4** (19 mg, 60 %).

5: To **4** (4.6 mg, 0.0028 mmol) in THF/water (10:1, 200 μL), DBU (3 μL) and lithium bromide (2 mg) were added. After stirring overnight at RT, DBU (4 μL) and lithium bromide (3 mg) were added again. After 5 h, the reaction was quenched with acetic acid (20 μL) and purified by reverse-phase HPLC (Beckman ODS ultrasphere 5 μ 10 mm × 25 cm, 0.1 % TFA/MeCN 70/30 → 10/90 in 30 min, 70 °C, 3 runs) to yield the peptide precursor of **5** (2.1 mg, 60 %). A solution of this peptide precursor (1.2 mg, 970 nmol), AOP[17] (4 mg, 0.009 mmol) and 2,6-lutidine (4 μL) in DCM (1.2 mL) was stirred for 48 h at RT. The reaction mixture was quenched with acetic acid (30 μL), the DCM evaporated, and the residue dissolved in acetonitrile and purified by reverse-phase HPLC (Beckman ODS ultrasphere 5 μ 10 mm × 25 cm, 0.1 % TFA/MeCN 70/30 → 10/90 in 30 min. 70 °C) to afford the pure cyclic peptide **5** (0.65 mg, 55 %).

Strong Binding of Paraquat and Polymeric Paraquat Derivatives by Basket-Shaped Hosts**

Albertus P. H. J. Schenning, Bas de Bruin, Alan E. Rowan,* Huub Kooijman, Anthony L. Spek, and Roeland J. M. Nolte

Clip-shaped host molecules of type **1** can bind uncharged aromatic guest molecules, for example resorcinol, by π–π stacking and hydrogen bonding interactions.[1] Basket-shaped derivates of **1** containing crown ether moieties (compounds of type **2**) are, in addition, able to bind alkali metal ions and protonated amines.[2] We report here on the binding affinities of these host molecules towards charged aromatic compounds, such as paraquat **3** and the polymeric paraquat derivatives **4** and

pound **2** is an exceptionally good host for paraquat. This opens the possibility of clipping host molecules of type **2** to polymeric chains containing paraquat units. The X-ray structure and properties of the complex between **2** and paraquat are also presented.

Compounds **1** and **2** were synthesized as described previously.[1, 2] For the synthesis of **2b**, 4,4'-dimethylbenzil was used as the starting material. Compounds **3** and **4** were prepared by using literature procedures.[3, 4] Compound **5** was prepared by the condensation of *N*,*N*'-bis(2-hydroxyethyl)-4,4'-bipyridinium hexafluorophosphate in acetonitrile with one equivalent of adipoyl chloride with triethylamine as the base,[5] and purified by precipitation from ethyl acetate.

Addition of **3**-Cl_2 to a solution of host **2b** in for example methanol/chloroform led to an immediate color change from colorless to yellow-orange, indicative of the formation of a charge-transfer complex.[3] ^{1}H NMR spectroscopic studies revealed that in this complex the paraquat guest is located in the cleft of the cavity.[6] Fast atom bombardment mass spectrometry (FAB MS) showed a peak at *m*/*z* 1094 (matrix: nitrobenzyl alcohol), which corresponds to the mass of the host–guest complex. Crystals of the complex between **2b** and **3**-$(PF_6)_2$ suitable for X-ray analysis were grown from a mixture of **2b** and tetrabutylammonium hexafluorophosphate dissolved in chloroform, which was layered with **3**-Cl_2 dissolved in methanol. The X-ray structure of complex is shown in Figure 1 (top).[7] It reveals a

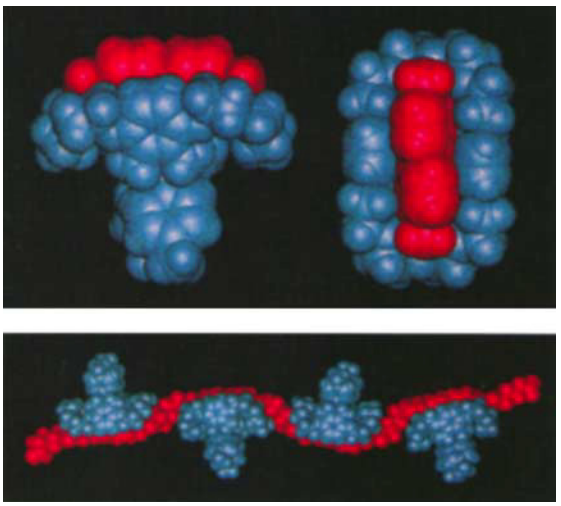

Fig. 1. Top: Crystal structure of the complex between **2b** and **3**-$(PF_6)_2$. Left top view, right side view [14]. Bottom: Computer-generated model of the complex between **2b** and **5**.

perfect complementarity between host and guest. The paraquat guest sits symmetrically within the walls of the basket; the methyl substituents are partially encapsulated by the crown ether rings. The crystal structure is different from that of the complex of paraquat with "bis(paraphenylene)-[34]crown-10" (the same macrocycle as compound **2a**, but without the diphenylglucoluril unit), as published by Stoddart et al.[3] In the case of the latter the bipyridinium guest is flat, whereas in the crystal structure described herein the two bipyridinium units are twisted by an angle of 22.5(3)°. This is a consequence of being less sterically constrained by the aromatic side walls of the basket. In Stoddart's compound the bipyridinium is tilted at an angle of about 28° with respect to the O–O axis of the paraphenylene unit; in our case the bipyridinium guest in the basket is not tilted. The binding constant of the bis(paraphenylene)-[34]crown-10 macrocycle with **3**-$(PF_6)_2$ in acetone is 730 M^{-1}. The binding properties of **1** and **2** were evaluated by recording the intensity of the charge-transfer absorption band at approximately 425 nm at different host–guest ratios. The results for different solvents are presented in Table 1. The basket-shaped host molecules **2** bind paraquat approximately 25–75 times stronger than the bis(paraphenylene)-[34]crown-10 macrocycle.[3] This result can be explained from the fact that compounds **2** are more preorganized for binding than Stoddart's compound.[8] Only a very small K_a of 80 M^{-1} was found for the binding of **3** in the cavity of clip molecule **1**. This clearly demonstrates the importance of the crown ether moieties in **2** for the complexation of paraquat.

Table 1. Binding constants [a] of the complexes between hosts **1** and **2** and guests **3**, **4**, and **5**.

Host	Guest	K_a [M^{-1}]
1	**3**-Cl_2	80 [b]
2a	**3**-$(PF_6)_2$	57000 [c]
2a	**3**-$(PF_6)_2$	20000 [d]
2b	**3**-Cl_2	22000 [b]
2a	**4a** [f]	1800 [c, e]
2a	**4b** [g]	4500 [c, e]
2a	**5** [h]	19000 [c, e]

[a] Association constants were calculated using the Benesi–Hildebrand equation [13]. Good correlations ($R > 0.995$) were obtained for all titration curves assuming a 1:1 host–guest complexation. Estimated error in K_a is 10%. For the K_a measured in acetone, the error is 50% due to the poor solubility of the host molecule in this solvent. [b] Methanol-chloroform (1:1, v/v). [c] Acetonitrile. [d] Acetone. [e] Per polymer repeat unit. [f] Intrinsic viscosity of polymer $[\eta] = 0.006$ dL g^{-1} (acetonitrile, 25 °C). [g] Intrinsic viscosity of polymer $[\eta] = 0.293$ dL g^{-1} (acetonitrile, 25 °C). [h] Average degree of polymerization = 4 (NMR, endgroup analysis).

The electrochemical behavior of the complex between **3**-$(PF_6)_2$ and compound **2a** was studied in acetonitrile. In this solvent the guest showed two reversible one-electron transfers: $E_{1/2}(2+/1+) = -0.423$ V, $E_{1/2}(1+/0) = -0.840$ V (vs. SCE, for both transitions $\Delta E_p = 60$ mV). Upon the addition of one equivalent of **2a** the first redox transfer shifted 100 mV to more negative potential, whereas the second electron transfer potential remained unaffected. These data indicate that **2a** binds and stabilizes the doubly charged paraquat species, which results in a more negative redox potential for the first redox transfer. It is well known that in this type of host–guest system the guest reduced by one electron dissociates form the host, and this explains the unaltered second redox potential.[3]

Polymeric paraquat derivatives have previously been investigated as redox-active films and more recently as optical data storage materials and show a wide variety of electrochromic and thermochromic behavior.[4, 9, 10] The polymeric paraquat derivative with tosylate counterions has been shown to possess liquid crystalline properties.[11, 12] We felt that host–guest complexation might be an interesting way to modify and control the physical properties of this interesting class of polymers. The results of binding studies carried out in acetonitrile, showed that **2a** can be clipped to polymeric paraquat derivatives **4a**, **4b**, and **5** with association constants of 1800 M^{-1}, 4500 M^{-1}, and 19000 M^{-1}, respectively (per polymer repeat unit, see Table 1, Fig. 1). The binding constants of **4a** and **4b** are lower than those observed for paraquat itself. Molecular modeling studies have revealed that in the case of **4a** and **4b**, complexation of a basket to a paraquat unit in the polymer is sterically hindered by baskets complexed to adjacent paraquat units. The overall lower binding constants reflect this steric hindrance, which is less for

the polymer with a longer spacer (**4b**) than for the one with the smaller spacer (**4a**). Viscosity measurements showed that the specific viscosity of the polymers solubilized in acetonitrile increases upon the addition of 0.03 equivalents of the host molecule **2a** per repeat unit: for example, **4a**: $\eta_{sp} = 0.006$, **4a** + **2a** $\eta_{sp} = 0.008$; **4b**: $\eta_{sp} = 0.068$, **4b** + **2a** $\eta_{sp} = 0.070$. These results indicate that the average molecular mass of the polymers increases on complexation with **2a**. The redox potentials of the polymers were also influenced by the hosts. Polymer **4a** displayed the following redox transitions in acetonitrile: $E_{1/2}(2+/1+) = -0.387$ V, $E_{1/2}(1+/0) = -0.840$ V (vs. SCE, for both transitions $\Delta E_p = 60$ mV). Upon the addition of one equivalent of **2a** per repeat unit the first redox transfer shifted 20 mV to more negative potential, whereas the second redox transfer remained unchanged. Addition of three equivalents of **2a** resulted in a 35 mV shift in the negative direction. These shift values are smaller than the 100 mV shift measured for paraquat (**3**) which may be the result of the lower binding affinity of **2a** for the polymeric paraquat derivatives. These preliminary results indicate that the electrochemical behavior of polymeric paraquat derivatives can easily be tuned by the addition of basket molecules. This may be of interest for future application of these polymers as optical data storage systems or as molecular switches, etc.

In conclusion, we have shown that host molecules of the type **2** strongly bind paraquat **3** and that it is possible to clip these molecules to polymeric paraquat derivatives. Further studies are underway.

Formation of a "*meso*-Helicate" by Self-Assembly of Three Bis(catecholate) Ligands and Two Titanium(IV) Ions

Markus Albrecht* and Sirpa Kotila

Double- or triple-helical oligonuclear coordination compounds that are formed spontaneously by self-assembly of two or three oligodentate ligands and several metal ions are called helicates. Due to their helicity, such molecules are chiral.[1] On the other hand, *meso*-helicates are analogous metal complexes with two differently configurated helical units and are thus achiral. In a topological sense, the *meso*-helicates are helices that inverse their helical twist.[2]

An octahedral complex formed by one metal center and three bidentate ligands is the most simple helical unit. It can have two configurations (Δ or Λ).[3] Triple bridging between the ligands of two such octahedrons results in the formation of three different coordination compounds: the enantiomeric Δ,Δ- and Λ,Λ-helicates, and the diasteromeric Δ,Λ-form—the most simple triple-stranded *meso*-helicate (Fig. 1).

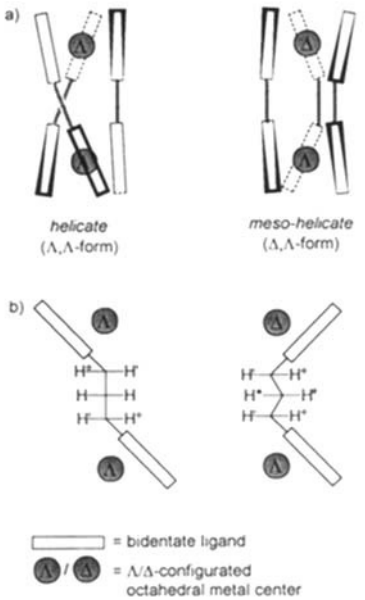

Fig. 1. Schematic representation of a) a helicate (here: Λ,Λ-form) and the corresponding *meso*-helicate (Δ,Λ-form) and b) a binuclear C_3-bridged helicate and *meso*-helicate (only one of the ligand strands is shown).

The coordination chemistry of linear oligodentate nitrogen donor ligands with soft metal ions has recently become the focus of a great deal of attention. To our knowledge, investigations towards the metal-directed self-assembly of helicates have resulted only in the characterization of double-[1, 4] and triple-helical[5] and double-stranded non-helical metal complexes, which do not possess units with helical chirality.[6] In this context, the triple-stranded *meso*-helicate is a missing structural motif.

This stimulated our interest in self-assembly processes based on oxygen donor ligands in combination with hard metal ions.[7, 8] The use of early transition metals should provide access to new supramolecular aggregates, whose properties should differ from those of the "traditional" compounds.

Catechol ligands seem to be ideal bidentate chelating units for this purpose.[8] Initially we chose the $(CH_2)_3$ group as a spacer

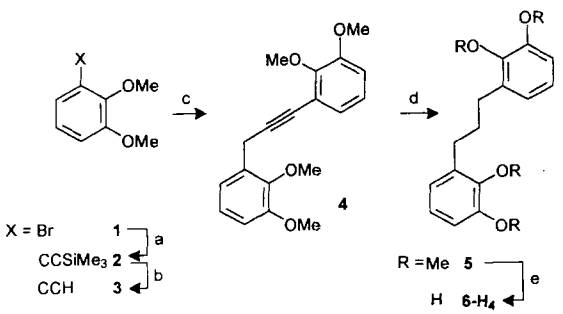
between the aromatic moieties. Additional work concerns the combination of oxygen and nitrogen donor systems in order to obtain sequential ligand strands for use in the formation of oligonuclear metal complexes with a high content of information.[9]

Figure 1b shows a schematic representation of the ligand orientation in triple-stranded helicates and *meso*-helicates with C_3 spacers between the chelating units. In both cases the benzylic protons (H°/H′) are diastereotopic. However, the protons of the central methylene group of the C_3 spacer only show diastereotopic behavior in the *meso*-helicate (H*/H#). In the case of the helicate, these protons (H/H) are enantiotopic. Thus, it should be possible to readily assign the structure in solution by ^{1}H NMR spectroscopy.

The C_3-bridged catechol ligand **6-H$_4$** was synthesized in a reaction sequence starting with a palladium-catalyzed Stephens–Castro coupling reaction of 1-bromo-2,3-dimethoxybenzene (**1**)[10] with trimethylsilylacetylene. Subsequent removal of the silyl group gave the terminal alkyne **3**, which was coupled in the critical step of the reaction with 2,3-dimethoxybenzyl bromide[9] to give 1,3-bis(2,3-dimethoxyphenyl) propyne (**4**). Catalytic hydrogenation of the triple bond and cleavage of the methyl ether of the resulting bis(veratrole) **5** yielded 3,3′-propane-1,3-diylbis(1,2-benzenediol) [1,3-bis(2,3-dihydroxyphenyl)propane] (**6-H$_4$**) (Scheme 1).[11]



Scheme 1. Synthesis of **6-H$_4$**: a) $[Ph_3P)_2PdCl_2]$, CuI, piperidine, trimethylsilyl acetylene (70%); b) K_2CO_3, methanol (96%); c) *n*BuLi, 2,3-dimethoxybenzyl bromide (21%); d) H_2, Pd/C (96%); e) BBr_3 (99%).

The reaction of three equivalents of **6-H$_4$** with two equivalents of titanoyl bis(acetylacetonate) in the presence of two equivalents of potassium or sodium carbonate as a base afforded quantitative yields of red-orange metal complexes. The compounds are highly soluble in methanol or water, indicating that not an unspecific coordination polymer but a well-defined metal complex is formed by self-assembly. The stoichiometry of the potassium salt $K_4[(\mathbf{6})_3Ti_2]$ was determined by elemental analysis, FAB(+) mass spectrometry, and measurement of the molar weight in solution.[11]

The reaction of three equivalents of **6-H$_4$** with only one equivalent each of titanoyl bis(acetylacetonate) and potassium carbonate resulted in the formation of the binuclear metal complex in "positive cooperativity".[1] In the crude product only $K_4[(\mathbf{6})_3Ti_2]$ and ligand **6-H$_4$** were detected (^{1}H/^{13}C NMR).

The ^{13}C NMR spectrum of $K_4[(\mathbf{6})_3Ti_2]$ ([D$_4$]methanol, 100 MHz) shows one set of aromatic resonances at $\delta = 159.2$, 157.3, 127.3 (3 C), 120.5, 118.6, and 110.8 (3 CH), and two signals of methylene groups at $\delta = 34.1$ and 33.3 (double intensity). Thus, the binuclear coordination compound has a high symmetry with six magnetically equivalent catecholate units. This is in accordance with both structures shown in Figure 1 (helicate and *meso*-helicate). It is possible to distinguish between the two structures by ^{1}H NMR spectroscopy in [D$_4$]methanol (400 MHz). At 296 K the resonances of the aromatic moiety are detected at $\delta = 6.38$ (4 H) and 6.23 (2 H) and those of the $(CH_2)_3$ spacer at $\delta = 2.85$ and 2.18 (2 H each, diastereotopic benzylic protons) and 2.15 and 1.57 (1 H each, diastereotopic protons of the central methylene group). The observation of two sets of diastereotopic alkyl protons clearly shows that the complex has two differently configurated metal centers in solution (*meso*-helicate; see Fig. 1).

The corresponding sodium salt $Na_4[(\mathbf{6})_3Ti_2]$ was characterized by an X-ray crystal structure analysis.[12] The crystal contained several partially disordered solvent molecules (six DMF, five water) resulting in a relatively high *R* value of $R = 0.130$. However, comments about the structure of the tetraanion and the positions of the sodium ions can be made unambiguously.

In the crystal, the $[(\mathbf{6})_3Ti_2]^{4-}$ ion adopts the same *meso*-helicate structure as observed in solution. Figure 2 shows the

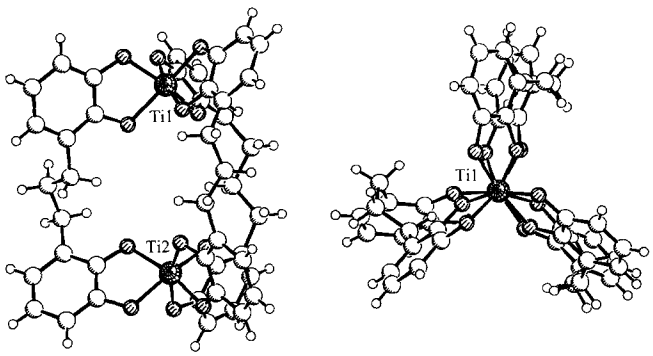


Fig. 2. Molecular structure (SCHAKAL) of the tetraanion $[(\mathbf{6})_3Ti_2]^{4-}$; side view (left) and view along the Ti–Ti axis (right).

two differently configurated pseudo-octahedral titanium(IV) tris(catecholate) moieties.[13] The two complex units are connected through three $(CH_2)_3$ groups. The length of the alkyl spacer might be the reason for the unusual *meso*-helicate structure of this triple-stranded binuclear metal complex. The most favorable conformation that a linear alkyl chain can adopt is a zigzag structure, as observed for two of the bridges in the crystal (the third spacer seems to deviate from this conformation because of interaction with a DMF molecule). This leads in the case of a C_3 chain to the observed *meso*-helicate. In contrast, a chain with an even number of members should favor the formation of helicates. Whether this is true requires further investigation.

Another unusual feature of the structure of the sodium salt are the positions adopted by the cations. Na4 is the only cation to be separated from the anion by coordination to solvent molecules (Fig. 3). Na1 and Na3 are exohedrally bound to the terminal oxygen functionalities of the *meso*-helicate anion. The remaining free valences of these two cations are saturated by solvent molecules. Na1, Na3, and Na4 are surrounded by ligands in a distorted octahedral fashion (Na–O = 219(2)–268(3) pm). However, the most striking position is taken by Na2. It is bound endohedrally in the cavity which is formed by the three ligands **6** and the two titanium(IV) centers. Interactions are observed with three oxygen atoms of the catecholates, one DMF, and one water molecule. The next closest contact to an O atom is observed at 340 pm. Similar to Na2, the water molecule is located inside the cavity and interacts through hydrogen

$m/z = 1021$ $[HK_4[(\mathbf{6})_3Ti_2]^+]$, 1059 $[K_5[(\mathbf{6})_3Ti_2]^+]$; $C_{43}H_{36}K_4O_{12}Ti_2 \cdot 7H_2O$ (1147.1): calcd. Radical C–C Bond Formation by Photoinduced Electron Transfer Addition of α-Silyl Carbamates to Acceptor-Substituted Alkenes**

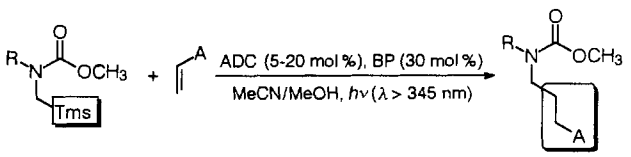
Eric Meggers, Eberhard Steckhan,* and Siegfried Blechert

Light-induced reactions between donor and acceptor molecules form an important chapter in radical ion chemistry.[1] Among these, photoinduced electron transfer (PET) is the basis of a modern method for the formation of radicals under mild conditions.[2] One-electron oxidation generates an intermediate radical cation, which fragments to split off an electrofuge. We have now developed a new method based on this principle for electron transfer catalyzed intermolecular C–C bond formation. On irradiation with UV/Vis light and in the presence of catalytic amounts of 9,10-anthracenedicarbonitrile (ADC) and biphenyl (BP), α-silyl carbamates add to acceptor-substituted alkenes. In this way, γ-acceptor-substituted amino derivatives are formed (Scheme 1).[3]



Scheme 1. PET-catalyzed reaction of α-silyl carbamates with acceptor-substituted alkenes. A = acceptor, Tms = trimethylsilyl. For A and R see Table 1.

We accomplished this transformation using the starting materials listed in Table 1.[4] The results of additional reactions with acceptor-substituted alkenes indicate that this reaction is general. Electron-rich alkenes like cyclohexene and 1-hexene, however, are unreactive.

The following mechanism can be assumed for the reaction: ET quenching between the primary electron donor BP ($E_{ox} = 1.98$ V vs. SCE) and photochemically excited ADC* (E_{red} (S1) = 2.0 V vs. SCE)[5] generates the biphenyl radical cation

Table 1. Addition reactions conducted.

α-Silyl carbamate	Alkene	Addition product [a]		Yield [%]
 **1**			**4**	62 [b]
			**5**	25 [b]
			**6**	46 [b]
			**7**	60–67 [c]
 **2**			**8**	32 [c, e]
 **3**			**9**	ca. 75 [d, e]

[a] All addition products were fully characterized by ^{13}C NMR (DEPT), ^{1}H NMR, and IR spectroscopy, MS and high-resolution MS, and CHN elemental analyses. Because of the instability of **9**, an elemental analysis could not be obtained. For typical data see Experimental Procedure. [b] Yields of isolated products. [c] Yields determined by gas chromatography. [d] The yield was estimated by gas chromatography using the calibration curve for **8**. [e] **9** is formed in a diastereomeric ratio of ca. 2:1, while for **8** only one diastereoisomer could be found.

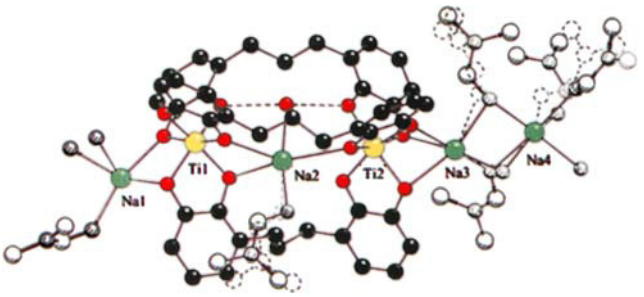

Fig. 3. Molecular structure (SCHAKAL) of the monomeric unit of $Na_4[(\mathbf{6})_3Ti_2]\cdot 6DMF\cdot 5H_2O$. Black: carbon, red: oxygen, yellow: titanium, green: sodium; H atoms are omitted for clarity; solvent molecules are not colored; disorder is indicated by dotted lines. The red-brown dashed lines denote hydrogen bonds.

bonds with two internal oxygen atoms of one of the ligands **6** (Fig. 3, the hydrogen bonds are indicated by dashed lines; $O_{water}\cdots O_{ligand} = 270(2)$ or 277(2) pm, respectively). Na2 shows a distorted trigonal bipyramidal geometry. Thus, $Na_4[(\mathbf{6})_3Ti_2]$ is a further example for a supramolecular device formed by self-assembly, which itself can act as a receptor (*exo* as well as *endo*) towards small ions.[14] The receptor properties of this molecule in solution are currently under investigation.

$Na_4[(\mathbf{6})_3Ti_2]\cdot 6DMF\cdot 5H_2O$ dimerizes in the solid state through bridging of DMF molecules between Na1 and Na1′. The resulting rodlike C_i-symmetric supramolecular species exhibits nanometer scale dimensions (length: 4 nm) and a nearly linear sequence of 12 metal ions (4 Ti and 8 Na) with well-defined intermetallic distances.

The results of ^{1}H NMR spectroscopic investigations of $K_4[(\mathbf{6})_3Ti_2]$ (D_2O, 400 MHz) at variable temperature are shown in Figure 4. At room temperature, the spectrum is similar to that

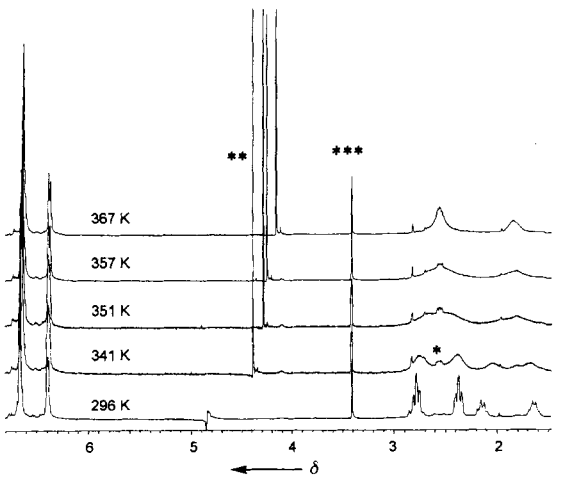

Fig. 4. ^{1}H NMR spectra of $K_4[(\mathbf{6})_3Ti_2]$ at variable temperature in D_2O (*impurity, **DOH, ***methanol).

measured in [D_4]methanol. On heating the sample in the NMR machine, a broadening of the alkyl resonances can be observed. The coalescence temperature of the central methylene group is reached at 356 K, that of the benzylic protons at 357 K ($\Delta G^{\ddagger} = 16.6$ kcal mol^{-1}). Two broad multiplets at $\delta = 2.50$ (4 H, benzylic protons) and 1.88 (2 H, central methylene group) are detected at 367 K. The signals of the aromatic protons do not show any significant changes on warming. The reason for the observed symmetrization of the diastereotopic protons is the inversion of the chiral centers, which are hidden in the achiral *meso*-helicate $[(\mathbf{6})_3Ti_2]^{4-}$ (Λ_1,Λ_2 inverts to Δ_1,Λ_2).[15] The use of the diastereotopic protons as a stereochemical probe allows the inversion of the configuration of the two titanium(IV) centers to be observed directly.

The above-mentioned results clearly reveal that metal-directed self-assembly is not limited to nitrogen donor ligands in combination with soft metal centers. Use of the C_3-bridged bis(catechol) system **6** and hard titanium(IV) ions leads in a highly diastereoselective reaction to the cooperative formation of a binuclear metal complex. This complex does not form the helicate structure, but the *meso*-helicate. With its two differently configurated metal centers, it represents a missing structural motif in the chemistry of helicates. The inclusion of helicate and *meso*-helicate domains in one linear oligonuclear coordination compound might lead to helices containing parts in which the helical twist inverts. This enables a fine tuning of the self-assembly of supramolecular architectures, which can undergo further supramolecular interactions (e.g. with small guest molecules), and therefore is a further step towards a working nanotechnology.[16]

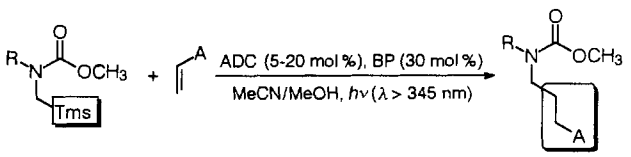
Radical C–C Bond Formation by Photoinduced Electron Transfer Addition of α-Silyl Carbamates to Acceptor-Substituted Alkenes**

Eric Meggers, Eberhard Steckhan,* and Siegfried Blechert

Light-induced reactions between donor and acceptor molecules form an important chapter in radical ion chemistry.[1] Among these, photoinduced electron transfer (PET) is the basis of a modern method for the formation of radicals under mild conditions.[2] One-electron oxidation generates an intermediate radical cation, which fragments to split off an electrofuge. We have now developed a new method based on this principle for electron transfer catalyzed intermolecular C–C bond formation. On irradiation with UV/Vis light and in the presence of catalytic amounts of 9,10-anthracenedicarbonitrile (ADC) and biphenyl (BP), α-silyl carbamates add to acceptor-substituted alkenes. In this way, γ-acceptor-substituted amino derivatives are formed (Scheme 1).[3]



Scheme 1. PET-catalyzed reaction of α-silyl carbamates with acceptor-substituted alkenes. A = acceptor, Tms = trimethylsilyl. For A and R see Table 1.

We accomplished this transformation using the starting materials listed in Table 1.[4] The results of additional reactions with acceptor-substituted alkenes indicate that this reaction is general. Electron-rich alkenes like cyclohexene and 1-hexene, however, are unreactive.

The following mechanism can be assumed for the reaction: ET quenching between the primary electron donor BP ($E_{ox} = 1.98$ V vs. SCE) and photochemically excited ADC* (E_{red} (S1) = 2.0 V vs. SCE)[5] generates the biphenyl radical cation

Table 1. Addition reactions conducted.

α-Silyl carbamate	Alkene	Addition product [a]		Yield [%]
 **1**			**4**	62 [b]
			**5**	25 [b]
			**6**	46 [b]
			**7**	60–67 [c]
 **2**			**8**	32 [c, e]
 **3**			**9**	ca. 75 [d, e]

[a] All addition products were fully characterized by ^{13}C NMR (DEPT), ^{1}H NMR, and IR spectroscopy, MS and high-resolution MS, and CHN elemental analyses. Because of the instability of **9**, an elemental analysis could not be obtained. For typical data see Experimental Procedure. [b] Yields of isolated products. [c] Yields determined by gas chromatography. [d] The yield was estimated by gas chromatography using the calibration curve for **8**. [e] **9** is formed in a diastereomeric ratio of ca. 2:1, while for **8** only one diastereoisomer could be found.

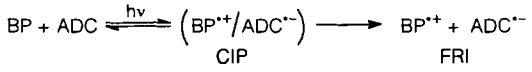
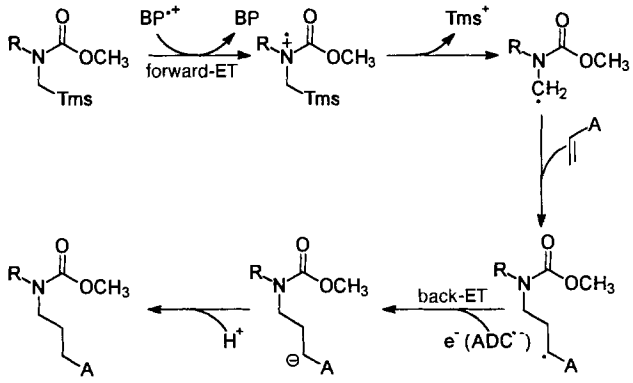
(Scheme 2), which subsequently oxidizes the α-silyl carbamate ($E_{ox} \approx 1.45$ V vs. Ag/AgCl)[6] to give its radical cation through a one-electron transfer reaction (redox photosensitization).[7] After cleavage of the silyl group,[8] the resulting nucleophilic radical is trapped by a compound having an electron-poor



Scheme 2. Redox photosensitization with ADC and BP. CIP = contact radical ion pair, FRI = free radical ions.

double bond. Back electron transfer from an ADC radical anion to the radical addition product and protonation complete the electron transfer catalytic cycle (Scheme 3). An alternative hydrogen abstraction from the solvent at the stage of the α-carbonyl radical cannot be excluded.



Scheme 3. Proposed mechanism for the ET-catalyzed replacement of the silyl group.

As a side product, a Tms/H substitution product is formed in small amounts.[9] The extent of this side reaction depends on the reactivity of the alkene and the alkene concentration. The reactivity of the alkenes towards the intermediate, strongly nucleophilic α-*N*-substituted radical correlates with the electron density at the double bond.[10] With very reactive alkenes oligo- and polymerization occurs. In these cases the reaction can be accomplished by modifying the reaction procedure. When the alkene is added continuously during the course of the irradiation, the yield of the reaction between **1** and *N*-methyl maleimide depends strongly on the rate of addition (Fig. 1).[11]

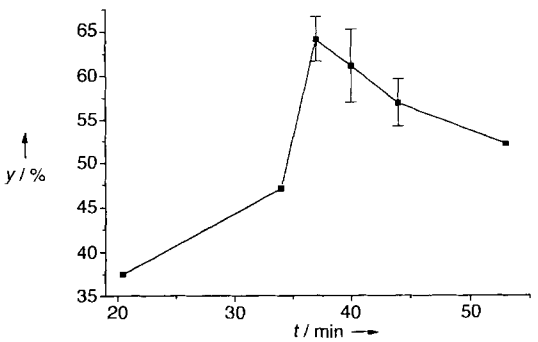


Fig. 1. Dependence of the yield y of **7** on the rate of addition t of the reactive *N*-methyl maleimide. Addition rate = time after which 1.1 equivalents of alkene had been added by continuous addition.

We conducted the reaction with other photosensitizers besides ADC and BP. The reaction between **1** and dimethyl maleate was applied as a test system.[12] Only with 2,4,6-triphenyl-*N*-methylpyridinium tetrafluoroborate (TPNMP)[13] as sensitizer could we obtain results comparable with those of the cosensitization by ADC/BP (Fig. 2). All of the tested excited

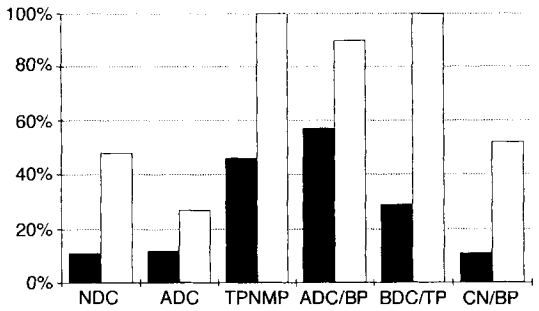

Fig. 2. Comparison of the results obtained with different sensitizers for the photosensitized reaction of **1** and dimethyl maleate giving **4**. NDC = 1,4-naphthalenedicarbonitrile, BDC = 1,4-benzenedicarbonitrile, TP = triphenylene, CN = 1-naphthalenecarbonitrile, black bar = yield, white bar = conversion.

sensitizers are thermodynamically capable of oxidizing the α-silyl carbamates.[14] However, the usually very fast back electron transfer within the intermediate solvated radical ion pair CIP is a substantial and often limiting problem (Scheme 2). In contrast, the sensitizer pair ADC/BP provides a very high quantum yield for the formation of the free radical ions after induction by SET.[15] The resulting free biphenyl radical cation is then able to oxidize the α-silyl carbamate under diffusion control. In this way, BP acts as a very efficient mediator for the PET reaction between ADC and a secondary electron donor.

The reaction described here obviously offers a general and mild method for PET-catalyzed intermolecular C–C bond formation. Presently we are studying the application of this reaction to other substrates like α-silyl ethers and α-silyl sulfides.

Experimental Procedure

A 450 W Xenon lamp with a wavelength filter was used as a light source. The solutions were degassed with argon prior to and during irradiation and thermostated in a water bath.

4 (analogous for **5** and **6**): α-Silyl carbamate **1** (122 mg, 0.5 mmol), dimethyl maleate (140 mg, 1 mmol), BP (23.1 mg, 0.15 mmol), ADC (11 mg, 0.05 mmol), and 6 mL of MeCN/MeOH (2:1) were mixed in a Duran glass test tube and irradiated with stirring and water cooling for 7 h (filter for $\lambda > 345$ nm). After one-half of the irradiation time another portion (11 mg) of ADC was added. Subsequently, the solvent was removed by distillation. The residue was dissolved in a small amount of diethyl ether and filtered to remove the precipitated ADC. Flash chromatography on silica gel using petroleum ether (40/60)/ethyl acetate (10:3) ($R_f = 0.25$) provided a light yellow oil (98.5 mg, 62%). ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.95$–1.85 (m, 10H), 2.5 (dd, $J = 17$, 4.8 Hz, 1H), 2.7 (dd, $J = 17$, 8.7 Hz, 1H), 3.1 (br., 1H), 3.4 (m, 2H), 3.66 (s, 6H), 3.68 (s, 3H), 3.7 (br., 1H); ^{13}C NMR (50.3 MHz, $CDCl_3$): $\delta = 25.14$, 25.76, 30.55, 33.32, 41.68, 44.84, 51.55, 51.74, 52.22, 56.89, 156.28, 171.91, 173.49; IR (NaCl): $\tilde{\nu} = 2934$, 2857, 1741, 1701, 1439, 1167, 1010, 895, 774 cm^{-1}; MS (180 °C, EI/DE): *m/z* (%): 315 (2), 272 (21), 256 (35), 202 (22), 200 (12), 170 (93), 159 (20), 127 (17), 114 (11), 88 (100), 83 (14), 71 (10), 59 (16), 55 (24); High-resolution MS (70 °C, EI/DE): calcd for $C_{15}H_{25}NO_6$) 315.1682, found 315.1682; CHN analysis: calcd C 57.11, H 7.99, N 4.44; found C 57.43, H 7.97, N 4.38.

7: Compound **1** (10 mg, 0.041 mmol), BP (2.5 mg, 0.016 mmol), and ADC (ca. 1 mg, 0.004 mmol) were mixed in 5 mL of MeCN/MeOH (3:2) in a Duran glass test tube. A solution of *N*-methyl maleimide (5 mg, 0.045 mmol) in 3 mL of MeCN/MeOH (3:2) was added dropwise and continuously while the reaction mixture was irradiated for 40 min ($\lambda > 345$ nm) (see Fig. 1). After flash chromatography on silica gel using cyclohexane/ethyl acetate (5:1), the addition product was obtained.

8: A solution of **2** (10 mg, 0.038 mmol), *N*-methyl maleimide (2.5 mg), BP (1.85 mg, 0.012 mmol) and ADC (ca. 1 mg, 0.004 mmol) in 5 mL of MeCN/MeOH (3:2) was

irradiated over 2 h ($\lambda > 345$ nm), during which additional *N*-methyl maleimide (3×2.5 mg, altogether 0.09 mmol) was added at 30 min intervals. The addition product was isolated by flash chromatography on silica gel with ether/cyclohexane (2:1).

9: A solution of **3** (15 mg, 0.051 mmol), *N*-methyl maleimide (4 mg), BP (2.3 mg, 0.015 mmol), and ADC (ca. 2 mg, 0.009 mmol) in 5 mL of MeCN/MeOH (3:2) was irradiated over a period of 2.25 h ($\lambda > 345$ nm). In analogy to the synthesis of **8** more *N*-methyl maleimide was added at 45 min intervals (2×4 mg, altogether 0.11 mmol).

The reactions were scaled up successfully; however, when the very reactive *N*-methyl maleimide was used (addition compounds **7**, **8**, and **9**), the reaction conditions had to be reoptimized.

Synthesis of the First Adducts of the Dimetallofullerenes $La_2@C_{80}$ and $Sc_2@C_{84}$ by Addition of a Disilirane**

Takeshi Akasaka,* Shigeru Nagase,* Kaoru Kobayashi, Toshiyasu Suzuki, Tatsuhisa Kato, Koichi Kikuchi, Yohji Achiba, Kazunori Yamamoto, Hideyuki Funasaka, and Takeshi Takahashi

Endohedral monometallofullerenes, fullerenes with a metal inside the carbon cage, have long attracted special interest because they could give rise to new species or materials with novel properties.[1] Considerable interest is now directed toward the characterization of dimetallofullerenes containing two metal atoms inside the cage.[2–6] Recent important progress is marked by the successful isolation and purification of $La_2@C_{80}$[3] and $Sc_2@C_{84}$[4a, 5] in large quantities. Little is known about the physical properties[3] of these dimetallofullerenes and there are no reports concerning the chemical properties of these species. Very recently, we succeeded in the chemical derivatization of the monometallofullerenes $La@C_{82}$[7] and $Gd@C_{82}$,[8] giving exohedral adducts. This has prompted us to investigate how the reactivities of fullerenes change when two metal atoms are inside the cage. We report here the first exohedral functionalization of $La_2@C_{80}$ and $Sc_2@C_{84}$.

A solution of $La_2@C_{80}$ and an excess of 1,1,2,2-tetramesityl-1,2-disilirane (**1**)[9] in 1,2-dichlorobenzene was irradiated ($\lambda > 400$ nm) at 20 °C. The positive-ion FAB mass spectrum of the product verifies the formation of the 1:1 adduct, $La_2@C_{80}(Mes_2Si)_2CH_2$ (*m/z* 1784–1788) (Fig. 1). No molecular ion peaks ascribable to the multiple-addition products such as $La_2@C_{80}[(Mes_2Si)_2CH_2]_2$ were observed. The ion peak at *m/z* 1238–1242 due to $[La_2@C_{80}]^+$ is a base peak similar to the $[La@C_{82}]^+$ base peak of the exohedral adduct $La@C_{82}(Mes_2Si)_2CH_2$.[7] In both cases strong fragmentation peaks result due to loss of the exohedral functional group $(Mes_2Si)_2CH_2$ from the adduct. The observed ion intensity ratio of a group of molecular peaks for $La_2@C_{80}(Mes_2Si)_2CH_2$ agrees with the ^{13}C isotope distribution.[10] Very similar results were also obtained with $Sc_2@C_{84}$. It is noteworthy that the dimetallofullerenes $La_2@C_{80}$ and $Sc_2@C_{84}$ are also functionalized by photochemical reaction with **1** to give the adducts $La_2@C_{80}(Mes_2Si)_2CH_2$ and $Sc_2@C_{84}(Mes_2Si)_2CH_2$, respectively. These successful exohedral derivatizations of endohedral dimetallofullerenes should open the way to new organodimetallofullerenes which may have applications in materials science and biochemistry.

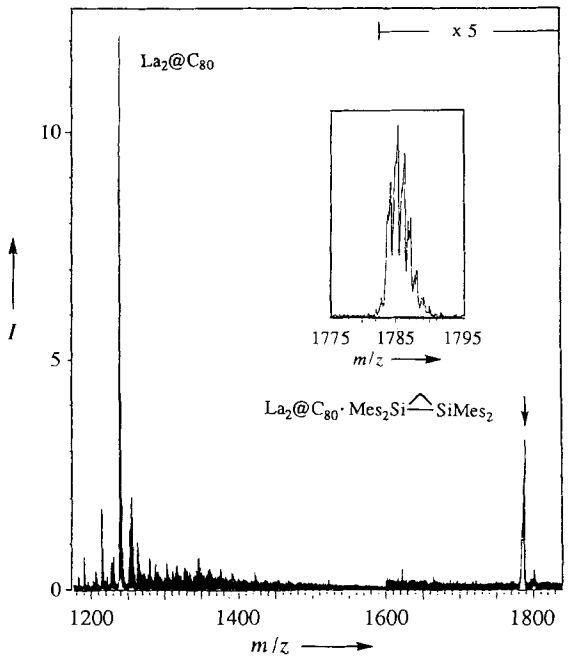

Fig. 1. FAB mass spectrum of the adduct $La_2@C_{80}(Mes_2Si)_2CH_2$ in the range m/z 1200–1850. Inset: Expanded view of the region m/z 1775–1795.

To disclose further interesting properties of dimetallofullerenes, we examined the thermal reaction with **1**. $La_2@C_{80}$ was revealed to have a remarkable feature not found for the empty fullerenes C_{60}, C_{70}, C_{76}, C_{78}, C_{82}, and C_{84} (Table 1). The empty fullerenes reacted with **1** only photochemically, whereas $La_2@C_{80}$ was also thermally reactive toward **1**. When a solution of $La_2@C_{80}$ and **1** in 1,2-dichlorobenzene was heated at 80 °C for 1 h, an adduct formed which was verified by FAB mass spectrometry. The thermal reaction of $La_2@C_{80}$ with **1** can be explained by its strong electron-acceptor character. Ab initio molecular orbital calculations show that the LUMO level of $La_2@C_{80}$ is 1–2 eV lower than those of the empty fullerenes. This is consistent with the fact that the reduction potential of $La_2@C_{80}$ (−0.31 V)[3] is lower than those of the empty fullerenes (Table 1).[11] Even though the oxidation potential of $Sc_2@C_{84}$ is almost as same as that of $La_2@C_{80}$, thermal addition of **1** onto $Sc_2@C_{84}$ is restrained, as in the empty fullerenes, due to its higher reduction potential. This can be also confirmed by the higher LUMO level of $Sc_2@C_{84}$.[12] In this context, it is not surprising that both $La@C_{82}$[7] and $Gd@C_{82}$[8] react thermally with **1**, since they have low reduction potentials comparable to that of $La_2@C_{80}$ (Table 1). This suggests that the thermal additions of **1** are initiated by electron transfer from **1** to metallofullerenes with strong electron-acceptor character.

Table 1. Reactivities, redox potentials [V], and HOMO and LUMO levels [eV] of selected metallofullerenes and empty fullerenes.

Cmpd.	Reactivity light	Reactivity heat	E_{ox} [b]	E_{red} [b]	HOMO	LUMO
$La_2@C_{80}$	+	+	+0.56 [c]	−0.31 [c]	−7.18	−2.55
$Sc_2@C_{84}$	+	−	+0.53	−0.97 [d, e]	−6.77	−1.38
C_{60}	+	−	+1.21 [d, e, f]	−1.12 [f]	−8.33	−0.63
C_{70}	+	−	+1.19 [f]	−1.09 [f]	−7.97	−0.84
C_{76}	+	−	+0.81 [c]	−0.94 [c]	−7.42	−1.13
C_{78}	+	−	+0.85	−0.73	−7.44	−1.49
C_{82}	+	−	+0.72	−0.69	−7.36	−1.52
C_{84}	+	−	+1.04 [d, e]	−0.75	−7.79	−1.34
$La@C_{82}$	+	+	+0.07 [f]	−0.42 [f]		
$Gd@C_{82}$	+	+	+0.09 [g]	−0.39 [g]		

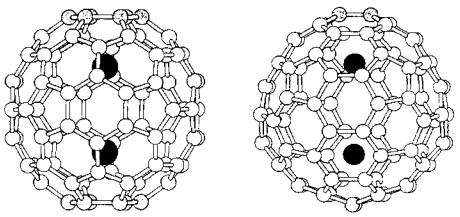
[a] +: formation of a 1:1 adduct; −: no formation of a 1:1 adduct and also no change of the starting fullerene. [b] Half-cell potentials obtained by cyclic voltammetry unless otherwise stated. [c] Ref. [3b]. [d] Values were obtained by differential pulse voltammetry. [e] Irreversible. [f] Ref. [16]. [g] Ref. [8].

The details of the structures of these adducts remain to be resolved, yet this successful chemical derivatization of dimetallofullerenes is an important stepping-stone on the way to a variety of new chemical entities with novel properties, and should enrich the chemistry of metallofullerenes. Especially interesting for future applications is the strong electron-accepting power of $La_2@C_{80}$,[13] since its reactivity should differ significantly from that of empty fullerenes.

Experimental Procedure

$La_2@C_{80}$ [3], $Sc_2@C_{84}$ [14], and the empty fullerenes [15] were produced and purified according to our recently developed method. A degassed solution of $La_2@C_{80}$ (0.1 mg, 10^{-4} M) and an excess of 1,1,2,2-tetramesityl-1,2-disilirane (**1**) [9] in 1,2-dichlorobenzene in a sealed tube was photoirradiated at 20 °C with a tungsten–halogen lamp ($\lambda > 400$ nm). The color of the solution did not change from dark brown. The reaction product was isolated by flash chromatography on silica gel using toluene as eluent and analyzed by positive-ion FAB mass spectrometry (JEOL SX-102) using *m*-nitrobenzyl alcohol as matrix. Redox potentials were measured according to the method reported before [3,8,16]. The FAB mass spectrum of $Sc_2@C_{84}(Mes_2Si)_2CH_2$, and the cyclic voltammograms and differential pulse voltammograms of $Sc_2@C_{84}$ are available from the author (T. A.) upon request.

Calculations were carried out at the Hartree-Fock level using the Gaussian 92/DFT program [17]. The effective core potentials were described by the basis sets (5s5p5d)/[4s4p3d] for Sc and by (5s5p3d)/[4s4p3d] for La in standard notation [18]. The split-valence 3-21G basis set was used for C [19]. The geometries were fully optimized for C_{60} (I_h), C_{70} (D_{5h}), C_{76} (D_2), C_{78} (C_{2v}), C_{82} (C_2), C_{84} (D_{2d}), $La_2@C_{80}$ (D_{2h}), and $Sc_2@C_{84}$ (D_{2d}). The initial geometries of $La_2@C_{80}$ [3] and $Sc_2@C_{84}$ [6], in which two metal atoms are placed inside the I_h and D_{2d} cages of C_{80} and C_{84}, respectively, were taken from our previous studies. The resultant optimized structures of $La_2@C_{80}$ and $Sc_2@C_{84}$ are shown in Figure 2. The frontier orbitals indicate that the disilirane can add at several positions.



$La_2@C_{80}$ $Sc_2@C_{84}$

Fig. 2. The optimized structures of $La_2@C_{80}$ (D_{2h}) and $Sc_2@C_{84}$ (D_{2d}). In $La_2@C_{80}$ the La-La distance is 3.655 Å, and the La atoms (black) are 2.567–2.598 Å away from the carbon atoms that are shaded gray in the representation (C–C = 1.453–1.479 Å). In $Sc_2@C_{84}$ the Sc–Sc distance is 4.029 Å, and the Sc atoms are 2.358 Å away from the carbon atoms that are shaded gray in the representation (C–C = 1.434 Å). The electronic structures in the singlet ground states are formally described as $(La^{3+})_2C_{80}^{6-}$ and $(Sc^{2+})_2C_{84}^{4-}$.

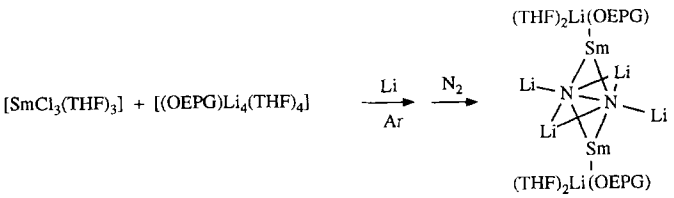
The First Dinuclear Low-Valent Samarium Complex with a Short Sm–Sm Contact**

Jae-Inh Song and Sandro Gambarotta*

The impressive variety of transformations discovered during the last decade for divalent samarium[1] has acted as a potent stimulus for the synthesis of further Sm^{II} complexes. In this paper, we describe the preparation and characterization of the dimer $[(OEPG)Sm_2(Et_2O)_2]$ (OEPG-H_4 = octaethylporphyrinogen). To our knowledge this is the first crystal structure of a dinuclear complex of a divalent lanthanide with a short intermetallic distance. Two aspects of our study are of particular interest.

Firstly, the remarkable chemical behavior of this divalent metal can be well-rationalized by assuming that samarium(II) has a radical-like nature[2] which, however, cannot be explained on the basis of its f^6 electronic configuration. No information is available for divalent lanthanides, but the f electrons are deep within the electron cloud and subjected to a small crystal field. Theoretical work has recently suggested that f orbitals may play an important role in forming metal–metal bonds in bridged actinide complexes.[3] Therefore, we became interested in probing the ability of low-valent lanthanides to form dimers with short M–M contacts.

Secondly, the reaction of OEPG-Li_4 with $[SmCl_3(THF)_3]$ forms a complex which, upon reduction, yielded a dinuclear complex with a side-on bound dinitrogen ligand.[4] In this structure, the dinitrogen ligand is encapsulated inside a Sm_2Li_4 octahedron (Scheme 1). The very long N–N distance (1.525 Å),



Scheme 1. OEPG-H_4 = Octaethylporphyrinogen.

indicative of a significant reduction of dinitrogen, is in sharp contrast to that found in $[(Cp^*_2Sm)_2(N_2)]$ ($Cp^* = C_5Me_5$), which also contains a side-on dinitrogen ligand but with a very short N–N distance (1.088 Å).[5] In addition, the recently reported reversible side-on coordination of dinitrogen to a cationic dilithium unit[6] suggested to us that the four lithium atoms of $[\{(OEPG)Sm[Li(THF)_2]\}_2(N_2Li_4)]$ may play an important role, not only for the assembly of the dinuclear structure through a network of bridging interactions, but also for the stabilization of the dinitrogen moiety itself. To evaluate the role of the lithium atoms in the stabilization of the dinitrogen units, it was important to attempt the preparation of a samarium(II) OEPG complex in the absence of alkali cations.

The reaction of $[(\{Me_3Si)_2N\}_2Sm(tmeda)]$,[7] conveniently prepared in situ, with 0.5 equiv of OEPG-H_4 proceeded at room temperature under either N_2 or Ar atmosphere. When the reactants were mixed the color changed from purple-blue to intense red, and well-formed, deep-red, very air-sensitive crystals formulated as **1** were isolated in reasonable yield (57%) upon crystallization from ether. While the IR spectrum of **1** shows the characteristic absorptions of the OEPG ligand at 3075, 1035, and 570 cm^{-1}, the ^1H NMR spectrum is uninformative, showing broad resonances spread over a rather large range. The formula of **1** was therefore inferred from the analytical data. The complex was EPR-silent in both the solid state and in solution, and showed unusually low paramagnetism[9] in the solid state ($\mu_{eff} = 1.95\ \mu_B$ per dimer, at room temperature),[9] possibly indicating the presence of a rather strong magnetic coupling. However, variable-temperature measurements of the magnetic susceptibility (162–288 K) carried out in toluene gave a plot in

good agreement with the Curie–Weiss law, with a large negative intercept ($\theta = -153$ K).

The molecular structure of **1**, as determined by X-ray diffraction methods,[10] consists of an almost linear $Sm_2(Et_2O)_2$ unit surrounded by an OEPG tetraanion ligand (Fig. 1). The porphyrinogen ligand is centered on the Sm–Sm vector and adopts an almost symmetric conformation; each pair of pyrrole rings at the opposite positions of the macrocycle are nearly parallel to

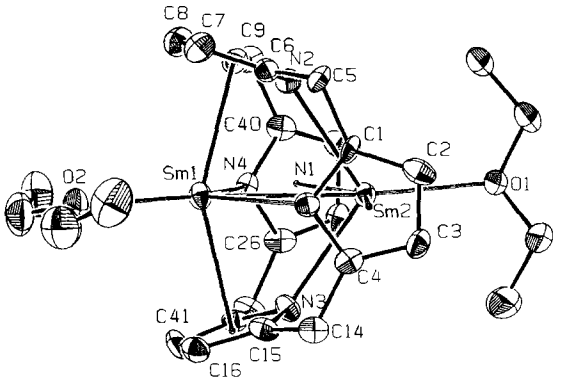

Fig. 1. Crystal structure of **1** (ORTEP representation; ethyl groups have been omitted for clarity). Selected bond lengths [Å] and angles [°]: Sm1-Sm2 3.3159(5), Sm1-N1 2.703(5), Sm1-N4 2.705(5), Sm2-N2 2.707(5), Sm2-N3 2.707(5), Sm1-N2 2.847(5), Sm1-C6 2.957(6), Sm1-C7 3.063(6), Sm1-C8 3.062(5), Sm1-C9 2.948(5), Sm1-O2 2.586(5), Sm2-O1 2.588(4); Sm1-Sm2-O1 173.5(1), Sm2-Sm1-O2 173.9(1), N1-Sm1-N4 109.8(1), N1-Sm1-O2 119.7(2), O2-Sm1-N4 130.4(1).

each other. Each pair of rings coordinates one of the two Sm atoms in an η^5 fashion, ultimately forming a bent samarocene-like structure. The two N atoms of each pair of parallel pyrrole rings are also σ-bonded to the second samarium atom, which is therefore connected to the four pyrrole rings in an η^1,η^5-bonding fashion. The second set of pyrrole rings displays an identical arrangement with the second samarium atom. The coordination environment around each samarium may be considered as severely distorted trigonal bipyramidal; the two σ-bonded nitrogens and the oxygen atom of the ether define the equatorial plane, and the two centroids of the two η^5-bonded rings occupy the axial positions.

Although complex **1** has two samarium(II) centers and the OEPG ligand, it has a short Sm–Sm contact and does not coordinate dinitrogen, thus indicating that Li cations indeed play a crucial role in N_2-fixing systems. Short intermetallic contacts are encountered only rarely in lanthanide chemistry even though these metals tend to form polynuclear aggregates.[11] Yet a Sm–Sm distance as short as 3.49 Å[13] and a Yb–Yb distance of 3.0 Å[12] have been found in two trivalent complexes. Conversely, complexes with divalent lanthanides are mainly mononuclear,[13] and the few dinuclear complexes reported in the literature have fairly long intermetallic distances.[7, 14] The Sm–Sm distance of complex **1** (Sm1–Sm2 = 3.3159(5) Å) is quite short, and given the size of the $Sm^{(II)}$ atom,[15] might be considered within the bonding range. For example, dinuclear and diamagnetic complexes of trivalent zirconium (with a covalent radius significantly smaller than that of samarium(II)[15] show intermetallic distances ranging from 3.2 to 3.6 Å[16] and are believed to have a Zr–Zr bond.[17] By analogy, the short Sm–Sm distance in **1** along with its low paramagnetism (consistent with one unpaired electron per dinuclear complex) suggest the presence of a Sm–Sm interaction.

Experimental Procedure

1: Upon addition of $(Me_3Si)_2NLi$ (6.0 g, 36.0 mmol) to an emerald-green suspension of $[SmI_2(tmeda)_2(THF)]$ (12.7 g, 17.9 mmol) in THF (100 mL) at room temperature the reaction mixture turned purplish-blue. The mixture was allowed to stir for 2 h at room temperature. Solid OEPG-H_4 (4.7 g, 8.8 mmol) was added to the suspension upon which it turned intense red. The mixture was stirred ca. 12 h at room temperature. The solvent was evaporated in vacuo and the residual solid resuspended in Et_2O (100 mL). The resulting intense red solution was filtered and cooled to −15 °C to give dark red crystals of **1** (5.1 g, 5.0 mmol, 57% based on OEPG). Anal. for $C_{44}H_{68}N_4Sm_2O_2 \cdot 0.5(Et_2O)$: calcd (found): C 54.02 (53.96), H 7.19 (7.17), N 5.48 (5.43). IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3075 (w), 1593 (w), 1261 (s), 1159 (m), 1091 (vs), 1035 (s), 1018 (s), 927 (w), 889 (m), 796 (s), 755 (s).

An Yttrium-Based Strong Lewis Acid for the Heterogeneous Catalysis of the Diels–Alder Reaction**

Alive Keshavaraja, Vishnumurthy R. Hegde, Bipin Pandey,* Arumugamangalam V. Ramaswamy,* Pradeep Kumar, and T. Ravindranathan*

While yttrium has gained considerable prominence in superconductivity research in recent times,[1] very little is known about its application in organic chemistry.[2] Indeed, recent efforts by Evans et al.[3] to use YI_3 as a catalyst for stereoselective reduction in the presence of a suitable auxiliary and by Kobayashi et al.[4] to use $Y(OTf)_3$ (Tf = trifluoromethanesulfonyl) as a Diels–Alder catalyst were unsuccessful. Since yttrium with its vacant d orbitals offers opportunities for forming strong Lewis acid sites in a heterogeneous catalyst, development of such a catalyst is highly desirable for organic synthetic transformations. Here, we report on the synthesis and characterization of the first yttrium-based strong Lewis acid catalyst and its applications mainly in Diels–Alder reactions and one example of a hetero-Diels–Alder reaction. The acidity of the catalyst has been demonstrated by FTIR studies,[5] potentiometric titration,[6] and temperature-programmed desorption (TPD)[7] of ammonia, whereas its surface area has been determined by the N_2 adsorption (BET) method.[8]

The catalyst was prepared by treating a mixture of aqueous solutions of yttrium nitrate and zirconyl nitrate (molar ratio 16:84) with aqueous ammonia (28%) under vigorous stirring until a pH value of 8.5 was achieved and a precipitate was formed. This precipitate was washed with deionized water, dried at 110 °C, treated with 2 N sulfuric acid, dried again at 120 °C for 24 h, and subsequently was heated to 500 °C at a programmed heating rate of 2 °C min^{-1} and then calcined for 3 h. This resulted in a highly acidic catalytic material, whose chemical composition (determined by X-ray fluorescence) was found to be 82.6 mol % Zr, 15.6 mol % Y, and 1.8 mol % S. The physicochemical characterization of the catalyst was carried out by X-ray powder diffraction, FTIR, potentiometric titrations, temperature-programmed desorption (TPD), scanning electron microscopy (SEM), and N_2 adsorption techniques. The X-ray powder diffraction profile of the catalyst shows the formation of a cubic phase (Fig. 1). The IR spectra of pyridine adsorbed on the catalyst show absorption bands at 1640, 1605, 1577, 1542, 1490, and 1444 cm^{-1} (Fig. 2). The strong absorption bands at

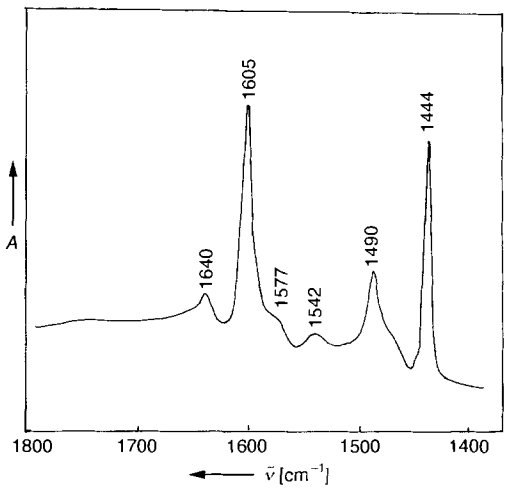

Fig. 2. FTIR spectrum of pyridine adsorbed on the yttrium-based catalyst, recorded on a Nicolet 60 SXB FTIR spectrometer. A = absorption (arbitrary units).

1605 and 1444 cm^{-1} indicate the presence of coordinated pyridine at the Lewis acid sites of the catalyst. The weak absorption at 1542 cm^{-1}, attributed to the pyridinium ion,[5] indicates the presence of a few Brönsted acid sites. The potentiometric titration of the acid sites with *n*-butylamine in nonaqueous medium (Fig. 3) shows the influence of yttrium in enhancing the number of acid sites. The amount of *n*-butylamine consumed was 7.7 mol equiv g^{-1} for the yttrium-based catalyst compared to 5.8 mol equiv g^{-1} for the yttrium-free catalyst. The presence of very strong acid sites in the catalyst is indicated by the peak maxima at 530 °C in the TPD profile (Fig. 4).[7] The scanning electron micrograph of the sample shows the presence of uni-

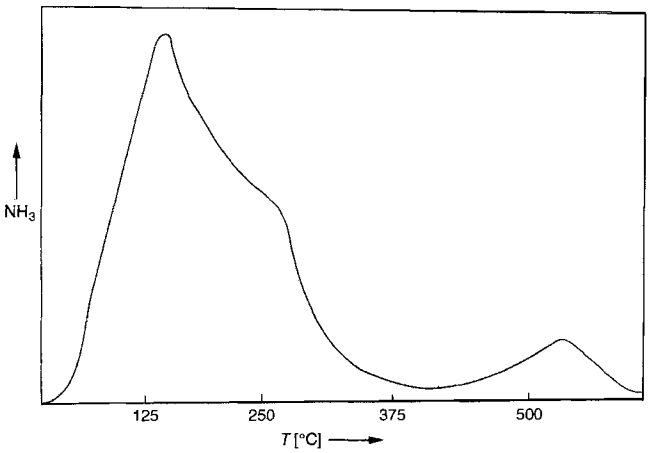

Fig. 4. TPD profile (ammonia) of the yttrium-based catalyst, recorded on a Sorbstar apparatus, Institute of Isotopes, Hungary, with He as the carrier gas, a flow rate of 50 mL min^{-1}, and a heating rate of 10 K min^{-1} from room temperature to 625 °C. NH_3 = amount of ammonia desorbed (arbitrary units).

form-sized (around 0.3 μm) particles (Fig. 5). The surface area[8] of the sample determined by the BET method was 150 m^{2}g^{-1}. The lattice defects caused by the incorporation of yttrium in the Zr^{4+} sites appear to enhance the number and strength of the Lewis acid sites of the catalyst.

The Diels–Alder reaction and its variants like the intramolecular, hetero-, inverse-electron demand, and asymmetric Diels–Alder reactions offer considerable opportunities to organic chemists for the construction of complex structures. In last few years there has been a tremendous upsurge in the interest in

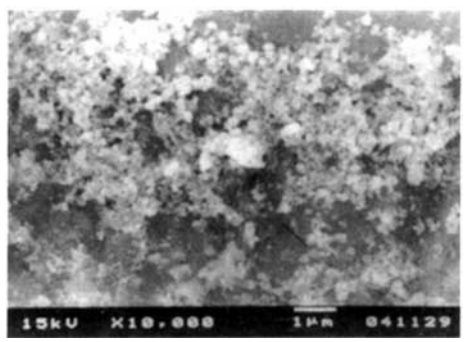

Fig. 5. Scanning electron micrograph of the catalyst.

increasing the reactivity[9] and altering the selectivity of Diels–Alder reactions.[10] Indeed, acceleration of the Diels–Alder reaction is one of the testing grounds for newly discovered Lewis acids.[11] One of the recent arrivals on the scene is $LiClO_4$ in ether,[12] where the strong Lewis acidity of the lithium ion is presumably responsible for the acceleration of the Diels–Alder reaction.[13] Since Kobayashi et al.[4] reported that $Y(OTf)_3$ was unable to accelerate the Diels–Alder reaction between cyclopentadiene **1** and 1,4-naphthoquinone **2a** (Scheme 1), we examined the reaction of this system with our catalyst as a test case. As shown in Table 1, stirring the reaction mixture (including our catalyst) at room temperature for 5 h gave exclusively the *endo* (100% *endo* selectivity) product in 93% yield (entry 1). For comparison, the reaction without the catalyst under identi-

cal conditions gave only 4% of the *endo* product **3a**. Under usual thermal Diels–Alder reaction conditions, that is heating to reflux in benzene, an *endo* to *exo* product ratio of 95:5 was obtained.[14] The enhanced *endo* selectivity and the reaction rate with our catalyst prompted us to examine the Diels–Alder reaction of **1** with 2-methylnaphthoquinone **2b**, which is known to be a troublesome reaction;[15] however, **2b** was converted quantitatively into **3b** and isolated in 85% yield (entry 2). The reaction of **1** with other demanding and structurally different dienophiles such as the spiro compounds **4** and **6** gave **5** (92%) and **7** (80%), respectively (entries 3 and 4). Mention must be made here that **6** reacts with **1** under a variety of Diels–Alder conditions such as, heating to reflux in high boiling solvents, neat heating, sealed tube heating, or ultra sound acceleration, with or without various well-known Lewis acids like BF_3, $TiCl_4$, etc., to give **7** in not more than 10% yield.[14] The generality of the Diels–Alder catalysis with the yttrium-based reagent has been demonstrated with other dienes and dienophiles (entries 5–9). However, our attempts to use our catalyst also for carboxylic acids as dienophile, instead of the corresponding esters have not been successful (entries 9, 10). The yttrium-based catalyst has also been found to be useful for hetero-Diels–Alder reactions (entry 11).[16]

A control experiment has shown that for the reactions 6, 7, and 11 without the catalyst, the reaction does not go at all under identical conditions. Literature evidence is also available for the failure of the Diels–Alder reactions of 2,[15] 3,[14] 4,[14] 6,[14] 8,[17] and 11[16] without Lewis acid. The catalyst can be recovered after the reaction and can be reused; comparable results for the Diels–Alder reaction were obtained in second runs.

As discussed earlier based on the results from the TPD studies and potentiometric titrations, the lattice defects introduced due to yttrium increase the number and strength of the active Lewis acidic sites. Furthermore the oxophilic nature of yttrium enhances the reactivity of oxygen-containing dienophiles, thereby lowering the LUMO and decreasing the gap between the HOMO of diene and LUMO of dienophile.[18] Surprisingly, in our reaction, only 20 mol % excess of diene is sufficient for the efficient Diels–Alder reaction, which is usually not the case. Indeed, the diene dimerization of either **1** or 1,3-cyclohexadiene was not observed with the catalyst.

In conclusion, a yttrium-based catalyst has been prepared by a novel methodology and has been fully characterized by XRD, SEM, and BET surface area studies. Its Lewis acidity has been demonstrated by the FTIR spectrum of adsorbed pyridine, the desorption of ammonia, and potentiometric titration studies. The general applicability of the new Lewis acid catalyst for Diels–Alder reactions has been established with several models. We are currently investigating its application as a strong Lewis acid in other organic reactions.

Experimental Procedure

In a typical experiment (Table 1, entry 1), cyclopentadiene **1** (0.198 g, 0.003 mol), 1,4-naphthoquinone (0.158 g, 0.001 mol) **2a**, and catalyst (0.075 g, 50% by weight with respect to dienophile) in dichloromethane (10 mL) was stirred at room temperature for 5 h. The progress of the reaction was monitored by TLC. The catalyst was filtered off, the solvent removed by rotary evaporation, and the residue chromatographed over a silica gel column by eluting with 5% acetone/petroleum ether to give 0.2083 g of the *endo* adduct **3a** (93% yield).

Enantioselective Reduction of Ketones with Sodium Borohydride, Catalyzed by Optically Active (β-Oxoaldiminato)cobalt(II) Complexes

Takushi Nagata, Kiyotaka Yorozu, Tohru Yamada, and Teruaki Mukaiyama*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

A wide variety of asymmetric reducing agents have been developed for the enantioselective reduction of prochiral ketones.[1] An asymmetric reduction of prochiral ketones catalyzed by chiral oxazaborolidines is noteworthy in this context.[2] Numerous successful applications taking advantage of the catalytic reduction have been shown: for example, various optically active secondary alcohols such as prostaglandin intermediates,[3a] agonists,[3b] potassium channel blockers,[3c] and the like were prepared by the enantioselective reduction with oxazaborolidine catalysts. On the contrary, few examples on the use of sodium borohydride with chiral metal complex catalysts in enantioselective reduction have been reported.[4, 5] It was recently shown that optically active β-oxoaldimines form a new class of effective ligand for aerobic enantioselective epoxidation

of simple alkenes with manganese(III) complexes as catalysts.[6] In this communication we report a novel method for the enantioselective reduction of ketones with a cobalt hydride species[7] generated from sodium borohydride and catalytic amounts of optically active cobalt(II) complexes having the β-oxoaldimine ligand, *N,N'*-bis(3-oxobut-2-enylidene)ethylenediamine.[6]

The optically active cobalt(II) complexes **1**–**4** were prepared by heating the corresponding β-oxoaldimine ligand with sodium

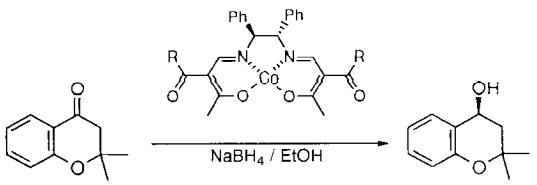
4

hydroxide and cobalt(II) chloride hexahydrate in methanol/water solution at 60 °C.[8] First the effectiveness of the ligand in the enantioselective reduction was examined relative to the reduction of 2,2-dimethylchroman-4-one with sodium borohydride [Eq. (a) and entries 1, 2, and 3 in Table 1]. The reduction was



(a)

carried out at −20 °C in the presence of a small amount of ethanol in chloroform solution, and the optical yield was determined by HPLC analysis. Catalyst system **3** containing bulkier acyl groups showed sufficient asymmetric induction (88% *ee*). An aldimine sterically hindered at the chiral C_2-symmetric diamine unit (**4**) was more efficient (92% ee, Table 1 entry 4).

In this catalytic system, a small amount of alcohol was indispensable for achieving a high enantiofacial differentiation.

Table 1. Effect of catalysts on yield and optical yield in the asymmetric reduction of 2,2-dimethylchroman-4-one (**5**) [a].

Entry	Catalyst	Yield [%]	*ee* [%] [b]
1	**1**	95	51
2	**2**	90	51
3	**3**	98	88
4	**4**	94	92

[a] Reaction conditions: 0.50 mmol **5**, 0.025 mmol (5 mol%) cobalt(II) complex, 0.75 mmol $NaBH_4$, 250 μL ethanol in $CHCl_3$ (9 mL), −20 °C. [b] Determination by HPLC (Daicel Chiralpak AD).

Ethanol was the most suitable alcohol with respect to both enantioselectivities and chemical yields. Other borohydride reagents ($LiBH_4$, KBH_4, $Ca(BH_4)_2$, and R_4NBH_4 (R = Me, Et, Bu) were also suitable for the asymmetric reduction catalyzed by the cobalt(II) complex. However, in general, sodium or potassium borohydride gave better results.

The catalyst system **4** was successfully applied in the asymmetric reduction of several aromatic ketones[9] (Table 2). High enantiomeric excesses were observed in the asymmetric reduction of chromanone derivatives having alkyl groups in 2-position (compounds **5**, **6**, and **7**). In the case of 2,2-dimethyltetralone (**10**), the catalyst system **3** with sodium borohydride afforded a higher optical purity (90% *ee*) than system **4** (66% *ee*). The use of potassium borohydride instead of sodium borohydride with this system gave an even better result (94% *ee*, Table 2 entry 6).

Table 2. Enantioselective reduction of prochiral ketones catalyzed by **4** [a].

Entry	Ketone		Yield [%]	*ee* [%] [b]
1		**5**	94	92 [c]
2		**6**	95	89 [c]
3		**7**	96	87 [c]
4		**8**	92	70 (*S*) [d]
5		**9**	99	73 (*S*) [e]
6 [f]		**10**	76	94 [d]
7		**11**	95	68 (*S*) [d]

[a] For reaction conditions see Experimental Procedure. [b] Absolute configurations are in parentheses and are based on the optical rotation; for **8** see Ref. [10], for **9** Ref. [11]; **11**: comparison with an authentic sample obtained from TCI. [c] HPLC on Chiralpak AD. [d] HPLC on Daicel Chiralcel OD-H. [e] HPLC on Chiralcel OB. [f] The catalyst **3** and KBH_4 was used instead of **4** and $NaBH_4$.

Both enantiomers of the optically active diarylethylenediamine ((*S,S*) and (*R,R*)) are commercially available or can be readily prepared by literature methods.[12] Since the enantiomers of the cobalt(II) complexes can be prepared from the corresponding diarylethylenediamine, the use of the present catalytic reducing system enables us to synthesize both enantiomers of the alcohols. The enantioselective reduction of prochiral aro-

matic ketones with sodium borohydride catalyzed by optically active *N,N'*-bis(3-oxobut-2-enylidene)ethylenediaminatocobalt(II) thus provides a practical method for the preparation of optically active secondary alcohols with good or very good enantiomeric excess. Further investigations into the design of chiral cobalt(II) complexes and their applications are now in progress.

Experimental Procedure

A typical procedure for the enantioselective reduction of **5** (Table 2 entry 1) using the cobalt complex **4** as catalyst is performed as follows: To a suspension of sodium borohydride (29 mg, 0.75 mmol) in chloroform (5.0 mL) was added ethanol (250 mL) under an argon atmosphere. After stirring for 1.0 h at room temperature, a solution of the (*S,S*)-cobalt(II) complex **4** (19 mg, 0.025 mmol, 5 mol%) in chloroform (2.0 mL) was poured into the mixture. Then it was cooled to −20 °C and **5** (88 mg, 0.50 mmol) in chloroform (2.0 mL) was added. The mixture was stirred for 120 h before the reaction was quenched by adding 1 M hydrochloric acid (2 mL). The reaction mixture was poured into a saturated aqueous solution of sodium hydrogen carbonate and extracted with ether. The organic layer was then washed with brine and dried over anhydrous sodium sulfate. Concentration in vacuo and purification by column chromatography on silica gel (hexane/ethyl acetate) afforded the corresponding optically active alcohol **2**: 98% yield, 87 mg; white crystals; 92% *ee* by HPLC analysis (Chiralpak AD, Daicel Ltd., Co.). $[\alpha]_D^{28} = +49.0$ ($c = 1.0$ in $CHCl_3$).

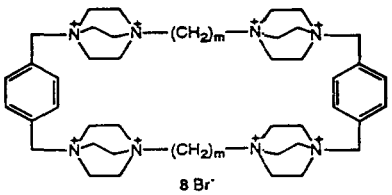
Octacationic Cyclophanes: Binding of ATP and Other Anionic Guests in Water**

Fredric M. Menger* and Kelly K. Catlin

Chloroform and methylene chloride, rather than aqueous solvents, have been the media of choice for most host–guest studies. This is because many types of associative forces (for example, hydrogen-bonding and cation/polyether attraction) are unfavorable in water where the solvent competes for the binding sites. Of course, in notable exceptions synthetic hosts have been designed to incorporate small guest molecules in water.[1] Hydrophobic bonding is often a major stabilizing factor in such complexes. Host–guest chemistry has also favored the use of neutral or cationic guests. Anionic guests are known[2] but, as with aqueous solvents, they are relatively uncommon despite their importance to biology. It was the purpose of the present foray into supramolecular chemistry[3] to bind anions in water. The hope was to accomplish this electrostatically with DABCO-based cyclophanes (**1**, DABCO = 1,4-diazabicyclo[2.2.2]octane) whose cavities are lined with eight positive charges. NMR and X-ray data show that the cyclophanes do indeed adsorb anions, including ATP, in aqueous media.



1, $m = 3,5,7$

The synthesis of the cationic cyclophanes is given in Scheme 1. Purification was the major obstacle. In fact, a previously reported DABCO-based macrocycle[4] was later taken to be a linear ionene (a polyquaternary polymer).[5] Published syntheses of water-soluble cyclophanes are commonly carried out with neutral polyamino macrocycles that are purified prior to quaternization of the nitrogen atoms. This strategy was obviously impossible with cyclophanes **1**. Ultimate success in securing pure compounds was achieved by observing the following

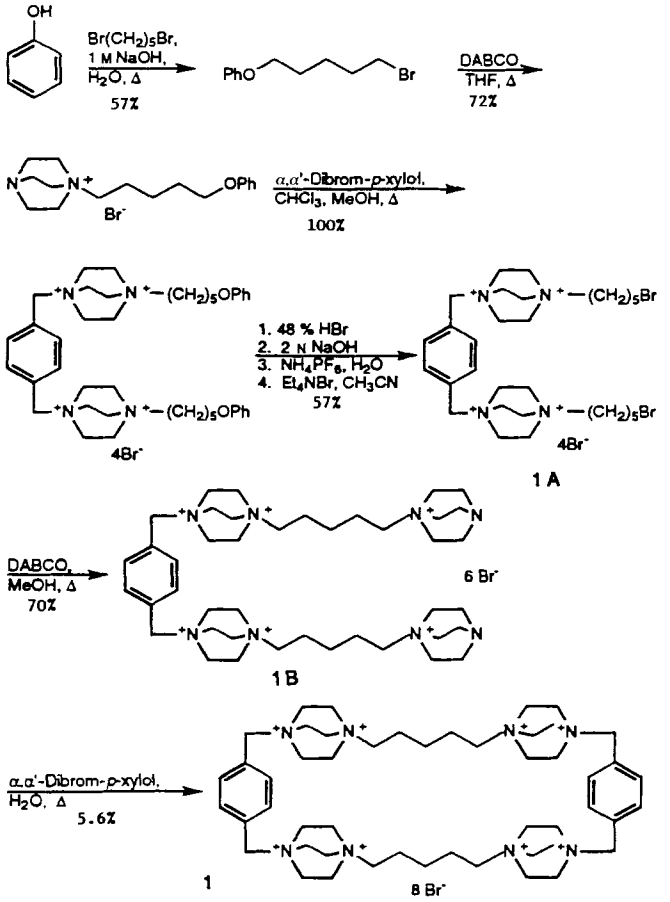
[**] This work was supported by the National Science Foundation.



Scheme 1. Synthesis of octacationic cyclophanes **1** ($m = 5$). Host molecules with three and seven methylene units ($m = 3, 7$) were prepared in an identical manner.

details: a) Great care was taken to define conditions that minimized unwanted side-reactions (for example, substitution reactions at the benzylic sites). b) Intermediate **1A**, being unpurifiable by crystallization or chromatography, was precipitated from water by addition of NH_4PF_6. The resulting tetra-PF_6 salt was filtered, dried, and dissolved in CH_3CN. Addition of Et_4NBr then reformed the tetrabromide salt, which fell out of solution and was collected by filtration and used for the next step. c) Intermediate **1B** was used without further purification except for trituration with hot EtOH. d) The final step, cyclization of **1B** to **1**, was run with either the hexabromide salt in water or the hexa-PF_6 salt in CH_3CN. In the former case, slow dissolution of α,α'-dibromo-*p*-xylene in water over several days ensured high dilution. In the latter case, high dilution was effected with the aid of a syringe pump. Product was then converted back into the octabromide or octachloride salts on an ion-exchange column.

Several methods were attempted to purify **1**. Chromatography on silica columns or preparative plates, with MeOH/aqueous NH_4OH as an eluent, gave reasonably pure material but in poor yields. Ion-exchange chromatography could not separate cyclic product from linear impurities. Size-exclusion chromatography, dialysis, and reverse phase chromatography were not successful. In the end, we contented ourselves with simple crystallization carried out three times from water or aqueous ethanol. This gave **1** with satisfactory ^1H and ^{13}C NMR spectra, elemental analyses, MS (FAB-MS with low resolution) and, in one case, an X-ray structure. Attempts to prepare several analogs of **1** (namely, compounds with even m values or with biphenyl and diphenylmethane spacers) failed owing to purification difficulties.

Figure 1 shows the dimensions of our three cyclophanes **1** ($m = 3$, 5, and 7) as modeled with Sybyl (Tripos force-field including electrostatic interactions). The cavity size for the $m = 3$ compound corresponds closely to that later determined by X-ray structural analysis. The cavity is about 4 Å deep. Note that the DABCO rings partially shield the aromatic spacers from the cavity, thereby reducing the possibility of $\pi-\pi$ stacking with an aromatic guest molecule. Nonetheless, ion–dipole interactions between an aromatic guest molecule and the quaternary nitrogen atoms, of a type described previously,[6, 7] could conceivably contribute to the binding of aromatic anions.

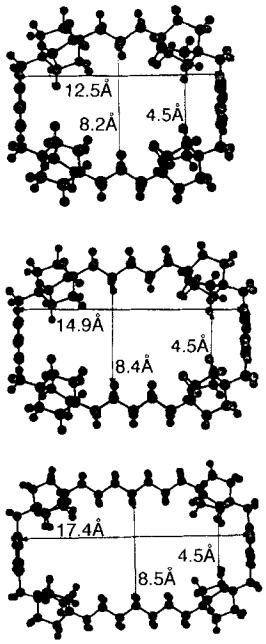


Fig. 1. Dimensions of the cyclophane cavities of **1** ($m = 3$, 5, 7, from top to bottom), determined by molecular mechanics simulations.

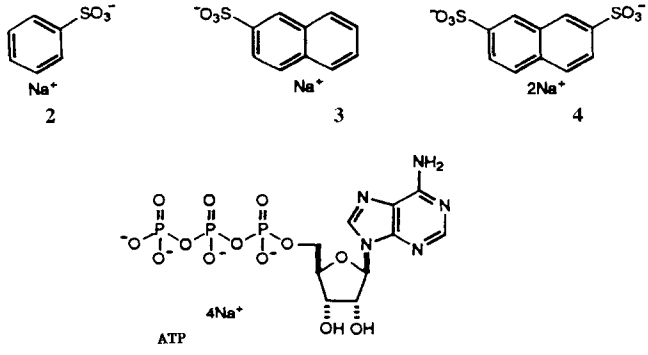
It was initially necessary to test for the possible aggregation of the cyclophanes in the absence of any guest.[8] Changes in the chemical shifts as large as $\delta = 0.04$ were observed when the concentration of **1** in pure water was increased from 1.3×10^{-5} to 2.4×10^{-3} M (GN-500 MHz spectrometer at 30 °C with CH_3CN as external reference). Since in 0.20 NaBr the NMR chemical shifts did not depend on concentration, these changes are probably caused by binding phenomena between the cyclophanes and their bromide counterions.[9] To obviate this complication, we operated exclusively at 5×10^{-5} M cyclophane in deionized water (a compromise between minimal counterion binding and a suitable signal-to-noise ratio).

Association constants for the cyclophanes and the guests in Scheme 2 were determined (somewhat unusually) by holding the host concentration constant while varying the concentration of excess guest. Accordingly, it was the chemical shift of the host that was monitored. The low concentration of host (5×10^{-5} M) required that the HDO peak be suppressed by a 1331 experiment or presaturation.[10] Host–guest complexation typically gave a $\Delta\delta = 0.1-0.2$ change in chemical shift as the guest reached mM levels. The shift vs. concentration data were converted into association constants with the aid of the Benesi–

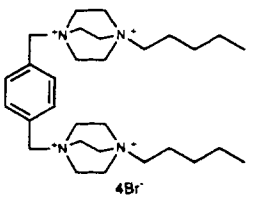


Scheme 2. Guest molecules that were used in binding studies with the octacationic host molecules.

Hildebrand equation.[11] Agreement among K_a values determined from different protons of a given host–guest system was satisfactory (±6%).

The following summarizes the key observations: a) Neutral aromatic guests (such as benzene, catechol, and 2,7-naphthalenediol) do not bind to the cyclophanes ($K_a < 100\ M^{-1}$). b) According to Job plots,[12] complexes between the cyclophanes and the anions in Scheme 2 all have 1:1 stoichiometries. c) $K_a = 61$, 447, and 3390 M^{-1} for complexation of **1** ($m = 3$) to **2**, **3**, and **4**, respectively. Coulombic forces clearly dominate the interactions. d) ATP (self-buffered at pH 8.0–8.5 where the compound exists as a tetraanion) binds to **1** ($m = 3,5,7$) with K_a values of 13300, 15900, and 12100 M^{-1}, respectively. Cavity size is, therefore, not critical. The numbers are much less than that measured for ATP and a macrocycle with six ammonium hydrogen-bonding sites,[13] but slightly larger than that reported for a tetraquaternary ammonium host.[14] K_a for ATP plus **1** ($m = 5$) diminishes to less than 100 M^{-1} in the presence of 0.2 N NaBr.

Detection of host–guest association does not, in and of itself, require that the guest resides *inside* the host's cavity. Since external binding was a possibility in our system, we examined the complexation of ATP with linear analogs of the cyclophanes. ATP will not associate with doubly N-alkylated DABCO salts, but will indeed bind efficiently ($K_a = 22200\ M^{-1}$) to the acyclic tetracation **5**. This is a strong indication that ATP never directly enters the cavity. Association between the ATP and cyclophanes appears to be a type of ion-exchange with the bromide counterions. Long-chain tetracationic DABCO derivatives have been shown by others to form 1:1 complexes with ATP in CH_2Cl_2.[15]



5

X-ray crystallographic studies are a particulary informative means of probing supramolecular complexes,[16, 17] the possible disparity between solution and solid-state structures notwithstanding. In the X-ray structure of **1** ($m = 3$), where chlorides were used as the counterions in order to minimize X-ray absorption, three water molecules were found to occupy the center of the cyclophane (Fig. 2). The cyclophane cavities line up to form parallel channels. Water molecules and chloride, sandwiched between the cyclophanes, may be responsible for this channel formation. The columns of cyclophanes lie side-by-side, and the distance between the neighboring aromatic rings is approximately 3.5–3.8 Å. The X-ray structure of the complex between **1** ($m = 3$) and **4** (Fig. 3) shows the formation of a 1:3 clathrate

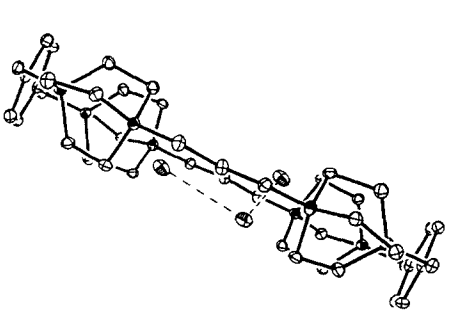


Fig. 2. The crystal structure of the octacationic host molecule **1** ($m = 3$) shows three water molecules within the cavity. The external counterions are not shown.

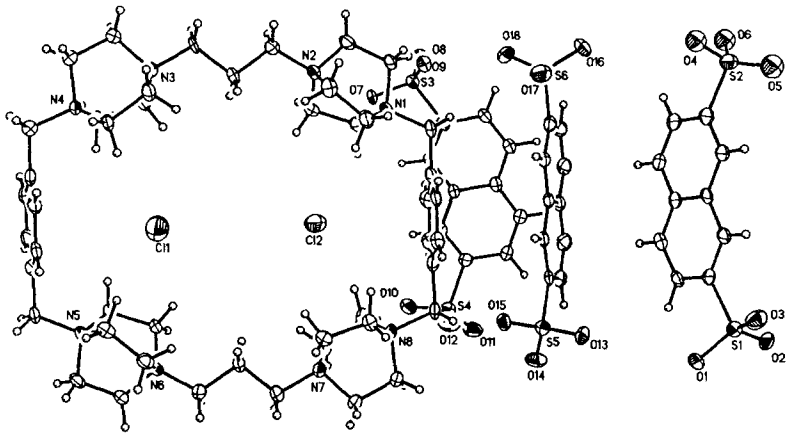

Fig. 3. The crystal structure of the complex of **1** ($m = 3$) and **4** shows three "guest" molecules outside the cavity. Two chloride counterions are present within the cavity.

between host and guest. No intracavity encapsulation of the guest was exhibited; only two chloride counterions reside within the cavity of the cyclophane. The three "guests" are considered to interact externally with the host through π–π stacking and/or electrostatic interactions. Thus, X-ray data further substantiate our NMR studies, which suggest that the guests do not enter the cavities. Association arises exclusively by an ion exchange between host and guest, a remarkably effective process considering the nonpolymeric nature of the host.[18]

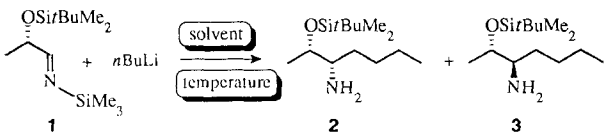
Temperature and Solvent Effect on the Nucleophilic Addition of *n*-Butyllithium to the *N*-(Trimethylsilyl)imine of (2*S*)-Lactal**

Gianfranco Cainelli,* Daria Giacomini, and Martin Walzl

Studies of the diastereoselective conversion of a trigonal carbon center into a tetrahedral one under the stereochemical influence of a nearby chiral center have provided valuable mechanistic and synthetic information for organic chemists. Among such studies, investigations of 1,2-asymmetric induction in additions of organometallic reagents to carbonyl compounds have been most intensive and fruitful.[1] The stereochemical outcome of these reactions is a critical issue, and models have been proposed to help to rationalize and predict the observed diastereoselectivity. Through experimental and theoretical analysis, Cram's original rules[2] have been reformulated and are now referred to as the Felkin–Anh model[3] and Cram's chelation model.[4] In the former, the argument is based mainly on steric and/or stereoelectronic considerations, in the latter, primarily on the substrate's bidentate ligation to the metal countercation. But all the models proposed suffer from the lack of any consideration of temperature and solvent effects.

Recently, we have demonstrated that the diastereoselectivity of the addition of organomagnesium compounds to O-protected (2*S*)-lactal at −78 °C, is highly dependent on the nature of the ethereal solvent.[5] Particularly in the case of the *O*-triisopropylsilyl derivative and MeMgBr, the diastereomeric excess could be completely reversed on going from THF (*syn*:*anti* = 36:64) to *tert*-butyl methyl ether (*syn*:*anti* = 84:16).

Stimulated by our interest in understanding and controlling the π-facial selectivity of α-hydroxymetalloimines,[6] we report here on the influence of temperature and solvent on the diastereoselectivity of *n*BuLi addition to *N*-(trimethylsilyl)imine **1** of (2*S*)-*O*-(*tert*-butyldimethylsilyl)lactal[7] (Scheme 1).



1 **2** **3**

Scheme 1. Solvents: THF, *n*-hexane, *t*BuOMe.

The addition reaction was performed by introducing a stoichiometric amount of *n*BuLi (1.6 M in *n*-hexane) to pure **1** in different solvents (tetrahydrofuran, *tert*-butyl methyl ether, *n*-hexane). The temperature was varied over a range of about 130 °C.

The diastereomeric excess of the products **2** and **3** was determined on the crude reaction mixture by ^{1}H NMR analysis.[8] Results are reported in Table 1.

Table 1. Influence of temperature and solvent on the diastereoselectivity of the nucleophilic addition of *n*-butyllithium to the *N*-(trimethylsilyl)imine of (2*S*)-*O*-(*tert*-butyldimethylsilyl)lactal. The *de* values were determined from ^{1}H NMR spectra.

Solvent	*T* [°C]	*t* [h]	*syn*/*anti*	*de* [%]	Yield [%]
THF	−90	2	98:2	96	61
THF	−78	2	94:6	88	41
THF	−70	2	93:7	86	64
THF	−65	2	92:8	84	57
THF	−60	2	84:16	68	53
THF	−55	2	84:16	68	78
THF	−50	2	78:22	56	57
THF	−40	2	73:27	46	76
THF	−35	2	72:28	44	57
THF	−30	2	66:34	32	65
THF	−20	2	67:33	34	65
THF	−10	1.5	65:35	30	61
THF	0	1.5	65:35	30	86
THF	16	1	65:35	30	49
THF	25	0.5	65:35	30	50
THF	31	0.5	65:35	30	45
*t*BuOMe	−90	2	73:27	46	79
*t*BuOMe	−70	2	73:27	46	78
*t*BuOMe	−50	2	73:27	46	89
*t*BuOMe	−20	2	67:33	34	80
*t*BuOMe	0	2	68:32	36	81
*t*BuOMe	30	0.5	64:36	28	80
n-hexane	−90	2	28:72	−44	70
n-hexane	−70	2	45:55	−10	65
n-hexane	50	2	44:56	−12	68
n-hexane	−30	2	68:32	36	74
n-hexane	0	2	75:25	50	70
n-hexane	32	0.5	78:22	56	75
n-hexane	54	0.1	78:22	56	72

Analysis of the data show that at low temperature the *syn*/*anti* ratio is dramatically dependent on the nature of the solvent, ranging from 98:2 in THF to 28:72 in *n*-hexane. In contrast, at higher temperature the three solvents show a similar behavior giving rise to a *syn*/*anti* ratio ranging only from 65:35 (THF) to 78:22 (*n*-hexane). The highest diastereoselectivity differences

[**] This work was supported by MURST (Fondi 40% and 60%) and the CNR.

with temperature were observed with THF and *n*-hexane, while in *tert*-butyl methyl ether as solvent, temperature shows little influence on the *syn*/*anti* ratio.

The temperature dependence of the *de* values was analyzed according to the modified Eyring[9] equation: $\ln P = -(\Delta\Delta H^{\ddagger}/RT) + (\Delta\Delta S^{\ddagger}/R)$, where $P = k(syn\text{-aminol})/k'(anti\text{-aminol}) = I(syn\text{-aminol})/I'(anti\text{ aminol})$, k and k' are the overall rate constants, and I and I' are the intensity of signals in the ^{1}H NMR spectra of **2** and **3**. The results are summarized in Figure 1.

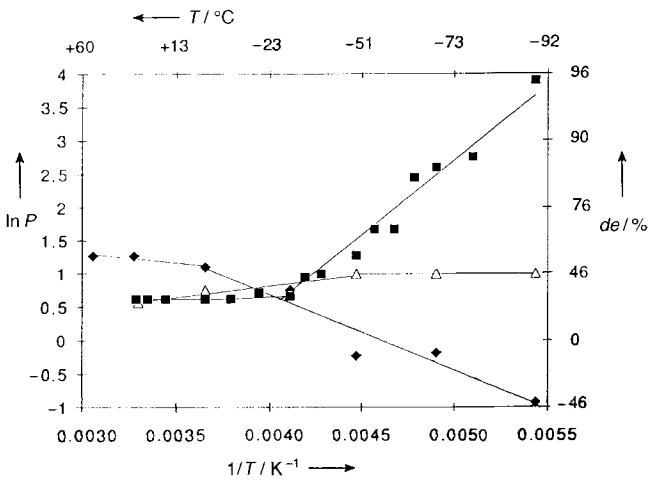

Fig. 1. Eyring plots for the diastereomeric excess obtained in the nucleophilic addition of *n*-butyllithium to **1** at various temperatures in THF (■), *t*BuOMe (△), *n*-hexane (◆)

In the Eyring plot each imine/solvent combination shows two linear regions with a characteristic inversion temperature, the inversion point T_{inv}. Inversion points have been observed in stereoselective processes,[10] but this is the first case for nucleophilic addition. According to Scharf et al.,[11] this indicates the presence of at least two selection steps in the reaction mechanism. Consequently two sets of activation parameters ($\Delta\Delta H_1^{\ddagger}$, $\Delta\Delta S_1^{\ddagger}$ for $T > T_{inv}$ and $\Delta\Delta H_2^{\ddagger}$, $\Delta\Delta S_2^{\ddagger}$ for $T < T_{inv}$) are obtained.

Considerable attention has been paid to the significance of the difference $\delta\Delta\Delta H^{\ddagger} = \Delta\Delta H_1^{\ddagger} - \Delta\Delta H_2^{\ddagger}$ values.[12] A plot of $\delta\Delta\Delta H^{\ddagger}$ against the corresponding entropy term $\delta\Delta\Delta S^{\ddagger}$ is linear. From the slope of this plot (Fig. 2) we can determine the isoinversion temperature $T_i = +252$ K (-21 °C). As stated by

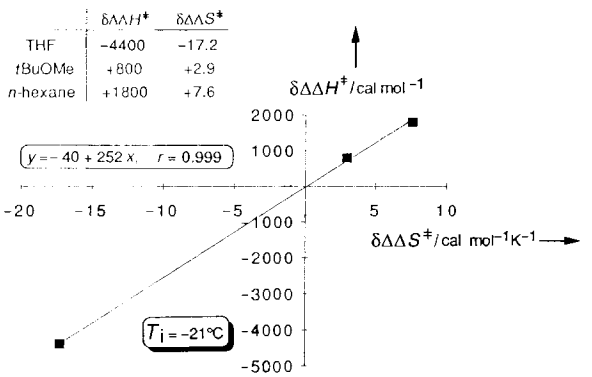

Fig. 2. $\delta\Delta\Delta H^{\ddagger}$ $\delta\Delta\Delta S^{\ddagger}$ plot for the determination of the isoinversion temperature T_i.

Scharf et al., systems show high stereoselectivity when T_{inv} is close to T_i. Indeed, the diastereoselectivity of our addition reaction with silylimine **1** is high in THF, for which T_{inv} is close to T_i, whereas in *n*-hexane and *t*BuOMe, with T_{inv} relatively far from T_i, low values of *de* are observed. Remarkably, in our case for a temperature corresponding to T_i, we observe a minimum in the diastereoselectivity.[13] Our results are consistent with a stepwise process with at least two diastereoselective steps that are affected differently by temperature and solvent. At this stage it is not easy to formulate a detailed mechanism, although it is apparent that the solvent should have a dramatic influence on the structure of the intermediates.[14] In view of the high charge density of the lithium cation, it is very reasonable, at least at low temperature, that the stereochemistry of this addition reaction should be controlled by lithium chelation. So lactic imine **1**, bearing two potentially chelating ancillary ligands,[15] could form chelates with *n*-butyllithium. In the high temperature region where the solvent appears to have little influence and entropy control is operative, the reaction mechanism could favor open intermediates with a higher degree of freedom. Nevertheless, in the absence of experimental evidence for the structures of the intermediates, our results emphasize the limits of current models for the interpretation of the 1,2-asymmetric induction observed in this kind of reactions. As a matter of fact, none of the classical models consider either temperature or solvent effects at all.

Experimental Procedure

In a typical experiment, **1** (0.259 g, 1.00 mmol) was dissolved in anhydrous solvent (5 mL, THF or *t*BuOMe or *n*-hexane) under inert atmosphere, and the solution cooled to the desired temperature; then *n*-butyl lithium (1.20 mmol, 0.75 mL of a 1.6 M solution in *n*-hexane) was added. After the stipulated reaction time (Table 1), the reaction was quenched at 0 °C with a saturated aqueous solution of NH_4Cl, extracted with CH_2Cl_2 (3×50 mL), and dried with $MgSO_4$. From the ^{1}H NMR analysis of the crude product the *syn*/*anti* ratio and the *de* value were obtained. Chromatography of the residue on a silica gel column afforded the mixture of the two aminols **2** and **3** so that the chemical yield could be calculated.

[13] The observed minimum value of *de* near the T_i appears to be rare. As reported in Ref. [11], most of the reactions examined show a maximum.
[14] The solvent effect observed could be attributed to a different aggregation state of the reactants and intermediates involved, and to the difference in the capacity of the solvent to coordinate the activated complexes of the process.

Influence of Lewis Base Complexation and the Degree of Aggregation of Alkyllithium Compounds on the Ratio in Which They Form Addition Products and Enolates with Ketones

Hendrikus Luitjes, Marius Schakel, Robert F. Schmitz, and Gerhard W. Klumpp*

Although the importance of the σ-organolithium compounds (σ-RLi) in synthetic chemistry can hardly be overstated, empirical observations and the rules of thumb still play an important role in their application. For instance, for one of their most important reactions, the reaction with aldehydes and ketones, it has been stated that[1] "Enolization is favoured by steric hindrance in either the carbonyl compound or the organometallic reagent[2]... Addition is favoured ... by non-polar solvents". Detailed reaction mechanisms, the real guidelines when reactions are planned, can only be obtained with difficulty due to the dynamic nature of σ-RLi: In the presence of frequently used Lewis bases [LB (ethers, tertiary amines)], these reagents are found as a mixture of several complexes $R_mLi_m \cdot n\,LB$ (*m,n*: 4, 1–4; 2, 4; 1, 3).[3] As the establishment of the equilibria between these complexes is often faster than the reaction under investigation, the individual contributions of the various particles towards the reaction rate and the chemo-, regio-, and stereoselectivity cannot be determined; proportions of the various complexes in the mixture are constant throughout the experiment.[4]

In our studies of the organolithium compounds **1**–**3**,[6] **4**, and *tert*-butyllithium, we have now obtained data for the first time regarding the influence of the LB-dependent aggregation of σ-RLi on the ratios in which they form addition products and enolates with ketones.

The NMR spectra of **1** (Li/N = 1/1) and **2** (Li/N = 1/2) show that they are tetrameric $\mathbf{1}_4$ and dimeric $\mathbf{2}_2$, respectively, under

1-4: $LiCH_2Si(Me)_2CH_2N(CH_2X)CH_2Y$

1: X = Y = H **2**: X = CH_2NMe_2, Y = H **3**: X = Y = CH_2NMe_2

4: X = $CH_2N(Me)CH_2CH_2NMe_2$, Y = H

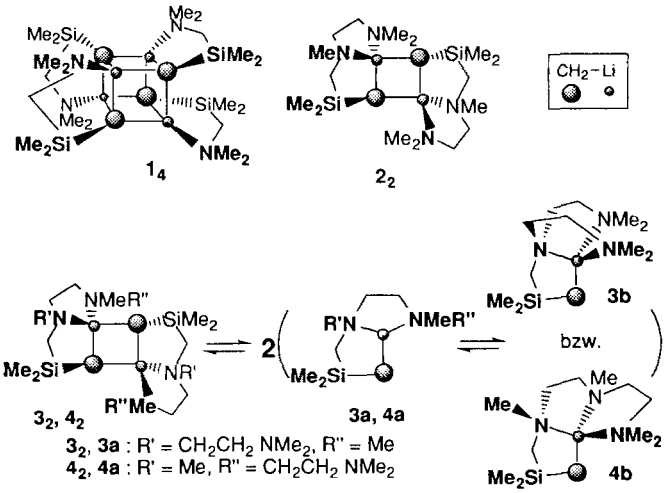
the reaction conditions (−70 °C, pentane), and at the very most take part only slowly (on the NMR time scale) in exchange processes with undetectable amounts of other species.[6] In contrast, **3**[6] and very probably **4** (Li/N = 1/3) as well are present as equilibrium mixtures of rapidly exchanging monomers **3a** and **3b** (**4a** and **4b**) and dimers $\mathbf{3}_2$ ($\mathbf{4}_2$) at −70 °C.[7]



Since the structural differences between **1**, **2**, **3**, and **4** are located far from the anionic carbon atom, on the nitrogen end of the common building block $^-CH_2Si(Me)_2CH_2N(CH_2-)_2$, we assume that differences in the reactivity can be attributed (almost) exclusively to differences in the degree of aggregation.

When one molar equivalent of ketone $R^1R^2C{=}O$ was added to each of the slightly yellow solutions of **1**–**4** in pentane at −70 °C, instantaneous decolorization occurred. After 30 min an excess of chlorotrimethylsilane was added; the mixture was allowed to reach room temperature and then worked up in the usual way. The ratio of the enolate to the addition product (E/A) was determined by gas chromatographic measurement of **5**:{**6** (R = H) + **6** (R = $SiMe_3$)}. The quantitative results of the reactions are shown in Table 1.

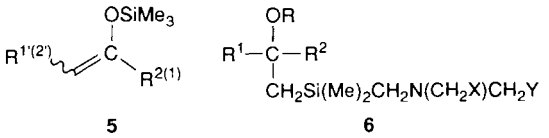


Table 1. The ratio of enolate to addition product (E/A) in the reactions of **1**, **2**, **3**, and **4** with ketones $R^1R^2C{=}O$ in pentane at −70 °C.

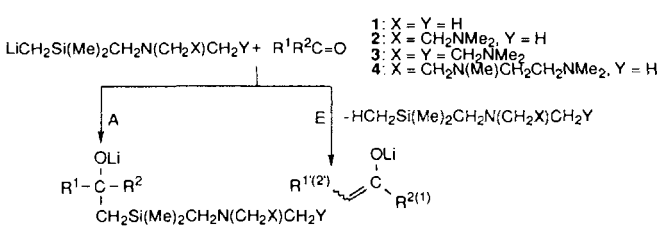

$R^1R^2C{=}O$	**1**	**1** [a]	**2**	**3**	**4**
pinacolone	5:95	68:32	44:56	45:55	96:4
cyclohexanone	29:71 [18]	56:44	40:60	69:31	94:6
3-hexanone [b]	5:95	50:50	35:65	48:52	86:14
2-hexanone [b]	5:95	46:54	5:95 [18]	46:54	62:38 [18]

[a] In THF/pentane (3:1). [b] Several enolates were formed with all lithium compounds. The structures were not determined.

In keeping with our suppositions, we interpret the different E/A profiles of **1**, **2**, and **4** in pentane as indications of the reacting tetramer $\mathbf{1}_4$, dimer $\mathbf{2}_2$,[8] and monomer **4**. The E/A profiles of **1** in THF/pentane (3:1) and **3** are similar to that of $\mathbf{2}_2$ ($1:2 < E/A < 2:1$) and thus indicate the reaction of dimers $\mathbf{3}_2$ and $\mathbf{1}_2 \cdot n$THF, as confirmed (for THF) by cryoscopic and NMR methods.[9] It is not known why, in contrast to **4**, which reacts as a monomer, dimeric $\mathbf{3}_2$ is the most reactive component in the $\mathbf{3}_2 \rightleftarrows 2(\mathbf{3a} \rightleftarrows \mathbf{3b})$ system. In the reaction with triphenylmethane, however, we found that monomeric **3** is only slightly more reactive than $\mathbf{2}_2$.[10] From this we deduce that slight differences, possibly of steric origin, can be decisive in determining which particle forms the most favorable transition state in dynamic dimer/monomer/LB equilibria. We also found similar E/A ratios for reactions of *tert*-butyllithium with cyclohexanone (−70 °C): *t*BuLi·TMTAN (TMTAN = 1,4,7-trimethyl-1,4,7-triazacyclononane), THF:[10] 88:12 (reaction of the monomer); *t*BuLi, THF: 46:54 (reaction of the dimer);[11] *t*BuLi, hexane: 0:100 (reaction of the tetramer).[3b, 12] The similarity of the E/A profiles of $\mathbf{1}_2 \cdot n$THF and $\mathbf{2}_2$ (pentane), and the cyclohexanone E/A values of *t*BuLi·TMTAN and $t\mathrm{Bu}_2\mathrm{Li}_2 \cdot n$THF and of **4** and $\mathbf{2}_2$, respectively, would seem to indicate that the E/A values of σ-RLi are aggregate-specific (tetramer: ca. 1:20, dimer: 1:2 – 2:1, monomer: > 6:1) and are only influenced by the Lewis base and R to a relatively small extent.[15, 17, 18] It is clear that high E/A values are not linked to the steric effects of the R group as one might have supposed from the rules of thumb mentioned at the beginning—it is rather improbable that the steric effects in the transition states of the additions of the monomer **4** and *t*BuLi·TMTAN are stronger than in those of the additions of $\mathbf{1}_4$ and $t\mathrm{Bu}_4\mathrm{Li}_4$—but rather mainly to the type of the aggregates, as might be surmised from the statement of the rule of thumb concerning the solvent (see ref. [3]).[18] Considerations of possible causes point to the character of the carbon–lithium bonds in the monomers and in the σ-RLi aggregates.[19] Theoretical investigations must answer the following questions: 1) Which bonding properties form the basis of the shift of the preferred reaction pathway from deprotonation in the case of monomers with C–Li two-center bonds to addition to the C=O bond in the case of aggregates with C–Li multiple-center bonds? 2) Of what type are the corresponding transition states?[20, 21]

[6] H. Luitjes, F. J. J. de Kanter, M. Schakel, R. F. Schmitz, G. W. Klumpp, *J. Am. Chem. Soc.* **1995**, *117*, 4179.

[7] The complicated low-temperature ^{13}C NMR spectra of **4** (containing ^{6}Li) in pentane show no splitting of the C_α signal (presumably due to the rapidity of the intermolecular exchange processes), but cryoscopic investigations in benzene showed the degree of aggregation to be 1.

[8] The following indicate that $\mathbf{2}_2$ is the only reactive species. 1) The order of reaction (0.83) of $\mathbf{2}_2$ with triphenylmethane (benzene, 23 °C) [6] rules out a reaction via rapidly regenerated, nondetectable, potentially more reactive **2** and $\mathbf{2}_4$. It therefore seems improbable that these particles play a role in the significantly faster reaction with ketones at −70 °C. 2) Based on the splitting of the NMR signal of the protons in the diastereotopic dimethylsilyl groups in $\mathbf{2}_2$ [$\Delta\nu$(22 °C) = 16 Hz] [6] and on known activation parameters [$\Delta H^{\neq}$, $\Delta S^{\neq}$ {$\mathbf{3}_2 \rightarrow 2(\mathbf{3a} \rightleftarrows \mathbf{3b})$}: 39 kJ mol^{-1}, 50 J K^{-1} mol^{-1}; H. Luitjes, unpublished), it is estimated that the average lifetime of $\mathbf{2}_2$ in the $\mathbf{2}_2 \rightleftarrows 2\,\mathbf{2}$ system at −70 °C is more than 40 s. 3) The mass spectrum of $\mathbf{2}_2$ shows no indication of dissociation into the monomer.

[9] Two dimers of unknown structure are apparent. $\mathbf{1}_2$, ^{13}C NMR (62.88 MHz, THF:[D$_8$]THF 10:1, −119 °C, TMS): δ = −11.51 (septet, $^1J(^7\mathrm{Li}, ^{13}\mathrm{C})$ = 14.6 Hz, CH_2Li), 3.41 + 3.56 (ca. 2:1, $SiCH_3$), ca. 5.49 + 5.59 (overlapping, ca. 1:2, $SiCH_3$), 47.88 + 48.64 (ca. 2:1, NCH_3), 52.23 (NCH_3), 56.20 + 56.53 (ca. 2:1, NCH_2).

[10] *t*Bu^{n}Li·TMTAN, ^{13}C NMR (62.88 MHz, [D$_8$]THF, −108 °C, TMS): δ = 17.49 (t, $^1J(^6\mathrm{Li}, ^{13}\mathrm{C})$ = 14.3 Hz, CLi), 39.85 (CH_3), 45.45 (NCH_3), 50.60 (NCH_2), 56.40 (NCH_2).

[15] The exclusive formation of enolates by "crown ether complexation" of alkyllithium compounds (J. L. Pierre, H. Handel, R. Perraud, *Tetrahedron Lett.* **1977**, 2013) may, in reality, be the reaction of lithium alkoxide, which is formed by the decomposition of the crown ether [16].

[16] W. Bauer, W. R. Winchester, P. von R. Schleyer, *Organometallics* **1987**, *6*, 2371.

[17] The experiments described here were conducted with normal working methods from preparative chemistry. Our dimer and tetramer E/A values are thus the results of the reactions of families of complexes $R_m{}_nR'O_nLi_m{}_{-n}$·*n* LB (m = 2, 4; $n \leq m$), which are gradually formed during an experiment by incorporation of the reaction products into the reacting aggregates. Detailed mechanistic conclusions require the determination of *initial* reaction rates of both the transformations (E, A) (relating solely to the $R_mLi_m \cdot n$ LB reagent used), and the corresponding *initial molecularities*. The role of precomplexes of ketone and reagent will also become apparent from the latter (D. R. Hay, S. G. Song, S. G. Smith, P. Beak, *J. Am. Chem. Soc.* **1988**, *110*, 8145 and references therein).

[18] The extreme positions of cyclohexanone and 2-hexanone on certain E/A profiles (e.g. $\mathbf{1}_4$ or $\mathbf{2}_2$ and **4**, see also ref. [21]) cannot be interpreted at this time.

[19] G. Graham, S. Richtsmeier, D. A. Dixon, *J. Am. Chem. Soc.* **1980**, *102*, 5759; E. Kaufmann, K. Raghavachari, A. E. Reed, P. von R. Schleyer, *Organometallics* **1988**, *7*, 1597.

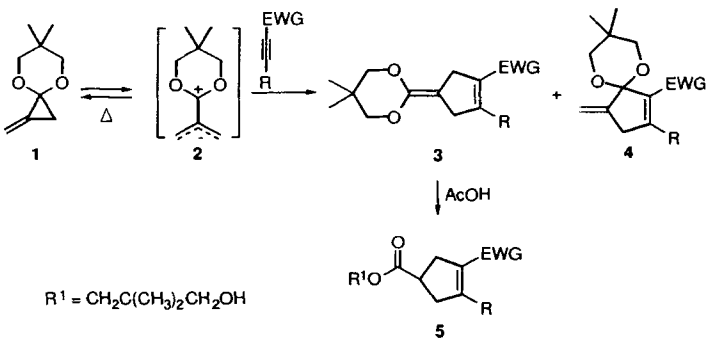
[20] In addition to the polar addition of RLi to ketones (E. Kaufmann, P. von R. Schleyer, K. N. Houk, Y.-D. Wu, *J. Am. Chem. Soc.* **1985**, *107*, 5560), the possibility of addition by means of single electron transfer is discussed [13].

[21] Postscript (July 6, 1995): In the meantime, we have found that **2** and **4** are monomeric in THF at −100 °C and show monomer E/A profiles in THF/pentane (3:1) at −70 °C: pinacolone, cyclohexanone, 3-hexanone, 2-hexanone (see Table 1): for **2**, respectively, 95:5, 65:35 [18], 77:23, 84:16; for **4**, respectively, 95:5, 25:75 [18], 95:5, 95:5. These results confirm our suppositions. Slight variations in the E/A profiles are the result of the replacement of Li–N with Li–THF.

A Concise Synthetic Route to Cyclopentenes by [3+2] Cycloaddition of Dipolar Trimethylenemethane to Alkynes**

Shigeru Yamago, Satoshi Ejiri, and Eiichi Nakamura*

Alkynes are known to be relatively unreactive dienophiles in Diels–Alder reactions.[1] Their performance as 2π-electron reactants is even poorer in isoelectronic cycloadditions with 4π-trimethylenemethane species (TMM, cf. **2**), giving the expected [3+2] cycloaddition products only under special conditions (i.e. with a large excess of a highly reactive alkyne).[2] The [3+2] cycloadditions of metal-complexed TMM[3] and related species[4] have also proven to be of rather restricted scope. This current situation is particularly unfortunate since this type of cycloaddition reaction would allow us to achieve an efficient single-step synthesis of substituted cyclopentenes, for which only a few reactions of some synthetic significance exist.[5] We report herein the first effective trapping of a TMM species with an alkyne, as demonstrated for the reaction of a dipolar TMM **2** generated reversibly by thermolysis of **1**.[6] Heating an equimolar mixture of an electron-deficient alkyne (EWG = electron-withdrawing group) and the readily available TMM precursor **1** (see Experimental Procedure)[7] at 80–100 °C afforded the cyclopentene carboxylic acid ester **5** after hydrolysis of the ketene acetal **3** with aqueous AcOH in CH_3CN. The reaction is purely thermal and proceeds under neutral conditions.



1 2 3 4 5

In the early stages of our studies we recognized that alkynes are indeed less reactive toward **2** than the structurally related alkenes.[7a, 8] Thus, the reaction of **1** with methyl 2-heptynoate in toluene proceeded only at 100 °C (56 h), while methyl (*E*)-2-hexenoate reacted at 80 °C.[9] Nonetheless, the cycloaddition to an acetylenic ester proceeded efficiently at 80–100 °C to afford the acid-labile ketene acetal **3** (EWG = CO_2Me or CO_2iPr), which was converted to the dicarboxylic ester **5** and isolated in good yield (Table 1, entries 1–4). A small amount of exo-methylene isomer **4** was also formed, suggesting the intervention of a single-electron transfer cycloaddition pathway.[10] The reaction rate increased as the polarity of the solvent was increased: octane < toluene < dimethoxyethane < CH_3CN < dimethylsulfoxide. This is in part due to faster formation of **2** in polar solvents.[6] The reaction was complete after 5 h at 80 °C when DMSO was used as a solvent. The ratio of **3** to **4** was not solvent dependent.

In line with the nucleophilic nature of **2**, the reaction rate increases as the electron demand of the alkyne increases. 1-Alkoxyalkyl and trimethylsilyl groups (which lower the LUMO

Table 1. Cycloaddition of **1** with electron-deficient alkynes[a].

Entry	Alkyne (equiv)	*T* [°C]	*t* [h]	Major product	Yield of **5** [%][b]	**3**:**4**[c]
1		(1.2)	100	56		49	(82:18)[d]
2		(0.91)	80	44		61	(82:18)
3		(1.2)	80	18		72	(93:7)[e]
4		(0.91)	80	29		58	(68:32)[f]
5		(1.0)	100	36		68	(83:17)
6		(1.0)	100	10		59 (74)[g]	(> 97:3)
7		(0.83)	80	27		85	(> 95:5)
8		(0.91)	80	26		66	(82:18)
9		(1.1)	80	14		88	(> 98:2)
10		(1.2)	100	27		63	(> 95:5)

[a] The reactions were carried out in CH_3CN or CD_3CN, except that in entry 6 which was carried out in toluene. [b] Yield of isolated product. The ketene acetal **3** (X = $OCH_2C(CH_3)_2CH_2O$) was not isolated but converted into the ester **5**. The yields are based on **1** except in entries 7 and 8 where they are based on the alkyne. The yield of the cycloaddition was found to concentration independent (up to 1.5 M). [c] Determined by capillary GLC and/or by ^1H NMR for the equivalent reaction carried out in CD_3CN. [d] The cycloadduct due to the cycloaddition to carbonyl group is also formed in ca. 10% yield. [e] The cycloadduct due to the cycloaddition to carbonyl group is also formed is ca. 3% yield. [f] The cycloadduct due to the cycloaddition to carbonyl group is also formed is ca. 3% yield. [g] Yield when 3 equiv of **1** is used.

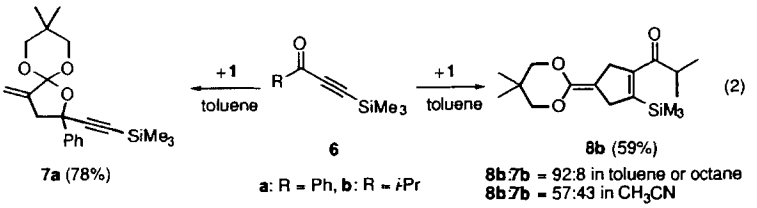
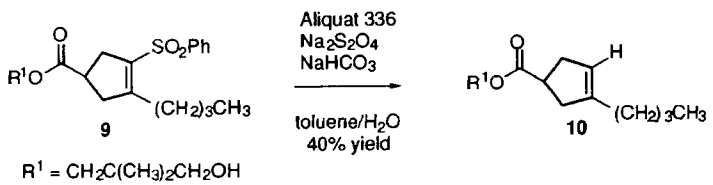
of acetylene)[11] accelerate the cycloaddition of acetylenic esters (entries 2 and 3). In contrast, an electron-donating *p*-alkoxyphenyl group retards the cycloaddition reaction (cf. entries 4 and 5).

The cycloaddition to acetylenic ketones revealed an interesting dichotomy. When ketone **6a** was allowed to react with **1** in toluene, we found that the cycloaddition reaction occurs exclusively on the carbonyl group to give the exomethylene product **7a**.[12] Only when the carbonyl group was deactivated electronically and sterically as in **6b**, did the desired cycloaddition in toluene take place on the acetylenic bond to give the ketene acetal **8b**.[13] The selectivity toward **8b**, however, decreased in a polar solvent (CH_3CN) and a significant amount of the exomethylene product **7b** also formed. This solvent effect suggests that the cycloaddition to the carbonyl group occurs through a polar (stepwise) reaction pathway,[14] which, in a polar solvent, is faster than the (presumably concerted) cycloaddition to the C≡C bond.



A drawback of the present cycloaddition for application in synthesis is the failure of unactivated alkynes to act as 2π-electron partners. For instance, phenylacetylene and hexyne are totally inert under these reaction conditions. We found however that sulfur-substituted alkynes can be used as synthetic equivalents of simple alkynes. Acetylenic sulfones and sulfoxides were found to be very reactive TMM acceptors at 80–100 °C; in fact, the former are the most reactive substrates examined in these studies (entries 7–10). After the cycloaddition, the vinyl sulfone cycloadduct **9** could be readily desulfurized under mild conditions; treatment of **9** with $Na_2S_2O_4$ in the presence of a phase transfer catalyst (Aliquat 336) in a water/toluene mixture afforded the cyclopentene **10**.[15]



Finally, preliminary studies on the regiochemistry of the cycloaddition of a substituted TMM, which was generated from an ethylidene homologue of **1**, with methyltrimethylsilylpropynoate showed rather poor regioselectivity; a 77:23 mixture of two regioisomeric ketene acetal cycloadducts formed.[16]

In summary, we found that alkynes are relatively poor acceptors of dipolar TMM species but can still be used as a useful two-carbon unit in the [3+2] cycloaddition with **2** to provide a new synthetic route to cyclopentene derivatives. We attribute the success of the cycloaddition to the well-defined singlet character of the dipolar TMM molecule,[6] which undergoes either the desired cycloaddition or the ring closure back to the starting material **1**. The other known TMM species,[2] on the other hand, tend to undergo side reactions (irreversible ring closure to unreactive methylenecyclopropane, intersystem crossing to the triplet state and subsequent rapid dimerization)[17] rather than reacting with unreactive acceptors.

Experimental Procedure

6,6-Dimethyl-4,8-dioxa-1-methylenespiro[2.5]octane (**1**): To a solution of solid $NaNH_2$ (minimum assay 95%; 57.60 g, maximum 1.48 mol) in ca. 650 mL of liq. NH_3 in a dry ice/acetone bath was added 2,2-bis-(chloromethyl)-5,5-dimethyl-1,3-dioxane [7b] (102.3 g, 0.48 mol) in 200 mL of dry Et_2O over 30 min. The mixture was warmed to the reflux temperature of NH_3, and after 2 h the mixture was cooled again to −78 °C. Methyl iodide (33.0 mL, 0.53 mol) in 200 mL of dry Et_2O was added over 1.5 h, and after 15 min the cooling bath was removed. After 30 min solid NH_4Cl (20 g) was added in several portions at −78 °C over 30 min. Ammonia was allowed to evaporate at room temperature, while a 1:1 mixture of ether and pentane (500 mL) was added. Inorganic salt was removed by filtration and **1** was obtained by distillation (53.2 g, 72%; b.p. 37–40 °C/1.7 Torr). This material contained 9% of unsubstituted cyclopropenone acetal and 3% of 2,3-dimethyl cyclopropenone acetal as judged by GLC.

A solution of potassium *tert*-butoxide (1.32 g, 12 mmol) in *t*BuOH (7.11 g, 96 mmol) and 40 mL of ether was added under nitrogen over 5 min to a solution of **1** (46.3 g, 0.30 mol) in ether (100 mL) at −78 °C. After 5 min the mixture was warmed to room temperature and stirred for 4 h. 1 N Hydrochloric acid (15 mL) was added and the mixture was subjected to extractive workup and distillation to obtain **1** (36.49 g, 79% yield, b.p. 57–59 °C/7.3 Torr).

General procedure for the cycloaddition illustrated by the preparation of 2,2-dimethyl-3-hydroxypropyl 4-butyl-3-methylsulfonylcyclopent-3-enecarboxylate (entry 7 in Table 7): A solution of **1** (0.113 mL, 111 mg, 0.72 mmol), and methyl hex-1-ynyl sulfone (96 mg, 0.6 mmol) in 0.5 mL of CD_3CN was heated in a sealed NMR tube at 80 °C for 27 h. ^1H NMR monitoring indicated the formation of an (acid-labile ketene) acetal **3** in high yield: ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 0.92 (t, J = 7.0 Hz, 3H), 1.00 (s, 6H), 1.24–1.57 (m, 4H), 2.59 (br. t, J = 7.4 Hz, 2H), 2.89 (s, 3H), 3.24 (br s, 2H), 3.34 (br s, 2H), 3.8 (br s, 4H). This primary cycloadduct was hydrolyzed to the corresponding ester **5** for further characterization. The crude $CDCl_3$ solution was treated with 35 mg of Amberlyst 15 and 40 mg of water and the mixture was stirred for 30 min. The resin was removed to give crude cyclopentenecarboxylic acid ester **5** (270 mg). Purification by chromatography (silica gel 8 g, 45% ethyl acetate/hexane) afforded the desired compound (169 mg, 85% yield). ^1H NMR (200 MHz, $CDCl_3$): δ = 0.92 (t, J = 6.9 Hz, 3H), 0.94 (s, 6H), 1.26–1.54 (m, 4H), 2.05 (br t, J = 6.1 Hz, 1H), 2.59 (br t, J = 7.4 Hz, 2H), 2.86–2.96 (m, 2H), 3.03–3.11 (m, 2H), 3.13–3.29 (m, 1H), 3.31 (br d, J = 6.1 Hz, 2H), 3.98 (s, 2H); IR (neat): $\tilde{\nu}$ = 3520, 1730, 1635, 1320, 1300, 1140, 1055 cm^{-1}; Anal. calcd. for $C_{16}H_{28}SO_5$: C 57.80, H 8.49; found C 57.58, H 8.28.

N-Hydroxypyridinethiones as Photochemical Hydroxyl Radical Sources for Oxidative DNA Damage**

Waldemar Adam, Daniel Ballmaier, Bernd Epe, Günther N. Grimm, and Chantu R. Saha-Möller*

For about five years it has been known that *N*-hydroxypyridine-2-thione (**1**) generates hydroxyl radicals on irradiation with visible light,[1] and that this reaction also takes place in aqueous buffer solution.[2] Thione **1** is a versatile antibacterial and antifungal reagent; furthermore, it exhibits in vitro cytotoxic activity in leukemia cells and is therefore a potential chemotherapeutic agent.[3] The biological activity of this reagent is probably due to the photochemical formation of hydroxyl radicals. Recently the genotoxicity of *N*-hydroxypyridinethiones has been investigated in cellular systems.[4] The preliminary results reveal that these reagents are indeed cytotoxic in mouse cells and Chinese hamster fibroblasts only in the presence of light.[4]

Among reactive oxygen species, hydroxyl radicals play a particularly important role in oxidative damage of biomolecules (for example, DNA, proteins, and lipids) in cellular systems.[5] Since the conventional methods for the generation of hydroxyl radicals are of limited scope for biochemical investigations,[6] in the last few years new, photochemical hydroxyl radical sources, the so-called photo-Fenton reagents, were developed.[7] In this context we have investigated the genotoxicity of the thiones **1** and **2** and observed significant DNA damage.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 172 "Molekulare Mechanismen kanzerogener Primärveränderungen") and the Fonds der Chemischen Industrie.

The damage profiles that are characteristic for hydroxyl radicals, namely, oxidation of DNA bases (mainly guanine) and single strand breaks, are shown in Figure 1. Analogous to 2-thiopyridone (**1**), which is an established photochemical hydroxyl radical source,[1,2] 4-thiopyridone (**2**) efficiently forms hydroxyl radicals on irradiation. Here we present our preliminary results.

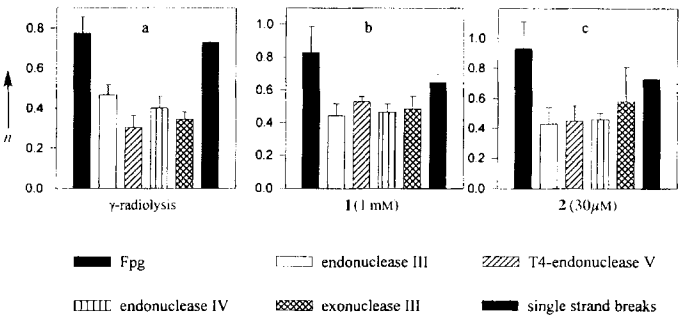

Fig. 1. DNA damage profiles after treating PM2 DNA with ionizing γ radiation (a), or light and **1** (1 mM) (b), or light and **2** (30 μM) (c). The columns show the number n of single-strand breaks and various repair endonuclease-sensitive modifications per 10000 base pairs [17].

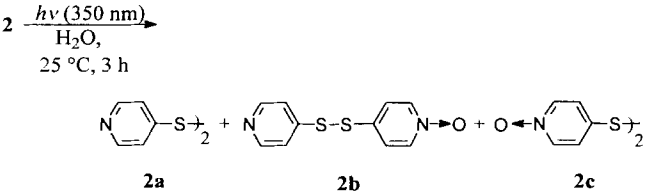
The irradiation of the *N*-hydroxy compound **2** (60.0 mg, 4.70 mmol) at 350 nm (Rayonet photoreactor) in water (10 mL) and acetonitrile (3 mL) yielded, after silica gel chromatography, the products **2a** (17%), **2b** (32%), and **2c** (42%) (Scheme 1).



Scheme 1.

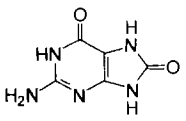
Additional products, which might be formed by incorporation of acetonitrile radicals generated by the reaction of hydroxyl radicals with acetonitrile,[8] were not observed. The formation of the photoproducts **2a–c** can be rationalized by the reported mechanism[1] postulated for the photolysis of *N*-hydroxypyridine-2-thione (**1**), which implies that the photoproducts are formed not only by N–O bond cleavage, but also through a radical chain reaction initiated by H abstraction from the thiol tautomer of the starting material. In the latter case, acetonitrile radicals may also be involved.

The following results confirm the formation of hydroxyl radicals by irradiation of thione **2**. In the photolysis (λ = 350 nm) of the *N*-hydroxypyridinethiones **1**[9] and **2** (40 mmol) in degassed, pure acetonitrile (4 mL) and benzene (5 mL) under inert atmosphere (nitrogen), phenol was detected by gas chromatography[10] (5.1 and 9.5%, relative to the amount of *N*-hydroxy derivative employed). In comparison, about five times higher amounts of phenol were formed in oxygen-saturated solutions. The lower yield of phenol in the absence of oxygen may readily be explained in terms of preferential dimerization of the initially formed hydroxycyclohexadienyl radicals, and consequently only a small fraction of the initial hydroxyl radicals produce phenol.[11]

To confirm the generation of hydroxyl radicals in aqueous solution, thiones **1** or **2**[9] (5.40 mg, 42.5 μmol) were irradiated in aqueous solution of benzoic acid (51.2 mg, 419 μmol in 20 mL), and the reaction products were quantified by HPLC analysis. In both cases, the 2-, 3- and 4-hydroxybenzoic acids were formed in a total yield of 6.2 and 8.8%.[12]

The direct spectral evidence for the formation of hydroxyl radicals in the photolysis of *N*-hydroxypyridine-4-thione (**2**) was obtained by ESR analysis through spin trapping with 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) in aqueous solution. The characteristic quartet for the hydroxyl radical adduct[13, 14] was observed ($a_N = a_H = 14.8$ G, $g = 2.0054$), while the trapping product of thiyl radicals was not detected under these reaction conditions. Recently, the detailed ESR spectral study of the photolysis of thione **1** has appeared,[14, 15] and our data agree well with the reported ones. These results confirm unequivocally that, like the *N*-hydroxypyridine-2-thione (**1**), the regioisomeric 4-thione **2** is also an efficient photochemical hydroxyl radical source.

As an indicator for the oxidative DNA damage, the formation of 7,8-dihydro-8-oxoguanine (**3**) by thiones **1** and **2** on UVA irradiation ($\lambda = 350$ nm) was examined in isolated DNA. For this purpose a solution of calf thymus DNA (0.1 μg μL^{-1}) and thione **1** or **2** in 5 mM phosphate buffer was irradiated at 6 °C for 20 to 60 min. Subsequently the modified DNA was precipitated, hydrolyzed with HF/pyridine, and submitted to HPLC analysis (electrochemical detection at 350 mV); the results are shown in Table 1. The *N*-hydroxypyridine-4-thione (**2**) formed more 8-OxoGua (**3**) than thione **1** after irradiation for 20 min. The addition of the hydroxyl radical scavenger *tert*-butyl alcohol[16] (2%) decreased the 8-OxoGua yield significantly in both cases (about 40%) (Table 1, entries 2 and 6). In the presence of 40 mM mannitol, which is also a hydroxyl radical scavenger,[2] the yield of 8-OxoGua was reduced as well (Table 1, entries 3 and 7). The moderate scavenging effect may emanate from the association of *N*-hydroxypyridinethiones with DNA.



3

Besides the scavenging experiments with *tert*-butyl alcohol and mannitol, additional control reactions were carried out, which confirm that hydroxyl radicals are responsible for the oxidative DNA damage. Thus, in the absence of light, the thiones **1** and **2** did not form any 8-OxoGua. Furthermore, at longer irradiation times the amount of 8-OxoGua did not increase, which indicates that the photoproducts of thiones **1** and **2** do not induce significant DNA oxidation.

Table 1. Photoinduced formation of 8-OxoGua by the *N*-hydroxypyridinethiones **1** and **2** in calf thymus DNA [a].

No.	Thione[b]	*t*BuOH[Vol.%]	Mannitol[mM]	*t*[min][c]	Yield (**3**)[%][d]
1	**1**	-	-	20.0	0.19±0.03
2	**1**	2.00	-	20.0	0.11±0.03
3	**1**		40.0	20.0	0.13±0.02
4	**1**		-	60.0	0.46±0.06
5	**2**	-	-	20.0	0.42±0.09
6	**2**	2.00	-	20.0	0.26±0.02
7	**2**		40.0	20.0	0.16±0.06

[a] 200 μL solutions of DNA and *N*-hydroxypyridinethiones in 5 mM phosphate buffer (pH 7.0) were irradiated at 6 °C (*t* = duration of irradiation). [b] The thione concentration was 62.5 μM (one equivalent, based on the guanine concentration in DNA). [c] Irradiation at $\lambda = 350$ nm in a Rayonet photoreactor. [d] Quantification by HPLC (electrochemical detection at 350 mV), yield relative to guanine (after subtraction of blank), this corresponds to the yield relative to 1 equiv *N*-hydroxypyridinethione.

Further evidence that hydroxyl radicals cause the damage was obtained by a relaxation assay with PM2 DNA and specific repair endonucleases.[17] The irradiation of superhelical PM2 DNA in the presence of *N*-hydroxypyridine-2-thione (**1**) or *N*-hydroxypyridine-4-thione (**2**) led to single strand breaks, apurinic sites (AP lesions), and numerous base oxidation products.[18] The damage profiles for the thiones **1** and **2** show the characteristic pattern (Fig. 1) for hydroxyl radicals (formed by γ radiolysis of water). The 4-thione **2** exhibited a significantly higher reactivity than the 2-thione **1**. For example, during the same irradiation time (10 min), the thione **2** caused the same extent of DNA damage at a concentration of 30 μM (Fig. 1c) as thione **1** formed at 1 mM (Fig. 1b). For comparison, the damage profile of hydroxyl radicals generated by γ radiolysis (Fig. 1a) is significantly different from that of photosensitizers.[17c] In the latter process the DNA is damaged predominantly through type II (singlet oxygen) and type I photooxidation (radical and electron transfer processes). While singlet oxygen causes mainly Fpg-sensitive[19] base modifications, hydroxyl radicals also form considerable amounts of single strand breaks and AP lesions.[17b, c 20, 21]

That other active oxygen species are not involved in the reaction of DNA with the *N*-hydroxypyridinethiones **1** or **2** was established through control experiments. Both the additives superoxide dismutase and catalase did not show any significant effects. In contrast, *tert*-butyl alcohol decreased the formation of single strand breaks and Fpg-sensitive modifications remarkably. This suggests that neither superoxide anions nor hydrogen peroxide appear to be involved, and consequently, hydroxyl radicals are the only DNA-damaging species in the photolysis of the thiones **1** and **2**.

Our study confirms that *N*-hydroxypyridine-2-thione (**1**), and even more its *para* regioisomer **2**, are efficient photochemical sources for hydroxyl radicals. For the first time their DNA-damaging activity was demonstrated. Their favorable properties, such as water solubility, availability, and absorption in the visible region, make them particularly suited as hydroxyl radical sources for the investigation of biochemically and biologically important reactions. Of relevance in the potential application of the *N*-hydroxypyridinethiones **1** and **2** as chemotherapeutics is their expected cytotoxity elicited through the specific oxidative alteration of biomolecules by the photochemically generated reactive oxygen species. Such applications require highest priority.

Generation of Enantiomerically Enriched Lithium Indenides by Means of (−)-Sparteine: Structure, Stereoselective Substitution, and Solvent Effects**

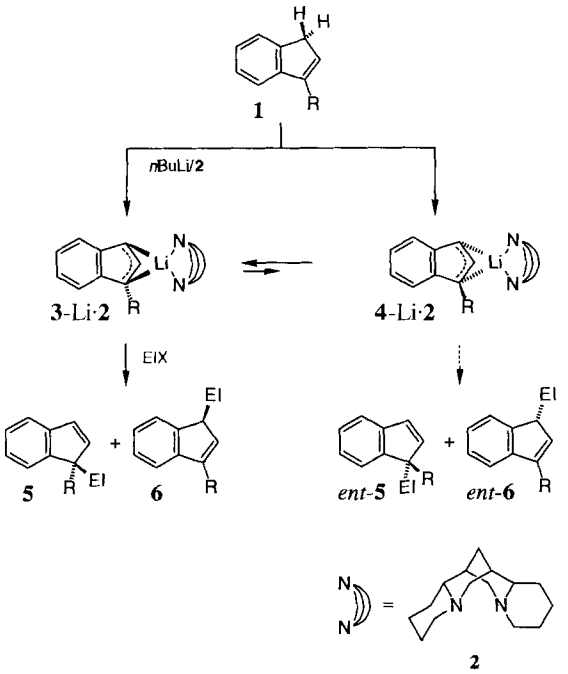
Inga Hoppe, Michael Marsch, Klaus Harms, Gernot Boche,* and Dieter Hoppe*

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

A number of enantiomerically enriched carbanionic building blocks that are stereogenic at the metal-carrying C atom have in the past been synthesized by deprotonation and substituted stereospecifically by electrophiles.[1] This has been achieved by four methods: 1) stereoselective deprotonation of chiral precursors to give configuratively stable ion pairs;[2] 2) asymmetric deprotonation of achiral precursors by a chiral base that differentiates between the enantiotopic protons;[3] 3) asymmetric deprotonation under kinetically controlled resolution of a racemic mixture;[4] 4) thermodynamically controlled equilibrium between configuratively labile, diastereomeric ion pairs in the presence of a chiral cation such as $Li^+ \cdot (-)$-sparteine ($Li^+ \cdot$ **2**),[5] often combined with the crystallization of the most favorable diastereoisomer[5a,b] ("second-order asymmetric transformation"[6]). The crystal structure of an allyllithium complex synthesized by this method has been solved.[7]

Alkali metal indenides are important intermediates in the construction of chiral metallocene catalysts.[8] Although the rates of the interconversion of the enantiomers of trialkylammonium–indenide ion pairs and the protonation of the anions are of the same order of magnitude,[9,10] enantiomerically enriched metal indenides have not been known until now. We report on the highly stereoselective, but strongly solvent-dependent, generation of lithium 1-alkylindenides by method 4, their structure, and their stereoselective substitution with electrophiles.

1-Methylindene (**1a**) was deprotonated by *n*-butyllithium/(−)-sparteine[11] (*n*BuLi·**2**) in *ether/hexane* at −70 °C. Crystallization began on warming to room temperature. Addition of acylchlorides or -in the presence of tetra(isopropoxy)titanium (TIPT)—aldehydes and ketones, yielded the 1-substituted indenes **5a–g,i** with >95% *ee* as major products, and generally favored by more than 97:3 over the 3-regioisomer **6** (Scheme 1,



Scheme 1. Synthesis of the functionalized indenes **5** and **6** in the presence of the chiral ligand (−)-sparteine (**2**) For **1a**, **3a**, and **4a**, R = Me. For **1b**, **3b**, and **4b**, R = nC_4H_9. For **5** and **6**, R and El are given in Table 1.

Table 1). The products **5** have the (1*R*) configuration, as shown by the X-ray crystal structure of the (*R*)-1-phenylethylamide formed from the ester **5a**[12] and by the chemical correlation of this amide with **5c**, **5i**, and **5m**.[13] Like **5a**, **5c**, **5i**, and **5m**, the other compounds **5** also have a high negative specific rotation $[\alpha]_D$. Thus it is highly probable that they belong to the same stereochemical series. In contrast, the α-branched aldehydes 2-methylpropanal and 2,2-dimethylpropanal give predominantly the regioisomeric adducts **6k** and **6l**. Due to the strongly positive optical rotation we ascribe to them the (1*S*) configuration (at the former C3 center).

[a] Yield after chromatographic separation. [b] Determined by ^{1}H NMR spectroscopy with Eu(hfc)$_3$. [c] In CH_2Cl_2. [d] Addition of tetra(isopropoxy)titanium to the reaction mixture. [e] Mixture of diastereomers. [f] The enantiomeric excess could not be determined. [g] Optical rotation of the mixture of diastereomers. [h] Diastereomeric mixture 55:45. [i] Diastereomeric ratio greater than 95:5. [j] Diastereomeric ratio of 61:39. [k] Data for **5m** (yield 11%); **6m** (25%), $[\alpha]_D^{20}$ = +16 (*c* = 1) for 10%*ee*. [l] R^1 = 
From **1b**, which like **1a** was deprotonated in *ether/hexane*, we obtained lithium/(−)-sparteine 1-butylindenide **3b**-Li·**2**, which also has a (1*R*) configuration at the C1 position according to the X-ray crystal structure (Fig. 1).[14] The distance from Li1 to C1 (243.2 pm) is longer than that to C3 (233.4 pm). Li1 forms only weak interactions to the C4 and C9 atoms of the annulated benzene ring (C4–Li1 251.0 pm; C9–Li1 254.5 pm). The distance to C2 is 229.9 pm.

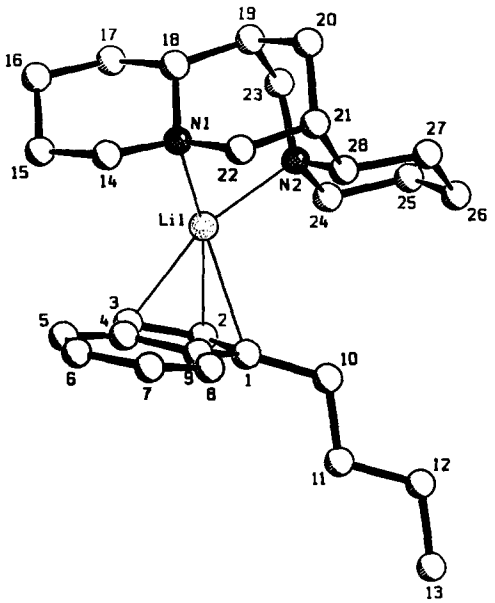

Fig. 1. Crystal structure of **3b**-Li·**2**. Some important bond lengths [pm]: Li1-C1 243.2(6), Li1-C2 229.9(6), Li1-C3 233.4(6), Li1-N1 209.5(6), Li1-N2 214.0(6), C1-C2 139.2(5), C2-C3 140.9(5).

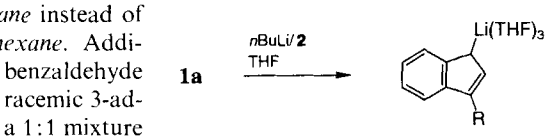
The reaction of **3b**-Li·**2** with benzoyl chloride gives the 1-adduct **5g**, which also has a strongly negative optical rotation (Scheme 1, Table 1). This implies that the crystallized lithium indenide complexes **3a**-Li·**2** and **3b**-Li·**2** have the same (1*R*) configuration at C1, and their reactions with carbonyl compounds give **5a**–**i** with retention of configuration. Diastereomeric complexes of the type **4**-Li·**2** appear to be of no great importance. Probably the Li cation captures the carbonyl compound through complexation, which is then inserted into the longer and therefore weaker C1–Li1 bond. Only for bulky electrophiles, for example 2-methylpropanal, is attack at the sterically less hindered 3-position favored. We do not have any evidence that TIPT reacts with the **3**-Li·**2** complexes. Presumably it merely prevents reversibility of the aldehyde addition.[20]

The importance of the choice of solvent is highlighted by the reaction of 1-methylindene (**1a**) with *n*BuLi/(−)-sparteine at −70 °C in *tetrahydrofuran/hexane* instead of in *ether/hexane*. Addition of benzaldehyde yields the racemic 3-adduct **6i** as a 1:1 mixture of diastereomers. Consequently (−)-sparteine (**2**) in THF solution seems to have no influence on the stereoselectivity of this reaction, probably because it is displaced from Li^+ by THF. This is in accord with the structure of crystals isolated from such a solution:[21] 1-methyl-3-lithioindene crystallizes with three THF molecules (**3a**-Li·3THF) (Fig. 2).[25] Due to the threefold coordination of Li1 by THF there is only η^1-bonding (C3–Li1 230.9 pm) to the "allyl anion" part of **3a**.



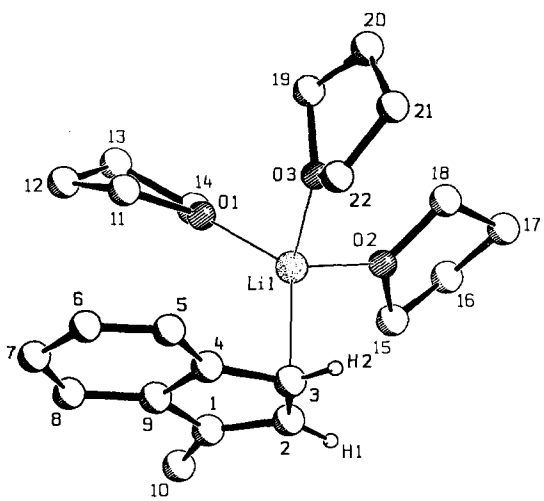


Fig. 2. Crystal structure of **3a**-Li·3THF. Some important bond lengths [pm]: Li1-C3 230.9(6), Li1-C2 252.6(6), Li1-C1 303.1(7), Li1-O1 193.8(5), Li1-O2 197.4(5), Li1-O3 197.7(5), C1-C2 139.3(5), C2-C3 139.2(5).

In this paper we have not only developed an easy and efficient method of preparing virtually enantiomerically pure, functionalized indenes, but have also demonstrated for the first time the solvent-dependent structures of the participating lithiated intermediates and the stereochemistry of their reactions with electrophiles.

Experimental Procedure

Successively, *n*-butyllithium (2.0 mmol, about 1.5 N in hexane), (−)-sparteine (2.0 mmol, dissolved in 3 mL diethyl ether), and 1-methyl-(3*H*)-indene (2.0 mmol in 2 mL diethyl ether) were added dropwise to diethyl ether (6 mL) below −70 °C. The reaction mixture was stirred and allowed to warm to 20 °C. After a further 30 min stirring it was cooled to −70 °C, and tetra(isopropoxy)titanium (4.0 mmol) and the acyl chloride or aldehyde (2.0 mmol) was added. The mixture was stirred for a further 2–6 h at this temperature. After addition of 2 N HCl (10 mL) to the reaction mixture the product was isolated and purified by chromatography on silica gel with ether/pentane.

3a-Li·3THF: 1-methyl-indene (100 mg, 0.77 mmol) was dissolved in THF (1 mL) followed by (−)-sparteine (**2**, 215 mg, 0.92 mmol). To this solution was added dropwise at −78 °C *n*BuLi (0.92 mmol, 1.6 M in hexane). After 12 h at −26 °C crystals had formed, which were good enough for X-ray analysis. Yield: 222 mg (82%).

3b-Li·**2**: To diethyl ether (2.5 mL) was added at −78 °C *n*BuLi (0.5 mmol, 1.6 M in hexane) and subsequently a solution of (−)-sparteine (**2**, 117 mg, 0.5 mmol) in diethyl ether (1 mL). After 15 min 1-butylindene (86 mg, 0.5 mmol) in diethyl ether (1.3 mL) was added. On warming to room temperature single crystals, good enough for X-ray analysis, were formed within 1 hour. Yield: 163 mg (79%).

[21] We have not yet examined (for example, with ^{6}Li^{1}H-HOESY experiments) whether a (small) equilibrium coucentration of a complex **3b**-Li·**2** (Fig. 1) analogous to **3a**-Li·**2** is present. Beak et al.[22] have shown by NMR spectroscopy that an isopropyllithium·(−)-sparteine complex exists in diethyl ether solution. Also the Li cation in [^{6}Li]-α-lithiobenzylphenylsulfide is coordinated by (−)-sparteine in THF/[D_8]THF (1/1)[23·24].

[24] There is no uniform picture on extent to which amine ligands are bound to the Li cation in THF solutions, since it is obviously dependent on the nature of the anion. Tetramethylethylendiamine (TMEDA), the most examined ligand, can be attached to Li^+ in THF solution or can be replaced by THF. A review of this topic is found in the article of D. B. Collum, *Acc. Chem. Res.* **1993**, *26*, 227–234.

Additions of Carbanions to a Cationic Cyclopentadienyl(naphthalene)iron Complex**

Ernst Peter Kündig,* Patrick Jeger, and Gérald Bernardinelli

Arenes bound to electrophilic transition metal complex fragments are activated for nucleophilic addition reactions.[1] When this type of complex contains a second unsaturated ligand, nucleophiles add to the more electron-deficient unit. In cationic arene(cyclopentadienyl)iron complexes, addition thus takes place on the arene rather than on the cyclopentadienyl ligand.[2] Some years ago, Davies, Green, and Mingos formulated concise rules for nucleophilic addition to cationic complexes having unsaturated organic ligands:[3] the selectivity in these reactions is based on charge control and the irreversibility of the addition. The predictions hold well for cationic complexes, because addition to this class of compounds generally proceeds under kinetic control. However, for complexes containing an electrophilic metal center, single electron transfer resulting in reduction of the metal center can be a competitive process. This can severely limit the scope of this C–C bond forming method. The reactivity of iron complex **1** (Cp = cyclopentadienyl) serves as an

$[(\eta^5\text{-Cp})(\eta^6\text{-naphthalene})\text{Fe}]PF_6$ **1**

example.[4] Unlike the benzene analogue, which reacts with carbanions to give η^5-cyclohexadienyl complexes,[5] complex **1** reacts with alkyllithium and Grignard reagents to give dark green solutions of the unstable 19e complex $[(\eta^5\text{-Cp})(\eta^6\text{-naphthalene})\text{Fe}^I]$.[6] We found that **1** is also reduced by stabilized carbon nucleophiles ($LiCMe_2CN$, $LiCH_2CN$, $LICH_2CO_2tBu$), and we did not succeed in isolating benzocyclohexadienyl complexes from the reaction mixtures. The naphthalene complex **1** behaves differently from the benzene complex in these reactions because complexes with condensed arenes as ligands are more easily reduced than those with monocyclic arenes. Cyclic voltammetry shows the naphthalene complex **1** to undergo one-electron reduction at -1.04 V,[7] whereas complexes with monocyclic arenes are reduced at more negative potentials (range -1.3 to -1.4 V).[7] We anticipated that methoxy substituents on naphthalene would make reduction more difficult and hopefully change the reaction pattern of the complex.

In this article we report on the synthesis of complex **2a** and on the observation that this complex, unlike **1**, reacts with

$[(\eta^5\text{-Cp})\text{-}\{(1\text{-}4,4a,8a\text{-}\eta)\text{-}5,8\text{-dimethoxynaphthalene}\}\text{Fe}]PF_6$ **2a**

carbanions by addition. Remarkably, depending on the nature of the carbanion, addition occurs to either or both of the ligands (arene and/or the cyclopentadienyl ring).

First attempts to synthesize complex **2a** and/or its (4a,5-8,8a-η) regioisomer **2b** by Lewis acid mediated ring exchange in ferrocene (**3**)[8] or by photolytic arene exchange[9] were not successful. We therefore turned to the thermal arene exchange reaction[10] and were pleased to obtain **2** from complex **4**[11] in

$[(\eta^5\text{-Cp})(\eta^6\text{-pyrene})\text{Fe}]PF_6$ **4**

nearly quantitative yield (ratio **2a**:**2b** = 19:1). Crystallization gave pure **2a** in 87% yield. Although the difference in reduction potential between **2a** ($E_1^0 = -1.11$ V) and **1** is only 70 mV,[7] the simple modification of substituting the noncomplexed ring is enough to change the reaction pathway from reduction to nucleophilic addition. Complex **2a** reacts readily with carbanions at low temperature. This was indicated by the formation of a red homogeneous solution when solid **2a** (insoluble in THF) was added to a solution of the organolithium reagent in THF at $-78\,^\circ$C. Neutral benzocyclohexadienyl complexes **5**–**7** were isolated from these reactions in high yield. The results are listed in Table 1 and they also include the reaction with $NaBH_4$.

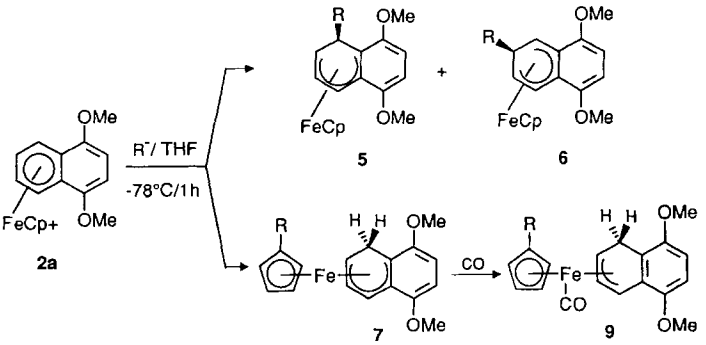

Table 1. Chemo- and regioselectivity of nucleophilic additions to complex **2a**.

Entry	Nucleophile R^- as salt	Products (and ratios) of addition to arene	to Cp	Yield [%]
1	$LiCH_2CN$	**5a** (91) : **6a** (9)	: **7a** (0)	85
2	$LiCH_2CO_2tBu$	**5b** (80) : **6b** (20)	: **7b** (0)	97
3	$NaBH_4$	**5c** (69) : **6c** (31)	: **7c** (0)	92
4	MeLi	**5d** (72) : **6d** (17)	: **7d** (11)	91
5	PhLi	**5e** (61) : **6e** (26)	: **7e** (13)	92
6	AllylLi	**5f** (75) : **6f** (7)	: **7f** (18)	98
7	$LiCMe_2CN$	**5g** (36) : **6g** (35)	: **7g** (29)	84
8	$LiCHS(CH_2)_3S$	**5h** (0) : **6h** (66)	: **7h** (34)	92
9	*t*BuLi	**5i** (0) : **6i** (0)	: **7i** (100)	77

Stabilized primary carbon nucleophiles and also hydride ions added exclusively to the naphthalene ligand to give the *exo* addition products **5** and **6**, where addition to C5 is favored over addition to C6. These results are analogous to those obtained previously with complex **8**.[12] Addition to C6 predominates

$[\{(1\text{-}4,4a,8a\text{-}\eta)\text{-}5,8\text{-dimethoxynaphthalene}\}\text{Cr}(CO)_3]$ **8**

with more reactive and/or more bulky nucleophiles. Again, there is precedence for this in reactions of the Cr complex **8**, with the difference that in the reactions reported here regioselectivity is independent of reaction time and temperature (-70 to $25\,^\circ$C), and we therefore assume that additions to **2a** are under kinetic control. The formation of **7** was unexpected. There is scarce precedence for addition to the Cp ring in this class of compounds.[13] Table 1 shows that the proportion of **7** increases with increasing size and reactivity of the nucleophile. *t*BuLi added selectively to the Cp ring.

η^5-Benzocyclohexadienyl ligands can undergo facile haptotropic rearrangement to an η^3-enyl coordination mode.[14] Complex **7i**, when subjected to a CO atmosphere, gave product **9**, whose structure is shown in Figure 1.[15]

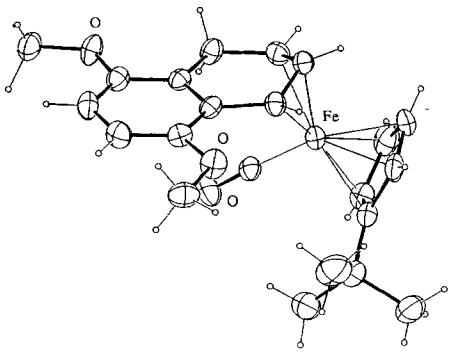

Fig. 1. Perspective view of the crystal structure of **9i**. Ellipsoids are at the 40% probability level.

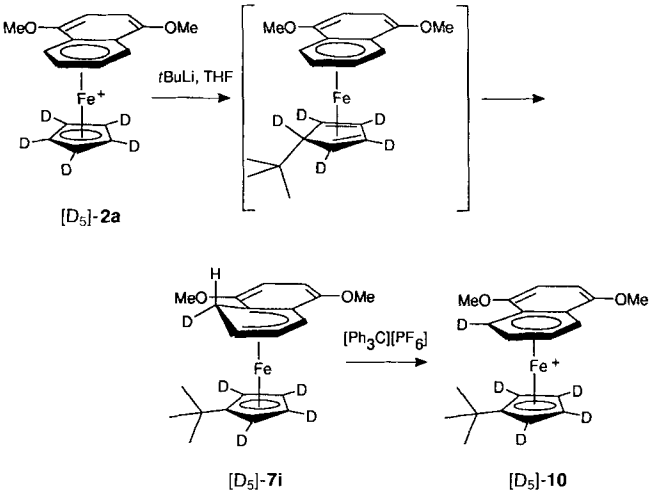
The pathway for the the formation of **7** was probed using [D_5]-**2a**. In accord with ^{1}H NMR data we deduce a pathway which involves nucleophilic addition to the Cp ring, followed by D^- transfer from the Cp to the C5 *endo* position of the naphthalene ligand.[21] In agreement with the proposed stereochemistry, $[Ph_3C]PF_6$ reacts with [D_5]-**7i** by abstracting the *exo* H atom from C1 to give the cationic arene complex [D_5]-**10i**.[22]



Experimental Procedure

2a: Under N_2, complex **4** [11] (11.6 g, 24.8 mmol) was added to liquid 1,4-dimethoxynaphthalene (23.3 g, 0.124 mol) at 130 °C. After stirring for 2.5 h at this temperature, the reaction mixture was cooled to room temperature and dissolved in CH_2Cl_2 (20 mL). On addition of hexane (100 mL) a dark precipitate formed which was collected by filtration and washed with toluene (3 × 20 mL). Extraction with CH_2Cl_2, filtration, and solvent removal yielded the crude complex, which consisted of **2a** and **2b** in a ratio of 19:1, according to the ^{1}H NMR spectrum. Recrystallization from CH_2Cl_2/toluene (5:1) gave red **2a** (9.83 g, 87%). M.p. 166 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 22 °C): δ = 7.29–7.33 (m, 2H; H_{Ar}), 7.06 (s, 2H; H-C(6,7)), 6.44–6.49 (m, 2H; H_{Ar}), 4.69 (s, 5H; H_{Cp}), 4.03 (s, 6H, H_{OMe}). ^{13}C NMR (50 MHz, [D$_6$]DMSO, 22 °C): δ = 149.2, 106.4, 88.6, 86.5, 79.4, 76.3, 56.6. ES-MS: *m/z* = 309 (M^+, 100). Anal. calc for $C_{17}H_{17}O_2FePF_6$ (454.1): C 44.96, H 3.77; found: C 44.87, H 3.80.

7i: Under N_2, complex **2a** (400 mg, 0.88 mmol) was added in one portion to a stirred, cold (−78 °C) solution of *t*BuLi (0.90 mmol) in THF (10 mL). A brown solution formed within minutes. The reaction mixture was stirred at −78 °C for 1 h and then hexane (50 mL) was added. After warming to ambient temperature, the reaction mixture was filtered over Celite. The ^{1}H NMR spectrum of the crude product showed 1,4-dimethoxynaphthalene and **7i**. During chromatography on Alox V (*n*-hexane/ether = 20/1) first the arene (33 mg, 20%), then **7i** (brown oil, 250 mg, 77%) eluted. ^{1}H NMR (C_6D_6, 200 MHz, 22 °C): δ = 7.47 (d, *J* = 5.3 Hz, 1H; H-C(4)), 5.79 (AB, *J* = 7.9 Hz, 2H; H-C(6,7)), 4.51–4.55 (*m*, 1H; H_{Cp}), 4.44 (dd, *J* = 6.3, 5.3 Hz, 1H; H-C(3)), 3.89 (dd, *J* = 13.2, 6.6 Hz; 1H, H_{endo}-C(1)), 3.67–3.70 (m, 1H; H_{Cp}), 3.59–3.62 (m, 1H; H_{Cp}), 3.53 (s, 3H; H_{OMe}), 3.49 (s, 3H; H_{OMe}), 2.74–2.77 (m, 1H; H_{Cp}), 2.65 (t, *J* = 6.5 Hz, 1H; H-C(2)), 1.86 (dd, *J* = 13.2, 1.2 Hz, H_{exo}-C(1)), 1.26 (*s*, 9H; H_{Me}). ^{13}C NMR (C_6D_6, 50 MHz, 22 °C): δ = 159.6, 151.5, 104.2, 98.7, 96.4, 91.0, 80.1, 76.1, 69.1, 68.9, 68.4, 55.0, 41.1, 31.6, 31.0, 24.1, 23.9. EI-MS (70 eV): *m/z*: 366 (M^+, 1), 309 (12), 188 (89), 173 (100).

9i: A solution of complex **7i** (250 mg, 0.68 mmol) in toluene (10 mL) was placed under CO (4.5 bar). After stirring for 5 h at 22 °C, the reaction mixture was filtered over Celite and the solvent removed in vacuo. Chromatography on Alox V (*n*-hexane/ether = 20/1) gave **9i** (170 mg, 63%), which was recrystallized from *n*-hexane. M.p. 113 °C. ^{1}H NMR (C_6D_6, 200 MHz, 22 °C): δ = 6.30 (AB, *J* = 8.8 Hz, 2H; H-C(6,7)), 5.26 (d, *J* = 6.1 Hz, 1H; H-C(4)), 4.76 (dd, *J* = 6.7, 6.1 Hz, 1H; H-C(3)), 4.49–4.58 (m, 1H; H-C(2)), 3.97–4.05 (m, 2H; H_{Cp}), 3.72–3.81 (m, 2H; H_{Cp}), 3.54 (s, 3H; H_{OMe}), 3.32 (s, 3H; H_{OMe}), 2.88–3.24 (m, 2H, H-C(1)), 1.22 (s, 9H; H_{Me}). ^{13}C NMR (C_6D_6, 50 MHz, 22 °C): δ = 222.9, 151.7, 149.0, 134.5, 119.1, 109.5, 108.8, 105.5, 79.6, 78.9, 78.6, 77.3, 67.9, 55.7, 55.0, 51.2, 44.1, 31.9, 30.8, 30.4. [15] Crystallographic data for **9** (crystals were grown from a *n*-hexane solution): $Fe(C_{12}H_{13}O_2)(C_9H_{13})(CO)$, M_r = 394.3; μ = 0.811 mm^{-1}, $F(000)$ = 1664, ρ_{calcd} = 1.38 gcm^{-3}, monoclinic, *C2/c*, *Z* = 8, *a* = 20.758(3), *b* = 10.966(1), *c* = 16.934(2) Å, β = 99.239(7)°, *V* = 3804.7(8) Å^3, from 30 reflections (20° < 2θ < 25°). A violet prism of dimensions 0.16 × 0.18 × 0.20 mm was mounted in a capillary to prevent degradation. Cell dimensions and intensities were measured at room temperature on a Stoe STADI4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71069 Å), ω – 2θ scans, scan width 1.05 + 0.35 *tg*θ. Two reference reflections measured every 45 min showed variation less than 3.1σ(*I*). −23 < *h* < 23; 0 < *k* < 12; 0 < *l* < 19; 3136 measured reflections, 3016 unique reflections, of which 2091 were observed ($|F_o| > 4\sigma|F_o|$). Data were corrected for Lorentz and polarization effects and for absorption [16]. The structure was solved by direct methods using MULTAN 87 [17]; all other calculations used XTAL [18] system and ORTEP [19] programs. Atomic scattering factors and anomalous dispersion terms were

taken from ref. [20]. Full-matrix least-squares refinement based on $|F|$ using the weighting $1/\sigma^2(F_o)$ gave final values $R = 0.043$, $wR = 0.023$, and $S = 1.78$ for 313 variables and 2091 contributing reflections. The maximum shift/error on the last cycle was 0.003. All coordinates of the hydrogen atoms were observed and refined with a fixed value of isotropic displacement parameters ($U = 0.05$ Å^2), and the 26 other atoms were refined with anisotropic displacement parameters. The final difference electron density map showed a maximum of $+0.45$ and a minimum of -0.50 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Highly Effective Hydrogen-Bonding Receptors for Guanine Derivatives**

Thomas W. Bell,* Zheng Hou, Steven C. Zimmerman,* and Paul A. Thiessen

Many artificial receptors have been designed and synthesized for the purpose of recognizing nucleobases.[1–4] Hydrogen-bonding receptors can bind nucleobase derivatives tightly in nonpolar organic solvents,[1, 2] but ionic or solvophobic interactions are usually needed for strong complexation of nucleosides and nucleotides in polar solvents.[1a, b, 3, 4] Hydrogen bonds are critical to biomolecular recognition of guanosine phosphates[5] and other nucleotides, but they are greatly weakened in polar solvents. Herein we show that receptors having hydrogen bonding sites positioned on a hexagonal lattice (hexagonal lattice receptors)[6] can bind guanine derivatives tightly through hydrogen bonds alone, even in a highly competitive solvent such as DMSO. Decreasing the preorganization or number of hydrogen bond donor or acceptor sites in the receptor weakens the complex.

Guanine derivatives **1**–**3**[7] were chosen as guests for the current study, and hosts **4**–**7** were designed to form hydrogen bonded complexes, as shown for **4** in structure **I**. Receptors **4**–**7** have varying degrees of flexibility and numbers of hydrogen-bonding sites, enabling estimation of enthalpic and entropic contributions to the binding free energy.[8] The design of **4** and **5** combines the fused pyridine framework of hexagonal lattice receptors for urea,[6e, f] guanidinium,[6d, e] and benzamidinium[6c] with *o*-aminonitrile hydrogen bond donors[6a] that are complementary to acceptor sites on guanine. Preorganized receptors **4** and **5** were synthesized from benzylidene ketone **8**[6b, e] by the methods shown in Scheme 1, and flexible analogue **6** was

prepared as shown in Scheme 2. Receptor **7** was prepared from acetophenone and 2,6-diamino-3-pyridinecarboxaldehyde[17] by analogy with the synthesis of **6**.[18]

Binary mixtures of $CDCl_3$ and [D_6]DMSO served as convenient solvents for ^{1}H NMR studies of complexation for the following reasons: 1) guests **1**–**3** and hosts **4**–**7** are soluble over wide concentration ranges; 2) the [D_6]DMSO/$CDCl_3$ ratio can be decreased to observe host and guest aggregation,[19] then increased to conduct binding studies without competing aggregation; and 3) the [D_6]DMSO/$CDCl_3$ ratio can be increased to weaken 1:1 complexes, enabling measurement of stability constants (K_a) by titration and dilution methods.[20] The stability constants of complexes listed in Table 1 were determined by addition of the guanine guests to solutions of the hosts or by addition of the hosts to solutions of the guests. The chemical shifts of the compound with the fixed concentration were used to model complexation equilibria. The stability constants were checked by dilution of the 1:1 complexes or by multiple titrations. A 1:4 mixture of [D_6]DMSO and $CDCl_3$ was found to be the best solvent for comparing the binding abilities of all four receptors, though only the lower limit of the stability constant could be estimated for the strongest complex (**4**·**2**) in this solvent.

The complexation shifts and relative stability constants in Table 1 are all consistent with the binding model shown in structure **I**. For example, extending receptor **5** to **4** or receptor **7** to **6** markedly increases the K_a value, indicating that the aminopyridine units contribute to the binding. Furthermore, stability constants are inversely related to the amount of [D_6]DMSO in the solvent mixture, showing that desolvation of host and guest is a significant factor. Finally, the K_a values for complexes between receptors **4**–**6** and **1** measured at Illinois were identical to those for the analogous complexes of **4**–**6** and **2** measured at

Table 1. Stability constants [M^{-1}] and free energies of association [kcal mol^{-1}], in parentheses) for 1:1 complexes of receptors **4**–**7** with guanine derivatives **1**–**3** (298 K) [a], as calculated from changes in ^{1}H NMR chemical shifts ($\Delta\delta$) on complexation.

Complex	Solvents	([D_6]DMSO/$CDCl_3$, v/v)		
$\Delta\delta_{max}$ [b]	1:0	1:1	1:4	1:19
4·**2**	140 ± 20	3800 ± 300	>190000 [d]	
0.14 [c]	(− 2.9)	(− 4.8)	(< − 7.1)

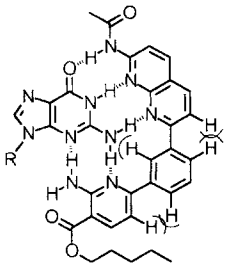
2.52, 1.33 [i]			(− 1.5)	(− 3.4)

[a] Errors given are σ values for the averages of K_a values calculated for each data point; duplicate measurements by nonlinear regression were within 20% of the K_a values, for which no errors are given. [b] Unless stated otherwise, chemical shifts on complexation for the species at a fixed concentration were calculated from analysis of the results of titrations in [D_6]DMSO/$CDCl_3$ (1:4); positive $\Delta\delta_{max}$ value for downfield shift. [c] H4 in **4**, [D_6]DMSO/$CDCl_3$ (1:1). [d] Estimated by assuming that the difference between the binding energies of **4**·**2** and **5**·**2** should be larger in 1:4 [D_6]DMSO/$CDCl_3$ than in the 1:1 solvent mixture. [e] H13 in **5**. [f] H1′, H2′, and H3′, respectively, in **1**. [g] H2 in **6**. [h] NH in **3**. [i] NH and NH_2, respectively, in **1**.

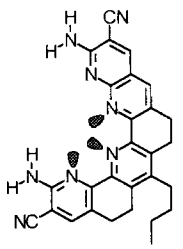
Stony Brook. These results indicate both that the minor structural difference between guests **1** and **2** is irrelevent to binding strength and that experimental variations between the different laboratories negligibly affect the binding analyses.

The most striking result shown in Table 1 is that receptor **4** binds triacylated guanosine **2** in 1:1 [D_6]DMSO/$CDCl_3$ with a K_a value of greater than 3000 M^{-1} by means of hydrogen bonding alone. Even in pure DMSO the complex **4**·**2** is moderately stable. Flexible receptor **6** can form the same number of primary hydrogen bonds with guanosine **2**, but in 1:4 [D_6]DMSO/$CDCl_3$ the complex **6**·**2** is at least 4.1 kcal mol^{-1} weaker than **4**·**2**. The source of the difference in the stabilities of these two complexes cannot be elucidated completely because receptors **4** and **6** have several structural differences. Nevertheless, it is instructive to consider the factors that may be responsible.[8] Two degrees of rotational freedom must be lost in **6** upon complexation. In a related host–guest study the energy cost of freezing an aryl–aryl bond was determined to be 0.9 kcal mol^{-1},[21] in line with Jencks's estimate of 0.5–1.4 kcal mol^{-1} per restricted rotation.[8d] This loss in entropy accounts for less than half of the difference between the stabilities of complexes **4**·**2** and **6**·**2**. The remainder can be attributed to enthalpic factors, including secondary electrostatic interactions[22] that stabilize **4**·**2** (structure **I**) and conformational strain in **6**·**2** caused by steric interactions involving the aromatic hydrogens (structure **II**). Additionally, the convergence of nonbonded electrons shown in structure **III** may weaken solvation of the host cleft per hydrogen bond acceptor, enhancing hydrogen bond strengths in complex **4**·**2**. The large increase in binding energy observed upon ligand extension from **5** to **4** apparently reflects the "intrinsic energy" described by Jencks[8d] and shows that much of the entropy cost in **4**·**2** is already paid upon formation of **5**·**2**.

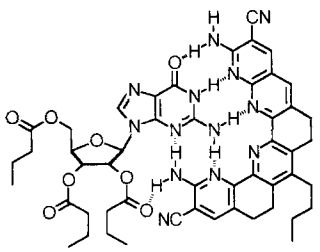
Although acetamido, *o*-aminoester, and *o*-aminonitrile groups are all expected to be good hydrogen bond donors, host series **4**–**7** does not allow comparison of relative donor abilities. To determine if **4**·**2** and **5**·**2** might be stabilized by an additional interaction between the 2′-ester group of **2** and the *o*-aminoni-



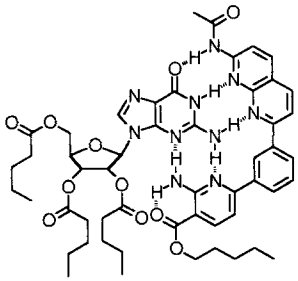
II



III



IV



V

trile group (cf. structure **IV**), the complexation studies were repeated using 9-octylguanine (**3**). Interestingly, **5·2** is 0.8 kcal mol^{-1} more stable than **5·3**, whereas **6** binds 9-octylguanine (**3**) as strongly as it does **1** or **2**. It is possible that intramolecular hydrogen bonding in the *o*-aminoester group of **6** (see structure **V**) weakens this additional interaction, which represents a final contribution to the remarkable stability of **4·2**.

This comparison of synthetic receptors for guanosine derivatives demonstrates that hydrogen-bonded complexes between neutral organic molecules can be stable in highly competitive solvents if some of the energy costs of binding are paid in advance during the synthesis of highly preorganized receptors. The synthetic price of preorganized receptors is comparable to that of flexible analogues explored in this study. Questions that remain are whether such hosts can select between different nucleosides and whether chromogenic or fluorogenic groups can be incorporated into their structures to optically signal the binding event.[6a, 23]

Corrigendum

In the communication "1,5-Anhydrohexitol Nucleic Acids, a New Promising Antisense Construct" by Arthur Van Aerschot,* Ilse Verheggen, Chris Hendrix, and Piet Herdewijn (*Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 1338–1339) the curves of Figure 3 were inadvertently exchanged in the legend. The dashed curve was determined at 260 nm (A_1) and the solid curve at 284 nm (A_2).

Compromises: Quality, Quantity, and Cost

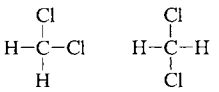
Biographical Encyclopedia of Scientists. 2nd Edition. Edited by *J. Daintith, S. Mitchell, E. Tootill* and *D. Gjertsen.* Institute of Physics, Bristol and Philadelphia, 1994. Two-volume set, 1075 pp., hardcover £ 95.00.—ISBN 0-7503-0287-9

Whereas book reviews are usually written by request of editors of learned journals, the present report has been prompted by my experiences while using this recently purchased two-volume encyclopedia. First I have to make a confession: I did not read the encyclopedia from cover to cover. I only perused it in the course of some work I am doing, which led me to consult only about 100 of its 2000 short biographies. Secondly, being a chemist with some physical leanings, my 5% sample concerns mainly chemistry and could therefore be a biased one. A mathematician or an astronomer may well get a different impression from that reported below.

According to the masthead, no fewer than seven proofreaders have read the encyclopedia's 1075 pages, compiled by 15 contributors. Despite this, the name of one of my teachers, Nobel prize winner Leopold Ruzicka, is consistently (eight times) misspelled "Ruicka", and that of another one, Christopher Longuet-Higgins, is always graced with a second "t" i.e. "Longuett". Heyrovsky is shortened to "Heyrovsk" and Benjamin Thompson, later Lord Rumford, has been renamed "Thomson". Gerd Binnig, who shared the Nobel prize for the invention of the scanning tunneling electron microscope, is renamed "Bining", Conrad Gessner becomes "Gesner", and in Newton's biography his mathematical rival is called "Liebnitz". Von Laue's coworker in the discovery of X-ray diffraction is named "Kipping" instead of Knipping. We are told that Professor Wittig worked in "Heidelberg", that Chaim Weizmann obtained his doctorate in "Freiburg, Germany" instead of Fribourg, Switzerland, and that Richard Stock died in 1946 "in Karlsruhe, now in Germany". Albert Einstein's biography mentions his four fundamental papers published in 1905 in *Annalen der Physik*. However, the one on Brownian movement, claimed to be the first one, was in fact the second (pp. 549–560 of Vol. 17) and its German title is quoted with four mistakes in it, whereas the paper on the photoelectric effect, said to be the second paper, was in fact the first one (pp. 132–148 of the same volume).

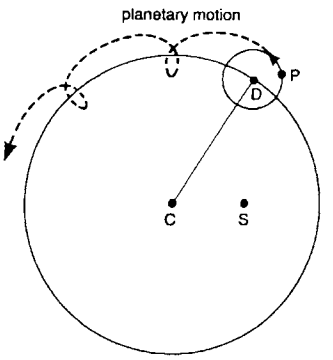
The two volumes are so very sparsely illustrated that the reader feels drawn almost automatically to look at the few figures. Leaving aside the fact that the reasons for the particular choice of some of these illustrations are not always obvious, it seems strange that they are not referred to in the text and that they lack a detailed explanatory caption, in particular with respect to the symbols used. One of these illustrations purports to show a two-dimensional section through the ground-state electron cloud of the hydrogen atom according to Schrödinger. Instead of having a maximum at the origin and falling off with increasing distance, the electron density is zero at the origin with a maximum at some unspecified distance r from it. Obviously the authors have confused the density function $\Psi\Psi^*$ with the radial distribution $4\pi r^2\Psi\Psi^*$. Augustin Fresnel's biography is followed by a figure allegedly showing the section through a Fresnel lens. If this were true, the lens would be about as effective as a window pane, the inner and outer faces of the individual rings being parallel to each other.

The work of Biot, who discovered in 1815 that certain liquids (e.g. turpentine, solutions of camphor) rotate the plane of polarized light, is illustrated by showing—without comment—the stereo-formulas of the enantiomers of tartaric acid! However, Pasteur's work on ammonium tartrate dates from 1848, and the two formulas shown were not known until Van't Hoff's and Le Bel's publications in 1874. Unfortunately, Le Bel's biography in the encyclopedia is accompanied by a linear formula for water, H–O–H, and by planar (!) formulas for methane, ethanol, and dimethylether with 90° HCH bond angles and a linear C–O–C bond. But these pale into insignificance compared with the following two formulas for methylene chloride, which are presumably supposed to illustrate the phenomenon of enantiomerism:



The account of Ziegler's Nobel prize winning research is illustrated by portions of isotactic and syndiotactic polypropylene chains. These should, of course, have accompanied the biography of Giulio Natta, who shared the Nobel prize with Ziegler. Also, the two formulas depicting Alfred Werner's coordination complexes lack a central metal atom. The author consortium's lack of appreciation of chemistry (see also the comment on "Chronology" below) is amusingly obvious from statements such as "[Willstaetter's] work on chlorophyll was justified in 1960 when Robert Woodward succeeded in synthesizing the compounds described by his formulae and came up with chlorophyll". You can almost see Woodward's surprised reaction.

The most remarkable illustration is that following the biography of Copernicus. To counter possible disbelief, this figure is reproduced directly from the encyclopedia:



COPERNICAN SYSTEM The epicyclic motion of a planet.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995* *0570-0833/95/3419-2167 $ 10.00+.25/0*

The whirring sound you hear is Copernicus rotating in his grave.

In the preface the editors discuss their selection criteria. With regard to 20th century candidates, many of them still living, they are "guided by lists of prizes and awards made by scientific societies..." and in addition the "compilers and editors have used their own judgement in choosing what is important or useful". However, it is sometimes rather difficult to appreciate the basis of such judgements. Whereas one will look in vain for chemists such as H. Meerwein, A. Katchalsky, S. Winstein, G. Olah, J. A. Pople, E. Wiberg, W. Reppe, T. Nozoe, G. Schwarzenbach, or G. Wilke—to name but a few at random—we are told at great length about F. Hurter whose only claim to fame (according to the authors) is that he became chief chemist at Holbrook Gaskell & Henry Deacon's alkali factory. Or take Lyon Playfair, 1st Baron, on whom I stumbled by accident. "As a politician he was reasonably successful" we are told, but as a scientist he was obviously a failure, nothing of relevance being reported. Even some physicists, such as W. Kossel, G. Wenzel, T. Koopmans (who, admittedly, gained his Nobel prize in economics), or even such an important contributor to the quantum theory as Friedrich Hund (!) were not considered worthy of inclusion, in contrast to Ernö Rubik (his first name is given as "Erno") whose invention of a toy, the Rubik cube, earns him a longer entry than those of many living scientists.

In a section entitled "Chronology" the authors have compiled year by year what they consider the most important discoveries in the fields of mathematics, physics, chemistry, biology, and medicine. During the last 40 years, roughly the span of an academic lifetime, chemists and in particular organic chemists must have been sound asleep. Whereas scientists working in other fields seem to have produced noteworthy results practically every year, chemistry is mentioned only ten times. Of these ten entries, three refer to fullerenes and three to the depletion of the ozone layer by chlorofluorohydrocarbons. The remaining four mentions concern the discovery of crown ethers by Pedersen, the preparation of rare gas compounds by Bartlett, Prigogine's work on irreversible thermodynamics, and the discovery of quasi-crystals by Shechtman. The latter's name is misspelled "Schectman", and although his important work is deemed worthy of mention in the chronology, a biographical note devoted to Shechtman is lacking.

These shortcomings may be regarded as nothing but nagging criticism of points of minor importance, but they do not inspire confidence in the reliability of biographies of scientists you know little or nothing about. In this connection, my major criticism is that the encyclopedia does not contain a single reference to primary or secondary literature. Not only are we not told the sources of the information given, but the reader is offered no help at all if he or she wants to follow up or complement—and check!!—the short biographies provided. Thus, if you want additional information, you must do what you would have done anyway without the encyclopedia, namely go to the library to search for reliable works of reference and biography.

Edgar Heilbronner
Herrliberg (Switzerland)

The Biographical Dictionary of Scientists. Second Edition. Edited by *R. Porter*. Oxford University Press, New York, 1994. LVII, 891 pp., hardcover $ 85.00 (also published in Great Britain as The Hutchinson Dictionary of Scientific Biography, Helicon, Oxford, 1994, £ 50.00).—ISBN 0-19-521083-2

In the mid-1980s Peter Bedrick (New York) published and Harper & Row (New York) distributed a six-volume set, *The Biographical Dictionary of Scientists,* edited by David Abbott, with volume titles *Astronomers* (1984), *Biologists* (1984), *Chemists* (1984), *Physicists* (1984), *Mathematicians* (1986), and *Engineers and Inventors* (1986). Now Roy Porter, Associate Director of the Wellcome Institute of the History of Medicine, London, and 34 other contributors have produced the second edition of this reference work in one convenient volume, which includes entries on men and women from ancient times to the present day in the above fields of science plus geology, ranging in length from seven lines (al-Sufi) to three pages (Sir Isaac Newton). Arranged alphabetically from Abbe to Zworykin, the entries not only provide basic biographical information in a historical and scientific context but also discuss the significance of the scientist's contribution and show how the scientist's personal, social, political, religious, and artistic concerns affected his or her life. The work also contains a short general introduction and succinct (6–7 page) historical reviews of the seven fields (in the case of chemistry, a panorama recounting highlights from contributions of the ancient Egyptians to the discovery of buckyballs), along with 107 illustrations (but unfortunately no portraits). Useful but unusual features for a biographical dictionary are an extensive (77-page) glossary of about 2000 items, and appendices listing Nobel laureates for chemistry, physiology or medicine, and physics through 1993 and the grounds for their awards. A detailed 47-page index (3 columns per page), with names of the biographees in capitals, facilitates quick access to information. British spelling is used consistently, and although the coverage is international, a surprisingly large amount of space is devoted to British scientists, some of whom are only minor figures.

Some closely associated scientists, 25 in all, are grouped together and discussed in single entries, e.g., Beadle, Tatum, and Lederberg; Crick, Watson, and Wilkins; Fischer and Wilkinson; Hall and Héroult. Many, but by no means all, Nobel laureates are the subjects of entries. Psychiatrists and psychologists such as Adler, Eysenck, Freud, Jung, and Piaget are included, as is Nicolas Bourbaki, the collective pseudonym for the group of mathematicians who have been publishing collectively and anonymously since the late 1930s. Although almost a third of the contributors to this volume are women, only 19 women are discussed, including well-known scientists such as Rachel Carson, Goeppert-Mayer, Hodgkin, Meitner, McClintock, and Yalow, and lesser-known ones such as Hyman and Morgan. Obviously, additional efforts are required to include women scientists in biographical dictionaries such as this and others.

Unlike the 18-volume *Dictionary of Scientific Biography* (DSB), which is the standard in this genre, the volume under review here includes living subjects such as science popularizers David Attenborough, Jacques Cousteau, Richard Dawkins, Stephen Jay Gould, Stephen Hawking, and Carl Sagan. Although Lysenko, Mendeleev, and Pavlov are included, Russian scientists such as Borodin, Butlerov, Chugaev, Kurnakov, Lomonosov, Vernadsky and Zinin are missing, as are some important chemists of other nationalities. The extent of coverage is still not always commensurate with the scientist's contributions, a defect noted by at least one reviewer of the "Mathematicians" volume of the first edition (D. V. Feldman, *Choice* **1986**, *23*, 1651). For example, Lavoisier rates only a page, while lesser figures, in chemistry and other fields, receive equal or greater coverage. Although touted as "updated and expanded," the entry on Henry Gilman (p. 277), who died in 1986, and the passing mention of Robert Mullikan, who died in 1986 (p. 440), do not reflect this fact.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3419-2168 $ 10.00+.25/0

With its coverage of 1178 scientists, this volume compares favorably with its primary competitors, e.g., Asimov's *Biographical Dictionary of Science and Technology* (2nd revised edition, Doubleday, Garden City, NY 1982—1510 entries, $ 39.95 paperback); David, Ian, John, and Margaret Millar's *Chambers Concise Dictionary of Scientists* (W. & R. Chambers Ltd., Edinburgh, Scotland, 1989—882 entries, $ 29.95), and John Daintith, Sara Mitchell, Elisabeth Tootill, and Derek Gjertsen's *Biographical Encyclopedia of Scientists* (2nd ed., 2 vols., Institute for Physics Publishing, Bristol, England and Philadelphia, PA,1994—ca. 2000 entries, $ 190). However, the hallmark of an encyclopedia is not only coverage but accuracy, and it is here that Porter's dictionary possesses serious deficiencies. A reviewer of the "Engineers and Inventors" volume of the first edition noted: "Proofreading is rather uneven," citing errors which have still not been corrected in the second edition (R. J. Havlik, *Choice* **1986**, *24*, 78). In the new edition the English chemist Nevil Vincent Sidgwick's name is consistently misspelled Sidgewick (pp. 486, 621), and the first names of Bosch (pp. 86, 293) and Scheele (p. 168) are given as Karl, not Carl. Other misspellings include "Marcelin" for Marcellin (Berthelot) (p. 62), "diamene" for diamine (p. 119), "Encyclopedia Britannica" for Encyclopaedia Britannica (p. 224), "CL" for Cl (pp. 233, 715), "Bresslau" for Breslau (p. 293), "van Neumann" for von Neumann (p. 317), "Handwortenbuch" for Handwörterbuch, and "practische" for praktische (p. 395), and the cross-reference for Count Rumford lists him as "Thomson" not Thompson. Diacritical marks are sometimes missing, as in Väversunda (p.65), Traité élémentaire (p. 167), and Ružička (p. 564). Several chemists are consistently referred to by their first names rather than by their more familiar names, e.g., Johann (not Adolf) von Baeyer (p. 382), Friedrich (not August) Kekulé (pp. 37, 232, 381, 685), Friedrich (not Wilhelm) Ostwald (p. 686), and Pierre (not Marcellin) Berthelot (p. 715).

However, the volume also contains errors of fact. The formula for adipic acid contains two N atoms instead of C atoms; that for nylon has a C–O bond missing (p. 119); those for 1-methylphenylhydrazone and an indole derivative lack N atoms (p. 233); that for benzene has a double bond missing (p. 382); and one of the Lewis structures for NO lacks formal charges (p. 429). Benzene was discovered in 1825 not 1835 (p. 224); Heisenberg was born in Sanderau, a suburb of Würzburg, not in Duisberg, a mistake also made by Asimov (p. 317); gallium was discovered in 1875, not 1871, and Moseley's work on atomic numbers as a basis for the Periodic System dates from the 1910s, not the 1920s (p. 477); Alfred Werner was too ill to work on coordination compounds after the end of World War I (p. 621); Guldberg and Waage announced their law of mass action in 1864, not 1867 (p. 686); and Werner considered only organic compounds, not coordination compounds, in his Habilitationsschrift (p. 715). Both inorganic and organic nomenclature and formulas do not adhere to IUPAC recommendations (e.g., pp. 119, 715). These errors among the chemist entries cast doubt on the accuracy of the entries on practitioners of the other fields, a point corroborated for biologists by another reviewer (J. Altman, *New Scientist*, 30 July **1994**, *143*, 41).

Finally, as reviewers of the first edition have stated, the lack of any citations to sources of biographical information is a serious flaw in this dictionary and makes it of little use to the historian of science. Yet this charge could be leveled at its competitors listed above, which also do not contain references. Furthermore, Professor Edgar Heilbronner, a respected chemist colleague, found Daintith et al.'s *Biographical Encyclopedia of Scientists* to contain numerous errors (for review see *Angew. Chem.* **1995**, this issue). Thus, the relatively modest price of Porter's *Biographical Dictionary* makes it a handy one-volume first-step reference work for the general public and for high school, college, and university students as well as practicing scientists with an interest in the history of their fields. However, the frequency of errors will make it necessary for the user to visit a library to consult other more authoritative sources such as the *Dictionary of Scientific Biography*, both to check specific facts and spellings and for additional, more detailed information.

Volatile Metal Alkoxides according to the Concept of Donor Functionalization

Wolfgang A. Herrmann,* Norbert W. Huber, and Oliver Runte

Dedicated to Professor Henri Brunner on the occasion of his 60th birthday

Since the fundamental works of D. C. Bradley and R. C. Mehrotra, metal alkoxides have attracted attention because of the diversity of their low- and high-molecular-weight structures; they are also generating increasing interest as precursor compounds for solving technical materials problems. The understanding of the hydrolytic nucleation behavior is a prerequisite for the optimization of materials from sol–gel processes. For metal alkoxides to be precursors in *c*hemical *v*apor *d*eposition (CVD) processes in the preparation of inorganic oxidic materials, they should be sufficiently volatile, and sublimation should occur without decomposition at as low a temperature as possible ($< 150\,^{\circ}C$). Only recently, using the "donor functionalization" concept, was a ligand type systematically developed that unifies the advantages of both steric demands and σ-donor stabilization and so stabilizes low-molecular-weight metal alkoxides. Even large metal ions of low charge (for example Ba^{2+}) can thus form volatile alkoxides. O- and N-donor functions in bidentate and multidentate alkoxo ligands are particularly advantageous; hence, for example, the vanadium derivative $[V(OCMe_2CH_2OMe)_3]$ is one of the most volatile metal alkoxides known to date. The first alkoxides of the alkaline earth metals calcium, strontium, and barium, which sublime without decomposition, have the formula $[M_2\{OC(CH_2OiPr)_2tBu\}_4]$. This article presents a critical inventory of the metal alkoxides with particular regard to the aspect of volatility. It also describes successes of the donor functionalization concept and shows—in perspective—how alkoxo ligands can be "tailor made" for metals according to their charge-to-radius ratio by further development of the concept.

Keywords: coordination chemistry · CVD precursors · donor functionalization · metal oxides

1. Introduction

It was more than 30 years ago that man learned how to prepare high purity oxides of the refractory metals by pyrolysis of metal alkoxides.[1, 2] Nowadays simple binary and ternary metal oxides of high purity are of considerable importance in the development of materials. Thin oxide layers are in demand particularly in electronic materials, and since the development of the high-temperature superconductors (for example $YBa_2Cu_3O_{7-\delta}$),[3] efforts to synthesize volatile metal alkoxide precursors have increased.[4] CVD techniques also promise the preparation of more complex inorganic materials by the gas-phase thermal decomposition of volatile (molecular) precursors.[5] Emphasis is being placed on defined decomposition routes and on the conservation of the given metal stoichiometry of the precursor molecule ("single-source precursor") in the deposition product.[6] As far as oxidic materials are concerned, a replacement is being sought for the β-diketonato metal complexes, which though partially volatile, often lead to considerable carbon contamination of the deposited products (or to the incorporation of fluorine in the case of the particularly volatile fluorinated β-diketonato metal complexes).[7] A special need exists here for rare earth metals that by doping can reduce the electronic work function for light bulb wires (tungsten) by orders of magnitudes, and thus improve the light yield (thorium substitutes). For this purpose carbidic materials (mixed carbides, "compulsory carbides") are feasible. The molecular precursor must therefore always be attuned to the desired materials result. In this respect, the strengths of inorganic molecular chemistry lie in its great constitutional variety.

Alkoxides are known for practically every element of the s, p, d, and f blocks of the Periodic Table. The standard work "Metal Alkoxides" from 1978 provides a first encompassing overview of the topic.[8] A series of relevant review articles followed.[1, 4, 9] *Aggregation*, that is, the formation of multinuclear structures—often polymeric—dominates the structural chemistry of the alkoxides. Whereas the concept of steric overcrowding had been favored for the verification of low-molecular-weight compounds, the donor functionalization concept now finds itself on the road to success: Mehrotra and Singh noted that "the bulky ligand

with side chains capable of donor functionality ... appears to combine the advantages of steric crowding as well as coordinative saturation within the same species"[10a] in reference to the preparation of the first volatile barium alkoxide $[Ba_2\{OC(CH_2OiPr)_2tBu\}_4]$.[10b]

A prerequisite for CVD applications is volatility. Other areas, however, are increasingly reported in which the use is dependent on the solubility. Hence the zinc alkoxide **1** can be transformed into very pure zinc oxide by using acetone as a condensation reagent in accordance with Equation (a).[11] In this area of research great emphasis is being placed on the kinetics of the nucleation in sol–gel reactions.[12]

$$\underset{\mathbf{1}}{[Zn\{OC(C_2H_5)_3\}_2]} + (CH_3)_2C{=}O \longrightarrow ZnO + (CH_3)_2C[OC(C_2H_5)_3]_2 \quad (a)$$

2. The Aims of Ligand Design

Volatility is based, in essence, on weak attractive interactions between molecules. Polar groups or polarizable groups and high molecular masses tend to reduce volatility. Metal alkoxides contain by definition at least one M–O–C structural unit. Because of the high effective nuclear charge of oxygen, alkoxides of metal elements have highly polar M–O bonds. The polarity of the alkoxides of the distinctly electropositive alkali, alkaline earth, lanthanide, and actinide metals (Pauling electronegativity = 0.9–1.2) is the highest; the proportion of ionic bonding can be as much as 80 %. The low volatility—or even the lack of volatility—of the alkoxides of these metals is mainly due to this fact. As a result most of these alkoxides have oligomeric and polymeric structures and are insoluble even in polar solvents such as ethers and amines. Other dimensions that can have an important influence are the size and the charge of the central metal ion. The steric and electronic shielding of the metal by the ligands have to be optimized taking these characteristics into account. A low charge on a metal ion combined with a large ionic radius (for example Ba^{2+}) causes considerable problems when attempting to achieve volatility. The strategies that are employed are introduced in the following sections.

3. Preparation and Structure of Metal Alkoxides

3.1. Synthetic Methods

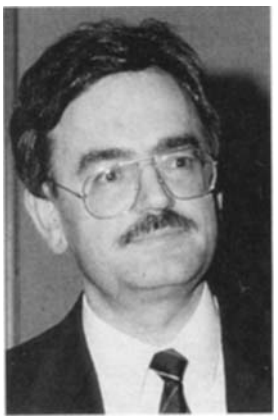
From a synthetic point of view, metal alkoxides have been well documented since the works of Bradley and Mehrotra.[8] Metal halides and metal halide complexes are most often the starting materials, as the standard method is salt metathesis [Eq. (b)]. The chlorides and bromides, but above all the iodides, are generally preferred (X = Cl, Br, I; L_n = other ligands). Complications can arise for metals in high oxidation states due to redox reactions and coordination reactions, because saltlike alcoholates act as (weak) reducing agents. In addition, they can lead to ionic (that is, nonvolatile) ate-complexes [Eq. (c)] by increasing the coordination number. This problem can be avoided by using the so-called amide route [Eq. (d)], which only requires a sufficiently acidic but not especially bulky alcohol to give the target product by elimination of an amine (usually a volatile amine, for example $HNMe_2$ or $HN(SiMe_3)_2$). The method is most potent when acidity and bulk—also as regards the metal amide—are mutually optimized (for example $SiHMe_2$ instead of $SiMe_3$).[13] This route is often pursued when quantitative yields are imperative, for example for workup reasons.

$$L_nM{-}X + Li(Na,K)OR \longrightarrow L_nM{-}OR + Li(Na,K)X \quad (b)$$

$$L_nM{-}OR + LiOR \longrightarrow Li^+[L_nM(OR)_2]^- \quad (c)$$

$$L_nM{-}NR_2 + HOR \longrightarrow L_nM{-}OR + HNR_2 \quad (d)$$

Metallocene chemistry has recently provided convincing examples of the amide route that also have practical importance. Whereas the classical salt metathesis causes unclear redox processes in this context, the metal amides lead to 75 % yields (Mo) or quantitative yields (Zr) of the alkoxo complexes **2a** and **2b** (X = hydrocarbon bridge) according to Equation (e). Analogously, the derivative **3** with forced C_2-symmetry ("helical shape") is accessible from $[Zr(NMe_2)_4]$ and two equivalents of the ligand.[14] The neodymium complexes **4a** and **4b** were prepared by salt metathesis;[15] the details of their constitution



Wolfgang A. Herrmann was born in 1948 in Kelheim on the Danube (Bavaria). After studying chemistry (Diplom: Technische Universität München) and completing a research thesis with E. O. Fischer in 1971, he obtained his doctorate in 1973 on a topic dealing with organometallic stereochemistry under H. Brunner at the Universität Regensburg. From 1975–1976 he carried out research with P. S. Skell at the Pennsylvania State University, and in 1978 completed his habilitation with a thesis titled "Organometallic Syntheses with diazoalkanes". He was appointed professor at the Universität Regensburg (1979), and full professor at the Universität Frankfurt (1982). In 1985 he accepted a chair at the Technische Universität München as the successor to E. O. Fischer. His area of research is synthetic and catalytic chemistry, primarily in organometallic chemistry. He is the author of 380 publications, and holds 30 patents. His work has frequently been the subject of special recognition, including the German–French Alexander-von-Humboldt Award (1988), the Otto-Bayer Award (1990), and the Max Planck Research Award (1991). He is a member of the Akademie der Wissenschaften und der Literatur zu Mainz (1990) and the Deutsche Akademie der Naturforscher Leopoldina (1995). He received honorary doctorates from the University of Lyon (1990) and the University of Veszprèm (1995). He is at present President of the Technische Universität München.

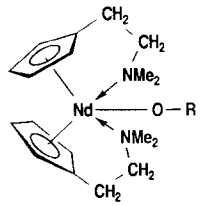
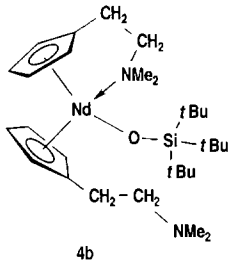
3





indicate the consequences of the spatial requirements of coordinated alkoxo ligands (cf. Section 5). The structural type **4a** is also observed for other types of small ligands (for example, Cl instead of OR).[115]

Finally, the deoxygenation of oxometal complexes (higher oxidation states; for example Mo^{VI}, W^{VI}, Re^{VII}) according to Equation (f) has also been employed. A variant, the defluorination route, is also known [Equation (g)]. As metal oxides mainly have to be prepared by hydrolysis of the halides, and metal fluorides from the chlorides or bromides, the metal halides are usually the primary precursors in metal alkoxide syntheses [Eq. (h), X = halogen]. For electropositive metals direct synthesis in accordance with Equation (i) can be carried out,[9e, 16] provided the alcohol is sufficiently acidic and the metal is finely divided (where appropriate, metal vapor in a "cocondensation reactor" or a freshly reduced metal iodide must be used).

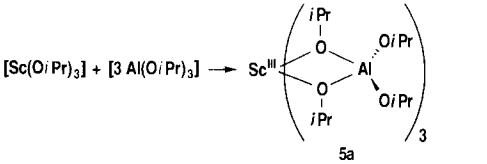
$$L_nM{=}O + 2\,ROSiMe_3 \longrightarrow L_nM(OR)_2 + Me_3SiOSiMe_3 \quad (f)$$

$$L_nM{-}F + ROSiMe_3 \longrightarrow L_nM{-}OR + Me_3SiF \quad (g)$$

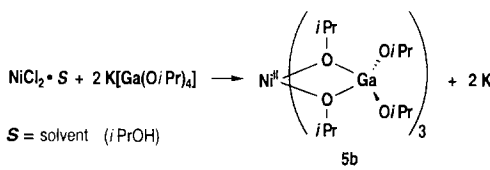
$$MX_n + m\,ROH \rightarrow M(OR)_mX_{n-m} + m\,HX \quad (h)$$

$$M + n\,ROH \rightarrow M(OR)_n + n/2\,H_2 \quad (i)$$

Heteronuclear alkoxides are accessible through acid–base and salt metathesis reactions.[9e] Chelate complexes such as **5a, b** can thus typically be obtained in accordance with Equations (j) or (k).[123, 18]



(j)



(k)

Like alkoxo ligands OR, amides NR_2 are hard ligands according to the definition of Pearson. For this reason they are particularly in demand as precursors in the chemistry of the rare earth metals ("one of the most prolific ligands"[128]), and numerous synthetic methods are now known, including those described in Equations (l)–(n) for divalent lanthanides.

$$LnI_2 + 2\,NaNR_2 \longrightarrow Ln(NR_2)_2 + 2\,NaI \quad (l)$$

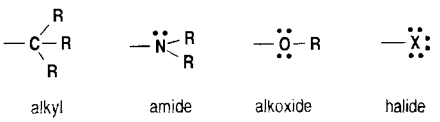
$$Ln + M[N(SiMe_3)_2]_2 \longrightarrow Ln[N(SiMe_3)_2]_2 + M \quad (M = Sn, Hg) \quad (m)$$

$$Ln + 2\,Hg(C_6F_5)_2 + 2\,HNR_2 \longrightarrow Ln(NR_2)_2 + 2\,Hg + 2\,C_6F_5H \quad (n)$$

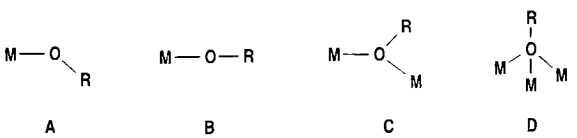
As a result of the three-connectivity of nitrogen, amido ligands can provide a more efficient spatial screening of the metal atom by the introduction of two groups at the β-position to the metal center (larger cone angle for NR_2 than for OR). The metal atom is thus more effectively protected (and usually has a higher stability with respect to oxygen and water).

3.2. Coordination Chemistry

The structural diversity of the metal alkoxides is based on the coordination chemistry of the OR ligand and the numerous possibilities that this provides. These can even be brought to bear when no other R groups capable of coordination with the metal are present. In the isovalence electronic series alkyl - amide - alkoxide - halide with increasing number of "lone electron pairs" (with the exception of alkyl groups **I**, which rather rarely are bridging ligands), the heteroatomic ligands **II**–**IV** are often bound to between two and six metal atoms (for example $[Nd_6(OiPr)_{17}Cl]$[19]). Intermolecular bridging produces aggregated systems, which are to be avoided in particular in the preparation of volatile metal alkoxides.



Terminal binding of the alkoxo ligand results in the bent structural type **A** (M–O–R < 170°). The standard type for bridge-forming, σ-donor interactions with other metals is less often available in the case of perfluorinated substituents R (for example $OCH(CF_3)_2$) with their reduced O-basicity. The frequently encountered structural type **B** has a linear M-O-R sequence primarily because of steric effects, but cases are known that can only be explained by electronic effects.[120] The bond angles of between 170 and 180° determined by X-ray diffraction methods on single crystals should be interpreted with caution; it is often crystal packing effects that lead to almost linear structures, as is the case in $[Yb(O\text{-}2,6\text{-}tBu_2\text{-}4\text{-}R\text{-}C_6H_2)_2]\cdot 3THF$ (R = Me, *t*Bu).[121] In the (edge-)bridging constitution **C**, the oxy-



gen atom takes on a pyramidal, or much more often a trigonal-planar configuration. With oxophilic metals, the structural type **D** exhibiting triply bridging alkoxo ligands is often encountered.

During the preparation of alkoxometal complexes it is not uncommon for side products containing "lone" oxo ligands to be formed, which are encapsulated in ensembles of between three and six metal atoms. Examples of these are the metal complexes **6a, b** (Fig. 1). The oxo ligands originate, as a rule, from spurious moisture in the reaction mixture. In rare individual cases, they have been confirmed to originate from OR ligands by cleavage of the O–R bond.[22, 44] As the determination of such complicated structures is dependent on X-ray diffraction methods on single crystals, attention must be drawn to the danger of confusing oxo with hydroxo ligands (O and OH).

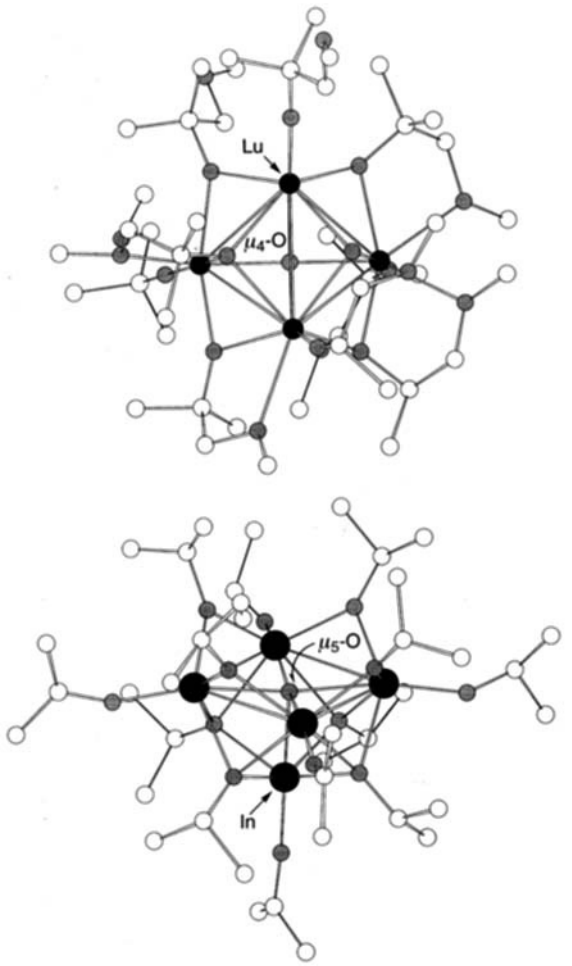


Fig. 1. Alkoxides of metals with "lone" oxo ligands. Top: Structure of the compound $[Lu_4(\mu_4\text{-}O)(OH)(OR)_9]$ (**6a**), R = CMe_2CH_2OMe, with Lu_4O_{15} substructure [184]. Bottom: Structure of the compound $[In_5(\mu_5\text{-}O)(O\mathit{i}Pr)_{13}]$ (**6b**) with In_5O_{14} substructure [172a]. Here as in all other structural diagrams carbon atoms are represented by white spheres, oxygen, nitrogen, and phosphorus atoms by gray spheres, and metal ions by black spheres.

4. Sterically Demanding Ligands—Volatility Versus Lability of the Complexes

The importance of steric ligand effects is just as well known in coordination chemistry (phosphanes, Tolman cone angle, dissociation equilibria, catalysis) as in the chemistry of main-group elements with low coordination numbers (for example silaolefins, phosphaalkynes, phosphaalkenes). Figure 2 shows ligands with increasing spatial requirements ranging from *tert*-butyl alcohol to the bulkiest alcohol "tris(*tert*-butyl)methanol" (tritox-H, molecular mass 200 u).[23] Tritox-H was introduced into coordination chemistry by Power et al. and Wolczanski et al.[24]

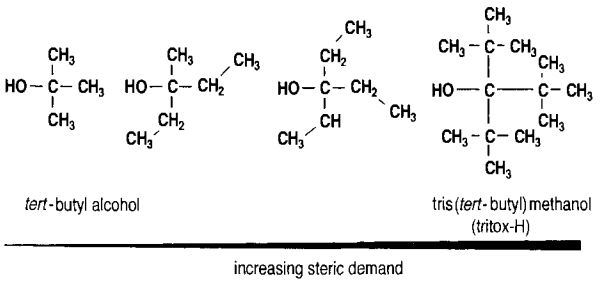

Fig. 2. Increasing spatial demands of nonfunctionalized alcohols from *tert*-butyl alcohol to tritox-H.

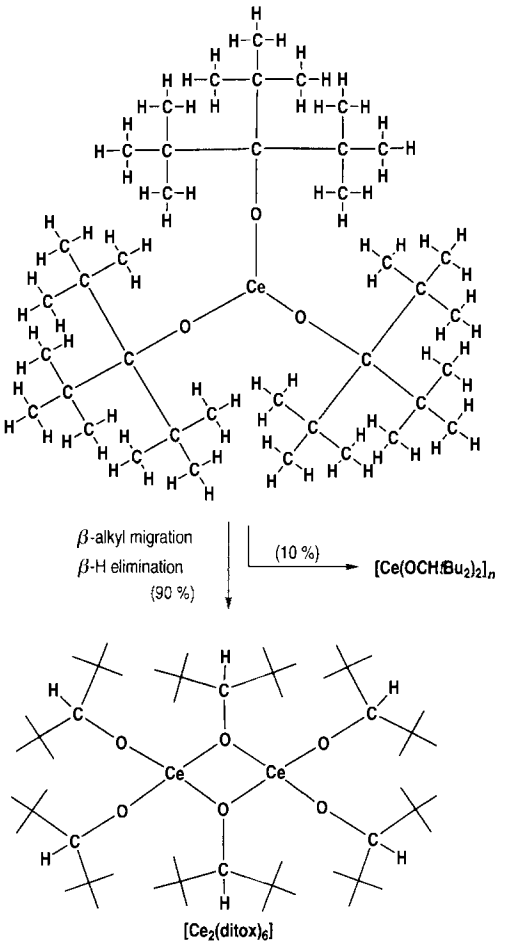
As was exemplified by $[Ce(tritox)_3]$, steric overcrowding of the ligand periphery entails an increasing fragility of the compound as a whole.[25] The grouping of 39 C atoms, 81 H atoms, 36 CC bonds and 81 CH bonds (!) in the closest of neighborhoods lowers the thermolysis temperature to such an extent that CC bonds are cleaved merely on sublimation of the metal complexes under vacuum (Scheme 1).



Scheme 1. Thermal decomposition of the sterically congested tritox complex $[Ce(tritox)_3]$ to the ditox complex $[Ce_2(ditox)_6]$; ditox-H = "bis(*tert*-butyl)-methanol".

4.1. Unproblematic Cases and the Limits of Steric Demands

In order to obtain volatile metal alkoxides $M_x(OR)_n$, the nuclearity x must be low—this is not typical for this class of molecular compounds. If possible, the complexes $M(OR)_n$ should be monomeric and the R group should not be too large in order to ensure that the molecular mass is low. These demands of large ligands and low molecular masses are conflicting and cannot, therefore, be easily satisfied simultaneously, in particular in the case of large low-valent metal ions (for example Ba^{2+}).

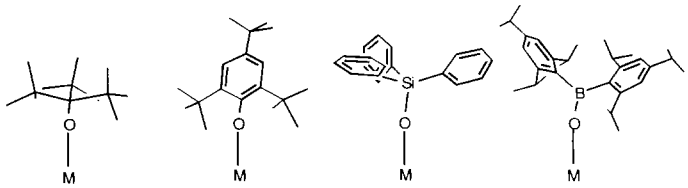
In contrast, the class of compounds $M(OR)_6$ of the hexavalent metals (W, Re) presents no problems. Even uranium, the largest representative, forms (like tungsten) a monomeric methoxide $[M(OMe)_6]$ in the solid state and in the gas phase.[117] Nevertheless, in as far as they are known for M = Nb, Ta, W and Re, the pentacoordinated M^V methoxides $[M(OCH_3)_5]$ exist as dimers and, in the case of uranium, as a trimer.[26, 27] $[U(OEt)_5]$, on the other hand, is dimeric, and the nuclearity for the analogous Pa^V derivative in solution is given as $x = 5.7$.[29, 30] For R = *i*Pr monomeric and dimeric Nb^V and Ta^V derivatives $[M(OiPr)_5]$ are obtained.[31] $[Nb(OiPr)_5]$ has a dimeric structure in the solid state.[32] For the larger uranium this occurs only with a ligand the size of R = *t*Bu ($x = 1.35$ in solution).[29] The importance of the extent of the ligand periphery can be seen here in convincing clarity.

Whereas $Si(OMe)_4$ and $Ge(OEt)_4$ already have monomeric structures even with their small ligands,[8] this first occurs for the higher congener $Sn(OR)_4$ when R = *t*Bu.[33] The same behavior can be observed for the Zr^{IV} and Hf^{IV} analogues, whereas $[M(OiPr)_4]$ monomers exist for Ti and V, at least in the gas phase.[34] For large ions (M = Th, U), the $[M(OR)_4]$ alkoxides are oligomeric even for R = *t*Bu.[35, 36] Monomeric thorium alkoxides are only obtained with larger groups such as $CMeEt_2$ and CMeEt*i*Pr.[35]

For the alkoxides of the trivalent elements, only the semimetals and nonmetals B, P, and As with methoxy or ethoxy substituents are monomeric and markedly volatile.[8] Even the *t*Bu derivatives of Al and Ga are dimeric,[39, 40, 84, 88] and those of Y and La form alcohol adducts with the formula $[M(OtBu)_3]_3 \cdot 2\,tBuOH$.[41] The bismuth derivative $Bi(OtBu)_3$ is monomeric in the gas phase.[42] The nuclearity of $In(OtBu)_3$ is unknown,[43] yet $In(OiPr)_3$—like the corresponding derivatives of Sc and Y, as well as of the rare earth metals La, Nd, and Yb—forms a pentameric oxo cluster.[44–46] The alkoxides that form dinuclear complexes with lanthanide metals range from $OCMe_2iPr$ to $OCiPr_2tBu$.[41] If monomeric alkoxides of the rare earth metals are desired, however, the synthetic chemist has to resort to bulky organic groups: tritox ($OCtBu_3$) and silox ($OSitBu_3$) produce mononuclear complexes. A mononuclear structure was attributed to the yttrium alkoxide $[Y(OCtBu_2iPr)_3]$ because of its volatility.[47]

The preparation of monomeric metal aryloxo complexes is generally simpler. These complexes are, however, normally much less volatile. For the 2,6-disubstituted phenoxides of the type $[M(O\text{-}2,6\text{-}tBu_2\text{-}4\text{-}R\text{-}C_6H_2)_3]$ (R = H, Me, *t*Bu) for example, monomeric formulas have been assigned to all trivalent metal ions: the Al,[48] Sc,[49] Y,[50] and Ce[38] derivatives have been structurally characterized. A perfect shielding of the metal is not achieved in this class of substances either, however, as can be deduced from the occurrence of adduct formation: $[Al(O\text{-}2,6\text{-}tBu_2\text{-}4\text{-}MeC_6H_2)_3]\cdot O{=}C(C_5H_{11})tBu$[37] and $[Ce(O\text{-}2,6\text{-}tBu_2C_6H_3)_3]\cdot 2\,tBuNC$[38] (cf. $[Nd(OCtBu_3)_3]\cdot 2\,NCMe$[47] and $[V(OSitBu_3)_3]\cdot THF$[51]).

The limits of steric shielding are reached with the ligands mentioned above. Only a few remaining $[M(OR)_2]$ complexes of divalent metals can be obtained in monomeric form and free of solvent: the aryloxo complexes $[M(O\text{-}2,6\text{-}tBu_2\text{-}4\text{-}Me\text{-}C_6H_2)_2]$ (M = Be,[52] Ge, Sn, Pb[53]) and the alkoxo complexes $[M(OCtBu_3)_2]$ (M = Ge, Sn).[54] In addition, as the (unstable) lead complex $[Pb(OCtBu_3)_2]\cdot tBu_3COH$ is known and structurally characterized,[85] there is a tendency to ascribe to the phenoxo ligand a somewhat higher steric shielding factor than to the alkoxo ligands; nevertheless, from considering models, Sen et al. deduce that the opposite is true.[25] All in all, the topic is not relevant for CVD studies because of the poor volatility of metal aryloxo complexes. Incidentally, the selected ligands shown in Figure 3 exist mostly either as dimeric species or as monomers with an additional two or three donor molecules coordinated to the metal.



tris(*t*-butyl)methoxo tris-2,4,6-*t*-butylphenoxo triphenylsiloxo bis(2,4,6-isopropylphenyl)-boryloxo

Fig. 3. Some metal complexes containing sterically highly demanding oxo ligands.

Wolczanski et al. reported a cone angle of 125° for the tritox ligand. This angle is also regarded as valid for silox and thus analogously for "silaz" ($NHSitBu_3$).[57] A comparison of silaz with the $N(SiMe_3)_2$ and $N(SiMe_2H)_2$ ligands demonstrates the relatively low steric requirements of ligands *without* α-branching (Fig. 4). Other ligands are significantly "smaller": Roesky et al. estimated a cone angle of 94° for the M-O-[2,4,6-$(CF_3)_3C_6H_2$] group.[59]

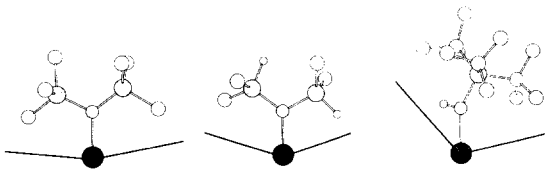


Fig. 4. A comparison of the steric requirements of the silylamido ligands $N(SiMe_3)_2$ (left) and $N(SiMe_2H)_2$ (middle), and the silaz ligand $NH(SitBu_3)$ (right), which is analogous to the tritox/silox ligands [58].

From the structural chemistry discussed for coordination numbers greater than or equal to 2, it follows that monoalkoxides can only be obtained in the form of oligomers or polymers. Lithium methoxide thus forms a layered lattice in the crystal.[60] $LiOtBu$ [61] exists as a hexamer in the gas phase as does $LiOCMe_2Ph$ in the condensed phase.[62] Hexameric and nonameric units have been found together in the crystal structure of $NaOtBu$.[63a] whereas $Na[OCH(CF_3)_2]$ forms a cubane-like

tetramer.[64] The larger alkali metal ions K^+, Rb^+, and Cs^+ are less acidic in the Lewis sense than Li^+ or Na^+ because of their smaller charge-to-radius ratios; their *tert*-butoxide derivatives are tetrameric.[56] Solvent-free dimers have as yet only been structurally characterized for lithium derivatives Li(OR) with the particularly bulky groups R = C*t*Bu$_3$ and B[CH(SiMe$_3$)$_2$]$_2$.[66] The Tl^I and In^I complexes [{M(O-2,4,6-{CF$_3$}$_3$C$_6$H$_2$)$_2$}$_2$][72, 74] are also binuclear, whereas the remaining Tl^I alkoxides—like the parent compound [{TlOMe}$_4$]—form cubane tetramers.[8] The Cu^I alkoxides such as [{(Cu(O*t*Bu)}$_4$] are also tetrameric, but of square-planar structure.[69] The planar, tetrameric [CuX]$_4$ unit can only be broken with sterically extremely demanding ligands such as N(SiMePh$_2$)$_2$: the resulting Cu^I amide is then trimeric.[70] Homoleptic,[*] solvent-free alkoxides of other monovalent elements are not known.

4.2. Thermal Stability and Decomposition Reactions

Alkoxo ligands are sterically rather undemanding because there is no possibility of α-branching—in this they differ from alkyl ligands. Hardly any steric interactions between ligands are therefore known. An example is [W(O*t*Bu)$_6$], which decomposes only in benzene under reflux to relieve the steric strain and forms [WO(O*t*Bu)$_4$].[71] In the analogous complex of the (larger) uranium, the metal center is shielded so well, that [U(O*t*Bu)$_6$] is stable to air and water (ionic radii: 60 pm, W^{VI}; 73 pm, U^{VI}).[8]

Steric intraligand interactions of alkoxo ligands, on the other hand, are known for complexes of mono-, di-, and trivalent metals. Aryloxides often lead to monomeric and dimeric metal complexes of high thermal stability but low volatility (see Section 4.1). Si(OPh)$_4$ can be distilled under normal pressure at 417–420 °C (!) without decomposition. In contrast, [Ln-{O-2,6-*t*Bu$_2$-4-MeC$_6$H$_2$}$_3$] (Ln = Sc, Y, La–Lu)[49, 50, 73] and [{M(O-2,4,6-*t*Bu$_3$C$_6$H$_2$)$_2$}$_4$] (M = Ca, Sr, Ba)[75] only sublime above 200–250 °C in vacuum (10^{-4} Torr). In spite of their thermal stability, aryloxo metal complexes are not nearly volatile enough for CVD purposes. This is due mainly to the polarizing character of the aryl groups, which reduces the volatility by means of intermolecular π–π interactions.

Against expectations, complexes of the silox ligand (OSi*t*Bu$_3$) are also nonvolatile,[51, 57, 76, 77] with the exception of the rare heteroleptic oxo complexes: [CrO$_2$(OSi*t*Bu$_3$)$_2$] (160 °C/1 Torr)[**] and [ReO$_3$(OSi*t*Bu$_3$)] (100 °C/0.5 Torr).[78] Unusually favorable volatility data were reported for [Ba$_2$(OSi*t*Bu$_3$)$_4$]·THF (80 °C/1 Torr),[79] but the ligand (60–90 °C/1 Torr[80]) sublimed here and not the metal complex.[68]

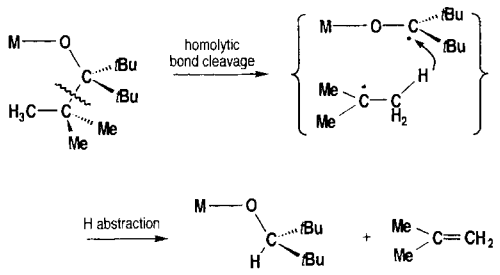
Silox and tritox complexes differ considerably in their thermal stabilities. The homoleptic Nd^{III} derivatives permit a comparison to be made: Whereas [Nd(OSi*t*Bu$_3$)$_3$] is still nonvolatile and thermally stable at 250 °C/10^{-3} Torr (sublimation) and decomposes at temperatures above 340 °C, [Nd(OC*t*Bu$_3$)$_3$] decomposes at 150 °C to give the dinuclear derivative [{Nd(OCH*t*Bu$_2$)$_3$}$_2$], which sublimes at 175 °C/10^{-3} Torr.[47] The particular strength of the Si–O bond and the less favorable cleavage of silyl cations than of carbocations are responsible for these differences. Table 1 shows that decomposition reactions of tritox complexes are not restricted to the example given for neodymium.[25, 81, 83, 85]

Table 1. Tritox complexes and their thermal decomposition products (R = C*t*Bu$_3$, R′ = CH*t*Bu$_2$).

Metal alkoxide	Conditions	Product	Ref.
[{Li(OR)}$_2$] [a]	$t_{1/2}$ (85 °C) = 80 min	[{Li(OR′)}$_n$]	[25]
[{Ca(OR)$_2$}$_2$] [a]	185 °C/10^{-3} Torr	[{Ca(OR′)$_2$}$_3$]	[81]
[Pb(OR)$_2$] · ROH	>0 °C	Pb	[85]
[Li(thf)$_2$][CrCl(OC*t*Bu$_3$)$_2$]	*n*-hexane/60 °C	[{Cr(OR′)(OR)}$_2$]	[24a]
[Ce(OR)$_3$]	150 °C	[{Ce(OR′)$_3$}$_2$]	[25]
[Nd(OR)$_3$]	150 °C	[{Nd(OR′)$_3$}$_2$]	[47]

[a] Due to the low temperatures of decomposition (approximately 120 °C), similar decomposition processes are also presumed for the Na and Mg derivatives mentioned only in a footnote [83].

Isobutene was found by Power et al. to be the main degradation product of the complex [Li(thf)$_2$][CrCl(OC*t*Bu$_3$)$_2$].[24a] This was confirmed by Sen et al. for the Li and Ce complexes.[25] In addition, a small amount of di-*tert*-butyl ketone was identified. The authors assume that the cleavage of ketone as a result of γ-H-migration plays only a minor role at best, because the kinetic isotope effect (k_H/k_D = 1.5 (Ce) and 1.8 (Li)) is relatively high. A possible β-alkyl migration is also regarded as improbable, because the rate of decomposition increases by two orders of magnitude when [12]crown-4 is added to [{Li(OC*t*Bu$_3$)}$_2$]. However, due to the increase in the Li···ligand distance caused by complexation by the crown ether, the rate of decomposition as a result of β-alkyl migration ought to decrease. The authors therefore favor homolytic cleavage of the OC–CMe$_3$ bond with subsequent abstraction of an H atom to give isobutene and a ditox fragment (Scheme 2).



Scheme 2. Mechanism of decomposition of metal tritox complexes according to Sen et al. [25].

This decomposition route has been experimentally confirmed, in as far as *tert*-butyl radicals have been captured with benzophenone. Whether the light-sensitive solvent adduct [Pb(OC*t*Bu$_3$)$_2$]·HOC*t*Bu$_3$ takes the same decomposition path as other tritox derivatives is not clear.[85] The formation of lead radicals could not be determined on irradiation of [Pb{N(SiMe$_3$)$_2$}$_2$], [Pb{CH(SiMe$_3$)$_2$}$_2$], and [Pb(S-2,4,6-*t*Bu$_3$C$_6$H$_2$)$_2$] at any rate, as was the case for the analogous Ge and Sn compounds. The ˙S-2,4,6-*t*Bu$_3$C$_6$H$_2$ radical was identified in the case of the lead thiolate; however, its occurrence indicates

[*] We use the term homoleptic (as introduced into coordination chemistry by Lappert et al. for metal alkoxides when just *one* type of metal and *one* type of alkoxo ligand are present (P. J. Davidson, M. F. Lappert, R. Pearce, *Acc. Chem. Res.* **1974**, *7*, 209–217).

[**] Unless stated otherwise, the data in parentheses indicate the temperature of sublimation and the pressure.

a Pb–ligand bond cleavage instead of a C–C bond cleavage.[86] For the tritox complexes of other more electropositive metals, the C–C bond cleavage clearly dominates.[25]

According to some authors, the instability of the tritox complexes is caused by a relatively weak $OC-CMe_3$ bond that itself results from intramolecular repulsion of the *t*Bu groups. These CC bonds are indeed unusually long (>160 pm). The effect can be studied for $[\{Cr(ditox)(tritox)\}_2]$ (**7**, Fig. 5), the only compound which has been structurally characterized and in which both these ligands are present.[24b]

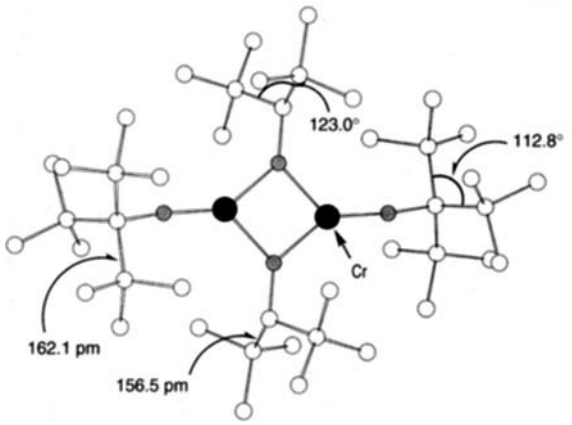


Fig. 5. Long (and therefore weak?) $C-CMe_3$ bonds in sterically congested metal complexes as exemplified by the Cr^{II} complex **7** with bridging ditox and terminal tritox ligands. Average values are given [24a].

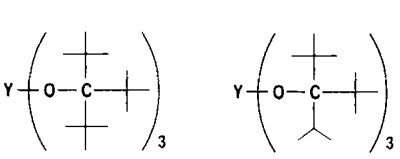
In our group, Anwander et al. used this knowledge to lower the steric strain by replacing just one *i*Pr group with a *t*Bu group. The yttrium complex with the proditox ligand, $[Y(OCtBu_2iPr)_3]$ (**8b**), is indeed so thermally stable that it can be sublimed at 160 °C/10^{-3} Torr without decomposition.[47] The tritox complex **8a** (Fig. 6) is unstable. Power et al. observed the formation of methanol during the preparation of $[\{Co(OCCy_3)_2\}_2]$ (Cy = cyclohexyl), which might indicate a thorough decomposition of this special alkoxo ligand.[89]



[Y(tritox)$_3$] **8a** [Y(proditox)$_3$] **8b**

Fig. 6. Comparison between complexes containing tritox and proditox ligands.

Summary: a) Even the most sterically demanding of the conventional alkoxo ligands cannot stabilize complexes of metal ions such as Ca^{2+} in a monomeric form, let alone the much larger Ba^{2+} ion (ionic radius 135 pm). b) Alkoxo ligands usually form complexes of low volatility with strongly oxophilic metals. c) Silox complexes are nonvolatile. Most tritox complexes decompose to give decomposition products of higher nuclearity (mainly binuclear) with ditox ligands.

A sound concept for volatile alkoxides of electropositive mono-, di-, and trivalent metals can, therefore, not be based solely on steric requirements.

5. Fluorinated Ligands

(Per)fluorinated or highly fluorinated ligands are a special case. The substitution of H, CH_3, or CR_3 groups with fluorine ligands causes intermolecular repulsion due to the resulting negative "charge envelope"—and thus an increase in the volatility. This effect is well known, for example from the chemistry of the metal β-diketonato complexes.[7, 90, 94] A comparison of the boiling points of $HOC(CF_3)_3$ (45 °C/760 Torr, $M_r = 236$) and $HOC(CMe_3)_3$ (85 °C/1.5 Torr, $M_r = 200$) speaks for itself. On the other hand, the van der Waals radius of fluorine is only approximately 10 % larger than that of hydrogen (135 vs. 120 pm),[67] which is why the CF_3 group is considerably less sterically demanding than the *t*Bu group. $[La_3\{OCMe(CF_3)_2\}_9]$[91] is thus trimeric like $[La_3(OCMe_3)_9]\cdot 2HOCMe_3$,[92] yet much more volatile (130 °C/10^{-2} Torr as against 240 °C/10^{-3} Torr). Similarly, Na and Cu alkoxides with fluorinated ligands are more volatile than the nonfluorinated analogues.[93, 64] $[Tl_4\{OCH(CF_3)_2\}_4]$ is in fact the only vaporizable alkoxide of the monovalent metal known to date (85 °C/10^{-2} Torr).[64] The examples $[Ba\{OC(CF_3)_3\}_2]$ (280 °C/<10^{-5} Torr) and $[Ba\{OCMe_3\}_2]$ (270 °C/<10^{-5} Torr) as well as $[Bi\{OCH(CH_3)_2\}_3]$ (90 °C/<10^{-4} Torr)[101] and $[Bi\{OCH(CF_3)_2\}_3]$ (110 °C/<10^{-2} Torr)[87] show quite clearly, however, that the expected increases in volatility are not always achieved.[95]

Alkoxides with fluorinated ligands often have short M···F contacts. These interactions are responsible for the undesired fluorine content that is found now and then in thin layers generated from fluorinated alkoxides by CVD techniques. Pure sodium fluoride layers have been prepared from $[Na_4\{OCH(CF_3)_2\}_4]$ by deposition onto SiO_2 at 285 °C.[64]

Summary: As a rule, metal (per)fluoroalkoxo complexes are extremely volatile. The incorporation of fluorine into decomposition products prepared by thermal and plasma-chemical methods is a disadvantage that can hardly be avoided, however. The concept is therefore no longer being intensively pursued in current materials research.

6. Donor Functionalized Alkoxo Ligands

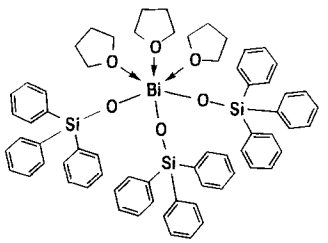
The use of polyetheralcohols both as solvent and as ligand for sol–gel processes has become standard practice. Ligands of this type are assumed to be less easily separated from the metal center by hydrolysis than monodentate ligands because of the chelate effect. The resulting improved solubility of the growing oxo cluster delays its gel point[*]. Alcoholysis reactions probably give rise to the same result when alcohols are used as solvent.[96]

Based on this experience, donor groups—preferably ether and amino functions—are taken into consideration for use in materials science applications, at least when the molecular chemistry approach is being applied. The first volatile metal alkoxide of this type was reported by Horowitz et al. in 1989: the blue-green compound $[Cu(OCH_2CH_2NEt_2)_2]$, volatile at 100 °C in a high vacuum.[97] This and the compound $[Cu(OCH_2CH_2OnBu)_2]$, which was also prepared, dissolve well in toluene.[97]

[*] The *gel point*, a term used in macromolecular chemistry, is defined as the point at which insolubility starts due to molecular cross-linking (for example polymerization, polycondensation).

Complexes of the metals relevant to oxidic ceramics (Ca, Ba, Pb, Bi, Cu, Zn, Cd, Y, and Ce) were prepared containing donor functionalized alkoxo ligands, especially in the groups around Buhro (St. Louis, USA), Caulton (Bloomington, USA) and Hubert-Pfalzgraf (Nice, France). The ligand most often used was 2-methoxyethanol $HOCH_2CH_2OCH_3$, the simplest in the series. After the molecular structures of the Ca,[98] Ba,[99] Pb,[100] Bi,[101] Cd,[102] and Y[103, 112] derivatives were known, the expectations were dashed to a large extent: a) Homoleptic metal complexes of these ligands are nonvolatile, which is explicitly acknowledged in most cases. A (rather improbable[68]) low sublimation temperature of 160 °C/10^{-1} Torr has been reported only in the case of the barium–solvent complex $[Ba_6O(OCH_2CH_2OMe)_{10}]\cdot 4HOCH_2CH_2OMe$.[99] b) The structural chemistry in the solid is characterized by infinite chains (Pb, Bi, Cu), oligomeric rings (Y), and units with nonmolecular structures (for example, CdI_2 type for Ca, Cd). c) Because of the frequently good solubility in nonpolar organic solvents, these special alkoxide complexes are of interest as variants in sol–gel processes, in particular in the case of Ca, Ba, Bi, and Y.

As regards solubility, it should be noted that derivatives with free ether functions, that is, not coordinated to the metal ("dangling ligands"), can be insoluble in aprotic organic solvents (Pb and Cu derivatives). The structures of the likewise insoluble Be and Zn derivatives are not known. In contrast, in case of the Bi derivative, Bi···O interactions ranging from 290 to 310 pm have been found; these are comparable with the Bi···THF bond lengths of 295 pm in $[Bi(OSiPh_3)_3]\cdot 3THF$ (**9**).[104]



9

In 1990 Buhro et al. quite clearly stated the view on alkoxo ligands that prevailed at that time:[98] "However, group 2 alkoxides with conventional, monodentate alkoxide ligands are generally nonvolatile and poorly soluble in nondonor solvents, probably as a result of nonmolecular structures. Bidentate alkoxide ligands may reduce molecularities sufficiently to allow soluble derivatives to be obtained. A simple extension of this reasoning above suggests that appropriate tridentate alkoxide ligands may produce molecularities as low as $n = 2$, perhaps inducing volatility as well."

As Rees et al. were able to show a little later for the complex $[Ba\{O(CH_2CH_2O)_nMe\}_2]$ ($n = 2, 3$) that the expectations placed in an increase in volatility were not fulfilled here either.[105] Cryoscopic molecular mass determinations in solution suggested that monomers were indeed present, but nevertheless, no increase in volatility was achieved. The copper and zinc derivatives $[M\{O(CH_2CH_2O)_2Me\}_2]$ are also nonvolatile (M = Cu,[106] Zn[107]). Primary polyetheralkoxo ligands all form nonvolatile metal complexes, in contrast to some metal alkoxides with the more strongly basic amino functions (Table 2). The Pauling electronegativities[67] for those metals for which volatile amino-functionalized alkoxides are known lie in the upper region [1.65 (Zn), 1.87 (Pb), 2.00 (Cu), 2.02 (Bi)]. To a first approximation, the volatility is also found to increase in the same order. Volatile alkoxides of electropositive metals such as barium with such ligands are not known, nor are they to be expected.

Table 2. Properties of metal alkoxides whose ligands are functionalized by amino groups.

Ligand/Metal	Structure (degree of aggregation)	Sbl. [°C]/Yield [%] [a] (Solubility)	Ref.
$OCH_2CH_2NMe_2$			
Be^{2+}	(8–11)	(slightly in benzene)	[139]
Bi^{3+}	(1.5)	85/38	[101]
Cu^{2+}	(1)	80/85	[161]
Zn^{2+}	oligomer	170/53	[107]
Cd^{2+}	–	(slightly in *n*-hexane)	[102]
$OCH_2CH_2NEt_2$			
Cu^{2+}		100/75	[97]
$OCHMeCH_2NMe_2$			
Pb^{2+}	(1.3)	106/80	[100]
Bi^{3+}	(1.1)	90/54	[104]
Cu^{2+}	$Cu(\mu_2\text{-}OR)_2$	60/85	[161]
Zn^{2+}	(3)	170/80	[107]
Cd^{2+}		(slightly in *n*-hexane)	[102]
$OC_2H_4N(CH_3)C_2H_4NCH_3$			
Cu^{2+}	$Cu(\mu_3\text{-}OR)(\mu_2\text{-}OR)$	110–112/85	[161]
Zn^{2+}	(2.4) $Zn(\mu_3\text{-}OR)_2\text{-}2H_2$	170/55	[107]

[a] The yield is the sublimation yield significant for practical purposes (for example CVD applications) at 10^{-4} Torr and the given temperature.

With the exception of the Cu complex, the sublimation yields of complexes with primary alcoholate ligands are less than 60 %. The secondary alcoholate ligand $OCH(CH_3)CH_2NMe_2$ often forms more volatile, but at any rate thermally more stable, metal complexes.

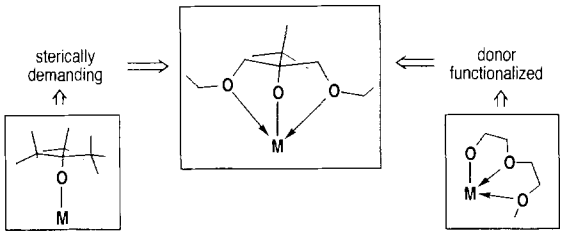
No volatilities are reported for the $[M(OCtBu_2CH_2PMe_2)_3]$ complexes (M = Y, Nd) with phosphino-substituted alkoxo ligands.[108] The ligand $HOCMe_2CH_2PPh_2$ has also been used in Pd^{II} chemistry. Whereas $[Pd(OCH_2CH_2PPh_2)_2]$ slowly decomposes at 0 °C with deposition of metallic palladium, $[Pd(OCMe_2CH_2PPh_2)_2]$ is stable under these conditions.[109] Seemingly unimportant constitutional details of the chelate ligand thus seem to influence the properties of the complex considerably.

Summary: Alkoxo ligands that have more than one ether function at their disposal tend to yield nonvolatile alkoxides, whereas amino groups in the alkoxide lead to sublimable complexes, at least for the less electropositive metals. The thermal stability of the complexes containing O,N-ligands is not quite as desired, however, which can clearly be seen in the poor sublimation yields.

6.1. Combination of Steric Demands and Donor Functionalization

Metal alkoxide bonds in metal oxo complexes have predominantly ionic character due to the mainly large differences in the electronegativities between metal and oxygen. This often results in saltlike solid-state structures. To achieve volatility, the strength of the polar interactions have to be minimized. This can be achieved by either increasing the distance between polar M–O units by means of large organic groups ("concept of steric shielding"), or reducing the polarizing strength of the metal ion by charge transfer from donor ligands (concept of donor functionalization). As neither of these principles alone leads to

optimal volatility and thermal stability, the approach followed in our group since the doctoral work of Anwander[110] therefore consists of the combination of steric demand and donor functionalization in one and the same ligand (Scheme 3).



Scheme 3. Concept of the combination of sterically and electronically shielding alkoxo ligands.

The Cr^{III} complex **10** (Fig. 7) prepared in this manner enters the gas phase at 65 °C/1.5 Torr without decomposition it is the most volatile compound of trivalent chromium known to date.[10b, 111] Bismuth exemplifies how delicate the balance of the exact ligand constitution really is: The nonvolatile chelate complex **11a** has a polymeric structure in the solid state,[169] whereas its β-dimethyl derivative **11b** is a monomer (60 °C/10^{-3} Torr).[68]

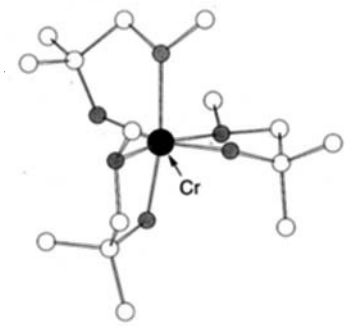


Fig. 7. Crystal structure of the Cr^{III} complex $[Cr(OCMe_2CH_2OMe)_3]$ (**10**) [10b, 111].

Donor-functionalized alkoxy ligands can perfectly surround large metals even with relatively small steric bulk, because they have at least two coordination sites at their disposal: an alcoholate function for charge neutralization, and a donor function to compensate the steric and electronic demands of the metal ion. The synthesis of the metal complex is thus easier, and the disadvantageous results of steric overcrowding (see tritox, above) are avoided. In addition, the chelate effect contributes to the stability, also with respect to moisture. The commercially available alcohols that are also predominantly used even in the newer literature do not fulfill these requirements. The concept cannot, therefore, fall back on commercially available ligands as yet, but well-elaborated syntheses have become available in the meantime.[68, 110] The constitution of the ligands can be tailor-made for the coordination chemistry of the metals under consideration, for example, with respect to electronegativity, charge, and ionic radius.

11b

6.2. Heteronuclear Alkoxides

The extension of this approach to include metal alkoxides that contain different metals ("heteronuclear alkoxides") seems realistic. Alkoxide ligands here fulfill not only their donor function, but also act as a tether between the metal atoms. The volatile Mg/Co alkoxide **12** was obtained at the first attempt and its structure is shown in Figure 8.[113] Heteronuclear alkoxides with the element combinations La^{III}/Co^{II}, Li^{I}/Nb^{V}, Fe^{II}/Mg^{II}, K^{I}/Co^{II}, Na^{I}/Ce^{IV}, Li^{I}/Co^{II}, and Fe^{II}/Zn^{II} were also prepared according to this concept.[113]

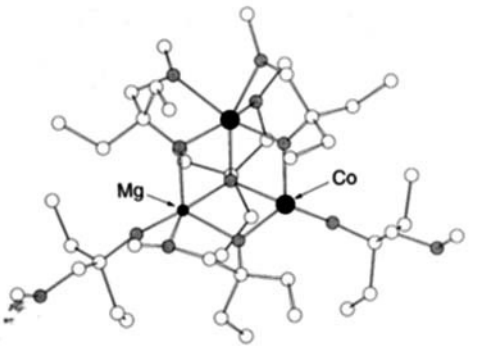

Fig. 8. Crystal structure of $[MgCo_2(OCEt_2CH_2OMe)_6]$ (**12**).

The first systematic investigations into the synthesis of heteronuclear alkoxides were performed by Meerwein and Bersin in 1929.[116] The double oxides ("Doppeloxide"), as they referred to the compounds, go back to the works of Copaux and Cambi, who synthesized the first boron alcoholate complexes at the turn of the century.[117] The technical importance of the heteronuclear alkoxides is indisputable today. The area of possible applications ranges from the synthesis of ferroelectric ($KTaO_3$) and dielectric materials ($SrTiO_3$) to the preparation of multimetallic "high-tech ceramics" ($YBa_2Cu_3O_{7-\delta}$).

Volatile molecular precursors are admittedly still rare. The heteronuclear transition metal complexes $[M\{Al(OiPr)_4\}_2]$ (M = Be, Zn, Cd, Hg[118]), $[Zn\{Al(OiPr)_4\}_2]$, $[Zn\{Al(OiPr)(OR)_3\}_2]$ (R = Me, Et, *n*Pr, *n*Bu, *i*Bu, *s*Bu, amyl[119]) and $[M^1(OiPr)_{5-x}\{M^2(OiPr)_4\}_x]$ (M^1 = Nb, Ta; M^2 = Al, Ga; $x = 1$, 2[121]), the alkaline earth metal complexes $[Be\{Al(OiPr)_4\}_2]$,[118] $[M\{Al(OtBu)_4\}_2]$ (M = Mg, Ca, Sr), $[M\{Al(OnBu)_4\}_2]$ (M = Mg, Ca), $[Mg\{Al(OEt)_4\}_2]$,[120] and the lanthanide complexes $[Ln\{Al(OiPr)_4\}_3]$ (Ln = Sc, Y, La, Pr, Nd, Sm, Gd, Dy, Ho, Er, Yb, Lu[122, 123]) described by Mehrotra et al. are some of the few examples known.

This class of compounds is naturally characterized by its great variety in terms of composition and structure. At this point only the aspect of the donor functionalization will be explored. Among the synthetic methods for 1:1-heterodimetallic systems, the ate-reaction [Eqns. (o) and (p)] are the most important. The difference in electronegativity between the metals involved and the steric demands of the alcohol influence the formation of the heterodinuclear alkoxide.

$$2\,LiO\mathit{t}Bu + 2\,Sn(O\mathit{t}Bu)_2 \rightarrow [Li_2Sn_2(O\mathit{t}Bu)_6] \quad \text{(o)}$$

$$2\,LiO\mathit{i}Pr + 2[Ti(O\mathit{i}Pr)_4] \rightarrow [Li_2Ti_2(O\mathit{i}Pr)_{10}] \quad \text{(p)}$$

The target of the synthesis is usually a "monomeric" 1:1-heterodimetallic alkoxide. This is not easy to achieve, because a difference in electronegativity and use of the individual components in stoichiometric ratios are rarely sufficient to guarantee its formation. A 1:1 mixture of $[Ba(OR)_2]$ and $[Ti(OR)_4]$ (R = Et, *i*Pr, Bu) thus does not lead to the expected $[BaTi(OR)_6]$, but to $[BaTi_4(OR)_{18}]$ (R = Et, C_6H_5). The solvent adducts $[BaTi_2(OEt)_{10}]\cdot 5EtOH$ and $[Ba_4Ti_2O(OEt)_{14}]\cdot 8EtOH$ have also been detected in solution.[124] None of these compounds is volatile, but instead they release $[Ti(OEt)_4]$ on heating. Similar problems are encountered in the synthesis of $[Sr_2Ti(OiPr)_8]\cdot 5HOiPr$ and $[NaW_2H(OR)_8]_8$ (R = *i*Pr, CH_2tBu).[125]

Donor-functionalized alcohols have had no importance as yet for the heterobinuclear complexes; at best they served to increase the solubility. The transfer of our ligand concept to complexes such as these should ensure volatility and thermal stability. We considered the alcoholysis of equimolar amounts of metal amides with subsequent ate-complex formation according to Equation (q) as synthetic method.[113]

$$[Fe\{N(SiMe_3)_2\}_2] + [Zn\{N(SiMe_3)_2\}_2] + 4HOCEt_2CH_2OMe \longrightarrow [FeZn(OCEt_2CH_2OMe)_4] + 4HN(SiMe_3)_2 \quad (q)$$

As metal amides are known for virtually all metals, this method promises wide access to the heteronuclear complexes. The element combinations Mg^{II}/Co^{II} and Fe^{II}/Zn^{II} were investigated first as model systems to sound out the influence of the electronegativities on the formation and thermal stability of heterodinuclear alkoxides. After reaction of $[M\{N(SiMe_3)_2\}_2]\cdot x$THF with $HOCEt_2CH_2OMe$ ($M = Mg^{II}$, $x = 2$; Co^{II}, $x = 0$), only the heteronuclear species could be identified by mass spectroscopy. In contrast, after treatment of the iron and zinc amides $[M\{N(SiMe_3)_2\}_2]\cdot x$THF with $HOCEt_2CH_2OMe$ ($M = Fe^{II}$, $x = 1$; Zn^{II}, $x = 0$), signals for the homodinuclear alkoxides were identified in addition to those for the heterodinuclear species. As the difference in electronegativities for the element combination Fe/Zn ($\Delta\chi = 0.18$) is considerably smaller than for Mg/Co ($\Delta\chi = 0.57$), it is assumed that large differences in electronegativity favor the exclusive formation of the heterodinuclear alkoxide. Based on this assumption we were able to synthesize the compounds **13**–**16**.[113]

$[LiCo\{OC(CF_3)(OiPr)_2\}_3]$ **13** (95 °C/10^{-2} Torr)

$[Na_2Ce(OCEt_2CH_2OMe)_6]$ **14** (95 °C/10^{-2} Torr)

$[KCo(OCEt_2CH_2OMe)_3]$ **15** (110 °C/10^{-3} Torr)

$[LaCo(OCEt_2CH_2OMe)_5]$ **16** (115 °C/10^{-3} Torr)

The K/Co complex **15** is dimeric (Fig. 9) and has great structural similarity with the K/Zn derivative $[\{KZn(OCMe_3)_3\}_2]$.[127] Attempts to prepare volatile heterodinuclear indium/tin and strontium/calcium alkoxides failed. We put this down to the relatively small differences in the electronegativities ($\Delta\chi = 0.1$ and <0.1, respectively[67]).

The synthetic method does not necessarily demand the use of "basic" and "acidic" alkoxides as a matter of course, however. In the reaction of $[Nb(OMe)_5]$ with $[Ta(OMe)_5]$ also the *heterodinuclear* alkoxide $[NbTa(OMe)_{10}]$ is formed ($\Delta\chi$(Nb/Ta) = 0.1).[128] Nevertheless, the electronegativity rule has proved to be a useful rule-of-thumb.

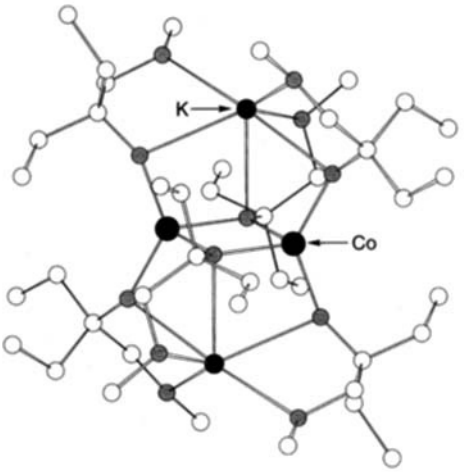

Fig. 9. Crystal structure of $[K_2Co_2(OCEt_2CH_2OMe)_6]$ (**15**). All alkoxo ligands are bridging.

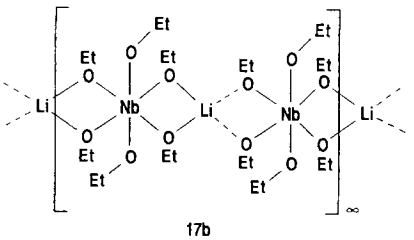
6.3. Lithium/Niobium Alkoxides

Lithium niobate ($LiNbO_3$) is an interesting heterodinuclear metal oxide from a materials science point of view due to its piezoelectrical and pyroelectrical properties as well as its nonlinear optical (NLO) properties. Molecularly defined precursors for the MOCVD (MOCVD = metal-organic chemical vapor deposition) and sol–gel processes have thus always been a priority synthetic goal. The first route providing access to lithium/niobium alkoxides was found by Mehrotra et al. in 1968 with the ate-reaction of niobium alkoxides $[Nb(OR)_5]$ (R = Me, Et, *i*Pr) with lithium alkoxides LiOR (R = Me, Et, *i*Pr).[115] On workup, however, these lithium/niobium alkoxides decomposed under the conditions of vacuum sublimation in the back reaction of their formation [Eq. (r)]. Bradley et al. confirmed this for

$$[LiNb(OR)_6] \overset{\Delta,\ \text{vacuum}}{\rightleftharpoons} LiOR + [Nb(OR)_5] \quad (r)$$

$[LiNb(OtBu)_6]$ (**17a**).[1] This "demixing" ("dismutation") is structure-related: lithium/niobium alkoxides, for example $[LiNb(OEt)_6]$ (**17b**), have chain structures in which lithium is tetracoordinated and niobium hexacoordinated.[129]



17b

The dinuclear precursor $[Li_2Nb_2O_2(OEt)_8]\cdot 2HOEt$ (**18**), originally formulated as the tetrameric hydroxo cluster $[Li_2Nb_2(OH)_2(OEt)_{10}]$,[142] is a structurally characterized (Fig. 10) intermediate on the way to **17b**. For this reason, multicomponent CVD precursors such as lithium-β-diketonate/niobium(v) ethoxide had to be used until now.[130] However, this route gave only amorphous $LiNbO_3$ layers that had to be made

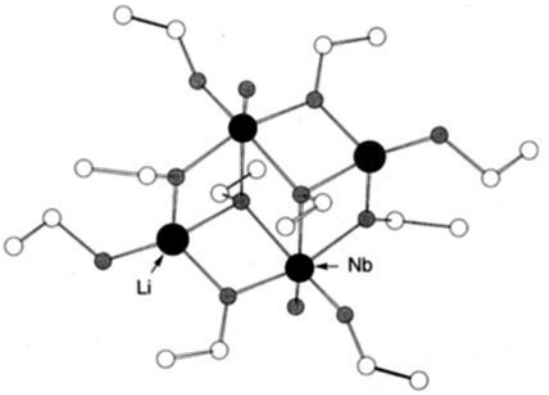


Fig. 10. Crystal structure of $[Li_2Nb_2(OEt)_{10}]\cdot 2\,HOEt$ (**18**).

crystalline by tempering at 1000 °C. $[LiNb(OEt)_6]$ is said to give monocrystalline layers in the spray-CVD process at 400 °C. Equation (r) arouses doubt about the integrity of the molecular precursor under these experimental conditions.[131] The reaction is therefore based on the concept of donor functionalization [Eq. (s)]. At 90 °C/10^{-3} Torr, **19** (Fig. 11) is volatile and does

$$Li^+[OCMe_2CH_2OMe]^- + NbOCl_3 \longrightarrow \underset{\mathbf{19}}{[Li_2Nb_2O_3(OCMe_2CH_2OMe)_6]} + \ldots \quad (s)$$

not decompose. At 600 °C it produces lithium niobate films that have the correct Li:Nb:O ratio of 1:1:3 (Fig. 12) after tempering at 700 °C in an oxygen plasma.[126] The alkoxide **19** does not, therefore, "demix" on vaporizing—an important criterion for every precursor philosophy that aims at predetermining the composition of the CVD product from the metal ratio in the molecular precursor.[114]

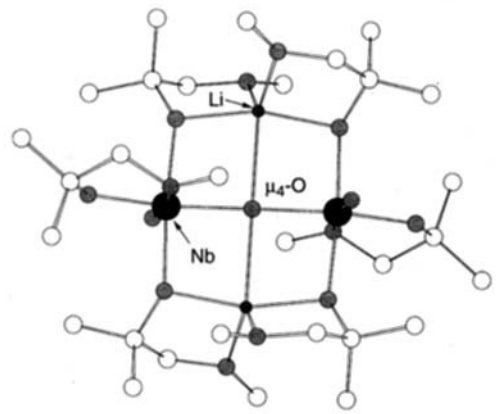

Fig. 11. Crystal structure of the Li_2Nb_2 alkoxo cluster compound **19** with a central ("lone") oxo ligand.

Fig. 12. $LiNbO_3$ from the molecular precursor **19**, deposited on steel at 350 °C and tempered at 650 °C in an O_2 plasma; scanning electron micrograph magnified 1000×. (The layer has caved in due to the different thermal expansion coefficients.)

Steel, glass, glass coated with vaporized gold, silicon, and lithium tantalate $LiTaO_3$ can be used as substrates. According to XPS data, the proportion of carbidic carbon is less than 5%.[126] The newer strategy for success for the introduction of donor functionalization is demonstrated by the reactions according to Equations (s) and (t). The heterodinuclear alkoxide **20** sublimes at 110 °C/10^{-2} Torr without decomposition and is monomeric according to EI-MS data.[126]

$$Li^+[OCHMeCH_2NMe_2]^- + [Nb(OiPr)_4(OCHMeCH_2NMe_2)] \longrightarrow \underset{\mathbf{20}}{[LiNb(OCHMeCH_2NMe_2)_2(OiPr)_4]} \quad (t)$$

7. Further Strategies

The polarity in metal alkoxides arising from M–O bonds can be reduced by the (partial) exchange of alkoxides with, for example, alkyl groups. $[Be_3(OtBu)_6]$ thus sublimes at 110 °C/10^{-3} Torr,[138] and $[Be_2tBu_2(OtBu)_2]$ at 50 °C/10^{-2} Torr.[149] Such compounds are not a subject of this article because of their homoleptic character, but this aspect will require more attention for CVD in the future.

If a metal center in M–O(R)–M units is replaced by one of higher electronegativity, the polarity of the M–O bond is reduced due to a decrease in the electron density on the alkoxide oxygen atom. The pentanuclear complex $[Sc_5O(OiPr)_{13}]$ (**21**) can be vaporized only above 210 °C/10^{-2} Torr,[44] the tetranuclear dinuclear complex $[Sc\{Al(OiPr)_4\}_3]$ (**5a**) (Section 3) under conditions as mild as 140 °C/0.5 Torr.[123]

8. Volatile Metal Alkoxides

As most metals within a period or group have neighbors whose alkoxides have similar properties, these will be summarized in the following discussion. In the context of volatile compounds, the limitation to homoleptic metal alkoxides is justifiable.

8.1. Alkoxides MOR of Monovalent Metals

Volatile alkoxides of the alkali and coinage metals, as well as those of thallium, are little known, mainly as a result of the unfavorable charge-to-radius ratio. Consequently, sterically undemanding ligands give rise to oligomeric, nonvolatile compounds.

8.1.1. Alkali Metal Alkoxides

Hexameric $[Li_6(OtBu)_6]$ sublimes at 110 °C/10^{-1} Torr.[8] The tetrameric K, Rb, and Cs derivatives can be vaporized at 140–195 °C/10^{-2} Torr.[8, 132] $[Li_6(OCMe_2Ph)_6]$ is less volatile (165 °C/10^{-3} Torr) than the *tert*-butoxide derivative $[Li_6(OtBu)_6]$ because of the phenyl group (cf. Section 4.1).[62] The O-donor-function-

alized $[Li_6(OMe_2CH_2OMe)_6]$, which sublimes at 110 °C/10^{-3} Torr, is also hexameric based on CI-MS data.[113] $[Na_4\{OCH(CF_3)_2\}_4]$ sublimes slowly at 75 °C/10^{-2} Torr,[64] $[Na\{OCtBu(CH_2OiPr)_2\}]$ quickly at 155 °C/10^{-3} Torr.[113] No volatility data were reported for the P-donor-functionalized complexes $[M_2\{OCtBu_2CH_2PR_2\}_2]$ (M = Li, Na; R = Me, Ph).[133]

8.1.2. Thallium(I) and Copper(I) Alkoxides

The heterocubane $[Tl_4\{OCH(CF_3)_2\}_4]$ is the only known vaporizable alkoxide of this metal (85 °C/10^{-2} Torr).[64] For monovalent copper only $[Cu_4\{OtBu\}_4]$ (110 °C/10^{-3} Torr) is known.[134] Fluorinated alcohols give more volatile derivatives such as $[Cu_4\{OtBu\}_2][\{OCR_{3-n}(CF_3)_n\}_2]$ (R = H, n = 2: 90 °C/10^{-3} Torr; R = Me, n = 2: 70 °C/10^{-3} Torr; R = Me, n = 1: 95 °C/10^{-3} Torr) on partial alcoholysis.[135] Other volatile homoleptic metal alkoxides are not known if the adduct $Me_3P\cdot[Au(OSiMe_3)]$ (which is described as being partially sublimable, although no details are given[136]) is disregarded.

8.2. Alkoxides $M(OR)_2$ of Divalent Metals

The heavy alkaline earth and the divalent rare earth metals are to be discussed together because of their large ionic radii (Fig. 13) and their electropositive character. Similar properties link magnesium (ionic radius Mg^{2+}: 72 pm) with divalent first row transition metals (69–80 pm), and the "soft" divalent main group metals Ge, Sn, and Pb form an additional unit. The current literature only justifies special consideration for Be^{II} (27 pm) and Cu^{II} (57 pm). Homoleptic alkoxides of Pd^{II}, Pt^{II}, and Hg^{II} are known but they are all nonvolatile.[118, 137, 152]

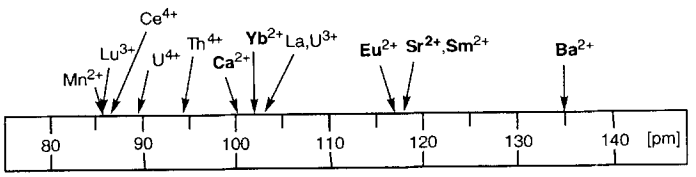

Fig. 13. Radii of large metal ions (C.N. 6) according to Shannon; data from Ref. [154].

8.2.1. Beryllium Alkoxides

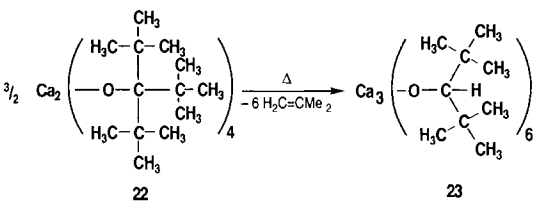
The alkoxides of beryllium, $Be(OR)_2$, are dimeric or trimeric even with bulky substituents such as R = CEt_3, CEt_2Me, $CEtMe_2$, and $CtBu$ and $C_2H_4NMe_2$[138, 139] because of the extremely high Lewis acidity in spite of the very small ionic radius. The only monomeric exception is $[Be(O\text{-}2,6\text{-}tBuC_6H_3)_2]$.[138] Besides $[Be_3Cl_2(OtBu)_4]$ and $[Be_2Br_2(OtBu)_2]\cdot 2OEt_2$,[139] in 1993 Power et al. reported $[Be(O\text{-}2,4,6\text{-}tBu_3C_6H_2)_2]\cdot OEt_2$, one of the few tricoordinate, structurally characterized beryllium complexes.[140] The reactions of $[Be\{N(SiMe_3)_2\}_2]$ with $HOCMe_2CH_2OMe$ and $HOCEt_2CH_2OMe$ led to volatile products (72 °C/10^{-2} Torr and 78 °C/10^{-3} Torr respectively)—products that show no fluxional behavior in their ^1H NMR spectra. As they are as volatile as $[\{Be(OCEt_3)_2\}_2]$, they are probably dimeric structures. The beryllium alkoxides thus belong to the few examples where the additional donor functionality does not produce an increase in volatility. As the coordination number 4 typical for beryllium is only rarely exceeded, the structure of the molecules is comparable to that of $[\{Sn(OCMe_2CH_2OMe)_2\}_2]$ (Section 8.2.3).

8.2.2. Calcium, Strontium, Barium, and Ytterbium(II) Alkoxides

Immediately after the discovery of the oxidic high-temperature superconductors, research into the alkoxides of the heavy alkaline earth metals experienced a dramatic upswing; no solution was forthcoming for the notorious lack of volatility, however. The following ligands were used: OMe, OEt,[141] OiPr,[8] OtBu,[144] OPh,[144b] $OCPh_3$, $OSitBu_3$, $OSiPh_3$,[143] $O(CH_2CH_2O)_nMe$ (n = 1, 2, 3)[98, 99, 105], $O(C_2H_4O)_2nBu$,[145] $OCH_2CH_2NMe_2$,[146] $OCH_2CHO(CH_2)_3$ (= 2-tetrahydrofurfuryl),[95] $OCH_2CH_2N(C_2H_4OH)_2$,[147] O-2,6-tBu_2-4-Me-C_6H_3,[148] O-2,4,6-$(Me_2NCH_2)_3C_6H_2$,[146] O-2,4,6-$(F_3C)_3C_6H_2$,[150] and $OSiPh_2OSiPh_2O$.[151] Little effort was expended on the synthesis of new alcohol derivatives: even today, the greater part of the alcohols used as ligand precursors come from the shelf and are not tailor-made for the particular metal concerned.

The difficulties in obtaining volatile Ca, Sr, and Ba alkoxides are as follows: a) The large size of these metal ions (100–135 pm, Fig. 13) makes the construction of a perfect ligand shell (only *one* alcoholate ligand can be bound per metal charge!) very difficult in view of the relatively low charge (+ 2). Decomposition processes arising from intermolecular interactions are often the result. The low charge-to-radius ratios require donor-functionalized ligands. b) The polarizability of the metal ions is low. Apart from Ca, Sr, and Ba, only the divalent rare earth metals Sm, Eu, and Yb have this property profile to such an extreme degree.

For this reason, volatile alkoxides of these metals have only been obtained in exceptional cases: 1) Purdy et al. were able to obtain barium alkoxides with standard ligands such as OtBu, which were volatile under drastic conditions (270 °C/$<10^{-5}$ Torr).[95] 2) The homoleptic aryl oxides $[M_2(O\text{-}2,4,6\text{-}tBu_3C_6H_2)_4]$ of calcium, strontium, and barium sublime at 250 °C/10^{-4} Torr with partial decomposition.[75] The monomeric THF adducts are thermally more labile; for example $[Ca(O\text{-}2,6\text{-}tBu_2\text{-}4\text{-}MeC_6H_2)_2]\cdot 2THF$ already decomposes at 90 °C, presumably releasing the solvent molecule THF.[155] 3) The siloxo complex $[Ba_3(OSiPh_3)_6]\cdot THF$ sublimes at 225 °C/10^{-2} Torr with cleavage of THF.[143a] The analogous Ca and Sr complexes were also described as sublimable, though no data was specified. In contrast, according to thermogravimetric data, the ammonia adduct $[Ca_2(OSiPh_3)_4]\cdot 4NH_3$ is nonvolatile and only expels NH_3 on heating.[156] 4) Dimeric $[\{Ca(OCtBu_3)_2\}_2]$ (**22**) decomposes like tritox derivatives of other metals, under cleavage of isobutene. Trimeric $[Ca_3(OCHtBu_2)_6]$ (**23**) is formed according to Equation (u). This sublimes in small yield at



22 23 (u)

185 °C/10^{-3} Torr. The analogous Yb^{II} derivative $[\{Yb(OCtBu_3)_2\}_2]$ was described recently, but nothing is known about its thermal properties.

The volatile alkoxides $[M_2\{OC(CH_2OiPr)_2tBu\}_4]$ (M = Ca, **24a**; Sr, **24b**; Ba, **24c**) were obtained in our laboratory according to Equation (v) from the THF adducts of the amides $[M\{N(SiMe_3)_2\}_2]$ and structurally characterized (Fig. 14). These

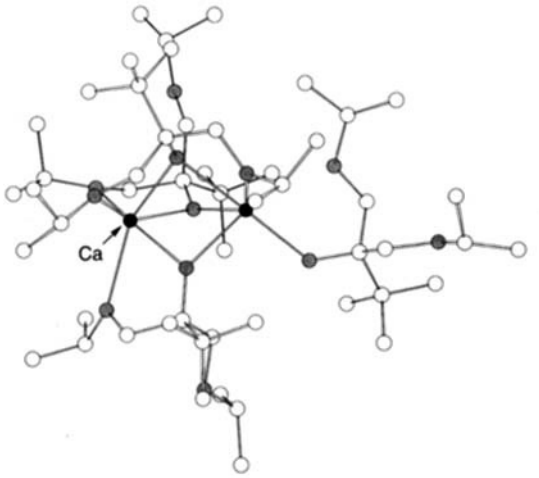


Fig. 14. Crystal structure of the first calcium alkoxide that sublimes without decomposition: $[Ca_2\{OC(CH_2OiPr)_2tBu\}_4]$ **24a** [68, 81].

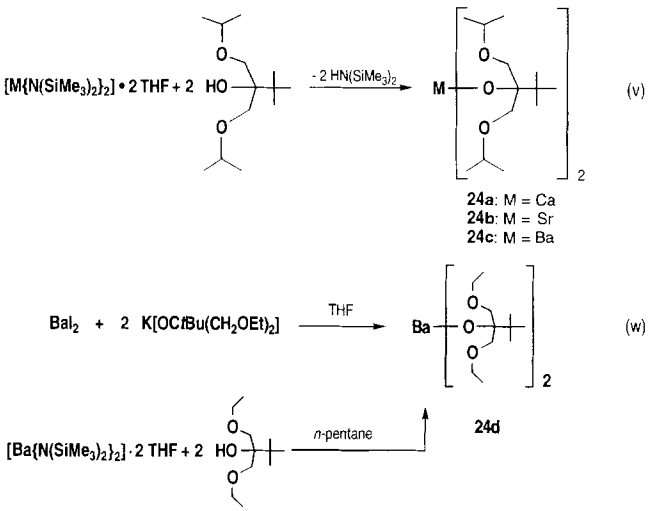
complexes sublime in vacuum (10^{-2} Torr) without decomposition at 150 °C (Ca), 170 °C (Sr), and 185 °C (Ba).[68] The barium derivative $[Ba_2\{OC(CH_2OiPr)_2tBu\}_4]$ (**24d**) [Eq. (w)] sublimes at 150 °C/10^{-2} Torr. Compounds **24a**–**d** are the first alkoxides of these alkaline earth metals that fully sublime without any decomposition.



Triple bridging, as shown in Fig. 14, is not at all unusual for the alkaline earth alkoxides. This structural characteristic has been determined for the complexes $[Ca_2(OSiPh_3)_4]\cdot 4NH_3$,[156] $[Ba_2(OSitBu_3)_6]\cdot THF$,[79] and $[Ba_3(OSiPh_3)_4]\cdot THF$.[143a] Apart from the alkaline earth metals, this coordination has only been observed for $[Y_2\{(cyclo\text{-}C_5H_9Si)_7O_{11}\}_2]\cdot OPPh_3$ and $[Lu_2(OCMe_2CH_2OMe)_6]$ as yet.[82]

The divalent lanthanides (Yb, Sm, Eu) display the same properties profile (ionic radius, electronegativity) as the alkaline earth ions. For this reason, no volatile alkoxide complexes of these elements are known as yet. Taking the smallest and "heaviest" of the lanthanide ions Yb^{2+} as an example, we were able to obtain the first volatile alkoxide complex by reaction of $[Yb\{N(SiMe_3)_2\}_2]\cdot DME$ with $HOC(CH_2OiPr)_2tBu$: $[\{Yb[OC(CH_2OiPr)_2tBu]_2\}_2]$ (115 °C/10^{-3} Torr). As can be seen from Fig. 13, the ionic radii of Yb^{2+} and Ca^{2+} are equally large. The somewhat higher volatility of the ytterbium alkoxide is likely to arise from its lower Lewis acidity.

8.2.3. Germanium, Tin, and Lead Alkoxides

From a coordination chemistry point of view, germanium(II), tin(II), and lead(II) usually form a group.[8] This does not apply for the alkoxides: $[M(OCtBu_3)_2]$ (M = Ge, Sn) and $[M_2(OtBu)_4]$ (M = Ge, Sn) have dimeric structures,[54] whereas the complexes $[Pb(OCtBu_3)_2]\cdot HOCtBu_3$[85] and $[Pb_3(OtBu)_6]$ (**25**)[55, 96, 100] are known (Fig. 15).

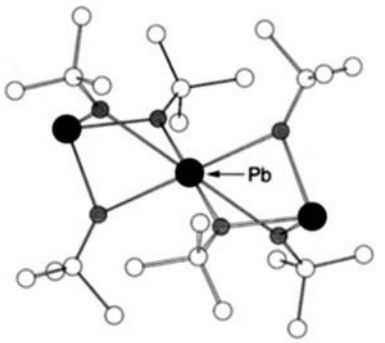


Fig. 15. Crystal structure of the trimeric lead(II) alkoxide $[Pb(OtBu)_2]$ (**25**).

The O-functionalized derivatives $[\{M(OCMe_2CH_2OMe)_2\}_2]$ (M = Sn, Pb) are quantitatively volatile.[113] The tin alkoxide **26a** (Fig. 16, top) sublimes completely and without decomposition at 70 °C/1.5 Torr. The only other volatile tin alkoxide is $[\{Sn(OtBu)_2\}_2]$ **26b** (Fig. 16, bottom), for which Veith et al. reported sublimation conditions of 60 °C/10^{-3} Torr[160] and Lappert et al. 103 °C/10^{-1} Torr.[157]

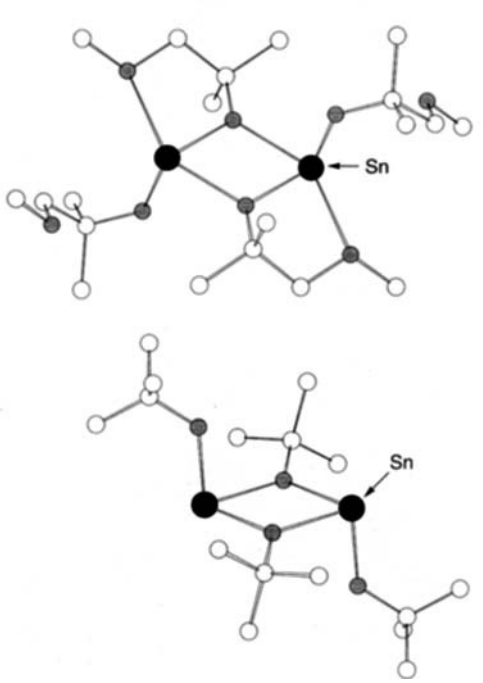

Fig. 16. Crystal structures of (dimeric) tin(II) alkoxides $[Sn_2(OCMe_2CH_2OMe)_4]$ (**26a**, top) and $[Sn_2(OtBu)_4]$ (**26b**, bottom).

These values are consistent with one another and correspond approximately to 140 °C/1.5 Torr, which demonstrates again the positive effect of alcoholate chelates on volatility. The lead alkoxide analogous to **26a** is less volatile, subliming at 80 °C/10^{-2} Torr. Although a dimeric formula has been confirmed for the gas phase, the lower volatility of the lead alkoxide (relative to the Sn derivative) would seem to indicate a higher nuclearity in the solid phase. Lead alkoxides do indeed have a greater tendency to aggregate. Freshly prepared $Pb(OiPr)_2$ is trimeric, for example, but rapidly ages and polymerizes. The same coordination was found for $[Pb(OCH_2CH_2OMe)_2]_\infty$ (**27**, Fig. 17).[100] To

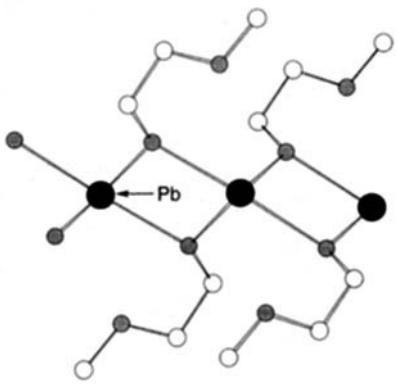

Fig. 17. Crystal structure of the polymeric Pb^{II} alkoxide $[Pb(OCH_2CH_2OMe)_2]_\infty$ (**27**).

increase the volatility, the chiral alcohol $HOCMe_2CHMeOMe$ was employed. Using the racemate should reduce the melting point of the resulting metal complex and increase the volatility. Moreover, the steric interligand interaction should facilitate the approach of the ligand to the metal and the coordination of the donor function.

The sublimation conditions of 95–115 °C/10^{-2} Torr contradict these considerations, but simultaneously reinforce the notion that the alkoxides $[Pb(OCMe_2CHMeOMe)_2]$ and $[Pb(OCMe_2CH_2OMe)_2]$ are isostructural. Attempts to prepare the analogous germanium(II) alkoxide surprisingly led to the oxo cluster compound $[Ge_6O_4(OCMe_2CH_2OMe)_4]$ (**28**, Fig. 18).[68] Presumably, this is the product of partial hydrolysis, as is expressly emphasized by the authors in the case of the structural analogue $[Sn_6O_4(OMe)_4]$.[158] Moreover, this structural type was also found for $[Pb_6O_4(OiPr)_4]$,[159] in which the origin of the oxo ligand is unknown.

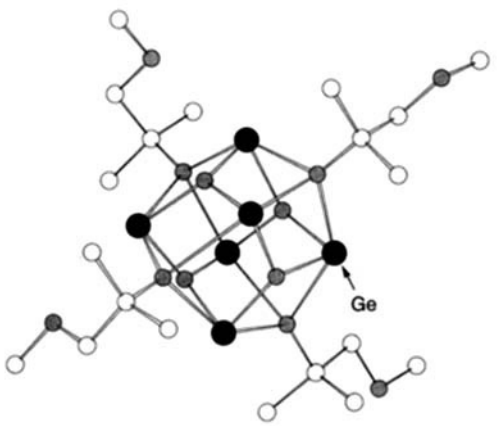

Fig. 18. Crystal structure of the hexameric alkoxo(oxo)germanium cluster $[Ge_6O_4(OCMe_2CH_2OMe)_4]$ (**28**).

8.2.4. Copper(II) Alkoxides

Just as for the alkaline earth metals, the development of the copper(II) alkoxides was influenced by the discovery of the high-temperature superconductors. Until 1989, the only known volatile copper alkoxide was the already mentioned $[Cu_4(OtBu)_4]$.[134] Horowitz et al., and later Buhro et al., were able to obtain monomeric volatile copper(II) alkoxides by using amino-functionalized ligands.[97, 161] The idea of using of O-functionalized ligands was discarded, because the ether function does not coordinate to the metal.[162] For this reason, $[Cu(OC_2H_4OMe)_2]$ is insoluble,[163] as are the simple homoleptic alkoxides of the type $[Cu(OR)_2]$ (R = Me, Et, *i*Pr, *t*Bu); it presumably has a polymeric chain structure as has already been confirmed for $[Pb(OC_2H_4OMe)_2]_\infty$ (**27**, Fig. 17). The $[Cu(OCMe_2CH_2OMe)_2]$ prepared by alcoholysis of $[Cu(OMe)_2]$ with $HOCMe_2CH_2OMe$ was sublimed at 85 °C/10^{-4} Torr in 40 % yield. In terms of volatility it is thus comparable to the monomeric $[Cu(OCMeHCH_2NMe_2)_2]$, but thermally much less stable. The observations made by Buhro and Horowitz on the O-functionalized ligands were thus confirmed.

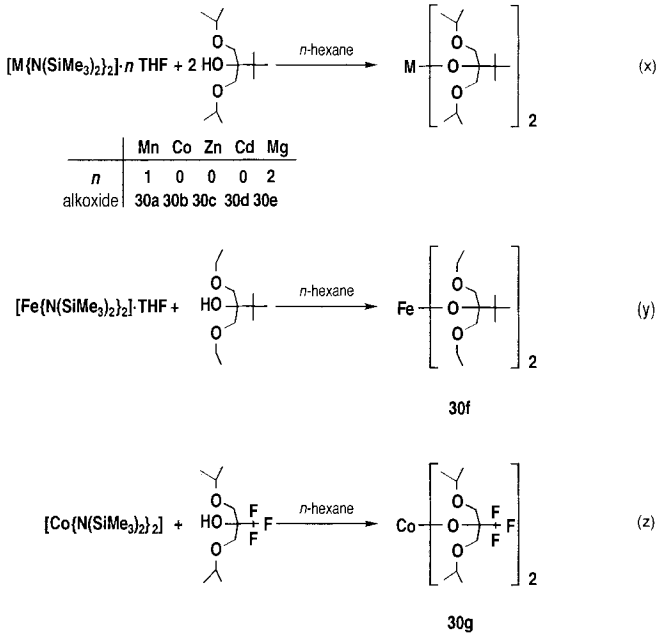
8.2.5. Magnesium, Manganese(II), Iron(II), Cobalt(II), Zinc(II), and Cadmium Alkoxides

The synthesis of volatile divalent transition metal alkoxides is no less complicated than the preparation of volatile alkaline earth or lanthanide alkoxides. This becomes especially apparent when making the comparison with the lanthanides (Section 8.3.2). The complexes with simple ligands such as OMe and O*t*Bu are polymeric and nonvolatile,[8] whereas the lanthanide alkoxides already form volatile complexes with isopropoxide ligands.[28] Ditox complexes of the lanthanides are all dimeric,[47] whereas the corresponding manganese compound is trimeric.[24b] The 2,6-tBu_2-substituted phenoxo lanthanide complexes are monomeric;[49, 50] the corresponding analogues of manganese, iron,[201] and zinc[165] are dimeric. The synthesis of volatile alkoxides of the above-mentioned metal ions thus requires the use of bischelating ligands that were also required for the alkaline earth metals [Eq. (x)].[199] In addition to the electronegativity, the ionic radius (Table 3) is also crucial for the volatility. The

Table 3. Sublimation temperatures *T* [a] of the alkoxides **30a–d**, the ionic radii *r* of the M^{2+} ions [b], and the electronegativities EN of the metals M.

Cmpd.	M	*T* [°C]	*r* [pm]	EN
30d	Cd	95	78	1.69
30a	Mn	90	66	1.55
30c	Zn	80	60	1.65
30b	Co	72	58	1.88
30e	Mg	80 [c]	57	1.31

[a] At 10^{-2} Torr. [b] Effective ionic radius according to Shannon. [c] At 10^{-3} Torr, which corresponds to 90 °C/10^{-2} Torr.



exchange of the *tert*-butyl group in **30b** for the sterically less demanding CF_3 group in **30g** leads to the dimeric cobalt alkoxide $[\{Co[OC(CH_2OiPr)_2CF_3]\}_2]$ (115 °C/10^{-3} Torr) [Eq. (z)]. The cadmium alkoxide **30d** has been structurally characterized (Fig. 19).[81]

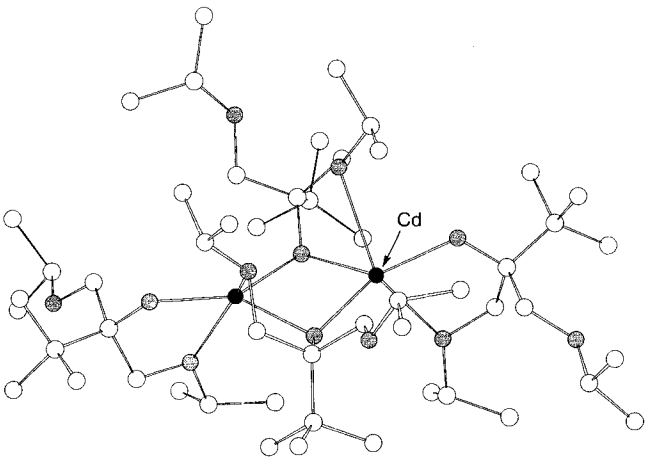


Fig. 19. Crystal structure of the (dimeric) volatile cadmium alkoxide $[\{Cd[OC(CH_2OiPr)_2OtBu]_2\}_2]$ (**30**).

The simple zinc(II) alkoxides $[Zn(OR)_2]$ (R = Me, Et, *i*Pr, *n*Bu, *t*Bu, *n*-octyl) are insoluble and nonvolatile.[8, 164] The first readily soluble homoleptic zinc(II) aryloxides $[Zn(OAr)_2]$ (Ar = 2,4,6-$tBu_3C_6H_2$) were reported in 1986.[165] The use of sterically demanding groups (R = CEt_3, CEt_2Me) made it possible to synthesize sublimable alkoxozinc complexes.[100, 166] Whereas the $[Zn(OR)_2]$ complexes (R = C_2H_4OMe, $C_2H_4OC_2H_4OMe$) are nonvolatile and only slightly soluble even in donor solvents such as THF, the complexes $[Zn(OCH_2CH_2NMe_2)_2]$ and $[Zn(OCHMeCH_2NMe_2)_2]$ with amino-substituted ligands can be partially sublimed at 170 °C/10^{-4} Torr. The greater volatility of the copper(II) complexes arises from the monomeric structure (both in solution and in the crystal). The chelating alcohol $HOCtBu(OiPr)_2$ allows a significant increase in the volatility, while at the same time improving the stability.

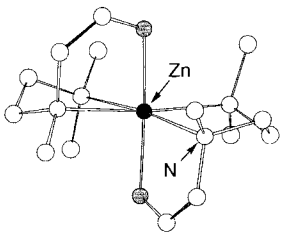

Fig. 20. Crystal structure of the zinc alkoxide **29** contaning the N-functionalized alkoxo ligand $OCHCHNMeCH_2CH_2NMe_2$.

The complex with an O,N,N-ligand, $[Zn(OCHCHNMeCH_2CH_2NMe_2)_2]$ (**29**), is a special case. The analytical data and the crystal structure of the sublimate show (Fig. 20) that hydrogen is eliminated during the sublimation. This was also observed for $[Y(OiPr)_3]$ by Mazdiyasni et al.[167]

8.3. Alkoxides $M(OR)_3$ of Trivalent Metals

The transition metals, the rare earth metals, and the metals of the third main group of the Periodic Table form their own classes of compounds, but only few structurally well-defined examples are known.

8.3.1. Bismuth, Vanadium, and Chromium Alkoxides

Bismuth oxides are components of the ceramic high-temperature superconductors. In contrast to $YBa_2Cu_3O_{7-\delta}$ systems, those containing bismuth, such as $Bi_2(Sr,Ca)_4Cu_3O_{10-\delta}$ are ductile and can be cast. Alkoxides of the type $[Bi(OR)_3]$ (R = Me, Et, *i*Pr) [168, 169] have been known since 1966 and were first used in sol–gel and MOCVD processes in 1988.[170, 188] $[Bi(OtBu)_3]$ was prepared[175] by Evans et al. and Hubert-Pfalzgraf et al. and is monomeric in the gas phase according to an electron diffraction analysis;[171a] the crystal structure has not yet been solved.[171b] A characteristic of all homoleptic bismuth alkoxides is their low thermal stability; they decompose partially during sublimation.[169] This problem was eliminated in the preparation of $[Bi(OCMe_2CH_2OMe)_3]$ (**11b**, see Section 6.1).[68] The compound can be sublimed without decomposition at 60 °C/10^{-2} Torr and is thus significantly more volatile and thermally more stable than the N-donor-functionalized complexes $[Bi(OR)_3]$ (R = $CHMeCH_2NMe_2$, 90 °C/10^{-4} Torr, R = $C_2H_4NMe_2$, 85 °C/10^{-4} Torr).[169] The complexes $[Cr(OCMe_2CH_2OMe)_3]$ (**10**, 65 °C/1.5 Torr; see Fig. 6 in Section 6.1) and $[V(OCMe_2CH_2OMe)_3]$ (**11**, 55 °C/1.5 Torr), originating from our Munich laboratory, are also considerably more volatile and thermally more stable than simple alkoxides of the composition $M^{III}(OR)_3$. The extraordinarily low sublimation points of both compounds are remarkable. The vanadium compound is the most volatile metal alkoxide yet known. Similar volatilities are only displayed by the methoxides and ethoxides of some nonmetals and semimetals. Compound **10** is the first monomeric homoleptic chromium(III) alkoxide with a known molecular structure.

8.3.2 Rare Earth Metal Alkoxides

The spectrum of the simple lanthanide alkoxides $Ln(OR)_3$ (R = Me, Et, *i*Pr) ranges from oligomeric structures to cluster-like structures.[8, 173] The selection of the ligand system for the synthesis of volatile lanthanide alcoholates is less troublesome than that of the alkaline earth metals for the following reasons: a) Even the largest (trivalent) lanthanide ion has an ionic radius only insignificantly larger than calcium (La^{3+} 103 pm, Ca^{2+} 100 pm). b) The rare earth metals are somewhat more electronegative than the alkaline earth metals [EN(Ln) ≈ 1.1, EN (Ca, Sr, Ba) = 0.8–1.0]. c) Three valences are available for the saturation of the ligand sphere instead of just two. Sterically demanding CH alcohols are therefore sufficient for the synthesis of volatile alkoxides (Table 4).

Table 4. Volatile rare earth alkoxides.

[a] Sublimation temperature at 10^{-3} Torr. [b] 10^{-2} Torr. [c] 10^{-4} Torr.

Fluorinated alkoxo ligands can increase the volatility of the lanthanide complexes considerably. Due to the incorporation of fluorine in pyrolytically formed layers as already mentioned, this type of ligand no longer seems attractive for the preparation of purely oxidic materials.[91, 179] Simple chelating ligands (OC_2H_4OR; R = Me, *i*Pr,[180] *n*Bu,[181] C_2H_4OMe, C_2H_4OnBu, $OC_2H_4NMe_2$, $OC_2H_4NMeC_2H_4NMe_2$[181–183]) do not offer significant advantages either. Ligands of this type lead to nonvolatile oligomeric compounds, for example the cyclic decamer $[\{Y(OC_2H_4OMe)_3\}_{10}]$.[103a]

Volatile, thermally stable lanthanide alkoxides can only be prepared by the use of tailor-made, donor-functionalized, sterically demanding alcohols. $[Nd(OCHiPr_2CH_2OEt)_3]$ already sublimes at 115 °C in a vacuum (approximately 10^{-3} Torr). The exchange of neodymium (Nd^{3+}, ionic radius 98 pm) for the smaller, lighter yttrium (Y^{3+}, 90 pm) causes a further drop in sublimation temperature (95 °C/10^{-3} Torr). Taking the information known about the structure of $[M(OCtBu_2CH_2PMe_2)_3]$ (M = Nd, **31a**; Y, **31b**) into account, both alkoxides probably occur as monomers in both the gas and solid phases (Fig. 21). $[\{Lu(OCMe_2CH_2OMe)_3\}_2]$ (**32**, Fig. 22) has the lowest sublimation temperature yet known for a lanthanide alkoxide complex (90 °C/10^{-3} Torr).[184]

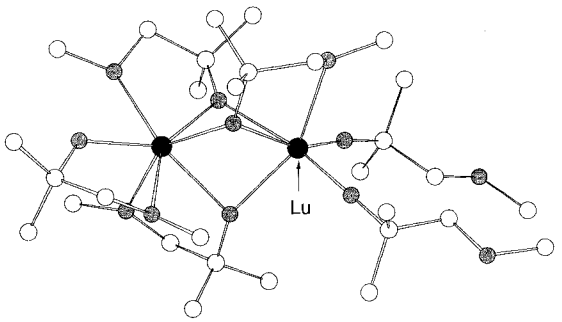

Fig. 22. Crystal structure of the (dimeric) volatile lutetium alkoxide $[\{Lu(OCMe_2CH_2OMe_3\}_2]$ (**32**).

8.3.3. Aluminium, Gallium, Indium, and Thallium Alkoxides

In contrast to aluminum,[185] gallium,[186] and thallium[187] alkoxides, homoleptic alkoxides of indium first became known in 1976.[43] In addition to some heteronuclear compounds of the type $[In\{M(OiPr)_4\}_3]$ (M = Al, Ga)[189] and dialkylindium alkoxides of the formula R_2InOR' (R = Me, *t*Bu; R' = Me,[190] Et,[191] *t*Bu,[192] $CMe(CF_3)_2$[193]), the alkoxide chemistry of indium is limited to simple, commercially available alcohols. Moreover, it occupies a special position in the third group of the Periodic Table: indium methoxides and ethoxides are insoluble in the usual solvents, and there are no volatile indium alkoxides.

The tendency to form cluster compounds, which is attributed to the larger ionic radius (In^{3+} 80 pm; Ga^{3+} 62 pm; Al^{3+} 54 pm) can best be illustrated by the isopropoxides: Bradley et al. isolated the pentameric oxo cluster with the formula $[In_5(OiPr)_5(\mu_2\text{-}OiPr)_4(\mu_3\text{-}OiPr)_4(\mu_5\text{-}O)]$ (cf. Fig. 1b),[172] whereas the corresponding Al and Ga derivatives are trimeric and dimeric, respectively.[189, 195] Sterically demanding donor-functionalized alcohols should reduce the nuclearity of the indium alkoxides and thus permit their synthesis. We were indeed able to obtain the first volatile indium alkoxides in the form of $[In(OCR_2CH_2OMe)_3]$ (R = Me: **33a**, 110 °C/10^{-3} Torr; R = Et: **33b**, 110 °C/10^{-3} Torr).[113] These are dimeric in the gas phase according to CI-MS.

8.4. Alkoxides of Tetravalent Metals and Metals of Higher Valency

The preparation of volatile alkoxides becomes easier with increasing oxidation number (increase in the coordination number). As was exemplified in Section 4.1, metal complexes that can be vaporized without decomposition can even be obtained with alkoxo ligands that are sterically relatively undemanding. This topic seems to be rounded off now, and we therefore refer the reader to the relevant literature.[1, 2, 4, 8, 196]

9. Conclusion and Perspectives

What have we learned? Putting increasingly larger ligands on metal centers is not a patent solution for achieving mononuclear metal complexes with sufficient volatility. Steric crowding also leads to fragility of the ligand sphere in terms of nonspecific bond cleavage. The concept of donor functionalization is a much more reliable strategy. It is satisfied with moderately bulky ligands and relies on the electronic σ-donor saturation of the metal centers through suitably positioned, electron-rich substituents (heteroatoms). This concept verified by using alkoxo ligands with ether and dialkylamino groups in β-positions is particularly important in the context of the preparation of oxidic materials, for which metal alkoxides are of great importance. As far as the volatility that can be attained by donor functionalization is concerned, the monomeric chromium and vanadium alkoxides $[M(OCMe_2CH_2OMe)_3]$ and the barium alkoxide $[Ba_2\{OC(CH_2OiPr)_2tBu\}_4]$, which sublime under vacuum at temperatures lower than 60 °C without leaving a residue, are convincing examples.[199]

The concept of the combination of donor functionalization and steric demand is proving itself not only in alkoxide chemistry: monomeric lanthanide complexes with amino-functionalized siloxy ligands have also now become accessible.[194] The "problem case" of barium in the β-diketonato series was countered with monomeric volatile β-ketoiminates that are ether-functionalized.[197] P-functionalized silylamide ligands now enrich the coordination chemistry of transition metal amides.[198] Topical works from the field of cyclopentadienyl chemistry, to which our laboratory has contributed,[110] confirm this trend. A breakthrough for this concept in the coordination chemistry of the alkyl[201] and hydroboranate complexes is to be expected.

Now that the preparation of volatile metal alkoxides seems to be feasible on all fronts, the future task is to bring in deliberately targeted "cleavage points" with a view to bringing about an orderly thermolytic (or, more rarely, photolytic) decomposition of these compounds. Experience to date would seem to indicate that plasma-chemical methods are insufficiently selective as regards definite decomposition paths. The decomposition methods coming into consideration from the materials science point of view have to be tuned to the chemical constitution of the molecularly defined precursors. Kinetic studies into their chemical decomposition should provide insight into the degradation and rearrangement mechanisms of metal alkoxides. This presents an open- and probably very fruitful- field of cooperation between synthetic chemistry and the material sciences.

The roots of this article are to be found in Dr. Rainer Anwander's pioneering Ph.D. thesis submitted to the Technische Universität München in 1992. We are deeply obliged to him for his stimulating discussions and persistent experimental results in the field of rare earth chemistry. Our thanks also go to doctoral students Florian Munck and Thomas Priermeier, and to Dr. Wolfgang Scherer for synthetic and structural chemical contributions to the "concept of donor functionalization", as well as to Wolfgang Wachter for the gas phase depositions and the scanning electron microscope photos. The correspondence author thanks the numerous supporters of his research work, in particular the Freistaat Bayern for equipment from the Bavarian long-term program "Neue Werkstoffe", the Fonds der Chemischen Industrie for equipment and a doctoral grant (N. W. H.), as well as the Bundesministerium für Forschung und Technologie, which supported us in the group project "MOCVD für Hartstoffschichten". We would also like to thank the research group of Dr. Roland Fischer for discussions on the application of organometallic chemistry in material sciences. Thanks also to Hoechst AG (Zentralforschung II), Frankfurt am Main, for generous support in the team project "Molekulare Supraleiter-Alkoxidvorstufen".

Carbon Dioxide as a Raw Material: The Synthesis of Formic Acid and Its Derivatives from CO_2

Walter Leitner*

Dedicated to Professor Henri Brunner on the occasion of his 60th birthday

The use of carbon dioxide as a raw material for chemical syntheses is an ecologically and economically valuable extension to the carbon sources used at the present time. In order to convert the thermodynamically stable and comparatively unreactive CO_2 molecule into the desired product in an efficient manner, suitable reaction conditions and activation mechanisms must be found. The catalytic reduction of CO_2 to formic acid and its derivatives has been intensively studied in recent years. A number of new approaches to the synthesis of formic acid from CO_2 have reached such a state of knowledge that continuing development may well lead to industrial-scale operation in the near future. This can to a large extent be attributed to the fruitful interaction between investigative work into reaction mechanisms and the development of new catalytic systems.

Keywords: CO_2 activation · formic acid · homogeneous catalysis · reductions · transition metal complexes

Then what can be done on the Day of Judgement, when human deeds are weighed, with three essays on formic acid, or with thirty?
On the other hand, what do we know of the Day of Judgement if we do not know everything that might come out of formic acid by that time?

Robert Musil, The Man without Qualities

1. Carbon Dioxide as a Raw Material

1.1. CO_2 as an Environmentally Friendly C_1 Building Block

The number of different chemical compounds produced worldwide at the present time is roughly in the range 20000–30000.[1] This large number of substances is produced from only a very few basic chemical raw materials, the source of carbon being almost exclusively fossilized matter, namely mineral oil, natural gas, and coal (Fig. 1). The fact that these resources are limited has led to a growth of scientific efforts to find alternative carbon sources since the early 1970s. Carbon dioxide has always attracted the greatest interest,[2, 3] as Nature uses this compound so successfully as a synthetic building block in photosynthesis—the basis of life on earth.

The carbon reserves on our planet in the form of CO_2 and CO_3^{2-} are for practical purposes inexhaustible, exceeding the carbon content of the deposits of fossil raw materials many times over. Since the beginning of industrialization in the second half of the last century, mankind has "produced" CO_2 in increasing amounts and released it into the atmosphere. The most important source of anthropogenic CO_2 emission is the combustion of fossil fuels for energy production. The destruction of biomasses also contributes indirectly to the increase in the concentration of atmospheric CO_2. In 1989, the total amount of CO_2 added to the atmosphere due to human activity was approximately 7×10^9 t carbon. The possible connections between anthropogenic CO_2 emission, the increasing CO_2 content of the atmosphere, and the global climate have for some years been exhaustively investigated[4] and discussed.[2g, 5, 6]

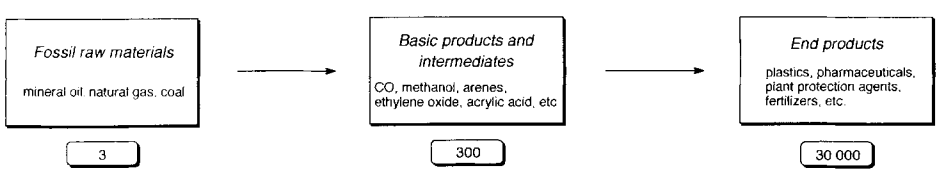

Fig. 1. The raw material basis of the chemical industry.

Estimating the risks that would follow from a global climatic change and developing strategies for the prevention of further increase in the atmospheric CO_2 concentration are undoubtedly important tasks. In this context, the use of CO_2 as a raw material for chemical synthesis can only make a very small contribution. Realistically, only a responsible use of primary energy and a greater utilization of nonfossil and ideally renewable energy carriers will ever be able to achieve a major reduc-

tion in the release of CO_2. At the same time, this also means that enough "waste CO_2" will be produced to provide a carbon source sufficient for a multitude of chemical requirements, even allowing for large reductions in anthropogenic carbon dioxide emissions. For example, a typical coal-fired power station with desulfurization of the exhaust gas produces 830 kg CO_2 per MWh electric power, and a power station fired with natural gas produces 400 kg CO_2 per MWh. In the exhaust gases from coal-fired power stations, the CO_2 concentration can reach 14%.[6]

In principle, an "anthropogenic CO_2 cycle" could therefore be achieved without making additional demands on the natural reservoir of carbon. However, most of the CO_2 bought and sold on the world market does not come from this over-abundance, but from hydrogen production [Eqs. (a) and (b)].[7] It is possible

$$CO + 3H_2 + H_2O(g) \longrightarrow CO_2 + 4H_2 \quad (a)$$

$$CH_4 + 2H_2O(g) \longrightarrow CO_2 + 4H_2 \quad (b)$$

in principle to extract CO_2 from power station exhaust gases by the same methods that have been developed for extracting it from process gases of hydrogen production.[2g, 6] The method that is growing most rapidly in importance in this context is absorption in aqueous solutions of amines. The trend towards recovery of CO_2 will probably greatly intensify in the future, leading to the increasing availability of large quantities of this cheap raw material.

Table 1. Properties of various C_1 building blocks [a].

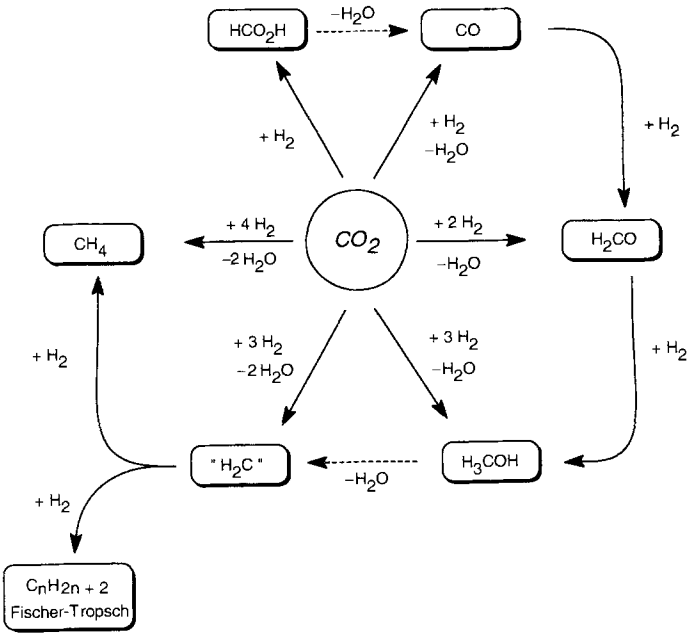
	CO	$COCl_2$	CO_2
MAK value	30 ppm	0.1 ppm	5000 ppm
toxicology	affinity for hemoglobin 210 times that of O_2	war gas	danger of asphyxiation at 10 vol% in air
LC_{50} (inhal. mouse)	2444 ppm (4 h)	110 ppm (30 min)	-
environmental hazard	yes	high	"negative"
flammability	12–74 vol%	no	no
boiling point	−192 °C	8 °C	−78 °C (subl.)
storage	only at pressure ≤3.5 MPa	very difficult, to be avoided	no problem
transport	gas bottles or tanks	only possible for kilogram quantities	gas bottles or tanks
solubility in 1 mL toluene at 20 °C	0.17 mL	miscible in all proportions	3.45 mL

[a] Data taken from refs. [8–10].

From the safety aspect, carbon dioxide is an ideal raw material, as can be seen from a comparison of its properties with those of the widely used C_1 starting compounds carbon monoxide (CO) and phosgene ($COCl_2$) (Table 1). For example, CO_2 is practically nontoxic, and can be stored, transported, and handled without problems.

1.2. Why Formic Acid?

Most current applications of carbon dioxide are based on its physical or physico-chemical properties.[7, 9] However, CO_2 is already being used as a raw material in some industrially important chemical reactions.[2b] For example, the direct hydrogenation of CO_2 plays an important role in the industrial synthesis of methanol from $H_2/CO/CO_2$ mixtures (ICI process).[11] In principle, the reduction of CO_2 also provides a potential approach to a number of other important products as shown in Scheme 1. The reduction equivalents required for the individual transformations can be made available by addition of hydrogen as shown in Scheme 1 or by electron transfer processes. The



Scheme 1. Reduction of CO_2 as a source for industrially important products.

Walter Leitner was born in 1963, studied chemistry in Regensburg, where he obtained his Doctorate under Prof. H. Brunner in 1989. After a period of post-doctorate research with John M. Brown at the Dyson Perrins Laboratory at the University of Oxford he returned to Regensburg in 1991 as a Liebig Fellow, and began his research into the catalytic hydrogenation of carbon dioxide. In 1992, he moved to the research unit "CO_2 chemistry" of the Max-Planck-Gesellschaft led by Prof. E. Dinjus at the University of Jena, where he habilitated in the Inorganic Chemistry Department. Since June 1995, he has been active at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr. His special field of research is the use of transition metal compounds in homogeneous catalysis and the understanding of their mode of action.

very first product of the reduction of CO_2 in this scheme is formic acid.

Approximately 300000 t formic acid is produced annually worldwide,[12] most of which is consumed in silage for animal feeds. Large amounts are also used in the leather and textile industries for tanning and dyeing. Formic acid is also employed as a coagulating agent in the production of latex rubber, and it is sometimes used as a food preservative (E236). The reducing properties of formic acid are often exploited in preparative synthetic chemistry, (Leuckart–Wallach reaction, Eschweiler–Clark methylation, transfer hydrogenolysis,[13] and transfer hydrogenation[14]). Nitro compounds can be reduced to amines batchwise in large-scale processes by catalyzed reduction with formic acid or ammonium formate. Many derivatives of formic acid, such as sodium formate (a component of de-icing salts and photographic fixing baths), methyl formate (DMF production), ethyl formate (flavoring), and dimethyl formamide (solvent) are also of considerable economic importance.

Formic acid was isolated in the pure state for the first time in 1749 by Markgraf by dry distillation of red ants. On an industrial scale, formic acid was for many years produced exclusively by the reaction of CO with hot sodium hydroxide solution at high pressure and subsequent acidification with dilute sulfuric acid. Large quantities of the unwanted by-product sodium sulfate are formed in this process. Considerable quantities of formic acid are obtained as the by-product of the oxidation of low boiling mineral oil fractions during the synthesis of acetic acid.

At present, the most widely used method of producing formic acid is based on the two-stage process of Equation (c).[12] In the

$$CH_3OH + CO \xrightarrow[NaOMe\ (cat.)]{80^\circ C,\ 45\ atm} HCO_2CH_3 \xrightarrow[-CH_3OH]{+H_2O} HCO_2H \qquad (c)$$

first stage, methyl formate is formed by the carbonylation of methanol, and this is then hydrolyzed to formic acid and methanol in the second stage. The methanol is recovered and returned to the first stage. The net process is therefore the addition of water to CO. This reaction can also be carried out directly under comparatively severe conditions in the presence of certain amines.[15]

The synthesis of formic acid by the reduction of CO_2 is an interesting alternative to these processes; the energy balance of the addition of H_2O to CO and the reduction of CO_2 with H_2 are very similar [Eqs. (d) and (e)].[10] The synthesis of formic

$$CO(g) + H_2O(l) \underset{}{\overset{\Delta H^0_{298} = -28.4\ kJ\ mol^{-1}}{\rightleftharpoons}} HCO_2H(l) \qquad (d)$$

$$CO_2(g) + H_2(g) \underset{}{\overset{\Delta H^0_{298} = -31.6\ kJ\ mol^{-1}}{\rightleftharpoons}} HCO_2H(l) \qquad (e)$$

acid from CO_2 offers the possibility of using carbon dioxide as a raw material to the extent of approximately 10^5 tonnes carbon per year. The state of development of the various approaches to the synthesis of formic acid and its derivatives from CO_2 is discussed below, with a strong emphasis on systems in which transition metal complexes are used as catalysts in a homogeneous phase.

2. Reduction of CO_2 by Electron Transfer

2.1. Electrochemical Reduction of CO_2 to Formate

The one-electron reduction of CO_2 to the radical anion $CO_2^{\bullet -}$ [Eq. (f)] requires a reduction potential of -1.9 V.[16] The high energy species $CO_2^{\bullet -}$ reacts readily with $H^\bullet$ sources to give the formate ion, but other possible reaction routes such as disproportionation, dimerization with formation of oxalate, or further reduction are difficult to suppress.

$$CO_2 + 1e^- \longrightarrow CO_2^{\bullet -} \qquad E^\circ = -1.9\ V \qquad (f)$$

An alternative and very promising approach to the electrochemical reduction of CO_2 involves the production of a suitable catalyst at the electrode to enable formate or formic acid to be formed directly from CO_2, H^+ ions, and two electrons [Eq. (g)]. Since the two-electron reduction to formic acid requires a considerably lower potential than the one-electron reduction, the electrolyses in the presence of catalysts can be carried out at considerably lower voltages. However, it is still a problem to control the selectivity between the various two-electron reductions [Eqs. (g)–(i)]. A general discussion of electrocatalytic CO_2 reduction can be found in reports and reviews of the original research.[16, 17]

$$CO_2 + 2H^+ + 2e^- \longrightarrow HCO_2H \qquad E^\circ = -0.61\ V \qquad (g)$$

$$CO_2 + 2H^+ + 2e^- \longrightarrow CO + H_2O \qquad E^\circ = -0.53\ V \qquad (h)$$

$$2H^+ + 2e^- \longrightarrow H_2 \qquad E^\circ = -0.41\ V \qquad (i)$$

Characteristic parameters of the electrocatalytic systems used to produce formates by this principle include the overvoltage required for the electrolysis, the current yield, and the number of catalytic cycles (turnover number (TON)) for the formate formation. For many years, the use of transition metal complexes as electrocatalysts has attracted much attention, and typical systems that form significant amounts of formate are listed in Table 2. In addition to the catalysts used in homogeneous phase or bonded in polymeric matrices, the use of metal complexes adsorbed directly onto an electrode surface to produce formate and formic acid has also been described.[18, 29]

With a number of catalysts, reaction conditions have a remarkable influence on product distribution of the two-electron reductions (g)–(i). In the case of the complex $[Ru(bpy)_2(CO)_2]^{2+}$, CO and H_2 are formed almost exclusively in the ratio 1:1 in H_2O/DMF at pH 6.0, whereas, at pH 9.5 and under otherwise identical conditions, all three possible products are formed in the molar ratio $CO/H_2/HCO_2^- = 2:3:3$.[32] In acetonitrile, the same catalyst causes formate to be produced in 44 catalytic cycles with a current yield of more than 80% (Table 2, entry 3),[23] and the formation of DMF by the electrocatalytic reduction of CO_2 in the presence of Me_2NH has also been reported.[33a] On the other hand, the structure of the nitrogen ligand has a relatively small influence on the product distribution.[33b] The highly selective reduction of CO_2 with the mono(bipyridine)complex $[Ru(bpy)(CO)_2Cl_2]$ results from the formation of a polymeric film of $[\{Ru^0(bpy)(CO)_2\}_n]$ at the surface of the electrode.[33c]

Similar observations were made with complexes of the type $[Re(L)(CO)_2X]$ (L = derivatives of bpy, X = halide). They lead

mainly to CO production by electrocatalytic reduction of CO_2 in organic solvents both in the homogeneous phase[17a, 34] and in polymer films.[35] They cannot be used for CO_2 reduction in aqueous solution as hydrogen is liberated preferentially. However, production of formate can successfully compete with the formation of H_2 in water, if the complexes are incorporated in a polymer matrix of Nafion and fixed to the electrode.[28]

2.2. Photochemical Reduction of CO_2 to Formate

The fundamental principles of the photochemical reduction of CO_2 to formate are largely identical to those described in Section 2.1. The one-electron reduction to $CO_2^{\bullet-}$ requires extremely strong reducing agents that are difficult to produce by photochemical means.[36] Kubiak et al. recently reported that irradiation even by diffuse daylight enables the trinuclear cluster $[Ni_3(\mu_3\text{-}I)_2(dppm)_3]$ to reduce CO_2 to the radical anion $CO_2^{\bullet-}$, whose presence was demonstrated inter alia by its subsequent reaction to give formate.[36b] However, the two-electron reduction [Eq. (g)] also represents the most energetically favorable route from CO_2 to formate in photochemistry. An approach closely related to electrocatalysis consists of using a photoactive system to convert light into electrical energy, which is then used with the help of a catalyst to reduce CO_2.[16, 37]

Semiconductor materials in the form of electrodes, colloids, or powders are able to reduce CO_2 to formate as the principal product when photochemically irradiated, even without catalysts.[38] Systems reported to catalyze the formation of formate in combinations with semiconductors include formate dehydrogenase,[39a] methylviologen,[39b] metals,[39c–i] and a ruthenium complex.[40] The formation of formic acid by photocatalytic reduction of CO_2 in a supercritical phase has recently been reported.[39h]

Organic photoactive systems also enable the direct[41] and catalyzed[42, 43] photochemical reduction of CO_2 to formate to be carried out in the presence of suitable reducing agents such as triethylamine. However, if *p*-terphenyl is used as the photosensitizer with cobalt(III) complexes as catalysts, there is an increase in the amount of CO produced relative to that of formate compared to the catalyst-free system.[43]

The most thoroughly investigated molecular photosensitizer for the photochemical reduction of CO_2 to formate is the complex cation $[Ru(bpy)_3]^{2+}$.[16, 44–47] In the preliminary experiments, $[Ru(bpy)_3]^{2+}$ was used with methylviologen, which was intended to perform the electron transfer.[45] However, it was found that the electron transfer was brought about by $[Ru(bpy)_2]$ species produced by photolabilization of the bpy ligands from $[Ru(bpy)_3]^{2+}$.[46a, 47a] Then, over a period of time, several systems for the photoreduction of CO_2 to formate were developed based on the combination $[Ru(bpy)_3]^{2+}/[Ru(bpy)_2(CO)(L)]^{n+}$ (L = CO, $n = 2$; L = H·Cl, $n = 1$).[46, 47] Triethanolamine in DMF is usually used as the reducing agent, and quantum yields of up to 15% are obtained. Irradiation of these systems with visible light ($\lambda > 320$ nm) produces up to 3700 mol formate per mol catalyst within 20 h.[47b] The formation of small amounts of formate has also been reported for the combination of $[Ru(bpy)_3]^{2+}$ with macrocyclic nickel complexes[48] and for photosensitizers based on vanadium complexes.[49]

2.3. Mechanistic Aspects of the Catalytic Formation of Formate by Electron Transfer

As shown schematically in Figure 2, the electrocatalytic and photocatalytic reductions of CO_2 to formate differ only in the method of producing the electrons required for the reduction. The catalytic cycle leading to formate is the same in both cases,

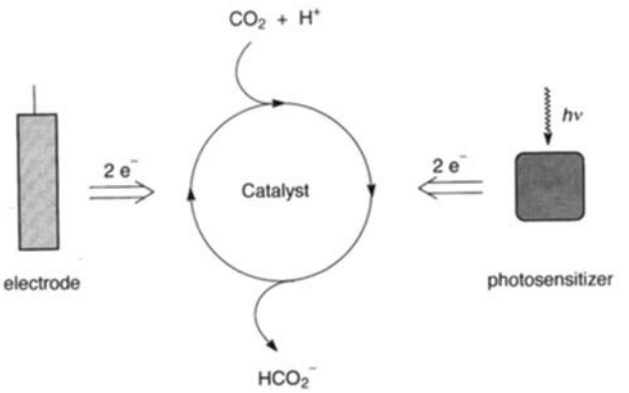

Fig. 2. Principle of the electrocatalytic and photocatalytic reduction of CO_2 to formate.

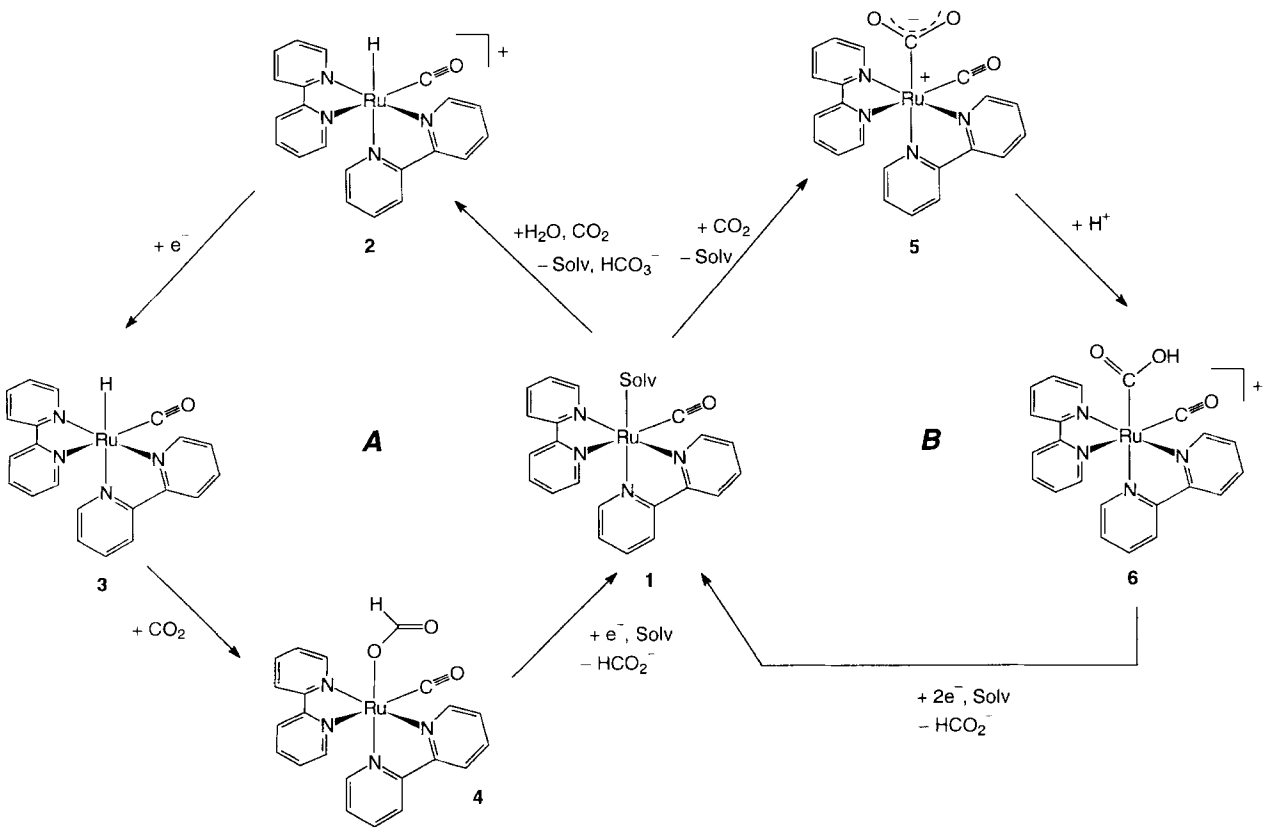

Scheme 2. Catalytic cycles in formate formation by electron transfer with Ru^{II}(bpy) catalysts $[Ru(bpy)_2(CO)(L)]^{n+}$ (L = CO, $n = 2$; L = H, $n = 1$) according to refs. [50, 51]; Solv = solvent.

and, in fact, the same catalysts can often be employed. However, a complex sequence of electron transfer steps and changes in the coordination sphere is necessary to build such a catalytic cycle[16, 17] and the understanding of these combinations is a field of great current interest.

The most extensively investigated catalysts for the electrochemical and photochemical reduction of CO_2 are of the type $[Ru(bpy)_2(CO)(L)]^{n+}$ (L = CO, $n = 2$; L = H, $n = 1$), and the mechanisms for the electron transfer in formate formation illustrated in Scheme 2 have been elaborated in recent years regardless of the type of excitation. Both cycles include a common catalytically active intermediate, namely the twice reduced solvent complex $[Ru^0(bpy)_2(CO)(Solv)]$ **1**.

In Cycle A, the formate group is formed by the insertion of CO_2 into the Ru–H bond of the hydrido complex **3**[50] in analogy to the hydrogenation of CO_2 (see Section 3.4). It was possible to detect all the individual steps of this cycle, which leads to the selective formation of formate, under catalytic conditions. However, it was found in this study that an additional cycle was responsible for the reduction of CO_2 to CO *and* formate. This becomes the dominant reaction route with $[Os(bpy)_2(CO)H]^+$.[24]

This second route presumably involves Cycle B in which formate is liberated from a metal carboxylic acid formed by protonation of the η^1-CO_2 complex **5**. Complex **5** was recently synthesized by an independent route and characterized by X-ray structural analysis.[51] The formation of **5** under the conditions of electrocatalysis was detected spectroscopically. The pH-dependent simultaneous formation of HCO_2^- *and* CO in the electrocatalytic reduction of CO_2 can be explained by the protonation equilibrium **5**/**6**.[47] Intermediates analogous to **5** and **6** have also been suggested for the electrochemical reduction of CO_2 to CO with $[Re(L)(CO_2)X]$ as catalysts, based on the results of an in situ IR investigation.[34d]

Two comparable cycles were recently shown to be responsible for the cobalt-catalyzed photochemical reduction of CO_2 with *p*-terphenyl as the photosensitizer.[43] In this case, formate is formed exclusively by a route analogous to A,[43c] while the formation of a CO_2 adduct eventually leads to CO only.[43d]

In addition to the difficulty of controlling the product selectivity, there is a further problem in the electrocatalytic and photocatalytic reduction of CO_2 to formate. The concentration of catalyst must be kept as low as possible to prevent deactivation processes. Even with the most active known catalysts, the concentrations of reduction products in the reaction solution are therefore usually only in the millimolar range. In contrast, the methods of catalytic hydrogenation of CO_2 to formic acid and its derivatives described in the following Section, can lead to product concentrations of up to several mol per liter.

3. Transition Metal Catalyzed Formation of Formic Acid and Its Derivatives from CO_2 and H_2

3.1. General Considerations

In the early 1970s, the pioneering work of several research groups showed that formic acid, its salts, esters, or amides are

accessible from hydrogen, carbon dioxide, and a possible third component in the presence of homogeneous transition metal catalysts [Eqs. (j)–(m)].

$$CO_2 + H_2 \rightarrow HCO_2H \quad (j)$$
$$CO_2 + H_2 \rightarrow HCO_2^- + H^+ \quad (k)$$
$$CO_2 + H_2 + HNR_2 \rightarrow HC(O)NR_2 + H_2O \quad (l)$$
$$CO_2 + H_2 + HOR \rightarrow HC(O)OR + H_2O \quad (m)$$

Since the synthesis of formic acid derivatives, unlike the formation of HCO_2H or HCO_2^-, requires not only the formation of the C–H bond but also the breaking and reforming of another covalent bond during the reaction, these processes will be dealt with separately.

3.2. Synthesis of Formic Acid and Formates from CO_2 and H_2

Table 3 summarizes typical catalytic systems used for the hydrogenation of CO_2 to formic acid and formates. The maximum total number of catalytic cycles per metal center (turnover number (TON)), and, where available, the maximum rate at which the catalytic cycles can take place at the beginning of the reaction (turnover frequency (TOF)) are also given. Further examples can be found in the original research cited.

3.2.1. *Hydrogenation of CO_2 in Organic Solvents*

The Catalytic Systems

In 1974, a Polish research group reported that a homogeneous titanium(II) catalyst produced from $TiCl_4$ and magnesium in THF promoted the catalytic formation of $Mg(HCO_2)_2$ by treatment with H_2 and CO_2 alternately.[52] Up to 15 equivalents of CO_2 per equivalent Ti^{II} could be fixed this way.

A little time later, Y. Inoue et al. reported the catalytic hydrogenation of CO_2 with phosphane complexes of transition metals of Groups 9 and 10.[53a] A yield of 22 mol formic acid per mol rhodium was obtained with Wilkinson's catalyst $[Rh(PPh_3)_3Cl]$ under the conditions detailed in Table 3 (entry 2). At the end of the reaction, there is approximately a 50-fold excess of amine relative to the concentration of the newly formed formic acid. The presence of small amounts of water favors the hydrogenation of CO_2. Later modifications to the process described in a series of patents gave only small improvements to the original system.[54a–e] The highest TON (314) was reported with $[Rh(PPh_3)_3Cl]$ in a mixture of isopropyl alcohol, water, and NEt_3.[54e] Very recently a complex with nitrogen ligands has been reported to act as an effective catalyst for CO_2 hydrogenation in alcoholic solution.[54f] Up to 5000 turnovers are observed with the complex *cis*-$[Ru(6,6'\text{-}Cl_2bpy)_2(H_2O)_2](CF_3SO_3)_2$ in EtOH/NEt_3. In the absence of amine, the drastic reaction conditions (60 atm, 150 °C) lead to formation of ethyl formate (see Section 3.3.3).

In 1992, Nicholas and Tsai discovered that the hydrogenation of CO_2 could also be carried out in the absence of bases.[55] However, with the catalyst $[Rh(PMe_2Ph)_3(nbd)]BF_4$ (nbd = norbornadiene) in THF under similar high pressures, only 64 mol HCO_2H per mol catalyst per day are formed. Again, the presence of small amounts of water increases the activity of the catalyst (Table 3, entry 6).

At about the same time, we were able for the first time to report a system for transition metal catalyzed hydrogenation of CO_2 to formic acid in which TONs greater than 1000 and TOFs of approximately 40 h^{-1} can be obtained under mild conditions (Scheme 3).[56a] The catalyst is produced in situ from the dimer-

ic rhodium complex $[\{(cod)Rh(\mu\text{-}Cl)\}_2]$ **7** (cod = 1,5-cyclooctadiene) and the bidentate phosphane $Ph_2P(CH_2)_4PPh_2$ (dppb). A mixture of DMSO and NEt_3 is used as the reaction medium. The final concentration of formic acid, under the conditions given in Scheme 3, is 2.1 mol L^{-1} and *exceeds* the concentration of the amine by 65%. In contrast to all other systems, water has a detrimental effect on the performance of this catalytic system. In the absence of amine, only small amounts of formic acid are formed, similar to those observed in THF.[57]

The Thermodynamics of CO_2 Hydrogenation

The drastic effect of the reaction medium on the maximum yield of formic acid can be explained by the thermodynamic balance[10] in the addition of H_2 to CO_2 [Eq. (n)]. Under stan-

$$H_2(g) + CO_2(g) \underset{\Delta G^0_{298} = +32.9\ kJ\ mol^{-1}}{\overset{\Delta H^0_{298} = -31.6\ kJ\ mol^{-1}}{\rightleftharpoons}} HCO_2H(l) \qquad (n)$$

dard conditions, this reaction is exothermic (approximately $-32\ kJ\ mol^{-1}$), but strongly endoergic ($+33\ kJ\ mol^{-1}$) because of the unfavorable entropy conditions (two gases reacting to form a liquid with strong intermolecular hydrogen bonds). To obtain high yields of formic acid, the entropy difference between the starting materials and the product must be reduced by a suitable choice of reaction conditions.

Full reversibility of formic acid formation was demonstrated experimentally for the first time for the catalytic system shown in Scheme 3. This enabled the effect of reaction conditions and the reaction medium on the yields and hence on the position of the equilibrium to be systematically investigated.[57] As expected for an exothermic reaction between two gaseous reactants, the equilibrium concentration increases as temperature decreases and pressure increases.

The solvent is very important for the yield of formic acid, as it can strongly influence the entropy difference by solvation of both the reactants and the product. The main reason for the special suitability of dipolar aprotic solvents for the hydrogenation of CO_2 to formic acid was shown to be the solvation of the product with cleavage of the hydrogen bonds. At the same time, it is assumed that these solvents also affect the catalytic activity by stabilizing intermediate stages of the catalytic cycle (see Section 3.4).

As mentioned above, the addition of trialkylamine is not absolutely necessary for the catalytic hydrogenation of CO_2 under the conditions given in Scheme 3, although it too leads to cleavage of the hydrogen bonds and hence to a drastic increase in the equilibrium concentration. With formic acid, trialkylamines do not form true 1:1 salts, but form liquid azeotropes with the composition $HCO_2H/NR_3 = 1.5\text{–}2:1$.[59] The final concentration of formic acid only exceeds the concentration of the amine when such azeotropes can be formed and ratios of approximately 1:1 are observed with secondary amines.[57] In contrast to the reactions described in Section 3.3, the use of dimethylamine as the amine component does not lead to further reaction of the formic acid to give dimethylformamide under the mild conditions indicated in Scheme 3.

The catalytic systems for the hydrogenation of CO_2 (Table 3) are, of course, not only characterized by the total number of possible catalytic cycles, but also by the rate at which these take place. Systematic studies of catalyst optimization have so far only been reported for the rhodium-catalyzed hydrogenation of CO_2 to formic acid in $DMSO/NEt_3$.[57, 58, 60]

Catalyst Optimization in the Rhodium-Catalyzed Hydrogenation of CO_2 to Formic Acid

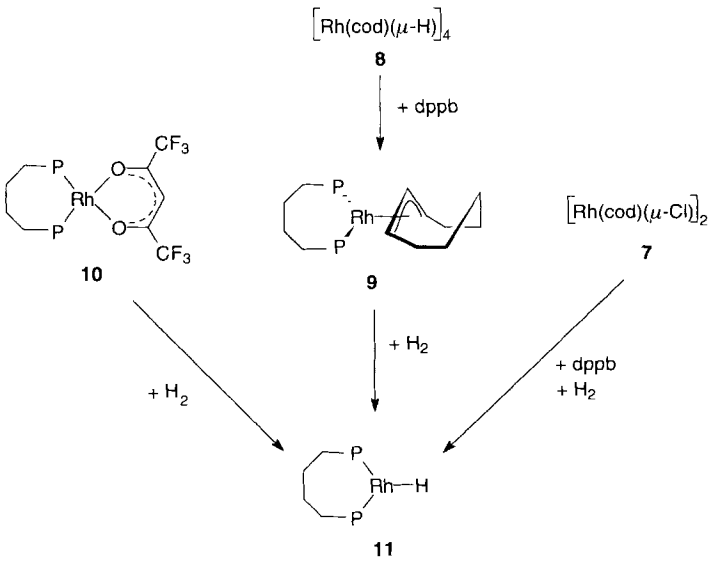
Variation of the phosphane component has a considerable effect on the activity of the catalyst formed with **7** (Scheme 3).[60] When in situ catalysts are formed from **7** and monodentate phosphane ligands PR_3 (Rh:P = 1:4), the observed ligand effects can be explained by classical ligand concepts such as basicity[61, 62] and steric demand[62] of the PR_3 groups. For PR_3 ligands of comparable size, the most active catalysts are obtained with phosphanes of medium basicity ($pK_a(HPR_3^+) \approx 4$). The activity of such catalysts corresponds approximately to that of the system **7**/dppb. Both more strongly acidic and more strongly basic phosphanes lead to rapid decrease in the activity. With similar basicity, the activity decreases with increasing bulkiness of the ligands, and phosphanes PR_3 with a cone angle[62a] greater than 180° are not suited as cocatalysts for in situ systems **7**/PR_3 in the hydrogenation of CO_2.

These rules cannot be applied to in situ catalysts with bidentate phosphanes, as with these ligands the size of the chelate ring formed on the metal center has a very important effect on the activity of the catalyst.[60, 63] However, even with constant chain length, the trends observed with monodentate phosphanes no longer apply, as can be seen from the increase in the activity of the in situ catalysts **7**/$R_2P(CH_2)_2PR_2$ in the sequence R = Ph < Me < Cy < *i*Pr.

When the in situ catalyst **7**/dppb is used, the catalytically active species is formed slowly compared with the rate of the actual catalytic cycle, as proved by the marked induction period on the first use of a catalyst solution.[57] This induction period can be avoided by treating the catalyst solution with H_2 or HCO_2H before reaction. However, even under these conditions, only some of the rhodium complex appears to be converted into the catalytically active species, as indicated by the effect of activation on the turnover frequency. It is therefore impossible to know to what extent the observed ligand effects are associated with the influence of the phosphanes on the course of the catalytic cycle or on the formation of the catalytically active intermediate.

As explained in detail in Section 3.4, it is highly probable that electronically and coordinatively unsaturated molecules of $[(P_2)RhH]$ **11** (Scheme 4; P_2 = bidentate phosphane) represent the catalytically active intermediate in the rhodium-catalyzed hydrogenation of CO_2 in $DMSO/NEt_3$. The aim of the development of catalysts must therefore be to produce these species under catalytic conditions in a rapid and well-defined reaction. At the same time, a stable and easily produced precursor should be used and wide variation in the phosphane component is desirable.

To avoid the reduction stage in the formation of the catalytically active intermediate **11**, the hydrido complex $[\{(cod)Rh(\mu\text{-}H)\}_4]$ **8** was tested as a precursor for in situ catalysts (Table 3, entry 8), which proved to be considerably more effective than systems formed with **7**.[57] A lower limit for the maximum



Scheme 4. Formation of the active intermediate **11** from the various catalyst precursors in the catalytic hydrogenation of CO_2 to formic acid in DMSO/NEt_3. P = PPh_2; maximum TOF: **7**/dppb: 39 h^{-1} [56a]; **8**/dppb: 370 h^{-1} [57]; **10**: 565 h^{-1} [58].

turnover frequency of the system **8**/dppb has been estimated to be 370 h^{-1} under the conditions indicated in Scheme 3, that is, it was possible to increase the activity of the catalyst by a factor of 10 compared with that of the system **7**/dppb (Scheme 4).

As shown in recent research,[64] and contrary to earlier opinion,[57] the catalytically active intermediate **11** is not formed directly from **8** and dppb (Scheme 4). Instead, the η^3-cyclooctenyl complex **9** is formed by the reaction of **8** with dppb by hydride transfer. Complex **9** was identified unambiguously by NMR spectroscopy and X-ray structural analysis (Fig. 3). Complex **9** is the actual catalyst precursor, reacting readily in a hydrogen atmosphere to form the neutral monohydride **11**.[64b, 65]

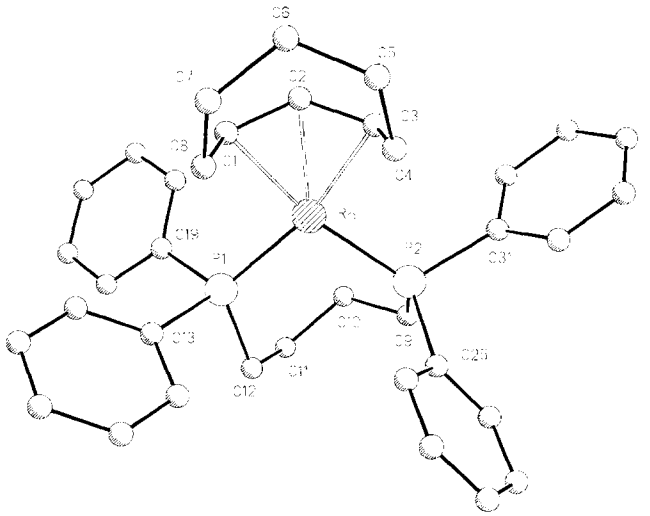


Fig. 3. Molecular structure of the η^3-cyclooctenyl complex **9** in the solid state. Selected interatomic distances [Å] and angles [°]: Rh–C(1) 2.219(10), Rh–C(2) 2.122(10), Rh–C(3) 2.209(10), Rh–P(1) 2.237(3), Rh–P(2) 2.228(3); C(1)-Rh-C(3) 68.8(4), P(1)-Rh-P(2) 98.63(10), C(2)-C(1)-C(3) 124.0(10), θ[P(1)-Rh-P(2)]/[C(1)-Rh-C(3)] 6.

Like allylrhodium complexes, acetylacetonatorhodium complexes are able to form neutral monohydrides by hydrogenolysis,[66] and in fact the hexafluoroacetylacetonatorhodium complexes of type **10** prove to be ideal catalyst precursors for the hydrogenation of CO_2 to formic acid.[58] The formation of formic acid starts at maximum velocity without an induction period, and the complex shows its full catalytic activity even at concentrations of 5×10^{-4} mol L^{-1}. The turnover frequency of 565 h^{-1} obtained with complex **10** corresponds to the lower limit of catalytic activity estimated for the in situ system **8**/dppb.

Interestingly, in complexes of type **10**, relationships are found between the P-Rh-P angles in the solid state, the ^{103}Rh NMR shifts in solution, and the catalytic activities in CO_2 hydrogenation.[58] The cyclohexyl derivative [{$Cy_2P(CH_2)_4PCy_2$}-Rh(hfacac)] (Table 3, entry 9), with a maximum TOF of 1335 h^{-1} under mild conditions (40 bar, 25 °C), is the most active catalyst so far reported for direct hydrogenation of CO_2 to formic acid or formates in organic solvents. Under comparatively mild conditions, similar high TOFs are obtained only in aqueous solution. The complex $[Ru(PMe_3)_4(H)_2]$ enables a TOF of 1400 h^{-1} to be obtained only at pressures exceeding 200 bar (Table 3, entry 13).

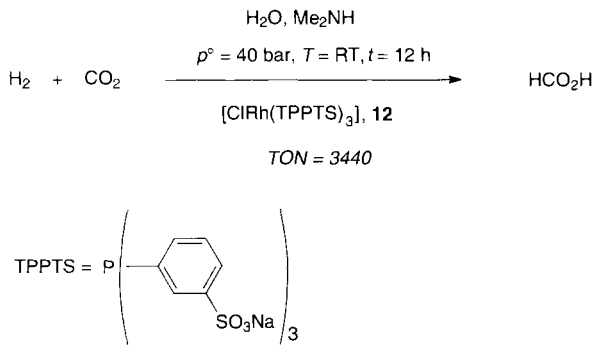
3.2.2. *Hydrogenation of CO_2 in Aqueous Solution*

The hydrogenation of CO_2 to formic acid in aqueous solution is a particularly attractive approach to the utilization of carbon dioxide as a raw material, as water is the usual solvent for the recovery of CO_2 from process flue gases (Section 1.1). Thus, aqueous solutions of amines could be used as both absorber and reaction solutions.

It has been known for some time that at temperatures above 200 °C in an atmosphere of CO_2 and hydrogen, potassium formate is formed in aqueous potassium hydroxide solution, $PdCl_2$ being the catalyst (Table 3, entry 10).[67] The formation of sodium formate from Na_2CO_3 and hydrogen in aqueous solution in the presence of a heterogeneous Pd/C catalyst can also be regarded as an example of CO_2 hydrogenation (Table 3, entry 11).[68] With K[Ru(EDTA-H)Cl]·H_2O as a catalyst for the water gas shift reaction in neutral aqeous solution, formic acid was observed as a possible intermediate in a stoichiometric and catalytic reaction.[69]

Phosphane complexes of transition metals successfully used as catalysts in organic solvents cannot be used in aqueous solution owing to their insolubility in water. Alcohol/water mixtures have been used as reaction media for phosphane-containing catalysts, although they have no particular advantages compared with purely organic solvents.[54e] We have been able to demonstrate that aqueous solutions of rhodium complexes of the water-soluble phosphane (C_6H_4-*m*-$SO_3^-Na^+)_3P$-(TPPTS)[70] give homogeneous catalytic systems that can lead to even higher activities and yields than obtained in organic solvents (Scheme 5).[71]

In situ catalysts can be employed for the hydrogenation of CO_2 in aqueous solution using TPPTS and the same rhodium precursors as in organic solvents. However, the most effective catalyst was found to be the water-soluble analogue of Wilkinson's catalyst [$(TPPTS)_3RhCl$] **12**, yielding up to 3440 mol formic acid per mol catalyst (Table 3, entry 12).[71a] The hydro-

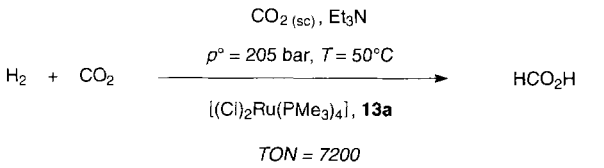


Scheme 5. Hydrogenation of CO_2 to formic acid in aqueous solution according to ref. [71a].

genation of CO_2 begins without an induction period at maximum velocity, TOFs of up to 1365 h^{-1} being reached.[71b] In contrast to the reaction in organic solvents, the concentration of the amine is never exceeded in aqueous systems, and no reaction occurs in the absence of amine.[71a] Formation of the free formate anion was confirmed by ^{13}C NMR spectroscopic measurements on the reaction product, and in agreement with thermodynamic considerations the formate anion was shown to be stable towards decomposition even in the presence of an active catalyst.[71b]

3.2.3. *Hydrogenation of CO_2 in the Supercritical Phase*

Carbon dioxide in its supercritical state is an interesting reaction medium,[72a, 72b] and the possibility of transition metal catalyzed CO_2 activation in the supercritical phase was demonstrated by Reetz et al., taking as an example the known synthesis of pyrones from alkynes and CO_2.[72c] Jessop, Noyori, and Ikariya recently reported that an efficient transition metal catalyzed hydrogenation of CO_2 to formic acid can take place in a supercritical mixture of H_2, CO_2, and NEt_3 without any additional solvent (Scheme 6).[73] With the ruthenium complexes



Scheme 6. Hydrogenation of CO_2 to formic acid in the supercritical phase according to ref. [73a].

$[(X)_2Ru(PMe_3)_4]$ (X = Cl, H) **13a** and **13b**, 7200 mol formic acid are formed per mol Ru with TOFs up to 1400 h^{-1}. The reaction rate in the supercritical phase is 18 times that in THF under comparable conditions. The authors assign this beneficial effect to special properties of the supercritical phase with respect to the miscibility and mass transport of the reactants.[73a]

To ensure a homogeneous supercritical phase during the reaction, comparatively drastic reaction conditions are necessary (205 bar total pressure, 50 °C). Rhodium(I) catalysts of the type used successfully in organic solvents and aqueous solution do not seem to be stable under these conditions,[73a] possibly because of the formation of inactive carbonate species.[57, 74]

The presence of triethylamine and small amounts of water is a necessary precondition for the production of formic acid by the hydrogenation of CO_2 in a supercritical phase.[73] After the equilibrium concentration has been reached, the HCO_2H/NEt_3 ratio is approximately 1.6:1, just as when DMSO is used as the solvent. In the presence of dimethylamine, HCO_2H reacts further to form DMF (see Section 3.3.2),[75a] whereas in the absence of an amine, no formic acid is formed at all. Other bases, such as K_2CO_3, which are immiscible with the supercritical phase, lead to TOFs of less than 10 h^{-1}.

3.2.4. *Isolation of Formic Acid Produced by the Hydrogenation of CO_2*

Thus, a series of extremely effective catalytic systems for the synthesis of formic acid from CO_2 and H_2 is now available. High yields of formic acid in the homogeneous transition metal catalyzed hydrogenation of CO_2 can be achieved if the equilibrium of Equation (n) can be shifted by minimizing the entropy difference between the starting materials and the product in favor of formic acid. Independently of the reaction conditions, the best method of achieving this seems to be the addition of amines to form either the corresponding azeotropes or ammonium formates.

From the reaction solutions of the rhodium-catalyzed hydrogenation of CO_2 in $DMSO/NEt_3$, the formic acid formed can be recovered as sodium formate, with the noble metal being recovered in catalytically active form.[56a] The liberation of formic acid from sodium formate is a well-known process, but involves ecological and economic problems that are intolerable today.

Free formic acid can also be recovered from mixtures with amines by a number of processes based on reamination of the formates and azeotropes to give thermally labile formic acid/amine adducts followed by distillative separation.[76] However, these methods can usually only be used on reaction solutions after deactivation of the catalyst,[76c] as formic acid would otherwise decompose under the workup conditions. The loss of costly noble metal that occurs and the laborious multistage workup and recycling processes are severe disadvantages of these methods. In addition to the search for even more effective catalysts it seems therefore essential to develop economic methods for the recovery of the formic acid from the reaction solutions from CO_2 hydrogenation processes in order to be able to operate the process on an industrial scale.

3.3. Synthesis of Formic Acid Derivatives by the Hydrogenation of CO_2

3.3.1. *General Considerations*

Under suitable reaction conditions, the hydrogenation of CO_2 in the presence of amines or alcohols can lead to amides or esters of formic acid, respectively (Table 4). In most cases where experimental data are available, it is found that the formation of derivatives proceeds by the intermediate formation of free formic acid,[75, 77] although other reaction routes are possible.[77c, 78, 79] The derivatization usually leads to products that

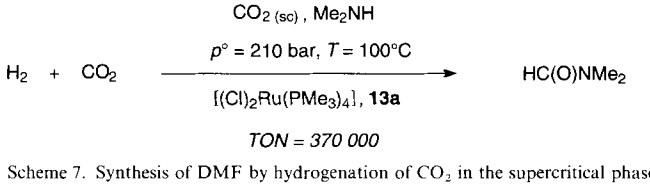
are stable in the presence of the catalyst at normal pressure, although the thermodynamics for the formation of, for example, formamides are similar to those of formic acid.

3.3.2. *Synthesis of Formamides*

As early as 1970, Haynes et al. synthesized dimethylformamide (DMF) from H_2, CO_2, and $HNMe_2$ by using transition metal phosphane complexes as the catalysts.[78] Using the complex $[(Ph_3P)_2(CO)IrCl]$, they were able to obtain a total of 1200 mol DMF per mol catalyst by repeated use of the reaction solution. In the years following, a number of other systems for producing formamides from CO_2, H_2, and the corresponding amines under similar conditions were described (Table 4).[79–81] The complex $[(\mu\text{-dppm})_3Pt_2]$ (Table 4, entry 4) is exceptional, as it catalyzes not only formation, but also cleavage of DMF, depending on the reaction conditions.[81b] Various other secondary amines can be used, and the formation of formamide itself in the presence of ammonia has also been reported.[81c]

A very efficient method of synthesizing DMF is to use dimethylamine as the amine component under conditions suitable for hydrogenating CO_2 in a supercritical phase.[75a] Using the catalyst $[Ru(PMe_3)_4Cl_2]$ **13a** (Table 4, entry 6), up to 370000 mol DMF per mol catalyst is formed in less than 37 h (Scheme 7).



Scheme 7. Synthesis of DMF by hydrogenation of CO_2 in the supercritical phase according to ref. [75a].

The solubility of the components of the mixture, which consists of two phases during the reaction, is of great importance for the high turnover numbers that are achieved with this system. The liquid adduct of dimethylamine and CO_2 (dimethylammonium carbamate, "Dimcarb"[82]), which acts as the dimethylamine source in the reaction in Scheme 7, is practically insoluble in supercritical CO_2 because of its high polarity. In the supercritical phase, which contains CO_2, H_2, Me_2NH, and the catalyst, HCO_2H is formed in analogy to the system using trialkylamines (Section 3.2.3).[73] Under the comparatively drastic reaction conditions (100 °C, 210 atm), condensation of dimethylammonium formate to DMF takes place in the liquid phase. Most of the DMF formed then dissolves in the supercritical phase, while the water content of the liquid phase increases. In this way, all the dimethylamine used is converted into DMF quantitatively and with high selectivity. Small amounts of formic acid and trimethylamine (formed by further reduction of DMF[81b,c]) are formed as by-products.

3.3.3. *Synthesis of Formic Acid Esters*

The transition metal catalyzed formation of alkyl formates from CO_2, H_2, and alcohols was first described by the Russian research group of Vol'pin and Kolomnikov.[83] Not only phosphane complexes of transition metals of Groups 8–10[54a,75b,83,84], but also the carbonyl metalates of Groups 8[85,77a] and 6[77b] show catalytic activity (Table 4). In many cases, amines or other basic additives have a positive effect on the course of the reaction.

The anionic ruthenium carbonyl clusters used by Darensbourg et al. show considerably higher catalytic activity in the formation of alkyl formates by carbonylation of alcohols than in the reaction of CO_2 with H_2.[77a] However, a possible reaction route via the intermediate reduction of CO_2 to CO was ruled out. In the presence of CO_2 and hydrogen, formic acid is formed initially, and then esterified under the reaction conditions.

The formation of methyl formate by esterification of formic acid obtained from CO_2 hydrogenation also takes place in the supercritical phase if methanol is added to the reaction mixture under conditions comparable to those in Scheme 6.[75b] Because of the high efficiency of the CO_2 hydrogenation under these conditions, the yield of methyl formate exceeds the yields obtained by the other methods. However, the esterification is incomplete, and the reaction product consists of a 2:1 mixture of formic acid and methyl formate.

Alkyl halides can be used instead of alcohols as the source of the alkyl groups for the formation of formic acid esters.[83,77c] In this case, the derivatization most likely takes place directly on an intermediate formate complex without the liberation of formic acid.[77c]

3.4. Mechanistic Aspects of the Addition of Hydrogen to CO_2 with Formation of Formic Acid

3.4.1. General Considerations

The key step in the catalytic formation of formic acid or its derivatives from CO_2 and H_2 is the formation of the formyl C–H bond. In all cases in which catalytically active intermediates in the CO_2 hydrogenation to formic acid were characterized spectroscopically, the formation of formate complexes was detected in this step.[55, 63, 77] Carbonate species[53, 67] and metallacarboxylic acids[69] were also suggested as possible intermediates of CO_2 hydrogenation, and the formation of the C–H bond by hydrolysis or hydrogenolysis of such intermediates cannot be excluded a priori in spite of the lack of experimental proof.

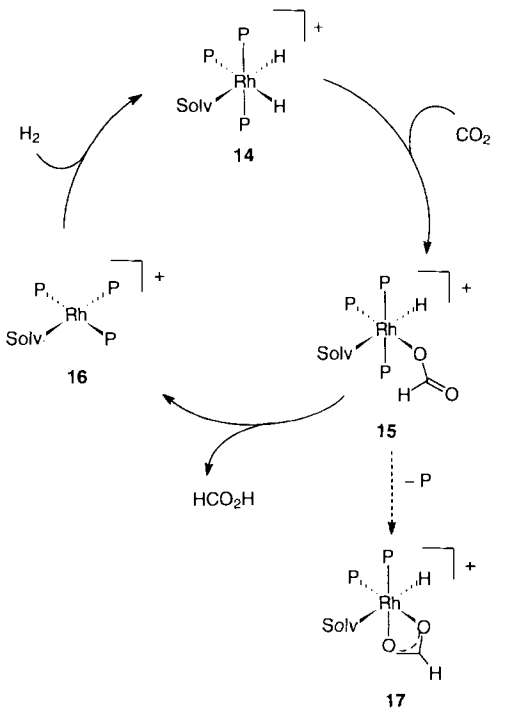
The formation of the formate group on the metal center can take place either by the insertion of CO_2 into a M–H bond or by hydride transfer to coordinated CO_2. A large number of stoichiometric examples confirm the general validity of the CO_2 insertion,[2b, 3g, 86] and its exact mechanism is well understood in the light of experimental[86a, 86b, 88] and theoretical[89, 90] investigations. Experimental evidence for the alternative pathway for the formation of a formate ligand, that is hydride transfer to coordinated CO_2, has emerged only most recently in the oxidation of $[(\eta^5\text{-}C_5H_4Me)_2M(CO)H]$ (M = Nb, Ta) to $[(\eta^5\text{-}C_5H_4Me)_2M(O_2CH)]$[87a] and in the formation of $[(\eta^5\text{-}C_5H_4Me)(PCy_3)Ru(\eta^2\text{-}O_2CH)]$.[87b] It should be noted, however, that CO_2 insertion cannot be definitely excluded to account for formate formation in both cases.

In this context, it is somewhat surprising that the insertion of CO_2 into a Rh–H bond could not be realized for a long time[74a, b, 91] despite the excellent catalytic activities observed in CO_2 hydrogenation using rhodium phosphane catalysts. It is only most recently that detailed information on the catalytic cycle of the rhodium-catalyzed hydrogenation of CO_2 to formic acid under various conditions has been collected.

3.4.2. The Mechanism of the Rhodium-Catalyzed Hydrogenation of CO_2 in Organic Solvents

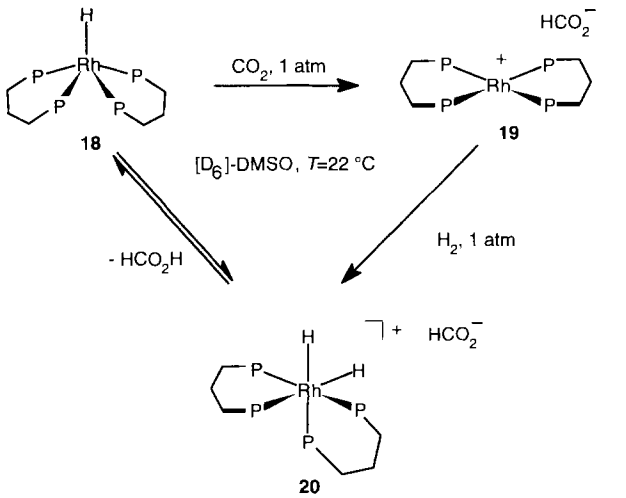
Nicholas and Tsai used IR and NMR spectroscopy at elevated pressure to investigate the mechanism of formation of formic acid from H_2 and CO_2 in THF with the catalyst $[Rh(Me_2PPh)_3(nbd)]BF_4$ in the absence of amines.[55] They were able to demonstrate the formation of the cationic dihydrido complex **14** and the subsequent insertion of CO_2 into the Rh–H bond to give complexes **15** and **17** with respectively η^1- or η^2-bonded formato ligands (Scheme 8). Only the η^1 complex **15** appears to be actively involved in the catalytic cycle. The subsequent step of reductive elimination of formic acid to give the square-planar cation **16** and regeneration of the dihydride **14** by oxidative addition of H_2 were postulated in analogy to known reactions.

It would appear likely at first sight that this mechanism could also be applied to the considerably more effectively catalyzed hydrogenation of CO_2 to formic acid by rhodium phosphane complexes in DMSO/NEt_3. However, cationic dihydrido complexes like **14** are deprotonated in the presence of amines, and



Scheme 8. Catalytic cycle of the hydrogenation of CO_2 with cationic rhodium complexes in THF according to ref. [55]. P = Me_2PPh, Solv = solvent.

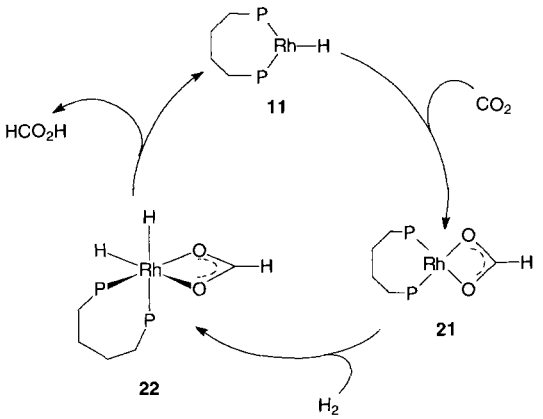
the monohydrido complexes formed are usually the more active catalysts in hydrogenation reactions.[92] Interestingly, the first example of an insertion of CO_2 into M–H bonds, discovered in 1968, involved a *neutral* monohydridocobalt complex, the homologous 3d metal to rhodium.[93] However, the reaction of neutral monohydridorhodium complexes with CO_2 in conventional organic solvents has been reported to lead to the formation of carbonato or bicarbonato complexes.[74a, 74b, 91] Only in the solvent DMSO, which is very suitable for catalytic hydrogenation, was it possible to observe by NMR spectroscopy not only the CO_2 insertion but also for the first time all subsequent steps of a catalytic cycle for CO_2 hydrogenation with the neutral hydrido complex $[(Ph_2P(CH_2)_3PPh_2)_2RhH]$ **18** (Scheme 9).[63]



Scheme 9. Reaction of $[(Ph_2P(CH_2)_3PPh_2)_2RhH]$ **18** with CO_2 and H_2 in $[D_6]$DMSO according to ref. [63]. P = PPh_2.

Formal insertion of CO_2 into the Rh–H bond of **18** leads to the complex **19**, which, unlike all other known transition metal formato complexes exists in dissociated form in solution. Nevertheless, the insertion is reversible, as shown by the rapid CO_2 exchange and incorporation of deuterium in the formate unit. Interestingly, the rates of these exchange reactions with complex **19** and its analogue bearing the phosphane ligand $Ph_2P(CH_2)_2PPh_2$ reflect the catalytic activity of the corresponding hydrido complexes in the hydrogenation of CO_2.[63] The oxidative addition of H_2 to the cation of **19** yields the dihydride **20**, which is in equilibrium with the monohydride **18** and free formic acid under the reaction conditions given in Scheme 9.

However, complex **18** is only a moderately active catalyst for the hydrogenation of CO_2, as it contains two chelating phosphane ligands per rhodium center.[57, 63] The catalytic cycle of Scheme 9 can be applied, however, in an analogous manner to the most active catalyst systems in which the ratio Rh/P_2 is 1:1 (Scheme 10).[57] The starting point for the catalytic cycle is now the hydrido complex **11**, which can be formed from all the catalyst precursors so far used under these conditions (Scheme 4).[57, 58]



Scheme 10. Application of the cycle in Scheme 9 to the most active catalyst system dppb/Rh with a ligand–metal ratio of 1:1 according to ref. [57]. P = PPh_2.

Electronically unsaturated 14e complexes like **11** were studied in detail by Muetterties et al.[94] and by Fryzuk et al.[65] They tend to form hydride-bridged clusters $[\{(P_2)Rh(\mu\text{-}H)\}_n]$ (n = 2–4), and both the monomers and the intact clusters can take part in catalytic reactions.[65d] The participation of bridged hydridorhodium clusters has to be taken into account for CO_2 hydrogenation, as insertion of CO_2 into a Rh–H bridge is a known process.[95] However, there is so far no experimental evidence for the involvement of oligomeric species in the catalytic cycle of the rhodium-catalyzed hydrogenation of CO_2.[64a] It is reported that for the rhenium complexes $[Re(bpy)(CO)_3H]$ and $[(\mu\text{-}H)\{Re(bpy)(CO)_3\}_2]^+$, CO_2 is inserted into the Re–H bond of the monomeric complex only, the reaction being stoichiometric.[17a]

Insertion of CO_2 into the Rh–H bond of **11** can produce a formate group in analogy to the model complex **18**, but the formate group acts as a coordinating ligand in **21** owing to the electron deficiency of the catalyst center. The η^2-carboxylato complex $[(iPr_3P)_2Rh(\eta^2\text{-}O_2CCH_3)]$ analogous to **21** was recently prepared and characterized by X-ray crystal analysis by Werner et al.[96] Starting from **21**, the catalytic cycle in Scheme 10 can be closed by the oxidative addition of hydrogen and reductive elimination. The bicarbonato complex $[(H)_2Rh(iPr_3P)_2(\eta^2\text{-}O_2COH)]$ related to **22** was characterized by Ibers et al. by X-ray structural analysis.[74b]

Sakaki et al. have have carried out theoretical studies on the CO_2 insertion into the Rh–H bond of $[(PH_3)_3RhH]$ and found that coordinated formate is formed and bound in a η^1 fashion owing to the presence of three additional phosphorus ligands.[90f] Very recent ab initio calculations by Dedieu et al. show that the η^2 formate group represents the most stable coordination form in the presence of only two P donor atoms as depicted for complexes **21** and **22** (Scheme 10).[97] However, it appears from this latter work that the η^1 form is the more reactive species which sustains the catalytic cycle. Most intriguingly, the study by Dedieu et al. points to an interesting alternative for the liberation of formic acid from formate complexes like **15** and **21**.[97] A σ-bond metathesis between the η^1 formate group and nonclassically coordinated H_2[98] seems feasible to by-pass the oxidative addition/reductive elimination sequence. The Rh–H bond required for the insertion of CO_2 is regenerated without changing the oxidation state of the metal center, and the calculated energy barriers for the σ-bond metathesis are considerably less than those of the mechanisms shown in Schemes 8 and 10. It should be noted that the oxidative addition of H_2 has so far only been demonstrated experimentally in the catalytic cycle of Scheme 9, where a σ-bond metathesis is impossible.

Furthermore, it is interesting to note that the two mechanisms of Scheme 8 and Scheme 10 differ not only in the charge and coordination number of the intermediate species, but also quite fundamentally in the order of events. Whereas in Scheme 8 the product-forming step takes place immediately after reaction with CO_2, in Scheme 10, product formation follows the reaction with hydrogen. One might speculate on the impact of this situation on the large difference observed in the activity of the two catalytic systems. Although questions of detail require further experimental investigation, we may conclude that the two mechanisms depicted in Schemes 8 and 10 present a clear and reliable picture of the actual catalytic cycle of the rhodium-catalyzed hydrogenation of CO_2 to formic acid under the individual reaction conditions. Building on the reaction mechanism proposed in Scheme 10, it was already possible to develop catalysts whose activity exceeds that of the original in situ systems by more than an order of magnitude (Scheme 4).[57, 58] Catalytic cycles for formic acid formation from CO_2 and H_2 involving metal centers other than rhodium have not yet been studied in great detail and it will be interesting to see what kind of general pattern will arise from future studies.

4. Summary and Outlook

The reduction of CO_2 to formic acid and its derivatives can be carried out by photochemical and electrochemical processes as well as by the direct addition of H_2. Transition metal complexes have been found to catalyze all these routes. With regard to the reduction of CO_2 by electron transfer, recent years have seen a growing understanding of the catalytic cycles that comprise the

competing reduction processes that lead to the formation of HCO_2^-, CO, and H_2. Taken in conjunction with the enormous number of possible combinations of catalysts with electron sources, this should lead to a rapid and fruitful growth in this area.

However, in the medium term, the use of hydrogen for the reduction of CO_2 to formic acid is certainly a more easily realized approach, as it is based on existing technical know-how. Even more so because even today very effective catalytic systems for this reaction are already available. This is partly a result of a judicious use of "thermodynamic tricks", which enable high yields of reduction products to be obtained in spite of the endoergic nature of this reaction under standard conditions. Equally important is the rapid progress in our understanding of the fundamental mechanisms of catalysis based on experimental and theoretical studies that has a continuing influence on the development of new and powerful catalysts. Both the turnover numbers and turnover frequencies of these catalytic systems can compete with those of other homogeneous transition metal catalysts that are already used on an industrial scale.

The principles explained in this review for the hydrogenation of CO_2 can also be applied in full analogy to the simultaneous activation of CO_2 and any X–H bonds. As can be seen from Equation (o), the thermodynamic conditions that apply, for ex-

$$CH_4(g) + CO_2(g) \underset{\Delta G^0_{298} = +55.2\ kJ\ mol^{-1}}{\overset{\Delta H^0_{298} = -16.2\ kJ\ mol^{-1}}{\rightleftharpoons}} CH_3CO_2H(l) \qquad (o)$$

ample, to the reaction of methane with CO_2 to form acetic acid are comparable to those for the formation of formic acid according to Equation (n). Possible single steps in a potential catalysis cycle such as oxidative addition of C–H bonds[99] or insertion of CO_2 into M–C bonds[2b, 3, 86a] are also known. The creativity and inventiveness of many dedicated chemists will be needed to put together the pieces of the mosaic, but achievement of the ultimate aim will fully justify the effort involved.[100]

My special thanks are due to Prof. H. Brunner for his generous support in the beginning, and for his constant interest as this work has progressed. I also thank the leader of the research unit "CO_2 Chemistry" of the Max-Planck-Society at the University of Jena, Prof. E. Dinjus, for the outstanding facilities provided by his laboratory, and for many interesting discussions. I must also extend sincere thanks to the co-authors of the publications cited, and especially to Drs. F. Gassner, R. Fornika, and H. Görls for their fruitful cooperation. Very special thanks are due to Dr. A. Dedieu, CNRS Strasbourg, for a stimulating exchange of ideas. Finally, I thank the Fonds der Chemischen Industrie (Liebig Stipendium), the Max-Planck-Gesellschaft, the BMBF and the DAAD for financial support, and Degussa AG and Hoechst AG for the donation of chemicals.

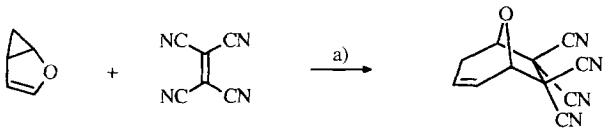
Transition Metal Catalyzed Synthesis of Seven-Membered Carbocyclic Rings**

Gerald Dyker*

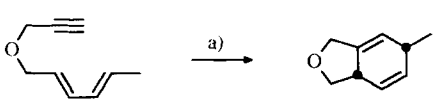
The Diels–Alder reaction is the most important method for the preparation of functionalized cyclohexenes and is characterized by an almost inexhaustible range of possible variations: numerous functional groups and even heteroatoms can be tolerated and both diastereoselective and enantioselective syntheses are possible. Thus, there has been no shortage of attempts to develop homologous variants and to extend the range of application to the synthesis of seven-membered carbocyclic rings. In specific cases it has been possible to employ vinylcyclopropanes as "homodienes" and to carry out a cycloaddition with appropriate alkenes.[1] However, the mild reaction conditions of the example shown in Scheme 1 are an exception. This special case apparently profits from the fixed, favorable geometry of the heterocyclic-bridged vinylcyclopropane **1**, from the high reactivity of the dienophile **2**, and from the initial association of the reactants in the form of a charge–transfer complex.



1 **2** **3**

Scheme 1. a) CH_2Cl_2, 20 °C, quantitative yield.

For a few combinations of less reactive dienes and dienophiles, transition metal catalyzed variants have been developed. An example is the cycloaddition of an apolar diene and an unactivated alkyne; however, except when the reaction is catalyzed with iron, nickel, cobalt, or rhodium(I) complexes, the temperature required often causes competing decomposition, even for the intramolecular version.[2] Wilkinson's catalyst[3]—tris(triphenylphosphane)rhodium(I) chloride—frequently used for hydrogenations and for decarbonylations, permits the cyclization of **4** to the annelated cyclohexadiene **5** in excellent yield in only 15 minutes at 55 °C in trifluoroethanol as solvent (Scheme 2).[2e]



4 **5**

Scheme 2. a) 10 mol % $[(PPh_3)_3RhCl]$, trifluoroethanol, 55 °C, 15 min, yield 96%.

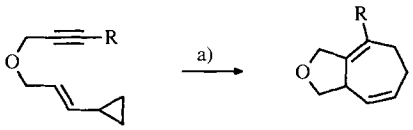
Lotharstrasse 1, D-47048 Duisburg (Germany)

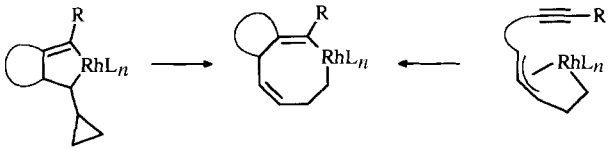
Recently, Wender, Takahashi, and Witulski[4] found that this rhodium complex also catalyzes the homologous Diels–Alder reaction[5] of vinylcyclopropanes with alkynes, leading to formation of cyclohepta-1,4-trienes. By this method, hitherto used exclusively as an intramolecular process, annelated and functionalized seven-membered carbocycles such as **7** have been synthesized simply and efficiently (Scheme 3).



6 **7**

Scheme 3. R = H, Me, Ph, trimethylsilyl (TMS), CO_2Me; a) 10 mol% $[(PPh_3)_3RhCl]$, toluene, 110 °C, 1.5 h, yield 50–88%.

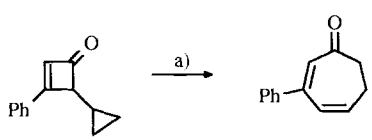
Acceleration of the reaction has been achieved by the use of the polar solvent trifluoroethanol and also by the addition of silver triflate; thus, it can be assumed that cationic rhodium complexes act as the active catalyst. Eight-membered metallacycles such as **9** are probably key intermediates.[6] Cyclopropyl-substituted five-membered metallacycles **8** and homoallyl complexes **10** can be considered as precursors of **9**[7] (Scheme 4).



8 **9** **10**

Scheme 4. Metallacycles as possible reactive intermediates of the reaction in Scheme 3. L = ligand.

Rhodium catalysis is also of crucial importance in the conceptually new type of synthesis of cyclohepta-2,4-dien-1-ones (e.g. **12**) by Huffman and Liebeskind.[8] The rearrangement of 4-cyclopropyl-2-cyclobutenones such as **11**, which are accessible in a few steps from squaric acid,[9] is similarly achieved with Wilkinson's catalyst (Scheme 5). This concept is particularly

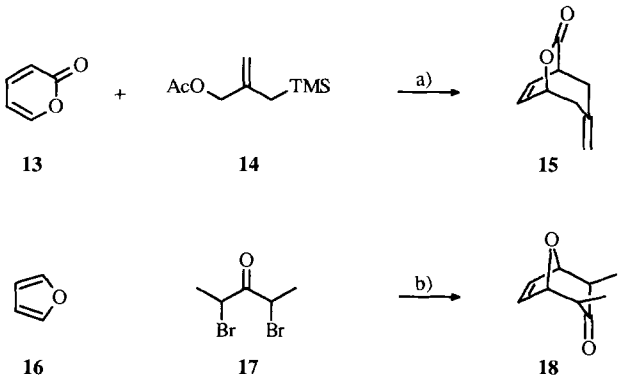


11 **12**

Scheme 5. a) 10 mol% $[(PPh_3)_3RhCl]$, toluene, 60 °C, yield 84%.

flexible in that the corresponding reaction of 4-cyclobutyl-2-cyclobutenones opens a route to eight-membered carbocyclic rings.

The new rhodium-catalyzed processes appear as competition to known and thoroughly tested methods for the synthesis of seven-membered carbocyclic rings, such as [4 + 3] cycloadditions catalyzed or induced by transition metals (Scheme 6).



13 **14** **15**

16 **17** **18**

Scheme 6. a) 5 mol% $Pd(OAc)_2$, $P(OiPr)_3$, benzene, 80 °C, yield 70%; TMS: b) NaI, Cu, CH_3CN, 4 h, 50 °C, yield 40–48%.

According to Trost et al.,[10] trimethylenemethane palladium complexes, which undergo cycloaddition with suitable dienes, can be prepared from the allylsilane **14** under catalytic conditions. Thus, the bridged cycloheptene **15**, containing an exocyclic methylene group, can be obtained from α-pyrone **13**. Cycloheptanones such as **18** can be prepared according to Hoffmann[11a–c] with α,α′-dibromoketones as coupling component.[11d,e] The preparative potential of such compounds for the diastereoselective synthesis of highly functionalized cycloheptanes and also of open-chain compounds has been demonstrated impressively quite recently.[12] It will be interesting to see whether the new rhodium-catalyzed processes also offer opportunities for enantioselective induction.[13]

Control of the Reactivity of Double Bonds through Their Fixed Geometrical Arrangement

J. Jens Wolff*

Chemists of all disciplines have always strived to maximize selectivities in their chemical reactions. From early on, they speculated that the mutual geometrical arrangement of the reactants might have a decisive influence on the rate and the outcome of a particular reaction. From this point of view, it is obvious to try to constrain the reactants to a well-defined geometrical arrangement before the actual reaction which—ideally—will then proceed only through a single reaction channel, predictable from the arrangement chosen. In a close to ideal way, such an arrangement exists in a molecular crystal. While the idea to peruse the high molecular order of crystals for directed chemical reactions in the solid phase seems logical enough, systematic investigations on reactions in the crystalline phase began quite late in the history of chemistry, namely only after the methods of X-ray structure analysis had been perfected to a degree that allowed the elucidation of the structures of even complex molecular crystals within a short time.

G. M. J. Schmidt and coworkers[1a] developed the concept of topochemical reaction control, using as an example the stereocontrolled [2+2]photodimerization of several cinnamic acid derivatives in the crystal.[1b] According to this principle, requirements for a successful reaction are minimum dislocations of the molecules with respect to the initial lattice, and—in the cases investigated—a maximum distance of about 4.2 Å for the reacting double bonds. Even though a fair number of research teams have focussed their research on this and related topics—the topotactical polymerization should be given extra credit[1c, 2]—only quite a small number of reactions can be realized in the crystalline phase proper. This limitation is aggravated by a still unresolved problem of solid-state organic chemistry:[3] how to predict the structures of molecular crystals from the molecular structure, or even more demanding, how to modify it at will—the term "crystal engineering", stressed far too often, should not gloss over this unfortunate situation. Thin films (like Langmuir–Blodgett films) or clathrates which are easier to control with respect to their stoichiometries and structures may be solutions to this problem.[4]

Therefore, by far the most attempts aimed at "geometrical reaction control" were directed towards reactions in solution. A well-known example for the use of this concept is given by the reduction in molecularity achieved through assembly of the reactants within the same molecule. Very recently, Hopf et al.[5] tried to combine this approach with the topochemical, or topotactical concept of solid-state chemistry in order to take advantage from both. To this end, two cinnamic acid esters and their vinylogous derivatives were grafted on a paracyclophane to give **1**. The rigid backbone of the cyclophane controls to a high degree the mutual arrangement of the double bonds in the form of a "microcrystal". Irradiation of a solution of **1** leads to dimerization in exceptionally high chemical and quantum yields to give compounds **2** with ladderlike structures.[6] The rigid σ-skeleton of the products may, for example, be used as a rigid spacer in studies of through-bond intramolecular electron transfer reactions.[7]

The choice of the system presented by Hopf et al. may not have been fortuitous: H. Meier's group[8] succeeded in the intermolecular dimerization of the divinylbenzene **3** to give **4**, and also obtained **5** in an analogous fashion; Japanese chemists[9] performed the intramolecular photoreaction of **6** to give **7**. In all these cases the arrangement of the reactant centers is probably

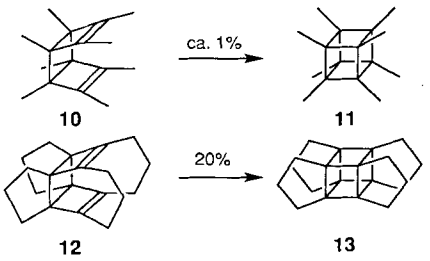
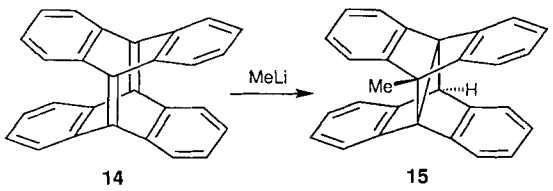
determined by the formation of excimers. Very recently, along the same line, H. Meier and coworkers dimerized derivatives of an analogous [18]annulene **8** to give substituted beltlike hydrocarbons of type **9**, thus demonstrating the broad applicability of this method.[10]

The proximity and geometrical fixation of two double bonds on its own is, however, not always sufficient to effect the desired [2 + 2]cycloaddition. Criegee et al.[11] previously attempted in vain to synthesize octamethylcubane (**11**) starting from the *syn*-dimer **10** of tetramethylcyclobutadiene. According to recent reinvestigations, a small amount of cubane may be isolated nevertheless,[12a] but the reaction **12** → **13** proceeds much better. The additional handles not only shorten the distance between the double bonds from 3.05 Å in **10** to 2.65 Å, but also effect a favorable change in the sequence of the π-molecular orbitals.[12b]



The placement of two double bonds in close spatial proximity also allows for unusual transannular reactions without the use of light. Of the great number of examples, the reactions of tetradehydrodianthracene (**14**)—for example, those affording **15**—are mentioned,[13] in which the distance between the two



double bonds (2.4 Å) is shorter than the sum of the van der Waals radii. The stabilization of otherwise reactive structures with four-center–three-electron bonds is also possible through cage structures: the unstable cyclobutyl cation, whose structure corresponds to the geometry of the symmetry-forbidden [2+1]addition of ethylene to ethylene cation, can be stabilized in the closed and the open form within the constraints of pagodane and isopagodane radical cations.[14]

The geometrical constraint, put in effect by many different methods, is still the most effective method to improve the selectivity of chemical reactions, but also to stabilize unusual structures. Many achievements in the development of catalytic processes are also based on this concept. Future research will probably be directed towards the understanding of self-assembly mechanisms in molecular crystals, clathrates, and thin layers, in order to make use of the enormous synthetic potential of these ordered structures.

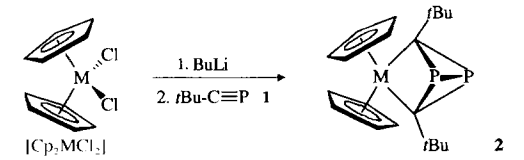
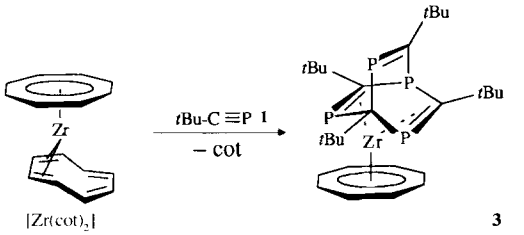
Selective Syntheses of 1,3-Diphosphacyclobutadiene, Dewar-1,3,5-triphosphabenzene, 1,3,5-Triphosphabenzene, and 1,3,5,7-Tetraphosphabarrelene by Cyclooligomerization of Phosphaalkynes**

Paul Binger,* Stefan Leininger, Jörg Stannek, Barbara Gabor, Richard Mynott, Joachim Bruckmann, and Carl Krüger

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

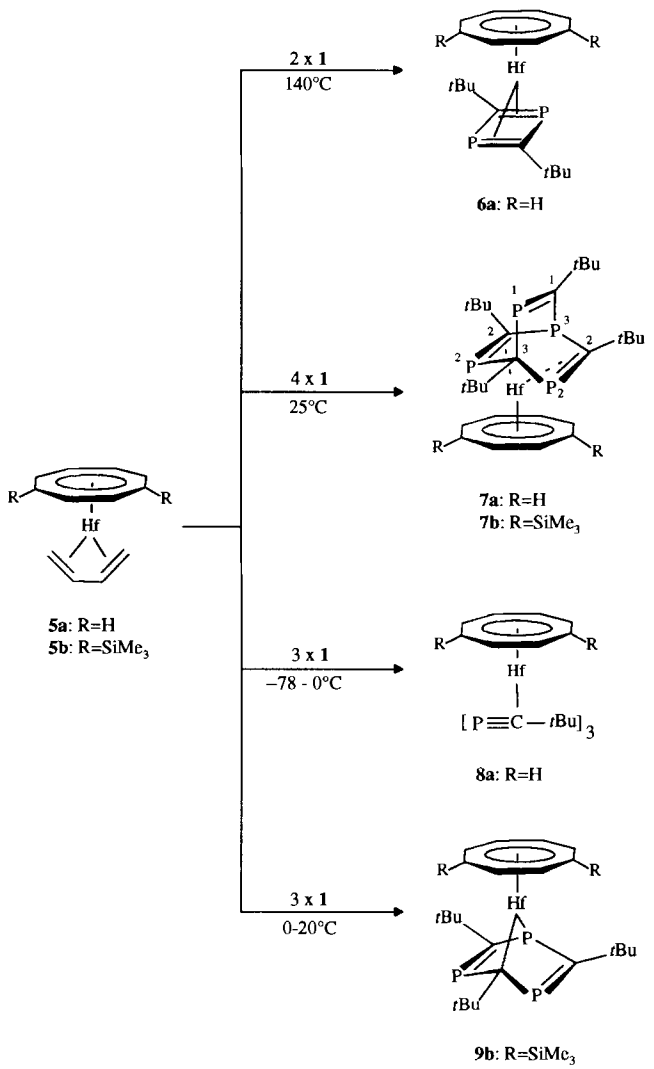
The recently described synthesis of the 1,3,5,7-tetraphosphabarrelene complex **3** from *tert*-butylphosphaacetylene **1** and bis(cyclooctatetraene)zirconium $[Zr(cot)_2]$[1] led to the assumption that the 12-valence electron fragment [cotM], formed as an intermediate by elimination of one of the two cot ligands, is an ideal template for cyclooligomerizations of phosphaalkynes. Phosphaalkynes are known to cyclodimerize on the 14-valence electron fragments $[Cp_2M']$ (M = Zr, Hf) to give the 1,3-diphosphabicyclo[1.1.0]butanediyl metallocenes such as **2**.[2]





In the coordination sphere of electron-rich transition metals (M = Ni, Co, Rh, Fe), phosphaalkynes prefer to cyclodimerize to give 1,3-diphosphacyclobutadiene metal complexes.[3, 4] Only two examples are known for the cyclotrimerization of phosphaalkynes on transition metal complexes: a η^6-1,3,5-triphosphabenzenemolybdenum complex is formed with tricarbonyl(η^6-cycloheptatriene)molybdenum,[5] which, however, was unsatisfactorily characterized and whose synthesis we could not follow.[6] In contrast, the structure of the dewar-1,3,5-triphosphabenzenevanadium complex, prepared from naphthalene(pentamethylcyclopentadienyl)vanadium and **1**, has been confirmed by an X-ray crystal structure analysis.[7]

A better access to coordinatively unsaturated transition metal templates [cotM] is provided by the known η^4-butadiene complexes of zirconium (**4a**) and hafnium (**5a**)[8] as well as their η^8-bis(trimethylsilyl)cyclooctatetraene derivatives **4b** and **5b**. Indeed, complexes **5a** and **5b** did react with the phosphaalkyne **1**[9] at room temperature. In these reactions **1** was cyclotetramerized in a few hours to give almost quantitative yields of the tetraphosphabarrelene complexes **7a** and **7b**, respectively (Scheme 1). The zirconium complex **4a** analogous to **5a** does



Scheme 1. Cyclooligomerization of **1** at the hafnium complexes **5a**, **b**.

not react with **1** under these conditions, in contrast, **4b** reacts with **1** to give the zirconium complex analogous to **7b**.

An investigation of the temperature dependence of this cyclotetramerization of **1** with the hafnium complexes **5a, b** revealed that **1** reacts already at low temperatures with **5a** or **5b** to give new hafnium complexes. From this finding the postulated stepwise course of the cyclotetramerization of **1**[1] can be partly experimentally understood. Thus, even at $-78\,^{\circ}C$, the hafnium complex **8a** is the sole product of the reaction of **5a** and **1**. It is formed as a green powder in 83% yield; in **8a**, three molecules of **1** are bound to the metal atom (*m/z* 584 (M^+)).

The ^1H NMR spectrum of **8a** recorded at $-30\,^{\circ}C$ shows two sharp singlets at $\delta = 1.35$ and 0.81 (ratio of intensities 2:1) for the three *tert*-butyl groups. These signals broaden significantly at 20 °C and collapse to one singlet at 60 °C at $\delta = 1.17$. In contrast, the position and multiplicity of the signal at $\delta = 6.60$ (s) for the H atoms of the cot ring are almost independent of the temperature. In the ^{31}P NMR spectrum of **8a** at $-30\,^{\circ}C$, there are only two signals at $\delta = 17.3$ and 357.1 ($J_{P,P} = 43.7$ Hz; ratio 2:1) for the three phosphorus atoms; these signals do not separate further down to temperatures of $-80\,^{\circ}C$; at 60 °C these signals are broadened. In the ^{13}C NMR spectrum at $-30\,^{\circ}C$, the weak signals of the P-bound C atoms could only be identified clearly under INEPT conditions[10] (a doublet of triplets at $\delta = 139.3$ and a triplet at $\delta = 93.8$ (half intensity)). The signals of the C atoms of the *tert*-butyl groups show a similar splitting pattern (Table 1). Together with the result of the ligand liberation with hexachloroethane, which affords the free 1,3,5-triphosphabenzene **13** (see below), the spectroscopic findings only allow the conclusion that a cyclic trimer of **1** is bound in the complex **8a**.

If the hafnium complex **5b** is allowed to react with **1** at 0 °C, the reaction likewise does not proceed further than the stage of a cyclotrimeric complex of **1**. The bonding between the metal atom and the phosphaalkyne trimer in the new hafnium complex **9b** evidently differs from that in complex **8a**, since two broad signals at $\delta = 263$ and 140 appear in the ^{31}P NMR spectrum of **9b** in the temperature range $-40\,^{\circ}C$ to 30 °C; the coupling constants, however, could not be determined. In the ^1H NMR spectrum of **9b**, the signals for the *tert*-butyl groups are resolved only at $-40\,^{\circ}C$; two singlets are observed at $\delta = 1.32$ and 1.34 in the ratio 2:1 (Table 1). A meaningful ^{13}C NMR spectrum of **9b** has not been obtained yet. According to the analytical results gathered to date, **9b** has the structure given in Scheme 1; the metal atom possibly interacts in a rapid exchange with one of the two P=C bonds. This proposed structure is supported by the liberation reaction with hexachloroethane, which affords the dewar-1,3,5-triphosphabenzene **14** (see below).

The course of the reaction between **5a** and **1** at higher temperatures is surprising. An approximate 1:1 mixture of the tetraphosphabarrelene complex **7a** and the 1,3-diphosphete complex **6a** is formed at about 80 °C, whereas at about 140 °C only **6a** is formed in 68% yield. The spectroscopic data of **6a** indicate that the π electrons are not completely delocalized in the η^4-bound 1,3-diphosphete ligand, as in the corresponding 1,3-diphosphete complexes of Co, Rh, or Fe.[4] In the ^{31}P and ^{13}C NMR spectra of **6a**, the signals of the phosphorus and carbon atoms of the four-membered ring are considerably shifted downfield in comparison to those in the spectra of the 1,3-diphosphacyclobutadienecobalt and -rhodium complexes (^{31}P: $\delta = 38-50 \rightarrow 201.7$; ^{13}C: $\delta = 108-113 \rightarrow 149.7$). Similar shifts were determined in the recently synthesized η^8-cyclooctatetraene(η^4-di-*tert*-butyl-1,3-diphosphete)titanium complex.[11] Our assumptions were confirmed by a crystal structure analysis of this compound: in the complex-bound 1,3-diphosphete, the P–C bond lengths alternate (1.748 and 1.828 Å).[11] A localization of the π electrons in the 1,3-diphosphete ligand of **6a** should result in a weaker interaction with the metal atom.

Table 1. Selected physical data of **6a**, **7a**, **8a**, **9b**, **13**, and **14** [a, b].

6a: ^1H NMR: $\delta = 1.20$ (s, 18H, *t*Bu), 6.89 (s, 8H, cot); ^{13}C NMR: $\delta = 149.7$ (t, J(C,P) = 55.4 Hz, ring-C), 37.7 (t, J(C,P) = 8.2, *t*Bu), 34.5 (q, t, J(C,H) = 125, J(C,P) = 5.0 Hz, *t*Bu), 91.6 (d, ^1J(C,H) = 171, cot); ^{31}P NMR: $\delta = 201.7$ (s); MS (70 eV): *m/z* [%]: 484 (M^+) [80], 469 ($M^+ - CH_3$) [100], 346 ($M^+ - C_2tBu_2$) [51], 284 ($M^+ - 2P{\equiv}CtBu$) [17]

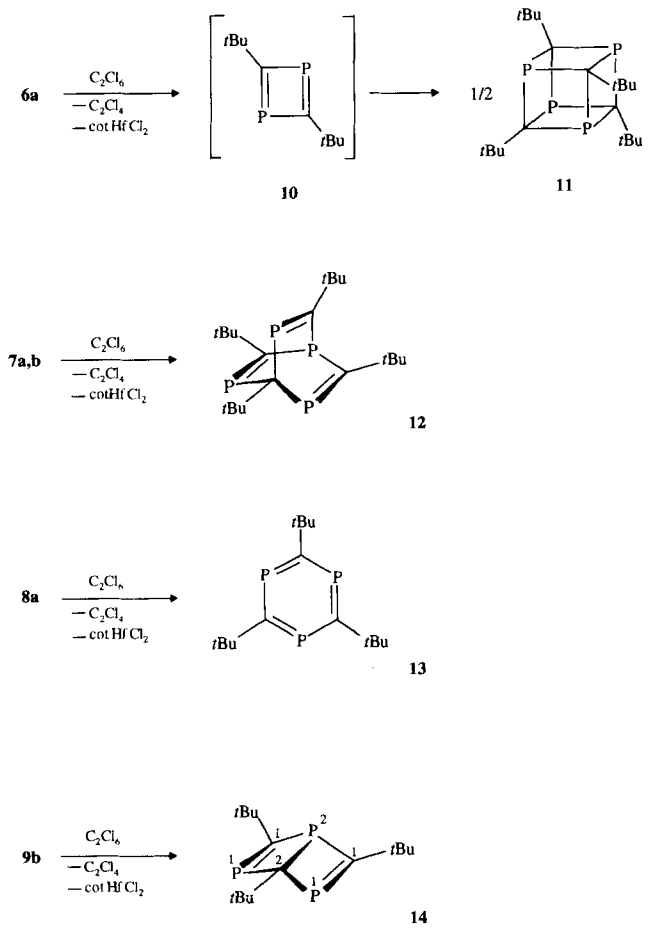
[b] For the numbering of the C and P atoms see Scheme 1 and 2.

An experimental test of the reactivity of **6a** towards hexachloroethane revealed that the 1,3-diphosphete **10** can be liberated from **6a** even at room temperature by a redox reaction. To date this has not been achieved with any of the other known η^4-1,3-diphosphete complexes.[3, 4, 11] However, as expected, **10** is so unstable that it cannot be isolated or detected by spectroscopy. The only isolable reaction product is the tetraphosphacubane **11**, [12] which is formed from **10** in 34% yield through a sequence of [4 + 2]- and [2 + 2]cycloadditions[2b] (Scheme 2).

Thus, **6a** shows the same reactivity towards hexachloroethane as the recently described cyclooctatetraene(tetraphosphabarrelene)zirconium complex **3**[1] and the two tetraphosphabarrelenehafnium complexes **7a** and **7b** described here for the first time. In all three cases two of the double bonds π-bound to the metal atom were liberated under oxidation of the metal to [(cot)MCl_2] and reduction of the hexachloroethane to give the tetrachloroethylene. In this way, as described recently for the



Scheme 2. Liberation of the phosphorus heterocycles **10**–**14**.

tetraphosphabarrelenezirconium complex **3**,[11] the 1,3,5,7-tetraphosphabarrelene **12** was obtained in over 80% yield from **7a** and **7b** (Scheme 2).

The structure of **12**, which had already been identified unambiguously on the basis of its spectroscopic data,[11] was confirmed by an X-ray structure analysis (Fig. 1).[13]

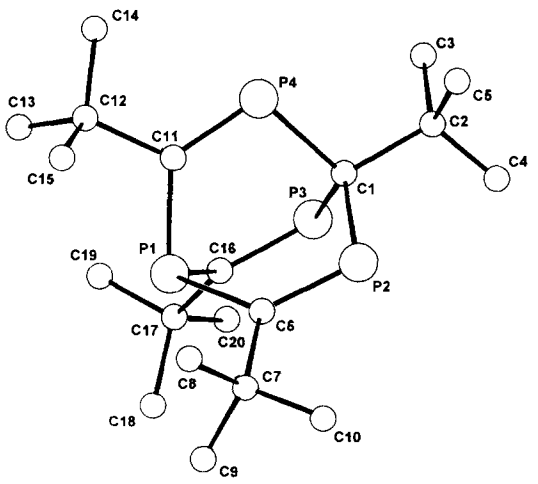


Fig. 1. Crystal structure of **12**. Selected bond lengths [Å] and angles [°]: P1-C6 1.862(1), P1-C11 1.851(1), P1-C16 1.858(1), P2-C1 1.877(1), P2-C6 1.671(1), P3-C1 1.871(1), P3-C16 1.667(1), P4-C1 1.869(1), P4-C11 1.668(1); C16-P1-C11 100.1(1), C16-P1-C6 98.8(1), C11-P1-C6 99.9(1), C6-P2-C1 104.7(1), C16-P3-C1 104.4(1), C11-P4-C1 104.5(1), P4-C1-P3 110.6(1), P4-C1-P2 110.0(1), P3-C1-P2 109.1(1), P2-C6-P1 122.3(1), P4-C11-P1 122.8(1), P3-C16-P1 122.8(1).

The two trimer complexes **8a** and **9b** also react readily with hexachloroethane at room temperature. Thus, in this way one example from the class of 1,3,5-triphosphabenzenes (**13**) and one from the class of dewar-1,3,5-triphosphabenzenes (**14**) could be synthesized and characterized for the first time. The triphosphabenzene **13** was obtained in 53% yield from **8a** in the form of a pale yellow, microcrystalline powder by stirring with hexachloroethane at room temperature for 12 h. Under similar conditions, the dewar-triphosphabenzene derivative **14** is formed in 70% yield from **9b** in the form of orange microcrystals. Both compounds are stable at room temperature under exclusion of air and moisture. An isomerization of **14** to **13** can be achieved by heating to 90 °C; after 5 h 20% of **14** had rearranged into **13**. For the parent compounds, the triphosphabenzene is 25 kcal mol^{-1} more stable than the dewar-triphosphabenzene.[14]

The structures of the two new compounds **13** and **14** were established unambiguously by mass spectrometry and ^1H, ^{13}C, and ^{31}P NMR spectroscopy. The mass spectra of the two compounds exhibit a molecular ion peak at m/z 300; the spectra of **13** and **14** differ only slightly in the intensities of the fragment ion signals (Table 1). The different structures of **13** and **14** are clearly evident in their ^{31}P NMR spectra; in the spectrum of **13** a singlet appears at $\delta = 232.6$ for all three phosphorus atoms, whereas in the spectrum of **14** a doublet appears at $\delta = 336.8$ ($J_{P,P} = 23.5$ Hz) for the two unsaturated phosphorus atoms P1 and a triplet appears at $\delta = 93.6$ for the bridgehead phosphorus atom P2 (for atom numbering see Scheme 2). All the NMR signals lie in the expected range.[1, 6, 15] The structure determinations of **13** and **14** were completed by their ^{13}C NMR spectra: the ring carbon atoms of **13** give rise to one signal at $\delta = 211.8$, whose coupling pattern corresponds to the X component of an A_2BX spin system (Table 1). A multiplet for the two sp^2 carbon atoms C1 at $\delta = 236.7$ ($^1J_{C,P} = 55.9, 47.5$ Hz, $^3J_{C,P} = 20$ Hz), which can be roughly analyzed as a first order signal (ddd), and a triplet of doublets at $\delta = 46.6$ ($^1J_{C,P} = 39.8, 28.0$ Hz) for the bridgehead carbon atom C2 appear in the spectrum for the differently bound carbon atoms of the bicycle **14**. The chemical shifts of the C atoms of the *tert*-butyl groups do not require an explanation. Neither do their signals in the ^1H NMR spectra (one signal for **13** and two singlets in the ratio 2:1 for **14**; Table 1).

According to its NMR spectra (^1H, ^{13}C, ^{31}P), the free 1,3,5-triphosphinine **13** is a π^6-heteroarene. Its relationship to the many known phosphinines[16] and the two recently synthesized 1,3-diphosphinines[15] is unmistakable. A 1,4-diphosphinine, 2,3,5,6-tetrakis(trifluoromethyl)-1,4-diphosphinine has so far only been detected in solution; NMR spectroscopic data of this compound are not known.[17] The spectroscopic data of a well-known $1\lambda^5,3\lambda^5,5\lambda^3$-triphosphinine differ considerably from those of the compound **13**.[18]

The NMR spectra of the dewar-1,3,5-triphosphabenzene (dewar-1,3,5-triphosphinine) **14** resemble those of dewar-1-phosphinine[19] and of dewar-2-phosphinine.[20] The only notable difference between the spectra is the position of the signal of the bridgehead phosphorus atom P2, which is considerably shifted downfield in **14**. However, the corresponding phosphorus atom in a dewar-1,3,5-triphosphabenzenevanadium complex adopts a similar position ($\delta = 84.4$).[6]

With the successful synthesis of the 1,3,5-triphosphabenzene **13** and its dewar benzene valence isomer **14**, we are now in the position to investigate the reactivity of these new phosphorus heterocycles. Our priorities in this respect are the study of the cycloaddition behavior and the properties of these compounds as complex ligands in transition metal chemistry.

Experimental Procedure

6a: **1** (1.12 g, 11.2 mmol) in xylene (10 mL) was added dropwise over 0.5 h to a boiling solution of **5a** (2.0 g, 5.6 mmol) in xylene (40 mL). The mixture was stirred for a further 0.5 h at about 140 °C and then the solvent was removed at 0.5 mbar. The resulting brown solid was suspended in pentane (20 mL), filtered with a D3 frit, washed with pentane, and dried at 10^{-3} mbar. Recrystallization from toluene afforded **6a** (1.83 g, 68%) as brown microcrystals; m.p. 163 °C (decomp.).

8a: **1** (3.4 g, 34 mmol) was added dropwise to a solution of **5a** (4.0 g, 11.2 mmol) in toluene (10 mL) and pentane (10 mL) at −78 °C and stirred for 18 h at −78 °C. The green-brown suspension was filtered at −78 °C and the residue washed twice with pentane (2 × 20 mL). Recrystallization from THF (10 mL) afforded **8a** (5.39 g, 83%) as green microcrystals; m.p. ca. 138 °C (decomp.).

9b: **1** (1.3 g, 13 mmol) was added dropwise to a solution of **5b** (2.08 g, 4.32 mmol) in Et_2O (30 mL) at 0 °C. After 1 h the reaction solution was cooled to −30 °C, the green crystals of **9b** which precipitated were filtered off and dried at 10^{-3} mbar; **9b** (2.8 g, 89%); m.p. 107 °C (decomp.).

13: Hexachloroethane (0.2 g, 0.86 mmol) was added to a suspension of **8a** (0.5 g, 0.86 mmol) in toluene (30 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature over the course of 12 h, filtered, and the filtrate was evaporated to dryness at 0.5 mbar. The residue was dissolved in pentane (20 mL) and small amounts of insoluble material were removed by filtration. The yellow filtrate was concentrated to 5 mL and cooled to −78 °C. After 8 h, 0.14 g of **13** (53%) had precipitated in the form of a yellow solid; m.p. 88 °C (decomp.).

14: Hexachloroethane (425 mg, 1.8 mmol) was added to a solution of **9b** (1.3 g, 1.8 mmol) in toluene (10 mL) at room temperature and the mixture was stirred for 2 h. The solvent was removed at 0.5 mbar, the residue was taken up in pentane (40 mL) and filtered over Celite to remove insoluble material. On cooling to −30 °C small amounts of [bis(trimethylsilyl)cyclooctatetraene]hafnium dichloride precipitated, which was likewise filtered off. The clear filtrate was concentrated to 20 mL, and subsequent cooling to −30 °C led to the precipitation of **14** (380 mg, 70%) in the form of orange microcrystals; m.p. about 128 °C (decomp.).

meso-Tetrakis[4-(diphenylphosphino)-phenyl]porphyrin and a Water-Soluble Octakis-(phosphonium salt) Porphyrin Double-Decker with a Cage Structure

Gottfried Märkl,* Martin Reiss, Peter Kreitmeier, and Heinrich Nöth

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

Water-soluble porphyrins are important because of their potential interactions with biological systems (e.g. double-stranded cleavage of DNA, photochemical oxidations, photodynamic tumor therapy, photoinduced intramolecular electron- and energy transfer).[1–3] As a result, a series of ammonio-substituted porphyrins,[4–6] porphyrinyl uridines,[7] and sugar-substituted porphyrins[8] have been reported. So far there are no reports of phosphinoporphyrins; we are only aware of complexes of octaethylporphyrin (OEP) and tri- or pentavalent phosphorus as the "metallic" central atom, $([P(OEP)]^+X^-$ and $([P[OEP)-(OH)_2]^+ClO_4^-)$.[9] Here, we describe a phosphino-substituted porphyrin for the first time, the tetrakis[4-diphenylphosphino)phenyl]porphyrin **2a**, whose cationic form represents a new type of water-soluble porphyrin.

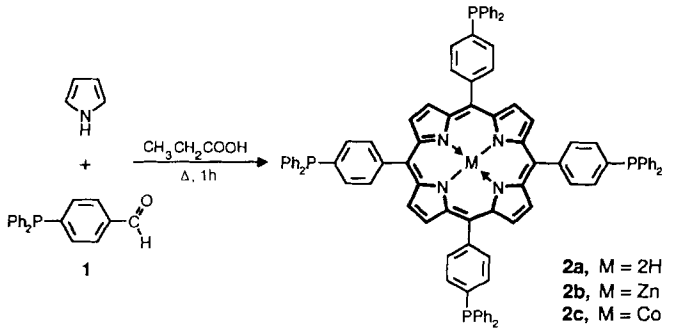
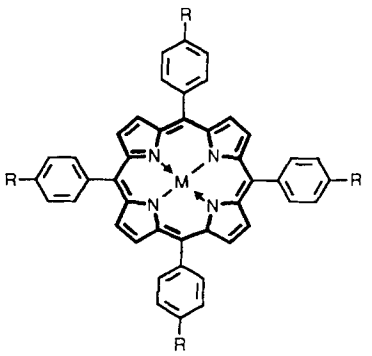
The synthesis of **2a** was achieved by using the universal method of A. D. Adler et al. [10], from (4-diphenylphosphino)benzaldehyde **1** and pyrrole.



In accordance with the method of G. Schiemenz et al.,[11] **1** is obtained from 4-bromobenzaldehyde-ethyleneglycolacetal via the Grignard compound, by reaction with chlorodiphenylphosphane[12a] and subsequent hydrolysis.[12b] The Adler condensation of **1** with pyrrole affords **2a** in 21% yield (purification by recrystallization from CH_2Cl_2/MeOH, m.p. >350 °C, black-red, shiny needles). The characteristic Soret band at 423 nm (benzene, $\varepsilon = 490000$) undergoes a bathochromic shift of 18 nm in the diprotonated species **2a** (solution of **2a** in benzene/HCl g; $\varepsilon = 412000$). The fluorescence spectrum of **2a** ($CHCl_3$)[13] shows absorption maxima at 650, 707, and 760 nm (the longest wavelength band is only weakly defined); the Stokes shift of 4 nm is very small due to the rigid structure of the system.

It is surprising that the tervalent phosphorus atoms in compound **2a** are slightly oxidizable, even though this is formally a triphenylphosphane unit. IR spectroscopic monitoring of the autooxidation of **2a** in $CHCl_3$ in daylight by oxygen in air—which leads to the tetraoxide **3a** (Table 1)—shows that formation of the phosphane oxide is about 1000 times faster than for triphenylphosphane. This apparent autocatalyzed oxidation of **2a** by the porphyrin system could be due to intramolecular, photoinduced activation of oxygen in air.[14] However, since triphenylphosphane is also rapidly oxidized by oxygen in air in the presence of catalytic amounts of *meso*-tetraphenylporphyrin (TPP) under the same conditions, an intermolecular catalysis cannot be ruled out for **2a**. Due to this extreme autooxidizability, reactions with **2a** must be performed under strict exclusion of oxygen. In the crystal structure of the oxide **3a**,[15] the *meso*-phenyl substituents are arranged propeller-like on the porphyrin and the $P(O)Ph_2$-oxygen atoms are oriented *syn*, *anti*, *syn*, *anti* to each other (Fig. 1a,b).

Porphyrin **2a** is also converted by H_2O_2/acetone into the tetraoxide **3a** and by sulfur in benzene to the tetrasulfide **4a** (Table 1). Compounds **3a** and **4a** can also be obtained by Adler condensation of the oxide (m.p. 104–106 °C) or the sulfide (m.p. 82–84 °C) of **1** with pyrrole (yields 12 and 16%, respectively).



3, R = $-\overset{\overset{O}{\|}}{P}Ph_2$, **3a**, M = 2 H; **3b**, M = Co **3c**, M = Zn

4a, R = $-\overset{\overset{S}{\|}}{P}Ph_2$, M = 2H

5, R = $-\overset{\overset{CH_3}{|}}{\overset{\oplus}{P}}Ph_2\ I^{\ominus}$, **5a**, M = 2H; **5b**, M = Zn

6a, R = $-\overset{H_2C}{\underset{PPh_2}{\overset{|}{\overset{\oplus}{|}}}}-C_6H_4-COOH\ Br^{\ominus}$, M = 2H

The formation of quaternary ions of **2a** in dimethylformamide can be achieved at room temperature, for example, with

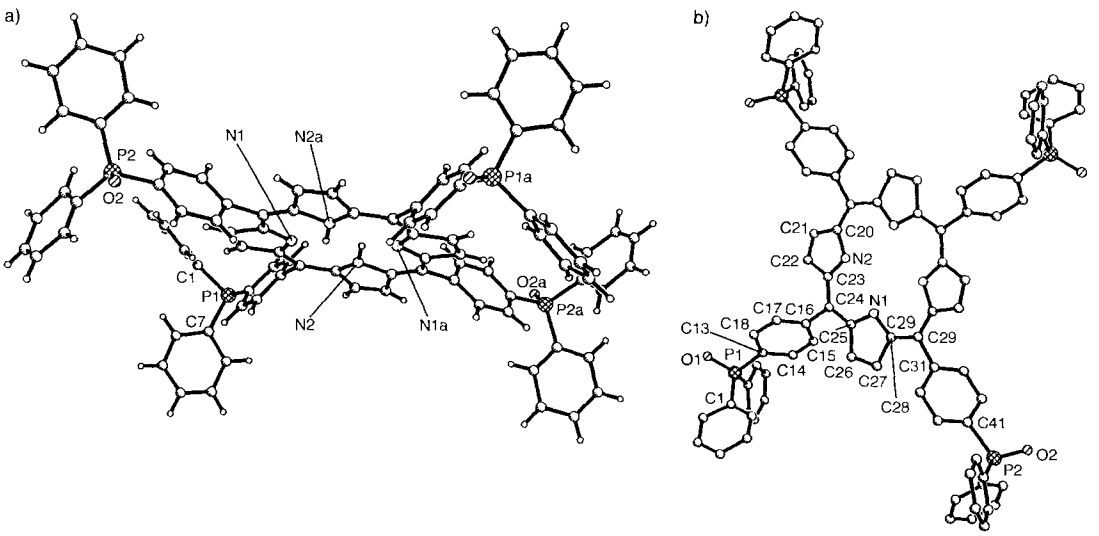


Fig. 1. Crystal structure of **3a**. a) Side view. b) Plan view. [a] ^{1}H NMR (400 MHz, CD_3NO_2): δ = 3.21 (d, ^3J(P,H) = 13.64 Hz, CH_3), 7.92–8.23 (m, 48H), 8.64 (d, 8H), 8.96 (s, 8H).

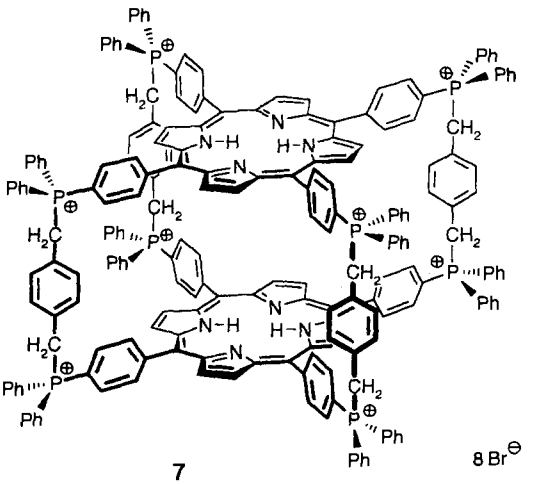
methyl iodide to give **5a** and with (4-bromomethyl)benzoic acid to give **6a** (Table 1). The phosphonium salts show normal Soret bands (**5a**, λ_{max} = 416 nm (ε = 420000), **6a**, λ_{max} = 417 nm (ε = 392500)). The salts do not precipitate from solutions in a little ethanol (**5a**) or DMF (**6a**) on dilution with water.

The reaction of **2a** with *para*-xylylene dibromide in the molar ratio 1:2 (DMF 100 °C, dilution method, dropwise addition of the bromide over 24 h, total reaction time 48 h) gives the octakis(phosphonium salt) **7**. Compound **7** can be isolated by precipitation with ether, leading to a dark violet crystalline powder, without by-products and in almost quantitative yield, which is readily soluble in DMF, alcohol, and water. The appearance of



7

a single signal in the ^{31}P NMR spectrum at δ = 25.0 indicates that all phosphorus atoms are in the same chemical and magnetic environment. The UV/Vis spectrum of **7** (MeOH: λ_{max}[nm] (ε) = 408 (468500), Soret bands, Q bands: 516 (21000), 547 (12000), 584 (7000), 650 (5600); MeOH/HCl: 428 (430000), 598 (14700), 649 (55300)) does not show any electronic interactions resulting from the porphyrin rings; however, a drastic increase in the ε value of the longwave Q bands at 649 nm is noteworthy. The extreme high-field shift of the NH signals in the ^{1}H NMR spectrum (from $\delta \approx -2.5$–3.0 to −6.5) clearly indicates that the NH protons in each ring are influenced by the ring currents of the other porphyrin ring.[16]

The mass spectrum ("TSQ/SSQ 7000 Atmospheric Pressure Ionization (API) System, Electrospray Ionization (ESI) process", Finnigan MAT[17]) establishes the structure of **7**.[18] The ions appearing in the ESI spectrum are listed in Table 2.

The octakis(phosphonium salt) **7** is the first example of an ionic, vertically stacked porphyrin. It can be classed as a "porphyrin double-decker" (separation of the porphyrin rings ca. 7 Å) with a cage structure. So far, to the best of our knowledge, only two neutral systems with two vertically stacked, covalently bound porphyrins are known.[19, 20] Depending on the length of the α,ω-dibromides, it should be possible to adjust the height of the porphyrin cage so that different guest molecules (organic molecules, complex fragments) can form stable host–guest complexes. Similarly, stacking of porphyrins which contain metal ions could enable formation of "molecular" metals.[21]

The reaction of **2a** with $Zn(OAc)_2$ in $CHCl_3$ gives the zinc complex **2b** (Table 1). The cobalt complex **2c** (reaction of **2a** with $Co(OAc)_2$ in $CHCl_3$) is much more readily autooxidizable than the metal-free phosphinoporphyrin **2a**, which has meant that until now, only the corresponding phosphane oxide **3b** could be isolated. This is plausible since cobalt complexes with nitrogen donor ligands readily react with molecular oxygen to form peroxo- and superoxo complexes. Some of these complexes can function as reversible oxygen carriers and may be used as models for biological oxygen transport systems.[22] (μ-O_2)-Cobalt complexes could therefore trigger the extremely facile intra- or intermolecular autooxidation of the phosphorus atoms in **2c**.

The zinc complex **2b** can be converted smoothly to the phosphonium salt **5b**, by using methyl iodide (DMF, 20 h, room temperature), and with careful exclusion of oxygen and light (Table 1).

Table 2. Electrospray ionization (ESI) mass spectrum of **7** [a].

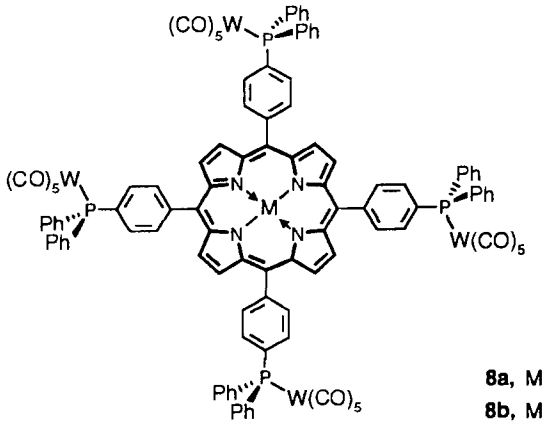
[a] $C_{216}H_{164}Br_8N_8P_8$, $M_r = 3758.75$ ($C_{216}H_{164}N_8P_8)^{8+}$, $M_r = 3119.52$; measurement conditions: solution in methanol/water (1/1), heated capillary (180 °C), 196 eV acceleration potential.

Compound **2a** reacts with $W(CO)_5 \cdot THF$ in THF at room temperature (reaction time 20 h) to form the tetrakis(pentacarbonyltungsten) complex **8a** (Table 1); the mass spectrum (PI-LISIMS, MNBA/CH_2Cl_2, MNBA = *m*-nitrobenzyl alcohol) confirms the chemical composition $C_{112}H_{66}N_4O_{20}P_4W_4$. The complex molecule peak observed[23] agrees with calculated values for the given isotope ratios.



8a, M = 2H
8b, M = Zn

Modeling studies show that the *meso*-phenyl substituents are perpendicular to the plane of the porphyrin ring and the $PPh_2W(CO)_5$ substituents are free to rotate. The molecule has a spatial expansion of about 20 Å.

Analogous to **2a**, the zinc complex **2b** can also react at room temperature with $W(CO)_5 \cdot THF$ in THF. This produces complex **8b** (Table 1), which can also be obtained from **8a** using $Zn(OAc)_2$ in boiling methanol (reaction time 1 h).[24] As far as we know, **8b** is the only porphyrin reported which contains a σ-bound transition metal complex fragment[25] (mono- and bis-$Cr(CO)_3$-π complexes of TPP were reported by N. J. Gogan et al.[26]).

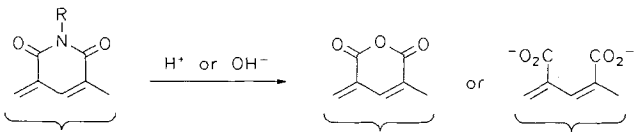
Tetracarboxylic Bisimide–Lactam Ring Contraction: A Novel Type of Rearrangement**

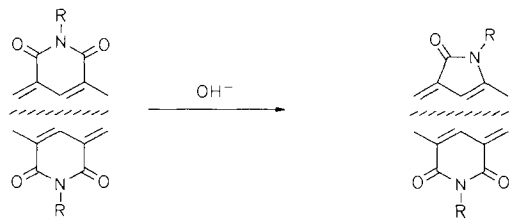
Heinz Langhals* and Petra von Unold

Dedicated to Professor Rolf Huisgen on the occasion of his 75th birthday

Six-membered ring dicarboximides **1** with aromatic substituents are commonly viewed as chemically very inert.[1] Strong hydrolyzing reagents such as hot, concentrated sulfuric acid or KOH/*tert*-butyl alcohol are required for their saponification to **2a** or **2b** as, for example, in the case of perylene-3,4-dicarboximides[2, 3] or perylene-3,4:9,10-tetracarboxylic bisimides **7**.[1] A completely different reaction pathway is observed if, under much milder conditions, alkali metal hydroxides in alcohol react with bisimides **3**: In this case, the loss of a C_1 fragment from one of the carboximide substructures leads to the formation of the corresponding ring-contracted lactamimides **4**. This reaction occurs with naphthalene-1,8:4,5-tetracarboxylic bisimides **5**[4] and with the related perylene bisimides **7**[5] and is discussed in more detail herein.

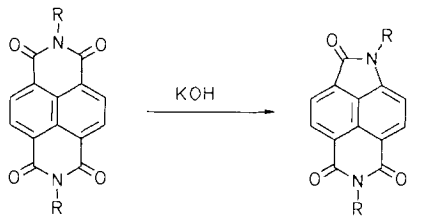


1 **2a** **2b**

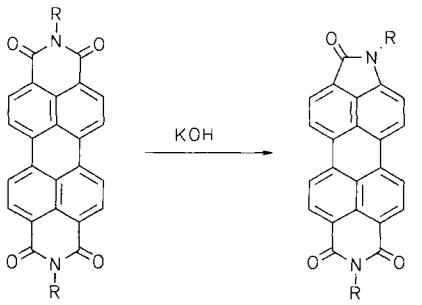


3 **4**

The reaction of **5** or **7** with KOH in *tert*-butanol leads to the corresponding lactamimides in only small amounts as by-products. However, in ethanol and especially in methanol ring contraction is the dominant reaction pathway. Addition of dimethyl sulfoxide (DMSO) further increases the yield and shortens reaction times, so that now the lactamimides **6** and **8**, of which only few derivatives are known,[3–7] are obtained in high yield, and only trace amounts of hydrolysis products are formed (Scheme 1).[8]



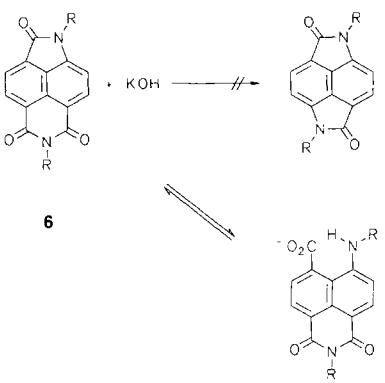
5 **6**



7 **8**

Scheme 1. Reaction of the bisimides **5** and **7** with KOH; **a**, R = 2,5-di-*tert*-butylphenyl; **b**, R = 4-*tert*-butylphenyl; **c**, R = 2-*tert*-butylphenyl; **d**, R = 5-*tert*-butyl-2-methylphenyl; **e**, R = 2,2-dimethylheptyl; **f**, R = (1-propylcyclohexyl)methyl.

Interestingly, ring contraction proceeds quite easily for R = aryl, but is more difficult for R = alkyl. In bisimides bearing aromatic and aliphatic substituents contraction of the aryl-substituted ring is favored. In both, **5** and **7** only one of the imide ring systems is transformed to the lactam, leaving the second one unchanged even under more vigorous conditions. Evidently, the second imide subunit is essential for the reaction to occur. In agreement with this conclusion is the finding that monoimide **1** does not undergo ring contraction.



6 **9**

Lactamimides **6** and **8** (and also the bisimides **5** and **7**) reversibly add OH^- in the presence of a large

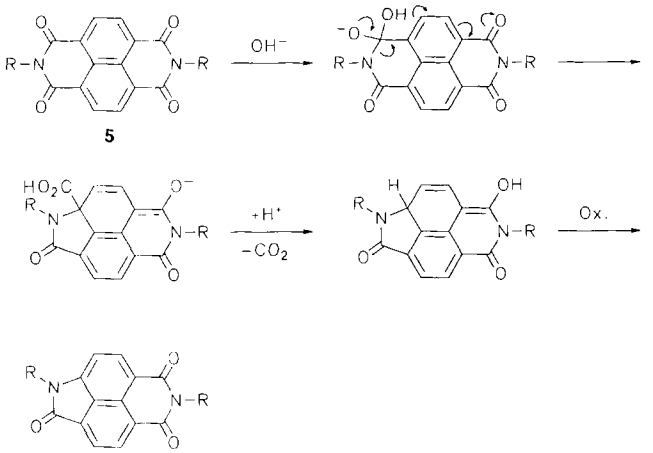
excess of alkaline metal hydroxide in alcohol to form either orange-red or blue salts **9**,[12] in which the lactam rings are hydrolyzed.

On the basis of these experimental findings, the following rearrangement mechanism is proposed (Scheme 2): The reaction is initiated by the addition of one equivalent of OH^- to one of the imide carbonyl groups. Subsequent ring contraction leads to the formation of a lactam followed by decarboxylation.[9, 10] In this step, the adjacent carbonyl group, possibly after the attack of another equivalent of OH^-, may function as an intramolecular base and accept the proton of the carboxylic acid group. In light of the present experimental data, however, this postulate can be neither supported nor excluded. The decarboxylated product is a dihydroaromatic species that is oxidized to the aromatic lactamimide. Presumably, the presence of air is enough to achieve this oxidation, but it is also possible that the cosolvent DMSO is involved.



5

Scheme 2. Mechanism of the ring contraction of **5**.

The proposed dihydroaromatic intermediates are difficult to characterize. If the ring contraction of **6c** (R = 2-*tert*-butylphenyl) is conducted under inert gas (argon), one can observe a transient, violet color of the reaction mixture that only persists under rigorous exclusion of oxygen[11] but otherwise instantly changes to pale yellow. In the presence of air, oxidation in the alkaline reaction medium is complete, and after aqueous workup (with 2–6 N HCl for example) the protonated aminocarboxylate **9c** (R = 2-*tert*-butylphenyl) can be isolated.[12] After treatment of a solution of **5c** in ethanol with concentrated HCl or refluxing glacial acetic acid one obtains, in addition to 50% unchanged starting material, lactam **6c** in 31% yield. Furthermore and in contrast to reactions performed in the presence of air, one can isolate the product formed by hydrolysis of one imide ring, namely *N*-(2-*tert*-butylphenyl)naphthalene-1,8:4,5-tetracarboxylic-1,8-anhydride-4,5-imide in 7% yield. If a corresponding reaction mixture starting from **5a** is treated with concentrated sulfuric acid,[14] the phenyl group on the lactam-nitrogen loses its *tert*-butyl group in position 2.

On the basis of these experimental findings it is clear that the base-induced ring contraction of bisimides constitutes a novel type of rearrangement. The first step of the reaction is similar to the benzilic rearrangement to which it is vinylogous. Preliminary experiments show that the reaction can be successfully extended to other bisimides and hence appears to be a general reaction principle.

The naphthalene-lactamimides **6** absorb in the visible region of the UV spectrum with absorption bands significantly shifted to longer wavelengths compared to the pale-yellow to colorless naphthalene-bisimides **5**. In the solid state and in solution compounds **6** exhibit strong fluorescence (quantum yields > 80%) that is described here for the first time. A characteristic UV/Vis absorption and fluorescence spectrum of **6** is depicted in Figure 1;

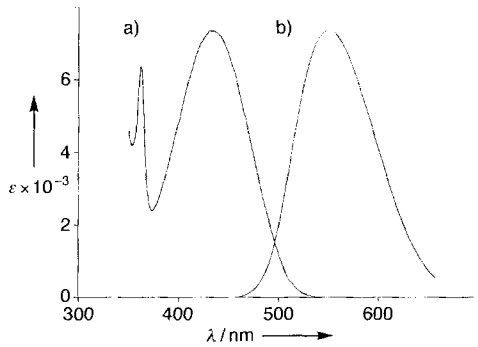


Fig. 1. Absorption (a) and fluorescence spectrum (b) of **6a** (R = 2,5-di-*tert*-butylphenyl) in $CHCl_3$.

further spectroscopic data are listed in Table 1. The photostability of the lactamimides **6** is considerable (at least 30% of the photostability of the corresponding derivatives of **7**)[14] typifying them as a novel class of fluorescent dyes. Remarkable are their large Stokes-shifts (112 nm for **6a**) rendering them promising compounds for dye lasers and other fluorescence applications.

Table 1. Yields, melting points, absorption (A) and fluorescence maxima (F) of lactams **6** [8].

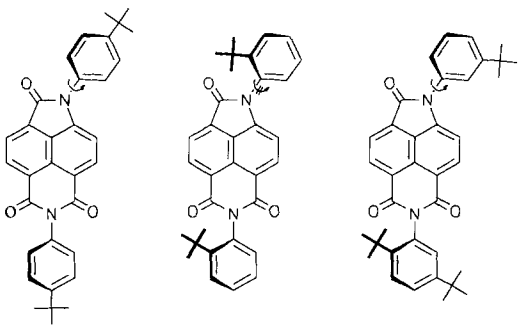
[a] KOH/MeOH/DMSO, 90 °C, 3 h. [b] KOH/EtOH, 90–100 °C, 8–18 h.

The nitrogen atoms of the naphthalene- and perylenetetracarboxylic bisimides **5** and **7** have nodes or at least very small coefficients.[13] This electronic structure has two important consequences: First, their UV/Vis spectra are influenced only little by substituents on the nitrogen and second, flexible substituents at this site do not lead to fluorescence quenching[13, 14] by the Loose–Bolt mechanism.[15, 16] The symmetry of the lactamimides, however, is sufficiently low so that larger atomic coefficients on the nitrogens result.[17] Hence, the Loose–Bolt mechanism can be readily studied for this class of compounds.

The lactamimides **6** with aliphatic substituents, for example **6e** and **6f**, show large fluorescence quantum yields without exception. This suggests that there is no electronic coupling between the flexible parts of the molecular skeleton and the π system of the chromophore. However, phenyl substituents on the nitrogen atoms of **6** couple their π systems with that of the chromophore. Fluorescence quenching by the Loose–Bolt mechanism can now occur after rotation about the $N-C_{Ph}$ bond. This applies, for example, to dye **6b**, for which no fluorescence can be observed (the *tert*-butyl groups in the 4-positions of the phenyl substituents serve to improve the solubility of the dye[18]). A *tert*-butyl group in the 2-position of the phenyl substituent (**6c**) completely obstructs rotation about the $N-C_{Ph}$ bond and leads to high fluorescence quantum yields. Similar conclusions can be drawn for **6a** with a 2,5-di-*tert*-butylphenyl substituent that efficiently hinders free rotation and gives rise to a strongly fluorescent dye. The requirement of hindered rotation is already met with a methyl substituent in position 2, as can be seen from dye **6d**, which shows intense fluorescence. Interestingly, complete fluorescence quenching is observed in the case of **6g**, in which only the $N-C_{Ph}$ bond of the lactam unit freely rotates, whereas that of the imide substructure is blocked. Free rotation in the lactam unit is therefore sufficient to induce fluorescence quenching.



6b **6c** **6g**

These results suggest that it should be possible to develop fluorescent dyes based on **6** with aromatic R or other π substituents in which free rotation about the $N-C_{Ph}$ bond is hindered. If, however, fluorescence is not a desired property of these systems, free rotation about this bond is a prerequisite.

Experimental Procedure

6a: A solution of **5a** (590 mg, 0.90 mmol) in aqueous KOH (85%, 1.4 g), DMSO (6 mL), and MeOH (8 mL) was heated at reflux (100 °C) for 3 h. The hot reaction mixture was stirred into distilled water (200 mL), further diluted with water to 300 mL, and, after treatment with conc. HCl (100 mL), left standing at room temperature for 16 h. The resulting precipitate was dissolved in ethanol (100 mL), the solution treated with conc. HCl (15 mL) and heated at reflux until the color changed from light red to orange-yellow. After dilution with water (300 mL) a precipitate was obtained that was chromatographed on silica with $CHCl_3$ and recrystallized from ethanol/water to yield **6a** (380 mg, 62%). IR (KBr): $\tilde{\nu}$ = 2962 cm^{-1} m, 2926 s, 1733 m, 1714 s, 1683 s, 1661 s, 1503 m, 1467 m, 1426 m, 1364 m, 1340 m, 1245 m, 1169 m, 765 m; ^1H NMR ($CDCl_3$): δ = 8.71 (d, J = 7.3 Hz, 1H, naph.), 8.44 (2d, J = 7.6 Hz, 1H, naph.), 8.32 (d, J = 7.3 Hz, 1H, naph.), 6.76 (d, J = 7.6 Hz, 1H, naph.), 7.61 (d, J = 8.5 Hz, 1H, Ph), 7.56 (2d, J = 8.5 Hz, 1H, Ph), 7.49 (dd, J = 8.6, J' = 2.2 Hz, 1H, Ph), 7.42 (dd, J = 8.6, J' = 2.2 Hz, 1H, Ph), 7.09 and 7.02 (2d, J = 2.2 Hz, 1H, Ph), 6.95 and 6.94 (2d, J = 2.2 Hz, 1H, Ph), 1.32 (s, 9H, *t*Bu), 1.31 (s, 9H, *t*Bu), 1.30 (s, 9H, *t*Bu), 1.26 (s, 9H, *t*Bu); ^{13}C NMR ($CDCl_3$): δ = 168.4, 164.4, 151.1, 150.0, 147.0, 146.0, 144.2, 135.0, 132.1, 131.7, 130.0, 128.9, 128.8, 127.9, 127.2, 126.6, 126.2, 125.8, 125.3, 117.0, 107.7, 35.6, 35.4, 34.4, 34.2, 31.8, 31.8, 31.2, 31.2; MS (70 eV): m/z (%): 614 (0.3) [M^+], 557 (100) [$M^+ - t$Bu].

First Reaction of 1,2-Dimethyl-*o*-silaborane: Nucleophilic Degradation**

Lars Wesemann,* Ulli Englert, and Dietmar Seyferth

1,2-Dimethyl-1,2-disila-*closo*-dodecaborane(12) (**1**)[1] is to date the only reported group 14 element analogue of the intensively investigated 1,2-dicarba-*closo*-dodecaborane(12) $C_2B_{10}H_{12}$[2] (more commonly known as *o*-carborane). From the fundamental work by Hawthorne et al.[3] it is known that the 1,2-dicarba-*closo*-dodecaborane(12) can be degraded by strong bases in the presence of a protic solvent to give 7,8-dicarba-*nido*-undecaborate(1−) $C_2B_9H_{12}^-$. We report here on the attack of bases on the icosahedral skeleton of 1,2-dimethyl-1,2-disila-*closo*-dodecaborane(12) (**1**).

[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG-Schwerpunktprogramm "Polyeder").

Treatment of 1,2-dimethyl-*o*-silaborane (**1**) in the two-phase mixture of diethyl ether/water with one equivalent of sodium hydroxide containing $[NMe_4]Cl$ as a precipitating agent leads to the degradation product $[NMe_4]$-**2** in 89% yield [Eq. (a)].

$$\underset{\mathbf{1}}{Me_2Si_2B_{10}H_{10}} \xrightarrow[-\,NaCl\ -\,[MeSi(OH)_3]]{+\,NaOH\ +\,2\,H_2O\ +\,[NMe_4]Cl} \underset{[NMe_4]\text{-}\mathbf{2}}{[NMe_4][MeSiB_{10}H_{12}]} \quad (a)$$

The immediate precipitation of the degraded silaborane from the aqueous solution is essential for high yields of $[NMe_4]$-**2**. If the anion **2** remains in water for only a few minutes, it is degraded further to the pentadecahydrodecaborate(1−) $B_{10}H_{15}^-$.[4] Compound **1** can also be degraded by the nucleophile methanolate in tetrahydrofuran at 50 °C, and in the presence of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) the salt [Li(TMEDA)]-**2** can be isolated in 46% yield [Eq.(b)].

$$\mathbf{1} \xrightarrow[-\,MeSi(OMe)_3]{+\,LiOMe\ +\,2\,MeOH\ +\,TMEDA} [Li(TMEDA)]\text{-}\mathbf{2} \quad (b)$$

$MeSi(OMe)_3$ formed by the extrusion of a MeSi cluster vertex from **1** can, after separation by vacuum distillation, be clearly detected by mass spectrometry. In analogy to this result $MeSi(OH)_3$ should be formed from the degradation by OH^- [Eq.(a)]. This, however, has not been proven since the product condenses to give polymeric methylsiloxanes.[5]

The spectroscopic data of the hitherto unknown 8,9:10,11-di-μ-hydrodecahydro-7-methyl-7-sila-*nido*-undecaborate(1−) **2** confirm the constitution of this *nido*-cluster anion shown in Figure 1. Six signals with an intensity ratio of 1:2:2:2:2:1 are observed for the ten B atoms in the ^{11}B NMR spectrum. Thus, the anion **2** has C_s symmetry in solution; the B atoms B1 and B5 lie on the mirror plane. All B atoms reveal a B–H coupling with a terminal H atom.

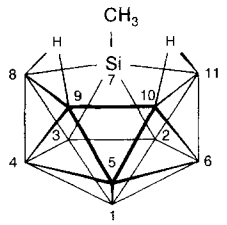

Fig. 1. Constitution of **2**.

The connectivities in the B_{10} framework can be established clearly from the 2D-^{11}B-^{11}B NMR spectrum. The lack of the cross peak between the B atoms B8–B9 and B10–B11 is a known phenomenon in bridging by H atoms.[6] Contrary to the expectations all cross peaks for the B–B edges bridged by the heteroatom silicon are visible.[7] The assignment of the signals in the ^1H NMR spectrum to the appropriate B atoms follows unambiguously from the 2D-^{11}B-^1H NMR spectrum; the cross peaks between the signal for the bridging H atoms and the signals for the B atoms B8,11 and B9,10 are particulary noteworthy.

The constitution of the anion **2** in solution determined from the spectroscopic data is consistent with the results of the crystal structure analysis (Fig. 2).[8] All B–B distances lie in the expected range of 1.74 to 1.90 Å; the three distances in the opened five-membered ring are the longest (1.86, 1.87, and 1.90 Å). The Si–B distances, which lie between 2.04 and 2.07 Å, correspond to those in 1,2-$Me_2Si_2B_{10}H_{10}$,[1] *commo*-3,3′-Si(3,1,2-$SiC_2B_9H_{11})_2$,[12] and $[(Me_3Si)_2C_2B_4H_4]_2Si$.[13] The Si atom lies 0.22 Å above the best plane through B8, B9, B10, and B11.

The anion **2** with 26 framework electrons is both isoelectronic and isostructural to 7-Me-7-$PB_{10}H_{12}$.[14] Other compounds of this structural type, all of which carry two bridging H atoms on the open, heteroatom-substituted pentagonal faces, are $CB_{10}H_{13}^-$[15] and $(NB_2tBu_3H)NB_{10}H_{12}$.[16] A corresponding silaborane of the composition $Me_2SiB_{10}H_{12}$ was claimed to be formed in the reaction of $Na_2B_{10}H_{12}$ with Me_2SiCl_2, but this compound has only been characterized unsatisfactorily.[17]

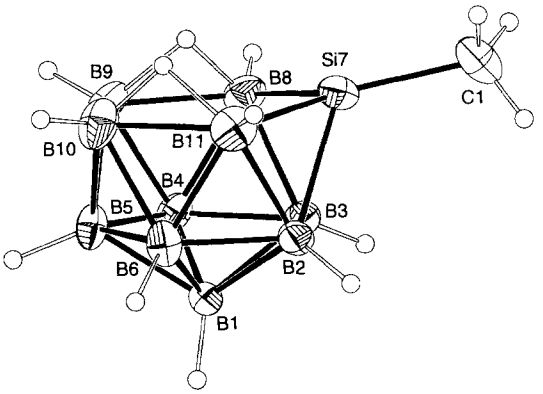

Fig. 2. Crystal structure of the anion **2** (PLATON representation [11]; thermal ellipsoids for 30% probability). Selected distances [Å], standard deviation in parentheses: B1-B2 1.762(4), B1-B3 1.762(5), B1-B4 1.782(5), B1-B5 1.742(6), B1-B6 1.781(6), B2-B3 1.783(5), B2-B6 1.773(6), B2-B11 1.843(6), B3-B4 1.773(5), B3-B8 1.840(5), B4-B5 1.751(6), B4-B8 1.796(5), B4-B9 1.796(6), B5-B6 1.783(5), B5-B9 1.747(5), B5-B10 1.758(6), B6-B10 1.801(7), B6-B11 1.778(5), B8-B9 1.870(7), B9-B10 1.857(7), B10-B11 1.895(7), Si7-C1 1.877(4), Si7-B2 2.048(3), Si7-B3 2.069(4), Si7-B8 2.045(4), Si7-B11 2.036(5).

1,2-Dimethyl-*o*-silaborane is attacked by nucleophiles with the loss of a MeSi vertex, whereas in *o*-carborane a B atom adjacent to the two C atoms reacts with the nucleophiles. A plausible explanation for this different pattern of reactivity follows from the consideration of the electronegativities of the participating elements. In the series carbon, boron, and silicon, the electronegativity decreases continually. Thus, the polarities in the examined heteroboranes are different, and this is the reason for the different nucleophilic degradation. As expected for the nucleophilic degradation of 1,2-diphospha-*closo*-dodecaborane(12) $P_2B_{10}H_{10}$, both degradation variants (that is, both the loss of a B atom and that of a P atom from the icosahedral framework) are known.[18]

In additional experiments we will study the reactivity of the anion **2**. These experiments will focus on the cluster formation by suitable main group element compounds and investigations on the coordination of **2** to transition metal complex fragments.

Experimental Procedure

2: **1** (306 mg, 1.50 mmol) [1] dissolved in Et_2O (70 mL) was treated with 0.1 N NaOH (15 mL), in which $[NMe_4]Cl$ (0.25 g, 2.3 mmol) was dissolved. $[NMe_4]$-**2** precipitated immediately as a white solid at the phase boundary. Et_2O was removed in vacuum from the two-phase mixture, $[NMe_4]$-**2** was filtered and washed (2 × 5 mL) with water. After drying, tetramethylammonium 8,9:10,11-di-μ-hydrodecahydro-7-methyl-7-sila-*nido*-undecaborate(1−) ($[Me_4N]$-**2**) was obtained in 89% yield (317 mg) [19]. MS (SIMS in 3,4-dimethoxybenzyl alcohol): *m/z* (%): 163 (29, M^-); NMR spectra at 25 °C in $[D_8]$THF; ^1H NMR (500 MHz, TMS): δ = 3.22 (s, Me_4N), 1.69 (H5), 1.52 (H8/11), 1.37 (H2/3), 0.95 (H4/6), 0.86 (H1/9/10), 0.51 (s, SiMe), −5.67 (broad, μ-H8/9, μ-H10/11), measurement and assignment of the B–H signals as cross peaks in the 2D-^{11}B-^1H NMR spectrum; ^{11}B NMR spectrum (160 MHz, $Et_2O{\cdot}BF_3$): δ = −12.3 (d, J = 140 Hz, B5), −14.7 (d, J = 134 Hz, B2/3), −21.9 (d, J = 140 Hz, B8/11), −23.8 (d, J = 140 Hz, B9/10), −25.3 (d, J = 140 Hz, B4/6), −32.5 (d, J = 140 Hz, B1); ^{13}C NMR (125 MHz, TMS): δ = 55.8 (s, NMe_4), −6.8 (s, SiMe); ^{29}Si NMR (100 MHz, TMS): δ = −36.4 (s).

The β-Lactam-Nucleoside Chimera

Alexander Dömling, Manfred Starnecker, and Ivar Ugi*

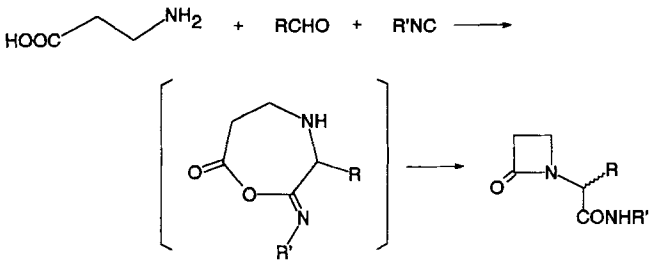
Dedicated to Professor Hubert Schmidbaur on the occasion of his 60th birthday

Multicomponent reactions (MCRs) have played a very important role since the beginning of organic chemistry.[1] The emergence of combinatorial chemistry[2] has revived the interest in these reactions. Furthermore, their applicability has been extensively broadened by the introduction of new MCRs[3] as well as novel concepts for the generation of MCRs.[1] Compared to conventional reactions, MCRs offer numerous advantages. For the rapid construction of large substance libraries, it is crucial that all compounds of a given component set can be combined with each other. In the case of the Ugi reaction (U-4CR), these libraries are prepared from a variety of commercially available compounds that represent all archetypes of chemical reactivity: oxo components, diverse acids, amines, and isocyanides. Building blocks that contain appropriate functional groups can be employed for the design of intelligent systems.

Nucleoside analogues are among the few agents that can be used against viral infections[4] and have therefore gained significance since the appearance of AIDS. β-Lactams, on the other hand, belong to the most efficient drugs for the treatment of bacterial infections by virtue of their ability to stop the cell-wall biosynthesis. An acylation by the β-lactam portion of the antibiotic deactivates the dipeptidase which effects the cross-linking of murein.[5] In addition, β-lactams have become a major focus in medicinal chemistry due to their ability to inhibit human leucocyte elastase (HLE).[6] Immunoconjugates consisting of monoclonal antibodies and β-lactam agents are discussed as very promising anticancer drugs.[7] The combination of the acylating activity of β-lactam antibiotics and the recognition ability of nucleoside bases results in a novel class of nucleoside analogues, which can be referred to as a chimera consisting of both classes of compounds.[8]

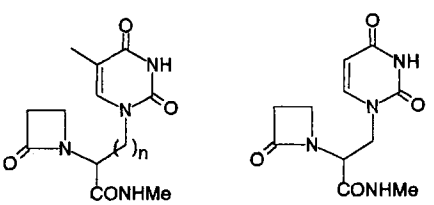
A concept called dual action drugs, which combines substance groups with different types of activity into a new drug, has been successfully applied by several research groups. For example, the combination of classical β-lactam antibiotics and gyrase inhibitors gives rise to extremely potent antibiotics.[9]

The reaction of β-amino acids with oxo components and isocyanides results in the formation of strained four-membered β-lactams by a ring contraction of the intermediate, nonisolable seven-membered rings (Scheme 1). When employing aldehydes



Scheme 1. β-Amino acids, oxo components, and isocyanides react to form intermediate, nonisolable seven-membered ring compounds that collapse to yield strained four-membered β-lactams.

based on nucleobases as oxo components, the chimeric nucleoside analogues **1**–**3** (Table 1) can be obtained in good yields (>80%). The aldehydes are readily available in two steps from the corresponding bases.[10] *O*,*N*-acetal **4** (Table 1) is formed



exclusively when 3-amino-4,4-dimethyl-5-hydroxyvaleric acid is used as the β-amino acid,[11] the expected β-lactam **5**, however, is not observed (Scheme 2). The relative configuration of **4** could be confirmed by NOESY experiments. All compounds

Table 1. Selected physical data of compounds **1**, **2**, and **4** [a].

1: $C_{12}H_{16}N_4O_4$, M = 280.28 g mol^{-1}; colorless powder; m.p. 224 °C (decomp.); R_F ($CHCl_3$/MeOH 4/1 v/v) = 0.69; ^{1}H NMR ([D$_6$]DMSO, 360 MHz): δ = 1.72 (s, 3H), 2.54 (m, 1H), 2.59 (d, 3H, ^3J = 4.5 Hz), 2.60–2.85 (m, 2H), 3.18 (m, 1H), 3.43 (m, 1H), 3.87 (m, 2H), 4.51 (dd, 1H, ^3J = 5.3, ^3J = 9.2 Hz), 8.26 (q, 1H, ^3J = 4.6 Hz), 11.26 (br.s, 1H); ^{13}C NMR ([D$_6$]DMSO, 90 MHz): δ = 11.6, 25.3, 35.8, 37.3, 46.4, 52.5, 108.4, 140.4, 150.7, 163.9, 166.5, 167.0

2: $C_{13}H_{18}N_4O_4$, M = 294.31 g mol^{-1}; colorless powder; m.p. 170 °C (decomp.); R_F ($CHCl_3$/MeOH, 4/1, v/v) = 0.85; ^{1}H NMR (D_2O, 360 MHz): δ = 1.78 (s, 3H), 2.19 (m, 2H), 2.61 (d, 3H, ^2J = 10.8 Hz), 2.88 (m, 2H), 3.35 (m, 2H), 3.76 (m, 2H), 4.16 (m, 1H), 7.38 (s, 1H), 8.06 (br.q, 1H, ^2J = 10.8 Hz), the NH proton of thymine apparently exchanges and therefore does not give a signal; ^{13}C NMR ([D$_6$]DMSO, 90 MHz): δ = 11.8, 25.4, 28.3, 35.8, 37.3, 44.6, 51.9, 108.3, 141.5, 150.7, 164.3, 167.1, 169.1

4: $C_{13}H_{19}N_3O_5$, M = 297.31 g mol^{-1}; colorless powder; m.p. 220 °C (decomp.); R_F (ethyl acetate/hexane 1/1 v/v) = 0.46; ^{1}H NMR ([D$_6$]DMSO, 360 MHz): δ = 0.66 (s, 3H), 0.86 (s, 3H), 1.89 (dd, 1H, ^2J = 14.9, ^3J = 10.7 Hz), 2.36 (dd, 1H, ^2J = 14.9, ^3J = 2.6 Hz), 2.91 (dd, 1H, ^2J = 10.4, ^3J = 2.6 Hz), 3.24 (d, 1H, ^3J = 11.0 Hz), 3.42 (d, 1H, ^3J = 11.0 Hz), 3.69 (d, 2H, ^3J = 5.8 Hz), 4.14 (t, 1H, ^3J = 5.8 Hz), 5.47 (d, 1H, ^3J = 7.8 Hz), 7.49 (d, 1H, ^3J = 7.8 Hz), 11.24 (br.s, 1H), two acidic protons do not give a signal; ^{13}C NMR ([D$_6$]DMSO, 90 MHz): δ = 17.9, 22.4, 31.6, 35.4, 50.3, 59.4, 77.6, 85.1, 100.2, 146.7, 151.0, 163.7, 173.4

[a] All compounds described in this communication were characterized by ^{1}H NMR and ^{13}C NMR spectroscopy (C-H correlation, NOESY, COSY), mass spectrometry and combustion analysis (C, H, N).

introduced herein are currently being screened for antiviral and antibacterial activity.

The described transformation provides a general access to a novel class of nucleoside analogues called β-lactam nucleoside chimera. The starting materials, which include natural and non-naturally-substituted nucleobase aldehydes and β-amino acids, are readily available in few steps and in a wide variety from commercially available compounds.[10, 12] We could furthermore establish that slightly modified β-lactam nucleoside chimera can also be used for the rapid and efficient construction of PNA-analogous (PNA = peptide nucleic acid) oligomers.[13] This work will be reported shortly.

Experimental Procedure

1 (1 mmol scale): Methyl isocyanide (0.1 mL) was added to a suspension of β-alanine (89 mg) and 1-thyminyl acetaldehyde hydrate (186 mg) in anhydrous methanol (20 mL) at 0 °C, and the reaction mixture was subsequently stirred for 72 h at room temperature. The solution became clear after several hours, and turned cloudy after 48 h. After 72 h, half of the solvent was removed, and the remaining solution placed into a refrigerator. The precipitated product was filtered and dried to obtain 270 mg of a colorless powder. Compounds **2**–**4** were prepared analogously.

A New Method for the Preparation of Nanostructured Metal Clusters

Manfred T. Reetz* and Stefan A. Quaiser

Nanostructured metal clusters and colloids are of interest as catalysts for organic and inorganic reactions, as electrocatalysts in fuel cells, and as components for materials with special electronic, optical, or magnetic properties.[1, 2] They are usually prepared by chemical reduction of metal salts. In order to prevent undesired agglomeration with formation of either large metal particles in the micrometer range or metal powders, stabilizers such as special ligands,[3] polymers,[4] or tetraalkylammonium salts[5] generally need to be used. Nevertheless, high yields, simple isolation and purification, and control of the cluster size is only seldom possible.[6] Recently we described an electrochemical process by which metal foils are anodically dissolved, and the metal salts formed as intermediates are cathodically reduced with quantitative formation of metal clusters stabilized by tetraalkylammonium salts.[7, 8] Besides the simple isolation and the high purity of the clusters, another advantage is the control of particle size (1–10 nm) by adjusting the current density, that is, the overpotential. Tetraalkylammonium salts serve simultaneously as supporting electrolyte and stabilizer for the cluster. Though this method can be employed for relatively easily oxidizable metals (for example, Pd, Ni, Cu, Au, etc.),[7, 8] for anodically less readily soluble metals like Pt, Rh, Ru, and Mo it functions poorly or not at all. This is unfortunate, because precisely these metals are of interest as potential catalysts.

We now report a solution to this problem based on the use of metal salts.[9] Initially a mixture of $PtCl_2$ and $(NR_4)Br$ in acetonitrile/THF (1:3) was electrolyzed in a simple electrolysis cell[10] consisting of a Pt anode and a Pt cathode. Unfortunately, only a small amount of Pt-containing material was formed, which was difficult to isolate. Because the oxidation process at the anode (for example, $Br^- \rightarrow Br^{\cdot}$) possibly caused problems, in a renewed attempt we used $PtCl_2$ as the metal source and $(NR_4)OAc$ as the supporting electrolyte and stabilizer, in the hope that the Kolbe electrolysis would ensure the chemical "disposal" at the anode (Scheme 1).

Cathode: $Pt^{2+} + 2e^- \longrightarrow Pt^0$

Anode: $2\,CH_3CO_2^- \longrightarrow 2\,CH_3CO_2^{\cdot} + 2e^-$

Scheme 1.

Indeed, this strategy led to the successful electrochemical reduction of $PtCl_2$, with nearly quantitative formation of Pt clusters. The average size of the clusters was determined by high resolution transmission electron microscopy (HRTEM) on 100 to 200 particles (Table 1). The same result was achieved with $RhCl_3/(Bu_4N)OAc$. Under these conditions, the $(Bu_4N)OAc$-stabilized Pt clusters precipitate as solids that can be conveniently isolated by decantation and washing (for example with ether), and when required, redispersed in DMF (up to 1 M solution). Other metals that are not easily oxidized can also be employed, for example, salts of osmium or ruthenium (Table 1). Furthermore, if metal carboxylates are used as the metal source, completely halide-free, stabilized metal clusters are obtained. Because the electrolysis also works with easily oxidizable metals like palladium, this new method is more general than our first process based on sacrificial metal anodes.[7, 8] If the betain 3-(dimethyldodecylammonio)propanesulfonate[7] is used as stabilizer (solvent H_2O or H_2O/THF), a very readily water-soluble metal cluster results (Fig. 1), which is of great industrial interest. For example, 6 nm large, betain-stabilized Pt clusters can be prepared as 1 M solutions in water.

Table 1. Metal clusters prepared by electrochemical reduction of metal salts (electrolyte: 0.1 M $(n\mathrm{Bu_4N})OAc$/THF). d = average diameter, EA = elemental analysis.

Metal salt	d [nm]	EA [a]
$PtCl_2$	2.5 [b]	51.21% Pt
$PtCl_2$	5.0 [c]	59.71% Pt
$RhCl_3 \cdot x\,H_2O$	2.5	26.35% Rh
$RuCl_3 \cdot x\,H_2O$	3.5	38.55% Ru
$OsCl_3$	2.0	37.88% Os
$Pd(OAc)_2$	2.5	54.40% Pd
$Mo_2(OAc)_4$	5.0	36.97% Mo
$PtCl_2 + RuCl_3 \cdot x\,H_2O$	2.5	41.79% Pt + 23.63% Rh [d]

[a] Based on stabilizer-containing material. [b] Current density: 5.00 mA cm^{-2}. [c] Current density: 0.05 mA cm^{-2}. [d] Pt–Rh dimetallic cluster.

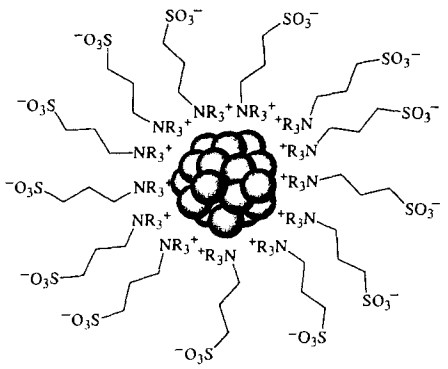

Fig. 1. Schematic view of a betain-stabilized, water-soluble metal cluster.

Preliminary experiments to control the cluster size by means of current density[7] were also successful. The higher the current density, the smaller the cluster (Table 1). The structure of the metal clusters is a spherical "metal core" surrounded by tetraalkylammonium salt that functions as a stabilizing mantle. Recently we were able to visualize such protective mantles of differently sized Pd clusters for the first time by means of the combination of HRTEM and scanning tunneling microscopy (STM).[11, 12]

If two metal salts are employed, for instance $PtCl_2$ and $RhCl_3$, dimetallic clusters are obtained (Table 1). Dimetallic clusters are also accessible by a combination of both electrochemical methods. In this synthetically useful variation the oxidative process at the anode corresponds to the dissolution of the metal sheet (Table 2).

Table 2. Dimetallic clusters prepared by electrochemical reduction of metal salts at sacrificial anodes (electrolyte: 0.1 M $(n\mathrm{Bu_4N})OAc$/THF). d = average diameter, Stoich. = stoichiometry.

Anode	Metal salt	d [nm]	Stoich. (EDX)
Sn	$PtCl_2$	3.0	$Pt_{50}Sn_{50}$
Cu	$Pd(OAc)_2$ [a]	2.5	$Cu_{44}Pd_{56}$
Pd	$PtCl_2$	3.5	$Pd_{50}Pt_{50}$

[a] Electrolyte: 0.1 M $(n\text{-octyl}_4\mathrm{N})OAc$/THF.

The use of a sacrificial tin electrode, for example, and $PtCl_2$ as the second metal component, in the presence of $(Bu_4N)Br$ as electrolyte and stabilizer, yields 3 nm large Pt–Sn clusters, whose Pt:Sn ratio is shown to be about 1:1 by the *e*nergy *d*ispersive *X*-ray (EDX) spot analysis of individual particles (Fig. 2). To prove the crystalline character of the dimetallic particles, a solution of the sample was first dip-coated onto a holey carbon grid on a copper net. Some clusters remain hanging on the edge of the grid and enable distinct visualization by a high-resolution TEM image (Fig. 3). The diffraction planes are clearly recognizable.

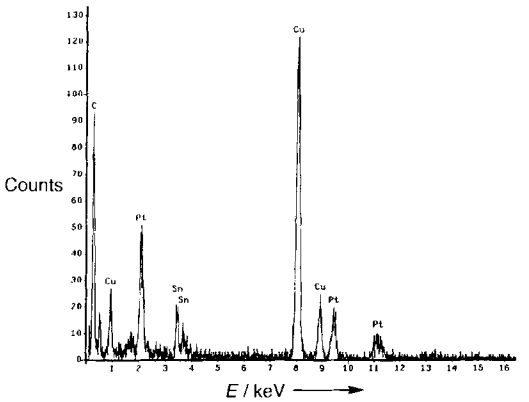

Fig. 2. EDX spectrum of a Pt–Sn dimetallic cluster (copper signals originate from the support net, carbon signals from the carbon grid and stabilizer).

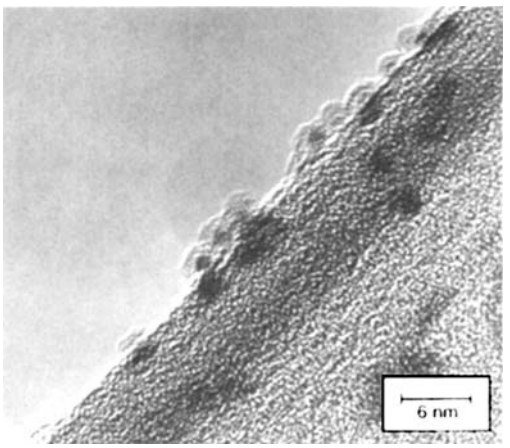

Fig. 3. HRTEM image of Pt–Sn dimetallic clusters (on the edge of a carbon grid).

To prepare supported metal clusters, solids like activated carbon or SiO_2 can be used as suspensions in the electrolysis cell. The clusters are immobilized in situ. Significantly, the size of the metal clusters is not affected by the process. Alternatively, the metal clusters can be conveniently immobilized on solid supports after synthesis: for example, if activated carbon is treated with the black aqueous solution of betain-stabilized Pt clusters (about 6 nm diameter), the metal clusters deposit quantitatively on the solid support within five hours. Simple decantation of the water and washing of the solid material affords the carrier-supported clusters and a colorless, metal-free, aqueous phase that contains about 90% of the betain. The adhesion between carrier and metal cluster is very strong, but no undesirable particle agglomeration occurs. Besides the conventional solid supports, materials like electrically conducting SnO_2 layers are also suitable for coating.

Experimental Procedure

Typical procedure: A solution of tetra-*n*-butylammonium acetate (0.1 M) in THF (90 mL) was placed in a universal electrolysis cell capable of holding 20–100 mL electrolyte. Two pure platinum sheets (3×3 cm^2 surface area, 0.5 mm thickness) about 5 mm apart served as electrodes. All operations were performed under inert atmosphere (argon or nitrogen). Palladium acetate (500 mg) was dissolved in the electrolyte with stirring, and a current of 5 mA was applied and increased to 30 mA within 10 min. The electrolysis cell was kept at 20 °C by means of a cooling mantle. During the course of the electrolysis the electrolyte became dark brown, and a black precipitate formed. After a current flux of 450 C the electrolysis was stopped, and the light brown supernatant was removed by pressure of inert gas. The precipitate was washed with two portions (10 mL each) of diethyl ether and dried under oil pump vacuum. A gray-black solid (406 mg) was obtained; particle size 2.5 nm; metal content according to elemental analysis: 54% palladium, based on stabilizer-containing material.

A Novel Hexanuclear Fe^{III}-*cis*-Inositolato Complex as a Model for Fe^{III}–Polyol Interactions in Aqueous Solution**

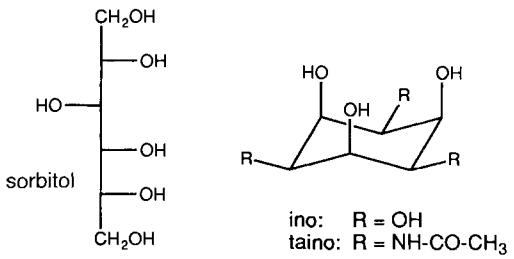
Kaspar Hegetschweiler,* Lorenza Hausherr-Primo, Willem H. Koppenol, Volker Gramlich, Léon Odier, Wolfram Meyer, Heiner Winkler, and Alfred X. Trautwein

It has been known for some time now that sugars, sugar alcohols, and sugar acids can effectively prevent the precipitation of only slightly soluble metal hydroxides in aqueous solution.[1] If alkali is added to a solution of a metal salt in the presence of a polyol, depending on the selected conditions, soluble polyolato metalates or solid metal polyolates can be obtained.[2] The hydrolytic polymerization of the metal cations can often be observed as a competitive reaction, although a combination of both reactions (that is, the formation of oxo- or hydroxo-bridged multinuclear polyolato complexes) can take place.[3] These compounds are of great interest, in particular with regard to the synthesis of new materials (sol–gel technology).[4]

The structures of many of the metal polyolates are not known as these compounds often crystallize poorly and are amorphous. We have now been able to obtain crystals of the potassium salt of the polyolato(oxo)iron complex **1** (which is stable in water) with the composition K_5-**1**$\cdot 14.5H_2O$ and to characterize it by

$K_5[OFe_6\{(ino)_6\text{-}2\,1H\}]\cdot 14.5H_2O$ $\quad$ K_5-**1**$\cdot 14.5H_2O$ (ino = *cis*-inositol)

means of X-ray structure analysis[5] and by magnetic susceptibility measurements.[6] The complex anion **1** containing the sorbitol ligand (depicted in Scheme 1) fits into a continually growing series of multinuclear Fe^{III} complexes, which are of interest as model compounds for proteins, such as ferritin.[7]



Scheme 1. Structural formulas of the ligands used here.

[**] Metal Complexes of Polyalcohols, Part 3. This work was supported by the company Vifor (International), St. Gallen, Switzerland, and by the BMFT (Project 05 5FLAXI4). We would like to thank Prof. S. J. Angyal, Sydney, Australia, for valuable suggestions, and Dr. H.-F. Nolting from the EMBL-Aussenstelle Hamburg for his helpful support. Part 2: L. Hausherr-Primo, K. Hegetschweiler, H. Rüegger, L. Odier, R. D. Hancock, H. W. Schmalle, V. Gramlich, *J. Chem. Soc. Dalton Trans.* **1994**, 1689–1701.

If two equivalents of *cis*-inositol are added to an aqueous solution of $FeCl_3$, and the mixture is subsequently neutralized with KOH, a pale yellow and barely soluble solid is initially obtained at pH = 7. This redissolves in alkaline medium to give a deep brown solution. We assume that the yellow compound is an uncharged mononuclear dipolyolato complex,[8] which then slowly reacts to give the hydrolysis product **1** described. The complex **1** is stable in water between pH 8 and 10.

The structure of **1** has no point symmetry, and the Fe_6O_{22} core can be considered a random netlike aggregate of FeO_x polyhedra (x = 5, 6). Though edge-bridged octahedra dominate in the structure, polyhedra with common faces or common apices also occur (Fig. 1). The pentacoordinate Fe(1) atom is located at the center of a distorted square pyramid;[9] the other Fe atoms are in a distorted octahedral environment. The central μ_3-oxo ligand bridges three of the six Fe centers. The remaining bridges are exclusively the eleven μ_2-alkanolato groups of the peripheral *cis*-inositol ligands, which provide an additional ten oxygen atoms for terminal coordination. All the hydroxy groups deprotonate on coordination.

The interactions between the metal ions and the ligands do not allow the recognition of a consistent coordination principle either. Binding of the iron ions to the *syn*-triaxial coordination site of the inositol ligand dominates, but a series of other structural elements can also be observed. It is striking that all the ligands are bound to several iron ions; two, three, and even four iron ions are simultaneously coordinated to a single ligand. Conversely, *cis*-inositol can act as a mono-, bi-, or tridentate ligand. In one case one ligand is coordinated in a tridentate fashion to two iron ions simultaneously; one iron center occupies the *syn*-triaxial binding site and the other the axial–equatorial–axial binding site.

The six *cis*-inositol ligands obviously shield the periphery of the complex so efficiently that no further aggregation can occur. When treated with Fe^{III} ions, the open-chain sugar alcohol sorbitol (Scheme 1) forms only low-molecular-weight complexes when the solution is strongly alkaline. If the pH is lowered to about 8, a continuous aggregation results, which finally leads to the formation of brown gels.[10] An EXAFS measurement[11] on the sorbitol complex **2**—which has a similar hydrodynamic radius[10]

$Na_x[Fe_xO_{2x}(sor)_x]$ **2**, sor = sorbitol $(5 \le x \le 8)$

to **1**—shows, however, that the two complexes have analogous local structures (Table 1). The magnetic properties of **1** and **2** are also similar between 10 and 250 K.[6]

When 1,3,5-triacetamido-1,3,5-trideoxy-*cis*-inositol (taino, Scheme 1) is treated with Fe^{III} ions in aqueous solution, the mononuclear complex **3** is formed exclusively. This complex was

$[Fe\{(taino)_2\text{-}3H\}]$ **3**

insoluble at pH = 7, and was isolated and structurally characterized.[8] The complex **3** can be readily dissolved in alkaline media; the pale yellow solutions are stable. The formation of multinuclear hydrolysis products has not been observed. In the series **3** → **1** → **2**, the number of the possible metal–ligand interactions increases drastically. The *cis*-inositol ligand is obviously just rigid enough to form a definite, stable hexanuclear complex. In the case of polyol ligands with a greater number of degrees of freedom, a large number of energetically almost equivalent structures can form; this hinders the crystallization process considerably.

In previous publications the Fe-(μ-OH)$_2$-Fe complex fragment has been postulated as a bridging unit for multinuclear polyolatoiron complexes.[12] The short Fe–Fe distance of 285(3) pm[13] in **2** is incompatible with this structural unit.[14] However, it falls within the same region as the Fe(3)–Fe(6)

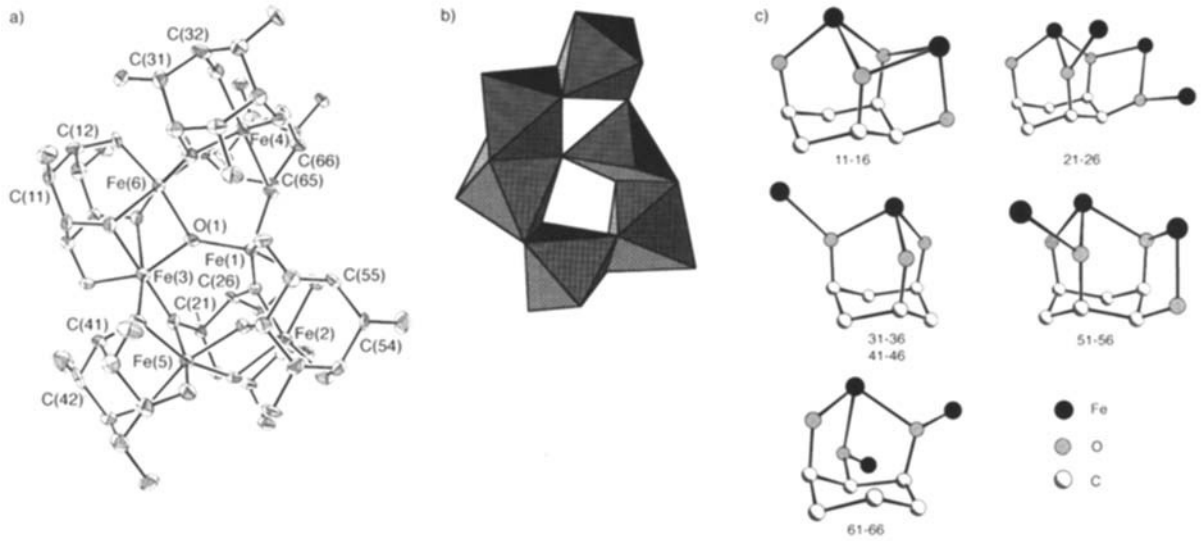

Fig. 1. Structure of $[OFe_6\{(ino)_6-2\,H\}]^{5-}$ (**1**). a) ORTEP representation of the complex anion with numbering scheme. The oxygen atoms of the inositol ligands are labeled O(11) O(66) in accordance with the C atoms of the cyclohexane ring to which they are bound. The thermal ellipsoids represent 50 % probabilities of occupation. b) Representation of the cyclic Fe_6O_{22} core. c) Individual Fe-inositol interactions (noncoordinated hydroxy groups are not shown). The numbering of the ligands is as in a). The average Fe–O distance is 197 pm at the pentacoordinate Fe(1), considerably shorter than at the hexacoordinate iron centers (202 pm). Fe–Fe distances [pm]: Fe(1)-Fe(2) 298.3(2), Fe(1)-Fe(3) 350.5(2), Fe(1)-Fe(4) 367.0(2), Fe(1)-Fe(6) 350.4(2), Fe(2)-Fe(5) 324.2(2), Fe(3)-Fe(5) 310.8(2), Fe(3)-Fe(6) 280.4(2), Fe(4)-Fe(6) 313.8(2). Average Fe–O bond lengths [pm]: $Fe-O_{oxo}$ 192.4, $Fe-O_{term}$ 192.9, $Fe-O_{br}$ 206.6.

Table 1. Averaged coordination numbers of the Fe atoms (N), mean Fe–O and Fe–Fe distances (R), and mean static and dynamic displacement parameters (σ) from the X-ray structure analysis of **1** and the EXAFS measurements [11, 13] of **2**. The average standard deviations are 1 pm for the Fe–O distances and 0.2 pm for the Fe–Fe distances in **1** (X-ray diffraction), and 2 pm and 3 pm respectively for the corresponding distances in **2** (EXAFS measurement).

Sample	**1**			**2**	
Fe-O					
N	2.0	3.83 [a]		2	4
R (pm)	192	206		194	202
σ (pm)	3	8		6	11
Fe-Fe					
N	0.67	1.0	1.0	1	1
R (pm)	290	316	356	285	312
σ (pm)	8	6	8	8	8

[a] This value results from an average of five hexacoordinate Fe centers and one pentacoordinate Fe center.

distance of 280.4(2) pm in **1** (octahedra with common face) and thus could indicate a multiple μ-alkanolato bridging mode in which the Fe atoms are bound to the same ligand. The structural properties of **1** thus permit a valuable insight into the build-up of polyolatoiron compounds.

[5] The dark brown triclinic crystals were obtained at pH = 9 by covering an aqueous solution with a layer of ethanol. Water of crystallization was lost on contact with air, so the crystals were measured in a glass capillary: space group $P\bar{1}$ (No. 2), $a = 1273.0(3)$, $b = 1385.0(3)$, $c = 1974.3(4)$ pm, $\alpha = 90.65(3)$, $\beta = 93.29(3)$, $\gamma = 112.34(3)$°, $V = 3212(1) \times 10^6$ pm^3, $Z = 2$, $Mo_{K\alpha}$ radiation, graphite monochromator, four-circle diffractometer Picker-Stoe, $2\theta = 3$–40°, **6019 reflections measured, 5982 independent, of which 4305 with $I > 2\sigma(I)$ were used for the refinement of 901 parameters. Structure solution using direct methods, numerical absorption correction. All non-hydrogen atoms were refined anisotropicically (least-squares, full matrix). The H(–C) positions were taken from the difference Fourier map, but not refined, however. $R = 0.0471$, $R_w = 0.0520$. Residual electron density + 0.68/–0.80 e A^{-3}. Further details of** the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ, on quoting the full literature citation.
[6] The magnetic susceptibility measurements were carried out on a polycrystalline sample of the inositol complex **1** and on a frozen solution of the sorbitol complex **2** using a SQUID magnetometer. For **1** it was found that $\mu_{eff} = 10.8\ \mu_B$ (250 K) and $10.0\ \mu_B$ (10 K). This result indicates at $S = 5$ ground state. Analogously, it was found for **2** that $\mu_{eff} = 11.8\ \mu_B$ (250 K) and $10.0\ \mu_B$ (10 K). The magnetic moments given are based on iron hexamers. This assumption is confirmed in the case of **1** by the crystal structure determination, whereas in the case of **2** it is supported by laser light scattering measurements [10]. It is quite possible that the sorbitol solution contains a great variety of species; the agreement of the two sets of results, however, indicates an analogy in the magnetic coupling structure too.

[13] The determination of the Fe–Fe distances is difficult, because several C atoms are situated at similar distances as those of the Fe neighbors. Differentiation between the different types of atoms is possible, however, because the amplitude of the back scattering as a function of the wave number k passes through a maximum at about $k = 0.08$ pm^{-1} in the case of Fe, whereas it decreases continuously in the case of C.
[14] A series of dinuclear Fe^{III} complexes with a μ-oxo bridge (Fe–Fe: 339–356 pm) or a μ-dihydroxo bridge (Fe–Fe: 308–316 pm) were structurally characterized. See for example: D. M. Kurtz, *Chem. Rev.* **1990**, *90*, 585.

Bis(trifluoromethyl)trioxide: First Structure of a Straight-Chain Trioxide**

Karina I. Gobbato, Martin Frank Klapdor, Dietrich Mootz, Wolfgang Poll, Sonia E. Ulic, Helge Willner, and Heinz Oberhammer*

Dedicated to Professor Herbert W. Roesky on the occasion of his 65th birthday

Straight-chain polyoxygen compounds of the type R_2O_n ($n = 1, 2, 3, 4 \ldots$) become less stable with increasing chain length. The parent compounds H_2O_n are of general and theoretical interest.[1] Numerous compounds of the type R_2O_2 are known, but polyoxygen compounds with $n \geq 3$ were reported almost exclusively with R = F, SF_5, alkyl, or perfluoroalkyl groups. At room temperature only trioxides with perfluoroalkyl groups can be isolated. The simplest derivative of this class of compounds, bis(trifluoromethyl) trioxide, CF_3OOOCF_3, which was reported for the first time in 1963[2] and isolated as pure substance shortly after,[3] is the best characterized trioxide. The colorless gas with a boiling point of $-16\,^{\circ}C$ and melting point of $-138\,^{\circ}C$ decomposes at room temperature within months to give CF_3OOCF_3 and oxygen.[3] Vibrational,[3,4] NMR,[3] mass,[3] and X-ray photoelectron spectra (XPS)[5] of this interesting compound are known, but the molecular structures of this and any other covalent straight-chain trioxide[6] have not been determined unequivocally. The result of an electron diffraction study of a mixture of CF_3OOCF_3 and CF_3OOOCF_3 appears to be uncertain,[7] as demonstrated by a later investigation of CF_3OOCF_3.[8] We therefore decided to synthesize this trioxide again and to determine its structure in the gas phase by electron diffraction and in the crystalline state by X-ray diffraction. The experimental studies are supplemented by ab initio calculations. The derived structural parameters are listed in Table 1.

Analysis of the radial distribution curve of CF_3OOOCF_3 (Fig. 1), calculated by Fourier transform of the molecular intensities, yields a skew structure with *trans* orientation of the two CF_3 groups (C_2 symmetry). This result agrees with the interpretation of Raman spectra,[4b] but is in contrast to the interpretation of IR spectra, which indicate C_1 symmetry.[4c] In the least-squares refinement local C_{3v} symmetry was assumed for the CF_3 groups with a possible tilt angle between the C_3 axis and the O–C bond. The fit of the experimental molecular intensities improves slightly if a small amount of impurity (5% CF_3OOCF_3), which was observed immediately after the synthesis, is taken into account in the structure analysis.

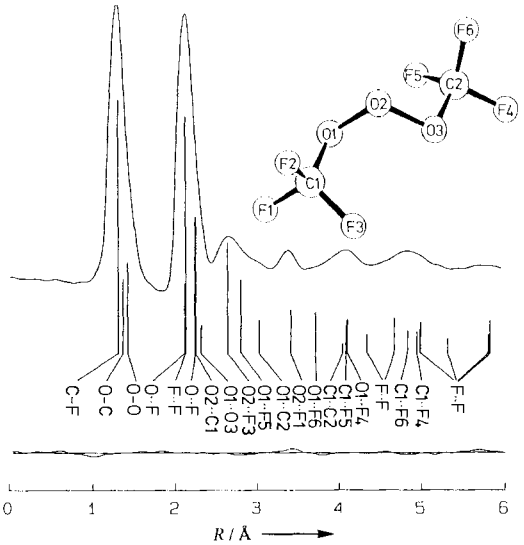

Fig. 1. Experimental radial distribution function and difference between experimental and calculated curve. The positions of interatomic distances are indicated by vertical bars.

Table 1. Experimentally and theoretically determined structural parameters of CF_3OOOCF_3.

In the crystal (unit cell in Fig. 2), the asymmetric unit comprises a whole molecule, twisted as in the gas phase and with a *trans* orientation of the CF_3 groups. Deviations from C_2 symmetry are only small. As an example, the dihedral angles C1-O1-O2-O3 and O1-O2-O3-C2 have been determined independently, but the obtained values of 96.8(1) and 95.1(1)° are quite similar. The same holds for the individual values of other geometric parameters (only their averages are listed in Table 1), as well as for the dihedral angles F1-C1-O1-O2 and O2-O3-C2-F4 of 178.1(1) and 176.7(1)°. These dihedral angles show that the *trans* position (antiperiplanar orientation) of the F atoms with respect to the central O2 is almost ideal. The distinct widening of all bond

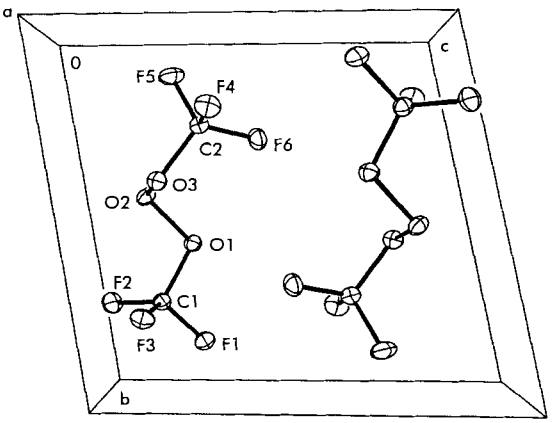

Fig. 2. Unit cell of a crystal of $CF_3COOOCF_3$ with two molecules (ellipsoids represent 25% probability; viewed down the x axis).

angles F-C-O when the F atom is *gauche* rather than *trans* (mean values 112.1(1) and 104.7(1)°, tilt angle $\alpha(CF_3) = 5.0(2)°$) correlates with the smallness of the nonbonding intramolecular distances: F(*gauche*) $\cdots$ O2 mean value: 2.65(3) Å; for F(*trans*) $\cdots$ O2: 3.399(2) Å.

Although systematic differences exist between structural parameters for the gaseous and crystalline state, the agreement of the results obtained with electron and X-ray diffraction is very good. In particular the bond angles and the O-O-O-C dihedral angle, which are most easily affected by packing effects in the crystal,[9] possess identical values within experimental uncertainties in both phases. The good agreement of the geometric parameters optimized with the HF/3-21G method with the experimental values is most likely due to a fortuitous compensation of several inadequacies of this method. Ab initio calculations for HOOOH with different basis sets result in O–O bond lengths between 1.373 and 1.539 Å.[10] The HF/3-21G calculations for CF_3OOOCF_3 predict the existence of a second stable conformer with *cis* orientation of the two CF_3 groups (C_s symmetry), 3.3 kcal mol^{-1} higher in energy.

The O–O bond in CF_3OOOCF_3 is slightly shorter than that in hydrogen peroxide (1.464 Å[10]), but longer than that in CF_3OOCF_3 (1.419(20) Å[8]). As expected, this distance is longer than in ozone (1.2716(2) Å[11]) or in the O_3^- ion (1.29–1.35 Å[12]). The O-O-O bond angle in the trioxide is smaller than a tetrahedral angle and considerably smaller than in O_3 (117.79(3)°) or in O_3^- (113–119°). The O-O-O-C dihedral angle is larger than the predicted value for HOOOH of about 80°,[11] but distinctly smaller than the C-O-O-C angle in CF_3OOCF_3 (123.3(40)°[8]). A value similar to that in the trioxide was observed for the S-S-S-C angle in CF_3SSSCF_3 (89(3)° in the gas[13] and 88.5(1)° in the crystal[14]).

Experimental Procedure

Caution: CF_3OOOCF_3 is potentially explosive, especially in the presence of organic or oxidizable materials. It should be handled only in millimolar quantities and with proper safety precautions. The synthesis was performed according to a modified literature method [15]. A 4 L round-bottomed flask, equipped with a water-cooled high-pressure mercury lamp (TQ150, Heraeus) at its center, was filled with a mixture of 100 mbar $CF_3C(O)CF_3$ (ca. 16 mmol), 200 mbar F_2, and 300 mbar O_2. After 24 hours photolysis, excess F_2 and O_2 was pumped off at −196 °C, and the residue fractionated in vacuo through a series of traps held at −80, −120, and −196 °C. In the trap at −120 °C CF_3OOOCF_3 was collected, which after repeated fractionation contained as the only impurity 5% CF_3OOCF_3, as determined by IR and ^{19}F NMR spectroscopy. Yield 1.2 g (6.5 mmol).

The electron diffraction intensities were recorded with a Gasdiffraktograph KD-G2 at nozzle-to-plate distances of 25 and 50 cm and with an accelerating voltage of ca. 60 kV. The electron wavelength was calibrated with ZnO powder. The temperature of the sample reservoir was −90 °C, that of the inlet nozzle 15 °C. The photographic plates were analyzed with the usual methods [16] and scattering intensities in the s ranges 2–18 and 8–35 Å^{-1} ($s = (4\pi/\lambda)\sin\theta/2$, λ = electron wavelength, θ = scattering angle) were used in the structure analysis.

Crystal growth was performed from the melt in a thin-walled quartz glass capillary. The sample was cooled at a rate of 1 °C min^{-1} in the cold gas stream of a diffractometer (Siemens/Stoe AED2) equipped for work at low temperatures; $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), graphite monochromator, Ω-θ scan, $2\theta_{max} = 65°$, $T = -170$ °C; space group $P\bar{1}$, $Z = 2$; $a = 4.810(2)$, $b = 7.477(4)$, $c = 7.993(4)$ Å, $\alpha = 78.91(3)$, $\beta = 86.12(3)$, $\gamma = 83.49(3)°$, $V = 280.0(2)$ Å^3. The structure was solved by direct methods with SHELXS-86 [17], and refined with 2026 independent $|F_o|^2$ values (of these 1763 with $|F_o| > 4\sigma_F$ were classified as observed) with SHELXL-93 [18]: $R(F^2) = 0.146$ with all and $R(F) = 0.048$ only with the observed reflections. The residual electron density was between −0.33 and 0.48 e Å^{-3}. The program SHELXTL PLUS [19] was used to draw the crystal structure (Fig. 2). Further details of the crystal structure investigation are available on request from Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) by quoting the depository number CSD-401780.

Electronically Tuned *trans* Labilization Controls the Substitution Behavior of Rhodoximes**

Carlos Dücker-Benfer, Renata Dreos, and Rudi van Eldik*

Substitutions of axial ligands of alkyl(aqua)bis(dimethylglyoximato)rhodium(III) complexes were studied in earlier reports [Eq. (a); Hdmg = dimethylglyoximate anion].[1–6] The reactivity of the rhodium complexes shows a strong dependence on the nature of the alkyl substituent R. The lability of these complexes is affected by the size of the alkyl group and the electronic

$$trans\text{-}[Rh(Hdmg)_2(R)(H_2O)] + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} trans\text{-}[Rh(Hdmg)_2(R)L] + H_2O \quad (a)$$

state of the nonlabile ligands. In all cases the reaction rate is nearly independent of the nucleophilicity of the incoming ligand. This observation as well as the thermal activation parameters suggest a dissociative interchange mechanism. The high lability of these complexes results from two effects, namely, the *trans* in-

fluence of the R group and the labilizing effect of the equatorial chelating ligands.

In an effort to obtain more insight into the transition state and the intimate mechanism of reaction (a), we have studied the pressure dependence of the substitution process for different substituents R and ligands L. The results demonstrated an unexpected changeover in mechanism controlled by the nature of the alkyl group R.

The kinetics of reaction (a) were studied at ambient pressure before.[1-3] The observed rate constants did not show a significant dependence on the nature of the entering ligand. In all cases the calculated activation entropies were significantly negative. We found a linear dependence of k_{obs} on ligand concentration in the presence of an excess of ligand for all reactions studied [Eq. (b)]. Only in the case of $L = I^-$ could a significant y-inter-

$$k_{obs} = k_1[L] + k_2 \qquad (b)$$

cept, k_2, due to the back reaction be observed. The rate constants at ambient conditions were in good agreement with those reported before.[1-3]

The pressure dependence of k_1 was estimated from the pressure dependence of k_{obs} at constant ligand concentration, except for $L = I^-$, where the dependence of the rate on the ligand concentration was studied in detail as a function of pressure. In the

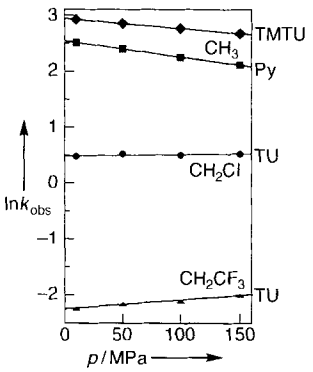

Fig. 1. Pressure dependence of k_{obs} for reaction (a). TU = thiourea, TMTU = tetramethylthiourea, py = pyridine, p = pressure. Experimental conditions: $[Rh] = (2-4) \times 10^{-4}$ M, $[L] = (5-10) \times 10^{-3}$ M, pH = 7.0 (phosphate buffer), ionic strength $I = 1.0$ M ($NaNO_3$), $T = 293$ K.

latter case k_1 and k_2 were determined from plots of k_{obs} versus $[I^-]$ [see Eq. (b)] as a function of pressure. Plots of $\ln k_1$ and $\ln k_2$ versus pressure were linear in all cases (see some typical examples in Fig. 1). The volumes of activation $\Delta V^{\neq}$, calculated from these plots in the usual way, are summarized in Table 1 together with the rate constants at ambient pressure and thermal activation parameters.

There is a definite trend in the $\Delta V^{\neq}$ data: the values are significantly positive for the faster substitution reactions ($R = CH_3$), but significantly negative for the slower substitution reactions ($R = CH_2CF_3$). This trend correlates well with the *trans* influence of the R groups in the ground state as observed for a series of pyridine (py) complexes.[4, 6] The Rh–py bond length decreased (222, 217.8, 214.5 pm) for $R = CH_3$, CH_2Cl, and CH_2CF_3.[4, 6] A similar trend is expected for the Rh–O bond in the corresponding aqua complexes studied here: faster reactions are thus associated with the stronger *trans* effect of the methyl group, and slower reactions with the weaker *trans* effect of CH_2Cl and CH_2CF_3. Furthermore, the *trans* labilization by R directly determines the nature of the ligand substitution mechanism. The stronger donor properties of CH_3 result in a dissociative substitution process as characterized by the significantly positve $\Delta V^{\neq}$ values. Similary, the weaker donor properties of CH_2CF_3 favor a more associative substitution mechanism as shown by the significantly negative $\Delta V^{\neq}$ data. The absolute magnitude of $\Delta V^{\neq}$ is such that the reactions are most probably of the interchange (I_d versus I_a) type, respectively.[7] Thus the transition state for such a ligand substitution process can be visualized as in Figure 2. Here both the degree of bond breakage ($Rh-OH_2$) and the degree of bond formation (Rh–L) are controlled by the donor properties of R.

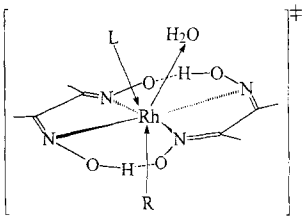

Fig. 2. A closer view of the transition state. R = CH_3, CH_2Cl, CH_2CF_3.

For the substitution reaction with iodide it was possible to measure $\Delta V^{\neq}$ for the forward and the reverse reactions [Eq. (c)],

$$trans\text{-}[Rh(Hdmg)_2(CH_3)(H_2O)] + I^- \rightleftharpoons trans\text{-}[Rh(Hdmg)_2(CH_3)(I)]^- + H_2O \qquad (c)$$

and these data enabled us to construct a volume profile for the overall process (Fig. 3).

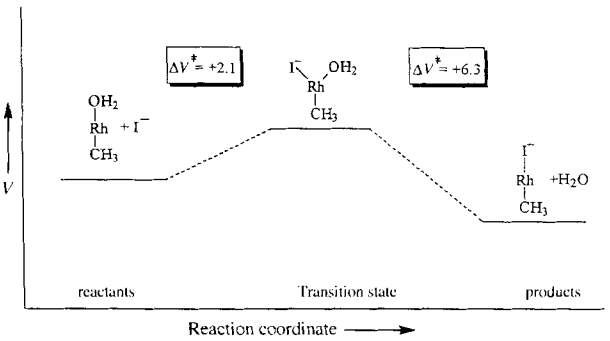

Fig. 3. Volume profile for reaction (c). V = relative partial molar volume in $cm^3\ mol^{-1}$. Experimental conditions: $[Rh] = 2 \times 10^{-4}$ M, $[L] = (5-10) \times 10^{-3}$ M, pH = 7.0 (phosphate buffer), $I = 1.0$ M ($NaNO_3$), $T = 282$ K.

The profile clearly demonstrates that the partial molar volume of the transition state is significantly larger than that of either the reactant or the product states. The *trans* labilization by the methyl group controls the dissociative nature of both the forward and reverse reactions. The more positive volume of activation for the release of I^- relative to the release of H_2O is probably related to the significantly larger partial molar volume of I^- and to the effect of electrostriction on the complex due to the charged ligand. The $\Delta V^{\neq}$ values support the assumption of an I_d mechanism.[7, 8]

A comparison of the activation parameters in Table 1 clearly shows that the $\Delta S^{\neq}$ values are all negative and suggest the operation of an interchange (I) mechanism, but they do not allow a further distinction to be made between an I_a or I_d mechanism. It is generally known that entropies of activation are intrinsically subject to large error limits due to the extrapolation required to determine these values. In contrast, volumes of activation are determined from the initial slope of a plot of $\ln k$ versus pressure and are in general subject to significantly smaller error limits.[7] Thus a too detailed interpretation of activation entropy data can be rather misleading. Similar conclusions have been reached in earlier kinetic studies dealing with the evaluation of thermal and pressure activation parameters.[7] The mechanistic changeover only shows up clearly in the $\Delta V^{\neq}$ data, and can be directly correlated with the donor properties of R, which in turn control the magnitude of the rate constants.

Volume of activation data have only been measured for a limited number of reactions that involve activation of metal–carbon bonds. In the case of square-planar Pt^{II} complexes, the introduction of a single Pt–C bond increases the lability of the metal center by five orders of magnitude, but does not cause a changeover in mechanism.[9] The introduction of a CMe_5 ligand onto the metal center leads to a tremendous labilization in the case of Rh^{III} and evidence for an I_d mechanism was reported.[10] For comparison, solvent exchange and ligand substitution reactions of $[Rh(NH_3)_5(OH_2)]^{3+}$ are extremely slow and follow an I_a mechanism.[11] Thus the introduction of the carbon bond in *trans* position (ligand R), as well as the dimethylglyoximate chelates in the present system, cause a significant labilization of Rh^{III} and even leads to a mechanistic changeover from I_a to I_d.

The mechanistic fine tuning caused by the nature of the R group is rather surprising. It is generally known that such groups labilize the *trans* position, and it was therefore logical to suggest the operation of an I_d mechanism previously.[1–3] However, our present results demonstrate very clearly that the labilization effect strongly depends on the donor properties of R. These properties are, for instance, controlled by electron-withdrawing substituents on R and can control the nature of the substitution mechanism. We conclude on the basis of these results that the substitution behavior of rhodoximes and related complexes is controlled by an electronically tuned labilization effect.

Experimental Procedure

All complexes were prepared by published methods [1–3]. Millipore water was used in the preparation of all solutions. All other materials were p.a. grade and used without further purification, except for pyridine, which was distilled before use. Kinetic measurements at ambient pressure were performed on a Durrum D 110 or a Biologic SFM-3 stopped flow instrument and those at elevated pressure on a homemade high-pressure stopped flow [11]. The temperature of all instruments was controlled to within 0.1 °C. For the analysis of the kinetic data we used the OLIS KINFIT set of programs [12].

The kinetic measurements were performed under pseudo-first-order conditions at 1 M *ionic strength* ($NaNO_3$). Solutions of the ligand and the complexes were buffered with phosphate at pH = 7. The rate of the reaction is independent of the pH in this range [2]. The pK_a values for the different complexes are 9.78 (R = CH_3), 9.06 (R = CH_2Cl), and 8.85 (R = CF_3CH_2); consequently a possible change in pH due to the effect of pressure on the buffer will not affect the measured data or the mechanism of the reaction [3]. The initial complex concentration was $(2–4) \times 10^{-4}$ M, and the initial ligand concentration varied between 5×10^{-3} and 10×10^{-3} M. The reactions were followed by the change in absorbance in the visible spectrum between 340 and 380 nm [1–3].

On the Mechanism of Catalysis by a Metal-Free Hydrogenase from Methanogenic Archaea: Enzymatic Transformation of H_2 without a Metal and Its Analogy to the Chemistry of Alkanes in Superacidic Solution**

Albrecht Berkessel* and Rudolf K. Thauer*

Hydrogenases are enzymes that catalyze reactions with molecular hydrogen (H_2) either as substrate or as product. All hydrogenases investigated so far are metalloenzymes: they all contain iron–sulfur clusters, and most of them also contain nickel.[1] Presumably the activation of the H_2 molecule takes place at one of the redox-active transition metal ions. The detailed structure of the active site is still unknown. Although an X-ray crystal structure of a nickel–iron hydrogenase exists,[2] it was performed on an inactive sample of the enzyme.[2] On the other hand, both the binding and the activation of molecular hydrogen effected by low molecular weight transition metal complexes is comparatively well understood.[3] Most likely, the mechanisms known from organometallic chemistry[3] will soon be proven valid for transition metal hydrogenases, too.

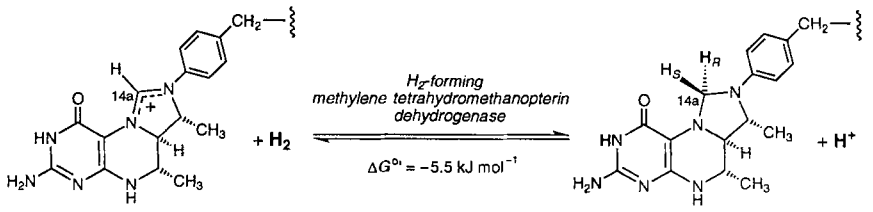
[**] This work was supported by the Bundesministerium für Forschung und Technologie (Förderprogramm "Biologische Wasserstoffgewinnung") and by the Fonds der Chemischen Industrie.

About five years ago, a new hydrogenase was found in methanogenic archaea that catalyzes the reversible reduction of N^5,N^{10}-methenyl tetrahydromethanopterin (methenyl-H_4MPT, **1**) with molecular hydrogen to N^5,N^{10}-methylene tetrahydromethanopterin (methylene-H_4MPT, **2**) and a proton (Scheme 1). This hydrogenase apparently contains neither nickel nor iron–sulfur clusters and can thus be considered metal-free.[4–8]

The reaction shown in Scheme 1 represents one step in the production of methane from CO_2 and H_2 by methanogenic archaea.[9, 10] Its stereochemical course was elucidated by NMR ("magnetic labeling") studies:[11–13] a) The substrate **1** is reduced stereoselectively. Hydride is formally transferred to or abstracted from the pro-*R* position of methylene-H_4MPT (**2**). The pro-*S* hydrogen atom remains unaffected. b) Furthermore, there is an exchange of the pro-*R* hydrogen atom of methylene-H_4MPT (**2**) with the solvent water. The rate of exchange with the solvent is approximately 2.4 times that of the reaction **2** → **1**.



Scheme 1. For complete structural formulas for **1** and **2**, including side chains, see refs. [11, 12].

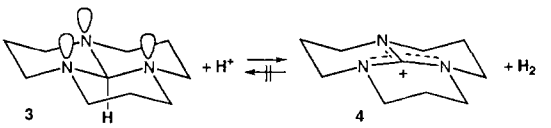
This result indicates that the proton exchange with the solvent takes place directly and is not a secondary reaction via initially formed hydrogen. These findings are in good agreement with other experiments showing that the dehydrogenation of methylene-H_4MPT (**2**) in D_2O results in the simultaneous formation of HD and D_2.[14, 15]

H_2-Forming methylene tetrahydromethanopterin dehydrogenase—as the enzyme is called—differs from all other hydrogenases not only by the absence of nickel and iron–sulfur centers, but also by the following features: CO, NO, cyanide, azide, nitrite, or acetylene are not inhibitors; H_2/H^+ exchange is not catalyzed in the absence of substrate; the enzyme does not catalyze the reversible reduction of dyes such as methylene blue or viologens with H_2; the enzyme shows a pure protein UV/VIS spectrum.

The absence of a redox-active transition metal clearly distinguishes H_2-forming methylene tetrahydromethanopterin dehydrogenase from all other hydrogenases: activation of the H_2 molecule by binding to a transition metal cannot account for its catalytic activity. Thus, the enzyme appears extremely interesting both from a mechanistic and a preparative point of view: the reduction of an organic substrate with molecular hydrogen (Scheme 1) is catalyzed without employing a redox-active transition metal!

We propose that the reaction between methenyl tetrahydromethanopterin **1** and H_2 is effected by enzymatic activation of the substrate **1**. This is a new mechanism of catalysis for hydrogenases, because transition metal containing hydrogenases activate the H_2 molecule. We demonstrate how the reaction shown in Scheme 1 can be catalyzed by conformational locking and protonation of the substrate **1** when bound to the enzyme. Furthermore we show that this mode of reaction has analogies in the chemistry of alkanes in superacidic solutions.[16–19]

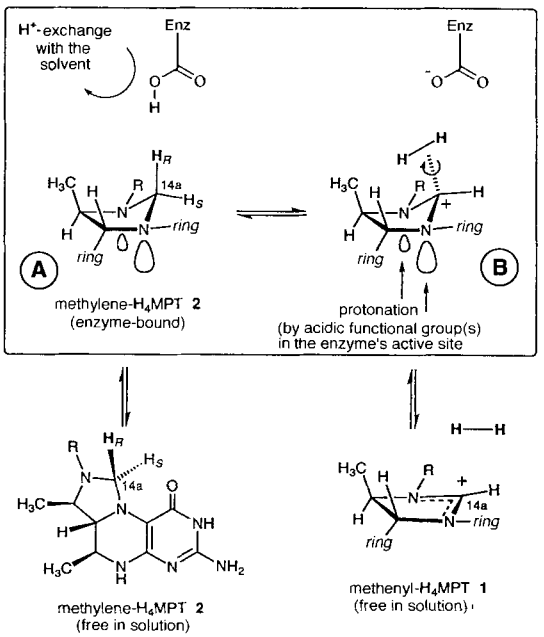
First, we shall consider the back reaction, that is, the formal elimination of hydride from methylene-H_4MPT (**2**) (Scheme 1). Similar transformations are known from the structurally related ortho amides like, for example, **3** (perhydro-3a,6a,9a-triazaphenalene).[20–22] As shown in Equation (a), the guanidinium



(a)

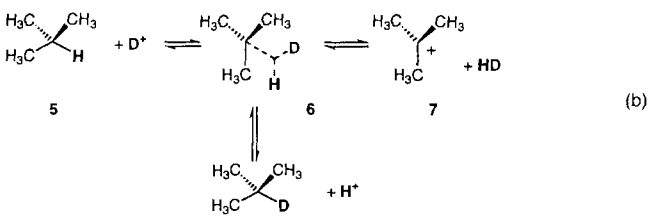
salt **4** and molecular hydrogen are formed quantitatively from the ortho amide **3** upon treatment with tetrafluoroboric acid or hydrochloric acid at 110 °C within 23 h.[20] The unusual reactivity of the ortho amide **3** can be explained by the interaction of the σ* orbital of the central C–H bond with the three antiperiplanar lone pairs of the nitrogen atoms. The weakening of this bond is manifested by its C–H stretching band in the IR at unusually high wavelength (4.0 μm, Bohlmann band[23]). As shown in Scheme 2, the five-membered imidazolidine ring of methylene-H_4MPT (**2**) can easily adopt a conformation in which the lone pairs of the neighboring nitrogen atoms are oriented antiperiplanar to the bond C–H_R (**A**, Scheme 2). An acidic functional group within the enzyme's active site, like the carboxyl group of an aspartate or glutamate residue, is assumed to provide the proton. The antiperiplanar arrangement of the nitrogen lone pairs and the C–H bond facilitates the protolysis (stereoelectronic effect). The stereoselectivity of the formal elimination of hydride from **2** is explained by this conformational locking of the five-membered ring upon binding at the enzyme's active site. Finally, in the free formamidinium ion methenyl-H_4MPT (**1**), the positive charge at C14a is optimally stabilized in the now flattened five-membered imidazolidine ring.

Whereas the "ortho amide analogy" explains the formal elimination of hydride from methylene-H_4MPT (**2**), as well as its



Scheme 2.

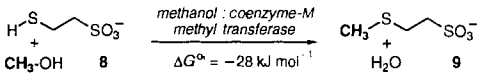
stereoselectivity, this analogy fails with respect to two further important aspects of the enzyme-catalyzed transformation shown in Scheme 1. a) As mentioned above, the exchange of the pro-*R* hydrogen atom of methylene-H_4MPT (**2**) with the solvent is about 2.4 times faster than its elimination with concomitant formation of methenyl-H_4MPT (**1**).[13] However, an analogous H/D exchange at the central C–H bond of ortho amides of type **3**, for example upon treatment with DBF_4 instead of HBF_4, has never been observed.[20–22] b) In contrast to the *reversible* enzymatic reduction of methenyl-H_4MPT (**1**) (Scheme 1), a reaction of guanidinium cations with molecular hydrogen to form ortho amides does not take place [Eq. (a)]; in other words, the ortho amide reaction in tetrafluoroboric acid or hydrochloric acid is irreversible. This dilemma is solved by the assumption that the stabilization of the cationic center at C14a of methenyl-H_4MPT (**1**) by the lone pairs of the neighboring nitrogen atoms can be turned off by binding to the enzyme. In Scheme 2, this hypothesis is indicated as the transition from free methenyl-H_4MPT (**1**) to the enzyme-bound state **B**; in the unbound state, the positive charge at C14a is stabilized by the two neighboring nitrogen atoms in the planar conformation of the five-membered ring. Upon binding of methenyl-H_4MPT (**1**) to the enzyme (**B**, Scheme 2), the lone pairs at the nitrogen atoms could be protonated, again by acidic residues in the enzyme's active site. An envelope conformation of the imidazolidine ring results. Because of this turning off of conjugative stabilization, the electrophilicity of the cationic center at C14a should be dramatically increased relative to that of the formamidinium ion **1** or the guanidinium ion **4** [Eq. (a)]. The reactivity of the resulting cation should more closely resemble that of carbocations that can be generated in solution under superacidic conditions.[16–19] The similarities are indeed striking. As shown by Olah et al.[24, 25] and by Hogeveen et al.,[26] alkanes can undergo H/D exchange in superacidic solution with retention of configuration and without carbocation formation or before the corresponding carbocations are formed. For example, the tertiary hydrogen atom exchanges rapidly in the case of isobutane [**5**, Eq. (b)].[16–19, 27] This



isotope exchange was explained by reversible protonation of the exchanging C–H bond, resulting in the formation of a transient 3-center, 2-electron bond[24] [**6**, Eq. (b)]. The reversible formation of an analogous species with a 3-center, 2-electron bond (**B**, Scheme 2) and the ability of the resulting "cation-bound H_2 molecule" to rotate, readily explain the rapid isotope exchange of the pro-*R* hydrogen atom of **2** with the solvent. Because in the course of the enzymatic reduction of **1** to **2**, the protons formed are given off to the solution, a proton path between the acidic functional group Enz-CO_2H in the enzyme's active site and the solvent must exist. Our hypothesis also explains why isotope exchange between the gas phase and the solution is catalyzed by H_2-forming methylene tetrahydromethanopterin dehydrogenase only in the presence of substrate (**1** or **2**).[12, 14] Hogeveen et al.[28] could show that molecular hydrogen reacts with carbocations like the *tert*-butyl cation, affording the corresponding saturated hydrocarbon [Eq. (b), reaction of **7** with hydrogen to **5**]. This transformation is analogous to the reaction of enzymatically activated methenyl-H_4MPT with hydrogen yielding methylene-H_4MPT and a proton. The latter proton would be accepted by the carboxylate anion in the enzyme's active site (**B** → **A**, Scheme 2). Walling and Bollyky achieved the reduction of benzophenone with H_2 in the presence of strong bases under drastic reaction conditions.[29a] This result indicates that heterolysis of the H_2 molecule may be further facilitated by the basic residue in the enzyme's active site. Hogeveen et al. did not observe a kinetic isotope effect in the reaction of the *tert*-butyl cation with D_2 or H_2.[28] Interestingly, H_2-forming methylene tetrahydromethanopterin dehydrogenase does not show a significant isotope effect either: the reduction of methenyl-H_4MPT (**1**) was found to proceed at identical rates with H_2 and D_2 at all the substrate concentrations and pH values studied.[29b]

At first glance, the assumption of intermediates in an enzymatic transformation that are otherwise found only under superacidic conditions may appear somewhat risky. However, reaction patterns characteristic of organic molecules under superacidic conditions, for example the isomerization of alkanes, are also observed in the presence of solid ion exchangers or zeolites carrying sulfonic acid functional groups.[19, 30, 31] Consequently, "superacidic reactions" are also possible without the typical superacids of solution chemistry –provided that an adequate, nonbasic environment and properly positioned acidic functional groups are present (possibly by "bi-" or even "multifunctional catalysis"[32]). Thus, why not in the course of an enzymatic transformation? Proteases hydrolyze amide bonds at room temperature and at pH 7 within minutes, whereas the analogous acid-catalyzed reaction in solution requires some hours of heating at reflux in 6 M hydrochloric acid.

In view of the chemistry of carbocations in superacidic solution, the catalysis effected by H_2-forming methylene tetrahydromethanopterin dehydrogenase is not mysterious any longer, but merely appears as a logical alternative to the activation of the H_2 molecule by metal-containing hydrogenases. Could substrate activation by protonation, as proposed here, also be of importance for other enzymatic reactions? The transformation of the only very poorly nucleophilic hydrogen molecule without the aid of a transition metal requires the intermediacy of a highly reactive, that is, highly energetic, carbocation. Thus, H_2-forming methylene tetrahydromethanopterin dehydrogenase surely is an extreme case. It may well be, however, that the following methyl group transfer reactions that take place only when catalyzed by the appropriate enzyme and not spontaneously in solution may be catalyzed by intermediary selective protonation of the methyl group donors: a) methyl group transfer from methanol to coenzyme M (**8**) affording methyl-coenzyme M (**9**, Scheme 3) in methanogenic archaea,[33] or b) the



Scheme 3.

methylation of homocysteine by N^5-methyl tetrahydrofolate, affording methionine in all living organisms.[34] This hypothesis appears quite reasonable, since under superacidic conditions the electrophilicity of, for example, methanol is increased to such an extent that it can methylate benzene[31] or can undergo ionic hydrogenation affording methane.[35] Similar reactivity patterns apply for the activation of methylamine.[19]

The Coexistence of the Reactivity–Selectivity Principle and of Linear Free Energy Relationships: A Diffusion Clock for Determining Carbocation Reactivities**

Michael Roth and Herbert Mayr*

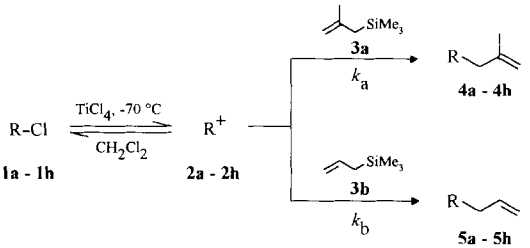
Dedicated to Professor Günter Schäfer on the occasion of his 60th birthday

The rates of reactions of carbocations with uncharged nucleophiles are given by Equation (a), where electrophiles are represented by a single electrophilicity parameter E, while nucleophiles are characterized by the nucleophilicity parameter N and the slope parameter s, which is usually close to 1.[1] For the

$$\lg k = s(N + E) \qquad \text{(a)}$$

determination of the strengths of electrophiles, we usually measure the rates of the reactions ($\lg k$) of these electrophiles with nucleophiles of well-known s and N, and we then use Equation (a) to calculate the electrophilicity parameter E.[2, 3] However, this method is only applicable to well-stabilized carbocations, that is cations that can be produced in organic solvents as persistent entities with lifetimes of more than one hour. We now introduce a general method for the determination of absolute rate constants and electrophilicity parameters of short-lived carbocations. It is based on the selectivities of carbocations that are generated from suitable precursors by chemical ionization and thus does not depend on the presence of certain chromophores as, for example, in the case of the flash-photolytic generation of carbocations.

We observed a decrease of the relative reactivities of the allylsilanes **3a** and **3b** toward the benzhydryl chlorides **1a–e** (Scheme 1) from 208 to 2.6 with decreasing electron-releasing



Scheme 1.

abilities of the aryl substituents (Table 1). The competition experiments were performed as described previously,[4–6] and yielded competition constants that were independent of the ratios of the nucleophiles **3a**:**3b**. Only in the case of **1a** (very large value which is difficult to determine) did the standard deviation exceed 10%. The agreement of the competition constants with the directly measured rate constants is shown by the entry for **1c**: While competition experiments yielded a value of $k_a/k_b = 42.7$ for the bis(*p*-chlorophenyl)carbenium ion **2c** (Table 1), a k_a/k_b value of 37 is calculated from the directly measured rate constants (CH_3CN, 20 °C).[7] As these reactions

Table 1. Relative reactivities of carbocations toward allylsilanes (CH_2Cl_2, $-70\,^{\circ}C$) and electrophilicity parameters.

RCl		k_a/k_b	k_a/k_c	E
(*p*-MeC_6H_4)PhCHCl	**1a**	208 ± 32		4.33
Ph_2CHCl	**1b**	39.9 ± 2.6		6.15
(*p*-ClC_6H_4)$_2$CHCl	**1c**	42.7 ± 3.8		5.95
(*m*-ClC_6H_4)PhCHCl	**1d**	7.03 ± 0.23		6.5–7.0
(*m*-ClC_6H_4)$_2$CHCl	**1e**	2.61 ± 0.20		7.0–7.5
	1f	2.41 ± 0.25	140 ± 13.5	7.50
	1g	1.10 ± 0.10	8.31 ± 3.61	8.5–9.0
	1h	1.85 ± 0.12		8.0–8.5

do not have an enthalpy barrier,[8] the comparison of these reactivity ratios is possible without correcting for temperature. The decrease of the competition constants k_a/k_b with increasing reactivities of the benzhydryl cations (Table 1) is in accord with the postulate of the reactivity–selectivity principle[9–12] and opposes Equation (a) which predicts constant selectivities for competing nucleophiles with the same s parameter.

This apparent contradiction is resolved in Figure 1, where the results of direct kinetic measurements and of competition experiments are presented side by side. A noticeable decrease of the selectivity does not occur until the rate constant k of one of the parallel reactions exceeds 10^8 L mol^{-1} s^{-1}, that is, when the more reactive competitor approaches the diffusion limit.[13] Figure 1 now unambiguously corroborates the conclusion that constant selectivity relationships and the reactivity–selectivity principle hold in different ranges of reactivity, as previously derived from studies of relative reactivities.[14, 15]

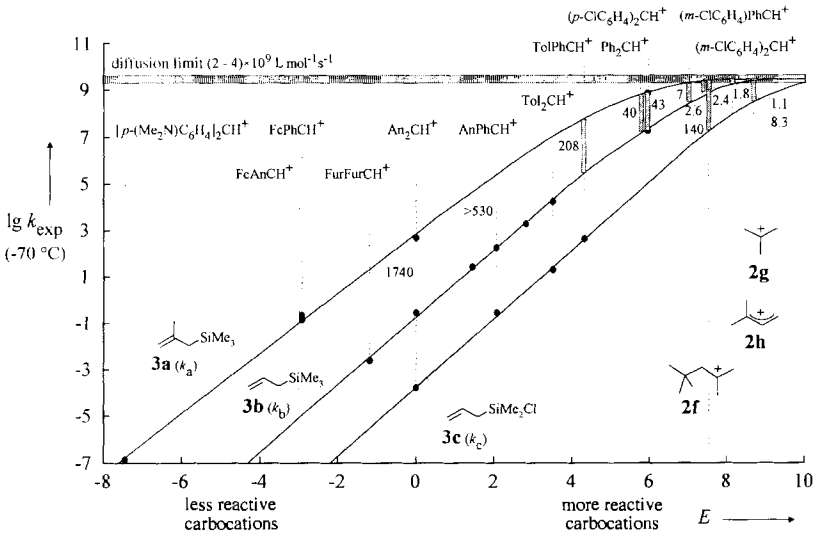

Fig. 1. Changeover from constant selectivity relationships to the reactivity–selectivity principle. An = *p*-$MeOC_6H_4$, Fc = ferrocenyl, Fur = 2,3-dihydrobenzofuran-5-yl, Tol = *p*-MeC_6H_4. Directly measured rate constants are marked by dots, results from competition experiments by shaded bars.

Kinetic investigations of laser-flash photolytically generated carbocations in acetonitrile at 20 °C showed that different types of highly reactive uncharged nucleophiles react with almost identical rate constants $k = (2–4) \times 10^9$ L mol^{-1} s^{-1},[7] indicating that this value corresponds to the diffusion limit. As acetonitrile and dichloromethane have almost identical viscosities at 20 °C ($\eta_{CH_3CN} = 0.39$ mPa s, $\eta_{CH_2Cl_2} = 0.43$ mPa s), one can expect the same diffusion rates in both solvents as a consequence of the Stokes–Einstein equation. The similar selectivities, which were determined for the carbenium ion **2c** by competition experiments at 20 °C ($k_a/k_b = 32.0$) and $-70\,^{\circ}C$ ($k_a/k_b = 42.7$), again demonstrate that an explicit treatment of temperature dependence is unnecessary.

It, therefore, becomes possible to determine absolute rate constants for reactions which cannot be followed directly. In the region where Equation (a) holds, that is, for "slow" reactions, k_a/k_b is generally greater than 1000. When the alkyl cation **2f** is generated from the alkyl chloride **1f** and titanium(IV) chloride in the presence of **3a** and **3b**, the products **4f** and **5f** are formed. Their ratio yields a competition constant of $k_a/k_b = 2.41$, indicating diffusion control of the faster reaction (**2f**+**3a**). Analogous generation of the carbocation **2f** in the presence of **3a** and **3c** yields the ratio $k_a/k_b = 140$, which can be combined with the diffusion-controlled $k_a \approx 3 \times 10^9$ L mol^{-1} s^{-1}, to give $k_c \approx 2.1 \times 10^7$ L mol^{-1} s^{-1}. Since this value of k_c is within the scope of the linear free energy relationships, the electrophilicity parameter E (**2f**) = 7.50 can be derived by substitution into Equation (a) or graphically from Figure 1. Analogously, for the *tert*-butyl cation **2g** the ratio $k_a/k_c = 8.31$ is obtained, and for the prenyl cation **2h** the ratio $k_a/k_b = 1.85$. Since none of these ratios refer to a reaction within the scope of the linear reactivity relationships, only approximate values of E for the corresponding cations can be derived from Figure 1.

The procedure presented herein basically corresponds to Jencks's diffusion clock,[16–19] which employs the fact that many carbocations undergo diffusion-controlled reactions with the azide ion in aqueous solution ($k \approx 5 \times 10^9$ L mol^{-1} s^{-1}).[20] Therefore, one can use the alkanol/alkyl azide ratio, which is obtained by solvolytic generation of carbocations in aqueous azide solution, for calculating the rate constant of the reaction of the carbocation with water. As the azide clock uses a single pair of competing nucleophiles, its scope for the determination of E parameters is limited, and it cannot be used to establish E values greater than 6.5 because of the large value of k_{H_2O} which then is outside the scope of the linear free energy relationships. Our previous investigations on the reactivities of π nucleophiles,[1] on the other hand, provide a large choice of reaction partners and allow the selection of suitable pairs of nucleophiles for determining the electrophilicity parameter E for any electrophile.

[13] The decrease of the competition constants cannot exclusively be due to diffusion control of one of the parallel reactions. There are indications that in this region the position of the transition state on the reaction coordinate is shifted (Hammond effect), that is the classical rationalization of the reactivity–selectivity principles may hold in this range [15].

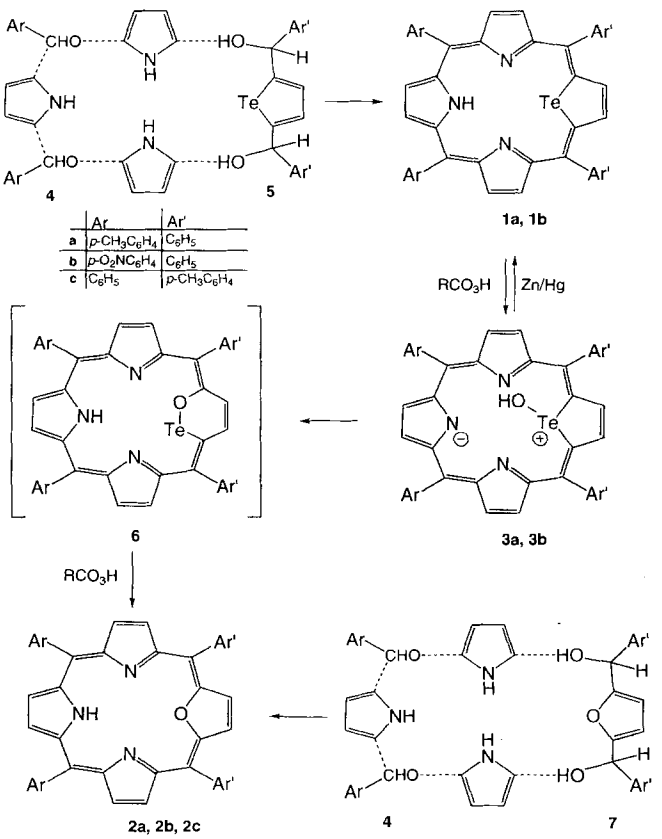

Scheme 1. Summary of the reactions of the core-modified porphyrins discussed in the text.

Alteration of the Reactivity of a Tellurophene Within a Core-Modified Porphyrin Environment: Synthesis and Oxidation of 21-Telluraporphyrin**

Lechosław Latos-Grażyński,* Ewa Pacholska, Piotr J. Chmielewski, Marilyn M. Olmstead, and Alan L. Balch*

Recent work on core-modified porphyrins, in which one or more heteroatoms O, S, Se, or CH replace some of the four nitrogen atoms, has produced new macrocycles with altered core sizes and metal ion binding properties.[1–4] The 21-thiaporphyrin has been utilized to produce η^1 coordination of the thiophene ring to a variety of transition metal ions.[2] Other studies have been concerned with the effect of heteroatom substitution on the aromaticity of the macrocycle.[3] Here we report on the synthesis of the 21-telluraporphyrins **1** and their conversion by oxidation into the 21-oxaporphyrins **2**,[5] which proceeds via the novel tellurium hydroxy compounds **3** as isolable intermediates. The reactions of the new macrocycle **1** demonstrate the remarkable ability of the porphyrin environment to alter the fundamental reactivity of the tellurophene portion.

The synthetic work is summarized in Scheme 1. The 21-telluraporphyrins **1a** and **1b** and the 21-oxaporphyrins **2a–c** have been synthesized by the condensation of pyrrole, a substituted benzaldehyde (**4a**, **4b**, or **4c**, respectively) and the appropriate α,α′-disubstituted tellurophene **5** or furan **6**. These procedures follow the methodology previously utilized for the preparation of 21-thiaporphyrin and 21-selenaporphyrin.[1, 3] After chromatographic workup, the macrocycles **1a** and **2a** were obtained in 20 and 15% yield, respectively. Both **1a** and **2c** have been characterized by X-ray crystallography (Figs. 1 and 2).[6, 7] The size of the tellurium atom (Te–C 2.083(9); Te–C4 2.065(9) Å) results in a distortion of the core of **1a** such that the non-

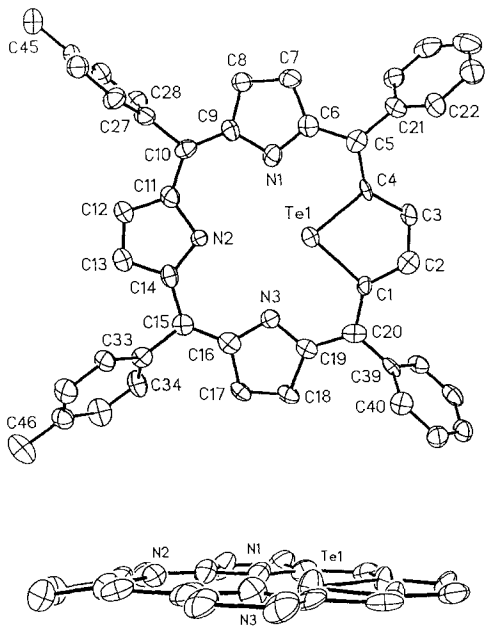

Fig. 1. Two views of the crystal structure of the 21-telluraporphyrin **1a** (thermal ellipsoids for all non-hydrogen atoms for 50% probability). The lower drawing, in which the aryl groups are omitted, emphasizes the deviations from planarity.

bonded N1 $\cdots$ N3 distance (4.65(2) Å) is elongated relative to that in a normal porphyrin. The nonbonded Te $\cdots$ N2 distance is 3.13(1) Å. Surprisingly, this macrocycle with the large core heteroatom is nearly planar, while the 21-oxaporphyrin **2c** is markedly nonplanar. However, similar nonplanarity is seen in one crystalline modification of tetraphenylporphyrin itself.[8] The C_β–C_β and C_α–C_β bond lengths in **1a** are 1.37(2) and 1.42(2) Å, respectively, in tellurophene 1.45(1) and 1.34(1) Å,[9] respectively, in **2c** 1.363(4) and 1.403(4) Å, respectively, and in furan 1.425 and 1.322 Å,[10] respectively. The reversal of the C_β–C_β and C_α–C_β bond lengths in **1a** and tellurophene as well as in **2c** and furan shows that the tellurophene or furan portions are involved in aromatic delocalization.

Unlike 21-thiaporphyrins and 21-selenaporphyrins, 21-telluraporphyrins are air sensitive. Red solutions of **1a** gradually turn green when exposed to the atmosphere for several minutes. This process is accelerated when **1a** is treated with *m*-chloroperoxybenzoic acid, and the reaction yields two products. With an excess of the peroxy acid, the red-brown 21-oxaporphyrin **2a** is formed. However, this process occurs through the formation of a green intermediate (**3a**) which can be isolated if the quantity of oxidant is limited. Treatment of **3a** with additional *m*-chloroperoxybenzoic acid or prolonged exposure to atmospheric dioxygen produces **2a**. The intermediate **3a** can also be reduced back to **1a** by treatment with either zinc amalgam or sodium dithionite. Green **3b** has been isolated in crystalline form. The results of an X-ray diffraction study are shown in Figure 3.[11] The new macrocycle consists of the telluraporphyrin with an oxygen atom attached to the tellurium atom and a proton transferred from the pyrrole nitrogen atom to the oxygen atom; this produces a zwitterion with a hydroxy group attached to the tellurium atom. The hydrogen atom of the hydroxy group was clearly located in a difference map and its position was subsequently refined with the O–H bond riding on the attached oxygen atom (bond length fixed at 0.92 Å and a $U = 0.03$ Å^2). Interestingly, the hydroxy substituent is positioned so that the Te–O bond passes through the porphyrin plane. The Te–O bond length (1.916(4) Å) is comparable to the shorter of the two Te–O bond lengths (1.890, 2.554 Å) in dimeric diphenyl telluroxide.[12] The hydroxy group attached to the tellurium atom interacts with the *trans*-pyrrole ring through a weak hydrogen bond. This *trans* pyrrole ring is tipped upward toward the hydroxy group so that the N $\cdots$ H distance is 2.243 Å.

The facile oxidation of the tellurium atom in the tellurophene unit in **1** and its eventual conversion into a furan upon treatment with a peroxy acid are unusual in tellurophene chemistry.[13] We suggest in Scheme 1 that the conversion of **3** to **2** proceeds via an intermediate in which the tellurophene ring is expanded to form the intermediate **6**. Related ring expansions of selenophene- and thiophene-containing compounds have been observed.[14] Organotellurium compounds with Te–O bonds are rare and difficult to obtain in pure crystalline form.[15] In the present case the porphyrin unit has served as a unique proton donor and stabilized a new form of tellurium coordination.

Experimental Procedure

1a: Boron trifluoride (1 mL) was added to a solution of 2,5-bis(phenylhydroxymethyl)tellurophene (**5a**) (1.1 g, 3 mmol), which was obtained according to the literature method [1], *p*-tolylaldehyde (**4a**) (2.0 g, 17 mmol), and pyrrole (1.3 g, 20 mmol) in dioxygen-free dichloromethane (0.5 mL). The mixture was stirred under dinitrogen in the dark for 1 h and then *p*-chloranil (4.0 g, 17 mmol) was added. The mixture was heated under reflux for 1 h. The solution was evaporated to dryness. The residue was dissolved in deoxygenated dichloromethane and chromatographed on basic alumina. The first red-brown fraction was collected and evaporated to dryness. The residue was then subjected to chromatography under dinitrogen on very fine silica under pressure with benzene/cyclohexane (3/1 v/v) as eluant. The first red band was collected and evaporated to dryness. The product was recrystallized from chloroform/methanol to give 425 mg, 20% yield of **1a**. MS(EI): *m/z* 756 (100%), 758 (95%). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 10.421$ (s, 2H), 8.642 (d, 2H, $^4J(H,H) = 1.8$ Hz), 8.579 (s, 4H), 8.230 (d, 4H, $^3J(H,H) = 7.5$ Hz), 8.105 (d, 4H, $^3J(H,H) = 7.8$ Hz), 7.815 (m, 4H), 7.724 (m, 2H), 7.554 (d, 4H), $^3J(H,H) = 7.5$ Hz), 2.690 (s, 6H), -1.544 (s, 1H). UV/Vis: λ_{max} [nm] (ε, $M^{-1}cm^{-1}$) = 440 (1.5×10^4); 533 (1.6×10^4); 574 sh; 622 (6.6×10^3); 681

(6.6×10^3). A similar procedure that utilized 2,5-bis(phenylhydroxymethyl)furan (**6**, 300 mg) produced **2a** (100 mg, 15%). MS(EI): *m/z* 643 (100%). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 9.132$ (s, 2H), 8.868 (s, 2H), 8.609 (d, 2H), 8.498 (d, 2H, $^3J(H,H) = 4.6$ Hz), 8.160 (m, 4H), 8.038 (d, 4H, $^3J(H,H) = 7.8$ Hz), 7.742 (m, 6H), 7.520 (d, 4H, $^3J(H,H) = 7.8$ Hz), 2.673 (s, 6H), −1.65 (s, 1H). UV/Vis, λ_{max} [nm] (ε, $M^{-1}cm^{-1}$) = 422 (9.3×10^4); 478 (2.1×10^3); 508 (9.9×10^3); 540 (2.2×10^3); 612 (1.7×10^3), 672 (1.8×10^3).

3a: A portion of **1a** (10 mg, 0.013 mmol) in chloroform (5 mL) was treated with two molar equivalents of *m*-chloroperoxybenzoic acid (11 mg of a 40% mixture with benzoic acid, 0.026 mmol) for 1 h. The green solution was subjected to chromatography on basic alumina with chloroform as eluant. The green band was collected and crystallized from chloroform/ethanol to produce dark green crystals of the compound **3a** (9 mg, 90%). MS(EI): *m/z* 774. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 10.425$ (s, 2H), 8.469 (d, 2H), 8.400 (d, 2H, $^3J(H,H) = 4.6$ Hz), 8.318 (s, 2H), 8.214 (m, 4H), 8.050 (m, 4H), 7.535 (m, 4H), 7.736 (m, 2H), 7.485 (m, 4H), 2.687 (s, 6H). UV/Vis, λ_{max} [nm] (ε, $M^{-1}cm^{-1}$) = 465 (8.2×10^4); 485 (6.2×10^4); 564 (9.7×10^3); 629 sh; 659 (1.7×10^4). A similar procedure with five molar equivalents of *m*-chloroperoxybenzoic acid produces **2a**.

Compounds with different substituents were obtained by similar procedures.

Acyclic 1,4-Diastereoselectivity in γ-Substituted α-Enones: Transmission of Chiral Information through Conjugation

Tsuneo Sato, Masaru Kido, and Junzo Otera*

Diastereoselectivity arising from stereogenic centers in the vicinity plays a central role in acyclic stereoselectivity. In this context, high 1,2- and 1,3-diastereoselectivities have been achieved so far,[1] and in particular, the 1,2-stereochemical relationship is well documented as Cram's rule. On the other hand, asymmetric induction between more remote sites remains a challenge. The approaches that met with success for the 1,4-relationship basically relied on chelation of metal atoms or steric origins (π-complexation of transition metals, neighboring group participation, or *gauche* interactions).[2] In particular, Reetz et al.[3] and Nakamura et al.[4] disclosed that γ-amino or γ-alkoxy enals undergo nucleophilic addition of cuprates to the carbonyl groups with significant levels of the diastereoselectivity. π-Complexation of copper was suggested to be essential for these reactions since only stereorandom behavior was observed by use of alkyllithium or Grignard reagents. Consistent with these results, complete loss of diastereoselectivity in hydride reduction and alkylation of 2-ene-1,4-diones or γ-methoxy enones or enals led Fleming et al. to conclude that "Cram's rule diastereoselectivity is either largely steric in origin or that chiral information is very inefficiently transmitted by conjugation".[5] Very recently, however, cyclic substrates were successfully invoked by Wipf et al.: nucleophilic addition to 4,4-disubstituted cyclohexadienones occurred *anti* to the oxygen substituent at C4 with a considerable level of selectivity.[6] We report here on the surprisingly high diastereoselectivities in the carbonyl reduction and alkylation of γ-sulfenyl α-enones. Consequently, we substantiate unprecedented acyclic 1,4-diastereoselectivity for which neither chelation nor steric demands are invoked. In addition, we show that even γ-alkoxy α-enones undergo appreciably stereoselective reaction by proper design of the substrate structures.

The reaction of γ-sulfenyl-substituted α-enone **1**[7] with Li-*s*Bu_3BH (2 equiv.)[8] in THF at −78 °C results exclusively in reduction of the carbonyl group. (The equations for the reactions and the representations are given for only one enantiomer.) The diastereomer ratio of the allylic alcohols obtained is constantly high irrespective of R^1 (Table 1, entries 1–7).[9]

[a] All reactions were carried out in THF at −78 °C for 0.5 h unless otherwise noted. [b] Isolated yields. [c] Determined by HPLC. [d] MeMgBr as nucleophile (5 h). [e] Based on consumed starting material. [f] Reaction time 1 h. [g] Reaction time 1.5 h.

The hydride attacks from the opposite side of the sulfenyl group to give **2** as the major isomers. The selectivity slightly decreases with decreasing bulk of R^2, indicative of the importance of the ground state geometry of the α-enone moiety for the high selectivity. The *tert*-butyl derivative (entry 1) possesses almost pure s-*cis* configuration, while contribution of the s-*trans* counterpart increases as R^2 becomes smaller.[10] Attack of a methyl Grignard reagent also takes place in a similar manner (entry 8). A chelate-controlled mechanism is incompatible with the sense of the observed diastereoselectivities. The X-ray crystal structure analysis of the enone **1** (R^1,R^2 = *tert*-butyl; Fig. 1) reveals that the C–S bond is directed almost perpendicular to the plane of the enone moiety with the S-C-C=C dihedral angle of 106°. This is completely consistent with the results of ab initio calculations for γ-substituted α-enals by Morokuma et al.[11] An electron-donating group is favorably situated orthogonal to the enone face so that such an arrangement could stabilize the enal fragment through the σ-π* interaction.[12] One may assume that

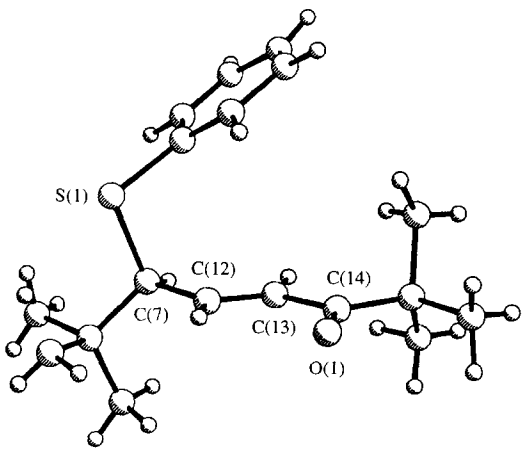

Fig. 1. Crystal structure of compound **1**. Selected bond lengths [Å] and angles [°]: S1-C7 1.83(1), O1-C14 1.19(1), C7-C12 1.50(1), C12-C13 1.34(1), C13-C14 1.53(1); S1-C7-C12 106.4(8), C7-C12-C13 123(1), C12-C13-C14 119(1), O1-C14-C13 121(1).

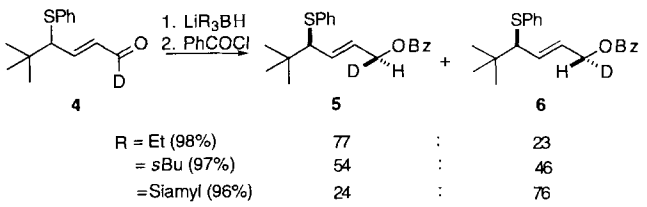
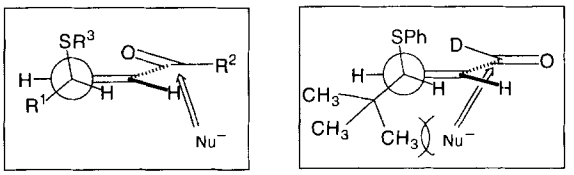
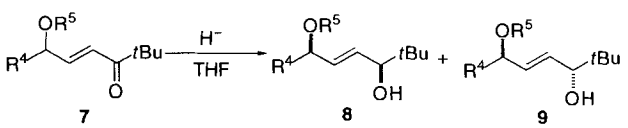
an aromatic ring of the phenylthio group sterically shields the "front side" of the carbonyl face to facilitate the "back-side" attack of the nucleophile. This assumption is proved invalid by the fact that a smaller methylthio-substituted derivative gives rise to the analogous outcome (Table 1, entry 9). It is apparent therefore that the asymmetric character is transmitted through the olefinic bond. The σ-π* interaction would perturb the electronic environments of the enone moiety, and hence the facial selectivity might be governed by this stereoelectronic effect.

The innate tendency of the back-side attack is further confirmed by the stereoselectivity of the nucleophilic addition to the γ-sulfenyl-α-enal **4**. Reduction of **4** with $LiEt_3BH$ affords **5** and **6** in a 77:23 ratio (Bz = PhCO) consistent with the above results.[9] Use of $LisBu_3BH$ leads to loss of the diastereoselectivity, and use of the more bulky Li(siamyl)$_3$BH (siamyl = 1,2-dimethylpropyl) results in the reversal of the selectivity. These results lend additional support to the rationalization that the back-side attack is not induced by the steric bulk of the sulfenyl group. These variations of the stereoselectivity are ascribed to the s-*trans* configuration of the enal **4**.[10] Since the α-enones **1** have basically an s-*cis* configuration, the Bürgi–Dunitz trajectory of the nucleophile[13] is not influenced by the R^1 group (**A**). On the other hand, the approach of the nucleophile towards the s-*trans* configurated enal **4** experiences steric hindrance from the *tert*-butyl group (**B**). Thus, the bulky reducing agent is forced to have a front-side access. In other words, nucleophiles discriminate the carbonyl face essentially in favor of the opposite side of the sulfenyl group in the absence of steric demands.

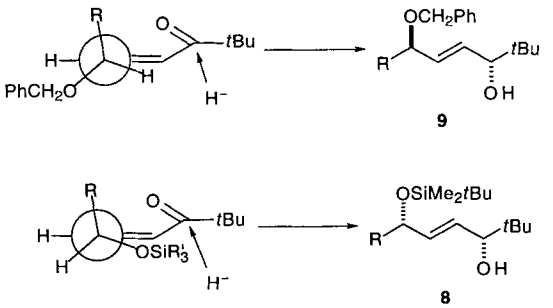




In contrast to previous results,[4,5,14] we have established that carbonyl additions to γ-alkoxy or -siloxy α-enones **7** exhibit a small degree of diastereoselectivity. Remarkably, the stereochemical outcome is dependent on the oxygen functions (Table 1, entries 10–13).[9] The benzyloxy derivatives **7** are reduced preferably to *anti* products, the siloxy analogues **7** to *syn* isomers. Again, the chelate-controlled mechanism is ruled out since chelation with (*E*)-γ-heteroatom-substituted enones is improbable because of the distant location of the two oxygen atoms.[15] The different stereochemical outcomes are attributable to the different ground state conformations of the



substrates. Gung et al. disclosed that γ-benzyloxy α,β-unsaturated carbonyl compounds prefer the CH eclipsed form, while the corresponding silyl ethers prefer the CO eclipsed form.[16] We therefore reasonably assume that the most electron-donating alkyl group is located perpendicular to the "front side" of the enone (Scheme 1), and the hydride attack from the opposite side leads to the *anti* isomer with the benzyl ethers and to the *syn* isomer with the siloxy ethers.



Scheme 1. Stereochemical consideration for the reduction of **7** ($R^5 = PhCH_2$, SiR'_3; $R^4 = R$).

This dependence of the diastereoselectivity on the heteroatom substituents contrasts sharply with the propensity in typical Felkin–Cram-type reactions where the alkoxy and alkylthio groups always work in the same manner as the largest substituents.[17] Apparently, the sulfur and oxygen functional groups exert electronic influences in different ways in the vinylogous Cram case. The superior selectivity and constant mode of diastereofacial discrimination of the sulfenyl starting materials can be attributed to the effective σ-π* interaction which fixes the C–S bond perpendicular to one side of the enone. On the other hand, the rotation of the C_β–C_γ bond in **7** cannot be completely suppressed by the weak hyperconjugative effect of the C–O, C–C, or C–H bond leading to the stereochemical fluctuation and lower diastereoselectivities.

In conclusion, the stereochemical sense of both γ-sulfenyl and -alkoxy substrates is consistently interpreted by situating the most electron-donating group[18] orthogonal to the enone face concurrent with the back-side attack of the nucleophiles. Although the back-side attack may possibly be induced simply by the steric bulk of the substituent in the orthogonal position, we rather advance that the stereoelectronic origin is more plausible on the basis of only a small difference between the phenylthio and methylthio derivatives as well as the results with α-enals. More significantly, the stereochemical outcome with γ-siloxy α-enones is not consistent with the steric argument because back-side attack should be hampered by the largest siloxy group and this should result in the opposite sense of the stereoselectivity if the steric origin is valid (see Scheme 1). Obviously, the precise picture of the mechanism would be drawn by dealing with transition states, not with the ground states. Studies along this line as well as synthetic applications are now in progress in our laboratories.

Experimental Procedure

To a solution of (*E*)-2,2,7,7-tetramethyl-6-phenylthio-4-octen-3-one (145 mg, 0.5 mmol) in THF (2 mL) was added $LisBu_3BH$ (1.0 M THF solution, 1 mL, 1 mmol) at −78 °C. After being stirred for 30 min, the reaction mixture was combined with MeOH (0.5 mL), 1 N NaOH (0.5 mL), and 30% H_2O_2 (0.5 mL). The resulting mixture was allowed to warm up to room temperature and stirred for 30 min. Extraction with ethyl acetate followed by evaporation provided an oil. HPLC analysis (Develosil Si 30, 3 mm, 4.6 × 250 mm, hexane/ethyl acetate (90/10), 1 mL min^{-1} showed that the crude product consisted of (3*S**,6*S**,*E*)- and (3*R**,6*S**,*E*)-3-hydroxy-2,2,7,7-tetramethyl-6-phenylthio-4-octene in a 97:3 ratio. Column chromatography on silica gel (hexane/ethyl acetate (95/5) provided (*E*)-3-hydroxy-2,2,7,7-tetramethyl-6-phenylthio-4-octene (140 mg, 96%): Anal. calcd. for $C_{18}H_{28}OS$: C 73.91, H 9.64; found: C 73.62, H 9.66. Preparative HPLC (Develosil Si 30, 10 mm, 20 × 250 mm, hexane/ethyl acetate (95:5)) afforded the pure isomers. (3*S**,6*S**,*E*)-3-Hydroxy-2,2,7,7-tetramethyl-6-phenylthio-4-octene: m.p. 67–69 °C; IR (CCl_4): 3680, 3460 cm^{-1}; ^{1}H NMR $CDCl_3$): δ = 0.66 (br.s, 1H), 0.75 (s, 9H), 1.07 (s, 9H), 3.36 (d, *J* = 10.3 Hz, 1H), 3.53 (d, *J* = 7.87 Hz, 1H), 5.05 (dd, *J* = 7.87, 15.1 Hz, 1H), 5.54 (dd, *J* = 10.3, 15.1 Hz, 1H), 7.2–7.4 (m, 5H); ^{13}C NMR ($CDCl_3$): δ = 25.5, 28.0, 34.3, 64.9, 80.4, 127.2, 128.5, 131.3, 131.8, 134.0, 135.4; MS: *m/z*: 292 (M^+); HRMS calcd for $C_{18}H_{28}OS$ (M^+) 292.1861, found 292.1818; HPLC: t_R = 7.5 min. The structure of this compound was confirmed by X-ray crystallography. (3*R**,6*S**,*E*)-3-Hydroxy-2,2,7,7-tetramethyl-6-phenylthio-4-octene: JR (CCl_4): 3500 cm^{-1}; ^{1}H NMR ($CDCl_3$): δ = 0.67 (s, 9H), 1.09 (s, 9H), 1.56 (br.s, 1H), 3.41 (d, *J* = 10.1 Hz, 1H), 3.58 (d, *J* = 7.33 Hz, 1H), 5.24 (dd, *J* = 7.33, 15.2 Hz, 1H), 5.64 (dd, *J* = 10.1, 15.2 Hz, 1H), 7.2–7.4 (m, 5H); ^{13}C NMR ($CDCl_3$): δ = 25.3, 28.0, 34.5, 34.6, 64.3, 80.4, 126.6, 128.6, 130.9, 131.5, 132.5, 135.6; MS: *m/z*: 292 (M^+); HRMS calcd for $C_{18}H_{28}OS$ (M^+) 292.1861, found 292.1863; HPLC: t_R = 11.1 min.

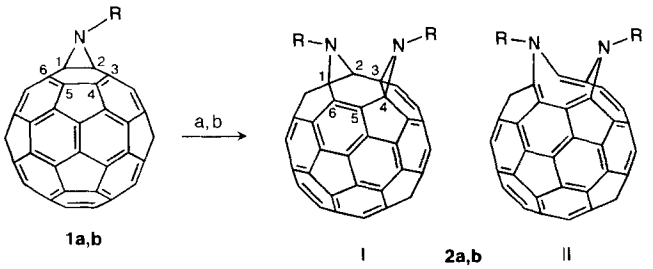
$C_{59}N^+$ and $C_{69}N^+$: Isoelectronic Heteroanalogues of C_{60} and C_{70}**

Iris Lamparth, Berthold Nuber, Georg Schick, Andreas Skiebe, Thomas Grösser, and Andreas Hirsch*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 70th birthday

For the structural variation of fullerenes three strategies can in principle be considered: 1) the synthesis of exohedral adducts, 2) the formation of heterofullerenes in which one or several C atoms of the fullerene core are replaced by, for example, N or B atoms, and 3) the generation of endohedral complexes. Whereas both exohedral and endohedral derivatives can be synthesized and isolated by a variety of methods,[1] it has not been possible so far to produce macroscopic amounts of heterofullerenes.[2] Even the mass spectrometric detection of heterofullerenes was accomplished only for boron fullerenes $C_{60-n}B_n^+$ ($n = 1-6$), which were generated in situ by laser vaporization of boron/graphite composite rods.[3] We now report for the first time on the formation of the nitrogen heterofullerenes $C_{59}N^+$ and $C_{69}N^+$, which are isoelectronic with C_{60} and C_{70}. These ions are formed by fragmentation (FAB-MS) of regioselectively synthesized iminofullerene derivatives. The specific arrangement of the nitrogen addends facilitates the removal of a carbon atom from the fullerene core and the incorporation of a nitrogen atom.

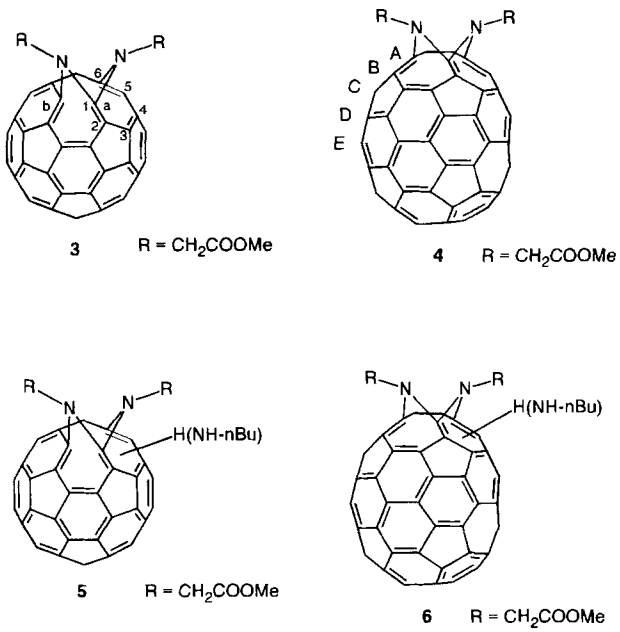
Bisazafulleroid **3**[4] served as a precursor for compounds leading to $C_{59}N^+$, and we synthesized for the first time the bisadducts **2**, which directly fragment to form this heterofullerene ion (Scheme 1, Table 1). The C_s-symmetric compounds **2**, which are



Scheme 1. **a**: R = COOEt; **b**: R = COO*t*Bu. Reaction conditions: a) N_3R, 1-chloronaphthalene, 60 °C; b) toluene, reflux.

green in solution, are the first examples of dicyclo adducts with addends bound *in cis-1* positions.[1] The adducts **2** are formed regioselectively from the reaction of **1**[5] with two equivalents of azidoformate in 1-chloronaphthalene at 60 °C and subsequent thermal extrusion of N_2 from the triazoline intermediate (Scheme 1). The structure of **2** was determined by ^{13}C NMR spectroscopy and was proven unambiguously by the use of 100% ^{15}N-labeled **2a** and **2a** in which only one imino bridge is ^{15}N-labeled (Table 1). The signals of C-1 and C-4 at $\delta = 128$ ($^1J_{(C,^{15}N)} = 14$ Hz) and of C-2 and C-3 at $\delta = 114$ ($^1J_{(C,^{15}N)} = 15$ Hz) exhibit a remarkable downfield shift. This shows that the bridged 6-6 bonds are open and that the 5-6 bonds in the corresponding six-membered ring have double-bond character. According to AM1 calculations the open structure II is 3 kcal mol^{-1} lower in energy even though a double bond has to be introduced formally into each of the three five-membered rings.

As a precursor for molecules suitable for the formation of $C_{69}N^+$ we synthesized for the first time the C_s-symmetric bisazafulleroid **4**. This C_{70} analogue of **3** is the major product from the



3 R = CH_2COOMe **4** R = CH_2COOMe

5 R = CH_2COOMe **6** R = CH_2COOMe

twofold reaction of C_{70} with azide. The preferred formation of **4** shows that the regioselective formation of bisazafulleroids[4] is also possible with C_{70}. In analogy to the ^1H NMR spectrum of **3**[4] we observe a quartet for the diastereotopic protons of the methylene groups in **4** (Table 1).

Whereas the mass spectra of the bisadducts **3** and **4** show the typical characteristics of fullerene adducts (a relatively small M^+ peak, the peak of the fullerene fragment ions C_{60}^+ or C_{70}^+ at $m/z = 720$ or 840 as the most intense signals), completely new behavior was observed with the bisadducts **2** (Fig. 1a). In this case the peak at $m/z = 722$ is the most intense signal, which is due to the formation of the heterofullerene ion $C_{59}N^+$.[6] The signal of $^{12}C_{60}^+$ at $m/z = 720$, which arises by the usual fragmentation, is less intense. After isotope correction, the spectrum of **2b** exhibits an intensity ratio of 5:4 for the ions $C_{59}N^+$ and C_{60}^+. The assignment of the peak at $m/z = 722$ to $^{12}C_{59}{}^{14}N^+$ is also confirmed by the observation that after the first "shrink-wrapping" the signal at $m/z = 698$ ($^{12}C_{57}{}^{14}N^+$) is still more intense than that at $m/z = 696$ ($^{12}C_{58}N^+$). Shrink-wrapping is the fragmentation of the fullerene core by successive elimination of C_2 units with retention of the fullerene structure.[3c, 7] This process requires such high energy (> 40 eV)[7b] that all exohedrally bound groups are removed first. Thus the peaks at $m/z = 722$ and 698 cannot be due to exohedral fullerene derivatives such as dihydrofullerenes. Trisadducts, which are formed by the reaction of azidoformates and **1** or of the corresponding 5-6-bridged azafulleroids having a mixed 5-6/6-6 addition pattern, show fragmentation behavior similar to that of **2**.[8]

The observation that heterofullerene ions are formed under these conditions from **2** and mixed 5-6/6-6 adducts but not from the bisadducts **3** and **4** or the 5-6 or 6-6 monoadducts such as **1**[4]

prompted us to further modify the fullerene core in **3** and **4** regioselectively and synthesize precursor molecules that are also able to fragment to give heterofullerene ions. According to AM1 calculations bonds *a* and *b* are the most polarized and attack of a nucleophile should take place there preferably. Hence, we treated **3** and **4** with one equivalent of butylamine in the presence of DBU. The initially formed precipitate became soluble upon the addition of acetic acid. The products are the monohydroamination products **5** and **6**, which are mixtures of regioisomers (attack at bond *a* or *b*) having identical R_f values. In analogy to dissolved **2** the solution of the hydroamination product **5** in $CHCl_3$ is green.

Under the conditions of FAB mass spectrometry **5** and **6** indeed fragment efficiently with formation of the ions $C_{59}N^+$ and $C_{69}N^+$ (Fig. 1b), which give rise to the most intense signals in the spectra. In the range of ions with cluster size 58, which are generated by shrink-wrapping, the same fragmentation features as those of **2** were observed. The signals of $C_{57}N^+$ and $C_{67}N^+$ are in general less intense than those of the corresponding ions with cluster size 60 and 70 (Fig. 1), which indicates that CN is eliminated more efficiently than C_2. The high-resolution signals of, for example, the fragment ions of **5** at 721.997 ($\pm$0.005) and of **6** at 841.997 ($\pm$0.006) clearly prove that these signals do not correspond to $^{12}C_{60}H_2^+$ (722.0157) and $^{12}C_{70}H_2^+$ (842.0157), because their calculated values are well outside the margin of error. The calculated masses of all possible combinations of $^{12}C_{58}{}^{13}C_2$ and $^{12}C_{59}{}^{14}N$ range between 722.0031 and 722.0067 and therefore very close to the range of the experimental values. The ions with cluster size 70 behave analogously. To finally prove unequivocally that a nitrogen atom is incorporated into the fullerene core under these conditions, we treated 100% ^{15}N-labeled **3** and **4** with unlabeled butylamine to convert them into the corresponding hydroamination products. Like in the FAB spectrum of [^{15}N]-**2a** the most intense fragmentation signals are

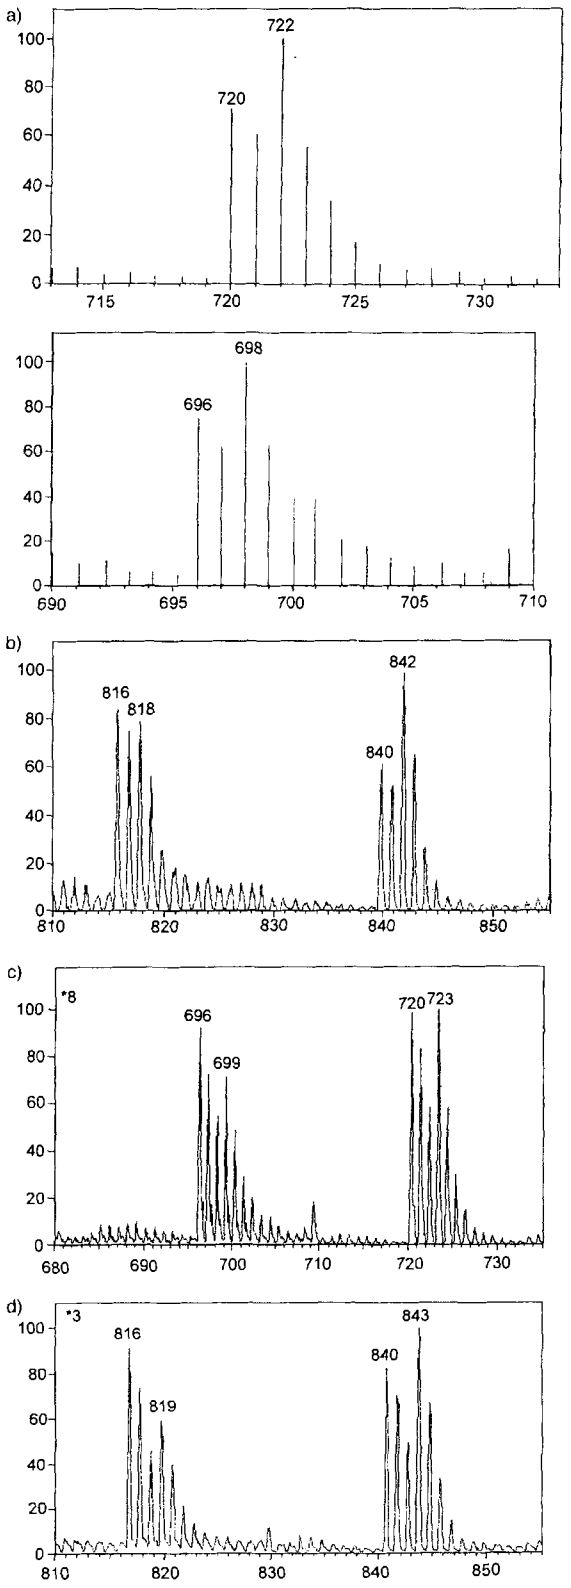

Fig. 1. FAB mass spectrum (Finnigan MAT 90; Cs gun, emission current 2 μA, acceleration voltage 20 kV, detection by secondary electron multiplier, matrix: 3-nitrobenzyl alcohol) in the range of the major fragmentation signals of a) **2b** (line spectrum), b) **6**, c) [^{15}N]-**5**, and d) [^{15}N]-**6** (profile mode).

due to the cluster ions $^{12}C_{59}{}^{15}N^+$ (m/z = 723) and $^{12}C_{69}{}^{15}N^+$ (m/z = 843) (Fig. 1c, 1d).

The parent ions $C_{59}N^+$ and $C_{69}N^+$ are isoelectronic with C_{60} and C_{70}. AM1 calculations show that $C_{59}N^+$ has almost the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3420-2258 $ 10.00+.25/0

same structure as C_{60} (Fig. 2). Also in this case there is bond length alternation[1] between 5-6 and 6-6 bonds. Like all 6-6 bonds in the molecule, the 6-6 C–N bond in $C_{59}N^+$ has double-bond character (1.37 Å) and is even shorter than the C–C double bonds (1.38 Å). The pyramidalization at the N atom is slightly stronger than that at the C atoms. The highest positive charge density of 0.159 is located at C-2 and the next lowest at C-4 (C-11) and C-6 (C-9). Therefore, the resonance structures I–IV (Fig. 2), in particular I and II, are the most important.

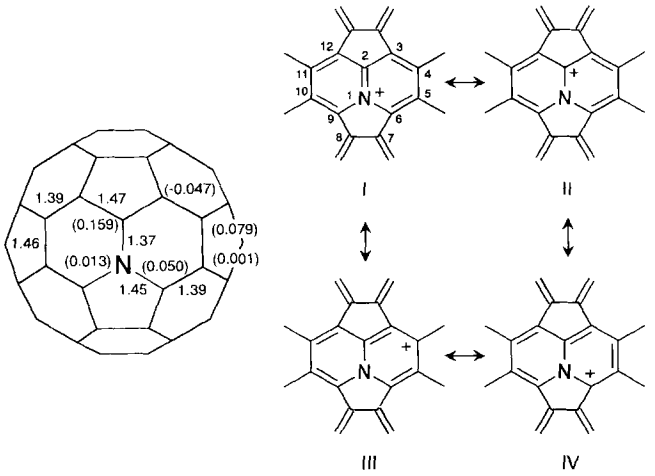

Fig. 2. Characteristic bond lengths in Å, Mulliken charges (in brackets), and the most important resonance structures of $C_{59}N^+$.

Based on this new observation on the generation of the free ions $C_{59}N^+$ and $C_{69}N^+$ we are now working on the synthesis and isolation of heterofullerene derivatives such as $C_{59}NR$ in macroscopic amounts.

[6] Independent of our investigations Mattay et al. recently showed that the azamono- and azadihydrofullerenes $C_{59}NH^+$ and $C_{59}NH_2^+$, respectively, can be generated from the 1,2-bridged aziridinofullerene $C_{60}NH$ by using DCI (desorptive chemical ionization) mass spectrometry and ammonia as reagent gas. Further functionalization by nitrogen through the reagent gas seems to be the decisive step in this case, too. But this method does not provide direct access to the parent compounds $C_{59}N^+$ and $C_{69}N^+$, which we achieved by fragmentation of systematically designed oligoadducts under conditions of FAB mass spectrometry. [8] The FAB mass spectrum of a polyimino adduct of C_{60}, which we obtained by exhaustive addition of azide and subsequent extrusion of N_2, shows the incorporation of at least three nitrogen atoms into the fullerene core; this is particularly evident from the fragment ions of cluster size 58.

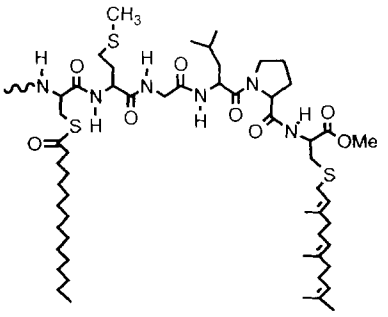
Synthesis of the Palmitoylated and Farnesylated C-Terminal Lipohexapeptide of the Human N-*Ras* Protein by Employing an Enzymatically Removable Urethane Protecting Group**

Herbert Waldmann* and Edgar Nägele

Dedicated to Professor Franz Effenberger on the occasion of his 65th birthday

Ras proteins form a class of membrane-bound lipoproteins that play a central role in the growth-factor-mediated transduction of extracellular signals across the cell membrane into the interior of the cell. By the so-called *Ras* pathway of signal transduction, organisms as diverse as mammals, flies, worms, and yeast regulate cell growth and proliferation.[1] If this regulation is disturbed or interrupted an uncontrolled proliferation may occur, which ultimately may result in the establishment of cancer. This is highlighted by the fact that point mutations in the respective *ras*-oncogenes may result in malignant transformation of the cell. A remarkable observation is that in about 40% of all human cancers such a point mutation is found, and in some of the major malignancies like lung, colon, and pancreas cancer this figure rises to 85%.[2] To study the biological phenomena associated with the functions of the *Ras* proteins, model peptides that embody the characteristic structural elements of their parent lipoproteins are urgently needed.[3] All *Ras*-proteins terminate in an S-farnesylated cysteine methyl ester and, except for Ki-*Ras*, towards the N-terminus one or more S-palmitoylated cysteines are present (see, for instance, the C-terminal lipohexapeptide part **1** of the human N-*Ras* protein; Fig. 1).[4]



-Cys(Pal)-Met-Gly-Leu-Pro-Cys(Far)OMe **1**

Fig. 1. Structure of the characteristic C-terminal lipohexapeptide (**1**) of the human N-*Ras* protein.

The presence of these sensitive side-chain functionalities excludes the use of classical acid- and base-labile protecting groups in the assembly of *Ras*-related lipopeptides. Thus, we found that upon acid-mediated removal of the Boc protecting group from S-farnesylated cysteinyl peptides, an attack of the acid on the double bonds of the farnesyl residue always occurs, and that the thioesters present in S-palmitoylated lipopeptides hydrolyze spontaneously even at pH 6–7 in aqueous solution.[5] Due to this pronounced lability, up to now a successful synthesis of a fully functionalized (that is, an S-farnesylated and S-palmitoylated) *Ras*-lipopeptide could not be achieved. For this purpose blocking functions have to be employed that can be selectively removed under the mildest, preferably neutral conditions. Previously we reported the development of enzyme-labile protecting groups[6] that fulfill these criteria. In particular, the phenyl-

acetamide (PhAc), which is cleaved by the enzyme penicillin G acylase, was introduced as an enzymatically removable blocking function for the N-terminal amino group of peptides.[7]

However, a major drawback of this non-urethane protecting group is that its application results in 2–5% racemization of the PhAc-masked amino acids upon activation by established peptide coupling reagents.[7] Therefore, in order to make full use of the attractive features of enzyme-mediated transformations in the construction of complex peptide conjugates like **1**, enzymatically removable urethane blocking functions have to be used.

Although in a few cases biocatalyzed hydrolyses of urethane-protected amino acids were observed,[8] to the best of our knowledge the selective enzymatic removal of simple urethane protecting groups from peptides and related compounds has not been reported yet. Therefore, a new strategy for the development of enzymatically removable urethane blocking groups for peptides and peptide conjugates had to be developed.

We now report that *p*-acetoxybenzyloxycarbonyl(AcOZ)-urethanes can be cleaved enzymatically under mildest conditions (pH 7, 45 °C) from peptides and that this protecting group technique can be advantageously applied for the construction of complex and sensitive, biologically relevant peptide conjugates like the characteristic S-farnesylated and S-palmitoylated C-terminal lipohexapeptide of the human N-*Ras* protein.

To develop a general class of enzyme-labile urethane blocking groups a strategy was chosen in which the urethanes embody a) a functional group that is recognized by the biocatalyst and that is bound by an enzyme-labile linkage to b) a functional group that undergoes a spontaneous fragmentation upon cleavage of the enzyme-sensitive bond (Fig. 2). In the fragmentation process, a carbamic acid derivative is liberated, which decarboxylates to give the desired deprotected peptide.[9] As a protecting function that might fulfill these criteria the *p*-acetoxybenzyloxycarbonyl (AcOZ) group was chosen.[10]

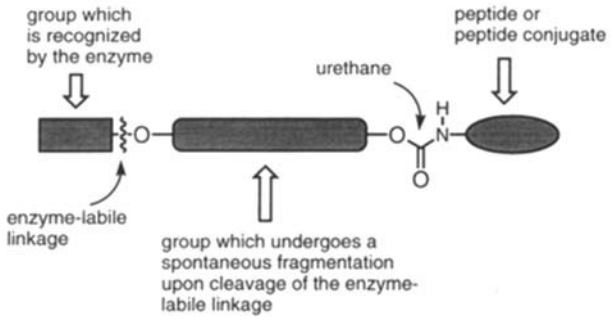

Fig. 2. Strategy for the development of a general class of enzyme-labile urethane protecting groups.

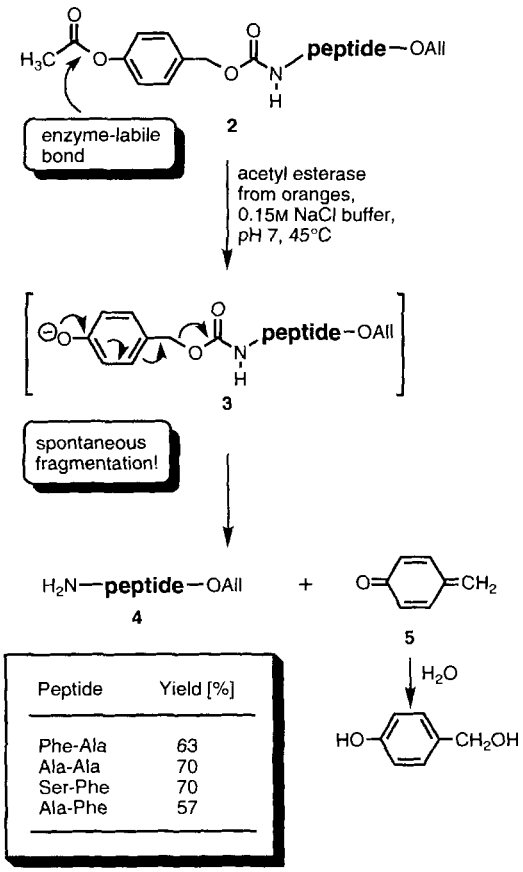
The AcOZ-protected peptide allyl esters **2** (Scheme 1) are readily synthesized from AcOZ-protected amino acids and amino acid allyl esters by employing established peptide coupling reagents like *N,N'*-diisopropylcarbodiimide/*N*-hydroxybenzotriazole. Contrary to the observations made for phenylacetamido-protected peptides[7] (vide supra) no racemization of the N-terminal amino acid of the AcOZ-blocked compounds **2** could be detected by high-field NMR techniques and HPLC investigations. The AcOZ-protected amino acids required are obtained in a straightforward manner from *p*-acetoxybenzyl chloroformate and *N,O*-bis(trimethylsilyl) amino acids.[11] Since the compounds **2** contain two esters (an acetic acid phenyl ester at the N-terminus and a peptide allyl ester at the C-terminus), for the desired N-terminal deprotection a biocatalyst had



Peptide	Yield [%]

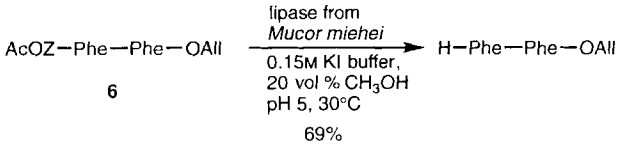
Ala-Ala	70
Ser-Phe	70
Ala-Phe	57

Scheme 1. Enzymatic cleavage of the *p*-acetoxybenzyloxycarbonyl (AcOZ) protecting group by means of acetyl esterase from oranges.

to be applied that can discriminate between these ester groups. For the hydrolysis of the acetates in **2** and the induction of the subsequent fragmentation, the enzyme acetyl esterase from the *flavedo* of oranges was chosen, because this biocatalyst attacks acetates but not longer acyl chains.[12] In addition, it does not display any amidase activity at all, so an undesired attack on the peptide bonds need not be feared. Upon treatment of the protected peptides **2** with acetyl esterase in aqueous buffer at pH 7 and 45 °C, the acetates in the N-terminal urethane protecting group are smoothly hydrolyzed to give the phenolates **3**. Under the reaction conditions these intermediates undergo a spontaneous fragmentation and thereby liberate the desired peptides **4**, which are isolated in analytically pure form in 60–70% yields. The quinone methide **5**, which is formed from the phenolate, is trapped by water and converted to *p*-hydroxybenzyl alcohol (Scheme 1). In this process no undesired attack of the enzyme on the allyl esters present or on the peptide bonds was observed; that is, the enzymatic transformations proceed with complete chemoselectivity. It was not a foregone conclusion that the fragmentation would occur at neutral pH, since in the previously reported nonenzymatic cleavage of the AcOZ group the pH had to be raised to 10–11 to deprotonate the phenol and induce its subsequent conversion into a quinone methide.[10] The enzyme-triggered removal of the AcOZ-group from peptides is not restricted to the use of acetyl esterase. The AcOZ-urethanes are also substrates for acetyl choline esterase from electrical eel and, in particular, for the lipases from *Mucor miehei* and *Rhizopus arrhizus*, which, for instance, selectively remove the N-terminal blocking group from the protected sterically demanding phenylalanyl peptide **6** in high yield (Scheme 2).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3420-2260 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1995, 34, No. 20



Scheme 2. Lipase-mediated cleavage of the *p*-acetoxybenzyloxycarbonyl (AcOZ) protecting group.

A particularly advantageous feature of the AcOZ protecting function is that the enzyme used can recognize the same structural element in all cases. The variable peptide part of the substrates is remote from the site of the biocatalyst's attack. Thus, possible sterically or electronically unfavorable interactions of the enzyme with the substrates (caused, for example, by bulky amino acid side chains) are guaranteed not to limit the substrate tolerance of the enzyme.

The AcOZ protecting group is orthogonally stable to the allyl ester function. Thus, from the dipeptides **2** the allyl ester can be selectively removed, for example, by treatment with $[(Ph_3)P]_3RhCl$ at 70 °C or with $[(Ph_3)P]_4Pd^0$/morpholine at room temperature.[13]

To demonstrate the full capacity of the enzymatic protecting group technique described above, the characteristic C-terminal lipohexapeptide **1** of the human N-*Ras* protein was constructed. To this end, S-farnesylated cysteine methyl ester **7**[14] was coupled with the C-terminally deblocked, AcOZ-protected peptide **8** (Scheme 3) by carbodiimide-mediated activation of the carboxylic acid to give the lipotripeptide **9** in high yield. From **9** the AcOZ urethane blocking group was removed quantitatively, and without any attack on the farnesyl residue and the C-terminal methyl ester, by treatment with lipase from *Mucor miehei*. The N-terminally deprotected farnesylated peptide **10** was isolated in analytically pure form in 65% yield. A further elongation of the peptide chain by the dipeptide **11** yielded the AcOZ-protected lipopentapeptide **12**. From **12** the N-terminal urethane could again be removed enzymatically without any detectable attack on the farnesyl residue or the C-terminal methyl ester. The enzymatic deprotection of the fairly hydrophobic lipopeptides **9** and **12** required the presence of 20 vol% of methanol to solubilize the organic substrate and make it accessible to the biocatalyst. Since acetyl esterase is unstable under these conditions[12] the removal of the protecting groups from **9** and **12** was carried out with lipase from *Mucor miehei*. To avoid an undesired attack of the amines **10** and **13**, liberated in these transformations, on the formed quinone methide, the enzymatic reactions were carried out at pH 5 (conditions under which the amines are protonated) and in the presence of NaHS and/or KI (reagents that trap the quinone methide by nucleophilic attack). The synthesis of the Aloc-protected *Ras* peptide **15** was finally completed by coupling the selectively deprotected peptide conjugate **13** to the S-palmitoylated cysteine **14** to give the fully functionalized lipopeptide **15**, which carries both a base-labile palmitic acid thioester and an acid-labile farnesyl thioether.

In conclusion we have developed a strategy for the enzymatic removal of urethane protecting groups from peptides and labile peptide conjugates and demonstrated its usefulness in the first synthesis of the sensitive C-terminal lipohexapeptide of the human N-*Ras* protein. By this technique further S-palmitoylated and S-farnesylated peptide conjugates are potentially accessible, which may open up new avenues of research in bioorganic chemistry and biology.

$CsPr_9NbBr_{15}N_6$: A New Type of Interstitially Stabilized Cluster Compound**

Michael Lulei and John D. Corbett*

Synthetic research conducted with some knowledge of electronic and structural principles has led to the discovery of a large variety of interstitially stabilized rare earth metal cluster halides.[1, 2] A characteristic structural feature of the vast majority of these compounds is rare earth element octahedra M_6 which occur either isolated (e.g. in $Pr_6Br_{10}Co$[3]) or condensed through common metal edges to oligomers (e.g. in $Y_{16}I_{20}Ru_4$[4]) or infinite chains (e.g. in Pr_4I_5Ru[5]). A smaller number of halides contain tetrahedra M_4 which may also be isolated from each other (e.g. in Yb_4OCl_6[6]) or formed into either edge-sharing dimers (e.g. in Gd_3Cl_6N[7]) or infinite chains (e.g. in $Na_2Pr_4Br_9NO$[8]). Except for the Gd_2Cl_3 structure type,[9] the foregoing octahedral and tetrahedral cluster units exist only with a centered (interstitial) heteroatom. While octahedra may be centered by either transition metals (e.g. Mn, Ru, Ir) or main group elements (e.g. B, C, N), the tetrahedra known so far only form with N or O as interstitial atoms, probably because of the size of the void. In all cases, the centered atoms provide not only central bonding to the cluster, but in the reduced examples, valence electrons as well that aid in fulfilling certain minimal electron counts necessary for metal–metal bonding of the electron-poor rare earth metals. As the recent examples of $Na_2Pr_4Cl_9O_2$[10] versus $Na_2Pr_4Br_9NO$ nicely illustrate, it appears possible to change the chemical and physical properties (e.g. conductivity, magnetic susceptibility, and color of the compound) by varying the interstitial atoms. Crystals of $Na_2Pr_4Cl_9O_2$ with the formulation $(Na^+)_2(Pr^{3+})_4(Cl^-)_9(O^{2-})_2(e^-)$ are black because of the surplus electron, and the compound can therefore be viewed as "reduced", while $Na_2Pr_4Br_9NO$ with the precise electron count $(Na^+)_2(Pr^{3+})_4(Br^-)_9(N^{3-})(O^{2-})$ crystallizes as green, transparent crystals and is an insulator or "simple" salt. However, the two compounds are isostructural with similar metal–metal distances within chains formed by edge-sharing tetrahedra centered by either O or disordered O and N, respectively. Instead of changing the interstitial atom, we have found that it is also possible to introduce heterometal atoms in the rare earth metal cluster framework to modify the structure and physical properties.

We report here the first example of a rare earth metal halide in which one rare earth metal atom has been substituted by a transition metal atom, leading to a new structure and cluster type. $CsPr_9NbBr_{15}N_6$ crystallizes as large, green, transparent crystals.[11] As shown in Figure 1,[15] the core of the new structure $[Pr_9NbN_6]$ consists of a niobium atom centering a tricapped trigonal prism of praseodymium atoms (six Pr1 as trigonal prism, three Pr2 as caps; distances: Pr1–Nb 3.405, Pr2–Nb 3.380, Pr1–Pr1 3.917, Pr1–Pr2 3.921 Å). Nitrogen atoms center the six tetrahedral Pr_3Nb cavities in this metal array (distances: Pr1–N 2.32, Pr2–N 2.25, Nb–N 2.13 Å). The $[Pr_9NbN_6]$ unit can therefore also be regarded as the condensation product of six $Pr_3Nb(N)$ tetrahedra that share three edges and the niobium atom with each other to form a trigonal prism of tetrahedra. Evidently, niobium substitution is responsible for this arrangement since M_4N tetrahedra usually form chains, as mentioned earlier. The reason might be the high formal ionic charge or oxidation state of niobium relative to the praseodymium atoms. According to Coulomb's Law, the gain for the Madelung part of the lattice energy[16] is maximized when each of the (formally) highly charged anions N^{3-} are bonded to Nb^{5+} but also have $3Pr^{3+}$ as nearest neighbors. This is efficiently achieved in the new cluster arrangement; of course, the real charges are doubtlessly lower but somewhat proportional.

All 18 Pr–Pr edges on the surface of this cluster are bridged by one of three crystallographically distinct bromine atoms (Fig. 2),

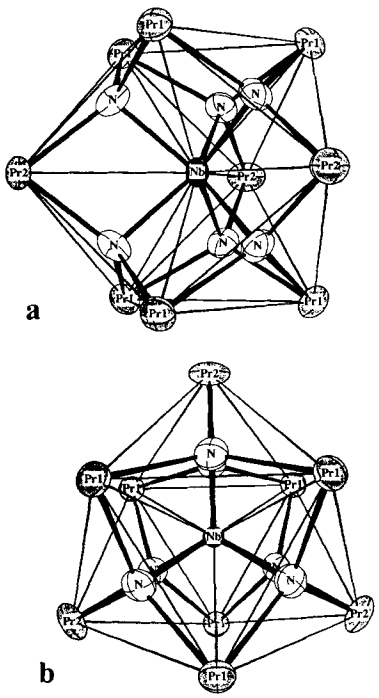

Fig. 1. Crystal structure of $CsPr_9NbBr_{15}N_6$: Views of the $[Pr_9NbN_6]$ unit approximately along [110] (a) and along [001] (b) ($\bar{6}(S_3)$ symmetry, ellipsoids at 99% probability; the lines between the metal atoms represent only geometric relationships).

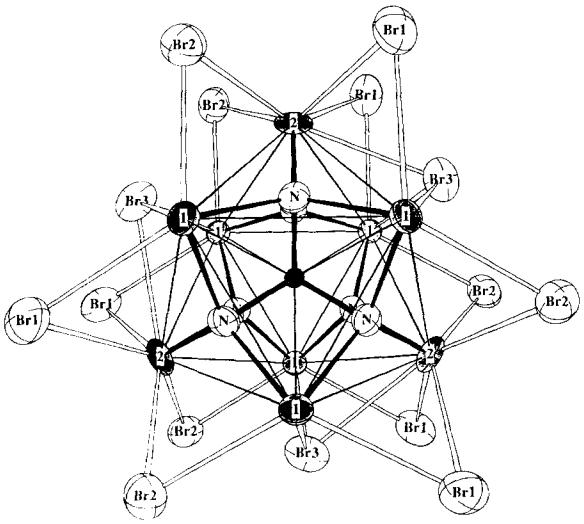

Fig. 2. Crystal structure of $CsPr_9NbBr_{15}N_6$: [001] view of the cluster unit with its bromine environment (99% ellipsoids, the Br1 atoms that bridge the Pr1–Pr1 edges normal to c have been omitted for clarity).

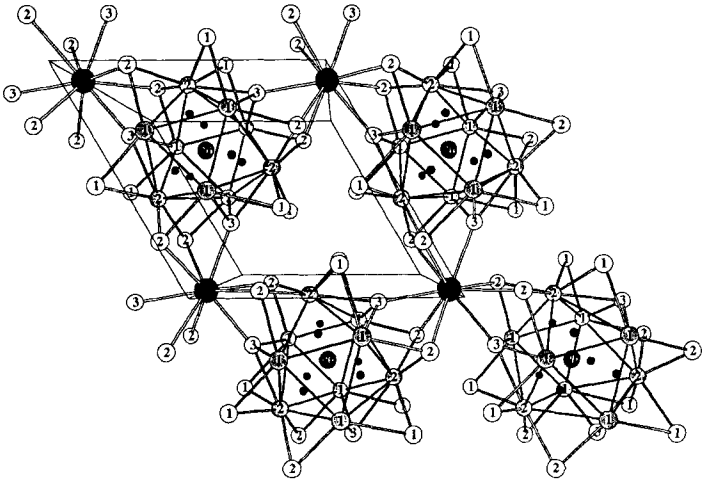

Fig. 4. Crystal structure of $CsPr_9NbBr_{15}N_6$: View of the unit cell along [001] with one layer about $z = 1/4$ to show the connectivity of Br2 and Br3 around Cs (atoms coded as in Figure 3, Cs: large black circles ($\bar{6}(S_3)$ symmetry).

which also serve to connect the clusters into a three-dimensional network. Br1 bridges both the Pr1–Pr1 edges that lie parallel to [110] and half of the Pr1–Pr2 edges and serves to link the clusters as $Br1^{i-i}$[11] only along the c axis (Fig. 3). Br2 bridges the remaining Pr1–Pr2 edges, while Br3 is located over the Pr1–Pr1 edge parallel to c and is also 0.4 Å more distant to Pr2 (Fig. 2). Both Br2 and Br3 connect the clusters through the cesium atom to form layers about (0, 0, 1/4) (Fig. 4) and (0, 0, 3/4) in the unit cell. The two layers are rotated 180° relative to each other around [001]. The result is a $Pr_9NbN_6(Br1^{i-i})_{12/2}(Br2^i)_6(Br3^i)_3 = [Pr_9NbN_6Br_{15}]^-$ complex unit (Fig. 2) complemented by only one Cs^+ ion which centers a tricapped trigonal prism of bromine atoms (six Br2 in the trigonal prism, three Br1 as caps).

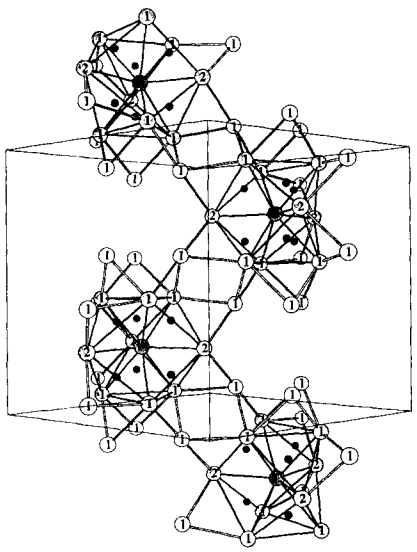

Fig. 3. Crystal structure of $CsPr_9NbBr_{15}N_6$: View of the unit cell approximately along [110] showing the $Br1^{i-i}$ connectivity (N: black; metal atoms: gray; Br1: white; Br2, Br3; Cs atoms are omitted).

The assumed oxidation state formulation $(Cs^+)(Pr^{3+})_9(Nb^{5+})(Br^-)_{15}(N^{3-})_6$ shows that there are no electrons left for metal–metal bonding, and $CsPr_9NbBr_{15}N_6$ can be regarded as a "non-reduced" closed-shell cluster compound or "simple" salt. However, the structure exhibits many features common to the traditional "reduced" cluster compounds: The Pr–Pr distances in the $[Pr_9NbN_6]$ unit (3.92 Å) are very similar to those in $Pr_6Br_{10}Ru$[3] ($\bar{d} = 3.94$ Å) and in Pr_3I_3Ru[17] ($\bar{d} = 3.93$ Å) with isolated Pr_6Ru octahedra and infinite chains of the same type of octahedra, respectively. The short Nb–Pr separations within the cluster are evidently caused by a matrix effect[18] from nitrogen and are therefore mainly determined by the Nb–N and Pr–N distances. This effect can also be observed in the shared edges of the *trans*-edge-sharing Pr_4 tetrahedra chain in $Na_2Pr_4Br_9NO$ and the isotypic but slightly reduced $Na_2Pr_4Cl_9O_2$. Furthermore, the connectivity of the bromines in $CsPr_9NbBr_{15}N_6$ is reminiscent of that in many other rare earth metal cluster compounds.

The discovery of this surprising cluster may therefore forecast still more novel chemistry and structures. The introduction of other high-valent heteroatoms like zirconium or molybdenum instead of niobium into the rare earth element network, or a change of all or some of the interstitial nitrogen atoms to oxygen (or other) atoms should be considered as a route to new (and perhaps "reduced") variants with different chemical and physical properties.

Experimental Procedure

The synthetic and sublimation techniques for $PrBr_3$ and the reaction procedures utilizing welded Nb tubing have been described before [19,20]. CsBr (Baker, 99.9%) was dried by slow heating under dynamic vacuum and then sublimed, while NaN_3 (Aldrich, 99.9%) was used as received as a source of nitrogen and as the oxidizing agent for the Nb container. Reaction mixtures with the overall stoichiometry $CsNaPr_3Br_{10}N_3$ were heated at 750 °C for 28 days. According to Guinier powder diffraction, the products were crystals of $CsPr_9NbBr_{15}N_6$ (70%) and NaBr (10%) besides an unknown phase ($\approx 20\%$). After the formula and structure were determined by single crystal diffraction, two crystals were analyzed by energy-dispersive X-ray spectroscopy to confirm the niobium content and the stoichiometry.

$[\{Ti(\mu\text{-}CH_3)_5(\mu\text{-}CH_2)\}\{(tmeda)Li\}_3] \cdot THF$: An Unusual and Highly Fluxional Titanium Organometallic Compound**

Pietro Berno, Hilary Jenkins, Sandro Gambarotta,* Johan Blixt, Glenn A. Facey, and Christian Detellier

The ability of transition and main group metal amides to function as precursors in the preparation of metal nitrides[1] with useful physical properties is one of the key points in the current revival of interest in the synthesis and characterization of these species. Our interest in the utilization of organic amides to support low-valent early transition metal complexes[2] has been prompted by the observation that these ligands may be directly involved in a variety of transformations, which include C–H σ-bond metathesis,[3] hydrogenolysis,[4] dehydrogenation,[5] hydrogen transfer reactions,[6] and the stabilization of methylidene functions.[7] In view of the relevance of this type of reactivity in the Ziegler–Natta process, we became interested in studying the chemical behavior of medium-valent titanium amides. In this paper we describe the unexpected formation of a rare example of an alkyl(alkylidene) titanium species from a homoleptic titanium(III) amide starting material.

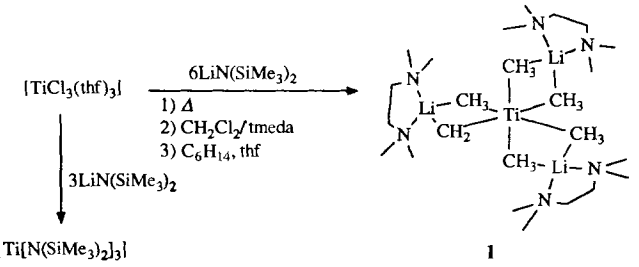
[**] This work was supported by the Natural Sciences and Engineering Research Council of Canada (operating and strategic grants). tmeda = *N,N,N',N'*-tetramethylethylenediamine.

In the attempt to prepare a titanaazacyclobutane complex by C–H σ-bond metathesis, the toluene solution obtained from the reaction of $[TiCl_3(thf)_3]$ with an excess of $[(Me_3Si)_2NLi]$ was thermolyzed (Scheme 1).[8] The initially intense blue color of $[Ti\{N(SiMe_3)_2\}_3]$ rapidly changed to green. After evaporation



Scheme 1. Synthesis of **1**.

of solvent, the residual waxy solid was treated with a mixture of CH_2Cl_2 and TMEDA and subsequently recrystallized from hexane to yield well-formed, extremely air-sensitive, colorless needles of a new compound (**1**). Surprisingly, the IR spectrum did not display the characteristic absorptions of the silazanide group. The complex tested negatively for chlorine and positively for lithium and combustion analysis data were in good agreement with the formulation $[\{Ti(\mu\text{-}CH_3)_5(\mu\text{-}CH_2)\}\{(tmeda)Li\}_3] \cdot THF$. Chemical degradation experiments with gaseous HCl carried out with a Toepler pump yielded about 77% of the expected amount of gas which was identified by gas chromatography as CH_4 (99.5% with small amounts of ethane, traces of propane, and no ethylene). Magnetic measurements in both the solid state and solution showed the complex to be diamagnetic and therefore either oxidation to the tetravalent state or reduction to the divalent state had to have occurred (see below). Compound **1** is stable at room temperature in both the solid state and solution but does react violently with moisture and air.

The molecular structure of **1** was elucidated by X-ray analysis[9] and consists of a monomeric $[Ti(\mu\text{-}CH_3)_5(\mu\text{-}CH_2)]$ unit in which the titanium atom resides in an octahedral environment surrounded by six carbon atoms, the position of only one having been determined, while the positions of the others were generated by the symmetry operators of the $R\bar{3}c$ space group (Fig. 1).

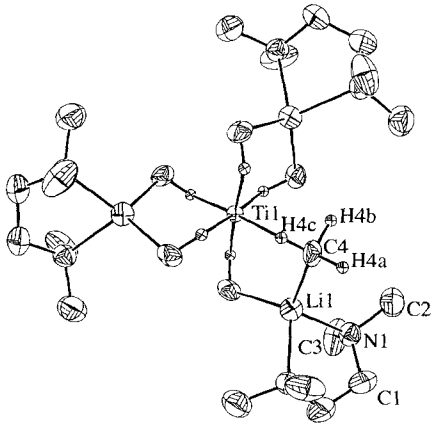


Fig. 1. Crystal structure of **1**. Selected bond lengths [Å] and angles [°]: Ti1-C4 2.615(4), C4-Li1 2.195(8), Li1-N1 2.137(9), Ti1-Li1 3.027(9), Ti1-H4c 2.229, C4-H4c 1.072, Ti1-H4c-C4 98.7, H4c-C4-H4b 110.8, H4a-C4-H4c 109.9, H4c-C4-Li1 108.7. Only two the hydrogen atoms not participating in hydrogen bonds are shown.

The Ti–C distance is remarkably long (Ti–C4 2.615(4) Å) and probably outside the bonding range. A tetrahedrally surrounded Li atom is bound to the two nitrogens of one TMEDA molecule and two carbon atoms (Li1–C4 2.195(8) Å). The positions of all the hydrogen atoms were revealed by the difference Fourier maps but were not refined. The C atoms surrounding Ti are placed in the center of a regular tetrahedron defined by three H atoms and the Li atom which occupies the fourth position. One of the three H atoms points toward the Ti atom, forming a rather short Ti–H distance (Ti1–H4c 2.229 Å). Therefore the connection between Ti and the six C atoms appears to have been realized through six hydrogen bonds. A disordered molecule of THF was also found in the lattice.

In order to account for the observed diamagnetism, one of the methyl groups must actually be a methylene disordered over the six C atom positions. The complex was found to be fluxional in solution, and the methylene resonance was not conclusively located in either the ^{1}H (500.1 MHz) or ^{13}C NMR (125.8 MHz) spectra. In fact, in addition to the THF and TMEDA resonances, the ^{1}H NMR spectrum showed only one resonance at $\delta = -3.2$. Variable-temperature experiments resulted in a broadening of this singlet on lowering the temperature from 298 K (8 Hz) to 180 K (20 Hz). However, the solid-state ^{13}C NMR (CP-MAS) spectrum (50.3 MHz) shows a resonance at $\delta = 125$, which is in the expected range for a methylene group,[7] in a ratio of approximately 1:5 with the methyl group resonance observed at $\delta = -12.3$. Conversely, the ^{13}C NMR spectrum of the solution shows only the resonances of TMEDA and THF. No resonances attributable to either methyl or methylene groups were detected. This can reasonably be explained by the large difference in chemical shift for the interconverting methyl ($\delta = -12.3$) and methylene ($\delta = 125$) groups which gives only a flattened resonance over a range of more than 137 ppm. The TMEDA methyl resonances were also found to be fluxional with a coalescence temperature T of 189 K.[14] The singlet at $\delta = 47.19$ split at 180 K into two resonances at $\delta = 45$ and $\delta = 50$ ($\Delta H^{\neq} = 19(3)$ kJ mol^{-1}, $\Delta S^{\neq} = -82(13)$ JK^{-1} mol^{-1}) attributed to rotational isomers of coordinated TMEDA. Interestingly, the signal of free TMEDA also appears at 180 K as a sharp resonance at $\delta = 46.5$. This resonance broadens at higher temperatures as a result of a fast dissociation/recombination equilibrium of TMEDA from the coordination sphere of lithium ($\Delta H^{\neq} = 17(3)$ kJ mol^{-1}, $\Delta S^{\neq} = -121(16)$ JK^{-1} mol^{-1}). The similarity of the activation parameters for the two independently measured processes (dissociation/recombination of TMEDA and internal rotation of the methyl groups) indicates that the two fluxionality trends belong to the same process. In other words, the internal rotation of TMEDA methyl groups proceeds through dissociation and is controlled by the cleavage of the Li–N bond. Moreover, the large negative activation entropies are plausibly indicative of a rather large reorganization of the solvent cage during the dissociation process.

It is difficult to envision at this stage a possible mechanism or rationalization for the formation of complex **1**. One possibility is that the methyl and methylene groups might originate from the silazanide groups similar to the previously reported cases of Al[10] and Pt.[11] However, the fact that treatment of the reaction mixture with CH_2Cl_2 is a necessary step for the successful isolation of **1**, possibly indicates that CH_2Cl_2 may also act as a source of both methyl or methylene groups. The structure, bonding, and spectroscopic features of complex **1** are unique not only in the organometallic chemistry of Ti but also with respect to closely related structures of tetravalent Zr and Hf complexes,[12] for which a non-octahedral coordination geometry is preferred. Even in the chemistry of trivalent lanthanides, which possess similar structures,[13] the bonding of the methyl groups to the metal is achieved through direct M–C bonds. Finally, we find remarkable that any attempt to form complex **1** in a more straightforward manner, for example by reaction of either $TiCl_4(L)_2$ [L = thf, 0.5 tmeda] or $TiCl_3(thf)_3$ with MeLi with or without TMEDA, and by using several different stoichiometric ratios and different reaction temperatures, invariably led to decomposition and an intractable mixture.

[8] Freshly sublimed [$(Me_3Si)_2NLi$] (50.1 g, 0.3 mol) was added to a stirred greenish suspension of [$TiCl_3(thf)_3$] (17.40 g, 47.0 mmol) in toluene (120 mL). The suspension slowly turned blue. The mixture was then boiled and filtered hot. The green–red solution was evaporated to dryness giving an orange oil which slowly solidified. The solid was redissolved in CH_2Cl_2 (30 mL) and treated with TMEDA (4.5 mL). The addition of hexane (110 mL) and of a very small amount of THF to the solution initialized the crystallization. The solution was left to stand at −30 °C which yielded pale yellow crystals of **1** (4.20 g, 17%). Elemental analysis calcd for $C_{28}H_{73}N_6Li_3OTi$ (found): C 58.02 (57.66), H 12.87 (12.21), N 14.50 (14.44). IR [nujol mull, cm^{-1}]: $\tilde{\nu}$ = 1357 (sp), 1291 (s), 1251 (m), 1180 (w), 1160 (m), 1129 (sp), 1106 (s), 1063 (s), 1038 (vs), 1021 (vs), 949 (vs), 909 (w), 838 (m), 790 (s), 770 (sh), 456 (vs, br.); ^{1}H NMR (C_6D_6, 500 MHz): δ = 3.60 (m, 4H, THF), 2.94 (s, 36H, TMEDA), 2.64 (s, 12H, TMEDA), 1.40 (m, 4H, THF), −3.00 (s, 17H); ^{13}C NMR (C_6D_6, 125.8 MHz): δ = 67.85 (THF), 58.08 (TMEDA), 47.19 (TMEDA), 27.52 (THF); ^{13}C NMR (CP-MAS, 50.3 MHz): δ = 64.5 (THF), 57.7 (TMEDA), 46.8 (TMEDA), 23.2 (THF), −13.4 (CH_3).

[9] Crystal data of **1**: $C_{28}H_{73}N_6Li_3TiO$, M_r = 578.64, trigonal, $R\bar{3}c$, a = 16.654(1), c = 24.959(1) Å, V = 5995.3(6) Å^3, Z = 6, ρ_{calcd} = 0.962 g cm^{-1}, μ = 2.34 cm^{-1}, $F(000)$ = 1932, R = 0.034 (R_w = 0.048), GoF = 1.39 for 61 parameters and 843 unique reflections. The positions of the non-hydrogen atoms were located and refined anisotropically. The hydrogen atom positions were located

from difference Fourier maps but not refined. One disordered molecule of THF was found in the lattice and the oxygen atom could not conclusively be identified. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-59063.

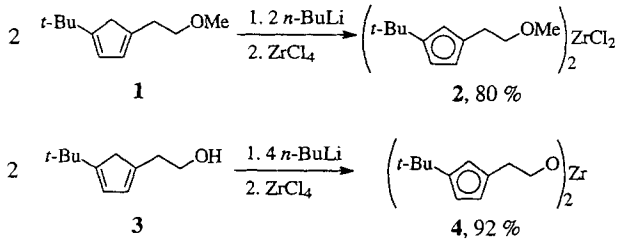
Stereoselective Synthesis of Chiral Zirconocenes from Doubly Substituted, Donor Functionalized Cyclopentadienes via Helical Chelate Complexes**

Jens Christoffers and Robert G. Bergman*

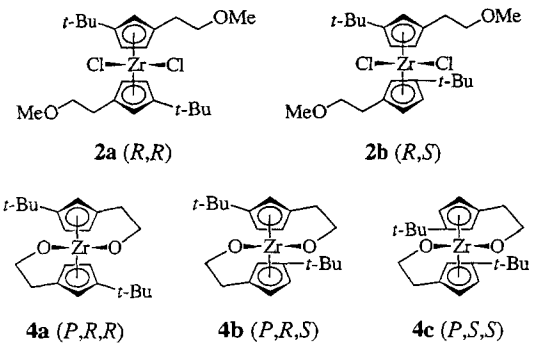
Metallocenes that carry two different substituents on one or both of their cyclopentadienyl rings exhibit "planar chirality".[1] Certain systems of this type (the *ansa*-metallocenes) are valuable catalysts for stereoregular Ziegler–Natta polymerization.[2] A second, and at present more unusual, way to produce chiral metallocenes is to connect each cyclopentadienyl ring to the metal center with a chelating chain, producing a helical structure.[3] However, in the latter case, breaking the metal–chelate bonds in the complexes known so far destroys the system's chirality. We report here on a simple, stereospecific conversion of a donor-substituted cyclopentadiene[4] into a doubly bridged metallocene **4a**, in which *both* planar chirality and helicity are present. Instead of eliminating the chirality of the system, cleavage of the metal–chelate bonds converts the planar chiral and helical starting material **4a** into single diastereomers of doubly planar chiral complexes **5** and **6**.

The two new cyclopentadiene derivatives **1** and **3** have been prepared from lithiated *tert*-butylcyclopentadiene[5] and *p*-$MeC_6H_4SO_2OCH_2CH_2OMe$[6] (**1**, yield 67%) or oxirane-$BF_3 \cdot OEt_2$ (**3**, yield 87%), respectively. Both compounds are isolated as mixtures of isomeric 1,3-disubstituted products (only one isomer of each compound is shown in Scheme 1). Upon reaction of either singly deprotonated **1** or doubly deprotonated **3** with $ZrCl_4$ in THF followed by removal of the solvent and redissolving in toluene to remove LiCl, the two metallocenes **2** and **4** are formed and isolated by crystallization from toluene/hexane at −40 °C.

Complex **2** is formed as a 3:1 mixture of two diastereomers **2a** and **2b** (Scheme 2), which have not been separated. In the *rac* isomer **2a** the C_5 ligands are homotopic and therefore one signal



Scheme 1. Synthesis of the zirconocenes **2** and **4**. ^{1}H NMR data see Table 1.



Scheme 2. Stereoisomers of the zirconocenes **2** and **4**. Only one enantiomer of each pair is shown.

set is observed in the ^{1}H NMR spectrum (Table 1). The ^{1}H NMR spectrum for the *meso* compound **2b** shows two independent sets of resonances for each C_5 ligand, although we expected that they might be enantiotopic. We believe that the doubling of resonances is due to the steric bulk of the *t*Bu substituents, preventing free rotation about the Zr–C_5 bond and leading to a relatively stable conformation of molecule **2b** in which the two ligands are diastereotopic. Although the zirconium center in **2** is electron deficient, we see no evidence for coordination of the MeO groups to the metal center in this case.[7]

Table 1. ^{1}H NMR data (300 MHz, C_6D_6) for **2a**, **2b**, **4a**, **5**, and **6**.

2a: δ = 1.32 (s, 9H; *t*Bu), 2.82–2.98 (m, 1H; CH_2CH_2O), 3.06–3.13 (m, 1H; CH_2CH_2O), 3.15 (s, 3H; OCH_3), 3.36–3.52 (m, 2H; CH_2CH_2O), 5.80 (t, J = 2.7 Hz, 1H; =CH), 5.93 (t, J = 2.7 Hz, 1H; =CH), 6.45 (t, J = 2.5 Hz, 1H; =CH)

2b: δ = 1.40 (s, 9H; *t*Bu), 1.51 (s, 9H; *t*Bu), 2.82–2.98 (m, 2H; CH_2CH_2O), 3.06–3.13 (m, 2H; CH_2CH_2O), 3.16 (s, 3H; OCH_3), 3.22 (s, 3H; OCH_3), 3.36–3.52 (m, 4H; CH_2CH_2O), 5.83 (t, J = 2.7 Hz, 1H; =CH), 5.94 (t, J = 2.8 Hz, 1H; =CH), 6.01 (t, J = 2.8 Hz, 1H; =CH), 6.13 (t, J = 2.8 Hz, 1H; =CH), 6.16 (t, J = 2.8 Hz, 1H; =CH), 6.24 (t, J = 2.7 Hz, 1H; =CH)

4a: δ = 1.39 (s, 9H; *t*Bu), 2.49 (ddd, ^3J = 7.2, ^3J = 11.0, ^2J = 13.0 Hz, 1H; $CHHCH_2O$), 2.65 (ddd, ^3J = 1.3, ^3J = 5.5, ^2J = 13.0 Hz, 1H; $CHHCH_2O$), 4.77 (ddd, ^3J = 1.5, ^3J = 7.3, ^2J = 10.0 Hz, 1H; CH_2CHHO), 5.10 (ddd, ^3J = 5.5, ^3J = 11.0, ^2J = 10.0 Hz, 1H; CH_2CHHO), 5.71–5.76 (m, 2H; =CH), 6.11 (t, ^4J = 2.5 Hz, 1H; =CH)

5: δ = 1.18 (s, 9H; *t*Bu), 1.20 (s, 9H; *t*Bu), 2.18 (ddd, ^2J = 13.2, ^3J = 9.0, ^3J = 7.5 Hz, 1H; $CHHCH_2O$), 2.58–2.69 (m, 2H; $CHHCH_2O$ and $CHHCH_2OCH_3$), 3.03 (dt, ^2J = 14.8, ^3J = 5.4 Hz, 1H; $CHHCH_2OCH_3$), 3.10 (s, 3H; OCH_3), 3.26–3.37 (m, 2H; $CH_2CH_2OCH_3$), 4.65 (ddd, ^2J = 10.6, ^3J = 7.4, ^3J = 3.3 Hz, 1H; CH_2CHHO), 5.40 (t, J = 2.7 Hz, 1H; =CH), 5.43 (ddd, ^2J = 10.6, ^3J = 9.1, ^3J = 6.7 Hz, 1H; CH_2CHHO), 5.75 (t, J = 2.7 Hz, 1H; =CH), 5.77 (t, J = 2.6 Hz, 1H; =CH), 6.00 (t, J = 2.6 Hz, 1H; =CH), 6.32 (t, J = 2.6 Hz, 1H; =CH), 6.43 (t, J = 2.5 Hz, 1H; =CH)

6: δ = 0.10 (s, d, $^2J(^1H,^{29}Si)$ = 3.3 Hz, 9H; $Si(CH_3)_3$), 1.29 (s, 9H; *t*Bu), 2.77–2.81 (m, 1H; $CHHCH_2O$), 3.00 (dt, ^2J = 14.6, ^3J = 5.9 Hz, 1H; $CHHCH_2O$), 3.64–3.73 (m, 2H; CH_2CH_2O), 5.77 (t, J = 2.7 Hz, 1H; =CH), 5.91 (t, J = 2.7 Hz, 1H; =CH), 6.37 (t, J = 2.5 Hz, 1H; =CH)

[**] We acknowledge the United States National Science Foundation (Grant No. CHE-91134261) for generous financial support of this work, the Alexander-von-Humboldt-Stiftung for a fellowship for J. C., and Dr. F. Hollander, Director of the University of California at Berkeley X-ray diffraction facility, for the determination of the X-ray structure. We are also grateful to Prof. C. H. Heathcock for helpful discussions on the stereochemistry of complex **4** and to Prof. J. Okuda for disclosure of results prior to publication.

In contrast to the two stereogenic elements in the planar chiral complex **2**, complex **4** bears three stereogenic elements: one helix represented by the (*t*BuCp)-CH_2-CH_2-O···O-CH_2-CH_2-(*t*BuCp) moiety and two planes of chirality represented by the two C_5 ligands. Of the four potential pairs of enantiomers for such a system, only three exist in this case (**4a**, **4b**, and **4c** in Scheme 2), because the two chiral planes in **4b** have a *meso* relationship with respect to one another. Complex **4** is formed completely stereospecifically: only one of the diastereomers, which by single-crystal X-ray diffraction analysis[8] is shown to be **4a** (Fig. 1), is observed. We believe the quantitative stereoselectivity is caused by a high degree of steric strain in the unseen isomers **4b** and **4c** attributed to the bulky *t*Bu substituents. Reduction of strain by rotation (as is possible in compound **2b**) is prevented by the conformational rigidity enforced by the chelating side chains.

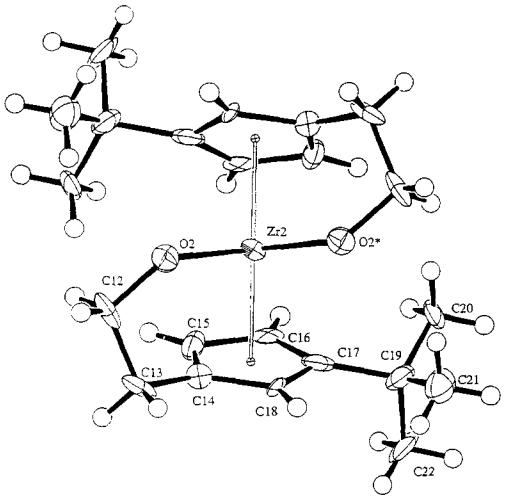

Fig. 1. ORTEP diagram illustrating the solid-state molecular structure of **4a** (one of two independent molecules in the unit cell). Selected bond lengths [Å] and angles [°]: Zr2–O2 2.006(6), Zr2–C102 2.237, C12–O2 1.44(1); O2-Zr2-O2* 103.6(4), Zr2-O2-C12 126.1(6), O2-C12-C13 109.4(8), C12-C13-C14 107.3(8), C102-Zr2-C102* 131.88 (C102 and C102* are the centroids of the Cp rings).

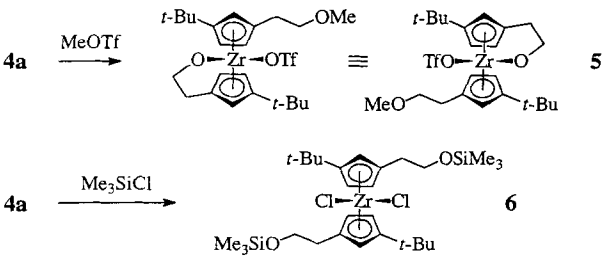
The oxygen atoms in **4a** are homotopic. Therefore, room temperature alkylation with excess methyl triflate at either alkoxy ligand of **4** gives only complex **5**; it is formed in quantitative yield (Scheme 3). The observation of the M^+ signal (85% rel. intensity at 70 eV) in the EI mass spectrum and of a very strong band at $\tilde{\nu} = 1384\ cm^{-1}$ in the IR spectrum[9] indicates that the triflate ligand is covalently bound to the Zr center. The replacement of an alkoxy with a sulfonato ligand increases the electrophilicity at the Zr center in **5**, resulting in a reduction of electron density at the attached oxygen atom compared with that in **4a**.[7] This makes the remaining chelate arm less reactive towards a second equivalent of methyl triflate. The ability to carry out cleavage of only one Zr–O bond in **4a** permits the helicity of this molecule to be stereospecifically converted into central chirality at the Zr atom in complex **5**, and thus this material is formed as only one diastereomer.



Scheme 3. Ring opening reactions of **4** (Tf = F_3CSO_2). ^1H NMR data see Table 1.

Reaction of complex **4** with excess Me_3SiCl at room temperature opens both chelate arms and yields the zirconocene dichloride **6** quantitatively. Only the *rac* compound is formed; no *meso* isomer is detectable by ^1H NMR spectroscopy. We conclude that the reaction proceeds with retention of stereochemical configuration at the planar chiral substituted cyclopentadienyl ligands.

The simple and diastereospecific preparation of complexes **5** and **6** in high yield in only two steps from $ZrCl_4$ exemplifies the useful synthetic potential of 1,3-disubstituted cyclopentadienes with a donor functionalized side chain and the novel stereochemical properties that arise when helical and planar chirality are combined in the same complex. Further chemical properties of these new chiral materials are being explored in our laboratory.

Detection and Reactions of Radical Cations Generated by Photolysis of Aromatic Compounds with Tetranitromethane in 1,1,1,3,3,3-Hexafluoro-2-propanol at Room Temperature**

Lennart Eberson,* Michael P. Hartshorn, and Ola Persson

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Radical cations of aromatic compounds ($ArH^{\bullet+}$) generated in 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) are extremely persistent, their half-lives in HFP often exceeding those found in trifluoroacetic acid by a factor of more than 100.[1] We have previously[2] generated and detected (by EPR spectroscopy) radical cations of moderately high reactivity by photolysis of ArH with tetranitromethane in dichloromethane at $-60\,^{\circ}C$ [Eq.(a)], most often with trifluoroacetic acid present in order to suppress the reactivity of trinitromethanide ion by protonation [Eq.(b)].[3] Under the conditions defined by Equation (a), the further course of the reaction is largely determined by the reactivity of the radical cation $ArH^{\bullet+}$ toward trinitromethanide ion. In Equation (b), this reaction has been ruled out and replaced by other, slower processes.

$$ArH\cdots C(NO_2)_4 \xrightarrow{h\nu} ArH^{\bullet+}NO_2(NO_2)_3C^- \quad (a)$$

$$ArH\cdots C(NO_2)_4 \xrightarrow{H^+,\,h\nu} ArH^{\bullet+}NO_2(NO_2)_3CH \quad (b)$$

In view of the extreme deactivation of radical cation reactivity towards nucleophiles found in HFP, we expected that the tetranitromethane method might be applicable at room temperature in HFP. In the event, we demonstrated that otherwise readily reacting radical cations can persist at room temperature in HFP in the presence of trinitromethanide ion.

When 1-methoxynaphthalene, **1**-H, is photolyzed with tetranitromethane in dichloromethane at temperatures below $-48\,^{\circ}C$, the radical cation of its 4,4'-connected dehydrodimer $(\mathbf{1})_2$ can be detected.[2b] Irradiation of solutions of **1**-H and tetranitromethane (0.4 mol dm^{-3}) in HFP at 22 °C, using light of $\lambda > 430$ nm gives rise to a broad singlet ($\Delta H_{pp} \approx 0.7$ mT; Fig. 1a) in the resulting EPR spectrum at relatively high concentrations of **1**-H (70 mmol dm^{-3}). The line broadening probably results from electron exchange of $(\mathbf{1})_2^{\bullet+}$ with **1**-H or $(\mathbf{1})_2$. The signal could be resolved at [**1**-H] = 5 mmol dm^{-3} (Fig. 1b). This spectrum was the same as that obtained by treatment of the dehydrodimer $(\mathbf{1})_2$ under similar conditions (Fig. 1c). Thus it appears that the reactivity of trinitromethanide ion has been strongly suppressed in HFP, permitting observation of $(\mathbf{1})_2^{\bullet+}$ in the presence of this nucleophile. This conclusion was supported by results from a preparative run in HFP ([**1**-H] = 0.5, [tetranitromethane] = 1.0 mol dm^{-3}, light of $\lambda > 430$ nm) at 20 °C which gave after 40% conversion a 72% yield of dehydrodimer $(\mathbf{1})_2$ and 28% yield of **1**-H with a nitro group in the 4-position (**1**-NO_2). A comparison with runs in dichloromethane[2b] reveals that no products derived from an initial reaction between trinitromethanide ion and $\mathbf{1}\text{-H}^{\bullet+}$ are formed in HFP. In dichloromethane, the same effect was obtained by conducting the photolysis in the presence of trifluoroacetic acid (0.4 mol dm^{-3}).[2b]

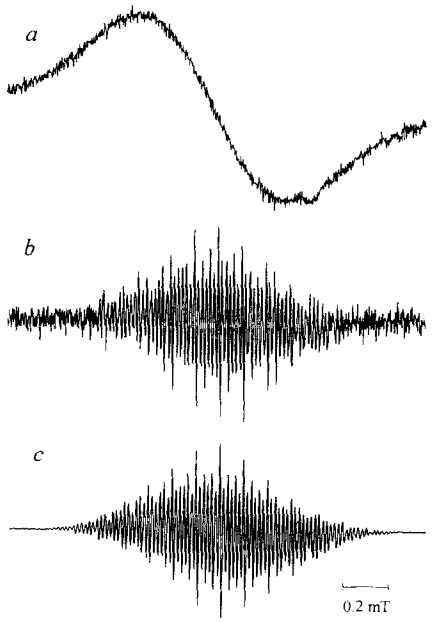

Fig. 1. EPR spectrum of the sample solutions from the photolysis ($\lambda > 430$ nm) of tetranitromethane (0.4 mol dm^{-3}) and a) 1-methoxynaphthalene (**1**-H, 70 mmol dm^{-3}), b) **1**-H (5 mmol dm^{-3}) and c) 4,4'-dimethoxy-1,1'-binaphthalene [$(\mathbf{1})_2$, 5 mmol dm^{-3}] in HFP.

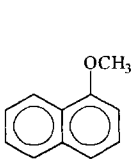
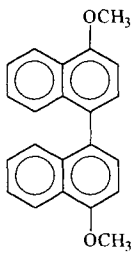


1-H



$(\mathbf{1})_2$

1,4-Dimethoxybenzene (**2**-H), the radical cation of which could not be detected by photolysis with tetranitromethane in dichloromethane at $-60\,^{\circ}C$,[2a] on photolysis with tetranitromethane in HFP at 22 °C gave a strong, well-resolved EPR spectrum corresponding to $\mathbf{2}\text{-H}^{\bullet+}$. The authentic dehydrodimer of **2**-H, 2,2',5,5'-tetramethoxybiphenyl $(\mathbf{2})_2$, was prepared in order to allow the reactions analogous to those of **1** and $(\mathbf{1})_2$ to be studied. The EPR spectrum recorded for $(\mathbf{2})_2^{\bullet+}$ (obtained by photolysis of a solution of $(\mathbf{2})_2$ and tetranitromethane in HFP)

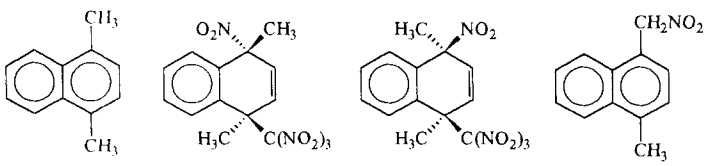
[**] Photochemical Nitration by Tetranitromethane. Part 28. This work was supported by the Swedish Natural Science Research Council and the Knut and Alice Wallenberg Foundation. Part 27: C. P. Butts, L. Eberson, M. P. Hartshorn, W. T. Robinson, *Acta Chem. Scand.* in press.

was distinctly different from the spectrum of **2**-H$^{\bullet+}$. Under preparative conditions, the photolysis of **2-H** with tetranitromethane in HFP at 20 °C gave after 2 h a 19% (after 4 h, 33%) conversion into 1,4-dimethoxy-2-nitrobenzene (**2**-NO_2) as the only product; the analogous reaction in dichloromethane gave under identical conditions a 47% (after 4 h, 82%) conversion into **2**-NO_2. Since the product in the two solvents is the same, one can only conclude that the higher efficiency of the conversion in dichloromethane points to a trinitromethanide ion initiated pathway, possibly leading to a transient adduct,[4] which is eventually transformed into **2**-NO_2. The markedly lower efficiency in HFP would then be caused by HFP blocking this pathway, leaving the fairly slow reaction between **2**-H$^{\bullet+}$ and NO_2 as a feasible route to **2**-NO_2.

1,4-Dimethylnaphthalene (**3**), which gave no EPR signal upon photolysis with tetranitromethane in dichloromethane at −60 °C,[2a] in HFP under the same conditions but at 5 °C gave a broad unresolved signal. A preparative run in HFP ([**3**] = 0.5, [tetranitromethane] = 1.0 mol dm^{-3}) at 20 °C after 40% conversion showed essentially quantitative formation of 1,4-dimethyl-2-nitro-naphthalene. Again it is evident that the formation of the **3**$^{\bullet+}$-trinitromethanide ion derived products obtained in dichloromethane at 20 °C,[5] namely the adducts **4** and **5** (in total 49% yield) and the side chain nitro substitution product **6** (48%), have been completely suppressed.



3 **4** **5** **6**

These examples demonstrate the unique high persistency of radical cations in HFP, which allows these radical cations to be observed in the presence of a nucleophile such as trinitromethanide ion even at room temperature. The reactivity of the radical cations that remain leads to dehydrodimer formation and/or radical coupling with NO_2 to give the "normal" product(s) of the reactions of ArH$^{\bullet+}$ with NO_2. Thus it appears that HFP will discriminate decisively between the radical and electrophilic reactivity of radical cations.

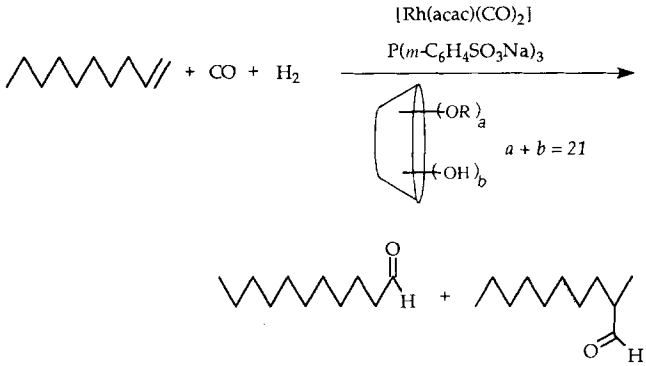
Molecular Recognition between Chemically Modified β-Cyclodextrin and Dec-1-ene: New Prospects for Biphasic Hydroformylation of Water-Insoluble Olefins**

Eric Monflier,* Georges Fremy, Yves Castanet, and André Mortreux

The development of water-soluble catalysts for the hydroformylation of olefins in a two-phase system has attracted a great deal of attention during the last years. The application of this concept to the hydroformylation of propylene has been developed industrially by Hoechst AG using a water-soluble rhodium catalyst containing triphenylphosphane trisulfonate as ligand.[1] Although hydroformylation of long-chain olefins can be achieved in good yields in the presence of organic solvent, these olefins are generally hydroformylated slowly with low selectivities in two-phase systems owing to their poor solubility in water.[2] To solve these problems, surfactants,[3] catalyst-binding ligands,[4] amphiphilic phosphanes,[5] supported aqueous-phase catalysts,[6] and/or cosolvents[7] have been used. However, despite these numerous efforts, the hydroformylation of water-insoluble olefins remains a challenge, and research in this field is still being pursued.

We have previously reported in this journal that the Wacker oxidation of higher α-olefins could be achieved in high yields (up to 95%) in an aqueous two-phase system in the presence of β-cyclodextrins functionalized with hydrophilic or lipophilic groups.[8] In this reaction, the chemically modified β-cyclodextrins behaved mainly as inverse phase-transfer catalysts. Indeed, owing to the formation of inclusion complexes, the chemically modified cyclodextrins can transfer the higher olefins into the aqueous phase and so improve the mass transfer between aqueous and organic layers. We wish now to report that these chemically modified β-cyclodextrins were also very effective for the hydroformylation of water-insoluble olefins in an aqueous two-phase system free of organic solvent (Scheme 1).[9]

The typical results obtained with and without chemically modified cyclodextrins are given in Table 1. The catalytic activ-



Scheme 1. Rhodium-catalyzed hydroformylation of dec-1-ene in a two-phase system. The chemically modified cyclodextrins are schematically represented by a hollow truncated cone. R = CH_3, $CH_2CH(OH)CH_3$, $COCH_3$.

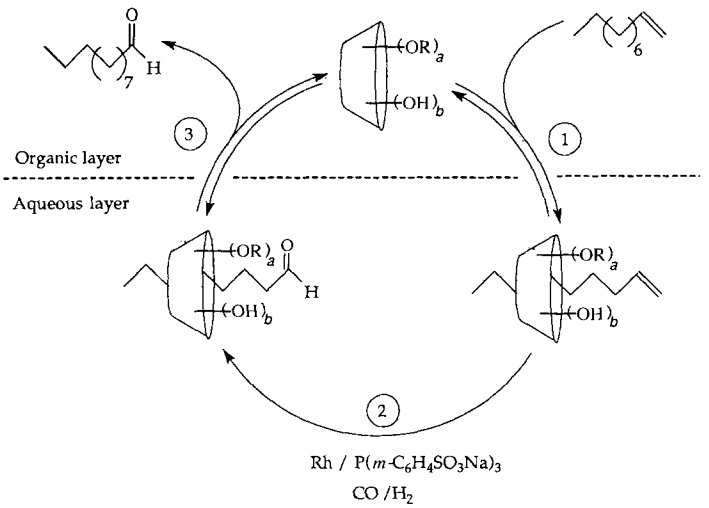
[a] Reaction conditions: $[Rh(acac)(CO)_2]$ (0.16 mmol), $P(m\text{-}C_6H_4SO_3Na)_3$ (0.8 mmol), cyclodextrin (1.12 mmol), H_2O (45 mL), dec-1-ene (80 mmol), undecane (4 mmol); $p(CO/H_2) = 50$ atm, $T = 80\,^{\circ}C$, $t = 8$ h. [b] For the structures of cyclodextrins see ref. [14]. a = no. of hydrophilic or hydrophobic groups R; b = no. of free OH groups (Schemes 1 and 2). The chemically modified cyclodextrins were supplied by Cyclolab (Budapest, Hungary) and Aldrich Chemical Co. and used without further purification. [c] Relative molecular mass of the cyclodextrin. [d] Ratio of linear (n) to branched aldehyde (iso). [e] (Yield aldehydes)/(dec-1-ene conversion); the side products were mainly dec-2-ene, dec-3-ene, and dec-4-ene. [f] Cyclodextrin (2.24 mmol); the time required for complete conversion was 6 h; at the end of the reaction the phase separation was excellent and the Rh and P content in the organic phase was <0.5 and 1.2 ppm, respectively; that is, the water-soluble catalysts can be easily and completely recovered after the reaction.

ities of the classical α-, β-, and γ-cyclodextrins are rather disappointing.[10] Actually, the only suitable cyclodextrin was the β-cyclodextrin, and the dec-1-ene conversion can only be enhanced by a factor of 2 (entry 4). Interestingly, the functionalization of this β-cyclodextrin with hydrophilic or hydrophobic groups such as methyl, acetyl, and 2-hydroxypropyl improved the dec-1-ene conversion greatly. The best results have been obtained with the dimethyl-β-cyclodextrin (entries 5 and 6). Indeed, in this case the dec-1-ene conversion reached 100%, and the aldehyde was formed with 95% selectivity (entry 6). However, the activity is strikingly dependent on the degree of substitution of the β-cyclodextrin. For example, the permethyl-β-cyclodextrin exhibited a much lower activity than the dimethyl-β-cyclodextrin. Acetylated cyclodextrins behaved similarly (entries 8 and 9).

As it has been suggested that hydroformylation under two-phase reaction conditions with water-insoluble olefins is limited by the rate of mass transfer,[11] we think that the beneficial effect of the chemically modified cyclodextrins on the dec-1-ene conversion can be mainly explained by an improvement of the transfer of material between aqueous and organic layers according to Scheme 2.



Scheme 2. Transfer of material between the aqueous and the organic phases in the presence of chemically modified cyclodextrin during the dec-1-ene hydroformylation.

The effectiveness of chemically modified cyclodextrins on the mass transfer is probably due to the solubility of these cyclodextrins in both the aqueous and organic layers. Indeed, in contrast to the β-cyclodextrin and the sulfonated β-cyclodextrin, which are totally insoluble in the organic phase, the dimethyl-β-cyclodextrin and the diacetylated-β-cyclodextrin dissolve well in water and partially in the organic layer, and can therefore transfer the olefin rapidly into the aqueous phase.[11] This hypothesis is in agreement with the results obtained with the peracetylated and the permethylated-β-cyclodextrins. These cyclodextrins are weakly soluble in aqueous layer and are preferably localized in the organic layer. Consequently, transfer of dec-1-ene into the aqueous layer is unlikely. Another possible explanation could be the lower stability of the host–guest complexes. The stability constant of the inclusion complex between the aldehyde and chemically modified cyclodextrin is probably weaker than that of the aldehyde–cyclodextrin complex (fewer hydrogen bonds). Therefore, the organic compounds and cyclodextrins would dissociate and associate more readily (step 1 and 3 in Scheme 2).

The unusually high selectivities (up to 90%) observed with the dimethyl-β-cyclodextrin could be explained by the deeper hydrophobic cavity in the host of this cyclodextrin, which would wrap the olefin efficiently and would so avoid isomerization by the rhodium catalyst.[12] Finally, the variations of the normal to branched aldehyde ratio (1.8 to 3.2) could be attributed to the ability of modified cyclodextrins to cause preorientation of the dec-1-ene in the host cavity and/or to interactions between the cyclodextrin and the catalyst. Indeed, interactions between transition metal complexes and cyclodextrins can give rise to the formation of inclusion compounds.[10, 13] To confirm this latter hypothesis, NMR investigations are now under way in our laboratory.

These results and our previous work on the Wacker oxidation of higher olefins support the idea that the beneficial effect of chemically modified cyclodextrins in an aqueous two-phase system is a phenomenon of general importance. As the chemically modified cyclodextrins are nontoxic, cheap, biodegradable, and bulk industrial chemicals, the use of these compounds in biphasic reactions catalyzed by transition-metal complexes should become general. Due to the chiral environment of cyclodextrins, some fruitful developments are possible, for example, in asymetric catalysis.

Experimental Procedure

In a typical experiment, $[Rh(acac)(CO)_2]$ (0.16 mmol), P(*meta*-$C_6H_4SO_3Na)_3$ (0.8 mmol; this sulfonated phosphane was synthesized as reported by R. Gärtner et al. [15]), and chemically modified cyclodextrin (1.12 mmol) were dissolved in water (45 mL). A stainless steel autoclave (100 mL) was charged under an atmosphere of N_2 with the resulting aqueous phase and an organic phase composed of dec-1-ene (80 mmol) and undecane (4 mmol, GC internal standard), and then heated at 80 °C and pressurized with 50 atm of CO/H_2 (1/1). A mechanical stirrer (1000 rpm) equipped with a multipaddle unit was then started. The pressure was kept constant throughout the whole reaction by using a gas reservoir along with a pressure regulator. The reaction was monitored by quantitative gas chromatographic analysis (CP Sil 5-CB, 25 m, inner diameter 0.32 mm).

Facial Diastereoselectivity in the Paternò–Büchi Reaction of Chiral Silyl Enol Ethers**

Thorsten Bach,* Kai Jödicke, Kristian Kather, and Jürgen Hecht

The [2 + 2] photocycloaddition of alkenes to carbonyl compounds commonly known as the Paternò–Büchi reaction provides an efficient and straightforward route to functionalized oxetanes.[1] By employing chiral auxiliaries it has become possible to photochemically produce enantiomerically pure oxetanes.[2] Studies by Scharf et al. impressively demonstrated that the two diastereotopic carbonyl faces can be well differentiated in phenyl glyoxylates of 8-phenylmenthol and related concave alcohols.[3] Besides the auxiliary-directed methodology there are several procedures that employ cyclic substrates to establish a stereoselective carbonyl photocycloaddition.[4] In these cases a stereogenic center within the ring system is responsible for a successful side differentiation. Contrary to the auxiliary-directed method, the chiral information is not removed after the reaction but is utilized for further synthetic operations. Analogously acyclic chiral substrates have not yet been employed for the preparation of enantiomerically pure oxetanes. Chiral aldehydes, which showed a remarkable Cram selectivity in nucleophilic addition reactions, proved less selective as carbonyl substrates in Paternò–Büchi reactions and yielded an unsatisfactory mixture of diastereoisomers.[5]

In connection with our studies on the regio- and stereoselective photocycloaddition of silyl enol ethers to aromatic aldehydes,[6] we were intrigued by a possible synthesis of enantiomerically pure oxetanes according to the principles of acyclic stereoselection. We started our investigations with a single carbonyl compound (benzaldehyde) and left the α-substituent on the silyl enol ether unchanged.[7] The only parameter varied was the γ-substituent on the silyl enol ether. The starting materials *rac*-**1** were readily accessible in racemic form by addition of the appropriate cuprates to 2,2-dimethyl-4-hexen-3-one and subsequent silylation. Upon irradiation of these substrates in the presence of benzaldehyde the desired oxetanes were produced as one of four possible pairs of diastereoisomers *rac*-**2**/*rac*-**3** (the formula of only one enantiomer is shown in each case). Based on our previous studies[6c, d] it appears likely that the relative configuration of the three substituents within the oxetane ring is fixed. The ratio of the two diastereoisomers found therefore reflects the facial diastereoselectivity which is induced by the stereogenic center. This ratio increases with increasing size of the substituent R and is considerably high for some examples (Table 1).

[+] X-ray crystallography

[**] This project was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Gesellschaft zur Förderung der Westfälischen Wilhelms-Universität, and the Dr. Otto Röhm-Gedächtnisstiftung. We thank Mrs. B. Wibbeling for her help with the X-ray crystallographic measurement. The continuing support of Prof. Dr. D. Hoppe is gratefully acknowleged.

Table 1. Yields and diastereomeric ratios (*d.r.*) observed in the photocycloaddition of benzaldehyde to the silyl enol ethers *rac*-**1** with benzene as solvent.

Alkene	R	*T*[°C]	*t*[h][a]	Yield[%][b]	*d.r.*(**2**:**3**)[c]
1a	Et	30	4	61	61:39
1b	*i*Pr	30	4	57	70:30
1c	*t*Bu	30	4	64	92:8
1d	Ph	30	4	72	69:31
1d	Ph	−30[d]	6	51	58:42
1e	$SiMe_2Ph$	30	9	44	95:5

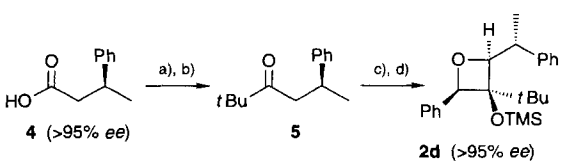
[a] Irradiation time. [b] Total yield of both diastereoisomers (*rac*-**2** and *rac*-**3**). [c] Diastereomeric ratios (*d.r.*) were determined by GLC analyses of the crude product mixture and were checked by ^{1}H NMR spectroscopy. [d] *n*-Hexane as solvent.

The 3-(silyloxy)oxetanes *rac*-**2** and *rac*-**3** are easy to identify by ^{1}H NMR spectroscopy because of their characteristic singlet (2-H of the oxetane). The detection and quantification of the regioisomeric 2-(silyloxy)oxetanes is difficult. In general, they are not produced stereoselectively in the examples under scrutiny and they are sensitive to hydrolysis. Based on the GLC data an upper limit for the amount of regioisomers formed may be estimated and one finds a decrease of regioselectivity with increasing size of the β-alkyl substituent. Silyl enol ether *rac*-**1e** gave the worst ratio (70:30), a result which explains at least partially the low yield obtained in this example.

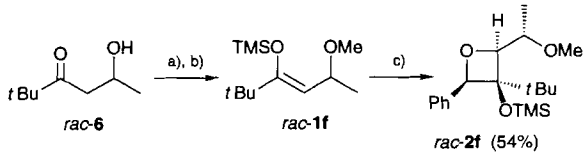
In order to elucidate the configuration of the major diastereoisomers, we have studied compound *rac*-**2d** by X-ray crystallography.[8] The preferred attack of the photoexcited carbonyl compound on the silyl enol ether can be obviously explained by invoking the influence of 1,3-allylic strain.[9, 10] The conformational rigidity facilitates the differentiation of the diastereotopic alkene faces, and the approach of the electrophile takes place preferentially from the less shielded side. Stereoelectronic considerations lead to a similar result.[11] In the course of the reaction, after addition of the carbonyl triplet to a putative 1,4-triplet biradical (^{3}D) the relative configuration of the oxetane ring is directed by previously discussed phenomena (free rotation in ^{3}D, intersystem crossing,[12] cleavage vs. ring closure in a 1,4-singlet biradical).[6b, d]

Since there is a plethora of methods for the stereoselective 1,4-addition to Michael acceptors,[13] enantiomerically pure silyl enol ethers can be synthesized in a few steps. As an example we converted the previously described acid **4**[14] into the corresponding ketone **5** from which the silyl enol ether was readily obtained. Photocycloaddition gave oxetane **2d** as the major product; its enantiomeric purity was determined by shift experiments as >95% *ee*[15] (Scheme 1). The reaction proceeds without racemization at the stereogenic center responsible for the stereoselectivity.

As a substrate with a polar substituent R we chose the silyl enol ether *rac*-**1f** which displayed a good diastereoselectivity (*d.r.* = 85/15) upon irradiation in the presence of benzaldehyde. The major diastereoisomer *rac*-**2f** was isolated in 54% yield and



Scheme 1. Preparation of the enantiomerically pure oxetane **2d**. a) $SOCl_2$ (1.5 equiv), reflux, 6 h, 92%; b) *t*BuMgCl (1.5 equiv), CuCl (0.2 equiv) in Et_2O, −78 °C, 2 h, 93%; c) TMSCl, lithium diisopropylamide (LDA) in THF, −78 °C to RT, 65%; d) PhCHO in benzene, *hv*, 5 h, 51% (+ 22% **3d**).



Scheme 2. Diastereoselective synthesis of the oxetane *rac*-**2f** from the ketone *rac*-**6**. a) Me_3OBF_4 (1.5 equiv), 1,8-bis(dimethylamino)naphthalene (2 equiv) in CH_2Cl_2, RT, 10 d, 58%; b) TMSCl, LDA in THF, −78 °C to RT, 72%; c) PhCHO in benzene, *hv*, 4 h, 54%.

has the depicted configuration (Scheme 2). To determine the relative configuration the noncrystalline product *rac*-**2f** was deprotected (K_2CO_3, MeOH) and the 3-oxetanol *rac*-**7** obtained in this way was crystallized from ether and characterized by a crystal structure analysis (Fig. 1).[16]

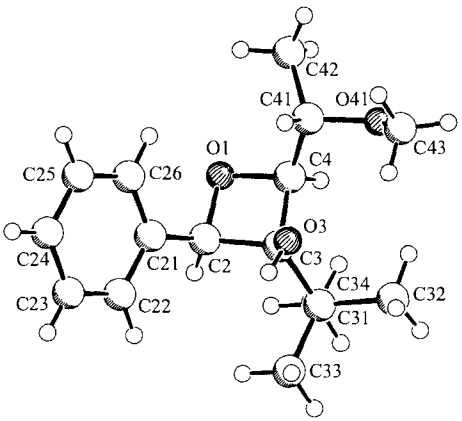


Fig. 1. Crystal structure of the 3-oxetanol *rac*-**7** obtained by desilylation from the 3-(silyloxy)oxetane *rac*-**2f**.

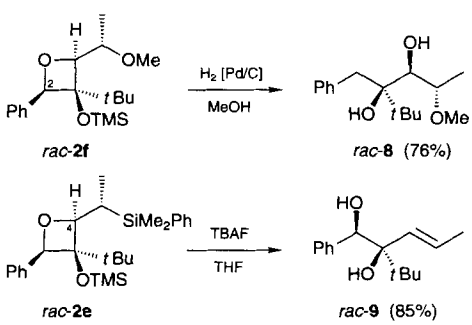
As a possible explanation for the mode of attack the "inside alkoxy" model first suggested by Houk may be invoked.[17] The steric difference between a methyl group and a hydrogen atom attached to the stereogenic center is responsible for the facial diastereoselectivity.

Two examples were used to demonstrate that the oxetanes which are available according to the methodology described herein may also be employed for the stereoselective construction of acyclic molecules. The hydrogenolytic ring opening[18] of oxetane *rac*-**2f** (cleavage of the bond between O and C-2) leads to a partially protected triol *rac*-**8** and the new fluoride-promoted fragmentation[19] of *rac*-**2e** (cleavage of the bond between O and C-4) to the (*E*)-alkenediol *rac*-**9**.



Experimental Procedure

Silyl enol ether (4.5 mmol) was dissolved in benzene (8 mL) in a quartz tube. The irradiation was started (300 nm; light source: Rayonet RPR 3000) and a solution of benzaldehyde (159 mg, 1.5 mmol, 152 μL) in benzene (2 mL) was slowly added to the reaction mixture by a syringe (within ca. 2 h). As soon as the aldehyde was fully consumed (TLC) the irradiation was stopped and the solvent evaporated in vacuo. The diastereomeric ratio was determined by GLC and ^{1}H NMR analyses. Excess silyl enol ether and the desired oxetane were obtained by column chromatography (flash chromatography; eluent: cyclohexane/ethyl acetate as a gradient 200/1 → 95/5). For oxetanes *rac*-**2d**/*rac*-**3d** and *rac*-**2f**/*rac*-**3f** a complete separation of diastereoisomers was possible. In the other examples only an enrichment of the major diastereoisomers could be achieved. All compounds not yet reported were characterized by spectroscopic methods (^{1}H, ^{13}C, IR, MS) and gave correct elemental analyses (C, H ± 0.3%).

A Tailor-Made Metallocene for the Copolymerization of Ethene with Bulky Cycloalkenes**

Walter Kaminsky,* Rüdiger Engehausen, and Jürgen Kopf

Dedicated to Professor Joachim Klein on the occasion of his 60th birthday

Metallocenes in combination with methylaluminoxane (MAO) have gained great prominence as catalysts for the polymerization of olefins. Remarkable is their ability to polymerize cycloolefins such as cyclopentene, norbornene, and dimethanooctahydronaphthalene (DMON) to give homo- and copolymers in which only the double bond is opened and not the ring.[1] This distinguishes catalysis with metallocenes from that with common Ziegler–Natta catalysts or metathesis catalysts which are known to produce polymers containing ring-opened structures and elastomeric polymers by ring-opening polymerization.[2] Polycycloolefins prepared with metallocene catalysts exhibit extraordinarily high melting points of 400 °C and above due to their rigid, tactic structures. The high melting points prevent melt processing of these polymers. However, the copolymerization of cycloolefins with ethene results in cycloolefin copolymers (COC) with interesting properties. These copolymers are amorphous if more than 15 mol% of cycloolefin is incorporated, feature glass transition temperatures exceeding 200 °C, have high mechanical strength, and are stable towards common solvents. Since they contain no aromatic groups or double bonds their interaction with light waves is modest. Therefore they are well suited for optoelectronic applications in data transfer and storage (polymer optical fibers, compact discs); other possible applications have been discussed recently.[3] C_2- and C_s-symmetric metallocenes perform much better in the homopolymerization of cycloolefins and their copolymerization with ethene than compounds with higher symmetry like bis(cyclopentadienyl)zirconium dichloride which shows only low polymerization activities.

Zirconocenes like **1**[4] and **2**[5] containing unequally sized π ligands incorporate sterically demanding cycloolefins at high speeds into the polymer chain. The best copolymerization results are obtained with the C_1-symmetric **3** which up to now has not been characterized in detail and has only been applied in the polymerization of styrene.[6]

The structure of **3**, which crystallizes as yellow needles, was elucidated by single-crystal X-ray diffraction studies (Fig. 1).[8] The zirconium atom resides in a tetrahedral environment surrounded by two chlorine atoms and the centroids (Cen) of the five-membered rings of the indenyl and the cyclopentadienyl groups. The centroid-Zr-centroid angle (117.14°) in **3** which is

Selected bond lengths [Å] and angles [°]: Zr1-Cl1 2.404(1), Zr1-Cl2 2.433(1), Zr1-C1 2.436(2), Zr1-C2 2.425(2), Zr1-C3 2.551(2), Zr1-C4 2.631(2), Zr1-C9 2.536(2), Zr1-C11 2.446(2), Zr1-C12 2.451(2), Zr1-C13 2.523(2), Zr1-C14 (2.536(2), Zr1-C15 2.459(2), C1-C10 1.536(2), C10-C11 1.534(2), C10-C16 1.533(3), C10-C22 1.534(2); Cl1-Zr1-Cl2 102.63(2), Cen-Zr1-Cen 117.14(2), C1-C10-C11 99.1(1), C16-C10-C22 107.3(2), C1-C10-C16 112.9(2), C1-C10-C22 111.8(2), C11-C10-C16 111.5(2), C11-C10-C22 114.3(2).

important for the polymerization of sterically demanding cycloalkenes, exactly matches that of the isopropyl-bridged analogue [{Me_2C(ind)(Cp)}$ZrCl_2$], while the Cl-ZrCl angle of 102.63° in **3** is 2.5° larger. Compared to the corresponding angle in **1**, this angle is 5° larger. This somewhat more open angle should facilitate the polymerization of sterically demanding cycloalkenes. This effect is strengthened by the presence of electron-rich phenyl groups in the bridge, since they cause an increased activity which probably originates from enhanced stabilization of a cationic active species.[7]

Metallocene **3** is well-suited for the copolymerization of ethene with bulky cycloolefins like 1,4,5,8-dimethano-1,2,3,4,4a,5,8,8a-octahydronaphthalene (DMON) and 1,4,5,8,9,10-trimethano-1,2,3,4,4a,5,8,8a,9,9a,10,10a-dodecahydroanthracene (TMDA) which are prepared from the Diels–Alder reaction of cyclopentadiene and norbornene. Table 1 summarizes the results of the copolymerization of ethene and DMON by selected metallocene/MAO catalysts. A comparison of the activities achieved by **3** to those attained by the fluorenyl-cyclopentadienyl systems (structures **1** and **2**) shows the latter to be more active at low temperatures, while at high temperatures **3** is superior.

[a] C_D/C_E: Molar ratio DMNO:ethene, A: Activity in kg copolymer per mol metallocene per hour, M_n: Average molecular weight determined from viscosity, calculated as polyethylene; n.d. = not determined, Incorp.: Incorporation of DMON in the copolymer, T_g: Glass transition temperature.

The hafnocene **4**[4] is less active than the zirconocenes by one order of magnitude. The average molecular mass of the polymer decreases with increasing temperature of polymerization, but interpretation is hindered by different copolymer compositions. Compound **3** behaves differently in the catalysis: The overall low molecular mass of the copolymer increases with rising temperature and only decreases at very high DMON/ethene ratios. The metallocene **3** always incorporates higher proportions of DMON in the copolymer under comparable conditions.

The copolymers have melting points of 60–70 °C at low DMON incorporation, if the incorporation rate exceeds 15 mol% only a glass transition is observed. Metallocene **3** is able to incorporate more than 80 mol% of DMON, forming a copolymer with a glass transition temperature of 215 °C. The various catalysts produce copolymers with different microstructures as revealed by ^{13}C NMR spectroscopy and WAXS.[9] The copolymers produced by catalysis with **3** exhibit a less-ordered structure; they are less crystalline than copolymers produced by C_s-symmetric metallocenes **1** and **2**.

The copolymerization is characterized by the copolymerization parameter r_1. This expresses how much faster ethene is incorporated than DMON in the copolymer. The parameter r_2 was also determined which gives the ratio of DMON to ethene incorporation. Further interpretation is not possible due to the lack of a model for the mechanism of insertion. The calculations were done according to Mayo–Lewis and Finemann–Ross models[10] from kinetic data and copolymer composition as detected by ^{13}C NMR spectroscopy. Table 2 gives the results for the three catalysts.

Table 2. Copolymerization parameters of the ethene/DMON copolymerization at 50 °C.

Catalyst	r_1	r_2	$r_1 \times r_2$
[{Ph_2C(fluo)(Cp)}$ZrCl_2$] **2**	7.0	0.02	0.14
[{Ph_2C(ind)(Cp)}$ZrCl_2$] **3**	6.4	0.10	0.64
[{Me_2C(fluo)(Cp)}$HfCl_2$] **4**	7.1	0.04	0.28

The zirconocene **3** inserts ethene only 6.4 times faster than DMON and therefore has the lowest r_1 value. Thus, it inserts the bulky cycloolefin better than the two C_s symmetric catalysts **1** and **2**. C_2-symmetric metallocenes like *rac*-[en(ind)$_2$]$ZrCl_2$ or *rac*-[en(indH_4)$_2$]$ZrCl_2$ give r_1 parameters of 15 and 50, respectively.[11] The product $r_1 \times r_2$ is less than 1 for all metallocenes tested. For the metallocene **3** this product is 0.63, which is closest to that of a statistical copolymer (1). The smaller $r_1 \times r_2$ values observed in case of the C_s-symmetric metallocenes indicate a tendency to alternation.

Analogous copolymerizations of ethene with the even more bulky TMDA were carried out using zirconocenes **2** and **3** as catalysts. Table 3 summarizes the results. As already observed for the DMON/ethene system, the activity and molecular mass decreases as the cycloolefin/ethene ratio and thereby the incorporation of cycloolefin increases. Again **3** incorporates more TMDA than the metallocene **2**. The observation of melting points by DSC measurements indicates a higher amount of crystalline polyethylene domains in these copolymers. The glass transition temperature of copolymers containing the same amount of cyclic monomer units is higher for TMDA/ethene

Table 3. Copolymerization of TMDA and ethene with two zirconocene/MAO catalysts at 50 °C [a].

Catalyst	C_T/C_E	A	M_n	Incorp. [mol %]	T_g [°C]
[{Ph_2C(fluo)(Cp)}$ZrCl_2$] **2**	0	1800	400000	0	(134.4)
	1.64	780	59000	9	65.5 (132.1)
	3.29	232	30000	18	96.1 (128.0)
	6.58	41	22000	27	110 (124.4)
[{Ph_2C(ind)(Cp)}$ZrCl_2$] **3**	3.29	33	17000	20	(128.2)

[a] C_T/C_E: Molar ratio of TMDA:ethene. A: Activity in kg polmyer per mol metallocene per hour. M_n: Average molecular weight determined from viscosity, Incorp.: Incorporation of TMDA in the copolymer. T_g: Glass transition temperature, melting point in parentheses.

copolymers than for DMON/ethene copolymers. At 50 °C the r_1 value for the TMDA/ethene copolymerization is 15.6, the r_2 value is 0.06, and $r_1 \times r_2$ is 0.94 (cf. Table 3).

The results presented here indicate that the performance of different metallocenes in the copolymerization of ethene and cycloolefins strongly depends on the metallocene used. The copolymers produced by the zirconocene **3** feature the highest incorporation rates of bulky comonomers.

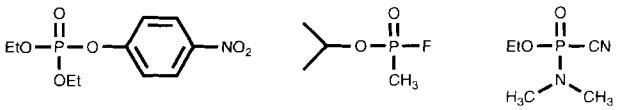
Antibody-Catalyzed Phosphate Triester Hydrolysis**

Jonathan S. Rosenblum, Lee-Chiang Lo, Tingyu Li, Kim D. Janda,* and Richard A. Lerner*

Dedicated to the memory of James D. Bain

Phosphate ester hydrolysis has challenged biologists and chemists for many years. While attention has focused on phosphate mono- and diesters since these have the best understood biological properties, phosphate triesters are also biologically relevant. The significance of phosphotriesters in biology ranges from their essential role in the adaptive response in *E. coli*[1] to their use as prodrugs for nucleoside analog pharmaceuticals.[2, 3] Derivatives of phosphate triesters are used as insecticides and are potent biological warfare agents. This class of compounds includes sarin, isopropyl(methyl)phosphonofluoridate, which was recently used in a deadly bombing in a Japanese subway.[4] Although there are phosphotriesterases in nature, their natural substrates are not known.[5]



Paraoxon Sarin Tabun

In addition to their biological importance, phosphate esters present fundamental chemical issues relating to their unique hydrolytic stability[6] and involvement of a pentacoordinate transition state for hydrolysis. Antibodies catalyzing the hydrolysis of phosphate triesters would be interesting from biological and chemical points of view. Such antibodies could be used to interfere with the response of *E. coli* to mutagenic methylating agents, activate prodrugs (carboxylate ester prodrugs have been hydrolyzed by catalytic antibodies[7, 8]) or treat or prevent organophosphate neurotoxin poisoning.[9, 10] Such catalysts should also help define the structural and electrostatic requirements of the transition states for phosphate ester hydrolysis. Herein we describe an antibody capable of catalyzing phosphate triester hydrolysis.

The pentacoordinate transition state for base-promoted phosphate di- and triester hydrolysis arises from attack of hydroxide and leaving group extrusion in-line on the apical axis (Scheme 1). Whereas the tetrahedral intermediate of carboxylate ester hydrolysis is accurately mimicked by many functionalities,[11, 12] pentavalent centers are rare in organic chemistry (for recent exceptions see refs. [13,14]). Additionally, many pentavalent species are either toxic or unstable, decreasing their utility as haptens for immunization. Conversely, the unique electrostatic features of the transition state anticipated on the

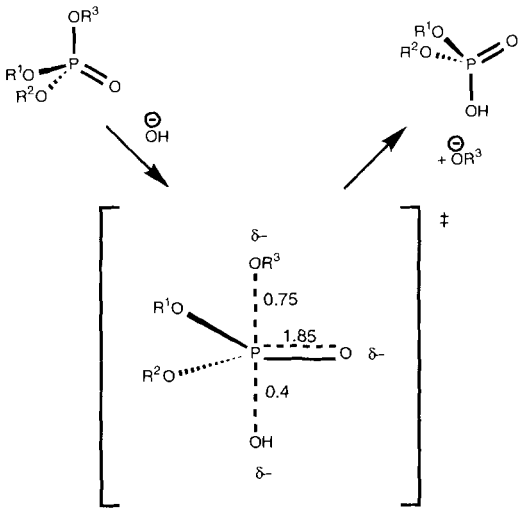


Scheme 1. Mechanism of phosphate triester hydrolysis emphasizing structure and electrostatics of the transition state. Numbers refer to bond order in the case of base-catalyzed paraoxon hydrolysis [27].

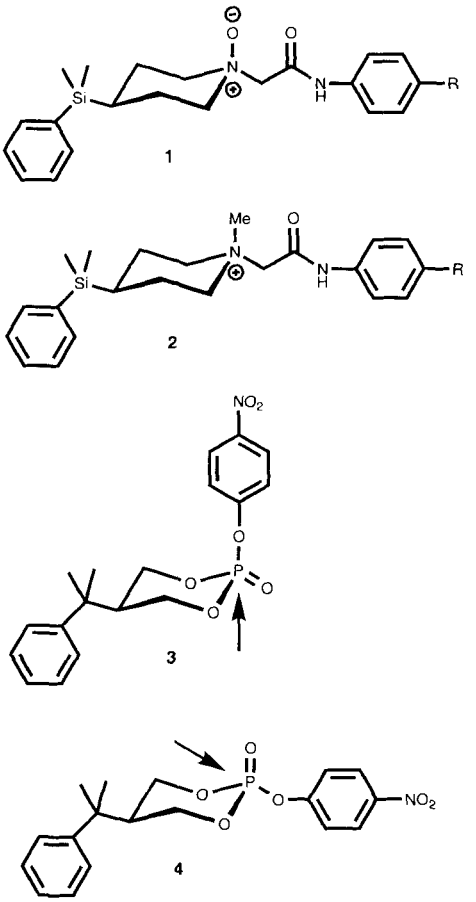
reaction coordinate are more easily mimicked. As such it is of interest to determine if a pentavalent species is a necessary feature of the hapten, or if addressing the electrostatic features of the transition state alone are sufficient to yield an efficient catalyst.

We have screened antibodies which recognize either an amine oxide-containing hapten or a quaternary amine-containing hapten for phosphotriesterase activity. Charged haptens are expected to induce antibodies that affect catalysis by either stabilization of a polar transition state or by elicitation of a reactive side chain that may act as a general base.[15-17] Hapten **1** contains an amine oxide whose dative bond overlaps with the scissile bond of **3** and the P=O bond of **4**. Any positive charge developing at the phosphorus center would be stabilized by anionic functionalities in the antibody combining site, induced by the positive pole of the amine oxide hapten **1**. The negative pole of the amine oxide corresponds to the developing negative charge on the oxygen atom of the leaving group in the transition state for the hydrolysis of **3**, or to a partial negative charge on the phosphoryl oxygen atom in the transition state for the hydrolysis of **4** (Scheme 2). As a result of regiospecific induction of countercharge, it may be possible, by comparing the hydrolysis of **3** and **4** by antibodies to **1**, to determine which of the partial negative charges in the transition state need to be stabilized.

Hapten **2** is a close analog of **1**, differing only in the substitution of a quaternary amine for the amine oxide functionality of **1**.[18] This hapten is expected to induce anionic but not cationic character in the antibody binding site and as such may help to further deconstruct the important charge parameters for transition state stabilization.

Twenty-five antibodies to **1** and 17 antibodies to **2**[19] were screened for their ability to catalyze the hydrolysis of **3** and **4**. Five antibodies to each hapten were catalytic. One antibody to **1**, Tx1-4C6,[19] was particularly efficient and was studied further. Reaction of Tx1-4C6 with **3** and **4** followed Michaelis–Menten kinetics (Fig. 1, Table 1). Antibody-catalyzed reactions were stoichiometrically inhibited by the hapten, could be saturated by substrate and displayed turnover. Antibody Tx1-4C6 bound hapten **1** with a K_d of 0.67 μM as determined by quenching of intrinsic antibody fluorescence by the hapten.

The rate of the uncatalyzed hydrolysis of **3** is slower than that of **4**, since **3** is stabilized by the generalized anomeric effect.[20]



Scheme 2. Structural formulas of the haptens **1** and **2** and substrates **3** and **4**. Arrows indicate orientation of attacking hydroxide for in-line triester hydrolysis. R = linkage to protein (for immunization). R = $NHCOCH_3$ (for inhibition studies).

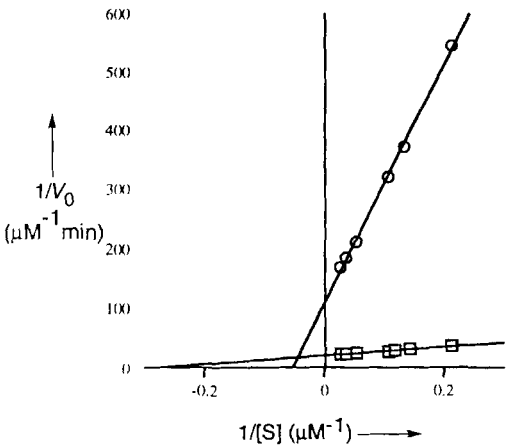


Fig. 1. Lineweaver–Burke plot of antibody Tx1-4C6 hydrolysis of **3** (□) and **4** (○). S = substrate, V_0 = initial rate.

Table 1. Kinetic parameters for Tx1-4C6-catalyzed hydrolysis of compounds **3** and **4**.

Substrate	k_{uncat} [min^{-1}]	k_{cat} [min^{-1}]	K_M [μM]
3	2.77×10^{-5}	1.01×10^{-2}	3.57
4	8.77×10^{-5}	1.85×10^{-3}	18.7

Interestingly, Tx1-4C6 was able to effect a reversal of intrinsic reactivity, catalyzing the hydrolysis of **3** more so than **4**, $k_{uncat}(\mathbf{3})/k_{uncat}(\mathbf{4}) = 0.316$; $k_{cat}(\mathbf{3})/k_{cat}(\mathbf{4}) = 5.46$. This reversal may be derived from either ground-state stabilization[21] or a tighter geometrical fit of the transition state for the hydrolysis of **3** than that of **4**. This differential accomodation can be rationalized in light of the structure of the eliciting hapten **1** (Scheme 2). For substrate **3**, the apical axis of the pentavalent phosphorus at the transition state overlaps with the axial orientation of the N–O bond in **1**.[19] thus stabilizing a mechanism in which the leaving group departs from a subtended angle of 180° relative to the three interacting atoms. By contrast, antibodies to amine oxide hapten **1** would be expected to polarize the P=O bond for substrate **4**. As **3** is a better substrate for Tx1-4C6, we suggest that polarization of the scissile bond for a concerted reaction is more profitable than polarization of the P=O bond which may favor a two-step reaction involving pseudorotation.[22]

Antibody Tx1-4C6 has a limited substrate range. It does not bind, and therefore does not hydrolyze, paraoxon. Likewise, Tx1-4C6 is not able to hydrolyze carboxylate esters related to **3** and **4**.

One of the powerful aspects of antibody catalysis is the ability to address selected features of the transition state of any chemical reaction. Here, we have demonstrated this principle and achieved phosphate ester hydrolysis by an antibody that was programmed to accomodate only the electrostatics of the transition state of the reaction. The best antibody catalysts were induced by amine oxide **1**, yet **2** also induced several catalysts, indicating that catalysis may be achieved by the singular event of lowering the energy of a developing positive charge in the transition state. But, as expected, better catalysis is achieved when additional features of the transition state, such as the developing negative charge at the leaving-group oxygen is addressed. In order to generate more efficient catalysts it will now be necessary to keep the electrostatic features of the antibody in place and address the more difficult geometric parameters. In this way we can learn about catalysis by building an enzyme piece by piece. Furthermore, through the development of antibodies we could explore whether the hydrolysis of phosphate diesters can be facilitated through a "triester-like" mechanism,[23, 24] in which the initial step is the protonation of the phosphate anion oxygen.

Experimental Procedure

3, **4**: *Alkylation of diethyl isopropylidenemalonate* [25]: To a solution of diethyl isopropylidenemalonate (10.0 g, 50 mmol) in anhydrous ether (20 mL) was slowly added phenylmagnesium bromide (50 mL, 50 mmol, 1.0 M in THF) at 0 °C. The reaction was kept at 0 °C for 30 min, then heated to reflux for 1 h. The reaction mixture was concentrated, poured into ice-cold diluted H_2SO_4, and extracted three times with EtOAc. The combined EtOAc solution was concentrated and the 1,4-addition product purified (3.8 g, 28%) by silica gel column chromatography eluted with hexane/EtOAc (8/1).

$LiAlH_4$ reduction of the diester: The diester (1.34 g) obtained was dissolved in anhydrous ether (42 mL), followed by slow addition of $LiAlH_4$ (0.37 g). The reaction was kept at room temperature overnight. Usual workup offered diol in 35% yield. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 7.34$–7.27 (m, 4 H; aromatic), 7.21–7.16 (m, 1 H; aromatic), 3.78 (dd, $J = 10.4$, 3.7 Hz, 2 H), 3.70 (dd, $J = 10.4$, 9.8 Hz, 2 H), 2.15 (m, 1 H), 2.00 (bs, 2 H; *OH*).

Phosphorylation of the diol: The diol (145 mg) in THF (2 mL) was added dropwise to a solution of pyridine (133 μL) and *p*-nitrophenylphosphorodichloridate (210 mg) in THF (5 mL). The mixture was stirred at room temperature for 2 h, then concentrated. The desired products **3** (70 mg, 25%) and **4** (72 mg, 26%) were separated by silica gel column chromatography eluted with hexane/EtOAc (2/1). Compound **3**: $R_f = 0.27$. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 8.22$ (d, $J = 9.2$ Hz, 2 H; aromatic), 7.39–7.24 (m, 7 H; aromatic), 4.32 (dd, $J = 10.9$, 4.9 Hz, 2 H), 4.26 (dd, $J = 10.9$, 4.9 Hz, 2 H), 2.68 (m, 1 H), 1.38 (s, 6 H; CH_3); ^{31}P NMR (300 MHz, $CDCl_3$, heteronuclear decoupled): $\delta = -13.37$. Compound **4**: $R_f = 0.20$, ^1H NMR (300 MHz, $CDCl_3$): $\delta = 8.22$ (d, $J = 9.2$ Hz, 2 H; aromatic), 7.38–7.22 (m, 7 H; aromatic), 4.48–4.36 (m, 4 H), 2.31 (m, 1 H), 1.47 (s, 6 H; CH_3); ^{31}P NMR (300 MHz, $CDCl_3$, heteronuclear decoupled): $\delta = -12.29$.

The stereochemistry of **3** and **4** was determined by comparing their R_f values, ^1H and ^{31}P NMR spectra with those of similar compounds from the literature [26].

Assays: All reactions were followed spectrophotometrically at 30 °C, following *p*-nitrophenolate production at 402 nm. The extinction coefficient determined under the reaction conditions was $1.80 \times 10^4\,M^{-1}\,cm^{-1}$. Typically, solutions of 50 mM Bicine, pH 8.5 with or without 5 μM 4C6 were equilibrated at the reaction conditions for 30 min. Reactions were initiated by addition of a constant volume of various concentrations of the substrate in DMSO. The final DMSO concentration was 0.375%. The reactions were followed for approximately 2 h, after which time less than ten percent of the substrate had been consumed.

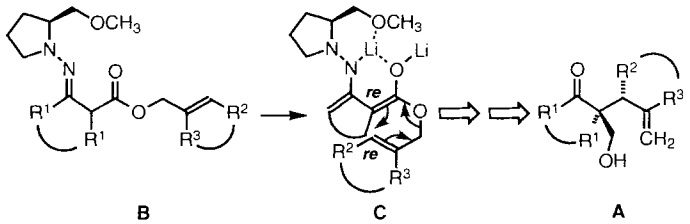
Diastereo- and Enantioselective Synthesis of Polyfunctional Ketones with Adjacent Quaternary and Tertiary Centers by Asymmetric Carroll Rearrangement**

Dieter Enders,* Monika Knopp, Jan Runsink, and Gerhard Raabe

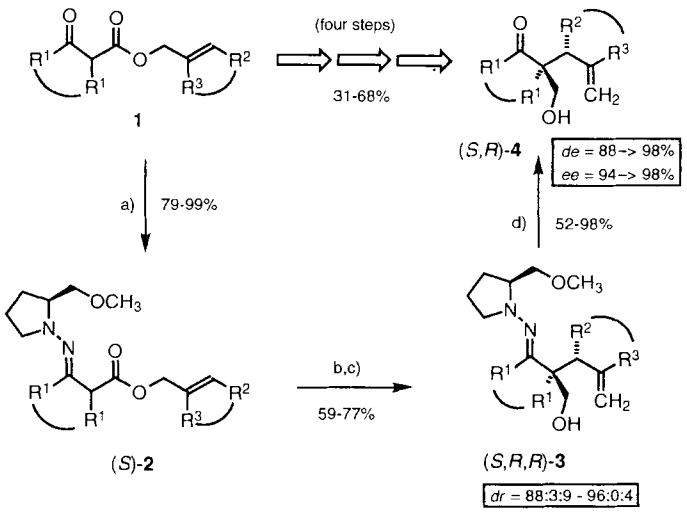
Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 70th birthday

The diastereo- and enantioselective generation of adjacent quaternary and tertiary stereogenic centers by C–C bond formation is a challenge in natural product and drug synthesis.[1] Recently, numerous methods for the introduction of quaternary stereogenic centers in highly functionalized building blocks have been developed.[2–7] But only a few variants allow the simultaneous preparation of an adjacent tertiary stereogenic center.[8] Intramolecular transformations such as sigmatropic rearrangements appear to be highly suited for this purpose. The [3,3]-sigmatropic Carroll rearrangement is an appropriate synthetic tool. Although discovered in 1940,[9] this reaction was first applied in drug synthesis only recently.[10] Many different variations of the Carroll rearrangement are known but most of them proceed with decarboxylation of the initially formed β-keto-acid.[11–13] Decarboxylation can be avoided by esterification or intramolecular lactonization of the β-keto acids at low temperatures, leading to the rearranged products with excellent *syn*/*anti* diastereoselectivities.[10, 14] Whereas so far only one diastereoselective variant, starting from (*S*)-pulegone, has been described for the preparation of optically active rearrangement products,[15] we have succeeded in the development of an asymmetric variant of the Carroll rearrangement.

We report here on a highly diastereo- and enantioselective synthesis of sterically demanding, functionalized ketones **A** with adjacent quaternary and tertiary centers starting from β-hydrazonoesters **B**. The key step is the stereoselective [3,3]-sigmatropic Carroll rearrangement of the hydrazonoester dienolate **C**. The ketones **A** are obtained after reductive workup and oxidative cleavage of the auxiliary.



As depicted in Scheme 1, reaction of β-ketoesters **1**[16] with the chiral auxiliary (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP) yields the corresponding SAMP hydrazones (*S*)-**2**. These are doubly deprotonated with 2.6 equivalents of lithium diisopropylamide at −100 °C in THF/TMEDA, allowed to rearrange, and then directly reduced with 5 equivalents of lithium



Scheme 1. Asymmetric Carroll rearrangement of allyloxycarbonyl ketones to polyfunctional ketones in four steps: a) 1.2 equiv SAMP, toluene, 5 mol% *p*-TosOH, molecular sieves, 110 °C, 1–2 h; column chromatography (silica gel, ether/petroleum ether/triethylamine 1/10/0.2); b) 2.6 equiv LDA, THF/TMEDA (8/1), −100 °C → 25 °C, 20 h; c) 5 equiv $LiAlH_4$, ether, 25 °C, 2 h; column chromatography (silica gel, ether/petroleum ether 1/2); d) ozone (2–3 min mmol^{-1}) pentane, −78 °C; column chromatography (silica gel, ether/petroleum ether 1/6). TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

aluminium hydride in ether to give the β-hydroxy hydrazones (*S*,*R*,*R*)-**3**.[17] Upon column chromatography the rearranged products are obtained in good yields (59–77%) as pale yellow oils (**3a–d, f, i**) or colorless crystals (**3e, g, h**). The hydrazone **3h** could be diastereomerically enriched by column chromatography to give the diastereomerically pure product. The ketone function was regenerated by ozonolysis of the rearranged products (*S*,*R*,*R*)-**3** at −78 °C in pentane, giving compounds **4a–g** in very good yields (89–99%). The ozonolysis occurred without racemization and chemoselectively without oxidation of the C=C bond. For the ketones **4h, i** the yields were only 52–57%, since in these cases the exocyclic C=C bond was partially oxidized.

The ratios of the diastereomeric products **3** resulting from the asymmetric Carroll rearrangement are very good [(*S*,*R*,*R*):(*S*,*S*,*S*):(*S*,*S*,*R*):(*S*,*R*,*S*) = 88:3:9:0 to 96:0:4:0] and were determined by ^{13}C NMR spectroscopy (Table 1).

The diastereomeric excesses of the ketones **4** were determined by ^{13}C NMR spectroscopy. The enantiomeric excesses were measured by ^{1}H NMR spectroscopy of the α-methoxyphenylacetic acid esters (MTPA esters) by comparison with the corresponding racemates.[18] The racemates were prepared by submitting

the respective *N,N*-dimethylhydrazones to the rearrangement (Table 2).

The absolute configuration of the rearranged hydrazones was determined to be (*S,R,R*) by means of the X-ray structure of the hydrazone **3e** (Fig. 1).[19] The absolute configuration of the hydrazones **3a**–**d**, **f**–**i**, and thus consequently of the final products **4**, was assigned accordingly based on the assumption that the

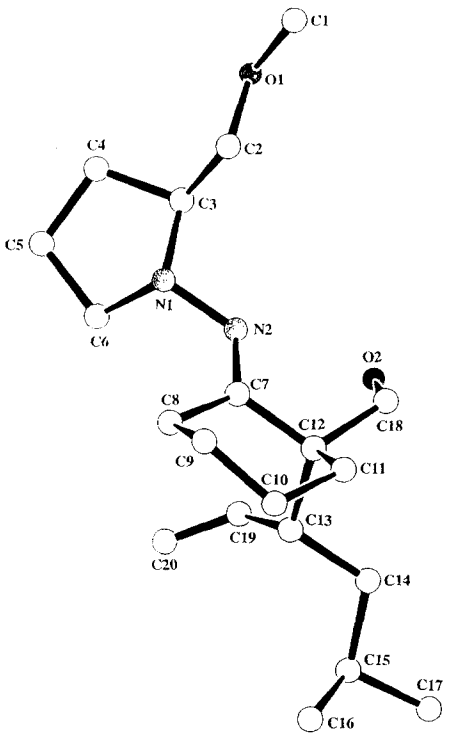

Fig. 1. Crystal structure of hydrazone **3e** [19] (SCHAKAL presentation [26]).

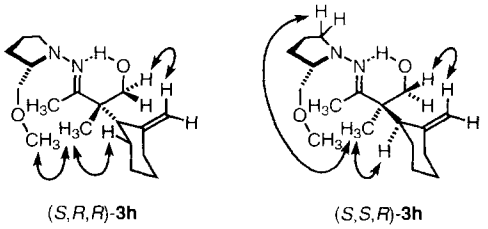
reaction proceeds analogously in all cases. For hydrazone **3h** the configuration of the major diastereomer and one minor diastereomer was investigated by NMR spectroscopy using NOE measurements (Fig. 2).[20]

The absolute configuration (*R*) at the quaternary stereogenic center, assigned by X-ray structure determination,[21] is in accordance with results concerning intermolecular electrophilic substitutions of β-hydrazonoesters.[22] As depicted for hydrazonoester dienolate **C**, we postulate an intramolecular chelation of the lithium by the methoxymethyl group and consequently, the



(*S,R,R*)-**3h** (*S,S,R*)-**3h**

Fig. 2. NOE measurements for hydrazone **3h**.

allylic moiety approaches from the sterically less hindered side[23] (*re–re* attack) with formation of a new σ bond. The configuration of the tertiary stereogenic center is easily assigned under the assumption that the [3,3]-sigmatropic rearrangement occurs via a chairlike transition state.[24]

The synthetic value of this [3,3]-sigmatropic rearrangement is due to the high flexibility possible through variation of the residues (R^1, R^2, and R^3). Not only cyclopentanone SAMP and cyclohexanone SAMP hydrazones (**2a–g, i**) but also acyclic hydrazones (e.g. **2h**) can be employed. The allylic alcohol moiety can be varied significantly too. Use of alcohols with an endocyclic double bond (**2h, i**) leads to rearranged products with exocyclic double bonds (**3h, i**).

The [3,3]-sigmatropic rearrangement presented here is, to the best of our knowledge, the first asymmetric Carroll rearrangement. It makes possible the C–C bond forming, intramolecular generation of two adjacent stereogenic centers in good yield with high diastereoselectivity and extremely high enantioselectivity. The γ,δ-unsaturated β′-hydroxyketones accessible with this method have a stereogenic center in the α position and variable substitution at the tertiary stereogenic center in the β position, and may serve as chiral building blocks in natural product and drug synthesis.

Experimental Procedure

SAMP hydrazones **2**: β-Ketoester **1** was heated to reflux for 1–2 h in toluene (1 mL mmol^{-1}) with 1.2 equivalents of SAMP in the presence of 5 mol% *p*-toluenesulfonic acid and molecular sieves. The reaction was monitored by thin-layer chromatography. Upon removal of the solvent, the residue was dissolved in ether (3 mL mmol^{-1}), washed twice with saturated aqueous NaCl solution, and dried over magnesium sulfate. Purification of the yellow crude products by column chromatography (silica gel, ether/petroleum ether/triethylamine 1:10:0.2) provided colorless liquids.

Hydrazones **3**: To 5.2 mmol of diisopropylamine in 8 mL of anhydrous THF was added dropwise 3.25 mL of a 1.6 N solution of *n*-butyllithium in hexane at 0 °C under an atmosphere of argon. After 5 min, 1 mL of TMEDA was added dropwise. Then 2 mmol of the hydrazone **2**, dissolved in 1 mL of THF, was added dropwise at −100 °C. The reaction mixture was allowed to warm to room temperature over 12 h. The reduction was carried out by dropwise addition of the reaction mixture to a suspension of 10 mmol of $LiAlH_4$ in 50 mL of ether at room temperature using a cannula. After 3 h the reaction mixture was hydrolyzed with 10 mL of 1% HCl solution, the aluminium hydroxide precipitate filtered, and the filtrate dried over magnesium sulfate. Upon purification by column chromatography (silica gel, ether/petroleum ether 1:2) pale yellow liquids (**3a–d, f, i**) or colorless crystals (**3e, g, h**) were obtained.

Ketones **4**: 1 mmol of hydrazone **3** was dissolved in 20 mL of pentane and cooled to −78 °C. Ozone was bubbled through the reaction mixture (flow rate 40 L h^{-1}) [25]. The reaction was interrupted by bubbling argon through the solution in order to monitor by thin-layer chromatography. Upon completion the reaction mixture was allowed to warm to room temperature whilst argon was bubbled through. After removal of the solvent, the residue was purified by column chromatography (silica gel, ether/petroleum ether 1:6).

[19] Suitable single crystals were obtained from ether at −20 °C. The compound crystallizes in the orthorhombic space group $P2_12_12_1$ (No. 19), $a = 6.7328(3)$, $b = 13.9095(6)$, $c = 22.3704(7)$ Å. For a cell volume of 2095.0 Å^3, $Z = 4$ and $M_{calcd} = 336.5$ the density is 1.067 g cm^{-3}. Total number of electrons per element unit F(000) = 744. Enraf-Nonius CAD4 diffractometer, graphite monochromator, $Cu_{K\alpha}$ radiation ($\lambda = 1.54179$ Å). The structure was solved by direct methods (GENSIN, GENTAN aus XTAL3.2 [21]). Some of the positions of the hydrogen atoms could be located, the others were calculated. 1915 observed reflections ($I > 2\sigma(I)$), 218 parameters refined, $R = 0.055$ ($R_w = 0.051$). Maximum residual electron density ±0.2 e Å^{-3}. The Absolute configuration was assigned using the known configuration at C3. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-59067.
[20] Both isomers are conformationally rigid due to hydrogen bonding of the alcohol proton to the sp^2-hybridized nitrogen atom. For the major diastereoisomer (*S,R,R*)-**3h** an NOE between the methyl group at the quaternary center and the methyl protons of the SAMP methoxy group is observed. For the minor diastereoisomer (*S,S,R*)-**3h** an NOE between the methyl group and the NCH_2 protons of the chiral auxiliary is found. Thus the two isomers differ from each other with regard to the configuration of the quaternary center. Further NOE measurements show that both isomers are substituted at the equatorial positions of the six-membered ring. The relative configurations of the two stereogenic centers were determined by means of the following NOEs: Firstly, both diastereoisomers show a strong NOE between one of the two protons of the exocyclic double bond and one of the two diastereotopic hydroxymethylene protons. Secondly, an NOE is observed between the protons of the methyl group at the quaternary stereogenic center and the equatorial proton of the CH_2 group in the six-membered ring in the α position to the tertiary stereogenic center in the major diastereoisomer, whereas in the minor diastereoisomer an interaction of the methyl group at the quaternary stereogenic center with the axial ring proton at the tertiary stereogenic center is found (Fig. 2).

Optimization of the Biological Activity of Combinatorial Compound Libraries by a Genetic Algorithm**

Lutz Weber,* Sabine Wallbaum, Clemens Broger, and Klaus Gubernator

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The key task in the initial phase of the discovery of biological effectors is to identify a tightly binding ligand for a given biological target molecule. Exploiting molecular diversity with combinatorial compound libraries has been proposed as a method to speed up the development of such new prototype ligands. Compound libraries are synthesized either as complex mixtures by the "split and combine" methodology (mainly by solid-phase syntheses) or as single compounds by "array" syntheses carried out in solution.[1] Whereas the "split and combine" method

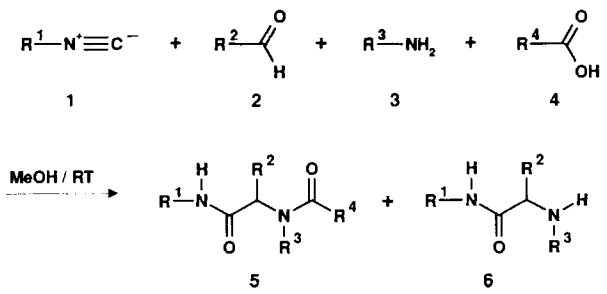
uses sequential synthesis schemes to generate a large number of compounds, synthesis of many compounds in an array ideally uses versatile one-pot reactions. Cycloadditions or reactions with even more components like the Asinger or Ugi cascade reactions provide diverse products in a one-pot procedure and are therefore especially suitable for parallel synthesis.[2, 3] Thus, the Ugi reaction allows the rapid set-up of many reactions in parallel by mixing an isocyanide, an aldehyde, an amine, and a carboxylic acid in methanol at room temperature (Scheme 1). The combination of 10 isocyanides (**1**), 40 aldehydes (**2**), 10 amines (**3**), and 40 carboxylic acids (**4**) results in 160000 different Ugi-type reactions. We present here a search and synthesis procedure that can be used to find biologically active compounds from this library of 160000 reactions by synthesizing and testing only a small fraction of all possible reaction products.

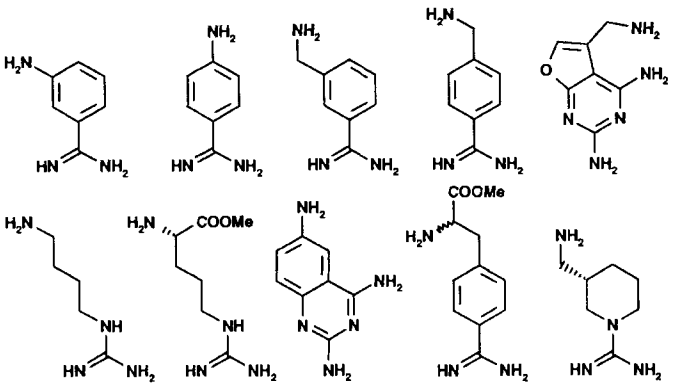


Scheme 1. The four-component Ugi reaction. RT = room temperature.

Genetic algorithms have proven to be extraordinarily efficient in optimizing complex, multidimensional problems. Adopting the rules of genetics (replication, crossover, and mutation), new generations of molecules that may show more favorable properties than their parents are synthesized in parallel.[4] Using an enzymatic assay to test the biological activity, this evolutionary feedback loop will search for those starting materials in the Ugi reactions whose reaction products have high inhibitory activity against the given enzyme. The serine protease thrombin was chosen as the target biochemical system.[5] Its pivotal role in the blood coagulation cascade and related pathogenic thrombotic processes makes the identification of thrombin inhibitors an attractive goal for therapeutic anticoagulants. Commercially available reagents **1** (10), **2** (40), **3** (10), and **4** (40 compounds) were selected to obtain a diverse set for each component **1**–**4** with respect to size, hydrophobicity, and donor and acceptor properties. This general library was limited only in that amine **3** has a donor-rich basic side chain (Scheme 2), which is known to mediate trypsin-like serine protease inhibitory activity.[6]

Experimental conditions were chosen after performing a series of test reactions and thrombin chromogenic assays of the crude reaction mixtures.[7] Weak nucleophilic amines like 4-aminobenzamidine afforded two main products upon dilution of the reaction mixture with the aqueous buffer assay medium, the four-component adduct **5** and a three-component product **6** lacking the carboxylic acid residue (Scheme 1).[8] Interference with residual unreacted reagents, which show only weak inhibitory activities in the enzyme assay, could be excluded by control experiments.

A simple genetic algorithm was implemented.[9] Individual reagents were encoded by an arbitrary bit pattern, for example 0010 for benzylisocyanide. The length of bit patterns was chosen to encode each of the possible substituents (or reagents) at each of the four positions R^1–R^4. Thus, the combined bit pattern encodes the reaction mixture of four specified reagents **1**, **2**, **3**, and **4**, for example, 0010 011100 0111 010011 for the starting materials benzylisocyanide, salicylaldehyde, agmatine [(4-amino-*n*-butyl)guanidine], and propionic acid. Survival of patterns, "replication", is ensured in our experiment by storing all experimental results in a database. Crossover and mutation however, are allowed only for those bit patterns (reactions) which showed high inhibitory activity in the thrombin assay. Crossover is performed by intersecting two bit patterns at a random position and exchanging the intersected parts, resulting in two new patterns. A mutation results in reversal of a bit at a random position of a given bit pattern. Reactions are then carried out if a new bit pattern corresponds to real starting materials otherwise the procedure is repeated. The adjustable parameters of the genetic algorithm, population size (number of reactions to be performed in parallel) and mutation rate, were chosen in a series of test runs against a database of 160000 virtual compounds, whose activities were calculated with different test functions, such as superimposed sinusoidal functions in four dimensions. For the four-component problem presented here the most active individual was obtained with a population size of 20, a crossover probability of 100%, and a mutation rate of 1% in 20 to 50 generations.



Scheme 2. The ten amines **3** used in the genetic algorithm.

The experiment was started by selecting the first 20 bit patterns randomly. The corresponding reactions were performed and the crude products were tested. The resulting data were entered into the genetic algorithm that calculated the next 20 bit patterns by crossover and mutation. From these 40 reaction products, the 20 most active were used as parents for the calculation and synthesis of the next generation. This was repeated for 20 generations such that a total of 400 different Ugi reactions were carried out.

Already after 16 cycles, the average effective inhibitory activity (EC_{50}) of the 20 best products at each generation was submicromolar in the thrombin assay (Fig. 1). The most active

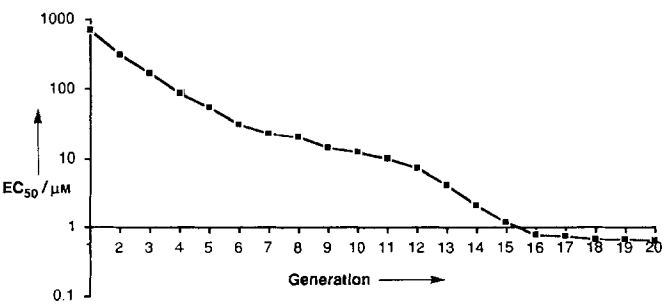


Fig. 1. Average inhibitory activity of the 20 best Ugi reaction products in the thrombin chromogenic assay. Effective inhibitory concentrations (EC_{50}) are given in micromolar concentrations.

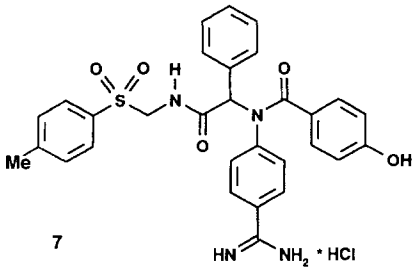
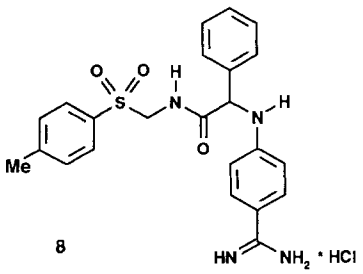
reaction product out of these 400 reactions was found in generation 18. This reaction was repeated on a larger scale and the expected products were isolated and purified. The inhibitory activities (K_i) of the novel racemic four-component adduct **7** and the three-component compound **8** were 1.4 and 0.22 μM, respectively. Both compounds exhibit structural features of already known thrombin inhibitors[5] and might be regarded as prototypic compounds which could be further optimized by classical medicinal chemistry methods.



7



8

We may not necessarily have discovered the most active compound out of all 160000 possible reactions by the described method. However, the method can easily be modified by synthesizing more generations, by varying the population size and/or mutation rate, or by introduction of other useful starting materials. Modern robotic bioassay systems may allow the easy implementation of this method including both automatic synthesis and testing. As a consequence, the design of multicomponent reactions and limited starting material libraries based on biostructural information will become an important tool in pharmaceutical research.

Experimental Procedure

General procedure: 25 μL of 0.1 M solutions of an isocyanide, aldehyde, amine, and a carboxylic acid in methanol were allowed to react at room temperature for 20 h. The crude reaction product was then dissolved in dimethyl sulfoxide (50 μL) and diluted with Britt–Robinson buffer (pH = 7.8) to obtain the desired concentration for the thrombin assay [7].

7: Solutions (each 1 mmol) of benzaldehyde, 4-amino-benzamidine dihydrochloride, 4-hydroxybenzoic acid, toluene-4-sulfonylmethyl isocyanide as well as triethylamine (2 mmol) in methanol were allowed to react at room temperature for 24 h. After addition of several drops of 25% HCl to the reaction mixture, the solvent was evaporated in vacuo and the resulting residue was separated on reversed-phase silica (RP18) using a water/methanol gradient. Yield 28%; yellow powder; ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C, TMS): δ = 2.41 (s, 3H), 3.72 (s, 2H), 5.61 (s, 1H), 6.72-8.01 (m, 18H), 8.82 (s, broad, 2H), 8.98 (s, broad, 2H); electrospray-MS: *m/z* 557.7 ([*M* + H]$^+$, 100%).

8: Using the same procedure as for compound **7** but without 4-hydroxybenzoic acid, **8** was obtained in 22% yield as a yellow amorphous powder. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25°C, TMS): δ = 2.37 (s, 3H), 3.67 (s, 2H), 5.50 (s, 1H), 6.83-7.69 (m, 13H), 8.88 (s, broad, 2H), 9.00 (s, broad, 2H); electrospray-MS: *m/z* 437.6 ([*M* + H]$^+$, 100%).

Mechanism of the Fe^+ Mediated C–C and C–H Bond Activations in Ethane from a Theoretical Viewpoint**

Max C. Holthausen, Andreas Fiedler, Helmut Schwarz, and Wolfram Koch*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 65th birthday

The activation of C–H and C–C bonds in hydrocarbons by transition metals is of paramount interest in organic chemistry, biochemistry, and catalytic research.[1] A sound understanding of the crucial steps and the complete characterization of the central intermediates are prerequisites, for example, for the de novo design of catalysts. However, the synergistic cooperation of experiment and theory, so successful in many areas of research, has had only limited impact in this field as of yet. The description of complicated electronic structures of open-shell transition metal compounds requires a very sophisticated treatment which, in the framework of conventional ab initio MO theory, usually exceeds nowadays computational capabilities, even for only moderately sized systems.[2] As promising alternative for an accurate and yet efficient computational treatment of such species, density functional theory (DFT)[3] and, in particular, DFT/Hartree-Fock (HF) hybrid methods[4] have recently attracted considerable attention.

The reaction of Fe^+ with ethane is a prototype for the activation of C–H and C–C bonds by transition metal cations, and extensive studies employing various mass spectrometric tech-

Morokuma for a preprint of ref. [12].

niques have been carried out.[5] While rather accurate thermochemical information on the entrance and exit channels of the potential energy surface (PES) are available,[5] very little is known about the actual reaction mechanisms, that is which elementary steps are involved and what are the geometries and relative energies of the corresponding saddle points and intermediates. In the following, we describe the stationary points on the $[Fe,C_2,H_6]^+$ PES relevant for the C–C and C–H bond activations at the DFT/HF hybrid level.[6] This study is not only the first attempt to employ quantum chemical calculations to this important reaction sequence,[7] but—at least to the best of our knowledge -also the first application of DFT/HF hybrid methods for elucidating mechanistic details involving open-shell transition metal compounds.

First of all, the level of accuracy that can be expected from our computational strategy has to be established. Tables 1 and 2 contain a comparison between the experimentally determined[8] and the theoretically predicted bond dissociation energies (BDEs) and energies of the exit channels relative to the separated system $Fe^+(^6D) + C_2H_6$.[9] While the data in Table 1 reveal a rather systematic (and, for transition metal complexes, DFT-typical[10]) overestimation of the computed BDEs by up to 18 kcal mol^{-1} for weakly bound complexes, the description of relative energies (Table 2) is much less problematic with a maximum deviation of only 6 kcal mol^{-1}. Thus, we are confident that the chosen DFT/HF approach correctly describes the qualitative features of the potential energy surfaces, which are based on relative energies.

Table 1. Experimental and calculated BDE values in kcal mol^{-1}.

Species	exp. [a]	calcd.	Species	exp. [a]	calcd.
$Fe(C_2H_6)^+$	16	27	H-H	104	113
Fe^+-C_2H_5	56	65	CH_3-H	105	113
$Fe(C_2H_4)^+$	35	53	CH_3-CH_3	90	92
Fe^+-CH_3	55	65	H_2C=CH_2	174	175
Fe^+=CH_2	82	86	C_2H_5-H	100	108
Fe^+-H	49	61			
$Fe(H_2)^+$	5	19			

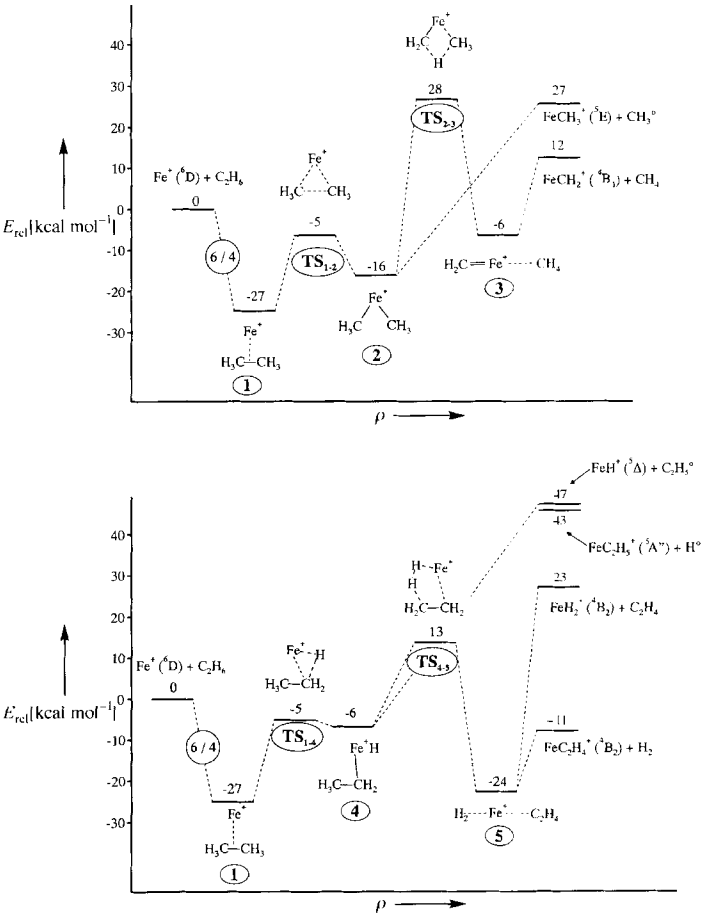
[a] Taken from ref. [8].

Table 2. Experimental and calculated energies of the exit channel relative to separated $Fe^+(^6D) + C_2H_6$ in kcal mol^{-1}.

Exit channel	exp. [a]	calcd.
$Fe^+ + C_2H_6$	0	0
$FeCH_3^+ + CH_3^\bullet$	31	27
$FeCH_2^+ + CH_4$	13	12
$Fe(H_2)^+ + C_2H_4$	27	23
$Fe(C_2H_4)^+ + H_2$	−5	−11
$FeH^+ + C_2H_5^\bullet$	51	47
$FeC_2H_5^+ + H^\bullet$	44	43

[a] Taken from ref. [8].

The course of the C–C and C–H bond activation on the $[Fe,C_2,H_6]^+$ PES is shown in Scheme 1. It should be noted that the initial interaction of the iron cation in the $Fe^+(^6D)$ ground state with ethane occurs on the sextet surface, while the remainder of the $[Fe,C_2,H_6]^+$ PES has only three unpaired electrons, that is it has quartet spin multiplicity. However, spin-orbit interaction is most probably large enough in this system to allow for efficient conversion to the energetically most favorable surface along the reaction coordinate.[11]

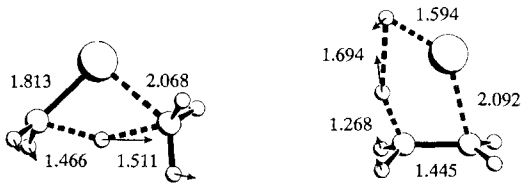


Scheme 1. Calculated course of the C–C bond activation (top) and C–H bond activation in the $[Fe,C_2,H_6]^+$ system (bottom). ρ = reaction coordinate.

No exothermic reaction of Fe^+ with ethane was observed in threshold collisional activation experiments.[5] At thermal energies, the only reaction that takes place is formation of the $Fe(C_2H_6)^+$ adduct ion. At higher kinetic energies, the reverse reaction, that is the loss of ethane, is the major process in competition with two minor processes which lead to the formation of $FeH^+ + C_2H_5^\bullet$ and $FeCH_3^+ + CH_3^\bullet$. Elimination of H_2 and methane observed in similar reactions for higher alkanes as exothermic processes does not occur, although these products are thermodynamically favored (Table 2). Thus, there must be sizable activation barriers along the reaction coordinate of these processes which prevent their occurrence. It is conceivable that these barriers are connected to the primary C–C and C–H insertion processes, and it is one of the major goals of the present investigation to shed more light on those parts of the PES decisive for the observed fragmentation patterns.

We commence the in-depth analysis of the computed stationary points for the C–C bond activation branch (Scheme 1 top). Here, the experiments point to the existence of two distinct $Fe(C_2H_6)^+$ minima, an iron–ethane complex **1** and a C–C inserted dimethyl structure **2**, the former being 3 kcal mol^{-1} lower in energy than the latter and separated by a barrier which is probably somewhat below the entrance channel.[5] In complete qualitative accord with these results, we find the iron–ethane encounter complex **1** and the C–C inserted structure **2** as initial products of the $Fe^+ + C_2H_6$ interaction. Complex **1** is 27 kcal mol^{-1} below the entrance channel, while **2** is 11 kcal mol^{-1} less stable. The activation barrier separating the two minima (transition state $\mathbf{TS_{1-2}}$ is located 5 kcal mol^{-1} be-

low the $Fe^+(^6D) + C_2H_6$ asymptote. Thus, TS_{1-2} is low in energy and cannot be responsible for the lack of observing the $FeCH_2^+ + CH_4$ fragmentation reaction. Rather, we find the saddle point TS_{2-3} of the [1,3]-H shift, which joins **2** with the complex of methane and the iron-carbene cation **3**, as the energetic bottleneck for the methane loss. TS_{2-3}, whose structure and transition vector are depicted in Figure 1, is located

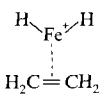


TS_{2-3} (i1502) TS_{4-5} (i642)

Fig. 1. Optimized structures (bond lengths in Å), transition vectors, and imaginary frequencies (in cm^{-1}) of TS_{2-3} and TS_{4-5}.

28 kcal mol^{-1} above the starting materials and thus prevents methane elimination. Instead, the direct fragmentation process cleaving a C–Fe bond in **2** and leading to $FeCH_3^+ + CH_3^{\bullet}$ occurs at this energy threshold, which is energetically similar (27 kcal mol^{-1} above $Fe^+(^6D) + C_2H_6$) but entropically much less demanding than TS_{2-3}. We note in passing that the threshold for this fragmentation from isomer **2** was measured as 43 kcal mol^{-1}, in perfect agreement with the calculated energy difference between **2** and $FeCH_3^+ + CH_3^{\bullet}$.

Turning to the second part of the PES, that is the C–H bond activation branch (Scheme 1 bottom), we first note that even less is known experimentally on intermediates and transition structures here than for its C–C bond activation counterpart. Structure **1** is common to both branches which then fork into the C–C bond activation route via TS_{1-2} and the C–H bond activation domain through TS_{1-4}. The computed height of the activation barrier TS_{1-4} is identical to that of TS_{1-2} (-5 kcal mol^{-1} relative to isolated $Fe^+ + C_2H_6$); thus from an energetical point of view both pathways have equal probability. Another consequence of the low activation energy of TS_{1-4} is that the absence of the exothermic H_2 elimination in the experiments cannot be explained by the assumption of an energetically demanding primary C–H insertion barrier. Structure **4** following the TS_{1-4} transition state is energetically less favorable than the C–C inserted product **2**. The PES in the vicinity of **4** is extremely shallow and located only a few kcal mol^{-1} below the saddle point. Actually, two distinct rotamers of **4** resulted from the geometry optimizations. The barrier for this rotation is, however, negligibly small and hence, the rotation around the C–Fe bond is virtually free. In most previous experimental studies on C–H bond activation of alkanes, a stepwise reaction pathway starting from the C–H-inserted species **4** has often been proposed.[1b] Coming from **4**, this mechanistic scenario would involve a transition structure for a β-H-shift resulting in a dihydrido species such as that schematically depicted in Scheme 2. This would be followed by a reductive elimination of molecular hydrogen which often has been considered as the rate-determining step.



Scheme 2. Previously postulated dihydrido species for the explanation of the activation of C–H bonds by Fe^+ ions.

However, all our attempts to locate an inserted dihydrido minimum for the $[Fe,C_2,H_6]^+$ system failed and rather led to the dihydrogen complex **5**. This result is corroborated by a careful and systematic evaluation of the H-Fe-H bending potentials of both, the parent system $Fe(H_2)^+$ as well as complex **5**, which gave no indication of a dihydrido minimum, regardless of the spin state (quartet or sextet) or the electronic configuration. A similar conclusion was recently drawn by Musaev and Morokuma[12] in the context of the reaction of $FeCH_2^+$ with H_2. Thus it seems to be a general feature that, in spite of being often proposed, the dihydrido species $(H)_2FeL^+$ does not exist as a stable intermediate. Instead, we located a transition structure TS_{4-5}, whose structure and transition vector are also depicted in Figure 1, directly connecting one of the rotamers of **4** and the complex of Fe^+ with molecular hydrogen and ethylene (**5**). The barrier for this four-centered H_2 activation lies 13 kcal mol^{-1} above the entrance channel and thus prevents the exothermic H_2 elimination at thermal energies in this system.[13] In the higher kinetic energy regime of the experiments, FeH^+ but not $Fe(C_2H_4)^+$ is generated, although the latter process is much more favorable on pure energetic grounds. It should, however, be kept in mind that at these energies, the observed fragmentation patterns are not solely determined by the energetics of the PES, but also by the dynamic behavior of the collision processes. While its interpretation is beyond the domain of the present quantum chemical approach, already from a qualitative point of view it seems very plausible that a direct bond cleavage producing $FeH^+ + C_2H_5^{\bullet}$ should be easier to accomplish on the time scale of the experiment than the complicated rearrangement via TS_{4-5} necessary for H_2 loss to produce $Fe(C_2H_4)^+$.

The preceding discussion of the relevant points on the $[Fe,C_2,H_6]^+$ potential energy surfaces is an important first step en route to an understanding of the basic reaction sequence of alkane activation by Fe^+. The DFT/HF hybrid method has not only proven to be a suitable tool for this purpose but also opened new vistas on the crucial mechanistic details of the C–C and C–H bond activations. Its application to the interaction of Fe^+ with larger, chemically more relevant alkanes seems to be in reach and is currently being pursued in our laboratory.

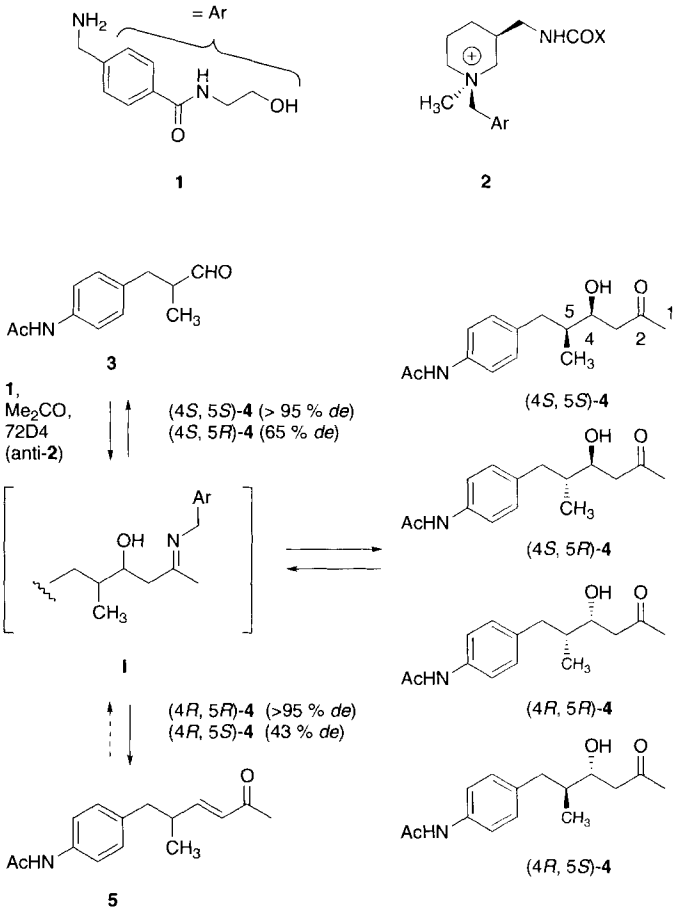
(*S*)-Selective Retroaldol Reaction and (*R*)-Selective β-Elimination with an Aldolase Catalytic Antibody**

Jean-Louis Reymond*

By virtue of microscopic reversibility, a catalytic pathway linking two chemical states can be used in both directions. This is well known for enzymes that catalyze reversible processes in vivo. By contrast, microscopic reversibility is rarely verified with designed biocatalysts because reactions tend to be highly exothermic and/or irreversible.[1] The reversible catalysis reported here for an aldolase catalytic antibody leads to an unexpected stereochemical consequence: the (*S*) selectivity of the catalyst in the aldol addition and cleavage is matched by a complementary (*R*) selectivity in the β-elimination.[2] An interpretation is advanced in terms of conformational control.

We recently reported the first aldolase catalytic antibody, which was obtained by linking primary amine **1** with an antibody against hapten **2**. This artificial aldolase catalyzed the aldol addition of acetone to aldehydes by an enzyme-like enamine mechanism, with rate-limiting formation of intermediate **I** within the antibody binding pocket.[3, 4] Starting with racemic aldehyde **3**, the reaction was *si* selective and produced the Cram aldol (4*S*,5*S*)-**4** in >95% *de* from (*S*)-**3** and the anti-Cram aldol (4*S*,5*R*)-**4** in 65% *de* from (*R*)-**3** in a ratio of 1:2.8 (Scheme 1).

The aldol addition, which is favored at high concentrations of acetone (1–10% v/v), can be reversed readily by removing acetone from the medium.[5] The retroaldol reaction of aldol **4** giving aldehyde **3** is catalyzed by the antibody–amine complex under these conditions. As in aldol addition, catalysis requires both amine **1** and the antibody (Ab 72D4, anti-**2**), with an apparent dissociation constant $K_D = 100$ μM for the dissociation of amine **1** from the antibody. Catalysis is quantitatively inhibited by addition of the hapten, ensuring that the reaction takes place in the antigen combining site. The stereoselectivity was determined by assaying the four stereoisomeric aldols **4** individually. As in the aldol addition,[3] preequilibrium binding of the aldols is weak, and the specificity constants k_{cat}/K_M were obtained as a measure of catalysis (Fig. 1). The substrate specificity for retroaldol reaction reproduced the enantioselectivity of the aldol addition (Table 1).



Scheme 1. The artificial aldolase assembled from antibody 72D4 (anti-**2**) and amine **1** catalyzes a (4*S*)-selective aldol cleavage from **4** giving **3** and a (4*R*)-selective β-elimination of **4** giving **5**.

Most interestingly, catalysis of the elimination of water from **4** to form (*E*)-enone **5** was also observed as a concurrent reaction. It was in fact the preferred reaction under hydroxide catalysis, with a 5:1 preference over retroaldol reaction for (4*R**,5*R**)-**4** and 2:1 for (4*R**,5*S**)-**4**.[6, 7] There the antibody–amine complex displayed a completely different stereoselectivity. For the pair of diastereomers of **4** derived from aldehyde (*R*)-**3**, the selectivity was complete for elimination in favor of (4*R*,5*R*)-**4** (>95% *de*), compared to an opposite 8:1 selectivity for (4*S*,5*R*)-**4** (77% *de*) over (4*R*,5*R*)-**4** in the retroaldol reaction. For the adducts stemming from aldehyde (*S*)-**3**, there was a 2.5:1 preference for (4*R*,5*S*)-**4** over (4*S*,5*S*)-**4** in the elimination (43% *de*), versus a complete selectivity for (4*S*,5*S*)-**4** (>95% *de*) in the retroaldol reaction. Thus a (4*S*) configuration at the β-carbon induces aldol cleavage, while a (4*R*) configuration results in β-elimination.

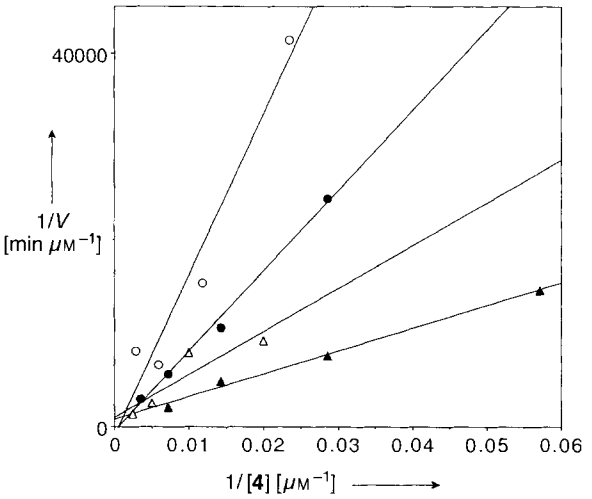

Fig. 1. Lineweaver Burk plot of the initial reaction rates V for catalysis by the complex of antibody 72D4 (anti-**2**) and amine **1**. $k_{cat}/K_M = 1/(\text{slope [anti-2]})$. Retroaldol reaction of isomer (4*S*,5*R*)-**4** (▲), β-elimination of water from isomer (4*R*,5*S*)-**4** (△), retroaldol reaction of isomer (4*S*,5*S*)-**4** (●), retroaldol reaction of isomer (4*R*,5*R*)-**4** (○). Conditions: 20 °C, 50 mM bicine, 100 mM NaCl, pH 9.2, [**1**] = 800 μM, [Ab72D4] = 18 μM. There is no apparent catalysis by amine **1** alone. The rate constants of the background reactions are 2.0×10^{-7} min^{-1} and 3.0×10^{-7} min^{-1} for the retroaldol reactions of (4*R**,5*S**)-**4** and (4*R**,5*R**)-**4**, respectively, and 1.0×10^{-6} min^{-1} and 7.0×10^{-7} min^{-1} for subsequent β-elimination giving enone **5**.

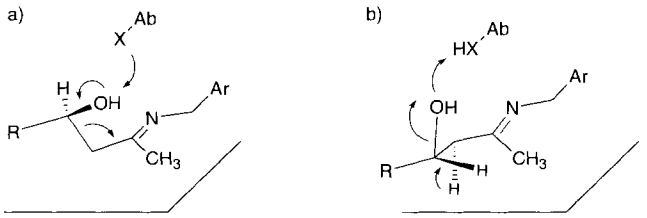
Table 1. Apparent specificity constants for catalysis by antibody 72D4 (anti-**2**) + amine **1** at pH 9.2, 20 °C (50 mM bicine, 100 mM NaCl).

Substrate	Aldol [a] [M^{-2} min^{-1}]	Retroaldol [b] [M^{-1} min^{-1}]	β-Elimination [b] [M^{-1} min^{-1}]
(4*S*,5*S*)-**4**	2.1	0.078	0.044
(4*S*,5*R*)-**4**	5.0	0.22	–
(4*R*,5*S*)-**4**	-	-	0.11
(4*R*,5*R*)-**4**	1.1	0.028	0.022

[a] Addition of acetone to the corresponding enantiomer of aldehyde **3**. From two-dimensional kinetics with respect to acetone and **3** at saturation with **1** ([**1**] = 1 mM), $k_{cat} = 4.1$ M^{-1} min^{-1} for the specificity constant [3b]. For catalysis by amine **1** alone, $k(\mathbf{1}) = 0.011$ M^{-2} min^{-1} and $k_{app}(OH^-) = 2.8 \times 10^{-7}$ M^{-1} min^{-1}, both with a Cram-sense stereoselectivity of 1.5:1. [b] Each constant is derived from saturation kinetics with respect to amine **1** ([**1**] = 100, 200, 400, 800 μM) at four concentrations of the aldol **4** isomer.

The conformations of aldol **4** leading to aldol cleavage ($\theta(N{=}C\text{-}C_\alpha\text{-}C_\beta) = 90°$) and to β-elimination ($\theta = 180°$) are very different. Therefore the chemoselectivity of the antibody–amine **1** catalyst probably results from conformational control. For example a localized hydrogen bonding residue assisting proton transfer at the 4-OH group could enforce complementary conformations on a pair of enantiomeric aldols (Scheme 2).



Scheme 2. Conformations favorable for aldol cleavage (a, (4*S*)) or β-elimination (b, (4*R*)) modeled by a hydrogen bonding interaction of a single group X of the antibody Ab with the C_β-OH group of the key intermediate **1**.

As a consequence of this chemoselectivity, the catalysis favoring the (4*S*)-configurated aldols in the aldol reaction is reinforced by selective removal of the (4*R*)-configurated aldols in the β-elimination. If this double induction follows the conformational model proposed here, it could also exist in other aldolase biocatalysts. Such a mechanism might have contributed to the emergence of optical activity for simple carbohydrates in the prebiotic era.[8]

In summary, the first investigation of antibody catalysis with a reversible process has been reported. The (*S*)-selectivity of the aldol cleavage is matched by an (*R*)-selectivity in the β-elimination, probably as a result of conformational control. The reactivity profile of the aldol product is not only straightforward to investigate, but also turns out to be more informative than the aldol addition in terms of enantio- and chemoselectivity of the catalyst. In general, following the reverse reaction with isolated stereoisomers is an attractive method for investigating new enantioselective catalysts, particularly if a large numbers of small-scale assays are required.[9] Future research will address the application of this principle to the aldol reaction and other reversible synthetic reactions.

Experimental Procedure

Isomer separation: A sample of chemically synthesized [3] aldol **4** (4 × 250 μg) was separated on a Chiralcel OJ column (Daicel) (0.45 × 22 cm, 1.0 mL min^{-1}, 2-propanol/hexane (3:1), detection at $\lambda = 250$ nm), giving three fractions: $t_R = 10$–12 min (F1, containing (4*S*,5*S*)-**4**), $t_R = 14$–15 min (F2), and $t_R = 15$–17 min (F3). Repurification of each fraction on a Chiralpak AS column (Daicel), gave $t_R = 23.3$ min ((4*R*,5*S*)-**4**), $t_R = 25.0$ min ((4*S*,5*R*)-**4**), $t_R = 28.5$ min ((4*S*,5*S*)-**4**), and $t_R = 29.3$ min ((4*R*,5*R*)-**4**). Pooled fractions for $t_R = 25.0$ min ((4*S*,5*R*)-**4**) were repurified once on the same column. Each stereoisomer was >95% pure (no other stereoisomer was detected on chiral column). After solvent removal, each isomer was dissolved in 100 μL of acetonitrile/water (1:1). These solutions contained >99.5% pure aldol **4** by RP-HPLC at concentrations of 1.5–2.5 mM, and were used in the kinetic assays.

Assay conditions: 50–350 μM **4**, 100–800 μM **1**, 18 μM Ab 72D4 in 100 mM NaCl, 50 mM bicine (bis(hydroxyethyl)glycine) pH 9.2, 20 °C. Product formation was followed by RP-HPLC (Microsorb-MV C-18, 0.45 × 22 cm, 1.5 mL min^{-1}, H_2O/CH_3CN (3:1), 0.1% CF_3COOH, t_R(**4**) = 3.9 min, t_R(**3**) = 4.8 min, t_R(**5**) = 11.6 min).

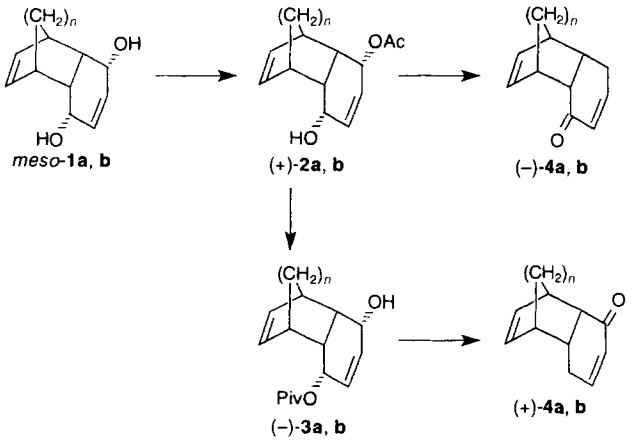
Asymmetrization of *meso* 1,4-Enediol Ethers by Isomerization with a Chiral binap–Rh^I Catalyst**

Kou Hiroya, Yuko Kurihara, and Kunio Ogasawara*

We recently reported a highly efficient enantioselective synthesis[1] of both enantiomers of the optically pure tetrahydro-*endo*-1,4-methano- and tetrahydro-*endo*-1,4-ethanonaphthalenones (**4a**, **b**) by lipase-mediated asymmetrization of the corresponding *meso* 1,4-enediols (**1a**, **b**), followed by a novel palladium-mediated rearrangement[2] of the resulting optically pure monoacylated intermediates (**2a**, **b**) and (**3a**, **b**) (Scheme 1). Owing to

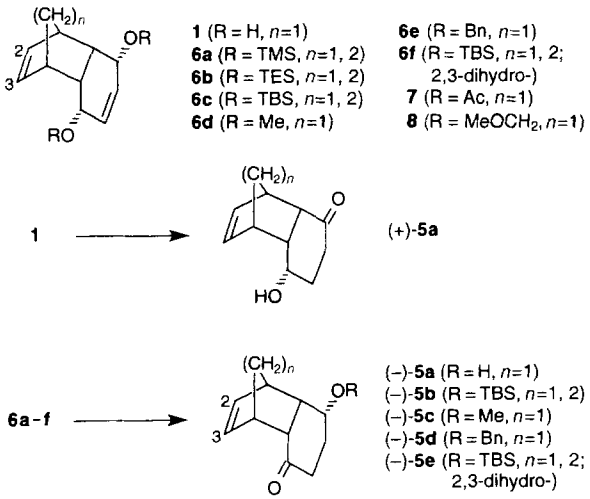


Scheme 1. Piv = pivaloyl. **1a**–**4a**: $n = 1$; **1b**–**4b**: $n = 2$.

its molecular bias, its α,β-unsaturated ketone functionality, and its facile thermal extrusion of cyclopentadiene, the naphthalenone **4a** allows stereoselective introduction of both nucleophiles and electrophiles from the convex face. Since the the masked double bonds can be regenerated **4a** may serve as a chiral synthon of 2,5-cyclohexadienone.[3] Because we have been interested in obtaining this highly versatile chiral synthon by a nonenzymatic procedure and because the catalytic asymmetric isomerization of a *meso* allylic 1,4-enediols such as **1** is not known, we examined the asymmetric isomerization of **1** and the related *meso* substrates using [Rh{(*S*)-binap}(cod)]ClO_4 (cod = 1,5-cyclooctadiene).[4] This catalyst has been successfully employed in the catalytic asymmetric isomerization of allylic amines.[5] Although use of this catalyst for the analogous reaction of allylic alcohols and other allylic oxygen substrates previously met with only limited success,[5–7] in the present study asymmetric isomerization of our *meso* substrates occurred with high enantioselectivity.

The products obtained can be transformed easily into the highly versatile, chiral 2,5-cyclohexadienone synthon **4**[1–3] as well as synthetically useful, chiral 4-*tert*-butyldimethylsilyloxy-2-cyclohexenone (**14**)[8] and 4-hydroxy-2-cyclohexenone (**15**),[8] which serve as starting materials for the synthesis of the medicinally important compounds ML-236A and FK-506, respectively.

We first treated the *meso* diol **1** (0.1 M in THF) with a catalytic amount of (*S*)-binap/Rh^I (5 mol%). At room temperature **1** isomerized cleanly giving the hydroxyketone (+)-**5a** in quantitative yield after 40 h (Scheme 2); its optical purity was deter-



Scheme 2. TMS = trimethylsilyl, TES = triethylsilyl, TBS = *tert*-butyldimethylsilyl.

mined to be 43.3% *ee* by hplc analysis of its benzoate derivative using a chiral column (Table 1, entry 1). Because **1** is insoluble in most solvents, further examination at lower temperature was not possible, and the reactions at higher temperatures in 1,2-dichloroethane (DCE) displayed decreased selectivity (Table 1, entries 2 and 3). Though **1** is soluble in acetonitrile, the reaction did not proceed at all. We therefore transformed **1** into the ethers **6a**–**f**; these were treated with the same chiral catalyst at concentrations of 0.1–0.2 M in DCE, because the reaction in this solvent was found to be more selective than that in THF. Of the examined substrates the silyl ethers showed the best results: after desilylation with aqueous HCl or nBu_4NF,[9] the products were obtained with 93–98% *ee* and in high yields[10] (Table 1, entries 4–9, 12, 13). The dimethyl and the dibenzyl ethers (Table 1, entries 10 and 11) also showed high selectivity; however, bisacetate **7** (R = Ac) and bis(methoxymethyl) ether **8** (R = $MeOCH_2$) did not form any isolable product. Similar results were obtained with the 1,4-ethano counterparts ($n = 2$) (Table 1, entries 5, 7, and 9). The best substrate was the bis-TBS ether **6c** ($n = 1$), which afforded the crystalline silyloxyketone **5b** (m.p. 32 °C, $[\alpha]_D^{29} = -27.0$ ($c = 1.08$ in $CHCl_3$)) on brief expo-

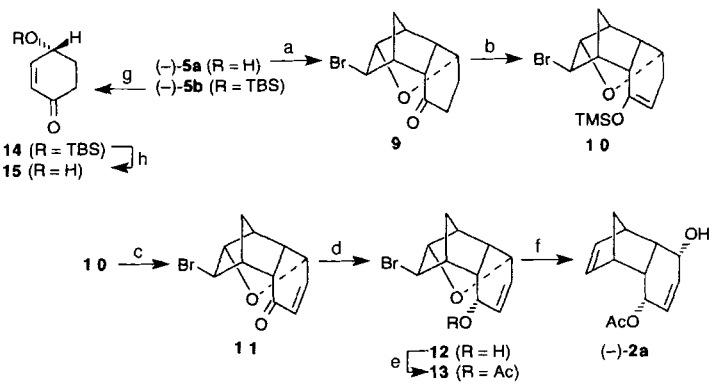
[a] DCE = 1,2-dichloroethane; in entry 1 THF was used instead of DCE. [b] Yield after conversion of the product into hydroxyketone **5a** by desilylation (dil. HCl in THF or nBu$_4$NF in THF). [c] Yield after conversion of the product into the silyloxyketone **5b** by treatment with dilute HCl. [d] About 30% of **6e** was recovered unchanged. [e] Enantiomeric excess was determined by converting the product into its benzoate derivative and analyzing by HPLC using a chiral column (CHIRALCEL OD; elution, *i*PrOH/hexane, 1:99 v/v). [f] Enantiomeric excess was estimated by comparison of the optical rotation values with those of authentic material.

sure (ca. 5 min) to nBu$_4$NF in THF at 0 °C (Table 1, entry 8). Interestingly, the enantioselectivity exerted by diol **1** and ethers **6a–d** is inverted. Moreover, the asymmetrization occurred with excellent selectivity with the 2,3-dihydro substrates (**6f**: $n=1$, 2), indicating the 2,3-olefin functionality is not critical for the reaction. It is particularly significant that this first successful asymmetrization of the *meso* allylic oxygen substrates proceeded with yields and selectivities comparable to those of the enzymatic reaction (Scheme 2 and Table 1).

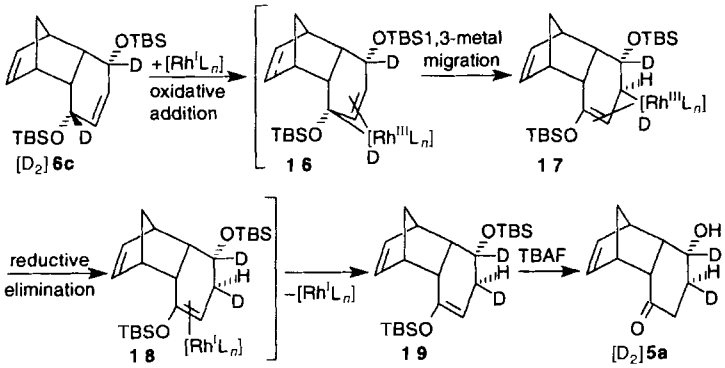
The absolute configuration of the 1,4-methano-bridged hydroxyketone **5a** ($n=1$) was determined by transforming (−)-**5a** ($n=1$) into the chiral 2,5-cyclohexadienone synthon (+)-**4a**[1, 2] via the monoacetate (−)-**2a**; (−)-**5b** ($n=1$) was converted into the known chiral 4-*tert*-butyldimethylsilyl-2-cyclohexenone (*R*)-**14**[11] and 4-hydroxy-2-cyclohexenone (*R*)-**15** (Scheme 3). Thus, (−)-**5a** (96% *ee*) was first treated with NBS[12] to give bromo ether **9** in 92% yield, which then was dehydrogenated to give enone **11** in 80% overall yield via the silyl enol ether **10** by employing the Saegusa conditions.[13] Further transformation of **11** into allyl acetate **13** via allyl alcohol **12**, followed by reductive cleavage of the bromo ether functionality[12] yielded monoacetate (−)-**2a** (m.p. 86.5–87.5 °C, $[\alpha]_D^{27} = -68.78$ ($c = 0.96$ in CHCl$_3$)), whose enantiomer (+)-**2a** (m.p. 87–88 °C, $[\alpha]_D^{30} = +70.05$ ($c = 1.02$ in CHCl$_3$)) was previously obtained by enzymatic transesterification of **1**.[1a] Quite similarly, the configuration of 1,4-ethano-bridged hydroxyketone (−)-**5a** ($n=2$) was determined by conversion into (−)-**4b**, which was identical with an authentic material obtained by the enzymatic procedure.[1b]

On the other hand, a solution of the ketosilyl ether (−)-**5b** (96% *ee*) in freshly distilled diphenyl ether was refluxed for 20 min to afford (*R*)-4-*tert*-butyldimethylsilyloxy-2-cyclohexenone [(*R*)-**14**][8] ($[\alpha]_D^{29} = +109.0$ ($c = 1.15$ in CHCl$_3$) (96.4% *ee* by hplc); literature value for the (*S*) enantiomer:[11a] $[\alpha]_D = -115.9$ ($c = 1.06$ in CHCl$_3$)) in 95% yield. The absolute configuration of (*R*)-**14** was confirmed by further transformation into (*R*)-4-hydroxy-2-cyclohexenone [(*R*)-**15**][8] ($[\alpha]_D^{29} = +109.0$ ($c = 1.29$, CHCl$_3$); literature value for the (*S*) enantiomer:[11a] $[\alpha]_D = -110$ ($c = 0.92$ in CHCl$_3$)) in 94% yield on exposure to hydrofluoric acid (48%) in acetonitrile[14] (1:19) (Scheme 3).

Although we could not explain the inversion of enantioselectivity on going from the free diol **1** to the bisethers **6a–f** in the presence of the same catalyst, the isomerization of the *meso* bisethers may be rationalized by a mechanism involving a suprafacial 1,3-hydrogen shift.[15] This hypothesis was supported by a deuterium labeling experiment using [D$_2$]**6c**. This 5β,8β-deuterium-labeled compound afforded the rearranged product 7β,8β-deuterium-labeled hydroxyketone [D$_2$]**5a** cleanly after desilylation without scrambling or loss of the original deuterium atoms. As shown in Scheme 4, oxidative addition occurs first to form the Rh^{III} complex **16**, which in turn is isomerized by 1,3-metal migration to give the alternative Rh^{III} complex **17** carrying a silyl enol ether functionality. Subsequent reductive elimination produces the Rh^{I} complex **18** and release of the Rh^{I} catalyst yields the disilyl ether **19**.



Scheme 3. a) *N*-Bromosuccinimide (1.1 equiv), CH_2Cl_2, 0 °C, 1 h; 91.5%; b) *i*Pr-NEt$_2$ (11 equiv), TMSOTf (2 equiv), CH_2Cl_2, 0 °C, 2.5 h; c) Pd(OAc)$_2$ (1.1 equiv), MeCN, room temperature (RT), 26 h; 80% based on **9**; d) $NaBH_4$ (1.5 equiv), $CeCl_3 \cdot 7H_2O$ (1.5 equiv), −78 °C, 4.5 h; 92%; e) Ac_2O (2 equiv), Et_3N (3 equiv), 4-dimethylaminopyridine (cat.), CH_2Cl_2, 0–25 °C, 12 h; f) Zn (8 equiv), AcOH (15 equiv), MeOH, reflux, 7 h; 76% based on **12**; g) 260 °C, diphenyl ether, 20 min; 95%; h) HF (45%)/MeCN (1:5 v/v), 0 °C, 4 h; 96%.



Scheme 4.

In conclusion, we have established a new highly efficient, enantioselective entry to the versatile chiral building blocks tetrahydro-*endo*-1,4-methano- and tetrahydro-*endo*-1,4-ethano-naphthalenones by isomerization of the bissilyl ethers of *meso* allylic 1,4-enediols using a cationic chiral binap-Rh^{I} catalyst. This result is remarkable for a number of reasons: 1) This is the first application of a catalytic asymmetric isomerization to an allyl ether substrate that reaches a practical level of enantioselectivity. 2) This is the first successful asymmetrization of a *meso* substrate by a catalytic isomerization. 3) The chemical and

enantiomeric efficiencies of this method are fully comparable to those of the enzymatic procedure. 4) This method can provide highly versatile cyclohexenone chiral synthons very efficiently. 5) The reaction mechanism has been proven to include a suprafacial 1,3-hydrogen migration pathway.

Experimental Procedure

Transformation of **6c** into **5b**: To a stirred solution of **6c** (405 mg, 1.0 mmol) in 1,2-dichloroethane (4.6 mL) was added [Rh{(*S*)-binap}(cod)]ClO_4 (18.6 mg, 19.9 mmol) in 1,2-dichloroethane (0.5 mL) dropwise at room temperature under argon and the mixture was refluxed for 17 h. The solvent was evaporated, the residue dissolved in THF (5 mL), and the resulting solution stirred with nBu$_4$NF (1.0 M in THF, 1.0 mL) at 0 °C for 5 min. The solution was diluted with ether and washed successively with water and brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was chromatographed on silica gel (EtOAc/hexane 1:9) to give **5b** as colorless crystals (276 mg, 94.9%) (96.1% *ee*). A single recrystallization from hexane gave the optically pure material (99.5% *ee*) as colorless prisms, m.p. 32 °C, $[\alpha]_D^{29} = -27.0$ ($c = 1.08$ in $CHCl_3$).

Radiofrequency Encoded Combinatorial Chemistry**

K. C. Nicolaou,* Xiao-Yi Xiao,* Zahra Parandoosh, Andrew Senyei, Michael P. Nova*

Combinatorial chemistry[1] has recently been recognized as a powerful tool in drug discovery[2] and materials science.[3] Although the potential of this method in these areas is enormous, its current scope is limited by several factors.[1] Particularly prohibitive is the lack of a general encoding system for following the synthetic sequence leading to the chemical constructs so that structural characterization can be facilitated. Despite the introduction of several encoding,[4] physical,[5] and deconvolution[6] techniques for identification of members in a chemical library, serious practical issues still remain and a more general and practical solution to this problem is needed.

We introduce here a new concept for encoding combinatorial chemical libraries based on radiofrequency signals and semiconductor memory devices using a multifunctional Microreactor. Radiofrequency Encoded Combinatorial (REC™) chemistry, as this new method is termed, combines recent advances in microelectronics, sensors, and chemistry and uses a Single or Multiple Addressable Radiofrequency Tag (SMART™) semiconductor unit[7] to record encoding and other relevant information along the synthetic pathway. This allows identification of library members by retrieval of the recorded history and other specific information relating to the construction of each compound. The practicability of the concept and the validity of the principles of REC chemistry are demonstrated here with a small peptide library generated by the "split and pool" method.[8]

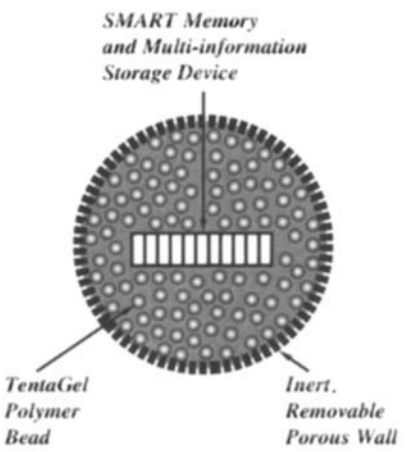

Fig. 1. Schematic cross-section of a Microreactor used in REC chemistry relying on SMART multi-information storage devices.

A SMART Microreactor™ (Fig. 1) was constructed from the following units: 1) a small (8 × 1 × 1 mm) semiconductor SMART memory device capable of receiving, storing, and emitting radiofrequency signals instantaneously from a distance of 75–150 mm; 2) several TentaGel-like polymer beads carrying an acid-cleavable linker; and 3) a chemically inert, surrounding porous support. A representative REC chemistry

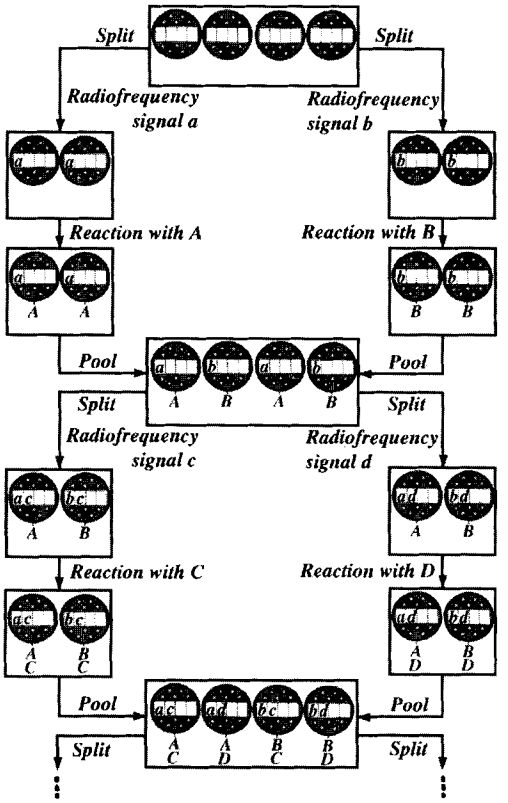
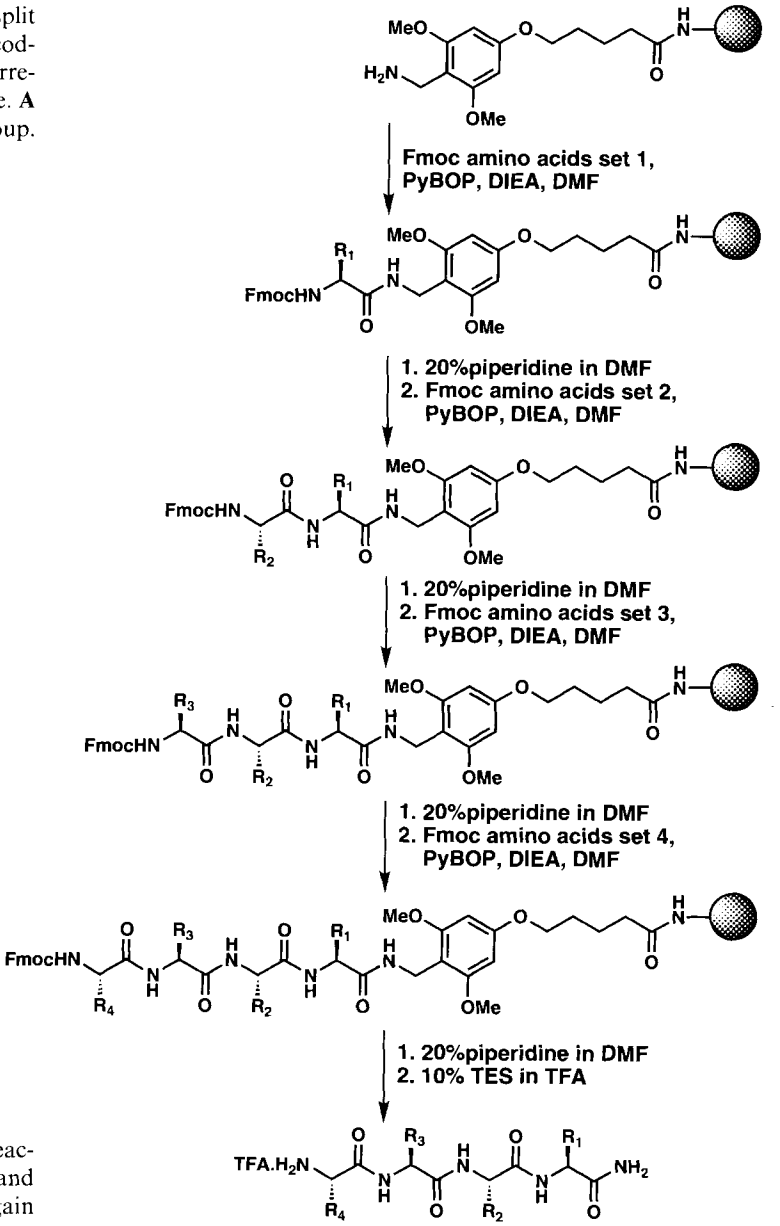
sequence is shown in Scheme 1. A pool of Microreactors is split into two groups. Each group is then addressed by write-encoding[9] with a unique radiofrequency signal (i.e. **a** or **b**) corresponding to the building block to be added to that group (i.e. **A** or **B**). The reactions are carried out separately with each group.



Scheme 1. A REC chemistry sequence using SMART semiconductor memory devices in Microreactors and the "split and pool" method. The order of the encoding and the chemical steps can be interchanged. The pool can be split into more than two groups.

The Microreactors are then pooled together, and common reactions and manipulations such as deprotections, washing, and drying are performed at this stage. The pool is then split again into two groups and encoded with a second set of radiofrequency signals (i.e. **c** or **d**) corresponding to the next set of building blocks to be introduced (i.e. **C** or **D**), and the reactions are performed accordingly. This process is repeated until the synthesis is completed. It should be noted that the large memory capacity of the SMART devices allows multiple splits at each stage of the combinatorial synthesis as well as multistep sequences to be carried out. Furthermore, the semiconductor devices record the temperature for each synthetic step and could potentially sense and store other important information relating to reaction conditions and compounds.

A specific example of the REC method is detailed in Scheme 2. Ninety-six Microreactors were used to construct a 24-member REC peptide library using a $3 \times 2 \times 2 \times 2$ "split and pool" strategy.[10] Each Microreactor of the final 96-member pool was decoded using a specially designed radiofrequency memory retrieving device to reveal the identity of the peptide on each Microreactor (Table 1). The identity of each peptide was confirmed by both mass spectrometry and ^{1}H NMR spectroscopy.[11] Peptide purity was shown by HPLC to be high in each crude sample even prior to purification (Table 1) and could be increased further by standard chromatographic techniques.



Scheme 2. Synthesis of a 24-member peptide library using REC chemistry. Fmoc = 9-fluorenylmethoxycarbonyl; DIEA = diisopropylethylamine; TES = triethylsilane; TFA = trifluoroacetic acid; PyBOP = benzotriazol-1-yloxy(trispyrrolidino)phosphonium hexafluorophosphate; amino acids set 1 = Asp(O*t*Bu)-OH (code D), Phe-OH (code F), or Lys(Boc)-OH (code K); amino acids set 2 = Gly-OH (code G), or Val-OH (Code V); amino acids set 3 = Glu(O*t*Bu)-OH (code E), or Ala-OH (code A); amino acids set 4 = Leu-OH (code L) or Ser(O*t*Bu)-OH (code S). All reactions were carried out at ambient temperature. Reaction times: Fmoc deprotection, 0.5 h; coupling, 1 h (two couplings per amino acid); cleavage, 2 h.

The Microreactor shown in Figure 1 is highly flexible and can be used in various sizes, shapes, and forms, including platforms in which the polymer support is coated directly on the SMART chips; other mobile and fixed reaction vehicles are also possible.[12] The feasibility of Microreactors consisting of directly polymer-coated SMART devices has already been demonstrated.

We have developed a new method of encoding combinatorial chemical libraries using a novel multifunctional platform for synthetic chemistry, relying entirely on chemically benign radiofrequency signals and semiconductor memory microchips for information storage. The obvious advantages of this method include: a) easy and rapid encoding, b) very large encoding

[a] Number of Microreactors containing the same peptide sequence. [b] The ambient temperature was recorded by the sensor device of the SMART chip in the Microreactors at various points during the synthesis. [c] *m/z* refers to $[M + H]^+$ or (for entries 1 and 8) $[M - H]^-$ (Electrospray MS); since each peptide has a unique mass (the calculated values are given in parentheses), the mass spectra confirm all peptide structures. [d] HPLC conditions: Shimadzu SCL 10A with a Microsorb-MV C-18 column (5 μm, 100 Å); isocratic elution with acetonitrile/water (1:1).

capacity, c) non-interference with chemical steps, d) storage of numerous types of information at each step, e) delivery of large libraries in amounts ranging from nano- to multimilligram quantities per compound, f) synthesis of pure compounds whose structures can be identified by decoding and confirmed by spectroscopic means, and g) versatility in both reactor configuration and scope of chemistry. The potential for automation and integration of such Microreactors for synthetic chemistry with assay platforms for high-throughput biological screening and data storage devices should make this technology the method of choice for many future combinatorial and other chemistry applications. Further applications of this basic technology in other areas of chemistry, biology, and medicine are also envisioned.

[12] The SMART chips are equipped with a standard EEPROM (Electrically Erasable, Programmable, Read-Only Memory) unit and temperature-sensing probe; they are passive devices deriving their required energy directly from the radiofrequency pulses used for encoding. These devices are enclosed in glass and are therefore completely inert to most reagents and conditions used in organic synthesis and can withstand temperatures between −78 °C and 150 °C. These devices will be available from IRORI Quantum Microchemistry.

A Fitting Legacy for All Time

The Lock and Key Principle. The State of the Art—100 Years on. Edited by *J.-P. Behr*. Wiley, Chichester, 1994. 325 pp., hardcover £ 85.00.—ISBN 0-471-93902-1

All scientists who work in the field of enzymology, or on its fringes, are familiar with the "Lock and Key" (L & K) principle of Emil Fischer. It is the foundation upon which the understanding of enzyme action still rests, despite having evolved significantly since first proposed approximately 100 years ago.

The new insights into, as well as the modern interpretations of this principle are the focus of the first volume in the series "Perspectives in Supramolecular Chemistry". One issue which must have concerned the founder and editor of this series (J.-M. Lehn and J.-P. Behr, respectively) is how to achieve the proper mix of enzymologists, molecular biologists, material scientists, and organic chemists to contribute chapters to this perspective.

Their answer has resulted in a text that is truly interdisciplinary, covering aspects of immunology, enzymology, molecular recognition, protein and nucleic acid structure, solid state chemistry, and molecular biology. This book impresses upon the reader the remarkable contribution from Emil Fischer, to whom all these fields must pay homage after 100 years for his original L & K notion.

The chapters vary widely in topic. The first one gives an imaginative analogy between several kinds of "locks", and the modern interpretation of the L & K principle. It analyzes cyclodextrin as a "classical lock", aminoacyl tRNA synthetases as "safety locks", and antisense gene therapy as a "magnetic lock". Chapter 2 discusses thermodynamic considerations for the L & K principle, including the mathematics of specificity and affinity distributions. It also focuses on the geometric fit between proteins and ligands, and the additivity and nonadditivity of protein–ligand interactions. Chapter 3 gives an excellent overview of chemical modification of enzyme active sites as a means of altering the shape of the "lock" to fit new "keys". A discussion of chemical mutagenesis, and an introduction to cofactors and site-specific nucleases are included. Chapter 4 gives a detailed analysis of the strategies for nucleic acid recognition using synthetic nucleic acids. The structure of nucleic acids is covered as an introduction to the design of receptors. The effectiveness of oligonucleotide analogs and derivatives is also presented. The chapter ends by introducing nucleic acid molecular devices, affinity modification, and the inhibition of gene expression. Chapter 5 is focused primarily on antibody catalysis, but gives some attention to catalysis by macrocycles. The similarities and differences between artificial enzymes and catalytic antibodies are well developed. Chapter 6 presents a fascinating description of the L & K principle as it applies to the solid state and crystalline interfaces. In this chapter the generation and amplification of chirality at surfaces is described in detail. Several well drawn diagrams, as well as photographs of crystals, allow the reader to easily understand the forces that drive molecular packing and aligning of neighboring molecules. The lessons are then extended to the packing of amphiphiles at air–water interfaces. Chapter 6 concludes with a discussion of the guiding principles for molecular recognition and molecular inclusion during crystal formation.

There are two remaining chapters, the first of which is concerned with the origin of life and concentrates on models for self-replicating and templating molecules. The lessons from the models are extended to DNA and proteins, and the chapter ends with strategies that chemists may use to develop molecular devices. The last chapter is an overview of the entire field of supramolecular chemistry, its new directions, and the interrelationships of recognition, catalysis, information storage, organization, and assembly.

In summary, this book is a truly fascinating perspective that ties together many fields under the L & K guiding principle. Particular chapters which stand out as unique are those dealing with nucleic acid structure, molecular devices, crystalline interfaces, and the origin of life.

The book will be useful to any scientist concerned with supramolecular chemistry, since it covers several new directions of this field and, as stated in the preface, "unlocks our thought" with regard to intramolecular interactions.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Supramolecular Synthons in Crystal Engineering—A New Organic Synthesis

Gautam R. Desiraju*

Dedicated to Professor David Y. Curtin and Professor Iain C. Paul

A crystal of an organic compound is the ultimate supermolecule, and its assembly, governed by chemical and geometrical factors, from individual molecules is the perfect example of solid-state molecular recognition. Implicit in the supramolecular description of a crystal structure is the fact that molecules in a crystal are held together by noncovalent interactions. The need for rational approaches towards solid-state structures of fundamental and practical importance has led to the emergence of crystal engineering, which seeks to understand intermolecular interactions and recognition phenomena in the context of crystal packing. The aim of crystal engineering is to establish reliable connections between molecular and supramolecular structure on the basis of intermolecular interactions. Ideally one would like to identify substructural units in a target supermolecule that can be assembled from logically chosen precursor molecules. Indeed, crystal engineering *is* a new organic synthesis, and the aim of this article is to show that rather than being only nominally relevant to organic chemistry, this subject is well within the mainstream, being surprisingly similar to traditional organic synthesis in concept. The details vary because one is dealing here with intermolecular interactions rather than with covalent bonds; so this article is divided into two parts. The first is concerned with strategy, highlighting the conceptual relationship between crystal engineering and organic synthesis and introduces the term *supramolecular synthon*. The second part emphasizes methodology, that is, the chemical and geometrical properties of specific intermolecular interactions.

1. Introduction

Chemistry constantly seeks analogies and connections and supramolecular chemistry has grown into a distinct field around Lehn's analogy that "supermolecules are to molecules and the intermolecular bond what molecules are to atoms and the covalent bond".[1] This analogy represents a departure from classical chemical thought in that it discards the notion that the molecular structure of an organic substance embodies all of its chemical and physical properties.[2–4] Supermolecules are not just collections of molecules; their structure and characteristic properties are distinct from the aggregate properties of the constituent molecular species.[5] Of course, the hydrogen bond has always been recognized by organic chemists as being significant, especially in biomolecular structures,[6] and it is known that the strongest intermolecular interactions are stronger than the weakest of covalent bonds.[7] However, in general it has been felt that the aims of supramolecular chemistry fall somewhat outside the mainstream of organic chemistry.[8]

Structural chemists and crystallographers have, however, been quick to realise that a crystal of an organic compound is the perfect supermolecule,[9, 10] according to Dunitz "a supermolecule par excellence", an assembly of literally millions of molecules self-crafted by mutual recognition at an "amazing level of precision".[11] If molecules are built by connecting atoms with covalent bonds, solid-state supermolecules (crystals) are built by connecting molecules with intermolecular interactions. So, the supramolecular equivalents of structural isomers are crystalline polymorphs, and the solid-state topochemical photodimerization of cinnamic acids a very good example that relates polymorphism (in the reactant) with structural isomerism (in the product).[12] Continuing the analogy further, a molecular isomerization may be compared with a phase transition and stereoisomers with enantiomorphous crystals. Again, disorder in a topochemically reactive crystal finds a molecular parallel in alternative reaction pathways.[13] Homology is not a

[**] With regard to organic synthesis, the practitioner of crystal engineering today seems to be in the position of M. Jourdain in "Le Bourgeois Gentilhomme" when he exclaims, "I've been talking prose for the last forty years and have never known it!"

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3421-2311 $ 10.00+.25/0

property restricted to molecules alone, and crystalline homologous series have been identified in which patterns of intermolecular interactions (rather than patterns of covalent bonds) are systematically graded; typical examples are benzene, naphthalene and anthracene, or alternatively, benzene, biphenyl, terphenyl.[14]

Given this background, it is instructive to consider the subject of crystal engineering, which has been defined as "the understanding of intermolecular interactions in the context of crystal packing and in the utilisation of such understanding in the design of new solids with desired physical and chemical properties".[15] Crystal engineering is concerned with the systematic architecture of crystal structures.[16] This architecture is governed by the rules of supramolecular valence, that is, by the chemistry and geometry of the intermolecular interactions, which are, in effect, the supramolecular cement.[17] Therefore, if crystals are the supramolecular equivalents of molecules, crystal engineering is the supramolecular equivalent of organic synthesis.

2. General Principles and Strategies

> *... structural units within molecules which can be formed and/or assembled by known or conceivable synthetic operations.*[*]
> Corey's definition of a synthon

Targets in organic synthesis are defined in terms of the connectivity of covalent bonds (that is, a molecular structural formula). At a supramolecular level, it should be recognized that targets in crystal engineering are defined in terms of interaction connectivity, that is, in geometrical and topological terms. One aims, for example, at particular patterns such as ribbons, sheets, layers, channels, tubes, and cavities, which may be appropriately functionalized to yield materials that act as templates for subsequent chemical transformations (catalysts, nanostructures, organic zeolites). Alternatively, the desired geometrical pattern may itself be of inherent significance, because it defines a useful physical property (electronic or proton conductivity, ferromagnetism, nonlinear optics).

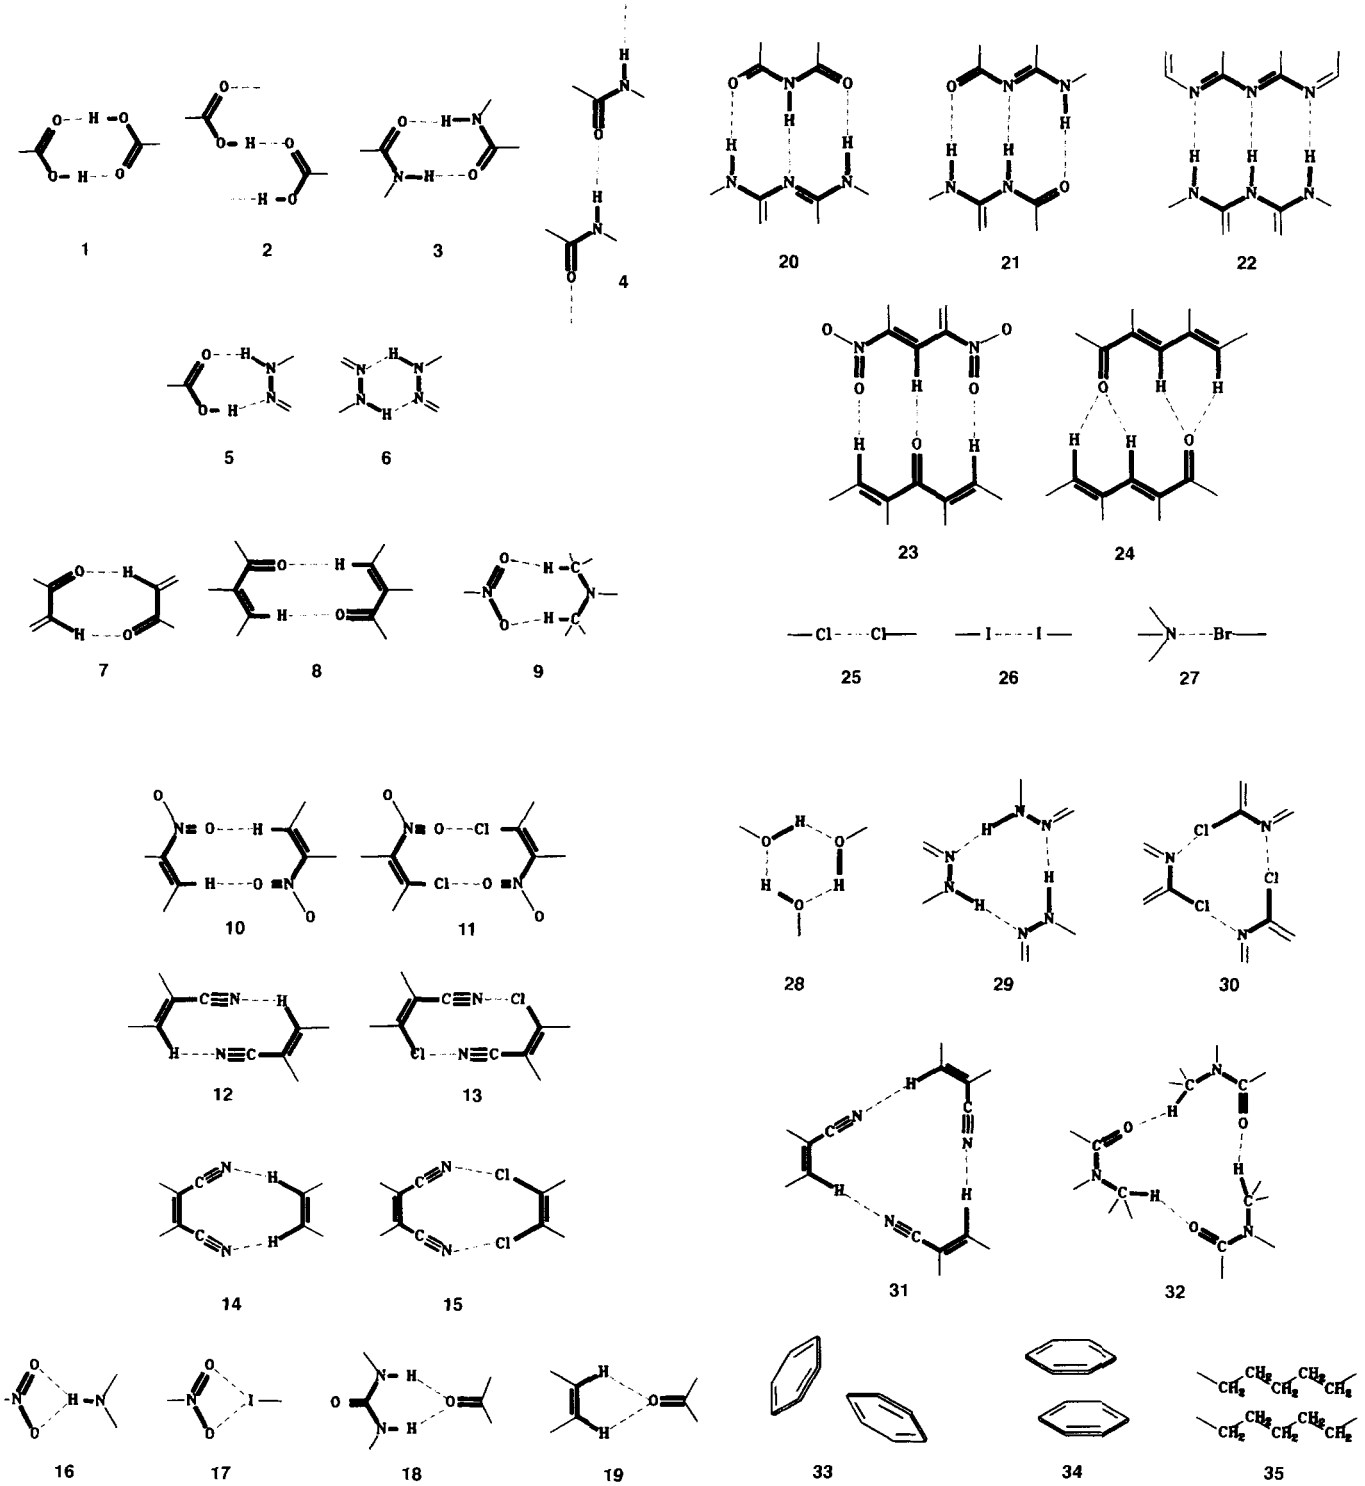
[*] This and succeeding quotations are taken from Refs. [18, 19].

All crystal structures of organic compounds may be formally depicted as networks with the molecules being the nodes and the intermolecular interactions representing node connections.[5] Therefore, the predictable self-organization of molecules into one-, two-, or three-dimensional networks is of the utmost importance in crystal engineering. For such rational design, hydrogen bonding of the conventional OH···O and NH···O variety has been the most commonly used supramolecular cement, yet weaker forces such as CH···O, CH···N, I···I, O···I, N···Cl, or even C···H and C···C can be used. All these interactions, be they strong or not so strong, are directional—anyway directional enough in combination that the orientation of molecules in the solid can be predicted with a reasonable degree of accuracy. These interactions can be combined by a designed placement of functional groups in the molecular skeleton to generate *supramolecular synthons*, examples of which are shown in Scheme 1.

The term "synthon" was introduced by Corey in 1967 in an article entitled "General Methods for the Construction of Complex Molecules".[18] This article was of extraordinary importance in shaping the course of organic synthesis. Corey's definition of a synthon is stated above, and the term was traditionally used to represent key structural features in a target molecule in organic synthesis. In later years the term fell into disuse as explained by Corey himself in 1988[19] and Seebach in 1990,[20] because it degenerated into a descriptor of synthetic intermediates. However, since crystal engineering and an appreciation of the properties of intermolecular interactions are probably today at that stage of sophistication that organic synthesis and an appreciation of the properties of covalent bonds were in the fifties and sixties, and also because the term synthon is so useful in the context of retrosynthetic analysis,[20] the supramolecular counterpart of which is crystallographic database analysis, the term "synthon" has been retained here and used in the manner originally intended. In keeping with modern organic synthetic parlance the term "retron" might have been more appropriate[21] but this is a subjective matter. Corey's definition of a synthon is so general and flexible that more than twenty-five years later it can be used with almost the same connotations but in a supramolecular sense. Thus *supramolecular synthons are structural units within supermolecules which can be formed and/or assembled by known or conceivable synthetic operations involving intermolecular interactions*, and crystal engineering is the new

Gautam R. Desiraju was born in Madras, India, in 1952 and received his B. Sc. at the University of Bombay in 1972. He was awarded his Ph.D. from the University of Illinois at Urbana-Champaign in 1976 under the supervision of Professor David Y. Curtin and Professor Iain C. Paul. From 1976–1978 he was a member of the research staff in the laboratories of Eastman Kodak Company in Rochester, New York. He joined the faculty at the University of Hyderabad as Lecturer in 1979, being appointed Reader in 1984 and Professor in 1990. He has published more than 100 research papers in the area of crystal engineering and solid-state supramolecular chemistry, and his interests include the study of weak hydrogen bonding and other intermolecular forces. He is the author of a book entitled "Crystal Engineering—The Design of Organic Solids" published in 1989 and the editor of multiauthor volumes on organic solid-state chemistry (1987) and supramolecular chemistry (1996). He is currently coeditor of Acta Crystallographica.

organic synthesis. To summarize, supramolecular synthons are spatial arrangements of intermolecular interactions and play the same focusing role in supramolecular synthesis that conventional synthons do in molecular synthesis. In effect, the goal of crystal engineering is to recognize and design synthons that are robust enough to be exchanged from one network structure to another, which ensures generality and predictability. Such structural predictability leads, in turn, to the anticipation of one-, two-, and three-dimensional patterns formed with intermolecular interactions. There is a particular relevance of the solid state to this kind of supramolecular chemistry, because many of the weaker interactions are probably deformed if not destroyed in solution. However, the persistent recurrence of patterns mediated by weak forces in crystals indicates that such interactions might still be important in solution for transient processes such as those associated with biomolecular structure and conformation.



Scheme 1. Representative supramolecular synthons.

2.1. Solid-State Architecture with Supramolecular Synthons

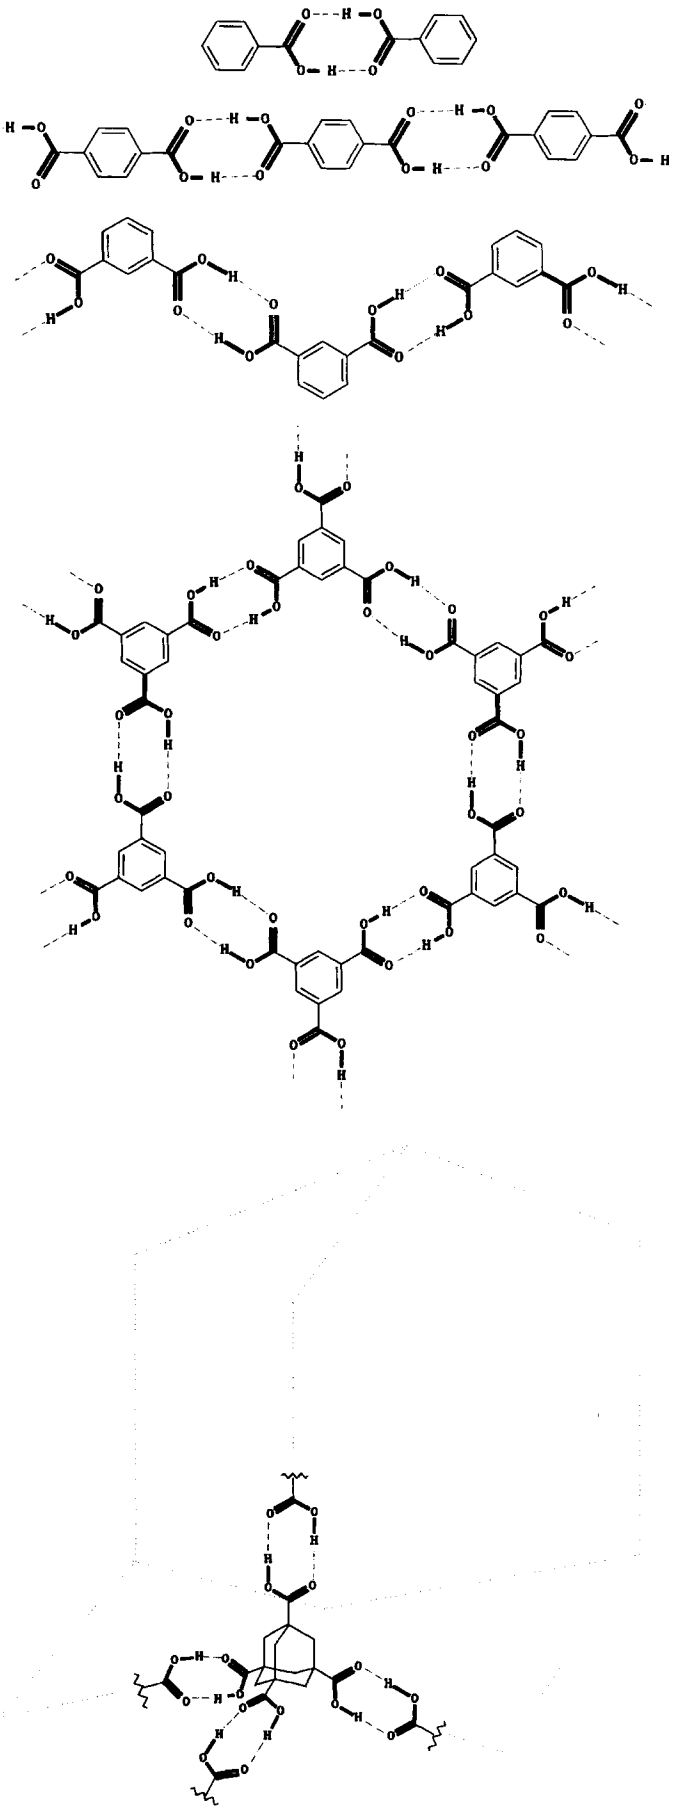
...recognition of some synthons (usually the larger or major synthons) normally is more useful in analysis than that of others.

Scheme 1 shows a variety of supramolecular synthons **1**–**35**, culled from the recent literature. A supramolecular synthon is an identifiable design element and should be, strictly speaking, distinguished from an intermolecular interaction. It must be emphasized that synthons are *derived* from designed combinations of interactions and are *not identical* to the interactions. For example, the carboxyl dimer synthon **1** is assembled with two centrosymmetrically related C=O···HO hydrogen bonds. In still other synthons, for example **33**–**35**, the involvement of the interactions is implicit. Though subtle, this distinction between an interaction and a synthon is real, because supramolecular synthons incorporate *both* chemical and geometrical recognition features of molecular fragments, in other words both explicit and implicit involvement of intermolecular interactions. On occasion, however, when chemistry and geometry are inextricably linked, a single interaction may be regarded as a synthon, for instance Cl···Cl, **25** or N···Br, **27**.

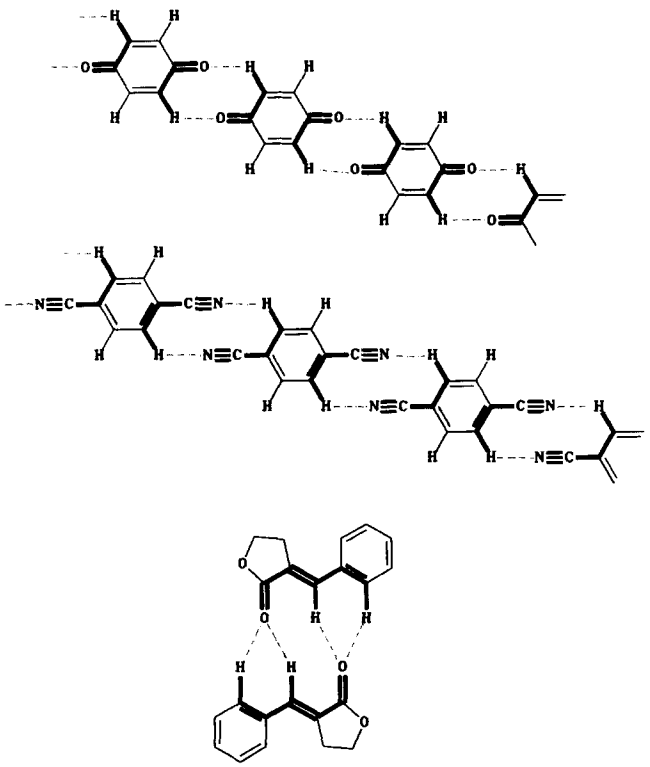
The supramolecular synthon concept is conveniently illustrated in the crystal structures of some aromatic carboxylic acids. Scheme 2 shows how the structures of benzoic, terephthalic, isophthalic, trimesic, and adamantane-1,3,5,7-tetracarboxylic acids (**36**) are built with phenyl rings and dimer synthons **1** in a logical progression. The benzoic acid dimer is zero-dimensional, the linear or crinkled ribbons in the dibasic acid structures are one-dimensional patterns, while the sheet structure in trimesic acid is two-dimensional.[22] The three-dimensional extension of these structures is the diamondoid structure of acid **36**, where synthons **1** are disposed tetrahedrally about the adamantyl nucleus to yield a network that is topologically similar to diamond, in which **1** replaces C–C bonds, and the adamantyl nucleus becomes a super-C atom.[23]

Weaker hydrogen bonding of the CH···X variety may now be considered. Although these bonds have energies only in the 2–20 kJ mol^{-1} range, their effects on crystal structure and packing are just about as predictable as the effects of conventional hydrogen bonding.[24] Scheme 1 includes several CH···X-mediated synthons, and Scheme 3 shows some typical crystal structures based on these synthons. In crystalline 1,4-benzoquinone, the symmetrical disposition of functional groups results in a linear ribbon pattern linked by synthon **7**. This pattern is carried over largely unscathed into the crystal structure of 2-methoxy-1,4-benzoquinone, while the CH···N≡C analogue **12** is observed in 1,4-dicyanobenzene.[25] Another common CH···O synthon **24** is seen in the crystal structure of α-benzylidene-γ-butyrolactone.[26]

A comparison of the crystal structures of solid chlorine and the monoclinic form of 1,4-dichlorobenzene (Fig. 1) is revealing and shows how the supramolecular synthon concept may be extended to lesser known intermolecular interactions.[15] The contacts between the halogen atoms define the Cl···Cl synthon **25** and are virtually identical in the two structures. The aromatic rings in 1,4-dichlorobenzene fulfill a spacer function.



Scheme 2. Construction of aromatic carboxylic acid crystal structures with synthon **1**.



Scheme 3. Construction of crystal packing patterns with CH···X synthons **7**, **12**, and **24**.

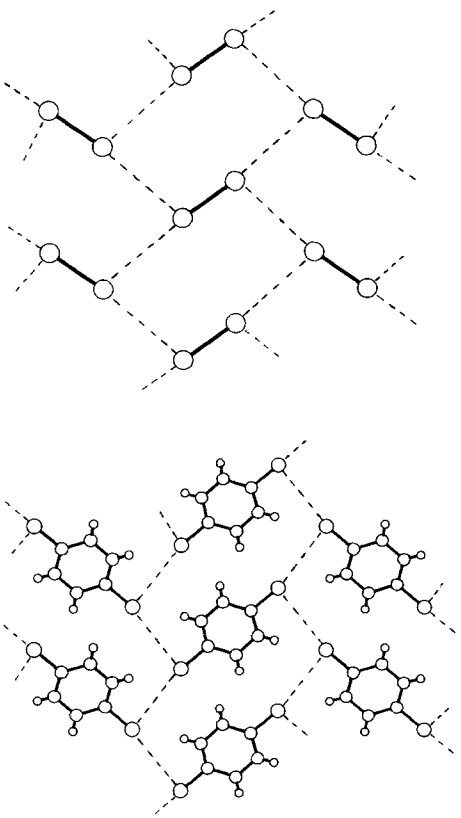


Fig. 1. Similarity between the crystal structures of chlorine (top) and 1,4-dichlorobenzene (bottom). Note the identical disposition of the Cl···Cl synthons **25** in the two cases.

The above examples cannot be exhaustive, but they illustrate the importance of being able to identify structurally significant synthons in a supermolecule. Such identification helps in the analysis of more complex crystal packings and the design of new target structures. These examples also highlight two other important features that should be noted in systematic crystal engineering. These are the following:

1) Consideration of a crystal structure in terms of supramolecular synthons can effect a simplification, which facilitates comparison with other seemingly different crystal structures. Accordingly, different molecular functionalities can result in similar crystal structures provided synthons in the various crystal structures possess shape or topological similarity.

2) The interference between the significant supramolecular synthons should be a minimum. Alternatively, the nature of such interference should be understood so that it may be exploited in the engineering strategy. These features will now be discussed in greater detail.

2.2. Simplification of Crystal Structures

...even in the earliest stages of the process of simplification of a synthetic problem, the chemist must make use of a particular form of analysis which depends on the interplay between structural features that exist in the target molecule...

Kitaigorodskii's close-packing principle implies that molecules undergo a shape simplification as they progress towards dimers, higher aggregates, and ultimately crystals.[27] Shape is a very powerful agent of molecular recognition that in crystals generally proceeds in a way such that supramolecular fragments of a crystal structure have simpler shapes than the constituent molecular species. Accordingly their packing patterns may be easier to predict (see Section 2.8). Molecules in organic crystals are surrounded typically by twelve to fourteen near-neighbors to define quasi-spherical clusters.[28] Similar shape-simplifying effects are seen in Rebek's "tennis ball" dimer,[29] and the tertiary structural features in globular proteins are responsible for converting an exceedingly complicated molecular structure into a nearly spherical unit.[30]

These geometrical consequences of shape recognition can be employed in crystal engineering. A comparison of the crystal structures of benzoic acid and *p*-terphenyl (Fig. 2) is pertinent. Because of the parallel hydrogen bonds in synthon **1**, the shape and size of the benzoic acid dimer mimics that of *p*-terphenyl. The two crystal structures are not identical but reasonably similar with the same space group $P2_1/n$, comparable cell dimensions and volumes, and most importantly, the benzoic acid dimers are packed together using the same herringbone C···H interactions that exist in *p*-terphenyl.[31] To be sure, there are differences in the two structures but these can be understood and rationalized. For example, *p*-terphenyl molecules are tilted along their molecular lengths to optimize herringbone interactions and form slabs that are themselves aligned parallel to optimize other herringbone interactions. In benzoic acid, the dimers are stacked rather than tilted to form slabs, which are then inclined in a herringbone fashion. Stacking rather than

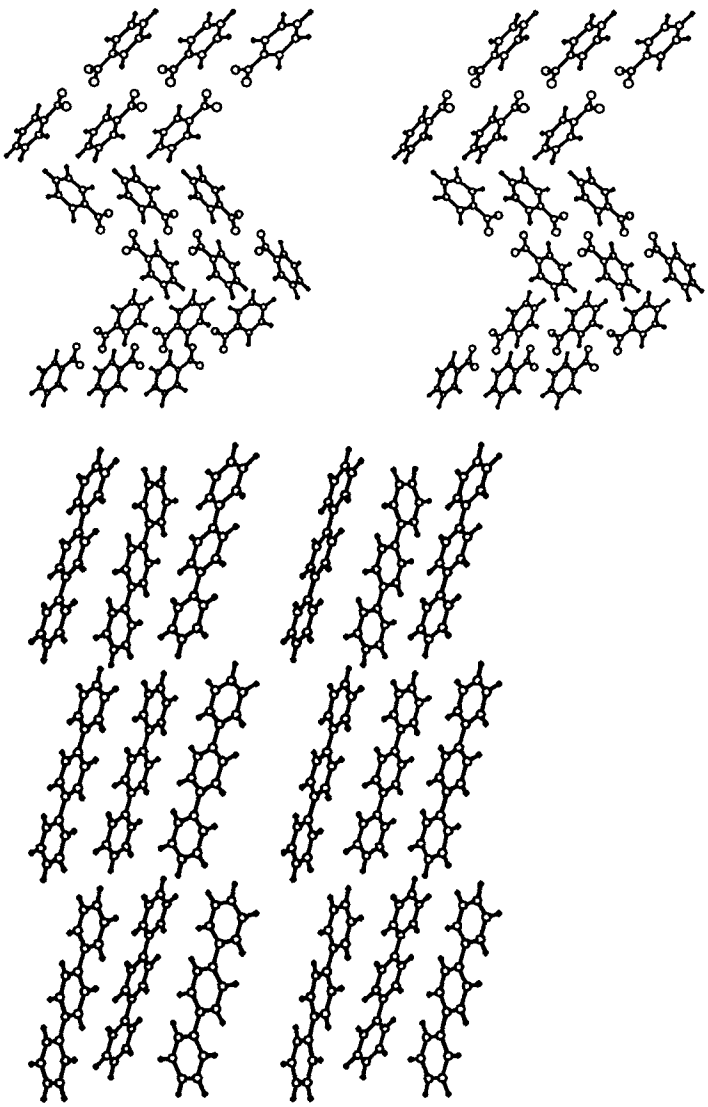

Fig. 2. Stereoviews of the crystal structures of benzoic acid (top) and *p*-terphenyl (bottom), each showing three slab sections. Notice that the benzoic acid dimer mimics the shape of the terphenyl molecule and also the similar herringbone dovetailing between slabs in the two structures.

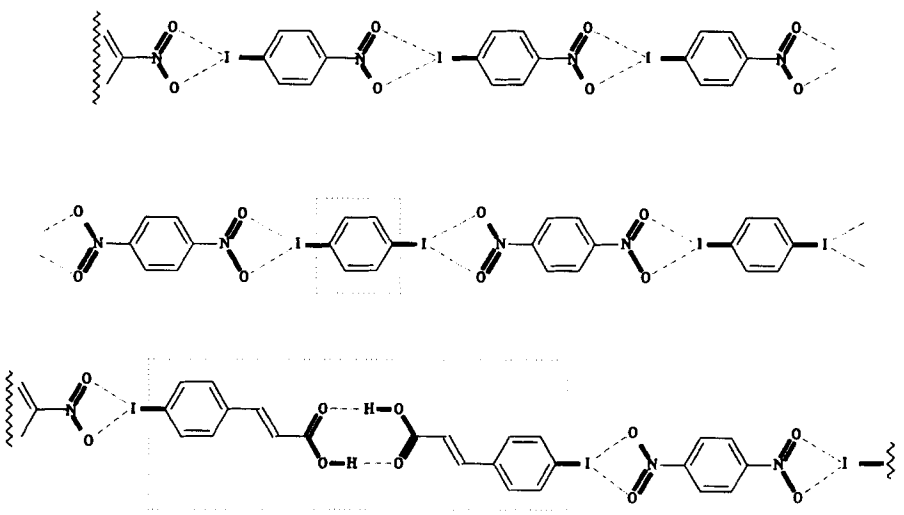
tilting occurs within the benzoic acid slabs because of the tendency of a phenyl ring to be overlaid on a carboxyl dimer ring.[32] However, the main message is clear—the carboxyl dimer synthon **1** can be used as a surrogate for a 1,4-disubstituted phenyl ring, and it is pertinent to compare this dissection of the benzoic acid dimer supramolecular skeleton with that of the squalene molecular skeleton by Corey.[18]

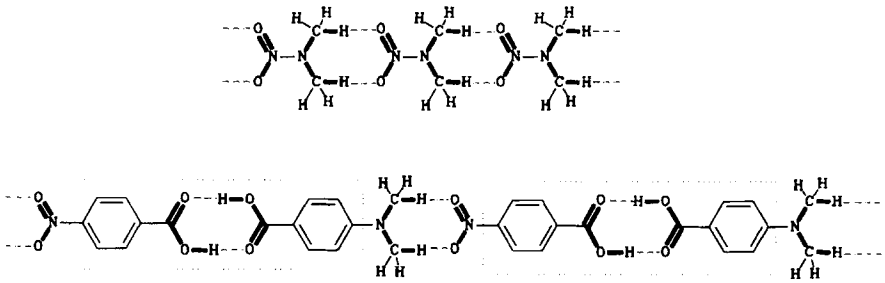
This strategy can now be used in the design of crystal structures. We found that halogen atoms, especially iodine, tend to form short polarization-induced contacts with nitro groups (synthon **17**) where the oxygen atoms of the nitro group grip the iodine atom in a two-pronged fashion.[33] This synthon was initially introduced in the crystal structure of 4-iodonitrobenzene, where it alternates with the phenyl rings to give a ribbon as expected (Scheme 4).[34] In fact, this molecule has few other crystallization options. The strategy was then extended to the crystal structure of the 1:1 complex of 1,4-dinitrobenzene and 1,4-diiodobenzene where again **17** alternates, but in opposite senses with phenyl rings.[35] At this stage the hydrocarbon spacer between the **17** synthons was extended by crystallizing a 2:1 complex of 4-iodocinnamic acid with 1,4-dinitrobenzene.[34] The carboxyl synthon **1** elongates the (now supramolecular) diiodo moiety, which is then able to link with the nitro moiety through synthon **17**. These results are surprising—acids are known to complex with bases or with other acids but not with neutral compounds; however, in this case the acid dimer behaves effectively like a neutral diiodohydrocarbon because the hydrogen bonding requirements of the monomers are completely satisfied by dimer formation.

A very similar exercise may be carried out with CH···O hydrogen bonds. Nitro and dimethylamino groups form a CH···O-mediated synthon **9**, and the crystal structure of *N*,*N*-dimethylnitramine is unique in that it consists exclusively of infinite ribbons of this synthon (Scheme 5).[36] The crystal structure of the 1:1 complex of 4-nitrobenzoic acid and 4-(*N*,*N*-dimethylamino)benzoic acid may now be anticipated as a ribbon consisting of synthon **9** alternating with an extended terphenyl surrogate formed by a linking of acid molecules with synthon **1**.[37] To summarize, the crystal packing properties of an aromatic carboxylic acid dimer are distinct from those of the monomer and are more reminiscent of an aromatic hydrocarbon.



Scheme 4. Use of the iodo···nitro synthon **17** in crystal engineering. Note how the 1,4-disubstituted phenyl ring and the extended carboxylic dimer are similarly employed.

Inherent in structural simplification is a reduction of a crystal structure to its interaction network information. The crystal structure of tetraacid **36** has been described in Section 2.1 in terms of a diamond network with synthons **1** tetrahedrally disposed about the adamantyl skeleton.[23] It is therefore possible to substitute other synthons for **1** on adamantyl or other tetrahedral templates and generate similar diamondoid structures (Fig. 3). Typical examples of such alternative synthons are metal···NC,[38] I···I **26**,[39,40] O–H···N,[41] and the *cis*-amide dimer synthon **3**.[42] We have



Scheme 5. Use of the dimethylamino···nitro synthon **9**. The strategy for the design of these structures is similar to that employed for the design of the structures in Scheme 4.

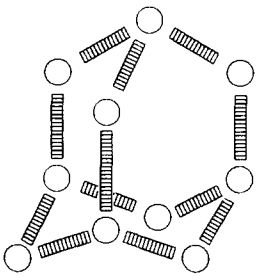


Fig. 3. Archetypical diamondoid network structure. ○ represents a tetrahedral molecular template (for example, adamantyl) and ▥ an appropriate supramolecular synthon.

used the same strategy with the much weaker N···Br synthon **27**;[43] the crystal structure of the 1:1 complex of hexamethylenetetramine (**42**) and CBr_4 contains a tetrahedral arrangement of synthon **27** resulting in a super-ZnS type structure (Fig. 4). That the N···Br and similar interactions are polarization-induced is well-known from the work of Hassel,[44] but their use in crystal engineering strategies is relatively new.[45]

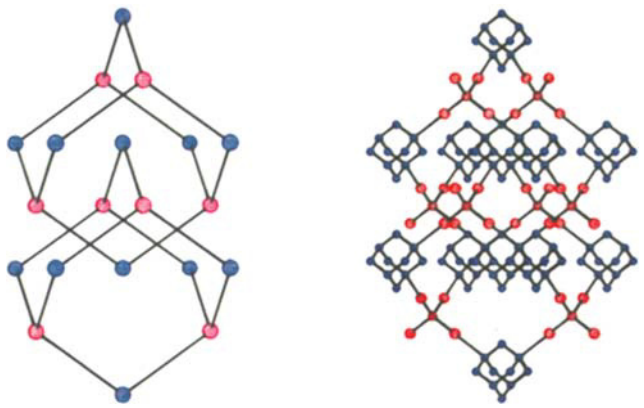

Fig. 4. Schematic (left) and complete (right) representations of the diamondoid network structure of the 1:1 complex hexamethylenetetramine (**42**, blue) and CBr_4 (red). Both intra- and intermolecular bonds are shown as solid lines. The N···Br synthon **27** connects molecules. Notice the catenation of networks and the similarity to Fig. 3.

A recurring theme in crystal engineering is that quite different covalent bond frameworks and chemical functionalities in the monomer building blocks can still result in similar supramolecular (crystal) structures. It has long been known that molecules with similar sizes, shapes, and functionalities have similar crystal structures; this principle of structural mimicry explains, for instance, phenomena such as solid-solution formation.[46] However, a more powerful generalization in the crystal engineering context is that *supramolecular fragments with similar sizes, shapes, and topologies have similar crystal structures*. Such a generalization is more useful, because it recognizes the interchangeability of supramolecular synthons within a particular family of crystal structures.

2.3. Synthon Interference and Structural Robustness

Proximity of reactive functional groups is of major importance in synthesis.

The examples discussed above might imply that supramolecular synthons are completely modular, capable of being introduced, removed, or replaced at will to generate new crystal structures. This would be an ideal, indeed a Utopian situation. However, chemistry is not geometry, and the major challenge in the practice of crystal engineering is that a crystal structure is a compromise, at times quite uneasy, between interactions of varying strengths, directionalities, and distance-dependence properties (see Section 2.9). Indeed, interference between synthons is *the* critical problem in crystal engineering, and structural robustness or the ability to use the same supramolecular synthon in a variety of situations is the key to a successful practice of the subject. A thorough understanding of the several ways in which intermolecular interactions interfere with one another is essential for a predictive control over crystal packing. Interactions in an organic crystal are numerous and weak. At a basic level, one attempts to insulate various types of interactions from one another so that their individual (geometrical) features are manifested more effectively. At a higher level, one can exploit the interfering effects of one interaction type on another to realize a supramolecular target structure very much as a synthetic chemist would use a neighboring or proximal group effect.

A discussion of structural robustness begins again with the carboxyl dimer synthon **1**. Generally, aliphatic and aromatic carboxylic acids RCO_2H adopt this dimer pattern in crystals, because its stability and packing efficiency are largely unaffected by the nature of the R group.[32] The robustness of **1** is revealed by considering the packing preferences of the patterns in Scheme 2. In benzoic, isophthalic, and terephthalic acids, the dimers and ribbons can close-pack without complications. In trimesic acid, however, the "holes" in the hexagonal hydrogen-bonded patterns pose a packing problem, which is solved by inclusion of a second molecular species (a guest).[22] This problem of voids is seemingly worse in acid **36**, but Nature solves it in a fascinating way by the catenation of as many as five distinct diamondoid networks.[23] Significantly, the close-packing problems caused by awkwardly shaped networks do not perturb the **1** synthons. However, even such a seemingly robust supramolecular synthon has limits on its use, and we have, in recent years, described four anomalous situations (Fig. 5) in which the centrosymmetric dimer synthon **1**, though expected, is not observed: 1) 4-Chloro- and 4-bromophenylpropiolic acids adopt a variation of the carboxyl catemer synthon **2** (actually 50:50 *syn:anti* O=C–OH conformations), while the corresponding cinnamic and benzoic acids adopt synthon **1**. This occurs because the phenylpropiolic acids cannot form CH···O hydrogen bonds.[47] 2) 3,5-Dinitrocinnamic acid forms a carboxylic dimer, but this pattern has two-fold rather than inversion symmetry. This occurs because of the dominance of CH···O bonding.[48] 3) In the 1:1 complex between

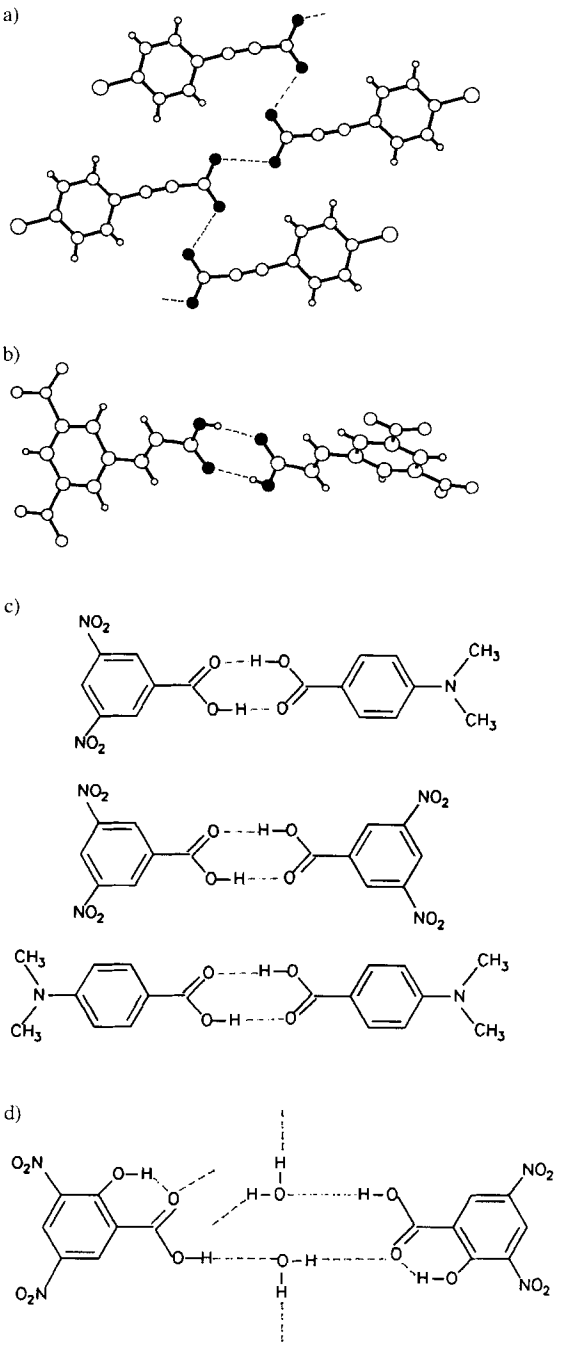

Fig. 5. Anomalously hydrogen-bonded carboxylic acid structures: a) modified catemer synthon **2** in 4-chlorophenylpropiolic acid; b) dimer located on a twofold axis in 3,5-dinitrocinnamic acid; c) observed homodimers (bottom) and unobserved, though expected, heterodimer (top) in the 1:1 complex 3,5-dinitrobenzoic acid and 4-(*N*,*N*-dimethylamino)benzoic acid; d) 3,5-dinitrosalicylic acid monohydrate with interrupting water molecules. In all cases, OH ··· O hydrogen bonds are shown as dashed lines.

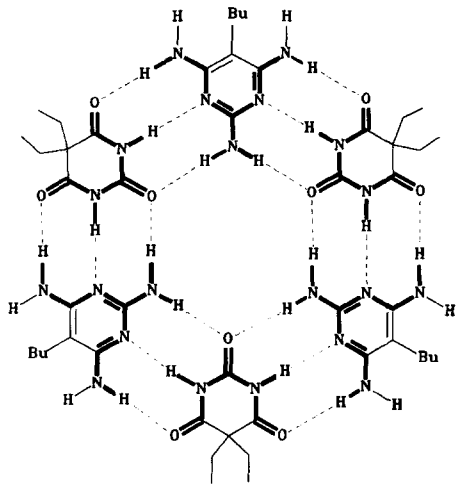
3,5-dinitrobenzoic acid and 4-(*N*,*N*-dimethyl)aminobenzoic acid, homodimers are formed between like acids rather than the expected heterodimers between unlike acid monomers. This occurs because of the importance of $\pi \cdots \pi$ interactions.[49] 4) Unlike other salicylic acids, which adopt the dimer pattern, 3,5-dinitrosalicylic acid crystallizes as a hydrate in which hydrogen-bonded water molecules interrupt the dimer network.[50]

Multipoint recognition of functional groups is expected to improve synthon robustness as in the triply hydrogen-bonded synthon **20**, which has been used by Lehn, Whitesides, Kunitake, Ringsdorf, and others.[51] The relationship of **20** to recognition patterns between nucleotide bases in DNA is unmistakable. The existence of three hydrogen bonds in **20** (rather than two bonds in, say, synthon **1**) means that it can be used to construct more intricate supramolecular structures. For example, **20** is a constituent of the rosette structures **37**–**39** in Scheme 6. Such rosettes themselves occur within the proposed infinite network structure of the 1:1 complex of cyanuric acid and melamine.[52] Rosettes **37**–**39** are supermolecules of intermediate hierarchy (see Section 4) in that they consist of a finite number of molecules and have become attractive goals in what is perhaps one of the first examples of a target-oriented supramolecular synthesis. While synthon **20** is quite robust, it can align with itself through further hydrogen bonding in at least three distinct ways to yield, in Whitesides's terminology, a linear tape, a crinkled tape, and the desired rosette.[53] Two possible approaches to the rosette have been described. Lehn et al. found that the molecular complex of 5,5-diethylbarbituric acid and 5-*n*-butylpyrimidine-2,4,6-triamine contains a linear tape pattern rather than **37**. Cocrystallization of unsymmetrical precursors was expected to yield rosette **38**, but the compounds crystallized separately instead.[54] Whitesides and co-workers, on the other hand, employed bulky *tert*-butyl substituents on the amine component. The buttressing effects of these groups disfavor linear and crinkled patterns for steric reasons, leading successfully to rosette **39**.[55] Further attempts to synthesize similar rosette structures based on hydrogen bonding[56] and other types of interactions are anticipated, but already a certain sophistication in the manipulation of supramolecular synthons is apparent, and the resemblance to logic-directed organic synthesis is clearly discernible.[57] As our knowledge about intermolecular forces increases, there can be no doubt that complex supramolecular structures will be synthesized with increasing reliability and regularity.

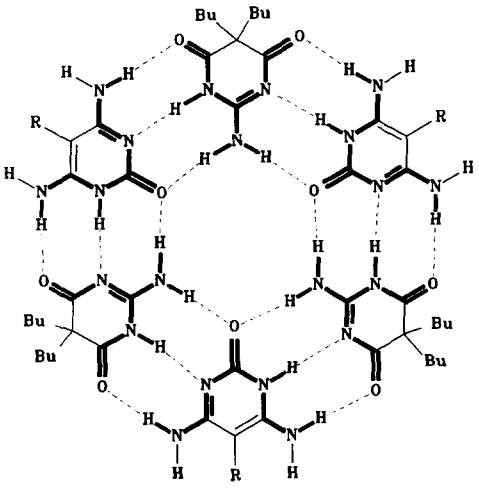
2.4. Subjectivity in Synthon Choice

The recognition of synthons within molecules is purely a utilitarian device; the derivation of all possible synthons in a molecule may never be required.

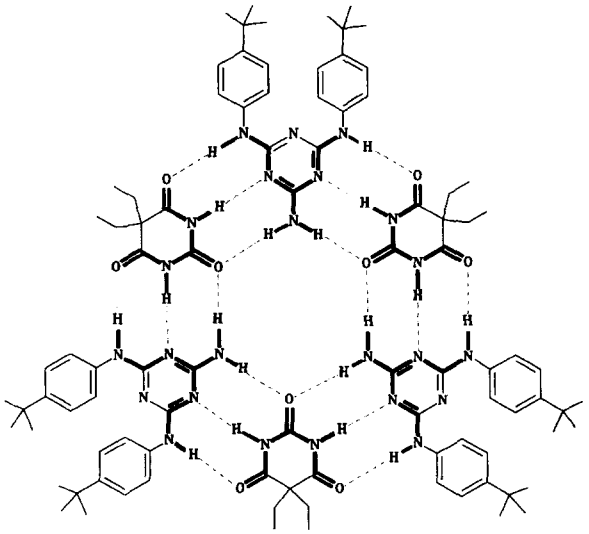
The dissection of a crystal structure and the identification of particular supramolecular synthons within it is entirely subjective. A variety of patterns may be derived from any given structure and none of these are fundamentally more significant than the others. Rather, all of them assist in what is hopefully a better comprehension of the crystal structure and better methods for the systematic design of related structures. The same intermolecular interaction may be a constituent of several overlapping supramolecular synthons. Assessments of the "significance" of a particular supramolecular synthon are related to the question of structure simplification and could be quite arbitrary. For instance, in the iodo–nitro structures discussed in Section 2.2, it is arguable whether synthon **1** or **17** is the more significant.



37



38 (R = C_8H_{17})



39

Scheme 6. Target rosette structures: **37**, **38** (not observed); **39** (observed). The synthons are highlighted. Notice the slightly different synthon structure in **38**.

It is particularly appropriate here to discuss the aryl···aryl synthons **33** and **34**, which are based, respectively, on herringbone and stacking modes of association of aromatic rings,[58] and the hydrophobic synthon **35**. The geometries of **33** and **34** are well-defined and occur in thousands of structures. If one were to assign significance to supramolecular synthons on the basis of specific interaction strengths, these synthons might not rank very high. However, it is known that they play an important role in determining stable crystal packing arrangements characterized by sparing solubility and high crystallinity.[59] Figure 6 shows the crystal structures of benzene and 2-aminophenol. The latter structure contains alternating polar and apolar bilayers. The structure of the apolar layer is almost identical to the benzene structure with aromatic rings mutually perpendicular. The identification of synthon **33** in both these structures confirms their close relationship.[60] The nature of aryl···aryl stacking interactions, as manifested in synthon **34**, has also been the subject of intensive studies, and their utilization in crystal engineering depends on the well-known proclivity of planar π donors and acceptors to form overlapped layered structures.[61] Hydrophobic effects are revealed by the appearance of synthons such as **35** and have been exploited in the design of monolayer structures.

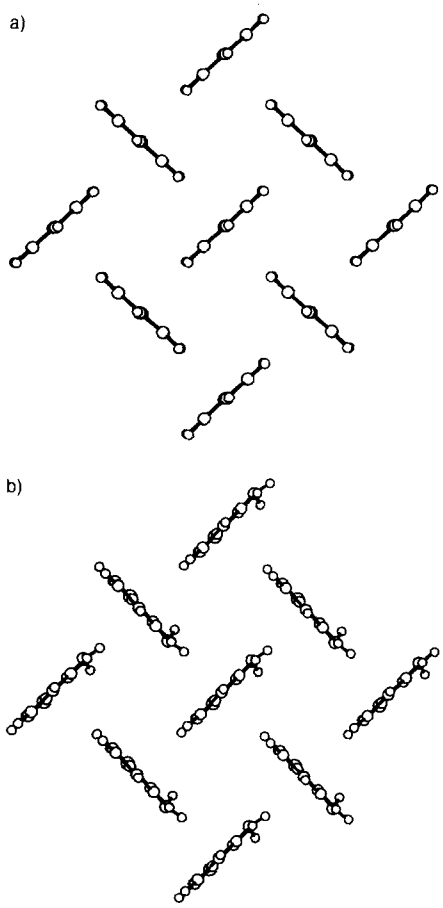


Fig. 6. Comparison of the crystal structures of benzene (top) and 2-aminophenol (bottom). Note the almost identical arrangement of phenyl rings (synthon **33**) in the two structures.

2.5. Conventional and Exotic Interactions

...it may be desirable to attempt a synthesis by the use of new reactions if a great simplification can result or if there is simply no alternative.

Reactions are used in organic synthesis to make covalent bonds, and if structural transformations are to be reliable and efficient, such reactions should evidently be of known mechanism and scope. In the supramolecular context, one would like to use interactions of known directionalities, which can be combined to give structurally robust synthons. Not surprisingly, many current studies in crystal engineering are centered around conventional hydrogen bonding of the OH···O or the NH···O type. But just as organic synthesis progressed by the study of new and (at the time) exotic reaction types, crystal engineering is also amenable to the use of lesser known or weaker and possibly less directional interactions. Gratifyingly, it appears that these weaker interactions are just as effective, especially if they are used in multipoint recognition.

A recent example of the use of CH···O interactions in supramolecular design is provided by the complexation of 1,3,5-trinitrobenzene with dibenzylidene ketones.[62] The target synthon **23** is obtained by replacing the conventional hydrogen bonds in **20** with CH···O hydrogen bonds. The precursor molecular components suggest themselves naturally, and **23** is obtained in the crystal structures of the molecular complexes formed by either 1,3,5-trinitrobenzene or picryl chloride with either dibenzylideneacetone or 2,5-dibenzylidenecyclopentanone (Fig. 7). Reference has already been made to diamondoid structures assembled with I···I synthons (**26**) and N···Br synthons (**27**, Section 2.2, Fig. 4).[39, 40, 43] The scope of ionic interactions in crystal engineering studies is only just beginning to be realized. The structures of organic malates and tartrates, for example, contain strongly hydrogen-bonded networks that are robust in two dimensions, permitting other structural variations in the third dimension.[63]

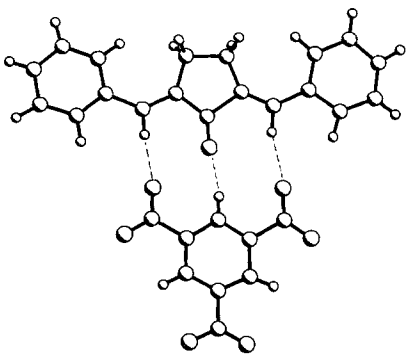

Fig. 7. CH···O-mediated recognition (synthon **23**) in the 1:2 molecular complex formed between 2,5-dibenzylidenecyclopentanone and 1,3,5-trinitrobenzene. Only one of the two symmetry-independent trinitrobenzene molecules is shown.

Conventional hydrogen bonding continues to be used in new and ingenious ways.[64] Two recent reports are based on the complementarity of the hydrogen-bonding capabilities of the OH and NH_2 groups. Ermer and Eling have pointed out that while an OH group has one hydrogen bond donor and two acceptors, an NH_2 group has two donors and one acceptor.[65] Accordingly, compounds or complexes that contain equal stoichiometric amounts of these groups are likely to have highly organized hydrogen-bonded networks with a tetrahedral environment about the O and N atoms. Ermer and Eling have utilized this fact in the design of several diphenol–diamine complexes. Hanessian et al. have discussed the crystal structure of the 1:1 complex between *trans*-1,2-cyclohexanediol and *trans*-1,2-diaminocyclohexane while recognizing again that half of the heteroatoms are fully tetracoordinated.[66]

In general, one may expect to witness several new and exciting developments in the systematic engineering of crystal structures based on interactions with boron, sulfur, and halogen atoms,[67, 68] on hydrogen bonding of the CH···X[24] and XH···π[69] type (in which X can also perhaps be C), and metal–atom interactions, the latter being, of course, exclusive to organometallic clusters and complexes.[70] These constitute the supramolecular reaction methodologies of the future.

2.6. Knowledge of Other Crystal Structures

Knowledge or enlightened speculation as to the way in which a molecule to be synthesized has previously been brought into existence can be extremely helpful in simplifying a synthetic problem.

As far back as 1961 Hassel commented on the hexagonal, layered network of weak N···Cl interactions (synthon **30**) in the crystal structure of cyanuric chloride,[71] which had been previously reported by Hoppe, Lenné, and Morandi in 1957.[72] More recently we noted that synthons such as **12** are common in cyanoaromatic compounds.[73] These ideas and the knowledge of the linearity of CH···N hydrogen bonds led to the identification of 1,3,5-tricyanobenzene as a potential candidate for the formation of similar hexagonal networks. Cocrystallization with hexamethylbenzene proved serendipitous, for the 1:1 complex of these two compounds contains the desired hexagonal network (synthon **31**; Fig. 8).[74] A comparison of **30** and **31** shows that they are interchangeable with a substitution of the N···Cl interaction by the CH···N interaction.

A knowledge of the 1,3,5-tricyanobenzene–hexamethylbenzene crystal structure leads to the possibility of obtaining similar hexagonal networks with related molecules. Trimethylisocyanurate (**40**) was identified, because it contains only CH···O donor and acceptor groups in its symmetrical framework, and the crystal structure of its 1:1 complex with 1,3,5-trinitrobenzene con-

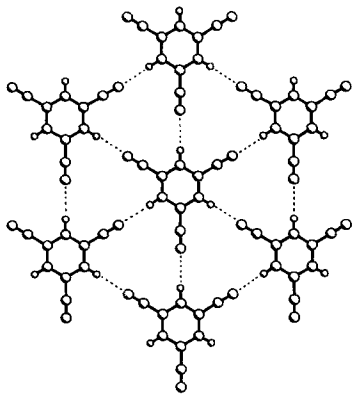

Fig. 8. CH···N network of 1,3,5-tricyanobenzene molecules (synthon **31**) in the crystal structure of the 1:1 complex formed by this substance with hexamethylbenzene. The interleaving hexamethylbenzene network is not shown.

sists of discrete molecular layers.[75] The layers of **40** are networked into a hexagonal pattern (synthon **32**), while the trinitrobenzene molecules are close-packed in two dimensions to yield another hexagonal pattern (Fig. 9).[76] Most interestingly,

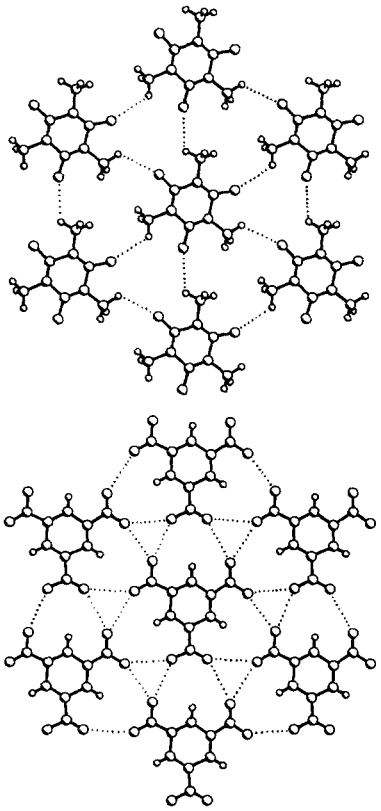

Fig. 9. Hexagonal CH···O network of trimethylisocyanurate (**40**, synthon **32**) (top) and O···O-mediated network of 1,3,5-trinitrobenzene (bottom) in the layered structure of the 1:1 complex formed by these substances.

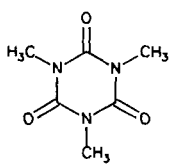
and unlike the 1,3,5-tricyanobenzene–hexamethylbenzene complex, which is monoclinic, this complex crystallizes in the hexagonal space group $P\bar{6}$; in other words the molecular symmetries have been fully retained in the crystal, a rare and exceptional event (see also Section 2.8). Why this happens is not clear—perhaps it has to do with a certain amount of structural insulation of the layers of **40** and trinitrobenzene, thereby reducing three-dimensional interference.

We have observed recently that tetrabromoadamantane (**41**) and hexamethylenetetramine (**42**) form a 1:2 complex in which the molecules of **41** and half those of **42** form a CH···N-mediated diamondoid network related topologically to that in tetraacid **36** (Fig. 10).[77] Instead of catenation as in acid **36**,[23] the other half of the molecules of **42** are clathrated within the



40

42

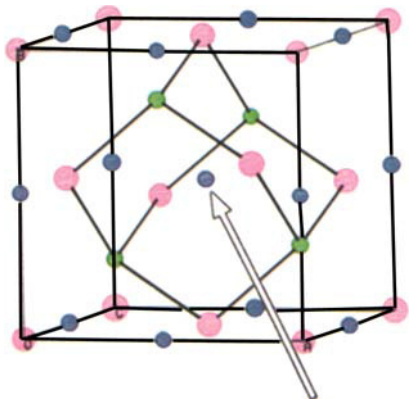

Fig. 10. Organic alloys; a molecule of hexamethylenetetramine (**42**, blue) may be replaced (arrow) by a CBr_4 molecule, leaving the diamondoid CH···N network of **42** (green) and 1,3,5,7-tetrabromoadamantane (**41**, pink) intact.

diamondoid cavities and are disordered. We therefore felt that these clathrated molecules of **42** could be replaced by another molecule of similar shape and size. Accordingly we cocrystallized a 1:1:1 complex of **41**, **42**, and CBr_4. The structure of this ternary complex was exactly as expected. The diamondoid network is retained and the CBr_4 molecules enter the cavities formerly occupied by the disordered molecules of **42**. Interestingly, the CBr_4 molecules are ordered, because they participate in auxiliary Br···Br interactions with the molecules of **41**.

2.7. Supramolecular Retrosynthesis—The Cambridge Structural Database

This is the oldest and most traditional of all synthetic strategies ...

Retrosynthetic analysis in organic synthesis associates synthons, the substructural units in the target structure, with precursor structures in a sequential pathway. This process eventually leads to an identification of one or more potential starting materials.[19, 21] In crystal engineering, target structures are geometrically and topologically defined, and so the equivalent thought process should associate these target networks with precursor molecules that when crystallized will yield appropriate supramolecular synthons that are compatible with the target network structure. Retrosynthetic analysis is at the heart of organic synthesis, because it uses what is known (target structure) to heuristically derive what is unknown (precursor structure). Supramolecular retrosynthesis is of equal importance in crystal engineering and for the same reason. It uses a particular target network and works backwards to identify molecules that by using their intermolecular interactions will crystallize in the target structure.

Traditional retrosynthetic analysis is based on the bedrock of knowledge of the various reactions (covalent bond-making processes) available to the synthetic chemist. This knowledge has been built up through the endeavors of generations of organic chemists.[20] The practice of supramolecular retrosynthesis must analogously depend on an intimate knowledge of the myriad ways in which intermolecular interactions are manifested in crystals. This knowledge has come to us through the endeavors

of generations of crystallographers who have bequeathed to us around 125000 accurate crystal structures of organic and organometallic small-molecules. To a large extent, the assimilation and digestion of the organic synthetic repertoire is still a manual, individual effort.[78] However, because of the peculiarly geometrical nature of intermolecular forces, supramolecular synthetic methodology is suited to computer storage and retrieval techniques, and the essential tool for retrosynthetic analysis in crystal engineering already exists in the form of the Cambridge Structural Database (CSD).[79]

The CSD is now more than ever suited to the purpose of supramolecular retrosynthesis, because it may be searched for patterns of intermolecular forces. Till very recently, the search protocols in the CSD were molecular in their bias; only questions based on covalent bond connectivity could be posed. In studies of interaction geometry, the hits that were thus obtained through molecular-type searches were manipulated with geometrical calculation programs. Today it is possible to code the supramolecular synthon structure directly (as shown in Scheme 1) *inclusive of geometrical attributes* in the search question and obtain all crystal structures that contain the chosen synthon. As a typical example, in attempting to extract all structures that contain dimer synthon **1**, one might typically, in former times, have retrieved all carboxylic acid structures using in the search question a molecular fragment such as CO_2H. This search would have yielded not only compounds that contain the desired **1**, but also acids that adopt the alternative catemer **2**. Yet, structurally related synthons like **3** would not have been obtained. In contrast, the distinctly supramolecular bias of the latest versions of the CSD surely takes into account its ever-increasing relevance in systematic crystal engineering.

The CSD is extremely useful in the study of intermolecular forces weaker than conventional hydrogen bonding. For any given interaction there is an ideal intermolecular orientation. However, this ideal geometry is deformed to a greater or lesser extent in crystals, because the crystal geometry is the result of interaction interference (see Section 2.3). Therefore a statistical analysis of crystal structures is mandatory when studying weak interactions. These statistical techniques minimize the crystallographic noise, that is, the effects of the various deformations, which are inevitable when the interactions are weak. The greater the sampling of crystal structures, the weaker the interaction that may be analyzed. It is reasonable to expect that the present size of the CSD is sufficient to permit an analysis of most types of intermolecular interactions that have been used in crystal engineering or are likely to be used in the foreseeable future.

2.8. Supramolecular Symmetry

...any synthetic scheme which does not take full cognizance of stereochemical possibilities or problems will have a correspondingly low expectation of success.

Stereochemistry is an expression of molecular topology, and its supramolecular equivalent is expressed in terms of the spatial and geometrical relationships between supramolecular fragments in the crystal. For instance, how does one obtain particular dispositions and arrangements *between* ribbons, layers and networks within a crystal structure? This is a matter of considerable importance in crystal engineering, because it results in the manifestation or disappearance of physical effects such as Second Harmonic Generation (SHG) or chemical effects such as host–guest complexation. For instance, crystallization in an enantiomorphous space group of an SHG-active material may be likened to a supramolecular asymmetric synthesis. Such considerations are closely linked to questions concerning symmetry. In general, three sorts of symmetry need to be considered: molecular symmetry, the symmetry of supramolecular fragments (tapes, helices, knots, sheets, channels, voids), and crystal symmetry. The first and the third kinds of symmetry are matters of fact, while the second is subject to individual interpretation.

The carry-over of molecular symmetry into the crystal is not a trivial matter, and in no aspect of crystal engineering is the practitioner of the subject quite so helpless today as in establishing connections between molecular and crystal symmetry. Indeed, Kitaigorodskii's laws of close-packing almost dictate that molecular symmetry is a very poor guide to the molecular site-symmetry in the crystal. The inversion center is the only molecular symmetry element that is routinely carried over into the crystal, because it is the only crystal symmetry element that does not entail loss of packing efficiency by its presence.[27, 80] In practice this means that higher symmetry molecules almost always do not adopt higher crystal symmetries. However, the shape factor is also important and when the molecular shape exceeds a certain awkwardness, which is still not really quantifiable, close-packing is problematic leading to the formation of open networks in which the full molecular symmetry is retained, and a second molecular species is included as a guest to improve packing efficiency. For example, 1,3,5-triphenylbenzene forms 1:3 host–guest complexes with benzene, whereas mesitylene, 1,3,5-trichlorobenzene, and 1,3,5-trinitrobenzene form single-component crystals.[10] The presence of high molecular symmetry coupled with a symmetrical interaction pattern is a more powerful combination for the engineering of host networks. In such cases, there is a pronounced conflict between close-packing and directional factors. Such a situation often arises when groups capable of hydrogen bonding are symmetrically disposed in a symmetrical molecular framework. The rigid scaffolding of hydrogen bonds is also compelled to be symmetrical, because the directionality of the hydrogen bonds cannot be compromised. Gross violations of the close-packing principle may sometimes result leading to guest-molecule inclusion (hydroquinone-C_{60}), catenation of networks (acid **36**), or simultaneous inclusion and catenation (hydroquinone with small guests, trimesic acid).

Consideration of spatial relationships between supramolecular fragments in a crystal reveal the following alternatives: 1) Translation versus inversion stacking of two-dimensional fragments such as ribbons and sheets.[81] 2) Packing of fragments of similar and opposite chiralities, for example helices.[82] 3) Alternative topologies of catenation of two- and three-dimensional networks.[83] 4) Segregated versus mixed stacks of planar donor and acceptor molecules in organic metal structures.[84] Many of these possibilities are influenced by extremely weak interactions and are not only poorly understood at present, but also not very amenable to computational techniques. Since the final outcome of crystallization is often governed by a combination of kinetic

and thermodynamic factors, stereoselective supramolecular synthesis remains a difficult though achievable goal for the future.

2.9. Polymorphism

...the possibility of competing reaction paths should be minimized...

No discussion of crystal engineering can sidestep the problem of polymorphism. This phenomenon is as mysterious and vexing as when a wrong isomer is obtained in a reaction sequence in spite of the best planning and effort. As in traditional synthesis, our inability to grapple with such a problem stems from an incomplete or incorrect knowledge of the factors that affect structure. On occasion it also appears to arise because of outright bad luck, a commodity that is probably as prevalent in crystal engineering as in organic synthesis.

Much has been said about the frequency of occurrence of polymorphism among small-molecule substances, on whether the proportion of polymorphic structures in the CSD is representative of the global proportion of polymorphs in all possible crystal structures (if such details could be ascertained reliably), or even if the number of polymorphs of a given substance increases with the amount of time and effort spent on studying the compound.[85] Many of these questions are rhetorical and quasi-philosophical and are not very helpful in solving the practical problems of crystal engineering. However, a few generalizations may be made: 1) The frequency of occurrence of polymorphic modifications is not uniform in all categories of substances. The phenomenon is probably more common among molecules that have flexible conformations or many different groups capable of hydrogen bonding. By the same token, rigid, flat molecules such as condensed aromatic hydrocarbons are unlikely to have many polymorphic modifications under normal conditions of temperature and pressure. Again, the likelihood of polymorphism may be greatest in an intermediate molecular weight range, approximately C_{10} to C_{20}. 2) Ingenious methods of crystal engineering that create several sites for (three-dimensional) multipoint recognition of molecules will probably decrease the likelihood of polymorphism. In such cases, the general strategy would be to ensure that there is a unique pattern of supramolecular synthons. 3) For the particular application under consideration, it may not really matter whether polymorphs exist, because the critical, property-defining supramolecular fragment (that is, the particular synthon) may be found intact in all the polymorphs. 4) Polymorphism is strongly solvent-dependent in some cases, and computer simulation of crystal structures with and without adhering solvent molecules may provide guidelines for the crystallization of a particular polymorph.

The study of polymorphism in organic crystals is still in a process of evolution, and much more data will be required before firm and general conclusions can be drawn. Recent computational approaches based on molecular dynamics calculations seem to show considerable promise. The Monte-Carlo-based Polymorph Predictor technique has been implemented in the Cerius^2 package from BIOSYM/Molecular Simulations to obtain ab initio predictions of a number of polymorphs.[85] Yet, crystallization almost certainly does not depend exclusively on energetics and may proceed through discrete stages with the result that multimolecular clusters are trapped in higher energy minima in the final crystal structure. A better understanding of polymorphism will depend on a better understanding of the crystallization process itself, and this in turn will rely on advances in spectroscopy (detection of crystal nuclei), physical chemistry (thermodynamics, chaos theory), and biophysics (protein folding). These are difficult issues, and only better experimental and theoretical insights will lead to any measure of control over the problem of polymorphism.

3. Methodology—Intermolecular Interactions

A number of intermolecular interactions, the nuts and bolts of crystal engineering, have been discussed implicitly in the preceding sections, and several detailed and definitive experimental CSD-based and theoretical studies of these interactions have been the subject of recent publications.[6–10, 13, 15, 24, 40, 58, 59, 67–70, 85, 86] The purpose of this section is therefore only to enumerate these forces and to very briefly highlight some of our own results especially those pertaining to the weaker interactions.

The most meaningful criteria for the classification of intermolecular forces from the crystal engineering standpoint are distance-dependence and directionality. Typically, the medium-range forces are isotropic in character and define molecular shape, size, and close-packing (implicit involvement of interactions). Generally, these forces are limited to C···H, C···C and H···H interactions. The long-range forces on the other hand are electrostatic and anisotropic and involve heteroatom interactions, that is, interactions among N, O, S, Cl, Br, I (rarely B, F, P, Se) or between any of these elements and C or H (explicit involvement of interactions). Ionic forces are extremely long-range in nature and are quite specific, directing supramolecular structure effectively.

3.1. Nondirectional Forces

Nondirectional forces (2–10 kJ mol^{-1}) traditionally, though not necessarily exclusively, include C···C, C···H and H···H interactions.[87] The relative importance of these interactions in any particular crystal depends on the C:H stoichiometry. Aromatic compounds (high C:H ratios) have a much stronger tendency to stack, since this would increase the number of C···C interactions. The coulombic character of the C···H interaction could account for its prevalence in a wide variety of aromatic and aliphatic compounds (Section 2.4). For planar aromatic compounds these interactions result in the characteristic T-shaped herringbone synthon **33**. Crystal structures are also known where an unusually acidic C–H group (alkyne) makes close contacts with conjugated π systems.[88] Whether these contacts are to be termed CH···π hydrogen bonds, like the recently studied OH···π hydrogen bonds (see Section 3.2.1), or whether they are merely extreme manifestations of the C···H herringbone interaction is an open question.

3.2. Hydrogen Bonding

Hydrogen bonding, the master key for molecular recognition, is the most reliable directional interaction in supramolecular construction, and its significance in crystal engineering can scarcely be underestimated. As a vast amount of work has been carried out on the various aspects of hydrogen bonding, it would be futile to attempt even a brief review of these efforts here. Hydrogen bonds of the type OH···O and NH···O may be termed "strong" or "conventional" (energies 20–40 kJ mol^{-1})[89] to distinguish them from the weaker CH···O and OH···π interactions (energies 2–20 kJ mol^{-1}), which share many of their characteristics and which are discussed in greater detail in Section 3.2.1.

The distinctive geometrical attributes of a hydrogen bond D–H···A–X (D = donor, A = acceptor) are the D···A and H···A lengths, the hydrogen bond angle D-H-A or θ, the H-A-X angle or ϕ and the planarity of the DHAX system. All these features have been discussed extensively.[6, 15] Typical values for the H···A distance are 1.80 to 2.00 Å for NH···O bonds and 1.60 to 1.80 Å for OH···O bonds. More relaxed definitions of these distance criteria permit a consideration of the slightly longer three-centered and four-centered bonds, which seem to be very common in several hydrogen-bonded structures. Ranges for θ and ϕ occur around 150–160° and around 120–130°, respectively. This marked directionality of hydrogen bonds is well-established and is the basis for efficient and reliable supramolecular construction using supramolecular synthons that contain groups such as –OH, $-CO_2H$, –CONHR, and $-CONH_2$. Synthon **28**, for instance, occurs in several phenols and in the water trimer and is related to other synthons such as $(OH)_4$ and $(OH)_6$.[90] We have found recently that many hydrogen-bonded synthons containing carboxyl and hydroxyl groups in organic crystals are retained largely intact in organometallic crystals.[91]

3.2.1. CH···O and OH···π Hydrogen Bonds

This discussion is also valid for the related CH···N and NH···π[69, 92] interactions. Furthermore, while there is some question whether the CH···Cl interaction is a viable one, recent reports provide evidence for CH···F[94] and CH···Se[95] hydrogen bonds.

There is little doubt that CH···O hydrogen bonds are important, even if subtle, determinants of crystal packing, especially when strong OH···O and NH···O hydrogen bonds are absent.[24, 96] As has been discussed in Section 2.3, CH···O hydrogen bonds may distort the geometry and topology of even the strong hydrogen-bond network in specific instances. Anomalies and puzzles in the strong hydrogen-bond patterns of certain crystal structures are explained on the basis of the interplay of strong and weak hydrogen bonds. In general, the strength and effectiveness of a CH···O hydrogen bond depends on C–H carbon acidity[97] and on O-atom basicity,[98] which is enhanced by cooperative effects. We have shown for instance that CH···O distances in crystals correlate so well with solution C–H group pK_a values that it is even possible to define a crystallographic scale of carbon acidity.[99]

The criteria for the significance of a particular CH···O geometry have also been the subject of some discussion. Recent analysis has shown that the angular characteristics of many longer CH···O contacts (C···O 3.50–4.00 Å) and their effects on crystal structures resemble those of the shorter contacts (3.10–3.50 Å).[24] It should be emphasized that the CH···O bond is not really a van der Waals contact but is primarily electrostatic; as its strength therefore falls off much more slowly with distance, it is viable at distances equal to or longer than the van der Waals limit. Therefore, even long C···O separations (about 4.00 Å) have to be considered seriously, and these weak hydrogen bonds are expected to have orienting effects on molecules prior to nucleation and crystallization. This underlines the important role of these bonds in crystal engineering especially in orchestration.

While CH···O hydrogen bonds are widespread, the complementary OH···π interactions are rare, because C is not as electronegative as O and also because unsaturated carbon atoms are not often situated in sterically unhindered positions, unlike carbonyl and ethereal O atoms, which permit easy access for C–H groups to form CH···O bonds. In spite of these limitations, a sufficiently electron-rich C atom (alkyne, alkene, aromatic) has a propensity to form a hydrogen-bond-like interaction with O–H groups thus contributing to crystal stability.[100] We have studied these interactions systematically with the CSD: around 50 unambiguous cases of intermolecular OH···π and NH···π hydrogen bonding were found in the 1993 update.[69]

3.3. Halogen Atom Interactions

It has long been known that the halogens Cl, Br, and I form short nonbonded contacts in crystals.[15] Not only are these contacts (synthons **25**, **26**) clearly manifested in the crystal structures of the elements themselves; they are also of historical importance in crystal engineering, because they form the basis of the so-called "4 Å chloro rule" enunciated by Schmidt for planar dichloroaromatic compounds.[101] The nature of these interactions is still somewhat obscure. Nyburg and Wong-Ng,[102] and more recently, Price et al.,[86] have held that these short contacts are the result of elliptically shaped atoms (anisotropy), while others including ourselves have maintained that there are specific attractive forces between halogen atoms in crystals.[40, 103] Certainly atomic polarization is an important factor here, because there are clear distinctions between Cl···Cl, Br···Br and I···I interactions and between these symmetrical interactions on the one hand and unsymmetrical interactions such as I···Cl, Br···F and I···F on the other. Directional interactions formed by the halogens with O and N atoms are also polarization-induced and have been used by us and others in systematic crystal engineering (Section 2.1).[33–35, 45]

3.4. Other Interactions: Hardness and Softness

As in the case of halogens, polarization effects are important for sulfur, which is known to form short directional contacts of the type S···N, S···S, and S···Cl. These contacts have been thoroughly studied in the crystal chemistry of the TTF–TCNQ family of compounds.[104] Intermolecular interactions that are

specific to organometallic compounds have only been the subject of very recent study.[105] Our systematic survey of Au···Au interactions has shown that they affect molecular conformation and crystal packing.[106] Hydrogen-bonding patterns in organometallic crystals are, in general, similar to those in simple organic compounds. However, the CO ligand is a base unique to organometallic compounds, and our results indicate that it is more important for CH···O bonding than for OH···O bonding.[91, 107] A possible explanation for such an observation considers the hardness and softness of intermolecular interactions. It appears that the hard and soft acid and base (HSAB) principle may be profitably extended to supramolecular chemistry. For instance, NH···O and OH···O could be considered hard hydrogen bonds, CH···O and CH···π soft hydrogen bonds, and NH···N have perhaps intermediate character.[107] Accordingly, it might be argued that the soft acceptor CO prefers to form a hydrogen bond with the soft donor C–H, or alternatively the hard donor O–H prefers to form bifurcated or solvated hydrogen bonds with hard acceptors rather than waste itself on the soft acceptor CO. Along these lines, the unexpected formation of the CH···Se may be understood in terms of the relative softness of both donor and acceptor species.[95] Again, Scheme 3 shows how the hard synthon **1** and the soft synthon **17** operate independently, but equally effectively, in the crystal.

4. Summary and Outlook

...although chemistry is a science of vast scope and countless specialties, it has no real boundaries...

In writing this article and drawing an analogy between crystal engineering and organic synthesis, I have tried to address two groups of chemists whose concerns and goals might at the outset appear to be somewhat unrelated. Yet, crystal engineering today seems to be poised at the point where organic synthesis was in the fifties and sixties. Empirical, largely intuitive strategies or manipulations within narrowly defined structural families dominate the scene even as one already discerns glimmers of a more logic-driven approach. All these developments have generated a substantial body of data on intermolecular interactions and crystal packing. It is from this corpus that more systematic strategies of crystal engineering will appear. I have attempted to show that the kernel of such strategies already exists in synthetic organic chemistry, and that with this foreknowledge, solid-state supramolecular chemists might well be able to create patterns of extraordinary finesse in crystals. On the other hand, it is hoped that synthetic organic chemists will recognize in crystal engineering a natural extension of so many principles in their canon and realize that with an appreciation of the properties of intermolecular interactions, they may be equally well-equipped to undertake research in this challenging discipline. In either case, crystal engineering, which has been recognized as the central issue in organic materials chemistry, is well set to become the breakthrough technology for industrial research and development.

The term "supermolecule" has been used synonymously with "crystal" in this article, and as mentioned at the very outset, a crystal is the *ultimate* example of a supermolecule in that it consists of an infinity of molecules divergently bound. Hierarchies of supramolecular species may accordingly be recognized, and the synthesis of lower hierarchy supermolecules consisting of two or more convergently bound molecular components has become an extremely attractive and competitive area of research combining molecular synthetic methodology with supramolecular ideas of molecular association.[108] However, such efforts must logically progress towards crystal engineering in the quest for complex three-dimensional networks based on complex polyfunctional molecules.

At one level it is remarkable that concepts and models which were developed in the sixties for organic synthesis can be so readily reapplied today, and in such minute and faithful detail, to a research area which was barely conceived at that time. This parallelism has continued to unfold itself for me even during the writing of this article—I have little doubt that other structural and synthetic chemists will be able to uncover more relationships between these two fascinating areas of chemistry. Yet, at another level such a striking resemblance only reaffirms the oneness or nonduality in the chemical thought process. Though I have quoted only a few sentences from Corey's 1967 article here,[18] almost the entire Part I can be reread and reassimilated in the context of crystal engineering and solid-state supramolecular chemistry, and perhaps even such an eventuality was foreseen, for it is stated while justifying the quest for a general strategy of synthesis that *"such an effort surely is more than an intriguing theoretical exercise; it is a prerequisite to a deeper comprehension of Synthesis and the methodologies which are fundamental to it, and it is likely to be the keystone in the rational development of Synthesis* ***to still higher forms.***"[*]

It is a pleasure to acknowledge the enthusiasm, hard work, and support of my former and present students and postdoctoral associates. Among these, the following have assisted me greatly during the preparation of this manuscript: C. V. K. Sharma, D. S. Reddy, B. S. Goud, K. Biradha, V. R. Thalladi. Much of the work described here would not have been possible without the skillful assistance of several crystallographic collaborators, especially H. L. Carrell and D. E. Zacharias (Fox Chase Cancer Center, Philadelphia), D. C. Craig (University of New South Wales, Sydney), J. A. K. Howard (University of Durham), T. Pilati (Università di Milano), W. T. Robinson (University of Canterbury, Christchurch), Y. T. Struchkov (Nesmeyanov Institute of Organoelement Compounds, Moscow), and others whose names appear as coauthors in the appropriate publications. I would like to thank G. Klebe (BASF AG, Ludwigshafen) for initial discussions, A. Nangia (University of Hyderabad) for many useful comments during the writing of this article, and C. B. Aakeröy (Queen's University, Belfast) for his willingness to prepare the cover illustration. The Cerius² software from BIOSYM/Molecular Simulations provides computational methods cited in this article and modeling tools used to produce some of the accompanying illustrations, and I wish to thank BIOSYM/Molecular Simulations for their support. Financial assistance from the Department of Science and Technology, Government of India, is gratefully acknowledged.

[5] However, inorganic crystal chemists have always appreciated the collective properties of molecules and ions and have traditionally viewed a crystal in terms of its network connectivity. See, for example, A. F. Wells, *Structural Inorganic Chemistry*, Oxford University Press, Oxford, 1975. Yet, these "organic" and "inorganic" perceptions are only parts of the whole! For an example which illustrates that organic and inorganic crystal structures are governed by the same grammar, see D. S. Reddy, D. C. Craig, G. R. Desiraju, *J. Chem. Soc. Chem. Commun.* **1995**, 339.

Supramolecular Inorganic Chemistry: Small Guests in Small and Large Hosts

Achim Müller,* Hans Reuter,* and Stephan Dillinger

Dedicated to Professor Jean-Marie Lehn

A key reaction in the biological and material world is the controlled linking of simple (molecular) building blocks, a reaction with which one can create mesoscopic structures, which, for example, contain cavities and display specifically desired properties, but also compounds that exhibit typical solid-state structures. The best example in this context is the chemistry of host–guest interactions, which spans the entire range from three- and two-dimensional to one- and "zero-dimensional", discrete host structures. Members of the class of multidimensional compounds have been classified as such for a long time, for example, clathrates and intercalation compounds. Thus far, however, there are no classifications for discrete inorganic host–guest compounds. The first systematic approach can be applied to novel polyoxometalates, a class of compounds which has only recently become known. Molecular recognition; tailor-made, molecular engineering; control of fragment linkage of spin organization and crystallization; cryptands and coronands as "cages" for cations, anions or anion–cation aggregates as sections of ionic lattices; anions within anions, receptors; host–guest interactions; complementarity, as well as the dialectic terms reduction and emergence are important terms and concepts of supramolecular inorganic chemistry. Of particular importance for future research is the comprehension of the mesoscopic area (molecular assemblies) –that between individual molecules and solids ("substances") –which acts in the biological world as carrier of function and information and for which interesting material properties are expected. This area is accessible through certain variations of "controlled" self-organization processes, which can be demonstrated by using examples from the chemistry of polyoxometalates. The comprehension of the laws that rule the linking of simple polyhedra to give complex systems enables one to deal with numerous interdisciplinary areas of research: crystal physics and chemistry, heterogeneous catalysis, bioinorganic chemistry (biomineralization), and materials science. In addition, conservative self-organization processes, for example template-directed syntheses, are of importance for natural philosophy in the context of the question about the inherent properties of material systems.

1. Introduction and the Current State of the Art

1.1. Supramolecular Chemistry:[1] Definitions

After the accidental discovery of crown ethers by Pedersen[2] nearly 30 years ago, the field of supramolecular organic chemistry, due to its close relationship with bioorganic chemistry and its research topics, such as receptors, enzymes, and carrier molecules,[3a] has not only brought forth a plethora of new classes of compounds (cryptands,[3b, c] spherands,[4] siderands[5]) with unusual structure–property relationships but has also developed an independent terminology to describe supramolecular phenomena. Consequently, this area of research has a quite homogeneous appearance, despite its wide span of activities. In contrast to this, the field of inorganic host–guest chemistry presents a rather more inhomogeneous picture. This stems in part from the lack of commonly accepted definitions and concepts and the fact that this field differs noticeably from its organic counterpart due to dissimilar notions of bonding and syntheses.

Supramolecular compounds (supermolecules and complexes) in organic chemistry are, specifically, aggregates of well-defined composition and structure, consisting of two or more different building blocks (see Fig. 1); host–guest compounds are a subgroup, hydrogen-bonded donor–acceptor aggregates another. These building blocks are –like those of molecular materials[6]– molecules or ions, which are stable in the pure or dissolved state and have well-defined physical and chemical properties. The intermolecular interactions between the host species

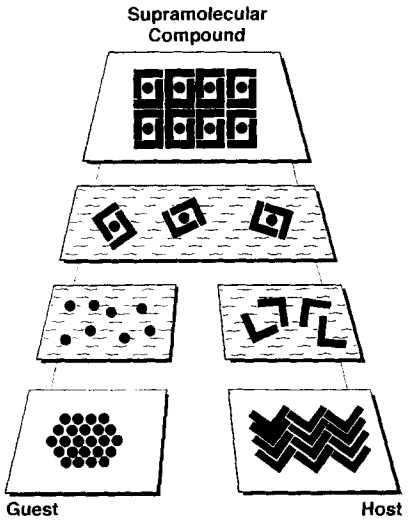

Fig. 1. Flow scheme depicting the construction of supramolecular compounds from molecular host and guest species. Beginning with well-defined starting materials (for which the crystalline state was chosen in this example), the reaction in solution leads to the supramolecular species. In general, it is desirable to isolate and characterize the compound in the crystalline form. Depending on the actual host–guest compound, some of the steps shown may be skipped or performed in a different order.

or between host and guest species as well as between donor and acceptor compounds—electrostatic attraction, van der Waals forces, hydrogen bonds—are strong enough to ensure the integrity of the supramolecular aggregates in solution. These forces, however, are in general still weak enough to enable the reversible decomposition of the aggregates into their primary building units under only slightly modified conditions.

As the important steps in the formation of organic host–guest compounds, as well as their reactions, occur in general in solution, supramolecular organic chemistry long limited itself to this phase. Only in borderline cases, for example, for structural determinations, was the solid phase included in studies. This tendency has recently been reversed in the context of "crystal engineering", that is, by studying the systematic creation of organic crystal structures, too.[7] In contrast, inorganic host–guest compounds were until recently[8] almost exclusively observed in the solid state. Today, there are indications that many zero-dimensional aggregates are also stable in solution. Therefore, for supramolecular inorganic chemistry not only stable (i.e., actually existing) discrete species as primary building blocks, but also hypothetical ones and even single atoms have to be considered and strong interactions (covalent or ionic bonds) between host fragments must also be taken into account. In this last case, however, it is necessary that the host–guest interactions are weak in order to constitute a "real" supramolecular compound, although deviations from this rule should be discussed in special cases, based on the experimental data on hand.

This somewhat modified definition leads to a conceptual change in the synthetic strategies for the construction of multidimensional inorganic host–guest compounds. In many cases, the host is synthesized first, after which the guest is allowed to interact with it. Conversely, sometimes the guest is utilized as the template for the synthesis of the host. The host structures in supramolecular inorganic compounds are often metastable phases, which could not have been created without the aid of the guest.

The entire field is best subdivided according to topological/structural aspects,[9] independent of the specific nature of the chemical bonds and the host-specific synthesis. This approach, formally, leads to four categories (see Fig. 2) of host–guest compounds, corresponding to the relevant dimensionality of the *three-*, *two-*, *one-*, or *"zero-dimensional" host structure.*

The host structure is determined primarily by the connectivity (e.g., two, three, four, or six bonds), by the geometric requirements (e.g., linear, square-pyramidal, tetrahedral, or octahedral linkage points), and by the type of linkage (corner-, edge-, or face-sharing) of the *molecular subunits.*

Achim Müller, born in 1938 in Detmold, studied chemistry and physics as the University of Göttingen and received his Ph.D. (1965) and his Habilitation (1967) there under the supervision of O. Glemser. He is now Professor of Inorganic Chemistry at the University of Bielefeld and is a member of several scientific academies, including the Deutsche Akademie für Naturforscher (Leopoldina) and the Polish Academy of Sciences. His research interests range from problems of molecular physics (theory of mass influence on molecular constants), vibrational spectroscopy (matrix isolation spectroscopy, band contour analysis, resonance Raman effect, metal isotope effects), bioinorganic chemistry (model compounds and biological nitrogen fixation by free-living organisms), and molecular metal chalcogenide complexes and clusters (synthesis, geochemical relevance, electronic and molecular structure, topological and supramolecular aspects, and their use in heterogeneous catalysis) to aspects of natural philosophy. He has published, besides numerous original papers, more than 30 reviews and is coeditor of eight books.

H. Reuter

A. Müller

Hans Reuter was born in 1952 in Niederoberweiler, a small community in the German region of the Vulkaneifel. He studied chemistry at the University of Bonn, where he completed his Ph.D. in 1987 working under the supervision of H. Puff on the hydrolysis of organotin halides. His Habilitation in the field of inorganic chemistry also took place in Bonn, in 1992. His research interests lie in the area of preparative solid-state chemistry, with emphasis on syntheses from molecular precursors at low temperatures, particularly the solution-sol–gel process. In 1990, Hans Reuter was awarded the Bennigsen-Foerder Award of the German state of Nordrhein-Westfalen for a research project on supramolecular organometallic chemistry. After a temporary appointment at the University of Münster, he received an offer for a chair at the Institute for Chemistry at the University of Osnabrück at the end of 1993.

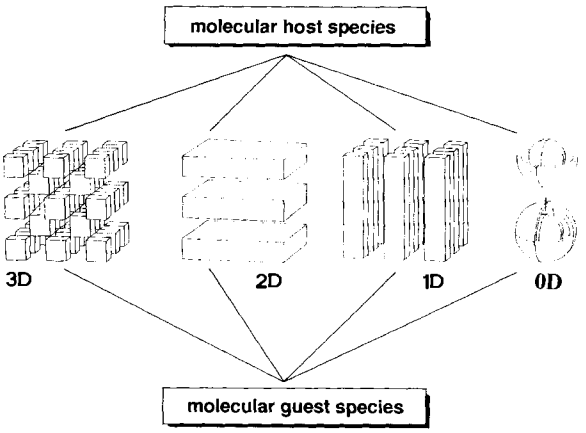

Fig. 2. Schematic representation of the four categories of host–guest compounds as a function of the dimensionality of the host. In the case of zero-dimensional hosts, one has to distinguish between closed (bottom) and open (top) hosts.

1.2. Retrosynthesis and Preliminary Synthetic Strategies

Upon analyzing the existing data, one finds that many basic building blocks form similar, if not identical structures, that is, their behavior is topologically/structurally equivalent, in spite of the different types of bonding and atomic distances involved (see Section 2.1.4). Using retrosynthesis, one often finds molecular building blocks in the host structures that are unknown as isolated species. These must, therefore, have formed from the starting materials by complex reaction mechanisms and reaction pathways.

In order to avoid potential linguistic confusion stemming from the constant switching between actually existing and hypothetical subunits, and to build a connection between the starting materials and the structural characteristics of the host species, it appears useful to comment on some basic aspects of retrosynthesis and synthetic strategies. Using the concept of retrosynthesis as a guide, which has been quite successful in organic chemistry,[10] an agreement on the definition and usage of terms should be reached that is appropriate for inorganic host–guest phenomena.

It is a frequent desire in preparative chemistry to tailor a host for a specific guest. In these cases, the chemist acts as the designer. If size, polarity, charge, etc. of the guest are given, it is possible to design a host with a matching surface topology and polarity. The actual synthetic strategy will be guided by this design and by the pool of known relevant reactions, reagents, and starting materials.

1.3. Tectons

The starting point of a successful synthesis of a host or a host–guest compound is its rational retrosynthesis. In the first step, the structural building blocks are reduced to simple geometric "figures", such as squares, tetrahedra, or cubes, with the corners acting as linkage points to other corresponding figures. In analogy to the term synthon in organic chemistry, these entities will be called *tectons*.[11] Just as in Corey's[12] original definition of synthon, the term tecton applies to basic structural units of the host that can be formed by known or presumed synthetic operations.[13]

Among the tectons shown in Figure 3, the T_1 tecton represents a certain exception in that it stands for an end group, which terminates the structure at this linkage point. Similarly, the T_2 tecton is less often used as a structure-forming element than as a spacer, that is, as a building block that increases the distance between two tectons and yields another linkage point, which can formally be viewed as a "ball joint" that freely rotates in all three spatial dimensions.

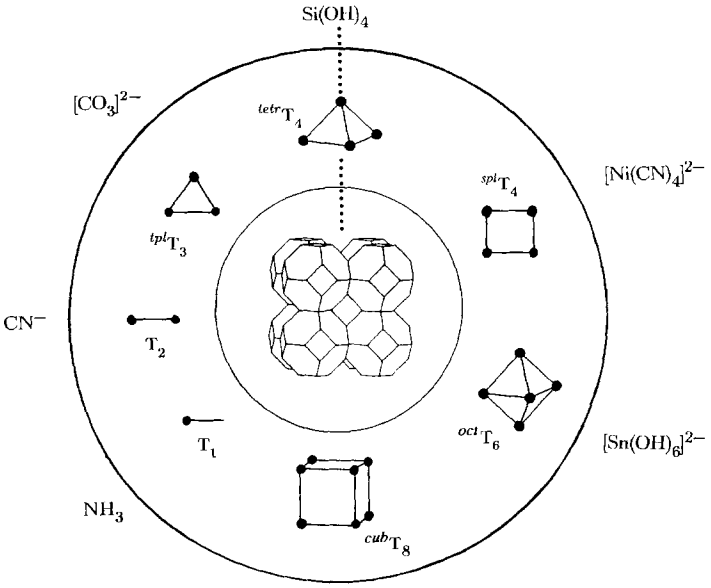

Fig. 3. Summary of common (basic) tectons and tecton equivalents in inorganic host–guest chemistry. The target compound (center) is decomposed by retrosynthesis into tectons (middle ring) which, in turn, should be accessible by simple reactions from either known stable inorganic tecton equivalents or from those that are postulated as intermediates (outer ring).

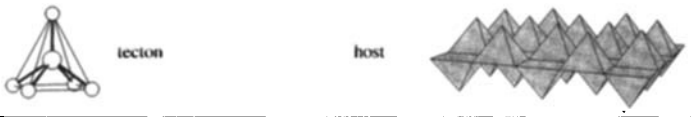
1.4. Tecton Equivalents

After these abstract considerations regarding the formation of a host structure, the next step includes the first fundamental considerations regarding their chemical realization, which crucially influence all further planning. We have to look for actually existing or hypothetical compounds for the tectons in the host structure. These are called *tecton equivalents*, based on the term synthetic equivalents in the retrosynthesis of organic molecules. The tecton equivalents should either contain the necessary tectons or they should be readily obtainable from them by simple reactions.

1.5. Reagents and Reaction Conditions

Once these planning steps are completed, the appropriate preparative conditions, that is, the *reagents*, *starting materials*, and *reaction conditions*, must be chosen so that they yield the desired tecton equivalents.

The above-mentioned considerations can be clarified by referring to the formation of two-dimensional host structures such as those shown in Figure 4. The layer topology of these host structures is known from α-tin(II) oxide which has the same layer structure as red PbO, and hence, is composed of edge-sharing



host topology	*alpha-SnO layers*		
layer formula	SnO	$[RSnO]^-$	$[RSnO]^+$
structural unit	spy-$\{SnO_4\}$	spy-$\{RSnO_4\}$	spy-$\{RSnO_4\}$
tecton	$^{scon}T_4$-4E		
	⇧ *condensation*		
tecton equivalent	$H_2[Sn^{II}(OH)_4]$	$H_3[RSn^{II}(OH)_4]$	$H[RSn^{IV}(OH)_4]$
	⇧ *hydrolysis*		
reagent	$SnCl_2$	?	$RSnCl_3$
reaction conditions	$SnCl_{2(aq)} + 2\ NaOH_{(aq)}$ $SnO_{2(s)} + 2\ NaCl_{(aq)}$	?	?

Fig. 4. Schematic representation of the retrosynthesis of planar, two-dimensional host structures with the topology of an α-SnO layer, based on a square-pyramidal, quadruply linked (edge-sharing) tecton. The position at the tip of the pyramid is occupied by a lone pair of electrons or an organic residue.

square-pyramidal (spy) $\{SnO_4\}$ units. The tin atoms at the tip of the pyramids occupy alternate positions above and below the central plane of oxygen atoms, in a chessboard-like manner. The corresponding tecton for this structural unit is, therefore, a square-concave (*scon*) one labeled as a $^{scon}T_4$-4E tecton, according to its linkage pattern (number of linkages/type of linkage: face = F, edge = E, point (corner) = P).

During the search for a suitable tecton equivalent, one first has to decide which chemical elements should build up the host. Those combinations of elements should be contemplated of which it is known or at least assumed that, under the right conditions, they can form the building blocks corresponding to the desired tecton. If we consider the elements tin and oxygen, a possible tecton equivalent for the purely inorganic SnO layer would be the hypothetical acid $H_2[Sn(OH)_4]$, which could form the desired product by a condensation reaction, cleaving off three H_2O molecules. The search for a possible starting material and a rational synthesis leads to tin(II) chloride as the cheapest tin(II) halide and to its reaction with sodium hydroxide. And, as we know, this approach turns out to be successful.

The layers of our target host can, at least formally, be modified by replacing the lone pair of electrons on the tin atoms by an organic residue R and by "manipulating" the oxidation state of the tin atoms. Both cases strongly affect the polarity and charge of our target host, as negatively ($[RSn^{II}O]^-$) and positively ($[RSn^{IV}O]^+$) charged layers must be formulated. These host layers should now exhibit very different (supramolecular) properties compared to the original, neutral ones. Possible relevant tectons are shown in Fig. 4. While, as yet, a rational starting material for the tin(II) case is not known, suitable starting materials for the tetravalent tin species in the form of alkyl- or aryltin trichlorides and related compounds are readily available.[14]

In the following discussions, some inorganic host–guest compounds will be presented, most of which have been discovered accidentally, some of which, however, are the result of successful, controlled synthetic strategies. This will demonstrate that inorganic chemistry has at its disposal a near inexhaustible supply of "materials", which can be used according to unit construction, a fact which has often fueled the imagination of chemists in the past, and will, indeed, provide future generations with countless opportunities for new developments.

Nevertheless, it remains the privilege of nature to determine—based on her numerous options regarding self-organization[1, 15]—whether the planned structure can be realized or whether a different reaction course is preferred, leading, due to kinetic constraints, to a different minimum on the energy hypersurface.

2. Multidimensional Host Structures

2.1. Three-Dimensional Host Structures

The host–guest compounds most readily understood with respect to primary building blocks and their linkage are the *clathrates*. This class encompasses crystalline lattice inclusion compounds with host structures that are composed of separate molecules. These are linked by hydrogen bonds in such a manner as to form cavities, connected by pores and channels, some or all of which contain small guest species. Since the interactions between the host matrix and the guest molecules are, by definition, limited to weak van der Waals forces, it is frequently observed that the guest species are very mobile and, as a result, disordered. Hence, the overall composition of clathrates varies within a certain range and different guest species can replace each other. In principle, the formation of clathrate-type host–guest compounds is not limited to three-dimensional host structures.

2.1.1. Clathrate Hydrates[16a]

Among the earliest known clathrate-type host–guest compounds in inorganic chemistry are the *gas* and *liquid hydrates* which in the formulation as "host·guest", have limiting compositions of **1** and **2**, respectively. The formation of a chlorine

$46H_2O{\cdot}8G$ **1** $136H_2O{\cdot}8G$ **2**

hydrate was first observed by Davy in 1811,[17] and its approximate composition determined by Faraday as early as 1823.[18] The structural details, however, were elucidated only in the middle of this century by the studies of von Stackelberg and Müller.[19] It was found that the water molecules form the primary building blocks in these classic examples of inorganic host–guest chemistry. Every water molecule functions, as shown in Figure 5, as a donor and an acceptor each for two

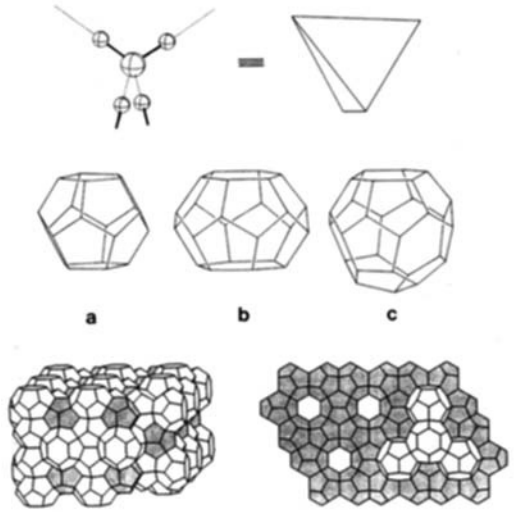


Fig. 5. Sections from the crystal structures of gas and liquid hydrates. The H_2O molecules (top) act as donor and acceptor for two hydrogen bonds each and, hence, are tetrahedrally connected to four other molecules. The polyhedra (center) thus formed are a) the pentagonal dodecahedron, b) the tetrakisdodecahedron, and c) the hexakisdodecahedron. The crystal structures (bottom) of the gas (left) and liquid (right) hydrates exhibit pentagonal dodecahedra which are either isolated or linked in a layer-type manner.

hydrogen bonds, and, thus, is surrounded by four other water molecules in a nearly tetrahedral manner. Similar arrangements are found for the various modifications of ice.[20]

Gas Hydrates

In the *gas hydrates* **1**, which crystallize in a cubic lattice, the 46 clathrand molecules form two cavities of different size: two smaller pentagonal dodecahedra [5^{12}] and six slightly larger 14-faced-polyhedra, which are formed by twelve pentagons and two hexagons [$5^{12}6^2$]. Oxygen atoms occupy the 20 or 24 corners of these polyhedra, respectively, while the hydrogen atoms are disordered along the edges of the polyhedra. The tetrakisdecahedra create, through common hexagonal faces, a system of three mutually perpendicular pipes which, in turn, are connected by common pentagonal faces. Finally, three pairs of these pipes enclose the smaller pentagonal dodecahedra which, therefore, are not interconnected.

Within the structures of gas hydrates the cavities are available in different numbers (2/6 per unit formula) and sizes (pentagonal dodecahedra/tetrakisdecahedra) for inclusion of guest species, which can be expressed by the description $46\,H_2O \cdot 2G^{12} \cdot 6G^{14}$. The limiting factor for the occupancy of these cavities by guest species is the ratio of steric requirements of the guest to the available volume in the host. The latter factor is not very flexible, according to the constant length of the hydrogen bonds of 280 pm. The van der Waals radii of the guests must of course be smaller than those of the cavities. These conditions are fulfilled by noble gases (G = Ar, Kr, Xe), gaseous elements of nonmetals (G = Cl_2, O_2, N_2), various inorganic molecules (G = CO_2, H_2S, PH_3, SO_2), and even by some organic species (G = CH_4, CH_3Cl, C_2H_6, C_2H_4O). Ethylene oxide[21] is a special case due to its three-membered-ring structure. Hydrogen, helium, and neon cannot be incorporated, most probably due to their weak interactions with the host and because, on account of their small size, they can readily diffuse out of the cavities by way of the small pentagonal and hexagonal polyhedral "windows".

Liquid Hydrates

The *liquid hydrates* **2**, which also crystallize in a cubic lattice, exhibit, in addition to pentagonal dodecahedra, polyhedral building blocks with sixteen faces and twenty-eight corners, which create twelve pentagons and four hexagons [$5^{12}6^4$]. In contrast to the isolated twelve-faced polyhedra in the gas hydrates, these units are linked through common faces to layers which exhibit the [ABC] sequence typical of cubic closest packing (ccp). The hexakisdecahedra fill the gaps between the layers and are linked to each other by their hexagonal faces, forming a diamond-like lattice.

The number and size of cavities leads to the formula $136\,H_2O \cdot 16G^{12} \cdot 8G^{16}$; only the larger cavities are occupied. The preferred guests are organic molecules (G = *n*-propane, nitromethane, cyclopentane, cyclobutanone), with one known exception (G = SF_6).

Double Hydrates

In the liquid hydrates, only the eight larger cavities are filled with guest species. In the *double hydrates*, for which the H_2S double hydrates can serve as example, one finds that hydrogen sulfide molecules, acting as "host helpers", occupy the 16 smaller cavities as well. This yields the limiting composition of **3**. Among the guests observed within these compounds are

$$136\,H_2O \cdot 16\,H_2S \cdot 8G \quad \mathbf{3}$$

chloroform, carbon tetrachloride, iodine, carbon disulfide, as well as larger organic molecules such as tetrahydrofuran[22] and benzene.

The clathrate hydrates are formed during the freezing of water in the presence of the corresponding guest species. Apart from steric considerations, electronic effects play a crucial role, as only those guest species will yield real clathrates that form relatively weak—if any—hydrogen bonds.[23]

Structurally, clathrates strongly resemble the ice modifications known to date. The guest-free hosts, however, are not known, which indicates that the guests are required as templates. The ambient-pressure modifications of ice exhibit smaller cavities, while the high-pressure modifications display much larger ones. This leads, in a formal sense, to mutually penetrating hosts, due to their high degree of "openness".

2.1.2. *Clathrasils, Zintl-Phases, and Polycations*

Even though gas and liquid hydrates are, from a chemical viewpoint, rather unimportant, they have gained a lot of prominence as prototypes for the structures of quite a large number of different compounds. This is surprising insofar as these compounds, often rather stable species, minerals, or metallic conductors, do not chemically resemble the labile hydrates.

The mineral melanophlogite, **4** (MEP),[25] and the synthetic zeolite ZSM-39, **5** (MTN)[24] exhibit a structural relationship to the liquid and gas hydrates that is not so surprising insofar as

the ice modifications—normal hexagonal ice (I_h) and cubic ice (I_c) are isostructural to the SiO_2 modifications β-tridymite and β-cristobalite, respectively.

$46SiO_2 \cdot nG$ **4** $136SiO_2 \cdot nG$ **5**

It has been known for some time that several alkali metal stannides, germanides,[26] and silicides such as Na_8Si_{46} **6** or $Na_{11}Si_{136}$ **7**[27], which belong to the class of *Zintl phases*, are topologically/structurally equivalent to the gas and liquid hydrates. These compounds exhibit nearly the same Si–Si distances (237 pm) as elemental silicon (235 pm). The alkali metals, in contrast to earlier assumptions, are most likely to be present as cations and are disordered over the two polyhedral cavities.

The compound $Ge_{38}P_8Cl_8$ **8**[28] shows that the inclusion of anions of suitable size and charge in *polycations* is also feasible. In this species, eight tetravalent germanium atoms of a Ge_{46} lattice have been replaced by pentavalent phosphorus atoms, making the host a polycation. In order to maintain electroneutrality, a corresponding number of chloride ions are incorporated as guests within the cavities.

Na_8Si_{46} **6** $Na_{11}Si_{136}$ **7** $Ge_{38}P_8Cl_8$ **8**

The formation of identical structural characteristics in the four classes of compounds listed in Table 1 can be understood in the following way: The primary building blocks (H_2O, SiO_4, Ge) are tetrafunctional, that is, they each form four "bonds" to neighboring blocks with tetrahedral orientation. These geometric factors are primarily responsible for the creation of the structures, while all other effects, such as distances between the building blocks and the type of linkage are only of secondary importance.

Table 1. Summary of the classes of compounds belonging to the structural families of the gas and liquid hydrates and of the average values of the observed distances $\bar{d}$ between tetrahedral centers.

Structure type	Gas hydrates	Liquid hydrates	$\bar{d}$(X–X) [pm]
clathrates	$46H_2O \cdot 8Cl_2$	$136H_2O \cdot 8CHCl_3$	280
framework silicates	$(SiO_2)_{46} \cdot nG$	$(SiO_2)_{136} \cdot nG$	306
Zintl phases	$Si_{46} \cdot 8Na$	$Si_{136} \cdot 11Na$	237
polycations	$[Ge_{38}P_8]^{8+} \cdot 8Cl^-$		

The existence of these compounds is critically determined by the ratio of cavity volume to guest size, as well as by the interaction between host matrix and guests. The drawings shown in Figure 6, which depict the position of some guest species in the different cavities of melanophlogite **4**, give an impression of the size relationships involved. This kind of knowledge regarding the nature and the orientation of the guest molecules, which are often statically/dynamically disordered, can only be gleaned from single-crystal X-ray structure analyses. These yield an interpretable distribution of the electron density throughout the various host cavities.[30]

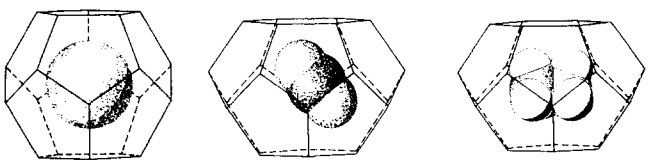

Fig. 6. Position of some guest species in the cavities of synthetic melanophlogite **4**: Left: xenon in a $[5^{12}]$ polyhedron; middle: carbon dioxide in a $[5^{12}6^2]$ polyhedron, and right: methylamine also in a $[5^{12}6^2]$ polyhedron. The guest species are shown as space-filling models to give an approximate impression of the van der Waals volumes of the atoms and molecules (from ref. [29]).

2.1.3. Silicates with Framework Structures

As mentioned above, compounds **4** and **5** belong to the class of clathrasils. Based on their composition and structural characteristics, these compounds belong—according to the "family tree" shown in Scheme 1—to the class of porous tectosilicates.[31] Compounds of this class with the general formula $mSiO_2 \cdot nG$ **9** are called porosils. The term *clathrasils*[32a] describes all host structures with pores and cavities whose dimensions are such that an exchange of the guests is not possible. The term *zeosils*, on the other hand, is used for compounds such as silica-ZSM-11 (MEL) **10**[33] or decadodecasil 3R (DDR) **11**[34] that exhibit channel-like pores with openings that are large enough to allow guest exchange.

$mSiO_2 \cdot nG$ **9** $96SiO_2 \cdot nG$ **10** $120SiO_2 \cdot nG$ **11**

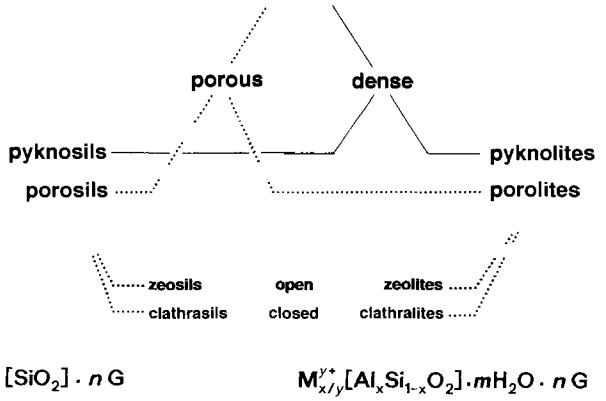
The frameworks of clathrasil hosts are neutral, so that only neutral species—in general, solvent molecules or more or less solvated ion pairs—can function as guests. As the guests in clathrasils cannot leave the host without destroying it, and as guests cannot enter the host once it is formed, the host structure must, correspondingly, be formed under some kind of template control by the guest.

A class of compounds that is closely related to porosils is that of the porolites. In these porolites some of the silicon atoms have been replaced by aluminum atoms; electroneutrality leads to the general formula **12**. Moreover, one can distinguish between

$M^{x+}_{x/y}[Al_xSi_{1-x}O_2] \cdot mH_2O \cdot nG$ **12**

open and closed porolite hosts. These are called *clathralites* and *zeolites*,[35] respectively, and exhibit properties similar to those of the corresponding classes of porosils. As their host lattices, however, are negatively charged, cations are incorporated into the host cavities, which in turn means that there are additional electrostatic interactions between guest and host system. In general, however, these interactions are rather weak, as the negative charges are "smeared" over the inner surface of the host, and because the cations are solvated. Therefore, the cationic guests can still be exchanged in these compounds.

The porous tectosilicates must be contrasted with the dense ones. In this sense, the family of pyknosils can, according to Scheme 1, be represented by the various modifications of SiO_2, such as quartz, coesite, or crystobalite, while the pyknolites are correspondingly represented, for example, by the feldspars. All these compounds are built primarily from $\{SiO_4\}$ or $\{AlO_4\}$



Scheme 1. Family tree of the classes of compounds belonging to the tectosilicates, showing the classification of clathrasils and zeolites. Only the porous tectosilicates can participate in supramolecular processes.

units, which are linked by shared corners. The structural variety arises from the various ways in which these units can be linked three-dimensionally. But this variety can be systematically ordered because the type of linkage is controlled by strict rules. Thus, it is only necessary to distinguish between a few small, so-called secondary building units (SBUs) and larger polyhedral blocks, which can be linked according to certain rules.

The mentioned classes of compounds have been described extensively with respect to syntheses,[36] structures,[37] properties (catalysis, ion exchange, host–guest chemistry, etc.), and industrial applications.[38] Therefore this review will be limited—apart from the systematic classification—to a few details, which illuminate the structural variety and, in particular, the host–guest phenomena. A relatively new branch of the host–guest chemistry of nanoporous tectosilicates and related compounds deals with the incorporation of dye molecules and molecules with high molecular hyperpolarizability.[39] The latter case refers to supramolecular compounds which are capable of doubling the frequency of incident laser radiation, making them attractive as potential materials for nonlinear optical applications.

The number of three-dimensional host structures has significantly increased over the last few years owing to the discovery of novel, zeolite-type classes of compounds. While these do not formally belong to the tectosilicates, they exhibit similar or new structures with comparable properties. *Aluminophosphates*[40] also belong to this group in which alternating phosphorous and aluminum atoms occupy the positions in the tetrahedral centers of the "primary building blocks", thus yielding the general formula for this class of compounds as **13**. The host structures of

$[AlPO_4] \cdot mH_2O \cdot nG$ **13**

these microporous materials, which are used as molecular sieves, are neutral, that is, they are organophilic. In contrast, the host structures of *silicoaluminophosphates*[41] are negatively charged, as some of the phosphorus atoms have been replaced by silicon atoms, corresponding to the general formula **14**. These compounds show a certain ability for cation exchange.

$M^{y+}_{x/y}[AlP_{1-x}Si_xO_4] \cdot mH_2O \cdot nG$ **14**

The structure of sodalite (SOD) occupies a special place within the multitude of structures of zeolites, as it formally serves as prototype for a number of other classes of compounds in nature (cf. Fig. 7). The mineral sodalite itself has the composition $Na_8Al_6Si_6O_{24}Cl_2$; the formulation as **15** indicates that it be-

$Na_6[Al_6Si_6O_{24}] \cdot 2NaCl$ **15**

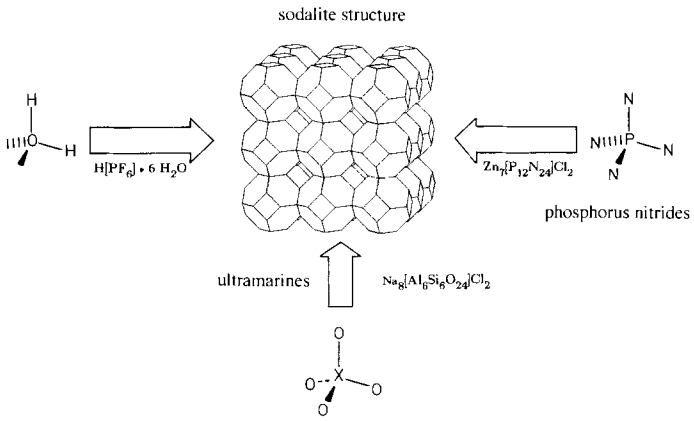


Fig. 7. Schematic summary of those classes of compounds with structures related to the sodalite structure.

longs to the class of zeolites. Sodalite is the only tectosilicate that is built from a single polyhedral unit; all other tectosilicates contain at least a second, often even a third polyhedral building block. The characteristic building unit is the sixfold truncated octahedron $[4^66^8]$, which is linked through the square faces in a three-dimensional and space-filling manner. The cations required for compensating the charges of the host, as well as additional cations and anions, are statistically distributed over the cavities. Not only the cations, but also the anions are susceptible to ion exchange reactions. In molten sodium sulfate, sodalite can be transformed into the mineral noselite **16**.

$Na_6[Al_6Si_6O_{24}] \cdot Na_2SO_4$ **16**

The same structural type is exhibited by the mineral lapis lazuli, and its synthetic equivalent, ultramarine. Both substances contain an S_3^- ion within their sodalite cages. The guest radical is responsible for the blue color of these species, which are highly valued as pigments.

Surprisingly, the structural characteristics of sodalite are also found in *phosphorus nitrides*, as exemplified by the compound **17**, which has only recently become known.[42] The primary

$Zn_7[P_{12}N_{24}]Cl_2$ **17**

building blocks are $\{PN_4\}$ tetrahedra. The pentavalent phosphorus atoms occupy the positions of the silicon and aluminum atoms, while the trivalent nitrogen atoms take the positions of the oxygen atoms. A chloride ion, which is tetrahedrally surrounded by four zinc ions, is located in the center of each so-

dalite cage. The positions of the zinc ions are statistically disordered with an occupancy of 7/8.

Apart from the *neutral* water clathrates just described, *cationic* water clathrates are known as well. An example is the hexahydrate of hexafluorophosphoric acid, **18**,[43] which has a crystal structure that also shows sodalite-like structural elements.

$H[PF_6]\cdot 6H_2O$ **18**

Based on the results known thus far, it is assumed that a PF_6^- ion is incorporated into a cage, while a proton is integrated into the lattice of water molecules, so that the formulation $[(H_2O)_5(H_3O)]^+[PF_6]^-$ describes the actual structure much better than the simple chemical formula given above.[44] The pentahydrate of tetramethylammonium hydroxide, **19**,[45] belongs to the *anionic* water clathrates. The hydroxide ion is part

$[Me_4N][OH]\cdot 5H_2O$ **19**

of the sodalite-like host lattice, into which the tetramethylammonium ion is incorporated, yielding the formulation $[(H_2O)_5(OH)]^-[Me_4N]^+$. The cation is a little too large for the sodalite cage, therefore the cage is slightly expanded at the site of incorporation.

2.1.5. Reaction Sites

One of the greatest challenges of modern chemistry is to perform transformations as efficiently and selectively as possible, primarily for environmental and monetary reasons. As transformations in biological systems are especially characterized by structurally organized reaction media and reactions that in general yield only *one* product, namely the desired one, nature itself is often used as a guide.[46] It should, needless to say, also be a goal of supramolecular chemistry to provide and utilize organized reaction sites.[47]

In inorganic chemistry, compounds that largely correspond to the ideas about structurally organized reaction sites exist, namely the zeolites. They possess cavities that are essentially isolated from each other and have a specific shape, a defined size, and inner surfaces with a given polarity. These cavities form ideal reaction sites, for instance, to stabilize unusual particles like certain radicals (e.g., in the case of ultramarine) or metal clusters. This requires that it is possible to incorporate these species, which are not accessible (or only with difficulty) by conventional means, into the lattice of the zeolite, or to create them within it. Once this difficulty has been overcome, the zeolite acts like a refrigerator that keeps its perishable contents "palatable" for some period of time.

Indeed, attempts are being made to solve this fundamental problem. For example, silver clusters have been created within zeolites.[48] Another example concerns the incorporation of CdS clusters in zeolites.[49] The starting point for the synthesis of these host–guest compounds is, among others, the commercially available zeolite Y, (FAU) **20**. This compound is built from sodalite cages with a pore size of 500 pm which are linked by hexagonal prisms as the second polyhedral building unit in such a way as to create a supercage at their center, exhibiting pores of 1.3 nm diameter (Fig. 8 left). After an ion exchange and loading with Cd^{2+}, this zeolite was first dried at high temperatures and subsequently treated at 100 °C with hydrogen sulfide gas.

$Na_{56}[(AlO_2)_{56}(SiO_2)_{136}]\cdot 250H_2O$ **20**

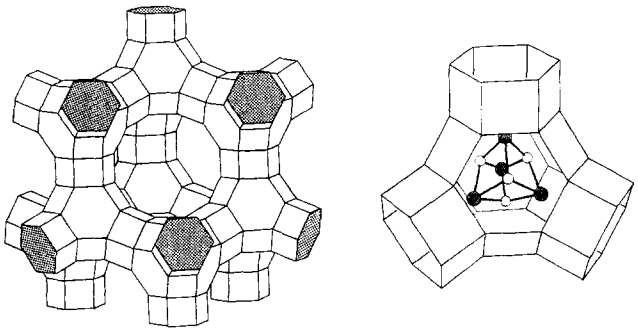

Fig. 8. Left: Section of the crystal structure of zeolite Y (FAU) **20** showing the view into one of the supercages. This supercage is formed by eight sodalite cages, which are linked by twelve hexagonal prisms. Right: Orientation of the cubane-type $(CdS)_4$ cluster encapsulated within the sodalite cages of the host–guest species FAU·CdS.

The X-ray crystallographic and optical data are interpreted to indicate that during the above-mentioned process at low loading, cubane-type $(CdS)_4$ clusters, with Cd–S bond lengths of 247 pm, are formed in the sodalite cages (Fig. 8 right). In each cage of the host structure, these cubes are arranged so that cadmium atoms of neighboring clusters point at each other through the hexagonal prism. The corresponding Cd–Cd distance here is about 600 pm.

In order to use zeolites as catalysts, for example, for catalytic cracking, it is essential that a better understanding of those chemical processes and relationships is reached that occur during the catalysis within the relevant inorganic reaction sites. As expected, the structure and properties of the reaction product are governed by the architecture of the zeolite. This role of the zeolite is not limited to the spatial arrangement and extent of the reaction sites (by limiting them to the nanodimensional area), but is also observed with respect to potential host–guest and guest–guest type interactions. In this case, the host creates or at least influences the structure of the guests.

The generation of a zeolite catalyst—suitable for a desired range of products—is, in turn, controlled by template-directed syntheses, that is, in this case the guest generates the host structure according to its own size, shape, charge, or polarity. For instance, the use of monomeric, oligomeric, or polymeric quaternary ammonium ions leads to the formation of lattice structures, which are complementary to the form of the template employed. Thus, it may be possible to create host structures with large cavities by employing spherical templates, or channel-like structures with the aid of cylindrical or rod-shaped guests.[50]

The dualism that characterizes the host–guest relationships of zeolites now becomes clear: On the one hand, a given guest controls the synthesis of the zeolite host, on the other hand, this zeolite later directs the synthesis of another guest type within its reaction cavities. The host itself, however, does not act as guest for the formation of an even larger host (cf. Sections 3.6 and

3.7). Instead, according to its size, it induces, for example in the context of a host–guest catalysis, the synthesis of smaller guest species; the host acts as template and controlling agent. The complexity of these reactions is currently nearly impossible to oversee. It is therefore not surprising that the development of zeolite catalysts up to now has primarily proceeded by trial-and-error methods.

2.1.6. *Molybdenum and Vanadium Phosphates*

Zeolite-type host structures are also observed when octahedra, square pyramids, or cubes are introduced as structure-determining units in addition to tetrahedra, as is the case in the numerous *molybdenum*[51] and *vanadium phosphates*. The multitude of possible combinations of the primary building blocks significantly increases the variety of structures observed for these classes of compounds as compared to zeolites. In addition, the structures are not limited to three-dimensional host edifices.[52] The anionic three-dimensional host structure in the compound **21**[53] consists of $\{[Mo_4O_8]^{4+}\}$ cubes and $\{PO_4^{3-}\}$

$(Me_4N)_{1.3}(H_3O)_{0.7}[Mo_4O_8(PO_4)_2]\cdot 2H_2O$ **21**

tetrahedra. These are linked such that a porous structure results, in which cation-occupied voids represent 25% of the total volume. Hence, this compound can reversibly incorporate water. The compound **22**[54] has similar properties. Its host structure,

$[Mo_8O_{12}(PO_4)_4(HPO_4)_2]\cdot 13H_2O$ **22**

however, is neutral, in contrast to its counterpart in **21**. The vanadium phosphates **23** and **24**[55] are built up from corner-sharing $\{VO_6\}$ octahedra and $\{PO_4\}$ units. This leads—similar to the case for **21**—to three-dimensional lattice structures with cavities that incorporate the alkali metal cations.

$Cs[V^{III}_2(PO_4)(HPO_4)_2(H_2O)_2]$ **23**

$K[(V^{IV}O)V^{III}(HPO_4)_3(H_2O)_2]$ **24**

Large cavities that are occupied by organic cations are also found in the compound **25**.[56] The crystal structure of the host, depicted in Figure 9, consists of undulating layers, which in turn are made up of rings formed by four square $\{OVO_4\}$ pyramids, two phosphate and two hydrogenphosphate units. The vanadium and phosphorus atoms of these eight-membered rings form a plane, with the vanadyl groups on one side and the phosphorus–oxygen units on the other. Two of the latter are P–OH groups, while the other two are linked to the $\{(H_2O)_2V^{III}O_4\}$ octahedra which connect the layers. This creates large ellipsoidal cavities between the layers. These cavities measure approximately 620–720 pm (O–O distance) along the short axis and about 1840 pm (V^{III}–V^{III} separation) along the long axis.

$(H_3NCH_2CH_2NH_3)_2(H_3NCH_2CH_2NH_2)$

$\cdot[V^{III}(H_2O)_2(V^{IV}O)_8(OH)_4(HPO_4)_4(PO_4)_4(H_2O)_2]\cdot 2H_2O$ **25**

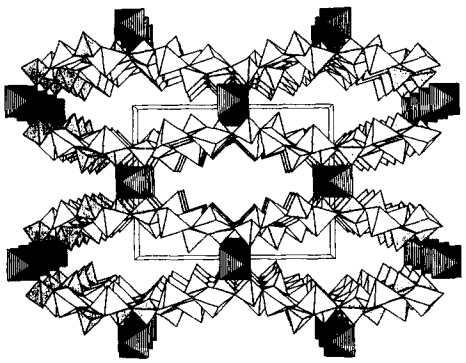

Fig. 9. View into the ellipsoidal cavities of compound **25**. The square $\{VO_5\}$ pyramids are shown as open polyhedra, the $\{PO_4\}$ tetrahedra are lightly shaded, and the octahedral $\{VO_6\}$ units are shown hatched.

2.1.7. *Cadmium Cyanide Compounds*[57]

A relatively new area of supramolecular inorganic chemistry deals with the three-dimensional lattice structures based on cadmium cyanide, $Cd(CN)_2$ (**26**). In the crystalline, guest-free state, this compound—like $Zn(CN)_2$—exhibits two mutually penetrating diamond-type networks. Formally, the metal ions occupy the positions of the carbon atoms, while the cyanide ions occupy the sites of the bonds (Fig. 10 left).[58] Each cadmium ion is, therefore, tetrahedrally coordinated, which means that **26**, in agreement with its AX_2 basic stoichiometry, structurally resembles H_2O and SiO_2. This similarity is quite far-reaching: Each of the two lattices is isostructural to β-crystobalite.

$Cd(CN)_2$ **26** $Cd(CN)_2\cdot$neopentane **27**

Starting with the host, supramolecular compounds can be readily prepared by bringing the desired guest into contact with an aqueous solution containing equimolar amounts of cadmium cyanide and potassium tetracyanocadmiate. In this manner a large number of host–guest compounds can be prepared.[59] The example $Cd(CN)_2\cdot$neopentane **27**[60] shows that the structure of the host–guest compound (Fig. 10 right) is derived from the guest-free host structure by completely removing one of the two networks. The adamantanoid voids thus created are occupied by the guests.

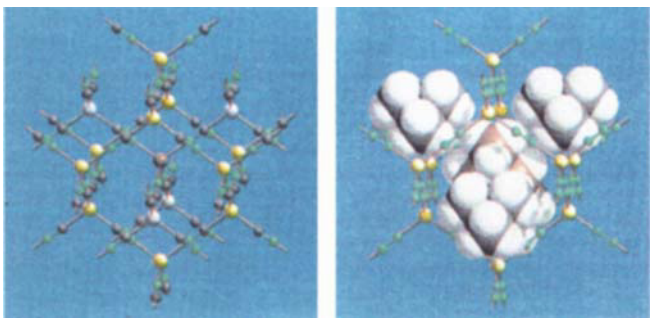

Fig. 10. Perspective views of the crystal structures of $Cd(CN)_2$ **26** (left) and its host–guest compound **27** with neopentane (right). The $Cd(CN)_2$ partial structures are shown as ball-and-stick models in both cases, the organic guest molecules are shown as space-filling models. The cadmium atoms are shown in yellow and white in the different networks of the host. The CN groups in the "pure" host are ordered (N green, C gray), while they are disordered in the host–guest compound (N, C green).

The incorporation of guests as large as neopentane molecules only becomes possible by the increase in the distance between the cadmium centers of the tetrahedra to about 550 pm. In contrast, the Si–Si distance in tectosilicates is only about 306 pm, the O–O distance in hydrate clathrates about 280 pm. The cyanide ion functions as a sterically undemanding spacer between the tetrahedrally coordinated cadmium ions, thus leading to the formation of the large voids within the host structure.

2.2. Two-Dimensional Host Structures

A comparison of the number of different compound classes and related compounds shows that there are far more two-dimensional host–guest species than their three-dimensional counterparts. The number of potential hosts, that is, compounds with layer structures, is comparatively large.[61]

Compared to three-dimensional hosts, many layer structures exhibit features that significantly simplify the synthesis of corresponding host–guest compounds as well as their subsequent modifications. The most important characteristic in this context is the ability of many two-dimensional hosts to vary their interlayer distance within wide boundaries according to the steric requirements and structure of any particular guest. In addition, some classes of compounds show strong tendencies not only to incorporate neutral species, but also ionic guests, with charges complementary to those of the host. Some of the hosts have electronic properties that allow them to accept electrons from the guest species in a redox reaction, thus leading to changes in the charges of the host layers and the incorporation of a corresponding number of cations in the space between the host layers.[9]

Correspondingly, the synthesis of two-dimensional host–guest compounds starts in most cases with the already completely preformed host. Topotactic reactions then, apparently, insert the guest species between the layers, which has led to the common acceptance of the term *intercalation compounds* as generic label for these supramolecular species. The synthesis concept requires a high mobility of the guest species in the interlayer space, as they have to diffuse from the edges into the interior of the host matrix in order to find the "free lattice sites" located there. This means, in turn, that the potential wells between the host layers must be rather shallow, otherwise the diffusion rate would be reduced too much. Usually there are strong covalent or ionic bonds within the layers, while between them there are only weak van der Waals interactions, at least in the case of neutral layers.

In the case of electrically charged hosts, in which ions and/or solvent molecules are incorporated between the layers, there are, of course, additional electrostatic interactions. In general, however, these are rather weak, and supramolecular chemistry, that is, an exchange of ions or solvent molecules is still possible. The high mobility of the guest species stemming from the shallow potential wells between the layers leads not only to the reversibility of their intercalation reactions, but frequently to nonstoichiometric compounds with a wide range of compositions. If the potential wells are relatively deep, or if the access to the interior of the host matrix is sterically encumbered, the corresponding intercalation compounds must be synthesized by the reaction of the molecular building units of the host with the guest species in homogeneous solution.

In the following, these principles, developed for two-dimensional host–guest species, will be demonstrated by using different classes of compounds, taking some recent developments into account. The selection of the compound classes presented herein is rather subjective, hence it cannot claim to be complete either with respect to the details presented or the number of classes examined. For instance, the classic textbook example for inorganic host–guest species, namely *graphite intercalation compounds*,[62] is not dealt with. This is justified because the entire area of two-dimensional host–guest compounds is fairly well documented.[63]

2.2.1. *Clays*[64]

Clays are among the host–guest species that are most important culturally and historically (manufacture of ceramics and porcelain) as well as of intense interest to modern and also prebiotic chemistry. A number of different groups of silicates and aluminosilicates with layered structures belong to this class. In spite of the nearly endless variety exhibited by clay minerals with respect to their chemical composition, it is possible to relate their layer structures to two fundamental types. These two basic phyllosilicate types are characterized by their layered structures, in which layers of corner-sharing $\{SiO_4\}$ tetrahedra are linked with layers of edge-sharing $\{M(O,OH)_6\}$ octahedra. One of the fundamental structures consists of one layer of octahedra and one layer of tetrahedra (TO type), while the other one consists of one layer of octahedra surrounded by two layers of tetrahedra (TOT type).

Typical examples for the TO structural type are serpentine (**28**) and caolinite (**29**). In serpentine, the magnesium ions occupy all available octahedral holes, while in caolinite the aluminum ions occupy only 2/3 of these holes. This composition results in individual layers that are neutral. No ions are incorporated between the layers, hence their host–guest chemistry is limited to the incorporation and release of neutral molecules.

$Mg_3[Si_2O_5](OH)_4$ **28** $Al_2[Si_2O_5](OH)_4$ **29**

$Mg_3[Si_2O_5]_2(OH)_2$ **30** $Al_2[Si_2O_5]_2(OH)_2$ **31**

Characteristic examples for the TOT structural type are talcum (**30**) and pyrophyllite (**31**). Except for the different ordering of the layers of octahedra and tetrahedra, these compounds correspond to serpentine and caolinite, respectively. The layers, which are wider in these cases, are still neutral, which means that the supramolecular activities also correspond to those exhibited by the two compounds of the TO structural type.

A completely different behavior is found for the class of *micas*, which comprises the layered aluminosilicates. Within these structures, as for example in biotite, **32**, and muscovite **33**, some of the tetravalent silicon atoms of the "tetrahedral layers" are replaced by trivalent aluminum atoms. This leads to negatively

$KMg_3[AlSi_3O_{10}](OH)_2$ **32** $KAl_2[AlSi_3O_{10}](OH)_2$ **33**

charged layers, and additional cations must be incorporated between them in order to reach electroneutrality. As these ions are bound to the layers by only relatively weak electrostatic interactions, they are subject to cation exchange reactions.

The interest in clays stems from their ease of modification and their excellent catalytic properties. Recent developments also deal with the incorporation of chiral molecules into such hosts with the aim of employing the resulting supramolecular materials in asymmetric syntheses or in the area of nonlinear optics.

Catalysts based on layered aluminosilicates with exchangeable cations between the layers are often not particularly thermally stable due to the fact that the cations in these species are generally solvated. When the solvent molecules evaporate from the interlayer space at higher temperatures, the layers move closer together, thus reducing the catalytic activity. Recent experiments have focused on incorporating supporting pillars in an effort to prevent the layers from coming closer together (Fig. 11). The later incorporation of such pillars is made possible by first introducing cations of suitable size (e.g., polycations such as the Keggin-type ion $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$, or other multinuclear species such as $Si_8O_{12}(OH)_8$) by ion exchange reactions, followed by "sintering". The increased thermal stability achieved this way is significant.[65]

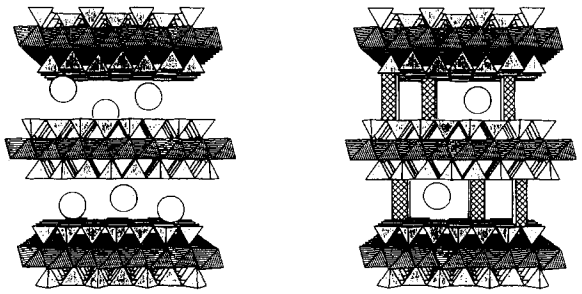

Fig. 11. Schematic representation of clay layers without (left) and with support structures (right). Ion exchange reactions build up the potential pillars, in the form of cations between the layers. These pillars are later made permanent by "sintering".

2.2.2. Transition Metal Dichalcogenides[66]

The early *transition metal dichalcogenides* MX_2 with readily polarizable chalcogen atoms (M = element of group 4, 5, or 6, X = S, Se) can also act as hosts due to their layered structures. These compounds have, therefore, been the subject of studies to this end for some time. Within the layers of these dichalcogenides, the metal atoms M occupy octahedral (e.g., in TiS_2 **34**) or trigonal-prismatic holes (e.g., in $TaSe_2$ **35** and MoS_2 **36**) between two planar, hexagonally closest packed layers of chalcogen atoms X, which are arranged either with holes stacked on top of holes (**35**, **36**) or on top of atoms (**34**). While there are very strong ionic/covalent bonds between the metal and chalcogen atoms within a layer, only weak van der Waals interactions exist between the layers. This explains why these compounds exhibit many variations of layer ordering (stacking variations) and, hence, many polymorphic modifications. The layers, about 600 pm wide, are neutral and their surfaces show little electronic or steric fluctuations.

TiS_2 **34** $TaSe_2$ **35** MoS_2 **36**

The incorporation of alkali metals between such packets of layers was first observed by Rüdorff in 1965, when he allowed alkali metals to react with the dichalcogenide in liquid ammonia.[67] This represents the prototype of a reversible, topotactic redox reaction, during which each alkali metal A injects one electron into the conduction band of the host MX_2. This dramatically changes the electronic properties of the host and causes the host layers to be negatively charged. The resulting compound must be described as the incorporation of alkali metal ions A^+ into the (now) anionic transition metal dichalcogenide $[MX_2]^-$. It is also possible to prepare many corresponding intercalation compounds by electrochemical means. The dichalcogenide acts as the cathode, the metal as the anode of an electrochemical cell. A solution of the corresponding alkali metal salt in a nonaqueous solvent (e.g., dioxolane, propylene carbonate) is employed as electrolyte.

The *alkali metal transition metal dichalcogenides* AMX_2 are true intercalation compounds. This is also demonstrated by the fact that the cations embedded between the layers are available for ion exchange and hydration or solvation reactions (e.g., with *N*-methylformamide, dimethyl sulfoxide). It is thus not surprising that during the synthetic process employed by Rüdorff ammonia molecules, which can later only be removed with difficulty, are incorporated into the reaction product. The capacity for ion exchange reactions can also be exploited to embed other, sometimes significantly larger, cations between the layers. This allows the controlled variation of the properties of these host–guest compounds. Out of a multitude of supramolecular compounds created by this type of reaction, the most remarkable examples, based on size and complexity of the guests, are those stemming from the metal clusters $[Fe_6S_8(PEt_3)_6]^{2+}$ and TaS_2[68] as well as from the species $[Co(\eta\text{-}C_5H_5)_2]^+$ and ZrS_2.[69] Even though the reaction products are often not well ordered, the crystallinity of samples of the first example was sufficient to determine the orientation of the Fe_6S_8 clusters between the layers by X-ray diffraction studies of oriented films (see Fig. 12).

Metallocene cations—as well as a number of other organic and organometallic compounds (*n*-alkyl amines, phosphanes)—can also be incorporated between the layers of alkali-metal-free dichalcogenides by the direct reaction of the components under anhydrous conditions at temperatures of up to 200 °C.

2.2.3. Metal Phosphorus Trisulfides[70]

Metal phosphorus trisulfides, MPS_3, represent a group of compounds that is closely related to the transition metal dichalcogenides. For many elements of the first transition metal series (M = V, Mn, Fe, Co, Ni, Zn), compounds of this composition exhibit layered structures. Within the layers of these trichalcogenides, the metal atoms M—as shown by the example of the cadmium compound[71] in Figure 13—occupy two thirds of the octahedral holes between two planar, hexagonally close packed layers of sulfur atoms, while the remaining third is occupied by the P_2 "dumbbells". These two structural elements are arranged in such a way that the $\{MS_6\}$ octahedra form a honeycomb-like network, in which the voids are filled by single $\{P_2S_6\}$ octahedra. Hence, each $\{P_2S_6\}$ octahedron is edge-linked (i.e., shares edges) with six $\{MS_6\}$ octahedra, while each $\{MS_6\}$ octa-

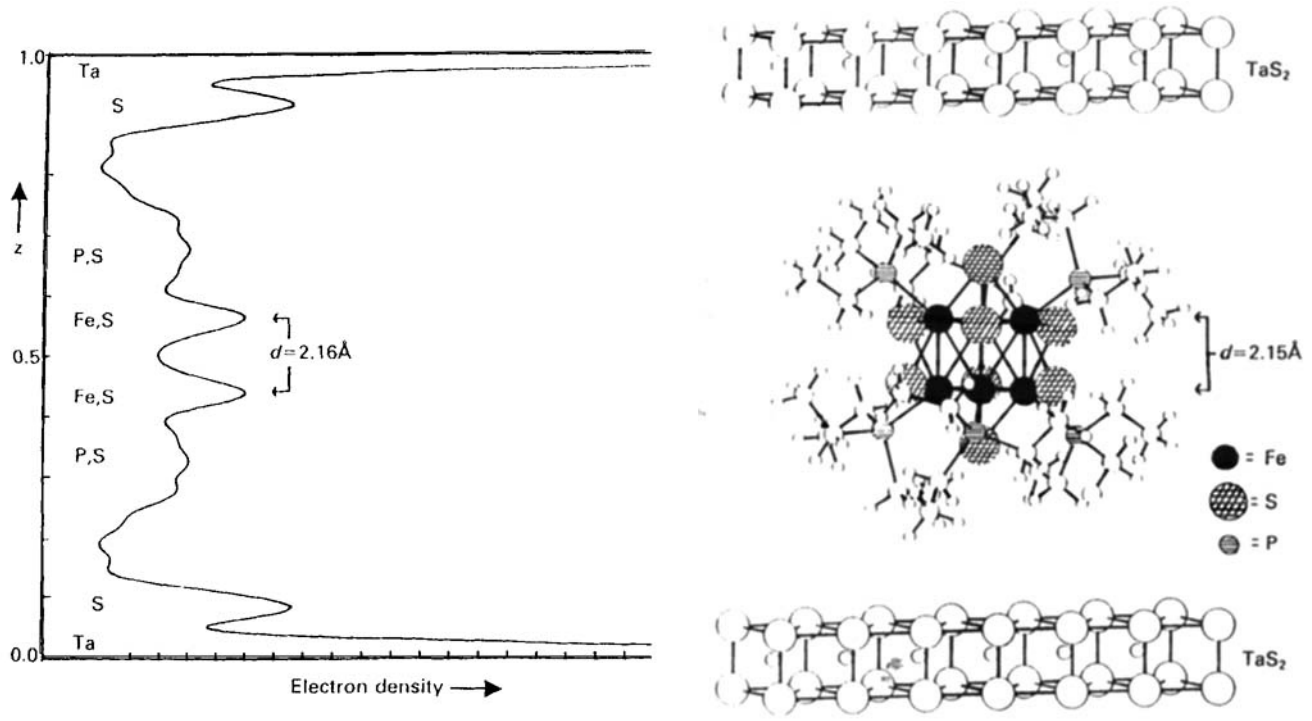

Fig. 12. Left: Experimentally determined electron density of oriented films of the inclusion compound of $[Fe_6S_8(PEt_3)_6]^{2+}$ in TaS_2; right: the thus deduced orientation of the guest between the layers of the host (from ref.[68]).

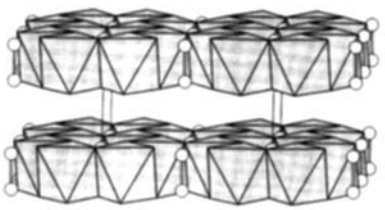

Fig. 13. Schematic representation of the layer structure of the potential host species $CdPS_3$; the $\{CdS_6\}$ octahedra are shaded and the P_2 "dumbbells" are shown as ball-and-stick models; the octahedra form a type of honeycomb network, with the phosphorus embedded into the voids; there are only weak van der Waals interactions between the layers.

hedron shares edges with three others of its kind and three $\{P_2S_6\}$ units. The ordering of the layers of sulfur atoms corresponds to cubic closest packing.

Similar to transition metal dichalcogenides, these metal phosphorus trisulfides are capable of incorporating alkali metals or their cations by reversible redox reactions. Typical for the host species described here is their ability to undergo unusual ion exchange reactions, in which some of the metal cations M^+ are dissolved out of the host layers, which, in turn, then do not only exhibit voids, but are also negatively charged. This necessarily requires that positively charged guest species are incorporated between the layers of the anionic host in order to achieve charge compensation. As is the case for ZrS_2, there is a cobaltocenium "adduct" of $MnPS_3$ (**37**), which in contrast to the disulfide, can also be prepared by a direct reaction of the host with a solution containing the cobaltocenium ion.[72]

$[Mn_{1-x}PS_3][CoCp_2]_{2x} \cdot nH_2O$ **37**

2.2.4. *Hofmann Clathrates*[57, 73]

The prototype of this class is a compound with the composition **38**. Its synthesis was first reported in 1897 by Hofmann and

$Ni(CN)_2 \cdot NH_3 \cdot C_6H_6$ **38**

Küspert,[74] but its structure was only determined more than half a century later by Rayner and Powell.[75] The structure (Fig. 14) consists of planar layers which are stacked in a parallel manner. The layers are based on a chessboard pattern of square-planar and octahedrally coordinated nickel(II) ions ligated by cyanide ions and ammonia molecules. The carbon atoms of the cyanide ions are bound to the four-coordinate metal ions, the

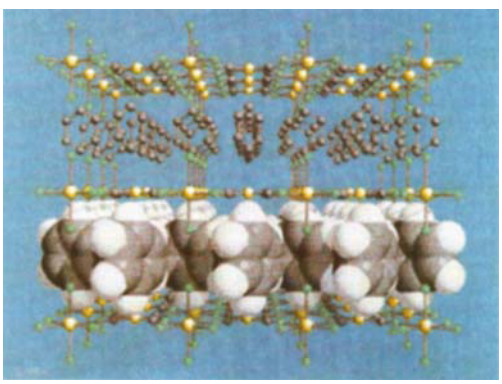

Fig. 14. Perspective view of the crystal structure of $Ni(CN)_2 \cdot NH_3 \cdot C_6H_6$ **38**. The top half of the figure depicts the benzene molecules as ball-and-stick models without hydrogen atoms, the bottom half shows them with the hydrogen atoms as space-filling models. The CN groups link the nickel atoms, while the ammine ligands are oriented perpendicular to the plane of the layers (N green, C gray, Ni yellow).

nitrogen atoms to the six-coordinate ones, which also have a pair of *trans*-located ammine ligands completing the coordination sphere. The ammine ligands stick out above and below each layer, thus segregating the space between the layers into block-shaped voids. The benzene molecules are incorporated into these voids in a clathrate-type manner.

The ammine ligands form steric obstacles to the diffusion of guest species. In addition, their strong electronic interactions with the arenes cause relatively deep potential wells. This compound can therefore only be prepared from solution and the guest-free host is not known.

After the structure was solved, a large number of further representatives of this structural type were prepared and examined by X-ray structure analysis. Based on these results, the general formula for clathrate compounds of the Hofmann type is **39**.

$M(NH_3)_2M'(CN)_4 \cdot 2C_6H_6$ **39**

Within the last few years, there have been studies to systematically modify the basic structure of Hofmann clathrates. Apart from, for example, the use of other guests, the terminal NH_3 groups were replaced by NH_2R ligands. One of the primary characteristics of the thus obtained structural types is that the layers are no longer planar, but more or less puckered. Similar layers are also found in the recently reported derivative **40** of a Hofmann clathrate.[76] The puckered layers in this compound serve to stabilize a very unusual two-dimensional network of water molecules. The water molecules in these layers are linked by hydrogen bonds. The oxygen atoms form a puckered network of edge-sharing, boat-shaped six-membered rings of the type also found in the hexagonal modification of ice. These layers are in effect a two-dimensional variation of three-dimensional clathrates, even though they are hitched to the cadmium ions.

$Cd(H_2O)_2Ni(CN)_4 \cdot 4H_2O$ **40**

2.2.5. *Alkali Metal Halide Intercalation Compounds*

This class of compounds is unusual at first glance. It has only recently become known by the structure determination of **41**.[77] This compound is generated by the reaction of cesium fluoride

$CsF \cdot Br_2$ **41**

with excess halogen at room temperature. The tetragonal structure (Fig. 15) consists of planar CsF layers in which each cesium and fluoride ion is surrounded by the respective counterion in a square-planar arangement. The layers, therefore, correspond to sections of the cesium fluoride with the NaCl-type structure. The Cs–F distances, however, are somewhat shorter (294.0 pm) than in the unmodified compound (300 pm). The layers are stacked directly on top of each other, with an interlayer distance of 736.4 pm. The Br_2 "dumbbells" are located between two fluoride ions and are oriented perpendicular to the layers. Their distance to the two neighboring fluoride ions is equal (252.1 pm) and significantly longer than a normal covalent fluorine–bromine bond. Therefore, the electronic interactions between the host system and guests are apparently rather weak. The

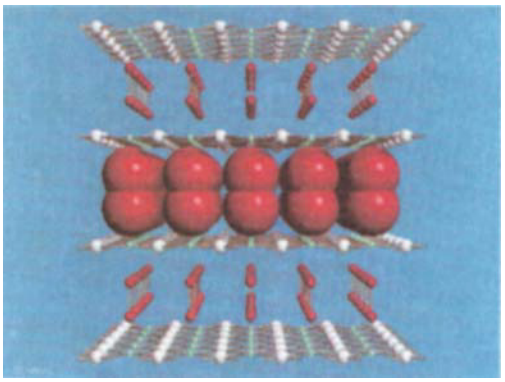

Fig. 15. Perspective view of the crystal structure of $CsF \cdot Br_2$ **41**. The embedded bromine molecules are shown in the middle layer as space-filling models to demonstrate the degree of space usage, while they are shown as ball-and-stick models in the upper and lower layers (Br = red, F = green, Cs = white).

Br–Br distance (232.4 pm) is, correspondingly, only slightly longer than in elemental bromine (228 pm). The surprising stability stems, apart from electronic effects, certainly also from steric reasons. The van der Waals surface of the host layers must be quite puckered due to the different sizes of cesium and fluoride ions, thus causing the bromine molecules to be tightly held and well ordered between the layers, like eggs in an egg carton.

2.2.6. *Metal(IV) Phosphates and Organoelement Derivatives*

Compounds of the type $Zr(RPO_3)_2$[78] lead into the area of organoelement layer structures, as they can formally be considered as organometallic derivatives of the zirconium phosphate in which an OH group has been replaced by an organic residue R. The layer organization of these *zirconium phosphonates* is analogous to that of α-zirconium phosphate **42**.[79]

$Zr(HPO_4)_2 \cdot H_2O$ **42**

The crystal structure of this compound, a section of which is shown in Figure 16, reveals nearly flat layers of $\{ZrO_6\}$ octahedra which are linked by corners to $\{PO_3(OH)\}$ tetrahedra. Three of these tetrahedra are located above, three of them below the plane of octahedra. As each tetrahedron is linked to three octahedral units, the OH groups jut out into the interlamellar space, perpendicular to the layer. The layers are stacked in such a way as to create small block-shaped voids between the phosphorus

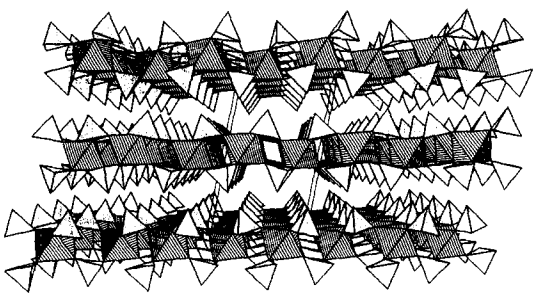

Fig. 16. Perspective view of the structure of α-$Zr(HPO_4)_2 \cdot H_2O$ **42**. The polyhedra are shaded as indicated in Figure 9.

and zirconium atoms of neighboring layers, in which water molecules are encapsulated. Since, relatively small windows represent the only access to these spaces, the mobility of the guests is rather restricted. It appears feasible to utilize some of these compounds as catalysts or proton conductors.

In this context, further very promising variations for supramolecular applications are offered by the use of diphosphonates as space-controlling columns between the layers and the construction of "organometallic layers" of the type of γ-zirconium phosphate **43**.[80] The combination of both concepts is realized, for example, in the zirconium phosphates phosphonates[81] and zirconium phosphite diphosphonates.[82]

γ-$Zr(H_2PO_4)(PO_4)\cdot 2H_2O$ **43**

2.2.7. *Molybdenum and Vanadium Phosphates*

The description of the three-dimensional host structures has already shown that the use of additional structural units (cubes, pyramids) leads to a significant increase in structural variety, and thereby also creates new potential applications. The same holds for two-dimensional host structures. For instance, the anionic host lattice of the *molybdenum phosphate* **44**[83] consists

$[N(C_3H_7)_4(NH_4)][(MoO)_4O_4(PO_4)_2]$ **44**

of layers of $\{Mo_4O_8\}$ cubes, which are linked by corner-sharing phosphate tetrahedra. The space between the layers is occupied by tetrapropylammonium ions as guests, while the NH_4^+ ions are encapsulated inside voids located within the layers.

A stair-shaped layer structure is found for the mixed-valence *vanadium phosphate* **45**.[84] The host structure, depicted in Figure 17, consists of parallel bands, in which corner-sharing

$K_2[(V^{IV}O)_2V^{III}(PO_4)_2(H_2PO_4)(HPO_4)(H_2O)_2]$ **45**

$\{VO_6\}$ octahedra, square $\{VO_5\}$ pyramids, and phosphate tetrahedra alternate. The potassium ions acting as guests are found within the individual steps as well as between them.

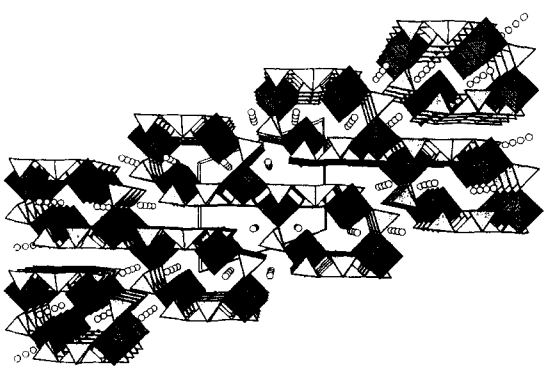

Fig. 17. Section of the crystal structure of compound **45** showing the view along the stair-shaped layers. The polyhedra are shaded as indicated in Figure 9.

2.2.8. *Diamond- and Carpet-Like Networks*

An aesthetic delight is presented by the structural aspects of compounds in which the host also functions as its own guest. This concept appears unproblematic at first glance. However, its full complexity only becomes apparent through a consideration of the requirements attached to the term supramolecular compound, namely, that in the crystalline state no translational relationship between host and guest species is allowed and only weak interactions, such as van der Waals forces may act between them. Both requirements taken together imply that host and guest structures must penetrate each other.

Indeed, such structural characteristics are not only laboratory oddities, but are also found in nature, as shown by the minerals cuprite (Cu_2O)[85] and neptunite, $(LiNa_2K(Fe,Mg,Mn)_2Ti_2[Si_8O_{22}]O_2)$.[86] The former exhibits two three-dimensional diamond-type networks, which penetrate each other—analogous to the situation in $Cd(CN)_2$ (See section 2.1.7).

In the case of two-dimensional hosts, this concept requires that the host shells are not closed within themselves. They must possess pores or openings that are large enough to allow the guest species to pass through. An interesting example which demonstrates this principle is Hittorf's phosphorus, which has a double layer structure formed by pentagonal tubes.[87]

The first attempts to create such three- and two-dimensional structures stem from organic chemistry.[88] However, inorganic chemists have started picking up on this idea as well. One of the highlights achieved thus far is the recently reported compound $Zn[Au_2(CN)_4]$ **46**, in which no less than six identical, but independent networks interpenetrate.[89] In each of the six networks, tetrahedrally coordinated zinc atoms occupy the positions of the silicon atoms, while linear $[Au(CN)_2]$ units have replaced the oxygen atoms in quartz.

$Zn[Au_2(CN)_4]$ **46**

$[M(CO)_3(\mu_3\text{-}OH)]_4$ **47**, M = Mn; **48**, M = Re

A second development stems from the cubane-like molecules **47** and **48**, which, by virtue of their four rigid hydrogen bond donors, can function retrosynthetically as tetrahedral T_4 tectons.[90] Together with linear bifunctional hydrogen bond acceptors as spacers, such as 1,4-diaminobenzene, 1,2-diaminoethane, or 4,4'-dipyridine, these building blocks form doubly, triply, or quadruply interpenetrating diamond-like networks.[91] In combination with nonlinear spacers, such as 1,3-diaminopropane (DAP) or hexamethylenediamine (HMTA), the compounds **47**·2DAP or **47**·1.5HMTA, respectively are formed, which exhibit two-dimensional, wire-mesh-like lattices.

In addition, spontaneous and strict self-organization of compound **48** in the presence of methanol and 4,4'-dipyridine (Dipy) leads to **48**·2Dipy·2MeOH, which exhibits two carpet-like intertwined networks (see Fig. 18). The dipyridine units act as linear bifunctional hydrogen bond acceptors, while methanol acts as a bent donor/acceptor unit.[90]

2.3. One-Dimensional Host Structures

In contrast to three- and two-dimensional host structures, *real* one-dimensional host–guest compounds are relatively rare, even though a number of potential hosts are known, which,

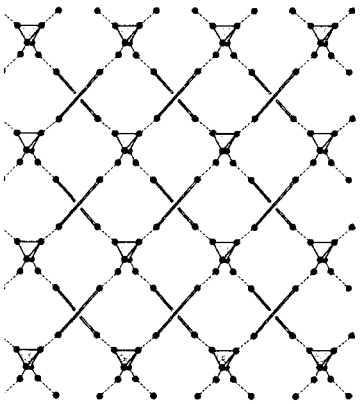

Fig. 18. Top view of the two intertwined networks of compound **48**·2Dipy·2MeOH; in this schematic representation, the cubane-type $[\{Mn(CO)_3(\mu_3\text{-}OH)\}_4]$ molecules are shown as tetrahedra based on the tetrahedral orientation of the OH groups, the 4,4'-dipyridine molecules are shown as sticks, and the methanol molecules are represented by black dots; the dashed lines indicate the hydrogen bonds between the different building blocks of the network.

based on their structure should display a high degree of structural flexibility with respect to the incorporation of guest species of different shape and size. Compounds with chain structures "suffer" from the disadvantage that they tend to show disorders or defects much more frequently than the higher dimensional hosts. In addition, the guest molecules within them "enjoy" a significantly higher mobility, which is only decreased if the host–guest interactions are significantly stronger than simple van der Waals interactions.

2.3.1. *Chevrel Phases*

Among the few one-dimensional host–guest compounds are ternary molybdenum chalcogenides of the type AMo_3X_3 (X = S, Se; A = alkali metal, In, Tl), which belong to the group of *Chevrel phases*, and, therefore, exhibit semiconductor properties. An example is the compound **49** [92] (see Fig. 19),

$TlMo_3Se_3$ **49**

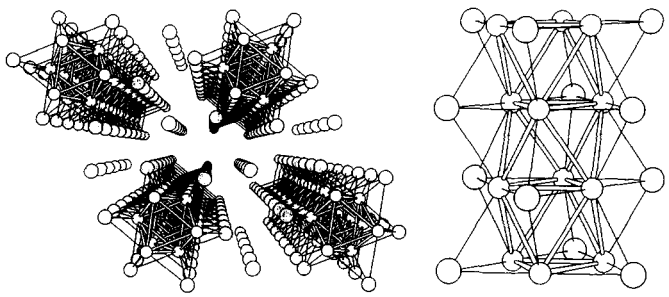

Fig. 19. Left: Perspective view of the crystal structure of $TlMo_3Se_3$ **49** (thallium atoms = large open spheres); the enlarged detail (right) shows that the Mo atoms (small open spheres) form face-sharing octahedral $\{Mo_6\}$ clusters. The edges of the common triangular faces are bridged by three Se atoms (large shaded spheres).

which consists of parallel columns of face-sharing molybdenum octahedra, which are surrounded by selenium atoms on the basis of $^1_\infty\{Mo_{6/2}X_{6/2}\}$ clusters. The monovalent metal ions are incorporated as guests between these columns, where they effect the stability of the crystal lattice by means of comparatively weak interactions, which still permit ion exchange reactions.

2.3.2. *Molybdenum and Vanadium Phosphates*

Molybdenum and *vanadium phosphates* form not only three- and two-dimensional host species, but also species in which the host exhibits only a chain structure. An example is found in the compound **50**,[93] which shows strands formed by cubane-type $\{Mo_4O_8\}$ units and tetrahedral $\{PO_4\}$ ones. The strands, however, are interlinked by hydrogen bonds in such a way that sheets result. The organic cations occupy positions between the chains.

$(Et_4N)_2[Mo_4O_8(PO_4)_{2/2}(H_{1.5}PO_4)_2]\cdot 2H_2O$ **50**

The fact that inorganic species can also mimic biologically relevant structures is demonstrated by compound **51**.[94] This species contains chiral double helices consisting of interpenetrating spirals, which, in turn, are formed by $\{VO_5\}$ units and tetrahedral phosphate groups. The double helices are arranged in such a manner as to create tunnels and cavities within the structure that are occupied by the organic and inorganic cations.

$(Me_2NH_2)K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7]\cdot 4H_2O$ **51**

2.3.3. *The Compound 2 HgS·SnBr$_2$*

In contrast to linear host structures, helical chain arrangements have the advantage that guest molecules are not only held between the chains, but that they can also get jammed, springlike, within the turns of the helix. A remarkable example displaying this feature was recently found by Blachnik et al.[95] in the species **52**.

$2HgS\cdot SnBr_2$ **52**

As can be gleaned from Figure 20, this compound consists of Hg–S chains that have a nearly square cross section. "Dimeric $SnBr_2$ molecules" are incorporated into these chains in such a way that the bonds to the *exo* bromine atoms penetrate into the interior of the helix. The interaction between guest and host is essentially limited to an increase in the pitch of the turns, as the three-sided helices of the guest-free host (cinnabar[96]) are apparently too small to accommodate the guest. The increase stems from the decrease of the bond angle at sulfur from 105° to 95.1°. The bond lengths (235.6 pm vs. 236 pm in HgS) and the bond angles at the Hg center (172.5°/180°) are nearly unaffected

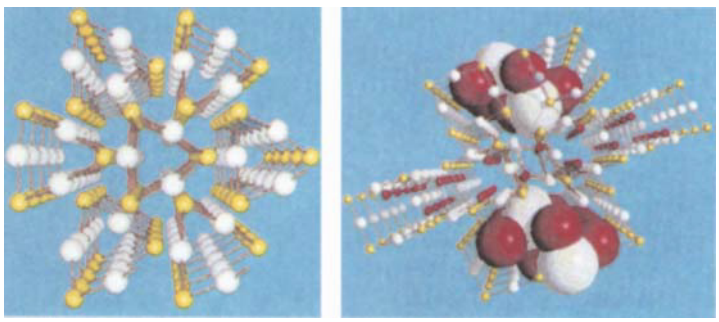

Fig. 20. Perspective view of the crystal structure of mercuric sulfide, HgS: guest-free (left) and loaded with molecular $SnBr_2$ dimers (right); some of the guest molecules are shown as space-filling, some as ball-and-stick models (Hg white, S yellow, Br red, Sn white); in the cinnabar modification, the Hg–S helices have a triangular cross section, in $2HgS\cdot SnBr_2$ **52** these helices have a nearly square cross section.

by this interaction. In the gas phase, the guest tin(II) bromide consists of monomeric molecules displaying a bent structure. In the crystalline state, $SnBr_2$ exhibits a polymeric chain structure.[97] From these chains the host "cuts" dimeric blocks, which correspond to edge-sharing units of trigonal-pyramidally coordinated tin atoms; no important changes in bond lengths and angles result.

3. "Zero-Dimensional" Host Structures

3.1. Definition of Terms

Until now the discussion has focused on one-, two-, or three-dimensional hosts, in which the guests are characteristically incorporated within extended column, layer, or lattice structures. If, however, only uniform, spatially restricted units are present, the resulting discrete host structures are formally defined as zero-dimensional. As will be shown in the following sections, the template-controlled linking of inorganic building blocks can lead to a wholly unexpected number and variety of zero-dimensional hosts, in which one finds various ways by which a small molecule or ion is embedded as guest within a larger one. The host–guest compounds discussed herein, many of which are of a mesoscopic nature,[98] can be classified according to their geometry and topology as either "closed" or "open" (see Fig. 2). Both terms are applied to species that contain cavities of the appropriate dimensions to hold the corresponding guests or ions in place. If such a guest species is located within a cavity formed by a spherical shell-like molecular aggregate in which the guest is permanently enclosed, this "host cage" is termed *closed*. Systems are termed *open* if the host function[99] is performed by a zero-dimensional structure that contains certain "portals" large enough to allow the guest to "leave" the host.

A further criterion for the formal classification of host structures is, according to historical terminology, the division into *electronically normal* and *electronically inverse hosts*. Electronic normality is present if the charge relationships in the host–guest system under consideration are the same as those in the classic crown ether/alkali metal systems. An electronically inverse system displays the inverse relationships which opens up the possibility of incorporating anions as guests. Host structures that incorporate neutral species are termed *electronically neutral hosts*, whereas host structures that can possess nucleophilic as well as electrophilic character are termed *electronically bifunctional hosts*.

3.2. Electronically Normal and Inverse Hosts

3.2.1. *Electronically Normal Hosts*

Closed Hosts

The mixed-valent (Mo^V/Mo^{VI}) complex anion **53a**[100] is a closed inorganic host. It exhibits a central ε-Keggin unit[101] with the composition $\{Mo_{12}O_{40}\}^{20-}$, which has as its basis a truncated Mo^V_{12} tetrahedron. Four facial $\{MoO_3\}$ "anti-Lipscomb" units (cf. the definition in ref. [101]) cap the four Mo_6O_6 faces of the ε-Keggin unit.[102] The flexibility of the anionic host **53a** is demonstrated by the existence of the two compounds **54**[100] and **55**[100] (see Fig. 21): The host **53a** possesses a tetrahedral cavity which can accept cations with very different coor-

$[(Mo^{VI}O_3)_4Mo^V_{12}O_{28}(OH)_{12}]^{8-}$ **53a**

$[Me_2NH_2]_6[H_2Mo_{16}O_{40}(OH)_{12}]$ **54**

$[H_2Mo_{16}O_{40}(OH)_{12}]^{6-}$ **54a**

$(NH_4)_7[NaMo_{16}O_{40}(OH)_{12}]\cdot 4H_2O$ **55**

$[NaMo_{16}O_{40}(OH)_{12}]^{7-}$ **55a**

$[Na(H_2O)_3Mo_{42}H_{15}O_{109}\{(OCH_2)_3(CCH_2OH)\}_7]^{7-}$ **56a**

$[Na(i\text{PrSn})_{12}O_4(OH)_{24}][Ag_7I_{11}]Cl\cdot 10\,DMSO\cdot H_2O$ **57**

$[Na(i\text{PrSn})_{12}O_4(OH)_{24}]^{5+}$ **57a**

dination requirements, such as protons and Na^+. Similar host–guest relationships are found in **56a**[103] (see Sections 3.5 and 3.7) and **57**.[104] The crystal lattice of the latter species contains the isopolycation **57a**. The tin–oxygen framework of this cation exhibits the γ-Keggin structure[101] and contains a cavity formed by four nucleophilic μ_3-O units, which holds a sodium ion, similar to **55a**. The condensation reactions leading to the formation of **54a** (see Fig. 21), **55a**, and **57a** appear to be under some kind of template control, where the host framework forms around the guest in solution.[105–109]

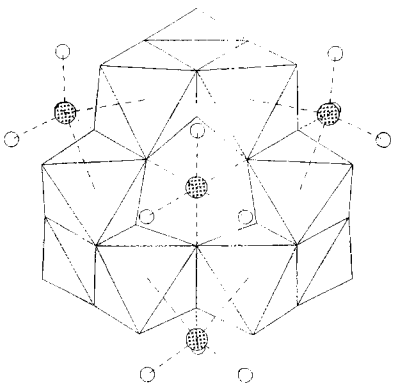

Fig. 21. Structure of the cluster anion $[H_2Mo_{16}O_{40}(OH)_{12}]^{6-}$ **54a** in crystals of **54**, viewed along the crystallographic threefold axis to clearly show the capping of the hexagonal faces of the $\{Mo_{12}O_{40}\}^{20-}$-ε-Keggin fragment (shown as a polyhedral representation) by the facial "anti-Lipscomb" trioxomolybdenum(VI) units (shown as ball-and-stick models) [102].

An interesting structural principle is found in the anion **58a**[110] (Fig. 22a) which exhibits an electronically normal, thirty-membered $[Pd_2S_{28}]^{4-}$ host framework; the closed structure is formed by the linking of two Pd^{II} atoms and four polysulfide chains. Hence, a relatively large cavity with an NH_4^+ ion at its center is formed (Pd–Pd distance 630 pm).

$[(NH_4)Pd_2(S_7)_4]^{3-}$ **58a**

α-$[Na_2Fe_{18}S_{30}]^{8-}$ **59a**

β-$[Na_2Fe_{18}S_{30}]^{8-}$ **59b**

$[Na_9Fe_{20}Se_{38}]^{9-}$ **60a**

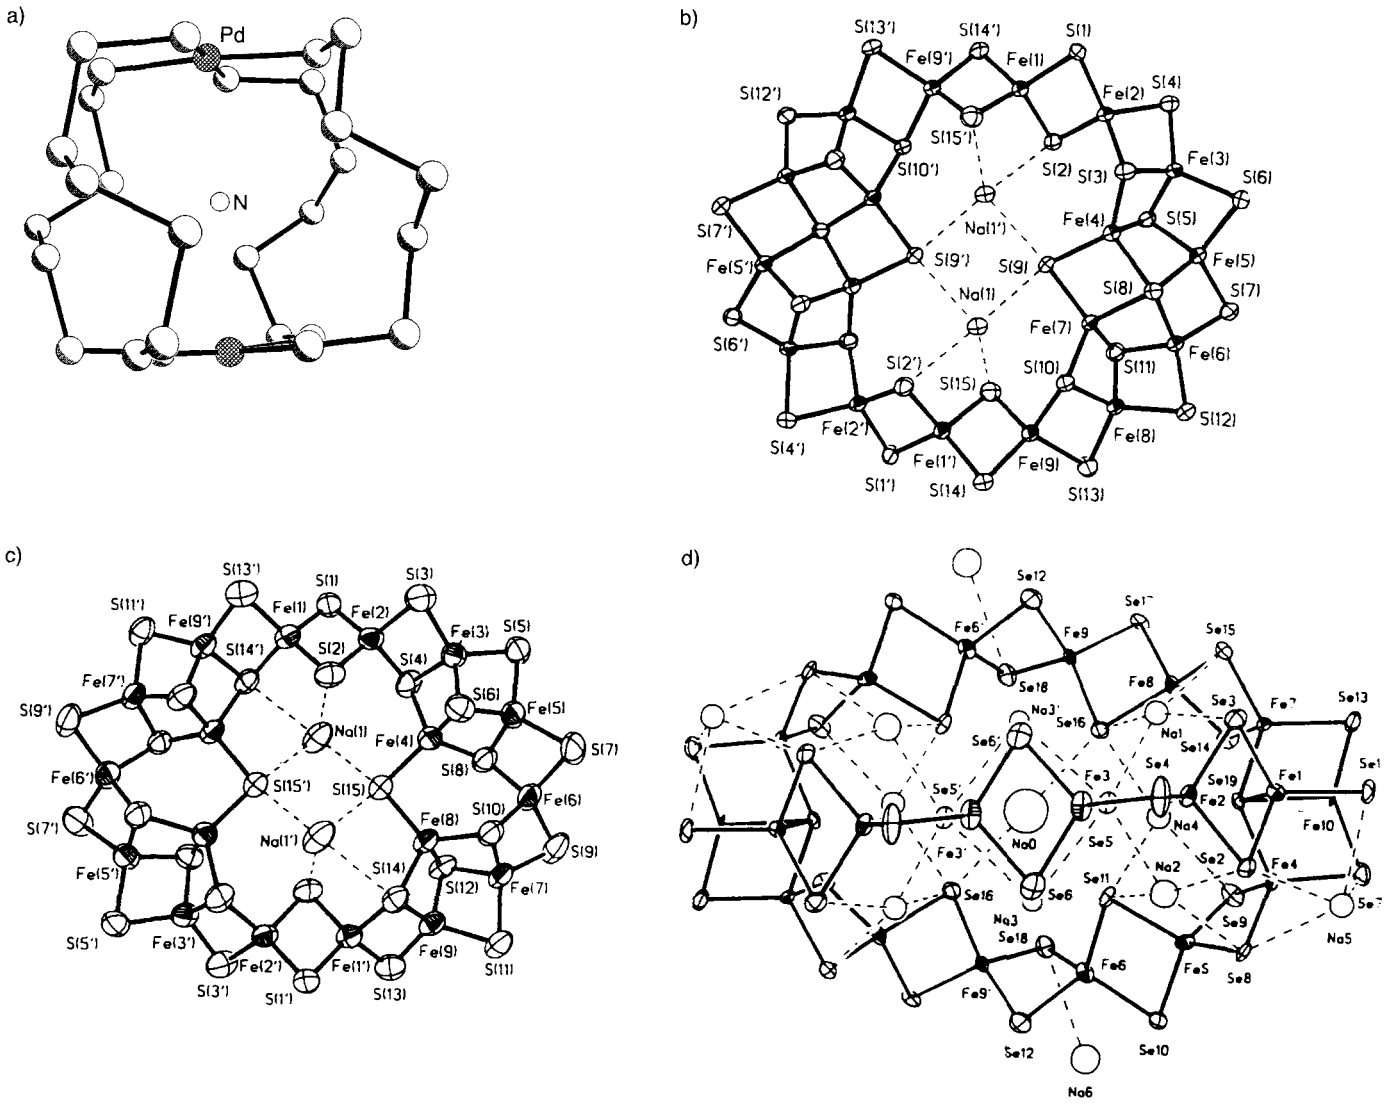

Fig. 22. Structures of the host–guest systems a) $[(NH_4)Pd_2(S_7)_4]^{3-}$ **58a**, b) α-$[Na_2Fe_{18}S_{30}]^{8-}$ **59a**, c) β-$[Na_2Fe_{18}S_{30}]^{8-}$ **59b**, and d) $[Na_9Fe_{20}Se_{38}]^{9-}$ **60a**.

Interesting host–guest relationships are found for the slice-shaped anions **59a**[111a] and **59b**[111b], as well as for the bicyclic anion **60a**.[111b] Compounds **59a** and **59b** (Figs. 22b,c) are formed by twenty-four nonplanar, corner- and edge-sharing Fe_2S_2 rhombi, respectively, such that all iron centers are localized in distorted tetrahedral FeS_4 units. Within the interior of **59a** and **59b**, there are two sodium ions coordinated to sulfur atoms of the Fe–S cage. Hence, the monocyclic species **59a** and **59b** can be considered as inorganic crown thioethers. The cluster structure of the α-isomer **59a** (Fig. 22b) contains two (linear) Fe_3S_4 and two Fe_6S_9 fragments. Fe_3S_4 and Fe_6S_9 units are linked to each other by a total of twenty μ_2-S, eight μ_3-S, and two μ_4-S atoms. In contrast, the structure of the β-isomer **59b** (Fig. 22c) consists of two Fe_2S_2, four cubic Fe_3S_4, and two tetrahedral FeS_4 units linked by eighteen μ_2-S and twelve μ_3-S atoms. The elliptical bicyclic species **60a** (Fig. 22d) is formed by twenty-one nonplanar Fe_2Se_2 rhombi, fifteen of which share corners through common iron centers, leading to three $Fe_6(\mu_2\text{-}Se)_{10}$ chains. This anion therefore exhibits thirty-six μ_2-Se atoms, two μ_4-Se centers, fifteen corner-sharing, and six edge-sharing Fe_2Se_2 rhombi. All iron atoms are grouped into distorted tetrahedral $FeSe_4$ units. The selenium-rich cavity of **60a** contains nine sodium ions, demonstrating that this nano-sized species is a host–guest system. The assignment to the closed hosts is provisional, since the host–guest behavior has not yet been studied in detail.

Open Hosts

The chemistry of polyoxotungstates yields several examples of electronically normal, open inorganic cryptands which can encapsulate electrophilic guest species. A representative of this host category is the anion **61a** (Fig. 23a),[112] which has a cyclic structure formed by the linking of four $\{AsW_9O_{33}\}$ subunits through WO_6 octahedra. If, for example, a sodium cation is located at the center of the aggregate **61a**, it can be replaced with other alkali and earth alkaline metals, as well as silver and ammonium ions. The host **61a** also possesses a lacunary structure and can incorporate transition metal centers into its framework.[113] For example, in the presence of Co^{2+} ions, the supramolecular host–guest structure **62a** is formed.[114] In

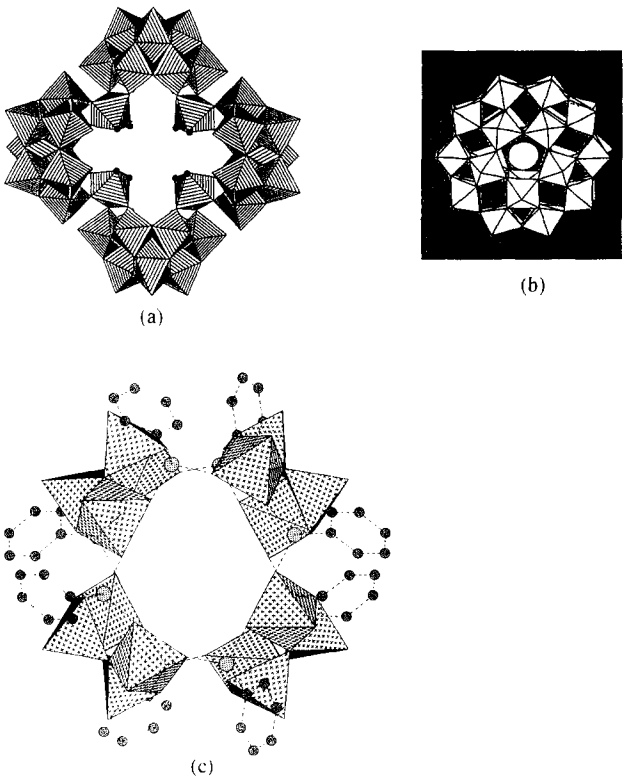

Fig. 23. a) Polyhedral representation of the cryptand $[As_4W_{40}O_{140}]^{28-}$ **61a**, viewed along the S_4 axis. The black circles mark those oxygen atoms that border the cavity of the host [114]. b) The structure of the host–guest system $[NaP_5W_{30}O_{110}]^{14-}$ **64a** (WO_6 octahedra shown as polyhedra; the five PO_4 tetrahedra are hidden), viewed along the C_5 axis. The exchangeable Na^+ ion inside the cavity is depicted by a circle [116]. c) Structure of the host of $[(Me_2NH_2)H_{11}(V^{IV}O_2)_{16}(PhAsO_3)_8]^{4-}$ **65a** with four units each of which is built up by four edge-sharing VO_5 pyramids [117].

the open host(–guest) structure **63a**[115], the nucleophilic coronand consists of two $\{Sb_3O_7\}$ and three $\{SbW_7O_{28}\}$ subunits, which are linked by oxygen atoms. The electrophilic guest (the sodium ion) is located at the center of the host, in an environment formed by eight oxygen atoms, which formally form a double-capped trigonal prism. Na^+ can be exchanged with earth alkaline metal and other alkali metal cations. The cryptate **64a**[116] consists of a ring of five $\{PW_6O_{22}\}$ units and encapsulates a sodium ion, which is located on the fivefold axis (Fig. 23b). Under relatively drastic conditions (aqueous solution, 140–180 °C), this Na^+ ion can be exchanged with other cations such as Ca^{2+} and Y^{3+}, and also with most trivalent lanthanide ions (all except La^{3+}, Ce^{3+}, and Pr^{3+}), as well as with Ce^{4+} and U^{4+}.

$[As_4W_{40}O_{140}]^{28-}$ **61a**

$[(NH_4)(Co\text{-}H_2O)_2As_4W_{40}O_{140}]^{23-}$ **62a**

$[NaSb_9W_{21}O_{86}]^{18-}$ **63a**

$[NaP_5W_{30}O_{110}]^{14-}$ **64a**

Open nucleophilic host structures with enclosed electrophiles are also known from the chemistry of oxovanadium phenylarsonates. This category of host–guest systems includes, for instance, the species **65a** (Fig. 23c).[117]

$[(Me_2NH_2)H_{11}(V^{IV}O_2)_{16}(PhAsO_3)_8]^{4-}$ **65a**

3.2.2. *Electronically Inverse Hosts*

Attraction and Repulsion (...) as principles of a natural system.
F. W. J. Schelling[118]

Closed Hosts

In our opinion, isopolyoxovanadates currently present the most instructive examples for the inorganic chemistry of host–guest species. The cluster anions of the type **66a–c**[119] and **67a**[107, 120] (Fig. 24) will be discussed in some detail. Similar host–guest systems include the complex anions **68a**[105–107, 120], **69a**,[107, 120] **70a**,[105, 120] and **71a**[125a], as well as the anion of the compound $[Et_4N]_6[HV_{22}O_{54}(HMoO_4)]$.[125b] The host shells are formed by using the template function of the (preferably) anionic guest and are dependent on its shape and size.[105–107, 121] The use of suitable basic fragments allows the formation of host–guest compounds which exhibit a cavity enclosing the template. *These closed hosts are only electronically inverse with respect to the observed "incarceration" of anions*: Studies of the electrostatic

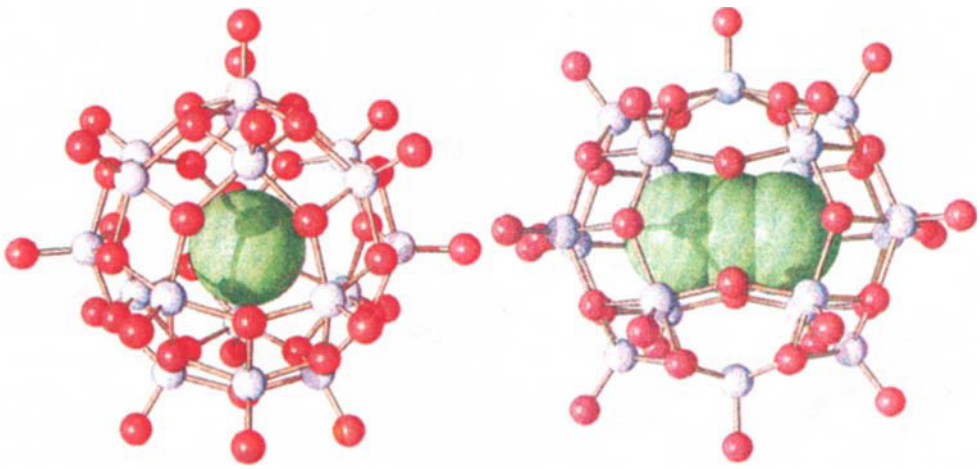

Fig. 24. Representation of host–guest relationships: structures of the cluster anions **66a–c** [119] (left) and **67a** [107, 120] (right) (V blue, O red, the central template green is shown as a space-filling model).

interactions in the hypothetical cluster anion $[V^{IV}_{18}O_{42}(Cl)]^{13-}$, based on extended Hückel calculations, have shown that the resulting electrostatic energy E_{res} is positive, indicating a destabilization and, hence, a repulsion in the case of the interactions of the Cl^- guest with the negatively charged oxygen–vanadium sphere.[122a] On the other hand, the significantly lower charge density on the encapsulated Cl^- ion indicates the presence of (only according to the calculation very weak) attractive interactions between the electrophilic vanadium centers and the chloride ion.[122b] The calculation of the charge distribution for $[V^{IV}_{18}O_{42}(Cl)]^{13-}$ (for a relevant unit cell) using the charge equilibration model with subsequent calculation of the electrostatic energies, suggests that attractive interactions with the cationic lattice are necessary to stabilize this host–guest system. This means, however, that the classification that ascribes an electronically inverse behavior to the isopolyoxovanadates is a consecutio ex eventu: Based on the above-mentioned dualism of attractive and repulsive interactions, one should talk about a primarily pseudo-mechanical incorporation of the guest by the host.[119–123] This point of view is supported by the fact that neutral molecules can be incorporated into cluster shells of appropriate size.[123] As expected the corresponding extended Hückel calculations indicate that the interaction of the H_2O guest in **72a**[124, 125] with the polyoxovanadate shell is infinitely small ($E_{res} \approx 0$).[122a]

$[V^{IV}_{18}O_{42}(H_2O)]^{12-}$ **72a**

Open Hosts and a Remarkable Synergism

The rigid electrophilic macrocycle "[12]-mercuracarborand-4" **73** is an example of such host compounds, as is demonstrated by the structure of the lithium salt **74** (Fig. 25).[126] The anion

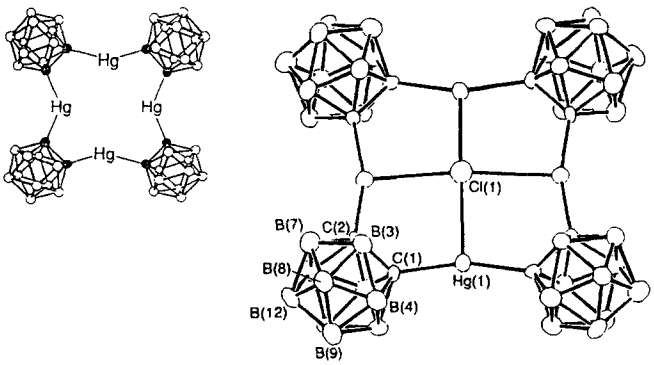

Fig. 25. Left: The electrophilic host "[12]-mercuracarborand-4" $(HgC_2B_{10}H_{10})_4$ **73**; the C atoms are denoted by black circles, the BH groups by white circles. Right: The structure of the anion $[(HgC_2B_{10}H_{10})_4Cl]^-$ in crystals of **74** (hydrogen atoms omitted) [126].

of **74** consists of four divalent 1,2-$C_2B_{10}H_{10}$ "cages" which are linked by four mercury atoms to form a cyclic tetramer with the chloride ion at the center. The related compounds **75**[127]

$(HgC_2B_{10}H_{10})_4$ **73**

$Li[(HgC_2B_{10}H_{10})_4Cl]$ **74**

$Li[(HgC_2B_{10}H_{10})_4I]$ **75**

$Li_2[(HgC_2B_{10}H_{10})_4I_2]$ **76**

and **76**[127] are known as well. The X-ray crystal structure analysis of **76** shows that the iodide ions are located above and below the plane formed by the four mercury atoms (average distance to this plane is 196 pm).[127] It is remarkable that the reaction of an ethanol solution of **76** with silver acetate yields, in addition to silver iodide and lithium acetate, the "template-free" host **73**.[127, 128]

An unusual type of inorganic host–guest system is represented by the cluster anion **78a** (Fig. 26).[129] This species is formed

$[(SCN)_9W_3S_4SnCl_3]^{6-}$ **78a**

through weak interactions between the *anionic* $[(SCN)_9W_3S_4]^{5-}$ receptor and also the *anionic* guest $[SnCl_3]^-$. In this context,

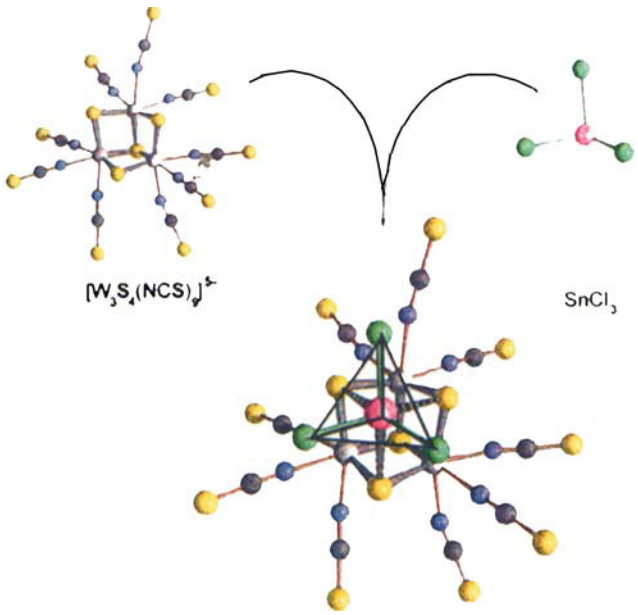

Fig. 26. The formation and structure of the cluster anion **78a**, a novel type of inorganic host–guest system (Sn pink, Cl green, W light gray, S yellow, C dark gray, N blue). Its formation is based on a synergistic effect (see text).

it should be noted that the two complementary anions are independently stable. This complementarity is reminiscent of a lock-and-key mechanism (lone pair of electrons of $[SnCl_3]^-$ as key, missing corner in the W_3S_4 cube as lock). The Sn^{2+} "reduction" of the $[W_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^{4+}$ fragment that is contained within the $[(SCN)_9W_3S_4]^{5-}$ ion increases the nucleophilicity of the three coordinatively unsaturated μ_2-S atoms. The affinity of the $[W_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^{4+}$ ligand for cations like Sn^{2+} increases with its increasing electron donor strength (i.e., according to the electron density at the S atoms), which is caused by the "reducing power" of the cation itself. The cluster aggregate **78a** is therefore to be viewed as an unusual host–guest system. Its guest and host components can exist independent of each other as stable anions, but they are nevertheless capable of forming host–guest structures, due to this *special* synergistic effect (special within the field of supramolecular chemistry).

3.2.3. $[As_4Mo_6V_7O_{39}(SO_4)]^{4-}$: A Model System for the Different Host–Guest Properties of Polyoxomolybdates and Polyoxovanadates

As a final example in this category the inorganic host–guest system **79a** will be discussed.[130] It consists formally of the "host" **79b** and the "guest" SO_4^{2-} and combines the pseudo-clathrate properties[131a] of some polyoxomolybdate shells (e.g., **80a**, see below) and the electrophilic character of polyoxovanadate host structures (cf. Section 3.2.2) within a single cluster species (Fig. 27).[131b] The host–guest species **79a** shows two special characteristics: The six Mo^{VI} centers are exclusively present as MoO_6 octahedra, while the seven V^{IV} atoms are found in the form of four VO_6 octahedra and three square VO_5 pyramids (Fig. 28). This indicates the remarkable property of V^{IV} centers to form octahedral as well as square-pyramidal coordination spheres. The second characteristic is that the shortest distances between a metal atom and $O(SO_3)$ are found between O42 and O43 of the central oxoanion and the molybdenum atoms Mo5 and Mo6 (only 238 and 244 pm), and not, as would have been expected, between the O atoms of the sulfate ion and the (closest) vanadium atoms V2, V3, V6, and V7 (cf. Fig. 27). This apparently indicates that at least these two molybdenum atoms interact more strongly with the sulfate oxygen atoms. These host–guest relationships, basically, reflect the various possibilities of interactions between electronically inverse polyoxovanadate host shells and their enclosed guest species on the one hand and polyoxomolybdate structures with a central oxoanion that are only capable of forming pseudo-clathrates on the other hand. The most "extreme" examples are anions like $[H_4V_{18}O_{42}(X)]^{9-}$ **66a–c**[119] and $[Mo_{12}O_{36}(PO_4)]^{3-}$ **80a**.[133]

$[As_4^{III}Mo_6^{VI}V_7^{IV}O_{39}(SO_4)]^{4-}$ **79a**

$[As_4Mo_6V_7O_{30}]^{2-}$ **79b**

$[Mo_{12}O_{36}(PO_4)]^{3-}$ **80a**

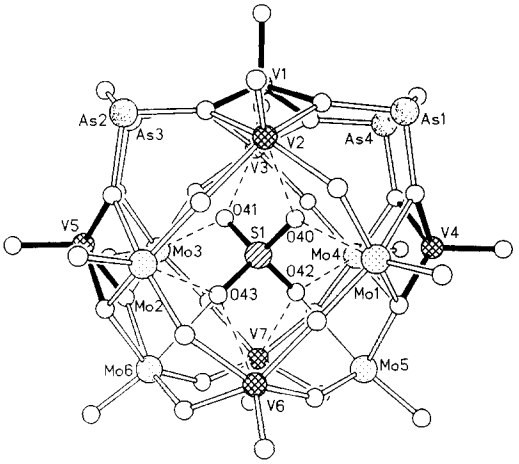

Fig. 27. The structure of the cluster anion **79a**. Metal atom–$O(SO_3)$ distances: $V\cdots O(SO_3)$ (V1, V4, and V5, square VO_5 pyramids): 325–333 pm, $M-O(SO_3)$ (M = Mo1–4, V2, V3, V6, and V7, MO_6 octahedra): 256–267 pm; $Mo-O(SO_3)$ (Mo5 and Mo6, MoO_6 octahedra): 238 and 244 pm.

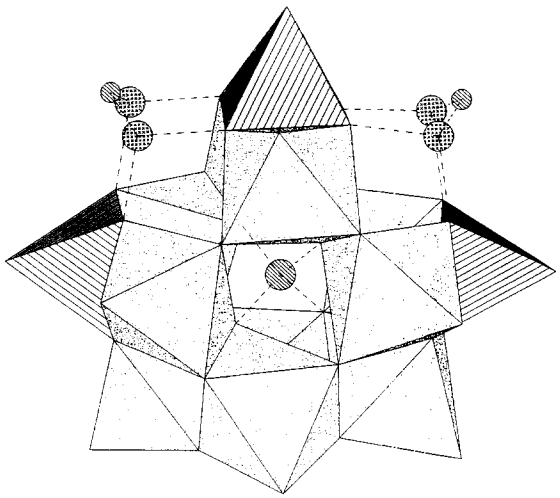

Fig. 28. Representation of the different characteristic polyhedra (octahedra and square pyramids) of the cluster anion **79a**. These polyhedra underline the model character of this compound for the electrophilic behavior of V^{IV} centers and the pseudo-clathrate properties of Mo^{VI}–oxygen aggregates, as well as for the hybrid behavior of V^{IV} centers discussed in the main text (randomly dotted: the six $OMoO_5$ and four OVO_5 octahedra; hatched: the three square OVO_4 pyramids; large circle with diagonal lines: the sulfur atom of the central SO_4^{2-} ion; small circles with diagonal lines: the oxygen atoms of the As_2O^{4+} units; cross-hatched circles: As^{III} centers of the As_2O^{4+} groups).

A comparison of the relevant chemistry of *reduced* polyoxomolybdates and -vanadates clearly shows, correspondingly, the different properties of *host–guest systems* that are exclusively built from MoO_6 octahedra or square OVO_4 pyramids, respectively: In the case of polymolybdates under reducing conditions, one obtains a nucleophilic, electronically normal host like **53a** in which sodium ions can be encapsulated (see Section 3.2.1). In contrast, square OVO_4 pyramids can be employed to construct "electrophilic", and thus electronically inverse host systems of the type **66a** (Section 3.2.2).

3.3. Electronically "Neutral" and Bifunctional Hosts

The large distances between guest species and the atoms in the cluster shell in isopolyvanadates (see Section 3.2.2) that contain an encapsulated anion with low charge density allow only weak interactions between the anionic guest and the surrounding host structure. This correlates with the idea that repulsive ($O\cdots$anion) and attractive ($V^{n+}\cdots$anion) forces are in an *approximate* balance[105, 109, 122] (with regard to the synthesis see also ref. [123]). These considerations also explain why the neutral solvent itself can take on the role as template during syntheses in aqueous and nonaqueous media where no anions are added to the reaction mixture. In this context, the formation of the remarkable basket-shaped open dodecavanadate **81a**[8] or closed isopolyvanadates such as $[V_{18}^{IV}O_{42}(H_2O)]^{12-}$ **72a**[124, 125a] may be recalled. Both are cluster species that consist of an "electronically neutral" host shell and an enclosed CH_3CN or H_2O molecule as guest.

$[V_{12}O_{32}(CH_3CN)]^{4-}$ **81a**

The relevance of the mentioned attraction/repulsion concept for the resulting weak interactions between a host and a weakly

nucleophilic as well as weakly basic guest is supported by additional observations. For example, the $\{V_4O_{16}\}$ unit is capable of coordinating cations as well as anions, as demonstrated by the syntheses of the compounds **82**[134, 135] and **83**[136] (see Fig. 29).

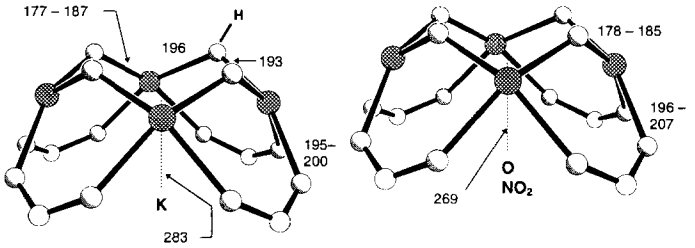

Fig. 29. A receptor for cations and anions: Left: Part of the structure of the cation $[K\{V_4O_7(OH)(O_2CR)_4\}]^+$ **82a**; right: Part of the structure of the anion $[(NO_3)\{V_4O_8(O_2CR')_4\}]^{2-}$ **83a**. (For **82a**: R = neopentyl; counterion: $[RCO_2]^-$; central unit: $V^{IV}(OH)V^V_3O_3$. For **83a**: R' = 2-thienyl; counterion: $[Et_4N]^+$; central unit $V^{IV}V^V_3O_4$.) The vanadium atoms are represented as cross-hatched circles and the oxygen atoms as shaded circles; some bond lengths are shown. All figures are according to ref. [135].

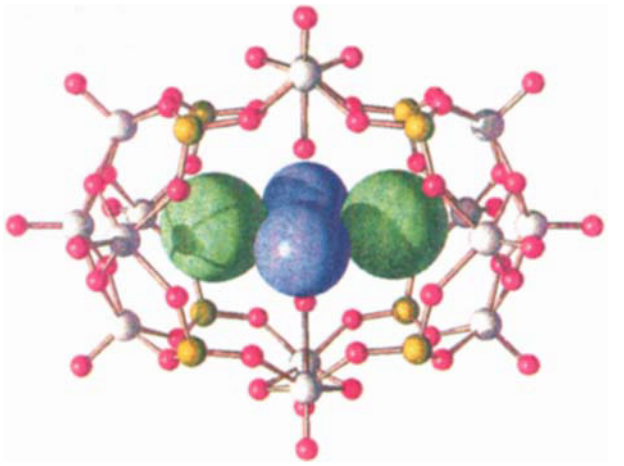

Fig. 30. Structure of the central cage of the cluster anion **84a**, viewed along one of the idealized C_2 axes (V gray, P yellow, O red, NH_4^+ blue, Cl^- green; central guest system shown as a space-filling model), demonstrating the host–guest relationship (see text). The phenyl rings of the phenylphosphonate units have been omitted for clarity.

Hence, this electronically bifunctional $\{V_4O_{16}\}$ unit can be formally submitted to a reversal of polarity by the judicious choice

$[K\{V_4O_7(OH)(O_2CCH_2tBu)_4\}][O_2CCH_2tBu]\cdot 2\,tBuCH_2CO_2H$ **82**

$[Et_4N]_2[(NO_3)\{V_4O_8(tca)_4\}]\cdot H_2O$ **83** (tca = thiophene-2-carboxylate)

of reaction conditions, even in the case of a constant degree of reduction (identical electron populations in **82** and **83**, one V^{IV} and three V^V centers). But, it must be noted that the electronic properties of the $\{V_4O_{16}\}$ host are also slightly influenced by the choice of organic ligands and by minor modifications of the basic host (e.g., the protonation of the $V^{IV}V^V_3O_4$ unit in **82** in contrast to that in **83**): Electronically normal or inverse charge conditions in our formal approach are properties of the *same* basic host structure in *different* host–guest systems (not in the *same* host–guest system, a topic that will be discussed in Section 3.4). The tendency of isopolyvanadates to incorporate anions is expected to increase with an increase in the number of Lewis acidic vanadium centers.

3.4. Hosts Comprising Electronically Normal and Inverse Subhosts

The coupling of electronically normal and inverse subhosts, as demonstrated by the synthesis of the host–guest species **84**,[109] opens up a new dimension in inorganic host–guest

$[Me_2NH_2]_5(NH_4)[2NH_4^+, 2Cl^-\subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]$
$\cdot 5H_2O\cdot 4DMF$ **84** (DMF = dimethylformamide)

chemistry. The cage of the cluster anion **84a** (Fig. 30) consists of two half-shells, which are formed from isopolyvanadate and phenylphosphonate units. The central neutral guest system $(2NH_4^+, 2Cl^-)$ is a cation/anion aggregate that can be interpreted as a section of the NH_4Cl ionic lattice. Thus anions and cations are both encapsulated within the same cavity, which is formally separated into two segments by two water molecules bound to V^{IV} centers. These water molecules apparently stabilize the $(2NH_4^+, 2Cl^-)$ guest system by hydrogen bonds. The formation of the host shell **84b** is possibly based on a conservative self-organization process.[137] During this process, the two chloride ions could induce the generation of the corresponding

$[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ **84b**

electrophilic isopolyvanadate fragments, while the ammonium ions could induce the formation of the nucleophilic coronands.

The (formal) removal of the two water ligands from **84b** yields the host shell **84c**. This transformation converts the initially octahedral coordination sphere of the vanadium atoms in the bridging $\{V_2O_2(OH)_2(H_2O)(PhPO_3)_4\}^{6-}$ units[109] into a square-

$[V_{14}O_{22}(OH)_4(PhPO_3)_8]^{6-}$ **84c**

pyramidal one. This creates further possibilities regarding the encapsulation of other guest species or guest systems. The syntheses of the cluster compounds **85**[138] and **86**[139] provide an impressive demonstration of that principle. The careful choice

$[PhCH_2NEt_3]_2[PhCH_2NMe_3]_4[(CH_3CN)_2\subset V_{14}O_{22}(OH)_4(PhPO_3)_8]$
$\cdot 2CH_3CN\cdot 2CH_3OH\cdot 2H_2O$ **85**

$[Et_3NH]_3[tBuNH_3]_2Na_2[(H_2O)_2, N_3^-\subset V_{14}O_{22}(OH)_4(PhPO_3)_8]$
$\cdot 6H_2O\cdot 2DMF$ **86**

of *reaction conditions* can lead to the controlled formation of a multitude of zero-dimensional host–guest structures, when combined with knowledge about the complex host–guest relationships that form the basis of these oxovanadiumphenylphosphonate systems and determine the genesis of the host lattices **84b** and **84c**.

It is remarkable that the organization of particles within the closed cavity of $V/O/PhPO_3^{2-}$ host–guest systems can be controlled from the "outside". For example, the addition of a thir-

teenfold excess of rubidium bromide to an aqueous DMF solution of **86** yields the species **87** (see Fig. 31).[139] During the

$[Et_3NH][tBuNH_3]_2(0.5\,Rb/0.5\,Na)_2$
$\cdot Rb_2[(H_2O)_2 \cdot N_3 \subset V_{14}O_{22}(OH)_4(PhPO_3)_8] \cdot 10\,H_2O \cdot 2\,DMF$ **87**

transformation of **86** to **87**, an exchange of the guests located in the truncated-cone-shaped ion channels takes place (see Fig. 31) which, in turn, leads to a reorganization of the guest system ($2\,H_2O$, N_3^-) within the closed cavity.[139] This shows how the organization of species within a closed host can be remotely controlled.

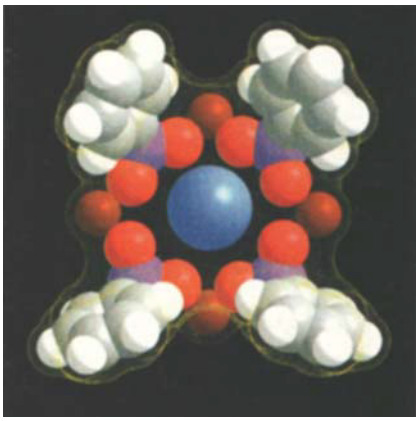

Fig. 31. Space-filling plot with a weakly outlined "Connolly surface" [140], of the ion channel of **87a**, built from four $PhPO_2$ units and four V atoms, showing the embedded Rb^+ cation in the coronand (viewing direction as in Figure 30; V brown, P violet, O bright red, Rb large central blue sphere, C gray, H white).

In these examples of host–guest systems, it appears to be irrelevant in terms of the control over the reaction whether the host forms around a guest template or whether the host is formed without a template effect and then itself stabilizes the guest system such as ($2\,NH_4^+$, $2\,Cl^-$). The detection of *rules* that underlie the reactions in question makes it possible to plan and control syntheses, even without an understanding of the fundamental principles that govern the formation of these V/O/Ph-PO_3^{2-} systems. This also allows the researcher to "play" with the host–guest relationships inherent to these cluster species. There are obvious potential applications of this kind of host–guest chemistry, for instance the template-controlled formation of oligomers from anions and cations. It also allows the study of intermolecular interactions within nano-sized aggregates.

3.5. "Cluster Within Cluster"—A Model for Nucleation Processes and Some Relevant Comments about the (Template) Conductor Principle

"Nothing originates by chance, but everything is due to a specific reason and the force of necessity."
Democritus[141]

Compounds that show "a cluster encapsulated within a cluster" are of particular interest.[142] These species can only be formally viewed as host–guest systems, as strong covalent interactions between the "guest template" and the "host shell" must be "ignored". But, this procedure is justified due to the general validity of the principles of molecular construction and organization that have been discussed thus far. The principles responsible for the formation of relevant nano-sized structures resemble the structure-determining schemes that result from the dominance of weak host–guest interactions in the area of "normal" host–guest systems.[142]

An example for such "cluster within cluster" compounds is the mixed-valent nano-sized polyoxovanadate **90a**.[105–108] It consists of a $V_{30}O_{74}$ shell formed by the linking of 30 tetragonal

$[V_{34}O_{82}]^{10-}$ **90a**

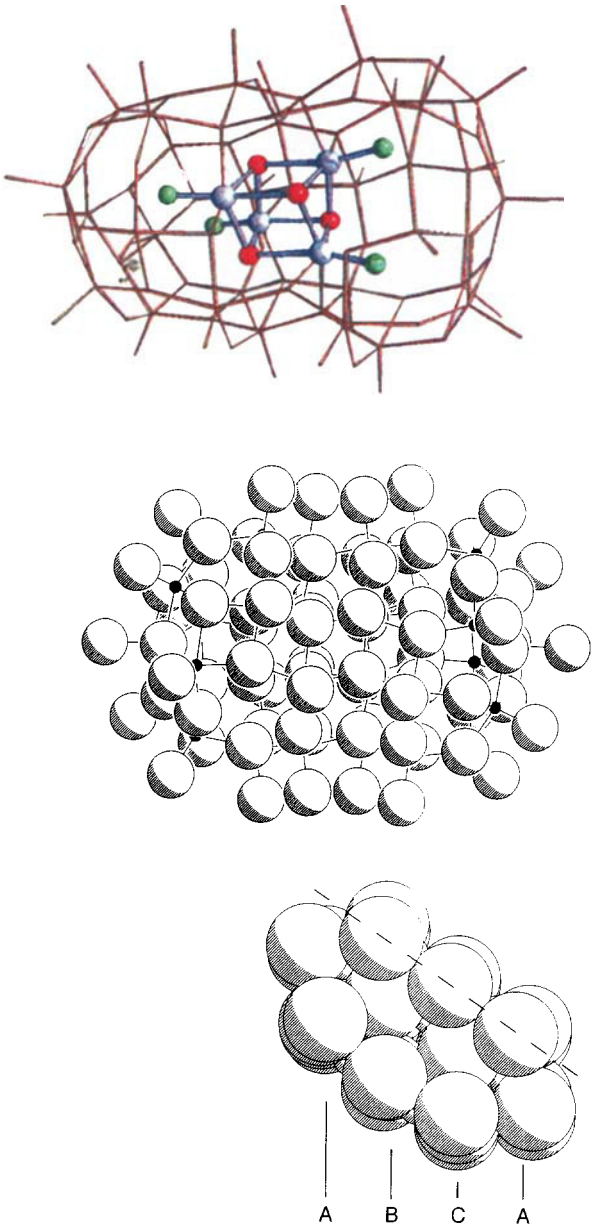

Fig. 32. Top: "Host shell" (brown stick model) of the cluster anion $[V_{34}O_{82}]^{10-}$ **90a** showing the central $\{V_4O_4\}(O_{term})_4$ cube as a ball-and-stick model (V blue, μ_3-O red, O_{term} green). Middle: The vanadium–oxygen system represents a section from a distorted and defect NaCl lattice; the layers of oxygen atoms in **90a** are shown as viewed perpendicular to the approximate S_4 axis. Bottom: View of the cubic closest packing of oxygen atoms, indicating the ABCA layer structure (one of the layers shown in the middle figure perpendicular to the approximate S_4 axis is indicated by the dashed line).

VO_5 pyramids and an incorporated central $\{V_4O_4\}(O_{term})_4$ cube that exhibits four V=O groups (Fig. 32 top). This cube, which is probably formed as an intermediate in the vanadate solution, acts as template and generates the structure of the $V_{30}O_{74}$ shell in a conservative self-organization process[137] according to its "own" shape and size. This $\{V^{IV}_4O_4\}(O_{term})_4$ unit, which has the same stoichiometry as amphoteric $V^{IV}O_2$ (and, hence, can be precipitated), in effect initiates the construction of the $[V_{34}O_{82}]^{10-}$ ion by acting as the "crystallization nucleus". The anion formed shows similarities to a segment of a disordered cubic solid-state structure of the NaCl type (see Fig. 32 middle and bottom). The process just described is important because the initial steps of crystal formation, for which it can serve as a model, are not yet properly understood.

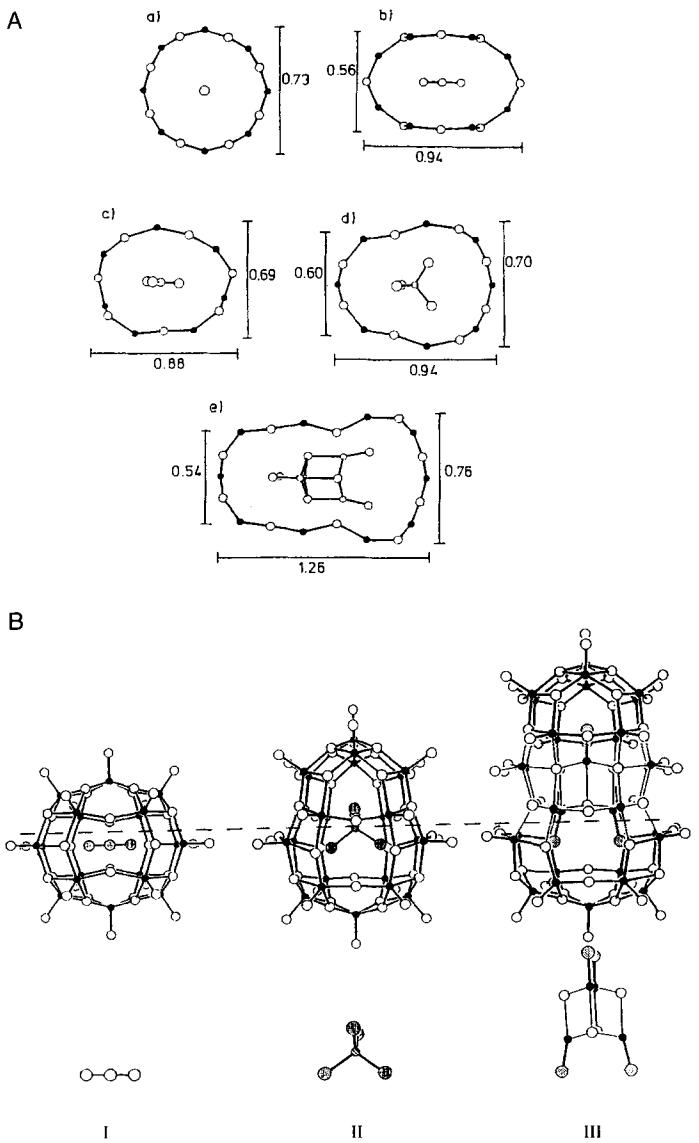

Fig. 33. Depiction of the template effect/conductor principle (see text) A) by a simplified representation of the shape and size of several different V–O cluster shells, showing measurements in nm. a) $[H_4V_{18}O_{42}(X)]^{9-}$ **66** (X = Cl, Br, I), b) $[H_2V_{18}O_{44}(N_3)]^{5-}$ **67a**, c) $[HV_{18}O_{44}(NO_3)]^{10-}$ **68a**, d) $[HV_{22}O_{54}(ClO_4)]^{6-}$ **69a**, e) $[V_{34}O_{82}]^{10-}$ **90a** (shown without the covalent V–O bonds between the central $\{V_4O_4\}(O_{term})_4$ cube and the cluster shell) and by B) structural comparison between $[H_2V_{18}O_{44}(N_3)]^{5-}$ **67a** (I), $[HV_{22}O_{54}(ClO_4)]^{6-}$ **69a** (II), and $[V_{34}O_{82}]^{10-}$ **90a** (III) and their central templates (V black; O white, for the shells; see text).

This method of constructing inorganic host–guest systems is "in effect" based on a type of *conductor principle*: The controlled linking of inorganic basic units for the purpose of generating larger stable mesoscopic structures is directed by *templates*. These can, essentially act as "seedlings" for the architectures to be created and are either added to the reaction mixture or are formed in it. Such templates regulate the mobility of the basic building blocks and guide, like a conductor, these usually freely mobile fragments into a well-defined order (cf. Figs. 33 and 34). A completely new supramolecular ensemble of different particles is thus formed, often displaying exceptional properties (a comparison with the term "slaving principle" in the terminology of Hermann Haken's synergetics is certainly worthwhile). The "conducting" influence of weak interactions in "cluster within cluster" type compounds such as **90a** even in the presence of strong covalent interactions becomes evident from the following comparison (see Fig. 33B): The formal removal of the two middle layers in **90a** (a $\{V_{12}O_{28}\}$ fragment containing the central $\{V_4O_4\}(O_{term})_4$ cube, Fig. 33 B III)), followed by the linking of the remaining $\{V_{11}O_{27}\}$ half-shells yields the shell of $[HV_{22}O_{54}(ClO_4)]^{6-}$ **69a** (Fig. 33 B II). The formation of the half-shells in **69a** and **90a**, together with their rotation by 90°, occurs in both cases after the recognition of the "$(O-O)_2$ unit": The arrangement of the four shape-determining terminal O atoms in the cube of **90a** (a tetragonal disphenoid) corresponds to that of the four O atoms in the ClO_4^- unit of **69a**. The cluster shell of $[H_2V_{18}O_{44}(N_3)]^{5-}$ **67a** can formally be created in a similar way by fusing two $\{V_{11}O_{27}\}$ half-shells (see Fig. 33 B I[107]). The linear azide ion with its $D_{\infty h}$ symmetry acts as template in this case and assures that the two shells are arranged as mirror images, that is, without the rotation observed in **69a** and **90a**. The entire cluster shell thus obtains an oblong shape with D_{2h} symmetry, which is complementary to the azide ion (D_{2h} is a subgroup of $D_{\infty h}$). With respect to these arguments, it must be noted that in the case of V–O inclusion compounds the apparently only weak interactions allow the central units to act as matrices or templates that determine the symmetry, the shape, and the structure of their respective shells (Fig. 33 A and B).

The weak part of the interaction between the $\{V_4O_4\}(O_{term})_4$ cluster and the shell of the $[V_{34}O_{82}]^{10-}$ anion ($O{=}V(shell)\cdots(O_{term}){=}V(cluster) > 254$ pm) can be compared to those that exist between the layers of the V_2O_5 lattice.[105, 143] Using the template principle, the V_2O_5 layers are "systematically arranged" in such a way as to "imagine" the layer $n+1$ on top of layer n according to the weak interactions $O{=}V\cdots O{=}V$

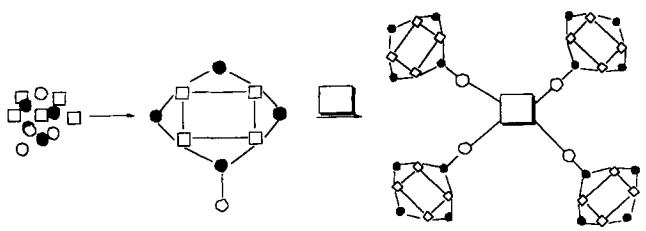

Fig. 34. Schematic representation of a reaction that could take place in solution during a self-organization process (see text). This scheme shows a possible template-directed synthesis (the large symbol □ represents a template) of supramolecular structures from prefabricated basic aggregates, which, in turn, are formed in primary reaction steps.

(distance between the layers $d = 279$ pm, layer n considered as template for layer $n+1$).

The giant cluster anion **91a**, which contains the $\{Mo_{16}O_{52}\}$ group of **54a** as central structural element,[100, 144] is another

$[Mo_{43}H_{15}O_{112}\{(OCH_2)_3CCH_3\}_5]^{8-}$ **91a**

example for a "cluster within a cluster" system. The four facial $\{Mo^{VI}O_3\}$ trioxomolybdenum units of **54a** function as *inorganic protecting groups* (with simultaneous protonation of twelve μ_2-O atoms) for the highly unstable negatively charged $\{Mo_{12}O_{40}\}^{20-}$ cluster fragment forming the reactive $\{Mo_{16}\}$ intermediate. This species can be "utilized" for the synthesis of cluster systems with higher nuclearities, such as **91a**.[100] It is, therefore, reasonable to view this $\{Mo_{16}\}$ unit as a structure-determining agent, which is formed as an intermediate in solution, and which enables the template-controlled synthesis of the complex cluster anion **91a**.[144]

3.6. Cavities in Giant Clusters and Molecular Models for Clathrates

The principle of the formation of ordered structures by template-controlled self-organization processes leads directly to the concept of syntheses of "large" systems as intermediates in the reaction solution. Under the structure-determining influence of host–guest relationships, these preorganized units have a "strengthening" and controlling effect on subsequent steps. Larger and larger molecular building blocks are formed by conservative self-organization processes. The aggregates formed by the intermediate steps are in effect linked to giant cluster species in a controlled manner. In certain cases, such structures also contain nano-sized cavities.

Examples for such novel host–guest systems are the highly symmetric, torus-shaped giant cluster anions **93a** and **94a**

$[\{Z(H_2O)\}_6\{Mo(\mu_2\text{-}H_2O)_2(\mu_2\text{-}OH)Mo\}_3\{Mo_{15}(MoNO)_2^{3+}O_{58}(H_2O)_2\}_3]^{n-}$

93a: Z = VO, $n = 21$

94a: Z = Fe(H_2O), $n = 15$

(Fig. 35 top).[146–150] These nano-sized or mesoscopic structures contain $\{Mo_{15}(MoNO)_2^{3+}O_{58}(H_2O)_2\}^{20-}$ units ($\{Mo_{17}\}$) (Fig. 35 middle) that formally function as ligands and are linked and stabilized by coordination to cationic species such as $\{(H_2O)V^{IV}O\}^{2+}$, $\{Fe^{III}(H_2O)_2\}^{3+}$ and $\{Mo^{V}(\mu_2\text{-}H_2O)_2(\mu_2\text{-}OH)Mo^{V}\}^{9+}$ (Fig. 35). The aggregation variability behavior of these $\{Mo_{17}\}$ units is also demonstrated by the synthesis of the polyoxomolybdate **95a**.[147, 154] It consists of two $\{Mo_{17}\}$

$[\{MoO_2\}_2\{H_{12}Mo_{15}(MoNO)_2^{3+}O_{58}(H_2O)_2\}_2]^{12-}$ **95a**

units, which are linked by two *cis*-MoO_2^{2+} groups, two NH_4^+ ions, and two H_2O molecules (Fig. 35 bottom). These ammonium ions and water molecules are located in a "space" formed by the two $\{Mo_{17}\}$ units which cannot be considered as a cavity. (The $\{Mo_{17}\}$ units are "formed" by the linking of two $\{Mo_8\}$ units by an Mo atom) (see also the incorrect formulas in refs. [151–153]).

This aggregation leads to the generation of a host, which contains a relatively large cavity (diameter perpendicular to the

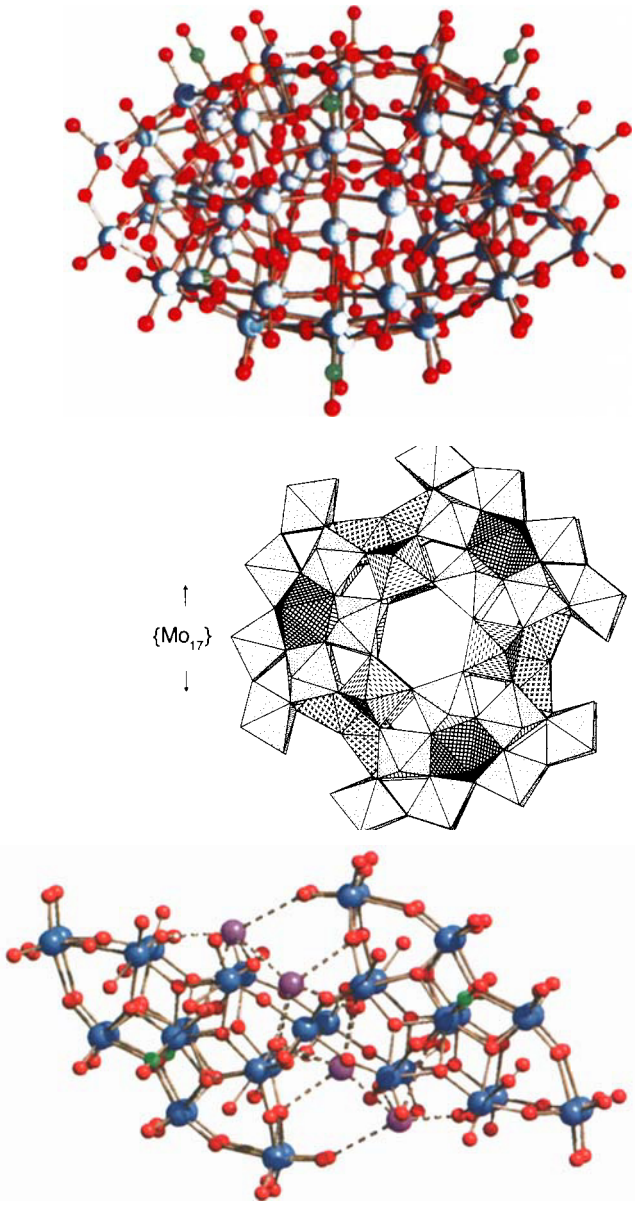

Fig. 35. Top: Ball-and-stick model of the cluster anions **93a** and **94a**, viewed approximately along the 2-(C_2) axis (Mo blue, V/Fe orange, O red, N green). Middle: Polyhedral representation of the cluster anions **93a** and **94a** (dashed polyhedra: $V^{IV}O_5(OH_2)$ and $Fe^{III}O_4(OH_2)_2$ octahedra, crossed polyhedra: $\{Mo(\mu_2\text{-}H_2O)_2(\mu_2\text{-}OH)Mo\}$ units, square-filled polyhedra: pentagonal $Mo(NO)O_6$ bipyramids, dotted polyhedra: MoO_6 octahedra). Bottom: Structure of the cluster anion **95a** (Mo blue, O red, N(NO) light green; in between the $\{Mo_{17}\}$ units NH_4^+ and H_2O violet).

$\bar{6}$-(S_3) axis approximately 0.9 nm, parallel to it approximately 0.5 nm (ignoring the H atoms)). This cavity in the interior of the cluster anions **93a** and **94a** is formed by a central O_{33} polyhedron and is bordered at both poles by alternating M-O-Mo-O twelve-membered rings (M = V, Fe), which are perpendicular to the $\bar{6}$-(S_3) axis (Fig. 36). Remarkably, the O_{33} polyhedron contains two six-membered H_2O rings, which are located between the planes of the twelve-membered M-O-Mo-O rings. Hence, the cavities of **93a** and **94a** are bordered by H_2O molecules, which are interlinked by hydrogen bonds. The question whether "some water" is present as disordered guest in the cavity cannot be answered conclusively either by X-ray crystallography (no significant residual electron density was found within

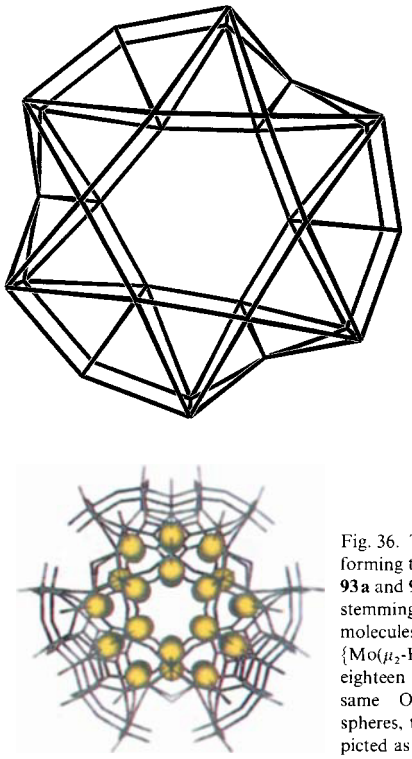

Fig. 36. Top: Central polyhedron forming the cavity in the cluster anions **93a** and **94a**, built up from 33 O atoms stemming from twelve terminal H_2O molecules, three μ_2-OH groups of $\{Mo(\mu_2\text{-}H_2O)_2(\mu_2\text{-}OH)Mo\}$ units, and eighteen μ_2-O atoms. Bottom: The same O_{33} polyhedron (O yellow spheres, the "rest" of the cluster is depicted as the blue-gray stick model).

the cavity) or by thermogravimetric data (the mass fraction per H_2O molecule is only approximately 0.2%). Such a disorder of guest species in the sense of the clathrate definition (see Section 2.1), however, would correlate with the expectation of weak van der Waals interactions between host structures and guests. This interpretation implies the conclusion that the giant cluster anions **93a** and **94a** are molecular models for clathrate hydrates.[155a] The H_2O molecules of the above-mentioned six-membered rings form a subhost $\{(H_2O)_6\}_2$. This subhost provides an "extramolecular cavity"[47] within the proper cavity of **93a** and **94a**, which serves as additional guest space for "further water" $(H_2O)_x$. This clathrate $[(H_2O)_x\{(H_2O)_6\}_2]$ is, in turn, incorporated as guest into the host $[Z_6\{Mo(\mu_2\text{-}H_2O)_2(\mu_2\text{-}OH)Mo\}_3\{Mo_{15}(MoNO)_2^{3+}O_{58}\}_3]^{n-}$ ($Z = VO$, $n = 21$; $Z = Fe(H_2O)$, $n = 15$). In this context, the giant cluster anions **93a** and **94a** can be viewed as double host–guest systems[155b] (the relevance of double host–guest systems for bioinorganic chemistry is discussed in Section 5).

3.7. The Shell Aufbau Principle

"Nature is to be considered as a system of steps, each of which is born out of the previous one."
G. W. F. Hegel[156]

The increasing complexity in the series of $\{Mo_7\}/\{Mo_8\}$, $\{Mo_{17}\}$, $\{Mo_{36}\}$, and $\{Mo_{57}\}$ units, as well as that of $\{Mo_2\}$, $\{Mo_6\}$, $\{Mo_{12}\}$, $\{Mo_{16}\}$, and $\{Mo_{42}\}/\{Mo_{43}\}$ units demonstrates a *shell Aufbau principle*: compare the change in complexity in **54a** → **91a** and in **54a** → **56a** (see Section 3.5). The shell Aufbau principle demonstrates the growth principle of complex systems in the antagonism "growth by accumulation and limitation of growth".

This concept is not limited to spherical compounds and applies to the category of compounds with weak host–guest interactions as well as to that of compounds with strong covalent and metal–metal interactions. It is, for instance, possible to describe the systematic construction of metal clusters of higher nuclearities on the basis of the shell Aufbau principle. Examples with idealized metal content include **96**,[157] **97**[158] (Phen* = 4,7-di(*p*-sulfophenyl)-1,10-phenanthroline), and **98**[159] (Phen = 1,10-phenanthroline)—species that have, however, not yet been

$[Au_{55}(PPh_3)_{12}Cl_6]$ **96** $[Pt_{309}Phen^*_{36}O_{30\pm10}]$ **97** $[Pd_{561}Phen_{36}O_{190\pm10}]$ **98**

characterized by X-ray structure analysis. Thus, a sequence of "magic numbers" is produced when a closed outer shape (a cuboctahedron for ccp and an anticuboctahedron for hcp) is reached in each case for a cubic closest packing (ccp) or hexagonal closest packing (hcp) of the metal atoms.[160] The Aufbau principle that forms the basis of this shell model states that a central metal atom is surrounded by n shells each with $(10n^2 + 2)$ atoms. The successful syntheses of *ligand-stabilized* single shell $\{M_{13}\}$, double shell $\{M_{55}\}$ (**96**), quadruple shell $\{M_{309}\}$ (**97**), and quintuple shell $\{M_{561}\}$ clusters (**98**) provide a striking demonstration of this principle.[160, 161] The ligands and the low nucleophilicity of the terminal oxygen atoms in the case of polyoxometalates serve to interrupt the growth processes, which lead to the formation of high-nuclearity clusters at a given aggregation level. In this manner, one obtains cluster aggregates of a defined level of complexity not only for metal–oxygen clusters (e.g., **56** and **91**) but also for metal clusters (e.g., **96**–**98**). The latter species, in turn, contain cluster fragments as subunits, which are known as stable, isolated compounds or as components of other, previously synthesized clusters. Examples include the three $\{Mo_{17}\}$ units in the giant anions **93a** and **94a**, the $\{Mo_{16}\}$ groups in **56** and **91**, as well as the $\{M_{13}\}$, $\{M_{55}\}$, $\{M_{147}\}$, and $\{M_{309}\}$ units in **98**. This general shell Aufbau principle does not prescribe the exact way in which the specific subunits are to be linked: The $\{Mo_{17}\}$ unit, for example, can be "used" to form the "double shell" $\{Mo_{17}\}_2$ species **95a** or the triple shell $\{Mo_{17}\}_3$ anions **93a** and **94a**. By suitable variation of the reaction conditions it is also possible to use the $\{M_{13}\}$ cores of $\{M_{55}\}$ clusters as building blocks for the generation of $\{M_{13}\}_{13}$ giant clusters.[161] The shell Aufbau principle is therefore by no means limited to spherical "cluster within cluster" compounds. Nature has apparently utilized such a principle for a long time in order to reduce the necessary amount of "genetic information" to a minimum, a principle exemplified by the tobacco mosaic virus.[162]

4. Potential Applications

4.1. Molecular Magnets: Controlling the Spin Organization in Host Molecules

The template syntheses of new cluster compounds utilizing intrinsic host–guest relationships open up new possibilities for chemists to create nano-sized host or cluster structures with novel magnetic properties. This is the case when the relative number of paramagnetic centers (e.g., the V^{IV}/V^{V} ratio) and,

hence, the type of exchange interactions can be influenced (in general, exchange interactions become stronger when, in clusters of the same size, the number of V^{IV} atoms is increased, due to the accompanying reduction in interatomic distances).[163] The cluster anion **99a**[164-166] is an example for such a "high-nuclearity spin cluster" with magnetic properties reminiscent of

$[V_{15}As_6O_{42}(H_2O)]^{6-}$ **99a**

those of extended two and three-dimensional inorganic solids, as it consists of a unique multilayer magnetic structure (Fig. 37). The host-guest system of **99a** exhibits 15 paramagnetic $V^{IV}(d^1)$

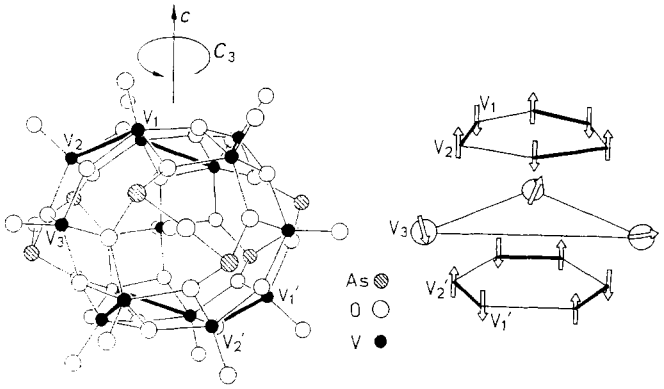

Fig. 37. Left: Structure of the cluster anion $[V_{15}As_6O_{42}(H_2O)]^{6-}$ **99a** showing the crystallographic C_3 axis. Right: Schematic representation of the spin organization at low temperatures ($T < 100$ K). The circled arrows indicate uncoupled spins (the phenomenon of spin frustration). The distance between coupled vanadium centers of V^{IV} V^{IV} pairs is 287 pm, other V···V distances are 302-305 pm (cf. ref. [165, 168]).

centers, which are grouped in such a way as to form two distorted, nonplanar hexagons with six V^{IV} atoms, between which a central triangle of three V^{IV} centers is located. This arrangement results in a sandwich-like structure with three planes of different magnetization at low temperatures ($T < 100$ K). While spin pairing occurs among the V^{IV} atoms of the two V_6 hexagons, the spins in the central V_3 plane are uncorrelated and exhibit—as expected—the interesting phenomenon of spin frustration. The spins of the host-guest system **99a** are, therefore, *formally* subject to a kind of self-organization process.[165, 168]

In this context it is important to note that by the combined synthetic strategy of a controlled V^{IV}/V^{V} ratio *and* the use of a template it is not only possible to adjust the ratio of paramagnetic to diamagnetic centers (this enables the planning of spin frustration effects by using an odd number of V^{IV} centers) but also to predetermine the topology and structure of the cluster in question. This possibility of controlling the magnetic properties of high-nuclearity spin clusters can be exploited in order to create host-guest systems displaying very different nuances in their magnetic behavior.[165-170]

Of particular importance in this context are large cluster surfaces that can be loaded with various paramagnetic centers. Examples for this procedure include the giant clusters **93a** and **94a** and their derivatives: Not only unusually strong antiferromagnetic exchange interactions have been observed in these species, but also an abundance of ferrimagnetic properties;[150b] the possibility of "tuning" these properties remains as well.

4.2. Molecular Anion Cages

The properties of ions in the solid state as well as in solution can only be evaluated in the presence of appropriate perturbing counterions due to the governing principle of electroneutrality. It is a very difficult undertaking to derive the properties of the free ion from spectroscopic data obtained in this manner. However, this dilemma can be avoided by encapsulating such a charged species, for example an anion, as guest within a rigid host that is also negatively charged, for example an isopolyvanadate. In this particular host structure, with a central weakly nucleophilic/basic anion as guest, repulsive (O···anion) and attractive (V^{n+}···anion) forces balance each other out, at least approximately (cf. the discussion in Section 3.2.2). This leads to relatively weak interactions and, hence, to rather large distances between the anion and the cluster shell. The resulting pseudomechanical fixation of the guest by the host offers the opportunity

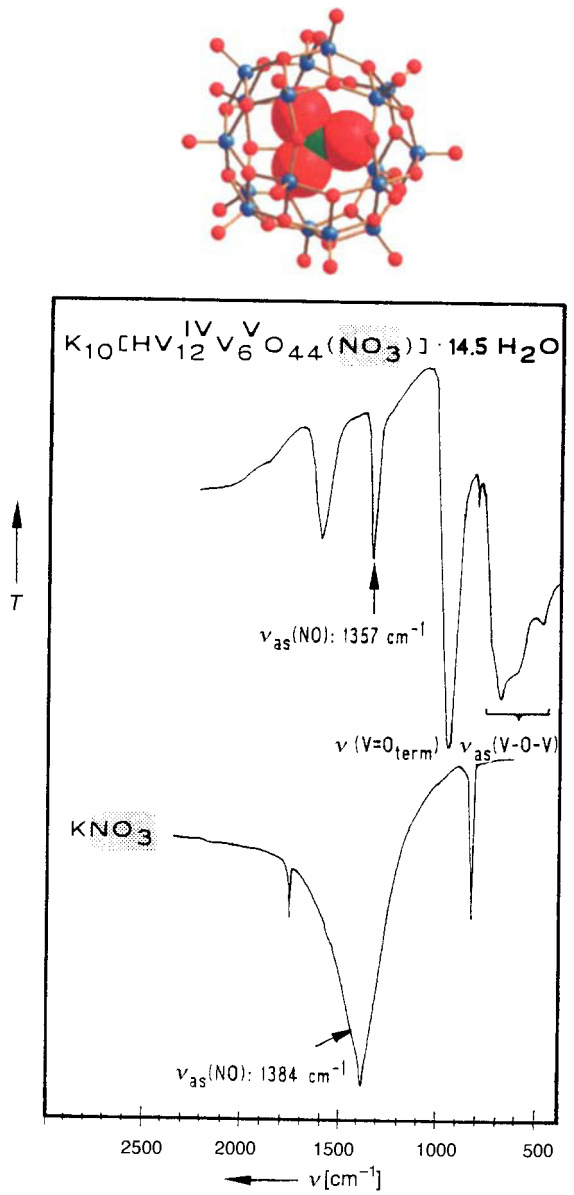

Fig. 38. Top: Structure of the cluster anion **68a**. Bottom: IR spectra of the cluster species $K_{10}[HV_{18}O_{44}(NO_3)] \cdot 14.5H_2O$ **68** and KNO_3 (both as KBr pellets). T = transmission.

to make an almost isolated anion, which is formally "floating" in the center of its cryptand, the object of scientific curiosity. The "corresponding counterion" in this case is located far away, outside the host–guest system, that is in the cationic lattice and has, therefore, no noticeable effect on the anion, which, while encapsulated, is nevertheless nearly "free" with respect to the above-mentioned interaction.

An example for this type of host–guest compound is the cluster species $[HV_{18}O_{44}(NO_3)]^{10-}$ **68a** (Fig. 38 top).[105–107, 120] With the aid of vibrational spectroscopy studies of the host–guest system **68a**, the weak interactions between guest and host shell can be confirmed. For this purpose, the IR band stemming from the asymmetric N–O stretching vibration of the NO_3^- ion was examined in different environments (in the host shell of **68a** and in crystalline KNO_3). The measured half width of this band in **68a** is smaller by a factor of about five than the corresponding $\nu_{as}(NO)$ stretching vibration band of the nitrate ion in KNO_3 (Fig. 38 bottom). This clearly shows the mentioned weak interactions between the NO_3^- ion and the cluster shell in **68a**.[120]

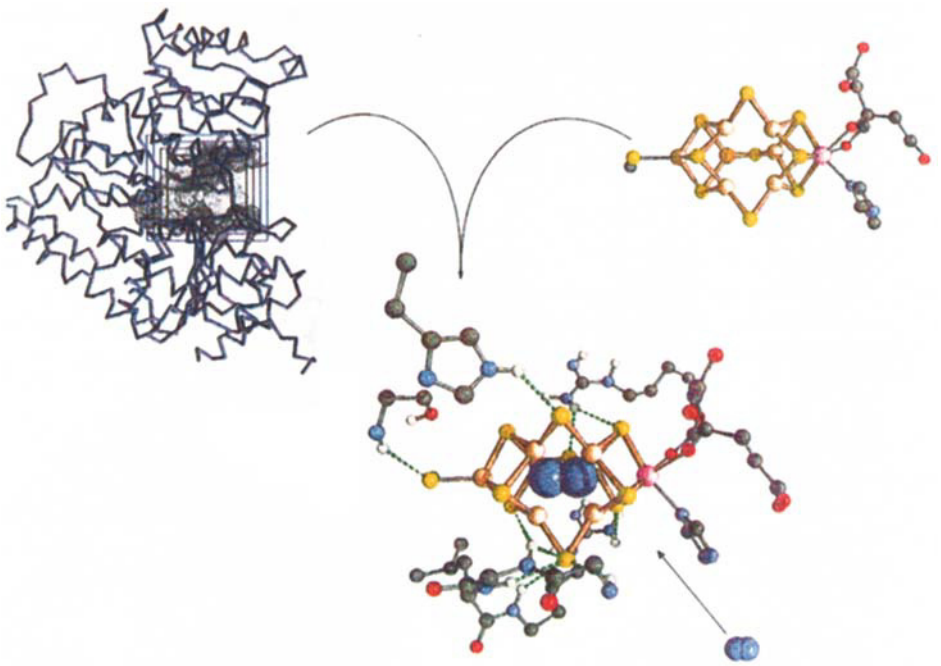

Fig. 39. Depiction of the host–guest relationships in the nitrogenase enzyme system, an "inorganic" double host–guest structure: the FeMo cofactor (i.e., the $MoFe_7S_9$/homocitrate cluster) acts as host for N_2 and simultaneously is formally incorporated as "guest" into the apoprotein.

5. Inorganic Host–Guest Chemistry and Bioinorganic Chemistry

Double host–guest systems, which have already been briefly mentioned in Section 3.6, also exist in the area of bioinorganic chemistry, for example in the form of the MoFe protein of the nitrogenase enzyme system with "fixed" nitrogen at the FeMo cofactor.[171] The principles governing the host–guest relationships of giant clusters apply likewise to these supramolecular aggregates, but in a somewhat modified form: The iron–molybdenum cofactor in the above-mentioned enzyme is synthesized by proteins using template-controlled syntheses. These proteins function to a certain extent as intermediate hosts. In the final step (formally speaking), the cofactor is incorporated as guest into the MoFe apoprotein.[171] This intermediary simple host–guest system, in turn, acts as host towards N_2, thus forming a bioinorganic double host–guest system: The protein hosts the cofactor, which contains a cavity, into which a guest can be incorporated, in this case the substrate N_2 (Fig. 39).[171] In contrast to the inorganic host–guest systems **56a**, **90a**, **91a**, **93a**, and **94a** (see Sections 3.2.1, 3.5, and 3.6), the components of this double bioinorganic host–guest structure can exist independently. In terms of the synergistic effects underlying the host–guest interactions, the nitrogenase system most likely resembles simple host–guest systems of the type $[(SCN)_9W_3S_4SnCl_3]^{6-}$ **78a** (see Section 3.2.2; the covalent bonds between the FeMo cofactor and the apoprotein by cystein and histidine have not been considered in this context). It is apparent that the concepts developed for inorganic host–guest chemistry through their application to biochemically relevant reaction processes can lead to first insights into the behavior of bioinorganic host–guest systems.

It is remarkable that the isolated cofactor, in contrast to the complete nitrogenase enzyme system, is not capable of reducing molecular nitrogen to NH_4^+ ions. But, once incorporated back into the apoprotein, the cofactor regains its full catalytic activity (cf. reconstitution test). The ability to reduce N_2 is, therefore, a new characteristic of the nitrogenase enzyme host–guest system, and not a property of its individual isolated components. The interaction of biosynthetic information carriers in the context of self-organization processes based on the initial properties of the individual components can lead, in the sense of emergent phenomena, to more complex host–guest systems with novel properties and new information content.

Another interesting example of a relevant bioinorganic host–guest system is ferritin,[172] an iron-storage protein that occurs in many higher organisms. Ferritin contains a core of about 4500 iron atoms and has a diameter of approximately 7.5 nm (its structure resembles the metastable mineral ferrihydrite and its stoichiometric composition that of an Fe^{III} hydroxydihydrogenphosphate $Fe_9O_9(OH)_8(H_2PO_4)$). This iron-containing core is enclosed by a protein shell that consists of 24 identical subunits (the whole structure has a diameter of about 12 nm). The subunits set up a spatial arrangement which is lined with channels. These channels serve to transport the iron atoms and, hence, have a *selective function* like their counterparts in zeolites. The nucleus formation (i.e. the nucleation phase) is most likely catalyzed by specific amino acid residues in the subunits of apoferritin and could start from an Fe^{III} oxide/hydroxide aggre-

gate.[172] Thus, this hypothetical "iron nucleus" would assume the *template function*. The subsequent growth phase, which leads to the formation of a quasi-crystalline assembly by a conservative self-organization process, is "terminated" by the finite size of the cavity. Formally speaking, ferritin is, therefore, an unusual host–guest system consisting of an organic host (the apoprotein) and a variable inorganic guest or guest system (the "iron" core). Depending on the external demand, "iron" can either be removed from this system or incorporated into it.

6 From Topology to Design of Supramolecular Compounds

The template-controlled linking of the simplest inorganic units can lead to a multitude of structures as is the case for the host–guest systems discussed in this article. In order to fully appreciate this variety of shapes, it is not enough to have an extensive knowledge of all interactions that regulate the concerted actions of host and guest fragments. During the analysis of structures, the boundary conditions that stem from metric and non-metric properties must also be considered. The methods of combinatorial topology and group theory should be utilized to determine which structures and shell formations (neglecting the terminal O atoms) are principally possible and which are not.[132b, 173] It was thus possible to demonstrate that the α-Keggin structure of the shell of the $[Mo_{12}O_{36}(PO_4)]^{3-}$ anion **80a** (Fig. 40 left) represents the only cluster shell which is

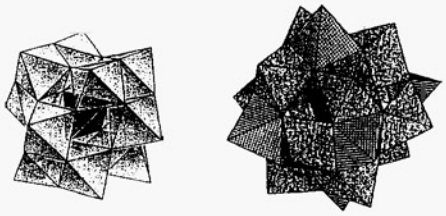

Fig. 40. Polyhedral representation of cluster anions with high symmetries which are built from MO_6 octahedra and exhibit a central O_4 tetrahedron: Left: $[Mo_{12}O_{36}(PO_4)]^{3-}$ **80a**; right: $[H_9V_{18}O_{42}(VO_4)]^{6-}$ **100a**.

formed by six octagons and eight hexagons *and* has tetrahedral symmetry.[174] A further example is given by the existence of a single polyhedron with tetrahedral symmetry and built up by eight hexagons and twenty-four rectangles, a structure that is found in the cluster shell of the anion **100a** (Fig. 40 right).[174, 175] On the other hand six rectangles, fourteen hexagons, and three octagons can form 539 different polyhedra with the lower D_{3h} symmetry.[174]

$[H_9V_{18}O_{42}(VO_4)]^{6-}$ **100a**

Evidently, such a combination of chemical knowledge, mathematical thinking, and computer methodology is also of significance for a synthetic strategy. For instance, the remarkable relationship between certain segments of the V_2O_5 layer structure and the surfaces of cluster shells of several polyoxovanadates (Fig. 41)[105, 143] can be used to gain an insight into the surface organization of host–guest systems, thus enabling the development of new ideas with respect to the prediction and

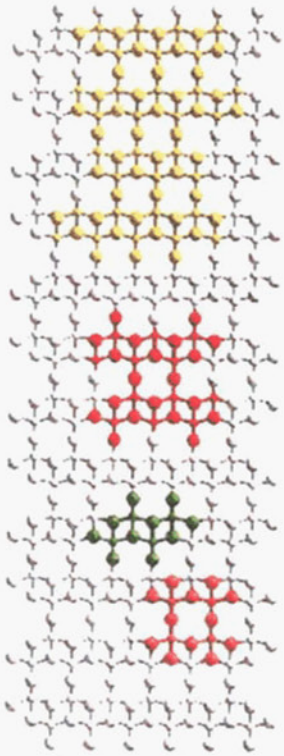

Fig. 41. Section of a layer of the V_2O_5 lattice; the terminal oxygen atoms are omitted (V small spheres, O large spheres). The $\{V_{30}O_{74}\}^{10-}$ cluster shell of **90a** can be derived from the yellow marked segment by removing the segment from one layer of the crystal lattice and linking these V–O segments in the appropriate manner (cf. ref. [143]). The same is valid for the $\{V_4O_{16}\}^{13-}$ shell of **82** and **83** (orange segment), the $\{V_{12}O_{32}\}^{4-}$ shell of **81** (red increment), and the $\{V_4O_{14}\}^{11-/12-}$ grouping [177] (green increment). The cluster shells $\{V_{15}O_{21}\}$, $\{V_{18}O_{24}\}$, and $\{V_{18}O_{28}\}$ of corresponding anions can also be interpreted as segments of the V_2O_5 layer structure [105].

discovery of novel supramolecular compounds. The application of the appropriate mathematical methods will not only contribute to the better understanding of the formation of metal–oxygen polyhedra, but also of other surface structures such as fullerenes.

Fullerenes are networks of sp^2-carbon atoms which are formed by 12 pentagons and n hexagons ($n > 1$; e.g., C_{60}: $n = 20$, C_{70}: $n = 25$). They resemble polyoxovanadates with respect to structure and cryptand functions. It is apparent that fullerenes, due to their large cavities, represent a promising starting point for a thus far largely unknown, but *preparatively accessible*, host–guest chemistry. The synthesis and characterization of endohedral fullerene complexes such as $Na_{12}C_{60}$, MC_{60}, MC_{70}, MC_{74}, (MC_{82}) (M = Y, Sc, La; Ce and other lanthanides), or La_2C_{82} indicate a rich potential for further developments.[176]

The variety of shapes that can be formed from oxygen atoms and/or metal centers is immense.[132b, 174] It is particularly remarkable that the 24 bridging oxygen atoms of two cluster shells with exactly the same stoichiometric composition $\{V_{18}O_{42}\}$ can appear either in the form of an Archimedean body (the O_{24} rhombicuboctahedron in $[H_9V_{18}O_{42}(VO_4)]^{6-}$ **100a**) or in that of the so-called "14th Archimedean body" (the O_{24} pseudo-rhombicuboctahedron in $[H_4V_{18}O_{42}(X)]^{9-}$ **66a–c** (see also ref. [8]).[119] Both cluster shells can formally be interconverted by the rotation of one half of the shell by 45° (see Fig. 42). Both types of polyhedra can also be formed, correspondingly by a Japanese cookie jar.[132a]

Topological considerations play an important role in the investigation of the template functions of multidimensional host structures that catalyze the generation of specific guest species such as zeolites (cf. Section 2.1.5). It would be advantageous to

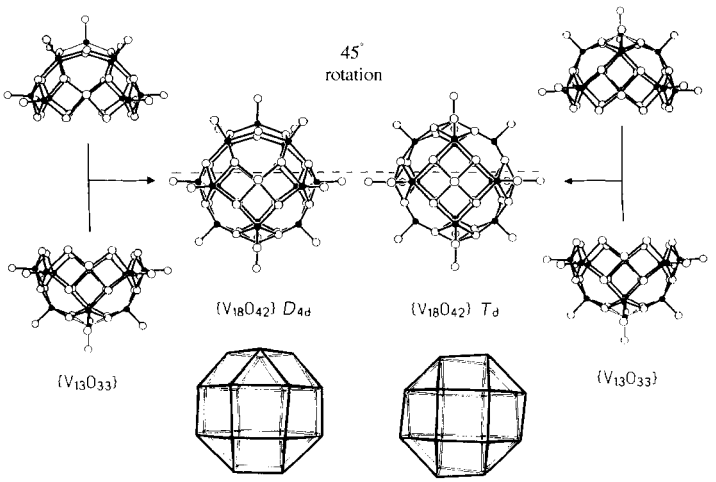

Fig. 42. Depiction of the $\{V_{18}O_{42}\}$ cluster shells in $[H_9V_{18}O_{42}(VO_4)]^{6-}$ in **100a** (right) and $[H_4V_{18}O_{42}(X)]^{9-}$ **66a–c** (left) using stick bonds (V black spheres, O white spheres) [119, 132a]. A rotation by 45° of one of the shell halves (the top part of the Japanese cookie jar mentioned in the main text) transforms the O_{24} rhombicuboctahedron (an Archimedean body) of the bridging oxygen atoms in **100a** into the O_{24} pseudo-rhombicuboctahedron (the so-called "14th Archimedean body") of the bridging oxygen atoms in **66a** (**81a** contains one VO group less than the $\{V_{13}\}$ fragment [8]).

know exactly how and why these reactions occur, and on what host–guest relationships they are based. This would enable the construction of a tailor-made host for the synthetic problem at hand.

7. Epilogue

"The sole task of the natural scientist is: to construct matter. (...) If the intent of a general theory of Nature would be to bring the infinite variations and depth of natural phenomena (...) to consciousness, it would have to be classified among the impossibilities."
F. W. J. Schelling[178]

The fundamental importance of chemistry for nearly all areas of science and even for society in general is nowadays rarely appreciated. However, the lack of appreciation for the importance of the sciences, and chemistry in particular, also appears to be a historical phenomenon, which can assume enormous significance in the context of a "rebelión de las masas". On May 8, 1794, Jean Baptiste Coffinhal, Vice-President of the Revolutionary Tribunal, decided on the fate of the chemist Antoine Laurent Lavoisier, who died on the guillotine the same day, with the following words: *"La République n'a besoin ni de savants ni de chimistes. Le cours de la justice ne sera pas interrompu."*[*] It therefore seems appropriate, along with the absolutely necessary intensive work in the laboratory, to recall the importance of the ideas of such men as Aristotle, Schelling, and Heisenberg. If the general public were to become aware of the importance and ubiquity of chemistry, the lack of acceptance, with which this science has to cope nowadays, would gradually disappear. Thus, let us recall the hylomorphism[180a] of Aristotle and the related scholastics, as well as Schelling's and others' romantic concepts of nature; this statement should, of course, be viewed within the context of the (contemporary) level of scientific knowledge at the particular time.[180b] We should attempt to find potentialities, propensities, or principles of material systems (e.g., in the sense of the results presented herein) in order to achieve a better understanding of how complex diversity arises from the linking of interacting basic structures (e.g., on the basis of reaction types that are of crucial relevance for both the (pure) material and biological world). Chemical research should consider principles and concepts that are of fundamental importance for events in the biosphere and also for the discovery of their primary causes; it should also consider terms of general importance such as complementarity,[181] emergence versus reduction,[182] intrinsic information, inherent properties of material systems, control, maybe even autopoiesis. Chemists have tended to forget that chemistry is a basic science. "He who has dedicated his life to the determination of individual connections and relations in nature is again and again, automatically, confronted by the question of how these individual connections fit harmoniously into the whole picture that is presented to us by *life* or the *world*."[183] We thus can and must (want to) learn from natural processes, also with respect to the development of new materials. In demand are substances with mesoscopic and supramolecular structures that exhibit novel complex interactions between their individual building blocks, which, in turn, can principally lead to ("unpredictable") emergent properties. In contrast to the "molecule-by-molecule" syntheses, these do not entail reactions that simply follow each other like a ceremonious changing of the guards, but rather which evolve one from the other in the sense of emerging developmental phenomena. The scientist is then challenged with respect to the possibility of reduction. The *dialectical unit of emergence and reduction* represents a guiding principle, which ought to be accepted as the essential basis for research, thinking, and comprehension in the area of empirical and semiempirical sciences. Even in our present special case of the formation and intentional creation of supramolecular inorganic host–guest systems, this "unit" can act as guiding principle: Small basic fragments with known properties can lead in the course of their reaction processes to very large complex (host–guest) aggregates with unexpected properties. We should realize that the mesoscopic area is relevant for information and functional carriers in nature.

The term *information*, according to the definition by Carl Friedrich von Weizsäcker ("Information is the measure of a certain amount of form. (...) Matter has form (...)."[184a]) can be used in this context to classify self-organization processes. In principle, reactions (processes) are based on the information that is stored —as previously noted by Monod[184b] —in the starting materials and on the type of interaction between these information carriers. Existing information thus creates new information: In chemical reactions, a growth phase can occur after a nucleation phase (as is the case, e.g., for the tobacco mosaic virus). This entails the opportunity to apply synthetic tricks or suitable strategies, depending on the information content, to further link large intermediates that have formed in the solution so as to finally yield giant systems such as those described in **93a** and **94a** (see Section 3.6). A simultaneous increase in the information content and the complexity as well as

[*] "The republic needs neither scholars nor chemists. The course of justice will not be halted" [179].

the differentiation on a nanoscale is observed. In terms of the validity of the algorithm "small becomes large and simple becomes complex", this corresponds to evolutionary processes in nature.

Conservative self-organization processes[137] play a major role during ontogenesis as non-gene-controlled reactions. Only a "clever" combination of dissipative and conservative self-organization, based on chance and necessity, could have initiated evolution within the possibility field of material systems. All real possibilities result from the preceding developments. This implies that there is no absolute, but only a relative chance.[185] The enormous importance of conservative processes, which in the final analysis lead to the multitude of appearances, has thus far not been realized in this context. For instance, the excellent writings of Eigen, Haken, and Prigogine lack detailed statements concerning the interacting dualism of conservative and dissipative self-organization.[186]

The ubiquity of chemical processes in our (pure) material and biological world is relevant for all areas of science. This fact must be acknowledged not only by the natural scientist, who, in the meantime, is in danger of becoming a slave to the modern trend towards specialization, but also by individuals concerned with the social sciences and humanities. It is, indeed, not surprising that on the one hand chemists ignore (or would like to do so) philosophical problems arising from the term matter, while on the other hand philosophers believe themselves to be able to investigate matter without any knowledge of chemistry whatsoever. (The philosophy of constructivism is of course in this context of no use.) An *extensive philosophy of chemistry* as companion to experimental chemistry which is itself always concerned with different kinds of interactions—maybe as causa finalis—would help to alleviate these deficiencies. (In fact, similar ideas were expressed by Boltzmann with respect to the necessary dialogue between philosophy and science.[187]) Only mutual interactions create that what could only be demonstrated here using a few simple examples, namely, the complexity of nature which is far from being understood in spite of the enormous growth of knowledge over the past few decades.

Dialogue poli entre un énergumène et un philosophe.[188]
L'Énergumène: *Qu'est-ce que la matière?*
Le Philosophe: *Je n'en sais pas grand'chose. Je la crois étendue, solide, résistante, gravitante, divisible, mobile; Dieu peut lui avoir donné mille autres qualités que j'ignore.*[*]
Voltaire

The financial support of the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, and the state of Nordrhein-Westfalen (Bennigsen-Foerder Award; H. R.) is gratefully acknowledged. H. R. is indebted to Dr. R. Hundt (Bonn) for numerous discussions concerning the graphic depiction of crystal structures[190] *and his constant efforts to adapt his program KPLOT according to the results of these discussions. A. M. and S. D. thank Dipl.-Chem. H.-J. Westphal for preparing several of the figures, Dipl.-Chem. E. Krahn for his valuable assistance in preparing Section 5, as well as all co-workers mentioned in the references.*

Received: October 28, 1994
Revised version: June 22, 1995 [A 921E]
German version: *Angew. Chem.* **1995**, *107*, 2505–2539
Translated by Dr. W. C. Wilisch, Ansbach, Germany

[*] Polite discourse between a possessed man and a philosopher.
The possessed: *What is matter?*
The philosopher: *I do not know much about it, either. In my opinion it is spread out, firm, resistant, heavy, divisible, and mobile. The Lord might have given it a thousand further properties, of which I know nothing* [189].

[11] This term was initially developed by Simard et al. to designate molecules that have the ability to form networks similar to H_2O (M. Simard, D. Su, J. D. Wuest, *J. Am. Chem. Soc.* **1991**, *113*, 4696). The definition proposed here implies that H_2O is the equivalent for a $^{[en]}T_4$-4P tecton, which is stable and can, therefore, also be utilized as an actual reagent.
[12] E. J. Corey, *Pure Appl. Chem.* **1967**, *14*, 19. While this term was initially used in its original meaning (cf. D. Seebach, *Angew. Chem.* **1979**, *91*, 259; *Angew. Chem. Int. Ed. Engl.* **1979**, *18*, 239), it was later applied in a more general sense (cf. E. J. Corey, *Chem. Soc. Rev.* **1988**, *17*, 111; D. Seebach, *Angew. Chem.* **1990**, *102*, 1363; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 1320).
[13] Many tectons will be recognizable as building blocks known from structural chemistry. It is important, however, to distinguish here between the two terms: Tecton should only be used in the area of retrosynthesis, while building block (or structural unit) should only be used in the context of structural descriptions. But the term tecton could not be consequently used in this review, since the relevant description of most of the structures, in the context of planning the synthesis, is not possible according to current knowledge.
[14] One of the authors (H. R.) is currently conducting studies to clarify this question.

[23] The *alkylamine hydrates* $m H_2O \cdot n$amine are closely related, both chemically and topologically, to the gas and liquid hydrates. In the few compounds that have been structurally characterized thus far, the host structure can be described within wide boundaries in analogy to the gas and liquid hydrates, that is, with the concept of face-linked water polyhedra. However, these polyhedra are very much more varied in the case of the alkylamine hydrates and the pentagonal dodecahedron, which is characteristic for the two other classes of compounds, is not found at all. There are only a few cases, such as the *tert*-butylamine hydrate $156\,H_2O \cdot 16\,t\mathrm{BuNH_2}$ (R. K. McMullan, T. H. Jordan, G. A. Jeffrey, *J. Chem. Phys.* **1967**, *47*, 1218), of real clathrates with only weak van der Waals interactions between guest and host. In most cases, the amine within a void is bound by hydrogen bonds to the framework of water molecules (e.g., propylamine hydrate $26\,H_2O \cdot 4\,n\mathrm{PrNH_2}$; cf. C. S. Brickenkamp, D. Panke, *J. Chem. Phys.* **1973**, *58*, 5284).

[44] New studies on ionic compounds of the type A_3X with large cations A (A. Müller, E. Diemann, E. Krickemeyer, H. Bögge, C. Menke, C. Kuhlmann, *Monatsh. Chem.*, in press) have shown that these ions form densely packed host structures which are mainly held together by van der Waals interactions. While these host structures cannot be compared topologically/structurally to classic clathrates, they do force the comparatively small anion into adapting its geometry to the cationic host matrix.

[102] The calculated sum of the bond valences indicates that the twelve μ_2-O atoms, each of which bridges two Mo^V centers of two neighboring Mo_2^V dumbbells are, in fact, μ_2-bridging hydroxyl groups. These form hydrogen bonds (270 pm) to the oxygen atoms of the $\{Mo^{VI}O_3\}$ moieties. This shows that the highly negatively charged, nucleophilic central $\{Mo_{12}O_{40}\}^{20-}$ unit is stabilized by both protonation and aggregation with electrophilic $\{Mo^{VI}O_3\}$ groups. The hydrogen bonds apparently play a crucial role in this stabilization.

[121] The increase of the proportion of V^V centers leads principally to a larger attraction between shell and central anion and can even lead to the formation of smaller shells like $\{V^V_2V^{IV}_8O_{36}\}^{5-}$ with an incorporated Cl^- or Br^- ion; cf. A. Müller, E. Krickemeyer, M. Penk, H.-J. Walberg, H. Bögge, *Angew. Chem.* **1987**, *99*, 1060; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1045.

[122] a) A. Müller, F. Diemann, C. Menke, unpublished; b) A. Müller, D. Sölter, unpublished.

[123] The reaction conditions employed are of prime importance. For instance, the cluster anions $[V^{IV}_{18}O_{42}(H_2O)]^{12-}$ **72a** [124, 125] and $[H_4V_{18}O_{42}(X)]^{9-}$ **66a–c** [119] (X = Cl, **66a**; Br, **66b**; I, **66c**) are formed at different pH values: While **66a** is formed as the sole product at a pH value of 8, at pH = 14 only **72a** is formed from the same reaction mixture (i.e., despite the presence of chloride ions). This result raises, principally, the question whether **72** might not be the mixed-valent species $K_{12}[V^{IV}_{17}V^{V}O_{42}(OH)]\cdot 15H_2O$ with an encapsulated OH^- ion rather than $K_{12}[V^{IV}_{18}O_{42}(H_2O)]\cdot 15H_2O$ **72**. In this context, it must be noted that neither X-ray crystal structure analyses, nor elemental analyses including manganometric titrations can distinguish for example between $\{V^{IV}_{18}O_{42}\}$ and $\{V^{IV}_{17}V^{V}O_{42}\}$ host shells (it has to be assumed that the incorporation of a negatively charged guest into a $\{V_{18}O_{42}\}$ shell is inhibited when only V^{IV} centers are present). Compounds which contain different numbers of disordered H atoms but otherwise have identical stoichiometries, such as $K_9[H_4V^{IV}_{18}O_{42}(Cl)]$, $K_9[H_3V^{IV}_{17}V^{V}O_{42}(Cl)]$, and $K_9[H_2V^{IV}_{16}V^{V}_2O_{42}(Cl)]$ can, according to current knowledge, predominantly be distinguished by ESR and magnetic susceptibility measurements. (This gives evidence for the abundance of $\{V^{IV}_{16}V^{V}_2\}$ shells in the case of **66a–c**). In the meantime, we have been able – in contrast to earlier work (cf. ref. [124])—to determine the exact number of cations in the compound with the anion **72a** by X-ray crystallography, a prerequisite to solve the problem at hand. The (correct) formula of **72** was estimated in ref. [124] and only recently proven in ref. [125] (see comments in ref. [131a], p. 39).

[131] a) Cf. M. T. Pope, *Heteropoly and Isopoly Oxometalates*, Springer, Berlin, **1983**; *Nature* **1992**, *355*, 27; b) The cluster anion **79a** can be derived from an O_{24} rhombicuboctahedron, one of the 13 Archimedean bodies (see also ref. [132]), by capping its twelve [110]-O_4 faces with four VO^{2+}, six MoO^{4+}, and two As_2O^{4+} units, and three of its six [100]-O_4 faces with a VO^{2+} group (Fig. 27). Formally speaking, the highly negatively charged pseudo-α-Keggin ion **79c** is stabilized in solution by the VO^{2+} moieties occupying the [100]-O_4 faces (see also ref. [133]).

$\{Mo^{VI}_6V^{IV}_4(As^{III}_2O)_2O_{34}(SO_4)\}^{10-}$ **79c**

[132] a) A. Müller, M. Penk, *Chem. Unserer Zeit* **1990**, *24*, 258; b) A. Müller, M. Penk, J. Döring, *Inorg. Chem.* **1991**, *30*, 4935; see also ref. [8].

[133] It should be noted in this context that in the host–guest systems $[H_4V_{18}O_{42}(X)]^{9-}$ **66a–c** [119] the V^{IV} centers exclusively form square VO_5 pyramids, while in the cluster anion $[Mo_{12}O_{36}(PO_4)]^{3-}$ **80a**, the Mo^{VI} atoms are all present in the form of MoO_6 octahedra. In addition, in **80a**, the interaction of the oxygen atoms of the formally encapsulated PO_4^{3-} tetrahedron with the neighboring Mo^{VI} centers is so strong that one can no longer talk about a host–guest interaction. On this basis, the encapsulated sulfate ion of **79a** occupies an intermediate position with respect to its nucleophilicity and basicity between the halide ions of **66a–c** and the phosphate ion of **80a**. This correlates with the fact that the extremely different interactions present in the host–guest system **66a–c** and the anion **80a** cannot fully develop between the isopolyoxometalate shell and the central unit in the cluster anion **79a**. Hence, **79a** occupies an intermediate position between the anions **66a** and **80a**. The strong interaction of the Mo^{VI} centers Mo5 and Mo6 with the oxygen atoms O42 and O43 (see Fig. 27) of the central sulfate ion causes the electron density at the two other oxygen atoms O40 and O41 to be reduced. Thus O40 and O41 can—even for this reason –only weakly interact with the V^{IV} centers which is evident from the corresponding distances. Only this combination of weak and strong interactions appears to enable the formation of **79a**, with its unusually low C_2 symmetry.

[134] W. Priebsch, D. Rehder, M. von Oeynhausen, *Chem. Ber.* **1991**, *124*, 761. In this report, compound **82** was incorrectly described as a $(V^V)_4$ cluster with a $V_4(\mu_2\text{-}O)_4$ central core. However, **82**, in fact, is a $V^{IV}(V^V)_3$ cluster with a central $V_4(\mu_2\text{-}O)_3(\mu_2\text{-}OH)$ group. Cf. the authors' correction in ref. [135].

[137] In this case, the term "self-organization" is applied to the phenomenon of the spontaneous formation of "ordered" structures in or close to equilibrium conditions. This is generally termed "conservative self-organization". During the syntheses of the cluster anions **84a** or $[V_{34}O_{82}]^{10-}$ **90a** (see Section 3.5) the "ordered" cluster structures are presumably formed by the influence of an initially formed moiety (possible examples are the cation/anion aggregate $(2NH_4^+, 2Cl^-)$ of **84a** or the central $\{V_4O_4\}(O_{term})_4$ cube in **90a**), which directs and "reinforces" the subsequent condensation processes. Because of weak interactions the central cores act as templates which determine, by a process of "molecular recognition", the symmetry, form, and structure of the cluster shells (see Sections 3.2.2, 3.3, and 3.5). This special case of a conservative self-organization process can thus be called a template-directed or "induced self-organization". The term "conservative self-organization" can also be formally applied to magnetic systems, such as the host–guest system $[V_{15}As_6O_{42}(H_2O)]^{6-}$ **99a** (see Section 4.1) which at low temperatures, exhibit layers of different magnetization. Another interesting aspect in the context of conservative self-organization processes is the following: The directing agent correlates the fragments, or "enslaves" them by forcing them into a certain system or order. But the term "correlation" is generally applied to dissipative structures by Prigogine: "The equilibrium state is a singular condition, in which the correlation between different parts of the system is zero." (cited from: I. Prigogine, I. Stengers in *Selbstorganisation, Bd. I*, (Eds.: U. Niedersen, L. Pohlmann) Duncker & Humblot, Berlin, **1990**, p. 3). In contrast to conservative self-organization processes, the term "dissipative self-organization" is applied to nonlinear, irreversible processes, which operate far from equilibrium and lead through the cooperative interactions of subsystems to the complex structures of the final system. A well-known example for such a dissipative self-organization process in chemistry is the Belousov–Zhabotinsky reaction.

[138] M. I. Khan, J. Zubieta, *Angew. Chem.* **1994**, *106*, 784; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 760.

[139] The exchange of the contents of the two truncated cones occurs in the following manner: **86** has a closed, nano-sized cavity with two attached open truncated cones (or ion channels), formed by the phenyl rings. Within each of the two truncated cones, there is a sodium ion with two coordinated water molecules and one dimethylformamide molecule. The distorted octahedral environment of the Na^+ ion is completed by two oxygen atoms of the coronand (a nucleophilic shell fragment of the [16]crown-8 type, built from four $(Ph\text{-}PO_2)$ units and four vanadium atoms) as well as by a water molecule positioned in the center of the coronand. If **86** is treated with an approximately thirteenfold excess of rubidium bromide in a 1:1.3 mixture of water and dimethylformamide, one obtains the compound **87**. In the center of the coronand of **87** there is now, instead of the water molecule in **86**, a Rb^+ ion which in contrast to the Na^+ ion, fits exactly into the coronand. This exchange of guests in the truncated cones of **86** leads to a significant reorganization and migration of the particles in the central cavity: During the reaction a water

molecule "migrates" from its position in **86** to the new position in **87**, where it serves as a bridging function between two vanadium centers. The azide ion "orients" itself between the electrophilic centers (the V^V atom of the $\{V_5O_9\}^{3+}$ unit and the Rb^+ ion in the center of the coronand). Hence, the reaction **86** → **87** occurs under retention of the host lattice (A. Müller, K. Hovemeier, E. Krickemeyer, H. Bögge, *Angew. Chem.* **1995**, *107*, 857; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 779). A further proof for the stability of the cluster anions derived from $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ **84b** lies in the isolation of the oxidized anion **88a**. One obtains **88a** by the air oxidation of the species **89a**; all V^{IV} atoms of the electrophilic $\{V_5O_9\}^{3+}$ unit of **89a** are oxidized to V^V

$[2\,Rb^+, 2\,Cl^- \subset V_{12}O_{20}(OH)_4(H_2O)_2(PhPO_3)_8]^{4-}$ **88a**
$[2\,Rb^+, 2\,Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ **89a**

centers and the $\{V^V{=}O\}^{3+}$ caps contained in **89a** are cleaved off (A. Müller, K. Hovemeier, H. Bögge, unpublished results). (The symbol ⊂ from set theory is only used for guests which represent aggregates.)

[140] M. L. Connolly, *Science* **1983**, *221*, 709; M. L. Connolly, *J. Appl. Cryst.* **1983**, *16*, 548.

[141] Cited by Aristotle, *De generatione animalium*, V 8. 789b, 2f. See also F. Jürss, *Griechische Atomisten*, Reclam, Leipzig, **1977**, p. 129, with respect to the Aristotelian works *De generatione animalium* and *Physica* (cf. in particular II 4, 195b 36ff.).

[142] The term "cluster within a cluster" appears justified to us in the case of **90a** due to the presence of $V{=}O_{term}$ groups in the central $\{V_4^{IV}O_4\}(O_{term})_4$ cube (with the stoichiometry of $V^{IV}O_2$; cf. ref. [108]). (The cluster definition used here corresponds to the usual procedure with respect to the topological and electronic requirements; the metal–metal interactions can vary from weak to strong.) The dark blue amphoteric VO_2 can be precipitated from the aqueous solution (cf. ref. [108]).

[143] W.G. Klemperer, T. A. Marquart, O. M. Yaghi, *Angew. Chem.* **1992**, *104*, 51; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 49.

[144] Similar arguments are valid for the anion $[Na(H_2O)_3Mo_{42}H_{15}O_{109}\{(OCH_2)_3(CCH_2OH)\}_7]^{7-}$ **56a** [103], which has a structure that differs from that of **91a** in that all seven $[(CH_2)_3CCH_3]^{3+}$ groups have been replaced by the corresponding number of $[(CH_2)_3CCH_2OH]^{3+}$ units and that the facial $\{Mo^{VI}O_3\}$ group, which is a remnant of the original $\{Mo_{16}O_{52}\}$ framework of **54a**, has been substituted with a $\{Na(H_2O)_3\}^+$ group (see also H. K. Chae, W. G. Klemperer, T. A. Marquart, *Coord. Chem. Rev.* **1993**, *128*, 209). The cluster anions **54a** and **55a** are, in turn, built up of $\{Mo_2^V\}_3$ hexagons. These can be "intercepted" under the right reaction conditions (given the required template *and* the appropriate Mo^V/Mo^{VI} ratio), as is demonstrated by the synthesis of **92**. Compounds **54**, **55**, and **92** contain formally the same $\{(Mo_2^VO_4)_3(\mu_2\text{-}OH)_3\}^{3+}$ units [145].

$Na_7(N_2H_4)_2[Na\{(Mo_2^V)_3O_{12}(\mu_2\text{-}OH)_3(PhPO_3)_3(PhPO_3H)\}_2]\cdot 26\,H_2O$ **92**

[145] A. Müller, S. Dillinger, H. Bögge, unpublished results. The cluster aggregate **92a** contained in **92** exhibits two $(Mo_2^V)_3$ units, which are linked by a

$[Na\{(Mo_2^V)_3O_{12}(\mu_2\text{-}OH)_3(PhPO_3)_3(PhPO_3H)\}_2]^{7-}$ **92a**

Na^+ ion in the crystal; cf. the similarly structured, sandwich-type compound $Na_3(H_3O)_4[NEt_4]_2[Na\{(Mo_2^V)_3O_{15}(PhPO_3)(PhPO_3H)_3\}_2]\cdot 14\,H_2O$ in G. Cao, R. C. Haushalter, K. G. Strohmaier, *Inorg. Chem.* **1993**, *32*, 127. In this direct self-organization process, the phenylphosphonic acid (component 1) directs the synthesis of **92** in concert with Na^+ ions (component 2). The reaction occurs under reducing conditions ($Mo^V/Mo^{VI} = 12{:}0$). If one of those two components is lacking, the anion **54a** is formed when the Mo^V/Mo^{VI} ratio is adjusted appropriately (3:1).

Schröter), 2nd main volume (Schriften zur Naturphilosophie 1799–1801), Beck'sche Verlagsbuchhandlung, München, **1927**, p.635. According to Schelling "to construct" implies a "rational catching up with the evolutionary process".

[179] For the judicial murder of the chemist Lavoisier see: J. B. von Weiss, *Die Französische Revolution, Vol. 4*, Styria, Graz, **1930**, p.294. Together with 31 other landlords, Lavoisier stood accused of alleged fraud during his term as supervisor of the regions of Lorraine and Flanders. He "foresaw the verdict and requested only a stay of execution for 14 days, in order to complete an important study on which he had worked for many years; he then would gladly die as he had sacrificed his life for his country" (*ibid.*, p.295). Coffinhal had no sympathy for this request and gave the cited response.

[180] a) Hylomorphism is based on the assumption that every natural object is composed in some manner of (unstructured) matter (Greek *hylè*) and form (Greek *morphé*); b) important are the Arabian natural scientists of the Middle Ages Averroës and Avicenna (Aristolian leftists).

[181] The principle of complementarity controls many important biological processes (e.g. immunological ones). With the help of computer models, it was, for instance, possible to confirm the complementarity between the fullerene C_{60} and the protease which is essential for the replication of the HI-virus. Cf. S. H. Friedman, D. L. DeCamp, R. P. Sijbesma, G. Srdanov, F. Wudl, G. L. Kenyon, *J. Am. Chem. Soc.* **1993**, *115*, 6506.

[182] In philosophy, the appearance of new qualities and developmental levels due to evolutionary processes is termed emergence (Latin *emergere* = to surface, to become visible, to come out, to come into being). Emergent developmental phenomena are characterized by the either sudden or slow generation of something new in the sense of the appearance of new qualities. Emergent properties of complex systems can no longer be described solely by those theories that apply to the isolated components that make up the complex system. The concept of emergence encompasses not only dissipative, but also conservative self-organization processes. This may be the case when the aggregation of small building blocks (e.g., MoO_4^{2-} and VO_4^{3-} ions) leads, by conservative self-organization, to the generation of extremely large cluster species (e.g., **93a**) which have new characteristics that can no longer be explained (or at least not be predicted) by the properties of the isolated components, but only exist due to the mutual interactions (e.g., magnetic exchange interactions) of these system components (cf. A. Müller, *J. Mol. Struct.* **1994**, *325*, 13).

F. von Weizsäcker, *Aufbau der Physik* (*Structure of Physics*), 1st ed., dtv, Stuttgart, **1988**, p.167; b) see also Monod's comments "Comme dans un cristal, c'est la structure même des molécules assemblées qui constitue la source d'*information* pour la construction de l'ensemble." (J. Monod, *Le Hasard et la Nécessité*, Éditions du Seuil, Paris, **1970**, p. 102).

[185] Cf. for example H. Hörz, *Zufall. Eine philosophische Untersuchung*, Akademie Verlag, Berlin, **1980**.

[186] See for example H. Haken, A. Wunderlin, *Die Selbststrukturierung der Materie*, Vieweg, Braunschweig, **1991**. Fundamental questions we have to ask are whether complex near-equilibrium systems were a necessary basis for the formation of dissipative structures during evolution and whether it is possible to create molecular complexity stepwise by a conservative growth process corresponding to the following schematic description:

$$\begin{array}{ccccccc} \mathbf{I} & \Rightarrow & \mathbf{III} & \Rightarrow & \mathbf{V} & \Rightarrow & \mathbf{VII} \qquad (2N-1) \\ \Updownarrow & & \Updownarrow & & \Updownarrow & & \\ \mathbf{2} & & \mathbf{4} & & \mathbf{6} & & \qquad (2n) \end{array}$$

Here, the uneven Roman numerals, $2N-1$, represent a series of maturation steps of a molecular system in growth or development and even Arabic numerals $2n$ stand for ingredients of the solution which react only with the relevant "preliminary" or intermediate product, $2N-1$. The species $2n$ can themselves be products of self-assembly processes. The target molecule at the "end" of the growth process would be formed by some kind of (near-equilibrium) symmetry breaking steps. The information it carries could, in principle, be transferred to other systems (A. Müller et al. unpublished).

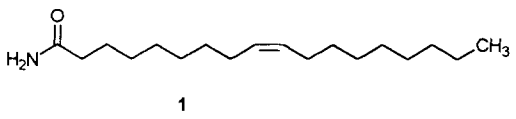
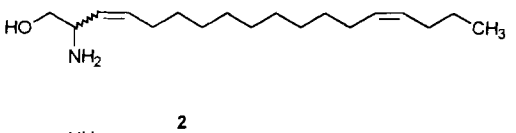
New Brain Lipids that Induce Sleep

Thomas Kolter and Konrad Sandhoff*

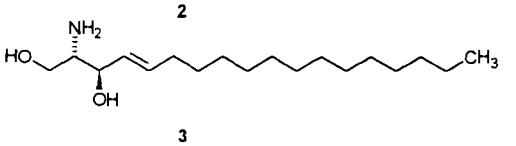
In search of endogenous factors with sleep-inducing properties, Lerner et al. isolated a substance from the cerebrospinal fluid of cats that had been deprived of sleep for 22 hours.[1] In a further publication the unknown compound was characterized as the amide **1** of an ω-9-unsaturated fatty acid with a (*Z*) double bond.[2] The substance, which could not be detected in cats under control conditions, was isolated by reversed-phase HPLC in amounts of 0.1 to 5 pmol per 100 µL of cerebrospinal fluid. Mass spectrometric analysis revealed *m/z* 304.2614 for the $[M + Na]^+$ ion, which best fits the formula $C_{18}H_{35}NO$ having two double-bond equivalents. The ready loss of a neutral 17 Da fragment from the $[M + H]^+$ ion suggests the cleavage of a primary amino group as ammonia. Based on these and further spectroscopic data (UV, ^{1}H NMR), the substance was initially proposed to be a "cerebrodiene", for example **2**.[1] The postulated structure suggested that **2** may arise biosynthetically from sphingosine **3** or other sphingolipids and thus attracted considerable attention,[3] since several intermediates of sphingolipid metabolism are currently discussed as potential signaling molecules.[4]



1



2



3

The final assignment of structure **1** to the unknown compound succeeded by comparison of the spectroscopic data to those of model substances.[2] The position of the double bond was determined after ozonolysis and its configuration by IR and ^{1}H NMR spectroscopy. Moreover, it could be shown in a functional assay that intraventricular injection of 10 nmol (2.8 µg) of synthetic **1** induced sleep in laboratory animals. Variation of double-bond configuration, position, and alkyl chain length resulted in decreasing extent and duration of the observed effect. Further, it was shown that membrane fractions isolated from brain rapidly degrade **1** into oleic acid.

The crucial assumption in this study is an idea that originated at the beginning of our century. Henri Piéron[5] postulated the existence of a sleep-inducing substance that is formed in the course of the day, accumulates, and is destroyed during sleep. To verify this hypothesis, Piéron collected cerebrospinal fluid from dogs that had been deprived of sleep for several days. He injected the fluid into the ventricles of other dogs, which then promptly fell asleep for two to six hours.

In recent years several substances with sleep-promoting factors have been discovered,[6] including the delta sleep inducing peptide,[7] which was isolated from the blood of sleeping rabbits and led to sleeplike behavior after intraventricular infusion into rabbit brain (δ-slow wave sleep). Prostaglandin D_2[8, 9] also meets most of the requirements of a sleep substance:[10] 1) The substance must induce sleep. 2) The induced sleep must be natural. 3) A dose–response curve must be demonstrated. 4) Sleep must be followed by appropriate wakefulness. 5) The substance must be present in the brain. 6) There should be binding sites for the substance in the central nervous system. 7) Receptor blockers should prevent sleep induction. 8) Direct application to regions of high binding should induce sleep. 9) The substance should have appropriate circadian changes. 10) Inhibition of synthesis of the substance should reduce sleep. 11) Metabolic pathways should be known. 12) Relevant enzymes should be present in appropriate regions. 13) The substance should accumulate with prolonged wakefulness. 14) Its concentration should decrease with prolonged sleep. 15) The substance should be present in several species. Additional substances[6, 12] discussed as potential sleep promoting factors include interleukin 1, interferon α2, lipopolysaccharides, muramyl peptides, serotonin, tumor necrosis factor, and vasoactive intestinal peptide. The relationship between substances apparently acting as neurotransmitters and neuromodulators and the phenomenon of sleep is far from clear.

Sleep is one of several circadian rhythms, which, genetically controlled, are synchronized with the change of day and night as the most important environmental factors.[11] Several stages of sleep can be distinguished, which follow each other in a predictable manner and appear to be controlled by different neurochemical systems.[12] The stages of sleep (and of other circadian

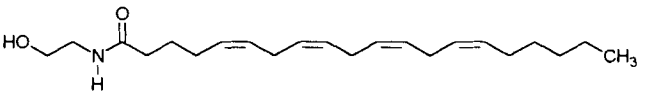
processes) are affected differently by drugs in pharmacological intervention.[13]

During a typical night's sleep, the adult human progresses through different sleeping periods in a predictable manner, which can be distinguished electrophysiologically (slow wave sleep) and by the occurrence of rapid eye movements (REM sleep). Slow wave sleep and REM sleep alternate four to six times a night with increasing duration of REM sleep but decreasing duration and depth of slow wave sleep.[12]

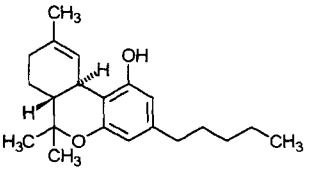
Slow wave sleep is characterized by progressively longer wavelengths and amplitudes in the electroencephalogram (EEG). During slow wave sleep, humans pass through up to four levels, which are accompanied by successive lower heart frequency, decreasing blood pressure, and deeper sleep. After about 45 minutes these levels are retraced in the opposite order. After a total of about 90 minutes several abrupt physiological changes occur, and the EEG becomes similar but not identical to that of the waking state. Different names are used for this state: REM sleep, paradoxical sleep, active sleep, and desynchronized sleep. The active EEG patterns are coupled with a loss of muscle tone and rapid eye movements occur. According to the criterion of arousability by external influences, REM sleep is the deepest; however, spontaneous waking occurs most easily. When humans are awakened from REM sleep, dreams are much more easy remembered than when they are awakened from slow wave sleep. On the other hand, definite nightmares occur predominantly in stages three and four of slow wave sleep, the so-called delta sleep.[12] Barbiturates and ethanol suppress REM sleep, while benzodiazepines, for instance, reduce the fourth and deepest stage of slow wave sleep to a much greater extent than REM sleep.

Just as unsuccessful as the search for a universal sleep-inducing substance was the search for a single sleep center in the brain.[12] Stimulation of neurons at different anatomical locations induced sleep. Selective destruction of these cells led to insomnia in laboratory animals. Neurons of the brain stem that use serotonin as neurotransmitter seem to responsible for induction and maintenance of slow wave sleep. Injection of serotonin into these regions induces sleep, and application of *para*-chlorophenylalanine, an inhibitor of serotonin biosynthesis, causes insomnia as expected. However, after one week of daily injection of the inhibitor it is observed that in spite of low serotonin levels sleeping behavior normalizes and reaches 70% of the control values.

Let us return to the relatively simple structure of **1**, which might play a role in the complex phenomenon of sleep. Several questions are still unanswered. It remains to be clarified how the substance is metabolized, how the metabolism is regulated, and whether it can be attributed to regions of the brain that are responsible for the induction and maintenance of sleep.[10] The isolation of another long-chain carboxylic acid amide with biological function from brain has attracted attention to this class of compounds. In a screening process, anandamide **4**, tee ethanol amide of arachidonic acid has been identified as an endogenous ligand of the cannabinoid receptor (K_i = 52 nM).[14] In a functional assay it gave the same physiological response and behavior as Δ^9-tetrahydrocannabinol (**5**), the active con-



4



5

stituent of hashish and marijuana. Brain membranes are able to synthesize **4** from ethanolamine and arachidonic acid, which should be accessible from phospholipids of the plasma membrane on action of phospholipase D or A2.[15] It remains to be seen whether more than a structural similarity exists between **1** and **4**, and further, whether the findings of the authors[1, 2] will contribute to the answer of the still-open question of how sleep "functions". Since nature, and maybe also sleep, is organized hierarchically, the question of why we need to sleep at all can presumably not be answered on the molecular level alone.

Aligning and Trapping Molecules with Light

Lothar Kador*

The investigation of absorbing particles (atoms, ions, or molecules) trapped in various environments has yielded important insight into the fundamental structure of matter and has opened the door to exciting new fields of spectroscopy. Trapping in vacuum is most easily accomplished for ionized atoms, which, due to their charge, can be confined in radio-frequency electromagnetic traps (Paul traps). In this way quantum-optical effects such as quantum jumps[1] and photon antibunching[2] were observed on single ions. Photon antibunching is the phenomenon of a two-level system's inability to emit two photons arbitrarily fast after one another. Neutral atoms can be trapped by a tightly focused laser beam, since the electric field of the light induces a dipole moment, which, in the classical picture, pulls the atom towards the region of the highest field strength. Results of quantum-mechanical calculations show that this works only if the laser frequency lies below the resonance frequency of an atomic transition.[3, 4] Typical numbers of stored atoms in such dipole force traps are on the order of 10^3; consequently, cold atomic collisions or collective effects, for instance, can be studied. The storage time of the atoms (around seconds) is usually limited by collisions with the residual gas.

For molecules the situation is less favorable. Ionizing molecules is often problematic, because the ionization tends to make them less stable and, hence, favors dissociation. Moreover, molecules have far more internal degrees of freedom than atoms. Thus, in addition to the electronic states, vibrations and rotations and combinations thereof can be excited. As a consequence, cooling molecules to below 1 K in vacuum is difficult, since all these possible excitations must be frozen out, in addition to drastically reducing the translational temperature.

A way around this problem is to investigate molecules that are not in vacuum but are embedded in a solid at liquid-helium temperatures. In the solid environment, rotations are usually not possible, and the molecule is spatially confined. The optical spectroscopy of single, large organic dye molecules in transparent crystals or glasses has almost become a standard technique.[5, 6] In a crystalline environment, the phase relaxation of the electronic transition is often negligible at low temperatures, with the result that the spectral linewidth can be very narrow and can reach the limit determined by the lifetime of the excited state. Nevertheless, the spectroscopic characteristics of the dopant molecules are still influenced by interaction with the solid environment to a large degree. A simple example is the spectral position of the absorption line, which differs from its value in vacuum by a solvent shift or gas-to-crystal shift. Therefore, trapping and cooling molecules in a vacuum chamber to avoid these interactions is still a challenging goal.

A recent theoretical article[7] showed that this should indeed be possible. A prerequisite for spatial trapping of molecules is a means to provide a localized region where an attractive potential exceeds the molecular kinetic energy. In principle, this might be done with a very strong static electric or magnetic field, provided that the molecules have permanent dipole moments. The remarkable new scheme proposed by Friedrich and Herschbach,[7] however, utilizes the high oscillating electric field strength of intense laser radiation to attract the molecules by means of induced dipole moments. Since all molecules are polarizable, this technique has a much wider applicability. When, as in most cases, the molecular polarizability is anisotropic, the interaction with the laser field will also align the molecules. In diatomic molecules, for instance, the polarizability along the molecular axis will always be larger than perpendicular to it. Friedrich and Herschbach's study was motivated by a previous experiment,[8] which provided evidence that CO molecules of thermal energy can be aligned by a strong pulsed laser field of intensity $I \approx 10^{14}\ \mathrm{Wcm^{-2}}$ and pulse duration between 1 and 30 ps. Yet, the calculation shows that even an intense, tightly focused continuous-wave (cw) infrared laser of a few kW power (with an intensity around $10^{11}\ \mathrm{Wcm^{-2}}$ in the focus) should be sufficient for trapping as well as alignment. Permanent electric dipole moments are not a factor, because the electric light field oscillates too fast to reorient a molecule according to its permanent moment. (Molecular rotational frequencies are located in the microwave spectral region.) The induced dipole moment causes a molecule to be pulled along the gradient of increasing field strength; consequently, in the focal region of the laser there is a conservative trapping potential, as in the case of neutral atoms.[4] Hence, the proposed method is extremely simple: both aligning and trapping of the molecules is performed by a single focused laser beam.

The Schrödinger equation of a linear molecule in a strong laser field is described by Equation (a),[7] where B denotes the rotational constant, $\boldsymbol{J}^2$ the squared angular momentum operator, and the angular potential is given by Equation (b).

$$[B\boldsymbol{J}^2 + V_a(\theta)]\,\Psi = E\Psi \qquad \text{(a)}$$

$$V_a(\theta) = -\tfrac{1}{2}\varepsilon^2(\alpha_{\parallel}\cos^2\theta + \alpha_{\perp}\sin^2\theta) \qquad \text{(b)}$$

The polarizabilities $\alpha_{\parallel}$ and $\alpha_{\perp}$ are the components parallel and perpendicular to the molecular axis, respectively, and θ is the angle between this axis and the polarization direction of the light. The electric field ε oscillates according to $\varepsilon = \varepsilon_0 \cos(2\pi\nu t)$. Note that its frequency ν must be off-resonant so that neither electronic nor vibrational transitions can be induced. Equation (a) cannot be solved in closed form. However, accurate numerical solutions are readily obtained, and analytical perturbation expansions are possible for the limiting cases of low and high field strength. For $\varepsilon = 0$, the problem reduces to that of a free rotor whose eigenfunctions Ψ are spherical harmonics and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1995 0570-0833/95/3421-2365 $ 10.00+.25/0

whose eigenenergies are given by $E = J(J+1)B$ with the rotational quantum number $J = 0, 1, 2, \ldots$

Equation (b) shows that the angular potential of the light field is purely attractive, since the polarizabilities $\alpha_{\parallel}$ and $\alpha_{\perp}$ are always positive. For $\alpha_{\parallel} \neq \alpha_{\perp}$, it has the form of a double-well potential with two minima and two maxima in a full circle of 360°. Hence, the molecular states that are bound by the wells occur in pairs, split by the tunneling matrix element. Apart from this tunneling splitting, the lowest states in the wells feel a potential that strongly resembles that of a harmonic oscillator. They were therefore dubbed "pendular states" by the authors.[7] The corresponding wave functions have their highest amplitudes in the vicinity of the potential minima. This means that the molecules are aligned (not oriented, though) along the polarization direction and perform nearly harmonic two-dimensional librations about it; the amplitude of the librations depends on the energy (or temperature) of the molecules. The free-rotor states are adiabatically transformed into these bound pendular states as the laser is turned on, and at sufficiently high intensities and low temperatures only the lowest states will be populated.

In the focus of a high-power cw laser, the calculated binding energy of the molecular trap corresponds to thermal energies of about 1 K for small molecules (CO and CS_2). Substantially deeper traps (50 K or more) can be obtained for larger molecules (for example, C_{60}). To be confined in the trap, the molecules must be cooled to temperatures below the trap depth. This can be accomplished by the interaction with a cold buffer gas, for instance the gas evaporating from liquid ^{3}He (240 mK).[9] The density of the trapped molecules can reach values between 10^8 and 10^{11} cm^{-3}, depending on the molecular polarizabilities, light intensity, and temperature of the buffer gas. These densities are comparable to those obtainable in atom traps.[4] They are high enough for thermal equilibration of the molecules to take place by collisions. This opens up the fascinating possibility of lowering the temperature of the trapped molecules much further by "evaporative cooling":[10] The binding energy of the trap is temporarily reduced by attenuating the laser power, and the molecules of highest energy are released. After removing the ^{3}He buffer gas and increasing the trap depth again, a new thermal equilibrium at a lower temperature will be established. Applied to trapped atoms, iteration of this cooling technique enabled the recent achievement of a macroscopic quantum state by Bose–Einstein condensation[11] (see also Ref. [12]). Such states, as well as many less exotic phenomena,[13] are among prospects that now may be envisioned for molecules trapped by light.

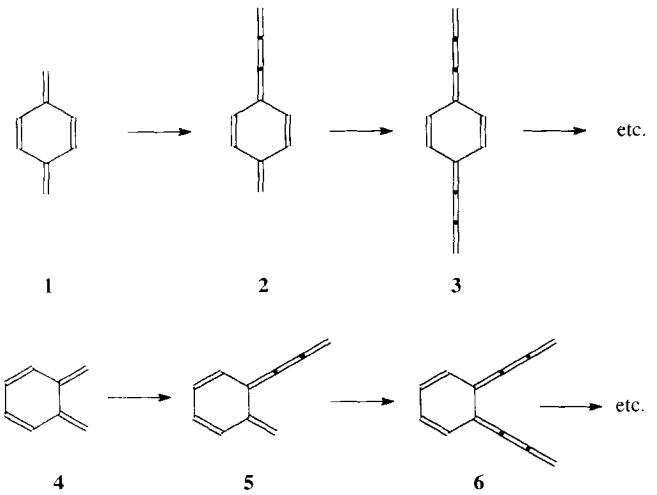
para- and *ortho*-Quinodimethane Intermediates with Cumulative Double Bonds**

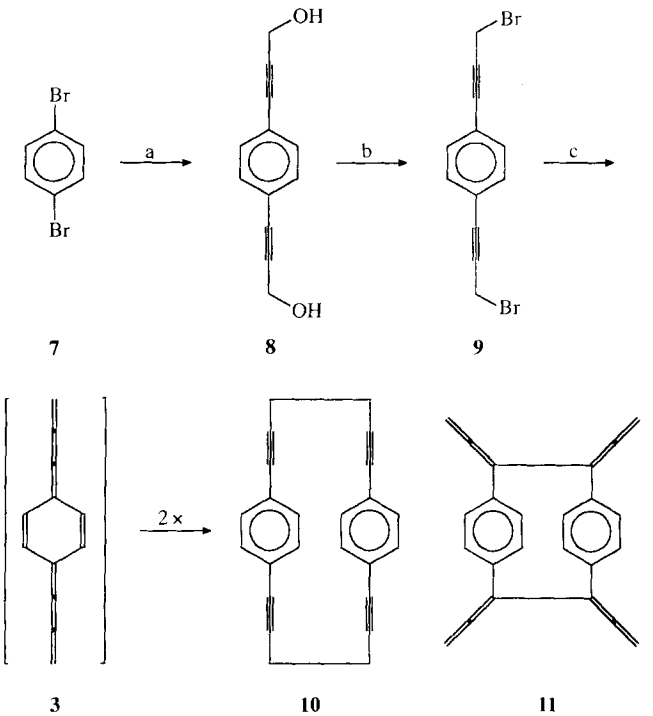
Henning Hopf,* Peter G. Jones, Peter Bubenitschek, and Christian Werner

In the construction of complex molecular structures *para*- and *ortho*-quinodimethanes **1** and **4** and countless of their derivatives play an important role, both in hydrocarbon[1] and natural product chemistry.[2] We were interested in whether the exocyclic double bonds of these parent compounds could be "extended" by the deliberate insertion of sp-hybridized carbon atoms, and also in the chemical behavior of the presumably highly reactive quinodimethanes **2**,[3] **3**, **5**, and **6**, which contain cumulative double bonds (Scheme 1). We report here on the synthesis of the intermediates **3** and **6** and their respective inter- and intramolecular cyclizations.



Scheme 1. Construction of quinodimethanes with cumulative double bonds from the parent *para*- and *ortho*-quinodimethanes **1** and **4**.

Coupling of *p*-dibromobenzene (**7**) with propargyl alcohol (for conditions see Scheme 2) afforded diol **8**,[4] which was converted into dibromide **9**[4] by standard procedures. In the reaction of **9** with the debromination reagent $Bu_3SnSiMe_3$/CsF described by Mori et al.[5] a hydrocarbon was formed (yield 7.5%), which is assigned the dimeric structure **10** on the basis of spectroscopic and analytical data.[6] The isomeric tetraallene **11**, which could equally have been formed by the dimerization of **3**, is not accessible by this method. The driving force of the dimerization is clearly the gain in resonance energy brought about by the formation of the cyclophane and the conversion of the thermodynamically unfavorable cumulene units into isolated triple bonds.[7]



Scheme 2. Preparation and dimerization of *para*-quinodimethane **3**. a) 2-Propynol, $[Pd(PPh_3)_4]$, *n*-propylamine, 72 h at reflux, 93%. b) PBr_3, diethyl ether, 30 min at 0 °C, 30 min at reflux, 68%. c) $Bu_3SnSiMe_3$/CsF, DMF, 6 h at 0 °C, 16 h at 25 °C, 7.5%.

To confirm the postulated structure unambiguously, **10** was recrystallized from methanol and the resulting crystals were analyzed by X-ray diffraction.[8] [6.6]Paracyclophanetetrayne **10** crystallizes as two independent inversion-symmetric molecules with different conformations. In molecule 1 (Fig. 1a) the C_6 rings are eclipsed (torsion angle C2-C1-C12-C11 10°) and the distance between the ring planes is 384 pm. In contrast, in molecule 2 (Fig. 1b) the rings are displaced laterally (torsion angle C2′-C1′-C12′-C11′ 42°) and separated by 343 pm. The aromatic rings are all planar (mean deviation < 2 pm). As a consequence of ring strain the substituents (cyclophane bridges) lie significantly out of the ring plane: C3 by 22, C10 by 21, C3′ by 25, and C10′ by 28 pm. For the same reason, the bond angles of the triple bonds deviate from the ideal value of 180° (169–172°).

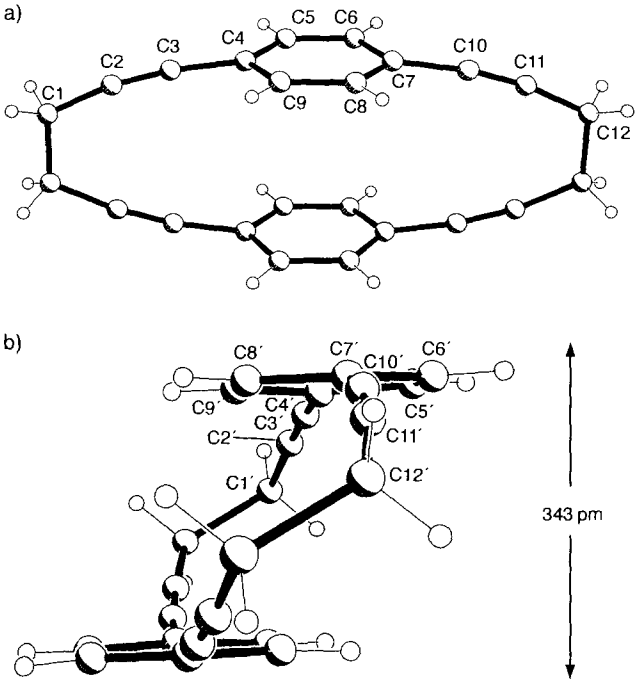

Fig. 1. Crystal structure of compound **10**: a) molecule 1; b) molecule 2. Radii are arbitrary.

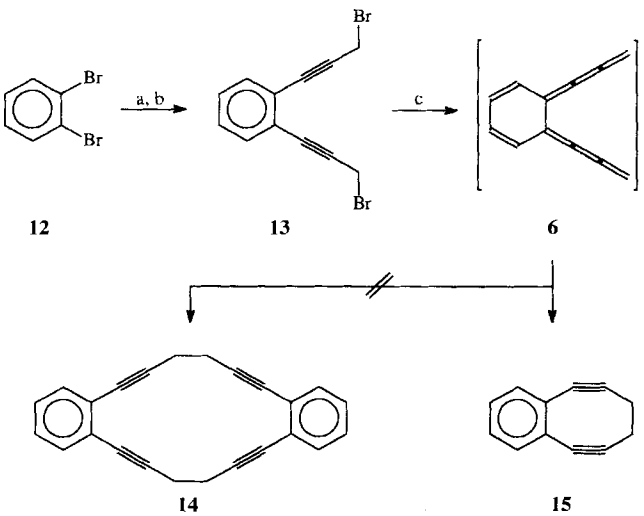
To prepare the *ortho*-quinodimethane **6**, *ortho*-dibromobenzene (**12**) was transformed into the dibromide **13**[4] by reaction with propargyl alcohol and subsequent bromination (Scheme 3). Compound **13** was debrominated as described above and a hydrocarbon, recrystallizable from methanol, was obtained in



Scheme 3. Preparation and dimerization of *ortho*-quinodimethane **6**. a) 2-Propynol, $[Pd(PPh_3)_4]$, *n*-propylamine, 5 d at reflux, 47%. b) PBr_3, diethyl ether, 1 h at 0 °C, 1 h at reflux, 60%. c) $Bu_3SnSiMe_3$/CsF, DMF, 1 h at 0 °C, 16 h at 25 °C, 61%.

good yield (61%), to which we assign the structure 3,4-benzocycloocten-1,5-diyne (**15**) on the basis of its spectroscopic properties.[9] The cyclophane dimer **14** was not formed. Presumably the termini of biscumulene **6** are in such close proximity that intramolecular ring closure is preferred. After recrystallization, compound **15** was obtained as colorless needles, which rapidly discolor and darken on standing. The structure of this decomposition product is as yet unknown. To the best of our knowledge, **15** is the first derivative of the highly strained C_8H_6 hydrocarbon cycloocta-3-en-1,9-diyne.[10]

[9] Spectroscopic data for **15**: ^1H NMR ($CDCl_3$, int. TMS, 400 MHz): $\delta = 2.99$ (s, 4H, 7-, 8-H), 7.27 (AA'BB'-m, 4H, C-9, -10, -11, -12); ^{13}C NMR ($CDCl_3$, 100 MHz): $\delta = 20.98$ (t, C-7, -8), 96.14 (s, C-1, -6), 110.99 (s, C-2, -5), 126.59 (d, C-10, -11), 127.42 (d, C-9, -12), 131.74 (s, C-3, -4); IR (KBr): $\tilde{\nu} = 3079$ (w), 2922 (w), 2830 (w), 2159 (s), 1555 (vs), 1540 (m), 1536 (m), 1450 (vs), 1438 (vs), 1420 (vs), 1282 (s), 1033 (s), 751 (vs), 447 (vs) cm^{-1}; UV (acenonitrile): λ_{max} (lgε) = 200 (4.38), 222 (4.28), 232 (4.43), 250 nm (sh, 3.86); MS (70 eV): *m/z* (%): 152 [M^+] (100), 126 (18).
[10] The energy of formation of **15** calculated by using MNDO methods is 592.7 kJ mol^{-1}. Thus this substance, whose minimum energy conformer is planar, is about 400 kJ mol^{-1} higher in energy than 3,4-benzocycloocta-1,3,5-triene ($\Delta H_f = 195.4$ kJ mol^{-1}). We thank Prof. Dr. H. Meier (Universität Mainz) for these calculations and for valuable discussions. The even more highly unsaturated hydrocarbon 5,6,9,10-tetrahydrobenzocyclooctene, a bisdehydro derivative of **15**, has been described in the literature as an oily substance stable for only a few minutes at 0 °C: H. N. C. Wong, F. Sondheimer, *Angew. Chem.* **1976**, *88*, 126–127; *Angew. Chem. Int. Ed. Engl.* **1976**, *15*, 117.

A Simple Route to the 1-Aza-3-Phosphaallyl System: Structure of a Dimeric Lithium Complex and Protonation to Give the First NH_2-Substituted Phosphaalkene**

Karin Paasch, Martin Nieger, and Edgar Niecke*

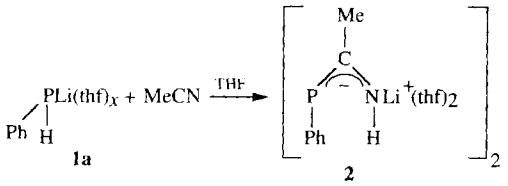
Dedicated to Professor Herbert Roesky on the occasion of his 60th birthday

N-Silylated derivatives of 1,3-diazaallyl anions[1] **I** are important chelate ligands for main group and transition metals[1] and have recently gained significance as cocatalysts for olefin polymerization.[1, 2] Compounds of the 1,3-diphosphaallyl system[3] (**II**) homologous to **I** are versatile complex ligands (σ and π coordination),[4] and activities in the olefin polymerization were detected for a nickel complex.[5] As an extension of our studies on 1-phosphaallyl anions,[6] we became interested in the 1-aza-3-phosphaallyl system[7] (**III**) which combines the reactivity of

I **II** **III**

both due to the presence of a "soft" (phosphorus) and a "hard" reaction center (nitrogen). We report herein on a simple route to this heteroallyl system, the crystal structure of a lithium complex, and its reaction with electrophiles.

The reaction of equimolar amounts of lithium phenyl phosphanide **1a** with acetonitrile in THF leads smoothly to the lithium complex of the 1-aza-3-phosphaallyl anion **2**, which was



1a **2**

isolated in the form of yellow, air- and moisture-sensitive crystals. According to the results of an X-ray structure analysis[8] **2** is dimeric in the crystal (Fig. 1). The two heteroallyl anions are linked through a planar Li_2N_2 unit; the lithium atoms attain a distorted tetrahedral geometry by the additional coordination of two THF molecules. The Li–N distances lie in the expected range[10] (203.1(8), 209.0(8) pm). The acute Li-N-Li angle (75.6(4)°), which results in the two lithium atoms (253(2) pm) approaching one another, is particularly noteworthy. The coplanar arrangement of the atoms H1-N1-C1-C2-P1-C11 (average deviation from the best plane: 0.5 pm) indicates the formation of a delocalized 4electron–3center-pπ system. This assumption is also supported by the short N1–C1 and C1–P1 distances (132.0(5) and 174.0(4) pm, respectively), which lie between those of a single and a double bond for these element

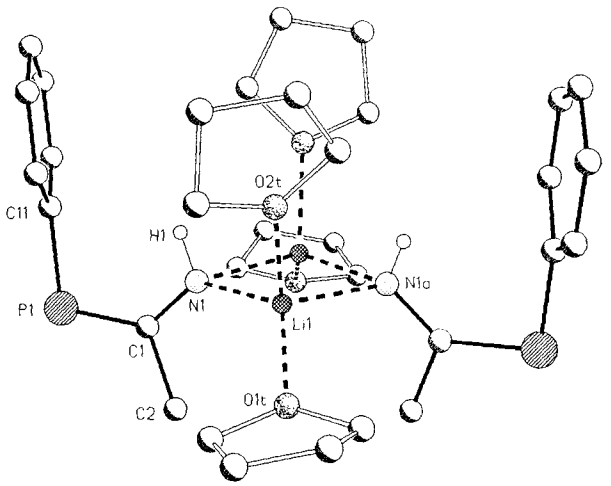


Fig. 1. Crystal structure of **2**. Selected bond lengths [pm] and angles [°]: P1–C1 174.0(4), C1–N1 132.0(5), N1–Li1 203.1(8), P1–C11 182.9(5), C1–C2 152.0(6), N1a-Li1 209.0(8); C1–P1–C11 100.3(2), N1–C1–P1 132.0(3), C1–N1–Li1 132.3(4), Li1–N1–Li1a 75.6(4), N1–C1–C2 113.6(4), C2–C1–P1 114.4(3), C1–N1–Li1a 119.0(4).

combinations. The phenyl substituent at the phosphorus atom is twisted out of the P-C-N plane by 116° and as in the 1-phosphaallyl system[6a, d] is located in the energetically favored[11] *endo* position.

The *trans* arrangement of the phosphorus substituent with respect to the methyl group in **2** confirmed in the solid state, is supported in solution by the large value for ^2J(C,P) (60.7 Hz). The ^{31}P chemical shift (δ = 34.3) resembles the shifts of similarly substituted 1-phosphaallyl anions.[6a, d] In contrast, the allyl carbon atom in **2** is more strongly deshielded by the nitrogen atom (δ = 201.3, ^1J(C,P) = 76.3 Hz). The strong deshielding of the NH proton (δ = 7.9) is indicative of a "tetrahedral" environment for the nitrogen atom and thus the presence of a dimeric structure in solution.[12]

The chemical behavior of **2** towards hard electrophiles reflects the higher basicity of the nitrogen center in comparison to the phosphorus center. Therefore, protonation and silylation of **2** lead smoothly to the phosphaalkenes **3** and **4**, respectively, which can be isolated as thermally stable products. To date an aminophosphaalkene of type **3** is unprecedented, and could be suitable as a starting material in the formation of heteropolyenes. The lithium complex of the *N*-silylated heteroallyl

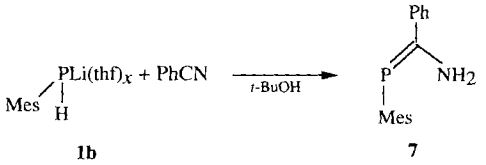
system **5** is accessible from lithium (phenyl)(trimethylsilyl)phosphanide **6** and acetonitrile or by metalation of the phosphaalkene **4**.

Compounds **3** and **4** were characterized on the basis of their elemental analysis, mass spectra (molecular ion peak) as well as ^{1}H, ^{13}C, and ^{31}P NMR experiments. Protonation as well as silylation of **2** lead to a significant deshielding of the phosphorus nucleus (δ = 74.7 (**3**), 94.7(**4**)), whereas the allyl carbon atom only experiences a slight shielding ($\delta(^{13}C)$ = 189.0, ^1J(C,P) = 63.3 Hz (**3**); 193.6, ^1J(C,P) = 64.1 Hz (**4**)). The *cis* position of the methyl group to the lone pair of electrons on the phosphorus atom is proven by the unchanged large value of ^2J(C,P) (**3**:43.5 Hz; **4**: 48.6 Hz). A configuration of this sort is also exhibited by the aminomethylenephosphane **7** in the crystal



1b **7**

(Fig. 2);[8] compound **7** is accessible in the same way from lithium mesityl phosphanide **1b** and benzonitrile.

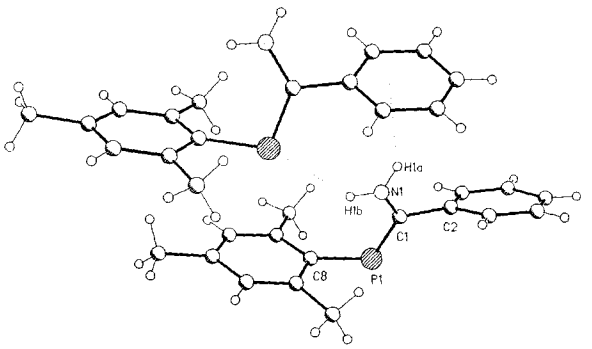


Fig. 2. Crystal structure of **7**. Selected bond lengths [pm] and angles [°]: P1–C1 170.4(2), P1–C8 183.9(2), C1–N1 135.7(3), C1–C2 148.7(2); C1–P1–C8 101.8(1), P1–C1–C2 116.6(1), P1–C1–N1 128.0(2), N1–C1–C2 115.2(2).

The molecules form a chain structure, in which the shortest intermolecular distances (H1 ··· C2–C7 272–316 pm) lie in the range of the sum of the van der Waals radii. An additional van der Waals contact (284 pm) occurs between the second hydrogen atom of the amino group and the phosphorus atom of a neighboring molecule. The C-P-C and P-C-N bond angles (101.8(1)° and 128.0(2)°, respectively) correspond to those in the anion of **2** (100.3.(2)° and 132.0(3)°, respectively). The bond lengths C1–N1 (135.7(3) pm) and P1–C1 (170.4(2) pm) corresponding to those in **2** indicate the presence of a pπ system delocalized over three centers also for **7**.

Experimental Procedure

2: Phenylphosphane (0.26 g, 2.4 mmol) dissolved in THF (6 mL) was treated with *n*BuLi (1.5 mL, 1.6 M in *n*-hexane) at 25 °C under constant stirring. After the reaction mixture had been stirred for 15 min, it was cooled to −30 °C and a solution of acetonitrile (0.1 g, 2.4 mmol) in THF (1.5 mL) was added dropwise. The reaction solution was allowed to warm to 25 °C over 30 min and then left for 16 h. During this time **2** had separated from the orange solution as a yellow microcrystalline solid. Filtration and cooling of the filtrate to −20 °C yielded additional product in the form of yellow extremely air- and moisture-sensitive crystals. Yield: 0.63 g (87%), m.p. 90–92 °C (decomp.); ^{31}P NMR (121.5 MHz, THF): δ = 34.3 (q, ^3J(P,H) = 11.4 Hz); ^{1}H NMR (300 MHz, THF, ext. ref., without Ph group): δ = 2.3 (d, ^3J(P,H) = 11.6 Hz, CH_3, 3H), 7.9 (b, NH, 1H); ^{13}C NMR (75.5 MHz, THF, ext. ref., without PH group): δ = 201.3 (d, ^1J(C,P) = 76.3 Hz, P-C-NH), 27.1 (d, ^2J(C,P) = 60.7 Hz, CH_3).

3, 4: *tert*-Butyl alcohol (**3**) (and trimethylsilyl chloride (**4**), respectively) was added dropwise to a solution of **2** (0.48 g, 1.6 mmol) in THF (10 mL) under ice cooling until decoloration; LiO*t*Bu (and LiCl, respectively) precipitated as a white solid. The solution was stirred again for 1 h at 25 °C, the volatile components were removed in vacuum, the residue was taken up in pentane and filtered through Celite. After removal of the pentane in vacuum, the phosphaalkene **3** was obtained as a white solid, **4** as a yellow oil.

3: Yield 0.20 g (83%); ^{31}P NMR (121.5 MHz, *n*-pentane): δ = 74.7 (q, ^3J(P,H) = 16.5 Hz); ^{1}H NMR (300 MHz, C_6D_6, without Ph group): δ = 2.0 (d, ^3J(P,H) = 16.8 Hz, CH_3, 3H), 4.7 (b, NH_2, 2H); ^{13}C NMR (75.5 MHz, C_6D_6, without Ph group): δ = 24.4 (d, ^2J(C,P) = 43.5 Hz, CH_3), 189.0 (d, ^1J(C,P) = 63 Hz, Ph-P=C); MS (EI, 70 eV): *m/z* (%): [M^+] 151 (100), [M^+−CH_3−H] 135 (9), [M^+−NH_3] 124 (4), [PhP^+] 108 (30), [CH_3CNH^+] 42 (70).

4: Yield 0.26 g (72%); ^{31}P NMR (121.5 MHz, *n*-pentane): δ = 94.7 (q, ^3J(P,H) = 18.3 Hz); ^{1}H NMR (300 MHz, C_6D_6, without Ph group): δ = 0.0 (s, $SiMe_3$, 9H), 2.3 (d, ^3J(P,H) = 18.3 Hz, CH_3, 3H), 5.8 (b, NH, 1H); ^{13}C NMR (75.5 MHz, C_6D_6, without Ph group): δ = 1.7 (s, $SiMe_3$), 24.7 (d, ^2J(C,P) = 48.1 Hz, CH_3), 193.6 (d, ^1J(C,P) = 64.1 Hz, P=C); MS (EI, 70 eV): *m/z* (%): [M^+] 223 (38), [M^+−$SiMe_3$ + H] 151 (13), [M^+−PhP−H] 114 (26), [$SiMe_3^+$] 73 (100).

5: *n*BuLi (1 mL, 1.6 mmol, 1.6 M in *n*-hexane) was added dropwise to a solution of phosphaalkene **4** (0.36 g, 1.6 mmol) in DME (10 mL) at −30 °C. The solution turned red-orange. The solution was slowly allowed to warm to 25 °C and then the solvent was removed in vacuum. The product was obtained in pure form as a yellow oil. Alternatively **5** was afforded in a less pure form (^{31}P NMR: ca. 80%) by reaction of **6** with acetonitrile. ^{31}P NMR (121.5 MHz, DME, −40 °C): δ = 28.5; ^{1}H NMR (300 MHz, DME, ext. ref., −40 °C, without PH group): δ = 0.83 (s, $SiMe_3$, 9H), 1.7 (d, ^3J(P,H) = 6.9 Hz, CH_3, 3H); ^{13}C NMR (75.5 MHz, DME, ext. ref., −40 °C, without Ph group): δ = 4.6 (s, $SiMe_3$), 15.3 (d, ^2J(C,P) = 21.6 Hz, CH_3), 199.1 (d, ^1J(C,P) = 57.4 Hz, P-C-N$SiMe_3$).

7: *n*BuLi (1 mL, 1.6 mmol, 1.6 M in *n*-hexane) was added to a solution of mesitylphosphane (0.24 g, 1.6 mmol) in DME (10 mL) and stirred for 15 min at 25 °C. Subsequently the solution was cooled to −30 °C and treated with a solution of benzonitrile (0.17 g, 1.6 mmol) in DME (1.5 mL). The solution was allowed to warm to 25 °C under constant stirring and then *tert*-butyl alcohol was added dropwise under ice cooling until decoloration. After the solution had been allowed to warm to 25 °C the volatile components were removed in vacuum, the residue was taken up in pentane and filtered through Celite. The product crystallized from the concentrated filtrate at −20 °C in the form of colorless crystals. Yield: 0.37 g (91%), m.p. 70–71 °C; ^{31}P NMR (121.5 MHz, *n*-pentane): δ = 64.4; ^{1}H NMR (300 MHz, C_6D_6, without aryl group): δ = 4.4 (NH_2, 2H); ^{13}C NMR (75.7 MHz, C_6D_6, without aryl groups): δ = 186.6 (d, ^1J(C,P) = 60.3 Hz, P=C); MS (70 eV): *m/z* (%): 255 (68.0) [M^+], 238 (75.2) [M^+-NH_3], 223 (21.9) [M^+-NH_3-CH_3], 119 (49.0) [Mes^+] 104 (100) [Mes-Me^+]; high resolution (M^+): 255.1176 (255.1177 calcd. for $C_{16}H_{18}NP$).

Metal Complexes of N-Heterocyclic Carbenes—A New Structural Principle for Catalysts in Homogeneous Catalysis**

Wolfgang A. Herrmann,* Martina Elison, Jakob Fischer, Christian Köcher, and Georg R. J. Artus

A basic functional principle in homogeneous complex catalysis is based on the fact that phosphane and phosphite ligands not only protect low-valent metal centers from aggregation (stabilization effect), but also create coordination sites in dissociation equilibria at which the catalytic elementary steps proceed (activation effect).[1] Examples of industrial importance are hydrocyanation ($Ni^0/P(OR)_3$) and hydroformylation (Co^I/PR_3, Rh^I/PR_3). Generally, as a result of the notorious phosphane degradation by P–C bond cleavage,[2] an excess of the ligand—often 100 times more than the metal—is required to control the equilibrium in the activation and propagation steps in homogeneous catalysis. This excess increases the running costs of technical plants.[3] Phosphane and phosphite complexes are also often water- and air-sensitive. Using the Heck coupling as example,[1c, 4] we now describe a new catalyst principle that does not have these disadvantages. It relies on the special ligand properties of N-heterocyclic carbenes and stands out because of its simplicity and efficiency.

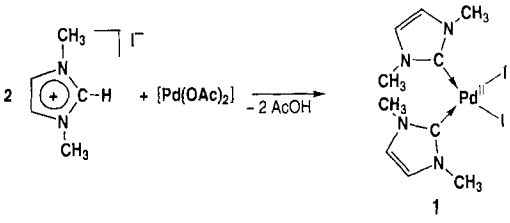
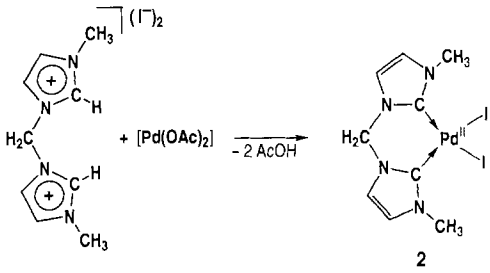
[**] Coordination Chemistry and Mechanisms of Metal-Catalyzed CC Coupling Reactions, Part 9. Part 8: W. A. Herrmann, C. P. Reisinger, K. Öfele, C. Brossmer, M. Beller, H. Fischer, *J. Mol. Catal.*, in press.

The carbene–palladium complexes **1** and **2** of the imidazole series were prepared from $[Pd(OAc)_2]$ and 1,3-dimethylimidazolium iodide or 3,3′-dimethyl-1,1′-methylenediimidazolium diiodide in more than 70 and 40% yield, respectively [Eq. (a) and (b)]. They are extraordinarily stable to heat, oxygen, and



(a)



(b)

moisture. Catalyst **1** melts at temperatures as high as 299 °C with partial decomposition and resists several days treatment with O_2 in boiling THF. The complex **2** melts at 280 °C, but decomposes noticably in solution (*N*,*N*-dimethylacetamide) at temperatures above 70 °C.

Besides the expected square-planar core geometry, a crystal structure analysis of **1** (Fig. 1)[5] shows that the two carbene

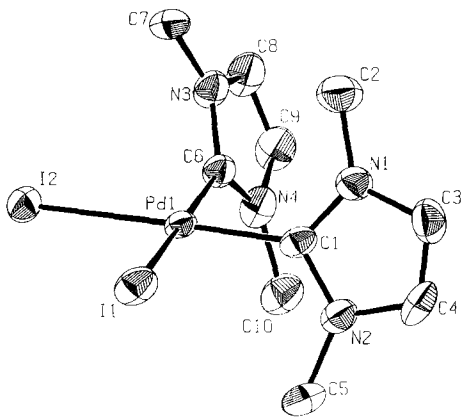


Fig. 1. PLATON representation of the crystal structure of the "carbene" complex **1**. The ellipsoids represent 50% probability; H atoms are omitted for clarity. Selected distances [Å] and angles [°]: Pd1-I1 2.6479(3), Pd1-I2 2.6572(3), Pd1-C1 1.990(3), Pd1-C6 1.997(3), N1-C1 1.347(4), N2-C1 1.363(4), N3-C6 1.357(4), N4-C6 1.336(4); I2-Pd1-I1 93.590(9), C1-Pd1-I1 87.32(8), C1-Pd1-I2 178.08(8), C6-Pd1-I1 175.52(9), C6-Pd1-I2 88.97(8), C6-Pd1-C1 90.2(1).

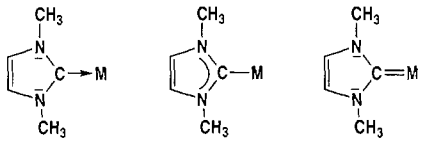
ligands are in a *cis* arrangement and twisted relative to the PdI_2 plane (70.5 and 69.4°). The $[(PR_3)_2PdX_2]$ (X = halogen) complexes with monodentate phosphane ligands that were known previously and characterized by crystal structure analyses have *trans* configurations, which reflects the greater steric demand of the phosphane ligand. In contrast to the planar carbene ligands, the phosphane ligands cannot relieve the steric congestion by rotation about the metal–ligand bond (Pd–P instead of Pd–C).

The Pd–C bond lengths (1.990(3)/1.997(3) Å) lie in the range of those of known carbene complexes (1.95–2.07 Å)[6]– true Pd–C single bonds (Pd–C(alkyl), Pd–C(benzyl)) are, however, hardly longer: 1.99–2.05 Å.[7] In accord with results from vibrational spectroscopy,[8] it is therefore certainly valid that heterocyclic carbenes of the imidazole type have pronounced donor properties similar to the electron-rich phosphanes and that π-backbonding is insignificant. The formal depiction of this class of compounds as **A** (σ-donor) and **B** (π-donor) probably most closely represents the bonding; on the contrary, the conventional, formal notation **C** is certainly inaccurate in that it does not reflect the apparent analogy between these "carbenes" and other donor ligands.



The Pd complexes **1** and **2** catalyze the Heck coupling of aryl halides [Eq. (c)].[9a] The higher turnovers are obtained with **1**

X	Br	Br, Cl	Br	Cl
R	CH_3O	C(=O)H	$C(=O)CH_3$	NO_2

because of its pronounced thermal stability in solution (see Table 1). As shown by kinetic measurements (see Fig. 2), the activity at the beginning of the reaction of bromoarenes (for example 4-bromobenzaldehyde) is lower than that of the particularly active palladacycles,[7b, 9b] but the advantages of the new catalyst **1** lie in the formation of stable active species and in the length of time it remains stable *even at high temperatures*, a property that is still essential for the activation of chloroarenes.

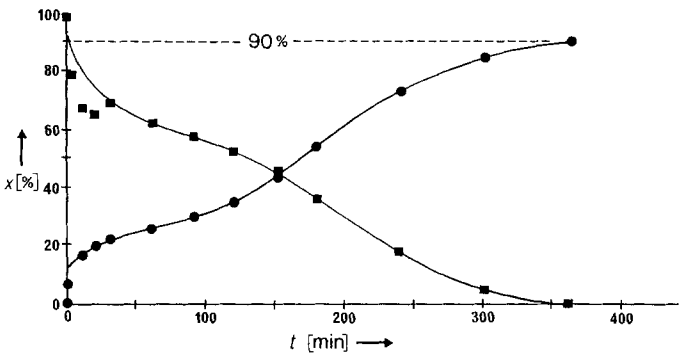


Fig. 2. Concentration/time diagram (amount of substance x[%], time t [min]) for the Heck olefination of 4-bromobenzaldehyde (■) with n-butyl acrylate to form n-butyl (*E*)-4-formylcinnamate (●); for reaction conditions see Experimental Procedure and Table 1. 0.5 mol% **1**. The loss of the starting material (approximately 10%) immediately after the start of the reaction is attributed to the formation of the Heck coupling product and appears to be correlated to the activation of the catalyst, for example by reduction through the aldehyde.

The sigmoidal turnover characteristics (concentration/time diagram; Fig. 2) result in an initially sluggish product formation. As the reaction proceeds the turnover per time increases markedly. An activating conversion step must thus be assumed for the catalytic activity of **1**. No inductive phase is observed for **1** after treatment with reducing agents: whereas 4-bromoacetophenone is converted only very slowly with **1** under mild conditions and no other additives (Fig. 3), the concentration of the starting material decreases suddenly and exponentially after addition of hydrazine (after 67 min). Sodium formate is a particularly advantageous reducing agent in this context (no metal complexation, nontoxic).

Table 1. Heck olefination of chloro- and bromoarenes with carbene–palladium catalysts [a].

Substrate	Catalyst	Amount of catalyst [mol%]	t[h]	Turnover[%]

[a] For reaction conditions, see Experimental Procedure. The catalyst **3** is the carbene complex $[Pd^0L_2]$ formed in situ from $[Pd(dba)_2]$ and free carbene L (see text). [b] With addition of $[N(n\text{-}C_4H_9)_4]Br$ (50 mmol).

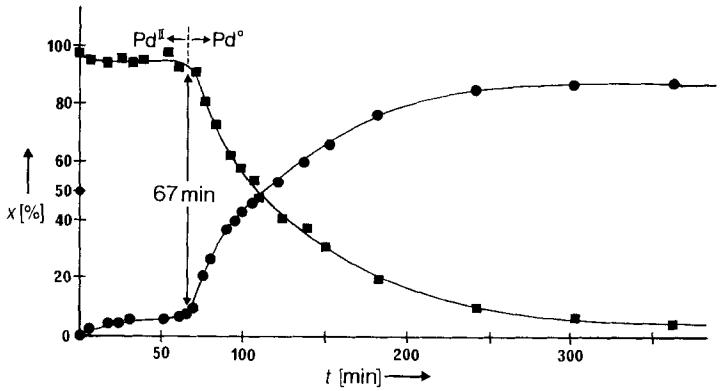

Fig. 3. Concentration/time diagram (amount of substance x[%], time t [min]) for the Heck olefination of 4-bromoacetophenone (■) with n-butyl acrylate to form n-butyl (*E*)-4-acetylcinnamate (●); for reaction conditions see Experimental Procedure and Table 1. 0.5 mol% **1**, addition of 85 μL hydrazine hydrate after 67 min.

The conversions of 4-chlorobenzaldehyde and 4-chloronitrobenzene with n-butyl acrylate [Eq. (c)] proceed quantitatively at 130 °C with **1** (1 and 0.1 mol%, respectively) on addition of $[N(n\text{-}C_4H_9)_4]Br$ (Fig. 4, Table 1). Here too, the usual induction period is absent. We conclude that the formyl group of the chloroarene or $[N(n\text{-}C_4H_9)_4]Br$ acts as reducing agent.

The results raise the expectation that a carbene complex $[Pd(carbene)_2]$ (**3**) with a zerovalent palladium center prepared in situ should be immediately active without induction period. $[Pd(dba)_2]$ (dba = dibenzylidene acetone) was therefore treated

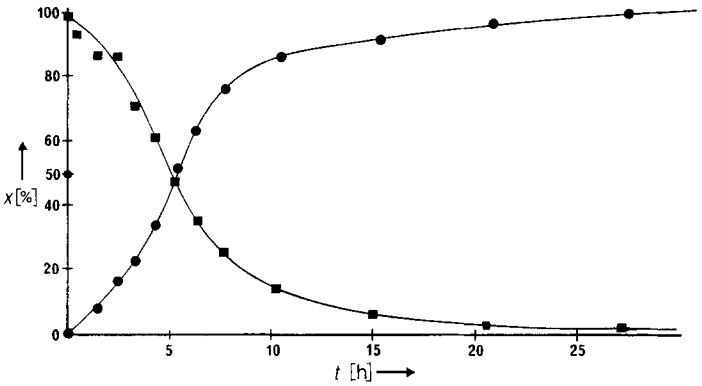

Fig. 4. Concentration/time diagram (amount of substance x[%], time t [h]) for the Heck olefination of 4-chlorobenzaldehyde (■) with *n*-butyl acrylate to form *n*-butyl (*E*)-4-formylcinnamate (●); for reaction conditions see Experimental Procedure and Table 1, 1 mol% 1, 50 mmol $[N(n\text{-}C_4H_9)_4]Br$.

with two equivalents of free 1,3-dimethyldihydroimidazole-2-ylidene (L) in toluene at room temperature. The coordination of the metal center by the carbene can be monitored by the color change from violet to red, as well as by ^1H and ^{13}C NMR spectroscopy ($\delta_{C(carbene)} = 180.2$, [D$_8$]toluene). The Pd^0–carbene catalyst **3** does indeed have an extremely large initial activity with long-term stability in the Heck olefination (Table 1): with only 4×10^{-4} mol% (!) catalyst, 50 mmol 4-bromoacetophenone can be completely converted in 43 h without palladium deposition. Because of the absence of an induction period and of the high activity, turnover numbers (TON) of more than 250000 can be achieved with **3** for activated bromoarenes, whereas with $[Pd(dba)_2]$ without the stabilizing carbene ligands turnovers are only low in the same time. In the catalytic conversion of 4-bromoanisol with $[Pd(dba)_2]$, inactive palladium separates quantitatively at room temperature already. Even with these deactivated bromoarenes the stabilizing influence of the carbene ligands is obvious: here the turnover numbers per hour (TOF = 15000) reach higher values than with all classical phosphane complexes.

The "carbenes" derived from imidazole appear to stabilize Pd^{II} and Pd^0 complexes because of their pronounced donor properties. This picture also encompasses the existence of the recently described complexes $[BeCl \cdot L_3]^+Cl^-$, $[TiCl_4 \cdot L_2]$, and $[MoO_2Cl \cdot L_3]^+Cl^-$, in which the carbene ligand L replaces conventional solvent ligands like acetonitrile, tetrahydrofuran, and *N*,*N*-dimethylformamide by formation of a stable dative bond, or breaks dimeric and polymeric structures.[10] In contrast to the common Pd/phosphane catalysts, in the new Pd/carbene systems the ligands do not undergo deactivating degradation reactions.[11] No deposition of (catalytically inactive) palladium can be detected.

The new catalyst type described here has a series of advantageous properties and potential for development: a) high thermal and hydrolytic durability resulting from exceptionally stable M–C bonds (long shelf-life, stability to oxidation); b) easy accessibility, and c) no need for an excess of the ligand. The prospects for derivatization to water-soluble catalysts (two-phase catalysis), immobilization, and chiral modification seem promising because of the constitution of the ligands.

Experimental Procedure

1: A solution of $[Pd(OAc)_2]$ (2.00 g, 8.9 mmol) and 1,3-dimethylimidazolium iodide (4.20 g, 18.7 mmol) in THF (150 mL) was heated for 30 min under reflux, during which time the initially brown solution bleached to yellow. After evaporation to dryness under vacuum, the residue was washed with diethyl ether (three 50 mL portions), taken up in CH_2Cl_2 (100 mL), and the solution layered with *n*-pentane (200 mL). At 25 °C **1** crystallized as a yellow solid that was very soluble in $CHCl_3$, and slightly soluble in THF and toluene. Yield: 3.70 g (75%). ^1H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta = 7.24$ (s, 4H, NCH), 3.92 (s, 12H, CH_3); ^{13}C NMR (100.1 MHz, $CDCl_3$, 20 °C): $\delta = 168.2$ (carbene-C), 122.3 (NCH), 38.2 (CH_3); correct C,H,N analysis.

2: $[Pd(OAc)_2]$ (200 mg, 0.89 mmol) was treated at 170 °C with 3,3'-dimethyl-1,1'-methylenediimidazolium diiodide (400 mg, 0.89 mmol). After heating for 5 min under vacuum the residue was extracted with THF and filtered over a frit covered with a layer of silica gel. The solvent was removed under vacuum, the residue washed with absolute diethyl ether (three 20 mL portions), taken up in CH_2Cl_2 (10 mL), and the solution carefully layered with *n*-pentane (30 mL). The yellow crystals of **2** were dried under vacuum. They dissolve well in $CHCl_3$, CH_2Cl_2, THF, and toluene, to give a yellow solution. Yield: 190 mg (40%). ^1H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta = 3.92$ (s, 6H, NCH_3), 6.61 (s, 2H, CH_2), 7.41, 7.43 (s, 4H, NCH); ^{13}C NMR (100.1 MHz, $CDCl_3$, 20 °C): $\delta = 36.31$ (NCH_3), 53.60 (CH_2), 121.87, 124.35 (NCH), 185.50 (carbene-C); correct C,H,N analysis.

General procedure for Heck olefination of chloro- and bromoarenes: In a 100 mL three-necked flask fitted with a septum, thermometer, and reflux condenser (with mercury overpressure valve) were placed the haloarene (50 mmol), anhydrous sodium acetate (4.51 g, 55 mmol) and diethyleneglycol di-*n*-butyl ether (GC standard, 1000 mg) in 50 mL *N*,*N*-dimethylacetamide. After repeated degassing under oil pump vacuum and flushing with argon, *n*-butyl acrylate (10 mL, 70 mmol) was injected through the septum. The charge was heated to 100 °C, whereupon the freshly prepared catalyst mixture or the solution of the Pd^{II}–carbene complex was added through the septum, and the mixture heated to the reaction temperature (125 °C with bromoarenes, 140 °C with chloroarenes). To monitor the reaction, 500 μL samples were taken at regular intervals, washed with 5 mL dilute hydrochloric acid (5%), and extracted with 3.5 mL CH_2Cl_2. The organic phases were analyzed by gas chromatography (GC-FID, GC-MS, GC-IR-MS). For quantitative analysis and the recording of concentration/time diagrams a gas chromatograph GC 5980A with flame ionization detector (FID), automatic sampler, and an HP-1 capillary column (12.5 m) from Hewlett Packard was used.

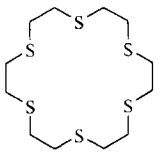
Self-Assembly of Polyanions at a Metal Cation Template: Syntheses and Structures of $[\{Ag([18]aneS_6)\}I_7]_n$ and $[Ag([18]aneS_6)]I_3$**

Alexander J. Blake, Robert O. Gould, Simon Parsons, Christian Radek, and Martin Schröder*

The formation and stability of extended polyiodide species has been found to be dependent on the size of the accompanying cation.[1] We have been interested over the past few years in the coordination chemistry of transition metal ions with homoleptic macrocyclic S-donor ligands.[2] In the context of this work we were interested in ascertaining whether metal macrocyclic cations could be used to template-synthesize extended polyiodide arrays. While numerous examples of small polyiodides such as I_3^-, I_4^{2-}, and I_5^- have been reported,[3, 4] only a few large and very large polyiodide species such as I_7^-, I_8^{2-}, I_9^-, I_{12}^{2-}, I_{14}^{2-}, I_{15}^{3-}, and I_{16}^{4-} are known.[5–10] We report herein the synthesis of a new polymeric $(I_7^-)_n$ polyiodide species assembled around a central macrocyclic cation, $[Ag([18]aneS_6)]^+$.



[18]anS$_6$

Reaction of $[Ag([18]aneS_6)]BF_4$ with I_2 afforded, after evaporation of the solvent in vacuo, a dark blue powder. No precipitation of AgI was observed, confirming the effective encapsulation of the Ag^+ ions by [18]aneS$_6$. The elemental analysis data are consistent with the stoichiometry $[Ag([18]aneS_6)]I_5$, while the FAB mass spectrum shows a peak at m/z 469 with an isotopic distribution consistent with $[^{109}Ag([18]aneS_6)]^+$. The ESR spectrum is featureless, showing that the dark blue color cannot be due to the formation of a radical Ag^{II} complex.[11] Recrystallization of the initial blue product from MeCN and EtOH affords lustrous red crystals of **1** and brown crystals of **2**, respectively. Analytical and spectroscopic data are consistent with these formulations. In order to fully establish the structure of these products, single-crystal X-ray determinations were undertaken.

$[\{Ag([18]aneS_6)\}I_7]_n$ **1**

$[Ag([18]aneS_6)]I_3$ **2**

The single-crystal structure of **1**[12] shows the $[Ag([18]aneS_6)]^+$ ions embedded in a three-dimensional polymeric polyiodide matrix (Fig. 1). The structure of the $(I_7^-)_n$ polyiodide network in the crystal lattice can best be described as

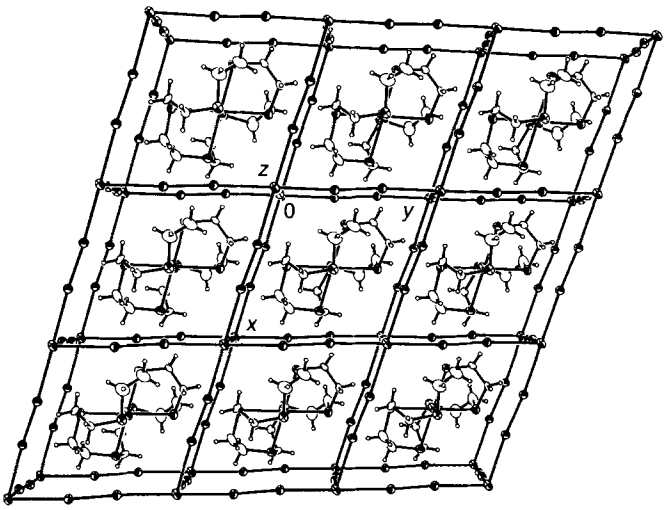


Fig. 1. View of the polymeric matrix of **1**.

a distorted cubic structure in which I^- ions occupy the lattice points of a primitive rhombohedral lattice with one I_2 molecule [I–I 2.7519(14) Å] placed along each edge, bridging two I^- ions, $I^- \cdots I$ 3.3564(15) Å. The I–I bond length in the I_2 molecule in **1** is longer than that in I_2 in the vapor [2.667(2) Å][17] and in the solid state [2.715(6) Å].[18] This elongation is attributable to donation of electron density from I^- into the σ^*-antibonding LUMO of the I_2 molecule. The structure is completed by an $[Ag([18]aneS_6)]^+$ ion sitting inside each rhombohedral interstice (Fig. 2).

I_7^- polyiodide species have been reported previously although none with the current cubic structure. The structures of $(Et_4N)I_7$[5] and $[(py)_2I]I_7$[6] (py = pyridine) show a three-dimensional network of symmetrical I_3^- anions and I_2 molecules and these are therefore better described as an adduct of $[(I_3^-)\cdot(I_2)_2]$. The two compounds $(Hpy)_2I_3I_7$[7] and $[(N\text{-methylbenzothiazole-2(3}H)\text{-thione})_2I]I_7$[8] feature I_7^- ions which are to a first approximation isolated species but linked through long-range $I \cdots I$ interactions of 3.545(13) and 3.502(1) Å, respectively, to give one-dimensional infinite chain structures. The I_7^- ion in these two structures can be described as adducts of $[(I^-)\cdot(I_2)_3]$. The structure of $(PPh_4)I_7$, however, does show discrete I_7^- units.[9]

The single-crystal structure determination of **2**[12] shows discrete metal macrocyclic cations $[Ag([18]aneS_6)]^+$ and symmetrical I_3^- ions [I–I 2.9137(3) Å] in the crystal lattice. The packing

[**] This work was supported by the Engineering and Physical Sciences Research Council, UK. [18]aneS$_6$ = 1,4,7,10,13,16-hexathiacyclooctadecane.

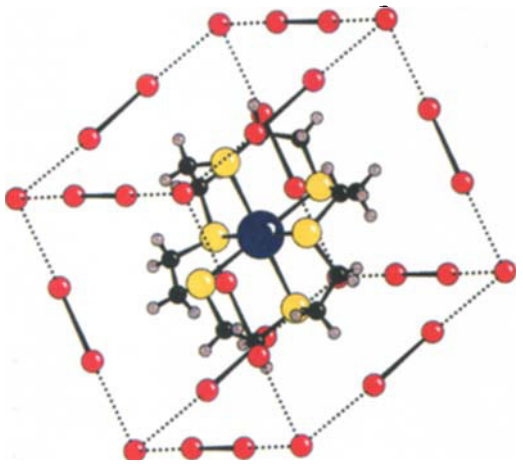

Fig. 2. Section of the structure of **1**. I⁻···I 2.7519(14) Å, I···I 3.3564(15) Å.

diagram (Fig. 3) shows a columnar stacking arrangement with parallel stacks of macrocycles and I_3^- ions. It is noticeable that the orientation of the long Ag–S(1) bond length in the cation of **2** is parallel to the axis of the I_3^- ion.

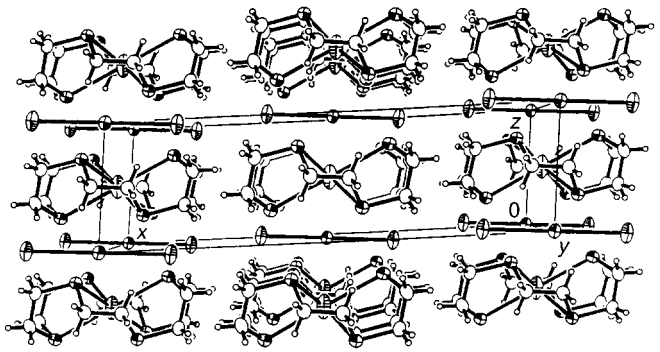

Fig. 3. Crystal structure of **2**.

As in $[Ag([18]aneS_6)]PF_6$,[11] the macrocyclic cations in **1** and **2** both adopt trigonally compressed octahedral coordination geometries; the S-Ag-S chelate angles are about 80° and non-chelate angles are about 100°. In the I_7^- salt **1**, however, all Ag–S distances are equivalent [2.754(2) Å], while the PF_6^- salt shows a tetragonal compression [$Ag-S_{ax} = 2.697(5)$, $Ag-S_{eq} = 2.753(4)$ Å][11] and the I_3^- salt **2** a tetragonal elongation [$Ag-S_{ax} = 2.8007(10)$, $Ag-S_{eq} = 2.7255(7)$ Å]. The template effect of the macrocyclic cation on the structure of the polymeric I_7^- anion in **1** may be demonstrated by comparing the diagonals of the unit cell with the spacing of the S_3 triangles making up the faces of the coordination polyhedron around Ag. The cell diagonal along the threefold axis is 11.850(5) Å, while the other diagonals are 17.635(7) Å. The thickness of the cation may be estimated as the separation of the S_3 triangles (2.48 Å) plus twice the van der Waals radius of sulfur (1.85 Å), giving 6.18 Å. Its mean diameter may be estimated as twice the mean distance of the carbon atoms from the threefold axis (3.55 Å) plus twice the van der Waals radius of carbon (1.50 Å), making 10.1 Å. Thus, the $[Ag([18]aneS_6)]^+$ cation represents a good fit within the cubic second-sphere framework formed by the I_7^- polyanion.

The structures of the anions in **1** and **2** can be compared to that observed in $(Me_4N)I_5$.[4] Thus, the structures of these I_3^-, I_5^-, and I_7^- polyanions can be considered as one-, two-, and three-dimensional structures of the adducts of I^- with one, two, and three I_2 molecules, respectively, with (I_2)-I-(I_2) angles of 90°. We are currently investigating the reaction pathway to the formation of the initial dark blue product assigned tentatively as $[Ag([18]aneS_6)]I_5$ and its conversion to other polyanionic species. The mechanism of formation of these polyanions around the macrocyclic complex cation is so far unclear. "Spontaneous" heterolytic cleavage of the I–I bond has, however, been reported in the gas phase preparation of the dark blue I_2-amylose complex which contains I_5^- ions.[19]

Experimental Procedure

$[18]aneS_6$ (90 mg, 0.25 mmol) was dissolved in $CHCl_3$ (3 cm^3) and a solution of $AgBF_4$ (48.6 mg, 0.25 mmol) in $MeNO_2$ (5 cm^3) added. The colorless solution was stirred vigorously for 15 min and a solution of I_2 (190 mg, 0.75 mmol) in $CHCl_3$ (5 cm^3) added, after which the reaction solution changed color to orange and then violet. The solution was filtered and solvent removed in vacuo to afford a dark blue solid. The product was soluble in DMF, DMSO, EtOH, and $MeNO_2$ to give yellow-brown solutions, and in CH_2Cl_2 to give a purple solution. Recrystallization of the blue product from EtOH afforded brown crystals of **2** (elemental analysis [%]: found C 17.34, H 2.77; calcd. C 16.97, H 2.85), while recrystallization in MeCN gave red **1** (elemental analysis [%]: found C 11.11, H 1.76; calcd. C 10.62, H 1.78). An amorphous green product could also be isolated from MeCN solution; the precise nature of this species was unclear although it seemed reasonable to assume that it was an alternative polyiodide adduct of $[Ag([18]aneS_6)]^+$. Compound **2** can be prepared more directly by addition of I_3^- to $[Ag([18]aneS_6)]PF_6$.

0.368), of which 383 unique data ($R_{int} = 0.060$) were used in all calculations. Individual cations are chiral with D_3 (32) point symmetry but are randomly distributed to give apparent D_{3d} ($\bar{3}m$) symmetry. At final convergence, R[380 data with $F \leq 4\sigma(F)$] = 0.0192, $wR[F^2$, all data] = 0.0390 and $S[F^2] = 1.112$ for 37 parameters and the final ΔF synthesis showed no feature above 1.07 e Å^{-3}. Crystal data for $C_{12}H_{24}AgS_6I_3$: $M = 849.29$, monoclinic, space group $C2/m$, $a = 18.5767(11)$, $b = 11.9188(7)$, $c = 5.2714(5)$ Å, $\beta = 95.634(9)°$, $V = 1162$ Å^3 [from 2θ values of 32 reflections measured at $\pm\omega$ ($2\theta = 29$–$32°$, $\lambda = 0.71073$ Å), $T = 280.0(1)$ K], $Z = 2$, $\rho_{calcd} = 2.428$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 5.389$ mm^{-1}. Brown columnar block ($0.38 \times 0.16 \times 0.16$ mm^3). 2740 absorption-corrected reflections ($2\theta_{max}$ 50°, T_{min} 0.131, T_{max} 0.164) of which 1074 unique data ($R_{int} = 0.0130$) were used in all calculations. At final convergence, R[988 data with $F \leq 4\sigma(F)$] = 0.0181, $wR[F^2$, all data] = 0.0422 and $S[F^2] = 1.081$ for 58 parameters and the final ΔF synthesis showed no feature above 0.58 e Å^{-3}. Both crystals were mounted on a Stoë Stadi-4 four-circle diffractometer in the stream of an Oxford Cryosystems low-temperature device [13]. Data collection used $Mo_{K\alpha}$ X-radiation ($\lambda = 0.71073$ Å), ω-2θ scans and the learnt profile method [14]. Patterson synthesis [15] was used to locate the iodine and silver atoms in each structure, from which point the structures were developed by iterative cycles of least squares refinement and difference Fourier synthesis. The structures were refined by full-matrix least squares (on F^2) with anisotropic thermal parameters for all fully occupied non-H atoms. H atoms were included in fixed calculated positions with U_{iso} 1.2 times U_{eq} for the parent C atom [16]. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK).

Alkali Metallocene Anions: Syntheses and Structures**

Jens Wessel, Enno Lork, and Rüdiger Mews*

Dedicated to Professor Herbert Schumann on the occasion of his 60th Birthday

Recently Harder and Prosenc reported on the synthesis of $[CpLiCp]^-$, the simplest metallocene, which is obtained from the reaction of $(LiCp)_n$ with $Ph_4P^+Cl^-$ in THF at room temperature [Eq. (a)].[1]

$$2/n\,(LiCp)_n + Ph_4P^+Cl^- \xrightarrow[RT]{THF} Ph_4P^+[CpLiCp]^- + LiCl \quad (a)$$

$$2\,CpSiMe_3 + 2(TAS)F \xrightarrow[-30\,°C]{CH_3CN} [(TAS)Cp(TAS)]^+Cp^- + 4\,Me_3SiF \quad (b)$$

Concurrently, we synthesized tris(dimethylamino)sulfonium cyclopentadienide, $(Me_2N)_3S^+Cp^-$, [(TAS)Cp] [Eq. (b)],[2] whose solid-state structure can be described as $[(TAS)Cp(TAS)]^+Cp^-$. The cation is present as an "inverse" sandwich complex, lying alongside the "naked" Cp^- ion. The aim of our studies was to generate cyclopentadienide anions in the presence of weakly interacting cations which are not coordinated by interfering auxiliary bases. With these systems we hoped to observe novel reactions, not normally seen for typical metallocyclopentadiene reagents. Herein we report the first unusual reactions of (TAS)Cp in the currently topical area of alkali metallocenes.[3, 4] The important results from the work of Harder and Prosenc and from our own work[1, 2] are that on the one hand, alkali metallocene anions are stable in the presence of weakly coordinating cations, but on the other hand "naked" Cp^- ions are extremely reactive, decomposing in organic solvents between -30 and $-10\,°C$. Thus, $Ph_4P^+Cp^-$ can be obtained from the reaction of $(LiCp)_n$ with $Ph_4P^+Cl^-$ in CH_3CN only at temperatures below $-30\,°C$[5].

Because of its thermal instability in solution, (TAS)Cp is only a useful synthetic reagent if the desired reaction occurs at low temperature. Breakdown of the polymeric ("supersandwich") structures of the alkali metal cyclopentadienides[6, 7] occurs rapidly at $-35\,°C$ in a (TAS)Cp-acetonitrile solution. On addition of diethyl ether, the salts **1a–c** precipitate quantitatively at this temperature [Eq. (c)].

$$2/n\,(MCp)_n + [(TAS)_2Cp]^+Cp^- \longrightarrow \underset{\mathbf{1a\text{–}c}\ (M = Li, Na, K)}{2\,TAS^+[CpMCp]^-} \quad (c)$$

$$1/n\,(NaCp)_n + n[(TAS)_2Cp]^+Cp^- \longrightarrow \underset{\mathbf{2}}{[(TAS)_2Cp]^+[CpNaCp]^-} \quad (d)$$

By changing the stoichiometry, the salt **2**, in which a sandwich and inverse-sandwich complex lie side by side, was obtained in quantitative yield [Eq. (d)]. Reactions of (TAS)Cp with polymeric alkali metal cyclopentadienide fragments of the type $[M_nCp_{n+1}]^-$, (e.g. the recently reported thallium system $[Cp_3Tl_2]^-$[8]) remain to be studied.

Single crystals of **1a** (M = Li) and **2** suitable for X-ray crystal structure analyses were obtained by recrystallization from CH_3CN/ether at $-30\,°C$. Complex **1a** crystallizes in the space group $P\bar{1}$ with two independent Cp_2Li units[9] in the unit cell (Fig. 1); the data were collected at $-100\,°C$. The structures of

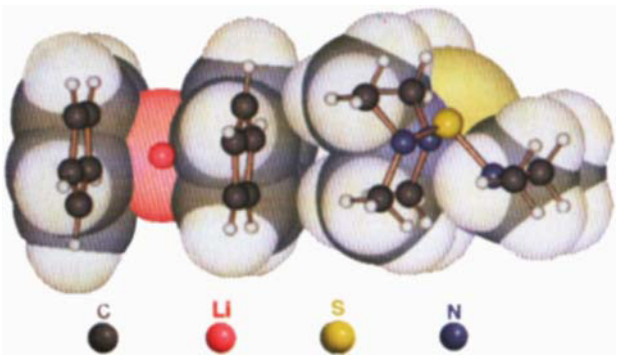

Fig. 1. Crystal structure of $TAS^+[CpLiCp]^-$ **1a** (SCHAKAL drawing).

the $[Cp_2Li]^-$ ions in **1a** are almost identical to those in $Ph_4P^+[Cp_2Li]^-$[1]; the cation appears to have no influence on the anion. The small variation in bond lengths can be rationalized in terms of thermal effects, since our data for **1a** were collected at lower temperature. In the lithocene unit with Li(1), the Li–C distances lie between 226.0 (2) and 233.4 (2) pm (average 229.7 pm), the average C–C bond length is 138.9 (3) pm, and the Li–Cp (ring centroid) distance is 196.9 pm. In the lithocene unit with Li(2), the corresponding values are 226.2 (3)–235.9 (2) pm (average 231.4 pm), 139.0 (8), and 198.9 pm, respectively (reported values for $Ph_4P^+[Cp_2Li]^-$[1] are: 226.2 (3)–236.6 (4) pm (average 231.8 pm), 136.2, and

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. U. Behrens, Hamburg, for helpful discussions.

200.8 (4) pm, respectively). In both centrosymmetric units $[Cp_2Li\ (1)]^-$ and $[Cp_2Li\ (2)]^-$ the rings are tilted away from the normal by 2.1° and 2.9°, respectively; these values are also in agreement with that of the Ph_4P compound (2.9 (3)°).[1] Isotropic refinement of the Cp-hydrogen atoms showed eight hydrogen atoms inclined toward the lithium atom in molecule 1, whereas only two are inclined toward the lithium atom in molecule 2, the other eight hydrogen atoms however are bent away.

Figure 2 shows the structure of compound **2**[10] and Figure 3 a section of the crystal lattice clearly showing the presence of sandwich and inverse-sandwich units. The distances between the sulfonium centers and the enclosed Cp ring (311.8 and 317.0 pm) are only marginally shorter than those in $[(TAS)_2Cp]^+Cp^-$.[2] The enclosed Cp ring in **2** is also disordered; the refinement as a perfect pentagon gave a C–C distance of 138.1 (3) pm.

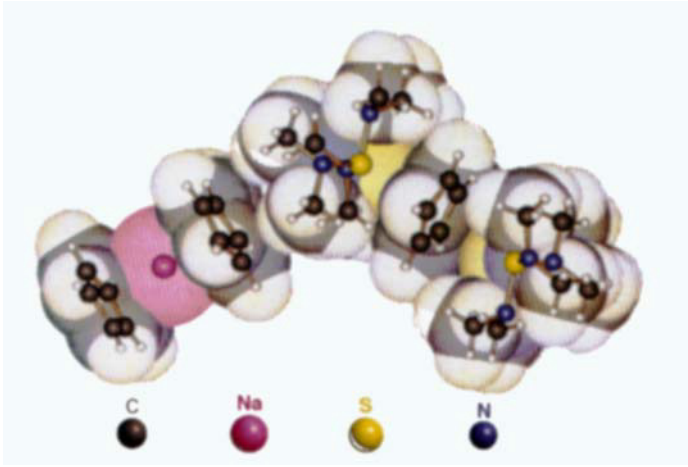

Fig. 2. Crystal structure of $[(TAS)Cp(TAS)]^+[CpNaCp]^-$ **2** (SCHAKAL drawing).

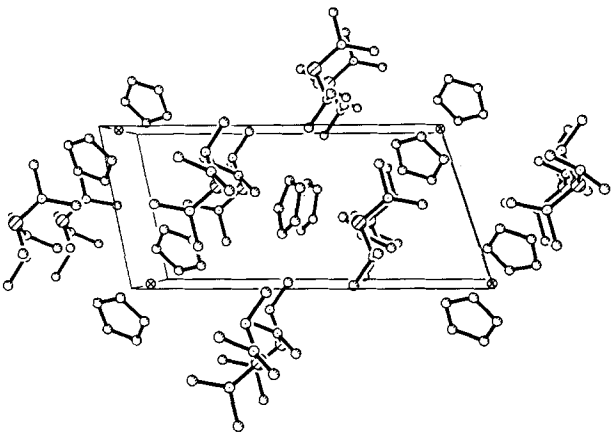

Fig. 3. View of the crystal lattice of **2**.

The natrocene (sodocene) anion in **2** has almost ideal D_{5d} symmetry. The tilt angle of the rings from the normal through the Na atom is only 1.1°. Correspondingly Na–C distances vary relatively little (259.6 (3)–263.9 (3) pm). In contrast to the Li–Cp compound **1a**, where the average Li–C distance is relatively large in comparison with other examples, the average Na–C distance in the $[Na_2Cp]^-$ unit of **2** of 261.6 pm is the shortest, crystallographically characterized Na–C distance reported.[11–15] Distances of 268 pm (in $Me_5C_5Na \cdot 3\ py$)[14] to 292 pm (in $NaCp \cdot TMEDA)_n$[12] are reported in the literature. This difference in behavior to that of the Li–Cp compound is rationalized by the fact that the considerably larger central atom in $[Cp_2Na]^-$ hinders intramolecular repulsion of the two Cp rings.

Experimental Procedure

1a: In a N_2-filled dry box, (TAS)Cp (2.5–3 mmol) and the corresponding stoichiometric amount of LiCp were weighed into a λ-shaped Schlenk tube, fitted with a Teflon valve. Subsequently CH_3CN (30 mL) was condensed onto this mixture through a vacuum line at −196 °C. The reaction vessel was allowed to warm to −40 °C and the reaction mixture was stirred at this temperature for 2 h. After removal of volatiles under vacuum, **1a** remained in quantitative yield as a red solid, m.p. 107 °. Single crystals for X-ray analysis were grown by slow diffusion of Et_2O into a CH_3CN solution of **1a** at −30 °C. ^1H NMR (CD_3CN, 233 K): δ = 5.49 (s, 10 H, Cp), 2.85 (s, 18 H, $(Me_2N)_3S^+$); ^{13}C NMR: δ = 104.6 (Cp), 38.5 ($(Me_2N)_3S^+$).

NaCp and KCp were treated in an analogous manner to **1a** to give **1b** (m.p. 109 °C) and **1c** (m.p. 113 °C), respectively, in quantitative yield. The ^1H NMR spectra (**1b**: δ = 5.56 **1c**: δ = 5.50 (Cp)) showed few differences to those of **1a**.

2: Compound **2** was prepared by an analogous route to **1a** from (TAS)Cp and NaCp in a molar ratio 2:1. After removal of volatiles, **2** remained in the reaction vessel as a violet solid (m.p. 85 °C), which decomposed at room temperature. Single crystals suitable for X-ray structure analysis were obtained at −30 °C by diffusion of Et_2O into solution of **2** in CH_3CN. ^1H NMR (CH_3CN, 233 K): δ = 5.50 (s, 10 H, Cp), 2.85 (s, 36 H, $Me_2N)_3S^+$).

their interlocked molecular structures. Specifically, we have examined the relative templating abilities of 1,5-dinaphtho[38]crown-10 (DN38C10)[9] and bis(*para*-phenylene)[34]crown-10 (BPP34C10)[10] for catenation by the components of the tetracationic cyclophanes[11–14] **A**, **B**, **C**, and **D**, which incorporate 4,4'-bipyridinium and/or bis(4-pyridinium)ethylene dications, linked by either *meta*- or *para*-xylyl spacer units

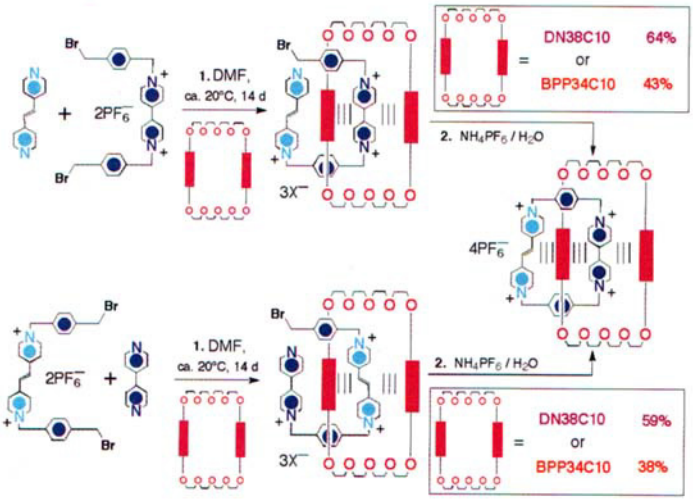

Fig. 1. The competitive self-assembly experiments involving the formation of the tetracationic cyclophanes **A**, **B**, **C**, and **D** in the presence of the template macrocyclic polyether DN38C10 and BPP34C10 to form [2]catenanes, showing the ratio of products formed. The components of the tetracationic cyclophanes used in these experiments can be deduced by disconnecting the covalent bonds indicated and adding a bromine atom to the methylene group.

Kinetic Selection in the Template-Directed Self-Assembly of [2]Catenanes**

David B. Amabilino, Peter R. Ashton, Lluïsa Pérez-García, and J. Fraser Stoddart*

Since natural systems employ the self-assembly[1, 2] of chemical components in a selective manner when they grow and regenerate themselves, it is a realistic challenge for the synthetic chemist to design entirely unnatural systems that will mimic the remarkable selection displayed in the construction of biological systems. Already, the groups led by Lehn[3, 4] and Whitesides[5] have described synthetic systems which self-assemble under equilibrium control by a mechanism of strict self-assembly.[1] Recently, we reported[6] the self-assembly of a wide range of catenanes containing between two and five interlocked rings. These wholly synthetic molecular compounds consist of macrocyclic polyethers incorporating π-electron-rich aromatic units, which act as templates[7] for the formation of tetracationic cyclophanes incorporating π-electron-deficient aromatic units.[8] The self-assembly mechanism that creates these catenanes operates[1] with intermittent processing: that is, a covalent bond is formed, followed by a binding event in volving molecular recognition before a second covalent bond is formed.

We describe here a series of competitive self-assembly experiments in which the precursors of [2]catenanes are given some choice as to which components they ultimately incorporate into

The competitive catenations were all carried out under identical conditions with equimolar amounts of BPP34C10, DN38C10, and the components of either **A**, **B**, **C**, or **D** (see Experimental Procedure). The mixture of [2]catenanes was then isolated quantitatively from the other materials present in the reaction mixture and analyzed quantitatively with ^{1}H NMR spectroscopy. All the [2]catenanes formed in the competitive reactions have at least one proton resonance that is unique and well-resolved relative to proton resonances in the other [2]catenanes. Integration of these resonances gave the ratio of the products from the competitive self-assembly processes. The ratio of the [2]catenanes, incorporating either BPP34C10 or DN38C10, reveals a pronounced preference for the the naphthalene-containing polyether. Furthermore, this preference depends on the nature of the tetracationic cyclophane to be templated. The tetracationic cyclophane **A**[12] self-assembles in the presence of the two macrocyclic polyethers with least selectivity, the ratio of the [2]catenanes incorporating DN38C10 and BPP34C10 being 62:38. The highest selectivity is observed when the components of the tetracationic cyclophane **C**[13] are treated in the presence of the two macrocyclic polyethers. Remarkably, 99% of the [2]catenane molecules formed in the reaction mixture contain DN38C10 and only 1% incorporate BPP34C10.[16]

Interestingly, the most efficient catenation performed under noncompetitive conditions (80% yield) involves[17] the templating of **B** by DN38C10. However, the competition experiment involving the components of **B** and the two macrocyclic polyethers is not the most selective. More important for the selectivities are the relative rates of reactions templated by the two macrocyclic polyethers present in the reaction mixtures.

The [2]catenanes incorporating the tetracationic cyclophanes **A** and **C** were self-assembled by two different routes. The efficiencies of the reactions leading to the [2]catenanes incorporating

A are sensitive to the constitutions of the tetracationic cyclophane precursors.[12] In addition the [2]catenane incorporating **C** can be self-assembled (Fig. 2) from two alternative starting materials—one with a bis(4-pyridinium)ethylene dication and the other with a 4,4′-bipyridinium dication. Despite the much lower association constants[13] for the complexation of

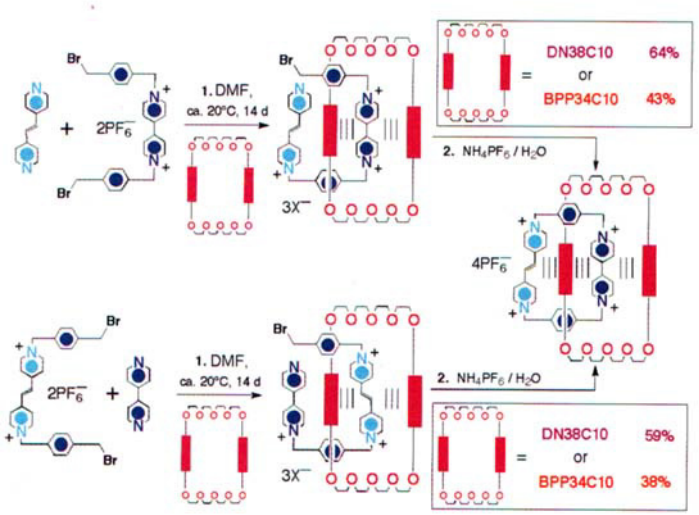

Fig. 2. The two routes to the [2]catenane incorporating cyclophane **C** with either DN38C10 or BPP3410 as template.

the ethylene-substituted bipyridinium dications with BPP34C10 relative to those for the bipyridinium dications, only a modest difference in chemical yields is observed between the two routes, irrespective of whether the template is BPP34C10 or DN38C10. These observations suggest very strongly that the factor governing the relative efficiencies of the self-assembly processes is predominantly a kinetic one.

In an attempt to shed further light on the selectivities observed in the competition studies, the components of the tetracationic cyclophane **A** were treated in an NMR tube under identical conditions to the competition experiments described already, except that [D_7]DMF (plus a drop of D_2O) was used as the solvent. To explain the results of this NMR experiment, it is first necessary to consider the course of the self-assembly processes responsible for the catenations. In principle, self-assembly can occur under either kinetic or thermodynamic control. The situation is illustrated in Figure 3 for the case of the templated self-assembly of **A**. One would expect that the binding (K and K') of the initially formed (k_1) tricationic intermediates would be approximately the same for a given macrocyclic polyether across the range of tetracationic cyclophanes **A** to **C**, since all possess at least one 4,4′-bipyridinium dicationic unit that is bound strongly by the macrocyclic polyethers. The initial precursors to the tetracationic cyclophanes, which contain two pyridyl–pyridinium moieties, are bound extremely weakly by the receptor.[13] The important factors are the rates (k_2 and k_3) of ring closure of the tricationic intermediates once they have been complexed. These rates will be dependent upon the abilities of the respective macrocyclic polyethers to lower the Gibbs free energies of the transition states associated with the ring-closure steps. The reactions, which were followed by ^{1}H NMR spectroscopy, showed that the rate of the ring closure of **A** is much slower than that of **B** under the same reaction conditions.[18] In the competitive ^{1}H NMR experiment, when a bipyridinium dication is formed, the chemical shifts of the resonances arising

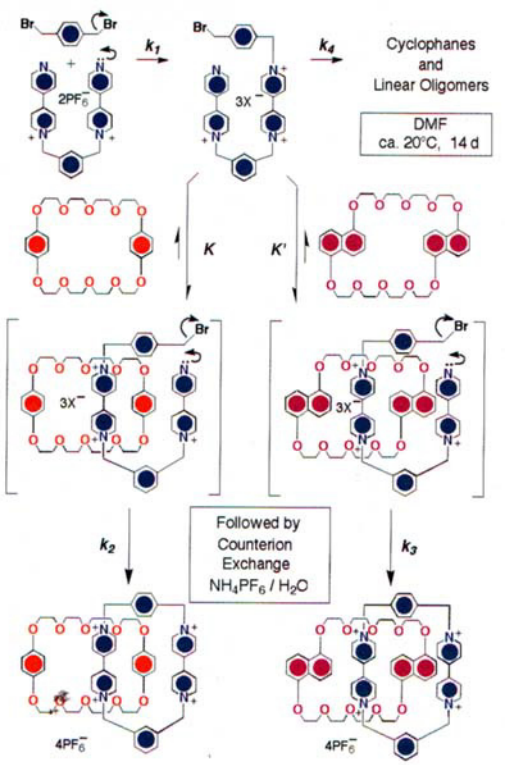

Fig. 3. The kinetically (k_1, k_2, k_3, k_4) and thermodynamically (K and K') controlled steps en route to the [2]catenanes incorporating the tetracationic cyclophane **A** and either BPP34C10 or DN38C10.

from both macrocyclic polyethers are shifted to high field, indicating molecular recognition. The presence of both the complexes of the tricationic intermediates **G** and **H** was also confirmed by FAB mass spectrometry (Fig. 4, FAB = fast atom bombardment),[19] which revealed peaks corresponding to the two [2]catenanes—containing BPP34C10 (**E**) and DN38C10 (**F**)—as well as the complexes of the tricationic intermediate with the two macrocyclic polyethers.

The results presented here suggest strongly that the preferences observed for the DN38C10 macrocyclic polyether over the

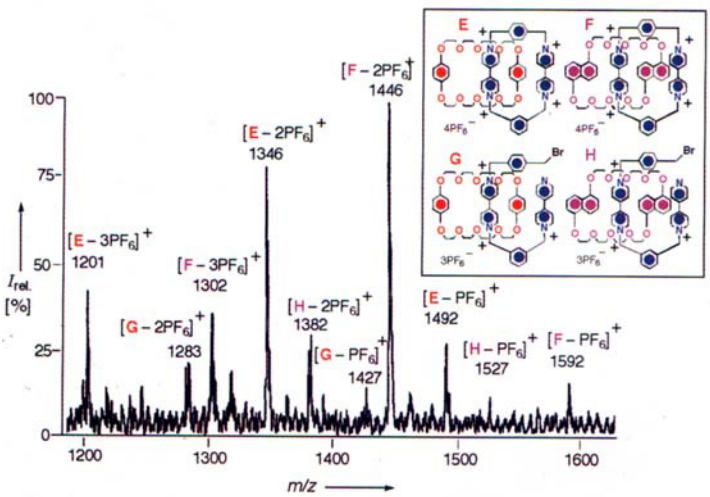

Fig. 4. The FAB mass spectrum of the reaction mixture relating to the scheme outlined in Fig. 3. The peaks that can be identified are attributable to the products of the self-assembly process—the [2]catenanes **E** and **F**, as well as the intermediates **G** and **H**. There was no evidence in the spectrum of the unbound tricationic intermediate to the tetracationic cyclophane **A**.

analogous BPP34C10 are a result of the greater ability of the former to stabilize the transition state for the tetracationic cyclophane ring closure. If the self-assembly was governed solely by the thermodynamics of the noncovalent binding, approximately the same selectivities would be expected for the [2]catenanes incorporating **A**, **B**, and **C**—since they are not, the Curtin-Hammett principle[20] is apparently valid. This hypothesis is supported by the observation of both the tricationic intermediates, namely the intermediates to the [2]catenanes with BPP34C10 and with DN38C10. The selection is dependent on the dimensions of the cyclophane formed.[15] A similar kinetic situation has also been observed in the formation of macrocycles assisted by metal ion templates—termed the *kinetic template effect*[21, 22]—as well as in the templated formation of carceplexes[23] and the self-assembly of monolayers.[24] The ratio of the products formed is determined by the relative stabilization of transition states.[25] The effective molarities[26, 27] of the reactive termini in the acyclic precursors are greater in complexed forms than they are in uncomplexed forms.

Lehn[4] and Whitesides[5] have demonstrated selection in self-assembly as a result of the thermodynamics of binding in solution. The selectivities associated with the self-assembly processes presented here are apparently not governed by the thermodynamics[28] of noncovalent interactions, but rather by the relative rates of covalent bond formation in the final cyclization steps to give the [2]catenanes. As such, the formation of [2]catenanes containing complementary recognition sites in their component rings provides a fascinating and rare example of kinetic selection operating during the intermittently processed self-assembly[1] of unnatural products.

Experimental Procedure

The components of the competition reactions (the two components of the tetracationic cyclophane and the two macrocyclic polyethers, initial concentrations of 20 mM in dry DMF) were introduced into a round-bottomed flask, and the solution was stirred at room temperature and ambient pressure for 14 days. The mixture of [2]catenanes incorporating the tetracationic cyclophane **A** was purified by column chromatography [SiO_2, MeOH/NH_4Cl (2 M)/$MeNO_2$ (7:2:1)]. All fractions containing [2]catenanes were worked up according to a previously described procedure [12]. The mixtures of [2]catenanes incorporating the cyclophanes **B**, **C**, and **D** were isolated by successive precipitation from Et_2O and washing with Et_2O and CH_2Cl_2 in order to obtain *all* the catenated compounds. The ^1H NMR spectra (CD_3CN, 400 MHz) of the mixtures of catenanes were run at temperatures at which all the relevant resonances in the spectra were least broadened by exchange processes and processed without line broadening. Comparisons were made with the spectra for the pure [2]catenanes—containing the tetracationic cyclophanes **A**, **B**, **C**, or **D**, severally, and either BPP34C10 or DN38C10—all of which had already been self-assembled separately under noncompetitive conditions and fully characterized.

[15] The tetracationic cyclophanes **A**, **B**, **C**, and **D** have approximately the same depths, but have different lengths and breadths. The approximate cross-sectional areas of **A**, **B**, **C**, and **D** are 69, 72, 81, and 88 Å^2, respectively. The values have been obtained from X-ray structural data (refs.: **A** [11], **B** [12], **C** [14]; **D**: [13b]) for [2]catenanes which incorporate them.
[16] We estimate that the total errors in the product ratios are no more than 2%. This value is a combination of the small uncertainty (<1%) in the NMR integration and errors associated with experimental manipulation.

[28] Building controlled reversibility into the self-assembly processes, such as those described in this communication, would allow thermodynamics to control the nature of catenane formation. Such developments would introduce error checking into the self-assembly processes leading to mechanically interlocked molecular compounds. We are now addressing this challenge.

A Molecular Composite Containing Organic and Inorganic Components—A Complex from β-Cyclodextrin and Hydrated Magnesium Chloride

Ioannis Nicolis, Anthony W. Coleman, Pierrette Charpin, and Colette de Rango*

Two distinct structural motifs are essential for biomineralization, namely, the crystalline systems of insoluble alkaline earth metal salts and the bioorganic matrix that directs the orientation of the crystalline inorganic components.[1] Two processes occur in biomineralization and these are crystallization, which is directed into the interior of vesicles,[2] and growth in the form of a columnar matrix, as is the case for collagen.[3]

Recently, S. J. Mann[4] considered, and subsequently correctly rejected, cyclodextrins (CDs) as models for host compounds for inward biomineralization. However, the strong tendency of CDs to form columnar (herringbone-like) structures bridged by hydrate zones suggested that they may serve as models for the second form of biomineralization mentioned above.[5] Since the salts usually found in biominerals—carbonates, phosphates, and sulfates—are only sparingly soluble, we chose to use chlorides in our studies. In the first β-CD composite containing a salt of a divalent cation ($CaCl_2$), modulation of the herringbone β-CD motif was observed;[6] however, a distinct structural motif for the mineral components was lacking.

We report here the crystal structure of a compound of the composition β-CD. $2[Mg(H_2O)_6]Cl_2$, and $3.5\,H_2O$,[7] a β-CD/$MgCl_2$ composite, which shows distinct, interlocking organic and inorganic matrices. The nature of the structure is such that it is difficult to say which substructure, organic or inorganic, determines the overall packing.

The Mg^{2+} ions are octahedrally coordinated by water molecules to form complex $[Mg(H_2O)_6]^{2+}$ cations, as normally observed in hydrated magnesium salt structures.[8] These $[Mg(H_2O)_6]^{2+}$ ions display a well-ordered arrangement and interact with the β-CD organic matrix in two distinct ways. On the two independent cations, Mg1 forms intermolecular bridges (see Fig. 4); the O atom of the aqua ligands link up to six β-CD units. In contrast, Mg2 displays second-sphere interactions essentially with mineral elements, through hydrogen bonding with its aqua ligands, and may be considered as undergoing partial inclusion. The chloride ions show different types of coordination; one of them, Cl4 (see Fig. 4), is the first free anion included within β-CD in a solid-state structure.

The intermeshing substructures from β-CDs and mineral elements form a unique organic–inorganic assembly (Fig. 1 left) comprising two distinct and interlocking networks: a novel chainlike arrangement of β-CD monomers held together by intermolecular hydrogen bonds and an infinite inorganic matrix passes through the cavities of the β-CDs (Fig. 1 right).

The $[Mg(H_2O)_6]^{2+}$ ions are arranged in a very regular geometry; part of the unit cell may be described as a pseudo face-centered orthorhombic lattice (Fig. 2), in which all octahedra are slightly displaced (< 0.9 Å) from the ideal positions. The majority of the inorganic components are arranged in layers, perpendicular to the *b* axis (Fig. 3). Within these inorganic layers, Mg1 and Mg2 octahedra are bridged by Cl3 anions to form a cluster. The anion Cl4, located between the inorganic layers, links two

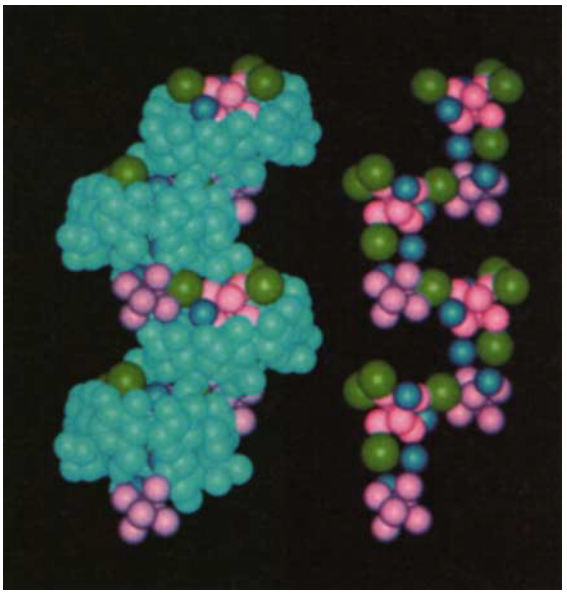

Fig. 1. Space-filling model of a section of the structure of the composite parallel to the *ab* plane (*a* horizontal). Left: The infinite intermeshing pattern of the β-CD monomer/inorganic matrix networks. Right: The infinite chain of the inorganic components separated from its β-CD environment for clarity (aqua ligands at Mg1 dark violet, those at Mg2 violet, Cl green, water of crystallization dark blue).

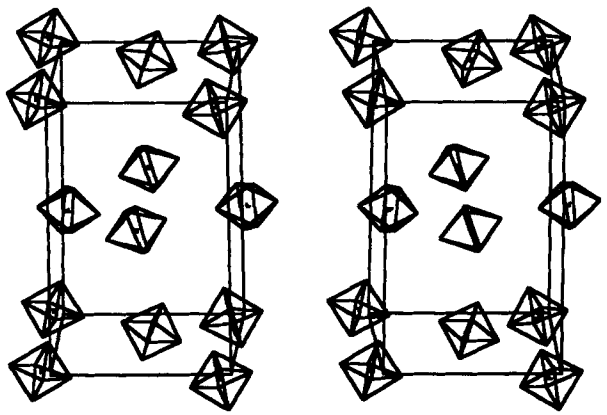

Fig. 2. Stereoview of the Mg^{2+} octahedra (*c* horizontal, *b* vertical) in a part of the unit cell (*a*, *b*, *c*/2); Mg1 are at *z* = 0 or 1/2 and Mg2 at *z* = 1/4 or 3/4. In an ideal arrangement, a cation would be surrounded by twelve neighbors; of the eight closest neighbors four are at 9.88 Å and four at 10.98 Å. Small distortions lead one neighbor of each group to be closer to the cation (Mg1 ··· Mg2 and Mg2 ··· Mg1′: 8.75 and 9.85 Å, compared to 10.35 and 11.40 Å, respectively).

symmetry-related clusters from adjacent layers, through the water molecule W14 (water of crystallization), to give infinite chains of Mg cations Mg1-Mg2-Mg1′-Mg2′. The mineral units are anchored along this basic structural motif (Fig. 4) and form, owing to the twofold screw axis parallel to the *b* axis, infinite chainlike structural motifs of inorganic units (see Fig. 1 right). Two antiparallel inorganic chains of this kind related by symmetry are alternately packed along the *c* axis (Fig. 3).

The two independent Mg cations possess quite different second coordination spheres. The Mg1 ion, located in the intermolecular CD interstices, has predominantly CD hydroxy groups as second neighbors: apart from the aqua ligand W4, which is hydrogen bonded to Cl3 and W14, the other five O atoms of aqua ligands are each directly hydrogen bonded to two hydroxy groups (ten interactions), thus simultaneously cross-

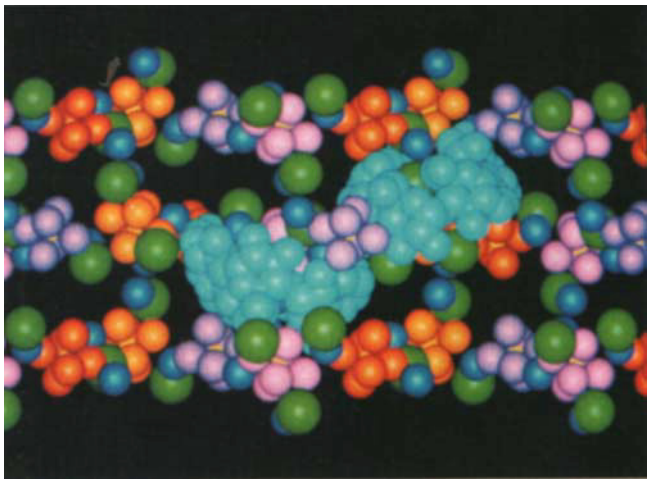

Fig. 3. View along the a axis (c horizontal) showing the packing of the inorganic layers parallel to the ac plane ($y = 0$ or $1/2$), the chloride ion Cl4 between the layers at $y = 1/4$ or $3/4$, and the β-CD monomers between adjacent inorganic layers. The chains of inorganic components run parallel to the vertical b axis (Mg^{2+}, yellow, barely visible) at $0 < z < 1/2$ (aqua ligands of Mg^{2+}, violet) and $1/2 < z < 1$ (aqua ligands of Mg^{2+}, orange). For clarity only one β-CD monomer is represented along each of the two antiparallel interlocking organic/inorganic chains in the unit cell.

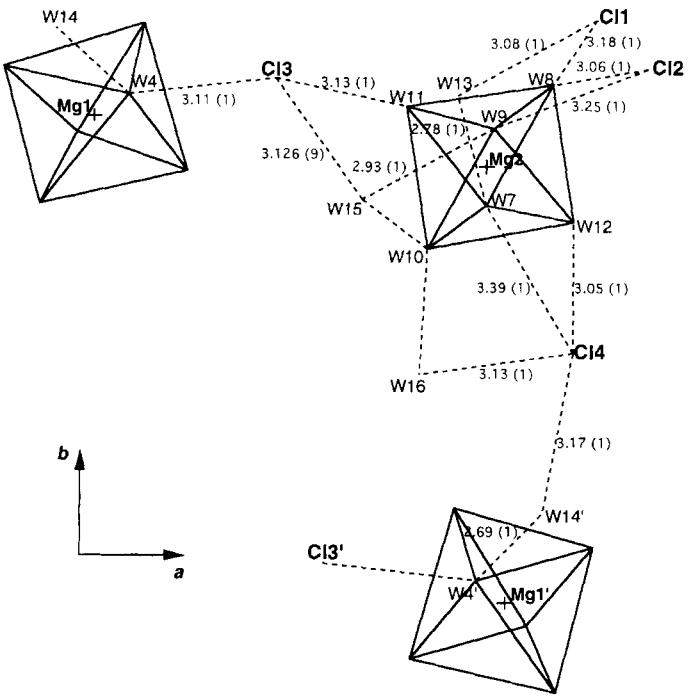

Fig. 4. A view of the inorganic structural motif indicating short contacts between the elements. It shows the intralayer Cl3 in the cluster formed by Mg1 and Mg2 octahedra (distance Mg1 $\cdots$ Mg2, 8.75 Å), and the interlayer Cl4 between clusters from adjacent layers (distances Mg2 $\cdots$ Mg(1'), 9.85 Å).

linking six β-CD monomers. These hydrogen bonds contribute to the three-dimensional cohesion of the structure. The environment about the Mg2 centers is particularly interesting, since these centers lie approximately at the level of the secondary O2/O3 hydroxy groups with a second-sphere coordination involving, through its hydration sphere, the four anions, three water molecules of crystallization, and only three O atoms from two different β-CD monomers. Three aqua ligands of the Mg2 octahedra are located in a β-CD cavity. This partial inclusion of the complex cation is stabilized by interactions through the anions: apart from Cl3, each chloride ion forms bridges to the aqua ligands coordinated to Mg2 and the secondary hydroxy groups of the host β-CD at hydrogen bonding distances.

The organic and inorganic parts of the structure interact through Cl anions, which form hydrogen bonds both with water molecules and with hydroxy groups of CDs: Cl1 and Cl2 form bridges between two or three β-CD monomers, the others, Cl3 and Cl4, have only one CD hydroxy group at hydrogen bonding distances. The chloride ion Cl3 links the Mg1 and Mg2 octahedra through W4 and W11 to give a cluster (Mg $\cdots$ Cl distances, 4.22 and 4.26 Å, respectively). Unexpectedly, the anion Cl4, which is located between the layers and forms part of the inorganic chain passing through the β-CDs, is in a real inclusion site within the cyclodextrin cavity.

The packing of the β-CD molecules likewise is a novel pattern of two "antiparallel" head-to-tail monomer helical chains related by symmetry. However, the β-CD monomers are embedded between two adjacent inorganic layers (Fig. 3), and the basic inorganic structural motifs pass through intramolecular CD cavities (Fig. 5).

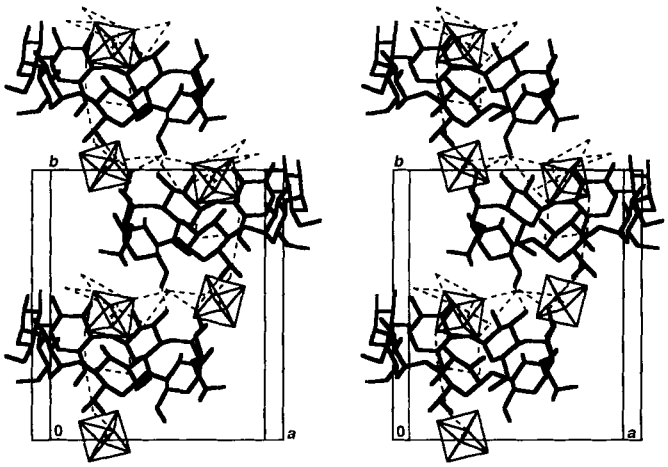

Fig. 5. Stereoview along the c axis showing the head-to-tail chain of β-CD monomers, through whose cavities the chain of inorganic components passes.

Indeed, the basic structure comprises two distinct and interlocking infinite helical chains running parallel to the b axis, one of β-CD monomers, the other involving the inorganic components (Fig. 1 left). The whole structure consists of two of these antiparallel "organic/inorganic chains" arranged alternately along the c axis (Fig. 3).

The structure may be considered in two ways: first, a novel arrangement of β-CD monomers into which an inorganic motif is inserted or second, a space-fitting arrangement of a β-CD assembly within an inorganic lattice.

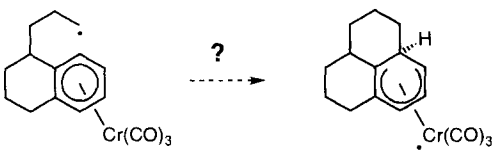
Radical Additions to (η^6-Arene)(tricarbonyl)-chromium Complexes: Diastereoselective Synthesis of Hydrophenalene and Hydrobenzindene Derivatives by Samarium(II) Iodide Induced Cyclization**

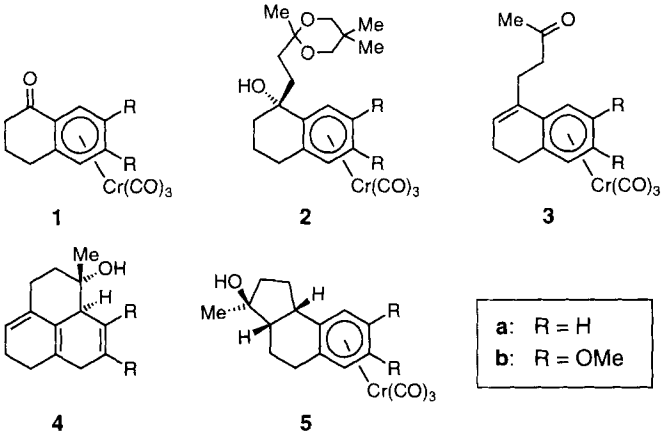
Hans-Günther Schmalz,* Stephan Siegel, and Jan W. Bats

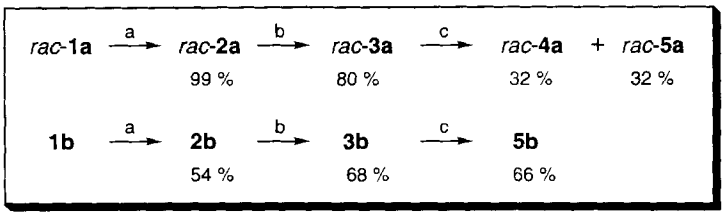
Arene–$Cr(CO)_3$ complexes have frequently proven their value for organic synthesis,[1] and the chemistry of this class of compounds has been the subject of intense investigations for many years.[2] In connection with our own work on the use of chiral tetralin–$Cr(CO)_3$ complexes as building blocks for the enantioselective total synthesis of compounds of biological relevance,[3] and with the intention of further exploring and developing the synthetic potential of this class of compounds, we wondered whether radical cyclizations[4] of the type shown in Scheme 1 can be utilized for the preparation of hydrophenalene derivatives.[5] We here report on the successful realization of such transformations and on the first examples of radical additions to arene–$Cr(CO)_3$ complexes.[6]



Scheme 1.

Due to the general sensitivity of Cr^0 complexes towards oxidation, we generated the radicals under reductive conditions. For this purpose the samarium(II) iodide mediated conversion of keto groups into ketyl radicals[7] appeared especially suitable to us. The first substrates we examined, 4-(3-oxobutyl)-1,2-dihydronaphthalene complexes of type **3**, are accessible from tetralone–$Cr(CO)_3$ derivatives **1**[8] in only two steps (Scheme 2).[9] The side chain was introduced by reaction with an organocerium reagent.[10] Treatment of the resulting alcohol intermediate **2** with *p*-toluenesulfonic acid on silica gel[11] led to (completely regioselective!) dehydration and deketalization.





Scheme 2. Preparation and cyclization of complexes of type **3**. a) 2-(2-Bromoethyl)-2,5,5-trimethyl-1,3-dioxane, Mg, THF, then $CeCl_3$·THF, 0 °C, 1.5 h, then addition of **1**, 0 °C, 45 min; b) *p*TsOH/SiO_2, benzene, 20 °C, 2 h; c) 2.5 equiv SmI_2, THF, HMPT, *t*BuOH, −78 °C, 2 h, then room temperature, 1 h. Characteristic data for compounds **4** and **5** are given in Table 1.

When complex *rac*-**3a** was treated with 2.5 equivalents of samarium(II) iodide in THF with hexamethyl phosphoric acid triamide (HMPA) as a cosolvent and *t*-butyl alcohol as a proton source at −78 °C,[12] the tricyclic compounds *rac*-**4a** and *rac*-**5a** were obtained (both as pure diastereomers[13]), together with some recovered starting material (Scheme 2). Under the same conditions, the (optically active) dimethoxy-substituted substrate **3b** selectively afforded complex **5b** in good yield; the structure of **5b** was established by X-ray crystallography (Fig. 1).[14]

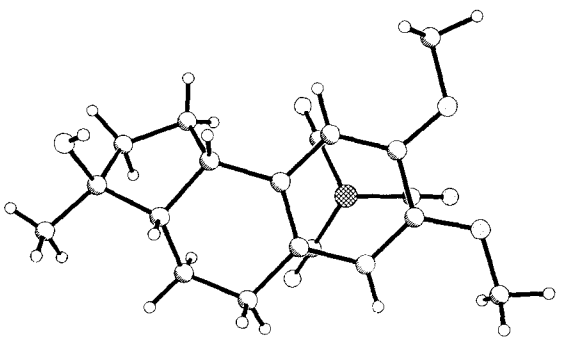


Fig. 1. X-ray crystal structure of **5b**.

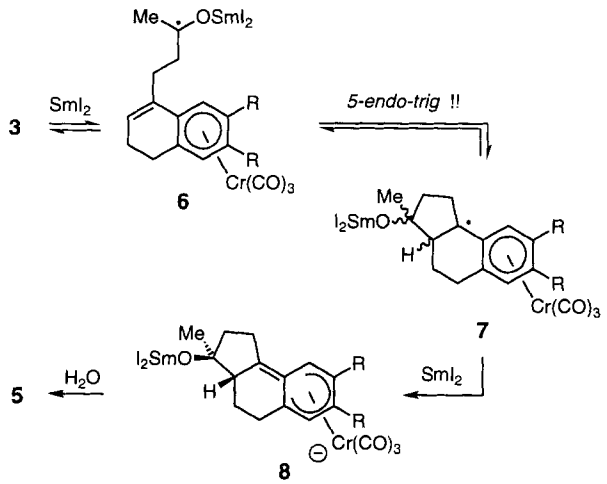
[**] This work was supported by the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, and Schering AG. We thank Prof. Dr. H. Schumann, Berlin, for a gift of samarium metal.

The formation of the hydrophenalene derivative *rac*-**4a** (formally the product of an alkylative Birch reduction[15]) can be rationalized as resulting from attack of the initially generated (relatively nucleophilic) ketyl radical **6** at the coordinated arene ring[16] according to Scheme 1 (see also Scheme 5). In contrast, the (unexpected) formation of the hydrobenzindenes *rac*-**5a** and **5b** can only be explained in terms of a (generally very unfavorable) 5-*endo-trig* cyclization[17, 18] of **6** to give the benzyl radical **7** (Scheme 3). We suspect that this cyclization is reversible (as is the formation of the ketyl radical **6**[19]) and that the second electron transfer (**7** → **8**) is actually the product-determining step.



Scheme 3. Mechanism of the formation of hydrobenzindenes of type **5**.

In this context, the diastereoselectivity (≥99% *de*) of the formation of *rac*-**5a** and **5b** can be explained as follows: During the cyclization step the bulky (HMPA-solvated) $OSmI_2$ group points into free space (e.g. **6A**). Of the two possible diastereoisomeric benzylic radicals **7** that could result, only one (**7A**) reacts further with samarium(II) iodide. In radical **7A** the unpaired electron at the radical center (which should be pyramidalized due to the preferred *cis* fusion of the rings) points away from the bulky $Cr(CO)_3$ fragment (Fig. 2). The resulting anionic complex

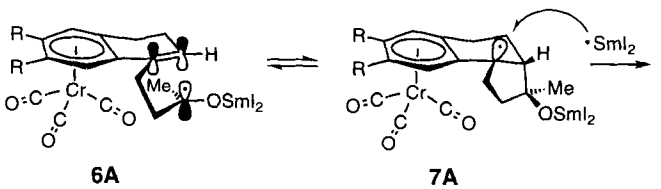


Fig. 2. Explanation of the diastereoselectivity of the formation of the hydrobenzindene derivative **5**.

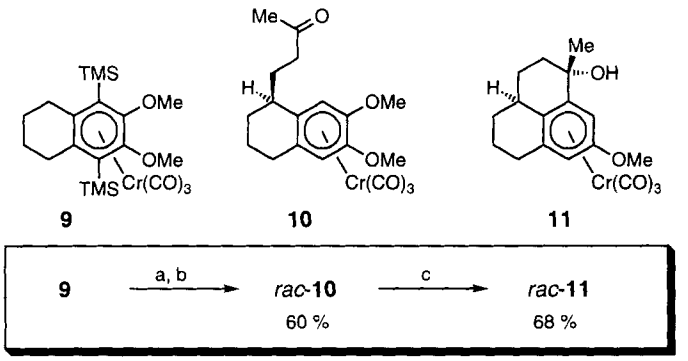
8 is then finally protonated from the *exo* face[20] (→ **5**). All in all, three new chiral centers are generated with virtually complete diastereoselectivity under the influence of the chiral metal complex substructure.

In the case of substrate **3b** only the hydrobenzindene derivative **5b** is formed, implying that the attack of the (nucleophilic) ketyl radical at the arene ring is suppressed as a consequence of the increased electron density of the methoxy-substituted aromatic ring. This is in accordance with the observation that the cyclization of the uncomplexed ketone, prepared by decomplexation of *rac*-**3a**, affords predominantly a single hydrobenzindene derivative (56% isolated yield), which proved to be identical with decomplexed *rac*-**5a**. At this point, the activating effect of the (electron-withdrawing) $Cr(CO)_3$ fragment for the addition of ketyl radicals to arene rings becomes evident. The advantage of complexed substrates (of type **3**) is that, in contrast to the free ligands, they are chiral and readily available in enantiomerically pure form, such that the absolute configuration of the cyclization products can be controlled.

The formation of a hydrophenalene derivative becomes the major cyclization pathway, when a tetralin complex is employed instead of a dihydronaphthalene complex (**3**) (Scheme 4). Thus, complex **9**,[21] obtained from the readily accessible complex *rac*-**10** by benzylic deprotonation, Michael addition, and desilylation, affords the hydrophenalene–$Cr(CO)_3$ derivative *rac*-**11** in high yield under the standard cyclization conditions (Table 1).



Scheme 4. Preparation and cyclization of *rac*-**10**. a) *n*BuLi, THF, HMPT, 0 °C, then $H_2C{=}C(SiMe_3)$-C(O)CH_3, then 2 N HCl; b) nBu_4NF, THF, H_2O; c) 2.5 equiv SmI_2, THF, HMPT, *t*BuOH, −78 °C, 2 h, then room temperature, 1 h. TMS = $SiMe_3$.

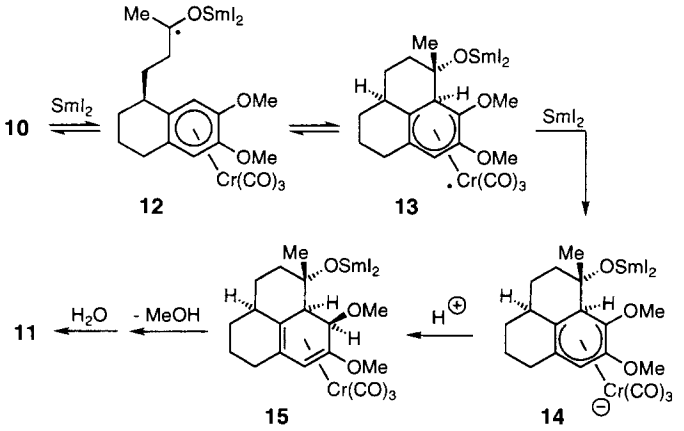
rac-**11**: M.p. 128 °C; IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 3592, 1959, 1893, 1866, 1535, 1459; ^{1}H NMR: δ = 1.13–1.28 (m, 1H), 1.33–1.47 (m, 1H), 1.55 (s, 3H), 1.72–1.90 (m, 3H), 1.93–2.13 (m, 3H), 2.14 (s, OH), 2.52 (pseudo-triplet, 1H, ^3J = 12 Hz), 2.8–2.9 (m, 2H), 3.68 (s, 3H), 4.99 (d, 1H, ^4J = 1 Hz), 5.38 (d, 1H, ^4J = 1 Hz), ^{13}C NMR: δ = 22.0 (CH_2), 28.8 (CH_2), 29.3 (CH_2), 29.8 (CH_2), 32.6 (CH_3), 37.0 (CH), 39.0 (CH_2), 55.5 (CH_3), 71.2, 74.7 (CH), 78.5 (CH), 100.9, 111.1, 121.6, 142.3, 234.3.

The formation of the demethoxylated complexes *rac*-**11**, which seems unexpected at first glance, resembles in some ways a nucleophilic aromatic (*cine*) substitution with methoxide as the leaving group.[22] Mechanistically, this reaction can be rationalized as follows (Scheme 5): In the first step the ketyl radical



Scheme 5. Mechanism of the formation of *rac*-**11** from *rac*-**10** (only one enantiomer shown).

12 is generated, which adds to the arene ring from the face opposite to the $Cr(CO)_3$ fragment (→**13**). The transfer of a further electron by samarium(II) iodide then leads to the anionic η^5-complex **14**, which is initially protonated at the chromium atom.[23] Rapid isomerization then gives the *endo*-protonated η^4 intermediate **15**, from which the stable (η^6-arene)–$Cr(CO)_3$ substructure is obtained by elimination of methanol.

We have shown that radical additions to arene–$Cr(CO)_3$ complexes can be employed in a preparatively attractive and mechanistically understandable fashion for the regio- and stereoselective synthesis of interesting products. Considering the 5-*endo-trig* cyclizations of ketyl radicals of type **6** observed during our investigations, one wonders whether analogous reactions (against all expectations) can eventually be realized in other cases.

A New Platform for Designing Ligands for Asymmetric Induction in Allylic Alkylations**

Barry M. Trost,* Bernhard Breit, Stefan Peukert, Jorge Zambrano, and Joseph W. Ziller

The design of ligands for asymmetric induction in transition metal catalyzed reactions has made great strides in reduction and oxidation processes. Success for the metal-catalyzed alkylation of allylic compounds by stabilized nucleophiles has been slower presumably because the bond-making or -breaking event in which the chirality is created occurs outside the coordination sphere of the metal and therefore distal to the chiral ligands.[1-5] Chiral phosphinoaryloxazoline ligands have had limited success; the best results are restricted to substrates that form π-allylpalladium complexes bearing bulky substituents like phenyl or isopropyl in the 1- and 3-positions.[1] Ligands based upon amides prepared from chiral diamines have proven more versatile.[2] Thus, cyclic allylic esters gave excellent results with a broad range of nucleophiles.[2b,c] In the desymmetrization of *meso* 1,4-enediol esters, which depended upon the nature of the ester, benzoates gave satisfactory results.[2a] However, the problem of the dependence of the enantiomeric discriminating step on leaving group became evident during cyclization of the biscarbamates to form oxazolidinones, which gave less satisfactory results.[1a] Enhancement of the process for asymmetric synthesis requires resolving those examples that have proven resistant to giving high *ee*'s with existing ligands. Designing new platforms chiral ligands should maintain a simplicity of synthesis. Based upon the model depicted in Figure 1, we now have developed a new platform for application to some of the systems that were previously less successful; our studies also revealed a most interesting dependence of the sense of chirality on the nature of the linker.

The availability of dicarboxylic acids in enantiomerically pure form, which could serve as the chiral scaffold, led to our consideration of a linker with an appropriate binding post. The success of amides in our first-generation ligands led to our choice of 2-diphenylphosphinoaniline (**1**) for the new linker, which is readily available in two steps from 2-chloroaniline and triphenylphosphane.[6] Acylation of **1** with the carboxylic acid chlorides derived from dicarboxylic acids **2a**–**5a**[7] gave the new diamindes **2b**–**5b** (see Table 2).[8] We began our tests of these ligands with the cyclization of the glycosidase precursor **6** [Eq. (a)].[2a] In each case, the diol **6a** was treated with *p*-toluenesulfonylisocyanate (*p*TsNCO) in THF at room temperature and then warmed to 60 °C. The resulting solution was added to a solution of the catalyst prepared from 2.5 mol% $[Pd_2(dba)_3]\cdot CHCl_3$ (**8**) (dba = dibenzylidenacetone) and 5–10 mol% of the ligand at 0 °C. The reaction was typically complete within 2–3.5 h. The results of the experiments with ligands **2b**, **3b**, and **5b** are given in Table 1 and compared to the results obtained with ligands **9**[2a] and **10**.[2a]

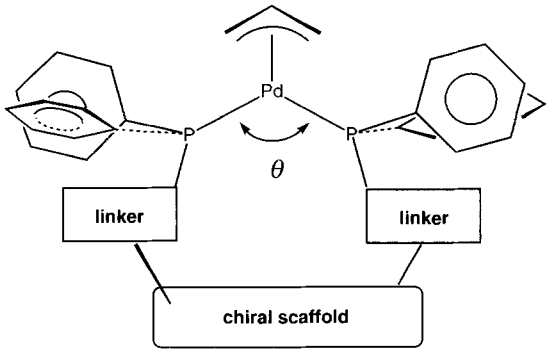

Fig. 1. Model of the ligand design.

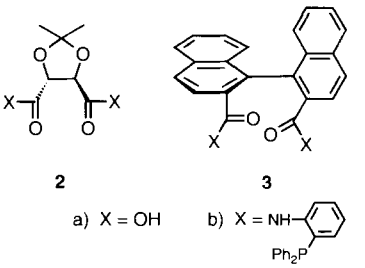

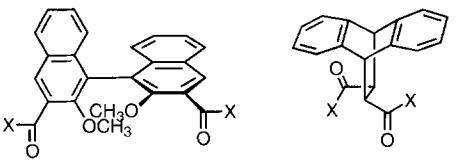

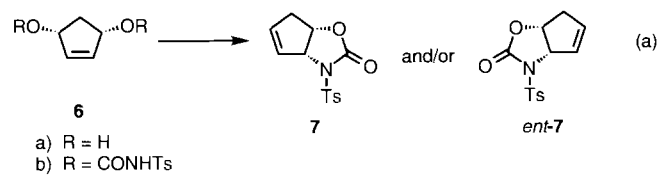

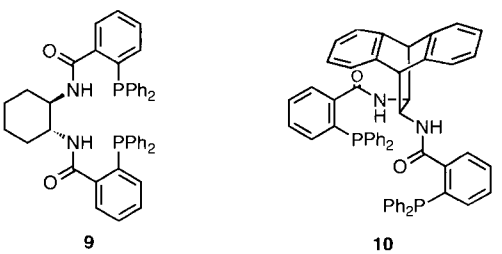

Table 1. Asymmetric induction in the Pd-catalyzed formation of oxazolidin-2-ones **7** and *ent*-**7**.

Entry	Ligand	Yield [%]	**7**:*ent*-**7** [a] (*ee*)
1	**2b**	29	56:44 (12)
2	**3b**	81	65:35 (30)
3	**5b**	99	6:94 (88)
4	**9**	97	11:89 (78)
5	**10**	94	94:6 (88)

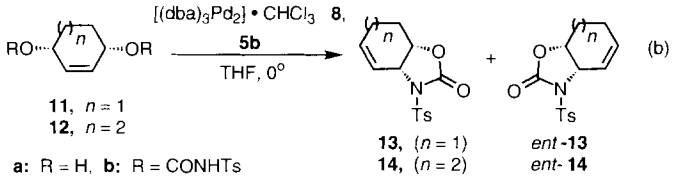
[**] We thank the National Science Foundation and the National Institutes of Health, General Medical Sciences, for their generous support of our programs. A postdoctoral fellowship for B. B. was provided by the BASF Aktiengesellschaft, a stipend for S. P. by the Studienstiftung des Deutschen Volkes, and a predoctoral fellowship for J. Z. by INTEVEP (Venezuela). Mass spectra were provided by the Mass Spectrometry Facility, University of California–San Francisco, which is supported by the NIH Division of Research Resources. Johnson Matthey Alfa Aesar provided palladium salts under a loan program.

Several interesting points are to be noted. Of the new ligands, only **5b** gave the product with acceptable levels of enantiomeric excess.[19] We previously suggested that the bite angle θ in the Pd complex (see Fig. 1) should be made as large as possible for higher selectivity; this bite angle may be related to the dihedral angle between the anchoring groups at the stereogenic centers of the chiral scaffold.[2a] Only in **5b** is the dihedral angle between the two carboxylate groups forced to be large. Completely surprising is the absolute configuration of the product. Comparing entries 3 and 5 (Table 1) show that maintaining the same sense of chirality of the chiral scaffold and only changing the orientation of the amide function reverses the sense of chirality in the product. Thus, from the same enantiomer of the dicarboxylic acid **5a**, which is the precursor of both **5b** and **10**, either enantiomer of the product is available with high *ee*.

The effectiveness of this new class of ligands in discriminating enantiotopic urethane leaving groups is revealed in examining examples with six- and seven-membered rings [Eq. (b)]. Following the same protocol as previously described, the bisurethanes



11b[2a] and **12b**[8] derived from diols **11a** and **12a** gave *ent*-**13**[8] and *ent*-**14**[8] in 97% *ee* (82% yield) and 95% *ee* (82% yield), respectively (Table 2).[9] By comparison, when ligand **10** was employed in these reactions, enantiomers **13** and **14** were obtained in 81% *ee* and 35% *ee*, respectively.

Table 2. Data for **5b**, *ent*-**13**, and *ent*-**14**.

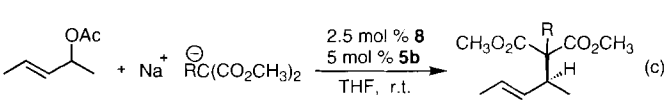
ent-**13**: M.p. 122 °C; $[\alpha]_D^{25} = +87.5$ ($c = 2.27$, CH_2Cl_2); IR (film): $\tilde{\nu} = 1778$, 1597, 1367, 1348 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz): $\delta = 7.95$ (d, $J = 8.3$ Hz, 2H), 7.34 (d, $J = 8.3$ Hz, 2H), 6.08 (m, 1H), 5.95 (m, 1H), 4.85 (m, 2H), 2.44 (s, 3H), 2.3–2.0 (m, 3H), 1.8 (m, 1H); HR-MS: calcd for $C_{14}H_{16}NO_3S$ ($M^+ + H$): 294.0800; found: 294.0791

ent-**14**: M.p. (racemate) 158 °C; $[\alpha]_D^{25} = +70.2$ ($c = 2.68$, CH_2Cl_2); IR (film): $\tilde{\nu} = 1767$, 1597, 1364, 1311 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz): $\delta = 7.97$ (d, $J = 8.4$ Hz, 2H), 7.35 (d, $J = 8.4$ Hz, 2H), 5.97 (dddd, $J = 11.1$, 6.6, 5.7, 2.0 Hz, 1H), 5.67 (ddd, $J = 11.1$, 3.4, 1.7 Hz, 1H), 5.21 (br.d, $J = 8.5$ Hz, 1H), 4.66 (ddd, $J = 9.9$, 8.5, 4.4 Hz, 1H), 2.45 (s, 3H), 2.18–1.83 (m, 4H), 1.70–1.53 (m, 2H); ^{13}C NMR ($CDCl_3$, 75 MHz): $\delta = 151.7$, 145.4, 135.3, 130.6, 129.7, 128.4, 125.8, 76.6, 58.7, 27.2, 26.6, 21.7, 17.6; Anal. calcd for $C_{15}H_{17}NO_4S$: C 58.62, H 5.57, N 4.56; found: C 58.53, H 5.71, N 4.53

We also examined 4-acetoxy-2-pentene as a substrate since, in contrast to 1,3-diphenylallyl acetate, the highest selectivity observed was only 71% *ee*.[1e] Using the sodium salt of dimethyl malonate in THF at room temperature gave the alkylated product **15**[1] in 74% *ee* (90% yield) [Eq. (c)] as determined by [Eu(hfc)$_3$] (hfa = heptafluoropropylhydroxymethylenecamphorato) NMR shift experiments. The *ee* jumped to 87% (93% yield) for the alkylation with the sodium salt of dimethyl



15 (R = H)
16 (R = CH_3)

methylmalonate to give **16**.[4] Thus, this new ligand gave the best results to date for asymmetric alkylation of the dimethylallyl system.

In trying to understand the contrasting chiral recognition of our normal carboxamide ligand **10** and our carboxamide "invertomer" ligand **5b**, we sought to obtain a crystal structure of one of the π-allyl complexes. The π-allylpalladium chloride dimer was mixed with **5b** and the anion was exchanged with perchlorate to give crystals suitable for X-ray analysis. Several striking features are revealed (Fig. 2).[11] The ligand moiety of

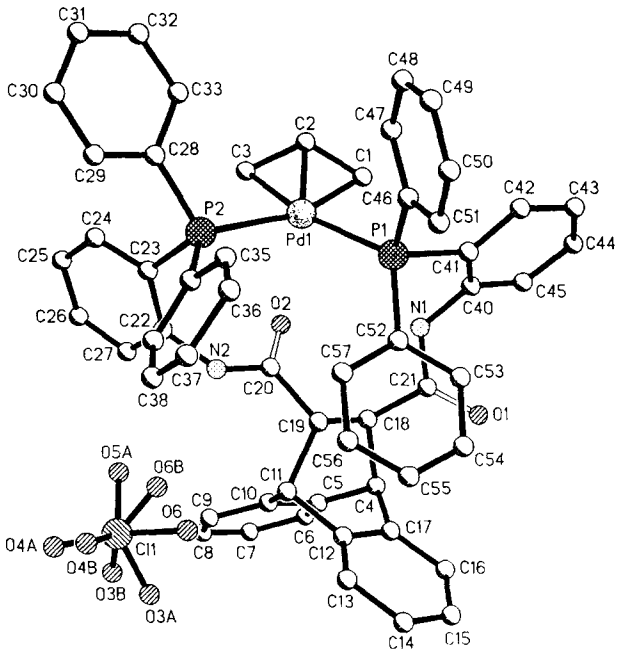


Fig. 2. Crystal structure of the Pd–allyl complex of the invertomer ligand.

the complex does not have C_2 symmetry even though it is feasible. NMR spectroscopy also indicates that the ligand lacks C_2 symmetry when bound to the π-allylpalladium unit in solution.[10] This clearly raises questions about the relevance of such symmetry for ligands designed for the Pd-catalyzed alkylation of allylic compounds. The bite angle indeed has opened from the typical 90° in square-planar palladium complexes to 110.5° in accord with our explanation of the enhanced selectivity of the reaction. As shown in Figure 3, these ligands, wherein the "chiral space" is defined by the grooves of the propellers formed by the bis(triarylphosphane) moieties, offer two types of cavities in which the palladium and substrate will reside, one flanked by Ar′ and Ar (the spaces labeled a and a*) and one flanked by only Ar groups (spaces b and b*). The X-ray structure for the complex formed from **5b** indicates that the π-allyl unit sits in a groove of the former kind. Based upon our molecular modeling, we have proposed that our normal ligands place the substrate in a groove of the latter type. While any definite conclusions must await an X-ray structure determination of a complex from **10**, the different positions of the π-allylpalladium in the two grooves

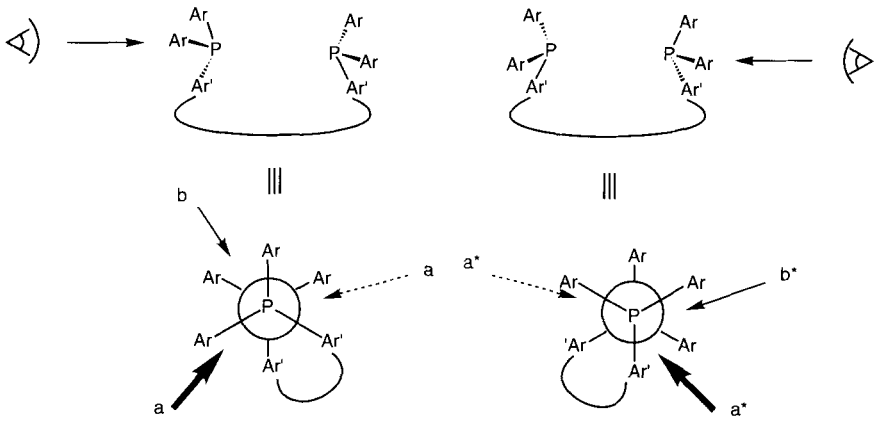

Fig. 3. Model of the different chiral spaces of the ligand.

may account for the change in chiral recognition. A rationalization traces back to the different properties of the linker aryl group, which is electron rich in **5b** and electron poor in **10**. Complexes of the latter would achieve some electronic stabilization by placing the π-allylpalladium cationic moiety closer to the more electron-rich aryl rings of the propeller. This new family of ligands provides a nice complement to our previous series and offers a new platform for further development.[12]

[10] Distortion of the preferred conformation of π-allylpalladium complexes with C_2-symmetric ligands in solution has been recently discussed: P. G. Andersson, A. Harden, D. Tanner, P.-D. Norrby, *Chem. Eur. J.* **1995**, *1*, 12.

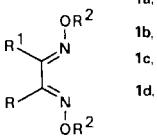
[11] X-ray data were collected at 296 K using a 0-2θ scan technique with $Mo_{K\alpha}$ radiation. All 3578 reflections were corrected for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was *mmm* with systematic absences $h00$ for $h = 2n+1$, $0k0$ for $k = 2n+1$ and $00l$ for $l = 2n+1$. The noncentrosymmetric orthorhombic space group $P2_12_12_1$ is therefore uniquely defined, $a = 12.2672$), $b = 17.735(2)$, $c = 23.861(9)$ Å, $V = 5191(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.356$ g cm^{-3}. All crystallographic calculations were carried out using either our locally modified version of the UCLA Crystallographic Computing Package or the SHELXTL PLUS program package. The analytical scattering factors for neutral atoms were used throughout the analysis; both the real ($\Delta f'$) and imaginary ($i\Delta f''$) components of anomalous dispersion were included. The quantity minimized during least-squares analysis was $\sum w(F_o - F_c)^2$ where $w^{-1} = \sigma^2(F) + 0.0009^2$. The structure was solved by direct methods and refined by full-matrix least-squares techniques. Hydrogen atoms were included using a riding model with d(C–H) = 0.96 Å, d(N–H) = 0.90 Å, and U(iso) = 0.08 Å^2. Those hydrogens associated with the allyl unit could not be located and were not included. The perchlorate anion is disordered. Refinement of positional and thermal parameters led to convergence with $R_F = 0.069$; $R_{wF} = 0.077$ and GOF = 1.62 for 325 variables refined against those 2575 reflections with $F > 4.0\sigma(F)$. The absolute structure was determined by refinement of the Rogers' h-parameter. A final difference-Fourier synthesis yielded ρ(max) = 0.61 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK) on quoting the full journal citation.

Peripherally Substituted Cobaloximes; X-ray Crystal Structure Analysis of σ-Hexylbis[1,8-di(*N*-morpholino)octane-4,5-dioximato]pyridinecobalt(III)**

Berthold Köhler, Martin Knauer, William Clegg, Mark R. J. Elsegood, Bernard T. Golding,* and János Rétey*

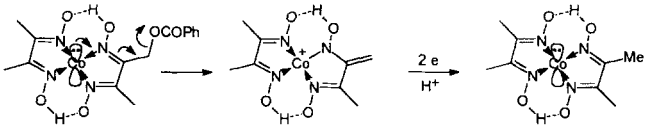
During our ongoing attempts to mimic the functions of the B_{12} coenzyme (5'-deoxyadenosylcobalamin, AdoCbl),[1,2] we synthesized several bridged, intramolecularly alkylated cobaloximes.[2] The homolysis of their Co–C σ bond is reversible, like that of the natural cofactor when bound to an enzyme. The development of supramolecular cobaloximes that exhibit molecular recognition and modeling the main features[3] of adenosylcobalamin-dependent enzymatic reactions requires the synthesis of bridged alkylcobaloximes with peripheral substituents to enable substrate binding. We have found that alkylcobaloximes bearing aminoalkyl substituents on the 1,2-dioxime units can be synthesized, provided the amino groups are γ-substituents, but not α- or β-substituents.

Most cobaloximes contain two dimethylglyoxime units.[4] Our attempts to synthesize alkylcobaloximes bearing α-amino substituents on methyl groups attached to the dioxime unit failed because of elimination of these substituents during the attempted preparation of an intermediate cobaloxime(I) species required for alkylation of the cobalt. Thus, oxime formation with 1,4-dibenzoyloxybutane-2,3-dione[5] gave the dioxime ligand **1a**, which was combined with cobalt(II) chloride



1a, R = R^1 = $PhCO_2CH_2$, R^2 = H
1b, R = Br, R^1 = Cl, R^2 = Tetrahydropyran-2-yl
1c, R = R^1 = $ClCH_2CH_2$, R^2 = H
1d, R = R^1 = $tBuPh_2SiOCH_2CH_2$, R^2 = H
1e, R = R^1 =  , R^2 = H

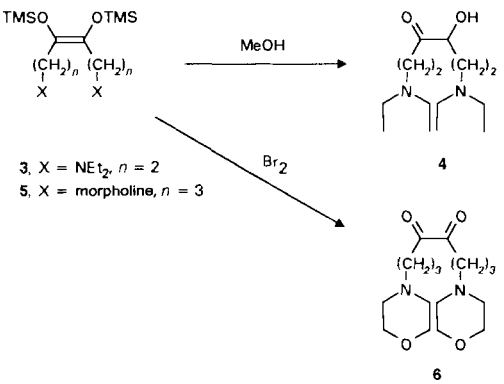
and pyridine in alkaline ethanol in the standard manner.[6] Addition of sodium borohydride followed by 2-bromopropane unexpectedly gave σ-isopropylbis(butane-2,3-dioximato)pyridinecobalt(III) (**2**) in 90% yield. Presumably, after cobalt is reduced to oxidation state 1, ejection of an α-substituent is triggered, and this is faster than reaction of the cobalt with the alkylating agent. The elimination is facilitated by conjugation of the filled d_{z^2} orbital on cobalt with the p orbitals of the dioxime, provided the bond to the leaving group is nearly perpendicular to the dioxime π system (Scheme 1). An analogous elimination occurred with a nitrogen function occupying the α-positions in the dioxime ligand.[7] In the corrin system reductive elimination of a peripheral bromine atom has been described[8a] and later interpreted[8b] as intramolecular electron transfer from the Co^I center. We therefore directed our attention to β-amino- and γ-amino-substituted alkylcobaloximes.



Scheme 1. Postulated mechanism for elimination of α-substituents during reduction of cobaloximes.

Protection of the hydroxy groups of 1-bromo-2-chloroglyoxime[9] as tetrahydropyranyl ethers gave **1b**, which was treated with ethene in the presence of aluminum trichloride to afford dioxime **1c**. The very low yield obtained in this Friedel–Crafts acylation (<5%) led us to investigate an alternative route to β-substituted dioximes based on the method of Criegee and Lederer.[5] This gave 1,6-dihydroxyhexane-3,4-dione bis-*t*-butyldiphenylsilyl ether, which was easily converted into the dioxime **1d**. However, all attempts to replace the β-oxygen functions of **1d** with amino functions failed.

In another approach we prepared 1,6-bis(*N*,*N*-diethylamino)-3,4-bis(trimethylsilyloxy)hex-3-ene (**3**) (TMS = trimethylsilyl) by sodium-induced acyloin condensation[10,11] of ethyl 3-(*N*,*N*-diethylamino)propanoate[12] in the presence of chlorotrimethylsilane. Numerous attempts to convert the bis(silyl) ether into the corresponding diketone (using bromine in dichloromethane,[11] thiocyanogen in chloroform,[11] or copper(II) acetate[13]) or derived 1,2-dioxime (for example using hydroxylamine hydrochloride in pyridine/ethanol[14] or dimethyl formamide[15]) failed. Methanolysis of **3** gave the very labile 1,6-bis(*N*,*N*-diethylamino)-4-hydroxyhexan-3-one (**4**), which could not be oxidized



(dimethyl sulfoxide/acetic anhydride[16]) to the corresponding diketone and did not give an isolable 1,2-dioxime on direct reaction with hydroxylamine. The lability of **4** (and **1d**) is ascribed to a tendency to undergo β-elimination. In contrast, the homologous system 1,8-di(*N*-morpholino)-4,5-bis(trimethylsilyloxy)oct-4-ene (**5**),[17] obtained by acyloin condensation[10,11] of ethyl 4-(*N*-morpholino)butanoate,[18] could be smoothly converted into the corresponding dioxime **1e**,[19] a relatively

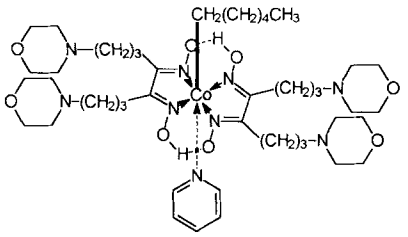
stable compound, from which the alkylcobaloxime 7[20] could be prepared by standard methodology.[6] Thus, reaction of ethyl 4-(*N*-morpholino)butanoate with four equivalents of sodium powder/chlorotrimethylsilane in diethyl ether afforded 1,8-di(*N*-morpholino)-4,5-bis(trimethylsilyloxy)oct-4-ene (**5**, 67%).



7

Oxidation of **5** with bromine[11] gave 1,8-di(*N*-morpholino)octane-4,5-dione (**6**), and the crude product was directly converted into the corresponding dioxime **1e** (49% overall yield) with hydroxylamine. The dioxime was treated with cobalt(II) bromide in methanol containing pyridine and sodium hydroxide to afford an intermediate cobaloxime(II) complex, which was reduced to cobaloxime(I) by addition of sodium borohydride. Alkylation with 1-iodohexane gave, after chromatogaphic purification, the crystalline alkylcobaloxime σ-hexylbis[1,8-di(*N*-morpholino)octane-4,5-dioximato]pyridinecobalt(III) (**7**, 40% yield). The ^{1}H and ^{13}C NMR spectra of **7** were consistent with the structure proposed, which was confirmed by X-ray analysis of single crystals[21] obtained from a solution of the complex in petroleum ether (Fig. 1). It is interesting that all the alkyl side chains contain one or two *gauche* elements. The Co–hexyl group exhibits the following arrangement for the major disorder component: Co-C1-C2-C3 *anti*, C1-C2-C3-C4 *gauche*, with C2-C3-C4-C5 and C3-C4-C5-C6 both *anti*. The Co–C1 bond length is 2.011(6) Å and the Co-C1-C2 bond angle is 123.6(6)°, which is unusually large[22] for a relatively unhindered Co–alkyl group.

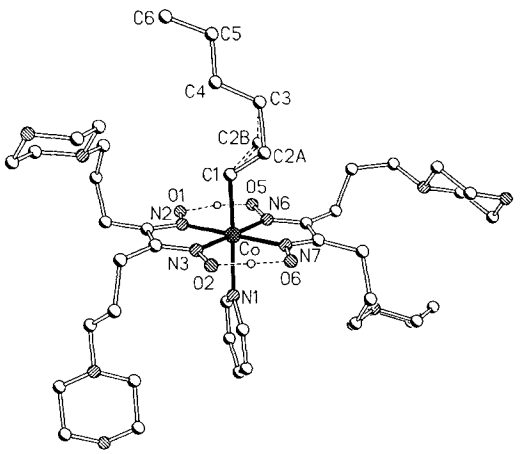


Fig. 1. Crystal structure of 7.

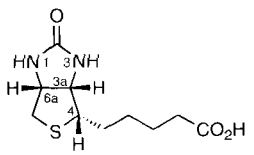
Synthesis of D-(+)-Biotin through Selective Ring Closure of *N*-Acyliminium Silyl Enol Ethers**

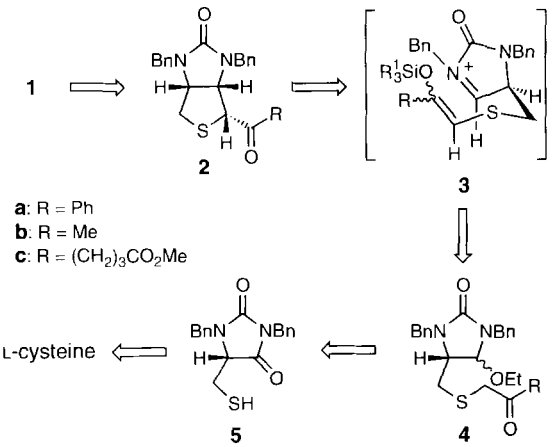
Marinus J. Moolenaar, W. Nico Speckamp,*
Henk Hiemstra, Eike Poetsch, and Michael Casutt

Over the years both the synthesis[1] and biosynthesis[2] of the nutritional cofactor D-(+)-biotin (**1**)[3, 4] have aroused continuing interest. As a result of its commercial value and increasing applications in medicine,[5] new syntheses continue to be published,[6] several of which are based on the ready availability of L-cysteine or L-cystine as a chiral starting material.[1c, 6d–f, h, i]



1

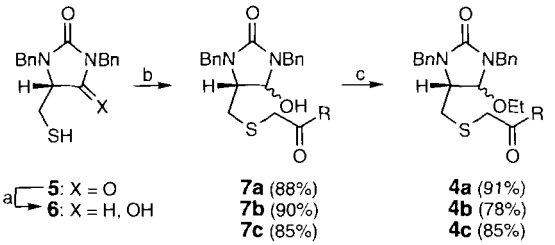
The condensation of silyl enol ethers with *N*-acyliminium intermediates is efficient not only in intermolecular reactions,[7] but also in intramolecular processes, as exemplified by our total synthesis of gelsemine,[8] where this reaction is the key transformation. Applying a similar strategy for (+)-biotin (**1**) leads to a retrosynthetic route as illustrated in Scheme 1, in which the



Scheme 1. Retrosynthesis of D-(+)-biotin (**1**). R^1 = protecting group.

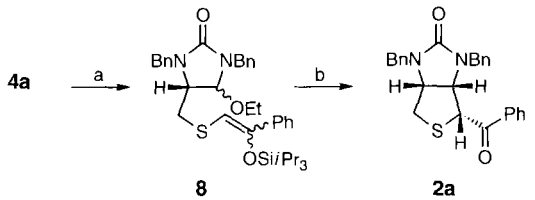
essential carbon–carbon bond-forming step is realized through cyclization of the intermediate **3c** (R = $(CH_2)_3CO_2Me$). The latter species is expected to be generated in a few steps from the known imidazolidinone **5**.[6d, 9] The following prerequisites must be met if such a cyclization process is to occur with maximum efficiency: 1) competing proton loss from intermediate **3c** has to be strictly avoided, 2) formation of the silyl enol ether from the appropriate ketone has to be regioselective, and 3) the presence of the adjacent stereogenic center has to direct the formation of the desired (6a*R*,3a*S*,4*R*) isomer via the shown chairlike transition state. To probe the feasibility of such a ring closure of iminium species **3c**, identical annulations through analogs **3a** (R = Ph) and **3b** (R = Me) were investigated first.

The preparation of the cyclization precursors **4a–c** starts from the readily available imidazolidinone **5** (Scheme 2). Reduction with diisobutylaluminum hydride (DIBALH) in THF gave the corresponding hydroxyimidazolidinone **6** in quantitative yield (*cis*:*trans* ≈ 10:1 according to ^{1}H NMR spectroscopy), which after coupling with the appropriate α-chloroketones was converted into thioethers **7a–c** in 85–90% yield. Conversion of these compounds into their ethoxy counterparts **4a–c** was achieved in 78–91% yields under carefully controlled conditions. This result already indicated the possibility of generating a cationic intermediate without affecting the adjacent sensitive stereocenter.[10]



Scheme 2. a) 2.2 equiv DIBALH, −70 °C, THF, 1 h, 99%; b) 1.05 equiv $RC(O)CH_2Cl$, 1.5 equiv Et_3N, 0 → 25 °C, 4 h; c) H_2SO_4/EtOH, methyl orange, pH = 3.1, 0 °C, 2 h.

Formation of the stable triisopropylsilyl (TIPS) enol ether **8** (Scheme 3) proceeded upon treatment of **4a** with an excess of TIPSOTf (Tf = SO_2CF_3) to give an 81% yield of a 46:54 mixture of *E*/*Z* isomers. The isomers of the readily separable *E*/*Z* mixture were subjected to the cyclization reaction separately to afford in each case the crystalline product **2a** (m.p. 143–144 °C, $[\alpha]_D^{25} = -77.6$ ($c = 1.1$, $CHCl_3$)) in 91% yield as a single isomer with the configuration corresponding to D-(+)-biotin (**1**) according to several ^{1}H NMR techniques (NOE-difference, COSY, NOSY). The formation of only one diastereoisomer is rationalized by assuming that both isomers cyclize via the aforementioned chairlike conformation, regardless of the geometry of the double bond.



Scheme 3. a) 5.5 equiv TIPSOTf, 6.0 equiv Et_3N, CH_2Cl_2, 25 °C, 18 h, 81% (*E*:*Z* = 46:54); b) 1.5 equiv TMSOTf, CH_2Cl_2, −78 °C, 1 h, 91%.

Prompted by this encouraging result, the methyl derivative **4b** was studied (Scheme 4) to investigate the effect of the enolizable methyl protons in the enol ether formation. Both the regio- and stereoselectivity of the enol ether formation varied dramatically with minor changes of the reaction conditions, to give *E*/*Z* mixtures of **9** and its regioisomer **10** in ratios that could not be sufficiently controlled. After it was found that cyclization of the pure (*Z*)-TIPS enol ether of **9**, as well as cyclization of *in situ* prepared trimethylsilyl (TMS) enol ethers, invariably produced mixtures of **2b** and **11**, our further efforts were only focused on the cyclization of **4c** and the synthesis of D-(+)-biotin (**1**) itself (Scheme 5).

It was anticipated that the presence of the ester side chain might favor the formation of the desired silyl enol ether by lowering the acidity of the α-methylene protons. Most gratifyingly, treatment of **4c** with TMSOTf (1 equiv, 1.05 equiv Et_3N,

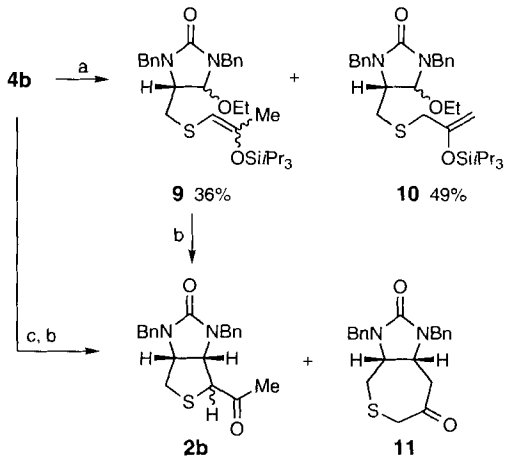
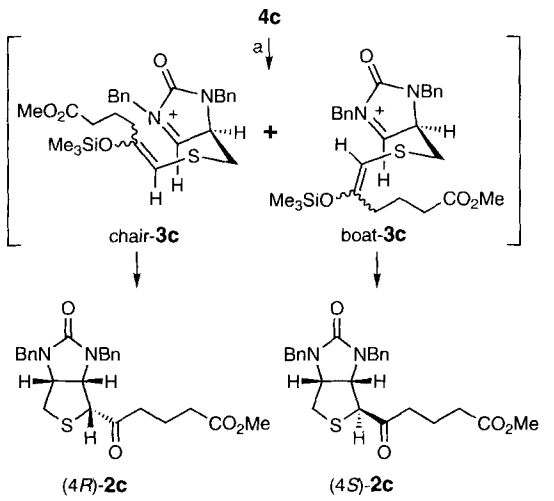
[**] We thank J. R. Frowijn for his experimental work.



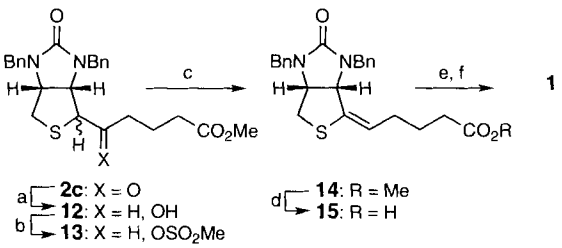
Scheme 4. a) 3.0 equiv TIPSOTf, 3.3 equiv Et_3N, CH_2Cl_2, 25 °C, 18 h; b) 1.5 equiv TMSOTf, CH_2Cl_2, −78 °C, 1 h; c) 2.2 equiv TMSOTf, 2.5 equiv Et_3N, CH_2Cl_2, −20 → 10 °C, 2 h.



Scheme 5. a) 2.1 equiv $TMSCH_2CO_2Et$, 0.03 equiv TBAF, THF, −78 → 25 °C, 18 h, then 1.5 equiv TMSOTf, CH_2Cl_2, −78 °C, 1 h, 78% (3:2 mixture of 4*R*:4*S* diastereomers).

CH_2Cl_2, −20 → 10 °C, 2 h) to form the enol ether in situ, followed by addition of a second equivalent of TMSOTf (CH_2Cl_2, −70 °C, 1 h) gave (4*R*)-**2c** and its 4*S* diastereoisomer in a 2:1 ratio and 69% yield. Optimization of the reaction conditions did not lead to an improvement of this ratio, but the use of $TMSCH_2CO_2Et$/TBAF (TBAF = tetra-*n*-butylammonium fluoride)[11] for the in situ enol ether formation and addition of TMSOTf to induce cyclization did lead to a slightly better yield (78%) for (4*R*)-**2c** and its 4*S* diastereoisomer (3:2 ratio). Apparently, this cyclization also proceeds partly through a boatlike conformation to give the 4*S* diastereoisomer. A single crystallization afforded pure (4*R*)-**2c** (m.p. 101.5–102.5 °C, $[\alpha]_D^{25} = -10.7$ ($c = 0.2$, $CHCl_3$)); the conformation was confirmed by ^1H NMR spectroscopy. These one-pot/two-step techniques constitute a novel extension of the useful applications of *N*-acyliminium intermediates in natural product synthesis.[12]

The loss of control of the stereochemistry at C4 did not influence the conversion of the diastereomeric mixture of **2c** into D-(+)-biotin (**1**) (Scheme 6). The sequence involved standard reactions: 1) reduction of the ketone with $NaBH_4$ to give the alcohol **12**, 2) formation of the mesylate **13**, 3) elimination of the



Scheme 6. a) 1.0 equiv $NaBH_4$, MeOH, 25 °C, 1 h; b) 5.0 equiv $MeSO_2Cl$, Et_3N/CH_2Cl_2 1/1, 0 → 35 °C, 1.5 h; c) DBU, 60 °C, 2 h; d) KOH/MeOH, 2 h, 87% (four steps); e) H_2 (10 bar), 10% Pd/C, 2-propanol, 50 °C, 18 h; f) 48% HBr, 100 °C, 2 h, 85% (two steps).

mesylate with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to give the olefin **14**, 4) hydrolysis of the methyl ester, 5) hydrogenation of the double bond of the carboxylic acid **15**, and finally 6) deprotection of the imidazolidinone moiety to give D-(+)-biotin (**1**) in 74% yield over the last six steps.

In this contribution we describe a novel, eleven-step total synthesis of the vitamin D-(+)-biotin (**1**) that proceeds in 42% overall yield starting from the imidazolidinone **5**.[9b] Particularly noteworthy is the regioselective, in situ enol ether formation, directly followed by an *N*-acyliminium ion cyclization producing the desired *cis*-fused bicyclic framework. Although there is some lack of selectivity with respect to the C4 center, the efficiency of the sequence as a whole is not affected.

Experimental Procedure

6: A solution of **5** (9.80 g, 30.0 mmol) in THF (200 mL) was treated dropwise with DIBALH (66.0 mL of a 1.0 M solution in CH_2Cl_2, 66.0 mmol) at −70 °C. After stirring at −70 °C for 1 h, water (50 mL), 10% NaOH (50 mL), and again water (150 mL) were added dropwise, and the mixture was stirred for 1 h at 25 °C. The organic layer was separated, washed with brine (3 × 100 mL), dried (Na_2SO_4), filtered, and concentrated to give the hydroxyimidazolidinone **6** (9.82 g, 99%) as a viscous colorless oil. **6**: $R_f = 0.40$ (ethyl acetate/petroleum ether 50/50); $[\alpha]_D^{25} = -14.8$ ($c = 0.87$ in $CHCl_3$); ^1H NMR (250 MHz, $CDCl_3$): $\delta = 7.40-7.10$ (m, 10H, ArH), 5.00 (d, $J = 6.2$ Hz, 1H, C*H*OH), 4.86 (d, $J = 15.0$ Hz, 1H, CH_2Ph), 4.82 (d, $J = 15.4$ Hz, 1H, CH_2Ph), 4.23 (d, $J = 15.0$ Hz, 1H, CH_2Ph), 4.04 (d, $J = 15.3$ Hz, 1H, CH_2Ph), 3.43–3.33 (m, 1H, C*H*CH_2), 2.85 (br.t, $J = 10.0$ Hz, 1H, C*H*$_2$SH), 2.64 (br.d, $J = 10.5$ Hz, 1H, C*H*$_2$SH), 2.37 (s, 1H, SH); IR ($CHCl_3$): $\tilde{\nu} = 3520-3170$, 1690 cm^{-1}.

7c: A solution of **6** (2.30 g, 7.00 mmol) in THF (15 mL) was treated at 0 °C with Et_3N (1.4 mL, 10.0 mmol), followed by methyl 6-chloro-5-oxohexanoate (1.31 g, 7.35 mmol), and stirred at 0 °C for 2 h. After stirring at 25 °C for 2 h, the mixture was filtered, concentrated, and filtered through silica (pretreated with ammonia, ethyl acetate/petroleum ether 60/40) to give **7c** (2.79 g, 85%) as a viscous colorless oil that was used directly for the next step.

4c: A solution of **7c** (4.70 g, 10.0 mmol) in EtOH (200 mL) was acidified dropwise at 0 °C with a H_2SO_4 (2 N)/EtOH solution to pH 3.1 (indicator methyl orange). After stirring at 0 °C for 2 h, the pH of the solution was raised carefully to pH 5.5 by adding a 2% solution of KOH in EtOH, and the mixture was concentrated. The residue was dissolved in EtOAc (100 mL), washed with water (100 mL), dried (Na_2SO_4), concentrated, and purified by flash column chromatography (silica, pretreated with ammonia, ethyl acetate/petroleum ether 50/50) to give **4c** (4.24 g, 85%, *trans*:*cis* = 9:1) as a viscous colorless oil. *trans*-**4c**: $R_f = 0.62$ (ethyl acetate/petroleum ether 50/50); ^1H NMR (250 MHz, $CDCl_3$): $\delta = 7.32-7.22$ (m, 10H, ArH), 4.92 (d, $J = 15.0$ Hz, 1H, CH_2Ph), 4.88 (d, $J = 14.9$ Hz, 1H, CH_2Ph), 4.50 (s, 1H, C*H*OEt), 4.12 (d, $J = 15.0$ Hz, 2H, CH_2Ph), 3.65 (s, 3H, OCH_3), 3.50–3.10 (m, 3H, C*H*CH_2S, OCH_2), 3.07 (s, 2H, $SCH_2C(O)$), 2.75–2.25 (m, 6H, $CH_2CO_2CH_3$, $CH_2C(O)$, CH_2S), 1.85 (quintet, $J = 7.5$ Hz, 2H, $CH_2CH_2CH_2$), 1.05 (t, $J = 7.5$ Hz, 3H, CH_2CH_3); IR ($CHCl_3$): $\tilde{\nu} = 1725$, 1700 cm^{-1}.

2c: A mixture of **4c** (249 mg, 0.500 mmol) and ethyl (trimethylsilyl)acetate (189 µL, 1.05 mmol) in THF (1 mL) was treated dropwise at −78 °C with TBAF (150 µL of a 0.1 M solution in THF, 15 µmol) over 20 min. After stirring at −78 °C for 20 min and at 25 °C for 18 h, the mixture was concentrated, and the residue dissolved in CH_2Cl_2 (2 mL). The solution was cooled to −78 °C, TMSOTf (135 µL, 0.750 mmol) added dropwise, and the mixture stirred at −78 °C for 1 h. The reaction was quenched with aqueous saturated ammonium chloride (5 mL) and diluted with CH_2Cl_2 (50 mL). The organic layer was washed with water (40 mL) and brine (40 mL), dried ($MgSO_4$), concentrated, and purified by flash column chromatography (ethyl acetate/petroleum ether 80/20) to give the imidazolidinone **2c** (175 mg,

78%) as a 3:2 mixture of isomers. Both isomers could be obtained in pure form as white solids by recrystallization from ethyl acetate/hexane. (4*R*)-**2c**: $R_f = 0.65$ (ethyl acetate/petroleum ether 60/40); m.p. 101.5–102.5 °C; $[\alpha]_D^{25} = -10.7$ ($c = 0.2$ in $CHCl_3$); ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 7.32-7.22$ (m, 10H, ArH), 4.78 (d, $J = 15.2$ Hz, 1H, CH_2Ph), 4.57 (d, $J = 15.0$ Hz, 1H, CH_2Ph), 4.22 (d, $J = 15.2$ Hz, 1H, CH_2Ph), 4.05 (d, $J = 15.0$ Hz, 1H, CH_2Ph), 4.04–4.02 (m, 2H, H6a, H3a), 3.65 (s, 3H, CH_3), 3.59 (d, $J = 5.7$ Hz, 1H, H4), 2.82–2.71 (m, 2H, H6), 2.56 (dt, $J = 17.5$, 7.5 Hz, 1H, $CH_2C(O)$), 2.25 (dt, $J = 1.7$, 7.5 Hz, 2H, $CH_2C(O)$), 1.95 (dt, $J = 17.5$, 7.5 Hz, 1H, $CH_2C(O)$), 1.78 (quintet, $J = 7.5$ Hz, 2H, $CH_2CH_2CH_2$); IR ($CHCl_3$): $\tilde{\nu} = 1725$, 1700, 1680 cm^{-1}; HRMS (EI, 70 eV) calcd for $C_{25}H_{28}N_2O_4S$ 452.1770, found 452.1766. (4*S*)-**2c**: $R_f = 0.70$ (ethyl acetate/petroleum ether 60/40); m.p. 82.5–83 °C; $[\alpha]_D^{25} = -21.2$ ($c = 1.3$ in $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.35-7.25$ (m, 10H, ArH), 4.75 (d, $J = 15.4$ Hz, 1H, CH_2Ph), 4.50 (d, $J = 15.2$ Hz, 1H, CH_2Ph), 4.45 (d, $J = 15.2$ Hz, 1H, CH_2Ph), 4.29 (d, $J = 7.9$ Hz, 1H, H3a), 4.21 (d, $J = 15.4$ Hz, 1H, CH_2Ph), 4.20 (dd, $J = 4.6$, 7.9 Hz, 1H, H6a), 3.65 (s, 3H, CH_3), 3.58 (s, 1H, H4), 2.75 (d, $J = 12.9$ Hz, 1H, H6), 2.69 (dt, $J = 7.5$, 17.3 Hz, 1H, $CH_2C(O)$), 2.56 (dd, $J = 4.8$, 12.9 Hz, 1H, H6), 2.26–2.19 (m, 3H, $CH_2C(O)$), 1.78 (quintet, $J = 7.3$ Hz, 2H, $CH_2CH_2CH_2$); IR ($CHCl_3$): $\tilde{\nu} = 1725$, 1700, 1680 cm^{-1}; HRMS (EI, 70 eV) calcd for $C_{25}H_{28}N_2O_4S$ 452.1770, found 452.1760.

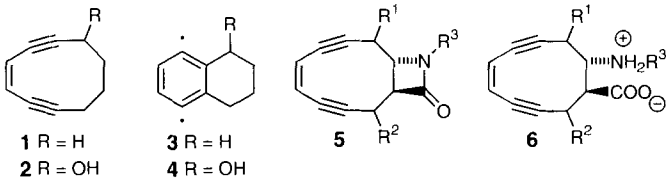
Lactendiynes: A New Class of Triggered Cyclic Enediynes**

Luca Banfi and Giuseppe Guanti*

After the recent discovery of the potent anticancer activity of naturally occurring cyclic enediynes, great efforts are now being made in the design and synthesis of analogues of these compounds characterized by a similar mode of action, but, at the same time, by low molecular complexity.[1] Ideally, these mimics should be endowed with a chemical "trigger", a structural element that locks the enediyne system in a stable form, but that can be removed in a controlled fashion, unveiling the DNA-damaging power of the enediyne unit. Moreover, to increase selectivity and effectiveness, these mimics should also preferably possess suitable handles for appending DNA-binding agents.[1c, 2]

With this aim we are exploring a new class of synthetic enediynes of general formula **5**, which we have christened "lactendiynes", and which are characterized by a β-lactam *trans*-fused to a ten-membered cyclic enediyne. These compounds are analogues of the known parent compounds **1**[3] and **2**,[4] which have been shown to undergo Bergman cycloaromatization at a moderate rate at 37 °C, affording the highly reactive aryl diradicals **3** and **4**, respectively. We reasoned that lactendiynes should be



1 R = H
2 R = OH

3 R = H
4 R = OH

5

6

completely stable toward cycloaromatization, whereas their hydrolysis products **6** should be even more reactive than the parent compounds **1** and **2**. The first prediction was based: a) on the previous work of Nicolaou, Bergman, et al.,[5] who demonstrated that a ten-membered enediyne *trans*-fused to a dioxolanone is not reactive; and b) on molecular mechanics calculations,[6] which indicated that the cycloaromatized product is highly strained. The second less obvious prediction was based on MM calculations,[6] which indicated that **6** should have a very short lifetime at 37 °C. Therefore, in vivo β-lactam opening could serve as the triggering event for transforming potential enediyne prodrugs **5** into the actually active species **6**. Further advantages of compounds **5** are their simple structure, which facilitates their total synthesis, and the possibility of appending DNA-binding agents by using the substituents R^1, R^2, and R^3 as handles.

To verify these assumptions we have now prepared the first compounds of this class. Scheme 1 shows the synthetic route, which starts from known 2-azetidinone **7**, prepared in six steps by reported procedures[7] from D,L-aspartic acid.[8] After protection of the nitrogen function,[9] the side chain at position 3 was introduced by condensation of the lithium enolate derived from **8** with 3-bromo-1-(trimethylsilyl)propyne. This reaction

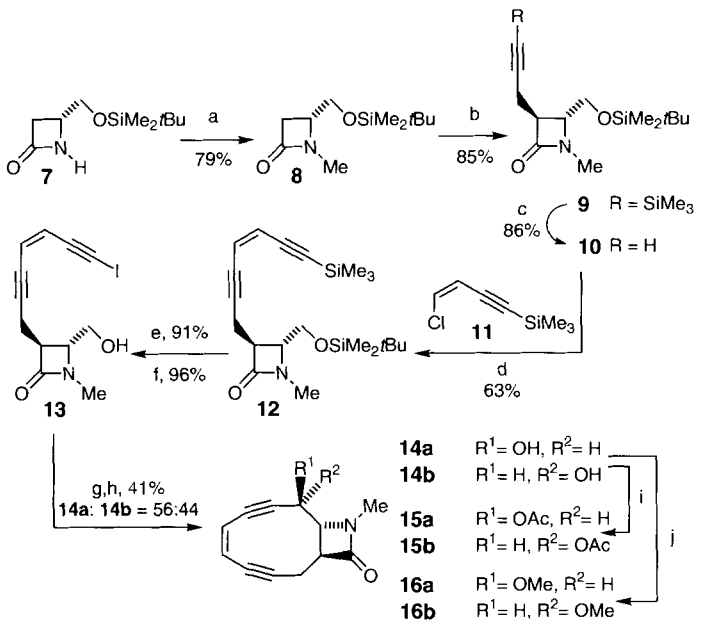
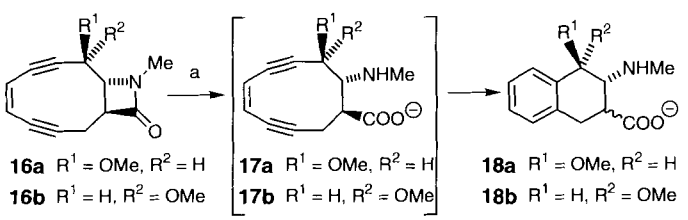
[**] We thank Andrea Basso for his valuable collaboration. This work was supported by the CNR and MURST.



Scheme 1. a) nBu$_4$NBr, MeI, KOH (pellets), THF, 0 °C; b) LDA, then BrCH$_2$C≡CSiMe$_3$; c) AgNO$_3$, NaCN, EtOH/H$_2$O; d) CuI, [(PhCN)$_2$PdCl$_2$], piperidine/THF; e) AgNO$_3$, NIS, DMF; f) HF, H$_2$O, CH$_3$CN, −20 °C → 0 °C; g) (COCl)$_2$, DMSO, Et$_3$N, CH$_2$Cl$_2$, −78 °C; h) CrCl$_2$, NiCl$_2$, THF; i) Ac$_2$O, pyridine/CH$_2$Cl$_2$ (76% for **15a**, 66% for **15b**); j) NaH, MeI, DMF (85% for **16a**; 76% for **16b**).

proceeded with complete stereoselectivity, affording only the desired *trans* product **9**. After selective removal of the trimethylsilyl group,[10] the stage was set for the construction of the enediyne system by Castro–Stephens coupling with chloroenyne **11**.[11] However, under standard conditions with [Pd(PPh$_3$)$_4$] as catalyst, the reaction was sluggish and **12** was obtained in at most 25–30% yield. In contrast, good yields were achieved by employing [(PhCN)$_2$PdCl$_2$] in THF/piperidine, according to a procedure by Alami and Linstrumelle.[12] One-pot transformation of enediyne **12** into the corresponding iodoacetylene using a method developed by Isobe et al.,[13] followed by deprotection of the primary alcohol, gave **13**. Oxidation and Nozaki cyclization[6, 14] afforded the diastereomeric mixture of alcohols **14a,b** in satisfactory yield (41%, 13% overall from **7**), which are easily separable by silica gel chromatography.

Alcohols **14a,b** are remarkably stable both in solution and in the solid state,[15] and have been smoothly transformed into the corresponding acetyl and methyl derivatives **15a,b** and **16a,b** (Table 1). Heating the methyl ethers **16a,b** at 100 °C for several hours in the presence of 1,4-cyclohexadiene gave no reaction. On the other hand, when **16a** was treated with 1 N NaOH in MeOH in the presence of 1,4-cyclohexadiene for two hours, complete transformation into the cycloaromatized products **18a** took place (Scheme 2). The product formed as a mixture of two



Scheme 2. a) 1–1.5 N NaOH in abs. MeOH, 1,4-cyclohexadiene, 50 °C, 2–5 h.

diastereoisomers (Table 1), presumably because of epimerization at the carbon α to the carboxylate group.[16] The reaction was monitored by ^{1}H NMR spectroscopy; no signals attributable to the intermediate enediynic amino acids **17a,b** were observed. Thus cycloaromatization seems to take place immediately after the β-lactam opens, in line with the theoretical predictions.[17] Under the same conditions **16b** is converted into **18b** (Table 1).[18]

Table 1. Physical data for **16a,b** and **18a,b**.

16a: ^{1}H NMR (200 MHz, CDCl$_3$, 25 °C, TMS): δ = 2.66 (dd, ^2J(H, H) = 17.9 Hz, ^3J(H, H) = 12.2 Hz, 1 H, C*H*HC≡), 2.88 (dd, ^2J(H, H) = 17.9 Hz, ^3J(H, H) = 3.9 Hz, 1 H, CH*H*C≡), 2.92 (s, 3 H, CH$_3$N), 3.24–3.38 (m, 1 H, CHC=O), 3.46 (s, 3 H, CH$_3$O), 3.73 (dd, ^3J(H, H) = 2.3, 9.1 Hz, 1 H, CHN), 4.25 (d, ^3J(H, H) = 9.1 Hz, 1 H, C*H*OMe), 5.91 (s, 2 H, C*H*=CH); ^{13}C NMR (50 MHz, CDCl$_3$, 25 °C, TMS): δ = 19.50 (*C*H$_2$C≡), 28.90 (CH$_3$N), 54.93, 56.87, 63.76, 64.19 (CH and OCH$_3$), 83.93, 88.30, 95.18, 100.00 (C≡C), 122.20, 124.57 (C=C), 167.45 (C=O); MS (70 eV): *m/z* (%): 215 (29) [*M*$^+$], 200 (76) [*M*$^+$−CH$_3$], 184 (14.6), 172 (21.9), 156 (43), 144 (25.5), 143 (32.5), 129 (21.2), 128 (17.6), 115 (66), 105 (100), 63 (39), 42 (82); IR (CHCl$_3$): $\tilde{\nu}$ = 2200 (very weak), 1747 cm^{-1}

16b: ^{1}H NMR (200 MHz, CDCl$_3$, 25 °C, TMS): δ = 2.59 (dd, ^2J(H, H) = 17.9 Hz, ^3J(H, H) = 13.1 Hz, 1 H, C*H*HC≡), 2.81 (s, 3 H, CH$_3$N), 2.89 (ddd, ^2J(H, H) = 17.9 Hz, ^3J(H, H) = 3.8 Hz, ^5J(H, H) = 1.7 Hz, 1 H, CH*H*C≡), 3.46 (s, 3 H, CH$_3$O), 3.64–3.80 (m, 2 H, CHC=O and CHN), 4.37 (t, ^3J(H, H), ^5J(H, H) = 1.8 Hz, 1 H, C*H*OCH$_3$), 5.96, 5.89 (br., AB system, ^2J(H, H) = 9.7 Hz, 2 H, CH=CH); ^{13}C NMR (50 MHz, CDCl$_3$, 25 °C, TMS): δ = 19.36 (*C*H$_2$C≡), 26.60 (CH$_3$N), 52.19, 57.20, 63.25, 67.72 (CH and OCH$_3$), 83.58, 87.28, 95.66, 100.79 (C≡C), 122.02, 126.26 (C=C), 167.82 (C=O); MS (70 eV): *m/z* (%): 215 (42) [*M*$^+$], 200 (100) [*M*$^+$−CH$_3$], 184 (15.7), 172 (24), 156 (45), 144 (31), 143 (32), 129 (22.5), 128 (19.4), 115 (67), 105 (94), 63 (40), 42 (83); IR (CHCl$_3$): $\tilde{\nu}$ = 2240, 2205, 1750 cm^{-1}

18a: ^{1}H NMR (200 MHz, CD$_3$OD, NaOD, 25 °C, TMS): δ = 2.42 and 2.49 (s, 3 H, CH$_3$N), 2.80–3.40 (m, 4 H, CH$_2$Ar, CHCOO, CHN), 3.23 and 3.49 (s, 3 H, CH$_3$O), 4.23 (d, ^3J(H, H) = 2.6 Hz, 1/2 H, C*H*OMe), 4.41 (d, ^3J(H, H) = 5.8 Hz, 1/2 H, CHOMe), 7.10–7.25 (m, 3 H, arom.), 7.25–7.35 (m, 1 H, arom.)

18b: ^{1}H NMR (200 MHz, CD$_3$OD, NaOD, 25 °C, TMS): δ = 2.44 and 2.49 (s, 3 H, CH$_3$N), 2.70–3.60 (m, 4 H, CH$_2$Ar, CHCOO, CHN), 3.33 and 3.38 (s, 3 H, CH$_3$O), 4.36 (br. s, 2/3 H, C*H*OMe) 4.43 (d, ^3J(H, H) = 4.0 Hz, 1/3 H, CHOMe), 7.05–7.30 (m, 4 H, arom.).

This study demonstrates the feasibility of employing lactendiynes as enediyne prodrugs. Although hydrolysis of inactivated β-lactams **14**–**16** is probably difficult to achieve in vivo, modification of the same synthetic scheme should lead to more reactive analogues of **5**, bearing suitable activating groups R^3 for facilitating azetidinone opening.

[6] We used the simplified approach proposed by Maier [1a], based on calculation of the difference of the strain energies (E_S) of the final product (the hydrogenated diradical) and the substrate. Performing the calculations with Chem3D Plus

(CSC, Cambridge, MA), we obtained for **14a,b**–**16a,b** values of ΔE_s that are 15–17 kcal mol^{-1} higher than for models compounds **1** and **2**. In contrast, calculated ΔE_s valued for **6** (R^1 = OH, OMe, OAc) are lower than those obtained for **1** and **2** by about 2–4 kcal mol^{-1}. (In general the ΔE_s values of the all-*trans* isomers were lower.)

[15] In contrast, the related alcohol **2** is unstable at room temperature and even at 20 °C in neat form, undergoing side reactions other than cycloaromatization (see ref. [4]).

[16] This epimerization takes place only after β-lactam opening, since the *cis* β-lactam is not evident by either NMR spectroscopy or by TLC. Moreover, the relative amount of the two epimers increases with time, reaching a final ratio of ca. 1:1.

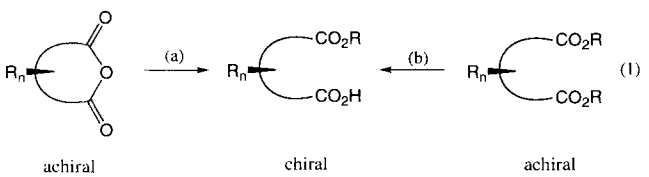
[17] As a comparison: at 50 °C, $t_{1/2}$ (**1**) = 3.6 h [3]. The reason for the higher reactivity of **17a,b** compared to **1** or **2** probably lies in the more unfavorable steric interactions between the carboxylate and NHMe groups in the cyclic enediyne (dihedral angle ca. 25°) than in the tetrahydronaphthalenes **18** (dihedral angle ca. 50°). Snyder has calculated that placing two *trans* methyl groups at positions 8 and 9 of **1** should decrease the activation energy for cycloaromatization of about 1.1 kcal mol^{-1}: J. P. Snyder, *J. Am. Chem. Soc.*, **1990**, *112*, 5367–5369.

[18] In this case, however, β-lactam opening was slower, and was complete only after 5 h with 1.5 N NaOH in MeOH. The ratio of the two epimers of **18b** (initially ca. 1:3) was inverted to ca. 3:1 by the end of reaction.

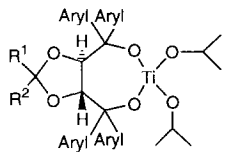
Highly Enantioselective Opening of Cyclic *meso*-Anhydrides to Isopropyl Hemiesters with Diisopropoxytitanium TADDOLates**

Dieter Seebach,* Georg Jaeschke, and Yan Ming Wang

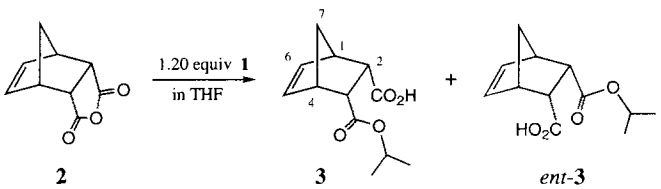
Based on the enormous structural diversity of readily accessible C_s-symmetrical anhydrides of dicarboxylic acids with enantiotopic carbonyl groups, a catalytic, enantioselective opening to give the corresponding hemiesters is of great significance for organic synthesis [Eq. (1a)]. The usefulness of such hemiesters becomes quite clear when the vast amount of literature dealing with the enantioselective enzymatic hydrolysis of the analogous diesters is considered [Eq. (1b)].[1]



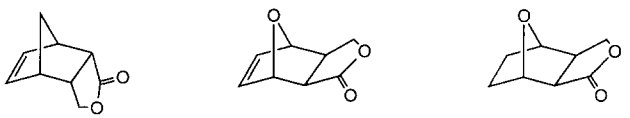
In this publication, we describe the reactions of anhydrides in THF to give isopropyl hemiesters (mono-isopropyl esters) of high enantiopurity; the reactions were initially carried out with stoichiometric amounts of chiral Lewis acids, namely the diisopropoxytitanium TADDOLates **1**.[2] The reaction conditions were optimized with the *endo*-Diels–Alder product **2** of maleic anhydride and cyclopentadiene, by using the β-naphthyl derivative **1a**.[2] After a reaction time of several days at a temperature of −30 °C, we obtained the hemiester **3** in a virtually enantiopure form (see Experimental Procedure) with yields exceeding 90%. Also, the hexaphenyl derivative **1b**,[2] as well as the original titanium TADDOLate **1c**[3] and **1d** (unsymmetrically substituted at the acetal center),[2] produced comparable selectivities (see Table 1). The isolation of the hemiester is quite simple; during work up, the carboxylic acid is extracted into an aqueous alkaline solution, this separates it from the TADDOL, which is subsequently quantitatively recovered from the organic phase. The configuration (1*R*,2*S*,3*R*,4*S*) of the dextrorotatory[4] monoester **3** was determined through reduction with $LiBEt_3H$ and lactonization to the known compound **4**.[5] Thus, the isopropoxy group has attacked the *Re*-carbonyl group of the anhydride **2** (Scheme 1).



1a ($R^1 = R^2 = CH_3$, Aryl = β-$C_{10}H_7$)
1b ($R^1 = R^2$ = Aryl = C_6H_5)
1c ($R^1 = R^2 = CH_3$, Aryl = C_6H_5)
1d ($R^1 = C_6H_5$, R^2 = H, Aryl = C_6H_5)



2 **3** *ent*-**3**



4 **5** **6**

Scheme 1. Opening of the anhydride **2** with titanium TADDOLates **1** to the isopropyl hemiesters **3** and *ent*-**3** and also lactones **4**–**6** obtained from **2**, **10**, and **11**, respectively, via the appropiate hemiesters.

Other tricyclic (**7**–**11**), bicyclic (**12**–**13**), and monocyclic (**14**) anhydrides react analogously, yielding hemiesters of high enantiopurity (Table 1). Only the anhydride **15** with a methyl substituent in the β-position to the carbonyl groups is opened with a moderate 3:1 selectivity. In all cases, the enantiomer ratio was determined by using CSP-GC (details see Table 1 and Experimental Procedure). Also, the absolute configuration (1*S*,2*R*,3*S*,4*R*) of the hemiesters obtained from **10** and **11** was determined by comparison of the sense of rotation from the corresponding lactones **5** and **6**,[6] while that of the hemiesters resulting from the reactions of the other substrates has not yet been established.[7] With two exceptions (products obtained from **14** and **15**) all hemiesters are dextrorotatory.

Table 1. Reaction conditions, yields and enantioselectivities of the isopropyl hemiesters obtained from the anhydrides **2** and **7**–**14** with 1.20 equiv diisopropoxytitanium TADDOLate **1**. Except with the products from **10** and **11** [a], all enantiomer ratios were determined by GC analysis (on various cyclodextrin columns) of the methylisopropyl esters obtained from the hemiesters and diazomethane.

anhydride	**1**	Reaction conditions time [d]	T [°C]	Hemiester yield [%]	enantiomer ratio
2	**1a**	7	−30	88	99:1
2	**1b**	6	−30	87	99:1
2	**1c**	5	−30	91	97:3
2	**1d**	5	−30	88	96:4
7	**1a**	6	−30	91	99:1
8	**1b**	6	−30	91	99:1
9	**1a**	6	−30	92	97:3
10	**1a**	6	−30	63	99:1 [a]
11	**1a**	6	−30	82	98:2 [a]
12	**1a**	5	−15	87	>95:5
13	**1a**	5	−15	76	97:3
14	**1a**	5	−18	73	98:2

[a] In these two cases the enantiomer ratio was determined by GC analysis of **6** (to which **5** was also hydrogenated).

Earlier experiments by other research groups on enantioselective ring-opening of suitable anhydrides were less successful.[8, 9] Preliminary tests with the anhydride **2** have shown that an enantioselective ring-opening is also possible using substoichiometric amounts of the titanium TADDOLate **1** and stoichiometric amounts of titanium tetraisopropoxide. Analogous reactions of other carboxylic acid derivatives such as phenolic esters[10] and *N*-sulfonylimides and the use of other chiral Lewis acids in these reactions will be reported in the near future. We believe it should be possible to use chiral titanium Lewis acids such as **1** in many other reactions, in which so-called hydrolytic enzymes[1b] are currently being employed.

Experimental Procedure

Hemiester **3**: $Ti(OCHMe_2)_4$ (2.4 mmol, 0.707 mL) was added dropwise to a solution of β-naphthyl-TADDOL (2.50 mmol, 1.67 g) in ether (20 mL) under argon and the mixture was stirred for 3 h at room temperature (RT) to produce **1a**. The solvent was removed under vacuum and the residue was dried for 30 min. The residue was dissolved in THF (10 mL) (distilled from K) and the solution was cooled to −30 °C. A cold solution (ca. −30 °C) of the anhydride **2** (2.0 mmol, 328 mg) in THF (5 mL) was added. The homogeneous solution was sealed and stored for 7 d in a freezer (−30 °C). Subsequently, the reaction mixture was poured into 0.5 N NaOH (80 mL), ether (ca. 100 mL) was added, and the aqueous phase was separated. The organic phase was extracted with further 0.5 N NaOH (80 mL), and the combined aqueous phases were washed with ether. Acidification with 1 N HCl to pH 1–2, followed by extraction with ether (2 × 100 mL), drying with $MgSO_4$, and evaporation of the solvent yielded 394 mg of **3** (88%); m.p. 89–90 °C, $[\alpha]_D^{RT}$ +7.5 (c = 2.5, $CHCl_3$); ratio of enantiomers = 99:1 (determined by GC-analysis on a β-3P-cyclodextrin column of the methylisopropyl ester obtained by reaction of **3** with diazomethane).

Total Synthesis of Natural (+)-SF2315A and Determination of the Absolute Configuration**

Kyungjin Kim and Gary A. Sulikowski*

The antibiotic SF2315A (**1**) was identified during the course of screening for new antibiotics from soil microorganisms.[1] Spectral analysis of **1** established a benz[*a*]anthracene core structure leading to the classification of SF2315A (**1**) as a member of the angucycline family of antibiotics.[2] The relative configuration of **1** was assigned based on a single-crystal X-ray analysis, while the absolute configuration was not assigned.[1b] Antibiotic SF2315A (**1**) exhibits weak activity against Gram-

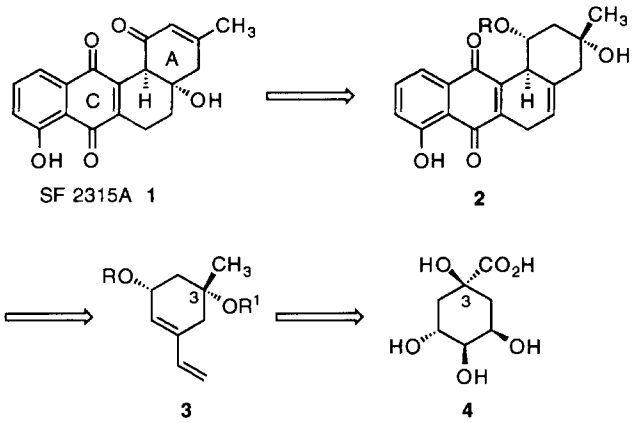
[**] This work was supported in part by the Welch Foundation (A-1230) and Texas A & M University. We thank Dr. Toru Sasaki (Meiji Seika Kaisha, Ltd.) for kindly providing an authentic sample of SF2315A. G. A. S. thanks the American Cancer Society for a Junior Faculty Research Award and the American Cyanamid Company for a Cyanamid Faculty Award.

positive bacteria and inhibits the reverse transcriptase of avian myeloblastosis virus (IC_{50} 100 $\mu g mL^{-1}$).[1a]

Efforts directed towards the total synthesis of angucycline antibiotics have led to the completion of angucyclinones of the benz[*a*]anthraquinone subclass.[3, 4] In contrast, no synthesis of a family member that possesses an angular oxygen, such as SF 2315A (**1**), has been reported.[5] Herein, we describe the first total synthesis of (+)-SF 2315A (**1**), which establishes the absolute configuration and represents the first synthesis of an angucycline antibiotic that bears an angular oxygen (that is, a nonaromatic B ring).

Our approach to SF 2315A (**1**) is outlined in a retrosynthetic sense in Scheme 1. Various derivatives of diene **3** are available



Scheme 1. Retrosynthetic analysis of SF 2315A (**1**).

starting from (−)-quinic acid (**4**).[6] The Diels–Alder cycloaddition of **3** and 5-acetoxy-2-bromojuglone (**7**) followed by minor functional group transformations would deliver quinone **2**.[7] The stereochemical course of the cycloaddition would be determined by the C1 allylic ether within the diene component.[8] Finally, oxidation of the C4a–C5 double bond of **2** from the α face, *cis* to the angular C12b hydrogen, would establish the *cis* AB ring fusion.

We recently described the preparation of dienol **5** starting from (−)-quinic acid.[4d, 6] Silylation of **5** under standard conditions afforded the silyl ether **6** in quantitative yield. Diels–Alder cycloaddition between **6** and 5-acetoxy-2-bromojuglone (**7**)[13] proceeded smoothly to deliver a single diastereomer (**8**). In this way the absolute configuration of the C12b stereocenter as well as the correct regiochemical arrangement between the A ring and the aryl substituent at C8 were established. Brief hydrogenation of **8** over palladium in ethanol followed by the introduction of a catalytic amount of K_2CO_3 effected the cleavage of the C3 benzyl ether, dehydrobromination, and the removal of the C8 acetyl group to give rise to quinone **9** in quantitative yield. Examination of molecular models revealed that oxidants would attack alkene **9** preferably from the α face (that is, *cis* to the C12b hydrogen). Indeed, epoxidation of **9** provided, exclusively, α-epoxide **10**. Epoxide **10** underwent rearrangement to the corresponding allylic alcohol upon treatment with 0.5 equivalents of tetrabutylammonium fluoride (TBAF) in THF. Peracetylation of this allylic alcohol then provided diacetate **11**. Reduction of the C5–C6 double bond proved problematic due presumably to the intermediacy of the dihydro(semi)quinone oxidation state of **11**. For example, competing elimination of the angular hydroxyl group or decomposition was observed when **11** was directly hydrogenated over Adam's catalyst. However, brief hydrogenation over 5% palladium–carbon generated the corresponding dihydroquinone, which following removal of the palladium catalyst, further hydrogenation over Adam's catalyst, and final oxidation with cerium ammonium nitrate (CAN), afforded **12** in 73% yield.

The remaining synthetic operations involved manipulation of the A ring functionality. To this end, removal of the C1 triisopropylsilyl (TIPS) group followed by Dess–Martin oxidation of the resultant alcohol provided ketone **13**.[14] Treatment of **13** with lithium hydroxide in THF produced an approximately equal mixture of **14** and SF 2315A (**1**). The former was again subjected to lithium hydroxide to afford SF 2315A (**1**). Synthetic **1** was identical in all respects to natural material (according to the 400 MHz ^1H and 50 MHz ^{13}C NMR spectra). The sign of optical rotation of synthetic SF 2315A (**1**) $\{[\alpha]_D^{25} = +112$ (*c* 0.05 in $CH_3OH)\}$ was also identical with that of natural **1** $\{[\alpha]_D^{25} = +106$ (*c* 0.05 in $CH_3OH)\}$. Thus the absolute configuration of (+)-SF 2315A is assigned as 4a*S*-(4aα,12bα). (Selected physical and spectroscopic data of compounds **8**–**13** and **1** are summarized in Table 1.)

In summary, we have completed the first total synthesis of SF 2315A (**1**), which constitutes the first assembly of an angucycline antibiotic possessing an angular hydroxyl group and de-

Evidence for a Mechanism Involving Transient Fragmentation in Carbon Skeleton Rearrangements Dependent on Coenzyme B_{12}**

Birgitta Beatrix, Oskar Zelder, Friedrich K. Kroll, Gissur Örlygsson, Bernard T. Golding,* and Wolfgang Buckel*

Dedicated to Professor Albert Eschenmoser on the occasion of his 70th birthday

We propose a new mechanistic hypothesis for the remarkable rearrangements of carbon skeletons catalyzed by adenosylcobalamin (coenzyme B_{12}) dependent glutamate mutase [EC 5.4.99.1] from *Clostridium tetanomorphum* and *C. cochlearium*, 2-methyleneglutarate mutase [EC 5.4.99.4] from *C. barkeri*, and methylmalonyl-CoA mutase [EC 5.4.99.2] from humans,

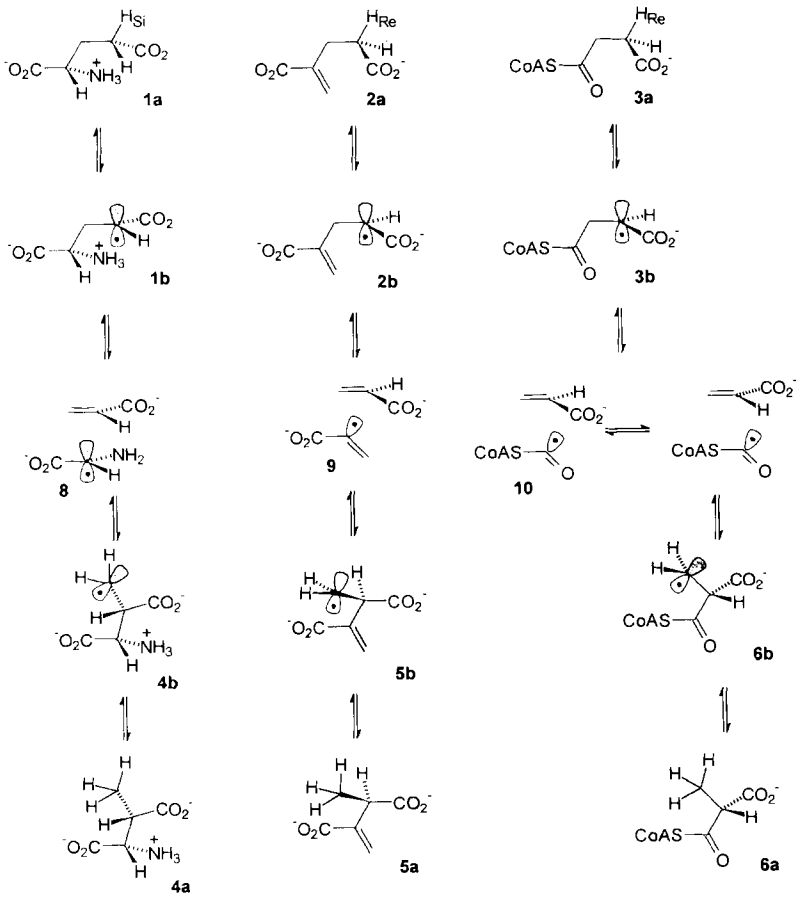
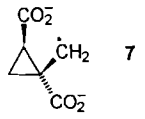


Scheme 1. Proposed reaction pathways for coenzyme B_{12} dependent reactions catalyzed by glutamate mutase (**1**⇔**4**), 2-methyleneglutarate mutase (**2**⇔**5**), and methylmalonyl-CoA mutase (**3**⇔**6**).

animals, and bacteria.[1] The substrate for glutamate mutase is (*S*)-glutamate (**1a**, Scheme 1), which is in equilibrium with the branched isomer (2*S*,3*S*)-3-methylaspartate (**4a**); with 2-methyleneglutarate mutase, 2-methyleneglutarate (**2a**) is converted into the more highly branched (*R*)-3-methylitaconate (**5a**); with methylmalonyl-CoA mutase, succinyl-CoA (**3a**) is in equilibrium with (*R*)-methylmalonyl-CoA (**6a**). Each of the substrates **1a**–**3a** contains a propionate residue within which the rearrangement occurs. A hydrogen atom migrates *inter*molecularly from C2 to C3 of the propionate residue via the 5′-carbon of the 5′-deoxyadenosyl moiety of coenzyme B_{12}, to form the methyl groups of the products **4a**–**6a**. The substituents at C3 of the propionate residues—glycinyl, ethenyl-1-carboxylate (2-acrylate), or formyl-CoA—migrate *intra*molecularly in the opposite direction. Determinations of the stereochemistry of each rearrangement have revealed that for substrate **1a**, H_{Si} is removed from the methylene group adjacent to the carboxyl function, whereas for substrates **2a** and **3a**, H_{Re} is removed. The migrating groups for substrates **1a** and **2a** move with inversion of configuration at the carbon atom from which the hydrogen atom is removed, whilst for substrate **3a** the migration occurs with retention of configuration. The methyl groups in products **4a**–**6a** appear to be formed with racemization.[2]

Despite the stereochemical differences, it is attractive to consider a unifying mechanism for the coenzyme B_{12} dependent rearrangements. It is generally accepted that the reactions are initiated by abstraction of the migrating hydrogen atom from the C2 atom of the propionate residue by the 5′-deoxyadenosyl radical, generated by homolysis of the Co–C σ bond of the coenzyme.[3] This process affords a substrate-derived radical, deoxyadenosine, and cob(II)alamin. Little is known, however, about the mechanism of the conversion of the substrate-derived radical into the product radical, to which a hydrogen atom from deoxyadenosine is donated to yield the product, with regeneration of the coenzyme. Chemical modeling[4] of the interconversion of 2-methyleneglutarate and (*R*)-3-methylitaconate suggested that the 1-methylenecyclopropane-1,2-dicarboxylate radical **7** is possibly an intermediate. This species could be formed by intramolecular addition at the double bond of the initially generated radical **2b**. Cleavage of the original 2,3-bond would lead to the product radical **5b**. Difficulties arise in the application of this mechanism to the rearrangement of glutamate to 3-methylaspartate, because neither amino acid contains a double bond at which a radical could add. It has been suggested[5] that glutamate may form a Schiff's base with a carbonyl group present in the enzyme. Isomerization of the Schiff's base to the ketimine of 2-oxoglutarate would yield an intermediate similar to 2-methyleneglutarate, and enable a rearrangement via an azacyclopropylcarbinyl radical.[6] However, attempts to trap such a Schiff's base by reduction with sodium borohydride have been unsuccessful.[7a] Moreover, microbiological and genetic experiments indicate the absence of a reactive carbonyl group in glutamate mutase.[8] A unifying mechanism valid for all three rearrangements is obtained by postulating the fragmentation of the substrate-derived radical (**1b**, **2b**, or **3b**) into acrylate and either the glycinyl radical **8**, the 2-acrylate radical **9**, or the formyl-CoA radical **10**. Readdition of the radical (**8**, **9**, or **10**) at C2 of acrylate would lead to the product radical **4b**–**6b**.[3a] We present data in favor of this hypothesis and show that it can readily explain the stereochemical details described above.



7

Glutamate mutase from *C. cochlearium* is composed of two components: E, a dimer (ε_2, $M = 100$ kDa); and S, a monomer (σ, 14.7 kDa).[7] The genes coding for the polypeptide chains ε (*glmE*) and σ (*glmS*) have been cloned and separately overexpressed in *Escherichia coli*.[9] Upon addition of coenzyme B_{12} to a mixture of the purified components, an enzymatically active complex, $\varepsilon_2\sigma_2$, is spontaneously formed, containing one mole of adenosylcobalamin per mole of tetramer.[9b] Component S alone is also able to bind the coenzyme, but much more weakly than the complex. On addition of the substrate glutamate to the complex, a paramagnetic species is formed, yielding a signal in the EPR (electron paramagnetic resonance) with a spin concentration of up to 50% of that of the enzyme concentration (Fig 1). Similar but not identical signals are generated by addition of either of the inhibitors 2-methyleneglutarate or (2*S*,4*S*)-fluoroglutamate,[7b] with spin concentrations up to 150%.[9b] The *g*-values ($g_{xy} \approx 2.15$) of these signals are different from those of free or enzyme-bound cob(II)alamin ($g_{xy} \approx 2.3$), but clearly attributable to Co^{II} compounds, as shown by the overall shape and the eightfold hyperfine splitting of the g_z-line. The signals have been interpreted as a coupling between Co^{II} and an organic radical, at least partly localized on the substrate or inhibitor.[9b] Less well resolved EPR signals have been obtained with methylmalonyl-CoA mutase[10] and 2-methyleneglutarate mutase[11]

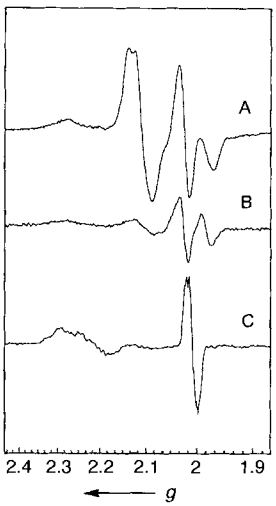


Fig. 1. EPR spectra of glutamate mutase. Component S (670 μM), 1.1 mM component E, and 4 mM coenzyme B_{12} were incubated with 13.3 mM 2-mercaptoethanol, 33 mM Tris/HCl (pH 8.3), and either 16.7 mM glycine (B) or 16.7 mM acrylate (C) or a mixture of both (A) to give a total volume of 300 μL [26]. All three spectra were obtained at identical instrument settings.

in the presence of coenzyme B_{12} and their corresponding substrates or inhibitors.

2-Methyleneglutarate mutase from *C. barkeri* is composed of only one polypeptide chain (α, 70 kDa).[12] The gene coding for the α-chain (*mgm*) has been cloned and overexpressed in *E.coli*.[13] The specific activity of the purified apo-enzyme was assayed after addition of an excess of coenzyme B_{12}, whereby active 2-methyleneglutarate mutase was immediately reconstituted. The activity of this reconstituted enzyme was twice as high as the best preparation from *C. barkeri*, which in addition to correctly bound coenzyme B_{12} also contains incorrectly bound coenzyme and air-stable cob(II)alamin.[11b] Upon gel filtration on a Superose 6 column the reconstituted enzyme was eluted with an apparent molecular mass of 180 kDa containing 1 mol coenzyme B_{12}, which suggests a homodimeric structure (α_2). Hence, the enzyme is of a size similar to glutamate mutase.

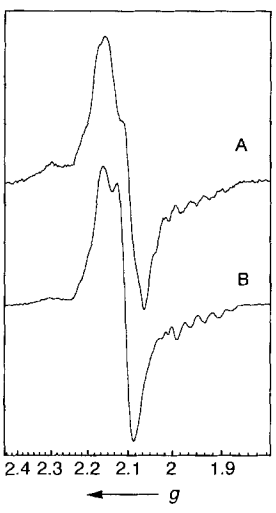

Fig. 2. EPR spectra of 2-methyleneglutarate mutase. The apoenzyme (270 μM) and 4 mM coenzyme B_{12} were incubated with 7 mM 2-mercaptoethanol, 33 mM potassium phosphate (pH 6.4), and either 16.7 mM 2-methyleneglutarate (A) or 16.7 mM acrylate (B) to give a total volume of 300 μL [26]. Spectrum A was recorded at a four times higher receiver gain than spectrum B.

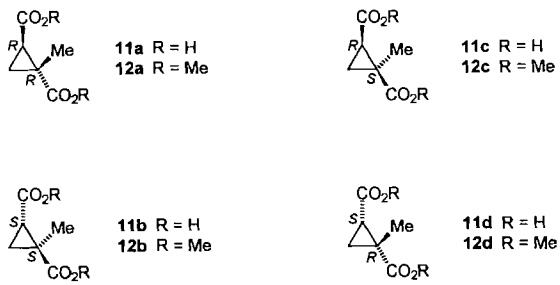
We have found that in the presence of 2-methyleneglutarate the reconstituted enzyme gives rise to an EPR signal (Fig. 2A) exhibiting the same high resolution as glutamate mutase with glutamate. The C-terminus of 2-methyleneglutarate mutase (about 100 amino acids) shows significant sequence homology to component S of glutamate mutase, to the C-termini of the methylmalonyl–CoA mutases, and to the cobalamin-binding domain of the methionine synthase (MetH) from *E.coli*.[13] X-ray analysis of this MetH domain revealed the coordination of the only conserved histidine residue to the cobalt atom of the coenzyme at the same position that in free coenzyme B_{12} is occupied by dimethylbenzimidazole.[14a] EPR experiments with ^{15}N-labeled component S indicated that this was also true for glutamate mutase.[14b] Finally, the H486Q mutant of 2-methyleneglutarate mutase, in which this histidine has been converted into glutamine, is completely inactive since it is not able to bind even a trace of coenzyme B_{12}.[14c]

In order to examine the hypothesis of fragmentation of glutamate during catalysis of glutamate mutase, acrylate and glycine were tested as inhibitors of the enzyme. Neither acrylate nor glycine *alone* at concentrations up to 20 mM influenced the enzymatic reaction significantly. However, the combination of the two efficiently inhibited the conversion of (2*S*,3*S*)-3-methylaspartate into (*S*)-glutamate as assayed with the auxiliary enzymes glutamate oxaloacetate aminotransferase (aspartate aminotransferase, [EC 2.6.1.1]) and (*R*)-2-hydroxyglutarate dehydrogenase (NADH, [EC 1.1.1.-]). The initial rate of this reaction decreased to 60, 42, and 20% in the presence of equimolar mixtures of acrylate and glycine (5, 10, and 15 mM each, respectively). A dramatic effect was observed by EPR spectroscopy: A mixture of component E, S, and coenzyme B_{12} with glycine or acrylate alone gave only weak signals around $g = 2$, (Figs. 1B and C; spin concentration less than 5% of the enzyme concentration), whereas the combination of both yielded an intense signal at $g = 2.15$ (Fig. 1A). Interestingly, the shape of this signal closely resembles those observed with other coenzyme B_{12} dependent enzymes and their substrates[15] rather than those observed with glutamate mutase and glutamate[9b] or with 2-methyleneglutarate mutase and 2-methyleneglutarate (Fig. 2A). Especially in the case of the coenzyme B_{12} dependent ribonucleotide reductase, the signal was successfully simulated as that of an interaction of an organic radical with cob(II)alamin.[15] The synergistic effect of acrylate and glycine suggests that together the compounds mimic the intermediate state (see Scheme 1) and are able to induce homolytic cleavage of the Co–C bond of the coenzyme.

We were intrigued by the reported inhibition[16] of 2-methyleneglutarate mutase by *trans*-1-methylcyclopropane-1,2-dicarboxylates **11a**/**11b**, but less so by the corresponding *cis* isomers **11c**/**11d**. Assumption of a pathway via radical **7** leads to

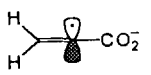


the conclusion that a particular stereoisomer of 1-methylcyclopropane-1,2-dicarboxylate should inhibit 2-methyleneglutarate mutase. Since the product of the rearrangement of 2-methyleneglutarate is (*R*)-3-methylitaconate[2c] and considering the above-mentioned report,[16] it can be concluded that the most active inhibitory 1-methylcyclopropane-1,2-dicarboxylate should be the (*R*,*R*)-isomer **11a**, which correlates with the configuration of **7**. However, no significant inhibition of 2-methyleneglutarate mutase was observed with any of the isomers at concentrations up to 20 mM.[17] Furthermore, a mixture of the two *trans* enantiomers of 1-methylcyclopropane-1,2-dicarboxylate did not induce an EPR signal with 2-methyleneglutarate mutase. However, acrylate alone inhibited 2-methyleneglutarate mutase. Interestingly, a plot of $1/v$ versus the square of the acrylate concentration rather than acrylate concentration itself gave a straight line (Dixon plot,[18] v = initial velocity). This linear correlation indicates that two acrylate molecules are involved in the inhibition of the enzyme. Assuming

competitive inhibition, at 2 and 10 mM acrylate the apparent K_i was 2 and 0.5 mM, respectively. Furthermore, acrylate induced a similar EPR signal, but with a higher spin concentration, than that obtained with 2-methyleneglutarate (Fig. 2b). This is consistent with a fragmentation of the 2-methyleneglutarate radical into acrylate and the 2-acrylate radical **9** (see Scheme 1). Based on the results described, we speculate that during catalysis of methylmalonyl-CoA mutase, acrylate and a formyl-CoA radical **10** are obtained by fragmentation of the succinyl-CoA or methylmalonyl-CoA radical (**3b** or **6b**, Scheme 1). Hence, a combination of acrylate and formyl-CoA should inhibit the enzyme and induce an EPR signal.

In Scheme 1 we present a unifying mechanism for the coenzyme B_{12} dependent mutases. Following binding of the substrate to the enzyme, homolytic fission of the Co-C bond of coenzyme B_{12} releases the 5'-deoxyadenosyl radical, which abstracts the nearest available hydrogen atom (slight differences in protein structure would suffice to place either H_{Re} or H_{Si} in position for hydrogen abstraction). In the conformation that permits maximal overlap of the radical center (π orbital) with the 2,3- (substrates **1a** and **2a**) or 1,2-σ bond (substrate **3a**), fragmentation to acrylate and a radical occurs (glycinyl radical **8** from **1b**, 2-acrylate radical **9** from **2b**, and formyl-CoA radical **10** from **3b**). Recombination of the radical with acrylate can generate product radicals **4b**–**6b**, which leads to product **4a**–**6a** by hydrogen abstraction from 5'-deoxyadenosine. The inversion of the configuration for the migratory step is in accord with this mechanism for substrates **1a** and **2a**, but the retention of configuration observed for **3a** requires a special explanation. We propose that two conformations of the acrylate formed from **3a** can equilibrate (see Scheme 1), for example by rotation about the 1,2-bond. The movement of the relatively small acrylate could be accommodated by the protein. This proposal can explain "the error in the cryptic stereochemistry of methylmalonyl-CoA mutase".[19] It was shown that in addition to the expected migration of H_{Re} at C3 of succinyl-CoA to the methyl group of methylmalonyl-CoA, the "exchangeable hydrogen" at C2 of methylmalonyl-CoA migrated to C3 of succinyl-CoA. This result was explained by invoking a 1,2-hydrogen shift in the intermediate succinyl-CoA radical, but can also be due to the occasional removal of H_{Si} from C3, leading *directly* to the correct acrylate conformation for further elaboration to (*R*)-methylmalonyl-CoA.

Some of the radicals proposed as the migrating entities in Scheme 1, or analogues thereof, have been characterized in other systems. The 2-acrylate radical is believed to have a structure (**13**) in which the three carbon atoms are colinear and the C2 atom is *sp* hybridized.[20] The glycinyl radical has been calculated[21] to be the glycine carbon radical with the lowest energy, stabilized in a captodative manner: the carboxylate withdraws electrons, whilst the amino group is an electron donor. The stability of the glycine radical at position 734 of the polypeptide chain of pyruvate formate lyase from *E.coli* has also been attributed to a captodative effect.[22]



13

In summary, the data presented here strongly support the fragmentation mechanism of coenzyme B_{12} dependent carbon skeleton rearrangements and are a basis for further experiments, especially with isotopically labeled substrates and inhibitors, which may help to elucidate the nature of the intermediate radicals. The most striking aspect of our proposal is that glutamate mutase, long considered to be the least explicable coenzyme B_{12} dependent mutase,[23] emerges as the paradigm![25]

[24] The components were mixed in an EPR tube in the dark, and the reaction was started by addition of the acids followed by incubation under N_2 at 30 °C for 5 min. The reaction was stopped by freezing in a mixture of liquid nitrogen and pentane. X-band EPR spectra were recorded with a Varian E-3 EPR spectrometer at a temperature of 77 K, microwave frequency 9.1 GHz, microwave power 2 mW (Fig. 1) or 20 mW (Fig. 2), modulation frequency 100 kHz, modulation amplitude 0.4 mT.

[25] Note added in proof: Reaction of diethyl 2-bromomethyl-2-methylmalonyl-monothiolate with cob(I)alamin yields, among other products, ethyl methacrylate. It was suggested that the latter is derived by the β-scission of intermediate radicals analogous to **3b** and **6b** [A. J. Scott, P. Karuso, H. J. Williams, J. Lally, J. Robinson, G. P. Nayar, *J. Am. Chem. Soc.* **1994**, *116*, 777–778].

Asymmetric Pictet–Spengler Reactions Employing *N,N*-Phthaloyl Amino Acids as Chiral Auxiliary Groups**

Herbert Waldmann,* Gunther Schmidt, Henning Henke, and Michael Burkard

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The Pictet–Spengler reaction is one of the most important methods in heterocyclic and natural product chemistry.[1] In particular, it has proven to be a very powerful tool for the construction of complex alkaloids, for example those belonging to the tetrahydroisoquinoline and β-carboline classes. Therefore, the development of methods that allow this transformation to be performed asymmetrically by employing a removable chiral auxiliary group is of great importance to organic synthesis. However, in only a few cases has this problem been addressed, and the techniques developed so far either remained restricted to a special application in a particular total synthesis, or they suffer from being not generally applicable.[2, 4] The purpose of this paper is to report that high levels of stereoselectivity (diastereomeric ratio can be greater than 99:1) are reached in Pictet–Spengler reactions employing both aliphatic and aromatic Schiff bases by using *N,N*-phthaloyl amino acids (Pht amino acids) as chiral auxiliary groups.

During a research program directed at the use of the readily available amino acid esters as chiral auxiliary groups,[3] we recently showed that asymmetric steering of the Pictet–Spengler reaction can be achieved by generating intermediate *N*-alkyliminium salts derived from amino acid esters.[4] But, because of the low reactivity of these Schiff base derivatives, only aromatic aldehydes could be converted into the desired products with preparatively useful yields. However, chiral nitrogen heterocycles derived from aliphatic aldehydes, which are much more relevant to the synthesis of alkaloids and their analogs, cannot be obtained by this method. In addition, the chiral auxiliaries can only be removed from the resulting N-alkylated Pictet–Spengler adducts by a laborious multistep procedure. We reasoned that these serious limitations might be overcome by the intermediacy of *N-acyl*iminium salts like **3** rather than *N-alkyl*-iminium salts. Because of the electron-withdrawing influence of the N-acyl group, these electrophiles should be more susceptible to a nucleophilic attack of aromatic residues on the C=N bond, and the resulting Pictet–Spengler adducts would be linked to the chiral auxiliary by an amide rather than an N-alkyl bond, thereby allowing for a straightforward removal of the mediator of chirality.

If the Schiff bases **1**, which are derived from tryptamine, are treated with the *N,N*-phthaloyl-protected amino acid chlorides **2**[5] in the presence of titanium alkoxides like $Ti(OnPr)_4$ and $Ti(OiPr)_4$ in CH_2Cl_2 at room temperature, the desired tetrahydro-β-carbolines **4** and **5** are formed in a smooth reaction in satisfactory yields and with excellent diastereoselectivity (Table 1). If imines of aliphatic aldehydes are employed the cyclization is complete within 5 min to 1 h; in the case of aromatic Schiff bases, however, several days are required. Presumably the reaction proceeds by attack of the acid chlorides on the nitrogen of the C–N double bond to give rise to the *N*-acyliminium intermediates **3**, which then are subject to a cyclization by attack of the electron-rich nucleophilic indole on the electrophilic carbon of the C=N bond. With aromatic Schiff bases, the diastereomer ratio increases with increasing steric demand of the amino acid side chain R^2 (Pht-alanine and Pht-valine are clearly less favorable auxiliaries than Pht-*tert*-leucine; Table 1, compare nos. 1, 2, and 4 as well as 5 and 6). The same observation is made for aliphatic Schiff bases if the aliphatic group R^1 is small (for example methyl: Table 1, nos. 9 and 10). However, with increasing steric demand of R^1 this trend may be reversed (Table 1, nos. 11 and 12) and for R^1 = *i*Pr, *N,N*-Pht-valine is an excellent auxiliary group, which makes the desired Pictet–Spengler adduct available in 99% yield in diastereomerically

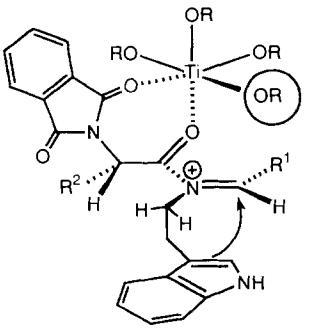
form (Table 1, no. 13; the second diastereomer could not be detected by 400 MHz NMR spectroscopy or by HPLC). The steric demand of the alkyl groups of the titanium Lewis acids employed may have a marked influence on the diastereoselectivity. Thus, although high diastereomer ratios can, in general, be induced with titanium tetra-*n*-propylate (see, for instance, Table 1, nos. 4, 6, 10–13), the stereoselectivity in some cases is more efficient in the presence of titanium tetra-*iso*-propylate (Table 1, compare no. 2 with 3 and 7 with 8).

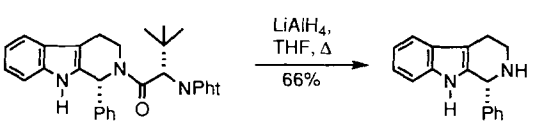
The best results are obtained if the amino acid chlorides **2**, the titanium alkoxide, and the imines **1**. Lowering the temperature to −40 °C reduces the rate of reaction, but does not improve the diastereoselectivity. The presence of the phthaloyl protecting group is important. If 9-fluorenylmethoxycarbonyl- (Fmoc) or benzyloxycarbonyl (*Z*)-protected Pht amino acid chlorides are used, the levels of stereoselectivity are consistently lower. In addition, *N*,*N*-phthaloyl amino acid chlorides are not prone to racemization[5] and, in contrast to the Fmoc- or Z analogs, the Pht-protected Pictet–Spengler adducts **4** and **5** are highly crystalline compounds from which the major isomers **4** are obtained in analytically and enantiomerically pure form by a single recrystallization (in general from a mixture of ethyl acetate and hexane or diethyl ether and hexane). These advantageous physical properties also enabled a rigorous determination of the absolute configuration of the major diastereomers by crystal structure analysis of the tetrahydro-β-carboline (**4d**).[6]

To explain the high stereoselectivity attained through the Pictet–Spengler reactions detailed above, we assume that the reaction proceeds preferentially via transition states **A**. In **A** the titanium atom coordinates to the carbonyl oxygen atoms of the amino acid and the phthaloyl group. An octahedral complex is thereby formed in which the top-side of the C=N bond is shielded by a substituent of the activating Lewis acid. This is in accord with a related finding for $TiCl_4$ mediated Diels–Alder reactions of α,β-unsaturated proline ester amides.[7] In this arrangement the bulky amino acid side chain points away from the ethylene bridge between the indole nucleus and the iminium nitrogen; consequently, unfavorable steric interactions are avoided. Furthermore, by analogy with the configuration of α,β-unsaturated amides,[7] substituent R^1 of the C–N double bond and the amino acid carbonyl function are in an *s-cis* orientation. If these two groups were in an s-*trans* orientation, R^1 would come close to the α-carbon of the amino acid , a situation which for steric reasons would also be unfavorable. In the 3-indolylethyl-substituted iminium intermediate **A**, the imine substituent R^1 is *trans* to the ethylene bridge. This is the favored configuration because a 1,3-interaction between R^1 and the protons of a CH_2 group would develop upon ring closure if R^1 was *cis* to the ethylene bridge.[4] Potential involvement of the transition states **A** also explains why stereoselectivity in the Pictet–Spengler cyclizations is more efficient if a bulkier alkyl residue is present in the titanium Lewis acid (for example, *i*-Pr vs. *n*-Pr): one of the diastereotopic faces of the C=N bond is more efficiently shielded.



A

From the Pictet–Spengler adducts **4** the chiral auxiliary can readily be removed by cleavage of the amide bond with reducing reagents like $LiAlH_4$. The enantiomerically pure tetrahydro-β-carboline **6**, for instance, is readily obtained from **4c** by this straightforward procedure.[8]



4c **6**

In conclusion, *N*,*N*-phthaloyl amino acids are the first generally applicable chiral auxiliary groups for the Pictet–Spengler reaction that efficiently control the stereochemical course of this important transformation of alkaloid chemistry.

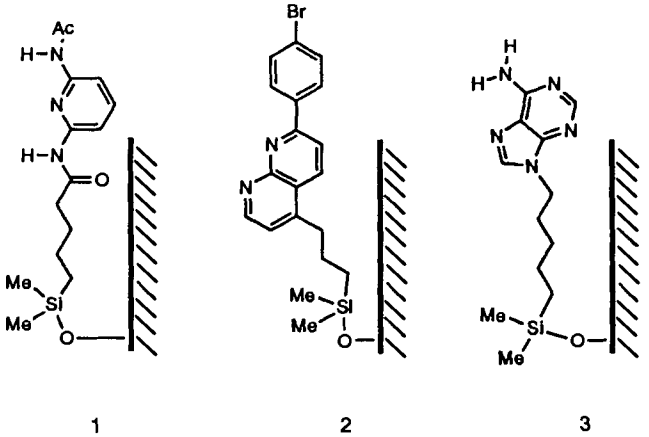
A Comparison of Enthalpies of Formation in Solution and Enthalpies for HPLC Retention for Hydrogen-Bonded Host–Guest Complexes**

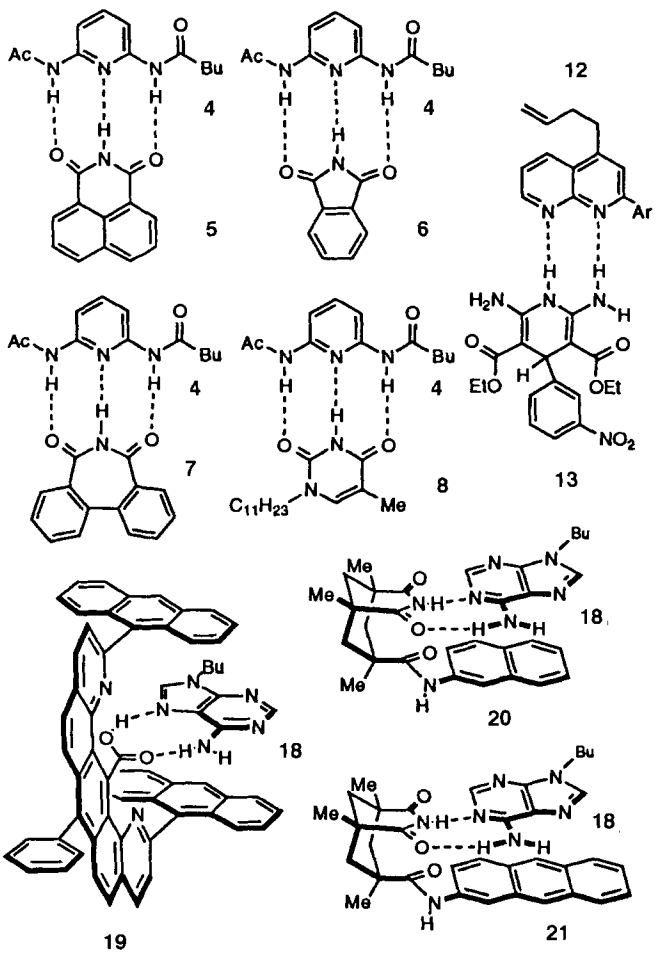
Steven C. Zimmerman* and Wing-Sum Kwan

New methods that rapidly and accurately measure the stability of molecular complexes can greatly assist molecular recognition studies. Enthalpies of complexation, in particular, have proven valuable in understanding the origin of stabilities of host–guest compounds.[1] We recently reported that enthalpies of retention of nitroaromatic analytes—conveniently determined by their temperature-dependent retention (vide infra) by tweezer molecules attached to HPLC stationary phases—were within experimental error of the analogous complexation enthalpies measured in free solution.[2, 3] This result required both a minimal amount of retention by nonspecific interactions and a similar molecular recognition event in solution and on the silica surface. To test the generality of this method, we have now examined host–guest systems in which complexation is driven by hydrogen bonding or a combination of hydrogen bonding and π-stacking. In contrast to the earlier study, the current hosts are more exposed for potential interaction with the silica surface, and nonspecific retention of the more polar heterocyclic analytes is more likely. A broad range of such host–guest systems has been examined, and we report herein a comparison of enthalpies determined in solution and by HPLC; the latter were determined on **1**–**3**, stationary phases containing chemically bonded hosts.



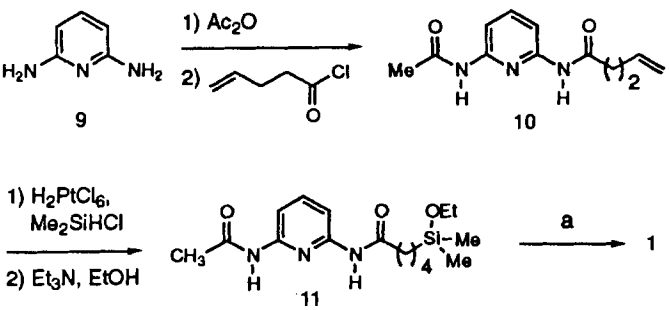
1 **2** **3**

Chemically bonded stationary phase **1** (CBSP **1**) is related to a 2,6-diamidopyridine phase studied by Feibush et al.[4] The diamidopyridine unit contains a donor–acceptor–donor array of hydrogen-bonding sites that is complementary to the acceptor-donor-acceptor array found in certain imides and thymine derivatives (see Scheme 1, **4**·**5**, **4**·**6**, **4**·**7**, **4**·**8**).[4, 5] To prepare **1**, 2,6-diaminopyridine (**9**) was monoacetylated with acetic anhydride and then treated with 4-pentenoyl chloride to produce



Scheme 1.

diamide **10** in 52% yield (Scheme 2).[6] Regioselective hydrosilylation with dimethylchlorosilane followed by treatment with ethanol and triethylamine afforded ethoxysilane **11**, which was purified by chromatography (33% yield). In order to test the



Scheme 2. Synthesis of CBSP **1**. a) 5 μM HPLC silica gel.

effect of loading, bonding to 5 μM Spherisorb silica was carried out twice to produce phases **1a** and **1b** that contained 0.11 and 0.055 mmol of host per gram of silica gel, respectively. The loadings were determined by elemental analysis and represent the average of carbon and nitrogen content.

Two more lightly loaded phases, **1c** and **1d**, were produced by capping **1a** with a 10% solution of hexamethyldisilazane in chloroform (50–60 °C) and diluting it (1:4 and 1:12 w/w, respectively) with trimethylsilyl-capped silica gel. These phases

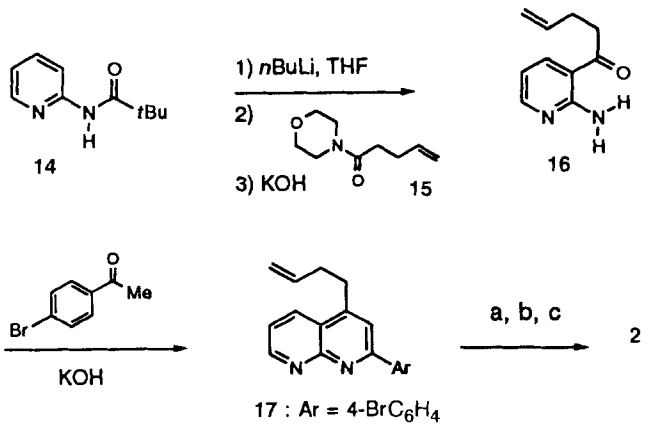
[**] Quantitative Host–Guest Complexation Studies Using Chemically Bonded Stationary Phases, Part 2. Part 1: Ref. [2]. This work was supported by the National Institutes of Health (GM38010).

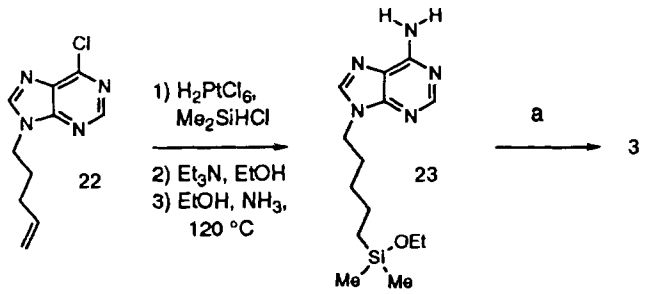
were designed both to provide convenient retention times with more highly retained analytes, and to investigate whether the physical dilution of the bonded phases with a nonretaining phase would affect the thermodynamics of retention. Phase **1a** was slurry-packed into a 250 mm × 4.6 mm O. D. stainless steel column, and **1b–d** into shorter columns with narrower bores (dimensions: 100 mm × 2.1 mm). In the case of **1a** and **1b**, the residual silanol groups were capped by passing a solution of hexamethyldisilazane in methylene chloride through the column.

CBSP **2** contained the 1,8-naphthyridine chromophore that was shown to bind dihydrodiaminopyridines (for example, **12·13**) with an association constant about an order of magnitude higher than that for the diamidopyridine–imide type complexes described above.[5b] The synthesis of this CBSP began with the ortho-lithiation of **14** followed by treatment with **15** and deprotection to aminoketone **16** in 65% overall yield (Scheme 3). Friedländer condensation of **16** and 4-bromoacetophenone gave **17** in 76% yield (the bromine substituent serves to increase the crystallinity of the product). The hydrosilylation of **17** (34% yield) and subsequent bonding and capping steps were performed as described for **10** in Scheme 1. A column with a loading of 0.05 mmol of host per gram of silica gel (CBSP **2**), retained analytes too strongly, so it was diluted ca. 1:2 and 1:9 (w/w) with trimethylsilyl-capped silica gel to produce CBSPs **2a** and **2b**, respectively, which were slurry-packed into 100 mm × 2.1 mm O. D. stainless steel columns.



Scheme 3. Synthesis of CBSP **2**. a) H_2PtCl_6/Me_2SiHCl; b) Et_3N, EtOH; c) 5 μM HPLC silica gel.

The last chemically bonded stationary phase, **3**, was of interest because of the availability of adenine hosts with a broad range of affinities (for example, **18·19**, **18·20**, **18·21**, Scheme 1) and very large enthalpies of complexation.[7, 8] The synthesis of CBSP **3** began by alkylating 6-chloropurine with 5-bromo-1-pentene to afford **22** in 76% yield (Scheme 4). As described for the previous CBSPs, regioselective hydrosilylation and treatment with ethanol and triethylamine gave the corresponding ethoxysilane (**23**, 73% yield). Heating **23** with ammonia converted it into the 9-substituted adenine in 94% yield, which was bonded to silica as described previously. The resultant CBSP **3**, with a loading of 0.11 mmol of host per gram of silica gel, was diluted 1:1, 1:9, and 1:99 (w/w) with trimethylsilyl-capped silica gel to produce CBSPs **3a**, **3b**, and **3c**, respectively. These CBSPs were slurry-packed into 100 mm × 2.1 mm O. D. stainless steel columns and capped as previously described.



Scheme 4. Synthesis of CBSP **3**. a) 5 μM HPLC silica gel.

Enthalpies of the retention process were measured on these HPLC columns with the general method described previously.[2] Retention times of most analytes were measured over temperature ranges greater than or equal to 50 °C in about 10 °C intervals. The peaks for host **19** on CBSP **3** showed significant tailing below 45 °C, limiting the range of temperatures studied. For all runs the t_M (t_0) was measured at each temperature as the retention time of 1,3,5-tri-*tert*-butylbenzene.[9] Using the relationship, $\ln k' = \Delta H^\circ/RT + \Delta S^\circ/R + \ln(\Phi)$, Van't Hoff plots were constructed by plotting $\ln k'$ against $1/T$.[10] Enthalpies of complexation in solution were determined by the van't Hoff method for which changes in the ^{1}H NMR spectrum at four to six temperatures indicated the extent of saturation. For the ^{1}H NMR technique, the chemical shift of the imide N–H proton in **5–8** and **20–21** (NH_2 in **13**) was followed to evaluate the association constants with the method described by Dougherty.[11a] Binding isotherms were generated so as to cover a saturation range of 20–80% with seven or more points. In chloroform and carbon tetrachloride, K_{assoc} and ΔH° values for complex **18·19** were so high that microcalorimetry had to be employed.[11]

Altogether, three types of CBSPs were studied and eight complexes (Scheme 1) were analyzed (Table 1). The eighteen comparisons made between solution complexation enthalpies and enthalpies of HPLC retention are represented graphically in Figure 1. Most significantly, a linear correlation was found; regression analysis gives a slope of 1.0 ± 0.2 and a y intercept of 0.14 ± 0.61 kJ mol^{-1}. Thus, the HPLC retention enthalpies for a

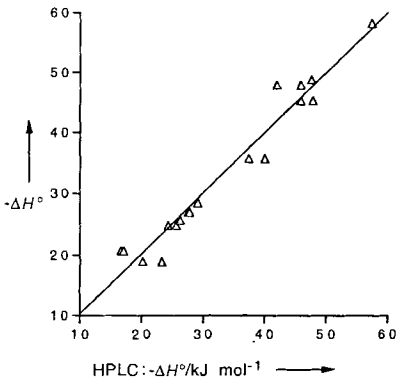

Fig. 1. Correlation between enthalpies of complexation in solution and enthalpies of retention on CBSPs **1**–**3**.

broad range of host–guest complexes are within experimental error of the corresponding complexation enthalpies measured in solution. The effect of loading of the CBSPs on the ΔH° values was negligible, suggesting that the change in enthalpy with loading seen by Pirkle[12] originates in the nature of the attachment to the silica surface. CBSPs **1**–**3** were prepared from monofunctional silanes that generate "brush phases", whereas the Pirkle CBSPs were derived from trifunctional silanes that produce polymeric phases.[12]

Our results suggest that enthalpies of complexation of host–guest systems that use hydrogen bonding, alone or with π-stacking, can be determined from normal-phase HPLC. Even very stable host–guest complexes (for example, **18**·**19**) can be evaluated without unreasonably long retention times, because the CBSP can be diluted without affecting the enthalpy of retention. Indeed, a wide range of enthalpies (about 40 kJ mol^{-1}) were determined. The method does have limitations, including the need for more than one column loading for complexes of very different stabilities and the obvious requirement for covalent linkage to silica. In addition, as the kinetics of complexation become slow (for example for very tight binding), band broadening or tailing can become a problem. In spite of these limitations, we believe the method will be of considerable value in assaying stabilities of several host–guest complexes, perhaps even for combinatorial host or guest libraries, or in investigating a single complex in a range of solvents.

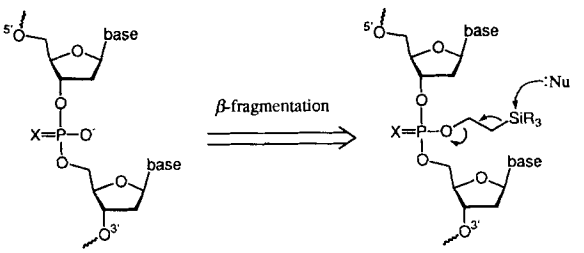
Phosphorothioates: β-Fragmentation versus β-Silicon Effect**

Achim H. Krotz,* Patrick Wheeler, and Vasulinga T. Ravikumar

Modified oligonucleotides are efficient antisense therapeutic agents.[1] Among the DNA modifications reported to date, phosphorothioates are the first class of compounds to undergo clinical trials in humans.[2] To maximize the efficiency of large-scale oligonucleotide synthesis we are currently investigating novel phosphorus-protecting groups.[3, 4] The most widely used approach in automated DNA synthesis employs β-cyanoethyl-3′-phosphoramidites.[5] Selective deprotection occurs through β-elimination.[6] The possibility of cleaving β-silylethyl-protected oligonucleotides selectively with nucleophiles through β-fragmentation[4, 7] (Scheme 1) prompted us to investigate a series of alkyl- and alkyl/aryl-substituted β-silylethyl phosphoramidites with regard to their applicability in oligonucleotide synthesis.



Scheme 1. Selective deprotection of β-silylethyl-protected oligonucleotides through β-fragmentation.

The synthesis of four 5′-*O*-(4,4′-dimethoxytrityl)thymidinyl-3′-[2-(trialkyl/arylsilyl)ethyl-*N*,*N*-diisopropyl] phosphoramidites **3a**–**d** (**a**–**d**: $R_3 = Me_3$, Et_3, Me_2tBu, Ph_2Me, respectively) is depicted in Scheme 2. The requisite β-(silyl)ethanols are either commercially available (**1a**, **1d**) or were synthesized from trialkylvinylsilane precursors (**1b**, **1c**).[8] In the case of **1c**, we first prepared *tert*-butyl(1-methoxyvinyl)dimethylsilane from

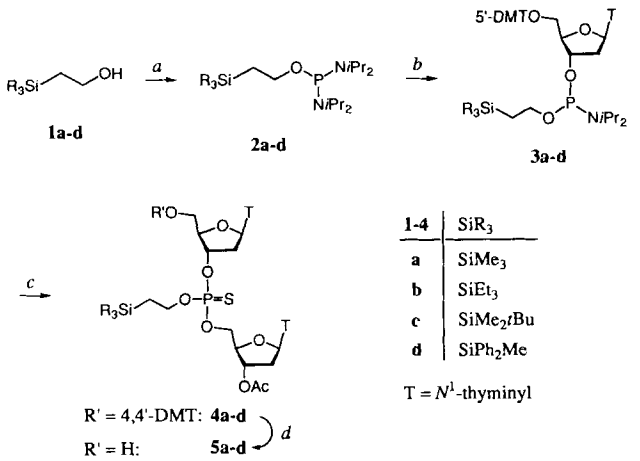
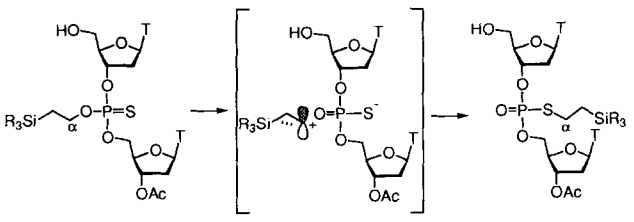


Scheme 2. Synthesis of β-silylethyl-protected phosphorothioates. a: PCl_3 (4 equiv), Et_2O, room temperature (r.t.), 2 h, then $HNiPr_2$ (7 equiv), Et_2O, r.t., 24 h, 85–95%; b: 1*H*-tetrazole, 5′-*O*-DMT-thymidine, CH_3CN, r.t., 2–3 h, 65–85%; c: 1*H*-tetrazole, 3′-*O*-Ac-thymidine, 3*H*-1,2-benzodithiol-3-one-1,1-dioxide, CH_3CN, r.t., 5 h, 77–88%; d: 2% DCA in CH_2Cl_2, r.t., 5 min, 95%. DMT = 4,4′-dimethoxytrityl; DCA = dichloroacetic acid.

*t*BuMe$_2$SiCl and (1-methoxyvinyl)lithium (76%). Subsequent regioselective hydroboration/oxidation with 9-borabicyclo-[3.3.1]nonane (9-BBN, 2 equiv)/H_2O_2 provided **1c** (92%). Following the standard procedure (see Experimental Procedure), PCl_3 (4 equiv) was first treated with **1a–d**, and, after a brief workup, treated with dry $HNiPr_2$ (7 equiv) to furnish bis(*N*,*N*-diisopropylamino)-2-trialkyl/arylsilylethoxyphosphanes **2a–d** in near quantitative yield. In the subsequent phosphitylation step, **2a–d** (2 equiv) in dry CH_3CN was first activated with 1*H*-tetrazole (0.8 equiv) for 20 min, and this mixture was added to 5′-*O*-DMT-thymidine (DMT = 4,4′-dimethoxytrityl). The hydrophobic reaction products were stable to both aqueous workup (0.5 M $NaHCO_3$) and flash chromatography on silica. Phosphoramidites **3a–d**, as mixtures of R_p/S_p diastereomers (ratio about 1:1), were obtained in good yield (65–85%; colorless glasslike solids). To evaluate the compatibility of the protecting groups with the conditions commonly employed in DNA automated synthesis (coupling, oxidation, 5′-deprotection, P-deprotection), we prepared homo-thymidinephosphorothioate dimers as model substrates. Coupling of **3a–d** (2 equiv) with 3′-*O*-acetylthymidine in the presence of 1*H*-tetrazole (4 equiv) in dry CH_3CN, followed by oxidation of the resulting trialkylphosphite with 3*H*-1,2-benzodithiol-3-one-1,1-dioxide[9] (5 equiv) afforded the protected phosphorothioates **4a–d** in high yield (77–88%) after column chromatography (^{31}P NMR δ = 67–68, two signals, R_p/S_p isomers).

Since one of the key steps in DNA synthesis involves cleavage of the 5′-*O*-DMT protecting group with organic acids, acid stability of the phosphorus protecting group is an important requirement. 5′-Deprotection of **4a–d** with 2% dichloroacetic acid (DCA) in CH_2Cl_2 for 5 min afforded **5a–d** in high yield. Prolonged exposure (several hours) of *O*,*O*,*O*-trialkylphosphorothioates **4a–d** or **5a–d** to the reaction conditions resulted in very efficient and selective O to S migration of the protecting group to furnish *O*,*O*,*S*-trialkylphosphorothioates **6a–d** (Scheme 3). Treatment of **5c** with 2% DCA/CH_2Cl_2 for 22 h afforded **6c** in 88% yield. The TOCSY spectrum of **6c** showed a strong coupling between the multiplet at δ = 3 (CH_2S) and δ = 1 (SiCH_2), confirming that the $R_3SiCH_2CH_2$ group and not any of the nucleosides was now attached to the sulfur atom. Treatment of **6c** under the same reaction conditions showed that the isomerization was irreversible. The O to S migration of alkyl



Scheme 3. Rearrangement of *O*,*O*,*O*-trialkylphosphorothioates. Hyperconjugative stabilization of the intermediate β-silyl-substituted cation may be provided through $(\sigma-p)_\pi$ overlap (β-silicon effect). Pseudo-first-order rate constants k_2 [10^{-5} s^{-1}] ($t_{1/2}$ [h]) for the rearrangement **5** → **6** in 2% DCA/CD_2Cl_2 at 20 °C are 3.3 (5.8) (**a**), 21 (0.9) (**b**), 3.5 (5.5) (**c**), and 0.05 (385) (**d**).

groups of *O*,*O*,*O*-trialkylphosphorothioates, commonly referred to as the thiono–thiolo rearrangement, is brought about thermally, by electron impact, by alkyl halides, or by Lewis or Brønsted acids.[10] Mechanistic studies provided good evidence that an (alkyl$^+$)(thiophosphate$^-$) ion pair is formed along the reaction pathway. Internal shift of the cation to the more nucleophilic sulfur of the ambident phosphorothioate anion then leads to formation of the thermodynamically more stable *O*,*O*,*S*-trialkylphosphorothioate.[10c, d] To assess the relative stability of the four β-silylethyl groups under 5′-DMT-deprotection conditions quantitatively, we analyzed the distribution of phosphorus-containing compounds in solutions of **5a–d** (0.01 mmol) in 2% DCA/CD_2Cl_2 (0.24 M, 0.6 mL) by ^{31}P NMR spectroscopy. The time course of the isomerizaton of **5b** is shown in Figure 1. Fast isomerization of **5a–c** (δ = 67) to **6a–c** (δ = 32) is observed (Scheme 3). Under the same conditions, **5d** isomerizes only very slowly ($t_{1/2}$ = 385 h). The unusually high isomerization rates of **5a–c** support an acid-catalyzed isomerization mechanism through an ion-pair intermediate (Scheme 3), as silyl substituents stabilize positive charges in the β position through $(\sigma-p)_\pi$ overlap (β-silicon effect).[11] In the case of **5d**, a decreased electron density of the C–Si σ bond caused by the electron-withdrawing phenyl groups and/or steric hindrance may be responsible for the lower isomerization rate.[12] Solutions of 2-(diphenylmethylsilyl)ethyl-protected phosphorothioates in $CDCl_3$, CD_2Cl_2, [D_6]acetone,

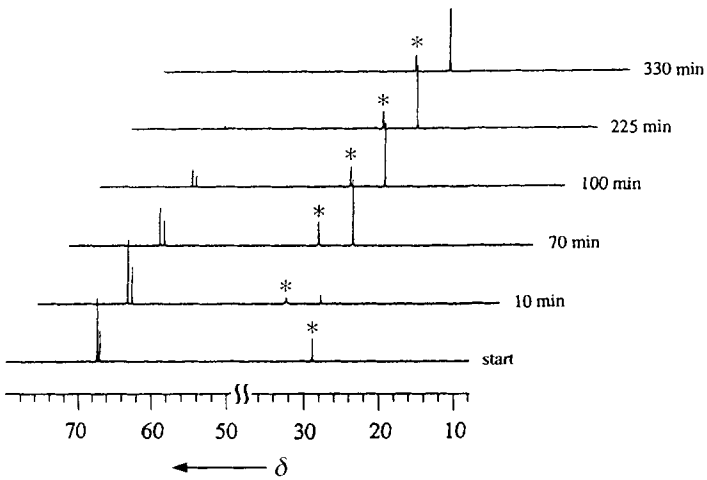


Fig. 1. ^{31}P NMR spectra (161.9 MHz) showing the thiono–thiolo rearrangement of **5b** in 2% DCA/CD_2Cl_2. The intensity of the signals for the two R_p/S_p diastereomers of *O*,*O*,*O*-trialkylphosphorothioate **5b** (δ = 67, 67.5) decreases, whereas that of the signal for the *O*,*O*,*S*-trialkylphosphorothioates **6b** increases (δ = 32) with time. The initial spectrum is taken in CD_2Cl_2. The peaks marked * are from triphenylphosphine oxide (δ = 36.7), which was used as internal standard for quantification.

[D_3]acetonitrile, [D_7]DMF, [D_6]DMSO, [D_4]MeOH, EtOH, and 1,2-dichloroethane did not show any rearrangement product after four weeks at 20 °C. In 80% acetic acid, solvolysis as well as rearrangement was observed.

The final step in oligonucleotide synthesis is the removal of protecting groups from the backbone and the bases. Treatment of **5a–d** with 30% NH_4OH/D_2O/ethanol 63:7:30 (v/v/v) resulted selectively in formation of phosphorothioates **7a–d** (^{31}P NMR $\delta = 56$) and appreciable quantities of phosphodiesters **8a–d** (3–40%, $\delta = 0.1$). This was especially surprising, since **5a–d** did not contain *O,O,O*-trialkylphosphate impurities. Following the time course of the deprotection by ^{31}P NMR shed light in this unexpected result (Fig. 2, bottom). Deprotection of **5a–d** furnishes **7a–d** through β-fragmentation, but in a competing reaction rearrangement of **5a–d** to **6a–d** also takes place (Fig 2, bottom). The disappearance of **5a–d** follows first-order kinetics, and pseudo-first-order rate constants (k_d) were calculated from the decrease in intensities of the ^{31}P signals of **5a–d** (Table 1). The constant k_d comprises the rate constant for hydrolysis of **5a–d** k_1 and the rate constant for rearrangement k_2 [Eq. (a)]. A higher electrophilicity of the phosphorothioate group of **6a–d** accelerates hydrolysis (k_3) at the phosphorus center to afford the corresponding phosphodiesters **8a–d** [Eq. (b)].[13] The maximum concentration (24%) of intermediate **6c** is observed after about 8 h and then decreases to 0%, while the dialkyl phosphate content approaches its final concentration. The ratio of phosphorothioate **7a–d** to dialkyl phosphate **8a–d** plus *O,O,S*-trialkylphosphorothioate **6a–d** reflects directly the relative rates of hydrolysis and rearrangement [Eq. (c)].

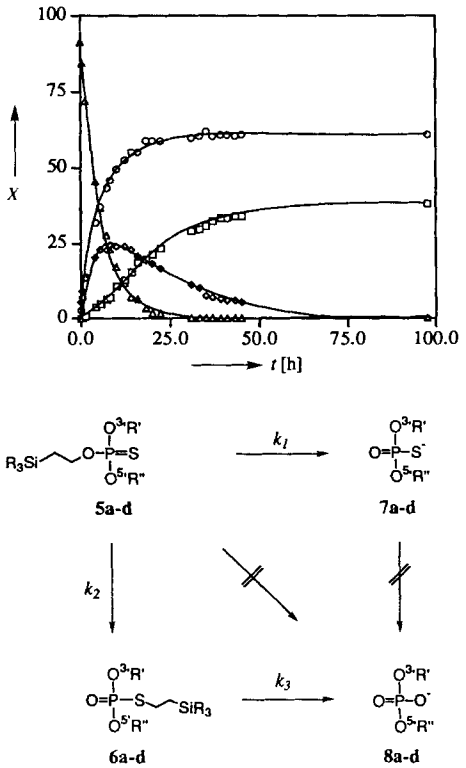

Fig. 2. Deprotection of **5c** in 30% ammonium hydroxide/D_2O/ethanol (63:7:30 *v/v/v*). Top: The relative abundance *X* (monitored by ^{31}P NMR spectroscopy) of *O,O,O*-trialkylphosphorothioate (**5c**, Δ, $\delta = 67.67.3, 67.4$), *O,O,S*-trialkylphosphorothioate (**6c**, $\diamond$, $\delta = 31.7, 31.8$), *O,O*-dialkylphosphorothioate (**7c**, $\circ$, $\delta = 56.07, 56.13$) and dialkylphosphate (**8c**, $\square$, $\delta = 0.1$) as a function of time. Bottom: The competing reactions under the conditions outlined above.

$$k_d = k_1 + k_2 \quad \text{(a)}$$

$$d[\mathbf{6}]/dt = k_2[\mathbf{5}] - k_3[\mathbf{6}] \quad \text{(b)}$$

Table 1. Pseudo-first-order rate constants ($\times 10^{-5}$) [s^{-1}] for the deprotection/rearrangement of **5a–d** in NH_4OH/ethanol at 20 °C.

	5a	5b	5c	5d
k_d	11.7	10.2	5.1 10[a]	0.23 fast[a, b]
k_1	10.2	7.5	3.1 10[a]	0.22 fast[a, b]
k_2	1.5 3.3[c]	2.7 21[c]	2.0 3.5[c]	0.007 0.05[c]

[a] Deprotection with Bu_4NF in THF (2 equiv, 25mM, r.t.). [b] Complete deprotection within minutes. [c] Rearrangement in 2% DCA/CH_2Cl_2.

$$[\mathbf{7a-d}]/[\mathbf{8a-d} + \mathbf{6a-d}] = k_1/k_2 \quad \text{(c)}$$

Equations (a) and (c) allow us to calculate the pseudo-first-order rate constants k_1 and k_2 (Table 1). The constant k_1 decreases with increasing steric demand of the substituents at the silicon [k_1(**5a**) > k_1(**5b**) > k_1(**5c**) > k_1(**5d**)]. Whereas k_2 is in the same order of magnitude for **5a–c**, it decreases dramatically for **5d**. In the case of **5d**, we did not observe intermediate **6d** in the ^{31}P NMR spectrum. The inverse proportionality between NH_4OH concentration and dialkyl phosphate content (Fig. 3) is consistent with the notion that **6d** is indeed formed as an intermediate, but is more rapidly hydrolyzed ($k_3 > k_2$). Lowering the NH_4OH concentration decreases the rate of hydrolysis, but does not affect k_2 to a great extent. Deprotection of **5d** in methylamine/water is about 20 times faster than in NH_4OH, and in 40% methylamine the formation of dialkylphosphates is completely suppressed. Deprotection with even more nucleophilic reagents, like $Bu_4N^+F^-$, is complete within minutes.

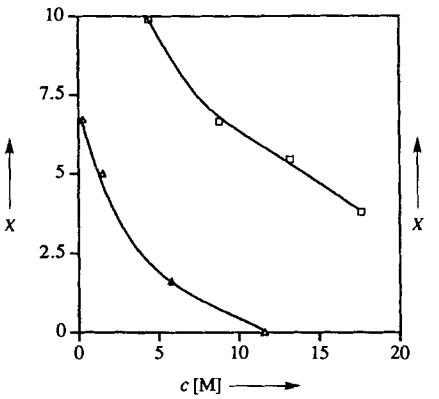

Fig. 3. Deprotection of **5d** in 30% ammonium hydroxide and aqueous methylamine solution at 62 °C. The dialkylphosphate-to-phosphorothioate ratio *X* depends upon the concentration and nucleophilicity of the base. In 40% aqueous methylamine, dialkylphosphate formation is not observed.

In conclusion, we have demonstrated that β-silylethyl protected *O,O,O*-trialkylphosphorothioates can be efficiently synthesized from phosphoramidites **3a–d**. Deprotection with nucleophilic agents (ammonium hydroxide, methylamine, fluoride[4, 7]) affords phosphorothioates **7a–d** through β-fragmentation. The phosphorus-protecting groups of **4/5a–c** are suscepti-

ble to a rapid thiono–thiolo rearrangement supported by the β-silicon effect with formation of *O,O,S*-trialkylphosphorothioates **6a–c**, which, under the deprotection conditions, form dialkylphosphates **8a–c**. The properties of the 2-(diphenylmethyl)silylethyl group in **5d**, however, are compatible with oligophosphorothioate synthesis, that is, the thiono–thiolo rearrangement driven by the β-silicon effect is largely suppressed under acidic as well as under basic conditions, while selective deprotection under mild conditions through a β-fragmentation mechanism is preserved.

Experimental Procedure

2a–d: All operations were performed under exclusion of moisture (Ar atmosphere). To a cold (ice bath) solution of PCl_3 (27.5 g, 200 mmol) in dry Et_2O (100 mL) was added dropwise a solution of the β-silylethanol derivatives **1a–d** (50 mmol) in dry Et_2O (50 mL). The ice bath was removed, and after 2 h the solution was concentrated in vacuo (20 Torr, then 1 Torr). Dry Et_2O (200 mL) was added, followed by dropwise addition of $HNiPr_2$ (50 mL). After stirring for 24 h at room temperature the mixture was filtered, and the solvent removed in vacuo to afford **2a–d** as colorless oils in near quantitative yield. ^{31}P NMR (81 MHz, $CDCl_3$): $\delta = 123.7$ (**2a**), 124.4 (**2b**), 123.9 (**2c**), 123.4 (**2d**).

3a–d: Under exclusion of moisture, 1*H*-tetrazole (12 mmol) was added to a stirred solution of **2a–d** (30 mmol) in dry CH_3CN (600 mL). After 20 min this solution was added to 5′-*O*-(4,4′-dimethoxytrityl)thymidine (15 mmol) within 30 min. After 2–3 h, triethylamine (30 mL) was added, and the solution was stored at −20 °C for 12 h. After filtration the solution was concentrated in vacuo. The oily residue was dissolved in ethyl acetate, and the solution extracted with $NaHCO_3$ (1 M) and H_2O. The organic phase was dried (Na_2SO_4), concentrated, and the remaining oil purified by flash chromatography on silica (eluent: *n*-hexanes/ethyl acetate/NEt_3 90/10/0.1 to 50/50/0.1) to furnish **3a–d**. ^{31}P NMR (81 MHz, $CDCl_3$): d = 145.9, 146.1 (**3a**), 145.8, 146.0 (**3b**), 145.9, 146.1 (**3c**), 146.0, 146.3 (**3d**).

4a–d: Under exclusion of moisture 1*H*-tetrazole (6 mmol) was added to a stirred solution of **3a–d** (2 mmol) and 3′-*O*-acetylthymidine (1 mmol) in dry CH_3CN (10 mL). After 2 h a solution of 3*H*-1,2-benzodithiol-3-one-1,1-dioxide (5 mmol) in dry CH_3CN (5 mL) was added. After 30 min triethylamine (1 mL) was added, and the mixture filtered. The filtrate was concentrated in vacuo. The residue was dissolved in ethyl acetate, and the solution extracted with aqueous $NaHCO_3$ (0.5 M) and H_2O. The organic phase was dried (Na_2SO_4), concentrated, and the residue purified by flash chromatography on silica (eluent: *n*-hexanes/ethyl acetate/NEt_3 50/50/0.1 to 20/80/0.1) to furnish **4a–d**. ^{31}P NMR (81 MHz, $CDCl_3$): $\delta = 67.5$, 67.6 (**4a**), 67.6, 67.7 (**4b**), 67.2, 67.5 (**4c**), 67.4, 67.5 (**4d**).

Direct Electrochemical Coupling of Components of the Biological Electron Transfer Chain to Modified Surfaces: Molecular Recognition between Cytochrome c Peroxidase and Cytochrome c**

Li Jiang, Calum J. McNeil, and Jonathan M. Cooper*

The modification of surfaces with proteins is established as a method for preparing analytical devices capable of biomolecular recognition. For example, research on ligand binding at interfaces has focused on the immobilization of both antibody–antigen and avidin–biotin couples,[1, 2] resulting in commercial biosensing methods[3] as well as in techniques for controlling molecular architectures.[2] Likewise, the immobilization of enzymes at electrodes has enabled the study of heterogeneous biocatalysis, and has produced an attractive sensing technology through the *indirect* measurement of either a cofactor associated with the biochemical activity,[4] or of an immobilized inorganic redox mediator in electrochemical communication with a protein.[5]

Over the last decade, there has been a large body of literature exploring direct electron transfer (ET) between immobilized proteins and conducting surfaces. To date, however, research has been limited to small model proteins,[6, 7] and it is now known that suitable modification of an electrode provides an appropriate environment for studying facile, quasi-reversible bioelectrochemistry. A particular example involves using a film of self-assembled ω-mercaptocarboxylic acid on gold to measure ET kinetics of cytochrome c (cyt c) across a "zero-length" carbodiimide coupling.[7] These architectures have proved exciting for those involved in biosensor research, as they offer the possibility of electrochemically "wiring" larger proteins to electrodes without ET mediators.

We now present a development of these ideas to produce more complex assemblies at which biomolecular recognition between redox proteins can be studied. We show the immobilization of components of the biological ET chain and demonstrate the direct electron transfer between the modified gold electrode and the immobilized heme proteins. We also measure the enhanced electrocatalytic response due to heterogeneous biomolecular recognition at the protein-modified surface.

Cytochrome c peroxidase (CcP, [EC 1.11.1.5]) is a heme-containing enzyme (35 kDa) that acts as an alternative terminal electron acceptor (complex IV) in anaerobic yeast (*Saccharomyces cerevisiae*). Its interaction with cyt c (12.6 kDa), another heme protein, has provided a model upon which an understanding of protein–protein ET has been established.[8] CcP reacts rapidly with H_2O_2 to form a doubly oxidized form of the enzyme containing a bound radical (compound II). This intermediate compound reacts further with two molecules of reduced cyt c ($cyt c_{red}$) to regenerate the reduced form of CcP (Fe^{III}). Long range ET between the two heme centers occurs across the cyt c–CcP complex, itself stabilized by ion-pairing between lysine groups in cyt c and a ring of acidic amino acid residues

around the heme edge of CcP.[8] The study of cyt c–CcP is of particular interest to us as it contains pathways along which electrons flow as a direct result of the interaction between the two proteins.

The proteins were immobilized using 3,3′-dithiobissulfosuccinimidyl propionate (DTSSP). DTSSP assembles spontaneously on a bare gold electrode with a surface coverage, estimated by integration of its oxidation peak at 150 mV vs. Ag/AgCl, of 1.5×10^{-10} mol cm^{-2}. In order to study the cyt c–CcP interaction electrochemically, in the first instance, cyt c was immobilized in a single-step reagentless procedure involving the reaction of its (surface) lysines with DTSSP. The biomolecular film assembles at a gold surface, providing electrochemical access to the heme redox center of cyt c, apparent in deoxygenated electrolyte (the experimentally measured half wave potential $E^{\circ}_{1/2} = -153$ mV vs Ag/AgCl, $\Delta E_p = 70$ mV, $v = 10$ mVs^{-1}, Fig. 1). Integration of the reduction current of the immobilized cyt c indicated that the surface concentration was 4.1×10^{-11} mol cm^{-2}. This value is generally in agreement with those obtained by others who have immobilized proteins at self-assembled monolayers.[5]

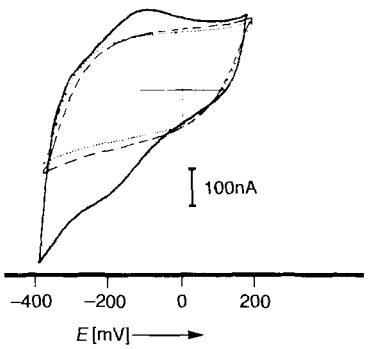

Fig. 1. DC cyclic voltammogram ($v = 10$ mVs^{-1}) depicting the direct electrochemistry of immobilized cyt c (Au\DTSSP\cyt c ——) in a degassed solution (0.1 mol dm^{-3} sodium phosphate buffer, pH 6.3). Also shown are control experiments: the DTSSP monolayer alone (Au\DTSSP ···), and Au\DTSSP\apo-cyt c in the presence of 0.5 μM CcP (– – –).

Cyt c has eighteen surface lysine groups able to bind to DTSSP. The ET route within the biomolecular film can be considered as a statistically averaged pathway, depending upon the probability of binding of particular primary amines on the protein surface. A weighted rate constant $k^{\circ\prime}_{ET}$ for ET between the protein and the electrode was estimated with Laviron's model as 0.18 s^{-1}.[9] The linear dependence of the peak currents on the potential scan rate, measured between 10 and 50 mVs^{-1} (data not shown), indicated that cyt c exists as a surface-bound species, [for example, for i_{pa}, y(/nA) = 9.7 x(/mVs^{-1}) + 0.8 (/nA)]. This fact was further confirmed by the persistence of the protein redox signal after exhaustive washing.

Upon addition of H_2O_2 to the Au–cyt c electrode, the reduction current is enhanced, consistent with previously characterized electrochemical reactions involving the reduction of hydroperoxide (Fig. 2b).[10] Subsequently, additions of CcP (Fig. 2c–f) resulted in substantial increases in the reduction currents due to enzymatic regeneration of immobilized cyt $c_{(ox)}$ and its electrocatalytic reduction at the electrode surface. The reaction scheme is illustrated in Figure 2.

The same Au–cyt c assembly was also used to study protein–protein recognition in the absence of H_2O_2. To this end, ET reactions between soluble $CcP_{(ox)}$ and the modified electrode

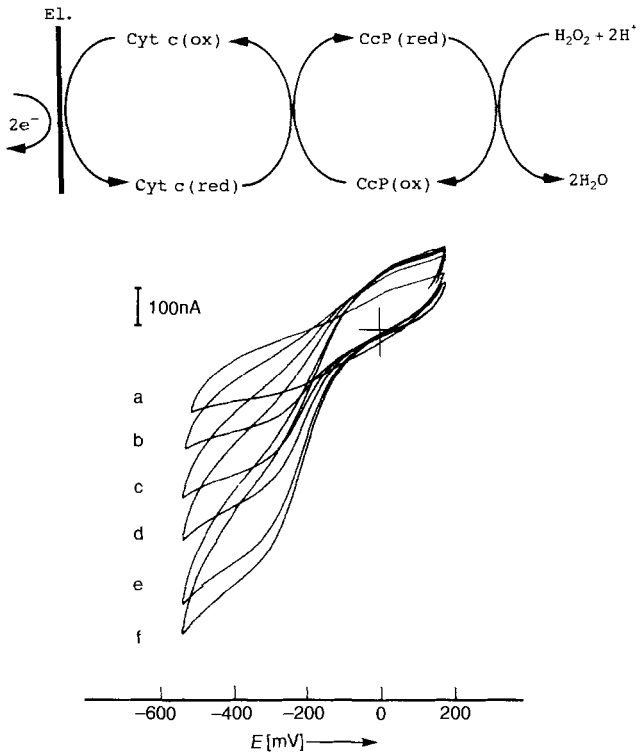

Fig. 2. Top: Scheme of the electrocatalytic reactions for the reduction of immobilized cyt c with enzymatic regeneration of cyt $c_{(ox)}$ by solution phase CcP in the presence of H_2O_2. Bottom: DC cyclic voltammograms of immobilized cyt c (vs. Ag/AgCl electrode): a) in 0.1 mol dm^{-3} sodium phosphate buffer, pH 6.3; b) on addition of 30 μM H_2O_2; and c)–f) in the presence of successive additions of 0.43, 0.86, 1.29, and 1.72 μM CcP, respectively ($v = 5$ mVs^{-1}). The reduction current for immobilized cyt c is enhanced, because the inter-protein ET rate is about 1000 s^{-1}, which is nearly four orders of magnitude faster than that at the electrode surface [16]. El. = electrode.

were measured (Fig. 3). As expected from its biological function, and due to the relatively free accessibility of the immobilized heme redox center, CcP serves to regenerate immobilized cyt $c_{(ox)}$ (via compound I), resulting in an enhanced reduction current at the electrode, as illustrated schematically in Figure 3.

In a series of complimentary experiments, CcP was immobilized using DTSSP, and its direct electrochemistry was characterized in deoxygenated electrolyte (Fig. 4). The weighted $k^{\circ\prime}_{ET}$ was calculated as 0.04 s^{-1}. The lower value for the ET rate constant for CcP (with respect to cyt c) is attributable to the longer probable ET pathway between the heme and the gold surface. Assignment of such a pathlength is, however, difficult as there are 23 lysines on the surface of CcP, available to bind with DTSSP.

Plots of i_{pa} or i_{pc} vs. v were linear [for example, for i_{pa}, y (/nA) = 9.1 x(/mVs^{-1}) + 2.7 (/nA), data not shown], thus confirming that the electrochemical reactions were confined to the surface. The $E^{\circ}_{1/2}$ for immobilized CcP was estimated as −254 mV vs. Ag/AgCl at $v = 10$ mVs^{-1}, relative to the reduction potential of CcP in solution (compound II containing Fe^{III} ions), estimated as 848 mV vs. Ag/AgCl.[11] This large shift in the enzyme's redox character is attributed to the substantial change in the local physical and chemical environment of the immobilized heme redox center. Integration of the reduction peak of CcP demonstrated that the surface coverage of the enzyme was 2.8×10^{-11} mol cm^{-2}, a lower apparent value than that measured for cyt c.

On addition of soluble cyt c to the Au–CcP electrode, the CcP reduction current is enhanced (Fig. 4). The redox conditions

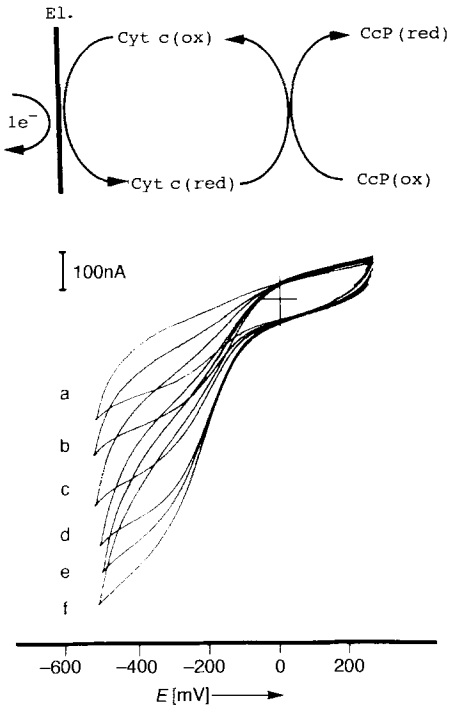

Fig. 3. Top: Scheme of the electrocatalytic reaction showing the one-electron enzymatic oxidation of immobilized cyt c by solution phase CcP, with subsequent electrochemical reduction. Bottom: DC cyclic voltammograms of immobilized cyt c (a), enhanced by the successive addition of 0.30 μM (b), 0.60 μM (c), 0.90 μM (d), 1.8 μM (e), and 2.4 μM (f) CcP, in the absence of H_2O_2 ($v = 5\ mV s^{-1}$, all the other conditions as in Fig. 2).

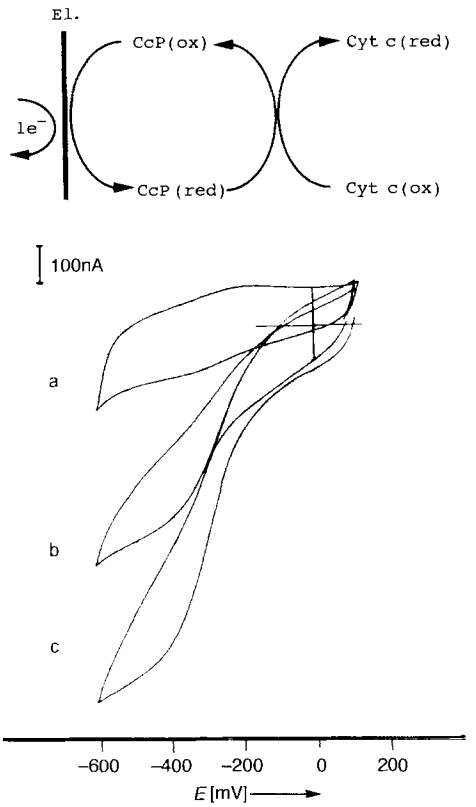

Fig. 4. Top: Scheme showing the one-electron enzymatic oxidation of immobilized CcP by solution phase cyt c, with subsequent electrochemical reduction. Bottom: DC cyclic voltammograms ($v = 5\ mV s^{-1}$) of immobilized CcP in 0.1 mol dm^{-3} sodium phosphate buffer, pH 6.3 (a) and after successive additions of 7.0 μM (b) and 42 μM cyt c (c).

within the electrochemical cell are such that the reaction is reversed from that in nature, where CcP acts as a terminal electron acceptor during the oxidation of $cyt\,c_{(red)}$ ($E_{1/2}$ cyt c = + 40 mV vs. Ag/AgCl).[12] This reverse reaction has been studied, for example by means of laser radiolysis.[8]

Previously, solution-phase components of the ET chain have been shown to communicate with monolayers at an electrode surface.[13–15] The novel electrode arrangement that we describe here for the electrochemical investigation of immobilized components of the ET chain offers potential advantages over such homogenous models. Not only does the system mimic that of nature, where different protein interactions occur at different phase interfaces, but from an experimental viewpoint, problems of solution resistance are negligible. Two aspects of the study are of particular interest: the work provides an example of direct faradaic signal transduction due to protein recognition at a protein modified surface; in addition, the techniques used can to manipulate the redox character of biological molecules through immobilization.

Experimental Procedure

Horse heart cyt c and CcP was immobilized by mixing 10 mg mL^{-1} of the protein within an excess of DTSSP (10 mM solution in 100 mM sodium phosphate buffer, pH 6.3) for 30 min. Alternatively, DSP was used (10 mM solution in dimethylsulfoxide, diluted 1:5 with water). A gold electrode ($A = 0.031\ cm^2$, polished with 0.05 μm alumina, treated with 25% H_2O_2 in H_2SO_4, and sonicated in water for 15 min) was incubated in the enzyme cross-linker solution overnight at 4 °C. All electrochemical measurements were made with a BAS CV-37 potentiostat and were collected either as digital or analog data sets. DC cyclic voltammetric experiments were performed in a sealed two-chamber electrolytic cell, which had a working solution volume of 500 μL.

The direct electrochemical measurements on protein were carried out in 0.1 mol dm^{-3} sodium phosphate buffer, pH 6.3, which was deoxygenated for 15 min with nitrogen prior to measurement. The solution was maintained under a nitrogen blanket during the experiment. Likewise, all stock solutions of reagents, prior to addition to the electrochemical cell, were treated in a similar fashion.

Exclusion of dioxygen from degassed solutions was confirmed independently with an unmodified gold electrode, poised at −300 mV vs. Ag/AgCl. Control experiments in which the heme redox center of the proteins were removed (by incubating the electrode in 4.0 M guanidine·HCl, pH 6.0 overnight followed by washing) were carried out for both electrodes, and are shown for cyt c in Figure 1.

Hydrolysis of a Phosphate Diester Doubly Coordinated to a Dinuclear Cobalt(III) Complex: A Novel Mechanism**

Daphne Wahnon, Anne-Marie Lebuis, and Jik Chin*

Metal ions play enormously important roles in both enzymic and nonenzymic[1] hydrolysis of phosphate diesters including DNA and RNA. Some enzymes such as 3′-5′ exonuclease from the Klenow fragment of DNA polymerase I,[2] RNAse H from the HIV reverse transcriptase,[3] Group I intron from *Tetrahymena* ribozyme,[4] P1 nuclease,[5] phospholipase C,[6] purple acid phosphatase,[7] and alkaline phosphatase[8] are activated by two or more metal ions. Functional models of phosphoesterases with two metal atoms in the active site may provide mechanistic insights into the role of the metal ions in the enzymes. We have shown that dinuclear copper(II) complexes, in which both Cu atoms reversibly coordinate the two phosphoryl oxygens of a bridging phosphate diester simultaneously, can be highly reactive for cleaving the ester.[9] Here we report on the hydrolysis of a phosphate diester that is doubly coordinated to a dinuclear cobalt(III) complex. Since this complex does not undergo rapid substitution, it is possible to examine the effect of the dinuclear complex alone on the hydrolysis of the coordinated phosphate diester.

The perchlorate salts of the dinuclear cobalt(III) complex cations **1** and **2**[10] with bridging dimethyl phosphate and

$[Co_2([9]aneN_3)_2(OH)_2\{O_2P(OCH_3)_2\}]^{3+}$ **1**

$[Co_2([9]aneN_3)_2(OH)_2\{O_2P(OCH_3)\}(OC_6H_4NO_2)]^{3+}$ **2**

bridging methyl *p*-nitrophenyl phosphate ligands, respectively, were synthesized by treating $[([9]aneN_3)_2Co_2(OH)_3](NO_3)_3$ ([9]aneN$_3$ = 1,4,7-triazacyclononane) (25 mM) with the sodium salt of the phosphate diester (25 mM) in aqueous $HClO_4$ (1 M).[11] ^{31}P NMR spectroscopy is a useful method for characterizing the bridging phosphate diester in **1** and **2**.[10] Monodentate coordination of dimethyl phosphate to mononuclear Co^{III} complexes results in a downfield shift of the phosphorus signal by about 7 ppm.[12] The phosphorus signals of the bridging phosphates in **1** and **2** are shifted about 14 ppm downfield relative to the signals of the corresponding free phosphates. Over the years many interesting dinuclear metal complexes structurally related to **1** and **2** that contain bridging carboxylate[11] rather than bridging phosphate groups have been reported. Many structures of substitutionally labile dinuclear metal complexes with bridging phosphate diesters have also been reported.[9, 13] Figure 1 shows the crystal structure of trication **1**.[14] This is the first structure of a complex in which a phosphate diester ligand bridges two substitutionally inert metal centers. The distance between the two cobalt(III) centers in **1** (2.9 Å) is somewhat shorter than intermetallic distances in dinuclear phosphodiesterases (ca. 4 Å)[2, 3] but comparable to that recently reported for a purple acid phosphatase (ca. 3.1 Å).[7d] The distances between the phosphorus and the bridging oxygen atoms (P1–O5, P1–O6 3.230(7) Å) are slightly shorter than the P–O van der Waals distance (3.3 Å).

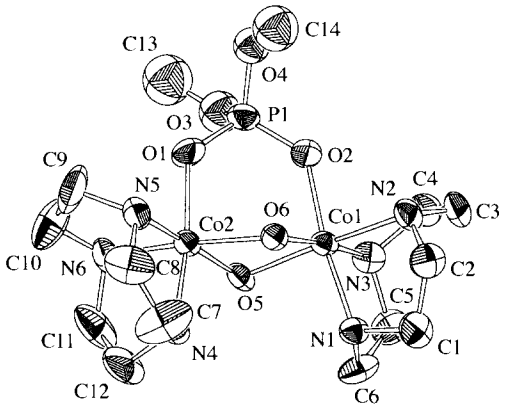

Fig. 1. X-ray structure of cation **1** (ORTEP representation; ellipsoids at the 40% probability level). Selected distances [Å] and angles [°]: Co1-Co2 2.903(2), Co1-O2 1.935(6), P1-O2 1.469(7), P1-O5 3.230(7), P1-O6 3.230(7), Co1-O6 1.927(6); O5-Co1-O6 79.5(3), Co1-O6-Co2 97.1(3), O6-Co1-O2 94.1(3), O6-Co1-N1 91.3(3), Co1-O2-P1 127.1(4), O2-P1-O1 117.4(4).

Hydrolysis of the phosphate diester in **2** was monitored by UV/Vis methods. The half-life for the hydrolysis reaction is about 6 s at pH 8. The pH–rate profile (Fig. 2) for the hydrolysis reaction was approximated with a linear equation having a slope of unity (intercept = −8.89; correlation coefficient = 0.996). The products of the hydrolysis reaction are *p*-nitrophenol and the dinuclear cobalt(III) complex $[Co_2([9]aneN_3)_2(OH)_2\{O_3P(OCH_3)\}]^{3+}$ having the bridging methyl phosphate, as confirmed by the ^{1}H and ^{31}P NMR spectra.[15] Methyl *p*-nitrophenyl phosphate does not dissociate from **2** to any observable extent, according to ^{31}P NMR spectroscopy.

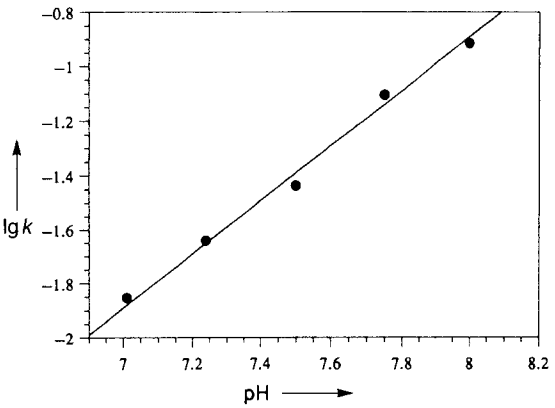

Fig. 2. Plot of the logarithm of the observed rate constants vs. pH for hydrolysis of the phosphate diester unit in **2** at 25 °C.

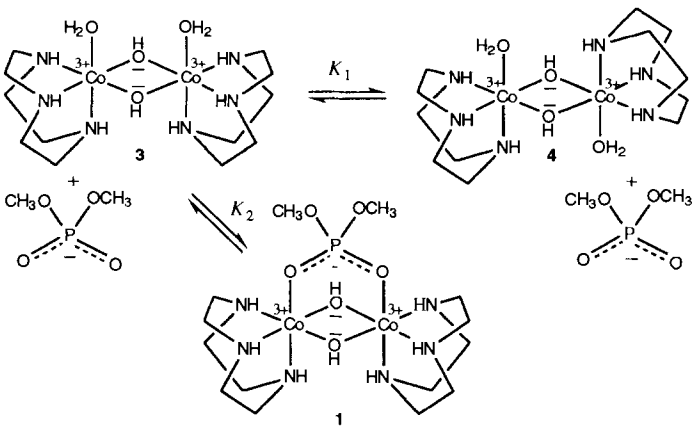
The second-order rate constant for hydroxide-catalyzed hydrolysis of the phosphate diester in **2** is 1.3×10^5 M^{-1}s^{-1} at 25 °C (Fig. 2), and the pseudo-first-order rate constant at pH 7.0 and 45 °C is 1.1×10^{-1} s^{-1}. The pseudo-first-order rate constant for the analogous hydrolysis of methyl *p*-nitrophenyl phosphate at pH 7.0 and 45 °C is 1.9×10^{-13} s^{-1}.[16] Hence, the phosphate diester in **2** is hydrolyzed about 6×10^{11} times more rapidly than the corresponding free phosphate diester. This is the greatest rate acceleration reported to date for the hydrolysis of phosphate diesters with a cobalt(III) complex. For comparison, ethyl *p*-nitrophenyl phosphate coordinated to a pentaamine–cobalt(III) moiety is hydrolyzed about 10^6 times faster than the free phosphodiester.[17] (*cis*-Diaqua)cobalt(III) com-

plexes (10 mM) provide up to 10^8-fold rate accelerations for the hydrolysis of phosphate diesters with good[18] or poor[19] leaving groups.

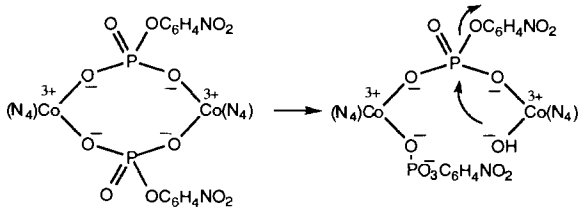
Under acidic conditions one of the four-membered rings in $[([9]aneN_3)_2Co_2(OH)_3]^{3+}$ is known to open to give **3**, which isomerizes to give **4**.[11b] Although the value of the equilibrium constant for the isomerization is not known, the *trans* isomer is favored ($K_1 \gg 1$, Scheme 1). Dimethylphosphate dissociates



Scheme 1. Equilibrium between and isomerization of **3** and **4**, and coordination of dimethyl phosphate.

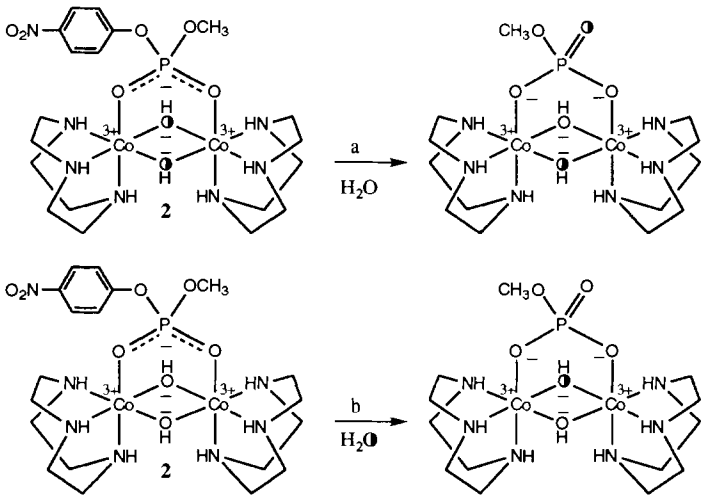
from **1** without hydrolysis of the diester group. The equilibrium constant for the binding of dimethyl phosphate to **4** to form **1** (K_2/K_1) as determined by ^1H and ^{31}P NMR spectroscopy[10, 15] is approximately 330 M^{-1}. The equilibrium constant (K_2) for the binding of dimethyl phosphate to **3** must be even greater than 330 M^{-1}, since $K_1 \gg 1$.[11b] In contrast, the equilibrium constant for the monodentate coordination of dimethyl phosphate to a mononuclear cobalt(III) complex is only about 4 M^{-1}.[12, 18, 19] Hence, there is significant cooperativity between the two metal centers in **3** for binding dimethyl phosphate.

In an interesting study, Hendry and Sargeson reported on the reactivity of a dinuclear cobalt(III) complex with two bridging phosphate monoesters.[20] They showed that one of the two bridging phosphate monoesters hydrolyzes rapidly by initial formation of a metal–hydroxide intermediate (Scheme 2). A rate acceleration of approximately 10^8-fold has been observed for hydrolysis of the phosphate monoester.[20]



Scheme 2. Initial step in the hydrolysis of a phosphoate monoester [20]. N_4 = 2 tn, tn = 1,3-diaminopropane.

The mechanism for hydrolysis of **2** may also involve initial dissociation of the bridging phosphate diester to form the monodentate phosphate diester followed by intramolecular attack of a metal-bound hydroxo ligand much like shown in Scheme 2. In order to investigate this possibility, ^{18}O-labeling experiments were performed (Scheme 3).



Scheme 3. ^{18}O-labeling experiments. a) Hydrolysis of **2**, in which 50% of the hydroxo ligand is labeled with ^{18}O, in unlabeled H_2O; b) hydrolysis of unlabeled **2** in 50% ^{18}O-labeled H_2O. ◑: 50% ^{18}O label (statistical distribution).

The incorporation of ^{18}O into phosphates can be detected by ^{31}P NMR spectroscopy since it results in an upfield shift of the phosphate signal by about 0.02 ppm.[21] We synthesized **2** in which the two bridging hydroxo ligands were labeled with 50% ^{18}O. Hydrolysis of labeled **2** with unlabeled water gave a product having two ^{31}P NMR peaks[22] (Scheme 3a, Fig. 3a). In contrast, hydrolysis of the unlabeled dinuclear complex **2** with 50% ^{18}O-labeled water gave a product with only one ^{31}P NMR peak (Scheme 3b, Fig. 3b). The mechanism for hydrolysis of **2** does not involve initial dissociation of the bridging phosphate diester to form the monodentate phosphate diester followed by intramolecular attack of a hydroxo ligand (see Scheme 2).[20] Such a mechanism would result in incorporation of ^{18}O in the phosphate from the solvent. A mechanism in which external hydroxide attacks the doubly coordinated phosphate in **2** is also eliminated by the labeling experiment. The ^{18}O-labeling studies together with the pH–rate profile (Fig. 2) clearly indicate that the bridging hydroxo ligand in **2** is first deprotonated to give the bridging oxo ligand, which then attacks the bridging phosphate diester (Scheme 4). The pK_a of the bridging hydroxo ligand in **2** is expected to be about 14.[23]

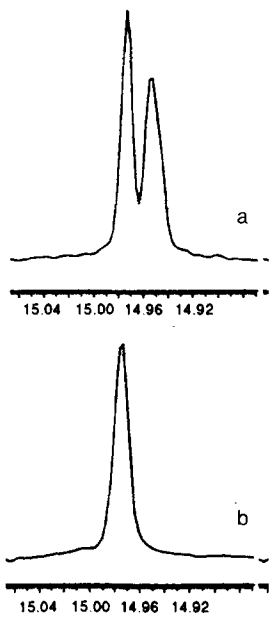


Fig. 3. ^{31}P NMR signal of the product formed from the hydrolysis of **2**·$(ClO_4)_3$. a) See Scheme 3a; b) see Scheme 3b).

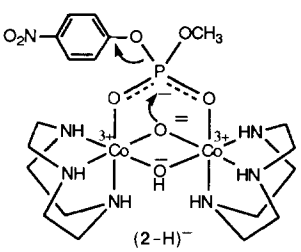
In conclusion, substitutionally inert dinuclear cobalt(III) complexes with bridging phosphate diesters (**1** and **2**) have been synthesized for the first



Scheme 4.

time. The distance between the two Co^{III} centers in **1** (2.9 Å) is roughly 1 Å shorter that that in dinuclear phosphodiesterases.[2, 3] The equilibrium constant for coordination of dimethyl phosphate to the dinuclear cobalt(III) complex **3** to form **1** ($K > 330\ M^{-1}$) is at least two orders of magnitude greater than that found for coordination of the diester to mononuclear cobalt(III) complexes ($K \approx 4\ M^{-1}$). Finally, the phosphate diester unit in the dinuclear cobalt(III) complex **2** is hydrolyzed by a novel mechanism involving double Lewis acid activation and the attack of a bridging, nucleophilic oxo ligand, which together lead to an unprecedented 10^{12}-fold rate accleration for the hydrolysis reaction.

Experimental Procedure

The perchlorate salts of **1** and **2** were synthesized by reacting $[([9]aneN_3)_2Co_2(OH)_3](NO_3)_3$ (25 mM) with the sodium salt of the phosphate diester (25 mM) in aqueous $HClO_4$ (1 M) [11]. The perchlorate salt of **1** was recrystallized from water yielding red block-shaped crystals.

Hydrolysis of the phosphate diester ligand in **2** was monitored by UV/Vis methods. In a typical experiment 10 µL of a stock solution of **2** (10 mM in DMSO) was injected into 2 mL of a buffered solution (5 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), pH 7 to 8, 25 °C), and the reaction was monitored by following the increase in the absorbance at 400 nm due to the release of *p*-nitrophenoxide. The rate constants were obtained by fitting the first three half-lives of the reaction according to a first-order kinetics equation.

A Framework Containing Ga-O-Ga Links: The Synthesis and Structure of Gallobicchulite $Ca_8(Ga_2SiO_6)_4(OH)_8$

Sandra E. Dann, Philip J. Mead, and Mark T. Weller*

The majority of framework structures formed from linked tetrahedral units are aluminosilicates with an upper limit on the Al to Si ratio of 1:1. Gallium may replace aluminum to various extents in these structures but again the systems are always silicon-rich. We have now prepared the gallium-rich silicate $Ca_8(Ga_2SiO_6)_4(OH)_8$ **1**, a framework material of the sodalite family containing Ga-O-Ga links, and report here its structure as investigated by powder neutron diffraction and MAS-NMR spectroscopy (MAS = magic angle spinning). The hydroxide groups trapped in the sodalite type cages show disordering with a weak hydrogen-bonded interaction with the framework.

The majority of framework structures constructed from linked TO_4 tetrahedra synthesized to date have been aluminosilicates, though more recently a large number of aluminophosphates have been discovered. However, frameworks may be formed from other tetrahedral oxoanions specifically BO_4, GaO_4, GeO_4, ZnO_4, BeO_4, and AsO_4. Examples of compounds containing these units include the sodalites $Na_8(GaSiO_4)_6(OH)_2$[1] and $Li_8(BeAsO_4)_6Cl_2$.[2] Aluminosilicates synthesized hydrothermally invariably obey Löwenstein's

[**] This work was supported by the Engineering and Physical Sciences Research Council under Grant GR/H 94900. We thank Dr A. Hewat (Institut Laue-Langevin Grenoble) for his help in collecting the neutron diffraction data.

rule of aluminum avoidance[3] in that Al-O-Al linkages are prohibited and the Si:Al ratio reaches 1:1 at best. However, some frameworks containing directly linked AlO_4 groups are known. The best characterized materials are the pure aluminate sodalites of the general composition $M_8(AlO_2)_{12}X_2$, where M is a divalent cation for example Ca^{2+}, Sr^{2+}, Cd^{2+}, and X is a divalent anion such as SO_4^{2-}, CrO_4^{2-}, WO_4^{2-}, O^{2-}, S^{2-}, Se^{2-}, and Te^{2-}.[4-6] These materials are prepared under dry, high-temperature conditions by direct reaction of alumina with metal oxides/salts. The only other well-authenticated framework structure containing Al-O-Al linkages is bicchulite, $Ca_8(Al_2SiO_6)_4(OH)_8$.[7, 8] This compound is synthesized under hydrothermal conditions at 540 °C and 2 kbar, rather higher temperatures and pressures than most framework-forming reactions. The successful synthesis of these high aluminium frameworks at elevated temperature indicates that obeyance of Löwenstein's rule is kinetic in origin; that is, formation of Al-O-Al units is possible under the correct synthetic conditions. Attempts to prepare gallium analogues of the pure aluminate sodalites have been unsuccessful: reactions of gallia at high temperatures with metal salts form a variety of complex products. This may be related to the preference of gallium for coordination geometries higher than fourfold in complex oxides, and until now no framework structure containing a GaO_3-O-GaO_3 link was known.

In the course of the investigation of the structure of bicchulite we have successfully synthesized the gallobicchulite $Ca_8(Ga_2SiO_6)_4(OH)_8$ **1**, in which the aluminum of the aluminum sodalite has been totally replaced by gallium in the framework (crystallographic data see Table 1). Compound **1** has

a sodalite type structure but unusually has four anions per β-cage. The calcium and hydroxide ions form two interpenetrating tetrahedral units in the β-cages (Fig. 1 left). The calcium ion is coordinated to three hydroxide oxygens plus three oxide ions of the framework, producing a roughly octahedral environment. Weaker interactions exist to a fourth hydroxide ion and three further framework oxygens. The hydroxide ions are not aligned directly along the threefold axis of the unit cell, which would produce an extremely unusual symmetrical trifurcated hydrogen bond. Displacement from the threefold axis occurs to produce one stronger interaction to just one of the framework oxygens (Fig. 1 right). The O–H···O bond angle of 149.3° is typical of such an environment with a weak hydrogen bond as found in hydrates.[9]

The gallobicchulite framework consists of a long-range disordered arrangement of the gallium and silicon atoms. The average bond length between the tetrahedrally coordinated atoms and oxygen atoms of 1.77 Å (Table 2) is close to that expected from the weighted average of typical Si–O and Ga–O distances in tetrahedral environments (Si–O 1.62 Å, Ga–O 1.85 Å).

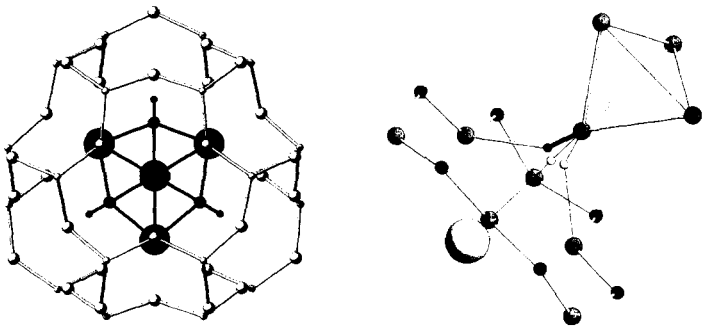

Fig. 1. The structure of $Ca_8(Ga_2SiO_6)_4(OH)_8$ **1**. Left: View along [111] with the cage contents highlighted; the cube formed from the four calcium and four hydroxide ions is shown. Right: The interaction of the hydroxide ion with a six ring of the cage (Ca: large spheres, O: medium-sized grey spheres, Ga/Si: small dark spheres in the six ring, H: small sphere). One of the three possible hydroxide ion orientations is shown in bold.

Table 2. Bond lengths [Å] and selected bond angles [°] in **1** (esd's are given in parentheses).

Bond	Bond length	n [a]	Bond	Bond angle	n [a]

HO-O:	2.227(7)				

[a] n shows how often the bond or angle occurs.

However, the ^{29}Si MAS-NMR data essentially consists of a single resonance ($\delta = -77.1$), which indicates that the distribution of the silicon and gallium atoms is not wholly random and which is consistent with the silicon atoms solely in $Si(OGa)_4$ environments. If the distribution of the silicon and gallium atoms were random, a number of Si environments $Si(\text{-}OSi)_n(\text{-}OGa)_{4-n}$ would occur, producing the characteristic multiline spectrum ($n = 0-4$; relative intensities 16:32:24:8:1, representing the probability of each $Si(\text{-}OSi)_n(\text{-}OGa)_{4-n}$ environment derived from binomial theorem with a Si:Ga ratio of 1:2). This indicates that in the gallium-rich framework of **1** that Si-O-Si and Ga-O-Ga links are avoided as far as possible. The latter can be derived from the fact that distributing the silicon such that each has an immediate environment of $Si(OGa)_4$ also minimizes the number of Ga-O-Ga links; distribution of the silicon in a gallium-rich framework such as that any Si-O-Si links are formed necessarily means that more Ga-O-Ga units remain elsewhere. The weak resonance at $\delta = -82$ in the ^{29}Si MAS-NMR spectrum indicates that this minimization is not perfect; a low level of $Si(OGa)_3(OSi)$ environments still remains in **1**. The ^{1}H chemical shift of $\delta = 6.89$ is typical of a free or weakly bound OH group.

The synthesis of gallobicchulite has shown that the formation of framework structures containing high levels of gallium and hence direct tetrahedral Ga-O-Ga links is possible. Within the framework the level of these Ga-O-Ga links is minimized as far as possible in accordance with a Löwenstein type rule.

Experimental Procedure

Gallobicchulite was prepared hydrothermally following the literature method for the synthesis of aluminobicchulite from gehlenite [10]. $CaCO_3$, Ga_2O_3, and SiO_2 in the correct molar ratios were fired at initially at 800 °C for two periods of 24 h and then 1330 °C for 48 h. Powder X-ray diffraction of the product was consistent with formation of $Ca_2Ga_2SiO_7$ which has a gehlenite type structure [10]. $Ca_2Ga_2SiO_7$ (2 g) was placed in a gold capsule with H_2O (0.5 mL) and sealed; the capsule was

heated to 538 °C under 1 kbar hydrothermal pressure for 7 days and then slowly cooled to room temperature. The product was dried at 160 °C and transferred to a dry box. The powder X-ray diffraction pattern of the product was consistent with the formation of cubic gallobicchulite. Whilst deuteration can be achieved under these synthetic conditions, bicchulite samples undergo extremely rapid proton exchange with moisture making preservation of full deuteration extremely difficult. However, with the relatively low overall level of hydrogen in the material, collection and refinement of powder neutron diffraction data from $Ca_8(Ga_2SiO_6)_4(OH)_8$ was possible (Fig. 2). Powder neutron diffraction data were collected on the D2B instrument at the Institut Laue-Langevin (ILL), Grenoble ($\lambda = 1.594$ Å, measurement time: 6 h, step size: 0.05°, angular range: 5–160°). The data were of good quality and only very minor amounts of impurity (reactant gallogehlenite) produced reflections which could not be indexed on the cubic unit cell gallobicchulite. These additional reflections were ignored in the subsequent refinement. Structure refinement was undertaken in the space group $I\bar{4}3m$ by using the structure of aluminobicchulite as the starting model [8]. Scattering lengths were taken as 7.29, 5.81, 4.90, and −3.74 fm for Ga, O, Ca, and H, respectively. No evidence was seen for ordering of the framework species and a mixed occupancy site with a scattering power equivalent to 2/3:1/3 Ga:Si was assigned to the framework. The large scattering power difference between Ga and Si would produce reasonably intense additional reflections if ordering occurred. The refinement was carried out with the GSAS package [11], and initial cycles involved instrumental parameters and positional parameters for all atoms. Refinement of temperature factors produced reasonable values for all atoms with the exception of hydrogen for which a value of 6 Å^2 was obtained. The O–H bond length with the hydrogen on (*x*,*x*,*x*) was also somewhat short at 0.84 Å. This indicated that the hydrogen atom distribution was poorly described by the (*x*,*x*,*x*) position, and disordering of this atom onto an (*x*,*x*,*z*) site (1/3 occupancy) was permitted. Refinement produced a small lowering in R_{wp} (from 0.0369 to 0.0365) and more significantly a marked reduction in temperature factor and a more reasonable O–H distance. Final refined atomic coordinates and derived bond lengths and angles are given in Tables 1 and 2.

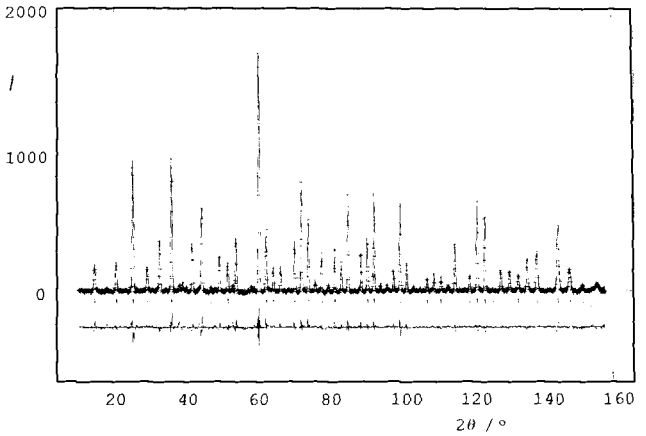

Fig. 2. Final fit to the powder neutron diffraction data. Observed powder diffraction (crosses), calculated (full line), and difference plot (lower line) for $Ca_8(Ga_2SiO_6)_4(OH)_8$ **1** ($\lambda = 1.594$ Å; the tick marks show the positions of the reflections).

The ^{1}H and ^{29}Si MAS-NMR spectra of gallobicchulite were collected with a Bruker AM300 spectrometer. Sample spin speeds were 4.5 KHz for ^{1}H and 4 KHz for ^{29}Si. The proton NMR spectrum consisted of a single resonance at $\delta = 6.89$ relative to TMS. The ^{29}Si NMR spectrum showed a strong resonance at $\delta = -77.1$ relative to TMS with a weak shoulder (5%) at $\delta = -82.0$. The IR spectrum of gallobicchulite was recorded on a Perkin Elmer FT-IR 1710 spectrometer equipped with a PE 3600 data station on a pressed KBr disc. In the OH stretching region a strong sharp band was observed centered at 3662 cm^{-1} consistent with a free or very weakly hydrogen-bonded hydroxide ion.

The Nonaaquabismuth(III) Cation**

Walter Frank,* Guido J. Reiss, and Jürgen Schneider

Almost 100 years ago, within the scope of his "Coordinationstheorie der hydratisierten Salze", Alfred Werner for the first time described water in its function as an aqua ligand for metal ions.[1] Today, more than 60 years after the first X-ray crystallographic characterization of an aqua complex,[2] there is conclusive evidence for the existence of $M(H_2O)_n^{m+}$ ions in solution[3] or in the solid state[4] for the sufficiently metallic elements, with only a few exceptions. The last of the main group metals for which knowledge is lacking in this respect, as has been indicated repeatedly,[5] is the element bismuth. From acid solutions containing Bi^{III}, which are supposed to contain aqua ions at Bi concentrations of less than 10^{-5} mol L^{-1} and pH values of less than 2,[6] only basic salts with polynuclear cations[7] or mononuclear cations with coordinated anions[8] could be isolated to date. In studies on the solvation behavior of bismuth(III) trifluoromethanesulfonate, we have now been able to isolate a compound containing a hydrated Bi^{3+} ion, to determine its solid-state structure including the positions of the hydrogen atoms, and hence to close the last gap in the systematics of aqua complexes of main group metals.

From a saturated solution of bismuth(III) trifluoromethanesulfonate (triflate) in aqueous trifluoromethanesulfonic acid (ca. 0.5 M), a colorless material **1** crystallizes at room temperature which has been shown by vibrational spectroscopy to contain no hydroxo groups and has been identified as an enneahydrate of bismuth(III) triflate by elemental analysis. It can already be concluded directly from the fact that **1** is isotypic to compounds of the type $[Ln(H_2O)_9](SO_3CF_3)_3$ (Ln = lanthanide)[9] that all of the water molecules are bound to the metal, that is **1** is a compound containing a homoleptic complex cation with nine monodentate ligands, unique in the chemistry of main group elements.

$[Bi(H_2O)_9](SO_3CF_3)_3$ **1**

Figure 1 shows the structure of the nonaaquabismuth(III) cation of **1** in the crystal at −140 °C.[10] It has crystallographic C_{3h} symmetry; the oxygen atoms, in good approximation, occupy the corner positions of a tricapped trigonal prism so that the symmetry of the coordination polyhedron of the bismuth atom

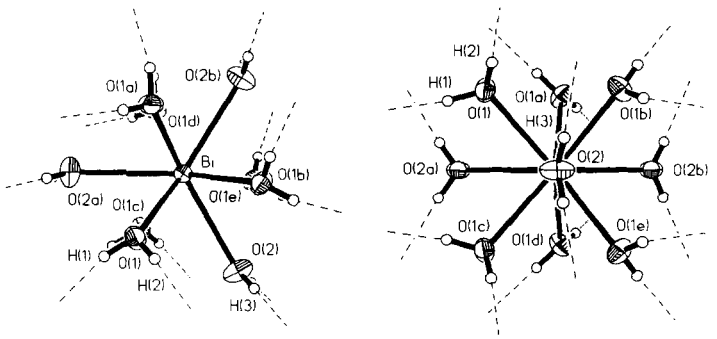

Fig. 1. The nonaaquabismuth(III) cation of **1**, view along [001] (left) and along [−1 −1 0] (right). The atoms were refined with anisotropic thermal parameters (ellipsoids at the 70% probability level); the radii of the H atoms were chosen arbitrarily, only the symmetry independent H atoms are labeled. The directions of the linkage of the cation in the crystal are illustrated. Bond lengths [Å] and angles [°]: Bi–O(1) 2.448(2), Bi–O(2) 2.577(2), O(1)–H(1) 0.85(3), O(1)–H(2) 0.82(2), O(2)–H(3) 0.81(2); O(1)-Bi-O(2) 73.4(1), O(1)-Bi-O(1a) 73.3(1), O(1)-Bi-O(1c) 92.9(1), O(1)-Bi-O(1d) 139.7(1), O(1)-Bi-O(2a) 66.4(1), O(1)-Bi-O(2b) 133.3(1) H(1)-O(1)-H(2) 111(3), H3-O(2)-H(3c) 109(2), Bi-O(1)-H(1) 114(2), Bi-O(1)-H(2) 125(2), Bi-O(2)-H(3) 124(2).

approaches D_{3h}. Thus, the molecular structure represents that which would be expected for a complex with coordination number 9 without recognizable stereochemical activity of the lone pair of electrons. The Bi–O distances lie in the expected range for a ratio of Bi–O(2) to Bi–O(1) of 1.05[11] and a sum of Brown bond orders of 3.12.[12] Each of the cations that are stacked along [001] in the crystal is linked to nine triflate anions through O–H···O hydrogen bonds of medium strength (O(1)···O 2.811(3) and 2.762(2) Å, respectively, O(2)···O 2.755(2) Å). The conformation-determining action of solid-state association on the ligand shell of the complex can be understood directly from the direction of the hydrogen bonds to the oxo functions of the anions (Fig. 1). The orientation of the hydrogen atoms at the O1 center, which is determined by hydrogen bonds, causes (for the entire complex) a significant deviation from the most similar of the conceivable arrangements with D_{3h} symmetry. By comparing the unit cell volume of **1** at room temperature[10] with the corresponding data of the isotypic lanthanide compounds,[9] the effective ionic radius (IR^{IX})[13] of the Bi^{3+} ion in **1** can be estimated to 1.15 Å. Thus, it may be arranged, with regard to its size, between Nd^{3+} (IR^{IX} = 1.163 Å) and Sm^{3+} ions (IR^{IX} = 1.132 Å). The $IR^{IX}(La^{3+})/IR^{IX}(Bi^{3+})$ ratio of radii (1.05) is typical of Bi^{III} compounds with no pronounced lone pair activity.[13]

The surprisingly low tendency of hydrated Bi^{3+} ions to undergo condensation in HSO_3CF_3 solution becomes more evident by the fact that even from the oily, highly supersaturated solutions which are sometimes obtained when the solvent is quickly evaporated, only **1** can be isolated, whereas compounds with hexanuclear "bismuthyl ions" $[Bi_6O_n(OH)_{12-2n}]^{6+}$ crystallize from correspondingly acidic $HClO_4$ or HNO_3 solutions already at very much lower Bi^{III} concentrations.[7] This suggests that the corresponding anions have a considerable influence on complex condensation.

The knowledge of **1**, in principle, offers the chance to study from the outset the basic hydrolysis and the condensation reactions of the Bi^{III} ion in aqueous solution. Investigations in this direction have already been initiated.

Experimental Procedure

1: To a suspension of bismuth(III) oxide (2.6 g, 5.58 mmol) in trifluoromethanesulfonic acid anhydride (5.0 g, 17.72 mmol), trifluoromethanesulfonic acid (5.0 g, 33.32 mmol) was added dropwise at 0 °C. Upon heating at room temperature, the reaction mixture solidified to give a yellowish substance which was dissolved in water (65 mL). Crystallization from this highly acidic solution at room temperature yielded a total of 7.4 g (81.0%, based on Bi_2O_3) of **1** in the form of colorless rods. Elemental analysis (M_r = 818.31): C 4.59 (4.40), H 1.99 (2.22), Bi 26.3 (25.54)%; IR (nujol, BaF_2): $\tilde{\nu}$ [cm^{-1}] = 3365 (sb), 3210 (shb), 1624 (m), 1246 (sb), 1172 (m), 1029 (s); (nujol, ZnSe): $\tilde{\nu}$ [cm^{-1}] = 1033 (s), 769 (m), 638 (s), 574 (w); Raman (powder): $\tilde{\nu}$ [cm^{-1}] = 1232 (w), 1195 (w), 1050 (s), 1030 (w), 775 (s), 580 (m), 522 (w), 358 (s), 320 (m), 237 (w).

Fascinating Alchemical History—A Labor of Love

Nucleophilic Aromatic Substitution of Hydrogen. By *O. N. Chupakhin, V. N. Charushin* and *H. C. van der Plas*. Academic Press, San Diego, 1994. 367 pp., hardcover $ 95.00.—ISBN 0-12-174640-2

The chemistry of aromatic compounds is presently not in the mainstream of organic chemistry research, although a substantial proportion of the products of the fine chemicals industry contain aromatic moieties, and there are still many challenging and important questions concerning reactions of aromatic compounds. Therefore the monograph *Nucleophilic Aromatic Substitution of Hydrogen* by O. N. Chupakhin, V. N. Charushin, and H. C. van der Plas is a very welcome and needed contribution.

The book is divided into four chapters: 1. Introduction (16 pp.), 2. Nucleophilic Substitution of Hydrogen in Arenes (70 pp.), 3. Nucleophilic Substitution of Hydrogen in Heteroaromatics (152 pp.), and 4. Reactivity of Arenes and Heteroarenes and Mechanisms of the S_N^H Reactions (40 pp.). The length of the third chapter, which forms more than half of the book, reflects the personal interest of the authors who are very active in the chemistry of azines. In the first chapter the authors formulate the theme of the book, present basic concepts of the reactions between nucleophilic agents and electrophilic arenes, and briefly discuss possible ways in which the σ^H adducts of nucleophilic agents to electrophilic arenes can be converted into products. In the second chapter these possibilities are discussed in detail for the reactions of nucleophiles with carbocyclic nitroarenes and complexes of arenes with transition metals. The third and longest chapter describes analogous reactions with electrophilic heteroarenes. This is mostly devoted to the various possibilities of nucleophilic amination, mainly the Chichibabin reaction—particularly its oxidative variant. The fourth chapter deals with mechanistic aspects of the nucleophilic substitution of hydrogen, formation of the σ^H adducts, and their conversion to the final products.

The book is well written and also contains examples of experimental procedures. It will be of great value to chemists working in research laboratories in academia and industry who need to be acquainted with possibilities of introducing substituents into aromatic rings via this process. The experimental procedures enable the reader to evaluate the practical usefulness of a variety of reactions without the necessity to consult the original literature. An additional advantage of this book, written partly by Russian chemists, is that it contains many references to the Russian literature, often not available in Western libraries and therefore somewhat neglected.

I also have some critical remarks about this book. First of all, in promoting the usefulness of nucleophilic substitution of hydrogen the authors should stress in a more unambiguous way that where there is competition from the S_NAr reaction of halogen this is just a secondary process. Also it seems that sigmatropic rearrangement reactions such as the Hauser–Sommelet rearrangement or the Gassmann reaction, which are included in the book, are close analogs of the Claisen aryl–allyl ethers rearrangement and should not be considered as the nucleophilic substitution of hydrogen. Also nucleophilic aromatic substitutions via arynes can hardly be considered as examples of nucleophilic substitution of hydrogen. The titles of the chapters are somewhat inconsistent because the general term "arenes" also embraces "heteroarenes". In the list of contents the title of Chapter 4 should be "Heteroarenes", not "Hetarenes". The mechanistic discussions in Chapter 4 are sometimes superficial. There are some rather questionable opinions; for example, orientation effects in nucleophilic addition to derivatives of nitrothiophene, nitrofuran, etc. (p. 256) should be explained as due to efficient conjugation, not as an anomeric effect. Also the preceding discussion concerning site selectivity (p. 255) appears doubtful. There is only a subject index, which is not sufficiently comprehensive. These minor flaws do not spoil my general positive impression of the book, which due to its great value should find a place not only in libraries but also in individual collections.

Warsaw (Poland)

The Jewish Alchemists. A History and Source Book. By *R. Patai*. Princeton University Press, Princeton, NJ, 1994. XVI, 617 pp., hardcover $ 35.00.—ISBN 0-691-03290-4

When I taught Sunday School at Fresno's Temple Beth Israel during the late 1950s and early 1960s, the consensus was that mysticism had never occupied more than a minor position in Judaism. This denigration of the Zohar and the Kabbalah was probably due to the earlier influence of the Jewish Enlightenment (Haskalah) and its attempt to distance Judaism from "unenlightened" superstition. Similarly, as Professor Raphael Patai, the eminent Hungarian-born octogenarian Jewish anthropologist, folklorist, Biblical scholar, and prolific author, points out, contemporary Jewish scholars have asserted that the participation of Jews in alchemy was likewise insignificant. Although there exists no inventory of alchemical manuscripts written by Jews, nor even a study of references to alchemy found in books written by Jews, and although the number of Jewish alchemists was small in comparison to the number of non-Jewish alchemists in the countries of the Jewish Diaspora, Jewish alchemists exerted an important influence on the origin, development, transmission, and spread of alchemy.

In fact, as Professor Patai's book effectively demonstrates, throughout much of

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

the history of alchemy, in order to provide a legitimation and respectable family tree for the "Great Art," there was a persistent tendency to attribute a Jewish or even biblical origin to alchemy as a whole, and numerous biblical figures, from Adam through the prophets (with Moses considered its greatest master), were regarded by later alchemists as adepts or recipients of its secrets by divine revelation. Alchemical efficacy was attributed to Hebrew divine, angelic, and demonic names, to Hebrew words, and even to the 22 letters of the Hebrew alphabet; and Hebrew was more important for the alchemist than was Latin for the physician. This overvaluation by gentiles of the Jewish role in the origin and development of alchemy survived the European Enlightenment and continued through the 18th and 19th centuries.

In order to counteract the negative attitude of Jewish scholars toward Jewish contributions to alchemy, Professor Patai has written this meticulously documented book, which is clearly a labor of love. In it he opens up a previously unexplored field in cultural history by tracing Jewish alchemy from Hellenistic times through the 19th century. Despite the book's length, broad scope, and the number of years spent and the number of archives consulted in writing it, the author modestly states: "it should not be considered more than a prolegomenon to the history of the Jewish work in alchemy and the role of Jews in contributing to its theory and practice." Patai cites two reasons for this limitation. First, he admits that he was unable to consult all existing Jewish alchemical writings, especially those still in manuscript and scattered throughout the world's libraries and archives. Many of these are probably in various languages, and the impression obtained from the vast amount of material in this book, viz., that Jews wrote most of their alchemical works in Hebrew characters, is probably incorrect. Second, Patai was able to refer only occasionally to the personal relationships between Jewish and non-Jewish alchemists and the literary influences between Jewish alchemical writings and the more numerous writings produced in the Moslem and Christian worlds.

The book, which is graced by 35 illustrations, consists of 40 chapters (ranging in length from $2\frac{1}{2}$ to 30 pages), arranged in 10 sections (ranging from 31 to 88 pages), each prefaced by a summarizing introduction. The material is arranged chronologically, which is sometimes problematic because authorship of manuscripts is often pseudepigraphic, e.g., Pseudo-Maimonides. Patai begins his first section (Prelude) with a careful explication of the multifaceted aspects of alchemy, both exoteric and esoteric, proceeds to show that the major biblical figures were considered as alchemists for centuries, and presents the very few occurrences of alchemical topics in the Bible and Talmud. In his second section (The Hellenistic Age) he devotes two chapters to Maria the Jewess (sometimes identified with Miriam, the sister of Moses), one of the earliest nonfictional alchemists of the Western world, who constructed and described various ovens and alchemical apparatus (her name is preserved in the Latin, French, and German terms for the water bath—balneum Mariae, bain Marie, and Marienbad, respectively). Zosimus the Panopolitan, the first Greek alchemical author whose writings have survived and who was the greatest authority among the Hellenistic alchemists, considered Maria the greatest authority among all the alchemists who preceded him. After a section on the early Arab world, and one on the 11th to 13th centuries (the golden age of Arab culture in general and Arab alchemy in particular), the remaining six sections consider individually the 14th to 19th centuries. The 14th century saw a marked increase in the number of alchemists as a shortage of precious metals for coinage produced a greater demand for alchemical gold and silver. Most Jewish alchemists were Sephardim (those who lived in the Mediterranean area), while Ashkenazim (the Jews of Northern Europe) did not participate in the art until the 18th century.

Patai presents exegetic translations of original Hebrew and Arabic documents and includes biographies not only of Jewish alchemists but of non-Jews who learned their secret art from Jewish masters, e.g., Nicholas Flamel from "Abraham the Jew" and Solomon Trismosin from an unnamed "Jew who knew German." Some Jewish alchemists combined alchemy with magic or kabbalistic practices, while others became forerunners of modern chemistry. Patai's book contains many facts and anecdotes of which I was unaware. Although I had written an article on the Comte de Saint-Germain with a student from my alchemy course, I did not know of the count's Jewish origins, for which Patai cogently argues. The book concludes with an 18-page alchemical vocabulary (Hebrew, Arabic, and Italian), the most valuable part of a manuscript from the Tunisian island of Jerba (Djerba) discussed in Chapter 39, followed by 45 pages of detailed notes and references and a 29-page (2 columns per cage) index, which adds to the utility of the volume.

According to Patai, Jewish alchemy possessed a number of specific characteristics. Because almost all the adepts were religiously observant, they considered their art closely interwoven with religious practice. They were scrupulously honest, for to be otherwise would be a religious transgression. Their search for the philosophers' stone was more associated with the humanitarian purpose of healing the sick than was the case among non-Jewish alchemists. Based on extant sources, Jewish alchemists were more concerned with practice than with theory and made few contributions to the latter. Their technical directions were precise and detailed. Also, the Kabbalah and its concomitant gematria (calculations based on the numerical values of Hebrew letters) helped transform medieval alchemy into the more mystically and religiously orientated discipline of the Renaissance.

This highly recommended book is a rich storehouse of information on a grossly neglected field of alchemical history. It demonstrates that from its earliest origins alchemy was a Jewish occupational specialization, comparable to the better known Jewish work on medicine. It shows that Jewish alchemists introduced new apparatus, techniques, and procedures, were employed as court alchemists, and achieved a high reputation in the Muslim and Christian worlds in which alchemy was practiced. Let us hope that it fulfills the author's hope that it "will stimulate younger scholars to devote their attention to this subject, and to carry on this fascinating task that time no longer permits me to undertake."

Synthetic Aspects of Metal-Catalyzed Oxidations of Amines and Related Reactions

Shun-Ichi Murahashi*

The metabolism of amines is governed by a variety of enzymes such as amine oxidase, flavoenzyme, and cytochrome P-450. A wide variety of compounds are produced such as ammonia and alkaloids in selective and clean oxidation reactions that proceed under mild reaction conditions. Simulation of the functions of these enzymes with simple transition metal complex catalysts may lead to the discovery of biomimetic, catalytic oxidations of amines and related compounds. Indeed, metal complex catalyzed oxidations have been found to proceed with high efficiency. The first section of this review discusses the dehydrogenative oxidations of amines with transition metal catalysts by transition metal catalysts that simulate amine oxidase. The second section highlights the catalytic oxidation of secondary amines to nitrones by simulation of flavoenzymes. The third section describes the simulation of the function of cytochrome P-450 with low-valent ruthenium complexes and peroxides. Biomimetic ruthenium-catalyzed oxidations of tertiary amines, secondary amines, and other substrates such as amides, β-lactams, nitriles, alcohols, alkenes, ketones, and even nonactivated hydrocarbons can be performed selectively under mild conditions. These three general approaches provide highly useful strategies for synthesis of fine chemicals and biologically active compounds such as alkaloids, amino acids, and β-lactams.

Keywords: catalysis · oxidations · synthetic methods

1. Introduction

Oxidation is one of the most fundamental reactions in organic synthesis.[1] Owing to the current need to develop forward-looking technology that is environmentally acceptable with respect to, for example, negligible formation of inorganic salts and efficient, highly selective formation of products, many aspects must be considered in the search for new catalytic oxidation reactions. The most attractive approaches are biomimetic oxidation reactions that are closely related to the metabolism of living things.

The metabolism of amines is promoted by various enzymes such as amine oxidase, hepatic flavoenzyme (**1**), and cytochrome P-450 (**2**). The metabolic routes of oxidation of a wide variety of amine compounds are of importance from both biological and synthetic points of view. Simulation of the functions of the enzymes catalyzing such metabolic routes with metal complex catalysts should provide novel biomimetic methods for catalytic oxidation of amines and related compounds, and hence highly useful strategies for organic synthesis can be explored.[2]

The catalytic systems used in practical organic synthesis and industrial processes are very simple and sometimes require high reaction temperatures of over 100 °C. But these conditions are a long way from those of biomimetic and/or enzymatic reactions, which occur at room temperature within a specific, complex reaction system. We laid our emphasis on exploring *simple*, *convenient*, and *general* catalytic reactions by using principles similar to those of enzymes, although the resulting catalytic reactions are in some cases far from enzymatic reactions.

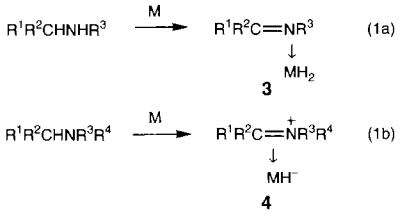
2. Amine Oxidase Type Oxidation Catalysts

Mitochondrial monoamine oxidase (MAO) is a flavin-dependent enzyme that catalyzes the oxidative deamination of biogenic monoamines to give the corresponding aldehydes.[3] MAO catalyzes the oxidation of amines by two one-electron transfers from the substrate to the flavin. Simulation of the function of MAO with metal complex catalysts can lead to the discovery of new types of transformations of amines. We have found that activation of amines with low-valent transition metal catalysts generally gives two types of key intermediates. The reaction of an amine that has a N–H bond gives an imine metal complex **3** [Eq. (1a)],[4] while that of an amine without a N–H bond gives an iminium ion complex **4** [Eq. (1b)].[5] Using these intermediates, various catalytic transformations of amines can be explored.



(1a)

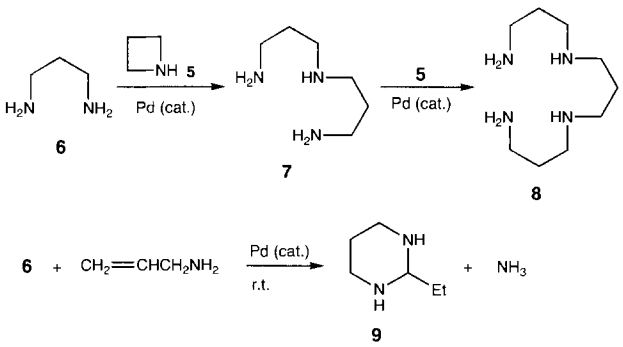
(1b)

2.1. Catalytic Oxidation of Primary and Secondary Amines

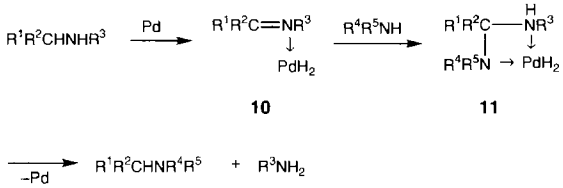
MAO catalyzes the oxidation of monoamines by two one-electron transfers from the substrate to the flavin. The first one-electron transfer from the amine to flavin (Fl_{ox}) gives the amine radical cation. Loss of a proton and the second transfer of one electron to the flavin yields the iminium ion and the reduced flavin FlH_2 [(Eq. (2a)].[3]

(2a)

The study of the generation of iminium ions by activating amines with metal complexes led to the discovery of catalytic alkyl group exchange reactions of amines [Eq.(2b)].[4] The reaction is simple to carry out and can be applied to the preparation of various nitrogen compounds. Palladium black, prepared by a modification of Willstätter's method, is an excellent catalyst, although the reaction is also catalyzed by other heterogeneous and homogeneous transition metal catalysts. Variation of the exchange reaction can open new processes for the synthesis of tertiary amines, diamines, polyamines, and heterocyclic amines. Typically, the palladium-catalyzed reaction of *N*-methylbenzylamine with *N*-methylbutylamine gives *N*-butyl-*N*-methylbenzylamine (95%). The treatment of azetidine (**5**) with the palladium catalyst in the presence of 1,3-propanediamine (**6**) gives *N*-(3-aminopropyl)-1,3-propanediamine (**7**), which undergoes a further palladium-catalyzed reaction with **5** at 120 °C to give the tetramine **8** (75%). Apparently, 1,*n*-diamines ($n = 2, 3$) are less reactive than azetidine towards palladium, because they are stabilized by bidentate chelation. Further, a new process for the synthesis of heterocyclic compounds can be explored. The palladium-catalyzed reaction of **6** with allylamine at 25 °C gives 2-ethylhexahydropyrimidine (**9**) (95%), which is a highly efficient hydrogen donor for selective hydrogenations.[6]



The reaction involves general, fundamental steps. The oxidative addition of a low-valent metal atom to the N–H bond and subsequent β-MH elimination gives the imine hydride complex **10**, which reacts with nucleophiles such as additional amines to give **11** (Scheme 1). Intramolecular reductive cleavage of **11**



Scheme 1. Catalytic transalkylation of primary and secondary amines.

S.-I. Murahashi was born in Osaka, Japan, in 1937. He received his Ph.D. degree under the supervision of Professor Ichiro Moritani with a thesis on the structure and reactivity of carbenes. In 1963 he was appointed assistant professor at Osaka University. He spent two years (1968–1970) at Columbia University as a postdoctoral fellow under the supervision of Professor Ronald Breslow. Since 1979 he has been a full professor at Osaka University. His research interests include organometallic chemistry directed towards organic synthesis, homogeneous catalysis, biomimetic oxidation, and carbene chemistry.

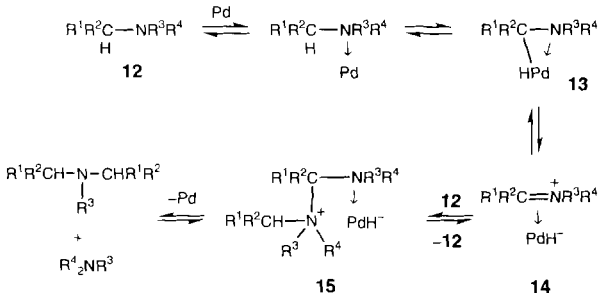
with the metal hydride provides amines with exchanged substituents. This is the crucial step for the activation of primary and secondary amines with metal catalysts and homogeneous metal complex catalysts.

2.2. Catalytic Oxidation and Hydrolysis of Tertiary Amines

Tertiary amines can be activated in the same way as primary and secondary amines.[5] Thus, the palladium-catalyzed amine exchange reaction of tertiary amines occurs at 200 °C with high efficiency [Eq. (3a)]. In a typical case, a mixture of dibutylhexylamine and a catalytic amount of palladium black was heated in

$$R^1R^2CHNR^3R^4 + R^5R^6R^7N \xrightarrow{Pd} R^1R^2CHNR^5R^6 + R^7NR^3R^4 \qquad (3a)$$

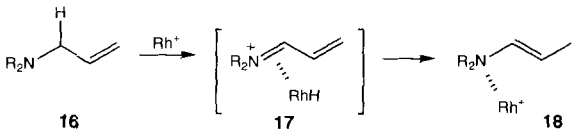
an autoclave at 200 °C for 16 h. After distillation a mixture of tributylamine (26%), dibutylhexylamine (37%), butyldihexylamine (26%), and trihexylamine (3%) was obtained; the alkyl groups are distributed statistically in these tertiary amines. This process may provide a convenient method for the synthesis of unsymmetrical tertiary amines because the desired products can be prepared simply and with high efficiency, and isolation is straightforward. These reactions can be rationalized by assuming that palladium coordinates to nitrogen and inserts into the adjacent C–H bond to give **13**, which is in equilibrium with a key intermediate, the iminium ion complex **14** (Scheme 2).[5]



Scheme 2. Catalytic transalkylation of tertiary amines.

Since an iminium ion presents an extremely electrophilic carbon for nucleophilic attack, the second tertiary amine attacks **14** to give **15**, from which the exchange amines are produced. This mechanism is supported by control experiments, loss of optical activity, deuterium distribution, and studies of metal complexes.[5, 7] Consequently, the reaction mechanism of tertiary amines contrasts that of primary and secondary amines, in which a complex of imine **10** is formed by insertion of palladium into the N–C bond.

The rhodium-catalyzed isomerization of allylamines **16** to enamines **18**, which is one of the key steps of the industrial

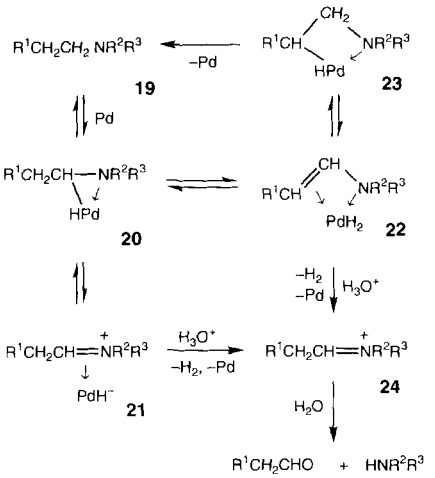


synthesis of menthol, is initiated by C–H activation to form a transient iminium–RhH π-complex **17**.[8]

In attempts to trap the iminium ion metal complexes **14** with an external nucleophile, we examined the effect of water. We hoped to achieve catalytic hydrolysis of tertiary amines, because this procedure is of principal importance with respect to biological deamination processes. Indeed, we discovered a novel palladium-catalyzed hydrolysis of tertiary amines [Eq. (3b)],[9] which is superior in certain cases to the current procedures that require stoichiometric quantities of oxidizing agents.

$$R^1CH_2NR^2R^3 + H_2O \xrightarrow{cat.} R^1CHO + R^2R^3NH + H_2 \qquad (3b)$$

A mechanism that may explain these results is shown in Scheme 3. The metal atom initially coordinates the nitrogen lone pair and then inserts into the adjacent carbon–hydrogen bond to form **20**, which is in equilibrium with the iminium ion

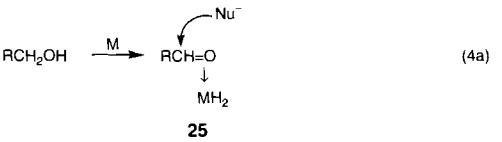


Scheme 3. Catalytic hydrolysis of tertiary amines.

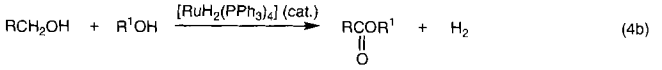
21 and the enamine intermediate **22**. In the absence of protons, the interconversions **20** ⇌ **21** and **20** ⇌ **22** ⇌ **23** proceed rapidly without change of configuration at the β-position of the amine. Under the hydrolysis conditions, protonolysis of complexes **21** and **22** gives the uncomplexed iminium ion **24**, which undergoes the acid-catalyzed hydrolysis steps typical for enamines to produce carbonyl compounds and secondary amines. It is noteworthy that a similar catalytic reaction proceeds in the presence of the homogeneous cluster catalyst $[Rh_6(CO)_{16}]$,[10] although a small distinction is observed between the palladium and $[Rh_6(CO)_{16}]$ catalysts.[9] (η^1-Ylide)palladium complexes[11] and unusual amino–carbene cluster complexes[7] have been isolated as key intermediates in these reactions.

This principle of activating amines by oxidative dehydrogenation can be extended to the activation of alcohols. Insertion of low-valent metal complexes into the oxygen–hydrogen bonds of alcohols followed by β-elimination gives an aldehyde metal hydride species **25** [Eq. (4a)], which reacts with nucleophiles in various catalytic transformations. The $[RuH_2(PPh_3)_4]$-catalyzed oxidative transformation of alcohols proceeds efficiently

and cleanly to give esters and molecular hydrogen [Eq. (4b)].[12] This reaction may thus be important in solving environmental and energy problems. In this reaction, the second molecule of alcohol acts as a nucleophile to trap **25**. If an amine serves as the

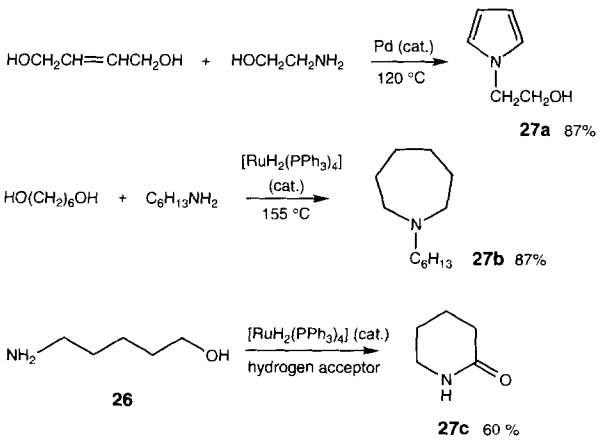


25 (4a)



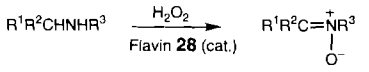
(4b)

nucleophile, palladium(0)- or ruthenium(II)-catalyzed amination reactions can be used, for example for constructing heterocyclic nitrogen compounds like **27a** and **27b**.[13, 14] Importantly, when the $[RuH_2(PPh_3)_4]$-catalyzed reaction of amino alcohols such as **26** is performed under similar reaction conditions, in the presence of a hydrogen acceptor such as benzalacetone, lactams like **27c** are formed instead of piperidines.[15]

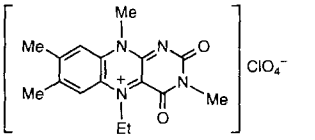


3. Hepatic Flavoenzyme Type Oxidation Catalysts

Mammalian liver contains microsomal FAD-containing monooxygenase (EC 1.14.13.8, FADMO), which oxygenates various amines.[16] The enzymatic oxygenation seems to involve the following catalytic cycle.[17] Oxygenation of enzyme-bound reduced flavin (Enz(FlH_2)) with molecular oxygen gives 4a-hydroperoxyflavin (Enz[4a-Fl(H)OOH]), which monooxygenates the substrates and is converted into 4a-hydroxyflavin (Enz[4a-Fl(H)OH]). Dehydration of Enz[4a-Fl(H)OH] gives oxidized flavin (Enz(Fl_{ox})),[17] which is reduced to Enz(FlH_2). The mechanism of FADMO has been studied extensively by use of 4a-hydroperoxyisoalloxazines (4a-FlOOH) and much has been learned;[18] however, the catalytic recycling step was ambiguous. We found that 4a-hydroxy-5-alkylflavins are readily transformed into 4a-hydroperoxyflavins upon treatment with hydrogen peroxide. This result led to the discovery of a novel biomimetic flavin-catalyzed oxidation with hydrogen peroxide.[19] Typically, the reaction of secondary amines with hydrogen peroxide in the presence of flavin catalysts such as flavinium perchlorate **28** gives nitrones **29** with high efficiency [Eq.(5)].



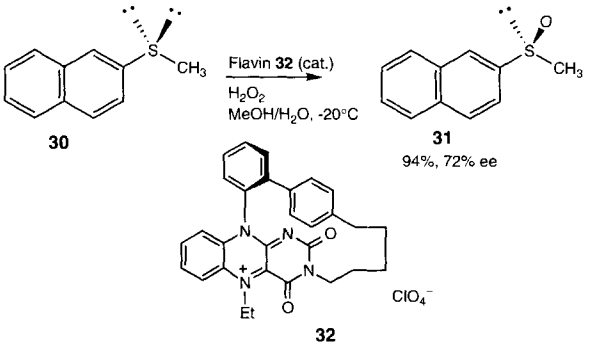
29 (5)



28

This biomimetic catalytic oxidation of secondary amines may correspond to the metabolism of amines. The application of this oxidation leads to new types of catalytic oxidation reactions using organic molecules.

Chiral flavins are attractive catalysts for asymmetric oxidation of sulfides and other substrates.[20] For example, oxidation of naphthyl sulfide **30** catalyzed by capped flavin **32** gives **31** with 72% *ee*.



30 **31** 94%, 72% ee

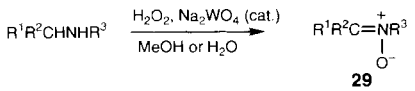
32

3.1. Catalytic Oxidation of Secondary Amines

Previously, little attention was paid to metal hydroperoxides (MOOH). But since their reactivity is expected to be similar to that of hydroperoxyflavins (FlOOH), the reactivity of metal hydroperoxides towards amines has been examined extensively. Metal hydroperoxides are formed either by treatment of metals (M) with hydrogen peroxide[21] or by oxidation of metal hydrides (MH) with molecular oxygen.[22]

In attempts to simulate the function of hydroperoxyflavin (FlOOH) with metal hydroperoxide (MOOH), the reactivity of metal hydroperoxides towards the oxidation of secondary amines was examined. We found that the hydroperoxytungstate, which is generated by the first method (reaction of H_2O_2 with tungstate), is an excellent reagent.[23] This biomimetic single-step synthesis of nitrones from secondary amines is extremely useful, since the products are highly valuable synthetic intermediates[24] and spin-trapping reagents.[25] Nitrones are difficult to prepare by other methods; they have been obtained by HgO-induced stoichiometric oxidation of hydroxylamines, themselves derived by tedious methods, and by condensation of hy-

droxylamines with aldehydes. When solutions of secondary amines in either methanol or water are treated with three molar equivalents of a 30% hydrogen peroxide solution in the presence of 4 mol% sodium tungstate under nitrogen, the corresponding nitrones are produced in good to moderate yields [Eq.(6); Table 1].[23] Usually methanol can be used as a solvent,



(6)

but water is the only solvent suitable for the preparation of cyclic nitrones. 2-Methylpiperidine was converted into the thermodynamically stable nitrone in 76% yield.

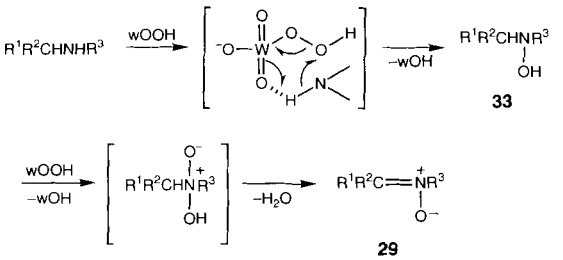
Table 1. Oxidation of secondary amines with H_2O_2 in the presence of $Na_2WO_4 \cdot 2H_2O$ and SeO_2 catalysts in MeOH.

Amine	Nitrone	Yield [%] Na_2WO_4 (cat.)	Yield [%] SeO_2 (cat.)
		89	80
		85	
		86	91
		44[a]	73[b]
		42[a]	57[b]
		76[a]	79[b]

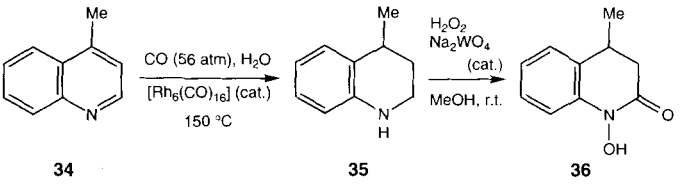
[a] Solvent: water. [b] Solvent: acetone.

This reaction can be rationalized by the mechanism shown in Scheme 4. The oxidation of secondary amines with tungstate hydroperoxide wOOH (w = WO_3^-, WO_4^-, WO_6^-) gives *N*-hydroxylamines **33**, which undergo further oxidation followed by dehydration to give nitrones **29**.[23]

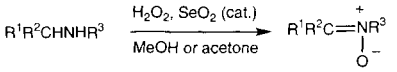
The tungstate-catalyzed reaction can be used to oxidize various substrates. Typically, the oxidation of tetrahydroquinolines provides a convenient method for the synthesis of cyclic hydroxamic acids.[26] The mechanism is rationalized by assuming the formation of nitrones and subsequent addition of third molecule of H_2O_2 to give 2-hydroperoxy-*N*-hydroxylamines, which undergo dehydration to give hydroxamic acids. For example, treatment of 4-methyl-1,2,3,4-tetrahydroquinoline (**35**) with H_2O_2 gives pure **36**, an antibacterial agent, in 83% yield after recrystallization. It should be pointed out that substrate **35** was obtained selectively in 98% yield from the $[Rh_6(CO)_{16}]$-catalyzed water–gas shift reaction of **34**.[27]



Scheme 4. Tungstate-catalyzed oxidation of secondary amines.

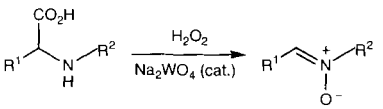


The yields of isolated cyclic nitrones are sometimes low because the extraction from water is difficult. In such cases, oxidation of secondary amines catalyzed by selenium dioxide is more convenient [Eq.(7); Table 1].[28] The oxidation seems to be induced by peroxyselenious acid, HOSe(O)OOH, which is derived from SeO_2 and H_2O_2.



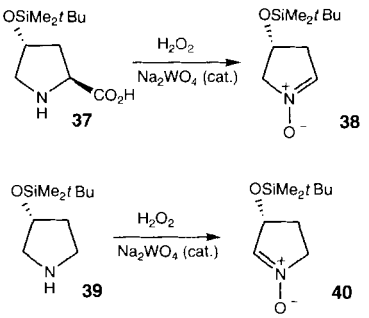
(7)

In an important variation of this nitrone synthesis, decarboxylative oxidation of *N*-alkyl-α-amino acids proceeds smoothly under similar conditions to give the corresponding nitrones regioselectively [Eq.(8)]. As a typical example, (*4R*)-4-



(8)

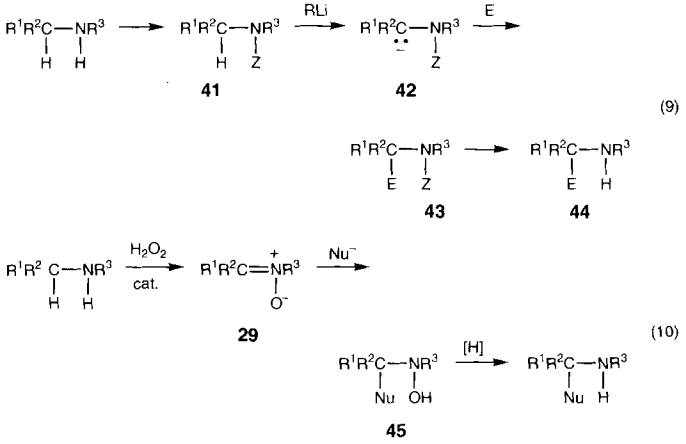
(*tert*-butyldimethylsiloxy)-1-pyrroline *N*-oxide (**38**), which is a versatile intermediate for the synthesis of optically active pyrrolidines, can be prepared simply in 70% yield by treating a solution of *trans*-4-(*tert*-butylsiloxy)-L-proline (**37**) in dichloromethane with hydrogen peroxide in the presence of Na_2WO_4



catalyst and tetraethylammonium chloride.[29] On the other hand, (3*R*)-3-(*tert*-butyldimethylsiloxy)-1-pyrroline *N*-oxide (**40**), a regioisomer of **38**, was obtained from amine **39** in 61% yield upon similar oxidation followed by chromatographic separation.

3.2. Substitution at the α-Position of Secondary Amines

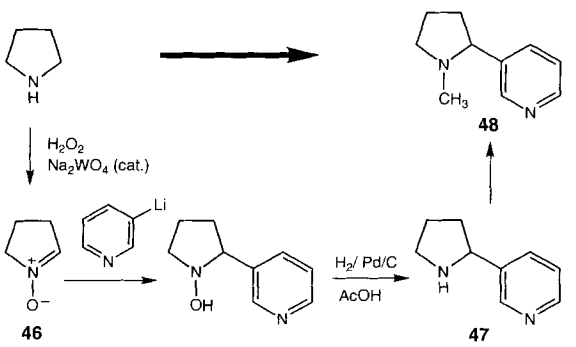
The oxidation discussed in Section 3.1 opens up powerful strategies for organic syntheses. The most important synthetic application of this oxidation is substitution at the position α to the nitrogen in secondary amines. Introduction of α-substituents has hitherto been performed by using electrophilic reagents. The N-protected secondary amine **41** with an electron-withdrawing group (Z) undergoes lithiation with an organolithium reagent to give carbanion **42**. Treatment of **42** with an electrophile (E) and removal of the protecting group (Z) gives the α-substituted amine **44** [Eq.(9)].[30] Our reaction provides an alternative method for substitution α to the nitrogen of amines. Catalytic oxidation followed by reaction of the resulting nitrone **29** with a nucleophile (Nu) leads to *N*-hydroxylamine **45**, which can be reduced catalytically [Eq.(10)].[23] Various nucleophiles



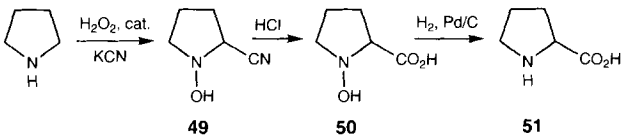
(9)

(10)

can be used to introduce substituents. Firstly, formation of the carbon–carbon bond at the α-position of secondary amines should be described. The usefulness of this reaction was demonstrated by the synthesis of nitrogen-containing, biologically active compounds from secondary amines. Nicotine (**48**) was prepared from pyrrolidine via nitrone **46**.[23]



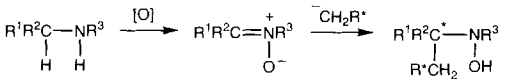
The nucleophiles employed are not limited to organolithium and Grignard reagents. Cyanide is used in a short synthesis of *N*-hydroxyamino acids and α-amino acids from secondary amines.[31] In one example *N*-hydroxyproline (**50**), which is only poorly accessible by conventional methods, is readily prepared from pyrrolidine in two steps without isolation of the nitrone. The yield of **49** (72%) is much higher than the yield of the isolated nitrone itself (44%), since extraction of the product in the workup is easier. Hydrolysis of **49** with dilute hydrochloric acid solution gives *N*-hydroxyproline (**50**) (93%), which undergoes catalytic hydrogenation over Pd/C to give proline (**51**)



(93%). Thus, *N*-hydroxyproline (**50**) and proline (**51**) can be prepared simply by sequential transformations with inexpensive reagents. Further, various [1-^{14}C]-labeled amino acids, which are important in tracer experiments for the study of metabolism and biosynthesis, can be readily prepared by using the present reactions and labeled K^{14}CN.[31, 32]

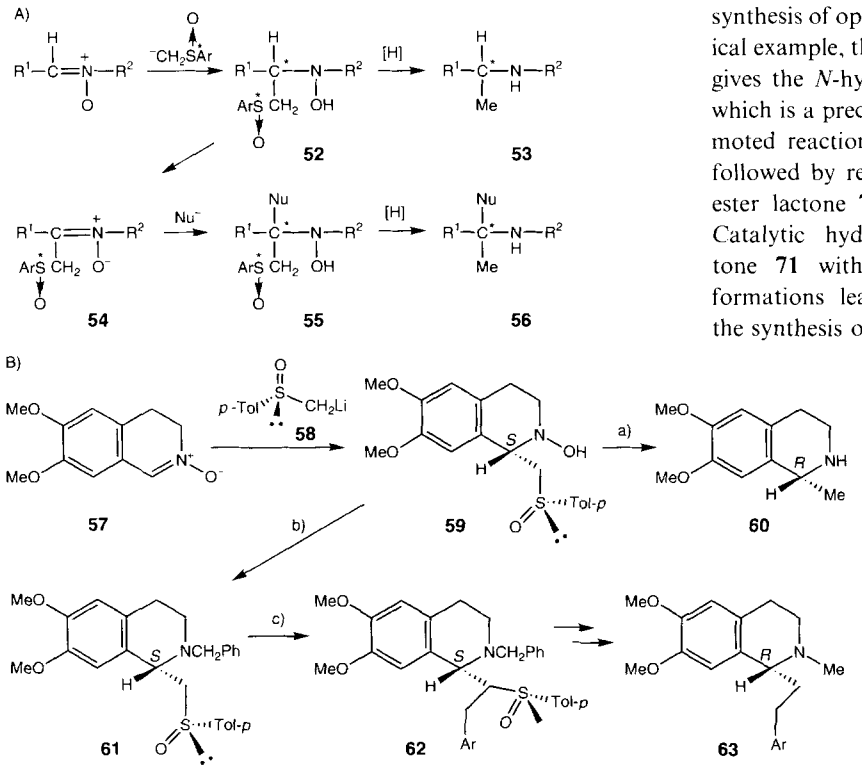
3.2.1. *Asymmetric Synthesis of α-Substituted Amines and β-Amino Acids*

Asymmetric induction at the α-position of amines is important for the synthesis of biogenic amines as well as chiral amine ligands. Various optically active nucleophiles can be utilized to introduce chirality through the enantiofacial differentiation of nitrones [Eq.(11)]. Optically active α-sulfinyl carbanions are



(11)

particularly attractive nucleophiles; they can be obtained by catalytic asymmetric oxidation of sulfides with, for example, chiral titanium catalysts[33] or our chiral flavin catalysts.[20a] The diastereoselective addition of an α-sulfinyl carbanion gives the optically active *N*-hydroxylamine **52**. The α-sulfinyl group can be removed under reducing conditions to give the optically active α-methyl-substituted amine **53**. The optically active nitrone **54** can be prepared by further oxidation of **52**. Diastereoselective addition of a nucleophile results in the introduction of the asymmetric quarternary carbon α to the nitrogen atom in secondary amine **56** (Scheme 5A).[34] Simple examples are the syntheses of (*R*)-(+)-salsolidine (**60**) and (*R*)-homolaudonosine (**63**) (Scheme 5B). The reaction of nitrone **57** with the α-sulfinyl carbanion **58** in the presence of quinidine in THF at −78 °C gave pure, crystalline sulfoxide **59** (68%). Treatment of **59** with Raney-Ni yielded **60**. Furthermore, benzylation of **59** followed by treatment with triphenyltin hydride afforded *N*-benzyl α-(sulfinyl)methylamine (**61**), which is a precursor of **63**.

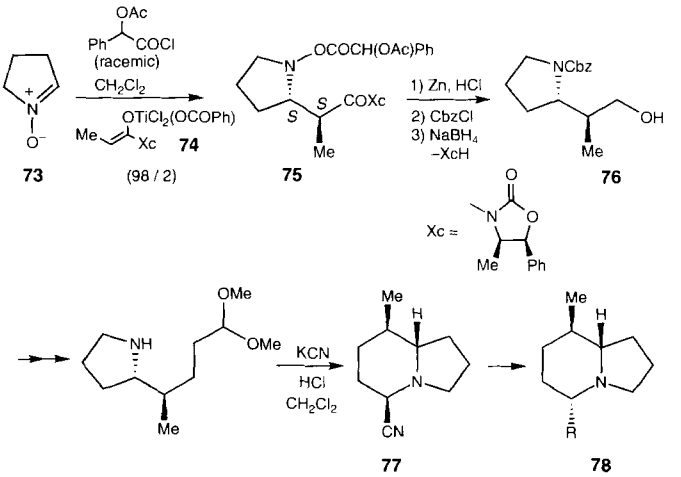


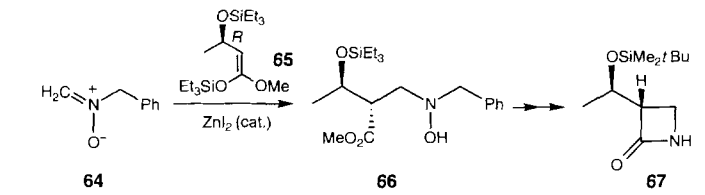
Scheme 5. A) Synthesis of optically active α-substituted amines. B) Synthesis of (*R*)-(+)-salsolidine (**60**) and (*R*)-homolaudanosine (**63**) (*p*-Tol = *p*-tolyl). a) Raney-Ni; b) $PhCH_2Br$, Ph_3SnH; c) LDA, $ArCH_2Br$, Ar = 3,4-$(MeO)_2C_6H_3$.

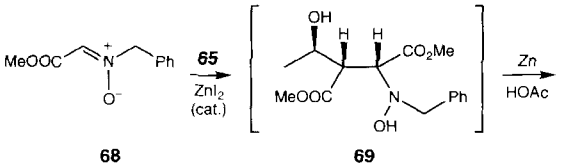
Chiral enolates are also attractive nucleophiles because they are readily accessible with high enantiomeric purity by asymmetric catalytic hydrogenation of β-ketoesters.[35] Optically active β-amino acids are important key intermediates for the synthesis of β-lactams and various antagonists.

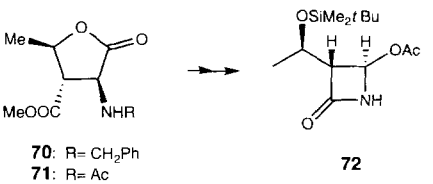
Lewis acid promoted reactions of nitrones with the optically active ketene silyl acetal **65** provide a convenient method for the synthesis of optically active *N*-hydroxy-β-amino acids. In a typical example, the ZnI_2-promoted reaction of nitrone **64** with **65** gives the *N*-hydroxy-β-amino acid **66** selectively (<99% *de*), which is a precursor of β-lactam **67**.[36] Further, the ZnI_2-promoted reaction of nitrone **68** with **65** in CH_2Cl_2 at −78 °C followed by reduction with zinc in acetic acid gives β-amino ester lactone **70** as a single isomer (99.5% *de*, 60% yield). Catalytic hydrogenation and acetylation then gives lactone **71** with high diastereoselectivity; subsequent transformations lead to compound **72**, a key intermediate for the synthesis of carbapenems.[37]

Next, we aimed at generating oxyiminium ions in order to increase the reactivity of nitrones. If oxyiminium ions can be generated by treatment of nitrones with acid chlorides, then α-substituted amino compounds can be obtained readily. Nitrone **73** was treated with racemic 2-acetoxy-2-phenylacetyl chloride at −78 °C, and the resulting oxyiminium ion was allowed to react with chiral titanium enolate **74** to give the *anti* isomer **75** with high selectivity.[38] This compound can be converted into the known precursor **77** of indolizidine alkaloids **78**, which are skin alkaloids of the neotropical dart-poison frog and inhibitors of the acetyl choline receptor.



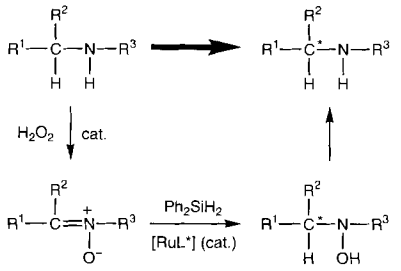






3.2.2. *Catalytic Asymmetric Synthesis of N-Hydroxylamines*

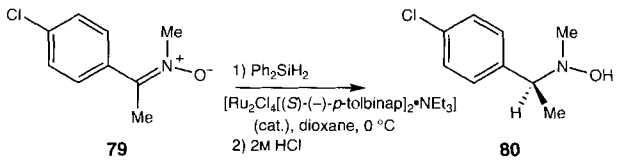
The catalytic asymmetric addition of nucleophiles to nitrones is the most attractive method for synthesizing optically active *N*-hydroxylamines bearing an asymmetric center α to the nitrogen function. These compounds are important since they are biologically active and may serve as precursors of chiral ligands for asymmetric synthesis. We found that the catalytic asymmetric hydrosilylation of nitrones proceeds with high efficiency. The catalytic oxidation of secondary amines and the subsequent asymmetric hydrosilylation of the resulting nitrones opens up a general and powerful strategy for the synthesis of optically active *N*-hydroxylamines from secondary amines (Scheme 6). The

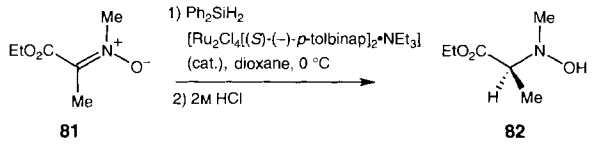


Scheme 6. Two-step asymmetric synthesis of *N*-hydroxylamines.

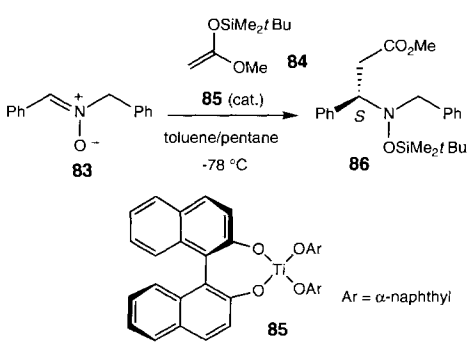
optically active secondary amines can be prepared by catalytic hydrogenation.

When (*E*)-*N*-[1-(4′-chlorophenyl)ethylidene]methylamine *N*-oxide (**79**), which was obtained from the catalytic oxidation of *N*-[1-(4′-chlorophenyl)ethyl]methylamine, was hydrosilalated with diphenylsilane in the presence of $[Ru_2Cl_4[(S)\text{-}(-)p\text{-tolbinap}]_2 \cdot NEt_3]$ (*p*-tolbinap = 1,1′-binaphthalene-2,2′-diylbis(di-*p*-tolylphosphane) in dioxane at 0 °C, (−)-hydroxylamine **80** was produced in 85% *ee*.[39] Furthermore, *N*-hydroxymethylalanine ethyl ester (**82**), an antimetabolite of the α-amino acid, was also prepared efficiently. Asymmetric hydrosilylation of **81** under similar conditions followed by hydrolysis afforded *N*-hydroxyamino acid **82** in 89% *ee*.



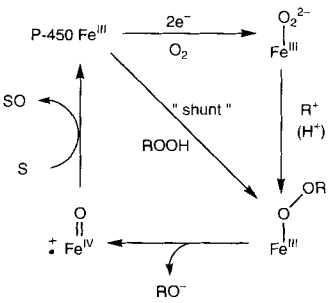


The asymmetric synthesis of *N*-hydroxy-β-amino acids is possible by treatment of nitrones with achiral ketene silyl acetals in the presence of chiral Lewis acid catalysts.[40] In a typical example, reaction of **83** with **84** in the presence of the titanium complex catalyst **85** furnished *N*-hydroxy-β-amino acid derivative **86** in 95% yield and with 62% *ee*.



4. Cytochrome P-450 Type Oxidation Catalysts

Cytochrome P-450 (**2**) has two major functions. One is the activation of molecular oxygen by iron porphyrin to generate oxoiron(IV) porphyrin; the other is the transfer of an oxygen atom to substrates.[41] The porphyrin moiety is required for the generation of a hydroperoxyiron(III) species, which undergoes cleavage to give an oxoiron(IV) species (Scheme 7). However a "shunt process" is often used for the oxidation of organic substrates, because oxoiron(IV) species can be formed readily upon treatment with oxygen donors such as iodosylbenzene.[42] In this shunt process, oxometal complexes can be generated without using porphyrins. Various catalysts such as those with salen ligands[43, 44] (salen = bis(salicylidene)ethylenediamine) and organometallic oxides[45, 46] have been examined and found to be successful.



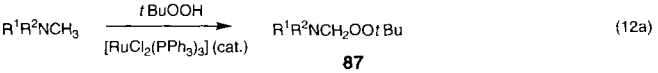
Scheme 7. Oxidation with cytochrome P-450. S = substrate.

Our approach for generating oxometal complexes, which may correspond to the oxoiron(IV) species of cytochrome P-450, is the oxidation of low-valent ruthenium complexes with the intention of generating of $L_nRu{=}O$ species. One important aspect that was focused on at the beginning of this review is the generation of middle-valent oxoruthenium species by using low-valent rather than high-valent ruthenium species.

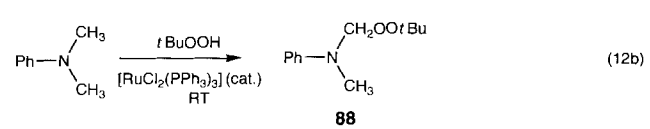
4.1. Ruthenium-Catalyzed Oxidation of Tertiary Amines

4.1.1. *Oxidation with tert-Butyl Hydroperoxide*

The oxidative N-demethylation of amines is one of the important reactions specific to cytochrome P-450,[41] and several model reactions using iron porphyrins have been reported.[47] We found novel cytochrome P-450 type oxidation behavior with tertiary amines in reactions without porphyrin catalysts. Thus, ruthenium-catalyzed oxidation of tertiary amines with *tert*-butyl hydroperoxide gives the corresponding α-(*tert*-butyldioxy)alkylamines **87** with high efficiency [Eq. (12a)].[48] This is in contrast to the usual catalytic oxidation of tertiary amines with peroxides to give *N*-oxides.[49] In a typical case, a solution of *t*BuOOH (2.1 equiv) in dry benzene was added dropwise to a mixture of *N*,*N*-dimethylaniline and $[RuCl_2(PPh_3)_3]$ (3 mol%)



(12a)



(12b)

in benzene at room temperature (r.t.). *N*-(*tert*-Butyldioxymethyl)-*N*-methylaniline (**88**) was obtained in 93% yield [Eq. (12b)]. Benzylic and allylic positions and carbon–carbon double bonds tolerate the oxidation.

To gain insight into the mechanism of the oxidation, the relative reaction rates of the oxidation of five substituted *N*,*N*-dimethylanilines ($XC_6H_4NMe_2$, X = *p*-MeO, *p*-Me, H, *p*-Cl, *m*-Cl) with *t*BuOOH in benzene were determined.[48] The rate data correlate well ($\gamma = 0.974$) with the Hammett linear free energy relationship with use of σ values. The ρ value is -0.84 (Table 2), which indicates a cationic intermediate in the rate-

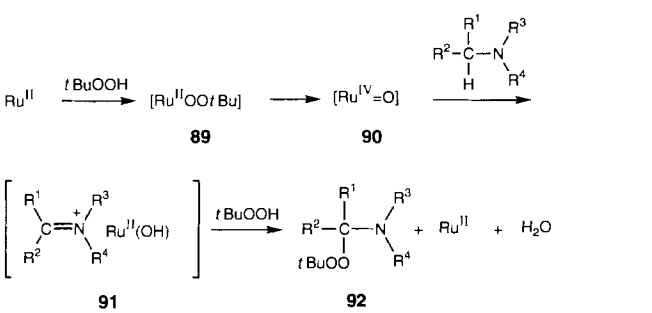
Table 2. Kinetics and isotope effects on the catalytic oxidation of *N*,*N*-dimethylanilines.

Catalyst	Oxidizing agent	ρ	k_H/k_D [a]	[b]	Ref.
cytochrome P-450		−0.74	1.6–3.1	1.0–1.1	[50, 51]
$[RuCl_2(PPh_3)_3]$	*t*BuOOH	−0.84	3.53	1.64	[48]
$RuCl_3 \cdot n H_2O$	H_2O_2	−3.26	3.47	3.72	[58]

[a] Intramolecular. [b] Intermolecular.

determining step. The intramolecular deuterium isotope effect (k_H/k_D) in the ruthenium-catalyzed oxidation of *N*-methyl-*N*-(trideuteriomethyl)aniline was determined to be 3.53. Furthermore, the intermolecular isotope effect in the oxidation of *N*,*N*-dimethylaniline was determined to be 1.64 by NMR analysis of the demethylated products of the competitive reaction of *N*,*N*-dimethylaniline and *N*,*N*-bis(trideuteriomethyl)aniline. The observed intra- and intermolecular isotope effects (3.53 and 1.64) are larger than the values observed for N-demethylation with cytochrome P-450 (1.6–3.1[50] and 1.0–1.1[51]), suggesting that in the present reaction cleavage of the C–H bond proceeds via an intermediate having more radical character.

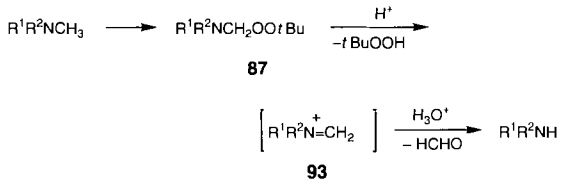
The reaction can be rationalized by assuming the cytochrome P-450 type mechanism[51, 52] shown in Scheme 8. A ruthenium(II) complex reacts with *t*BuOOH to give an oxoruthenium(IV) species.[53] Thus, the reaction of the Ru^{II} complex with *t*BuOOH yields $Ru^{II}OO$*t*Bu **89**, which is transformed into the $Ru^{IV}{=}O$ complex **90** by cleavage of the O–O bond. Electron transfer and subsequent proton transfer results in the iminium ion complex **91**. Nucleophilic attack of *t*BuOOH on **91** gives the product **92**, water, and the Ru^{II} species to complete the catalytic cycle.[48]



Scheme 8. Reaction pathway for the ruthenium-catalyzed oxidation of tertiary amines with *t*BuOOH.

4.1.2. *Selective N-Demethylation of Tertiary Methylamines*

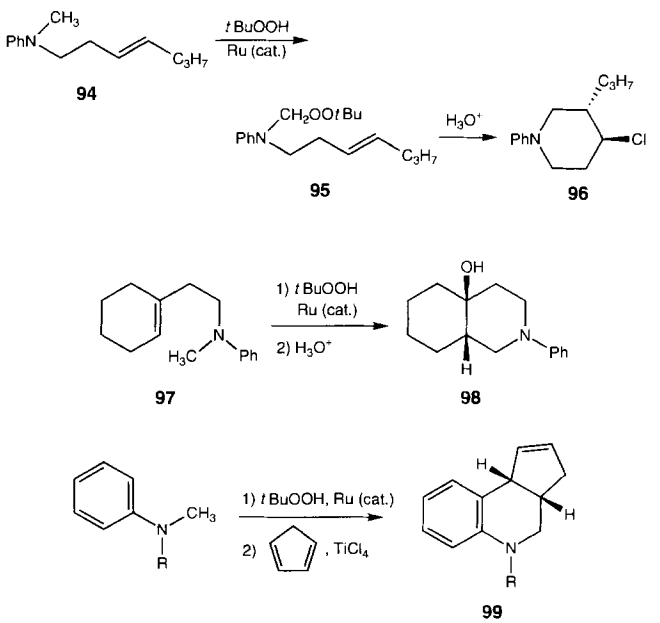
The N-demethylation of tertiary amines is a typical function of cytochrome P-450. The selective N-demethylation of tertiary methylamines is performed by the ruthenium-catalyzed oxidation previously described to give α-*tert*-butyldioxymethylamines **87**, and subsequent hydrolysis with an aqueous HCl solution yields the secondary amines via iminium ion **93**.[48] This is the first synthetically practical method for the N-demethylation of tertiary methylamines, although several other catalytic and stoichiometric reactions have been reported.[47] Catalytic oxidation of *N*-ethyl-*N*-methylaniline followed by treatment of the reaction mixture with 2 M HCl solution gives *N*-ethylaniline. The methyl group is removed chemoselectively in the presence of various alkyl groups. The reaction seems to involve protonation, removal of *tert*-butyl hydroperoxide, and hydrolysis of the iminium ion to give the secondary amine and formaldehyde [Eq. (13)].



(13)

4.1.3. *Biomimetic Synthesis of Piperidines*

N-Demethylation of tertiary amines provides a novel, biomimetic method for the construction of piperidine skeletons from *N*-methylhomoallylamines by means of an olefin/iminium ion cyclization reaction.[54] The ruthenium-catalyzed oxidation of *N*-methyl-*N*-(3-heptenyl)aniline (**94**) gives peroxide **95** (87%), which can be converted into *trans*-4-chloro-1-phenyl-3-propylpiperidine (**96**) (77%) by treatment with 2 M HCl at room temperature.[48] It is noteworthy that homoallylamines are



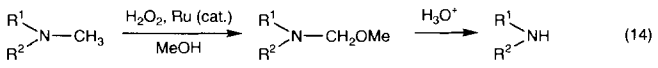
readily obtained by either palladium-catalyzed carbonylation of allylamines[55] or carboamination of allyl esters[56] and subsequent $LiAlH_4$ reduction of the resulting amides.

Reactions with cyclic amines give *cis*-fused bicyclic amines. Thus, *cis*-4α-hydroxy-2-phenyldecahydroisoquinoline (**98**) was obtained selectively in 85% yield from *N*-methyl-*N*-2-(1-cyclohexenyl)ethyl aniline (**97**) by treating the corresponding peroxide with an aqueous CF_3CO_2H solution.

The intermolecular reaction of the iminium ions with olefins or dienes provides a convenient method for synthesizing quinoline derivatives. Thus, the ruthenium-catalyzed oxidation of *N*-methyl-*N*-alkylanilines with *t*BuOOH, followed by treatment with cyclopentadiene in the presence of titanium tetrachloride, affords **99** highly efficiently.[57] These biomimetic reactions provide a second method for introducing a substituent at the α-position of amines by using nucleophiles [see Eq.(10)].

4.1.4. Oxidation of N-Methyl Tertiary Amines with Hydrogen Peroxide

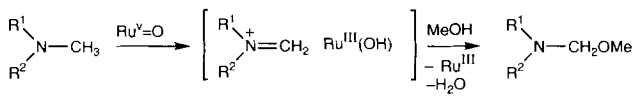
Based on Scheme 8, generation of the oxoruthenium species **90** by using other oxidizing reagents and trapping the iminium ion intermediate **91** with other nucleophiles can be expected. Indeed, a catalytic system that satisfies these two points has been found. The ruthenium-catalyzed oxidation of tertiary methylamines with hydrogen peroxide in the presence of methanol gives the corresponding α-methoxymethylamines with high efficiency [Eq.(14)].[58] The reaction provides an efficient



(14)

method for the selective N-demethylation of tertiary methylamines and construction of quinoline skeletons from tertiary methylamine. As an example, p-$MeOC_6H_4NMe_2$ can be converted into p-$MeOC_6H_4N(Me)CH_2OMe$ in 87% yield by treatment with a 30% H_2O_2 solution in methanol in the presence of 5 mol% $RuCl_3 \cdot nH_2O$ at room temperature.

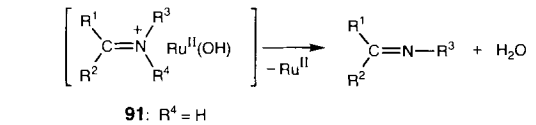
Considering the kinetic data and isotope effects shown in Table 2, the present reaction can be rationalized by assuming a cytochrome P-450 type mechanism. The ruthenium(II) complex reacts with H_2O_2 to give an oxoruthenium species, which undergoes electron transfer followed by proton transfer to afford an iminium ion complex. Nucleophilic attack of methanol then gives the methoxylated amines (Scheme 9).



Scheme 9. Ruthenium-catalyzed oxidation of *N*-methylamines.

4.2. Oxidation of Secondary Amines

The mechanism of the ruthenium-catalyzed oxidation of tertiary amines with *t*BuOOH can be rationalized as shown in Scheme 8. If secondary amines are subjected to the same reaction conditions, they can be oxidized to give imines. Electron transfer from secondary amines to oxoruthenium(IV) species leads to the iminium ion complex **91** (R^4 = H), which decomposes to give the product imines, the Ru^{II} species, and water to complete the catalytic cycle (Scheme 10). Indeed, the same catalytic system can be used to convert secondary amines into the corresponding imines (**100**) with high efficiency [Eq.(15)].[59] This is the first catalytic oxidative transformation of secondary



91: R^4 = H

amines into imines. Treatment of a secondary amine with two equivalents of *t*BuOOH in benzene in the presence of 2 mol% $[RuCl_2(PPh_3)_3]$ at room temperature gives the corresponding imines in high yields. The present reaction is particularly useful for the preparation of 1-azadienes and 3,4-dihydroisoquinolines **101**, which are important precursors of isoquinoline alkaloids. Similar catalyst systems such as $[RuCl_2(PPh_3)_3]$/PhIO,[60] [Schiff base·Co]/*t*BuOOH,[61] and $[Pr_4NRuO_4]$[62]/*N*-methylmorpholine *N*-oxide[63] have been reported.

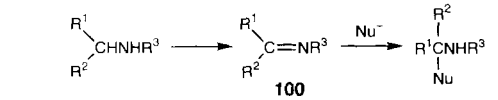
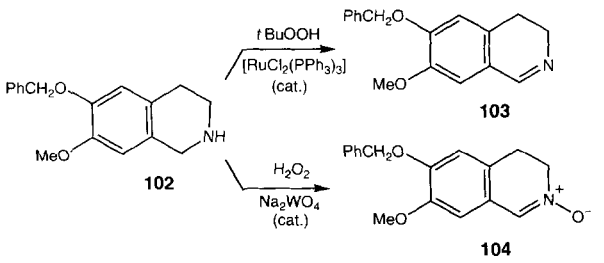
The catalytic oxidation of secondary amines provides the third key method for nucleophilic substitution α to the nitrogen of amines; the oxidation affords imines, which react with various nucleophiles [Eq.(16)]. Even the asymmetric catalytic addition of nucleophiles to imines has been explored.[64]

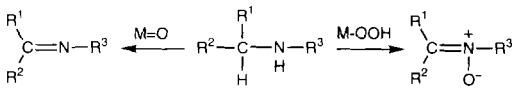
We have already shown that flavoenzyme-type oxidation of secondary amines gives nitrones. Thus, secondary amines can be converted into either imines or nitrones depending on the catalytic system employed. For example, the ruthenium-catalyzed oxidation of amine **102** gives imine **103** in 93% yield.[59] In contrast, the tungstate-catalyzed oxidation of the same amine with hydrogen peroxide gives nitrone **104** in 86% yield.[23] We are able to prepare either imines or nitrones from secondary amines by simply changing the catalyst.



(16)



It is worthwhile to comment on the catalytic species. The contrasting formation of nitrones and imines depends on the oxidizing agent. The oxidation of secondary amines with hydroperoxymetal complexes (MOOH) gives nitrones, while the oxidation with oxometal complexes (M=O) gives imines. This is the first demonstration that the MOOH and M=O species have different reactivities [Eq.(17)]. Detection of the oxidation prod-

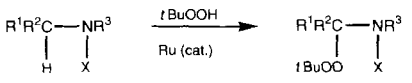


(17)

ucts of a secondary amine may be a convenient means of distinguishing the active species, that is, metal hydroperoxide (MOOH) or oxometal species (M=O).

4.3. Oxidation of Amides

Cytochrome P-450 catalyzes the specific oxygenation of amides;[50a,65] however, the only practical oxidation of amides is an electrochemical process.[66] We have found that the ruthenium-catalyzed oxidation of amides and lactams **105** with *t*BuOOH under mild conditions gives the corresponding *tert*-butyldioxyamides **106** in high yields [Eq.(18), Table 3].[67] The



(18)

105 **106**

X = Ac, CO_2CH_3

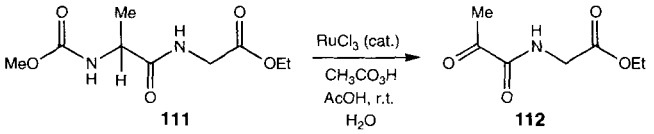
tert-butyldioxyamides of isoquinolines **108** and indoles **109** thus obtained are important synthetic intermediates. The oxidation of γ-substituted γ-lactams gives γ-(*tert*-butyldioxy)lactams **110**. The oxidation of ω-substituted lactams such as δ-valerolactam gives the corresponding cyclic imide (80% yield).

Application of this catalytic system for oxidations of drugs, peptides, and other compounds provides a powerful method for

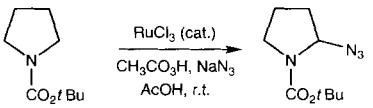
Table 3. Ruthenium-catalyzed oxidation of amides and lactams.

Substrate	Product	Yield [%]
	 **107**	60
	 **108**	
	R^1, R^2 = H; R^3 = OMe	91
	R^1 = OCH_2Ph; R^2 = OMe; R^3 = Me	98
	R^1 = OCH_2Ph; R^2, R^3 = OMe	97
	 **109**	92
	 **110**	80

studying metabolic pathways. In one study the ruthenium-catalyzed oxidation of *N*-methoxycarbonylalanylglycine ethyl ester (**111**) with peracetic acid gave *N*-pyruvoylglycine ethyl ester (**112**) (48% yield), which is derived from oxidation of the C–H bond followed by hydrolysis.[68]



111 **112**



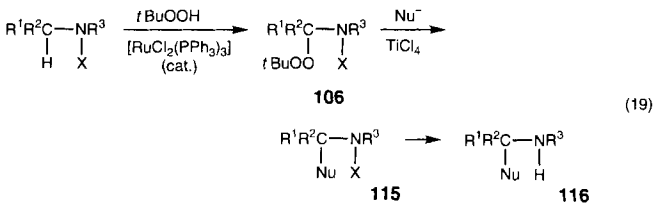
113 **114**

It is very important that the intermediate iminium ions generated by the oxidation of amides can be trapped by other nucleophiles such as N_3^-. As an example, the ruthenium-catalyzed oxidation of *N-tert*-butoxycarbonylpyrrolidine (**113**) with peracetic acid in acetic acid in the presence of sodium azide gave α-azido-*N-tert*-butoxycarbonylpyrrolidine (**114**) in 57% yield.[69]

4.3.1. Substitution at the α-Position of Amides

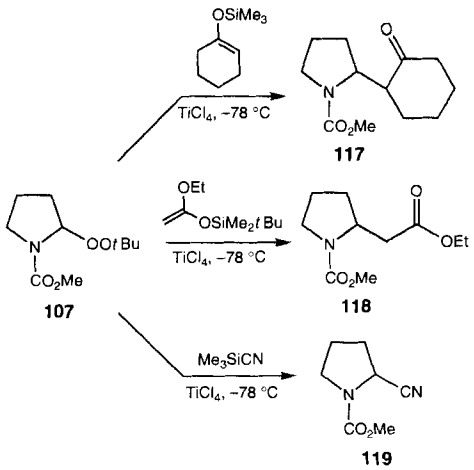
tert-Butyldioxyamides **106** [see Eq.(18)] undergo substitution reactions with various nucleophiles to give α-substituted amides **115**. Therefore, we now have a fourth method for the transformation of amines into the corresponding α-substituted amines.[70] The catalytic oxidation of an N-protected amine with *t*BuOOH gives α-*tert*-butyldioxyamide **106**, which undergoes nucleophilic substitution to give the α-substituted amide

115. Hydrolysis of the amide yields the corresponding α-substituted amine **116** [Eq. (19)].



(19)

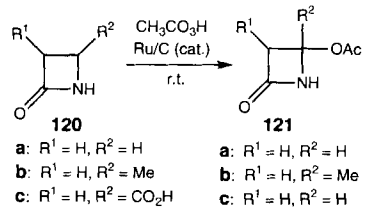
The most important transformation of α-*tert*-butyldioxyamides is the formation of a carbon–carbon bond at the position α to the nitrogen atom. A typical example is the transformation of pyrrolidines into the α-substituted derivatives. Titanium(IV)-promoted reactions of α-*tert*-butyldioxypyrrolidine **107** with a silyl enol ether, a ketene silyl acetal, and a silylated cyanide gave keto amide **117** (81%), β-amino ester **118** (55%), and α-cyano amide **119** (77%), respectively. These reactions clearly show the efficiency of the present oxidation reaction for the synthesis of various key synthetic intermediates.



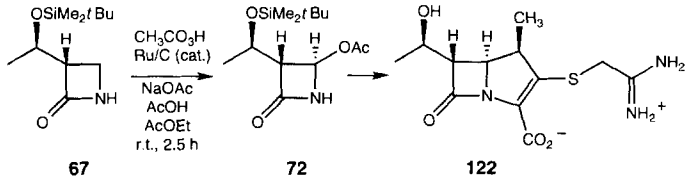
4.4. Oxidation of β-Lactams

4.4.1. Oxidation with Peracetic Acid

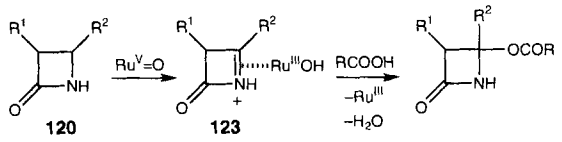
One of the most interesting oxidations of amides is the catalytic oxidation of β-lactams. Specific reaction conditions are required because of the higher strain of the four-membered acyliminium ion intermediates. Direct β-acetoxylation of β-lactams can be achieved by ruthenium-catalyzed oxidation with peracetic acid in acetic acid. Thus, the ruthenium-catalyzed oxidation of 2-azetidinones **120** with CH_3CO_3H in acetic acid in the presence of sodium acetate at room temperature gives 4-acetoxy-2-azetidinones **121** [Eq. (20)].[67] Importantly, (1′*R*,3*S*)-3-[1′-(*tert*-butyldimethylsilyloxy)ethyl]azetidin-2-one (**67**) can be converted into the corresponding 4-acetoxyazetidinone **72** with extremely high diastereoselectivity (99% yield, 99% *de*). The latter is a versatile and key intermediate for the synthesis of thienamycin and carbapenems **122**, which are important antibiotics.[71]



(20)



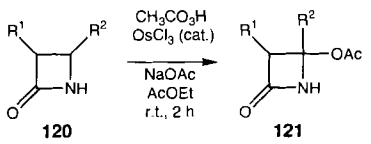
The oxidation can be rationalized as proceeding by a cytochrome P-450 type mechanism (Scheme 11). However, in the oxidation of β-lactams with CH_3CO_3H, more reactive oxoruthenium(IV) species may be formed. The nucleophilic attack



Scheme 11. Ruthenium-catalyzed oxidation of β-lactams.

of acetic acid dominates because it is much more nucleophilic than CH_3CO_3H. Formation of a four-membered acyliminium ion **123** has been confirmed by exclusive formation of the corresponding dichloroacetate upon oxidation of **120** in a mixture of CH_3CO_2H and Cl_2CHCO_2H (1:1).

The osmium-catalyzed oxidation of β-lactams with peracetic acid proceeds efficiently to give 4-acetoxyazetidinone in excellent yield [Eq. (21)].[72] This is the first example of an osmium-

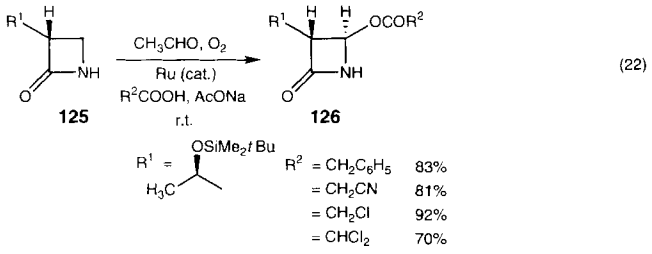


(21)

catalyzed oxidation of C–H bonds, although osmium-catalyzed reactions involving vicinal hydroxylation and vicinal oxyamination of alkenes have been reported.[73] The oxidations of **120a** (R^1, R^2 = H) and **67** in the presence of $OsCl_3$ and anhydrous sodium acetate in ethyl acetate at room temperature gave **121a** and **72** in 78% and 92% yields, respectively.[72] Suitable oxidizing agents for the oxidation of **67** are CH_3CO_3H (92%), *m*CPBA (73%), methyl ethyl ketone peroxide (70%), PhI(OAc)$_2$ (70%), and PhIO (67%). This oxidation is different from the OsO_4-catalyzed oxidation and can be rationalized by assuming the intermediacy of oxoosmium(V) species $L_nOs{=}O$ **124**, which seems to function in the same way as the oxoruthenium species **90**. Cobalt salts such as $CoCl_2$, Co(OAc)$_2$, and Co(acac)$_2$ (acac = acetylacetonate) can also be utilized as catalysts.

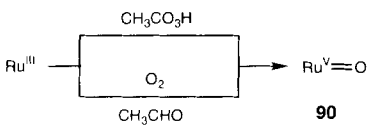
4.4.2. Oxidation with Molecular Oxygen

The ruthenium-catalyzed oxidation of β-lactams requires peroxides such as peracetic acid and methyl ethyl ketone peroxide; however, these peroxides are not always available and sometimes contain undesirable materials. We therefore examined the catalyzed formation of peroxides in situ from aldehydes and molecular oxygen. It is well known that peracetic acid can be prepared by treating acetaldehyde with molecular oxygen in the presence of catalysts such as cobalt salts.[74] We discovered that the ruthenium-catalyzed oxidation of β-lactams with molecular oxygen can be performed in the presence of acetaldehyde, an acid, and sodium acetate with high efficiency.[75] For example, 4-acetoxy- and 4-cyanoacetoxy-β-lactams (**126**, $R^2 = CH_2CN$) were obtained in 91% and 81% yields, respectively [Eq. (22)].



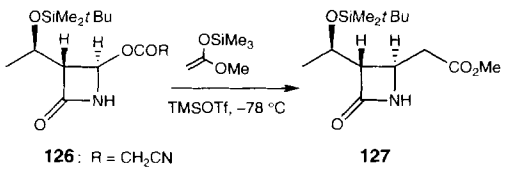
(22)

The active species in this oxidation seems to be oxoruthenium(v) species **90** (Scheme 12). The reaction of ruthenium with either peracetic acid or acetaldehyde and molecular oxygen leads to **90**, which abstracts the H atom from C4 of the β-lactam, and subsequent electron transfer gives acyliminium ion **123**. Nucleophilic reaction of **123** with an acid gives 4-acyloxyazetidinones.



Scheme 12. Formation of oxoruthenium species.

The trimethylsilyltriflate (TMSOTf) promoted reaction of 4-cyanoacetoxy β-lactam (**126**, $R = CH_2CN$) with ketene silyl acetal gives 4-methoxycarbonylmethyl β-lactam (**127**) (92%) stereoselectively.



4.5. Oxidation of Hydrocarbons

The selective oxidation of hydrocarbons is an important topic in view of the economical and ecological use of natural raw materials. Direct oxidation of nonactivated hydrocarbons is one of the typical and important reactions of cytochrome P-450,[76] and model monooxygenases based on cytochrome P-450 have been thoroughly investigated.[41b,77-80] In analogy to the use of (tetraphenylporphyrinato)iron(III) chloride/PhIO for the oxidation of alkanes by a shunt process,[42a] many similar oxidation systems based on metalloporhyrins and various reactive oxygen donors have been explored, including iodosylbenene,[81] hypochlorites and chlorites,[82] H_2O_2,[83] $KHSO_5$,[84] alkylperoxides and peracids,[85] and amine *N*-oxide.[86] An alternative method is the metalloporphyrin-catalyzed oxidation with molecular oxygen in combination with reducing agents such as dihydrogen,[87] sodium ascorbate,[88] and zinc powder[89] (Table 4).

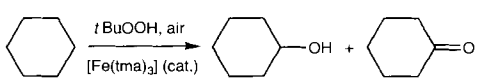
Table 4. Metalloporphyrin-catalyzed oxidations of alkanes with reactive oxygen donors or with molecular oxygen and a reducing agent.

Substrate	Catalyst[a]	Oxidizing agent	Product (ratio)	Yield [%]	Ref.
cyclohexane	[Fe(tpp)Cl]	PhIO	cyclohexanol, cyclohexanone (10:1)	26[b]	[81a]
cyclohexane	[Mn(tfpp)Cl]	NaOCl	cyclohexanol, cyclohexanone, cyclohexyl chloride (1:1.3:3.8)	24[c]	[82a]
cyclohexane	[Mn(tdcpp)Cl] + Im	H_2O_2	cyclohexanol, cyclohexanone (3:1)	40[c]	[83]
cyclohexane	[Mn(tdcpp)Cl] + 4-*t*BuPy	$KHSO_5$	cyclohexanol, cyclohexanone (8:1)	90[c]	[84]
cyclohexane	[Fe(tpp)Cl]	$PhCMe_2OOH$	cyclohexanol, cyclohexanone (2:1)	60[c]	[81a]
adamantane	[Ru(tmp)(O_2)] + HCl	2,6-$Cl_2C_5H_4NO$[e]	1-adamantanol, 1,3-adamantanediol, 2-adamantanone	94[c]	[86a]
cyclooctane	[Mn(tpp)Cl] + *N*-Me-Im	O_2/Zn, AcOH	cyclooctanol, cyclooctanone (1.8:1)	0.5[d]	[89]

[a] tpp = Tetraphenylporphyrinato; tfpp = tetrakis(pentafluorophenyl)porphyrinato; tdcpp = tetrakis(2,6-dichlorophenyl)porphyrinato; tmp = tetramesitylporphyrinato; Im = imidazole. [b] Based on oxidizing agent consumed. [c] Based on substrate. [d] Rate in cycles per minute. [e] 2,6-dichloropyridine *N*-oxide.

The unique structural characteristics of metalloporphyrins have been used for the regioselective and/or asymmetric oxidations of hydrocarbons. Thus, remote oxidation of steroids can be performed with the synthetic porphyrins covalently attached to steroidal substrates.[90] Asymmetric hydroxylations at the benzylic position of ethylbenzene and indane have been achieved with PhIO in the presence of a vaulted binaphthyl iron porphyrin catalyst and give (*R*)-phenylethanol and (*R*)-1,2,3,4-tetrahydro-1-naphthol in 41% and 72% *ee*, respectively.[91]

Simple and practical catalyst systems based on non-metalloporphyrins and various reactive oxygen donors such as H_2O_2[92] and alkylperoxides[93] have been explored. The oxidation of cyclohexane with *t*BuOOH and molecular oxygen catalyzed by soluble iron(III) tris(2,2,2-trimethylacetate) [Fe(tma)$_3$] proceeds efficiently to give cyclohexanol and cyclohexanone [Eq. (23)].[94]



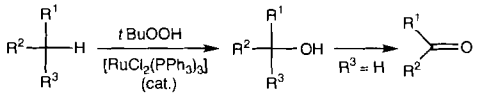
(23)

4.5.1. Oxidation with Peroxides

As described in the preceding sections, we are now able to generate oxoruthenium species without using porphyrins by 1) *t*BuOOH/[$RuCl_2(PPh_3)_3$], 2) H_2O_2/$RuCl_3$, 3) peracetic acid/Ru, and 4) aldehyde/O_2/Ru. These catalyst systems are expected

to promote cytochrome P-450 type oxidations of hydrocarbons efficiently.

First, the oxidation of hydrocarbons using the *t*BuOOH/ruthenium system was examined. Treatment of hydrocarbons with *t*BuOOH in benzene at room temperature in the presence of 3 mol% $[RuCl_2(PPh_3)_3]$ under argon gives the corresponding alcohols or ketones in good yields [Eq. (24)] (Table 5).[95]



(24)

The oxidation of fluorene gives fluorenone (**128**) in 86% yield. It is noteworthy that the oxidation of 9-methylfluorene gives 9-*tert*-butyldioxy-9-methylfluorene (**129**) selectively (98%). These reactions are very simple and clean. The oxidation of cyclohexane gives cyclohexanol and cyclohexanone. Control experiments show that the ketones are derived from the alcohols under the reaction conditions. The oxidation of adamantane affords the corresponding tertiary alcohols predominantly. The selectivity for the oxidation of tertiary C–H bonds over that of secondary C–H bonds is 6.7:1. For the oxidation of heptane the selectivity for the oxidation of the secondary C–H bonds over that of primary C–H bonds is 13:1 (Table 5).

Table 5. Ruthenium-catalyzed oxidations of alkanes using *tert*-butyl hydroperoxide and peracetic acid.

Substrate	Conversion [%]		Product	Yield [%]	
	[a]	[b]		[a]	[b]

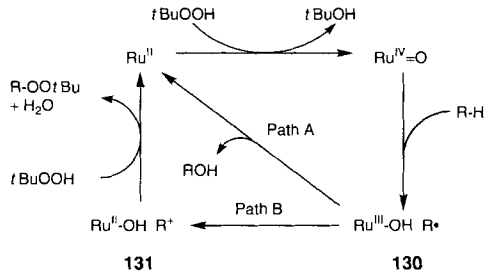
cyclohexane	49	62	cyclohexanol	5	1
			cyclohexanone	23	67
adamantane	79	67	1-adamantanol	40	49
			2-adamantanol	4	9
			2-adamantanone	14	9
n-heptane	26	49	heptanols	3 [c]	71 [e]
			heptanones	19 [d]	4 [f]

[a] $[RuCl_2(PPh_3)_3]$, *t*BuOOH. [b] Ru/C, peracetic acid. [c] Ratio of the 2-, 3-, 4-heptanols 50:33:17. [d] Ratio of the 2-, 3-, 4-heptanones 49:36:15. [e] Ratio of the 2-, 3-, 4-heptanols 40:40:20. [f] Ratio of the 2-, 3-, 4-heptanones 36:44:22.

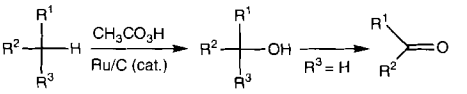
The data from kinetic and isotope effect studies (see Table 7) support the intermediacy of oxoruthenium(IV) species.[53] Hydrogen abstraction by an oxoruthenium(IV) species to give **130** is the rate-determining step. Subsequent coupling gives alcohols. Further electron transfer from **130** results in cation **131**, which undergoes nucleophilic attack by *tert*-butyl hydroperoxide to give the *tert*-butyldioxy compound, water, and a ruthenium(II) species (Scheme 13).

The ruthenium-catalyzed oxidation of nonactivated hydrocarbons can be also performed with other peroxides such as peracetic acid, cumene hydroperoxide, and *m*-chloroperbenzoic acid. The oxidations are dependent on the peroxides used. Apparently, more reactive peroxides produce highly reactive oxoruthenium species. Representative results of the ruthenium-



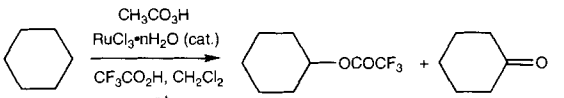
Scheme 13. Ruthenium-catalyzed oxidation of alkanes with *t*BuOOH.

catalyzed oxidation with peracetic acid [Eq. (25a)] are shown in Table 5.



(25a)

The intra- and intermolecular isotope effects are smaller than those obtained for the oxidation of the same substrates with *t*BuOOH (see Table 7), indicating that the oxoruthenium species in the present reaction is more reactive than that produced by *t*BuOOH and cytochrome P-450.[96] It is noteworthy that a more reactive species seems to be generated when the oxidation with peracetic acid is carried out in the presence of trifluoroacetic acid, and the corresponding alcohol products are trapped by trifluoroacetylation. As an example, the $RuCl_3$-catalyzed oxidation of cyclohexane in trifluoroacetic acid and dichloromethane (5:1) with 30% peracetic acid (2 equiv) in ethyl acetate gave cyclohexyl trifluoroacetate (**132**) in 69% yield based on cyclohexane, along with cyclohexanone (12%) (90% conversion of cyclohexane) [Eq. (25b)].[96] Rhodium-catalyzed oxidation of alkanes with peracetic acid gives similar results.[97]

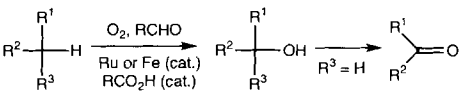


(25b)

132

4.5.2. Oxidation with Molecular Oxygen

The catalytic oxidation of alkanes has been explored by using various oxidizing agents,[81–86,92,93] and oxidations with molecular oxygen under mild conditions are especially rewarding goals.[87–89,98,99] Ruthenium- and iron-catalyzed oxidations of alkanes at room temperature with molecular oxygen (1 atm) in the presence of an aldehyde and a catalytic amount of an acid give the corresponding ketones and alcohols with high efficiency [Eq. (26)].[100] Iron powder has proved to be an effective catalyst, although $Fe(OAc)_3$, $FeCl_3 \cdot 6H_2O$, $RuCl_3 \cdot nH_2O$, and $[RuCl_2(PPh_3)_3]$ can also be used. An aldehyde such as heptanal,



(26)

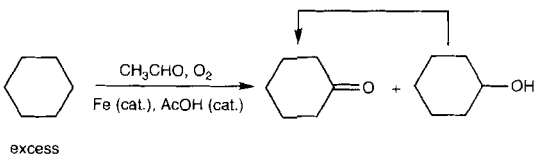
2-methylpropanal, or acetaldehyde is effective. A weak acid such as acetic acid is suitable for the iron-catalyzed oxidation. Representative results for the iron- and ruthenium-catalyzed oxidations of various alkanes and alkylated arenes with molecular oxygen (1 atm) in dichloromethane, in the presence of heptanal and a catalytic amount of acetic acid at room temperature, are listed in Table 6.

The kinetic results of these reactions and other related systems are listed in Table 7. These data indicate the following pathway. The reaction of an aldehyde with molecular oxygen[74] in the presence of either ruthenium complexes or iron acetate (derived from iron powder and acetic acid) leads to a peracid, which subsequently reacts with the metal complex to afford an oxometal species[67,101,102] along with a carboxylic acid. The oxometal species abstracts a hydrogen from the alkane, and a hydroxy ligand is transferred to the resulting radical giving an alcohol. Alcohols can be converted into ketones under the same reaction conditions.

The oxidative transformation of cyclohexane into cyclohexanone is of industrial importance. The cobalt-catalyzed aerobic oxidation of cyclohexane has been used commercially; however, the total yield of cyclohexanone and cyclohexanol is quite low.[103] Our oxidation method provides a powerful industrial strategy for the synthesis of cyclohexanone, since the Wacker oxidation of ethylene [Eq. (27a)] can be combined with the iron-catalyzed oxidation of cyclohexane. Another practical point: the oxidation of cyclohexane can be performed without a solvent under slightly modified conditions. The oxidation of cyclohexane in the presence of iron powder catalyst, acetic acid, and acetaldehyde at 70 °C under 8 atm of molecular oxygen gave cyclohexanone (60%) and cyclohexanol (40%) with a high turnover number (146) [Eq. (27b)]. The combined yield of cyclohexanone and cyclohexanol is almost 100%.[100] Cyclohexanol can be converted into cyclohexanone under the same reaction conditions.

$$CH_2{=}CH_2 + O_2 \xrightarrow{\text{Pd-Cu (cat.)}} CH_3CHO \qquad (27a)$$



(27b)

4.5.3. Copper-Catalyzed Oxidation

Model studies for the copper-containing monooxygenases such as peptidylglycine α-amidating monooxygenase, which catalyze the oxidation of aliphatic C–H bonds, are limited to a few

Table 7. Kinetics and isotope effects for the catalytic oxidation of hydrocarbons.

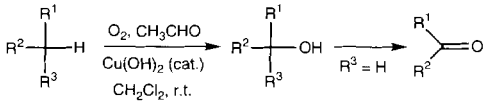
cases.[104] As part of our study on the simulation of enzymes, we have found that novel copper salt catalyzed oxidations of alkanes and alkenes with molecular oxygen (1 atm) proceed efficiently at room temperature in the presence of aldehydes [Eq. (28)].[105] $Cu(OH)_2$ is an effective catalyst for this aerobic

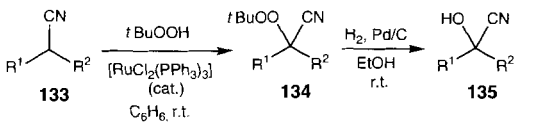


(28)

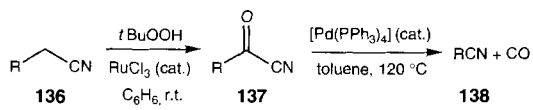
oxidation of alkanes (Table 6). The reaction of an aldehyde with molecular oxygen in the presence of $Cu(OH)_2$ yields a peracid,[74] which subsequently reacts with the copper salt to afford the active species Cu=O,[106,107] and a carboxylic acid. Hydrogen abstraction from the alkane and electron transfer leads to the cationic intermediate $[Cu^{II}(OH)(R^+)]$, which is converted into the alcohol and Cu^{II}. Importantly, addition of [18]crown-6 to the catalyst system results in higher turnover numbers and selectivities.[108]

4.6. Oxidation of Nitriles

The ruthenium-catalyzed oxidation of α-substituted nitriles **133**, with two equivalents of *t*BuOOH at room temperature gives 2-(*tert*-butyldioxy)alkanenitriles **134** (42–97% yield) [Eq. (29a)]. In contrast, oxidation of nitriles **136** having an α-substituent gives acyl cyanides **137** (89–97% yield) [Eq. (29b)].[109]



(29a)



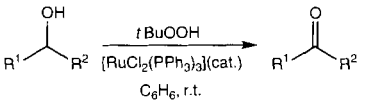
(29b)

The reaction provides a convenient method for transforming nitriles into either cyanohydrins **135** or nitriles **138** whose chain length decreases by one carbon. Catalytic hydrogenation of **134** over Pd/C catalyst in ethanol gives the corresponding cyanohydrins **135** (97–98% yield).[109] Interestingly, treatment of aromatic and heteroaromatic acyl cyanides **137** with $[Pd(PPh_3)_4]$ catalyst (3 mol%) in toluene at 120 °C, gives the shortened nitrile **138** (94–99% yield).[110]

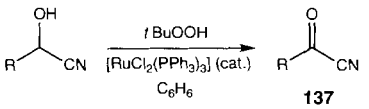
4.7. Oxidation of Alcohols

4.7.1. Oxidation with Peroxides

Ruthenium-catalyzed oxidation of alcohols has been conducted with various oxidizing agents.[111] In particular, the oxidative transformation of primary and secondary alcohols by tetrapropylammonium perruthenate (TPAP)/*N*-methylmorpholine *N*-oxide (NMO) is an excellent method.[62] The $[RuCl_2(PPh_3)_3]$-catalyzed reaction of secondary alcohols with *t*BuOOH gives ketones in 50–90% yield under mild conditions [Eq. (30a)].[112,113] This oxidation can be also applied to the transformation of cyanohydrins (**135**, $R^2 = H$) into acyl cyanides **137** (65–99% yield),[112] which are versatile synthetic intermediates [Eq. (30b)].[114] It is worth noting that acyl cyanides are excellent reagents for the chemoselective acylation

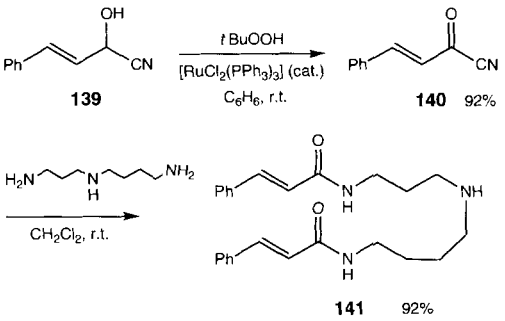


(30a)

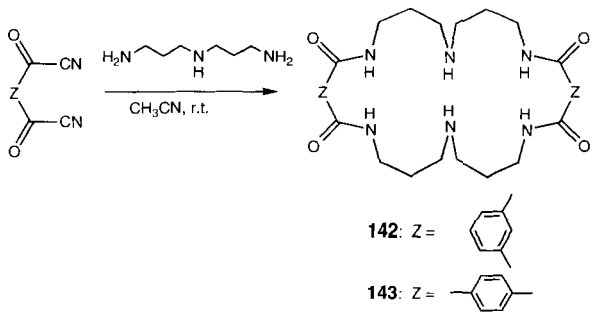


(30b)

of amino alcohols[112] and polyamines.[112b,115] The selective protection and functionalization of polyamines are particularly important for the synthesis of naturally occurring polyamines such as spermidine and spermine alkaloids,[115,116] which have potent antibiotic and antineoplastic properties. The efficiency of this oxidation is illustrated by the synthesis of maytenine (**141**),[117] which was isolated from *Maytenus chuchuhuasha*. Thus, the $[RuCl_2(PPh_3)_3]$-catalyzed oxidation of *trans*-cinnamaldehyde cyanohydrin (**139**) with *t*BuOOH gives *trans*-cinnamoyl cyanide (**140**) in 92% yield. Spermidine reacts with two equivalents of **140** in dry CH_2Cl_2 at room temperature to afford **141** in 92% yield. The Ru-catalyzed oxidation is also highly



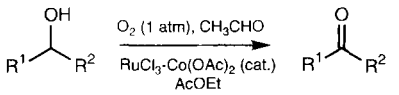
useful for a single-step synthesis of macrocyclic polyamides, which have received considerable attention because of their cation- and anion-binding properties. Indeed, the reactions of iso- and terephthaloyl cyanides with 3,3′-diaminopropylamine in acetonitrile, followed by treatment with hydrogen chloride, gave **142** and **143** in 46 and 42% yields, respectively.



4.7.2. Oxidation with Molecular Oxygen

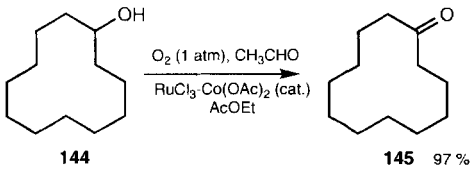
The aerobic oxidation of alcohols with metal catalysts is highly attractive for economical and environmental reasons. However, most of the reported methods are applicable only to activated alcohols such as benzylic[118] and allylic alcohols.[119] General methods are limited to a few reactions catalyzed by Pt,[120] $[Ru_3O(O_2CR)_6L_3]^-$,[111h] and $PdCl_2 \cdot NaOAc$,[121] and these require rather high reaction temperatures, high O_2 pressures, or long reaction times.

Considering the high reactivity of oxoruthenium complexes towards alcohols, the aerobic oxidation of alcohols in the presence of aldehydes under mild conditions seems feasible. Unfortunately, under these conditions, the oxidation does not occur because the formation of peracids seems to be prevented by the strong coordination of alcohols to the ruthenium. Therefore, we examined catalysts that are effective for the formation of peracids from molecular oxygen and aldehydes and do not coordinate alcohols strongly. $Co(OAc)_2$ is an efficient catalyst for the formation of peracetic acid from acetaldehyde and molecular oxygen, and seems to have no strong affinity to alcohols.[74] We discovered that a ruthenium–cobalt catalyst is excellent for the oxidation [Eq. (31)].[122] When a solution of acetaldehyde

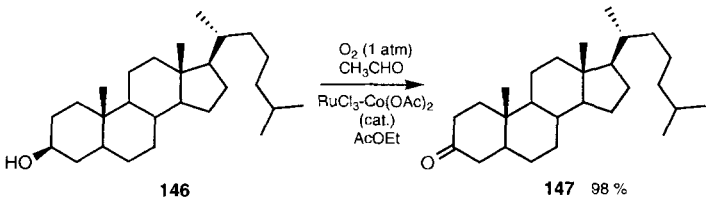


(31)

(4 equiv) in ethyl acetate at room temperature is added to a mixture of an alcohol, $RuCl_3 \cdot nH_2O$ (1 mol%), and $Co(OAc)_2 \cdot 4H_2O$ (1 mol%) in ethyl acetate under an oxygen atmosphere (1 atm), the corresponding ketone is produced with high efficiency. The workup, extraction with a small amount of water to remove the catalyst, is very simple. As typical examples, **144** and **146** gave ketones **145** and **147**, respectively, in 97–98% yield.

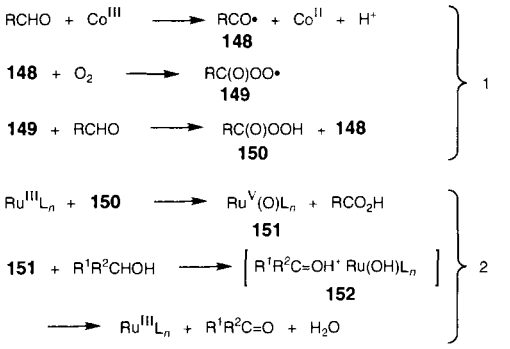


144 **145** 97%



146 **147** 98%

The mechanism of this aerobic oxidation can be rationalized by assuming the following two sequential transformations: 1) formation of peracids by a cobalt-mediated radical chain reaction of aldehydes with molecular oxygen (Scheme 14),[74a] 2) ruthenium-catalyzed oxidation of alcohols[112] with the peracids thus formed. Thus, the reaction of an aldehyde with the

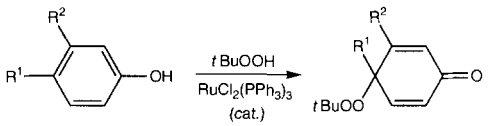


Scheme 14. Aerobic oxidation of alcohols with Co–Ru catalysts.

Co^{III} complex, derived from a Co^{II} complex,[74a] gives acyl radical **148**, which reacts with molecular oxygen to afford acylperoxy radical **149**. This radical abstracts hydrogen from the aldehyde to give peracid **150** and radical **148**. Reaction of the Ru^{III} complex with the peracid **150** leads to $Ru^{III}OOCOR$, which undergoes cleavage of the O–O bond to give the oxoruthenium(v) intermediate **151**.[53,100] Abstraction of a hydrogen atom and subsequent electron transfer provides intermediate **152**, which collapses to give Ru^{III}, a carbonyl compound, and water to complete the catalytic cycle.

4.8. Oxidation of Phenols

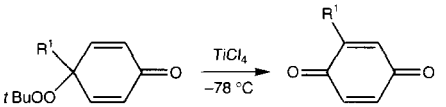
The catalytic oxidation of phenols usually gives complex oxygenated products[123] and coupling products,[124] except when the substrate has bulky substituents such as *tert*-butyl and isopropyl groups at the 2- and 4-positions or 2- and 6-positions. We found that oxidation of *p*-substituted phenols **153** with *t*BuOOH in the presence of $[RuCl_2(PPh_3)_3]$ catalyst gives 4-(*tert*-butyldioxy)-4-substituted cyclohexadienones **154**, which are versatile synthetic intermediates [Eq. (32)].[125] Treatment of phenols with four equivalents of *t*BuOOH in benzene at room temperature in the presence of 3 mol% $[RuCl_2(PPh_3)_3]$ catalyst



(32)

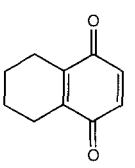
153 **154**

a: R^1 = Me, R^2 = H 85%
b: R^1 = Ph, R^2 = H 76%
c: R^1, R^2 = -$(CH_2)_4$- 85%



(33)

154a, b **155**

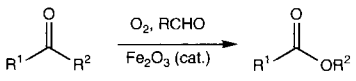


156

affords **154** in good yields. The reaction is an efficient method for the selective oxidation of the phenols that have no substituents at the 2- and 6-positions. Interestingly, when the hexadienones **154** thus obtained are treated with $TiCl_4$ at $-78\,^{\circ}C$, a novel rearrangement occurs. Thus, 2-substituted quinones **155** can be prepared highly efficiently from phenol **153a, b** via **154a, b** [Eq. (33)],[125] and peroxide **154c** can be converted into quinone **156** very efficiently (99%).

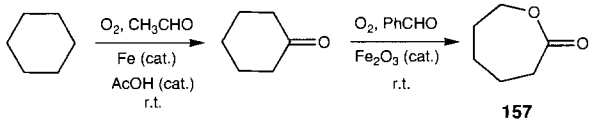
4.9. Oxidation of Ketones

The Baeyer–Villiger oxidation of ketones to lactones or esters is a widely used synthetic method.[126] This oxidative transformation has been performed with various peroxides such as peracids,[127] hydrogen peroxide,[128] and bis(trimethylsilyl)peroxide.[129] However, the catalytic Baeyer–Villiger oxidation of ketones with molecular oxygen has been limited to only a few cases.[130] A precise mechanistic study on the iron-catalyzed oxidation of alkanes led to the discovery of a highly efficient Baeyer–Villiger oxidation of ketones with molecular oxygen (1 atm), in the presence of Fe_2O_3 catalyst and benzaldehyde [Eq. (34)].[131] When a solution of cyclohexanone in benzene is

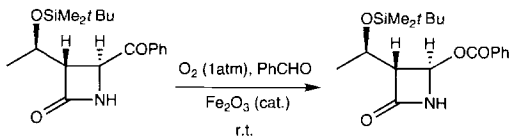


(34)

treated with benzaldehyde at room temperature in the presence of Fe_2O_3 catalyst (1 mol%) under oxygen (1 atm), ε-caprolactam (**157**) is produced in 92% yield. The Fe_2O_3-catalyzed aerobic oxidation of 4-benzoyl β-lactam **158** gives 4-benzoyloxy β-lactam **159** with complete retention of configuration in 93% yield.



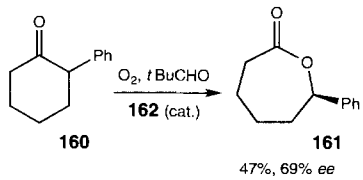
157



158 **159**

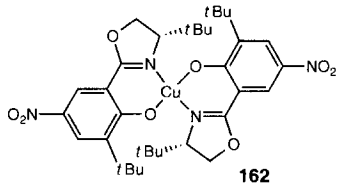
$Cu(OAc)_2$[132] and heteropolyoxometalates[133] have also been shown to be good catalysts, although Baeyer–Villiger oxidation of ketones using molecular oxygen and benzaldehyde can occur in the absence of metal catalysts,[134] and its mechanism has been reported.[135] Recently, an asymmetric Baeyer–Villiger oxidation of **160** with molecular oxygen was reported with the Cu^{II} catalyst **162**.[136]

As described in Section 4.5.2, the iron(0)-catalyzed oxidation of cyclohexane with molecular oxygen in the presence of acetaldehyde gives cyclohexanone with high efficiency. In contrast, the oxidation of cyclohexane does not occur with the Fe_2O_3 catalyst. We wish to emphasize that both transformations, the aerobic oxidation of hydrocarbons to ketones (or alcohols) and the aerobic oxidation of ketones to lactones, were explored by using iron catalysts, though the catalyst systems differed.



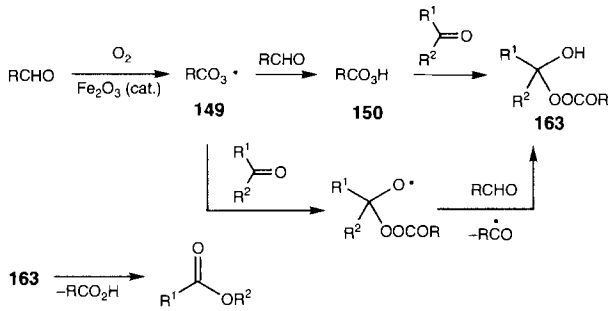
160 **161**

47%, 69% *ee*



162

The oxidation giving lactones can be rationalized by assuming the pathways shown in Scheme 15. The Fe_2O_3-catalyzed reaction of an aldehyde with molecular oxygen[74] gives the acylperoxy radical **149**, which is a key intermediate in the autoxidation of an aldehyde. The radical **149** abstracts hydrogen from the aldehyde to afford peracid **150**, which reacts readily with the ketone to yield **163**. Alternatively, the radical **149** reacts first with the ketone and then with the aldehyde to give **163**. The intermediate **163** thus formed rearranges to give the ester and the carboxylic acid.



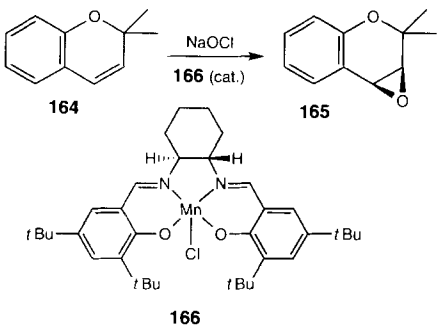
Scheme 15. Fe_2O_3-catalyzed aerobic Baeyer–Villiger oxidation of ketones.

4.10. Oxidation of Alkenes

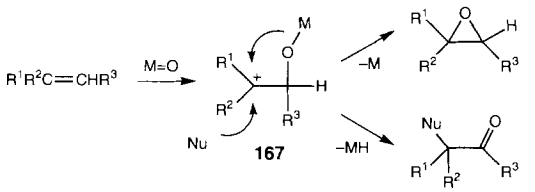
The epoxidation of alkenes is one of the typical reactions of cytochrome P-450.[41] Metalloporphyrin-catalyzed epoxidation of alkenes with various oxidizing agents have been investigated extensively.[41b,137,138] One of the most important aspects is asymmetric epoxidation. A variety of characteristic, synthetic Fe^{III} complexes of chiral porphyrins such as (*R*)-$\alpha,\beta,\alpha,\beta$-tetrakis(*o*-hydratoamidophenyl)porphyrin,[139] vaulted chiral binaphthyl porphyrin,[91] and "basket-handle",[140] "picnic basket",[141] "twin-coronet",[142] "strapped",[143] and "chiral wall" porphyrins[144] have been designed and used successfully for epoxidation.

Of the catalysts not based on porphyrins, the chiral catalyst in the Sharpless epoxidation of allylic alcohols, which is prepared from $[Ti(OiPr)_4]$ and diethyl tartrate, is particularly important. This reaction is the first practical method for asymmetric epoxidation.[145] In this catalytic system, the substrate should bear

specific polar groups in order to precoordinate the active metal center. The success here stimulated the development of enantioselective catalysts for the epoxidation of unfunctionalized alkenes. The enantioselective epoxidation of these substrates described by Jacobsen, Katsuki, Berkessel, and Mukaiyama have greatly expanded the synthetic scope of metal-catalyzed asymmetric oxidations.[44] In these approaches oxygen transfer to the olefin is effected by chiral manganese(III) complexes with chiral salen ligands,[43] and iodosylbenene or hypochlorite,[146-149] hydrogen peroxide,[150] and even molecular oxygen/aldehydes is used.[151] As a typical example, the epoxidation of **164** with NaOCl in the presence of catalyst **166** gave **165** with 98% *ee* in 72% yield. These catalytic epoxidations have become very important reactions in synthetic organic chemistry.

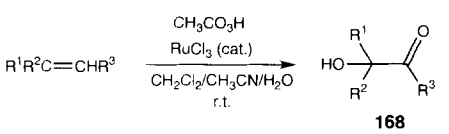


We wish to discuss another aspect of the cytochrome P-450 type oxidation of alkenes, namely, the catalytic oxidative transformation of alkenes into α-ketols. According to the proposed mechanism of cytochrome P-450 epoxidations, cationic intermediate **167** is formed before ring closure leading to epoxides (Scheme 16).[152] If **167** could be trapped with nucleophiles such



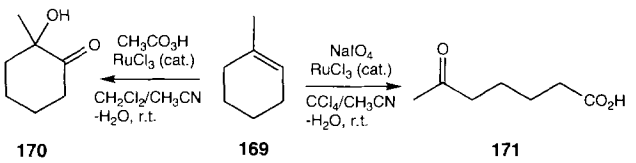
Scheme 16. Oxidation of alkenes catalyzed by a metal oxide.

as water before the ring closure, a new type of catalytic oxidation of alkenes would be possible. Indeed, the novel oxidative transformation of alkenes into α-ketols has been found to proceed very efficiently. Thus, the oxidation with peracetic acid in an aqueous solution catalyzed by low-valent ruthenium under mild conditions yields the corresponding α-ketols **168** [Eq. (35)].[153] The methods for the preparation of α-ketols from enol ethers[154] and enolates[155] have been studied extensively; however, the synthesis from alkenes is limited to oxidations with



(35)

$KMnO_4/CuSO_4$[156] and with isobutyraldehyde/O_2 in the presence of OsO_4 and bis(3-methyl-2,4-pentanedioate)nickel catalysts.[157] This oxidation is quite different from that promoted by ruthenium tetraoxide.[111a] Indeed, the oxidation of 1-methylcyclohexene (**169**) under the present reaction conditions gives 2-hydroxy-2-methylcyclohexanone (**170**) (67%), while the oxidation of the same substrate under the conditions in which



ruthenium tetraoxide is generated catalytically gives 6-oxoheptanoic acid (**171**) (91%). Importantly, allylic acetates can be oxidized to give the corresponding acetoxy α-ketols in good to excellent yields.

Table 8. Ruthenium-catalyzed oxidation of alkenes to α-ketols with peracetic acid.

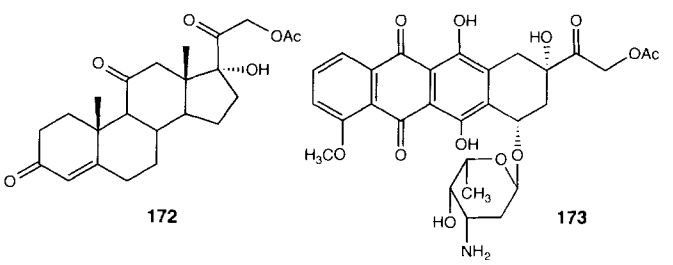
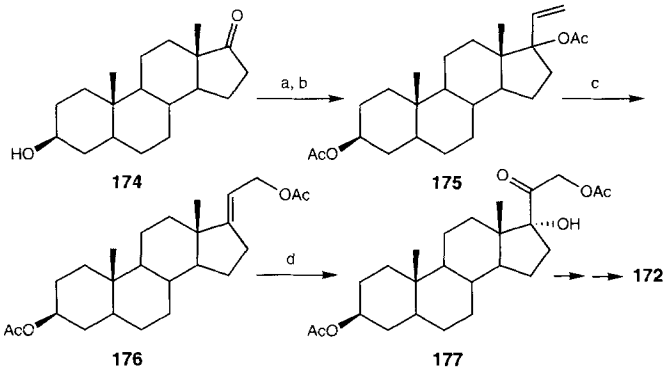
α-Ketols are important synthetic intermediates and partial structures of various biologically active compounds such as cortisone acetate (**172**) and adriamycin acetate (**173**). The efficiency of the present reaction has been demonstrated by the synthesis

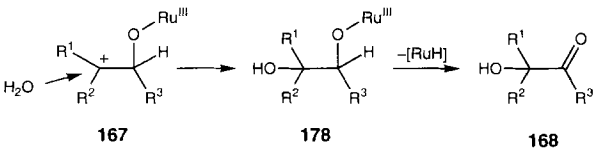


of cortisone acetate (**172**), which is a valuable antiinflammatory agent. Our synthesis started with the conversion of epiandrosterone (**174**), which is commercially available, into 3β,17ξ-diacetoxy-5α-pregn-20-ene (**175**) (Scheme 17). Rearrangement of **175** with $[PdCl_2(CH_3CN)_2]$ catalyst[158] in THF at room temperature gave 3β,21-diacetoxy-5α-pregn-17-ene (**176**) in 92% yield. The ruthenium-catalyzed oxidation of **176** proceeded stereoselectively to give 20-oxo-5α-pregnane-3β,17α,21-triol 3,21-diacetate (**177**) in 57% yield. Conventional treatment of **177** followed by microbial oxidation with *Rhizopus nigricans* gave **172**.



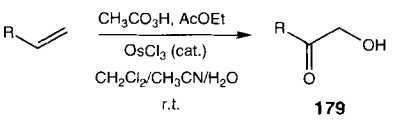
Scheme 17. Synthesis of cortisone acetate (**172**): a) $CH_2{=}CHMgBr$; b) Ac_2O, 4-*N*,*N*-dimethylaminopyridine/pyridine; c) $[PdCl_2(CH_3CN)_2]$ (cat.); d) $RuCl_3$ (cat.), CH_3CO_3H.

The oxidation leading to **177** can be rationalized by assuming the pathway shown in Scheme 18. The reaction of the Ru^{III} complex with peracetic acid gives a $Ru^V{=}O$ species,[67] which reacts with alkenes to give the cationic species **167**. Nucleophilic attack of water, before ring closure to give epoxide, and subsequent β-elimination of a ruthenium hydride species from **178** affords the α-ketol.



Scheme 18. Reaction process for the catalytic oxidation of alkenes to give α-ketols.

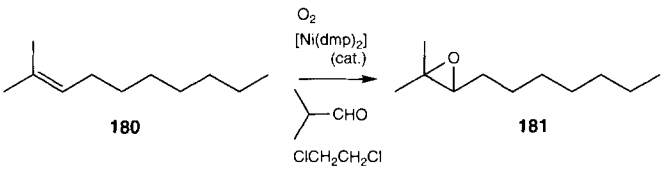
As described in Section 4.4.1, the osmium-catalyzed oxidation of β-lactams with peracetic acid proceeds smoothly. In this reaction a non-porphyrin oxoosmium species seems to play a key role, and hence we extended the catalytic system to the oxidation of alkenes. The $OsCl_3$-catalyzed oxidation of alkenes with peracetic acid in an aqueous solution gives the corresponding α-ketols [Eq. (36)].[159] This reaction is quite different from the OsO_4-catalyzed oxidation of alkenes. The catalytic asymmetric Sharpless dihydroxylation of unfunctionalized *trans*-alkenes with osmium tetraoxide/alkaloid complexes has now become a very powerful method for organic synthesis because of its extremely high enantioselectivity.[73b]



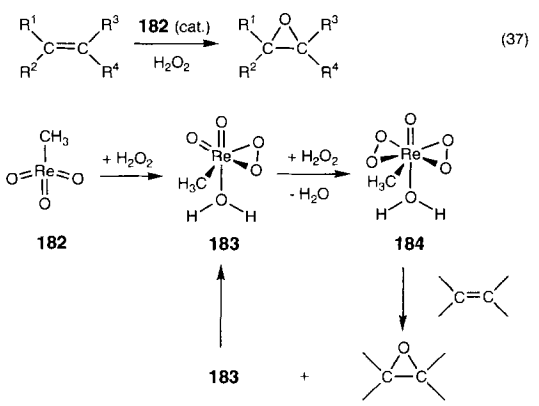
(36)

Both cyclic and acyclic alkenes are converted into the corresponding α-ketols conveniently in the presence of 1–3 mol% $OsCl_3$. Oxidation of 1-octene with peracetic acid in the presence of 1 mol% $OsCl_3$ in $CH_2Cl_2/CH_3CN/H_2O$ (1:1:1) at room temperature gave 1-hydroxy-2-octanone **179** ($R = C_6H_{13}$) in 88% yield. Importantly, the oxidation of monosubstituted alkenes proceeds smoothly to give α-ketols with high regioselectivity, although the reactivity is low. Electron-deficient alkenes are also converted into the corresponding α-ketols. The high reactivity towards less reactive 1-alkenes is due to the high electrophilicity of the $Os^V{=}O$ species.

For the aerobic epoxidation of alkenes a nickel(II) 1,3-diketone catalyst system[160] in the presence of an aldehyde is extremely efficient. Bis[1,3-bis(*p*-methylphenyl)-1,3-propanedionato]nickel(II) $[Ni(dmp)_2]$ was used in the aerobic oxidation of alkene **180** in 1,2-dichloroethane in the presence of 2-methylpropanal to give epoxide **181** in 100% yield; the turnover number was 10^7.[160a] Under similar conditions, cobalt(III)–salen systems[151,161] and heteropolyoxometalate systems[133] can be used. $RuCl_3$,[100] Fe,[100] and $Cu(OH)_2$[105] have been explored as simple catalytic systems for oxidations of alkenes in the presence of acetaldehyde.



Methyltrioxorhenium (MTO, **182**) can be used to catalyze the oxidation of alkenes with hydrogen peroxide to give epoxides very efficiently.[46] This reaction is particularly interesting since the intermediates have been well defined by trapping experiments. Thus, treatment of **182** with hydrogen peroxide gives Re^{VII} peroxo complex **184** via **183**. Complex **184**, which surprisingly could be isolated in the solid state, is the active species in the olefin epoxidation catalyzed by **182** [Eq. (37)]. Compound **183** is formed rapidly from **184** in the presence of olefins. Since the chemistry of organometallic oxides is compatible with that of classical inorganic oxides, chemists from both areas of chemistry will soon be working together closely.[46]



(37)

5. Summary and Outlook

Simulation of the functions of amine oxidase, hepatic flavoenzyme, and cytochrome P-450 with transition metal catalysts has resulted in the discovery of novel and selective catalytic reactions that are simple, clean, and practical. In addition, a variety of related reactions, including four new methods to introduce a substituent at the α-position of amines, using nucleophiles, have been explored.

For oxidations in the laboratory sodium dichromate or potassium permanganate may be used. But when these reactions are scaled up, they are costly and produce large volumes of effluent containing toxic metal salts that must be treated. For this reason more environmentally friendly oxidizing agents such as hydrogen peroxide, *tert*-butyl hydroperoxide, and acetaldehyde/O_2 (peracetic acid) have been examined for oxidations catalyzed by trace amounts of transition metal catalysts. The biomimetic oxidation reactions presented here can be worked up easily and result in only water, *tert*-butanol, or acetic acid as by-products, and, hence, will be widely used in the future. *tert*-Butanol can be consumed as a precursor of the gasoline additive methyl *tert*-butyl ether, in place of aromatic hydrocarbons.

I thank the Ministry of Education, Science and Culture, Japan, for financial support. It is a pleasure to acknowledge the experimental and intellectual contributions of the authors whose names are cited in the references.

Cyclopentadienyl-Free Organolanthanide Chemistry

Frank T. Edelmann*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

During the past ten years the organometallic chemistry of the lanthanides has witnessed enormous growth. One of the main reasons for this development was the finding that lanthanide metallocenes can exhibit an unusually high catalytic activity. Considerable advances have also been achieved in the chemistry of organolanthanide complexes that are not stabilized by cyclopentadienyl ligands. For example, the successful synthesis of the first unsolvated homoleptic trialkyllanthanides, $[Ln\{CH(SiMe_3)_2\}_3]$, has recently been reported. Anionic allyl complexes of the lanthanides show promising catalytic properties and cyclooctatetraene complexes of these elements are also under active investigation. This review is intended to provide an overview of this rapidly developing area of research.

Keywords: cyclooctatetraene complexes · homogeneous catalysis · lanthanides · organolanthanide compounds

1. Introduction

Organolanthanide chemistry is currently one of the most rapidly developing areas of organometallic chemistry. This is even more surprising, as only twenty years ago it was stated in inorganic chemistry textbooks that the lanthanide elements do not form stable organometallic compounds. Meanwhile it has become quite clear that organolanthanide chemistry follows its own rules and often differs significantly from organometallic chemistry of the 3d transition metals. In recent years numerous unprecedented reaction pathways and novel molecular structures have been discovered, which demonstrate the unique character of organolanthanide chemistry. The impressive advance in this area has already been documented in several reviews.[1–6] The current research in the field of homogeneous catalysis with organolanthanide complexes is particularly exciting. It is now well established that certain lanthanide metallocenes can exhibit an unusually high catalytic activity. This is particularly true for olefin transformations such as hydrogenations, cyclizations, polymerizations, and addition reactions. Traditionally, for these purposes attention focused on cyclopentadienyl complexes of the lanthanides. Approximately 90% of all previously described organometallic complexes of the 4f elements are compounds containing cyclopentadienyl ligands.[4–6] Anionic π ligands are ideally suited for stabilizing highly reactive alkyl- and hydridolanthanide complexes. More recently, however, increasing use has been made of other ligand systems in organolanthanide chemistry. Among these ligands are bulky σ-alkyl groups and allyl ligands as well as pentadienyl anions ("open cyclopentadienyl"), neutral arenes, and anionic heterocycles. η^8-Cyclooctatetraene complexes of the lanthanides are a particularly large class of compounds. This review is intended to provide an overview of the current developments by illustrating synthetic and structural aspects as well as possible applications. Without trying to be fully comprehensive, it will present the most interesting results and show the main objectives.

Table 1 shows the assignment of the various lanthanide elements in the numbering of the compounds. As usual, scandium and yttrium have been included because of their chemical similarity with the lanthanides. The radioactive element promethium has been omitted as no organometallic compound without cyclopentadienyl ligands has so far been reported.[6] Compounds in which the formal oxidation state of the lanthanide is zero have also been excluded.

2. Carbonyl Complexes

In sharp contrast to the organometallic chemistry of the 3d transition metals, binary carbonyllanthanide compounds are unstable under normal conditions.[5] Ln^{3+} ions are considered good σ acceptors but poor π donors. Simple lanthanide carbonyls $[Ln(CO)_n]$ have so far only been detected in matrix inves-

tigations.[11] The only structurally characterized compound, for which coordination of a CO ligand to a lanthanide element was proven, is the heteronuclear erbium complex **1m** (Fig. 1).[7] Weak

$[Er(EtOH)(H_2O)_4\{Mo(CO)_3(C_5H_5)\}_3]$ **1m**

metal–metal interactions and semibridging carbonyl ligands between molybdenum and erbium characterize this compound, which resembles the previously described heterobimetallic complexes with isocarbonyl bridges between lanthanides and transition metals.[8] Even today there is still a long way to go before the main goal is reached, namely, the synthesis of "true" carbonyl complexes of the lanthanides with C-bonded CO.

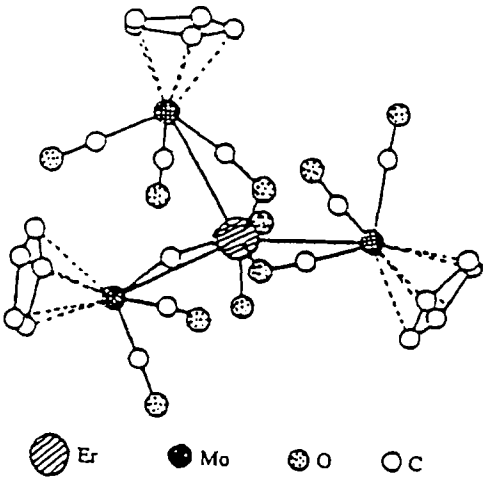

Fig. 1. Molecular structure of $[Er(EtOH)(H_2O)_4\{Mo(CO)_3(C_5H_5)\}_3]$ **1m** in the crystal.

3. Alkyl and Aryl Complexes

Once again in contrast to the countless π complexes of 3d transition metals, the lanthanides exhibit virtually no tendency to coordinate neutral alkenes, dienes, allenes, or alkynes.[1–6] The reasons for this behavior are the limited radial extension of the 4f orbitals and the fact that the Ln–C bond in organolanthanide complexes is predominantly ionic. Thus early attempts to prepare lanthanide complexes of unsaturated hydrocarbons were mostly unsuccessful. Likewise, the synthesis of simple organolanthanide complexes containing only σ-bonded ligands is quite problematic. One of the major challenges in the field of organolanthanide chemistry was (and continues to be) the synthesis of unsolvated, homoleptic trialkyl- and triaryllanthanides LnR_3. The main reason for the instability of such compounds is the tendency of the lanthanide to adopt high coordination numbers. Because of the large ionic radii of the Ln^{3+} ions, three-coordinate compounds with simple alkyl or aryl ligands are sterically highly unsaturated. Normally this leads to the formation of solvent adducts, "ate" complexes, or oligomeric species. A significant breakthrough was achieved only very recently through the use of sterically demanding alkyl ligands such as $CH(SiMe_3)_2$.

3.1. Neutral Homoleptic Compounds

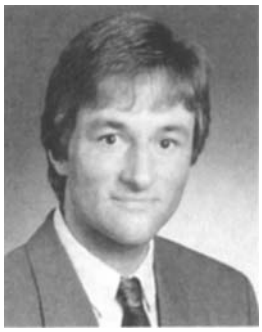
In addition to neutral, unsolvated compounds of the composition LnR_2 and LnR_3, solvent adducts thereof will also be discussed in this section, although per definition these materials are heteroleptic complexes. The most thoroughly investigated lanthanide(II) compound in this group is bis(pentafluorophenyl)ytterbium(II), $[Yb(C_6F_5)_2]$ **2o**, which was described by Deacon et al.[8–10] This compound is easily accessible by a

$[Yb(C_6F_5)_2]$ **2o** $[Yb(o\text{-}C_6F_4H)_2]$ **3o** $[Yb(p\text{-}C_6F_4H)_2]$ **4o**

transmetalation reaction between metallic ytterbium and bis(pentafluorophenyl)mercury. The corresponding europium(II) compound **2h** can be obtained analogously [Eq. (1)].

$$Ln + [Hg(C_6F_5)_2] \longrightarrow \underset{\mathbf{2},\ Ln = Eu,\ Yb}{[Ln(C_6F_5)_2]} + Hg \qquad (1)$$

The comparably high stability of the pentafluorophenyl derivatives has been explained by the formation of metal–fluorine interactions. Partially fluorinated derivatives such as **3o** and **4o** are significantly less stable than **2o**. Compounds **2h** and **2o** are both very useful intermediates in various subsequent reactions, for example, as starting materials for the preparation of lanthanide(II) amides and phenoxides.[11] Furthermore, the σ-bonded pentafluorophenyl groups in **2o** can be transferred to



Frank T. Edelmann, born 1954 in Hamburg, studied chemistry from 1974–1979 at the University of Hamburg. He received his doctorate in 1983 under the supervision of U. Behrens with a Ph. D. thesis entitled "Die Chemie der Tricarbonyl(fulven)chrom-Komplexe" (The Chemistry of Tricarbonyl(fulvene)chromium Complexes). This was followed by two years of postdoctoral research as a Feodor Lynen Fellow of the Alexander-von-Humboldt-Stiftung in the groups of J. Takats (University of Alberta, Edmonton, Canada), J. W. Gilje (University of Hawaii, Honolulu, USA), and T. Chivers (University of Calgary, Calgary, Canada). In 1991 he finished his Habilitation in the group of H. W. Roesky at the University of Göttingen and in 1995 he was appointed a full professor of Inorganic Chemistry at the Otto-von-Guericke-University in Magdeburg. His research interests include the organometallic and coordination chemistry of the lanthanides, the development of novel metallocene catalysts and organometallic precursors for new materials, as well as fluorine chemistry.

transition metals.[10, 12] Recently Lappert et al. reported on an interesting new representative of this small class of compounds.[13] The first well-characterized dialkyllanthanide(II) compound **5o**, was prepared according to Equation (2). The

$[Yb\{CH(SiMe_3)_2\}_2(Et_2O)_2]$ **5o**

coordinated diethyl ether can be replaced by the chelating phosphane ligand 1,2-bis(dimethylphosphino)ethane (DMPE) [Eq. (3)]. Subsequent reactions with pivalonitrile or anionic azaallylic ligands indicate that **5o** is a very promising starting material for the preparation of novel organolanthanide(II) complexes.

$$YbI_2 + 2\,NaCH(SiMe_3)_2 \xrightarrow[-2\,NaI]{Et_2O} \underset{\mathbf{5o}}{[Yb\{CH(SiMe_3)_2\}_2(Et_2O)_2]} \quad (2)$$

$$\mathbf{5o} + DMPE \longrightarrow \underset{\mathbf{6o}}{[Yb\{CH(SiMe_3)_2\}_2(dmpe)]} + 2\,Et_2O \quad (3)$$

By using the sterically more demanding tris(trimethylsilyl)methyl ligand it was even possible to isolate an unsolvated homoleptic dialkyllanthanide(II) compound. The reaction of YbI_2 with two equivalents of $KC(SiMe_3)_3$ in benzene afforded **7o** in the form of orange, sublimable crystals, which were

$[Yb\{C(SiMe_3)_3\}_2]$ **7o**

characterized by X-ray structure analysis (Fig. 2).[14] A particularly surprising and interesting structural feature of **7o** is the C-Yb-C angle of 137°. All other bis[tris(trimethylsilyl)methyl] metal species, for example $[Mg\{C(SiMe_3)_3\}_2]$[15] and $[Na\{C(SiMe_3)_3\}_2]^-$[16], have been reported to be linear. Just a few years ago an unsolvated dialkyllanthanide(II) compound like **7o** was considered to be impossible to isolate.

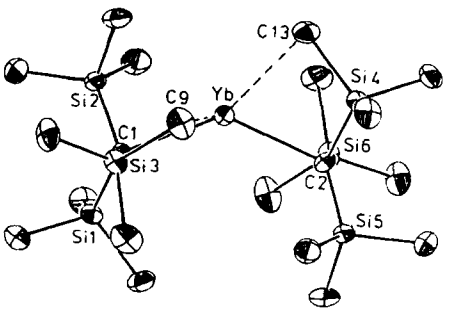


Fig. 2. Molecular structure of $[Yb\{C(SiMe_3)_3\}_2]$ **7o** in the crystal.

Organolanthanide(II) complexes can also be stabilized by σ-bonded carborane ligands.[17] The compound **8o** was synthesized by a transmetalation reaction [Eq. (4)], but an unambiguous structural characterization is still lacking.

$$Yb + [Hg(o\text{-}C_2H_2B_{10}H_9)_2] \xrightarrow[-Hg]{THF} \underset{\mathbf{8o}}{[Yb(o\text{-}C_2H_2B_{10}H_9)_2]} \quad (4)$$

Attempts at synthesizing homoleptic trialkyllanthanides were made some 50 years ago.[1] The first indications that such compounds might form came from the observation that lanthanum reacts with methyl radicals.[18] However, it was not possible to isolate a product of the composition $LaMe_3$. Early reports on the synthesis of $ScEt_3$ and YEt_3 have also never been verified.[19] It is anticipated that the reported triphenyl derivatives $ScPh_3$ **9a** and YPh_3 **10b** are oligomeric or polymeric materials.[20, 21] The reason for the inherent instability of all such compounds is that the formally three-coordinate central atom is sterically unsaturated. Only recently a well-defined σ-phenyl derivative of ytterbium became available in which the metal atoms attain the formal coordination number 6 through formation of a dinuclear complex. The highly remarkable mixed-valent Yb^{II}/Yb^{III} compound **11o** was obtained by treatment of "naphthaleneytterbium" **12o** with either diphenylmercury or triphenylbismuth.[22, 23] The crystal structure analysis revealed the presence of an asymmetric complex, in which both ytterbium atoms are coordinated in a distorted octahedral fashion (Fig. 3). Three phenyl groups act as bridging ligands by forming σ bonds to the first ytterbium atom, while being η^2-coordinated to the second ytterbium atom.

$ScPh_3$	YPh_3	$[Ph_2(thf)Yb(\mu\text{-}Ph)_3Yb(thf)_2]$	$[(C_{10}H_8)Yb(thf)_2]$
9a	**10b**	**11o**	**12o**

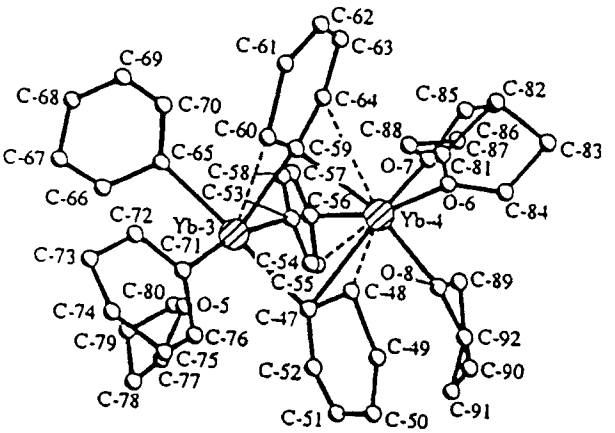

Fig. 3. Molecular structure of $[Ph_2(thf)Yb(\mu\text{-}Ph)_3Yb(thf)_2]$ **11o** in the crystal.

Recently the first structural characterization of two triphenyllanthanide complexes was reported by Bochkarev et al.[24] The THF adducts **13** were obtained according to Equation (5) by

$$2\,Ln + 3\,Ph_2Hg \xrightarrow[]{THF,\ LnI_3} \underset{\mathbf{13},\ Ln = Er,\ Tm}{2[Ph_3Ln(thf)_3]} + 3\,Hg \quad (5)$$

treatment of elemental lanthanides with diphenylmercury in the presence of small amounts of LnI_3. After reaction times of approximately 120–150 h, the products were isolated as pink (**13m**) or colorless (**13n**) highly air-sensitive crystals. Monomeric, distorted octahedral molecules with a facial arrangement of the ligands are present in the erbium derivative **13m** (Fig. 4).

Generally, however, low-coordinate organolanthanide complexes with simple σ-bound alkyl or aryl ligands are unstable. Compounds with a significantly higher stability are obtained by

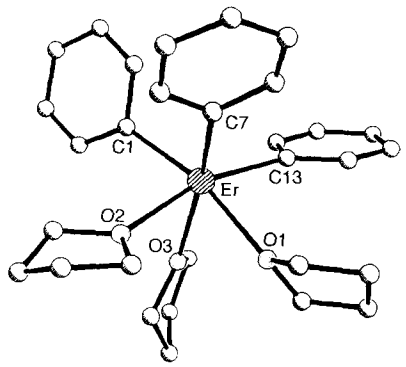

Fig. 4. Molecular structure of $[Ph_3Er(thf)_3]$ **13m** in the crystal.

using chelating ligands. Especially useful for this purpose are chelating ligands that contain an additional donor function and thus allow a coordinative saturation of the central metal atom. In this way homoleptic lanthanide complexes containing the chelating *o*-dimethylaminomethylphenyl substituent and related ligands were prepared in the 1970s. The six-coordinate complexes **14** and **15** can be isolated without any additional donor

$[Ln(o\text{-}Me_2NCH_2C_6H_4)_3]$ **14** $[Ln(o\text{-}Me_2NC_6H_4CH_2)_3]$ **15**

Ln = Sc, Y, La, Nd, Er, Yb, Lu

ligands such as THF.[25-27] Methoxy groups function as the additional donors in the complexes **16**.[28] A novel development

$[Ln(o\text{-}MeOC_6H_4)_3]$ **16**, Ln = Ce, Pr, Nd

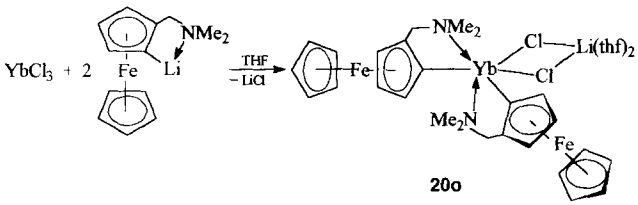
in this area is the use of the chelating 2-dimethylaminomethylferrocenyl (FcN) ligands. FcN compounds contain cyclopentadienyl ligands, but these are not *pentahapto* coordinated to the lanthanide central atoms. Among the hitherto described organolanthanide complexes with σ-bonded FcN ligands are the compounds **17c**, **18**, and **19o**,[29] which were obtained by treatment of anhydrous lanthanide trichlorides with Li(FcN) [Eqs. (6)-(8)].

$$LaCl_3 + 2\,Li(FcN) \longrightarrow \underset{\mathbf{17c}}{[(FcN)_2LaCl]} + 2\,LiCl \quad (6)$$

$$LnCl_3 + 3\,Li(FcN) \xrightarrow{THF} \underset{\mathbf{18},\ Ln = Ce, Pr, Nd}{[(FcN)_3Ln \cdot LiCl \cdot THF]} + 2\,LiCl \quad (7)$$

$$YbCl_3 + 3\,Li(FcN) \longrightarrow \underset{\mathbf{19o}}{[Yb(FcN)_3]} + 3\,LiCl \quad (8)$$

The crystallographically characterized ytterbium "ate"-complex **20o** was obtained by reacting anhydrous ytterbium trichloride with two equivalents of Li(FcN) [Eq. (9)].[30] The product



(9)

20o is the first bis(organo)lanthanide(III) halide containing only σ-bonded ligands (Fig. 5, Yb-C 265.1, 237.2 pm). This compound resembles the lanthanide metallocenes $[(C_5Me_5)_2Ln(\mu\text{-}Cl)_2Li(thf)_2]$[1-6] and thus an interesting derivative chemistry is also expected in this case.

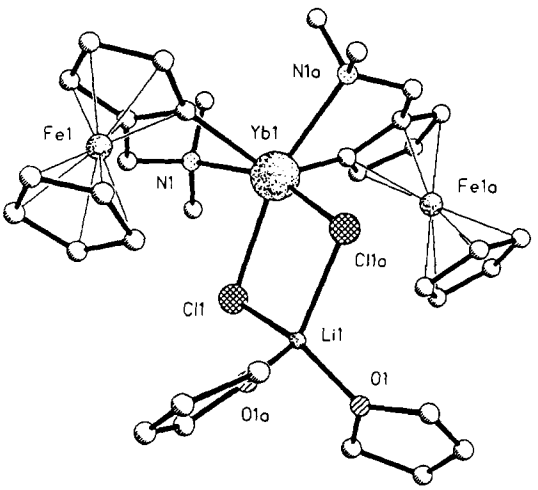


Fig. 5. Molecular structure of $[(FcN)_2Yb(\mu\text{-}Cl)_2Li(thf)_2]$ **20o** in the crystal.

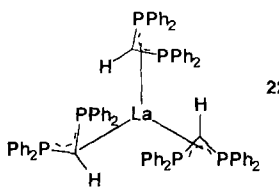
Chelating phosphorus ylide anions should also be suitable for the synthesis of six-coordinate organolanthanide complexes. However, the products made according to Scheme 1 were polymeric and no structural characterization could be achieved. Even with the sterically demanding ligand $[(CH_2)_2PtBu_2]^-$ only oligomeric products were obtained.[31]

$$LnCl_3 + 3\,Me_3P{=}CH_2 \longrightarrow [Ln\{CH_2PMe_3Cl\}_3] \xrightarrow[-3\,C_4H_{10}\ -3\,LiCl]{+3n\,BuLi} \underset{\mathbf{21},\ Ln = La, Pr, Nd, Sm, Gd, Ho, Er, Lu}{[Ln\{(CH_2)_2PMe_2\}_3]}$$

Scheme 1. Synthesis of $[Ln\{(CH_2)_2PMe_2\}_3]$ **21**.

Allyl-like diphosphinomethanide ligands have been demonstrated to be much better suited for the synthesis of homoleptic organolanthanide complexes. The lanthanum derivative **22c** was structurally characterized in 1986.[32]



22c

With samarium as the central atom mono- or dinuclear diphosphinomethanide complexes can be isolated depending on the nature of the substituents on phosphorus [Eqs. (10) and (11), respectively].[33, 34] Both products have been unequiv-

$$[SmCl_3(thf)_3] + 3\,LiCH(PPh_2)_2 \xrightarrow[-3\,THF]{-3\,LiCl} \underset{\mathbf{23g}}{[Sm\{CH(PPh_2)_2\}_3]} \quad (10)$$

$$2\,Sm(O_3SCF_3)_3 + 6\,LiCH(PMe_2)_2 \xrightarrow[-6\,LiO_3SCF_3]{} \underset{\mathbf{24g}}{[\{\mu\text{-}\eta^2\text{-}CH(PMe_2)_2\}_2\{Sm[CH(PMe_2)_2]_2\}_2]} \quad (11)$$

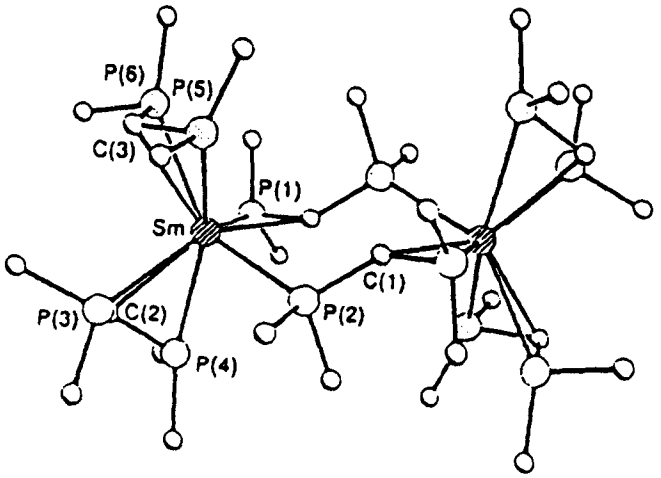


Fig. 6. Molecular structure of $[\{\mu\text{-}\eta^2\text{-}CH(PMe_2)_2\}_2\{Sm[CH(PMe_2)_2]_2\}_2]$ **24g** in the crystal.

ocally characterized by crystal structure analyses. In the centrosymmetric dimer **24g** the two samarium atoms are bridged by two diphosphinomethanide ligands through a carbon and a phosphorus atom (Fig. 6).

A second strategy for stabilizing lanthanide compounds with low coordination numbers (3–6) is the use of sterically demanding alkyl ligands. However, for this, alkyl groups such as *tert*-butyl, neopentyl, or trimethylsilylmethyl are not sufficiently bulky to allow the isolation of unsolvated trialkyllanthanides.[1] For example, treatment of lanthanide trichlorides with $LiCH_2SiMe_3$ in THF solution affords the THF adducts **25** as the final products [Eq. (12)], from which the coordinated solvent cannot be removed without decomposition.[35–39] The products are thermolabile and decompose upon heating under elimination of THF and tetramethylsilane. It was proposed that the resulting pyrophoric and presumably polymeric materials are lanthanide carbene complexes, although nothing is known about the molecular structure of these products.

$$LnCl_3 + 3\,LiCH_2SiMe_3 \xrightarrow{THF} [(Me_3SiCH_2)_3Ln(thf)_2] + 3\,LiCl \qquad (12)$$

25, Ln = Er, Tm, Yb, Lu

The results discussed above make quite clear that base-free homoleptic alkyllanthanide compounds are accessible only with the use of very bulky alkyl substituents. The synthesis of the trialkyl compounds $[Ln\{CH(SiMe_3)_2\}_3]$ **26** by Lappert et al. can be considered a milestone in organolanthanide chemistry.[40–42] Their successful preparation was made possible by a combination of two favorable factors: First, the bis(trimethylsilyl)methyl substituent was employed as a sterically highly demanding alkyl ligand. In addition, by using the low-coordinate phenoxides $[Ln(2,4,6\text{-}tBu_3C_6H_2O)_3]$ as starting materials it was possible to avoid the formation (and incorporation) of alkali metal halides. When the reactions are carried out in pentane, the lithium phenoxide by-product precipitates quantitatively and can be separated readily from the highly soluble trialkyllanthanide **26** [Eq. (13)].

$$[Ln(2,4,6\text{-}tBu_3C_6H_2O)_3] + 3\,LiCH(SiMe_3)_2 \xrightarrow[-3\ 2,4,6\text{-}tBu_3C_6H_2OLi]{pentane} [Ln\{CH(SiMe_3)_2\}_3] \qquad (13)$$

26, Ln = Y, La, Sm, Lu

The molecular structures of the lanthanum (Fig. 7) and samarium derivative have been determined by X-ray diffraction.[40–42] Like the homoleptic silylamides $[Ln\{N(SiMe_3)_2\}_3]$ the trialkyl compounds **26** adopt a flat pyramidal coordination geometry. The average metal–carbon distances for **26c** and **26g** are 251.5(9) (La–C) and 233(2) (Sm–C) pm, respectively.

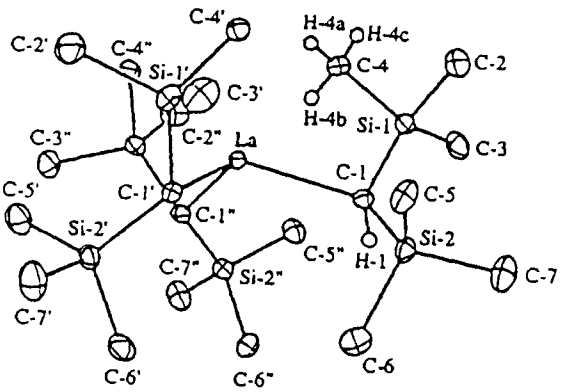

Fig. 7. Molecular structure of $[La\{CH(SiMe_3)_2\}_3]$ **26c** in the crystal.

The deviation from trigonal-planar coordination in the complexes **26** is somewhat surprising. Several explanations have been proposed for this unexpected coordination geometry. Initially, it was proposed that interligand repulsion would be minimized in a pyramidal structure. More important, however, is the possibility of forming agostic Ln-H-C interactions. In fact, short γ-agostic Ln···Me interactions have been found in both structurally characterized compounds (La···C 312.1 pm, Sm···C 285 pm). In this way, the extreme electronic and coordinative unsaturation can be diminished. A different, yet just as plausible, explanation would be the creation of a dipole moment in the pyramidal geometry which would then result in a higher lattice energy in the crystal.

Interestingly, the complexes **26** are not accessible directly from lanthanide trichlorides by conventional reactions. Instead of homoleptic trialkyl compounds, products containing incorporated lithium chloride are formed in these reactions [Eq. (14); PMDETA = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine].[40]

$$LaCl_3 + 3\,LiCH(SiMe_3)_2 \xrightarrow[-2\,LiCl]{PMDETA} [\{(Me_3Si)_2CH\}_3La(\mu\text{-}Cl)Li(pmdeta)] \qquad (14)$$

27c

The LiCl adduct **27c** contains a nearly linear La-Cl-Li unit (La-Cl-Li 165.1°, La–Cl 276.2 pm, Li–Cl 228 pm). In comparison with the neutral compound **26c**, the $[Ln\{CH(SiMe_3)_2\}_3]$ fragment in **27c** exhibits no significant structural changes. An analogous reaction with ytterbium trichloride affords the salt-like product **28o**, which consists of separated ions in the solid

$[Li(thf)_4][YbCl\{CH(SiMe_3)_2\}_3]$ **28o**

state.[35] Evidently, the formation of the various types of complexes depends on a subtle balance of certain factors. These factors include the nature of the alkali metal, the presence of

halide ions, and the ionic radius of the lanthanide element. A similar situation was recently described for some low-coordinate lanthanide alkoxides and amides.[43] For example, the chloro-bridged **27c** is closely related to the neodymium compounds **29f** and **30f**, whereas **28o** is comparable to the compound **31f**.

$[\{(Me_3Si)_2N\}_3Nd(\mu\text{-}Cl)Li(thf)_3]$ **29f**

$[(tBu_3CO)_3Nd(\mu\text{-}Cl)Li(thf)_3]$ **30f**

$[Li(thf)_4][NdOSiMe_3\{N(SiMe_3)_2\}_3]$ **31f**

Recent papers by Schaverien et al. provided additional evidence on how minor changes of the reaction conditions or the choice of the reagents can influence the product formation.[44,45] In this case instead of $LiCH(SiMe_3)_2$, the more reactive $KCH(SiMe_3)_2$ was allowed to react with the lanthanide trichlorides. Owing to the enhanced solubility of the potassium compound it was possible to perform the reaction with lutetium trichloride in diethyl ether instead of THF (Scheme 2).

$$LuCl_3 + 3\,KCH(SiMe_3)_2 \xrightarrow{\text{ether}} [Lu\{CH(SiMe_3)_2\}_3(\mu\text{-}Cl)K(Et_2O)]$$
32p

ether ↑↓ −ether

$$[Lu\{CH(SiMe_3)_2\}_3(\mu\text{-}Cl)K(\eta^6\text{-}C_7H_8)] \xleftarrow{\text{toluene}} [Lu\{CH(SiMe_3)_2\}_3(\mu\text{-}Cl)K]$$
34p **33p**

Scheme 2. Interconversion of alkyllutetium compounds.

In contrast to the analogous LiCl adduct **27c**, the coordinated diethyl ether in **32p** can easily be removed under vacuum to produce the complex **33p**. In this compound the potassium is coordinatively unsaturated and readily adds solvent molecules such as diethyl ether or even toluene.[44,45]

Very little is known about heavier homologues of the alkyllanthanides such as homoleptic silyl and germyl derivatives or their solvent adducts. In the case of divalent ytterbium the preparation of such compounds was achieved by reacting metallic ytterbium with Ph_3ECl (E = Si, Ge) [Eq. (15)].[46] In both

$$2\,Yb + 2\,Ph_3ECl \xrightarrow{THF} [(Ph_3E)_2Yb(thf)_4] + [YbCl_2(thf)_2] \quad (15)$$
34o, E = Si
35o, E = Ge

cases the crystal structure determination showed the presence of centrosymmetric octahedral molecular structures, in which the Ph_3E ligands are arranged in the axial positions.

A small number of σ-stannyl complexes are also known. The ytterbium(II) compound **36o** was prepared by treatment of YbI_2 with the stannylpotassium reagent $K[Sn(CH_2tBu)_3]$ and structurally characterized by X-ray diffraction.[47] The structures were determined also for the stannyl complexes **37** (DME = 1,2-dimethoxyethane);[48,49] however, thus far no further reactions of these interesting products have been reported.

$[Yb\{Sn(CH_2tBu)_3\}_2(thf)_2]$ **36o**

$[Ln\{Sn(CH_2SiMe_3)_3\}_3(dme)]$ **37**, Ln = Pr, Nd

3.2. Anionic Homoleptic Compounds

As a result of the desire of the lanthanide ions to achieve high coordination numbers in their complexes, simple alkyllanthanide(III) complexes very easily add solvent molecules or anionic ligands and form so-called "ate" complexes. Such anionic alkyl complexes are often the only isolable products, when anhydrous lanthanide trichlorides are treated with alkyl- or aryllithium reagents. Quite often the anionic ate complexes are formed preferentially, regardless of the stoichiometric ratio of the starting materials. In a series of fundamental papers, Schumann et al. described the most simple compounds of this type, which formally contain $[LnMe_6]^{3-}$ ions.[50,51] The octahedral complexes **38** and **39** are formed when anhydrous lanthanide trichlorides are treated with six equivalents of methyllithium in the presence of a coordinating solvent. It was possible to prepare the complexes **38** for the entire lanthanide series except promethium and europium.(Owing to the subsequent facile reduction to undefined europium(II) species, the europium derivative **38h** cannot be isolated.) The chelate ligands TMEDA (TMEDA = *N,N,N′,N′*-tetramethylethylene-1,2-diamine) and DME serve to coordinatively saturate the lithium ion.

$$LnCl_3 + 6\,MeLi + 3\,TMEDA \xrightarrow[-3\,LiCl]{Et_2O} [Li(tmeda)]_3[LnMe_6] \quad (16)$$
38, Ln = Sc, Y, La, Sm, Gd–Lu

$$LnCl_3 + 6\,MeLi + 3\,DME \xrightarrow[-3\,LiCl]{Et_2O} [Li(dme)]_3[LnMe_6] \quad (17)$$
39, Ln = Ce, Pr, Gd, Tb, Dy, Er, Lu

The crystalline compounds are extremely air sensitive and reveal the characteristic colors of the respective lanthanide ions. The X-ray crystal structures were determined for the complexes **38l** (Fig. 8), **38m**, and **39p**.[50,51] Six methyl groups surround

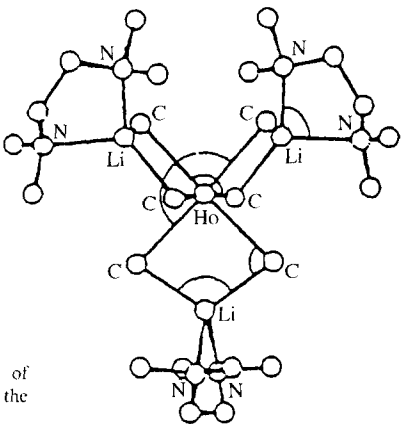

Fig. 8. Molecular structure of $[Li(tmeda)]_3[HoMe_6]$ **38l** in the crystal.

the central lanthanide ion in a slightly distorted octahedral arrangement. Two methyl ligands form bridges between the lanthanide ion and each lithium ion, which, in turn, is coordinatively saturated by chelating TMEDA or DME. All Ln–C bonds are the same length.

Very little has been reported about the reactivity of the complexes **38** and **39**. The first applications in organic synthesis were the reactions with α,β-unsaturated aldehydes and ketones. The

reaction of the samarium derivative **38g** with *tert*-butyl alcohol in diethyl ether afforded the alkoxide $[Li_5Sm(OtBu)_8]$.[52]

$[Li(tmeda)]_3[SmMe_6]$ **38g**

Lower coordination numbers than those in the $[LnMe_6]^{3-}$ ions can be achieved with sterically demanding alkyl ligands such as *tert*-butyl or trimethylsilymethyl. The synthesis of anionic tetra-*tert*-butyl complexes was achieved in a conventional way by reaction of $LnCl_3$ or $Ln(OtBu)_3$ with four equivalents *t*BuLi [Eqs. (18)–(20)]. Diethyl ether, THF, or TMEDA can be used as the coordinating solvent in these reactions.[50, 53, 54] An X-ray crystal structure determination of the lutetium compound **40p** revealed the presence of solvent-separated ions in the crystal.[55]

$$LnCl_3 + 4\,tBuLi \xrightarrow[-3\,LiCl]{pentane/Et_2O} \underset{\mathbf{40},\ Ln = Tb,\ Er,\ Lu}{[Li(Et_2O)_4][LntBu_4]} \quad (18)$$

$$LnCl_3 + 4\,tBuLi \xrightarrow[-3\,LiCl]{THF} \underset{\mathbf{41},\ Ln = Er\ (n = 4),\ Yb\ (n = 3)}{[Li(thf)_n][LntBu_4]} \quad (19)$$

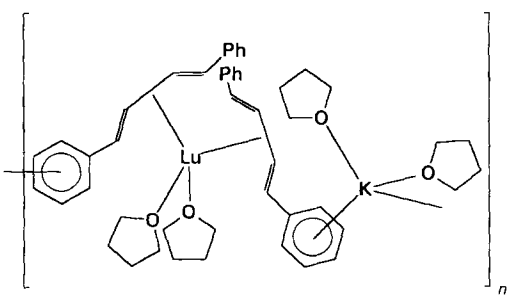
$$Ln(OtBu)_3 + 4\,tBuLi \xrightarrow[-3\,LiOtBu]{pentane/TMEDA} \underset{\mathbf{42},\ Ln = Er,\ Lu}{[Li(tmeda)_2][LntBu_4]} \quad (20)$$

Four-coordinate anionic lanthanide(III) complexes are also accessible with σ-aryl ligands.[21] A typical example is the reaction of anhydrous lanthanide trichlorides with excess phenyllithium, which affords the tetraphenyl complexes **43** [Eq. (21)]. The proposed tetrahedral coordination geometry has been confirmed unambiguously by a crystal structure analysis of the ring-substituted derivative **44p**.[56]

$$LnCl_3 + 4\,PhLi \xrightarrow[-3\,LiCl]{THF} \underset{\mathbf{43},\ Ln = La,\ Pr}{Li[LnPh_4]} \quad (21)$$

$[Li(thf)_4][Lu(2,6\text{-}C_6H_3Me_2)_4]$ **44p**

The structurally characterized lutetium compound **45p** has recently been reported and is an unprecedented example of an anionic diene complex of a lanthanide element.[57] In **45p** two η^4-diphenylbutadiene ligands and two THF molecules are coordinated to the central lutetium ion; the diphenylbutadiene is bonded in its s-*cis* conformation. In the crystal, a polymeric chain structure results from additional η^6-coordination of two phenyl rings to potassium.



45p

3.3. Heteroleptic Compounds

Although THF adducts of alkyllanthanide compounds are formally heteroleptic complexes, only organolanthanide compounds containing additional anionic ligands will be discussed in this section. Until just a few years ago this class of compounds was fairly obscure; however, more recently a substantial number of highly interesting results in this area have been reported. Well-defined lanthanide(II) derivatives are still virtually unknown. The dimeric alkylytterbium(II) ethoxide **46o** was made by treatment of ytterbium(II) iodide with $KC(SiMe_3)_3$ in diethyl ether and characterized by X-ray crystallography.[13] Alternatively, **46o** is also accessible from **7o** by an ether cleavage reaction [Eq. (22)].[14]

$$2[Yb\{(Me_3Si)_3C\}_2] + 4\,Et_2O \xrightarrow[-(Me_3Si)_3CH,\ -CH_2=CH_2]{\mathbf{7o}} \underset{\mathbf{46o}}{[(Me_3Si)_3CYb(OEt)(OEt_2)]_2} \quad (22)$$

$[(Me_3Si)_2CHYb(OAr)(thf)_3]$ **47o**

The monomeric phenoxide **47o** is formed in the reaction of $[Yb(OAr)_2(thf)_3]$ with $KCH(SiMe_3)_2$. In this case the very bulky ArO ligand prevents the formation of a phenoxide-bridged dinuclear complex (Ar = 2,6-tBu_2-4-MeC_6H_2).[13]

Grignard-type organolanthanide complexes represent a synthetically important though structurally not fully understood class of compounds. Grignard analogues of the type RLnX (R = alkyl, aryl; Ln = Sm, Eu, Yb; X = halogen) have been thoroughly investigated since 1970 and are now widely used in organic synthesis.[5] The ytterbium compounds RYbI, in particular, are easily accessible from RI and elemental ytterbium in THF. The resulting deeply colored THF solutions are usually used in situ for subsequent reactions. These organolanthanide(II) compounds behave somewhat like typical Grignard compounds, although there are several interesting differences in reactivity. Until recently compounds of the type RLnX had never been isolated as pure materials nor had they been characterized spectroscopically or by X-ray diffraction. In 1994 Eaborn et al. reported the first preparation and structural characterization of such compounds.[14] The homoleptic dialkylytterbium(II) complex $[Yb\{(Me_3Si)_3C\}_2]$ **7o** reacts with iodomethane or 1,2-diiodoethane to give the ytterbium Grignard compound **48o**, which can be isolated in the form of greenish-yellow, exceedingly air-sensitive crystals. In complete analogy to normal Grignard compounds, **48o** could be prepared by direct reaction of elemental ytterbium with the corresponding silyl-substituted alkyl iodide [Eq. (23)].[14, 58] The crystal structure determination of **48o** revealed that the central Yb_2I_2 ring is planar (Fig. 9).

$$2\,Yb + 2(Me_3Si)_3CI \xrightarrow{Et_2O} \underset{\mathbf{48o}}{[\{[(Me_3Si)_3C]Yb(\mu\text{-}I)(Et_2O)\}_2]} \quad (23)$$

Several other compounds of this class were synthesized by varying the substituents.[58] The ytterbium complexes **49o**

$[\{[(Me_3Si)_2(Me_2XSi)C]Yb(\mu\text{-}I)(Et_2O)\}_2]$ **49o**, X = OMe, Ph, $CH{=}CH_2$

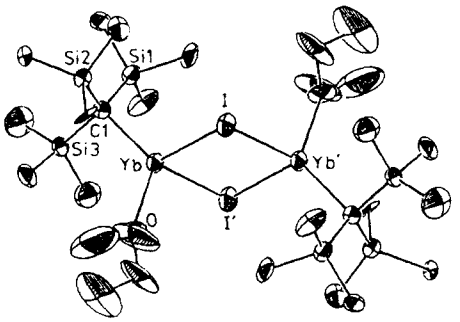


Fig. 9. Molecular structure of $[\{[(Me_3Si)_3C]Yb(\mu\text{-}I)(Et_2O)\}_2]$ **48o** in the crystal.

have been prepared according to Equation (23). Figure 10 depicts the unusual molecular structure of **49o** (X = $CH{=}CH_2$), in which the very rare lanthanide-vinyl π interaction occurs.

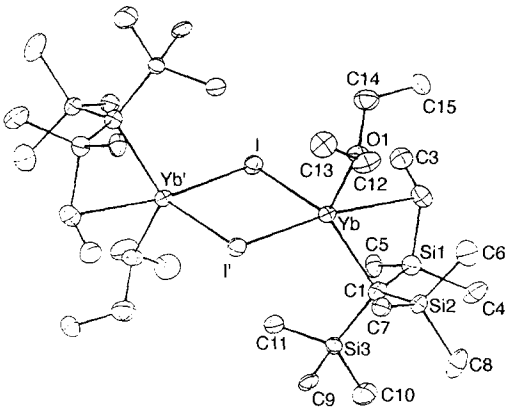

Fig. 10. Molecular structure of $[\{[(Me_3Si)_2(Me_2SiCH{=}CH_2)C]Yb(\mu\text{-}I)(Et_2O)\}_2]$ **49o** (X = $CH{=}CH_2$) in the crystal.

A typical Schlenk-equilibrium could be detected for all Grignard-type ytterbium(II) complexes in nonpolar organic solvents such as toluene [Eq. (24)].

$$[RYbI]_2 \rightleftharpoons R_2Yb + YbI_2 \qquad (24)$$

Until recently monoorganolanthanide(III) dihalides, $RLnX_2$, were still only poorly characterized. These compounds can likewise be considered as Grignard-type analogous compounds. They can be easily prepared in situ by alkylation of $LnCl_3$ or LnI_3 with organolithium compounds.[5] A remarkable result from an organometallic viewpoint was the first crystal structure determination of a "lanthanide(III) Grignard compound" of this type, which was reported by Chen et al.[59] Anhydrous gadolinium trichloride reacts with phenyllithium in a 1:1 molar ratio to give the well-defined seven-coordinate phenyl complex **50i**. The length of the gadolinium–carbon σ bond is 242(2) pm (Fig. 11).

$[PhGdCl_2(thf)_4]$ **50i**

Organolanthanide complexes containing different σ-alkyl ligands are still virtually unknown. A structurally characterized example is the heteroleptic anionic samarium complex **51g** with

$[\{(Me_3Si)_2CH\}_3Sm(\mu\text{-}Me)Li(pmdeta)]$ **51g**

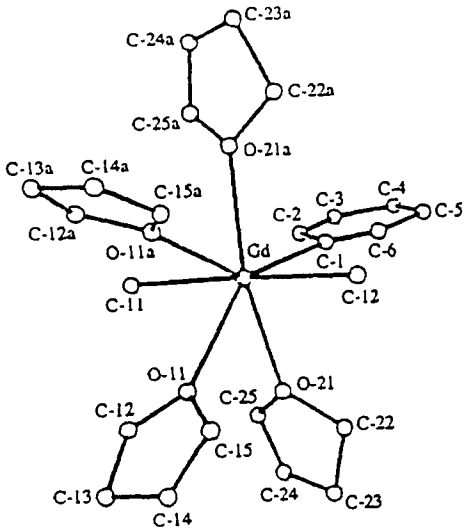

Fig. 11. Molecular structure of $[PhGdCl_2(thf)_4]$ **50i** in the crystal.

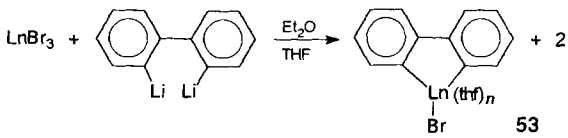
a methyl group bridging samarium and lithium.[60] Likewise, metallacycles containing a lanthanide atom in the ring are very rare species. Five-membered "lanthanols" such as **52f** and **52i** have been described, but are insufficiently characterized.[61]

$[Ph_4C_4Ln(\mu\text{-}Cl)_2Li(thf)_n]$, **52f**, Ln = Nd; **52i**, Ln = Gd

The same was true until recently for the metallacyclic products obtained by reacting anhydrous lanthanide tribromides with *o*-dilithiobiphenyl. The compounds **53** isolated as THF adducts were initially thought to be five-membered metallacycles [Eq. (25)].[62]



(25)

The reaction of $SmBr_3$ with *o*-dilithiobiphenyl $Li_2C_{12}H_8$ was recently reinvestigated and the true nature of the reaction product **54g** elucidated.[63] Contrary to the originally proposed structure, the product does not contain a five-membered metallacycle. Instead, a dimetalated *o*-quaterphenyl ligand is formed through dimerization [Eq. (26), Fig. 12], which with samarium

$$6SmBr_3 + 6Li_2C_{12}H_8 \xrightarrow[-H_2,\ -12\,LiBr]{-2\,Sm,\ -2\,SmBr_3} [(C_{24}H_{16})Sm(\mu\text{-}Br)(thf)_2]_2 \cdot C_{24}H_{14} \qquad (26)$$

54g

forms a nine-membered metallacycle. Dimerization through bromide ligands leads to the formation of the dinuclear product. The hydrocarbon dibenzonaphthacene ($C_{24}H_{14}$), which is formed as a by-product during the reaction, is intercalated in the crystal lattice.

Alkyllanthanide(III) alkoxides form a small, though very promising class of compounds. Such compounds are of great interest as intermediates in the lanthanide-catalyzed polymerization of 1,3-dienes. A typical multicomponent catalyst system

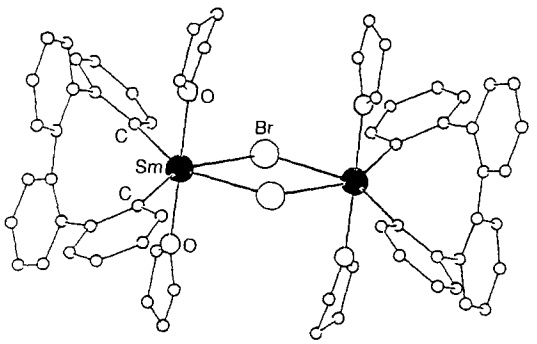


Fig. 12. Molecular structure of $[(C_{24}H_{16})Sm(\mu\text{-}Br)(thf)_2]_2 \cdot C_{24}H_{14}$ **54g** in the crystal (intercalated $C_{24}H_{14}$ omitted).

for diene polymerization is $Nd(OiPr)_3/AlEt_3/Et_2AlCl$. The heterobimetallic alkyllanthanide(III) alkoxide **55f** could be isolated

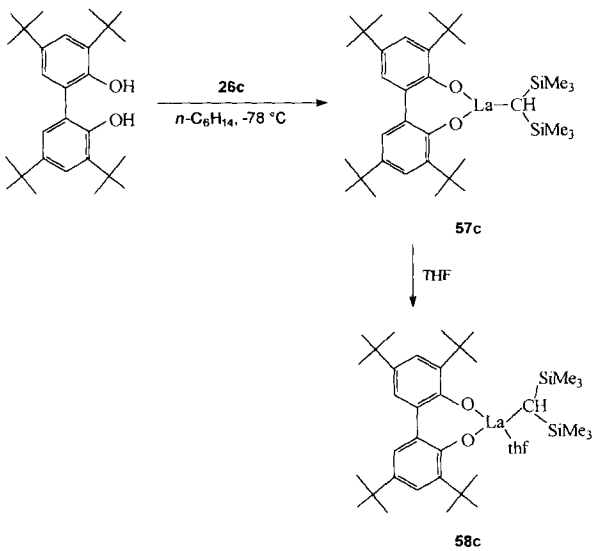
$[\{Nd_6Al_3(\mu\text{-}Cl)_6(\mu\text{-}Et)_9Et_5(OiPr)\}_2]$ **55f**

from this system and characterized by X-ray crystallography.[64] The complex structure of this catalytically active intermediate underlines the fact that lanthanide alkoxides tend to aggregate as clusters. Only in very rare cases is the constitution of lanthanide alkoxides as simple as implied by the formula $Ln(OR)_3$.[65] A series of heterobimetallic alkyllanthanide(III) alkoxides has been synthesized in a simple way by alkylation of lanthanide alkoxides [Eq. (27)].[66] The yttrium compound **56b** is also obtained by alkylation of the alkoxide cluster $[Y_3(OtBu)_9(thf)]$ with excess $AlMe_3$.[67]

$$Ln(OtBu)_3 + 3\,AlMe_3 \longrightarrow [Ln\{(\mu\text{-}OtBu)(\mu\text{-}Me)AlMe_2\}_3] \quad (27)$$

56, Ln = Y, Pr, Nd

The stabilization of monomeric alkyllanthanide(III) alkoxides was first achieved by employing the sterically demanding chelate ligand 3,3′,5,5′-tetra-*tert*-butyl-biphenyl-2,2′-diolate. In this case unsolvated $[La\{CH(SiMe_3)_2\}_3]$ **26c** served as a useful starting material (Scheme 3).[68]



Scheme 3. Synthesis of alkyllanthanum(III) diolates.

Special nitrogen ligands are also suitable for stabilizing heteroleptic alkyllanthanide compounds. In recent years porphyrin ligands have been successfully employed. For example, treatment of $[ScCl_3(thf)_3]$ with $[Li(thf)_4][Li(oep)]$ or $[Li_2(OEP)(thf)_2]$ affords the chloro complex [ScCl(oep)] **59a** (oep = octaethylporphyrin dianion). Substitution of the chloride ligand in **59a** leads to the corresponding scandium amides, alkoxides, or σ-alkyl derivatives. Alkylation affords the unsolvated alkyl complexes [ScR(oep)] **60**.[69, 70] Evidently, the small ionic radius

[ScCl(oep)] **59a** [ScR(oep)] **60**, R = Me, CH_2tBu, $CH(SiMe_3)_2$

of the respective lanthanide facilitates the synthesis of porphyrin derivatives. Thus porphyrin-stabilized alkyllanthanide compounds can also be obtained with yttrium and lutetium as central atoms.[41] The thermal reaction of the homoleptic alkyl complexes $[Ln\{CH(SiMe_3)_2\}_3]$ with H_2oep in toluene has been demonstrated to be an elegant and effective access to such complexes [Eq. (28)]. This method completely circumvents compli-

$$[Ln\{CH(SiMe_3)_2\}_3] + H_2oep \xrightarrow[-2\,CH_2(SiMe_3)_2]{} [(oep)LnCH(SiMe_3)_2] \quad (28)$$

(26b, p) **61**, Ln = Y, Lu

cations that may arise from the formation of solvent adducts and/or incorporation of halide ions. The lutetium derivative **61p** has been characterized by an X-ray crystal structure analysis. Figure 13 depicts the square-planar coordination geometry.

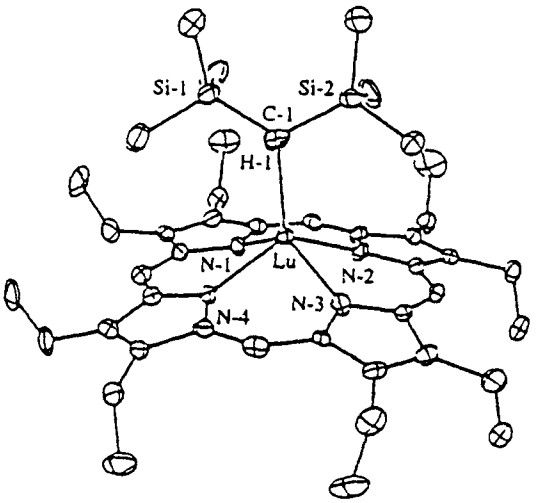


Fig. 13. Molecular structure of $[(oep)LuCH(SiMe_3)_2]$ **61p** in the crystal.

Alternatively, the porphyrin-stabilized alkyllanthanide(III) compounds **61** are accessible by a two-step synthetic procedure, in which the presence of coordinating solvent or alkali metal halides can also be avoided [Eqs. (29) and (30)].[41]

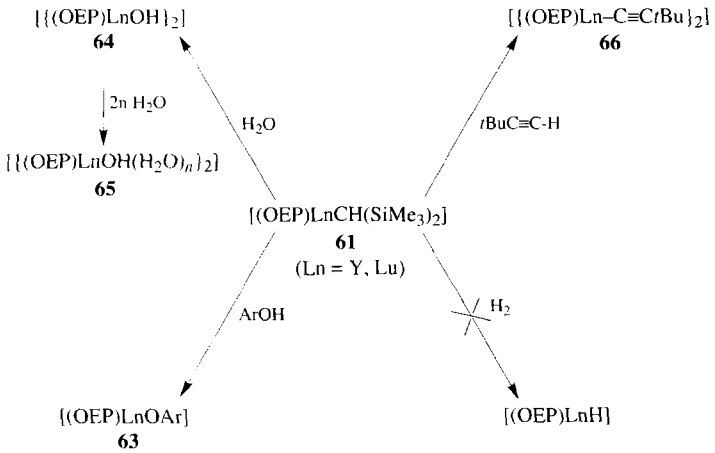
$$[Ln(2,6\text{-}tBu_2C_6H_3O)_3] + H_2oep \xrightarrow[-2\,2,6\text{-}tBu_2C_6H_3OH]{} [(oep)LnOC_6H_3tBu_2] \quad (29)$$

62 **63**

$$\mathbf{63} + LiCH(SiMe_3)_2 \xrightarrow[-2,6\text{-}tBu_2C_6H_3OH]{} [(oep)LnCH(SiMe_3)_2] \quad (30)$$

61, Ln = Y, Lu

Just like other highly reactive alkyllanthanide(III) compounds, the complexes **61** are interesting starting materials for subsequent reactions, which are summarized in Scheme 4.[41] The very facile hydrolysis leads to the dimeric hydroxo complexes **64**, and the σ-alkyl groups are easily substituted in reactions



Scheme 4. Derivative chemistry of the complexes **61**.

with phenols or terminal alkynes. In contrast, hydrogenolysis to the corresponding hydrides cannot be achieved even under a hydrogen pressure of 20 bar. This unexpected result is in marked contrast to the chemistry of the related metallocenes $[(C_5Me_5)_2LnCH(SiMe_3)_2]$, which readily react with hydrogen at normal pressure to give the dimeric hydrides $[\{(C_5Me_5)_2Ln(\mu\text{-}H)\}_2]$.[71–73]

The heteronuclear alkyl complexes **68b** can be prepared by stepwise reaction of the yttrium alkoxide **63b** with methyllithium and trimethylaluminum (Scheme 5).[41]

$$[(oep)YOC_6H_3tBu_2] + 2\,MeLi \xrightarrow[-LiOC_6H_3tBu_2]{Et_2O} [(oep)Y(\mu\text{-}Me)_2Li(Et_2O)]$$
63b **67b**

$$\xrightarrow{Al_2Me_6} [(oep)Y(\mu\text{-}Me)_2AlMe_2]$$
68b

Scheme 5. Synthesis of $[(oep)Y(\mu\text{-}Me)_2AlMe_2]$ **68b**.

The reaction sequence shown in Scheme 5 parallels the multistep synthesis of $[(C_5Me_5)_2LuMe]$[74] with the only exception that the final step, that is the elimination of trimethylaluminum with Lewis bases, cannot be reproduced in the porphyrin series. Treatment of **68b** with Lewis bases such as pyridine only leads to the formation of adducts and not to unsolvated [YMe(oep)]. O_2 selectively attacks the bridging methyl groups in **68b** leading to the formation of the YAl alkoxide **69b**.

$[(oep)Y(\mu\text{-}OMe)_2AlMe_2]$ **69b**

More recently several other auxiliary ligands have been found that are capable of stabilizing σ-alkyllanthanide(III) complexes. These ligands include sterically demanding amido ligands as well as benzamidinate and pyrazolylborate ions. For example, an alkyllanthanide(III) amide is formed upon treatment of

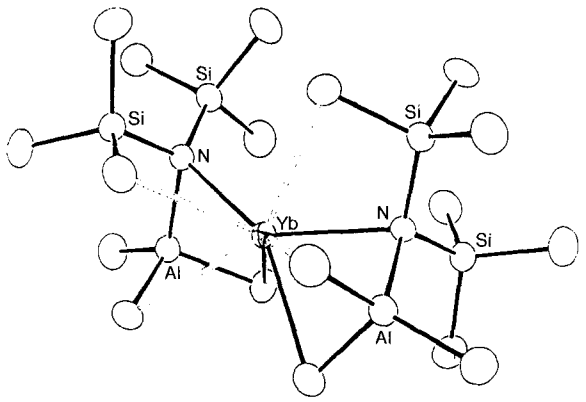


Fig. 14. Molecular structure of $[Yb\{N(SiMe_3)_2\}_2(AlMe_3)_2]$ **70o** in the crystal.

$[Yb_2\{N(SiMe_3)_2\}_4]$ with two equivalents of Al_2Me_6.[75] The reaction product **70o** contains four Yb-Me-Al and two Yb-Me-Si bridges (Fig. 14).

$[Yb\{N(SiMe_3)_2\}_2(AlMe_3)_2]$ **70o**

The potentially tridentate silylamide ion $[N(SiMe_2CH_2PMe_2)_2]^-$ developed by Fryzuk et al. has also been successfully employed in organolanthanide chemistry.[76–78] The stepwise preparation of heteroleptic alkyllanthanide(III) amides is illustrated in Scheme 6. The σ-alkyl complexes **72** are fluxional in solution and decompose upon heating under elimination of the hydrocarbon RH.

$$LnCl_3 + 2\,KN(SiMe_2CH_2PMe_2)_2 \xrightarrow[-2\,KCl]{} [LnCl\{N(SiMe_2CH_2PMe_2)_2\}_2]$$
71

$$\xrightarrow[-LiCl]{RLi} [LnR\{N(SiMe_2CH_2PMe_2)_2\}_2]$$
72

(Ln = La, Lu)

Scheme 6. Synthesis of $[LnR\{N(SiMe_2CH_2PMe_2)_2\}_2]$ **72**.

The synthesis of bis-σ-alkyllanthanide complexes containing only one chelating ligand proved to be more difficult. Such complexes have only become available by combining the very bulky silylamide ion $[N(SiMe_2CH_2PiPr_2)_2]^-$ with the small Sc^{3+} ion.[79] The complexes **73a** and **74a** have

$[\{N(SiMe_2CH_2PiPr_2)_2\}ScEt_2]$
73a

$[\{N(SiMe_2CH_2PiPr_2)_2\}Sc(CH_2SiMe_3)_2]$
74a

been prepared (cf. Scheme 6) and structurally characterized by X-ray diffraction (Fig. 15). A high reactivity and catalytic activity can be expected for these 10-electron complexes.

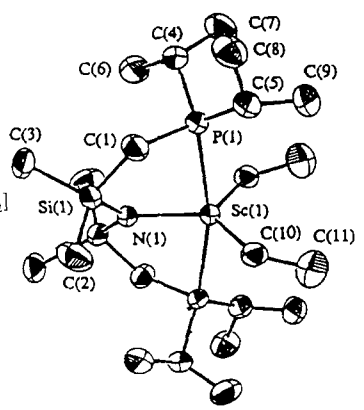

Fig. 15. Molecular structure of $[\{N(SiMe_2CH_2PiPr_2)_2\}ScEt_2]$ **73a** in the crystal.

Hydrotris(pyrazol-1-yl)borate ligands are enjoying increased popularity in the organometallic chemistry of lanthanides. By using the sterically demanding anion $[HB(3\text{-}t\text{Bu-}5\text{-Me-pz})_3]^-$, Takats et al. recently succeeded in preparing soluble, monosubstituted ytterbium(II) alkyl complexes.[80] The compounds **76o** (Fig. 16) and **77o** have been made by treatment of the precursor

$[\{HB(3\text{-}t\text{Bu-}5\text{-Me-pz})_3\}YbI(thf)]$ **75o**

$[\{HB(3\text{-}t\text{Bu-}5\text{-Me-pz})_3\}YbCH(SiMe_3)_2]$ **76o**

$[\{HB(3\text{-}t\text{Bu-}5\text{-Me-pz})_3\}Yb\{CH(SiMe_3)_2\}(Et_2O)]$ **77o**

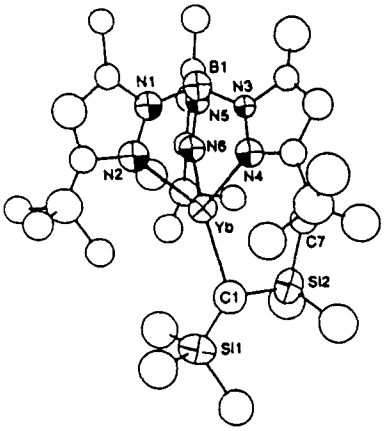

Fig. 16. Molecular structure of $[\{HB(3\text{-}t\text{Bu-}5\text{-Me-pz})_3\}YbCH(SiMe_3)_2]$ **76o** in the crystal.

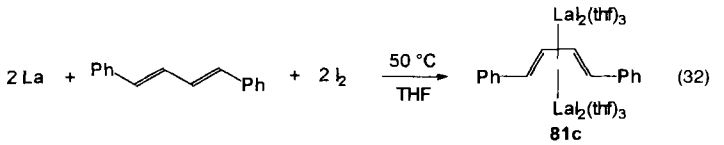
75o with alkyllithium reagents. These compounds are rare examples of organolanthanide(II) complexes with σ-bonded alkyl ligands.

Bulky heteroallylic ligands such as the benzamidinate ions $[RC_6H_4C(NSiMe_3)_2]^-$ have recently been established as useful alternatives to the cyclopentadienyl ligands. Thus, the yttrium(III) benzamidinates **80b** can be regarded as analogues of the metallocene $[(C_5Me_5)_2YCH(SiMe_3)_2]$. All these compounds exhibit comparable catalytic activities, for example, in olefin polymerizations. The alkyl derivatives **80b** are easily accessible by alkylation of the corresponding chloride or triflate precursors [Eq. (31)].[81–83]

$$[\{RC_6H_4C(NSiMe_3)_2\}_2YX(thf)_n] + LiCH(SiMe_3)_2$$
78b, X = Cl, $n = 1$
79b, X = O_3SCF_3, $n = 0$
$$\xrightarrow[-LiX]{} [\{RC_6H_4C(NSiMe_3)_2\}_2YCH(SiMe_3)_2] \quad (31)$$
80b, R = H, OMe, CF_3

In contrast to the organometallic chemistry of the d-block transition metals, diene complexes are particularly rare in the case of the lanthanides.[1–6] This is especially true for complexes without supporting cyclopentadienyl ligands. The first successful approaches in this direction have been reported in two recent papers: The diene-bridged dilanthanum complex **81c** was obtained by reacting finely divided elemental lanthanum with 1,4-diphenylbutadiene and iodine in THF [Eq. (32)].[84] The samarium analogue **81g** had already been made earlier using a similar synthetic procedure.[85]



81c (32)

An X-ray structure determination of the isolated red crystals of **81c** revealed the presence of an "inverse sandwich complex" in which the two lanthanum atoms are symmetrically bridged by the $\eta^4:\eta^4$-coordinated diene ligand.[84] Structurally related "inverse sandwich complexes" have been prepared according to Equations (33) and (34) from naphthalene ($C_{10}H_8$).[86]

$$2[LaI_3(thf)_3] + 2Li + C_{10}H_8 \xrightarrow[-2LiI]{THF} [(\mu_2\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)\{LaI_2(thf)_3\}_2] \quad (33)$$
82c

$$2[EuI_2(thf)_2] + 2C_{10}H_8Li \xrightarrow[-2LiI\ -C_{10}H_8]{DME} [(\mu_2\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)\{EuI(dme)_2\}_2] \quad (34)$$
83h

The complexes **82c** (Fig. 17) and **83h** have been characterized by X-ray structure analyses. In both cases the lanthanide atoms are bridged by nonplanar naphthalene units bonded in diene-like fashion.

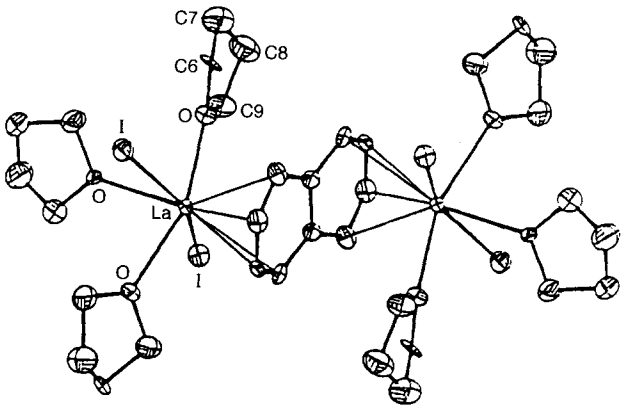


Fig. 17. Molecular structure of $[(\mu_2\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)\{LaI_2(thf)_3\}_2]$ **82c** in the crystal.

4. Alkenyl and Alkynyl Complexes

Well-characterized alkenyl- and alkynyllanthanide complexes remain a relatively unexplored class of compounds. Ytterbium reacts with $Hg(CH{=}CHCl)_2$ to give the insufficiently characterized bis(β-chlorovinyl)ytterbium **84o**.[87] However, a well-defined alkynyl complex of divalent ytterbium could be synthesized by using the sterically demanding hydrotris(3,5-dimethylpyrazol-1-yl)borate ligand. The dark red phenylacetylide **86o** was obtained in good yield by reaction of the amide **85o** with phenylacetylene.[80]

$[Yb(CH{=}CHCl)_2]$ **84o**

$[\{HB(3,5\text{-}Me_2pz)_3\}Yb\{N(SiMe_3)_2\}]$ **85o**

$[\{HB(3,5\text{-}Me_2pz)_3\}YbC{\equiv}CPh]$ **86o**

It was reported that the blue solutions of elemental europium or ytterbium in liquid ammonia react with alkynes with terminal triple bonds to give bis(alkynyl)lanthanide(II) complexes. Alkynyl derivatives of divalent europium and ytterbium are also available by transmetalation of $Hg(C{\equiv}CR)_2$ with the respective metals [Eq. (35)].[88, 89]

$$Ln + Hg(C{\equiv}CR)_2 \xrightarrow{THF} [Ln(C{\equiv}CR)_2] + Hg \quad (35)$$
87h, o
R = *n*Bu; Ln = Eu, Yb
R = Ph; Ln = Yb

In the case of trivalent lanthanides the tris(alkynyl) complexes **88p**[27] and **89**[90, 91] have been described. Virtually nothing is known about the molecular structures of all these compounds; however, it is likely that the unsolvated complexes $[Ln(C{\equiv}CR)_2]$ and $[Ln(C{\equiv}CR)_3]$ are polymeric materials with bridging alkynyl ligands.

$[Lu(C{\equiv}CtBu)_3]$ **88p**

$[Ln(C{\equiv}CPh)_3]$ **89**, Ln = Pr, Sm, Eu, Gd, Tb, Er, Yb

A well-defined μ-ethynyl complex of yttrium is formed by protolysis of the alkyl derivative **80b** (R = H) with acetylene [Eq. (36)]. Figure 18 shows the dimeric structure of **90b** with bridging ethynyl ligands.

$$2[\{PhC(NSiMe_3)_2\}_2YCH(SiMe_3)_2] \quad \textbf{80b} \xrightarrow[-2\,CH_2(SiMe_3)_2]{2\,HC{\equiv}CH} [\{[PhC(NSiMe_3)_2]_2Y(\mu\text{-}C{\equiv}CH)\}_2] \quad \textbf{90b} \qquad (36)$$

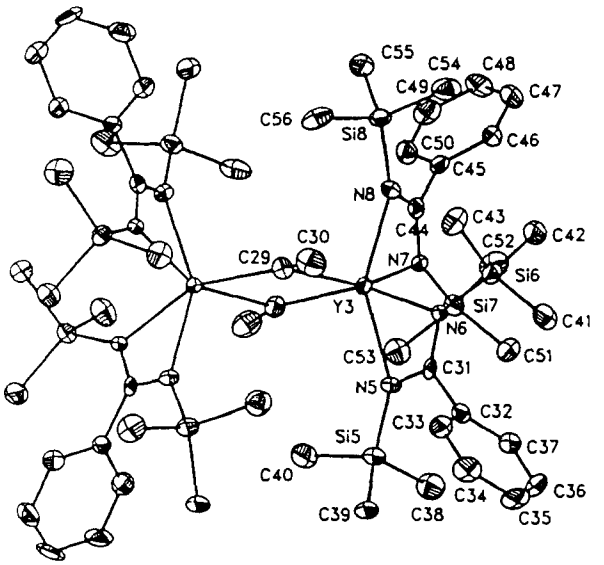

Fig. 18. Molecular structure of $[\{[PhC(NSiMe_3)_2]_2Y(\mu\text{-}C{\equiv}CH)\}_2]$ **90b** in the crystal.

5. Allyl Complexes

Homoleptic tris(η^3-allyl)lanthanides are unknown. Evidently, the steric bulk of three relatively small allyl ligands is not sufficient to coordinatively saturate the large lanthanide ions. Instead, reactions of anhydrous lanthanide trichlorides with allyllithium have produced a series of interesting anionic allyl complexes. The complexes **91**–**93** have been obtained depending on the reaction conditions and the solvents used.[92–94] Only recently it has been shown that such complexes are also available by a one-pot reaction in which the allyllithium reagent is prepared in situ from tetraallyltin and *n*-butyllithium [Eq. (37)].[92]

$[Li(dioxane)_n][Ln(\eta^3\text{-}C_3H_5)_4]$ **91**, Ln = Ce, Pr, Nd, Sm, Gd, $n = 2$; Ln = Y, $n = 2.5$; Ln = La, $n = 3$

$[Li_2(thf)_n][Ln(\eta^3\text{-}C_3H_5)_5]$ **92**, Ln = Y, La, $n = 2.5$; Ln = Ce, Pr, Nd, Sm, $n = 3$

$[Li_2(dioxane)_n][Ln(\eta^3\text{-}C_3H_5)_5]$ **93**, Ln = Ce, Nd, Sm, Gd, Dy, Ho, Er; $n = 1,3$

$$LaCl_3 + 2Sn(C_3H_5)_4 + 4n\text{BuLi} \xrightarrow[2.\ Et_2O/\text{dioxane}]{1.\ \text{toluene}} [Li(\mu\text{-dioxane})_{3/2}][La(\eta^3\text{-}C_3H_5)_4] + 3\,LiCl + 2n\text{Bu}_2Sn(C_3H_5)_2 \qquad (37)$$

In compound **94c** the central lanthanum atom is surrounded by the four η^3-allyl ligands in a distorted tetrahedral fashion (Fig. 19). The bridging dioxane molecules and the lithium ions form a two-dimensional sheet in the crystal lattice.

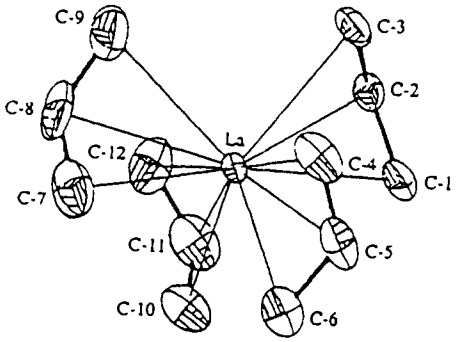

Fig. 19. Structure of the anion in $[Li(\mu\text{-dioxane})_{3/2}][La(\eta^3\text{-}C_3H_5)_4]$ **94c** in the crystal.

By partial protolysis one allyl ligand in **94c** can be selectively replaced by a cyclopentadienyl derivative, and in this way, the complexes **95c** can be isolated.[95] Such anionic allyllanthanide(III) complexes are valuable homogeneous catalysts for diene polymerizations.[5] More complicated coordination compounds containing η^3-allyl ligands have been obtained by reactions of anhydrous lanthanide trichlorides with allyl-Grignard reagents in the presence of TMEDA.[96] Among the structurally characterized products are **96d** and **97**.

$[Li(dioxane)_2][CpLa(C_3H_5)_3]$ **95c**, Cp = C_5H_5, C_5Me_5, indenyl, fluorenyl

$[(\eta^3\text{-}C_3H_5)_2Ce(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_3Mg_2(tmeda)_2]$ **96d**

$[(\eta^3\text{-}C_3H_5)_2Ln(\mu_3\text{-}Br)_2(\mu\text{-}Br)_3Mg_2(Et_2O)_4]$ **97**, Ln = Ce, Nd

The use of the tridentate amido ligand $[N(SiMe_2CH_2PMe_2)_2]^-$ also allowed the synthesis of a heteroleptic allyllanthanide complex.[77, 78] Treatment of **71b** with $(C_3H_5)MgCl$ led to elimination of one chelating amido ligand and formation of the chloro-bridged binuclear complex **98b**.

$[(\eta^3\text{-}C_3H_5)Y\{N(SiMe_2CH_2PMe_2)_2\}(\mu\text{-}Cl)]_2$ **98b**

6. Complexes Containing Cyclopentadienyl Analogues as Ligands

Cyclopentadienyl-analogous ligands are increasingly being employed in organolanthanide chemistry. Among these ligands are pentadienyl anions as well as five-membered anionic hetero-

cycles containing nitrogen, phosphorus, or arsenic in the ring. η^5-Cyclohexadienyl ligands, which have been reported to form interesting coordination compounds with uranium,[97,98] have so far not been used in organolanthanide chemistry.

6.1. Pentadienyl Complexes

In many cases transition metal complexes with pentadienyl ligands closely resemble the corresponding cyclopentadienyl complexes. Due to this relationship bis(pentadienyl) metal complexes are often termed "open metallocenes". One lanthanide derivative with "open cyclopentadienyl ligands" was synthesized as long ago as 1982. Bright green tris(2,4-dimethylpentadienyl)neodymium **99f** is formed when anhydrous neodymium trichloride is treated with three equivalents of potassium 2,4-dimethylpentadienide (KC_7H_{11}) in THF [Eq. (38)].[99]

$$NdCl_3 + 3KC_7H_{11} \xrightarrow{THF} \underset{\mathbf{99f}}{[Nd(C_7H_{11})_3]} + 3KCl \qquad (38)$$

A crystal structure analysis of the homoleptic complex **99f** revealed the presence of three equivalent η^5-coordinated 2,4-dimethylpentadienyl ligands. Meanwhile several other pentadienyllanthanide complexes have been reported, including the compounds **99**–**101**.[100,101] The tris(η^5-2,4-dimethylpentadienyl) complexes **99f**, **99i**, and **99p** have been structurally characterized. While the gadolinium complex adopts the same molecular structure as the neodymium compound, an interesting structural difference is found for the coordination mode of the three pentadienyl ligands in **99p**. Due to the smaller ionic radius of lutetium only two 2,4-dimethylpentadienyl ligands in this molecule are η^5-coordinated, while the third ligand is η^3-bonded (Fig. 20). This example nicely illustrates how the flexible pentadienyl ligands are able to adapt to the different ionic radii of the lanthanides.[101]

$[Ln(C_7H_{11})_3]$ **99**, Ln = La, Sm, Gd, Tb, Lu

$[(C_7H_{11})LnCl_2(thf)_3]$ **100**, Ln = Nd, Sm, Gd

$[(C_7H_{11})_2LnCl(thf)]$ **101**, Ln = Nd, Sm, Gd

A novel way of modifying pentadienyl ligands involves the connection of two of these anions through a hydrocarbon chain.[102] A bridged bis(pentadienyl) dianion (bpd) of this kind could be generated by deprotonation of two methyl groups in 2,4,7,9-tetramethyl-1,3,7,9-decatetraene. Subsequent reaction of the resulting potassium salt with ytterbium diiodide afforded the "open" ytterbium(II) metallocene **102o** (Fig. 21), which can be regarded as a pentadienyl analogue of $[(C_5Me_5)_2Yb(thf)_2]$. Thus far nothing has been reported about the reactivity of **102o**.

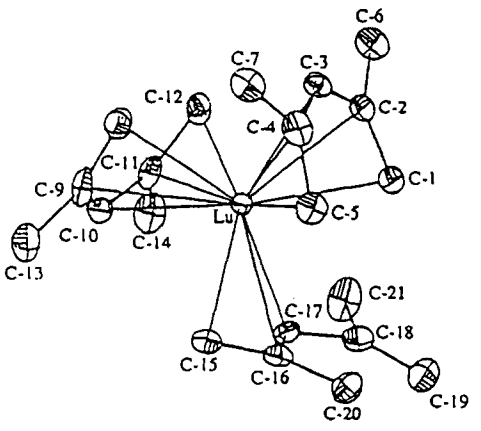

Fig. 20. Molecular structure of $[Lu(C_7H_{11})_3]$ **99p** in the crystal.

$[(bpd)Yb(thf)_2]$ **102o**

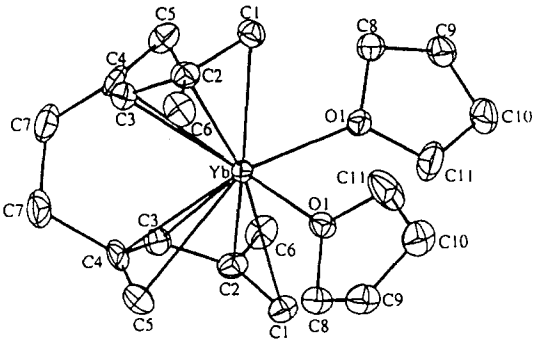

Fig. 21. Molecular structure of $[(bpd)Yb(thf)_2]$ **102o** in the crystal.

6.2. Complexes Containing Five-Membered Heterocycles as Ligands

A completely new development in organolanthanide chemistry is the use of anionic nitrogen, phosphorus, or arsenic heterocycles as ligands. Substituted pyrrolyl, phospholyl, or arsolyl ligands may turn out to be interesting alternatives to the ubiquitous pentamethylcyclopentadienyl ligands. Furthermore, the additional donor function could open up new possibilities for the construction of heteronuclear complexes.

At first glance nitrogen heterocycles appear to be less suited as π ligands for lanthanide complexes. Since the Ln^{3+} ions are known to be hard Lewis acids one would expect a preferred σ-coordination through the nitrogen atom. By introducing suitable substituents at the ring Schumann et al. succeeded in the first synthesis of organolanthanide complexes with π-bonded pyrrolyl ligands. Pyrrolyl-analogues of the known bis(pentamethylcyclopentadienyl)lanthanide(II) complexes are easily accessible according to Equation (39).[103]

$$[LnI_2(thf)_x] + 2Na[2,5\text{-}tBu_2C_4H_2N] \xrightarrow[-2NaI]{} \underset{\mathbf{103},\ Ln = Sm,\ Yb}{[(2,5\text{-}tBu_2C_4H_2N)_2Ln(thf)]} \qquad (39)$$

Mono- and bis(2,5-di-*tert*-butylpyrrolyl) complexes have been synthesized starting from anhydrous lanthanide trichlorides [Eqs. (40) and (41), respectively].[103,104] Complex **104o**

$$[YbCl_3(thf)_2] + Na[2,5\text{-}tBu_2C_4H_2N] \xrightarrow[-NaCl]{} \underset{\mathbf{104o}}{[(2,5\text{-}tBu_2C_4H_2N)YbCl_2(thf)_2]} \qquad (40)$$

$$2NdCl_3 + 4Na[2,5\text{-}tBu_2C_4H_2N] \xrightarrow[-2NaCl]{THF} \underset{\mathbf{105f}}{[(2,5\text{-}tBu_2C_4H_2N)_2Nd(\mu\text{-}Cl)_2\{Na(thf)\}_2(\mu\text{-}Cl)_2Nd(2,5\text{-}tBuC_4H_2N)_2]} \qquad (41)$$

is monomeric in the crystal (Fig. 22); in **105f** two [2,5-tBu$_2$C$_4$H$_2$N]$_2$NdCl "molecules". These results demonstrate that *N*-coordination of pyrrolyl ligands can be successfully avoided by introduction of bulky substituents, thus allowing the preparation of η^5-azacyclopentadienyl complexes of the lanthanides.

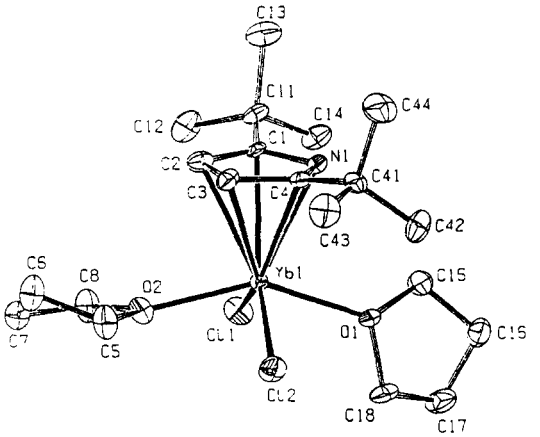

Fig. 22. Molecular structure of [(2,5-tBu$_2$C$_4$H$_2$N)YbCl$_2$(thf)$_2$] **104o** in the crystal.

Lanthanide(II) complexes containing tetrasubstituted phospholyl and arsolyl ligands have been obtained by treatment of lanthanide diiodides with two equivalents of K(C$_4$Me$_4$E) (E = P,As) [Eq. (42)].[105, 106]

$$[LnI_2(thf)_2] + 2K(C_4Me_4E) \xrightarrow[-2KI]{} [(C_4Me_4E)_2Ln(thf)_2] \quad (42)$$

106, **107**, Ln = Sm, Yb; E = P, As

[(2,5-Ph$_2$C$_4$H$_2$P)$_2$Yb(thf)$_2$] **108o**

Reductive cleavage of the E–E bond in the corresponding biphospholyl or biarsolyl derivatives by ytterbium affords the same products. The molecular structure of **108o** (Fig. 23) was determined by X-ray diffraction and illustrates the close relationship to analogous lanthanide(II) metallocenes such as [(C$_5$Me$_5$)$_2$Sm(thf)$_2$].[105]

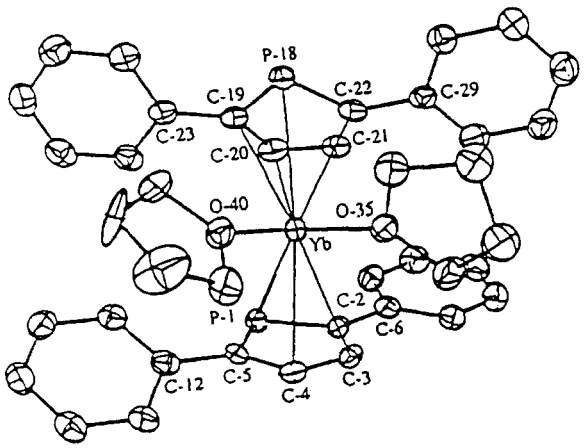

Fig. 23. Molecular structure of [(2,5-Ph$_2$C$_4$H$_2$P)$_2$Yb(thf)$_2$] **108o** in the crystal.

Of special interest with regard to derivative chemistry and possible catalytic applications are phospholyl analogues of the well-known bis(pentamethylcyclopentadienyl)lanthanide(III) halides [(C$_5$Me$_5$)$_2$Ln(μ-Cl)$_2$Li(solv.)$_2$] (solv. = solvent). First examples of such complexes have already been reported.[107] Thus, Li(C$_4$Me$_4$P) was generated in situ from bis(tetramethylphospholyl)butane, and subsequent treatment with LnCl$_3$ in a 2:1 molar ratio afforded the disubstituted products **109** in moderate yields [Eq. (43)].

$$LnCl_3 + 2Li(C_4Me_4P) \xrightarrow[-LiCl]{solv.} [(C_4Me_4P)_2Ln(\mu\text{-}Cl)_2Li(solv.)_2] \quad (43)$$

109b, Ln = Y; solv. = 1/2 DME
109p, Ln = Lu; solv. = Et$_2$O

These reactions are not always as straightforward as implied by Equation (43). This was demonstrated by the recently reported reaction of SmCl$_3$ with three equivalents of K(C$_4$Me$_4$P) in toluene, which led to the polymeric product **110g** (Fig. 24).[108]

[(C$_4$Me$_4$P)$_6$Sm$_2$(KCl)$_2$(C$_7$H$_8$)$_3$]$_n$ **110g**

A different result was obtained when the sterically less demanding 3,4-dimethylphospholyl ligand was used. The reaction of SmCl$_3$ with K(C$_4$Me$_2$H$_2$P) in a 1:3 molar ratio yielded a red crystalline material which was shown by X-ray diffraction to be dimeric **111g**.[108]

[(η^5-C$_4$Me$_2$H$_2$P)$_4$\{μ-(η^5,η^1)-(C$_4$Me$_2$H$_2$P)\}$_2$Sm$_2$] **111g**

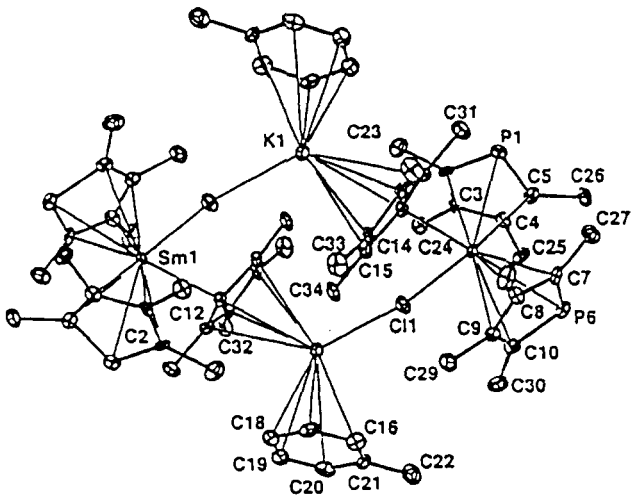

Fig. 24. Molecular structure of [(C$_4$Me$_4$P)$_6$Sm$_2$(KCl)$_2$(C$_7$H$_8$)$_3$]$_n$ **110g** in the crystal.

7. Arene Complexes

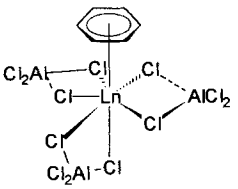
Lanthanide ions can participate in η^6 interactions with benzene derivatives, although the number of well-characterized arene complexes is still fairly small. The most important and best-known compounds are bimetallic arene complexes of the type [(η^6-arene)Ln(AlCl$_4$)$_3$] **112**–**114**.[109–114] In contrast to the anhydrous lanthanide trichlorides, these substances are soluble in hydrocarbons. The synthetic route involves treatment of anhydrous lanthanide trichlorides with AlCl$_3$ in the presence of

the arene ligand. Most conveniently these preparations are carried out in the appropriate benzene derivative as solvent [Eq. (44)].

$$LnCl_3 + 3AlCl_3 + C_6R_6 \longrightarrow [(\eta^6\text{-}C_6R_6)Ln(AlCl_4)_3] \quad (44)$$

112, **113**, Ln = La, Nd, Sm, Gd, Yb; R = H, Me

The bonding in these arene complexes can be described as an ion–dipole interaction between the Ln^{3+} ion and the π-electron system of the aromatic ring. Preferably electron-rich arenes such as benzene, toluene, and hexamethylbenzene are used. Among the well-characterized and in some cases structurally analyzed examples are the complexes **112**–**114**, which are usually monomeric in the crystal.[111, 112] The compounds **112f** and **112g** are isostructural with the uranium(III) analogue $[(\eta^6\text{-}C_6H_6)U(AlCl_4)_3]$. An exception is the tetramer $[\{(\eta^6\text{-}C_6H_6)Er(AlCl_4)_3\}_4]$ **112m**, in which the erbium ions are bridged by η^2-tetrachloroaluminate ligands.[115]



112

$[(\eta^6\text{-}C_6H_6)Ln(AlCl_4)_3]$ **112**, Ln = Nd, Sm, Yb

$[(\eta^6\text{-}C_6Me_6)Ln(AlCl_4)_3]$ **113**, Ln = Sm, Er, Yb

$[(\eta^6\text{-}C_6H_5Me)Ln(AlCl_4)_3]$ **114**, Ln = Y, Pr, Nd, Sm, Gd

Recently the first derivatization reactions of the arene complexes were reported. Addition of AlR_3 (R = Me, Et) to a toluene suspension of **114** results in the formation of clear solutions from which the alkylated products **115** and **116** can be isolated in good yields [Eq. (45)]. The synthesis of the complexes

$$[(\eta^6\text{-}C_6H_5Me)Ln(AlCl_4)_3] + 3AlR_3 \xrightarrow[-3AlCl_2R]{} [(\eta^6\text{-}C_6H_5Me)Ln(AlCl_3R)_3] \quad (45)$$

114 → **115**, R = Me; Ln = Y, Nd, Sm
116, R = Et; Ln = Pr, Nd

$[(\eta^6\text{-}C_6H_2Me_4)Nd(AlCl_3R)_3]$ **117f**, R = Me, Et

117f has been achieved in a similar way.[116] The neodymium complex **115f** was characterized by an X-ray crystal structure determination (Fig. 25). Initial experiments show that the complexes **115** and **116** catalyze the polymerization of ethylene and butadiene.

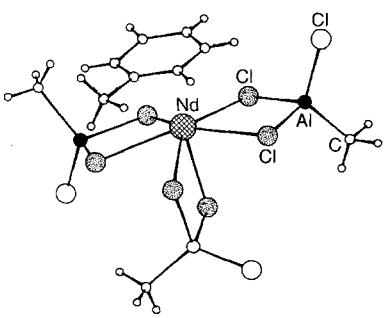


Fig. 25. Molecular structure of $[(\eta^6\text{-}C_6H_5Me)Nd(AlCl_3Me)_3]$ **115f** in the crystal.

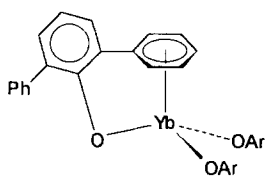
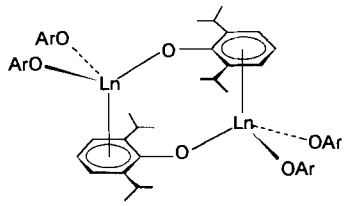
In several recent papers some interesting cases of η^6-arene coordination between lanthanide ions and phenyl groups of certain phenoxide ligands have been reported. Thus far two types of this novel bonding have been described.[117, 118] Treatment of lanthanide metal powders with $[Hg(C_6F_5)_2]$ and 2,6-diphenylphenol in THF affords the lanthanide(III) phenoxides **118** and their THF adducts **119**. No unusual structural features were noted in the crystallographically characterized THF adduct **119o**. However, in the unsolvated compound **118o** one phenyl substituent is in a geometrically favorable position which allows this ring to engage in a novel π-interaction with the central ytterbium atom. The reason for this additional η^6-arene coordination most likely lies in the sterically unsaturated character of the three-coordinate species $[Ln(2,6\text{-}OC_6H_3Ph_2)_3]$.

$[Ln(2,6\text{-}OC_6H_3Ph_2)_3]$ **118**, Ln = Nd, Sm, Er, Yb, Lu

$[Yb(2,6\text{-}OC_6H_3Ph_2)_3(thf)_2]$ **119o**



118o, Ar = $2,6\text{-}Ph_2C_6H_3$



120, Ar = $2,6\text{-}iPr_2C_6H_3$

Another variant was found in the lanthanide derivatives **120** (Ln = Nd, Sm, Er, Yb) of 2,6-diisopropylphenol, which have been synthesized in an analogous manner.[118] Centrosymmetric dimers are present in the crystal; the monomeric units are each linked through a Ln–O bond and η^6-arene coordination. These results demonstrate that the formation of lanthanide arene complexes occurs more frequently than originally anticipated.

8. Cyclooctatetraene Complexes

The first cyclooctatetraene lanthanide complexes were reported in 1969.[1–6] These materials were lanthanide(II) compounds of the type $[Ln(C_8H_8)]$ **121** (Ln = Eu, Yb). Initial synthetic achievements in this area were followed by a period of stagnation, which in recent years has been replaced by a significant increase in the research activity. Today it is generally accepted that the large, flat cyclooctatetraene ligand is an especially valuable alternative to the cyclopentadienyl ligands. This is an area of organolanthanide chemistry where numerous interesting results can be expected in the future.[119]

8.1. Lanthanide(II) Complexes

Well-defined lanthanide(II) complexes with cyclooctatetraene ligands are rare. Cyclooctatetraene reacts with the dark blue solutions of europium or ytterbium in liquid ammonia to give $[Ln(C_8H_8)]$ **121** [Eq. (46)].[1] The orange products are extremely

$$Ln + C_8H_8 \xrightarrow{NH_3(l)} [Ln(C_8H_8)] \quad (46)$$

121, Ln = Eu, Yb

$[(C_8H_8)Yb(C_5H_5N)_3]$ **122o**

air sensitive and insoluble in organic solvents. This behavior suggests a polymeric structure of the compounds. Polymeric $[Sm(C_8H_8)]$ **121g** is more easily available by reacting $[SmI_2(thf)_2]$ with $K_2C_8H_8$.[120]

The polymeric structure can be broken up by treatment of **121o** with pyridine. This results in the formation of soluble, monomeric **122o**, for which a crystal structure determination has been reported (Fig. 26).[121] The structural characterization of the anionic sandwich complexes **123o** and **124o** revealed that

$[K(diglyme)]_2[Yb(C_8H_8)_2]$ **123o** $[K(dme)]_2[Yb(C_8H_8)_2]$ **124o**

in these compounds cyclooctatetraene dianions act as bridging ligands between ytterbium and potassium.[122]

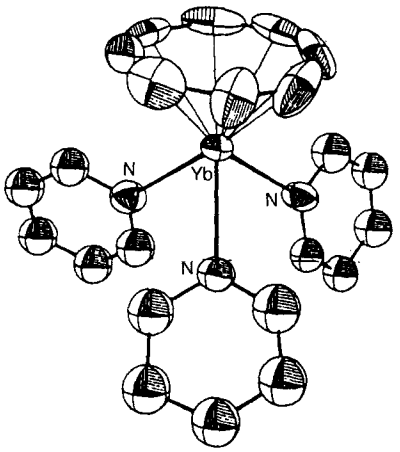


Fig. 26. Molecular structure of $[(C_8H_8)Yb(C_5H_5N)_3]$ **122o** in the crystal.

8.2. Lanthanide(III) Complexes

The first mono(cyclooctatetraene)lanthanide(III) halides were reported in 1971.[119, 123, 124] They are still among the most important starting materials for the preparation of other half-sandwich complexes of the lanthanides with cyclooctatetraene ligands. The complexes **125** are easily accessible by reaction of anhydrous lanthanide trichlorides with $K_2C_8H_8$ in a molar ratio of 1:1 [Eq. (47)].[125]

$$2LnCl_3 + 2K_2C_8H_8 \longrightarrow [\{(C_8H_8)Ln(\mu\text{-}Cl)(thf)_2\}_2] + 4KCl \quad (47)$$

125

Purification of the crystalline, intensely colored products can be achieved by Soxhlet extraction with THF. A crystal structure determination of the cerium compound **125d** revealed the presence of centrosymmetric, Cl-bridged dimers with η^8-coordinated cyclooctatetraene ligands.[1, 2, 119, 123, 124] The coordinated THF cannot be removed from the compounds without extensive decomposition.

An interesting change in the molecular structure is observed when the sterically highly demanding 1,4-bis(trimethylsilyl)-cyclooctatetraene ligand is used.[126, 127] The THF adducts $[LnCl_3(thf)_3]$ (Ln = Y, Sm, Ho, Lu) react with equimolar amounts of the dilithium salt $[Li(thf)]_2[1,4\text{-}(Me_3Si)_2C_8H_6]$ to afford the dimeric mono(cyclooctatetraene)lanthanide(III) chlorides **126**, of which the holmium derivative **1261** was characterized by X-ray crystallography. The single-crystal X-ray structural analysis of the scandium complex **127a** revealed the presence of an

$[\{Ln[1,4\text{-}(Me_3Si)_2C_8H_6](\mu\text{-}Cl)(thf)\}_2]$ **126**, Ln = Y, Sm, Ho, Lu

$[(\mu\text{-}Cl)_2(\mu\text{-}thf)\{Sc[1,4\text{-}(Me_3Si)_2C_8H_6]\}_2]$ **127a**

unusual semibridging THF ligand (Fig. 27). Evidently, the reason for the coordination of only one THF molecule is the increased steric demand of the substituted cyclooctatetraene ligands.[126]

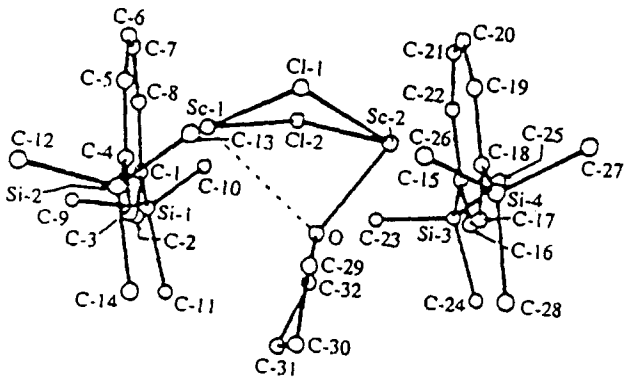

Fig. 27. Molecular structure of $[(\mu\text{-}Cl)_2(\mu\text{-}thf)\{Sc[1,4\text{-}(Me_3Si)_2C_8H_6]\}_2]$ **127a** in the crystal.

The complexes **125** are often used as starting materials for subsequent reactions because the bridging chloro ligands are easily replaced by other anions.[119] A certain disadvantage, however, is the very low solubility of these compounds even in THF. In the search for more soluble alternatives, preparative routes to mono(cyclooctatetraene)lanthanide(III) iodides and triflates have been developed. Mononuclear iodo complexes **128** are accessible in two ways [Eqs. (48) and (49)].[128–130] The

$$LnI_3 + K_2C_8H_8 \longrightarrow [(C_8H_8)LnI(thf)_n] + 2KI \quad (48)$$

128, Ln = Nd, Sm

$$Ln + C_8H_8 + 1/2I_2 \xrightarrow{THF} [(C_8H_8)LnI(thf)_n] \quad (49)$$

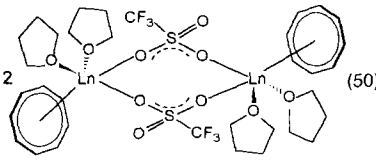
128

Ln = La, Ce, Pr, Nd, Sm,
$n = 1, 2, 3$

second procedure offers the advantage that the metal powders can be directly used as starting materials.[129, 130] Depending on the ionic radius of the lanthanide, the complexes are coordinated by a different number of THF molecules. The molecular structures of **128d** and **128f** have been determined by X-ray diffraction.

In contrast to the dimeric chloro complexes **125**, the iodides **128** are highly soluble in THF. The same is true for the recently described triflates. Schumann et al. and Fischer et al. had already shown that triflates are valuable alternatives to the previously used chloro complexes in the cyclopentadienyl chemistry of the lanthanides.[131, 132] Dimeric organolanthanide triflates **129** [Eq. (50)] are obtained in good yields in a smooth reaction between anhydrous lanthanide(III) triflates and equimolar

$$2\,K_2C_8H_8 + 2\,Ln(O_3SCF_3)_3 \xrightarrow[-4\,KO_3SCF_3]{THF} 2 \quad (50)$$



129, Ln = Ce, Pr, Nd, Sm

amounts of $K_2C_8H_8$.[128, 133] The intensely colored products which crystallize well are also highly soluble in THF. With yttrium as central atom the bis(tetrahydrofuran) complex **130b** is isolated due to the smaller ionic radius of the metal.[133]

$[\{(C_8H_8)Y(\mu\text{-}O_3SCF_3)(thf)\}_2]$ **130b**

The molecular structures of **129d** (Fig. 28) and **129f** have been determined by X-ray diffraction. A central eight-membered $Ln_2O_4S_2$ ring is formed by bridging of the lanthanide ions

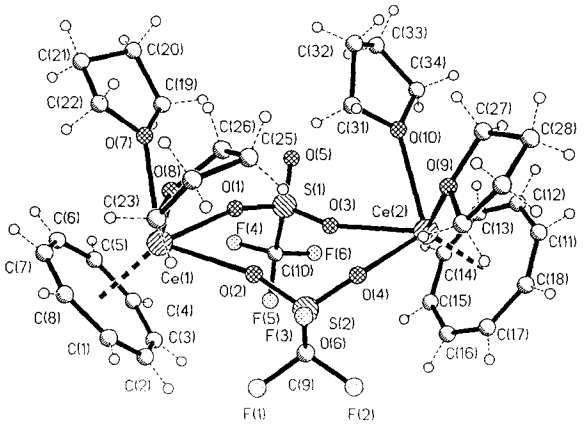


Fig. 28. Molecular structure of $[\{(C_8H_8)Ce(\mu\text{-}O_3SCF_3)(thf)_2\}_2]$ **129d** in the crystal.

by bidentate triflate ligands. Thus, the compounds **129** are structurally closely related to the bis(cyclopentadienyl)lanthanide(III) triflates $[\{(C_5H_5)_2Ln(\mu\text{-}O_3SCF_3)\}_2]$.[132] As expected, the cyclooctatetraene ligands are η^8-coordinated. Besides the improved solubility, the triflate complexes **129** and **130b** offer additional preparative advantages. First, the triflate anion is a good leaving group and thus facilitates substitution reactions with other ligands, second, LiO_3SCF_3 and NaO_3SCF_3 are more easily removed by filtration than finely divided LiCl or NaCl. Most of the subsequent reactions of the chloro complexes **125** described below have already been carried out with the corresponding triflates, and in many cases higher yields have been obtained.

In a series of recent papers an impressive number of mono(cyclooctatetraene)lanthanide(III) complexes has been reported. For example, the synthesis of some dinuclear complexes with bridging alkoxide ligands has been achieved according to Equation (51). The derivatives **131b** and **133k** have been structurally characterized.[134, 135] The compounds **134** and **135** were prepared with sterically more demanding alkoxide and siloxide ligands. These compounds are monomeric in the solid state,[134] as are the 1,4-bis(trimethylsilyl)cyclooctatetraene complexes $[Ln\{1,4\text{-}(Me_3Si)_2C_8H_6\}(2,6\text{-}tBu_2\text{-}4\text{-}MeOC_6H_2)(thf)]$ (Ln = Sc, Y).[127]

$$[\{(C_8H_8)Ln(\mu\text{-}Cl)(thf)_2\}_2] \xrightarrow[-2\,NaCl]{2\,NaOR} [\{(C_8H_8)Ln(\mu\text{-}OR)(thf)\}_2] \quad (51)$$

125

131, R = Ph; Ln = Y, Lu
132, R = 2,6-$Me_2C_6H_3$; Ln = Y, Lu
133k, R = $(CH_2)_3CH{=}CH_2$; Ln = Dy

$[(C_8H_8)Ln(OCtBu_3)(thf)]$ **134**, Ln = Y, Lu

$[(C_8H_8)Ln(OSiPh_3)(thf)]$ **135**, Ln = Y, Lu

The heterodinuclear alkoxide **136d** is formed in the reaction of $Ce(OiPr)_4$ with triethylaluminum in the presence of cyclooctatetraene [Eq. (52)].[11] During the course of this reaction Ce^{IV} is reduced to Ce^{III}. In the product, isopropoxide ligands act as bridges between cerium and aluminum.

$$Ce(OiPr)_4 \xrightarrow{AlEt_3,\ C_8H_8} [(C_8H_8)Ce(\mu\text{-}OiPr)_2AlEt_2] \quad (52)$$

136d

The synthesis of mono(cyclooctatetraene)lanthanide(III) thiolates and selenolates has been reported very recently.[130] Their preparation was achieved by using a procedure similar to that in Equation (49); diaryldisulfides or diaryldiselenides were used as oxidizing agents instead of iodine [Eq. (53)]. Catalytic amounts

$$2\,Sm + C_8H_8 + ArEEAr \xrightarrow{THF} [\{(C_8H_8)Sm(\mu\text{-}EAr)(thf)_n\}_2] \quad (53)$$

137g, n = 1, EAr = 2,4,6-$iPr_3C_6H_2S$
138g, n = 2, EAr = SPh, 2,4,6-$Me_3C_6H_2S$, SePh

of iodine accelerate the reactions by activating the metal surface. The X-ray structure analysis of $[\{(C_8H_8)Sm(\mu\text{-}SePh)(thf)_2\}_2]$ **138g** (EAr = SePh) revealed the presence of a dimer with phenylselenolate bridges (Fig. 29).

Nitrogen donor ligands are also increasingly used in connection with lanthanide cyclooctatetraene complexes. For example, interesting results were obtained with the sterically demanding

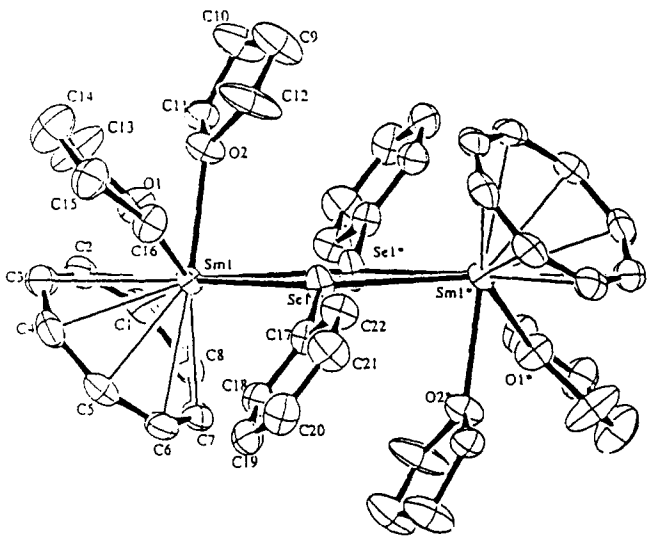

Fig. 29. Molecular structure of $[\{(C_8H_8)Sm(\mu\text{-}SePh)(thf)_2\}_2]$ **138g** (EAr = SePh) in the crystal.

bis(trimethylsilyl)amido ligand. The monomeric amido complexes **139** were isolated for yttrium and the "late" lanthanides [Eq. (54)].[136]

$$[\{(C_8H_8)Ln(\mu\text{-}Cl)(thf)_2\}_2] + 2\,NaN(SiMe_3)_2 \xrightarrow[-2\,NaCl]{} 2[(C_8H_8)Ln\{N(SiMe_3)_2\}(thf)] \quad (54)$$

125 → **139**, Ln = Y, Gd, Er, Lu

When the same reaction is carried out with the samarium derivative **125g** [Eq. (55)], an unusual "inverse sandwich complex" is formed, in which two $Sm[N(SiMe_3)_2]_2$ units are symmetrically bridged by a cyclooctatetraene ligand (Fig. 30).[136]

$$3[\{(C_8H_8)Sm(\mu\text{-}Cl)(thf)_2\}_2] + 8\,NaN(SiMe_3)_2 \xrightarrow[-6\,NaCl]{\text{toluene}} [(\mu\text{-}C_8H_8)\{Sm[N(SiMe_3)_2]_2\}_2] + 2[Na(thf)_n][Sm(C_8H_8)_2] \quad (55)$$

125g → **140g**

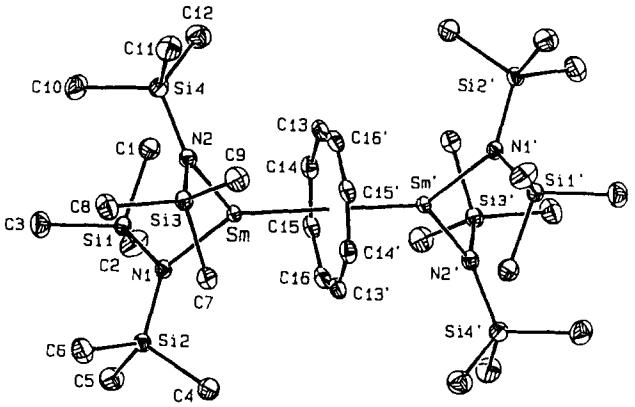

Fig. 30. Molecular structure of $[(\mu\text{-}C_8H_8)\{Sm[N(SiMe_3)_2]_2\}_2]$ **140g** in the crystal.

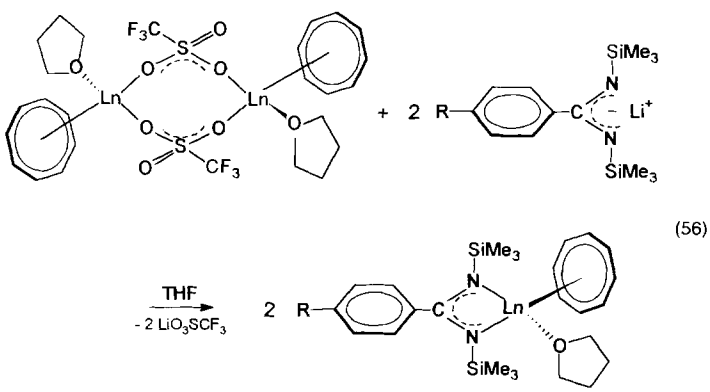
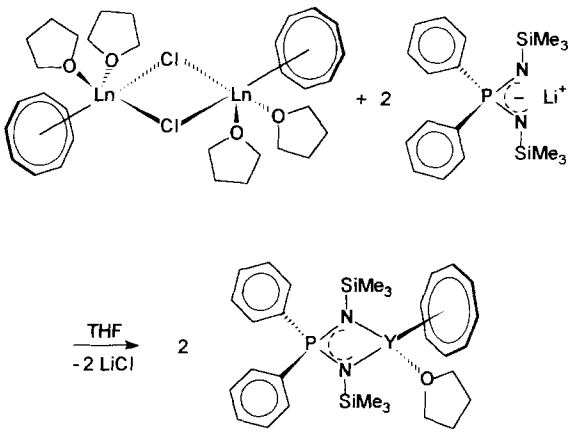
Mono(cyclooctatetraene)lanthanide(III) complexes containing polydentate nitrogen ligands are also currently being investigated. These include silylated benzamidinate and diiminophosphinate anions as well as tridentate pyrazolylborate ligands.[133, 137–140] Typical preparations are outlined in the Equations (56)–(58).



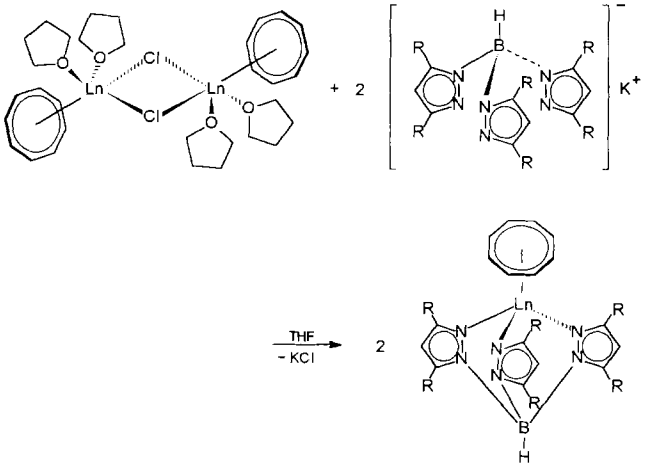
(56)

141, R = H; **142**, R = MeO; **143**, R = CF_3
Lw = Y, Ce, Pr, Nd, Sm, Tm, Lu



(57)

144, Ln = Ce, Pr, Nd, Sm



(58)

145, R = H; **146**, R = Me,
Ln = Ce, Pr, Nd, Sm

The first pyrazolylborate complexes of the type **145** had already been synthesized some years ago by Takats et al.[138] Depending on the ionic radius of the lanthanide element, these compounds can either be unsolvated or may contain a coordinated THF molecule. The complexes **145** and **146** are formed as highly crystalline, intensely colored substances and several representatives have already been characterized by crystal structure analyses.[140] Figure 31 shows the molecular structure of the THF adduct of the cerium compound **146d**.

The first σ-alkyl complexes with η^8-cyclooctatetraene ligands were isolated starting from the lutetium compound **125p** [Eq. (59)].[141, 142] The formation of mononuclear complexes is facilitated by the small ionic radius of lutetium as well as the high steric demand of the organic ligands.

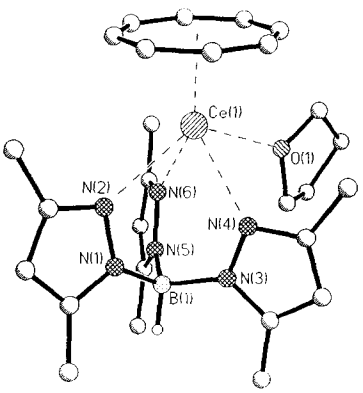


Fig. 31. Molecular structure of $[(C_8H_8)Ce\{HB(3,5\text{-}Me_2pz)_3\}(thf)]$ **146d** in the crystal.

$$[\{(C_8H_8)Lu(\mu\text{-}Cl)(thf)_2\}_2] + 2\,LiR \xrightarrow[-2\,THF]{-2\,LiCl} 2[(C_8H_8)LuR(thf)] \quad (59)$$

125p → **147p**, R = CH_2SiMe_3; **148p**, R = *o*-$Me_2NCH_2C_6H_4$

Similar alkylations of **125** (Ln = Y, Sm, Lu) with $LiCH(SiMe_3)_2$ did not lead to the expected neutral σ-alkyl complexes.[143] Instead, the "inverse sandwich complexes" **149** were

$[Li(thf)_2\{\mu\text{-}\eta^2,\eta^8\text{-}C_8H_8\}Ln\{CH(SiMe_3)_2\}]$ **149**

formed. Figure 32 shows the unusual zwitterionic structure of the samarium compound **149g** with a bridging cyclooctatetraene ligand which is η^2-coordinated to a $Li(thf)_2$ unit. The question of whether σ-alkyl complexes containing η^8-cyclooctatetraene ligands such as **147**, **148**, and **149** exhibit catalytic activities still remains to be answered.

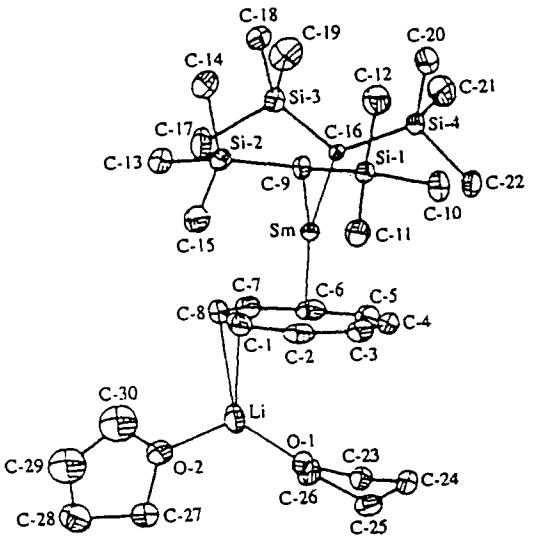

Fig. 32. Molecular structure of $[Li(thf)_2\{\mu\text{-}\eta^2,\eta^8\text{-}C_8H_8\}Sm\{CH(SiMe_3)_2\}]$ **149g** in the crystal.

The formation of neutral σ-alkyl complexes should be facilitated by the increased steric demand of the cyclooctatetraene ligand. This was recently verified by Cloke et al. with the 1,4-bis(trimethylsilyl)cyclooctatetraene complexes. Alkylation of the dimeric chloro complexes **126** with $LiCH(SiMe_3)_2$ afforded the monomeric σ-alkyl derivatives **150**.[127]

$[Ln\{1,4\text{-}(Me_3Si)_2C_8H_6\}\{CH(SiMe_3)_2\}(thf)]$ **150**, Ln = Sc, Y

Symmetrical sandwich complexes containing $[Ln(C_8H_8)_2]^-$ ions have been described previously for a series of lanthanides.[119, 123, 124] Potassium salts of these anions are easily accessible by treatment of anhydrous lanthanide trichlorides with two equivalents of $K_2C_8H_8$ [Eq. (60)]. The products are readily soluble in THF and can be isolated by extraction with this solvent. The potassium salts **151** are thermally very robust, but decompose almost explosively upon contact with traces of oxygen.

$$LnCl_3 + 2\,K_2C_8H_8 \xrightarrow[-3\,KCl]{} K[Ln(C_8H_8)_2] \quad (60)$$

151, Ln = Sc, Y, La, Ce, Pr, Nd, Sm, Gd, Tb

All structurally characterized compounds of this series contain coordinated solvent molecules. The structural chemistry of the cerium(III) anion $[Ce(C_8H_8)_2]^-$ has been investigated in detail. The crystallographically characterized lithium salt of this anion (**152d**) was obtained in the form of needlelike, bright green crystals as a by-product in the reaction of **125d** with $LiCH(SiMe_3)_2$.[144] The crystal structure reveals the presence of separated ions; the Li^+ ion is coordinated by four THF molecules (Fig. 33).

$[Li(thf)_4][Ce(C_8H_8)_2]$ **152d** $[Na(thf)_3][Ce(C_8H_8)_2]$ **153d** [K(diglyme)][$Ce(C_8H_8)_2$] **154d**

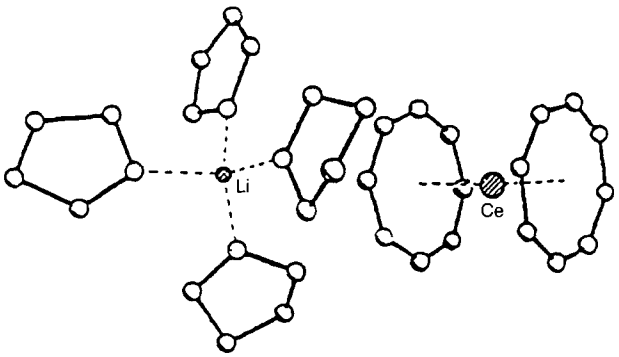

Fig. 33. Molecular structure of $[Li(thf)_4][Ce(C_8H_8)_2]$ **152d** in the crystal.

The sodium salt forms a sort of "double sandwich" **153d** (Fig. 34).[144] Two cyclooctatetraene ligands and the two metal ions are arranged as a linear unit. In this case three THF ligands are sufficient for the coordinative saturation of the sodium. A very similar structure was reported for the potassium salt **154d**.[145]

The stacking of cyclooctatetraene ligands in organolanthanide complexes can be further extended, as has been demonstrated by the structure determination of the unusual erbium complex **155m** (Fig. 35).[146] However, compounds of this type are not accessible by rational syntheses. The compound **155m** was isolated serendipitously from a reaction of $[(C_5H_4CH_2Ph)ErCl_2(thf)_3]$ with $K_2C_8H_8$.

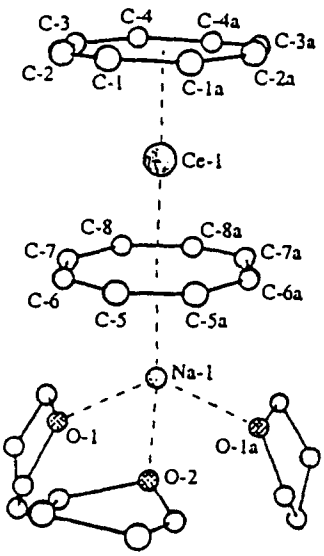

Fig. 34. Molecular structure of $[Na(thf)_3][Ce(C_8H_8)_2]$ **153d** in the crystal.

$[(C_8H_8)Er(\mu\text{-}C_8H_8)K(\mu\text{-}C_8H_8)Er(\mu\text{-}C_8H_8)K(thf)_4]$ **155m**

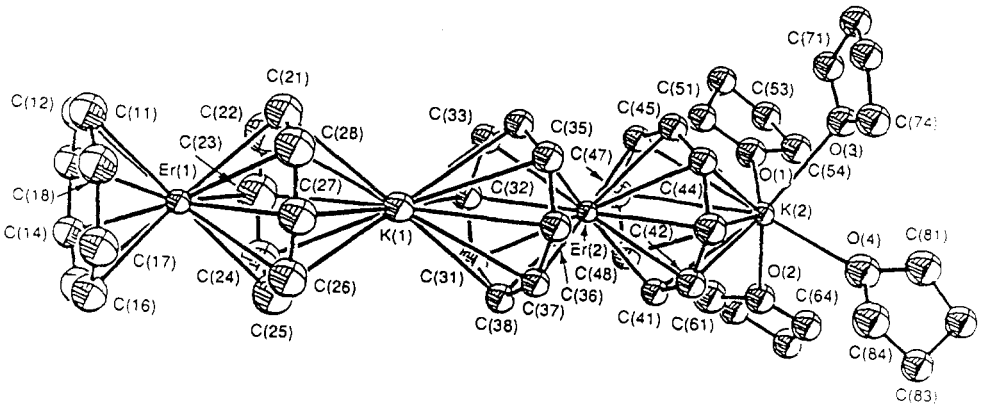

Fig. 35. Molecular structure of $[\{(C_8H_8)Er(\mu\text{-}C_8H_8)K(\mu\text{-}C_8H_8)Er(\mu\text{-}C_8H_8)K(thf)_4]$ **155m** in the crystal.

8.3. Lanthanide(IV) Complexes

Cerium is the only lanthanide that has been shown to form stable organometallic complexes in the formal oxdation state + IV; however, even well-defined organocerium(IV) compounds are very rare.[119, 123, 124] Many organic ligands are simply oxidized in the presence of Ce^{IV} ions. The longest known compound of this type is the so-called cerocene **156d**.[145–147]

$[Ce(C_8H_8)_2]$ **156d** $[Ce(MeC_8H_7)_2]$ **157d**

Cerocene was first made by the reaction of $Ce(OiPr)_4$ with cyclooctatetraene in the presence of triethylaluminum and isolated as a black-red, pyrophoric product.[1, 119] An improved synthetic route to cerocene involves controlled oxidation of the anionic sandwich complex with silver iodide or allyl iodide.[150] A thorough investigation of this interesting complex was complicated by its difficult accessibility as well as by its low solubility and pyrophoric nature. Except for the reduction by alkali metals, which leads to known derivatives of the cerium(III) anion $[Ce(C_8H_8)_2]^-$, no further reactions of cerocene have been reported. A novel development in the organometallic chemistry of tetravalent cerium was recently initiated through the use of substituted cyclooctatetraene ligands. The introduction of suitable substituents leads to an improved solubility as well as a significantly higher stability of the products toward oxygen. For instance, with the 1,1′-dimethyl compound **157d** Streitwieser et al. succeeded in the first structural characterization of a cerocene derivative; the result clearly established the proposed sandwich structure.[145] The angle between the central cerium atom and the ring centroids is 176.03°. Even better results can be obtained with the sterically demanding ligand 1,4-bis(trimethylsilyl)cyclooctatetraene as well as the novel 1,3,6-tris(trimethylsilyl) derivative.[151] Schemes 7 and 8 illustrate the syntheses of the silyl-substituted cerocene derivatives **159d** and **161d**. In both cases silver iodide has proven successful as the mild oxidizing agent. The compound **159d** is isolated as a dark purple oil,

$$CeCl_3 + 2[Li(thf)_n]_2[1,4\text{-}(Me_3Si)_2C_8H_6] \xrightarrow[-3\,LiCl]{THF}$$

$$Li[Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2] \xrightarrow[-Ag,\,-LiI]{+AgI} [Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$$

158d **159d**

Scheme 7. Synthesis of $[Ce\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ **159d**.

$$Ce(O_3SCF_3)_3 + 2[K(thf)_n]_2[1,3,6\text{-}(Me_3Si)_3C_8H_5]$$

$$\xrightarrow[-3\,KO_3SCF_3]{THF} K[Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$$

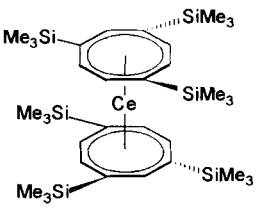
160d

$$\xrightarrow[-Ag,\,-KI]{+AgI} [Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$$

161d

Scheme 8. Synthesis of $[Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$ **161d**.

while **161d** forms permanganate-colored crystals. The two cerocenes are highly soluble in nonpolar organic solvents due to the presence of the trimethylsilyl substituents.



161d

The crystalline hexakis(trimethylsilyl)cerocene **161d** was characterized by a crystal structure analysis (Fig. 36);[151] the angle between cerium and the ring centroids is 176.1°. The compounds **159d** and **161d** are the first cerocene derivatives that are reproducibly accessible in synthetically useful amounts; thus, they allow the study of what is expected to be interesting derivative chemistry.[152]

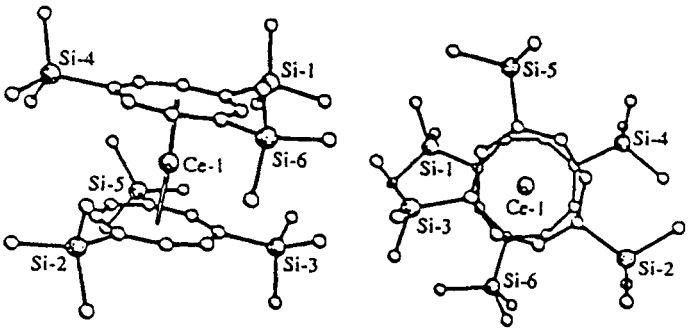


Fig. 36. Molecular structure of $[Ce\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$ **161d** in the crystal.

9. Organolanthanides in Homogeneous Catalysis

Applications of organolanthanide complexes in homogeneous catalysis have been initiated by the observation that some of these complexes exhibit high catalytic activities in olefin polymerizations.[5, 74, 153] In the preliminary experiments in that di-

rection the catalytically active species were generated by activating lanthanide oxides, halides, or alkoxides with co-catalysts such as alkyllithium or alkylaluminum compounds. The intermediately formed σ-alkyl complexes were capable of catalyzing the cracking of hydrocarbons as well as oligomerizations and polymerizations of olefins. Since then well-defined organolanthanide complexes have become available, and many other cases of interesting catalytic activities have been discovered. It was found, for example, that (cyclooctatetraene)cerium complexes catalyze the polymerization of ethylene and butadiene.[153] Anionic tetrakis(η^3-allyl)lanthanide complexes are also highly active catalysts for the production of polybutadiene. In the meantime, however, it has become quite clear that catalytic activity is almost generally limited to cyclopentadienyl complexes of the lanthanides. Metallocene derivatives of trivalent lanthanides such as $[(C_5Me_5)_2LnCH(SiMe_3)_2]$ or $[\{(C_5Me_5)_2Ln(\mu\text{-}H)\}_2]$, in particular, have been found to display very high activities.[5] In contrast, the number of catalytically useful organolanthanide complexes without cyclopentadienyl ligands is still very limited.

The majority of the hitherto investigated reactions that are catalyzed by organolanthanide complexes are olefin transformations such as hydrogenations, polymerizations, or addition reactions. For example, a catalyst for the hydrogenation of ethylene was prepared from a samarium/magnesium alloy.[1] $SmMg_3$ reacts with anthracene in THF to afford a complex of unknown structure. This product absorbs hydrogen and is then able to catalyze the hydrogenation of ethylene.

The main field of application for organolanthanide catalysts without cyclopentadienyl ligands is diene polymerization. In earlier reports on the polymerization of butadiene, catalyst systems such as "$Ph_3Nd_2/Al_2Et_2Cl_3$",[154] neodymium-2-ethylhexanoate/$AlEt_2Cl/AlEt_3$,[155] or $LnCl_3/n$BuLi[156] were used. However, very little is known about the nature of the intermediately formed σ-alkyllanthanide species. Only in one case, that is the catalyst system $Nd(OiPr)_3/AlEt_3/AlEt_2Cl$, could a defined intermediate be "fished out" and structurally characterized.[64, 157] It was shown to be the heteronuclear alkyllanthanide(III) alkoxide **55f** (see Section 3.3). Promising results have been obtained in recent years with anionic allyl complexes of the type $[Ln(\eta^3\text{-}C_3H_5)_4]^-$.[95] Lithium salts of these anions catalyze the polymerization of butadiene and alkylbutadienes with moderate to high activity and high *trans* selectivity. Highly active catalysts for the production of *cis*-1,4-polybutadiene have been obtained by combining tris(2,4-dimethylpentadienyl)-neodymium **99f** with Lewis acids such as $AlEtCl_2$, $AlBr_3$, $SnCl_4$, or Ph_2SnCl_2. In this case the crystal structure analysis provided valuable insight about the constitution of an active pre-catalyst, since the hexanuclear complex **162f** could be isolated and characterized by X-ray diffraction.[158] Figure 37 shows the molecular structure of this unusual cluster, in which two hexagonal-bipyramidal Nd_3Cl_5 units are linked through two chloro bridges. All 2,4-dimethylpentadienyl ligands are η^5-coordinated to neodymium.

$[Nd_6Cl_{12}(C_7H_{11})_6(thf)_2]$ **162f** (C_7H_{11} = 2,4-dimethylpentadienyl)

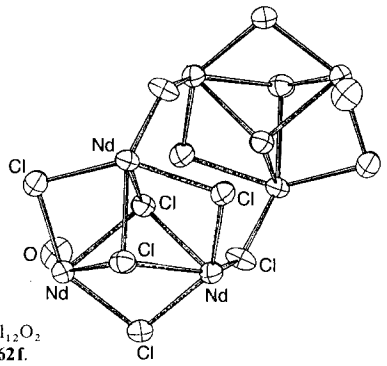

Fig. 37. Structure of the $Nd_6Cl_{12}O_2$ unit in $[Nd_6Cl_{12}(C_7H_{11})_6(thf)_2]$ **162f**.

10. Future Outlook

In the past 10–15 years organolanthanide chemistry has been developed into a highly dynamic area of research that continues to produce fascinating novel results. Until recently most of the research was focused mainly on the discovery of new types of structures and reaction pathways. Indeed, organolanthanide chemistry is characterized by a great diversity of novel and unusual molecular structures, and the extraordinarily high reactivity of certain organolanthanide complexes is without precedent in the chemistry of the d-block transition metals. Today an increased interest in possible applications of organolanthanides is apparent. For example, an enormous potential lies in the use of organolanthanide complexes in homogeneous catalysis. Lanthanide catalysts combine several favorable aspects such as very high activities, excellent environmental compatibility, and low costs. Possible applications in the area of materials science are also apparent and it should be worthwhile to consider future work in that direction. A conceivable application, for example, is the use of organolanthanide complexes in the doping of semiconductor materials, which has already been successful in the case of cyclopentadienyl lanthanide complexes.[5] There is a good chance that volatile organocerium compounds will turn out to be useful precursors for the vapor deposition of cerium dioxide. In addition, many interesting questions of a more academic nature still warrant further investigation: To what degree do f-orbitals participate in the bonding in (cyclooctatetraene)lanthanide complexes? Is it possible to construct multidecker sandwich complexes with cyclooctatetraene ligands? Will it ever be possible to synthesize organometallic complexes containing a direct Ln–Ln bond or to realize unusual oxidation states (e.g. Nd^{II}, Pr^{IV}, Tb^{IV}, Tm^{II}) in organolanthanide complexes? What are the structures of "Grignard-like" complexes RLnX with simple alkyl substituents? In any case, research in the area of "lanthanide chemistry without cyclopentadienyl" will continue to be exciting.

Our own investigations which have been carried out in Göttingen would not have been possible without the enthusiasm of my highly talented co-workers, whose names appear in the list of references. To them I owe my sincere gratitude. Special thanks are also due to Prof. Dr. H. W. Roesky for his continuing generous support. I have learned a lot from him. I also thank Prof. Dr. Josef Takats (University of Alberta, Edmonton, Canada) for initiating my interest in organo-f-element chemistry. Many stimulating discus-

sions with Prof. Dr. John W. Gilje (James Madison University, Harrisonburg, USA) are also gratefully acknowledged. I thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for the financial support of our research.

New Surprises in Metal Carbonyl Chemistry**

John E. Ellis* and Wolfgang Beck*

Anionic and *cationic* metal carbonyls[1, 2] have been the focus of much attention for the past several years, however, recent exciting developments involving *neutral* metal carbonyls have again placed the spotlight on this historically rich and vital area of chemistry. The first study on the reaction of a metal, namely potassium, with carbon monoxide was reported by Justus von Liebig in 1834.[3] On the basis of this seminal study and later extensions by others,[4] it was widely believed in the 19th and early 20th centuries that alkali and alkaline earth metals reacted with CO under standard conditions to form binary metal carbonyls. Although all of these substances were later shown by E. Weiss et al. to be ionic in nature and to contain reductively coupled CO units, such as the acetylenediolate dianion, $^{-}O-C\equiv C-O^{-}$[5] and related oxocarbon anions $[C_nO_n]^{2-}$ ($n = 3-6$),[6] the idea that the reactions of carbon monoxide with metals could be quite interesting was firmly established. However, to the best of our knowledge until 1993, there were no reports in the literature on the existence of relatively stable neutral main group metal or metalloidal carbonyls.

Bona fide neutral metal carbonyls have been known since Schützenberger's synthesis of $[Pt(CO)_2Cl_2]$ in 1868.[7] Quite interestingly, this "classic" complex, and related platinum(II) carbonyl compounds (e.g. $[Pt(CO)_4]^{2+}$) are now considered to be examples of "nonclassical" carbonyl complexes, in which the CO ligand functions exclusively as a σ-donor.[8] The first examples of "classical" carbonyls in which the CO group simultaneously functions as both a σ-donor *and* π-acceptor ligand were Mond's $[Ni(CO)_4]$ and $[Fe(CO)_5]$ reported in 1890 and 1891, respectively.[9]. These first examples of metal carbonyls were all made by the direct combination of metallic compounds (e.g. $PtCl_2$) or pure metals (e.g., Ni and Fe) with carbon monoxide, a route which is still of key importance in the syntheses of new types of metal carbonyl complexes.

The chemical properties of metal carbonyls were first investigated in detail by Walter Hieber, who is deservedly known as the "father of metal carbonyl chemistry". Primarily through Hieber's and his students' extensive and systematic research,[10, 11] metal carbonyls ultimately were transformed from mainly laboratory curiosities into precursors of key importance throughout science, engineering, and commerce. Metal carbonyl chemistry represents an excellent, although not uncommon example of where pure or "curiosity-driven" scientific research has eventually led to many and largely unanticipated rewards for mankind (e.g. for homogenous catalysis).

Until very recently, all isolable examples of pure neutral metal carbonyls required stabilization by d-block transition metals (through formation of strong metal $\rightarrow$ CO back bonds). As shown in Figure 1, *neutral* binary or substituted metal carbonyl compounds have been isolated for all d-block metals, except Sc, Y, and Ag and for the f-elements La–Lu; however stable carbonyl cations of silver are now known.[12] For other metals or metalloids, except uranium, vide infra, only exceedingly unstable matrix-isolated carbonyls were reported before 1993. For example, binary carbonyls of uranium, several lanthanides,[13] alkali metals,[14] and recently beryllium[15] have been prepared by condensation of appropriate metal atoms with CO and inert gases such as argon or krypton. All of these compounds decom-

NON METALS

Fig. 1. Survey of metal and metalloid carbonyls. [a] Metals combine with CO under normal conditions to produce salts of oxocarbon anions [3–6]. [b] Only known as thermally unstable matrix-isolated species ($T \leq 77$ K) with metal atoms, halides or oxides. [c] No known carbonyls in condensed phases. [d] $[(C_5Me_5)_2M]$ form labile monocarbonyls in solution under CO atmosphere (>1 bar). [e] Isolable binary and/or substituted carbonyls known; Ag, Hg as cations only [2, 8, 12].

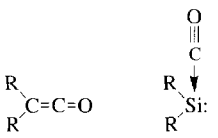
pose above 45 K and thus seem unlikely to ever be useful as reagents in conventional synthetic chemistry. Somewhat more stable are $Al(CO)_2$ and Me_2SiCO which survive at 77 K in an adamantane[16] or other frozen hydrocarbon matrices,[17] respectively. It is of interest to compare Me_2SiCO with similar organic compounds. Although carbenes are well known to combine with CO to give relatively stable ketenes $R_2C{=}C{=}O$ (Scheme 1), vibrational spectra of the formally analogous dimethylsilene-CO adduct indicated relatively little Si–C multiple bonding to be present.[7] Thus, ketenes prefer to adopt a "normal" structure containing trigonal-planar carbon and a strong C=C double bond, while the silicon analogues are likely to contain pyramidal silicon with a weak Si–CO interaction.



Scheme 1. R = Me.

All of this is understandable in terms of the reluctance of silicon to participate in p_π–p_π multiple bonding, along with the great strength of the CO triple bond in carbon monoxide. So the "silaketene" is really best described as being a silicon carbonyl. While these simple silylene–carbonyl adducts are only stable in solid matrices at low temperature, recently the first solutions of such a compound have been reported by Tacke and coworkers.[18] The reaction of Jutzi's stable silene, $[Cp^*_2Si]$ ($Cp^* = C_5Me_5$), with CO (1.5 bar) in liquid xenon at -20 to $-30\,^\circ C$ provides small amounts of $[Cp^*_2Si(CO)]$ [Eq. (a)]. An

$$[Cp^*_2Si] + CO \xrightleftharpoons{\text{LXe/253 K/1.5 bar}} [Cp^*_2Si(CO)] \qquad \text{(a)}$$

indication of the relatively weak Si–CO bond in this species is the observed $\tilde{\nu}$(CO) stretch at 2065 cm^{-1} in the IR spectrum; the corresponding CO stretching frequency in the related 16-electron titanium complex $[(C_5H_5)_2Ti(CO)]$ is 1890 cm^{-1}. While the coordinated CO is easily lost from $[Cp^*_2SiCO]$, binding of the CO to the titanocene unit is quite strong, in accord with the greater degree of back bonding from titanium to CO compared to the situation in the silicon carbonyl.

Equally impressive was the recent report by Selg, Brintzinger, Andersen, and Horvath of an alkaline earth metal carbonyl stable in solution.[19] All previously known alkaline earth metal carbonyl complexes were exceedingly unstable matrix-isolated species.[20] The reaction of $[Cp^*_2Ca]$ with CO (>2.5 bar) in toluene at -30 to $+30\,^\circ C$ led to the formation of $[Cp^*_2Ca(CO)]$ [Eq. (b)]. This substance was unambiguously characterized in

$$[Cp^*_2Ca] + CO \xrightleftharpoons{\text{toluene/246–305 K/2.5–70 bar}} [Cp^*_2Ca(CO)] \qquad \text{(b)}$$

toluene by IR and ^{13}C NMR spectroscopy. The rather high $\tilde{\nu}$(CO) value of 2158 cm^{-1} observed for $[Cp^*_2Ca(CO)]$ compared to that of free CO, 2134 cm^{-1} in toluene, as well as the upfield shift in the ^{13}CO resonance ($\delta = 180.4$) of the complex compared to that of free ^{13}CO ($\delta = 184.7$) justifies the authors' assertion that this Ca^{2+} complex is a σ-only carbonyl compound, in contrast to the aforementioned $[Cp^*_2Si(CO)]$, $\tilde{\nu}(CO) = 2065\ cm^{-1}$, in which some degree of back bonding from Si to CO is indicated. The relative weakness of Ca–CO binding is suggested by the inability of CO to displace ether from $[Cp^*_2Ca(OEt_2)]$ even at high pressures (120 bar). Selg et al. also found that a similar strontium carbonyl $[Cp^*_2Sr(CO)]$ was accessible under the same conditions employed for the calcium reaction, while no evidence could be obtained for the interaction of $[Cp^*_2Mg]$ with CO.

These reports on the first relatively stable metalloidal and main group metal carbonyls constitute remarkable advances and give hope that isolation of related materials may be possible in the near future with judicious choice of ligands. Most certainly they will also stimulate additional research in a totally new area of main group carbonyl chemistry! The results emphasize the continued importance of the pentamethylcyclopentadienyl ligand in helping to establish new and exciting chemistry since its main introduction in the research of King, Bercaw and Brintzinger more than 20 years ago.[21]

Nearly ten years ago, Andersen et al. reported the synthesis of the first relatively stable actinide carbonyl, $[(Me_3SiC_5H_4)_3U(CO)]$.[22] Under an atmosphere of carbon monoxide this substance was remarkably robust near ambient temperatures in solution and in the solid state, although it could not be isolated as a pure substance. This discovery was an important event in metal carbonyl chemistry, since it engendered much new interest in the prospects for developing f-block carbonyl chemistry. Now, quite remarkably Parry, Carmona, Coles, and Hursthouse have obtained the first isolable uranium carbonyl, $[(C_5Me_4H)_3U(CO)]$,[23] by the same direct synthesis procedure employed by Schützenberger for $[Pt(CO)_2Cl_2]$, more than 125 years ago![7] Treatment of the cherry red-brown solutions of $[U(C_5Me_4H)_3]$ with CO at 1 bar and 20 °C immediately resulted in the formation of a purple carbonyl adduct, which was isolated as an analytically pure substance [Eq. (c)]. One

$$[(C_5Me_4H)_3U] + CO \xrightarrow{\text{toluene/293 K/1 bar}} [(C_5Me_4H)_3U(CO)] \qquad \text{(c)}$$

striking feature is that the ν(CO) value in the IR spectrum for this complex, 1900 cm^{-1} in petroleum ether, is 76 cm^{-1} lower than that of Andersen's presumably analogous complex. Thus, the seemingly simple change from a trimethylsilylcyclopentadienyl group to the tetramethylcyclopentadienyl unit in this case had profound effects on the stability of the complex, possibly for both electronic *and* steric reasons. The coup de grace in the present study, however, was the X-ray structural characterization of the complex, which showed an essentially linear uranium–carbonyl unit and a quite short U–C distance of 2.383(6) Å, compared to a corresponding U–C(isonitrile) distance of 2.57(3) Å previously observed in $[(Me_3SiC_5H_4)_3U(CNEt)]$.[22, 24] This information, the low ν(CO) value, and a long C–O distance of 1.142(7) Å indicate that uranium in the proper ligand environment can participate in backbonding to carbonyl groups as effectively as d-block transition metals! Clearly Parry et al. have uncovered a potentially rich new area of chemistry filled with many treasures in the form of 5f- and possibly even 4f-block metal carbonyl chemistry.

Whether this newly discovered stable f-block metal carbonyl chemistry will be limited to neutral monocarbonyls only is a question of substantial interest. However, an even more interesting issue is whether the chemistry of 5f-block carbonyls will

differ in any substantial way from that of the familar d-block species except for the obvious fact that the 18-electron rule will be flagrantly violated!

Carbonyls of the transuranium elements are unknown presently; however, Nash and Bursten have recently predicted that the hexacarbonyl of zerovalent element 106, a member of the chromium family, should electronically resemble $[W(CO)_6]$ much more than the extremely unstable $[U(CO)_6]$.[25]

In summary, over the past two years our knowledge of relatively stable neutral carbonyl complexes has been dramatically enriched by the synthesis of the first metalloidal and alkaline earth metal carbonyls in solution, namely $[Cp^*_2Si(CO)]$ and $[Cp^*_2Ca(CO)]$, respectively, and by the isolation and X-ray structural characterization of the first f-block carbonyl complex, $[(C_5Me_4H)_3U(CO)]$. Undoubtedly, these remarkable new results will stimulate much new basic "curiosity-driven" research in a field that continues to provide excitement and drama!

Sunlight-Damaged DNA Repaired with Sunlight

Thomas Carell*

DNA, the carrier of genetic information, is continuously subjected to damaging environmental influences. As a consequence, genetic information is lost and the reliable function of cells is threatened.[1] To counter these potentially deadly effects, organisms have developed a number of sophisticated DNA repair mechanisms.[2] Since the discovery that errors in the repair process contribute directly to carcinogenesis, the investigation of the molecular events of damage removal inside the genome have attracted widespread interest.[3] Currently, DNA repair is one of the hottest topics in biochemical research.

Very recently H. W. Park, S.-T. Kim, A. Sancar, and J. Deisenhofer solved the X-ray structure of one of the most unusual DNA repair enzymes, the *Escherichia coli* DNA photolyase.[4] This accomplishment represents a landmark in an interdisciplinary effort to gain deeper insight into one of the major genome repair processes in nature. Photolyases are enzymes capable of repairing major DNA lesions introduced into the genome by irradiation of cells with sunlight (UV light with $\lambda = 200-300$ nm).[5] They are unusual because the repair reaction is also driven by sunlight ($\lambda = 300-500$ nm). In this way the repair reaction is similar to photosynthesis, where sunlight is transformed into chemical energy.[6] Photolyases are found in a variety of organisms including archaebacteria, amphibians, goldfish, rattlesnakes, and marsupials but are absent from others including man.[7] In many species the photolyase repair reaction (photoreactivation) is the only known mechanism for repairing the deleterious effects of sunlight.

The DNA lesions incurred upon UV irradiation of cells have been widely studied and are now well understood.[5] Through irradiation of double-helical DNA two neighboring pyrimidine bases undergo a photochemically allowed $[2\pi_s + 2\pi_s]$ cycloaddition of their C5–C6 double bonds, resulting in the formation of *cis-syn* cyclobutane pyrimidine dimers (Scheme 1). The major

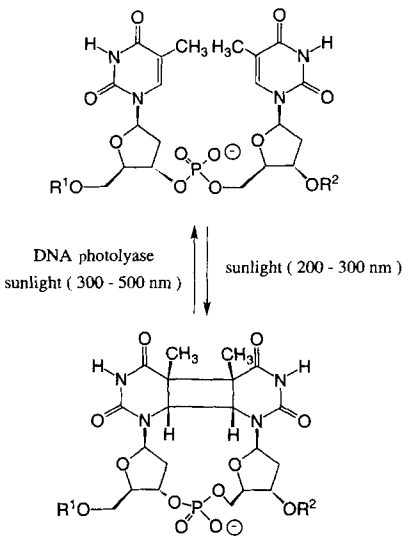
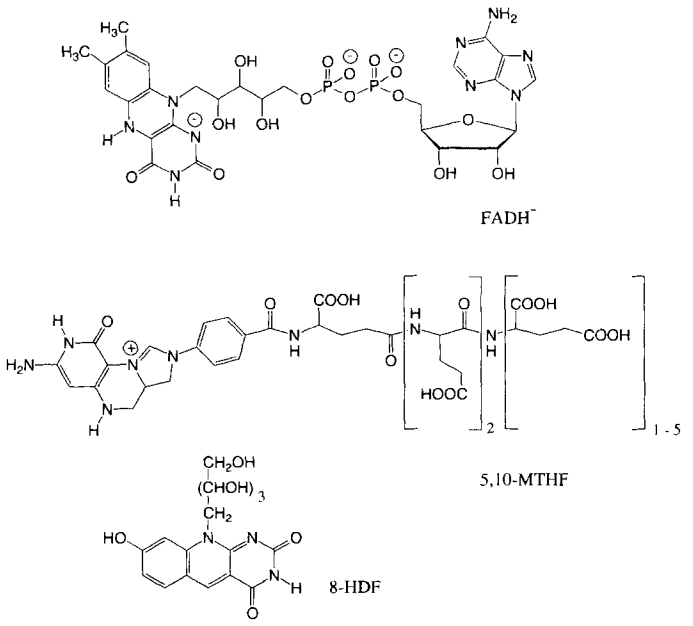


Scheme 1. Formation of a *cis-syn* cyclobutane thymine dimer upon UV irradiation (200–300 nm) of DNA containing a TpT segment. R_1 = 5′-terminus, R_2 = 3′-terminus.



Scheme 2. Structures of photolyase cofactors. The folate class of photolyases contains one $FADH^-$ and one 5,10-MTHF unit; the deazaflavin class of photolyases contains one $FADH^-$ and one 8-HDF unit.

photolesions are *cis-syn* thymine photodimers, which cause structural distortion of the corresponding DNA region.[8] This DNA structure alteration blocks replication and transcription, and thus leads to cell death. The high frequency of skin cancer in patients with *Xeroderma pigmentosum*, a condition characterized by deficient capabilities for repairing UV-damaged DNA, show dramatically that UV-induced lesions are also directly involved in cancer development.[9]

Normal cells have developed sophisticated methods for repairing pyrimidine dimer lesions either by excision repair, whereby the damaged nucleotides are removed and replaced by new bases, or by photoreactivation.[3] Whereas excision repair requires several enzymes in a complicated multistep repair process, photoreactivation is exceptional, relying on only one enzyme, DNA photolyase.[10, 11] In recent years, research on photoreactivation has focused on the elucidation of the enzyme's repair mechanism by studying various photolyases, their cofactors, and specifically designed model compounds that mimic certain aspects of the repair process. A variety of techniques including time-resolved absorption and fluorescence spectroscopy have been used to this end.[12, 13] The sequencing of photolyases from various organisms, subsequent cloning, and overexpression together with mutagenesis studies are milestones on the way to a more detailed understanding of the enzyme's mode of action.[5]

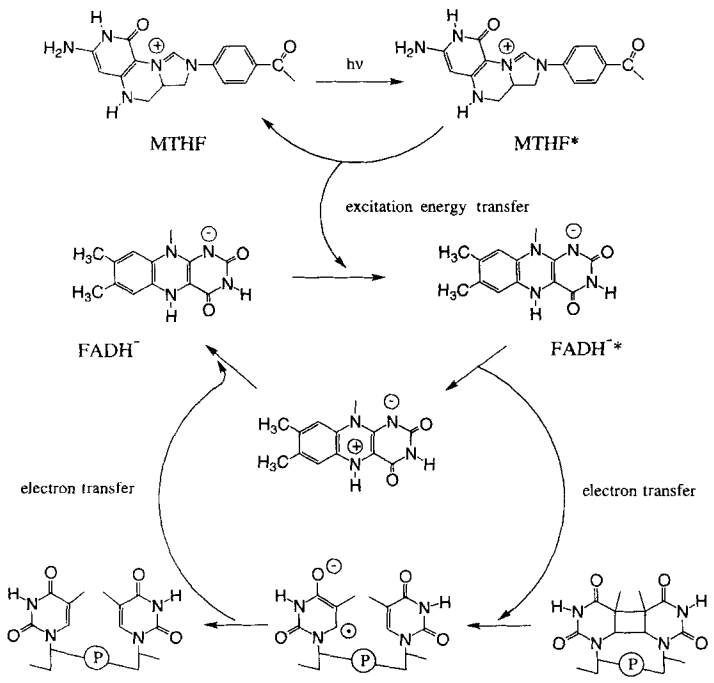
The results have established that photolyases are monomeric enzymes with molecular weights between 55000 and 60000 Da. They contain two noncovalently bound chromophores as cofactors (Scheme 2). One of these is a flavin adenine dinucleotide in the unusual $FADH^-$ form, which is tightly bound to the enzyme ($K_d < 10^{-11}$ M).[5] All photolyases known to date contain as the second chromophore either 8-hydroxy-5-deazariboflavin (8-HDF) or 5,10-methenyltetrahydrofolylpolyglutamate (5,10-MTHF). Accordingly, photolyases are divided into two subgroups, the deazaflavin group, for example from *Methanobacterium thermoautotrophicum*, and the folate group, for example from *Escherichia coli*.

The recently published X-ray crystallographic analysis of a DNA photolyase reveals a number of interesting structural features.[4] The $FADH^-$ cofactor is bound to the enzyme in a surprising U-shaped conformation, and the flavin and adenine rings are in close proximity inside the protein pocket; both are partially solvent accessible. Responsible for the tight binding of $FADH^-$ are a network of hydrogen bonds around the riboflavin moiety and eight ionic interactions with the phosphates. The fact that the residues that participate in the binding of the flavin cofactor are conserved in eight of the ten known photolyase sequences demonstrates the importance of the $FADH^-$ binding site for the enzyme's function. The second chromophore is much more weakly bound inside a shallow protein groove, and in general a considerable amount of this second cofactor is lost during purification of the enzyme. In the *Escherichia coli* photolyase, the 5,10-MTHF molecule is bound at the periphery of the enzyme approximately 16.8 Å away from the flavin unit.

The peptide chain of the *Escherichia coli* photolyase is folded into five β-strands, twenty α-helices, five 3_{10} helices, and connecting segments.[4] Sequence and structure homology studies revealed that bacterial photolyases bear close resemblance only to the blue photoreceptors, a class of proteins analyzed in detail just recently.[14] No other sequence similarities were observed with other flavin binding proteins or animal photolyases. A characteristic feature of all photolyases is their *nonsequence*-specific binding to damaged DNA. In contrast to proteins involved in gene regulation, which are highly sequence specific, photolyases bind DNA in a *structure*-specific manner: they recognize defect sites. More puzzling is the fact that photolyases bind equally strongly to single- and double-stranded DNA ($K_d = 10^{-8}$ M and 10^{-9} M, respectively).[15] Based on the overall structure of the *Escherichia coli* photolyase, a plausible explanation for this phenomenon can now be proposed. The folding of the peptide chain results in the formation of a cavity that has the

correct size, shape, and polarity distribution for accommodating a thymine dimer. It is now speculated that after the binding of the photolyase to the damaged DNA strand, the thymine dimer "flips out" of the double helix into the photolyase cavity, where it is in van der Waals contact with the flavin. It is widely accepted that the hydrogen bonds between the thymine photodimer and their opposing adenines within the double helix are weaker than those in undamaged DNA. The reduced strength of the hydrogen bonds at the damaged site is thought to facilitate the flipping process. Further support for the flipping-out process was recently obtained through X-ray crystallographic analysis of four other proteins. Exonuclease III[15] and two uracil-DNA glycosylases,[16, 17] all three involved in DNA repair, have cavities potentially capable of binding the DNA lesions in a flipped-out conformation. In the case of the uracil-DNA glycosylase from *Herpes simplex* virus, a co-crystal structure of the protein with uracil bound in the proposed active site cavity strongly supports the flipping-out mechanism. Recently the X-ray crystal structure of HhaI methyltransferase, a protein not involved in DNA repair, was solved.[18] Here a modified substrate was used to trap a reaction intermediate covalently bound to the enzyme. Surprisingly the substrate was flipped out from the DNA double-helix and directed into the active site of the enzyme. All these investigations seem to indicate that DNA lesions within the double helix may be recognized by various repair enzymes and factors in a flipped-out conformation.

The proposed mechanism for the repair of thymine photodimers through the action of DNA photolyase is shown in Scheme 3. Upon irradiation of the photolyase–DNA complex, a quantum of light is captured either directly by the flavin moiety or more likely by the second chromophore, a folate or deazaflavin, due to their higher molar extinction coefficients in the spectral region between 300 and 500 nm. The second chromophore relays the excitation energy to the flavin, which subsequently transfers an electron to the thymine dimer. Computational studies (Hückel molecular orbital calculations) show that the activation barrier for the thermal, concerted collapse of the cyclobutane substructure into its radical anion is significantly reduced. Thus the electron transfer leads to efficient cleavage of the C5–C5′ and C6–C6′ σ bonds of the thymine dimer and restoration of the two thymines.[19] Indeed, recent observations confirm that the dimer is cleaved in a concerted fashion.[20] An electron is then transferred back to the flavin and the photolyase–DNA complex dissociates, presumbly due to the higher steric requirements of the two thymines in the active site.



Scheme 3. Schematic representation of the proposed DNA repair mechanism for the *Escherichia coli* photolyase [5,12].

Time-resolved spectroscopic measurements on *Escherichia coli* photolyase yielded a rate constant for the energy transfer from the 5,10-MTHF to the flavin of $k = 4.6 \times 10^9\ s^{-1}$ and an efficiency of 62%.[5, 13] The process occurs by the radiationless resonant mechanism described by the Förster theory.[21] In the deazaflavin-containing photolyases, the energy transfer is significantly faster ($k = 1.9 \times 10^{10}\ s^{-1}$) and more efficient (100%). The rate constant for the electron transfer between the flavin and the thymine dimer was measured as $k = 5.5 \times 10^9\ s^{-1}$. The electron transfer efficiency is similar in both enzyme classes (90%).

Two other residues within the photolyase are directly involved in the repair process. Trp277 has been identified as the essential substructure for the repair function at 280 nm in a modified photolyase with an inactive flavin.[22] Model studies showed that indoles are indeed capable of splitting pyrimidine dimers in solution and in covalently linked indole–pyrimidine dimer systems at this wavelength.[23] The X-ray structure offers an explanation for the Trp277-mediated photorepair. Trp277 is located inside the proposed thymine dimer binding site and would come into van der Waals contact with the bound substrate with its flipped-out conformation. The role of Trp306, which is essential for the photoreduction of the excited FADH (a process required for the conversion of the flavin into its reduced state), is still unclear. It is widely assumed that the reduction of the flavin involves an electron transfer from Trp306 to the excited flavin. Since the Trp306 residue is located near the protein surface 13 Å away from the flavin, an efficient electron transfer between these chromophores is unlikely. Further studies are necessary to establish the function of Trp306 in the repair process.
