# Cover Picture

Jason P. Rolland, Erik C. Hagberg, Ginger M. Denison, Kenneth R. Carter,* and Joseph M. De Simone*

High-performance imprint lithographic applications are ideally suited for perfluoropolyether-based elastomers. The cover picture shows sub-100-nm sized features replicated by these materials whose successful application comes from their remarkably low surface energy and their high flexibility. The performance of the materials suggests that replication at even smaller sizes may be possible. For more information, see the Communication by J. M. De Simone, K. R. Carter, and co-workers on page 5796 ff.
Enzyme Chemistry

The enzymatic cleavage of sulfate esters is the crucial process in the regulation of sulfation patterns. The current state of research is summarized by C.-H. Wong and co-workers in their Review on page 5736 ff.
Reaction Mechanisms

The mechanism of the Hajos–Parrish–Eder–Sauer–Wiechert reaction, the prototype for asymmetric organocatalytic reactions, is discussed by K. N. Houk and F. R. Clemente in their Communication on page 5766 ff.
Peptide Mimetics

In their Communication on page 5789 ff., A. Geyer and P. Tremmel describe how highly functionalized bicyclic dipeptide analogues in oligopeptide mimetics form an ordered network of hydrogen bonds.

Highlights

Beyond classical immobilized catalysts, metal–ligand polymers self-assembled through coordination are easily prepared, have a robust chiral structure, and display a high density of catalytically active units. These heterogeneous catalysts give excellent results for enantioselective reactions and can be recovered and recycled without significant loss of selectivity.
Beyond the shadow of a doubt: Detecting
antigens, antibodies, pathogens, tumor
markers, and potential therapeutics on
the femto- to attomolar concentration
level is still challenging. Nanostructured
materials and the innovative combination
of immunoassays with (real-time) PCR
and magnetic separation techniques hold
promise for the field of ultrasensitive
protein analytics.

Reviews

Through the cleavage of sulfate esters
sulfatases modulate the activity of a broad
range of small molecules and proteogly-
cans (see picture). These enzymes play
critical roles in a number of biological
events, including lysosomal degradation,
hormone regulation, and signaling pro-
cesses. The structures of sulfatases, their
mechanisms of action, their potential as
targets for small-molecule intervention,
and applications in synthesis are dis-
cussed.

Communications
**A comparison of previously proposed
models** of the C–C bond-forming step of
the title reaction with density functional
methods indicate that the most favored
one involves an enamine intermediate
undergoing a concerted aldol cyclization
with proton transfer from the proline
carboxylic acid group (see structure). This
step is equal in energy to the intramole-
cular deprotonation leading to the enam-
ine, and both are partially rate-determin-
ing steps.

A stream of water molecules, held together by hydrogen bonding, forms a left-handed helix within the helical channels of a left-handed staircaselike metal coordination polymer. The result is a novel helix-in-a-helix structure. The water-filled channel can be seen on viewing the coordination polymer along the *b* axis (see picture; C gray, N blue, Ni green, O red).
Mimicking magnetic minerals: Controlled hydrolysis of iron(III) salts leads to all-ferric molecular fragments with the iron and oxygen topology of magnetite and large spin ground states (see structure; yellow Fe, red O, blue N, gray C).

Tetrathiometalates $[WS_4]^{2-}$ are the nodal building blocks in a new kind of hetero-metallic interpenetrating three-dimensional cluster coordination polymer (see picture) that has interesting nonlinear optical properties. The polymer exhibits optical self-focusing behavior and reverse saturable absorption effects.

The non-native states of the model protein hen lysozyme (native state shown in picture) were investigated by using site-directed mutagenesis in combination with high-resolution NMR spectroscopy. The disruptions of the interactions between hydrophobic clusters by single point mutations dramatically alter the overall compactness of the unfolded state: single point mutations can turn a compact unfolded state into an extended state.
Contents

Made to order: The synthesis of well-defined porous carbon films involves four steps: 1) monomer–block copolymer film casting, 2) structure refining through solvent annealing, 3) polymerization of the carbon precursor, and 4) carbonization. The resulting films, such as that depicted, have potential as separation membranes, chemical sensors, and catalysts.
Information transfer: Crystal structures of bicyclic dipeptide analogues within oligopeptides are described for the first time. The bicyclic dipeptides occupy the i to $i+1$ positions of either βI or βII turns. The rigidified dipeptides form hydrogen-bonding networks which transfer structural information along chains of ambident proton donors and acceptors over several Å (see structures; arrows: hydrogen bonds, red O, blue N, yellow S).
Bridging alcohols, tunneling protons: The intrinsic proton-transfer dynamics of cyclic H-bonded 1:1 7-azaindole/alcohol complexes in *n*-alkanes has been investigated at the lowest-lying excited singlet state with variation of alcohol, solvent, isotope, and temperature by using static and time-resolved spectroscopy. The proton transfer occurs asymmetrically, and the rate is governed by tunneling although it is assisted by heavy-atom motions.
Making a good impression: Photocurable, liquid perfluoropolyethers (PFPEs) are ideal materials for high-resolution (<100 nm) pattern transfer and imprint lithographic processes (see pictures). PFPEs possess attributes of both elastomers and rigid materials, exhibit a remarkably low surface energy, mold extremely small features with high fidelity, resist swelling by organic solvents, and endure repetitive molding procedures.

Contents

A particularly challenging task is the design of anion receptors, because anions are larger than cations and are pH- and solvent-sensitive. The first host for anionic guests is a dendritic octadentate N ligand, which upon reaction with $CuCl_2$, encapsulates chloride ions (Cl6, see picture) as guests by means of anion–π interactions in an electron-deficient cavity formed by four pyridine rings.

Rapidly mixed reaction
Stirring stuff: The morphological evolution of polyaniline from nanofibers to agglomerates during its chemical polymerization shows that the key to producing pure nanofibers is to suppress secondary growth after formation of the nanofibers. A simple and effective method for the synthesis of nanofibers was thus developed in which the polymerization is carried out in a rapidly mixed single-phase reaction (see scheme).
apicularen A

A macrocyclization–transannulation strategy is the crux of an efficient total synthesis of the benzolactone enamide apicularen A (see scheme; Bn = benzyl). Key steps include a four-component coupling, a Stille cross-coupling to introduce the aromatic moiety, and the formation of the enamide from a hemiaminal. The size-selective macrolactonization of the ethoxyvinyl ester shown was followed by transannular etherification in excellent yield.

Reaction lubrication? The reaction between [Ni(1,5-cod)$_2$] (cod = cyclooctadiene) and 1,3-bis-*tert*-butylimidazol-2-ylidene in the presence of silicone grease affords the siloxane bridged dimer [{Ni[C(NtBuCH)$_2$][O(Me$_2$SiOSiMe$_2$)-μ-O]}$_2$]. In a greaseless apparatus, the same reaction yields the dimer **1** (see structure), via two structurally characterized intermediates.

1
The modular assembly of metalloporphyrin oligomers through the stepwise addition of Ru–porphyrin units and a bidentate linking ligand (L, see graphic) onto a surface-confined isonicotinate ligand is reported. Electrochemical measurements of the resulting oligomer show that electrons are transported along the length of its backbone.

(As^{III})$_2$L$_3$

An As$_2$L$_3$ metallocryptand is the result of a new predictive design strategy for forming self-assembled supramolecular arsenic complexes. The assembly is remarkably stable to a variety of competing metal ions, harsh acid, and excess ligand. X-ray crystallographic studies and density functional calculations suggest that a strong arsenic–π interaction adds stability to the structure.
yA•T
Room for expansion: Insertion of a benzene ring into the natural adenine heterocycle to generate the analogue yA results in the formation of base pairs that are 2.4 Å wider than natural ones (see structure). Melting temperature and free energy data show that yA·T and T·yA pairs can self-assemble into cooperative helices that are considerably more stable than natural DNA. Thus, yDNA may be a candidate for a new genetic system.
Rhenium reactions: A reaction under mild conditions between oxo(dithiolato)rhenium(v) complex **1** and triphenylphosphine gives **2**. In the reaction a Re≡O bond is cleaved, P=O and Re≡S bonds are formed at the expense of a CH$_2$S—Re bond, and a new Re—C bond is formed converting a six-membered chelate ring into a five-membered one.

Contents
Blockers, anchors, and reporters: A solid-phase method for the synthesis of lipidated peptides (see scheme) relies on the base-labile Fmoc group to block the N-terminus, an oxidation-labile hydrazide linker for anchoring to the solid support, and lipidated amino acid building blocks incorporating labels or photoactivatable groups.

Band substances: The polymerization of C_3O_2 (see picture left, at $-10\,°C$) into a red-brown, solid polymer (right) having identical composition has been known for almost 100 years. However, the constitution of the polymer remained unknown. Small-angle X-ray scattering studies of the dissolved polymer show that it forms a stiff bandlike molecule with approximately 40 monomeric units, thus confirming the predicted bandlike structure with condensed α-pyrone rings.
Cobalt studs the beltenes shown ($R = H$, CO_2Me, $SiMe_3$, 5 Me), which consist of annelated, conjugated four- and eight-membered rings. These strained molecules were synthesized in a one-pot reaction by a template supported trimerization of 5,6,11,12-tetrahydrodibenzo[*a,e*]-cyclooctene.
The chiral complexing reagent 1 used in the reductive cyclization of 3-(ω-iodo-alkylidene)piperidin-2-ones in the presence of Bu_3SnH and with BEt_3 as the initiator (see scheme) leads to good enantioselectivities thanks to its hydrogen bond mediated association with the radical intermediate. As this example shows, high stereoselectivities are possible for radical reactions proceeding through H-bonded intermediates.

Maintaining neutrality: A perchlorinated triarylmethyl radical and a triarylamine redox center were combined in the design of a neutral organic mixed-valence compound (see picture). The neutral character of this compound facilitated a detailed study of its solvatochromic behavior and the direct determination of the electronic coupling and the dipole moments in the ground and excited state by electrooptical absorption measurements.

Apology

This Communication contains content that overlaps significantly with a Full Paper by the same group "Assembling of Amphiphilic Highly Branched Molecules in Supramolecular Nanofibers" *J. Am. Chem. Soc.* **2004**, *126*, 9675–9684. Although submitted at the same time the authors did not provide the Editors of *Angewandte Chemie* with a copy of the Full Paper. This oversight resulted in the simultaneous appearance of the same information in two publications. The authors apologize for this mistake.

Nobel Prize in Chemistry 2004

The Nobel Prize in Chemistry is awarded to Aaron J. Ciechanover (Technion, Haifa, Israel), Avram Hershko (Technion, Haifa, Israel), and Irwin A. Rose (University of California, Irvine, USA) for the discovery of ubiquitin-mediated protein degradation. Ciechanover, Hershkom, and Rose

A. Hershko and A. J. Ciechanover (right)

I. A. Rose

have demonstrated that the cell functions as a highly efficient checking station where proteins are built up and broken down at a very high rate. Far less research has been done on protein degradation than on protein synthesis. The degradation is not indiscriminate but takes place through a process that is controlled in detail so that the proteins to be broken down at any given moment are given a molecular label: ubiquitin, a protein which consists of 76 amino acid residues. This unit fastens to the protein to be destroyed, accompanies it to the proteasome where it is recognized as the key in a lock, and signals that a protein is on the way for disassembly. Shortly before the protein enters the proteasome, its ubiquitin label is disconnected for re-use. Thanks to the work of the three laureates it is now possible to understand at the molecular level how the cell controls a number of central processes by breaking down certain proteins and not others. When the degradation does not work correctly, diseases result, such as certain forms of cancer.[1]

Ciechanover (b. 1947) obtained an M. Sc. degree (1971) and a doctorate in medicine (M. D., 1974) from Hadassah Medical School in Jerusalem. He obtained a D. Sc. from Technion in Haifa in 1982 and was appointed professor of biochemistry at its Rappaport Institute for Research in the Medical Sciences, as was Hershko (b. 1937). Hershko obtained M. D. (1965) and Ph. D. (1969) degrees from Hadassah Medical School. Rose (b. 1926) has been an emeritus professor at the Department of Physiology and Biophysics of the University of California in Irvine since 1997, and is a member of the US National Academy of Sciences. A major part of the research was done during a series of sabbatical leaves in the late 1970s and early 1980s that Hershko and Ciechanover spent as visiting scientists in Rose's laboratory at Fox Chase Cancer Center in Philadelphia, where he was employed from 1963 to 1995. Rose earned a Ph. D. in biochemistry in 1949 from the University of Chicago. Subsequently, he worked as a Post-Doc at Case Western Reserve University in Cleveland and New York University and served on the faculty of the Department of Biochemistry of Yale Medical School from 1954 to 1963. This is the first time a Nobel Prize in science has been awarded to Israelis.

Physiology or Medicine

Richard Axel (Columbia University, New York, USA) and Linda B. Buck (Fred Hutchinson Cancer Research Center, Seattle, WA, USA) were awarded the Nobel Prize in Physiology or Medicine 2004 for their discoveries of odorant receptors and the organization of the olfactory system. They discovered a large gene family, which consists of some 1000 different genes (three per cent of our genes) that give rise to an equivalent number of olfactory receptor types. These receptors are located on the olfactory receptor cells, which occupy a small area in the upper part of the nasal epithelium and detect the inhaled odorant molecules.

Physics

Their research on the very fundaments of physics has brought this year's Nobel Prize in Physics to David J. Gross (University of California, Santa Barbara, USA), H. David Politzer (California Insitute of Technology, USA), and Frank Wilczek (Massachusetts Institute of Technology, USA): The particle physicists are recognized for the discovery of asymptotic freedom in the theory of the strong interaction, which keeps the quarks in neutrons and protons together. In a way that resembles releasing a rubber band, this force weakens when the particles move closer together. Eventually, they behave almost like free particles. This discovery was formulated in an elegant mathematical way in 1973 and led to a completely new theory: quantum chromodynamics.

This year, the Prizes are worth 1.1 million Euros each. They are given traditionally on December 10, the anniversary of Alfred Nobel's death.

Chiral Metal–Organic Assemblies—A New Approach to Immobilizing Homogeneous Asymmetric Catalysts

Li-Xin Dai*

*H*omogeneous asymmetric catalysis has the advantages of high enantiose-lectivity and catalytic activity for a variety of asymmetric transformations conducted under relatively mild reaction conditions.[1] However, since the catalyst loadings employed in most cases have ranged from 1 to 10 mol %, homogeneous methods remain impractical due to the high cost of the chiral noble metal catalysts and the difficulty of their recovery and reuse.[2] The other problem with homogeneous catalysis stems from the trace contaminants leached from the catalysts in the products, which is particularly unacceptable for pharmaceutical production. The immobilization of homogeneous catalysts should resolve the problems of recovering and recycling.[3,4] Many approaches have been employed with this aim, including using inorganic materials, organic polymers, dendrimers, and membranes as supports, as well as conducting the reactions in ionic liquid and biphasic systems.[3,4]

In the classical immobilization with organic polymers,[3,4] the chiral ligands or the catalytically active units are anchored randomly onto irregular polymers (Type 1, Scheme 1). The resulting immobilized catalysts often display reduced enantioselectivity and less efficiency than their homogeneous counterparts. The incorporation of chiral ligands on the main chain of the polymers

Scheme 1. Three types of polymer-immobilized chiral catalysts. Type 1: Pendant ligands anchored on a polymer; prepared by polymer reaction. Type 2: Ligands on the backbone; prepared by copolymerization. Type 3: Ligand and metal on the backbone; prepared by coordination.

is another approach (Type 2, Scheme 1). Here, the chiral ligand unit is copolymerized with a specific linker.[5] Although the use of chiral polymers for asymmetric catalysis has a long history,[3] successful examples were realized at the end of last century by incorporating the rigid binaphthyl skeleton in the main chain. For example, Chan and Fan et al. incorporated the binap skeleton (binap = 2,2′-bis(diphenylphosphanyl)-1,1′-binapthyl) into a polyester chain,[6] and Lemaire et al. used a polyamide to copolymerize with the binap skeleton.[7] On the other hand, the backbone of the catalyst developed by Pu and co-workers was a wholly rigid aromatic system, comprising a large portion of the binaphthyl skeleton.[5] All of these catalysts showed excellent enantioselectivity. Moreover, Chan and Fan et al. also showed that the leaching of metal from the polymer-supported catalyst is almost negligible (< 16 ppb).[6] This strategy is indeed successful,[8] but it is necessary to

synthesize the polymeric ligands beforehand.

Very recently, the third type of polymer-immobilized chiral catalyst (Type 3, Scheme 1) was described.[9] Several examples showed very high enantioselectivity and efficiency.[10–12] This type of catalyst is called a metal–ligand polymer[13] for the sake of simplicity and in the context of asymmetric catalysis. The concept is to transform a ligand from a homogeneous catalysts which has one coordination site into a ligand with two or more coordination sites and then react it with metal species to ensure the self-assembly of the metal–ligand polymer (or oligomer).

Recent extensive research on the design and synthesis of metal–organic frameworks has led to the increasing numbers of such metal–organic assemblies. Accordingly, many novel metal–organic assemblies with high stability, organic functionality, and porosity have been reported in the last decade. The research groups led by Lehn,[14] Yaghi,[15] Stang,[16] and Fujita,[17] among others[18] have significantly forwarded the development of this challenging area and have demonstrated that these metal–organic assemblies based on discrete or infinite networks with well-defined coordination geometries and functions can be rationally designed and synthesized by the combination of organic bridging ligands and metal ions. Aoyama and co-

workers have demonstrated the catalytic properties of nonchiral metal–organic materials for Diels–Alder reactions.[19] With a few exceptions,[20] homochiral metal–ligand polymers have not been tested for applications in asymmetric catalysis up to the beginning of this century. In any case, the design and synthesis of chiral metal–organic frameworks or polymers might provide a new strategy for asymmetric heterogeneous catalysis, because the chiral bridging ligand can spontaneously form a chiral environment inside the cavities of the materials or on the surface of the solids for enantioselective control of the reaction, and the metal ion acts as the catalytically active center. These solid-state metal–organic materials usually have extremely low solubility in the reaction medium even when other supports are not used and thus fulfill one of the basic prerequisites of heterogeneous catalysis. Accordingly, the use of chiral metal–ligand assemblies can be considered as a "self-supported" strategy[21] for the heterogenization of homogeneous catalysts in enantioselective reactions. This type of chiral metal–organic assembly would not only have the advantages of heterogeneous catalysts, such as easy recovery and convenient recycling, but also of facile preparation and robust chiral frameworks, as well as high density of the catalytically active units.

Kim and co-workers first demonstrated the application of a homochiral metal–organic porous material to enantioselective separation and catalysis in 2000.[9] The homochiral open-framework solid having the formula of $[Zn_3(\mu_3\text{-}O)(1\text{-}H)_6]\cdot 12\,H_2O$ (**2**) was prepared by the reaction of Zn^{2+} with the enantiopure chiral building block **1** derived from D-tartaric acid (Scheme 2). Although the enantiomeric excess in the product of transesterification was rather low ($\approx 8\%$ *ee*), the enantioselectivity was unprecedented because this asymmetric induction was observed for a reaction promoted by a modular porous material. This creative work triggered interest in using self-supported metal–organic systems to immobilize homogeneous catalysts.[22]

The success of asymmetric catalysis with this kind of metal–ligand polymer was realized only very recently. Lin and co-workers reported that the heteroge-

nization of Noyori's catalysts could be achieved by in situ formation of chiral porous hybrid solids such as **8** and **9** through the reaction of zirconium *tert*-butoxide with chiral bisphosphine/Ru complexes functionalized with phosphonic acid groups (**7**) (Scheme 3).[10a]

Nitrogen adsorption measurements demonstrated that these hybrid solids are highly porous with rather wide pore-size distributions. The total BET surface areas of the solids range from 328 to $475\,m^2\,g^{-1}$ with microporous surface areas of 60–$161\,m^2\,g^{-1}$ and pore volumes

Scheme 2. Chiral metal–organic porous materials for the enantioselective transesterification of **3** with racemic **4**.
Scheme 3. Chiral metal–ligand polymer in the catalysis of enantioselective hydrogenation of ketones.

of 0.53–1.02 cm^{3}g^{-1}. The heterogenized catalysts **8a** and **8b** exhibited exceptionally high activity and enantioselectivity in the hydrogenation of aromatic ketones. With 0.1 mol% of catalyst **8a**, the conversion of the substrates was quantitative and the enantioselectivity approached 99% *ee*. Particularly, the catalyst loading can be reduced to 0.005 mol% without significant loss of the enantioselectivity. Remarkably, these binap-derived porous Zr phosphonates provide enantioselectivity superior to that of the parent homogeneous counterpart, the binap/RuCl$_2$/dpen (dpen = 1,2-diphenylethylenediamine) system developed by Noyori et al.[23] The other two catalyst systems, **9a** and **9b**, were also used for the asymmetric hydrogenation of a series of β-keto esters. Under optimized conditions, the hydrogenation with 1 mol% of **9b** afforded the corresponding β-hydroxy esters in quantitative yield and good to excellent enantioselectivities.[10b] For the asymmetric hydrogenation of methyl acetoacetate the catalyst **9b** could be recycled five times without significant loss of enantioselectivity. Catalysts **8a** and **9b** showed better catalytic activity and enantioselectivity than catalysts **8b** and **9a**, respectively, which demonstrates the importance of the position of the linker on the backbone of binap in the formation of the microporous catalyst.

Almost at the same time, the research groups led by Sasai[11] and Ding[12] independently reported an alternative approach to generating chiral metal–organic coordination polymers for enantioselective catalysis. As shown in Scheme 4, the rigid chiral ligands having two 1,1′-2,2′-binaphthol (binol) units react with metal ions, resulting in the spontaneous formation of assembled metal–organic polymers in which the metal ions not only play the role of the bridging linker, but also act as the catalytically active sites. Moreover, the chirality of the binol units in the ligands can provide the asymmetric environment around the catalytically active centers in the polymers. These assembled metal–organic coordination polymers are insoluble in common organic solvents. This offers an excellent opportunity for running heterogeneous catalysis with these "self-supported" cata-

lysts. The metal–ligand polymer of the Sasai and Ding groups is somewhat different from that of Lin et al. In the latter, the catalytic metal center, Ru, is situated as a pendant group on the Zr-linked backbone,[10] while the catalytically active metal of Sasai, Ding, et al. is located on the backbone of the polymer.[11, 12]

The success of this strategy was demonstrated in asymmetric Michael additions[11] and carbonyl-ene reactions.[11, 12] The heterogeneous Al-bridged polymers **15** prepared by the reaction of LiAlH$_4$ with bis(binol) ligands **14** was employed in the enantioselective Michael addition of dibenzyl malonate (**19**) to 2-cyclohexenone (**18**) in THF. Adduct **20** was obtained with results comparable to those obtained with a homogeneous

Al-Li-bis(binaphthoxide) (ALB) catalyst (100% yield, 97% *ee*). After the reaction was complete, catalyst **15a** could be recovered conveniently and reused at least three times with a slight decrease of enantioselectivity (from 96% *ee* for the first run to 85% *ee* for the third run). Similarly, the heterogeneous Ti-bridged catalysts (**16** and **17**) prepared by the reaction of ligands **14** with Ti(O*i*Pr)$_4$ (**14**:Ti = 1:2 or 1:1) gave excellent enantioselectivity (up to 96.5% *ee*) in the carbonyl-ene reaction of **21** with **22**.[11, 12] The reusability of this type of catalyst (**16a**) in the carbonyl-ene reaction was also demonstrated by Sasai et al. After being reused five times the Ti-bridged polymer exhibited consistent catalytic selectivity, affording **23** with an *ee* value of 88% at a catalyst

Scheme 4. Self-supported chiral metal–ligand polymer as catalyst in Michael addition and carbonyl-ene reactions. Bn = benzyl. Y = single bond (**a**); 1,4-phenylene (**b**); 1,3-phenylene (**c**); 1,2-phenylene (**d**).

loading of 20 mol%. It seems that catalyst **17a** prepared with **14**:Ti = 1:1 (1 mol%, up to 99% yield and 96% *ee*) possesses higher activity and enantioselectivity than **16a** prepared with **14**:Ti = 1:2 in the presence of 1 equiv of H_2O (20 mol%, up to 72% yield and 92% *ee*). This phenomenon probably arises from the activating effect of additional binol unit in **17a**.[24] In both the Michael addition and carbonyl-ene reaction, the linkers between two binol units in the ligands have significant impact on the enantioselectivity of the assembled catalysts prepared from them. The heterogeneous catalysts derived from **15a,b** and **17a,b**, in the pairs of the phenolic hydroxy groups are situated at opposite sites in the symmetric, multidentate ligands, gave the Michael adduct or carbonyl-ene adduct with higher enantioselectivity than that attained with the catalysts from ligands **15c,d** and **17c**, respectively. The dramatic influence of the linking spacer on the enantioselectivities of the reactions reflects that the linkers between two binol units of the ligands probably significantly alter the supramolecular structure of the assemblies in the catalysts. Therefore, the frameworks of assembled catalysts can be optimized by the rational design of chiral ligands to improve the catalytic activity and enantioselectivity of the "self-supported" catalyst.

Obviously, the "metal–ligand polymer" strategy for the immobilization of homogeneous catalysts developed by the Lin,[10] Sasai,[11] and Ding groups[12] represents a significant breakthrough in the heterogeneous asymmetric catalysis, since it satisfies many requirements for the immobilized catalysts. Their performance is comparable to or better than that of the parent catalysts, they are easy to separate and reuse, and there is minimum leaching of the catalyst. Furthermore, the metal–ligand polymer was prepared by an in situ self-assembling process, a really simple manipulation. This strategy might provide a new direction in asymmetric catalysis, particularly for the development of practical syntheses of optically active compounds. Meanwhile, the use of chiral "metal–ligand" assemblies for chiral recognition

and separation may be another exciting area in chiral chemistry.[25]

Highlights

DNA-Based Barcodes, Nanoparticles, and Nanostructures for the Ultrasensitive Detection and Quantification of Proteins

Susanne Brakmann*

Keywords:
antibodies · antigens · immunoassays · proteins

*I*mmunoassays are techniques that employ labeled or nonlabeled antibodies for the quantitative assessment of analytes. These techniques have become most popular in clinical and medical research laboratories because they are precise, sensitive, and relatively inexpensive. Increasingly important, however, is the detection of proteins at extremely low concentrations, especially in biofluids containing very low titers of disease markers and in food or environmental samples containing toxic or ineligible proteins. Although classical tests such as ELISA (enzyme-linked immunosorbent assay; Figure 1a) and RIA (radioimmunoassay) are capable of providing relatively high sensitivity and very low limits of detection (1 fmol), they may not be applicable to all possible samples, for example, antigenic species present at very low concentrations. Currently, this is the problem with prion diseases. A major improvement in the sensitivity of immunoassays was achieved by Cantor and his colleagues about ten years ago: Rather than coupling the detection antibody to an enzyme, these researchers linked the antibody to one or more DNA fragments, which can then be amplified specifically by polymerase chain reaction (PCR) before detection, for example, by gel electrophoresis (Figure 1b). Instead of the

Figure 1. a) Principle of the ELISA assay. b,c) Principle of immuno-PCR with conventional detection of the PCR product (b) and with quantitative detection using a FRET probe (c, real-time IPCR).

linear signal amplification achieved by the ELISA test, the PCR process yields an exponential amplification, thus lowering the detection limit by three to four orders of magnitude.[1]

Since then, this technique, called immuno-PCR (IPCR), has proved to be suitable for the highly sensitive detection of antigens, antibodies, pathogens, tumor markers, and potential therapeutics in the femto- to attomolar concentration range and therefore, is of interest predominantly for clinical diagnostics. A number of different IPCR protocols have been developed showing that this technique can be adapted for a broad range of analytes and immunoassay techniques (a recent review is found in ref. [2]). Due to the tremendous amplification power of PCR, IPCR is extremely sensitive not only in detecting specific proteins but also in detecting cross-contaminations of extrinsic nucleic acids or false-positive signals resulting from unspecific binding of the antibody. Application of IPCR as a routine method thus requires the elimination or inactivation of impurities to the greatest possible extent and the use of highly standardized protocols.

In combination with "real-time" PCR techniques[3] that have become highly popular during the past years, IPCR has been extended to a robust technique for the quantitative detection of antigens and is suited for routine diagnostics as well as for the parallel analysis of large numbers of samples. For these applications PCR mixtures are supplied with DNA intercalators like SYBR-Green or FRET probes like Taqman that bind to the nascent DNA chain and consequently, fluoresce. Since machines exist that can monitor fluorescence directly during amplification and evaluate the data relative to a calibration curve, real-time IPCR (rtIPCR) can be used for the reproducible and quantitative detection of analytes in microplate formats (96 wells, or 384 wells) and also, for the recording of melting curves that support the characterization of amplicons.

An important example that illustrates the sensitivity and impact of the rtIPCR technique was recently presented with the detection of only 30 000 molecules of the potent cytostatic anticancer drug rViscumin (concentration ca. 100 $fg\,mL^{-1}$) in standardized human serum samples.[4] Supramolecular IPCR reagents—oligomeric conjugates made from streptavidine, bisbiotinylated dsDNA, and biotinylated antibodies that were recently developed by Niemeyer and colleagues[5]—made the impressive sensitivity possible because they enabled the binding to multiple analytes, which resulted in an entropic advantage. Additionally, the authors improved their rtIPCR assay by adding a competitively replicating DNA fragment that serves as an internal standard and also, increases the signal-to-noise ratio (Figure 1 c).[6]

Unfortunately, rtIPCR has not as yet found its way into routine diagnostics despite impressive sensitivity and successful demonstration of its efficiency in highly reproducible analyses. This could be due to the still-complex preparation of IPCR probes. These conjugates of DNA and antibodies are typically strongly bound either through covalent interactions or streptavidine–biotin binding. While DNA–antibody conjugates are synthesized by means of the sulfhydryl and amino functions of DNA or the antibody,[7,8] streptavidine–biotin conjugates are usually made starting from biotinylated antibody and biotinylated DNA.[5,9] Both approaches require complex modifications to link DNA and antibody proteins that are only occasionally commercialized.

Nanoparticle-Based Barcodes for the Identification of Proteins

Further improvements in IPCR sensitivity could be limited by the low ratio of detection antibody to DNA identification sequence (usually 1:1) as well as slow target-binding kinetics that are due to the heterogeneous nature of the target-capture procedure.[10] For this reason many new concepts concerning amplified biosensing combine the immunoassay with techniques for the immobilization of biopolymers at the surfaces of micro- and nanoparticles. The combination is advantageous not only for the formation of recognition complexes in suspension; commercially available and meanwhile widespread magnetic microparticles can also be used for the physical isolation of the immunocomplexes using an external magnet. Therefore these techniques are ideally suited for the separation and enrichment of antigen–antibody conjugates from complex mixtures (see ref. [11] and references therein).

In a recently published approach, Mirkin and colleagues demonstrated the detection of a tumor marker (PSA, prostate-specific antigen) with a system of antibody-linked microparticles and gold nanoparticles functionalized with anti-PSA antibodies and double-stranded DNA.[14] In the presence of PSA a specific complex forms connecting the magnetic microparticles and gold nanoparticles (Figure 2). The functionalization of gold nanoparticles with a combination of both DNA and antibody had already been described.[12] Mirkin et al. were able to show that 180 molecules (concentration 30 am) of free PSA, usually present at (sub-)femtomolar concentration in the sera of breast cancer patients,[13] can be detected without PCR amplification, while ten times less, that is, a minimum of 18 molecules (concentration 3 am) were detectable with amplification.[10]

Mirkin's astonishingly sensitive approach is characterized not only by an enrichment of the immunocomplex by means of magnetic separation techniques but also by a high ratio of recognition antibody to marker DNA (approx. 1:100). The signaling immunocomplex is a "sandwich" of magnetic microparticles functionalized with PSA monoclonal antibodies (mABs), antigenic PSA, and gold nanoparticles functionalized with one or a few copies of a polyclonal antibody directed against PSA as well as multiple copies of double-stranded marker DNA. After formation of the sandwich complex, all magnetic particles or particle complexes are separated by application of an external magnet, leaving unreacted nanoparticles and antigens in solution. Marker DNA that is attached to the enriched complexes serves as a template in PCR amplifications and can be detected easily by standard techniques (such as gel electrophoresis and staining with ethidium bromide). However, Mirkin achieved greater sensitivity in detecting DNA by melting the double-stranded marker DNA, optional PCR
Figure 2. Essential steps in a bio-barcode immunoassay. The first (monoclonal) antibody is linked to the surface of magnetic microparticles, which are employed for separating and enriching the protein from the sample solution. The second (polyclonal) antibody is bound to gold nanoparticles, which also are functionalized with multiple double-stranded DNA fragments. Following formation and magnetic separation of the sandwich complex, these DNA strands are detached and can be detected either after PCR amplification or by using DNA chips.

a distinct marker DNA sequence. Therefore, these DNA sequences were called "bio-barcodes" by Mirkin.[14]

Similar to rtIPCR, the bio-barcode approach requires the synthesis of antibody conjugates such as the noncovalent, equimolar coupling of gold nanoparticles to polyclonal antibody prior to the covalent coupling with a 10- to 100-fold excess of barcode DNA. Both compliance with the desired stoichiometry as well as stabilization and handling of the resulting conjugates are exceedingly difficult. The immobilization of monoclonal antibody on the surface of magnetic microparticles can be achieved in a straightforward fashion using well-established glutaraldehyde–amine coupling chemistry (efficiency 90%).

Another difficulty associated with Mirkin's procedure may arise from the utilization of polyclonal antibodies for the recognition of the antigen. This type of antibody can also bind to other proteins. The resulting reduction in the signal-to-noise ratio would lead to a loss of sensitivity and, in particular, would compromise the parallel detection of analytes. However, it will be tantalizing to see whether the ultrasensitive bio-barcode technique will be suitable for "real life".

Bioelectronic Coding and Detection of Proteins

Promising alternatives to optical detection techniques are possible with electronic approaches, which in addition can be triggered and controlled using magnetic microparticles.[11] These techniques are based on the electroactivity of nucleic acids, which adsorb strongly to electrodes where they undergo charge-transfer reactions.[15] Thereby, predominantly the nucleobases are reduced at mercury electrodes and oxidized at graphite electrodes. Because nucleobases that accumulate at the electrode surface come off during oxidation, they can be detected using potentiometric stripping analysis (PSA) at very low concentrations (nM).[15]

Wang and colleagues utilized this DNA property for the development of a highly sensitive immunoassay-based method to detect proteins that is closely related to the technique presented by

amplification, and chip-based detection, which comprises the hybridization of marker DNA with immobilized complementary strands, silver staining of the resulting double-stranded DNA, and scanometric detection. The assay is also suited for the parallel analysis of multiple analytes if every antigen is coded by

Mirkin et al.[16] The "bioelectronic" protocol also is based on the formation of a sandwich immunocomplex starting from antibody-linked magnetic microparticles and DNA-functionalized polystyrene particles which also are coupled to the detection antibody. Following magnetic separation and enrichment of particle-bound immunocomplexes, marker (barcode) DNA is detached by alkaline denaturation of the double-stranded DNA and subsequently submitted to acid-catalyzed depurination. Free purines (adenine, guanine) can then be detected quantitatively using chronopotentiometric stripping analysis at a pyrolytic graphite electrode (Figure 3).

The authors demonstrated that they were able to detect as few as 40000 molecules of an analyte (concentration 13 fM) by their bioelectronic approach without amplification, for example, by PCR. By including an amplification step, the already high sensitivity could be increased additionally by two orders of magnitude. Due to high sensitivity, selectivity (that is, no background signal in the absence of analyte or in the presence of a 1000-fold excess of bovine serum albumine) as well as high reproducibility (standard deviation of ca. 5% in six analogous experiments), the electronic detection of barcode DNA appears promising. However, it remains to be seen whether the probes will become commercially available so that this approach could become a routine method for diagnostics or proteome analysis. Ultimately, the market for new technologies, which almost always responds slowly to innovations, will be decisive for the distribution of all three methods, rtIPCR, bio-barcodes, and bioelectronic barcodes.
Figure 3. In the case of the bioelectronic barcode assay, the second antibody is coupled to plastic beads which, again, are functionalized with many short DNA fragments. After detachment of the DNA, the purines adenine and guanine are released and can be detected by electrochemical analysis, by which adenine is clearly distinguishable from guanine.

Sulfatases: Structure, Mechanism, Biological Activity, Inhibition, and Synthetic Utility

Sarah R. Hanson, Michael D. Best, and Chi-Huey Wong*
*S*ulfatases, which cleave sulfate esters in biological systems, play a key role in regulating the sulfation states that determine the function of many physiological molecules. Sulfatase substrates range from small cytosolic steroids, such as estrogen sulfate, to complex cell-surface carbohydrates, such as the glycosaminoglycans. The transformation of these molecules has been linked with important cellular functions, including hormone regulation, cellular degradation, and modulation of signaling pathways. Sulfatases have also been implicated in the onset of various pathophysiological conditions, including hormone-dependent cancers, lysosomal storage disorders, developmental abnormalities, and bacterial pathogenesis. These findings have increased interest in sulfatases and in targeting them for therapeutic endeavors. Although numerous sulfatases have been identified, the wide scope of their biological activity is only beginning to emerge. Herein, accounts of the diversity and growing biological relevance of sulfatases are provided along with an overview of the current understanding of sulfatase structure, mechanism, and inhibition.

From the Contents

1. Introduction

Whereas sulfotransferases have been the subject of intense investigation for the past several years, sulfatases have received considerably less attention. Sulfatases were discovered sporadically in eukaryotes and prokaryotes throughout the 20th century, but for a long time this class of enzymes was undervalued, as their biological function was thought to be limited mainly to the degradation of organic sulfates in soil. An abundance of new information regarding human sulfatases became available in the 1960s after it was discovered that sulfatase deficiencies led to a number of inherited lysosomal disorders. Since then, sulfatases have emerged as important components in processes such as hormone regulation (and deregulation in hormone-responsive cancers), gamete interactions, and proper bone and cartilage development.

Most recently, sulfatases have been implicated in the modification of sulfate moieties on glycosaminoglycans (GAGs),[+] which dictate developmental cell signaling and patterning phenomena in the extracellular matrix (ECM). Furthermore, new functions of invertebrate and prokaryotic sulfatases have been discovered, including potential roles in bacterial pathogenesis. This Review takes a comprehensive look at the sulfatase family, examining structure, mechanism, and inhibition. Information on the substrates and biological roles of sulfatases, focusing on emerging topics and potential therapeutic targets, is also provided. Finally, the synthetic utility of these enzymes for probing the biological interactions of sulfated carbohydrates and GAGs within the extracellular matrix is discussed.

2. The Sulfatase Family

Sulfatases (EC 3.1.5.6) catalyze the hydrolytic desulfonation of sulfate esters (CO–S) and sulfamates (CN–S) [Eq. (1)

$$\text{ROSO}_3^- + \text{H}_2\text{O} \rightarrow \text{ROH} + \text{HSO}_4^- \tag{1}$$

and (2), respectively].

$$\text{RN(H)SO}_3^- + \text{H}_2\text{O} \rightarrow \text{RNH}_2 + \text{HSO}_4^- \tag{2}$$
They comprise a class of enzymes that is highly conserved sequentially, structurally, and mechanistically across eukaryotic and prokaryotic species. The remarkable similarities shared by sulfatases include: 1) 20–60% sequence homology over the entire protein length, 2) a highly conserved N-terminal region containing the consensus sulfatase motifs, and 3) a unique active-site aldehyde residue, α-formylglycine (FGly), which is installed post-translationally.

The high degree of sequence and structural likeness observed thus far amongst sulfatases has led to the proposal that they emerged long ago from a common ancestral gene.[1,2] The human enzymes (15 are known, 13 genes have been cloned, Table 1) and the invertebrate, lower eukaryotic, and prokaryotic enzymes (many are known, 13 genes have been cloned, Table 2) are typically between 500 and 600 amino acids in length; the newly discovered human Sulf enzymes

[a] The genes for human sulfatases marked with asterisk have not yet been cloned. In addition to human genes, orthologues with equivalent roles have been cloned from many other vertebrates (mice, rats, cats, pigs, quails, and goats). [b] ER = endoplasmic reticulum, ECM = extra cellular matrix. [c] References for gene cloning or discovery (*).

have a slightly longer sequence of around 800 residues (Figure 1). In eukaryotes, sulfatases are targeted for the secretory pathway and are extensively glycosylated before being transported to the extracellular matrix (ECM) or to subcellular locations, such as the endoplasmatic reticulum (ER), Golgi complex, and lysosome (Table 1). The lysosomal and extracellular sulfatases are soluble, whereas the residents of the ER and Golgi network are membrane bound. All known invertebrate, lower eukaryotic, and bacterial sulfatases are soluble and have been found to reside in cytoplasmic, periplasmic, and extracellular regions (Table 2).[3]

Sulfatases catalyze the hydrolysis of a diverse range of sulfate ester substrates, including hydrophobic glucosinolate, steroid, and thyronine sulfates; amphiphilic sulfated carbohydrates found in GAGs, proteoglycans, and glycolipids; and water-soluble mono- and disaccharide sulfates. The identification of physiological substrates of sulfatases has often trailed behind the initial discovery of these enzymes by using small aryl substrates; hence, many of them carry the generic name aryl sulfatase (ARS).[3–5] Eight disorders in humans are known that result from a deficiency in a single sulfatase (Table 3).[1,6,7] Furthermore, a rare autosomal recessive disorder known as multiple sulfatase deficiency (MSD) results from severely decreased activity in all sulfatases.[8]

Chi-Huey Wong received his B.S. and M.S. degrees from the National Taiwan University and completed his PhD in chemistry at the Massachusetts Institute of Technology. After a postdoctoral year at Harvard University, he moved to Texas A&M University in 1983, and became Professor of Chemistry at The Scripps Research Institute in 1989 (Ernest W. Hahn Chair). His research interests include bioorganic and organic methods in synthesis, as well as biocatalysis with a particular focus on the study of carbohydrate-mediated biological recognition.

Sarah R. Hanson received her B.S. in chemistry in 1999 at the University of California, Berkeley, with research on antiproliferative purine derivatives with Prof. Peter G. Schultz. She also spent a summer as an NSF Undergraduate Fellow with Prof. Maria C. Linder. After graduating, she took an industrial position at Diversa, where she was involved in the development of novel enzyme catalysts. Since 2002, she has been enrolled in the Chemistry Graduate Program at The Scripps Research Institute under the guidance of Prof. Chi-Huey Wong.

Figure 1. Signature sequences of sulfatases. Partial alignment of sulfatases from all sulfatase genes cloned shows a homology of the sulfatase signature sequences (PS00523). This consensus sequence is important for directing the first amino acid residue to the catalytically active FGly for oxidation. Highly conserved residues are shown in white letters on a black background; other significantly conserved residues are shown in gray. The accession codes for ExPASy are given, or the reference to the literature for those proteins not deposited with ExPASy.

Two highly homologous amino acid motifs, recognized as the sulfatase signature sequences I and II, are found within the first third of the N-terminal sequence of all known hydrolytic sulfatases.[9] The signature sequence I, comprising the 12 amino acids C/S-X-P-S/X-R-X-X-X-L/X-T/X-G/X-R/X, is critical for directing the post-translational modification of the initial cysteine or serine residue into the catalytically active residue FGly.[10, 11] The specialized role of these residues is underscored by their highly conserved nature from eukaryotic to prokaryotic organisms, as shown by the partial alignment of sequences Figure 1. The core motif C/S-X-P-X-R is conserved throughout the entire enzyme class. The arginine residue in this pentapeptide sequence has been shown to act as: 1) an important director in FGly modifica-

Michael Best received his B.S. in chemistry in 1997 from Boston College, where he worked with Prof. Lawrence T. Scott on the synthesis of fullerene derivatives. He completed his PhD in 2002 at the University of Texas at Austin on the design and synthesis of fluorescent sensors for biomolecules in the research group of Prof. Eric V. Anslyn. He has since been carrying out postdoctoral research with Prof. Chi-Huey Wong at The Scripps Research Institute on the development of small organic molecules which perturb biological systems.

Table 3: Inherited disorders resulting from deficiency in a single sulfatase.[a]

Subcellular location	Sulfatase	Genetic disorder[b]
lysosome	ARSA	metachromatic leukodystrophy (MLD)
	IdoAS	Hunter's disease (MPS II)
	GlcNS	Sanfilippo A (MPS IIIA)
	GlcN6S	Sanfilippo B (MPS IIIB)
	GalN6S	Morquio A (MPS IVA)
	ARSB	Maroteaux-Lamy (MPS VI)

	ARSE	chondrodysplasia punctata (CDPX)

[a] In addition to the diseases resulting from a deficiency in a single sulfatase, a rare genetic disorder known as multiple sulfatase deficiency (MSD) shows markedly diminished activity in all sulfatases. [b] MPS = mucopolysaccharidoses.

tion,[10] 2) an integral member of the active site that stabilizes the FGly residue,[12] and 3) a critical structural element.[11] The conserved proline residue also plays a key role in directing FGly modification[10] and is believed to be part of an α helix that precisely situates FGly within the active site.[11] Interestingly, two enzymes that are not sulfatases, a phosphate monoester hydrolase (U44852) and an alkaline phosphatase (AF047381), have also been found to contain the core directing sequence C/S-X-P-X-R. Given the potential evolutionary link between sulfatases and the alkaline phospha-

tases,[13] these enzymes could be the most likely candidates outside the sulfatase class to harbor an FGly residue. The second sulfatase signature sequence contains the 12-mer consensus sequence G-Y/V-X-S/T-X-X-X-G-K-X-X-H. The conserved lysine and histidine residues within this motif are active-site residues that are important for sulfate ester catalysis.[14]

3. Structure

The structures of four sulfatases have been solved to date by X-ray crystal-structure analysis: HARSA (2.1 Å),[15] HARSB (2.5 Å),[16] and HARSC (2.6 Å)[17] from humans, as well as PARS (1.3 Å) from the gram-negative bacterium *Pseudomonas aeruginosa*.[12] The structures are strikingly similar, revealing a nearly spherical globular monomer with mixed α/β topology, which is divided into two domains (Figure 2). ARSC additionally contains a unique transmembrane domain from which the soluble domain "sprouts", giving the enzyme a "mushroomlike" morphology. The larger, N-terminal domain consists of α helices surrounding a large mixed β sheet, which consists of 10 strands in the HARSA, HARSB, and PARS structures and 11 strands in HARSC. The smaller, C-terminal domain contains a four-stranded antiparallel β sheet tightly packed against a long, solvent-exposed C-terminal α helix. As is typical for the α/β family of enzymes,[18] the active-site cavity is nestled at the C-terminal end of the large β sheet, with the FGly residue located at the bottom of a narrow cleft lined with charged amino acids. The catalytic N-terminal domain of sulfatases shows a high degree of structural similarity to that of the alkaline phosphatases (APs) but differs dramatically in sequence.[19] When the structures of ARSA and AP are superimposed, 169 contiguous C^{α} atoms overlap, including the large β sheets and several key active-site residues, with a root-mean-squared deviation (rmsd) of 1.9 Å. Similar values are obtained when comparing HARSB and PARS.[15]

Crystallographic and mutagenesis studies have provided valuable information about the active site of sulfatases (Figure 3). In each of the structures solved thus far the catalytic residues and geometry are conserved to a remarkable extent (rmsd < 0.45 Å), which supports the notion of a
Figure 2. Crystal structures of sulfatases (red cylinders: α helices, yellow arrows: β sheets). A) Structure of PARS, characterized by two subdomains with mixed α/β topology. B) Same structure of PARS, rotated 90°; the strands of the large β sheet within the N-terminal domain (numbered 1–10) and the small β sheet in the C-terminal domain (labeled a–d) are visible. C) Structure of HARSC, which shares high structural homology with PARS within the globular domains. This ER-resident protein also contains a transmembrane domain comprising two highly hydrophobic helices of 40 Å in length.

conserved mechanism for sulfate ester hydrolysis. The active site is comprised of 10 highly interconnected polar residues and a divalent metal cation; the positions and proposed functions of these components are summarized in Table 4. In the case of HARSA, the importance of each of these residues was further established in a mutational scanning experiment.[14] A metal-binding region is formed by the generic residues AspA, AspB, AspC, and AsnA, which is conservatively replaced by a glutamine residue in ARSC. In HARSB, HARSC, and PARS these metal-binding residues, along with FGly and an oxygen atom of the sulfate (or water in its absence), coordinate a Ca^{2+} cation heptavalently; in HARSA an Mg^{2+} ion is coordinated octahedrally. However, in the latter case it can not be excluded that the magnesium ions, which were present in high concentrations during the purification of the enzyme, replaced the native cation,[15] as was observed in a more recent refinement of the ARSA
Figure 3. A generic rendition of the sulfatase active site depicting the highly conserved residues found in the crystal structures. Key hydrogen-bonding interactions are shown with dotted lines. For the sake of clarity some details are not shown in the diagram, including localized charges, some double bonds, and several interactions, such as a salt bridge between LysA and the noncoordinated oxygen atom of AspC, a hydrogen bond between sulfate and the nitrogen atom in the main chain of FGly, and several sulfate–FGly interactions. Table 4 lists the positions and proposed functions of the residues in each solved structure.

structure by another research group.[20] Severe decreases in binding and catalytic activity were observed upon mutation of any of the metal-binding residues in HARSA, underscoring the central role the metal plays in cleaving sulfate esters, presumably by both binding the substrate and activating it for nucleophilic attack.[14]

The catalytic pocket is lined with several positively charged residues, including LysA and LysB, which are involved in binding the anionic sulfate. Along with the divalent metal ion and HisB, these residues probably neutralize the sulfate anion and withdraw electron density to create an electrophilic sulfur center. They also position the tetrahedral sulfate for an in-line nucleophilic attack by FGly.[21] Furthermore, HisB and LysB are implicated in the protonation of the exocyclic oxygen atom on the alcoholate leaving group released in the transesterification. The catalytic

FGly residue rests at the bottom of the pocket as an FGly hydrate (FGH). The geminal diol performs two distinctive functions: FGH-Oγ1, which interacts with the metal center and AspA, is orientated ideally for nucleophilic attack on the sulfur atom of the substrate; FGH-Oγ2, which is anchored by HisA, ArgA, and LysA, points toward the center of the pocket and is involved in the elimination of the enzyme–sulfate ester intermediate. The critical functions of the geminal hydroxy groups are thought to be mediated by protons, shuffling between AspA and FGly-Oγ1, in addition to HisA and FGly-Oγ2 (Section 4).

To date, no crystal structures of sulfatases bound to their natural substrates have been solved, leaving the residues that play a role in substrate specificity largely unknown. Presumably, the recognition of natural substrates must occur outside the narrow cleft containing the conserved active-site residues. The cocrystal structure of Cys69Ala-HARSA (a mutant with the catalytic FGly residue replaced by alanine) with *p*-nitrocatechol sulfate (pNCS, a general substrate for sulfatases) exhibited a tightly bound sulfate group (coordinated by the metal center, LysA, LysB, and HisA; Figure 3) and a highly disordered phenyl ring outside the sulfate-binding pocket.[21] Indeed, the fact that many sulfatases accept small aryl substrates could mean that extensive binding sites on their surfaces discriminate between and properly align large substrates, but do not necessarily hinder access to the active site.

Typically, the C-terminal region of sulfatases bears the highest structural diversity and is a likely candidate for a substrate-discerning region. Interestingly, the HSulf sulfatases and HGlcN6S, which catalyze the hydrolysis of glucosamine-6S (GlcNAc$_{6S}$) residues, contain C-terminal stretches of amino acids that exhibit high homology with a region of the GlcNAc transferase from *Arabidopsis thaliana*, suggesting that this region may play a role in the recognition of the GlcNAc substrate.[22] The C-terminal region of the membrane-bound sulfatases may also serve an additional purpose. According to the crystal structure of ARSC, the small subdomain is involved in several key interactions between hydrophobic loop structures and the lipid bilayer. These polypeptide segments could potentially act as "swinging doors" to recognize substrates and lead them to the active-site gorge, which is buried near the membrane surface. The active-site gorge of ARSC contains a host of nonpolar

Table 4: Positions and proposed functions of amino acids and metal cations in the active site.

Residue[a]	PARS	HARSA	HARSB	HARSC	Proposed function
FGly	51	69	91	75	catalytic nucleophile as FGH

residues that are capable of forming hydrophobic interactions with the steroid backbone when the sulfate is properly aligned in the sulfate-binding cleft.[17]
4. Mechanism

4.1. Sulfate Ester Hydrolysis

The most salient feature of the sulfatase family of enzymes is the presence of the FGly residue (2-amino-3-oxypropanic acid, α-formylglycine) in the active site. FGly is present in the active site of all prokaryotic and eukaryotic sulfatases characterized to date and is essential for catalytic activity.[23] Its importance was initially identified by von Figura and co-workers during their extensive studies on multiple sulfatase deficiency (MSD).[8] The researchers correctly speculated that a common structural feature in the sulfatase active site, generated by a post-translational modification, was deficient in MSD patients, thus resulting in the global inactivation of sulfatases.[24] In a landmark study, the novel aldehyde modification was detected in the position in which a cysteine residue was encoded in the cDNA for HARSA and HARSB enzymes.[25] Later, it was determined that the residue destined for modification can be either cysteine in eukaryotes[25,26] and prokaryotes,[27] or serine[28] in prokaryotes. Prokaryotic sulfatases are therefore further categorized as Cys-type or Ser-type.[29–32]
The mechanism of sulfate ester hydrolysis remained a mystery for years, as nothing was known about the underlying post-translational modification required to generate the key active-site aldehyde. The elucidation of the mechanism was greatly facilitated by the discovery of this modification and by the crystal structures of the sulfatases.[12,15–17] Although it was immediately clear that the novel FGly residue was crucial for catalysis,[25,33] its mode of action was the subject of debate for some time.[23] Structural similarity with the alkaline phosphatases (APs) provided initial insight into the mechanism of the sulfatases, and after the first sulfatase structure was solved in 1995 (HARSB) an addition–hydrolysis (AH) mechanism was proposed.[16] As depicted in Scheme 1a, the mechanism begins with a nucleophilic attack by a sulfate group oxygen atom at the electrophilic aldehyde group of FGly to form a sulfate diester. The alcohol conjugate is then released through the action of a nucleophile, such as an activated water molecule (akin to the AP mechanism). The FGly–sulfate adduct (FGS), which was observed in the HARSB crystal structure, was proposed to be the resting state of the catalytic cycle, although equilibrium with the aldehyde was assumed. The HARSA resting-state structure was interpreted differently: Its structure showed a twofold-disordered electron-density pattern at the FGly residue, leading to the postulation that the FGly functions catalytically as an

Scheme 1. Proposed mechanistic schemes for the hydrolysis of sulfate esters by the active-site aldehyde FGly. a) An addition–hydrolysis (AH) mechanism was proposed based on the interpretation of a sulfate hemiacetal (FGS) in the crystal structure of HARSB as the resting state of the catalytic cycle. b) A transesterification–elimination (TE) mechanism was presented for hydrated aldehyde group (FGH) present in the crystal structure of HARSA. See text and Scheme 2 for details.

aldehyde hydrate.[15] Based on these data, a transesterification–elimination (TE) mechanism was presented, in the first step of which one of the geminal hydroxy groups of the FGly hydrate (FGH) acts as a nucleophile. As shown schematically in Scheme 1b, an S_N2 attack at the sulfur atom of the sulfate hydrolyzes the conjugate alcohol and creates a transient FGS. The second geminal hydroxy group then reacts to eliminate sulfate and re-form the aldehyde. Finally, the catalytic cycle is completed by hydration of the aldehyde to reform the FGH. Unfortunately, poor resolution within the vicinity of the crucial FGly residue in both structures left the general model for sulfate ester hydrolysis open for debate.

Support for the TE mechanism was provided by studies of HARSA and HARSB mutants containing a serine residue in place of FGly. When exposed to [^{35}S]-p-nitrocatechol sulfate, the serine mutants released p-nitrocatechol, but the labeled sulfur atom remained bound, whereas wild-type enzymes showed no residual radioactivity.[34] These results suggested that the first step of the TE enzymatic process, namely transesterification of the substrate by serine to form a sulfoenzyme intermediate, was possible. However, the second step was not. Serine mutants were unable to eliminate sulfate, underscoring the importance of the second FGH hydroxy group for sulfate ester catalysis. The experiment also provided strong evidence against the AH mechanism, as nucleophilic attack at serine by an oxygen atom of the sulfate group is highly unlikely. Further evidence for the TE mechanism was provided when a cocrystal structure of an FGly-alanine HARSA mutant with pNCS was superimposed with wild-type HARSA: The comparison showed that the the sulfate group was optimally orientated for an in-line nucleophilic attack by the Oγ1 hydroxy group, which was positioned 2.85 Å from the sulfur center.[21]

Another key discriminating feature between the two mechanisms is the configuration of the chiral sulfate released from the substrate after catalysis. The TE mechanism would

cause an inversion of configuration at the sulfur atom, as it proceeds through a pentagonal intermediate in the S_N2 transition state. In contrast, the AH mechanism, which proceeds without chemical modification at the sulfur center, would produce a sulfate group with retention of configuration. In a study of chiral sulfates as the substrates for an aryl sulfatase from *Aspergillus*, inversion of configuration was observed, thus providing further evidence for a TE mechanism.[35] To date, the experiment has not been reproduced with other better characterized sulfatases.

Particularly strong support for the TE mechanism was derived from the elucidation of the X-ray crystallographic structure of PARS at atomic resolution (1.3 Å).[12] The structure clearly showed that the FGly hydrate was near to, but independent of, a coordinated inorganic sulfate. The sulfate moiety is probably present as a result of the high concentrations of exogenous sulfate used to procure the PARS crystals. Not surprisingly, high sulfate concentrations are well known to inhibit hydrolytic sulfatases.[3,5] Again, the orientation of the sulfate was found to be optimal for nucleophilic attack, with one face of the tetrahedron situated at a distance of 2.96 Å from FGH-Oγ1, similarly to the pNCS-Cys69Ala-HARSA cocrystal.[21] Presently, it is believed that the sulfate hydrolysis proceeds by the TE mechanism depicted in Scheme 2.

The question of whether the transition state of sulfate ester hydrolysis is primarily associative (S_N2-like) or dissociative (S_N1-like) has not been addressed directly. However, several studies have shown that the nature of the alcohol leaving group is important. In studies with bacterial sulfatases, linear free-energy relationships were established that showed a strong correlation between substrates with better phenolic leaving groups and improved binding and catalysis (see the review by Dodgson et al.).[3] These results were mirrored in more recent studies on the inhibition of ARSC with aryl and alkyl sulfamates.[36] Irreversible inhibition by these compounds occurs after the rate-limiting hydrolytic step, although the exact course of events leading to the dead-end adduct is unknown. The results showed that the presence of electron-withdrawing groups (EWGs) at the α position of alkyl groups or on the phenolic chain resulted in much better inhibition, indicating that a better stabilized leaving group is important for the initial hydrolysis and subsequent inhibition. This behavior closely mirrors the trends observed for the dissociative mechanisms of APS, which have benefited from over 25 years of biochemical probing.[37]

Recently, the uncatalyzed hydrolysis of sulfate esters has also been found to be more dissociative than associative in nature.[38] In a dissociative transition state for sulfate ester hydrolysis, the bond forming between the incoming nucleophile and the sulfur atom would be expected to be weak,
Scheme 2. The TE mechanism involving FGly and key active-site residues based on the crystal structure of PARS and mutagenesis studies on HARS. a) In its resting state the FGly residue forms an FGly hydrate (FGH) stabilized by hydrogen bonds. a→b: Positively charged residues and the metal center bind, orientate, and activate the substrate sulfate for in-line nucleophilic attack by one of the FGH geminal hydroxy groups, HOγ1, which is positioned 2.96 Å from the sulfur center. The transesterification is promoted by proton transfer between Oγ1 and AspC. b→c: An S_N2 substitution (shown by arrows in (b)) proceeds through a pentacoordinated intermediate with inversion of configuration at the sulfur center and release of the conjugate alcoholate, which accepts a proton from HisB and diffuses from the pocket (LysB, Oγ2, and H$_2$O could also serve as proton sources, depending on the pH). Elimination of the sulfate hemiacetal (FGS) is favored by the electron-withdrawing groups coordinated to the sulfate. c→d: Abstraction of the H–Oγ2 proton by HisA induces the elimination of sulfate and regeneration of the aldehyde, which is subsequently rehydrated to complete the catalytic cycle (d→a). See Table 4 for the numbering of the residues and Figure 2 for a schematic of the residues in the active site.

whereas a more pronounced bond dissociation between the sulfuryl group and the leaving group would result in the accumulation of negative charge on the phenolate oxygen atom. Electron-withdrawing groups would help delocalize this charge, thereby stabilizing the dissociative transition state. The results accumulated to date seem to support the model of a dissociative transition state for sulfate ester hydrolysis, implying that the mechanism proceeds with some S_N1 character, probably with the assistance of the nucleophilic FGly hydrate. However, this interpretation should be treated with caution, as only limited studies have been carried out.

4.2. Other Sulfatase Mechanisms

At least two other mechanisms for sulfate ester cleavage have been identified in prokaryotes. Several bacterial alkyl sulfatases have been found that cleave the C−OS bond of sulfate esters, as opposed to the CO−S bond cleaved by hydrolytic enzymes.[39,40] Interestingly, some of these secondary alkyl sulfatases have been reported to produce an inversion of configuration at the stereogenic carbon center.

suggesting a nucleophilic attack takes place at this position (see the review by Dodgson et al.[3]). Making use of this stereoinversion, one research group has recently developed a method for deracemizing secondary alkyl sulfates.[41–43] The oxidative cleavage of alkyl sulfate groups to aldehydes and inorganic sulfate has also been reported.[44–46]

Genes for C−O cleaving[47,48] and oxidative sulfatases have been cloned.[46] Not surprisingly, these enzymes do not share significant sequence homology with the hydrolytic S−O cleaving sulfatases and do not contain the characteristic consensus sequences for FGly modification. Several other S−O cleaving alkyl sulfatases are known,[49,50] but information on their sequences is not yet available, and it is unclear if they operate by a FGly-mediated hydrolytic process or by other mechanisms of sulfate ester cleavage. Another potential mechanism for sulfate cleavage may be at work in the aryl sulfatases isolated from *A. Carrageenovora* and *Campylobacter jejuni*.[51,52] These enzymes do not contain the sulfatase consensus sequence required for FGly generation and bear little overall sequence similarity to the hydrolytic aryl sulfatases. At this point, the mechanistic details pertaining to these enzymes have not been elucidated.

5. The Post-Translational FGly Modification

5.1. The Cys–FGly Modification in Human ARSA

The catalytic integrity of sulfatase enzymes rests in the FGly residue. Normally, this unique residue is generated through the oxidation of a cysteine precursor found in the encoded peptide sequence of all human sulfatases. However, in multiple sulfatase deficiency (MSD) this critical modification is absent, resulting in categorically inactive sulfatases and severe clinical manifestations.[25] The MSD factor (MSDF) was postulated to be a defect in the post-translational modification machinery or in the FGly-generating enzyme (FGE).[7] Recently, a major breakthrough occurred when the FGE gene was identified and characterized as the causative agent of MSD.[31,32]

As components of the secretory pathway, sulfatases are directed to the ER during protein synthesis where the key catalytic residue, FGly, is generated from a cysteine residue.[53,54] All the information necessary to initiate modification is contained in the autonomous linear sequence C-T-P-S-R-A-A-L-L-T-G-R, which begins with the cysteine residue destined for modification.[10,53] Mutation and truncation of this targeting sequence revealed that a core motif, C(X/T)P(X/S)R, is the minimum sequence required to direct modest amounts of oxidation. Mutations of P and R within this motif greatly reduced efficiency, whereas mutations of T and S were tolerated individually, but not simultaneously. Of the seven auxiliary residues, the LTGR sequence was found to be the most important, and it is hypothesized that this sequence plays a role in molecular recognition. Apart from mutations of the cysteine residue, no single mutation was capable of abolishing modification activity altogether.[10,11]

Several experiments have demonstrated that the oxidation event occurs during late co- or post-translation, after translocation to the ER, and before protein folding.[10,11,53–55] The modification of ribosome-bound nascent polypeptide chains (RNCs) in vitro occurred after translocation to microsomes or after they had been exposed to soluble extracts from the ER. These results show that translocation and exposure to the luminal components of the ER are required to initiate the transformation. In translocation-arrested RNCs containing engineered N-glycosylation sites, the FGly residue was created after glycosylation and chemical release from the ribosome, and even after the cleavage of the signal peptide. These observations indicate that the oxidation step takes place during a late cotranslational phase. Finally, the finding that FGly is also expressed in truncated and heterologous protein constructs implies that the conversion is not influenced greatly by other portions of the peptide or by protein folding. That modification occurs in a largely unfolded state was also supported by the fact that small exogenous peptides comprised of the targeting sequence effectively inhibit FGly expression in RNCs.[55] In vitro oxidation of these small peptides (ARSA65-80) has even been observed recently as well, which provides further evidence for an autonomous interaction of the linear directing sequence with the FGE.[31]

Recently, the long-sought-after FGE was discovered by two research groups independently.[31,32] The FGE gene, *sumF1* (sulfatase-modifying factor 1), encodes for an ER-localized protein with 374 amino acids belonging to a class of proteins of previously unknown function. Preliminary biochemical characterization suggests that SUMF1 acts as a mixed-function oxygenase that is both essential and limiting for the expression of active sulfatases (Scheme 3a).[31] Highly conserved SUMF1 homologues were found in many eukaryotic and prokaryotic species, which is not surprising given the importance of the FGly modification.[31,32] Catalytic and functional conservation among FGE homologues was demonstrated by the production of active human sulfatases coexpressed with SUMF1 cDNAs from mice and *Drosophila*.[32] Paralogues of SUMF1, known as SUMF2, were also identified by sequence homology. These proteins also showed FGE activity, albeit much less efficient than that of SUMF1, and it is postulated that they are responsible for the weak, residual sulfatase activity observed in MSD.[32]

5.2. The FGly Modification in Prokaryotes

Several sulfatase genes from prokaryotes have been cloned and characterized (Table 2). The sequences show a high degree of similarity with those of eukaryotic sulfatases, especially within the FGly-targeting signature sequence. However, unlike in the case of eukaryotic enzymes, which exclusively encode cystein as their FGly progenitor, prokaryotic sulfatases derive FGly residues from serine as well as cysteine precursors. The modification of the Ser-type and Cys-type enzymes occurs by different routes, and several studies have been designed to identify and characterize the underlying FGE.

The bacterial Cys-type FGE (C-FGE) is likely to be a homologue of the conserved family of SUMF1 proteins, which were recently discovered in eukaryotes (Scheme 3a).[31,32]

Eukaryotes and Prokaryotes

Scheme 3. Mechanisms for FGly generation by eukaryotic and prokaryotic FGEs. The SUMF genes have been preliminarily characterized as mixed-function oxygenases that are essential for the generation of FGly residues from cysteine progenitors in eukaryotes (route A). FGly residues in pro-karyotes can be generated from cysteine and serine precursors by C-FGE and S-FGE, respectively. The C-FGE might be of the same type as the eukaryotic FGE; however, other pathways have also been suggested (route b; see text for details). The S-FGE (route c) has been identified as the iron–sulfur protein AtsB, which catalyzes the transformation by the proposed redox process outlined in steps 1–3.

Putative SUMF1 genes were detected in some bacteria by sequence analysis; however, the cloning and characterization of a bacterial C-FGE has not yet been achieved. Most of the information available about the bacterial Cys-modification system has been garnered from the recombinant expression of sulfatases in *Escherichia coli*, which does not produce an endogenous aryl sulfatase.[56] Although an active sulfatase has not been isolated from *E. coli*, both Cys- and Ser-type genes and putative activity have been described.[29,57] It is clar that the bacteria have an active C-FGE, which installs FGly residues exclusively from cysteine precursors. The recombinant expression of Cys-type PARS and FHS2S (FHS2S = heparan-2-sulfatase from *Flavobacterium heparinum*) in *E. coli* results in active enzymes,[27,58] whereas Ser-type sulfatases are inactive.[59,60] Likewise, the mutation of PARS and FHS2S to Ser-type enzymes also renders inactive proteins.[27,61]

The efficiency of the C-FGE in prokaryotes appears to differ dramatically from that in eukaryotes. The modification of PARS proceeds to completion in native and *E. coli* hosts.[27] In contrast, the human FGE has been found to be a limiting factor[62] where efficient modification requires the co-over-expression of SUMF1, and even then, oxidation is incomplete.[31,32] Such a discrepancy indicates some fundamental differences in the C-FGEs of bacteria and eukaryotes.

It is even possible that another FGE, distinct from SUMF1, is harbored in some bacteria. One bioinformatics study located a gene cluster, *yidHGF*, in *E. coli* near a putative Cys-type sulfatase, *yidJ*. Based on the sequence homology and mechanistic similarity, the cluster has been proposed to catalyze the oxidative desulfurization of the sulfanyl group of cysteine to an aldehyde, in analogy with the

oxidative deamination of aspartate to oxaloacetate (Scheme 3 b).[29]

Relatively more is known about the Ser-type FGE (S-FGE) in bacteria. Early experiments on the expression of the aryl sulfatase from *Klebsiella pneumoniae* (KARS) showed that the production of an active enzyme in *E. coli* required the coexpression of an adjacent gene, *astB*, which forms a bicistronic operon with the KARS gene.[63] Initially, AstB was speculated to be a positive regulator of KARS or a transcriptional factor.[64] Later, it was recognized to have high homology with oxidoreductases and was found to be critical for the expression of FGly residues, indicating that it might be the S-FGE.[27,59] The possible role of AstB homologues as S-FGEs was further substantiated by the fact that the Ser-type sulfatase PMdS (PMdS = mucin sulfatase from *Prevotella* sp. RS2) was inactive when expressed in *E. coli*, but active during heterologous production in *Bacteriosides thetaiotao-micron*.[60] *B. thetaiotaomicron* harbors the gene *chuR*, which encodes for a protein that is highly homologous with AstB. Indeed, endogenous sulfatase activity is inhibited when *chuR* is knocked out.[65] Sequence analysis of the regions flanking the PMdS gene showed that it has an adjacent gene which encodes for an AstB homologue. It is tempting to speculate that the coexpression of this gene in *E. coli* might produce active PMdS. In fact, similar operons were identified when the sequences of several putative Ser-type sulfatases were analyzed, suggesting that the S-FGE is commonly bicistronic with the sulfatase that it modifies.[29] In each case, the second gene encodes for an iron–sulfur protein that contains conserved cysteine clusters. These proteins have recently been linked with oxidoreductase activity and are capable of oxidizing a serine residue to an aldehyde (Scheme 3 c).[29,30]

The role of AstB in modulating the transformation of serine residues into FGly was firmly established when KARS was expressed independently and with AstB in *E. coli*.[59] FGly was only formed in the presence of AstB. The observed modification efficiency of 60% corresponds to the yield with natively expressed KARS.[28] More recently, AstB was shown to be a cytoplasmic enzyme that directly interacts with the FGly-targeting sulfatase signature sequence in a serine-dependent manner, and was proposed to catalyze the transformation through oxidoreductase activity (Scheme 3c).[30] The transformation process is facilitated by the presence of a signal peptide that targets protein translocation to the periplasm. Removal of this sequence dramatically decreased the efficiency of the FGly modification of the periplasmic KARS enzyme. Also the FGly transformation was introduced into a mutant Ser-PARS when the enzyme was also recombinantly adorned with the KARS signal sequence.[28] All known and several putative Ser-type sulfatases contain N-terminal signal peptides which direct the enzyme to the periplasm; most Cys-type sulfatases, however, are localized in the cytoplasm.[29]

The fact that bacteria are capable of the post-translational generation of FGly from both cysteine and serine residues by separate mechanisms is intriguing, as the sequences surrounding the FGly progenitors are essentially identical.[29] According to an early theory the enzymes do not differentiate between the nearly identical targeting sequences on the basis of binding processes, but instead implement specific catalytic domains that oxidize the cysteine and serine residues to FGly.[59] Indeed, in the purification of the mammalian (Cys-type) FGE a binding matrix containing the Ser-targeting sequence was exploited.[31] It appears that subcellular distribution might also have an influence on which FGE is operative in bacteria. The periplasmic targeting sequence helps to facilitate a fruitful connection between Ser-type sulfatases and the S-FGE, and it is possible that other translocational components are also involved in this process.[30]

6. Substrates and Biological Functions of Eukaryotic Sulfatases

Many eukaryotic sulfatases were initially identified based on their enzymatic activity with small aromatic sulfates, such as *p*-nitrophenol sulfate (pNPS), *p*-nitrocatechol sulfate (pNCS), and 4-methylumbelliferone sulfate (4MUS). This activity led to a long-running misunderstanding about the physiological roles of sulfatase enzymes, but is now used for the general classification of sulfatases into ARS and non-ARS types.[4,5] Both classes of enzymes are active with aryl substrates, but the ARS type effect hydrolysis at much higher rates. Steroid sulfates and a variety of sulfonated carbohydrates, including monosaccharides, oligosaccharides, proteoglycans, and glycolipids, count among the natural substrates of the human sulfatases (Table 1). As shown in Table 5, the enzymes show a strong specificity for their biological substrates despite their promiscuity with aryl substrates.

Human sulfatases have been found in several subcellular locations, where they play key roles in important biological processes, including the synthesis of hormones in the ER, the degradation of glycosaminoglycans and glycolipids in the lysosome, and the modulation of developmental-cell signaling in the ECM. Several other human sulfatases have been identified, but their biological functions are unknown. Potentially these enzymes might be involved in the desulfonation of other important biomolecules, such as sialyl Lewis^X-6S (sLe^X-6S) and tyrosine *O*-sulfate. The sulfatases of invertebrates and lower eukaryotes are largely unexplored. Several genes have been cloned (Table 2), and in some cases exhibit activities, including a role in the development of sea-urchin embryos, the inactivation of endogenous plant toxins, and involvement in the sulfur metabolism in algae and fungi.

6.1. Lysosomal Sulfatases

The lysosomal sulfatases were the first to be associated with physiological functions and are by far the best characterized of human sulfatases. They are ubiquitous housekeeping enzymes that are synthesized in the secretory pathway and are targeted to the lysosome through the mannose 6-phosphate receptor pathway.[66] Characteristic of their subcellular location, the enzymes exhibit pH optima in the acidic region (Table 5). They also demonstrate exquisite substrate specificity and little functional redundancy. Catalytic desulfonation is critical to the catabolism of several sulfate-bearing metabolites. Indeed, six physiological disorders in humans are known to arise from the accumulation of toxic levels of nondegradable sulfated compounds, owing to deficiencies in single lysosomal sulfatases (Table 3).[24] Because of their role in certain diseases, a number of lysosomal genes from humans[2,67–72] and other mammals have been cloned and characterized extensively.[1,7,8]

As shown in Table 5, ARSA hydrolyzes a number of sulfated substrates.[73,74] The major physiological substrates are sulfatides, specifically sphingolipids with galactose-3S (Gal-3S) head groups.[75,76] It has been suggested that ascorbic acid 2S is another natural substrate.[77] ARSA has been associated with the inherited genetic disorder metochromatic leukodystrophy (MLD), which is characterized by extensive demylination in the nervous system.[7] This disorder results from improper catabolism of the sulfatide cerebroside-3S (**1**, Figure 4), which is one of the major structural components of the myelin sheath. The cleavage of the cerebroside-3S ester in vivo requires the presence of the solubilizing agent, sphingolipid activator protein B (sapB), which forms a 1:1 complex with the substrate prior to hydrolysis.[78] More recent studies indicate that ARSA may also play a role in non-lysosomal environments as well: It has been detected on sperm surfaces, where it is thought to adhere to sulfated egg glycoproteins and modulate steps in the fertilization process.[79–82]

The human lysosomal sulfatases ARSB, GalN6S, GalN3S, GlcN6S, GlcA2S, GlcNS, and IdoA2S have been studied extensively. They play a role in mucopolysaccharidosis (MPS), a group of lysosomal storage disorders resulting from deficiencies in GAG catabolism (Table 3).[1] GAGs are

comprised of long chains of repeating disaccharide units consisting of uronic acid (U) and hexosamine (H) sugars. These chains are highly polydispersed owing to their varying length, glycosidic connections, epimerization, *N*-acetylation, and the degree of *O*- and *N*-sulfation (Figure 5).[83,84] Table 1 lists the substrates of the various lysosomal sulfatases, most of which are named based on their residue specificity within the GAG chain. The exceptions are ARSB, heparan *N*-sulfatase,

and galactosamine-6-sulfatase. ARSB, originally regarded as a generic aryl sulfatase,[85] is now known to specifically cleave sulfate esters at the 4-position of *N*-acetyl galactosamine (GalNAc) residues found in dermatan sulfate (DS) and chondroitin sulfate (CS).[86,87] Heparan *N*-sulfatase (GlcNS) catalyzes the hydrolysis of *N*-linked sulfamates of glucosamine residues in heparin and heparan sulfate (HS).[62] GalN6S, initially named for its ability to hydrolyze the GalNAc$_{6S}$ residues of DS and CS, is also responsible for the hydrolysis of galactose-6S (Gal$_{6S}$) residues of keratan sulfate (KS).[88,89]

Within the lysosome, degradation pathways involve sulfatases and glycosidases that act sequentially to break down GAG structures from the nonreducing ends.[90] Figure 6 depicts some generic GAGs; the sites of sulfate ester cleavage by lysosomal sulfatases are marked with arrows. Although several sites are indicated on the GAG structures for the sake of brevity, it must be emphasized that each lysosomal sulfatase acts on the GAG in an exoenzymatic fashion, only as specific residues are exposed at the nonreducing terminus by a glycosidase. The glycosidases, in turn, require desulfonation of the nonreducing residue before the next processing step can occur. Table 5 lists some kinetic parameters known for specific substrates of these sulfatases.[91–96]

6.2. Extracellular Sulfatases and Developmental Signaling

Recently, a new class of ECM sulfatases, known as the Sulfs, have been attributed a pivotal role in signaling and embryonic development based on the modulation of interactions between GAGs and signaling molecules. Initially, QSulf1 was discovered in the search for sonic hedgehog (shh) responsive genes in quail embryos.[97] Shh is an extracellular signaling molecule that influences the development of stem cells into specific tissues and organs.[98] QSulf1 is induced by Shh, but does not participate directly in Hedgehog (Hh) signaling. However, it was shown to induce Wingless/Int (Wnt) signaling and is

Figure 5. GAG disaccharide units with modification sites indicated. The GAGs are sophisticated polydisperse macromolecules that consist of unbranched repeating disaccharide units of uronic acid (U) and hexosamine (H). The GAG sulfate esters are separated into three major classes distinguished primarily by the identity and linkage of the sugar residues; examples are heparan sulfate (HS) and heparin sulfate (HSGAG, which generally contains more sulfates on average than HS), keratan sulfate (KS), and chondroitin and dermatan sulfate (CS and DS). Several modifications can be introduced into the disaccharide units, including the C5 epimerization of GlcA residues to IdoA, N-acetylation, and O- and N- sulfonation. Subscripted symbols are used to denote positions that are sulfated or unsubstituted (X); or sulfated, acetylated, or unsubstituted (Y).

suspected to participate in the signaling of fibroblast growth factor (FGF) and epidermal growth factor (EGF).[97,99,100]

The extracellular Wnt and FGF signaling molecules, which are intimately linked with proper cell differentiation and embryo patterning, are known to bind heparan sulfate

proteogycans (HSPGs) in the ECM.[101,102] Specifically, their interactions with HS have been associated in part with the 6-*O*-sulfate groups on GlcNAc residues.[103–106] As enzymes targeted for the cell surface, Sulfs are poised to play a role in remodeling these critical sulfates in the ECM.[97,100] Indeed, overexpression of QSulf1 has been directly correlated with an increase in Wnt signaling, and this activity was shown to depend on catalytic sulfatase activity. Based on these results, Dhoot et al. speculated that HSPG-bound Wnt was released for signaling after 6-*O*-sulfate cleavage by QSulf1 (Figure 7).[97] Recently, this hypothesis was substantiated and further characterized in biochemical and cell-expression studies wherein a two-state "catch and present" model was suggested for the regulation of Wnt signaling by QSulf1.[99] In this model, desulfonation by QSulf1 is proposed to stimulate a shift from a high-affinity HS–Wnt complex (the catch phase) to a low-affinity HS–Wnt complex, which interacts with Frizzled receptors (the present phase) to initiate the Wnt signaling cascade. Desulfonation of HSPGs by HSulf1 also influences other signaling pathways, including EGF and FGF.[100] In the past, HS-based signaling was thought to be primarily controlled by sulfonation of HS during biosynthesis in the Golgi.[107] The Sulfs represent a new pathway for dynamically regulating these sulfonated ligands.
Figure 7. Proposed mechanism for the amplification of Wnt signaling by Sulf1. In the extracellular matrix (a), Wnt (purple) binds to HS proteoglycans (blue) at the glucosamine-6S residues. Sulf1 (green) cleaves the $GlcN_{6S}$ sulfate (b), thereby releasing HS-bound Wnt (c) and allowing the interaction of Wnt with Frizzled receptors (shown generically in gray). Upon binding, important signaling cascades begin. Recent experiments suggest that HS may also interact with the receptor in the form of a low-affinity HS–Wnt complex.

Extracellular *Sulf1* orthologues from rats, mice, and humans have been identified and cloned.[22,108] An analogous gene, *Sulf2*, was also isolated from mice and humans.[22] Studies showed that HSulf1 and HSulf2 hydrolyze the substrate 4MUS more slowly than typical ARSs, but at least an order of magnitude faster than non-ARSs (Table 5). The high sequence similarity with lysosomal GlcN6S and the key signal modulation by $GlcN_{6S}$ residues in HS strongly suggested that the Sulfs would be active with these substrates. Indeed, such activity was observed. The Sulfs display endo activity at neutral pH values (Table 5). Functional selectivity for a subset of 6-*O*-sulfates in HS, including the trisulfated motif $IdoA_{2S}$-$GlcN_{S6S}$ and the doubly sulfated GlcA-$GlcN_{S6S}$ disaccharide unit, was identified in biochemical studies of both human and quail enzymes.[97,99] Interestingly, the $IdoA_{2S}$-$GlcN_{S6S}$ sequence is known to be important in both the binding of FGF and the dimerization of the FGF-dependent receptor.[109,110] Thus, desulfonation by a Sulf enzyme would be expected to negatively regulate this process, although the exact nature of this relationship remains to be established.

In addition to their roles in proper growth and development, growth factors, such as FGF, and morphogens, such as Wnt, have been implicated in pathophysiological conditions including tumor onset and progression.[111] The involvement of these molecules in both normal and disease processes is highly regulated by the HSPGs, which bind these agents and modulate their activity.[112] As the Sulfs are key players in regulating these binding events, they might also be involved with deregulation during disease states, such as cancer. As such, they might serve as novel candidates for therapeutic intervention in the future.

Sulfatases have been implicated in the development of sea-urchin embryos, although their direct involvement in cell signaling events has not yet been demonstrated. Three highly similar ARS genes cloned from the distinct sea-urchin species *Hemicentrotus pulcherrimus*, *Strongylocentrotus purpuratus*, and *Heliocidaris erythrogramma* (Table 2), were shown to localize on cell surfaces in a cell-lineage-specific and cell-stage-specific manner during embryosis.[113–115] Their expression was found to coincide with important cell-differentiation events.[116,117] It has been suggested that sulfonated proteoglycans are the substrates of these extracellular ARSs, but this activity has not been verified.[118] The sea urchin has long been a model system for the study of embryonic patterning,[119] and it might prove useful to investigate a possible role of the sea-urchin aryl sulfatases in HS-related signaling pathways.

6.3. Steroid Sulfatase

The levels of steroid hormones are modulated in part by the microsomal sulfatase ARSC, also commonly known as steroid sulfatase (STS).[120] ARSC is a ubiquitously expressed, membrane-bound, lumen-oriented protein, which is primarily localized in the rough ER.[121] It has a neutral pH optimum and processes several aryl and steroidal substrates efficiently (Table 5).[122] The broad range of substrates hydrolyzed by ARSC has raised the question of whether multiple ARSC isoforms, or even distinct enzymes, are involved in processing the different sulfate conjugates. However, convincing evidence from several studies points to a single housekeeping ARSC protein that is fully capable of hydrolyzing disparate steroid sulfates.[6] ARSC releases systemic steroid precursors from inactive 3-*O*-sulfate conjugates, such as estrone and dehydroepiandrosterone sulfate (**2**, Figure 4), that feed into pathways for hormone-based signaling.[123] Upregulation of ARSC activity has been implicated in hormone-dependent breast cancer,[124–126] whereas a deficiency in the enzyme has been observed in the inherited disorder X-linked ichtosis.[6] The former has made ARSC an attractive target for small-molecule therapeutics (see Section 8).[127,128]

6.4. Novel Sulfatases of the ER and Golgi Network

Several recent additions to the human sulfatase family have been reported. The ARSD, ARSE, and ARSF genes, for example, were isolated from a positional cloning experiment aimed at mapping the causative gene(s) for the congenital disorder chondrodysplasia punctata (CDPX).[129,130] The genes are located together with the gene for ARSC in a cluster on the distal short arm of the X chromosome (Xp22.3) and have a similar genomic organization, suggesting an evolutionary duplication event.[131,132] The gene for another sulfatase, ARSG, was also cloned recently after being identified in bioinformatics searches.[133] All four of these newly discovered genes encode for membrane-bound sulfatases of the ER and Golgi network with a neutral pH optimum. Each of these sulfatases received the ARS designation because of structural similarities with known ARSs, even though only ARSE and ARSF have shown activity with

aromatic substrates.[130,133–135] The natural substrates of these sulfatases are as yet unknown.

A deficiency in ARSE alone was found to be responsible for the disorder CDPX (Table 3).[134,136] Interestingly, ARSE is inhibited by warfarin, the causative agent of warfarin embryopathy, which has clinical manifestations strikingly similar to CDPX.[129,130] Both disorders are characterized by bone and cartilage dysplasia, suggesting that ARSE plays a critical role in the proper development of these tissues.[6,137] Given the subcellular location of ARSE and the critical roles that GAGs play in bone and cartilage structure and development, it is tempting to speculate that ARSE might function along with other anabolic enzymes of the Golgi network in the construction of GAGs and cell-surface HSPGs.[138–140]

Iodothyronine sulfate (**3**) is a potential substrate of ER sulfatases (Figure 4). Recent research has indicated that the biological activity of thyroid hormone might be modulated by sulfonation akin to steroid hormones.[141] A reversible sulfonation pathway has been proposed in which the action of a sulfatase leads to the release of active thyroid from inactive sulfonated conjugates.[142,143] The steroid-hormone regulator ARSC possesses some ability to hydrolyze iodothyronine sulfate; however, recent studies showed that the hydrolysis is primarily carried out by a sulfatase (or possibly several sulfatases) isolated from human liver microsomes that are biochemically distinct from ARSC.[142,144] A likely candidate for iodothyronine sulfatase activity is ARSD, which shows a similar gene expression pattern to that of ARSC.

6.5. Sulfatases of Invertebrates and Lower Eukaryotes

Few sulfatases from invertebrates have been characterized. However, sulfatases have been identified in a number of gastropods and echinoderms (including the ARSs from sea urchins), and it is likely that many more exist and have analogous roles to those in vertebrates.[3,145–151] Furthermore, some divergent roles for sulfatases in invertebrates have come to light. In recent studies on herbivore–plant interactions, a unique sulfatase was isolated from *Plutella xylostella*, an insect commonly known as the diamondback moth. Diamondback moths are able to feed on cruciferous plants by circumventing an inbuilt defense mechanism of the plant that releases toxic isothyocyanates, nitriles, and thiocyanates from a precursory glucosinolate sulfate (GS, **4**, Figure 4) upon insect feeding.[152] Diamondback moth resistance results from the activity of a glucosinolate sulfatase (GSS), which efficiently desulfonates several GSs to innocuous by-products. The GSS gene has not been formally identified in other pests, but GSS and ARS activity in *Helix pomatia*, the common garden snail, is known.[153,154] One gene and a partial gene (*HpSulf1* and *HpSulf2*, which have no established relation to the Sulf enzymes involved in signaling) were recently cloned from *Helix pomatia*, but neither appeared to encode for the GSS enzyme.[155] As an enzyme common to pests, the novel GSS sulfatase might serve as a potential target for pesticides.

Sulfatase activity has been identified in several lower eukaryotic organisms,[156,157] and three aryl sulfatase genes from fungi[158] and algae[159–161] have been cloned and partially

characterized (Table 2). These enzymes are upregulated during sulfur starvation and are believed to play a role in sulfur scavenging. For example, NARS and choline sulfatase (ChoS) isolated from the filamentous fungus *Neuroposa crassa* are known to hydrolyze tyrosine-*O*-sulfate and choline-*O*-sulfate under sulfur-limited conditions.[162,163] The NARS enzyme has also been shown to be 30 times more active during germination, regardless of sulfur availability, suggesting that it might play a developmental role.[164]

7. Substrates and Biological Functions of Prokaryotic Sulfatases

High levels of ARS, alkyl sulfatase, and glycosulfatase activity have been identified in many different types of bacteria.[3,50] However, only a handful of bacterial sulfatase genes have been cloned and characterized (Table 2). These enzymes typically function as scavengers, removing sulfate groups from exogenous substrates to provide sulfur and carbon sources for their hosts.[3] Recent studies have demonstrated further functions of bacterial sulfatases in osmoprotection and pathogenic processes.

7.1. Sulfate Scavenging in Bacteria

ARS activity has been identified in several species of enterobacteria (*Klebsiella*,[63,165] *Salmonella*,[166,167] *Proteus*,[146,168] *Pseudomonas*,[169] and *Serrati*[170]), aquatic bacteria (*Alteromonas*[52]), pathogenic bacteria (*Mycobacteria*[171,172] and *Pseudomonas*[173,174]), extremophilic bacteria (*Plectonema*[175]), and soil bacteria (*Comamonas*[176] and *Pseudomonas*[176]). Indicative of their role in scavenging, most of the bacterial ARS enzymes are upregulated during sulfur starvation.[3,50] Although their preferred substrates are unknown, it is thought they may be sulfated carbohydrates. The most thoroughly characterized ARS enzymes are from *Pseudomonas aeruginosa*[173] and *Klebsiella pneumoniae*[63] (formerly classified as *Klebsiella aerogenes* and *Aerobacter aerognes*). Early studies on these enzymes focused on genetic induction under sulfur-limited conditions, whereas recent studies have probed KARS involvement in sulfate transport.[50,177] Studies of the PARS and KARS enzymes have provided invaluable mechanistic and structural information on the sulfatase enzyme class as a whole.[12,27,59]

One bacterial alkyl sulfatase traditionally categorized as a sulfate scavenger has been shown to have an additional role. Choline-*O*-sulfatase (ChoS) is primarily involved in breaking down choline sulfate into carbon, nitrogen, and sulfur sources,[178–180] but it also participates in the synthesis of an osmoprotectant.[181] The *bet* operon in the rhizobium *Sinhorhizobium meliloti* encodes for several enzymes that orchestrate the synthesis of glycine betaine, a common bacterial osmoprotectant derived from choline.[182] In a cloning scheme for this operon, a ChoS homologue was isolated unexpectedly, thus indicating that the versatile ChoS enzyme can perform two functions: the assimilation of nutrients as needed and the synthesis of osmolytes to protect the organism.[181]

7.2. Glycosaminoglycan-Degrading Sulfatases

The ability of bacteria to survive on glycosaminoglycans (GAGs) as a sole nutrient source has long been known.[3] It was also recognized early on that bacterial degradation pathways might prove useful in deconvoluting the complex nature of GAGs, thus prompting the characterization of several enzymes from *Proteus Vulgaris*, *Bacteriosides theitomicron*, and *Flavobacterium heparinum* (Table 6). Much of the research on GAG-degrading enzymes has focused on bacterial lyases,[183–185] but sulfatases have also been characterized.[3,50] Generally, the degradation is initiated by several unique lyases that cleave GAG chains at the hexosamine–uronate (H-U) linkage by elimination to give Δ4,5-U-H (dU-H) disaccharide units. (Note that the stereochemical information that distinguishes IdoA from GlcA is lost upon formation of the dU unit.)[183] The sulfatases then desulfonate these units in an order that depends on the nature of the glycosaminoglycan (Figure 8).

In the processing of HS, the disaccharide units must be desulfonated at the dU2S position by the HS2S enzyme before it is cleaved by a hydrolase into monosaccharide units.[186] Any sulfate groups remaining on GlcN units are then sequentially cleaved by the monosaccharide sulfatases HS3S, HS6S, and HSNS.[187–189] In the degradation of CS, CS6S and CS4S act on the nonreducing end of GalNAc residues before it is cleaved into monosaccharide units.[190,191] Additionally, it has been shown that CS6S is capable of endoenzymatic cleavage on larger CS chains.[192] CS also contains uronic acid residues with 2-*O*-sulfate groups, although fewer than HS. The activity of a sulfatase specific for disaccharides, trisaccharides, and tetrasaccharides with dU2S residues, irrespective of the sulfation profile, has been reported.[186,192–195] It is

believed that the dU2S residues of HS and CS substrates are processed by the same sulfatases; indeed, the FHS2S enzyme from *F. heparinum* recently showed activity for both substrates.[58,61] FHS2S cleaves the 2-*O*-sulfate functionality of the HS disaccharide unit dU$_{2S}$(β-1,4)H$_{NS,6S}$ preferentially, but is also active for substrates with a lesser degree of sulfation and different glycosidic connections, such as the α-1,3 linkage of CS. This behavior shows that the enzyme is primarily specific for dU$_{2S}$ residues at nonreducing ends of GAG chains.

7.3. Mucin Sulfatases

Mucin sulfatases (MdSs, mucin-desulfating sulfatases) are bacterial enzymes that cleave the sulfate esters on the mucin proteoglycans in the gastrointestinal (GI) lining. Like glycosaminoglycans, mucin oligosaccharides contain numerous sulfate groups that collectively influence their physical properties.[196] Sulfate esters have been identified on interior and exterior GlcNAc, Gal, and occasional GalNAc residues at the 3-, 4-, or 6-positions of mucins.[197] Mucins contain blood-group antigens, including various sialyl and sulfosialyl groups that are known to be involved in bacterial recognition processes and leukocyte trafficking.[198] One of the primary functions of mucins is to act as a protective barrier between endothelial cells and potentially harmful agents in the GI lumen, such as colonizing bacteria.[199] Accumulating evidence suggests that sulfonation might preserve mucin structures against bacterial breakdown, as desulfonation by MdSs is the rate-limiting step in bacterial degradation.[200] This might be the link between the increased levels of sulfate esters in mucins (known as sulfomucins) that are the most heavily inhabited by bacteria, such as the colon and mouth.[201]

Table 6: Bacterial sulfatases involved in the degradation of glycosaminoglycans.

Organism	GAG	Sulfatase[a]	Residue specificity[b]	pH optimum	K_m [µM]	Position, type of cleavage	Ref.

[a] Enzymes marked with an asterisk have been detected, but not isolated. [b] Enzymes are specific for the sulfate residues shown in bold.
Figure 8. The role of bacterial sulfatases in the degradation of HS (a) and CS (b). The sites of sulfate ester hydrolysis are demarked by arrows.

MdS enzymes have been identified in strains of enterobacteria capable of growing on ^{35}S-labeled mucin as the sole carbon source (Table 7).[202–204] Three enzymes with unique characteristics have been purified to date. The first, a 30-kDa protein isolated from the extracellular environment of a *Helicobacter pylori* culture, has a pH optimum of 5.7 and catalyzes the desulfonation of GlcNAc$_{6S}$ and Gal$_{6S}$ in mucins, as well as Glc$_{6S}$ in glyceroglucolipids.[205] Another 15-kDa enzyme, purified from fecal extracts, has a pH optimum of 4.5

and cleaved approximately 25% of the radiolabelled sulfate from a human colonic mucin.[206] The third, isolated from *Prevotella* RS2, is a 58-kDa periplasmic enzyme with a pH optimum of 7.0 that removed 33% of the radiolabelled sulfate from a human colonic mucin.[207] This enzyme, whose gene was recently cloned, was shown to be an exoenzyme specific for GlcNAc$_{6S}$ residues.[60, 208]

With crude cell extracts from *Prevotellova*, 79% of the radiolabelled sulfate could be cleaved from mucin substrates,

Table 7: Bacterial mucin sulfatases.

Organism	Host, substrate[a]	Residue specificity	pH optimum	Subcellular location[b]	Infection	Ref.
Prevotella RS2	S*-rat, gastric mucin	Glc$_{6S}$, GlcNAc$_{6S}$	7.4	periplasm		[60, 207–209]
		Gal$_{6S}$	7.0	cytoplasm		
Bacteroides thetaiotamicron	S*-human, colonic mucin	Glc$_{6S}$, Gal$_{3S}$	5.0	extracellular		[202, 206]
Bacteriosides fragilis	human, colonic mucin	Gal$_{6S}$	7.0			[208, 209]
unknown (human feces)	S*-human, colonic mucin	Glc$_{6S}$	4.5	extracellular	ulcerative colitus	[206, 210, 211]
Helicobacter pylori	S*-human, gastric mucin	Glc$_{6S}$, GlcNAc$_{6S}$, Gal$_{6S}$	5.7	extracellular	peptic ulcer, gastric cancer	[205, 212]

[a] S* = radioactive ^{35}S isotope used to label the mucin. [b] Extracellular location was assumed based on the presence of enzymatic activity in supernatants of the culture and/or of feces.

suggesting that more than one MdS enzyme may exist in this organism.[207] *Prevotella RS2* possibly contains another MdS enzyme specific for Gal$_{6S}$, as lysates harvested from cells grown on colonic mucin showed increased activity for both Glc$_{6S}$ and Gal$_{6S}$ substrates.[209] Two separate MdS enzymes that desulfonate Gal$_{3S}$ and Gal$_{6S}$ substrates were also found in partially purified extracts from *Bacteriods fragilis*.[208,209] Other sulfated carbohydrates within the GI tract (i.e. glycosaminoglycans and sialyl substrates) have certain sugar residues in common with mucins. The mechanisms by which mucin sulfatases differentiate between these substrates remains to be clarified.[197,200]

7.4. Bacterial Sulfatases and Pathogenicity

Accumulating evidence suggests that MdS enzymes might be involved in numerous clinical manifestations. For example, they have been implicated in the phenomenon of bowel inflammation.[200] Elevated MdS activity was observed in the fecal extracts of patients with ulcerative colitus (UC).[210,211] This observation is consistent with the results of another study that correlated increased mucin degradation with increased MdS activity in UC patients.[210] Additionally, decreased sulfomucin levels were observed in gastric samples of patients infected with *H. pylori*, a causative bacteria in gastric diseases.[212] Although it is not known if mucin degradation by mucin sulfatases is the primary contribution to these conditions, it is thought to contribute to their severity.[201] It has also been suggested that MdS enzymes may play a role in the invasion of opportunistic pathogens *P. aeroginosa* and *Burkholderia cepacia* in lung tissue, especially in patients with impaired mucosal clearance, which is common in cystic fibrosis (CF).[57,213]

In addition to providing access to sources of sulfur and nutrients, it has been proposed that these sulfatases expose sites of adhesion. For example, *P. aeurginosa* may use MdSs to remove the sulfate groups shielding its requisite mucin-binding motifs, Gal(β-1,3)GlcNAc and Gal(β-1,4)GlcNAc.[57,214,215] Sulfomucin inhibits the binding of *H. pylori* to its normal adhesion elements (galactosphingolipid-3S), suggesting that the desulfonation of mucins might be critical for initial pathogenic colonization.[216] This assumption was substantiated by the finding that two common antiulcerative drugs, nitecapone and sulcrasulfate, which are efficacious against infection by *H. pylori*, significantly decrease desulfonation activity by MdSs.[205,212]

Remodeling of the sulfate structure has also been proposed as a mechanism for the pathogenicity of certain strains of *Mycobacterium*. A bioinformatics study suggested that the ubiquitous sulfatase sequences found in these organisms could potentially encode for enzymes that modify gycosaminoglycans to generate binding sites required for infection.[217] Such an adaptation would give a competitive edge to especially pernicious bacteria. A quick search of the Entrez database[310] reveals that putative sulfatase genes are harbored by many pathogens, including *Yersinia pestis* (bubonic and pneumonic plague),[218] *Salmonella enterica* (typhoid fever),[219] *Enterococcus faecalis* (vancomycin-resist-

ant pathogen),[220] *Bacillus anthracis* (anthrax, potential biological weapon),[221] and *Streptococcus agalactiae* (leading cause of sepsis, pneumonia, and meningitis in neonates), to name a few.[222] Interestingly, a putative sulfatase gene identified in *E. coli* K1, one of the causative agents of meningitis, endows the bacteria with an increased ability to colonize cerebrospinal fluid.[223] Although the exact role of the putative sulfatase is unknown, this work establishes another intriguing link between bacterial sulfatases and pathogenicity. As more connections between infections and bacterial sulfatases are established, it seems increasingly likely that these enzymes might serve as targets for therapeutic intervention.

8. Sulfatase Inhibition

Most studies on the inhibition of sulfatases have focused on blocking the activity of estrone sulfatase (ARSC), which releases active steroid hormones from inactive sulfate conjugates, such as estrone sulfate (E1S) and dehydroepiandrosterone (DHEAS). Increased release of E1 and DHEA has been connected with the development of mammary tumors, and upregulation of ARSC has been noted in several forms of cancer. As a result, steroidal sulfatase inhibitors show potential as therapeutics for these hormone-dependent cancers. The treatment of breast cancer, in particular, with small-molecule therapeutics aimed at ARSC inhibition has been under intense investigation over the past several years.[36]

After 2-(hydroxyphenyl)indoles were recognized as inhibitors of mammary tumors,[224,225] sulfate derivatives of 2-phenylindoles were evaluated as inhibitors of steroid sulfatases.[226] Combinatorial synthesis (Scheme 4) yielded compound **5** as the most potent inhibitor with an IC$_{50}$ value of 120 μM. The inhibitors were assayed by detection of the amount of 6,7-[^{3}H]estrone sulfate that was hydrolyzed by liquid scintillation counting. More recently, a sulfamyloxy-substituted derivative was found to inhibit ARSC with an IC$_{50}$ value of 200 nM. The antiestrogen tamoxifen and related metabolites,[227] as well as daidzein sulfoconjugates[228] and danazol,[229,230] have also been reported as ARSC inhibitors.
Scheme 4. Combinatorial synthesis of 2-(hydroxyphenyl)indole inhibitors.

Estrone 3-phosphonates and thiophosphonates were ana-
lyzed for their activity as inhibitors of steroid sulfatases.[231, 232]
The best inhibitor was found to be the methylthiophospho-
nate (**6**, E1-3-MTP, Figure 9) with an IC_{50} value of less than

9: $R^1 = H$, $R^2 =$

10: $R^1 = SO_2NH_2$, $R^2 =$

11: $R^1 = SO_2NH_2$, $R^2 =$

100 nM. The pure R_P diastereomer was obtained through
selective digestion of the S_P stereoisomer with snake-venom
phosphodiesterase. The pure R_P inhibitor was less active than
the original mixture, suggesting that the S_P isomer was more
potent. In general, hydrophobicity, basicity, size, and charge
were found to affect the potency of this class of inhibitors.[233]
Dehydroepiandrosterone phosphate (**7**) was reported to have
an IC_{50} value of 140 nM at pH 6.0. It has a higher activity than
the corresponding sulfate analogue, but is not susceptible to
enzymatic hydrolysis.[234] In a study of nonsteroidal phosphate
esters, hydrophobicity was again found to be an important
factor in the activity of the inhibitor. A K_i value of 520 nM was
reported for *n*-lauroyltyramine phosphate (**8**) at pH 7.0.[235]

Another series of compounds that were evaluated as
ARSC inhibitors were 17α- and 17β-alkylated or benzylated
estradiols.[236] It was determined that the introduction of alkyl
and substituted benzyl groups at these positions led to
increased activity. The most potent inhibitor, **9**, had a 3′-
bromobenzyl substituent and an IC_{50} value of 24 nM
(Figure 10). Inhibitory activity increased when sulfamate
groups were added to these compounds, as evidenced by the
IC_{50} value for **10** against ARSC of 150 nM.[237, 238] The effect of
long alkyl chains on the activity of estradiol was also
determined. The potency increased with increasing chain
length up to octyl substitution ($IC_{50} = 440$ nM).[239] In later
work, the 4′-benzyloxybenzene derivative **11** was found to
have an IC_{50} value of 22 nM. Benzyl-substituted analogues of
androstane and pregnane were also synthesized and ana-
lyzed.[240] More recently, 17α-substituted estradiol sulfamates
were prepared by split-pool combinatorial synthesis on a solid
phase.[238] As illustrated in Scheme 5, a piperazine group was
attached to the steroid to provide a core structure for the
library. Sequential acylations were then performed by adding
an amino acid followed by a carboxylic acid. The compound
containing the most hydrophobic groups, **12**, was once again
the best inhibitor.

The substitution of estrone with a sulfamate group yielded
the potent, irreversible inhibitor EMATE (**13**, Figure 11),
which irreversibly inhibits ARSC with an IC_{50} value of
80 nM.[241, 242] The bridging oxygen atom of the sulfamate
group was found to be important for the activity, as the
corresponding thiophosphonate, *N*-sulfamate, and *S*-sulfa-
mate analogues all exhibited decreased inhibition.[243] N-
Alkylation of the sulfonamide group also led to weaker,
reversible inhibitors. A shift in research towards nonsteroidal
inhibitors took place after EMATE was found to be an
estrogen-receptor agonist.[244] A study of coumarin sulfamate
scaffolds uncovered the potent non-estrogenic, irreversible
ARSC inhibitor COUMATE (**14**, $IC_{50} = 380$ nM).[245] This
motif was enhanced through the introduction of increased
hydrophobic character: the tricyclic coumarin sulfamate **15**
has an IC_{50} value of 8 nM.[246] Other efforts towards non-
steroidal inhibitors have focused on sulfamate derivatives of
tetrahydronaphthalene, indanones, and tetralones.[247] Mod-
ifications to a known aromatase inhibitor, including the
introduction of sulfamate groups, led to the development of
dual estrogen sulfatase/estrogen aromatase inhibitors.[248] The
best inhibitors were **16** (IC_{50}(STS) = 2.3 nM, IC_{50}(aroma-

tase) = 20 nM) and **17** (IC$_{50}$(STS) = 0.82 nM, IC$_{50}$(aromatase) = 39 nM, Figure 11).

Other nonsteroidal estrone sulfatase inhibitors are chromen-4-one sulfamates. The most potent compounds had highly branched aliphatic substituents diagonally opposite to the sulfamate moiety, as evidenced by the good inhibitory activity of 2-(1-adamantyl)-4*H*-thiochromen-4-one-6-*O*-sulfamate (**18**, IC$_{50}$ = 340 pM, Figure 11).[249,250] Benzophenone sulfamates were also prepared, including 4,4'-benzophenone-
Figure 11. EMATE (**13**), COUMATE (**14**), and nonsteroidal sulfamate inhibitors.

O,O'-disulfamate (**19**, Figure 11) with an IC$_{50}$ value of 190 nM.[251] Finally, thiosemicarbazone derivatives of madurahydroxylacetone, a secondary metabolic product produced by the soil bacterium *Nonomuria rubra*, were studied.[252] The most potent compound was the cyclohexylthiosemicarbazone **20** (Scheme 6) with a K_i value of 350 nM. This inhibitor was found to act in a noncompetitive fashion and showed low acute toxicity.
Scheme 6. Thiosemicarbazone inhibitors.

An alternative approach to the discovery of ARSC inhibitors has focused on developing a better understanding of the active site and transition state through modeling and structure–activity relationships.[253] One study suggested that a sulfonate group at C3 was necessary for tight binding, whereas a polar group at C17 may not be required.[254] Analysis of a series of phenol sulfamates with different substituents showed a correlation between the basicity of the phenoxide leaving group and inhibition.[36,255,256] The most effective inhibition was observed for sulfamates with phenolic leaving groups with a pK_a value of 8. In a related study on a series of 4-sulfamated phenyl alkyl ketones, the best IC$_{50}$ value found was 3.4 μM (octyl substituents).[257] Structure–activity relationships for phenyl ketones[258–260] and biphenyl sulfamates[261,262] indicated the importance of hydrophobicity for activity.

Most work on sulfatase inhibition has focused on ARSC because of its involvement in hormone-dependent cancers. Several potent inhibitors with various hydrophobic scaffolds have been developed. Although permutations of the core structure have been shown to affect substrate binding, it is ultimately the presence of the sulfamate moiety that leads to irreversible inhibition of the enzyme. Several theories have been proposed for the mechanism of the affinity label; however, the precise dead-end product is unknown.[36,246] It would be helpful to discern the location of the affinity label, as this position would certainly give telling information about the mechanism of sulfate ester hydrolysis.

The inhibition of sulfatases other than ARSC by sulfamate-based inhibitors has yet to be demonstrated. Because of the conserved mechanism and the general acceptance of small aryl substrates by sulfatases, it is tempting to speculate that a phenyl sulfamate pharmocophore would be a good general sulfatase inhibitor. The design of specific inhibitors might be a much more difficult task, but one of great importance, as therapeutic targets must be selectively disabled in the presence of critical sulfatase activity, such as lysosomal catabolism (see Table 5). The development of specific inhibitors is certainly not an unreasonable goal. Warfarin, for example, has been shown to inhibit ARSE selectively, without affecting other ARSs in the ER.[129,130] Cocrystal structures of sulfatase–substrate or sulfatase–inhibitor complexes would supply critical information about substrate-binding regions within the sulfatase structure and would facilitate avenues for optimizing inhibitor specificity.

9. Synthetic Utility

9.1. Sulfatases in Glucosaminoglycan Sequencing

Sulfated oligosaccharides are receiving a great deal of attention as a result of their involvement in numerous biological processes.[139,263,264] Heparan sulfate (HS) in particular serves as an important mediator in many biological processes, including embryogenesis and developmental signaling,[140,265] inflammation,[266,267] coagulation,[268,269] angiogenesis,[270] cancer metastasis,[111] and microbial and viral adherence and invasion.[271–273] With a growing list of interesting interactions to study, the development of analytical tools

for the structure determination of complex oligosaccharides has become a primary objective.[274,275] The sequencing of complex oligosaccharides is by no means a trivial task. For example, HS contains 32 unique disaccharide units owing to variations in glycosidic connection, epimerization, and sulfonation (Figure 5). This structural diversity qualifies HS as one of the most information-dense biomolecules. By way of comparison, DNA is made up of just four and proteins of 20 different units. Furthermore, unlike these well-studied biomolecules, HS and GAG sequences are not templated and are non-amplifiable, necessitating the quantification of sub-milligram samples. Finally, the highly anionic character of these molecules has made them notoriously difficult to purify. It has become increasingly apparent that specific epitopes within the HS sequence are generated in a tissue-specific manner for selective interactions with certain important proteins, including growth factors, cytokines, receptor proteins, and enzymes.[139,276] Many sequencing strategies have therefore targeted HS to enable the characterization of these interactions.[274,277]

Several techniques in which sulfatase enzymes are invaluable tools have been developed to decode HS sequences. Two recent advances, integral glycan sequencing (IGS)[278] and property-encoded nomenclature in conjunction with matrix-assisted laser desorption mass spectrometry (PEN–

MALDI),[279] have proved very useful in the rapid determination of HS structures from small amounts of pure sample. The IGS sequencing format entails fluorescent labeling of the reducing end of the HS chain followed by iterative chemical and enzymatic degradation steps that are analyzed by gel electrophoresis (Figure 12). After labeling, the oligosaccharide is partially cleaved at GlcN-(α-1,4)-H residues by treatment with nitrous acid to generate several intermediate-sized fragments. These fragments are then subjected to stepwise degradation with a series of exoenzymes that cleave monosaccharide units (glycosidases) or sulfate groups (lysosomal sulfatases) from the nonreducing end. Characteristic electrophoretic shifts after each step can be used to decipher the original HS sequence. Similar methods utilize high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE) for analysis of the fragments. Methods for the radiolabeling of HS from in vivo samples have also been reported.[280–282]

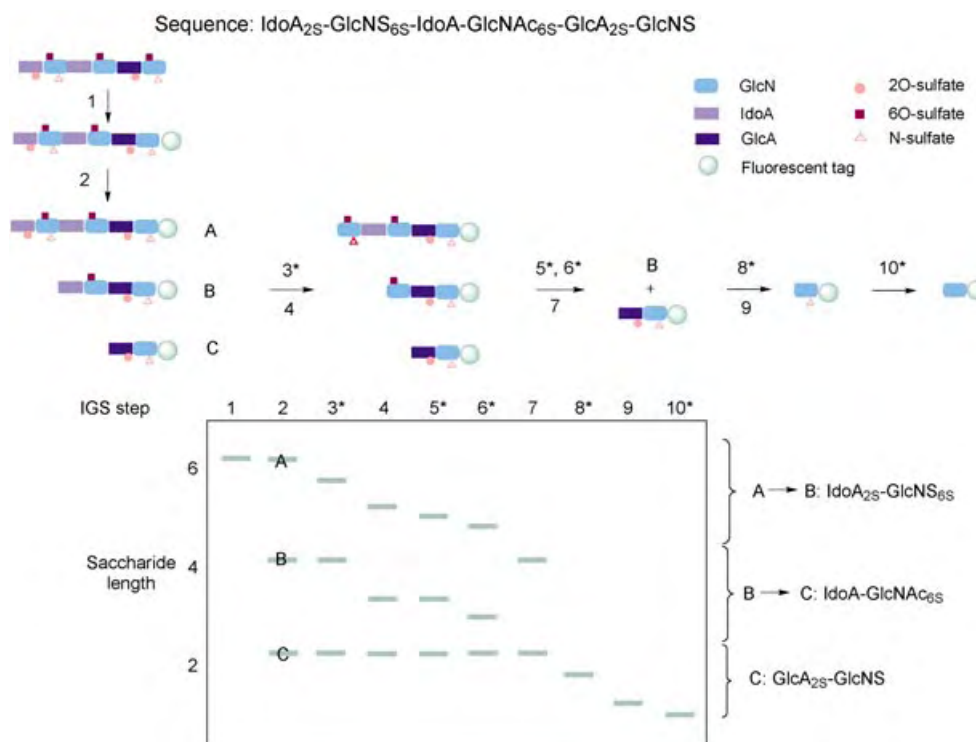
PEN–MALDI uses a slightly different approach, incorporating mass spectrometry and bioinformatic techniques with chemical and enzymatic degradation.[279] The enzymes used in this process include exoglycosidases and sulfatases from eukaryotic sources in addition to bacterial lyases, hydrolases, and sulfatases from *F. heparinum*. The process begins with an initial mass spectrometric reading from which


Figure 12. The integral glycan sequencing (IGS) strategy for decoding heparan sulfate (HS) sequences. Isolated HS saccharides can be sequenced rapidly through a combination of chemical and enzymatic steps followed by electrophoretic separation of the products. This schematic example shows the elucidation of a simple hexasaccharide sequence (top). The saccharide is labeled at its reducing end with a fluorescent tag (step 1). Partial chemical cleavage at GlcN residues with nitrous acid creates fragments A, B, and C, each differing in size by a disaccharide unit (step 2). In steps 3–10, specific sulfate groups or monosaccharide residues are removed from the nonreducing end of A, B, and C by specific exosulfatases (labeled with an asterisk) and exoglycosidases. The enzymes used are the lysosomal sulfatases IdoA2S (step 3), GlcN6S (step 6), GlcA2S (step 8), and GlcNS (steps 5 and 10) and the appropriate glycosidases. The separation of the enzymatic products on a high-density polyacrylamide gel produces fluorescent band patterns that are characteristic for the saccharide sequence.

a master list of all possible HS sequences is generated. The list is rapidly whittled down as the iterative actions of well-defined chemical and enzymatic agents provide new constraints for the sequence. The power and utility of these HS sequencing methods have been demonstrated in several important studies that have helped elucidate the interactions of HS with FGF,[278,283,284] antithrombin III (AT-III),[285–287] and herpes simplex virus.[288] These sequencing methods can also be adapted for the study of other glycosaminoglycans. Several similar techniques have been developed for the analysis of chondroitin sulfate and dermatan sulfate,[289,290] and it is conceivable that the further characterization of mucin-degrading enzymes and mucin sulfatases could aid in the sequencing of biologically pertinent sulfomucin sequences.
Scheme 7. Use of sulfatases to generate different sulfation patterns on monosaccharide donors. Following global sulfonation by chemical and/or enzymatic synthesis (a), sulfatases can be used independently or in combination to generate the desired sulfation pattern. The sulfatases used are a 4-O-sulfatase from abalone (b), a 2-O-sulfatase from the limpet (c), and a 3-O-sulfatase from the snail (d).

9.2. Sulfatases in Synthesis

With the increased sophistication of the sequencing strategies, several key HS-binding motifs have emerged. There are also many well-described sulfonated carbohydrate structures, such as sLe^X-6S, that are of biological interest.[291] Often, it is desirable to explore the biological activity of these molecules through the combinatorial synthesis of libraries that facilitate the establishment of structure–activity relationships. Another approach that is also frequently used is the targeted synthesis of analogous structures as potential therapeutic agents. The bottleneck in such endeavors consistently lies in the notoriously difficult synthesis of oligosaccharide libraries,[292,293] and the use of enzymes is often sought.[294,295] In this regard, there are a number of ways in which sulfatases might be exploited to facilitate the chemical synthesis of sulfate-bearing oligosaccharides.

As is the case for many processes in carbohydrate chemistry, the sulfonation of saccharides in a regioselective manner often requires arduous protecting-group manipulations. Although a few methods for regioselective sulfonation already exist,[291,296–299] the use of sulfatases has recently been shown to be a viable alternative. Uzawa et al. synthesized *p*-nitrophenol galactose derivatives with multiple sulfate groups and subjected them to enzyme-catalyzed desulfonation with commercially available sulfatases from mollusks.[300,301] By studying the activity of several enzymes, conditions were found under which various sulfation patterns could be generated selectively, thus providing facile access to a library of sulfated monosaccharides. These compounds could be subsequently converted into glycosyl donors for the construction of more complex sulfated oligosaccharides (Scheme 7).[302]

The discovery of the Sulf enzymes provided further possibilities for the application of sulfatases in synthesis. Most GAG-specific sulfatases known prior to Sulf discovery demonstrate strict exo specificity, which has proven useful in sequencing schemes and in the synthesis of sulfated monosaccharide donors. The Sulfs, on the other hand, show unique endo activity.[22] Their ability to cleave sulfate esters in a regiospecific manner within GAG chains might be useful for the generation of diversity in libraries or in the custom synthesis of oligosaccharide epitopes of interest.[275] For example, a sensitive gel shift assay was recently used to quantify the binding of proteins to HS targets by coupling sulfates enzymatically to an unadorned oligosaccharide backbone.[303] A complementary sequence could potentially be generated with specific sulfatase enzymes by beginning with a known ligand and HS target and systematically cleaving the sulfate residues. In fact, the interaction between Wnt, HS, and Sulf1 is a prime candidate for investigation by using the gel shift assay. Such a study could provide solid evidence that Sulf1 directly modulates the binding affinity of HS for Wnt by cleaving a key sulfate ester (Figure 7).[97] Clearly, the discovery and development of novel sulfatases with distinct specificities would greatly add to the potential of this method; one can envisage the use of an assortment of enzymes, including sulfatases and sulfotransferases, for the dynamic manipulation of sulfated oligosaccharide structures with the aim of elucidating HS activities at the cell surface.

Several other applications of sulfatases have been established. One chemoenzymatic approach took its cue from the functional role of sulfatases in the body. In a procedure patented by Bristol-Myers Squibb, a tumor-specific sulfatase-conjugated antibody and a sulfated prodrug were used for tissue-specific drug delivery.[304] In this process the active therapeutic is released only in the vicinity of the tumor cell

requiring treatment, thus limiting nonspecific activity. The glucosinolate sulfatases from the diamondback moth and the snail *H. pomatia* have been used to help analyze and classify glucosinolates (**4**, Figure 4) from various plant sources.[152] Extracts from *H. pomatia* have been used in many other analytical applications, from the examination of soil organic matter[305] to the identification of steroids and psychotropic drugs from urine and hair samples.[306,307] Other applications of prokaryotic sulfatases include the bioremediation of alkyl sulfate waste products[48,308,309] and the deracemization of secondary alkyl sulfates.[41–43]

10. Conclusion and Outlook

A primary aim of this Review was to provide a comprehensive overview of the various areas of sulfatase research. Sulfatases are intriguing in many respects, and their scope is rapidly expanding. Regarding their catalytic activity, a key active-site aldehyde group endows sulfatases with the unique ability to hydrolyze sulfate esters. The post-translational generation of this residue, which is lacking in multiple sulfatase deficiency, is of great clinical interest and requires further mechanistic investigation.

Regarding their structure, the sulfatases exhibit a highly similar three-dimensional fold and highly similar catalytic-cleft geometry, underscoring their functional conservation from prokaryotes to eukaryotes. Such mechanistic homogeneity is interesting given the wide range of substrates and pH optima over which sulfatases operate. Currently, little is known regarding the nature of the catalytic transition state or the basis for substrate specificity. Such information would undoubtedly provide valuable insight for the development of potent, specific inhibitors for sulfatases.

Sulfatases play important roles in a number of biological processes. However, it is becoming clear with the discovery of novel sulfatases and the elucidation of new biological roles that a great deal of research will be necessary to complete the functional picture of this enzyme class. One of the most exciting new areas in which sulfatases are emerging is in the remodeling of important sulfonation states on HS chains, which govern crucial signaling pathways and molecular-recognition events. The study of heparan sulfates is a challenging field in which sulfatases have already proven to be of great value in HS-sequencing strategies. Sulfatases also have the potential to serve as powerful tools in synthetic endeavors with biological and therapeutic objectives.

A diverse range of biological interactions are known to be dependent on sulfate groups, including 1) the participation of heparan sulfate and other sulfated glycosaminoglycans in developmental signaling, as well as bacterial and viral infections, 2) the role of protein tyrosine-*O*-sulfate in the activity of peptide hormones and the entry of HIV into cells, and 3) the role of sLe^X-6S in inflammation. The physiological synthesis of these sulfonated biomolecules by sulfotransferases has been under intense investigation in recent years. It will be very interesting to see if eukaryotic, prokaryotic, or viral sulfatases can also participate in the modulation of these processes.

Abbreviations

AP	alkaline phosphatase
ARS	aryl sulfatase
ECM	extracellular matrix
EGF	epidermal growth factor
ER	endoplasmatic reticulum
FGE	FGly-generating enzyme
FGF	fibroblast growth factor
FGH	α-formylglycine hydrate
FGly	α-formylglycine
FGS	FGly–sulfate adduct
GAG	glycosaminoglycan
HS	heparan sulfate
HSPG	heparan sulfate proteogycan
MSD	multiple sulfatase deficiency
MSDF	MSD factor
pNCS	*p*-nitrocatechol sulfate
SUMF	sulfatase-modifying factor
Wnt	Wingless/Int

Communications
Theoretical evidence now suggests that the mechanism of the long-debated Hajos–Parrish–Eder–Sauer–Wiechert reaction, the prototype for asymmetric organocatalytic reactions, involves a proline enamine intermediate (center) which undergoes a concerted aldol cyclization with proton transfer. For more details see the Communication by K. N. Houk and F. R. Clemente on the following pages.

Communications

Computational Evidence for the Enamine Mechanism of Intramolecular Aldol Reactions Catalyzed by Proline**

*Fernando R. Clemente and K. N. Houk**

The first examples of enantioselective intramolecular aldol cyclizations catalyzed by proline (Scheme 1) were independently reported by Hajos and Parrish[1] and by Wiechert and co-workers[2] in 1971. Useful synthetic intermediates, such as the Wieland–Miescher ketone (**3b**) are easily obtained by this reaction. This reaction constitutes a cornerstone in the emergent field of enantioselective organocatalysis. A variety of C–C bond-forming reactions have been achieved with chiral organocatalysis in recent years.[3]
Scheme 1. Enantioselective intramolecular aldol cyclization.

In spite of the classic status of this reaction, the mechanism remains controversial. Herein we provide definitive theoretical evaluation of the various mechanisms proposed for the reaction; by computation of all six steps in the reaction we show how the reaction conditions may influence the rate-determining step and the stereoselectivity.

In their original paper,[1b] Hajos and Parrish proposed two mechanisms (Scheme 2): **A**, which requires the formation of a carbinolamine intermediate followed by nucleophilic substitution at this center by the enol form of the acyclic carbonyl; and **B**, with an enaminium intermediate and C–C bond-formation accompanied by N-H-O hydrogen transfer and nucleophilic assistance by the carboxylate group of proline. Hajos still argues for mechanism **A**,[1c] on the basis of his experiments with ^{18}O-labeled water where no incorporation of [18]O in the products was observed.[1b] However, List et al. have reinvestigated these experiments recently under care-

Scheme 2. Relative energies (E + ZPE, kcal mol^{-1}; ZPE = zero-point energy) of proposed proline-catalyzed aldolization transition states. Values in parentheses include solvation energies in DMSO using the PCM/UAKS model.

fully controlled conditions, and they found efficient (> 90 %) [18]O incorporation.[4]

In the 1980s, Agami supported the mechanisms involving enamine intermediates[5] on the basis of accumulated experience in amine catalysis of similar reactions.[6] Mechanism **B** was criticized, since it involves a protonated enamine that must reduce the nucleophilicity of the C=C bond. They proposed mechanism **C**, which involves a second molecule of proline to assist in the hydrogen transfer.[5] While model **C** was supported by the observation of a kinetic nonlinear effect, List and co-workers have reported evidence that show the absence of nonlinear effects in these reactions and support a one-proline mechanism.[7]

Mechanism **D** involves an enamine intermediate with concerted C–C bond formation and proton transfer from the carboxylic acid group to the carbonyl acceptor. This transition state, initially proposed by Jung in a review in 1976,[8] was

almost abandoned in favor of mechanism **C** until 2000. In their pioneering work on enantioselective proline catalysis of intermolecular aldol reactions, List, Barbas, and co-workers proposed a model similar to **D**.[9] Our preliminary computational studies on the origins of the stereoselectivity of the intramolecular aldol reactions depicted in Scheme 1 also support mechanism **D**, since transition states computed for this reaction provide a satisfactory explanation of the stereochemical outcome.[10]

We have located the transition structures for the C–C bond-forming step of the different mechanisms proposed (Scheme 1), which is the presumed rate-determining step for the transformation. All the geometries were fully optimized with GAUSSIAN[11] at the B3LYP/6-31G(d) level followed by frequency calculations to determine the nature of the stationary points. The reported energies come from B3LYP/6-31 + G(d,p) energy calculations on the geometries optimized at the lower level.[12] Free energies of solvation were computed as the energy difference of HF/6-31 + G(d,p) single point energy calculations in DMSO (PCM model[13] and UAKS radii)[11b] and in the gas-phase on the DFT gas-phase geometries.

The relative energies of the different transition states or intermediates are given in Scheme 2. The carboxylic acid catalyzed enamine mechanism (**D**) is energetically the most favorable. The transition structure for C–C bond formation by this mechanism is more than 10 kcal mol^{-1} lower in energy than the corresponding one for the uncatalyzed process (**E**). Mechanism **B**, which involves the zwitterionic form of the enamine (enaminium), is disfavored by about 30 kcal mol^{-1} over mechanism **D**. The nucleophilic substitution TS (**A**) could not be located, and all our optimization attempts led to structures similar to **E**, the uncatalyzed process. However, the carbinolamine intermediate preceding this C–C bond-forming TS is more than 12 kcal mol^{-1} higher in energy than TS **D**. It is thus expected that a structure such as TS **A**, if it exists, would be even higher in energy than this intermediate.

The enhanced nucleophilicity of the enamine C=C bond together with the activation of the carbonyl electrophile by the carboxylic acid constitute the basis of the catalytic activity of the amino acid acting through mechanism **D**. Protonation of the enamine nitrogen atom (**B**) drastically reduces the reactivity of the C=C bond. On the other hand, the mechanism originally supported by Hajos (**A**) appears very unlikely since the carbinolamine intermediate is already higher in energy than the transition structure for the uncatalyzed process (**E**).

Scheme 3 depicts the proposed pathway for the enantioselective aldol cyclization of **1a** catalyzed by (*S*)-proline involving the formation of an enamine intermediate (**12**) and
Scheme 3. Proposed pathway for the (*S*)-proline-catalyzed cyclization of **1a** into (*S,S*)-**2a** with the relative gas-phase energies (kcal mol^{-1}). Values in parentheses include solvation energies in DMSO using the PCM/UAKS model.

Communications

carboxylic acid catalysis in the C–C bond-forming step ((*S*,*S*)-**14**). Boyd and co-workers have reported a similar study but for the intermolecular reaction.[14] The last stage in the formation of enamine intermediate **12** is the intramolecular deprotonation by the carboxylate group (**11**). This process and the subsequent C–C forming step have equal energies in solution and represent the rate-determining steps (Figure 1). The C–C bond forming step ((*S*,*S*)-**14**) is the stereochemistry-determining step of the reaction. The preferential formation of the *S*,*S* enantiomer was rationalized in an earlier computational study from our research group.[10]
Figure 1. B3LYP/6-31G(d)-optimized transition-state geometries of the rate-determining steps for enamine formation (**11**) and aldol cyclization ((*S*,*S*)-**14**). Interatomic distances are given in Å.

After the formation of the C–C bond, the hydrolysis of iminium (*S*,*S*)-**15** is achieved in a series of easy steps that leads to the release of the aldol product (*S*,*S*)-**2a** and recovery of the catalyst. These steps are analogous, but in reverse order, to those at the beginning corresponding to the formation of iminium intermediate **10**. As expected, the most difficult step in the hydrolysis of (*S*,*S*)-**15** is the nucleophilic attack of water ((*S*,*S*)-**17**). This step will compete with the reversal of the C–C bond-forming step ((*S*,*S*)-**14**) at a low concentration of water. This result has significance on the stereoselectivity.

Recent experimental work,[4,7] together with these computational studies, have established the previously controversial mechanism of aldol reactions catalyzed by proline.

Helical Water Chain

Helix inside a Helix: Encapsulation of Hydrogen-Bonded Water Molecules in a Staircase Coordination Polymer**

Bellam Sreenivasulu and Jagadese J Vittal*

Inspired by the fascinating structural features of helices that exhibit cooperative self-assembly and recognition, as well as remarkable functions such as chemical transport and screening by membrane channels in biological systems, helicity has been successfully introduced into artificial systems by chemists working in the field of metallo-supramolecular chemistry.[1] As a result, today helical polymers are among the most explored and best investigated supramolecular architectures.[2] As hydrogen bonds and other noncovalent interactions are the main driving forces behind this self-assembly process, supramolecular chemistry is now in a phase of characterizing and understanding various hydrogen-bonded water clusters in the form of hexamers,[3,4] octamers,[5,6] decamers,[7] $(H_2O)_{15}(CH_3OH)_3$ clusters[8] and one-dimensional (1D) infinite water chains[9,10] in diverse environments of various crystal hosts. Zeolite-like 3D network structures with chiral channels filled with highly ordered water molecules are well known.[11]

At this juncture, 1D water chains are attracting a great deal of attention because of their vital role in the biological transport of water, protons, and ions.[12] It was recently found that transport of water or protons across the cell involves the assembly of highly mobile hydrogen-bonded water molecules into a single chain at the positively charged constricted pore of the membrane-channel protein aquaporin-1.[13] While 1D water chains play crucial roles in stabilizing the native conformation of biopolymers, such helical water chains are extremely rare in synthetic crystal hosts.[9,10] Here we report an interesting staircaselike helical coordination polymeric architecture of a Ni^{II} complex that hosts a 1D helical chain of lattice water molecules in a helical pore through hydrogen bonding.

The single-crystal X-ray structure of $[(H_2O)_2\subset\{Ni(Hsglu)(H_2O)_2\}]\cdot H_2O$ (**1**; $H_3sglu = N$-(2-hydroxybenzyl)-L-glutamic acid) was determined unambiguously.[14] Compound **1** crystallizes in the monoclinic system with two independent molecules in the asymmetric unit. Each Ni^{II} unit has octahedral geometry (Figure 1), and the Hsglu^{2-} ligand is coordinated through the phenolic oxygen atom (Ni1–O1

H₃sglu
Figure 1. A view of the coordination environments at the two Ni^{II} centers in **1**. Selected bond lengths [Å]: Ni1-O(12) 2.043(4), Ni1-O2 2.047(4), Ni1-O(11) 2.051(4), Ni1-O(9) 2.059(3), Ni1-N1 2.084(4), Ni1-O1 2.089(4), Ni2-O(14) 2.039(4), Ni2-O(7) 2.042(4), Ni2-O(5) ($-x+1$, $y-\frac{1}{2}$, $-z+1$) 2.048(4), Ni2-O(13) 2.070(3) Ni2-N2 2.082(4), Ni2-O6 2.101(3).

2.089(4) Å, Ni2–O6 2.101(3) Å), secondary amine N atom (Ni1–N1 2.084(4) Å, Ni2–N2 2.082(4) Å), and carboxylate α-oxygen atom (Ni1–O2, 2.047(4) Å, Ni2–O7 2.042(4) Å) in a *fac* manner, along with two aqua ligands, and another carboxylate oxygen atom from the neighboring molecule. The intermolecular connectivity via the second carboxylate O atom generates a left-handed staircaselike coordination polymeric architecture with a pseudo-4_1 screw axis. In this helical staircase, the aqua ligands *trans* to phenolic oxygen atoms (i.e., O11 and O13) point into the tube, normal to the helical axis. The NH and OH protons form hydrogen bonds to the carboxylate oxygen atoms along the surface of the helical staircase, as shown in Figure 2; hydrogen-bond parameters are given in Table 1.

The square-shaped chiral channel has dimensions of 7.654×7.529 Å (based on Ni···Ni distances; Figure 3). Of the six lattice water molecules present in the asymmetric unit, four are inside the helical pore, and two outside. Two of the former water molecules (O15 and O16, Figure 1) are hydrogen-bonded to produce a 1D helical polymer with a pseudo-4_1 screw axis. This helical water chain, as the pole of the helical staircase, supports and stabilizes its orientation by maintaining hydrogen bonding to aqua ligands. The other two water molecules (O17 and O18) propagate hydrogen bonding with both the helical water chain and the aqua ligands, and their hydrogen bonding tendency appears to have facilitated the positioning and orientation of the water molecules forming the helical chain.

The total solvent volume in the lattice, including that occupied by the helical-chain and lattice water molecules, is 405.1 Å^3 (22.7% of the unit cell).[14] All the tubular coordi-
Figure 2. a) Hydrogen-bonded helical water chain inside the staircase coordination polymer in **1**. b) Hydrogen-bonded helical water stream in the channel. c) Top view of the staircase polymer filled with the helical water stream.

nation polymers are aligned along the *b* axis, and two more water molecules (O19 and disordered O20) occupy the empty space in the lattice outside the helical channels. The TG analysis of **1** revealed weight loss in the temperature range 26–232 °C. The total weight loss observed (21.6%) agrees with the calculated value (22.5%) for the loss of five water molecules per Ni atom. The single crystal crumbles on removal of water and on cooling to −50 °C.[15] The structure is not expected to be robust when dehydrated, because these coordination polymers are not supported by strong non-covalent interactions (Figure 3).

In contrast to **1**, in the crystal structure of [Cu(Hsglu)-(H₂O)]·H₂O (**2**)[16] the connectivity of the neighboring carboxylate oxygen atoms with Cu^{II} centers results in a 1D zigzag coordination polymer (Figure 4).

As in the majority of the supramolecular syntheses, self-assembly of metal ions and ligands resulted in the formation of single-, double-, triple-, and quadruple-stranded helical structures.[2] However, a helical chain inside a helical structure is very rare. Recently a hydrogen-bonded helical supramolecular host was found to be anchored by hydrogen bonding to alternate water molecules in a single-stranded, both right- and left-handed, helical chain of water molecules.[17] However, the structure of **1** has a hydrogen-bonded helix inside a helical 1D coordination polymer. This highly ordered helical stream of water molecules inside another helical polymer is striking and is a unique structural feature among existing porous helical structures[2c, 18–20] and other patterns of water structures observed in diverse environments of inorganic[5,7] and organic hosts[3,4,9] and 2D supramolecular (H₂O)₁₂ rings.[21] Whereas designing chiral materials from achiral molecular compounds is a promising theme in materials science, using simple and available chiral precursors as an alternative is another practical approach. The structure of **1** exemplifies the feasibility of such an approach.[22]

In conclusion, the structure of the left-handed helical coordination polymer **1**

[a] A = acceptor, D = donor. [b] The hydrogen atoms have been placed in the calculated positions.
Figure 3. Packing of the staircase polymer viewed along the *b* axis. The water molecules in the channels are omitted for clarity.
Figure 4. a) A view showing the coordination environment of Cu^{II} in **2**. Selected bond lengths [Å]: Cu1-O4 1.921(1), Cu1-O6 1.964(2), Cu1-O2 1.969(1), Cu1-N1 1.978(2), Cu1-O1 2.345(2). b) A portion of the 2D sheets formed by hydrogen bonding between the zigzag coordination polymer.

encapsulating a hydrogen-bonded helical stream of water molecules exhibits novel cooperative assembly and recognition of water molecules in the inorganic crystal host. These results exemplify the maxim that the structural constraints acting on the orientation of water by its surroundings and vice versa can be very significant. The captivating structure of **1**, in which a helical chain of water molecules supports a helical coordination polymer staircase, suggests another fascinating model for the water chains in membrane aquaporin proteins for the transport of water or protons, and it appears to be extremely rare among metal coordination polymers till now.[23] The 1D zigzag coordination polymeric structure containing the same ligand in **2** demonstrates that the overall topology depends on the nature of the metal and the coordination geometry at the metal centers.

Experimental Section

H$_3$sglu: Salicylaldehyde (0.57 g, 4.7 mmol) was added to a solution of L-glutamic acid (0.69 g, 4.7 mmol) and NaOH (0.37 g, 9.4 mmol) in MeOH/H$_2$O (v/v (1:1), 20 mL), and the resulting yellow solution was stirred for 30 min and cooled in an ice bath prior to reduction with a slight excess of NaBH$_4$ (0.19 g, 5.1 mmol). The yellow color disappeared immediately, and stirring was continued for a further 20 min. The pH of the mixture was adjusted to 5–6 by adding acetic acid, and it was to stirred for a further 45 min. The solvent from the resulting clear solution was completely removed on a rotary evaporator. The sticky mass was treated with EtOH (25 mL). The white product was collected by filtration, washed with EtOH and Et$_2$O, and dried under vacuum. Yield: 0.85 g (71%). M.p. 247–248 °C (decomp). Elemental analysis (%) calcd for C$_{12}$H$_{15}$NO$_5$: C 56.9, H 5.9, N 5.5; found: C 56.4, H 5.8, N 5.6. ^{1}H NMR (300 MHz, D$_2$O): $\delta =$ 6.78–7.27 (m, 4H, ArH), 3.92–4.12 (m, $J_{AB} = 13.2$ Hz, 2H, CH$_2$), 3.36–3.55 (t, $J = 6.42$ Hz, 1H, CH), 2.24–2.30 (t, $J = 8.4$ Hz, 2H, CH$_2$), 2.0–2.02 ppm (m, $J = 6.4$ Hz, 2H, CH$_2$). IR (KBr): $\tilde{\nu} = 3460$ (OH), 2960 (NH), 1573, 1388 (COO$^-$), 1276 cm^{-1} (phenolic CO).

1: A clear solution of H$_3$sglu (0.25 g, 1 mmol) in water (2.5 mL) was allowed to diffuse slowly into a clear solution of nickel nitrate hexahydrate (0.29 g, 1 mmol) in water (2.5 mL). Greenish rodlike crystals suitable for X-ray diffraction studies were obtained after one week from the solution on slow evaporation. Yield: 0.28 g (70%). Elemental analysis (%) calcd for C$_{12}$H$_{23}$NNiO$_{10}$: C 36.0, H 5.8, N 3.5; found: C 36.2, H 5.6, N 3.7. IR (KBr): $\tilde{\nu} = 3368$ (OH), 2746 (NH), 1623, 1348 (COO$^-$), 1253 cm^{-1} (phenolic CO). UV/Vis (Nujol): $\lambda_{max} = $ 385 (CT), 737 nm (d–d). TGA: weight loss (%) calcd for 5H$_2$O: 22.5; found: 21.6.

2: A clear solution of H$_3$sglu (0.25 g, 1 mmol) in water (2.5 mL) was allowed to diffuse slowly into a clear solution of copper nitrate trihydrate (0.24 g, 1 mmol) in water (2.5 mL). Dark blue blocks suitable for single-crystal X-ray diffraction studies were obtained after 1 d. Yield: 0.26 g (74%). Elemental analysis (%) calcd for C$_{12}$H$_{17}$CuNO$_7$: C 41.0, H 4.9, N 4.0; found: C 40.7, H 4.8, N 4.2. IR (KBr): $\tilde{\nu} = 3429$ (OH); 3118 (NH); 1650, 1429 (COO$^-$), 1262 cm^{-1} (phenolic CO). UV/Vis (Nujol): $\lambda_{max} = 285$ (CT), 613 nm (d–d). TGA: weight loss calcd for 2H$_2$O: 10.4; found: 10.8.

Building Molecular Minerals: All Ferric Pieces of Molecular Magnetite**

Guy W. Powell, Hannah N. Lancashire,
Euan K. Brechin,* David Collison,* Sarah L. Heath,*
Talal Mallah, and Wolfgang Wernsdorfer

Currently, there is a great deal of interest in the synthesis of transition-metal clusters that can behave as single-molecule magnets (SMMs).[1] An SMM requires effectively a combination of large spin ground state with a negative zero-field splitting (D value), which leads to magnetic bistability (hysteresis) that is the property of an individual molecule. These clusters may find potential uses in the information storage industry or as qubits in quantum computing.[2] One logical way to prepare SMMs is by synthesizing fragments of the naturally occurring magnetic oxides. This synthesis can be by either a top-down or bottom-up approach, that is, the breaking down or building up of a mineral lattice. Herein we report the synthesis of two iron oxy hydroxy clusters that represent two related portions of the magnetite lattice,

constructed by a bottom-up approach and utilizing ligand-controlled hydrolysis of a metal salt to determine the extent of cluster aggregation.

$[Fe_9O_4(OH)_5(heia)_6(Hheia)_2]\cdot 3.5\,CH_3OH\cdot 8\,H_2O$ (**1**; $H_2heia = HN\{CH_2COOH\}CH_2CH_2OH$; Figure 1) was synthesized by reaction of iron(III) nitrate nonahydrate with H_2heia and tetramethylammonium hydroxide in methanol. The
Figure 1. The molecular structure of the cluster in **1** (left), the core of **1** (middle), and its relation to magnetite (right); yellow Fe, red O, blue N, gray C.

hydrolysis was gradually stopped by evaporating the reaction mixture to dryness. Crystals of **1** suitable for single crystal X-ray diffraction were obtained after 2 weeks by crystallization from a MeOH solution of **1** in the presence of liquid drying agent (diethoxymethane) to hinder further hydrolysis.[3] $Hpy[Fe_{17}O_{16}(OH)_{12}(py)_{12}Cl_4]Cl_4\cdot 4.5\,CH_3OH$ (**2**; py = pyridine; Figure 2) was prepared by the reaction of anhydrous iron(III) chloride in pyridine in a flask open to the atmosphere at room temperature, and crystals of **2** suitable for single crystal X-ray diffraction were isolated in low yield after diffusion of methanol over 2 weeks.[3]

The complex in **1** is constructed from a central tetrahedral Fe^{III} ion which links, by four μ_3-oxo bridges, to the outer eight iron atoms. Each of the outer iron ions is capped by a facially coordinated heia ligand and has distorted octahedral coordination geometry. Six of the heia ligands are fully deproto-

nated and the alcohol arm of these ligands (O5, O8, O13 and their symmetry equivalents) bridges between pairs of outer irons: the second bridge between these irons is from the inner μ_3-oxo ligands. The remaining two Hheia ligands have protonated alcohol arms (O16 and its symmetry equivalent) that coordinate terminally. Two of the outer irons (Fe3 and Fe4) are bridged by two μ_2-hydroxo ligands (O9 and O10) and two others, Fe5 and Fe5A, are bridged by a single hydroxo ligand (O17). This asymmetry in the mode (and hence angle) of the bridging between the outer iron ions has consequences for the magnetic exchange pathways in **1** (see below). The bromide analogue of **2** can be prepared by a similar route in higher yield and has a cluster that is isostructural with the chloride; this will be reported in detail elsewhere.

The complex in **2** also has at its core a central tetrahedral Fe^{III} ion, but in contrast to **1** this is linked by μ_4-oxo bridges to twelve outer octahedral Fe^{III} ions, which form a truncated tetrahedron: the octagonal faces of this tetrahedron (Fe2, Fe3, Fe5, Fe7, and symmetry equivalents) are capped by four further iron ions (Fe4, Fe6, and symmetry equivalents), linked by a combination of μ_3-oxo and μ_2-hydroxo ligands. The inner Fe^{III} ion and the four outer Fe^{III} ions of **2** sit in the tetrahedral sites of the lattice with the others occupying the octahedral sites. The chloride ions cap the outer tetrahedrally coordinated Fe^{III} ions with the pyridine molecules capping the octahedrally coordinated Fe^{III} ions.

A closer inspection of the cores of **1** and **2** reveals that both are fragments of the iron and oxygen positions defined by the magnetite lattice as shown in the comparison of **1** and **2** to their corresponding fragments of magnetite in Figures 1 and 2. Compound **1** is formally converted into **2** by adding a layer of Fe ions through the conversion of μ_3-oxo into μ_4-oxo
Figure 2. The molecular structure of the cluster in **2** (left), the core of **2** (middle), and its relation to magnetite (right); yellow Fe, red O, blue N, gray C, green Cl).

ligands. Many of the polynuclear transition-metal clusters isolated to date, that resemble mineral units, are fragments of the $M(OH)_2$ brucite lattice.[4] In our case, **1** is formed by restricting the hydrolysis from a hydrated iron(III) salt using a facially capping tridentate ligand with "arms" of very different pK_a values. In contrast, **2** is produced by restricting the amount of hydrolytic source in a basic, strongly coordinating medium. The isolation of **2**, in particular, suggests that larger fragments of "molecular magnetite" can be isolated by using coordinating bases of differing strengths.

In both **1** and **2** all the iron centers (both tetrahedral and octahedral) are Fe^{III} ions, this is confirmed by charge-balance considerations and bond valence sum (BVS) calculations.[5] This result is in contrast to the situation in magnetite where half the octahedral sites in the lattice are occupied by Fe^{II} ions. The assignment of hydroxo versus oxo was achieved on the basis of geometry and BVS calculations.

The magnetic properties of **1** and **2** were examined using variable-temperature magnetic measurements on bulk powdered samples (300–1.8 K, 0.1–5.5 T) and on single crystals to mK temperatures on a micro-SQUID. Susceptibility data for both **1** and **2** indicate the presence of antiferromagnetic interactions, with low-temperature maxima suggesting large spin ground states. To determine the value of the spin ground state for **1** and **2**, magnetization measurements were performed at 2–6 K between 0.1 and 5.5 T. For **1** the best fit (first made for each temperature independently and second by simultaneously fitting the data for the three temperatures for an isolated ground state) was obtained for $S = 25/2$, $g = 1.99$, and $D = -0.07$ cm^{-1} (Figure 3). For **2** the initial best fit was for $S = 35/2$ as the ground state with the following parameters: $g = 1.96$ and $D = +0.33$ cm^{-1} (Figure 4), see below. The occurrence of such large spin ground states for both complexes arises from the presence of competing antiferromagnetic and ferromagnetic exchange-coupling interactions between the octahedral and tetrahedral Fe^{III} ions. Closer

Figure 4. Plot of magnetization (M) versus H/T for **2** in the ranges 0.1–5.5 T and 2 (○), 3 (○), and 6 K (○). The solid lines are fits to $S = 35/2$, $g = 1.96$, $D = +0.33$ cm^{-1}. Inset: magnetization of **2** plotted as a fraction of the saturation value M_s versus applied magnetic field (μ_0H) at sweep rates of 0.001 Ts^{-1} and T = 0.04–0.5 K.

examination of the structure of **1** reveals that the Fe-O-Fe bridges fall into two clear categories: those that connect the central tetrahedral Fe^{III} centers to the outer octahedral Fe^{III} centers (by the oxo ligands) are all characterized by angles in the range 125–130°, and those that bridge between the Fe^{III} ions in the outer octametallic "twisted ribbon" are characterized by angles in the range 97–101°. If we assume that the largest Fe-O-Fe angles promote the strongest antiferromagnetic interaction then we are left with a situation where the central tetrahedral Fe^{III} center is antiferromagnetically coupled to all the octahedrally coordinated Fe^{III} ions, which leads to an $S = 35/2$ spin ground state. However, there is one anomaly in the bridging angles connecting the outer octahedrally coordinated Fe ions: the angle between Fe5 and Fe5A through O17 is 130°. This angle is bigger than the angle connecting either Fe5 or Fe5A to the central metal ion and so we might consider the exchange between the Fe5/Fe5A pair to be dominant, and antiferromagnetic. This situation would lead to a molecule with two "spin up" and seven "spin down" $S = 5/2$ centers and an overall spin ground state of $S = 25/2$, consistent with that obtained from the magnetization measurements.

For complex **2**, the same argument applies: the antiferromagnetic interactions between the tetrahedrally and octahedrally coordinate Fe^{III} ions (through Fe-O-Fe angles of 122–126° compared to 94–98° between the octahedral Fe centers) dominate, which leads to a situation in which the five tetrahedrally coordinated Fe^{III} ions are "spin up" and the twelve octahedrally coordinated Fe^{III} ions are "spin down" giving an overall $S = 35/2$ ground state.

To examine the low-temperature magnetic behavior of **1** and **2**, single crystal magnetization measurements were performed on them using an array of micro-SQUIDs.[6] Relaxation data for **1** were determined from direct current (dc) relaxation-decay measurements: a large dc field of 1.4 T was applied to the sample at 5 K to saturate the magnetization in one direction, and the temperature lowered to a specific value between 1.0 and 0.04 K. When the temperature was stable the field was swept from 1.4 T to zero at a rate of

Figure 3. Plot of magnetization (M) versus H/T for **1** in the ranges 0.1–5.5 T and 2 (○), 3 (○), and 6 K (○). The solid lines are fits to $S = 25/2$, $g = 1.99$, $D = -0.07$ cm^{-1}. Inset: magnetization of **1** plotted as a fraction of the saturation value M_s versus applied magnetic field (μ_0H) at sweep rates of 0.007 Ts^{-1} and T = 0.1–0.5 K. S = Spin quantum number of the cluster, g = g value of cluster, D = axial zero-field splitting parameter.

$0.14\,\mathrm{T\,s^{-1}}$ and the magnetization in zero-field measured as a function of time. This method allows the construction of an Arrhenius plot of $\ln\tau$ versus $1/T$, which shows that above approximately 0.15 K the relaxation rate is temperature dependent. The fit to an Arrhenius law yields $\tau_0 = 6 \times 10^{-10}$ s and $U_{\mathrm{eff}} = 7.6$ K. However, below approximately 0.15 K the relaxation rate is temperature independent with a value of 8×10^3 s, indicative of quantum tunneling of the magnetization (QTM) between the lowest energy $M_{\mathrm{s}} = \pm 25/2$ levels of the ground state. Hysteresis loops for **1** (inset, Figure 3) are observed at temperatures below 0.5 K and at sweep rates of $0.001\,\mathrm{T\,s^{-1}}$, with the field applied in the direction of the easy-axis of the molecules. The hysteresis loops do not show steps at regular intervals of field, indicative of resonant QTM, but are smooth. The steps may be present, but simply broadened out by intermolecular antiferromagnetic interactions between the separate Fe$_9$ molecules. Indeed, a Curie–Weiss plot suggests antiferromagnetic intermolecular interactions in the order of approximately -0.7 K. Further geometric analysis of **1** shows that the metallic cluster approximates to an oblate spheroid of estimated core dimensions 6.38×6.25 Å, and the nearest neighbor intercentroid separations in the lattice are 12.13 and 15.49 Å.

Low-temperature single-crystal magnetic measurements on **2** (inset, Figure 4) using the methods described in the investigation of **1**, show no signs of SMM behavior. The small hysteresis loops observed below approximately 0.5 K result from long-range ferromagnetic ordering between the individual Fe$_{17}$ molecules and not from the presence of molecular anisotropy. The anomalously large zero-field splitting and low g value (for Fe$^{\mathrm{III}}$, typical parameters are $g \approx 2.00$ and $|D| \leq 0.2\,\mathrm{cm^{-1}}$) obtained for **2** using a model for magnetization in an isolated spin state (see above) might also suggest the presence of long-range interactions. We would expect the cluster g and D values to be similar to those of the isolated Fe$^{\mathrm{III}}$ centers in this case. In **2** the core of the cluster is much more spherical than that in **1** (although it has 12 protruding pyridine rings) with a diameter of the metallic core of approximately 6.96 Å and nearest neighbor intercentroid separations of 14.89 and 16.12 Å. The pyridine rings show no obvious π-stacking interactions between clusters.

For both **1** and **2** the magnetic behavior is comparable to that observed in magnetite, wherein the iron ions in the octahedral and tetrahedral holes are antiferromagnetically coupled, but net magnetization results from the noncompensated spin of the Fe$^{\mathrm{II}}$ ions which occupy one quarter of the octahedral sites.

In conclusion, it is possible to construct high-spin molecules, single-molecule magnets, and molecular mineral analogues using a simple bottom-up, controlled hydrolysis approach. That the iron ions in **1** and **2** are all ferric and hence almost electronically isotropic (i.e. $|D|$ is small), probably prevents more exciting magnetic behavior. However, since these clusters form part of a naturally occurring mixed-valence mineral, the reduction of some Fe$^{\mathrm{III}}$ ions to form complexes more reminiscent of the parent mineral, remains a possibility, as does incorporation of Fe$^{\mathrm{II}}$ during synthesis. Thus, inclusion of some of the much more anisotropic Fe$^{\mathrm{II}}$ ions into this new structural family might be expected to increase substantially the overall zero-field splitting of the clusters.

Experimental Section

1: A solution of heiaH$_2$ (0.595 g, 5.0 mmol) and N(CH$_3$)$_4$(OH)·5H$_2$O (2.265 g, 12.5 mmol) in MeOH (10 mL) was added slowly to a stirred solution of Fe(NO$_3$)$_3$·9H$_2$O (1.01 g, 2.5 mmol) in MeOH (10 mL). The reaction mixture was allowed to evaporate to dryness over a period of 2 days, before extracting into diethoxymethane (3.1 mL, 25 mmol) and MeOH (6.9 mL). Solids (N(CH$_3$)$_4$(NO$_3$)) were removed by filtration and acetone diffused slowly into the filtrate to yield crystals suitable for single-crystal X-ray diffraction after 2 weeks. Elemental analysis calcd (%) for Fe$_9$C$_{35.5}$H$_{93}$O$_{44.5}$N$_8$: C 23.09, H 5.08, N 6.07, Fe 27.22; found: C 23.65, H 5.35, N 6.38, Fe 27.48.

2: FeCl$_3$ (0.910 g, 3.09 mmol) was added to stirred pyridine (30 mL), the reaction mixture became dark upon dissolution. After stirring for 2 h the reaction mixture was filtered, the filtrate was collected and methanol diffused in slowly to afford single crystals suitable for X-ray diffraction after two weeks. Elemental analysis calcd (%) for Fe$_{17}$C$_{69.5}$H$_{102}$O$_{35.5}$N$_{13}$Cl$_8$: C 28.71, H 2.62, N 6.70, Fe 35.03; found: C 28.62, H 2.59, N 6.75, Fe 35.84.

Communications

Self-Assembly of Interpenetrating Coordination Nets Formed from Interpenetrating Cationic and Anionic Three-Dimensional Diamondoid Cluster Coordination Polymers**

Kai Liang, Hegen Zheng,* Yinglin Song, Michael F. Lappert, Yizhi Li, Xinquan Xin, Zixiang Huang, Jiutong Chen, and Shaofang Lu

The design and synthesis of metal–organic coordination polymers has become an exciting field in the past decade, and numerous interesting coordination polymers based on metal ions and organic bridging ligands have been synthesized by many research groups.[1] Many of these compounds contain channels or voids that are similar to those in porous materials such as zeolites and clays.[2] Tetrathiometalate clusters $[MS_4]^{2-}$ (M = W, Mo) have long been explored for their diverse coordination modes and potential applications in catalysis, biological processes, and nonlinear optical (NLO) materials.[3] Rather few polymeric heterothiometallic cluster coordination polymers based on the thiometalates have been synthesized.[4] Such coordination polymers have invariably contained polymer aggregates that were: 1) anionic, such as $[NH_4]_n[AgWS_4]_n$,[5] $\{[N(CH_2C_6H_5)(C_2H_5)_3][MoAgS_4]\}_n$,[6] $\{[NEt_4][Mo_2O_2S_6Cu_6I_3(4,4'\text{-bipy})_5]\cdot MeOH\cdot H_2O\}_n$ (4,4'-bipy = 4,4'-bipyridine),[7] or $\{[Et_4N]_2[MoS_4Cu_4(CN)_4]\}_n$,[8] 2) cationic, as in the transition metal coordination polymers, or 3) neutral, as in $[MoS_4Cu_6I_4(py)_4]_n$ (py = pyridine),[9] $\{[MoOS_3(CN)(py)_3]\cdot0.5\,C_6H_6\}_n$,[10] or $[Cu(4,4'\text{-bipy})Cl]_n$.[11] Structures containing interpenetrating nets that have different topologies and/or chemical compositions are known,[1] although no example has previously been reported of a coordination polymer containing both cationic and anionic coordination polymer aggregates.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

We report here such an unprecedented cluster coordination polymer, namely compound **1**, which contains interpenetrating cationic and anionic 3D diamondoid cluster coordination polymers.

$$\{[WS_4Cu_4(4,4'\text{-bipy})_4][WS_4Cu_4I_4(4,4'\text{-bipy})_2]\cdot4\,H_2O\}_n \quad \mathbf{1}$$

Compound **1** was obtained from the reaction between $[NH_4]_2[WS_4]$, CuI, $[nBu_4N]I$, and 4,4'-bipy, in a ratio of 1:2:2:2, in DMF/CH_2Cl_2 solution, followed by filtration and slow diffusion of diethyl ether into the filtrate to give single crystals suitable for an X-ray diffraction study. The crystallographic analysis of compound **1**[12] revealed that the 3D cationic cluster coordination polymer can be considered as comprising square, pentanuclear $[WS_4Cu_4]^{2+}$ building blocks, each linked by four pairs of parallel 4,4'-bipy ligands (Figure 1). The W and the four Cu atoms are coplanar in
Figure 1. The cationic cluster coordination polymer unit $[WS_4Cu_4(4,4'\text{-bipy})_4]^{2+}$.

each $[WS_4Cu_4]^{2+}$ building block, and the $\{WS_4\}^{2-}$ unit has a tetrahedral structure with W2–S2 bond lengths of 2.235(2) Å, and S2–W2–S2 angles ranging from 108.60(11)° to 110.50(12)°. Each of the four Cu atoms is also tetrahedrally coordinated by two N atoms from two 4,4'-bipy ligands and two μ_3-S atoms, with Cu2–N2, Cu3–N3, Cu2–S2, and Cu3–S2 bond lengths of 2.023(7) Å, 2.043(7) Å, 2.272(2) Å, and 2.280 Å, respectively.

The angles N2–Cu2–N2B and N3–Cu3–N3AA are 106.1(4)° and 112.3(4)°, respectively, hence the four 4,4'-bipy molecules are almost tetrahedrally disposed, which results in a diamondoid network with a large channel dimension of 24.482 Å × 21.009 Å (Figure 2a). Each six-membered ring contains six $[WS_4Cu_4]^{2+}$ nodes and six pairs of 4,4'-bipy connecting rods. The separation between each pair of 4,4'-bipy units is nearly 3.7 Å, thus implying weak π–π interactions.

In fact, there is a twofold interpenetrating 3D network in the cationic coordination polymer (Figure 3a and 3b). Similar interpenetrating diamondoid frameworks have also been

Figure 2. a) The diamondoid structure of the cationic cluster coordination polymer {[WS$_4$Cu$_4$(4,4′-bipy)$_4$]$^{2+}$}$_n$. b) The diamondoid structure of the anionic cluster coordination polymer {[WS$_4$Cu$_4$I$_4$(4,4′-bipy)$_2$]$^{2-}$}$_n$. Hydrogen atoms have been omitted for clarity. W violet, S yellow, Cu blue, N green, C black line.

Figure 3. a) View of the cationic cluster coordination polymer. Each node and rod represents a cluster cation [WS$_4$Cu$_4$]$^{2+}$ and a pair of 4,4′-bipy ligands, respectively; b) space-filling picture showing the twofold interpenetrating cationic cluster coordination polymer {[WS$_4$Cu$_4$(4,4′-bipy)$_4$]$^{2+}$}$_n$; c) view of the anionic cluster coordination polymer. Each node and rod represents a cluster anion [WS$_4$Cu$_4$I$_4$]$^{2-}$ and a single 4,4′-bipy ligand, respectively; d) space-filling picture showing the twofold interpenetrating anionic cluster coordination polymer {[WS$_4$Cu$_4$I$_4$(4,4′-bipy)$_2$]$^{2-}$}$_n$.

found in some other coordination polymers containing transition metal ions.[13] The 3D anionic cluster coordination polymer is almost exactly analogous to the cationic cluster coordination polymer, except that the building block is the [WS$_4$Cu$_4$I$_4$]$^{2-}$ ion, which is nearly tetrahedrally coordinated by four N atoms of four 4,4′-bipy molecules (Figure 4). Each Cu atom is tetrahedrally coordinated by two μ$_3$-S atoms, one I atom, and one N atom from one of the 4,4′-bipy ligands, with Cu1−N1 and Cu1−I1 bond lengths of 2.090(7) Å and

2.5516(13) Å, respectively, which leads to another diamondoid network with a larger channel dimension of 24.828 Å × 24.217 Å (Figure 2b). Each six-membered ring contains six [WS$_4$Cu$_4$I$_4$]$^{2-}$ nodes and six 4,4′-bipy connecting rods. The anionic cluster coordination polymer also exists as a twofold interpenetrating framework (Figure 3c and 3d).

It is noteworthy that the two pyridine rings of each 4,4′-bipy ligand are coplanar, except that two C atoms, C$_1$ and C$_2$, are disordered and were refined to an occupancy ratio of 0.5 in the anionic cluster coordination polymer; in the cationic cluster coordination polymer the pyridine rings of each 4,4′-bipy

Figure 4. The anionic cluster coordination polymer unit [WS$_4$Cu$_4$I$_4$(4,4′-bipy)$_2$]$^{2-}$.

ligand are not coplanar, with the pyridine rings twisted by 25.8°, 46.4°, and 63.9°, respectively. The whole molecule has an intricate, fourfold interpenetrating diamondoid structure (Figure 5), containing large 11.124 Å × 11.129 Å channels; all the solvent water molecules are disordered along the *c* axis (Figure 6). The channel volume is about 293 Å^3,[14] and the water molecules interact with the frameworks through hydrogen bonds.

Thermogravimetric analysis (TGA) of compound **1** under a nitrogen flow showed that the frameworks are rigid, with no weight change observed up to 203 °C. The solvent water and some of the organic ligands were lost between 203 °C and 268 °C (residue 68.1 %), then most of the remaining ligands were gradually removed from 268 °C to 337 °C (residue 54.4 %) and from 337 °C to 571 °C (residue 41.4 %). No further weight change was observed above 700 °C. The unit-cell parameters of a single crystal are nearly identical up to 180 °C, which is consistent with the TGA results. However,
Figure 5. Schematic view of the cluster coordination polymer **1**. The cationic and anionic cluster coordination polymers are shown in blue/yellow and red/green, respectively. (The blue/yellow node and rod represent the cluster cation and the double 4,4′-bipy ligand, respectively; the red/green node and rod represent the cluster anion and the single 4,4′-bipy ligand, respectively.)
Figure 6. Packing diagram of compound **1**, viewed along the *c* axis. Hydrogen atoms have been omitted for clarity. Blue/yellow and red/green represent the cationic and anionic cluster coordination polymers, respectively. The red balls are the O atoms of the water molecules.

heating compound **1** to 230°C and then cooling again causes a change in the X-ray powder diffraction (XRPD) pattern compared to that of **1** at room temperature, which indicates that the frameworks are only partially retained.

Two peaks at $\lambda_{max} = 292$ and 411 nm, observed in the UV/Vis spectrum of **1**, showed that the polymer has a relatively low linear absorption in the visible and near-IR region. We therefore performed a *Z*-scan experiment to investigate its nonlinear optical properties.[15] The compound was dissolved in DMSO at a concentration of 5.8×10^{-5} mol dm^{-3}. This solution was then placed in a 2-mm-thick cuvette. The linear transmittance of the sample was 76%. The results of the

open-aperture and the normalized transmittance are shown in Figure 7a.

The open circles are the experimental data, and the solid curves are the fit given by the *Z*-scan theory described in
Figure 7. *Z*-scan data of cluster **1**: a) NLO absorption; b) NLO refraction.

ref. [15]. The open-aperture *Z*-scan curve of the compound has a deep valley, and the transmittance drops to the lower value of 57%. This result suggests that the compound has a strong nonlinear absorption; it may therefore be a promising candidate for use in optical limiting. It should be pointed out that both the excited-state population (and absorption) and the two-photon absorption could be responsible for the measured NLO effect. It is evident that the theoretical curves qualitatively reproduce the general pattern of the observed experimental data. This suggests an effectively third-order behavior for the experimentally detected NLO effects. The *Z*-scan data measured with the aperture are depicted in Figure 7b. The normalized curve has a sharp peak and a valley, which identifies compound **1** as a self-focusing material. A reasonably good fit between the experimental data and the theoretical curves, as described in ref. [15], was obtained. The effective third-order NLO absorptive index β and refractive index n_2 value were 1.6×10^{-10} mW^{-1} and 6.4×10^{-11} esu, respectively; this shows that polymer **1** exhibits optical self-focusing behavior and reverse saturable absorption (RSA) effects.

In summary, a new kind of interpenetrating 3D cluster coordination polymer based on the tetrathiometalates has been obtained. Its NLO properties show that **1** exhibits

 www.angewandte.org

optical self-focusing behavior and reverse saturable absorption effects. Further work is in progress.

Experimental Section

A well-ground mixture of [NH$_4$]$_2$[WS$_4$] (0.5 mmol), CuI (1.0 mmol), [*n*Bu$_4$N]I (1.0 mmol), and 4,4′-bipy (1 mmol) was added to a mixture of DMF and CH$_2$Cl$_2$ (15 mL; v/v 2:1) under a purified nitrogen atmosphere. After stirring for 10 h, the filtrate was layered with diethyl ether. A few red crystals were separated several days later. A red prismatic single crystal (0.02 g, 15%) suitable for X-ray diffraction was obtained when the filtrate was allowed to slowly evaporate in air. Elemental analysis calcd (%) for **1**: C 27.20, H 2.13, N 6.34; found: C 27.84, H 1.89, N 6.71. Modulation of Compactness and Long-Range Interactions of Unfolded Lysozyme by Single Point Mutations**

*Julia Wirmer, Christian Schlörb, Judith Klein-Seetharaman, Ryoma Hirano, Tadashi Ueda, Taiji Imoto, and Harald Schwalbe**

Non-native states of proteins are not only the starting point of protein folding, but they are also implied in misfolding, transport through membranes, protein turnover, and degradation processes. An increasing number of intrinsically unstructured or natively unfolded proteins have been identified, some of which exert their function in this unstructured state.[1] Unlike the native state of a protein, non-native states cannot be described by a single conformation, but rather they exist as an ensemble of rapidly interconverting conformers. The individual members of this ensemble may differ substantially in their structural and dynamical properties, and different parts of the polypeptide chain may change conformation at different rates.[2] Previous studies showed that the conformational ensemble samples the preferred regions of the Ramachandran φ,ψ space. This sampling, however, can be restricted by varying degrees of residual structure: Secondary structure elements in unfolded proteins have been identified in a large number of proteins by comparison of local NMR parameters with values expected in a random coil.[3–9] In contrast, the identification of longer-range interactions is not as straightforward. The conformational averaging in unfolded proteins renders it only possible to detect short- or medium-range NOE (nuclear Overhauser effect) interactions. Long-range interactions can only be identified by using mutations in combination with NMR spectroscopic techniques such as relaxation rates,[10] spin labels, residual dipolar couplings, or diffusion rates.

NMR spectroscopic studies of non-native states of hen lysozyme have revealed the existence of clusters of residual secondary structure.[6,10] The locations of these clusters strongly correlate with clusters of hydrophobic amino acids, a correlation that was also observed for other proteins.[11–13] These hydrophobic clusters in non-native lysozyme are stabilized by long-range interactions.[10] However, the extent to which each of these clusters contributes to the stability of the entire conformational ensemble is an important, yet unanswered question. Herein we study the effects of point mutations in the major hydrophobic clusters on the ensemble of structures that are present in unfolded lysozyme. The results show that nonconservative single point mutations in the hydrophobic clusters dramatically change the overall compactness of non-native lysozyme by the modulation of long-range interactions between hydrophobic clusters.

The distribution of hydrophobic amino acids in the lysozyme sequence is shown in Figure 1a. The hydrophobicity predictions were fitted to six distinct clusters with maximal hydrophobicity around (1) C6, (2) W28, (3) L56, (4) L83, (5) W108, and (6) W123 (C = cysteine, W = tryptophan, and L = leucine) by using Gaussian models. Mapping of the hydrophobic clusters onto the structure of lysozyme[14] showed that the clusters ultimately result in the hydrophobic cores of the α- and β-domains of the protein. The location of the hydrophobic clusters has an impact on the unfolded states: 1) Experimentally determined folding-core residues map to the central parts of clusters 1–4.[15–18] 2) Residual nonrandom secondary structures tend to cluster at similar positions (Figure 2A). 3) The positions of hydrophobic clusters overlap to a remarkable extent with the average restrictions in conformational space in unfolded ensembles of lysozyme as identified by relaxation rate measurements (Figure 3a). In contrast to the excellent correlation between the positions of the experimentally determined clusters of residual structure and those of all of the hydrophobic clusters, the intensities of the clusters do not match well for clusters 1 and 4, for which barely elevated relaxation rates were found. Interestingly, these two clusters are the only two regions of predicted increased hydrophobicity (Figure 1a) that do not contain tryptophan residues.

We investigated the effects of two types of single point mutations on the compactness and interaction of clusters: 1) replacement of tryptophan residues with either tyrosine (Y) or glycine (G) moieties (W62Y/G) and 2) replacement of a central amino acid, with emphasis on tryptophan units, in clusters 1, 3, 5, and 6 with glycine (A9G, W62G, W111G, and W123G (see Figure 1b). The Trp28 mutant protein was too unstable for sufficient amounts of protein to be obtained and was therefore not investigated. Cluster 4 was not studied because the wild-type (WT) protein already displays very little deviation from the random coil in this region. To obtain a model system for the study of non-native states of lysozyme, WT and mutant lysozyme were denatured, the four native

Figure 1. a) Distribution of hydrophobicity in lysozyme: normalized values (0–1) of hydrophobicity according to the scheme of Abraham and Leo;[32] Gaussian least-squares fitting of hydrophobic clusters is shown as a black line, and the clusters are numbered 1–6. b) Positions of Ala9 (A9) and tryptophans (W) in the native state: the crystal structure of lysozyme (deposited in the Protein Data Bank (193L) [14]) shown is colored according to the hydrophobicity values that were obtained from the Gaussian fit (red: nonhydrophobic (0–0.46); blue: hydrophobic (0.52–1); for comparison: glycine = 0.49).

disulfide bonds were reduced and methylated (indicated by S^Me), and the products were studied in water at pH 2, at which hydrogen exchange is slowed down. This variant of lysozyme remained unfolded in the absence of denaturant even at near-native conditions (pH 6, data not shown), but measurements were carried out at pH 2 owing to the slow rates of amide exchange.

NMR H^N, H^α, and C^α chemical shifts were used for secondary-structure prediction.[19,20] In WT-S^Me, all the chemical shift values were close to those of the random coil which indicates that the reduced protein is unstructured. Remaining small perturbations in the chemical shift values of H^N and H^α atoms of WT-S^Me, relative to chemical shifts measured in small unstructured peptides,[21,22] are shown in Figure 2 A, parts a and b, respectively. Deviations were found for Gly22 (H^N), for Val29 and Cys-S^Me 30 (both H^α), around Trp62/Trp63 (R61 (H^α); W62, W63, and C64 (H^N)), and around Trp108/Trp111 (V109, R112 (H^α); W111, N113, and R114 (H^N)); (V = valine, R = arginine). The degree of helicity was estimated by a comparison of the measured C^α chemical shifts[23] with those values expected for the random coil[19] and those derived statistically for α-helices.[24] High induced helicity was found for residues 8–12 and around Trp108/Trp111. A mean degree of helicity of 12.3% was calculated (Figure 2 A, part c). This value is in excellent agreement with a global value of 14.4% derived from circular dichroism (CD) spectroscopy measurements (Figure 2 A, part d).

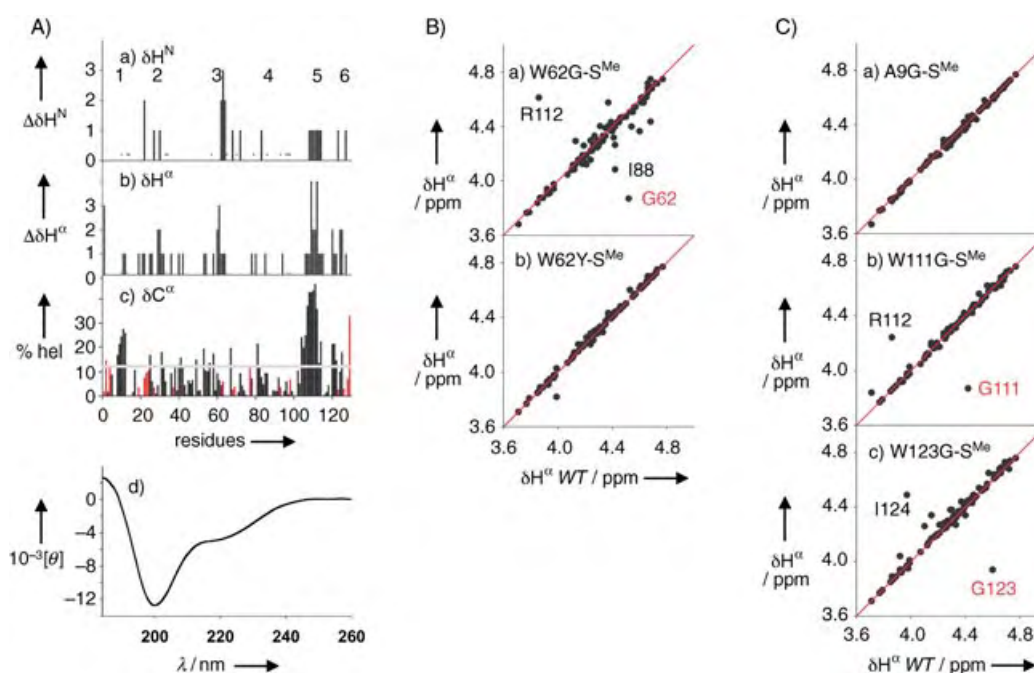
The effect of the replacement of a single amino acid, namely Trp62 in W62G and W62Y in cluster 3, and the mutations A9G, W111G, and W123G, on the H^α chemical shift is shown in Figure 2, B and C, respectively. The data are presented as correlations between the chemical shift values of H^α atoms in the single point mutants with those in WT-S^Me. The H^α atoms of the conservative mutations W62Y and A9G


Figure 2. Residual secondary structure in unfolded lysozyme. A) Normalized values of the differences between the chemical shifts of a) H^N and b) H^α centers in WT-S^Me relative to those in the random coil ($\Delta\delta = \delta$exp$-\delta$rc).[6] Residues for which chemical shifts could not be determined are indicated by an asterisk. c) The percentage of residual helicity (% hel) in WT-S^Me are shown as black (positive) and red (negative) vertical bars as a function of the number of residues. A mean value of the induced positive helicity of 12.3% is indicated by the horizontal line. d) CD spectrum of WT-S^Me ($[\theta]$/deg cm² mol⁻¹); a helicity of 14.4% was estimated by using the approach of Rohl and Baldwin.[36] Correlation between the chemical shift values of Hα in B) W62G-S^Me and W62Y-S^Me, and C) A9G-S^Me, W111G-S^Me, and W123G-S^Me in WT-S^Me with those of the wild-type (WT) protein; strongly deviating residues are indicated (black) as well as the mutated amino acids (red).

Communications

display chemical shift values that are virtually identical to those of the WT. The largest deviations in these correlations were found for W62G, which has longer-range effects in particular on R112 and I88 (I = isoleucine), which are distant from the point of mutation at position W62. W111G and W123G show predominantly local deviations, including the mutation site and immediate neighbors in the sequence. However, overall, the deviations of the chemical shifts of the protons from the mutants relative to those of the WT proteins are small for all mutants, even for the regions around the chosen mutation sites which have correlation coefficients that range between 0.996 (A9G) and 0.849 (W62G). We conclude that local regions of residual secondary structure are not disturbed by the mutations.

Because non-native states of proteins are the "averages" of interconverting fluctuating conformations, a single set of tertiary contacts in the unfolded state cannot be determined. However, averaged restrictions in conformational space were measured by the ^{15}N NMR spectroscopic transverse relaxation rates (R_2) and the diffusion-derived hydrodynamic radius (R_h). R_h is determined by the diffusion of the polypeptide chain and is therefore averaged over the ensemble of conformers. R_2 relaxation rates depend on the anisotropic rotational correlation time (τ_c) and are sensitive to motions of the backbone on the subnanosecond timescale and also to slow conformational exchange on the millisecond timescale.[25–27] Previously, by comparison of R_2 and $R_{1\rho}$, we showed that the effect of slow conformational exchange on R_2 rates in WT-S^{Me} is negligible.[6] In the fully unfolded state of a protein, the internal motions can be described as arising from segmental motions, and the profile of relaxation rates for the random coil R_2^{rc} can be predicted from polymer theory,[28] which is independent of the molecular weight. In compact unfolded states, the interactions of some segments lead to deviations from random-coil behavior. Therefore, the extent of deviation from the random-coil model can be used to delineate long-range, tertiary interactions.[6,10]

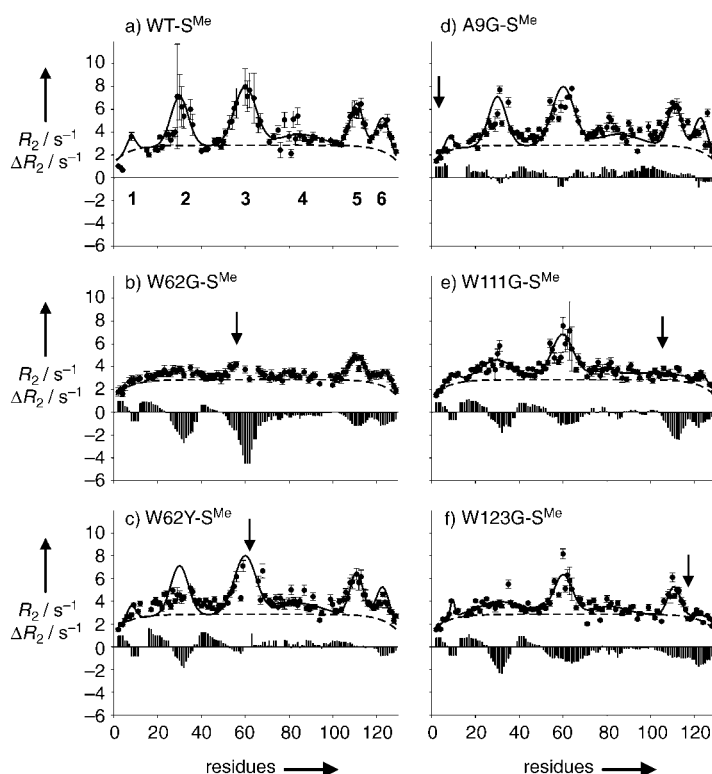
Figure 3 shows the heteronuclear ^{15}N transverse relaxation rates (R_2^{exp}) of WT-S^{Me} and the mutants that were studied. For comparison, the rates that were determined previously[10] for WT-S^{Me} and W62G-S^{Me} are also reproduced. Increased relaxation rates in WT-S^{Me} coincide with the six hydrophobic clusters and the positions of residual secondary structure, which were identified from measurements of the chemical shift values. Replacement of Trp62 by glycine essentially abolishes not only its own cluster 3 (Figure 3b), but also clusters 1–4 and diminishes clusters 5 and 6.[10] Long-range interactions between Trp62 and the other hydrophobic clusters of lysozyme therefore must be present and stabilized by the tryptophan moiety. To test if this property of Trp62 is unique to tryptophan or whether it may be more generally attributable to aromatic amino acids, the effect of replacing Trp62 by tyrosine on the relaxation behavior of unfolded lysozyme was studied (see Figure 3c). The W62Y mutation


Figure 3. Residual tertiary interactions in unfolded lysozyme (hydrophobic clusters are indicated by numbers 1—6). a–f) ^{15}N R_2 relaxation rates in WT-S^{Me} and W62G-S^{Me}, W62Y-S^{Me}, A9G-S^{Me}, W111G-S^{Me}, and W123G-S^{Me}, respectively. The experimental rates are shown as scatter plots, whereas the rates fitted by a segmental motion model and expected for a random coil with R_2^{rc} ($R_{int} = 0.2$ s^{-1} and $\lambda_0 = 7$) are shown as dashed lines; black lines show the Gaussian fits for WT-S^{Me} (a, c, and d), W111G-S^{Me} (e), and W123G-S^{Me} (f). Deviations of R_2 relaxation rates of the mutants from relaxation rates of WT-S^{Me} ($\Delta R_2 = R_2$(mutant-S^{Me}) $-R_2$(WT-S^{Me})) were averaged over 7 residues and are shown as bars.

has a very minor effect on the relaxation properties of WT-S^{Me} relative to W62G-S^{ME}. This result suggests that aromatic residues play an important role in the stabilization of long-range interactions in unfolded states of lysozyme. A9G-S^{Me} displays even more similar properties to WT-S^{Me}, and there is not even an effect on its own cluster, cluster 1. The size and the position of the hydrophobic clusters remain virtually identical which indicates that Ala9 is not important in the stabilization of the hydrophobic core.

In contrast, the replacement of tryptophan residues at positions 111 and 123 led to significant results. Upon replacement of Trp111 (cluster 5) by glycine, the cluster in which the mutation is located, namely cluster 5, disappeared entirely and cluster 6 also decreased significantly in intensity. A loss in the intensity of cluster 2 (surrounding Trp28) was observed as well as a very small decrease in the intensity of cluster 3 (surrounding Trp62 and Trp63). Similarly, when Trp123 at the C terminus (cluster 6) was changed to glycine, the cluster around the mutation site essentially disappeared, and the intensities of clusters 2, 3, and 5 were lessened. The effect of the replacement in W123G is less significant than that of W111G, as seen by the complete loss of cluster 5 in W111G-S^{Me} but not in W123G-S^{Me}. The largest changes in the

distribution of R_2 relative to WT-S^{Me} were observed with W62G-S^{Me}.

The decrease in the R_2 values upon single point mutations indicates that changes in the conformational ensembles of lysozyme occurred. Thus, it is predicted that those point mutations which cause a change in relaxation profiles can also cause a change in the compactness of the average unfolded state. A loss of conformational restriction in one or more of the hydrophobic clusters would increase the overall propensity for extended states in the ensemble. This hypothesis was tested directly by measuring the averaged hydrodynamic radii R_h from NMR diffusion measurements of the different reduced and methylated proteins. WT-S^{Me} and W123G-S^{Me} diffuse quickly, W111G-S^{Me} diffuses at intermediate velocity, and W62G-S^{Me} diffuses the slowest. Figure 4a shows the
Figure 4. Changes in compactness as a result of point mutations. a) Diffusion experiments that were used to determine the hydrodynamic radii (R_h). The intensity of the NMR signal is shown as a function of gradient strength (g) for WT-S^{Me} (black) and W62G-S^{Me} (red). The decay of the signal was fitted to a function of the form $I = Ae^{-Dg^2}$. R_h values were calculated from decay rates (D, see Experimental Section). b) Randomly chosen conformations with the amino acid sequence of lysozyme in relation to their hydrodynamic radius. Conformations with increasing (experimental) R_h values are shown. The radii of different conformations were calculated using the program Hydropro.[40]

diffusion measurements for WT-S^{Me} and W62G-S^{Me}. The R_h values that were calculated from the diffusion rates (see the Experimental Section) are 26.9 ± 0.6, 25.4 ± 1.2, 29.3 ± 1.3, and 32.1 ± 0.6 Å for WT-S^{Me}, W123G-S^{Me}, W111G-S^{Me}, and W62G-S^{Me}, respectively (these values are concentration-independent (40–60 μM)). All R_h values are considerably larger (at least 25%) than the R_h value of folded lysozyme ($R_h = 20.5$ Å)[29] which indicates the extended nature of the reduced and methylated states. However, the overall average shape of the ensemble of conformers markedly varies with the position of the single point mutations in the different hydrophobic clusters. Whereas similar hydrodynamic radii were measured for WT-S^{Me} and W123G-S^{Me}, the hydrodynamic radius of W111G-S^{Me} was larger ($R_h = 29.3 \pm 1.3$ Å)

and that of the W62G-S^{Me} mutant was the largest ($R_h = 32.1 \pm 0.6$ Å; see Figure 4b). Conformations were calculated by unbiased molecular dynamics simulations. As one can see, the R_h value of 32.1 Å for W62G-S^{Me} corresponds to a very extended, almost linear conformation, which is consistent with the essentially random-coil behavior observed for the relaxation rates of this mutant (Figure 3b). The radii observed for the other mutants correspond to rather compact states with a clear presence of tertiary contacts. These states are much closer to the native state with a R_h value of 20.5 Å than the very extended conformation that has a R_h value of 32.1 Å.

The comparison between experimental NMR parameters and those expected for a true random coil show that there are six areas that display strong deviations from random-coil behavior in WT-S^{Me}. The observed hydrodynamic radius of 26.9 ± 0.6 Å indicates that the average conformations in WT-S^{Me} are rather compact (Figure 4b) which supports the presence of extensive tertiary contacts in the unfolded state. These contacts are both nativelike and non-nativelike. Non-native contacts between cluster 3—around Trp 62 and Trp 63, which form part of the β-domain in the native structure (see also Figure 1b)—and the clusters 1, 2, and 4, which form the α-domain, must be present because deviations from random-coil relaxation behavior are decreased in the W62G mutant. Breakage of these long-range interactions results in a dramatic increase by 12% in the measured R_h values from WT-S^{Me} to W62G-S^{Me} which reflects a shift towards very extended conformations (Figure 4b). The presence of native-like contacts is suggested by the effect of the W123G mutation which simultaneously diminishes clusters 6 and 2, indicating nativelike contacts between Trp 123 and sites at or around Trp 28. The importance of native-like contacts is consolidated by the central role of the Trp 111 interactions in WT-S^{Me}. Disruption of the contacts between Trp 111 and the cluster that surrounds Trp 28 by the W111G mutation results in a large increase in R_h of $\approx 9\%$. Tryptophan residues or aromatic residues in general apparently play a special role in the stabilization of contacts in compact states of unfolded lysozyme. A comparison of the effects of replacing Trp 62 with glycine and with tyrosine shows that there are little changes in the relaxation behavior of W62Y-S^{Me} relative to WT-S^{Me}, in contrast to W62G-S^{Me}, which shows the strongest deviations from WT-S^{Me}. Aromatic residues play a significant role in the organization of nearby residues into arrangements that have restricted motions compared to a completely unfolded polypeptide chain.

Point mutations induce a shift in the distribution of conformers from compact to more-extended states to differing degrees depending on the location of the mutation with respect to the hydrophobic clusters present. Such changes are expected to result in differences in the rates at which folding and misfolding events take place. Extended structures will clearly have different propensities, for example, in the formation of disulfide bonds. Similarly, the time that is needed for an extended stretch of amino acids within the protein sequence to rearrange into another extended or into a more-compact state will be affected by the change in compactness induced by the different mutations.

Communications

Experimental Section

Hydrophobicity calculations were performed with the 'protscale' tool from the ExPAsy (Expert Protein Analysis System)[30,31] molecular biology server (http://us.expasy.org/cgi-bin/protscale.pl) by using the Abraham and Leo scale.[32] A window size (i.e., length of the interval used for profile computation) of 7 was used, and the weight at the edge of the window was set to 100%; the degrees of hydrophobicity shown were normalized from 0–1. Centres of elevated regions were identified by the fitting of Gaussian clusters to the data with the program SigmaPlot.

The construction of single point mutants of hen egg-white lysozyme, the expression and purification of ^{15}N-labelled protein in the yeast *Pichia pastoris*,[33,34] and the methylation of reduced lysozyme[35] were performed according to reported methods.

CD spectra were recorded as described,[23] and the mean helix content was calculated by using the approach of Rohl and Baldwin.[36] NMR experiments were recorded at 293 K on a four-channel Bruker DRX600 spectrometer, which was equipped with a cryoprobe, with z-gradients. Samples of the proteins (≈ 60–100 μM) were prepared in water (10% D_2O, pH 2). 3D NOESY–HSQC (heteronuclear single quantum coherence) experiments were recorded and analyzed as previously reported.[6] Perturbations of the chemical shifts of H^N and H^α atoms were derived as previously described.[6] Residual helicity is defined by the percentage of induced helicity (% hel), which is obtained from a comparison of the C^α chemical shifts in WT-S^{Me} (C^α_{exp}) with the C^α chemical shifts in the random coil (C^α_{rc})[19,20,23] and those derived statistically for α-helices (C^α_{hel}),[24] according to Equation (1):

$$\% \text{ hel} = 100 \, \frac{\delta C^\alpha_{exp} - \delta C^\alpha_{rc}}{\delta C^\alpha_{hel} - \delta C^\alpha_{rc}} \qquad (1)$$

Diffusion measurements were performed using 40–60 μM protein in D_2O at pH 2 (corrected for D_2O),[37] with 1,4-dioxane (200–300 μM) as internal standard (hydrodynamic radius: 2.12 Å; it has been shown that dioxane does not interact with proteins[38]). PFG (pulse field gradient)-NMR diffusion measurements were performed as reported.[29,38,39] Hydrodynamic radii (R_h) were calculated from the decay rates derived from NMR spectra by using Equation (2), in which D_{diox} and D_{prot} are the decay rates of dioxane and the protein, respectively.

$$R_h^{prot} = \frac{D_{diox}}{D_{prot}} R_h^{diox} \qquad (2)$$

It was reported that the aggregation of methylated lysozyme (WT-S^{Me}), which is in exchange with the unfolded form, is observed as an increase in the apparent R_h for concentrations of the protein of 0.2–0.25 mM.[29] However, here, at concentrations of the protein of 40–60 μM for each mutant, R_h remained constant, which excludes aggregation processes. Predicted hydrodynamic radii (Figure 4) were calculated from the structures by using the program Hydropro.[40]

Transverse relaxation rates R_2 were measured and analyzed as previously reported.[6] Relaxation rates in an extended polypeptide can be described by a simple model, which is derived from polymer theory[28] and is referred to as the segmental motion model. The segmental model assumes that the influence of the neighboring residues decays exponentially as the distance (in terms of the number of peptide bonds) from a given residue increases.[6] Therefore, R_2 relaxation rates of unfolded proteins can be fitted to Equation (3), in which R_{int} is the intrinsic relaxation rate, which depends also on the temperature and viscosity of the solution, λ_0 is the persistence length of the polypeptide chain (in terms of the numbers of residues), and N is the total chain length of the polypeptide:

$$R_2^{rc}(i) = R_{int} \sum_{j=1}^{N} e^{-\frac{|i-j|}{\lambda_0}} \qquad (3)$$

Experimental R_2 rates of lysozyme show that there are regions of positive deviation from the segmental model that can be fitted by Gaussian distributions. Thus, a model is proposed that includes two components: the segmental motion part [Eq. (3)] and a Gaussian term, as shown in Equation (4).

$$R_2^{exp}(i) = R_{int} \sum_{j=1}^{N} e^{-\frac{|i-j|}{\lambda_0}} + \sum_{cluster} R_{cluster} e^{-\left(\frac{i-x_{cluster}}{2\lambda_{cluster}}\right)^2} \qquad (4)$$

These Gaussian clusters are characterized by the position of the cluster in the protein (residue number) $x_{cluster}$, the width of the cluster $\lambda_{cluster}$, and a distinct relaxation rate for each cluster $R_{cluster}$.

Nanoporous Films

Synthesis of a Large-Scale Highly Ordered Porous Carbon Film by Self-Assembly of Block Copolymers**

*Chengdu Liang, Kunlun Hong, Georges A. Guiochon, Jimmy W. Mays, and Sheng Dai**

Elemental carbon materials exhibit unique electronic, mechanical, and chemical properties that make them attractive, for example, for nanoelectronic devices,[1] strength-enhancing materials,[2] separation media,[3–6] catalyst supports,[7] energy storage/conversion systems,[8] proximal probes,[9] optical components.[10] Well-defined nanoporous carbon materials are essential for a number of these

applications. Ordered porous carbon materials have previously been replicated by using colloidal crystals[10] and presynthesized mesoporous silicas as scaffolds.[7] These methodologies are extremely difficult to adapt to the fabrication of large-scale ordered nanoporous films with controlled pore orientations. Although numerous methods (e.g., chemical vapor deposition,[11] ultrasonic deposition,[3a] silica template synthesis,[3b, 7] hydrothermal decomposition of carbide compounds,[12] and polymer coating and pyrolysis[13]) have been developed for the fabrication of carbon films, no ordered nanoporous carbon films have been obtained with such methods. Accordingly, the large-scale alignment of the carbon nanostructural films is still a big challenge. Herein, we demonstrate a stepwise self-assembly approach to the preparation of large-scale, highly ordered nanoporous carbon films. The carbon precursor molecules are spatially arranged into well-defined nanostructures by the self-assembly of block copolymers (BCPs). A hexagonally packed carbon-channel array whose orientation is normal to the carbon film surface has been successfully synthesized. Large-scale crack-free carbon films of up to 6 cm^2 can be readily fabricated on common substrates such as silica, copper, silicon, and carbon.

The self-assembly of BCPs has proven to be a versatile approach to the selective organization and nanoscale regulation of the concentration distribution of target molecular species for the fabrication of nanoporous materials.[14–16] The mechanism for such organization involves hydrogen-bonding,[17] ion-pairing,[18] and/or dative interactions[19] between supramolecular assemblies of BCPs and target molecular species. The resulting composites can give rise to various nanostructures according to the structural and phase behaviors of the BCPs. The target molecular species are spatially concentrated in selected microdomains and can eventually serve as nanostructured catalysts,[20] spacers,[21] or precursors[22] for the further fabrication of ordered nanostructures. Highly ordered nanoporous materials, such as polymer,[22] silica,[23,24] and organic–inorganic hybrid materials,[25,26] have been created through polymerization in the presence of the self-assembled BCPs.

Although BCPs contain high atomic carbon concentrations, ordered nanoporous carbon films have not been successfully fabricated through the direct pyrolysis of self-assembled BCPs.[27] This inability is attributed to the fact that linearly structured BCP compounds have very poor carbon yields in carbonization reactions. Furthermore, the survival of the nanostructures during high-temperature pyrolysis (> 800 °C) is extremely challenging for the self-assembled BCP structures. This deficiency is associated with the linearly structured BCPs, which melt before carbonization reactions occur. The cross-linking of BCPs can significantly stabilize the self-assembled nanostructures. However, it is still difficult for the limited cross-linkage to preserve the preorganized nanostructures, because of the massive loss of carbon in the form of volatile carbon-containing species during pyrolysis.

Highly cross-linked resorcinol–formaldehyde resin (RFR) is a well-known carbonization source.[6,10] This rigid polymeric carbon precursor can retain the preorganized structures during pyrolysis. However, the low solubility of the highly cross-linked RFR in solvents makes it impossible to directly

Communications

blend RFR with BCPs for the formation of nanostructured RFR. To overcome this limitation, we developed a stepwise assembly approach to fabricate highly ordered nanoporous carbon films. The essence of this methodology is to first preorganize the resorcinol monomers into a well-ordered nanostructured film with the assistance of polystyrene-*block*-poly(4-vinylpyridine) (PS-P4VP) self-assembly and solvent-induced structural annealing, which is followed by the in situ polymerization of the resorcinol monomers with formaldehyde vapor to form ordered nanostructured RFR. Upon carbonization, the nanostructured RFR is transformed into a highly ordered nanoporous carbon film with the concomitant decomposition of the PS-P4VP template to gaseous species. Figure 1 schematically illustrates the procedure for the
Figure 1. Schematic representation of the synthesis protocol used to prepare well-defined carbon nanostructures. Step 1: film casting of PS-P4VP/resorcinol supramolecular assembly. Step 2: completion of microphase separation by solvent annealing at 80°C in DMF/benzene mixed vapor. The resorcinol is organized in the well-defined P4VP domain. Step 3: in situ polymerization of resorcinol and formaldehyde by exposing the film to formaldehyde gas. Highly cross-linked RFR is formed within the P4VP domain. Step 4: pyrolysis of the polymeric film in N_2. A hexagonal carbon-channel array is formed by sacrificing the block copolymer.

fabrication of ordered porous carbon films. The synthesis protocol involves four basic steps: 1) monomer–BCP film casting, 2) structure refining through solvent annealing, 3) polymerization of the carbon precursor, and 4) carbonization.

In step 1, the precursor films can be cast from a solution containing a mixture of PS-P4VP and resorcinol onto silica, silicon, glassy carbon, or copper, which can withstand the high temperature required by the final carbonization step. Both *N,N*′-dimethylformamide (DMF) and cyclohexanol are good solvents for PS-P4VP and can be used to cast the precursor films. The concentration of PS-P4VP is in the range of 0.5–10 wt %. The final film structures are not dependent on the casting method (dip coating or spin coating). The BCP template used in the synthesis has equal lengths of PS and P4VP blocks. The bulk material of this PS-P4VP copolymer has a lamellar structure.[15] The self-assembly of the PS-P4VP/resorcinol mixture is essentially driven by the hydrogen-bonding interaction between resorcinol and the P4VP block.[21,28] This strong hydrogen-bond association between the basic P4VP blocks and the acidic resorcinol monomers enriches the resorcinol molecules selectively in the P4VP

domain. Accordingly, the volume fraction of the P4VP domain is significantly increased relative to that of the PS domain, resulting in a hexagonal structure.[15,21] The PS block in the PS-P4VP/resorcinol complex is the minor component, which forms cylindrical microdomains in the self-assembled film. Figure 2 compares the Fourier-transform infrared
Figure 2. FTIR spectra of PS-P4VP and PS-P4VP/resorcinol mixture in the region from 900 to 1650 cm^{-1}. The characteristic peaks of the pyridine ring in PS-P4PVP at 993, 1415, and 1597 cm^{-1} shift to 1007, 1419, and 1602 cm^{-1}, respectively, as a result of the hydrogen-bonding interaction with resorcinol. T = transmittance.

(FTIR) spectrum of PS-P4VP and that of the PS-P4VP/resorcinol mixture (molar ratio of pyridine groups to resorcinol 1:1). The characteristic stretching modes of the P4VP block at 993, 1415, and 1597 cm^{-1} shift to 1007, 1419, and 1602 cm^{-1}, respectively, for the PS-P4VP/resorcinol mixture. These vibrational frequency shifts are consistent with a hydrogen-bonding interaction between the pyridine groups and the resorcinol molecules.[28]

The second step involves solvent annealing,[21,29] which is the key to the formation of highly ordered and well-oriented nanostructures. Russell and co-workers reported an efficient method based on solvent annealing for refining self-assembled block copolymer nanostructures.[29] The controlled evaporation of the solvent results in highly ordered nanostructures oriented normal to the substrate. The as-cast film is annealed in DMF/benzene vapor at 80°C through a slow evaporation of the solvents over a period of 24 h, to give a final carbon film having a highly ordered hexagonal structure with all pores oriented perpendicular to the substrate. DMF is a highly miscible solvent for the PS and P4VP blocks, and both blocks have quite good mobility when the film is swollen in DMF vapor. As a result of this mobility, the swollen PS and P4VP blocks repel one another and tend to organize into a well-defined structure.[29] However, the repulsion of these two blocks is damped by DMF, which is highly miscible with both blocks. We found that the addition of benzene vapor greatly accelerates the self-assembly process and significantly enhances the order of the film.[29] Benzene is a good solvent only for the PS block, so the absorbed benzene vapor is most likely enriched in the PS block domain. Therefore, the repulsion

between the PS and P4VP domains is enhanced by benzene. A fast microphase separation is thus achieved in the DMF/benzene mixed vapor.

In step 3, the solvent-annealed nanostructured film was exposed to formaldehyde vapor to cross-link the resorcinol molecules into a highly cross-linked phenolic resin located in the P4VP domain. The cross-linking was carried out by vapor/solid reactions with minimum perturbation of the self-assembled nanostructures. The reaction rate can be readily controlled by the vapor pressure of formaldehyde.

The final step involves the decomposition of the BCP template to generate ordered nanopores, and the carbonization of the nanostructured RFR to form the carbon pore walls. This pyrolysis process was studied by using thermogravimetric analysis (TGA) to continuously measure the mass loss upon heating from room temperature to 800°C under argon at 20°C min⁻¹. Figure 3 shows the thermograms (TGs)
Figure 3. TGA and dTG curves for PS-*block*-P4VP (black), PS-*block*-P4VP/resorcinol mixture (molar ratio of pyridine groups to resorcinol 1:1) (green), resorcinol–formaldehyde resin (RFR) (blue), and PS-*block*-P4VP plus RFR (red). The top and right-hand axes are the temperature and wt% for the thermogram (TG). The left-hand and bottom axes show the weight loss rate and time for the derivative thermogram (dTG).

and the derivative thermograms (dTGs) of four samples: PS-P4VP, PS-P4VP/resorcinol mixture, RFR, and PS-P4VP plus RFR. The pure PS-P4VP sample starts to decompose at 328°C and finishes at 430°C with only negligible residue (0.7 wt%). Both the decomposition temperature and the reaction rate of the PS and P4VP blocks are too close to be resolved in the TG and dTG curves. Therefore, the pyrolysis of PS-P4VP exhibits only one peak in the dTG curve of the pure PS-P4VP sample. The TG curve of the PS-P4VP/resorcinol mixture has two weight-loss stages with corresponding dTG peaks at 195 and 392°C. The weight loss for the first stage starts at 120°C, which is only 10°C above the melting point of resorcinol. The first weight-loss stage ends at 284°C with the loss of about 34 wt%. The mixture of PS-P4VP and resorcinol has 33.87 wt% of resorcinol. Accordingly, this weight loss in the TG curve indicates that all the resorcinol molecules evaporated before the temperature

reached 284°C. The second weight-loss stage of the PS-P4VP/resorcinol mixture starts at 328°C and ends at 430°C. This part of the weight loss is attributed to the decomposition of the PS-P4VP copolymer. The TGA curve of the RFR sample exhibits a continuous weight loss from 200 to 750°C. The carbonization yield for pyrolysis of RFR is 57.59 wt%. The TGA curve of the PS-*block*-P4VP and RFR sample, prepared by cross-linking the PS-P4VP/resorcinol mixture using formaldehyde vapor, shows a complex pyrolysis behavior. A significant weight loss was found in the range of 200 to 750°C. The major weight loss occurs from 320 to 430°C, which is attributed to the decomposition of the PS-P4VP copolymer. The two dTG peaks emerge in this zone, which indicates two different types of decomposition behavior. Comparison of these peaks with the dTG peak of the pure PS-P4VP suggests that the RFR affects the pyrolysis of the PS-P4VP. The decomposition of the PS domain is the least affected, as the RFR is localized in the P4VP domain. The P4VP chain is tangled with the RFR; as a result, the decomposition rate of P4VP may be retarded by RFR because of the interaction between RFR and P4VP. Therefore, the P4VP block may decompose after the PS block. The pyrolysis of the PS-P4VP/RFR mixture yields 22.16% carbon at 800°C. After taking into account the weight gain in the polymerization with formaldehyde, the weight percentage of the RFR in the PS-P4VP/RFR mixture rises from 33.87% (resorcinol wt% in PS-P4VP/resorcinol mixture) to 37.34%. If one assumes that RFR in the P4VP domain has the same carbon yields as the pure RFR (57.59%), the PS-P4VP part only accounts for 1.05 wt% carbon in the final product. Clearly, the RFR is the predominant carbon source of the porous carbon film and the BCP is sacrificed as pores.

A crack-free nanoporous carbon film with thickness from several tens of nanometers up to ~1 μm and size up to 6 cm² can be obtained. The nanoporous carbon film strongly adheres to substrates and is homogeneous in thickness. The nanopores are oriented perpendicular to the film surface (Figure 4a,d). An enlarged Z-contrast image of the carbon film is shown in Figure 4b. The Fourier transform of this Z-contrast image of the film shows a pattern of multiple reflections, which confirms that the film has a highly ordered hexagonal-pore array. Based on Figure 4c, the pore diameter is 33.7 ± 2.5 nm and the wall thickness is 9.0 ± 1.1 nm. The volume fraction of the straight channels is about 0.565 (see Supporting Information for details). The pore diameter and thickness can be controlled by the volume fractions of PS in BCP and carbon-forming resin, respectively. The cross section of the film scratched from a film substrate is shown in Figure 4d. All straight channels are across the whole film. The inset in the lower right-hand corner is the Fourier transform of the high-resolution scanning electron microscopy (SEM) image of the film cross section, which reflects parallel periodical channels. No graphitic structure was found in the high-resolution transmission electron microscopy (HRTEM) mode, which suggests that the wall is amorphous carbon. Wide-angle X-ray diffraction (WAXD) shows broad peaks at 23.6, 43.76, and 80.24°, which are characteristic of amorphous carbon. The Raman spectrum shows a broad D band at 1333 cm⁻¹, which overlaps with the G band at 1600 cm⁻¹. Such

a broad D band is reminiscent of the glassy carbon texture. The HRTEM image, WAXD pattern, and Raman spectrum are included in the Supporting Information.

In conclusion, a facile methodology based on stepwise self-assembly has been successfully developed to prepare highly ordered and well-oriented mesoporous carbon films through carbonization of a nanostructured phenolic resin and BCP composite. The BCPs play two important roles in the synthesis: 1) directing the formation of the phenolic resin nanostructure and 2) serving as templates for nanopores. The orientation of the ordered carbon nanopores was successfully aligned normal to the substrates using a solvent annealing process. The unique structural feature of this oriented nanoporous carbon film highlights opportunities in areas such as separation membranes, chemical sensors, and catalysts.

Experimental Section

PS-P4VP (0.1 g)—with number average molecular masses (M_n) of 11 800 g mol^{-1} for PS and 11 500 g mol^{-1} for P4VP, and M_w/M_n of 1.04 for both blocks—and resorcinol (0.0512 g) were dissolved in DMF (2 g). This solution was heated at 100°C for 4 h to ensure the formation of hydrogen bonds. After cooling to room temperature, a drop of solution was cast into a film on a silica plate by spin coating at 1000 rpm for 2 min. The film was dried in a hood, then placed in a preheated chamber at 80°C along with two small vials which contained DMF and benzene. The film was kept in the sealed chamber for 24 h to allow the completion of microphase separation by

a slow evaporation of the solvents. The microphase-separated film was sequentially cured by exposure to formaldehyde gas at 100°C for 4 h. The cured film was finally carbonized in nitrogen using a temperature ramp of 1°C min^{-1} to 800°C.

Coupled Hydrogen-Bonding Networks in Polyhydroxylated Peptides**

*Peter Tremmel and Armin Geyer**

In memory of Murray Goodman

The active sites of proteins contain networks of hydrogen bonds which are functionally coupled to perform the enzyme function.[1] The side chains of short peptides cannot align in comparable microenvironments because they are too flexible to form more than transient hydrogen bonds. Dipeptides which are highly decorated with ring-constrained hydrogen-bond donors and acceptors can be assembled to oligocyclic peptidomimetics which are then confined to only a few modes of flexibility. Two such peptides are presented herein which have stable hydrogen-bonding networks involving several side-chain hydroxy groups and backbone amide groups. The side-chain hydroxy groups are pushed against each other to cooperatively align in a chain of hydrogen bonds bridging two backbone amide groups which are 7 Å apart. The inversion of the chirality of a single amino acid results in a flip of the entire hydrogen-bonding network with an exchange of proton donor and acceptor groups. Both peptides are characterized by crystal structures and by NMR spectroscopy. The conformational homogeneity and the existence of a hydrogen-bonding network in solution is corroborated by the dispersion of NMR spectroscopic data.

The synthesis of the bicyclic dipeptide (Bic) starting from D-glucurono-3,6-lactone was described recently.[2] C-terminal coupling with L-Phe, D-Phe, or Gly yielded three tripeptides which were coupled to hexapeptides and finally cyclized to either **1** or **2**.

In a first approximation, cyclic hexapeptides can be regarded as the antiparallel combination of two β turns (Figure 1a) or two tripeptides (Figure 1b).[3] This differentia-
Figure 1. Schematic representations of two possible conformations of C_2-symmetric cyclic hexapeptides with arrows indicating antiparallel hydrogen bonds of the central mini β sheet. The 7,5-bicyclic dipeptide mimetics can occupy the central $i+1$ and $i+2$ positions of the β turns (a) or occupy the i and $i+1$ positions (b).

tion makes sense when asking for the preferred positions of bicyclic dipeptides in a cyclic hexapeptide. The dipeptide can end up either in the central positions of the β turn as traditionally proposed for so-called β-turn mimics[4] or in the long side of the antiparallel mini β sheet. Crystal structures of the β-turn dipeptide (BTD)[4b] or of analogues[5c] are known but no crystal structures of unprotected oligopeptides containing bicyclic dipeptides are published to date. The concept of β-turn mimics was challenged by detailed experimental analyses[5] and modeling studies[6] and therefore the more general label bicyclic dipeptide mimetics is used herein. Oligomers of Bic assume an extended polyproline-II-helical structure[2c] indicating that Bic will prefer the long side of a cyclic hexapeptide (Figure 1b) irrespective of the chiralities of the other amino acids.

The crystals of cyclopeptides **1** and of **2** show an overall C_2-symmetric rectangular backbone structure with Bic occupying the i to $i+1$ positions of βI and βII turns, respectively (Figure 2).[7] Thus, **1** and **2** fit the general structure of Figure 1b. In peptide **1**, D-Phe is found in the $i+2$ position of βII turn and Gly in the $i+2$ position of a βI turn. Although only one out of 13 stereocenters was changed in peptide **2**, a mirrored backbone structure is observed with L-Phe occupying the $i+2$ position of a βI turn while Gly is found in the $i+2$ position of βII turn. Four side chain hydroxy groups (7-OH and 9-OH of BicA and BicB) are in close contact in each cyclopeptide. They are aligned in a zipperlike fashion forming a chain of hydrogen bonds connecting the two central amide bonds of the β turns. The inversion of the chirality of the Phe
Figure 2. Crystal structures of peptides **1** (left) and **2** (right). Green arrows indicate the chains of intramolecular hydrogen bonds connecting the central amide bonds of the two β turns (red O, blue N, yellow S).[7, 9]

residue is accompanied by an 180° flip of the neighboring amide bond between BicA and L-Phe. As a consequence, the two cyclopeptides exhibit a reversed hydrogen-bonding network with exchanged donor and acceptor groups. Several water molecules and many intermolecular hydrogen bonds are found in both crystals.[7] To separate potential influences of the crystal environment on the peptide conformations, **1** and **2** were investigated in isotropic solution, too.

In both peptides, the two hydrogen bonds spanning the antiparallel mini β sheet (BicA-6NH–BicB-5CO and BicB-6NH–BicA-5CO) are protected from chemical exchange and therefore no cross-peaks between the two NH protons and the water signal are detectable in the expansion from the ROESY spectrum of **1** (Figure 3).[8] All residual protons are accessible to water. The mini β sheet is retained in the organic solvent [D$_6$]DMSO, as shown by the temperature dependence of the ^{1}H NMR spectroscopy chemical shifts ($\Delta\delta/\Delta T$) of the amide protons. They are close to zero for the amide protons involved in hydrogen bonds **1**BicA-6NH ($+0.2$ ppb/K),
Figure 3. ROESY spectrum (watergate, 600 MHz, 300 K, H$_2$O/D$_2$O, 10:1). Expansion of the NH region. All the protons of the hydrogen-bonding network are exchange broadened at room temperature. Both 6NH protons are protected from chemical exchange and therefore no cross-peaks with the solvent signal are observed. D-PheNH and Gly-NH are solvent accessible and show intense cross-signals with water together with chemical exchange broadening.

1BicB-NH (-1.3 ppb/K), **1**Gly-NH (-0.6 ppb/K), **2**BicA-6NH (-1.0 ppb/K), **2**BicB-NH (-0.1 ppb/K), and **2**Phe-NH (-0.5 ppb/K). They are significantly larger for the residual amide protons **1**Phe-NH (-5.7 ppb/K) and **2**Gly-NH (-4.1 ppb/K). Similar to the crystal structures, the exchange of the $i+2$ amino acid D-Phe against L-Phe is accompanied by a 180° flip of the amide bond preceding this amino acid. Rotating-frame NOEs and ^3J coupling constants unequivocally identify the main backbone conformations of **1** and of **2** which match the crystal structures. Even the preferred side-chain rotamers of L-Phe and D-Phe in solution are the same as in the crystals, as determined from the $^3J_{H\alpha,H\beta}$ coupling constants. Hydrophobic stacking between the aromatic side chain and the neighboring thiaproline ring may contribute to stabilize the observed rotamers.

The organic solvent [D$_6$]DMSO slows down chemical exchange and therefore the ^{1}H NMR spectroscopy resonance signals of the hydroxy protons are better resolved than in water. As a consequence, even ^4J couplings become observable for **1**: $^4J_{7\text{-OH},6\text{-CH}} = 1.4$ Hz in BicA and $^4J_{9\text{-OH},9a\text{-CH}} = 1.0$ Hz in BicB. $^4J_{H,H}$ long-range couplings are immediately lost upon deviation from the fixed W-arrangement of the four atoms involved and therefore $^4J_{H,H}$ long-range couplings can be regarded as another indicator of conformational homogeneity. The δ_H chemical shifts, the ^3J coupling constants, the rotating-frame NOEs, the temperature gradients ($\Delta\delta_H/\Delta T$) of the 7-OH, 9-OH, and NH protons distinguish the network of hydrogen bonds of **1** from that of **2**. Differences between crystal structure and solution structure are detected for the 9-OH moiety of BicA in **1** which forms an intermolecular hydrogen bond in the crystal but finds a different proton acceptor in solution. The $^3J_{9\text{-CH},OH}$ coupling constant of 12.4 Hz identifies the inward orientation of BicA 9-OH towards the central carbonyl group of the βII turn. This type of hydrogen bond has been observed in the linear oligomers of Bic.[2c] Two views of **1** from opposite directions showing all relevant hydrogen-bonding contacts are given in Figure 4. Clearly, all four 7-OH and 9-OH hydroxy groups and two amides are linked by hydrogen bonds and polar contacts in solution. The solution structure of **2** resembles its crystal structure with BicB 7-OH group donating a proton to the carbonyl of the βII-turn and BicA 7-OH accepting a proton from the NH of the βI-turn. Conformational averaging can be excluded for both cyclic hexapeptides in water and in [D$_6$]DMSO solution, too. Diastereomers **1** and **2** differ in only a single stereocenter but exhibit remarkably stable and significantly different conformations. The overall C_2 symmetry of the cyclic hexapeptides **1** and **2** is broken by the benzyl side chains of the phenylalanines, a minor disturbance which locks the overall conformations through the alignment of all amide and OH groups except for the 8-OH groups which are directed outwards (Figure 2; the numbering of the OH groups corresponds to the numbering of the carbon atoms to which they are bound, see the formula of Bic).

In conclusion, the crystal structures of bicyclic dipeptide analogues within unprotected oligopeptides are described for the first time. The bicyclic dipeptides can occupy the i to $i+1$ position of either βI or βII turns. The rigidified amino acids derived from sugars are able to form stable hydrogen-bonding
Figure 4. Solution structure of **1** in [D₆]DMSO. Two views from opposite directions perpendicular to the central amide bond of each β turn (cyan C, red O, blue N, yellow S). For clarity only selected atom positions are shown. Red arrows indicate hydrogen bonds and polar contacts. The schematic representation in the middle shows the entire hydrogen bonding network. Each of the two bifurcated hydrogen bonds cannot be distinguished from fast averaging between one hydrogen bond together with a polar contact to the second proton acceptor. The model (HyperChem 7.0) is based on NOEs and ³J coupling restraints. The geometry of the two Bic-6NH–Bic-5CO hydrogen bonds was taken from the crystal structure.

Asymmetric Double Proton Transfer of Excited 1:1 7-Azaindole/Alcohol Complexes with Anomalously Large and Temperature-Independent Kinetic Isotope Effects**

*Oh-Hoon Kwon, Young-Shin Lee, Han Jung Park, Yongho Kim, and Du-Jeon Jang**

Proton transfer has been attracting considerable attention because it plays a key role in a wide variety of biological and chemical processes.[1–4] Since the discovery of the double-helix structure of DNA by Watson and Crick in 1953, it has been suggested that the tautomerization of DNA base pairs causes inappropriate pairing of bases to result in point mutations. Photo-induced proton transfers are often considered to be useful for understanding the causes of mutagenesis in DNA replication. Thus, proton transfers in the dimers of 7-azaindole (7AI), structurally similar to H-bonded DNA base pairs, have been studied extensively.[5] 7AI is a chromophoric moiety of 7-azatryptophan, a novel in situ optical probe for the structures and dynamics of proteins.[6] Metal–7AI complexes are reported to have potential applications in electroluminescent devices.[7] A number of researchers have shed light on the excited-state double proton transfer (ESDPT) of 7AI, catalyzed by the H-bonded counterpart of a protic solvent molecule or a 7AI molecule in a dimer.[4–6,8–13]

The mechanism of solvent involvement in the excited-state tautomerization of 7AI in water and alcohols has attracted considerable attention.[4,6,9–12] In particular, the two-step model described in Scheme 1 has been discussed widely.[9–11] The first step is solvent reorganization (k_r) about the normal (**N**) 7AI molecule to form a cyclic H-bonded 1:1 7AI/solvent complex (**Nb**), and the second step is intrinsic

proton transfer (k_{pt}) relayed by the complexed protic solvent molecule to give the tautomer (**T**). Intrinsic proton transfer is often presumed to be very fast and governed by tunneling.[9c,10] In one limit, solvent reorganization is the rate-limiting step such that the observed rate constant becomes k_r. In the opposite limit when equilibrium (k_r/k_{-r}) between solvent reorganization and solvent randomization (k_{-r}) is rapid relative to k_{pt}, the observed rate constant is independent of solvent dynamics and is expressed as ($k_r/k_{-r})k_{pt}$.[10] In water and alcohols 7AI has been proposed to undergo ESDPT following the latter scenario.[9–11] Although 7AI/water complexes formed in aprotic solvents have been suggested to undergo ESDPT as well,[13a] the intrinsic proton-transfer dynamics of **Nb** has been rarely studied experimentally and is not well understood.[12]

Since the unusual catalytic activity of 2-pyridinone in epimerization reactions was found in 1952 by Swain and Brown,[14] concerted and stepwise motions of protons have been long-standing subjects. Schowen[4] reviewed this issue to assert that double proton transfer obeys Jencks's principle: if an intermediate along a stepwise route has a very high-energy structure, a transition state with a lower energy can exist for a concerted reaction to occur. The tautomerization of photo-excited 7AI dimers is reported to take place in a stepwise manner in which the zwitterionic intermediate is stabilized by charge delocalization in aromatic rings.[5b,c] On the other hand, the ESDPT of 7AI in neat water and alcohols was proposed to proceed in a concerted manner.[16] However, because the ESDPT rates of 7AI in neat protic solvents were revealed later to rely on thermodynamic solvation properties,[9–11] the harmony and the dissonance of proton motions in **Nb** deserve revisiting. In this paper, we present the dynamics and the nature of ESDPT initiated by the direct excitation of cyclically H-bonded 1:1 7AI/alcohol complexes at the ground state.

Figure 1 shows that the lowest absorption band of 7AI in *n*-heptane shifts to the red and grows at 310 nm with an increase in the concentration of methanol. The spectral changes imply that 7AI molecules associate with methanol molecules by H-bonding to produce complexes in the nonpolar solvent.[13] The linear Benesi–Hildebrandt plot of the

Scheme 1. The widely discussed ESDPT mechanism of 7AI in alcohols (ROH) and water. In this study **Nb** is directly photo-generated from the ground state.

Figure 1. Absorption and emission ($\lambda_{exc} = 288$ nm) spectra of 7AI (1.6×10^{-5} M) in *n*-heptane having methanol concentrations of 0 (black), 8.2 (red), 33 (green), and 260 mM (blue). Inset: the Benesi–Hildebrandt plot ($\lambda_{abs} = 310$ nm) yields 50 M^{-1} for the association constant of 7AI with methanol to form **Nb** at 19 °C.

inset in Figure 1 indicates that 7AI and methanol molecules form 1:1 complexes in *n*-heptane with an association constant (K_a) of 50 M^{-1}.[5a] Compared with the K_a values of 7AI dimers ($2.2 \times 10^3 M^{-1}$) and 1:1 7AI/acetic acid complexes ($1.8 \times 10^4 M^{-1}$) in nonpolar media,[13b] the K_a of 7AI/methanol complexes is quite small, implying that the hydrogen bonds of the complexes at the ground state are not strong owing to the relatively weaker H-bonding ability of methanol. The structures of ground-state H-bonded complexes with single methanol molecules in nonpolar solvents have been simulated to predict that **Nb** is a cyclic 1:1 complex having reasonably loose hydrogen bonds, especially between the pyridinic nitrogen of 7AI and the protic hydrogen of methanol (N···H−O).[9c,11]

Only the UV emission at 315 nm from **N** monomers appears in the absence of methanol. However, with methanol addition, the UV fluorescence shifts to 350 nm and decreases with the concomitantly growing fluorescence at 500 nm from **T**.[5a,13] Thus, we attribute the UV emission at 350 nm to H-bonded 1:1 complexes. The excitation spectrum of 7AI in *n*-heptane with 260-mM methanol, monitored at 500 nm, is spectrally identical with its lowest absorption band, indicating that both fluorescence bands at 350 and 500 nm originate from the same ground-state species. Therefore, we can infer that excited-state **T** molecules are generated by means of ESDPT from the 1:1 complexes of **Nb**.

The fluorescence at 350 nm of 7AI in *n*-heptane with 67-mM methanol[17] shows a biexponential decay profile composed of 88 (76%) and 450 ps (24%), while the fluorescence at 550 nm rises within 88 ps and decays in 1560 ps (Figure 2).
Figure 2. Fluorescence kinetic profiles of 7AI (1.6×10^{-5} M) in *n*-heptane with CH_3O^1H (red circles) and CH_3O^2H (blue squares) of 67 mM. Samples were excited at 288 nm and kinetic profiles were measured with instrumental response functions (IRF) of 25 ps at 550 nm. The lines fitting the circles and the squares were simulated with the rise time of 88 ps followed by the decay time of 1560 ps and the rise time of 1280 ps followed by the decay time of 1900 ps, respectively.

The rise time is identical with the fast-decay time at 350 nm, indicating that k_{pt} is $(88\,ps)^{-1}$.[18] Quite intriguing is that the k_{pt} of 1:1 complexes isolated in the nonpolar solvent is not as large as the expected values of $\geq (5\,ps)^{-1}$.[9c,10] The slow-decay time at 350 nm is assigned to the fluorescence lifetime of noncomplexed 7AI.[17]

The ESDPT process of **Nb** occurs by the concerted relay of the two hydrogens through a single transition state or by the stepwise transfer of the two protons by forming a charged

cationic or anionic intermediate. Proton-inventory experiments for the rates of ESDPT by varying the deuteration degree of protic hydrogen atoms in 1:1 7AI/alcohol complexes can give a clue to this issue.[16] We consider that four possibly different cyclic complexes of $^1H\cdots N_7N_1-^1H$, $^1H\cdots N_7N_1-^2H$, $^2H\cdots N_7N_1-^1H$, and $^2H\cdots N_7N_1-^2H$ in isotopically mixed systems have the intrinsic rate constants of $k_{pt}(^1H^1H)$, $k_{pt}(^1H^2H)$, $k_{pt}(^2H^1H)$, and $k_{pt}(^2H^2H)$, respectively. If $X_D = $ [protic ^2H]/([protic ^1H] + [protic ^2H]), then we can deduce Equations (1) and (2).

$$d[^1H\cdots N_7]/dt = -\{(1-X_D)k_{pt}(^1H^1H) + X_D k_{pt}(^1H^2H)\}[^1H\cdots N_7] \tag{1}$$

$$d[^2H\cdots N_7]/dt = -\{(1-X_D)k_{pt}(^2H^1H) + X_D k_{pt}(^2H^2H)\}[^2H\cdots N_7] \tag{2}$$

Because the isotope exchange of hydrogen is much slower than ESDPT, we expect that the fluorescence of **T** changes with time following Equation (3).

$$\mathbf{T}(t) = \{1-A_1 \exp(-k_f t)-A_2 \exp(-k_s t)\}\exp(-t/\tau_d) \tag{3}$$

While the composition of protic-hydrogen isotopes gives the ratio of A_1/A_2, the fitted parameters of k_f and k_s consist of rate constants as described by Equations (4) and (5), respectively.

$$k_f = k_{pt}(^1H^1H) + \{k_{pt}(^1H^2H)-k_{pt}(^1H^1H)\}X_D \tag{4}$$

$$k_s = k_{pt}(^2H^1H) + \{k_{pt}(^2H^2H)-k_{pt}(^2H^1H)\}X_D \tag{5}$$

Finally, $k_{pt}(^1H^1H)$, $k_{pt}(^1H^2H)$, $k_{pt}(^2H^1H)$, and $k_{pt}(^2H^2H)$ can be extracted from the plots of k_f and k_s with variation of X_D to be $(93\,ps)^{-1}$, $(196\,ps)^{-1}$, $(700\,ps)^{-1}$, and $(1200\,ps)^{-1}$, respectively (Figure 3). To assert the concerted mechanism of ESDPT, it is necessary to show that $k_{pt}(^1H^2H) = k_{pt}(^2H^1H)$ and that $\{k_{pt}(^1H^2H)\}^2 = k_{pt}(^1H^1H)\,k_{pt}(^2H^2H)$.[4,16] However, our data suggest that two hydrogens move in succession. We also infer that one of the two steps, presumably the first step, is rate-limiting, as suggested from the kinetically insignificant formation of cationic or anionic intermediate species (vide infra).

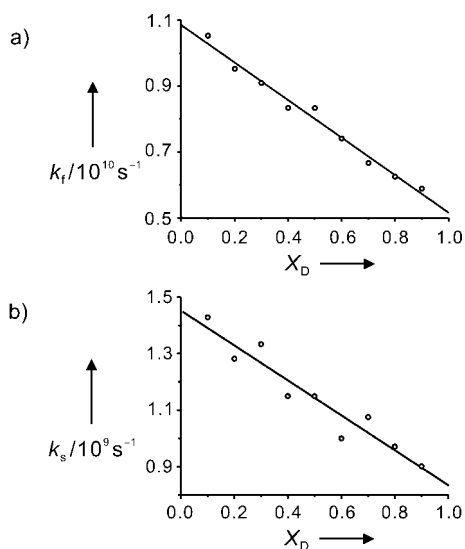
In a nonpolar medium 1:1 7AI/methanol complexes are theoretically shown to possess weakly H-bonded structures, the substantial fraction of which have the H-bond length of N···H−O longer than the nominal H-bond length of 2.5 Å.[9c,11] However, 1:1 7AI/acetic acid complexes undergo very facile ESDPT through short and strong hydrogen bonds.[13c] Thus, we have also obtained k_{pt} and kinetic isotope effect (KIE) values with diverse alcohols having different values of Kamlet–Taft acidity (α) and basicity (β).[19,20] The magnitudes of α and β provide explicit measures for the respective donating and the accepting abilities of the hydrogen bonds. It is evident from Table 1 that k_{pt} tends to decrease, whereas KIE tends to increase with an increase in α. Even for the complexes with alcohols having $\beta = 0$, ESDPT is very facile and the rate increases profoundly with an increase in α. Thus, the acidity of an alcohol is inferred to control the energetics of


Figure 3. Plots of a) k_f and b) k_s with variation of X_D for 7AI $(1.6 \times 10^{-5}$ M) in *n*-heptane with 67 mM of methanol consisting of CH_3O^1H and CH_3O^2H, where k_f and k_s are the fast and the slow components of k_{pt}, respectively, and X_D is [protic ^2H]/([protic ^1H] + [protic ^2H]). The obtained values of $k_{pt}(^1H^1H)$, $k_{pt}(^1H^2H)$, $k_{pt}(^2H^1H)$, and $k_{pt}(^2H^2H)$ are $(93 \text{ ps})^{-1}$, $(196 \text{ ps})^{-1}$, $(700 \text{ ps})^{-1}$, and $(1200 \text{ ps})^{-1}$, respectively.

Table 1: Alcohol-dependent variation of k_{pt} and KIE.[a]

Alcohol	α	β	k_{pt} [ps^{-1}]	KIE
1,1,1,2,2,2-hexafluoroisopropyl alcohol	1.96	0	$\geq 6^{-1}$	[b]
2,2,2-trifluoroethanol	1.51	0	62^{-1}	5.8
methanol	0.93	0.62	88^{-1}	14.5
ethanol	0.83	0.77	95^{-1}	15.3
2-propanol	0.76	0.95	108^{-1}	17.6
tert-butanol	0.68	1.01	114^{-1}	20.2

[a] Alcohol concentrations and experimental conditions are described in Figure 2, and the values of α and β are taken from ref. [19]. The α and β values measured from bulk alcohols are given here because those from monomeric alcohols, showing similar trends, are not available for all the alcohols employed.[20] The average deviations of k_{pt} and KIE are $\pm 5\%$ and $\pm 10\%$, respectively. [b] Not measurable due to our limited IRF.

ESDPT. The less acidic alcohol makes ESDPT less exoergic, that is, energetically more symmetric, reducing the overall rate but enhancing the relative contribution of tunneling in the reaction. This suggests that the H-bond donating ability of alcohol in the coordinate of N···H–O plays the key role for the dynamics of ESDPT. Keeping in mind that the decay time of **Nb** and the rise time of **T** coincide and that k_{pt} is dependent on the acidity of alcohol, we propose that the tautomerization of 7AI is initially triggered by the transfer of a proton from the alcohol molecule to the pyridinic nitrogen (N7) of 7AI, forming a cationic 7AI intermediate species, and completed by rapid proton transfer from the pyrrolic nitrogen (N1) of the intermediate to the transient alkoxide moiety. The intermediate complexes are unstable enough to be kinetically insignificant because both the alkoxide moiety and the 7AI cation are energetically unfavorable. Note that our results are consistent with the suggestion that cyclic H-bonded 1:2 7-

hydroxyquinoline/alcohol complexes undergo excited-state tautomerization in a stepwise manner.[21] Thus, we infer that the observed kinetic results of ESDPT originate mainly from single-proton transfer in the O–H···N7 of **Nb**.

The kinetic isotope effect (KIE) of k_{pt}, $k_{pt}(^1H^1H)/k_{pt}(^2H^2H)$, for a 1:1 7AI/methanol complex is observed to be as great as 14.5 at 19°C (Figure 2). The large KIE and the small k_{pt} of ESDPT imply the existence of an appreciably high barrier and the importance of tunneling through hydrogen bonds. The Arrhenius plots of k_{pt} in Figure 4 clearly show that
Figure 4. Arrhenius plots for the k_{pt} of 7AI $(1.6 \times 10^{-5}$ M) in *n*-heptane having CH_3O^1H (circles) and CH_3O^2H (squares) of 67 mM.

not only k_{pt} but also KIE is independent of temperature within our experimental errors. This suggests that tunneling is operative certainly in the ESDPT of 7AI.[22,23] These types of temperature-independent Arrhenius plots have been reported in the enzymatic proton transfer of lipoxygenase.[24] Temperature-independent KIEs have also been observed in the proton transfers of thermophilic alcohol dehydrogenase[25] and solid-state porphyrin at low temperature.[26] Temperature-independent and large KIEs in enzymes have been explained with a model employing vibrationally enhanced proton tunneling[27] originally suggested by Dogonadze et al.[28,29] When the tunneling contribution is large, the ratio of the Arrhenius preexponential factors, $A(^1H)/A(^2H)$, is much less than unity in general. However, if tunneling becomes large enough to be equally effective for both ^1H and ^2H, then the ratio becomes much greater than unity. We have found $A(^1H)/A(^2H)$ to be 37 from Figure 4, which suggests that the ESDPT of 7AI/methanol complexes takes place with extensive tunneling contribution (vide infra).

The intrinsic double proton transfer, which is governed mostly by tunneling, requires optimized angles and proper H-bond lengths in addition to a cyclic H-bonded structure. The formation of such a precursor configuration for tunneling from the 1:1 7AI/alcohol complex of **Nb** is not sensitive to isotope effects and consists mostly of heavy-atom motions with a little reorganization energy. The precursor-configuration optimization and the intrinsic tunneling are in two orthogonal reaction coordinates of the potential hypersurface, and solvent fluctuations play a crucial role in the formation of such a pretunneling configuration. In the regime that only the motions of hydrogen including tunneling limit the rate, KIE is predicted to be neither dependent on solvent viscosity nor equal to unity. Alternatively, when heavy-atom reorganization assists quantum tunneling, KIE depends on

viscosity. The heavy-atom reorganization that is required to reach the optimal pretunneling configuration becomes slow as viscosity increases. Thus, the tunneling contribution is reduced and KIE tends to be small with increased viscosity.[30] Table 2 shows that both k_{pt} and KIE tend to decrease as

Table 2: Viscosity-dependent variation of k_{pt} and KIE.[a]

Solvent	Viscosity [cP]	k_{pt} [ps^{-1}]	KIE
n-heptane	0.41	88^{-1}	14.5
n-decane	0.92	93^{-1}	13.7
n-dodecane	1.45	97^{-1}	12.5

[a] Methanol concentrations and experimental conditions are described in Figure 2, and viscosity values measured at 20°C are taken from ref. [31].

solvent viscosity increases. These trends suggest that the rate of the overall proton-transfer reaction is affected by the configuration-optimization rate of **Nb** more at higher viscosity. If the motions of hydrogen limit the rate, KIE increases in general as k_{pt} becomes smaller. However, our results are opposite to this, supporting the idea that solvent fluctuations assist tunneling in the ESDPT of **Nb**.

Tunneling in our systems is conceptually identical to the vibrationally assisted tunneling suggested in enzymatic reactions.[25,27–29] The solvent fluctuations replace the low-frequency protein motions. Furthermore, the picture of the proton transfer in **Nb** is in line with that of 7AI dimers in which the heavy-atom motions of N⋯N coupled to N−H vibrations are crucial for tunneling.[5b,c] Also in accord with our picture is the acid–base reactions of 1-naphthol/ammonia clusters, which are strongly correlated to acid–base vibrational couplings assisted by solvent fluctuations.[32] It should be pointed out that proton transfer in the tautomerization of a 1:1 7AI/water complex has not been reported in the gas phase although it is observed in condensed phases.[13a,33,34] This discrepancy hints at the role of solvent fluctuations on the tautomerization of a 7AI monomer assisted by a protic guest molecule.

The ESDPT of a 1:1 7AI/alcohol complex in nonpolar *n*-alkanes occurs consecutively on a time scale of 100 ps with unusually large, temperature-independent, and viscosity-dependent KIEs near room temperature. The ESDPT is initially triggered by the proton transfer of the alcohol molecule to the pyridinic nitrogen of 7AI, forming a cationic 7AI intermediate species, and completed by rapid proton transfer from the pyrrolic nitrogen of the intermediate to the transient alkoxide moiety (Scheme 2). The H-bond between the pyridinic nitrogen atom of a 7AI molecule and the protic hydrogen atom of an alcohol molecule is suggested to play the
Scheme 2. ESDPT mechanism of a 7AI molecule cyclically H-bonded to an alcohol molecule.

central role for ESDPT. The intrinsic proton transfer of the complex is governed by single-proton tunneling from the alcohol molecule to the pyridinic nitrogen atom, although heavy-atom motions assist the complex to reach the optimized precursor configuration. The detailed dynamics of this process requires multidimensional reaction coordinates to be described properly and thus has great theoretical challenge.

Experimental Section

7-Azaindole ($\geq 99\%$) from Sigma-Aldrich, *n*-alkane (anhydrous), and alcohols were used as purchased. The protic hydrogen atoms of both 7AI and ROH of **Nb** were exchanged with ^{2}H atoms by dissolving 7AI in nonpolar solvents containing RO^{2}H (isotopic purity $\geq 99.5\%$) for the measurements of k_{pt} in proton-inventory experiments. Absorption and emission spectra were obtained by using a UV/Vis spectrometer (Scinco, S-3100) and a fluorimeter consisting of a 75-W Xe lamp (Acton Research, XS432) and two monochromators (Acton Research, Spectrapro), respectively. Fluorescence kinetic profiles, excited with Raman-shifted 288-nm pulses of a mode-locked Nd:YAG laser (Quantel, YG701), were detected using a 10-ps streak camera (Hamamatsu, C2830). Emission wavelengths were selected by combining band-pass filters and cut-off filters. Fluorescence kinetic constants were extracted by fitting profiles to computer-simulated exponential curves convoluted with IRF (fwhm: 25 ps). Sample temperature was controlled using a refrigerated bath circulator (Jeio Tech, RC-10V). Unless specified otherwise, all the measurements were carried out at a temperature of 19°C.

[17] Of the 7AI molecules 93% and 77% are expected to form 1:1 complexes with methanol at methanol concentrations of 260 and 67 mm, respectively. To avoid the possible formation of poly-solvated complexes, we have measured fluorescence kinetics at a concentration of 67 mm.[13a] The lifetime (450 ps) of noncomplexed 7AI in our system differs from reported values (~1.7 ns) of 7AI monomers in alcohol-free nonpolar solvents.[9a] However, the Benesi–Hildebrandt plot of **T** fluorescence shows good linearity, yielding $K_a = 45\,\text{M}^{-1}$. This eliminates the possibility of collision-induced ESDPT processes.

[18] The overall proton-transfer time of 7AI in neat methanol is obtained to be 130 ps, which is very close to the reported value of 124 ps.[9b]

Communications

High-Resolution Soft Lithography: Enabling Materials for Nanotechnologies**

Jason P. Rolland, Erik C. Hagberg, Ginger M. Denison, Kenneth R. Carter, and Joseph M. De Simone*

The availability of commercially viable nanofabrication processes is key to realizing the potential of nanotechnologies, especially in the fields of photonics, electronics, and proteomics. The imprint lithographic (IL) technique is a case in point, an alternative to photolithography for manufacturing integrated circuits, nanofluidic and other devices with sub-100-nm features. However, it is becoming increasingly clear that new materials are needed to advance IL methods to their putative limits.[1–5] We recently reported the fabrication of organic-solvent resistant, microfluidic devices with features on the order of hundreds of microns made from photocurable perfluoropolyethers (PFPEs).[6] PFPE-based materials are liquids at room temperature and can be photochemically cross-linked to yield highly fluorinated, solvent resistant, chemically robust, durable, elastomers with a modulus of 4.0 MPa. Herein we report the successful use of PFPE-based materials in high-resolution imprint lithography.

Imprint lithography can be roughly broken into two areas: 1) so-called soft lithographic techniques,[1] such as solvent-assisted micro-molding (SAMIM), micro-molding in capillaries (MIMIC), and microcontact printing (MCP), and 2) rigid imprint techniques, such as nanocontact molding (NCM),[7] "step and flash" imprint lithography (S-FIL),[5] and nano-imprint lithography (NIL).[8] Polydimethylsiloxane (PDMS)

based networks have served as the material of choice for much of the work in soft lithography.[9,10] The use of soft, elastomeric materials, such as PDMS, offers numerous attractive properties in several lithographic techniques. PDMS is highly UV-transparent and has a very low Young's modulus which gives it the flexibility required for conformal contact, even over surface irregularities, without the risk of cracking.[11] Furthermore, flexibility in molds facilitates release from masters and replicates without cracking and allows the mold to endure multiple imprinting steps without damaging fragile features. While PDMS offers some advantages, there are a number of properties inherent to PDMS which severely limit its capabilities in soft lithography. First, PDMS-based elastomers swell significantly when exposed to most oil-soluble organic compounds.[12] With the exception of MCP,[1] resistance to swelling is critically important in nearly all soft lithographic techniques where a mold is brought into contact with a small amount of curable organic monomer or resin. Second, the surface energy of PDMS ($\approx$ 22–25 mN m^{-1}) is not low enough for procedures which require high fidelity. Thus, the patterned surface of PDMS-based molds is often fluorinated using a plasma treatment followed by vapor deposition of a fluoroalkyl trichlorosilane.[1] Third, the most commonly used commercially available form of the material (Dow Corning's Sylgard 184) has a modulus that is too low ($\approx$ 1.5 MPa) for many applications which results in collapse of features. Although elegant solutions to address this last problem have been developed,[13,14] the materials chosen still exhibit poor solvent resistance and require fluorination steps to allow for mold release.

Rigid materials, such as quartz glass and silicon, have also been utilized in imprint lithography.[1,3,5,7,8,15–23] Such materials are superior to PDMS in modulus and swelling resistance but lack flexibility and therefore conformal contact with the substrate. Another major drawback of such materials is the direct use of a valuable and difficult to fabricate hard mold which is typically made by using conventional photolithography or e-beam lithography.[7] Carter and co-workers[20] and Resnick et al.[21] have eliminated the requirement to repeatedly use expensive quartz glass or silicon molds in NCM processes by utilizing an acrylate-based mold generated from casting a photopolymerizable monomer mixture against a silicon master.[7] Despite such advances, there are other

serious disadvantages of rigid materials used as molds which include the necessity to use fluorination steps, or thermoformed rigid fluoropolymers themselves[24] to lower the surface energy of the mold[3] and the inherent problem of releasing a rigid mold from a rigid substrate without breaking or damaging it.[3, 10]

The photochemically curable fluoropolymer that we utilize herein is a α-,ω-methacryloxy functionalized PFPE (PFPE-DMA) (Figure 1).[6] We have previously reported the synthesis of novel functionalized PFPEs.[24] However, herein we treated a commercially available hydroxy-terminated PFPE (Solvay Solexis, M_n = 3800 g mol^{-1}) with isocyanato ethyl methacrylate (Aldrich) to yield a methacryloxy-functionalized polymer which is a pourable liquid of low viscosity (0.36 Pa s) at room temperature. A photoinitiator, 1-hydroxy-cyclohexyl phenyl ketone (1 wt%, Aldrich), was dissolved into the PFPE-DMA to make a photocurable liquid resin. A thermally curable polydimethylsiloxane-based material, Sylgard 184, (Dow Corning) was used for comparative controls.

Swelling is a commonplace issue with PDMS based molds since most organic liquids will swell PDMS, and it is organic liquids that are the materials most desirable to mold. To demonstrate the utility of a fluoroelastomer-based material in imprint lithography, we first generated replica molds made from both PDMS as well as from PFPE-DMA and used these to micromold an organic photopolymer resin, trimethylopropane triacrylate (TMPTA).[26] A patterned silicon-wafer master was used which had features with a width of 2 µm, a depth of 5 µm, and a spacing of 2 µm (Figure 2 A). The fluoroelastomer-based mold was made by pouring an approximately 1 mm thick liquid film of PFPE-DMA, which contained photoinitiator, onto the clean, patterned silicon wafer master. The material was then subjected to UV light (λ = 365 nm, 35 mW cm^{-2}) for 1 min under a nitrogen purge. After curing, the approximately 1 mm thick mold was easily peeled from the master without employing a surface fluorination step. In an analogous fashion, PDMS molds were generated by first mixing the Sylgard 184 precursors (10:1 base:curing agent) and degassing under vacuum. An approximately 1 mm thick layer of the PDMS-based material was then poured onto the same clean, patterned silicon wafer master and was placed in a vacuum oven at 80°C for about 15 h. For the PDMS molds, a vapor-deposition pretreatment
Figure 1. A) Formula of the UV curable PFPE liquid precursor used to generate high resolution stamps. B) Schematic representation of the imprint lithography process. First, a small drop of UV-curable liquid is placed on a silicon wafer. A patterned mold is then brought into contact with the drop and pressure is applied during UV exposure. The mold is then peeled from the wafer leaving the cured resin in the desired pattern.
Figure 2. Images of a silicon master with 2-μm features (A), PFPE and PDMS molds made from this master (B, E), and replicate molds of TMPTA using the corresponding stamps (C, D, F, G). While both elastomers produced molds of high quality, the TMPTA replicate made with the PDMS mold contains residual PDMS that was ripped from the mold presumably because of adhesion (F, G). In contrast, the low surface-energy PFPE mold was easily released from the TMPTA replicate (D). The sub-micron striated features on the replicate in (D) are present on the silicon master and are a result of multiple etching steps used during its fabrication.

to the patterned silicon wafer using trichloro(1H,1H,2H,2H-perfluorooctyl) silane was applied to allow release of the mold. Replica molds of high quality with good feature fidelity were generated from both the PFPE-based elastomer (Figure 2B) as well as the PDMS-based elastomer (Figure 2E) when the feature sizes were this large.

Once both of the elastomeric molds were generated, they were each independently brought into contact with a small drop (≈ 2 mm in diameter) of the uncured TMPTA which was first placed on a flat, unpatterned silicon wafer as illustrated in Figure 1B. A fixed pressure was exerted on the mold with a modified Instron to ensure conformal contact. UV light was then passed through the back of each mold for 1 min to fully cure the TMPTA while in contact with the mold. Each mold was then peeled from the wafer revealing the patterned TMPTA replicate.

The TMPTA replicates generated from the PDMS molds were of very poor quality. SEM images (Figure 2F and G) of these replicates reveal pieces of the PDMS mold that were ripped out during the release as a result of swelling of the PDMS mold by the TMPTA prior to curing. In contrast, those replicates made from the PFPE-based mold look identical to the master with no tear out (Figure 2C and G) because it is not swollen by the organic-soluble TMPTA photopolymer resin. Additionally, the PFPE-based mold was extremely easy to peel away from the micromolded TMPTA, presumably because of the extremely low surface energy of the PFPE-based mold[24] and its elastomeric nature. The intrinsically oleophobic nature of this fluoropolymer-based mold material enables for the first time

imprint lithographic applications of commonplace organics using soft elastomeric mold materials.

In addition to the intrinsic swelling problems illustrated above for PDMS-based materials, previous attempts to perform 1:1 sub 1-micron patterning using PDMS-based elastomers, such as Sylgard 184, does not give replicas of high fidelity. Indeed, accurate replication of patterns using molds of features less than 1-micron in size with PDMS-based elastomers has had only limited success[1,4,10] even when using elaborate pre-treatment methods to reduce the interfacial adhesion between the object being molded and the PDMS-based replica.

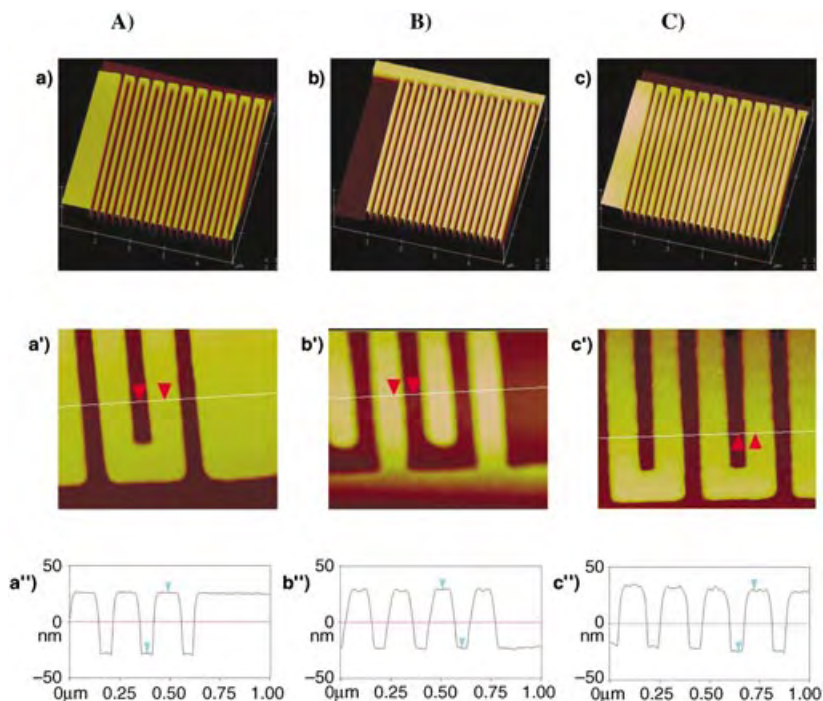
To test the viability of PFPE-based elastomers to perform accurate nanometer-scale molding we chose to fabricate replica molds from a patterned silicon-wafer master with features having a width of 140 nm, a depth of approximately 50 nm, and a separation of 70 nm (Figure 3A). We found we could cast excellent molds using the PFPE-based fluoroelastomer materials with exact preservation of the nanoscale features of the patterned silicon-wafer master (Figure 3B). The features on the PFPE-based mold had an average height of 51 nm which was in excellent agreement with a measured height of 54 nm for the features in the silicon master. The widths of the features on the PFPE-based molds seem to vary from the top of the


Figure 3. High-resolution AFM images of A) a silicon master with lines of 140 nm width separated by 70 nm (a, a'), B) PFPE mold with 70-nm wide lines separated by 140 nm (b, b'), C) replicate made with PFPE mold with 140-nm wide lines separated by 70 nm (c, c'). Beneath each picture is a representative height profile (a'', b'', c'').

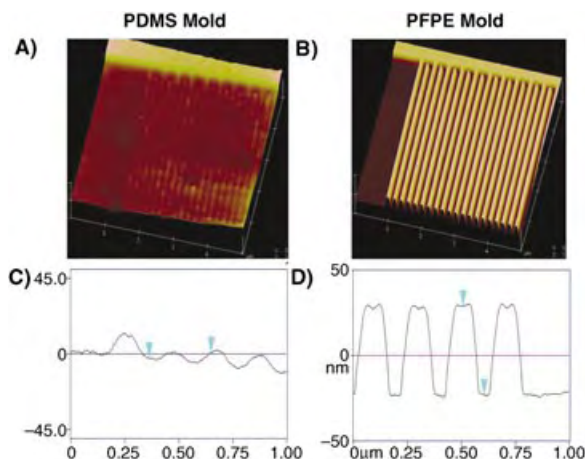
channel through to the bottom (Figure 3B). This is presumably due to some slight relaxation of the polymeric material upon release of its confinement from the patterned silicon wafer master. In contrast, attempts to fabricate PDMS-based molds from the same silicon master failed (Figure 4). The features on the PDMS molds are irregular, rounded, and only 5–10 nm in height.


Figure 4. High-resolution AFM image of a PDMS mold (A) and a PFPE mold (B) generated from the silicon master shown in Figure 3. Representative height profiles are shown underneath the respective images (C, D).

The ability of these soft elastomeric replica molds to be useful in the patterning of nanoscale features using NCM imprint lithographic techniques was explored (see Figure 3). The high-fidelity PFPE-based molds having 70-nm wide lines separated by 140-nm spaces (see Figure 3B) were used to contact mold the TMPTA photopolymer resin in a manner identical to that used above for imprinting micron-sized features. Remarkably, when using between 5 and 25 psi of pressure on the PFPE-based mold, we were able to easily imprint a drop of TMPTA photopolymer resin to generate patterns (Figure 3C) having nanometer-sized features that looked identical to the original patterned silicon wafer master (Figure 3A). In addition, the PFPE-based mold was easy to peel off of the nano-molded TMPTA replicates presumably because of the flexibility and low surface-energy of the PFPE-based elastomer and its oleophobic nature which prevented adsorption of the TMPTA into the mold. When using quartz molds, such release processes can take from tens of seconds to minutes and requires large separation forces that often result in delamination failures.

In summary, we have demonstrated the capabilities of PFPE-based elastomers to be used as ideal materials for advanced, high-performance imprint lithographic applications. Such highly fluorinated materials enable both soft lithographic techniques as well as more demanding submicron imprint techniques. They are easily fabricated, have the ability to make conformal contact, have a remarkably low surface energy, are resistant to swelling by small organic molecules, and endure multiple printing procedures. We have shown that while replica molds with 2-μm features can be generated from both PFPE-based and PDMS-based elastomers, only the PFPE-based materials could be used as molds to imprint and mold desirable organic-soluble materials because of the intrinsically oleophobic nature of such highly fluorinated materials. Furthermore, these PFPE-based materials were able to replicate sub-100-nm sized features with no indications of limits to going to even smaller in size. In addition, the low surface energy of the PFPE-based materials allows for unprecedented ease of release from both silicon masters as well as from patterned replicates-without the need for complex surface functionalization-making it good material to use in the routine fabrication of nanometer-scale structures and devices.

Photocontrol of Smad2, a Multiphosphorylated Cell-Signaling Protein, through Caging of Activating Phosphoserines**

Michael E. Hahn and Tom W. Muir

The ability to activate proteins with spatial and temporal control inside live cells allows for quantitative kinetic measurements of protein function to be made in a biologically relevant context. Proteins that contain photolabile protecting groups appended to functionalities required for biological activity can be activated by light and provide a means to enable such analyses. Few reports of these reagents, known as caged proteins, have appeared in the literature because of difficulties in the preparation of such complex macromolecules.[1] Herein, we describe a semisynthetic route to the preparation of caged phosphoproteins. This strategy has been applied to the cellular signaling protein Smad2.

Smad2 is a key element of the intracellular response to cytokines of the transforming growth factor β (TGF-β) superfamily, which are involved in a myriad of normal and disease processes, including development, tissue homeostasis, and cancer.[2] Binding of TGF-β to its cognate receptor complex results in phosphorylation of the last two serine residues of the C-terminal sequence CSSMS of Smad2 (residues 463–467).[2] These phosphorylation events activate Smad2, which then disengages from the cytosolic retention factor SARA (Smad anchor for receptor activation), thus rendering the protein competent to both homotrimerize and interact with Smad4, a binding partner required for downstream functions.[2,3] Activated Smad2 accumulates in the nucleus, where it regulates transcriptional programs by interacting with a host of other proteins and target promoters.[2]

These differential protein–protein interactions and the localization of Smad2 provide a basis for understanding how this molecule functions in a cell. However, these descriptions are static and do not adequately describe the dynamics underlying these signaling events. Little is known about where many of these protein–protein interactions are initiated and for how long they exist. The kinetics of nuclear import and export as well as the importance of signal strength, duration, and localization are all poorly understood. We therefore targeted Smad2 for caging because the ability to activate this protein with temporal and spatial control allows one to directly address some of these fundamental issues.

Our caging strategy takes advantage of protein phosphorylation, the post-translational modification most often used to regulate protein activity.[4] Much recent effort has been directed at the preparation of caged analogues of phosphopeptides and phosphoproteins.[5,6] We used expressed protein ligation (EPL) as the center point of a semisynthetic scheme for the preparation of Smad2 whose activating phosphorylated residues were caged (Figure 1).[7] This approach offers several advantages, including the ability to produce caged proteins of any size in quantities sufficient for various biological applications without the need for mutagenesis.[7] Additionally, EPL readily allows for the installation of
Figure 1. Semisynthesis of caged Smad2-MH2. Expressed protein ligation was used to ligate a recombinant Smad2-MH2-α-thioester/SARA-SBD protein complex to the doubly caged phosphopeptide **1** to give the caged Smad2-MH2/SARA-SBD heterodimer. Caged Smad2-MH2 is activated by exposure to UV light and subsequently releases SARA-SBD and forms a homotrimer. Smad2-MH2 is shown in globular form, SARA-SBD is shown in orange, phosphorylated residues are symbolized by yellow circles, and caging groups are symbolized by red crescents.

multiple caged phosphate groups in a homogenous manner.[7,8] This characteristic is of significant importance since many proteins, including Smad2, are controlled by multisite phosphorylation.[9]

In this study we chose to work with the MH2 domain of Smad2 (residues 241–467, M_W = ca. 25 kDa), since its size enables precise characterization by chromatography and electrospray mass spectrometry (ESMS). The MH2 domain mediates many of the functions of Smad2, including receptor recognition, homo- and hetero-oligomerization, and nuclear import.[2] Full-length semisynthetic Smad2 has previously been prepared by EPL[3] and, therefore, we expect that the caging strategy outlined herein will translate effectively to the complete molecule.

Preparation of the caged phosphoprotein commenced with the synthesis of the corresponding doubly caged phosphopeptide **1** by using the 9-fluorenylmethoxycarbonyl (Fmoc) strategy (Scheme 1). Key to the synthesis was 1) orthogonal trityl (Trt) protection of the side chains of the two serine residues to be phosphorylated and 2) incorporation of the N-terminal cysteine (Cys) group required for EPL as *tert*-butoxycarbonyl-1,3-thiazolidine-4-carboxylic acid (Boc-Thz). The latter allowed for the thiol group of Cys to be protected during the critical phosphorylation step and provided a convenient method for deprotection of the Cys residue following cleavage of the peptide from the solid support.[10] Following chain assembly and selective unmasking of the two serine residues, the resulting peptidyl resin **2** was dried extensively and treated with *O*-1-(2-nitrophenyl)ethyl-*O*′-β-cyanoethyl-*N,N*-diisopropylphosphoramidite,[5] which contains the 2-nitrophenylethyl (NPE) caging group. *tert*-Butylhydroperoxide was then used to oxidize the intermediate phosphites to the desired phosphates, thus yielding **3**. Notably, the undesired oxidation of the thioether of methionine to the sulfoxide was largely avoided (< 5 %) by limiting the oxidation time to 20 minutes (see the Supporting Information). Attempted on-resin removal of the β-cyanoethyl protecting groups from two juxtaposed phosphates resulted in significant amounts of β-elimination of the protected phosphate moiety.[11] Interestingly, this side reaction was not found to occur when the deprotection step was carried out in solution following cleavage from the resin. This observation suggests that the elimination was facilitated by the C-terminal ester linkage between the peptide and the solid support. Smooth removal of the β-cyanoethyl groups was therefore carried out under optimized conditions in solution using the hindered amidine 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).

Methoxylamine was then added in situ to convert Thz into Cys. The crude product contained one major compound (ca. 75 % by reversed-phase high-performance liquid chromatography (RP-HPLC), see the Supporting Information), which was subsequently purified to homogeneity to give the desired peptide that was caged on two phosphorylated serine residues (**1**) in 10 % yield.

The caged peptide **1** was labeled with fluorescein-5-maleimide (thus generating peptide **1-Fl**)[12] and subjected to low-intensity UV irradiation (312 nm, 2 mW cm^{-2}) followed by RP-HPLC to determine the kinetics and quantum yield of uncaging. Photolysis followed first-order kinetics with a rate constant of 4.9×10^{-3} s^{-1}, which corresponds to a quantum yield of uncaging of 0.16 per caging group (Figure 2). Interestingly, both possible singly caged peptides were observed in approximately equal amounts after irradiation for an intermediate length of time, thus indicating that the efficiency of photolysis was equivalent for both caging groups (see the Supporting Information). Brief (< 5 s) exposure of the peptide to the output of a He-Cd laser (325 nm, 4.74 W cm^{-2}) resulted in near quantitative conversion (> 97 %) into the uncaged peptide (see the Supporting Information).

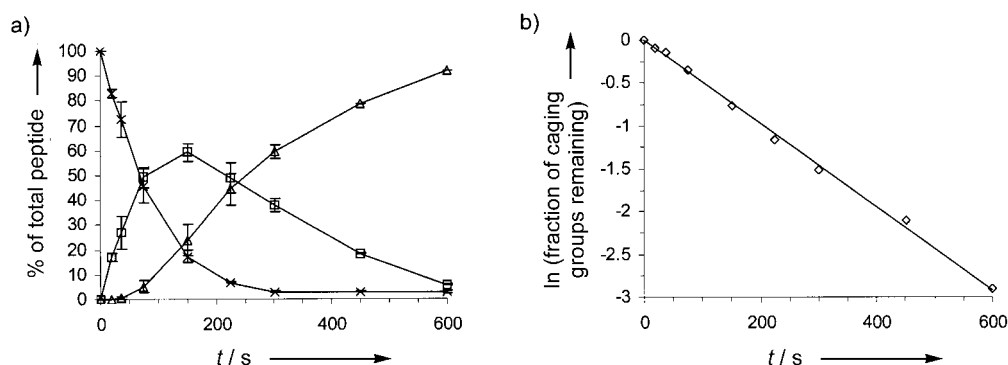
A recombinantly expressed Smad2-MH2 domain (residues 241–462) bearing a C-terminal thioester was prepared as previously described.[3] A complex of this protein with the minimal Smad binding domain of SARA (SARA-SBD, residues 665–721) was formed by incubation with excess SARA-SBD and purified by cation-exchange chromatography. The resulting pure protein complex was concentrated to 0.25 mM and a fourfold molar excess of the caged peptide **1** was added to initiate the ligation reaction (Figure 1). The reaction was monitored by RP-HPLC, ESMS, and sodium
Scheme 1. Synthesis of doubly caged phosphopeptide **1**. a) 1. *O*-1-(2-nitrophenyl)ethyl-*O*′-β-cyanoethyl-*N,N*-diisopropylphosphoramidite, 4,5-dicyanoimidazole, DMF (anhydrous); 2. 1 M *t*BuOOH, CH$_2$Cl$_2$ (anhydrous); b) 92.5 % TFA, 2.5 % EDT, 2.5 % TIS, 2.5 % H$_2$O; c) 1 % DBU, DMF then 0.5 M MeONH$_2$·HCl, H$_2$O. TFA = trifluoroacetic acid, EDT = 1,2-ethanedithiol, TIS = triisopropylsilane.


Figure 2. Photolysis kinetics of doubly caged phosphopeptide **1** labeled with flourescein-5-maleimide (**1-Fl**). a) A solution of **1-Fl** at 10 μM was irradiated with low-intensity UV light (312 nm, 2 mWcm^{-2}) for the times indicated and subjected to RP-HPLC for quantitation of the doubly caged (×), singly caged (□), and uncaged forms (△). The percentage of each is plotted versus time of irradiation. b) The fraction of caging groups remaining was calculated and the natural logarithm at each time point plotted versus time of irradiation, along with a line of best fit, which yielded a first-order rate constant for photolysis of 4.9×10^{-3} s^{-1} and an r^2 value of 0.99. The mean of two experiments is plotted for both (a) and (b), and the standard deviation is represented by error bars in (a).

dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE) and was complete after 12 h. The caged protein was purified by preparative size-exclusion chromatography (SEC) and its identity was confirmed by ESMS (Figure 3c).

To be deemed effective, the caged protein should behave as if it was nonphosphorylated in the absence of UV light and should display all the properties of the active, doubly phosphorylated Smad2-MH2 when uncaged by UV light. We therefore proceeded with studies designed to determine the oligomerization state of the caged protein before and after UV irradiation. Gratifyingly, the caged protein mimicked nonphosphorylated Smad2-MH2, since it bound SARA-SBD in a 1:1 molar ratio (Figure 3a). This heterodimeric arrangement of Smad2-MH2 and SARA-SBD was verified by SEC coupled with multi-angle laser light scattering (MALLS) detection at a loading concentration of 5 μM (see the Supporting Information).[13] MALLS analysis indicated that

the caged protein had a slight residual tendency to form homotrimers at higher loading concentrations (25–50 μM; see the Supporting Information). Indeed, in preliminary studies where only one caging group was installed on either phosphoserine 465 or 467, this tendency to oligomerize was even more pronounced (data not shown). Importantly, the tendency of the doubly caged protein to homo-oligomerize is concentration-dependent, such that at physiologically relevant concentrations (< 5 μM)[14] this behavior is no longer observed. Brief irradiation (< 5 s) of the caged protein with the output of the He-Cd laser followed by SEC, RP-HPLC, and ESMS demonstrated that the caging groups were quantitatively removed from the protein and that SARA-SBD was released from Smad2-MH2 in favor of homotrimerization (Figure 3).

As a step toward our ultimate goal of using caged phosphoproteins in live cells to study the kinetics of biological
Figure 3. Characterization of caged (top panels) and uncaged (bottom panels) Smad2-MH2. Caged Smad2-MH2 was converted into uncaged Smad2-MH2 by irradiation for 5 s with a He-Cd laser (325 nm, 4.74 Wcm^{-2}). a) The ratio of caged and uncaged Smad2-MH2 to SARA-SBD was determined by subjecting the caged and uncaged proteins to RP-HPLC with detection at 214 nm and integrating the peaks corresponding to SARA-SBD (*) and Smad2-MH2 (**). The peak area ratio of caged Smad-MH2:SARA-SBD is 4:1, which at 214 nm indicates a 1:1 molar ratio. b) The homo-oligomeric status of caged and uncaged Smad2-MH2 was assessed by SEC with detection at 280 nm. The elution positions of doubly phosphorylated Smad2-MH2 (2P) and nonphosphorylated Smad2-MH2 (0P) controls are indicated. c) The reconstructed molecular weight from ESMS indicates that the caged protein (calcd $M_W = 25818$ Da) was assembled successfully. ESMS of the uncaged protein (calcd $M_W = 25519$ Da) indicates quantitative removal of the caging groups after laser irradiation. Observed molecular weights are also shown.

signaling and transport processes, we set out to determine the behavior of caged Smad2-MH2 in a nuclear import assay. When incubated with digitonin-permeabilized HeLa cells in the presence of SARA-SBD, nonphosphorylated Smad2-MH2 (OP) is excluded from the nucleus, whereas phosphorylated Smad2-MH2 (2P) accumulates in the nucleus (Figure 4).[14] UV irradiation had no effect on the localization
Figure 4. Nuclear import assay of Smad2-MH2 variants labeled with Texas Red C_2–maleimide. Nonphosphorylated (OP), doubly phosphorylated (2P), and caged Smad2-MH2 before (top panels) and after UV (bottom panels) laser irradiation (as in Figure 3) were incubated separately at 1.5 μm with digitonin-permeabilized HeLa cells for 20 minutes at room temperature in the presence of 4.5 μm GST-SARA-SBD (GST = glutathione S-transferase), an ATP-regenerating system, and 1 mg mL^{-1} bovine serum albumen (BSA). After the import reaction, cells were washed, fixed, and analyzed by confocal microscopy for the localization of each Smad2-MH2 variant. A control experiment was performed in which the import reactions were carried out on ice. This treatment prevented nuclear accumulation (data not shown), which is consistent with nuclear import of Smad2 being an energy dependent process, as previously demonstrated.[14]

pattern of phosphorylated and nonphosphorylated Smad2-MH2 control proteins (Figure 4). In the same assay we found that caged Smad2-MH2 was excluded from the nucleus, whereas uncaging of the protein with UV light led to dramatic nuclear accumulation (Figure 4). This demonstrates that the caged and uncaged proteins behave as desired in a biological context.

In summary, we have prepared Smad2-MH2 caged on two activating phosphate residues by a semisynthetic route. The molecule described represents the first report of a protein caged on a phosphate group. In principle, this approach can be applied to the construction of a caged version of any protein activated by phosphorylation. We are currently investigating this and other strategies of molecular photocontrol over protein function with live cell-imaging techniques.[15] These studies are expected to yield quantitative insight into the kinetics of Smad2 nuclear import and export. Additionally, we plan to address fundamental questions regarding the importance of signal strength and duration in biological processes.

Self-Assembly of Cyclic Metal–DNA Nanostructures using Ruthenium Tris(bipyridine)-Branched Oligonucleotides**

*Debbie Mitra, Nicolas Di Cesare, and Hanadi F. Sleiman**

One of the promises of nanoscience is the creation of ordered structures that contain addressable molecular components, which are designed to accomplish complex operations.[1] However, whereas many functional molecular components have already been constructed, methods to assemble them in a deliberately designed manner on the nanometer scale have yet to be devised.[1,2] In this respect, DNA has emerged as a promising template to accomplish this task because of its uniquely selective self-assembly, ready programmability, and facile synthesis.[3–5] In principle, short (10–30-bases long) strands of DNA can rapidly self-assemble into relatively rigid, programmable, higher-order DNA structures.[5] Pioneering work by Seeman demonstrated the use of modified Holliday junctions as oligonucleotide-based vertices in the assembly of complex two- and three-dimensional nanostructures.[3a–c] DNA nanostructures have also been constructed[3] through the use of oligonucleotide–gold colloidal particles,[3d–f] biotin–avidin interactions,[3g] guanine quartets,[3h,i] and organic vertices.[3j–l]

We are interested in the creation of cyclic transition-metal–DNA nanostructures that contain short DNA duplexes as arms and transition-metal centers as vertices. In these well-defined supramolecular structures, DNA serves as a nanoscale rigid molecule to spatially position addressable transition metals, which have intrinsic properties such as luminescence and redox activity,[6] into an ordered array. Whereas transition metals have been used to generate 3D DNA networks,[4a–c] linear DNA arrays,[4d] and metalated DNA,[4g–h] to our knowledge, discrete cyclic metal–DNA structures have not been previously accessed.[4] Herein, we report the synthesis and properties of a branched ruthenium(II)–DNA complex, in which two parallel DNA strands are linked to a

relatively rigid Ru^{II} tris(bipyridine) center.[9] Self-assembly of this molecule leads to the formation of a discrete metal–DNA cyclic nanostructure, which contains two DNA duplexes and
1: n=DNA nucleotide

two redox- and photoactive $[Ru(bpy)_3]^{2+}$ centers (bpy = bipyridine). Furthermore, we show that branched oligonucleotides based on the non-metalated ligand undergo less-selective association, which illustrates the role of the transition metal in this self-assembly process.

In a preliminary report,[10] we described the synthesis of an oligonucleotide-branched transition-metal complex through a convergent, solid-phase approach. In its initial design, a ruthenium(II) center was linked to two d[T_{10}] DNA strands through flexible six-carbon spacers and two monodentate imidazole ligands. To better control the self-assembly of these complexes, we needed to expand this solid-phase strategy to access relatively rigid, branched DNA complexes with mixed DNA sequences.[11] The vertex used here was based on the complex, cis-[Ru(bpy)$_2$(4,4'-bis(hydroxymethyl)-2,2'-bipyridine)][PF$_6$]$_2$ (**2**, see Scheme 1),[8] which exhibits both luminescence and redox activity. Examination of a number of X-ray crystal structures reported for related complexes indicates that the ruthenium center should orient the 4,4'-carbon centers at an angle of $\approx 70°$ (C$\cdots$Ru$\cdots$C), whereas in the free ligand the carbon centers are directed in a transoidal fashion.[9] Complex **2** was first converted into the bis(phosphoramidite) derivative **3** by reaction with chloro(cyanoethyl)-*N,N*-diisopropylphosphoramidite.[7] In parallel, a number of DNA sequences were synthesized on a high-density controlled-pore glass (CPG, 56–64 μmol g^{-1}) support (Scheme 1). After the removal of the protecting dimethoxytrityl groups from the DNA sequences, the ruthenium complex **3** was added to the oligonucleotide-functionalized CPG support. After oxidation, the DNA-linked Ru complexes were then cleaved from the support.[7]

The products of this convergent synthesis were isolated by using denaturing polyacrylamide gel electrophoresis (PAGE), and their structures were analyzed by using PAGE, anion-exchange HPLC, and MALDI-TOF mass spectrometry. The fastest moving band in the gel was identified as unmodified DNA, and the next band was identified as the mono(DNA)-functionalized Ru complex **4** (Scheme 1), which resulted from the coupling of the ruthenium vertex **3** to only one oligonucleotide strand on the solid support. The slowest moving species was confirmed as the desired DNA-branched ruthenium conjugate **1** by MALDI-TOF MS. In parallel to the

oligonucleotide conjugates **1** showed an emission peak at $\lambda = 615$ nm which was identical to that of the unconjugated Ru complex **2** (Figure 2c).[7] Thus, the fluorescence properties of the ruthenium–bipyridine species are retained in the DNA-branched Ru conjugates.

Because of the branched architecture of the Ru–DNA complexes **1**, it was important to assess the propensity of the DNA arms to form stable duplexes upon hybridization with their complementary partners. Thermal denaturation experiments of complex **1b** in the presence of two equivalents of the complementary oligonucleotide **c** showed the conventional sigmoidal melting-temper-

generation of the ruthenium–DNA conjugates, DNA-branched bipyridine conjugates **5d–e** were also prepared by a similar solid-phase convergent strategy and were isolated and purified by denaturing PAGE (Figure 1).[7] The UV/Vis absorption spectra of the Ru–DNA conjugates **1** exhibited transitions at $\lambda = 260$ nm which are characteristic of the heterocyclic DNA bases. The bipyridine π–π^* and metal-to-ligand charge-transfer (MLCT) transitions were observed at $\lambda \approx 280$ and 454 nm, respectively.[7] Upon irradiation at $\lambda = 454$ nm, the fluorescence spectra of the ruthenium–

ature curves for a DNA duplex (Figure 2a).[7] Interestingly, a slight increase (1–4°C) in the melting temperature was observed for the oligonucleotides in the Ru–DNA conjugates **1** relative to the melting temperature of the Watson–Crick control duplex.[5] Thermal denaturation experiments were also carried out for the mono(DNA)-functionalized Ru complexes **4**, which do not possess a branched architecture. These complexes exhibited a similar enhancement in duplex stability (melting temperatures were increased by 4°C) which indicates that the positively charged Ru center is likely responsible for this effect in both the mono- and the branched DNA–Ru[II] complexes.[7] Further evidence for the formation of a B-DNA duplex was obtained by circular dichroism (CD) spectroscopy (Figure 2b).[12]

Figure 2d shows an image from the native PAGE analysis of the hybridization product of complex **1d** with two equivalents of a complementary DNA, **e** (Scheme 2). This

copy; upon excitation at 454 nm, an emission at $\lambda = 616$ nm was observed which showed a $\approx 6\%$ decrease in its intensity relative to that of the unhybridized DNA–Ru complex **1** (Figure 2c).[14] Thus, upon hybridization with their complementary partners, the branched Ru[II] complexes form stable bis(duplex) systems and retain their fluorescence properties.

In light of the ability of complexes **1** to form stable duplexes, we explored the self-assembly of two complementary Ru[II]-branched oligonucleotides. In principle, this association can result in either discrete cyclic structures or linear oligomeric/polymeric species.[15] We anticipated that the relative rigidity of the ruthenium vertex in complexes **1** would result in a more efficient formation of cyclic products. Self-assembly was first examined by heating equimolar solutions of the DNA-branched Ru complex **1d** and its complement **1e** to 90°C, followed by slow cooling of the mixture to 4°C (1.8°C min^{-1}, 12 h). PAGE analysis revealed the formation of products of extremely slow mobility which correspond to at least 330 base-pairs for the molecular-weight marker (Scheme 2, Figure 3a). This points to the formation of

Scheme 2. a) Discrete [Ru(bpy)$_3$]$^{2+}$–DNA nanostructures through the self-assembly of **1**, and b) discrete bpy–DNA nanostructures from **5**.
Figure 3. Native PAGE analyses: a) Hybridization from 90 to 4°C overnight: lane 1) 10–330 base-pair ladder; lane 2) solution of **1d–1e** (20 μM) in TMS; lane 3) solution of **1d–1e** (40 μM) in TMS. b) Hybridization at 4°C overnight: lane 1) solution of **1d–1e** (40 μM) in TMS; lane 2) solution of **1d–1e** (20 μM) in TMS; lane 3) 10–330 base-pair ladder.

gives rise to a band with electrophoretic mobility similar to that of a duplex that contains 40 nucleotides in the molecular-weight marker ladder. This band can thus be assigned to the Ru–bis(duplex) conjugate **6** (that contains 44 bases, Scheme 2).[13] Molecular modeling studies of complex **6** show no apparent steric barrier to the formation of two duplex arms at the 4,4'-positions of the bipyridine ligand.[7] Ru–bis(duplex) **6** was examined by fluorescence spectros-

linear polymeric DNA–Ru species **7** (Figure 3a). Interestingly, when the self-assembly of **1d** with **1e** was carried out under milder conditions (4°C, 12 h), one major discrete product formed along with small amounts of polymeric species. The mobility of this Ru–DNA structure corresponds to a 44-base molecular-weight marker and is consistent with the formation of a dimer, **8**, which contains two DNA duplexes (44 nucleotides) and two [Ru(bpy)$_3$]$^{2+}$ vertices (Scheme 2, Figure 3b). To determine whether this dimer was an open, linear product or a cyclic molecule, enzymatic digestion with Mung Bean Nuclease was conducted.[16] This enzyme is selective to the degradation of single-stranded DNA. It is thus expected to degrade open, oligomeric species that contain single DNA strands, but to leave closed, cyclic species that contain double DNA strands intact. Under conditions that cause the degradation of single-stranded

DNA, the dimer **8** remained unmodified by the enzyme.[7] Thus, the self-assembly of the DNA-branched Ru complexes **1** generates a discrete metal–DNA cyclic nanostructure.[17]

To probe the role that the transition-metal ion plays in the self-assembly process, a hybridization experiment was carried out with the unmetalated bipyridine–bis(DNA) conjugates **5**. The DNA-branched bipyridine molecules **5** are expected to show a higher flexibility than the DNA-branched Ru complexes **1** and a twist of the two DNA strands into a transoidal arrangement.[9] Samples **5d** and **5e** were combined under similar hybridization conditions (4 °C, 12 h, Scheme 2, Figure 4). In addition to a band that was assigned to a dimeric

Figure 4. Native PAGE analyses: a) Hybridization with unmetalated-bipyridine–DNA conjugates **5** at 4 °C overnight: lane 1) 10–330 base-pair ladder; lane 2) solution of **5d–5e** (20 μM) in TMS; lane 3) solution of **5d–5e** (20 μM) in TMS with added enzyme. b) Hybridization at 4 °C overnight of oligonucleotides from the metalated complex **1** with those of the unmetalated conjugates **5**: lane 1) 10–330 base-pair ladder; lane 2) solution of **5d–1e** (20 μM) in TMS; lane 3) solution of **5d–1e** (20 μM) in TMS solution with added enzyme.

species **9**, which contains two bipyridine moieties and two DNA duplexes, several bipyridine assemblies that ranged from tetramers to significant amounts of higher-order oligomers/polymers were observed (Figure 4, Scheme 2). Enzymatic digestion of the hybridized products did not affect the discrete bands that correspond to the dimer and tetramer, which indicates that they therefore correspond to cyclic products. These results are in contrast to the behavior of the DNA-branched Ru complexes **1,** which form the dimer **8** as the sole cyclic product, and illustrate the active role of the transition-metal ion in the self-assembly of these higher-order DNA structures.

Finally, to create hybrid DNA structures that contain both [Ru(bpy)$_3$]$^{2+}$ units and unfunctionalized bipyridine vertices, the self-assembly of the DNA-branched Ru complex **1d** with the DNA-branched bipyridine **5e** was examined (4 °C, 12 h, Scheme 2). This led to the formation of a cyclic dimer **10**, which contains two DNA duplexes and one ruthenium–bipyridine and one bipyridine vertex, along with higher molecular-weight oligomeric species (Figure 4, Scheme 2). The cyclic nature of the dimer **10** was also confirmed by enzymatic digestion with Mung Bean Nuclease. As they

contain a bipyridine ligand as one of their vertices, structures **9** and **10** can potentially be further functionalized with other transition-metal ions (such as Cu$^+$, Ag$^+$, and Zn^{2+}), and thus they have the potential to form hybrid multimetallic DNA nanostructures and networks.[4]

In conclusion, we have demonstrated the solid-phase, convergent synthesis of DNA-branched Ru^{II} complexes **1** and their self-assembly into the first cyclic metal–DNA nanostructures.[18] These supramolecular structures contain two DNA duplex arms and two relatively rigid photo- and electroactive [Ru(bpy)$_3$]$^{2+}$ vertices. We have also shown that branched DNA complexes with unmetalated bipyridine vertices undergo less-selective self-assembly, which illustrates the role of the transition metal in this process. The transition-metal units in these nanostructures are readily addressable by means of light or electrical energy. Thus, this study represents a new method to use the selective association of DNA to organize functional molecular components on the nanometer scale. Efforts towards understanding the factors that govern the self-assembly process, the isolation of these cyclic structures and the study of their properties, as well as scanning probe microscopy experiments are currently underway.

[12] The product from the hybridization of complex **1b** with 2 equivalents of complementary DNA exhibits a characteristic CD spectrum of a B-DNA: a negative band at $\lambda = 253$ nm, a crossover point at $\lambda = 265$ nm, and a positive band at $\lambda = 277$ nm (Figure 2b, solid line). This is very similar to the CD spectrum of the control duplex, **b–c**, which exhibits a negative band at $\lambda = 255$ nm, a crossover point at $\lambda = 267$ nm, and a positive band at $\lambda = 280$ nm (Figure 2b, dashed line); N. Berova, K. Nakanishi, R. W. Woody, *Circular Dichroism: Principles and Applications, 2nd Ed.*, Wiley-VCH, Weinheim, **2000**.

[13] The products of the hybridization of the mono(DNA)-functionalized Ru complexes **4** with their single-stranded DNA complements are observed to have similar electrophoretic mobility to that of a control duplex. Thus, the positive charge of the Ru center does not appear to affect the migration of the Ru–DNA samples.

[14] Please see the Supporting Information for changes in the fluorescence spectra of the Ru–bis(homopolymeric) sequence, **1a**, upon hybridization to complementary DNA. The results show a 10% decrease in fluorescence intensity upon hybridization.

Ru(II) Tris(bipyridyl) Complexes with Six Oligonucleotide Arms as Precursors for the Generation of Supramolecular Assemblies

Kristen M. Stewart, Javier Rojo, and Larry W. McLaughlin*

Nucleic acids can assemble into higher-order structures on the basis of complementary Watson–Crick base pairing. This self-assembly process has been exploited by a number of researchers[1–4] in the "bottom-up" approach to the generation of nonbiological structures of nanoscale dimensions.[5] In some studies, these assemblies have been based solely upon complementary DNA hybridization in which branch points are created by double-crossover structures[6,7] (generated as immobile junctions[8–10]) that are similar to those of DNA recombination intermediates; higher-order DNA networks can be made by this approach.[11,12] In other cases, DNA sequences have been tethered to multifunctional organic cores[13,14] or inorganic complexes[15–19] that are capable of self-assembling into more-complex networks such as dendrimers.[20,21] Oligonucleotides have been tethered to gold nanoparticles,[2,22,23] and complementary hydrogen bonding resulted in the formation of large assemblies that were used for diagnostics.[24,25] Nucleic acids can also be functionalized by conjugation, and this approach has led to the development of nanostructures and devices,[26,27] DNA–protein conjugates,[24] and the assembly of two- and three-dimensional networks. DNA-based nanoscale assemblies have been used for the construction of nanowires.[28,29] Herein we describe the preparation of six-oligonucleotide-armed ruthenium(II) tris(bipyridyl)-centered complexes as precursors for the generation of supramolecular nanoscale assemblies.

In the present monomer design, we chose $[\text{Ru(bpy)}_3]^{2+}$ with a Ru^{II} ion bound to three bipyridine (bpy) ligands as a core, and the DNA arms were tethered at the 4- and 4'-positions of each bipyridine ligand (Figure 1). Although $[\text{Ru(bpy)}_3]^{2+}$ exists in two enantiomeric forms, substitution at all three 4 and 4' sites results in an octahedral arrangement of the substituents in both enantiomers. First, enantiomerically pure DNA–$[\text{Ru(bpy)}_3]^{2+}$ conjugates should be attainable by appropriate chromatographic resolution of the Ru complexes as has been described for related ruthenium complexes,[30–32] followed by their incorporation into DNA conjugates. However, such chromatographic separations are not yet routine, and successful isomer resolution still depends in part upon the nature of the complex. The choice of sequences

Figure 1. A [Ru(bpy)$_3$]$^{2+}$ center with six DNA sequences tethered at the 4 and 4′ positions.

for the present building blocks is quite general, but self-assembly of monomers into higher-order structures requires either monomers that tether self-complementary sequences, or two or more monomers that tether complementary sequences.

Modeling studies suggested that a linker was required between the octahedral core and the DNA duplex to reduce steric crowding between the six termini of the tethered duplexes. A Ru^{II} complex **1** with six nine-carbon-atom linkers was prepared and then incorporated into a single, support-bound DNA sequence (Scheme 1). Subsequent extension of the remaining five linkers by solid-phase DNA synthesis completed the assembly of the monomers (Scheme 1). To generate a complex with six arms of the same sequence and

uniform polarity, we synthesized the initial sequence on a solid support in the conventional 3′ to 5′-direction (Scheme 1). The Ru^{II} complex was then incorporated into the support-bound 20-mer by a reverse-coupling protocol.[33,34] Synthesis of DNA in the unconventional 5′ to 3′-direction by using the reverse nucleoside monomers[35] (3′-dimethoxytrityl, 5′-phosphoramidites) allowed the functionalization of the remaining five linkers at the metal complex. During this latter process, the reaction times for the coupling reactions were extended to 60 min. With six hydroxy-terminated linkers present in **1** (see Scheme 1), it is conceivable that cross-linking of the synthesis support might occur; that is, one Ru^{II} complex could react with two (or more) support-bound DNA sequences. We believe this to be, at most, a minor reaction pathway, but for the described complexes it is also relatively unimportant with respect to the nature of the final product. Because all six sequences attached to the Ru tris(bipyridyl) center are identical both in sequence and polarity, complexes formed by either a single coupling or a cross-linking event to the support-bound sequence are all identical after deprotection. Control reactions with the Ru tris(bipyridyl) complex confirmed that [Ru(bpy)$_3$]$^{2+}$ was stable to the basic conditions encountered during the deprotection of the DNA sequences.

The desired six-arm complexes **2** and **3** were purified by a combination of HPLC and PAGE (polyacrylamide gel electrophoresis) techniques. The reversed-phase HPLC traces typically resulted in three peaks (see Supporting Information). The third peak (37.9 min) corresponded to an orange-colored species and contained the product, namely **2** or **3** (see Scheme 1). The first peak (22.7 min) contained DNA without any ruthenium which resulted from the growth of DNA strands that had not coupled with the Ru complex **1**, whereas the second peak (33.1 min) remains unidentified. The desired complexes were isolated by HPLC with a C$_{18}$ fast-flow Poros column, which gave essentially the same peak pattern as the analytical HPLC traces but broader peaks.

Isolation by PAGE was necessary to resolve the 5-arm and 6-arm DNA–Ru(bpy)$_3$ monomers because the eluted fraction corresponding to the third peak during HPLC isolation comprised both species. The identity of the two conjugates was tentatively assigned from their relative migration in the gel, and this assignment was confirmed by using a hybridization assay (see below). The ratio of the 6-arm to 5-arm complex varied for each synthesis, but it was always at least 2:1. Yields of the 6-arm complex varied typically from 5–10 A$_{260}$ units (absorbance units measured at 260 nm). This relatively low yield is at present largely a result of the need to use wide-pore (2000 Å) supports in the synthesis of the DNA; the initial DNA loading on these supports was generally no more than 8 µmol g^{-1}. Furthermore, the reverse coupling step used to incorporate the Ru tris(bipyridyl) complex **1** into the DNA strand is not the high yielding reaction typical of phosphoramidite couplings. The six-arm DNA–Ru^{II} complex was characterized by MALDI-

3: R = −O(CH$_2$)$_9$OPO$_3$–TCGACTCGACCAGCTCAGCT-3′
Scheme 1.

TOF mass spectrometry and UV/Vis and fluorescence spectroscopies.

The number of DNA arms present in the isolated Ru-centered monomers was confirmed by stepwise hybridization with the complementary 20-mer (Figure 2). The desired six-arm complex (Figure 2, left panel) exhibited six hybridization products, each leading to a stepwise reduction in the mobility.
Figure 2. Nondenaturing PAGE analysis of DNA–[Ru(bpy)$_3$]$^{2+}$ conjugates ($\approx$ 25 nM) that result from the synthesis of **3**. Left panel, hybridization results for the 6-arm conjugate; right panel, hybridization results for the 5-arm conjugate. Lane a: 20 bp ladder; lane b: isolated 6-arm conjugate; lanes c–i: 6-arm conjugate with increasing amounts of the complementary 20-mer; lane j: isolated 5-arm conjugate; lanes k–q: 5-arm conjugate of lane 10 with increasing amounts of the complementary 20-mer. bp = base-pairs.

The hybridization bands on the gel are thought to correspond to six-arm-monomer complexes that have from one to six arms hybridized to the complementary 20-mer. Besides the identified six-arm complex, a second complex with slightly greater electrophoretic mobility was also isolated. The hybridization assay of this complex with the complementary 20-mer indicated that this material contained only five arms (Figure 2, right panel). These hybridization assays not only confirm the number of arms present, but they also confirm the ability of the arms to participate in hybridization reactions and exist as duplexes. Thermal melting studies were less helpful in the characterization of the hybridization products as a single transition resulted for all six duplexes.

The PAGE analyses of the DNA hybridization products in Figure 2 were complicated by migration anomalies. Migration of the hybridized complexes was only effective upon reduction of the cross-linking in the gels by using a 75:1 acrylamide:bisacrylamide mixture in place of the more conventional 19:1 mixture. However, even with reduced cross-linking, and presumably the presence of larger gel pores, the complexes appeared to migrate anomalously. The complex with six single-stranded arms exhibited a minimal anomaly of 1.13 (Table 1, 0 duplex arms): a moderate effect which suggests that the complex is still relatively flexible and that the geometry of placing six DNA arms about a central core does not significantly alter the nature of the gel migration. That is, the complex appears to be flexible enough to pass through the pores in a similar fashion to single- or double-stranded (ss or ds) DNA even though the geometry of the DNA complex is more starlike rather than linear. The observed small anomaly might be explained by the

Table 1: Migration Anomalies for [Ru(bpy)$_3$]$^{2+}$ Complexes that Tether up to Six DNA Duplexes.[a]

DNA Duplex Arms	0	1	2	3	4	5	6
Sequence Size	120	140	160	180	200	220	240
Apparent Size[b]	135	190	270	355	453	511	638
Migration Anomaly[c]	1.13	1.36	1.69	1.97	2.27	2.32	2.66

[a] Ratio of acrylamide to bisacrylamide 75:1. [b] Apparent size relative to a 20 bp standard ladder. [c] Migration anomaly = apparent size/sequence size.

presence of the ruthenium metal ion and the additional mass of the bipyridine ligands and the six nine-carbon-atom linkers. However, the migration anomaly becomes greater with increasing numbers of hybridized arms; that is, as the single-stranded sequences are converted into duplexes, the complexes migrate more slowly than expected for the lengths of the sequences. One 20-mer hybridization event increases the size of the initial 120-residue complex to 140 residues, but the 140-mer complex migrates as a 190-mer (a migration anomaly of 1.36). With each subsequent hybridization event the sequence size increases by 20 residues, but the apparent size increases by 110, 175, 253, 291, and 398 residues relative to its actual size. The fully hybridized complex is a 240-mer but it migrates as a 638-mer—a migration anomaly of 2.66 (Table 1). This phenomenon may reflect a greater extent of entanglement in the gel fibers by the "starshaped" Ru^{II}–bpy–DNA-duplex complexes relative to the linear shapes of ss and dsDNA or even relative to the more flexible nature of the single-stranded DNA–Ru conjugates. The dramatic migration anomalies observed with an increase in the number of duplexes tethered to the Ru tris(bipyridyl) center suggest that the hybridization events generate a complex that displays a greater rigidity than the unhybridized six-stranded complex; the more rigid the multi-arm complex, then the more entanglement there will be between the complex and the gel, and thus the more difficulty the complex will have in migrating through the matrix. The rigidity of the monomer has been suggested[4] as an important parameter for the formation of higher-order DNA assemblies.

In this first study of a Ru center that tethers six DNA strands, we employed a nine-carbon-atom linker between the DNA duplexes and the [Ru(bpy)$_3$]$^{2+}$ center. The linker and the [Ru(bpy)$_3$]$^{2+}$ moiety taken together have a maximum extension of $\approx$ 15 Å from the center of the complex, whereas the diameter of the duplex DNA is $\approx$ 20 Å. The length of the linker may introduce some floppiness to the system, but even at this length, rotation of the DNA duplexes about the linker relative to one another can still result in significant restrictive steric or electronic effects with neighboring helices. To examine a more restrictive system, we prepared the [Ru(bpy)$_3$]$^{2+}$ center with six hydroxyethyl (two-carbon-atom) linkers and attempted to prepare the corresponding complex that tethers six DNA sequences. However, we were unable to obtain any material that contained all six DNA sequences tethered to the Ru–bipyridyl center. The optimal length of the linker for complexes of this type therefore lies between the 9-carbon-atom linker with which the target complex was obtained and the 2-carbon-atom linker that was unsuccessful.

A second hybridization assay (in an agarose gel) was performed with the monomers **2** and **3** (see Scheme 1), each of which contained six identical DNA arms that were complementary to those of the other monomer. As size markers, the respective hybridization products of **2** and **3** with six equivalents of the corresponding complementary 20-mer were used. These samples (Figure 3, lanes a and e, respectively) each provided a species with 240 residues (6×20 bp) that binds ethidium bromide to yield intensely fluorescent
Figure 3. Hybridization of **2** and **3** as visualized by ethidium bromide after agarose gel electrophoresis. Lane a: **2** + excess 20-mer; lane b: **2** + **3** (2:1); lane c, **2** + **3** (1:1); lane d: **2** + **3** (1:2); lane e, **3** + excess 20-mer.

bands in the gel. The hybridization assay was performed with varying ratios of **2:3**. When both **2** and **3** were present, much of the resulting DNA was present as high-molecular-weight assemblies that did not migrate from the gel wells (Figure 3). In the presence of ethidium bromide, the DNA in the gel wells was intensely fluorescent which suggests the presence of conventional duplexes that are capable of intercalative binding. When either of the monomeric complexes was present in excess (Figure 3, lanes b and d), the excess unhybridized monomer was observed at the bottom of the gel with a greater mobility than those of the hybridized standards present in lanes a and e. However, the fluorescence intensity of the starting materials was significantly reduced relative to the standards in lanes a and e because they contain single-stranded arms that do not bind ethidium bromide as effectively. These observations suggest that the high-molecular-weight assemblies in lanes b–d were not simply non-specific aggregates. The absence of any low-molecular-weight species (dimers, trimers, etc.) in lanes b–d (Figure 3) may indicate that the assembly process, which involves multiple hybridization events for each monomer, may mimic crystallization processes in which the monomers readily assemble into a macroscopic system after initiation by a seed structure. We cannot determine at this time whether the assemblies formed by hybridization have an ordered (i.e., cubic) geometry or whether they contain significant amounts of linear hybridization products or other types of nonspecific assemblies such as those resulting from interpenetration.

In conclusion, this study suggests that multi-arm DNA complexes might be useful for the assembly of regular DNA lattices of nanoscale dimensions.

The Catalytic Activity of "Naked" Gold Particles**

*Massimiliano Comotti, Cristina Della Pina,
Roberto Matarrese, and Michele Rossi**

The metal–support interaction in catalysis is of relevance both for academic studies and for industrial applications, and theoretical concepts have contributed to understanding the basic principles behind this interaction.[1] In most cases, however, the metal–support interaction is only described in terms of catalytic behavior and its nature often remains debatable. In recent years interest in gold catalysts for various applications in organic and inorganic chemistry[2] has increased and, our and other research groups have investigated the liquid-phase oxidation of polyol,[3–7] aminoalcohols,[8] and glucose[9] to carboxylates, and the gas-phase oxidation of alcohols to the corresponding carbonyl derivatives[10] using metal particles supported on different materials.

In liquid-phase applications, carbon was found to be the support of choice, and in the case of ethane-1,2-diol oxidation, by comparing different commercial carbons, a tentative hypothesis of metal–support interactions, connected to the density of phenolic groups at the carbon surface, was formulated.[11] However, the synergism between gold particles and carbon was not demonstrated and this point remained unresolved.

Although gold colloids have widely been employed to prepare supported gold catalysts, no report of particles derived from colloidal dispersion being used as catalysts has appeared. We have now found that, under controlled conditions, water-dispersed gold sol exhibits a surprising activity when used as "naked particles", that is, in the absence of common protectors as polyvinylalcohol (PVA), polyvinylpyrrolidone (PVP), tetrahydroxymethylphosphonium chloride (THPC). As a model reaction, we have investigated the aerobic oxidation of glucose to gluconate which occurs under mild conditions.

As shown in the conversion–time plot (Figure 1), naked gold particles having a mean diameter of 3.6 nm behave as an active catalyst allowing 21% glucose conversion in the first 200 s.

These particles are produced as a colloidal sol by reducing $HAuCl_4$ in the presence of a large excess of glucose acting either as reagent or protector. From the initial rate, a specific molar activity of 18043 mol gluconate $[mol Au]^{-1} h^{-1}$ (calcu-

lated with respect to the total gold) can be derived. Under similar conditions, Cu, Ag, Pd, and Pt colloidal particles of similar dimension (3–5 nm) were scarcely active. During the catalytic test, gold coagulated into larger particles owing to the formation of sodium gluconate that, as is common with other electrolytes, promoted sol coagulation leaving a colorless, inactive solution after about 400 s. The growth of gold crystallites during the reaction has been followed by X-ray diffraction (XRD) analysis at various time intervals, after sol immobilization on carbon (Figure 2).
Figure 2. Growth of gold particles during glucose oxidation.

Gold particles are also poisoned by sulfur compounds, such as sulfides and sulfites, and inhibited by protecting molecules, such as polyvinyl alcohol. Although the short life of the gold sol does not allow its use as a practical catalyst, its activity is of relevance both for assigning the catalytic role in the oxidation reaction and for evaluating metal–support interactions. For the latter purpose, a 0.5% w/w gold-on-carbon catalyst **II** was prepared by contacting the gold sol **I** with carbon powder. The size of gold particles remained unchanged after immobilization on carbon, as derived by

XRD. Under kinetic control, and using the same amount of gold, the curve of glucose oxidation with supported particles is quite similar to that of unsupported particles during the first 100 s (Figure 3a). This result means that both catalytic

systems are similarly efficient and, therefore, metal–support interactions, if present, are negligible in terms of enhancing gold activity. However, a benefit was obtained by using the supported gold particles as their morphology and activity were preserved for long time allowing the total conversion of glucose (Figure 3b). In particular, the gold dimension resulted unchanged at the end of the first catalytic cycle.

In principle, the knowledge of particle size in the sol allows the calculation of the turnover frequency (TOF) of gold. For this purpose, a series of experiments were undertaken to better characterize the kinetics of glucose oxidation with gold sol. Using colloidal particles having a mean diameter of 3.6 nm, a linear correlation between gold concentration (10^{-5}–10^{-6} M) and catalytic activity was found (Figure 4), which indicates that the rate is not limited by mass-transport phenomena.
Figure 4. Conversion versus [Au]; $t = 100$ s, [glucose] = 0.1 M. $T = 303$ K.

Furthermore, colloidal particles of different size have been produced by changing the chloroauric concentration from 50 to 600 mg L^{-1}, and the mean dimension of coherent scattering crystallites was determined by XRD (using the Scherrer equation[11]) after immobilization on carbon. For comparing activity with size, this technique allows a better correlation than that obtained by TEM where a broad distribution is observed in the case of larger particles (5–10 nm) owing to the formation of aggregates after deposition on carbon. These aggregates, however, retain their XRD identity. The chemical nature of gold particles under reaction conditions has been investigated by X-ray photoemission spectroscopy (XPS) after deposition on carbon. The presence of a sharp peak centered at 83.9 ± 0.2 eV, relative to the Au 4f7/2 signal, suggests the existence of the metallic state only.[12] By using gold particles of different size in the range 3–6 nm, we observed a catalytic activity inversely proportional to the diameter at the total gold concentration of 3.2×10^{-5} M (Figure 5). Particles larger than 6 nm deviate from linearity and a sharp cut off is observed at approximately 10 nm. We have no arguments that give a satisfactory interpretation for the sudden loss of activity. However, discontinuity at the nanometric scale has been observed in the case of other physicochemical properties of gold, for example, the sharp

Communications

decrease of the melting point, related to the transition from nonmetallic to metallic bonding, which occurs at a lower sizes, approximately 1–2 nm.[2] For particles smaller than 6 nm the observed correlation between activity and diameter agrees with the concept that only exposed atoms are catalytically active. By using the simple model of spherical particles, the total surface area, and therefore the number of exposed atoms, at a given metal amount, is in inverse proportion with particle diameter. By assuming in the first instance uniform particles of 3.6 nm present in the gold sol, 0.288 nm being the atomic diameter, the fraction of atoms lying at the surface should be approximately 36%.[2,13] Therefore, considering the initial specific activity of 18043 mol of gluconate formed per mol of total gold per hour, the initial TOF calculated for gold in the glucose oxidation is $50120\ h^{-1}$. Further investigation, based on a more appropriate model and using detailed particle size distribution in the liquid matrix, would give a more accurate result. A high activity can be preserved for a long time during the oxidation of glucose with the supported particles (Figure 3b). The estimated TOF value for carbon-supported particles should be similar to the unsupported particles, considering the similar catalytic efficiency (Figure 3a), and observing that dimension and form are in both cases identical (as derived by TEM), whereas diffusion in the carbon-supported catalyst is not a rate-limiting factor. This latter point has been experimentally verified by observing a linear increase of the reaction rate either on increasing the amount of catalyst (0.5% Au on C) or on increasing the loading of gold (0.1–1%) on the carbon.

The catalytic behavior of unsupported gold nanoparticles which interact with dissolved oxygen and glucose under conditions which are at the boundary between homogeneous and heterogeneous conditions, is also of interest for making comparisons with homogeneous catalysis. In fact, homogeneous enzymatic systems, containing the oxidase-catalase proteins derived from *Aspergillus Niger* mould, are the basis of the industrial process for the production of gluconate.[14] Catalytic tests were carried out, in the same apparatus as for the gold reactions, using a commercial enzymatic system (hyderase, Amano) containing 1.3×10^{-6} mol g^{-1} (hydrase) of flavine-adenine dinucleotide (FAD) as the rate-limiting factor. Operating at 303 K and 101.3 kPa, the pH value was fixed at 7 and a glucose/FAD molar ratio of 6.7×10^5 was used for optimizing the activity.

Under these conditions, the enzymatic system was about one order of magnitude more active than gold, its initial TOF value being $7.0 \times 10^5\ h^{-1}$ referenced to FAD (Figure 6) compared to $5.0 \times 10^4\ h^{-1}$ for the inorganic catalysis referenced to the exposed gold.

Despite the higher molecular efficiency of the enzymatic catalysis, for practical application gold seems to be a competitive alternative for glucose oxidation owing to the simplicity of catalyst manufacturing, nontoxicity of the metal and possibility of recycling.

In conclusion, the catalytic role and the properties of unsupported gold nanoparticles towards glucose oxidation have been investigated, allowing the evaluation of the specific activity of the metal which resulted comparable to that of enzymatic systems.
Figure 6. Rate of glucose oxidation with hyderase. [Glucose] = 1 M, [FAD] = 1.5×10^{-6} M, T = 303 K.

Experimental Section

A colloidal dispersion of gold **I**, was prepared by treating a 1.25×10^{-4} M aqueous solution of gold (as $HAuCl_4$) with $NaBH_4$ ($NaBH_4$:Au = 5:1) under N_2 atmosphere, in the presence of a large excess of glucose (0.35 M). The resultant brown sol contained metal particles, stable for several hours in the absence of dioxygen, having a mean diameter of 3.6 nm, as determined by TEM performed on a drop of dispersion evaporated on copper grid. In a similar manner Cu, Ag, Pd, and Pt colloidal particles (3–5.5 nm) were prepared. Supported 0.5% (w/w) gold on carbon catalyst, **II**, was prepared by contacting 2 g of carbon powder (X40S, Camel, 1200 $m^2 g^{-1}$) with sol **I** containing the appropriate amount of Au. Inductively coupled plasma (ICP) analysis showed total depletion of gold from the solution in a few minutes, and the residue material collected by filtration was used for the catalytic test without washing.

Hyderase: a glucose oxidase preparation produced by *Aspergillus Niger* fermentation (Amano Enzyme Co.) contained 1 mg g^{-1} of FAD. The oxidation of glucose was carried out in a thermostatted, magnetically stirred reactor (80 mL) purged with dioxygen at atmospheric pressure. The reaction was started by adding the catalyst to the O_2 saturated solution. Gluconic acid was continuously titrated at fixed pH value (9.5 for gold and 7 for hyderase) with NaOH, using a GPD 751 Titrino apparatus (Metrohm). Catalyst amount, stirring speed (1600 rpm), gas flow (60 L h^{-1}), and temperature (303 K) were chosen to carry out the test under catalyst-controlled kinetics. As the reaction product only gluconate was detected by HPLC as previously reported.[8]

Host–Guest Systems

An Aromatic Anion Receptor:
Anion–π Interactions do Exist**

Paul de Hoog, Patrick Gamez, Ilpo Mutikainen,
Urho Turpeinen, and Jan Reedijk**

Noncovalent supramolecular interactions involving aromatic rings play a significant role in both chemical and biological recognition.[1] For example, π-stacking interactions between the aryl rings of nucleobase pairs help to stabilize the DNA double helix.[2,3] It is well known that cation–π interactions are of great importance for many biological systems.[4,5] Thus, the binding of the agonist acetylcholine to its receptor is very selective and involves cation–π interactions between a quaternary ammonium group and a tryptophan amino acid residue.[6] Design and preparation of supramolecular host–guest compounds involving neutral or cationic entities have therefore received much attention during the last two decades.[7] In contrast, the chemistry of noncovalent anion–π interactions is much less developed.[8,9] This is most likely

due to the electron-donating character of anions, which is expected to lead to repulsive interactions with aromatic π clouds. However, in the last few years, an increasing number of aryl hosts for anionic guests have been studied, probably because of their potential medicinal and biological applications.[8] Indeed, more than 70% of enzyme substrates and cofactors are anions.[10]

Interactions between π-electron-poor aromatic moieties and anions were first demonstrated by NMR studies.[11–13] Several recent articles have reported theoretical investigations on the binding of halides with electron-deficient π systems such as fluorobenzene derivatives,[14–16] fluoro-*s*-triazine[17] and *s*-tetrazine derivatives,[18] and tetrafluoroethene.[19] All calculations clearly indicated an energetically favorable noncovalent interaction between halide and π system.[20] Lately, the first crystallographic evidence was reported for such interactions, between the 1,3,5-triazine group of the ligand 2,4,6-tris(di-2-pyridylamino)-1,3,5-triazine[21,22] and chloride and tetrachlorocuprate[23] anions.

In the course of research on the preparation of triazine-based coordination polymers[24,25] and their physical and catalytic properties,[26,27] the dendritic octadentate ligand *N,N′,N″,N‴*-tetrakis{2,4-bis(di-2-pyridylamino)-1,3,5-triazinyl}-1,4,8,11-tetraazacyclotetradecane (azadendtriz) was synthesized.[27]
Layering an aqueous solution of CuCl$_2$ (2 mL, 32 mм) with a solution of azadendtriz in dichloromethane (2 mL, 3.6 mм) gave blue prismatic crystals of [Cu$_4$(azadendtriz)Cl$_4$](Cl)$_4$(H$_2$O)$_{13}$ (**1**) in 54% yield by slow diffusion of the ligand into the aqueous phase, which gradually turned from colorless to dark blue (see Supporting Information).

The structure of **1** (Figure 1) shows a cationic tetranuclear copper moiety formed by one dendritic ligand, where the four *s*-triazinyl groups stack two by two in a parallel fashion. Consequently, the copper ions are coordinated by two 2,2′-dipyridylamino units belonging to two different *s*-triazine rings. The coordination spheres of the square-pyramidal ($\tau =$ 0.11, 0.13, 0.11, and 0.13 for Cu1, Cu2, Cu3, and Cu4, respectively)[28] metal centers are completed by a chloride anion at the apical position at a distance varying from 2.406(6) to 2.431(5) Å. The Cu–N distances of 1.991(9)–2.056(12) Å can be considered normal for square-pyramidal Cu^{II} ions. In

Communications

Figure 1. Representation of **1**, showing the four pentacoordinate Cu^{II} ions and the two encapsulated chloride anions Cl5 and Cl6.

addition, four chloride anions and thirteen water molecules are located in the crystal lattice. Some of these noncoordinated entities are disordered, for example, two carbon atoms of the azacrown group. The triazine rings are π–π stacked in pairs with nearly perfect face-to-face alignment (Figure 1), which is quite a rare phenomenon.[23,29] The distances between the triazine centroids of 3.65 (rings A) and 3.60 Å (rings B) are slightly longer than the usual values for π–π interactions (ca. 3.5 Å). However, such elongation is commonly observed with N-heteroaromatic ligands, especially when the nitrogen atoms of one ring face the nitrogen atoms of the other, which leads to unfavorable electrostatic interactions.[3] A shorter distance has been observed with a less repulsive N/C face-to-face alignment between two s-triazine rings.[30]

The most fascinating feature of this supramolecular species is its ability to encapsulate two chloride anions. Indeed, Cl5 and Cl6 are the guests of two host cavities formed by four pyridine rings of the ligand (Figure 1). The centroid⋯Cl$^-$ distances vary from 3.521(6) to 3.559(5) Å for Cl5, and from 3.466(5) to 3.697(5) Å for Cl6. These distances are longer than the values calculated for the model s-triazine anion.[17,19] Unfortunately, no theoretical investigations are yet available for the pyridine ring, which is a much less electron deficient aromatic ring, but one would reasonably expect longer ring–anion bonds. The anion–π interactions observed here are favored by the fact that the pyridine rings involved are coordinated to copper ions, which enhances their electron-poor character. In addition to the π interaction, the chloride ions are close to the neighboring triazine rings. Indeed, the Cl5⋯N92 and Cl6⋯N106 distances of 3.013(12) and 3.119(13) Å, respectively, suggest some electrostatic interactions between the guest anions and the electron-deficient triazine rings. The combination of both electronic effects confers electrophilic character on the host cavity. The angles of the Cl$^-$⋯centroid axis to the plane of the different pyridine rings are 78 and 80° for Cl5, and 74 and 82° for Cl6. The ideal anion–aromatic plane angle of the extensively studied s-triazine moiety is 90°. However, again, no theoretical calculations have been performed on the pyridine ring, and thus the optimal angle has not yet been determined.

In summary, the first coordination compound of the ligand azadendtriz is reported. The supramolecular copper complex **1** shows unusual intramolecular π–π interactions between 1,3,5-triazine rings. Furthermore, this tetranuclear complex exhibits host–guest properties, and the first encapsulation of a chloride anion by four pyridine rings is described, which demonstrates the possible existence of anion–π interactions. The encapsulation of the bromide anion is currently being investigated. A theoretical approach to study this non-hydrogen bonding artificial anionic receptor is also proposed. Understanding how nature can selectively bind, functionalize, and transport anionic species in biological systems would undoubtedly be of great importance for the design of new drugs.

branes[7] or zeolites[8] where the templated polymerization of aniline occurs in the 1-D nanochannels. Films containing polyaniline nanofibers can also be made by using electrospinning[9] or electrochemical methods to control the polymerization rate.[10–12] Nanostructures of polyaniline are of great current interest since they combine the properties of low-dimensional organic conductors with high surface area materials. This situation can lead to enhanced properties in applications such as chemical sensors.[13–16]

Recently we have developed a general chemical route to polyaniline nanofibers by using interfacial polymerization at an aqueous/organic interface.[15,17] The reactants—aniline, ammonium peroxydisulfate, and a doping acid such as HCl—are separated by the interface between an organic solvent containing aniline and an aqueous phase containing the oxidant plus the doping acid. The polyaniline product, polymerized at the interface, contains almost exclusively nanofibers with relatively uniform diameters. The nanofiber diameter is determined by the doping acid used in the polymerization.[17] This synthesis is very general and does not require any template, special dopant, or specific solvent. Careful analysis of polyaniline made in a conventional single-phase polymerization reaction by microscopy have shown the presence of a small amount of nanofibers.[17] This observation indicates that the formation of nanofibers is not necessarily determined by the interface but more likely by the nature of the oxidative polymerization of aniline. To more fully understand the formation mechanism of polyaniline nanofibers, several important questions need to be addressed. These include: 1) Why does interfacial polymerization produce "pure" nanofibers while conventional synthesis produces irregularly shaped particles? 2) Why can small amounts of nanofibers be found in polyaniline made by conventional synthesis? 3) Why does polyaniline form such extended, elongated fiberlike nanostructures? Herein we provide answers to these questions by reporting experimental results on the factors affecting the morphology of chemically polymerized polyaniline.

To address the first question we studied the morphological evolution of polyaniline during traditional chemical oxidative polymerization. A solution of the oxidant ammonium peroxydisulfate dissolved in 1M HCl was fed continuously into a solution of aniline dissolved in 1M HCl by using a syringe pump at a preset flow rate. This procedure is analogous to the "drop by drop" titration used in traditional synthesis (Figure 1) but with a precisely controlled feeding rate. The reaction vessel was kept in an ice bath at between −5 and 0 °C. Small amounts of product for transmission electron microscopy (TEM) studies were periodically extracted from the reaction bath as soon as the green color of polyaniline was visible. At this point, the samples were immediately diluted with distilled water, cast onto TEM grids, and dried in air to quench the polymerization. Polyaniline nanofibers form at an early stage in the polymerization process (Figure 2a). These nanofibers have average diameters of 30–35 nm, which is consistent with those obtained using interfacial polymerization.[17] As more ammonium peroxydisulfate is fed into the reaction, the nanofibers become scaffolds for secondary growth of polyaniline (Figure 2b) and finally turn into

Nanofiber Formation in the Chemical Polymerization of Aniline: A Mechanistic Study**

*Jiaxing Huang and Richard B. Kaner**

Polyaniline is unique among conducting polymers because of its simple nonredox doping/dedoping chemistry based on acid/base reactions.[1,2] The conventional chemical oxidative polymerization of aniline is carried out in an aqueous solution in which aniline is dissolved in a strong acidic solution (for example, 1M HCl) at about 0 °C and the polymerization is initiated by adding an oxidant (for example, ammonium peroxydisulfate) into the solution.[1] Polyaniline nanostructures, such as nanofibers/-wires/-rods/-tubes, can be made by introducing "structural directors" into the chemical polymerization bath. These structural directors include "soft templates" such as surfactants,[3] organic dopants,[4,5] or polyelectrolytes[6] that assist in the self-assembly of polyaniline nanostructures, and "hard templates" such as porous mem-

Figure 1. Schematic diagram illustrating the formation of polyaniline agglomerates during conventional chemical synthesis. a) The oxidant (open circles) dopant solution is added slowly to the aniline (solid circles) dopant solution. b) Polyaniline nanofibers form as soon as the polymerization begins. Since the nanofibers are exposed to aniline and oxidant, they are subject to secondary growth. c) Agglomerates of polyaniline particles plus a few nanofibers are found because of severe secondary growth.

irregularly shaped agglomerates containing nanofibers and particulates (Figure 2c). The whole process is illustrated schematically in Figure 1. Therefore, if secondary growth can be suppressed, the yield of nanofibers in the final product could be greatly increased.

Interfacial polymerization represents one effective method to suppress secondary growth (Figure 3).[17] Since the monomer aniline and the initiator ammonium peroxydisulfate are separated by the boundary between the aqueous and the organic phase, polymerization occurs only at this interface where all the components needed for polymerization come together.[14,15,17] Polyaniline then forms as nanofibers. Since these newly formed nanofibers are in the doped emeraldine salt form, they are hydrophilic and can rapidly move away from the interface and diffuse into the water layer (Figure 3b). In this way, as the nanofibers form they are continuously withdrawn from the reaction front, thus avoiding secondary growth and allowing new nanofibers to grow at this interface. This effect explains why nanofibers are obtained no matter which solvent is used as the organic phase in interfacial polymerization. Hence, the interface between the immiscible aqueous/organic layers does not contribute directly to the formation of nanofibers; it simply separates nanofiber formation from secondary growth.

With the knowledge that the key to synthesizing polyaniline nanofibers is preventing secondary growth, we have now designed a new, even simpler method to make pure polyaniline nanofibers (Figure 4). The idea is that if all the reactants can be consumed during the formation of nanofibers, secondary growth will be greatly suppressed since no reactants will be available for further reaction. To achieve this goal, the initiator solution (ammonium peroxydisulfate in 1M HCl) was added into the monomer solution (aniline in 1M HCl) all at once (Figure 4a), rather than slowly feeding it in by titration or syringe-pumping. Sufficient mixing can be achieved with a magnetic stirrer or shaker to evenly distribute the initiator and monomer molecules before polymerization
Figure 2. Typical TEM images showing the morphological evolution of polyaniline during chemical oxidative polymerization in 1 M HCl at about 0 °C. The samples were extracted: a) as soon as the green color of polyaniline became visible, b) after 25 minutes, and c) after 100 minutes.

(Figure 4b). As the polymerization begins, the initiator molecules induce the formation of nanofibers by rapidly polymerizing aniline monomers in their vicinity. Therefore, all the initiator molecules are consumed to form polyaniline nanofibers, thus suppressing the secondary growth of polyaniline. The product from a fast-mixing reaction in an ice bath is
Figure 3. A schematic illustration of the synthesis of polyaniline nano-fibers by using interfacial polymerization. a) An interface is set up between an organic phase containing dissolved aniline (solid circles) and an aqueous phase containing the oxidant (open circles). b) Poly-aniline nanofibers form at the interface, where aniline meets the oxi-dant and diffuse into the water phase. Note that this carries the nano-fibers away from the reactive interface so they are not subject to fur-ther secondary growth. c) As the polymerization proceeds, nanofibers accumulate in the aqueous phase.
Figure 4. A schematic illustration of the synthesis of polyaniline nano-fibers in a rapidly mixed reaction. a) The oxidant (open circles) dopant solution is quickly added into the aniline (solid circles) dopant so-lution and mixed. b) A homogenous solution is obtained where all the aniline and oxidant molecules are evenly distributed, thus leading to fast polymerization across the entire solution. c) Since all the reactants are consumed in the formation of nanofibers, secondary growth is sup-pressed.

Figure 5. SEM images showing the morphology of polyaniline synthe-sized from a) a rapidly mixed reaction and b) a slowly mixed reaction. High-quality nanofibers are obtained in the rapidly mixed reaction, while irregular agglomerates form in the slowly mixed reactions.

almost exclusively polyaniline nanofibers of uniform sizes as observed using scanning electron microscopy (SEM; Fig-ure 5a). The nanofibers formed are similar to those obtained by interfacial polymerization. In contrast, agglomerates of nanofibers and irregular particulates are produced by using traditional slow-mixing reactions (Figure 5b). Comparable results are obtained when monomer solution is fed into the initiator solution.

Reactions that are rapidly mixed using other doping acids, including sulfuric, camphorsulfonic, and perchloric acids also produce "pure" nanofibers with comparable shapes and sizes to those made by interfacial polymerization.[17] Fast-mixing reactions carried out at different temperatures, including in an ice bath (ca. 0°C), at room temperature (ca. 20°C), and at 100°C, all yield high-quality nanofibers. When the reactant concentrations are increased, the induction time of the reaction is reduced, but no apparent difference in the morphology of the product is observed. It is now clear that nanofibers of polyaniline form naturally during chemical oxidative polymerization in aqueous solutions. By suppress-

ing the secondary growth of irregular particles, either through interfacial polymerization or rapid-mixing reactions, essen-tially pure polyaniline nanofibers can be obtained without the need for any templates or seeds.[18] Nanofibers appear to be a basic morphological unit for chemically polymerized polyani-line as they are for polyacetylene.[19]

The next question is why does polyaniline favor an elongated, well-extended 1-D nanofiber morphology in water? The successful rapid-mixing reaction route to making polyaniline nanofibers in water is also applicable to other solvents, which is difficult to do using interfacial polymerization. Figure 6 shows the morphology of polyani-line obtained through rapid-mixing reactions in water, ethanol, and isopropanol at room temperature. Well-defined, relatively long nanofibers are created in water (Figure 6a). The product formed in ethanol is a mixture of short nano-fibrils with many irregular particles attached to them (Fig-ure 6b). The reaction in isopropanol produces only agglom-erates of 100–300-nm particulates with no discernable nano-

Figure 6. Typical TEM images showing the morphology of polyaniline obtained in different solvents through rapidly mixed reactions in a) water, b) ethanol, and c) isopropanol.

In summary, polyaniline preferentially forms as nanofibers in aqueous solution during chemical oxidative polymerization. The nanofibers produced in the early stage of polymerization during slow-feeding reactions are subject to secondary growth, which leads to the large agglomerates containing irregularly shaped particles and nanofibers. Pure nanofibers can be obtained by preventing the secondary growth. In interfacial polymerization secondary growth is suppressed when freshly formed nanofibers diffuse away from the reactive interface. Secondary growth is limited in rapid-mixing reactions by quickly consuming the reactants during the initial polymerization. Rapid-mixing reactions in less-polar solvents produce less-perfect nanofibers, which indicates that water is the best solvent for the synthesis of nanofibers. The rapid mixing reaction route is an even simpler method than interfacial polymerization to make polyaniline nanofibers, especially on a laboratory scale where sufficient mixing can be easily achieved by stirring or shaking before the polymerization starts. This mechanistic study may offer important insights into the synthesis of other conducting polymer nanostructures. It may also help to explain the variation in the properties of polyaniline made in different reactions, since the rate of addition of reactants affects the final morphology, thus resulting in different fractions of nanofibers in the final product.

Experimental Section

Synthesis and purification: All chemicals were of analytical grade and used as received. Reactions were generally carried out in 20-mL vials. Typically, an aqueous solution of aniline (3.2 mmol) in 1M doping acid (10 mL) and another solution of ammonium peroxydisulfate (0.8 mmol) in the same doping acid (10 mL) were prepared and mixed using a syringe pump. HCl was used as the dopant unless otherwise mentioned. The feeding rate of one solution into another was set at 5 mL h^{-1} so that it took 2 h to completely feed into the solution. Reactions were carried out at different temperatures: ca. 0°C (using an ice bath), ca. 20°C (at room temperature), and at ca. 100°C (using boiling water). Sulfuric acid was used as the dopant for reactions at ca. 100°C because of its thermal stability. Rapid-mixing reactions were performed by pouring the two solutions together and immediately stirring or shaking to ensure sufficient mixing before polymerization begins. Polymerization can be observed when the characteristic green color of polyaniline emeraldine salt became visible. More reactions were carried out by increasing or decreasing the reactant concentrations by 10 times; in all cases uniform nanofibers were observed. For reactions in ethanol and isopropanol, the monomer and ammonium peroxydisulfate solutions were prepared in the solvent. Solutions of 1M HCl in ethanol and isopropanol were prepared by diluting a concentrated aqueous solution of HCl (12.1M) with the corresponding alcohols. The products were purified by centrifugation using the reaction solvent until the suspension reached a neutral pH value.

Morphology: The morphologies of the product were examined by TEM (JEOL 100CX) and SEM (JEOL 6700). For the morphological evolution experiments (Figure 2), samples (0.1 mL) were extracted from the reaction at different times and diluted immediately in distilled water (0.5 to 2 mL). An appropriate amount of this suspension was then cast onto copper TEM grids (Formvar coated, 300 mesh, Ted-Pella Inc.). The grids were placed on filter paper to absorb any extra suspension and facilitate rapid drying, therefore quenching the polymerization. Other TEM samples were prepared by diluting the purified products and casting suspensions onto TEM

fibers. Note that since the as-prepared polyaniline is in its doped, hydrophilic emeraldine salt form, the affinity of the polyaniline salt for the solvent will decrease from water to ethanol to isopropanol as the polarity decreases. Therefore, it is not surprising that polyaniline favors more compact morphologies in ethanol and isopropanol, while in water elongated 1-D nanofibers form.

grids. Samples for SEM experiments were made on conducting stages and observed without gold coatings.

Natural Products Synthesis

Total Synthesis of Apicularen A through Transannular Pyran Formation**

*Andreas F. Petri, Alexander Bayer, and Martin E. Maier**

Natural products that show cytotoxic effects are important in cancer treatment. As resistance can occur, and not all tumor cells are equally sensitive to a certain drug, there is a need for compounds that have novel modes of action. Such compounds include the benzolactone enamides,[1] for example, apicularen A (**1**) and salicylihalamide A (**2**). Salicylihalamide A was

apicularen A (**1**)   salicylihalamide A (**2**)
isolated from the sponge *Haliclona* sp.,[2] whereas apicularen A has been found in various myxobacteria strains.[3] Both compounds were shown to be selective inhibitors of mammalian V-ATPases, which are important as proton pumps for regulating intracellular pH.[4] Depending on the cell type studied, other downstream effects were observed, such as the phosphorylation of mitogen-activated protein kinases, which results in apoptosis.[5,6] The structure of apicularen A is characterized by the salicylic acid portion, a *trans* tetrahydropyran embedded in a macrolactone, and an enamide side chain. Several total syntheses of apicularen A,[7] formal total syntheses,[8] and synthetic studies[9,10] have been reported.

Some time ago we proposed that the pyran ring of apicularen A is probably formed by a transannular reaction of a macrolactone precursor through the opening of an epoxide or addition to an enone.[10a] Herein we describe the application of the transannular etherification strategy for the total synthesis of apicularen A (**1**).

As described previously,[10b] the dithiane **3**, the epoxides **4** and **5**, and trimethylsilylacetylene (**6**) were combined in a four-component coupling[11,12] to give the alkyne **7**

(Scheme 1). Hydrolysis of the dithiane and desilylation yielded a β-hydroxyketone, which was converted by *syn* reduction and acetalization into the alkyne **8**.
Scheme 1. Synthesis of the alkyne **8** by a four-component coupling strategy. Bn = benzyl, TBDMS = *tert*-butyldimethylsilyl.

The conversion of the alkyne **8** into a suitable vinyl metal species for cross-coupling turned out to be quite challenging (Scheme 2). For example, the palladium-catalyzed hydro-
Scheme 2. Synthesis of the vinylstannane **11** via an intermediate vinyl borane: a) *n*Bu₃SnH, AIBN (cat.), toluene, reflux (56%); b) (C₆H₁₁)₂BH, THF, 0°C, 1 h; c) NaOH, [Cu(acac)₂] (cat.), *n*Bu₃SnCl, −15→23°C (>93%).

stannylation[13] of **8** gave an inseparable mixture of the internal and terminal stannane. The hydrostannylation under radical conditions led to the tetrahydrofuran **9** through an atom-transfer and cyclization process. This difficulty was overcome by generation of the vinyl borane **10**[14] followed by transmetalation to the stannane **11**.[15] In this way the vinyl stannane was obtained exclusively as the *E* isomer in excellent yield.

The subsequent cross-coupling reaction of the triflate **12**[10a] with the stannane **11** proceeded smoothly to furnish the salicylate **13** in excellent yield (Scheme 3). Hydrolysis of the acetal and ester functionalities then gave the dihydroxy acid **14**. As we had observed in this and related cases,[10] the size-selective macrolactonization under Yamaguchi conditions[16] gave selectively the larger of the two macrolactones, but the chemical yield was only in the range of 50%. Therefore, the method of Trost and Chisholm was investigated.[17] In this case, an ethoxyvinyl ester, prepared by the ruthenium-catalyzed addition of the carboxylic acid **14** to ethoxyacetylene, serves as the precursor. The best results for the macrolactonization were obtained at 80°C (5 mM, 63%
Scheme 3. Cross-coupling, size-selective macrolactonization, and transannular etherification to yield the building block *trans*-**18**: a) P(furyl)₃, [Pd₂(dba)₃], LiCl, NMP, 60°C, 48 h (93% from **8**); b) 80% AcOH, 23°C, 80 min (99%); c) LiOH, MeOH/H₂O, 60°C, 72 h (99%); d) [{RuCl₂(*p*-cymene)}₂], ethoxyacetylene, toluene, 0°C; e) CSA, toluene, 80°C (63% from **14**); f) Hg(O₂CCF₃)₂, CH₂Cl₂, 23°C, 30 min, then NaCl, 23°C; g) Et₃B, LiBH₄, THF, −78°C, 1 h (89% from **16**). CSA = camphorsulfonic acid, NMP = 1-methyl-2-pyrrolidinone, Tf = trifluoromethanesulfonyl.

yield). In contrast to the results of our previous model study,[10a] the treatment of the macrolactone **16** with *N*-(phenylseleno)phthalimide left the starting material unchanged.[18] Eventually, it was found that treatment with mercuric trifluoroacetate in dichloromethane gave the cyclized organomercurial intermediate within minutes. To suppress the undesired retrocyclization[19] of the mercurial intermediate during the reductive demercuration, it was necessary to change the solvent from CH₂Cl₂ to THF and to perform the reduction with LiBH₄ in the presence of Et₃B.[20] The origin of the high selectivity in the transannular ether-ification has not yet been clearly ascertained. However, on the basis of previous work, we believe that the transition state of the kinetically controlled reaction is productlike, thus leading to the less strained product.[8d, 10a]

The synthesis continued with the cleavage of all ether protecting groups with 9-iodoborabicyclononane (9-I-9-BBN; Scheme 4).[21] A sequence of complete silylation and selective desilylation generated the primary alcohol **20**, which was oxidized to the aldehyde **21**[7c] with tetra-*n*-propylammonium perruthenate (TPAP).[22] The stage was set for the attachment of the enamide side chain.[23] The addition of the aluminum carboximidoate derived from the amide **22**[23b] and diisobutyl-aluminum hydride[24] to the aldehyde **21** provided the hemi-aminal **23** in 86% yield (1:1 mixture of diastereomers). When a solution of the hemiaminal **23** in THF was heated at reflux in the presence of acetic anhydride and pyridine, the enamide **24** was obtained as a separable *E/Z* mixture (*E/Z* = 75:25). The removal of the silicon protecting groups from (*E*)-**24** with
Scheme 4. Synthesis of apicularen A via the hemiaminal **23**: a) 9-I-9-BBN, CH$_2$Cl$_2$, 23 °C, 90 s, MeOH; b) TBDMSCl, imidazole, DMAP (cat.), DMF, 23 °C, 48 h (72 % from **18**); c) CSA (cat.), CH$_2$Cl$_2$/MeOH, 0 °C, 3 h (85 %); d) TPAP, NMO, 0 °C, 1 h (98 %); e) **22**, DIBAL, THF, 0 °C, 30 min, add **21**, 0 °C, 18 h (86 %); f) THF, pyridine, Ac$_2$O, reflux, 48 h ((*E*)-**24**: 46 %, (*Z*)-**24**: 15 %); g) TASF, DMF, 23 °C, 21 h (75 %). DIBAL = diisobutylaluminum hydride, DMF = *N,N*-dimethylformamide, NMO = 4-methylmorpholine *N*-oxide, TASF = tris(dimethylamino)sulfonium difluorotrimethylsilicate.

TASF[25] gave pure apicularen A (**1**). Another method for the conversion of an aldehyde into the corresponding enamide via a bisamide derivative through a base-induced elimination[26] proved unsuccessful in the case of apicularen.[7b,c]

In summary, we have developed a concise total synthesis of apicularen A, featuring a number of key transformations: a) a four-component coupling that combines a 1,3-dithiane, a terminal epoxide, an acetylide, and epichlorohydrin, b) a Stille cross-coupling reaction with the vinylstannane generated from a vinylborane, c) a size-selective macrolactonization of an ethoxyvinyl ester, d) a transannular etherification, and e) formation of the enamide from a hemiaminal. This successful strategy underscores the close relationship between salicylihalamide and apicularen.

Unusual Reactivity of a Nickel N-Heterocyclic Carbene Complex: *tert*-Butyl Group Cleavage and Silicone Grease Activation**

Stephen Caddick,* F. Geoffrey N. Cloke,*
Peter B. Hitchcock, and Alexandra K. de K. Lewis

During the past decade there has been considerable interest in N-heterocyclic carbene ligands (NHCs), particularly as alternative to phosphanes for both palladium-[1] and ruthenium-mediated[2] catalysis of a range of organic transformations. Recently, the use of Ni^{II}/imidazolium salt/base or Ni^0/ NHC combinations for catalytic aminations, in which the active catalyst is believed to be a Ni^0–NHC complex, has also been described.[3] Our interest in this area to date has focused on the use of isolated, two-coordinate bis(NHC) palladium(0) complexes for catalytic amination[4] and mechanistic studies; in the latter context we have recently reported a detailed mechanistic study on the oxidative addition of 4-chlorotoluene to bis(1,3-bis-*tert*-butylimidazol-2-ylidene)palladium.[5] Thus we were interested in extending such studies to the nickel analogue, and herein we report the highly unusual reactivity associated with the attempted conventional synthesis of bis(1,3-bis-*tert*-butylimidazol-2-ylidene)nickel.

We have already reported the preparation of [Ni{C(N*t*-BuCH)$_2$}$_2$] (**1**) by metal vapor synthesis (MVS), although the compound was not structurally characterized at that time.[6] We have now determined the structure of **1** (Figure 1).

Ardeungo et al. have reported the molecular structure of an analogue of **1** derived from 1,3-bis-mesitylimidazol-2-ylidene, synthesized by the treatment of [Ni(1,5-cod)$_2$] (COD = cyclooctadiene) with the free NHC.[8] Comparison of **1** with the former shows that both structures display linear geometry around the nickel center, although the nickel–carbene bond length is slightly longer in **1** (1.874(2) Å for **1**, compared to 1.827(6) Å). However, they differ in that the planes of the ligands in **1** are twisted 75° from coplanarity whereas in the Arduengo complex the twist angle is 53°. The bonding in such compounds is predominantly σ in nature, with minimal π bonding,[9] so the twist angle is almost certainly

Figure 1. ORTEP diagram of **1** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles[°]: Ni-C(1) 1.874(2); N(1)-C(1)-N(1) 102.25(15).[7]

governed by subtle steric interactions and/or crystal packing forces in the solid state. In solution, NMR spectroscopy studies on asymmetrically substituted bis(NHC)-Group 10 M^0 indicate rapid rotation about the metal–carbene bond on the NMR timescale down to −90°.[10]

Since we wished to develop a conventional, solution-phase route to **1**, [Ni(1,5-cod)$_2$] was treated with an excess of 1,3-bis-*tert*-butylimidazol-2-ylidene in THF in a Schlenk tube sealed with a greased stopper. After a two-week reaction time, work-up and crystallization from hexane afforded purple crystals of [{Ni[C(N*t*BuCH)$_2$][O(Me$_2$SiOSiMe$_2$)-μ-O]}$_2$] (**2**; Figure 2) in low yield.
Figure 2. ORTEP diagram of **2** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: Ni-C(1) 1.883(6), Ni-O(1) 1.958(4), Ni-O(1′) 1.896(4), Ni-O(3) 1.839(4); N(1)-C(1)-N(2) 105.2(15).[7]

The structure reveals a dinuclear nickel(II) complex, with distorted square-planar geometry about nickel, in which the two metal centers are bridged by disiloxane units derived from silicone grease (see Scheme 1). The central $Ni_2(\mu\text{-O})_2$ core is folded by 21° out-of-plane about the O–O axis, with the bond lengths of the asymmetric μ-O bridges, Ni-O(1) 1.958(4), Ni-O(1′) 1.896(4) Å, comparable to those found in the μ-O unit in [{Ni[C(SiMe$_3$)(2-SiMe$_2$C$_5$H$_4$N)(SiMe$_2$O)]}$_2$] (1.918(4), 1.891(45) Å);[11] the non-bridging oxygen–nickel bond length in **2** (Ni–O(3) 1.839(4) Å) is very close to that in [Ni(η²-OCHMeCH$_2$NMe$_2$)$_2$] (1.829(3) Å).[12] The nickel–carbene Ni(1)–C(1) bond length (1.883(6) Å) in **2** is identical to that in **1** (within estimated standard deviations (esds)),

despite the change in nickel oxidation state. Serendipitous activation of silicone grease by lanthanides and early transition metals is not uncommon, but rare for late transition metals and unprecedented for nickel.[13]

The reaction of [Ni(1,5-cod)$_2$] with 1,3-bis-*tert*-butylimidazol-2-ylidene in THF was repeated in greaseless apparatus for two weeks, which resulted in the isolation of deep blue, crystalline **3** (see Scheme 1), whose X-ray structure is shown in Figure 3.
Figure 3. ORTEP diagram of **3** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: Ni(1)-C(1) 1.960(5), Ni(2)-C(12) 1.954(5), Ni(2)-C(23) 1.927(5), Ni(1)-C(30) 1.922(5), Ni(1)-N(6) 1.900(5), Ni(2)-N(8) 1.904(5), Ni(1)-Ni(2) 2.4354(9); N(1)-C(1)-N(2) 102.9, N(6)-C(23)-N(5) 105.9; Σ_{angle} N(5) 360.0, Σ_{angle} N(6) 359.7, Σ_{angle} N(7) 359.8, Σ_{angle} N(8) 359.7.[7]

Compound **3** is a second binuclear species (the first being **2**), in which the two nickel centers are ligated by terminal NHC ligands and symmetrically bridged by *tert*-butylimidazol-2-ylidene ligands arising from *tert*-butyl group cleavage from the parent NHC (see Scheme 1). The Ni–Ni separation of 2.4354(9) Å is consistent with a Ni–Ni single bond,[14] and the compound is accordingly diamagnetic by NMR spectroscopy.[15] The geometry about the nickel centers is square planar with the terminal NHC ligands lying perpendicular to the plane of the Ni$_2$C$_2$N$_2$ central core. The terminal NHC–Ni bond lengths (Ni(1)–C(1) 1.960(5), Ni(2)–C(12) 1.954(5) Å) are considerably longer than that in **1**, owing to the increased steric bulk around the metal centers. Within the bridging NHC-derived ligands, the nickel–nitrogen bond lengths (Ni(1)–N(6) 1.900(5), Ni(2)–N(8) 1.904(5) Å) are in the range of other reported Ni−N single bonds (e.g. [Ni(*t*-Bu$_2$PC$_2$H$_4$P*t*Bu$_2$){N(Ar)H}], 1.881(2) Å;[16] [NiCp*(PEt$_3$){N-(tol)H}], 1.903(5) Å[17] (Cp* = C$_5$Me$_5$)) whilst the carbene carbon–nickel distances (Ni(1)–C(30) 1.922(5), Ni(2)–C(23) 1.927(5) Å) are comparable to those for the terminal NHC ligands in **3** (within esds). The sum of bond angles around the amido nitrogen atoms N(6) and N(8) are essentially 360°.

The reaction to generate **3** was repeated, but halted after five days; work-up afforded mainly starting materials but also a low yield of a new, yellow compound **4** (see Scheme 1). Crystals suitable for X-ray diffraction were obtained from a hexane solution of **4** (Figure 4).
Figure 4. ORTEP diagram of **4** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: Ni-C(1) 1.951(4), Ni-C(12) 2.046(5), Ni-C(13) 2.012(5), Ni-C(21) 2.045(5), Ni-C(20) 2.024(4); N(1)-C(1)-N(2) 103.3(3).[7]

Compound **4** is a 16-electron Ni^0 complex in which the nickel center is ligated by one NHC ligand and two η^2-cycloocta-1,3-diene ligands in a distorted trigonal-planar arrangement. The nickel–olefin bond lengths range between 2.012(5) and 2.046(5) Å, slightly shorter than those in the [Ni(1,5-cod)$_2$] precursor (2.117(5)–2.130(9) Å),[18] but identical (within esds) to those in [Ni(PCy$_3$)(η^2-C$_2$H$_4$)$_2$].[19] As is the case for [Ni(PCy$_3$)(η^2-C$_2$H$_4$)$_2$], in **3** the coordinated C=C axis and the NHC–Ni axis are coplanar. The NHC–Ni bond length (Ni–C(1) 1.951(4) Å) in **4** is significantly longer than that in **1**, and **4** is highly unstable, particularly in solution. NMR spectroscopy studies show that **4** rapidly converts into a new compound **5**, accompanied by the appearance of free 1,3-COD; nOe experiments and mass spectrometry suggested the structure for **5** shown in Scheme 1, resulting from 1,3-COD loss, C−H activation of a *tert*-butyl substituent on the NHC and subsequent H-atom transfer to the bound 1,3-COD to form a cyclooctenyl ligand (Scheme 1). Isolation of orange crystals of **5**, suitable for X-ray diffraction confirmed the structure (Figure 5).

Compound **5** has a distorted square-planar geometry and is a 16-electron diamagnetic Ni^{II} complex. The Ni–C1 bond length (1.905(4) Å) is slightly shorter than that in the precursor **4** (1.951(4) Å) owing to the change in oxidation state and the metal center being less sterically crowded. The bond between Ni and the central allylic carbon C13 is 1.963(3) Å, which is shorter than those between Ni and C12 and C14 (2.108(3) Å and 2.034(4) respectively), as expected. These values are very similar to those of the reported bis(η^3-methallyl)nickel and the C12-C13-C14 bond angle (123.4(3) Å) is only slightly more obtuse than the idealized value of 120°.[20] The Ni−C bond in the C−H activated *tert*-butyl group (Ni−C5, 1.958(3) Å) is identical (within esds), to the Ni−CH$_3$ bond length (1.965(5) Å) in [Ni(*t*Bu$_2$PC$_2$H$_4$-P*t*Bu$_2$)Me$_2$].[21]

The successful isolation of complexes **4** and **5** suggests a mechanism for the formation of **3**, summarized in Scheme 1. The reaction to form the intermediate **4** clearly involves isomerization of 1,5-COD to 1,3-COD, presumably initiated by sunlight—this reaction does not work in the dark and [2+2] cycloaddition of 1,5-COD by radical formation readily occurs under UV irradiation).[22] The conversion of **4** into **5**

Communications
Scheme 1. Formation of compounds **2–5**. Proposed mechanism for the formation of **3** via **4** and **5**.
Figure 5. ORTEP diagram of **5** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: Ni-C1 1.905(4), Ni-C5 1.958(3), Ni-C13 1.963(3), Ni-C14 2.034(4), Ni-C12 2.108(3); N1-C1-N2 103.5(3).[7]

proceeds by rapid loss of a 1,3-COD ligand (detected by NMR spectroscopy) and subsequent activation of a *tert*-butyl group, probably by classic C−H activation to generate a Ni−H species (although no resonance signals for Ni−H were detected by NMR spectroscopy during the reaction) followed by hydride migration to the 1,3-COD ligand. The final formation of **3** then requires addition of 1,3-bis-*tert*-butylimidazol-2-ylidene, elimination of isobutene, and loss of the cyclooctenyl ligand. Evidence for this hypothesis was obtained by treating isolated **5** with excess 1,3-bis-*tert*-butylimidazol-2-ylidene. The reaction was monitored by ¹H NMR spectroscopy. Heating the mixture to 70°C led to the clean formation of **3** and isobutene; however, although the spectrum contained additional peaks in the olefinic and aliphatic regions, the fate of the cyclooctenyl fragment could not be unambiguously deduced.

In conclusion, attempted conventional synthesis of **1** by ligand substitution of [Ni(1,5-cod)₂] with 1,3-bis-*tert*-butylimidazol-2-ylidene leads to *tert*-butyl group cleavage from the NHC via the novel, highly reactive monocarbene bis(olefin) complex **4**; in the presence of vacuum grease, the product is

the disiloxane bridged dimer **2**, an unprecedented example of activation of silicone grease by nickel. Improved synthetic routes to **4** and a study of its reaction chemistry are in progress.

Experimental Section

2: [Ni(1,5-cod)₂] (100 mg, 0.4 mmol), 1,3-bis-*tert*-butylimidazol-2-ylidene (144 mg, 0.8 mmol), THF (35 mL), and a stir bar were added to a Schlenk (100 mL), which was sealed with a stopper coated with silicone vacuum grease. The mixture was left to stir for two weeks at room temperature. The THF was then removed in vacuo; the remaining solid was dissolved in hexane, and the resultant solution collected by filtration, concentrated, and cooled to −25°C to afford bright, purple crystals of **2**. Yield approximately 5%. ¹H NMR (300 MHz, 20°C, [D₆]benzene): δ = 6.33 (4H, s, CH), 3.05 (36H, s, *t*Bu), 0.13 (6H, s, SiCH₃), −0.16 ppm (6H, s, SiCH₃); ¹³C NMR (75 MHz, [D₆]benzene): δ = 143.8 (Ni*C*(N*t*BuCH)₂), 118.6 (NiC(N*t*BuCH)₂), 59.4 (*C*CH₃), 32.8 (C*C*H₃), 2.4 (Si*C*H₃), 1.0 ppm (Si*C*H₃). Elemental analysis (%) calcd for C₃₀H₆₄N₄Ni₂O₆Si₄: C 44.67, H 8.00, N 6.94; found C 44.31, H 7.43, N 7.47.

3: [Ni(1,5-cod)₂] (100 mg, 0.4 mmol) and 1,3-bis-*tert*-butylimidazol-2-ylidene (432 mg, 2.4 mmol) were added to an ampoule (50 mL) equipped with a greaseless stopcock, THF (35 mL) was added through a cannula, and the reaction mixture left to stir for two weeks on the window sill. The THF was removed in vacuo and excess 1,3-bis-*tert*-butylimidazol-2-ylidene removed by sublimation in vacuo onto a liquid nitrogen cooled probe. The remaining solid was dissolved in hexane, and the resultant solution collected by filtration, concentrated, and cooled to −25°C to afford deep blue crystals of **3**. Yield 55 mg, 38% in two crops. ¹H NMR (300 MHz, 20°C, [D₆]benzene): δ = 6.72 (4H, s, CH), 6.37 (2H, d, J = 1.5 Hz, CH), 5.76 (2H, d, J = 1.5 Hz, CH), 2.42 (36H, s, *t*Bu), 1.30 ppm (18H, s, *t*Bu); ¹³C NMR (75 MHz, [D₆]benzene): δ = 193.3 (Ni*C*(N*t*BuCH)₂), 161.9 (Ni*C*(N*t*BuCHCHN)), 127.5 (NiC(N*t*Bu*C*HCHN)), 116.8 (NiC(N*t*Bu*C*H)₂), 111.7 (NiC(N*t*BuCH*C*HN), 57.7 (*C*CH₃), 54.6 (*C*CH₃), 32.5 (C*C*H₃), 31.8 ppm (C*C*H₃). Elemental analysis (%) calcd for C₃₆H₆₂N₈Ni₂: C 59.70, H 8.63, N 15.46; found C 59.55, H 8.73, N 14.87.

4: the synthesis of **3** was repeated, but terminated after 5 days. Extraction with hexane, filtration, concentration, and cooling to −25°C yielded a mixture of starting materials; further cooling of the mother liquors yielded **4** as a yellow, crystalline solid in small amounts

(ca. 10 mg). The extreme thermal instability of **4** precluded further characterization, other than by low-temperature (173 K) X-ray diffraction studies.

5: concentration and further cooling ($-25\,^{\circ}$C) of the mother liquors from the isolation of **3** (see above) afforded orange crystals of **5** in modest (20 %) yield. **5** was also obtained quantitatively from decomposition of a solution of **4** in [D$_6$]benzene at 20 °C over 1 h. ^{1}H NMR (300 MHz, 20 °C, [D$_6$]benzene): $\delta = 6.53$ (1 H, d, $J = 1.8$ Hz, CH), 6.40 (1 H, d, $J = 1.8$ Hz, CH), 5.15 (1 H, t, $J = 8.4$ Hz, CHCHCH), 3.81–3.72 (1 H, q, $J = 8.4$ Hz, CHCHCH), 3.40–3.34 (1 H, q, $J = 8.4$ Hz, CHCHCH), 2.46–2.24 (10 H, br m, CH$_2$), 2.30 (1 H, d, $J = 10.7$ Hz, C(CH$_3$)$_2$CHH), 1.76 (1 H, d, $J = 10.7$ Hz, C(CH$_3$)$_2$CHH), 1.67 (3 H, s, C(CH$_3$)$_2$CH$_2$), 1.47 (3 H, s, C(CH$_3$)$_2$CH$_2$), 1.45 ppm (9 H, s, *t*Bu); ^{13}C NMR (75 MHz, [D$_6$]benzene): $\delta = 184.4$ (Ni*C*(N*t*BuCHCHNC(CH$_3$)$_2$CH$_2$)), 117.1 (NiC(N*t*-BuCHCHNC(CH$_3$)$_2$CH$_2$)), 114.2 (NiC(N*t*BuCHCHNC(CH$_3$)$_2$CH$_2$)), 106.8 (Ni*C*HCHCH), 73.9 (NiCH*C*HCH), 66.1 (*C*(CH$_3$)$_3$), 59.1 (NiCHCH*C*H), 56.7 (Ni*C*H$_2$), 34.6 (C(*C*H$_3$)$_2$CH$_2$), 32.9 (CH$_2$), 32.4 (CH$_2$), 32.2 (C(CH$_3$)$_2$*C*H$_2$), 30.9 (C*C*H$_3$), 30.4 (CH$_2$), 29.9 (CH$_2$), 24.2 ppm (CH$_2$). MS (EI): 346 [M^+], 238 [M^+–cyclooctenyl], 182 [M^+–*t*Bu and cyclooctenyl]. Elemental analysis (%) calcd for C$_{19}$H$_{32}$N$_2$Ni: C 65.73, H 9.29, N 8.07; found C 65.24, H 9.46, N 8.25.

Communications

directed towards the production of supramolecular rods.[3,4] Metalloporphyrin oligomers in various forms can be used as self-assembling blocks to make discrete, ordered arrays.[5,6] These are then combined with other molecules to create supramolecular structures,[7] which have applications as sensors[8] or as nanoporous materials,[9,10] or which exhibit electronic properties that are unique to fully π-conjugated systems of this size.[11,12] We recently developed a modular method for the assembly of metalloporphyrins on surfaces.[13] Herein we report the preparation of surface-confined, axially-linked metalloporphyrin oligomers and aspects of the electronic coupling along the oligomer backbone.

Our experimental approach is outlined in Figure 1 and is detailed in the Experimental Section. In this modular scheme, we used a monolayer of decanethiol, which contained a low
Figure 1. Schematic representation of the modular assembly of ruthenium—porphyrin, (POR)Ru, oligomers onto **1**, which is supported within an alkanethiol monolayer on a Au surface. a) Immersion in a solution of **2** or **3** (1 μM) in toluene for 20 min; b) immersion in a solution of the linker (L), **4** or **5** (1 mM), in toluene for 5 min; steps a) and b) may be repeated to extend the oligomer.

mole fraction of 11-mercaptoundecylisonicotinate (**1**), as the substrate for the chemisorption of a sub-monolayer of metalloporphyrin. Bis(acetonitrile)-*meso*-tetratolylporphyrinatoruthenium(II) (**2**) or bis(acetonitrile)octaethylporphyrinatoruthenium(II) (**3**) were anchored to the surface by the exchange of an axial acetonitrile group for the monolayer-bound isonicotinate group. After attachment of the metalloporphyrin, the remaining axial acetonitrile group was exchanged for a linking bidentate ligand such as *trans*-1,2-bis(4-pyridyl)ethylene (**4**) or pyrazine (**5**). The oligomer was extended by repeating the treatment of the surface-bound conjugate with **2** or **3**, followed by linking with **4**; in such a manner, we prepared oligomers that were up to five repeat units long.

The underlying monolayer of the alkanethiolate and the first monolayer of metalloporphyrin have been characterized extensively by a range of techniques, which include optical ellipsometry, contact angle goniometry, X-ray photoelectron spectroscopy, grazing-angle FT-IR spectroscopy, UV/Vis spectroscopy, and scanning tunneling microscopy.[14] The modular assembly of linkers and metalloporphyrins on top of this substrate was monitored with cyclic voltammetry measurements. Figure 2 shows the cyclic voltammograms of
Figure 2. Cyclic voltammograms (*E* versus SCE) of a) the monomer Au–**1**–**2**–**4** (——); b) the trimer Au–**1**–**2**–**4**–**2**–**4**–**2**–**4** (----); and c) the pentamer Au–**1**–**2**–**4**–**2**–**4**–**2**–**4**–**2**–**4** (•••••). Scan rate: 0.8 V s^{-1}.

ruthenium-based oxidation and reduction processes in the surface-bound monomer, trimer, and pentamer of **2** linked with **4**. The formal potential of each additional conjugate as another metalloporphyrin is added to the oligomer is similar to that of the original isonicotinate-bound monomer. Integration of the charge under the wave at $E = +0.35$ V allowed the surface coverage of this one-electron couple to be calculated. The surface coverage of **2** in Figure 2a corresponds to 3.4 μC cm^{-2}, that is, 50% of a compact, non-overlapping metalloporphyrin monolayer.[13] The surface coverage of the first layer of chemisorbed metalloporphyrin was controlled by the variation of the mole fraction of **1** in the underlying alkanethiol monolayer. After a further four cycles of the modular assembly process (Figure 2c), five tiers of metalloporphyrin were present on the surface. The resulting coverage, which is based on the total number of immobilized metalloporphyrins in the stacks, corresponded to 225% of the coverage for a single close-packed monolayer.

A control experiment was performed in which an electrode was subjected to five sequential treatments of **2** according to step a in Figure 1 without intervening treatment with the linker (step b). This showed that further added metalloporphyrin units formed oligomer stacks, rather than inserting into unoccupied **1** sites on the underlying monolayer. As illustrated in Figure 3, the final surface coverage of the five-layer control assembly of **2** was identical to that of the monomer. This control experiment shows that further elec-

Figure 4. Cyclic voltammograms (*E* versus SCE) of Au–**1**–**2**–**4**–**3**–**4** (——) and Au–**1**–**3**–**4**–**2**–**4** (·····) dimers. Scan rate: 0.4 Vs⁻¹.

troactive material arised from the elongation of the oligomer, rather than from an increased coverage in the chemisorbed metalloporphyrin monolayer or by the physisorption of the metalloporphyrin onto the original chemisorbed layer.

The electrochemical properties of the oligomer are strongly influenced by the mole fraction of **1** in the underlying alkanethiol monolayer and by the choice of the linking ligand. At higher mole fractions of **1**, a second oxidation wave at $E = +0.65$ V becomes more prominent which eventually yields an integrated area of $\approx 30\%$ of the larger peak observed at $E = +0.35$ V. The increased prominence of this secondary oxidation peak at higher surface coverages of the metalloporphyrin is attributed to the incomplete electrostatic screening of the charge on the oxidized metalloporphyrins in the solvent of low dielectric constant employed here. At higher surface coverages, a greater fraction of unoxidized, neutral metalloporphyrins have a large number of oxidized, cationic nearest-neighbors during the oxidation process; the electrostatic work required to oxidize a neutral metalloporphyrin in an environment of poorly screened positive charge is greater than that required to oxidize an isolated neutral metalloporphyrin.

By the use of a shorter linking ligand such as pyrazine (**5**), a similar effect was observed. Incomplete screening and neutralization of the charge along the backbone of the oxidized metalloporphyrin led to an additional wave of fractional area at more-positive potential. In the case of **5**-linked homogeneous trimers, we observed up to three additional waves. Similar additional waves were observed in the solution-based cyclic voltammetry analysis of axially-linked metalloporphyrin oligomers of undefined length.[1,2,15,16] Whereas the observation of these waves has been taken as evidence of multivalence effects,[15] we believe that these additional waves result from electrostatic artifacts.

Heterogeneous surface-confined metalloporphyrin dimers can also be produced with our modular assembly method. Figure 4 shows the near-identical cyclic voltammo-

grams for the Au–**1**–**2**–**4**–**3**–**4** and Au–**1**–**3**–**4**–**2**–**4** dimers. The waves at $E = +0.14$ and $+0.36$ V correspond to ruthenium-based redox chemistry at **3** and **2**, respectively. The surface coverage of each of the metalloporphyrins is $\approx 1.9\ \mu\mathrm{C\,cm}^{-2}$, which corresponds to 25% of a compact monolayer. In both cases **3** is oxidized before **2**, regardless of their relative positions in the stack. In a similar fashion, on the return scan **2** is always reduced before **3**. Let us consider the Au–**1**–**2**–**4**–**3**–**4** dimer under an oxidative scan: The first electron-transfer event corresponds to the tunneling of an electron from the outer metalloporphyrin **3** through the linking ligand, the inner metalloporphyrin, and the backbone of the alkane chain to the underlying Au surface at the formal potential of **3**. This event is independent of the identity or the oxidation state of the inner metalloporphyrin **2**. In other words, neither of these structures exhibits current rectification, which is observed in less-tightly coupled systems;[17,18] these structures are not viable redox-switched molecular diodes.
Whereas the present solvent system is not ideal for studying the kinetics of the electron-transfer processes, the minimal splitting of the peak at elevated scan rates suggests facile electron-transfer kinetics. Also, it suggests that the electronic coupling along the backbone of the alkanethiolate is at least as strong as that of $[\mathrm{Ru(NH_3)_5}]^{2+}$ coordinated to pyridine-terminated alkanethiolates of a comparable length to those employed here.[19–21] Furthermore, the lack of any marked decrease in the rate of transfer of an electron from the outer metalloporphyrin relative to the inner metalloporphyrin argues that the coupling between the two metalloporphyrins by the fully conjugated linker is significantly stronger than that offered by an alkane chain of similar length. For reference, fully conjugated, ferrocene-terminated oligophenylenevinylenes display no decrease in their rates of electron-transfer owing to electronic coupling over distances up to 2.8 nm.[22]

As shown in Figure 2, any differences in the formal potentials for metalloporphyrins within the homogeneous oligomer linked with **4** are smaller than we can resolve with cyclic or square-wave voltammetry. On the basis of the

Communications

minimal peak broadening (as measured by the full width at half maximum) that is observed upon moving from the monomer to the pentamer, we estimate the differences in formal potential to be less than 0.06 V, which corresponds to an upper limit of 10 for the conproportionation constant[23] associated with the reaction (POR represents the porphyrin and L represents the linker):

$$Ru^{II}(POR)-L-Ru^{II}(POR) + Ru^{III}(POR)-L-Ru^{III}(POR) \rightleftharpoons$$
$$2 Ru^{II}(POR)-L-Ru^{III}(POR) \qquad (1)$$
This means that the electronic coupling contribution between the metal centers in the dimer is small and it falls into the Robin–Day class I or a weak-interaction regime.[24] However, as the outer metalloporphyrin can be oxidized regardless of the oxidation state of the inner metalloporphyrin (see Figure 4), the electronic communication along the backbone of the oligomer chain from the outer metalloporphyrin, through the inner metalloporphyrin, along the supporting alkane chain, and into the underlying gold substrate can still be considered as substantial.

In conclusion, we have presented a modular method for the assembly of surface-confined metalloporphyrin oligomers. Such structures exhibit electronic communication along their backbone and offer the potential to control charge transfer over long distances. This is of interest for materials or sensing applications, especially when interfacing with a surface is a concern.

Experimental Section

Compounds 1,[25] 2, and 3[14] were prepared according to reported methods. Polycrystalline Au electrodes were evaporated onto titanium-coated silicon substrates, and then the conjugates were cleaned by immersion in a solution of H_2SO_4:30% aqueous H_2O_2 (3:1 v/v) for 10 s and rinsed with deionized water and ethanol, immediately before use. Supported monolayers of 1 were formed by the immersion of the clean Au electrodes into a solution of decanethiol (1.25 mM) and 1 (0.2 equiv) in ethanol. The electrodes were rinsed with ethanol and blown dry with nitrogen prior to transfer to a glove box. The first monolayer of 2 or 3 was chemisorbed to the electrodes in a solution of the metalloporphyrin (1–3 µM) in toluene for 20 min under a nitrogen atmosphere, and the assembly was rinsed with toluene. The distal axial ligand was exchanged in a solution of 4 (1 mM) or pyrazine (5, 1 mM) in toluene for 5 min, and the assembly was again rinsed in toluene. Subsequent additions to the oligomer were performed in a similar fashion. Electrochemistry was performed on the benchtop under air with a Princeton Applied Research model 263 potentiostat and model 250 software by using a cell that was formed by pressing a bored-out cone of poly(tetrafluoroethylene) against the electrode. A platinum counter electrode and a silver quasi-reference electrode were used with a solution of tetrabutylammonium hexafluorophosphate (0.1M) as the supporting electrolyte in CH_2Cl_2. Potentials were checked periodically with a saturated calomel reference electrode (SCE), which was sheathed in the supporting electrolyte and separated from the cell by a cracked-bead junction.

Metallocryptands

Arsenic–π Interactions Stabilize a Self-Assembled As₂L₃ Supramolecular Complex[**]

*W. Jake Vickaryous, Rainer Herges, and
Darren W. Johnson**

The self-assembly of supramolecular coordination compounds has resulted in structures with a diverse range of properties, shapes, sizes, and stoichiometries, including helicates (M_2L_2, M_2L_3, etc.), triangles (M_3L_3), squares (M_4L_4), rings (e.g., M_6L_6), and polyhedra (M_4L_4, M_4L_6, M_6L_6, M_8L_{12}, etc.).[1] These assemblies almost exclusively contain metals with square-planar, tetrahedral or octahedral coordination geometries. Metals that can exhibit more peculiar coordination geometries have typically been avoided as components for a supramolecular design strategy,[2] most likely because of their variable coordination spheres. Herein we describe a supramolecular design strategy for forming arsenic-based assemblies, which relies on the self-assembly of arsenic(III) with thiol ligands—and hence the reversibility and lability of arsenic–sulfur bonds—and we report the first member of this class, $[As_2L_3]$ ($H_2L = \alpha,\alpha'$-dimercapto-*para*-xylene). The design strategy incorporates the unusual, yet predictable trigonal-pyramidal coordination geometry of As^{III} featuring a stereochemically active lone pair when coordinated by sulfur-based ligands (Figure 1 a).[3–6]

We selected arsenic(III) as a design component because of its unusual coordination geometry and a general lack of specific and powerful chelators for this highly toxic ion.[7] Arsenic compounds are legendary for their toxicity, and hydrated As^{III} is recognized as a known human carcinogen. Arsenic is abundant in the earth's crust and is all-too-frequently present as an environmental health hazard;[8–10] however, specific chelators for environmental and in vivo remediation and sensing applications are lacking. Furthermore, the stereochemically active lone pair of As^{III} adds a novel feature to the targeted supramolecular assemblies: for instance, lone pairs directed into the cavity would provide a unique soft, Lewis-basic cavity environment (Figure 1 b).[11]

Figure 1 illustrates the design strategy for forming C_{3h}-symmetric $[As_2L]$ assemblies, which is based on rigid, twofold

Figure 1. a) Top: Representation of the preferred trigonal coordination geometry of As^{III} with sulfur-based ligands; the stereochemically active lone pair on arsenic is highlighted. Bottom: Structure of [As(thiophenol)₃] from a single crystal X-ray structure analysis adapted from the Cambridge Structure Database showing an example of this trigonal coordination geometry. b) Two examples of how this As^{III} coordination geometry could be used to form As_2L_3 assemblies with rigid, twofold symmetric dithiolate ligands (solid rods). The arsenic lone pairs can be directed either into or out of the cavity.

symmetric dithiols capable of acting as bridging ligands. Dithiol ligand H_2L[12] (Scheme 1) was the initial bridging ligand investigated, because it is easily prepared and thiolates show a well-known affinity for As^{III}.[12] Using a ligand such as H_2L allows for two possible orientations of the arsenic lone pairs: *into* or *out of* the cavity of the complex. Molecular models (CAChe, MM3) indicated that the lone pairs would be directed into the cavity with an As–As distance of about 6 Å.[13]
Scheme 1. Synthesis of $[As_2L_3]$ assemblies.

H_2L, synthesized by a literature procedure,[12] forms a yellowish white solid in 52% yield when treated with stoichiometric amounts of $AsCl_3$ and KOH in THF/methanol mixtures. The product has very simple ^1H and ^{13}C NMR spectra, indicative of formation of the desired high-symmetry C_{3h} complex, and the parent ion peak $[H\{As_2L_3\}]^+$ is present in the electrospray ionization mass spectrum. Interestingly, $[As_2L_3]$ also forms in the absence of any base; however, the dominant product under these conditions is a mixture of $[As_2L_2Cl]$ macrocycles (Scheme 1), which are presumably kinetically stable intermediates on the self-assembly pathway to forming $[As_2L_3]$.[14]

A single crystal X-ray diffraction study performed on crystals grown by diffusing pentane into a $CHCl_3$ solution of $[As_2L_3]$ at $-4°C$ confirms the solid-state structure of the supramolecular assembly (Figure 2).[15] $[As_2L_3]\cdot CHCl_3$ crystallizes in space group $C2/c$ with eight molecules per unit cell. Therefore, one complex makes up the asymmetric unit and the discrete structure has no crystallographic symmetry. However, $[As_2L_3]$ has very nearly C_{3h} symmetry. Consistent

Figure 2. Structure of [As$_2$L$_3$] in the crystal. a) ORTEP representation with 50% thermal ellipsoids. b) and c) Wireframe representations with arsenic atoms shown as space-filling spheres, the view in (c) is along the pseudo-threefold axis of the assembly showing the twist directions of the methylene groups being of opposite configurations at the two arsenic centers.

with predictions from molecular models, the arsenic lone pairs indeed are directed into the cavity of the complex. The two As^{III} ions are coordinated in a tripodal fashion by the three thiolate ligands, with the stereochemically active lone pairs directed at each other in the cavity.

The arsenic atoms in [As$_2$L$_3$] are quite a bit closer together than molecular models indicated; they are separated by 5.03 Å (models predicted 6 Å). The average As−S distance is 2.25 Å and the angles between the mean planes of the phenyl rings are 57.3°, 64.2°, and 58.6° showing the complex has very nearly threefold symmetry. Furthermore, the As−C$_{Aryl}$ distances are quite short, with six close contacts between 3.18 and 3.33 Å, suggesting an attractive interaction between the phenyl rings of the ligands and the arsenic ions helps stabilize the assembly.

Previous work by Schmidbaur et al. has shown that As^{III} and other heavier main group elements with stereochemically active lone pairs can form close contacts with arene rings in the solid state.[16–18] To analyze this attractive interaction, DFT calculations were performed on the AsCl$_3$–benzene dimer.[19] These studies revealed a lower limit for the binding energy of 7.4 kcal mol^{-1} for the arsenic–arene interaction, with C−As distances of 3.2–3.4 Å. Furthermore, although the preferred geometry of the interaction orients the arsenic lone pair at a 68° angle to the phenyl ring, this structure is only 0.5 kcal mol^{-1} more stable than the two C$_{3v}$-symmetric arrangements. This suggests that, while this interaction is quite strong, its geometry is flexible. Calculations at a higher level of theory to include dispersion energy (Moeller–Plesset and coupled cluster) are currently underway as are efforts to quantify the strength of this interaction in solution.

Figure 2 c shows that the orientation of the methylene groups provides a "twisted" arrangement of the sulfur atoms around the arsenic atoms. These twists have opposite directions at the two arsenic centers in one complex, which results in a *meso* static structure with C$_{3h}$ symmetry. The ^{1}H NMR spectrum (CDCl$_3$) of [As$_2$L$_3$] shows one singlet in the aromatic region for the phenyl rings of the ligands and one singlet for the methylene protons, both shifted relative to the signals of the free ligand. That the methylene resonance is a singlet shows that the twisted orientations interconvert quickly on the NMR timescale, otherwise the methylene protons would be inequivalent because they are diastereotopic with one proton closer to the arsenic center than the other. Therefore, the [As$_2$L$_3$] structure determined in the solid

state is stable in solution on the NMR timescale. Furthermore, the NMR spectrum does not change down to −80°C, indicating that none of the possible dynamic solution behavior of this assembly is frozen out at this temperature. This is markedly different from the behavior of analogous organic π-prismands and bicyclophanes. Gleiter et al. reported that torsional motion in related nitrogen-based systems is frozen out at −20°C and the rotation of the π systems ceases at −82°C.[20]

[As$_2$L$_3$] is remarkably robust in solution, suggesting this self-assembled compound is indeed the thermodynamic product of the reaction between As^{III} and H$_2$L. No ligand exchange occurs between [As$_2$L$_3$] and excess ligand on the NMR timescale, [As$_2$L$_3$] is air- and water-stable, and it is even stable to a variety of competing metal ions (including Ag^I, Cu^I, Pd^{II}, and Zn^{II}). Remarkably, even extended heating in CHCl$_3$ at reflux in the presence of an excess of trifluoroacetic acid or *p*-toluenesulfonic acid gave neither decomposition nor protonation of [As$_2$L$_3$] according to ^{1}H NMR spectroscopy.

The robustness of the [As$_2$L$_3$] assembly is exciting for several reasons. Firstly, this provides the first proof of principle for the design strategy to form supramolecular assemblies using As^{III} as a building block, and reveals that the coordination chemistry of arsenic–sulfur interactions is sufficiently labile to allow for the self-assembly of discrete species to occur. This is an unusual use of arsenic(III) as a metalloid in coordination chemistry, rather than as a phosphine ligand analogue. Secondly, the intriguing observation that the arsenic lone pairs are oriented into the cavity of the complex hints at exciting host–guest applications. Because guests in encapsulation complexes experience a nonpolar, asymmetric environment, providing functionality to them in a synthetic receptor is challenging. Exposing functional groups to the cavities of synthetic receptors has also been referred to as "endohedral" and "introverted" functionality, and the presence of the arsenic lone pairs inside the cavity is an excellent first step in introducing functionality to a guest from its host shell.[11b, 21]

That [As$_2$L$_3$] forms in a nonoptimized yield of 52% suggests this reaction indeed occurs by a self-assembly mechanism. It is quite unlikely that six arsenic–sulfur bonds would spontaneously form to yield a discrete species as a kinetic product, and in fact the yields of the stepwise syntheses of related organic π-prismands are much lower.[20] The isolation of an intermediate [As$_2$L$_2$Cl$_2$] macrocycle in the absence of base sheds light on the mechanism of this self-assembly reaction. Presumably, this stable macrocycle, which is preorganized for an incoming ligand **L** to bridge the two arsenic ions to form [As$_2$L$_3$], forms as one of the many possible intermediates. Favorable arsenic–π interactions likely add further stability to the resulting assemblies and suggest that this interaction may help preorganize the arsenic atoms near the sulfur atoms to facilitate formation of the As−S bonds.

We have presented a self-assembled inorganic analogue of the bicyclophanes and,[22] specifically, the π-prismands.[20, 23] The self-assembly strategy allows for increased yields in the macrobicyclization reaction and is a proof of principle of the design strategy to form arsenic-based supramolecular assem-

blies from simple, identical starting compounds. The success of this strategy augurs well for the formation of larger arsenic-based capsules resulting from expanded two- and threefold symmetric ligands. We are pursuing these studies, as well as attempting to prepare host–guest complexes of $[As_2L_3]$.

Experimental Section

General: All NMR spectra were measured using a Varian INOVA 300-MHz spectrometer. Single crystal X-ray diffraction studies were performed on a Bruker SMART APEX diffractometer. Mass spectra were recorded on an Agilent 1100 LC/MSD mass spectrometer.

[As_2L_3]: H_2L (0.763 mmol, 130 mg) was added to a degassed solution of THF (80 mL) and KOH (2.43 mmol, 136 mg) in MeOH (24 mL). This solution was heated to 50 °C and $AsCl_3$ was added dropwise. The reaction was stirred under N_2 for 2.5 h. The resulting white precipitate was removed by filtration and the filtrate was dried in vacuo (yield 87 mg, 52%). Crystals suitable for X-ray diffraction were grown by pentane diffusion into a chloroform solution of $AsCl_3$ and H_2L at −4 °C. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 7.09$ (s, 12 H, CH), 3.81 ppm (s, 12 H, CH_2); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 137.5$ (C), 128.9 (CH), 35.0 ppm (CH_2); API-ES MS: m/z (MH,%): 655.2 ($[H\{As_2L_3\}]^+$ 654.9 calcd, 23%), 715.2 ($[H\{As_2L_3\} + AcOH]^+$, 714.9 calcd, 27%).

yDNA: A New Geometry for Size-Expanded Base Pairs**

*Haige Lu, Kaizhang He, and Eric T. Kool**

Previous studies have explored whether it is possible to replace the information-encoding part of DNA—the bases and base pairs—with other molecular replacements, and whether such new base pairs might function in recognition and in replication processes, two of the defining character-istics of the natural genetic system.[1–6] Many of these studies have been aimed at designing base pairs that can function within the content of the natural genetic system, for expansion of nature's genetic alphabet. However, recent studies have moved beyond the purine–pyrimidine frame-work of the natural system. Examples of this new approach include metal-bridged base pairs,[4] nonpolar base pairs,[2,4] and pairs containing more than the three different types of hydrogen bonds found in nature.[5] We recently adopted a different strategy and described a molecular design in which the dimensions of the natural pairs are stretched by insertion of a benzene ring into the natural heterocycles, thus rendering base pairs 2.4 Å wider than the natural ones.[6] Such broad alterations of the natural design are not necessarily expected to be compatible with the natural genetic system. Rather, such studies are useful as a test of researchers' understanding of how genetic systems function in general, and they may also lead to useful new applications in biotechnology and in self-assembling nanostructures.

Herein we evaluate whether size-expansion of DNA base pairs can be carried out using a new geometry. Our previous design of expanded DNA-like bases (xDNA) involved a linear extension of pyrimidines and purines by addition of a benzene ring to each of the four DNA base heterocycles.[6] However, examination of models suggested that at least one other design strategy involving benzohomologation also appeared to allow for reasonable base-pair geometries and stacking with neighboring pairs. This new design, termed "yDNA" (an abbreviated form of "wide DNA"; Scheme 1) involves a different extension vector, but yields a similar degree of perturbation from the framework formed by the natural pair. Analogous designs for the other three nucleobases can be envisioned (not shown). In this initial study we

Supporting information for this article (synthesis and structure characterization, thermal denaturation curves, CD spectra) is available on the WWW under http://www.angewandte.org or from the author.
Scheme 1. a) Structures of the free deoxyribonucleosides yA and natu-ral A; b) proposed base-pair pattern for yA·T (left), compared with the natural A·T base pair (right). The arrow shows the extension vector for the yA base which adds about 2.4 Å to the length of natural adenine base.

tested the concept with one example, that of the expanded adenine base analogue (yA) and the corresponding deoxy-riboside (dyA), both of which were previously unknown.

We developed a synthetic route to prepare the phosphor-amidite derivative of the new nucleoside analogue dyA in 10 steps (6% overall yield on a gram scale, Scheme 2). Methylation of indole **1** at the 5 position was achieved by addition of three equivalents of methylmagnesium chloride to the unprotected indole **1**, followed by ring oxidation to restore aromaticity.[7] The transformation of methylindole **3**[8] to indole-5-carboxaldehyde **4** was a key step; tris(dimethyla-mino)methane converted **3** into the enamine intermediate which was then oxidized by $KMnO_4$ in one pot to afford compound **4**.[9] The protected 2′-deoxyriboside **7** was formed in three subsequent steps from the indole-5-aldehyde **4**. Conventional methods were then used to convert the deoxyriboside **7** into the amidine-protected dyA phosphor-amidite **11**.

Studies showed that the yA base is fluorescent, where as its natural congener is not. The yA free nucleoside was found to have absorption maxima at 262 and 355 nm in methanol. A fluorescence spectrum in methanol revealed that the nucleo-side emits blue fluorescence ($\lambda_{max} = 433$ nm) with a quantum yield of 0.12 (Figure 1). Thus the yA fluorescence is red-shifted by about 40 nm relative to the xA analogue.[6]

We prepared a short oligomer of sequence 5′-TyAT-3′ to confirm that dyA could be incorporated intact into a DNA by automated DNA synthesis. The expected trimer structure was confirmed by ^{1}H NMR spectroscopy and electron spray ionization (ESI) mass spectrometry after deprotection with concentrated ammonium hydroxide and partial purification by dialysis.

We then investigated the stacking and pairing properties of dyA in the context of natural DNA oligonucleotides. Thermodynamic data from thermal denaturation studies (Table 1) showed that yA (like xA)[6] stacks more strongly than natural A at the terminus of the duplex formed by 5′-

Figure 1. Emission and excitation spectra of the free nucleoside yA in methanol.

CGCGCG-3'. This result may be a consequence of the expanded surface area and higher hydrophobicity of the new analogue. We then tested the pairing properties of yA opposite natural bases in DNA (Table 1, entries 4–15). With a single substitution in DNA, yA was found to be destabilizing to some extent, which may be a result of the distortion of the DNA backbone caused by the increased size of yA relative to A. Interestingly, when yA was paired with T, the duplex was less destabilized by 1.5–2.1 kcal mol^{-1} than when yA was paired opposite A,G, and C. This result suggests that, despite some destabilization, yA may be able to form a selective hydrogen-bonded pair with T in the natural duplex.

Although the yA·T pair was found to be destabilizing in natural DNA, probably because of backbone distortions, we expected that such strain might be avoided if all pairs were expanded in a homologous way. Thus, further studies were performed to test whether it is possible to construct fully expanded helices composed of yA·T and T·yA base pairs. This was tested in two contexts. The first one contained a self-complementary sequence (Table 1, entry 16) and the second one (Table 1, entry 18) contained a non-self-complementary pair of oligonucleotides. Both assays showed distinct cooperative transition curves in thermal denaturation experiments (see Supporting Information). In the first case, the non-natural helix displayed a higher melting temperature (T_{m}, by 25 $^{\circ}$C) and more favorable free energy (by 4.1 kcal mol^{-1} at 37 $^{\circ}$C) relative to the natural helix of the analogous sequence. Similarly, the helix formed with the second sequence gave a T_{m} value 23 $^{\circ}$C higher and a free energy 4.9 kcal mol^{-1} higher than the natural helix. We hypothesize that the added stability of these helical complexes arises from the strong stacking of the larger base pairs; further experiments will be needed to better understand this.

Circular dichroism spectra of the duplex formed in the second case (Table 1, entry 18) suggest an overall helical form resembling that of B-DNA of the analogous sequence (see Supporting Information), but with positive and negative bands red-shifted by 5–20 nm, presumably as a consequence of the extended π system of yA. Interestingly, the single component strands of the putative yDNA duplex also show similar spectra, which is indicative of strong helical stacking in the single-stranded state.

Our study has demonstrated that the new geometric design for benzo-fused bases is successful for at least one such base analogue (yA), and the data show that yA·T and T·yA pairs can self-assemble into cooperative helices that are considerably more stable than natural DNA. Thus, yDNA

[a] φ in entries 8 and 13 denotes an abasic tetrahydrofuran site. [b] Entries 1, 2, 15, 16: the buffer contained 1 M NaCl and 10 mM Na$_2$HPO$_4$ at pH 7.0; DNA concentration: 5.0 μM; error in the T_m value: ±0.5 °C or less. Entries 3–14, 17, 18: buffer contained 100 mM NaCl, 10 mM MgCl$_2$, and 10 mM sodium 1,4-piperazinediethanesulfonate at pH 7.0; DNA concentration: 5.0 μM. Error in the T_m value: ±0.5 °C or less. [c] Data were obtained by averaging free energies from curve fits and a van't Hoff plot. The van't Hoff data were obtained by plotting $1/T_m$ versus $\ln(C/4)$ (where C is the total oligonucleotide concentration) with data from five concentrations. Curve fits data were averaged from fits of five denaturation curves.

may be a candidate for a new genetic system, distinct from the recently described xDNA design.[6, 10] Like xDNA, it appears that the sugar–phosphate backbone in yDNA can tolerate the stretched size of bases and the altered pairing direction, while retaining the structure of the duplex. However, beyond the hypothesized base pairing, the structure of yDNA is unknown and needs to be studied. Also unknown is whether other analogously expanded bases and base pairs could be constructed; studies are underway to test these.

C–S Bond Cleavage

Phosphine-Promoted Conversion of Oxo(dithiolato)rhenium(V) into Thio(thiolatoalkyl)rhenium(V) Compounds**

Ming Li, Arkady Ellern, and James H. Espenson*

The cleavage of C–S bond is the most important step for removing sulfur from petroleum feedstocks.[1] The common strategies include thermal decomposition,[2] photolysis,[3] reduction and/or protonation[4] of sulfur-containing metal complexes. We have now found that reaction under mild conditions between oxo(dithiolato)rhenium(v) complexes and triphenylphosphine cleaves a C–S bond, giving a thio(thiolatoalkyl)rhenium(v) product. This reaction, to our knowledge, is unprecedented.

Treatment of **1a** or **1b** with triphenylphosphine leads to **2a** or **2b**, as in Equation (1). The reaction follows second-

order kinetics; $k_{1a} = 3.61(2) \times 10^{-3}$ and $k_{1b} = 2.61(5) \times 10^{-4}$ L mol^{-1} s^{-1} (benzene, 25.0 °C). In the reaction in Equation (1) the Re≡O bond is cleaved and P=O and Re≡S bonds are formed at the expense of a CH$_2$-S-Re bond, and a new Re–C bond is formed; consequently, the six-membered chelate ring becomes a five-membered one.
$$1a(1b) + PPh_3 \rightarrow 2a(2b) + Ph_3PO \qquad (1)$$

On the other hand **1c** does not undergo this reaction, thus avoiding formation of a four-membered chelate ring. Additionally, but incidental to the new chemistry, all three versions of **1** exchange PAr$_3$ for PPh$_3$, as do their methyl analogues [MeReO(dithiolato)PPh$_3$].[5]

Both **2a** and **2b** were characterized spectroscopically and analytically (Experimental Section). The methylene resonance signals shift downfield: $\delta = 4.95$ and 3.30 ppm for **1b** as compared to $\delta = 5.89$ and 3.61 ppm for **2b**. Further, the ν_{ReO} frequencies change from the typical values for oxorhenium(v) complexes,[6] 947 cm^{-1} (**1b**) to ν_{ReS} 500 (**2a**) and 510 cm^{-1} (**2b**).[7] The ^{31}P NMR spectrum in C$_6$D$_6$ showed the slow disappearance of the resonance signal of **1b** at $\delta = 19.0$ ppm and the growth of new signals for **2b** at $\delta = 34.8$ ppm and for Ph$_3$PO at $\delta = 26.0$ ppm. Compounds **2a** and **2b** were also characterized by X-ray crystallography.[8] Their molecular structures are based on a square pyramid with an apical thio ligand (Figure 1). The rhenium–element bond lengths are
Figure 1. Molecular structures of **2a** and **2b** (thermal ellipsoids set at 50% probability). Selected bond lengths [pm]: **2a**, Re-S(2) 208.08(15), Re-S(1) 228.49(15), Re-S(3) 228.98(15), Re-C 214.0(6), Re-P 241.56(14); **2b**, Re-S(3) 208.83(9), Re-S(2) 229.50(9), Re-S(1) 229.12(8), Re-C 215.6(3) Re-P 242.02(8).

comparable to those found in related rhenium(v) complexes,[7,9] save for reported Re≡O bonds of 168(3) pm, compared to the Re≡S bonds of 208 pm in **2a**, **2b**. Note that in **1b** the phosphorus atom and the phenolic sulfur are in *trans* positions whereas in the product **2b** they lie *cis* to one another (see below).

On the basis of the data obtained, we suggest the mechanism shown in Scheme 1. The first step comprises nucleophilic attack on the oxo group of **1a**, a process which is reasonable given the formal charges, Re$^-$≡O$^+$; moreover, attack of phosphine at a terminal oxo group has precedent.[10] The resulting intermediate is assisted to the product by the Re$^-$=S$^+$Ph resonance form. The intervention of this resonance form may be the ultimate reason for the failure of [MeReO(dithiolato)PPh$_3$] complexes to undergo parallel
Scheme 1. Proposed mechanism for the conversion of **1a** into **2a**.

Communications

reactions. Reaction of **1a** or **1b** with PAr$_3$ always leads to PAr$_3$ products analogous to **2a** or **2b**, because phosphine exchange in **1** occurs more rapidly than the reaction in Equation (1). We have found no precedent for the reaction in Equation (1), although certain features are common to an organic rearrangement.[11]

Finally, there is an issue for **2b** not accounted for by the mechanism shown in Scheme 1, namely that the crystal structure establishes that the PhS group lies *trans* to the phenolic sulfur atom (S1), opposite to its location in **1b**. Isomerization is not an issue for the reaction of **1a**, of course, because it has equivalent sulfur atoms. It has been shown that geometrical isomerization accompanies the bimolecular, associative ligand substitution reactions between [MeReO(mtp)PPh$_3$] and PAr$_3$, Equation (2).[5] This precedent constitutes the basis for **2b** not being obtained the same isomer as **1b**; it leaves unanswered the question as to whether **2b**, as isolated, is the more stable geometric isomer.

Experimental Section

2a: As a mixture of [{PhSReO(pdt)}$_2$] (the precursor of **1a**[12] (165 mg, 0.20 mol) and PPh$_3$ (484 mg, 1.85 mmol) in toluene (100 mL) was stirred for two days, the solution changed gradually from brown to yellowish. During removal of the solvent a yellowish solid precipitated. This solid was dissolved in the minimum volume of CH$_2$Cl$_2$, loaded onto a silica gel column, and eluted with diethyl ether/hexanes. Yield 71%; ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.77 (b, 6H), 7.56 (dd, J = 7.2 Hz, 2H), 7.52–7.43 (m, 9H), 7.30 (t, J = 7.6 Hz, 2H), 7.23 (t, J = 7.6 Hz, 1H), 5.40 (dd, J = 13.6 Hz, 1H), 3.37–3.33 (m, 1H), 3.24–3.18 (m, 1H), 3.02–2.90 (m, 1H), 2.39–2.31 (m, 1H), 1.74–1.66 ppm (m, 1H), ^{31}P NMR (162 MHz, external reference 85% aq. H$_3$PO$_4$, CD$_2$Cl$_2$): δ = 31.2 ppm, IR (KBr pellet) 500 cm^{-1}. Elemental analysis (%) calcd for C$_{27}$H$_{26}$S$_3$PRe·0.5 (C$_2$H$_5$)$_2$O: C 49.69, H 4.46, S 13.72; found: C 50.17, H 4.05, S 12.98. Crystals of C$_{27}$H$_{26}$S$_3$PRe·0.5 C$_6$H$_6$ suitable for diffraction were grown from benzene solutions of **2a**.

2b: The analogous procedure was used to prepare the brown compound **2b** in 61% yield, from **1b**[12] (50 mg, 0.07 mmol) and PPh$_3$ (92 mg, 0.35 mmol) in toluene (20 mL). Yield 61%, ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.83 (b, 6H), 7.61–7.56 (m, 3H), 7.52–7.45 (m, 11H), 7.30 (t, 1H), 7.22 (d, 1H), 7.07 (t, 1H), 6.99 (t, 1H), 5.89 (dd, J_1 = 1.2 Hz, J_2 = 17 Hz, 1H), 3.61 ppm (dd, J_1 = 9 Hz, J_2 = 17 Hz, 1H), ^{31}P NMR (162 MHz, external reference 85% aq. H$_3$PO$_4$, CD$_2$Cl$_2$): δ = 34.4 ppm (34.8 ppm in C$_6$D$_6$). IR (KBr pellet), 510 cm^{-1} (m, $\nu_{Re=S}$). Elemental analysis (%) calcd for C$_{31}$H$_{26}$S$_3$PRe·0.5 C$_7$H$_8$: C 54.73, H 3.99, S 12.69, P 4.09; found: C 55.67, H 3.76, S 11.52, P 3.25. the solvent contained in the powdered sample for analysis was detected by ^{1}H NMR spectrosocpy. The red-brown single crystals of C$_{31}$H$_{26}$S$_3$PRe that were grown from toluene-hexanes solutions of **2b** contained no solvent of crystallization.

Solid-Phase Synthesis of Lipidated Peptides**

*Goran Kragol, Maria Lumbierres, Jose M. Palomo, and
Herbert Waldmann**

The Ras proteins serve as central molecular switches in biological signal transduction cascades regulating cell growth and differentiation.[1] They incorporate both acid-labile farnesyl thioethers and base-sensitive palmitic acid thioesters, which are required for biological activity and terminate in a cysteine methyl ester (Scheme 1).

For the efficient and rapid synthesis of tailor-made lipidated peptides representing the characteristic partial structures of their parent proteins[2,3] a flexible solid-phase technology is required. Ideally such a technique would:

1. give access to peptides carrying different combinations of acid- and base-labile lipid groups; this requires the application of a set of suitable orthogonally stable protecting groups and a linker to the solid support, all of which can be cleaved under the mildest conditions;[3]
2. allow for the introduction of additional reporter and/or linking groups required for application of the target peptides in further biological investigations;
3. allow for release of the peptide as a methyl ester, or—if required—equipped with a different functional group, for example, a fluorophore at the C-terminus.[2d]

The only method currently available for this purpose[4] requires a large excess of lipidation reagent, is not readily automatable, and is not suitable for the preparation of longer peptides. Thus attempts to prepare peptides with > 10 amino acids by this method failed in our hands.

Here we describe the successful development of a solid-phase synthesis method that meets the demands and overcomes the drawbacks described above. It employs pre-lipidated amino acid building blocks together with the base-labile 9-fluorenylmethyloxycarbonyl (Fmoc) group as a blocking function for the N-terminus, and the oxidation-labile hydrazide linker for anchoring to the solid support.

The lipidated building blocks required for the new solid-phase method were synthesized in high overall yields as shown in Scheme 2 employing in part transformations described earlier.[5] Notably only one equivalent of farnesyl chloride and, in particular, of the *N*-methylanthraniloyl (Mant)-functionalized farnesyl analogue GerMantCl were employed.

Building blocks **2** and **4** were then used in the solid-phase synthesis of H- and N-Ras peptides **9** and **10** (Scheme 3). The hydrazide unit[6] was employed as a linker to the solid support since it can be cleaved under mild oxidative conditions and gives access to lipopeptide esters and acids.[4] Fmoc-hydrazinobenzoic acid functionalized aminomethyl polystyrene resin is commercially available (NovaBioChem). In order to avoid racemization of cysteines DIC/HOBt or HBTU/HOBt/TMP cocktails in CH_2Cl_2/DMF 1:1 were used for coupling the cysteine building blocks.[7]

Coupling of Fmoc-Cys(Far)OH and Fmoc-Cys(Pal)OH proceeded with > 90 % efficiency if a coupling time of 4 h was allowed and if for Fmoc-Cys(Pal)OH a double coupling was performed (monitored by Fmoc determination employing the established UV-based method). After oxidative cleavage with $Cu(OAc)_2$ and release from the resin by treatment with

CH₃OH followed by filtration of the crude product through a short silica cartridge, the peptide methyl esters corresponding to immobilized peptides **9** and **10** were obtained in overall yields of 69% and 60%, respectively, and with >90% purity.

For further elongation of the peptide chain the central problem of the entire method had to be solved. After removal of the Fmoc group from the N-terminal S-palmitoylated cysteine a rapid S→N acyl shift had to be feared,[8] and, in addition, the base-labile Fmoc group had to be removed under conditions that leave the thioester intact, although this group is very sensitive to nucleophilic attack.[2]

Substantial experimentation revealed that the desired elongated and S-palmitoylated peptides can be obtained in a very practical and efficient manner if the Fmoc group is cleaved by treatment with a solution of 1% DBU in DMF[9]
Scheme 3. Solid-phase synthesis of lipidated peptides employing pre-lipidated amino acid building blocks. a) 1. 20% piperidine/DMF, 2. Fmoc-Cys(Far)-OH (4 equiv), DIC/HOBt or HBTU/HOBt/TMP, CH₂Cl₂/DMF (1:1), 4 h; b) Standard solid-phase synthesis: 1. 20% piperidine/DMF, 2. Fmoc-AA-OH (4 equiv), DIC/HOBt or HBTU/HOBt/DIPEA, CH₂Cl₂/DMF (1:1) or DMF, 2 h; c) 1. 20% piperidine/DMF, 2. Fmoc-Cys(Pal)-OH (4 equiv), DIC/HOBt or HBTU/HOBt/TMP, CH₂Cl₂/DMF (1:1), 4 h for **10**, overnight for **9**; d) 1% DBU/DMF, 2×30 s; e) Fmoc-AA-OH (5 equiv), HATU (5 equiv), DIPEA (20 equiv), CH₂Cl₂/DMF (4:1), 2 h; f) Cu(OAc)₂, pyridine, acetic acid, methanol, CH₂Cl₂, oxygen atmosphere, 3 h. DIC = 1,3-diisopropylcarbodiimide, DIPEA = N,N-diisopropylethylamine, DMF = N,N-dimethylformamide, HATU = O-(7-azabenzotriazol-1-yl)-N,N,N′,N′-tetramethyluronium hexafluorophosphate, HBTU = N-[(1H-benzotriazol-1-yl)-(dimethylamino)methylene]-N-methylmethanaminium hexafluorophosphate N-oxide, HOBt = 1-hydroxybenzotriazole, TMP = tetramethylpiperidide.

for 2×30 s followed each time by fast washing with DMF (6× 5 s) and immediate coupling for 2 h employing five equivalents of preactivated (10 min) amino acid building block, five equivalents of HATU, and twenty equivalents of diisopropyl-

ethylamine in CH$_2$Cl$_2$/DMF 4:1 as solvent. Under these conditions the desired elongated peptides **12** and the analogue **13** resulting from S→N acyl shift were formed in a ratio of 95:5.

In order to demonstrate the scope of the method, the lipid-modified peptides shown in Table 1 were prepared. In general, a resin with a loading of 0.35–0.37 mmol g^{-1} was employed, and the peptides were prepared in 5- to 20-mg amounts. Immediately after release from the resin and filtration through a silica cartridge the peptides were > 80 % pure (determined by HPLC analysis; see the Supporting Information).

The peptides shown in Table 1 display different lipidation patterns; in other words, they are mono- or dilipidated and correspond to the C-termini of the H- or N-Ras protein. In addition to the lipid groups they incorporate a fluorescent label (NBD, Mant) or a photoactivatable group (benzophenone) and/or a maleimidocaproyl group (MIC), and a biotin group or an unmasked N-terminal cysteine which can be employed for coupling to expressed proteins by expressed protein ligation.[2e] Three peptides (**18–20**) incorporating the GerMant analogue of the farnesyl group were synthesized. Due to the laborious preparation of the GerMant residue (see above) in the coupling steps employing Fmoc-Cys(GerMant)OH only 1.5 equivalents of the building block were employed to ensure efficient use.

Finally, the applicability of the method to the synthesis of long lipidated peptides was investigated. To this end, decapeptide **27** and tetradecapeptide **28** were prepared, which both mimic the C-terminus of N-Ras. Both were obtained in milligram amounts and characterized by ^{1}H NMR spectroscopy and mass spectrometry (**27**: ESI-MS: m/z_{calcd} for [M+H]$^+$ = 1887.0, m/z_{found} = 1887.3; **28**: MALDI-MS (DHB): m/z_{calcd} for [M+Na]$^+$ = 2481.3, m/z_{found} = 2481.8; m/z_{calcd} for [M+K]$^+$: 2497.3, m/z_{found} = 2497.9). These peptides represent the longest S-palmitoylated and S-farnesylated peptides synthesized so far. Both were not accessible by the previously reported solid-phase method,[4] which demonstrates the superiority of the method reported in this article.

In conclusion we have developed an efficient solid-phase method for the synthesis of differently lipidated and additionally modified peptides. This methods meets the requirements of a widely applicable

Table 1: Lipidated peptides synthesized by means of the solid-phase method.

potentially automatable methodology and overcomes the limitations of earlier procedures. In terms of efficiency and flexibility this solid-phase method is superior to the solution-phase synthesis. It gives pure peptides more quickly and with superior overall yield.

Polymers

Analysis of Poly(carbon suboxide) by Small-Angle X-ray Scattering**

Matthias Ballauff,* Sabine Rosenfeldt,
Nico Dingenouts, Johannes Beck,* and
Petra Krieger-Beck

Carbon forms different oxides, of which carbon monoxide and carbon dioxide are among the most widely studied chemical compounds. The most stable oxide with more than two cumulative double bonds, known as carbon suboxide C_3O_2 (**1**; Scheme 1), was synthesized for the first time nearly 100 years

$$O=C=C=C=O$$

ago. In 1906, Diels et al. discovered that the dehydration of malonic acid with P_4O_{10} yields a colorless, pungent gas which they later identified as C_3O_2.[1] The molecule, whose electronic structure suggests it to be linear, after intensive spectroscopic studies, was found to be quasilinear with a

very small energy barrier of approximately 30 cm^{-1} for the bending vibration of the central carbon atom.[2–4] Recently the structural analysis has been carried out using crystalline C_3O_2.[5]

A specific property of carbon suboxide is its spontaneous polymerization, which results in the formation of a red to black solid, with an unaltered composition of C_3O_2.[1] In spite of a number of studies, the structure of poly(carbon suboxide) $(C_3O_2)_n$ is not well understood at the atomic level. Owing to the amorphous nature of the polymer, conventional diffraction methods cannot be employed. The polymerization is highly exothermic (-136 kJ mol^{-1}) and may result in explosions.[6] The reaction follows first-order kinetics and can be catalyzed by traces of water, acids, bases and γ-rays.[7] In absence of an initiator, the polymerization depends on the nature of the surface of the reaction vessel.[8] The polymer is paramagnetic, the susceptibility of which follows the Curie–Weiss law. The spin density reaches a value of 10^{19} g^{-1}, although the polymerization does not follow a radical mechanism.[9] The IR spectra show identical band patterns independent of the way of preparation. Under highly anhydrous conditions, the IR spectra show a band at 2180 cm^{-1}, which can be assigned to the ketenyl group, C=C=O. Exposure of the polymer to small quantities of humid air results in the disappearance of the band along with the paramagnetic moment.[7]

A number of proposed structures exist. Of which the earlier hypothesis of poly(spirocyclobutanediones)[10] and of an unordered, planar molecule, whose edges are occupied by carbonyl and ketenyl groups,[11] were discarded on the basis of spectroscopic findings.[12] In 1960 Ziegler[13] postulated for the first time a poly(α-pyronic) structure, (**2**; Scheme 1) which was later confirmed by other studies,[8, 12] and has since found its way into a number of textbooks. This proposed structure has recently been questioned, since the acid–base titration of the polymer shows the presence of two different weakly acidic groups, which are attributed to the coexistence of α- and γ-pyrones.[14]

The discussion regarding the structure of $(C_3O_2)_n$ is not complete, as the most important parameter in understanding the structure, the degree of polymerization n is not yet well defined. Prepared at temperatures below 100 °C poly(carbon suboxide) is soluble in various solvents, such as, water, dimethylsulfoxide (DMSO), or dimethylformamide (DMF). The determination of molecular weight of the polymer $(C_3O_2)_n$ was carried out by Haubenstock and co-workers, who obtained a molecular weight of 311 to 358 g mol^{-1} in DMF solution using vapor-pressure osmometry, and molecular weight of 312 g mol^{-1} in DMSO using cryoscopy.[7] The degree of polymerization n should therefore be very small, about five units of C_3O_2. In the sixties, Blake et al. had reported similar results, but with relatively high errors, obtaining a value of $n = 5$ to 10 for amorphous solids by using wide-angle X-ray diffraction.[12] Recent investigations for the degree of polymerization of polymers treated with NH_3, by vapor-pressure osmometry in water, gave $n = 6$–8.[14]

According to the above results, $(C_3O_2)_n$ cannot be represented as a polymeric substance. If the structure of $(C_3O_2)_n$ is indeed as shown Scheme 1, then the polymerization

Communications

process must result in higher molecular weights and the degree of polymerization must be much greater than $n = 5$.

To explain the structure of poly(carbon suboxide) in solution, and to arrive at a comprehensive and meaningful conclusion, we have used small-angle X-ray scattering method, which is suitable for the analysis of dissolved polymers.[15] It is possible with the help of this method, to determine the degree of polymerization and the shape of the molecule. The details of such an analysis have been discussed recently.[16] First, the scattering intensity $I(q,c)$ of dilute solutions of poly(carbon suboxide) is measured. The scattering vector q can be described by the scattering angle θ and the wavelength of the incident radiation ($q = (4\pi/\lambda)\sin(\theta/2)$; $\lambda =$ wavelength, $\theta =$ scattering angle).[15] The weight concentrations are typically 0.5–1 % and the analysis of the data follows according to Equation (1) where K is the optical constant,

$$I(q,c) = k\,c\,M_{\mathrm{w}}\,P(q)\,S(q,c) = k\,c\,I(q)\,S(q,c) \tag{1}$$

which can be given through the partial molar volume of the dissolved polymer (see *Experimental Section*). M_{w} is the weight-average molecular weight to be determined and $P(q)$ is the form factor, which describes the intramolecular interactions of the dissolved molecules and provides information about the form of the polymer. The term $S(q,c)$ is the structure factor, which describes the effect of the intermolecular interactions at finite concentrations. By extrapolating $I(q)/c$ to infinite dilution this effect can be eliminated, and the scattering intensity $I_0(q)$ of a single dissolved molecule can be obtained. According to Guinier's law, in the region of small scattering angles, an extrapolation to vanishing scattering angles could be given as Equation (2)[15], where R_{g} is the

$$I(q)/c = k\,M_{\mathrm{w}}\exp\left[-\frac{R_{\mathrm{g}}^2 q^2}{3}\right];\ q\,R_{\mathrm{g}} < 1 \tag{2}$$

radius of gyration, which is a measure of the average extension of the dissolved molecule under consideration.

Figure 1 shows the Guinier plot, where the scattering intensities are extrapolated to infinite dilution. A mixture of 90 % DMF and 10 % water was used as solvent. Along with
Figure 1. Guinier plot showing the scattering intensities of dissolved poly(carbon suboxide) extrapolated to infinite dilutions.

the optical constant K, determined by the density measurements (see *Experimental Section*), the y-axis intercept gives a molecular weight M_{w} 2750 ± 600 g Mol^{-1}. In spite of the relative error in the measurements, as a result of the weak scattering intensities, it can be concluded that the value obtained is approximately higher by one order of magnitude than those obtained by Haubenstock et al. who obtained a value of 311 g mol^{-1}. The radius of gyration R_{g}, is found to be 1.7 nm, which is indicative of a polymeric structure. These results suggest the polymer structure to be as shown in Scheme 1.

The above analysis is not sufficient to prove the bandlike structure for the poly(carbon suboxide). It is necessary to carry out the analysis of the form factor $P(q)$ at higher scattering angles: first, the form factor must be corrected for the finite diameter of the molecule, as the X-ray scattering interferences, which contribute to the angle dependence of $I_0(q)$, could also result from the finite cross-section of the molecule.[16] The corrected form factor $P_0(q)$, which then refers to an infinitely thin chain, in which there as only intramolecular interactions along the chains, could then be compared to the theoretical models. The main result of this analysis is the persistence length a, which is a measure of the stiffness of the polymer chain under consideration: if a is smaller than the contour length L_{c} of the chain, the polymer is a flexible coil, whereas, if a is identical to L_{c}, then the macromolecule is a rod.

Following Ref. [16] a plot of the scattering intensities $I_0(q)$ measured at higher scattering angles can be carried out according to Equation (3), where M_{L} is the mass of the

$$\frac{I_0(q)}{k\,c} \to \frac{\pi M_{\mathrm{L}}}{q}\exp[-\frac{1}{2}R_{\mathrm{c}}^2\,q^2] \tag{3}$$

polymer chain per unit length and R_{c} is the radius of gyration across the chain, in which the interferences owing to the finite cross-section are taken into consideration. The mass per unit length M_{L} can be divided directly by the formula weight of the repeating unit to obtain the length which then provides a good consistence check for the analysis. The form factor $P_0(q)$ corrected for the effect of the finite diameter, could then be given as Equation (4).[16] This term can be compared directly to the theoretical models.[16]

$$I_0(q) = k\,c\,M_{\mathrm{w}}\,P_0(q)\exp[-\frac{1}{2}R_{\mathrm{c}}^2\,q^2] \tag{4}$$

Figure 2 shows the plot of the scattering data according to Equation (3). At higher q values a linear relationship was found as expected, this allows a reliable estimation of M_{L} and R_{c}. From Figure 2 $M_{\mathrm{L}} = 360 \pm 20$ g Mol^{-1} nm^{-1} and $R_{\mathrm{c}} = 0.3 \pm 0.05$ nm. For the proposed structure **2** (Scheme 1) $M_{\mathrm{L}} = 340$ g Mol^{-1} nm^{-1}. The value obtained for R_{c} is exactly equivalent to the cross-section, derived from the proposed Structure.

The next step of this analysis is demonstrated in Figure 3, which shows the Holtzer plot. Kholodenko's model was used for the theoretical description of $P_0(q)$, which in comparison with simulations[16] has already been demonstrated to be the
Figure 2. Plot of the scattering intensities corrected according to Equation (3) for the determination of mass per length M_L and the cross-sectional radius of gyration R_c. The y-axis intercept of this plot leads directly to πM_L, and the slope gives the value of R_c according to Equation (3).
Figure 3. Holtzer plot $P_0(q)qL_c$ of the corrected form factor $P_0(q)$. The points correspond to the experimental data, while the lines show the fits of the experimental data with the form factor from the Kholodenko theory. The dashed line depicts the fit with the dimensionless quantity $L_w/L_n = 1.1$, while the solid line shows the assumption of the dimensionless quantity $L_w/L_n = 1.5$. In both the cases $L_w = 7.7$ nm, the value, which is determined directly from M_w and M_L. The persistence length a is given as 1.5 nm for $L_w/L_n = 1.1$, if $L_w/L_n = 1.5$ then a is 1.3 nm.

optimal theory.[16] Fit-parameter of this model is the persistence length a, as the contour length used for this model $L_c = 7.7 \pm 1$ nm is given by the molecular weight M_w and the mass per unit length M_L as determined above. The breadth of the molecular-weight distribution must be considered, this is given from the ratio of the weight-average contour length L_W and the number-average contour length L_N. Since no information is available for L_W and L_N, the fit was carried out by assuming $L_W/L_N = 1.1$ (dashed line in Figure 3) and with $L_W/L_N = 1.5$ (solid line in Figure 3). As can be seen in Figure 3, both the assumptions deliver identically good fits, which are within the limits of error. The persistence length $a = 1.5$ nm for $L_W/L_N = 1.1$, if $L_W/L_N = 1.5$ then a slightly smaller value $a = 1.3$ nm is obtained.

In conclusion, small-angle X-ray scattering measurements in solution allow us to fully confirm the suggested polypyronic structure **2** (Scheme 1). The degree of polymerization $n \approx 40$, is in contradiction to the earlier determination of the molecular mass and confirms that $(C_3O_2)_n$ is a one-dimensional bandlike polymer. Hence, a solution to the structure of poly(carbon suboxide) has been obtained.

Experimental Section

1: C_3O_2 was obtained by the thermolysis of malonic acid bis(trimethylsilylester) in presence of P_4O_{10} at 160 °C.[17] The gaseous carbon suboxide was collected in a cold-trap thermostated at the temperature of liquid N_2, which was then purified by distilling two times using two cold-traps in series.

2: For the polymerization, C_3O_2 (1 to 2 mL) was condensed in glass ampules of 15 cm length, with an inner diameter of 1.5 cm and a wall thickness of 2 mm, and dry CCl_4 (3 mL) was added. After freezing with liquid N_2, the ampule was evacuated and sealed. Storage at room temperature for a few days led to a complete transformation into the brown red polymer.[18] After opening the ampule under an inert gas, CCl_4 was first evaporated at room temperature for 24 h under vacuum, and then for further 2 h at 50 °C. The red brown powder was preserved in an argon filled glove box and weighed there for the preparation of solutions.

Small-angle X-ray scattering: all the scattering intensities shown herein, were obtained using a Kratky compact camera. The measurements were carried out and analyzed analogously to experiments on dissolved polymers reported elsewhere,[16] as was the extrapolation to infinite dilutions and the desmearing of the scattering intensities, which is necessary owing to the slit geometry of the X-ray beam obtained with a Kratky camera.

The optical constant K could be given as Equation (5).[16]

$$N_A \Delta z_2^2 = N_A \left(\frac{n_e}{M_0} - \frac{\bar{v}_2 \rho_{0,e}}{N_A} \right)^2 \qquad (5)$$

N_A is the Avogadro number and Δz is the number of excess electrons per mass of the dissolved polymer under consideration. The term n_e is the number of electrons per mass, which can be obtained through the formula weight, and $\bar{v}_2$ is the partial specific volume, which can be obtained through the density measurements of dilute solutions. For the solutions studied here, in the mixture of 90 % DMF and 10 % water a value of $\bar{v}_2 = 0.61 \pm 0.02$ cm^{3}g^{-1} and $K = 0.0204$ mol g^{-2} was obtained.

[18] The use of an inert solvent for the polymerization reaction was found to be necessary. If the reaction was carried out in glass ampules in the absence of solvent, most of the time our experiments lead to violent, explosive bursts, which could be avoided by the dilution of C_3O_2 with approximately the same volume of CCl_4. The analysis showed the carbon content to be 2% lower than the expected value, likewise a small hydrogen content of about 1% (elemental analysis calcd (%) for C_3O_2: C 52.9, O 47.1; found: C 50.9 C, H 1.1). This result is in agreement with the observations by Diels[19] and Schmidt et al.,[11] according to which, only the highly purified, gaseous C_3O_2 results in the polymer with exact stoichiometry. The X-ray fluorescence analysis of our samples did not indicate the presence of chlorine from the adsorption of CCl_4.

Cyclophanes

Synthesis of Beltenes by Reactions of 5,6,11,12-Tetradehydrodibenzo[*a,e*]cyclooctene with [CpCo(CO)₂] Derivatives**

Björn Hellbach, Frank Rominger, and Rolf Gleiter

Paracyclophanes with [1.1] and [0.0] bridges are of considerable interest due to their high strain energy and because the π systems are strongly bent.[1] Tricyclohexaene **1** can be looked at as either a superphane[2] with ethylene as the π system or as a [0.0]-paracyclophane (Scheme 1). Hexaene **1**

can be expanded by incorporating the peripheral double bonds into four benzene rings, which leads to tetradehydrodianthracene **2**.[3] Replacing the central double bond by a cyclic conjugated π system such as a metal-stabilized cyclobutadiene moiety or a benzene ring leads to **3** and the tetrabenzannelated 1,2,4,5-cyclophane (**4**), respectively. The synthesis and structural properties of **4** were reported recently (Scheme 1).[4] Extending the building units to two *ortho*-substituted benzene rings and one conjugated system leads to conjugated beltenes[1a,5] as indicated in **5** and **6**. In this communication we report the preparation of four beltenes related to **5** which are the first examples of genuine beltenes[1a] consisting of annelated conjugated four- and eight-membered rings.

In our previous studies on nonconjugated beltlike macrocycles[6] we noticed that highly strained cyclic diynes such as **7** react with [CpCo(C₂H₄)₂] preferentially under trimerization to yield **8** (Scheme 2) or the corresponding tetramer.[6] When the reaction of **7** was carried out with [Cp*Co(C₂H₄)₂] (Cp* = pentamethylcyclopentadienyl) the dimerization to give the corresponding superphane was preferred.[6] This result was ascribed to the larger size of the Cp* ligand relative to that of Cp. From these experiments we concluded that the reaction of the highly strained cyclodiyne (**9**)[7] with [CpCoL₂] might lead to a tri- or tetramer. Indeed, the irradiation of **9** at 254 nm in the presence of [CpCo(CO)₂] in decalin for three days gave a yellow colored product in 14% yield (Scheme 3).

The assignment of the structure to the trimer **10** is based on its spectroscopic data (see the Experimental Section), the molecular weight determined by mass spectrometry, and X-ray structural analysis[8] (Figure 1). The NMR data (three singlets in the ¹H NMR spectrum, five in the ¹³C NMR spectrum) suggest D_{3h} symmetry for **10** in solution. This conclusion is supported by the X-ray diffraction data, which show that substituents at the cyclobutadiene ring are bent by about 11° out of the plane of this ring, away from the {CpCo} unit. The phenyl rings are twisted out of the cyclobutadiene plane around the interconnecting C–C bond by about 60°. This angle is larger than that reported for {CpCo}-stabilized tetraphenylcyclobutadiene, which varies from 32° to 42°.[9] The strong twisting in **10** indicates a weak interaction between the cyclobutadiene rings through the benzene bridges. The distance of the centers of the cyclobutadiene rings to the center of **10** amounts to 2.1 Å. From this value an inner diameter of 4.2 Å was calculated. To probe possible interactions between the {CpCoCb} units in **10**, we have carried out studies by means of cyclovoltammetry, which indicated an irreversible oxidation.[10]

By using [Cp*Co(CO)₂] instead of [CpCo(CO)₂] we hoped to favor the dimerization of the cyclic diyne **9** resulting in superphane **12**. Still the main product remained the trimer **11** besides traces of the dimeric product **12** which have not yet been isolated. The yield of **11** (41%) in this one-pot trimerization is quite remarkable. We were also able to isolate single crystals of **11** suitable for X-ray structure analysis. The data obtained for **11** resemble very much those of **10**[11] except the cyclic voltammogram of **11** revealed a reversible redox process at 590 mV and 840 mV (vs. ferrocene/ferricinium in CH₂Cl₂). In further synthetic work, the

trimers **13** and **14** were prepared by using [(CpCOOMe)-Co(CO)₂] and [(CpSiMe₃)Co(CO)₂].

To elucidate the mechanism of the one-pot reaction shown in Scheme 3 we investigated the crude reaction products of the synthesis of **11**, **13**, and **14** by means of mass spectrometry. We found evidence for the presence of the Cp*, CpCO₂Me, and CpSiMe₃ congeners of **15** and **16** based on HRMS data. This let us postulate that first a cobalt-supported dimerization of **9** to **15** takes place. In this intermediate the substituents at the (Scheme 4) cyclobutadiene ring should be bent away from

---

the CpCo moiety. The reaction of **15** with a third equivalent of **9** in the presence of CpCo(CO)$_2$ leads to the product **16** which will finally close the ring to **10**. Crucial for the ring closure is the adoption of a boat conformation of the heptacyclic ligand as sketched in **15**. Model calculations at the BP86/STO-3G level[12, 13] on **15** are fully in line with these assumptions. They predict a boat shaped conformation for the C$_{32}$H$_{16}$ ligand.

To sum up, we accomplished the synthesis of four examples of the first conjugated beltenes consisting of annelated rings. This was achieved by a one-pot reaction between the diyne **9** and the corresponding cobalt templates. In case of **10** and **11** we were able to obtain single crystals for X-ray structural analysis. For the mechanism we assume a stepwise annelation of {CpCo}-capped cyclobutadiene rings.

Experimental Section

The reactions were carried out under Ar in predried glassware using Schlenk techniques. Decalin was distilled over Na and was transferred under Ar. [CpCo(CO)$_2$] and its derivatives were prepared according to literature procedures.[14–16]

General procedure: A 250-mL irradiation flask was charged with a solution of **9** (0.72 mmol) in decalin (225 mL). [CpRCo(CO)$_2$] (1.60 mmol) was then added. The solution was magnetically stirred and cooled to 10°C. After three days of irradiation the solvent was evaporated in vacuo, and the residue was purified by column chromatography (dichloromethane).

10: Thin yellow crystals (plates) in 14% yield. ^{1}H NMR (500 MHz, CDCl$_3$): $\delta = 5.19$ (s, 15H, H$_{Cp}$), 7.08 (t, ^3J(H,H) = 4.41 Hz, 12H, H$_{arom}$), 7.69 ppm (t, ^3J(H,H) = 4.23 Hz, 12H, H$_{arom}$); ^{13}C NMR (125 MHz, CDCl$_3$): $\delta = 82.37$ (C$_{Cb}$), 82.58(C$_{Cp}$), 126.88 (C$_{arom}$), 131.70 (C$_{arom}$), 133.93 ppm (C$_{arom}$); MS (FAB +): $m/z = 973$ [M^++H], 972 [M^+]; HRMS: m/z calcd for C$_{63}$H$_{39}$Co$_3$: 972.1047, found: 972.1094.

11: Yellow-orange crystals in 41% yield. ^{1}H NMR (500 MHz, CDCl$_3$): $\delta = 1.87$ (s, 45H, H$_{Cp*}$), 6.94 (m, 12H, H$_{arom}$), 7.37 ppm (t, 12H, H$_{arom}$); ^{13}C NMR (125 MHz, CDCl$_3$): $\delta = 11.21$ (CH$_3$), 78.70

Asymmetric Synthesis

Hydrogen Bond Mediated Enantioselectivity of Radical Reactions**

*Tobias Aechtner, Martina Dressel, and Thorsten Bach**

The renaissance in radical chemistry during the last years and decades can be explained in large part by the improved prediction and control of the important parameters chemo-, regio-, and stereoselectivity.[1] Recent investigations show that radical reactions can be carried out enantioselectively without an auxiliary being attached covalently to the substrate.[2] Two different strategies have been reported. On the one hand, it is possible to differentiate the enantiotopic faces of a prochiral radical with chiral reagents (reagent control). For this purpose chiral hydrogen-atom donors have been used most often.[3] On the other hand, face differentiation is possible by a Lewis acid, which forms a chelate complex with the substrate, and which is in turn coordinated to chiral ligands.[4] Alternative chiral templates that are based upon noncovalent interactions and are similarly effective have, to the best of our knowledge, not yet been established. In a recent study we were able to show that high enantioselectivity (up to 84% *ee*) in radical reactions can be achieved with the help of a hydrogen-bonding chiral template. Our preliminary results are presented in this communication.

We investigated the enantioselectivity of the reductive radical cyclization of 3-(ω-iodoalkylidene)piperidin-2-ones (**1**). These compounds can be synthesized by the aldol

a	X = CH_2
b	X = CH_2CH_2
c	X = CH_2CMe_2
condensation of *N-tert*-butyloxycarbonyl(Boc)piperidin-2-one with ω-*tert*-butyldimethylsilyl(TBDMS)oxyaldehydes followed by conversion of the protected hydroxy group into an iodo group (1. tetrabutylammonium fluoride (TBAF), THF; 2. PPh_3, imidazole, I_2).[5]

In the presence of an initiator and Bu_3SnH the alkenyl iodides reacted in a 5- or 6-*exo*-trig-cyclization[1,6] (e.g. **2a**→ **3a**, Scheme 1). The intermediate radicals **3** exhibit a prostereogenic center in α-position to the carbonyl function which is transformed by an intermolecular reaction with Bu_3SnH to a stereogenic saturated carbon atom. In the case of the alkenyl iodide **1a** both enantiomeric cyclization products **4a** and *ent-***4a** are formed during the reaction.

The reaction proceeded smoothly for the three substrates investigated. The appropriate cyclization products were

Scheme 1. Mechanism of the radical cyclization 1a→4a/*ent*-4a. The hydrogen transfer is the enantioselectivity-determining step.

obtained in good yields (77–83%) albeit in racemic form. The two enantiotopic faces of the radical center in α-position to the carbonyl function become diastereotopic when linked to a chiral environment. We hoped to achieve such face differentiation by using the chiral complexing reagent 5,[7,8] which coordinates to lactams through hydrogen bonds.[9] For that purpose the radical cyclization of 1a to give 4a and *ent*-4a was carried out in a series of experiments in the presence of compound 5. BEt₃ was used as the initiator as it allowed the reactions to be carried out at low temperature.
The reaction was indeed enantioselective. The enantiomeric excess of product 4a in the radical cyclization[10] of iodide 1a was dependent on three parameters (Table 1). 1) The temperature should be as low as possible since this leads to a remarkable increase of selectivity (e.g. entries 5 and 9). 2) The amount of initiator BEt₃ must be held to a minimum to achieve optimum enantioselectivity (entries 2 and 3, entries 4–6). 3) The amount of complexing reagent used should preferably be high (entries 7 and 9). These observations are reasonable considering the fact that the enantiomeric excess directly reflects the ratio of bound to unbound substrate.[9a,d] The association by means of hydrogen

[a] Reaction temperature. The reaction was carried out at the cited temperature in toluene with Bu₃SnH (2 equiv). The concentration of substrate was 5×10^{-2} mol L⁻¹. The initiation occurred by addition of the cited amount of BEt₃.[10] [b] Equivalents of chiral complexing reagent 5. The reagent was completely (>90%) recovered. [c] The *ee* values were calculated from the enantiomeric ratios determined by HPLC analysis (Daicel ChiralCel OD).

bonding is ideal if the reaction is run in nonpolar solvents and at low temperatures. Unfortunately, the reaction did not take place at −78°C with only 10 mol% BEt₃. Despite good reproducibility the results are not completely coherent. Thus the minimal increase in selectivity upon decreasing the temperature is hard to explain (entries 2 and 5). The interactions of BEt₃ and its decomposition products with the substrate, complexing reagent, and product are apparently complex and must be investigated in further experiments. Selectivity in the reaction 1a→4a did not improve upon photochemical initiation (Original Hanau TQ 150, duran filter, −65°C).

Compounds 1b and 1c were also reductively cyclized under optimized conditions (Scheme 2). For the reaction of
Scheme 2. Enantioselective reductive cyclization of substrates 1b and 1c.

1b we observed an insignificant increase of enantioselectivity upon photochemical initiation ($c = 5 \times 10^{-2}$ mol L⁻¹, light source: Original Hanau TQ 150, duran filter). In the reaction of 1c under the same conditions[10] as those used for the reaction of 1a→4a, initiation catalyzed by BEt₃ was preferred. In every case we obtained the dextrorotatory 3-cycloalkylpiperin-2-ones as products. The *ee* values were calculated from HPLC analysis (for 4b) or chiral shift experiments (for 4c).[11]

The comparison with literature data shows that dextrorotatory α-monoalkyl-substituted five to seven membered ring lactams with the priority order CONH > alkyl > CH₂ > H are *R* configurated.[12] This configuration assignment corroborates the hypothesis that the hydrogen transfer from Bu₃SnH to radical 3, which is linked to template 5 by means of hydrogen bonding, occurs from the *Si* side. The *Re* side is shielded by the tetrahydronaphthalene residue. This is illustrated in Figure 1 for the enantioselective hydrogen transfer from Bu₃SnH to the prochiral radical 3a.
Figure 1. Model to explain the face differentiation in the intermediate radicals 3.

Electron Transfer

Synthesis and Photophysics of a Neutral Organic Mixed-Valence Compound**

Alexander Heckmann, Christoph Lambert,*
Mark Goebel, and Rüdiger Wortmann

Dedicated to Prof. Jörg Daub
on the occation of his 65th birthday

Purely organic mixed-valence (MV) compounds are of great interest for the investigation of intramolecular electron-transfer (ET) processes.[1–5] Usually these MV compounds are radical ions consisting of two redox centers connected by a saturated or unsaturated bridge. In this communication we present the synthesis and photophysical properties of the first organic MV compound that is neutral rather than charged.

Communications

MV compounds are characterized by a so-called inter-valence charge-transfer (IV-CT) band (usually in the near-IR (NIR) region) which is associated with the optically induced charge transfer from one redox center to the other. The electronic coupling V between the two diabatic (formally noninteracting) states (charge localized on the one and on the other redox center, respectively) is a measure for the electronic communication between these states and can be calculated from the IV-CT band by Equation (1), where μ_{eg}

$$V = \frac{\mu_{eg}}{\Delta\mu_{12}} \tilde{\nu}_{max} \qquad (1)$$

and $\tilde{\nu}_{max}$ are the transition moment and the energy of the IV-CT band, respectively, and $\Delta\mu_{12}$ is the diabatic dipole moment difference between the two diabatic states mentioned above. The diabatic quantity $\Delta\mu_{12}$ can either be estimated by the effective electron-transfer distance e $\times$ r or can be traced back to purely adiabatic (measurable) quantities by Equation (2)

$$e\,r = \Delta\mu_{12}\sqrt{\Delta\mu_{eg}^2 + 4\mu_{eg}^2} \qquad (2)$$

(generalized Mulliken–Hush theory, GMH),[6–8] where $\Delta\mu_{eg}$ is the difference between the adiabatic dipole moments of the ground and excited IV-CT state. However, while both the estimate of e $\times$ r by, for example, the distance of the redox centers r and the determination of $\Delta\mu_{eg}$ by quantum-chemical methods involves major inaccuracies,[9] the experimental determination of $\Delta\mu_{eg}$ can be achieved by means of electro-optical absorption measurements (EOAM).[10] Unfortunately, this method is complicated for charged species because of ion migration in the electric field, which can be circumvented by using glass matrices.[11–13] Further disadvantages of charged MV compounds are the low solubility especially in nonpolar solvents[14–16] and ion-pair effects.[17,18] These disadvantages can be avoided by using neutral MV compounds, a class of compounds that has not been described and studied so far to the best of our knowledge,[19] which is therefore the subject of this communication.

While MV radical cations based on two triarylamine centers[20–22] and MV radical anions based on perchlorinated triarylmethyl radicals[23,24] are well known, it was obvious to link the two redox centers by, for example, an ethylene bridge to create a neutral MV system. In the neutral, purely organic MV compound **1** a perchlorinated triarylmethyl radical center acts as the acceptor and a triarylamine redox center as the donor (Scheme 1).

The synthesis of compound **1** is outlined in Scheme 2. Compound **2** was prepared by a Pd-catalyzed Buchwald–Hartwig amination of the stilbene derivate **3**[24] and bis(4-methoxyphenyl)amine in 46% yield. Because of the low acidity of the α-H atom of **2**, KOtBu in DMSO was required to form the corresponding carbanion salt, which was subsequently oxidized with p-chloranil to obtain the air-stable radical **1** in 60% yield.

The cyclic voltammogram of **1** in dichloromethane/tetrabutylammonium hexafluorophosphate (TBAH) solution shows one reversible oxidation process at $E_{1/2} = +240$ mV versus ferrocene (Fc), which is assigned to the oxidation of the
Scheme 1. Optically induced ET process in **1**.
Scheme 2. Synthesis of the neutral radical **1**.

triarylamine center to the radical cation (Figure 1).[25] Furthermore, a reversible reduction wave at $E_{1/2} = -670$ mV can be observed, which corresponds to the reduction of the carbon radical center to the carbanion.[24] The large splitting of the two redox processes reflects the pronounced non-degeneracy of the two redox centers in contrast to the degenerate bis(triarylamine) and bis(perchlorotriphenyl-methyl) MV compounds mentioned above.

The excellent solubility of neutral **1** gave us the unique chance to investigate the UV/Vis/NIR absorption spectra in thirteen different solvents ranging from totally apolar (*n*-hexane) to strongly polar (acetonitrile). The electronic absorption spectrum of **1** (Figure 2) shows an intense band at 25 500 cm^{-1}, which is typical of perchlorinated benzene derivatives[26–28] and a weaker band at 24 900 cm^{-1}, which is assigned to methoxy-substituted triarylamine systems.[29] Furthermore, two weak absorption bands at 19 000 cm^{-1} and 17 500 cm^{-1} can be observed which are characteristic for perchlorinated triaryl-methyl radical systems.[26] Even more interesting is the observation of a weak absorption band in the NIR region at about 12 000 cm^{-1} which can be assigned to an IV-CT associated with an intramolecular electron transfer from the triarylamine to the radical unit (Scheme 1).
To our surprise the absorption maximum $\tilde{\nu}_{\max}$ of the IV-CT band of **1** shows a weak and superficially nonsystematical dependence on the solvent polarity (Table 1). The extinction coefficient of the IV-CT band is larger and the band width at half-height is smaller in nonpolar solvents such as *n*-hexane than in polar solvents like acetonitrile (Figure 3). To explain this unexpected behavior we used the Jortner model[30–32] to simulate the IV-CT band in each solvent. In this calculation an average molecular vibration is treated quantum-mechan-

Table 1: Absorption maxima, extinction coefficients, and other parameters[a] for **1** in solvents of different polarity.

Figure 3. IV-CT bands of **1** measured in solvents of different polarity.

Figure 2. UV/Vis/NIR absorption spectrum of **1** in CH$_2$Cl$_2$.

ically, and a classical solvent coordinate is used.[5] An excellent least squares fit of the IV-CT band of **1** in each solvent was achieved by varying the parameters for the inner-sphere reorganization energy λ_{v} and the outer-sphere reorganization energy λ_{o} as well as the parameters for the difference of the free energy between the diabatic ground and excited state ΔG^{00} and for the average molecular vibrational mode $\tilde{\nu}_{\mathrm{v}}$ in Equation (3). In Figure 4 the fits of

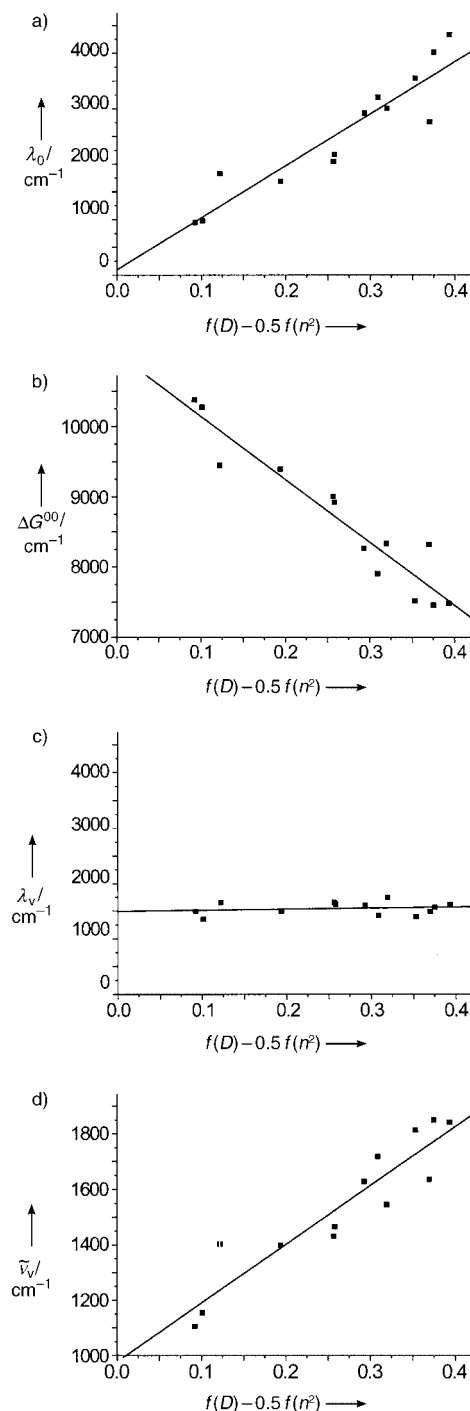
$$\varepsilon = \frac{8 N \pi^3}{3000\, h \ln 10} n \tilde{\nu} \mu_{\mathrm{eg}}^2 \sum_{j=0}^{\infty} \frac{e^{-s} S^j}{j!} \sqrt{\frac{1}{4\pi\lambda_{\mathrm{o}} R T}} \exp\left[-\frac{(j\tilde{\nu}_{\mathrm{v}} + \lambda_0 - \tilde{\nu} + \Delta G^{00})^2}{4\pi\lambda_{\mathrm{o}} R T} \right] \quad (3)$$

with the Huang-Rhys factor $S = \dfrac{\lambda_{\mathrm{v}}}{\tilde{\nu}_{\mathrm{v}}}$
Figure 4. Least squares fit of the IV-CT bands of **1** (experimental data
——) in *n*-hexane (●), benzonitrile (■), and acetonitrile (♦) according
to the method of Jortner.

Figure 5. Plots of a) λ_o, b) ΔG^{00}, c) λ_v, and d) $\tilde{\nu}_v$ versus the solvent
polarity function $f(D) - 0.5 f(n^2)$ with $f(D) = (D-1)/(2D+1)$ and
$f(n^2) = (n^2-1)/(2n^2+1)$.

the IV-CT band in *n*-hexane, benzonitrile and acetonitrile are
shown. The results of all fits are also summarized in Table 1.
From these data it becomes apparent that the surprisingly low
total reorganization energy is dominated by the solvent part
λ_o in all solvents with exception of the hexanes.[33]

A plot of each parameter against a term describing the
solvent polarity $(D-1)/(2D+1)-0.5(n^2-1)/(2n^2+1)$, where
D is the permittivity and n is the refractive index, reveals
linear correlations for both ΔG^{00} and λ_o (Figure 5a and b).[34]
As initially expected from Marcus' theory,[35] an increase of
the solvent reorganization energy λ_o with solvent polarity is
found. The solvent reorganization energy approaches zero for
totally apolar environments. Concomitantly, ΔG^{00} decreases
due to the fact that the excited state has zwitterionic character
while the ground state is apolar (see below). Therefore, the
usually observed negative solvatochromism of degenerate
ionic compounds is covered (compensated for) by the positive
solvatochromism of ΔG^{00} which leads to the weak solvent
dependence of the IV-CT band described above. The analysis
yields directly ΔG^{00} in CH_2Cl_2 (8350 cm^{-1}) which is in
reasonable agreement with the redox potential difference in
$CH_2Cl_2/0.1M$ TBAH ($\Delta E = 910$ mV $\cong 7340$ cm^{-1}). As
expected, the inner-sphere reorganization energy λ_v is inde-
pendent on the solvent polarity (Figure 5c). We also recorded
a weak but systematic solvent dependence of $\tilde{\nu}_v$ (Figure 5d),
which could be due to the varying importance of different
molecular modes contributing to the averaged mode $\tilde{\nu}_v$. On
the other hand, this shift may also compensate for inaccur-
acies of the theory in general.

Furthermore, the adiabatic dipole moment of the ground
state ($\mu_g = 13 \pm 2 \times 10^{-30}$ Cm $= 3.9 \pm 0.6$ D) and the difference
between the adiabatic ground and excited state ($\Delta\mu_{eg} = 64 \pm
4 \times 10^{-30}$ Cm $= 19 \pm 1$ D), and the transition moment ($\mu_{eg} =
11.0 \times 10^{-30}$ Cm $= 3.30$ D) of **1** were determined by EOAM
in 1,4-dioxane as previously described.[10] With these values
and Equation (2) the diabatic dipole moment ($\Delta\mu_{12} = 67.8 \times
10^{-30}$ Cm $= 20$ D) was calculated, which corresponds to an
effective diabatic ET distance of 4.2 Å; this is significantly less
than the C–N distance between the redox centers (12.3 Å).
With these transition moments the electronic coupling V was
calculated with Equations (1) and (2). Given the rather short
effective ET distance, the transition dipole moment $\mu_{eg} =
11.0 \times 10^{-30}$ Cm $= 3.30$ D and consequently the electronic


coupling $V = 2000$ cm^{-1} are noticeably small. This implies
that the electronic interaction between the two redox centers
in **1** is weak compared to that in an analogous MV compound
consisting of two triarylamine redox centers.[33] The AM1-
UHF calculation of **1** shows the reason for the weak
interaction between the two redox centers: steric interactions
among the perchlorinated ring systems cause a twist of the π
system.[36] This effect and the fact that the β-LUMO is largely

concentrated on the central triarylmethyl carbon p orbital while the β-HOMO is delocalized over the triarylamino group results in a weak conjugation of the aromatic redox centers (Figure 6).
Figure 6. AM1-UHF-optimized structure of radical **1**; β-HOMO (bottom) and β-LUMO (top).

Using the diabatic parameters determined by Jortner's theory as well as the electronic coupling V determined by the GMH theory, we computed the adiabatic potential energy surfaces for *n*-hexane and acetonitrile (Figure 7). It is obvious from these curves that the solvent has a dominating influence on the shape of the potential surfaces and thus also has an impact on the deactivation pathways of the excited state.

In summary we have presented the synthesis and a detailed study of the photophysical properties of the first neutral organic MV compound. Only by using Jortner's one-
Figure 7. Adiabatic potential energy surfaces of **1** in *n*-hexane (——) and acetonitrile (- - - -) calculated with Equation (3) of ref. [1] with $\mu_{eg} = 11.4 \times 10^{-30}$ Cm = 3.4 D and $V = 2070$ cm^{-1} in *n*-hexane and $\mu_{eg} = 11.4 \times 10^{-30}$ Cm = 3.4 D and $V = 2120$ cm^{-1} in acetonitrile. x = ET coordinate.

mode model were we able to analyze the IV-CT band and to reveal the compensating trends of the solvent reorganization energy λ_o and the free energy difference ΔG^{00}. Both effects are rather strong due to the highly zwitterionic character of the excited IV-CT state. The analysis demonstrates that a lack of solvatochromism is no indication for a negligible change of dipole moment upon excitation. This large change of dipole moment upon excitation was also directly proved by EOAM. These measurements also revealed that the effective diabatic ET distance is much smaller than the formal separation of the redox centers. The uncharged character of this prototypical neutral MV compound enabled us to perform the presented measurements quite easily. Our findings will be useful for the design of molecular storage and switching devices where a neutral character is of practical advantage.

Experimental Section

2: Pd$_2$(dba)$_3$·CHCl$_3$ (74.0 mg, 71.5 μmol, 0.05 equiv), P(*t*Bu)$_3$ (173 μL, 0.33 M in *n*-hexane, 57.2 μmol, 0.04 equiv), and NaO*t*Bu (344 mg, 3.58 mmol, 2.50 equiv) were added to a solution of stilbene **3**[24] (1.30 g, 1.43 mmol, 1.00 equiv) and bis(4-methoxyphenyl)amine (361 mg, 1.58 mmol, 1.10 equiv) in absolute toluene. The reaction mixture was stirred for 24 h under reflux in the dark under a nitrogen atmosphere. The solvent was removed in vacuo, and the residue was dissolved in CH$_2$Cl$_2$ (50 mL) and washed with water (2 × 50 mL). The organic layer was dried over MgSO$_4$, and the solvent was removed under reduced pressure. The residue was purified by flash chromatography on silica gel (petroleum ether/CH$_2$Cl$_2$ 1:1). The crude product was precipitated by adding a concentrated solution of **2** in acetone dropwise to methanol which gave 690 mg (0.65 mmol, 46%) of a yellow solid, m.p. 174°C. ^{1}H NMR (400 MHz, [D$_6$]acetone, 295 K): δ = 7.47 (AA′, CH=CHCC*H*CH, 2H), 7.11 (s, 1H, (C$_6$Cl$_5$C*H*), 7.10 (AA′, NCC*H*CHCO, 4H), 7.08 (d, $^3J_{HH}$ = 16.5 Hz, 1H, C=C*H*), 7.01 (d, $^3J_{HH}$ = 16.5 Hz, 1H, C=C*H*), 6.94 (BB′, OCC*H*CH, 4H), 6.85 (BB′, CH=CHCCHC*H*CN, 2H), 3.80 ppm (s, 6H, OC*H*$_3$); ^{13}C NMR (151 MHz, [D$_6$]acetone, 295 K): δ = 157.6 (q), 150.7 (q), 141.0 (q), 139.44 (H*C*=CH), 139.44 (2 C, q), 137.79 (q), 137.77 (q), 136.3 (q), 135.9 (2 C, q), 135.5 (q), 134.9 (q), 134.8 (q), 134.6 (q), 134.34 (q), 134.29 (q), 134.27 (q), 134.25 (q), 134.1 (q), 133.20 (q), 133.17 (q), 133.0 (q), 128.8 (*C*H=CHCCHCH), 128.1 (OC*C*HCH), 120.4 (H*C*=CH), 120.0 (CH=CHCCHCH*C*N), 115.7 (NCC*H*CHCO), 57.6 (C$_6$Cl$_5$-*C*H), 55.7 ppm (O*C*H3); IR (KBr): $\tilde{v}$ = 3037 (w), 2997 (w), 2929 (w), 2869 (vw), 2832 (w), 1599 (m), 1504 (vs), 1463 (w), 1323 (w), 1294 (w), 1241 (s), 1176 (w), 1105 (w), 1037 (m), 966 (w), 827 (m), 808 (m), 649 (w), 575 (w), 521 cm^{-1} (w); MS (EI, 70 eV) [*m/z*, %]: 1055 (74, M^+), 1040 (8, M^+−Me), 1021 (45, M^+−Cl), 987 (20, M^+−Cl−Me), 807 (36, M^+−C$_6$Cl$_5$). Elemental analysis calculated for C$_{41}$H$_{21}$Cl$_{14}$NO$_2$: C 46.64, H 2.00, N 1.33; found: C 46.35, H 2.23, N 1.39.

1: Stilbene derivate **2** (50.0 mg, 47.4 μmol, 1.00 equiv) was dissolved in absolute DMSO (10 mL) under a nitrogen atmosphere. KO*t*Bu (10.6 mg, 94.8 μmol, 2.00 equiv) was added, and the deep purple solution that formed immediately was stirred for 1.5 h in the dark at room temperature. Then *p*-chloranil (11.7 mg, 47.4 μmol, 1.00 equiv) was added, and the solution was stirred for further 1.5 h in the dark at room temperature. The deep brown suspension was purified by flash chromatography on silica gel (CH$_2$Cl$_2$/petroleum ether 4:1). The crude product was precipitated twice by adding a concentrated solution of **1** in acetone dropwise to methanol to obtain 30.0 mg (28.4 μmol, 60%) of a brown solid, m.p. 165°C (decomp.). IR (KBr): $\tilde{v}$ = 3040 (w), 2999 (w), 2945 (w), 2930 (w), 2909 (w), 2832 (w), 1595 (s), 1504 (vs), 1463 (vw), 1440 (vw), 1322 (s), 1242 (vs), 1174 (m), 1105 (w), 1037 (m), 945 (w), 816 (m), 707 (w), 653 (w), 575 (w), 521 cm^{-1} (w); MS (FAB, 70 eV, 2-(octyloxy)nitrobenzene) [*m/z*, %]:

1054 (< 1, M^+); Elemental analysis calculated for $C_{41}H_{20}Cl_{14}NO_2$: C 46.68, H 1.91, N 1.33; found: C 46.53 H 2.11 N 1.27.

[33] The analogous *N,N,N',N'*-tetraanisylstilbenediamine radical cation has an IV-CT band at $\tilde{\nu}_{max} = 6150$ cm^{-1} in CH$_2$Cl$_2$, which equals the total reorganization energy and which has a transition dipole moment of $\mu_{eg} = 43.4 \times 10^{-30}$ Cm $= 13.0$ D. See also C. Lambert, G. Nöll, *Angew. Chem.* **1998**, *110*, 2239; *Angew. Chem. Int. Ed.* **1998**, *37*, 2107.

[34] The usually employed Pekar factor $\gamma = 1/n^2 - 1/D$ from Marcus theory yields a quite similar linear correlation. We refrain from using the Pekar factor as it is negative for very apolar solvents and as it refers to an ion in a spherical cavity. The Onsager model employed here refers to the more realistic situation of a dipole in a spherical cavity, see ref. [32]. If one uses the Marcus theory for calculating the solvent reorganization energy with $\lambda_0 = (\Delta e)^2 (r^{-1} - d^{-1})\gamma$, where $\Delta e = 1$ is the charge transferred, $r = 7$ Å is the mean radius of the redox centers, and $d = 12.3$ Å is the distance between the nitrogen of the triarylamine group and the methyl carbon of the triarylmethyl radical (both values estimated from the AM1 computation), a linear correlation with λ_0 from Jortner theory is obtained with a slope of almost unity. However, this good correlation is to some extent fortuitous because the dipole moment differences measured by EOAM indicate a much smaller electron-transfer distance than the geometric distance of the redox centers.

Cover Picture

Anna Rencurosi, Edward P. Mitchell, Gianluca Cioci, Serge Pérez, Rogelio Pereda-Miranda,* and Anne Imberty*

In traditional Mexican farming the morning glory "heavenly blue" (*Ipomea tricolor* Cav.) is used as a cover crop. The structure of tricolorin A, one of several phytotoxic resin glycosides present in this plant, has now been determined crystallographically. The lipopolysaccharide contains one macrolactone ring and forms channel structures, which could be responsible for the biological activity of this compound, as reported by R. Pereda-Miranda, A. Imberty, and co-workers in their Communication on page 5918 ff.

Carbene Dimerization
R. W. Alder et al. give an overview of the thermodynamics, kinetics, and mechanisms of the dimerization of diaminocarbenes in their Review on page 5896 ff., in which they consider both experimental results and those from DFT calculations.
Bioinorganic Chemistry
In their Communication on page 5914 ff., P. J. Sadler and co-workers describe how a trinuclear oxo–zirconium(iv) cluster forms in the binding site of bacterial transferrin.
Mesoporous Materials
The directed synthesis of two- and three-dimensional mesoporous iron oxide structures by varying the aging conditions is presented by F. Jiao and P. G. Bruce in their Communication on page 5958 ff.

Highlights

Pores for effect: Hierarchical zeolites combine the high activity, shape selectivity, and hydrothermal stability of conventional zeolites with the efficient mass transport that is typically achieved in mesoporous materials. The mesopores can be templated with carbon during zeolite synthesis (see scheme).
Primed! Secondary phosphine oxides are able to tautomerize in situ to phosphinous acids and then coordinate to soft transition metals through the trivalent phosphorus atom (see scheme). The presence of a chiral backbone allows this reaction to run stereoselectively and be used for the generation of highly enantioselective homogeneous catalysts.

Essays
Discovery is a two-step process—finding and comprehending (see scheme). The history of chemistry contains incorrect attributions, mistakes, and problems created by conflicting interpretations. But retrospective analyses can set matters straight and give credit where credit is due. Language and naming also convey a fascinating human side to research and illustrate that chemical discovery is multifaceted, evolutionary, and very much alive.

Reviews
It's amazing what a little help can do: Simple diaminocarbenes, such as $(Et_2N)_2C$, do not dimerize at room temperature in THF, even though thermodynamics favor the dimer. Dimerization occurs rapidly in the presence of proton sources, however (see scheme), and the possibility of catalysis by Li^+ is discussed. DFT calculations give a good account of the thermodynamics and kinetics of dimer formation.

Communications

Filling a gap: A trinuclear oxo–zirconium(IV) cluster readily assembles in the "venus fly trap" binding cleft of bacterial transferrin (see picture; cluster: Zr green, O red, P yellow; protein: β sheets cyan, Tyr pink, Arg dark blue). Its structure was determined by EXAFS and X-ray crystallography.

0D→2D→3D oriented attachment has been exploited to prepare octahedra of rutile-like SnO_2 with a central cavity by a template-free hydrothermal route. The synthesis is based on the two-dimensional attachment of nanocrystallites and stabilization of a family of {111}-like crystal planes in 2-propanol/water in the presence of ethylenediamine. In TEM images of the octahedron (see picture), the central cavity is evidenced by lighter regions.
Mother Nature knows best! Silaffins (silica-associated proteins) from the diatom *Eucampia zodiacus* (see picture) were found to contain novel lysine modifications that carry quaternary ammonium groups. It appears that the very special interaction between quaternary ammonium groups and silica is exploited in the natural biomineralization of silica.
A filling that makes the sandwich: Large aromatic molecules are sandwiched by two π-conjugated ligands (L) that are joined together by six {(en)Pd}$^{2+}$ units (M; en = 1,2-ethanediamine; see picture; guest red, {(en)Pd}$^{2+}$ yellow, ligand blue). This host has an M_6L_2 composition and is distorted by the concave shape of the ligand. Without a guest, it releases the distortion by forming the dimeric $M_{12}L_4$ in a reversible fashion.

A box of magnetic tricks: By using the anionic precursor $[(Tp)Fe(CN)_3]^-$ (Tp^- = hydrotris(pyrazolyl)borate), the title compound, which is a new face-centered-cubic cluster, has been synthesized (see structure; red Fe, turquoise Cu, orange B, gray C, blue N, dark red O). Magnetic studies show that it exhibits single-molecule-magnet behavior with substantial axial magnetic anisotropy ($D = -0.16\ cm^{-1}$).
Turning on the light: Remarkable photoluminescence enhancement is observed upon intercalation of cetyltrimethylammonium cations (CTA$^+$) among the surface aromatic groups of a complex formed from the phenyl-capped semiconductor CdS cluster molecule [Cd$_{10}$S$_4$(SPh)$_{12}$] (**1**) and tetraoctylammonium bromide (TOAB) (see scheme).
Caminoside A

Information technology: The configuration at C10-OH of the caminoside aglycone (see formula) was shown to be *R* by interpretation of exciton coupling in the circular dichroism (CD) spectrum of the tetraphenylporphyrin carboxylate diester of (2*R*,10*R*)-2,10-nonadecanediol. This compound is derived from the title compound and was embedded in highly uniform nanometric liposomes for the CD measurements.
Spontaneous oxidation of the marine-sponge-derived peptide (+)-milnamide A (**1**) to (+)-milnamide D (**2**), which is also a natural product, was observed during the total synthesis of **1**. The absolute configurations of the structures were determined and are also reported.

Avidin–NP bioconjugate
Approximately eight avidin molecules are conjugated to each Ce/Tb-doped lanthanum phosphate nanoparticle (NP) through the formation of amide bonds (see scheme). This biofunctionalization process comprises modification of the LaPO$_4$ NPs with 6-aminohexanoic acid (AHA) to confer colloidal stability, activation of the AHA carboxy groups by 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide, and avidin conjugation.

Contents
Age concern: Alkyl amine templates act as bifunctional surfactants which can template mesostructures with microporous walls. Ordered two-dimensional hexagonal mesoporous iron oxide with $P6mm$ symmetry and three-dimensional cubic mesoporous iron oxide with $Fm3m$ symmetry (see TEM image) have been prepared by using decylamine as the template, iron(III) ethoxide as the precursor, and different aging conditions.
Do-it-yourself oxidation: The Rh^{III} complex **1** undergoes a self-oxidative coupling process, in which the phenolate oxygen atom serves as the oxidant, to give **2** and the hydride complex **3** (**2:3** = 1:3). This reaction involves cleavage of a strong aryl–oxygen bond. X-ray analysis of **2** reveals that the two quinonoid C=O bonds are η^2-coordinated to the metal centers.

Addition of the radical generated from the sodium salt of hypophosphorous acid to difluoroalkenes results in the formation of α,α-difluoro-*H*-phosphinates. These intermediates can be transformed into different phosphorus-centered isosteres, such as difluorophosphonates, difluorophosphonothioates, and difluorophosphinates (see scheme).
A twist in the final stage: Chiral, conjugated metallamacrocycles can be formed in excellent yield in a single step from achiral precursors by ligand exchange between (R,R)- or (S,S)-chiraphos and *trans* platinum acetylide complexes (see scheme).
A short and modular synthesis of novel
P,N ligands (pinap; see scheme; X = O or
NH) is presented. A covalently bound
chiral group allows the separation of the
atropisomeric diastereomers, thus avoiding resolution involving chiral Pd–amine
complexes. The utility of the ligands is
demonstrated for three reactions catalyzed by different transition metals; in
each case products are obtained with high
enantiomeric excess (up to 99% ee).

Weighing in: Multiple kinases can be
assayed simultaneously by using a
method that combines peptide chips and
MALDI-TOF mass spectrometry (MS).
The method uses self-assembled monolayers that present a set of peptides that
are each selective for a kinase. The kinase
phosphorylates the peptide, changing its
mass. MS analysis of the surface resolves
each peptide and gives the activity of each
kinase.
In the presence of an Evans oxazolidinone
as the chiral auxiliary, the anion derived
from α-diazoacetamide adds to aromatic
N-tosylimines with high stereoselectivity
(see scheme). The addition products can
be used in a concise and stereoselective
synthesis of *syn*- and *anti*-α-hydroxy-β-
amino acid derivatives.
Large pore volumes and highly accessible
mesopore surface areas are present in
highly ordered mesoporous bioactive
glasses (MBGs) prepared by a block
copolymer templating approach under
non-aqueous conditions. These glasses
have a high bone-forming bioactivity
in vitro, as shown by immersing them in
simulated body fluid (SBF) and monitoring the formation of hydroxycarbonate
apatite (HCA) on the surface (see electron
micrographs).

Contents
Aldol products with quarternary centers have been obtained with up to 99% *ee* in high yields by using copper(II) catalysts bearing C_1-symmetric aminosulfoximines as ligands (see scheme). In terms of *ee* values and yield the new catalysts compare well with established systems based on metal complexes with bis-(oxazoline) and pyridylbis(oxazoline) ligands.
Packed to capacity: The incorporation of mesoporous structures as a buffer layer enhances the structural stability of tin phosphate and alleviates the volume expansion of the tin phosphate anode during Li alloying/dealloying (see TEM image). The mesoporous tin phosphate/ $Sn_2P_2O_7$ composite anode shows a large initial capacity (721 mAh g^{-1}) and excellent cyclability (587 mAh g^{-1} at the 30th cycle).

R = H : (–)-eriolanin
R = Me : (–)-eriolangin
Sultones of swing: A sultone served as the key intermediate in the first enantioselective total syntheses of the bioactive title compounds (see scheme), the absolute configuration of which is now established. Starting from 2-bromo-1-(2-furyl)ethanone, 24 steps were required to generate the common basic structure, and in each case two additional steps yielded the natural products.
Centered by a nitride ion: The oxidation of ytterbium with 2,2′-dipyridylamine in liquid ammonia at low temperatures leads to the novel compound [Yb$_3$N(dpa)$_6$][Yb(dpa)$_3$], which is unique among homoleptic dipyridylamides of the rare-earth metals. The complete deprotonation of NH$_3$ provides the first molecular nitride of a rare-earth metal with a Yb$_3$N unit (see picture; C blue, N green, Yb silver).
In one fell swoop: the reaction of alkynyl-allyl alcohols with aryl halides in the presence of [Pd(PPh$_3$)$_2$Cl$_2$] under Heck reaction conditions provides cyclic γ,δ-enals (see scheme). This reaction serves as the starting sequence for the one-pot synthesis of diene esters and β-amino-substituted tetrahydrofurans.

J. T. Hynes Receives Hildebrand Award

James T. (Casey) Hynes is the recipient of the 2005 Joel Henry Hildebrand Award in the Theoretical and Experimental Chemistry of Liquids, administered by the American Chemical Society (ACS). The award recognizes distinguished contributions to the understanding of the chemistry and physics of liquids. Hynes completed his PhD in 1969 at Princeton University (USA). In 1971, following an NIH Postdoctoral Fellowship at the Massachusetts Institute of Technology (MIT), he moved to the University of Colorado, Boulder, where he is currently Professor of Chemistry and Biochemistry. Since 1999 he has also been CNRS Director of Research in the chemistry department of the École Normale Supérieure, Paris (France).

J. T. Hynes

Hynes's research on the theory of chemical reactions in solution, vibrational-energy transfer in solution, and intramolecular energy flow in highly vibrationally excited isolated molecules has had significant impact on the field. Other research interests include chemical reactions in enzymes and other biomolecules, electronic structure in condensed phases, and heterogeneous reactions important in the depletion of atmospheric ozone. One current topic of investigation and the subject of a recent article in *ChemPhysChem*[1] is the dissociation of aromatic radical anions in solution. Hynes is Co-Chairman of the Editorial Advisory Board of *ChemPhysChem*.

Cope Scholar Award to R. F. Ismagilov

Arthur C. Cope Scholar Awards, administered by the ACS, aim to recognize and encourage excellence in organic chemistry. The highly interdisciplinary research of one recipient for 2005, Rustem F. Ismagilov, includes aspects of chemistry, physics, biology, and engineering. His research group develops new microfluidic technology, which they use to study time-dependent processes in chemistry, biochemistry, and

R. F. Ismagilov

biophysics, as well as the dynamics of complex chemical systems. His most recent Communication in *Angewandte Chemie* about a composite microfluidic system for screening protein crystallization conditions in droplets inside capillaries by on-chip X-ray diffraction was featured on the cover of issue 19/2004.[2]

Ismagilov was born in Ufa (Russia) in 1973 and completed his BSc in chemistry at the Higher Chemical College of the Russian Academy of Sciences in Moscow. He then moved to the USA, where he completed his PhD at the University of Wisconsin, Madison under the guidance of S. F. Nelsen in 1998. After postdoctoral studies at Harvard University with G. M. Whitesides, he became assistant professor in 2001 at the University of Chicago.

P. Knochel Receives Cope Scholar Award

Paul Knochel is also to receive an Arthur C. Cope Scholar Award in 2005. Born in Strasbourg (France) in 1955, Knochel has had a very international career: He completed his studies in chemistry in 1979 at the École Nationale Supérieure de Chimie in Strasbourg, and his PhD in 1982 at the ETH Zürich (Switzerland) under the guidance of D. Seebach. Following several years as a CNRS researcher in the research group of J. F. Normant at the

Université Pierre et Marie Curie in Paris, he moved to the USA to undertake postdoctoral research with M. F. Semmelhack at Princeton University. In 1988 he was appointed assistant professor at the University of Michigan, Ann Arbor

P. Knochel

(USA), where he became full professor before returning to Europe in 1992 to a position at Philipps-Universität Marburg (Germany). Since 1999 he has been Professor of Organic Chemistry at Ludwig-Maximilians-Universität München.

Knochel's research interests focus on the development of novel organometallic reagents and methods for organic synthesis and asymmetric catalysis. Main group metals, such as lithium, magnesium, and boron, as well as late transition metals, such as copper and zinc, have been used for the synthesis of complex synthetic building blocks. He recently reported in *Angewandte Chemie* the preparation of polyfunctional arynes via 2-magnesiated diaryl sulfonates.[3] His Review on highly functionalized Grignard reagents prepared by halogen–metal exchange reactions appeared in 2003.[4]

Hierarchical Zeolites: A Proven Strategy to Combine Shape Selectivity with Efficient Mass Transport**

Martin Hartmann*

Keywords:
carbon · ethylbenzene · mesoporous materials · zeolites

Although a variety of chemical reactions of industrial interest are catalyzed by zeolites or zeolite-analogue materials, zeolite-based catalysts have almost exclusively found application in refinery and petrochemical processes where the shape-selective properties of the microporous zeolites are exploited.[1] One of the reasons that zeolites have not yet found a wider range of industrial applications is the sole presence of micropores which imposes diffusion limitations on the reaction rate. Mass transport to and from the active sites located within the micropores is slow (even compared to Knudsen diffusion) and limits the performance of industrial catalysts. To overcome this limitation, there has been a long-standing drive to either minimize the size of the zeolite crystals or to increase the pore size of zeolites. The latter strategy has led to the discovery of various large-pore zeolites and zeolite analogues (i.e. VPI-5,[2] UTD-1,[3] and more recently ECR-34,[4] SSZ-53, and SSZ-59[5]) and also to the discovery of mesoporous molecular sieves.[6] However, the use of these novel materials in industrial applications is rather limited. Another possibility is to decrease the size of the zeolite crystals and several synthesis schemes have been reported which allow the preparation of very small (< 50 nm) zeolite crystals.[7] However, none of these attempts has produced an easy means of controlling the crystal size. Moreover, separation of the small zeolite crystals from a reaction mixture by filtration is difficult owing to the colloidal properties of these materials.

Zeolites with hierarchical pore architecture (that is, zeolites containing both micro- and mesopores) have been found to present a solution to this problem. The effect of the presence of mesopores is already used in a number of industrial processes that make use of zeolite catalysts, such as, the cracking of heavy oil fraction over zeolite Y, the isomerization of the C_5/C_6 cut of the light naphtha fraction to increase the octane number, and cumene production over dealuminated mordenite.[8]

To prepare zeolites with hierarchical pore structure four approaches can be followed: 1) Small zeolite crystals are supported, for example, on latex spheres, carbon fibers, or surfactants, the support is then removed by calcination.[9] 2) The walls of mesoporous silicates (e.g. MCM-41 or SBA-15) are recrystallized or zeolite precursors are deposited on the walls of mesoporous supports.[10] 3) A widely applied method to generate mesopores involves steaming and acid-leaching treatments of zeolite crystals.[8] These methods generate mesopores by extraction of aluminum from the zeolite lattice. However, the mesopores formed during steaming are predominantly cavities in the zeolite crystals rather than cylindrical pores connecting the external surface with the interior of the crystal.[8] 4) Mesopores are templated with carbon during zeolite synthesis. This method was recently developed by researchers from Haldor Topsoe.[11–14] A carbon source, for example, carbon black, carbon nanotubes, or nanofibers,[15] is impregnated with a zeolite precursor solution after which the material is subject to a hydrothermal treatment to grow the zeolite crystals. In a subsequent calcination step, the carbon and the template are burned away resulting in intracrystalline mesopores in the zeolite (Figure 1). Proper choice of the carbon source and the synthesis conditions allows tuning of size, shape, and connectivity of the mesopores in the system. Furthermore, the mesoporosity and composition of

Figure 1. Growth of zeolite crystals around carbon particles. Nucleation of the zeolite occurs between the carbon particles; the crystal grows continues within the pore system of the carbon template.

the material can be varied independently.[11–14] In this context, the recent publication from the group of Christensen is worth mentioning.[16] They report the performance of zeolites with a hierarchical pore structure in an industrially relevant reaction, namely the ethylation of benzene to ethylbenzene, and compare the results to a conventional microporous HZSM-5 catalyst. The worldwide demand for ethylbenzene, which is the raw material for styrene production, is roughly 22×10^6 t per year and is almost exclusively produced by this reaction. The alkylation of benzene with ethylene over the HZSM-5 catalyst constitutes the heart of the Mobil–Badger process, which was first brought on stream in 1980. This high-temperature vapor-phase alkylation process offers various advantages over liquid-phase processes (by Monsanto or UOP) based on $AlCl_3$ or BF_3 catalysts. Compared to these Friedel–Craft catalysts, zeolites have the clear advantages of being noncorrosive and harmless to the environment. With the HZSM-5 catalyst an excellent selectivity for ethylbenzene of more than 98% is obtained at a benzene conversion level of about 20%. The uniform channels (dimensions $(d_p) = 0.51 \times 0.55$ nm) of zeolite ZSM-5 permit the entrance of the feed molecules as well as departure of the product molecules ethylbenzene and diethylbenzene isomers, while higher alkylated products are restricted from leaving. Any of the higher alkylated products formed within the ZSM-5 channels are forced to undergo transalkylation or dealkylation to facilitate their diffusion back to the bulk. Steric hindrance of the necessary transition states is also believed to inhibit the formation of polyalkylated products. Although these are the clear advantages of using a shape-selective microporous catalyst, the problems of catalyst deactivation by coke formation and low reaction rates owing to mass transport limitations are major obstacles to overcome.

Christensen et al. showed convincingly that the zeolite catalyst with the hierarchical pore architecture is significantly more active than the conventional zeolite catalyst under the reaction conditions employed ($T_R = 583$ to 643 K; $p_R = 0.25$ MPa), which are sufficiently close to the conditions employed in the industrial process ($T_R \approx 700$ K; $p_R = 2$ to 5 MPa).[16] Moreover, the selectivity to ethylbenzene increases by 5 to 10% depending on the benzene conversion. The increased activity is ascribed to the improved mass transport in the mesoporous zeolites which is indicated by an increase of the apparent activation energy from 59 to 77 kJ mol^{-1}. Attributing the higher activity to improved mass transport is further substantiated by the differences in selectivities observed for the two catalysts. The higher selectivity to ethylbenzene is explained by Christensen et al. in the following way: Whenever an ethylbenzene molecule is formed, it can either be transported into the product stream or undergo further alkylation. However, in a mesoporous zeolite the diffusion path is significantly shorter than in the conventional zeolite and further alkylation is suppressed.

The hierarchical catalyst used in this study was prepared by impregnating carbon black pearls (particle diameter = 12 nm) to incipient wetness with a clear zeolite synthesis gel. After a hydrothermal treatment at 180°C for 72 h in a stainless steel autoclave, the product was collected by filtration, washed, and the carbon black was removed by controlled combustion in air at 550°C for 8 h. The mesoporous zeolite obtained is characterized by a significantly higher specific pore volume (0.59 versus 0.10 cm^3 g^{-1}) and the presence of mesopores with a diameter of approximately 12 nm.[16] The size of the mesopores is predefined by the primary carbon particles which are encapsulated by the growing zeolite crystal and are later removed by the controlled combustion in air. The shape, size and tortuosity of the mesopores can be controlled by the carbon source used. To produce large zeolite crystals (with a hierarchical pore architecture) rather than nanosized zeolite crystals, it is essential that an excess of sufficiently concentrated gel is used and that the carbon matrix has pores of a size that allows crystal growth to proceed through the pore system. It is still not fully understood which synthesis parameters promote the formation of large mesoporous crystals over nanosized crystals located in the carbon pores. However, it seems reasonable to assume that the ration of the nucleation rate relative to the growth rate is of primary importance.[11]

Hierarchical zeolites have also been shown to be superior catalysts in the epoxidation of oct-1-ene and cyclohexene[12, 17] as well as in the isomerization of *n*-hexane and *n*-heptane.[18] In both cases, the activity as well as the selectivity for the desired products is higher than with the conventional zeolite catalyst.

In conclusion, the primary advantages of these new mesoporous zeolites compared with conventional micronsized zeolite crystals are related to their higher specific external surface area causing 1) higher reaction rates for diffusion-limited reactions, 2) better transport properties resulting in improved selectivities for the target molecules, 3) better contact between active components in bifunctional catalysts, 4) slower deactivation caused by blocking of the pore mouth, and 5) easier burn-off of coke deposits. Compared with nanocrystal zeolites, the advantages of hierarchical zeolites are related to their larger crystal size, that is, easier processing owing to noncolloidal properties and higher stability in high-temperature processes including catalyst regeneration. While the effect of mesoporosity on the catalytic performance of zeolite catalysts has been known for some time and is already employed in commercial catalysts, the major achievement in the work by Christiansen et al. is that the mesopores can be produced in a more controlled manner. Moreover, the direct connection of the mesopores to the external surface represents a significant improvement compared to the (predominantly internal) mesopores generated by steaming or acid leaching. However, different areas can be identified where further research and development are required, that is, tailoring the properties of the carbon source with respect to particle size and morphology and the use of different zeolites. The effect of a mesoporous secondary pore system on mass transport is expected to be much larger for zeolites with one-dimensional pore systems. In selecting materials used in industrial processes, mordenite or zeolite L might be prime targets. Moreover, synthesis strategies for hierarchical zeolites need to be developed for

Ligand Design

Enantioselective Catalysis with Chiral Phosphine Oxide Preligands

Natalia V. Dubrovina and Armin Börner*

Another new chiral ligand! The search for new construction principles for enantiomerically pure trivalent phosphorus compounds for enantioselective metal catalysis continues unabated. This statement may well give rise to astonishment since the number of chiral P ligands in the literature has in the interim entered the thousands.[1] Both academic and economic reasons are responsible for this phenomenon. Since the first use of chiral phosphines in Rh hydrogenation catalysts more than 30 years ago[2] new metal-catalyzed reactions that can be controlled by chiral P ligands have been continuously discovered.[3,4] Numerous applications of enantioselective syntheses in the pharmaceutical industry as well as in the production of chiral fragrances and agrochemicals also now bear witness to the considerable potential of this methodology in the chemical industry.[5] Important are a high enantioselectivity and productivity of the catalyst. Unfortunately theory has thus far offered scant help as to which substituents on the trivalent phosphorus atom give rise to the desired catalytic properties. This uncertainty has hitherto challenged the creativity of the catalyst chemist, and as a consequence has thrust many a "treas-

ure" of almost forgotten phosphorus chemistry into the light of day. Meanwhile the palette of phosphorus ligands ranges from electron-rich alkylphosphines[6], through phosphinites,[7] and phosphonites,[8] to electron-deficient phosphites.[9] The replacement of oxygen substituents in P-OR compounds with amino groups made further electronic and steric variants available.[10]

The number of choices is extended by the division into monodentate,[11] bidentate,[1] and tridentate[12] ligands, which in turn can coordinate with the catalytically active metal center with a wide range of bite angles.[13] Each newly discovered ligand class offers the guarantee of its patenting, an important aspect for an exclusive industrial exploitation in the future.

From a preparative viewpoint many trivalent phosphorus compounds are affected by one problem: they are subject to oxidation. It is therefore frequently necessary to work in an inert gas atmosphere, not exactly an advantage for routine use and scale-up. Repeatedly transient protection of the phosphorus atom is advised. However, only the BH$_3$ protective group, which when required can be removed in situ shortly before coordination to the metal center, has achieved any significance.[14] A disadvantage is that the P−BH$_3$ adduct is unstable towards a series of acids and Lewis bases. Moreover, commonly used deprotecting reagents such as strongly basic amines also attack hydrolyzable P−O bonds.

Significantly more robust is the protection of the phosphorus atom in the form of the P=O bond. Removal of the "oxygen protective group" takes place by reduction, which is normally carried

out with silanes in a separate reaction step prior to catalysis. However, in this way the problem of handling oxidation-sensitive phosphorus compounds is merely postponed, not solved.

One way out is offered by phosphine oxides (**1**; Scheme 1), about which will
Scheme 1. Pre-established tautomerization equilibrium for the generation of a P-ligand–metal complex.

be reported here. These phosphorus derivatives can be synthesized simply by, for example, a P–C coupling reaction with phosphine halides and subsequent hydrolysis of a remaining P−X bond.[15] They are stable to oxidation and inert to water. Naturally compounds of type **1** are not suitable to coordinate sufficiently strongly to soft transition metals through the hard oxygen atom. Their potential as ligands arises in the first instance through the tautomerism illustrated in Scheme 1 in which the pentavalent phosphine oxides **1** are in chemical equilibrium with the trivalent phosphinous acids **2**. As early as 1968 Chatt and Heaton pointed out that this equilibrium which lies far to the left-hand side can be displaced in favor of **2** by coordination to a suitable metal center.[16] In catalysis the term precatalyst is used for stable precursors of a catalyst, we therefore logically propose the term "preligand" for compounds of type **1**.

Roundhill and co-workers utilized the displacement of this tautomeric equilibrium (Scheme 1) to construct

the Pt hybrid complex **6** by reaction of the platinum tetrakisphosphine complex **4** with diphenylphosphine oxide (**5**)(Scheme 2).[17] One interesting detail of the ligand coordination is the intramolecular hydrogen bond in the backbone that leads to the formation of a quasi-chelate which confers additional conformational stability on the complex.[18]

In 1986 van Leeuwen et al. demonstrated for the first time the catalytic potential of preligands, namely in the Pt-catalyzed hydroformylation of olefins with terminal and internal double bonds.[19] Comparable catalysts were used later by Parkins for the hydrolysis of nitriles.[20] Although these results already indicated the value of this method for the in situ generation of trivalent P
Scheme 3. Solid-phase synthesis of preligands

resolution of the racemate. In principle these methods can be used for both tautomeric forms. Of potential for resolution of the racemate are, for example, salt formation or esterification of the phosphinous acid with chiral alcohols.[26]

The groups of Feringa and de Vries isolated the enantiomerically pure SPOs **10**–**12** on the 100 mg scale by preparative HPLC on chiral phases.[27] The new, monodentate preligands were used in the Ir-catalyzed enantioselective hydrogenation of prochiral acetophenone imines, for
Scheme 2. Construction of a Pt complex with a phosphinous acid as ligand by complexation of isomerized phosphine oxides.

ligands, it is only since 2001 that preligands have been used to a greater extent in homogeneous catalysis. Since this time they have been abbreviated to "SPOs" (secondary phosphine oxides).[21]

The first highlight point was Li's use of SPOs in Pd-catalyzed cross-coupling reactions with non-activated aryl chlorides.[22] The syntheses of the preligands received particular impetus through the use of combinatorial methods. An extensive palette of phosphine oxides **9a** was prepared by the addition of Grignard reagents or metal alkyl compounds to the heterogenized dichlorophosphinamines **7a** and hydrolysis of the products **8a** (Scheme 3). Secondary phosphine oxides (**9b**) with four different substituents on the phosphorus center were accessed by the use of mono-alkylchlorophosphines (**7b**).

Shortly afterwards Wolf and Lerebours too used SPOs in Pd-catalyzed coupling reactions of arenes.[23] At the same time they reported the high stability of the catalysts to hydrolysis in Stille couplings in water as solvent.[24]

The work of Li had already established the ready accessibility of SPOs with a stereogenic phosphorus atom, whose most prominent area of application should be enantioselective catalysis. An old problem of synthetic chemistry could also be a step closer to a solution: the synthesis of ligands with a stereogenic phosphorus atom is still more difficult than that of P ligands with a chiral carbon backbone,[25], even though significant improvements have been achieved recently.[6]
Two possibilities for the synthesis of enantiomerically pure SPOs, which fortunately are highly stable towards epimerization, appear especially promising: the diastereoselective generation of the stereogenic phosphorus atom and

which up to 83 % ee was obtained with phosphine oxides of type **10**.

Whereas the enantiomerically pure preligands in the above example had to be prepared by tedious HPLC separation, Hamada and co-workers recently succeeded in synthesizing the enantiomerically pure diaminophosphine oxide **15** by highly diastereoselective in situ hydrolysis of the triaminophosphine **14** (Scheme 4).[28] The starting material for this conversion, the triamine **13**, is accessible in a few steps from L-aspartic acid. The formation of **15**, which was
Scheme 4. In situ synthesis of a diamidophosphorus acid silyl ester ligand. Bn = benzyl.

isolated in 60% yield as the main product of the hydrolysis on moist SiO$_2$, could be monitored by ^{31}P NMR spectroscopy.

The preligand **15** was tested in the Pd-catalyzed enantioselective alkylation of unsymmetrical diketones in the presence of bis(trimethylsilyl)acetamide (BSA).[29,30] Surprisingly, the best results were obtained with an excess of four equivalents of BSA. Detailed investigations showed that in the presence of Pd^{II}, complete tautomerization with subsequent coordination of the phosphorus acid **16** to the metal ion did not, as expected, take place; the displacement of the equilibrium is first enforced by in situ O,N silylation with BSA. The ligand **17** subsequently coordinates at the palladium center. This compound could also be prepared and isolated in a comparison experiment by silylation of **15**.[31] Thus, at the end of this new and fascinating reaction sequence a nitrogen analogue of ligand classes recently well established in enantioselective homogeneous catalysis is obtained: that of the chiral, monodentate triesters of phosphorus acid (phosphites)[9] and diesters of amidophosphorus acid (amidophosphites).[32,33]

It remains to add that high yields and up to 94% *ee* were achieved with ligand **17** in the alkylation of cinnamyl acetates with β-substituted cycloalkanones. Kinetic investigations confirmed that two monodentate ligands coordinate at the Pd center. The exocyclic aminoethyl group which was already essential in the diastereoselective formation of the preligand **15** has possibly a directing effect upon the attacking nucleophile within the context of an attractive secondary interaction.[34]

Essays

The Road to Chemical Names and Eponyms: Discovery, Priority, and Credit

*Pedro Cintas**

Dedicated to Professor Jerome A. Berson for his "discoveries" of scientific discovery

Introduction

What's in a chemical name? Tracing the origins and significance of such names often requires careful detective work. The naming of a theory, chemical substance, transformation, or unit of measurement dates back at least to the alchemists. The history of science has demonstrated that language is not only the means by which the practitioners communicate, but it also conveys a fascinating and instructive social dimension that enriches our culture. The origins of element names along with the etymology of traditional chemical names (which have been progressively replaced by more systematic ones) constitute representative examples.[1] In addition, the naming after a scientist reflects a description of the more human side of research and says much about two intertwined issues: discovery and proper recognition. Consider, for instance, a series of 20th century chemists who are credited with discovering some selected and useful organic reactions: Grignard, Robinson, Wittig, Brown, Stille, Heck, and Suzuki. Nowadays, recognition mostly comes naturally because an academic or industrial chemist may use multiple publications to describe the work and because of the present trend of putting value and weight on frequency of citation. But such bibliometric indexes were absent when the landmark discoveries were made that propelled an obscure branch of natural philosophy into modern chemistry.

In an earlier perspective on discoveries missed and discoveries made, Berson admirably addressed this concern and wrote that the defining property, which is also the immutable precondition of creativity, is the proper conflation of rational and imaginative elements.[2] In a more recent essay on carbon skeletal rearrangements, he again discussed the act of discovery and disputes over priority.[3] What is more, Berson formulated a thought-provoking question: why worry about proper attribution of credit?

"A candid response would be that it is good to be first for some easily listed reasons: our grant proposals, our patent applications, and…our egos. … However, there is another purpose. That is the need to understand the dynamics and temporal course of the process of discovery itself. Only by this kind of analysis is it possible to apprehend the mutual influences of scientific theories and experiments."

Both premises are likely to be correct. Numerous scientists claimed a particular discovery or invention as their own, while being fully aware of previous (or almost simultaneous) work. In fact, renaming has been a common practice in the history of science. On the other hand, the correct assignment of credit places a discovery within a particular historical context. However, the intriguing question to be addressed is to what extent such an assignment reflects the entire intellectual and imaginative process. Some authors simply describe an isolated, yet remarkable, experimental observation but overlook its importance entirely.

Even worse, our modern interpretation of a particular phenomenon may often differ from the original statement. This essay is a brief journey through some historical episodes, illustrating that chemical discovery is in fact a domino reaction, in many ways a portrait of the evolution of chemistry through the researchers who claim credit. Here, the philosophy of science, rather than narrative history, can be of further help. It is not my goal to discuss whether discovery is consistent with philosophical theories, an aspect that some chemists will no doubt debate.[4] Instead we should catch a glimpse of the human side of discovery and credit, which leads to relevant conclusions. Probably the main point is that individual contributions are often overestimated and only a broader perspective contributes to the advancement of science.

Elementary, My Dear Uncle Tungsten[5]

Many elements have been known since the ancient times and their names have therefore an obscure origin; others with miscellaneous origins were named after a place or a peculiar property; and finally some elements were named after people. These include bohrium, curium, einsteinium, fermium, gadolinium, lawrencium, meitnerium, mendelevium, nobelium, and rutherfordium. None of them were actually discovered by the corresponding scientists, which supports the so-called Stigler's law of eponymy claiming that no scientific discovery is named after its original discoverer.[6] (It

should be noted, nonetheless, that eponymy holds for names derived from real or mythical figures, not necessarily the discoverer.[7]) Perhaps, there is a notable exception: seaborgium (element 106). It was named after nuclear chemist Glenn Theodore Seaborg (1912–1999). The element was first created by a team led by Albert Ghiorso at the Lawrence Berkeley National Laboratory in 1974. The team also included Glenn Seaborg as co-discoverer. A few months earlier, Russian scientists in Dubna reported to have synthesized the same element. However, credit was given to the Berkeley group in 1993. Dubnium (after Dubna) is now the name of element 105, its production being first reported by Russian scientists in 1967, although in 1970 both the Dubna team and a group from Berkeley confirmed the discovery.[8]

But if an element is at the heart of disputes on priority, it must surely be oxygen. In their play *Oxygen*,[9] Carl Djerassi and Roald Hoffmann present their 21st century vision of the act and importance of discovering. As we know, the fictional play recreates an encounter of the three independent discoverers—Scheele, Priestley, and Lavoisier—and their wives in Stockholm in 1777 where they critically discuss their chemical experiments. Then the story launches into the second act with the establishment of a retro-Nobel prize in 2001, on the occasion of the centenary of the prizes. The Nobel committee investigates and analyzes the conflicting claims of the three scientists. At first, this seems to be a story about human psychology, but it is really about human-defined value judgments on science and the sometimes unexpected consequences of their use.

This play is also instrumental in questioning what we call discovery and who deserves proper recognition. Historical records[8,10] suggest that the discovery should be credited to Joseph Priestley (1733–1804; Figure 1), who isolated oxygen in 1774. It was obtained earlier, in 1771, by Carl Wilhelm Scheele (1742–1786) but published later. Priestley believed that oxygen was "dephlogisticated air" and continued to believe it until his death in 1804, even though Antoine-Laurent Lavoisier (1743–1794) disproved experimentally the phlogiston
Figure 1. J. Priestley (1733–1804) was a codiscoverer of oxygen. Like Columbus, he died without realizing the importance of his discovery.

theory in 1783. Likewise, Scheele believed that the gas he isolated reacted with phlogiston in combustion reactions. It took several years and a good deal of experimentation before Lavoisier arrived at the conclusion that the gas was a new element, which he called "oxygène". Only the French chemist truly understood what the discovery meant.[10] Thus, discovery is really a two-step process: finding and comprehension, although some discoverers should be credited with only the former.

To be honest, it is reasonable to assume that neither Scheele nor Priestley were the first to obtain oxygen. That recognition should go to unknown European or Arabic alchemists who were skilled in thermal reactions. Some scholars have attributed that honor to the Dutch engraver, glassworker, and inventor Cornelius Jacobszoon Drebbel (1572–1633), who reported in 1621 the pyrolysis of saltpeter, a process producing oxygen.[11] Remarkably, Drebbel also suggested a method of making sulfuric acid by the oxidation of sulfur.

Some scholars hold that chemistry evolved from a metaphysical idea of composition into an empirical idea of composition, which was pioneered by Lavoisier and settled by Dalton's atomic theory.[12] The phlogiston theory was one interpretation among others to cope

with such an empirical concept. Neither phlogiston nor combustion itself was a dominating issue before Lavoisier, nevertheless. From the 1770s onwards, investigations on the composition of air boosted combustion as a recurrent theme with theoretical implications, and it was thereby susceptible to refutation. Lavoisier knew that something essential was missing in the phlogiston theory. Unlike the work of Scheele or Priestley, Lavoisier's discovery was not a matter of experimental skill; he relied on intuition and creative leaps in drawing conclusions.

The story of another gas, radon, equally illustrates this thesis on finding and recognizing phenomena. Radon is a radioactive and hazardous gas, the heaviest of the noble gases. Most noble gases were discovered by Sir William Ramsay (1852–1916) and co-workers between 1895 and 1898. Radon, however, is attributed to the German chemist Friedrich Ernst Dorn (1848–1916), who apparently called it *radium emanation* in 1900. Surprisingly, this erroneous attribution arises from a flawed translation of Dorn's original paper published in a local journal. This fact was pointed out by Partington almost six decades later[13] and investigated in detail in a very recent study.[14]

Dorn certainly noticed a previous observation of Ernest Rutherford (1871–1937) on the emanation from thorium. Dorn also repeated Rutherford's experiments and found that while uranium and polonium did not show the emanation phenomenon, thorium and radium did. The nature of such an emanation was not investigated by Dorn; it was, however, by Rutherford and Pierre and Marie Curie from 1902 on. Together with Frederick Soddy (1877–1956), Rutherford studied the physico-chemical and nuclear properties of the emanation, noting that it passed unaffected through physical barriers (cotton and water) and chemical substances (phosphorus pentoxide, sulfuric acid, heated magnesium, and even almost-molten platinum). By 1903 they claimed the existence of a new element.[15] "*It will be noticed that the only gases capable of passing in unchanged amount through all the reagents employed are the recently discovered members of the argon family.*" Two decades

later, the then International Committee on Chemical Elements replaced the term radium emanation by radon.[16]

A further story on credit and priority comes from the discovery of vanadium (element 23), first isolated by the Spanish chemist and mineralogist Andrés Manuel del Río in 1801 but officially credited to the Swedish chemist Nils Gabriel Sefström, who rediscovered it in 1831.[8,17] Del Río (1764–1849) was born in Madrid and after studying chemistry, geology, and mineralogy, he traveled through Germany, France, and England. In 1791 he became an assistant to Lavoisier. By 1794 he moved to Mexico as a teacher at the Real Colegio de Minas en Ciudad de Mexico. In 1801 Del Río analyzed lead ores and, after successive chemical tests, he believed to have discovered a new element, which he called panchromium (from the Greek: all colors) in view of the wide range of colors of its oxides, salts, and solutions. Later, he named it erythronium (from the Greek: red) due to the intense red color of its salts when heated with acids. Del Río gave a sample of the ore containing erythronium to Alexander von Humboldt (1769–1859), who visited the Colegio de Minas in 1803. Humboldt had received instruction in mineral chemistry and convinced Del Río that the new element was presumably chromium, which also forms similar colored derivatives. Del Río withdrew his previous assignment and published a correction in a Spanish journal in 1804.[18] But Humboldt vacillated, and after returning to Europe, he gave a sample of the lead ores to a French chemist for further analyses, who concluded that no new element was present.[19] Humboldt finally accepted that erythronium was chromium and forwarded these results to Del Río. It took a long time, however, before this analysis reached Mexico, and Del Río felt frustrated as he had already published the conclusion that the element present in the brown ore was chromium.

The lack of recognition for Del Río adds a critical element of reflection. Chemistry throughout the 19th century was largely influenced and dominated by French and German scientists. Very few Spanish chemists had much contact with other European scientists. The reasons for this lack of contact are not clear, although at that time cultivated people in Spain often grouped chemistry with astrology and magic. Spaniards turned their attention to practical activities like mineralogy in which they gained reputation.[20] Del Río's annoyance for the lack of proper credit was expressed in a letter forwarded to Humboldt several years later.[17] "*We Spaniards should not make any discovery, no matter how small, either in chemistry or mineralogy, these being a foreign monopoly. … Did I lose all credit for not having known in 1802 all the properties of chromium in a country so lacking in books, where for the same reason the sciences are so little cultivated?*"

Despite this, Del Río and Humboldt professed reciprocal admiration. That Humboldt was not fully convinced that the salt isolated was a chromate is evidenced by the fact that he also gave a sample to Friedrich Wöhler (1800–1882) to reinvestigate its composition. In the meantime Nils Sefström (1787–1845) obtained a new element from an iron mineral and gave it the name of vanadium (after Vanadis, a Scandinavian goddess of love). Sefström gave some vanadium pentoxide to Jöns Jacob Berzelius (1779–1848), who also sent it to Wöhler. The German chemist conclusively demonstrated that vanadium was identical to erythronium, the element isolated by Del Río 30 years earlier.

Renamed Laws

Like elements, some of the most important physico-chemical laws and theories reveal the issues of priority and proper recognition. In most cases incorrect attributions arise from misunderstanding, neglect, and controversy, for which scientists and historians alike are responsible. The forgotten scenarios and actors of physical chemistry have been the subject of scholarly studies by Laidler.[21] This analysis is reminiscent of that of Nobel prizes, which may certainly be awarded to undeserving scientists whereas deserving ones may be overlooked. In a recent book[22] Hargittai classes nonwinners into those whose discovery was never honored by a Nobel prize and those who participated in a recognized discovery but who were not

awarded the prize. Similar observations are often made in the history of science.

It might be surprising to state that Robert Boyle (1627–1691) did not discover Boyle's law, but anticipation of the phenomenon should correctly be attributed to Richard Townley (1628–1707) and Henry Power (1623–1668) who, in 1660, established the relationship between pressure and the volume of an expanded gas.[23] Boyle began his studies on the properties of gases several years earlier with the invaluable help of his assistant Robert Hooke (1635–1701), who helped him to construct a vacuum pump.[24,25] Boyle described the properties of air and that air is necessary for respiration, combustion, and propagation of sound. Such results were published in 1660 in *New Experiments Physico-Mechanical, Touching the Spring of the Air and its Effects*.[26] In 1661 Boyle submitted a report to the Royal Society, in which he presented improved experimental results on the relation, now known as Boyle's law, that the pressure of a gas is inversely proportional to its volume at constant temperature. The second edition of his 1660 work containing this result appeared in 1662.

Two of the most salient chemical laws, Le Chatelier's principle and the Arrhenius equation, were not deduced by the scientists who have become recognized by the naming of these laws. In both cases, the proper recognition must go to Dutch chemist and first recipient of the Nobel prize in chemistry, Jacobus Henricus van't Hoff (1852–1911; Figure 2), who suggested these relationships in his pioneering studies on physical chemistry in 1884.[27]

Henry-Louis Le Chatelier (1850–1936) also published his results the same year stating that if a system in an equilibrium state is disturbed, the system will readjust in such a way as to neutralize the perturbation and restore equilibrium.[28] In praise of Le Chatelier, it is fair to say that he explicitly mentioned van't Hoff as the pioneer of this conclusion. Some related ideas, yet in a vague form, were anticipated by Josiah Willard Gibbs (1839–1903), whose works Le Chatelier later translated into French.

The equation that correlates the effect of temperature on reaction rates

 www.angewandte.org

Figure 2. J. H. van't Hoff (1852–1911) was a key figure in modern stereochemistry and physical chemistry but never claimed priority and recognition.

was also suggested by van't Hoff,[27] as a consequence of the equation for equilibrium constant. Svante August Arrhenius (1859–1927), quoting van't Hoff, applied this equation to numerous reactions, thereby demonstrating its general value.[29] Perhaps due to his previous and bitter experience with Kolbe, van't Hoff was always a quiet and modest man. He never claimed priority and shared credit with his contemporaries. This reveals an exceptional and appealing attribute, unusual in most scientists.

Play It Again, Alexander!

The legendary image of scientists as brilliant encyclopedic minds has been progressively replaced by the image of people competent in a narrowly defined domain, at least from the 19th century on. Thus, no one would imagine any modern chemist pursuing chemistry with along with another professional activity. A notable exception, however, was the great Russian composer and chemist Aleksandr Porfirevich Borodin (1833–1887). The author of *Prince Igor* and other operas and symphonies received his doctorate in 1858 from the Medico-Surgical Academy in St. Petersburg. From 1859 to 1862 he studied in western Europe. On returning to Russia

he became adjunct professor of chemistry at the Medico-Surgical Academy and was named full professor in 1864.[30]

Borodin largely investigated oxygenated compounds, and his most important contribution, which was once called the Borodin reaction, involves the combination of a silver carboxylate with bromine to afford an alkyl bromide, CO_2, and $AgBr$.[31] Borodin should be credited with this transformation, even though he did not prove that the product was an alkyl bromide. Most organic chemists have forgotten Borodin and refer to this process as the Hunsdiecker reaction. The Hunsdieckers, husband and wife, reinvented and really developed the Borodin reaction in the 1940s.[32]

Russian chemists also experienced a lack of recognition as time went on. This is ironic as modern chemistry owes a great debt to Russian chemists ranging from Mendeleev to Arbuzov, and other key figures who are seldom acknowledged. The lack of credit has often been attributed to the insular nature of Russian industry along with unfamiliarity of the West with the Russian language. Recent studies also point to an academic culture in Russia based on theory with little emphasis on the practical uses of basic research.[33]

Chemists will probably find less compelling those reasons dealing with social, economic, and political factors, which cannot be dismissed anyway.[34] Thus, in the 20th century the impact of wars, the reaction to the economic depression, and the tragedy of the Jews in the 1930s and 1940s contributed to the oversight and even denial of the role of some scientists. A still controversial factor is the fact that credit and priority are chiefly attributed by a dominant culture.

Consider, for instance, Fritz Georg Arndt (1885–1969), best known for the Arndt–Eistert homologation reaction, who also made significant contributions to the development of resonance theory and the emergence of physical organic chemistry. Christopher Ingold and his associates have been credited as the main protagonists in the field. Arndt was born in Germany in a Jewish family and pursued a significant part of his career in Turkey. He clarified the difference between tautomerism and reso-

nance, and introduced the currently accepted representations of reversible arrows for tautomerism and double-headed arrows for resonance.[35]

Likewise, olefin formation by means of phosphonate carbanions is often referred to as the Wadsworth–Emmons or Horner–Wadsworth–Emmons modification of the Wittig reaction, although the pioneering studies were carried out by Horner.[36] Horner's work was subject to another relevant oversight. Homogeneous asymmetric hydrogenation was initiated by Knowles and Horner with their 1968 publications. Subsequent

Figure 3. V. V. Markovnikov (1838–1904). He would hardly recognize the rule now bearing his name.

breakthroughs were made by Kagan and Knowles in the 1970s. This sequence of events has now been acknowledged in modern studies on enantioselective hydrogenation,[37] though only Knowles has received proper recognition.

Did You Say That?

The assignment of priority and credit to the discoverers in the teaching and learning of the underlying principles of a law or theory, although desirable from a historical point of view, may also be inaccurate. This situation exists when the original statement differs substantially from its subsequent formulation or interpretation, regardless of whether the author deserves recognition. What we

always call the Markovnikov rule is probably a striking example of such an inaccuracy.[38] Named after a giant of the structural theory and isomerism, Vladimir Vasilyevich Markovnikov (1838–1904; Figure 3), the rule predicts the regiochemistry of addition reactions to unsymmetrical alkenes. Ask any undergraduate student of organic chemistry what the rule says, and the answer will almost certain be that in the addition of a protic acid to the double bond of an alkene, the proton adds to the less substituted carbon atom of the double bond.

This principle is found in most sophomore and advanced organic chemistry textbooks. Surprisingly, *Markovnikov never wrote this corollary in such a way.* In 1870 Markovnikov published a long paper containing work from his doctoral thesis (1869) at the University of Kazan.[39] In this paper he described the addition of hypochlorous acid to propene and correctly assigned the structure of the resulting chlorohydrin as 1-chloro-2-propanol. However, he was cautious in formulating a general rule because his PhD mentor Aleksandr Mikhaylovich Butlerov (1828–1886) had previously suggested a structure of a primary alcohol for the addition product of HOCl to isobutene. Markovnikov stated: "*While it is impossible at this time … to detect a clear general rule on the manner of addition of the elements of hypochlorous acid to unsaturated hydrocarbons, for hydrohalic acids such a general rule is available … the halide adds to the less hydrogenated carbon atom, that is, to the carbon which is more under the influence of other carbons.*"[*]

He continued, on the basis of previous studies with Kolbe,[40] adding that

"*… in the addition of a hydrohalic acid to vinyl chloride, chlorinated propylene, and other analogs, the halide will always add to the carbon atom which is already attached to a halide.*"[*]

It should be emphasized that Markovnikov focuses invariably *on the fate of the halide ion* in the product. One might argue that our modern citation of the rule, that is, the hydrogen going to the less substituted carbon, is simply an equivalent statement. This change of the perspective is nevertheless especially puzzling within the historical context. In 1874 Henry, without giving credit to Markovnikov, proposed that in the addition of a reagent XY to unsymmetrical substrates, the more negative radical (X) becomes attached to the less hydrogenated carbon and the less negative radical (Y) to the more hydrogenated carbon.[41] This agrees with the result suggested by Markovnikov for hydrohalic acids; but for HOCl, Henry proposed the polarity $HO^+ Cl^-$, and this would add in inverse form to Markovnikov's rule. Markovnikov was forced to reformulate his observations in a more extended way:[42] "*[In the addition of YZ to unsaturated molecules] at low temperature, the more negative element or group (Y) combines with the less hydrogenated carbon atom, or with that which was already attached to some negative element; but at higher temperatures, it is the element Z which becomes attached to the less hydrogenated carbon … the reaction follows a course entirely opposite from the first case.*"[**]

After Markovnikov's death, "his rule" was seldom cited for nearly three decades.[38a] In the 1930s Kharasch and his associates began their detailed studies on halogen acid addition reactions. Little use was made of the rule, as numerous substrates led to exceptions. On the basis of the peroxide effect in HBr additions, they then referred to "normal" and "abnormal" additions.[43]

What is especially astonishing throughout this story is the widely used term "anti-Markovnikov", which is difficult to interpret according to what Markovnikov did say. Anti-Markovnikov additions were popularized after the seminal works on hydroboration by Herbert Brown and his associates.[44] As strange as it may be, *addition of a borane to an alkene does take place according to Markovnikov's rule* of 1875,[42] that is, the more negative hydride ion becomes attached to the less hydrogenated carbon in the transition state of this concerted process. It is only after conversion of the borane-addition product into the resulting alcohol that a conflicting result emerges.

We have now learned that a sound interpretation of the regiochemical outcome of addition reactions lies in the principles of physical organic chemistry. The modern rule can thus be extended to electrophiles other than protic acids, by saying that the electrophilic addition to an alkene occurs in such a way as to generate the most stable intermediate, usually a carbocation.[45]

It comes as a surprise that some scholars question honoring Markovnikov by naming a rule after him.[38] Markovnikov had great influence on structural chemistry in the 19th century and made important contributions to structure and isomerism for which he should be remembered. But the rule bearing his name draws attention away from the logical principles of modern chemistry. Perhaps Markovnikov himself would have objected to a recognition that misused his words.

What Have We Learned?

In short, a discovery is a complex event. Recognition usually brings a wave of smugness about the superiority of a few scientists. In reality, there is no

---

[*] This citation appears as follows in the original article:[39] "*Wenn es wegen der ungenügenden Zahl der Beobachtungen unmöglich ist, jetzt eine gewisse Gesetzmäßigkeit für die Art der Verbindung der Elemente der unterchlorigen Säure mit ungesättigten Kohlenwasserstoffen auszusuchen, so ist für die Haloïdwasserstoffsäuren eine solche Regelmäßigkeit vorhanden. … wenn ein unsymmetrisch constituierter Kohlenwasserstoff sich mit einer Haloïdwasserstoffsäure verbindet, so addiert sich das Haloïd an das weniger hydrogenisirte Kohlenstoffatom, d. h. zu dem Kohlenstoff, welcher sich mehr unter dem Einflusse anderer Kohlenstoffe befindet.*"

[*] The original article[40] reads: "*daß bei der Addition der Chlor-, Brom- oder Jodwasserstoffsäuren zu dem Vinylchlorür, gechlorten Propylen und anderen Analogen, sich das Haloïd immer zu dem Kohlenstoffatom addiren werde, welches schon mit einem Haloïd verbunden ist.*"

[**] This citation appears as follows in the original article:[42] "*Lorsqu'à une molécule non saturée $C^n H^m X$ s'ajoute un autre système moléculaire YZ à une température basse, l'élément ou le groupe le plus négatif Y se combine avec l'atome de carbone le moins hydrogéné, ou avec celui qui était déjà en liaison directe avec quelque élément négatif; mais, à des températures comparativement plus hautes, c'est l'élément Z qui se fixe sur le carbone le moins hydrogéné, c'est-à-dire que, pour les mêmes substances, la réaction prend une marche tout à fait opposée à la première.*"

such thing. Forgotten geniuses have made huge and often unrecognized contributions to the advancement of science and scientific thought. A discovery is, above all, a domino reaction, in which successive pieces ultimately make up the whole. This metaphor was highlighted in this essay by examples of elements, reactions, and laws which illustrate the distinction between finding and comprehension. The first protagonist may come across an unexpected outcome in the course of a particular topic, while others make efforts to understand and explain the whole phenomenon. Moreover, discoveries (or reformulations) have been the test of many of the theories and techniques of chemistry, which were once accepted. The concluding lesson can be extracted from an insightful Baconian aphorism: "*Experiments that yield light are more worth while than experiments that yield fruit.*"[46] As a chemist often turned an apprentice of history, I have nothing more to add.

Reaction Mechanisms

When and How Do Diaminocarbenes Dimerize?

Roger W. Alder,* Michael E. Blake, Leila Chaker, Jeremy N. Harvey,
François Paolini, and Jan Schütz

half-life (at ≈1M) » 2 weeks
at 25 °C in THF
calculated 10⁷ years
N̄o example of a simple uncatalyzed dimerization of a diami-nocarbene has been clearly established, so it is timely to ask what factors control the thermodynamics of this reaction, and what mechanisms are responsible for the observed dimerizations? In agreement with qualitative experimental observations, the dime-rizations of simple five- and six-membered-ring diaminocarbenes are calculated to be 100 kJ mol^{-1} less favorable than those of acyclic counterparts. This large difference is semiquantitatively accounted for by bond and torsional angle changes around the carbene centers. Carbenes such as $(Et_2N)_2C$ are kinetically stable in THF at 25°C in agreement with calculated energy barriers, but they rapidly dimerize in the presence of the corresponding formamidinium ion. This proton-catalyzed process is probably the most common mechanism for dimer formation, and involves formation of C-protonated dimers, which can be observed in suitable cases. The possibility of alkali-metal-promoted dimeri-zation is raised, and circumstantial evidence for this is presented.

From the Contents

1. Introduction

Since the first observation of a stable imidazol-2-ylidene in 1991,[1] derivatives of diaminocarbene have become the focus of intense study,[2–4] and have also entered the market-place as extremely valuable ligands for catalytically active transition-metal complexes.[5–7] One fundamental aspect of their behavior, their dimerization to derivatives of tetraami-noethene, remains poorly understood however. Herein, we review current knowledge of both equilibria and kinetics for diaminocarbene dimerization; the very limited knowledge about thiazol-2-ylidenes and related species will be men-tioned where appropriate. We will use the set of simple diaminocarbenes, **Me5–iPrA** (**5** denotes the ring size, **A**

Me5, R = Me
Et5, R = Et
iPr5, R = iPr
tBu5, R = tBu

Me6, R = Me
Et6, R = Et
iPr6, R = iPr

Me7, R = Me
Et7, R = Et
iPr7, R = iPr

MeA, R = Me
EtA, R = Et
iPrA, R = iPr
stands for acyclic) to illuminate the factors which control the answers to two questions:

When do diaminocarbenes dimerize? (Equilibria)

How do they dimerize? (Kinetics and mechanism)

We will show that dimerization is typically 100 kJ mol^{-1} more favorable for acyclic and seven-membered-ring car-benes than for five- and six-membered cyclic carbenes, and discuss the reasons for this unexpected result. With respect to kinetics and mechanism, we will argue that most dimers are formed by proton-catalyzed or possibly metal-ion-catalyzed routes and that the classic dimerization mechanism[8] for a singlet carbene (Figure 1) in which the filled sp^2 orbital of

each carbene interacts with the for-mally empty p orbital on the other has yet to be established experimen-tally and may be extremely uncom-mon for diaminocarbenes.

We first review the evidence concerning the dimerization of imi-dazol-2-ylidenes **1**, benzimidazol-2-ylidenes **2**, and dihydroimidazol-2-ylidenes (e.g. **Me5–tBu5** and related derivatives with more complex R substituents).

Probably well over 90% of all studies of diaminocarbenes concern five-membered-ring compounds, but we will argue that the N-C-N angle (necessarily small in five-membered-ring compounds) is an important parameter in controlling the behavior of diaminocarbenes, and that more attention should be paid to acyclic diaminocarbenes and to other ring sizes.

We then briefly review methods of preparation of diaminocarbenes with particular reference to the generation of **Me5**–*i*PrA, and provide experimental evidence that proton-catalyzed mechanisms (Scheme 1) are common routes to dimers. The mechanism for dimerization in Scheme 1 has been discussed in other contexts. Thus Arduengo et al.[9] reported that the dimerization of a relatively stable thiazol-2-ylidene was catalyzed by proton sources, and the elegant labeling experiments of Chen and Jordan[10] demonstrate dimer formation by nucleophilic thiazol-2-ylidene addition to a thiazolium ion during thiazolium-ion-catalyzed benzoin condensation.

and seven-membered-ring species, and we show that unexpected stability trends among the carbenes, rather than the dimers, is responsible for this. An attempt is made to identify the structural factors responsible for these trends. DFT studies of the transition states for the uncatalyzed dimerization of carbenes **Me5**, **Et5**, **Me6**, **MeA**, and **EtA** show that the energy barriers are generally high, but also vary strikingly with carbene structure, so that very few diaminocarbenes are likely to dimerize by the classic mechanism, in agreement with current experimental understanding. Some aspects of the proton-catalyzed mechanism (Scheme 1) will be discussed in the light of the results of DFT calculations which point to the importance of the relative basicity of carbenes and dimers. Finally, we will provide circumstantial evidence that Li species, while stabilizing diaminocarbenes thermodynamically, may also provide metal-catalyzed pathways for dimerization.

Scheme 1. Proton-catalyzed mechanism for carbene dimerization.

We will then discuss density functional calculations on the thermodynamics for dimerization of carbenes **Me5**–*i*PrA; these reveal that dimerization is relatively unfavorable for five- and six-membered-ring carbenes, compared to acyclic

2. Diaminocarbene/Tetraaminoethene Equilibria; Previous Experimental and Computational Evidence

Simple unhindered imidazol-2-ylidenes such as **1** (R = R′ = Me) are thermodynamically stable towards dimerization to tetraazafulvalenes.[11] This extraordinary fact should be fully appreciated at the outset of any discussion of diaminocarbene dimerization. Replacing the four hydrogen atoms of ethene with two RN−CR=CR−NR bridges leads to the complete disappearance of the $>700\ kJ\,mol^{-1}$ bond energy of the C=C double bond! This can be seen as the consequence of the enormous stabilization of the singlet state of each imidazol-2-ylidene. Part of this stabilization arises from the

Roger Alder has been at the University of Bristol (UK) since 1965 and is now an Emeritus Professor of Organic Chemistry. His major research interest has been in the physical organic study of novel molecules, including proton sponges, medium-ring bicyclic structures and in/out isomerism, novel types of polymers with strong conformational control and, most recently, stable carbenes.

Leila Chaker was born in Tunisia. She received her Maitrise from the Joseph Fourier University (France) and her PhD from the Claude Bernard University (France). She was a postdoctoral research fellow at the University of Auckland, New Zealand (1996–2000) in the area of supramolecular fullerene–porphyrin chemistry and then at the University of Bristol, (2000–2002). She is currently a research associate at the University of Wollongong (Australia), developing new strategies for regioselective multifunctionalization of the fullerene cage with designed tethers.

Jeremy Harvey has been a Lecturer in Theoretical Chemistry in Bristol (UK) since 1999, and an EPSRC Advanced Research Fellow since 2003. His research uses computational methods to understand reaction mechanisms, especially in organometallic and bioinorganic chemistry. As a former organic chemist, he also maintains a strong interest in organic reactivity.

Michael Blake was born in 1973 in Ilseworth (UK). He completed his undergraduate studies at the University of Bristol (UK) where he also obtained his PhD for studies on diaminocarbenes in the group of Prof. R. W. Alder. He held a two-year postdoctoral research position with Prof. M. Jones, Jr. at Princeton University (USA) investigating reactive intermediates. He is currently working at the University of Exeter (UK) within the field of asymmetric catalysis with Dr. R. Bedford.

aromaticity of imidazol-2-ylidenes, and Heinemann and Thiel[12] calculated the singlet–triplet gap to be 354 for imidazol-2-ylidene, 290 for dihydroimidazol-2-ylidene, and 245 kJ mol^{-1} for diaminocarbene itself. This leads to estimates of the C=C bond strengths of **3**, **4**, and **5** to be 4, 130, and 222 kJ mol^{-1} respectively. Gibbs free energies (at the MP2/6-
311G** and B3LYP/6-311G** levels) for dimerization of a number of carbenes, including those giving **3–5**, have been reported recently.[13] The most convincing experimental proof of the weakness of the C=C bond in tetraazafulvalenes comes from elegant experiments by Taton and Chen.[14] The tightly constrained compound **6** exists as the tetraazafulvalene, whereas the homologue with longer tethers dissociates into the dicarbene **7**. Perhaps equally remarkable is the fact that the central C=C bond in **6** is of normal length (1.337 Å), even though the strength of this bond can be only a few kJ mol^{-1}.

Benzoimidazol-2-ylidenes **2** lose less of their aromatic stabilization than imidazol-2-ylidenes when they dimerize, and unhindered examples exist as dimers at ambient temperatures. However, two studies have demonstrated that equilibria between carbene and dimer can be established. Dissociation of (**2**)$_2$ (R = Et) in [D$_{14}$]diglyme was observed in the temperature range 313–383 K;[15] the thermodynamic parameters for dissociation are $\Delta H° = 57.3 \pm 2.5$ kJ mol^{-1} and

$\Delta S° = 127 \pm 7$ J mol^{-1} K^{-1}. The more sterically hindered dimer (**2**)$_2$ (R = CH$_2$CHMe$_2$) dissociates in solution at ambient temperature, reaching an equilibrium of 90% carbene and 10% dimer after 24 h.[16] In non-aromatic five-membered-ring diaminocarbenes, substantial steric hindrance is required for the carbene to be thermodynamically stable to dimerization.

Thus *t*Bu5 is a stable crystalline solid, but **Me5**, **Et5**, and **iPr5** dimerize.[17] Cheng and Hu[18,19] have calculated E_a and ΔE values for the dimerization of some imidazol-2-ylidenes and dihydroimidazol-2-ylidenes at the B3LYP/6-311G(d,p)//B3LYP/6-31G* level of theory. Our results reported in Section 7 agree satisfactorily with theirs.

Six-membered-ring carbenes have received much less attention,[20, 21] but the dimer of carbene **Me6** has been known since 1965,[22, 23] and (**Et6**)$_2$ is also known.[24] We found that **iPr6** shows no evidence of dimerization[25, 26] so the boundary line for six-membered-ring diaminocarbenes is clearly established. No seven-membered-ring carbenes such as **Me7**–**iPr7** have been studied previously.

The boundary line beyond which acyclic carbenes are thermodynamically stable to dimerization has not been clear. Bis(diisopropylamino)carbene (**iPrA**) does not dimerize,[27] whereas bis(dimethylamino)carbene (**MeA**) is clearly unstable with respect to its well-known dimer tetrakis(dimethylamino)ethene. Dipiperidinocarbene, which may be considered with the acyclic carbenes, has been shown[28, 29] to dimerize slowly to the known tetrakis(piperidino)ethene.[30, 31] The situation with respect to **EtA** will be discussed in Section 4.

3. The Controversy Concerning the Kinetics of the Wanzlick Equilibrium[32]

In his early papers,[33–35] Wanzlick proposed that tetra-aminoethenes dissociated reversibly to generate diaminocarbenes to account for the reaction of the former with electrophiles to give products apparently derived from the carbene (his examples were all dihydroimidazol-2-ylidenes). However in 1964 Lemal et al.[36] showed that typical tetraaminoethenes did not dissociate, even under much more drastic conditions than used by Wanzlick et al., by carrying out a negative crossover experiment (Scheme 2a, Ar = *p*-tolyl). Lemal et al. proposed that the reactions with electrophiles proceeded by electrophilic attack on the dimer which then dissociated (Scheme 2b) into one equivalent of product and one of carbene, subsequently also attacked by E$^+$.

François Paoloni was born in 1980, and studied Chemistry at the University of Montpellier (France). He worked under the supervision of Prof. R. W. Alder as part of an Erasmus exchange at Bristol University. He is now doing a PhD in polymer chemistry at the University of Reading under the supervision of Prof. H. Colquhoun.

Jan Schütz was born in 1976 in Langen (Germany) and studied chemistry at the Universities of Darmstadt, Bristol, and Munich. He completed his Diploma studies in Stanford under the supervision of Prof. R. M. Waymouth. Since 2002 he has been working on his PhD thesis with Prof. W. A. Herrmann. His research is focused on new organometallic carbene complexes and their application in catalyses.

Scheme 2. Crossover experiment carried out by Lemal et al. and explanation for the reaction of electrophiles with dimers.

Denk et al.[37] recently carried out some related crossover experiments and claimed to find crossover under conditions similar to or milder than those used by Lemal et al. This work has been subsequently challenged by Lemal and Liu,[38] who showed that no crossing over took place when the reactions were run in the presence of potassium hydride to prevent electrophilic catalysis. Lemal and Liu pointed out that a trace impurity "however nefarious" could not prevent the occurrence of unimolecular dissociation, and therefore could not prevent crossover. On the other hand it could catalyze crossing over, for example by the mechanism in Scheme 2b. It seems therefore that unimolecular tetraaminoethene dissociation has not been convincingly observed so far. In their study of equilibration of benzoimidazol-2-ylidenes with dimers, Hahn et al.[16] suggested that unimolecular dissociation was involved, but Lemal et al.[15] were more cautious, suggesting that electrophilic catalysis of equilibration might be occurring. Clearly, the mechanism for proton catalysis of the dimerization of a diaminocarbene (Scheme 1) is simply the reverse of Lemal's mechanism.

4. Diaminocarbene Preparation; The Example of Bis(diethylamino)carbene

Diaminocarbenes are strong bases,[39,40] powerful nucleophiles, and complex strongly with most metals in the periodic table.[5] They are normally rapidly destroyed by moisture,[41] although they do not react with normal triplet oxygen,[42] and they can usually only be handled in hydrocarbon or ether solvents. Two general methods for the generation of diaminocarbenes have been reported: a) deprotonation of tetraalkylformamidinium salts with bases, and b) the reaction of potassium metal in THF with the appropriate thiourea.[43] Bertrand et al.[44] have recently reported a new general method which involves the reaction of chloroamidinium salts with $Hg(SiMe_3)_2$; some important results from this method will be discussed in Section 5. Method (b) above has the advantage that potassium sulfide is insoluble in THF, and so complexation of the carbene with metals should be minimized. However it has the major disadvantage that the reaction is quite slow, even in refluxing THF. For this reason method (a) is usually employed for sensitive diaminocarbenes which may dimerize.

In their original work,[3] Arduengo and co-workers used NaH or KH in THF, usually in the presence of additives like KOtBu or DMSO (to generate the soluble dimsyl anion). Herrmann et al.[45] reported that sodium amide in liquid ammonia/THF at −40 °C was also effective for the preparation of imidazol-2-ylidenes. However the amidinium salts that are precursors to carbenes **Me5–iPrA** are much more susceptible to nucleophilic attack than the aromatic imidazolium salts used to generate imidazol-2-ylidenes, so that even hexamethyldisilazide bases frequently lead to addition reactions in competition with deprotonation. For the generation of diaminocarbenes **Me5–iPrA**, it is generally necessary to use sterically hindered alkali metal amide bases, such as lithium diisopropylamide (LDA) and lithium 2,2,6,6-tetramethylpiperidide (LiTMP). The experimental situation is further complicated by complexation of the carbenes to the alkali metal counterions of the bases. The first X-ray structural evidence for a carbene–lithium adduct, **8**, obtained by

(Ar = 2,4,6-trimethylphenyl)
Arduengo, Tamm and co-workers, was reported in a paper by Boche et al.[46] Other reported lithium complexes include **9**,[47] and a homoleptic complex containing two of the anionic tripod ligands **10** wrapped around two lithium ions.[48] We showed that **iPr6** complexed to lithium, sodium, and even potassium species in THF and in toluene and obtained the X-ray structure of the potassium complex **11**.[25,26]

The preparations of **iPrA**[27] and **iPr6**[25] which are stable to dimerization are relatively straightforward, as they can be purified by sublimation or distillation. We have also described the generation of a solution of **MeA** in THF by the addition of a solution of LiTMP in THF to a suspension of tetramethylformamidinium chloride in the same solvent.[49] A full description of our procedures will be published elsewhere, but the methods and results for the case of bis(diethylamino)carbene, **EtA**, will be described here (Scheme 3), since they are highly relevant to a discussion of diaminocarbene dimerization.

Following our standard procedure, an equivalent of LDA in THF is added to a solution of tetraethylformamidinium hexafluorophosphate (**A**) in THF.[50] The THF is removed by evaporation and the residue taken up in hexane and filtered to remove as much of the inorganic salts as possible (all operations are carried out under an atmosphere of dry nitrogen). The filtrate is evaporated, and the residue taken up in [D$_8$]THF for the NMR spectroscopic studies. As shown in Scheme 3, this generally results in mixtures of carbene B and the known dimer **C**,[51] each recognized by their distinctive ^{13}C NMR shifts; the ratio of **C** to **D** is typically about 70:30, but is somewhat irreproducible (see below). Addition of one equivalent of [2.1.1]cryptand results in the ^{13}C resonance for the carbene center shifting from 244 to 252 ppm. Addition of more cryptand does not lead to any further shift in the ^{13}C resonance, so free carbene is clearly now present (we have reported[25] that crown ethers are inadequate for removing lithium complexation). Once formed, the free **EtA** remains essentially unchanged in THF at ambient temperature for at least a week. A small degree of general decomposition is observed, but no dimer beyond that already present is formed. It is clear that **EtA** is kinetically stable to dimerization even though we know equilibrium favors the dimer.

Hexamethyldisilazide bases are too nucleophilic to be used to generate **EtA** (see Scheme 3, **E**), but we have devised a more hindered base, which yields the free carbene directly.
Scheme 3. Generation of bis(diethylamino)carbene (**EtA**). Reverse addition denotes the addition of **A** to LDA.

Potassium di-*tert*-butyltetramethyldisilazide (**F**) in THF can be generated by sonicating potassium hydride (freed from oil) with a solution of di-*tert*-butyltetramethyldisilane[52] in THF overnight (the corresponding lithium derivative is easily generated by using *n*-butyllithium). Unlike potassium diisopropylamide which decomposes THF rapidly, **F** only causes a slow decay over several hours. Moreover, it emerges that **EtA** does not complex significantly to potassium, so we obtain the free carbene directly.

5. Experimental Evidence for Dimer Formation from the Reaction of Diaminocarbenes with Formamidinium Ions

The observation that free carbene does not dimerize, even though the dimer is thermodynamically stable, is not confined to diaminocarbene **EtA**; we see similar behavior with carbenes **Me6** and **Et6**. Once prepared, these carbenes appear to be so stable in THF at room temperature that alternative decomposition pathways intrude before any dimer formation is seen. Bertrand et al.[44] have recently reported that free **Me6**, generated by reaction of 2-chloro-1,4,5,6-tetrahydro-1,3-dimethylpyrimidinium chloride with Hg(SiMe$_3$)$_2$ is indefinitely stable and can be sublimed at 40°C. Preliminary studies show that generation of the seven-membered-ring carbene *i*Pr7 by addition of base to the corresponding amidinium salt does result in the formation of dimer as well as carbene; the dimerization of *i*Pr7 in the absence of metal ion complexation, and the generation of carbenes **Me7** and **Et7** have not been examined yet. Denk et al.[17] reported that carbenes **Me5**–*i*Pr5 persist in solution (in C$_6$D$_6$), but slowly dimerize. It was reported[17] that these dimerizations obey a second-order rate law, and that pure carbenes dimerize within minutes, but that frozen solutions in benzene at −20°C can be stored indefinitely. A forthcoming kinetic investigation was mentioned in this work, but has not appeared to our knowledge. We find that when carbene *i*Pr5 is generated from the formamidinium tetraphenylborate precursor, using a slight excess of **F** in THF, it shows no sign of dimerization after 24 h in ~1M solution in [D$_8$]THF; the

^{13}C NMR peak at $\delta = 235.5$ ppm suggests that the carbene is essentially free of complexation. When prepared by using lithium di-*tert*-butyltetramethyldisilazide in THF, carbenes **Me5** and **Et5** show no sign of dimerization after 24 h in ~1M solution in [D$_8$]THF, but are present as Li complexes(^{13}C NMR peak at $\delta = \sim 222$ ppm); we have not yet studied the decomplexation of these carbenes.

Bis(dimethylamino)carbene, **MeA**, does not survive when [2.1.1]cryptand is added at room temperature to solutions containing its Li complex but the dimer, tetrakis(dimethylamino)ethene, is not formed. Instead a remarkably complex ^{13}C NMR spectrum is seen, with many lines in the 0–100 ppm region, and characterization of the products has proved impossible so far. Bertrand et al.[44] have recently found that free **MeA**, generated by reaction of 2-chloro-1,1,3,3-tetramethylformamidinium chloride with Hg(SiMe$_3$)$_2$ at low temperatures, does not yield tetrakis(dimethylamino)ethene when warmed to 0°C, but decomposes over a few hours again producing a complex mixture of products. What alternative pathways might there be for the decomposition of **MeA**? Bertrand's group[53] have recently described the isomerization of a stable aminoaryl carbene into a transient azomethine ylid, and it is possible that **MeA** is converted by rearrangement or by proton transfer reactions into an azomethine ylid, which then reacts further (the unsymmetrical nature of products expected from the ylid might help explain the numerous ^{13}C NMR resonances). Calculations at the B3LYP/6-31G* level predict that **12** and **13** are 47.8 and 58.3 kJ mol^{-1}, respectively, less stable than **MeA**. While it is hard to assess
how reliable these values might be, they probably do not rule out the involvement of azomethine ylids in the decomposition. Azomethine ylids are less likely to be involved in the reactions of five-membered-ring carbenes; we calculate that **14** is 111.9 kJ mol^{-1} less stable that **Me5**, reflecting the unusual stability of diaminocarbenes in five-membered rings.

Clearly the dimer observed in the earlier experiments does not come from direct carbene plus carbene dimerization. The obvious alternative is reaction of carbene with its precursor formamidinium ion (see Scheme 1 above). By choosing to add the base to the amidinium salt, we are giving this alternative route to dimer the best chance to occur, and it is likely that the rate of addition affects the carbene/dimer ratio. Addition of solutions of the amidinium salt to the base should result in more carbene and less dimer. In practice the procedure described above was normally used because many amidinium salts are more or less insoluble in THF or any other solvent (ethers or hydrocarbons) which is unreactive towards diaminocarbenes. Fortunately tetraethylformamidinium hexafluorophosphate is relatively soluble in THF, and the reverse procedure with slow syringe pump addition of the salt solution to LDA in THF does lead to the formation of nearly pure carbene (<5% dimer).

A good test of the mechanism in Scheme 1 would be the direct observation of a protonated dimer, and we have indeed found that this is possible in some cases. Addition of 0.5 equivalents of lithium bis(trimethylsilyl)amide to a solution of *N,N'*-diethyl-3,4-dihydroimidazolium hexafluorophosphate in THF, while stirring at 0 °C, followed by removal of the solvent, gave an off-white solid with the ^{1}H and ^{13}C NMR (in CD$_2$Cl$_2$) shifts shown for **15** in Scheme 4. The
Scheme 4. Protonated dimer formation and structure.

chemical shifts are entirely in accord with expectations for the structure shown; Chen and Jordan[10] report shifts of $\delta = 66$ and 173 ppm for the two conjoined carbon atoms in their protonated dimer derived from a thiazol-2-ylidene. The observation of nonequivalence for the methylene groups associated with the aminal ring in **15** is particularly convincing. As far as we are aware, this is the first observation of a C-protonated tetraaminoethene derivative. The DFT-calculated conformation shown on the right of Scheme 4 is typical of protonated dimers; the two rings are more or less mutually perpendicular.

When the same experiment of adding 0.5 equivalents of base is repeated with tetraethylformamidinium hexafluorophosphate, protonated dimer is *not* observed. Instead, the reaction cleanly results in the formation of a 1:1 mixture of the tetrakis(diethylamino)ethene dimer and unchanged amidinium salt. We suggest that in this case there is rapid deprotonation of the protonated dimer intermediate by free carbene. We will provide computational evidence in Section 9 that the different behaviors observed for the experiments associated with carbenes **Et5** and **EtA** are in agreement with the relative basicities of carbene and dimer in the two cases.

6. Structures for Diaminocarbenes Me5–iPrA, and Their Dimers

We have computed structures for carbenes **Me5–*i*PrA**, the corresponding formamidinium ions, and for the carbene dimers in the gas phase at the B3LYP/6-31G* level.[54] Many of these species, especially the dimers, can exist in a number of conformations, and this was carefully assessed by carrying out MCMM conformational searches using the MMFFs force field in MacroModel for dimers and for amidinium ions (used as steric models for the carbenes) to locate low-energy conformations before optimizing these by DFT calculations. Calculated structural data is given in Table 1, together with experimental data, where known, and the structures of the simple methyl-substituted carbenes **Me5**, **Me6**, **Me7**, and **MeA** are illustrated in Figure 2.

B3LYP/6-31G*-calculated structures for the carbenes and formamidinium ions agree well with the limited experimental data. Formamidinium ions have C−N bond lengths of 1.32 ± 0.01 Å, while in the carbenes the C−N bond lengths are 1.35 ± 0.02 Å, and these values are reproduced to within 0.02 Å in the calculations. Denk's group reported the X-ray crystal structure of carbene ***t*Bu5**[17] and the corresponding formamidinium thiocyanate.[55] We have reported the X-ray crystal structures of carbene ***i*PrA** and of the corresponding formamidinium triflate;[27,50] we also determined the structure of the formamidinium hexafluorophosphate corresponding to **Et6**.[50] A number of structures contain the tetramethylformamidinium ion; in Table 1 data is shown for the salt $(Me_2N)_2CH\cdot[(H_2C(NMe_2)_2)NiCl_3]$.[56]

In the complex **11**, comprising ***i*Pr6** and KN(SiMe$_3$)$_2$,[25] the carbene is coordinated to the potassium ion through a bond 3.00 Å in length that is surely mainly electrostatic in nature. The calculated bond lengths and angles for ***i*Pr6** agree with those for the carbene moieties in the complex. In complex **11**, the isopropyl methyl groups are oriented away from the carbene center, which could reasonably be ascribed

to steric repulsion from the hexamethyldisilazide anions. Surprisingly however, the isolated carbene *i*Pr6 is calculated to prefer the same conformation, although the corresponding formamidinium ion prefers the alternative structure with the isopropyl methyl groups clustered around the formamidinium proton according to the calculations. Weak attractive interactions between the isopropyl hydrogen atoms and the carbene sp^2 lone pair might be present in *i*Pr6.

Acyclic and seven-membered-ring carbenes and formamidinium ions are somewhat twisted about the C-N-C-N bonds, and this may reduce their stability (see Section 7). One notable trend in Table 1 is that N-C-N angles are typically 10° smaller in the carbenes than in the amidinium ions. The parent diaminocarbene, $(H_2N)_2C$, is calculated to have an N-C-N angle of 112.2°, whereas in $(H_2N)_2CH^+$ this angle is 125.4° according to a B3LYP/6-31G* calculation. These structural differences could have major consequences for the fundamental properties of diaminocarbenes. The singlet–triplet (S–T) gap decreases sharply as the N-C-N angle increases, whereas the proton affinity (PA) increases, as shown in Table 1. Even for acyclic diaminocarbenes such as **MeA** however, the S–T gap is still so large that there is no evidence this has any effect on reactivity. On the other hand, there is little doubt that the basicity of diaminocarbenes is of major significance. Larger ring and acyclic formamidinium ions are likely to require stronger bases for deprotonation, but be more reactive as bases and nucleophiles once prepared. This is in agreement with qualitative observations. As described above, the generation of acyclic diaminocarbenes generally requires the use of the strongest amide bases, and when competitive deprotonation of five- and six-membered-ring formamidinium ions is attempted, only the five-membered-ring carbene is formed, although this preference may be kinetic rather than thermodynamic. Richeson et al.[21] have shown that carbene **16** (N-C-N angle 115.3°) is a better donor than dihydroimidazol-2-ylidenes, as judged by the value of v_{CO} in a $Rh(CO)_2Cl$ complex. By the same criterion however,[57] it is not as good a donor as the acyclic carbene *i*PrA, which has the largest known N-C-N angle.
Tetraaminoethenes have attracted considerable attention, due to their ease of oxidation and chemiluminescent reactions,[58] and X-ray crystal structures of a number of these compounds have been reported, although most of these have additional rings and/or aromatic substituents on the nitrogen atoms. Calculated structural data for a number of dimers are given in Table 2 and selected structures are illustrated in Figure 3.

The experimental structures for $(MeA)_2$[59,60] and $(Me5)_2$[17] show conformational differences from the calcu-

lated structures. This may reflect deficiencies in the calculations, but they might also be caused by crystal packing forces, and the calculated structures all seem reasonable. Note that whereas (**Me6**)$_2$ adopts a double-chair structure with one axial and one equatorial methyl group in each ring, in the preferred structures for (**Et6**)$_2$ and (**iPr6**)$_2$ the six-membered rings adopt twist-boat conformations to alleviate the serious interactions between the attached alkyl groups.

7. Dimerization Equilibria for Diaminocarbenes Me5–iPrA; B3LYP/6-31G* Computations

We have used B3LYP calculations to a) study dimerization thermodynamics for all diaminocarbenes **Me5**–**iPrA** (discussed in this Section), b) find the transition states for the uncatalyzed dimerization (see the Section 8), and c) look at some aspects of the proton-catalyzed mechanism (Scheme 1), particularly in the light of computed proton affinities of carbenes and dimers. The energies (ΔE), enthalpies (ΔH), and free energies (ΔG) for the dimerization of carbenes **Me5**–**iPrA** from B3LYP/6-31G* calculations in the gas phase are shown in Table 3.

Table 3: ΔE, ΔH, and ΔG values for carbene dimerization at 298 K and 1 atm pressure from B3LYP/6-31G* calculations.

Carbene	ΔE [kJ mol^{-1}]	ΔH [kJ mol^{-1}]	ΔG [kJ mol^{-1}]
Me5	−123.9	−113.0	−42.1
Et5	−116.2	−105.6	−39.6
iPr5	−116.5	−105.7	−43.0
tBu5	36.0	47.0	127.3
Me6	−107.4	−98.8	−36.4
Et6	−88.3	−78.1	−12.0
iPr6	−64.1	−54.7	8.3
Me7	−194.3	−188.1	−132.8
Et7	−172.1	−164.1	−101.8
iPr7	−133.2	−123.2	−52.9
MeA	−209.6	−202.0	−138.5
EtA	−161.1	−154.3	−95.1
iPrA	−54.9	−40.7	40.9

The calculated values for ΔG are in striking agreement with the experimental evidence in THF. Thus **tBu5**, **iPr6**, and **iPrA** are the only carbenes for which ΔG is positive, and these carbenes are indeed the only ones known not to dimerize significantly. Note that **Et6** and **iPr6** are predicted to lie on either side of the borderline, and experimentally we see complete dimerization for the former, but have not observed the dimer of **iPr6**. In spite of this striking agreement of experiment and theory, we recognized that B3LYP/6-31G* calculations represent quite low-level theory, and moreover that we are comparing gas-phase calculations with experimental results from solution. We have therefore sought to calibrate our calculations further from two directions:

There is experimental data for one actual carbene/dimer equilibrium: In the case of **2** (R = Et) Lemal et al.[15] report $\Delta H = -57.3$, $\Delta G = -19.4$ kJ mol^{-1} at 298 K in [D$_{14}$]diglyme. B3LYP/6-31G* calculation of this equilibrium *in the gas phase*

yields $\Delta H = -62.7$ and $\Delta G = +4.0$ kJ mol^{-1} in rather satisfactory agreement with the solution data.

For the parent diaminocarbene, we have carried out CCSD(T)/6-311G** calculations, followed by MP2 calculations with a larger basis set and the application of an additional correction (the "G2(B3LYP/MP2/CC)" method[61]). This method is expected to give a value that is reliable to within 10 kJ mol^{-1}, barring unexpected (and very rare) major problems. The value of ΔE for the dimerization is −198 kJ mol^{-1}, compared with −225.5 kJ mol^{-1} from the B3LYP/6-31G* calculation; thus the latter appears to favor the dimer by about 30 kJ mol^{-1}. Carbenes should be favored in polar solution relative to their dimers (calculated dipole moments for **MeA** and **Me5** are 2.5 and 2.8 Debye, respectively). We therefore ran B3LYP/6-31G* calculations for carbenes **Me5**, **Me6**, **MeA**, and **EtA** and their dimers in THF, employing the Poisson–Boltzmann continuum solvent model as implemented in the Jaguar program, with the assumption that zero-point energy and thermodynamic parameters can be transferred from the gas-phase calculations. All the ΔE and ΔG values became more positive (favoring the carbenes) by between 20 and 40 kJ mol^{-1}. This error due to the neglect of solvation in the gas-phase computations is rather similar in magnitude to the intrinsic error in the B3LYP/6-31G* calculations suggested by the comparison with the values obtained with the G2(B3LYP/MP2/CC) method, but of opposite sign, so that the two should cancel out. In conclusion, this calibration work suggests that the gas-phase B3LYP/6-31G* computations we have used to assess carbene dimerization thermodynamics fortuitously give rather accurate predictions of the solution behavior.[49,62]

In any event, it is likely that the *relative* effects of ring size and alkylation on these equilibria can be modeled with useful accuracy at the B3LYP/6-31G* level, and we now return to consider the trends revealed in Table 3. The effects of increasing the size of the alkyl groups on the equilibria in each series are significant but relatively straightforward. As expected, the effects are greatest in the series of acyclic compounds, since four groups are being changed and particularly since larger alkyl groups are being introduced in the hindered "*endo*" positions. Increasing the size of the alkyl group has little effect in the five-membered-ring series, where the group will be most severely tied back from the carbene center, until *t*Bu groups are introduced. Alkyl group effects are roughly equal in the six- and seven-membered-ring series, but the calculations clearly predict that **iPr7** will dimerize, unlike its six-membered-ring counterpart **iPr6**.

Comparison of the five-, six-, seven-membered-ring and acyclic carbenes with methyl substituents reveals that ΔE and ΔG values for carbene dimerization increase in the surprising order **Me6** ≈ **Me5** ≪ **Me7** ≈ **MeA**, and dimerization of **Me6** is 100 kJ mol^{-1} less favorable than that of **MeA**—a remarkably large difference considering the apparent similarity of these two carbenes.

These striking effects on the dimerization equilibria might be due to unexpected structure and stabilization preferences in either the carbene or the dimers (or in both). As we will show in Section 9, (**Me7**)$_2$ and (**MeA**)$_2$ have proton affinities that are about 100 kJ mol^{-1} lower than those of (**Me5**)$_2$ and

(Me6)$_2$, and so we initially believed that (Me7)$_2$ and (MeA)$_2$ possessed unusual stability and were therefore favored in the respective dimerization equilibrium. In addition, we noticed that these two dimers adopt unusual structures (Figure 3) that involve substantial twisting about both the C=C bond and the C(sp^2)−N bonds, whereas the nitrogen atoms remain almost planar. In twisted tetraaminoethenes, the nitrogen lone pairs interact with both σ* and π* orbitals of the C=C bond, as well as with the σ* orbital of the geminal C−N bond, as shown by NBO analysis, and these interactions vary substantially according to the dimer geometry. However careful study of these electronic effects and also the steric interactions failed to reveal any clear reasons for the calculated unusual stability of (Me7)$_2$ and (MeA)$_2$.

To resolve this problem a clear-cut way is needed of dissecting the observed equilibria into relative stabilities associated with the carbenes and with the dimers. This can be achieved by comparing both with a single set of reference compounds that can be confidently assumed to show no unusual electronic effects. In the isodesmic equations described below, the reference compounds are Me$_2$N(CH$_2$)$_n$NMe$_2$ (n = 2, 3, and 4) for cyclic carbenes Me5, Me6, and Me7, and 2(Me$_3$N) for MeA. These strain-free open-chain amines should be well-behaved and have standard bond energies.[63] In support of this, we find that the energies calculated for the isodesmic reaction given in Equation (1) are negligibly differ-

$$Me_2N(CH_2)_nNMe_2 + 2CH_4 \rightarrow 2Me_3N + H(CH_2)_nH \qquad (1)$$

ent: 6.6, 6.9, and 7.9 kJ mol^{-1} for n = 2, 3, and 4, respectively. The slightly unfavorable energy change of these processes is expected given the stronger bond of the electronegative nitrogen atom with the primary alkyl group than with the methyl group.[64]

The carbenes and dimers are related to the reference compounds by isodesmic reactions given in Equations (2) and

$$carbene + 2CH_4 \rightarrow Me_2N(CH_2)_nNMe_2 + H_2C \qquad (2)$$
(3) (for acyclic carbene MeA, Me$_2$N(CH$_2$)$_n$NMe$_2$ is replaced

$$dimer + 4CH_4 \rightarrow 2Me_2N(CH_2)_nNMe_2 + H_2C=CH_2 \qquad (3)$$
by 2Me$_3$N). The energy changes for reactions (2) and (3) in Table 4 clearly demonstrate that it is the relative carbene stability that has the dominant effect on the dimerization equilibria. Carbenes Me5 and Me6 are relatively ∼50 kJ mol^{-1} more stable than Me7 and MeA and in particular this is the only source of difference in the equilibria

Table 4: Energies for isodesmic reactions (2) and (3) (B3LYP/6-31G* energies in kJ mol^{-1}).

Carbene	Me5	Me6	Me7	MeA
ΔE for reaction (2)	424.2	421.6	377.4	371.5
ΔE for reaction (3)	103.4	81.7	80.2	83.7
ΔE for dimer formation	−123.9	−107.4	−194.3	−209.6
$E_{(H_2N)_2C}$[a]	(25.5)	3.4	16.7	22.2

[a] Energy of (H$_2$N)$_2$C with the geometry of an alkylated carbine; see text.

for carbenes Me6 and MeA. The energies calculated for reaction (2) are negligibly different for (Me6)$_2$, (Me7)$_2$, and (MeA)$_2$, but dimer (Me5)$_2$ is about 20 kJ mol^{-1} more stable than the others, probably because of reduced van der Waals interactions between the methyl groups.

The relative stabilities of the carbenes are very different— what are the reasons? The N-C-N angle (see Table 4) surely plays some part, but cannot be the only factor or a clear break might be expected between carbenes Me5 and Me6, whereas it actually comes between Me6 and Me7. Carbenes Me7 and MeA are significantly twisted about the N−C$_{carbene}$ bonds (Table 4), although the nitrogen atoms remain almost planar, and this could destabilize these carbenes. To see what the combined effects of these geometric changes might have on carbene stability, we carried out single-point calculations of (H$_2$N)$_2$C at the heavy-atom geometries of carbenes Me5, Me6, Me7, and MeA and with a fixed N−H distance of 1.01 Å. For (H$_2$N)$_2$C at the geometry of Me5, the endo-hydrogen atoms are only 1.74 Å apart, and this must destabilize this structure substantially, so no useful conclusions can be drawn in this case. However, for (H$_2$N)$_2$C at the geometry of carbene Me6, this H···H non-bonded distance is 2.43 Å and non-bonded repulsion should be negligible for this case and for those corresponding to Me7 and MeA. The energies of these structures relative to the equilibrium structure for (H$_2$N)$_2$C (N-C-N 112.2°) are listed in Table 4. The combined effects of the N-C-N angle and the C-N-C-N torsion for (H$_2$N)$_2$C do indeed show a marked change between carbenes Me6 and Me7, but the size of the effect for the (H$_2$N)$_2$C model is only about 40% of that seen for the fully alkylated carbenes. However the increase in N-C-N angle and C-N-C-N torsion for Me7 and MeA is undoubtedly caused by steric effects in these carbenes (e.g. non-bonded repulsion between the endo-methyl groups in MeA), and the structures adopted by these carbenes is presumably a compromise between steric and electronic requirements. The single-point calculations for (H$_2$N)$_2$C should therefore only be expected to account for part of the differences. While there is no simple way of discovering if steric effects can quantitatively account for the remainder of the energy differences, we believe that overall this approach accounts for the dimerization equilibria in a reasonably satisfactory way.

8. Calculations on the Direct Mechanism for Carbene Dimerization

Singlet carbenes cannot dimerize by a least motion, head-to-head, approach, as was first pointed out by Hoffmann, Gleiter, and Mallory in 1970.[8] The filled sp^2 lone pair orbital needs to approach the empty p orbital of the other carbene (see Figure 1). This mechanism has been confirmed for methylene itself by calculations of varying sophistication over the years. One thorough study suggested that there might be an energy barrier of 170 kJ mol^{-1} to the dimerization of singlet H$_2$C.[65] On the other hand, it has been known since the 1960s that dimerization of CF$_2$ to tetrafluoroethene is rapid, with a second-order rate constant of $2.54 \pm 0.26 \times 10^7$ M^{-1} s^{-1} at 298 K,[66] only about three orders of magnitude below the

diffusion limit. B3LYP/6-31G* calculations for this reaction do not yield a discernable energy barrier along the approach geometry shown in Figure 1 Nevertheless for diaminocarbenes, this approach geometry may lead to extra steric problems in the transition state, and it is also worth noting that it is relatively unfavorable from the point of view of dipole–dipole interactions.

We have reported density functional calculations of the transition states for the dimerization of diaminocarbene itself.[49] A substantial barrier (36.6 kJ mol^{-1} at BPW91/cc-pVDZ) was found even for this unsubstituted case. The calculated transition state had C_2 symmetry rather than the C_{2h} that might be expected and the nitrogen atoms were pyramidalized in such a way that the lone pairs were *anti* to the forming C–C bond. This brings approaching hydrogen atoms into close proximity and this geometry will be unfavorable once alkyl groups are added. We also reported finding a transition state for the tetramethyl derivative **MeA**.

We now report B3LYP/631G* calculations relating to the kinetics of dimerization of several other diaminocarbenes (Table 5). In all cases, the transition states were found to have C_2 symmetry and the length of the forming C–C bond varied from 1.89 to 2.14 Å. The transition state for dimerization of **Me6** is shown in Figure 4.

Table 5: B3LYP/6-31G*-calculated ΔE^+, ΔH^+, and ΔG^+ values for carbene dimerization at 298 K (kJ mol^{-1}).

Carbene	ΔE^+	ΔH^+	ΔG^+	C⋯C [Å]
Me5	39.6	43.5	104.9	1.952

EtA	98.0	101.1	156.5	2.142
Figure 4. Transition state for the dimerization of **Me6**.

Energies of activation, ΔE^+, vary over a wide range, but they are all large. Based on the calculated ΔG^+ values, half-lives for carbenes at a concentration of 1M in THF at 298 K would be **Me5**: 100 h; **Me6**: 5000 years; **MeA**: 2 months; **EtA**: 1×10^7 years. If anything, these half-lives may be underestimates, given that solvent stabilization of the transition states is likely to be smaller than that of the dipolar carbenes (see above). While these values are highly speculative, it seems clear that room-temperature dimerization of six-membered ring carbene **Me6** and, especially, **EtA** is unlikely to be observed. This is exactly what we find (See Sections 4 and 5).

9. Calculations on Tetraaminoethene Formation from the Reaction of Diaminocarbenes with Formamidinium Ions

In this Section we examine several aspects of the proposed proton-catalyzed dimerization of diaminocarbenes in the light of DFT calculations. In the first step (Scheme 5), the carbene,
Scheme 5. Pathways for reaction of diaminocarbenes with formamidinium ions.

a powerful nucleophile, attacks its amidinium ion precursor to generate the C-protonated dimer. We suggest that the formamidinium ion/carbene reaction may have a lower energy barrier than direct carbene dimerization, since a) there will be electrostatic attraction even at long distance, as the negative end of the carbene dipole points at the positive charge of the ion, and b) the carbene can approach the formamidinium ion more or less perpendicularly and this is always likely to be most favorable sterically.

For five- and six-membered-ring carbenes, B3LYP/6-31G* calculations suggest that, in the gas phase, formation of the protonated dimer is more or less as exothermic as direct dimerization of two carbenes, although this is not the case for acyclic and seven-membered-ring carbenes. Equilibrium will be much less favorable in solution, since the solvation of a cation and a dipolar species (the carbene) is replaced by solvation of one larger cation. Simulation of THF solvation using the Poisson–Boltzmann continuum model as implemented in Jaguar suggests that equilibria are shifted about 50 kJ mol^{-1} towards starting materials (Table 6).

Arduengo et al.[67] have shown that certain imidazol-2-ylidenes can form hydrogen bonds to the corresponding imidazolium ion, and this offers an alternative trajectory to the C-protonated dimer. We have located a transition state (see Figure 5) for the formation of the protonated dimer from

Table 6: B3LYP/6-31G*-calculated ΔE, ΔH, and ΔG values for protonated dimer formation at 298 K and 1 atm pressure in the gas phase and THF solution (kJ mol^{-1}).

Carbene	Gas phase			THF solution		
	ΔE	ΔH	ΔG	ΔE	ΔH	ΔG
Me5	−125.8	−115.9	−53.0	−70.6	−60.7	−3.5
Et5	−120.9	−111.3	−53.3			
iPr5	−106.5	−96.4	−31.4			
Me6	−96.2	−86.7	−24.0	−47.0	−37.3	23.9
Et6	−77.6	−67.4	1.4			
iPr6	−34.2	−23.1	50.8			
Me7	−95.7	−86.5	−20.7			
MeA	−106.3	−97.9	−34.9	−57.4	−48.5	15.3
EtA	−46.4	−37.6	20.8	−2.8	6.6	67.3
Figure 5. Transition state for the formation of the protonated dimer from **Me5** and the corresponding formamidinium ion.

carbene **Me5** and the corresponding formamidinium ion which appears to correspond to the latter process. In the two cases we examined, C–C bond formation is only slightly more favorable than hydrogen bonding; thus for hydrogen bonding between carbene **Me5** and the corresponding formamidinium ion, $\Delta E = -89.9$, $\Delta H = -84.2$, and $\Delta G = -41.8$ kJ mol^{-1} at 298 K, while the values for **MeA** are $\Delta E = -84.9$, $\Delta H = -78.0$, and $\Delta G = -31.5$ kJ mol^{-1}.

The second step of the mechanism in Scheme 1 is simply a proton transfer. Imidazol-2-ylidenes have been shown to be strongly basic,[39,40,68,69] but attempts to measure the basicity of simple diaminocarbenes such as **Me5**–*i*PrA have failed so far, due to competing addition reactions of the formamidinium ions. Tetraaminoethene derivatives should also be strongly basic, but we are not aware of any previous experimental evidence for their conversion to C-protonated cations, and so pK_a values are unknown. We have therefore resorted to comparison of calculated proton affinities (PA, Table 7); it is

Table 7: B3LYP/6-31G*-calculated proton affinities (PA, kJ mol^{-1}) values for carbenes and dimers.

Carbene	PA of carbene	ΔE for reaction (4)	PA of dimer	ΔE for reaction (5)
Me5	1112.8	652.1	1115.8	541.8
Et5	1124.6		1130.4	
***i*Pr5**	1135.4		1126.1	
***t*Bu5**	1143.0			
Me6	1145.8	683.2	1133.7	540.7
Et6	1156.2		1163.7	
***i*Pr6**	1166.8		1135.2	
Me7	1157.4	650.9	1055.8	463.7
MeA	1149.8	637.8	1045.7	455.3
EtA	1171.2		1054.5	
***i*PrA**	1183.7			

reasonable to expect pK_a values to follow these PA trends. Comparison of the PA values for carbenes and the corresponding dimers shows clear differences between acyclic and five- and six-membered-ring cases. In acyclic and seven-membered-ring cases **Me7**, **MeA**, and **EtA**, the PA for the carbene is approximately 100 kJ mol^{-1} higher than for the dimer, whereas five- and six-membered-ring dimers have PAs that are almost as high (or higher) than the corresponding carbene. These PA values can be usefully analyzed with the

aid of the reference compounds used earlier and two additional isodesmic reactions according to Equations (4) and (5).

$$\text{formamidinium ion} + 2\,CH_4 \rightarrow Me_2N(CH_2)_nNMe_2 + CH_3^+ \qquad (4)$$

$$\text{protonated dimer} + 4\,CH_4 \rightarrow 2\,Me_2N(CH_2)_nNMe_2 + C_2H_5^+ \qquad (5)$$

The greater N-C-N angle in $(H_2N)_2CH^+$ (125.4°) compared with $(H_2N)_2C$ (112.2°) might lead one to expect that the PA would rise as the N-C-N angle increases. While this is true for carbenes **Me5** and **Me6**, further increases for **Me7** and **MeA** are small, and the failure of a simple correlation is partially explained by reference to the isodesmic reactions. Reaction (4) shows that formamidinium ion stability peaks at the six-membered ring, but the fall for larger N-C-N angles almost parallels that for the carbenes (isodesmic reaction (2)). The low PA values for the dimers $(\text{Me7})_2$ and $(\text{MeA})_2$ seem to be mainly due to decreased stabilities for the protonated forms (reaction (5)). We believe that this is largely due to non-bonded interactions in these quite severely crowded ions. It is worth noting that we calculate that for a simple aromatic carbene, 1,3-dimethylimidazol-2-ylidene, the (unstable) dimer has a markedly higher PA (1157) than the carbene (1113 kJ mol^{-1}).

Based on this data, it is simple to calculate the energetics for disproportionation of C-protonated dimers to dimers and formamidinium ions (Scheme 6). It is highly favorable in the
Scheme 6. Disproportionation of the C-protonated dimers to the dimers and formamidinium ions.

gas phase for the case involving the protonated dimer from **EtA** ($\Delta E = -68$ and $\Delta G = -137$ kJ mol^{-1}), but quite unfavorable for five-membered-ring cases such as **Et5** ($\Delta E = +126$ and $\Delta G = +67$ kJ mol^{-1}), although disproportionation should be favored by solvation. The rate of the actual proton transfer step may be slowed by the need for substantial structural reorganization of the C-protonated dimers to create the favored geometry of the dimers themselves, and by steric constraints in highly crowded examples. Overall, however, our observation that protonated dimer can be observed from **Et5**, but not from **EtA**, seems to be supported by the calculations.

10. Possible Mechanisms for Metal-Promoted Dimerization

A huge variety of metal complexes of diaminocarbenes are now known and decomposition of these to form tetraaminoethene dimers is certainly not generally observed. We have reported[25] that the rate of dimerization of bis(dimethylamino)carbene was slowed by the addition of extra lithium diisopropylamide, and by changing the solvent from

THF to toluene. Both these observations are in agreement with increased Li complexation stabilizing the carbene.

It may therefore seem perverse to suggest that metals such as lithium may catalyze dimer formation, but we believe that a free diaminocarbene may react more rapidly with a Li-complexed carbene than with another free carbene molecule. Coordination of diaminocarbenes to lithium should increase the reactivity of the p orbital on the carbene center towards nucleophiles such as a free carbene, as in route a in Scheme 7. Alternatively, if two carbenes are transiently coordinated to one lithium center, ligand coupling to form dimer might occur (route b in Scheme 7). These mechanisms require the presence of free carbene, and so rates of dimerization would decrease as all carbenes became complexed.
Scheme 7. Possible mechanisms for metal-promoted dimerization.

One serendipitous observation provides significant support for these ideas. While examining lithium complexation to 2-^{13}C-*iPr6*, we observed the slow conversion of the "normal" complexed carbene signal at $\delta = 216$–220 ppm to a species showing a remarkable multiplet in the ^{13}C NMR spectrum at $\delta = 177$ ppm (Figure 6).

This conversion only happens in the presence of a substantial excess of LiHMDS and when toluene is used as the solvent (it is not observed in THF). Other bases such as LiTMP and LDA do not lead to related species. In the presence of 10 equivalents of LiHMDS, we eventually observe about 80% conversion to the new species. The multiplet is an AB quartet split by a single ^{7}Li nucleus (spin $^{3}/_{2}$) and it can be simulated with the following parameters:
Figure 6. ^{13}C NMR multiplet from reaction of 2-^{13}C-1,3-diisopropyl-3,4,5,6-tetrahydropyrimid-2-ylidene with excess LiHMDS.

$\Delta_{C(1)} = 177.84$; $\Delta_{C(2)} = 176.88$; $J_{Li,C(1)} = 79.3$ Hz, $J_{Li,C(2)} = 80.5$ Hz and $J_{C(1),C(2)} = 54.4$ Hz. The size of these coupling constants, especially $J_{C(1),C(2)}$, suggests the presence of a three-membered LiC$_2$ ring. Calculations[70] on complex **17** of two
(Me$_2$N)$_2$C carbenes coordinating separately to LiN(SiMe$_3$)$_2$, led to a predicted $J_{C(1),C(2)}$ value of only 2 Hz. Note that carbene *iPr6* has not been observed to form dimer, so it is appealing to assume that this complex represents a foiled dimerization reaction. Unfortunately, all attempts to crystallize the new complex have failed, so further discussion of the structure is speculative. There has to be some lack of symmetry to get the ^{13}C–^{13}C AB quartet, and at Li/carbene ratio of at least 3:2 to account for the requirement for a large excess of LiHDMS; a cluster such as **18** might provide this.

Returning to tetrakis(dimethylamino)ethene formation, we found this to be cleanly second-order in carbene, and a study over the temperature range 0–40°C led to a satisfactory Arrhenius plot with $E_{act} = 77.7$ kJmol^{-1}, and $\log A = 10.6$ M^{-1}s^{-1} at a formal lithium ion concentration of approximately 2 M in THF. When however similar THF solutions are treated with [2.1.1]cryptand to sequester lithium species, the ^{13}C NMR signal for the carbene disappears immediately, but formation of dimer is not observed, as described above.

While none of the evidence cited above proves the involvement of Li in the dimerization of simple diaminocarbenes, we do believe that further investigation is warranted.

11. Summary and Outlook

This review set out to answer two questions:

When do diaminocarbenes dimerize?

How do they dimerize?

It is known that dimerization is thermodynamically unfavorable for imidazol-2-ylidenes, and evenly balanced for benzimidazolylidenes, depending on steric effects. We have shown here that for non-aromatic diaminocarbenes, significant steric hindrance is required for dimerization to be unfavorable, and carbenes *iPr5*, **Et6**, *iPr7*, and **EtA** can all dimerize. However dimerization of **MeA** is 100 kJmol^{-1} more favorable than for **Me6**, even though similar levels of steric hindrance in the dimers are involved. We have proposed, on the basis of DFT calculations, that this is due to the lower stability of acyclic (and seven-membered-ring) carbenes, and that this can be explained in part by increased N-C-N angles and some loss of conjugation through twisting about the N−C$_{carbene}$ bonds.

Several diaminocarbenes (**iPr5**, **Me6**, **Et6**, and **EtA**) do not dimerize within a reasonable timeframe at ambient temperature in THF, and the simplest diaminocarbene **MeA** does not form a dimer when allowed to decompose in the absence of alkali metal species. Calculations show that energy barriers to the uncatalyzed dimerization mechanism may be prohibitively high, in agreement with these observations. We believe it is timely to issue a challenge to find any example of this classic dimerization mechanism, and predict that it is most likely to be found with five-membered-ring diaminocarbenes (dihydroimidazol-2-ylidenes) such as **Me5**.

Diaminocarbenes can dimerize by a proton-catalyzed mechanism. We have observed the protonated dimer intermediate in a favorable case, and we believe that in practice this is by far the most common mechanism for dimer formation. We find that a carbene, which cannot dimerize, **iPr6**, nevertheless forms a complex containing a C_2Li ring in the presence of excess LiHMDS. This raises the possibility that alkali metal species, while thermodynamically stabilizing diaminocarbenes, may nevertheless catalyze dimer formation.

Finally, we have drawn attention in several places to the importance of the N-C-N angle in determining the properties of diaminocarbenes. Larger ring and acyclic diaminocarbenes are likely to require stronger bases for their generation, but be more reactive as bases and nucleophiles once prepared.

12. Addendum

A number of relevant papers have appeared since this review was prepared. The important influence of ring size on carbene reactivity has been mentioned several times in our review, and Grubbs et al. have recently reported the first examples of stable four-membered-ring carbenes, together with some information on their dimerization.[71] Bertrand et al. have continued to explore novel types of carbenes including stable monoaminocarbenes.[72–74]

The evidence that **EtA** and several other simple carbenes are kinetically stable to dimerization in THF at ambient temperatures has been published.[75] The work by Magill, Cavell, and Yates mentioned in reference [69] has now been published;[76] these authors calculate the pK_a values in DMSO of **Me5**, **Me6**, and **MeA** to be 22.3, 27.1, and 27.9, respectively, using the high-level CBS-QB3 complete basis set method in conjunction with the CPCM solvation model. Further experimental[77] and computational[78] evidence that acyclic and six-membered-ring carbenes are better σ donors has appeared.

[62] Single-point B3LYP calculations with the larger 6-311+G(d,p) basis set favor the carbenes relative to the dimers by, typically, 30 kJ mol^{-1}. Thus, increasing the basis set leads to smaller predicted bond energies, and hence actually makes the B3LYP results deviate more from the G2(B3LYP/MP2/CC) results. There is little doubt that these higher level calculations are wrong so far as absolute values for ΔE and ΔG are concerned. This is not an unknown problem with density functional theory calculations (W. Koch, M. C. Holthausen, *A Chemist's Guide to Density Functional Theory*, Wiley-VCH, Weinheim, **2001**); it has been found that B3LYP/6-311+G** calculations lead to an error of similar magnitude for ΔE for the simplest Diels–Alder reaction (butadiene plus ethene). The simpler B3LYP/6-31G* calculation was in better agreement with experiment. Significantly perhaps for our subsequent discussion of energy barriers for carbene dimerization, the calculated activation energy (ΔE^+) for the Diels–Alder example is in quite good agreement with experiment with both basis sets. We also carried out single point MP2 calculations for several of these species and find that ΔE now shifts in the other direction, thus ΔE for dimerization of carbene MeA in the gas phase becomes a massive 278.3 kJ mol^{-1}. Carried across the series, this would lead to the incorrect prediction that *i*Pr6 would surely dimerize. Our earlier report of dimerization energies for diaminocarbene (−181.5 from B3LYP/cc-pVDZ, and 229.8 from MP2/cc-pVDZ) are incorrect, as a less stable structure with D_2 symmetry was used for the dimer.

[63] The obvious reference compounds are perhaps the corresponding aminals (CH_2 in place of the carbene center), but these were avoided because of potential problems with variable anomeric effects. Note that energies for methane, ethane, singlet methylene, and the methyl and ethyl cations were calculated at the B3LYP/6-31G* level, but are unimportant as far as internal comparison of **Me5**, **Me6**, **Me7**, and **MeA** are concerned. The ethyl cation is actually protonated π-protonated ethene at the B3LYP/6-31G* level.

Assembly of an Oxo–Zirconium(IV) Cluster in a Protein Cleft**

Weiqing Zhong, Dmitriy Alexeev, Ian Harvey, Maolin Guo, Dominic J. B. Hunter, Haizhong Zhu, Dominic J. Campopiano, and Peter J. Sadler*

There is a wide range of potential uses for small, well-defined oxo–metal clusters, including magnetic devices, optical materials, and catalysts.[1] The challenge is to discover synthetic methods that allow their size, composition, and, importantly, also the external coating (peripheral ligands) to be controlled. These features determine the chemical and physical properties of the metals in the cluster, including recognition by interacting partners, such as substrates and surfaces. We are exploring the use of flexible protein clefts as templates for assembly of polyoxometalate clusters, in particular that of bacterial transferrin (ferric-ion-binding protein, Fbp). Recently we,[2,3] and others,[4] have shown that the "venus fly trap" interdomain cleft of Fbp can accommodate clusters of metal ions, which are effectively small fragments of oxo/

hydroxo minerals. Herein we show that oxo–zirconium clusters are readily assembled on Fbp by reaction with a mononuclear Zr^{IV} complex and nucleated by a dityrosyl (diphenolate) motif in the interdomain binding cleft. We have determined the structures of these multinuclear zirconium–Fbp adducts by EXAFS and X-ray crystallography, and have studied the influence of phosphate and carbonate on the assembly process.

Native, holo-Fbp (34 kDa, 309 amino acids) contains an Fe^{III} center bound to the phenolate oxygen atoms of Tyr195 and Tyr196, a carboxylate oxygen atom of Glu57, and the imidazole nitrogen atom of His9, together with oxygen atoms from phosphate (the "synergistic anion") and water (Figure 1), in a closed binding cleft.[5] The cleft is formed by
Figure 1. The iron(III)-binding site in holo-Fbp.

two alternating α helix/β sheet domains hinged by a pair of antiparallel β strands. Serum transferrin and lactoferrin have similar Fe^{III}-binding sites, but use carbonate as the synergistic anion. Carbonate can replace phosphate in holo-Fbp, but binds less strongly.[6,7]

We prepared Zr–Fbp by treating apo-Fbp with various molar ratios of $[Zr(NTA)_2]^{2-}$ (NTA = *N,N*-bis(carboxymethyl) glycine, ion (3−)) in HEPES (HEPES = 2-(4-(2-hydroxyethyl)-1-piperazinyl)ethanesulfonic acid) buffer pH 7.4 for 24 h followed by extensive ultrafiltration to remove unbound Zr^{IV}. Reaction with 1, 2, and 6 mol equivalents of $[Zr(NTA)_2]^{2-}$ gave proteins containing an average of 0.8, 1.5, and 3.9 mol Zr, respectively, together with approximately 1 mol of phosphate per mol protein, as determined by inductively coupled plasma atomic emission spectroscopy (ICP-AES; Table 1). Similar results were obtained using Tris (Tris = 2-amino-2-(hydroxymethyl)-1,3-propanediol) buffer at pH 8 (Table 1). Chromatographic studies suggested that the products from these reloading reactions contain both apo and multinuclear forms of Zr–Fbp (see Supporting Information).

The presence of bound clusters was confirmed by Zr K-edge EXAFS studies. The products from 1:1 and 6:1 reactions of $[Zr(NTA)_2]^{2-}$ with apo-Fbp gave essentially the same EXAFS spectra (Figure 2), and clearly show the presence of Zr–Zr scattering between 3.3–3.6 Å, consistent with the presence of {Zr_3} clusters in both preparations. The apparent slight difference in the distances observed in the Fourier

1:1[c]	0.84	—[d]
2:1[e]	1.5	1.4
6:1[e]	3.9	1.1

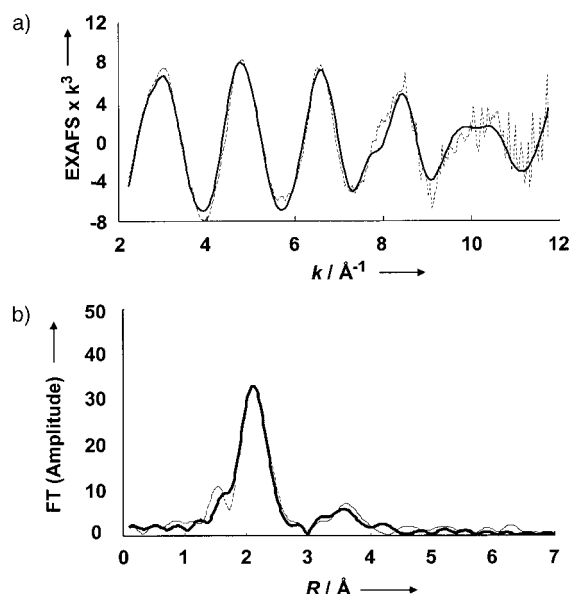
[a] Reactions carried out for 24 h in 10 mM HEPES buffer containing 5 mM phosphate and 5 mM carbonate, pH 7.4, 298 K. [b] Fbp concentration determined from A_{280}. [c] Similar analyses obtained for reactions in 10 mM phosphate and carbonate. [d] Not determined. [e] Similar analyses obtained for reactions in 10 mM Tris buffer pH 8.0.


Figure 2. a) EXAFS data, and b) and the Fourier transform data for Zr–Fbp (prepared from 6:1 Zr:apo-Fbp reaction). The data are modeled using the cluster derived from the X-ray data (see Figure 3) but with carbonate as the capping ligand, and full multiple scattering (see Supporting Information for details). Dashed line = experimental data, bold line = model. The peak at approximately 1.5 Å in (b) is an artifact of background subtraction and Fourier truncation (finite EXAFS data range).

transforms for the two samples (see Supporting Information) reflects small differences in the geometry of the clusters (as is also seen in the crystallographic data, see below). The EXAFS data represent an average of the {Zr₃} local environments and could also reflect a higher Zr loading at some centers. The first shell can be fitted with 1 oxygen atom at approximately 2.0 Å, 4 oxygen atoms at approximately 2.15 Å, and a further 2 oxygen atoms at approximately 2.3 Å (see Table 2). However, this leaves an unfilled contribution to the first shell at approximately 2.66 Å. This contribution can be fitted with a carbon atom, which reduces the *R* factor by 6%. A light atom at this distance is consistent with bound carbonate, rather than phosphate. Indeed, inclusion of carbonate rather than phosphate in the final EXAFS model leads to significantly lower *R* factors (29.1% versus 36.5% for 1:1, 25.0% versus 32.2% for the product from the 6:1 reaction) as well as much better matches to the Fourier

Table 2: Refined average EXAFS interatomic distances from the Zr "central atom", modeled with carbonate as a capping ligand, including multiple scattering.

transforms (see Figure 2). However, owing to the strength of the Zr–Zr scattering and the averaging of the EXAFS data over three zirconium atoms per cluster, a proportion of clusters with bound phosphate cannot be ruled out. Evidence that carbonate can bind to Zr–Fbp in solution was obtained by NMR spectroscopy. The ^{13}C-{^{1}H} NMR spectrum of apo-Fbp (0.4 mM) in the presence of 2 mol equivalents of $[Zr(NTA)_2]^{2-}$ and 20 mM $NaH^{13}CO_3$ contained a small resonance signal at $\delta = 168.2$ ppm assignable to zirconium-bound $[^{13}CO_3]^{2-}$ (see Supporting Information).[8]

Crystallization of Zr–Fbp was successful only using a malate/imidazole buffer system and a slightly higher pH value (8–8.2). Crystals were grown at 290 K by the hanging-drop vapor-diffusion technique, using Zr–Fbp obtained by reaction of apo-Fbp with either 1, 4, or 6 mol equivalents of Zr^{IV}, again after ultrafiltration to remove unbound metal. These preparations all gave similar crystals, which contain nine independent molecules in the asymmetric unit. In the 1.5 Å resolution structure (Table 3), all the molecules contain {Zr₃} clusters, with minor differences in bond lengths and angles. The interdomain binding cleft remains open and Zr1 and Zr3 are coordinated directly to Tyr195 and Tyr196, respectively, and to a capping anion which appeared to be best modeled as phosphate, Figure 3 (and Supporting Information). The

[a] Numbers in parentheses are for the highest resolution shell. [b] $R_{sym} = \Sigma |I_h - \langle I_h \rangle| / I_h$, where $\langle I_h \rangle$ is the average intensity over symmetry equivalent reflections. [c] $R_{cryst} = \Sigma |F_o - F_c| / \Sigma F_o$, where summation is over the data used for refinement. [d] R_{free} was calculated using 5% of data excluded from refinement.
Figure 3. The crystal structure of Zr₃–Fbp. a) Stereo pair of the electron density map (contoured at the 3.5σ level) of the oxo–Zr₃ phosphate cluster (Zr cyan). The map was averaged between all nine molecules in the asymmetric unit. Only the electron density around Tyr 195, Tyr 196 and the cluster is shown. The only direct coordination to the Zr^{IV} ions in the cluster is by Tyr 195 and Tyr 196, although the oxygen atoms of the oxo cluster are H-bonded to several amino acids including residues 139–141 on the right side of the cluster in the phosphate-binding loop. b) Ribbon diagram of the protein (molecule D) showing α helices (dark green), β sheets (gold), and the {Zr₃} cluster in the interdomain cleft. Residue and atom colors: Tyr 195 and Tyr 196 green, Arg 101 and Arg 262 blue, P (phosphate) pink, oxygen red, Zr cyan. c) The anchoring of the trinuclear cluster by the dityrosyl motif, showing Zr labelling.

cluster structure resembles those found in the oxo–zirconium methacrylate clusters, $[Zr_6(OH)_4O_4(OMc)_{12}]$ and $[Zr_4O_2(OMc)_{12}]$ (OMc = methacrylate),[9] and in the oxo–zirconium biphenolate cluster $[(L_2Zr)_3(OH)_3(O)$-$Li_5(thf)_8(H_2O)_5]$ (L = 2,2′-biphenolato dianion),[10] and is based on a triangular Zr_3O_4 unit with a central bridging μ_3-oxygen atom and three bridging μ_2-oxygen atoms. Each zirconium atom in Zr₃–Fbp is bound to seven oxygen atoms (in agreement with the EXAFS data) in a pentagonal bipyramidal geometry. The five equatorial oxygen atoms are (hydr)oxides, and the axial oxygen atoms are from tyrosinate for Zr1 and Zr3, water for Zr2, and from phosphate (Figure 3c). The Zr···Zr separations range from 3.4 to 3.7 Å, and the Zr−O bond lengths from 2.1–2.4 Å, with the zirconium–tyrosinate bonds being the shortest (1.9–2.1 Å). The positively charged side-chains of Arg 101 (which is fully conserved in bacterial transferrins[3]) and Arg 262 are hydro-

gen-bonded to oxygen atoms of the oxo–Zr₃ cluster, as are the side-chains or main chain NH groups of several other amino acids including S139, N175, and N193 (see Figure 3a). The relatively high homogeneity of the zirconium clusters can be contrasted with the heterogeneity of the clusters in Hf-Fbp which were tri- and pentanuclear, either with or without capping phosphate.[2]

We studied reactions of apo-Fbp (14 μM) with $[Zr(NTA)_2]^{2-}$ in 10 mM HEPES buffer containing 5 mM NaHCO₃, 5 mM phosphate, pH 7.4, 298 K, by UV/Vis spectroscopy. Two new peaks appeared in the difference spectrum at 247 nm and 295 nm (Figure 4a,b). These bands are assignable to π–π transitions of Tyr residues deprotonated by binding to Zr^{IV}. Similar bands are seen when both bacterial and serum transferrins bind to a wide variety of metal ions.[8,11,12] Titration studies (Figure 4c,d) suggested that a zirconium:protein mol ratio of 1:1 is sufficient to deprotonate both Tyr 195 and Tyr 196 if phosphate is present as the synergistic anion, but only one Tyr residue when only (bi)carbonate is present (Figure 4b). Phosphate is known to bind in the interdomain cleft of the apo protein and may prepare the cleft for metal entry.[13] Beyond a 1:1 $[Zr(NTA)_2]^{2-}$:apo-Fbp ratio there was little increase in the absorption at 247 nm (Figure 4d). These data therefore suggest that the initial reaction with apo-Fbp involves Zr^{IV} binding to Tyr 195 and Tyr 196 followed by subsequent formation of (hydr)oxo–zirconium clusters, and hence little increase in the absorption at 247 nm beyond a 1:1 $[Zr(NTA)_2]^{2-}$:apo-Fbp ratio. Thus the clusters appear to be formed by stepwise insertion of Zr^{IV} ions into the interdomain cleft. ESI-MS studies of $K_2[Zr(NTA)_2]·2H_2O$ (5 mM) in aqueous solution and HEPES buffer gave a major peak at m/z 582.88 (calcd. 582.82 for $\{K_3Zr(NTA)_2\}^+$), with appropriate isotope splitting pattern, showing that the complex is monomeric under the conditions used for MS (50% CH₃CN/H₂O, 0.1% formic acid). The mobility of Tyr 196 (as observed in crystals of oxo–Fe^{III}–Fbp)[3] in particular may be important for capturing Zr^{IV} ions at the protein surface and delivering them into the binding cleft. The possibility that the protein can also capture preformed oxo–tri-Zr^{IV} clusters cannot be ruled out.

Low-molecular-weight alkoxide and aryloxide ligands have been used in the synthesis of small organically functionalized oxo–Zr^{IV} clusters.[1,14–17] The experiments described herein show that oxo–trizirconium clusters anchored by a dityrosyl (diphenolate) motif readily assemble in the hinged cleft of a protein, bacterial transferrin. The provision of a protein coat for a polyoxometalate cluster could have several advantages. For example, the protein can readily be engineered to allow the environment of the cluster to be modified, including the electrostatic potential and hydrophobicity of the outer coordination sphere. Also the amino acids on the protein surface can be mutated to facilitate attachment to other surfaces (e.g. for array experiments), or to promote solubilization in various media. It is apparent that Fbp is a versatile metal-binding scaffold. The remarkable ability of the dityrosyl motif to selectively nucleate the formation of oxo–metal clusters in a positively charged binding cleft is likely to be a useful and widely exploitable property of the protein.

Experimental Section

HEPES, H_3NTA, and Fe and Zr atomic absorption standard solutions were purchased from Aldrich, $NaH^{13}CO_3$ (>99% enriched) from MSD isotopes, and $ZrOCl_2$ hydrate from Strem Chemicals (Zr content determined by ICP-AES). Crystalline $K_2[Zr(NTA)_2]\cdot2H_2O$ was prepared according to a literature method.[8,18] Holo- and apo-Fbp were prepared and purified by modifications of described methods.[6,19]

Zr–Fbp: Typically, microlitre aliquots of $NaHCO_3$ (0.25 M) and KH_2PO_4 (0.25 M, pH 7.4, final concentrations 5 mM) were added to apo-Fbp (25–100 μM) in 10 mM HEPES buffer pH 7.4 (or Tris buffer pH 8.0), followed by addition of freshly prepared aqueous $K_2[Zr(NTA)_2]$ (10 mM) to give ratios of [Zr]:[Fbp] = 1:1, 2:1, 4:1, or 6:1. The mixture was incubated for 24 h at 310 K, and the buffer was exchanged into 0.1 M KCl by ultrafiltration 8× (to remove unbound Zr, carbonate, and phosphate) and the solution was concentrated to approximately 8 mg protein mL^{-1}.

Crystals were grown by the hanging-drop vapor-diffusion technique at 290 K by mixing protein solution (5 μL; 3.7–4.0 mg mL^{-1} in 0.1 M KCl) with an equal amount of a reservoir solution containing approximately 20–22% polyethylene glycol (PEG) 4000, 0.2 M NaCl, 0.4 M imidazole/malate buffer, pH 8.0–8.2.

Crystals were flash-frozen in liquid nitrogen and X-ray data were collected on station 14.2 (SRS, Daresbury Laboratory; $\lambda = 0.978$ Å) using an ADSC Quantum4 CCD detector and processed and scaled using HKL2000.[20] Crystals belong to the space group $P3_2$ (cell dimensions $a = b = 146.2$ Å and $c = 113.56$ Å). The structures were solved using the methods previously described.[2]

Coordinates have been deposited in the Protein Data Bank (accession code 1XC1).

X-ray spectra were recorded at the Zr K-edge on EXAFS station 9.3 at Daresbury Laboratory Synchrotron Radiation Source (operating at 2 GeV), at 80 K, and in fluorescence mode. Data collection times were 11 h per sample.

A computer-controlled Perkin-Elmer Lambda 16 UV/Vis spectrometer was used together with 1 cm path-length cuvettes maintained at 298 ± 0.1 K or 310 ± 0.1 K with a PTP-1 Peltier temperature programmer. Aliquots (2 or 5 μL) of a $[Zr(NTA)_2]^{2-}$ solution were added to apo-Fbp (10–20 μM) solutions in HEPES buffer (10 mM), and $NaHCO_3$ (5 mM) and left to equilibrate for 1 h at 298 K or 310 K. The UV/Vis spectra were then recorded. A buffer solution containing the same amounts of $NaHCO_3$ and $[Zr(NTA)_2]^{2-}$ was used as the reference.

The time courses for the reactions of apo-Fbp with $[Zr(NTA)_2]^{2-}$ were also recorded in HEPES buffer (10 mM). Apo-Fbp (13–15 μM) in HEPES buffer (10 mM, pH 7.4) containing $NaHCO_3$ (5 mM) and/or KH_2PO_4 was treated with $[Zr(NTA)_2]^{2-}$ (2 mol equivalents) at 298 K and UV/Vis spectra were recorded at 2.5 min intervals against the same buffer solution containing the same amount of $[Zr(NTA)_2]^{2-}$.

The products from reaction of apo-Fbp (180 μM) with 0.5, 1.0 and 6.0 mol equiv of $[Zr(NTA)_2]^{2-}$ at 310 K for 24 h were applied to a Mono S HR5/5 column equilibrated with HEPES buffer (10 mM; pH 7.4, 25 mL), followed by gradient elution with 0–1 M KCl in HEPES (10 mM; pH 7.4) flow rate 0.5 mL min^{-1}). Fractions of 0.5 mL were collected and analyzed by ICP-AES, and of 0.1 mL by inductively coupled plasma (ICP)-MS.

Zr and P content was determined by ICP-AES (Thermo Jarrell Ash IRIS spectrometer) calibrated with standard solutions using the emission lines at 349.621 nm and 213.618 nm for Zr and P, respectively. For some samples, ^{90}Zr was determined on a PlasmaQuad ICP-MS. Samples from reactions of apo-Fbp with $[Zr(NTA)_2]^{2-}$ (Table 1) were purified by ultrafiltration (Centricon MW cut-off 10 kDa), washing 3× with HEPES or Tris buffer as appropriate before Zr and P analysis.

Details of ESI-MS, NMR, chromatography and pH measurements, and further details of protein preparation, X-ray crystallography and X-ray absorption spectroscopy are given in the Supporting Information.

Crystal Structure of Tricolorin A: Molecular Rationale for the Biological Properties of Resin Glycosides Found in Some Mexican Herbal Remedies**

Anna Rencurosi, Edward P. Mitchell, Gianluca Cioci, Serge Pérez, Rogelio Pereda-Miranda,* and Anne Imberty*

The traditional uses of several Mexican members of the morning glory family (Convolvulaceae), combined with ecological field observations, have been helpful in the design of an efficient approach for sampling plant materials and the selection of plants for investigation as potential sources of novel biodynamic natural products.[1] The Mexican variety of the morning glory plant named "heavenly blue" (*Ipomea tricolor* Cav.) has been used for centuries as a cover crop in traditional mesoamerican agriculture because it inhibits the growth of invasive weeds. We now know that the phytotoxins involved are the resin glycosides, collectively called tricolorins.[2,3] Until recently, the structural complexity of these mixtures seriously hampered the isolation of their individual constituents. The application of recycling high-performance liquid chromatography has allowed no less than 10 lipooligosacharides to be isolated from the aerial parts of "heavenly blue".[2–4] Tricolorin A was the first member of the series to be fully characterized through a combination of NMR and MS methods.[2,3] This compound consists of the tetrasaccharide L-rhamnopyranosyl-(1→3)-*O*-α-L-rhamnopyrasonyl-(1→2)-*O*-β-D-glucopyranosyl-(1→2)-*O*-β-D-fucopyranoside linked to jalapinolic acid to form a macrocyclic ester with a 19-membered ring (Scheme 1). Following the elucida-

tion of its chemical structure, total syntheses of tricolorin A in its natural enantiomeric form were developed by Larson and Heathcock, and by Lu and collaborators. Both teams used a macrolactonization approach.[5,6] Fürstner and Müller later used a ring-closing-metathesis strategy to form the macrolactone moiety and succeeded in synthesizing tricolorin A[7] and several other resin glycosides.[8,9]

Tricolorin A demonstrates several biological activities of therapeutic interest, such as mammalian cytotoxicity against cultured P-338 and human breast cancer cells,[2] antibacterial activity against *Staphyloccocus aureus* and *Mycobacterium tuberculosis*,[1] and antifungal potential correlated to its (1→3)β-D-glucan synthase inhibitory activity.[10] In the cover crop, tricolorin A acts as a nonprotonophoric uncoupler of photophosphorylation and inhibits electron transport in the photosystem II of chloroplasts.[11] All the bioactivities of this lipopolysaccharide are associated with its macrocyclic structure; the glycosidic acid derived by saponification of the lactone has been shown to be inactive in all resin glycosides biologically tested.[1]

The difficulty involved in obtaining a useable pure sample of an individual resin glycoside,[12] in addition to that related to oligosaccharide crystallization,[13] represented an enormous challenge for the structural investigation reported herein. Protein crystallization techniques were used to avoid wastage of the isolated tricolorin A (20 mg). The compound is insoluble in water, which was therefore selected as the precipitating agent.[14] The size of the crystal unit cell indicated the presence of four independent tricolorin A molecules per asymmetric unit.[15] Each unit contains a total of 284 nonhydrogen atoms and is therefore similar in size to a small protein of about 30 amino acids. The size of the asymmetric unit, together with that of the crystal, demanded the use of intense synchrotron radiation to collect the diffraction data. The SIR2002 method was used to solve the structure. Refinement with the SHELX program indicated the presence of 18 water molecules in the asymmetric unit in addition to the four independent tricolorin molecules (Figure 1). All atoms in the structure were clearly visible in the electron density maps, with the exception of two carbon
atoms in the lipid part of molecule 4. A detailed view of one of the tricolorin A molecules is shown in Figure 2, with ellipsoids representing thermal vibration. The largest temperature

factors were measured for the two methylbutyroyl groups that form esters with the internal rhamnose unit. The macrocyclic aglycon core of molecule 4 displayed slightly more disorder than those of the other molecules.

Figure 3 shows a superposition of the four tricolorin A independent molecules, all of which share the same global shape, albeit with slightly different conformations of the aglycon moiety stacked under the β-D-glucopyranosyl-(1→2)-O-β-D-fucopyranoside moiety. The glycosidic linkages are superimposed on the corresponding energy maps[16] (Figure 3c). Although the energy maps of the three disaccharides differ, all three display low-energy regions centered around a Φ-axis *gauche* conformation, as dictated by the *exo*-anomeric effect. A higher level of conformational freedom is apparent along the Ψ axis: the lowest energy region corresponds to a plateau ranging from Ψ = −60 to 180°. While the externally placed L-rhamnopyranosyl-(1→3)-O-α-L-rhamnopyranoside moeity shows rather different conformations for each of the four molecules in the asymmetric unit, the internal trisaccharide subunit (α-L-rhamnopyrasonyl-(1→2)-O-β-D-glucopyranosyl-(1→2)-O-β-D-fucopyranoside) has limited conformational freedom. The four molecules each display slightly different sets of torsion angles (see the Supporting Information) but all of these angles yield very similar pseudo-elongated shapes for the macrocyclic aglycon portion of the molecule between the lactone end and the anomeric oxygen atom of the fucose unit. In contrast, the terminal pentyl chain is very flexible. We compared the observed conformations of the tricolorin A molecules to those of the only related molecule that has been crystallized, a synthetic chemical intermediate of tricolorin A consisting of the β-D-glucopyranosyl-(1→2)-β-D-fucopyranoside subunit with all its hydroxy groups protected.[17] The first notable difference is that the lack of the amphipathic properties of the natural sample limits the solubility of the analogue to low-polarity organic solvents. Five independent molecules were refined for the asymmetric unit of the analogue, as opposed to the four molecules found in tricolorin A crystals. This difference resulted in a totally different conformation and molecular packing for the analogue. The lack of water molecules produces a piled parallel arrangement of glycoside residues on one side of the analogue structure, whilst the macrolactone rings stack on the other side with alternating alpha and beta faces. The natural compound structure consists of a succession of hydrophilic and hydrophobic layers.

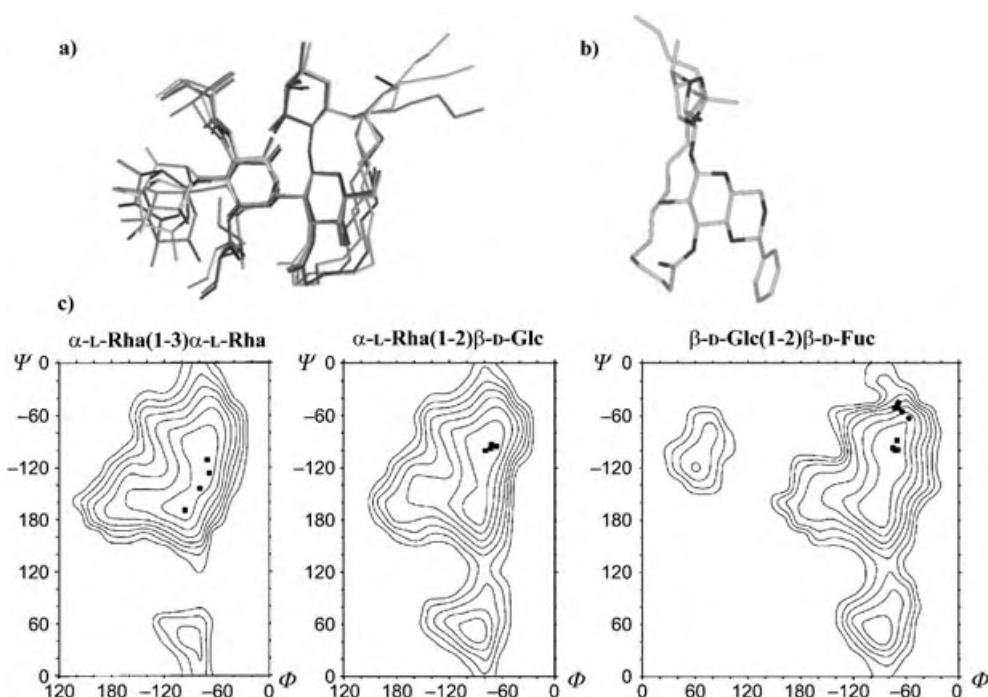
The most notable feature of tricolorin A in the solid state is the anisotropic repartitioning of the hydrophobic and hydrophilic sections in the crystal packing arrangement (Figure 4). One face of the molecule exhibits an almost flat hydrophobic wall formed by the aglycon unit, the methyl group of the fucose unit, and the three lipophilic inner rhamnose residues (the methyl group and the two esterified methylbutyric acid groups). The other face presents two small hydrophilic areas: one composed of the hydroxy groups of the fucose and glucose residues and the other of those of the external rhamnose unit. The 18 water molecules form a dense network that creates a dividing layer between the hydrophilic faces of the structure (Figure 4). The high water content of the crystal, which is similar to that found in the accepted view of protein crystals, means that the tricolorin A molecular


Figure 3. a) Superposition of the four independent molecules of tricolorin A. b) One of the molecules from the crystal structure of the synthetic analogue,[17] shown with the glucose ring in the same orientation as in (a). c) Glycosidic linkage energy maps for each of the constitutive disaccharide subunits of tricolorin A. The conformations observed in the crystal structure of tricolorin A are indicated by squares and those of the synthetic analogue by circles.

made up of four tricolorin A molecules.

conformation in the solid state is not dominated by inter-
molecular forces and hence might be indicative of the
conformation in solution and in supermolecular aggregates.

It has been suggested that the cytotoxic properties of the
resin glycosides could be caused by their ability to perturb cell
membranes through nonselective pore formation. These
compounds have a somewhat peculiar organization in aque-
ous solution and form micelles or aggregates comparable to
those displayed by tricolorin A in the crystalline state. It is
therefore of interest to compare the architecture of the water
channel formed by the four tricolorin A molecules, which pile
up in two pairs along the *c* axis, with the spatial arrangement
of a lipid bilayer. The hydrophobic surface exposed externally
and elongated along the axis of the water channel is ideally
oriented for parallel interaction with the lipids of a biological
membrane upon insertion of tricolorin A into the membrane.
This hypothesis differs from predictions made by molecular
dynamics simulations and NMR studies of micellar solutions

of calonyctin A, another plant-growth-regulating resin glyco-
side,[18] which inserts perpendicularly into micelle lipid
membranes. The total extension of the channel created by
tricolorin A molecules in our study is about 30 Å, which is
comparable to the width of a biological membrane such as
that of the hydrocarbon core elongation in fluid phospholipid
bilayers.[19] A schematic representation of our insertion model
is depicted in Figure 4.

The macrolactone ring is essential to the biological
activities of all resin glycosides[1] since without it the spatial
arrangement needed to form aggregates, as well as the above-
mentioned channels, probably could not take place. The dried
tubers of the medicinal members of the morning glory family
yield a purgative remedy of which the main active ingredients
are resin glycosides.[1] All the biological effects displayed by
this type of amphipathic oligosaccharide suggest that the
activity could be the result of a possible ion flux perturbation
in the target cell membrane induced by nonselective pore
formation, as illustrated by the insertion model. This model
for transmembrane channel formation is based on the crystal
structure of tricolorin A and is still speculative in nature.
Experimental and theoretical studies are called for to provide
substantiation for this hypothesis, as well as to investigate
whether other types of architecture could allow better
interaction. This first crystallographic analysis of a natural
convolvulaceous resin glycoside not only opens avenues for
further structural investigations but may also lead to impor-
tant applications of such compounds in drug design.

[12] The experimental procedures, including preparative HPLC,
handling of the plant material, and extraction of the resin
glycosides from the aerial parts of *Ipomoea tricolor*, have been
described previously.[2,3] Preliminary fractionation of the crude
resins (100 mg) was achieved by standard column chromatog-
raphy. The chloroform-soluble pool was subjected to preparative
HPLC (Waters column, 150 × 19 mm, μBondapak-amino,
10 μm). This separation was performed to eliminate impurities
appearing before and after the selected peak ($t_R = 18$ min).
Isocratic elution was applied, with CH_3CN/H_2O (92:8) and a
flow rate of 6 mL min^{-1}. The tricolorin A peak was collected by

heart-cutting and independently reinjected (40 mg) into the same column. The HPLC system was operated in the recycle mode to achieve the maximal possible purity of the sample.[3] This process of purification was monitored by using a refractive index detector. The sensitivity setting of the refractometer was increased from $8\times$ to $64\times$ to facilitate the detection of all minor impurities. Elution was conducted isocratically with CH_3CN/H_2O (95:5; flow rate $= 8$ mL min^{-1}) and complete separation of tricolorin A to homogeneity (20 mg) was achieved after twelve consecutive cycles on the same aminopropyl column.

[13] S. Pérez, C. Gautier, A. Imberty in *Oligosaccharides in Chemistry and Biology: A Comprehensive Handbook* (Eds.: B. Ernst, G. Hart, P. Sinay), Wiley-VCH, Weinheim, **2000**, pp. 969.

[14] The first microcrystals were obtained by vapour diffusion with a modified version of the hanging drop method. An ethanolic solution (3 μL) of tricolorin A (20 mg mL^{-1}) was mixed with pure poly(ethyleneglycol) 200 (PEG 200; 1 μL, Sigma) and deposited on a glass coverslide. This drop of solution was covered with a layer of mineral oil (Sigma), then the slide was sealed above a reservoir containing a solution of 10 % PEG 200 in water. Crystals suitable for x-ray analysis were grown by using the same method and a sample solution (2 μL, 10 mg mL^{-1} in EtOH) mixed with PEG 200 (2 μL) and mineral oil (2 μL). The drop was seeded with the microcrystals obtained previously. The reservoir solution was composed of 75 % water, 10 % PEG 200, and 15 % EtOH.

[15] A needle-shaped crystal ($0.5\times 0.01\times 0.01$ mm^3) was soaked in a 60 % PEG 6000/water solution for three minutes then cryo-cooled at 100 K. Data were collected from a single crystal on beam line ID29 ($\lambda = 0.8157$ Å) at ESRF (Grenoble) by using an ADSC Q210 CCD detector with a resolution of 0.87 Å ($\Theta_{max} = 28.3°$). A total of 38 162 reflections were measured, of which 18 424 were independent, with $R_{int} = 0.071$. Data were processed with the MOSFLM package.[20] The structure was solved by direct methods (SIR-2002).[21] Refinement was performed with the Shelx-97 program.[22] The nonhydrogen atoms of the sample (four monomers with the formula $C_{50}H_{86}O_{21}$ and $18 H_2O$) were refined with anisotropic displacement parameters, except the water oxygen atoms, for which isotropic refinement parameters were used. A few restraints were included on selected C$-$C distances. Hydrogen atoms were placed on the model molecules (except the water molecules), which yielded a total of 2770 parameters. All 18 424 independent reflections were used in the full matrix least-squares calculations against F^2. Final refinement cycles yielded factors $R1 = 0.0998$ and $wR = 0.2283$ for 16 993 reflections with $I > 2\sigma(I)$. The crystals belong to space group $P2_1$ and have the cell dimensions $a = 14.025(1)$, $b = 33.337(1)$, and $c = 25.512(1)$ Å. $\beta = 91.07(1)°$, $V = 11 926.1(1)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.211$ g cm^{-3}. CCDC 228071 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB21EZ, UK; fax: ($+44$) 1223-336-033; or deposit@ccdc.cam.ac.uk).

[16] Energy maps were calculated for each constituent disaccharide moiety as a function of two glycosidic linkage torsion angles defined as $\Phi = \Theta$ (O5$-$C1$-$O1$-$Cx) and $\Psi = \Theta$ (C1$-$O1$-$Cx$-$C($x + 1$)). Each disaccharide was built with the POLYS software[23] and energies were calculated by using the MM3 program[24,25] and employing a previously described procedure[26] involving full optimization of the structure at each point of the (Φ,Ψ) map except for the two driven angles. To allow consideration of the three possible orientations of the hydroxymethylene group of the glucose unit and the clockwise or anticlockwise possibilities for the hydrogen bonding network around each ring, several starting structures, a step of 20°, and a dielectric constant $\varepsilon = 80$ were used for these calculations. The single relaxed maps were combined to provide unique adiabatic maps by a procedure designed by our group.[26] The corresponding plots were generated with the X-Farbe program.[27]

[+] Crystal structure analysis.

Supporting information for this article (including the crystallographic data for *cis*-[W(CO)$_4$(piperidine)$_2$], an ORTEP view, a powder X-ray diffraction pattern, and its IR spectrum (KBr pellet and pure solid)) is available on the WWW under http://www.angewandte.org or from the author.

most diagnostic. In addition to the relationship derived from group theory between the stereochemistry of a metal carbonyl complex and the number and activity of its ν_{CO} modes, their frequency range correlates with the bonding mode of the CO ligands. In general, terminal CO groups absorb between 2100–1850 cm^{-1}, whereas doubly bridging CO ligands absorb between 1850–1750 cm^{-1} and triply bridging CO ligands absorb below 1730 cm^{-1}. This spectral shift arises as a consequence of the progressive decrease in C–O bond order.[1] Infrared spectroscopy is far more sensitive than X-ray diffraction to small changes in bond orders, despite the irreplaceable value of the latter for establishing the spatial arrangement of atoms and molecules in the solid state. We show below, in a case study, that an archetypal complex with terminal carbonyl ligands has unusual ν_{CO} frequencies below 1770 cm^{-1}, and that this observation can be rationalized by the presence of a remarkable and unexpected supramolecular, bifurcated N-H···OC-M network in the solid state.

Some metal complexes enjoy the privilege of being ubiquitous precursors to wide ranges of new molecules. This has been the case in metal–carbonyl chemistry with *cis*-[M(CO)$_4$(piperidine)$_2$] (M = Mo, W), which have been used for almost 30 years to prepare octahedral metal carbonyl complexes of the type *cis*-[M(CO)$_4$L$_2$]; the lability of the piperidine ligands allows the synthesis of the desired products under much milder conditions and in better yields than when starting from the parent hexacarbonyl compounds.[2,3] It is therefore not surprising that these complexes have been very highly cited and their synthesis has even been published several times—with only minor variations, since it simply results from the thermal or photochemical activation of [M(CO)$_6$] in the presence of excess piperidine [Eq. (1)].[4]

$$M(CO)_6 + \text{excess NHC}_5H_{10} \xrightarrow[-2\,CO]{\text{thermal or photochemical activation}}$$
$$cis\text{-}[M(CO)_4(NHC_5H_{10})_2] \qquad (1)$$
The most common characterization methods have been elemental analysis and IR spectroscopy in the ν_{CO} region, where four bands are expected for a C_{2v} local symmetry ($\Gamma_{vib} = 2A_1 + B_1 + B_2$). To the best of our knowledge, the only IR data available for *cis*-[W(CO)$_4$(piperidine)$_2$] are those published by Tripathi et al. who reported values of 2000, 1865, 1844, and 1814 cm^{-1} (in mulls, no intensities given),[4c] which are different from our own data (see below).

Recent studies on the reaction of *p*-benzoquinonediimine ligands with *cis*-[W(CO)$_4$(piperidine)$_2$] revealed an interesting metal-coordination-induced *para–ortho*-quinone isomerization and relocalization of the π system.[5] We were surprised to find a solid-state (KBr pellet) IR spectrum (see the Supporting Information) for *cis*-[W(CO)$_4$(piperidine)$_2$] with ν_{CO} bands down to 1768(vs) cm^{-1}, that is, at energies much lower than expected for terminal CO ligands in a neutral complex.[1,6] After performing purity controls and triggered by the lack of any previous report on this most unusual observation,[7] we grew single crystals of *cis*-[W(CO)$_4$(piperidine)$_2$] by slow diffusion of heptane into a THF solution and subjected them to an X-ray diffraction study. The ORTEP view of the crystal structure (see the Supporting Information) confirms that the piperidine ligands are in a *cis* arrangement

and that all the carbonyl groups are of the linear type, with M–C–O angles of 174.1(4) and 179.1(3)°. Figure 1 also reveals the existence of a remarkable network of intermolecular bifurcated H-bonds. Figure 2 shows a projection of the structure in the *a,b* plane, with the channel-like 3D structure evident. Each octahedral complex molecule acts as a bridge between two other molecules: each N–H proton interacts with two carbonyl groups, each belonging to a different molecule. Conversely, each CO ligand *trans* to a piperidine
Figure 1. Partial view of the crystal structure of *cis*-[W(CO)$_4$(piperidine)$_2$] resulting from a bifurcated H-bonding network involving all the N–H protons and the CO ligands *trans* to the piperidine ligands. The carbon skeleton of the piperidine ligands has been omitted for clarity.
Figure 2. Projection of the crystal structure of *cis*-[W(CO)$_4$(piperidine)$_2$] in the *a,b* plane. The carbon skeleton of the piperidine ligands has been omitted for clarity. Color coding: W purple, O red, N blue, N–H green.

moiety on each complex interacts with the two N–H protons from another molecule (Table 1). The observation that these H-bonding interactions selectively involve the two carbonyl ligands which are *trans* to the strong σ-donating/weak π-

accepting piperidine ligands is perfectly consistent with their more electron-rich nature. This results in a) a considerable reduction in the electron density at these oxygen atoms, which leads therefore to ν_{CO} absorptions much more typical of bridging carbonyl groups or isocarbonyl linkages than of terminal CO ligands,[1] and b) an IR ν_{NH} vibration as low as 3254 cm⁻¹ in KBr. The X-ray diffraction pattern of a microcrystalline powder of *cis*-[W(CO)₄(piperidine)₂] was recorded at 300 K and could be completely indexed on the basis of the extinction conditions of the tetragonal system in the space group $P4_32_12$ with $a = 11.864(1)$ and $c = 11.058(1)$ Å. This observation is in complete agreement with the data obtained from the single crystal study (see the Supporting Information). To ensure that no special matrix effect was caused by the KBr pellets, drops of a solution of the complex in THF were evaporated on a single crystal of KBr and the IR spectrum recorded. The ν_{CO} values found were almost identical (see the Supporting Information). These H-bonding interactions also remain in a Nujol mull (ν_{CO}: $\tilde{\nu} = 2005(m)$, 1900(sh), 1874(vs), 1829(s), 1787(sh), 1769(vs) cm⁻¹, and these values are at variance with those reported in the literature,[4c]) but as expected, they disappear in solution, as shown by the IR spectrum showing four ν_{CO} absorptions in the usual range ($\tilde{\nu} = 1998(w)$, 1920(w), 1860(vs), 1823(s) cm⁻¹ in THF). The hydrogen-bonding capability of carbonyl ligands versus C–H bond donors is well-documented[8a,b] and increases with increasing basicity: terminal M-CO < μ₂-CO < μ₃-CO.[8c,d] A search of the Crystallographic Cambridge Data Base for analogous N–H···OC–M (M = Group 6 metal) interactions involving terminal carbonyl groups identified 225 hits with a median value of 2.582 Å (a value which is consistent with our data), but none for *cis*-[M(CO)₄(piperidine)₂] complexes. Interestingly, Kraihanzel and Cotton noted that the "solid-state spectrum of [Mo(CO)₄(ethylenedi-

amine)₂] is strikingly different from the solution spectrum" and suggested that the extreme insolubility of this compound might be a result of NH···OC hydrogen bonding, but this was not (and has never been since) substantiated by X-ray diffraction data.[9] It was stated on the basis of the X-ray structure of *cis*-(diethylenetriamine)tricarbonylmolybdenum that "clearly, there are no strong intermolecular NH···O bonds".[10] Although Shiu et al. noted a low frequency ν_{CO} absorption at 1790 cm⁻¹ in the solid-state spectrum of the complex [Mo(CO)₄(N-N)] (N-N = PhCH₂NHCH₂CH₂NMe₂), they concluded from the X-ray data that "an intermolecular H-bond between the N–H atom of one molecule and a carbonyl oxygen atom of another molecule is negligible in this compound".[11] However, such an intermolecular bonding interaction was cautiously discussed in [Mo(di-2-pyridylamine)(CO)₄] although it involved only one CO ligand,[12] whereas no H-bonding was observed in [Mo(bipy)(di-2-pyridylamine)(CO)₃].[13] An intermolecular N-H···O distance of 2.15 Å has been reported for the pyridine-4(1H)-thione complex [W(C₅H₅NS)(CO)₅] but no IR data are available, which precludes any correlation between H-bonding and ν_{CO} shifts.[14] The IR spectra of *cis*-[W(CO)₄(piperidine)₂] were compared to those of *cis*-[Mo(or W)(CO)₄(pyridine)₂] (in THF solution, KBr pellets, or Nujol mulls).[15a,b] As expected, the latter display no unusual features, which is consistent with the X-ray structure of the tungsten complex which shows "no particularly short intermolecular contacts".[15c] Although ion-pair interactions between an oxygen atom of a carbonylmetalate anion and its associated cation are known to produce significant ν_{CO} shifts to lower energies, this represents a very different situation to that involving a neutral molecule.[16]

Since the space group in which this molecule crystallizes is chiral, we investigated its nonlinear optical (NLO) properties, but no second order effect was observed.

In conclusion, we have shown that supramolecular H-bonding interactions can dramatically affect the ν_{CO} frequencies of metal–carbonyl compounds, and consequently can make structural assignments based on vibrational spectroscopy alone misleading or incorrect. In a case study, we have established that the long-known and archetypal carbonyl complex *cis*-[W(CO)₄(piperidine)₂] displays most unusual, low-frequency ν_{CO} absorptions in the solid state which are not the result of the strong σ-donor/weak π-acceptor properties of the amine ligands but of supramolecular interactions involving the piperidine N–H proton and the carbonyl oxygen atom of the two CO ligands *trans* to the piperidine ligands. Although the crystal structure of *cis*-[Mo(CO)₄(piperidine)₂] was reported very recently, no mention was made of either intermolecular H-bonding interactions or unusual IR data in the solid state.[17] We examined a freshly prepared sample of *cis*-[Mo(CO)₄(piperidine)₂] and found that the IR spectra recorded in KBr pellets or Nujol mull were very similar to those of the tungsten derivative (see Experimental section), but at variance with literature values.[4f] It is therefore most likely that similar intermolecular N-H···O interactions are also present in the Mo derivative. It would not be surprising that other metal–carbonyl complexes containing H-bond donors, even with the less-basic terminal CO ligands, reveal similar features to *cis*-[W(CO)₄(piperidine)₂]. In other cases

where solid-state IR data have been reported for complexes of the type *cis*-[W(CO)$_4$(amine)$_2$] and low values found for their ν_{CO} frequencies, no comment was made or explanation offered.[18] Such questions are of clear relevance to crystal engineering. In a different context, it is interesting to note that the activation of organic carbonyl compounds by double H-bonding is increasingly used in asymmetric catalysis.[19]

Experimental Section

All reactions were carried out under purified N$_2$ in freshly distilled solvents by using Schlenk techniques. A solution of *cis*-[W(CO)$_4$-(piperidine)$_2$], prepared by a slightly modified standard procedure[4d] (using xylene as a solvent), in THF was layered with heptane and unsolvated, pale yellow crystals were obtained by slow diffusion. ^{13}C{^{1}H} NMR (125 MHz, CD$_3$CN, 298 K): $\delta = 211.23$ (s), 210.93 ppm (s, CO). These values are consistent with those reported for similar complexes.[20]

Crystal data: C$_{14}$H$_{22}$N$_2$O$_4$W, $M_r = 466.19$, tetragonal, space group P4$_3$2$_1$2, $a = 11.936(1)$, $b = 11.936(1)$, $c = 11.210(1)$ Å, $U = 1597.1(2)$ Å^3, $Z = 4$, μ(Mo$_{K\alpha}$, $\lambda = 0.71073$ Å) = 7.249 mm^{-1}, $T = 173$ K, 2339 unique reflections collected, $R = 0.0224$ for 2173 reflections with $I > 2\sigma(I)$, wR2 = 0.0559. Data collection on a Nonius Kappa-CCD area detector diffractometer using Denzo software. The structure was solved by direct methods (SIR97) with full-matrix least-squares refinement on F^2 using SHELXL97 software. The absorption was corrected empirically.[21] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms, except H1, which was found by Fourier differences, were generated according to the stereochemistry and refined using a riding model in SHELXL97.[22] CCDC 234274 contains the supplementary crystallographic data (excluding structure factors). These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

The IR spectrum of solid *cis*-[W(CO)$_4$(piperidine)$_2$], deposited by evaporation of a THF solution on a single crystal of KBr, contains the expected four ν_{CO} absorptions at $\tilde{\nu} = 2004$(m), 1875(vs), 1830(s), 1774(vs) cm^{-1}, similar to those found for this complex in a KBr pellet.[6]

The complex *cis*-[Mo(CO)$_4$(piperidine)$_2$] was prepared in a similar manner to the W complex (shorter reaction times) and its IR spectrum was recorded for comparison: ν_{CO} (KBr): $\tilde{\nu} = 2012$(mw), 1913(sh), 1887(vs), 1838(s), 1792(sh), 1774(vs) cm^{-1}. ν_{CO} (solid deposited by evaporation of a THF solution on a single crystal of KBr): $\tilde{\nu} = 2010$(mw), 1942(w), 1911(sh), 1882(vs), 1835(s), 1778(vs) cm^{-1}.

Individual Molecules of Dye-Labeled DNA Act as a Reversible Two-Color Switch upon Application of an Electric Field[**]

Samuel S. White, Liming Ying,
*Shankar Balasubramanian, and David Klenerman**

Over the past few years, molecular switches have been heavily researched in the quest for molecular electronic devices. Some switching systems operate by a conformational change in the molecule which is induced by either an electric field,[1,2] an STM (scanning tunneling microscope) tip,[3] an electrochemical reaction,[4] or light.[5] Alternatively, molecular switches can be operated nonconformationally by redox reactions[6] or a chemical binding event.[7] Biomolecules have recently been adapted for new purposes; for example, DNA has been used as part of a conducting wire,[8] a molecular machine,[9–12] a crystal template,[13] a scaffold for nanoscale construction,[14] and even as a component of a "computing machine".[15,16] Herein we show that the fluorescence of individual dye-labeled DNA molecules can be reversibly switched from green to red and vice versa upon application of an electric field.

The use of nucleic acids as molecular switches is a relatively new concept and, so far, has had limited success. The use of an electric field to modulate the fluorescence of labeled DNA adsorbed onto an electrode[17] and the use of a magnetic field to control the hybridization state of DNA[18] are known. Conformational switching of DNA by the variation of buffer conditions,[11,19] the binding of adenosine to an aptamer sequence on DNA,[20] or the binding of single-stranded DNA (ssDNA) to a DNA quadruplex[9] have also recently been reported. The main limitation with the current mechanisms for DNA conformational switches is that they require bimolecular hybridization or a change of buffer, thus switching is slow. Furthermore, in some cases switching is not reversible[20] or the process creates undesirable "waste" DNA.[9,10] Our DNA switch overcomes these problems by using an electric field to alter the DNA–dye interaction which renders the switching process rapid (< 100 ms) and reversible with no by-products.

Here a controllable electric field and single-molecule fluorescence detection were used to probe the switching of the fluorescent states of individual DNA molecules that were labeled with two different fluorophores at the same end of the DNA duplex. We previously utilized the very high electric-field gradients generated at the tip of a nanopipette to

controllably concentrate and deliver DNA.[21–23] The pipettes have an inner diameter of 100 nm and the voltage drop occurs in the last few microns of the tip owing to its tapered shape. By application of a potential of 1 V between the electrode in the bath and the electrode in the pipette, a very high electric field of ≈ 8000 V cm^{-1} is generated at the tip of the pipette.[22]

The fluorescence of both fluorophores was detected simultaneously with either two-color direct excitation of both fluorophores or single-color excitation of the donor fluorophore only. In the latter experiments, the excited-state energy is transferred nonradiatively from a donor to an acceptor fluorophore by FRET (fluorescence resonance energy transfer). The efficiency of transfer, E, depends on the relative orientation of the fluorophores and the distance that separates them, R, according to Equation (1). R_0 is the Förster distance and this was calculated to be 53 Å for the dye-pair used in these FRET experiments. This inverse-sixth-power separation dependency of energy transfer allows FRET to be used as a sensitive probe of intramolecular distances over the 10–100 Å range.

$$E = R^6/(R^6 + R_0^{\,6}) \tag{1}$$

In FRET, the principle property of interest is not the intensity of fluorescence, but rather the proximity ratio, P. The FRET proximity ratio of each DNA molecule was calculated according to Equation (2), in which I_A and I_D are the intensities of the acceptor and donor fluorescence, respectively. This ratio is strongly dependent on the distance between the fluorophores, whereas it is independent of diffusional motion.[24] If the excitation power is kept low, photodriven processes such as photobleaching can also be neglected and the proximity ratio becomes independent of the laser intensity.[25]

$$P = I_A/(I_A + I_D) \tag{2}$$

We studied a 40-base double-stranded DNA (dsDNA) labeled with a donor fluorophore, Rhodamine Green, and an acceptor fluorophore, Alexa 647. Both fluorophores were attached to the bases by C6 linkers that do not constrain the motion of the fluorophore. DNA 1 is a dsDNA with the donor and acceptor fluorophores directly opposite each other on separate strands; it is able to undergo FRET owing to the close proximity of the strands (Figure 1). DNA 2 has the donor and acceptor fluorophores at opposite ends of the duplex and is unable to undergo FRET as their separation is larger than the Förster distance for the dye-pair used (53 Å; Figure 1). A single-molecule study of DNA 1 in solution unexpectedly revealed two peaks in the FRET histogram (Figure 2a), one at $P = 0.05$ and the other at $P = 0.95$, both of which had approximately equal amplitudes. The average single-molecule proximity ratio ($P = 0.40$) gave a value that was almost identical to that of the bulk value ($P = 0.44$). Experiments in which the laser power was varied by two orders of magnitude and in which a radical scavenger (ascorbic acid, 200 μM) was introduced did not lead to any changes in the single-molecule FRET histogram (data not shown). This indicates the absence of photobleaching in this

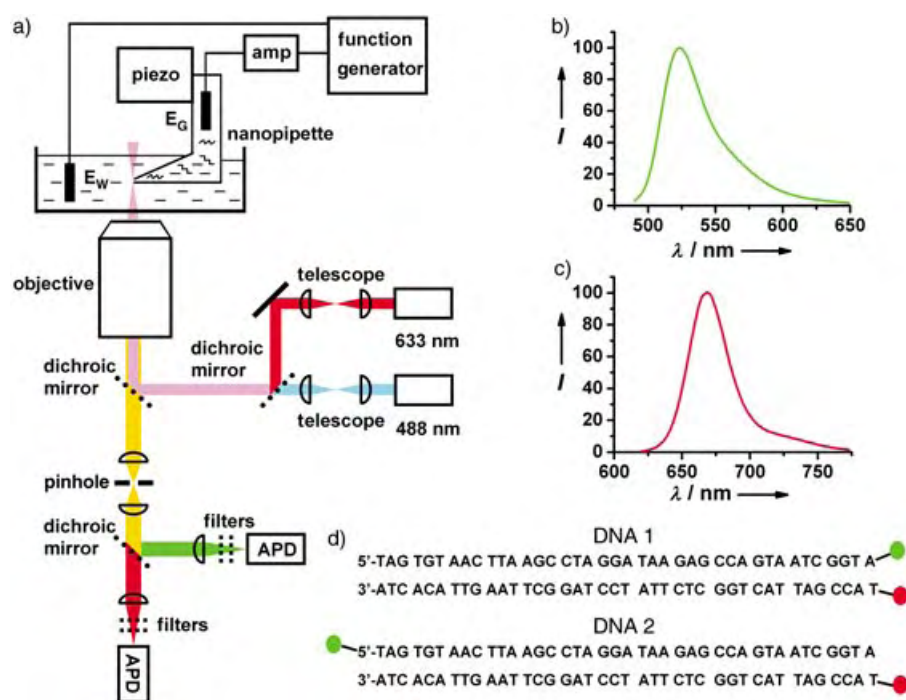

Figure 1. a) A schematic of the experimental setup used (E_G = ground electrode, E_W = working electrode, APD = Avalanche Photo Diode detector); b) and c) the fluorescence emission spectra of the fluorophores Rhodamine Green (donor) and Alexa 647 (acceptor), respectively; d) the two DNA samples labeled with the donor (green circle) and the acceptor (red circle) dyes.
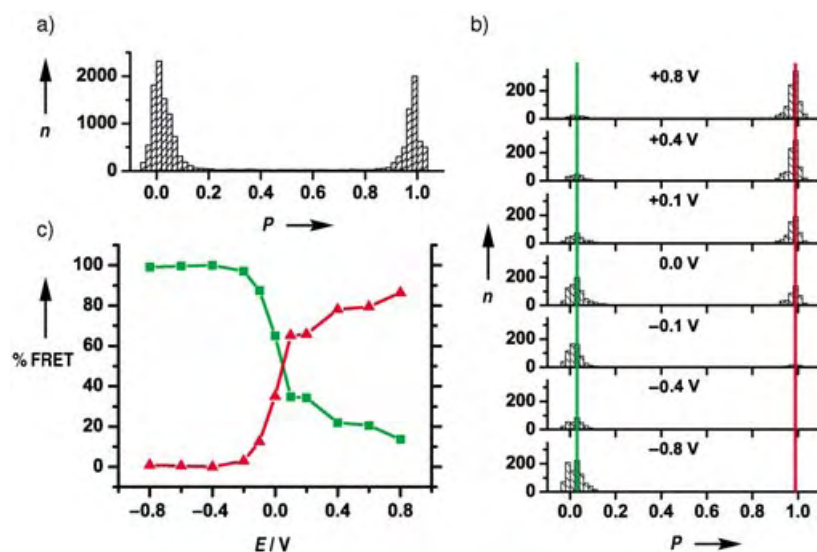

Figure 2. a) Single-molecule FRET histogram of DNA 1 (50 pM) in solution; b) single-molecule FRET histogram of DNA 1 (1 nM) in a nanopipette upon excitation at $\lambda = 488$ nm (on the tip); P = FRET proximity ratio, n = number of molecules. c) Variation of the percentages of the low-FRET peak (green; donor emission) and the high-FRET (red; acceptor emission) with the applied dc potential, E.

experiment. A temperature-dependent study over the range 12–38 °C also revealed no variation in the two FRET peaks (data not shown). These results indicated that two equally occupied conformational states are present in solution: one low-FRET state that is green-fluorescent and one high-FRET state that is red-fluorescent.

The possibility of altering the populations of these two fluorescent states through the generation of an electric field in the nanopipette was then explored. Indeed, the amplitudes of the two FRET peaks were dramatically altered by the application of different potentials Figure 2b. No additional states were observed. The pipette in these experiments was earthed, and a potential was applied to the electrode in the bath. At a negative potential below −0.2 V only the low-FRET peak was observed, whereas a positive potential above 0.4 V favored almost entirely the high-FRET peak. This implies that the low-FRET peak is not due to the presence of DNA labeled only with the donor, but that it is a true FRET state because its population can be altered by an applied voltage. The absolute values in Figure 2b cannot be compared because of the slight differences in the alignment of the pipette, thus the percentage of each FRET population at a given voltage is displayed in Figure 2c. This shows a clear switching between the two states with the applied voltage. To determine if the change was reversible, the laser was then focused outside the pipette at approximately 20 μm from the tip, and a positive voltage was applied so that the DNA flowed out of the pipette. The DNA is in a high-FRET state in the pipette tip, however, the measured single-molecule FRET histogram and the mean proximity ratio value were identical to those in free solution which indicates no irreversible processes (e.g. redox reactions) had taken place in the tip. Switching was determined to be rapid (< 100 ms) from the application of a square wave (± 0.8 V, 0.25 Hz) and from measurement of the time taken for the FRET to change from low to high and vice versa.

Fluorophore excimers,[26,27] exciplexes,[28] and excitonic interactions[29,30] have previously been observed in DNA or RNA. The main characteristic of an excitonic interaction is a change in the UV/Vis absorption spectrum, whereas the main characteristic of an excimer or exciplex is a change in the fluorescence spectrum. No changes in the UV/Vis absorption or fluorescence spectra were

observed for DNA 1 compared to the control sample, DNA 2, which indicates that neither a fluorophore exciplex nor an exciton interaction between the two fluorophores is likely to be present in solution. No perturbation of the electronic state of the Alexa 647 dye attached to the DNA could be detected in the absorption or fluorescence spectra relative to the free dye. The melting temperatures for DNA 1 and 2 were $68 \pm 0.2\,°C$ and $67 \pm 0.3\,°C$, respectively. This also suggests that there is no significant dye–dye interaction in solution.

Each fluorophore was then excited directly by using a two-color setup. When a negative potential was applied to DNA 1 in a nanopipette and upon excitation at $\lambda = 488$ nm, fluorescence from Rhodamine Green was observed. However, emission from Alexa 647 was not detected even upon direct excitation at $\lambda = 633$ nm. The same behavior was observed with DNA 2. In contrast, it was possible to excite directly the Alexa 647 moieties in both DNA 1 and 2 upon application of a positive potential. An experiment was then performed to determine if dsDNA was required to observe this effect. A 5′-Alexa 647-labeled ss40-mer and a Rhodamine Green-labeled noncomplementary ss65-mer (used as a control to check the presence of DNA at the tip) were excited at $\lambda = 488$ and 633 nm in the nanopipette. A square-wave waveform was applied, and the fluorescence was monitored. Many bursts of Alexa 647 emission were observed during the positive half-cycle because of the electrophoretic flow to the pipette tip, and fewer bursts were detected during the negative half-cycle. However, when the fluorescence counts per burst were individually analyzed, no differences were observed in the fluorescence amplitude histogram (Figure 3a). Double-stranded DNA would therefore seem to be a prerequisite for the switching process. These experiments suggest that dye–dye interactions are not the reason for the observed switching, but rather switching occurs upon a change in the interaction between the Alexa 647 moiety and the duplex DNA upon application of an electric field.

Quenching of the donor was ruled out by analysis of the individual fluorescence counts from the donor per burst of DNA 1 (upon selection of only the low-FRET bursts) and DNA 2 in free solution. No differences in the fluorescence amplitude histogram were seen (Figure 3, b and c), and mean amplitudes of 46 and 50 counts were obtained for DNA 1 and DNA 2, respectively, which indicate that the donor is not quenched.

We postulate that there are two states for the Alexa 647 dye: 1) Under a positive potential, the dye is free to move such that the Rhodamine Green donor can transfer energy to Alexa 647 through FRET with nearly 100 % efficiency owing to the proximity of the fluorophores. 2) Under a negative potential, the Alexa 647 dye interacts with the duplex DNA, possibly by base-stacking on the end of the DNA duplex, whereupon it is quenched by the DNA. Base-stacking of the Alexa dye that results in restricted movement of the dye is suggested by the high bulk fluorescence anisotropy value (0.204 ± 0.004). Rhodamine Green has a low bulk fluorescence anisotropy value (0.090 ± 0.008) which implies that it is
Figure 3. a) Fluorescence amplitude histogram of 5′-Alexa 647-labeled ss40-mer DNA; excited at $\lambda = 633$ nm with a ± 1.2-V square-wave (0.125 Hz) applied. b) and c) Donor fluorescence amplitude histograms of DNA 1 (only the low-FRET population is selected, that is, $P < 0.5$; mean fluorescence burst amplitude = 46) and DNA 2 (mean fluorescence burst amplitude = 50), respectively, in free solution.

relatively mobile. The fluorophore Cy3, a cyanine dye like Alexa 647, is known to stack onto the end of DNA helices in a similar manner to that of an additional base pair.[31] Base-stacking has been observed for other dyes, with millisecond-range rates of conversion between the stacked and unstacked states observed at room temperature.[32,33] In this case, the Alexa dye is closer to the Rhodamine Green moiety and is not free to rotate. Only Rhodamine Green emission is observed in this state for two possible reasons: First, the weak coupling assumed in the Förster transfer process breaks down, and an excitonic state is formed whose fluorescence originates entirely from the Rhodamine fluorophore. This excitonic state was not observed in solution so the interactions, separation, or orientation of the fluorophore must be altered in the presence of the high electric field. Alternatively, weak coupling between the dyes may still occur, but Rhodamine Green cannot transfer energy to the Alexa dye owing to the relative orientation of the two dyes, and thus Rhodamine Green fluorescence is observed.

In conclusion, we have shown that duplex DNA with donor and acceptor fluorophores at the same end can be reversibly switched between a donor-emitting green state and an acceptor-emitting red state on the application of an electric field. The electric field appears to alter the conformation of the acceptor dye only which results in a significant change in its fluorescence quantum yield presumably owing to interactions with the DNA strand. This is important for applications as a two-state switch in single-molecule optoelectronic devices and indicates that the conformations of other

biological molecules as well as voltage-gated ion channels may be switched by the application of an electric field.

Experimental Section

HPLC-purified 40-base oligonucleotide 5′-TAG TGT AAC TTA AGC CTA GGA TAA GAG CCA GTA ATC GGT A-3′ (MWG–Biotech, Ebersberg, Germany) was labeled at the 3′ terminus with the fluorophore Rhodamine Green; a 5′-labeled and unlabeled versions were also purchased. Its 40-base complementary oligonucleotide, modified at the 5′ terminus with a C6 linker chain (IBA, Göttingen, Germany), was desalted (NAP 5 column; Amersham, U.K.) and labeled by using an Alexa Fluor 647 Oligonucleotide Amine Labeling Kit (Molecular Probes, Eugene, USA). Dimethylsulfoxide was removed from the labeled DNA solution by using a NAP 5 column. The labeled oligonucleotide was separated from excess dye by precipitation in ethanol and further purified by HPLC to remove unlabelled DNA and any remaining dye. Acetonitrile (from the HPLC fractions) was removed with a NAP 10 column (Amersham, U.K.). All oligonucleotides were prepared in a buffer solution containing Tris-HCl (10 mM; Amersham, U.K.), EDTA (1 mM; Amersham, U.K.), and NaCl (100 mM; Acros Organics, Fairlawn, USA) at pH 7.4. The concentration of the dye-labeled DNA was determined by the absorbance at $\lambda = 260$ nm; the absorbances at $\lambda = 505$ (Rhodamine Green) or 650 nm (Alexa 647) were used as internal references. Double-stranded DNA (dsDNA) samples were prepared by mixing two complementary single-stranded oligonucleotides, heating the mixture to 90 °C and then slowly cooling this to room temperature. Melting temperatures of 68 °C and 67 °C (in NaCl–Tris–EDTA buffer) for DNA 1 and DNA 2, respectively, were observed by the evolution of UV/Vis spectra with temperature.

The nanopipettes were made by using a laser-based pipette puller (Model P-2000, Sutter Instrument Co.). A two-line program was used to pull borosilicate glass capillaries (0.58- and 1-mm inside and outside diameters, respectively) with the following parameters: Heat = 350, Fil = 3, Vel = 30, Del = 220, Pull = ; Heat = 330, Fil = 2, Vel = 27, Del = 180, Pull = 250. For the pipette experiments, a solution of DNA (1 nM) was back-filled into the bent nanopipette by a microfiller (Microfil 34, World Precision Instruments, Sarasota, USA). A coverglass-bottomed dish (Willco Wells GWST-1000) that contained buffer solution (2–3 mL) was used as the bath. The pipette tip was placed 5 to 10 μm above the surface of the dish. Two Ag/AgCl electrodes, one placed in the bath and the other placed inside the pipette, served as the working and reference electrodes, respectively. The ion current flowing through the pipette was the same in the presence and absence of DNA because the ion current is dominated by the flow of sodium and chloride ions. Furthermore, no reduction in the ion current could be detected with DNA present in the pipette (from partial blocking). The same buffer solutions (Tris-HCl, 10 mM; EDTA, 1 mM; NaCl, 100 mM) were used both in the pipette and in the bath. EDTA served to remove multivalent cations in the solution. For experiments in solution, DNA was diluted to 50 pM in the NaCl–Tris–EDTA buffer solution (pH 7.4) and Tween 20 (0.01 %) was added to prevent surface adhesion of the DNA molecules.

The two-color setup and apparatus for the experiments performed in the pipette were described previously.[34] The potential waveforms applied to the electrodes were created by using a function generator (Model DS345, Stanford Research Systems, Sunnyvale, USA). This function generator was also used to provide a trigger for the MCS (Multi Chanel Scalar) cards. Solution experiments were performed on the same setup, except that the laser beams were focused 5 μm into a 1-mL aliquot of the solution of the sample supported in a Lab-TeK chambered coverglass (Scientific Laboratory Suppliers Ltd, U.K.). All experiments were performed at room temperature with a 1-ms bin time(data-acquisition time) used on both MCS cards. A threshold of 35 counts per millisecond bin for the sum of the donor and acceptor fluorescence signals was used to differ-entiate between the signal bursts of the background and the single-molecules. A background of 1–2 counts per millisecond, obtained from independent measurements of buffer solution that did not contain labeled DNA, was subtracted from each burst. The emission spectra of the two fluorophores are very well separated (see Figure 1 which reduces the cross-talk to a negligible level.[34]

Steady-state fluorescence measurements were recorded on an Aminco-Bowman Series 2 fluorimeter, which was equipped with a water bath set to 20 °C. A 50-nM concentration of DNA was used. Fluorescence anisotropies, r, for Rhodamine Green and Alexa 647 were calculated from the polarization of the emission components $I_{\parallel\parallel}$, $I_{\parallel\perp}$, $I_{\perp\parallel}$, and $I_{\perp\perp}$ ($\parallel$ and $\perp$ denote the parallel and perpendicular orientations, respectively, of the excitation and emission polarisers) according to Equation (3), with $G = I_{\perp\parallel}/I_{\perp\perp}$.

$$r = (I_{\parallel\parallel} - G I_{\parallel\perp})/(I_{\parallel\parallel} + 2 G I_{\parallel\perp}) \tag{3}$$

For the fluorescence anisotropy of Rhodamine Green, excitation was carried out at $\lambda = 505$ nm and the emission was monitored at $\lambda = 530$ nm. For Alexa 647, excitation was carried out at $\lambda = 649$ nm and the emission was monitored at $\lambda = 666$ nm.

and designable inner space for meeting new technological challenges. Among many preparative methods,[1–14] template-assisted synthesis is an effective approach in which hard templates, such as polymeric core supports or sacrificial metal substrates, and soft templates, such as micelles in emulsions or ionic liquids, have been utilized.[1–11] Recent developments in this area show that hollow structures can also be created via direct solid evacuation with Ostwald ripening,[12] and the Kirkendall effect,[13] or formed from self-assembly of building blocks through hydrophobic interactions.[14] It would also be desirable to search for one-pot syntheses, preferably by template-free routes.

"Oriented attachment" has attracted increasing interest in recent years as a new means for fabrication and self-organization of nanocrystalline materials under one-pot conditions.[15–19] As summarized in Figure 1, recent examples
Figure 1. Various organizing schemes for self-construction of nano-structures by oriented attachment.

Tin Oxide Nanooctahedra

Self-Construction of Hollow SnO₂ Octahedra Based on Two-Dimensional Aggregation of Nanocrystallites**

*Hua Gui Yang and Hua Chun Zeng**

The past few years have witnessed an increasing trend toward synthetic fabrication of micro- and nanostructures with hollow interiors, owing to their potential applications as photonic crystals, host materials for intercalants, drug-delivery carriers, sensors, and chemical reactors.[1–14] These hollow structures, which normally consist of inorganic materials such as metals or metal oxides, provide both chemical functionality

include formation of one-dimensional (1D) nanorods (e.g., TiO₂ and ZnO) from their respective 0D nanocrystallites (Figure 1a).[15,16] The formed 1D nanorods or nanoribbons can also further self-attach through stacking by planar van der Waals interaction (for layered compounds, e.g., α-MoO₃; Figure 1b)[17] or lateral "lattice fusion" (for ionic compounds, e.g., ZnO; Figure 1c)[16,18] to generate either length-multiplied 1D nanostructures or 2D crystal sheets and walls. Recently, this size-amplifying mechanism was extended to 3D architectures of 2D crystal strips (formed from 1D nanoribbons; Figure 1d),[19] in which rhomb-shaped 2D building blocks can self-aggregate into "dandelion"-like hollow spheres. Here we report another novel organizing principle (Figure 1e) with an underlying oriented-attachment mechanism in which complex geometrical structures (e.g., polyhedra) can be built by the assembly route 0D→2D→3D. Using the wide-band-gap semiconductor tin dioxide as an example,[11,20,21] we demonstrate that hollow geometrical

objects of micro- and nanoscales can be prepared by one-pot solution routes without using templates. This strategy is based on the ability to stabilize certain crystallographic planes while the 0D nanocrystallites form and undergo 2D self-aggregation.

The crystallographic structure and chemical composition of the SnO_2 octahedra were determined by powder XRD and energy-dispersive X-ray spectroscopy (EDX; Supporting Information). These data show that the prepared SnO_2 has a rutile-like tetragonal symmetry and a strictly stoichiometric atomic ratio (space group $P4_2/mnm$, $a_o = 4.738$, $c_o = 3.188$ Å; JCPDS file no. 21-1250;[11,20,21] Sn/O = 1:2). In particular, the broad XRD peaks of (110), (101), (200), (211), and (112) reflect the nanocrystalline nature of samples, but no lattice relaxation was detected.

The field-emission scanning electron microscopy (FESEM) images in Figure 2a show the general morphology of the hollow SnO_2 octahedra synthesized in this work. A high yield (> 95 %) of this polyhedral form can be easily achieved after only one sedimentation run (Figure 2e). Interestingly,
Figure 2. FESEM images of hollow SnO_2 crystal octahedra. a) General sample morphology (the framed area indicates the joined part of two intersecting octahedra). b) A tilted SnO_2 octahedron. c) Ridge opening (indicated by arrows) on a SnO_2 octahedron. d) Interior morphology. e) Overall product morphology after only one sedimentation run (SEM image).

geometrical parameters of the bipyramidal octahedra, such as interplanar angles and edge-length ratios, are essentially identical regardless of the actual sizes of the hollow structures (Supporting Information). This observation indicates that an overall crystallographic relationship exists among the nanocrystallites that constitute the octahedra. The isosceles-triangular crystal planes (Figure 2b) have angles of 56 ± 1 and $68 \pm 1°$,[22] that is, the crystallographic planes of each octahedral surface are similar to the {111} family (Figure 3d). There is a total of 16 {111}-like planes per octahedron: eight for inner surfaces, and eight for outer ones. The interior space of the hollow SnO_2 octahedra was examined directly by FESEM for incomplete or cracked SnO_2 crystal octahedra (Figure 2d). The size of these hollow octahedra can be as small as 150 nm to as large as several micrometers (Figure 2e), and the thickness of the shell walls is in the range of 20–200 nm, depending on synthetic conditions (see also Supporting Information). In general, higher initial concentrations of SnF_2 and longer reaction times lead to the formation of larger octahedra.

The hollow interior and geometrical symmetry of the as-synthesized octahedra were further elucidated by TEM (Figure 3). In agreement with the above FESEM findings, a
Figure 3. Sequential TEM images (a–c) for a hollow SnO_2 octahedron taken with different tilt angles (a) was viewed perpendicular to the top crystal plane), and a schematic illustration of crystal orientation of an SnO_2 octahedron (d). Edge outlines of the octahedra are depicted in the insets.

high geometric symmetry of the examined octahedron can be seen from the image evolution, while the inner cavity is clearly revealed by the changes in contrast on tilting the sample.

Individual crystal sheets that formed the SnO_2 octahedra can be obtained by sonication (5–10 min in an ultrasonic water bath; Supporting Information). High-resolution TEM (HRTEM; Figure 4a) indicates that triangular SnO_2 sheets are composed of fine crystallites in a size range of only

Communications
Figure 4. a) Representative HRTEM image of triangular SnO_2 crystallite aggregates (white arrows indicate twin boundaries within a crystallite; spacing $= d_{110}$). b) TEM image of a detached SnO_2 nanocrystalline triangle. c) SAED pattern of the SnO_2 sheet in b). d) Formation of triangles (framed with white dashed lines) from SnO_2 nanocrystallites. Brighter spots (circled) in c) belong to the same set of [111] zone spots.

3–5 nm. These particles were well crystallized, as shown by clear lattice fringes ($d_{110} = 3.3 \pm 0.1$, $d_{101} = 2.6 \pm 0.1$, $d_{200} = 2.4 \pm 0.1$ Å, etc.) and relatively sharp selected-area electron-diffraction (SAED) rings. Although individual crystallites within a local area seem to be random, the overall crystalline aggregates still exhibit global features of {111} vicinal surfaces that suggest long-range ordering of nanocrystallites owing to oriented attachment.[15–19] As can be seen in Figure 4b and c, for example, diffraction spots of (-110) and $(1-10)$ of the [111] zone are visible on the 110 diffraction ring, and they are aligned parallel to the baseline of the triangle, that is, a clear crystalline relationship exists among these [111]-oriented crystallites. Indeed, the lattice fringe of d_{110} is also prominent among the observed nanocrystallites (Figure 4a).

To understand the formation mechanism of the octahedral hollow structures, time-dependent experiments were carried out, which revealed that the hollow octahedra were grown by a plane-by-plane process. As shown in Figure 4d, growth starts with the formation of triangular crystallite aggregates. With appropriate changes in direction at the edges of the triangle (i.e., interplanar angle of 95.2 or 117.1°), further

planar coalescence leads to three-dimensional construction of octahedra (Figure 1e and Supporting Information). When two or more such initial sheets are close to each other under low-fluidity conditions, the chance of joining exists (Figure 2a and Figure 4d), that is, the octahedra grow into each other, a process which can be utilized as a means for fabricating even more complex hollow polyhedra. About 5–10% of the octahedra are in this type of joined configuration. It is believed that the addition of ethylenediamine, in combination with the present solvent system, is crucial for stabilizing the {111}-like sheets of SnO_2 while maintaining the small crystallite size. With longer reaction times, smoother crystal facets can be attained for the hollow octahedra, because of continuous surface flattening. Liplike slits arising from accumulated crystal imperfections (twins, disoriented crystallites, etc.), are often found on the edges of the octahedra (e.g., Figure 2c) as a result of mismatched closure. This type of opening may serve as a gateway for materials/chemicals exchange between the interior cavity and exterior space, which is of interest for potential applications of the hollow structures.

In summary, octahedra of rutile-like SnO_2 with a central cavity have been prepared by a template-free hydrothermal route. The synthesis is based on the two-dimensional attachment of nanocrystallites giving an overall {111}-like termination for each octahedral surface in the presence of ethylenediamine and 2-propanol/water. In principle, other hollow polyhedra could also be prepared by stabilizing selected crystal orientations.

Experimental Section

In a typical experiment, SnF_2 (0.24 g) was added to deionized water (50 mL) with vigorous stirring; the pH value was 2.83. The fresh solution (1–2 mL, 0.03 M), deionized water (3–6 g), 2-propanol (13–15 g), and ethylenediamine (1–2 g) were added to a Teflon-lined stainless steel autoclave. The autoclave was kept at 180°C for 6–50 h in an electric oven. After reaction, white octahedral products were harvested by sedimentation (to separate them from smaller irregular SnO_2 aggregates), washed three times with deionized water, and dried under vacuum overnight. The crystallographic phase of the SnO_2 products was determined by powder XRD (Shimadzu XRD-6000, $Cu_{K\alpha}$ radiation). The products were further investigated by scanning electron microscopy and energy dispersive X-ray spectroscopy (SEM/EDX, JSM-5600LV), field-emission SEM (FESEM/EDX, JSM-6700F), transmission electron microscopy and selected area electron diffraction (TEM/SAED, JEM-2010F, 200 kV), and high-resolution transmission electron microscopy (HRTEM/SAED/EDX, Tecnai-G^2, FEI).

[22] Theoretical values are 54.1 and 71.8°, respectively; the observed deviation is probably due to the presence of disoriented crystallites and crystal defects in the triangular sheets that result in mismatched planes.

Bioinorganic Chemistry

Quaternary Ammonium Groups in Silica-Associated Proteins[**]

*Stephan Wenzl, Rainer Deutzmann, Robert Hett, Eduard Hochmuth, and Manfred Sumper**

The formation of inorganic minerals under the control of an organism (biomineralization) is a widespread phenomenon in nature. Silica biomineralization on earth is dominated by simple aquatic life-forms, which include unicellular organisms such as diatoms, radiolarian, and synurophytes as well as multicellular sponges.[1] These organisms produce silica based exo- and endoskeletons. In diatoms, the silica-based cell walls exhibit intricate patterns in the nano- to micrometer range. As these patterns are precisely reproduced in each generation of

a diatom, genetic control of this process is evident. Cell-wall formation in diatoms has been regarded as an example for the controlled production of nanostructured silica. Therefore, understanding the underlying mechanism of silica fabrication may inspire synthetic routes to produce novel silica-based materials under mild reaction conditions.[2,3] Diatom biosilica is mainly composed of amorphous, hydrated SiO_2 (silica) that contains a small proportion of proteins, which have long been speculated to be involved in silica deposition.[4,5] Remarkably, more than three decades ago, Volcani's group recognized the existence of unusual amino acid derivatives such as ε-*N,N,N*-trimethyl-δ-hydroxylysine in diatom biosilica.[6,7] However, proteins associated with biosilica from *C. fusiformis* have only recently been purified to homogeneity and found to be the source of a number of unusual amino acid modifications. Typically, these proteins (denoted as silaffins) contain a high percentage of lysine and serine groups and all of these residues are modified.[8–10] The serine residues are phosphory-lated, whereas the lysines are converted into three different derivatives: ε-*N,N*-dimethyllysine, ε-*N,N,N*-trimethyl-δ-hydroxylysine, and lysines that are covalently linked to long-chain polyamines (*N*-methylated polypropyleneimines). As well as silaffins, many cell walls in diatoms contain the same type of long-chain polyamines that are bound to putrescine.[11] Silaffins as well as long-chain polyamines have been shown to promote the formation of silica nanospheres from silicic acid in vitro.[8,11,12] A model which is based on phase-separation processes of polyamines explains the for-mation of patterns during silica formation.[13] Recently hexagonal silica structures were produced in vitro under the influence of polyamines.[14] Polyamines are known to affect silica formation in several ways: they catalyze the formation of siloxane bonds and act as flocculating agents.[15,16]

More than 40 years ago, quaternary ammonium ions were recognized as structure-directing agents in the synthesis of zeolites.[17] The tetramethylammonium cation favors the formation of symmetric oligosilicate anions, such as the cubic octamer $Si_8O_{20}^{8-}$, and this control of silicate speciation influences the nucleation phase of silica formation.[18] Fur-thermore, these organic cations exhibit a high affinity to silica surfaces. The existence of the ε-*N,N,N*-trimethyl-δ-hydroxy-lysine residue in silaffins from *C. fusiformis* indicates that nature exploits this very special interaction in the biominer-alization of silica.

Herein we demonstrate that quaternary ammonium cations are indeed a characteristic feature of silica-associated proteins. Three novel lysine derivatives, which contain quaternary ammonium groups, were identified in silaffins that were purified from silica shells of the diatom *Eucampia zodiacus* (Figure 1A). Silica was removed from the purified shells by treatment with anhydrous hydrogen fluoride, and the remaining silica-associated proteins were analyzed by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE). The protein extract from *Eucampia* shells exhibited one major protein band with an apparent molecular mass of 22 kDa and three or four additional minor components (Figure 1B). These proteins were then analyzed for the presence of unusually modified amino acids. After acid hydrolysis, the resulting amino acid mixture was directly

Figure 1. The silica cell wall of the diatom *Eucampia zodiacus* and its protein components: A) SEM image of the cell wall. subjected to high performance anion-exchange chromatography (Figure 2 A). Remarkably, a significant fraction of the amino acid mixture (Figure 2 A,
Figure 2. Amino acid analysis of silaffins: A) High performance anion-exchange chromatography of amino acids obtained by acidic hydrolysis of silaffins; the elution times of amino acid standards are indicated on the upper bar; peak a represents amino acids that contain a cationic modification. peak a) did not bind to the anion-exchange matrix even under the extremely alkaline conditions (NaOH, 60 mM) which indicates the existence of amino acid derivatives with a permanently cationic modification that compensates the charge of the carboxylate anion. Electrospray ionization mass spectrometry (ESI-MS) of this fraction revealed the presence of two main components at *m/z* 246 and 317 as well as a further component at *m/z* 260 (Figure 2 B). The chemical structures of these derivatives were analyzed by MS/MS analysis. The resulting fragmentations of all three species are documented in Figure 3 A, Figure 4 A, and Figure 5 A. Each
Figure 3. Structural analysis by mass spectrometry of the fragment with *m/z* 246. Ions were isolated by the ion-trap mode and were subjected to collision-induced fragmentation. Fragmentation patterns obtained A) before and B) after reductive ethylation (*m/z* after ethylation was 302 which indicates the introduction of two ethyl groups). *m/z* values shown in green indicate the results of (MS)[3] fragmentations of selected ions.

of the spectra displays a fragment at *m/z* 130 that subsequently (MS/MS/MS) decays into a species of *m/z* 84 (elimination of 46 mass units, which corresponds to the loss of H_2O and CO). This indicates the presence of a lysine moiety. Aminopropylations as well as methylations of the ε-amino groups of lysine residues were previously found to take place in silaffins isolated from the diatom *C. fusiformis*.[8] Aminopropylation followed by exhaustive methylation of the terminal amino group would create a lysine derivative of *m/z* 246 that contains a quaternary ammonium group as depicted (**1a**; Figure 3). Further methylation of the ε-amino group of the lysine moiety would create a derivative with *m/z* 260 (**2a**; Figure 4). These proposed structures are able to account for all of the remaining mass fragments observed in MS/MS analysis (Figure 3 A and Figure 4 A).

To prove the correctness of this interpretation, both of the components at *m/z* 246 and *m/z* 260 were converted into their fully methylated derivatives by reductive alkylation. As expected, reductive methylation converted both species into a derivative with *m/z* 288, which corresponds to the introduction of three and two methyl groups, respectively (data not

shown). Reductive ethylation is known to be less efficient and converted the α-amino group of the lysine moiety only into the secondary amine.[19] Under the conditions employed, only two ethyl residues were introduced into the component at *m/z* 246 and only one ethyl residue was introduced into the component at *m/z* 260. The resulting fragmentation patterns of the partially ethylated derivatives (Figure 3 B and Figure 4 B) confirm the proposed structures (**1 b**; **2 b**).

Introduction of a second aminopropyl residue into the species at *m/z* 260 would create a homologous structure with *m/z* 317 (**3 a**; Figure 5). The fragmentation pattern of the component at *m/z* 317 supported this interpretation (Figure 5 A). As expected, reductive methylation introduced
Scheme 1. Proposed mechanism of internal proton transfer to explain the production of a fragment with *m/z* 246 (see also Figure 5 A) in the collision-induced fragmentation of **3 a**.

three methyl groups into the compound and reductive ethylation introduced two ethyl groups. The fragmentation spectra of the partially ethylated derivative again confirmed the proposed structure (**3 b**). Remarkably, the compound with *m/z* 317 produced an unexpected fragment (*m/z* 246) that appears to result from N–C bond cleavage at the quaternary ammonium site. In the partially ethylated derivative, the corresponding fragment (calculated *m/z*: 274) was no longer observed in the fragmentation pattern. This behavior is likely to be caused by a favored internal proton transfer from the terminal secondary amino group as depicted in Scheme 1. This proton transfer would no longer be possible after ethylation, and this observation strongly supports the proposed structure. Furthermore, ^{1}H NMR analysis of the compound with *m/z* 317 at pH 11.8 gave rise to a signal at $\delta = 3.14$ ppm (methyl) whose position did not shift upon lowering the pH (pH 5). This is characteristic of methyl groups attached to a quaternary ammonium group (data not shown) and confirms the conclusion drawn from mass spectrometry.

The characterization of novel lysine derivatives with quaternary ammonium groups indicates that this cationic modification represents a special structural feature of silica-associated proteins from diatoms. It is well documented that quaternary ammonium ions exhibit very unusual behavior in silica systems which is probably owed to the high affinity of the ions to silica surfaces and their inability to form coordinate bonds with the oxygen of SiOH groups as sodium does.[16] Nature probably uses these special properties to design proteins with high affinities for silica surfaces.

Experimental Section

Culture Conditions: *Eucampia zodiacus* was isolated from the North Sea and cultivated in an artificial seawater medium according to the protocol from the North East Pacific Culture Collection (www.ocgy.ubc.ca/projects/nepcc/media.htm).

Purification of Silaffins: A 20-L culture of silaffins was harvested by filtration through a nylon screen (40 μm). The diatom colonies were suspended in 10-mL lysis buffer (EDTA (100 mм), SDS (2 %)), and the suspensions were incubated at 95°C for 10 min. The resulting silica shells were collected by

centrifugation ($2\,500 \times g$; 10 min), washed extensively with water, and dried in vacuo. Silica shells (100 mg) were dissolved in anhydrous hydrogen fluoride and the solution was incubated at 0°C for 30 min. Hydrogen fluoride was evaporated, and the remaining material was neutralized with Tris-HCl (250 mm, pH 7.5; 2 mL). HighS cation-exchange resin (NH_4^+ form; Bio-Rad; 100 µL) was added to this extract, and the mixture was incubated at 4°C for 1 h. The resin was washed with H_2O, followed by NH_4OH (4 N), and again with H_2O. The silaffins were then eluted with NaCl (2 M)/Na_2CO_3 (20 mm). After dialysis against H_2O (Spectra/Por CE dialysis tubing; molecular-mass cutoff: 500 Da), the eluted proteins were size-fractioned on a Superdex-Peptide HR 10/30 column (Amersham Pharmacia; running buffer ammonium acetate (250 mm); flow rate: 0.3 mL min^{-1}). Fractions were analyzed for silaffins by 12-% SDS PAGE with subsequent staining with Coomassie blue. Silaffin-containing fractions were pooled and dried by lyophilization.

Purification of Basic Amino Acids: Purified silaffins were hydrolyzed in HCl (6 N; Pierce; Sequanal Grade; 1 mL) at 110°C for 24 h. After evaporation, the material was dissolved in H_2O (300 µL), filtered (Millipore; Millex PV 0.22 µm), and loaded onto an Amino-Pac PA10 4/250 mm anion-exchange column (Dionex; elution gradient: NaOH/NaOAc). Amino acids were detected electrochemically (Dionex ED40). Basic amino acids modified with a quaternary ammonium group eluted with NaOH (60 mm). To eliminate Na^+ ions, this fraction was loaded onto a Biorex 70 cation-exchange column (H^+-form; Bio-Rad; 0.6 mL), washed with H_2O (1.0 mL) and NH_4OH (0.15 N; 3.4 mL), and eluted with NH_4OH (0.5 N; 0.7 mL). After filtration and drying, the residue was dissolved in H_2O (200 µL).

Alkylation of Modified Lysine Residues: A dried sample, which contained lysine residues modified with a quaternary ammonium group, was dissolved in sodium phosphate (50 mm, pH 7.0), and the solution was treated with sodium cyanoborohydride and acetaldehyde (reductive ethylation) according to a previously described protocol.[19] Reductive methylation was similarly carried out with sodium cyanoborohydride and formaldehyde.[19]

Mass Spectrometry of Basic Amino Acids: Electrospray ionization MS and fragmentation were performed by using an Ion Trap ESQUIRE LC instrument (Bruker, Billerica, MA). Samples were infused by a nanospray source in MeOH (50%)/AcOH (0.5%).

A Palladium(II)-Clipped Aromatic Sandwich**

Michito Yoshizawa, Takahiro Kusukawa, and
Makoto Fujita**

Enclathration of large π-conjugated molecules by a synthetic receptor is an interesting task because the properties of these molecules, such as stability, reactivity, solubility, and photo- and electroresponse, can be controlled.[1] To enclathrate large π-conjugated molecules, however, a synthetic receptor with a cavity is required, whose dimensions should be larger than that of the π-conjugated guests. While there are many examples of three-dimensional receptors,[2] large two-dimensional receptors have been less explored.[3] Herein we describe the self-assembly of a π-stacked host–guest system in which large aromatic guests are sandwiched by metal-clipped π-conjugated ligands. The ligand **1** is a roughly 2-nm-sized hexagonal planar molecule that consists of ten aromatic rings with six pyridyl donor sites at the periphery. Upon complexation with $[(en)Pd(NO_3)_2]$ (en = 1,2-ethanediamine) this ligand is assembled to give large two-dimensional receptors. In the presence of D_{3h}-symmetric guests (**2**), sandwich complexes $[2 \subset 3]^{12+}$, where 3^{12+} has a composition of $[\{(en)Pd\}_6(1)_2]^{12+}$, are quantitatively assembled. The guest molecule is wrapped by two ligands whose pyridyl donor sites

are fully clipped by six {(en)Pd}$^{2+}$ units at the rim of the structure (Scheme 1).
Scheme 1. The self-assembly of [2⊂3]$^{12+}$ complex.

Figure 1. ^{1}H NMR spectrum of [2a⊂3]$^{12+}$. Assignments of H$_a$–H$_j$ are given.
Figure 2. CSI-MS spectrum of [2a⊂3]$^{12+}$ (H$_2$O:CH$_3$CN:DMF = 12:6:1, RT).

An excess of **2a** (suspension) was treated with **1** (3.5 µmol) and [(en)Pd(NO$_3$)$_2$] (15 µmol) in D$_2$O:CD$_3$CN (2:1; 0.7 mL) for 2 h at 60 °C. After filtration of non-enclathrated **2a**, a simple ^{1}H NMR spectrum was obtained from the clear solution, which indicated the formation of a single product (Figure 1). The seven signals observed in the aromatic region (H$_{a-g}$) agree with the D_{3h} structure of **3**$^{12+}$. Highly upfield-shifted signals (H$_{h-j}$), showing a typical phenyl splitting pattern, were assigned to guest **2a** accommodated within the cavity of **3**$^{12+}$. The [2a⊂3]$^{12+}$ structure was strongly supported by NOESY experiment, which showed correlation between H$_f$ of **3**$^{12+}$ and H$_j$ of **2a**.[4]

Cold spray ionization mass spectroscopy (CSI-MS) clearly suggested the formation of [2a⊂3]$^{12+}$, it showed a series of prominent peaks corresponding to [2a⊂3+(NO$_3^-$)$_m$+(dmf)$_n$]$^{12-m+}$ (m = 5–9, n = 0–14). For example, in 4$^+$ and 5$^+$ regions, two intense peaks at m/z 872.3 and 729.4 were assigned to [2a⊂3+(NO$_3^-$)$_8$+(dmf)$_2$]$^{4+}$ and [2a⊂3+ (NO$_3^-$)$_7$+(dmf)$_5$]$^{5+}$, respectively (Figure 2).[5] Note that,

under CSI-MS conditions, there was little indication for the presence of either guest-free species or fragmented species, which shows the remarkable stability of the [2a⊂3]$^{12+}$ complex in solution.

When guest **2a** was replaced by 1,3,5-triphenylbenzene (**2b**), single crystals suitable for X-ray analysis were obtained by slow diffusion of THF into an aqueous solution of the complex.[6] The X-ray analysis revealed the expected structure where two molecules of **1** are clipped by six {(en)Pd}$^{2+}$ units allowing the complete wrapping of the large planar guest (Figure 3). The conformation of **1** is not planar but slightly concave. The pyridine ring centers are situated above the face of the core benzene ring at an average separation of 1.2 Å. The 3-pyridyl groups are tilted by 31–42° with respect to adjacent phenyl groups so that they coordinate to Pd^{II} centers with ideal bite angles (89–91°). Thus, host distortion exists not around the Pd^{II} centers but along the large framework of **1**, which suggests that close host–guest packing generates a
Figure 3. X-ray crystallographic structure of [2b⊂3]$^{12+}$. a) Space-filling representation (top view), b) top view showing the D_3 orientation of guest **2b**. Around the phenyl group **P**, π–π stacking with pyridine rings **A** and **C**, and CH–π contact with pyridine rings **B** and **D** are observed; c) A side view.

Scheme 2. Self-assembly of the dimeric structure, 4^{24+}.

greater distortion. The core benzene ring of **2b** is tightly stacked with the two ligands (3.5 Å van der Waals contact). In the crystal, D_3 symmetry is observed (not D_{3h}), each phenyl group of the guest being tilted by 30–36° allowing efficient π–π and CH–π interactions with four surrounding pyridine rings (Figure 3b). As a result, **2b** is fully wrapped by 3^{12+}.

While [2⊂3]$^{12+}$ complexes are stabilized by sufficient host–guest interactions, the host framework itself is considerably distorted. In the absence of a guest, therefore, less distorted structure 4^{24+} is formed (Scheme 2). Compound 4^{24+} is a dimer of 3^{12+} generated through the breaking of two Pd−N bonds. The high-yield formation of 4^{24+} was confirmed by NMR spectroscopy and CSI-MS spectrometry. When **1** and [(en)Pd(NO$_3$)$_2$] were mixed in a 1:3 ratio without guest molecules, 19 resonance signals, corresponding to half the framework of **1**, appeared in the aromatic region indicating the reduction, after complexation, of the inherent D_{3h} symmetry of **1** into D_{2h} symmetry (Figure 4a). CSI-MS measurement showed the molecular weight of 6562 Da, which is exactly twice as much as 3^{12+}[NO$_3^-$]$_{12}$, supporting the proposed M$_{12}$L$_4$ dimeric structure 4^{24+}.

A smaller aromatic guest, triphenylene (**5**), is included in the cavity of 4^{24+} (which is expanded compared to that of 3^{12+}) in a 1:2 ratio upon treating it with a solution of 4^{24+} for 2 h at 60 °C. The formation of the [(5)$_2$⊂4]$^{24+}$ complex was revealed by NMR spectroscopy with the highly upfield-shifted signals of **5** ($\delta = 6.9$ and 6.0 ppm) and the slightly shifted 19 signals in the aromatic region of the host (Figure 4b). Some minor signals in Figure 4b may be assigned to other host–guest complexes, such as 1:1 complex [5⊂4]$^{24+}$ or monomer complex [5⊂3]$^{12+}$. CSI-MS also indicated the required stoichiometry for the [(5)$_2$⊂4]$^{24+}$ complex (see Supporting Information).

When guest **2a** was suspended in the solution of the [(5)$_2$⊂4]$^{24+}$ complex, guest exchange took place at 60 °C within 24 h concomitant with host monomerization.[7] That is, [(5)$_2$⊂4]$^{24+}$ was converted into [2a⊂3]$^{12+}$, as shown by NMR spectroscopy (Figure 4b–e). Clearly, the self-assembly of hosts 3^{12+} and 4^{24+} is dynamic owing to the labile nature of the Pd−N bond. The host–guest stabilization in [2a⊂3]$^{12+}$ dominates over the distortion of the host framework, whereas less distorted 4^{24+} is favored when a guest is absent or less efficiently trapped by the host.

In summary we have constructed a large π-conjugated, expanded two-dimensional receptor by self-assembly. Extension of this study could ease the handling of very large π-molecules, such as molecular graphites, which are in general tedious to treat in solution because of their very poor solubility. The chemical and physical properties of such large π-molecules may be restricted within large two-dimensional cavities.

species, called single-molecule magnets (SMMs), have gained considerable attention because they retain information in a single molecule rather than in a magnetic particle or array of particles[1] and can potentially be used in quantum computers.[2] Furthermore, understanding the magnetic properties of these molecules is important to help bridge the gap between the quantum and classical understanding of magnetism.[3] The most thoroughly studied SMMs are [Mn$_{12}$O$_{12}$(CH$_3$CO$_2$)$_{16}$(H$_2$O)$_4$] and its derivatives,[4] but there are a number of other clusters containing Fe^{III},[5] V^{III},[6] Co^{II},[7] or Ni^{II} [8] ions that have been reported to be SMMs. These species are all homometallic systems in which magnetic exchange interactions occur through bridging oxygen atoms.

Important to the future of the field of SMMs is the development of new synthetic schemes that can yield clusters with a large spin and/or anisotropy. Metal–cyanide cluster systems offer an advantage for achieving such control, through the substitution of various metal ions into a given structure type. Moreover, the nature of the magnetic exchange coupling between different metal ions in the resulting cluster is readily predicted.[9] One approach to synthesizing high-nuclearity metal–cyanide clusters employs multidentate capping ligands to inhibit growth of an extended solid and direct the structure of the product. Many clusters have been prepared by this method,[10–12] including the face-centered-cubic species [(Me$_3$tacn)$_8$Cr$_8$Ni$_6$(CN)$_{24}$]$^{12+}$ (Me$_3$tacn = N,N',N''-trimethyl-1,4,7-triazacyclononane)[11b] and [(tach)$_8$(H$_2$O)$_6$Cu$_6$Co$_8$(CN)$_{24}$⊃THF]$^{12+}$ (tach = 1,3,5-triaminocyclohexane).[11d] However, as far as we know, there are only a very few cyanide-bridged SMMs,[13] and none of the established SMMs exhibit cubic symmetry.

In an effort to extend this chemistry, we have chosen to employ the precursor compound (Bu$_4$N)[(Tp)Fe(CN)$_3$] (**1**; Tp$^-$ = hydrotris(pyrazolyl)borate), featuring a low-spin Fe^{III} center octahedrally coordinated by three CN$^-$ groups and the tridentate ligand Tp$^-$. This monoanionic complex has also been utilized by Julve and co-workers as the tetraphenylphosphonium salt.[14] Tp$^-$ is a classical scorpionate ligand with a C_3 axis, and in contrast to neutral capping ligands, such as Me$_3$tacn and tach, is negatively charged which should help alleviate the build-up of excessive positive charge in clusters. Thus, [(Tp)Fe(CN)$_3$]$^-$ is anticipated to direct the formation of new cyanide-bridged compounds with interesting structures and magnetic properties. Indeed, we have recently reported its use in the preparation of [(Tp)$_2$Fe$_2$(CN)$_6$Cu(CH$_3$OH)·2 CH$_3$OH]$_n$, a single-chain magnet with a blocking temperature of approximately 6 K.[15] Herein, we disclose its use in the synthesis of [(Tp)$_8$(H$_2$O)$_6$Cu$^{II}_6$Fe$^{III}_8$(CN)$_{24}$]$^{4+}$, a face-centered-cubic cluster exhibiting SMM-type behavior.

The compound [(Tp)$_8$(H$_2$O)$_6$Cu$_6$Fe$_8$(CN)$_{24}$](ClO$_4$)$_4$·12 H$_2$O·2 Et$_2$O (**2**) crystallizes in space group *Immm*,[16] with the well-isolated [(Tp)$_8$(H$_2$O)$_6$Cu$_6$Fe$_8$(CN)$_{24}$]$^{4+}$ molecules residing on special positions of *mmm* site symmetry. As shown in Figure 1, the clusters adopt a face-centered-cubic geometry, in which eight Tp$^-$-capped Fe^{III} ions are arranged in a cube and linked through cyanide to six Cu^{II} ions located just above the center of each cube face. Here, each octahedral [(Tp)Fe(CN)$_3$]$^-$ unit uses the three cyanide groups to connect with three Cu^{II} ions, which are further ligated by water to give

Figure 1. Structure of the face-centered-cubic cationic cluster in **2**. Top: repeat unit, thermal ellipsoids are set at 50% probability. Bottom: red Fe, turquoise Cu, orange B, gray C, blue N, dark red O; hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe1-C1 1.879(7), Fe1-C2 1.925(7), Fe1-C3 1.937(10), Cu1-N2 1.955(6), Cu2-N3 1.971(6), Cu3-N1 1.972(5), Cu1-O1 2.146(9), Cu2-O2 2.224(10), Cu3-O3 2.108(9); Fe1-C1-N1 173.6(6), Fe1-C2-N2 174.2(6), Fe1-C3-N3 174.6(7), Cu1-N2-C2 177.6(6), Cu2-N3-C3 171.3(6), Cu3-N1-C1 172.6(6), O1-Cu1-N2 99.59(17), O2-Cu2-N3 92.74(17), O3-Cu3-N1 97.68(15).

a square pyramidal $\{Cu(NC)_4(H_2O)\}$ coordination sphere. The Fe—C bond lengths (1.879(7)–1.937(10) Å) are in good agreement with those observed previously in related compounds.[14,15] The Cu—N bonds range from 1.955(6) to 1.972(5) Å, and the Cu—O bonds vary from 2.108(9) to 2.224(10) Å. The O-Cu-N bond angles are 92.7(2)–99.6(2)°. All of the cyanide bridges deviate slightly from strict linearity, as reflected in the Fe-C-N and Cu-N-C angles, which are distributed within the range 171.3(6)–177.6(6)°. The C≡N stretching region in the IR spectrum of **2** is consistent with the presence of only bridging cyanide ligands (a peak of medium intensity at 2176 cm^{-1}) and the high symmetry of the structure. In all, the cluster closely approaches cubic (O_h) symmetry, with Fe···Fe cube edge distances in the range 6.827–6.938 Å and crystallographically imposed Fe···Fe···Fe angles of 90°.

Importantly, the Cu_6Fe_8 cluster represents the first structurally characterized example of a face-centered-cubic cluster in which both metal sites are occupied by paramagnetic ions. Magnetic measurements were therefore per-

formed on a sample of pulverized single crystals of **2** in the temperature range of 1.8–300 K. The variation of $\chi_M T$ with temperature is plotted in Figure 2. At room temperature its value is 5.77 emu K mol^{-1}, somewhat above the spin-only
Figure 2. Temperature dependence of $\chi_M T$ for compound **2**, as measured in an applied DC field of 2000 G. The solid line corresponds to a simulation of the data with $J = 15$ cm^{-1}, $g = 2.00$, and temperature-independent paramagnetism (TIP) $= 0.00070$ emu mol^{-1}.

value of 5.25 emu K mol^{-1} expected for eight low-spin Fe^{III} ($S = 1/2$) and six Cu^{II} ($S = 1/2$) ions in the absence of any exchange coupling. With decreasing temperature, $\chi_M T$ increases, reaching a maximum of 27.94 emu K mol^{-1} at approximately 5 K, after which point it decreases to 23.57 emu K mol^{-1} at 1.8 K. This magnetic behavior is indicative of the expected ferromagnetic interactions between the orthogonal spin orbitals of the Fe^{III} and Cu^{II} ions,[9] resulting in an $S = 7$ ground state. This conclusion is confirmed by the field dependence of the magnetization of **2** at 1.8 K, which saturates at a value of $M_S = 13.78\ N\mu_B$ (see the Supporting Information). The sudden decrease in $\chi_M T$ below 5 K is attributed to the presence of zero-field splitting, the effects of which are also discernible in the magnetization data shown in Figure 3. The $\chi_M T$ data above 5 K were simulated employing
Figure 3. Plot of reduced magnetization, $M/N\mu_B$ (N is Avogadro's number and μ_B is Bohr magneton) versus H/T for **2**. Data were measured in the 1.8–10 K range and at seven magnetic fields: (×) 10.0, (+) 20.0, (△) 30.0, (▽) 40.0, (◇) 50.0, (○) 60.0, and (□) 70.0 kG. The solid lines resulted from least-squares fitting of the data in the 1.8–10 K range; see text for fitting parameters.

Communications

MAGPAK[17] and an exchange Hamiltonian of the form given in Equation (1).

$$\hat{H} = -2J[\hat{S}_{Fe1} \cdot (\hat{S}_{Cu1} + \hat{S}_{Cu2} + \hat{S}_{Cu3}) + \hat{S}_{Fe2} \cdot (\hat{S}_{Cu1} + \hat{S}_{Cu3} + \hat{S}_{Cu4}) +$$
$$\hat{S}_{Fe3} \cdot (\hat{S}_{Cu1} + \hat{S}_{Cu4} + \hat{S}_{Cu5}) + \hat{S}_{Fe4} \cdot (\hat{S}_{Cu1} + \hat{S}_{Cu2} + \hat{S}_{Cu5}) +$$
$$\hat{S}_{Fe5} \cdot (\hat{S}_{Cu6} + \hat{S}_{Cu2} + \hat{S}_{Cu3}) + \hat{S}_{Fe6} \cdot (\hat{S}_{Cu6} + \hat{S}_{Cu3} + \hat{S}_{Cu4}) +$$
$$\hat{S}_{Fe7} \cdot (\hat{S}_{Cu6} + \hat{S}_{Cu4} + \hat{S}_{Cu5}) + \hat{S}_{Fe8} \cdot (\hat{S}_{Cu6} + \hat{S}_{Cu2} + \hat{S}_{Cu5})] \qquad (1)$$

The best simulation was obtained with $J = +15 \; cm^{-1}$, which indicates significantly stronger coupling than previously observed for complexes containing more bent Fe^{III}-CN-Cu^{II} bridges.[18]

To assess the zero-field splitting associated with the $S = 7$ ground state, magnetization data were collected on compound **2** at a variety of fields in the temperature range 1.8–10 K (see Figure 3). The seven isofield data sets were fitted using ANISOFIT[11c] to give zero-field splitting parameters of $D = -0.16 \; cm^{-1}$ and $E = 0.0055 \; cm^{-1}$ with $g = 1.93$. Thus, despite the near cubic symmetry of the cluster, the presence of orbitally degenerate low-spin Fe^{III} centers enables the development of significant axial magnetic anisotropy. Indeed, if the sign and magnitude of D obtained from the fit are correct, then the Cu_6Fe_8 cluster should behave as an SMM with a spin reversal barrier of $U = S^2 |D| = 7.8 \; cm^{-1}$.

One of the defining characteristics of an SMM is the observation of a frequency-dependent out-of-phase AC magnetic susceptibility (χ_M'') signal. To determine whether the slow magnetization relaxation behavior occurs in **2**, AC magnetic measurements were performed in the temperature range of 1.8–6 K (Figure 4). Although no maximum was
Figure 4. Temperature dependence of the out-of-phase component of the AC susceptibility for **2** in zero applied static field and with a 5 G field oscillating at frequencies between of 10 and 1500 Hz. The lines are to guide the eye.

observed down to 1.8 K, frequency-dependent χ_M'' signals were observed below 3 K, which indicates the superparamagnet-like slow relaxation of an SMM. The results are similar to those observed for $[(tmphen)Mn_5(CN)_{12}]$ (tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline),[13b] and place an upper bound of 20 cm^{-1} (assuming an attempt frequency of $1/\tau_0 < 10^{10}$ Hz) on the effective spin-reversal barrier for the Cu_6Fe_8 cluster.

In summary, the use of Tp⁻ as a capping ligand has permitted isolation of a face-centered-cubic cluster, with a well-isolated $S = 7$ ground state. Despite its cubic symmetry, the molecule possesses substantial axial magnetic anisotropy ($D = -0.16 \; cm^{-1}$), which leads to single-molecule-magnet behavior.

usually bear multiple surface organic ligands, which are utilized not only for stabilizing the cluster core but also for the construction of conjugates with chemical and biochemical reagents.[2,3] Although a variety of ligands with covalently appended functionalities have been designed to date,[3] there have been few examples of the host–guest-type conjugation involving guest penetration into the surface organic shell. Herein we show that simple aromatic groups at the cluster surface are capable of trapping organic cations in an intercalative fashion, allowing guest penetration close to the cluster core without direct bonding interactions. We also report the notable effects of this guest penetration on the cluster photoluminescence.

Aryl- and alkyl-capped molecular clusters of cadmium chalcogenides have been of interest as models and precursors of colloidal particles.[4,5] The clusters we use in this case are neutral $[Cd_{10}S_4(SPh)_{12}]$ (**1**) and $[Cd_{10}S_4(SC_6H_{13})_{12}]$ (**2**) bearing a truncated tetrahedral $\{Cd_{10}S_{16}\}$ core and twelve surface substituents.[5] The four unsaturated cadmium atoms at the apexes serve as coordination sites for donating ligands. Accordingly, these clusters easily formed ionic complexes with organic bromide salts by coordination of bromide anions to the apex cadmium atoms.[5b] When the cation moiety has a long alkyl chain, such as cetyltrimethylammonium (CTA^+), 1-cetylpyridinium (CP^+), or tetraoctylammonium (TOA^+), the

resulting complexes were very soluble in chloroform, in contrast to the original clusters (**1**, **2**).

^{1}H NMR spectroscopic studies of the phenyl-capped cluster **1** upon complexation with the bromide salts of CTA^+ and CP^+ (CTAB and CPB, respectively) indicated the close cation proximity to the surface phenyl groups. For example, when CTAB (9.2 mM) was mixed with **1** (2.3 mM) in $CDCl_3$, clear upfield shifts were observed for the signals arising from the N-CH_3 ($\delta = 3.48 \rightarrow \delta = 3.04$ ppm) and N-CH_2 ($\delta = 3.57 \rightarrow \delta = 3.17$ ppm) of the cation (Figure 1a: 1, 3). Similar upfield shifts were observed when CPB was used in place of CTAB. These upfield shifts indicate that the cations are bound to **1** in an intercalative fashion (Figure 2), where the cationic center is located in close proximity to the SPh

b)

c)

Figure 1. a) ^{1}H NMR spectra of 1) CTAB (9.2 mM), 2) 1/CTAB (2.3/46.0 mM), and 3) 1/CTAB (2.3/9.2 mM) in CDCl$_3$ at 25°C; b) Job plots for the intercalative complexation between SPh of 1 and CTAB. Plots of [complexed CTA$^+$] versus [SPh]$_0$/([SPh]$_0$+[CTAB]$_0$) with [SPh]$_0$+[CTAB]$_0$ kept constant (38 mM); c) ^{1}H NMR titration of CTAB (4.3 mM) with 1/TOAB (1:4 molar ratio) in CDCl$_3$ at 25°C. Plots of δ values for *N*-CH$_3$ protons versus [1]$_0$/[CTAB]$_0$.

accommodate small cations. The intercalative binding of CTA$^+$ and CP$^+$ towards the preformed **1**/TOAB complex occurred similarly to that towards **1** alone. Job plots for the complexation with CTAB in the presence of TOAB,[6] where the sum of [SPh]$_0$($=12 \times$ [**1**]$_0$) and [CTAB]$_0$ was kept constant, exhibited a maximum at a [SPh]$_0$:[CTAB]$_0$ ratio of unity (Figure 1b), indicating the 1:1 stoichiometry of SPh and CTA$^+$ ions. Likewise, CPB gave a similar Job diagram to show a 1:1 complexation with SPh. Thus, considering twelve SPh groups at the surface of **1**, multiple, up to twelve, cations participate in the complexation with a single cluster molecule. From the NMR spectroscopy titration data (Figure 1c),[6] the association constants for the 1:1 complexation were estimated to be 94 M^{-1} for CPB and 70 M^{-1} for CTAB.[7]

The cation accumulation near the CdS core of **1**, thus observed, is considered to be the results of cation–π interaction with the surface phenyl groups and/or direct cation adsorption on the polar sites of the anionic cluster [Cd$_{10}$Br$_4$S$_4$(SPh)$_{12}$]$^{4-}$ (e.g., the Br, S sites). The latter has been claimed as a possible driving force in surfactant-stabilized colloid systems,[8] but seems not dominant in the present case. This assumption was supported from the photoluminescence quenching profiles of **1** and the alkyl-substituted control **2** by using CP$^+$ ion as the electron acceptor: Upon excitation of the cluster moieties at 360 nm, **1** and **2**, in the presence of TOAB in CHCl$_3$, showed trap emissions at 560 and 530 nm, respectively. Both emissions were quenched by the addition of CPB, but the Stern–Volmer plots of the two systems were different. As expected from the intercalative binding of the quencher CP$^+$ near the cluster core, **1** gave a clear saturation behavior (Figure 3). On the other hand, **2**

CPB

[Cd$_{10}$S$_4$(SPh)$_{12}$] (1)

Figure 2. Schematic illustration of the complexation between **1** and CTAB or CPB showing cation intercalation among the surface phenyl groups.
Figure 3. Stern–Volmer plots for the photoluminescence quenching of CdS clusters (**1** (■), **2** (●); 6.7 μM) by CPB in the presence of TOAB (3.3 mM) in CHCl$_3$ at 25°C. The fluorescence intensities (*I*, $\lambda_{ex}=360$ nm) were monitored at 560 nm for **1** and 530 nm for **2**.

groups and thus near the cluster core, while the C$_{16}$ chain is extended away from the cluster surface.

On the other hand, when sterically hindered TOAB was used for the complexation with **1**, only very small shifts of the signals arising from the cation were observed. Owing to the severe steric bulk around the cationic center, TOA$^+$ seems reluctant to intercalate into the interstitial space and is therefore located outside the cluster periphery. This "outside-cation" complex still has vacant intercalation sites that can

showed a less efficient luminescence quenching with a linear Stern–Volmer correlation ($r=0.996$; Figure 3) characteristic of a dynamic process. This situation indicates there exists no particular static interaction leading to the close proximity of the quencher to the cluster-anion moiety of **2**.[9] Therefore, a π-mediated force associated with the surface phenyl groups is most likely to be responsible for the cation intercalation towards the phenyl-capped cluster **1**.

The photoluminescence changes upon complexation with CTAB were also investigated. In colloidal systems, the addition of tetraalkylammonium salts induces some degree of dynamic quenching.[10] In contrast, the intercalative binding

of CTA$^+$ ions with **1** caused notable luminescence enhancement. For example, when CTAB (2.0 mM) was added to a mixture of **1** and TOAB in CHCl$_3$ under Ar, the emission intensity was drastically increased with a shift to a longer wavelength (570 nm; Figure 4 (b)),[11] whereas the absorption
Figure 4. Absorption (a), photoluminescence ($\lambda_{ex} = 360$ nm; (b)), and excitation ($\lambda_{em} = 570$ nm (c)) spectra of **1**/TOAB (6.7/26.8 μM) before (dotted line) and after (solid line) the addition of CTAB (2.0 mM) in degassed CHCl$_3$ at 25 °C.

spectrum showed a small change (Figure 4a). Excitation spectra before and after the addition of CTAB were similar in shape with a maximum at approximately 360 nm (Figure 4c), which indicates that the strong luminescence of the CTAB complex arises from the cluster core. On the other hand, alkyl-substituted **2** under similar conditions showed a small decrease of the luminescence intensity, which is similar to that reported for colloidal system.[10] Thus, the large luminescence enhancement with **1** is not due to simple salt effects, but is caused by the intercalative cation binding near the cluster core.

The luminescence enhancement reported above appears to be correlated to the structural changes of the phenyl-group shell surrounding the cluster core upon intercalation. In connection with this, in the ¹H NMR spectrum the SPh signals showed a significant change upon cation intercalation: The nonintercalative complex **1**/TOAB showed broad and complicated pattern of signals at $\delta = 6.0$–7.8 ppm (Figure 5a), which reflects the disordered orientation of the SPh groups arising from S−C bond rotation. On the other hand, upon
addition of 20 equivalents of CTAB to this solution, the SPh signals converged into three major signals assignable to the *ortho*, *meta*, and *para* protons (Figure 5b), which suggests that the cation intercalation restricts the phenyl-ring rotation and so induces a uniform arrangement. Such ordered orientation and/or enhanced conformational rigidity of the surface substituents may suppress the quenching path to the medium by effective core protection and thus increase the luminescence intensity.[11,12]

In conclusion, we have demonstrated π-interaction mediated cation accumulation around a phenyl-capped CdS cluster and the guest-responsive photoluminescence properties of this cluster. Application to sensing systems by rational tuning of the π-functionalities as well as the sizes and structures of the clusters is worthy of further investigations.

Experimental Section

1: $[Cd_{10}S_4(SPh)_{16}](NMe_4)_4$[4b] (1.16 g, 0.35 mmol) was heated under vacuum at 180°C for 6 h, and the resulting solid was washed with hexane and chloroform to give **1** as a pale-yellow solid (0.87 g, 97%), which gave satisfactory IR and ¹H NMR spectra. Elemental analysis calcd (%) for $C_{72}H_{60}Cd_{10}S_{16}$: 33.75, H 2.36, S 20.02; found: C 33.56, H 2.37, S 19.87; no nitrogen was found.

2: Compound **2** was prepared by the thiolate-exchange reaction of **1** with $C_6H_{13}SH$ in the presence of TOAB. 1-hexanethiol (21 mmol) was added to an MeCN solution of **1** (100 mg, 0.039 mmol/5 mL) containing TOAB (0.16 mmol), and the mixture was stirred at RT for 12 h. The mixture was evaporated to dryness and the residue was washed copiously with MeOH to give **2** as a white solid (81 mg, 78%), which gave satisfactory IR and ¹H NMR spectra. Elemental analysis calcd (%) for $C_{72}H_{156}Cd_{10}S_{16}$: C 32.52, H 5.91, S 19.29; found C 32.27, H 5.47, S 18.89; no nitrogen was found.

Figure 5. Aromatic region of the ¹H NMR spectra of a) **1** (2.3 mM) and b) **1**/CTAB (2.3/46 mM) in the presence of TOAB (9.2 mM) in CDCl$_3$ at 25 °C.

[9] Other weak interactions, such as van der Waals forces also seem not to be dominant. No signs of guest (cation)–cluster close proximity were detected in the ^{1}H NMR spectra of the **2**/CTAB(CPB) and **1**/dimethylhexadecylamine systems in the presence of TOAB.

[10] M. Hamity, R. H. Lema, C. A. Suchetti, *J. Photochem. Photobiol. A* **1998**, *115*, 163.

[11] Titration of **1** with CTAB under the conditions given in Figure 4 showed saturation of the emission intensities at $[CTAB]_0/[\mathbf{1}]_0 \approx$ 400. At this molar ratio, it is estimated that, from the NMR-spectroscopy-determined association constant, at most, two of twelve intercalation sites were occupied by the CTA^+ ions, which suggests that steric isolation of the core by the intercalated cations is not a critical factor for the photoluminescence enhancement. When the $[CTAB]_0/[\mathbf{1}]_0$ ratio was increased over 600, the intensity was inversely decreased probably a result of the reverse-micelle formation of CTAB.

[12] For an analogous phenyl-capped CdS cluster, increase of the luminescence intensities upon lowering temperature has been reported: N. Herron, A. Suna, Y. Wang, *J. Chem. Soc. Dalton Trans.* **1992**, 2329.

Stereochemical Assignment in Acyclic Lipids Across Long Distance by Circular Dichroism: Absolute Stereochemistry of the Aglycone of Caminoside A**

*John B. MacMillan, Roger G. Linington, Raymond J. Andersen, and Tadeusz F. Molinski**

In memory of D. John Faulkner

The glycolipid caminoside A (**1**, Figure 1), isolated from the marine sponge *Caminus sphareoconia* from Dominica, was shown to be an inhibitor of a type III bacterial secretory system.[1] The components of type III secretory pathways mediate insertion of virulence factors into host cells by pathogenic bacteria including *Bordetella pertussis*, *Chlamydia trachomatis*, *Salmonella typhi*, and enterohemorrhagic *Escherichia coli* (EHEC); the later being responsible for "hamburger" disease. Caminoside A is an unusual marine glycolipid[2] with a non-glycerol aglycone (the C_{19} hydroxy-ketone **2**) that is glycosylated at the C10 hydroxy group by a tetrasaccharide consisting of D-deoxytalose, two D-glucose units, and L-quinovose that are linked through 1,2′ and 1,6′-O-glycosidic bonds. The secondary C10 OH group of **2** is separated from the chain termini by at least seven CH_2 groups, consequently, the configuration could not be assigned by conventional NMR spectroscopic methods. This situation typifies a well-recognized problem in natural products structure elucidation—assignment of stereochemistry at remote stereocenters in acyclic molecules.[3]

The problem can be described in terms of the logical order of analysis employed by natural products chemists when addressing absolute configuration by NMR spectroscopy. Assignment of configuration at stereogenic centers along an acyclic carbon chain requires reliable chemical shift assignments to reduce the problem to one of defining the stereotopicity of groups flanking the left and right sides of each substituted carbon in the chain (Figure 2). For example, the configurations of many secondary alcohols are conveniently assigned from their derived Mosher[4] or mandelate esters[5]

Figure 1. Caminoside A (**1**), the aglycone **2**, and the four possible stereoisomers of reduced aglycone (**6a–d**) and 5-(4′-carboxy)-5,10,15,20-tetraphenylporphyrin (TPP, X = OH, **3**).
Figure 2. Acyclic 1,n-glycol. The configuration of C1 can deduced from NMR spectroscopic assignments of the stereotopicity of the two families of chemical shifts [α, β, γ...] and [α′, β′, γ′...]. To obtain the relative configuration of the 1,n-glycol, similar conditions must be satisfied for Cn, or the C1 and Cn configurations must be cross-correlated.

by interpretation of anisotropic shifts ($\Delta\delta$) of the families of chemical shifts [α, β, γ...] and [α′, β′, γ′...]. Data are fitted to an empirical model which orders the diastereotopic groups located to the left and right of the CH(OH) group by the sign of their $\Delta\delta$ values. The use of integrated ^{1}H-^{1}H and ^{1}H-^{13}C coupling constant analysis (Karplus-like analysis) provides assignments of stereochemistry from defined dihedral angle dependencies (*J*-based methods).[6] *J*-based analysis can relay stereochemical information along the chain (α to β to γ…) to

reveal relative stereochemistry at contiguous carbon atoms (1,2-disubstituted) or even alternating substituted carbon atoms (1,3-disubstituted). The requirement (and limitation) of these methods is that stereotopicity of the signals of intervening CH$_2$ groups must be made by measurements of *J* coupling constants under favorable conditions of NMR spectroscopy signal dispersion and dihedral angles that conform to all-staggered molecular conformations. These methods, although usually successful for polyketides bearing contiguous 1,2 or 1,3-disubstituted stereoelements, become less reliable for molecules containing two or more stereocenters separated by three or more methylene bridges because the two diastereotopic chain segments subtended at each stereocenter cannot always be differentiated by NMR spectroscopy.[7]

We describe, herein, the configurational assignment of the aglycone of caminoside A (**2**) in which these limitations are overcome by exploiting long-range exciton-coupling circular dichroism (ECCD) of 1,n-glycol diesters in acyclic lipid chains that are formulated in highly uniform liposomes prepared from 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DPC). The success of the method (defined here as liposomal exciton-coupling circular dichroism, LECCD) relies on the structural order imposed on the long-chain lipid by the hydrophobic alignment of the 1,n-glycol diesters of *O*-tetraphenylporphyrincarboxylic acid (TPP, X = OH **3**) upon being constrained by the fatty acyl chains in small diameter, uniform DPC liposomes (average $\varnothing \approx 30$ nm, Figure 3). Partial ordering of the
Figure 3. Imposing order upon random coiled, long-chain 1,n-diol TPP-carboxylate esters (a) by chain alignment within liposomes (b). Red circles TPP chromophores, blue DCP, R = alkyl

lipid chain limits conformational averaging and allows detection of ECCD that would not be observable in isotropic solution. The TPP chromophore was chosen from the many chromophores useful in ECCD[8] because of its exceptionally strong charge-transfer band and successful applications across long distances in conformationally rigid diols and amino-alcohols.[9] Since the TPP ester chromophore dipole moments are aligned predominantly along the C–O bond vectors of the ester groups at defined angular orientations, the sign of the resulting bisignate CD bands reveals the sign of the absolute helicity or "screw" angle subtended by the C–O bonds and the stereochemistry at the OH substituted carbon atoms.[10] Herein, we demonstrate an application to an otherwise intractable problem of natural product stereochemical assignment: the relative and absolute configurations of a natural product containing an OH group isolated within an acyclic

Communications

lipid chain. The LECCD achieves exceptional sensitivity (limit of detection ≈ 40 pmol) through two factors: the use of liposomes with uniform, small diameters ($< \lambda_{max}$) that reduce CD signal loss from non-Rayleigh scattering and the colossal charge-transfer dipole moment of the TPP chromophore ($\lambda = 418$ nm, ε 350 000[9b]) which allows propagation of relative stereochemical information in substituted acyclic lipids over distances of at least 10 Å.

We recently showed that the stereochemistry of *meso* and C_{2v} symmetric 1,5-glycols can be assigned based on the LECCD spectra of their derived TPP esters and that the method can be extended to 1,7- and 1,9-glycols.[10] To apply the bis(TPP glycol) method to **2**, the C2 carbonyl group was asymmetrically transformed to introduce a stereodefined C2 OH group that would be used to "interrogate" the remote C10 OH configuration. A sample of **1** was methanolyzed under acidic conditions (Scheme 1, MeOH, HCl, reflux) and the resulting mixture of aglycone and *O*-methyl glycosides separated by silica gel chromatography (7:3 hexanes/EtOAc) to afford pure **2**.[11] A convenient UV chromophore (2-naphthoic acid: $\lambda = 234$ nm, ε 58 000 $M^{-1}cm^{-1}$) was first attached at the C10 hydroxy group to assist detection of intermediates during each of the following conversions. Esterification of **2** (≈ 0.6 mg, *N*-2-naphthoylimidazole, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), CH_3CN) gave **4** that was reduced (NaBH$_4$, EtOH) to a mixture of C2 epimeric glycol mononaphthoates (**4a,b**). The mixture was resolved by enzyme-catalyzed acetylation (Novozym 435, vinyl acetate, CH_3CN, 45°C) to give the product (2R)-*O*-acetate ester **5a**

(48%) and residual (2S)-alcohol **4b** (45%), which were easily separated by silica chromatography. The configurations at C2 of **5a** and **4b** followed from the enantiopreference of Novozyme 435 for (2R)-methyl carbinols[12] and were supported by Mosher ester analysis of synthetic homologues (see below).[13]

The configuration of the natural product-derived glycol diester **5a** corresponds to one of the family of stereoisomers **6a–d** depicted in Figure 1. As expected, the relative stereo relationship of the known C2 center to C10 in **5a** or **4b** could not be determined at this stage owing to the large distance between the two OH groups, however, the correct natural product configuration was successfully elucidated as follows: The ester groups in **5a** were removed (NH$_3$, MeOH, 15 min, 97%) to give the 1,9-glycol **6a**. Glycol **6a** was converted into the purple TPP ester **7a** (Scheme 1; λ_{max} 416 nm, ε428 000, HRFABMS *m/z* 1582.9874, [*M*H]$^+$) via the mixed TPP anhydride (*O*-pivaloyl TPP, CH_2Cl_2, 8 h, Et$_3$N) followed by HPLC purification (74%). CD measurement of a sample of **7a** that had been constituted into liposomes (DPC 2 mg mL^{-1}, average diameter $\varnothing \approx 30$ nm, $c = 0.65$ μM based on the extinction of TPP, ε 428 000) showed strong exciton coupling (Figure 4) characterized by a high intensity positive bisignate CD signal ($A = +22$), however, the CD of **7a** in MeOH showed only baseline as expected from conformational averaging of the lipid chains of **7a** in isotropic solution.

We propose that the lipid chains are partially oriented in the extended conformation by hydrophobic packing with the fatty acyl chains of DPC. Assuming that the liposomal bilayer
Scheme 1. Conversion of **1** into nonadecane-1,10-diol TPP-carboxylate diester (**7a**).

  www.angewandte.org *Angew. Chem. Int. Ed.* **2004**, *43*, 5946–5951
Figure 4. CD spectra of TPP esters formulated in MeOH or DPC liposomes (2 mg mL^{-1}, 1,2-distearoyl-*sn*-glycero-3-phosphocholine), $T = 22\,°C$. a) "pseudo-C_{2v}" **9a** in liposomes. b) **7a** in liposomes. c) "pseudo-*meso*" **9b** in liposomes. d) **7a** in MeOH.

orients the long-chain bis(TPP ester) **7a** in an extended conformation and that the *O*-TPP groups subtend torsional angles as shown in Figure 5, the observed positive bisignate
Figure 5. Predicted sign of exciton coupling CD for extended conformation of long-chain 1,*n*-glycol TTP diesters (*n* = 7,9). a) *anti* conformation, positive helicity ("pseudo-C_{2v}" symmetric)→positive split CD. b) synperiplanar ("pseudo-*meso*")→zero signal; c) *anti* conformation, negative helicity ("pseudo-C_2" symmetric)→negative split CD.

signal would be expected for the (2*R*,10*R*)-**7a** where the two TPP groups are oriented *anti* with respect to the plane of the extended chain conformation (Figure 5a). Conversely, a negative signal would be expected for the *anti*-oriented TPP groups of the enantiomeric (2*S*,10*S*)-**7c** (Figure 5c) and a weak or baseline signal would be observed for the synperiplanar TPP groups of the remaining "pseudo-*meso*" stereomers, (2*S*,10*R*)-**7b** and (2*R*,10*S*)-**7d** (Figure 5b). Indeed, the configurational assignment of **7a** was entirely supported by measurements of the corresponding TPP esters of synthetic

homologues **8a** and **8b**, each prepared from (*R*)-1,2-epoxy-nonane (Scheme 2).[10,13] The CD spectrum of liposomal formulations of the corresponding TPP ester (2*R*,10*R*)-**9a** (Scheme 2) was virtually identical to that of the natural product derived **7a**, but the synthetic epimer, (2*S*,10*R*)-**9b**, gave only baseline signal.
Scheme 2. Synthesis of model 1,9-diols.

In conclusion, the C10 configuration of caminoside A is assigned as *R*, which completes the entire configurational assignment of **1**.[14] The advantage of LECCD lies in partial ordering of the lipid chains that induces a non-averaged net ECCD signal in 1,9-glycol TPP diesters that communicates the relative configuration of the 1,9-glycol, derived from aglycone **2** in a stereodefined manner. Since the C2 configuration of **6a** is securely established, the absolute configuration at C10 is communicated by the relative stereochemistry revealed from LECCD measurements of the corresponding 1,9-glycol TPP diesters **7a** and **7b**. In principle, the method maybe extended to other suitably derivatized acyclic hydroxy-substituted long-chain lipids that defy conventional methods for stereochemical interrogation because they contain remotely located stereocenters, such as the antiviral glycolipids, fattiviracin[15] from *Streptomyces microflavus* No. 2445 and cycloviracins from *Kibdelosporangium albatum* so. nov. (R761-7).[16] We have estimated, by extrapolation of the A magnitudes from LECCD spectra of 1,*n*-glycol TPP esters (*n* = 7, 9), that a measurable LECCD signal should be observed up to *n* = 13,[10] however, refinements of methods for ordering of long-chain esters in liposomes may extend transmission of stereochemical information beyond this limit.

Experimental Section

All the new compounds were purified by HPLC and gave satisfactory high-resolution mass spectra (HRMS) and ^{1}H NMR spectra.

LECCD: General procedures for liposome preparation and characterization of the materials by TEM are described in detail, elsewhere.[10] Briefly, measured aliquots of DPC and TPP ester **7a** were dissolved in CHCl$_3$ and "shell-evaporated" in a round bottom flask. Water (2 mL) was added and the mixture sonicated (ultrasound bath). The crude liposomes were annealed by thermal cycling (60→ 25°C→60°C, × 3) before repeated passage through a porous nylon membrane (100 nm pore, Liposofast, Avestin). CD spectra were on purified material were measured at room temperature (23°C) in a 1-

[13] Synthetic 10-O-acetyl-10-hydroxyheptadecan-2-one was prepared as described in detail, elsewhere.[10] Briefly, addition of 6-(2-methyl-1,3-dioxolan-2-yl)hexyl magnesium bromide to (R)-1,2-epoxynonane (> 95% ee, prepared from 1-nonene and Jacobsen's catalyst, S. E. Schaus, B. D. Brandes, J. F. Larrow, M. Tokunaga, K. B. Hansen, A. E. Gould, M. E. Furrow, E. N. Jacobsen, *J. Am. Chem. Soc.* **2002**, *124*, 1307–1315) followed by acetylation (Ac₂O, pyridine), transketalization (4-methyl benzenesulfonic acid (p-PTS), acetone) and reduction (NaBH₄, EtOH) of the resultant ketone provided synthetic (2ξ,10R)-heptadecan-2,10-diol. Sequential acetylation (Novozym 435, vinyl acetate), separation of the products by SiO_2 chromatography and ammoniolysis of the esters, using a procedure similar to that described in the text, gave samples of (2R,10R)-**8a** and (2S,10R)-**8b**. The diastereomeric ratios at C2 were measured as 99% and 98%, respectively, from their corresponding Mosher diester (R or S α-trifluoromethyl-α-methoxyphenylacetic acid, N,N′-dicyclohexyl methanediimine (DCC), CH_2Cl_2, N,N-dimethyl-4-pyridinamine (DMAP), yields 63–73%). Note that although a Mosher O-ester group acylated on the C10 OH of either **8a** or **8b** induced differential anisotropic $\Delta\delta$ shifts for the ^1H NMR signals of H9 and H11, these signals could not be assigned and, thus, were considered interchangeable. Consequently, the $\Delta\delta$ values are not informative for the configuration at C10.

[14] Three other analogues from *C. sphaeroconia* (caminosides B–D) are homologues of **1** that differ only by replacement or interchange of O-acetyl or butanoyl groups at C3 and C4 of

the second glucose residue.[11] Since the constitution of the aglycone is the same in each of the caminosides A–D, we assume that the configuration is also the same (10R).

Natural Product Synthesis

Enantioselective Total Synthesis of (+)-Milnamide A and Evidence of Its Autoxidation to (+)-Milnamide D**

*Chaomin Liu, Makoto N. Masuno, John B. MacMillan, and Tadeusz F. Molinski**

Milnamides A,[1a] C,[1b] and D[1c] (**1–3**), (−)-hemiasterlin (**4**),[2a–d] and hemiasterlins A–C (**5–7**)[2b,d] (Figure 1) comprise a small family of exceptionally cytotoxic tripeptides that were isolated from marine sponges *Auletta* sp., *Hemiasterella minor*, *Cymbastella* sp. and *Siphonochalina* sp. Compounds **1–7** are powerful antimitotics that disrupt microtubule assembly during cell division and inhibit growth of cultured tumor cells (e.g. **4**, $IC_{50} < 1$ nM, MCF-7 breast tumor cells).[4] Hemiasterlin is a more potent cytotoxin in vitro than paclitaxel (Taxol) and is comparable to dolastatin 10.[2c] As a consequence of this exceptional activity, a synthetic analogue of **4**, SPA110, has entered advanced phase I clinical trials for the treatment of solid tumors.[4] X-ray crystallographic analyses confirmed the relative stereochemistries of **2** and (−)-**4**, and by the total synthesis of (−)-**4**, the *S* configurations at each α-amino acid residue were verified.[3,4] Very

recently, the X-ray crystal structure of **2** was reported,[1c] however, the absolute stereochemical configurations of **1–3** were not defined. Comparison of the ¹H NMR spectroscopic data of **1–3** suggests that the differences from (−)-**4** are located solely within the region of the heterocyclic amino acid. Because the highly methylated β-carboline amino acid **8**, which is found in **1–3**, has no precedent in other natural products, the preparation of both 3*R* and 3*S* (β-carboline numbering) stereoisomers of **1** would inform stereochemical determinations of the milnamide family. Herein, we report the first enantioselective total syntheses of (3*S*)-**1** and (3*R*)-**1** that employs an expedient synthesis of the requisite **8** through an oxazoline–dihydrooxazinone rearrangement. The synthesis confirms the absolute configuration of natural (+)-**1** as (3*S*,12*S*,15*S*) and demonstrates the first use of the aforementioned rearrangement in natural peptide synthesis. Furthermore, we show that **1** undergoes facile autoxidation to milnamide D (**3**) which thus correlates the absolute configurations of both natural product peptides and suggests a nonbiogenic origin for the iminium salt **3**.

Retrosynthetic analysis of **1** (Scheme 1) suggests disconnections to a pivotal intermediate, namely the β-carboline amino acid (**8**), and the known dipeptide **9**.[3a] The precursor **10** to the heterocyclic amino acid arises from aromatic electrophilic substitution of *N*-methylindole (**11**) by an epoxide **12**, which itself is obtained by a Darzen's-type condensation of (4*R*)-2-chloromethyl-4-phenyloxazoline and acetone.

The synthesis of **1** is outlined in Scheme 2. The pivotal step relies upon our SeO_2-promoted oxidative rearrangement of 2-alkyl- or 2-(arylmethyl)oxazolines to 3,5-disubstituted dihydro-2*H*-oxazinones.[5] The required oxazinone **10** was synthesized in two steps as follows. *N*-methylindole and the epoxide **12**[6] were coupled under Lewis acid conditions ($SnCl_4$, CH_2Cl_2, −78 °C, 56 %)[7] to provide the requisite oxazoline

phenylglycinol that is used in the preparation of the oxazoline **12**. Thus, reduction of (5*R*)-**10** or (5*S*)-**10** would provide (3*S*)-**1** or (3*R*)-**1**, respectively. After experimentation under different conditions (Table 2), we found that **10** underwent hydrogenation (PtO$_2$, H$_2$, 4 atm, MeOH, RT, 90%) to give **14** with excellent diastereoselectivity ($\approx$70:1). The major isomer, **14a**, which was separated from the mixture by column chromatography (silica gel), was shown to have the expected *cis* configuration by NOE studies; irradiation of the H3 center (CDCl$_3$, $\delta = 4.39$, s) resulted in an NOE enhancement of the benzylic proton H5 (oxazinone numbering). Condensation of **14a** with H$_2$C=O under optimized Pictet–Spengler[10] conditions (paraformaldehyde, MgSO$_4$, benzene, 75 °C) gave **15** in quantitative yield. Removal of the chiral auxiliary from **15** by hydrogenolysis–hydrolysis (Pd(OH)$_2$/C, H$_2$, 4 atm, TFA/H$_2$O, 89%),[11] followed by reductive methylation (paraformaldehyde, Pd/C, H$_2$, MeOH, 50 °C, 78%)[12] provided the key amino acid **8**.

The amide coupling of **8** and **9**[3a] was far more troublesome than expected. Attempted amide bond formation with a variety of coupling reagents (dicyclohexyl carbodiimide (DCC), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide) hydrochloride (EDC), *O*-(7-azabenzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU), bromotripyrrolidinophosphonium hexafluorophosphate (PyBrOP)) all failed to produce the expected tripeptide. Clearly, the highly hindered molecule **8** precluded the formation of the amide bond with the sterically crowded *tert*-leucyl amino terminus of **8** under conditions that were similar to those employed by Andersen et al in the synthesis of **4** from the less hindered (2*S*)-*N*-Boc-*N*,*N*′*C*,*C*-tetramethyltryptophan (52%).[3a] Eventually, amide coupling was possible under mixed anhydride conditions (pivaloyl chloride, *i*Pr$_2$EtN, THF, 0 °C, 10%) to give the ethyl ester **17**.[13] Saponification of **17** (LiOH, MeOH, H$_2$O, degassed, N$_2$,

3	CH$_3$OH	4	72	72:1	90[a]

[a] Isolated yield of **14a**. [b] From integration of ^{1}H NMR spectra.

13 as a mixture of epimers.[8] Attempted oxidative rearrangement of **13** to the required 5,6-dihydro-2*H*-1,4-oxazin-3-one **10** with SeO$_2$ under standard conditions (dioxane, reflux) was disappointing ($\leq$23% yield), probably owing to decomposition of the indole ring.[9] A survey of varying conditions (Table 1) identified that SeO$_2$ in CHCl$_3$ or ethyl acetate at reflux provided rapid reactions and the highest yields. Accordingly, oxazoline **13** was smoothly converted (SeO$_2$, CHCl$_3$, reflux) into **10** in 90% yield.

Control of the correct configuration at the C3 center in **8** was anticipated from the diastereofacial hydrogenation of the C=N bond directed by the Ph substituent at the C5 center of the dihydrooxazinone **10**. The synthesis of either enantiomer of **8** is possible by the choice of the configuration of the

RT, 92%) completed the synthesis of (3*S*)-**1**. Its counterpart (3*R*)-**1**[14] was synthesized by the same route starting with the (4*S*)-oxazoline **12**. Synthetic (3*S*)-**1** was identical to natural (+)-**1** from ¹H NMR and circular dichroism (CD; see Figure 2) spectroscopic analysis, ESI-MS measurements, and LC–MS retention times.[15] However, the CD spectrum of epi-milnamide A ((3*R*)-**1**) differed significantly from that of natural (+)-**1**.
Figure 2. CD spectra of milnamides: a) synthetic milnamide A [(3*S*)-**1**] (——), synthetic epi-milnamide A [(3*R*)-**1**] (– – –), and natural milnamide A [(3*S*)-**1**] (- - - -); b) synthetic milnamide D [(3*S*)-**3**] (– – –) and natural (+)-milnamide D [(3*S*)-**3**] (——).

Over time, **1** slowly autoxidized to **3** upon standing in solvent. Both (3*S*)-**1** and (3*R*)-**1** were oxidized at similar rates, but the apparent rate of autoxidation was greatly accelerated when samples were stored in aged CDCl₃ or CHCl₃.[16] As the analyses of this autoxidation product **3** were identical to those of natural milnamide D by CD (Figure 2) and ¹H NMR spectroscopy and LCMS, we conclude that the latter also has the 3*S* configuration. Given the ease of this oxidation, it is plausible that **3**, which is obtained from natural sources, originates from the autoxidation of **1** during its isolation–purification process, although we cannot exclude **3** as a "true" natural product or an intermediate precursor in the biosynthesis of **1**.

The key feature of this synthesis of (+)-milnamide A (**1**) is the high-yielding preparation of the highly methylated β-carboline amino acid **8**, which is made possible through the facile oxidative rearrangement of oxazoline **12** to the corresponding substituted dihydrooxazinone. This rearrangement reaction was exploited for the first time in natural product synthesis for the preparation of amino acid **8** and should find application in the synthesis of other marine-derived peptides that containing rare *tert*-alkyl amino acids.[17]

Biofunctionalization of Fluorescent Rare-Earth-Doped Lanthanum Phosphate Colloidal Nanoparticles**

*Felix Meiser, Christina Cortez, and Frank Caruso**

In recent years, the utilization of nanoparticles (NPs) for conjugation with biomolecules has attracted widespread interest.[1–7] In particular, fluorescent semiconductor colloidal nanoparticles, or quantum dots (QDs), have played an important role in the application of NPs in biomedical applications.[1–3] Compared with their organic fluorophore counterparts, QDs can be prepared with high chemical stability, high quantum yield, and can exhibit high resistance to photobleaching. In addition, the optical properties of QDs can be tuned by controlling their size through synthesis. A range of biomolecules, such as deoxyribonucleic acid (DNA) and proteins, have been conjugated to QDs and used in labeling studies.[1] For example, QD bioconjugates have been used in the fluorescent labeling of cells,[2,3] agglutination assays,[3] in vitro detection assays,[8] and most recently, in selective and generalized imaging of live cells.[9–11] Despite the wide and successful use of QDs in diverse biomedical studies,

commercial preparations of QDs face challenges associated with reproducible QD preparation, suitable surface coatings, and, in certain cases, cytotoxicity issues, particularly in vivo.[12,13]

An alternative class of colloidal NPs that are potentially promising for biolabeling studies are those based on rare-earth-doped lanthanum phosphates (LaPO$_4$). Recent work by Haase and co-workers reported the synthesis of monodisperse fluorescent LaPO$_4$ NPs.[14–16] These NPs, approximately 7 nm in size, have fluorescence that originates from their bulk properties—transitions between d and f electron states and their local symmetry—and is independent of their size.[14–16] The optical properties of the LaPO$_4$ NPs can also be tuned by the rare-earth dopant used—different colors are available by varying the dopants used in their synthesis (e.g., Ce, Tb, Eu, Dy).[14–17] The high chemical stability, high quantum yield (up to 61 %),[16] and expected low toxicity[18] of these NPs make them potentially suitable for biological labeling applications. In addition, the application of rare-earth-doped LaPO$_4$ thin films (from micron-sized powders) as coatings for luminescent lamps points to a high photostability of such materials.[19,20] Herein, we report the first demonstration of the biofunctionalization of nanometer-sized colloidal LaPO$_4$ NPs. Green (Ce/Tb-doped) LaPO$_4$ NPs[17] were conjugated to the model protein avidin, a tetrameric protein that can bind with high affinity to four biotin molecules. NP functionalization was examined by using a suite of techniques, including analytical ultracentrifugation (AUC), microelectrophoresis, absorption and fluorescence spectroscopy, dynamic light scattering (DLS), and transmission electron microscopy (TEM).

Figure 1 illustrates the conjugation of LaPO$_4$ NPs with avidin. A primary requirement was to first obtain stable, aqueous colloidal dispersions of the NPs. This was achieved by dispersing the LaPO$_4$ NPs in an aqueous solution contain-
Figure 1. Schematic illustration showing the biofunctionalization of fluorescent Ce/Tb-doped LaPO$_4$ NPs with avidin. The NPs were first modified with AHA, and the carboxy groups of AHA were then activated by EDC to conjugate avidin through the formation of amide bonds. The binding of avidin–NP bioconjugates with biotinylated molecules is also shown.

ing the bifunctional spacer 6-aminohexanoic acid (AHA). AHA imparts a negative charge on the surface of the NPs, as confirmed by the strongly negative ζ-potential at basic pH values (Figure 2). The isoelectric point (pI) of 4.5 obtained for
Figure 2. ζ-potential of the functionalized Ce/Tb-doped LaPO₄ NPs as a function of pH: after modification with AHA (■); and after AHA-modification and avidin bioconjugation (●). The plot shows the shift in isoelectric point upon AHA modification and avidin coating. The curves drawn are to guide the eye.

the AHA-modified LaPO₄ NPs is close to values reported for particles bearing carboxy groups,[21,22] which suggests that the amine group of AHA is attached to the particle surface, whereas the carboxy group is directed into the surrounding solution. Modification of the LaPO₄ NPs with AHA serves two important purposes. First, it confers sufficient colloidal stability to the nanoparticles where subsequent biofunctionalization is to be performed (pH 7). Support for this is also provided by examination of the AHA-coated LaPO₄ NPs by TEM, which reveals no signs of significant NP aggregation (Figure 3). Second, the terminal carboxy group at the particle surface allows the immobilization of amine-containing ligands, such as proteins. The protein avidin was chosen in this study to make use of the highly specific interaction between avidin and biotin ($K_d = 10^{-15}$ M),[23] since a wide variety of biotinylated molecules are commercially available. Avidin is composed of four identical subunits with each subunit folded in the form of a barrel (β-barrel).[24] The biotin-binding site is positioned near one end of the avidin barrel, hence two biotin-binding sites are present on each end of the protein.
Figure 3. TEM image of AHA-modified Ce/Tb-doped LaPO₄ NPs.

The covalent coupling of avidin to the NP surface was facilitated by the crosslinker 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide (EDC), which activates the carboxy groups on the NPs and leads to the formation of amide bonds with avidin. The avidin-coated AHA-modified LaPO₄ NPs showed a pI of 7.5, with a positive ζ-potential (30 mV) at pH 4.75 (Figure 2). The shift in ζ-potential after exposure to avidin (pI of 10–10.5)[25] indicates the successful conjugation of avidin to the NP surface.

Figure 4 shows the absorption and fluorescence spectra of the LaPO₄ NPs before and after conjugation with avidin. Three washing steps after the reaction ensured the removal of
Figure 4. Absorption (*A*; a, b, c) and fluorescence (*F*; d, e) spectra of AHA-modified Ce/Tb-doped LaPO₄ NPs before (——) and after (----) avidin functionalization. The absorption peaks of the NPs at 257 and 274 nm are evident. The absorption spectrum of pure avidin (c, •••••) is also shown.

unconjugated avidin in solution. The absorption spectrum of the AHA-modified Ce/Tb-doped LaPO₄ NPs (Figure 4, spectrum a) shows intense peaks at 257 and 274 nm, which are due to the absorption of the cerium dopant.[16] As expected, the avidin/AHA-LaPO₄ NP bioconjugates (Figure 4, spectrum b) show absorption features characteristic of both the AHA-functionalized NPs (peaks at 257 and 274 nm) and of pure avidin (major peak at ~200 nm, Figure 4, spectrum c). These results support the microelectrophoresis data for avidin conjugation to the NP surface. For the AHA-modified NPs three distinct fluorescence peaks are observed at 545, 585, and 622 nm (Figure 4, spectrum d). These fluorescence peaks are due to the d–f orbital transitions of the dopants.[14–16] An additional peak was also observed at 490 nm (not shown).[26] The same characteristic fluorescence peaks can also be observed after avidin biofunctionalization (Figure 4, spectrum e). These data are in agreement with our previous work where the characteristic fluorescence peaks of LaPO₄ NPs interacting with polyelectrolytes in multilayer thin films appear at the same spectral positions as those for the corresponding NPs in solution.[17]

To verify the increase in diameter as a result of bioconjugation, AUC was used to measure the size distribution of the NPs before and after avidin coating (Figure 5 a). Assuming a density of 5.0 g cm⁻³ for the LaPO₄ NPs,[27] we determined an average diameter of 7.6 nm for the AHA-

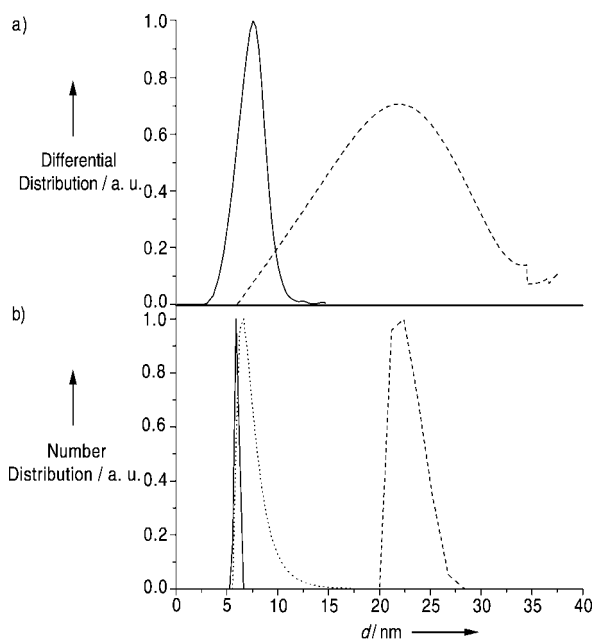
Communications


Figure 5. Diameter distribution of AHA-modified Ce/Tb-doped LaPO₄ NPs before (——) and after (----) avidin functionalization, as determined by a) AUC and b) DLS methods. In the AUC measurements (a), a particle density of 5.0 g cm^{-3} was used. In (b), the diameter distribution of avidin is also shown (·····).

modified NPs. This value is close to that derived from TEM (mean size 6–8 nm; see Figure 3 and ref. [17]).[28] After bioconjugation, if the same density is assumed, the diameter increases to 21.8 nm, which is consistent with having a monolayer of avidin molecules, approximately 7 nm in size. This value is slightly higher than the size of avidin (dimensions $6.0 \times 5.5 \times 4.0$ nm[29]). Since the exact density of avidin-coated NPs is not known, the method of DLS was also employed to yield information on the hydrodynamic radius of the NPs. Figure 5b shows the DLS diameters of the individual AHA-modified LaPO₄ NPs and avidin, as well as the avidin–LaPO₄ NP bioconjugate. The measured diameter for the AHA-modified NPs (~7 nm) is in good agreement with that determined from TEM and AUC, while the measured diameter of avidin (~7 nm) is similar to that determined from AUC experiments. The DLS diameter of about 22 nm for the bioconjugate closely agrees with the AUC data when assuming a density of 5.0 g cm^{-3} for the AUC experiments (Figure 5b). Both the AUC and DLS data further support avidin functionalization of the LaPO₄ NPs.

We also performed an assay utilizing biotin covalently linked to the organic dye fluorescein (biotin-FITC) to test the binding capacity of the avidin-functionalized NPs to biotin. The bioconjugates were mixed with biotin-FITC in the presence of 2-[*N*-morpholino]ethanesulfonic acid (MES) buffer (pH 4.75) and phosphate buffer (PB, pH 9) in a 9:1 volume ratio, and then centrifuged to sediment the particles, leading to the formation of a pellet. The supernatant fluorescence was measured and compared against a standard of known biotin-FITC concentration. A decrease in the amount of biotin-FITC in the supernatant (i.e., decrease in fluorescence intensity) was observed after incubation with the bioconjugates, indicating biotin-FITC binding to the avidin-functionalized LaPO₄ NPs. The decrease in fluorescence intensity is directly correlated to the amount of biotin-FITC bound, and the point at which the fluorescence begins to appear in the supernatant corresponds to saturation binding of the avidin-coated LaPO₄ NPs. From these experiments, we calculated that 29 biotin molecules are bound per particle (see Supporting Information). Assuming that each avidin can bind four biotin molecules, the number of avidin molecules conjugated to each NP is calculated as about seven.

A second approach, the micro BCA protein assay, was performed to determine the amount of avidin conjugated to the NPs. This method is based on a colorimetric measurement and involved the comparison of the amount of avidin per NP with a standard concentration series of avidin (see Supporting Information). Approximately 6.2×10^{17} avidin molecules were calculated to be present in a sample of 7.7×10^{16} avidin-functionalized NPs, which equates to approximately eight avidin molecules per NP. This value is in good agreement with that determined from the fluorescence assay. The protein-to-nanoparticle ratio obtained is similar to that reported for bioconjugation of a maltose binding protein, which is slightly smaller than avidin (size $3 \times 4 \times 6.5$ nm), with 6-nm diameter QDs, where it was found that about ten proteins were coupled to each QD NP.[30]

In conclusion, fluorescent Ce/Tb-doped LaPO₄ NPs with a diameter of about 7 nm have been prepared as stable colloidal dispersions by modification with AHA, and subsequently biofunctionalized with the model protein avidin. Assays show that approximately eight avidin molecules are conjugated to each LaPO₄ NP. The avidin molecules on the NP surface remain active, as demonstrated by the ability of these avidin–NP conjugates to bind biotin. Since biotinylated molecules are easily obtained, we envisage the applicability of these bioconjugates in biosensing and biolabeling applications where their photostability and fluorescent properties should prove useful. Binding to biotinylated antibodies would demonstrate their use in immunofluorescence assays, particularly in ELISA-type applications. The successful bioconjugation of the AHA-functionalized LaPO₄ NPs with avidin suggests that, in principle, coupling of other biomolecules (such as protein A, antibodies, and DNA) to the rare-earth-doped LaPO₄ NPs through the same protocol is possible. Other features, such as dopant-tunable emission,[14–17] photon-upconversion properties,[31] and the possibility to detect multiple labels using a single excitation wavelength with no spectral overlap,[17] offer considerable promise for the use of biofunctionalized rare-earth-doped lanthanide phosphate NPs in various biotechnological applications.

Experimental Section

Ce/Tb-doped LaPO₄ NPs, as a powder, were kindly provided by Nanosolutions GmbH, Hamburg, Germany. The NPs were synthesized according to the method of Haase and co-workers.[16] Modification of the NPs was achieved by dispersing them with AHA in 0.1 M NaOH. The NPs were washed several times in 0.1 M tris(hydroxymethyl)aminomethane hydrochloride (Tris) buffer (pH 9) and ethanol, and then redispersed in 0.1 M Tris buffer (pH 9). For details see Supporting Information. This dispersion was colloidally stable for at

least two months when stored at 4 °C. The AHA-modified NPs were functionalized with avidin in a reaction mixture containing EDC dissolved in *N*-methyl-imidazole buffer (0.05 M, pH 7), and then redispersed in 0.05 M MES buffer, pH 4.75. For details see Supporting Information.

ζ-potentials of the NPs in aqueous solution were measured by using a ZetaSizer 2000, Malvern Instruments. DLS data were obtained with a High Performance Particle Sizer from Malvern Instruments. AUC measurements were performed on a Beckman-Coulter Optima XL-1 ultracentrifuge. UV/Vis spectra were obtained with a 8453 spectrophotometer from Agilent Technologies. The LaPO$_4$ NP molar extinction coefficient at a wavelength of 274 nm was calculated as 9.0×10^5 M^{-1} cm^{-1}, using a density of 5.0 g cm^{-3} and a radius of 3.8 nm. Fluorescence spectral measurements were performed by using a Cary Eclipse fluorescence spectrophotometer. The excitation wavelength for the LaPO$_4$ NPs was set at 254 nm. Excitation of biotinylated fluorescein was at 494 nm. TEM experiments were carried out on a Philips CM120 BioTWIN TEM operated at an acceleration voltage of 120 kV. Samples for TEM experiments were prepared by placing 3 μL of the NPs diluted 1/100 in 0.01 M Tris buffer (pH 9) on a TEM copper grid and allowing them to air dry overnight.

Binding of biotinylated fluorescein (biotin-FITC) to the avidin-functionalized NPs was tested by mixing the two components in the presence of buffer and centrifuging at 15 000 g for 15 min to sediment the NPs containing bound biotin-FITC. The fluorescence of the supernatant was measured and compared against a standard containing the same initial amount of biotin-FITC. The concentration at which the avidin-coated NPs were saturated with biotin was determined by performing the assay with final concentrations of biotin-FITC ranging from 0.05 μM to 2.5 μM. An adsorption isotherm was plotted and the amount of biotin bound to the avidin-coated NPs was determined, and hence the amount of avidin per NP (see Supporting Information). The Micro BCA Protein Assay Reagent Kit was obtained from Pierce (Rockford, IL) and used as described in the protocol (see Supporting Information)

Two- and Three-Dimensional Mesoporous Iron Oxides with Microporous Walls**

Feng Jiao and Peter G. Bruce

There is intense interest in preparing mesoporous transition-metal oxides—in part because of their potential applications, including for catalysis, electron transfer, energy conversion and storage, and as magnetic materials.[1,2] Several mesoporous transition-metal oxides have been prepared, such as TiO_2, ZrO_2, Nb_2O_5, WO_3, and MnO_x,[3,4] however, mesoporous iron oxides are of particular interest. Reversible intercalation of Li can occur for nanoparticulate Fe_2O_3, but it is much more difficult to carry out such intercalation with Fe_2O_3 of normal particle size. Similar behavior may be possible with mesoporous iron oxides since the walls are of nanodimensions. The limited dimensions of the walls will also alter the magnetic behavior from that of bulk Fe_2O_3. Although disordered iron oxides with high surface areas (ca. $270\ m^2 g^{-1}$) have been prepared, to the best of our knowledge no ordered mesoporous iron oxides have been synthesized directly.[5] Herein, we report the synthesis of ordered mesoporous Fe_2O_3 with controllable pore structures. Ordered two-dimensional (2D) hexagonal mesoporous iron oxide (2DMIO) with *P6mm* symmetry and three-dimensional (3D) cubic mesoporous iron oxide (3DMIO) with *Fm3m* symmetry have been prepared by using decylamine as the template and Fe^{III} ethoxide as the precursor. Different aging conditions were used for 2DMIO and 3DMIO, and in both cases, the walls exhibit a microporous structure.

We first confirmed successful removal of the template from 2DMIO and 3DMIO by elemental analysis. As-prepared 2DMIO contained C 44.0%, H 9.69%, and N 4.82% by weight, while the 2DMIO after ethanol extraction contained C 6.48%, H 2.17%, and N 0.28%. As-prepared 3DMIO contained C 37.9%, H 8.80%, and N 4.14%, while the values for 3DMIO after ethanol extraction were C 7.08%, H 1.71%, and N 0.35%. Based on the elemental analysis for nitrogen, about 94% and 92% of the template had been removed from 2DMIO and 3DMIO, respectively. Slightly high C and H contents were observed after removal of the template, which may correspond to a small amount of ethanol remaining in the pores ($<7\%$ by weight in both cases).

A transmission electron microscopy (TEM) image of ordered 2DMIO was recorded along the (001) direction (Figure 1a) and the corresponding electron diffraction pat-

tern (Figure 1b) confirmed a hexagonal structure over a large area. Examination of a wide range of particles demonstrated that they all had similar structures. Combining these results with the TEM result recorded along the (110) direction (Figure 1c) led to the conclusion that our 2DMIO has a large-scale well-ordered 2D hexagonal array of mesopores, similar to those typically observed in 2D hexagonal mesoporous silica materials, such as MCM-41 and SBA-15.[6] The TEM results recorded along the (110) direction confirmed that the mesoporosity exists throughout the particles, not just near surface regions. An average pore size of 70 Å and wall thickness of 40 Å, with a cell parameter a_0 of 110 Å, were estimated from the high-resolution transmission electron microscopy (HRTEM) image recorded along the (001) direction of as-prepared 2DMIO (Figure 1d). The low-angle powder X-ray diffraction (PXRD) pattern (Figure 2a) of as-prepared 2DMIO exhibits a diffraction peak at $2\theta = 1.14°$, which translates to a *d* spacing of 97.6 Å ($Fe_{K\alpha_1}$, $\lambda = 1.936$ Å). The peak may be indexed as the (100) reflection, based on the hexagonal space group *P6mm* identified by TEM/electron

Figure 2. Low-angle PXRD patterns: a) as-prepared 2DMIO; b) as-prepared 3DMIO.

diffraction analysis. The (100) reflection corresponds to a unit cell parameter a_0 of 113 Å, which is in good agreement with the TEM data. From the well-ordered hexagonal arrangement of mesopores revealed in Figure 1 a–c, peaks might also be expected in the PXRD pattern at $2\theta = 1.97$ and 2.29°, which corresponds to d spacings of 56.4 and 48.4 Å for the (110) and (200) reflections, respectively. These peaks are not evident. This appears to result, at least in part, from the existence of a broad peak in the range of 2θ from 2.2 to 4°, which corresponds to d spacings between 25 and 45 Å. Such a broad peak is consistent with disordered microporous regions within the walls as observed by HRTEM (Figure 1 f) and discussed later. After removing the template by ethanol extraction, the HRTEM image of 2DMIO (Figure 1 e) shows a smaller average pore size of 54 Å and a wall thickness of 51 Å; the reduced pore diameter is a consequence of shrinkage accompanying removal of the decylamine. Such a pore size is larger than those previously reported for mesoporous transition-metal oxides templated by alkyl amines of comparable size, such as TiO_2 and Nb_2O_5,[1,4,7] which indicates the formation mechanism may be different in the present case. Samples of 2DMIO were calcined at various temperatures to investigate the thermal stability. TEM analysis confirmed that the mesostructure was thermally stable up to 250 °C. Moessbauer measurements indicate that the Fe oxidation state is +3 (high spin) and that the iron is in an octahedral environment of oxygen atoms. More details concerning the Moessbauer studies will be published subsequently, along with magnetic measurements; however, the Moessbauer data suggest superparamagnetic behavior consistent with the small (approximately 51 Å) dimensions of the walls.

A detailed examination of the HRTEM image (Figure 1 f) for as-prepared 2DMIO shows a large quantity of disordered micropores within the walls and with pore sizes of around 10 Å. This observation suggests that the mechanism for the formation of 2DMIO mesopores may involve self-assembly of microporous structures. Further extensive studies will be

required to understand the exact nature of the formation mechanism for this micro-/mesoporous solid, including the role of the template and self-assembly of microporous structures into the micro-/mesoporous solid; this is beyond the scope of the present study. The microporosity of 2DMIO is further confirmed by nitrogen adsorption/desorption analysis. The N_2 adsorption/desorption isotherms (Figure 3 a) for
Figure 3. Nitrogen adsorption/desorption isotherms: a) 2DMIO and b) 3DMIO after ethanol extraction. The inset shows an enlarged region of the curves between relative pressures of 0.6 and 0.8.

2DMIO after removal of the template show predominantly a type I curve, thus indicating that the dominant surface area is in fact the micropores. There is a small step at a relative pressure of 0.7–0.8, which corresponds to mesoporous adsorption in 2DMIO. The identification of microporosity in the walls of mesoporous materials has only occasionally been observed before, particularly in SBA-15, MAS-7, and MTS-9.[8] There is an important and unique difference between SBA-15, MAS-7, and MTS-9 and our materials: The ratio of micropores to mesopores is much higher in the transition-metal oxides, as is evident from the small mesopore adsorption at relative pressures of 0.7 and 0.8. As the TEM image clearly indicates significant mesoporosity, we propose that the surfaces of the mesoporous walls may themselves be highly microporous so that N_2 "sees" a mainly microporous material during adsorption. The Brunauer–Emmett–Teller (BET) surface area of 2DMIO is 340 m^{2}g^{-1}.

Our approach can also be used to prepare three-dimensional mesoporous iron oxides by adjusting the aging temperature. Ordered 3D cubic mesoporous iron oxide (3DMIO) with *Fm3m* symmetry is obtained when the Fe^{III} ethoxide/decylamine mixture is further aged at 150 °C. TEM images recorded from different directions (Figure 4 a–c) confirmed the large area of ordered cubic F*m3m* mesoporous iron oxides, and Moessbauer measurements confirmed that the oxidation state is +3. The low-angle PXRD spectra (Figure 2 b) show a main diffraction peak at $2\theta = 1.06°$, which corresponds to a d spacing of 104.6 Å. The unit cell parameter a_0 calculated from the PXRD pattern is 182 Å, which is in reasonable agreement with the value of 192 Å determined

Communications

from the TEM analysis. Microporosity similar to that observed in 2DMIO is seen in 3DMIO by HRTEM (Figure 4 d) and in the N_2 adsorption/desorption analysis (Figure 3 b). The BET surface area calculated from the desorption isotherm is approximately $610 \ m^2 g^{-1}$, which is about twice that for 2DMIO, perhaps because of the higher accessible pore surface in the three-dimensional structure.

The simultaneous presence of micro- and mesoporous structures is not common. This is the first time alkyl amine templates have been used as bifunctional surfactants which can template micro- as well as mesostructures.

Experimental Section

The synthesis procedure was adapted from that employed for Nb_2O_5.[4] In a typical synthesis of 2D hexagonal ordered mesoporous Fe_2O_3, Fe^{III} ethoxide (0.573 g, 3 mmol; 99%, ABCR) was dissolved in ethanol (35 mL), with stirring for 5 minutes, followed by addition of decylamine (0.472 g, 3 mmol; 95%, Aldrich). After stirring the mixture at 40°C for 2 h, it was maintained at 40°C for 24 h, and further aged at 80°C for 6 h. In the case of 3DMIO, additional aging at 150°C was carried out. The products were then filtered and washed with ethanol. The template may be removed by extraction with excess ethanol. As-prepared material (0.1 g) was added to ethanol (100 mL) with stirring at RT for 30 min, followed by filtration and drying at 70°C under vacuum for 1 h. The materials before and after template removal were characterized by elemental analysis (Carlo Erba CHNS analyzer), TEM (Jeol JEM-2011), PXRD (Stoe STADI/P diffractometer operating in transmission mode with $Fe_{K\alpha_1}$ radiation, $\lambda = 1.936$ Å), N_2 adsorption (Hiden IGA porosimeter), and Moessbauer spectroscopy (^{57}Fe Moessbauer spectra, collected at RT on a EG&G constant accelerator spectrometer in transmission mode).

[9] Note after publication of this manuscript online on August 20, 2004 in the Early View mode: The TEM data shown in Figures 1 and 4 indicate an ordered mesostructure prior to template removal and suggest the presence of mesopores in the material after template removal, yet the N_2 isotherms do not show the typical behavior expected for large mesopores of around 5 nm. It
Figure 5. Low-angle PXRD patterns: a) as-prepared 2DMIO and b) 2DMIO after removal of the template.

should, however, be noted that pore dimensions are not well-determined by TEM. The N_2 isotherms are consistent with smaller mesopores (M. Kruk and M. Jaroniec, *Chem. Mater.* **2001**, *13*, 3169), as observed in mesoporous TiO_2 (D. M. Antonelli, *Micropor. Mesopor. Mater.* **1999**, *30*, 315), and the presence of microporosity; they also indicate that the pores are distributed in size. Further work is required to rationalize the isotherms and TEM data in detail. One possible explanation is that the pores shrink unevenly on removal of the template, thus leading to distortion of the pores and rough walls; some material may even detach from the walls and locate within the pores. As a result the pores cannot be described as regular cylinders and exhibit a smaller effective diameter than suggested by TEM. The TEM data after template removal (for example, Figure 1e) are consistent with pores that are more distorted than prior to removal of the template. An X-ray diffraction pattern after removal of the template shows one low-angle peak (see Figure 5) indicating that the pore order is not sufficient to generate higher angle peaks.

tive oxidative C−C coupling of alkylated phenols to stilbene-quinones is rare[3] and this process often requires strong oxidants.[4] To our knowledge, self-oxidation of phenols or phenol derivatives, in the absence of external oxidant, has not been reported. Herein we report an unprecedented oxidative-coupling process in which a phenolate oxygen atom serves as the oxidant, which results in cleavage of the aryl–oxygen bond. This process involves a phenolate metal complex and results in the synthesis and crystallographic characterization of a new bimetallic stilbenequinone complex having two quinonoid C=O bonds η^2-coordinated to the metal centers.[5] The metal oxidation state in the C−O cleaved product is retained. Oxidative coupling of the metal complex, can also be affected by an external oxidant, and, significantly, it is metal selective.

Treatment of the 4-methylphenol bisphosphine ligand **1**[6] with 0.5 equivalents of [{RhCl(cyclooctene)$_2$}$_2$] in CH$_2$Cl$_2$ at room temperature for 15 min followed by addition of Ag$_2$O (2–3 equiv) and continuous stirring for 5 h resulted in the selective formation of the bimetallic stilbenequinone complex **2** [Eq. (1)]. Formation of **2** was indicated by a change of the green reaction mixture to deep blue.

Self-Oxidation of a Phenolate Complex to a Bimetallic Stilbene Quinone**

Milko E. van der Boom, Tatiana Zubkov, Atindra D. Shukla, Boris Rybtchinski, Linda J. W Shimon, Haim Rozenberg, Yehoshoa Ben-David, and David Milstein*

Oxidation chemistry of phenol derivatives is of interest,[1–4] mainly since it affords convenient routes to a variety of basic chemicals.[1] Widely used phenolic food antioxidants, such as 4-methyl-2,6-di-*tert*-butylphenol (butylated hydroxy toluene, BHT) are known to form a diversity of compounds upon oxidation, including colored stilbenequinone systems.[2] Selec-

The diamagnetic complex **2** was formed quantitatively as judged by ^{31}P{^{1}H} NMR spectroscopy, isolated as a blue solid in 50% yield, and fully characterized by a combination of ^{1}H and ^{31}P{^{1}H} NMR spectroscopy techniques, UV/Vis spectroscopy, FAB mass spectrometry, and by single-crystal X-ray crystallography. The ^{31}P{^{1}H} NMR spectrum showed a doublet at $\delta = 44.18$ ppm ($^1J_{\text{Rh,P}} = 117.7$ Hz), which indicates that the phosphorus atoms are chemically equivalent and coordinated to a metal center. FAB-MS measurements showed the signal for the molecular ion (m/z 1118.307) and a correct isotope pattern. The UV/Vis spectrum of **2** exhibited one broad charge-transfer band at $\lambda_{\text{max}} = 576$ nm ($\omega_{1/2} = 77$ nm, $\varepsilon = 29 \times 10^3$ in acetone).

Dark blue crystals of complex **2** were obtained upon slow evaporation of a CH$_2$Cl$_2$ solution under a nitrogen atmosphere at room temperature. The X-ray structure of **2** reveals the formation of the bimetallic stilbenequinone structure and the rare η^2 coordination mode of the metal centers to the quinonoid C=O double bonds (Figure 1).[17]

The fourteen carbon atoms of the stilbenequinone backbone are located in the same plane with the two metal-coordinated oxygen atoms out of the plane by about 0.3 Å. The relatively short C(14)-C(14A) bond length of 1.404(5) Å may indicate a contribution of other resonance structures.[3] The phosphine groups are mutually *trans* with a significantly distorted P-Rh-P angle of 167.84(2)°. Distorted P-M-P angles are common for pincer complexes.[7] The C−O, Rh−O, and Rh−C bonds of 1.325(3), 2.0562(16), and 2.186(2) Å, respec-

Figure 1. Ortep diagram of complex **2** (thermal ellipsoids set at 50 % probability). Selected bond lengths [Å] and angles [°]: Rh(1)-O(6) 2.0562(16), Rh(1)-C(5) 2.186(2), Rh(1)-Cl(2) 2.3156(8), Rh(1)-P(3) 2.3290(7), Rh(1)-P(4) 2.3457(7), C(5)-O(6) 1.325(3), C(13)-C(14) 1.395(3), C(14)-C(14A) 1.404(5); P(3)-Rh(1)-P(4) 167.84(2).

tively, compare well with those observed for a monomeric Ir^I phenoxonium cation.[8] Other coordination modes in quinonoid systems are much more common.[9–12]

^{1}H, ^{31}P{^{1}H}, and ^{13}C{^{1}H} NMR spectroscopy measurements of a sample of the reaction mixture before addition of the oxidation reagent indicated the initial formation of the unstable Rh^{III} hydride complex **3** as the only detectable phosphorus-containing product [Eq. (2)]. Remarkably, continuous stirring of the reaction mixture for three days without Ag$_2$O in a sealed vessel with rigorous exclusion of air resulted in the disappearance of intermediate **3** with formation of the stilbenequinone **2** and complex **5** in a 1:3 molar ratio as judged by ^{31}P{^{1}H} NMR spectroscopy.
Complex **5** shows very similar spectroscopic properties to an analogous complex lacking the *p*-methyl group on the aromatic ring.[13] The ^{1}H NMR spectrum clearly shows a characteristic rhodium-hydride double triplets at $\delta = -27.53$ ppm ($^1J_{Rh,H} = 52.8$ Hz, $^2J_{P,H} = 12.0$ Hz), which collapse into a doublet in the ^{1}H{^{31}P} NMR spectrum, whereas the ^{31}P{^{1}H} spectrum shows a doublet at $\delta = 74.9$ ppm ($^1J_{Rh,P} = 115.1$ Hz). The product distribution does not change after consumption of intermediate **3**, and the stoichiometry is consistent with the formation of water. Water has been detected by GC-MS. Performing this reaction at 60 °C for three days resulted in the same outcome. Formation of complex **5** by activation of the strong aryl C–O bond at room temperature is unexpected. Only a few cases of aryl–O bond cleavage of ethers or phenols under mild homogeneous reaction conditions have been reported.[6,14,15]

Formation of complex **2** is a clear example of transition-metal-based selectivity. Treatment of compound **1** with 0.5 equivalent of [{IrCl(cyclooctene)}$_2$] resulted in O–H

activation and quantitative formation of the fully characterized Ir^{III} phenoxy hydride complex **4** [Eq. (2)]. Orange crystals of **4** were obtained from a benzene solution by slow evaporation of the solvent under N$_2$ at room temperature (Figure 2).[17] The C–O, Ir–O, Ir···C separations of 1.334(9), 2.083(5), and 2.363(8) Å are in agreement with a phenoxy type structure.[16]
Figure 2. Ortep diagram of complex **4** (thermal ellipsoids set at 50 % probability) Selected interatomic distances [Å] and angles [°]: Ir(1)-O2 2.083(5), Ir(1)···C1(1) 2.363(8), Ir(1)-Cl(1) 2.349(3), Ir(1)-P(2) 2.354(1), Ir(1)-P(3) 2.363(72), C1(1)-O(2) 1.334(9); P(2)-Ir(1)-P(3) 163.97(8).

In sharp contrast to the aforementioned reactivity of the analogous Rh^{III} hydride complex **3**, no formation of bimetallic compounds or other iridium complexes was detected even after three days of heating at 60 °C in THF in a sealed pressure tube. Attempts to oxidize complex **4** with Ag$_2$O, O$_2$, ferrocenium hexafluorophosphate, and cyclic voltammetry resulted in an indicative color change from red to purple but ^{31}P{^{1}H} NMR spectroscopy measurements showed mixtures of unidentifiable compounds. Apparently the metal center plays an important role in the stilbenequinone complex formation. Although in both cases (**3**, **4**) a d^6 metal center is used, the second-row metal hydride complex **3** is less stable and readily undergoes stilbenequinone formation whereas the third-row metal hydride complex **4** is far more thermally robust but exhibits an unselective reactivity pattern.

Mechanistically, it is likely that the room-temperature dearomatization and dimerization of complex **3** at the methyl group to form **2** proceeds via a *p*-quinonemethide intermediate. An unusual series of monomeric phosphorus–carbon–phosphorus(PCP)-type Rh^I and Ir^I quinone methide complexes (C=C bond bound to the metal center) have been isolated.[11] Formation of a strong metal–olefin bond may contribute to the stability of these compounds, whereas the Rh^I intermediate proposed herein (C=O bond bound to the metal center) undergoes oxidative coupling to afford **2**. However, other mechanistic pathways are also possible. The steric hindrance provided by the two bulky CH$_2$PtBu$_2$ groups and stabilization of the *p*-quinonemethide structure by η^2-C=O bond coordination to the low-valent rhodium center may allow this postulated intermediate sufficient lifetime to

interact with a second intermediate. No coupling products with complex **5** or solvents were detected. It is remarkable that quantitative formation of the stilbenequinone complex **2** occurs even in the absence of an added oxidant. The Rh[III] hydride intermediate **3** plays a dual role—as precursor for formation of stilbenequinone complex **2** and as an oxygen-transfer agent. Examples of chemical processes wherein one metal complex fulfills two or more distinctly different tasks are not common.

In summary, a unique oxidative dimerization process of a phenolic compound has been observed with a pincer model system, in which the phenolic oxygen atom itself serves as an oxidant by aryl–oxygen and C–H cleavage, leading to a new metal complex. The oxidative dimerization process can also be affected by an external oxidant. The process is metal selective.

α,α-Difluoro-*H*-phosphinates: Useful Intermediates for a Variety of Phosphate Isosteres

Arnaud Gautier,* Goulnara Garipova, Carmen Salcedo, Sébastien Balieu, and Serge R. Piettre*

Dedicated to Professor Clayton Heathcock

Research efforts have long since established *H*-phosphinates **1** as important and valuable intermediates for the preparation of bioactive analogues of natural phosphates (Scheme 1).[1] Despite various methodologies for their easy preparation, the synthesis of phosphonate **2**, phosphonothioates **3**, and phosphinates **4** remains an area of intense activity.[2]

Moreover, major progress has been made in the chemistry of α,α-difluorophosphonates **7** since their introduction slightly more than two decades ago.[3] Indeed, physicochemical studies have provided some rationale for the isosteric behavior of the above functional group to the phosphate group, and numerous applications have flourished.[4] Among these, analogues targeting phospholipase C (PLC), purine nucleoside phosphorylase (PNP), and protein phosphotyrosine, phosphoserine, or phosphothreonine phosphatases have been reported.[5] This functional group has also been success-

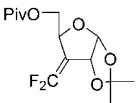
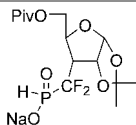
fully used to mimic the phosphate group in nucleotide monophosphates and triphosphates: analogues of adenosine monophosphate, cyclic adenosine monophosphate, adenosine triphosphate, and adenosyl adenosine triphosphate, as well as structurally related potent inhibitors of the reverse transcriptase of human immunodeficiency virus (HIV), have been described in the literature.[6]

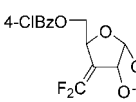
Despite their potential both as a new class of isosteres of natural phosphates and as important intermediates in the synthesis of numerous α,α-difluorinated organophosphorus compounds, reports on fluorinated *H*-phosphinates **5** are scarce.[7] The main reasons behind this situation are the synthetic problems underlying their preparation. Indeed, processes such as nucleophilic substitution of halodifluorinated centers (including the Arbuzov reaction) have long been known to be disfavored,[8] and we and others have confirmed the sluggishness of phosphorus-centered radicals with respect to addition onto difluoroalkenes, when compared to their nonfluorinated analogues.[9] In this context, we found that the sodium salt **6** of hypophosphorous acid behaves in a unique way, and have developed an efficient and practical preparation of α,α-difluoro-*H*-phosphinates. As shown below, these compounds can be easily transformed into difluorophosphonates **7**, difluorophosphonothioates **8**, and difluorophosphinates **9** (Scheme 1).

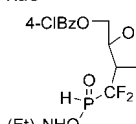
When a solution of **6** (0.2 M, 1.3 equiv) in methanol was refluxed for four hours with difluoroalkene **10–13** in the presence of *tert*-butyl peroxypivalate (TBPP) or *tert*-butyl 2-ethylhexyl peroxycarbonate (TBEC)[10] as a radical initiator, complete consumption of the substrate occurred and led to the formation of a single product in each case. A simple workup led to the isolation of products **14–17** in 75, 85, 83, and 80% yield, respectively, in the case of TBPP (Table 1). Later, we found that the Et$_3$B/O$_2$ system also allows a smooth conversion to take place.[11] The α,α-difluoro-*H*-phosphinates are stable for weeks under standard conditions (room temperature and air). As expected, the ^{31}P NMR spectra of compounds **14–17** displayed signals around 20 ppm with a P,H coupling constant of 590 Hz and P,F coupling constants of about 120 Hz. Similarly, the ^{19}F NMR spectra were characterized by signals with two-bond F,P and three-bond F,H couplings, in accordance with the depicted structures. Additionally, FTIR signals were detected at 1250(s) and around 2370(m) cm^{-1}, which correspond to the P=O and P–H bonds, respectively.[7]

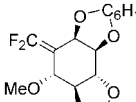
The weak phosphorus–hydrogen bond present in adducts **14–17** renders it prone to homolytic cleavage and highlights the possibility of generating yet another phosphorus-centered radical by treating these compounds with a radical initiator, and of a second radical addition on an alkene. Thus, interaction of a 1.6 M methanolic solution of **15** with methylenecyclohexane in the presence of a catalytic amount of radical initiator (TBPP) led to the formation of the expected α,α-difluorophosphinic acid, which was isolated in the form of its methyl ester **18** (diazomethane) in 53% yield (Scheme 2). A similar two-step process involving sequential addition of 4-phenylbut-1-ene and diazomethane gave methyl difluorophosphinate **19** in 80% yield.

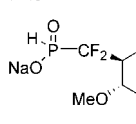
The documented tautomeric equilibrium between an *H*-phosphinate and the corresponding phosphite led us to envision the possible transformation of α,α-difluoro-*H*-phosphinates into the corresponding bis-*O,O*-silylated difluoroal-
Scheme 2. Transformation of α,α-difluoro-*H*-phosphinates into difluorophosphonates, difluorophosphonothioates, and difluorophosphinates. a) 1. Alkene, **6** (0.3 equiv), C$_6$H$_6$, 55 °C, 18 h; 2. CH$_2$N$_2$, Et$_2$O, 12 h; b) bis(trimethylsilyl)acetamide (BSA, 3 equiv), CH$_2$Cl$_2$, 25 °C, 1 h; c) O$_2$, CH$_2$Cl$_2$, 25 °C, 0.5 h; d) S$_8$, CH$_2$Cl$_2$, 25 °C, 0.5 h; e) 1. but-3-en-2-one, BSA (3 equiv), CH$_2$Cl$_2$, 25 °C, 18 h, 2. CH$_2$N$_2$, Et$_2$O, 12 h; f) 1. pivaldehyde, BSA (5.5 equiv), CH$_2$Cl$_2$, 25 °C, 3 h; 2. CH$_2$N$_2$, Et$_2$O, 12 h.


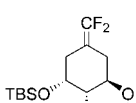


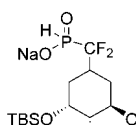












kylphosphites, and the use of the nucleophilic P^{III} species.[12] Accordingly, treatment of **16** with a threefold excess of trimethylsilyl chloride (TMSCl) and pyridine led to quantitative formation of the corresponding air-sensitive phosphites **20** and **21**, as demonstrated by a shift of the ^{31}P NMR signals to about 130 ppm, and the lack of any one-bond P,H coupling. Exposure of the bis-*O,O*-trimethylsilyl phosphites to oxygen or elemental sulfur quickly transformed these products into difluorophosphonates **22** or difluorophosphonothioates **23**.

Interactions between bissilylated difluoroalkylphosphites and electrophilic carbon atoms were exemplified through the 1,2- and 1,4-addition reactions (Abramov and Pudovic reactions, respectively).[13] Thus, a degassed solution of **15**, methyl vinyl ketone, BSA, and TMSCl in dichloromethane was stirred at room temperature, and the crude sample was sequentially subjected to a classical workup and treatment with diazomethane, which delivered difluorophosphinate **24** in 57% yield. Similarly, trimethylacetaldehyde (pivalaldehyde) reacted with **21** to furnish α,α-difluoro-α′-hydroxyphosphinate **25** (64% yield). Few examples of difluorophosphinates have so far been reported,[2b,9a,14] and the present methodology constitutes the first general preparation of these compounds. It was particularly gratifying to note that the presence of the fluorine atoms did not prevent the P^{III} species from interacting with electrophiles.

The scope of the methodology was investigated by developing an application in the field of ribofuranosyl and cyclitol phosphates. Thus, reaction between **6** and ribofuranose derivatives **26** or **27** resulted in complete conversions, and the desired adducts **30** and **31** could be isolated in yields of 78 and 63%, respectively (Table 2). Similarly, cyclitol derivatives **28** and **29** reacted smoothly with **6** to deliver compounds **32** and **33** in good yields. These results are significant in light of the complete lack of reactivity of both diethyl phosphite and diethyl thiophosphite under similar conditions.[15]

Table 2 clearly indicates the complete failure of any addition process in the case of phosphonyl and phosphonothioyl radicals, despite the demonstrated higher reactivity of the latter.[9a–b,16] The involvement of a tautomeric P^{III} species of the radical generated from **6** has been ruled out by Beckwith,[17] and the nature of this radical and those generated from phosphites and thiophosphites should therefore be similar. Additional physicochemical studies will be needed to explain the peculiar, but synthetically useful, behavior of **6** and shed light on the steric and electronic factors at play in this reaction.[18] α,α-Difluoro-*H*-phosphinates **30** and **31** are useful intermediates to various compounds with potential applications in the fields of modified nucleotides and oligonucleotides (hence the antisense and

antigene strategies). For example, *H*-phosphinate **30** was easily transformed into difluorophosphonate **34** and difluorophosphonothioate **35** by treatment with TMSCl, pyridine, and the requisite O$_2$ or S$_8$ (Scheme 3).[2a,15,19] In addition, *H*-phosphinate **31** could easily be esterified by reaction with ribofuranose **36** in the presence of dicyclohexylcarbodiimide (DCC) and trifluoroacetic acid (TFA). The resultant *H*-phosphinate was treated with sulfur and TMSCl in pyridine to

Communications

afford difluorophosphonothioic acid monoester **37** in 50 % yield (a 1:1 mixture of two diastereoisomers at the phosphorus center).[2a] This last result demonstrated the efficacy of the methodology in providing precursors of modified dinucleotides with new phosphorus-centered linkers.

In summary, radical addition of **6** on *gem*-difluoroalkenes constitutes a powerful method of constructing the previously unreported α,α-difluoro-*H*-phosphinates. This new functional group is easily and efficiently transformed into difluorophosphonates, difluorophosphonothioates, and difluorophosphinates. The methodology can be expected to have a major impact on the preparation of difluorophosphonyl, difluorophosphonothioyl, and difluorophosphinyl analogues of natural phosphates.

Experimental Section

General procedure for the synthesis of α,α-difluoro-*H*-phosphinates using *tert*-butyl peroxypivalate or *tert*-butyl 2-ethylhexyl peroxycarbonate as initiator: The requisite 1,1-difluoroalkene[20–22] (1.0 equiv) and initiator (0.3 equiv) were added to a solution of hypophosphorous acid sodium salt monohydrate (0.2 M, 1.3 equiv) in degassed methanol. The solution was refluxed for 4 h under a nitrogen atmosphere and cooled to room temperature. The solution was poured into water and the aqueous phase was extracted with diethyl ether and lyophilized after separation of the layers. The solid was dissolved in aqueous $NaHSO_4$ (2.0 M) and extracted with dichloromethane. The organic layer was dried and evaporated to give a viscous oil.

Gram-scale synthesis of **31**: Hypophosphorous acid sodium salt monohydrate (1.24 g, 1.7 mmol, 4.0 equiv) was added to a solution of **27** (1.0 g, 2.8 mmol, 1.0 equiv) in nondegassed methanol (25 mL) at room temperature in an open flask. Triethylborane (5 mL, 1 M solution in hexane, 5.0 mmol, 5.0 equiv) was added under vigorous stirring, and the solution was stirred for 10 min. This operation was repeated twice. The fast addition of Et_3B solution was crucial. After the third addition of Et_3B, the solution was stirred for 1 h and then the solvent removed by evaporation. Water (50 mL) was added and the aqueous layer was extracted with ethyl acetate (20 mL). The aqueous layer was lyophilized and the crude solid was dissolved in aqueous triethylammonium carbonate (1.0 M, 30 mL). The solution was extracted twice with dichloromethane (30 mL); the organic layer was dried and evaporated to give a viscous oil (930 mg, 63 %). $[\alpha]_{20}^{D} = +33.9$ (*c* = 1.08 in $CHCl_3$); ^1H NMR (200 MHz, $CDCl_3$): δ = 7.10 (dd, *J* = 556 Hz, *J* = 6 Hz, 1 H), 7.92 (d, *J* = 8.7 Hz, 2 H), 7.33 (d, *J* = 8.7 Hz, 2 H), 5.80 (d, *J* = 3.9 Hz, 1 H), 5.04 (t, *J* = 3.9 Hz, 1 H), 4.8 (m, 1 H), 4.73 (d, *J* = 12 Hz, 1 H), 4.32 (dd, *J* = 12 Hz, *J* = 5.5 Hz, 1 H), 3.00 (q, *J* = 7.3 Hz, 6 H), 2.70 (m, 1 H), 1.50 (s, 3 H), 1.26 (s, 3 H), 1.26 ppm (t, *J* = 7.3 Hz, 9 H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 165.1, 139.1, 130.9, 128.4, 128.1, 120.2 (td, *J* = 257 Hz, *J* = 121 Hz, CF_2), 112.5, 104.7, 79.4 (d, *J* = 7.6 Hz), 74.4, 64.6, 49.0 (td, *J* = 22.7 Hz, *J* = 13.6 Hz), 45.3, 26.3 (d, *J* = 6.1 Hz), 8.26 ppm; ^{31}P NMR (81 MHz, $CDCl_3$): δ = 9.7 ppm (dd, *J* = 92 Hz, *J* = 86 Hz); ^{19}F NMR (188 MHz, $CDCl_3$, C_6F_6): δ = 51.5 (ddt, *J* = 301 Hz, *J* = 85 Hz, *J* = 10 Hz), 47.4 ppm (ddd, *J* = 301 Hz, *J* = 92 Hz, *J* = 23 Hz); IR (NaCl): $\tilde{\nu}$ = 2986, 1721, 1455, 1275, 1091 cm^{-1}. MS (MALDI, matrix: 2,4,6-trihydroxyacetophenone) *m/z* = 425.1 [*M*−102.1].

37: Compound **24** (58 mg, 0.28 mmol, 1.5 equiv), DCC (118 mg, 0.76 mmol, 4.0 equiv), and trifluoroacetic acid (72 μL, 0.95 mmol, 5.0 equiv) were added to a solution of **31** (100 mg, 0.19 mmol, 1.0 equiv) in degassed dichloromethane (3 mL). A white precipitate immediately formed and the slurry was stirred for 10 min. Powdered S_8 (200 mg, 6.2 mmol, 32.6 equiv), pyridine (1 mL, 12.2 mmol, 43.8 mmol), and TMSCl (1 mL, 7.9 mmol, 28.1 equiv) were then added sequentially. The reaction was stirred for an additional 15 min, then water (1 mL) was added, and the solution was filtered. The filtrate was extracted with ice-cold aqueous HCl (0.1 M, 10 mL), washed with aqueous triethylammonium carbonate (1.0 M), and evaporated. The residue was purified by flash chromatography over silica gel (AcOEt/MeOH/triethylamine 90:8:2) to give a viscous oil (70 mg, 50 %) as a 1:1 mixture of two diastereoisomers (stereogenic phosphorus atom). A second chromatography procedure was performed which allowed partial separation of one of the diastereoisomers from the mixture. $[\alpha]_{25}^{D} = +17.2$ (*c* = 0.5 in $CHCl_3$); ^1H NMR (200 MHz, $CDCl_3$): δ = 8.00 (d, *J* = 8.4 Hz, 2 H), 7.30 (d, *J* = 8.4 Hz, 2 H), 5.80 (d, *J* = 3.7 Hz, 1 H), 5.10 (t, *J* = 3.7 Hz, 1 H), 4.90 (s, 1 H), 4.82 (d, *J* = 5.8 Hz, 1 H), 4.70 (dd, *J* = 10.2 Hz, *J* = 3.6 Hz, 1 H), 4.54 (d, *J* = 5.8 Hz, 1 H), 4.40–3.90 (m, 4 H), 3.30 (s, 3 H), 3.10 (q, *J* = 7.3 Hz, 6 H), 1.50 (s, 3 H), 1.4 (s, 3 H), 1.3–1.2 ppm (m, 16 H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 165.4, 139.2, 131.0, 128.6, 128.4, 112.5, 111.9, 109.0, 104.5, 85.4, 84.9, 81.6, 80.4(m), 75.0, 66.7, 65.1, 54.6, 47.4(m), 45.4, 26.8, 26.3, 26.3, 24.8, 8.3 ppm (CF_2 not observed); ^{31}P NMR (81 MHz, $CDCl_3$): δ = 61.5 ppm (dd, *J* = 93 Hz, *J* = 90 Hz); ^{19}F NMR (188 MHz, $CDCl_3$, C_6F_6): δ = 56.4 (ddd, *J* = 306 Hz, *J* = 97 Hz, *J* = 14 Hz), 50.0 ppm (ddd, *J* = 306 Hz, *J* = 97 Hz, *J* = 17 Hz); IR (NaCl): $\tilde{\nu}$ = 2987, 2935, 1722, 1274, 1108, 1093, 1013 cm^{-1}; MS (MALDI, matrix: 2,4,6-trihydroxyacetophenone) *m/z* = 643.1 [*M*−103.1].

Metallamacrocycles

A Simple, One-Step Procedure for the Formation of Chiral Metallamacrocycles**

Katie Campbell, Charles A. Johnson II,
Robert McDonald, Michael J. Ferguson,

Dedicated to Professor Larry Scott
on the occasion of his 60th birthday

Metal-directed self-assembly reactions have become a powerful method used for the construction of supramolecular architectures including molecular squares, cages, and other polygons, as well as numerous polymeric and dendrimeric species.[1] In the last decade, scientists have become particularly intrigued with the effect of incorporating chiral ligands/groups into metallosupramolecular systems. These materials have demonstrated potential in numerous enantioselective processes including asymmetric catalysis,[2] chemical sensing,[3] and selective guest inclusion.[4]

Communications

In most cases, the synthesis of metal-containing chiral supramolecules involves derivatization of an enantiopure building block, as in the numerous chiral binaphthyl-based molecules. Using a typically step-wise process, these chiral segments are elaborated with functionality capable of binding to a metal or metal ion, such as pyridyl and alkynyl moieties.[5] These larger segments are then assembled into the desired supramolecule, and this ultimately provides a chiral metal-containing architecture of predictable size, shape, and function.

The most costly component of a chiral framework is nearly always the optically pure building block. Thus, a synthetic sequence that initiates from a chiral building block will inherently suffer from losses due to subsequent synthetic and purification steps.[2,3] A more attractive approach would be a method that introduced chirality after construction of the desired supramolecular assembly. This approach would not only circumvent waste of the chiral building block prior to the ultimate synthetic step, but would also facilitate the divergent preparation of both enantiomers of a given target from a common precursor. Described herein is a simple and general protocol that provides economical access to chiral metal-containing molecules by ligand exchange between *trans* platinum acetylide complexes (**1**) and the chiral diphosphine ligands (*R,R*)- and (*S,S*)-chiraphos (Scheme 1).

Metal-organic frameworks can be expediently accessed by the conversion of terminal acetylenes (**2**) into *trans* platinum acetylide complexes (**1**) by reaction with [PtCl$_2$(PR$_3$)$_2$].[6] It has been established that transformation of *trans* complexes **1** into their *cis* counterparts **3** can be readily accomplished by ligand exchange with a chelating diphosphine ligand,[7] provided the lability of the exiting phosphine ligand is carefully controlled. In the case of *trans* acetylides with PEt$_3$ ligands (e.g., **1**, R = Et), ligand exchange to give the *cis* derivatives **3** is either extremely slow or completely retarded in reactions with dppee.[7] The *trans* complexes **1** with pendant PPh$_3$ ligands, on the other hand, are readily converted to their *cis* counterparts **3** in good to excellent yield, when using dppee to effect ligand exchange.

For the current study, formation of requisite *trans* platinum complexes **4a–e** (Schemes 2 and 3) was effected by treating the appropriate terminal acetylene with [PtCl$_2$(PPh$_3$)$_2$] in degassed Et$_2$NH with a catalytic amount of CuI.[8] In the case of cyclic derivatives such as **4b–e**,
Scheme 1. Construction of achiral and chiral *cis* platinum acetylide complexes by ligand exchange.
Scheme 2. Synthesis of chiral *cis* acetylide complex **5a**.
Scheme 3. Synthesis of chiral macrocycles **5b–f**. a) (*S,S*)-chiraphos, CH$_2$Cl$_2$, RT; b) (*R,R*)-chiraphos, CH$_2$Cl$_2$, RT.

high dilution was used to facilitate closure of the macrocyclic skeleton. All *trans* complexes were readily purified by either selective precipitation or flash chromatography on silica gel.

To probe the transformation of the achiral complexes into chiral supramolecules, the acyclic system **4a** was used as a model system. Treatment of **4a** with (*S,S*)-chiraphos in CH$_2$Cl$_2$ at RT for 14 h cleanly formed the chiral *cis* complex **5a** in 89% yield (Scheme 2). This protocol was next applied to a structurally diverse selection of metallamacrocycles **4b–e**.[9] Gratifyingly, the reaction of these *trans* acetylide complexes with (*S,S*)-chiraphos under analogous conditions led to the *cis* acetylide macrocyclic complexes **5b–e** in good to excellent yields. The reaction of **4e** with the ligand (*R,R*)-chiraphos to give **5f** was equally successful, highlighting the economy of our methodology which allows for the divergent generation of both enantiomeric macrocycles, **5e** and **5f**, from **4e** by simply changing the ligand system in the final step of the synthesis. Thus, this one-step transformation is equally effective for carbocyclic systems such as **5b,c** and complexes with pyridine rings containing one (**5d**) or two metal centers (**5e**,**f**). The successful formation of **5d–f** is noteworthy as they are excellent candidates for use as chiral building blocks in self-assembly reactions, through coordination through the pyridine unit(s).[10]

The formation of **5a–f** is easily monitored by ^{1}H and ^{31}P NMR spectroscopy. The alkyl protons of the free ligand, (*S,S*)-chiraphos, appear as a multiplet (methine) and quartet (methyl) at $\delta = 2.50$–2.43 and 1.17 ppm, respectively. Upon binding to the metal center, these protons are shifted upfield and appear as broad multiplets centered at $\delta = 2.49$–2.16 and 0.95–0.84 ppm, respectively. Even more diagnostic are the ^{31}P NMR spectra. The free chiraphos ligand gives rise to a singlet at $\delta = -8.7$ ppm that diminishes in intensity as ligand exchange proceeds, while the resonance of uncoordinated PPh$_3$ emerges at $\delta = -4.4$ ppm. Concurrently, the intensity of the ^{31}P NMR resonance from the ligated PPh$_3$ of the *trans* acetylide complex **4**, observed at $\delta = 18$–21 ppm, disappears as the reaction proceeds. It is replaced by a new resonance at $\delta = 42$–47 ppm from the chiraphos ligand bound to platinum in complex **5**. As the coordination geometry about the platinum center changes from *trans* to *cis*, a diagnostic change in the coupling constant $J_{P\text{-Pt}}$ is also observed (2600–2720 Hz for **4a–e**, 2190–2250 Hz for **5a–f**).

It is well known that five-membered chelate rings can adopt two puckered, chiral conformations (Figure 1).[11] In the presence of stereogenic centers (as is the case with chiraphos), these two conformations become diastereomeric, and one conformation is therefore energetically more favorable. For (*S,S*)-chiraphos, the most stable conformation is the one in
which the substituents of the chelate ring are equatorially disposed (the δ conformation). As a result of this conformational preference, the phenyl groups on the phosphorus centers are locked into a chiral arrangement. It is through this arrangement that the chiraphos ligand can convey chirality to the entire molecular framework by the steric influence of the phenyl groups of the phosphine, which is relayed to other ligands bonded to platinum.

Conclusive structural proof of the chiral structures of **5a** and **5d** as a result of the chiraphos ligand has been provided by single crystal X-ray crystallographic analysis. The ORTEP drawing of **5a** (Figure 2) shows that the complex is in the
Figure 2. ORTEP drawing of **5a** (20% probability level; solvent molecules and all but the *ipso* carbon atoms of the phenyl rings have been removed).

expected δ conformation in which the two methyl groups of the chiraphos ligand are pseudoequatorial.[12] The coordination geometry about the platinum center is square planar with angles of 86.29(2)° (P1-Pt-P2) and 87.93(9)° (C3-Pt-C5) which are comparable to other Pt^{II}–chiraphos complexes.[13] All other angles and bond lengths are unremarkable.

The solid-state structure of **5d**, by contrast, shows several unexpected features. Complex **5d** crystallizes with two independent molecules in the unit cell (molecule A is shown in Figure 3).[14] While much of the macrocyclic core is nearly planar, the structure pivots dramatically at the alkylidene carbons C17 and C23 to accommodate the *cis* acetylide linkage to platinum. In spite of the inherent strain, the coordination geometry about the platinum center remains unchanged with bond angles about the metal of 87.5(6)° (C20-Pt1-C21) and 86.04(16)° (P1-Pt1-P2). The strain imparted by the *cis* conformation is therefore borne almost exclusively by the enyne core of the macrocycle, as evidenced by the alkylidene and alkyne bond angles, which have mean values of 112.2° and 172.3°, respectively.

The most remarkable feature of the solid-state structure of **5d** is that the Chiraphos ligand has adopted a λ conformation, which places the two methyl groups in pseudodiaxial positions with a dihedral angle C43-C41-C42-C44 between the methyl groups of 166.2° (molecule B is similar, with C43-C41-C42-C44 = 167.4°). This is only the second example of Chiraphos adopting this conformation (in

Figure 1. δ and λ conformations resulting from bonding of (*S,S*)-chiraphos to platinum.

Communications
Figure 3. ORTEP drawing of molecule A of **5d** (20% probability level; solvent molecules and all but the *ipso* carbon atoms of the phenyl rings have been removed).

the solid-state) that could be found in the Cambridge structural database.[15] It is speculated that this unusual result is directed by steric interactions between the phenyl groups on the diphosphine ligand and the pendant diphenylalkylidene groups of the macrocycle.

The CD spectra for chiral *cis* complexes **5a–f** are shown in Figure 4. The CD curve for complex **5b** shows the strongest
Figure 4. CD spectra for **5a–f** in CH_2Cl_2.

response and is dominated by two intense Cotton effects that form a negative couplet centered at $\lambda = 358$ nm, attributable to the $\pi \rightarrow \pi^*$ transition.[16,17] A third, positive Cotton effect is observed at high energy ($\lambda \approx 260$ nm). The CD curves for complexes **5e** and **5f** demonstrate several moderately strong signals, and the two spectra mirror each other in both form and intensity, consistent with an enantiomeric relationship. More specifically, these spectra show two bisignate signals, centered at $\lambda \approx 360$ and 305 nm. The lower energy couplet likely arises from the MLCT absorption band, whereas the high-energy band is associated with an unassigned transition

in the UV/Vis absorption spectrum at $\lambda = 305$ nm. Unlike complexes **5b** and **5e,f**, the remaining complexes, acyclic **5a** and the more strained macrocycles **5c** and **5d**, show only weaker, high-energy signals in the lower energy region of the CD spectra.

The solid-state and CD spectroscopic data for **5a–f** unambiguously demonstrate the ability of the chiraphos ligand to efficiently transfer chirality to the conjugated molecular framework of platinum acetylide complexes. There are, however, several important design considerations that appear to govern this process. As demonstrated by CD spectroscopy, the chiral influence from chiraphos is strongest when the acetylenic chromophore attached to the platinum metal center is large and sufficiently rigid to interact with the chiral array of phenyl groups on the diphosphine ligand, as observed for macrocycles **5b** and **5e–f**. The macrocycle must also, however, maintain sufficient conformational mobility to be biased by this interaction, that is, when the macrocycle is too strained or rigid, the chiral influence is minimal, as observed for **5c** and **5d**. Optimization of this process and the formation of chiral, conjugated frameworks using ligand-exchange methodology with other chiral phosphine ligands are currently underway.

available atropisomeric P,N ligands (pinap)[5] that are structurally similar to quinap and have parallel reactivity. They
have the additional advantage, however, that, unlike quinap, they are conveniently prepared and resolved as well as easily amenable to structural and electronic modifications. We describe their synthesis, as well as applications in reactions involving Rh, Ag, and Cu catalysts, which demonstrate their utility. In the Cu-catalyzed coupling of acetylenes and imines they are superior to quinap and afford products with the highest enantioselectivity reported to date.

Quinap was developed by Brown and co-workers in 1993.[6] The six-step sequence for its synthesis includes a Pd-catalyzed coupling of 2-methoxy-1-naphthylboronic acid and 1-chloroisoquinoline to generate the biaryl scaffold. After introduction of the phosphinyl group, the resolution of the enantiomeric atropisomers is carried out as the final step by treatment of (±)-quinap with a preformed chiral Pd complex prepared from (R)- or (S)-N,N-dimethyl-1-naphthalen-1-ylethylamine.[7] Quinap is commercially available, but it is rather expensive.[8] The design and synthesis of related biaryl P,N ligands has been the focus of numerous research groups.[2a, c] However, resolution of the ligands has proven difficult and has inevitably involved fractional crystallization of diastereomeric Pd complexes. This has limited the extent of structural and electronic modification that can be examined with this scaffold.

Key to our ligand design is the use of a covalently bound chiral group, which facilitates resolution at any of the various steps of the ligand synthesis. As shown in Scheme 1, the core of the ligand is easily accessed by coupling 1,4-dichlorophthalazine with 2-naphthol to give **1** in 77% yield.[9] Importantly, the use of the dichlorophthalazine allows both convenient construction of the biaryl unit and subsequent introduction of a chiral amine or an alcohol.

Treatment of **1** with (R)-phenylethanol afforded the diastereomeric aryl ethers (82% yield, d.r. = 1:1), which were subsequently converted into triflates **2** (91% yield). Ni-catalyzed coupling of **2** with HPPh₂ furnished ligands **3a** and **3b** in 70% combined yield. The two atropisomeric diastereomers were separated at this stage either by chromatography on silica gel or, alternatively, by crystallization.[10] The absolute configuration of **3a** was shown to be *R,M* by X-ray structure analysis.[11]

The synthesis of a related structure incorporating (R)-(+)-α-phenethylamine was carried out similarly (Scheme 1). Ligands **5a** and **5b** were isolated in 69% yield over three

Readily Available Biaryl P,N Ligands for Asymmetric Catalysis**

*Thomas F. Knöpfel, Patrick Aschwanden,
Takashi Ichikawa, Takumi Watanabe, and
Erick M. Carreira*

The discovery and development of new chiral ligands for transition-metal complexes is critical for expanding the scope of catalytic asymmetric synthesis.[1] The P,N ligands are a highly successful class,[2] in which quinap[3] holds a special place because it displays unique reactivity and selectivity[4] (e.g. in hydroboration,[4a] alkyne addition,[4c] diboration[4d] and azomethine cycloaddition).[4e] Herein, we present new, readily

steps (d.r. = 1:1.2). These ligands are conveniently separated by crystallization or chromatography on silica gel.[10] The stereochemistry of **5a** was assigned unambiguously by X-ray structure analysis.[11]

We tested these ligands in three different reactions. In the Rh-catalyzed hydroboration[12] the cationic Rh^I complex formed with **3a** proved to be optimal,[13] leading to optically active alcohols in 2 h using 1 mol% catalyst (room temperature). The regio- (86:14 to >99:1) and enantioselectivity (84–92% *ee*; Table 1) are comparable to those reported for

Table 1: Rh-catalyzed hydroboration.

Entry	R	Yield [%]	*ee* [%]	Quinap [% *ee*][4a]
1	Ph	73	92	92
2	*p*-Tol	94	92	89
3	*m*-Tol	85	84	86
4	*o*-Tol	81	91	92
5	*p*-MeO-C$_6$H$_4$	80	90	94
6	*p*-Cl-C$_6$H$_4$	87	87	78

quinap, which is the ligand that demonstrates the broadest scope for this reaction.[4a] Interestingly, an important difference in reactivity was observed for the Rh^I complex of **3a** when compared to previous work. Thus, in contrast to reactions with quinap, the electronics of the aryl substrate exerted little influence on the *ee* value of the product (Table 1, entries 5 and 6), indicating an unanticipated advantage of the complex derived from **3a**.

The asymmetric, Ag-catalyzed azomethine cycloaddition reaction with acrylates first reported by Zhang et al.[14] was examined next. Its substrate scope has been recently expanded by using a Ag–quinap catalyst.[4e] We have observed

that 3 mol% of the putative Ag^I complex of **3a** catalyzes the reaction, affording adducts with high yields and enantioselectivities (Scheme 2).[15]
Scheme 2. Ag-catalyzed azomethine cycloaddition reaction with acrylates.

Our interest in the chemistry of terminal acetylenes[16] compelled us to examine the ligands in the Cu-catalyzed reaction of alkynes and imines. First reported in 1963,[17] these additions have been recently investigated by Knochel et al. with the complex formed by quinap and CuBr.[4c] We have observed that the Cu^I complexes of **5a** and **5b** catalyze the formation of the propargylic amines in 90–99% *ee*,[18] which are the best values obtained to date (Table 2).

Table 2: Cu-catalyzed addition of alkynes to imines.

R	R'	Ligand	Yield [%]	*ee* [%]	Quinap [% *ee*][4c]
*i*Pr	Me$_3$Si	**5a**	84	98 (R)	92
		5b	82	99 (S)	
*i*Pr	Ph	**5a**	88	90 (R)	84
		5b	82	95 (S)	
*i*Bu	*n*Bu	**5a**	74	91 (R)	82
		5b	72	94 (S)	

In the examined reactions, the configuration of the biaryl moiety dictates stereoinduction. It is noteworthy that in this process subtle remote effects are observed with respect to the stereogenic center in the phenethyl group. Thus, when compared to **5a**, the use of the diastereomeric ligand **5b** can lead to a measurable and consistent increase (up to 5%) in the *ee* value of the product (Table 2). Interestingly, in these additions it is the *R,P*-configured ligand that affords the higher selectivities, whereas in the hydroboration and cyclo-addition reactions the *R,M*-configured ligands proved superior.

In conclusion, we have presented a new class of P,N ligands and demonstrated their utility in three different asymmetric reactions with three different metals. The efficiency (four steps from commercially available material) and modular nature of the synthesis should permit fine tuning of the ligand to accommodate a broad scope of asymmetric transformations. Further studies aimed at diversifying the structure of the ligands and their application in new reactions are underway in our laboratories.

[10] Depending on the scale, different separation procedures were applied. Typically on >2 g scale either **3a** or **5a** was selectively crystallized from the mixture (see Supporting Information for details), and the residue was purified by flash chromatography. On a smaller scale the diastereomers were separated by flash chromatography; for example, 1.21 g of a mixture of **3a/3b** was separated by flash chromatography to give **3a** (595 mg) and **3b** (501 mg; 91% mass recovery).

Label-Free Assay

Profiling Kinase Activities by Using a Peptide Chip and Mass Spectrometry**

Dal-Hee Min, Jing Su, and Milan Mrksich

Herein we describe a strategy that combines peptide chips with matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (MS) to evaluate kinase activities rapidly and semi-quantitatively. We have already shown that monolayers of alkanethiolates on gold are well-suited as substrates for MALDI-TOF MS, and could be used to measure enzyme activities and to perform high-throughput screenings.[1,2] A significant aspect of this approach—which we term SAMDI (*s*elf-*a*ssembled *m*onolayers for MAL*DI*) MS—is that it avoids the use of labels, greatly simplifying the formatting of assays. Herein we establish two important

Communications

benefits that make this method well-suited to profiling multiple enzyme activities. First, SAMDI allows different classes of analytes, which may normally each require separate labeling strategies, to be evaluated by using a single method. Second, by using peptide substrates that are mass-resolved, the substrates can be immobilized on a single surface as mixtures, and do not need to be patterned into arrays.

Protein kinases are enzymes that catalyze the transfer of a phosphate group to tyrosine, serine, or threonine residues of substrate proteins. Protein kinases serve important regulatory functions in essentially all cellular processes including cell growth, migration, differentiation, and death.[3] Hence, assays that measure kinase activities are important in research and in the identification of lead compounds in drug discovery. Traditional kinase-activity assays follow one of two formats. In the first, a radioactive ^{32}P atom is used to label the phosphorylated substrates. Separation of the phosphorylated products using gel electrophoresis, phosphocellulose binding, or liquid chromatography then allows quantitation of the extent of phosphorylation and therefore of the kinase activity.[4] In the second format, the phosphorylated peptides are detected with antibodies that recognize the phosphopeptide. The assays can employ many strategies to analyze the binding of the antibody, including enzyme linked immuno sorbent assay (ELISA) formats and fluorescence polarization.[5] These techniques provide reliable methods for measuring kinase activities, but they do require substantial manipulation and are not readily extended to multikinase formats. Recent efforts have recognized that mass-spectrometric techniques could prove useful for measuring the activities because these techniques avoid labels, which leads to simpler assay formats.[6] A remaining challenge with these methods is to ease the requirement for sample enrichment, including by HPLC and affinity chromatography, prior to MS analysis.

We illustrate the SAMDI assay with the c-Src kinase.[7] We prepared mixed self-assembled monolyers (SAMs) presenting maleimide groups among a background of tri(ethylene glycol) groups.[8] A peptide substrate for c-Src (Pep1, 1 mM) was immobilized by the reaction of the terminal cysteine residue with the maleimide groups. Analysis of the monolayer by MALDI-TOF MS showed a single major peak at m/z 2079 ([P1+H]$^+$) corresponding to the mixed disulfide derived from the peptide-terminated alkanethiol and a glycol-terminated alkanethiol (termed P1 (from Pep1)). An identical monolayer was treated with c-Src kinase (0.4 U μL^{-1} N-(2-hydroxyethyl)-N'-(2-ethanesulphonyl)piperazine (HEPES)

buffer (pH 7.5) containing 80 μM adenosine-5′-triphosphate (ATP), 15 mM MgCl$_2$) for 1 h at 30°C. The monolayer was then rinsed, treated with matrix (2,4,6-trihydroxyacetophenone (THAP), 2 μL, 5 mg mL^{-1} in methanol) and analyzed by MALDI-TOF MS.[9] The original peak arising from the substrate peptide was absent and a new peak resulting from phosphorylation of the peptide was observed at m/z 2159 ([PP1+H]$^+$; Figure 1a). Importantly, all of the original peptide underwent phosphorylation, which shows that the ligands, when immobilized to the structurally well-defined monolayers, retain full activity towards the enzyme.

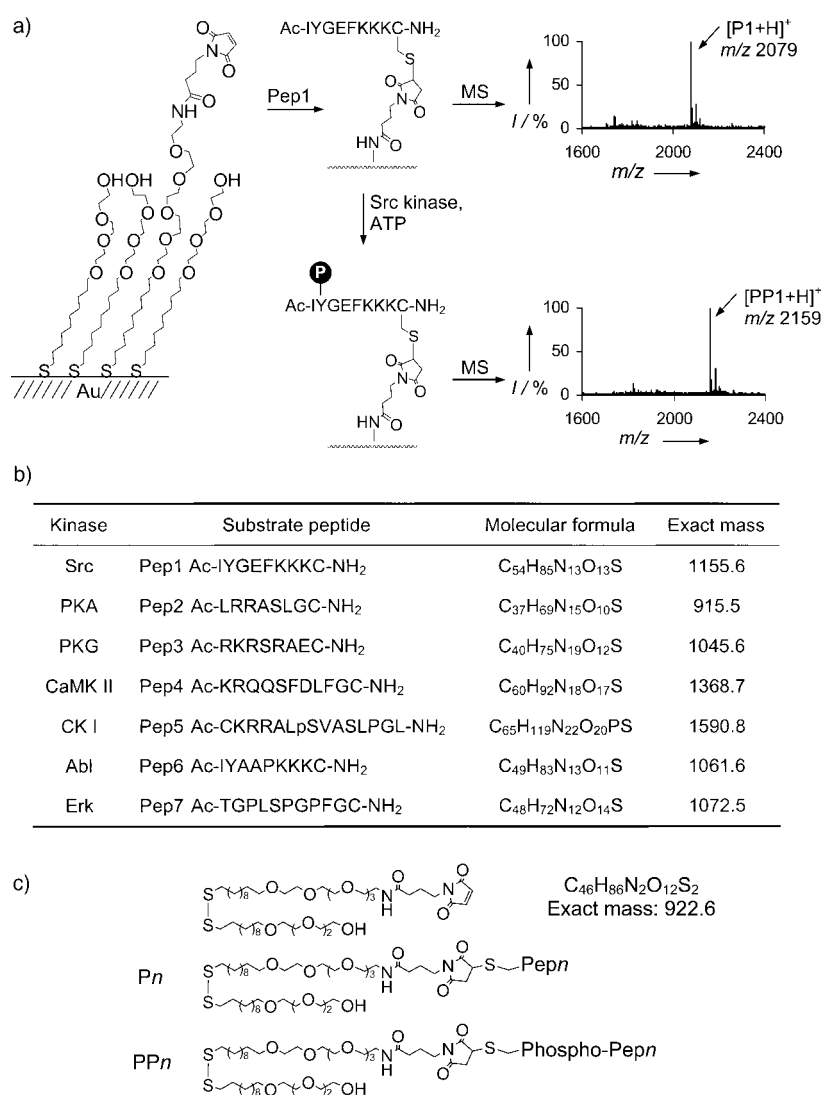
We assayed the catalytic subunits of protein kinase A (PKA), protein kinase G (PKG), calmodulin-dependent protein kinase II (CaMK II), casein kinase I (CK I), and Abl


Figure 1. Design of monolayers for characterizing enzyme activities by MALDI-TOF MS. a) A peptide substrate for c-Src kinase (Pep1) was immobilized on a SAM presenting maleimide groups. The monolayer was treated with c-Src kinase. Both monolayers before and after the kinase treatment were analyzed by MS, which showed one major peak corresponding to the mixed disulfide containing the peptide ([P1+H]$^+$) and phosphorylated product([PP1+H]$^+$), respectively. b) Sequences and masses of substrate peptides used in this work are listed. c) Molecular structures corresponding to mass peaks observed in this study are shown.

kinase by using the set of selective substrate peptides in Figure 1 b.[10] The enzymatic reaction conditions were chosen to give complete phosphorylation by each kinase. Representative mass spectra are shown in Figure 2. We found that in each case, the kinase reactions resulted in the expected mass change of 80, which confirms the addition of phosphate groups to each of the peptide substrates.

Multiple kinase activities can be measured simultaneously by using monolayers that present mixtures of kinase-specific peptide substrates. We treated a maleimide-terminated monolayer with a mixture of four peptides (Pep2, Pep4, Pep5, and Pep7). The ratio of the peptides in the mixture was adjusted to give monolayers that displayed the four peptides at similar intensities in MALDI-TOF spectra.[11] Indeed, a mass spectrum of the monolayer showed four well resolved peaks corresponding to disulfides derived from each peptide-terminated alkanethiolates ([P2+H]+ m/z 1839, [P4+H]+ m/z 2292, [P5+H]+ m/z 2514, [P7+Na]+ m/z 2018; Figure 3 a). An identical monolayer was treated with the CK I kinase, which is expected to phosphorylate only Pep5. Mass analysis revealed that the original mass peak for the CK I substrate peptide ([P5+H]+) was absent and gave rise to a new peak corresponding to phosphorylation of this peptide ([PP5+H]+ m/z 2594), while the other peptides remained unmodified by the kinase (Figure 3 b). In an additional example, we treated the same chip with PKA and found that the peptide substrate for this kinase was phosphorylated ([PP2+H]+ m/z 1919), but the other peptides were not modified (Figure 3 c). These examples show that the SAMDI approach can be applied to peptide chips for rapid and easily interpretable characterization of enzymatic reactions in a multi-analyte format.

The SAMDI assay can be used to quantitatively characterize the inhibition of kinases by known inhibitors. We prepared several solutions containing CK I (1 UμL^{-1}) and the inhibitor N-[2-((p-bromocinnamyl)amino)ethyl]-5-isoquinolinesulfonamide (H-89) at concentrations ranging from 0.001 to 1 mM in assay buffer (pH 7.5 2-amino-2-(hydroxymethyl)-1,3-propanediol (Tris) buffer containing 10 mM MgCl$_2$ and 0.2 mM ATP). A portion of each reaction mixture (1 μL) was applied onto a circular region (2 mm in diameter)
Figure 3. Enzymatic reactions on monolayers presenting multiple peptide substrates. a) The monolayer was prepared by applying a mixed solution of the four peptides (Pep2, Pep4, Pep5, and Pep7) to monolayers presenting maleimide groups. Molecular ion peaks corresponding to disulfides containing each substrate peptide were well resolved. b) Treatment of the monolayer with CK I resulted in phosphorylation of only the CK I substrate peptide Pep5 ([P5+H]+). c) Treatment of the monolayer with PKA resulted in phosphorylation of only Pep2 ([PP2+H]+). Dotted vertical line indicates the position of the peak for the substrate peptide.

of a monolayer presenting CK I selective substrate peptide, Pep5. The array was incubated for 30 min at 25 °C to allow the kinase reactions to proceed and then each spot was characterized by SAMDI to determine the extent of reaction. Figure 4 a shows the relationship between the concentration of H-89 and the extent of the phosphorylation reaction. The data are fit well by a 1:1 inhibition model and give an IC$_{50}$ value of 93 μM.[12] We followed the same procedure to
Figure 2. Characterization of three different kinase reactions with MALDI-TOF MS. MS spectra of the monolayers presenting substrate peptides are shown before (top) and after (bottom) treatment with a) PKA onto Pep2-immobilized SAMs, b) PKG onto Pep3-immobilized SAMs, and c) CaMK II onto Pep4-immobilized SAMs. After treatment with kinases, the original peaks ([Pn+H]+) were absent and gave rise to new peaks corresponding to the phosphorylated product peptides ([PPn+H]+).
Figure 4. Dose-dependent inhibition curves of kinase reactions determined by SAMDI MS. a) Solutions of CKI and H-89, ranging in concentrations from 0.001 to 1 mM, were applied to the SAMs presenting substrate peptide (Pep5). The relative amount of phosphorylated peptide χ, is plotted versus H-89 concentrations. b) Abl kinase and Gleevec also show dose-dependent inhibition.

characterize inhibition of Abl kinase by the approved drug Gleevec (also known as STI571, a 2-phenylaminopyrimidine derivative) on a monolayer presenting a selective substrate peptide of Abl kinase, Pep6.[13] A dose-dependent inhibition curve showed an IC_{50} value of 0.13 μM (Figure 4b).[14] These data show that the SAMDI approach enables quantitative analysis of kinase activities to evaluate inhibition kinetics.

The method reported herein advances a significant body of work in which MS was employed to analyze enzyme activities. Siuzdak and co-workers, for example, have characterized enzymatic glycosylation by β-1,4-galactosyltransferase and showed that enzyme inhibitors could be quantitatively characterized with electrospray ionization (ESI) MS.[15] Leary and co-workers have evaluated enzyme kinetics of the carbohydrate sulfotransferase and hexokinase, and screened a mock library to identify possible inhibitors of hexokinase by using ESI MS.[16] Henion and co-workers have quantitatively evaluated the hydrolysis of dinucleotides by ribonuclease A and the hydrolysis of lactose by β-galactosidase using HPLC MS.[17] Additionally, phosphorylated proteins and peptides have been characterized by MS after enriching samples by affinity chromatography or liquid chromatography before MS analysis.[6] The features that distinguish our method is that the peptide substrate is immobilized on an inert surface. The immobilization simplifies the preparation of the sample for MS analysis, since the spectator molecules can be removed by rinsing. The use of an inert surface permits quantitative enzyme reactions in a solid-phase format.[18]

The high sensitivity for detecting analytes and the avoidance of labels have led many researchers to apply MS to biochemical studies, including enzyme assays, protein-ligand interactions, and biomarker characterization from biological samples.[6, 15–17, 19–21] One limitation with these practices is that the preparation of samples for MS analysis is not straightforward. Our goal is to develop relatively simple processes that can be routinely used in biological research. The use of immobilized substrates together with surfaces that provide for specific interactions, is an advance in this direction. We believe that the ability to conduct multiple assays on a single surface will prove useful in chemical biology and signal transduction research.

base-promoted, aldol-type nucleophilic addition of acyldiazomethane to aldehydes or ketones to afford diazoketols.[3] A similar addition to *N*-tosylimines gives α-diazocarbonyl compounds bearing a β-(*N*-tosyl)amino substituent, which demonstrate a novel reactivity in various transition-metal-catalyzed reactions.[4] To further explore the chemistry of this type of nucleophilic addition, we decided to study the stereocontrol of the reaction. Herein, we report a highly diastereoselective base-promoted condensation of an α-diazocarbonyl compound and *N*-tosylimines in the presence of Evans' chiral oxazolidinone auxiliary.[5] The condensation products can be further converted into *syn*- and *anti*-α-hydroxy-β-amino esters.[6]

Our investigation began with the reaction of *N*-tosylbenzaldimine (**2a**) with the α-diazocarbonyl compounds **1a–d**[7] that contain chiral auxiliaries (Scheme 1, Table 1). The

α-Diazocarbonyl compounds have found wide application in organic synthesis as a result of their diverse reactivities.[1] The previous research activities in this area have mostly concentrated on the transition metal complex catalyzed diazo decompositions, which generate metal–carbene intermediates. In addition to serving as metal–carbene precursors, however, the relatively stable α-diazocarbonyl compounds can tolerate a variety of transformations with retention of the diazo functionality, thus allowing the chemical modification of α-diazo compounds.[1c,2] One such transformation is the

Communications

reaction with diazo esters **1a** and **1b** gave the addition products in moderate yields, although with essentially no stereoselectivity (Table 1, entries 1 and 2). The reaction with diazoamides **1c** and **1d**, on the other hand, gave good diastereomeric ratios of 17:83 and 88:12, respectively (Table 1, entries 3 and 4). Further improvement of the reaction was then focused on *N*-(diazoacetyl)oxazolidinone (**1d**). The reaction temperature was found to have an influence—reaction at higher temperature (−23°C) resulted in a lower yield (Table 1, entry 5), presumably because of the instability of the diazo compounds. A slightly higher selectivity can be achieved at −98°C without affecting the yield or the reaction time (Table 1, entry 6). Changing the base from lithium diisopropylamide (LDA) to sodium hexamethyldisilazide (NaHMDS) gave an improved yield, but with lower stereoselectivity (Table 1, entry 7). Both 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and Et$_2$Zn, which are known to promote condensation of acyldiazomethane with aldehydes and imines,[3i, 8] failed to promote the reaction of **1d** with **2a** (Table 1, entries 8 and 9). Commonly used additives, such as LiCl or MgBr$_2$, were found to have no effect on the stereoselectivity. However, we quite unexpectedly found that HMPA, which binds strongly to lithium ions,[9] significantly improved the stereoselectivity (Table 1, entry 12).[10] It is likely that HMPA disrupts the ion pairing by coordinating to lithium, thus allowing the α-diazocarbonyl anion to react more efficiently at low temperature.

Table 2 illustrates the scope and limitation of the optimized reaction conditions for the reaction of **1d** with a series of aryl *N*-tosylimines **2a–m**. The reaction of most imine

[a] Reaction was carried out with LDA (1.2 equiv), **1d** (1.0 equiv), and HMPA (5.0 equiv), followed by slow addition of a solution of **2** (1.5 equiv) in THF at −98°C. [b] The diastereomeric ratio was determined from the ^{1}H NMR (400 MHz) spectrum of the crude product. [c] Yield after purification by silica gel column chromatography.

substrates gave high diastereoselectivities and yields, although the stereoselectivities were lower with *N*-tosylimines bearing *ortho* substituents (Table 2, entries 8–10). In the case of *N*-tosyl-2,6-dichlorobenzaldimine, the reaction was essentially nonselective (Table 2, entry 10).

Although most of the addition products were isolated as amorphous solids, one of them (**3dm**) yielded crystals that

allowed us to determine the stereochemistry of the newly created chiral center. A single-crystal X-ray diffraction study of this product indicated that the new chiral center has an *R* configuration.[11]

Preliminary experiments also indicated that the LDA-promoted diastereoselective reaction of **1d** with imines can be further extended to aliphatic *N*-tosylimines. Thus, *N*-tosyl-*n*-butylimine, which was generated in situ from the sulfonamide sulfone **5**,[12] was treated with **1d** under similar reaction conditions, but without HMPA additive, to give the addition product **6** in 81% yield and a diastereomeric ratio of 94:6 (Scheme 2).
Scheme 2. LDA-promoted reaction of **1d** with sulfonamide sulfone **5**.

The stereochemical outcome of the reaction can be rationalized by the transition states depicted in Scheme 3.
Scheme 3. Plausible stereochemical pathway for the addition of deprotonated **1d** to **2a**.

Initial deprotonation of **1d** generates the diazocarbonyl anion or enolate.[13] Since the HMPA additive coordinates strongly to the lithium ion, the diazocarbonyl anion becomes less associated.[14] Moreover, the *N*-tosylamino group coordinates only weakly to lithium because of the strongly electron-withdrawing tosyl group. Consequently, the nucleophilic addition proceeds through a nonchelated open transition state in which the *N*-tosylimine approaches from the less sterically hindered side of the anion with an orientation that avoids steric repulsion between the aryl group and the oxazolidinone auxiliary. The anions derived from diazo amides **1c** and **1d** are conformationally more rigid than the corresponding anions derived from diazo esters **1a** and **1b** because of the rotational restriction of the amide C−N bond. The rigid structure of the anion might be responsible for the high diastereoselectivities observed for the reactions of **1c** or **1d** in the absence of chelation,[15] while the reaction with

diazo esters **1a** or **1b** is nonselective because of the flexibility of the anion conformation. This stereochemical process is in contrast with the addition of the enolates of acyl oxazolidinones to C=O or C=N bonds,[5,16] where complexation is usually responsible for the high stereoselectivities. Interestingly, the reaction of aromatic aldehydes with **1d** under similar conditions gave rather poor diastereoselectivities and low yields.

The utility of the addition products **3** was demonstrated by the concise synthesis of *syn*- and *anti*-α-hydroxy-β-amino acid derivatives. Thus, the chiral oxazolidinone auxiliary was removed by addition of lithium methoxide in THF to give the chiral methyl α-diazoesters **7a–g,k–m**, and **8** (Table 3).[17]

Table 3: Removal of the chiral oxazolidinone auxiliary.

3da–dg,dk–dm, 6 → **7a–g,k–m, 8**

Entry	R	Product	*ee* [%][a]	Yield [%][b]

12	*n*Pr	**8**	87	60

[a] *ee* value determined by chiral HPLC (see Supporting Information for details). [b] Total yield.

The diazo groups of **7a–c** were subsequently oxidized with dimethyldioxirane (DMD) to give α-ketoesters **9a–c**, respectively (Scheme 4). Reduction of the oxo group with NaBH$_4$ in
Scheme 4. Synthesis of both *anti*- and *syn*-α-hydroxy-β-amino acid derivatives from chiral methyl α-diazoesters **7a–c**.

THF at −10°C was highly efficient and stereoselective to afford the *anti*-α-hydroxy-β-amino esters **10a–c**.[18,19] Pd/C-catalyzed hydrogenation of the α-ketoesters **9a–c**, on the other hand, gave the *syn*-α-hydroxy-β-amino esters **11a–c**,[20] respectively, also with high yields and selectivities (Scheme 4).[18,19b]

In summary, this study is the first example of the highly diastereoselective nucleophilic addition of the anion derived from α-diazocarbonyl compounds to a C=N bond. This reaction can be successfully applied to the synthesis of both *anti*- and *syn*-α-hydroxy-β-amino acid derivatives. Since the diazo group has diverse reactivity, it should be possible to apply the addition products obtained by this reaction to other organic syntheses.

Highly Ordered Mesoporous Bioactive Glasses with Superior In Vitro Bone-Forming Bioactivities**

Xiaoxia Yan, Chengzhong Yu,* Xufeng Zhou, Jiawei Tang, and Dongyuan Zhao*

Bioactive glasses (BGs) have attracted much attention since the pioneering work by Hench et al. in 1971.[1] Glass ceramics with CaO-P_2O_5-SiO_2-MO (M = Na, Mg, etc) compositions have been widely studied and used in clinical applications because such materials can chemically bond with living bone.[2,3] The inorganic part of the human bone is hydroxy-carbonate apatite (HCA), and when BGs are implanted in the human body an HCA layer with the ability to bond with living bone is formed on the surface of the bioactive material. For the sol–gel-derived BGs[4,5] to exhibit in vitro behaviour, it has been shown that both the composition and structure are important,[6–9] while melt-derived glasses show a direct dependence on composition. Increasing the specific surface area and pore volume of BGs may greatly accelerate the kinetic deposition process of HCA and therefore enhance the bone-forming bioactivity of BGs.[6] More importantly, precise control over porosity, pore size, and internal pore architecture of BGs on different length scales is essential for the understanding of the structure–bioactivity relationship and the rational design of better bone-forming biomaterials. However, a multicomponent glass system is quite complex and consists of mainly amorphous oxides, and thus the synthesis of ordered mesoporous BGs by using a well-studied surfactant-templating route[10] has not been reported. Herein we demonstrate that highly ordered mesoporous bioactive glasses (MBGs) have been successfully synthesized by templating with a block copolymer.[11] MBGs lead to superior bone-forming bioactivities in vitro compared to normal BGs derived from sol–gels. Moreover, the mesostructure of MBGs is also shown to be important with regard to their bioactivities. Such MBGs are important in both mesoporous material and biomaterial research and may open up new opportunities

in implanting, drug delivery, and as coating-materials in tissue engineering.[12–16]

Highly ordered MBGs were synthesized by using nonionic block copolymers as structure-directing agents[11] through an evaporation-induced self-assembly (EISA) process.[17] The powder X-ray diffraction (XRD) pattern of the calcined MBG 80S15C (80S and 15C represents the molar fraction of Si and Ca, respectively) shows three diffraction peaks in the small-angle regime ($2\theta = 1.19$, 2.11, 2.41°), which can be indexed to the (100), (110), and (200) diffractions of a two-dimensional hexagonal (*p6mm*) lattice with a cell parameter *a* of 8.50 nm (Figure 1a). Transmission electron microscope

Figure 2. TEM images of calcined hexagonal MBG 80S15C recorded along the a) [001] and b) [100] directions.

by using P123 as the template in an EISA process possess ordered hexagonal structures. Furthermore, the pore sizes of MBGs can be tuned in the range of 4–7 nm by varying the structure-directing agent, for example, F127 or B50-6600. The physicochemical properties of the MBGs studied are summarized in Table 1.

Figure 1. a) XRD pattern and b) N$_2$ sorption isotherm of calcined MBG 80S15C synthesized in the presence of P123 template. The inset shows a plot of the pore size distribution (calculated by BdB method).

Table 1: Physicochemical properties of MBGs and BGs.

	Structure	d (100) [nm]	BET surface area [m^{2}g^{-1}]	Pore volume [cm^{3}g^{-1}]	Pore size [nm]
100S-P123	*p6mm*	6.9	300	0.40	4.4
80S15C-P123	*p6mm*	7.4	351	0.49	4.6
70S25C-P123	*p6mm*	7.4	319	0.49	4.6
60S35C-P123	*p6mm*	6.9	310	0.43	4.3
70S25C-F127	wormlike	9.2	300	0.36	5.0
60S35C-B50-6600	wormlike	10.5	228	0.42	7.1
80S15C	–	–	9.8	0.07	–

(TEM) images along the [001] and [100] directions also reveal a highly ordered hexagonal arrangement of one-dimensional channels (Figure 2a and b, respectively). Nitrogen sorption isotherms further confirm the existence of uniform mesopores (Figure 1b). The BET surface area, pore volume, and pore size is calculated to be 351 m^{2}g^{-1}, 0.49 cm^{3}g^{-1}, and 4.60 nm, respectively. For comparison, calcined BG 80S15C synthesized without surfactants has a relatively lower pore volume of 0.067 cm^{3}g^{-1}. MBGs synthesized in a range of compositions

Thermogravimetric analysis (TGA) and differential TGA (DTGA) curves for MBG 80S15C and BG 80S15C are shown in Figure 3. As the heating process proceeds, four clear mass losses are observed for BG samples between 18 and 150 °C, 150 and 300 °C, 300 and 430 °C, and 440 and 560 °C. For the MBG samples, two mass losses are observed between 25 and 125 °C as well as between 140 and 270 °C; a steep weight loss stage occurs between 300 and 325 °C. Larger mass losses (70 %, between 25 and 700 °C) are observed in the case of MBG compared to BG (55 %) as a result of the extra weight loss of the surfactants. A comparison of the TGA and DTGA profiles of two samples suggests that MBG samples are more homogenous in composition than BG samples.[18] The peak appearing around 300–325 °C most likely arises from the simultaneous decomposition of inorganic precursors and block copolymers.

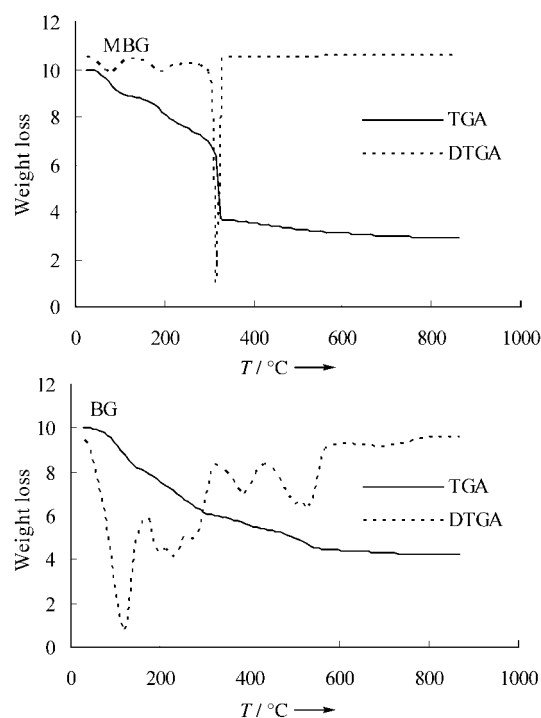
Most of the previous syntheses of sol–gel-derived BGs were carried out under aqueous conditions, and a high-temperature (>100 °C) drying process was required to remove the solvents; therefore, ordered MBGs were not


Figure 3. TGA and DTGA curves of MBG 80S15C obtained with a P123 template and BG 80S15C synthesized in the absence of surfactant.

obtained, even in the presence of surfactants. Performing the EISA process in near non-aqueous conditions in the current strategy is essential for the assembly of highly ordered MBGs. It is important to note that the MBGs fabricated in our study are unique compared to conventional BGs for the following two reasons. Firstly, the mechanism for the generation of the mesopore is different: Conventional BGs also possess mesopores which arise from the random distribution of CaO within the network of SiO_2.[6] The self-assembly of surfactants in MBGs gives rise to uniform mesopores as well as ordered mesostructures. To support this point, MBG 60S35C and 80S15C show similar N_2 adsorption isotherms and pore diameters (5.0 and 4.6 nm, respectively; see Table 1), while BG 60S35C and 80S15C synthesized by Vallet-Regi et al. have a mean pore size of 12 and 5 nm, respectively.[6] Accordingly, BG 80S15C shows H_2-type hysteresis loops associated with inkbottle-like pores[6] while MBG 80S15C shows H_1-type hysteresis loops typical of one-dimensional channels (Figure 1 b). Secondly, the compositional homogeneity of the framework is different. The microphase separation and heterogeneity is common in normal sol–gel-derived BGs,[18] and is also observed in our BGs obtained by the EISA process. The TGA, energy dispersive spectroscopy (EDS), and scanning electron microscopy (SEM) results (see below) indicate that all the components are homogeneously distributed in the network in the case of MBGs. Since ordered mesostructured materials are formed by the regular packing of composite micelles on the nanometer scale, it is suggested that the homogeneous dispersion of inorganic species on this length scale may lead to a more homogeneous material (MBG) than conventional BGs. Inorganic salts have also been

employed in the EISA process to produce macro- and mesoporous materials[19] as well as metal oxide nanowire arrays within mesostructured frameworks[20] where the crystallization of the salt/metal oxide and phase separation of a crystalline phase from amorphous sol–gel materials is unavoidable. In our case, the utilization of calcium nitrate in the synthesis gives rise to transparent monoliths and films before calcination (see Supporting Information), and a homogeneous glassy state is obtained after thermal treatment at 700 °C, as evidenced by wide-angle XRD measurements. It is important to note that the use of a nitrate salt and its subsequent decomposition during calcination is another essential factor in the fabrication of homogeneous MBGs.[21]

MBGs with high specific surface area and pore volume should have a greatly enhanced bone-forming bioactivity than conventional BGs.[6] It is believed that the prerequisite for glasses and glass ceramics to bond to living bone is the formation of a biologically active HCA layer on the surface of the BGs in the body. Therefore, the bone-forming activity of MBGs (and BG for comparison) in vitro was tested in simulated body fluid (SBF)[22] to monitor the formation of HCA on the surface of MBGs over time. SEM images of MBG 80S15C before soaking shows a smooth and homogenous surface (Figure 4a), which is in accordance with the results suggested by EDS and TGA analysis. The growth of nanoparticles (< 100 nm in diameter) is observed after soaking the sample for 4 h (Figure 4b). It is surprising to note that a rodlike morphology (ca. 100 nm in length) which is similar to the morphology of HCA in human bones is exclusively observed after 8 h (Figure 4c). TEM examination reveals that such rods consist of even smaller nanorods about 5 nm in diameter (Figure 4g). EDS analysis shows that the molar ratio of Ca/P is 1.53:1 within such rods (Figure 4g, inset). Fourier transform infrared spectroscopy (FTIR) analysis of MBG 80S15C after immersing in SBF for 8 h shows the absorption bands of the phosphate group at 1040, 962, 603, and 562 cm^{-1}, together with the absorption bands of the carbonate group at 1488, 1432, and 870 cm^{-1}, which is in accordance with the IR spectra of HCA (see Supporting Information).[6] High-resolution TEM studies further confirms the existence of crystalline HCA nanorods (Figure 4h); however, some amorphous rodlike morphology is still observed, which is in agreement with the diffraction rings in the electron diffraction (ED) pattern (Figure 4h, inset). The rodlike morphology is maintained with increasing immersion time and the crystallinity of HCA increases as reflected by FTIR results (data not shown). EDS analysis shows a molar ratio of Ca/P = 1.66:1 in the rodlike HCA materials after seven days, a ratio almost equal to that of perfect HCA materials. The surface of BG 80S15C synthesized in the absence of surfactant and before soaking is heterogeneous (Figure 4d), which is very different from the MBG samples. The induction time for the formation of amorphous HCA and the subsequent deposition rate of HCA on the surface of BG is much slower than for MBG (Figure 4e, f), a result which is in accordance with the inductively coupled plasma (ICP) atomic emission spectroscopy results (see Supporting Information).[6,23] The rodlike HCA materials cannot be observed even after three days in the case of BG samples. It is
Figure 4. SEM images of MBG 80S15C (P123 template) after immersing in SBF for 0, 4, and 8 h (a)–(c). SEM images of BG 80S15C after soaking in SBF for 0, 8 and 48 h (d)–(f). TEM images of MBG 80S15C after soaking in SBF for 8 h at different magnifications (g) and (h). The EDS result (inset of g) and ED pattern (inset of h) of HCA deposited on MBG samples are also shown.

concluded that MBG with its larger pore volume and more accessible mesopore surface area has a much better bone-forming bioactivity in vitro than BG materials. The fast (ca. 8 h) and biomimetic HCA formation behavior (morphology of HCA similar to that in human body formed in simulated biological conditions) of MBGs means that the MBGs synthesized by the current strategy possess an outstanding bone-forming activity in vitro compared to other reported BGs.

The composition of MBGs is another important factor for their bioactivity. SEM results (see the Supporting Information) reveal that the bioactivity of MBGs in vitro follows the following sequence: 80S15C > 70S25C > 60S35C > 100S. The type of mesostructure in MBGs of the same composition is also important to the in vitro bioactivity. MBGs with the same composition (70S25C) have been synthesized in the presence of F127 and P123 (denoted MBG-F127 and MBG-P123, respectively) and their in vitro bioactivity compared. The dominant morphology of HCA deposited on MBG-P123 after immersing the MBG in SBF for 4 h is nanoparticles (see the

Supporting Information), but a rodlike morphology is already observed in the case of MBG-F127 (see the Supporting Information). Since the composition, the pore volume, and pore size of both MBG materials are similar, the observed difference in bioactivity is most likely attributed to their pore structures (Table 1): MBG-F127 with 3-dimensional pore structures may facilitate the transportation of dissolved Ca^{2+} and O-Si-O species as well as the subsequent deposition of HCA materials. More importantly, since the pore size and pore structure is important in the protein-adsorption behavior for mesoporous materials,[24] it is believed that MBGs with a tunable pore size and pore structure may greatly influence the protein adsorption and nutrient delivery behavior for better in vivo bioactivity.

In conclusion, highly ordered mesoporous bioactive glasses have been synthesized with superior bone-forming bioactivity in vitro. Successful control of the mesostructure of MBGs adds a new dimension to the art of designed synthesis of bioactive glass materials. By carefully tuning the pore size, pore structure, and composition of MBGs, it is anticipated that MBGs with better in vivo bioactivity may be synthesized. MBGs with controllable morphologies may also be used for drug delivery, implant coating materials, and tissue engineering.

Experimental Section

MBGs were synthesized by using nonionic block copolymers such as $EO_{20}PO_{70}EO_{20}$ (P123), $EO_{106}PO_{70}EO_{106}$ (F127), and $EO_{39}BO_{47}EO_{39}$ (B50–6600) as structure-directing agents (EO is poly(ethylene oxide), PO is poly(propylene oxide), and BO is poly(butylene oxide)). In a typical synthesis of MBG, P123 (4.0 g), tetraethyl orthosilicate (TEOS, 6.7 g), $Ca(NO_3)_2\cdot4H_2O$ (1.4 g), triethyl phosphate (TEP, 0.73 g; Si/Ca/P = 80:15:5, molar ratio), and 0.5 M HCl (1.0 g) were dissolved in ethanol (60 g) and stirred at room temperature for 1 day. The resulting sol was introduced into a Petri dish to undergo an evaporation-induced self-assembly (EISA) process.[17] The dried gel was calcined at 700 °C for 5 h to obtain the final MBG products (denoted 80S15C according to the molar fraction of Si and Ca). For comparison, BG 80S15C was synthesized by an identical process but without surfactants.

MBG and BG materials were ground and sieved. Granules with sizes in 76–38 μm fractions were selected. The bone-forming activity of MBGs (and BGs) in vitro was tested by immersing selected granules (100 mg) in simulated body fluid (SBF, 100 mL)[22] to monitor the formation of HCA on the surface of MBGs over time. The solids were separated by filtration, washed three times with acetone, and dried in air.

Relevant intermediates in copper-catalyzed cycloaddition reactions were recently identified by spectroscopic means.[9] We have now investigated the use of sulfoximines in Mukaiyama-type aldol reactions and found novel benzene-bridged aminobenzyl-substituted sulfoximines **3** (Mes = mesityl) to be excellent ligands for this synthetically important C–C bond-forming reaction.

We chose the reaction between 1-phenyl-1-(trimethylsilyloxy)ethene (**4**) and methyl pyruvate (**5a**, Scheme 1) as a model reaction to allow meaningful comparisons to be made with well-established systems such as [Cu(*t*Bubox)]²⁺ or [Sn(pybox)]²⁺ (box = bis(oxazoline), pybox = pyridylbis(oxazoline)) catalysts.[10] The initial experiments were performed in THF with copper(II) triflate as the metal source.

To our disappointment complexes based on C₂-symmetric bissulfoximines **1** and *N*-quinolyl-substituted sulfoximine **2**,

C₁-Symmetric Sulfoximines as Ligands in Copper-Catalyzed Asymmetric Mukaiyama-Type Aldol Reactions**

Martin Langner and Carsten Bolm*

Since the report of the discovery of sulfoximines by Whitehead and Bentley in 1952,[1] they have found numerous applications in organic synthesis.[2] For example, they have been used as building blocks in

which previously had been successfully applied in copper-catalyzed cycloaddition reactions,[8] led to rather unsatisfying results and gave products with low or moderate enantioselectivities.[11] On the basis of the hypothesis that an amino group would improve the metal-binding properties of the ligands, novel C₁-symmetric benzene-bridged benzylaminosulfoximines **3** were designed. Their syntheses are summarized in Scheme 2. Starting from 2-bromonitrobenzene (**7**) and enantiopure (*S*)-*S*-methyl-*S*-phenylsulfoximine (**8**),[12] the desired sulfoximines **3** were readily available by a three-step reaction sequence involving first a Buchwald–Hartwig-type
Scheme 2. Synthesis of benzene-bridged aminosulfoximines **3**. Binap = 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl.

coupling reaction,[13] followed by reduction of the nitro group and a reductive amination. Aniline **10** reacted readily with a wide variety of aldehydes, and thus a library of sulfoximine analogues became easily accessible. The high modularity of this synthetic approach becomes apparent when it is considered that other aromatic core units, various sulfoximines, and a number of aldehydes could be combined in the synthetic scheme.

In the test reaction shown in Scheme 1, the use of aminosulfoximine **3a**, which was prepared by reductive amination of **10** and benzaldehyde in 81% yield, yielded aldol product **6a** with a promising *ee* value of 70% (Table 1,

Table 1: Influence of the ligand structure on the Mukaiyama-aldol reaction shown in Scheme 1.[a]

Entry	Aminosulfoximine	R of 3	Yield [%][b]	ee [%][c]
1	**3a**	Ph	64	70
2	**3b**	1-Naph	77	83
3	**3c**	2-MeO-Ph	72	86
4	**3d**	Mes	88	93
5	**3e**	2,4,6-iPr$_3$-Ph	>99	93

[a] Reaction conditions: **4** (0.6 mmol), **5a** (0.5 mmol), Cu(OTf)$_2$ (0.05 mmol), aminosulfoximine (0.05 mmol), THF, RT, 24 h. [b] After column chromatography. [c] Determined by HPLC on a column with a chiral stationary phase (Chiralcel OD).

entry 1). Aminosulfoximines **3b** and **3c** were prepared (in 85 and 81% yield, respectively) for the conversion of **10**, with the expectation that the introduction of an electron-donating substituent on the *N*-benzyl arene group would provide a sterically more demanding environment at the metal center and further increase the metal–ligand interaction.[14] Confirmation of this hypothesis was obtained when **6a** was generated with higher enantioselectivities in both cases (83% and 86% *ee* for catalysis with **3b** and **3c**, respectively; Table 1, entries 2 and 3) than when **3a** was used. The introduction of a substituent with two *ortho* groups improved the enantioselectivity even further, and the use of mesitylene derivative **3d** (prepared in 81% yield) led to aldol product **6a** with 93% *ee*. Finally, the best result in terms of both enantioselectivity and yield was obtained with triisopropyl-substituted analogue **3e** (prepared in 82% yield), which gave **6a** with 93% *ee* in >99% yield (Table 1, entry 5).

Next, we focused our attention on the optimization of the reaction conditions. First the effect of the solvent was investigated. It was deduced from studies with **3d** in various solvents (such as THF, diethyl ether, dioxane, toluene, dichloromethane, and chloroform) that weakly coordinating or aromatic solvents were important for achieving high enantioselectivity. THF proved to be the most suitable solvent in terms of catalytic activity.[15]

Additional optimizations (with **3d**) in regard to the copper(II) salt and the reaction temperature were also performed. In general, the application of counterions other than triflate (for example, PF$_6$, BF$_4$, SbF$_6$, or ClO$_4$) resulted in a significant decrease in the *ee* value of the product.[15] In terms of product yield, Cu(ClO$_4$)$_2$ was superior to all other metal sources (>99%). With this copper salt, however, the enantioselectivity (81% *ee* for **6a**) was always lower than that obtained with the catalyst based on copper(II) triflate (93% *ee*). The enantioselectivity of the reaction was improved to 98% *ee* by performing the reaction at −55°C instead of ambient temperature. However, long reaction times (>9 days) were necessary under those reaction conditions to obtain the product in acceptable yields. Since 2,2,2-trifluoroethanol had been reported to facilitate the turnover in catalytic Mukaiyama-type reactions,[16] its capability to accelerate the copper(II)–sulfoximine catalysis at low temperature was studied. To our delight we found that in the presence of this additive (1.2 equiv) the catalysis proceeded smoothly even at −30°C to afford **6a** with 98% *ee* in 89% yield after only 15 h (Table 2, entry 1). This result clearly confirmed the acceler-

Table 2: Effect of the substrate in reactions between **4** and **5** to give **6** (Scheme 1).[a]

Entry	Product	T [°C]	t [h]	Yield [%][b]	ee [%][c]
1	**6a**	−30	15	89	98
2	**6b**	−50	47	86	98
3	**6c**	−40	28	90	99
4	**6d**	RT	24	78	89
5	**6e**	−20	40	86	96

[a] Reaction conditions: **4** (0.6 mmol), **5a–e** (0.5 mmol), CF$_3$CH$_2$OH (0.6 mmol), Cu(OTf)$_2$ (0.05 mmol), aminosulfoximine **3e** (0.05 mmol). [b] After column chromatography. [c] Determined by HPLC.

ation effect, which occurred without affecting the enantioselectivity.

The substrate scope was evaluated under the conditions optimized for the reaction between **4** and **5a** (use of **3e** as the ligand, THF as the solvent, Cu(OTf)$_2$ as the copper source, and 2,2,2-trifluoroethanol as the additive at low temperature). Gratifyingly, we found that other α-keto esters also reacted well with enolsilyl ether **4**. Thus, the reaction between benzyl pyruvate (**5b**) and **4** at −50°C yielded the corresponding aldol product **6b** with 98% *ee*, and use of isopropyl pyruvate (**5c**) furnished **6c** with 99% *ee* (Table 2, entries 2 and 3, respectively). These results showed that the efficiency of the catalyst was independent of the size of the ester moiety. Substrates

bearing more bulky acyl substituents were also investigated. The reaction between methyl α-keto butyrate (**5d**) and **4** gave **6d** with 89% *ee* at room temperature (Table 2, entry 4). No conversion was observed at lower temperatures. The sterically more-demanding ethyl 2-oxo-4-phenyl butyrate (**5e**) yielded **6e** with 96% *ee* at −20°C (Table 2, entry 5). Apparently, the catalyst tolerates an enlarged alkyl chain adjacent to the acyl function, although in some cases higher temperatures are required.

To test the applicability of another enolsilane, benzyl pyruvate (**5b**) was treated with 1-methyl-1-(trimethylsilyloxy)ethane (**11**) to afford the corresponding product **6f** with 91% *ee* in 71% yield (Scheme 3).
Scheme 3. Synthesis of **6f**. Tf = trifluoromethanesulfanyl.

In summary, we have described the synthesis of new C_1-symmetric benzene-bridged aminosulfoximines, which are capable of serving as efficient ligands in copper-catalyzed enantioselective Mukaiyama-type aldol reactions. Aldol products with quarternary centers, which are commonly difficult to prepare in enantiomerically enriched form,[17] have been obtained with up to 99% *ee* in high yields. In terms of *ee* values and yield, the new catalysts compare well with the established [Cu(*t*Bubox)]$^{2+}$ or [Sn(pybox)]$^{2+}$ systems.[10,18] Ongoing studies are directed to further expand the substrate scope and to demonstrate the applicability of the novel aminosulfoximines in other enantioselective catalyses.

Experimental Section

Representative example for the syntheses of aminosulfoximines 3a–e: Preparation of **3e**: Glacial acetic acid (172 μL, 3.00 mmol) was added to a solution of aniline **10** (3.00 mmol, 739 mg) and 2,4,6-triisopropylbenzaldehyde (3.60 mmol, 837 mg) in MeOH (20 mL) at RT. The solution was stirred for 3 h and then cooled to 0°C. Subsequently, NaBH$_4$ (7.50 mmol, 284 mg) was added over 20 min, and the mixture was stirred at RT overnight. The solution was partitioned between 10% aqueous K$_2$CO$_3$ (20 mL) and CH$_2$Cl$_2$ (20 mL), and the aqueous layer was extracted with CH$_2$Cl$_2$ (3 × 20 mL). The combined organic layers were dried over MgSO$_4$, and the solvent was evaporated. The product was purified by flash chromatography on silica gel (pentane/EtOAc 10:1) to afford 1.14 g (2.46 mmol, 82%) of **3e** as a colorless solid. For analytical data see the Supporting Information.

General procedure for the Mukaiyama-type aldol reaction: A flame-dried Schlenk flask under Ar atmosphere was charged with Cu(OTf)$_2$ (18.1 mg, 0.05 mmol) and the aminosulfoximine **3a–e** (0.05 mmol). Dry THF (2 mL) was then added and the resulting deep green solution was stirred for 30 min at RT. The mixture was subsequently cooled to the selected temperature, and the α-keto ester **5a–e** (0.5 mmol), silylenol ether **4** (0.6 mmol, 123 μL), and 2,2,2-trifluoroethanol (0.6 mmol, 44 μL) were added. After stirring the reaction mixture for the indicated period of time, it was warmed to RT, diluted with diethyl ether (50 mL) and filtered through a plug of silica gel. The solvent was evaporated, and the product was purified by flash chromatography. For analytical data and determinations of the *ee* values see the Supporting Information.

[18] Compound **6a** was obtained with a comparable *ee* value (98 versus 99%) but in higher yield (89 versus 77%) with respect to the previously reported results obtained with [M(box)] complexes. In the case of **6f**, the *ee* value and the yield were similar with both systems (91 versus 93% *ee* and 71 versus 76% yield). To the best of our knowledge, **6b–e** have not yet been prepared.

Electrochemistry

A Mesoporous/Crystalline Composite Material Containing Tin Phosphate for Use as the Anode in Lithium-Ion Batteries**

Eunjin Kim, Dongyeon Son, Tae-Gon Kim,
Jaephil Cho,* Byungwoo Park,* Kwang-Sun Ryu, and
Soon-Ho Chang

Since Idota et al. first discovered in 1997 that Sn anodes containing amorphous $SnB_{0.56}P_{0.4}Al_{0.42}O_{3.46}$ have a capacity of about 600 mA h g^{-1}, compared to a value of 372 mA h g^{-1} for

graphite,[1] many studies on Sn-based materials for use as anode materials have been performed.[2–4] Courtney et al. have reported the overall reaction of Sn-containing anode materials using SnO as Equation (1).[2]

$$6.4 Li + SnO \rightarrow Li_{4.4}Sn + Li_2O \leftrightarrow 4.4 Li + Sn + Li_2O \qquad (1)$$
The tin atoms aggregate during cycling, and the Li–Sn alloys embedded in the Li_2O matrix exhibit rapid loss of capacity.

The presence of substantial amounts of other "spectator atoms", such as the B and P atoms in Sn_2BPO_6, apparently prevents Sn aggregation.[2] However, these materials show an initial capacity of about 500 mA h g^{-1}, with a relatively high irreversible capacity of about 500 mA h g^{-1} during the first cycle. Xiao et al. prepared a crystalline $Sn_2P_2O_7$ phase, and proposed the decomposition reaction [Eq. (2)].[3]

$$12.8 Li + Sn_2P_2O_7 \rightarrow 2 Li_{4.4}Sn + Li_3PO_4 + LiPO_3 \leftrightarrow$$
$$8.8 Li + 2 Sn + Li_3PO_4 + LiPO_3 \qquad (2)$$
However, the irreversible capacity of this material is high (523 mA h g^{-1}), and the initial capacity of 544 mA h g^{-1} decreases quickly even at a low current (C) rate (20 mA g^{-1}). Behm and Irvine have reported that crystalline $Sn_2P_2O_7$ (obtained by heating $SnHPO_4$ to 550 °C) exhibits an initial charge capacity of 519 mA h g^{-1}, which decreases rapidly to 148 mA h g^{-1} after 30 cycles.[4] They proposed that lithium phosphates (Li_3PO_4 and $LiPO_3$), as reaction products, could not play a similar role as Li_2O in the SnO system, which is as a "glue" that keeps the Li–Sn particles mechanically connected during the large volume changes during alloying/dealloying. The mesoporous SiO_2/SnO_2 composite reported by Chen et al.[5] has a good cycling stability, as evident from the cyclic voltammogram recorded with a single-powder microelectrode.

Herein we report the synthesis of a mesoporous tin phosphate/crystalline $Sn_2P_2O_7$ composite as a novel anode material. This material has the highest initial charge capacity (721 mA h g^{-1}) of the known tin-based anode materials, and shows an excellent cycling stability. The mesoporous structure was incorporated to improve the structural/electrochemical properties by alleviating the volume change of the tin during the alloying/dealloying process.

Figure 1 shows small-angle X-ray scattering (SAXS) patterns of the mesoporous tin phosphates prepared in the presence of cetyltrimethylammonium bromide (CTAB, $CH_3(CH_2)_{15}N(CH_3)_3Br$) as a structure-directing agent, before and after annealing at 400 °C for 8 h. The three resolved peaks indexed as (100), (110), and (200) confirm a well-ordered hexagonal mesoporous structure.[6,7] The intense (100) peak at $2\theta = 2.18° \pm 0.09°$ of the as-synthesized mesoporous tin phosphate corresponds to a d spacing of 4.0 ± 0.2 nm (from $2d \sin\theta = \lambda$), with a nearest-neighbor distance of 4.7 ± 0.2 nm. The high-angle XRD pattern shown in the inset of Figure 1a indicates the formation of crystalline $SnHPO_4$ with a space group $P2_1/c$ (monoclinic).[8]

The appearance of small-angle diffraction peaks corresponding to a hexagonal structure for the annealed meso-

Communications

porous sample indicates that the mesostructure is preserved upon removal of the CTAB surfactant after annealing. However, the meso periodicity is contracted; the corresponding d spacing of the annealed mesoporous tin phosphate is 3.5 ± 0.3 nm.[6,9,10] The high-angle XRD pattern of the annealed sample clearly shows the presence of Sn$_2$P$_2$O$_7$ (inset of Figure 1 b).[4] The crystal size of the sample both before and after annealing, calculated using the Scherrer formula, was estimated to be approximately 100 nm,[11] which is two orders of magnitude larger than the wall thickness of the pure mesoporous phase (ca. 1 nm). These results indicate the formation of a mesoporous tin phosphate mixed with a crystalline phase.

Figure 2 shows the TEM micrographs of the samples before and after annealing, and clearly shows the presence of hexagonal mesoporous materials. The corresponding d spacings (by TEM) are approximately 3.8 nm before annealing and about 3.3 nm after annealing; these values are consistent with the SAXS data. The TEM image of the annealed tin phosphate clearly shows that the hexagonal mesostructure is preserved after heating to 400°C.[12,13] The light stripes in Figure 2 can be considered as projections of the mesopore channels, whereas the dark lines are from the tin phosphate walls.[14]

The nitrogen-adsorption isotherm of the annealed sample, which has a Brunauer–Emmett–Teller (BET) surface area of 75.6 m^{2}g^{-1}, is shown in Figure 3. The measured surface area is smaller than that of other mesoporous metal oxides reported

in the literature because of the coexistence of a crystalline phase. The nitrogen isotherm curve of the mesoporous tin phosphate/Sn$_2$P$_2$O$_7$ composite has a well-defined step, which is characteristic of framework-confined mesopores.[15–17] A rough estimation of the mass ratio for mesoporous tin phosphate versus crystalline Sn$_2$P$_2$O$_7$ is approximately 1:3. (This ratio was estimated from the BET surface areas of both the mesoporous tin phosphate and crystalline Sn$_2$P$_2$O$_7$ by considering the pore diameter and wall thickness.) As shown in the inset of Figure 3, the average pore size in the annealed sample is approximately 2.3 nm (Barrett–Joyner–Halenda (BJH) analysis), which is consistent with the SAXS and TEM data (Figures 1 and 2, respectively).

Figure 4 compares the voltage profiles of pure crystalline Sn$_2$P$_2$O$_7$ and mesoporous tin phosphate/Sn$_2$P$_2$O$_7$ composite anodes, which were cycled up to the 30th cycle at a rate of 144 mA g^{-1} (first cycle at 72 mA g^{-1}) between 2.5 and 0 V. The crystalline Sn$_2$P$_2$O$_7$ anode shows a large initial irreversible capacity (389 mA h g^{-1}) and poor retention property after 30 cycles (from 704 to 146 mA h g^{-1}). On the other hand, the mesoporous tin phosphate/Sn$_2$P$_2$O$_7$ composite anode shows an initial charge capacity of 721 mA h g^{-1}, which is much larger than the tin phosphate anodes reported previously.[1–4] Moreover, the irreversible capacity of the sample during the first cycle is 297 mA h g^{-1}, which is far superior to the previous
Figure 4. Voltage profiles of a) a crystalline $Sn_2P_2O_7$ anode and b) a mesoporous tin phosphate/$Sn_2P_2O_7$ composite anode in coin-type half-cells during the 1st, 2nd, 5th, 10th, 20th, and 30th cycles between 2.5 and 0 V. The C rate was maintained at 144 mAg^{-1} (first cycle at 72 mAg^{-1}; V: cell potential).

Figure 5. Plots of: a) cell potential of the mesoporous tin phosphate/$Sn_2P_2O_7$ composite anode in coin-type half-cells during the first discharging and charging, and b) the corresponding d spacing of the composite electrode at the cell potential indicated by the arrow. The inset shows small-angle X-ray diffraction patterns of the electrode at 1.1 V and 0.07 V (V: cell potential; d: d spacing; I: intensity).

studies on Sn-based oxides or alloys.[1–4] In addition, the mesoporous tin phosphate/$Sn_2P_2O_7$ composite exhibits excellent cyclability: the retentive capacity up to 30 cycles is 587 mAhg^{-1}. This result indicates that the mesoporous tin phosphate plays a significant role in retaining the capacity. The XRD patterns of the cycled electrodes show that the crystalline $Sn_2P_2O_7$ peaks disappear during the first discharge (at ca. 1.1 V) and give only weak and broad diffraction patterns. The amorphous or nanocrystalline electrode in the phosphate matrix may prevent formation of large Sn clusters.[18,19] The measured discharge and charge capacities are higher than the theoretical values (834 mAhg^{-1} and 572 mAhg^{-1}, respectively).[3] The formation of a solid-electrolyte interface layer[20] and a reversible lithium phosphate matrix[18] may induce these higher values, although the exact mechanisms need to be identified.

Figure 5 shows the cell potential of the mesoporous tin phosphate/$Sn_2P_2O_7$ composite anodes during the first discharging/charging together with the corresponding changes of the mesopore periodicity. Surprisingly, the d spacing expands and shrinks with Li alloying/dealloying. We believe that the lithium-tin phosphates form a flexible, three-dimensional mesoporous framework such that the mesopores do not collapse during discharge and charge. The cutoff voltage in Sn-based oxides has been typically limited to 1.2 V as a consequence of rapid tin aggregation above 1.2 V. The mesopores play an important role in reducing possible aggregation of Sn particles, and act as a "buffer zone" which accommodates the volume change of the Sn phase during Li alloying/dealloying. More detailed experiments with the optimum microstructures are currently underway to improve the electrochemical properties shown in Figure 4.

In conclusion, our mesoporous tin phosphate/$Sn_2P_2O_7$ composite anode shows superior electrochemical properties, such as a large initial capacity (ca. 721 mAhg^{-1}) and excellent cyclability (ca. 587 mAhg^{-1} at the 30th cycle). Our approach

for enhancing the structural stability of tin phosphate is to incorporate mesoporous structures as a buffer layer to alleviate the volume expansion of the tin phosphate anode during lithiation/delithiation. We believe that this novel mesoporous tin phosphate/$Sn_2P_2O_7$ composite has an enormous potential for use in Li-battery anode materials.

Experimental Section

The mesoporous tin phosphate/$SnHPO_4$ composite was prepared by mixing SnF_2 (6.0 g) and H_3PO_4 (13.8 g) and dissolving this mixture in distilled-deionized water (DDW, 40 mL). CTAB (5.5 g) was then dissolved in DDW (20 mL), and this solution was added to the first solution. The mixture was stirred at 40 °C for 1 h and then loaded into an autoclave and heated to 90 °C for 12 h. After cooling the mixture to room temperature, the precipitate was recovered by filtration, washed with distilled water and ethanol, and vacuum-dried at 100 °C for 10 h. The as-prepared powders (mesoporous tin phosphate/$SnHPO_4$ composite) were then annealed at 400 °C for 8 h to give the mesoporous tin phosphate/$Sn_2P_2O_7$ composite.

The procedure for assembling a coin-type half-cell with Li as an anode has been described in detail elsewhere.[21–24] The electrode consisted of 60 wt-% active materials, 20 wt-% Super P carbon black, and 20 wt-% poly(vinylidene fluoride). A mixture of ethylene carbonate/diethylene carbonate and 1M LiPF$_6$ salt was used as the electrolyte. The SAXS patterns were measured using Cu$K\alpha$ radiation (40 kV, 35 mA) on a Bruker Nanostar instrument. The nitrogen-adsorption isotherm was measured at 77 K with a Micromeritics ASAP 2010 analyzer.

Sesquiterpene Lactones

Enantioselective Total Synthesis of the Highly Oxygenated 1,10-*seco*-Eudesmanolides Eriolanin and Eriolangin**

*Jörn Merten, Roland Fröhlich, and Peter Metz**

Dedicated to Professor Johann Mulzer
on the occasion of his 60th birthday

The highly oxygenated 1,10-*seco*-eudesmanolides eriolanin (**1**) and eriolangin (**2**, Scheme 1) isolated from the plant

Scheme 1. Representatives of the 1,10-*seco*-eudesmanolides.

Eriophyllum lanatum inhibit the growth of the human KB tumor cell line in vitro and additionally display a significant antileukemic activity in vivo in mice.[1] While several syntheses for racemic **1**[2,3] and one for racemic **2** have been published,[2] the absolute configuration of these sesquiterpene lactones was unknown prior to our work. Here we report an efficient enantioselective sultone route[4] to **1** and **2** that also opens a synthetic access toward the less highly oxygenated, cytotoxic britannilactone derivatives **3** and **4**.[5–7] As the central intermediate, δ-sultone **10** (Scheme 2) was employed, the racemic mixture of which already enabled a short and highly diastereoselective synthesis of the 1,10-*seco*-eudesmanolide ivangulin (**5**).[8]

Alcohol **9**,[9] required as the starting material for the enantiomerically pure sultone **10**, was available on a multigram scale by catalytic enantioselective transfer hydrogenation[10] of 2-bromo-1-(2-furyl)ethanone (**6**)[11] to **7** (> 98.5% *ee*

ride[13] and triethylamine, a mixture of **10** and a further *exo* sultone isomer was formed in a domino process consisting of elimination, esterification, and intramolecular Diels–Alder reaction, from which pure **10** could be isolated in excellent yield after thermal equilibration.[8] Conversion of **10** to methylenecyclohexene **13** succeeded by a sequential transformation consisting of elimination, alkoxide-directed 1,6-addition of lithiosilane **12**,[14,15] and desulfurization with simultaneous methylenation in a one-pot procedure.[16] In a single synthetic operation, the prefunctions for a γ-lactone were unfolded, activation for 1,4-dioxygenation was created by virtue of the 1,3-diene, and the primary hydroxy group was liberated for side-chain elongation.

For side-chain elongation, diol **13** was first bissilylated, and then the primary hydroxy group was selectively deprotected (Scheme 3). After conversion[17] of the resulting alcohol **15** to iodide **16**, the required C$_2$ unit was attached by alkylation with dimethyl malonate in the presence of proazaphosphatrane **17**[18,19] and demethoxycarbonylation[8,20] of **18**. An intramolecular protocol was eventually decisive for the efficient generation of the enediol fragment of the target molecules. Carboxylic acid **20**, obtained after saponification of **19**, was treated successively with bis(*sym*-collidine)iodine(ı) hexafluorophosphate[21] followed by silver acetate in dimethylformamide[22] in a one-pot procedure, whereupon the formyloxy ε-lactone **21**[23] was isolated as the major product. Substitution of the formylation by a reduction[24,25] of the intermediate allyl iodide should allow concise access to

britannilactones **3** and **4**. Iodolactone **22**, which was formed in small amounts next to **21**, can be reductively eliminated[26] to return **20**. The undesired configuration at C6 (eudesmane numbering) in **21** set up in a completely stereoselective fashion during the sequential iodolactonization/allyl formate generation from **20** was subsequently corrected by an oxidation/reduction strategy.[27] Reduction of diester **21** with lithium aluminum hydride to give a hydroxy lactol[28] and further reduction with lithium borohydride afforded triol **23**. Chemoselective tritylation of the two primary hydroxy groups (→**24**), Dess–Martin oxidation[29] (→**25**), and mild desilylation[30] led to β-hydroxy ketone **26**. Hydroxy-directed[31] reduction of the latter with the sodium aluminum dihydride Red-Al furnished the desired 6α allyl alcohol **27** with excellent diastereoselectivity.[32] After Tamao–Fleming oxidation,[33,34] the completely oxygenated skeleton of the target molecules with correct configuration at all stereogenic centers was finally available in the form of triol **28**.

The final stage of the synthesis was initiated with a chemoselective oxidation[35] of triol **28** to give hydroxy γ-lactone **29** (Scheme 4). After protection of the secondary hydroxy group, a one-step α-methylenation of lactone **30** succeeded with sodium hydride and paraformaldehyde,[36] and

following desilylation, lactone **31** was isolated in good overall yield. Preparation[2] of methacrylate **32** as well as detritylation to give **1** proceeded uneventfully and delivered (−)-eriolanin, which proved to be identical to the natural product by comparison of optical rotation data.[37] Thus, our synthesis of **1** also clarifies the previously unknown absolute configuration of this sesquiterpene lactone, since the absolute configuration of **9** was unambiguously established.[9] In addition, an X-ray diffraction analysis of our synthetic product **1** provided a further independent proof of the absolute configuration by anomalous X-ray scattering.[38] Using a modified Yamaguchi esterification,[39] **31** could also be transformed smoothly to angelate **33** without *Z/E* isomerization. Deblocking to give **2** delivered (−)-eriolangin, which also turned out to be identical to the natural product by comparison of optical rotation data.[40]

Due to the sultone strategy applied, our enantioselective route to the 1,10-*seco*-eudesmanolides **1** and **2** requires only 26 steps from 2-bromo-1-(2-furyl)ethanone (**6**). Average yields of 87% for **1** and 86% for **2** highlight the efficacy of the route reported. Moreover, the selective manipulation of the diverse hydroxy groups on the 1,10-*seco*-eudesmanolide framework possible here offers great flexibility with respect

[Yb₃N(dpa)₆][Yb(dpa)₃]: A Molecular Nitride of a Rare-Earth Metal with a Yb₃N Unit**

Catharina C. Quitmann and Klaus Müller-Buschbaum*

Rare-earth compounds containing a nitrogen center have so far only been known in solid-state chemistry, for example, in the nitrides of metal-rich rare-earth halides.[1] In these compounds the nitride ions are surrounded in a tetrahedral manner by rare-earth ions,[2a,b] with a few exceptions showing an octahedral environment.[2c] Nitride ions with a triangular coordination are only found in $Ce_{15}N_7I_{24}$.[3] In coordination chemistry neither molecular nitrides nor equivalent Ln_3N species were known.

Although liquid ammonia was used in the synthesis of divalent ytterbium and europium metallocenes in the early days of organometallic chemistry,[4] it no longer plays an important role as a reaction medium or as a reactant for obtaining new coordination compounds of these elements. The significance of liquid ammonia is, however, evident in the synthesis and stabilization of many Zintl anions.[5] Nonethe-

less, syntheses in standard solvents dominate all preparative approaches to organometallic rare-earth compounds,[6] including rare-earth amido compounds.[6d]

Similar to the alkaline metals,[7] europium und ytterbium can be dissolved in liquid ammonia under normal pressure.[8] Because of the formation of an electride solution, these metals can be oxidized by amines at $-50\,°C$.[9] Thus, the solvent-free melt and solvothermal syntheses that are employed for the preparation of homoleptic amides of rare-earth elements[10] [Eq. (1), Ln = lanthanoid] can be extended to two consecutive steps in a different temperature range [Eq. (2), (3)].

$$Ln + x\,H\text{-}NR_2 \xrightarrow{\Delta T} [Ln(NR_2)_x] + \frac{x}{2}H_2 \tag{1}$$

$$Ln + (6+y)\,NH_{3(l)} \rightarrow [Ln(NH_3)_6]^{x+} + x\,[e^-(NH_3)_y] \tag{2}$$

$$[Ln(NH_3)_6]^{x+} + x\,[e^-(NH_3)_y] + x\,H\text{-}NR_2 \rightarrow$$
$$[Ln(NR_2)_x] + \frac{x}{2}H_2 + (6+y)\,NH_3 \tag{3}$$
The formation of homoleptic ammine complexes[11] [Eq. (2)] offers the possibility of inserting NH_3 and its deprotonation products into the coordination sphere of the rare-earth metals. This approach supplements the high-temperature synthetic routes commonly used in solid-state chemistry[10] and also renders redox chemistry feasible at low temperatures.

Here we report the reaction of ytterbium with 2,2′-dipyridylamine (Hdpa, $(C_5H_4N)_2NH$) in liquid ammonia and demonstrate how the oxidation of rare-earth metals with amines at low temperatures leads to rare-earth metal compounds with unusual nitrogen coordination. The product of this reaction is [Yb₃N(dpa)₆][Yb(dpa)₃] (**1**), a novel dipyridylamide of ytterbium that consists of two different neutral molecular building units.

Hdpa
Centered by a nitride ion, the three Yb^{3+} atoms in the [Yb₃N(dpa)₆] unit of **1** form an approximate equilateral triangle with no metal–metal bonds (Yb⋯Yb 359 pm). Because the nitride ion is almost in the plane of the Yb^{3+} ions, the Yb–N distances are particularly short, ranging from 207(1) to 209(1) pm. Taking into consideration the different radius of Ce^{3+}, these values are in good agreement with the Ce–N(nitride) distances of 217–220 pm observed for $Ce_{15}N_7I_{24}$.[3] Owing to the voluminous dipyridylamide ligands surrounding the Yb₃N unit the nitride ion shows only a slight deviation from the triangular plane (4 pm). In comparison, tetrahedrally coordinated nitride ions exhibit longer Ln–N distances, for example, 226–229 pm in Gd_2NCl_3, in which the nitride ion is in the center of the tetrahedron.[2b] The very short Yb–N distances within the Yb₃N unit indicate that a π-bonding component may be possible.

The Yb₃N triangle is surrounded by six dipyridylamide anions that employ all nitrogen atoms for coordination: Each ligand is coordinated to one Yb atom in a 1,3-chelating mode and to another Yb atom through a single bond (Figure 1). This results in a distorted pentagonal-bipyramidal coordina-

Figure 1. The triangular nitrido unit [Yb₃N(dpa)₆] (left) and the distorted pentagonal-bipyramidal coordination sphere of the Yb atoms in the [Yb₃N(dpa)₆] unit in **1** (right). The nitride ion lies in the plane of the three Yb atoms. Lines connecting Yb—Yb and N—N are meant to highlight the triangular unit and a coordination polyhedron and do not represent bonds. Selected distances [pm] and angles [°]: Yb1–N1 207(1), Yb2-N1 207(1), Yb3-N1 209(1), Yb1-Yb2 359.4(1), Yb1-Yb3 359.0(1), Yb2-Yb3 359.4(1), Yb1-N18 240(2), Yb1-N15 241(2), Yb1-N19 243(2), Yb1-N14 244(2), Yb1-N4 245(2), Yb1-N2 250(2), Yb2-N3 240(2), Yb2-N8 249(2), Yb3-N11 241(2), Yb3-N17 250(2); Yb2-Yb1-Yb3 60.04(2), Yb1-Yb2-Yb3 59.93(2), Yb1-N1-Yb2 120.5(5), Yb1-N1-Yb3 119.2(5), N2-Yb1-N19 55.9(7), N14-Yb1-N15 54.4(6), N5-Yb2-N6 54.8(5), N7-Yb2-N8 55.7(6), N11-Yb3-N12 54.7(5), N16-Yb3-N17 55.2(7), N4-Yb1-N18 169.8(6). C white, N dark gray, Yb light gray.
Figure 2. Structure of the homoleptic [Yb(dpa)₃] unit of **1** in the solid state. The metal/amide ratio of 1:3 results in a disorder of the ligands, because the Yb5 atom is positioned on a center of symmetry. The positions of the ligand atoms are occupied to 50%. Selected distances [pm] and angles [°]: Yb5-N29 223(2), Yb5-N32 229(3), Yb5-N35 237(3), Yb5-N33 242(2), Yb5-N/C30 260(2); N32-Yb5-N33 62(1), N35-Yb5-N/C30 65(1). N dark gray, Yb light gray.

tion sphere of seven nitrogen atoms around the Yb atoms. Therefore, with regard to coordination mode as well as coordination number, [Yb₃N(dpa)₆] is not equivalent to the homoleptic rare-earth dipyridylamides,[12] dipyridylamides of transition metals,[13] or related aminopyridinato complexes.[14] The coordination number of seven as in [Yb₃N(dpa)₆] is also

found in the Ce₃N units of Ce₁₅N₇I₂₄;[3] here each Ce³⁺ ion is coordinated by six additional iodide ions.

The second molecular unit in **1**, the homoleptic monomer [Yb(dpa)₃], does not coincide with the dimeric structure of the homoleptic rare-earth dipyridylamides[12] either. The Yb atoms are coordinated by 1,3-chelating dpa ligands (coordination number six) and positioned on symmetry centers. Because of the Yb:N ratio of 1:3 the atoms of the dpa ligands are disordered (Figure 2).[15,16]

To verify that **1** is indeed a molecular nitride of a rare-earth metal and to exclude the participation of oxygen in the coordination sphere—as is seen in units containing oxygen, such as {Eu₄O} in Eu₄OCl₆[17] or {Yb₄O} in Yb₄OCl₆[17] and [K(thf)₃]₂[Yb₄O-{Ph₂C(C₄H₃N)₂}₄]·2THF[18]—the compound was investigated by IR spectroscopy and EDX analysis. There was no indication for the presence of oxygen in **1** (see the Supporting Information). Furthermore, the absence of oxygen is supported by the electron neutrality as well as the oxygen-free synthesis in liquid ammonia,[19] and this therefore renders the identification of the center ion as a nitride ion plausible.

The deprotonation of ammonia proceeds more readily with cations of higher charge than alkaline metal ions,[20] but had not yet been observed for the nitride ion. With compound **1** it was shown that with low-temperature oxidation of ytterbium in liquid ammonia, completely different products can be obtained and stabilized than with the direct high-temperature oxidation of a melt synthesis.[12]

In conclusion the approach presented here offers possibilities for obtaining molecular nitrides of the rare-earth metals. Enclosure by amide ligands results in different nitrido amides.

Experimental Section

1: Ytterbium metal chips (173 mg, 1 mmol, ChemPur, 99.9%) and 2,2′-dipyridylamine (Hdpa; 514 mg, 3 mmol, Aldrich, 99%) were filled in a glass ampoule, and then NH₃ (6 mL) was condensed into the ampoule with liquid nitrogen. Upon warming to approximately −50°C the solution turned dark blue. The color changed from dark blue to green and then yellow upon dissolution of 2,2′-dipyridylamine and further warming of the reaction mixture (red streaks appeared which also turned yellow). Evaporation of excess NH₃ gave a green-yellow solid. The ampoule was sealed under vacuum. The reaction mixture was heated to 150°C in 5 h and then to 190°C in 4 h, and then held at this temperature for 168 h. It was then cooled to 120°C in 270 h and to then room temperature within 30 h. When the reaction was complete (based on Yb), **1** was obtained as a yellow crystalline solid; small amounts of a red, X-ray amorphous material were also observed. [16] Crystal structure analysis of **1**: $(C_{90}H_{72}N_{28}Yb_4$, $M_r = 2237.9 \text{ g mol}^{-1})$: crystal size $0.2 \times 0.1 \times 0.1$ mm^3; space group $P\bar{1}$ (no. 2), $a = 1858.0(3)$, $b = 1860.7(3)$, $c = 1877.9(3)$ pm, $\alpha = 90.04(1)$, $\beta = 119.65(2)$, $\gamma = 119.91(1)°$, $T = 170$ K, $Z = 2$, $V = 4619.6(3) \times 10^6$ pm^3, $\rho_{calcd} = 1.857$ g cm^{-3}, $2\theta_{max} = 54.68°$, STOE IPDS II diffractometer, φ scan with $\Delta\varphi = 2°$ and $\Omega = 0.90°$, Mo$_{K\alpha}$ radiation, $\lambda = 0.71073$ Å; of 18795 measured reflections, 18767 were unique and 5701 with $I > 2\sigma(I)$; 1168 refined parameters. The structure was solved with direct methods (SHELXS-97[21a]) and refined with the least-squares method (SHELXL-97[21b]) for all unique reflections against $|F^2|$, $R_1 = 0.0614$ for 5701 reflections with $I > 2\sigma(I)$, $wR_2 = 0.1520$ for all 18767 unique reflections; max./min. residual electron density $+1.82/-1.47$ e Å^{-3}. The hydrogen atoms were placed in preset positions with adjustment of the thermal parameters by a factor of 1.2 with respect to those of the neighboring carbon atoms (AFIX 43). The atoms of the ligands in the [Yb(dpa)$_3$] units were disordered, with each occupying two positions, which made the use of "rigid bond" models necessary to refine the ligand positions.[21b] All non-hydrogen atoms were anisotropically refined by least-square techniques. There was no indication of a possible non-centrosymmetry of the structure or hemihedral twinning.[15] Because **1** exhibits a pseudo-hexagonal metric, powder diffraction was used to exclude the possibility that the metrics was falsely determined due to twinning. CCDC-232899 contains the supplementary crystallographic data for this paper. [19] Although it is difficult to distinguish a nitride ion from an oxide anion in the crystal structure analysis, the presence of the latter can be largely excluded: The formation of the electride in liquid ammonia allows no oxygen contamination and therefore forces an oxygen-free synthesis, and the assumption of an O^{2-} ion in place of the N^{3-} ion would not result in a neutral charge for this trivalent ytterbium compound (see also the Supporting Information).

One-Pot Syntheses

Novel Three-Component Reactions Based on a Heck Carbopalladation/Cyclization Domino Reaction**

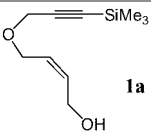
Christoph J. Kressierer and Thomas J. J. Müller*

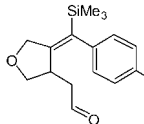
Dedicated to Professor Armin de Meijere
on the occasion of his 65th birthday

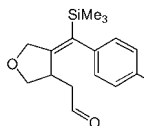
Palladium-catalyzed domino reactions based on sequences of insertions of organopalladium species into multiple bonds (carbopalladation) have fundamentally revolutionized synthetic concepts for the formation of carbo- and heterocyclic systems.[1,2] These transformations proceed under exceptionally mild reaction conditions and are highly compatible with polar functional groups. Conceptually, multicomponent reactions[3] initiated by palladium-catalyzed carbon–carbon bond-forming reactions[2,4] address very fundamental principles of synthetic efficiency and reaction design and, therefore, they have recently attracted considerable and steadily increasing academic, economic, and ecological interest. Besides, the prospect of extending one-pot reactions for combinatorial and solid-phase applications[3c,5] promises manifold opportunities for developing novel lead structures for pharmaceut-

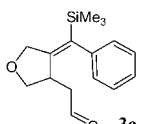
icals, catalysts, and even novel molecule-based materials. Therefore, mastering unusual combinations of elementary organic reactions is a major conceptual challenge in engineering novel types of sequences. As part of our program directed toward developing new one-pot sequences and domino processes based upon transition-metal-catalyzed in situ activation of alkynes by cross coupling[6] or cycloisomerization,[7] we report herein on the first Heck carbopalladation/cyclization sequence of ynallyl alcohols and aryl halides to give γ,δ-enals. Two novel consecutive three-component reactions initiated by this new domino reaction serve as illustrations.

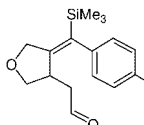
Although intramolecular Heck reactions[8] have a broad range of applications culminating in domino sequences like the impressive Negishi zipper reactions,[1a] and since the use of enynes as relays for Heck carbopalladation/cyclization sequences has been thoroughly studied,[9, 10] the transformation of ynallyl alcohols that could furnish γ,δ-enals has remained unexplored to date. However, the generation of an aldehyde functionality en route could enormously enhance the degree of molecular diversity possible in multicomponent reactions.

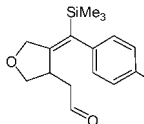
The reaction of alkynylallyl alcohols **1**[11] and aryl halides **2** in the presence of 2 mol% of [Pd(PPh₃)₂Cl₂] in boiling triethylamine under Heck reaction conditions furnished the cyclized γ,δ-enals **3** (the tetrahydrofuran derivatives **3a–i** and chromane derivatives **3k–m**) in moderate to good yields (Scheme 1, Table 1).[12]


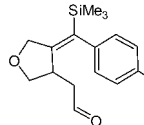


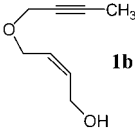


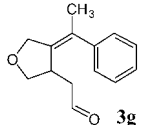


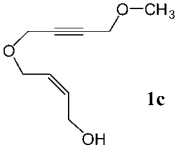


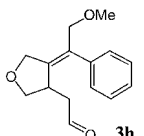


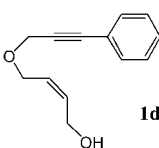


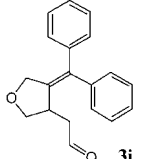


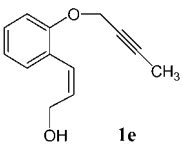


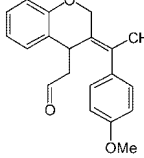


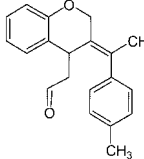


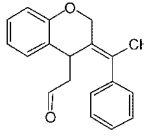












Scheme 1. The palladium-catalyzed Heck carbopalladation/cyclization sequence for the conversion of ynallyl alcohols **1** into γ,δ-enals **3**.

The structures of the ethylidenetetrahydrofuranyl and ethylidenechromanyl acetaldehydes **3** were supported unambiguously by spectroscopic analyses (¹H, ¹³C and DEPT, COSY, NOESY, HETCOR, and HMBC NMR experiments, IR, UV/Vis, mass spectrometry). The configuration of the tetrasubstituted double bonds can be deduced unequivocally from the appearance of significant cross peaks (between the signals of the exocyclic trimethylsilyl, methyl, and methylene substituents and endocyclic methylene proton resonances in α-position to the ether bridge) in the NOESY spectra.

For footnotes, see next page.

This new palladium-catalyzed domino reaction has precedence in its elementary steps, such as intramolecular insertion of tethered alkynes and alkenes,[1a] and the Heck reaction of allyl alcohols to furnish 3-arylpropanals,[13] and can therefore be rationalized as follows (Scheme 1): After the oxidative addition of the aryl halide **2** to the in situ generated Pd⁰ species, the arylpalladium halide **4** coordinates and the triple bond of the ynallyl alcohol **1** is inserted by means of a *syn* carbopalladation to furnish the vinylpalladium species **5** in a stereospecific fashion. Coordination and cyclizing insertion of the allyl alcohol fragment generates the alkylpalladium species **6** which then undergoes a β-hydride elimination to give the dienol **7**. Instantaneously tautomerization of **7** gives the enal product **3**, and the hydridopalladium halide species **8**, which reductively eliminates hydrogen halide with base assistance to regenerate the Pd⁰ species. After the oxidative addition of **2** the catalytic cycle starts again. Interestingly, the reaction with the trimethylsilyl-substituted alkynylallyl alcohol **1a** gives considerably higher yields (Table 1, entries 1–6 and entries 7–9). The rigidified phenylene-bridged ynallyl alcohol **1e** readily participates in the sequence furnishing chromanylacetaldehyde derivatives in reasonable yields (entries 10–12). Since the Heck carbopalladation/cyclization sequence is considerably hampered with electron-deficient aryl halides—as reflected by either the longer reaction times or, alternatively, microwave irradiation to achieve complete conversion (entries 5 and 6)—the arylpalladium species exerts a strong electronic effect in the carbopalladation step.

This new Heck carbopalladation/cyclization domino sequence of alkynylallyl alcohols to give γ,δ-enals forms the basis for sequential one-pot three-component reactions that are compatible with the mild reaction conditions of the initial Pd-catalyzed process. The newly formed aldehyde functionality is perfectly suited for a subsequent Wittig olefination. Thus, the reaction of alkynylallyl alcohols **1a** and **1e** with the aryl halides **2** in the presence of a catalytic amount of [Pd(PPh₃)₂Cl₂] in boiling triethylamine followed by addition of a stabilized phosphorus ylide of type **9** at room temperature furnishes the 2,3,6,7-diene esters **10** in moderate to good yields (Scheme 2).[12]

Additionally, upon reducing the amount of triethylamine to only two equivalents, the new Heck carbopalladation/cyclization sequence can serve as an entry for a subsequent reductive amination under Leuckart–Wallach conditions[14] in a sequential one-pot reaction. Thus, the reaction of alkynylallyl alcohol **1a** in the presence of a catalytic amount of [Pd(PPh₃)₂Cl₂] and 2 equiv of triethylamine in boiling 1,2-dichloroethane followed by addition of various secondary amines **11** and formic acid at 60 °C results in the formation of β-aminoethylalkylidenetetetrahydrofurans **12** in moderate to excellent yields (Scheme 3).[12]

In conclusion, we have developed a Heck carbopalladation/cyclization domino reaction starting from ynallyl alcohols **1** and aryl halides to give γ,δ-enals **3**. This new domino

process was readily elaborated into two consecutive one-pot three-component sequences in which a Heck carbopalladation/cyclization/Wittig sequence and a Heck carbopalladation/cyclization/reductive amination sequence give rise to heterocyclic 2,3,6,7-diene esters and β-aminoethylalkylidenetetrahydrofurans, respectively. Studies addressing the scope of these novel sequences and related sequential transformations to enhance molecular diversity in pharmaceutically interesting targets are currently under investigation.

Experimental Section

Heck carbopalladation/cyclization sequence (**3b**): In a 50-mL screw-top pressure vessel [Pd(PPh₃)₂Cl₂] (15 mg, 0.02 mmol) was dissolved in degassed triethylamine (10 mL). Then, **1a** (198 mg, 1.00 mmol) and **2b** (240 mg, 1.10 mmol) were added successively to the solution. The

Table 1: [a] Reaction conditions: 1.0 equiv ynallyl alcohol **1**, 1.1 equiv aryl halide **2** (0.1 M in triethylamine), and 0.02 equiv [Pd(PPh₃)₂Cl₂] were heated at reflux for 2–28 h. [b] Yields refer to yields of isolated compounds **3** after flash chromatography on silica gel; purity was estimated to be ≥ 95 % by NMR spectroscopy and elemental analysis and/or HRMS. [c] The reaction was performed in a microwave oven (0.50 mmol **1a**, 0.55 mmol **2 f**, 2 mol% [Pd(PPh₃)₂Cl₂]; heating rate: 160 s with 300 W to 150 °C, 30 min of reaction time at 150 °C, cooling rate: 240 s to 45 °C). [d] [Pd(PPh₃)₄] as a catalyst.

reaction mixture was heated at reflux for 2.5 h then allowed to cool to room temperature before diethyl ether (150 mL) was added, and the resulting precipitate was filtered. The solvents were removed from the filtrate in vacuo, and the residue was flash chromatographed on silica gel to give analytically pure **3b** (239 mg, 85% yield) as a pale yellow oil, $R_f = 0.59$ (hexane/diethyl ether 1:1). ^{1}H NMR (CDCl$_3$, 500 MHz): $\delta = -0.17$ (s, 9H), 2.34 (s, 3H), 2.50–2.55 (m, 1H), 2.76–2.81 (m, 1H), 2.93 (ddd, $J = 1.6, 9.7, 17.8$ Hz, 1H), 3.68–3.72 (m, 1H), 3.81 (dd, $J = 1.6, 11.3$ Hz, 1H), 4.08 (d, $J = 17.1$ Hz, 1H), 4.20 (dd, $J = 2.3, 17.2$ Hz, 1H), 6.97–7.01 (m, 2H), 7.10–7.14 (m, 2H), 9.86–9.87 ppm (m, 1H); ^{13}C NMR (CDCl$_3$, 125.8 MHz): $\delta = 0.2$ (CH$_3$), 21.1 (CH$_3$), 31.2 (CH), 46.8 (CH$_2$), 67.3 (CH$_2$), 70.6 (CH$_2$), 128.5 (CH), 128.7 (CH), 133.8 (C$_{quat.}$), 137.2 (C$_{quat.}$), 137.4 (C$_{quat.}$), 149.5 (C$_{quat.}$), 201.5 ppm (CH); HRMS calcd for C$_{17}$H$_{24}$O$_2$Si: 288.1546, found: 288.1543; Elemental analysis calcd for C$_{17}$H$_{24}$O$_2$Si (288.5): C 70.78, H 8.39; found: C 70.61, H 8.43.

Heck carbopalladation/cyclization/Wittig sequence (**10b**): In a 50-mL screw-top pressure vessel [Pd(PPh$_3$)$_2$Cl$_2$] (14 mg, 0.02 mmol) was dissolved in degassed triethylamine (10 mL). Then, **1a** (198 mg, 1.00 mmol) and **2b** (241 mg, 1.10 mmol) were added successively to the solution. The reaction mixture was heated at reflux for 2.5 h then allowed to cool to room temperature before THF (5 mL) and **9** (523 mg, 1.50 mmol) were added successively, and the reaction mixture was stirred at room temperature for 18 h. The precipitates were removed by filtration, the solvents were removed from the filtrate in vacuo, and the residue was flash chromatographed on silica gel to give the analytically pure **10b** (301 mg, 86%) as a yellow oil, $R_f = 0.72$ (hexane/diethyl ether 1:1). ^{1}H NMR (CDCl$_3$, 250 MHz): $\delta = -0.16$ (s, 9H), 1.30 (t, $J = 7.1$ Hz, 3H), 2.23–2.61 (m, 6H), 3.58–3.66 (m, 1H), 3.81 (dd, $J = 1.9, 11.2$ Hz, 1H), 4.02–4.26 (m, 4H), 5.92 (dt, $J = 1.4, 15.6$ Hz, 1H), 6.91–7.15 ppm (m, 5H); ^{13}C NMR (CDCl$_3$, 75.5 MHz): $\delta = 0.4$ (CH$_3$), 14.2 (CH$_3$), 21.1 (CH$_3$), 35.2 (CH$_2$), 36.0 (CH), 60.1 (CH$_2$), 66.0 (CH$_2$), 70.5 (CH$_2$), 122.8 (CH), 128.6 (CH), 128.7 (CH), 134.5 (C$_{quat.}$), 137.1 (C$_{quat.}$), 137.6 (C$_{quat.}$), 147.1 (CH), 149.2 (C$_{quat.}$), 166.4 ppm (C$_{quat.}$); HRMS calcd for C$_{21}$H$_{30}$O$_3$Si: 358.1964, found: 358.1950; Elemental analysis calcd for C$_{21}$H$_{30}$O$_3$Si (358.6): C 70.35, H 8.43; found: C 70.31, H 8.42.

Heck carbopalladation/cyclization/reductive amination sequence (**12b**): In a 50-mL screw-top pressure vessel [Pd(PPh$_3$)$_2$Cl$_2$] (28 mg, 0.04 mmol) was dissolved in a mixture of degassed 1,2-dichloroethane (10 mL) and triethylamine (202 mg, 2.00 mmol). Then, **1a** (198 mg, 1.00 mmol) and **2c** (240 mg, 1.10 mmol) were added successively to the solution. The reaction mixture was heated at reflux for 3 h then allowed to cool to room temperature before formic acid (552 mg, 12.0 mmol) and pyrrolidine (**11b**) (356 mg, 5.00 mmol) were added successively, and the reaction mixture was heated to 60 °C for 12 h. The reaction mixture was allowed to cool to room temperature, diethyl ether (150 mL) and anhydrous potassium carbonate were added, and the precipitates were removed by filtration. The solvents were removed from the filtrate in vacuo, and the residue was flash chromatographed on basic alumina (Brockmann activity IV) to give the analytically pure **12b** (261 mg, 79%) as a yellow-red oil, $R_f = 0.31$ (hexane/diethyl ether 1:2). ^{1}H NMR (CDCl$_3$, 500 MHz): $\delta = -0.22$ (s, 9H), 1.67–1.85 (m, 6H), 2.09–2.18 (m, 1H), 2.42–2.60 (m, 6H), 3.60–3.67 (m, 1H), 3.83 (dd, $J = 2.2, 11.0$ Hz, 1H), 4.04 (d, $J = 16.9$ Hz, 1H), 4.20 (dd, $J = 2.2, 16.9$ Hz, 1H), 7.04–7.11 (m, 2H), 7.20–7.30 ppm (m, 3H); ^{13}C NMR (CDCl$_3$, 125.8 MHz): $\delta = 0.4$ (CH$_3$), 23.4 (CH$_2$), 31.5 (CH$_2$), 35.3 (CH), 54.3 (CH$_2$), 54.9 (CH$_2$), 66.8 (CH$_2$), 70.4 (CH$_2$), 127.2 (CH), 127.9 (CH), 128.8 (CH), 135.8 (C$_{quat.}$), 141.0 (C$_{quat.}$), 148.2 ppm (C$_{quat.}$); HRMS calcd for C$_{20}$H$_{31}$NOSi: 329.2175, found: 329.2167; Elemental analysis calcd for C$_{20}$H$_{31}$NOSi (329.56): C 72.89, H 9.48, N 4.25; found: C 73.36, H 9.71, N 3.91.

Cover Picture

Ariel Ismach, Lior Segev, Ellen Wachtel, and Ernesto Joselevich*

The assembly of nanowire arrays is a critical prerequisite for the large-scale fabrication of nanocircuitry. In their Communication on pp. 6140 ff., E. Joselevich and co-workers show how single-wall carbon nanotubes are formed along the atomic steps of vicinal surfaces, to give highly aligned, dense arrays of discrete, nanometer-wide wires. The cover picture shows how the nanotubes (blue AFM image) reproduce the atomic features of the surface (red model).

Nanobiotechnology
The recent advances in the preparation of biomaterial–nanoparticle conjugates, as well as the organization of these systems as functional devices, are presented by E. Katz and I. Willner in their Review on page 6042 ff.
Biomimetic Synthesis
The assembly of water-soluble carbohydrate-functionalized polymers designed to mimic the structures of mucin glycoproteins on carbon nanotubes is described by A. Zettl, C. R. Bertozzi et al. in their Communication on page 6111 ff.
Cluster Compounds
In their Communication on page 6202 ff Klinkhammer et al. report the formation of two neutral lead clusters bearing σ-bonded substituents from the reaction of a plumbylene with a hydride source.

Cluster Chemistry

[Nb₆Cl₁₈]⁴⁻ early-transition-metal halide clusters

1

[Rh₆(CO)₁₆] late-transition-metal carbonyl clusters

Six of one and half a dozen of the other: A late-transition-metal octahedral cluster $[Rh_6(PiPr_3)_6(\mu\text{-}H)_{12}]^{2+}$ (**1**) with six phosphine ligands has been reported with a structure and electron count akin to that of early-transition-metal halide clusters, and provides a unique link between the two classes of cluster (see scheme). Cluster **1** is also decorated with 12 hydride ligands.

Minireviews

Reaction Specificity of Enzymes
Unfaithful enzymes, that is, enzymes that catalyze alternative reactions, play a natural role in evolution and occasionally in the biosynthesis of secondary metabolites. In one example pyruvate decarboxy-lase catalyzes not only the natural reaction (**A**) but also the enantioselective acyloin condensation of acetaldehyde and benzaldehyde (**B**).

Reviews
Blue-sky research bears down-to-earth applications: this describes the integration of biological materials with nanomaterials to yield systems that can be applied as biosensors or as building blocks for electronic circuitry. This review describes recent advances in the preparation and the applications of biomolecule–nanoparticle conjugates. The picture shows one such example with the magneto-mechanical analysis of DNA.

Communications
Biocompatible nanotubes: Glycosylated polymers designed to mimic natural mucins were assembled on carbon nanotubes (see picture). Carbon nanotubes coated with mucin mimics were soluble in water, resisted nonspecific protein binding, and bound specifically to biomolecules through receptor–ligand interactions.
The dynamics of reversible photoinduced electron transfer in individual perylene-diimide–triphenylamine-based donor–acceptor dendrimers immobilized in polystyrene were investigated by single-molecule spectroscopy. By changing the local concentration of oxygen, it was possible to influence the transition of the charge-separation state (CSS) either to the locally excited state (LES) or to the ground state (GS, see graphic).

A subtle electronic balance between covalent and dative interactions involving coordinated phosphanyl iminolate ligands results in the formation of an oriented, 1 D coordination/organometallic heterodimetallic polymer with Pd–Ag interactions (shown as purple and green, respectively). In the solid-state, the lipophilic aromatic rings of the infinite zigzag chains are all on one side of the planes of metal ions, which results in an unusual layered structure.
A rational tuning of the arene sulfonamide moiety (by introducing isopropyl groups onto the phenyl ring) brought about high enantioselectivity in the asymmetric synthesis of diarylmethyl amines by the title reaction (see scheme). $Ar^1 =$ 4-$CF_3C_6H_4$, 4-ClC_6H_4, 4-FC_6H_4, 3-$MeOC_6H_4$, 4-$MeOC_6H_4$, 2-MeC_6H_4, 1-naphthyl, Ph; $Ar^2 =$ Ph, 4-FC_6H_4, 3-$MeOC_6H_4$, 4-$MeOC_6H_4$.

A triangular arrangement of gold atoms is observed in the complex $[Au_3(\mu\text{-}GaI_2)_3(Cp^*Ga)_5]$, which results when a mixture of Cp^*Ga and GaI_3 capture the reduced Au fragments from [LAuX] (L = ligand, X = halide). The Au atoms are bonded only to Ga atoms and each other: two Au atoms are coordinated by two Cp^*Ga units and one Au atom is coordinated by a single Cp^*Ga unit.
Ringing the changes: Complexes of azamacrocycles were used for the template synthesis of extraordinary new cyclic and acyclic chromium–nickel chains, which include the "S"-shaped cluster shown (see picture) obtained when a cyclen-based template is used. The results suggest a new method for making sophisticated polymetallic architectures.

Contents
In the solid state at room temperature, reversible control of magnetic properties was achieved with photo-illumination of a composite material made up of γ-Fe$_2$O$_3$ nanoparticles encapsulated with *n*-octyl-amine and an azobenzene-containing amphiphilic compound (see picture).
Mind the step! Single-wall carbon nanotubes grow along the atomic steps of vicinal α-Al$_2$O$_3$ surfaces to give highly aligned arrays of nanometer-wide wires on a dielectric material. The nanotubes (see blue background image) reproduce the atomic features of the surface including steps, facets, and kinks (see model). The direction and morphology of the atomic steps can be controlled by the crystal miscut.
No extra functionalization step is required for palladium(II)-catalyzed oxidative carbocyclizations like that shown, which provide highly substituted benzofuran and dihydrobenzofuran derivatives by net dehydrogenation. The mechanism is similar to that of Heck cyclizations. Products containing quaternary carbon stereocenters can be obtained in diastereomerically pure form.
The binding of a guest (metal ion, M$^+$) to a single host molecule (peptide) was studied by the measurement of the conductance of the peptide (see picture). The conductance of the peptide in the metal–peptide complexes increases by an amount that is dependent on the sequence and the length of the host.
Manganese magnets: Trimethylammonio groups appended to the surface of a Mn_{12} single-molecule magnet lead to a highly charged magnetic cluster that behaves as an electron reservoir. This cluster spontaneously forms its two-electron reduced species which has a ground spin state $S=11$. The cluster is a precursor for the synthesis of network materials containing Mn_{12} and for their deposition onto metal and metal oxide surfaces.
It takes two: The complementary sulfate and guanidinium ions in $[C(NH_2)_3]$ $[N(CH_3)_4][SO_4]$ both act as 3-connecting nodes to give a 3D hydrogen-bonded network with the chiral (10,3)-*a* topology (see X-ray crystal structure; O red, S yellow, H pink, N blue, C black). In contrast, the 3-connected hydrogen-bonded network in the much-studied guanidinium sulfonates is 2D.
Vacancies: Protonation of the ruthenium carbide compounds $[Cl_2(L)(PR_3)Ru\equiv C:]$ gives the 14-electron four-coordinate ruthenium phosphonium alkylidenes $[Cl_2(L)Ru=CH(PR_3)]^+[B(X)_4]^-$ (see scheme). These compounds which already have a vacant coordination site provide direct access to the active species in olefin metathesis catalysis and thus very fast initiation.

Particularly effective: The self-assembly of triazacyclonane-functionalized thiols on the surface of nanosize gold particles provides a facile entry to functional gold nanoparticles that, upon complexation with Zn^{II}, turn into powerful catalysts for the cleavage of phosphate esters (see scheme). Because of their RNase-like behavior they are dubbed nanozymes.
Contents
Pulling the rug out! A templated electro-deposition technique has been applied to prepare stable 3D, organized networks of metal or semiconductor nanowires (see scheme). The process involves a) the deposition of mesoporous silica onto an electrode, b) the introduction of metals or semiconductors into the pore channels, and c) removal of the silica template to yield the nanowire network.

An amphiphilic manganese salen complex forms Langmuir films that catalyze the epoxidation of cinnamyl alcohol with the urea/hydrogen peroxide complex (UHP) dissolved in the subphase (see picture). Compression of the monolayer changes the organization of the film and thus strongly modifies the rate of the reaction, which is enhanced for molecular areas of about 140–160 Å^2.
2-Monosubstituted tetrahydrofurans 2 are obtained with 73–95 % *ee* through the catalytic enantioselective mercuriocyclization of γ-hydroxy-(Z)-alkenes **1** by using Hg(OAc)$_2$ in the presence of Hg^{II} complexed with tartrate-derived 4-(2-naphthyl)bisoxazoline **3**. The chiral complex was prepared from Hg(tfa)$_2$ (0.2 equiv) and **3** (0.3 equiv). The amount of MeOH greatly influences the enantioselectivity.
Essential additives: The addition of bis(1,3-butadienyl) compounds (tetraenes) was essential in the efficient Ni-catalyzed cross-coupling of organozinc reagents with alkyl bromides and a tosylate (see scheme, X = C(CO$_2$Me)$_2$ or NCH$_2$Ph). The efficiency of the Ni-catalyzed cross-coupling of an alkyl fluoride with a Grignard reagent was also improved by using these tetraenes.

R = aryl; R' = H, Me, Ph, CO$_2$Et
M = Sc^{3+}, In^{3+}, Y^{3+}, Yb^{3+}, Lu^{3+}, Hf^{4+}
A simple and highly efficient method for the Friedel–Crafts alkenylation of aromatic compounds has been developed by using a metal triflate (OTf) catalyst in an ionic liquid (see scheme, bmim = 1-butyl-3-methylimidazolium). Not only is the catalytic activity significantly enhanced in the ionic liquid and by-product formation decreased, but some reactions that were not possible in conventional organic solvents were shown to proceed smoothly.
Latex: Nitroxide-mediated emulsion polymerizations of *n*-butyl acrylate and styrene were successfully carried out in a multistep process, with a novel water-soluble SG1-based alkoxyamine as initiator. Fast reactions lead to stable latex particles containing polymers with controlled molar masses.

Pieces of eight: The reaction of [LAl^I] with elemental sulfur yields the crown shaped complex [LAl(μ-S$_3$)$_2$AlL] (L = HC(CMe-NAr)$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) containing an Al$_2$S$_6$ eight-membered ring, in which two (μ-S$_3$) chains are bridging two aluminum atoms (see structure). The relative stabilities of the possible [L$_2$Al$_2$S$_n$] (*n* = 2–8) species are estimated by theoretical calculation.
Sulfur bridges: The reactions of [LAl(SH)$_2$] (L = HC(CMeNAr)$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) with LiN(SiMe$_3$)$_2$ in molar ratio 1:2 and 1:1, respectively, lead to species with the formula [{LAl[(SLi)$_2$(thf)$_3$]}$_2$]·2 THF and [{LAl(SH)[SLi(thf)$_2$]}$_2$] in high yields. These lithium salts react further with [Cp$_2$MCl$_2$] (M = Ti, Zr; Cp = C$_5$H$_5$) to give unique heterobimetallic sulfides of composition [LAl(μ-S)$_2$MCp$_2$] (see structure; M = Ti).

Contents

Like a bolt from the blue, the blue photoluminescence of novel phosphole-based materials is extraordinarily intense. The optoelectronic properties show great stability and broad flexibility with respect to wavelength, intensity, and tuneability. The special features of the dithieno-phosphole system were incorporated in a high-molecular-weight smart polymer potentially suitable for optoelectronic applications.
Feats of lead: The cluster compounds [$Pb_{12}Hyp_6$] (**1**; see structure) and [$Pb_{10}Hyp_6$] (**2**) result from the reaction of the plumbylene [Pb{Si(SiMe$_3$)$_3$}$_2$] ([PbHyp$_2$]) with hydride sources, such as PH$_3$ or [{(Ph$_3$P)CuH}$_6$]. They are the first examples of neutral lead clusters bearing σ-bonded substituents. Whereas **2** is isolated from the reaction mixture on a multigram scale, **1** is only obtained in traces.

= Pb
= Si(SiMe$_3$)$_3$
Advantage organocatalysis: N-heterocyclic carbenes can generate homoenolate equivalents under mild conditions by conjugate umpolung of α,β-unsaturated aldehydes. This organocatalytic reaction allows an efficient one-step synthesis of substituted γ-butyrolactones **1** (see scheme, Mes = mesityl).

Sandwich any one? The bis(butenyltetramethylcyclopentadienyl) complexes of calcium (**2**), strontium and barium exhibit an interaction of the alkaline-earth metals with olefin double bonds. Whereas the magnesium derivative (**1**) crystallizes as a sandwich complex with coplanar cyclopentadienyl ligands and free butenyl side chains, these coordinate to the metal in the analogous but open sandwich complexes of the larger metals calcium, strontium, and barium.

Cluster Chemistry

An Octahedral Rhodium Cluster with Six Phosphine and 12 Hydride Ligands and 10 Too Few Electrons

Paul J. Dyson* and J. Scott McIndoe*

Late-transition-metal (low-oxidation state) clusters, with π-acceptor ligands and early-transition-metal (high-oxidation state) clusters, with π-donor ligands, have been intensively studied for several decades.[1] Apart from the fascinating structural aspects of cluster compounds and rationalization of their bonding, much motivation for their study has been driven by potential applications. It was suggested that transition-metal clusters might prove to be effective catalysts, filling the void between mononuclear species and colloidal (or heterogeneous) catalysts and open up new possibilities in catalysis and organic synthesis.[2]

Research at the interface of late- and early-transition-metal cluster chemistry has not been forthcoming although polyoxometalates have been combined with organometallic fragments[3] and late–early-transition-metal bonds are well known.[4] However, in a recent communication by Weller et al., a late-transition-metal cluster based on an octahedral rhodium core was reported that has a structure and an electron count similar to that of an early-transition-metal cluster, and thus bridges the two largely separate and distinct re-

gimes.[5] The cluster was isolated after a remarkably simple synthesis involving reduction under hydrogen of the complex, $[RhL_2(nbd)]^+$, where L is a phosphine and nbd is norbornadiene. The rhodium precursor represents a widely used class of hydrogenation catalyst, especially for asymmetric reductions where L_2 is a chiral bisphosphine.[6] Therefore, apart from the absence of any substrate, what is so different about the synthesis which leads to such an intriguing cluster? The answer to this question remains to be confirmed, but three factors appear to be important. First, commencing with a rhodium salt comprising a weakly coordinating anion, that is, $[1\text{-H-}closo\text{-CB}_{11}\text{Me}_{11}]^-$ or $[B(Ar_F)_4]^-$ $(Ar_F = 3,5\text{-bis(trifluoromethyl)phenyl)}$. Second, the use of relatively weakly coordinating solvents, that is, C_6H_5F or CH_2Cl_2. Third, the utilization of a phosphine which appears to have the ideal topology to form a protective sheath over the cluster (see below). The cluster in question, $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$, is prepared according to Scheme 1, and accounts for about 20% of the starting material—the other compounds formed in the reaction remain uncharacterized.

each edge bridged by a hydride (Figure 1). It resembles the early-transition-metal cluster $[Zr_6(\mu\text{-Cl})_{12}(PMe_2Ph)_6(H)_x]$ in the arrangement of ligands.[7]
Figure 1. Ball-and-stick representation of the structure of $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$. For clarity the *iso*-propyl groups are represented by a single carbon atom. POV-RAY diagram drawn using ORTEP-3.8.[8]

What is perhaps most interesting, and could indicate why the cluster is stable, is that the *iso*-propyl groups attached to the phosphine ligand appear to cloak the metal core almost completely as can be appreciated from the space filling representation shown in Figure 2. While there are approximately 90 structurally characterized examples of $[M_6(PR_3)_6L_x]$ clusters known, the vast majority have sterically undemanding ligands (typically PEt_3) and only one, $[W_6(\mu_3\text{-S})_8(PCy_3)_6]$ $(Cy = cyclohexyl)$[9] has a

$$[Rh(PiPr_3)_2(nbd)][Y] \xrightarrow{H_2\ (\approx 4\ atm)} [Rh_6H_{12}(PiPr_3)_6][Y]_2 + [HPiPr_3][Y]$$

$$Y = 1\text{-H-}closo\text{-CB}_{11}Me_{11}\ or\ B(Ar_F)_4$$
Scheme 1. The preparation of $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$.

The structure of the $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$ dication comprises an essentially regular octahedron in which each vertex is capped by a phosphine ligand and

Figure 2. Space-filling representation of the structure of $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$.

ligand more bulky than $PiPr_3$. Packing six bulky phosphines around the cluster core does have a distorting effect on the geometry of the octahedral core, but the efficient packing probably helps considerably to stabilize the numerous labile hydride ligands.

The electronic structure of the cluster bears closer resemblance to early-transition-metal clusters with π-donor ligands than to late-transition-metal clusters with π-acceptor ligands. Most octahedral clusters with π-acceptor ligands have 86 electrons, and deviations from this rule for late-transition-metals are rare and usually involve clusters with unusual ligand assemblies, or Group 10 or 11 metals, or both, such as the 90 electron $[Ni_6(\eta^5\text{-}C_5H_5)_6]$.[10] There are many clusters known of the type $[M_6(\mu_3\text{-E})_8(PR_3)_6]$ (M = Group 6, 7, 8, or 9 metal; E = S, Se, or Te)[11] that span the early–late-transition-metal divide, and these have electron counts[12] ranging from 79 for $[W_6(\mu_3\text{-S})_8(PEt_3)_6]^+$[13] to 98 for $[Co_6(\mu_3\text{-S})_8(PEt_3)_6]$.[14] However, $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$ has an electron count of just 76 electrons, a value entirely without precedent for the late-transition-metals and comparable only to early-transition-metal halide clusters, such as $[M_6(\mu\text{-Cl})_{12}Cl_6]^{4-}$ (M = Nb, Ta; also 76 electrons).

In addition, the ratio of hydrides to rhodium is remarkably high, and represents one of the highest ratios observed to date. High hydride to metal ratios are important with respect to hydrogen (hydride) storage and also have implications in hydrogenation catalysis where hydrogen spillage could account for accelerated reductions.[15]

It is probably not unfair to say that cluster chemistry has been in decline since its peak in popularity in the late 1980s. However, without the high expectations that once dominated the field it remains healthy and some of the best work has since been carried out. High-nuclearity clusters, such as $[Os_{20}(CO)_{40}]^{2-}$,[16] $[Ni_{35}Pt_9(CO)_{48}]^{6-}$,[17] $[Pd_{145}(CO)_x(PEt_3)_{30}]$[18] and $[Cu_{146}Se_{73}(PPh_3)_{30}]$,[19] the larger ones exceeding the size of many colloids, have been prepared and characterized by X-ray crystallography. A fascinating series of ruthenium–palladium and ruthenium–platinum clusters prepared by condensation of preformed ruthenium clusters with the $\{M(PtBu_3)_2\}$ unit (also an active catalyst precursor—but for carbon–carbon coupling reactions) have been reported,[20] and related compounds have been used as precursors to highly active supported naked nanoparticle catalysts.[21] Also, the on-going question of whether intact clusters can act as catalysts has finally been resolved, at least for hydrogenation reactions. The answer is yes, demonstrated directly by para-hydrogen NMR spectroscopy, but the process is highly solvent dependent and this might explain why there has been so much controversy in the literature surrounding this topic.[22] However, the isolation of $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$ from $[Rh(PiPr_3)_2(nbd)]^+$ under a hydrogen atmosphere raises another question. Could clusters, especially one so electronically unsaturated and presumably as reactive as $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$, be the active catalysts in hydrogenation reactions commencing with the widely used $[Rh(PiPr_3)_2(nbd)]^+$ precursors, that operate under similar conditions to those in which the cluster was isolated, merely in the presence of a suitable substrate? It is already well established that homogeneous (mononuclear) pre-catalysts often decompose to nanoparticles which are the active catalysts,[23] but little attention has been paid to the mechanism and whether molecular cluster intermediates play an influential role. The distinctive spectroscopic properties of $[Rh_6(PiPr_3)_6(\mu\text{-H})_{12}]^{2+}$ may well facilitate such investigations.

Further development of the unique cluster chemistry introduced by Weller et al. could take many paths. The X-ray data notwithstanding, a neutron diffraction study to pinpoint the exact hydride locations is clearly desirable. Similarly, extension of the structural motif to other late-transition-metals, other bulky two-electron donor ligands, and perhaps other hydride ligand counts, will all provide interesting insights into what represents a new frontier for cluster chemistry.

Catalytic Promiscuity in Biocatalysis: Using Old Enzymes to Form New Bonds and Follow New Pathways

Uwe T. Bornscheuer* and Romas J. Kazlauskas*

*B*iocatalysis has expanded rapidly in the last decades with the discoveries of highly stereoselective enzymes with broad substrate specificity. A new frontier for biocatalysis is broad reaction specificity, where enzymes catalyze alternate reactions. Although often under-appreciated, catalytic promiscuity has a natural role in evolution and occasionally in the biosynthesis of secondary metabolites. Examples of catalytic promiscuity with current or potential applications in synthesis are reviewed here. Combined with protein engineering, the catalytic promiscuity of enzymes may broadly extend their usefulness in organic synthesis.

1. Introduction

The realization that many enzymes have broad substrate specificity fueled much of the growth in biocatalysis over the last twenty years, especially in organic synthesis. Identifying a few enzymes that show high stereoselectivity toward a broad range of synthetically useful molecules enabled organic chemists to rapidly develop new synthetic applications for these enzymes.

One current frontier for biocatalysis is reaction specificity. Can a single active site catalyze more than one distinct chemical transformation? Can small changes in the active site enable new chemistry in that active site? Over the last few years evidence has mounted that such catalytic promiscuity exists not just among a few enzymes but is rather common.[1] This Minireview will focus on catalytic promiscuity related to biocatalysis—enzyme-catalyzed reactions that are or might be useful in organic synthesis. We will give examples of individual proteins with several catalytic abilities and also examples in which small changes (typically metal-ion substitutions or site-directed mutagenesis) introduce new catalytic activity. The most successful examples are carbon–carbon bond-forming reactions, oxidations catalyzed by hydrolytic enzymes, and glycosyl transfer reactions.

2. Classifying Catalytic Promiscuity

Catalytic promiscuity in enzymes is the ability of enzyme active sites to catalyze distinctly different chemical transformations. The chemical transformations may differ in the functional group involved, that is, the type of bond formed or cleaved during the reaction and/or may differ in the catalytic mechanism or path of bond making and breaking. Most examples of catalytic promiscuity include both changes. For example, adding a vanadium ion to a phosphatase converts it into an oxidase capable of the enantioselective oxidation of sulfides (this is discussed in more detail in Section 4.2). These two reactions involve different functional groups—breaking the O−O bond in hydrogen peroxide instead of the P−O bond in a phosphate ester. In addition, the reaction mechanism differs significantly because one reaction is a hydrolysis while the other is an oxidation.

In Figure 1 catalytic promiscuity is organized according to differences in the functional groups involved and differences in the mechanisms of catalysis (for selected examples see Table 1). The placement of a reaction on this graph is subjective because the degree of similarity of functional groups and reaction pathways, whose details are likely unknown, is a subjective judgment. Nevertheless, this classi-

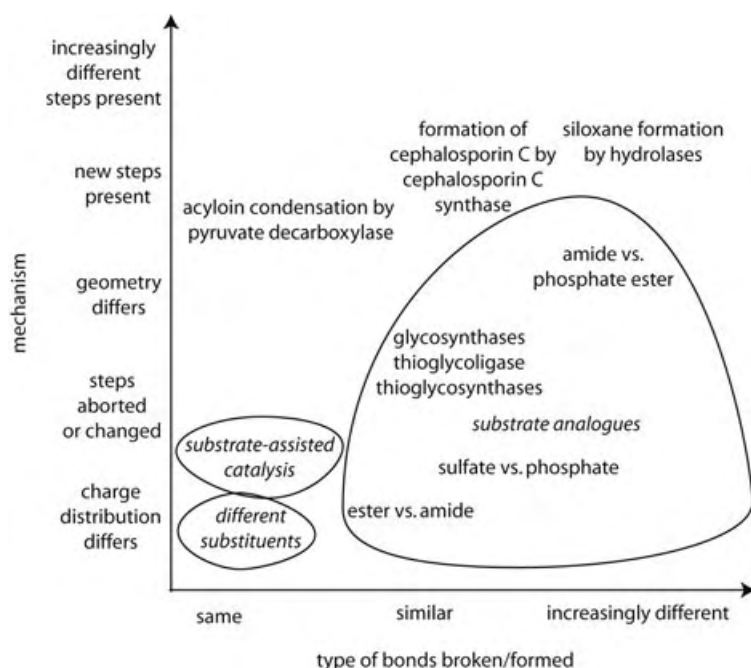

Figure 1. Classifying catalytic promiscuity. Catalytic promiscuity may involve reaction of a different functional group, a change in the catalytic mechanism, or both. The balloons indicate the types of catalytic promiscuity labeled in italics. Table 1 lists selected examples, a few of which are also included in this figure.

fication helps distinguish different types of catalytic promiscuity.

The largest group of reactions involves functional group analogues. For example, many proteases also catalyze ester hydrolysis. The bonds broken in the two cases (C−N vs. C−O) differ, but the catalytic mechanism is likely very similar. Several metalloproteases also catalyze the hydrolysis of P−O[2] or P−F[3] bonds. Conversely, several esterases cleave the C−N bond in β-lactams,[4] and proteases can cleave the S−O[5] in sulfites or the S−N bond in sulfinamides.[6] On a commercial scale, BASF uses a lipase, which normally cleaves C−O bonds in triglycerides, to resolve amines by enantioselective acylation, which forms a C−N bond.[7] Asparaginase, which cleaves the primary amide in the side chain of asparagine, also cleaves a nitrile in an analogous substrate, β-cyanoalanine.[8]

Pyruvate kinase, which catalyzes phosphoryl group transfer, can also catalyze sulfuryl group transfer.[9] Some phosphatases also catalyze sulfate ester hydrolysis.[10] Enzyme inhibitors such as phosphonate inhibitors of serine hydrolases will not be included because they rarely involve a complete catalytic turnover.

Other reaction classes must involve changes in mechanism. For example, removal of a catalytically essential amino acid residue dramatically slows the reaction but does not eliminate it. The remaining, less efficient reaction must follow a different path. For example, a Cys-to-Asp mutation in a phosphatase retains some activity.[11] Another group of reactions involve substrate-assisted catalysis, where the only substrates converted are those that restore the missing functional group so that it can actively participate in catalysis.[12] In some reactions stereochemistry reveals alternate paths. For example, epoxide hydrolase converts one enantiomer by inversion of the stereocenter, while the other reacts by retention.[13] These pathways must differ, even though the details are not clear.

Binding proteins can sometimes catalyze reactions, which is clearly a change in mechanism— from no bond breaking to some bond breaking. For example, bovine serum albumin catalyzes Kemp elimination, β-elimination of 3-ketobutyl umbelliferyl ethers (a useful reaction in enzyme assays),[14] and moderately enantioselective oxidation of amines to amine oxides with sodium periodate.[15] Myoglobin (an oxygen-carrying iron heme protein) catalyzes slow oxidation in the presence of hydrogen peroxide.[16] Site-directed mutagenesis to shift the position of the distal histidine (Leu29His/His64Leu) increased the rate of reaction more than 20-fold and enantioselectivity significantly. Oxidation of thioanisole yielded the sulfoxide with 97% *ee*, and oxidation of *cis*-β-methylstyrene gave the epoxide in 99% *ee*.[17]

All catalytic antibodies are examples of binding molecules that can catalyze a reaction. Interestingly, a catalytic antibody that catalyzes an aldol addition by nucleophilic catalysis (formation of an imine between the substrate carbonyl and a lysine residue) also catalyzes the Kemp elimination, which

Romas Kazlauskas was born in 1956 and studied chemistry at the Massachusetts Institute of Technology (PhD) and Harvard University (postdoc with George Whitesides). He worked at General Electric Company (1985–1988) and McGill University, Montreal, Canada (1988–2003) and is currently an associate professor in Biochemistry, Molecular Biology, and Biophysics at the University of Minnesota, Twin Cities. He is an expert in enantioselective organic synthesis using enzymes.

Uwe Bornscheuer was born in 1964 and studied chemistry at the University of Hannover, Germany, where he graduated with his Diploma in 1990. After receiving his PhD in Chemistry in 1993 at the Institute of Technical Chemistry at the same university, he spent a postdoctoral year at the University of Nagoya, Japan. He then returned to Germany and joined the Institute of Technical Biochemistry at the University of Stuttgart, where he finished his Habilitation in 1998. Since 1999 he has been Professor for Technical Chemistry and Biotechnology at the University of Greifswald. His main research interest is the application of biocatalysts in the synthesis of optically active compounds and in lipid modification.

Table 1: Selected examples of catalytic promiscuity in a single enzyme.

Enzyme	Enzyme class	Normal activity	Promiscuous activity	Ref.
proline aminopeptidase	metallohydrolase (two Mn^{2+} centers)	C–N hydrolysis in proline amides	P–F hydrolysis in diisopropyl fluorophosphate	[3]
aminopeptidase	metallohydrolase (two Zn^{2+} centers)	C–N hydrolysis in amides	P–O hydrolysis in bis-*p*-nitrophenylphosphate	[2]
pyruvate kinase	metalloenzyme (Mn^{2+}, K^+, Mg^{2+} centers)	phosphoryl transfer from phosphoenolpyruvate	sulfuryl transfer from sulfoenolpyruvate; also phosphoryl transfer to fluoride, hydroxylamine, or α-hydroxycarboxylic acids	[10]
o-succinylbenzoate synthase	metalloenzyme (Mn^{2+} center)	dehydration of 2-hydroxy-6-succinyl-2,4-cyclohexadiene carboxylate	racemization of *N*-acylamino acids	[36]
methane monooxygenase	non-heme diiron	hydroxylation of methane	epoxidation, *N*-oxide formation, dehalogenation, desaturation of benzylic substrates	[48]
plant steroyl acyl carrier protein Δ^9 desaturase	non-heme diiron	desaturation of the C9–C10 link in stearic acid to give oleic acid	sulfoxidation of 9-thia or 10-thia analogues of stearate and the hydroxylation of 9-fluoro analogues	[46, 47]
cephalosporin C synthase	metalloenzyme (non-heme Fe center, 2-oxo-glutarate-dependant)	oxidative ring expansion of the five-membered ring to a six-membered, hydroxylation of a methyl group	one of the two normal activities	[43]
lipase, esterase	serine hydrolase	ester hydrolysis	β-lactam hydrolysis	[5]
lipase, chymotrypsin	serine hydrolase	triglyceride or peptide hydrolysis	aldol addition or Michael addition	[27, 30]
subtilisin	serine hydrolase	peptide hydrolysis	sulfinamide hydrolysis	[7]
lipase, trypsin	serine esterase	triglyceride or peptide hydrolysis	oligomerization of $(Si(CH_3)_2(OEt)_2)$, dimerization of $Si(CH_3)_3OCH_3$	[32, 33]
pepsin	aspartate hydrolase	amide hydrolysis	sulfite hydrolysis	[4]
asparaginase	Thr-Lys-Asp triad	C–N hydrolysis in asparagine to give aspartate	C≡N hydrolysis in β-cyanoalanine to give aspartate	[9]
epoxide hydrolase	Asp-His-Asp triad	hydrolysis of epoxides with inversion of configuration	hydrolysis of epoxides with retention of configuration	[14]
oxynitrilase	Ser-His-Asp triad	addition of cyanide to aldehydes	addition of cyanide to imines	[35]
aldolase catalytic antibody	Lys	aldol reaction	Kemp elimination	[19]
serine hydroxymethyltransferase	pyridoxal-dependent	transfer of C_β of serine to tetrahydropteroylglutamate	threonine retroaldol reaction, decarboxylation of aminomalonate, racemization of alanine, transamination of alanine and pyruvate	[26]
pyruvate decarboxylase	thiamine-dependent	decarboxylation of pyruvate	acyloin condensation of acetaldehyde and benzaldehyde	[22–24]

requires the lysine to act as a base.[18] Another catalytic antibody that catalyzes decarboxylation also catalyzes ester hydrolysis.[19]

In principle, changes in substrate specificity cause subtle changes in the electron distribution in the transition state and could be considered as examples of catalytic promiscuity. However, these differences are usually much smaller than the examples considered here.

3. Catalytic Promiscuity within the Same Protein

A classic example of catalytic promiscuity is yeast pyruvate decarboxylase, which not only decarboxylates pyruvate but also links acetaldehyde and benzaldehyde (a lyase activity) to form (*R*)-phenylacetylcarbinol, a precursor for ephedrine manufacture (Scheme 1).[20] This acyloin condensation involves an additional step—formation of a carbon–carbon bond—that does not occur in the natural reaction. Although Neuberg and Hirsch discovered this reaction in whole yeast cells in 1921,[21] researchers more recently identified pyruvate decarboxylase as the responsible enzyme.[22] This reaction also demonstrates that the alternate
Scheme 1. Pyruvate decarboxylase, a thiamine-dependent enzyme, also catalyzes the enantioselective acyloin condensation of acetaldehyde and benzaldehyde.

substrates (acetaldehyde plus benzaldehyde) can be much larger than the natural substrate (pyruvate only). More recently, a single amino acid substitution in the more stable pyruvate decarboxylase from *Xymomonas mobilis*, which does not catalyze the lyase reaction, added this lyase ability.[23]

The pyridoxal-dependent enzymes are another classic example of catalytic promiscuity. In most pyridoxal-dependent enzymes the additional functional groups in the active site

direct the aldimine intermediate toward a single pathway.[24] But in some cases, the aldimine can react by multiple paths. For example, serine hydroxymethyltransferase also catalyzes threonine retroaldol reaction, decarboxylation of aminomalonate, and racemization of alanine.[25] Site-directed mutagenesis of alanine racemase decreased its racemase activity and enhanced its minor transamination activity.[26]

Another carbon–carbon bond-forming reaction is an aldol addition of hexanal catalyzed by lipase B from *Candida antarctica* (Scheme 2).[27] Although the reaction was not enan-
Scheme 2. Lipase B from *Candida antarctica* (CAL-B) catalyzes an aldol addition of hexanal. Although this side reaction is >10^5 times slower than the normal reaction (hydrolysis of triglycerides), it is at least ten times faster than aldol additions catalyzed by a catalytic antibody with aldolase activity. The calculated transition-state structure for enolate formation is on the right.

tioselective, the diastereoselectivity differed from that of the spontaneous reaction. The authors hypothesized that the aldol addition did not require the active site serine, and indeed, replacement with alanine (Ser105Ala) increased the aldol addition approximately twofold.

One reaction that forms several new types of bonds is a Michael addition with alternate nucleophiles catalyzed by *O*-acetylserine sulfhydrylase (Scheme 3). The normal role of this pyridoxal-containing enzyme is cysteine biosynthesis from *O*-acetylserine by the elimination of acetate to give an amino acrylate intermediate. Michael addition of the nucleophile sulfide to this intermediate yields cysteine. However, other nucleophiles also react including thiols, selenols, azide, cyanide, and some aromatic N-heterocycles yielding unnatural amino acids. Thus, besides catalyzing formation of a C–S bond, this enzyme can also catalyze formation of C–Se, C–C, and C–N bonds using a similar mechanism.[28] Recently, Maier engineered an *E. coli* strain for these unnatural reactions. Normal fermentation produced the starting material *O*-acetylserine and the enzyme; addition of nucleophile yielded the unnatural amino acids in 45–91% yield.[29] Lipases also catalyze Michael addition of various nucleophiles to 2-(trifluoromethyl)-propenoic acid.[30]

Lipase[31] and trypsin[32] catalyze the condensation of silanols and alkoxysilanes, respectively, which involves formation of Si–O–Si bonds. Trypsin catalyzed the hydrolysis and condensation of trimethylethoxysilane to hexamethylsiloxane in water (Scheme 4). Al-
Scheme 3. Michael addition of alternate nucleophiles by *O*-acetylserine sulfhydrylase to give an amino acrylate intermediate yields unnatural amino acids.
Scheme 4. Trypsin-catalyzed hydrolysis and condensation of trimethylethoxysilane to give hexamethyldisiloxane in water.

though silanols and alkoxysilanes are inherently reactive and can undergo spontaneous condensation or peptide-promoted condensation,[33] the trypsin-catalyzed reaction was at least ten times faster than the spontaneous reaction. The condensation involves the trypsin active site because addition of trypsin-specific inhibitors eliminated catalysis and because not all trypsins catalyze this reaction: porcine trypsin was effective, but trypsin from Atlantic cod was not.

Oxynitrilase, which catalyzes addition of cyanide to aldehydes, also catalyzes the addition of cyanide to imines with moderate stereoselectivity (3:1–4:1).[34]

A case of mistaken identity due to catalytic promiscuity is an enzyme originally identified as a *N*-acyl amino acid racemase.[35] Gerlt and co-workers recently discovered that this enzyme is 1000 times more efficient as a catalyst for a dehydration to form *o*-succinylbenzoate, suggesting that succinylbenzoate formation is its true role (Scheme 5). By changing the *N*-acyl amino acid from *N*-acetyl methionine (the previous best substrate for racemase activity) to *N*-succinyl phenylglycine, which better resembles the succinyl-
Scheme 5. An enzyme discovered as an *N*-acyl amino acid racemase is 1000-fold more efficient in the dehydration to form *o*-succinylbenzoate. Both reaction mechanisms involve a similar anionic intermediate.

benzoate precursor, the efficiency of the racemization reaction increased 1000-fold, making it similar to the succinyl-benzoate reaction.

Esterases and lipases, which catalyze hydrolysis of esters, have overlapping catalytic activities with non-heme haloperoxidases, which catalyze oxidations by hydrogen peroxide via a peroxycarboxylic acid (Scheme 6). For example, esterase from *Pseudomonas fluorescens*,[36] a lactonase,[37] and many lipases,[38] show low peroxidase activity in the presence of a carboxylic acid and hydrogen peroxide. Conversely, at least one haloperoxidase shows low esterase activity.[39]

The overlapping catalytic activity of these enzymes stems from common transition states and acyl enzyme intermediates in both reactions (Scheme 7). In esterases, the acyl enzyme
Scheme 6. Non-heme haloperoxidases catalyze the formation of a peroxocarboxylic acid by means of an esterase-like mechanism. The subsequent oxidation of substrates with the peracid may not be enzyme catalyzed.

intermediate undergoes hydrolysis, while in haloperoxidases, it undergoes perhydrolysis to yield a peroxycarboxylic acid. The subsequent oxidation of halide to hypohalous acid by this peroxycarboxylic acid may not be enzyme catalyzed. In spite of this overlap, esterases and lipases are more efficient at ester hydrolysis, while haloperoxidases are more efficient at generating peroxycarboxylic acids. Detailed structural analysis of a related haloperoxidase[40] and an esterase[41] showed only

subtle differences in the two active sites and did not reveal why one is a better haloperoxidase and the other a better esterase.

Catalytic promiscuity has a natural role in the biosynthesis of several secondary metabolites. For example, the synthesis of the antibiotic cephalosporin C in eukaryotes uses a single enzyme with a single active site to catalyze two different oxidative reactions—an oxidative ring expansion of the five-membered ring to a six-membered and a hydroxylation of a methyl group (Scheme 8). Single amino acid substitutions can inactivate either activity.[42] In contrast cephalosporin synthesis in prokaryotes uses separate enzymes for the two steps, but both of these enzymes are closely related to the bifunctional one in eukaryotes.
Scheme 8. A non-heme iron(II) and 2-oxoglutarate-dependent cephalosporin C synthase in eukaryotes catalyzes two different catalytic steps with the same active site.

These non-heme iron(II) and 2-oxoglutarate-dependent oxidative enzymes can even have trifunctional roles. Gibberellin 20-oxidase catalyzes three successive oxidations of the C20 methyl group to the alcohol, aldehyde and finally to the carboxylate.[43] Clavaminic acid synthase catalyzes a hydroxylation, an oxidative cyclization, and desaturation.[44]
Scheme 7. Mechanisms for ester hydrolysis and peroxidation by non-heme haloperoxidases both involve an acyl enzyme intermediate. In esterases (X=H), the H2O attacks this intermediate to complete a hydrolysis. In haloperoxidases (X=OH), the acyl enzyme intermediate comes from acetate added to the reaction mixture. Hydrogen peroxide attacks this intermediate to form a peracid. R=Ph for esterase, H for haloperoxidase.

Other non-heme diiron oxidative enzymes also catalyze a wide range of oxidations. For example, the plant steroyl acyl carrier protein Δ^9 desaturase normally catalyzes the desaturation of stearic acid to oleic acid but also catalyzes sulfoxidation of 9-thia or 10-thia stearate analogues[45] and the hydroxylation of 9-fluoro analogues.[46] Methane monooxygenase, another non-heme diiron enzyme, catalyzes methane hydroxylation as well as a wide range of other oxidations including epoxidation, N-oxide formation, dehalogenation, and desaturation of benzylic substrates.[47] Degradation enzymes, such as cytochrome P450 enzymes, which contain a heme iron, also catalyze a wide range of oxidations.

4. Catalytic Promiscuity within Modified Proteins

4.1. Natural Evolution of New Catalytic Activity

Divergent evolution is a natural process that creates different species from a common ancestor. This process also works on a molecular scale to create enzymes with new catalytic activities. New enzymatic activities arise by gene duplication followed by evolution of new activity for the copy.[48] Two examples of divergent evolution are the α/β-hydrolase-fold superfamily[49] and the enolase superfamily.[50] The α/β-hydrolase-fold enzymes all involve nucleophilic catalysis but include a wide range of substrates and reaction types including ester or peptide hydrolysis (serine nucleophile), dehalogenase, and epoxide hydrolase (aspartate nucleophile). The enolase enzymes have similar active sites and catalyze divalent-metal-assisted general-base-catalyzed removal of a proton α to a carboxylic acid to form an enolic intermediate. Examples of different reactions catalyzed by the enolase superfamily include racemization (mandelate, *N*-acyl amino acids) and β-eliminations (*o*-succinyl benzoate synthase). An example of a "misassigned" enolase enzyme was mentioned in Section 3.

One example of a surprisingly rapid natural evolution of new catalytic activity is an atrazine chlorohydrolase (Scheme 9).[51] Researchers initially found that atrazine, an herbicide widely used since the late 1950s, did not readily degrade in soils, but since 1993 a number of groups have reported rapid degradation. The key enzyme in this biodegradation—atrazine chlorohydrolase, which cleaves the C−Cl bond—differs by only eight amino acid substitutions from melamine hydrolase, which catalyzes the hydrolysis of a C−N bond in melamine. Melamine hydrolase has low atrazine

chlorohydrolase activity, but the new enzyme has no detectable melamine hydrolase activity. Directed evolution further expanded the substrate range of this atrazine chlorohydrolases to include C−S and C−O bond cleavage.[52] Another example of rapid natural evolution is the evolution of a phosphotriesterase that degrades the insecticide paraoxon.[53]

4.2. Changing the Metal Ion

Metal substitutions can also change catalytic activity. One of the earliest examples from 1976 shows that replacement of the Zn^{2+} ion in the active site of a carboxypeptidase with a Cu^{2+} ion converted this peptidase into a slow oxidase.[54] Replacement of the Zn^{2+} ion in the active site of thermolysin with much larger ions such as tungstate, molybdate, and selenate created enzymes that catalyze oxidation of thioethers to sulfoxides with hydrogen peroxide.[55] Replacing the active-site serine in subtilisin with selenomethionine resulted in peroxidase activity.[56]

Other examples of overlapping catalytic activity are acid phosphatases and vanadate-dependent haloperoxidases.[57,58] The amino acid sequence, three-dimensional structure, and active site are similar in both classes of enzymes. Vanadate binds to the same site as a phosphate ester presumably because it readily adopts a five-coordinate structure that resembles the transition state for phosphate ester hydrolysis. The vanadate ion catalyzes peroxidation by binding peroxide to the vanadium center, thereby increasing its electrophilicity. Further support for the similarity of the two active sites is the ability of vanadate to inhibit phosphatases and the ability of phosphate to inactivate vanadate-dependent haloperoxidases by displacing the vanadate. This exchange of active sites also exchanges the catalytic activity of these two classes of enzymes. Several acid phosphatases show low haloperoxidase activity upon addition of vanadate,[59] and conversely, apo-haloperoxidases show low phosphatase activity.[60] Sheldon and co-workers reported an enantioselective oxidation of sulfides to sulfoxides using a vanadate-substituted phytase.[61] However, the altered enzymes were much less effective catalysts than the true enzyme: the turnover numbers were 10^3–10^4 times lower for the haloperoxidase activity of a vanadate-containing phosphatase than for a true haloperoxidase, or for the phosphatase activity of apo-haloperoxidase as compared to that of a true phosphatase. This large difference shows that each enzyme is optimized for the reaction it catalyzes. However, like the esterase/non-heme haloperoxidase case mentioned above, even with the available X-ray crystal structures, it is not clear which structural features are responsible for the different optimized activity.

4.3. Engineering of Enzymes

A number of groups mimicked divergent evolution by using site-directed mutagenesis. By comparing related enzymes with different catalytic activity, they identified substitutions that change the catalytic activity. Making these changes in one of the enzymes altered the catalytic activity.
Scheme 9. An atrazine chlorohydrolase recently evolved naturally from a melamine hydrolase. The starting melamine hydrolase (C−N bond cleavage) has low atrazine chlorohydrolase activity (C−Cl bond cleavage), but the new atrazine chlorohydrolase has lost its melamine hydrolase activity.

For example, four amino acid substitutions in a fatty acid desaturase by their equivalents in a fatty acid hydroxylase yielded an efficient hydroxylase (Scheme 10).[62] In another
Scheme 10. Both desaturases and hydroxylases have a diiron center and oxidize C12 of oleic acid. Mutating four amino acids in a desaturase turned it into a hydroxylase.

example, single amino acid changes in L-Ala-D/L-Glu epimerase introduced *ortho*-succinyl benzoate synthase activity or muconate-lactonizing enzyme activity.[63] Within the family of glutathione transferases, mutations changed a transferase that catalyzes a Michael addition into one that catalyzes a nucleophilic aromatic substitution.[64] Similarly, a glutathione transferase with peroxidase activity gained steroid isomerase activity after five mutations to mimic the active site in a related steroid isomerase.[65] Mutations within an oxidosqualene cyclase changed the site of proton loss, thereby yielding different steroids.[66] A much more challenging task is converting a noncatalytic protein into a dehydratase with low activity.[67]

4.4. Glycosynthases, Thioglycoligases, and Thioglycosynthases

Retaining β-glycosidases normally catalyze the hydrolysis of β-glycosidic links, but they also catalyze glycoside exchange under conditions of low water concentration. The reaction involves a starting β-glycoside (sugar-OR) reacting with an incoming nucleophile (HOR′, Scheme 11). The incoming nucleophile is water in the case of hydrolysis and a second glycoside in the case of glycoside exchange. Retaining
Scheme 11. Glycoside exchange using retaining β-glycosidases involves a double displacement. A glycosyl donor (β-sugar-OR) forms an α-linked glycosyl enzyme, which then reacts with an incoming nucleophile or acceptor (HOR′) to make a new β-glycosidic link (sugar-OR′).

glycosidases use a double displacement mechanism with a catalytic acid/base and a catalytic nucleophile. In the initial step an α-linked covalent intermediate is formed by attack of the catalytic nucleophile on the starting β-glycoside. The catalytic acid assists this step by protonating the leaving group. In the second step this covalent intermediate is released by the catalytic-base-assisted attack of the incoming nucleophile—water or a new glycoside.

By disabling key steps in the mechanism, Withers and colleagues made three new catalysts (Scheme 12). The first,
Scheme 12. Disabling key mechanistic steps in a retaining β-glycosidase creates new catalytic activities. Removal of the catalytic nucleophile creates a glycosynthases where only α-glycosyl fluorides react presumably by a single displacement mechanism. Removal of the catalytic acid/base creates a thioglycoligase (only strong incoming nucleophiles such as thiols react), and removal of both catalytic nucleophile and catalytic acid/base creates a thioglycosynthase (only α-glycosyl fluorides and strong incoming nucleophiles react). DNP = 2,4-dinitrophenyl.

glycosynthase, results upon removing the catalytic nucleophile (e.g., a Glu-to-Ala mutation).[68] This removal prevents formation of the key covalent intermediate, dramatically altering the mechanism. Normal glycosides no longer react, but α-glycosyl fluorides do react, likely by a direct displacement mechanism. Glycosynthases, like the starting enzyme, form β-glycoside links. However, glycosynthases no longer catalyze hydrolysis of product, which is a nonactivated glycoside, and thus give higher yields. Five different glycosynthases have been reported with differing glycosyl fluoride specificity and differing regioselectivity (formation of β-1,3 vs. β-1,4 links). The second type of new catalyst, thioglycoligase, results upon removing the catalytic acid/base.[69] One role of this catalytic acid/base is activation of the incoming nucleophile. Absence of this activator precludes reaction with normal incoming nucleophiles and requires strong nucleophiles such as thiols. Introducing single amino acid mutations into β-glycosidases from *Agrobacterium sp.* Abg (mutation: E171A) created a variant that formed S-glycosidic linkages in high yield (Scheme 13). The wild-type enzyme gave no product, possibly due to steric hindrance caused by the larger sulfur atom. Finally, removing both the catalytic nucleophile
Scheme 13. A thioglycoligase lacking the catalytic acid/base no longer catalyzes hydrolysis. However, using an activated glycosyl donor overcomes the lack of a proton donor for the leaving group, and using a nucleophilic thiol overcomes the lack of base to activate the incoming nucleophile. Thus, the mutant now catalyzes formation of an *S*-glycosidic link.

and the catalytic acid/base creates a thioglycosynthase, which requires both an α-glycosyl fluoride and a thiol acceptor.[70]

5. Summary and Outlook

Catalytic promiscuity in enzymes is more common than generally appreciated. The dense collection of catalytic groups in an active site can accept alternate functional groups in the substrate and follow alternate reaction pathways. Small modifications in an active site can further dramatically expand the range of alternative pathways. In most, but not all, cases these alternate reactions are slower than the natural reactions. We hope that this review will encourage others to both search more extensively for catalytic promiscuity in existing enzymes and to use the current tools of protein engineering and directed evolution to extend the useful applications of enzymes.

Nanobiotechnology

Integrated Nanoparticle–Biomolecule Hybrid Systems: Synthesis, Properties, and Applications

Eugenii Katz and Itamar Willner*
Angewandte
Chemie

Angewandte *Chemie*

*N*anomaterials, such as metal or semiconductor nano-particles and nanorods, exhibit similar dimensions to those of biomolecules, such as proteins (enzymes, antigens, anti-bodies) or DNA. The integration of nanoparticles, which exhibit unique electronic, photonic, and catalytic properties, with biomaterials, which display unique recognition, catalytic, and inhibition properties, yields novel hybrid nanobiomate-rials of synergetic properties and functions. This review describes recent advances in the synthesis of biomolecule–nanoparticle/nanorod hybrid systems and the application of such assemblies in the generation of 2D and 3D ordered structures in solutions and on surfaces. Particular emphasis is directed to the use of biomolecule–nanoparticle (metallic or semiconductive) assemblies for bioanalytical applications and for the fabrication of bioelectronic devices.

From the Contents

1. Introduction

The unique electronic, optical, and catalytic properties of metal and semiconductor nanoparticles (1–200 nm), together with the different methods available for the preparation of nanoparticles of controlled shape and size, provide exciting building blocks for nanoscale assemblies, structures, and devices. Nobel Laureate Richard Feynman in his visionary lecture *"There is plenty of room at the bottom"*[1] inspired the concepts for the rapidly exploding research topic of nano-technology. Although the term "nanotechnology" had not appeared on the horizon, Feynman said: "What I want to talk about is the problem of manipulating and controlling things on a small scale… What I have demonstrated is that there is room—that you can decrease the size of things in a practical way… I will not discuss how we are going to do it, but only what is possible in principle… We are not doing it simply because we haven't yet gotten around to it." Four decades later, scientists have learnt that the manipulation of atoms, molecules, and clusters on surfaces is feasible and that new fundamental physics governs the properties of nanoobjects.

The miniaturization of structures by conventional[2] and electron-beam lithography[3] is reaching the theoretical limits of about 50 nm. For the further miniaturization of chemical objects, alternative approaches must be developed. Following Feynman's vision, one may employ atoms and molecules as building units for the "bottom-up" assembly and construction of architectures with nanometer dimensions. Nanoparticles (NPs) that consist of metals[4] (e.g. Au, Ag, Pt, and Cu) or semiconductors[5] (e.g. PbS, Ag_2S, CdS, CdSe, and TiO_2) seem to be attractive units for the engineering of such structures. The unique electrical properties of these particles[6] as well as their optical and photophysical features,[7] such as size-controlled plasmon absorbance, photonic electron–hole pair generation, and fluorescence, allow the particles to be addressed by means of electronic and photonic signals.

A variety of synthetic methodologies for the preparation of NPs within a narrow size distribution are available.[4] Often,

the NPs are prepared by "wet chemistry" procedures, in which clusters of metal atoms or semiconductor molecules are formed in the presence of a surface-capping ligand. This capping ligand binds to the metal/semiconductor clusters, prevents aggregation of the particles into bulk material, and controls the final dimensions of the NPs. Many capping systems are available: hydrophobic monolayers,[8] positively or negatively charged hydrophilic monolayers,[9] and polymer layers.[10] Association of molecular units to the NPs introduces chemical functionalities that can provide recognition or affinity interactions between different appropriately modified particles and thereby dictate the structure when aggregation occurs.[11] New collective properties of aggregated NPs,[7] such as coupled-plasmon absorbance, interparticle energy transfer, and electron transfer or conductivity, may be observed in the clustered assemblies.

The chemical functionalities associated with nanoparticles enable the assembly of 2D and 3D NP architectures on surfaces.[7] On the basis of the tremendous success in supramolecular chemistry,[12] NPs functionalized with various molecular and biomolecular units were assembled into complex hybrid systems. Composite layered or aggregated structures of (macro)molecule-cross-linked NPs on surfaces

have been prepared,[13] and specific sensing of substrates,[13a] tunable electroluminescence,[13b] and enhanced photoelectrochemistry[14] have been observed. The assembly of NP architectures on surfaces has also led to the fabrication of nanoscale devices such as single-electron transistors,[15] NP-based molecular switches,[16] and metal–insulator–nanoparticle–insulator–metal (MINIM) capacitors.[17] Several reviews have addressed the recent advances in the synthesis and properties of nanoparticles[7,18] and the progress made in the integration of composite nanoparticle systems with surfaces.[7,19]

The convergence of biotechnology and nanotechnology has led to the development of hybrid nanomaterials that incorporate the highly selective catalytic and recognition properties of biomaterials, such as proteins/enzymes and DNA, with the unique electronic, photonic, and catalytic features of nanoparticles. The conjugation of NPs and other nanoobjects (e.g. nanorods and carbon nanotubes) with biomolecules is an attractive area of research within nano-biotechnology.[20,21] Biomolecules are fascinating macromolecular structures in terms of their unique recognition, transport, and catalytic properties. The conjugation of NPs with biomolecules could provide electronic or optical transduction of biological phenomena in the development of novel biosensors.[22] Enzymes, antigens and antibodies, and biomolecular receptors have dimensions in the range of 2–20 nm, similar to those of NPs, thus the two classes of materials are structurally compatible.

Because of several fundamental features, biomaterials are important future building blocks for NP architectures: 1) Biomaterials display specific and strong complementary recognition interactions, for example, antigen–antibody, nucleic acid–DNA, and hormone–receptor interactions. The functionalization of nanoparticles with biomolecules could lead to biomolecule–nanoparticle recognition interactions and thus to self-assembly. 2) Various biomolecules contain several binding sites, for example, antibodies exhibit two Fab (antigen-binding fragment) sites, whereas streptavidin or concanavalin A each display four binding domains. This allows the multidirectional growth of NP structures. 3) Proteins may be genetically engineered and modified with specific anchoring groups. This facilitates their aligned binding to NPs or the site-specific linkage of the biomaterial to

surfaces. Consequently, the directional growth of NP structures may be dictated. Furthermore, other biomaterials, such as double-stranded DNA, may be synthetically prepared in complex rigidified structures that act as templates for the assembly of nanoparticles by intercalation, electrostatic binding to phosphate groups, or association to functionalities tethered to the DNA. 4) Enzymes are catalytic tools for the manipulation of biomaterials. For example, the ligation or the endonuclease scission processes of nucleic acids provide effective tools for controlling the shape and structure of biomolecule–NP hybrid systems. In this context, it is important to note that Mother Nature has developed unique biocatalytic replication processes. The use of biocatalysts for the replication of biomolecule–NP conjugates may provide an effective system for the formation of nanostructures of predesigned shapes and compositions.

Modern efforts in biotechnology involve the application of combinatorial methods for the synthesis of new biocatalysts or drugs. The simultaneous analysis of many pathogens, mutants, or therapeutic drugs is a major challenge in bioanalytical chemistry. Thus, the unique optical or electronic properties of metal or semiconductor NPs are of key interest for the development of high-throughput techniques for the parallel analysis of numerous components in samples. The possibility to control and tune these unique optical and electronic properties of metal or semiconductor NPs through their dimensions paves the way to the application of NPs as versatile analytical probes. That is, the application of size-controlled metal or semiconductor nanoparticles as libraries of probes for different analytes promises a great potential in future biosensing assays.

The importance of functionalized nanoparticles for biomedical applications cannot be overestimated. For instance, targeted entry into cells is an increasingly important area of research.[23] The nucleus is a desirable target because the genetic information of the cell and transcription machinery resides there. Targeted nuclear delivery is a challenging task because a nuclear probe must, at least, satisfy the following requirements: 1) it should enter the cell (e.g. through receptor-mediated endocytosis), 2) it should escape endosomal/lysosomal pathways, 3) it should possess a nucleus localization signal to interact with the nuclear-core complex, and 4) the probe should be small enough (< 30 nm) to cross

Itamar Willner, born in 1947, completed his PhD in Chemistry in 1978 at The Hebrew University of Jerusalem. After a postdoctoral stay with M. Calvin at the University of California, Berkeley, he joined the Institute of Chemistry at The Hebrew University of Jerusalem in 1982 and was appointed Professor in 1986. He is a member of several editorial boards, the Israel Academy of Sciences, and the European Academy of Sciences. He is the recipient of the Kolthoff Award, the Max Planck Research Award for International Cooperation, the Israel Chemical Society Award (2001), and the Israel Prize in Chemistry (2002).

Eugenii Katz, born in 1952 in Moscow, completed his PhD in 1983 at the Frumkin Institute of Electrochemistry, Moscow, and then worked as a senior scientist at the Institute of Photosynthesis, Pushchino. In 1991 he joined the The Hebrew University of Jerusalem as a postdoctoral researcher and in 1993, as a recipient of the Humboldt scholarship, he moved to the Technische Universität, München. He returned to the Hebrew University in 1994 as a senior research associate in the group of Professor I. Willner. His research interests include electroanalytical chemistry and functionalized nanoparticles.

the nuclear membrane. The most-efficient nuclear targets in biology are viruses, which commonly utilize different peptides for crossing each cell-membrane barrier. Artificial systems that model viral behavior could be designed on derivatives of functionalized nanoparticles. In a biologically inspired model system, Au NPs (20 nm) were modified with shells of bovine serum albumin (BSA) which were conjugated to various cellular targeting peptides to provide functional nanoparticles that penetrate the biological membrane and target the nuclei.[23b] Various NPs are applied as targeted biomarkers and drug-delivery agents to tumors in the analysis and medical treatment of cancers.[24] Hybrids of silver NPs with amphiphilic hyperbranched macromolecules exhibit antimicrobial properties and are used as drugs.[25]

One-dimensional nanostructures, wires, rods, belts, and tubes with lateral dimensions in the range of 1 to 100 nm, have recently received attention as potential components for nanotechnology and particularly nanoelectronic devices.[26] 1D structures of various compositions can be produced in copious quantities by chemical and physical methods. A range of unique properties (thermal, mechanical, electronic, optoelectronic, optical, nonlinear optical, and field emission) associated with different types of 1D nanostructures have been discovered. Some of the unique properties have already been applied in novel nanodevices, whereas others are still awaiting practical applications. The combination of 1D nanostructures with biomolecules paves the way to novel nanobioelectronic elements that could, for example, transport bioelectronic signals along 1D nanowires.

The combination of nanoobjects, nanotools, and nanotemplates[27–29] with biomolecules yields new facets of bioelectronics[30] to open new horizons of nanobioelectronics. Herein, we aim to review the synthesis and properties of biomolecule–nanoparticle/nanorod hybrid systems as well as the organization of these systems as functional devices (Figure 1). We discuss their properties and the methods to assemble two-dimensional and three-dimensional nanoparticle structures on surfaces, and we describe the operation of these biomolecule–nanoparticle structures as functional devices. Specifically, we discuss the use of the systems as sensors, as building blocks for electronic circuitry, and as electronic and optoelectronic elements. We highlight the findings of the past few years that have already established the core elements of the new research area—nanobiotechnology.

2. Synthesis and Properties of Biomolecule-Functionalized Nanoparticles

Biological molecules have been immobilized on polymer matrices and inorganic supports through a variety of techniques that includes physical adsorption, electrostatic binding, specific recognition, and covalent coupling.[31,32] These supports, which are modified with biological molecules such as proteins/enzymes, antigens/antibodies, and DNA/oligonucleotides, have been used for numerous biotechnological applications: affinity separations, biosensing, bioreactors, and the construction of biofuel cells. Recently, these immobilization techniques—developed for the functionalization of
Figure 1. The conceptual generation of biomolecule–nanoparticle/nanorod conjugates to yield functional devices.

macrosize supports—have been applied to bring together biomolecules and nanoparticles.

2.1. Functionalization of Nanoparticles with Biomolecules Through Electrostatic Adsorption

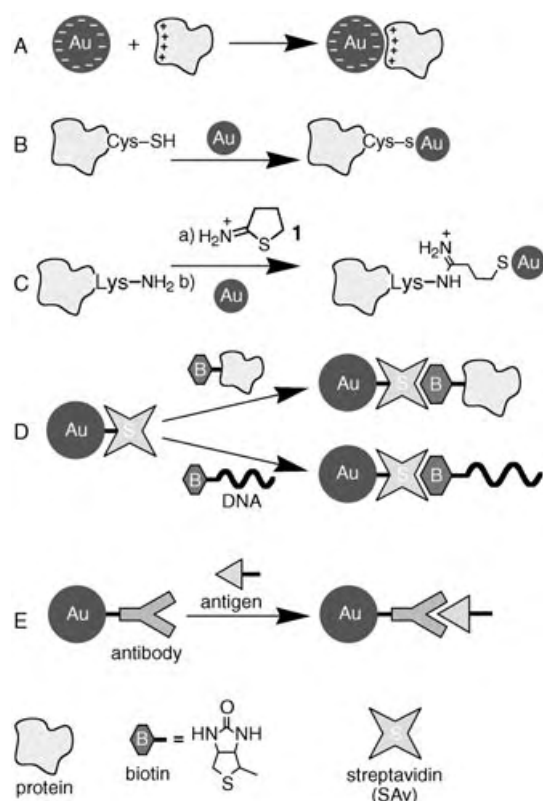
The simple adsorption of biomolecules on NPs has frequently been performed and studied for biomolecules, which range from low-molecular-weight organic substances (e.g. vitamin C)[33] to large protein/enzyme molecules.[34–37] In the case of NPs that are stabilized by anionic ligands such as carboxylic acid derivatives (citrate, tartrate, lipoic acid), the adsorption of positively charged proteins originates from electrostatic interactions (Figure 2 A).[38–43] Gold and silver NPs produced by citrate reduction were functionalized with immunoglobulin G (IgG) molecules at pH values that lie slightly above the isoelectric point of the citrate ligand.[38] This allowed effective binding between the positively charged amino acid side chains of the protein and the negatively charged citrate groups of the colloids. Other examples of protein coating through electrostatic interactions include the direct adsorption of heme-containing redox enzymes at citrate-stabilized Ag NPs[34,39] and the binding of basic leucine zipper proteins to lipoic acid stabilized semiconductor $CdSe_{core}/ZnS_{shell}$ particles.[40] Au NPs coated with a negatively charged phospholipid were prepared by the photoreduction of $NaAuCl_4$ in the presence of dimyristoyl-L-alpha-phosphatidyl-DL-glycerol,[41] which could provide further electrostatic


Figure 2. Formation of the biomolecule–nanoparticle (NP) hybrids:

binding of positively charged proteins, to yield a nanosized model of a biomembrane. Differential scanning calorimetry (DSC) was used to demonstrate the electrostatic nature of the bond of the adsorbed proteins on silica particles, and these measurements allowed the calculation of the thermodynamic binding parameters.[42] A theoretical model was developed to correlate the structure of metal$_{core}$/protein$_{shell}$ NPs with the experimental data obtained from the light-scattering spectra.[37] The method of rapid expansion of a supercritical solution into a liquid solvent was applied for the preparation of BSA protein-conjugated Ag or Ag$_2$S NPs.[43] Monodispersed BSA-functionalized nanoparticles were produced. As the protein underwent pH-dependent association and dissociation, the BSA–nanoparticle hybrids also assembled and disassembled with changes in pH of the solution in a reversible fashion. Ethylene glycol monolayer-protected NPs were used for the elimination of nonspecific binding to biological molecules.[44] Also, Au NPs were used as templates for the assembly of peptides to yield de novo proteins connected to the nanoparticle support.[45]

The electrostatic deposition of biomolecules, particularly proteins or enzymes, can also be extended to multilayer-level assemblies.[46] Proteins that are electrostatically attracted to the charged nanoparticles can provide an interface for the

further deposition of an oppositely charged polyelectrolyte polymer, which again allows the deposition of a secondary protein layer. Multilayer films of BSA,[47] IgG,[47] β-glucosidase,[48] glucose oxidase (GOx),[49,50] urease,[51] and horseradish peroxidase (HRP)[50] have been assembled on polystyrene NPs by the alternate deposition of the proteins and an oppositely charged synthetic polyelectrolyte as a linker (e.g. poly(diallyldimethylammonium chloride) or poly(sodium 4-styrenesulfonate) were used as positively or negatively charged polyelectrolytes, respectively). The protein/polymer multilayer shell could be varied from several to hundreds of nanometers in thickness. This strategy permits the preparation of functional films on nanoparticles with a high density of enzyme molecules. An increase in the loading of NPs by organic materials upon layer-by-layer deposition enhances the sensitivity of the analytical protocol to which the NPs are applied. For example, polystyrene particles were functionalized with a multilayer assembly of polyelectrolytes functionalized with a fluorescent dye. The assembly was terminated with a layer of IgG, which allowed the use of the modified particles as labels in fluorescence immunoanalyses.[52] The increase in the loading of the particles with the dye owing to the multilayer deposition resulted in a higher fluorescence output and thus in a higher sensitivity of the analysis.

The electrostatically driven adsorption of negatively charged DNA on positively charged Cd^{2+}-rich CdS NPs has been studied in detail.[53–57] The photoluminescence of semiconductor quantum dots was used to probe the effect of DNA structure on its binding to the nanoparticles.[53–55,58] It was found that "kinked" oligonucleotides, which exhibit a curvature of ≈3 nm from crystallographic and biochemical experiments, bind more tightly and faster to NPs that display curvatures of similar dimensions relative to straight or bent DNA.[53,54] The understanding of the binding modes and their separation into static and dynamic components is still a topic of investigation.[59] Negatively charged DNA was found to substitute citrate ions around Au NPs to form a DNA shell.[60]

2.2. Functionalization of Nanoparticles with Biomolecules by Chemisorption of Thiol Derivatives and by Covalent Binding through Bifunctional Linkers

The primary binding of functionalized thiolated molecules, such as oligopeptides, to Au NPs could provide a means for the covalent tethering of biomolecules to nanoparticles. Gold NPs were functionalized with L-cysteine through the thiol groups. Subsequent oligomerization of the cysteine moieties in an aqueous solution resulted in the binding of oligopeptides to the Au NPs.[61] Elsewhere, CdS NPs were capped with glutathione through the strong binding of its thiol groups to Cd^{2+} ionic sites on the surface of the nanoparticles.[62]

In some cases, tight chemisorption of proteins on Au NPs can originate from the binding of thiol groups from cysteine residues that exist in the proteins (e.g. serum albumin)[63] to the Au surface (Figure 2B). If no thiolated residues are available in the native proteins, thiol groups can be incorporated by chemical means, for example, with 2-iminothiolane

(Traut's reagent, **1**; see Figure 2C)[64] or through genetic engineering.[65] Some proteins and enzymes preserve their native structures and activities when they are directly adsorbed on nanoparticles. A surface-enhanced resonance Raman (SERR) study of native hemoglobin adsorbed on citrate-stabilized Ag colloids was reported[36] in which reversible dioxygen and carbon monoxide binding to the R hemoglobin conformation resulted in a transition to the T conformation. A non-heme iron enzyme, chlorocatechol dioxygenase, physically adsorbed on citrate-reduced Ag colloids also showed its native structure and biocatalytic activity through SERR spectroscopy.[34] However, physically adsorbed biomolecules can be readily lost from the surface, and adsorbed proteins are often prone to denaturation and thereby lose their biocatalytic or biorecognition activities. Some proteins and enzymes that were directly adsorbed on NPs showed conformational changes and loss of biological activity. Studies on bovine fibrinogen, which was adsorbed on TiO_2 nanoparticles, by circular dichroism (CD) spectroscopy, DSC, and fluorescence spectroscopy indicated that the α-helical content of the protein decreased markedly upon its adsorption.[35]

Reversible binding with specific alignment was observed with pepsin as a model enzyme on alumina NPs through the interaction of the phosphoryl group and the alumina surface.[66] One phosphoryl group is attached to the Ser68 residue in the native porcine pepsin. The crystal structure of the enzyme indicates that this modified residue is positioned at the protein surface, far away from the active site that comprises Asp32 and Asp215. This feature enabled the oriented coupling of the phosphoryl group on Ser68 to alumina. Furthermore, phosphate ions in aqueous solution were found to compete with the phosphorylated protein–alumina bonds to induce the release of the enzyme. Thus, protein–alumina nanoparticle hybrids that exhibit a similar controlled-release behavior open an interesting possibility in the design of new drug-delivery methods. That is, the immobilization of functionalized therapeutic proteins on alumina nanoparticles may generate vehicles for delivery in vivo and allow the targeted release of the drug by added phosphate ions.

By covalent attachment of proteins to nanoparticle surfaces, problems of instability and inactivation can be overcome.[46] Low-molecular bifunctional linkers, which have anchor groups for their attachment to NP surfaces and functional groups for their further covalent coupling to the target biomolecules, were extensively used in the generation of covalent-tethered conjugates of biomolecules with various NPs.[21a] Anchor groups such as thiols, disulfides, or phosphine ligands are often used for the binding of the bifunctional linkers to Au, Ag, CdS, and CdSe NPs. These anchor groups may readily substitute weakly adsorbed molecules to stabilize the NPs or may be incorporated in the synthesis of the NP to yield a nanoparticle surface that is functionalized for further reactions. Alkoxy- or halosilane groups are used for the covalent attachment of bifunctional linkers to the surfaces of NPs coated with SiO_2 and other oxides. Au NPs that are covered with polysiloxane shells and functionalized with a variety of functional groups for covalent binding to biomo-

lecules have been synthesized.[67] A wide variety of terminal functional groups are available in different bifunctional linkers. The most common amine, active ester, and maleimide groups are used to couple biological compounds covalently by means of carbodiimide-mediated esterification and amidation reactions or through reactions with thiol groups.[21a] Single functional groups (e.g. active ester or amine units) on Au NPs are available either by a statistical approach or by the modification of chemically defined clusters.[68] These structures provide unique synthetic routes for the covalent binding of a single target biomolecule per nanoparticle. A versatile method for the monofunctionalization of Au NPs (≈ 2 nm) with L-lysine residues through solid-phase reactions was reported recently.[68d] The Au NPs, which were functionalized with a single L-lysine residue, were suggested as building blocks for 1D nanoparticle–peptide chains.

Nucleic acids can be synthesized with tethered alkanethiol groups by using appropriate phosphoramidite precursors in a solid-phase synthesis. The *n*-alkylthiolated nucleic acids have been extensively used in the preparation of DNA-functionalized gold NPs[69] and $CdSe_{core}/ZnS_{shell}$[70] or CdS[56] semiconductor NPs. DNA functionalized with a steroid–disulfide derivative can readily bind to Au NPs and demonstrates a high adsorption stability because two sulfur atoms of the disulfide anchor group are involved in the attachment process.[71] Phosphorothiolate anchor groups were also utilized to bind oligonucleotides to CdS NPs.[72] The conformation of single-stranded DNA (ss-DNA) attached to Au NPs through thiol anchor groups was reported to be dependent on the length of the DNA and the loading. Thiolated single-stranded nucleic acids of different lengths (8 to 135 bases) were attached to 10-nm-diameter Au nanoparticles at different ratios of nucleic acid/Au NPs (1, 2, …, saturation).[73] The effective diameter and electrophoretic mobility of the conjugates were followed on 2% agarose gels and were found to be controlled by the conformation of the nucleic acids associated with the Au NPs. At low surface coverages of the nucleic acids, they were found to wrap around the nanoparticles. At high surface coverages of short nucleic acids, stretched, perpendicularly oriented DNA configurations were observed. At high surface coverages of long oligonucleotides, a dense, stretched structure with the inner part of the DNA oriented perpendicular to the nanoparticles was suggested, whereas the outer region of the chains revealed random, flexible coil-shaped orientations.

2.3. Functionalization of Nanoparticles with Biomolecules by Specific Affinity Interactions

Nanoparticles functionalized with groups that provide affinity sites for the binding of biomolecules have been used for the specific attachment of proteins and oligonucleotides. For example, streptavidin (SAv)-functionalized Au NPs have been used for the affinity binding of biotinylated proteins (e.g. immunoglobulins and serum albumins) or biotinylated oligonucleotides (Figure 2D).[21a, 74] Likewise, biotinylated $CdSe_{core}/CdS_{shell}$ NPs can be bound to SAv.[75] Protein A conjugate bound to Ag NPs was used as a versatile linker to Fc

fragments of various immunoglobulins.[76] Also, NP–antibody conjugates were used for affinity binding of their respective antigens (Figure 2E).[77] This may be advantageous because upon association with their respective antigens, nanoparticle-conjugated antibodies can demonstrate association constants that are even higher than those of the free antibody.[77b]

Recently, metal NPs have been used to tether a variety of carbohydrate ligands.[78–81] Such 3D multivalent ligands provide a globular structure on which clustering and orientation effects may be studied.[79] Furthermore, the properties of the metal core can be applied for the development of methods to study molecular recognition between carbohydrates and their respective binding proteins. For example, mannose-stabilized Au NPs have been used to visualize FimH proteins on type 1 pili of *Escherichia coli* by using electron microscopy.[80a] The further development of stabilized colloidal systems for the colorimetric detection of carbohydrate binding proteins was reported.[82] A mannose derivative was self-assembled onto preformed citrate-capped, water-soluble gold nanoparticles. Through the use of a short (C_2) hydrocarbon tether between the gold surface and the mannose recognition center, a selective, quantitative, and, importantly, rapid colorimetric detection method for the carbohydrate-binding protein concanavalin A has been developed. Surface plasmon resonance (SPR) spectroscopy was also used to follow the recognition process between carbohydrate-functionalized Au NPs and concanavalin A.[80b] Multivalent interactions between Au NPs, which were modified by galactosyl and glucosyl head-groups, with HIV-associated glycoprotein gp120 were also studied.[83] These particles were prepared from disulfides, which contained C-glycosides linked to triethylene glycol through an amide bond, by using a modification of the Brust method.[8b] Gold NPs capped with a monolayer of the synthetic drug vancomycin demonstrated multivalent affinity binding to membranes of Gram-negative bacteria that resulted in antimicrobial activity.[84]

Nanoparticles could be encapsulated by some natural proteins to provide their affinity binding. The chaperonin proteins GroEL (from *Escherichia coli*) and *T.th* cpn (from *Thermus thermophilus* HB8) encapsulate denatured proteins inside cylindrical cavities and later release them upon addition of ATP, which stimulates conformational changes of the cavities. It was also demonstrated that GroEL and *T.th* cpn encapsulate CdS semiconductor NPs to provide them with high thermal and chemical stability in aqueous media.[85] In a similar fashion to the ATP-induced release of proteins from the chaperonin proteins, ATP stimulates the release of the CdS NPs from the cavities. The integration of such biological mechanisms into materials science-based applications could open the door to new bioresponsive devices. The chaperonin protein GroEL comprises a double-decker architecture formed from two stacked rings, which consist of seven 60-kDa protein subunits each (Figure 3A, part a), to yield a cylindrical cavity that has a diameter of 4.5 nm and a wall thickness of 4.6 nm. The chaperonin protein *T.th* cpn comprises a tetradecamer protein subunit (840 kDa), which is end-capped by a $[cpn10]_7$ (70 kDa) protein unit on one side of the supramolecular cylindrical cavity (internal diameter ≈ 5 nm; Figure 3A, part a). These cavities may also act as containers for the controlled release of semiconductor nanoparticles (Figure 3B). The release of the CdS NPs in the presence of ATP, Mg^{2+}, and K^+ (Figure 3A, part b) activates their photoelectrochemical function (e.g. photoinduced electron transfer).

2.4. Synthesis of Nanoparticles by Biochemical and Microbial Systems

The use of bacteria as a novel biotechnology to facilitate the production of NPs is in its infancy. In contrast to purely chemical procedures for the manufacture of NPs, biological

[85], with permission.)

and, particularly, microbial reactions that are characterized by their selectivity and precision for NP formation[86] provide environmentally friendly "green" technological processes.[86f] In most bioprocesses, it is assumed that highly specific structures such as enzymes and proteins exist on the bacterial membrane which, in turn, drive highly specific interactions with the culture medium. These biological processes could rapidly produce copious amounts of nanoparticles. Many details of the underlying biology remain unanswered, but from an electrochemical viewpoint, bacteria may be thought of as electrodes that operate at a relatively fixed potential. The range of inorganic nanosized products that are observed is consistent with this model. The NPs produced by bacteria could be isolated with the parent biomaterial shells to demonstrate the use of bacteria as living reactors for the preparation of nanomaterials.

Microorganisms, particularly prokaryotic bacteria, are often exposed to extreme environmental conditions that force them to resort to specific defense mechanisms to quell such stresses as the toxicity of foreign metal ions or metals. The toxicity of metal ions is reduced or eliminated by a change in the redox state of the metal ions and/or precipitation of the metals intracellularly. This forms the basis of many important applications of microorganisms such as bioleaching, bioremediation, microbial corrosion, as well as the synthesis of nanoparticles. A number of biological systems have developed highly orchestrated detoxification mechanisms towards the bioreduction and mineralization of noble metals. These systems incorporate small peptides and proteins as nucleation sites to bind metals and stabilize NPs. For example, silver nanoparticles in the 2–5-nm range were synthesized extracellularly by a silver-tolerant yeast strain MKY3 when challenged with Ag^+ ions (1 mM) in the log phase of growth.[86d] Live fungus and plants could also be used to generate metallic and semiconductive NPs.[87] It was found that the fungus *Fusarium oxysporum* is able to synthesize CdS semiconductor NPs extracellularly by a purely enzymatic process.[87a] Similarly, the formation and growth of Au NPs inside Alfalfa plants has been reported.[87b] Also, semiconductive nanoparticles (e.g. CdSe and $CdSe_{core}/ZnS_{shell}$) of controllable sizes and unique shapes were generated with the use of genetically engineered predesigned proteins.[88] Biomineralization, particularly with the use of ferritin, is widely used for the preparation of magnetic nanoparticles (see Section 7.1.).

2.5. Properties of Nanoparticle–Biomolecule Hybrid Systems

The functionalization of NPs with biomolecules results in changes in the properties of the NPs and their interactions with the environment. Upon adsorption of vitamin C on TiO_2 NPs, the optical properties of the particles were red-shifted by 1.6 eV as a result of charge transfer that originates from the specific binding of the electron-donating modifier to corner defects on the surface of the nanoparticles.[33] The solubility of NPs in water can be greatly improved by the functionalization of their surfaces with highly hydrophilic biomolecules.[9] Whereas Au NPs modified with long chain alkanethiols are

only soluble in low-polarity organic solvents, Au NPs with ω-carboxylic acid functionalized alkanethiolate ligand shells are soluble in polar organic solvents such as ethanol and acetone. Furthermore, Au NPs that are modified with biomolecules such as tiopronin or coenzyme A demonstrate excellent solubility in water.[9c]

Intrinsic properties of biomolecules can be changed upon their association with metal nanoparticles. For example, vibrations of the biologically active prosthetic heme groups of myoglobin or hemoglobin are selectively enhanced by adsorption of the proteins on metal NPs relative to the vibrational modes characteristic of the protein backbone as recently shown in a SERR spectroscopic studies.[89]

Alteration by external signals (e.g. electrical, optical) of the chemical properties of the biomolecules or the biomaterial analogues that modify nanoparticles can be used to control the interactions of the modified nanoparticles with the environment. Thereby, the binding properties of the modifier or the aggregation of the nanoparticles can be controlled. For example, the formation of a complex between a diaminopyridine derivative and a flavin derivative was studied at the surface of a Au NP.[90] It was shown that more-stable hydrogen bonding occured when the flavin derivative was electrochemically reduced (Figure 4). This allowed the electrochemically controlled switching of the binding of the bioorganic molecules to the organic-functionalized shell of the nanoparticle.
Figure 4. The electrochemically controlled recognition of flavin by a pyridinediamide-functionalized nanoparticle.

Energy and/or electron transfer processes between NPs and coupled biomolecules may proceed upon photoexcitation of one of the hybrid components so affecting the properties of the biomolecule–NP hybrid systems. Efficient photoinduced electron transfer between a carotenoid shell and the TiO_2 NP core has been demonstrated.[91] In another system, photoexcitation of TiO_2 NPs resulted in the oxidation of hemin molecules that were bound to the semiconductive core which induced further heme-catalyzed oxidation of organic hal-

ides.[92] Efficient resonance energy transfer from tryptophan moieties of proteins to the semiconductor NP core (e.g. in a BSA–CdTe conjugate)[93] resulted in a significant increase in the fluorescence of the nanoparticle upon photoexcitation of the protein shell.

3. Biomolecule-Functionalized Nanoparticles for Controlled Chemical Reactivity

The interactions of functionalized nanoparticles with biomaterials or within biomaterial structures can control the chemical reactivity of the biomolecules. Alternatively, they can report on the state of the reaction or reactants and allow the reactivity to be controlled externally. It is well known that small molecules and polymers can affect the chemical reactivity of biomolecules. If there are several possible parallel reactions, the effect produced by a promoter/inhibitor on a specific chemical reaction can change the effective chemical path of the whole process to result in the regulation of the biochemical system. Molecular labels such as fluorescent dyes incorporated into biomolecules can report on the state of the biomolecule through transduction of the molecular transformations into an output signal: this is used, for example, in biomaterial-based diagnostics. Functionalized NPs can operate in the same way, demonstrating properties of a biopromoter/bioinhibitor or a reporter with some advantages over their molecular-sized counterparts owing to the unique photophysical and electronic properties of the NPs. Nanomechanical devices based on NPs functionalized by biomolecules (particularly DNA) are also feasible.[94]

3.1. Biomolecule-Functionalized Nanoparticles for Controlling DNA Reactivity

Enzymatic manipulations of DNA bound to metal NPs, such as the enzymatic extension of the DNA chain, present some challenges. The extension reaction requires not only the efficient hybridization of a template to the particle-bound primer, but also accessibility to the DNA polymerase enzyme (the 68-kDa Klenow fragment). Thus, the extension reaction might be expected to show greater sensitivity to steric effects than hybridization alone. Extension efficiencies as high as 100 % were observed for DNA primers bound to Au NPs by a HSC_6H_{12} linker.[95]

Biocatalytic reactions that occur on DNA, such as transcription or translation, require the association of enzymes with the DNA chain. The competitive association of other molecules to the DNA chain may decrease the binding of the enzyme and thus inhibit the process which finally results in gene regulation. It has been shown that small molecules,[96] dendrimers,[97] and polymers[98] efficiently bind to DNA and, in some cases, lead to the inhibition of the transcription machinery. In these systems, however, the creation of suitably preorganized scaffolds for controlled binding to DNA presents a significant design challenge. For small molecules, this challenge arises from the detailed synthesis required for a rigid scaffold that contains several functional groups. For

polymer systems, the precise placement of substituents along the backbone as well as the macroconformation of the polymer in solution are difficult to control. An excellent solution to these problems is the application of "mixed monolayer-protected (Au) clusters" (MMPCs).[99] The self-assembled monolayer coating of the Au NPs presents a highly organized surface for the recognition of DNA which is of a similar size (6–10 nm) to that of DNA-binding proteins. The central metal core rigidifies the particle to limit the organic components to a much smaller subset of structures than a similarly sized polymer. The mobility of thiols on the surface of the NP also allows the formation of recognition elements to be controlled in subsequent steps.[100] NPs for the recognition of double-stranded DNA (ds-DNA) were prepared by the partial displacement of octanethiol on the Au surface with 11-mercaptoundecyltrimethylammonium.[101] The mixed monolayer of this MMPC system is designed to electrostatically attract the negatively charged DNA to the surface-confined positively charged ammonium groups. These MMPCs bind to the ds-DNA and inhibit the binding of the enzymes involved in gene regulation, thus resulting in effective inhibition of the biocatalytic transcription process.

A simple method to protect DNA from cleavage was developed by using bioconjugated amine-modified silica NPs (45 ± 4 nm).[102] Negatively charged DNA molecules could be easily concentrated onto the positively charged surface of the NPs for further manipulation. The DNA strands were protected from enzymatic cleavage and had the same properties as the free DNA strands when released from the NPs.

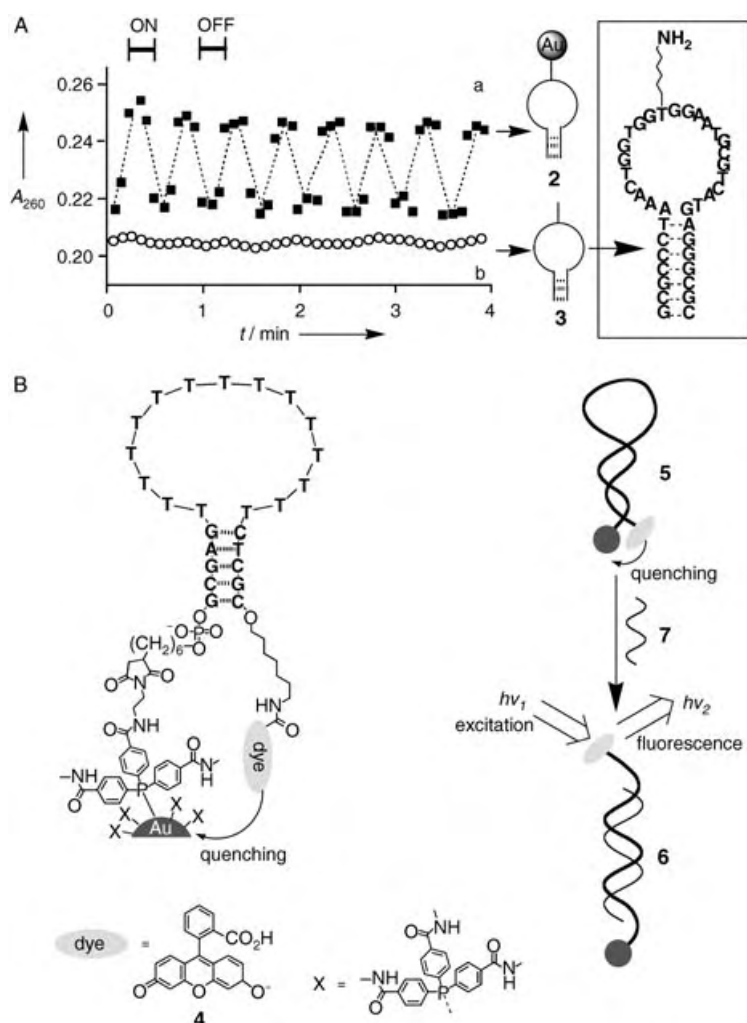
A gold NP–DNA molecular beacon conjugate, **2**, has recently been exploited for the remote electronic control of DNA hybridization.[103] By the inductive coupling of a radiofrequency (1-GHz) electromagnetic field to the 1.4-nm Au NP, which functions as an antenna in the DNA conjugate, the local temperature of the bound DNA is increased and thereby induces denaturation whilst leaving surrounding molecules relatively unaffected. Figure 5 A, curve a, shows the absorbance of a solution of the Au NP–DNA molecular beacon conjugate **2** at 260 nm as a function of the time in which the electromagnetic field is switched on and off. The increase in the absorbance reflects the denaturation of the DNA double-helix upon local heating, whereas the decrease in the absorbance corresponds to the DNA rehybridization when the electromagnetic field is switched off. The switching between two distinct states is fully reversible. A control experiment revealed that the DNA molecular beacon, **3**, which lacks the Au nanoparticle, is not affected by the electromagnetic field (Figure 5 A, curve b). Although inductive heating has already been applied to macroscopic samples as well as to the treatment of cancer cells with electromagnetic field-induced excitation of biocompatible superparamagnetic nanoparticles,[104] the use of Au NP–DNA conjugates should allow extension of this concept. Complex operations, such as gene regulation, biomolecular assembly, and enzymatic activity, of distinct portions of nucleic acids or proteins might be controlled, whereas the rest of the molecule and neighboring species would remain unaffected. Moreover, since the addressing method is not optical, this technology could even be applicable in highly scattering media.


Figure 5. A) a) The reversible change of the Au NP–DNA molecular beacon conjugate **2** between denatured and hybridized conformations upon switching "ON" and "OFF", respectively, the radiofrequency electromagnetic field; b) The DNA hairpin molecule **3**, which lacks the Au nanoparticle, is not affected by the electromagnetic field. B) Fluorescence emission controlled by the transformation from the hairpin conformation **5** to the extended state **6** of a DNA chain upon hybridization with the complementary oligonucleotide **7**. (Part A is adapted from Ref. [103], with permission).

3.2. Biomolecule-Functionalized Nanoparticles for Reporting DNA Reactivity

DNA molecules that are functionalized at specific positions with a fluorescence dye and a quencher can produce a fluorescence output, which is controlled by the distance that separates the two, to act as a reporter of the conformation of the DNA chain. Au nanoparticles can quench the fluorescence of chromophores 100-fold better than molecular quenchers and they also exhibit higher quenching efficiencies for dyes that emit in the near-infrared region. A gold NP, which was functionalized with a single maleimide group, was covalently linked to a $(CH_2)_6SH$ group that was tethered to the 5′ end of a DNA oligonucleotide, which was functionalized with a fluorescent dye (e.g. fluorescein (**4**) or rhodamine 6G) at the 3′ end.[105] The molecule could adopt two

conformations (Figure 5B): a stem–loop structure with the fluorophore and the Au nanoparticle held in close proximity (hairpin state) and a rodlike structure with them far apart (open state). The hairpin state, **5**, is self-generated by the intramolecular complementarity of the terminal parts of the DNA chain that induces a double-stranded structure within the same molecule. On the other hand, the open state, **6**, is produced upon the interaction and hybridization with an analyte DNA molecule **7**, which exhibits complementarity to the central part of the DNA chain. This target DNA hybridizes with the modified DNA and results in the formation of ds-DNA, thereby opening the hairpin and increasing the distance between the fluorophore and the NP and therefore enhancing the fluorescence. The process and the reporting signal only occur in the case of complementarity between the analyte DNA and the central part of the sensing DNA. The system was successfully applied for the detection of single-base mismatches in DNA sequences.[105] Competitive hybridization assays revealed that the ability to detect single-base mutations is about 8-fold greater than that with conventional molecular beacons, which use a molecular quencher instead of a Au NP, whereas the sensitivity of detection is enhanced up to 100-fold.

Au NPs have been used to develop a new class of nanobiosensors that are able to recognize and detect specific DNA sequences and single-base mutations in a homogeneous assay.[106] The Au NPs were used as nanoscaffolds to tether ss-DNA that were functionalized with an organic dye at the opposite end of the nucleic acid chain. The flexible DNA chain yields a short distance between the dye and the Au NP which leads to the efficient quenching of the fluorescence of the dye by the metal NP. Hybridization of the ss-DNA with the complementary DNA analyte resulted in a rigidified spacer between the dye and the Au NP thus inhibiting the quenching process and restoring the fluorescence. Unlike conventional molecular beacons with a stem-and-loop structure, the NP probes do not require a stem and their background fluorescence increases little with temperature.

3.3. Biomolecule-Functionalized Nanoparticles for Controlling Enzyme Reactivity

Functionalized nanoparticles may affect the activities of enzymes: for example, they could effectively inhibit some enzymatic reactions. It has been shown that anion-functionalized NPs are highly effective surface-based inhibitors of chymotrypsin (ChT) by a two-step inactivation mechanism.[107] This inhibition occurs through electrostatic complementarity between the negatively charged carboxylate end-

groups of the shell and the positively charged cationic residues located around the periphery of the enzyme active site. The primary reversible inhibition step yields a complex between the enzyme and the NPs. The secondary step results in the irreversible denaturation of the enzyme associated with the functionalized NPs. Complete inhibition of the enzyme activity was observed at a ratio of 1:5 of the nanoparticle/ChT and arises from the large surface area of the anion-functionalized NP (≈ 110 nm^2). However, this irreversible inhibition of chymotrypsin could be reversed through modification of the surface of the NP in situ by using cationic surfactants.[107b] Up to 50% of the original chymotrypsin activity was retained upon the addition of a long-chain surfactant, and dynamic light-scattering studies demonstrated that chymotrypsin was released from the NP surface.

The controlled release of inhibitors, promoters, or cofactors into a reaction medium may be employed as a general strategy to deactivate or activate enzymes, respectively. Also, controlled delivery of drugs or neurotransmitters is essential for the regulation of complex physiological biocatalytic processes. Functionalized CdS NPs were used to entrap drugs or neurotransmitters in the channels (average diameter ≈ 2.3 nm) of MCM-41-type mesoporous silica nanospheres (MSNs) in a configuration that enabled the controlled release of the entrapped substances (Figure 6).[108] Vancomycin or adenosine triphosphate (ATP) were loaded in the channels of the MSN. The MSN matrix was functionalized with an amine-terminated tether that contained a disulfide group and was linked to the matrix by a siloxane anchoring site, **8**. The MSN matrix loaded with the respective substrate was then treated with carboxylic acid modified CdS NPs **9** (≈ 2.0 nm). The covalent coupling of the CdS NPs to the amine functions of the matrix **10** and the steric fit between the CdS NPs and the channels in the matrix resulted in the entrapment of the substrates in the channels. The chemical splitting of the disulfide bonds that bridge the NPs to the MSN matrix by dithiothreitol (DTT; **11**) removed the CdS NP stoppers and released the substrates stored within the MSN channels. This new MSN system could play a significant role in the development of new generations of site-selective, controlled-release delivery nanodevices.

4. The Aggregation of Biomolecule-Functionalized Nanoparticles

The organization and patterning of inorganic nanoparticles into 2D and 3D functional structures is a fundamental prerequisite for the assembly of chemical, optical, magnetic, and electronic devices.[7] Many approaches have been described for the formation of 2D and 3D arrays of metal and semiconductor NPs: 1) by evaporation of the solvent of hydrophobic colloids,[109] 2) by random inclusion of the nanoparticles into gel and glassy matrices,[110] 3) by template-directed synthesis at structured surfaces[111] in porous protein crystals[112,113] or in bacterial superstructures,[114] and 4) through chemical coupling in solution by means of bifunctional cross-linkers.[115,116] An example of the latter is the alkanedithiol-directed aggregation of Au NPs.[115,116] The

aggregation of NPs induced by specific biological interactions attracts interest as a self-assembly process for the construction of complex nanostructures that exhibit new collective properties.

Several reasons support the concept of utilizing biomolecules as building blocks of NP structures: 1) The diversity of biomolecules enables the selection of building units of predesigned size, shape, and functionality. 2) The availability of chemical and biological means to modify and synthesize biomolecules. For example, the synthesis of nucleic acids of predesigned composition and shape, the elicitation of monoclonal antibodies, or the modification of proteins by genetic engineering to allow the construction of biomaterials for the directed assembly of nanoparticles. 3) Enzymes may act as biocatalytic tools for the manipulation of the biomaterials. The hydrolysis of proteins, the scission or ligation of DNA, or the replication of nucleic acids may be employed as tools for the assembly of NP architectures through manipulation of the biomaterial. 4) Mother Nature has developed routes for the repair of biomolecules that may be applied to stabilize the biomolecule–NP structures. 5) Nanoparticles that are cross-linked with enzyme units may generate biocatalytic assemblies of predesigned functionality. These different features of the biomolecule cross-linking units provide a flexible means

of generation of NP structures of tunable physical, chemical, and functional properties. For the generation of biomolecule-cross-linked NPs, two types of biomolecule-functionalized NPs with complementary units should participate in the assembly process. Biomaterials utilized in the fabrication of such biomolecule–NP aggregates include biological protein host–guest pairs such as biotin–streptavidin,[117] antigen–antibody,[118] and complementary oligonucleotide pairs.[117, 119, 120] A large variety of methods including optical methods, such as differential light-scattering spectroscopy,[121] has been used to study the biospecific assembly of NPs with proteins and oligonucleotides. Electrophoretic and structural studies of the DNA-directed aggregation of Au NPs have been published recently.[122]

4.1. Receptor-Induced Aggregation of Guest-Functionalized Nanoparticles

Protein-based recognition systems can be used to organize inorganic NPs into network aggregates. For instance, the interaction between D-biotin and the biotin-binding protein streptavidin (SAv) was utilized to induce the aggregation of NPs.[117] The recognition between water-soluble biotin and the homotetrameric protein SAv is characterized by an extraordinary affinity constant, $K_a > 10^{14} \, \text{M}^{-1}$, that makes it the strongest ligand–receptor binding interaction presently known.[123] Another great advantage of SAv is its extremely high chemical and thermal stability. The applicability of the biotin–SAv system to generate supramolecular aggregates is enhanced by the availability of various avidin analogues[124] and recombinant SAv mutants.[125] A wide range of rate and equilibrium constants ($10^0 \leq K_a \leq 10^{15} \, \text{M}^{-1}$) are available that allow the construction of carefully designed NP aggregates. Many biotinylated materials are commercially available or can be prepared under mild conditions. Two routes to the aggregation of NPs by biotin–SAv interactions are possible: 1) NPs functionalized with biotin groups can be cross-linked with the tetravalent SAv receptor (Figure 7A), and 2) NPs functionalized with SAv can be cross-linked with the dibiotin derivative **12** (Figure 7B). Metal and semiconductor NPs can be functionalized with biotin derivatives by one of several synthetic routes. In the simplest method, thiol or disulfide derivatives of biotin are directly adsorbed onto metal NPs (e.g. Au, Ag). Alternatively, NPs can first be coated with an organic "shell" (e.g. by the polymerization of a trialkoxysilyl derivative or by polymer adsorption) and then covalently modified with biotin, for example, by carbodiimide coupling.

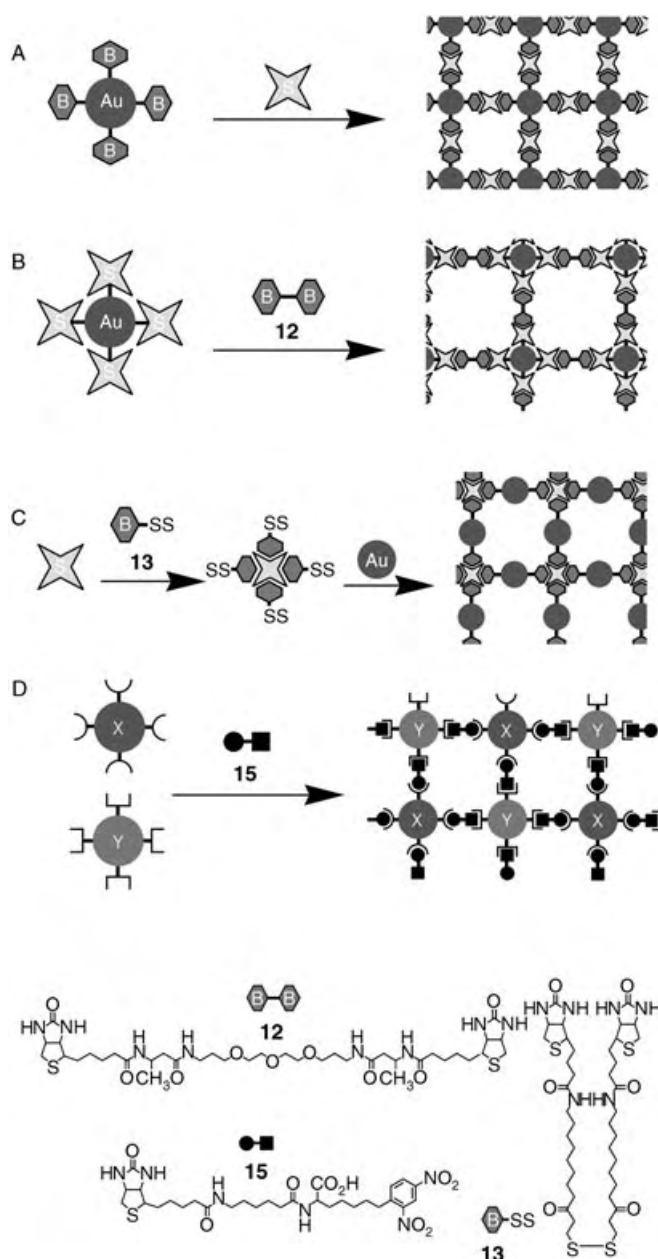
Au NPs functionalized with adsorbed biotin units and then cross-linked with SAv units have been shown to yield aggregates of Au NPs with the biotin–SAv recognition pairs between the individual NPs (Figure 7A).[117, 126] A similar architecture can be built by reversing the steps: SAv was interacted with the biotin disulfide derivative **13** to produce a complex, which was then treated with Au NPs (Figure 7C).[126a] In both cases, fast, spontaneous aggregation of the Au NPs was observed which resulted in a nonordered network of particles. Dynamic light-scattering spectroscopy, small-angle X-ray scattering studies, and TEM were used to


Figure 7. The use of biotin–streptavidin (SAv) interactions to build nanoparticle networks: A) Streptavidin as a linker between biotin-functionalized Au NPs; B) A biotin dimer used to link streptavidin-functionalized Au NPs; C) Streptavidin-linked thiolated biotin used to build NP networks; D) The formation of a network from two types of NPs that are functionalized with different recognition units and cross-linked with a bifunctional linker, **15**, which is composed of a biotin unit and a dinitrophenyl-antigen unit.

follow the aggregation process and to characterize the product. The kinetics of this process was fitted to the theoretical Smoluchowski model of aggregation, which was modified for nanoparticles.[126b] This kinetic analysis allows the control of the aggregate structure by the optimization of the conditions, that is, the molar ratio of the biotin-functionalized NPs and the SAv cross-linker.

A related SAv-induced aggregation of Au nanorods was reported recently.[127] Gold nanorods (aspect ratio = 18) were

prepared in water in the presence of a shape-directing surfactant, cetyltrimethylammonium bromide (CTAB), and were further functionalized with a biotin disulfide derivative. The addition of a streptavidin linker to the biotin-modified Au nanorods produced an unexpectedly high proportion of end-to-end-linked Au nanorods that were separated by 4–5 nm spacing, which corresponds to the size of a streptavidin molecule ($\approx 4.5 \times 4.5 \times 5.8$ nm^3), and were at angles expected for the four biotin binding sites on the streptavidin projected into two dimensions (Figure 8 A). The mechanism behind the
Figure 8. A) End-to-end assembly of biotin-functionalized Au nanorods that are cross-linked by streptavidin (SAv). B) Transmission electron micrograph of the SAv-interconnected Au nanorods. C) Biotin-functionalized ferritin. (Part B is adapted from Ref. [127], with permission; Copyright American Chemical Society, 2003).

higher-than-expected proportion of end-to-end linkages of the Au nanorods is not understood yet. However, there are two possible explanations of the phenomenon: 1) The biotin disulfide was unsuccessful at displacing the CTAB bound to the length of the gold nanorods. Thus, the biotin preferentially binds to the {111} ends of the Au rods which results in preferential end-to-end linkages upon the addition of streptavidin. The bilayer structure of CTAB on the nanorod surface may make the surfactant less easy to displace than at the end defects. 2) The biotin indeed binds all over the rods, but streptavidin is sterically constrained to bind only to the sides of the rods. Nevertheless, the generated nanostructures (Figure 8 B) provide evidence that chemical linkages can organize nanorods in a nonrandom fashion, which may be exploited for the assembly of higher-order arrays of nanomaterials. By the future use of metal NP-modified SAv,

catalytic protein cross-linkers may be envisaged, and Au nanorods may be connected by other metals, such as Ag^0, to continuous wires.

Another example of biotin–SAv cross-linked NPs involves the native protein ferritin, which consists of a hollow polypeptide shell (8- and 12-nm internal and external diameters, respectively) and a 5-nm-diameter ferric oxide core ($5Fe_2O_3 \cdot 9H_2O$).[128] The ferric oxide NP can be easily removed from the protein shell by reductive dissolution, and the empty cage of apo-ferritin can be remineralized in vitro with a range of inorganic oxides, sulfides, and selenides (e.g. MnO, FeS, CdS, CdSe)[129,130] or more-complex compounds (e.g. Prussian Blue).[131] A succinimidyl active ester derivative of biotin, **14**, was covalently linked to the amine groups of lysine residues of the polypeptide shell of ferritin to yield a biotin-functionalized protein shell that contained the ferric oxide core (Figure 8 C). Addition of SAv resulted in the cross-linking and therefore the aggregation of the functionalized ferric oxide NPs.[132] Considering the library of core NPs possible, this ferritin-based aggregate is a very promising material for the production of electronic, magnetoelectronic, and optoelectronic devices.

Nanoparticle aggregates have also been produced by means of the interaction between antigens and antibodies.[38,118] In the simplest approach, anti-DNP IgE antibodies (DNP = dinitrophenyl) were adsorbed onto 12-nm Au NPs, and these conjugates were then cross-linked with a synthetic antigen (*N*-2,4-bis(dinitrophenyl)octamethylenediamine), which comprised two hapten DNP head groups that were separated by a spacer. A more sophisticated approach allows the association of two different types of NPs. For this purpose, two different NPs that are functionalized with different kinds of bioreceptors (e.g. different antibodies, or an antibody and SAv) are cross-linked with a ligand, which contains two different head groups to provide affinity binding to the two respective receptors. As an example, two types of Au NPs were functionalized, one with anti-DNP IgE and the other with SAv.[38,118] They were cross-linked with the linker **15**, which contains a biotin unit at one end and a DNP group at the other end of a spacer (Figure 7 D). Each ligand recognizes its respective receptor—biotin binds to SAv; DNP binds to anti-DNP IgE—to create a network composed of both nanoparticles.

The aggregation of NPs by antigen–antibody interactions in solution was applied to develop immunoassay procedures with optical detection of the association process. A laser-based double-beam absorption detection system for aggregation immunoassays has been developed.[133,134] The assay was based on the aggregation of gold NPs, which were coated with protein antigens, in the presence of the corresponding antibodies. The aggregation of the gold NPs resulted in a change in the absorption bands which enabled the assay to be monitored at 635 nm with a detection limit for an antibody of 3×10^{-8} M. A rapid immunoassay for the detection of an analyte within complex biological media without any sample preparation was demonstrated with gold nanoshells, namely, layered dielectric-metal NPs, whose optical resonance is a function of the relative size of their constituent layers.[135] The aggregation of antibody–nanoshell conjugates, which exhibit

absorption spectra in the near-infrared region, was monitored spectroscopically in the presence of the analyte. Immunoglobulins were successfully detected from saline, serum, and whole blood media.

Complementary bioconjugates that consist of an antibody–antigen pair were immobilized on luminescent CdTe NPs (quantum dots) of variable sizes, and these were used for the examination of interparticle energy-transfer processes.[136] The antigen bovine serum albumin (BSA) was conjugated to red-emitting CdTe NPs, whereas the corresponding anti-BSA antibody (IgG) was linked to green-emitting CdTe NPs. The formation of the BSA–IgG immunocomplex resulted in fluorescence resonance energy transfer (FRET) between the two different nanoparticles. The luminescence of the green-emitting nanoparticles was quenched, whereas the emission of the red-emitting nanoparticles was enhanced. The luminescence of the green-emitting quantum dots could be recovered upon exposure of the complex to unlabeled antigen. The antigen–antibody–CdTe-NP aggregate may, thus, be considered as a functional superstructure for the competitive optical detection of antigens or antibodies.

A novel approach to induce the cross-linking of NPs involves the application of predesigned de novo proteins that display specific affinities to inorganic crystal surfaces.[21a] These structures can specifically and directly bind to unmodified surfaces of various semiconductive nanoparticles to act as bridges and result in the aggregation of the NPs. From a combinatorial library of $\approx 10^9$ random 12-mer peptides, de novo proteins that exhibit specific binding capabilities to single-crystal semiconductors including GaAs(100), GaAs(111), InP(100), and Si(100) have been discovered.[137]

4.2. Nucleic Acid Functionalized Nanoparticles for Controlled Aggregation

DNA molecules are very powerful and versatile linkers for the controlled aggregation of nanoparticles.[119,120,138] DNA chains are of a controllable length and composition and provide predictable properties and enormous control over complementarity. Double-stranded DNA provides rigid spacers that allow control over the distances between nanoparticles. Long DNA chains can act as templates, ready to accommodate complementary DNA-functionalized nanoparticles in a controlled order and with controlled distances between the nanoparticles.

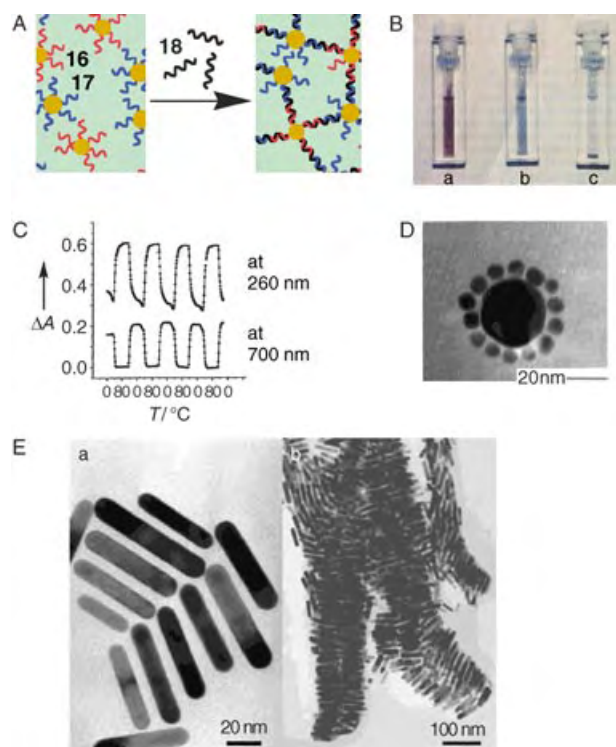
To demonstrate the DNA-mediated binding of NPs, two batches of 13-nm-diameter Au NPs were separately functionalized with two thiol-derivatized noncomplementary DNA oligonucleotides: 3′-thiol-TACCGTTG-5′ and 5′-AGTCGTTT-3′-thiol (**16** and **17,** respectively; Figure 9A).[69a] A DNA linker, **18**, composed of ds-DNA in the center and two single-stranded fragments on the ends was constructed. The two single-stranded sections were complementary to the oligonucleotides connected to the two different NPs. The addition of the linker to a mixed solution of the two DNA-functionalized Au NPs resulted in the cross-linking and aggregation of the nanoparticles. The resulting NP aggregate should theoretically have some degree of regularity, but this


Figure 9. A) The aggregation of oligonucleotide-functionalized Au NPs by the addition of a DNA strand **18** which has sections that are complementary to the DNA strands **16** and **17**. B) Cuvettes with a mixture of the Au NPs and the added DNA strand responsible for the assembly process: a) at 80 °C, the DNA-functionalized NPs are in the unhybridized state; b) soon after cooling to room temperature, the NPs undergo association, but the precipitate has not yet settled; c) after the associated NPs have settled to the bottom of the cuvette. C) Variations in the absorption spectrum of the DNA-linked NP networks as a function of temperature. D) A "satellite" system that consists of two different sizes of nanoparticles. E) Transmission electron micrographs of gold nanorods that are organized by DNA hybridization. (Parts A–C are adapted from Ref. [69a]; Part D is adapted from Ref. [142]; Part E is adapted from Ref. [144]; Reproduced with permission of the Royal Society of Chemistry).

could not be observed as both NPs had identical cores. Aggregation changed the color of the solution owing to a collective phenomenon originating from the short distance of the interparticle separation. Separate Au NPs have a red color as a consequence of their plasmon absorbance, but upon aggregation, another absorbance arises at lower energies because of interparticle plasmon coupling (Figure 9B). The association process is temperature-dependent, and the aggregated Au NPs can reversibly dissociate upon elevation of the temperature through melting of the double-strands and associate again upon a decrease in the temperature through the rehybridization process which results in the reversible changes of the spectrum (Figure 9C). In a control experiment, a noncomplementary linker was added to the solution of the mixed particles and no color changes were observed.

Changes in the optical and electronic properties of NPs upon their aggregation provide a way to detect the association process and thus allows the design of optical DNA biosensors.[139–141] The color change lies in the background of the

simplest and most powerful analytical tool to monitor the aggregation of Au NPs, namely, the "Northwestern" spot test, developed by Mirkin and co-workers.[139] This is an extremely sensitive method to discriminate between aggregated and nonaggregated gold NPs in aqueous solution and it relies on a perceptible color change from red to blue upon aggregation. The test consists of the evaporation of a droplet of an aqueous solution of particles on a reverse-phase thin-layer chromatography plate. A blue spot indicates aggregation, whereas a red spot indicates the presence of freely dispersed particles.

In a more sophisticated investigation, a mixture of DNA-functionalized Au NPs of 40-nm (A) and 5-nm (B) diameters were cross-linked with a DNA linker.[142] The larger NP A accommodates many small NPs B around it to produce a so-called "satellite" AB_n system (Figure 9 D). Interconnections between these "satellite" aggregates yield a 3D network $(AB_n)_m$. An important factor that controls the optical properties of the network is the length of the cross-linking DNA oligonucleotide bridge—it controls not only the interparticle distances, but also the rate of aggregation and thus, the number of NPs per aggregate.[143] In a similar approach, DNA-functionalized CdSe/ZnS NPs and Au NPs were cross-linked with a complementary linker to yield a binary network.[70] Fluorescence and absorption spectroscopy indicated cooperative optical and electronic phenomena within the resulting material. The application of DNA-functionalized Au nanorods instead of spherical nanoparticles resulted in microsized rods, which were composed of many cross-linked nanounits (Figure 9 E),[144] that exhibited unusual anisotropic properties.

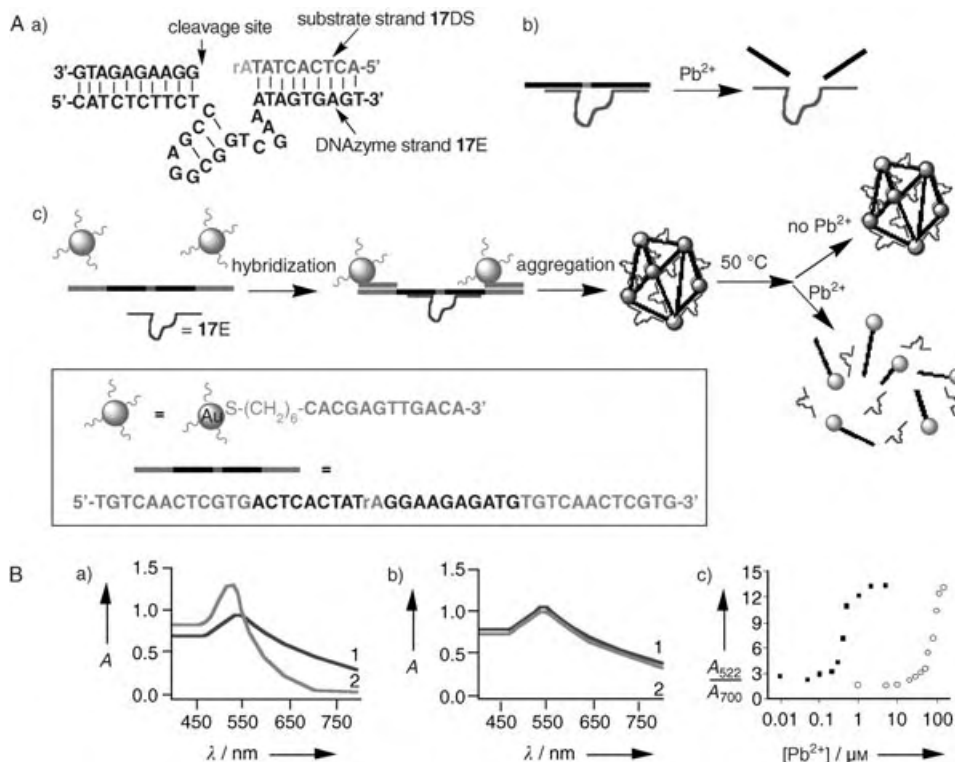
Au NPs were applied as colorimetric reporter groups that show distinctive color changes upon different aggregation states for DNA sensing.[139–141] The sensitivity and selectivity of this method rivals other methods, such as those based on fluorescence spectroscopy. Whereas this method plays an increasingly important role in genomic research, the nanoparticle aggregation methodology has expanded beyond the detection of DNA to the analysis of other analytes such as heavy metal ions,[145] potassium ions,[146] and protein A.[134] Interesting recent examples have demonstrated the controlled aggregation of nucleic acid functionalized Au NPs as optical labels for the detection of Pb^{2+} ions or adenosine by DNAzymes.[147] Catalytic deoxyribonucleic acids (catalytic DNAs or DNAzymes) attract substantial recent research efforts, and specific DNAzymes that bind Pb^{2+}, Cu^{2+}, or Zn^{2+} ions were elicited by the combinatorial in vitro selection method.[148] Particularly, "8–17" DNAzyme has demonstrated high activity and specificity towards Pb^{2+} ions.[149] The nucleic acid sequence **17E** was found to exhibit high affinity for Pb^{2+} ions, and the resulting complex revealed catalytic activity towards the specific scission of the complementary nucleic acid **17DS** that includes mostly deoxyribonucleosides as bases as well as one adenosine ribonucleoside (rA) entity at the cleavage site (Figure 10 A a).[147a] Upon the


Figure 10. A) DNAzyme system for the analysis of metal ions. a) Secondary structure of the "8–17" DNAzyme system that consists of the enzyme strand **17E** and a substrate strand **17DS**. Except for a ribonucleoside adenosine (rA) at the cleavage site, all other nucleosides are deoxyribonucleosides; b) Cleavage of **17DS** by **17E** in the presence of Pb^{2+} ions; c) DNAzyme-directed assembly of the oligonucleotide-functionalized Au NPs, and the application of the assemblies for Pb^{2+} sensing. B) UV/Vis absorbance spectra of a) the active **17E** DNAzyme–NP sensor and b) an inactive **17Ec** DNAzyme–NP sensor. The spectra were recorded in the absence (1) or in the presence (2) of Pb^{2+} ions (5 μm); c) Calibration plots for the analysis of Pb^{2+} ions, in which the enzyme strand is the active **17E** only (■) and when the ratio of **17E**/**17Ec** is 1:20 (○). cleavage of the double-stranded nucleic acid, the melting point of the cleaved duplex is lowered, and the single strands are easily separated (Figure 10 A b). Accordingly, the complementary substrate of the DNAzyme, **17DS**, was elongated with nucleic acids that are complementary to secondary nucleic acid labeled Au NPs. Mixing of all three components—the DNAzyme **17E**, the complementary nucleic acid substrate **17DS**, and the nucleic acid labeled Au NPs—resulted in the hybridization of the respective components, and the aggregation of the hybrid system into clusters

(Figure 10 A c). In the aggregate, the characteristic interparticle-coupled plasmon absorbance was observed (Figure 10 B a, curve 1). The addition of Pb^{2+} ions resulted in the DNAzyme-assisted cleavage of the complementary nucleic acid, which led to the separation of the Au NP aggregates and the formation of the localized plasmon absorbance of the nonaggregated Au NPs (Figure 10 B a, curve 2). With this approach, Pb^{2+} ions could be detected in the concentration range of 0.1–4 μM (Figure 10 B c, ■). In a control experiment, the function of the DNAzyme as the active component for the detection of Pb^{2+} ions was nicely demonstrated. The T base at the tenth position in the sequence was exchanged by a C base which led to complementarity in the loop region of the DNAzyme (**17**Ec). This resulted in a very poor scission activity of the duplex structure in the presence of Pb^{2+} ions (Figure 10 B b, curves 1 and 2) and in a substantial decrease in the sensitivity of the system (Figure 10 B c, ○).

To expand the methodology to a broader range of analytes, a colorimetric biosensor for adenosine was tailored on the basis of the aptazyme-directed assembly of gold NPs.[147b] The aptazyme was bound on a 8–17 DNAzyme that is allosterically activated by the adenosine aptamer. In the absence of adenosine, an inactive aptazyme is formed, and the DNA strand operates as a linker for the assembly of a blue-colored aggregate of 13-nm Au NPs. In the presence of adenosine, however, the aptazyme is activated, and the DNA strand is cleaved. This prevents the aggregation of the Au NPs which results in a red-colored system characteristic of the discrete individual nanoparticles. Concentrations of up to 1 mM of adenosine could be semiquantitatively measured by the extent of blue-to-red color changes, or quantitatively measured by the ratios of the absorbances at 520 and 700 nm. The addition of guanosine, cytidine, or uridine (all 5 mM) in place of adenosine did not affect the aggregation of the DNA-bound Au NPs which indicates the specificity of the system towards adenosine. Because aptamers may be developed for different analytes, the rational design of aptazymes through the incorporation of aptamer units and upon coupling to Au NPs may lead to versatile colorimetric biosensors.

Biocatalyzed transformations of functionalized oligonucleotide assemblies were used to perform controlled association of NPs and to provide stabilization of the particulate aggregates.[150] Au NPs (15 nm) were functionalized with thiolated single-stranded DNA of 45 bases, **19** (Figure 11 A). The Au NP-bound DNA was then converted into the double-stranded form through hybridization with the complementary ss-DNA, **20**. The DNA sequence was chosen so that the double strands that were formed on the particles would contain recognition sites for a number of restriction endonucleases. After DNA hybridization, the system did not contain any single-stranded DNA capable of further hybridization with complementary linker strands. To create reactive sites by deprotection, the restriction enzyme *Eco*RI was used to cleave the double strands on the particles at specific recognition sites to leave a cohesive end for further hybridization (Figure 11 A, step a). After this first enzymatic step, hybridization between the newly created cohesive ends through the relatively labile overlap of only four complementary base pairs resulted in the formation of weakly
Figure 11. A) Controlled association of Au NPs based on biocatalytic transformations of oligonucleotides. a) Au NPs that are derivatized with ds-DNA are treated with the restriction enzyme *Eco*RI, which cleaves the DNA to yield cohesive ends (the gray color represents the recognition site of the enzyme, and the arrows indicate the sites of cleavage on each strand); b) Two cohesive ends hybridize, which leads to a weak association of particles; c) The DNA backbones are covalently joined at the hybridized site by DNA ligase to yield a stable 40-base-pair double-stranded link between the particles. B) TEM analysis of the DNA–NP complexes before (a) and after (b) treatment with *Eco*RI and after subsequent treatment with DNA ligase (c). (Adapted from Ref. [150], with permission).

associated aggregates of particles (Figure 11 A, step b). This process was investigated by TEM as shown in Figure 11 B, images a and b. The formation of small aggregates is clearly seen in comparison to the randomly distributed individual particles prior to enzyme treatment. To stabilize the system at this stage, the DNA backbones at the hybridized cohesive ends were covalently joined in a second enzymatic step by using T-4 DNA ligase (Figure 11 A, step c). The resulting TEM image shows the presence of significantly larger aggregates that are formed as a consequence of much stronger interparticle binding by the newly formed 40-base-pair double-stranded linker (Figure 11 B, image c). In this sequence of biocatalytic reactions, randomly dispersed DNA-coated Au NPs were converted first into weakly associated structures and subsequently into an aggregated system through simple and predictable manipulation with DNA-processing enzymes.

Proteins such as bacterial DNA methyltransferases (M.*Eco*RI and M.*Hha*I) or restriction endonuclease (R.*Eco*RI) are known to bind and produce specific conformational changes in DNA. M.*Eco*RI recognizes the GAATTC sequence and methylates the second adenine by bending the DNA strand by approximately 55–59° and flipping the target adenine out of the DNA duplex. This process could affect significantly the distance between nanoparticles bridged by the ds-DNA. For example, a 40-mer duplex DNA with an incorporated base-pair target site (GAATTC) was used as a rigid spacer between two 1.4-nm Au NPs to separate them by
Figure 12. 11–14 nm (Figure 12 A a).[151] Upon addition of M.*Eco*RI to a solution of the ds-DNA–Au NP hybrid, the binding of the protein and the biocatalytic methylation of the adenine base produces a drastic decrease in the Au–Au separation distance to 6–8 nm (Figure 12 A b). The measured distances correlate with the expected topological changes that are induced by the binding of M.*Eco*RI to the DNA chain.

Long DNA molecules that are capable of accommodating several complementary DNA fragments in different domains on the strand can serve as templates for the construction of specific linear assemblies.[152, 153] To prevent the microscopic cross-linking of nanoparticles which results in a network, Au NPs functionalized with a single maleimide group, **21**, were reacted with thiol-derivatized DNA oligonucleotides **22**. The resulting mono-DNA-functionalized Au NPs, **23**, were associated with the respective complementary domains on the DNA template molecule (Figure 12 B). Individual placement of the nanoparticles at specific complementary domains of the template allows control of the distances between them as well as controlled placement of different types of NPs (different sizes and materials) on the template to result in a variety of properties of the NPs assemblies. For example, two DNA-functionalized Au NPs can be placed on the DNA template in three different orientations, "head-to-head" (**24**), "head-to-tail" (**25**), and "tail-to-tail" (**26**), thus providing different distances between the nanoparticles.

Recently, a newly discovered aggregation phenomenon of DNA-functionalized gold nanoparticles induced by the

hybridization of a DNA target was reported in which the NPs are not cross-linked.[154] The Au NPs (15 nm) were functionalized with a single-stranded DNA (≈ 200 DNA probes per particle). Whereas bare Au NPs without the probe DNA immediately aggregated in NaCl solution (0.1M), the DNA-functionalized NPs did not exhibit any visible change in solutions of NaCl (concentrations up to 2.5M). Thus, the surface-immobilized probe DNA stabilizes the nanoparticle dispersion. An equivalent amount of a complementary target DNA was added to the system and resulted in the hybridization of the DNA probe that was associated with the Au NPs. The subsequent addition of aqueous NaCl at concentrations higher than 0.5M resulted in a fast (< 3 min) color change to purple that represents an aggregation of the particles. Although the mechanism of this phenomenon is not fully understood at present, the conformational transition of the immobilized DNA probably plays an essential role— formation of the probe-target duplex makes the conformation more tight and more rigid. This conformational transition may decrease two contributions of the repulsive interactions between the nanoparticles. First, electrostatic repulsion may be decreased by the screening effect because the tight conformation raises the binding constant with counterions. Second, steric repulsion may be decreased by the stiffening of the DNA which lowers the entropic effect. In this non-cross-linking system, the aggregation is driven by London–van der Waals attractive forces between the nanoparticles in which the repulsive interaction is greatly reduced by the formation of duplexes on the surfaces of the NPs. The attractive force works from a distance and leads to the rapid aggregation.

The use of peptide nucleic acids (PNAs), which are DNA analogues in which the entire sugar-phosphate backbone is replaced by a polypeptide backbone, as a means to control the aggregation of nanoparticles was reported recently.[155] Au NPs (13 ± 1.2 nm) were functionalized with various PNA primers, and these were used for the self-assembled aggregation of the particles upon hybridization of the complementary PNA sequences. PNA complexes offer two important advantages for biomaterials-based nanofabrication: 1) PNA complexes exhibit enhanced stability relative to their respective DNA analogues and 2) the amino acid unit may be easily altered in the PNA backbone to enable a higher degree of complexity in the strands. For example, by the substitution of glycine with other amino acids in the PNA, the structural and electrostatic properties of the PNA complex may be regulated and the dynamics of assembly may be controlled. Besides the possible applications of PNA complexes for nanofabrication, PNA–NP conjugates may offer advantages over DNA–NP conjugates for biosensing. The enhanced base-pair mismatch selectivity of PNA may improve the specificity of the sensors in the analysis of sequence-specific nucleic acids.

4.3. Composite Assemblies of Nucleic Acids, Proteins, and Nanoparticles

A combination of the synthetic methods to prepare biomolecule-functionalized nanoparticles (See Sections 2.1–

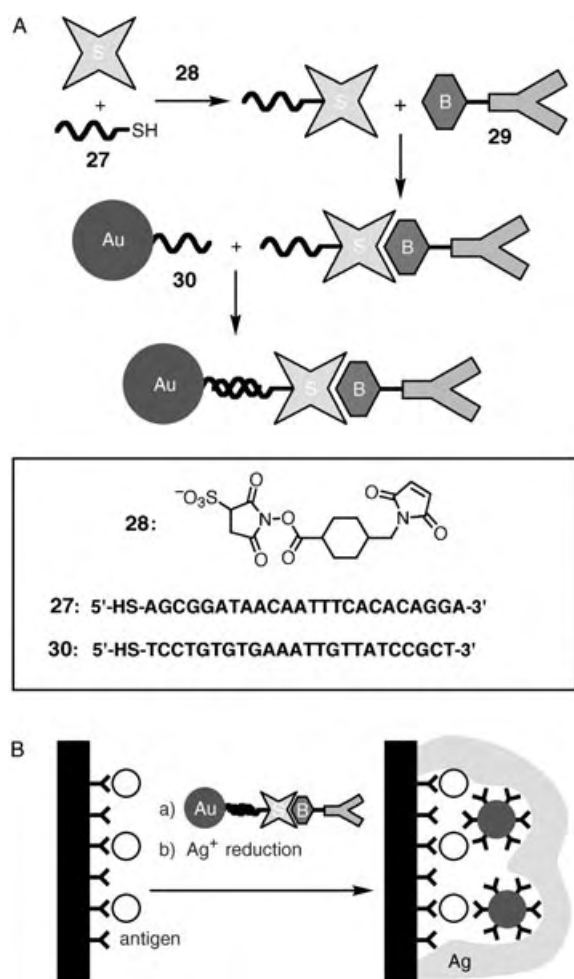
2.3) and the application of proteins, which have affinity properties (e.g. SAv, antibodies), oligonucleotides, and nanoparticles as building blocks allows the construction of very sophisticated biomolecule–NP hybrid clusters (Figure 13A).[21a] To functionalize Au NPs with antibodies, a


Figure 13. A) The formation of a Au nanoparticle–IgG-antibody conjugate. B) The use of the conjugate for the sensing of antigens.

multistep procedure was developed.[156] The 5′-thiol-modified oligonucleotide, **27**, was covalently bound to SAv through the heterobifunctional cross-linker sulfosuccinimidyl-4-(maleimidomethyl)cyclohexane-1-carboxylate (**28**). The resulting conjugate had four binding sites for biotin ligands and one nucleic acid function. The SAv receptor sites were treated with biotinylated antibodies, **29**, which were directed against mouse IgG (αM-IgG) or rabbit IgG (αR-IgG), to yield DNA-tagged antibody conjugates that could bind to a complementary DNA strand from one side and to the respective antigens from the other. This architecture was treated with Au NPs that were functionalized with oligonucleotides **30**, which were complementary to the DNA tag, to yield Au NPs that were modified with the antibody molecules. The resulting conjugate was then applied as a label for the immunoassay of the respective antigens, which were bound to

a surface. The linkage of the Au NPs to the antigen–antibody complex was further amplified by the electroless deposition of Ag on the Au NPs (Figure 13B).[156]

A combination of receptor proteins and oligonucleotides as bridging units for the directed aggregation of nanoparticles allows the complex structuring of the assemblies.[157] As an example, SAv was interacted with biotinylated DNA to result in a four-DNA–Sav conjugate.[157a] Application of this conjugate as a building block for the aggregation of DNA-functionalized Au NPs yielded a network with a motif that was different from that which resulted upon the direct aggregation of DNA-functionalized NPs bound by the complementary oligonucleotide. Even more fascinating aggregation resulted when Au NPs were primarily associated with SAv to yield nanoclusters, which were then placed on a DNA template (Figure 14A).[158] 1.4-nm Au NPs with a single
Figure 14. A) The construction of four-nanoparticle clusters, and their assembly into linear composites along a DNA template. [159], with permission).

amine substituent were derivatized with a biotin group, and the biotin moiety was used to organize the nanoclusters into a tetrahedral superstructure defined by the geometry of the biotin-binding sites of the SAv. Prior to cluster formation, SAv was derivatized with a single DNA molecule. The resulting tetrahedral four-Au NP clusters, **31**, each with a single DNA tail, were assembled on a DNA template molecule, **32**, which dictated the positions and distances. This approach could allow the formation of almost any imaginable structure from nanoparticles of different sizes and various materials. NPs were also applied for the site-specific labeling of complex biological species such as viruses; for instance, a 30-nm-diameter sphere of the cowpea mosaic virus (CPMV) was labeled with 1.4-nm Au NPs (Figure 14B).[159]

Inorganic nanostructures were crystallographically controlled by using synthetic biomolecular templates that consisted of anionic DNA and cationic lipid membranes. These membranes self-assembled into a multilamellar structure in which a periodic 1D lattice of parallel DNA chains was confined between stacked 2D lipid sheets.[160] Positively charged Cd^{2+} ions were electrostatically bound within the interhelical pores between the DNA strands and they were subsequently treated with H_2S to form CdS nanorods of controlled widths and crystallographic orientation. The strong

electrostatic interactions align the templated CdS (002) polar planes parallel to the negatively charged sugar-phosphate DNA backbone to ensure that the inorganic nanostructures are imprinted into the biomolecular matrix.

5. Assembly of Biomolecule–Nanoparticle Architectures on Surfaces

The immobilization of biomolecules on transducers such as electrodes, piezoelectric crystals, or field-effect transistors is attractive in the development of biosensors and bioelectronic devices.[161–165] Several methods for the surface functionalization of electronic elements have been developed, and the means to couple the active sites or recognition processes of biomaterials with the electronic elements to yield the electronic transduction of the biological events have been demonstrated. Biosensors,[166] biofuel-cell elements,[167] and optobioelectronic systems[168] have been constructed. Also, the deposition of biomaterials on nonconductive surfaces (e.g. plastics, glasses), and especially the patterning of such surfaces with biomaterials,[165, 169] is of great interest in tailoring protein and DNA chips for proteomic and genomic analyses, respectively. Diverse methods for the assembly of 2D and 3D nanoparticle structures on surfaces have been developed. Various applications of these systems, such as in the fabrication of photoelectrochemical cells (e.g. solar cells), light-emitting diodes, electrochromic systems, and computing devices, as well as the organization of different nanometric single-electron devices have been discussed.[7a]

The integration of biomolecule–nanoparticle hybrid systems with surfaces paves the way for the generation of ordered architectures with new functionalities. The unique photonic properties of NPs may be employed to detect and probe biological recognition events on surfaces. Biomaterial structures adsorbed on the surfaces of nanoparticles may be probed by means of surface plasmon resonance (SPR), surface-enhanced Raman spectroscopy (SERS), and surface-enhanced fluorescence spectroscopic techniques. Also, the unique electronic (conductive) and catalytic properties of NPs may be used to provide electron transfer from or to redox centers of enzymes or to enhance the chemical reactivities of biomaterial structures.

Biomaterial constituents on surfaces also provide unique features for the formation of hybrid biomolecule–NP structures. Biomaterials, such as nucleic acids, and streptavidin–biotin or antigen–antibody complexes assembled on surfaces can provide templates for the immobilization of nanoparticles. Enzymes may be used as catalytic tools for the manipulation of biomaterials on surfaces; the ligation, scission, or polymerization of nucleic acids may be used to tailor nucleic acids of specific lengths and compositions. Thus,

complex biomaterial-based structures on surfaces may be engineered by the genetic manipulation of biomaterials, the synthesis of nucleic acids, and the biocatalytic manipulation of the biomaterial on the surface. The incorporation and integration of NPs in surface-confined biological templates can then yield new functional materials; as an example, the catalytic deposition of metals on NP seeds can generate circuitry with the shape of the biomaterial. Thus, hybrid biomolecule–NP composites on surfaces provide functional interfaces that could be important as materials for bioelectronic, electronic, optobioelectronic, and photonic applications.

The association of functionalized NPs and biomaterials with solid supports and liquid/liquid or liquid/air interfaces can be driven by charge interactions[170] or by specific bioaffinity binding.[21a] The subsequent sections address the methods to organize these composite biomolecule–NP systems on surfaces and discuss recent activities that utilize these systems for sensory, photoelectrochemical, and electronic circuitry applications.

5.1. Assembly of Layered Nanoparticle–Protein Arrays on Surfaces

Multilayer systems, which are composed of proteins and nanoparticles and assembled on solid supports,[171] have been fabricated by the layer-by-layer deposition of the biological and inorganic components. Cytochrome c (cyt c)–TiO$_2$ NP layers were reported[171a] in which the TiO$_2$ NP layers were deposited by boric acid promoted hydrolysis of hexafluorotitanate ions from aqueous solution (liquid-phase deposition process, LPD; Figure 15 A).[172] The LPD technique enables the preparation of anatase TiO$_2$ without the need for organic
Figure 15. A) Method for the construction of TiO$_2$/cyt c multilayers on a QCM electrode. B) Optical absorbance at $\lambda = 409$ nm of assemblies of different thicknesses: the buildup of layers of cyt c is shown. (Part B is adapted from Ref. [171a], with permission).

solvents: this is essential for the codeposition of the biomaterial. The TiO$_2$ NPs on the surface produced by this technique are negatively charged. The subsequent deposition of the positively charged protein cyt c (isoelectric point, $pI = 10.1$) results in electrostatic attraction between the TiO$_2$ NPs and the protein which leads to the formation of multilayers. The deposition of the multilayers was followed by quartz crystal microbalance (QCM) microgravimetric measurements, which demonstrated a linear increase of the mass upon deposition of each double layer of TiO$_2$/cyt c. This

observation was also verified by absorbance spectroscopy (Figure 15 B). This method could be widely extended to the preparation of other protein/metal-oxide multilayers that would facilitate the creation of photofunctional protein–inorganic superlattices. In another approach, assemblies of polyurethane$_{core}$/Au$_{shell}$ NPs were used as permeable high-surface supports for the immobilization of enzymes such as pepsin to provide easy access of the substrate molecules to the enzyme active centers in the multilayer enzyme assembly.[173]

Scanning electron microscopy (SEM) was applied for the quantitative analysis of protein chips.[174] Interactions between biotin and streptavidin, and between an antibody with its cognate hapten, were used as model systems. The number of target-coated gold NPs that interact specifically with proteins arrayed on a derivative microscope glass slide were counted by utilizing backscattering electron detection. This approach facilitated the determination of the absolute, rather than relative, number of biomolecules bound to the chip.

5.2. Nucleic Acid–Nanoparticle Architectures on Surfaces

As discussed in Section 4.2, nucleic acids can serve as templates that bind DNA-functionalized nanoparticles at complementary segments. When DNA templates are fixed at a surface of a solid support, the resulting assemblies of NPs can yield a pattern that is dependent on either the shape produced by the DNA template itself or on the pattern produced upon its immobilization.

A natural single-stranded long-chain viral DNA, M13mp18 phage vector, **33**, which contains 7249 bases, was hybridized with a biotinylated short-chain target oligonucleotide, **34**, which was complementary to a specific segment of
Figure 16. A) The controlled association of a SAv-coated Au NP with a ss-DNA template by means of the hybridization of a biotinylated ss-DNA with the template DNA. B) AFM image of a DNA strand with Au NPs that are specifically bound to the template through biotin–SAv interactions. (Part B is adapted from Ref. [175], with permission).

the viral DNA (Figure 16 A).[175] It should be noted that the template viral DNA **33** can have more than one complementary domain, thus it is capable of accommodating more than one biotinylated DNA chain. The hybridized DNA-holding biotin units **35** were then treated with SAv-coated Au NPs **36** (5 nm). The resulting negatively charged Au NP-labeled DNA template **37** was adsorbed on a surface of positively charged Mg^{2+}-coated mica substrate and was subjected to atomic force microscopy (AFM) measurements (Figure 16 B). The images obtained clearly show Au NPs associated with the DNA template, yet the number of Au NPs per DNA chain was not perfectly defined; this reflects either incomplete hybridization of the template with the biotinylated target DNA or incomplete association of the SAv-functionalized Au NPs with the biotinylated domains. As different biotinylated nucleic acid segments may be hybridized with the M13mp18 DNA, the entire viral DNA may be decorated with SAv–Au NPs. Indeed, such experiments revealed that the Au NP-functionalized viral DNA was formed on the solid support.

The electrostatic association of CdS NPs with DNA was applied as the driving force for the formation of a semiconductor NP–DNA wire on the surface.[176] Negatively charged ds-DNA molecules associated with the water/air interface of a solution that contained cationic surfactant molecules (dioleoyltrimethylammonium propane, **38**; Figure 17). The layer at the interface was compressed by
Figure 17. Electrostatic deposition of CdS NPs on a DNA chain at the air/water interface by using the Langmuir–Blodgett technique.

using the Langmuir–Blodgett technique to provide a high-density packing of the DNA molecules. Positively charged CdS NPs (3 nm) capped with thiocholine, **39**, were then added to the aqueous phase which resulted in their aggregation with the DNA. The formed DNA–CdS aggregates were transferred to a solid support, and electron microscopy images revealed the formation of densely packed CdS NPs along the DNA template. These generated chains were composed of semiconductor NPs with a diameter of ≈3 nm and an average separation of ≈3.5 nm.

Several other methods were reported to generate DNA–semiconductor (or metal) hybrid nanostructures on surfaces. The circular plasmid ds-DNA pUCLeu4 (3455 base pairs) was treated with Cd^{2+} ions, and the resulting Cd^{2+}/DNA complex was adsorbed by spin-coating onto a polylysine-coated glass slide. The complexed Cd^{2+} ions were treated with S^{2-} ions to yield CdS, and electron microscopy images revealed the formation of CdS NPs that followed the circular shape of the DNA template.[177] In another example, Au NPs capped with positively charged lysine were deposited onto a surface that was coated with a thick, negatively charged DNA film.[178, 179] Electrostatic interaction between the positive charges associated with the Au NPs and the negatively charged phosphate groups of the DNA template led to the assembly of the nanoparticles into linear superstructures. The DNA, which are locked into a fairly rigid structure prior to the addition of the lysine-capped Au NPs, are rendered mobile owing to solvation during the addition of the solution of NPs to the surface of the DNA film. This process facilitates reorganization into highly regular linear NP superstructures during electrostatic complexation. Visualization by means of AFM and STM of the surface-confined DNA can be greatly improved through the addition of complementary-DNA-functionalized Au NPs. These latter particles introduce not only clearly visible Au clusters associated with the DNA that lies on the surface, but can also change the orientation of the long DNA molecules at the surface to produce tethered, rather than flat-lying, DNA chains.[180] Both of these effects can ease the visualization of DNA molecules at surfaces.

Negatively charged DNA molecules can form complexes with positively charged metal ions that are later reduced to the metallic state to produce a metal wire across the DNA template. For example, upon reduction of Pd^{2+} cations loaded on a DNA template, nanoscale Pd clusters formed on the DNA.[181] Depending on the duration of the reduction process, either well-separated Pd clusters or a quasi-continuous Pd wire with a grainlike structure could be produced.

A system which utilizes DNA that cross-links into a continuous network has been investigated in an attempt to improve structural control over a longer distance (Fig-
Figure 18. A) The 2D assembly of Au NPs by using a DNA-based method: a) A gold NP is attached to oligonucleotide **40** through a Au–thiol interaction; b) The oligonucleotide **40** is hybridized with oligonucleotide **41**, which possesses a complementary base sequence; c) The components are incorporated into a DNA network that consists of oligonucleotide **42**. B) AFM image of the resulting 2D Au NP–DNA network. (Adapted from Ref. [182], with permission).

ure 18 A).[182] Three types of oligonucleotides were used: **40**, **41**, and **42**. Oligonucleotide **40** had a sequence of 17 bases, and its 3′ end was modified with a thiol group (5′-GTAAAAC-GACGACGGCCAGT-SH-3′). The 57-base oligonucleotide **41** included a central sequence complementary to **40** and side sequences of alternating A and T bases. Oligonucleotide **42** was a 50-base poly(dA-dT) (poly(deoxyadenylic acid–deoxythymidylic acid)) that forms a network structure and is hybridized upon contact with **41**. All three oligonucleotides were mixed with 5-nm Au NPs. The resulting network was adsorbed onto a mica surface, and the surface was probed by AFM (Figure 18 B). These images resembled a nanocircuit that lacked organization and direct contact between the Au NPs. To construct real microsized DNA-templated wires, microwires prepared by electrochemical metal deposition in a porous alumina membrane were bound to thiolated DNA molecules and were treated with a solid support functionalized with a complementary DNA oligonucleotide.[183] The hybridization process between the surface-confined DNA and the DNA linked to the microwires yielded ds-DNA bridges that bound the microwires to the surface. It should be noted that in this case, the DNA molecules were used as "molecular glue" to bind microsized predesigned wires to the surface instead of individual nanoparticles which provides a significant advance to microscale circuitry.

Another approach to the directed placement of nanoparticles on solid supports by means of DNA is based on the micropatterning of a surface with DNA molecules. This approach provides the specific binding of complementary-DNA-functionalized NPs at specific domains of the pattern. An amine derivative of an oligonucleotide was deposited in a pattern onto a chemically modified glass surface by a nanoliter dispensing device and was then covalently bound to the surface.[184] Au NPs (34 nm) functionalized with a complementary oligonucleotide were then treated with the DNA-patterned surface to yield a Au NP pattern that followed the shape of the DNA pattern. Even more precise placement of Au NPs was demonstrated by the "dip-pen nanolithography" method, which was applied for the patterning of the addressable primary DNA on a surface.[185] Two types of amine-functionalized DNA oligonucleotides TCTCAACTCGTAA$_{10}$ (**43**) and A$_{10}$CGCATTCAGGAT (**44**) were deposited and then covalently bound to a gold surface that was functionalized with 1,16-mercaptohexadecanoic acid (Figure 19 A). The deposition was performed in two sequential steps to yield a pattern that was composed of spots of both oligonucleotides. This primary pattern was treated with an oligonucleotide of sequence TACGAGTTGA-GAATCCTGAATGCG (**45**), which was composed of two domains—one was complementary to **43** and the other was complementary to **44**. The resulting DNA-functionalized surface provided addressable complementary DNA chains for two kinds of DNA-functionalized Au NPs: **43**–Au (13 nm) and **44**–Au (31 nm) particles. A pattern was observed on the DNA-functionalized surface by AFM: **43**–Au NPs were specifically bound to the spots of **44/45**, and **44**–Au NPs were bound to the spots of **43/45** that were periodically located on the solid support (Figure 19 B). A similar procedure was used to pattern a surface with functionalized Au NPs
Figure 19. A) The use of dip-pen lithography and DNA to produce a predesigned multinanoparticle pattern. B) AFM image of the assembly, which consists of large and small nanoparticles (scale bar = 1 µm). (Part B is adapted from Ref. [185], with permission).

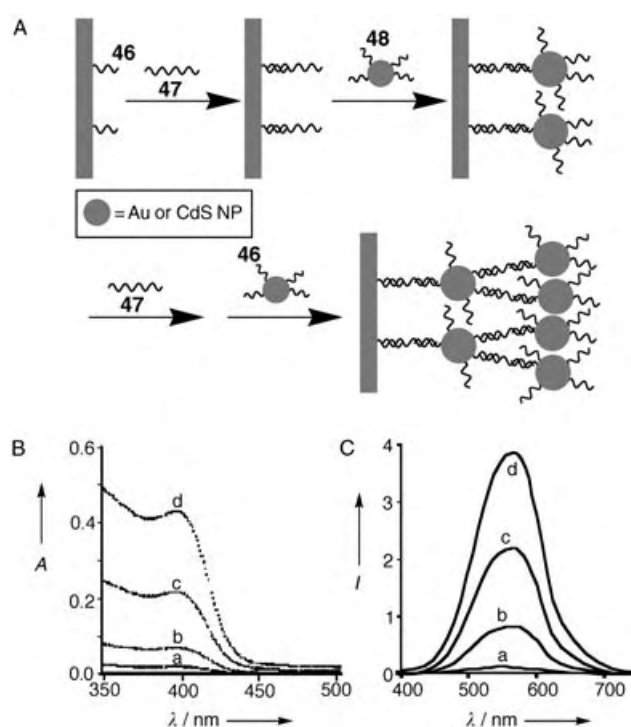
by direct-write dip-pen nanolithography based on antigen–antibody specific recognition.[186]

Multilayers of nanoparticles can be assembled on solid supports by utilizing DNA complementarity.[187] For this purpose, a glass surface was functionalized with a monolayer of an oligonucleotide, **46**, and then the surface was treated with an oligonucleotide, **47**, which was composed of two domains—one domain was complementary to **46**, whereas the second provided complementarity for **48**. Au nanoparticles (13 nm) that were functionalized with oligonucleotide **48** were then added to yield a monolayer of ds-DNA (ds-**47/48**) attached to the Au NPs (Figure 20 A). As many of the DNA chains (**48**) around the Au NP are not treated with the surface-confined DNA **47**, they can be reacted with further complementary domains of oligonucleotide **47** to provide binding sites for **46**. A second type of Au NP modified with the oligonucleotide **46** was treated with this first layer assembly to result in a second layer of Au NPs. The repetitive stepwise deposition of Au NPs functionalized with the oligonucleotides **46** and **48** resulted in a multilayer assembly of Au NPs. Each hybridized Au NP layer imparted a deeper red color onto the substrate. This method could allow the layer-by-layer deposition of different (sizewise or in chemical nature; e.g. Ag, CdS, CdSe) types of nanoparticles.

A similar approach was applied to construct a multilayer of CdS NPs (2.6 nm) on a glass support (Figure 20 A).[188] The absorbance and the intensity of the fluorescence emission of the multilayer structure of the NPs increased as the number of layers of the nanoparticles increased (Figure 20 B and C). Gold NPs functionalized with several different thiolated oligonucleotides provided complementarity for more than one DNA sequence.[189] These multioligonucleotide-functionalized Au NPs were applied to address DNA arrays, which were modified with oligonucleotide libraries to allow the simultaneous sensing of many DNA analytes and to construct


nanoparticle multilayers that were bound to a solid support and cross-linked by various oligonucleotides.[189a] Also, Au NPs which were functionalized with two different oligonucleotides were used as building blocks that contained two independently addressable DNA sequences: one of the sequences was utilized for attaching the Au NPs at the solid support, whereas the other sequence was used to establish lateral cross-links between the adjacently immobilized NPs.[189b] AFM analyses proved the functionality of the interparticle cross-links that led to the enhanced surface coverage of the monolayered DNA–Au NP assembly attached to the solid support. The methods for the assembly of nanoparticle layers on surfaces may be expanded to other nanoparticles and have important implications in the design of active electronic, photonic, and photoelectrochemical sensors (see Sections 6.2 and 6.3).

6. Functional Biomolecule–Nanoparticle Structures on Surfaces for Application as Sensors

The unique properties of nanoparticles render biomolecule–nanoparticle conjugates attractive labels for applications as sensors. The optical and electronic sensing of biomaterials on surfaces is a common practice in analytical biochemistry. Thus, the immobilization of biomolecule–NP conjugates on surfaces provides a general route for the development of optical or electronic biosensors. Metal NPs such as Au or Ag NPs exhibit plasmon absorbance bands in the visible spectral

region that are controlled by the size of the respective particles. Numerous studies on the labeling of bioassays and the staining of biological tissues by metal particles as a means to image and visualize biological processes have been reported.[190] The spectral shifts which originate from adjacent or aggregated metal nanoparticles, such as Au NPs,[139–141] are of increasing interest in the development of optical biosensors based on biomolecule–NP hybrid systems. As an example, NPs that were functionalized with two kinds of nucleic acid, which were complementary to two segments of an analyzed DNA, were hybridized with the analyzed DNA. This led to the aggregation of the NPs and to the detection of a red-shifted interparticle plasmon absorbance of the nanoparticle aggregate.[69a]

An alternative approach for the optical detection of biorecognition processes that involved the use of metallic NPs as local quenchers of the fluorescence of dyes was reported. In a DNA molecular beacon, which was terminated at its ends with a Au NP and a dye, intramolecular quenching of the dye fluorescence persists. Opening of the DNA molecular beacon by hybridization with an analyte DNA molecule led to the regeneration of the fluorescence of the dye because of the spatial separation of the nanoparticle and dye units.[105] Similarly, semiconductor NPs exhibit size-dependent tunable fluorescence. Their favorable properties—high fluorescence quantum yields, their photostability, and their tunable fluorescence bands—evoked substantial research efforts for the application of semiconductor NPs as fluorescence labels for biorecognition processes.[75]

The extensive use of metal and semiconductor NPs in biosensing applications suggests that the unique catalytic or photoelectrochemical properties of the NPs could be used to develop electronic biosensors.[191] The catalytic electroless deposition of metals on biomolecule–NP hybrid labels could be used to generate conductive domains and surfaces, and the conductivity properties of the systems may then transduce the biosensing processes.[156] Functionalized NPs are extensively used in bioelectroanalytical chemistry.[192] Also, the localized plasmon of metal NPs, which act as bioconjugate labels, may interact with the surface plasmon of a gold support[193] to result in the amplification of the biorecognition events that occur on the surface. Furthermore, charging of the NPs through biological transformations may lead to a perturbation of the surface plasmon resonance (SPR) spectra. These effects may then be utilized to develop new transduction methods for the signals that originate from the biotransformations at interfaces. The following sections address the recent advances in the application of biomolecule–nanoparticle conjugates as active components in bioelectronic and biosensing systems.

6.1. Bioelectronic Systems Based on Nanoparticle–Enzyme Hybrids as Sensors

The electrical contacting of redox enzymes with electrodes is a key process in the design of enzyme electrodes for bioelectronic applications such as biosensors[162,165,194] or biofuel-cell elements.[167] Redox enzymes usually lack direct electrical communication with electrodes,[165] but the electrical contacting of redox proteins with electrodes has been reported by the application of diffusional electron mediators,[195] the tethering of redox-relay groups to the protein,[196] or the immobilization of the enzymes in redox-active polymers.[163,197] Relatively inefficient electrical contacting of the enzymes with the electrode is observed because of the nonoptimal modification of the enzymes by the redox units,[196f] or the lack of appropriate alignment of the enzymes with respect to the electrode. On the other hand, very efficient electrical communication between redox proteins and electrodes was observed upon the reconstitution of apo-enzymes on relay cofactor monolayers associated with electrodes.[198–200] Apo-glucose oxidase was reconstituted on a relay FAD (flavin adenine dinucleotide) layer,[198,199a] and apo-glucose dehydrogenase was reconstituted on a pyrroloquinoline quinone (PQQ)-modified polyaniline film that was associated with an electrode.[199b] Effective electrical communication between the redox centers of the biocatalysts and the different electrodes was observed, and high-turnover electron-transfer rates from the redox sites to the electrodes were noted. The effective electrical contacting of these redox enzymes was attributed to the alignment of the proteins on the electrodes and to optimal positioning of the intermediary electron-relay units between the redox centers of the enzyme and the electrode.

Biocatalytic electrodes for biosensor applications have been prepared by the codeposition of redox enzymes/proteins and Au nanoparticles on electrode supports.[201,202] In one example, direct electron transfer between hemoglobin and a glassy carbon electrode was facilitated by lipid-protected Au NPs.[202] The biocatalytic electrodes were reported to operate without electron-transfer mediators. However, the random and nonoptimized positioning of the redox proteins on the conductive NPs did not allow efficient electron transfer between the active sites of the enzyme and the electrode support. Highly efficient electrical contacting of the redox enzyme glucose oxidase (GOx) through a single Au NP was demonstrated by the reconstitution of the apo-flavoenzyme, apo-glucose oxidase (apo-GOx), on a 1.4-nm Au_{55} nanoparticle that was functionalized with N^6-(2-aminoethyl)flavin adenine dinucleotide (FAD cofactor, amine derivative; **49**). The resultant conjugate was assembled on a thiolated monolayer by using different dithiols as linkers (**50–52**, Figure 21 A).[203] Alternatively, the FAD-functionalized Au NP could be assembled on a thiolated monolayer associated with an electrode, and apo-GOx could be subsequently reconstituted on the functional NPs (Figure 21 B). The enzyme electrodes prepared by these two routes reveal similar surface coverages of about 1×10^{-12} mol cm^{-2} of the protein. The nanoparticle-reconstituted glucose oxidase layer was found to be electrically contacted with the electrode without any additional mediators, and the enzyme assembly stimulated the bioelectrocatalyzed oxidation of glucose (Figure 21 C). The resulting nanoparticle-reconstituted enzyme electrodes revealed unprecedented efficient electrical communication with the electrode (electron-transfer turnover rate ≈ 5000 s^{-1}). This electrical contacting renders the enzyme electrode insensitive to oxygen or to common
Figure 21. The electrical "wiring" of glucose oxidase (GOx) by apo-enzyme reconstitution with a gold nanoparticle that is functionalized with a single FAD cofactor unit. A) Reconstitution of apo-GOx performed prior to the adsorption of the assembly onto a dithiol-modified Au electrode. B) Adsorption of the Au–FAD conjugate onto a dithiol-modified Au electrode followed by the reconstitution of apo-GOx at the interface. C) Calibration plot of the electrocatalytic current developed by the reconstituted GOx electrode in the presence of different concentrations of glucose.

oxidizable agents such as ascorbic acid. The rate of electron transfer from the enzyme active center through the Au NP is limited by the structure of the dithiol molecular linker that bridges the particle to the electrode. The conjugated benzene dithiol **52** was found to be the most efficient electron-transport unit among the linkers **50**–**52**. The application of effective molecular wires such as oligophenylacetylene units could further improve the efficiency of electrical contacting processes.

Whereas the previous system employed the metal nano-particle as a nanoelectrode to electronically link the enzyme redox site to the macroscopic electrode, one may also use enzyme–nanoparticle hybrid systems, in which the product generated by the biocatalytic process activates the functions of the NP. This has recently been demonstrated by tailoring an acetylcholine esterase (AChE)–CdS NP hybrid monolayer on a Au electrode, and activation of the photoelectrochemical functions of the NPs by the biocatalytic process.[204] The CdS–AChE hybrid interface was assembled on a gold electrode by the stepwise coupling of cystamine-functionalized CdS to the electrode, and the secondary covalent linkage of the enzyme AChE to the particles (Figure 22 A). In the presence of acetylthiocholine (**53**) as the substrate, the enzyme catalyzes the hydrolysis of **53** to thiocholine (**54**) and acetate. Photoexcitation of the CdS semiconductor yields an electron–hole pair in the conduction band and the valence band, respectively. The enzyme-generated thiocholine (**54**) acts as an electron donor for valence-band holes. The scavenging of the valence-band holes results in the accumulation of the electrons in the conduction band and their transfer to the electrode with the generation of a photocurrent, which is controlled by the concentration of the substrate (Figure 22, B and C). The addition of enzyme inhibitors such as 1,5-bis(4-allyldimethylammoniumphenyl)pentan-3-one dibro-mide (**55**) blocks the biocatalytic functions of the enzyme and, as a result, inhibits the photocurrent formation in the system (Figure 22 D). Thus, the hybrid CdS–AChE system provides a functional interface for the sensing of the AChE inhibitors by means of photocurrent measurements and is thus applicable to the analysis of chemical warfare. A similar system that was composed of photoactivated CdS NPs and coimmobilized formaldehyde dehydrogenase, which utilizes formaldehyde as an electron donor, has been reported.[205] In this hybrid system, the direct electron transfer from the active center of the enzyme to the photogenerated holes of the CdS was possible, and the steady-state photocurrent signal in the system was reported to be directly related to the substrate concentration.

6.2. Bioelectronic Systems Based on Nanoparticles as Sensors of Biorecognition Events

The unique optical,[206] photophysical,[7a] electronic,[6,207] and catalytic[208] properties of metal and semiconductor nanoparticles render them ideal labels for biorecognition and biosensing processes. For example, the unique plasmon absorbance features of Au NPs and, specifically, the interparticle-coupled plasmon absorbance of conjugated particles have been widely used for DNA[209] and antibody–antigen[210] analyses. Similarly, the tunable fluorescence properties of semiconductor NPs were used for the photonic detection of biorecognition processes.[21a,75] Also, electrochemical methods were used to monitor NP labels bound to biomolecules. Differential pulse voltammetry signals (≈ 1.2 V), which correspond to the oxidation of Au NP

labels that are connected to the target DNA molecules, were applied for the electrochemical analysis of DNA.[211]

Metal and semiconductor NPs coupled to biomaterials generate solubilized entities. The solubility of the biomolecule–NP structures allows washing procedures to be performed on surfaces that contain a sensing interface, and thus nonspecific adsorption processes can be eliminated. Also, even nanoscale particulate clustered systems include many

atoms/molecules in the clusters. The specific capturing of biomolecule–nanoparticles on the respective sensing interfaces allows the secondary dissolution of the captured nanoparticles and thus enables the amplified detection of the respective analyte by the release of many ions/molecules as a result of a single recognition event.

Most of the detection schemes employed until now have commonly relied on a highly sensitive electrochemical stripping transduction/measurement of the metal tracer. Stripping voltammetry is a powerful electroanalytical technique for trace-metal measurements.[212] Its remarkable sensitivity is attributed to the "built-in" preconcentration step, during which the target metals are accumulated (plated) onto the working electrode. The detection limits are thus lowered by 3–4 orders of magnitude compared to pulse-voltammetric techniques, which were used earlier to monitor DNA hybridization. Such ultrasensitive electrical detection of metal tags has been observed with a variety of novel DNA-linked particle nanostructure networks. The clustered systems could be loaded with additional markers, including redox-active moieties. Silica nanoparticles loaded with tris(2,2′-bipyridyl)-cobalt(ɪɪɪ)[213] or Au NPs functionalized with tethered ferrocene units[214] were applied for the labeling of DNA and for the further electrochemical detection of DNA on the basis of redox processes of the redox-active complex units.

Powerful nanoparticle-based electrochemical DNA-hybridization assays were developed using Au, Ag, Cu, or In metal tracers.[215–219] Such protocols have relied on capturing the gold,[215,216] silver,[217] or Cu_{core}/Au_{shell}[218] NPs, or In nanorods[219] on the hybridized target followed by anodic stripping electrochemical measurement of the metal tracer. Immobilization of the probe or the target has been performed directly on carbon or indium–tin oxide (ITO) electrodes.[220,221] Alternatively, the DNA probe was linked to streptavidin-coated magnetic beads[215] or adsorbed onto the walls of polystyrene microwells.[216] The DNA-functionalized beads were collected on an electrode surface, and picomolar levels of the DNA target were electrochemically detected. An electrochemical method was employed for the Au NP-based quantitative detection of the 406-base human cytomegalovirus DNA sequence (HCMV DNA).[216] The HCMV DNA was immobilized on a microwell surface and hybridized with the complementary oligonucleotide-modified Au NP. The resulting surface-immobilized Au NP–ds-DNA assembly was treated with HBr/Br_2 which resulted in the oxidative dissolution of the gold particles. The solubilized Au^{3+} ions were then electrochemically reduced and accumulated on the electrode, and the Au was subsequently determined by anodic stripping voltammetry by means of a sandwich-type screen-printed microband electrode (SPMBE). The combination of the sensitive detection of Au^{3+} ions at the SPMBE (owing to nonlinear mass transport of the ions) and the release of a large number of Au^{3+} ions upon the dissolution of the particles associated with a single recognition event provides an amplification path: the HCMV DNA was detected at a concentration of 5×10^{-12} м. The sensitivity was further enhanced by the catalytic growth of the gold tracer, which was associated with the double-stranded DNA assembly, by the deposition of gold[215] or silver.[222] Combining

such growth of the metal-particle tags with the effective "built-in" amplification of electrochemical stripping analysis paved the way to subpicomolar detection limits.

An electrochemical protocol for the detection of DNA hybridization that is based on the deposition of metal clusters along the DNA backbone rather than attaching them at the end of the duplex was described recently.[223] This protocol relies on the DNA-template-induced generation of conducting nanowires as a result of DNA hybridization. The use of DNA as a metallization template[224] has evoked substantial research activity directed towards the generation of conductive nanowires and the construction of functional circuits.[181,225–227] Such an approach was applied to grow silver,[225,226] palladium,[181] or platinum[227] clusters on DNA templates. Aspects of the methods used to generate metal nanocircuitry from DNA templates were adapted to develop DNA detection schemes as outlined in Figure 23. The short DNA primer **56** which is attached to the electrode hybridizes with the target DNA **57** (step a). The phosphate groups associated with the long target DNA **57** collect Ag^+ ions from the solution by electrostatic interaction (step b). The bound Ag^+ ions are then reduced by hydroquinone which results in the formation of metallic silver aggregates along the DNA (step c). The subsequent dissolution and stripping electrochemical detection of the nanoscale silver clusters (step d) thus allows detection of the hybridized DNA. It should be noted, however, that the short DNA primer might also bind some Ag^+ ions which would yield a background response. The background signal could be avoided and the sensitivity provided by this method could be improved upon application of peptide nucleic acids (PNA), which lack phosphate groups and thus do not bind Ag^+ ions, as the primer for the hybridization of the target DNA.

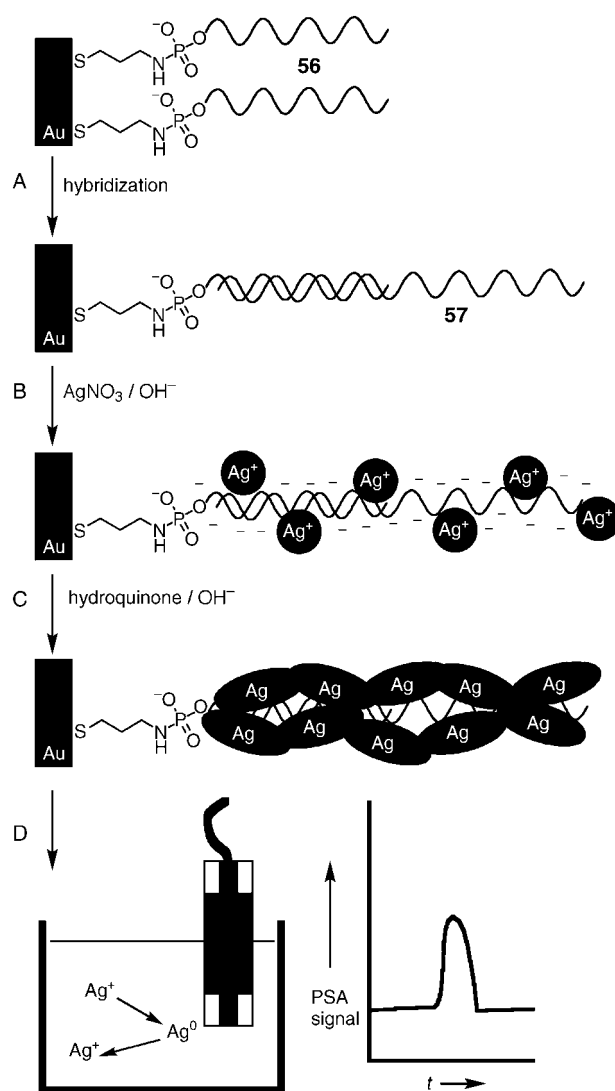
The catalytic features of metal NPs that enable the electroless deposition of metals on the NP clusters allows the enlargement of the particles to conductive interparticle-connected entities. The formation of conductive domains as a result of biorecognition events provides then an alternative path for the electrical transduction of biorecognition events. This was exemplified by the design of a miniaturized immunosensor based on Au NPs and their catalytic properties (Figure 24 A).[228] Latex particles which were stabilized by an anionic protective layer were attracted to a gap between micron-sized Au electrodes upon the application of a nonuniform alternating electric field between the electrodes (dielectrophoresis). Removal of the protective layer from the latex particles by an oppositely charged polyelectrolyte resulted in the aggregation of the latex particles and their fixation in the gap domain. Adsorption of protein A on the latex surface yielded a sensing interface for the specific association of the human immunoglobulin (IgG) antigen. The association of human IgG on the surface was probed by the binding of the secondary Au NP-labeled antihuman IgG antibodies to the surface, followed by the catalytic deposition of a layer of silver on the Au NPs. The silver layer bridged the gap between the two microelectrodes to result in a conductive "wire". Typical resistances between the microelectrodes were 50–70 Ω, whereas control experiments conducted without the specific catalytic enlargement of the domain by the Au NP–antibody


Figure 23. Outline of the steps involved in the amplified electrochemical detection of DNA by the deposition of catalytic silver clusters on the DNA strand: A) Hybridization of the complementary target DNA **57** with the DNA probe **56**, which is covalently linked to the electrode surface through a cystamine monolayer; B) Loading of the Ag^+ ions onto the immobilized DNA; C) Reduction of Ag^+ ions by hydroquinone to form silver aggregates on the DNA backbone; D) Dissolution of the silver aggregates in acidic solution, and transfer of the solution to the detection cell for stripping potentiometric measurement (PSA = potentiometric stripping analysis).

conjugate yielded resistances $> 10^3$ Ω. The method enabled the analysis of human IgG with a detection limit of $\approx 2 \times 10^{-13}$ M.

A related DNA detection scheme was developed by using microelectrodes fabricated on a silicon chip (Figure 24B).[229] A probe nucleic acid, **58**, was immobilized on the SiO_2 interface in the gap that separates the microelectrodes.[229a] The target 27-mer nucleotide **59** was then hybridized with the probe interface, and Au NPs that were functionalized with a nucleic acid **60** were subsequently hybridized with the free 3' end of the target DNA. The Au NPs catalyzed the reduction of Ag^+ ions by hydroquinone which resulted in the deposition
Figure 24. A) Immunosensing at microsized Au electrodes by the change of conductivity between the Au strips upon the binding of Au NPs and the deposition of silver. of silver on the Au NP assembly and the decrease of the resistance between the electrodes. Single-base mutants of the analyte oligonucleotide **59** were washed away from the probe nucleic acid **58** with a buffer of appropriate ionic strength. A difference of 10^6 in the gap resistance was observed upon analysis of the target DNA and its mutant by this method. The low resistances between the microelectrodes were found to be controlled by the concentration of the target DNA, and the detection limit for the analysis was estimated to be $\approx 5 \times 10^{-13}$ M. This sensitivity translates to $\approx 1\ \mu g\,\mu L^{-1}$ of human genomic DNA or $\approx 0.3\ ng\,\mu L^{-1}$ of DNA from a small bacterium. The sensitivity suggests that the DNA extracted from pathogens may be analyzed with no pre-PCR (polymerase chain reaction) amplification. Elsewhere, the hybridization of DNA was analyzed by capacitance measurements on a chip.[229b] A collection of DNA targets was simultaneously analyzed with a chip socket that included 42 electrode gaps and appropriate different nucleic acid sensing probes between the electrode gaps.[230]

The immobilization of nanoparticles on surfaces may also be used to yield high-surface-area electrodes[231] and hence to increase the hybridization capacity of the surface.[232] Such use of NP supporting films relied on the self-assembly of 16-nm-

diameter Au NPs on a cystamine-modified gold electrode and resulted in surface densities of oligonucleotides as high as 4×10^{14} molecules per cm^{-2}. The detection of the ferrocenecarboxaldehyde tag (conjugated to the target DNA) resulted in a detection limit of 500 pM. The roughening of a Au–quartz crystal with a monolayer of Au NPs was employed for the enhanced microgravimetric analysis of DNA.[233] Similarly, electrode surfaces roughened by the deposition of Au or SiO_2 NPs were employed as platforms for enhanced immunoassays that used microgravimetric, impedimetric, or amperometric readout signals.[234]

Efficient methods for the preparation of semiconductor NPs (e.g. CdS, CdSe, PbS, ZnS) and their functionalization with biomolecules were recently developed.[235] These NPs were applied as labels of biomaterials in biorecognition processes such as DNA sensing. For instance, CdS semiconductor NPs that were modified with nucleic acids were employed as tags for the detection of hybridization events of DNA.[236] Dissolution of the CdS NPs (in the presence of 1M HNO_3), followed by the electrochemical reduction of the Cd^{2+} to Cd^0, which accumulates on the electrode, and the removal of the generated Cd^0 (as Cd^{2+}) provided the electrical signal for the DNA analysis. Figure 25 A shows the chrono-
Figure 25. C) Stripping voltammogram recorded upon the simultaneous analysis of three different 60-mer DNA targets (T1–3; 54 nM each), which are related to the BRCA1 breast cancer gene. The DNA molecules are labeled with ZnS NPs (T1), CdS NPs (T2), and PbS NPs (T3). (Part A is adapted from Ref. [236]; Parts B and C are adapted from Ref. [237], with permission; Copyright American Chemical Society, 2003).

potentiograms that result from the analysis of different concentrations of the complementary target DNA by using the CdS NPs as tags. A further development has been the use of magnetic particles, which are functionalized with the sensing nucleic acid, and CdS NPs, which are functionalized with the complementary oligonucleotide, as labels. The hybridization of the complementary nucleic acids allowed the separation of the duplex from the reaction mixture and the determination of its concentration on the electrode surface followed by the electrochemical detection. Electroless deposition of Cd^0 onto CdS NPs allowed their enlargement and, thus, a further amplification of the electrochemical signal to result in a sensitivity level as low as 100 fmol of the analyte DNA.

An interesting aspect of these systems is, however, the future possibility of a combination of different metal or semiconductor tags, which are linked to different nucleic acids, for the simultaneous high-throughput analysis of different DNA targets that are linked to different magnetic beads. By this approach,[237] different nucleic acid probes that are complementary to a series of DNA targets are linked to different magnetic particles. Similarly, different semiconductor- or metal-NP tags, which were complementary to segments of the series of the target DNAs, were used as amplifying detection units for the primary hybridization process. The hybridization of the nucleic acid functionalized semiconductor or metal particle to the specific DNA targets followed by the dissolution of the NPs and the electrochemical accumulation and removal (stripping off) of the metals enables the determination of the specific DNA targets that are present in the sample. That is, the characteristic potentials needed to strip off the metal provide electrochemical indicators for the nature of the analyzed DNA. A model system that follows this principle was developed[237] in which three kinds of magnetic particles modified with three different nucleic acids, **61a–c**, were hybridized with the complementary analyte nucleic acids, **62a–c**. The particles were subsequently hybridized with three different kinds of semiconductor NPs, ZnS, CdS, and PbS, that were functionalized with nucleic acids, **63a–c**, which were complementary to the free ends of the analyte DNA molecules (Figure 25B). The magnetic particles allow easy transportation and purification of the analyte sample, whereas the semiconductor particles provide nonoverlapping electrochemical signals that transduce the specific kind of hybridized DNA. Stripping voltammetry measurements of the metals that originated from the semiconductor NPs yielded well-defined and well-resolved stripping peaks at -1.12 V (Zn), -0.68 V (Cd), and -0.53 V (Pb; all versus Ag/AgCl reference electrode) that allow the simultaneous electrochemical analysis of several DNA analytes that are tagged with the semiconductor NP labels. Figure 25C depicts the stripping voltammograms for a solution that contains three DNA samples that are labeled with the ZnS, CdS, and PbS NP tracers, respectively. The functionalization of the nanocrystal tags with thiolated oligonucleotide probes offered the voltammetric signature with distinct electrical hybridization signals for the corresponding DNA targets. The position and size of the resulting stripping peaks provided the desired identification and

quantitative information, respectively, of a given target DNA molecule. The multitarget DNA detection was combined with the amplification feature of stripping voltammetry to yield femtomolar detection limits and an efficient magnetic removal of nonhybridized nucleic acids to offer high sensitivities and selectivities. Up to 5–6 targets can thus be measured simultaneously in a single run in connection with ZnS, PbS, CdS, InAs, and GaAs semiconductor particles. The performance of parallel assays in microwells of microtiter plates or by using multichannel microchips in which each microwell or channel carries out multiple measurements could thus lead to a high-throughput analysis of DNA.

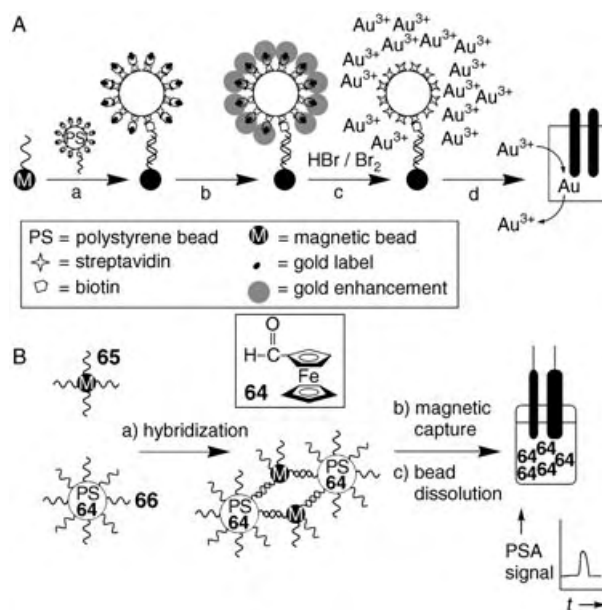
The amplification paths for the electrochemical analysis of DNA that were discussed in the previous sections have employed a single reporter unit, such as a metal or semiconductor NP, per hybridization event. To further enhance the sensitivity of DNA detection, it is possible to load multiple tags per binding event[238,239] by linking the biorecognition units to polymeric microbeads, which carry multiple redox tracers in external positions (on their surface) or internal positions (through encapsulation). A triple-amplification bioassay that couples the carrier-sphere amplifying units (loaded with numerous gold NP tags) with the "built-in" preconcentration feature of the electrochemical stripping detection and the catalytic enlargement of the multiple gold particle tags was demonstrated (Figure 26A).[238a] The gold-tagged beads were prepared by binding biotinylated Au NPs to streptavidin-coated polystyrene spheres. These beads were functionalized with a single-stranded oligonucleotide, which


Figure 26. A) The amplified detection of DNA by using nucleic acid–Au NP-functionalized beads as labels and electroless catalytic deposition of gold on the NPs as a means of amplification: a) Hybridization of the nucleic acid–Au NP-functionalized beads with the target DNA, which is associated with a magnetic bead; b) The enhanced catalytic deposition of gold on the NPs; c) Dissolution of the gold clusters; d) The detection of the Au^{3+} ions by stripping voltammetry. B) The amplified detection of DNA with polystyrene beads, which are loaded with a ferrocene redox marker **64**.

was further hybridized with a complementary oligonucleotide that was linked to a magnetic particle (Figure 26 A, step a). The numerous Au NP labels associated with one ds-oligonucleotide pair were enlarged by the electroless deposition of gold (Figure 26 A, step b) and transported to the electrode array with the use of the magnetic particle. Then, the Au assembly was dissolved upon treatment with HBr/Br$_2$ and electrochemically analyzed by using the electrochemical deposition/stripping procedure (Figure 26 A, steps c and d). Such a triple-amplification route offered a dramatic enhancement of the sensitivity. In another approach, carbon nanotubes that were loaded with many CdS NPs were employed as labels for DNA hybridization.[238b] Dissolution of the bound CdS NPs in 1M HNO$_3$ solution followed by the electrochemical detection of the released Cd^{2+} ions provided an amplified signal for the hybridization event.

The internal encapsulation of electroactive tags within carrier beads offers an alternative means to label the probes and it might offer some advantages relative to the external labeling of the probes by nanoparticles. Ultrasensitive electrical DNA detection based on polystyrene beads impregnated with ferrocenecarboxaldehyde (**64**) as a redox marker (Figure 26 B) was recently reported.[239a] The probe DNA **65** was linked to magnetic particles, whilst the polystyrene beads were functionalized with the complementary nucleic acid **66**, and the conjugates were then hybridized with the nucleic acid modified magnetic particles. Collection of the hybridized system and dissolution of the beads in an organic solvent released the immobilized redox label **64**. This allowed the chronopotentiometric detection of the target DNA with a sensitivity of 5.1×10^{-21} mol ($\sim 31\,000$ molecules) under experimental conditions that involved hybridization during 20 minutes and dissolution of the modified beads in an organic medium to "release" the marker. The amplified electrochemical readout signal was observed with the remarkable discrimination of a large excess (10^7-fold) of noncomplementary nucleic acids to highlight the analytical advantages of this sensing process. Further efforts were directed to encapsulate different redox-active NPs (ZnS, GaAs, CdS, InAs, and PbS) in polystyrene host beads to provide libraries with electrochemically readable encoding to allow parallel multitarget DNA detection.[239b] Other marker-encapsulation routes hold great promise for electrical DNA detection. Particularly attractive are the recently developed nanoencapsulated microcrystalline particles prepared by the layer-by-layer technique which offer large marker/biomolecule ratios and superamplified bioassays.[240] Related analytical procedures that combined multiple amplification pathways based on enzyme-functionalized liposomes and the accumulation of the biocatalytic reaction product were reported as ultrasensitive DNA assays.[241] Such bioassays relied on the large surface area of the liposomes that carry a large number of enzyme molecules; the accumulated product was detected by means of chronopotentiometry.

The photoelectrochemical transduction of DNA recognition processes has been demonstrated by using semiconductor (CdS) nanoparticles modified with nucleic acids.[188] Semiconductor CdS NPs (2.6 ± 0.4 nm) were functionalized with one of the two thiolated nucleic acids **67** or **68** that are
Figure 27. A) The construction of CdS NP–DNA superstructures and their use for the generation of photocurrents. B) Dendritic amplified DNA sensing by the use of oligonucleotide-functionalized Au NPs, which are assembled on a quartz crystal microbalance (QCM) electrode.

complementary to the 5′ and 3′ ends of a target DNA molecule, **69**. An array of CdS NP layers was then constructed on a Au electrode by a layer-by-layer hybridization process (Figure 27 A). A primary thiolated DNA monolayer of **68** was assembled on a Au electrode, and the target DNA **69** was used as a cross-linking unit for the association of the **67**–CdS NPs to the electrode. The subsequent association of the CdS nanoparticles that were functionalized with **68** and hybridized with **69** resulted in the second generation of CdS particles. By the stepwise association of the two different kinds of nucleic acid functionalized CdS NPs with **69**, an array with a controlled number of nanoparticle generations could be assembled on the electrode. This array was characterized by absorbance and fluorescence spectroscopy upon the assembly of the array on glass supports (as in Figure 20, parts B and C), and by microgravimetric quartz crystal microbalance analyses on Au–quartz piezoelectric crystals. Illumination of the array resulted in the generation of a photocurrent. The photocurrents increased with the number of generations of CdS NPs associated with the electrode, and the photocurrent action spectra followed the absorbance features of the CdS NPs which implies that the photocurrents originated from the photoexcitation of the CdS nanoparticles. That is, photoexcitation of the semiconductor induced the transfer of electrons to the conduction band and led to the formation of an electron–hole pair. Transfer of the conduction-band electrons to the bulk electrode and the concomitant transfer of electrons from a sacrificial electron donor to the valence-band holes yielded the steady-state photocurrent in the system. The ejection of the conduction-band electrons into

the electrode occurred from the NPs that were in intimate contact with the electrode support. This was supported by the fact that Ru(NH$_3$)$_3^{6+}$ units **70** ($E^0 = -0.16$ V versus saturated calomel electrode, SCE), which were electrostatically bound to the DNA, enhanced the photocurrent from the DNA–CdS array. In other words, the Ru(NH$_3$)$_6^{3+}$ units acted as electron-wiring elements that facilitate the hopping of conduction-band electrons from CdS particles, which lack contact with the electrode, through the DNA tether. The system is important not only because it demonstrates the use of photoelectro-chemistry as a transduction method for DNA sensing but also as the system reveals the nanoengineering of organized DNA-tethered semiconductor NPs on conductive supports. These latter nanoengineered structures comprise the first step towards electronic nanocircuitry (see Section 8.2).

Nanoparticles as components of metal NP–nucleic acid hybrids represent high-molecular-weight units that render these conjugates ideal labels for the analyses of biorecognition processes on the surfaces of piezoelectric crystals by quartz crystal microgravimetry (QCM). Furthermore, as NPs act as catalysts for the deposition of metals, even higher mass changes may be stimulated and thus the microgravimetric detection of biorecognition processes may be amplified. For a quartz piezoelectric crystal (AT-cut), the crystal resonance frequency changes by Δf when a mass change Δm occurs on the crystal according to the Sauerbrey equation, Equation (1),[242] in which f_0 is the fundamental frequency of the quartz crystal, Δm is the mass change, A is the piezoelectrically active area, ρ_q is the density of quartz (2.648 g cm^{-3}), and μ_q is the shear modulus (2.947 × 10^{11} dyn cm^{-2} for AT-cut quartz).

$$\Delta f = -2f_0^2 \frac{\Delta m}{A (\mu_q \rho_q)^{1/2}} \qquad (1)$$

The microgravimetric (QCM) detection of DNA was possible by using nucleic acid functionalized Au NPs as "nanoweights". A target DNA molecule **69** was hybridized to a Au–quartz crystal that was modified with a probe oligonu-cleotide **68**. This was followed by the hybridization of the interface with Au NPs that were functionalized with the DNA **67**, which is complementary to the free 3′ segment of the target DNA, **69** (Figure 27 B).[243] Further amplification of the response was reported by the use of a secondary Au NP that was functionalized with the nucleic acid **68**, which is complementary to the 5′ segment of the target DNA **69** and which enabled a layer-by-layer deposition of the Au NPs. The hybridization of the **68**-Au NPs with the analyzed DNA **69** followed by hybridization of the complex to the primary nanoparticle layer yielded a "second generation" of Au NPs—a process that is reminiscent of the growth of dendri-mers.[243b, 244] Concentrations of DNA as low as 1×10^{-10} M could be detected by the amplification of the target DNA by the nucleic acid functionalized Au NP labels. It has been shown that the increase in the size of the Au NP labels from 10 nm up to ≈ 40–50 nm results in an enhanced Δf signal, which increases the amplification factor of the DNA analy-sis.[245] Further increase in the size of the Au NPs, however, resulted in smaller changes in the microgravimetric signal

because of the incomplete hybridization of the DNA analyte as a result of the labeling particles being too large.

A further method for the amplified microgravimetric QCM analysis of DNA utilized catalytic metal deposition on the NP labels.[246] Figure 28 A depicts the amplified detection

[247]; Reproduced with permission of the Royal Society of Chemistry).

of the 7249-base M13mp18 DNA by using the catalytic deposition of gold on a Au NP conjugate.[247] The DNA primer **71** was assembled on a Au–quartz crystal. After hybridization with M13mp18 DNA **72**, the double-stranded assembly was replicated in the presence of a mixture of nucleotides (deoxynucleotide triphosphates, dNTP mix) that included dATP, dGTP, dUTP, biotinylated dCTP (B-dCTP), and polymerase (Klenow fragment). The resulting biotin-labeled replica was then treated with a streptavidin–Au NP conjugate **73**, and the resulting Au-labeled replica was subjected to the Au NP-catalyzed deposition of gold by the NH$_2$OH-stimu-

lated reduction of $AuCl_4^-$. The replication process represents the primary amplification step as it increases the mass associated with the crystal and simultaneously generates a high number of biotin labels for the association of the streptavidin–Au NP conjugate. The binding of the conjugate represents the secondary amplification step for the analysis of M13mp18 DNA. The third step, which involves the catalyzed precipitation of the metal, led to the greatest amplification in the sensing process as a result of the increase in the mass of the Au NPs. The M13mp18 DNA could be sensed by this method with a lower detection limit of $\approx 1 \times 10^{-15}$ M.

This means of amplification was also applied to the analysis of a single-base mismatch in DNA as depicted in Figure 28B. This was exemplified with the analysis of the DNA mutant **74a**, which differs from the normal gene **74** by the substitution of a G base with an A base. The analysis of the mutant was performed by the immobilization of the probe DNA **75**, which is complementary to the normal gene **74** as well as to the mutant **74a** (up to one base prior to the mutation site), on the Au–quartz crystal. Hybridization of the normal gene or the mutant with this probe interface, followed by the reaction of the hybridized surfaces with biotinylated dCTP (B-dCTP) in the presence of polymerase (Klenow fragment) led to the incorporation of the biotin-labeled base only into the assembly that included the mutant **74a**. The subsequent association of the SAv–Au conjugate **73** followed by the catalyzed deposition of gold on the Au NPs amplified the analysis of the single-base mismatch in **74a**. Figure 28C, curve a, shows the microgravimetric detection of the mutant **74a** by this method, whereas the normal gene **74** does not alter the frequency of the crystal (Figure 28C, curve b). With this method, the mutant could be detected with a detection limit of 5×10^{-13} M.

6.3. Nanoparticle–Biomolecule Conjugates for Optical Sensing and Analysis

Metal or semiconductor nanoparticles that are linked to bioreceptors provide labeled conjugates that can be used to optically follow the biorecognition events at biosensor surfaces. Various optical methods have been employed to detect the association of NPs on biochips, including the scanometric detection of light scattering, surface plasmon resonance spectroscopy, resonance-enhanced absorption by NPs, nanoparticle fluorescence, and enhanced Raman scattering. Although not limited, most of these detection schemes have been applied in the detection of DNA.

In a typical setup for scanometric detection, a modified glass slide was mounted on a microscope stage and was illuminated in the plane of the slide with white light. In this configuration, the slide served as a planar waveguide to prevent any light from reaching the microscope objective by total internal reflectance. Wherever NP probes were attached to the surface, evanescently coupled light was scattered from the slide and was observed as bright, colored spots. This approach was used for the detection of Au NP-labeled DNA molecules that were specifically bound to a DNA-functionalized surface.[248] Enlargement of the Au NPs by the catalytic

reduction of silver ions and the deposition of silver metal on the Au NPs resulted in a 100-fold amplification of the signal and thus increased the sensitivity.[248a,d] Two different DNA sequences could be detected at once when two Au NPs of different sizes were used to label different oligonucleotides.[248c] Spots with different colors, corresponding to the primary association of two kinds of Au NPs, were detected on the glass support when domains functionalized with different DNA probes were treated with the corresponding complementary DNA labeled with Au nanoparticles of 50- and 100-nm diameter. This method was used to detect single-base mismatches in oligonucleotides, which were hybridized to DNA probes that were immobilized at different domains of a glass support.[248a] High analytical sensitivity was provided by the deposition of silver, whereas the selectivity was demonstrated by examination of the "melting" profiles of the spots: the mismatched spot reveals a lower "melt" temperature owing to its lower association constant. The melting properties of DNA-linked nanoparticle aggregates are affected by a number of factors, which includes DNA surface density, nanoparticle size, interparticle distance, and salt concentration.[249] A theoretical model that describes this process was recently developed.[249a] The sharpness of the melting profile is highly dependent on the size of the nanoparticle; with 50-nm Au NPs, a melting transition of one degree was observed.[249b] As the sharpness of the melting transition correlates directly with the selectivity of the respective assay, this latter observation points a way for greatly improving the selectivity of DNA detection systems based on nanoparticles.

Ag NPs have similarly been used as antibody labels for the detection of antigens. This setup provided high-enough sensitivity to perform immunoassays based on single-target detection.[250] A simple desktop flatbed scanner was used to read out signals from the immunosensing surface upon pesticide immunoassay with Au NP-labeled antibodies.[251] Also, a low-cost image analyzer was used for a genomic analysis to capture evanescent wave-induced light scatter from silver-amplified Au nanolabels.[248d]

A real-time DNA detection method that utilizes single-strand DNA-modified Au NP probes and micropatterned chemoresponsive diffraction gratings interrogated simultaneously at multiple laser wavelengths was recently reported.[252] The surface-bound NP-probe-based assay with the chemoresponsive diffraction grating signal transduction scheme resulted in a simple DNA detection protocol that combines the high sensitivity and selectivity afforded by NP probes with the experimental simplicity, wavelength-dependent resonant enhancement features, and miniaturization potential of the diffraction-based sensing technology.

Resonance enhancement of the optical absorptive properties of metal NPs upon biorecognition interactions was also used as an effective means for biosensing.[253] Ag NPs were used as a support for further biorecognition binding,[253b] or metal NPs (Ag, Au, Pt) were employed as labels bound to the sensing interface upon the biorecognition events.[253a] A good agreement between the experimental observations and the extended Mie theory provided a theoretical approach to the quantitative estimation of the amount of bound biomolecules.[253c] The unique optical properties of gold NPs were

applied to the development of a reagent-dry strip-type biosensor that enables visual detection of double-stranded DNA within minutes.[254] Sensitive naked-eye detection of immunoglubulin G by the enlargement of Au NPs has been reported.[255] Au NPs were also used as spectroscopic enhancers for in vitro studies on single viruses.[256] Extrinsic parameters, such as the dielectric properties of the immediate environment (nanoenvironment) of the particle or charge distributions, decisively influence the position of the nanoparticle plasmon resonance.[257] Protein or DNA binding events cause a change in the refractive index of the nanoenvironment of a gold NP that results in a shift of the position of the NP plasmon resonance. This shift was used as a reporter signal of biorecognition events on a single NP.[258]

An interesting application of submicrometer metallic "barcodes"[259] for the analysis of biomaterials such as DNA or antigens has recently been reported.[259b] "Barcodes" that are a few hundred nanometers in diameter, several microns long, and composed of many different metals (Pt, Pd, Ni, Co, Ag, Cu, and Au) were prepared by the electrochemical deposition of the metals in a porous Al_2O_3 membrane. The length of the respective metal segments in the strips was controlled by the charge applied in the electrochemical process (Figure 29 A). The structure of the "barcode" could be identified by optical reflectivity or field emission SEM. Figure 29 B shows an optical image of a Au–Ag multistripe barcode that consists of 240-, 170-, 110-, and 60-nm Ag stripes that are separated by ≈550-nm Au stripes. It was suggested that with the available optical resolution, the number of possible readable "barcodes" that comprise two metals with a coding length of 6.5 μm is 4160, whereas for three-metal barcodes, 8.0×10^5 distinctive striping patterns are possible. The use of a mixture of "barcodes", each used to identify a specific biomaterial adsorbed on it, could enable the simultaneous analysis of numerous components in biological mixtures. Thus, the "barcode" concept introduces a NP-based analysis method that competes with chip arrays and encoded microbeads.

As the identification of the label can be performed optically, fluorescence spectroscopy can be used to characterize a biorecognition event.[259b] Figure 30 A outlines the fluorescence detection of an analyte DNA, **76**, by a primer

Figure 30. A) Detection of DNA with "barcodes". B) Fluorescence (a) and reflectivity (b) images of "barcodes" with bound fluorescent DNA; Fluorescence (c) and reflectivity (d) images of "barcodes" in the absence of analyte DNA. C) Multiple immunoassay by using "barcodes". D) a) Reflectivity and fluorescence images produced by b) fluorescein (FITC)-labeled anti-human-IgG and c) Texas Red-labeled anti-rabbit-IgG. (Adapted from Ref. [259b], with permission).

nucleic acid **77** that is linked to the Ag stripes of a Ag–Au–Ag "barcode". A nucleic acid, **78**, that is labeled with a fluorophore (TAMRA dye; TAMRA = tetramethylrhodamine) hybridizes with the free segment of the analyte DNA. Figure 30 B, images a and b show the fluorescence and reflectivity images, respectively, of the fluorophore-labeled DNA complex confined to the Ag–Au–Ag "barcode". The fluorescence image characterizes the binding event, whereas the reflectivity image identifies the "barcode" and thus the attached DNA probe. When the analyte DNA **76** is omitted, a very low fluorescence background is observed and the

particles are visible only in the reflectivity image (Figure 30 B, images c and d).

The simultaneous analysis of different biological analytes was exemplified with the immunoassay of human immunoglobulin G (IgG) and rabbit IgG.[259b] Two different "barcodes", namely, a Au–Ag–Au (4-μm length) and a Au–Ni–Au (8-μm length), were employed. The Ag stripes of the Au–Ag–Au "barcode" were modified with the anti-human IgG antibody **79**, and the Au stripes of the Au–Ni–Au "barcodes" were derivatized with the anti-rabbit IgG antibody **80** (Figure 30 C). Challenging the mixture of "barcodes" with the mixture of antigens followed by the labeling of the antibodies with fluorescein-labeled anti-human IgG **81** and Texas Red-labeled anti-rabbit IgG **82** allows the optical detection of the respective "barcodes" and the fluorescence detection of the two antigens. Figure 30 D, image a, shows the image of the two kinds of "barcodes" by optical reflectance, whereas Figure 30 D, images b and c, show the specific fluorescence from the fluorescein-labeled antibodies that are bound to the Au–Ag–Au "barcodes" and the Texas-Red-labeled antibodies that are linked to the Au–Ni–Au "barcodes", respectively.

Selective noncovalent binding of proteins to specific domains of bimetallic Ni–Au nanorods was demonstrated.[259c] Gold surfaces of the bimetallic nanorods were functionalized with alkanethiols that were terminated with hexa(ethylene glycol) groups, which prevent the adsorption of proteins, whereas nickel domains were functionalized with palmitic acid, a 16-carbon fatty acid that, on the other hand, allows the effective adsorption of proteins. Thus, "solution arrays" of highly encodable and chemically diverse nanorods provide an interesting approach for the future analysis of complex biological samples (e.g. genomics, proteomics).

The label encoding for the analysis of multiple biospecies can be performed in a different way. Nanoparticle labels encoded with DNA molecules were used for ultrasensitive multianalyte immunosensing.[260] This has been demonstrated for the analysis of a prostate-specific antigen (PSA; Figure 31). An antibody which is complementary to PSA was linked to magnetic beads to give **83** as the primary sensing interface. After the association of PSA to the sensing interface, a gold nanoparticle that was functionalized with a second antibody, which was complementary to another domain of PSA, and with the double-stranded nucleic acids
Figure 31. Application of Au nanoparticle labels that are encoded with DNA for the amplified immunosensing of prostate-specific antigen (PSA).

84 was linked to the magnetic bead–antibody–PSA complex to form a triple-component sandwich assay configuration, **85**. The assembly was separated by an external magnet and was washed free from any nonspecific adsorbates. The subsequent thermal dissociation of the nucleic acid duplex yielded the free nucleic acid, **86**, and the single-stranded-oligonucleotide-functionalized Au NPs, **87**. Two different routes were then employed to analyze the assay sample: a) The Au NPs, **87**, which held the assay components, were hybridized on a chip surface that was functionalized with the complementary oligonucleotides. Then the Au NPs were enlarged by the electroless deposition of Ag and were further analyzed by optical means (Figure 31, route A). b) The free oligonucleotides **86** were multiplied by the PCR procedure and then analyzed upon their deposition on a chip surface. The sequence analysis of the dissociated nucleic acid then provided a specific signal for the analyzed antigen (Figure 31, route B). This analytical protocol includes an intrinsic amplification feature as numerous nucleic acid barcodes are released in the thermal dehybridization step as a result of a single PSA recognition event. Furthermore, the subsequent PCR amplification of the released nucleic acid provides an invaluable tool to further amplify the PSA detection, and the antigen can be detected with an unprecedented sensitivity of 3 attomolar by this approach. A multianalyte immunoassay could therefore be performed when each specific antigen analyte is encoded with a different oligonucleotide sequence.

Au NPs have been extensively used for the detection of bioaffinity binding by virtue of nanoparticle-enhanced sur-

face plasmon resonance (SPR) spectroscopy.[261] The SPR signals were dramatically enhanced when Au nanoparticles were used as labels in immunosensing[210b,c] and DNA sensing applications.[209] A sensing interface that was modified with antibody units was employed to bind the complementary antigen component, and the resulting affinity complex was treated with a secondary antibody labeled with a Au NP. Whereas the association of the antigen to the antibody-functionalized surface yielded a small shift in the SPR spectrum, a substantial shift in the SPR spectrum was detected upon the binding of the secondary Au NP-labeled antibody. As the secondary antibody associates with the modified surface only if the antigen is bound to the sensing interface, the Au NP-labeled antibody provides a means of amplification of the primary recognition event. The binding of Au NPs to the immunosensing interface led to a large shift in the plasmon angle, a broadening of the plasmon resonance, and an increase in the minimum reflectance, all of which thereby allowed picomolar detection of the antigen. Similarly, the sensitivity of DNA analysis was enhanced by ≈ 3 orders of magnitude when Au NP-functionalized DNA molecules were used as probes (Figure 32).[209] Au NPs have been used to
Figure 32. Surface plasmon resonance (SPR) spectroscopy enhanced by Au NPs for DNA analysis ($R =$ reflectance). A) SPR spectrum of the DNA primer-functionalized surface, B) SPR spectrum after hybridization with the target DNA molecules, and C) SPR spectrum after hybridization with the target DNA molecules conjugated with Au NPs. label polypeptides, and the assembly of a de novo protein from the labeled polypeptide fragments has been followed by the SPR technique. Changes in the SPR spectrum are also observed upon the chemically directed association of the Au NP labels in the de novo protein structure.[262]

A novel class of fiber-optic evanescent-wave sensor was constructed by the modification of the unclad part of an optical fiber with self-assembled gold NPs that were functionalized with biomolecules to provide selectivity for the substrate molecules that bind to the sensing interface.[263] The optical properties and, hence, the attenuated total reflection (ATR) spectrum of self-assembled Au NPs on the optical fiber change upon alteration of the refractive index of the local environment of the Au NPs. Accordingly, biorecognition events that take place on the NPs change the refractive index of the interface and result in a change in the total reflection

spectrum of the system. In a model system, the modification of the Au NP interface with biotin enabled the detection of streptavidin with a detection limit of 9.8×10^{-11} M.

A DNA sensor was based on enhanced transmission surface plasmon resonance (ET-SPR) spectroscopy.[264] ET-SPR spectroscopy is based on the high sensitivity of the surface plasmon absorption band of gold NPs to their environment. Indeed, advantage has been taken of gold "nanoislands" that are deposited onto glass slides to provide an inexpensive and simple method for sensing medium changes (such as air versus water) and for quantifying adsorbed or chemically bound molecules or both. Changes in the ET-SPR spectra were observed upon hybridization of Au NP-labeled DNA with the complementary DNA primer immobilized on Au nanoislands thus allowing spectral detection of the hybridization process.

Triangular silver nanoparticles, ≈ 100-nm wide and 50-nm high, are formed (Figure 33 A) and these show very unique
Figure 33. Localized surface plasmon resonance (LSPR) nanobiosensor that uses triangular silver NPs for the labeling of biomaterials. A) AFM image of the triangular Ag NPs. B) Amplified LSPR analysis of streptavidin (SAv) with the triangular Ag NPs: a) Ag NPs after modification with biotin (1 mM); b) Biotinylated Ag NPs after reaction with SAv (100 nM); c) SAv-loaded Ag NPs after reaction with biotinylated Au NPs. (Adapted from Ref. [265a], with permission; Copyright American Chemical Society, 2002).

optical properties (Figure 33 B).[265] In particular, the maximum absorbance wavelength, λ_{max}, of their localized surface plasmon resonance (LSPR) spectrum is unexpectedly sensitive to the size, shape, and local (≈ 10–30 nm) external dielectric environment of the nanoparticle. The sensitivity of λ_{max}(LSPR) to the nanoenvironment has allowed the development a new class of nanoscale affinity biosensors[265] that operate in a totally analogous manner to their SPR counterparts by transducing small changes in the refractive index near the noble-metal surface into a measurable wavelength-shift response. The novel affinity biosensor based on the LSPR wavelength shift was tested using the streptavidin–biotin recognition system.[265a] Triangular silver NPs were functionalized with biotin units, and the changes in the LSPR spectra were followed upon the binding of streptavidin molecules (Figure 33 B). The detection by LSPR was further amplified by the secondary coupling of biotinylated Au NPs to the streptavidin-saturated interface. A similar method was applied to design an immunosensor.[265b]

SPR spectroscopy was used to follow biocatalytic reactions with amplification of the signal by Au nanoparticles. Au NPs that were functionalized by the covalent binding of *N,N'-*

bipyridinium (viologen) units to the tio-pronin shell were coupled to the redox processes of NAD$^+$/NADH cofactors.[266] The viologen–shell units were biocatalytically reduced by the NADH cofactor in the presence of diaphorase. The reduced viologen units were adsorbed onto a SPR plate which brought the Au cores closer to the sensing interface. Plasmon coupling between the Au SPR plate and the Au NPs resulted in an amplified change in the SPR spectrum that depended on the concentration of NADH. In the opposite setup, the viologen–shell units were electrochemically reduced and precipitated onto the surface of the SPR electrode. In the presence of NAD$^+$ cofactor and diaphorase, the reduced viologen units were reoxidized by NAD$^+$ and redissolved. The decrease of the loading of the Au NPs on the SPR electrode again resulted in the NAD$^+$ concentration-dependent amplified change in the SPR spectrum. It should be noted that application of molecular viologen unbound to Au NPs under the same conditions results in only minute changes to the SPR spectrum which do not allow the detection of the NAD$^+$/NADH cofactors.

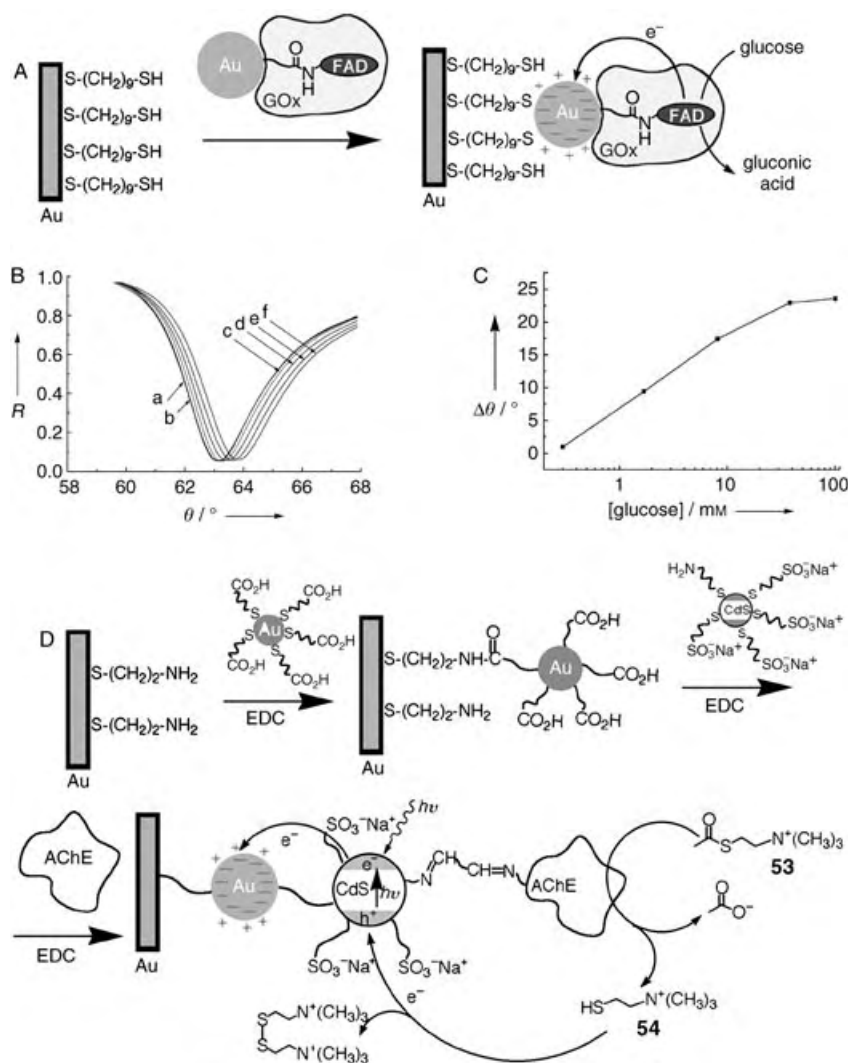
The electrical charging of Au nanoparticles that are associated with a SPR interface results in changes in the SPR spectra which depend on the extent of the electrical charge on the Au NPs. Therefore, coupling biocatalytic reactions, which involve an electron-transfer process, to Au NPs which results in their charging allows the analysis of the processes by SPR spectroscopy.[267] Au NPs (1.4 nm) that were functionalized with N^6-(2-aminoethyl)flavin adenine dinucleotide (FAD cofactor, amine derivative; **49**) were reconstituted with apo-glucose oxidase (apo-GOx). The nanoparticles were then self-assembled on a gold thin-film (SPR electrode) by using a long-chain dithiol, HS(CH$_2$)$_9$SH, monolayer as a linker. This yielded the biocatalytically active glucose oxidase (GOx) bound to the Au NPs in an aligned configuration (Figure 34 A).[267a] The biocatalyzed oxidation of glucose resulted in the formation of the reduced form of the cofactor, FADH$_2$. In the absence of O$_2$, which is a natural electron acceptor for GOx, electron transfer proceeds from the reduced cofactor to the Au NPs to result in their charging. The long-chain dithiol monolayer provided a barrier for the electron tunneling from the Au NPs to the bulk Au support to preserve the electrical charge that was produced on the Au NPs. The plasmon coupling between the charged Au NPs and the Au support resulted in a shift of the SPR spectrum which was dependent on the charge generated on the NPs (Figure 34 B). As the


Figure 34. A) Assembly of Au NP-bound reconstituted glucose oxidase (GOx) on a dithiol monolayer that is associated with a SPR-active surface, and biocatalytic charging of the Au NPs in the presence of glucose. B) SPR spectra of the Au NP–GOx hybrid system upon the addition of various concentrations of glucose: a) 0, b) 0.3, c) 1.6, d) 8, e) 40, and f) 100 mM. C) Calibration plot of the SPR spectra minimum shift as a function of glucose concentration. EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide.

charge value was controlled by the rate of the biocatalytic reaction, the shift in the SPR spectrum was enhanced upon elevation of the glucose concentration (Figure 34 C). This optical transduction of the glucose concentrations upon the "biopumping" of electrons into the Au NPs is a new concept in biosensing.

A related system has employed the photoelectrochemical charging of Au nanoparticles by CdS nanoparticles as a method to detect acetylcholine esterase inhibitors.[267b] A bilayer that consists of Au NPs covalently bound to CdS NPs was assembled on a SPR-active Au surface by using a cystamine monolayer as a linker (Figure 34 D). The enzyme acetylcholine esterase (AChE) was covalently coupled to the CdS NPs to yield the Au/CdS nanoparticles–AChE enzyme biocatalytic assembly. Hydrolysis of acetylthiocholine (**53**) by

the enzyme yields thiocholine (**54**), which acts as an electron donor. Photoexcitation of the CdS nanoparticles results in the generation of electron–hole pairs in the conduction band and valence band, respectively. The electron donor **54**, which is generated by the enzyme in situ, scavenges the valence-band holes to enable the transport of the conduction-band electrons to the Au NPs. As the cystamine linker provides a tunneling barrier against further electron transfer to the bulk Au support, the charge is preserved on the Au NPs and thus results in changes in the SPR spectrum of the system. The changes in the SPR spectra are controlled by the extent of the NP charging, which itself is dominated by the concentration of the electron donor **54** generated in situ. In the presence of AChE inhibitors, such as 1,5-bis(4-allyldimethylammonium-phenyl)pentan-3-one dibromide (**55**), the biocatalyzed generation of the electron donor declined as the concentration of the inhibitor increased which altered the electrical charging of the Au NPs and the resulting SPR spectrum of the system. Therefore, this system allowed the optical assay of AChE activity and quantitative analysis of the enzyme inhibitors.

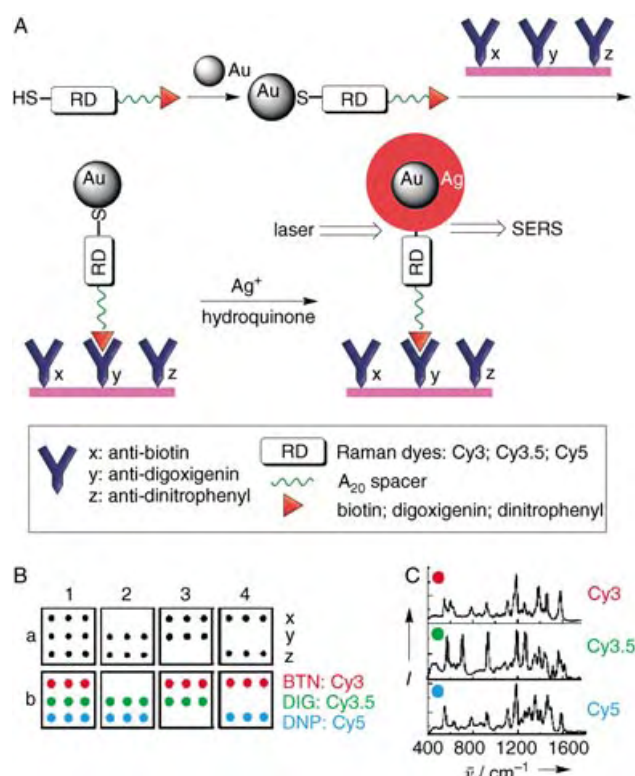
Surface-enhanced Raman (SER) scattering of nanoparticle-bound substrates allows the amplification of molecular vibrational spectra by up to 10^5-fold.[21a, 268] Some early studies demonstrated the enhanced Raman scattering spectra of cytochrome c that was coupled to Au NPs, which were associated with aggregated Ag clusters.[269] Also, SER spectra were observed for hemoglobins bound to Ag NPs.[36] Modification of metal NPs with different Raman dyes could generate multiply coded NPs[270] that allow thousands of codes to be written and read by means of surface-enhanced resonance Raman (SERR) scattering without the need for spatial resolution of components of the code.[270a] The use of surface enhanced Raman spectroscopy (SERS) for the analysis of biorecognition events was demonstrated with the application of Au NPs that were functionalized with Raman dyes and recognition elements.[270b,c] Formation of the complementary recognition complex on surfaces followed by the electroless deposition of Ag^0 islands on the Au NPs enabled the readout of the biorecognition events by SERS. The concept was applied for the parallel detection of various analytes on surfaces in an array configuration. For example, three different thiol-functionalized Raman-active dyes, Cy3, Cy3.5, and Cy5, were linked through a spacer, which comprised twenty adenine bases (A_{20}), to the three small molecules, biotin, digoxigenin, and dinitrophenyl, respectively.[270b] These functional units were then coupled to Au NPs (13 nm) to yield three different Raman dye-labeled Au NPs (Figure 35 A). These labeled nanoparticles were then employed to detect the specific interactions with the complementary mouse monoclonal antibodies for biotin, digoxigenin, and dinitrophenyl, respectively, by SERS. The different kinds of antibodies were spotted on a surface and the specific binding of Au NPs was followed by the electroless deposition of Ag^0 on the Au NPs and analysis by SERS (Figure 35 B). The selective analysis of the three different Au NP labels by the prepatterning of the surface with the antibodies is depicted in Figure 35 C. A similar concept was also used to identify protein–protein interactions by using Au NPs that were functionalized with specific antibodies and encoded with


Figure 35. A) Application of Raman dye-functionalized Au NPs for amplified multitarget immunosensing. B) Flatbed scanner images of silver-enhanced microarrays upon the immunosensing of different antibodies by Au NPs that are functionalized with the respective antigens and various Raman dyes. specific Raman dyes.[270b] Further development of the SERS technique allowed highly sensitive immunoassay procedures[271] such as femtomolar detection of a prostate-specific antigen (PSA) by using Au NPs labeled with the respective antibody.[271a]

Semiconductor nanoparticles (e.g. CdS, CdSe, ZnS) can be used as fluorescent labels for immunosensing and DNA sensing as they provide tunable wavelengths, narrow emission peaks, and 100-fold higher stability relative to molecular fluorescent dyes.[21a, 75, 272] $CdSe_{core}/ZnS_{shell}$ NPs were functionalized with avidin and these were used as fluorescent labels for biotinylated antibodies. Fluoroimmunoassays utilizing these antibody-conjugated NPs were successfully used in the detection of protein toxins (staphylococcal enterotoxin B and cholera toxin).[272f]

Four different-sized $CdSe_{core}/ZnS_{shell}$ NPs that exhibit nonoverlapping emission wavelengths in the region 530–640 nm were used to modify four different nucleic acids.[272g] The NP-labeled nucleic acids were selectively collected by specific hybridization with a spotted array of the complementary DNA and were analyzed by fluorescence imaging of the array. Another approach for DNA hybridization assays that uses metal-enhanced fluorescence was reported recently.[273] For this, thiolated oligonucleotides were bound to silver NPs that were associated with a glass substrate.

Addition of the complementary fluorescein-labeled oligonu-cleotide in the presence of the Ag NPs resulted in a 12-fold increase in the fluorescence intensity. The enhanced steady-state fluorescence was attributed to the shortening in the lifetime of the dye as it entered into proximity of the Ag NPs. Thus, hybridization could be followed by the analysis of the decay kinetics of the emission of the dye. These results suggest that silver particles could be used as a versatile label for the amplified detection of DNA hybridization. Similarly, Ag nanoparticle-enhanced fluorescence was applied in the immunoassay of insulin in serum.[274]

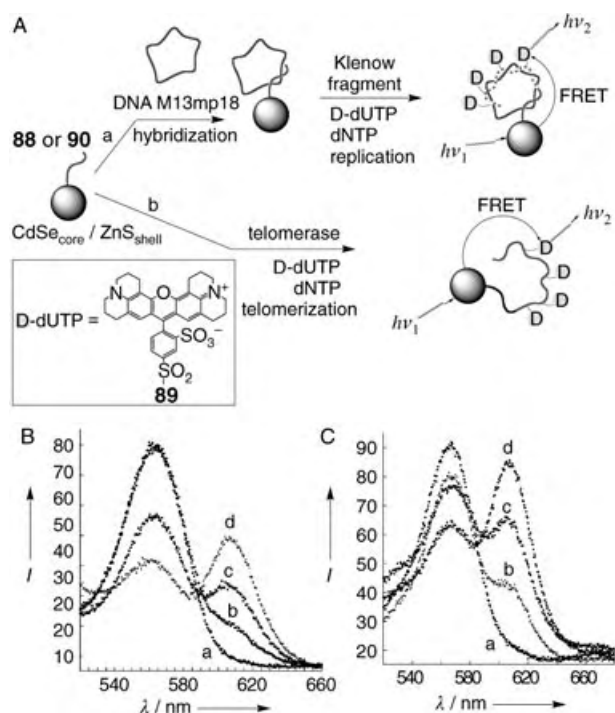
CdSe$_{core}$/ZnS$_{shell}$ NPs were also applied as photochemical centers for lighting-up the dynamics of DNA replication or telomerization processes that occur on the nanoparticles. Dye units were incorporated into the newly synthesized DNA replica or telomer to act as energy acceptors for fluorescence resonance energy-transfer (FRET) processes.[275] CdSe$_{core}$/ZnS$_{shell}$ NPs were functionalized with the primer **88**, which is complementary to a section of M13mp18 DNA. Hybrid-ization of the M13mp18 DNA with the nanoparticle interface followed by the replication of the assembly in the presence of polymerase enzyme (Klenow fragment) and the nucleotide (dNTP) mixture that included Texas Red-functionalized dUTP (**89**) resulted in the concomitant incorporation of the dye labels into the DNA replica (Figure 36A, route a). A FRET process from the semiconductor NPs to the incorpo-rated dye units resulted in emission from the dye with concomitant quenching of the fluorescence of the NPs (Figure 36B).


Figure 36. A) Replication (path a) and telomerization (path b) of nucleic acid functionalized CdSe$_{core}$/ZnS$_{shell}$ NPs with incorporated Texas Red-labeled dUTP followed by FRET from the photoexcited quantum dots to the incorporated dye molecules. B) Emission spectra upon the time-dependent DNA replication: a) 0, b) 10, c) 30, and d) 60 min. C) Emission spectra upon the time-dependent DNA telomerization: a) 0, b) 10, c) 30, and d) 60 min.

Telomerase activity in cancer cells was monitored by an identical method.[275] The CdSe$_{core}$/ZnS$_{shell}$ NPs were function-alized with the nucleic acid **90**, which is recognized by telomerase. Treatment of the NPs with a HeLa cancer-cell extract in the presence of the dNTP mixture that contained the Texas Red-functionalized dUTP (**89**) resulted in the telomerization of the primer with incorporation of the dye labels (Figure 36A, route b). The incorporation of the dye units into the telomer enabled FRET from the excited semiconductor NPs to the dye units. The time-dependent increase in the dye emission was used to follow the dynamics of telomerization and to probe the telomerase activity in the cancer cells (Figure 36C). Similarly, the FRET process was applied to follow the binding of dye-functionalized proteins to the CdSe$_{core}$/ZnS$_{shell}$ NPs,[276] thus opening the way to FRET-based immunosensing. Functionalization of a protein back-bone with photoisomerizable photochromic units yielded a hybrid system, in which the FRET efficiency was controlled by the isomeric state of the photochrome to allow modulation of the fluorescence intensity from the bound nanoparticle.[277]

Recently, dye-doped silica NPs were developed as labels for bioanalytical applications.[278] The SiO$_2$ NPs, sized between 2 and 100 nm, provide a versatile matrix for the immobiliza-tion of biomaterials, such as proteins or DNA, and the entrapped fluorophores reveal an enhanced stability towards photodegradation. Also, the accumulation of numerous entrapped fluorescence labels in a single SiO$_2$ NP provides a means of signal amplification path in biosensing because a single biorecognition event is imaged by the emission of numerous fluorophore units.

7. Biomolecule-Functionalized Magnetic Particles

Magnetic particles (microspheres, nanospheres, and fer-rofluids) are widely studied and applied in various fields of biology and medicine such as magnetic targeting (of drugs, genes, and radiopharmaceuticals), magnetic resonance imag-ing, diagnostics, immunoassays, RNA and DNA purification, gene cloning, and cell separation and purification.[279] These magnetic particles generally exist in a "core/shell" config-uration in which biological species, such as cells, nucleic acids, and proteins, are bound to the magnetic "core" through organic linkers, which are often organized as a polymeric "shell" around the core.[280] The efficiency of the binding of a biomaterial to the primary organic shell that surrounds the magnetic core was analyzed by various techniques including capillary electrophoresis with laser-induced fluorescence detection.[280a] Most of the applications of biomaterial–mag-netic-particle hybrid conjugates involve the concentration, separation, regeneration, mechanical translocation, and tar-geting of biomaterials. Phospholipid-coated magnetic NPs with a mean magnetite core size of 8 nm were used for the recovery and separation of proteins from protein mixtur-es.[280b] Antibodies were adsorbed on synthetic Fe$_3$O$_4$ mag-netic particles, and these particles were then used for specific binding to cells and the separation of the cells by an external magnetic field.[281] Magnetic NPs (FePt, ≈4-nm diameter) that were functionalized with vancomycin (Van) were used to

capture selectively Gram-positive bacteria cells through molecular recognition between Van and the terminal peptide, D-Ala-D-Ala, on the surface of the cells.[282] Unexpectedly, the Van-modified magnetic particles were also found to associate to Gram-negative bacteria such as *E. coli*.

A magnetic nanocapturer has been developed for the separation and collection of trace amounts of DNA/mRNA from mixtures and cancer cells. The nanocapturer was fabricated by using a magnetic NP as a magnetic carrier that was then functionalized with a molecular beacon as a DNA probe for gene recognition and collection.[283] High sensitivity detection of molecular recognition was observed by using magnetically labeled biomolecules and magneto-resistive sensors.[284] The layer-by-layer deposition of enzymes and magnetic particles was applied to prepare a bioreactor and allowed the biocatalytic layer to be stripped out with an external magnet when it was deactivated so that the surface could be reloaded with a new active biocatalyst layer.[285]

Magnetic NPs could be applied to design magnetoelectronic materials and devices with improved properties. In this context, biomaterials can be used as a template for the synthesis of the magnetic NPs. As an example, monodisperse Co/Pt magnetic NPs were produced inside the apo-ferritin cavity. These assemblies were subsequently self-organized as a thin-film array on a glass support to yield a magnetic recording media with the potential to support Terabit inch^{-2} recording densities.[286]

Some recent research, however, has been directed to the coupling of functional magnetic particles with biomaterials to yield magnetically controlled functions of the biomaterial–magnetic particle hybrids. The results of these studies are outlined in the following chapters.

7.1. Synthesis of Biomolecule-Functionalized Magnetic Particles

The core of magnetic particles is usually composed of Fe_3O_4 or γ-Fe_2O_3, and its primary modification with an organic shell can include the adsorption of an organic polymer or the covalent attachment of a functionalized organosilane film. Convenient syntheses of magnetic particles with controlled size and magnetization have been developed.[287, 288] The size-controlled synthesis of magnetite (Fe_3O_4) NPs was reported in organic solvents.[289] Gold-coated iron NPs with a specific magnetic moment of 145 emu g^{-1} and a coercivity of 1664 Oe were prepared and tested for biomedical applications.[290] The gold shell allows the further modification of the magnetic NPs with biomolecules by using the self-assembly method. Elsewhere, silica particles that carry encapsulated magnetic NPs were used to bind proteins to the outer sphere of the inorganic beads for biocatalysis.[291]

Organic functional groups introduced by these techniques allow the coupling of biomolecules to the organic shell.[292] Several synthetic approaches to couple biomolecules to magnetic particles and to use the hybrid assemblies for various bioanalytical applications have been reported. The preparation and characterization of magnetic NPs that are coated by organic shells for the covalent immobilization of enzymes (e.g. HRP or lipase) was described recently.[293] The

immobilization of enzymes on magnetic particles yields biocatalytically active particles. In one example, alcohol dehydrogenase was covalently bound to Fe_3O_4 magnetic particles, and the immobilized enzyme demonstrated high biocatalytic activity.[294] Enzyme-modified magnetic particles could also demonstrate bioelectrocatalytic activities while being in contact with an electrode surface.[293d] The reversible association of proteins with negatively charged polyacrylic$_{shell}$/Fe_3O_{4core} magnetic particles was demonstrated.[295] The binding of proteins was controlled by electrostatic interactions between the proteins and the negatively charged shells. The protein molecules, which were positively charged at low pH values (pH < pI; pI = isoelectric point), were electrostatically attracted to the negatively charged shells, whereas at higher pH values (pH > pI), the negatively charged protein molecules were repelled from the functionalized magnetic particles. The reversible association/dissociation of the proteins to and from the magnetic particles, respectively, was used to collect, purify, and transport proteins. DNA molecules were treated with a mixture of Fe^{2+}/Fe^{3+} ions, which were electrostatically associated with DNA chains.[296] The Fe^{2+}/Fe^{3+} ions were then reacted to give Fe_3O_4 magnetic particles associated with the DNA molecules. The labeled DNA could hybridize with complementary oligonucleotides, and the magnetic particles linked to the DNA molecules allowed the separation of the labeled DNA from nonlabeled strands.

The cooperative assembly of magnetic NPs in the presence of amino acid based polymers was studied, and it was demonstrated that electrostatic interactions between block copolypeptides and NPs could control the organization of these components.[297] The presence of polyaspartic acid initiated the aggregation of maghemite NPs into clusters without the formation of a precipitate. The addition of the block copolypeptide poly(EG$_2$-Lys)$_{100}$-b-poly(Asp)$_{30}$ induced a controlled organization of the magnetic NPs (possibly through the formation of micelles) with cores that consisted of the NPs electrostatically bound to the polyaspartic acid end of the block copolypeptide. In this case, the poly(EG$_2$-Lys) ends of the copolymers formed the micelle shell, and the micelles both stabilized the clusters and controlled their size. By altering the composition of the block copolypeptide, it should be possible to control both the size and the stability of the resulting dispersed NP clusters to thereby greatly expand the potential applications and usefulness of these cooperatively assembled nanocomposite materials.

Inorganic nano- and microsized particles including magnetic particles could be generated by biochemical means. The field of biomineralization has highlighted the possibility to synthesize materials based on the molecular interactions between supramolecular organic or bioorganic assemblies and inorganic materials.[21a,298] Protein cages,[299] and particularly viral protein cages,[299d–f] provide structurally constrained reaction nanoenvironments that act as templates for the generation of inorganic nanomaterials. Viral protein cages exist in a wide variety of sizes and shapes and have structural transitions that allow controlled access to the interior of the protein cage.[299f] Genetic and chemical modifications of protein templates provide a further flexibility to the syntheses of nanomaterials.[299g] The natural

protein ferritin provides a structurally constrained reaction medium for the syntheses of both natural and synthetic inorganic nanomaterials.[129, 299a–c, 300] In particular, ferritin can be used to generate precisely sized and shaped magnetic particles in the protein cavity.[301] For this purpose, the nonmagnetic natural core that was composed of $5Fe_2O_3 \cdot 9H_2O$ was chemically removed from the protein cavity, and an artificial magnetic core that was composed of magnetite (Fe_3O_4)[129c] or magnetite/maghemite $(Fe_3O_4/\gamma\text{-}Fe_2O_3)$[302] was generated inside apo-ferritin. The direct electrochemistry of ferritin adsorbed on an ITO electrode was studied.[303] It was shown that the iron-oxide core of ferritin is electrically contacted with the electrode and its reductive dissolution yielded the apo-ferritin. Genetic engineering was employed to tune the size of the cavity to provide monodisperse ferric oxide magnetic NPs of variable size.[304]

The unusual ferritin-like protein from the bacteria *Listeria innocua* has been shown to form a twelve-subunit cage structure around a 5-nm-diameter interior cavity.[305] This small cage structure has the capacity to hold only 500 Fe atoms in the form of a ferric oxyhydroxide NP.[306] This cage provides a new size regime and holds promise for tuning size-dependent material properties. The natural protein shell that surrounds the NPs provides binding groups for the covalent attachment of biomolecules. The well-characterized cowpea chlorotic mottle virus (CCMV), which is devoid of nucleic acid, was used as the starting material to create a new cage with specific chemical functionality that mimics the iron-storage protein ferritin.[307] The CCMV protein cages are composed of 180 identical 20-kDa subunits that self-assemble into an empty virion that has icosahedral symmetry (Figure 37 A). Structural analysis indicated that the viral protein cage should allow access to small molecules through pores that are created at the interfaces of the protein subunits. This empty protein cage has an outer diameter of 28 nm and an inner diameter ranging from 18–24 nm (Figure 37 B). Thus, CCMV has a cavity of approximately twice the diameter of ferritin. The CCMV coat protein was genetically modified by replacing 9 basic residues at the N terminus with glutamic acid. The mutant assembled readily into a cagelike architecture similar to the wild-type protein. This electrostatically altered viral protein cage catalyzed the rapid oxidation of Fe^{2+} which led to the formation of a spatially constrained iron oxide NP, 24.0 ± 3.5 nm, within the cage.
Figure 37. A) Ribbon diagram of the 180-subunit protein cage of the cowpea chlorotic mottle virus (CCMV). B) Cut-away view that shows the central cavity of the protein cage. (Adapted from Ref. [307], with permission).

Biomineralization which is performed by many microorganisms yields various micro- and nanostructured magnetic materials that are included into biological structures.[308] For example, some bacteria (e.g. *Magnetospirillum magnetotacticum* MS-1,[309] *Magnetospirillum* sp. MGT-1,[310] *Magnetospirillum* sp. AMB-1,[311] and *Magnetospirillum gryphiswaldense*[312]) produce natural magnetic particles $(Fe_3O_4, 50–100$ μm in size$)$ that are aligned in chains and enveloped by a lipid membrane.[313] These naturally produced lipid-coated magnetic particles could be isolated from the parent bacteria[314] and modified with biomolecules by the use of bifunctional coupling reagents (e.g. glutaric dialdehyde). These magnetic particles have been applied as active components in fluoroimmunoassays,[315] chemiluminescence immunoassays,[316] mRNA recovery,[317] and as DNA carriers.[318]

7.2. Antigen- or Antibody-Functionalized Magnetic Particles Applied as Immunosensors

Magnetic particles functionalized with antigens or antibodies have been applied in various immunoassay schemes.[319] In most of these applications, the functionalized magnetic particles were used for the isolation and concentration of the sensing materials as well as for the exchange of the sensing interface at the end of the analysis. As an example, magnetic NPs were functionalized with antigens or antibodies and these were then attracted to a quartz crystal microbalance by the use of an external magnet and used for immonosensing.[319a] The method allowed the rapid regeneration of the sensing interface by simple exchange of the modified magnetic particles. In another application, Au NPs were coated with dinitrophenyl-functionalized mercaptodextrans, which bind specifically to magnetic beads that are modified with the corresponding DNP-antibody.[320] The hybrid system allowed the spectral detection of immunorecognition reactions by following the absorbance spectra of the Au NP labels. The magnetic beads provided an easy means of purification and concentration of the analyte samples. Magnetic particles with an encoding symbol introduced by functionalization were applied to a parallel multianalyte immunoassay that used a self-assembled addressable microparticle array on a chip.[321]

The intrinsic magnetic properties of the particles were also used as a means of detection in biosensing. For example, adenovirus (ADV) species were cross-linked by anti-ADV-functionalized magnetic NPs to yield an aggregated system.[322] The formation of the ADV–magnetic NP assembly was detected by measurement of the changes of the T_2 relaxation times of water. The method allowed the detection of as few as five viral particles in 10μL of 25% protein solution.

7.3. DNA Analysis by Oligonucleotide-Functionalized Magnetic Particles

The separation and purification steps that are performed prior to the electrochemical analysis of DNA were simplified

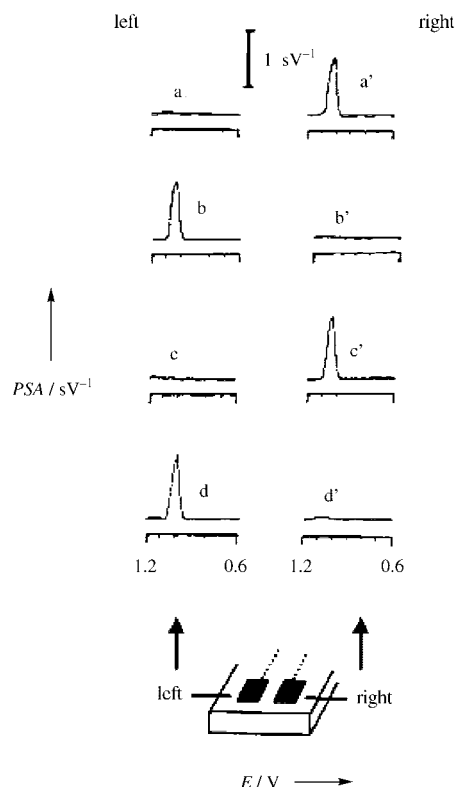
by the attachment of the DNA analyte to magnetic particles.[323] The reversible, magnetically controlled oxidation of DNA was accomplished in the presence of nucleic acid-modified magnetic particles.[324] Avidin-modified magnetic particles were functionalized with the biotinylated probe nucleic acid, and these were subsequently hybridized with the complementary DNA. Two carbon-paste electrodes were patterned on a surface and applied as working electrodes. Spatial deposition of the functionalized magnetic particles on the left or right electrode enabled the magneto-controlled oxidation of the DNA by chronopotentiometric experiments (potential pulse from 0.6 to 1.2 V; Figure 38). Changing the


Figure 38. Chronopotentiometric (PSA = potentiometric stripping analysis) signals for the DNA-oligomer-functionalized magnetic particles by the dual carbon-paste electrode assembly: a–d) Potentiograms obtained at the left electrode; a′–d′) Potentiograms obtained at the right electrode. [324], with permission).

position of the magnet (to below the planar printed electrodes) allowed "ON" and "OFF" switching of the oxidation of the DNA (through attraction and removal of DNA-functionalized magnetic particles). Such magnetic triggering of the DNA oxidation holds great promise for the analysis of DNA on arrays.

Several protocols for the detection of DNA have combined the inherent signal amplification of stripping analysis with an effective discrimination against nonhybridized

DNA.[215,239a] Besides the efficient isolation of the duplex, magnetic spheres can open the door to elegant ways to trigger and control electrical DNA detection.[324,325] An interesting magnetic triggering of the electrical DNA detection was demonstrated by the "magnetic" collection of the magnetic bead–DNA hybrid metal tracer assembly onto a thick-film electrode transducer that allowed the direct electrical contact of the silver precipitate.[325] By this approach, a biotinylated nucleic acid is linked to avidin-modified magnetic particles that act as the capturing particles. Hybridization of the analyzed DNA with the capturing nucleic acid is followed by the secondary association of metal or semiconductor NPs, which are functionalized with a nucleic acid that is complementary to a free segment of the analyzed DNA. The binding of the NP labels to the biorecognition assay provides amplifying cluster tags that enable the release of numerous ions upon dissolution. Furthermore, the metal NPs associated with the sensing interface may act as catalytic sites for the electroless deposition of other metals. This leads to the amplified detection of DNA by the intermediary accumulation of metals that are stripped off or by the generation of an enhanced amount of dissolved product that can be electrochemically analyzed.[223,326]

Figure 39 A depicts the amplified detection of DNA by the application of nucleic acid functionalized magnetic beads and Au NPs as catalytic seeds for the deposition of silver.[325] A biotin-labeled nucleic acid, **91**, was immobilized on avidin-functionalized magnetic particles, and these conjugations were then hybridized with the complementary biotinylated nucleic acid **92**. The hybridized assembly was then treated with a Au NP–avidin conjugate. The magnetic separation of the particles by an external magnet concentrated the hybridized assembly from the analyzed sample. Treatment of the magnetic particles–DNA–Au NP conjugate with silver ions (Ag^+) in the presence of hydroquinone resulted in the electroless catalytic deposition of silver on the Au NPs, with the latter acting as the catalyst. The deposition process provided amplification because the catalytic accumulation of silver on the Au NPs originated from a single DNA-recognition event. The current which resulted from the accumulated silver being stripped off then provided the electronic signal for the detection of the target DNA.

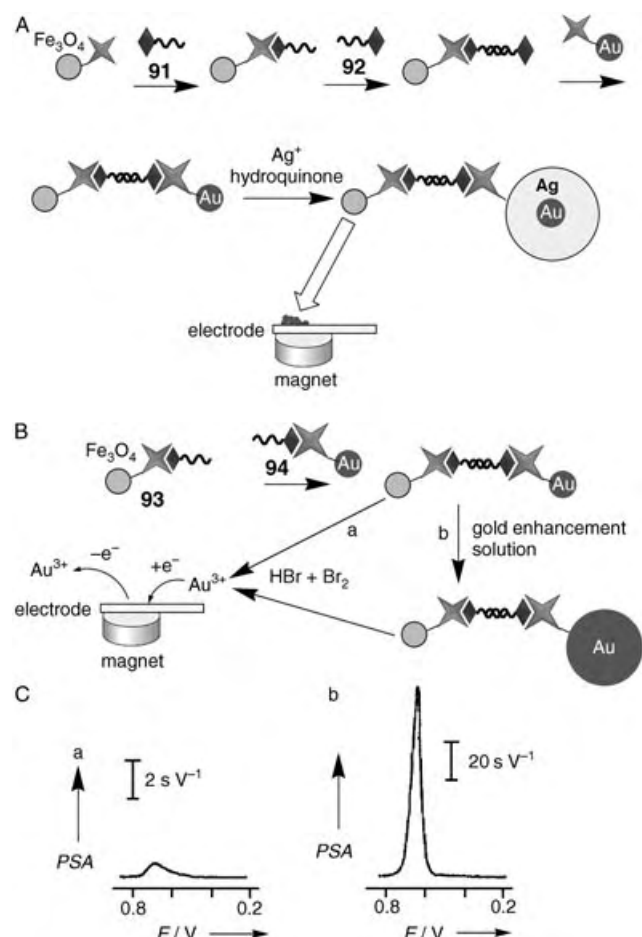
In a related system (Figure 39 B),[215] DNA was electrochemically detected by the use of Au NPs as electroactive and catalytic tags. The primer biotinylated nucleic acid **93** was linked to magnetic beads through an avidin bridge, and the conjugate was hybridized with the nucleic acid **94** functionalized with Au NPs. The hybridization was detected after the dissolution of the Au NPs in a solution of HBr/Br$_2$, followed by the electrochemical reduction of the generated Au^{3+} ions onto the electrode, and the subsequent electrochemical "stripping" of the surface-generated gold (Figure 39 B, route a). This analytical procedure was further amplified by the intermediary deposition of gold on the Au NPs (Figure 39 B, route b). The higher gold content after the catalytic deposition led to a higher chronopotentiometric signal. Figure 39 C, a and b, respectively, show the potentiograms that correspond to route a) the stripping of the gold generated on the electrode upon the analysis of the nucleic acid that is


Figure 39. Electrochemical analysis of DNA upon the assembly of DNA molecules at magnetic particles followed by their association with Au NPs. A) Au NPs are used for the deposition of silver, and the DNA analysis is performed by the electrochemical stripping of Ag. B) The Au NPs are chemically dissolved, then the resulting Au^{3+} ions are electrochemically reduced, and the deposited gold is electrochemically stripped (path a); The intermediate enlargement of the Au NPs results in the further amplification of the signal (path b). C) The effect of gold enhancement upon the stripping response for the DNA analyte: PSA signals prior to treatment of the system with gold enhancement solution (a) and after 10 minutes of reaction (b). samples provided convenient analytical schemes for complicated purposes. Single nucleotide polymorphism genotyping of the aldehyde dehydrogenase 2 gene was studied by using a single bacterial magnetic particle.[328]

7.4. Application of Redox-Functionalized Magnetic Particles for the Triggering and Enhancement of Electrocatalytic and Bioelectrocatalytic Processes

Micro- and nanosized magnetic particles that are functionalized with redox-active units were used to control biocatalytic reactions that are particularly important for bioelectroanalysis. A series of electroactive relay units, which consist of 2,3-dichloro-1,4-naphthoquinone (**95**), *N*-(ferrocenylmethyl)aminohexanoic acid (**96**), *N*-methyl-*N'*-(dodecanoic acid)-4,4'-bipyridinium (**97**), pyrroloquinoline quinone (PQQ, **98**), or microperoxidase-11 (MP-11, **99**), were covalently linked to magnetite (Fe_3O_4) particles (Figure 40).[329,330] The electrochemical activities of the func-

associated with 5-nm Au NPs, and route b) after the deposition of gold on the Au NPs for 10 minutes.

It is also possible to use the magnetic beads as reporters (tags) in association with stripping voltammetry measurements of the iron content for the detection of DNA hybridization.[327] A related protocol, which was developed in the same study, involved probes that were labeled with gold-coated iron core/shell NPs. In both cases, the captured iron-containing particles were dissolved after hybridization, and the released iron was quantified by cathodic stripping voltammetry in the presence of a 1-nitroso-2-naphthol ligand and a bromate catalyst. The application of functionalized magnetic particles as carriers for DNA

tional magnetic particles were triggered by means of an external magnet as schematically outlined in Figure 41 A. Attraction of the magnetic particles to the electrode surface by means of the external magnet activates the electrical contact between the redox units, R, and the electrode that switches on the redox features of the redox components. Positioning of the magnet above the electrochemical cell retracts the magnetic particles from the electrode, and the electrochemical activity of the functional magnetic particles is switched off. Figure 41 B exemplifies the reversible activation and deactivation of the redox features of magnetic particles that are functionalized with the ferrocene derivative **96** ($E^0 = 0.32$ V vs SCE), upon the attraction of the magnetic particles to the electrode support or their retraction from the electrode surface, respectively, by means of the external magnetic field. Similarly, reversible "ON" and "OFF" switching was observed for the electrochemical response of magnetic particles that were functionalized with aminonaphthoquinone (**100**, $E^0 = -0.39$ V vs SCE at pH 7.0).

The electrochemical activation of redox units that are associated with magnetic particles enables the secondary magneto-controlled switchable activation and deactivation of bioelectrocatalytic processes. PQQ (**98**; $E^0 = -0.16$ V at pH 8.0 vs SCE) acts as an electrocatalyst in the oxidation of 1,4-dihydro-β-nicotinamide adenine dinucleotide (NADH).[331] Accordingly, the magnetic particles funtionalized with **98** (average surface coverage of 7.5×10^3 PQQ units per particle) were employed to control the electrocatalyzed oxidation of NADH by means of an external magnet.[329b] In a similar way, magnetic particles functionalized with microperoxidase-11, **99**, were employed for the magnetically switched electrocatalytic reduction of hydrogen peroxide.[329b]

Electron-relay units act as electron-transfer mediators that electrically communicate the active sites of redox enzymes with electrode supports. Ferrocene or bipyridinium redox-relay units were reported to electrically contact oxidative redox enzymes, such as glucose oxidase, or reductive biocatalysts, such as nitrate reductase, respectively.[195] The

A) Switching "ON" and "OFF" the electrochemical reaction of the redox-relay groups (R) that are covalently bound to the magnetic particles and the electrocatalytic function that is provided by the redox groups. B) Differential pulse voltammograms of a Au electrode in the presence of the ferrocene (**96**)-functionalized magnetic particles. The particles are magnetically attracted to (a) or retracted from (b) the electrode surface. Inset: Reversible changes of the peak current upon magnetic activation (□) and deactivation (●) of the electrochemical process. C) Switching "ON" and "OFF" either the bioelectrocatalytic oxidation of glucose in the presence of glucose oxidase (GOx) and ferrocene (**96**)-functionalized magnetic particles or the oxidation of lactate in the presence of lactate dehydrogenase (LDH) and PQQ-NAD⁺-functionalized magnetic particles. D) Cyclic voltammograms at a Au electrode in the presence of ferrocene (**96**)-functionalized magnetic particles (10 mg), glucose (10 mM), and GOx (1 mg mL⁻¹). The redox functions of the particles are switched "ON" by their attraction to the electrode (a) and "OFF" by their retraction from the electrode (b). Inset: Reversible changes of the electrocatalytic current (measured at $E = 0.45$ V vs SCE) upon attraction (□) or retraction (●) of the magnetic particles to/from the electrode. (Adapted from Ref. [329b], with permission).

activation of the redox functionalities of the relay-modified magnetic particles enabled the subsequent switchable activation and deactivation of enzyme bioelectrocatalytic transformations by means of an external magnet.[329] Figure 41 C shows the schematic magnetoswitchable activation of redox enzymes in the presence of electron-relay-functionalized magnetic particles, such as the bioelectrocatalyzed oxidation of glucose by glucose oxidase in the presence of ferrocene (**96**)-functionalized magnetic particles. The magnetic attraction of the ferrocene-functionalized magnetic particles to the electrode results in the oxidation of the ferrocene units to ferrocenyl cations. The ferrocenyl cation relay units oxidize the redox center of glucose oxidase and activate the bioelectrocatalyzed oxidation of glucose. Figure 41 D shows the magnetic activation of the bioelectrocatalyzed oxidation of glucose which is reflected by the electrocatalytic anodic current upon attraction of the functional magnetic particles to the electrode. Retraction of the magnetic particles from the electrode support by means of an external magnet blocks the electrical communication between the electrode and the ferrocene units which inhibits the secondary bioelectrocatalyzed oxidation of glucose. The reversible attraction and removal of the magnetic particles to and from the electrode, respectively, allowed cyclic "ON" and "OFF" activation and deactivation of the bioelectrocatalytic process.

A similar approach was applied to the magnetic switching of the bioelectrocatalyzed reduction of nitrate to nitrite by using nitrate reductase as a biocatalyst and magnetic particles that were functionalized with bipyridinium **97** ($E^0 = -0.57$ V vs SCE) as mediator units.[329b] Upon attraction of the **97**-functionalized magnetic particles to the electrode and application of a potential of $E = -0.7$ V to the electrode, the bipyridinium radical-cation-mediated bioelectrocatalyzed reduction of nitrate to nitrite occurred at a rate of 6.5×10^{-3} mM min^{-1}, whereas retraction of the particles from the electrode by positioning the magnet above the electrochemical cell blocked the bioelectrocatalytic process. By switching the position of the external magnet from below to above the electrode surface, the electrocatalyzed reduction of NO_3^- was reversibly switched between "ON" and "OFF" states, respectively.

Functional magnetic particles were also employed for the cyclic activation and deactivation of NAD$^+$-dependent enzymes by means of an external magnet. It was reported that a covalently linked monolayer of pyrroloquinoline quinone (PQQ)–NAD$^+$ units associated with an electrode provides an active interface for the activation of NAD$^+$-dependent enzymes such as lactate dehydrogenase.[332] The biocatalyzed oxidation of the substrate yields NADH, which is oxidized to NAD$^+$ by PQQ. The resulting PQQH$_2$ is electrooxidized to PQQ, which thus stimulates the electrochemically driven biocatalyzed oxidation of the substrate (e.g. lactate). As an example, PQQ (**98**)-functionalized magnetic particles were treated with N^6-(2-aminoethyl)-β-nicotinamide dinucleotide (**101**)[333] to yield PQQ–NAD$^+$-modified particles (Figure 40 C).[329b] The resulting particles were then applied to the magnetoswitching of the bioelectrocatalytic functions of the NAD$^+$-dependent enzyme lactate dehydrogenase (LDH) by means of an external magnet Figure 41 C.

Attraction of the PQQ–NAD$^+$-functionalized magnetic particles to the electrode in the presence of lactate dehydrogenase (LDH) activated the bioelectrocatalyzed oxidation of lactate to pyruvate. The biocatalyzed reduction of the NAD$^+$ cofactor unit by lactate was followed by the oxidation of the resulting NADH by the PQQ electrocatalyst. An appropriate potential ($E = 0.05$ V vs SCE) was then applied to oxidize the resulting PQQH$_2$ and to regenerate the electrocatalyst. This enabled the continuous bioelectrocatalyzed oxidation of lactate to pyruvate in the presence of LDH. The electrocatalytic anodic current developed by the system increased as the lactate concentration was elevated, and it leveled off to a saturation value of the current density of $i_{max} = 1.8$ μA cm^{-2} at a lactate concentration of 50 mM. Analysis of the electrocatalyzed oxidation of lactate to pyruvate by LDH under steady-state electrolysis indicated that pyruvate is generated at a rate of 0.13 mM min^{-1}. Retraction of the functionalized magnetic particles from the electrode by an external magnet prohibited the bioelectrocatalyzed oxidation of lactate. By the cyclic positioning of an external magnet below and above the cell, the process was reversibly switched between "ON" and "OFF" states, respectively.

The concept of controlling bioelectrocatalytic transformations by an external magnet was utilized to develop selective dual biosensing systems.[334] The specific simultaneous electrochemical sensing of two substrates in an overlapping redox-potential region is a challenging topic in bioelectronics. The bioelectrochemical dual sensing of lactate and glucose in the presence of the two oxidative enzymes, lactate dehydrogenase (LDH) and glucose oxidase (GOx), was performed by using an electrode that was functionalized with a monolayer of ferrocene, NAD$^+$–PQQ-functionalized magnetic particles, and an external magnet. Application of a potential on the electrode ($E > 0.32$ V vs SCE) while retracting the magnetic particles from the electrode resulted in the ferrocene-mediated bioelectrocatalyzed oxidation of glucose, whereas the bioelectrocatalyzed oxidation of lactate was prohibited. Magnetic attraction of the NAD$^+$–PQQ-functionalized magnetic particles to the electrode followed by sweeping the potential on the electrode in the range -0.13 V $< E <$ 0.32 V (vs SCE) allowed the PQQ–NAD$^+$-mediated oxidation of lactate in the presence of the NAD$^+$-dependent lactate dehydrogenase. As the ferrocene units are not oxidized in this potential range, the bioelectrocatalyzed oxidation of glucose was prohibited.

An important advance in the magnetic control of electrocatalytic and bioelectrocatalytic transformations involves the attraction of magnetic particles to an electrode support, followed by the rotation of the magnetic particles on the electrode by means of an external rotating magnet.[335] The rotation of the magnetic particles turns the redox-functionalized magnetic particles into circular-rotating microelectrodes. As a result, redox-activated electrocatalytic or bioelectrocatalytic processes mediated by the functional particles are controlled by convection rather than by the diffusion of the respective substrates onto the microelectrodes. Accordingly, enhanced amperometric responses of the particle-mediated electrocatalytic processes are anticipated, and the resulting currents should be controlled by the rotation speed of the

particles. Figure 42 A depicts schematically the amplified amperometric analysis of glucose by the rotation of magnetic particles, which are functionalized with ferrocene (**96**), on the electrode support. As the interaction of glucose oxidase (GOx) with the electron-transfer mediator, which is associ-

B) Cyclic voltammograms of a Au electrode with the magnetically attracted **96**-functionalized magnetic particles (6 mg) in the presence of GOx (1×10^{-5} M) and glucose (50 mM) and upon rotation of the magnet: a) 0, b) 10, c) 100, and d) 400 rpm (potential scan rate: 5 mVs^{-1}). C) Calibration plots for the amperometric detection of glucose ($E = 0.5$ V vs SCE) upon rotation of the magnet: a) 0, b) 100, and c) 400 rpm. (Adapted from Ref. [335], with permission; Copyright American Chemical Society, 2002).

ated with the rotating magnetic particles, is convection-controlled, the resultant electrocatalytic currents relate to the square root of the rotation speed ($I_{cat} \propto \omega^{1/2}$). Figure 42 B shows the bioelectrocatalytic currents observed in the system at different rotation speeds of the external magnet. Clearly, the amperometric responses increased as the rotation speed was elevated. Figure 42 C shows the amperometric responses of the system at different concentrations of glucose with the rotation of particles at speeds of 400 and 100 rpm (curves c and b, respectively) relative to when the particles are in a steel, nonrotating configuration (curve a). The rotation of the particles (400 rpm) resulted in a ≈ 15-fold increase in the amperometric responses of the bioelectrocatalytic process. The responses of the bioelectrocatalytic transformations were analyzed with the conventional rotating-disc electrode (RDE) theory.[336] Analysis using Levich theory of the experimental currents that were obtained at different rotation

speeds of the redox-functionalized magnetic particles allowed the interfacial electron-transfer rate constant to be estimated.

The enhanced electrocatalysis and bioelectrocatalysis in the presence of rotating magnetic particles can be used to amplify biosensing events. This is schematically depicted in Figure 43 A in which an analyte, **a**, is sensed by magnetic particles functionalized with the complementary unit **b**. Binding of a second recognition element **c** for **a**, which is conjugated to horseradish peroxidase (HRP), yields the biocatalytic sandwich structure for analyzing **a**. The magnetic attraction between a mixture of magnetic particles, which comprises magnetic particles that are functionalized with aminonaphthoquinone (**100**), with the sandwich structure that is generated between the magnetic particles that contain the components **b/a/c**–HRP" enables the amplified detection of the analyte by electrogenerated chemiluminescence. Electroreduction of the aminonaphthoquinone (**100**) units leads to the electrocatalyzed reduction of O_2 to H_2O_2, which, in the presence of luminol (**102**) and HRP, yields the biocatalyzed generation of light. Upon the rotation of the magnetic particles, O_2 and luminol interact with the functionalized magnetic particles by convection which leads to the amplified generation of chemiluminescence (Figure 43 B). The biosensing affinity interactions that occur on the magnetic particles may be antigen–antibody, nucleic acid–DNA, or any other host–guest intermolecular binding process. The amplified detection of immunological interactions, such as the analysis of the dinitrophenyl (DNP) antibody in the presence of magnetic particles that are functionalized with the DNP antigen **103**, and the ultrasensitive detection of DNA have been demonstrated in the presence of rotating functionalized magnetic particles.[337]

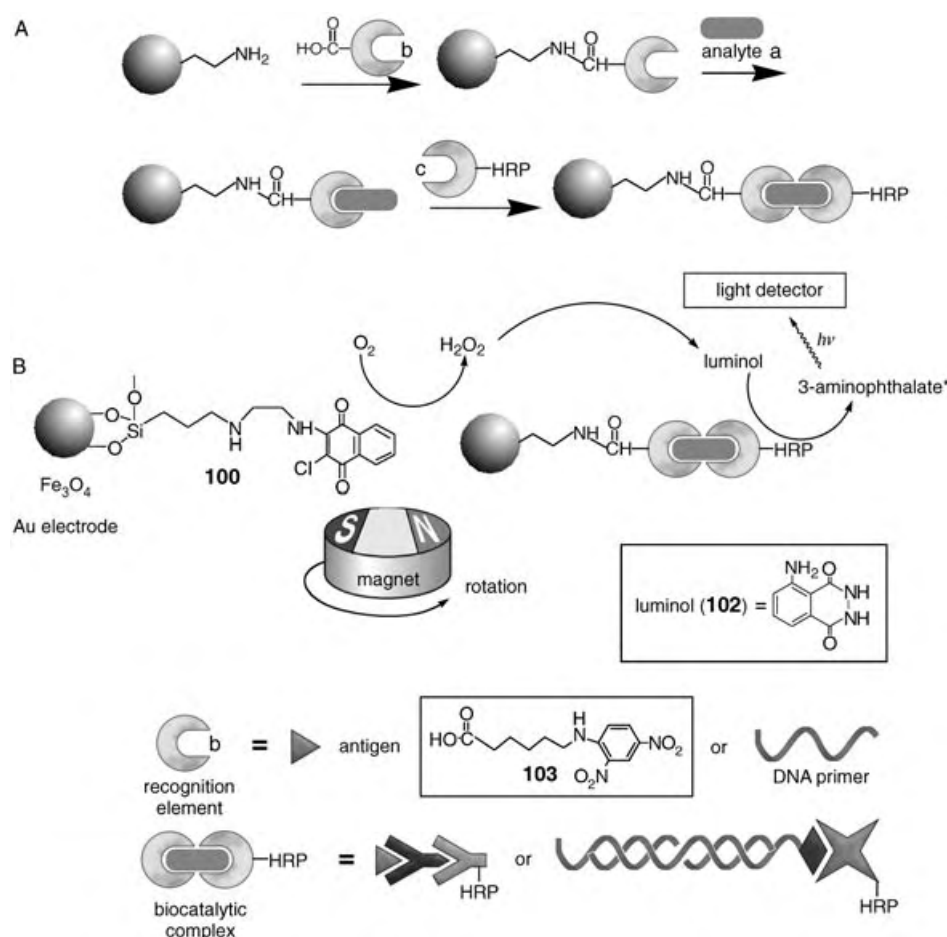
A modified scheme for the amplified detection of viral DNA by functional magnetic particles is exemplified in Figure 44 A with the analysis of the 7249-base M13mp18 DNA.[338] The 27-base DNA primer **104**, which is complementary to a segment of the analyte DNA, was associated with the magnetic particles. The hybridization of **104** with the M13mp18 DNA **105** was followed by a polymerization process in the presence of the dNTP mixture, which included biotin-labeled dUTP (deoxyuridine triphosphate). The replication process introduced biotin labels into the replicated nucleic acid on the magnetic particles. This replication process was followed by a sequence of thermal cycles by which the M13mp18 DNA was dissociated, rehybridized with another primer on the particle, and further replicated to incorporate the biotin labels. The resulting particles were then interacted with the avidin–HRP bioconjugate, and the resulting functionalized magnetic particles were collected by means of an external magnet on the electrode surface and then mixed with the aminonaphthoquinone (**100**)-labeled particles. The electrocatalyzed reduction of O_2 by the quinone units yielded H_2O_2, which, in the presence of luminol and HRP, led to the generation of chemiluminescence. Furthermore, rotation of the magnetic particles led to amplified light emission. Figure 44 B shows the intensity of the emitted light upon the analysis of the M13mp18 DNA (8×10^{-9} M) at different rotation speeds of the particles. With this method, the target DNA was analyzed with a detection limit of 8×10^{-18} M


Figure 43. Amplified detection of bioaffinity recognition processes by multilabeled rotating magnetic particles. A) Synthesis of the functionalized magnetic particles for the biorecognition assay. B) Amplified biorecognition assay upon the rotation of the functionalized magnetic particles. HRP = horseradish peroxidase, * denotes an excited state.

(Figure 44 C). The intensity of the chemiluminescence light, which was generated in the system, correlated linearly with the square root of the rotation speed ($\omega^{1/2}$) and is consistent with the fact that the luminescence intensity was controlled by the convection of the substrates to the rotating particles. A similar approach has been applied to detect single-base mismatches in DNA[338] and to follow telomerase activity in cancer cells.[339]

7.5. Magnetomechanical Detection of Biorecognition Events

The possibility of chemically modifying cantilevers and optically monitoring their nanometric deflections render these microelements ideal mechanical sensors.[340] Indeed, stress interactions that occur on the surface of the cantilevers were reported to induce their mechanical deflection. For instance, a thin polyaniline film associated with a lever was reported to act as a reversible electrochemically driven mechanical device.[341] Oxidation of the polymer film led to the electrostatic repulsion of the polymer chains which resulted in stress on the cantilever and its deflection. The

reduction of the oxidized polymer removed the surface stress, and the lever was retracted to its original position. Biorecognition events such as antibody–antigen[342] or nucleic acid–DNA[343] binding processes were similarly reported to stimulate the mechanical deflection of cantilevers. The electrostatic repulsions between surface-hybridized DNA were reported to induce a surface stress that resulted in the mechanical deflection of the lever.[343] The use of a cantilever array for the parallel micromechanical detection of different target DNAs or different mutants was also suggested. The force exerted on a lever that is modified with magnetic particles and subjected to an external magnetic field could drive the deflection of the cantilever. Indeed, upon mounting magnetic particles on a cantilever, a highly sensitive magnetic-field sensor was developed.[342] The deflection of the cantilever could monitor changes in the magnetic field as low as 10 nT. The extensive use of magnetic particles as supports for biosensing processes[344] suggests that the amplified magnetomechanical detection of biorecognition processes is feasible.

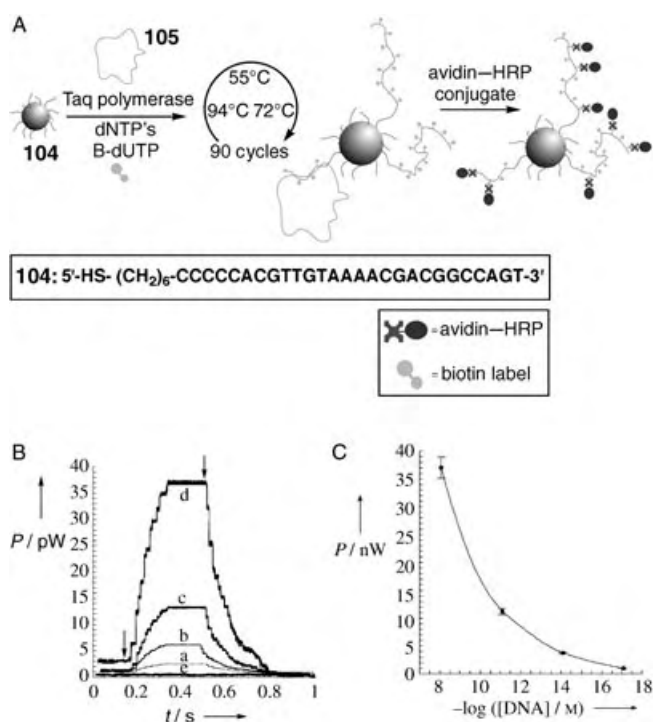
The ultrasensitive magnetomechanical detection of DNA and single-base-mismatches in nucleic acids and the assay of telomerase activity were performed by monitoring the magnetically induced deflection of a cantilever, which was functionalized with magnetic beads that were associated with the biosensing interfaces.[345] The analyzed M13mp18 DNA was hybridized with nucleic acid functionalized magnetic beads and then subsequently replicated in a similar process to that shown in Figure 44 A in the presence of dNTPs (including biotin-labeled dUTP, B-dUTP). The DNA primer-functionalized magnetic particles were interacted with the M13mp18 DNA and subjected to 90 cycles of replication with the incorporation of biotin labels. By this, the particles were hybridized with M13mp18 DNA, which was then replicated in the presence of Taq polymerase and the dNTPs mixture and then melted to dissociate the double-stranded DNA assembly before repeating the cycle (90 times). This procedure resulted in a linear amplification of the biotin-labeled chains that were associated with the magnetic particles. The resulting beads were then attached to an avidin-coated cantilever, and the modified cantilever was deflected by an external magnetic field (Figure 45 A). Figure 45 B shows the reversible magne-


Figure 44. A) Labeling of the nucleic acid replica with biotin units by thermal cycles for the amplified detection of viral DNA by multilabeled rotating magnetic particles. B) Chemiluminescence intensities upon the analysis of M13mp18 DNA (8×10^{-9} M) at different rotation speeds: a) 0, b) 60, c) 400, and d) 2000 rpm.; e) Chemiluminescence signal observed by applying the protocol in the absence of M13mp18 DNA and with a rotation speed of 2000 rpm. C) Calibration curve for the chemiluminescence intensities upon the analysis of different concentrations of M13mp18 DNA at 2000 rpm. In all experiments, the chemiluminescence was generated by the application of a potential step from $E = 0.0$ V to -0.5 V and back under air. Arrows indicate the times for switching the potential to -0.5 V and to 0.0 V. (Parts B and C are adapted from Ref. [338], with permission).

Figure 45. A) Schematic configuration of the instrumental setup and concept for the magnetomechanical analysis of biorecognition processes on functionalized cantilevers (X = deflectance). B) Magnetomechanical deflection or retraction of the cantilever in the analysis of M13mp18 DNA (7.1×10^{-12} M) by using Taq polymerase and thermal cycles for replication and labeling processes. a) The cantilever is subjected to the external magnet; b) The external magnet is removed. C) Dependence of the deflection signal on the concentration of the M13mp18 DNA. (Adapted from Ref. [345], with permission; Copyright American Chemical Society, 2004).

tomechanical deflection and retraction of the avidin-modified cantilever, which was interacted with the preamplified biotin-labeled magnetic particles. Placement of the external magnet below the lever led to the attraction of the lever to the magnet and resulted in its mechanical deflection, whereas the removal of the external magnet retracted the lever to its original position. The extent of the magneto-induced deflection of the cantilever depended on the amount of the functionalized magnetic particles bound to its surface which, in turn, was dependent on the concentration of the analyzed M13mp18 DNA. Thus, this allowed the magnetomechanical biosensing of DNA with a sensitivity limit of 7.1×10^{-20} M (Figure 45 C).

Similarly, a magnetomechanical process for the detection of single-base mismatches in nucleic acids was developed.[345] The concept was also applied to the magnetomechanical detection of telomerase activity that originates from cancer cells.[345] A nucleic acid primer that is recognized by telomerase was linked to the magnetic particles, and the telomerization of the primer was performed in the presence of the HeLa-cell extract and the dNTPs mixture, which included the biotin-

labeled dUTP. The process led to the incorporation of the biotin labels into the telomers and the association of the resulting magnetic particles to the avidin-modified cantilever. This enabled the magnetomechanical detection of the telomerase activity. The telomerase activity that originates from approximately 100 cancer cells could be detected by this method.

8. Biomolecule-Based Nanocircuitry

The miniaturization of objects by lithographic methods has reached its theoretical limits, and it is generally accepted that the development of different miniaturization methodologies is necessary to overcome this barrier. Whereas lithographic methods use a "top–down" miniaturization of

patterns, the alternative approach of the "bottom–up" construction of objects has been suggested as a means to overcome the limitations of lithography. That is, the construction of objects at the molecular or supramolecular level could be used to generate templates or "seeds" for nanometer-size features. Nanowires are considered as building blocks for the self-assembly of logic and memory circuits in future nanoelectronic devices.[346] Thus, the development of methods to assemble metal or semiconductor nanowires is a basic prerequisite for the construction of nanocircuits and nanodevices. Furthermore, the nanowires should include functional sites that allow their incorporation into structures of higher complexity and hierarchical functionality. The use of biomaterials as templates for the generation of nanowires and nanocircuitry is particularly attractive. Besides the ingenious structures that Mother Nature provides us which may act as templates for the generation of nanoobjects, the unique recognition features of biomaterials may act as driving forces for self-assembly and for the generation of complex functional structures.

Biological templates such as DNA,[182,225,347] viruses,[299d,e,348] antibodies,[38] S-layers (surface layers),[112,349] protein cages,[130] bacterial rhapidosomes,[350] and microtubules[351] have been used to direct the nucleation, deposition, and assembly of inorganic micro- and nanostructures. Besides microtubules, a variety of other polymorphic tubulin assemblies such as sheets, macrotubules, and S-ribbons are also known.[352]

Biomolecules exhibit dimensions that are comparable to those of the envisaged nanoobjects. Besides the fascinating structures of biomaterials that may lead to new inorganic or organic materials, templates of biological origin may act as "factories" for the production of "molds" for nanotechnology. The proliferation of cells, the replication of DNA, the synthesis of proteins, and the association of protein monomers into sheets, tubules, or ribbons all represent biological processes for the high-throughput synthesis of potential biomaterial templates for nanotechnology. The further application of genetic engineering to manipulate proteins and the application of chemical methods to synthesize new de novo proteins, modify proteins by synthetic amino acids, or modify DNA by synthetic nucleotides provides us with a flexible arsenal of means to tailor the templates for the desired nanostructures. Although this topic is in its infancy, it attracts substantial research efforts, and the already visible results promise exciting future developments.

8.1. Protein-Based Nanocircuitry

Natural protein structures such as microtubules[351] were applied as templates for the deposition of metal nanoparticles. Microtubules are cylindrical proteins that consist of characteristically arranged αβ-heterodimeric tubulin subunits. The length of the tubulin dimer is about 8 nm and its diameter is 4–5 nm. Depending on the conditions of the in vitro assembly, thirteen or fourteen protofilaments are aligned in an almost parallel configuration to form hollow cylinders, which exhibit outer diameters of 25 nm and lengths of several micrometers.

These assemblies were used as biotemplates for the generation of metal nanowires by the deposition and catalytic enlargement of NPs (Figure 46).[353]
Figure 46. TEM image which shows the quasi-continuous coverage of a microtubule surface with Pt NP aggregates. (Adapted from Ref. [353], with permission).

Many proteins comprise well-defined channels or cavities (e.g. ferritin)[128] or are organized in the form of pore-containing layers on surfaces (e.g. S-layers).[354] These channel- or pore-containing materials may act as templates for the generation of nanostructures, nanorods, and even circuitry. Ferritin, for example, consists of a hollow polypeptide shell that is 8 and 12 nm in its internal and external diameters, respectively, and a 5-nm-diameter ferric oxide ($5Fe_2O_3 \cdot 9H_2O$) core.[128] After the reduction of the ferric oxide core, the reduced material can be washed away from the protein and the apo-ferritin channel can be remineralized with different inorganic oxides, sulfides, or selenides that form nanorods (e.g. MnO, FeS, CdS, or CdSe).[129,130]

Aromatic short-chain peptides, such as Alzheimer's diphenylalanine β-amyloid (**106**), form well-ordered nanotubes that have been used as templates for growing Ag nanowires (Figure 47A).[355] The peptide nanotubes were loaded with Ag^+ ions, which were reduced with citrate to yield metallic silver nanowires inside the peptide nanotubes (Figure 47B). The peptide coating was then removed by enzymatic degradation in the presence of proteinase K to yield micrometer-long Ag nanowires with a diameter of ≈ 20 nm (Figure 47C). Upon the application of D-phenylalanine-based peptide fibrils, which are resistant to proteinase K, the peptide coating of the Ag nanowires was preserved. Various kinds of biomaterial nanotubes have been applied to generate metallic nanowires that are protected by a biomolecule "skin". For example, Au NPs of 3–10-nm width were organized in a glycolipid hollow cylinder nanotube by filling the internal channel of the lipid nanotube with an aqueous solution of $HAuCl_4$ by capillary force and subsequently photochemically reducing the $[AuCl_4]^-$ to give metal–lipid nanotube wires.[356]

Crystalline bacterial-cell surface layers (S-layers)[354] have exhibited a broad potential for applications owing to the following features: 1) Pores passing through S-layers show identical size and morphology and are in the range of

[354c]; part B is adapted from Ref. [354e], with permission).

ultrafiltration membranes. 2) Functional groups on the surface and in the pores are aligned in well-defined positions and orientations and are accessible for chemical modifications and binding of functional molecules in a very precise fashion. 3) Isolated S-layer subunits from a variety of organisms are capable of recrystallizing as closed monolayers onto solid supports such as metals, polymers, and silicon wafers. 4) Functional domains can be incorporated in S-layers proteins by genetic engineering. Thus, S-layer technologies particularly provide new approaches for biotechnology, biomimetics, molecular nanotechnology, the nanopatterning of surfaces, and the formation of ordered arrays of metal clusters or NPs as required for nanoelectronics. S-layers have been patterned by deep ultraviolet radiation or by the application of a soft lithography technique:[357] micromolding in capillaries (MIMIC; Figure 48 A).[354c] The patterned S-layers were used as matrices for the immobilization of functional biomaterials or as templates for the formation of ordered arrays of NPs that are important for nanoelectronics and nonlinear optics. Monodisperse gold particles, 4–5 nm, were formed in the pore region of the S-layer, and the interparticle spacing of the gold superlattice resembled the S-layer lattice (Figure 48 B). MIMIC technology was applied to pattern the S-layers to produce nanocircuits of high complexity. Following recrystallization of the S-layer and removal of the mold, human IgG was covalently attached to active carboxylate groups on the S-layer track surface. Subsequent binding of fluorescein isothiocyanate-labeled anti-human IgG enabled fluorescence imaging of the pattern that was produced by the modified S-layer (Figure 48 C).

Alternatively, metallization could be performed on the exterior sides of peptide-based templates.[358] Bis(*N*-α-amido-

glycylglycine)-1,7-heptane dicarboxylate molecular units were self-assembled into nanotube templates through intermolecular hydrogen bonds between the amide and carboxylic acid groups.[359] The sequenced histidine-rich peptide **107** was then assembled on the nanotubes, where it selectively trapped Au ions (chlorotrimethylphosphinegold salt, ClAuPMe₃; Figure 49 A).[358a,b] After the Au ions were reduced, highly monodisperse Au nanocrystals were grown on the nanotubes. The conformations and the charge distributions of the histidine-rich peptide were determined by pH measurements, and the concentration of the Au ions in the growth solution was responsible for the size and the packing density of the Au nanocrystals. The diameter of the Au nanocrystals was limited by the spacing between the neighboring histidine-rich peptides on the nanotubes. This simple metal–nanotube fabrication by the biomineralization method could be applied to various metals and semiconductors by using peptides with sequence-specific groups for the association of metal ions.

Similarly, a histidine-rich epitope (HRE) AHHAH-HAAD from HRP II was used as a peptide that was suitable to mediate the synthesis of a variety of metal sulfide, metal oxide, and zerovalent metal clusters in aqueous solutions.[360] Screening of the resulting clusters against a monoclonal antibody for HRP II revealed molecular recognition of the ligand epitope along the nanocluster surfaces by some of the peptide-encapsulated nanoclusters. The peptide, Asn-Pro-Ser-Ser-Leu-Phe-Arg-Tyr-Leu-Pro-Ser-Asp, recognized and
Figure 49. A) Structure of the Au NP–peptide complex on the histidine-rich polypeptide nanotube template. B) Immobilization of avidin units at the ends of peptide nanotubes by using Au NPs as protective masks to yield only end-to-end interconnected peptide nanotubes.

effected the growth of hexagonal Ag nanocrystals on the (111) face.[358c] Upon the sequencing and the incorporation of the peptide onto the surface of the nanotube template, the biomineralization of Ag$^+$ ions on the polypeptide nanotubes led to an isotropic coating of hexagonal Ag nanocrystals.

Peptide nanotubes[359] incorporate many free amide and carboxylic groups on the surfaces as binding sites to anchor biological molecules and metal ions in order to produce various other functional nanotubes. Also, thiol groups could be introduced into the protein backbone to anchor Au NPs. Usually these binding sites are distributed on the entire surface of the nanotube to provide a uniform attachment of modifying units along the entire length of the nanotube. As an example, amyloid protein fibers (10-nm wide) were generated by the self-assembly of the prion determinant from *Saccharomyces cerevisiae* (the N-terminal and middle (NM) regions of Sup35p), which was genetically engineered to include thiol groups on the protein surface. Gold NPs were associated to the activated surface of the protein fibers, and by the subsequent catalytic deposition of silver on the Au NPs, micrometer-long wires with a diameter of about 100 nm and with good electrical conductivity were generated.[361]

A novel method has been developed for the directional functionalization of peptide nanotubes at their ends, whilst the sidewalls remain untouched.[362] The approach involved, first, the thiolation of the nanotube sidewalls by the carbo-

diimide coupling of 2-mercaptoethylamine to carboxylic groups of the polypeptide nanotubes (Figure 49B, step a). Then, Au nanoparticles were coated as a mask on the sidewalls of the nanotube (Figure 49B, step b), and the assembly was incubated in a solution of sulforhodamine-labeled avidin (Figure 49B, step c). After avidin was immobilized at the ends (not masked by Au nanocrystals) and the sidewalls (masked by Au NPs) of the nanotubes, the Au NPs on the sidewalls were chemically etched (Figure 49B, step d). The chemical etching of the Au nanocrystal masks on the sidewalls of the nanotubes led to the removal of avidin from the sidewalls, whereas avidin at the ends of the nanotube remained bound. The chemical etching process did not denature avidin, and the nanotube ends could recognize and immobilize the complimentary biotin units (Figure 49B, step e). This fabrication method is useful to guide each individual nanotube to each corresponding location on complementary protein-patterned surfaces. End-to-end specific coupling of peptide nanotubes, such as through biotin–avidin interactions, could allow the formation of a template that could yield a conductive nanocircuit upon further metallization.

The specific assembly of protein subunits into template structures could provide a means of patterning the generated metal nanowires. An f-actin filament provides specific binding of the biomolecular motor protein, myosin, which forms a mobile complex with the filament and whose motility along the filament is driven by ATP.[363] The f-actin filament is formed by the reversible association of g-actin subunits in the presence of ATP, Mg^{2+}, and Na$^+$ ions. Recently, the f-actin filament was used as a template for the formation of Au nanowires,[364] whereby the filament was covalently modified with Au NPs (1.4 nm) that were functionalized with single *N*-hydroxysuccinimidyl ester groups **108**. Removal by dialysis of the ATP, Mg^{2+}, and Na$^+$ ions that were used to assemble the g-actin monomer units into the filament resulted in the separation of the filament and the formation of Au NP-functionalized g-actin subunits. The association of Au NPs to the polymeric form of the actin followed by its dissociation was essential to protect the binding sites of the monomeric actin subunits. The Au NP-functionalized g-actin subunits were then used as versatile building blocks for the Mg^{2+}/Na$^+$/ATP-induced polymerization of the functionalized monomers to yield the Au NP-functionalized filaments of a predesigned pattern (Figure 50A). Electroless catalytic gold deposition on the Au NP-functionalized f-actin filament yielded 1–3-μm-long gold wires of 80–150-nm-heights, which depended on the time elapsed during the gold deposition. By sequential polymerization of the naked actin filament on the preformed Au–NP–actin wire and the subsequent electroless catalytic deposition of gold on the Au NPs, patterned actin/Au wire/actin filaments were generated (Figure 50C). A related approach was applied to yield the inverse Au wire/actin/Au wire patterned filaments (Figure 50B). The latter configuration suggests that the two Au wires may act as contacts for the deposition of a semiconductor nanotube and the fabrication of a transistor element. The gold deposited on the actin filament exhibited metallic conductivity with a resistance similar to the value obtained for bulk gold.
Figure 50. A) The assembly of patterned actin-based Au nanowires: Left: a Au wire/actin/Au wire filament; Right: an actin/Au wire/actin filament. B) AFM image of the Au wire/actin/Au wire filament. C) AFM image of the actin/Au wire/actin filament.

The specific binding interactions of proteins can provide specific cross-linking or bridging properties for the generation of nanoparticle circuits. The homotetrameric protein streptavidin (SAv) is characterized by four high-affinity ($K_a >$ $10^{14}\,\mathrm{M}^{-1}$) binding sites for biotin. By the appropriate functionalization of Au NPs[126] (or ferritin particles)[132] with biotin units, 3D NP aggregates were generated. Nanoparticle aggregates that exhibit 3D ordering were also generated by the use of complementary antigen–antibody binding interactions.[38,118] The simplest antigen–antibody–metal NP-ordered aggregate involved the cross-linking of Au NPs (12 nm), which were functionalized with the anti-dinitrophenyl antibody (anti-DNP), with a bifunctional bis(dinitrophenyl) antigen (bis-(*N*-2,4-dinitrophenyloctamethylenediamine)). Circuits of greater complexity were generated by the application of different protein receptors and different metals for the ordered organization of the NP systems.[38,118] A nanoparticle aggregate was formed from two NPs that were differently functionalized, namely with streptavidin (SAv) and anti-DNP groups. The oligomeric aggregates generated from bioorganic SAv particles and bisbiotinylated ds-DNA spacers were used as model

systems to study the properties of complex particle networks. SAv functioned as a 5-nm model particle that could undergo a limited number of interconnections to other particles within the network. Either one, two, three, or four biotinylated DNA fragments were conjugated with SAv by means of the high-affinity SAv–biotin interaction to result in dimers, trimers, and oligomers that were interconnected in a network as observed by scanning force microscopy (SFM; Figure 51).[21a]

8.2. DNA as a Functional Template for Nanocircuitry

Among the different biomaterials, DNA is of specific interest as a template for the construction of nanocircuits.
Figure 51. SFM images of nanoparticle networks that were prepared with ds-DNA as spacer groups. The ds-DNA fragments contain two biotin-binding sites at the two 5′ ends of the ds-DNA which allow the cross-linking of the biotin-binding protein SAv as a model nanoobject. (Adapted from Ref. [21a], with permission).

Several arguments support the use of DNA as a future building block of nanostructures: 1) Nucleic acids of predesigned lengths, base-orderings, and shapes can be synthesized, and complex structures have been generated by self-assembly methods.[365] Whereas the variable DNA shapes may be used as predesigned templates for the nanocircuits, the base-sequence may be used as specific addressable domains for the binding of the reactants that form the nanowires. As a result, patterned nanocircuits may be envisaged. 2) Nature provides us with numerous biocatalysts that can manipulate DNA. These enzymes may be considered as tools for shaping the desired DNA and eventually for the generation of nano-circuits. For example, the enzyme ligase ligates nucleic acids, endonucleases affect the specific scission of nucleic acids, telomerase elongates single-stranded nucleic acids by telomer units, and polymerase replicates DNA. These biocatalysts represent "cut and paste" tools for the formation of DNA templates. By the application of the replication biocatalyst, the design of future factories of nanowires may be envisaged. 3) The intercalation of molecular components into DNA and the binding of cationic species such as metal ions to the phosphate units of nucleic acids allows the assembly of chemically active functional complexes. These linked molecular components may be used as precursors for the formation of the nanowires. Specifically, intercalators that selectively bind to appropriate base pairs may be used as directing units for the selective deposition of chemicals on the nucleic acids. Such directed assembly of reactive sites may then lead to patterned nanocircuits. 4) Different proteins bind specifically to certain nucleic acid sequences. This allows the addressable assembly of complex DNA–protein structures. Such protein–DNA complexes may act either as addressable domains for the selective deposition of metals or semiconductors, or alternatively as temporary shielding domains that protect the DNA from metal deposition. These insulated domains may then be used for the deposition of other metals or semiconductors to enable the fabrication of patterned complex structures.

The interaction of metal NPs with DNA is a well-known phenomenon,[179,181,347,366] and the microscopic mechanism of the nucleation of metal nanoclusters on DNA templates has been studied.[227] Usually, single or double-stranded DNA is decorated by the metal particles, which can easily be imaged by TEM or AFM.[367] Upon the interaction of DNA with Au NPs that are stabilized with phosphane ligands $(Au_{55}(Ph_2PC_6H_4SO_3H)_{12}Cl_6)$, the formation of Au-decorated wirelike DNA structures was demonstrated by AFM (Figure 52 A).[367a] Molecular-modeling studies of the interactions between the DNA and Au_{55} and Au_{13} NPs showed that the NPs could be arranged inside the grooves of DNA (Figure 52 B). Some of the phosphane ligands could be substituted by the DNA phosphate groups which provided strong binding of the Au NPs to the DNA. Au NPs capped with other phosphane ligands such as tris(hydroxymethyl)phosphine-capped Au NPs[368] were also used to decorate DNA templates that yielded nanowires. 1D chains of Au NPs (4.4 nm) coated with cationic trimethyl(mercaptoundecyl)ammonium mono-layers were electrostatically assembled along DNA molecules in solution by the careful control of the relative molar
Figure 52. A) a) AFM image of λ-DNA, which is partially linked with Au_{55} clusters; b) Height profile of both the bare DNA and a decorated part. B) Energy-minimized structure of the DNA fragment with Au_{55} clusters arranged along the phosphate backbone of the DNA major grooves. (Adapted from Ref. [367a], with permission).

quantities of NPs and DNA base pairs.[367b] TEM images of the dried droplets of solutions of the DNA-base-pair/MPC (monolayer-protected cluster) in a molar ratio of 20:1 displayed chains of NPs that were a few microns long in which the Au cores were lined up with nearly contacting cationic monolayer edges along the anionic DNA template.

With the vision that DNA can act as a template for the generation of nanocircuits, attempts were made to explore the possibility to organize DNA-cross-linked semiconductor NPs and DNA-based metal NP nanowires on surfaces. As nano-particles are loaded on the DNA template with gaps between the adjacent particles, the issue of electrical conductivity of the DNA matrix itself is important. Electron transport through DNA has been one of the most intensively debated subjects in chemistry over the past ten years,[224,369] and the subject is still under extensive theoretical[370] and experimental[371] investigation. Despite some optimistic observations that show highly conductive properties of the entire DNA backbone,[372] most of the studies report poorly conductive[373] or insulator[374] properties of the DNA. To examine the electrical conductivity of DNA, the conductivity of double-stranded DNA that connects Au NPs was analyzed. Thiol-derivatized oligonucleotides were linked to Au NPs, and then the DNA-functionalized Au NPs were bridged with DNA chains that were composed of double-stranded helices of various lengths (24, 48, or 72 bases). These helices were terminated on both sides with single-stranded domains, which were complementary to the oligonucleotides bound to the Au NPs.[69b] The resulting Au NP aggregates, which were linked

with ds-DNA spacers, were deposited on an electrically nonconductive solid support, and their conductivity was measured by the four-probe method. Surprisingly, the conductivities of the aggregates generated by all three linkers ranged from 10^{-5} to 10^{-4} S cm^{-1} at room temperature, and the linkers all showed similar temperature-dependent behavior. The similarity of the electrical properties of the aggregates originates from the fact that the DNA spacers are compressed and thus yield small and similar distances between the Au NPs. Accordingly, the measured conductivity parameters reflect the electrical properties of the metallic NPs separated by small gaps.

The conductivity of metallic NP aggregates on a DNA template can be enhanced by the chemical deposition of another metal, such as the deposition of Ag on Au aggregates, to fill the gaps and to form a continuous conductive nanowire. DNA metallization is based on the association of metal complexes or metallic NPs with the DNA template and the further growth of the metal seeds with either the same or a different metal upon chemical reduction of the respective metal ions in the presence of strong reductants, such as dimethylaminoborane, hydroquinone, or sodium borohydride.[224] When metal ions or metal complexes, such as silver or copper ions,[375] or platinum or palladium complexes,[227] which are electrostatically associated with a DNA template, are used as the active sites for the metallization of the DNA, the formation of the continuous nanowire proceeds over a period of time which ranges from several hours up to one day.[181,347] Application of pre-prepared metal NPs that are associated with the DNA template makes this process significantly shorter.[368] The binding of the primary metallic clusters to the template DNA for the subsequent catalytic deposition of wires on the DNA frame may be performed by several means: 1) By the reduction of metal ions that are linked to the phosphate groups to metallic seeds that are linked to the DNA. 2) By the use of metal or semiconductor NPs that are functionalized with intercalator units—intercalation of the molecular components into ds-DNA leads to the association of the NPs with the DNA template. 3) By the synthesis of DNA that have functional tethers, which enable the covalent attachment of the metal or semiconductor NPs to the DNA. 4) By the synthesis of ss-DNA that includes constant repeat units (e.g. telomers) and the hybridization of metal or semiconductor NPs that are functionalized with short nucleic acids, which are complementary to the ss-DNA repeat units.

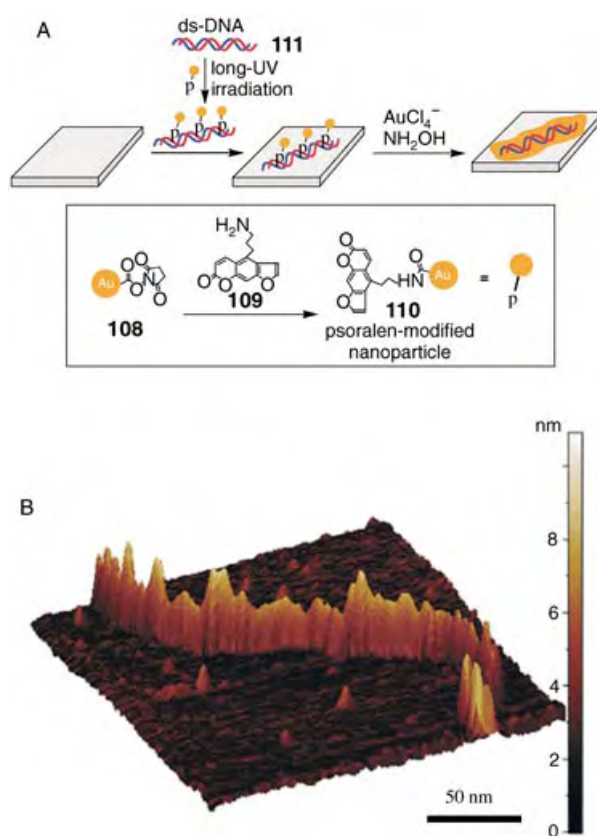
Figure 53 A exemplifies the method for the assembly of Au NPs on a DNA template by using Au nanoparticles that are functionalized with an intercalator.[376] The psoralen-amine derivative **109** was treated with the Au$_{55}$ nanocluster (1.4 nm-diameter), which includes a single *N*-hydroxysuccinimidyl ester group **108**, to yield the psoralen-functionalized Au$_{55}$ nanoparticle **110**. As psoralen acts as a specific intercalator for A–T base pairs, the functionalized Au$_{55}$ nanoparticles were treated with the pA-pT–ds-DNA **111** (pA-pT = polyadenylic acid–polythymidylic acid). Subsequently, the assembly was irradiated with UV light to induce the $2\pi + 2\pi$ cycloaddition reaction between the psoralen units and the thymine base sites of DNA. This latter


Figure 53. A) Assembly of a Au NP wire in the pA/pT template by using Au NPs that are functionalized with intercalator (psoralen) molecules. B) AFM image of the Au NP wire in the pA/pT template. pA/pT = polyadenylic acid/polythymidylic acid.

process covalently fixed the Au$_{55}$ NPs to the DNA matrix. Figure 53 B depicts the AFM image of the resulting NP wire. A NP wire that was approximately 600–700-nm-long was formed. Its width corresponds to around 3.5–8 nm and is controlled by the width of the DNA template. The height of the wire was about 3–4 nm, which is consistent with the fact that the Au NPs intercalate into the DNA on opposite sides of the double-stranded DNA template. The continuous appearance of the Au NP wire is owed to the dimensions of the scanning AFM tip, and in reality, most of the particles are not in intimate contact with one another. The possibility to arrange the Au NPs on the DNA template allows the further catalytic enlargement of the particles by an electroless deposition process (e.g. reaction of AuCl$_4^-$ with NH$_2$OH) to yield continuous conductive nanowires.

Another approach involved the electrostatic association of metastable Au NPs with a DNA template to yield a conductive wire along the DNA matrix.[377] Gold NPs were capped with thiocholine, HS(CH$_2$)$_2$N$^+$(CH$_3$)$_3$ (**54**), as a cationic stabilizer to provide the electrostatic association of the nanoparticles with the negatively charged DNA template. Then, the unstable Au NPs underwent self-fusion into the conductive wire structures. Au$_{core}$/aniline$_{shell}$ NPs were self-assembled onto a DNA template, which was stretched on a surface, to yield aligned assemblies that were ordered over a

long range.[378] The aniline shell provided a positive charge on the NPs which resulted in their electrostatic binding to the negatively charged phosphate backbone of the DNA template. Linear arrays of the aniline-coated Au NPs with interparticle spacing were organized on DNA to form a necklacelike nanostructure. By the deposition of different metals or NPs in the interparticle spacings, it should be possible to tune the electrical or optical properties of linear arrays.

A high-throughput synthesis of DNA templates for the generation of metallic nanowires was demonstrated by the use of HeLa cancer cell generated telomerase. Telomers are nucleic acids of constant repeat units (5′-TTAGGG-3′) that protect the chromosome ends from erosion.[379] Their stepwise degradation during the normal cell life cycle results in a cellular signal for the termination of the cell life-cycle and proliferation.[380] In certain cells, the ribonucleoprotein telomerase can be accumulated, and this enzyme elongates the telomer ends with the constant repeat units which results in the production of immortal malignant or cancer cells. Thus, telomerase is a characteristic biomarker for cancer cells.[381] The constant repeat units that exist in the telomers provided addressable domains for the application of the telomers, which were generated from HeLa cells, as templates for the

formation of metallic nanowires.[382] In one approach, the primer **112** was telomerized in the presence of the dNTPs nucleotide mixture, which contained (aminoallyl)dUTP **113** (Figure 54 A). The resulting amine-containing telomers were treated with Au NPs (1.4 nm; **108**), which were functionalized with single *N*-hydroxysuccinimidyl ester groups, to yield Au NP-modified telomers. The Au nanoparticle-decorated DNA wires were then enlarged by electroless gold deposition to generate a metallic nanowire (Figure 54, C and D). In a different approach, the telomer was hybridized with the complementary nucleic acid segments **114** that were functionalized with Au NPs (Figure 54 B). The resulting Au NP-modified DNA duplex was enlarged by the electroless deposition of gold on the nanoparticles to generate a metallic nanowire (Figure 54 E).

Practical applications of the nanowires require their electrical contacting with macro- or microelectrodes. Towards this goal, a single nanowire, which was produced on a DNA template that bridges two microsize electrodes, was constructed.[225,226] Two microelectrodes, which were positioned opposite each other with 12–16-μm separation, were functionalized with 12-base oligonucleotides that were then bridged with a 16-μm-long λ-DNA (Figure 55 A). The resulting phosphate units of the DNA bridge were loaded with Ag⁺

ions by ion-exchange, and the bound Ag$^+$ ions were reduced to Ag metal with hydroquinone. The small Ag aggregates which were produced along the DNA backbone were then used as catalysts for the further reductive deposition of silver, which eventually led to the formation of a Ag nanowire. This micrometer-sized element had a typical width of 100 nm and a granular morphology (determined by AFM). Electrical measurements revealed nonlinear graphs of *I* versus *V* (Figure 55 B). The nonlinear current–voltage graphs and the observed hysteresis are not understood at present. This behavior may originate from quantum effects of the nanoscale wire. Alternatively, local defects in the generated wire morphology may introduce a tunneling barrier for the transport of electrons through the wire.

A similar approach was used to generate highly conductive DNA-templated nanowires that bridged macroscopic Au interdigitated electrodes.[383] DNA molecules were positioned between macroscopic Au electrodes and were loaded with Pd^{2+} ions,[383a] which were then chemically reduced into continuous metallic wires. The Pd wires provided specific conductivity that was only one order of magnitude lower than that of bulk palladium. Also, the vectorial immobilization of linear M13mp18 ds-DNA ($\approx$ 2.5-μm-length) between interdigitated electrodes with 2.0-μm spacings was performed by the nonsymmetrical modification of the opposite electrode surfaces.[383b] One side of the interdigitated electrodes was selectively modified with a coating of streptavidin, whereas the second side was coated with Au NPs. An asymmetric double-stranded M13mp18 DNA strand that carries a 5′-thiol group at one end and a 5′-biotin at the other end was obtained through polymerase chain reaction (PCR) by using two differently labeled primers. The DNA interaction with the electrode system resulted in the selective bridging of the electrode surfaces owing to the biotin–streptavidin coupling at one side and the adsorption of thiol on the Au NPs at the other side. Further metallization of the DNA bridges yielded electrical contacting between the interdigitated electrodes.

Molecular electronics, however, requires more elaborate manipulations that include the formation of richer geometries, wire patterning with nanometer resolutions, and molecularly accurate device localization. The binding of

proteins such as RecA to DNA has been used as a means for the patterning of nanoscale DNA-based metal wires with nonconductive or semiconductive gaps.[384] The biomolecular lithography used for this process is based on homologous recombination processes carried out by the RecA protein, which operates on ds-DNA substrate molecules. The information that guides the lithography is encoded in the 48 502-base-pair ds-DNA substrate **115** and in the auxiliary 2027-base ss-DNA probe **116**. The RecA proteins were polymerized on the ss-DNA probe **116** to form a nucleoprotein filament **117**. This filament was then mixed with the ds-DNA substrate **115** (Figure 56 A, steps a and b). The polymerization of RecA on the ss-DNA probe **116** is not sequence-specific. However, the binding specificity of the nucleoprotein filament **117** to the ds-DNA substrate **115** is dictated by the base-sequence and its homology to the substrate molecule. Subsequently, Ag$^+$ ions were bound to the protein-deficient DNA domains of the nucleoprotein filament, and these were reduced into Ag clusters that were associated with free domains of the DNA assembly (Figure 56 A, step c). The ds-DNA **115** was modified with aldehyde groups prior to this process to allow the chemical reduction of the electrostatically bound Ag$^+$ ions to Ag clusters. The localized RecA proteins, which served as a resistance, prevented the deposition of Ag on the nucleoprotein filament **117** domain and created a gap of predefined sequence length between the Ag-loaded segments of the substrate molecule. The Ag clusters served as catalysts for the subsequent electroless deposition of Au (Figure 56 A, step d), and this process produced two continuous gold wires separated by the predesigned gap (Figure 56 B). The domain of the nucleoprotein filament **117** could be further functionalized by using various protein-recognition reactions (based on biotin–streptavidin or antigen–antibody affinity) which led to the formation of complex metal (or semiconductor)–biomaterial hybrid nanowire structures. In a similar approach, the nucleoprotein filament **117** was used to protect the DNA from the aldehyde derivatization process rather than the metallization process.[385] The binding of RecA to the DNA prohibited its reaction with glutaraldehyde which created an underivatized region on the DNA. After the removal of excess glutaraldehyde, the RecA

[384], with permission).

networks. Further complexity was introduced into the generated 2D arrays of DNA by means of a molecular "cut and paste" technique by using an AFM tip as an instrument for molecular manipulation.[387] A DNA strand was cut at a certain point (Figure 57D) and a part of the DNA was swept away by an AFM tip. The residual DNA structure was manipulated with the AFM tip to yield various patterns (Figure 57E and F). Metallization of the generated DNA patterns yielded nanocircuit junctions of different structures and high complexity.

The possible variability and complexity in DNA design establishes unique opportunities for programming the shape and structure of the DNA templates.[365] A cross structure of eight ds-DNA units that exhibits four wings with appropriate "sticky" ends was used as a tile for the self-assembly of a 2D lattice of nanogrid morphology or a nanoribbon morphology of uniform width.[388] Both morphologies displayed periodic square cavities. The resulting nanoribbons acted as scaffolds for the metallization and formation of highly conductive silver wires. Also, DNA lattices were generated by using a linear array of DNA triple crossover molecules to yield templates for the formation of Au NP arrays.[389]

protein was disassembled and the DNA was purified. The resulting DNA molecules, which possessed a predesigned aldehyde-derivatization pattern, were combed onto a passivated silicon wafer and these were incubated in a silver solution. The patterned aldehyde derivatization served as a blueprint for the creation of an insulating gap in the DNA metallization process.

Recently, 1D and 2D metallic nanowire arrays have been obtained by the combination of molecular combing and DNA metallization.[386] The method involved three steps: 1) A fluid flow was used to prepare parallel unidirectional DNA arrays of controlled density (Figure 57A); to create 2D arrays of DNA, a second alignment was made along another direction. 2) Pd^{2+} ions were absorbed onto the negatively charged DNA backbones. 3) Chemical reduction of the absorbed Pd^{2+} ions produced palladium nanowires. The resulting Pd nanowires followed the patterns defined by the DNA array to produce either parallel or crossed networks of Pd nanowires on a mica substrate. The resulting nanowires were composed of NPs with an average diameter of about 30 nm. It should be noted that the actual diameter may be even smaller because of the limited lateral resolution of the AFM tip. A section analysis (Figure 57B) showed that these nanowires are about 5 nm in height. Figure 57C also presents an AFM image at high magnification that shows a well-defined meshlike 2D Pd nanowire array. This method could be especially useful for the parallel assembly of nanosized building blocks into functional

8.3. Viral Matrices as Functional Templates for Nanocircuitry

It has been shown that several types of rodshape viruses form well-controlled liquid-crystalline phases.[390] Recently, a method of fabrication of a self-assembled, ordered nanocrystal film that used a nanocrystal-functionalized M13 virus was reported.[391] Through genetic-engineering techniques, one end of the M13 virus was functionalized to nucleate or bind to a desired semiconductor material (specifically II–VI semiconductor nanoparticles).[392] These semiconductor nanocrystal-functionalized viral liquid-crystalline building blocks were grown into ordered hybrid self-supporting films. The resulting nanocrystal-hybrid film was ordered at the nano- and microscales into 72-μm periodically striped domains. To align other materials, such as metallic and magnetic nanoparticles, another general approach has been suggested which includes the genetic-engineered formation of a virus that specifically binds streptavidin, SAv. The anti-SAv M13 viruses, which have specific binding moieties for SAv, were prepared by genetic engineering and were further treated with Au NP–SAv hybrids. Smectic-ordered self-supporting Au NP/virus films were obtained and were characterized by AFM. Because the modification of the DNA insert allows the controlled modification of the virus length, the spacing in the smectic layer can be genetically controlled.

Viruses were also used as templates to assemble NPs with precise placement of the clusters.[393] For example, Pt, Au, or Ag metal NPs were organized into nanowires by using Tobacco Mosaic Virus (TMV) as templates.[393a,b] The respective precursor ions, $PtCl_6^{2-}$, $AuCl_4^-$, or Ag^+, were associated with the virus surface and were chemically reduced to yield the specific decoration of the external surface of wild-type TMV rods with metallic NPs that were less than 10 nm in size. Similarly, Ni and Co nanowires that were only a few atoms in diameter and up to the micrometer range in length, were generated by using the central channel of TMV as a template.[394] Elsewhere, different mutants of Cowpea Mosaic Virus (CPMV) have been used as scaffolds to bind 2- and 5-nm Au NPs through gold–sulfur bonds at specific locations on the virus to produce 3D patterns of specific interparticle distances.[393c]

8.4. The Integration of Nanowires into Nanodevices

The ultimate goal of nanobioelectronics is the integration of nanowires into operating electronic systems or functional devices. Until now, most of the studies have addressed the structural features of nanocircuitry and the conductivity properties of the nanostructures. The fabrication of functional devices is still in its infancy, although recent developments suggest potential advances in this area.

Nanoscale biosensors that are based on functionalized nanowires[395] and nanotubes[396] have recently received considerable attention. Functionalized silicon nanowires were used for DNA analysis on the basis of conductance measurements.[397] Silicon nanowires (p-type) were synthesized by using gold nanocluster-catalyzed chemical vapor deposition, and then the wires were assembled into sensor devices that

consisted of electrically addressable nanowires (Figure 58 A, inset).[397a] A PNA (peptide nucleic acid) probe with the sequence 5′-ATCATCTTTG-3′, which is fully complementary to the wild-type cystic fibrosis transmembrane receptor (CFTR) sequence, was bound to a nanowire surface and
Figure 58. A) Real-time conductance response from a Si nanowire device that is functionalized with a PNA (peptide nucleic acid) receptor. The arrow marks the point in time when the sample of the analyte DNA (wild-type CFTR; 60 fM) was added; Inset: SEM image of a typical Si nanowire device with source (S) and drain (D) indicated. B) Conductance of the device as a function of the concentration of the analyte DNA. The data points shown ■ and ● were obtained from two independent Si nanowire devices. (Adapted from Ref. [397a], with permission; Copyright American Chemical Society, 2004).

was used as the receptor for the analysis of the wild-type and mutant oligonucleotide sequences that spanned the ΔF508 region of the CFTR (5′-CATAGGAAACACCAAAGAT-GATATTTTCTTT-3′ and 5′-CATAGGAAACACCAAT-GATATTTTCTTT-3′, respectively). Formation of the negatively charged double-stranded complex between the surface-confined PNA receptor units and the complementary analyte DNA resulted in a change in the conductance of the nanowire (Figure 58 A). On the other hand, the noncomplementary mutant DNA did not yield any conductance change, which suggests that the electronic signal originated from the specific, rather than nonspecific, binding of the analyte DNA. Concentration-dependent measurements show that the detection limit is in the femtomolar range (Figure 58 B). This analytical method with nanowires represents an important advance towards a direct, label-free, selective, and highly sensitive means of analyzing DNA. The method could thus provide a route to the high-throughput, multiplexed analysis of DNA; a process that will be important for genetic sensing, clinical diagnostics, and for the detection of biothreats.

An actin/Au nanowire/actin filament that was generated by the stepwise polymerization of Au nanoparticle-functionalized g-actin, followed by the polymerization of naked g-actin at the nanoparticle–filament ends, and the subsequent enlargement of the Au NPs to a continuous Au bar (see Section 8.1) was used as a nanotransport system.[364] Towards this goal, the actin/Au nanowire/actin filament was rigidified with phalloidin and deposited on a myosin interface that was linked to a glass support. Upon addition of ATP to the system, the actin-linked Au nanorods moved on the surface, and the motility of the nanoobjects was followed by reflectance

microscopy (Figure 59). The Au nanorods were found to move at a speed of 250 nm s^{-1}. In a related approach, CdSe NPs were assembled on microtubules and the generated filaments were driven in the presence of kinesin.[398] In the future, such systems may be employed as nanotransporters.

9. Conclusions

This review has summarized recent advances in the rapidly developing area of functional biomolecule–nanoparticle/nanorod hybrid systems. This topic represents an interdisciplinary effort to combine the unique optical, electronic, and catalytic properties of nanoobjects with the naturally optimized recognition and reactivity functions of biomaterials. The fact that NPs and biomaterials such as enzymes, antibodies, or nucleic acids are of similar dimensions makes the hybrid systems attractive nanoelements or building blocks of nanostructures and devices.

Several functions and applications of biomolecule–NP hybrid systems have been discussed, including analytical applications, signal-triggered electronic functions, nanostructures for circuitry, and the assembly of devices. Some of these functions represent viable technologies, whereas others are still in an embryonic phase and require additional fundamental research. The analytical applications of biomolecule–NP systems have advanced tremendously in the last decade. The understanding of the unique optical properties of NPs and the photophysics of coupled interparticle interactions has enabled the use of these particles as optical labels for recognition events. Similarly, the catalytic properties of nanomaterials have enabled the amplification of biorecognition events.

Upon the assembly of biomolecule–NP hybrid systems on surfaces, the electronic detection of biorecognition events can become feasible by means of electrical conductivity or piezoelectric or photoelectrochemical transduction. Alternatively, the unique size-controlled optical properties of semiconductor NPs imply that the organization of combinatorial libraries of biomolecule—semiconductor NP hybrid systems or the assembly of different biomolecule–NP hybrids in array configurations may lead to the high-throughput parallel analysis of numerous analytes.

Novel uses of biomaterial–magnetic particle conjugates for analytical applications were also discussed. Whereas the concentration and separation of substances by magnetic particles is a common practice, novel concepts such as the amplification of electronic sensing through the rotation of the magnetic particles by an external magnetic motor represents a new analytical concept. Many future applications of rotating magnetic particles are envisaged in the detection of antigen–antibody, nucleic acid–DNA, protein–DNA, or receptor–cell interactions. Also, enhanced reactivity at rotating magnetic particles (e.g. accelerated hybridization or polymerization) may facilitate analytical processes. Future analytical perspectives of hybrid NP systems may involve the mechanical actuation of microelements. The detection of biomaterials, such as antibodies[399] or DNA,[400] by the mechanical movement of microlevers owing to surface-stress interactions is well established. The integration of charged NPs or magnetic particles as labels for such biorecognition events may enhance the surface stress and provide mechanical activation of microobjects.

The electronic triggering of redox proteins by the incorporation of nanoparticles represents a novel strategy for the electrical contacting of redox enzymes with their macroscopic environment. The use of other nanoobjects, such as metal or semiconductor nanorods and carbon nanotubes, for the electrical contacting of redox enzymes may be envisaged. Also, the magnetic triggering of redox proteins will certainly find applications in tailoring complex sensor systems and the development of new surface-patterning methods.

The use of biomaterials as templates for the generation of nanostructures and nanocircuitry in the presence of NPs is in an early phase of development. The viability of the concept has been proven, and nanowires of controlled shapes and electronic functions have been generated by the incorporation of nanoparticles on template biomaterials. However, the biggest challenges are ahead of us, and exciting systems are envisaged for the future. Besides the interesting nanoarchitectures that may be generated, fundamental problems, such as probing charge-transport phenomena in such biomolecule–NP systems, may be highlighted. Nonetheless, the organization of NP architectures on biomaterial templates involves relatively simple motifs that do not make full use of the catalytic functions of the biomaterial. The replication of NP-labeled DNA, and specifically, the tailoring of PCR for the formation of NP wires, represents a novel approach to design biological machines for the synthesis of nanoparticle wires and circuitry. Finally, the use of biomolecule–NP composite systems for the fabrication of nanodevices is at a very early

stage. Nevertheless, it is already clear that fascinating new phenomena may be discovered.

For the future development of biomolecule–NP systems, it is mandatory to develop new synthetic methodologies. At present, most NPs are capped with a stabilizing layer. The synthesis of NPs that have a single functionality is a challenging goal, yet the successful synthesis of monofunctionalized Au_{55} clusters implies that the preparation of such particles is feasible. Once particles are modified with a controlled number of chemical functionalities, the programmed vectorial growth of biomolecule–nanoparticle structures should be possible. In this context, the specific chemical functionalization of the edges of nanorods with biomaterials could be a means to grow nanostructures of controlled shape and composition.

Biomolecule-functionalized NPs and nanorods could be exploited for numerous applications in biomolecular electronics,[401] biosensors,[402,403] bioactuators,[345,364] and medicine, namely in photodynamic anticancer therapy,[404] targeted delivery of radioisotopes,[405] drug delivery,[406] electronic DNA sequencing, nanotechnology of gene-delivery systems,[407] and gene therapy.[408] Novel fascinating areas of technologies are feasible with the use of bionanomaterials. For example, nanorobotics, which is still at an embryonic stage, encompasses the design, fabrication, and programming of robots with overall dimensions below a few micrometers and the programmable assembly of nanoscale objects.[409] Nanorobots are quintessential nanoelectromechanical systems and raise all the important issues of sensing, actuation, control, communications, power, and interfacing across spatial scales and between the organic/inorganic and biological/mechanical systems. Nanorobots are expected to have revolutionary applications in such areas as environmental monitoring and health care. The novel field of nanoelectronics and nanoelectromechanical quantum circuits and systems is also emerging.[410] The field exploits progress in techniques for the fabrication (of down to nanometer-length scales) of freestanding device structures, which incorporate mechanical motion and which may be designed to perform a variety of functions (such as optical, electrical, and, in particular, mechanical). To fully exploit the potential of this technology in sensing, computation, and signal processing applications, the use of bionanohybrid systems is essential.

A combination of the unique properties of nanoobjects (such as nanoparticles and nanorods) and biomaterials provides a unique opportunity for physicists, chemists, biologists, and material scientists to mold the new area of nanobiotechnology.[411] Based on recent advances in the field, exciting new science and novel systems can be anticipated from this interdisciplinary effort.

Biomimetic Engineering of Carbon Nanotubes by Using Cell Surface Mucin Mimics**

Xing Chen, Goo Soo Lee, A. Zettl,* and Carolyn R. Bertozzi*

One of the most exciting applications of nanoscale science and technology is in the exploration of biological systems.[1] Carbon nanotubes (CNTs) have unique structural, mechanical, and electrical properties, and consequently numerous potential applications in biology, including sensing,[2] imaging,[3] and scaffolding for cell growth.[4] Few of these applications have yet been realized, however, because of the incompatibility of the CNT surface, which is hydrophobic and prone to nonspecific bioadsorption, with biological components such as cells and proteins. In addition, the aqueous environment required for biological materials are not suitable for unfunctionalized CNTs.[5] In nature, cells are faced with a similar challenge of resisting nonspecific biomolecule interactions while engaging in specific molecular recognition. These functions can be simultaneously fulfilled by mucin glycoproteins, defined by their dense clusters of O-linked glycans. Here we describe a biomimetic surface modification of CNTs using glycosylated polymers designed to mimic natural cell-surface mucins. CNTs modified with mucin mimics were soluble in water, resisted nonspecific protein binding, and bound specifically to biomolecules through receptor–ligand interactions. This strategy for biomimetic surface engineering provides a means to bridge nanomaterials and biological systems.

Mucins coat the surfaces of numerous cell types[6] and present epitopes for receptor-mediated cell–cell recognition.[7] Their dense glycosylation confers rigidity to the polypeptide backbone and thereby extends the mucin polymer well above the cell surface.[8] In addition, the glycans provide for strong hydration and passivation against biofouling. We have recently developed glycosylated polymers that share many properties with natural mucins (Figure 1a).[9] In native mucins, the clustered α-*N*-acetylgalactosamine (α-GalNAc) residues proximal to the peptide are the major contributors to the rigidification of peptide backbones. Although the core α-GalNAc residue is usually elaborated with additional sugars, removal of those sugars does not affect the mucin architecture.[10] The importance of the α-GalNAc residue for mucin structure has also been suggested by NMR analysis of synthetic glycopeptides.[11] Accordingly, we designed a synthetically tractable mucin mimic in which α-GalNAc residues were linked through an oxime bond to a poly(methyl vinyl ketone) [poly(MVK)] backbone (Figure 1a). The synthesis involved chemoselective ligation of poly(MVK) with an aminooxy-functionalized GalNAc analogue.[12] Light-scattering analysis indicated that the α-GalNAc-conjugated polymers adopt a rigid extended structure in water, similar to native mucin, whereas the unconjugated polymers adopt a more conventional globular structure.[9]

We introduced a C_{18} lipid at one end of a mucin mimic polymer with a molecular weight of about $75\,000$ g mol^{-1} to enable surface modification of CNTs (Figure 1b; see Supporting Information for synthetic details). The hydrated diameter of the lipid-terminated mucin mimic was determined by light-scattering analysis to be about 54 nm. Lipids are known to self-assemble on the surface of CNTs through hydrophobic interactions in the presence of water[13] and lipid-functionalized glycopolymers have been shown to form ordered arrays on graphite surfaces.[14] We envisioned that lipid-functionalized mucin mimics could assemble on CNTs in a similar manner as the organization of native mucins in the cell membrane, with the glycosylated polymers projecting into the aqueous medium (Figure 1c).

We first subjected single-walled carbon nanotubes (SWNTs) to ultrasonication in the presence of an aqueous solution of the C_{18}-functionalized mucin mimic bearing α-GalNAc residues (C_{18}-α-MM, Figure 1b). The SWNTs were fully solubilized during the procedure (Figure 2a), which suggests the formation of a hydrophilic surface coating. A similar procedure was applied to multiwalled carbon nanotubes (MWNTs) with the same outcome (Figure 2c). The suspensions of C_{18}-α-MM-functionalized CNTs were stable for more than three months, while unfunctionalized CNTs precipitated very quickly (within hours) in aqueous solutions (Figure 2b and d). The C_{18} lipid on the mucin mimic polymer was essential to solubilize the CNTs: they rapidly precipitated from solutions of polymers identical to the above mucin mimics but lacking the lipid tail (not shown). These observations are consistent with a model in which C_{18}-α-MMs coat the CNTs as shown in Figure 1c.

The CNTs coated with mucin mimics (C_{18}-α-MM-SWNTs, for example) were directly characterized by atomic force microscopy (AFM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). As produced,

Figure 1. a) The structural features of native mucin (left) as well as the designed and synthesized mucin mimic (right). Natural mucins are characterized by dense clusters of O-linked glycans bound to Ser/Thr residues of the polypeptide. The α-GalNAc residues attached to the Ser/Thr residues are elaborated with additional sugars but only the initial GalNAc residues are required for the mucin structure. b) Synthesis of C_{18}-α-MM. The C_{18} lipid was conjugated to 4,4′-azobis(4-cyanopentanoic acid) (ACPA) and the amide-linked product was used to initiate radical polymerization of MVK to produce C_{18}-poly(MVK). C_{18}-α-MM was obtained by chemoselective ligation of C_{18}-poly(MVK) with aminooxy-GalNAc. c) A model for the self-assembly of C_{18}-MMs on the surface of carbon nanotubes (right), which is similar to the proposed arrangement of cell-surface mucins (left).

SWNTs usually exist as bundles that are heavily entangled with one another to form three-dimensional (3D) networks.

After functionalization with C_{18}-α-MM, the entangled SWNT bundles dissociate to form much finer bundles and even
Figure 2. Photographs of vials containing a) a stable suspension of C$_{18}$-α-MM-SWNTs in H$_2$O after more than three months, b) as-produced SWNTs in H$_2$O, which precipitate in several hours, c) stable suspension of C$_{18}$-α-MM-MWNTs in H$_2$O after more than three months, d) as-produced MWNTs in H$_2$O, which precipitate over several hours.

individual nanotubes, as observed by all three imaging techniques. AFM permitted analysis of the modified tubes at ambient pressure and in an hydrated form, which is important for maintaining the structure of the mucin coating. As shown in Figure 3a, tapping mode AFM images on a silicon substrate revealed C$_{18}$-α-MM-SWNTs with fairly uniform diameters of 65–70 nm. The idealized model shown in Figure 1c would predict a diameter on the order of 100 nm,
Figure 3. a) Tapping mode AFM image of C$_{18}$-α-MM-SWNTs on a silicon substrate. b) SEM image of C$_{18}$-α-MM-SWNTs. The arrows indicate damaged regions of the mucin mimic coating caused by the electron beam. c), d) TEM images of C$_{18}$-α-MM-SWNTs stained with 0.5% methylamine vanadate.

roughly twice that of the polymer mimiking the mucin (the SWNT itself is only ca. 2 nm in diameter). However, distortions to the soft mucin coating imposed by the AFM tip or substrate, or a nonperpendicular angle of projection of the mucin polymer from the SWNT surface could account for the discrepancy.

SEM analysis of C$_{18}$-α-MM-SWNTs also provided evidence of the mucin coating. Exposure of the sample to the 5-keV electron beam led to visible sites of damage along the SWNT surface, as indicated by the arrows in Figure 3b. This result was expected based on the sensitivity of organic species to decomposition induced by an electron beam. The damage induced by the electron beam increased with longer exposure times, and culminated in near-complete destruction of the coating after 15 minutes (see the Supporting Information). By contrast, unmodified CNTs are fairly stable under the electron beam, and showed no visible change in surface morphology after prolonged exposure.

TEM analysis of C$_{18}$-α-MM-SWNTs provided a direct visualization of the mucin coating (Figure 3c and d). The thickness of the coating varied from 10 to 25 nm under these conditions, in which the sample is dehydrated under high vacuum. The coating was associated with the CNT surface (Figure 3c), and was not observed in regions of the image lacking CNTs. A single tube (or small bundle) coated with C$_{18}$-α-MM is shown in Figure 3d. The coating was not entirely uniform along the length of this SWNT, perhaps the result of damage induced by the electron beam (100 keV) or collapse of the mucin polymers under high vacuum. In this regard, AFM imaging is a superior technique for visualizing mucin-coated SWNTs as they would exist in a functionally relevant aqueous environment.

On cells, mucins serve the dual role of molecular recognition and resistance to biofouling. We sought to determine if these same functions could be realized in the context of the nanotube surface. The C$_{18}$-α-MM coating introduces α-GalNAc residues onto the CNT surface, which could be recognized by an α-GalNAc-specific receptor such as the lectin *Helix pomatia* agglutinin (HPA).[15] To test this we incubated C$_{18}$-α-MM-SWNTs with a solution of HPA conjugated with fluorescein isothiocyanate (HPA-FITC; shown schematically in Figure 4a I). The C$_{18}$-α-MM-SWNTs were dialyzed to remove excess HPA-FITC and then analyzed for bound lectin by fluorescence spectroscopy. The C$_{18}$-α-MM-SWNTs showed significant fluorescence, which was attributed to bound fluorescein (trace I of Figure 4b). HPA-FITC labeling of the C$_{18}$-α-MM-SWNTs was inhibited when 0.2 M free GalNAc was present in solution (Figure 4a III and trace III of Figure 4b), thus confirming that fluorescent labeling was dependent on the receptor–ligand interaction.

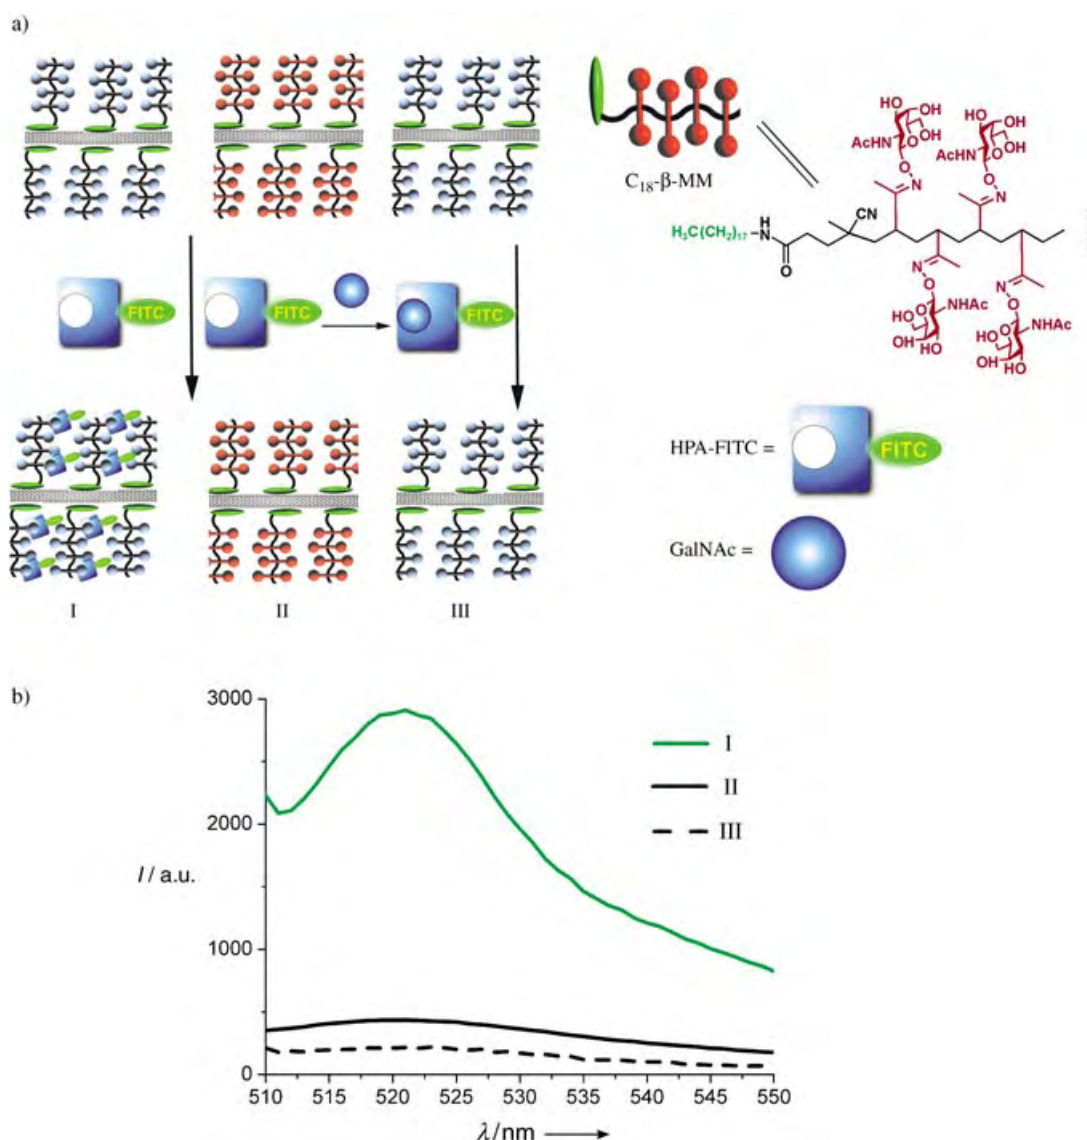
In addition, we prepared a similar mucin mimic in which the GalNAc residues were conjugated to the polymer backbone through a β-anomeric linkage (C$_{18}$-β-MM; see Supporting Information for synthetic details). This mucin mimic was physically identical to its α-linked counterpart but should not be capable of binding HPA.[16] We coated SWNTs with C$_{18}$-β-MM and incubated them with HPA-FITC (shown schematically in Figure 4a II). No significant fluorescence labeling was observed (trace II in Figure 4b), thus indicating that the lectin


Figure 4. Specific binding of HPA to C_{18}-α-MM-coated nanotubes. a) Scheme for: I) specific binding of HPA to the surface of C_{18}-α-MM-SWNTs, II) lack of binding of HPA to C_{18}-β-MM-SWNTs, III) inhibition of HPA binding by soluble GalNAc. b) Fluorescence spectra (510–550 nm) showing the specific binding of HPA to the surface of C_{18}-α-MM-SWNTs. Trace I: spectrum showing bound HPA-FITC on the surface of C_{18}-α-MM-SWNTs; trace II: spectrum showing the lack of bound HPA to C_{18}-β-MM-SWNTs; trace III: spectrum showing fluorescence associated with HPA-FITC binding in the presence of soluble GalNAc. The excitation wavelength was 492 nm. Spectra were corrected for background fluorescence by subtracting the fluorescence spectrum of C_{18}-α-MM-SWNTs or C_{18}-β-MM-SWNTs alone. These data are representative of results observed in triplicate experiments.

does not interact with the tubes coated with the mucin mimic in the absence of its preferred ligand. These results demonstrate that CNTs coated with a mucin mimic can engage in specific molecular recognition with protein receptors and resist nonspecific protein binding.

In summary, we have developed a practical and general approach to engineering biomimetic surfaces on CNTs. The mucin mimics used in this study endowed the CNT surfaces with properties shared by cell surfaces, including the display of carbohydrates capable of molecular recognition. The synthetic process leading to the mucin mimic allows for the introduction of myriad functional epitopes, in addition to sugars, that could encode interactions with numerous receptor types. This work should facilitate the integration of CNTs into aqueous biological systems that include proteins and cells.

Probing the Influence of O$_2$ on Photoinduced Reversible Electron Transfer in Perylenediimide–Triphenylamine-Based Dendrimers by Single-Molecule Spectroscopy**

Mircea Cotlet, Sadahiro Masuo, Marc Lor, Eduard Fron, Mark Van der Auweraer, Klaus Müllen, Johan Hofkens,* and Frans De Schryver*

Room temperature single-molecule fluorescence detection has evolved as a powerful tool to monitor dynamic processes in individual molecules.[1] Probing single molecules through their spectroscopic properties removes the inherent averaging factor that is present in ensemble experiments to render single-molecule detection as the method of choice to yield information at the most detailed level. Phenomena which are not necessarily predictable by ensemble experiments, such as fluctuations in the fluorescence intensity, lifetimes, or emission maxima, can be obtained by single-molecule detection. Here we use single-molecule detection to probe the influence of molecular oxygen (O$_2$) on the dynamics of photoinduced electron transfer (PET) in a dendrimer. PET is usually an efficient mechanism for fluorescence quenching, which renders single-molecule detection difficult, if not impossible. Therefore reports on PET in single molecules are rather limited.[2, 3a,b]

A particular aspect of the electron-transfer (ET) process occurs in the case where the locally excited singlet (LES) state and the charge-separated state (CSS) lie close in energetic terms to each other (Figure 1a, with the CSS at level 2). Normally, upon excitation, the LES is deactivated mainly through forward electron transfer (FET) to the CSS. If the radiationless deactivation of the CSS to the ground state (GS) is slow and inefficient, the CSS decays mainly through the LES by a reverse electron-transfer (RET) process. If so, fluorescence is delayed but it is still characterized by a high quantum yield. This allows the electron-transfer process to be

Figure 1. Scheme accounting for photoinduced reversible electron transfer in PN8 under a) deaerated (N₂; τ≈40 μs) and b) aerated (O₂;τ<1 μs) atmospheric conditions; thick arrows indicate the pathways enhanced by the presence of O₂; τ represents the decay time; LES = locally excited singlet state; LET = locally excited triplet state; GS = ground state; ¹CSS = singlet charge-separation states; ³CSS = triplet charge-separation states; k_A, k_F, k_{FET}, k_{RET} are the rate constants for absorption, fluorescence, forward-, and reverse-ET, respectively. ¹CSS is drawn at different levels within a Gauss-type density of states induced by polymer chain motion (see text); for simplicity, the ³CSS in both schemes is shown together with ¹CSS at level 2. c) Structures of PN8 and PN0.

decay times of 0.07 (70% amplitude), 1.2 (12%), 6.5 (11%), and 14 ns (7%). Upon deaeration of the solution of PN8 in toluene, the fluorescence quantum yield increases to 0.38. The fluorescence decay of the deaerated solution of PN8 is also multiexponential, with decay times of 0.07 (62% amplitude), 1.2 (10%), 6.5 (9%), and 22.2 ns (19%) (see Supporting Information). For PN8 as well as for similar electron-donor–acceptor compounds, short decay times—that is, relative to the lifetime of unquenched PDI (6.5 ns)—reflect FET from the LES to the CSS, whereas longer decay times are associated with RET from the CSS to the LES.[3a–c] For such compounds, delayed fluorescence (long decay times) is a characteristic of RET (Figure 1a, with the CSS at level 2). Upon deaeration of the solution of PN8 in toluene, the long decay time related to delayed fluorescence increases both in value and in contribution (see Supporting Information) as does the fluorescence quantum yield. This suggests that O₂ influences the deactivation of the CSS and therefore plays a role in the dynamics of RET in PN8. Nanosecond-transient absorption data of the deaerated and aerated solutions of PN8 in toluene strongly support the previous assumption (see Supporting Information).

For PN8, because of a rather large edge-to-edge donor–acceptor distance,[3b] the singlet (¹CSS) and the triplet (³CSS) charge-separated states lie close in energy, which allows intersystem crossing (ISC) to occur through hyperfine coupling interactions.[4,5] Moving from the unsubstituted PDI to PN8, the quantum yield of fluorescence in toluene drops from 1 to 0.38, which suggests that charge recombination in PN8 does not take place only through the LES state. From ¹CSS, charge recombination can also occur through ISC to the locally excited triplet (LET) state, either directly or, more likely, via ³CSS (Figure 1a).[3c,4] Nanosecond-transient absorption data (see Supporting Information) strongly suggest that the triplet and the charge separation states are interconnected in PN8. O₂ enhances ISC from the ¹CSS to the ³CSS and LET states (Figure 1b, pathways indicated by thick arrows) which leads to enhanced charge recombination and a decrease in the fluorescence quantum yield of PN8.[4,5]

probed at the single-molecule level if the excited chromophore shows both a high quantum yield of fluorescence and long-term photostability. We have shown previously that single molecules of a perylenediimide–triphenylamine (PDI–TPA)-based dendrimer, which are embedded in polystyrene, undergo photoinduced reversible electron transfer upon excitation at λ = 543 nm.[3a,b] Herein we focus on a first generation rigid polyphenylene dendrimer, PN8, which contains a PDI core as an electron acceptor and eight TPA electron donor moities at the rim (Figure 1c)—a system we have shown previously to be capable of undergoing photoinduced reversible electron transfer.[3b]

In an apolar solvent (methylcyclohexane), PN8 shows a quantum yield of fluorescence that approaches unity, and the fluorescence (λ_exc = 543 nm, λ_em = 600 nm) decays monoexponentially with a lifetime of 6.5 ns (see Supporting Information): a value that is characteristic for unquenched PDI. In this case, the CSS lies at a higher energy than the LES and no ET occurs (Figure 1a, with the CSS at level 1). In aerated toluene, the fluorescence quantum yield of PN8 drops to 0.14 and the fluorescence decay becomes multiexponential with

Communications

According to time-correlated single-photon counting (TCSPC) data from the entire ensemble of PN8 molecules in solution in deaerated toluene, 9% of the molecules do not undergo ET processes—they have a fluorescence lifetime that is characteristic of that of unquenched PDI. By single-molecule detection, we can selectively identify molecules that do undergo RET because this phenomenon relates to the observation of delayed fluorescence.

Observation of single molecules on a longer timescale requires their immobilization. Here we immobilized single molecules of PN8 in polystyrene (PS) as this polymer is comparable to toluene in terms of polarity and polarizability.[3a,b] Figure 2 shows a fluorescence lifetime image of single PN8 molecules in PS ($\lambda_{exc} = 543$ nm, 20×20 μm^2, see Supporting Information). In the image, single PN8 molecules that undergo RET can be easily identified by their decay times, which are longer than the lifetime of unquenched PDI ($\tau \approx$ 6 ns). This allows the dynamics of RET in PN8 as well as the role of O_2 on the radiationless deactivation of the CSS to be probed at the single-molecule level.
Figure 2. Fluorescence lifetime image ($\lambda_{exc} = 543$ nm; 20×20 μm^2, 100×100 pixels^2, 10 ms pixel^{-1}) of a polystyrene (PS) film that contains single molecules of PN8.

Figure 3. A) Fluorescence intensity (*I* represents the number of counts per 10 ms) and B) decay time (τ) trajectories recorded from a single molecule of PN8 in PS by alternating the atmosphere from (a) N_2 to (b) air and (c) back to N_2. C), D), and E) show the autocorrelations (AC) of the fluorescence intensity (parts (a), ○) and the fluorescence decays (I_F (a.u.), parts (b), ○, 1000 photons) that correspond to part A) (a), (b), and (c), respectively. Exponential fits (——) are also shown.

Figure 3, A and B, show the fluorescence intensity and decay time trajectories, respectively, of a single molecule of PN8 (immobilized in PS) undergoing reversible photoinduced electron transfer. The data were recorded by alternating a stream of either nitrogen (N_2) or air over the sample of the single molecule. Initially, under N_2 atmosphere (Figure 3 A and B, a), an average photon count rate of 30 counts per 10 ms and a decay time of 22 ns were detected. After switching to an air atmosphere (Figure 3 A and B, b), decreases in both the count rate, to 10 counts per 10 ms, and the decay time, to 10 ns, were observed Switching back to a N_2 atmosphere (Figure 3 A and B, c) resulted in a partial increase in both the count rate, to 20 counts per 10 ms, and the decay time, to 16 ns.[6] Typical single-molecule fluorescence decay profiles (1000 photons) that correspond to the regions a, b, and c are shown in Figure 3 C–E, parts b, respectively. Data for a single PN8 molecule that undergoes RET in an alternating atmosphere prove that O_2 influences the decay of the CSS by enhancing ISC, which leads to radiationless deactivation of

the CSS to the ground state. Indeed, both the fluorescence intensity (Figure 3 A) and the decay times of RET decrease (or increase) when the concentration of O_2 is increased (or decreased).

For the single molecule of PN8 under an alternating atmosphere, on/off dynamics can be seen in the fluorescence intensity trajectory, especially under a N_2 atmosphere (Figure 4 a). To capture the timescale of such dynamics, we computed the autocorrelation (AC) of the fluorescence intensity $AC = \langle I(t)I(t+\Delta t)\rangle/\langle I\rangle^2$ with the intensities $I(t)$ and $I(t+\Delta t)$ at times t and $t+\Delta t$, respectively (see Supporting Information). Figure 3 C–E, parts a, show the autocorrelation of the fluorescence intensity (AC) for the regions a, b, and c, respectively. For region a, the AC decays biexponentially with offtimes of 0.4 ms (90% weight) and 700 ms (10%). When O_2 is present (b), the AC shows only a slow and low contributing component of 900 ms. Restoring the N_2 atmosphere (c), we again detect fast on/off dynamics with an offtime of 0.35 ms (90% weight), together with slow on/off dynamics with an offtime of 1000 ms (10%).

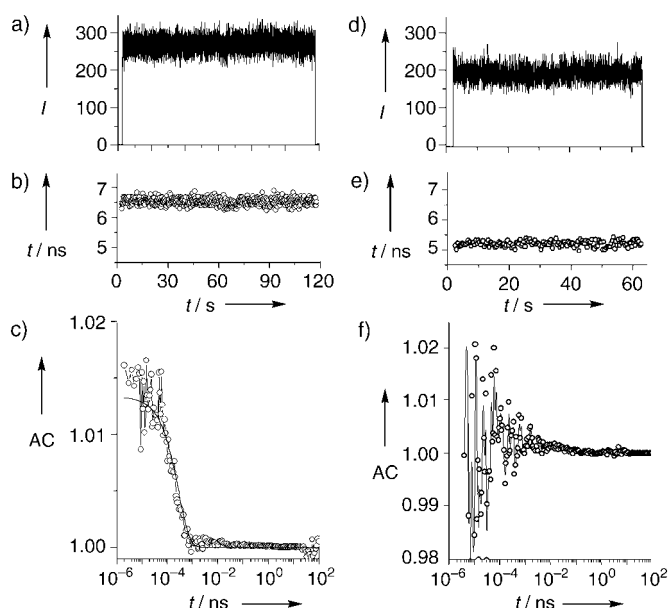
a) ... d) ...
b) ... e) ...
c) ... f) ...


Figure 4. a) Fluorescence intensity ($I =$ counts per 10 ms) and b) lifetime (1000 photons per decay) trajectories from a single molecule of PN0 in polystyrene under a N_2 atmosphere; c) the autocorrelation (AC) of the single molecule which corresponds to parts a–b; d) fluorescence intensity and e) lifetime (1000 photons per decay) trajectories from a single molecule of unsubstituted PDI in polystyrene under an O_2 atmosphere; f) the AC of the single molecule that corresponds to panels d–e.

The fast on/off dynamics that were detected in the fluorescence intensity of single PN8 molecules that undergo RET, which is only observed under a N_2 atmosphere, relates to the population of the LET state (Figure 1a). Similar fast on/off dynamics were detected in the fluorescence intensity of single molecules of a model compound, which did not have rim-substituted amine groups (PN0) and which was embedded in PS, again only under N_2 atmosphere (Figure 4a–c). Under N_2 atmosphere, a single molecule of PN0 emits fluorescence with one stable intensity level (Figure 4a, average count rate: 280 counts per 10 ms) and a lifetime of ≈ 6.5 ns (Figure 4b), and the AC from such a single molecule of PN0 decays monoexponentially with an offtime of 0.3 ms, which relates to the population of the triplet state (Figure 4c). In the presence of O_2, a small decrease in both the fluorescence intensity and lifetime of a single PN0 molecule was detected (Figure 4, d and e) as well as the disappearance of the fast on/off dynamics in the related AC (Figure 4f). The decay of the triplet was faster than the time resolution of the experiment (µs). However, the contribution of the off-events was significantly smaller in single molecules of PN0 (Figure 4c) relative to single molecules of PN8 (Figure 3C, a), which suggests that triplet formation in PN8 (in PS) is strongly enhanced through the formation of a radical-ion-pair that can recombine through ISC to the LET state (Figure 1a). In an aerated atmosphere, because O_2 is an efficient triplet quencher, the off-events become shorter than the experimental bin time (µs) and do not contribute to the decay of the AC (Figure 3D, a) for PN8; Figure 4f for PN0). On/off dynamics on the timescale of 0.1–1 ms with offtimes that are sensitive to

the concentration of O_2 were reported previously for single dye molecules, which were embedded in polymers, and these were related to the population of the triplet.[7] The data reported here demonstrate, on a single-molecule level, that 1) O_2 influences the dichotomy between the return from the CSS to the LES or to the GS and 2) owing to the formation of a radical anion, the population of the triplet state and hence the quantum yield for ISC are strongly enhanced. From the data for single molecules under a N_2 atmosphere, we estimate quantum yields for the ISC process of 10^{-4} and 10^{-2} for PN0 and PN8, respectively.[8]

Single molecules of PN0 in PS do not show slow on/off dynamics (Figure 4, c and f). Therefore, the slow on/off process present in the fluorescence emission of single molecules of PN8 that undergo reversible photoinduced electron transfer must be related to the interaction between the PDI acceptor and the rim-substituted TPA donors—that is, to the presence of the radical anion. RET occurs in a single molecule of PN8 only if the local environment—that is, the polymer—has a polarity such that the CSS and the LES lie close in energy (Figure 1a, with the CSS at level 2). We have shown previously in a single-molecule study on RET that motion of the polystyrene chain can induce fluctuations on the second timescale in the RET-related decay times of single molecules of PN8.[3b] The polymer can therefore modulate the local polarity of the rim-substituted donors through its chain motion to influence the feasibility of charge separation. This can be regarded as a density of states in which the energy of the CSS of the single molecule fluctuates with the motion of the polymer (Figure 1a, with the density of states for the CSS drawn as a Gauss envelope). If the CSS becomes more stabilized than the LES owing to polymer chain motion (Figure 1a, with the CSS at level 3), charge recombination from the CSS will take place only to the ground state (GS) either directly or via the LET state; that is, only through a nonradiative pathway. If so, the fluorescence of a single molecule of PN8 will be interrupted as long as the CSS lies at lower energy than the LES, with a time interval in which the molecule can undergo many optical excitation cycles. If the polymer chain reorients such that the CSS and the LES state become close again in energy, the pathway for charge recombination through the LES state becomes available again and fluorescence is restored. Polymer chain motion will impose, with its own timescale,[9] the length of the dark periods in the fluorescence emission of a single molecule of PN8 that undergoes reversible photoinduced electron transfer. Indeed, the timescale of the slow dynamics is independent of the presence/absence of O_2, within experimental error (Figure 3C–E, a), as it is dictated by the polymer motion. Only the frequency of such off-events will be influenced by O_2 whose presence enhances ISC from the ^{1}CSS to the ^{3}CSS and LET states. Slow on/off dynamics were observed in the fluorescence intensity of single perylenediimide dimers, and this observation was suggested to be connected to the population of a nonfluorescent ion-pair state.[2g]

In summary, we have shown that the deactivation of the CSS either to the LES state or to the GS for a single molecule can be influenced in a reversible fashion[6] by the modification of the local O_2 concentration. Furthermore, we have shown

Communications

that polymer chain motion can induce "off" periods in the emission of a single molecule that undergoes ET; the length of such periods reflects the timescale of the polymer motion. This suggests that electron donor–acceptor systems such as PN8 can be used as single-molecule probes for polymer dynamics. To our knowledge, this is the first report, which involves single molecules, that demonstrates the influence of molecular oxygen on the radiationless deactivation of the CSS to the GS for an electron donor–acceptor system as well as of the role of polymer motion on the dynamics of fluorescence of a single molecule that undergoes electron transfer.

Experimental Section

PN8 and PN0 were prepared according to reported methods.[10] Ensemble experiments were performed on aerated and degassed (freeze–pump–thaw cycles) of solutions (10^{-5} M) in toluene. Details on bulk-phase stationary and time-resolved experiments are provided in the Supporting Information. For single-molecule detection, a solution of either PN8 or PN0 (10^{-10} M) in chloroform was mixed with the polymer (PS), and the mixture was spin-coated onto a cover glass. Single-molecule experiments were performed upon 543-nm pulsed (laser) excitation on a scanning stage confocal microscope.[11] Experimental details and data analysis are provided in the Supporting Information.

[6] For the single molecule of PN8 in an alternating air/N_2 atmosphere, the fluorescence intensity and decay times from (c) do not recover completely to the original values from (a). Possible reasons for this observation are either differences in the local O_2 concentration, mainly because not all of the O_2 was removed, or long-lived fluctuations of the polymer that lead to an energetically different CSS of the single molecule.

[+] Crystal structure analysis.

coordinated P,O-phosphanyl enolates in a moiety such as **1** also display a very rich reactivity based on their intrinsic ambient behavior.[1–3] Harder electrophiles, such as chlorophosphanes, generally react at the oxygen atom,[4] whereas softer electrophiles, for example, activated alkynes,[5] CO_2, or RNCO,[6] bind to the prochiral carbon center.

Figure 1. ORTEP view of the structure of complex **4** in **4**·SO_3CF_3·0.5CH_2Cl_2. Only the *ipso* aryl carbon atoms on P1 and P2 are shown for clarity. Thermal ellipsoids enclose 50% of the electron density.
The latter selectivity also applies to late-transition metals and opens an interesting route to (hetero)dimetallic complexes in which the PC carbon atom has become sp^3 hybridized.[7] Although control of the stereochemistry at the PC carbon atom is possible,[8] the generation of both the *R* and *S*-configured stereogenic P-C centers is generally expected.

We thus considered that replacing the PCH functionality with the isoelectronic PN group of phosphanyl iminolates (**2**) might simplify this issue, since the nitrogen atom could retain a planar coordination geometry. Furthermore, the simple exchange of a CH group by an N atom can bring about interesting electronic and geometric differences in molecular complexes, as shown with the phosphanes $Ph_2PNHC(O)R$ and $Ph_2PCH_2C(O)R$,[9] or induce unexpectedly large effects in supramolecular chemistry.[10]

We have now found that metal coordination at the nitrogen atom of the P,O chelate in a complex of type **2**: 1) readily leads to (μ-P,N)-bridged heterodimetallic complexes, 2) occurs with retention of the planar coordination geometry at the nitrogen atom, and rather unexpectedly 3) opens an unprecedented route to ordered structures containing alternating metals in heterodimetallic units to form oriented, 1D coordination/organometallic polymers.

The new, air-stable complex **3**[11] was treated with one equivalent of [Au(PPh$_3$)]BF$_4$ in THF to afford **4**·BF$_4$ [Eq. (1)] and the structure of the analogous complex **4**·SO_3CF_3 was determined by X-ray diffraction analysis (Figure 1 and see the Supporting Information).[11]
N-metalation leads to an Au···N distance of 2.085(6) Å, similar to those found in complexes with a covalent Au–N bond in an Au-NPPh$_2$ moiety.[12] The coordination geometry around the nitrogen atom is planar, with the sum of the three bond angles around N(2) being 360.0(3)° (max deviation out of the mean plane containing the atoms Pd, P1, N2, C10, O1,
and Au: 0.01 Å).[13] Accordingly, the NCH$_2$ protons only show a doublet in the ¹H NMR spectrum as a result of coupling to the P atom. The O1–C10 and N2–C10 bond lengths of 1.273(9) and 1.353(9) Å, respectively, are consistent with C⚌O and N⚌C bond orders intermediate between single and double bonds.[7,9,14]

A solution of **3** in THF was then treated with pure, acid-free AgSO$_3$CF$_3$ in a 1:1 stoichiometry, and slow crystallization afforded high yields of a beige product **5**·SO$_3$CF$_3$ [Eq. (2)], which was shown by X-ray diffraction studies to be an unprecedented Ag-Pd coordination polymer (Figure 2 and see the Supporting Information).[11]

(2)
The Ag$^+$ ion is, as anticipated, linked to the iminolate nitrogen atom, which retains its planar coordination geometry (sum of the three bond angles around N2 = 359.5(3)°; Ag···N = 2.133(3) Å; see the Supporting Information). If only a covalent Ag–N interaction was present, the silver center would remain, with 12 electrons, coordinatively unsaturated. It was therefore expected to interact with the triflate oxygen atom(s),[15] as observed in other cases,[16] but it prefers to find the required additional electron density in the Pd–C1 σ bond involving the cyclometalated ligand of another complex molecule (Figure 2). This situation is best described as a multicentered interaction resulting in the donation of σ- and π-electron density from the Pd–C1 (p_z orbital) and Pd-bound aryl regions to the coordinatively unsaturated silver center.

Figure 2. ORTEP view of the structure of the "repeat unit" Ag₂Pd₂ of the polymeric complex **5** in **5·SO₃CF₃·2CH₂Cl₂**. Only the *ipso* aryl carbon atoms on P are shown for clarity. Thermal ellipsoids enclose 50% of the electron density.

The electronic transfer occurs from the d^8 Pd^{II} center to the d^{10} Ag^I center and results in a relatively short Ag–C1 bonding distance of 2.263(4) Å,[17] and in one of the shortest Pd–Ag bonds (2.884(1) Å) reported in the literature.[17a, 18] Since two consecutive square-planar Pd^{II} units are almost orthogonal to each other (see the Supporting Information), the structural repeating unit in the extended structure is Ag₂Pd₂ (Figure 2), which results in a novel, oriented, 1D coordination/organometallic wire structure in which the metal centers are situated in the *ab* plane (Figure 3). A view along the *a* axis (see the Supporting Information) shows the adjacent rows of silver atoms flanked by two rows of palladium atoms and illustrates another remarkable feature resulting from the arrangement of these infinite zigzag chains in the solid state: the lipophilic aromatic rings are all on one side of the metal planes and this results in an unusual layered structure (see Figure 4). Attempts to obtain an analogous Ag-Pd extended structure from the isovalent phosphanyl enolate/Pd^{II} complex have remained unsuccessful, which emphasizes the differences that may result from the replacement of the CH group in **1** by an N atom in **2**.

The mass spectrum (MALDI-TOF) of **5·SO₃CF₃** contains two main peaks at *m/z* 483 for [**3**+H]⁺ and 1073, whose characteristic isotopic pattern indicates the composition [Ag(**3**)₂]⁺. The structure of [Ag(**3**)₂]⁺ cannot be predicted
Figure 3. View in the *ab* plane of the zigzag wire structure of the polymeric complex structure of **5** in **5·SO₃CF₃·2CH₂Cl₂**.

with certainty to reproduce the alternate bonding pattern observed for **5** and is referred as the type II structure in Scheme 1.

Indeed, two bonding modes in which an Ag⁺ ion is coordinated to the same site of two molecules of **3** should also be considered. In a type I structure, the donation pattern can be viewed as intermediate between two limiting forms in which one nitrogen atom acts as a two-electron donor and the other as a two-electron or one-electron donor ligand, respectively. In such a model, part of the electron density from the nitrogen lone pair of electrons is transferred to the π system, thus increasing the covalent character of the Ag–N bond and affecting in return the geometry of the phosphanyl iminolate ligands. A further possibility to be considered is the
Scheme 1. Hypothetical discrete structures formed from **3** and Ag⁺ ions in a 2:1 ratio. Type (I) corresponds to the actual structures of complex **6**.
Figure 4. Projection in the *a,c* plane of the layered structure of **5** in **5**·SO$_3$CF$_3$·2CH$_2$Cl$_2$. The space between the pairs of metal-rich layers contains the phenyl rings, the triflate anions, and solvent molecules (Ag green, Pd pink, N blue, P yellow, O orange).

formation of a complex of type (III), in which each neutral molecule of **3** behaves as an electron donor through its Pd—C σ bond and its extended Pd—aryl π system (only the transoid structure is depicted in Scheme 1).

Extended Hückel (EHT) and density functional theory (DFT) calculations have been carried out on a series of discrete structures featuring the various types of attachment that can be expected between the Ag$^+$ ion and one or two molecules of **3′**, a model of **3** in which the methyl and phenyl substituents have been replaced with hydrogen atoms. A model (**4′**) of the gold complex was also investigated. Technical details of the calculations, Cartesian coordinates of the optimized structures with selected interatomic distances, and an extensive discussion of the results are available in the Supporting Information. The most important conclusions of the theoretical study are as follows:

a) The amount of electron transfer to the Ag$^+$ ion is equivalent in the two bonding modes symbolized as Ag$^+$—N and Ag$^+$—(Pd—C). However, the nature of the two donation processes is quite different: concentrated, directional, and originating from a single source (the in-plane p orbital of N) for N→Ag$^+$; soft, diffuse, multicentered, and long-range for (Pd—C)→Ag$^+$. In the latter case, a variety of donor centers could interact with the Ag$^+$ ion, with the most important being the Pd—C1 σ bond (20%); the d shell of Pd (17%) and the π orbitals of C1 (20%), C2 and C6 (27%), and C4 (10%). Both types of calculations predict that the Ag$^+$—N and the Ag$^+$—(Pd—C) bonding modes are competitive in terms of electron-transfer and bonding energy. This description confirms the dual bonding ability of **3′** and **3**, which was substantiated by the synthesis of (**5**·SO$_3$CF$_3$)$_n$, and suggests that the production of monocationic, trinuclear Pd/Ag/Pd complexes could be achieved by a careful tuning of the

Ag$^+$ supply. Such a discrete complex was indeed obtained subsequently (see below).

b) The complexation of an Ag$^+$ ion to one molecule of **3′** is computed to be exothermic by 2.88 eV and 2.79 eV for the Ag$^+$—N and Ag$^+$—(Pd—C) forms, respectively, compared to 1.82 eV calculated for the η^1 coordination of an Ag$^+$ ion to benzene. The complexation energies calculated for the three forms of [Ag(**3′**)$_2$]$^+$ are −5.15 eV for N-Ag$^+$-N (type I in Scheme 1), −4.71 eV for type II, and −4.36 eV for type III. The energy associated with the coordination of a second molecule of **3′** is just slightly reduced with respect to the first complexation for the type I system, but somewhat more for type III. At variance with the polymer, it was clear from these results that a type I structure should be predicted for [Ag(**3**)$_2$]$^+$.

This theoretical prediction was actually verified by the reaction between AgSO$_3$CF$_3$ and two equivalents of **3** affording the AgPd$_2$ complex **6**·SO$_3$CF$_3$ in 92% yield. The crystal-structure analysis of this complex established indeed that the coordination of both molecules of **3** to Ag$^+$ occurred through their nitrogen atoms (type I in Scheme 1; see Figure 5
Figure 5. ORTEP view of the structure of **6**·SO$_3$CF$_3$. Only the *ipso* aryl carbon atoms on P1 and P2 are shown for clarity. Thermal ellipsoids enclose 50% of the electron density.

and the Supporting Information).[11] The N2-Ag-N4 angle of 175.4(2)° allows a coordination number of two to be formally assigned to the silver ion, a situation which occurs in less than 25% of the structures of Ag^I complexes.[19] However, a weak electrostatic interaction probably exists between the triflate anion and the Ag$^+$ ion, with the Ag···O3 distance of 2.82(1) Å being nevertheless in the upper range of those found on the CSD (version 5.25) which are in most cases between 2.38 and 2.55 Å (for comparison, the nearest triflate oxygen atom is at 3.86(2) Å from Ag$^+$ in **5**·SO$_3$CF$_3$·2CH$_2$Cl$_2$). The dihedral angle between the two best Pd^{II} square planes is 75(2)°.

Although the term "coordination polymers" was first coined 40 years ago,[20] the corresponding research area continues to gain increasing importance.[21] Furthermore, the considerable current interest in extended metal atom chains (EMACs)[22] is partly a consequence of their expected unique and challenging physical properties.[17c,23–27] While the linking

Communications

of *homo*dinuclear units through (weak) metal–metal bonding or suitable ligands allows the formation of exciting coordination polymers,[24,25,27] we believe that the structure of **5·SO₃CF₃** is not only an unprecedented example of perfectly alternating and ordered 1D *hetero*dimetallic polymeric structure, and the first molecular wire containing Ag–Pd bonds, but that its synthesis reaches beyond the realm of extended structures in purely inorganic chemistry[28] and opens up new perspectives in coordination/organometallic supramolecular chemistry.

Amine Synthesis

Asymmetric Synthesis of Diarylmethyl Amines by Rhodium-Catalyzed Asymmetric Addition of Aryl Titanium Reagents to Imines**

Tamio Hayashi,* Masahiro Kawai, and Norihito Tokunaga

Asymmetric synthesis of diarylmethyl amines has attracted growing attention owing to their importance in biological activity.[1] Among several methods for performing the asymmetric synthesis,[2,3] catalytic asymmetric addition of aryl metal reagents to imine derivatives seems to be most promising, provided that both high enantioselectivity and high catalytic activity are realized.[4] After our publication on the rhodium-catalyzed asymmetric addition of aryl stannanes to *N*-sulfonylimines,[5] two reports appeared on catalytic asymmetric arylation: 1) Bräse, Bolm, and co-workers described the addition of a phenylzinc reagent to masked *N*-formylimines in the presence of a chiral ketimine catalyst,[6] and 2) Tomioka illustrated the rhodium-catalyzed addition of aryl boroxines to *N*-tosylimines in which high enantioselectivity was observed for sterically tuned aryl imines.[7] Herein we report another rhodium-catalyzed asymmetric arylation in which the addition of aryl titanium reagents to sulfonylimines proceeds with high enantioselectivity under mild conditions (20°C, 1 h) to give diarylmethyl amines with up to 96% *ee*.

During our studies on rhodium-catalyzed asymmetric 1,4-additions to α,β-unsaturated ketones,[8] we found that the phenyltitanium reagent $PhTi(OiPr)_3$ is highly reactive toward transmetalation and forms a phenyl–rhodium bond. In the presence of a rhodium/(*S*)-binap catalyst in THF at 20°C, the catalytic 1,4-addition gives titanium enolates as 1,4-addition products with high enantioselectivity.[9] Under similar reaction conditions (Scheme 1), the addition of $PhTi(OiPr)_3$[10] (**4a**) to *N*-tosylarylimine **1a**, which was prepared from 4-trifluoromethylbenzaldehyde and 4-toluenesulfonamide,[11] took place rapidly to give the tosylamide of diarylmethyl amine **5aa** after aqueous workup, unfortunately with only 28% *ee* (Table 1, entry 1). The use of (*S*)-H_8-binap[12] and (*S*)-segphos[13] in place of (*S*)-binap[14] improved the enantioselectivity up to 43% and 76% *ee*, respectively (Table 1, entries 4 and 6). The relatively narrow dihedral angle of the biaryl bisphosphine ligand segphos[14] is considered to exert a positive influence on the enantioselectivity in the present

[a] The reaction was carried out in THF at 20 °C for 1 h with **4a** (2 equiv) in the presence of the catalyst generated from [{RhCl(C₂H₄)₂}₂] and a chiral phosphine ligand. [b] Yields of isolated amines (column chromatography: silica gel, hexane/EtOAc (2:1)). [c] Determined by HPLC analysis with a chiral stationary phase column (Chiralcel OD-H: hexane/2-propanol = 80:20 for **5aa** and **6aa**; hexane/2-propanol = 98:2 for **7aa**.). [d] The configurations of the amines were assigned by consideration of the stereochemical reaction pathway (see text).

asymmetric phenylation, although the enantioselectivity is still not satisfactory.

For the asymmetric 1,4-addition to α,β-unsaturated ketones,[15] esters,[16] and alkenylphosphonates[17] catalyzed by a rhodium complex coordinated with (S)-binap, we have proposed stereorecognition models that successfully rationalize the absolute configuration of the products. By applying this type of model to the present reaction of N-alkylidene sulfonamides,[18] it is evident that the enantioface of the imine is recognized by steric repulsions between one of the phenyl rings on the diphenylphosphino group and the aromatic ring on the arene sulfonamide (Scheme 2). Steric tuning of the arene sulfonamide moiety by introduction of sterically bulky groups onto the aromatic ring actually brought about enhancement of the enantioselectivity to an acceptable level. Thus, the asymmetric addition of phenyltitanium **4a** to mesitylenesulfonamide **2a** and triisopropylbenzenesulfonamide **3a** catalyzed by rhodium/(S)-binap gave the corre-

sponding phenylation products **6aa** and **7aa** with 49 and 71% ee, respectively (Table 1, entries 2 and 3). The higher enantioselectivity in the asymmetric addition to triisopropylbenzenesulfonamide (**3a**) was also observed in the reaction catalyzed by the rhodium complexes of (S)-H₈-binap and (S)-segphos (Table 1, entries 5 and 8). The combination of (S)-segphos and triisopropylbenzenesulfonamide **3a** gave the diarylmethylamine (R)-**7aa** with 93% ee (Table 1, entry 8).
The present asymmetric phenylation with phenyltitanium **4a** catalyzed by rhodium/(S)-segphos was also successful for triisopropylbenzenesulfonamides of other aromatic imines **3**. The aromatic imines substituted with chloro (**3b**), fluoro (**3c**), and methoxy (**3d**) at the 4-position of the phenyl and the imines **3e–g** derived from 2-MeC₆H₄CHO, 3-MeOC₆H₄CHO, and 1-naphthaldehyde, respectively, gave the corresponding sulfonamides of diarylmethyl amines (R)-**7** in high yields (Scheme 3). The enantioselectivity ranged from 86 to 96% ee
Scheme 3. Asymmetric arylation of imines **3** with ArTi(O*i*Pr)₃ (**4**) catalyzed by rhodium/(S)-segphos.

(Table 2, entries 2–7). The reaction of aryl titanium reagents **4b–d** (with the fluoro or methoxy group at the 3- or 4-position on the phenyl ring) also proceeded with high enantioselectivity (Table 2, entries 8–11). The reaction of imine **3h** with 4-fluorophenyltitanium **4b**, which is a reverse combination of the reaction of **3c** with **4a**, gave the *S* isomer of (4-fluorophenyl)(phenyl)methylamine **7ca** (93% *ee*) in quantitative yield (Table 2, entry 8). The reaction of 4-methoxyphenyltitanium **4d** with imines **3a** and **3b** proceeded as well to give diarylmethyl amines in which both aryl groups are substituted phenyls (Table 2, entries 10 and 11).

Table 2: Asymmetric arylation of imines **3** with ArTi(O*i*Pr)₃ (**4**) catalyzed by rhodium/(*S*)-segphos.[a]

Entry	3	4	T [°C]	Yield [%][b]	ee [%][c, d]

[a] The reaction was carried out in THF at the given temperature for 1 h with **4** (2 equiv) in the presence of the catalyst (3 mol%) generated from [{RhCl(C₂H₄)₂}₂] and (*S*)-segphos. [b] Yields of isolated amines (column chromatography: silica gel, hexane/EtOAc (2:1)). [c] Determined by HPLC analysis with a chiral stationary phase column (Chiralcel OD-H: hexane/2-propanol = 98:2 for **7aa**, **7ba**, **7ca**, **7da**, **7hb**; hexane/2-propanol = 100:1 for **7ga**, **7ad**, **7bd**. Chiralcel AD-H: hexane/2-propanol = 98:2 for **7ea**, **7fa**). [d] The absolute configurations of **7ba**, **7da**, **7ga** were determined by comparison of the specific rotations of free amines **8** or their derivatives (see text). For other products, the configurations were assigned by consideration of the stereochemical reaction pathway. [e] The sulfonamide of (phenyl)(4-biphenylyl)methylamine was formed in 3% yield. [f] For 5 h. [g] Enantiomer of **7ca**. [h] Enantiomer of **7ea**.

The 2,4,6-triisopropylbenzenesulfonyl group[19] was removed from the diarylmethyl amines by standard methods for the deprotection of *p*-toluenesulfonamides (Scheme 4).[20] Treatment of **7da** (Ar¹ = 4-MeOC₆H₄) with lithium in liquid ammonia at −78°C gave free amine **8da** in quantitative yield without loss of its enantiomeric purity. For **7ba** (Ar¹ = 4-ClC₆H₄) and **7ga** (Ar¹ = 1-naphthyl), the deprotection with
For **7ba** (Ar¹ = 4-ClC₆H₄): SmI₂, HMPA, THF, reflux, 1 h: 53%
For **7da** (Ar¹ = 4-MeOC₆H₄): Li/NH₃ (liq), THF, −78 °C, 20 min: 100%
For **7ga** (Ar¹ = 1-naphthyl): RedAl, toluene, 80 °C, 5 h: 76%

Scheme 4. Deprotection of the sulfonamide.

lithium in ammonia was accompanied by reduction of the aryl groups to a considerable extent: 4-ClC₆H₄ and 1-naphthyl gave phenyl and tetrahydronaphthyl, respectively. The deprotection was more selective with samarium iodide in HMPA/THF and RedAl in toluene for **7ba** and **7ga**, respectively.

In summary, the asymmetric synthesis of diarylmethyl amines was realized by rhodium-catalyzed asymmetric addition of aryl titanium reagents to *N*-alkylidene sulfonamides. A rational tuning of the arene sulfonamide moiety by introducing isopropyl groups onto the phenyl ring brought about high enantioselectivity (86–96% *ee*).

Communications

M = Ga, Al) reagents to prepare gold cluster complexes of gold–electropositive metals.

First, "[Cp*Ga/GaI]", which was prepared by the addition of Cp*K·DME (DME = 1,2-dimethoxyethane) to GaI[20] in a ratio of $\approx$1:2, was added to a solution of [(Ph$_3$P)AuCl] in dichloromethane. The resulting orange solution contained the known[21,22] gold cluster [(Ph$_3$P)$_6$Au$_6$]$^{2+}$, which indicated that the gallium reagent had reduced the gold(I) centers but failed to coordinate the resulting reduced Au species. In contrast, reversing the order of addition of the components such that [(Ph$_3$P)AuCl] was added to excess "[Cp*Ga/GaI]" instead yielded a yellow solution from which air-sensitive orange-yellow crystals of the phosphine-free gold–gallium cluster complex [Au$_3$(μ-GaI$_2$)$_3$(Cp*Ga)$_5$] (**1**, see Scheme 1) were isolated.[23]

A Gallium-Coated Gold Cluster**

U. Anandhi and Paul R. Sharp

There is much interest in the properties of gold in heterogeneous catalysis,[1–3] supramolecular chemistry,[4] nanochemistry,[1] cluster-complex chemistry,[5] luminescent complexes,[6] and intermetallic compounds and alloys.[7–12] Much of this interest centers on gold–gold and gold–other metal interactions. For applications in catalysis and intermetallic chemistry, the combination of gold—the most electronegative metal—with electropositive metals yields gold in formal negative oxidation states (aurides) or materials with strongly polarized gold–electropositive metal bonds.[2, 9–13] In this report, we describe the first complex that contains a Au–Ga bond which is also the first gold cluster complex in which the gold atoms are bonded only to an electropositive main-group metal.[14]

Recent advances in group 13 chemistry have provided reagents of low-valent electropositive group 13 metals that can function as ligands and as reducing agents.[15–19] With these properties in mind, we investigated reactions of gold(I) complexes with Cp*M (Cp* = pentamethylcyclopentadienyl;

Scheme 1. Isolation of the gold–gallium cluster complex [Au$_3$(μ-GaI$_2$)$_3$(Cp*Ga)$_5$] (**1**).

A yellow solid **2** was also isolated which spectroscopic data suggested was [(Ph$_3$P)$_n$Au]$^+$ (n = 2–3)[24–26] The addition of PCy$_3$ (Cy = cyclohexyl) to solutions of **2** gave rise to peaks in the ^{31}P NMR spectrum which were associated with free PPh$_3$ and [(Cy$_3$P)$_2$Au]$^+$; PCy$_3$ does not form *tris* adducts.[27] The nature of the anion in **2** in solution was more difficult to define. The data obtained indicated the presence of several different Cp*Ga-containing ions at ambient temperatures that were exchanging rapidly on the ^{1}H and ^{13}C NMR timescale. At ambient temperature, ^{1}H and ^{13}C NMR spectra showed a single peak for Cp*, whereas ^{1}H NMR spectra at low temperature showed several peaks for Cp*, and ^{71}Ga NMR measurements at ambient temperature displayed several peaks for Ga. To eliminate the possibility of a contribution from chloride ion to this mixture, [(Ph$_3$P)AuI] was used instead of [(Ph$_3$P)AuCl] in the preparation of **1**. The yield of **1** was improved, but the properties of the side product **2** were not significantly altered. Finally, the use of [(Cy$_3$P)AuI] in the preparation yielded a mixture of crystals of **1** and [(Cy$_3$P)$_2$Au]$^+$[Cp*GaI$_3$]$^-$ (**3**) from NMR spectroscopic and X-ray crystal structural analysis.[23] These results point to the presence of several different [(Cp*)$_x$Ga$_y$I$_z$]$^-$ anions (x, y, z = integers) in solutions of **2**. Although anions that comprise polynuclear Ga complexes with Cp* have not been reported, anions which consist of polynuclear Ga complexes with Si(SiMe$_3$)$_3$ have been isolated.[28] Cluster **1** was also prepared in a similar yield from [(Ph$_3$P)AuI] and a mixture of Cp*Ga and GaI$_3$, but in this case, **2** was not formed and the co-products were not isolated or identified.[29]

The molecular structure of cluster **1** in the solid-state[23] is shown in Figure 1. The structure consists of a triangle of gold atoms which is bridged by GaI$_2$ units on its edges. A two-fold

Figure 1. Drawing of [Au₃(μ-GaI₂)₃(Cp*Ga)₅] 1. Hydrogen atoms are omitted for clarity. Only one orientation of the twofold disordered Cp* of Ga2 is shown. Selected distances [Å] and angles [°]: Au1-Au2 2.7256(6), Au1-Au1′ 2.8045(8), Au1-Ga1 2.3840(12), Au1-Ga3 2.6199(13), Au2-Ga2 2.3773(17), Au1-Ga5 2.5325(13), Au2-Ga4 2.5322(12); Au2-Au1-Au1′ 59.04(1), Au1-Au2-Au1′ 61.93(2), Ga1-Au1-Ga3 101.93(5), Au2-Ga4-Au1 65.18(3), Au1-Ga5-Au1′ 67.24(4).

axis along the Ga2–Au2–Ga5 vector relates the two halves of the molecule. The two symmetry-related Au atoms (Au1 and Au1′) are each coordinated by two Cp*Ga units, whereas the third unique gold atom (Au2), which lies on the two-fold axis, is coordinated by only one Cp*Ga unit (Ga2). This Cp*Ga unit also lies on the two-fold axis and results in the disorder of the Cp* group over two positions. The Cp*Ga units are arranged around the Au₃ triangle in approximately axial and equatorial positions. The unique Cp*Ga unit (Ga2) and the Cp*Ga units of Ga1 and Ga1′ occupy axial positions in, or nearly in, the Au₃ plane. The other two Cp*Ga units (Ga3 and Ga3′) are nearly perpendicular to the plane in opposite axial positions to Au1 and Au1′. The absence of an axial Cp*Ga unit on Au2 may result from steric crowding because with three axial ligands, two must be on the same side of the Au₃ plane. The axial Cp*Ga groups lie at a greater distance (Au1–Ga3 = 2.6199(13) Å) from the gold atoms than the equatorial Cp*Ga groups (Au1–Ga1 = 2.3840(12) Å, Au2–Ga2 = 2.3773(17) Å) which suggests a weaker interaction with the former. The axial distance is close to the sum of the single-bond covalent radii of 2.58 Å for Au–Ga.[30] The shorter equatorial distances are comparable to the Pt–Ga bond lengths (average = 2.335 Å) in [Pt(Cp*Ga)₄] after correction for the slightly larger (0.04 Å) covalent radius of Au.[31]

The Cp*(centroid)–Ga distance in Cp*Ga–metal complexes is thought to correlate with the degree of charge transfer from the Ga center to the metal atom.[32] Greater charge transfer results in a smaller radius for gallium and a smaller Cp*(centroid)–Ga distance. The axial Cp*(centroid)–Ga distance of 2.01(1) Å is somewhat smaller than those of Cp*Ga in the solid state (2.081 Å)[33] or in the gas phase (2.081(5) Å)[34] and is similar to [(Cp*Ga)₄Ni] (2.003(4) Å)[32]—a complex which is thought to involve relatively little charge transfer from the Cp*Ga ligand. The

corresponding equatorial distances of 1.89(1) and 1.88(1) Å indicate a greater degree of charge transfer to the gold centers and are similar to that found in [Cp*GaFe(CO)₄] (1.863(4) Å).[35] The two Au–Au distances in 1 (2.7256(6) and 2.8045(8) Å) are shorter than those found in metallic gold (2.884 Å) and are well within the range associated with Au–Au cluster bonds.[5] DFT (density functional theory) calculations also support the presence of Au–Au bonds (see below). The three other known Au₃ clusters have, on average, similar Au–Au distances, although [(dppe)₂Au₃In₃Br₇(thf)]⁻ and [(dppe)₂Au₃In₃Cl₆(thf)₆] (dppe = 1,2-bis(diphenylphosphino)ethane) show much greater variation with one very short distance (2.575(1) and 2.562(1) Å, respectively) and two longer distances (2.860(1) and 2.858(1), and 2.939(1) and 2.931(1) Å, respectively).[36,37] The Au–Au distances (2.764(2), 2.780(3), and 2.757(2) Å) for the symmetric Au₃ cluster [(Cp′Nb)₃Au₃(μ-H)₆] (Cp′ = C₅H₄SiMe₃) are very regular and lie between the two values for 1.[38]

In contrast to the results obtained for 1 in the solid state that indicate three different types of Cp*Ga groups, ¹H and ¹³C NMR spectra of 1 in CD₂Cl₂ show only one signal for the Cp*Ga ligands at 25°C. Lowering the temperature down to −90°C leads to increased broadening of the peak without the resolution of the 1:2:2 pattern expected for the three different Cp* groups. This most likely indicates rapid exchange of the different Cp*Ga groups. No signals were detected in the ⁷¹Ga NMR spectrum at 25°C or at −70°C; the absence of signals in the ⁷¹Ga NMR spectra for several Cp*Ga–Pt complexes has also been reported.[39] Addition of free Cp*Ga to a solution of 1 at 25°C yielded a single peak in the ¹H NMR spectrum which lies between the values for 1 and Cp*Ga. This indicates exchange of free and coordinated Cp*Ga groups. Fluxional behavior and exchange with free Cp*M units has been observed with the linear Pd₃ cluster [Pd₃(Cp*In)₄(μ-Cp*In)₄],[40] but not with dinuclear [Pt₂(Cp*Ga)₂(μ-Cp*Ga)₃] complexes.[31,41]

The above data show the presence of a Au₃ triangular cluster with neutral electron-donor Cp*Ga ligands. However, the presence of the bridging GaI₂ units allows an alternative interpretation of the structure as a six-membered Au–Ga ring without Au–Au bonds.[42] Furthermore, there is ambiguity in the assignment of the oxidation states of the Au centers. With neutral Cp*Ga ligands, the GaI₂ units may be assigned a positive, neutral, or negative charge which corresponds to the oxidation states +3, +2, or +1 of gallium. Corresponding oxidation states for the Au centers would then be −1, 0, or +1. To assist in the resolution of these ambiguities, DFT calculations with the LAN2DZ basis set, which has been shown to be effective for Au clusters,[43] were performed on an analogue of 1 with Cp ligands (Cp = cyclopentadienyl).[29] The optimized structure (no symmetry constraints) corresponded closely to the structure for 1 showing the same axial–equatorial distribution of the CpGa ligands. Isodensity surfaces of the electron-density distribution show the topological features expected for Au₃ and Au₂Ga rings (see Figure 2). Ring critical points in the centers and bond paths[44a] along the Au–Au and Au–Ga bonds are clearly visible and support the view of 1 as a Au₃ cluster ligated by Ga centers. Natural population analysis[44b] atom charges are
Figure 2. Isodensity surfaces of the electron-density distribution (0.035 e a.u.^{3} (top) and 0.039 e a.u.^{3}). Hydrogen atoms are not shown. Atoms and density from slightly above the Au$_3$ plane have been removed for clarity.

provided in Table 1. A small positive charge is assigned to the gold atoms. This charge is nearly equal to those of the bridging gallium atoms (Ga4 and Ga5) which indicates an essentially nonpolar covalent bond and suggests the oxidation assignment of $+2$ for the Ga centers of the GaI$_2$ units and 0 for the Au atoms. Large positive charges are assigned to the Ga atoms of the CpGa ligands (Ga1, Ga2, Ga3) and indicate substantial bond polarization for these Ga–Au bonds. Negative charges reside on the Cp groups and the iodine centers.[29] The polarity of the axial CpGa–Au bond is somewhat less than those of the equatorial bonds; this

Table 1: Calculated atom charges in the Cp analogue of **1**.

Atom	Charge	Atom	Charge
Au1	0.12	Ga1	0.86
Au2	0.16	Ga2	0.90
		Ga3	0.78
		Ga4	0.11
		Ga5	0.11

observation is consistent with the Cp*(centroid)–Ga distances discussed above.

In conclusion, low-valent Ga species are effective reducing reagents for [LAuX] (L = ligand, X = anion) and, when present in excess, they effectively trap the reduced gold centers by ligation. Given the large number of phosphine–gold cluster complexes reported,[22, 45] this bodes well for the synthesis of a new family of group 13 ligated gold cluster complexes. DFT calculations on the Cp analogue of **1** show a Au$_3$ cluster with Au–Au bonds with near-charge-neutral gold atoms and strongly polarized CpGa–Au bonds. Efforts are now underway to prepare the aluminum analogue of **1** and other Au–electropositive metal cluster complexes through a similar approach.

Experimental Section

All manipulations were performed under N$_2$ atmosphere in a dry box (Vacuum Atmospheres Co.) with anhydrous, dioxygen-free solvents.

[Cp*Ga/GaI]:[46] A mixture of Ga metal particles (0.50 g, 7.17 mmol) and I$_2$ (0.91 g, 3.58 mmol) in benzene (10 mL) was sonicated for 12 h at 50°C. KCp*·DME (0.983 g, 3.71 mmol) was added to the resulting pale green suspension of GaI,[20] and the mixture was stirred for 48 h to give a yellow solution and a light gray precipitate. After filtration, the solid was washed with benzene (20 mL), and the combined yellow filtrates were concentrated to yield the title compound as a green-yellow solid, which was used without any further purification (Cp*Ga was not obtained on attempted sublimation of the solid). ^{1}H NMR (C$_6$D$_6$, 250 MHz, 25°C): $\delta = 1.93$ (s, Cp*), 3.01 (s, DME), 3.10 ppm (s, DME); integration ratio of 10:3:2, respectively; ^{71}Ga NMR (C$_6$D$_6$, 91.5 MHz, −70°C): $\delta = -645.6$ ppm (br s, $\omega_{1/2} = 9800$ Hz); no signal was observed at 25°C.

1: [(Ph$_3$P)AuI] (12.5 mg, 21.3 mmol) in CH$_2$Cl$_2$ (4 mL) was added dropwise to [Cp*Ga/GaI] (35.2 mg) in CH$_2$Cl$_2$ (2 mL). Small amounts of gray solid formed and the initial yellow color faded. The reaction mixture was stirred for 5 h and was then passed through diatomaceous earth. The volatiles were removed in vacuo. Addition of diethyl ether to the resulting oily residue gave a pale yellow solid, **2**, and a dark yellow-colored solution, which were separated by filtration. Solid **2** was washed several times with ether until the washings were colorless, and then dried (20.6 mg). The dark yellow filtrate and the ether washings were combined; on standing overnight at room temperature, orange-yellow crystals of **1**, which were suitable for X-ray crystal structure analysis, formed (8.5 mg, 47% based on Au). (The same procedure repeated with [(Ph$_3$P)AuCl] gave similar results.)

Data for **1**: ^{1}H NMR (CD$_2$Cl$_2$, 250 MHz, 25°C): $\delta = 1.15$ (t, 6H, (C*H$_3$*CH$_2$)$_2$O), 2.12 (s, 75H, Cp*), 3.45 ppm (q, 4H, (CH$_3$C*H$_2$*)$_2$O); ^{13}C NMR (CD$_2$Cl$_2$, 75.47 MHz, 25°C): $\delta = 10.17$ (Cp*-*C*H$_3$), 14.98 ((C*H$_3$*CH$_2$)$_2$O), 65.54 ((CH$_3$C*H$_2$*)$_2$O), 114.79 ppm (Cp*-ring); at −70°C, the peaks broaden slightly; Far-IR (Nujol mull, polyethylene plates): $\tilde{\nu} = 468$ cm^{-1} (br, Au–GaCp*); elemental analysis: calcd for C$_{50}$H$_{75}$Au$_3$Ga$_8$I$_6$·C$_4$H$_{10}$O: C 24.38, H 3.22; found: C 24.65, H 3.22.

Data for **2**: ^{1}H NMR (CD$_2$Cl$_2$, 250 MHz, 25°C): $\delta = 1.79$ (s), 7.53–7.22 ppm (m); relative integrations 1.7:1.0; ^{1}H NMR (CD$_2$Cl$_2$, 250 MHz, −70°C): $\delta = 1.74$ & 1.71 (s), 1.63 (s), 7.50–7.06 ppm (m); relative integrations 0.8:0.9:1.0; ^{13}C NMR (CD$_2$Cl$_2$, 62.9 MHz, 25°C): $\delta = 9.16$ (Cp*-CH$_3$), 113.93 (Cp*-ring), 128.88 (t, $J_{C-P} = 15$ Hz), 130.08 (s), 133.17 ppm (d, $J_{C-P} = 50$ Hz); ^{31}P NMR (CD$_2$Cl$_2$, 101.25 MHz, −70°C): $\delta = 19.45$ ppm (s); no signal is observed at 25°C. ^{71}Ga NMR (CH$_2$Cl$_2$, 91.5 MHz, 25°C): $\delta = -457.74$ (s, $\omega_{1/2} = 164$ Hz), −236.53 (s, $\nu_{1/2} = 401$ Hz), −40.81 (s, $\omega_{1/2} = 328$ Hz), 123.15 ppm (s, $\omega_{1/2} = 255$ Hz).

Templating Open- and Closed-Chain Structures around Metal Complexes of Macrocycles**

*Sarah L. Heath, Rebecca H. Laye,
Christopher A. Muryn, Nicola Lima, Roberta Sessoli,*
Rachel Shaw, Simon J. Teat, Grigore A. Timco,* and
Richard E. P. Winpenny**

The ability to control the structures of polymetallic complexes is a key concern if we are ever to exploit their properties. A lot of beautiful science has emerged with this challenge, as shown by the grid structures created by Lehn[1] and Thompson,[2] or the panel structures created by Fujita.[3] A particularly attractive idea is to template the structure about an otherwise innocent ion to modify the structure without changing electronic properties. The work of Saalfrank et al. in which different sized metallocryptands were templated is particularly relevant here,[4] as is the work of Raymond and co-workers in which the geometry of the molecule is varied from a dimetallic helix to a tetrahedron depending on the presence of a tetrahedral counterion.[5] Our work has concerned new methods to influence structure, and, in the case of cyclic chromium fluoride cages, we have shown that the size of metal rings can be influenced by the choice of secondary ammonium cations.[6,7] Here we use metal complexes of macrocycles as templates to show that further unusual structures can be formed.

Previously we reported the first heterometallic rings of the type $[NH_2R_2][Cr_7MF_8(O_2CCMe_3)_{16}]$ (R = alkyl sidechain; M = Ni^{2+}, Co^{2+}, Fe^{2+}, Mn^{2+}, or Cd^{2+}).[6] The facile synthesis of these compounds led us to look more widely at a reaction matrix that contains chromium fluoride, pivalate ion, a second metal ion, and templates that contain NH groups. When the second metal is nickel and the template is a simple azacrown ether, either 1,4,7-triazacyclonane (tacn) or 1,4,7,10-tetraaza-

cyclododecane (cyclen), the macrocycle binds the nickel ion and the resultant complex then acts as the template.

Initially, chromium fluoride, nickel carbonate, and tacn were treated in pivalic acid to give $[Ni(tacn)_2][Cr_8Ni_2F_{10}(O_2CCMe_3)_{20}]$ (**1**),[8] in which the dicationic mononuclear nickel complex was found within a dianionic ring (Figure 1).
Figure 1. The crystal structure of **1**: the M_{10} wheel contains two disordered Ni atoms (see text for details). Hydrogen atoms have been omitted for clarity. Selected bond-length ranges: M–F 1.930–1.949, M–O 1.874–2.111, Ni–N 2.115–2.135 Å (average estimated standard deviation: 0.009 Å). Colors: Cr, purple; Ni, green; F, yellow; O, red; N, blue; C, grey lines.

A better route to **1** involved the prior preparation of $[Ni(tacn)_2](O_2CCMe_3)_2$ and addition of this complex to the reaction mixture (CrF_3, $NiCO_3$, and pivalic acid). The metal sites within the dianion are disordered: two Ni^{2+} ions are present according to microanalytical measurement and charge-balance considerations. The structure of the mononuclear dication is very similar to that of $[Ni(tacn)_2]^{2+}$ crystallized with simpler anions,[10] however, disorder in the structure renders a meaningful comparison of bond lengths difficult. Each of the M···M edges of the ten-metal ring, which is almost planar, is bridged by one fluoride and two pivalate ions in a similar manner to $[Cr_7NiF_8(O_2CCMe_3)_{16}]^-$. Each of the NH groups of the two tacn ligands are involved in hydrogen bonds; these bonds are longer than the hydrogen bonds found when simpler amines are used (N···F contacts range from 2.98 to 3.30 Å rather than 2.7–2.9 Å).[6]

With the Cr–F–pivalate system, octa-,[6] nona-,[7] and decanuclear metal rings could be synthesized by variation of the template. If 1,4,7,10-tetrazacyclododecane (cyclen or [12]-ane-N_4) is used as a template in this chemistry, [{Ni(cyclen)}$_2$Cr$_{12}$NiF$_{20}$(O$_2$CCMe$_3$)$_{22}$] (**2**, see Figure 2)[8] results. The fifteen metal sites define an "S", in which a Ni^{2+} ion is located at the center of the "S" and two Ni^{2+}–[12]-ane-N_4 complexes lie at the termini. The cyclen macrocycles bind in the usual

DOI: 10.1002/anie.200461006

Figure 2. The crystal structure of **2**. Hydrogen atoms have been omitted for clarity. Bond-length ranges: Cr–O 1.824–2.003, Cr–F 1.893–1.966, Ni–O 1.995–2.073, Ni–F 2.015–2.093, Ni–N 2.063–2.116 (average estimated standard deviation: 0.005 Å). Colors: Cr, purple; Ni, green; F, yellow; O, red; N, blue; C, gray lines.

manner to leave *cis* vacancies on the coordinated Ni^{2+} ions, and it is the two atoms that occupy these *cis* sites which link the $[Ni([12]\text{-ane-}N_4)]^{2+}$ fragments to the termini of the metal chain. An analogous molecule with 2,2-dimethylbutyrate as the carboxylate moiety was also prepared.

The twelve Cr^{3+} ions form two hexametallic chains, which are very similar to the anionic Cr_6 horseshoes we have previously reported.[11] However, in the previous structures, the horseshoes were linked by hydrogen bonds to secondary ammonium cations, whereas here fluoride ions directly bridge to a nickel site to create the "S" shape. The Cr···Cr vectors in the structure are all bridged by two pivalate ions and one fluoride ion, whereas the two Cr···Ni contacts at the center of the "S" are each bridged by two fluoride ions and one pivalate ion. The terminal $[Ni(cyclen)]^{2+}$ units are each attached by one μ-F bridge and the oxygen atom of a pivalate ion, which chelates the final Cr^{3+} ion of the chain and also bridges to the Ni site. The metal core is almost planar with a mean deviation from planarity of 0.25 Å. There is a single N–H··F hydrogen bond (N··F contact of 2.94 Å) between the cyclen unit and the bridging fluoride ion.

Preliminary magnetic studies of **1** and **2** were performed. A χT value of 16.2 emu K mol^{-1} was obtained for **1** at room temperature which is slightly smaller than the uncorrelated

value for three $S = 1$ ($g_{Ni} \approx 2.2$) and eight $S = 3/2$ ($g_{Cr} \approx 2.0$) centers (18.6 emu K mol^{-1}) and suggests that an antiferromagnetic interaction is present as often found in fluoro-bridged Cr^{3+} rings.[13] Whereas χT decreases, the χ value reaches a plateau around 30 K and undergoes a steep increase below 10 K (Figure 3). The χT value levels off at low
Figure 3. Temperature dependence of the magnetic susceptibility, χ (○), and its product, χT (■), for **1**.

temperature and the lowest measured value, 1.27 emu K mol^{-1}, is compatible with an uncoupled spin for Ni^{2+} (1.21 emu K mol^{-1} for $g = 2.2$). This behavior can be rationalized if we assume that the antiferromagnetic-coupled ring has a $S = 0$ ground state, and its contribution is superimposed on the paramagnetic ground state of the isolated $[Ni(tacn)_2]^{2+}$ cation. The ring is expected to have a diamagnetic ground state only if the two Ni^{2+} ions occupy an even and an odd site of the ring. In a random distribution, the ions have a significant probability (4/9 versus 5/9) to occupy sites of the same parity to give an uncompensated $S = 1$ ground state, which is not observed. Impurities, such as rings with Cr:Ni stoichiometries of 9:1 or 7:3, would also influence the value of χT at low temperature, but the presence of such impurities is not compatible with the observed behavior. The most likely explanation for the $S = 0$ ground state of the ring is that the Ni^{2+} ions, even if they are disordered, are always located next to each other within the rings as observed in $[(VO)_2Cr_6]^{[11]}$ and $[(VO)_2Cr_7]$ ring systems.[7]

To our knowledge, **2** is the longest open-chain structure prepared (except for infinite 1D chains)—the longest finite acyclic chain previously reported contained seven metal ions.[14] The magnetic behavior of **2** was measured from 1.8 to 300 K (Figure 4). The χT value at room temperature of 23.0 emu K mol^{-1}, which is smaller than the uncorrelated value (27.3 emu K mol^{-1}), is consistent with moderate antiferromagnetic exchange between the metal centers within the chain. The curve for χ versus T (Figure 4) is qualitatively similar to that of **1**, with a plateau at ≈ 30 K and a rapid increase at lower temperature. At low temperature, the curve tends to a constant value of ≈ 1 emu K mol^{-1}, which is consistent with a ground state of $S = 1$.

The odd-member open-chain structure of **2** should stabilize a ferrimagnetic structure with a resultant spin of $S = 1$. To confirm this, the magnetic data were fitted by employing a classical Monte Carlo simulation together with the MINUIT[15] minimization routine. A full quantum mechanical treatment was hampered by the large number of spins in the cluster. However, a quantum correction was used on spin values, and a combination of Metropolis[16] and
Figure 4. Temperature dependence of the product χT for **2** (1 kOe = 0.1 T). The solid line represents the fitting performed with a classical Monte Carlo simulation. Inset: magnetization (**M**) versus applied field (**H**) curves recorded at three different temperatures: 2 K ■, 5 K ○, 10 K ——.

overrelaxed algorithms[17] were applied to reduce the correlation time. The Hamiltonian ($\mathscr{H}$) that was used for the calculation is shown in Equation (1), in which $S_i = [S_i(S_i+1)]^{1/2}$ ($i = Ni^{2+}, Cr^{3+}$) is the scaled classical spin and J is the exchange interaction:

$$\mathscr{H} = -J_{Ni-Cr}(S_{Ni} \cdot S_{Cr}) - J_{Cr-Cr}(S_{Cr} \cdot S_{Cr}) \tag{1}$$

Values of $S_{Ni} = 1$, $g_{Ni} = 2.2$, $S_{Cr} = 3/2$, and $g_{Cr} = 2.0$ were used. The best-fit values obtained were $J_{Ni-Cr} = -20.8$ and $J_{Cr-Cr} = -20.3$ cm^{-1}, with an agreement factor of $R = 1.03 \times 10^{-3}$. Despite there being two distinct Cr···Ni interactions, no significant improvement in the fitting was observed upon including two Cr···Ni exchanges. The classical Monte Carlo simulation did not provide information about the energy spectrum of the spin levels. However, the curves of magnetization (**M**) versus field strength (**H**) recorded at different temperatures (Figure 4, inset) show some features typical of level crossings, which are induced by the field, that stabilize states with larger spins.[13, 18] The magnetization at 2 K, relative to that at 5 K, rapidly reaches 2μ$_B$ and then begins to level off. Above 80 kOe, the slope of the curve slightly increases, as expected for a level crossing occurring in this field range. As the energy spacing is not expected to follow a regular trend like the Landeé rule,[18] fitting of the data was not attempted. Nevertheless, the data from **M** versus **H** confirm that the ground spin state has $S = 1$, and this state is well separated, by 5–10 cm^{-1}, from the first excited state as expected for the ferrimagnetic structure of this unusual open-chain cluster.

Experimental Section

All reagents were used as received from Aldrich, except cyclen, which was obtained from Strem Chemicals. 1,4,7-triazacyclononane[19] and [Ni$_2$(μ-OH$_2$)(O$_2$CCMe$_3$)$_4$(HO$_2$CCMe$_3$)$_4$][20] were prepared according to reported methods. Complexes **1** and **2** were prepared in teflon flasks supplied by Fisher.

[Ni(tacn)$_2$][(O$_2$CCMe$_3$)$_2$]·2Me$_3$CCO$_2$H·H$_2$O (complex **A**): [Ni$_2$(μ-OH$_2$)(O$_2$CCMe$_3$)$_4$(HO$_2$CCMe$_3$)$_4$] (0.70 g, 0.74 mmol) in toluene (5 mL) was added to a solution of tacn (0.35 g, 2.7 mmol) in toluene (5 mL), and the resultant blue solution was stirred for 5 min. Pink crystals of **A** began to form during this time. The solution was allowed to stand at room temperature for one day, then the crystals were collected by filtration, washed with toluene, and dried in air

(0.44 g, 40%). Elemental analysis: calcd for C$_{32}$H$_{70}$N$_6$NiO$_9$: Ni 7.91, C 51.82, H 9.51, N 11.33; found: Ni 7.81, C 51.96, H 9.73, N 11.33 %.

1: Complex **A** (0.25 g, 0.34 mmol), Me$_3$CCO$_2$H (10.0 g, 98 mmol), CrF$_3$·4H$_2$O (0.8 g, 4.4 mmol), and basic nickel carbonate [2NiCO$_3$·3-Ni(OH)$_2$·4H$_2$O] (0.07 g, 0.12 mmol) were heated with stirring at 140°C for 0.5 h, then the temperature was increased to 160°C and the mixture was heated for 5 h. The mixture was cooled to room temperature, acetone (30 mL) was added and the contents were stirred for 15 min. The product was filtered, washed with a large quantity of acetone, and dried in air. The solid (0.5 g)was then added to a solution of Me$_3$CCO$_2$H (0.5 g) in THF (50 mL) and the solution was heated at reflux for 15–20 min with stirring. The green mixture was filtered hot, and the filtrate was diluted at room temperature with CH$_3$CN (1–2 mL) until it became cloudy and then reheated to obtain a clear solution. Slow cooling and then partial evaporation of the solvent at ambient temperature produced light green crystals. After 1 week, the crystals were collected by filtration, washed with THF/CH$_3$CN (10:1), and dried in air (0.18 g, 17.5%). Elemental analysis calcd (%) for C$_{112}$H$_{210}$Cr$_8$F$_{10}$N$_6$Ni$_3$O$_{40}$: Cr 13.58, Ni 5.75, C 43.92, H 6.91, N 2.74, F 6.20; found: Cr 13.61, Ni 5.74, C 43.84, H 7.00, N 2.60, F 6.20.

2: Basic nickel carbonate (1.0 g, 1.7 mmol) was dissolved in pivalic acid (15 g, 147 mmol) at 100°C, and the solution was stirred for 15 min to produce a lime-green solution. The temperature was then raised to 120°C and cyclen (0.7 g, 4.0 mmol) was added to produce a blue solution, which indicates the production of Ni(cyclen)(piv)$_2$. The temperature was then maintained at 140°C for 10 min before CrF$_3$.4H$_2$O (5.0 g, 28 mmol) was added. The temperature was increased to 160°C for 5 h and the mixture was then left to cool overnight. The product was collected by filtration, washed with acetone, dried, and then recrystallized from hot THF/MeCN (4.2 g, 53%). Elemental analysis calcd (%) for C$_{136}$H$_{256}$Cr$_{12}$F$_{18}$N$_8$Ni$_3$O$_{48}$: Cr 15.94, Ni 4.50, C 41.74, H 6.59, N 2.86, F 8.74; found: Cr 15.89, Ni 4.51, C 41.39, H 6.74, N 2.74, F 8.64.

The byproducts of the syntheses of **1** and **2** have very high solubility in acetone and have not yet been fully characterized. The magnetic properties of polycrystalline samples of **1** and **2** were investigated by using a Cryogenic M600 SQUID magnetometer and a VSM magnetometer based on the Oxford Instruments MAGLAB platform.

Photo-Switching

Reversible Photo-Switching of the Magnetization of Iron Oxide Nanoparticles at Room Temperature**

*Rie Mikami, Minori Taguchi, Koji Yamada, Koji Suzuki, Osamu Sato, and Yasuaki Einaga**

Optically switchable magnetic materials are becoming increasingly important in the field of high-density information storage media.[1–3] We have been trying to prepare new types of magnets in which the magnetic properties can be controlled by photo-illumination. Our previous work has shown that cobalt–iron cyanide exhibits photoinduced magnetization effects due to an internal electron transfer.[4] However, practical examples of such photo-magnetic systems are limited in number[5] because the strategies that are necessary to achieve photoinduced switching in the solid state are yet to be clarified.

The use of organized organic assemblies to direct the formation of mesoscopic inorganic structures under mild conditions and the attempts to intercalate inorganic materials into functional organic molecules are also of topical interest.[6] We have focused our attention on composite materials as a novel strategy for realizing such photo-functional magnetic systems. These include the incorporation of organic photo-chromes into magnetic systems, for example, photo-controllable magnetic vesicles and Langmuir–Blodgett films containing Prussian blue (a ferromagnet at low temperature) and azobenzene.[7]

Although the examples described above show interesting photo-responsive phenomena, the results were only achieved at low temperature. It is evident that the temperature at which photo-switching occurs needs to be increased to room temperature in order to realize devices for practical applications. In the present work we have focused on iron oxide

nanoparticles as magnetic materials that can function at room temperature. We recently reported our results for photo-responsive spiropyran vesicles containing iron oxide particles.[8] Although we were able to increase the magnetization values of these materials by carrying out photo-illumination at room temperature, the reversible photo-switching of their magnetic properties was far below our expectations. This was because the photoinduced increase in the magnetization was due to aggregation of the iron oxide particles, and we guess that it is difficult for aggregated particles to be separated.

To realize reversible photo-switching of magnetization at room temperature, we have now focused on a surface modification of nano-scale iron oxide particles and a combination of azobenzene-containing amphiphilic compounds and γ-Fe$_2$O$_3$ magnetic nanoparticles. Surface modification of nanoparticles is a useful technique for functionalizing the material properties.[9] For example, Rotello et al. reported that alkylamines in a monolayer could be displaced by harder Lewis base ligands such as alcohols.[9b]

Our strategy was to synthesize an appropriate azobenzene derivative for preparing the target photo-responsive nano-magnetic materials. In addition to encapsulating the surface of the γ-Fe$_2$O$_3$ nanoparticles with the azo moiety, we incorporated n-octylamine. The amphiphilic azo compound 8-[4-{4-butoxy-phenyl(azo)-phenoxy}octan-1-ol] (Azo) was synthesized according to literature methods[10] and then used to prepare the photo-responsive composite magnetic nanoparticles 1 (see the Experimental Section).

Figure 1. The TEM image of 1.

line). After 5 min of UV illumination, the intensity of the band at 360 nm decreased and the intensity of the band at 480 nm increased, indicating the *trans*-to-*cis* photoisomerization (blue line). A photostationary state was obtained after 5 min of illumination, that is, the photoisomerization had saturated. Following subsequent illumination with visible light for 5 min, the reverse process, the *cis*-to-*trans* isomerization, proceeded to completion (red line). The *trans*-to-*cis* photoisomerization cycles were repeated several times by alternately illuminating with UV and visible light (Figure 2b).

Because the photoisomerization of azobenzene derivatives (in particular the *trans*-to-*cis* isomerization) is normally accompanied by an increase in molecular volume, the solid-state reaction is greatly inhibited due to the close packing of the chromophores. In practical terms, when the solid-state compound contains only Azo, it does not exhibit any photoisomerization behavior. In the case of 1, sufficient free volume is guaranteed by the dilution of the azo moieties with n-octylamine to allow photoisomerization to take place. Another important point is the Lewis basicity of the capping ligands. n-Octylamine, which functions as an encapsulating agent for the γ-Fe$_2$O$_3$ nanoparticles,[11] contains an amino group, while Azo contains a harder Lewis basic hydroxy group. This means that Azo takes precedence over n-octylamine, resulting in the successful preparation of composite nanoparticles 1.

The transmission electron microscope (TEM) image of 1 indicates the global presence of γ-Fe$_2$O$_3$ nanoparticles with almost homogeneous diameters (5 nm, Figure 1). We estimated the diameter of 1, including the encapsulating agent, to be 9 nm by means of a dynamic light-scattering method.

The photoisomerization of 1 on the quartz substrates was monitored by UV/Vis absorption spectroscopy at room temperature (Figure 2a). Before illumination, 1 exhibited two absorption peaks at about $\lambda = 360$ nm and a weak band at about 480 nm, which correlate to the π–π* and the n–π* transitions, respectively, in the *trans* form of the azo compound. The spectra demonstrate that the π–π* absorption at 360 nm remains invariant with respect to passivation of the nanoparticles, which proves that the azo components are protected during the synthesis of the γ-Fe$_2$O$_3$ nanoparticles. The absence of any shift in the absorption bands also indicates that there was no π stacking between the azo molecules (black

The magnetic properties of 1 on a glass substrate were studied by SQUID measurements. The temperature dependence of the magnetization of 1 exhibits a cusp around 12 K in the zero field cooled (ZFC) susceptibility as well as a blocking temperature T_B determined from the branching of the ZFC and field-cooled (FC) data (Figure 3); thus, 1 exhibits superparamagnetic behavior. According to Néel's superparamagnetic model[12] at high temperatures, the magnetic moments of spin clusters are free to respond to an external field but freeze when the temperature is low enough. This freezing of the spin clusters over a wide temperature range can be visualized in terms of the progressive blocking of the cluster moments, depending on their size and magnetocrystalline anisotropy. Below the freezing temperature, the clusters freeze in random orientations dictated by the magnetocrystalline anisotropy.
Figure 2. a) Changes in the optical absorption spectra due to photo-isomerization for **1** cast on quartz substrates at room temperature: before illumination (black line), after illumination with UV light for 5 min (blue line), after subsequent illumination with visible light for 5 min (red line). The inset shows a magnified region. b) Changes in the absorbance *A* at 360 nm by alternating illumination with UV and visible light (5 min each).
Figure 3. The plot of magnetization *M* versus temperature *T* for **1** at 5 G: ▲: zero-field cooled (ZFC), ○: field cooled (FC).

Figure 4. a) The plot of magnetization *M* versus applied magnetic field for **1** at 5 K and a magnified region (1 G = 10^{-4} T). b) Change in the magnetization for **1** induced by alternating illumination with UV and visible light (10 min each) at 5 K with an external magnetic field of 10 G.

Since the magnetic moments of the spin clusters are frozen in a direction where magnetization occurs easily at low temperatures, this gives rise to a low value of magnetization. In contrast, the magnetization decreases (as T^{-1}) at high temperatures due to thermal fluctuations of the magnetic moments. Therefore, a peak occurs in ZFC susceptibility between these two regions.[13] The ^{57}Fe Mössbauer spectra for **1** at room temperature and at 8 K revealed the presence of γ-Fe_2O_3 nanoparticles (see the Supporting Information).

Based on these data, **1** exhibits typical superparamagnetic behavior of magnetic particles, with a particle size that is consistent with that observed by TEM (5 nm).[14] Generally speaking, iron oxide nanoparticles exhibit superparamagnetic behavior because of the infinitely small coercivity arising from the negligible energy barrier in the hysteresis of the magnetization loop of the particles.[12,15]

The magnetization curve of **1** was measured at 5 K (Figure 4a) in the field-cooled (FC) state. A small hysteresis

loop with remanence (5.67 emu g^{-1}) and coercivity (300 G) was observed. Below T_B the superparamagnetic transition is blocked, that is, the magnetization cannot relax during the time frame of the measurement and therefore cannot appear on the plot of magnetization as a function of the magnetic field.

We next investigated the influence of photo-illumination on the magnetic properties of **1** at 5 K (Figure 4b). Compound **1** was cooled from room temperature to 5 K in an external magnetic field of 10 G. The initial magnetization value of **1** at 10 G increased from 0.279 to 0.305 emu g^{-1} upon UV illumination. The sample was exposed to UV light until saturation, that is, until the change in magnetization was complete (10 min). Even after the illumination was stopped, this increased magnetization was maintained for several hours. Compound **1** was then illuminated with visible light for a further 10 min. The magnetization value decreased from 0.305 to 0.280 emu g^{-1}. This UV light induced increase and visible light induced decrease in the level of magnetization was repeated several times. The total change of the magnetization value resulting from photoinduced switching was about 9.3%, which is larger than that achieved by our first photo-functional magnetic vesicles system.[7a]

To investigate the feasibility of using **1** for practical applications, corresponding measurements were performed at

room temperature (300 K). No saturation of the magnetization was found at 300 K with a field of 50 000 G. Characteristics that are typical of superparamagnetic behavior were observed, such as almost immeasurable coercivity and remanence (Figure 5a). This was consistent with the notion that, above T_B, the magnetization should be free to align with the field during the measurement time.
Figure 5. a) The plot of magnetization M versus applied magnetic field for **1** at 300 K. b) Change in the magnetization for **1** induced by alternating illumination with UV and visible light (30 min each) at 300 K with an external magnetic field of 10 G.

Next, the influence of photo-illumination on the magnetic properties of **1** at 300 K was examined. The same changes in magnetization upon photo-illumination were noted, that is, the magnetization increased upon illumination with UV light and decreased upon illumination by visible light (Figure 5b). The changes in the magnetization values do not give rise to a distinct trace because of the superparamagnetic properties. These changes in magnetization are consistent with the changes in the UV/Vis spectra and can be explained in the same fashion. The reversible control of the magnetic properties of **1** at room temperature was also confirmed by EPR and ^{57}Fe Mössbauer spectroscopy (see the Supporting Information).

To confirm the effect of the azo moiety, γ-Fe_2O_3 nanoparticles that were only encapsulated with *n*-octylamine were prepared (**2**). The TEM image of **2** also showed the presence of global γ-Fe_2O_3 nanoparticles with almost homogeneous diameters (5 nm), and **2** exhibited almost the same magnetic properties as **1** (not shown). However, when **2** was illuminated with UV or visible light, no changes were observed in the total magnetization. This result suggests that the azo moiety in **1** plays an important role in the photocontrol of the magnetization.

It appears that photoinduced changes in the electrostatic field around the γ-Fe_2O_3 magnetic nanoparticles affect the magnetization. Examples from our previous work could also be explained by similar interactions.[7] Changes in the dipole

moments induced by the photoisomerization of the Azo moieties resulted in magnetic fields and moments in the materials. We have previously observed that the change in the dipole moments of the azo compounds did not affect the magnetization value in the paramagnetic region.[7] Those results were consistent with the present results in terms of the temperature dependence (at 5 K and room temperature): The stronger the magnetic exchange interactions between spins are, the greater the effect the dipole moment has on the magnetization values.

The relationship between the electronic polarization (including the charge or the dipole moments) and the magnetization has been discussed by several physicists.[16, 17] The origins of the behavior of magneto-electric materials are the electric field induced g shift, the spin-orbit interactions, the exchange energies, and the electric field induced shift in the single-ion anisotropy energy. The underlying electrodynamics are complicated by induced fields interacting with electric and magnetic moments. That is, the spin orientation is coupled to the electric multi-pole through the lattice. Morup et al. also discussed the existence of significant collective effects in a magnetic nanoparticle system and made several speculations regarding a spin-glass-like phase at low temperatures on dipole–dipole interacting systems.[17b] Moreover, the surface magnetic phase diagram of the tetragonal manganites depends on the electrostatic interactions caused by the surface environment, such as surface termination.[15]

In 1999 Alivisatos et al. described the preparation of soluble crystalline γ-Fe_2O_3 nanoparticles by high-temperature organic-phase decomposition of an iron precursor.[18] The process was then extended to the synthesis of monodisperse MFe_2O_4 (M = Fe, Co, Mn) nanoparticles by Sun et al.[19] through the use of oleic acid and oleylamine. They studied the stability of the nanoparticles by varying the ratio of the capping agents and described how γ-Fe_2O_3 nanoparticles can be stabilized by alkylamine surfactants,[9b, 11] suggesting that NH_2 coordinates with Fe^{III} on the surface of the particles. Furthermore, Zhang et al. studied the effects of surface coordination chemistry on the magnetic properties of $MnFe_2O_4$ nanoparticles.[20a,b] They observed that the coercivity of magnetic nanoparticles decreased upon coordination of the ligands on the nanoparticle surface, whereas the saturation magnetization increased. They concluded that the magnetic properties of the nanoparticles change with the functional group bound onto the nanoparticle surface. The correlation suggests a decrease in the spin-orbital coupling and surface anisotropy of magnetic nanoparticles due to surface coordination.

Gedanken et al. also studied the magnetic properties, especially the blocking temperature T_B, of iron nanoparticles coated by various surfactants.[20c] They observed large variations in T_B for various functional groups attached to the iron nanoparticles. For example, the magnetization values for alcohols and carboxylic acids were different from those for sulfonic and phosphonic acid. These differences could be explained by the variation in particle size as well as the effect of the iron-bound functional group on the *d* electrons of iron. The functional groups interact strongly with the *d* electrons and cause a large splitting of the doubly and triply degenerate

d levels. This affects the spin state and the magnetization values as a result of exchange interactions between the spins of the iron center.

The above discussion also suggests that photoinduced changes in the electrostatic field around the γ-Fe$_2$O$_3$ magnetic nanoparticles affect the magnetization. Photo-switchable magnetic films—Prussian blue intercalated in Langmuir–Blodgett films consisting of an amphiphilic azobenzene and a clay mineral,[7c] which was one of our previous photo-functional systems—supplied data that support these mechanisms. A band corresponding to intervalence charge transfer (IVCT) between Fe^{II} to Fe^{III} in the Prussian blue layer was changed reversibly by alternate UV and visible illumination, accompanied by photoisomerization of the azo compound. That is, changes in the electrostatic field driven by the photoisomerization of the azobenzene chromophore led to changes in the Coulomb energy (which is necessary to transfer an electron) and this might affect the superexchange interaction between the spins in the Prussian blue magnet.

In conclusion, we have designed novel photoresponsive γ-Fe$_2$O$_3$ nanoparticles that are encapsulated by an azo compound and *n*-octylamine. To photo-control the magnetization, the design of the interfaces between the photoresponsive materials and the magnetic materials is important. The advantage of the current system is that nano-scale particles, from which much larger areas of photoresponsive interfaces might be expected, were used as the magnetic materials. Another important aspect was the dilution of the azo moieties with *n*-octylamine. The free volume gained is responsible for the ideal photoreaction. Use of azo compounds with appropriate end groups and alkyl chain length for direct interaction with the metal oxide surface was also mportant. Finally, we have succeeded in switching the magnetization value of composite magnetic nanoparticles by photo-illumination in the solid state at room temperature.

Experimental Section

The amphiphilic compound Azo[10] and the γ-Fe$_2$O$_3$ nanoparticles[11] were synthesized according to literature methods.

1: FeCl$_3$·6H$_2$O (0.47 g), sodium acetate (0.43 g, used as a hydrolyzing agent), H$_2$O (0.35 mL), *n*-octylamine (0.61 mL), and Azo (0.01 g) in 1,2-propanediol (6 mL) were heated under reflux at 150°C for 5 h. The materials were then precipitated by the addition of a large volume of 2-propanol (ca. 20 mL). After being washed with 2-propanol, the solids were collected by centrifugation, washed with Et$_2$O, and dried in air. The crude product was re-dissolved in toluene (5 mL) containing a small amount of the encapsulating agents *n*-octylamine and Azo (0.3 mL, 100:1). Most of the crude product went into solution within 13 h. A solution of **1** in toluene was then cast onto the substrates for further study.

The UV/Vis spectra were recorded on a V-560 spectrophotometer (JASCO). UV illumination (filtered light, $\lambda_{max} = 360$ nm, 1.0 mW cm^{-2}) was applied with an ultra-high pressure mercury lamp (HYPERCURE 200, Yamashita Denso). Visible light (400–700 nm, 1.0 mW cm^{-2}) was provided by a xenon lamp (XFL-300, Yamashita Denso). The magnetic properties were investigated with a SQUID magnetometer (model MPMS-5S Quantum Design). The lamps were guided into the SQUID magnetometer by an optical fiber to study the photomagnetic effects. The ^{57}Fe Mössbauer spectra were measured at room temperature and at low temperature with a Topologic Systems Model 222 constant-acceleration spectrometer with a ^{57}Co/Rh source in transmission mode. A closed-cycle helium refrigerator (Nagase Electronic Equipments Service Co., Ltd.) was used for measuring the spectra at low temperature.

Atomic-Step-Templated Formation of Single Wall Carbon Nanotube Patterns**

*Ariel Ismach, Lior Segev, Ellen Wachtel, and Ernesto Joselevich**

Following recent advances in the control of the electronic properties of nanowires,[1–4] nonlithographic organization of nanowire arrays on surfaces remains a critical prerequisite for the large-scale fabrication of nanoscale circuitry.[5,6] Current strategies[7] include the application of physical means, such as electric fields,[4,8,9] gas[10] and liquid[11,12] flows, and super-lattices,[13] as well as chemical means including self-assem-bly[14,15] and biotemplated assembly.[16] Step decoration[15,17] is another attractive chemical approach that exploits the selective deposition of atoms, ions, or molecules at the oriented, periodic steps present on high-index crystalline surfaces. However, the general scheme, in which nanowire growth propagates transversely from the steps, is not com-patible with nanowire materials that form by axial growth mechanisms, such as carbon nanotubes.[18–20] Here we dem-onstrate and characterize the longitudinally propagating decoration of atomic steps by a nanowire material. Single-wall carbon nanotubes that are catalytically produced on miscut C-plane sapphire wafers, grow along the 2-Å-high atomic steps of the vicinal α-Al_2O_3 (0001) surfaces to yield highly aligned, dense arrays of discrete, nanometer-wide, conducting or semiconducting wires on a dielectric material. The nanotubes reproduce the atomic features of the surface, such as steps, facets, and kinks. These findings open up the possibility of assembling nanotube architectures by atomic-scale surface engineering.

The phenomenon of atomic step decoration by single-wall carbon nanotubes (SWNTs) was first observed while inves-tigating the effects of electric field and gas flow on the catalytic growth of SWNTs on different materials. Surpris-ingly, nanotubes grown on C-plane sapphire wafers, that is, α-Al_2O_3(0001) surfaces, showed the highest degree of alignment

Supporting information (experimental methods, XRD data, statis-tical histograms, and a table of comprehensive results) for this article is available on the WWW under http://www.angewandte.org or from the author.

(Figures 1a, 2a, 3a–c, and 4a), but not in the directions of the field or the flow. When the same surface was precoated with a thin layer (20 nm) of amorphous SiO_2, the nanotubes were
Figure 1. Alignment of SWNTs grown under an electric field (2×10^6 V m^{-1}) on sapphire (a) and on SiO_2-coated sapphire (b). The low-voltage field-emission SEM micrographs (scale bar: 5 μm) show the SWNTs (light) lying on the dielectric surfaces (dark), and the Pt electrodes (light, top and bottom). Arrows indicate the directions of the field E and flow. The alignment of the SWNTs on sapphire is unre-lated to the electric field, whereas on the same sapphire that was pre-coated with 20 nm of amorphous SiO_2, the alignment is parallel to the electric field. c) Schematic representation of the atomic steps on vici-nal α-Al_2O_3(0001), and definition of the step vector $\mathbf{s} = (\mathbf{c}/c)\times\mathbf{n}$, miscut inclination θ, and miscut azimuth ϕ. d) Idealized structure of atomic steps in different low-index directions, based on the bulk crystal structure, that is, without relaxation and reconstruction. Oxygen atoms (red) are colored darker at lower atomic layers.

aligned with the electric field (Figure 1b), as previously observed on SiO_2-coated silicon.[8] This result indicated that the nanotubes grow in contact with the Al_2O_3 surface, which dictates their alignment. On the other hand, the nanotubes were not aligned along a particular crystallographic direction. Moreover, α-Al_2O_3 is a trigonal crystal of the $R\bar{3}c$ space group and an ideal α-Al_2O_3(0001) surface has C_3 symmetry, from which one would expect alignment in at least three directions, not one. These facts ruled out the possibility of lattice-oriented SWNT growth.[21] However, commercial "C-plane" sapphire wafers are often cut and polished in a plane that slightly deviates from the actual C plane. The resulting vicinal α-Al_2O_3(0001) surfaces are terminated with parallel, regularly spaced atomic steps.[22] The atomic steps of most materials are generally more reactive than atomically flat areas.[23] We then hypothesized that SWNTs could have grown along such atomic steps. This is proven below for the case where no electric field was applied. Application of an electric field was shown to have no effect.

The morphology and dynamics of vicinal α-Al_2O_3(0001) surfaces have been investigated by several research groups.[22,24] The atomic steps, with a height equal to one

sixth of the hexagonal unit cell, that is, $h = c/6 = 0.219$ nm, follow a general direction perpendicular to the miscut direction (Figure 1 c). Their average spacing is $d = h/\sin\theta$ where θ is the miscut inclination. For convenience, we define a step vector $\mathbf{s} = (\mathbf{c}/c) \times \mathbf{n}$, where $\mathbf{c}$ is the principal lattice vector and $\mathbf{n}$ is a unit vector normal to the surface. Then, $\mathbf{s}$ points along the general step direction so that steps descend to the right, and its modulus equals the slope of the steps ($s = h/d$). We define the miscut azimuth ϕ ($-60° < \phi < +60°$) as the angle of $\mathbf{s}$ relative to the [11$\bar{2}$0] direction, which is perpendicular to the (11$\bar{2}$0) c-glide plane, so that the sign of ϕ expresses the handedness of chiral miscuts. The atomic step structure depends on the miscut azimuth ϕ. This is illustrated by Figure 1 d, which represents different unreconstructed steps based on the bulk structure. The actual structure of the atomic steps is still unknown,[22] although the high-temperature reconstruction of α-Al$_2$O$_3$(0001) surfaces was recently characterized.[25]

The characterization of a typical sample of aligned SWNTs on sapphire is shown in Figure 2. Figure 2 a displays an AFM topographic image of the highly aligned SWNTs. The apparent diameter distribution of the SWNTs is 1.0 ± 0.4 nm, which is 0.2 nm smaller than the value determined from Raman spectra (1.2 ± 0.5 nm). An asymmetric double-exposure back-reflection X-ray diffraction (XRD) method was used to determine the orientations of both the lattice and the miscut of the α-Al$_2$O$_3$(0001) substrate (Figure 2 b), in which a long and a short exposure were taken before and after 180° rotation of the sample, respectively. The miscut inclination and azimuth are $\theta = 2.1 \pm 0.2°$ and $\phi = 0 \pm 5°$, respectively, and the general step direction, expressed by $\mathbf{s}$, matches the direction of the nanotube alignment. In addition, a destructive characterization by thermal annealing at 1100 °C in air (Figure 2 c) was performed. Then, the thermodynamically unstable $c/6$ atomic steps, which could not be resolved by AFM, bunch into visible macrosteps with heights of $c-3c$.[22,24] The step orientation and miscut inclination are independently determined from these images, thus yielding results ($\theta = 1.9 \pm 0.2°$) similar to those obtained from XRD studies. The angular distribution of the nanotubes and macrosteps with respect to reference marks are $108 \pm 4°$ and $109 \pm 2°$, respectively (see Supporting Information for histograms). This precise coincidence is a clear indication of step decoration. The apparent reduction in SWNT height is consistent with the size of $c/6$ atomic steps.

Similar experiments were performed on about twenty samples of SWNTs grown on either side of seven different C-plane sapphire wafers of random miscut inclinations (up to $\theta = 4°$). Some representative results are displayed in Figure 3 (see Supporting Information for comprehensive data). In all cases, except for $\theta < 0.5°$, SWNTs grow parallel to the atomic steps and not to a particular lattice direction. The degree of alignment correlates with the miscut inclination. However, SWNTs grown on substrates having similar miscut inclinations show better alignment when the atomic steps run along low-index directions, such as [11$\bar{2}$0] (Figure 3 c) or [10$\bar{1}$0] (Figure 3 b), than along high-index directions (Figure 3 d). This phenomenon may be attributed to the fact that straighter steps can have a closer interaction with the SWNTs. The
Figure 2. Comprehensive characterization of a typical sample of aligned SWNTs on miscut sapphire. a) AFM topographic image of the SWNTs (scale bar: 1 μm). Note the high degree of alignment and the straight conformation of most SWNTs, beyond the persistence length (ca. 1 μm). Polishing scratches (randomly oriented dark lines) of approximately 1-nm depth do not affect SWNT alignment. b) Asymmetric double-exposure back-reflection XRD indicating relevant low-index directions and the resulting step vector (**s**). The green and red triangles indicate the reference reflections arising from the first exposure (2 h) and second exposure (1 h, after 180° sample rotation), respectively (see Supporting Information for reference XRD). The **s** vector is +90° from the vector connecting the green-to-red pattern centers. c) AFM topographic image of a piece of sample after annealing at 1100 °C (scale bar: 100 nm). The darker blue indicates lower terraces, whose edges correspond to the $c-3c$ macrosteps. The inset shows a section analysis along the red line. Note that both the **s** vector from (b) and the macrosteps from (c) are parallel to the SWNTs in (a) (all the images are displayed in the same orientation with respect to reference marks).

density of the SWNT arrays also correlates with the value of θ. The samples with the lowest miscut inclination (Figure 3 f) have visible atomic steps decorated by nanoparticles, but no nanotubes. The steps could play a role in stabilizing the catalyst nanoparticles, so that a higher density of steps leads to a higher yield of SWNTs.

Interestingly, certain samples show kinked nanotubes running in zigzags along two different low-index directions. In Figure 4 a, alternating long and short segments of the same
Figure 3. SWNTs on miscut sapphire. Comparative analysis of representative samples with different miscut inclination and azimuth angles (see Supporting Information for XRD and full data table):
a) $\theta = 3.4 \pm 0.3°$, $\phi = 42 \pm 5°$; b) $\theta = 2.3 \pm 0.2°$, $\phi = -33 \pm 5°$;
c) $\theta = 2.1 \pm 0.2°$, $\phi = 0 \pm 5°$; d) $\theta = 1.7 \pm 0.1°$, $\phi = 18 \pm 5°$;
e) $\theta = 0.4 \pm 0.2°$, $\phi = -5 \pm 5°$; and f) $\theta = 0.3 \pm 0.2°$, $\phi = -50 \pm 5°$
(image sizes are 2.5 μm, except (e), 5 μm). The vectors indicate the relevant lattice directions and the step vector **s** (blue) obtained from XRD (except in (e) and (f), where **s** is from AFM). Insets show AFM topographic images of the respective annealed samples (inset scale bars 100 nm) with macrosteps. In (f), the atomic steps are spaced enough to be observed, and are decorated with inactive catalyst nanoparticles.

SWNTs run along the [11$\bar{2}$0] and [10$\bar{1}$0] directions, respectively, in accordance with their proximity to the general step direction (a few segments along the [01$\bar{1}$0] and [2$\bar{1}\bar{1}$0] directions are occasionally seen too). This result can be attributed to SWNT growth along faceted atomic steps (Figure 4b). Since the sharp 30° kinks presumably occur during growth, they could involve pentagon–heptagon defects, which are an energetically favored alternative to bending or buckling. The energy associated with pentagon–heptagon defects was calculated to be about 7 eV,[26] whereas the minimum strain energy required to produce a 30° buckle in a 1-nm-dimater SWNT was estimated to be about 13 eV.[27] Single-nanotube Raman spectra from these samples exhibit a high intensity of D-band peaks, which indicates a significant
Figure 4. SWNT growth along atomic steps. a) AFM amplitude image of kinked SWNTs growing along the [11$\bar{2}$0] direction (blue) with short segments along the [10$\bar{1}$0] direction (red), and occasionally [2$\bar{1}\bar{1}$0] (yellow) and [01$\bar{1}$0] (green; image size 5 μm). The short arrows in the respective color point to a few such segments. b) Illustration of a (10,0)-(6,6)-(10,0) kinked nanotube along [11$\bar{2}$0]-[10$\bar{1}$0]-[11$\bar{2}$0]. c) Model of a 1-nm-diameter SWNT along a [11$\bar{2}$0] atomic step. The color gradient represents an estimated SWNT–step electrostatic interaction energy per unit of nanotube length as a function of SWNT axis position, $U(x,z)$. This was calculated from the force exerted on a polarizable body by an inhomogeneous field, $\mathbf{F} = (\alpha\mathbf{E}\cdot\nabla)\mathbf{E}$. Averaging the potential along the direction of the step and the SWNT (y) gives $U(x,z) = -\frac{1}{2}\alpha_{xx}E^2(x,z)$, where α_{xx} is the transverse polarizability of the SWNT per length[31] and $E(x,z)$ is the local field. The latter was derived from the unreconstructed atomic step, by summation of Coulomb potentials from bulk Mulliken charges, averaged along the y axis and corrected for slab edge effects by subtracting a similar potential without the step. (The blue-to-red scale is 0–750 eVnm^{-1}.)

loss of translational symmetry, that is consistent with this picture. Pentagon–heptagon defects are known to cause structural changes along the SWNTs,[28] thus producing interesting metal–semiconductor heterojunctions.[29] In addition, the right-handedness of the kinked nanotubes reveals the chirality of the miscut substrate, which could in principle distinguish between enantiomorphic SWNTs. A different intriguing aspect is that faceting of vicinal α-Al$_2$O$_3$(0001)

atomic steps has not yet been observed,[22] because of their relatively low anisotropy energy below $\theta = 1°$. The anisotropy is expected to increase at higher miscut inclinations as a result of step–step interactions, but could not be resolved by AFM. Here, the decoration by SWNTs reveals a faceting that would otherwise remain unseen.

We propose a "wake-growth" mechanism to describe the atomic-step-templated formation of SWNTs, in which the catalyst nanoparticle slides along the atomic step and leaves the growing SWNT behind as a wake. This would involve three main factors: 1) higher nanotube-surface van der Waals (vdW) interactions near the step that result from increased contact area; 2) electrostatic interaction between the local electric fields created by uncompensated dipoles at the atomic steps and the induced dipoles across the SWNTs; and 3) better wetting of the atomic steps by the Fe metal catalyst nanoparticles, because of capillarity and higher coordination. The vdW contribution to the interaction energy per unit of nanotube length can be theoretically extrapolated from previous calculations on Si surfaces (2.2 eV nm^{-1}),[30] by assuming proportionality with the substrate polarizability[31] and a Clausius–Mossotti relation,[31] which yields 1.4 eV nm^{-1} on SiO_2 and 2.2 eV nm^{-1} on $\alpha\text{-Al}_2O_3$ surfaces. This small difference cannot account for the results in Figures 1a and b. Moreover, the lack of alignment by the approximately 1-nm-deep polishing scratches (Figure 2a) suggests that vdW interactions may not be the only aligning factor. On the other hand, electrostatic interactions may be especially high as a result of the ionic character of $\alpha\text{-Al}_2O_3$. The electrostatic nanotube–step interaction was modeled, as a first approximation, by applying theoretical SWNT polarizabilities[32] and a Coulomb potential near an unreconstructed step (Figure 4c). This electrostatic interaction is about 50 eV nm^{-1} at a reasonable vdW distance (0.34 nm) from the step. Although this remarkable value should be diminished by surface relaxation and reconstruction, it may still significantly account, along with vdW forces, for the strong SWNT–Al_2O_3 interaction compared to that of SWNT–SiO_2 (Figure 1a,b), as well as for the high degree of nanotube alignment along the atomic steps.

The present study shows that atomic-scale surface features can direct the orientation and conformation, and possibly also the structure, of single-wall carbon nanotubes. The direction and morphology of the atomic steps can be macroscopically controlled in the crystal cutting process by two degrees of freedom, namely the miscut inclination θ and azimuth ϕ. Although the nanotubes are not yet regularly spaced, the atomic steps are. Therefore, an improved catalyst should in principle be able to yield periodic arrays of SWNTs with controllable spacing. Lastly, step-templated assembly may not be limited to carbon nanotubes and vicinal surfaces, but could be generally applicable to other axial-growth nanowires as well as to other controllable surface defects, such as etch pits, grain boundaries, and screw dislocations. This will enable new strategies for the large-scale fabrication of nanoscale devices from the bottom up.

Direct Oxidative Heck Cyclizations: Intramolecular Fujiwara–Moritani Arylations for the Synthesis of Functionalized Benzofurans and Dihydrobenzofurans**

Haiming Zhang, Eric M. Ferreira, and Brian M. Stoltz*

Over the past two and a half decades, the intramolecular Heck reaction has proven to be an integral process for the formation of C–C linkages in the synthesis of complex molecules.[1] While the reaction provides desirable products by the coupling of an aryl or vinyl halide with an olefin by extrusion of the hydrohalic acid, the overall process involves two discrete functionalization events: 1) halogenation of an aryl or vinyl precursor and 2) palladium(0)-catalyzed C–C bond formation (Scheme 1a). A potentially more efficient process would involve oxidative coupling of an unfunctionalized arene directly with an olefin, thus obviating the necessity for prehalogenation of the substrate (Scheme 1b). Although the intermolecular version of this reaction was discovered in 1967 by Fujiwara and Moritani,[2] subsequent studies have largely focused on couplings of benzene with activated olefins (e.g., acrylate esters).[3] In fact, the direct intramolecular oxidative arene/olefin coupling (i.e., oxidative Heck cyclization[4]) has not been studied thoroughly.[5]

In the course of our efforts to develop palladium(II)-catalyzed dehydrogenation as a general oxidation method,[6,7] we recently described the catalytic oxidative cyclization of unsaturated indoles to give annulated derivatives (Scheme 1c).[8] Our studies determined that the indole cyclization

Table 1: Screening of oxidants for the intramolecular oxidative Heck cyclization.[a]

Entry	Oxidant [1 equiv]	Yield [%][b]	Entry	Oxidant [1 equiv]	Yield [%][b]
1	O$_2$ (1 atm)	56	5	Tl(OCOCF$_3$)$_3$	<10
2	benzoquinone	62	6	K$_2$S$_2$O$_8$	30
3	Cu(OAc)$_2$	31	7	H$_2$NC(S)NH$_2$	<10
4	AgOAc	29	8	PhCO$_3$tBu	42

[a] All reactions were carried out with 0.10 mmol **1**, 10 mol% Pd(OAc)$_2$ (0.01 mmol), 40 mol% ethyl nicotinate (0.04 mmol), and 0.10 mmol or 1 atm oxidant in 1.0 mL 4:1 tAmOH:AcOH (0.1 M in substrate). [b] Yield determined by gas chromatography.

mechanism most likely involves initial arene palladation with subsequent olefin insertion and β-hydrogen elimination.[9] Importantly, this mechanism is analogous to that of the Heck cyclization, since a similar aryl–Pd^{II} species is believed to be the key intermediate in both processes; however, the new process is oxidative due to the initial C–H bond functionalization event and net dehydrogenation of the substrate. Furthermore, since Pd^0-mediated oxidative addition to electron-rich aryl halides is typically slower than that to electron-poor arenes,[10] this direct oxidative process (initiated by electrophilic palladation by Pd^{II}) is complementary to the Heck technology. We envisioned that electron-rich arenes other than indoles could participate in such oxidative cyclizations with unactivated olefins under similar catalysis.

DOI: 10.1002/anie.200461294

Herein, we report a direct method for the synthesis of benzofurans and dihydrobenzofurans by palladium-catalyzed intramolecular Fujiwara–Moritani/oxidative Heck reactions.[11,12]

In order to test the viability of applying the intramolecular oxidative Heck cyclization to a nonindolic system, we prepared allyl phenyl ether **1** by alkylation of the corresponding phenol. Ether **1** was subjected to our optimized conditions for the aforementioned indole cyclization in the presence of a variety of stoichiometric oxidants (Table 1). We were gratified to observe that in the presence of a range of oxidants, ether **1** cyclized to give benzofuran **2** at 80°C, presumably by palladium-catalyzed C–C bond formation and β-hydride elimination, followed by isomerization of the olefinic product to the thermodynamically more stable benzofuran. As we observed for indole cyclization, it was found that molecular oxygen was a competent stoichiometric oxidant for the cyclization **1→2**. However, in the case at hand, benzoquinone provided the highest yield of **2** (62% yield by GC) and thus was used for further optimization.

Having found benzoquinone to be the optimal oxidant in the cyclization **1→2**, we examined the other parameters in the process (Table 2).[13] It was found that a 1:2 ratio of Pd:ethyl nicotinate was ideal (entries 1–4) and that inclusion of a substoichiometric amount of NaOAc (20 mol%) provided increased yields (entries 5 and 6). Finally, increasing the

Table 2: Optimization studies for the intramolecular oxidative Heck cyclization.[a]

8	20	20	120	12	67

[a] All reactions were carried out with 0.10 mmol **1**, 10 mol% Pd(OAc)$_2$ (0.01 mmol), 0–40 mol% ethyl nicotinate (0–0.04 mmol), 0–0.10 mmol NaOAc, and 0.10 mmol benzoquinone in 1.0 mL 4:1 *t*AmOH:AcOH (0.1 M in substrate). [b] Yield determined by gas chromatography. [c] Yield of isolated product in parentheses.

temperature to 100°C led to optimal results, providing benzofuran **2** in 77% yield after 12 h (entry 7).

Table 3: Oxidative benzofuran synthesis.[a]

[a] All reactions were carried out with 0.50 mmol substrate, 10 mol% Pd(OAc)$_2$ (0.05 mmol), 20 mol% ethyl nicotinate (0.10 mmol), 0.10 mmol NaOAc, and 0.50 mmol benzoquinone in 5.0 mL 4:1 *t*AmOH:AcOH (0.1 M in substrate) at 100°C. [b] Yield of isolated product. [c] Produced as a single regioisomer.

With a viable oxidative cyclization to produce benzofuran **2** in hand, we set out to explore the generality of the transformation. As shown in Table 3, the scope of the oxidative benzofuran synthesis is quite broad, leading to highly substituted products by selective *ortho* reactivity. The methodology is currently limited to the use of electron-rich arenes; however, the aryl subunit tolerates several alkoxy and alkyl groups and substitution patterns. Likewise, the allylic portion may be functionalized at both the proximal and distal positions relative to the ether linkage with a variety of groups (e.g. alkyl, aryl, functionalized alkyl).

We next investigated the feasibility of synthesizing quaternary carbon-containing dihydrobenzofurans by employing tri- and tetrasubstituted olefins in the process to avoid olefin isomerization after the cyclization step. As shown in Table 4, an array of highly functionalized dihydrobenzofuran derivatives can be synthesized in good yields with as little as 5 mol % Pd(OAc)$_2$ (Table 4, entry 2).[14]

In order to probe the mechanism of these carbocyclizations, we prepared substrate **3** and subjected it to the oxidative cyclization conditions (Scheme 2). Cyclization of this substrate can distinguish between two mechanistically distinct pathways (Scheme 2, A and B) by formation of diastereomeric products (i.e., either **4** or **5**). Specifically, a mechanism

proceeding by means of olefin activation, *anti* nucleophilic attack of the arene on the Pd π complex, and *syn* β-hydride elimination (Scheme 2, pathway A) can be differentiated from one involving aryl-palladation, *syn* olefin insertion, and *syn* β-hydride elimination (Scheme 2, pathway B). Under our standard reaction conditions, ether **3** cyclized to produce a diastereomerically pure product in 60 % yield, which was determined to be dihydrobenzofuran **5** by ¹H NMR NOE experiments.[15] The outcome of this mechanistic study suggests that pathway B is operative and that C–H bond functionalization precedes olefin insertion and β-hydride elimination.[16] Additionally, this reaction demonstrates that quaternary carbon stereocenters can be generated diastereoselectively, by chirality transfer, from a tertiary carbon center.

In summary, we have developed a method for intramolecular oxidative C–C bond formation that relies on Pd(II) catalysis to access electron-rich, highly substituted benzofuran and dihydrobenzofuran derivatives. These oxidations produce important heterocyclic ring systems[11] by direct C–H bond functionalization of the aromatic ring and cyclization with unactivated olefins. Based on mechanistic insight (i.e. the proposed intermediacy of an aryl Pd(II) species), we have illustrated the analogy of such oxidative carbocyclizations to the corresponding intramolecular Heck reaction, and we thus

Table 4: Oxidative dihydrobenzofuran synthesis.[a]

[a] All reactions were carried out with 0.50 mmol substrate, 10 mol % Pd(OAc)$_2$ (0.05 mmol), 20 mol % ethyl nicotinate (0.10 mmol), 0.10 mmol NaOAc, and 0.50 mmol benzoquinone in 5.0 mL 4:1 *t*AmOH:AcOH (0.1 M in substrate) at 100 °C. [b] Yield of isolated product. [c] Performed with 5 mol % Pd(OAc)$_2$ and 10 mol % ethyl nicotinate. [d] An inseparable mixture of roughly 66 % product (*E/Z* = 3:1) and 10 % starting material was isolated after 18 h. This mixture was subjected to another reaction with 5 mol % Pd(OAc)$_2$, 10 mol % ethyl nicotinate, 20 mol % NaOAc, and 50 mol % benzoquinone in 4:1 *t*AmOH:AcOH (0.1 M) for 12 h after which only the *E* isomer was observed. The yield presented is the overall yield of isolated product. [e] A 2.3:1 mixture of diastereomers was isolated with the major isomer shown.
Scheme 2. Mechanistic probe for the oxidative cyclization.

classify these transformations as Fujiwara–Moritani/oxidative Heck cyclizations. Furthermore, this methodology may be considered orthogonal to the traditional Heck reaction in that highly electron-rich arenes may be employed directly. In certain cases, halogenated derivatives of such arenes may be difficult to access selectively or may have undesirably low reactivity toward Pd⁰ catalysts. While the method is currently limited to the synthesis of five-membered ring ethers, the utilization of the oxidative Heck cyclization for the synthesis of complex molecules and the demonstration of its orthogonality to the Heck reaction should help to further elucidate the scope; these remain primary goals of our laboratory.[17]

[4] Recently, a number of catalytic intermolecular oxidative Heck arylations have been reported. These protocols typically employ main-group organometallic arenes with a range of olefinic coupling partners and Pd^{II} catalysis. As in the typical Heck cases, these also require the prefunctionalization of the arene substrate. For examples, see: a) M. M. S. Andappan, P. Nilsson, H. von Schenck, M. Larhed, *J. Org. Changes in the Conductance of Single Peptide Molecules upon Metal-Ion Binding**

Xiaoyin Xiao, Bingqian Xu, and Nongjian Tao

As the field of silicon-based microelectronics attempts, with difficulty, to head towards the nanoscale, the construction of electronic devices with individual molecules becomes an attractive alternative[1] and has stimulated a recent surge of interest in the study of the electronic properties of single molecules.[2,3] As well as displaying excellent electronic properties, single molecules can also recognize other molecules through specific binding interactions, which is something that current silicon-based technology is unable to offer. This capability of molecular recognition is used with astonishing accuracy and efficiency in biological systems and serves as an important design principle for chemical and biological sensors. Various molecular recognition processes have been studied and applied to sensor applications, but most methods to date measure an optical, electrochemical, or mechanical signal that arises from a large number of molecules.[4–8] Herein we demonstrate that the binding of a guest species onto a single host molecule can be studied electrically by wiring the host molecule to two electrodes. The measurement of electron-transport processes through a single molecule also allows the rectification properties of asymmetric host molecules and host–guest complexes to be studied.

Peptides were chosen as the host molecules because of the unlimited choice of different sequences that can be tuned to obtain optimal binding strength and specificity for a metal ion—our chosen guest.[7] Four peptides were studied, cysteamine-Cys, cysteamine-Gly-Cys, Cys-Gly-Cys, and cysteamine-Gly-Gly-Cys (Cys = cysteine, Gly = glycine), which each have two thiol termini that can form reproducible contact to Au electrodes for electrical measurement. These peptides were expected to bind transition-metal ions, such as Cu^{2+} and Ni^{2+}, specifically through deprotonated peptide bonds.[9] The binding configuration and the binding constant are sensitive to the pH of the peptide local environment. To form the most stable metal–peptide complexes and also to avoid the precipitation of metal hydroxides on the Au electrodes, the pH of the solution was maintained at 8 and 9 for Cu^{2+} and Ni^{2+}, respectively. Under the experimental conditions, the metal ions and the peptides were expected to form mainly 1:1 metal-to-ligand complexes. For cysteamine-Cys, cysteamine-Gly-Cys, and Cys-Gly-Cys, the peptide bonds are completely deprotonated so the number of deprotonated

peptide bonds is 1, 2, and 3, respectively, whereas for cysteamine-Gly-Gly-Cys, the number of deprotonated bonds is 2 or 3.[10]

To reliably measure the conductance of a single molecule,[11–15] we used two complementary approaches. The first was a statistical approach, which has been described in detail elsewhere.[16,17] Briefly, individual molecular junctions were created by repeatedly moving an Au scanning tunneling microscope (STM) tip into and out of contact with an Au substrate in a solution that contained the sample molecules (1 mM, pH $\approx$ 8, Figure 1 a). The process was controlled by a feedback loop that started by driving the electrode into contact with the substrate by using a piezoelectric transducer (PZT). Once the contact was established, the feedback loop activated the PZT to pull the electrode out of contact. After breaking the contact, a series of steps appeared in the conductance that signaled the formation of the molecular junctions (Figure 1 b for cysteamine-Gly-Cys). The conductance steps correspond to the breakdown of the contact of individual molecules to the electrodes.[18] When the last molecule was broken, we then repeated the above process to

Figure 1. a) Schematic illustration of a molecular junction formed by the separation of two electrodes (PZT = piezoelectric transducer); b) several typical conductance curves of cysteamine-Gly-Cys during the stretching of the molecular junctions; c) conductance histogram constructed from over 500 individual conductance curves.

quickly obtain a large number of conductance curves. The histogram of the conductance curves exhibit well-defined peaks that are located at integer multiples of a fundamental conductance value, which is identified as the conductance of a single molecule (Figure 1 c). The first peak for cysteamine-Gly-Cys is located at $4.2 \times 10^{-6} G_0$ ($G_0 = 2e^2h^{-1} \approx 77\ \mu S$), which gives a conductance of ≈ 0.3 nS or a resistance of ≈ 3 GΩ. This statistical approach has allowed us to determine the single-molecule conductivity values for a variety of systems,[16,17,19] but important features associated with the individual molecular junctions may be lost. For example, the current–voltage (I–V) curve in the statistical approach is assembled from the positions of the peaks in the conductance histograms, which are obtained at different bias voltages and which smears out possible rectification behavior of asymmetric peptides. To overcome this difficulty, we used a second approach, which is similar to the break-junction method,[11] to measure the I–V characteristics of the peptides in this work. First, the Au tip was brought into contact with the substrate and then the tip was gently pulled out of contact by controlling the PZT whilst the conductance was measured continuously. Once the conductance dropped to the last step, which corresponds to the formation of a single molecule bridged between the electrodes, the position of the tip was fixed and I–V curves were measured.

Figure 2, a–c, shows the I–V curves obtained for three of the peptide sequences. The slopes of the I–V curves near zero bias voltage give the conductance values of these peptides, which agree with the conductance values extracted from the conductance histograms. The most striking feature shared by all the peptides is asymmetry in the I–V curves. For clarity, only the I–V curves with the same polarity (i.e. the current at negative bias is greater than the current at positive bias) are shown in Figure 2. In reality, the polarity of the asymmetric I–V curves varies from one junction to another owing to the random orientation of the molecules in these individual molecular junctions. Rectification behavior in peptides is expected because of the asymmetry and the electric dipoles of the molecules. In a control experiment, I–V curves were measured for 1,8-octanedithiol, which gave rather symmetric curves (Figure 2 d). Rectification is one of the most actively pursued goals in molecular electronics because of its potential application in molecular diodes.[1] Reichert et al. reported asymmetric I–V curves for asymmetric molecules by using a break-junction method.[11] Early observation of rectification behavior in a molecular system was observed on a Langmuir–Blodgett film of molecules that contained donor and acceptor groups.[20] More recently, Whitesides and co-workers demonstrated rectification behavior in a molecular junction, which involved two molecular layers sandwiched between silver and mercury electrodes.[21] In general, the observation of rectification requires asymmetric molecular junctions.[22–24]

The binding of Cu^{2+} to each of the peptides, which were self-assembled on the gold substrate, was studied by the introduction of Cu^{2+} (2 mM) into $NaClO_4$ (0.1M) and adjustment of the pH to 8 with NaOH at which value Cu^{2+} is expected to bind to the peptides.[10,25] Figure 3 shows the conductance curves of cysteamine-Gly-Gly-Cys during the formation of individual molecular junctions in the absence

Figure 2. Asymmetric I–V curves of a) cysteamine-Gly-Cys, b) Cys-Gly-Cys, and c) cysteamine-Gly-Gly-Cys; I–V data which were determined from conductance histograms for cysteamine-Gly-Cys are also shown (□); d) symmetric I–V curves of symmetric 1,8-octanedithiol.

after exposure to Cu^{2+} were observed. As shown in Figure 4, the quasi-reversible peaks around 160 mV (half of the sum of the potentials of the anodic and cathodic peaks) correspond to Cu^{2+}/Cu^{+} redox processes, which is in agreement with a similar Cu–peptide complex,[26] and confirms the formation of the Cu–peptide (deprotonated) complex. Previous cyclic voltammetry studies also reported such redox process for Cu^{2+}–diglycine and Cu^{2+}–triglycine complexes, but at potentials below −200 mV.[27,28] The positive shift of the redox potential may arise from surface adsorption.[26,29] No other redox features were observed which indicates the absence of Cu^{2+} ions that are simply coordinated with carboxyl or amine groups.[30,31] This is reasonable because all of the peptides studied here are flexible so they can fully use their binding sites. As a result, the complexes have high binding constants at pH 8. In a further control experiment, after conductance measurements of solutions of the free peptide and Cu^{2+}–peptide complex, respectively, we acidified the solutions with $HClO_4$ (10 mM) to pH ≈ 2 and again measured the conductance values of the substrates. As expected, the conductance of the single

(Figure 3 a) and presence (Figure 3 b) of Cu^{2+}. The last conductance steps in these curves correspond to the formation of single molecule junctions. The conductance steps of the peptide occur at values that are two orders of magnitude higher in the presence of Cu^{2+} ion than those in the absence of Cu^{2+} ion which shows that the Cu^{2+} binding event drastically changes the conductance of the peptide. From the corresponding conductance histograms (Figure 3, a and b, insets), conductance values of the peptide and the peptide–Cu^{2+} complex are 5×10^{-7} and 1.6×10^{-4} G_0, respectively. A typical I–V curve of the peptide complex is shown in Figure 3 d which is also asymmetric, but its slope (conductance) near zero bias voltage is much greater than that of the peptide itself (Figure 3 c).

Cyclic voltammetry measurements were also made on an Au substrate, which was coated with monolayers of the peptides, before and after exposure of the substrate to Cu^{2+}. Pronounced redox peaks

Figure 3. Individual conductance curves of cysteamine-Gly-Gly-Cys a) before and b) after binding to Cu^{2+}; the insets show the conductance histograms. I–V curves of cysteamine-Gly-Gly-Cys c) before and d) after binding to Cu^{2+}.
Figure 4. Cyclic voltammogram (vs. Ag/AgCl) of a (Cys-Gly-Cys)-modified electrode before (——) and after (- - - - and •••••) exposure to copper(II) solution recorded in Cu^{2+}-free buffer solution (pH ≈ 8). Cu^{2+} was accumulated at the (Cys-Gly-Cys)-modified electrode at open circuit for 10 min and then removed. Sweep rates: —— and -----: 100 mVs^{-1}; •••••: 500 and 1000 mVs^{-1}.

The binding of a metal ion to a peptide changes the conductance of a peptide in several ways. First, it affects the charge distribution of the peptide owing to the presence of the metal ion and the associated deprotonation of the peptide bonds. We recently observed that a change in the charge distribution of peptides can indeed change the conductance through a change in the tunneling barrier for the electrons, but the effect alone is usually small.[19] Furthermore, the effect of charge distribution cannot easily explain the sensitive dependence of the conductance of the metal-ion–peptide complex on the length of the peptide. Second, the presence of metal ions introduces new energy levels along the electron-transport pathway which may dramatically enhance the electron transport through a resonant tunneling effect.[32–36] Cyclic voltammograms indicate that the redox levels of Cu^{2+}–peptide complexes are closer to the Fermi energy levels of the electrode than those of corresponding Ni^{2+}–peptide complexes. This seems to explain the different changes induced by Cu^{2+} and Ni^{2+} in the conductance of the peptides. However,

molecule complex returned to the value found for the free peptide, an indication of the dissociation of Cu^{2+}–peptide complex in acidic solution.

The binding of different metal ions, such as Na$^+$, K$^+$, Cu^{2+}, Ni^{2+}, and Zn^{2+} to the different peptides in similar ways were also investigated. For Na$^+$ and K$^+$ ions, no changes in the conductance of the peptide were observed, which is expected because these ions do not bind to peptides. In the case of Zn^{2+}, a small increase in the conductance of the longest peptide was observed, which may be due to the weak Zn–peptide binding. However, the peaks in the conductance histograms for the Zn^{2+}–peptide complex are not well-defined and prevented further more-quantitative studies. The changes in the conductance upon the binding of Cu^{2+} and Ni^{2+} ions are rather dramatic, and the results are summarized in Table 1. The binding of the metal ions to the peptides increases the conductance, but the magnitude of the increase depends on the length and the sequence of the peptides as well as on the nature of the metal ions. For example, the change in the conductance is only ≈ 10 % for the shortest peptide, cysteamine-Cys, and ≈ 300 times for cysteamine-Gly-Gly-Cys. The change in the metal-ion-binding-induced conductance also depends on the sequence of the peptides. Cysteamine-Gly-Cys and Cys-Gly-Cys have the same length, but the binding of Cu^{2+} changes the conductance of the two peptides by 2 and 4 times, respectively. This dependence on the sequence may be attributed to the difference in the number of Cu^{2+} ion binding sites in the two peptides (2 in cysteamine-Gly-Cys and 3 in Cys-Gly-Cys). The binding of Ni^{2+} ions to the peptides also increases the conductance of the peptide but by a smaller amount than Cu^{2+} ions. This difference between the binding of Cu^{2+} and Ni^{2+} ions shows that the measurement of conductance can be used to distinguish different metal ions with similar binding configurations to a host molecule.

Table 1: Effects of the binding of metal ions (Cu^{2+} and Ni^{2+}) on the conductance of peptides of various lengths and sequences.

Peptide	No. of binding sites	Conductance of peptide [G_0]	Conductance of peptide–ion complex [G_0]	Conductance ratio
Cysteamine-Cys	2	1.8×10^{-4}	1.9×10^{-4} (Cu^{2+})	≈ 1
Cysteamine-Gly-Cys	3	4.2×10^{-6}	9.1×10^{-6} (Cu^{2+})	2.2
			6.5×10^{-6} (Ni^{2+})	1.5
Cys-Gly-Cys	4	5.3×10^{-6}	2.3×10^{-5} (Cu^{2+})	4.3
Cysteamine-Gly-Gly-Cys	4	5.0×10^{-7}	1.6×10^{-4} (Cu^{2+})	320
			6.0×10^{-5} (Ni^{2+})	120

like the charge distribution model, this metal-ion-induced resonant tunneling mechanism alone cannot easily explain the sensitive dependence of the conductance of the metal-ion–peptide complex on the length of the peptide. Finally, the binding of a metal ion to a peptide can significantly change the conformation of the peptide. As we discussed in the previous sections, metal ions, under the experimental conditions, have a tendency to coordinate to all of the peptide binding sites which thus forces the peptide to adapt a new conformation (illustrated in Figure 3). This has been observed by X-ray crystallographic measurements and supported by other experimental data.[37,38] As the binding process does not significantly change the bond lengths and angles of the peptide bonds, one may argue that the conformational change should not change the conductance if electron transport through the peptide backbone is considered as the dominant conduction pathway.[39] However, the electrons may be transported through the chelate bonds, mediated by the metal ion, and thus provide a new pathway for electron transport. As the amount of conformational change increases with the peptide length, the metal-ion-mediated transport pathway is more efficient than the peptide backbone pathway for long peptides. On the basis of these considerations, we believe that the dominant mechanism for the observed changes in the conductance arises from conformational change together with

Communications

metal-ion-mediated tunneling, although effects such as changes in charge distribution may also play a role.

In conclusion, the conductance and *I–V* characteristics of single peptide molecules covalently bound to two Au electrodes have been measured. The *I–V* curves are highly asymmetric, which reflects the asymmetric structures and electric dipoles of the peptides. Upon binding of metal ions, the conductance of the peptides increases by an amount that depends on the sequence and length of the peptides. This work demonstrates a method to study molecular recognition on a single-molecule level.

energy barrier for reversal of the direction of magnetization. At low temperatures, the spin of a single cluster can be permanently magnetized in the direction of the applied field.[1] Switching off the field leads to typical magnetic relaxation phenomena and hysteresis loops are observed. Magnetic clusters of this kind are called single-molecule magnets (SMM). These systems provide a remarkable example of macroscopic quantum tunneling,[2] but their interest lies also in their possible application as nanomagnetic devices.

A well-known type of SMM is the family of dodecanuclear manganese complexes (Mn_{12}) of formula $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$.[3,4] These mixed-valence compounds contain four Mn^{IV} centers and eight Mn^{III} centers that are exchange-coupled to give a large-spin ground state ($S = 10$). The axially distorted Mn^{III} centers provide the source for magnetic anisotropy and are also involved in the redox activity of the system. They can easily undergo reduction to Mn^{II}, so that the neutral Mn_{12} species can be transformed into the corresponding SMM Mn_{12}^- and Mn_{12}^{2-} ions with spin ground states $S = 19/2$, $21/2$ and $S = 10$, respectively.[5,6] A modification of the magnetic behavior of the system is observed when these anions are combined with appropriate cations (paramagnetic and/or redox-active).[7,8] In this context, we have recently developed a strategy to synthesize and characterize polycationic Mn_{12} SMMs bearing 16 quaternary ammonium substituents in the periphery[9] by a carboxylate-exchange reaction between the acetate precursor $[Mn_{12}O_{12}(O_2CCH_3)_{16}(H_2O)_4]$ ($Mn_{12}Ac$) and tributylammonium salt $ZHPF_6$.
The redox behavior of Mn_{12} derivatives is strongly correlated to the electron-withdrawing ability of the carboxylate ligands located in the periphery.[5b] A shorter separation between the cations and the $Mn_{12}O_{12}$ core should result in more stable reduced forms, as a result of the strong inductive effect caused by the cationic shell. We thus turned our attention to betaine hexafluorophosphate salt ($betHPF_6$) as the incoming carboxylic acid in the synthesis of $[Mn_{12}O_{12}(bet)_{16}(EtOH)_4](PF_6)_{14} \cdot 4CH_3CN \cdot H_2O$ (**1**), a two-electron reduced polycationic single-molecule magnet.

Complex **1** crystallizes in the centrosymmetric $P2/c$ space group.[10] The structure of the $Mn_{12}O_{12}$ core (Figure 1) is similar to that found in all Mn_{12} derivatives and comprises a central Mn_4O_4 cubane core surrounded by a nonplanar Mn_8O_8 ring held together with μ_3-oxo bridges. Peripheral bridging is
Figure 1. View along the *b* axis (ORTEP, ellipsoids are set at the 50% probability level) of the Mn_{12} polycation of **1** showing the propeller-like arrangement of the equatorial ligands (axial betaines and disordered EtOH molecules are omitted for clarity).

ensured by sixteen η^2-μ-carboxylate anions which provide a positive charge of $z = +16$ per cluster. The high charge is partially compensated by the presence of 14 hexafluorophosphate anions in the crystal lattice. Electroneutrality can thus be achieved if the Mn_{12} molecules are considered as two-electron reduced species. Bond valence sum (BVS) calculations[11] (see Supporting Information) were performed to confirm this hypothesis. The structures of the central cubane units compare well with previous results and are characteristic of Mn^{IV} centers. Half of the manganese ions located in the Mn_8 rings (Mn3 and Mn5) are clearly Mn^{III} centers and exhibit Jahn–Teller distortion, with the anisotropy axes lying almost perpendicular to the mean plane of the cluster.[12] The four remaining coordination sites (Mn4, Mn6, and their symmetry equivalents) do not show axial distortion and exhibit longer Mn—O bonds, which indicates partial reduction to Mn^{II}. These four Mn atoms are in a $+2.5$ oxidation state according to BVS analysis. Interestingly, one of these Mn atoms (Mn6) is coordinated to two ethanol molecules located in axial positions. This arrangement yields four ethanol molecules per Mn_{12} species distributed in a "*trans*" (0:2:0:2) arrangement as a result of the local C_2 symmetry of the cluster. The polycations exhibit a propeller-like arrangement of the equatorial betaine ligands around the Mn_8 ring. All the magnetic clusters have the same orientation in the crystal lattice, with their symmetry axis situated parallel to the crystallographic *y* axis. Hexafluorophosphate anions and solvent molecules fill the intercluster space.

AC magnetic susceptibility measurements of **1** were performed at different frequencies on crystals dried under vacuum and dispersed in oil. Figure 2a shows the temperature dependence of $\chi'T$, where χ' is the real part of the AC molar magnetic susceptibility. The plateau observed in the 5–8 K range (68–69 emu K mol^{-1}) lies considerably above the typical values (45–50 emu K mol^{-1}) found for other Mn_{12} compounds and is close to the expected value for an $S = 11$ ground state (66 emu K mol^{-1}). Frequency-dependent out-of-phase signals

spins of the Mn_8 ring) determined by the strong Mn^{IV}–Mn^{III} antiferromagnetic coupling mediated by the double μ-oxo bridge.

To verify this hypothesis, DC magnetization data were collected at $H = 0.1$–5 T at different temperatures between 2 and 5 K (Figure 3). A spin Hamiltonian including a Zeeman

Figure 3. Plots of reduced magnetization M versus H/T for **1** at different field strengths H. The isofield lines are least-squares fits to the data according to ref. [13]. The best-fit values for the different parameters are $S = 11$, $g = 2.05$, $D = -0.22$ cm^{-1}, $B_4^0 = 0.41 \times 10^{-4}$ cm^{-1}.

term and axial and quartic zero-field splitting was used to fit the isofield data.[13] The value of the zero-field splitting parameter ($D = -0.22$ cm^{-1}), obtained by assuming an $S = 11$ ground state, compares well with the existing data for doubly reduced species.[6b] This value gives an activation energy $E = M_S^2 D = 38$ K, which is higher than the effective energy barrier obtained from the AC data ($U_{eff} = 34$ K). This difference points to the presence of quantum tunneling through the barrier.

Low-temperature magnetization measurements were performed on single crystals of **1** down to 0.04 K. The applied field was set parallel to the experimentally observed easy axis of magnetization. The SMM character of the sample was confirmed by the observation of hysteresis loops in the 1.6–0.25 K range that are strongly temperature dependent (Figure 4) and field sweep rate dependent (not shown). In contrast to the situation found in most Mn_{12} derivatives, hysteresis was only observed below 2 K, a fact that correlates with the decrease of the energy barrier that occurs upon reduction. The magnetization is saturated down to zero field, which indicates a well-defined spin ground state. Quantum tunneling of the magnetization is evidenced by the observation of temperature-independent loops below 0.25 K that remain strongly dependent on the field-sweep rate. Quantum steps are observed with regular spacings of 0.24 T magnetic field. This yields a $|D|$ parameter of 0.23 cm^{-1} that matches the value obtained from magnetization measurements. The smearing of the quantum steps at high temperatures and/or low magnetic fields can be interpreted in terms of a distribution of energy barriers. This has been confirmed by

with very broad maxima in the 2–4 K range were observed (see Supporting Information), which indicates partial desolvation of the sample. Measurements on wet samples (Figure 2 b) afforded better results, and the presence of well-defined maxima in the 2–3 K range was confirmed. An effective energy barrier $U_{eff} = 34$ K for reversal of the magnetization was determined from the frequency dependence of these maxima. The out-of-phase AC results are similar to those obtained for $(PPh_4)_2[Mn_{12}O_{12}(O_2CCHCl_2)_{16}(H_2O)_4]$ (**2**), the only two-electron reduced Mn_{12} species reported to date,[6b] and clearly support a reduced state for **1**. Upon reduction, some of the anisotropic Mn^{III} ions become Mn^{II}, and the intrinsic energy barrier for reversal of the spins is lowered compared to neutral Mn_{12} molecules. The $\chi''(T)$ maxima are then shifted to lower temperatures. A novel aspect of this work is that, whereas **2** seems to have the same $S = 10$ ground state as its neutral analogue, two-electron reduction results in a higher-spin ground state $S = 11$. This result is consistent with the usual spin topology of the cluster (spins of the Mn_4O_4 cubane core oriented antiparallel to the

Figure 4. Single crystal measurement of magnetization *M* (normalized to its saturation value) versus field *H* applied in the direction of the easy axis of magnetization. The sweep rate was 0.035 Ts^{-1}.

relaxation measurements and is another indication of possible crystal defects subsequent to solvent losses.

The unusual oxidation state of this polycationic Mn$_{12}$ compound is related to the strong electron-withdrawing ability of the trimethylammonium groups. Note that betaine hydrochloride has a very low pK_a value of 1.8, compared with the value for acetic acid (4.76). This electron-accepting character pushes the first and second reduction potentials of **1** to more positive values relative to most Mn$_{12}$ compounds, as has been observed for the dichloroacetic acid derivative **2** with pK_a = 1.29. The differential pulse voltammogram (DPV) of **1** exhibits first and second reduction waves at $E = +0.49$ and $+0.21$ V (versus ferricinium/ferrocene couple), respectively. A third quasi-reversible reduction signal appears at -0.72 V (see Supporting Information). Thus, the stability range of the two-electron reduced species is extremely wide (ca. 1 V!) as compared with previous examples.

An interesting feature is that all of the reported syntheses of Mn$_{12}$ reduced species employ iodide as reductant. It is possible that ethanol plays this role in the present example as manganese oxides are common reagents for the oxidation of alcohols.[14] Also, coordination of ethanol to the Mn$_{12}$ core is unprecedented, and suggests further studies in which the nature of the ligands that occupy the four "water sites" is changed. Finally, preliminary results show that the polycationic compound **1** with an $S = 11$ ground state opens the way to the preparation of a variety of crystalline SMM salts by simple metathesis reactions, and that it is a useful precursor for the deposition of these magnetically active entities onto metal and metal oxide surfaces.

Experimental Section

All chemicals and solvents were used as received. [Mn$_{12}$O$_{12}$(O$_2$CCH$_3$)$_{16}$(H$_2$O)$_4$] (Mn$_{12}$Ac$_{16}$) was prepared as previously described.[15]

betHPF$_6$: A solution of potassium hexafluorophosphate (5.4 g, 2.93 mmol) in hot water (33 mL) was slowly added to a stirred solution of betaine hydrochoride (4.5 g, 2.93 mmol) in hot water

(18 mL). As the mixture cooled, betHPF$_6$ precipitated as a white crystalline powder. The product was filtered, washed with cold water, and dried under vacuum. Yield: 50%. ^{1}H NMR (300.1 MHz, CD$_3$CN): $\delta = 3.95$ (s, 2H), 3.20 ppm (s, 9H); ^{13}C NMR (75.5 MHz, CD$_3$CN): $\delta = 166.90$ (COOH), 64.84 (CH$_2$), 54.53 ppm (CH$_3$); IR (KBr): $\tilde{v} = 1739$ (s), 1479 (s), 1420 (m), 1266 (m), 1223 (m), 841 (s), 558 cm^{-1} (s); elemental analysis calcd (%) for C$_5$H$_{12}$F$_6$NO$_2$P (263.1): C 22.82, H 4.60, N 5.32; found: C 22.28, H 4.07, N 5.10.

1: Mn$_{12}$Ac$_{16}$ (0.25 g, 0.125 mmol,) was added to a solution of betHPF$_6$ (0.60 g, 2.3 mmol) in C$_6$H$_5$CN (35 mL) and CH$_3$CN (20 mL). The mixture was stirred overnight, filtered, and the solvent was evaporated under reduced pressure to complete precipitation. The solid was collected by filtration and dissolved in a small amount of CH$_3$CN. After addition of toluene, the solution was evaporated to dryness to remove the acetic acid as the toluene azeotrope. This stage was repeated twice. The product was then dissolved in C$_6$H$_5$CN (35 mL) and CH$_3$CN (20 mL) and treated again with excess betHPF$_6$. The entire process was repeated. Finally, the product was dissolved in CH$_3$CN (35 mL). The resulting solution was then filtered and layered with EtOH. Black plates suitable for X-ray crystallography formed after a few days at room temperature. ^{1}H NMR (300.1 MHz, CD$_3$CN): $\delta = 42$–39 (CH$_2$), 39–33 (CH$_2$), 30–25 (CH$_2$), 16.9–15.5 (CH$_2$), 15.5–14.2 (CH$_2$), 6.3–4.6 (CH$_3$), 4.0 (CH$_3$), 3.01 (CH$_3$), 2.12 (CH$_3$), 2.03 (CH$_3$), 0.80 ppm (CH$_3$); ^{19}F NMR (282.4 MHz, CD$_3$CN): $\delta = 68.52$ ppm (d, $J_{F,P} = 709$ Hz); ^{31}P NMR (121.5 MHz, CD$_3$CN): $\delta = -142.20$ ppm (m, $J_{P,F} = 709$ Hz); IR (KBr): $\tilde{v} = 3065$ (w), 2967 (w), 1626 (s), 1495 (w), 1436 (m), 1410 (m), 1341 (m), 1240 (w), 967 (w), 910 (w), 837 (s), 725 (w), 619 (w), 558 (m), 461 cm^{-1} (w); ESI-MS (CH$_3$CN, 30 V): m/z: 2159 {[Mn$_{12}$O$_{12}$(bet)$_{16}$](PF$_6$)$_{11}$+1e^{-1}}$^{2+}$; 2086 {[Mn$_{12}$O$_{12}$(bet)$_{16}$](PF$_6$)$_{10}$+2e^{-1}}$^{2+}$; 2028 {[Mn$_{12}$O$_{12}$(bet)$_{15}$]-(PF$_6$)$_{10}$+2e^{-1}}$^{2+}$; 1956 {[Mn$_{12}$O$_{12}$(bet)$_{15}$](PF$_6$)$_9$+3e^{-1}}$^{2+}$; 1007 {[Mn$_{12}$O$_{12}$(bet)$_{16}$](PF$_6$)$_9$+1e^{-1}}$^{4+}$, 777 {[Mn$_{12}$O$_{12}$(bet)$_{16}$](PF$_6$)$_8$+1e^{-1}}$^{5+}$; elemental analysis calcd (%) for [Mn$_{12}$O$_{12}$(bet)$_{16}$](PF$_6$)$_{14}$ (4755.1): C 20.21, H 3.73, N 4.71; found: C 19.86, H 4.26, N 4.46.

Physical measurements: NMR spectra were recorded on a Bruker Avance DRX 300-MHz spectrometer. ESI mass spectra were recorded on a Waters ZQ mass spectrometer using nitrogen as the drying and nebulizing gas. The equipment was calibrated with appropriate standard samples. All the magnetic measurements were carried out on polycrystalline samples with a magnetometer (Quantum Design MPMS-XL-5) equipped with a SQUID sensor. The samples were dispersed in oil to avoid torquing of the crystals. Variable-temperature susceptibility measurements were carried out at 2–300 K in a 0.1 T magnetic field. The susceptibility data were corrected for the diamagnetic contributions of the salts, as deduced by using a Pascal constants table. The AC measurements were performed in the temperature range 2–8 K at different frequencies with an oscillating magnetic field of $H = 0.395$ mT. The magnetization data were collected in the $H = 0$–5 T field range at different temperatures between 2 and 5 K. The hysteresis studies were performed at $T = 2$ K with H between 5 and -5 T, at, with sample cooling at zero field. Low-temperature magnetization measurements were performed on single crystals of **1** at 0.04–7 K using a micro-SQUID apparatus at different sweep rates between 0.1 and 0.001 Ts^{-1}.[16] The applied field was parallel to the experimentally observed easy axis of magnetization. IR transmission measurements of pressed KBr pellets were recorded at room temperature with a Nicolet Avatar 320 FTIR spectrophotometer ($\tilde{v} = 4000$–400 cm^{-1}). C,H,N elemental analysis was carried out on samples dried under vacuum in a CE instruments EA 1110 CHNS analyzer.

[10] Crystal data for **1**: $C_{96}H_{214}F_{84}Mn_{12}N_{20}O_{49}P_{14}$, $M_r = 5121.73$, monoclinic, space group $P2/c$, $a = 20.7870(4)$, $b = 18.3190(4)$, $c = 31.1280(7)$ Å, $\beta = 117.0730(10)°$, $V = 10554.6(4)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.612$ Mg m^{-3}, $\mu(Mo_{K\alpha}) = 0.939$ mm^{-1}. A dark brown platelike single crystal of **1** of dimensions $0.25 \times 0.10 \times 0.04$ mm^3 was used for data collection on a Nonius Kappa CCD diffractometer ($3.54° < 2\theta < 50.74°$) equipped with a graphite monochromated Mo$_{K\alpha}$ radiation source ($\lambda = 0.71073$ Å). Data collection was performed at 180(2) K. Of 112612 measured reflections, 19136 were independent ($R_{int} = 0.0868$) and used to refine 1278 parameters and 89 restraints. A multiscan absorption correction, based on equivalent reflections, was applied to the data using the program SORTAV[17] ($T_{max}/T_{min} = 0.9626/0.7613$). The structure was solved by direct methods (SIR97)[18] and refined against F^2 with a full-matrix least-squares algorithm using SHELX-97[19] and the WinGX (1.64) software package.[20] One ethanol molecule shows orientational disorder that was modeled with a set of two positions for each carbon atom having refined occupancies close to 0.5. These occupancies were fixed to 0.5 in the last cycles of refinement and refined isotropically. The disordered C atoms were presumed to have the same isotropic displacement parameters. Furthermore, C−C and C−O distances were restrained so that they were the same for both orientations within the same molecule. This kind of disorder in the coordinated ethanol molecule has also been observed in several Mn^{III}–Schiff base complexes.[21] A water molecule with an occupancy of 0.5 was located near this disordered ethanol molecule. The other ethanol molecule coordinated to Mn6 is not disordered and was refined anisotropically. Nine different hexafluorophosphate anions were located, three of them on special positions and one (on a general position) with a refined occupancy of 0.5, thus accounting for the +14 charge of the Mn$_{12}$ complex. Four acetonitrile solvent molecules were also located, which had refined occupancies of 0.5 that were fixed to this value in the last cycles of refinement. Geometrical restraints were applied to some of the hexafluorophosphate anions and solvent molecules which had high anisotropic displacement parameters. All the remaining non-hydrogen atoms were refined anisotropically. The positions of the H atoms on the C atoms were added into the calculated positions and refined on the corresponding atoms. H atoms on the O atoms of ethanol molecules were refined using the AFIX 147 instruction of SHELX-97. The H atoms of the water molecule were placed in theoretical positions using Nardelli's method. These H atoms were included in structure-factor calculations with fixed positional parameters and isotropic displacement parameters of 0.05 Å^2. Final R ($I > 2\sigma(I)$), $R_1 = 0.0853$, $wR_2 = 0.2284$; final R (all data), $R_1 = 0.1304$, $wR_2 = 0.2723$. Max./min. residual electron density 1.135/−1.378 e Å^{-3}. CCDC-235825 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

[13] The complete spin Hamiltonian is given by the following expression:[22]
$$\hat{\mathbf{H}} = -g\,\mu_B\,H\,\hat{\mathbf{S}} + D[\hat{S}_z^2 - \tfrac{1}{3}S(S+1)] + B_4^0\hat{\mathbf{O}}_4^0.$$
The best-fit values for the different parameters are $g = 2.05$, $D = -0.22$ cm^{-1}, $B_4^0 = 0.41 \times 10^{-4}$ cm^{-1}. The g value obtained is slightly higher than expected for a Mn$_{12}$ cluster ($g < 2$). A scaling factor of 3% can solve this problem, which lies within experimental uncertainty.

Cubic, Hydrogen-Bonded (10,3)-*a* Networks in the Family [C(NH₂)₃][N(CH₃)₄][XO₄] (X = S, Cr, and Mo)**

*Brendan F. Abrahams, Marissa G. Haywood,
Timothy A. Hudson, and Richard Robson**

The guanidinium cation $C(NH_2)_3^+$ serves as a powerful structure-determining component in a number of networks, both metal/ligand-bonded and hydrogen-bonded. The six hydrogen atoms of the cation are nicely disposed to form a pair of hydrogen bonds to each of three oxyanions, as shown in the generalized representation **1**. In an extensive family of

2

1
carbonate-bridged coordination polymers reported recently, the guanidinum cation plays the crucial structural role represented in **1** (Z = C), thus promoting the formation of highly symmetrical metal/carbonate networks with cubic symmetry and sodalite-like topology.[1] The arrangement seen in **1** (Z = B) is present in some highly symmetrical cubic guanidinium borate derivatives we discovered recently which have the boracite topology.[2] A closely related hydrogen-bonding mode, again as in **1** (Z = S), is seen in a range of guanidinium sulfonates in which the sulfonate units, as well as the guanidinium components, act as 3-connecting nodes, each being attached to three guanidinium units as in **2**. In some of the nicest examples of true crystal engineering, Ward and co-workers have elegantly exploited this complementarity between the guanidinium cation and various sulfonate anions to generate an extensive family of solids having a common, predictable, yet pliable, underlying hydrogen-bonded 3-connected sheet structure with the (6,3) topology or hexagonal grid topology.[3] We report here a new family of
hydrogen-bonded frameworks related to these guanidinium sulfonates in which the guanidinium cation again acts as in **1** (Z = S) and a sulfur oxyanion (in this case SO_4^{2-}) again acts as a second type of 3-connecting node; however, the network generated is the most symmetrical 3-connected 3D network possible, namely the (10,3)-*a* net,[4] rather than the most symmetrical 3-connected 2D network possible that was seen by Ward and co-workers.

Solvent-free crystalline products of composition [C(NH₂)₃][N(CH₃)₄][XO₄], (X = S, Cr and Mo) suitable for single-crystal X-ray diffraction studies were obtained directly from mixtures containing the component ions in the following solvents or solvent mixtures: X = S, from methanol; X = Cr, from aqueous DMSO; X = Mo, from methanol/DMF.[5] All our attempts to generate the analogous tungsten derivative [C(NH₂)₃][N(CH₃)₄][WO₄] have failed. In all cases, the crystals appear almost exclusively as well-formed tetrahedra, space group $P2_13$, $a = 10.5828(6)$ Å (X = S), 10.7589(5) Å (X = Cr), or 10.8802(4) Å (X = Mo).[6] The three compounds are isostructural and the following observations pertaining to the sulfate apply equally well to the chromate and molybdate, except for minor differences in some distances and angles. All the guanidinium cations in [C(NH₂)₃][N(CH₃)₄][SO₄] are equivalent and act as 3-connecting nodes, each being attached to three sulfate anions by hydrogen-bond pairs as represented in **1** (Z = S). Each sulfate unit is attached by hydrogen-bond pairs to three guanidinium cations (Figure 1), and therefore acts as a second type of 3-connecting node. Figure 2a shows the extended 3D network and Figure 2b shows the net generated by linking together the carbon centers of the

Figure 1. Three guanidinium cations each provide a pair of hydrogen bonds to a sulfate ion in the structure of [C(NH₂)₃][N(CH₃)₄][SO₄]. The three equivalent hydrogen bonds to the oxygen atom at the apex of the SO₄ tetrahedron are slightly longer (N−H···O, 2.899 Å) than the other three (2.792 Å); this expands the C-S-C angle to 97.5°.

guanidinium units and the sulfur centers of the sulfate units that are hydrogen-bonded to them. The net has the intrinsically chiral (10,3)-*a* topology.[4] The guanidinium nodes are slightly pyramidal (S-C-S angle 118.6°) but the sulfur nodes are much more so (C-S-C angle 97.5°). We have noted previously that it is possible to construct strain-free (10,3)-*a* nets and still retain the cubic symmetry not only when all the nodes are trigonal planar but also when all the nodes are trigonal pyramidal;[7] the present case brought to our attention the fact, previously unrecognized we believe, that it is also possible to construct strain-free (10,3)-*a* nets, again conserving cubic symmetry, in which half the nodes are trigonal planar and the other half are pyramidal, provided the latter retain a threefold axis of symmetry. These variants on the (10,3)-*a* net highlight the distinction that should be drawn (in considerations of networks in general) between geometry and topology: from the geometrical point of view, the three variants—1) all nodes trigonal planar, 2) all nodes trigonal pyramidal, and 3) alternate nodes trigonal planar and trigonal

pyramidal—appear to be very different, but from a topological point of view they are of course identical.

The tetramethylammonium cations, all of which are equivalent, are snugly accommodated in cavities within the framework (Figure 3). In the imaginary transition from a (10,3)-*a* net in which all the nodes are trigonal planar (Figure 4a) to one in which every other node is made trigonal pyramidal (Figure 4b), half the cavities centered on the

a)

b)
Figure 4. The imaginary transformation of a (10,3)-*a* net in which all nodes are trigonal planar (a) to one in which alternate nodes are trigonal planar and trigonal pyramidal (b). In the latter net, which retains cubic symmetry, half the cavities centered on the threefold axes are expanded (site A) and the others (site B) are contracted.

threefold axes are increased in size (A in Figure 4b) and the others (B) are contracted: the [N(CH₃)₄]⁺ units are found in the expanded cavities of type A and the sites on the threefold axes at the centers of the contracted cavities are empty. One C—N bond of the tetramethylammonium cation is oriented along one of the threefold axes with its carbon atom very

close to the center of an equilateral triangle of sulfur atoms (Figure 3a). Each of the C−H bonds of this methyl group located on the threefold axis is directed towards a sulfate oxygen atom (C···O 3.324 Å; angle at hydrogen atom ca. 168°; Figure 3b), thus indicating significant directional C−H···O hydrogen-bonding interactions in addition to the electrostatic attraction. Desiraju has drawn attention to the significance of C−H···O hydrogen bonding as a supramolecular motif in a variety of crystalline solids and to its importance in crystal engineering.[8] As can be seen in Figure 3b, two hydrogen atoms on each of the other three methyl groups are also directed towards a sulfate oxygen atom (C···O, 3.447 and 3.455 Å), thus providing additional C−H···O hydrogen-bonding interactions. All but three of the twelve C−H atoms of the $N(CH_3)_4^+$ ion are therefore involved in this hydrogen-bonding arrangement. Every sulfate ion is associated in this way with three tetramethylammonium ions by three trios of C−H···O hydrogen bonds and every tetramethylammonium ion is likewise associated with three sulfate ions. A 3-connected, 3D network of C−H···O interactions can therefore be envisaged in which the sulfur atoms and the nitrogen centers of the tetramethylammonium ions provide the nodes. This net also has the chiral (10,3)-*a* topology, but it is of the opposite sense to that of the primary (10,3)-*a* net composed of guanidinium and sulfate nodes. The C−H···O interactions between the tetramethylammonium cation and the sulfate anion are very likely much weaker than the N−H···O interactions that support the primary (10,3)-*a* network. In discussions of many networks it is convenient for simplicity to focus on certain selected interactions as constituting "the net" and to set aside other weaker interactions, whilst recognizing that these may nevertheless be structurally important. Such is the case here—the (10,3)-*a* net involving the stronger $[C(NH_2)_3]^+/[SO_4]^{2-}$ interactions is conveniently regarded as the primary net, but the secondary $[N(CH_3)_4]^+/[SO_4]^{2-}$ (10,3)-*a* net of the opposite chirality is of undoubted, possibly crucial, structural importance.[9]

In guanidinium sulfate itself,[10] every cation is attached by pairs of hydrogen bonds, again as in **1** (Z = S), to three sulfate anions. However, since in this case there are twice as many guanidinium cations as sulfate anions, each anion is connected to six guanidinium cations in the manner represented in the idealized form shown in **3**. The environment of the sulfate ion in guanidinium sulphate, as seen in **3**, can be envisaged in terms of guanidinium cations associated by a pair of hydrogen bonds at each of the six edges of the sulfate O_4 tetrahedron. In the guanidinium sulfonates, as represented in **2**, a cation
provides a pair of hydrogen bonds at each of the three edges of an O_3 triangle, thus disposing the system to form a 2D network, since the CN_3 planes of the three guanidinium cations surrounding any sulfonate are close to coplanar with the plane that includes all three guanidinium carbon centers. In the case of $[C(NH_2)_3][N(CH_3)_4][SO_4]$ reported here the $[C(NH_2)_3]^+$ and $[SO_4]^{2-}$ ions are present in equal numbers and only three of the six edges of the O_4 tetrahedron are required to participate in the hydrogen-bonding network and, as can be seen in Figure 1, the particular edges used are those that share an apex of the O_4 tetrahedron. This arrangement disposes the system to form a 3D network, rather than the 2D network seen in the sulfonates because, as can be seen in Figure 1, the CN_3 planes of the three guanidinium units are now close to perpendicular to the plane containing the three carbon atoms. If the two N−H···O hydrogen bonds in any particular $[C(NH_2)_3]^+/[SO_4]^{2-}$ association had been equal in length the C-S-C angles would have been 90°. The observed C-S-C angle of 97.5° is achieved by slightly stretching the three equivalent hydrogen bonds to the apex oxygen atom (to N−H···O = 2.899 Å) relative to the other three hydrogen bonds (2.792 Å). The C-S-C angle dictates the size of the cavity where the tetramethylammonium cation is located and presumably the inequality in the two hydrogen-bond lengths is such as to optimize the fit of the tetramethylammonium cation therein. It is significant in our view that guanidinium sulfate, itself a relatively stable, multiple hydrogen-bonded crystal lattice and therefore relatively insoluble, can be converted in the presence of $[N(CH_3)_4]^+$ into $[C(NH_2)_3][N(CH_3)_4][SO_4]$: this presumably reflects the snug fit of the $[N(CH_3)_4]^+$ ion into the expanded cavities within the $[C(NH_2)_3]^+/[SO_4]^{2-}$ (10,3)-*a* framework, with the formation of nine C−H···O interactions.

Only very minor differences are seen between the sulfate, chromate, and molybdate structures, consequences presumably of the different bond lengths within the anion (S−O, 1.449(2) and 1.486(4) Å; Cr−O, 1.631(4) and 1.657(7); Mo−O, 1.752(3) and 1.780(4) Å). For each of the structures, the longer Z−O bond corresponds to the unique bond lying on the threefold axis. Given the fact that this oxygen atom is involved in three hydrogen bonds to guanidinium ions this is not surprising. Differences in hydrogen-bonded N···O separations are very minor (sulfate: 2.792(3), 2.899(4) Å; chromate: 2.790(6), 2.887(5) Å; molybdate: 2.790(5), 2.914(4) Å).

The (10,3)-*a* net, being the most symmetrical of all possible 3-connected 3D nets, should occupy a position comparable in importance and significance to that of its better known 4-connected counterpart, the (6,4) diamond net; both are cubic in their undistorted forms and Wells long ago drew attention to their close relationship.[4] No doubt the (10,3)-*a* net has been accorded less significance by chemists than its topology warrants simply because the number of examples known is not large, but, with the current burgeoning interest in the generation of new 3D networks, this situation is likely to change. Although numbers of metal/ligand-bonded frameworks with the (10,3)-*a* topology are now increasing, hydrogen-bonded examples such as the ones reported here remain rare.[11] The results presented here, together with others,[1,2] indicate the potential of the guanidinium cation as a

3

Communications

structure-directing ion for the generation of new networks of high symmetry. These are possibilities we are actively pursuing.

[5] $[C(NH_2)_3][N(CH_3)_4][SO_4]$: A solution of guanidinium chloride (110 mg, 1.15 mmol) in hot methanol (10 mL) was added to a solution of tetramethylammonium chloride (1.52 g, 13.9 mmol) and tetramethylammonium sulfate (225 mg, 0.93 mmol) in hot methanol (40 mL) on the steambath. The crystals of $[C(NH_2)_3]$ $[N(CH_3)_4][SO_4]$ that separated on cooling were collected after 3 h and washed with methanol. Yield: 80 mg, 38%. The X-ray powder pattern of the bulk solid was in good agreement with that calculated on the basis of the single-crystal data. Elemental analysis calcd for $C_5H_{18}N_4O_4S$ (%): C 26.1, H 7.9, N 24.4; found: C 26.1, H 7.9, N 24.3. $[C(NH_2)_3][N(CH_3)_4][CrO_4]$: Na_2CrO_4 (150 mg, 0.925 mmol) together with excess guanidinium chloride and tetramethylammonium chloride were dissolved in hot water (2 mL) on the steambath. Hot dimethylsulfoxide (4.5 mL) was added on the steambath. The yellow crystals of $[C(NH_2)_3]$ $[N(CH_3)_4][CrO_4]$ which formed upon cooling were collected after 5 h and washed with a minimal amount of water. Yield: 70 mg, 30%. The X-ray powder pattern of the bulk solid was in good agreement with that calculated on the basis of the single crystal data. Elemental analysis calcd $C_5H_{18}N_4O_4Cr$ (%): C 24.0, H 7.2, N 22.3; found: C 23.9, H 7.3, N 22.2. $[C(NH_2)_3][N(CH_3)_4]$ $[MoO_4]$: MoO_3 (130 mg, 0.925 mmol) and guanidinium chloride (160 mg, 1.85 mmol) were dissolved in a hot solution of tetramethylammonium hydroxide (1 mL of 25% w/w in methanol, 2.4 mmol) and water (1 mL). Hot dimethylformamide (4 mL) was added and colorless crystals, which were deliquescent, separated after one day at room temperature. A single crystal was removed, immersed in oil and cooled as quickly as possible prior to collecting X-ray diffraction data.

[6] Crystal data for $[C(NH_2)_3][N(CH_3)_4][SO_4]$: $0.50 \times 0.50 \times 0.50$ mm, cubic, space group $P2_13$, $a = 10.5828(6)$ Å, $V = 1185.2(1)$ Å^3, $\rho_{calcd} = 1.291$ g cm^{-3}, $2\theta_{max} = 49.9°$, $\lambda = 0.71073$ Å, $T = 293$ K, no. of measured (and independent) reflections: 6294 (708), $\mu = 0.273$ mm^{-1}, min./max. apparent transmission ratio: 0.867, no. of parameters: 50, $R1$ $[I > 2\sigma(I)] = 0.0476$, $wR2$ (all data) = 0.0899, max./min. residual electron density: 0.198/ −0.159 e Å^{-3}. Crystal data for $[C(NH_2)_3][N(CH_3)_4][CrO_4]$: $0.08 \times 0.08 \times 0.08$ mm, cubic, space group $P2_13$, $a = 10.7589(5)$ Å, $V = 1245.4(1)$ Å^3, $\rho_{calcd} = 1.335$ g cm^{-3}, $2\theta_{max} = 49.9°$, $\lambda = 0.71073$ Å, $T = 293$ K, no. of measured (and independent) reflections: 6547 (737), $\mu = 0.918$ mm^{-1}, min./max. apparent transmission ratio: 0.837, no. of parameters: 49, $R1$ $[I > 2\sigma(I)] = 0.0673$, $wR2$ (all data) = 0.1399, max./min. residual electron density: 0.325/−0.19 e Å^{-3}4. Crystal data for $[C(NH_2)_3][N(CH_3)_4][MoO_4]$: $0.10 \times 0.10 \times 0.10$ mm, cubic, space group $P2_13$, $a = 10.8802(4)$ Å, $V = 1287.98(8)$ Å^3, $\rho_{calcd} = 1.517$ g cm^{-3}, $2\theta_{max} = 55.0°$, $\lambda = 0.71073$ Å, $T = 130$ K, no. of measured (and independent) reflections: 8159 (996), $\mu = 1.018$ mm^{-1}, min./max. apparent transmission ratio: 0.925, no. of parameters: 49, $R1$ $[I > 2\sigma(I)] = 0.0398$, $wR2$ (all data) = 0.0668, max./min. residual electron density: 0.591/−0.370 e Å^{-3}. In all cases all independent reflections were included in the refinement; multiscan absorption corrections were applied, all structures were solved by using direct methods and refined against F^2 using a full-matrix least-squares refinement;[12] hydrogen atoms were included at geometrically estimated positions. CCDC-247060–247062 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

Olefin Metathesis

Rapidly Initiating Ruthenium Olefin-Metathesis Catalysts**

Patricio E. Romero, Warren E. Piers, and
Robert McDonald*

Olefin metathesis is arguably the most powerful carbon–carbon bond breaking and making reaction in chemical synthesis.[1] Depending on the nature of the reacting partners, olefin metathesis can be used for ring-opening polymerization (ROMP),[2] to create advanced polymeric materials,[3] transformation of acyclic diene substrates into complex cyclic organic molecules (in ring-closing metathesis (RCM))[4] or polymers (in acyclic diene metathesis (ADMET))[5] or in cross metathesis (CM) to generate unsymmetrical olefins.[6,7] Although olefin metathesis is fully reversible, RCM, ADMET, and CM rely on the elimination of ethylene, the simplest olefin, as a thermodynamic driving force. Used by itself or in tandem with other synthetic transformations,[8,9] olefin metathesis is a versatile method for the modern synthetic chemist.

It is generally acknowledged that a metal carbene species, $\{L_nM{=}CRR'\}$, is required and that interaction with an olefin substrate leads to four-membered metallacyclobutane intermediates or transition states, $\{L_nM(CRR')_3\}$, by a 2+2 cycloaddition; cleavage of this intermediate in the opposite sense by which it was formed leads to olefin metathesis, creating a new carbon–carbon double bond and regenerating an active metal carbene. Metal carbenes are generally classified as being nucleophilic (electron rich) or electrophilic (electron poor) in character at the carbene carbon atom, but an effective olefin-metathesis catalyst exhibits behavior between these two extremes. Two carefully tuned classes of mediator have evolved into the catalysts of choice for olefin metathesis. Schrock catalysts[10,11] are molybdenum- or tungsten-based alkylidenes with a fairly specific ligand set designed to modulate the properties of the carbene (Figure 1). These catalysts display high activities and stabilities, but are sensitive to ambient air and moisture and are relatively intolerant of polar functionalities. The Grubbs-catalyst portfolio[12] consists of a variety of ruthenium-based systems of
Figure 1. Commercially available olefin-metathesis catalysts. Cy = cyclohexyl, Mes = 2,4,6-trimethylphenyl.

general formula $[Cl_2(L)(L')Ru{=}C(H)R]$ (compounds **1**) which are significantly more functional-group tolerant, but do not exhibit the same levels of activity or longevity as the Schrock catalysts.

The root of the lower activities of the Grubbs systems lies in their mode of initiation and the accessibility of the reactive species, which has been shown experimentally[13,14] and computationally[15,16] to be the 14-electron alkylidene $[Cl_2(L)Ru{=}C(H)R]$ formed upon reversible dissociation of L'. The reaction temperatures required to overcome this initiation step can lead to decreased catalyst lifetimes. Successful improvements to the "Grubbs first-generation" catalyst $[Cl_2(PCy_3)_2Ru{=}C(H)Ph]$ (**1b**) are modifications that either encourage loss of L'[17] or reduce the tendency of $[Cl_2(L)Ru{=}C(H)R]$ to re-capture the liberated L',[18] which competes with the olefin substrate for the unsaturated metal center in $[Cl_2(L)Ru{=}C(H)R]$. Alternatively, Hoveyda and co-workers have developed catalysts **1d**, in which L' is incorporated into a loosely chelating group associated with the carbene ligand that is removed upon the first metathesis event.[19,20] Fast-initiating improvements on this motif have been devised by Blechert and Wakamatsu.[21]

Herein we report a surprising twist on the Grubbs-catalyst motif that improves the kinetics of initiation dramatically by circumventing the initiation step in commercially available Grubbs catalysts completely, thus providing direct access to the reactive 14-electron catalyst species with no free L' present to interfere with the operation of the catalyst. This new generation catalyst precursor is easily prepared from existing Grubbs catalysts and brings their activity into the realm of the Schrock family, while retaining the favorable functional-group tolerance associated with the ruthenium systems.

Recently, Heppert and co-workers reported a stoichiometric metathesis reaction between catalyst precursors **1b** and **1c** and a methylene cyclopropane olefin known as Feist's ester.[22] Metathesis and elimination of diethyl fumarate provides the unusual ruthenium carbides **2a–c** (Scheme 1).

Communications

Scheme 1. Synthesis of rapidly initiating metathesis catalysts **3**; H₂IMes = N-heterocyclic carbene ligand.

Heppert and co-workers reported the preparation of carbides **2b** and **2c** in low yields; we have found this to be fairly a general reaction and a variety of carbides containing other combinations of L and L′ can be prepared in improved yields (90–96%) from **2b** and **2c**. We became interested in the reactivity of these carbides with electrophiles and discovered that protonation with $[H(OEt_2)_2]^+[B(C_6F_5)_4]^-$, Jutzi's acid,[23] leads to the cationic four-coordinate, 14-electron phosphonium alkylidenes **3a–c** by transfer of a trialkylphosphine ligand (that is, L′, Scheme 1) to the protonated carbide carbon atom in high yields (87–95%).[24]

Evidently, protonation of the carbide carbon atom switches it from being electron rich to electron poor; the electrophilicity of the protonated carbide carbon atom is quenched by transfer of the phosphine (L′) from the metal center, generating the observed phosphonium alkylidenes. For **3a** and **3b** (L = PR₃, R = iPr or Cy), the signal for the alkylidene proton appears as a distinctive doublet of doublets in the proton NMR spectrum at $\delta = 17.35$ ppm for **3a** and 17.46 ppm for **3b** ($^2J_{H,P} = 36$ Hz; $^3J_{H,P} = 1.5 \pm 3$ Hz). In **3c**, where L = H₂IMes, the three-bond hydrogen–phosphorus coupling is lost and the alkylidene hydrogen resonance signal appears as a doublet at $\delta = 17.70$ ($^2J_{H,P} = 36$ Hz). In the $^{31}P\{^1H\}$ NMR spectra, the signals for the phosphonium phosphorus atoms appear in the region around $\delta = 54$–58 ppm, while those of the phosphorus nuclei bonded to ruthenium appear at $\delta = 97.6$ (**3a**) and 88.7 ppm (**3b**). These latter resonance signals, while shifted about 60 ppm downfield relative to those found for **1b** and **1c**, are similar to that observed for the four coordinate complex $[(tBuO)_2(P-Cy_3)Ru=C(H)Ph]$ prepared by Grubbs and co-workers.[25] In **3c**, rotation of the IH₂Mes ligand about the Ru-C2 bond (see

Figure 2) is fast on the NMR timescale, with a free energy barrier of 11.5(5) kcal mol⁻¹ at 236 K calculated from the coalescence behavior of the NMR signals arising from the inequivalent mesityl groups at low temperature. This contrasts with the behavior for the parent compound **1c**, which exhibits slow rotation with a barrier of 21.8 kcal mol⁻¹.[26] Remarkably, when solutions of **3c** are exposed to the atmosphere, the NMR spectra remain unchanged for several hours, which indicates that the compound is stable to oxygen and ambient moisture. Indeed, introduction of water into these samples results only in minor perturbations to the spectra, owing to reversible coordination of H₂O to the ruthenium center. The compounds are thermally stable indefinitely in the solid state at room temperature and can be heated under refluxing CD₂Cl₂ (45°C, sealed tube) for several hours with no evidence of decomposition. Heating at 75°C in C₆D₅Br results in clean decomposition to an unidentified species ($^{31}P\{^1H\}$ NMR $\delta = 37$ ppm) with a half-life of approximately 5 h; the nature of this process is under investigation.[27] Preliminary studies show that the carbides can be converted into more economically viable BF₄ salts of cations **3a–c** by protonation with $[H(Et_2O)_x]^+[BF_4]^-$ with little change in the behavior of the compounds.

The precise structure of **3c** was determined by X-ray crystallography (Figure 2).[28] Compounds **3** represent the closest structural models for the proposed four-coordinate,
Figure 2. ORTEP diagram of **3c** (thermal ellipsoids set at 50% probability; counteranion and hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ru-C1 1.817(2), Ru-C2 1.988(2), Ru-Cl1 2.2951(5), Ru-Cl2 2.2809(5), P-C1, 1.805(2); C1-Ru-C2 100.07(7), Cl1-Ru-Cl2 150.51(2), Cl1-Ru-C1 103.15(6), Cl2-Ru-C1 102.79(6), Cl1-Ru-C2 96.14(5), Cl2-Ru-C2 92.90(5). 14-electron active species in the Grubbs-catalyst family; the only other structurally characterized example, the *bis-tert*-butoxide derivative $[(tBuO)_2(PCy_3)Ru=C(H)Ph]$,[25] relies on the replacement of the chloride ligands with sterically bulky groups for kinetic stabilization, but is essentially inactive as an olefin metathesis catalyst. As in the *bis-tert*-butoxide complex, the geometry about the ruthenium center in **3c** is a distorted trigonal pyramid with the H₂IMes ligand occupying the apex; however, the Cl1-Ru-Cl2 angle is at 150.51(2)° substantially larger than the O1-Ru-O2 angle of 133.19(6)° in

[(*t*BuO)$_2$(PCy$_3$)Ru=C(H)Ph]. The Ru-C1 and Ru-C2 bonds of 1.817(2) and 1.988(2) Å, are slightly shorter than those in **1c**,[17] a difference accounted for by the reduced coordination number in **3c**. The phosphonium alkylidene unit is oriented such that the PCy$_3$ group is pointing away from the IH$_2$Mes ligand. Angles and separations are normal within this part of the molecule and although C32 is positioned near a vacant ruthenium coordination site, any stabilization of the ruthenium center from the C–H sigma bonds of C32 is weak (Ru···C32 3.001 Å). No evidence for a C–H agostic interaction is observed in the proton NMR spectra, nor are low-frequency C–H vibrations apparent in the IR spectra of compounds **3**, which would be expected if any of the C–H bonds were donating electron density to the unsaturated ruthenium center.[29] Four-coordinate ruthenium complexes not stabilized by C–H agostic interactions are rare;[30] thus, apart from being models for the 14-electron active species in olefin metathesis, compounds **3** are unusual coordination compounds.

Metal carbenes are classified according to the donor qualities of the atoms directly bonded to the carbene carbon atom. Fischer carbenes incorporate π-donating groups (OR, NR$_2$), while the nucleophilic Schrock carbenes have π-neutral groups, such as H or alkyl substituents.[1] The phosphonium substituted carbenes of compounds **3** are a less common third class since the [PR$_3$]$^+$ group is a π acceptor.[31] Formally, this CHPR$_3$ ligand can be viewed as a deprotonated phosphorus ylid species (ylene resonance structure **A**, inset Scheme 1), but according to experimental[32] and computational[33] studies and the parameters for **3c** discussed above, a more realistic depiction is the dicarbanionic ylid resonance structure **B**. The ruthenium centers in compounds **3** may thus be viewed as formally Ru^{IV} with the carbene ligand functioning as a four-electron donor.

The electron-withdrawing nature of the phosphonium substituent in the carbene ligands of compounds **3** does not impede their ability to conduct olefin metathesis; they are exceptionally active RCM catalysts in comparison to catalyst precursors **1**. Using the RCM of diallyldiethylmalonate as a benchmark reaction, catalysts **1c** (Grubbs 2nd Generation), Schrock's molybdenum-based catalyst (Figure 1), the fast-initiating Grubbs catalyst [(IH$_2$Mes)Cl$_2$(3-Br-py)$_2$Ru=CHPh],[34] and compounds **3b** and **3c** were compared at 0°C by monitoring reaction progress to the cyclized product (Figure 3). At 0°C **1c** is a poor initiator[18] and only reaches approximately 25% conversion after 4 h. Compound **3b** fares somewhat better, providing about 90% conversion after 4 h, while Schrock's catalyst mediates the reaction to a similar point in this time. The sigmoidal shape of the curve for **3b** is reflective of the different activities of initiating versus propagating species at 0°C for this catalyst.[13] The transformation is very rapid for compound **3c**, however, which brings the reaction to >90% conversion after only 2 h at 0°C, twice as fast as the Schrock catalyst under these conditions and, significantly, it out-performs the fast-initiating Grubbs catalyst incorporating more labile 3-bromopyridine ligands. Furthermore, the rate of RCM for **3c** is qualitatively similar to the best Blechert catalyst,[21b] a less conveniently available metathesis catalyst.
Figure 3. Relative rates of conversion for RCM of diethyldiallylmalonate at 273 K by (■) **1c**, (◆) Schrock's molybdenum alkylidene, (✱) the Grubbs fast-initiating catalyst [(IH$_2$Mes)Cl$_2$(3-Br-py)$_2$Ru=CHPh], (▲) **3b**, and (●) **3c**.

We have also explored additional substrates for the RCM process with catalyst **3c** and initial results are summarized in Table 1. The reactions are completed within 2–60 min at room temperature (1% mol catalyst loading, except entry 2 and 6). Diethyldiallylmalonate (entry 1) is ring-closed in under 2 min, this is determined as an upper limit since the reaction time is too fast to be accurately measured at room temperature. Using 0.1% mol catalyst loading, a 100% conversion is reached within 30 min (entry 2). Similar results are found in the formation of a six-membered ring (entry 4 and 5), while higher catalyst loadings are required to push the closing of a seven-membered ring to acceptable conversions (entry 6). Notably, the closing of trisubstituted olefins proceeds to high conversion, under very mild conditions (entries 3 and 5). In particular, formation of the trisubstituted cyclopentene is complete in less than 10 min (entry 3); this particular substrate allows a more direct comparison with Blechert's catalyst, which accomplished this conversion in 40 min, under otherwise identical conditions.[21]

The reason **3c** is so active is that the need to dissociate a ligand for the ruthenium complex to enter the catalytic cycle[13, 18] has been completely obviated and initiation is now the much more energetically favorable binding of the substrate C=C bond to the ruthenium center. Rate constants for this process have been measured by monitoring the reaction of **3c** with varying excesses of *ortho*-isopropoxy styrene (10–40 equiv) at −30 to 0°C by proton NMR spectroscopy. This substrate was chosen since it produces the Grubbs–Hoveyda catalyst **1d** (Figure 1), which is inactive towards further metathesis reactions at the temperatures used; the other product is [(CH$_2$=CH)PCy$_3$][B(C$_6$F$_5$)$_4$], which was identified by separate synthesis and comparison of ^{1}H and ^{31}P NMR spectroscopy data. Use of this less-active substrate slows the reaction down, but also avoids complications in the kinetics arising from the presence of multiple active species in the reaction.[35] These studies indicate that the reaction is second order, first order in each of [**3c**] and [styrene]

Communications

Experimental Section

Complete experimental details, including synthesis and characterization of all the new compounds, can be found in the Supporting Information.

substrate, with a second order rate constant of $5.9 \pm 0.3 \times 10^{-4} \, \text{M}^{-1} \text{s}^{-1}$ at $-10\,°\text{C}$.[36] By evaluating this rate constant as a function of temperature (30 equiv of styrene), the thermodynamic activation parameters of the reaction were measured as $\Delta H^{\ddagger} = 8.6(4) \, \text{kcal mol}^{-1}$ and $\Delta S^{\ddagger} = -55(6)$ eu. The large, negative activation entropy is consistent with a bimolecular initiation step, which supports the notion that the measured barrier corresponds to rate-limiting olefin binding. Nevertheless, even for this very unreactive substrate,[20] the magnitude of the second-order rate constant at $-10\,°\text{C}$ is comparable to the initiation rate of $4.6 \pm 0.4 \times 10^{-4} \, \text{s}^{-1}$ measured at $35\,°\text{C}$ for the widely used Grubbs second-generation catalyst **1c**.[18]

These results are an advance in the evolution of ruthenium-based olefin-metathesis catalysis. Slow initiation has been a limiting factor for the existing Grubbs-catalyst portfolio and the phosphonium alkylidene compounds disclosed herein circumvent this problem by effectively eliminating the phosphine-dissociation initiation step altogether. In essence, all of the ruthenium added is actually operating as a catalyst in these reactions as compared to the traditional Grubbs catalysts, where the majority of ruthenium is tied up as the non-active **1c**. In compounds **3**, initiation consists of the much lower barrier olefin-binding event; subsequent metathesis to liberate $[(\text{CH}_2{=}\text{CH})\text{PR}_3][\text{B}(\text{C}_6\text{F}_5)_4]$ provides rapid and direct access to the propagating 14-electron ruthenium alkylidene complexes without any free phosphine present to drain the catalyst pool of active ruthenium.

The benefits of fast-initiating catalysts for a variety of metathesis applications are many. Lower catalyst loadings can be achieved which improves the economics and the environmental impact associated with use of these catalysts. Reactions can be performed at much lower temperatures, potentially providing greater enantioselectivity in asymmetric RCM reactions[37] and better chemoselectivity in commercially important CM processes.[38] In ROMP applications, rapid initiation leads to polymer products with narrower molecular-weight distributions.[39] Finally, the new compounds

[35] Attempts to determine rate constants by monitoring the ring closing of diallyldiethylmalonate gave nonlinear plots because, even at $-60°C$, the alkylidene product of initiation was active for turning the reaction over, as evidenced by the slow build-up of ethylene in the sample over time.

[36] The pseudo first-order plots from which the rate constants were obtained are linear for the duration of the reaction after a region of curvature at the beginning of the reaction (see Supporting Information). The origins of this kinetic behavior are not currently understood; further investigations are underway.

Nanoparticles and Catalysis

Nanozymes: Gold-Nanoparticle-Based Transphosphorylation Catalysts**

Flavio Manea, Florence Bodar Houillon, Lucia Pasquato, and Paolo Scrimin**

In his review on catalysis by colloid aggregates that appeared in this journal more than ten years ago, Menger wrote:[1] "…groups of molecules, properly assembled, can obviously accomplish much more than an equal number of molecules functioning separately". This observation is becoming more and more important as evidence is mounting that many biological systems interact and function through multiple simultaneous interactions.[2] On these bases a number of multivalent synthetic systems have been designed and studied for the recognition of simple molecules or more challenging biological targets. However, multivalent catalysts in which real cooperativity between the components is observed remain elusive, particularly in the case of self-assembling systems. For instance, most of the relevant rate accelerations often observed with aggregation colloids (such as, micelles and vesicles) appear to be related to concentration effects in the reaction loci (which include effects on the local pH value as well as on reactants and catalytic units) rather than to cooperativity.[3] Nevertheless, cooperativity is a rule in biological systems, such as enzymes. The reason for this lack of cooperativity in colloidal systems is largely entropic, and is related to the mobility of the constituent units (lipids/surfactants) that does not allow a catalytic site to last the time required for the catalyzed process to occur. Synthetic, functional polymers (synzymes)[4] allowed this problem to be solved, at least in part. Indeed cooperative catalysts based on these systems have been described.[5] However, a polymer presents other problems related to the difficulty in controlling its composition and conformation in solution.[6] Note that, as in the natural systems, not only the sequence of the building blocks (amino acids or any other) but also the conformation of the polymer are key requisites for catalysis. Alternatively,

Communications

dendrimers functionalized on the periphery may constitute a suitable alternative for which. contrasting results have been reported.[7]

It occurred to us that by exploiting the well known ability of thiols to bind to gold nanoparticles we could have facile access to multivalent, functional systems[8,9] anchored on a support, and yet fully soluble, with limited mobility and conformationally constrained and, hence, suitable to act cooperatively in a catalytic process. To test this hypothesis we have chosen one of the most challenging reactions: the cleavage of the phosphate bond of phosphodiesters as a model of a RNase. Most of these enzymes require for their activity at least two metal ions that act cooperatively.[10]

Gold nanoparticles (MPC) protected by a monolayer of 1-sulfanyloctane (MPC-C8) were prepared by the procedure reported by Brust and co-workers[11] and optimized by Murray and co-workers.[12] They were subsequently subjected to site exchange[13] with the azacrown-functionalized thiol 1 to yield functional nanoparticles 2 (Scheme 1).[14] Proton NMR spectroscopic analysis of the monolayer composition of 2 revealed a 1:1.2 ratio of 1-sulfanyloctane and 1, respectively. The core size of these ligand-functionalized MPC was 2.5 ± 0.7 nm as determined by transmission electron microscopy (TEM), see Supporting Information. Because of the presence of the triazacyclononane units, gold MPC 2 are expected to be able to bind transition-metal ions (such as, Cu^{II}, Zn^{II}) with high binding constants.[15] In the case of Cu^{II} the binding process can be followed spectrophotometrically at 648 nm, the maximum of the absorption band of the triazacyclonane–Cu^{II} complex. This property was used to determine the concentration of the ligand units (1) in stock solutions of 2.

Transphosphorylation activity of 2 was tested with Zn^{II} ions because of the relevance of these ions in biological phosphate-cleavage catalysis.[10] A thorough analysis of the system was carried out by using 2-hydroxypropyl p-nitrophenyl phosphate (HPNP) as the substrate, an activated phosphate diester frequently used as a model of RNA.

With HPNP the release of p-nitrophenol (or p-nitrophenolate, depending on pH) is accompanied by the formation of a cyclic phosphate[16] and can be easily followed spectrophotometrically. Figure 1 shows the reactivity profile obtained by progressively adding Zn^{II} ions to a solution of 2 up to the saturation of the metal-ion binding subunits. This kinetic analysis reveals that a) the most active system is the one fully loaded with Zn^{II} ions, b) the sigmoidal profile of the curve supports cooperativity[18] between the metal centers because the catalytic efficiency becomes much higher after the first 30% of Zn^{II} ions is added. The plot also indicates that possible cooperativity between a metal ion and an ammonium ion[19] (owing to the presence of the uncomplexed and hence protonated azacrown) is less important than the cooperativity between Zn^{II} ions. The presence of such a contribution to the catalysis would have resulted in a bell-shaped profile, the maximum corresponding to a nanoparticle where Zn^{II} complexes and ammonium ions coexist in close proximity.

The real catalytic nature of the process was assessed by carrying out experiments with excess substrate. No formation of an intermediate was detected and first-order kinetics were observed up to the complete cleavage of all the substrate present. By varying the initial substrate concentration a kinetic profile of the reaction towards saturation was observed. These kinetics allowed the determination of the apparent Michaelis–Menten parameters $K_M = 0.93$ mM and $k_{cat} = 4.2 \times 10^{-3}$ s^{-1}. Zinc(II)-nanoclusters 2 (Zn^{II}-2)[20] are, however, not selective in the binding of anions and, in fact, they also bind zwitterionic HEPES used as buffer for the experiments, which acts as an inhibitor of the catalytic process (see Supporting Information).[21]

The formal second-order rate constant for HPNP cleavage (k_{cat}/K_M) by Zn^{II}-2 is 4.4 s^{-1}M^{-1} which is more than 600-times

Scheme 1. Reaction scheme for the synthesis of ligand thiol 1, and ligand-functionalized gold nanoparticles 2; BOP = (1H-benzotriazol-1-olato-O)tris(N-methylmethanaminato)-phosphorus hexaflurophosphate, DIEA = N,N-diisopropylethylamine.
Figure 1. Dependence of the rate constant for the cleavage of HPNP by **2** on the amount of Zn^{II} ions. Conditions: 40°C, pH 7.5 (5 mM N-(2-hydroxyethyl)-N'-(2-ethanesulphonyl)piperazine (HEPES) buffer), [**1**] = 0.1 mM.[17]
Figure 2. Dependence of the rate of cleavage of HPNP by **2**-Zn^{II} as a function of pH value. Conditions: 40°C, [buffer] = 5 mM, [**1**-Zn^{II}] = 0.1 mM.

higher (see Table 1) than that determined under identical conditions for the mononuclear catalyst Zn^{II}-**3**, which corresponds to the "active unit" on the surface of MPC **2**.
Table 1: Rate constants for the cleavage of HPNP by different Zn^{II}-based catalysts.

Catalyst	k_{cat} [10^{-4} s^{-1}]	k_2 [M^{-1} s^{-1}]	Relative rate[a]
Zn-**3**[b]	–	0.007	1
Zn-**2**[b,c]	42	4.4	629
Zn-**4**[b]	–	0.028	4
Calix[4]arene-2Zn[d,e]	7.7	43	3071
Calix[4]arene-3Zn[d,f]	24	2.9	138

[a] Relative second-order rate constant normalized for the number of metal centers present in the catalyst; [b] At pH 7.4 and 40°C; [c] The activity of MPC-C8 (if any) could not be tested because of the insolubility of these nanoparticles in the aqueous environment; [d] At pH 7.0, 25°C, and 50% aqueous CH$_3$CN; [e] Dinuclear Zn^{II} complex of 2,6-diaminomethylpyridine-functionalized calix[4]arene reported in ref. [25]; [f] Trinuclear Zn^{II} complex of 2,6-diaminomethylpyridine-functionalized calix[4]arene reported in ref. [25].

Micellar Zn^{II}-**4** scores slightly better than Zn^{II}-**3** but still the second-order rate constant determined for this catalytic system is approximately 160-fold lower than that of the nanoparticle-based catalyst. To study the origin of this impressive rate acceleration we have run kinetics at different pH values to assess the pK_a of the active nucleophile in the process (Figure 2). Available data from our[22] as well as from other[23] laboratories indicate that the close proximity of several metal centers induces the decrease of the pK_a of metal-ion-bound protic species with respect to monomeric complexes. The apparent pK_a value for the active nucleophilic

species is 7.4 which is 0.4 units lower than that reported[24] for the Zn^{II} complex of triazacyclononane.

Thus part of the reactivity gain is due to a decrease of the pK_a value of the nucleophile. Allowing for this difference in pK_a value, catalyst Zn^{II}-**2** is still 380 times more effective than Zn^{II}-**3**. Indeed the k_{cat} of Zn^{II}-**2** is comparable to that of the best multinuclear Zn^{II} catalysts for HPNP cleavage reported so far (see Table 1).[25] These systems are based on calyx[4]-arene functionalized with two or three 2,6-diaminomethyl-pyridine units and are thus able to bind up to three Zn^{II} ions. They show a rate versus pH-value profile that goes through a maximum at approximately pH 7. This behavior indicates that cooperativity between the metal centers may be due to the occurrence of general-acid/general-base catalysis or nucleophilic catalysis and substrate binding.[26] In our case, on the contrary, the plot indicates that the role of the metal ions is in stabilizing the complexed substrate towards the transition state where a further negative charge develops and in facilitating deprotonation of the nucleophilic species.[22] Note that the efficiency of catalyst **2** was estimated on the basis of the total concentration of the active monomers, **1**, and not on that of the nanoparticles, in analogy to what is conventionally carried out with aggregation colloids. We do not know the number of Zn^{II} ions that actually take part in the catalytic process and that would define the catalytic site of the system (we estimate, on the basis of elemental analysis and particle size, the presence of about 45 thiol units **1** per nanoparticle). Accordingly, the reactivity reported is per single Zn^{II} complex and clearly underestimates the intrinsic reactivity of the active catalytic cluster. For comparison it is as if the reactivity of the calyx[4]arene systems were divided by two or three, that is, the number of metal centers present in the systems. In contrast with the nanoparticles, these latter systems are more efficient in the binding of the substrate because of the presence of the calyx[4]arene cavity.

With such an outstanding catalyst in hands we turned to more appealing substrates such as RNA dinucleotides (3',5'-NpN), namely ApA, CpC, and UpU. Their uncatalyzed cleavage is extremely slow with rate constants (at pH 7) ranging from 9.8×10^{-9} s^{-1} (UpU)[27] to 1.7×10^{-9} s^{-1} (ApA),[28] that is, about two orders of magnitude less reactive
than HPNP. The cleavage process was followed by HPLC monitoring the disappearance of the substrates and the formation of cyclic ribonucleoside monophosphate (2′,3′-cNMP) and the corresponding nucleoside. As in the case of HPNP, the process is an intramolecular transesterification, in this case by the hydroxy group at the 2′-position of the ribose. At pH 7.5 (5 mM HEPES buffer) and 40°C, Zn^{II}-**2** cleaves ApA, CpC, and UpU with second-order rate constants of $3.0 \times 10^{-4}\, s^{-1}M^{-1}$ (ApA), $3.6 \times 10^{-4}\, s^{-1}M^{-1}$ (CpC), $1.2 \times 10^{-2}\, s^{-1}M^{-1}$ (UpU).[29] Thus catalyst Zn^{II}-**2** is fairly active in the cleavage of RNA dinucleotides. The activity of Zn^{II}-**2** is, in this case too, subjected to inhibition by anions. We also observed relevant inhibition by the internal standard used for the HPLC analysis (sodium 3-nitrophenylsulphonate, see Supporting Information). The much higher activity observed with UpU may be related to a tighter binding of this substrate to the catalyst as suggested in the case of the above mentioned calyx[4]arene-based catalysts.[30] However, for UpU, Zn^{II}-**2** is less active the best calyx[4]arene-based catalyst.[31] Since UpU binding probably occurs by coordination to a Zn^{II} ion of the unprotonated amide of the base[32] it is possible that the geometry of binding of the substrate to the nanocluster is less appropriate than that obtained with the calyx[4]arene-based systems. These are just speculations and a more detailed analysis of the system is necessary.

In conclusion, we have shown that the self-assembly of ligand-functionalized thiols on gold nanoclusters provides a straightforward entry to a Zn^{II}-based catalyst that is extremely effective in the cleavage of phosphate diesters, such as HPNP and 3′,5′-NpN. In the case of HPNP, gold nanoclusters Zn^{II}-**2**, constitute one of the best Zn^{II}-based catalyst described to date. The facile synthesis of these systems and their outstanding catalytic properties induce us to call them "nanozymes" in analogy to the nomenclature of catalytic polymers (synzymes). Changing the nature of the functional units present on the gold-protecting monolayer may afford easy access to a variety of powerful, self-assembled catalysts (nanozymes) of which Zn^{II}-**2** is just a prototype.[33]

Experimental Section

1: 1,1-Dimethylethoxycarbonyl (Boc) diprotected ATANP methyl-amide[34] (152 mg, 0.35 mmol; ATAMP = (S)-2-amino-3-[1-(1,4,7-tri-azacyclononane]propionic acid) was treated with 8-acetylsulfanyloc-tanoic acid (91 mg, 0.36 mmol) under coupling conditions (BOP) in CH_2CH_2 to yield 97 mg of a oily product (43%) after column chromatography (SiO_2, ethyl acetate:light petroleum 7:3). This material was treated with 33% HBr in acetic acid (6 h, amine deprotection) and the precipitate obtained by addition of ethyl ether was treated with a solution of acetylchloride in methanol (24 h, thiol deprotection). The solid obtained was passed through an IRA-410 Amberlite resin (acetate) to give the diacetate salt of **1** in quantitative yield. ^1H NMR (250 MHz, D_2O): $\delta = 1.30$ (bm), 1.55 (bm), 2.17–2.31 (m), 2.76–2.98 (m), 4.65 ppm (m). ESI-MS, m/z: $[M+H]^+$, 387 $[M^+]$.

2: In a thermostated reactor kept at 28°C MPC-C8 (26 mg), prepared according to Murray's procedure,[12] was dissolved in CH_2CH_2 (15 mL). Compound **1** (13 mg) dissolved in methanol (15 mL) was added to the solution which was then stirred for five days. Removal of the solvent and triturating the waxy solid with water gave a dark solution that was passed through a Sephadex G-50 resin eluting with water. Liophilization of the appropriate fractions gave 19 mg of MPC **2** whose authenticity was ascertained by ^1H NMR (300 MHz, D_2O) and IR (KBr) spectroscopy (see Supporting Information).

Kinetics: For the cleavage of HPNP, kinetic experiments were recorded by monitoring the absorbance of released p-nitrophenol (317 nm) or p-nitrophenate (400 nm) against the pH value of the solution with a Perkin-Elmer Lambda 16 instrument equipped with a thermostated cell holder. Rate constants were determined by interpolation of the absorbance versus time data using MicroMath Scientist version 2.01 software whenever the kinetics were followed to completion. For kinetics in the presence of excess substrate the initial-rate method was used monitoring at least 20% product formation. Reproducibility within ±15% was observed in repeated runs. For the cleavage of ApA, CpC, and UpU the reaction was followed by HPLC by withdrawing 10 µL of the reaction solution which was mixed with 40 µL of a 10 mM solution of ethylenediaminetetraacetic acid (EDTA). Reaction vessels were carefully sterilized before use at 130°C for 1 h. Separation conditions: column Alltech LiChrospher RP-18 (150 mm × 4.6 mm); eluent gradient (0–20% of B in A; A = H_2O 0.075% trifluoroacetic acid (TFA); B = 1:1 CH_3CN/H_2O 0.075% TFA). For a typical chromatogram see the Supporting Information.

[17] It is convenient to report the concentration in terms of the active component, that is, **1**. This concentration was determined by spectrophotometric titration as mentioned in the text.

[18] We do not know if a higher concentration of **1** on the surface of **2** would produce more active nanoparticles because the 1:1.2 ratio between 1-sulfanyloctane and **1** was the highest ratio we could obtain; furthermore the sorting of the components (that is, an uneven distribution of **1**), if it occurs, cannot be assessed.

[20] Zn^{II}-**2** denotes nanoclusters **2** to which a stoichiometric amount of Zn^{II} has been added with respect to the concentration of **1** present in the monolayer.

[21] Product inhibition was also observed at very high substrate loadings; nevertheless the turnover number (TON) is ≥ 100 for Zn^{II}-**2** and HPNP.
