structures, such as nanomesh and superlattices, have been studied intensively not only because of their interesting intrinsic properties, which arise from low dimensionality and quantum effects, but also their capability for direct nano-system integration. To date, nanoscale building-block assemblies for applications such as nanocomputing and nanophotonics have been developed by using microfluidic,[1] Langmuir–Blodgett,[2] and other techniques.[3] These 2D structures that are assembled through weak noncovalent interactions[4,5] or external fields (e.g. shearing[6] and electric fields[3]) are unsuitable for devices that require intensive interwire communications (e.g. efficient charge transport), high surface areas, excellent accessibility, and mechanical robustness. Fabrication of 3D nanowire networks with controlled diameters and arrangements of the wire, tailored pore structures, and effective interwire connectivity is therefore paramount for new device applications. Current inverse opal networks[7] are limited by the large diameters of the wire that may preclude quantum effects, and recent biomimetic approaches have also resulted in networks of large, randomly connected wires.[8]

We report here a general synthetic route to stable, 3D continuous, hierarchically organized networks of metals or semiconductors that are composed of nanowire-like elements which uses a templated electrodeposition technique. Although reverse surfactant liquid-crystalline[9] and 2D hexagonal mesoporous silica templates[10] have been used to electrochemically deposit 2D nanowires, removal of the templates has resulted in aggregated nanowires with poor structural control. Here we have electrochemically replicated the bicontinuous surfactant liquid-crystalline (LC) phases to obtain a robust nanowire network. Figure 1 outlines the approach: first, a film of mesoporous silica is coated onto a conductive substrate through the co-assembly of the silicate and surfactant molecules followed by removal of the surfactant,[11] then, the pore channels are filled with metals or semiconductors by electrodeposition, and lastly, the silica template is removed to create a replicated mesoporous nanowire network. Besides the excellent control over the composition, this approach enables precise structural tuning by replication of the complicated but well-studied silicate/surfactant LC mesophases. For example, the diameter of the nanowire can be tuned from 2 to 20 nm depending on the pore sizes of the template, and 3D networks of nanowires can be controlled by the 3D cubic mesostructure. Pore sizes of the

nanowire networks can be tuned from 1 to 4 nm depending on the thickness of the pore walls of the templates.[12,13] Hierarchical pore structures can be readily obtained by the incorporation of colloidal silica porogens, which range in size from a few to several hundred nanometers, or by the incorporation of templates with various shapes, such as particles, rods, and plates, into the self-assembled surfactant/silicate mesophases followed by their removal.

The replication of ordered 3D crystalline nanowire networks can be analyzed by transmission electron microscopy (TEM) and X-ray diffraction (XRD) measurements. Figure 2, a–c show TEM images of cubic mesoporous templates, which were prepared by using Brij 58 surfactant (unit cell parameter of 8.4 nm), along the [111], [211], and [100] orientations. The diameter and wall thickness of the pores of the templates were estimated from nitrogen sorption, XRD, and TEM studies to have values of around 4–6 nm and 2–3 nm, respectively. Small angle XRD shows the presence of a (211) reflection, which corresponds to a d-spacing of 34.6 Å, for both the nanowire networks and the template and indicates good fidelity of the replication process. The broadening of the (211) reflection and the absence of the (210) reflection from the nanowire networks are due to a partial destruction of long-range mesostructural order upon removal of the template (see Supporting Information). Figure 2, d–f show TEM images of the replicated Pd (parts d and e) and Pt (part f) 3D nanowire networks. The average diameters of the nanowire (5 nm) and the pore (2–3 nm) agree well with the pore sizes (4–6 nm) and pore-wall thickness (2–3 nm), respectively, of the templates. The crystalline lattice of the Pt nanowire networks is clearly revealed in the high-resolution TEM (HRTEM) image (Figure 2 g). The ring patterns from selected area electron diffraction (SAED) studies of the Pd and Pt nanowire networks (insets of Figure 2 d and f, respectively) indicate that these nanowire networks possess randomly oriented *fcc* crystalline domains. The crystallite sizes estimated from XRD and TEM are ≈ 5 nm, which is similar to the pore size of the template.

Macroscopic connectedness of the networks was confirmed by field emission scanning electron microscopy (FESEM) studies as shown in Figure 3. The Pt nanowire network shows a continuous, homogeneous surface morphology (Figure 3 a) with an ordered mesostructure (Figure 3 b). Electronic continuity was demonstrated by cyclic voltammetry measurements performed upon an acidic aqueous solution in which hydrogen adsorption–desorption occurred at the surface of the Pt nanowire (Figure 4 a). The charge associated with hydrogen adsorption and oxidation is proportional to the active surface area of the Pt nanowire network. By this approach, an average active surface area of 27 ± 2 m^{2}g^{-1} was determined, which is comparable to that of mesoporous Pt.[14] Three anodic hydrogen oxidation peaks were present at relative potentials of 0.03, -0.03, and -0.08 V (vs.
Figure 1. Schematic showing the formation of 3D continuous macroscopic metal or semiconductor nanowire networks by a templated electrodeposition technique. a) 3D cubic mesoporous template, b) 3D nanowire/silica nanocomposites, c) 3D nanowire network.
Figure 2. TEM images of the 3D cubic mesoporous silica templates prepared using Brij 58 surfactant, and the replicated metal or semiconductor nanowire networks. a), b), and c) TEM images of the cubic structured template along the [111], [211], and [100] directions, respectively. The pore-to-pore distances measured from the TEM images are ≈4.8, 3.4, and 8.2 nm, respectively, and agree well with the results of XRD studies (a = 8.4 nm). d) and e) TEM images of the Pd nanowire network replicas along the [111] and [211] directions, respectively, which indicate the formation of a highly ordered Pd nanowire network; the inset in (d) shows a SAED pattern of the Pd nanowire network with a typical Pd *fcc* crystal structure. f) TEM image of a Pt nanowire network replica along the [100] direction; the inset in (f) shows the SAED pattern of the Pt nanowire network with a typical Pt *fcc* crystal structure. g) HRTEM image of a Pt nanowire network. h) TEM image of a [111]-oriented CdSe nanowire network; the inset of (h) shows the SAED pattern of a polycrystalline CdSe network with a randomly oriented crystalline structure. i) HRTEM image of a CdSe nanowire network showing crystalline lattice fringes.

nanowire networks shown in Figure 3,c–e. FESEM and TEM images (Figure 3,d and e, respectively) of the hierarchical Pt nanowire networks clearly indicate the formation of secondary pores (20–100 nm). Highly porous nanowire networks with spongelike (Figure 3c) and grasslike (Figure 3e) morphologies are clearly revealed. As the silica particles which are added may significantly affect the nucleation and growth of the silicate/surfactant assemblies, more-complicated structures were created by varying the size and shape of the silica additives.

Besides the precise structural control over relatively large distances, this method can be extended to synthesize nanowire networks with various chemical compositions such as other metals (e.g. Co), alloys (e.g. PtNi), and semiconductors (CdSe, CdS, and Bi_2Te_3). An example of CdSe nanowire networks is shown in Figure 2,h and i. The images suggest an ordered (Figure 2h) and crystalline (Figure 2i) replicated mesostructure in the semiconductor nanowire networks. The SAED pattern (Figure 2h, inset) indicates a randomly oriented zinc blende crystalline structure. Crystalline CdSe networks composed of ≈11-, 5-, and 3-nm diameter nanowires were synthesized by using cubic templates which offered the corresponding pore

SCE, saturated calomel electrode), which is consistent with the isotropic polycrystalline nature of the nanowire network. The cyclic voltammetry studies demonstrate catalytic activity, pore accessibility, and electrical continuity of the nanowire networks.

Device applications often require hierarchical pore structures that may provide higher surface areas and more-efficient mass transport. The strategy presented here has particular advantages in the preparation of such hierarchical nanowire networks because silica templates with hierarchical structures can easily be made through the surfactant–assembly process.[15] For example, hierarchical templates used in this research were prepared by the introduction of colloidal silica spheres (20–100-nm diameters) into the surfactant/silicate thin-film assemblies, followed by calcination. Electrodeposition and template removal resulted in the hierarchical

diameters. The ability to control the nanowire diameter in turn allows continuously tuned optical absorption owing to quantum confinement. The first excitonic peaks in the absorption spectra of the CdSe nanowire network shift from $\lambda = 640$ to 470 nm upon decreasing the diameters of the nanowire from 11 to 3 nm (Figure 4b). As the nanowires are arranged in a stable network through strong metallic or covalent bonds, as-synthesized networks are stable in organic solvents and remain unaffected after thermal treatments. Crystallized semiconductor nanowire networks with 3D interconnected hierarchical structures and tunable optical properties are great candidates for optical hosts, photovoltaics, and other applications.

Figure 4c shows magnetization hysteresis loops measured at room temperature of a Co 3D nanowire network by using a field applied either parallel or perpendicular to the substrate.
Figure 3. Top-view FESEM and TEM images of Pt nanowire networks of controlled macroscopic morphologies. a) and b) Low- and high-magnification FESEM images of 3D Pt nanowire networks, prepared by using the Brij 58-directed mesoporous silica template, which show homogeneous surface morphology and the ordered mesostructure, respectively. c) and d) FESEM and TEM images of a hierarchically porous Pt nanowire network cotemplated by Brij 58-directed mesoporous silica and dense colloidal silica particles with an average diameter of 20–70 nm. e) FESEM image of a Pt nanowire sponge cotemplated by P123-directed mesoporous silica and dense colloidal silica (70–100 nm). This sponge structure consists of intertwined 3D nanowires that form an interconnected hierarchical pore network.

superparamagnetic behavior is due to the randomized particle magnetic polarizations at a temperature higher than the blocking temperature.[18] The unique continuous 3D nanowire network structure may enhance the dipolar interactions between magnetic domains or the intercoupling along nanowire chains, which may result in increased blocking temperatures and room temperature ferromagnetic behavior.[20,21] A 3D Co nanowire network with a smaller diameter of the nanowire (3–4 nm) also shows ferromagnetic behavior at room temperature.[22] Detailed studies are underway to understand fundamentally the magnetic behaviors. Nevertheless, such room temperature ferromagnetic nanowire networks with small nanowire dimensions and enhanced coercivities show potential for high-density information storage applications.

The presence of the hysteresis loop in both directions indicates that the Co nanowire network is ferromagnetic at room temperature. A higher coercivity (255 Oe) than that of Co thin films (≈ 10 Oe)[16] is observed. Furthermore, the 3D nanowire network, different from Co thin films or 2D wire arrays with uniaxial anisotropic magnetization,[16,17] gives isotropic magnetism as indicated by its similar coercivity and remanent magnetization behaviors shown in the inset of Figure 4c. In comparison, diluted Co nanoparticles of 2–11-nm diameter and 2D Co nanoparticle superlattices show superparamagnetic behavior at room temperature.[18,19] Such

In conclusion, we have developed a rapid and effective approach to fabricate stable macroscopic nanowire networks with controllable composition, tunable hierarchical structure, and unique properties. The dimensions of the nanowire and the network structure are tunable by the precise replication of the self-assembled silica/surfactant liquid-crystalline structure. Hierarchical pore morphology can be obtained by using secondary silica porogens that have desired shapes and sizes. This versatile approach is applicable to a variety of materials such as polymers, metals, and semiconductors. Robust 3D nanowire networks fabricated with this low-cost templated electrodeposition technique are of great interest for photo-

voltaic and thermoelectric devices, fuel cells, hydrogen separation membranes, sensors, high-density information storage media, and other device applications.

Experimental Section

Mesoporous silica films were spin- or dip-coated onto conductive glass substrates (ITO (indium tin oxide) or F-doped SnO_2) by using surfactant/silicate sols that were prepared by mixing tetraethoxysilane (TEOS), H_2O, surfactant, HCl, and ethanol in a molar ratio of 1:5:0.02–0.05:0.028:22 at room temperature for 2 h. As-deposited films were calcined in air at 400°C for 1 h to remove the surfactants and to create mesoporous networks. The nonionic surfactant, Brij 58 ($C_{16}H_{33}(OCH_2CH_2)_{20}OH$), was used as the pore-structure directing agent to synthesize 3D mesoporous templates with pore diameters of 5 nm. Triblock copolymer Pluronic F127 ($EO_{106}PO_{70}EO_{106}$; $EO =$ ethylene oxide, $PO =$ propylene oxide), P123 ($EO_{20}PO_{70}EO_{20}$), and cationic surfactant cetyltrimethylammonium bromide (CTAB) were used to synthesize 3D mesoporous templates with different pore diameters. Commercial solutions (adjusted to pH 1) of dense silica particles with controllable diameters of 20–100 nm were added to the precursor sols to synthesize templates with hierarchical pore structures.

Electrodeposition was conducted in aqueous precursor solutions by using a galvanostatic or potentiostatic electroplating circuit in a conventional three-electrode cell. Electrodeposition of Pd was carried out with a periodic galvanostatic pulse current (0.5 mA cm^{-2} for 100 ms and 1 s at 0 mA cm^{-2}) by using an aqueous solution of $PdCl_2$–HCl (0.5 wt.%). Pt deposition was conducted under similar conditions by using a 2-wt.% H_2PtCl_6 precursor solution. Deposition of Co was conducted at −1.2 V vs. SCE by using aqueous solutions containing methanol (20 vol.%), $CoSO_4$ (1.3 M), and H_3BO_3 (0.7 M). Typical CdSe deposition was conducted at 85°C at −0.65 V vs. SCE by using a deposition solution (pH 2.5) that contained $CdSO_4$ (0.2 M) and SeO_2 (1.0 mM).[23] The electrodeposited films of the metal nanowire networks were annealed at 400°C in forming gas (N_2 with 10% H_2) for 30 min. The silica templates were removed with HF (1%) or NaOH solution (2 M) at 80°C, and the networks were rinsed with distilled water. Nanowire networks were characterized by XRD, TEM, SEM, UV/Vis, cyclic voltammetry, and SQUID techniques (see Supporting Information).

A Catalytic Langmuir Film as a Model for Heterogeneous and Homogeneous Catalytic Processes**

*Andrea Pasc-Banu, Claudia Sugisaki, Thierry Gharsa, Jean-Daniel Marty, Ignacio Gascon, Gianluca Pozzi, Silvio Quici, Isabelle Rico-Lattes, and Christophe Mingotaud**

The design and optimization of new catalytic systems continue to inspire a tremendous amount of work due to the importance of catalysis in many scientific fields and especially in industry. In particular, development of recoverable catalysts,[1] for example, by immobilization of a homogeneous catalyst on a solid surface[2] or by means of surface organometallic chemistry,[3] offers interesting perspectives. Pseudohomogeneous systems such as dendritic catalysts have also been recently developed.[4] They exhibit many of the advantages of homogeneous catalysts, but also some of the benefits of heterogeneous catalysts (e.g., easy recovery after the reaction). Their well-controlled synthesis allows one to tune their chemical properties by adjusting their core and peripheral structure. In several cases, the dendrimer generation also has a strong influence on the reaction catalyzed by the dendrimer.[5,6] This is supposedly related to an increased density of external groups or to lesser accessibility to reactants.

Regardless of the type of catalytic system, it is difficult to perfectly control or characterize the density and orientation of the catalytic centers, as well as the accessibility of these centers to reactants. Yet the influence of these structural parameters on the catalytic properties is paramount. Therefore, there is a clear lack of a chemical system in which the orientation and density of the catalytic sites can be easily modified, so that the effect of those parameters on catalysis efficiency can be measured. We propose using the gas/water interface as a model for such catalytic processes. Indeed, the organization and molecular density in a monolayer at this interface are readily adjustable through compression of the layer and choice of amphiphilic compound. Chemical reactions (e.g., hydrolysis, polymerization) have indeed been performed in Langmuir films,[7–10] but in all cases the surfactants forming the monolayer were themselves the reactants. Langmuir films have also been used to organize molecular catalysts on a solid substrate to generate well-defined supported catalytic systems.[11–13] However, to our knowledge, no attempt has been made heretofore to form monolayers at the gas/water interface in which the Langmuir film is the catalyst.

We chose to study olefin epoxidation as a model reaction considering the scientific and industrial importance of this class of reaction. For this purpose, we selected a salen complex **1** bearing two fluorinated chains (Scheme 1) as a
Scheme 1. Salen complex **1** and the chemical reaction studied in this work.

potential catalyst. Metal salen complexes are chemically robust, and their catalytic activity in epoxidation reactions is well documented for various substrates in many solvents.[14] Furthermore, fluorinated tails are well known for their ability to facilitate the formation of stable Langmuir films.[15] Finally, compound **1** is an efficient catalyst for the epoxidation of alkenes in bulk solution.[16] To assess the catalytic properties of a Langmuir film of **1** in such a reaction (Scheme 1), we chose as reactants a vinylic compound which is slightly soluble in water, namely, cinnamyl alcohol, and the urea/hydrogen peroxide complex (UHP) as an oxygen source for the oxidation, because of its stability and ease of handling.[17]

When spread at the gas/water interface, salen complex **1** formed stable monolayers up to its collapse at about $24 \; mN \, m^{-1}$ (Figure 1 and Table 1). Before the onset of the surface pressure (at about 183 $Å^2$ molecule^{-1}), Brewster-angle microscopy (BAM) demonstrated that the monolayer is in a biphasic state (inset of Figure 1) in which gaseous domains are in equilibrium with liquid domains. After the onset, the monolayer appeared quite homogeneous. The molecular area at collapse was around 115 $Å^2$, which is comparable to the average area of a salen complex with a conformation in which the average MnN_2O_2 plane is more or less perpendicular to the surface.[18] The monolayer of **1** was also transferred onto a calcium fluoride substrate in order to check its chemical

Figure 1. Compression isotherm of **1** at room temperature on pure water (●) and on a solution of UHP (5×10^{-5} mol L^{-1}) and cinnamyl alcohol (10^{-5} mol L^{-1}) (○). Inset: Typical morphology of the film observed by BAM at low surface pressure (dark domains: gaseous phase; light domains: liquid phase; real size: 430×536 μm^2).

Table 1: Analysis of the compression isotherms of **1** on various subphases at 20°C.

Subphase solution	Surface pressure onset [Å^2]	Collapse area [Å^2]	Collapse surface pressure [mN m^{-1}]
pure water	183	115	24.4
cinnamyl alcohol[a]	189	119	22.5
UHP solution[b]	165	123	15.7
UHP and cinnamyl alcohol[c]	163	129	12.3

[a] Concentration: 10^{-5} mol L^{-1}. [b] Concentration: 5×10^{-5} mol L^{-1}. [c] Concentrations: 5×10^{-5} mol L^{-1} and 10^{-5} mol L^{-1}, respectively.

stability at the gas/water interface: the equivalence of the IR spectra of **1** in a KBr pellet and in the LB film proved the chemical integrity of the catalyst at the interface.

When cinnamyl alcohol was added to the subphase in a concentration of 10^{-5} mol L^{-1} (molar ratio catalyst/alkene close to 1/50), the isotherm was slightly shifted towards larger areas per molecule (Table 1). This may be related to some interaction or adsorption of cinnamyl alcohol molecules at the interface due to their partial lipophilic character. The effect of UHP (5×10^{-5} mol L^{-1}) was clearly stronger: the collapse pressure decreased to about 16 mN m^{-1}, and the monolayer was more dense at a given surface pressure. These changes suggest strong interactions between salen **1** and the oxidant and could be an indication of the formation of oxidized forms of **1**. Adding cinnamyl alcohol to this UHP solution did not induce any further important modification of the isotherm (Table 1).

When a solution of cinnamyl alcohol and UHP (10^{-5} and 5×10^{-5} mol L^{-1}, respectively) was kept for 18 h in the Langmuir trough without any monolayer spread at its interface, no oxidation of the cinnamyl alcohol could be detected by GC after extraction of the subphase with dichloromethane (see Experimental Section). To assess the effect of a mono-

layer of **1**, a shorter reaction time was used (typically 6 h) to limit any (undetected) bulk oxidation. After spreading and compression of the monolayer (if necessary), GC analysis demonstrated that some epoxide of the cinnamyl alcohol had formed in the subphase. The area of the epoxide peak (a few tenths of a per cent to a few per cent of the peak for unconverted cinnamyl alcohol) varied with compression of the monolayer (see below) and the reaction time. Preliminary experiments suggested a linear dependence of this peak area on time in the range 6–24 h. Thus, this oxidation was not an artefact due to the extraction/analysis process but was directly related to the Langmuir film.

Consequently, it can be stated that the monolayer of **1** plays the role of a catalytic surface for the epoxidation of cinnamyl alcohol dissolved in the subphase. Direct comparison of the kinetics in this system (without stirring) and in bulk solution is clearly difficult. Therefore, we concentrated on the relative effect of the compression of the Langmuir film on the reaction by measuring the area of the epoxide peak relative to the alkene peak (%A) in the GC chromatogram for different molecular areas of the catalyst at the interface. When the monolayer was compressed, the Langmuir film did not cover the whole surface of the subphase (which was, however, entirely recovered for the GC analysis). To take this experimental limitation into account, we assumed that the quantity of formed epoxide is proportional to the surface area S of the catalytic monolayer, and therefore we defined an apparent rate of reaction ρ [Eq. (1)], where τ is the reaction time. Figure 2 shows the experimental variation of the apparent rate with the molecular area of **1** in the monolayer.

$$\rho = \%\text{A} \, (S\tau)^{-1} \tag{1}$$

For low surface pressures and large molecular areas (greater than ca. 155–160 Å^2), the apparent rate increased slowly with compression of the film. For such low surface pressures, the monolayer was in a biphasic state. Compression of the Langmuir film leads only to changes in the proportions
Figure 2. Apparent rate ρ of the catalyzed reaction (see text) versus the molecular area of catalyst **1** spread at the gas/water interface (the line is a guide to the eye). The inset plots ρ versus the molecular density for molecular areas larger than 155 Å^2 (linear fit).

of the liquid phase and the gaseous phase, but should not modify the organization within the liquid domains. Thus, the small increase in reactivity can not be ascribed to a change in the molecular orientation in the Langmuir film, but should be simply related to the variation of the average molecular density. Because the epoxidation of cinnamyl alcohol should be roughly first order in catalyst concentration, as was demonstrated in the bulk for indene,[19] we can assume that the reaction along the monolayer is also first-order in the average catalyst surface density. Therefore, the apparent rate of reaction should be proportional to the surface molecular density of **1**. Experimentally, this rate is indeed found to be reasonably proportional to the surface molecular density (i.e., the reciprocal molecular area) of **1** at the interface (inset in Figure 2).

When the monolayer was in a monophasic state (i.e., for molecular areas below ca. 160 Å²), the apparent rate deviated strongly from the previous simple law, and the formation of epoxide was clearly enhanced. Contrary to the previous case, such a change can not be only related to the increase in the molecular density. Even if a definitive explanation of this higher catalytic activity can not be given at this stage of the study, one can propose a simple hypothesis. The increase in molecular density when the monolayer is compressed in its liquid phase can be achieved only by a reorientation of various chemical groups of **1**. In particular, the manganese salen complex should be less and less tilted versus the normal to the interface with increasing compression. Therefore, the access (ease and main relative orientation) of hydrogen peroxide or cinnamyl alcohol to the manganese center should depend on the mean molecular area of **1**. This effect alone may explain the observed change in the catalytic activity.[20]

For molecular areas below about 135 Å², the apparent rate ρ of the reaction was strongly decreased. Again, this may be due to changes in the orientation of the catalytic center. However, most probably, this is simply related to the slow collapse of the monolayer. Indeed, the collapse area at constant compression rate was found to be around 129 Å² molecule⁻¹ (Table 1). Given that this value depends on the exact compression mode and that the collapse process is not abrupt (Figure 1), the observed change in reaction rate was more or less simultaneous with collapse of the monolayer. Such a process, which should lead to multilayer formation, decreases the number of catalyst molecules in close contact with the subphase, and this explains the experimental drop in catalytic activity.

These results demonstrate that the monolayer of **1** catalyzes the epoxidation of cinnamyl alcohol dissolved in the subphase with a rate strongly related to the molecular density and organization within the Langmuir film. For this particular catalyst/substrate pair, the highest efficiency is obtained for an average molecular area of about 140–145 Å². Further experiments will try to determine the molecular orientation within the monolayer and relate this to the molecular structure of the catalyst and the apparent rate of reaction. Finally, similar experiments will be performed with chiral salen complexes to check whether the architecture of the Langmuir film has any effect on the stereoselectivity of the epoxidation.

More generally, the present study proves that a soft and controllable interface like a Langmuir film is a powerful model of reactive surfaces and may help understand the reactivity in various heterogeneous and homogeneous catalytic systems.

Experimental Section

Amphiphilic complex **1** was prepared by metalation of the corresponding racemic salen ligand derived from *trans*-1,2-diaminocyclohexane by following a procedure previously described for the chiral analogue.[16] The crude compound was recrystallized from EtOH to give a brownish solid in 85% yield. UV/Vis (10^{-5} mol L⁻¹, CH₃OH): λ_{max} (lg ε) = 235 (4.72), 405 nm (3.71). Elemental analysis (%) calcd for $C_{44}H_{34}ClF_{34}MnN_2O_2$ (1359.1): C 38.88, H 2.52, N 2.06; found: C 39.02, H 2.44, N 2.36.

All other compounds were obtained from Aldrich and used without further purification. The water of the subphase, purified by a Purite Select apparatus, had a resistivity higher than 16 MΩ cm. Chloroform (HPLC-grade from SDS) was the spreading solvent, and the solutions of the amphiphilic complex were kept at −18°C between experiments to limit solvent evaporation.

Isotherms were obtained with a NIMA trough (type 601BAM) equipped with a Wilhelmy plate and maintained at 20°C. The compression rate of the monolayer was close to 3 Å² molecule⁻¹ min⁻¹. A BAM2plus from NFT was used for the Brewster-angle microscopy experiments.

The reactions were performed on a laboratory-made Langmuir–Blodgett trough (maximum available surface area ca. 1100 cm², volume of the subphase ca. 340 ± 40 mL including a ca. 30 mL dipping well) working at room temperature and under partial nitrogen atmosphere.[21] For the catalysis experiments, the subphase was an aqueous solution containing 5×10^{-5} mol L⁻¹ of UHP and 10^{-5} mol L⁻¹ of cinnamyl alcohol. Shortly after spreading, the monolayer was compressed (if necessary) at a rate of ca. 35 Å² molecule⁻¹ min⁻¹, and the area per molecule was kept constant during the experiment. After 6 h, the whole subphase was recovered and extracted with ca. 20 mL of HPLC-grade dichloromethane. The solvent of the organic solution was evaporated under reduced pressure, and the residue was kept at −18°C until GC analysis.

Built-up films were obtained by the vertical lifting method with a dipping speed set to 1 cm min⁻¹. Films (19 layers) were transferred from the gas/pure water interface onto optically polished calcium fluoride substrate (Y-type transfer with a transfer ratio of ca. 0.7 for a transfer pressure of 10 mN m⁻¹).

GC analysis was performed with a Varian Chrompack (CP-3800) apparatus equipped with an SGE nonpolar capillary column (BPX5 30 m × 0.25 mm) (injector temperature: 250°C; splitless injection mode; carrier gas: helium at 1 mL min⁻¹; initial oven temperature: 30°C, 2 min; rate 1: 15°C min⁻¹; final temperature 1: 150°C, 15 min; rate 2: 20°C min⁻¹; final temperature 2: 250°C, 2 min; detector temperature: 300°C). The retention times were found to be ca. 12.5 min for the cinnamyl alcohol, and 13.6 min for the corresponding epoxide.

Infrared spectra were recorded on a Perkin Elmer FT 1760-X spectrometer. For spectra of the pristine powder of **1**, KBr pellets (containing ca 0.5 wt% of **1**) were used.

Oxygen Heterocycles

Catalytic Asymmetric Mercuriocyclization of γ-Hydroxy-*cis*-Alkenes**

Sung Ho Kang,* Mihyong Kim, and Suk Youn Kang

Conversion of prochiral olefinic double bonds into the corresponding chiral functional groups is one of the most influential fields of study in modern synthetic organic chemistry, which has been realized preeminently through asymmetric epoxidation,[1] dihydroxylation,[2] aminohydroxylation,[3] hydrogenation,[4] and hydroboration.[5] Another versatile process can be evolved from electrophile-promoted additions.[6] Whereas few studies into intermolecular asymmetric additions have been carried out, the intramolecular version has been explored to some extent. The latter asymmetric cyclizations have been achieved by substrate-controlled means, but rarely through reagent-controlled methods. Although the reagent-controlled approach has been recognized as more challenging and beneficial, progress has lagged behind owing to lack of lucid strategic clues. Examples include organoselenylation with chiral selenium reagents,[7] iodocyclization with iodonium ion/dihydriquinine complexes,[8] iodocyclization with Co^{II}–salen complexes,[9] and mercuriocyclization with Hg^{II}–bisoxazoline complexes.[10] Most of the aforementioned methods have some limitations such as poor enantioselectivity, multistep synthesis of the involved reagent, and excessive use of the expensive reagent. Since our reported intramolecular mercurioetherification also requires 1.2 equivalents of chiral Hg^{II} complexes, even though the reaction itself is highly enantioselective,[10] development of the corresponding catalytic version would no doubt have a significant impact. Herein we describe asymmetric mercuriocyclization by using catalytic amounts of chiral bisoxazoline to prepare highly enantiopure 2-substituted tetrahydrofurans.

To develop a catalytic version of asymmetric mercuriocyclization, we proposed the use of catalytic amounts of a chiral bisoxazoline together with excess amounts of readily available achiral ligand, which can hold all the existing Hg^{II} ions tightly enough to transfer preferentially not to the olefinic substrate but to the chiral ligand. After assaying several kinds of additives, amine bases were found to retard the cyclization significantly. Based on the observation, structural tuning led us to choose oxazoline as the prospective achiral ligand. Since our proposed relaying process was shown experimentally to work with a complex between Hg^{II} and oxazoline **2** (1:2), mercuriocyclization of the model substrate **1** was implemented with this complex composition in the

presence of various oxazolines to evaluate which one would be effective. Some of the results are presented in Table 1. Although **4** and **5** promoted the cyclization to a greater extent (Table 1, entries 3 and 4), the use of **2**, **3**, **6**, and **7** seemed to induce more-encouraging progress (Table 1, entries 1, 2, 5, and 6).

Table 1: Mecuriocyclization of **1** in the presence of oxazoline–Hg^{II} complexes (L₂Hg^{II}; 1.2 equiv).

4	**5**	55	41
5	**6**	8	90
6	**7**	11	83

With the promising relay ligands in hand, catalytic asymmetric mercuriocyclization of **1** was attempted with the corresponding Hg^{II} complexes in the presence of bisoxazoline **9**. The outcomes are summarized in Table 2. As reported

Table 2: Mecuriocyclization of **1** by using oxazoline L–Hg^{II} complexes (L$_2$Hg^{II}; 1.2 equiv) in the presence of bisoxazoline **9** (0.3 equiv) and MeOH (2.5 equiv).

before, MeOH (10 equiv) and K$_2$CO$_3$ (5 equiv) were employed as additives and resulted in good chemical conversion and remarkable stereoselectivity (Table 2, entry 1). Later, it was found that the addition of 2.5 equivalents of MeOH was sufficient to give comparable results (Table 2, entry 2). The best cyclization was attained with oxazolines **2**

and **6** (Table 2, entries 2 and 4). The reaction conditions in Table 2, entry 2 were applied to substrates **10–12**. The experimental data in Table 3 reveal that the enantioselectivity

The absolute configuration was not determined.

reached a more satisfactory level than the chemical conversion. When the cyclization proceeded further, it became slower, probably as a result of the gradually increasing oxazoline concentration. All attempts to suppress the ligating power of the generated excess oxazoline with acidic additives proved futile.

To ameliorate the incomplete conversion, a different protocol was elicited. In the second approach, **1** was treated with the complex between **9** and Hg^{II} (1:1; 0.2 equiv) in the presence of Hg(OAc)$_2$ (1.0 equiv) and additive(s). The use of MeOH (10 equiv) with or without K$_2$CO$_3$ resulted in moderate enantioselectivity (Table 4, entries 1 and 2). The use of allyl alcohol instead of MeOH led to improved stereoselectivity, notably with poorer chemical yield (Table 4, entry 3). The best cyclization resulted when the amount of MeOH was adjusted to 1.5 equivalents (Table 4, entry 5).

Table 4: Mecuriocyclization of **1** with **9**–Hg^{II} (0.2 equiv) in the presence of Hg(OAc)$_2$ (1.0 equiv) and additive(s).

Entry	Additive (equiv)	Yield (sm) [%]	ee [%]
1	MeOH (10), K$_2$CO$_3$ (5)	84 (10)	54
2	MeOH (10)	92 (5)	43

resulted in poor enantioselectivity (Table 5, entries 2 and 7). To overcome the inferior asymmetric induction, it was necessary to maintain the concentration of the free Hg^{II} ion as low as possible. As a consequence, the cyclization conditions were optimized by increasing the amount of **9** to 0.3 equivalents with 2.0 equivalents of MeOH (Table 5, conditions B). The enantioselectivity under the established conditions was improved considerably from 48 to 84 % *ee* for **13** and from 22 to 73 % *ee* for **15** (Table 5, entries 2 and 7). Most of the remaining substrates also underwent cyclization with significant enantiomeric enhancement.[11] Scrutiny of the data suggests that not only the steric bulk of the substituent but also the distance of the bulky region from the olefinic double bond seem to be greatly influential. It is possible that the two factors are involved in forming the tight coordination bond between the substrate and **9**–Hg^{II} complex, which is thought to be crucial for high facial selectivity.

Finally, the newly developed cyclization conditions were employed for the asymmetric mercurioetherification of the *trans* alkene **30** (isomeric to **1**) and the racemic terminal alkene (±)-**32** as a kinetic resolution experiment. The former proceeded somewhat more sluggishly to afford the expected tetrahydrofuran **31** in 74 % yield with 73 % *ee* (15 % of recovered **30**) [Eq. (1), tfa = trifluoroacetate].

(1)

30

31 (73% ee)
On the other hand, the latter produced 43 % of the *trans*-2,5-disubstituted tetrahydrofuran **33** with 63 % *ee*, and 47 % of starting alcohol **32** with 61 % *ee* [Eq. (2)].

(2)

(±)-**32**

33 (63% ee)

32 (61% ee)
In conclusion, we have established a highly enantioselective catalytic mercuriocyclization of γ-hydroxy-*cis*-alkenes employing Hg(OAc)$_2$ in the presence of catalytic amounts of the 4-(2-naphthyl)bisoxazoline–Hg^{II} (**9**–Hg^{II}) complex to obtain 2-monosubstituted tetrahydrofurans with up to 95 % *ee*.

cross-coupling reaction of alkyl halides with organozinc reagents[4–6] in a THF/N-methylpyrrolidone (NMP) mixed solvent containing magnesium bromide. It was also found that these tetraenes (**2**) were effective also for the nickel-catalyzed cross-coupling of alkyl fluorides with Grignard reagents.
Synthetic Methods

Nickel-Catalyzed Cross-Coupling Reaction of Alkyl Halides with Organozinc and Grignard Reagents with 1,3,8,10-Tetraenes as Additives**

*Jun Terao, Hirohisa Todo, Hideyuki Watanabe, Aki Ikumi, and Nobuaki Kambe**

Transition-metal-catalyzed cross-coupling reactions between organic halides and organometallic reagents is a powerful tool for constructing carbon skeletons.[1] Significant advances have been achieved in this field over the last decade that have enabled cross-coupling reactions to be effected between alkyl groups by using either a nickel or palladium catalyst.[2] We have contributed to this progress by developing a unique catalytic system that proceeds efficiently under mild conditions by using 1,3-butadiene as an additive in the absence of phosphane ligands, where bis-π-allylnickel or -palladium intermediates (**1**) are proposed to be involved [Eq. (1)].[3] This system facilitates the cross-coupling of a wide variety of alkyl tosylates and halides, such as fluorides, chlorides, and bromides, with Grignard reagents. However, a drawback of this methodology is the range of functional groups that are tolerant to this system because of the high reactivity of the Grignard reagents. Herein, we reveal a solution to this problem by employing 1,3,8,10-tetraenes (**2**) that serve as extremely efficient ligands to promote the nickel-catalyzed

First we examined a cross-coupling reaction of alkyl halides with organozinc reagents that used 1,3-butadiene as the additive. For example, n-decyl bromide (1 mmol), diethylzinc (2 equivalents, 1 M in hexane), $NiCl_2$ (0.03 equiv), and 1,3-butadiene (1 equivalent) were added sequentially to a solution of THF (8 mL) and NMP (4 mL) at $-78\,°C$ and the mixture stirred at $25\,°C$ for 48 hours. However, this reaction gave only a trace amount of the cross-coupling product, n-dodecane ($< 1\%$), as shown in Table 1 (entry 1). Addition of magnesium bromide increased the yield of n-dodecane to 45%, but side reactions (reduction and HBr elimination) could not be suppressed (entry 2). Only a trace amount of dodecane was obtained without 1,3-butadiene even in the presence of magnesium bromide (entries 3 and 4). The salts Bu_4NBr, Bu_4NI,[5] and LiBr were also shown to be not effective as additives (entries 5–7). The yield of dodecane was increased up to 73% by adding four equivalents of 1,3-butadiene; however, formation of by-products, n-decane and decenes, could not completely be suppressed (entries 8 and 9). Under similar conditions, $[Ni(acac)_2]$ (acac = acetylacetonate) afforded a slightly better yield of the product (entry 10), while nickel catalysts bearing phosphane ligands were less efficient (entries 11 and 12). $PdCl_2$ did not show a high catalytic activity (entry 13). The coupling products were obtained in yields of only 37 and 7%, respectively (entries 14 and 15), when isoprene and p-fluorostyrene[5] were employed as additives under the same conditions as entry 10.

It is noteworthy that this cross-coupling reaction proceeded very rapidly and quantitatively when 2,2-bis(penta-2,4-dienyl)malonic acid dimethyl ester (**2a**) was employed as an additive in place of 1,3-butadiene, with complete suppression of the formation of decane and decenes (entry 16). The $NiCl_2$ catalyst also gave a satisfactory result under identical conditions (entry 17). The excellent performance of tetraene **2a** is demonstrated readily as the reaction was completed within 1 h at $25\,°C$ with only 9 mol% of **2a** and 1.3 equivalents of diethylzinc (entry 18). N,N-Bis(penta-2,4-dienyl)benzylamine (**2b**) also showed high activity (entry 19). The yield of dodecane decreased when the amount of magnesium bromide was decreased (entry 18).

Reactions of various alkyl halides and a tosylate with organozinc reagents were examined with **2a** as an additive

[a] Conditions unless otherwise stated: *n*-Decyl bromide (1 mmol), catalyst (3 mol%), additive (equivalents based on the substrate), diethylzinc (2 equiv, 1 M in hexane), mixed solution of THF (8 mL) and NMP (4 mL), 25°C, 48 h. [b] Determined by GC analysis. [c] A mixture of 1-decene and 2-decenes. [d] *n*-Decyl bromide (1 mmol), diethylzinc (1.3 equiv, 1 M in hexane), mixed solution of THF (8.4 mL) and NMP (4.2 mL), 25°C, 1 h. [e] The yields were decreased to 41 and 11% when the amount of $MgBr_2$ was decreased to 1.3 and 0.65 equivalents, respectively.

(Table 2). This catalytic system tolerates unsaturated heteroatom functional groups, such as nitriles, ketones, amides, and esters (entries 1–4). The use of the secondary alkyl zinc reagent iPr_2Zn (entry 5) or an aryl zinc reagent (entry 6) also afforded the corresponding products in good yields. An alkyl tosylate was also shown to undergo this cross-coupling reaction under the same conditions (entry 7). Secondary alkyl halides and tosylates were found to react sluggishly. For example, treatment of 2-octyl bromide with diethylzinc afforded decane in a yield of only 3%, along with octane (6%) and octenes (3%), and 82% of 2-octyl bromide was

recovered. Cyclohexyl tosylate also gave butylcyclohexane in a yield of only 5% after treatment with dibutylzinc.

We have shown that nickel catalyzes cross-coupling reactions of alkyl fluorides with Grignard reagents in the presence of 1,3-butadiene. However, this reaction is less efficient than those of the alkyl bromides, as they afford only moderate yields of the coupling products.[3b] For example, treatment of *n*-nonyl fluoride with 1.5 equivalents of $nPrMgBr$ in the presence of 3 mol% of $[Ni(acac)_2]$ and 30 mol% of 1,3-butadiene gave dodecane in a yield of only 11% (Table 3, entry 1). Increasing the amount of 1,3-butadiene improved the yield moderately; however, satisfactory yields could not be attained (Table 3, entries 2–4). These poor yields were probably because the Ni^0 center will react with more than two equivalents of

[a] Conditions: RX (1 mmol), R'_2Zn (1.3 equiv), $NiCl_2$ (3 mol%), **2a** (9 mol%), $MgBr_2$ (3 mmol), mixed solution of THF (8.4 mL) and NMP (4.2 mL), 25°C, 1 h. [b] Yield of isolated product. [c] GC yield.

1,3-butadiene in the presence of a high concentration of 1,3-butadiene and will form complexes composed of C_{12}-butadiene-oligomer units. The formation of these units will then predominantly result in a low concentration of **1**.[7] To prepare the bis-π-allylnickel complex structure exclusively, we applied tetraene **2b** as an additive and found that the yield was dramatically improved by the use of only 0.6 mol% of nickel catalyst and 15 mol% of **2b** (entry 5).

A plausible reaction pathway is shown in Scheme 1. A bis-π-allyl-nickel structure **3** is constructed by the oxidative cycloaddition of Ni^0 with two butadiene moieties of a

Communications
Scheme 1. A plausible reaction pathway.

1,3,8,10-tetraene.[8] An organomagnesium or -zinc reagent attacks the bis-π-allyl complex **3** to generate the η^1,η^3-octadienediylnickelate complex **4**, which then reacts with alkyl halides to give a complex **5**. Subsequent reductive elimination affords the coupling product along with **3** to complete the catalytic cycle. Selective and efficient formation of **3** from Ni^0 and **2** would, in comparison to 1,3-butadiene,[7] facilitate the generation of complex **4** and so accelerate the subsequent oxidative addition process that leads to **5**.

In conclusion, it was found that tetraenes **2** exerted dramatic effects that improved the cross-coupling reactions of organozinc reagents with alkyl halides catalyzed by nickel. This reaction proceeds efficiently by the use of primary and secondary alkyl or aryl zinc reagents under mild conditions. The use of tetraene **2b** as an additive also resulted in high yields of products in the cross-coupling of an alkyl fluoride with a Grignard reagent.

Experimental Section

Heptadecan-5-one: A solution of nOct$_2$Zn (0.33 M in THF, 3.9 mL, 1.3 mmol) was added to a solution of 1-bromononan-5-one (221 mg, 1.0 mmol), MgBr$_2$ (552 mg, 3.0 mmol), NiCl$_2$ (4 mg, 0.03 mmol), **2a** (24 mg, 0.09 mmol), and NMP (4.2 mL) in THF (4.6 mL) at 25 °C under nitrogen. After stirring the mixture for 1 h, 1 M HCl (ca. 2 mL) was added to the solution at 0 °C and the mixture was warmed to 25 °C. Saturated aqueous NaHCO$_3$ solution (20 mL) was then added, and the product was extracted with diethyl ether (20 mL), dried over MgSO$_4$, and evaporated to give the crude product. Purification by silica gel column chromatography with hexane/diethyl ether (15:1) as an eluent afforded 233 mg (87%) of octadecan-5-one. ^{1}H NMR (400 MHz, CDCl$_3$): $\delta = 2.39$ (t, $J = 7.6$ Hz, 2H), 2.38 (t, $J = 7.4$ Hz, 2H), 1.59–1.51 (m, 4H), 1.34–1.21 (m, 22H), 0.90 (t, $J = 8.4$ Hz, 3H), 0.88 ppm (t, $J = 8.8$ Hz, 3H); ^{13}C NMR (100 MHz, CDCl$_3$): $\delta = 211.1$, 42.7, 42.4, 31.8, 29.60, 29.57, 29.56, 29.54, 29.40, 29.35, 29.28, 29.20, 25.9, 23.8, 22.6, 22.3, 14.1, 13.8 ppm; MS (EI) m/z (relative intensity, %) 268 (M^+, 0.4), 211 (25), 113 (20), 101 (33), 85 (74), 71 (39), 58 (100); HR-MS: calcd for C$_{18}$H$_{36}$O: 268.2766, found 268.2758; elemental analysis (%): calcd for C$_{18}$H$_{36}$O: C 80.53, H 13.52; found: C 80.46, H 13.40.

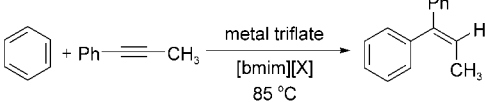
Synthetic Methods

Dramatic Enhancement of Catalytic Activity in an Ionic Liquid: Highly Practical Friedel–Crafts Alkenylation of Arenes with Alkynes Catalyzed by Metal Triflates**

Choong Eui Song,* Da-un Jung, Su Yhen Choung, Eun Joo Roh, and Sang-gi Lee*

The Friedel–Crafts alkylation of aromatic compounds with alkenes is one of the fundamental methods for incorporating carbon skeletons into aromatic systems and, thus, has been extensively studied and is well established.[1] In contrast, the corresponding alkenylation process with alkynes still remains to be solved. One major drawback from the direct Friedel–Crafts alkenylation of arenes is alkyne polymerization, which results in the formation of a variety of undesirable side products.[2] Well-known Lewis acidic metal chlorides, such as $ZrCl_4$ and $AlCl_3$, produce the desired alkenylated products but in extremely low yields (for example, 1 and 6% yields of 1-phenyl-1-(*p*-xylyl)ethene for the reaction of *p*-xylene with phenylacetylene at 85 °C, respectively).[3] Recently, a number of catalysts, such as the solid acid zeolite HSZ-360,[4] phenoxymagnesium bromide,[5] and $SnCl_4$/NBu_3,[6] were found to be active for the *ortho* selective alkenylation of phenols with a limited range of alkynes (only aryl-substituted terminal alkynes underwent this reaction). It has been also found that $GaCl_3$ can promote the alkenylation of arenes with silylethyne, but excessive amounts of this Lewis acid (3 equiv) are required.[7] Recently, Tsuchimoto et al. made a break-through on this important reaction by finding that some metal triflates $[M(OTf)_n; M = Sc, Zr, In]$ catalyze the alkenylation of arenes with internal alkynes as well as terminal alkynes through an alkenyl cation intermediate.[3] However, the catalytic activity of these metal triflates is far too low for preparative use. For example, the reaction of benzene and phenylacetylene in the presence of 10 mol% of $Sc(OTf)_3$ at 85 °C requires 186 hours to give 1,1-diphenylethene in 73% yield.[3] Moreover, $Sc(OTf)_3$ was totally inactive for electron-deficient alkynes, such as *p*-trifluoromethylphenylacetylene and *p*-chlorophenylacetylene. Therefore, a more efficient and practical catalytic system for Friedel–Crafts alkenylation is still highly desirable. Herein, we report that the use of ionic liquids in Friedel–Crafts alkenylations of aromatic compounds by alkynes catalyzed by metal triflates not only enhanced catalytic activity markedly but also decreased by-product formation, which resulted in higher yields of the monoalkenylated arenes. Moreover, in some cases, reactions that do not usually occur in conventional organic solvents were found to proceed smoothly in ionic liquids.

Room-temperature ionic liquids (RTILs) are now regarded as eco-friendly alternatives to volatile organic solvents in chemical processes.[8] During the course of our extensive efforts on the utilization of RTILs in various catalytic reactions, we found that switching from an organic solvent to an ionic liquid often resulted in significant improvements in catalytic performance (for example, increased reaction rates, improved selectivities, etc.) as well as catalyst recycling.[9] Recently, we found that the $Sc(OTf)_3$-catalyzed Friedel–Crafts alkylation of aromatic compounds with alkenes is dramatically accelerated in the presence of hydrophobic ionic liquids, such as $[bmim][PF_6]$ or $[bmim][SbF_6]$ (bmim = 1-butyl-3-methylimidazolium).[9a] This result encouraged us to investigate the metal triflate catalyzed Friedel–Crafts alkenylation of aromatics with alkynes in ionic liquids.

[bmim][X] (X = PF_6, SbF_6)
To investigate the effect of ionic liquids on the catalytic activity of metal triflates in Friedel–Crafts alkenylation we first examined the reaction between benzene and 1-phenyl-1-propyne under various conditions (Table 1).


As observed by Tsuchimoto et al.,[3] the alkenylation of benzene with 1-phenyl-1-propyne in the presence of 10 mol% of $Sc(OTf)_3$ without an ionic liquid proceeded very slowly with a yield of only 27% after 96 hours (entry 1). Moreover, this long reaction time resulted in increased the formation of undesired side products. On the other hand, when the reaction was carried out in hydrophobic ionic liquids, such as $[bmim][PF_6]$ or $[bmim][SbF_6]$, the catalytic activity of $Sc(OTf)_3$ was dramatically enhanced: the reaction was completed within 4 hours to afford the desired product (1,1-diphenyl-1-propene) in excellent yields (91 or 90%, respectively; entries 2 and 3).[10,11] Among the various metal triflates investigated for catalytic activity, indium triflate, hafnium triflate, and yttrium triflate in particular were found to exhibit higher activity than scandium triflate, with the reaction completed within 2.5, 1, and 2 hours, respectively (entries 4, 7, and 10). The reactions proceeded smoothly with excellent yields even in the presence of smaller amounts of these metal triflates (5 and 2.5 mol%; entries 5, 6, 8, and 9). Ytterbium triflate and lutetium triflate also exhibited similar catalytic acivities to that of scandium triflate (entries 11 and 12). This

[a] All reactions were carried out with an alkyne (1 mmol), an arene (6 mL), and [bmim][SbF$_6$] (1 mL) in the presence of the metal triflate catalyst (10 mol%) at 85°C. [b] Yield of isolated product based on the alkyne. [c] cis/trans ratios were determined by ^{1}H NMR spectroscopy as follow: 96/4 (entry 1), 88/12 (entry 10), and 87/13 (entry 20). [d] Reaction was carried out with the recovered ionic liquid phase from entry 6 without further addition of Sc(OTf)$_3$. [e] The reaction gave an inseparable mixture of four isomers of ortho and para regioisomers, including the corresponding cis/trans isomers. The isomer ratios determined by GC-MS analysis are as follows; 2/33/32/32 (entry 11); 2/35/31/32 (entry 12); 8/18/34/40 (entry 13).

significant rate acceleration may be ascribed to the stabilization of the unstable vinyl cationic intermediate in a highly polar ionic liquid, in which the polar vinyl cation may gain a longer lifetime. The catalytic activities of other metal triflates were also investigated, for example (yields are given in parentheses), Ag(OTf) (4%), Cu(OTf)$_2$ (27%), Mg(OTf)$_2$ (21%), Zn(OTf)$_2$ (2%), Sn(OTf)$_2$ (69%), La(OTf)$_3$ (62%), Pr(OTf)$_3$ (19%), Nd(OTf)$_3$ (37%), Sm(OTf)$_3$ (15%), Eu(OTf)$_3$ (16%), Gd(OTf)$_3$ (23%), Tb(OTf)$_3$ (34%), Dy(OTf)$_3$ (28%), Ho(OTf)$_3$ (30%), Er(OTf)$_3$ (40%), and Tm(OTf)$_3$ (22%). However, their catalytic activities were much lower than those of Sc(OTf)$_3$, In(OTf)$_3$, Hf(OTf)$_4$, Y(OTf)$_3$, Yb(OTf)$_3$, and Lu(OTf)$_3$.

To study the scope of this reaction a series of Friedel–Crafts alkenylations of arenes with various types of alkynes were carried out in [bmim][SbF$_6$] (Table 2). In all cases, the reactions proceeded successfully within a few hours to afford the corresponding alkenylated products in good to excellent yields. In particular, Sc(OTf)$_3$, In(OTf)$_3$, and Hf(OTf)$_4$ effectively catalyzed the alkenylation of the electron-deficient alkynes, such as p-tifluoromethylphenylacetylene and p-chlorophenylacetylene, which were totally inactive without the presence of an ionic liquid (entries 14–18).[3] Similarly, the reaction of arenes with ethyl phenylpropiolate in the presence of Hf(OTf)$_4$ proceeded smoothly in [bmim][SbF$_6$] (entries 19 and 20), whereas without [bmim][SbF$_6$] a conversion of only <5% was observed. It should also be noted that the ionic liquid phase containing the metal triflate could be readily recovered by simple decantation of the organic layer (the upper phase) after reaction. The recovered ionic liquid phase containing the metal triflate was reused without further addition of metal triflate. However, a decrease in catalytic activity over successive reactions was observed and, thus, the reaction time became longer upon reuse (compare entries 6 and 7 in Table 2).

Finally, our protocol has been further extended to intramolecular Friedel–Crafts alkenylations. The intramolecular reaction of aryl phenyl propiolates catalyzed by Hf(OTf)$_4$ (10 mol%) in a mixture of [bmim][SbF$_6$] and methylcyclohexane at 85°C for 9–10 hours resulted in the formation of the 4-phenylcoumarins in moderate yields (Scheme 1). Surprisingly, the reaction of aryl-2-butynoates also was successfully performed to afford the corresponding coumarin in an excellent yield (89%; Scheme 1). The smaller stabilizing influence of the alkyl group on the vinyl cation intermediate
Scheme 1. Synthesis of 4-phenylcoumarins by intramolecular Friedel–Crafts alkenylations.

resulted in the alkyl-substituted alkynes usually undergoing self-oligomerization rather than the desired alkenylation reaction. Intramolecular alkenylation allowed us to synthesize 2(1*H*)-quinolinones from the corresponding aryl amides of phenylpropiolic acid in good yields (Scheme 2).
Scheme 2. Synthesis of 2(1*H*)-quinolinones by intramolecular Friedel–Crafts alkenylations.

In conclusion, we have found that the employment of hydrophobic ionic liquids dramatically enhanced the catalytic activities of metal triflates in Friedel–Crafts alkenylations, and thus allowed the development of a simple and highly efficient method for coupling aromatic compounds with various alkyl- and aryl-substituted alkynes. In some cases, reactions that were not possible in conventional organic solvents also proceeded smoothly in the presence of ionic liquids. To our knowledge, the described protocol could be the most efficient preparative Friedel–Crafts alkenylation method published to date for the synthesis of a range of alkenylated arenes,[12] such as styrenes, *cis*-aryl-α,β-unsaturated carbonyl compounds, coumarines, and 2(1*H*)-quinolinones. Studies into the origin of the effects of ionic liquids on catalytic activity are in progress.

Experimental Section

Typical procedure for intermolecular Friedel–Crafts alkenylations in an ionic liquid: 1-Phenyl-1-propyne (178.2 mg, 1 mmol) was added to a mixture of Sc(OTf)$_3$ (49.2 mg, 0.1 mmol), benzene (6 mL), and [bmim][SbF$_6$] (1 mL) under a nitrogen atmosphere. Two phases formed and the mixture was heated to reflux for 4 h. After completion of the reaction, the reaction mixture was cooled to room temperature. The organic layer (upper phase) was separated by extraction with benzene to leave the ionic liquid phase containing the catalyst, which could be reused. All the volatile organic compounds were then removed under reduced pressure and the residue was purified by flash column chromatography on silica gel (hexane) to give 177 mg (91%) of pure 1,1-diphenyl-1-propene as a pale yellow solid.

Typical procedure for intramolecular Friedel–Crafts alkenylations in an ionic liquid: A mixture of Hf(OTf)$_4$ (77.4 mg, 0.1 mmol), phenyl 3-phenylpropiolate (222.1 mg, 1 mmol), methylcyclohexane (6 mL), and [bmim][SbF$_6$] (1 mL) was heated to reflux for 9 h under a nitrogen atmosphere. The reaction mixture was then cooled to room temperature. All the volatile organic compounds were then removed under reduced pressure and the residue was purified by flash column

chromatography on silica gel (hexane/diethyl ether) to give 113 mg (51%) of pure 4-phenylcoumarin as a pale yellow solid.

Mol. Catal. A* **2003**, *194*, 49.

[10] In sharp contrast to these results, only very small amounts of the alkenylated product was obtained (<2% yield) in the hydrophilic ionic liquids, [bmim][BF$_4$] or [bmim][OTf].

[11] Recently, Rogers and co-workers reported the instability of the ionic liquids' counterion PF$_6$ towards moisture, which resulted in hydrolysis and the formation of HF (R. P. Swatloski, J. D. Holbrey, R. D. Rogers, *Green Chem.* **2003**, *5*, 361). Therefore, to examine the possible catalytic effect of HF on this reaction, we also carried out the reaction only in [bmim][SbF$_6$] or in a mixture of [bmim][SbF$_6$] and water (1:1, v/v) without any metal triflate catalyst. However, the reaction did not occur at all.

[12] A new synthetic route to alkenylated arenes involving Pd- and Pt-catalyzed addition of arenes to alkynes in the presence of trifluoroacetic acid was recently reported: a) C. Jia, D. Piao, J. Oyamada, W. Lu, T. Kitamura, Y. Fujiwara, *Science* **2000**, *287*, 1992; b) C. Jia, W. Lu, J. Oyamada, T. Kitamura, K. Matsuda, M. Irie, Y. Fujiwara, *J. Am. Chem. Soc.* **2000**, *122*, 7252.

Nitroxide-Mediated Controlled Free-Radical Emulsion Polymerization of Styrene and *n*-Butyl Acrylate with a Water-Soluble Alkoxyamine as Initiator

Julien Nicolas, Bernadette Charleux,* Olivier Guerret, and Stéphanie Magnet

Controlled free-radical polymerization (CRP) in water-based systems has been studied intensely during the last ten years as it combines the environmental and technical advantages of polymerization in aqueous dispersed media with the ability to synthesize tailor-made macromolecular architectures.[1–4] Most CRP methods, however, have not been applied in traditional macroemulsion polymerization processes (usually called simply emulsion polymerization),[5] but in miniemulsion polymerization,[1–4,6] as the latter process offers benefits from the mechanistic viewpoint and can be regarded as a simplified model of emulsion polymerization. Indeed, nucleation takes place directly in the monomer droplets, which become polymer particles upon initiation with either a hydrophobic or a hydrophilic initiator, and subsequent propagation. However, the formation of small, stable monomer droplets requires the application of high shear to the initial monomer-in-water emulsion and the addition of a highly hydrophobic molecule to the monomer phase.[6] Many authors have demonstrated the great success of this method for all CRP techniques.[1–4] However, industrial applications usually demand an easier process; in particular, the use of a high shear device in large-volume reactors is usually avoided, and furthermore, the introduction of a hydrophobic additive, which is sometimes a volatile organic compound, is not encouraged. Consequently, true emulsion polymerization is usually the technique of choice owing to its simplicity: this process does not require any special manipulation of the initial monomer-in-water emulsion, only the use of a water-soluble initiator,[5] and particles are generated in the aqueous phase, independently from the oil droplets, which only act as a monomer reservoir. Mainly due to the sensitivity of the nucleation step, CRP in emulsion systems often leads to unstable latexes, and is therefore still a challenge.[1–4] The formation of these unstable latexes has been explained by the very specific features of the chain growth in CRP with respect to a classical free-radical polymerization—a large number of oligomers undergo slow and simultaneous growth in the early stage of the polymerization, which completely modifies the particle-formation mechanism.

The goal of this work was to apply nitroxide-mediated polymerization in an emulsion process. This CRP method[7] takes advantage of the reversible deactivation of the propagating radicals by nitroxide, which gives alkoxyamine-terminated dormant chains and induces a controlled chain-growth. This method has recently been improved significantly with the discovery of very efficient acyclic nitroxides, such as SG1 (Scheme 1),[8] which can control the polymerization of a
Scheme 1. Structure of the nitroxide SG1 and of the SG1-based water-soluble alkoxyamine initiator (**A**-H for the displayed acidic form; **A**-Na for the corresponding sodium salt).

much broader range of monomers than cyclic nitroxides like TEMPO (2,2,6,6-tetramethylpiperidinyl-1-oxy).[7] To perfectly control the chain growth and polymerization kinetics, a monocomponent alkoxyamine initiator should be selected rather than a normal bicomponent initiator system (classical radical initiator along with free nitroxide), because the latter suffers from poorly controlled initiator efficiency.[7] Consequently, the real challenge in nitroxide-mediated emulsion polymerization is first to select an appropriate water-soluble alkoxyamine initiator, and second to find the appropriate conditions to form a stable latex with sufficiently high solids content.[9] The very few reports on nitroxide-mediated ab initio emulsion polymerization have mainly concerned the application of a water-soluble radical initiator in conjunction with free nitroxide, either TEMPO[9–11] or SG1.[12] Marestin et al.[10] are the only group to report the use of a TEMPO-based water-soluble alkoxyamine in a diluted emulsion polymerization of styrene. However, the polymerization was rather slow and the use of TEMPO restricted its use to styrene.

In this paper we present a new and simple way to perform nitroxide-mediated emulsion polymerization of both *n*-butyl acrylate (BA) and styrene (S), as well as the synthesis of a block copolymer, using a novel, water-soluble, SG1-based alkoxyamine (Scheme 1),[13] which can also be successfully applied in a miniemulsion.[14] The solubility in water is imparted by the sodium carboxylate group, providing the pH remains above about 6 ($pK_a = 4.98$),[15] at least during the nucleation step. Due to the hydrophobicity of the SG1 capping agent, **A**-Na exhibits surface activity in aqueous solution[14] but undergoes homolytic dissociation to the highly water-soluble 2-(hydroxycarbonyl)prop-2-yl sodium salt radical, which initiates the polymerization in the water phase.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

In a preliminary study, emulsion polymerizations initiated with the water-soluble **A**-Na alkoxyamine were performed in a single-batch step with 20 wt% monomer content and 2.2 wt% of various surfactants (see Supporting Information). In all cases the latexes underwent destabilization after about 50% monomer conversion, most probably due to the partition of the initially formed oligomeric alkoxyamines between the water phase and the oil phase, leading to unwanted droplet nucleation. Nevertheless, all polymers were well controlled, demonstrating the efficiency of the selected initiator. Consequently, improvement of the colloidal characteristics of the latexes was the main issue to address. This was done by making the process a multi-step polymerization.

The first polymerization step was the preparation of a living poly(*n*-butyl acrylate) seed latex, from a very dilute monomer-in-water emulsion (0.7 wt%; apparent concentration of 0.055 mol L^{-1}), with two different surfactant concentrations above the critical micelle concentration (experiments **1** and **2** in Table 1). The pH of the water phase was 7.4 and 6.9 for experiments **1** and **2**, respectively, that is, above the lower limit of 6 needed for a high ionization degree of the initiator. The majority of the *n*-butyl acrylate monomer was located either in the water solution[16] or in the swollen micelles. If present, the monomer droplets should therefore remain in only very small quantities. Indeed, with both the selected surfactant concentrations a clear solution was obtained at the polymerization temperature before the start of the reaction. The main purpose was to favor micellar nucleation over droplet nucleation. In both experiments the oligomers were obtained reproducibly with controlled molar masses in almost perfect agreement with the theoretical value (conversion at 8 h was close to 60% and theoretical $M_n =$ 1100 g mol^{-1}; experimental $M_n = 1060$ g mol^{-1} for experiment **1** with $M_w/M_n = 1.14$; experimental $M_n = 1080$ g mol^{-1}

for experiment **1**′, with $M_w/M_n = 1.17$; experimental $M_n = 1120$ g mol^{-1} for experiment **2**, with $M_w/M_n = 1.20$; experimental $M_n = 1110$ g mol^{-1} for experiment **2**′, with $M_w/M_n = 1.17$). The molar masses indicate a high initiator efficiency, meaning that all **A**-Na molecules are consumed and turned into the hydrophobic polymer chains that form the particles.

Both seed latexes are stable, with an average particle diameter, given by dynamic light scattering (DLS), of 210 nm for the lowest amount of surfactant used (experiment **1**) and 150 nm when the amount of surfactant was multiplied by a factor of 2.3 (experiment **2**). As shown in Table 1, both experiments are also reproducible from the particle-size viewpoint, although the diameters are rather large and the particle-size distribution broad, in contrast to what is expected in a classical emulsion polymerization. Nucleation might lead to a change in the thermodynamic properties of the system, in close analogy with the theory of "super-swelling" proposed for miniemulsions by Luo et al.[17] The presence of a large concentration of oligomers in the growing particles during the early stages of the reaction would lead to a lower chemical potential than in the non-nucleated micelles or droplets, which would enhance swelling of the former by the monomer. This would favor the formation of large particles with a broad particle-size distribution. The low amount of monomer, however, allowed us to limit the effects of this unwanted trend.

The low-solids-content poly(*n*-butyl acrylate) latexes produced in the first step were further used as a seed for the batch emulsion polymerization of *n*-butyl actylate and styrene (Table 1). As illustrated by the conversion versus time plots in Figure 1 and Figure 2, the dispersed oligomeric alkoxyamines initiate the polymerization and lead to fast and nearly complete polymerizations (85 to 95% conversion within 8 h), with very good reproducibility (see Table 1 and

Figure 2. Seeded emulsion polymerizations of styrene (experiment **4**: ◆, ◇; experiment **6**: ■, □): a) monomer conversion versus time; b) number-average molar mass and polydispersity index versus conversion. Straight line: theoretical evolution of M_n versus conversion.

the Supporting Information for the comparison of experiments **3** and **3′**). Moreover, controlled molar masses and narrow molar-mass distributions were observed (Figure 1 and 2): the M_n values were close to the predicted ones, indicating a good reinitiation efficiency. For n-butyl acrylate polymerization, broadening of the molar-mass distribution was observed at the end of the reaction, possibly due to irreversible termination and/or to intermolecular chain transfer to the polymer, which are not unexpected at such large conversions.[18]

From the colloidal viewpoint, the important result is that the latexes are all stable for months. The final average diameters are given in Table 1. They are strongly dependent on the seed used (i.e. to the initial concentration of surfactant) and on the amount of polymer, but do not depend much on the type of monomer polymerized in the second step. DLS gave an average diameter of 660 nm for the poly(n-butyl acrylate) latex **3** and 530 nm for the polystyrene latex **4**, both extended from seed **1** (the calculated final diameter is 600 nm, on the basis of the DLS seed diameter and the amount of polymerized monomer). Moreover, the diameter increases with conversion in such a way that the total number of latex

particles remains fairly constant throughout the polymerization. For latex **4**, transmission electron microscopy (TEM) was performed: $D_n = 450$ nm and $D_w = 830$ nm, indicating a broad particle-size distribution. For the latexes extended from seed **2**, DLS gave an average diameter of 270 nm for the poly(n-butyl acrylate) latex **5** and 260 nm for the polystyrene latex **6**, whereas the calculated diameter is 400 nm (TEM measurements on the latter gave $D_n = 90$ nm and $D_w = 350$ nm). The large discrepancy between DLS and TEM in those experiments comes from the existence of very small particles that are barely detectable by DLS. Although these results do not indicate a perfect control over the particle size and particle-size distribution, they are essentially the same as those currently obtained in analogous miniemulsion polymerizations.[1–4]

The process was also applied to the three-step synthesis of a block copolymer with a 1:1 molar composition. The first two steps were identical to those for the poly(n-butyl acrylate) latex **5**. Before the end of the second step (5.5 h, 55% n-butyl acrylate conversion), the polymerization was stopped by cooling the reaction medium. The unreacted BA monomer was not removed, part of the styrene was added, and the mixture was stirred gently overnight at room temperature.

      www.angewandte.org

After addition of the remaining styrene, the temperature was raised again to 112 °C. All the features of a controlled polymerization were maintained, with the continuous increase of the average molar masses with monomer conversion, the low polydispersity indexes (Figure 3), and the

Figure 3. Synthesis of a poly(*n*-butyl acrylate)-*b*-poly(*n*-butyl acrylate-*co*-styrene) block copolymer in a three-step emulsion polymerization (experiment **7**): a) monomer conversion versus time; b) number-average molar mass and polydispersity index versus conversion. Vertical dotted line: time when styrene was added. Straight line: theoretical evolution of M_n versus conversion.

shift of the size-exclusion chromatography (SEC) peaks toward larger molar masses (see Supporting Information). Again, a stable latex was recovered, with 26% solids content.

Nitroxide-mediated emulsion polymerization of *n*-butyl acrylate and styrene was successfully carried out in a multi-step process in the presence of a novel water-soluble alkoxyamine initiator based on the nitroxide SG1. Fast reactions were observed, leading to polymers with controlled molar mass and narrow molar-mass distribution, which could be further extended by monomer addition. The process allowed us to form stable latexes with a solids content as high as 26 wt%. Such a true emulsion polymerization process in living conditions, which was previously a real challenge in the field of controlled free-radical polymerization, is of high academic and industrial relevance.

[LAl(μ-S₃)₂AlL]: A Homobimetallic Derivative of the Sulfur Crown S₈**

*Ying Peng, Hongjun Fan, Vojtech Jancik,
Herbert W. Roesky,* and Regine Herbst-Irmer*

*Dedicated to Professor Tobin J. Marks
on the occasion of his 60th birthday*

Metal polysulfides, synthesized by a variety of methods using various reagents as sulfur source, such as S_8, M_2S_n (M = alkali metal), P_4S_{10}, H_2S, and organic polysulfanes, have attracted much attention not only regarding their structure and reactivity but also owing to their potential uses.[1] Metal polysulfide complexes[1b] may be viewed as derivatives of the S_x^{2-} ($x \geq 2$) ion. Transition-metal polysulfides have attracted interest as catalysts and intermediates in enzymatic processes and in catalytic reactions of industrial importance, such as the hydrodesulfurization (HDS) of fossil fuels.[2] Furthermore, the metal polysulfides can be used as precursor for metal–sulfur clusters. In contrast, such complexes containing heavier main-group elements, such as the Group 13, 14, and 15 metals have been much less explored.[1a,d] Among the numerous investigations of the metal polysulfides, complexes with the (μ-S₃) chain are rarely reported. The most common examples are those of transition-metal complexes $[\{(\eta^5\text{-RC}_5\text{H}_4)_2\text{Ti}(\mu\text{-}S_3)\}_2]$ (R = H, Me)[3] and $[\{(\eta^5\text{-MeC}_5\text{H}_4)\text{Ru}(\text{PPh}_3)(\mu\text{-}S_3)\}_2]$[4] which were obtained by treatment of $[(\eta^5\text{-RC}_5\text{H}_4)_2\text{TiS}_5]$ (R = H, Me) with PPh₃, and $[\{(\eta^5\text{-MeC}_5\text{H}_4)\text{Ru}(\text{PPh}_3)_2\text{S}\}_2]$ $[\text{SbF}_6]_2$ with $(\text{NBu}_4)_2\text{S}_6$, respectively. $[\text{LAl}^{\text{I}}]$ (1) (L = HC(CMeNAr)₂, Ar = 2,6-iPr₂C₆H₃)[5] with its nonbonding lone pair of electrons at aluminum has a singlet carbene-like character and may show unprecedented chemical reaction behavior.[6] Herein, we describe the synthesis and structural characterization of [LAl(μ-S₃)₂AlL] (2) containing two (μ-S₃) chains.

Compound 2 was synthesized by the reaction of 1 with sulfur in a molar ratio of 2:6[7] (Scheme 1). Cold toluene was added to the mixture of 1 and sulfur at −78 °C. After several minutes a suspension was obtained which was kept at −78 °C for 2 h. Subsequently the suspension was slowly warmed to room temperature under formation of more precipitate. The compound [LAl(μ-S)₂AlL][8] was isolated from the precipitate

Scheme 1. Synthesis of 2.

and characterized by its characteristic melting point and EI mass spectrum. Pale yellow crystals of 2 were obtained from the concentrated filtrate at 4 °C, as well as at room temperature. It is noted that even when the above reaction was employed in a molar ratio of 2:3,[7] the isolated product is also 2 however in lower yield (about 10 %). Compound 2 was characterized by ¹H and ¹³C NMR spectroscopy, EI mass spectrometry, and elemental analysis. The most intense peak in the EI mass spectrum of 2 appears at m/z 508 $[M^+\text{–LAlS}_4]$. The signals at 540 (38 %) and 572 (15 %) are assigned to the $[M^+\text{–LAlS}_3]$ and $[M^+\text{–LAlS}_2]$ fragments, respectively. Compound 2 is sparingly soluble in $[\text{D}_6]$benzene, and the solubility does not improve even when heated. 2 does not dissolve in hexane and pentane. When the reaction mixture or the isolated compound is exposed to traces of moisture, the free ligand LH can be detected by ¹H NMR spectroscopy.

Single crystals of 2[9] suitable for X-ray structural analysis were obtained in toluene at 4 °C. Compound 2 crystallizes in the monoclinic space group $P2_1/n$ with two co-crystallized molecules of toluene per molecule of 2 (Figure 1). Two (μ-S₃) chains connect two aluminum atoms to form an aluminum polysulfide with an Al_2S_6 eight-membered ring. The two L ligands are almost coplanar. The symmetry of the structure is C_i. In the S_8 structure,[10] the two S_3 units are eclipsed, whereas in 2 they are staggered, thus we cannot simply argue that the two aluminum atoms are replacing the corresponding sulfur atoms in S_8. The S–S bond length (av 2.08 Å) in 2 is
Figure 1. Thermal ellipsoids plot of 2 (thermal ellipsoids set at 50 % probability). Hydrogen atoms and solvent molecules are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)-N(1) 1.882(2), Al(1)-N(2) 1.904(2), Al(1)-S(1) 2.223(1), Al(1)-S(3A) 2.248(1), S(1)-S(2) 2.095(1), S(2)-S(3) 2.073(1); N(1)-Al(1)-N(2) 97.7(1), S(2)-S(1)-Al(1) 98.0(1), S(1)-Al(1)-S(3A) 116.9(1), S(3)-S(2)-S(1) 104.7(1).

Table 1: The reaction energy of $[L_2Al_2S_n]$ ($n = 2$–8).[a]

				n			
	2	3	4	5	6	7	8
reaction energy [kJ mol^{-1}]	−648 (S1 S1)	−641 (S1 S2)	−644 (S1 S3)	−602 (S1 S4)	−621 (S1 S5)	−594 (S1 S6)	−609 (S1 S7)
			−571 (S2 S2)	−581 (S2 S3)	−608 (S3 S3)	−570 (S3 S4)	−524 (S4 S4)

[a] The reaction energy is obtained from $E([L_2Al_2S_n]) - 2\,E([LAl]) - n/8\,E(S_8)$. The notes next to the energies show the conformations. For example, S3 S4 means one bridge has three S atoms, while the other one has four S atoms

slightly longer than that in S_8[10] (av 2.05 Å), $[\{(\eta^5\text{-MeC}_5\text{H}_4)_2\text{-Ti}(\mu\text{-S}_3)\}_2]$[3] (av 2.06 Å), and $[\{(\eta^5\text{-MeC}_5\text{H}_4)\text{Ru(PPh}_3)(\mu\text{-S}_3)\}_2]$[4] (av 2.05 Å). The Al−S bond lengths (av 2.24 Å) are comparable with those in the dimer $[LAl(\mu\text{-S})_2AlL]$ (av 2.24 Å)[8] and in $[LAl(SH)_2]$ (av 2.22 Å).[11] The Al−N bond length (av 1.89 Å) falls within the range of those in aluminum derivatives bearing the L ligand.[12] The S-S-S angle (104.7°) is close to those found in $[\{(\eta^5\text{-MeC}_5\text{H}_4)_2\text{Ti}(\mu\text{-S}_3)\}_2]$[3] (109.1°) and $[\{(\eta^5\text{-MeC}_5\text{H}_4)\text{Ru(PPh}_3)(\mu\text{-S}_3)\}_2]$[4] (105.2°).

The S_8 ring can have different cleavage patterns and thus forms various types of structures.[1a] For $[L_2Al_2S_n]$ species the product with $n = 2$ is known,[8] and herein compound **2** has $n = 6$. Theoretical calculations were carried out to estimate the relative stability of the compounds with $n = 2$–8. The method used is RI-BP86/TZVP within the TURBOMOLE[13] program. The optimized structure of $[L_2Al_2S_6]$ is in good agreement with the X-ray values for **2** (mean deviation < 0.04 Å), which shows the reliability of the selected theoretical method. In the calculation the CHMe$_2$ groups in the ligand L were replaced by H atoms. The relative stability of $[L_2Al_2S_n]$ was estimated by the reaction energy of $2[LAl] + n/8\,S_8 \rightarrow [L_2Al_2S_n]$. The calculated reaction energies are listed in Table 1. All the reactions are exothermic. Compound $[L_2Al_2S_2]$[8] is the most stable. However, there are quite a few conformations with only a slightly smaller reaction energy, and thus thermodynamically they are all possible. Most $[L_2Al_2S_n]$ species prefer only one bridging S atom, while all the other S atoms are arranged in the second bridge (Table 1). We could isolate **2** but not the (theoretically favored) S1 S5 isomer, this might be due to the very low solubility of the latter species.

Therefore, the theoretical work shows that all $[L_2Al_2S_n]$ ($n = 2$–8) species have rather stable conformations (and that there can be more than one).[14] These compounds may coexist in the product, and under different reaction conditions another species may be preferentially formed. To obtain a single crystal out of such a mixture is difficult except for $n = 2$ where one can use excess of **1** to react with sulfur.

In summary, we report herein the first compound of Group 13 with two (μ-S$_3$) chains connecting two aluminum atoms under formation of an eight-membered Al$_2$S$_6$ ring. Studies of the other possible conformations of $[L_2Al_2S_n]$ estimated by calculation are underway.

Experimental Section

All manipulations were performed under a dry and oxygen-free nitrogen atmosphere using Schlenk-line and glovebox techniques.

2: Toluene (30 mL) was added to a mixture of **1** (0.580 g, 1.3 mmol) and S_8 (0.125 g, 3.9 mmol) at −78°C. The resulting suspension was stirred at this temperature for 2 h and slowly warmed to room temperature. The mixture was stirred for additional 15 h. After removal of the precipitate by filtration, the concentrated solution was kept at room temperature for 3 days to afford pale yellow crystals of **2**. (0.150 g, 22%). M.p. 185°C (decomp); EI-MS: *m/z* (%) 508 (100) [*M*$^+$−LAlS$_4$], 540 (38) [*M*$^+$−LAlS$_3$], 572 (15) [*M*$^+$−LAlS$_2$]. ^{1}H NMR (500.13 MHz, C$_6$D$_6$): $\delta = 7.20$–6.90 (m, 12 H, Ar-H), 4.72 (s, 2H, γ-H), 3.30 (sept, 8H, $J = 6.8$ Hz, C*H*Me$_2$), 1.50 (s, 12 H, *Me*), 1.37 (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$), 1.00 ppm (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$); ^{13}C NMR (125.77 MHz, C$_6$D$_6$): $\delta = 171.78$ (CN), 145.74, 143.69, 128.20, 123.83 (Ar), 97.74 (γ-C), 28.92 (*C*HMe$_2$), 25.45(CH*Me*$_2$), 23.93 (CH*Me*$_2$), 23.55 ppm (*Me*); ^{27}Al NMR: resonance is silent. [9] Crystal data for **2**·2 toluene: $C_{72}H_{98}Al_2N_4S_6$, $M_r = 1265.86$, monoclinic, space group $P2_1/n$, $a = 14.277(1)$, $b = 16.387(1)$, $c = 15.786(1)$ Å, $\beta = 109.66(1)°$, $V = 3478(1)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.209$ Mg m^{-3}, $F(000) = 1360$, $\lambda = 1.54178$ Å, $T = 100(2)$ K, $\mu(Cu_{K\alpha}) = 2.386$ mm^{-1}. Data for the structure were collected on a Bruker three-circle diffractometer equipped with a SMART 6000 CCD detector. Intensity measurements were performed on a rapidly cooled crystal (dimensions $0.30 \times 0.20 \times 0.10$ mm^3) in the range of $7.24 \leq 2\theta \leq 117.84°$. Of the 15352 measured reflections, 4907 were independent ($R(int) = 0.0363$). The structure was solved by direct methods (SHELXS-97)[15] and refined with all data by full-matrix least-squares methods on F^2.[16] The hydrogen atoms of C−H bonds were placed in idealized positions. The final refinements converged at $R1 = 0.0328$ for $I > 2\sigma(I)$, $wR2 = 0.0868$ for all data. The final difference Fourier synthesis gave a min/max residual electron density $-0.263/+0.619$ e Å^{-3}.[14] CCDC-241840 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

[14] The residual electron density 0.619 e Å^{-3} can be explained by the presence of a higher homologue in the crystal (ca. 3%). It can be refined as either $[L_2Al_2S_7]$ or $[L_2Al_2S_8]$. Owing to the inversion center it is not possible to distinguish between these two homologues. Although this disordered model shows good geometry and leads to a lower R value, the ordered model for **2** was used for the discussion and theoretical calculations.

Preparation of [LAl(μ-S)₂MCp₂] (M = Ti, Zr) from the Structurally Characterized Lithium Complexes [{LAl(SH)[SLi(thf)₂]}₂] and [{LAl[(SLi)₂(thf)₃]}₂]·2 THF**

Vojtech Jancik, Herbert W. Roesky,* Dante Neculai, Ana M. Neculai, and Regine Herbst-Irmer

Dedicated to Professor Hubert Schmidbaur on the occasion of his 70th birthday

Recently, we reported the preparation of the unique monomeric [LAl(SH)₂] (**1**) (L = HC(CMeNAr)₂; Ar = 2,6-iPr₂C₆H₃) comprising two terminal SH moieties.[1] This unusual species led us to explore the substitution pattern of the SH protons, their exchange with transition metals would open a new route for the preparation of heterobimetallic sulfides containing aluminum. To date very few examples with aluminum bridging sulfide are known. Such species include [(tBuAl)(tBuAlMe)₂(μ₃-S)₃ZrCp₂] (Cp = C₅H₅), prepared by degradation of the [{tBuAl(μ₃-S)}₄] cage with two equivalents of [Cp₂ZrMe₂].[2] Moreover, there are known aluminum sulfides with [AlS]$_n$ core, which can be either planar (n = 2), cubic (n = 4), drum (n = 6), or possess more complex structures with an Al:S molar ratio different from 1:1.[3]

Attempts to prepare heterobimetallic sulfides with **1** and ZnMe₂ or CdMe₂ through alkane elimination failed, in spite of the high affinity of these elements towards chalcogens.[4] We observed even at low temperature only the formation of an inseparable mixture of products and the free ligand. This situation is in contrast to the successful preparation of [LAl(μ-S)₂AlL] from **1** and [LAlH₂].[3] Following the protocol of Nöth et al. on the preparation of aluminum–lithium salts from LiAlH₄ and thiols,[5] we chose the lithiation of **1** with MeLi and nBuLi in diethyl ether or THF as an alternative route to the desired compounds. Unfortunately, under the given conditions the decomposition of **1** was observed. However, the difficulties encountered in the preparation of the dilithium salt [{LAl[(SLi)₂(thf)₃]}₂]·2 THF (**2**) were overcome by direct reaction of **1** with two equivalents of LiN(SiMe₃)₂ in THF at 0°C. The extremely sensitive pale yellow product **2** is a dimer solvated by eight molecules of THF as demonstrated by X-ray structural analysis. It has low solubility in THF and forms a microcrystalline precipitate within a few seconds of starting materials being mixed. The recovery of the crystals

was performed within 15 min of the addition of the solvent to avoid decomposition caused by free HN(SiMe$_3$)$_2$. However, compound **2** loses THF upon drying in vacuo, leading to a dimeric product [{LAl[(SLi)$_2$(thf)$_2$]}$_2$] (**2′**) containing only four molecules of THF as determined by ^{1}H NMR spectroscopy. This final product proved to be stable upon storage for several months under an inert atmosphere. After the successful isolation of **2′**, we became interested in the preparation of the monolithium salt [{LAl(SH)[SLi(thf)$_2$]}$_2$] (**3**). To our knowledge such systems are not known for any kind of metal and, could be precursors for substitution reactions. For the preparation of **3** a similar method was used as for **2′**. After removal of all volatiles in vacuo compound **3** was isolated in 84% yield. Moreover, no decomposition was detected in the presence of HN(SiMe$_3$)$_2$ or during the removal of the solvent, thus demonstrating a higher stability of **3** compared to that of **2**. As expected, **3** has a dimeric arrangement in the solid state, with each lithium coordinated to two molecules of THF and two sulfur atoms. The amount of THF in **3** remains unchanged even after keeping **3** for several hours in vacuo (Scheme 1).
Scheme 1. Synthesis of compounds **2′–5**.

We focused on reactivity studies of **2′** and **3** towards the transition-metal halides, namely [Cp$_2$TiCl$_2$] and [Cp$_2$ZrCl$_2$]. When a solution of [Cp$_2$MCl$_2$] (M = Ti, Zr) in THF was added dropwise to the solution of **2′** in THF at −20°C, the color of the resulting mixture became brownish-green, M = Ti, and deep yellow for M = Zr. After removal of the THF, extraction of the crude product with toluene and several purification steps, compounds [LAl(μ-S)$_2$MCp$_2$] (M = Ti (**4**), M = Zr (**5**)) were isolated in 89% and 85% yield, respectively.

Surprisingly the reaction of **3** with [Cp$_2$TiCl$_2$] or [Cp$_2$ZrCl$_2$] in a molar ratio 2:1 does not yield the expected [{LAl(SH)S}$_2$MCp$_2$] but rather a mixture of **1** and **4** (or **5**) is formed. This result suggests that the formation of the four-membered ring [LAl(μ-S)$_2$MCp$_2$] is preferred over a LAl(SH)-S-M(Cp)$_2$-S-Al(SH)L chain arrangement containing free SH groups. One pathway for the formation of **1** and **4** (or **5**) in the above reaction may involve the intermediate

[LAl(SH)(μ-S)M(Cl)Cp$_2$], followed by a translithiation with a second molecule of **3**, yielding **1** and [LAl(SLi)(μ-S)M(Cl)Cp$_2$]. Subsequently, [LAl(SLi)(μ-S)M(Cl)Cp$_2$] undergoes an intramolecular elimination of LiCl to yield [LAl(μ-S)$_2$MCp$_2$]. A second possible mechanism is an in situ formation of [{LAl(SH)(μ-S)}$_2$MCp$_2$] followed by its rapid rearrangement to yield **1** and **4** (or **5**) (Scheme 1).

X-ray quality crystals of **2** and **3** were obtained by slow cooling their THF solutions.[6] Both derivatives crystallize in the monoclinic space group *P*2$_1$/*n* as pale yellow crystals. Compound **3** shows a simple coordination environment for the Li atoms [LAl(SH)(μ$_3$-S)(μ-Li·2THF)$_2$(μ$_3$-S)Al(SH)L], while the structure of **2** is more complex and none of the four lithium atoms are equivalent. As depicted in Figure 1, the lithium atoms Li(1), Li(2) and Li(4) are coordinated by two, one, and three THF molecules, respectively, whereas Li(3) is not coordinated to THF. This diversity is due to the steric bulk of the ligand L.
Figure 1. Molecular structure of [{LAl[(SLi)$_2$(thf)$_3$]}$_2$]·2THF (**2**); thermal ellipsoids set at 50% probability. All hydrogen atoms, noncoordinated THF molecules and carbon atoms of the coordinating THF molecules are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)-S(1) 2.186(1), Al(1)-S(2) 2.182(1), Al(2)-S(3) 2.173(1), Al(2)-S(4) 2.181(1), Li(1)-S(1) 2.482(2), Li(1)-S(3) 2.414(2), Li(2)-S(1) 2.544(2), Li(2)-S(3) 2.449(2), Li(2)-S(4) 2.565(2), Li(3)-S(1) 2.502(2), Li(3)-S(2) 2.345(2), Li(3)-S(4) 2.323(2), Li(4)-S(2) 2.343(3); S(1)-Al(1)-S(2) 111.6(1), S(3)-Al(2)-S(4) 113.0(1), Al(1)-S(1)-Li(1) 149.6(1), Al(1)-S(1)-Li(2) 126.3(1), Al(1)-S(1)-Li(3) 74.3(1), Al(1)-S(2)-Li(3) 77.7(1), Al(1)-S(2)-Li(4) 152.1(1), Al(2)-S(3)-Li(1) 114.8(1), Al(2)-S(3)-Li(2) 76.3(1), Al(2)-S(4)-Li(2) 73.7(1), Al(2)-S(4)-Li(3) 118.0(1), Li(1)-S(1)-Li(2) 68.2(1), Li(1)-S(1)-Li(3) 92.5(1), Li(1)-S(3)-Li(2) 70.8(1), Li(2)-S(1)-Li(3) 66.0(1), Li(2)-S(4)-Li(3) 68.2(1), Li(3)-S(2)-Li(4) 116.8 (1), S(1)-Li(1)-S(3) 112.1(1), S(1)-Li(2)-S(3) 108.9(1), S(1)-Li(2)-S(4) 107.8(1), S(1)-Li(3)-S(2) 96.4(1), S(1)-Li(3)-S(4) 117.6(1), S(2)-Li(3)-S(4) 134.6(1), S(3)-Li(2)-S(4) 92.8(1).

The two THF molecules coordinated to Li(1) require there to be more space between the 2,6-*i*Pr$_2$C$_6$H$_3$ moieties of L and thus force the substituents on the opposite side closer together. This steric pressure results in Li(4) being pushed out of the central area of the dimer. Subsequently the coordination of three THF molecules covers the unsaturated sites on Li(4). For the two remaining Li atoms, the situation is similar.

Communications

Li(2) can still be coordinated by one THF molecule whereas Li(3) is coordinated only to three sulfur atoms. These different coordination sites of lithium atoms are compensated by the variation of the Li−S bond lengths (2.323–2.565 Å). The $Al_2S_4Li_4$ core can also be described as being a six-membered AlS_3Li_2 ring with alternating sulphur and metal atoms, which is capped by another lithium atom and a bent Al-S-Li unit is joined to one of the S–Li edges of this hexagonal pyramid to form a condensed four-membered AlS_2Li ring. The shortness of the S(4)−Li(3) bond (2.323 Å) is caused by the unsaturated coordination sphere of Li(3) which contains only three sulfur atoms and is one of the shortest S−Li bonds observed to date.[7a–c] All the other S−Li bonds of **2** (2.343–2.565 Å) and **3** (2.424 and 2.478 Å) are in the range observed for similar species (2.327–2.964 Å).[5,7] Figure 2 shows the molecular structure of **3** in which the S_2Li_2 core is essentially planar owing to the crystal symmetry.
Figure 2. Molecular structure of [{LAl(SH)[SLi(thf)$_2$]}$_2$] (**3**); thermal ellipsoids set at 50% probability. All hydrogen atoms (except those of the S−H moieties), and the carbon atoms of the THF molecules are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)-N(1) 1.928(2), Al(1)-N(2) 1.935(2), Al(1)-S(1) 2.268(1), Al(1)-S(2) 2.123(1), H(1)-S(1) 1.28(5), Li(1)-S(2) 2.478(5), Li(1)-S(2A) 2.424(5); S(1)-Al(1)-S(2) 115.7(1), Al(1)-S(2)-Li(1) 151.6(1), Al(1)-S(2)-Li(1A) 111.7(1), Li(1)-S(2)-Li(1A) 78.0(2), S(2)-Li(1)-S(2A) 102.0(2).

This S_2Li_2 motif can be found in many substances containing these two elements including **2**.[5,7] The free SH groups are not involved in any kind of hydrogen bonding and are orientated *trans* to each other.

Crystals of **4** were obtained by slow cooling of its toluene/hexane solution.[6] **4** crystallizes in the monoclinic space group $P2_1$ and its molecular structure is shown in Figure 3.

The AlS_2Ti ring is essentially planar with the sum of inner angles of 360°. The widest angle (102.5°) corresponds to that at the aluminum center, while the one at the titanium center is almost a right angle (89.3°). The Ti–X_{Cp} separations (X_{Cp} is the centroid of the Cp group) are 2.091 and 2.090 Å and the X_{Cp1}-Ti-X_{Cp2} angle is 130°. All these data are in good agreement with those reported for [Cp$_2$Ti(μ-S)$_2$ML′L″] (e.g. M = Si, Ti, Ru, L′ = Cp, L″ = Cl) species (2.425–2.458 Å for
Figure 3. Molecular structure of [LAl(μ-S)$_2$TiCp$_2$] (**4**); thermal ellipsoids set at 50% probability. All hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)-N(1) 1.918(2), Al(1)-N(2) 1.921(2), Al(1)-S(1) 2.208(1), Al(1)-S(2) 2.197(1), Ti(1)-S(1) 2.416(1), Ti(1)-S(2) 2.473(1), Ti(1)-X$_{Cp1}$ 2.091(3), Ti(1)-X$_{Cp2}$ 2.090(3); S(1)-Al(1)-S(2) 102.5(1), Al(1)-S(1)-Ti(1) 84.7(1), Al(1)-S(2)-Ti(1) 83.6(1), S(1)-Ti(1)-S(2) 89.3(1), X$_{Cp1}$-Ti(1)-X$_{Cp2}$ 130.0(2); X = centroid of Cp ring.

Ti−S, 2.059–2.093 Å for X_{Cp}–Ti, 129.6–131.6° for X_{Cp1}-Ti-X_{Cp2} and 86.5–95.9° for S-Ti-S).[8] The substitution of the SH protons by Li or Ti has a significant influence on the Al−S bond length. The Al−S bond lengths decrease in the series from **1** (2.223 Å and 2.217 Å)[1] to **4** (2.208 and 2.197 Å), to **2** (2.173–2.186 Å) and finally to **3** (2.123 Å). The partial negative charge on the substituted S atom in **3** causes a shortening of the Al−S bond and thus, increases the electron density on the aluminum center resulting in an elongation of the Al−S(H) bond (2.268 Å).

In summary, we have developed a new strategy for the preparation of heterobimetallic sulfides containing aluminum and isolated four new species. Furthermore, the lithium salts [{LAl[(SLi)$_2$(thf)$_2$]}$_2$] and [{LAl(SH)[SLi(thf)$_2$]}$_2$] are promising precursors for further reactions.

Experimental Section

CH(CH_3)$_2$), 1.25 (d, ^3J(H,H) = 6.8 Hz, 24 H, CH(CH_3)$_2$), 1.51 (s, 12 H, CH_3), 1.77 (m, 16 H, O(CH_2CH_2)$_2$), 3.62 (m, 16 H, O(CH_2CH_2)$_2$), 4.00 (sept, ^3J(H,H) = 6.8 Hz, 8 H, CH(CH$_3$)$_2$), 5.01 (s, 2 H, CH), 7.00–7.01 ppm (m, 12 H, m-, p- Ar(H)); ^{13}C NMR (125.8 MHz, [D$_8$]THF, 25 °C, TMS): δ = 24.7 (CH(CH_3)$_2$), 24.8 (CH(CH_3)$_2$), 26.4 (O(CH_2CH_2)$_2$), 27.4 (CH(CH_3)$_2$), 28.7 (CH_3), 68.2 (O(CH_2CH_2)$_2$), 98.1 (γ-CH), 124.2, 126.2, 145.1, 146.1 (i-, o-, m-, p-C of Ar), 168.1 ppm (C=N); ^{7}Li NMR (116.6 MHz, [D$_8$]THF, 25 °C, LiCl, 1 M in D$_2$O): δ = 1.26 (SLi). Elemental analysis calcd (%) for C$_{74}$H$_{114}$Al$_2$Li$_4$N$_4$O$_4$S$_4$ (1333.71): C 66.64, H 8.62, N 4.20; found: C 65.70, H 8.57, N 4.27.

3: Compound **1** (1.000 g, 1.958 mmol) and LiN(SiMe$_3$)$_2$ (0.328 g, 1.958 mmol) were mixed as solids in a flask and subsequently THF (30 mL) was added at ambient temperature. The mixture was stirred for 5 min, all the volatiles were removed in vacuo. The crude product was washed with cold hexane (5 mL) to remove the remaining HN(SiMe$_3$)$_2$, yielding **3** as a pale yellow powder. Yield 1.11 g (85 %). M.p. 230 °C (decomp.). ^{1}H NMR (500 MHz, [D$_8$]THF, 25 °C, TMS): δ = −1.00 (s, 2 H, SH), 1.04 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.21 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.25 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.40 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.69 (s, 12 H, CH_3), 1.77 (m, 16 H, O(CH_2CH_2)$_2$), 3.62 (m, 16 H, O(CH_2CH_2)$_2$), 3.77 (sept, ^3J(H,H) = 6.8 Hz, 4 H, CH(CH$_3$)$_2$), 3.85 (sept, ^3J(H,H) = 6.8 Hz, 4 H, CH(CH$_3$)$_2$), 5.13 (s, 2 H, CH), 7.06–7.16 ppm (m, 12 H, m-, p-Ar–H); ^{13}C NMR (125.8 MHz, [D$_8$]THF, 25 °C, TMS): δ = 24.3 (CH(CH_3)$_2$), 24.4 (CH(CH_3)$_2$), 25.1 (CH(CH_3)$_2$), 25.1 (CH(CH_3)$_2$), 26.4 (O(CH_2CH_2)$_2$), 28.0 (CH(CH$_3$)$_2$), 28.5 (CH(CH$_3$)$_2$), 29.6 (CH_3), 68.2 (O(CH_2CH_2)$_2$), 97.6 (γ-CH), 124.1, 134.3, 126.4, 143.6, 145.7, 146.0 (i-, o-, m-, p-C of Ar), 169.0 ppm (C=N); ^{7}Li NMR (116.6 MHz, [D$_8$]THF, 25 °C, LiCl, 1 M in D$_2$O) δ = 0.32 (SLi). IR(KBr pellet): 2552 vw (SH) cm^{-1}. Elemental analysis calcd (%) for C$_{74}$H$_{116}$Al$_2$Li$_2$N$_4$O$_4$S$_4$ (1321.84): C 67.24, H 8.85, N 4.24; found: C 66.45, H 8.45, N 4.52.

4: A solution of [Cp$_2$TiCl$_2$] (0.224 g, 0.900 mmol) in THF (20 mL) was added dropwise to a solution of **2′** (0.600 g, 0.450 mmol) in THF (40 mL) at −20 °C. During the addition, the color of the solution changed to deep brown-green. After the addition was complete, the reaction mixture was stirred for additional 5 min at −20 °C and than allowed to warm to ambient temperature. The solvent was removed in vacuo and the crude product was extracted twice with cold toluene (15 mL, 5 °C). After filtration, removing of the toluene from the filtrate, washing of the product with a cold toluene:pentane (5 mL, 1:4) mixture and drying in vacuo, **4** was obtained as a brown-green powder. Yield 0.55 g (89 %). Decomposition without melting at 270 °C. ^{1}H NMR (500 MHz, C$_6$D$_6$, 25 °C, TMS): δ = 1.06 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.64 (s, 6 H, CH_3), 1.88 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 3.57 (sept, ^3J(H,H) = 6.8 Hz, 4 H, CH(CH$_3$)$_2$), 4.84 (s, 1 H, CH), 5.71 (s, 10 H, C$_5$H$_5$), 7.30(-7.37 ppm (m, 6 H, m-, p-Ar(H)); ^{13}C NMR (125.8 MHz, C$_6$D$_6$, 25 °C, TMS): δ = 24.0 (CH(CH_3)$_2$), 25.7 (CH(CH_3)$_2$), 25.7 (CH(CH_3)$_2$), 29.1 (CH_3), 94.9 (γ-CH), 118.3 (C$_5$H$_5$), 125.0, 128.0, 140.6, 146.0 (i-, o-, m-, p-C of Ar), 170.2 ppm (C=N); ^{27}Al NMR (78.2 MHz, C$_6$D$_6$, 25 °C, [Al(H$_2$O)$_6$]$^{3+}$) δ = 94 ppm. MS (70 eV): m/z (%): 686 (8) [M^+], 621 (100) [M^+(Cp]. Elemental analysis calcd (%) for C$_{39}$H$_{51}$AlN$_2$S$_2$Ti (686.83): C 68.20, H 7.48, N 4.08; found: C 67.61, H 7.46, N 4.02.

5: preparation like that of **4** from [Cp$_2$ZrCl$_2$] (0.263 g, 0.900 mmol) and **2′** (0.600 g, 0.450 mmol). The product was isolated as a deep yellow powder. Yield 0.56 g (85 %). Decomposition without melting at 180 °C. ^{1}H NMR (500 MHz, C$_6$D$_6$, 25 °C, TMS): δ = 1.06 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 1.65 (s, 6 H, CH_3), 1.82 (d, ^3J(H,H) = 6.8 Hz, 12 H, CH(CH_3)$_2$), 3.59 (sept, ^3J(H,H) = 6.8 Hz, 4 H, CH(CH$_3$)$_2$), 4.87 (s, 1 H, CH), 5.65 (s, 10 H, C$_5$H$_5$), 7.22–7.32 ppm (m, 6 H, m-, p-Ar(H)); ^{13}C NMR (125.8 MHz, C$_6$D$_6$, 25 °C, TMS): δ = 24.4 (CH(CH_3)$_2$), 25.7 (CH(CH_3)$_2$), 25.7 (CH(CH_3)$_2$), 29.0 (CH_3), 95.1 (γ-CH), 114.4 (C$_5$H$_5$), 124.9, 128.0, 140.1, 146.1 (i-, o-, m-, p-C of Ar); ^{27}Al NMR (78.2 MHz, C$_6$D$_6$, 25 °C, [Al(H$_2$O)$_6$]$^{3+}$) δ = 101 ppm. MS (70 eV): m/z (%): 728 (58) [M^+], 663 (100) [M^+(Cp]).

Elemental analysis calcd (%) for C$_{39}$H$_{51}$AlN$_2$S$_2$Zr (730.17): C 64.15, H 7.04, N 3.84; found: C 63.09, H 7.30, N 3.83.

[6] Crystal data for **2**: C$_{90}$H$_{146}$Al$_2$Li$_4$N$_4$O$_8$S$_4$, M_r = 1622.07, monoclinic, space group P2$_1$/n, a = 22.746(1), b = 16.414(1), c = 26.111(1) Å, β = 106.45(1)°, V = 9350(1) Å^3, Z = 4, ρ_{calcd} = 1.152 Mg m^{-3}, F(000) = 3520, λ = 1.54178 Å, T = 100(2) K, μ(Cu$_{K\alpha}$) = 1.525 mm^{-1}. Of the 50723 measured reflections, 13679 were independent (R_{int} = 0.0214). The final refinements converged at $R1$ = 0.0288 for $I > 2\sigma(I)$, $wR2$ = 0.0747 for all data. The final difference Fourier synthesis gave a min/max residual electron density of −0.187/+0.250 eÅ^{-3}; crystal data for **3**: C$_{74}$H$_{116}$Al$_2$Li$_2$N$_4$O$_4$S$_4$, M_r = 1321.78, monoclinic, space group P2$_1$/n, a = 12.558(1), b = 19.423(1), c = 16.862(1) Å, β = 111.29(1)°, V = 3832(1) Å^3, Z = 2, ρ_{calcd} = 1.145 Mg m^{-3}, F(000) = 1432, λ = 1.54178 Å, T = 100(2) K, μ(Cu$_{K\alpha}$) = 1.721 mm^{-1}. Of the 14831 measured reflections, 5403 were independent (R_{int} = 0.0567). The final refinements converged at $R1$ = 0.0441 for $I > 2\sigma(I)$, $wR2$ = 0.1219 for all data. The final difference Fourier synthesis gave a min/max residual electron density of −0.238/+0.277 eÅ^{-3}; crystal data for **4**: C$_{39}$H$_{51}$AlN$_2$S$_2$Ti, M_r = 686.82, monoclinic, space group P2$_1$, a = 11.831(1), b = 8.727(1), c = 17.776(1) Å, β = 99.10(1)°, V = 1812(1) Å^3, Z = 2, ρ_{calcd} = 1.259 Mg m^{-3}, F(000) = 732, λ = 1.54178 Å, T = 100(2) K, μ(Cu$_{K\alpha}$) = 3.525 mm^{-1}. Of the 6417 measured reflections, 3178 were independent (R_{int} = 0.0189). The final refinements converged at $R1$ = 0.0235 for $I > 2\sigma(I)$, $wR2$ = 0.0591 for all data and the absolute structure parameter was refined to 0.013(5). The final difference Fourier synthesis gave a min/max residual electron density of −0.199/+0250 eÅ^{-3}. Data for the structures were collected on a Bruker three-circle diffractometer equipped with a SMART 6000 CCD detector. Intensity measurements were performed on a rapidly cooled crystal (0.3 × 0.2 × 0.1 mm^3) in the range $4.56 \leq 2\theta \leq 120.08°$ (**2**), (0.2 × 0.1 × 0.1 mm^3) in the range $7.24 \leq 2\theta \leq 118.02°$ (**3**), and (0.5x0.2x0.2 mm^3) in the range $8.40 \leq 2\theta \leq 113.68°$ (**4**). The structures were solved by direct methods (SHELXS-97[9]) and refined against all data by full-matrix least-squares on F^2[10]. The hydrogen atoms of C–H bonds were placed in idealized positions, whereas the hydrogen atom from the SH moiety in **3** was localized from the difference electron-density map and refined isotropically. Disordered THF molecules (**2**, **3**) were refined with distance restraints and restraints for the anisotropic displacement parameters. CCDC-244078 (**2**), CCDC-244079 (**3**), and CCDC-244080 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crys-

tallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

Phospholes

The Dithieno[3,2-b:2′,3′-d]phosphole System: A Novel Building Block for Highly Luminescent π-Conjugated Materials**

Thomas Baumgartner,* Toni Neumann, and Bastian Wirges

The incorporation of phosphorus centers into polymeric materials has recently attracted a great deal of attention.[1] The versatile reactivity and electronic properties of phosphorus offer considerable promise for the development of new functional materials with novel properties. Exploring the use of phosphole in this context should be of particular interest, as materials possessing the structurally related pyrrole and thiophene moieties are already well-established in the field of molecular electronics.[2] For example, thiophene-based materials show significant potential for application in electronic devices such as photovoltaic cells, organic and polymer light-emitting diodes (OLEDs, PLEDs), polymeric sensors, and TFT-based flat-panel displays.[3]

Careful consideration of the HOMO–LUMO gap, which strongly influences the optical and electronic properties of these materials, is essential for their utility.[4] The ability to fine-tune the electronic structure of the π-conjugated system is therefore highly desirable in order to achieve the required material properties. Recent work by Réau and co-workers incorporating the phosphole moiety into extended thiophene-containing π-conjugated systems (**1**, see Scheme 1), has demonstrated the advantageous electronic features of the phosphorus situated in this system.[1e, 5] Due to the pyramidalization of the phosphorus center, orbital interaction with the conjugated π system is reduced. As a result, the lone pair at the phosphorus atom only functions as an n-dopant for the π system. Conveniently, the doping mode can be inverted easily from n- (electron donor) to p-type (electron acceptor) by simple chemical modifications such as oxidation or complexation at the phosphorus center.[1e, 5] Although these intriguing features as well as theoretical calculations[6] strongly support the advantages of incorporating phosphole moieties into polymeric systems, only three examples of phosphole-containing macromolecules have been reported to date.[1e, 7]

We now report on the synthesis and optoelectronic properties of novel dithieno[3,2-b:2′,3′-d]phospholes[8] and the preparation of a well-defined dithienophosphole-containing polymer built on a polystyrene backbone. The dithieno[3,2-b:2′,3′-d]phosphole **2** (Scheme 1) was chosen as

Scheme 1. Synthesis of dithienophosphole derivatives and precursors: a) 2 nBuLi, 2 tBuMe$_2$SiCl, THF, −78°C (**6**: R = SitBuMe$_2$); b) 2 nBuLi, R′PCl$_2$, Et$_2$O, −78°→RT (**2**: R = H, R′ = Ph, **4**: R = H, R′ = 4-tBuC$_6$H$_4$); c) 2 n-BuLi, (4-vinylphenyl)PCl$_2$, TMEDA, Et$_2$O, −78°→RT (**7**: R = SitBuMe$_2$, R′ = 4-vinylphenyl); d) BH$_3$·SMe$_2$ (1 M in CH$_2$Cl$_2$), CH$_2$Cl$_2$, RT (E = BH$_3$; **8**: R = H, R′ = Ph, **9**: R = H, R′ = 4-tBuC$_6$H$_4$); e) H$_2$O$_2$ (30% in H$_2$O), pentane, RT (E = O; **10**: R = H, R′ = Ph, **11**: R = H, R′ = 4-tBuC$_6$H$_4$, **12**: R = SitBuMe$_2$, R′ = 4-vinylphenyl).

a synthetic target since the annelation of aromatic rings has been found to be a powerful approach for tuning the band gap of conjugated materials.[4,9] This is further supported by a recent theoretical investigation in which thiophene-based, fused tricyclic polymers were found to have a much more favorable band gap than the related polythiophenes.[10] The incorporation of the phosphole moiety into a rigid, tricyclic dithieno system should therefore lead to a significantly higher degree of π conjugation than that reported for comparable systems.[11]

To verify the synthetic accessibility of the dithienophosphole system as well as to explore its optoelectronic properties, we initiated our studies on model compounds and functionalized monomers. Dithienophospholes **2** and **4** are accessible by reaction of 3,3′-dibromo-2,2′-dithiophene (**3**) with nBuLi, then subsequent addition of the corresponding dichlorophosphine at low temperatures, followed by purification by filtration over neutral alumina (yields: **2**: 70%, **4**: 72%). Both compounds exhibit signals in the ^{31}P NMR spectrum (**2**: $\delta = −21.5$ ppm; **4**: $\delta = −22.5$ ppm) that are shifted significantly upfield from those of related phospholes, for example, those reported by Réau et al. (δ^{31}P = 11–45 ppm).[1e] The ^{1}H and ^{13}C NMR data, on the other hand, are not significantly different than data previously reported for related dithieno systems.[12] To our satisfaction, both **2** and **4** display strong,

Communications

blue photoluminescence, and should thus have the desired optoelectronic properties (vide infra). We were able to obtain light-yellow crystals of **2** suitable for X-ray structure analysis[13] from a concentrated pentane/toluene (1:1) solution cooled to −30°C. As expected, the rigid tricyclic dithienophosphole is planar and displays an *anti* configuration of the two thiophene moieties and the phosphole unit (see Figure 1). The high degree of π conjugation is apparent in the
Figure 1. Molecular structure of **2** (50% probability level) in the solid state. Selected bond lengths [Å] and angles [°]: P1–C3 1.8193(14), P1–C6 1.8218(14), P1–C11 1.8367(13), C3–C4 1.3842(19), C5–C6 1.3817(18), C4–C5 1.4397(19); C6–C7 1.4228(18), C7–C8 1.364(2); C3-P1-C6 89.25(6), C3-P1-C11 103.82(6), C6-P1-C11 99.92(6).

shortened single bonds {C2−C3 1.427(2), C4−C5 1.440(2), C6−C7 1.423(2) Å} as well as the elongated double bonds (C1−C2 1.365(2), C3−C4 1.384(2), C5−C6 1.382(2), C7−C8 1.364(2) Å) of the fused ring system. It is interesting to note that the bond shortening/elongation is significantly more pronounced in **2** than in the thienyl-substituted phosphole **1**,[5a] supporting the positive effects of the rigid ring system on the π conjugation. The endocyclic P−C bonds P1−C3 (1.8193(14) Å) and P1−C6 (1.8218(14) Å) are only slightly shorter than the exocyclic P1−C11 bond (1.8367(13) Å) due to minimal hyperconjugation of the phosphorus lone pair with the π system, which affords a reduced aromatic phosphole unit. This structural feature strongly supports the role of the phosphorus center as a dopant for the π-conjugated system, which is potentially interesting for the optoelectronic properties of the material.

To gain access to polymeric systems we functionalized the phosphorus center of the dithienophosphole with a vinyl-phenyl group. We also investigated silyl functionalization of the dithienophosphole ring to provide increased solubility for the targeted polymer. An additional benefit with respect to the optoelectronic properties was anticipated, as the silyl center provides an acceptor component expected to further extend the delocalized π system, thus optimizing the electronic structure of the dithienophosphole.[11]

The vinylphenyl-functionalized monomer **7** is accessible in a two-step reaction starting from 3,3′,5,5′-tetrabromo-2,2′-bithiophene (**5**). In the first step, the silyl functionalities were introduced by treating **5** with two equivalents of *n*BuLi and then adding *tert*-butyl(dimethyl)silyl chloride in THF at −78°C to provide **6** in almost quantitative yield. The silyl-functionalized dithiophene **6** was then treated with another two equivalents of *n*BuLi in Et₂O at −78°C, and dichloro(4-vinylphenyl)phosphane[14] was then added in the presence of an excess of TMEDA to afford the vinylphenyl-functionalized dithienophosphole **7** in good yields (ca. 80%) after filtration over neutral alumina. The dithienophosphole monomer **7** exhibits a resonance in the ^{31}P NMR spectrum of $\delta = -26.4$ ppm that is shifted slightly upfield from those observed for **2** and **4**. The ^{1}H and ^{13}C NMR data confirm the expected structure and are very similar to those recorded for **2** and **4**.

As previously noted, it should be possible to alter the electronic structure, thus inverting the doping mode of the phosphole, by either oxidation or complexation of the phosphorus atom. We therefore investigated the reaction of the dithienophospholes **2** and **4** with borane (applied as BH₃·SMe₂) to afford the phosphole–borane adducts **8** and **9**, and hydrogen peroxide to give the phosphole oxides **10** and **11**, all in almost quantitative yields.[15] The NMR data for the borane adducts show downfield resonances in the ^{31}P NMR spectrum ($\delta(^{31}$P$) = 13.5$ (**8**), 14.6 ppm (**9**)) in correlation with the electron-withdrawing effect of the BH₃ group. This is even more pronounced in the case of the oxide functionality ($\delta(^{31}$P$) = 18.8$ ppm (**10**),[8] 19.1 (**11**)). The same effect was observed for the silyl-functionalized phosphole oxide **12** ($\delta(^{31}$P$) = 14.7$ ppm) that was synthesized in an analogous manner.[15] The ^{1}H and ^{13}C NMR data for all compounds show a similar trend, and fall within the range of values previously reported for related phospholes.[1e,5]

As indicated earlier, the dithienophosphole derivatives exhibit a strong blue photoluminescence. Fluorescence spectroscopy reveals the dependence of the optical properties on the electronic structure of the phosphorus center (Table 1). All compounds show a maximum excitation wavelength in the UV region, whereas the emission spectra show a maximum wavelength in the visible blue region. The dithienophosphole derivatives exhibit Stokes shifts of 70–80 nm similar to the related systems reported by Réau et al. (70–90 nm).[1e] It is interesting to note that the silyl-functionalized dithieno-phosphole monomer **7** shows a significant red shift of about

10–15 nm for the maximum excitation and emission wavelengths ($\lambda_{ex} = 352$, $\lambda_{em} = 422$ nm) compared to the model compounds **2** ($\lambda_{ex} = 338$, $\lambda_{em} = 415$ nm) and **4** ($\lambda_{ex} = 336$, $\lambda_{em} = 408$ nm), supporting the electron-accepting character of the silyl center. The same trend is observed when the doping mode of the phosphorus center is inverted to p-type in the borane adducts **8** and **9** and the phosphole oxides **10–12**. In correlation with the low-field shift of the ^{31}P NMR resonances, the maximum wavelengths for excitation and emission experience a red shift of about 10 nm for the borane adducts and an even stronger red shift of about 30 nm (excitation) and 40 nm (emission) for the phosphole oxides. In the case of the silyl-functionalized phosphole oxide **12**, a cumulative effect of both electron-accepting centers (Si and P) is observed (see Table 1). It should be mentioned that the observed photoluminescence is very intense, particularly for the borane adducts and the phosphole oxides. More importantly, the quantum yields for all compounds range between 55 and almost 90%, which is unprecedented for phospholes[1e] and dithieno systems.[12a, 16] Therefore, the optoelectronic data strongly emphasize the potential of the dithienophosphole system for applications in optoelectronic devices such as blue-light-emitters and sensory materials.

The favorable properties of macromolecules in terms of processability (e.g. as thin films) would be an added benefit for future materials applications. We therefore investigated the possibility of generating a polymer that would display the extraordinary blue photoluminescence of the model compounds by incorporating the dithienophosphole system as side-chain functionalities. Radical polymerization of functionalized styrene seemed to be the method of choice since it is usually not affected by the presence of phosphine centers.[14b] To reduce the steric bulk in the polymeric material caused by the dithienophosphole ring system, which could potentially terminate the polymerization process at an early stage, we targeted the copolymer **13** by using styrene as solvent for the reactions (**7**/styrene ca. 1:30, Scheme 2). The resulting "dilution" of the dithienophosphole centers in the polymeric material was expected to also enhance the optoelectronic properties, due to the great distance between the emitting centers, reducing the potential for quenching processes that could occur at higher densities.[17] The polymerization was performed in a sealed ampule under vacuum at 110°C for 16 h using a catalytic amount of 2,2,6,6-tetramethylpiperidinyl-1-oxy (TEMPO)[18] as the initiator
(Scheme 2). The material obtained after precipitation into degassed pentane was a white amorphous solid. Analysis by gel permeation chromatography (GPC) revealed a high molecular weight of $M_n = 147650$ g mol^{-1} with a relatively narrow polydispersity (PDI) of 2.46. Analysis of the smart polystyrene **13** by differential scanning calorimetry (DSC) showed a glass transition temperature of $T_g = 114.2$°C (cf. native polystyrene: < 100°C[19]) and a thermal decomposition temperature of 428.2°C. The ^{31}P NMR spectrum for **13** shows a broad signal at $\delta(^{31}P) = -25.0$ ppm (cf.: $\delta = -26.4$ ppm for **7**), confirming the existence of dithienophosphole units within the polymeric material. ^{1}H and ^{13}C NMR data revealed a ratio of ca. 1:30 for dithienophosphole/styrene as was expected from the reaction conditions.

The smart polymer **13** exhibits a very strong blue photoluminescence upon irradiation with UV light. The maximum of the excitation and emission wavelengths of **13** ($\lambda_{ex} = 352$ nm; $\lambda_{em} = 424$ nm; dissolved in CH$_2$Cl$_2$) nicely match the values observed for the vinylphenyl-functionalized monomer **7** (Figure 2), supporting the expected side-chain functional-
Figure 2. Excitation (A) and emission (E) spectra of **7** and **13** in CH$_2$Cl$_2$.

ization. The dithienophosphole-containing polymer **13** can be oxidized conveniently with hydrogen peroxide (in analogy to the model compounds) to afford the phosphole oxide containing polymer **14**. It should be mentioned that the same oxidation process is observed within a day when a solution of **13** is exposed to air, whereas the solid material does not show any significant signs of oxidation—even after several weeks.

We were also interested in the optoelectronic properties of a thin film of **13** with regards to applications as a PLED material. A thin film was obtained from a concentrated solution of **13** in CH$_2$Cl$_2$ by slow evaporation of the solvent. Relative to the properties of the CH$_2$Cl$_2$ solution, the very intense blue photoluminescence of the thin film of **13** is red-shifted approximately 20 nm for excitation and roughly 30 nm for emission ($\lambda_{ex} = 374$ nm; $\lambda_{em} = 452$ nm). Surprisingly, the emission wavelength for a

Scheme 2. Synthesis of the dithienophosphole-containing polymer **13**: cat. TEMPO, 110°C, 16 h. TBDMS = *tert*-butyl(dimethyl)silyl.

thin film of the oxidized polymer (**14**, $\lambda_{em} = 456$ nm) almost matches that observed for the nonoxidized material **13**, whereas the value for the excitation wavelength is blue-shifted to 352 nm in **14** (cf. 374 nm for **13**; Figure 3). With
Figure 3. Excitation (A) and emission (E) spectra of **13** and **14** as thin films.

respect to resistance to light, **13** was found to exhibit fairly good stability; this is intrinsically important for the lifetime of optoelectronic devices. Irradiation of a solution of **13** in CH$_2$Cl$_2$ at 352 nm for 2 h results in a stable emission (intensity detected at 424 nm) within a loss of at most 3 %, suggesting a potential use in optoelectronic devices. The same is true for a thin film of the oxidized polymer (**14**) with a margin of 5 %.

In conclusion, we have synthesized novel dithieno[3,2-*b*:2′,3′-*d*]phosphole derivatives in a convenient one- or two-step synthesis, demonstrating that a broad variety of functionalized systems are accessible by this method. The optoelectronic properties of the dithienophospholes are extraordinary with respect to wavelength, intensity, and tuneability, allowing for the possibility of fine-tuning the electronic structure by simple chemical modifications. Additionally, we have shown that it is possible to incorporate the dithienophosphole moiety into polymeric systems, opening up potential applications in optoelectronic devices such as blue-light-emitting PLEDs and polymeric sensors. We are currently probing the range of dithienophosphole-based sensory materials by tuning the optoelectronic properties with different functionalities and modifications of the phosphorus center. Furthermore, the incorporation of polymers **13** and **14** into optoelectronic devices is currently under investigation.

Experimental Section

Dithienophospholes: To a solution of **3** (1.62 g, 5 mmol) in Et$_2$O (100 mL) was added *n*BuLi (4 mL, 10 mmol) dropwise at −78 °C. Subsequently, RPCl$_2$ (R = Ph: 0.90 g, 5 mmol; R = 4-*t*Bu-C$_6$H$_4$, 1.18 g, 5 mmol) dissolved in Et$_2$O (10 mL), was added slowly to the reaction mixture, and the resulting suspension was allowed to warm quickly to room temperature. The solvent was then removed under vacuum, the residue taken up in pentane (ca. 60 mL) and filtered over neutral alumina to remove LiCl and a small amount of brown impurities. The

filtrate was evaporated to dryness, and **2** and **4** were obtained as light-yellow solids (**2**: 1.1 g, 70 % yield; **4**: 1.2 g, 72 % yield).

4: ^{31}P{^{1}H} NMR (162.0 MHz, 25 °C, CDCl$_3$): $\delta = -22.5$ ppm; ^{1}H NMR (400 MHz, 25 °C, CDCl$_3$): $\delta = 7.28$–7.23 (m., 6H; Ar-H), 7.13 (d, ^2J(H,H) = 4.9 Hz, 2H; Ar-H), 1.24 ppm (s, 9H; *t*Bu); ^{13}C{^{1}H} NMR (100.6 MHz, 25 °C, CDCl$_3$): $\delta = 152.4$ (s; *p*-Ar), 147.0 (d, J(C,P) = 8.7 Hz; Ar), 141.6 (d, J(C,P) = 2.1 Hz; Ar), 132.1 (d, J(C,P) = 20.5 Hz; *o*-Ar), 129.7 (d, ^1J(C,P) = 11.4 Hz; Ar), 126.5 (d, ^2J(C,P) = 16.9 Hz; *o*-Ar), 125.9 (d, ^3J(C,P) = 5.7 Hz; *m*-Ar), 125.7 (d, ^3J(C,P) = 8.5 Hz; *m*-Ar), 34.5 (s; *C*Me$_3$), 31.0 ppm (s; C(*C*H$_3$)$_3$). MS (70 eV): *m/z* (%) 328 (100) [*M*$^+$], 271 (50) [*M*-*t*Bu]$^+$, 195 (90) [*M*−C$_{10}$H$_{13}$]$^+$, 57 (25) [*t*Bu]$^+$; elemental analysis calcd (%) for C$_{18}$H$_{17}$PS$_2$: C 65.83, H 5.22, S 19.53; found: C 65.42, H 5.39, S 19.46.

7: To a solution of 3,3′-dibromo-5,5′-bis(*tert*-butyldimethylsilyl)-2,2′-bithiophene (1.11 g, 2 mmol) and TMEDA (1.51 mL, 10 mmol) in Et$_2$O (50 mL) was added *n*BuLi (1.6 mL, 4 mmol) dropwise at −78 °C. Subsequently, (4-vinylphenyl)PCl$_2$ (0.41 g, 2 mmol), dissolved in Et$_2$O (10 mL), was added slowly to the reaction mixture, and the resulting mixture was allowed to warm quickly to room temperature. The solvent was then removed under vacuum, and the residue taken up in pentane (ca. 60 mL) and filtered to remove LiCl. The filtrate was concentrated and left for crystallization at −30 °C. **7** was obtained as white amorphous powder in 80 % yield (0.84 g).

^{31}P{^{1}H} NMR (162.0 MHz, 25 °C, CDCl$_3$): $\delta = -26.4$ ppm; ^{1}H NMR (500 MHz, 25 °C, CDCl$_3$): $\delta = 7.32$ (br, 2H; Ar-H), 7.31 (s, 2H; Ar-H), 7.26 (s, 2H; Ar-H), 6.65 (dd, ^3J(H,H) = 17.7 Hz, ^3J(H,H) = 11.3 Hz, 1H; C*H*=CH$_2$), 5.73 (d, ^3J(H,H) = 17.7 Hz, 1H; CH=C*H*H), 5.73 (d, ^3J(H,H) = 11.3 Hz, 1H; CH=CH*H*), 0.93 (s, 18H; Si*t*Bu), 0.31 (s, 6H; SiMe$_2$), 0.30 ppm (s, 6H; SiMe$_2$); ^{13}C{^{1}H} NMR (125.7 MHz, 25 °C, CDCl$_3$): $\delta = 148.7$ (d, ^1J(C,P) = 10.3 Hz; *ipso*-Ar), 147.0 (s; Ar), 139.8 (d, ^2J(C,P) = 6.2 Hz; Ar), 139.5 (d, ^1J(C,P) = 19.6 Hz; Ar), 138.4 (s; *p*-Ar), 136.3 (s; *C*H=CH$_2$), 134.3 (d, ^2J(C,P) = 16.6 Hz; *o*-Ar), 132.8 (d, ^2J(C,P) = 21.7 Hz; *o*-Ar), 126.4 (d, ^3J(C,P) = 8.3 Hz; *m*-Ar), 114.7 (s; CH=*C*H$_2$), 26.4 (s; SiC(*C*H$_3$)$_3$), 17.0 (s; Si*C*(CH$_3$)$_3$), −4.9 ppm (s; SiMe$_2$); elemental analysis calcd (%) for C$_{26}$H$_{37}$PS$_2$Si$_2$: C 63.83, H 7.46, S 12.17; found: C 63.66, H 7.68, S 12.14.

Polymerization: To a solution of **7** (0.26 g, 0.5 mmol) dissolved in styrene (2 mL, 17.5 mmol) in an ampule was added a catalytic amount of TEMPO. The ampule was then evacuated, sealed, and kept overnight at 110 °C. The resulting yellowish solid obtained after the reaction mixture had cooled to room temperature was then dissolved in ca. 10 mL of dichloromethane and precipitated into degassed pentane. After the solvent had been decanted off and the residue dried under vacuum, polymer **13** was obtained as a white solid (1.76 g, ca. 85 %). GPC: $M_n = 147650$ g mol^{-1}, PDI = 2.46; DSC: $T_g = 114.2$ °C, $T_{decomp} = 428.2$ °C; ^{31}P{^{1}H} NMR (162.0 MHz, 25 °C, CD$_2$Cl$_2$): $\delta = -25.0$ ppm; ^{1}H NMR (500 MHz, 25 °C, CD$_2$Cl$_2$): $\delta = 7.09$ (m br, ca. 132H; Ar-H), 6.53 (m br, ca. 88H; Ar-H), 1.84 (m br, ca. 48H; C*H*CH*H*); 1.48 (m br, ca. 96H; CHC*HH*), 0.98 (br, 18H; Si*t*Bu), 0.35 ppm (br, 12H; SiMe$_2$); ^{13}C{^{1}H} NMR (125.7 MHz, 25 °C, CD$_2$Cl$_2$): $\delta = 149.3$ (br; Ar), 145.0 (br; Ar), 140.2 (br; Ar), 134.9 (br; Ar), 132.2 (br; Ar), 128.4 (br; Ar), 128.0 (br; Ar), 126.0 (br; Ar), 45.0 (m br; *C*HCH$_2$), 40.8 (m br; CH*C*H$_2$), 26.6 (br; SiC(*C*H$_3$)$_3$), 17.2 (br; Si*C*(CH$_3$)$_3$), −4.7 ppm (br; SiMe$_2$).

Molecular Lead Clusters—From Unexpected Discovery to Rational Synthesis

Karl W. Klinkhammer, Yun Xiong, and Shenglai Yao*

In memory of Peter Böttcher

Anionic cluster compounds of lead have been known for more than one century.[1] The first species, $NaPb_4$ and KPb_2, were obtained as early as 1891 by Joannis from the reaction of alkali metals with lead in liquid ammonia.[2] Extensive exploration of this chemistry was done by Kraus, Zintl, and others during the first decades of the 20th century.[3] Addition of cryptands finally allowed for the isolation of macrocrystalline material and the structural characterization of several species, such as $[Pb_5]^{2-}$, $[Pb_9]^{4-}$, and $[Pb_9]^{3-}$.[4] The structures observed may all be understood using Wade's electron-counting rules. Molecular lead clusters bearing hydrocarbon or related substituents are unknown to date. There are some reports, however, about transition-metal carbonyl complexes of anionic lead clusters.[5] Only for the lighter congeners germanium and tin, are organic- or organoelement-substituted species available.[6] For most of these compounds the synthesis was not by derivatization of anionic clusters, but proceeded through cluster formation from smaller units.[7] Wade's rules are usually, but not generally obeyed for such compounds or for the related clusters of the neighboring elements of Group 13.[8]

We have investigated the reaction of dihypersilylplumbylene $[\{(Me_3Si)_3Si\}_2Pb]$ ($[Hyp_2Pb]$) with phosphine in inert solvents, such as toluene or *n*-pentane. As main product the heterocubane $[(HypPPb)_4]$ (Hyp = hypersilyl, $Si(SiMe_3)_3$) was isolated.[9] At short reaction times and low temperature several intermediates could be detected by NMR spectroscopy. In attempts to isolate one of these species, the initial reaction mixture was stored at $-60\,°C$ for several days. Indeed a few dark brown well formed crystals were found in a matrix of unconsumed blue Hyp_2Pb. To our surprise, the structure analysis revealed that the compound contains no phosphorous, but is the molecular lead cluster $[Pb_{12}Hyp_6]$ (1).[10] Despite of disordering of the lead core about the crystallographic threefold axis, it can be shown that the model in Figure 1 is the only one having sensible Pb–Pb separations that is consistent with the diffraction data. The hypersilyl groups are well ordered, however, and clearly determine the arrangement of the molecules within the crystal. The enveloped twelve lead atoms constitute a distorted icosahedron. Six atoms (Pb_A) bear no substituent and form a puckered ring with chair conformation (the belt). Each of the remaining six

Figure 1. Structure of **1** (C and H atoms omitted for clarity). Selected bond lengths [pm]: Pb1-Pb2 336.83(10), Pb1-Pb3 332.39(9), Pb1-Pb4 311.33(13), Pb1-Pb5 310.7(5), Pb1-Pb6 334.81(12), Pb2-Pb3 338.87(11), Pb2-Pb4 319.99(10), Pb2-Pb5* 321.6(2), Pb2-Pb6* 305.61(13), Pb3-Pb6 323.21(12), Pb3-Pb4* 310.21(12), Pb3-Pb5* 311.4(9), Pb4-Pb5 326.9(6), Pb4-Pb6* 324.49(10), Pb5-Pb6 322.9(9), Pb1-Si1 269.5(2), Pb2-Si1' 308.5(2), Pb3-Si1'' 263.7(2), Pb6-Si1' 328.3(2).

atoms ($Pb_B,Pb_{B'}$) bears a hypersilyl group. Together they form two three-membered rings above and below the central Pb_6 belt. The Pb–Pb separations between neighboring lead atoms range from 305.6(1) to 339.0(1) pm. The largest distances are found between the lead atoms of type Pb_B (av. 336.1 pm), shorter ones between the lead atoms of the belt (Pb_A) (av. 324.8 pm), and the shortest between Pb_A and Pb_B (av. 316.5 pm). Although there is some overlap between these ranges, the description of the polyhedron as an icosahedron with two opposite open faces would be in line with Wade's rules, since with 30 electrons for the Pb_{12} skeleton a *arachno*-type cluster is expected. A further structural detail of compound **1** is noteworthy. Whereas four hypersilyl groups are bonded in the expected terminal fashion, the other two substituents each bridge two lead atoms. As a consequence the bridged edge (Pb2–Pb6*) is the shortest within the cluster.

Unfortunately, compound **1** can only be obtained in traces and no spectroscopic data may be provided to date. The question arises how this cluster is formed in the reaction of $PbHyp_2$ and PH_3 and if there are alternative routes giving access to larger quantities.

NMR spectroscopy data of the reaction mixture as well as the composition of the isolated intermediates, such as the cyclic dimer $[\{Hyp(H)PPbHyp\}_2]$ and of the main products [Eq. (1)] indicate that after the initial addition step, ligand

$$[PbHyp_2] + PH_3 \rightarrow [(HypPPb)_4] + Hyp_2 + HypH + HypPH_2 + \\ Pb + \mathbf{1}(traces) + \ldots \quad (1)$$
exchange between the lead and phosphorus centers occurs, which leads to the adduct $[Hyp(H)Pb \leftarrow PH_2Hyp]$. After elimination of HypH and/or H_2 this adduct may either give the Pb–P heterocycles or on dissociation may yield $HypPH_2$ and the elusive hydridoplumbylene $[Pb(H)Hyp]$. Recently a

related hydridoplumbylene with an extremely bulky *meta*-terphenyl substituent was postulated by Power et al. as the key intermediate in the formation of the first diplumbyne.[11] In contrast to this particular kinetically stabilized diplumbyne, we expect that the analogous but less-shielded $[Pb_2Hyp_2]$, which would form from dimerization and hydrogen loss of $[Pb(H)Hyp]$, would not be stable under ambient conditions, but owing to its bis(plumbylene) nature would undergo addition and insertion reactions, thus possibly resulting in the formation of stable or less stable lead cluster compounds.

To support our assumption we looked for a rational synthesis of $[Pb(H)Hyp]$. At first we investigated the reaction of the $[PbHyp_2]$ with several hydride sources, such as B_2H_6, $[BH_4]^-$ and $[AlH_4]^-$ under various conditions, but only found the formation of lead and HypH (with B_2H_6) or the reversible formation of adducts (with $NaBH_4$ and $LiAlH_4$). Finally we succeeded by treating $[PbHyp_2]$ with the triphenylphosphine adduct of copper hydride [Eq. (2); $L = PPh_3$].[12] During the reaction at $-20\,°C$ almost no lead precipitated, and from the resulting dark brown solution appreciable amounts of dark brown crystals were isolated. The structural analysis reveals that indeed a lead cluster had been formed, not the expected $[Pb_{12}Hyp_6]$ (**1**), however, but the novel cluster $[Pb_{10}Hyp_6]$ (**2**).

$$[PbHyp_2] + [CuH \cdot L]_6 \rightarrow$$
$$\mathbf{2} + [HypCuL_2] + [Hyp_3H_6Cu_9L_2] + HypH + \ldots \quad (2)$$
The NMR spectroscopic data from the crude reaction mixture shows that ligand exchange has taken place, since the main products, beside cluster compound **2** are HypH and the new hypersilyl copper(I) derivatives $[HypCu(PPh_3)_2]$ and $[Hyp_3H_6Cu_9(PPh_3)_2]$. Small amounts of further products are present, however, which give rise to lowfield shifted ^1H NMR signals ($\delta = 0.6–0.8$ ppm) as does compound **2** ($\delta = 0.64$ ppm). We therefore assume that a mixture of several cluster compounds is produced, from which only the predominant and less-soluble species crystallizes easily. The best structural parameters were derived from specimens with cocrystallized benzene.[10] The whole molecule has crystallographic C_s symmetry and the Pb_{10} core approximately C_{3v} symmetry (Figure 2). The Pb_{10} polyhedron is best derived from a Pb_{12} icosahedron by replacing one trigonal face by a single lead atom. This picture would match the prediction made by Wade's rules which only hold for cluster compound **2** if it is formally composed from a $[Hyp_6Pb_9]$*hypho*-type cluster dianion (26 skeletal electrons) and a Pb^{2+} countercation (Figure 3). The Pb–Pb separations within the *hypho*-Pb_9 fragment (Pb1 to Pb6) of **2** differ only slightly (312.36(4)–320.99(5) pm) and are all within the same range found for compound **1** and lead cluster anions, whereas the three bonds to the capping atom Pb7 are significantly shorter (299.80(4)–300.58(6) pm) indicating higher bond orders, that is, less delocalized bonds. In contrast to **1**, all six hypersilyl groups are located at the puckered six-membered ring (Pb_A), whereas the capping Pb_3 triangle (Pb_B) only consists of "naked" Pb atoms. The hypersilyl groups are all bonded in a terminal fashion. The three Pb–Si bonds to the silicon atoms (Si4, Si4′, Si6) that lie more or less in the plane the
Figure 2. Structure of **2** (C and H atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: Pb1-Pb2 320.11(5), Pb2-Pb2′ 320.99(5), Pb1-Pb3 314.00(6), Pb1-Pb4 320.45(4), Pb2-Pb4 319.39(4), Pb2-Pb5 312.36(4), Pb2-Pb6 319.44(5), Pb3-Pb4 314.98(3), Pb3-Pb7 300.58(6), Pb4-Pb5 315.38(4), Pb5-Pb6 316.05(4), Pb5-Pb7 299.80(4), Pb3-Si3 270.0(3), Pb4-Si4 276.4(2), Pb5-Si5 268.8(2), Pb-Si6 277.8(4); Pb3-Pb7-Pb5 86.94(1), Pb5-Pb7-Pb5′ 86.46(1).
Figure 3. The $Pb_{10}Si_6$ skeleton of **2** illustrating the applicability of Wade's rules.

unsubstituted lead triangle (Pb1, Pb2, and Pb2′), perhaps for steric reasons, are significantly longer (276.4(2)–277.8(4) pm) than the remaining ones (268.8(2)–270.0(3) pm).

The ^1H NMR spectrum of **2** in $[D_8]$toluene at room temperature has only one signal at $\delta = 0.59$ ppm for all the hypersilyl groups indicating a dynamic behavior of the $Pb_{10}Si_6$ core. On cooling, the resonance signal splits into two signals of equal intensity ($\delta\nu = 18$ Hz; $T_c = 243–248$ K) giving an approximate activation barrier of 50 kJmol$^-$ for the scrambling process. By ESI mass spectroscopy of compound **2** the molecular ion $[Pb_{10}Hyp_6]$ was not found, instead the ion $[Pb_{10}Hyp_5]^+$ could be detected as particle of highest mass (m/z 3311). The UV/Vis spectra of **2** show strong absorptions across the whole visible spectral range with only two weakly pronounced maxima at 656 and 770 nm (both: $\varepsilon = 49\,000$).

Communications

At ambient temperature and if light is excluded, solid **2** is indefinitely stable under argon. In solution at room temperature **2** quickly decomposes, yielding elementary lead and initially nearly equal amounts of the octasilane Hyp-Hyp and the plumbylene [PbHyp$_2$].[13] Since the reaction rate is first order in **2**, the initial formation of "naked" lead clusters can be postulated. To get more information on this species we are currently studing the decomposition of **2** in inert polymer matrices.

Experimental Section

1: In a typical experiment LiPH$_2$·0.86 DME (1.0 g, 8.53 mmol) was treated with 2,6-di-*tert*-butylphenol (1.76 g, 8.53 mmol) at −70 °C in DME (25 mL). The solution was warmed slowly to room temperature, and the produced gaseous PH$_3$ fed into a Schlenk tube containing a dark blue solution of [PbHyp$_2$] (1.60 g, 0.89 mmol) in *n*-pentane (25 mL) at −60 °C. After warming it to −30 °C for 30 min the solution turned deep red and dark red solid material precipitated. The solution was decanted to another Schlenk tube and concentrated to about 3 mL. After storage of the solution at −60 °C for two weeks several dark brown rod-shaped crystals of **1** were found among large amounts of dark blue crystals of unconsumed [PbHyp$_2$].

2: A solution of [PbHyp$_2$] (3.01 g, 4.28 mmol) in toluene (20 mL) was added to a suspension of [{HCuPPh$_3$}$_6$] (1.40 g, 4.28 mmol) in toluene (30 mL) at −25 °C under intense stirring. After 25 min the reaction mixture was warmed to room temperature and stirred for another 20 min. The suspension turned from deep violet to brown. After the filtration and washing with toluene the filtrate was concentrated to 9 mL and cooled to −60 °C for 24 h. Dark brown rhombus-shaped crystals of **2** are obtained (0.73 g, 0.20 mmol, 47.0 %). ^{1}H NMR (400.13 MHz, [D$_6$]benzene, 25 °C): δ = 0.63 ppm; ^{13}C NMR (100.62 MHz, [D$_6$]benzene, 25 °C): δ = 9.1 ppm. [12] An analogous ligand exchange between [Hyp$_2$Pb] and aryl copper complexes has been successfully used in the synthesis of other heteroleptic plumbylenes: J. Klett, K. W. Klinkhammer, M. Niemeyer, *Chem. Eur. J.* **1999**, *5*, 2531.

[13] [PbHyp$_2$] decomposes within several hours also giving lead and Hyp-Hyp as the only products. Both decomposition reactions—of **2** and of [PbHyp$_2$]—are first order in starting material. The half-life periods were determined by ^{1}H NMR spectroscopic monitoring to be 4 (**2**) and 47 h ([PbHyp$_2$]).

Organocatalysis

Organocatalyzed Conjugate Umpolung of α,β-Unsaturated Aldehydes for the Synthesis of γ-Butyrolactones**

Christian Burstein and Frank Glorius*

Most reactions in organic synthesis are polar and can be described as the reaction of a nucleophile (donor d) with an electrophile (acceptor a).[1] The umpolung[2] of the "natural" reactivity of a functional group opens up an avenue to a new set of reactions. It has been known for a long time that the umpolung of electrophilic aldehydes is possibly by using catalysts such as cyanide or thiazolium carbenes.[3] The resulting d^1-nucleophiles can react with aromatic aldehydes (benzoin condensation[4]) or with electron-poor, polarized olefins (Stetter reaction[5]).[6] In contrast to this a^1-to-d^1-umpolung, the term "conjugate" umpolung describes the transformation of α,β-unsaturated aldehydes into d^3-nucleophiles (homoenolate equivalents[7]) by attack of nucleophilic catalysts on the aldehyde function (Scheme 1). Herein we report the organocatalyzed, chemo- and stereoselective reaction of conjugate "umpoled" α,β-unsaturated aldehydes with aromatic aldehydes and ketones to give γ-butyrolactones **1** and **4** (see Schemes 1 and 4).

We started our investigation with the reaction of cinnamaldehyde and 4-chlorobenzaldehyde. As a result of the organocatalyzed umpolung of both aldehydes, numerous products can be formed (Scheme 2, $R^1 = 4\text{-ClC}_6\text{H}_4$, $R^2 =$ Ph). The use of the commercially available thiazolium salt **2**[8] as a catalyst does not provide lactone **1a**, but results in the formation of several benzoin products in low yield (Table 1, entry 1). Recently, imidazolium derived N-heterocyclic carbenes (NHCs) have been very successfully used as ligands in transition-metal catalysis[9] and as organocatalysts of transesterification reactions.[10] We were pleased to find that the

use of 1,3-di(2,4,6-trimethylphenyl)imidazolin-2-ylidene (IMes), derived from **3** by deprotonation, results in the selective formation of γ-butyrolactone **1a**. Under optimized conditions, IMes (5 mol%) was added dropwise to a 1:1 mixture of the aldehydes, and the reaction was stirred at ambient temperature for 16 h, allowing the isolation of the *cis* and *trans* diastereomers of **1a** in 44% and 9% yield, respectively (Table 1, entry 2). Larger amounts of potassium cyanide also catalyze this transformation. A combination of KCN (30 mol%) and [18]crown-6[11] (10 mol%) leads to the formation of lactone **1a** in 33% yield (Table 1, entry 3). A variety of differently substituted lactones can be synthesized through this method. With the exception of 2-chlorobenzaldehyde (Table 1, entry 10), the *cis* diastereomer[12] was formed predominantly in all cases (Table 1, Figure 1).

Currently, the scope of reactions that involve the umpolung of aldehydes, for example, the benzoin condensation or the Stetter reaction, is generally[13] limited, as self-condensation or intramolecular reactions are required for good chemoselectivity. In stark contrast, the reaction of aromatic aldehydes with conjugate umpoled α,β-unsaturated aldehydes allows the selective linking of two different aldehydes in an intermolecular manner, representing a one-step formation of γ-butyrolactones with two new stereocenters.[14]

Table 1: Reaction of cinnamaldehyde ($R^2 = Ph$) with aromatic aldehydes according to Scheme 2.[a]

Entry	R^1	1	Yield [%]	cis/trans[b]
1[c]	4-ClC$_6$H$_4$	a	0	–
2	4-ClC$_6$H$_4$	a	53	80:20
3[d,e]	4-ClC$_6$H$_4$	a	33	81:19
4	4-BrC$_6$H$_4$	b	49	80:20
5	4-MeO(CO)C$_6$H$_4$	c	70	79:21
6	4-F$_3$CC$_6$H$_4$	d	44	77:23
7	3-FC$_6$H$_4$	e	52	78:22
8	3-ClC$_6$H$_4$	f	61	79:21
9	3-BrC$_6$H$_4$	g	60	79:21
10[e]	2-ClC$_6$H$_4$	h	32	23:77

[a] General reaction conditions: **3** (0.05 mmol), KOtBu (0.1 mmol), THF (3 mL); cinnamaldehyde (1.0 mmol), substituted benzaldehyde (1.0 mmol), 16 h, room temperature. Yields of the isolated products given as the sum of separately isolated *cis* and *trans* isomers. [b] Determined by GC–MS. [c] **2** was used as catalyst instead of **3**. [d] KCN (0.3 mmol) and [18]crown-6 (0.1 mmol) were used as catalyst instead of **3**. [e] Isolated as mixture of diastereomers.
Figure 1. X-ray crystal structure of *cis*-**1d**.[12]

A plausible mechanism is depicted in Scheme 3. Reaction of the NHC with the α,β-unsaturated aldehyde gives rise to a zwitterionic structure **I**, which isomerizes by protonation/deprotonation to the conjugated dienamine **II**. Nucleophilic attack of **II** or its zwitterionic homoenolate tautomer at the aromatic aldehyde results in the formation of alcoholate **III**,

followed by isomerisation to the corresponding tautomer **IV**. These activated carboxylates are thought to be intermediates in NHC-catalyzed transesterification reactions, leading to ester formation when attacked by alcohol nucleophiles.[10] Analogously, intramolecular attack of the alkoxide of **IV** or its protonated form at the carbonyl group leads to the closing of the lactone ring and the regeneration of the nucleophilic catalyst.

Fortunately, ketones[15] also react as electrophiles with α,β-unsaturated aldehydes in good yield, thereby significantly increasing the scope of this reaction (Scheme 4).[16] The
Scheme 4. NHC-catalyzed reaction of the conjugate umpoled unsaturated aldehyde with a ketone.[16]

reaction of cinnamaldehyde and α,α,α-trifluoroacetophenone (1 equiv) results in the formation of γ-butyrolactone **4a** in 70% yield, with the generation of one quaternary stereocenter. *l*- and *u*-diastereomers[12] (Figure 2) can be separated by column chromatography. By using 2 equivalents of ketone, the yield can be increased to 84% (Scheme 4); the reaction can also be run on a 30-mmol scale.[17] Furthermore, substituted cinnamaldehyde derivatives such as 4-methoxy- and 4-dimethylaminocinnamaldehyde react equally well.[17]

Recently, chiral triazolium salt derived NHCs were successfully used in the highly enantioselective benzoin

Scheme 3. Plausible mechanism of the NHC-catalyzed γ-butyrolactone formation. Mes = mesityl.
Figure 2. X-ray crystal structure of *u*-**4b** (minor diastereomer).[12]

condensation[18] and Stetter reaction.[19] Interestingly, triazolium salts **5**[18] and **6**[19] are not suitable catalysts for the synthesis of **4a** under standard conditions (0% and 10% yield, respectively). In contrast, the NHC derived from imidazolium salt **7** (Tf = trifluoromethanesulfonyl)[20] is a competent catalyst for this transformation. In the presence of **7** (5 mol%), **4a** is formed in 70% yield[17] with an improved *l/u* ratio of 74:26 and with 12 and 25% *ee*, respectively.
In summary, the organocatalyzed conjugate umpolung of α,β-unsaturated aldehydes allows the direct, intermolecular, and crossed linking of an α,β-unsaturated aldehyde with another aldehyde or ketone, resulting in a flexible one-step synthesis of substituted γ-butyrolactones.[21]

Experimental Section

Typical procedure: Generation of the catalyst solution (for multiple reactions): Under an atmosphere of argon, IMes·HCl (85.1 mg, 0.25 mmol) and potassium *tert*-butoxide (56.1 mg, 0.5 mmol) were dissolved in THF (5 mL) and stirred for 45 min at room temperature.

A part of the preformed catalyst solution (1 mL, 0.05 mmol IMes) was added over a period of 1 min to a solution of 4-formylbenzoic acid methyl ester (164 mg, 1 mmol) and *trans*-cinnamaldehyde (126 μL, 1 mmol) in THF (5 mL). The solution was stirred for 16 h at ambient temperature, after which MeOH (2 mL) was added and the solution was stirred for a further 15 min. The solvent was evaporated in vacuo, and the residue was distilled in a Kugelrohr apparatus (5×10^{-2} mbar, 150–200°C). Purification of the distillate by column chromatography (SiO$_2$, 2.5 cm × 12 cm, MTBE/hexane 1:3) yielded *cis*-**1c** (164 mg, 56%) and *trans*-**1c** (41 mg, 14% after crystallization from CH$_2$Cl$_2$/hexane) as colorless solids.

[12] The stereochemistry of the lactones **1** and **4** was assigned by X-ray crystal-structure and NMR spectroscopy analysis. The ^{1}H NMR data for the lactone ring hydrogen atoms of **1a–h** is very similar within the *cis* and *trans* series. The stereochemistry of the products **1** was therefore assigned by comparison of the NMR data for these compounds with that of *cis*-**1d**, whose structure was unequivocally established by X-ray crystal-structure analysis. The stereochemistry of lactones **4** was assigned in an analogous manner (see Supporting Information). Crystal data for *cis*-**1d**: C$_{17}$H$_{13}$F$_3$O$_2$, from CH$_2$Cl$_2$/hexane, M_r = 306.27 g mol^{-1}, crystal size: $0.07 \times 0.05 \times 0.02$ mm^3; orthorhombic, space group $P2_12_12_1$, a = 5.6377(2), b = 15.4285(5), c = 16.3106(5) Å, V = 1418.72(8) Å^3, ρ_{calcd} = 1.434 g cm^{-3}, Z = 4, T = 100 K, $\mu(Mo_{K\alpha})$ = 0.119 mm^{-1}, 21 653 measured and 4520 independent reflections, 3217 with $I > 2\sigma(I)$, θ_{max} = 30.99°, (R_{int} = 0.0674), 199 parameters, H atoms placed on ideal positions, R_1 ($I > 2\sigma(I)$) = 0.0536, wR^2 (all data) = 0.1049, S = 0.988, $\Delta\rho_{max/min}$ = 0.222/−0.226 e Å^{-3}, structure determination by direct methods (G. Butenyl-Substituted Alkaline-Earth Metallocenes: A First Step towards Olefin Complexes of the Alkaline-Earth Metals**

Herbert Schumann,* Stefan Schutte, Heinz-Jürgen Kroth, and Dieter Lentz*

The coordination of an α-olefin to the metal center of a 14-electron metallocene alkyl complex,[1] for example to zirconium complexes of the type $[Cp_2ZrR]^+$ is assumed to be the primary reaction step in the polymerization of olefins catalyzed by such metallocenes.[2] In the case of zirconium, however, thus far only the isolation and X-ray characterization of complexes with chelating η^1,η^2 or $\eta^5\eta^2$ olefin ligands have been successful.[3–5] The formation of vanadium,[6] niobium,[7] and the yttrium complexes investigated by Casey et al.[8–10] with non-chelating olefins have until now only been detectable by NMR spectroscopy. Both ourselves and Evans et al. have been able to show recently that chelating η^5,η^2-cyclopentadienyl ligands such as $C_5Me_4CH_2CH_2CH{=}CH_2$[11] or $C_5Me_4SiMe_2CH_2CH{=}CH_2$[12] in the form of their alkali metal salts form metallocenes with the diiodides of Eu, Sm, and Yb in which the terminal olefin groups of the side chains coordinate to the metal center.

No olefin complexes of Ba^{II}, which is isoelectronic with these lanthanoids at the oxidation level Ln^{II} (apart from the occupation of the 4f shell), and the other alkaline-earth metals are thus far known. An interaction between the alkyne ligand and the magnesium could be detected only with $[TiCp][MgCp][\mu{-}\eta^2{:}\eta^2{-}C_2(SiMe_3)_2]_2$[13] and $[(C_5HMe_4)_2Ti(\eta^1{-}C{\equiv}CSiMe_3)_2][Mg(thf)Cl]$[14] from X-ray structural data, and for $[(C_5Me_5)_2Ca(Me_3SiC{\equiv}C{-}C{\equiv}CSiMe_3)]$[15] a coordination of the diyne to calcium. Alkaline-earth metallocenes such as $[(C_5HMe_4)_2Mg(Me{-}carb)]$ or $[(C_5HMe_4)_2Sr(Pr{-}carb)]$ (Me-carb and Pr-carb = 1,3,4,5-tetramethylimidazol-2-ylidene and 1,3-di(isopropyl)-4,5-dimethylimidazol-2-ylidene, respectively) are highly active catalysts for the polymerization of acrylates;[16] therefore it appeared obvious to assume that the solvent-free alkaline-earth metallocenes as 12-electron complexes could also seek to compensate their electron deficiency

by coordination to olefinic π systems. Herein we confirm this assumption with the synthesis of the first alkaline-earth metal complexes with alkenyl-substituted chelating η^5,η^2-cyclopentadienyl ligands.

$C_5Me_4HCH_2CH_2CH=CH_2$ may be readily deprotonated with KH in THF at room temperature with the formation of $K[C_5Me_4CH_2CH_2CH=CH_2]$, a pyrophoric, beige-colored powder.[11a] This reacts with alkaline-earth diiodides (MI_2) in THF suspension with loss of KI and formation of the corresponding metallocenes $[M(C_5Me_4CH_2CH_2CH=CH_2)_2]$, M = Mg (**1**), Ca (**2**), Sr (**3**), Ba (**4**) (Scheme 1, A). The latter

Figure 1. Molecular structure of **1** (ORTEP,[19] ellipsoids at 30% probability).
Scheme 1. A) Synthesis of the metallocenes **1–4** from alkaline-earth diiodides and K[C_5Me_4CH_2CH_2CH=CH_2]; M = Mg (**1**), Ca (**2**), Sr (**3**), Ba (**4**). B) Synthesis of **1** from dibutylmagnesium and 5-but-3-en-1-yl-1,2,3,4-tetramethylcyclopenta-1,3-diene.

are isolated as colorless, solvent-free crystals after precipitation from hexane and subsequent crystallization from hexane (**1–3**) or toluene (**4**) at −78°C. Compound **1** may also be obtained by the reaction of dibutylmagnesium with 5-but-3-en-1-yl-1,2,3,4,-tetramethylcyclopenta-1,3-diene in heptane after heating for 12 h under reflux (Scheme 1, B). Compound **1** melts at 37°C with the formation of a colorless liquid that rapidly turns yellow. Compounds **2**, **3**, and **4** decompose above 138 (**2**), 208 (**3**), and 157°C (**4**) with yellow coloration without previously melting.

The isolation single crystals was very difficult and required special care since all four metallocenes are highly sensitive and decompose immediately with yellow coloration on contact with very small amounts of moisture and oxygen. The structural investigations show that only the magnesium complex **1** satisfies the strict arrangement of a sandwich structure with a parallel arrangement of the cyclopentadienyl ring planes above and below the central metal atom, an arrangement that was also found for $[Mg(C_5H_5)_2]$[17] and $[Mg(C_5Me_5)_2]$.[18] Two independent molecules are located in the unit cell that differ only slightly in the angles $Cp1_{cen}$-Mg1-$Cp2_{cen}$ (175.84°) and $Cp1_{cen}$-Mg2-$Cp2_{cen}$ (180°) and in the torsion angles: $C1r$-$Cp1_{cen}$-$Cp2_{cen}$-$C6r = -32.1(1)°$ and $C1r$-$Cp1_{cen}$-$Cp1'_{cen}$-$C1r' = -180°$ (Figure 1, cen = ring centroid). The respective distance between the centers of the two cyclopentadienyl ligands (3.930 and 3.926 Å, respectively, Table 1) corresponds to the value determined for $[Mg(C_5Me_5)_2]$ (3.94 Å).[18] The two butenyl
side chains are directed away from the magnesium center above and below, respectively.

The compounds with the heavy alkaline-earth metals, **2–4**, have in principal the same molecular structure with C_2 symmetry (**3**) or approximate C_2 symmetry (**2**, **4**; see Figure 2). Unlike in **1**, but in agreement with the structures of $[Ca(C_5Me_5)_2]$,[20] $[Sr(C_5Me_5)_2]$,[21] and $[Ba(C_5Me_5)_2]$,[20,21] the cyclopentadienyl rings in **2–4** are inclined towards each other; furthermore, the butenyl side chains of the cyclopentadienyl ligands are directed towards the metal center. This bent structure, which all metallocenes of the heavy alkaline-earth metals and also metallocenes of Eu^{II},[22] Sm^{II},[22] and Yb^{II}[23] exhibit, cannot be attributed here to a lone pair of electrons at the metal center as in the likewise bent metallocenes of Ge, Sn, and Pb. On the contrary, it is accounted for by a slight polarizability of the original spherically symmetrical distribution of the positive charge of the large metal cations caused by the negatively charged Cp ligands, which reduces their mutual repulsion.[22] Further explanations for the bent arrangement of the Cp ligands are their Van der Waals attractions[24,25] or the $(n-1)$d orbital involvement of the metal centers in the sense of an $(n-1)$dns hybridization.[26]

The centers of the Cp ligands and the double bonds in **2–4** form a strongly distorted tetrahedral coordination sphere around the metals. The centers of the cyclopentadienyl ligands form an angle of almost exactly 140° with the metal center in all three compounds (Table 1): 140.9° (**2**), 139.3/140.4° (**3**), and 139.1° (**4**). In contrast very different Cp_{cen}-M-

Communications
Figure 2. Molecular structure of **2** (left) and **4** (right; ORTEP,[19] ellipsoids at 30% probability).

Cp$_{cen}$ angles, dependent upon the size of the central metal atom are found for both the solvent-free alkaline-earth compounds [M(C$_5$Me$_5$)$_2$] and the alkaline-earth carbene complexes [(C$_5$Me$_5$)$_2$ML] (L = 1,3,4,5-tetramethylimidazol-2-ylidene): 147.7° for [Ca(C$_5$Me$_5$)$_2$] and 131° for [Ba(C$_5$Me$_5$)$_2$] at 116 and 118 K, respectively, in the crystal,[20] 149° for [Sr(C$_5$Me$_5$)$_2$] and 148° for [Ba(C$_5$Me$_5$)$_2$] in the gas phase,[21] and 143.9° for [(C$_5$Me$_5$)$_2$CaL] and 137.0° for [(C$_5$Me$_5$)$_2$BaL] at −70°C in the crystal.[27]

This difference and, with consideration of the metal radius, the almost identical M−C distances of the olefin-carbon atoms coordinated unsymmetrically to the metal center (M−C3s and M−C8s = 3.23/3.08 (**2**), 3.25/3.20 (**3**), 3.44/3.38 (**4**) and M−C4s and M−C9s = 3.05/2.94 (**2**), 3.04/2.99 (**3**), 3.18/3.21 Å (**4**)) are a clear confirmation that this orientation of the butenyl side chains directed towards the metal center is caused by a coordination of the olefin to the alkaline-earth metal center and not perhaps by crystal packing effects. The distances to the terminal carbon atoms C4s and C9s are generally shorter than to C3s and C8s, but significantly longer than to the cyclopentadienyl carbon atoms. The range of the distances, which is moreover relatively large, and the constant C=C lengths in the open magnesium derivative **1** and in **2–4** suggest, however, a very labile coordination of the olefin ligands. Crystallization of the complexes from THF is not possible because they are too soluble. No crystals suitable for X-ray structure analysis could be isolated even by the addition of small amounts of THF to hexane or toluene solutions of **2–4**. Therefore it was not possible in this way to determine whether the olefin side chains are displaced from the coordination sphere of the metals by the Lewis basic THF and whether THF complexes with non-coordinated olefin side chains are formed.

The ^{1}H NMR spectra of **1–4** recorded in [D$_6$]benzene (selected data in Table 2) show almost identical chemical shifts for the C$_5$Me$_4$, α-CH$_2$, β-CH$_2$, and γ-CH protons of the ligands. The respective chemical shifts of the signals of the *cis*-

and *trans*-δ-CH_2=CH protons of **3** and **4** are also practically identical, although they are shifted by up to 0.3 ppm to higher field compared to the corresponding signals of **1** (with the butenyl groups orientated away from the magnesium center). With the addition of [D$_8$]THF, which as σ-donor ligand should displace the olefin from the coordination sphere of the metal, the chemical shifts of all signal groups of **1** change only marginally, in the case of **4**, however, the signal of the *cis*-CH_2=CH protons shifts by 0.11, and that of the *trans*-CH$_2$=CH proton by 0.17 ppm to lower field and thus in the direction of the signals of **1**. With [Yb(C$_5$Me$_4$SiMe$_2$CH$_2$CH=CH$_2$)$_2$] too a low field shift of the same order of magnitude for the CH_2=CH protons was observed with the change from benzene to THF as solvent, although with a simultaneous high field shift of the CH$_2$=CH protons.[12] These small signal shifts do not allow any prediction about whether the olefin coordinates to the alkaline-earth metal or ytterbium center, since unlike the transition-metal–olefin complexes no electron density modifying backbonding is possible. In low-temperature ^{1}H NMR spectra of **4** in [D$_8$]THF the position of the CH$_2$=CH and CH_2=CH signals remain constant to −83°C. Over the same temperature range in [D$_8$]toluene, however, they are shifted successively to higher fields by up to 0.16 ppm. Compound **3** also shows high-field shifts of up to 0.2 ppm for these signals in [D$_8$]toluene at −83°C.

Table 2: ^{1}H and ^{13}C NMR data [ppm] of **1–4**.

			^{1}H NMR		^{13}C NMR	
	Solvent	δ=CH	δ CH=CHH (*trans*)	δ CH=CHH (*cis*)	δCH=	δCH$_2$=
1	[D$_6$]benzene	5.83 (ddt)	5.07 (ddt)	4.97 (ddt)	138.93	114.64
1	[D$_8$]THF	5.78 (ddt)	4.98 (ddt)	4.89 (ddt)	139.56	114.57
2	[D$_6$]benzene	5.82 (ddt)	4.81 (m)		147.63	115.03
3	[D$_6$]benzene	5.83 (ddt)	4.73 (ddt)	4.70 (ddt)	149.82	115.20
4	[D$_6$]benzene	5.89 (ddt)	4.79 (ddt)	4.73 (ddt)	148.80	115.92
4	[D$_8$]THF	5.83 (ddt)	4.96 (ddt)	4.84 (ddt)	142.17	113.78

The ^{13}C NMR spectra of **1–4** recorded in both [D$_6$]benzene and [D$_8$]toluene as well as in [D$_8$]THF show the expected nine signals, which depending upon the metal and the solvent show no substantial shifts apart from the inner olefin-carbon atom. The γ-C signal in the spectra measured in [D$_6$]benzene shifts from δ = 138.93 (**1**) through 147.63 (**2**) and 149.82 (**3**) to 148.80 ppm (**4**). In contrast in the ^{13}C NMR spectrum of a solution of **4** in [D$_8$]THF the signal for the γ-C atom shows a chemical shift of δ = 142.17 ppm, a value that is close to the value for **1**. In the coordinating solvent THF the olefin is clearly displaced from the coordination sphere of the barium center. This effect also corresponds to that for the high-field shift found for the inner olefin-carbon atom in [Yb(C$_5$Me$_4$SiMe$_2$CH$_2$CH=CH$_2$)$_2$] on comparison of the spectrum in [D$_6$]benzene (δ = 147.6 ppm) with that in [D$_8$]THF (δ = 140.5 ppm).[12]

The X-ray structure analyses of these olefin complexes of the alkaline-earth metals (**2–4**) synthesized for the first time show an orientation of the terminal olefin double bonds of both ligands in the direction of the Ca, Sr, and Ba ions. Owing to the lack of (*n*−1)d electrons of the alkaline-earth metal

ions, this weak coordination cannot be interpreted as a σ-donor–π-acceptor interaction as in classical olefin complexes of transition metals. The NMR spectra measured in $[D_6]$benzene and $[D_8]$toluene show, however, a weak high-field shift of the signals of the δ-CH_2 protons; this may be interpreted by the influence exerted upon the double bond attracted towards the alkaline-earth metal center by the electron shell of the metal negatively polarized in the direction of the olefin, as is suggested by the electrostatic model for the explanation of the bent structure of the metallocenes of the heavy alkaline-earth metals.[22] A reduction in the Cp-M-Cp angle to 140.92(6)° in **2** and 140.4(4)° in **3** compared with 147.7 and 149°, respectively, for the non-olefin-coordinated analogues $[Ca(C_5Me_5)_2]$ and $[Sr(C_5Me_5)_2]$ is in agreement with this. The widening of this angle of 131° in the case of $[Ba(C_5Me_5)_2]$ to 139.1(1)° in **4** is attributable to the enlarged ionic radius of Ba^{II}. σ-Donor ligands such as THF displace the weakly coordinated olefin from the alkaline-earth metal ion, which is demonstrated for the barium derivative **4** by its ^{1}H and ^{13}C NMR spectra in $[D_8]$THF. Analogous structural and bonding relationships are found in the corresponding Yb^{II} derivative $[Yb(C_5-Me_4CH_2CH_2CH=CH_2)_2]$[11a] and in $[Ln(C_5Me_4Si-Me_2CH_2CH=CH_2)_2]$,[12] which suggests a remarkable similarity between the organyls of the heavy alkaline-earth metals and the lanthanoids in the oxidation state Ln^{II}. This was discussed in detail recently for the chemistry and catalytic behavior of Ca^{II} and Yb^{II} compounds.[28]

Experimental Section

The synthesis and the comprehensive spectroscopic characterization of the alkaline-earth complexes **1–4** and their crystal data are available in the Supporting Information.

Cover Picture

Akihiko Tsuda,* Eri Hirahara, Yeong-Sang Kim, Hiroyuki Tanaka, Tomoji Kawai,* and Takuzo Aida*

A generous host describes the fully inorganic doughnut-shaped polyoxometalate crown cluster illustrated in the cover picture which has a 2.3-nm-wide and 1.3-nm-deep nanoscopic cavity and serves as a novel host for three metalloporphyrin molecules that contain 3- or 4-aminophenyl groups. A. Tsuda, T. Kawai, T. Aida, and co-workers describe in their Communication on page 6327 ff. how this new organic/inorganic hybrid complex forms through multiple hydrogen-bonding interactions.
Intermetalloid Clusters
T. F. Fässler and S. D. Hoffmann describe in their Minireview on page 6242 ff. the formation of large, endohedral clusters (e.g. $[Pt@Pb_{12}]^{2-}$) in the context of fullerenes and fullerides.
Microwave Chemistry
Heating reactions with microwaves offers a noteworthy alternative to conventional heating methods. In his Review on page 6250 ff., C. O. Kappe highlights recent applications of this procedure in organic synthesis.
Nanoporous Materials
In their Communications on pages 6285, 6290, and 6296 ff., C. Serre, C. Mellot-Draznieks, G. Férey, and co-workers demonstrate a solvothermal route involving metal(III) trimeric secondary building units and how the crystal structures of hybrid organic–inorganic structures can be predicted.

Angewandte EarlyView®

The following Communications are available online (in Wiley InterScience). You can find them, as well as forthcoming Reviews, Highlights, and Essays, at www.angewandte.org, under Early View.

Articles judged by the referees or the editor as being either very important or very urgent are immediately edited, proof-read, and electronically published once the manuscript has arrived in the editorial office in its final form. As long as there is no page number available these articles should be cited in the following manner:

Author(s), *Angew. Chem. Int. Ed.*, online publication date, DOI.

Books

Highlights

Versatile strategies of multicomponent coupling reactions to synthesize variously substituted pyrroles **1** are summarized. These heterocycles are important targets as molecules in their own right, for their pharmacological properties, as well as intermediates for more elaborate syntheses.
Minireviews

The close race between Zintl ions and fullerides has gone into the second round, initialized by the synthesis of the soluble endohedral cluster $[Pt@Pb_{12}]^{2-}$ (see picture, left). The structural characterization of an anion with almost ideal icosahedral symmetry illustrates that many heteroatomic clusters observed in the gas phase can, indeed, be regarded as endohedral clusters.

Reviews

Out of the kitchen into the laboratory:
Direct heating by microwave irradiation
(see picture) in many cases enables
synthesis to be carried out in a fraction of
the time required with conventional heat-
ing techniques. The use of microwave
heating in organic synthesis is growing
rapidly and the advantages not only
include faster reaction times, but also
higher product yields, cleaner reactions,
better controllability, and reproducibility.
Communications
Prefabricated construction techniques: A
solvothermal route involving iron(III) tri-
meric secondary building units has been
developed. Two new open-framework iron
(III) dicarboxylates have been character-
ized from X-ray powder diffraction stu-
dies. Their 3D structures are built up from
trimers of iron polyhedra related through
dicarboxylates, thus creating cationic fra-
meworks with 1D pore systems filled with
solvent molecules and anions (see exam-
ple).

Structure prediction of hybrid organic–
inorganic frameworks is now computa-
tionally possible. The employed method
embraces the concept of hybrid frame-
work through the automated assembly of
predefined organic and inorganic building
units in 3D space. Crystal structures of
hybrid candidates are predicted (space
group, cell parameters, atomic positions;
see picture), together with an estimate of
their lattice energies.

A perfect combination: The association of a chromium(III) trimeric building unit and 1,3,5-benzenetricarboxylate led to the powdered solid MIL-100. Simulations provided a crystal structure solution, which matched the experimental powder XRD pattern. This unique simulation/diffraction combination allowed the structure determination of a giant-pore solid with a zeotype architecture, built up from hybrid supertetrahedra (see picture).

$[Ni^{II}(PyBz_2)(tBu_2SQ)](PF_6)$ **1** $[Ni^{III}(MePyBz_2)(tBu_2Cat)](PF_6)$ **2**
Fine-tuning the N-donor ability of a bidentate aminopyridyl ligand facilitated the selective synthesis of complexes **1** (no methyl substituent) and **2** (with a methyl substituent) which possess valence tautomeric nickel(II) semiquinonato and nickel(III) catecholato frameworks, respectively.
Small world: Metallic nanomagnets (MNMs) dispersed in spherical colloids can be prepared by the aerosol evaporation of an aqueous sol containing mineralized ferritin and a colloidal matrix precursor (see picture). Essential to the success of the method is the template effect provided by ferritin.

Robust porous frameworks are formed by the dipeptides L-Ala-L-Val (see structure) and L-Val-L-Ala that have a high capacity and selectivity for gas sorption. The dipeptides assemble through hydrogen bonds as a 6_1 helix to form channels with average diameters of 5.13 and 4.90 Å, respectively.

Contents
The data fit, but the structures are different. Two methods for the interpretation of NMR data of a β-hexapeptide are compared. While the simulated annealing procedure suggests the formation of a (P)-2_8-helix, unrestrained molecular dynamics simulations indicate that the NMR data can also be described by a much broader ensemble of conformations, in which (P)-2.5_{12}-helical structures are prominent (see diagram).

Illuminating phase changes: Absorption of X-ray photons induces reversible internal charge-transfer processes in the mixed-valence Mn/Fe cyanide $Rb_{0.7}Mn^{II}_{1.15}[Fe^{III}(CN)_6]\cdot 2\,H_2O$ over a broad temperature range. Both continuous and abrupt phase transformations can be triggered (see scheme; HS = high spin, LS = low spin) and because the X-rays simultaneously probe the structural properties of the material, the resulting phase diagram can be elucidated in detail.
^{129}Xe NMR spectroscopy meets protein engineering: NMR spectroscopy with laser-polarized ^{129}Xe can be used to report protein conformations only if a protein has a conformationally sensitive xenon-binding cavity. However, many proteins lack such reporter sites. A straightforward design process is used to engineer a xenon-binding cavity into the ribose-binding protein (see picture) that allows the ^{129}Xe NMR spectroscopic report of protein conformation and ligand binding.
Targeting micelles: Cyclic pentapeptide cRGDfK (red triangles), which targets integrin $\alpha_v\beta_3$, was conjugated to the outer shell of doxorubicin-loaded (red hexagons) polymeric micelles by using a post-micelle modification method. The modified micelles significantly enhanced their internalization (up to 30-fold) by receptor-mediated endocytosis in tumor endothelial cells overexpressing the $\alpha_v\beta_3$ receptor.
Filled doughnuts: Molybdenum crown cluster MC accommodates up to three molecules of aminophenyl-substituted metalloporphyrins through hydrogen-bonding interactions, to form discrete inorganic–organic nanocomposite materials (see picture; blue polyhedra = MC, space-filling model = metalloporphyrin). Ultrahigh-vacuum scanning tunneling microscopy, in conjunction with scanning tunneling spectroscopy, at 80 K confirms the formation of the inclusion complex.
The combinatorial approach: A library of fluorescent styryl dyes (320 compounds) was prepared by solid-phase chemistry. The dyes were screened for their detection of amyloid aggregates, which are associated with diseases such as Alzheimer's, and two of the 320 compounds screened, 2C40 and 2E10, showed promise as brain-imaging agents (see microscopy image).
A brighter future for siloles. Luminescent silole chromophores with the highest quantum efficiencies reported for a fully substituted monomeric silole are generated by altering the steric properties of the substituent groups. Treatment of 1,1-dimethylsiloles with Bu_4NF (TBAF) in THF rapidly gives stereospecific desilylation at room temperature (see scheme). Intense solid-state photoluminescence is observed in thin films of the silole fluorophores.

Axes of power: Jahn–Teller isomerism (that is, Jahn–Teller distortion along different axes) accounts for the presence of both faster and slower relaxing magnetization dynamics of the title compound (see core structure; blue Mn, red O, gray C), which is a single-molecule magnet (SMM). The new compound is a structural variant of the [Mn$_{12}$] family of SMMs and is prepared by a reductive aggregation of [MnO$_4$]$^-$ in a mixture of MeOH/PhCO$_2$H.

Modification of tetrathiafulvalene with an imidazolyl substituent as a hydrogen-bond donor allows the generation of a hydrogen-bonded 2:1 charge-transfer complex with chloranil. This complex forms a three-dimensional network with columnar stacking of each component and multiple S···S interactions (see picture). This strongly hydrogen-bonded purely organic conducting material is the first to display metallic behavior.
Get turned on: Fluorescent photochromic organic nanoparticles (FPONs) of **1** (see picture) show a strongly enhanced fluorescence emission with increasing concentration and bistable photochromism. High-contrast on/off fluorescence switching has been successfully implemented in size-tuned FPONs of **1** and also in a photo-rewritable polymer film highly loaded with **1**.

Supramolecular polymerization of dendritic zinc porphyrins with two carboxylic acid functionalities leads to the formation of *J*-aggregates through multipoint π-stacking interactions. Spin-coating of the *J*-aggregate solutions gives optically active films, whose sense of chirality can be selected by the spinning direction (see picture). The chiroptical memory is thermally stable up to the melting temperatures of the spin-coated films.
Rapid screening: For optimizing the weight fraction of enzyme in enzyme electrodes, the scanning electrochemical microscopy (SECM) screening method described gives results (see picture) in good agreement with those obtained by the traditional rotating-disk-electrode method but in one tenth of the time and with a reduction in the amount of polymer and enzyme required by a factor of 100 000.

Lactone Synthesis
α,α-Disubstituted β-lactones can be obtained by the cycloaddition of the corresponding ketenes with aldehydes (see scheme). For the first time, a chiral PPY derivative, **1**, serves as an efficient catalyst for the asymmetric synthesis of β-lactones (PPY = 4-pyrrolidin-1-ylpyridine). To date, this is the only catalyst that is effective for enantioselective cycloadditions of disubstituted ketenes with aldehydes.
Nanostructures

The chemical reduction of H[AuCl$_4$] with *ortho*-phenylenediamine in aqueous media at room temperature and ambient pressure allows the synthesis of Au nanoplates with lengths of several micrometers (see SEM image). The as-prepared nanoplates are single crystals with a preferential growth direction along the Au (111) plane and mainly hexagonal in shape.
Electron Transport
Taking up the semiconducting baton: Organic field-effect transistors fabricated with a new class of extremely electron-deficient cyanated perylene diimides are air-stable and exhibit n-type mobilities as high as 0.64 cm^{2}V^{-1}s^{-1} (see scheme). Devices can be fabricated from vapor-deposited and solution-cast films as well as top- and bottom-contact electrode configurations.
Iridium Complexes

Deprotonation of the trifluoroacyl hydride complex **1** with *tert*-butyllithium leads to difluoroketene adduct **2**. Coordination of the difluoroketene to iridium through the C—C bond is confirmed by X-ray diffraction (see scheme). This complex is the first isolated and characterized dihaloketene complex and provides the only structural data for difluoroketene.

Contents
Magnetic hollow Fe_3O_4–polymer hybrid nanospheres (see figure) were prepared by adding Fe_3O_4 nanoparticles to an aqueous solution of polymer–monomer pairs composed of a cationic polymer (chitosan) and an anionic monomer (acrylic acid), followed by polymerization of acrylic acid and selective crosslinking of chitosan at the end of the polymerization.

Substituents on both the nucleoside aryl-sulfonate as well as the aryl amine component have a significant impact on their coupling to form 2,6-diaminopurine-2′-deoxyribonucleosides (see scheme). A systematic study of ligands for the Pd catalysts in amination and C—C cross-coupling reactions gives insight into the structural elements that lead to effective catalysis.

Competing reactions, not consecutive processes, are the oxidation of styrene to styrene epoxide and the formation of phenylacetaldehyde (PADH). In situ NMR and EPR spectroscopic analysis of styrene oxidation on TS-1 zeolite (see picture) demonstrated that Brønsted acid sites provide the active centers needed to transform an intermediate hemiacetal species into PADH.
A question of identity: A palladium complex featuring a carbenic S,C,S-based pincer ligand is reported (see scheme). DFT calculations show that, unlike classical carbene complexes, coordination occurs through donation from a d orbital at the metal into the empty n_p orbital of the carbene fragment, with the n_σ orbital essentially acting as a nonbonding orbital. The complex is shown to have nucleophilic character.

Communications labeled with this symbol have been judged by two referees as being "very important papers".

Creativity Rewarded: J. M. DeSimone

Joseph M. DeSimone is to receive the ACS (American Chemical Society) Award for Creative Invention in 2005. The award, worth US$5000, is sponsored by the chemical industry and awarded annually to an inventor in recognition of the application of research in chemistry or chemical engineering that "… contributes to the material prosperity and happiness of people". For a recipient to qualify for the award, a patent must have been granted for the work.

J. M. DeSimone

DeSimone studied chemistry at Ursinus College in Collegeville, PA (USA). Upon completion of his PhD in 1990 under the guidance of J. E. McGrath at Virginia Polytechnic Institute and State University in Blacksburg (USA), he became assistant professor at the University of North Carolina in Chapel Hill (USA). He is currently William R. Kenan, Jr. Distinguished Professor of Chemistry and Chemical Engineering and Director of the Institute for Advanced Materials, Nanoscience and Technology there. His research focuses on polymer synthesis, green chemistry, and methods based on liquid and supercritical carbon dioxide. He reported on this last topic in a Review in *Angewandte Chemie* and an article in the *Encyclopedia of Polymer Science and Technology*.[1] DeSimone is a member of the Editorial Board of the *Journal of Polymer Science A*.

Creative Synthesis: C.-H. Wong

Chi-Huey Wong, Professor at The Scripps Research Institute in La Jolla, CA (USA), will receive the ACS Award for Creative Work in Synthetic Organic Chemistry for his "… pioneering contributions to preparative biocatalysis and programmable one-pot organic synthesis." Wong studied chemistry at the Taiwan National University and completed his PhD in 1982 at Massachusetts Institute of Technology (Cambridge, MA,

C.-H. Wong

USA) in the research group of George M. Whitesides. As a postdoctoral fellow he moved, together with his PhD supervisor, within Cambridge to Harvard University. In 1983 he began his independent career as assistant professor at the Texas A&M University. There he moved up through the ranks to become full professor, and transferred to The Scripps Research Institute in 1989 to take up his current position as Ernest W. Hahn Professor of Chemistry.

Wong's research interests encompass a broad spectrum of bioorganic and synthetic chemistry, from the interactions of small molecules with RNA and other biologically important molecules, and the design and synthesis of inhibitors of receptors and enzymes, to the development of synthetic methods, including programmable one-pot reactions for the synthesis of oligosaccharides and glycoarrays. His research on biocatalysis has a special focus on carbohydrate-mediated biological recognition. He recently contributed a comprehensive Review on sulfotransferases[2a] to *Angewandte Chemie*, followed by a related Review on sulfatases.[2b] Wong is a member of the Editorial Board of *Advanced Synthesis & Catalysis* and the Editorial Advisory Board of *ChemBioChem*.

S. I. Stupp Receives Polymer Award

Samuel I. Stupp is the recipient for 2005 of the ACS Award in Polymer Chemistry, sponsored by ExxonMobil. Stupp studied chemistry at the University of California in Los Angeles and completed his PhD in materials science and engineering in 1977 under the guidance of Stephen H. Carr at Northwestern University in Evanston, IL (USA). He remained there as Professor of Biological Materials until 1980, when he moved to the University of Illinois, Urbana-Champaign as Professor of Materials Science. In 1999, he returned to Northwestern University as Professor

S. I. Stupp

of Materials Science, Chemistry, and Medicine, and since 2000 he has directed the Institute for Bioengineering and Nanoscience in Advanced Medicine there.

Stupp's research has four main focuses: the self-assembly of inorganic structures on organic templates, biomaterials for regenerative medicine (interactions of cells with ordered structures), devices and properties of materials (e.g. liquid-crystal templates for conducting polymers,[3] lithography), and the synthesis of novel self-assembling molecules. He is a member of the Editorial Advisory Board of *Small*.

Pyrrole Syntheses by Multicomponent Coupling Reactions

Geneviève Balme*

Pyrroles represent an important class of heterocycles that display remarkable pharmacological—antibacterial, antiviral, anti-inflammatory, antitumoral, and antioxidant—activities.[1] Furthermore, they are useful intermediates in the synthesis of natural products as well as in heterocyclic chemistry[2] and they are widely used in materials science.[3] As a consequence, many synthetic methods are known for the construction of the pyrrole structure.[4] The most frequently used methods include the classical Hantzsch procedure,[5] the cyclocondensation of primary amines with 1,4-dicarbonyl compounds (Paal–Knorr synthesis),[6] and various cycloaddition strategies.[7] Whereas these methods have proven very useful for the synthesis of pyrrole derivatives, they generally involve multistep synthetic operations that limit the scope of these reactions. Multicomponent strategies offer significant advantages over classical linear syntheses by combining a series of reactions from easily available and simple precursors without the need for isolation of the intermediates[8] to allow the construction of complex molecules. Such reactions are thus economically and environmentally attractive and have become an important area of research in organic chemistry.

Within this context, an elegant four-component reaction for the construction of substituted pyrroles was recently reported by Müller and co-workers.[9] This new multicomponent approach developed on from their earlier discovery that the Sonogashira coupling reaction of 1-arylprop-2-yn-1-ols **1** with electron-deficient aryl or heteroaryl halides **2** followed by a base-catalyzed isomerization reaction of the coupled products leads to the corresponding chalcones **3** (Scheme 1).[10] Building on the results of
Scheme 1. Coupling–isomerization sequence that leads to chalcones: a) [PdCl$_2$(PPh$_3$)$_2$] (2 mol%), CuI (1 mol%), Et$_3$N, THF, reflux; b) Et$_3$N.

these pioneering studies, Müller and collaborators developed an integrated procedure for the synthesis of pyrroles based on the reactivity of the newly formed enone functionality. To this end, the palladium-catalyzed enone synthesis was combined with a Stetter reaction to give 1,4-diketone intermediates,[11] which were treated with primary amines in a subsequent Paal–Knorr cyclocondensation reaction. These three reactions were efficient-

ly integrated in a one-pot domino sequence to yield highly substituted pyrrole derivatives in rather good yields (Scheme 2). Thus, after the reaction of various 1-arylprop-2-yn-1-ols **1** with electron-deficient aryl bromides **2** under the reaction conditions of the Sonogashira coupling–isomerization sequence in boiling triethylamine, the newly formed enones **3** were treated with an aldehyde **4** in the presence of a catalytic amount of a thiazolium salt. After the complete conversion of **3** into the corresponding diketone **5**, the subsequent addition of primary amines **6** and acetic acid to the reaction mixture yielded the expected tri- or tetrasubstituted pyrroles **7**. Three or four diverse functionalities (one from each of the components **1**, **2**, and **4**, as well as **6** when R$^2 \neq$ H) were introduced into the products.

One of the limitation of the Paal–Knorr reaction for the construction of the pyrrole ring is the accessibility of the 1,4-dicarbonyl precursors. As illustrated in the previous example, the classical Stetter addition of aldehydes to unsaturated carbonyl electrophiles is often
Scheme 2. Palladium-catalyzed four-component assembly of pyrroles starting from 1-arylprop-2-yn-1-ols: a) [PdCl$_2$(PPh$_3$)$_2$] (2 mol%), CuI (1 mol%), Et$_3$N, reflux; b) AcOH, Δ. R^1 = aryl, heteroaryl; R^2 = H, Bn (benzyl), (CH$_2$)$_2$OH, CH$_2$C(O)NH$_2$.

used for this purpose. However, during the condensation reaction, a self-condensation of aldehydes (benzoin condensation) often occurs. Recently, Scheidt and co-workers demonstrated that the reaction of acylsilanes **8** with unsaturated conjugate acceptors **9** promoted by a thiazolium salt **10** in the presence of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) provides an attractive alternative to the classical Stetter addition of aldehydes (Scheme 3).[12] This reaction is thought to proceed through the addition of the carbene catalyst **11** to **8** followed by a 1,2-silyl group shift (Brook rearrangement) to give the silylated intermediate **12**. The alcohol (*i*PrOH) then generates the acyl anion nucleophile **13**, which undergoes selective addition to the conjugate acceptor **9** that then, after elimination of the heterocyclic catalyst, leads to the corresponding diketones **14**. During this process, the formation of benzoin products is not observed owing to the lower electrophilicity of the acylsilanes **8** relative to aldehydes.

Based of this concept, a novel three-component approach to the synthesis of pyrrole derivatives was developed by the same group by the combination of
Scheme 5. Ruthenium-catalyzed propargyl alkylation of 1-arylprop-2-yn-1-ols with ketones: a) **19** (10%), NH$_4$BF$_4$ (20%). Cp* = pentamethylcyclopentadienyl.

this new variant of the Stetter reaction with a Paal–Knorr condensation.[13] To this end, the thiazolium-catalyzed coupling reaction of an aryl or alkyl acylsilane with a chalcone was monitored to completion by TLC (thin-layer chromatography) analysis. Treatment of the resulting 1,4-dicarbonyl compound in situ with a primary amine in the presence of *p*-toluenesulfonic acid and molecular sieves produces the corresponding trisubstituted pyrrole derivative **15** (Scheme 4). Remarkably, in this process, various electron-donating or electron-withdrawing aryl substituents may be incorporated on either side of the unsaturated ketone.

Another creative convergent approach to pyrrole derivatives that starts from 1-arylprop-2-yn-1-ols **1** was recently developed by Uemura, Hidai, and co-

workers.[14] In an early example, this group reported a ruthenium-catalyzed substitution of the propargyl group in the 1-aryl-substituted propargyl alcohol of type **1** with a dialkyl ketone such as acetone (**16**) in the presence of NH$_4$BF$_4$ which leads to the corresponding γ-ketoacetylene **17** (Scheme 5).[15] The proposed mechanism involves the formation of the allenylidene complex **18** from the reaction of propargyl alcohol **1** with the thiolate-bridged diruthenium complex **19**. This is followed by a nucleophilic attack of the enolate carbon of the ketone on the electrophilic γC atom of the reactive intermediate **18**. Taking advantage of the formation of water during this process, Uemura, Hidai, and co-workers further developed an ingenious strategy for the one-pot synthesis of substituted furans **21** by a combination of the above Ru-catalyzed reaction with the hydration of the alkyne moiety of **17** which was promoted by a second catalyst in the medium (Scheme 6). Under the reaction conditions, an intramolecular cyclization of the newly formed 1,4 diketone **20** results in the formation of the expected furans. The success of this domino reaction is highly dependent on the ability of the two catalysts to promote *sequentially* the three specific reactions: the ruthenium catalyst **19** and PtCl$_2$ give the best results.

The authors have extended these elegant studies to the one-pot synthesis of pyrroles **24** by carrying out this novel ruthenium/platinum-catalyzed multicomponent reaction in the presence of various aniline derivatives **22**. The reaction is considered to proceed through the platinum-catalyzed nucleophilic attack of anilines on the carbon–carbon triple bond of the γ-ketoalkyne intermediate that leads to **23**, followed by an intramolecular cyclization to yield the pyrroles **24**.[16]

Scheme 3. Thiazolium-catalyzed addition of acylsilane to unsaturated carbonyl electrophiles to yield 1,4-dicarbonyl products: a) DBU, THF; b) *i*PrOH. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; R = (CH$_2$)$_2$OH.

Scheme 4. A sequential three-component synthesis of pyrrole derivatives by using a Sila–Stetter/Paal–Knorr strategy: a) **10** (10 mol%), DBU (30 mol%), THF, *i*PrOH (4 equiv), 70°C; b) TsOH, molecular sieves (4 Å), 70°C. Ts = *p*-toluenesulfonyl; R^1 = aryl, alkyl; R^2 = H, aryl, alkyl.

Scheme 6. Sequential ruthenium/platinum-catalyzed three-component assembly reactions of furans and pyrroles starting from 1-arylprop-2-yn-1-ols: a) **19** (10 mol %), NH$_4$BF$_4$ (20 mol %); b) PtCl$_2$ (20 mol %).

More recently, a convergent four-component assembly of substituted pyrroles was developed by Dhawan and Arndtsen.[17] The strategy is based on the ability of münchnones (1,3-oxazolium-5-oxides) to react with acetylenic dipolarophiles to produce bicyclic intermediates that undergo a cycloreversion reaction to yield pyrroles.[18] A recent paper from this laboratory[19] described the first catalytic synthesis of münchnones from a palladium-mediated three-component coupling of an imine, an acid chloride, and carbon monoxide (Scheme 7). A new synthesis of diprotected α-amino acid derivatives **30** was developed by the addition of methanol in the reaction mixture to trap these reactive intermediates. In this process, oxidative addition of imine **25** and acid chloride **26** to palladium(0) gives the Pd-chelated amide complex **27**. Then, insertion of carbon monoxide into the Pd–C bond followed by a β-hydride elimination via the metalloketene complex **28** produces a metal-free münchnone **29**.

The combination of the three-component assembly of münchnones **29** with a cycloaddition process with acetylenic dipolarophiles **31** present in the reaction mixture leads to a remarkably concise and efficient synthesis of pyrrole derivatives (Scheme 8). It was found that the success of this methodology depends on the nature of the Pd–phosphine com-

plex. Strong ligands such as triphenylphosphine were ineffective for the preparation of münchnones. A more labile ligand such as the bulky tri(*o*-tolyl)phosphine played a significant role in sufficiently stabilizing intermediate **27** while still allowing subsequent catalysis steps (Scheme 5). In a typical procedure, a mixture of imine **25**, acid chloride **26**, alkyne **31**, EtN*i*Pr$_2$, P(*o*-tolyl)$_3$ (15 mol %), and the palladium catalyst **32** (generated by the pretreatment of Pd$_2$(dba)$_3$·CHCl$_3$ (5 mol %) with the imine and the acid chloride) in acetonitrile/THF was stirred under CO (4 atm) at 65 °C during 16 h. This optimized protocol produced substituted pyrrole derivatives **33** in good yields. This strategy tolerates the presence of many func-

tional groups: Most combinations of aliphatic/aromatic imines, acid chlorides, and electron-rich or electron-poor alkynes are compatible with the mild reaction conditions and give access to a variety of densely substituted pyrroles. Interestingly, the reaction was found to proceed with complete regioselectivity with unsymmetrical alkynes and even acetylene participated efficiently in this process.

The four creative metal-catalyzed multicomponent one-pot assemblies of pyrroles highlighted herein elegantly demonstrate that multicomponent reactions are a powerful tool for the introduction of molecular diversity in an efficient, economic, and environmentally friendly way. Without doubt many innovative methodologies for the synthesis of this important structure will continue to emerge from this very stimulating research area.

[16] This reaction could also be considered as a formal Paal–Knorr reaction. Indeed, another possible mechanistic hypothesis is that the formation of imines, by the reaction of anilines on the carbonyl of intermediate **17** to generate water, occurs first. This would be followed by hydration of the alkyne moiety to lead to the corresponding ketoimine, which is closely related to intermediate **23**.

Endohedral Clusters

Endohedral Zintl Ions: Intermetalloid Clusters

Thomas F. Fässler and Stephan D. Hoffmann*

Dedicated to Professor Hans-Jörg Deiseroth on the occasion of his 60th birthday

Tetrels can be regarded as most promising candidates for the construction of larger clusters. Recent examples have shown that larger clusters are particularly stable if they contain interstitial atoms (e.g. [Pt@Pb_{12}]^{2-}). Many salts of the polyhedral anions are soluble, but a number of examples—usually those with higher charges—occur only as quasi-discrete units in saltlike crystals (Zintl phases) or as building blocks in intermetallic phases. In this Minireview, the chemistry of intermetalloid clusters is reviewed with reference to the endohedral Zintl ions, Zintl phases, and polyhedral building blocks of inter-metallic compounds, including heteroatomic species in the gas phase. We focus on selected examples and discuss the new findings in the context of recent advances in the field of metalloid clusters and (endohedral) fullerenes and fullerides.

Soluble Main-Group-Element Deltahedra

According to Wade's rules, closed polyhedra with triangular faces (deltahedra) and n vertices are particularly stable whenever $2n+2$ valence electrons are available for the formation of the cluster framework.[1] Starting from the corresponding boranes, ligand-free homoatomic main-group-element polyhedra can readily be described by replacing the B–H units by a lone pair of electrons localized at each vertex atom. With N referring to their group number, each of these atoms contributes $N-2$ electrons to the framework formation of the polyhedron. The charge of the cluster q acts as a variable, which adjusts the number of electrons of the neutral cluster to the optimum configuration. Consequently, the resulting number of electrons provided by these atoms for the formation of the framework is given by $n(N-2)-q$. According to Wade's rules, *closo*, *nido*, *arachno*, and *hypho* clusters with n vertices and $2n+m$ electrons are particularly stable for $m=2, 4, 6$, and 8, and from $2n+m=n(N-2)-q$ the resulting overall charge of the cluster is given by $q=-(n(N-4)+m)$. As a direct consequence, the charge q for $N=4$ (Group 14

elements) is independent of n and hence of the size of the cluster (Figure 1),[2] whereas clusters that contain Group 13 and Group 15 elements exhibit increasingly negative and positive charge, respectively.[2]

Despite the constant and relatively low charge, the number of examples of larger homoatomic clusters that contain Group 14 elements (tetrels) is rather limited. One reason may be the growing size of the cavity inside the cluster as a consequence of the increase in cluster size. In contrast to the larger fullerenes, the deltahedra of the heavier Group 14 element congeners (Si to

Pb) do not have a rigid stable σ-bonding framework, and the bonding of the atoms is delocalized over the whole polyhedron. This fluctional bonding allows a rapid exchange of atomic positions, as shown by NMR spectroscopy experiments for the anions $[Sn_9]^{4-}$ and $[Pb_9]^{4-}$.[3] Although the so-called Zintl ions and the fullerenes show some parallel properties concerning the delocalized framework bonds and π electrons,[4] respectively, the stability of the fullerenes is based to a major extent on the energy of the σ bonds.

As a consequence of weaker framework bonding, larger cavities inside the clusters become less stable and the deficit must be compensated by the incorporation of atoms or small molecules into the cluster, as demonstrated, for example, in the synthesis of a number of nanoporous materials. Recently, this type of stabilization was realized for the first time through the synthesis of "filled" main-group-element clusters.

The largest soluble clusters described to date are based on the well-established Zintl ions $[Sn_9]^{4-}$ and $[Pb_9]^{4-}$,[5,6] which—with their singly capped square-antiprismatic structure—represent a *nido*-type cluster (Figure 2 a).[7–9] Addition of a transition-metal fragment $M(CO)_3$—which according to the isolobal principle does not contribute any electrons to the framework and therefore simply acts as a vertex atom—to the open square face of this cluster leads to closed polyhedra with 10 vertices (Figure 2 b). In the latter case, isomeric structures (Figure 2 c) as well as exchange of the vertex atoms, which is rapid on the NMR timescale, are possible.[10]

The soluble clusters described herein are stable up to a size of 10 atoms, without a central host; the first filled examples are also observed for $n = 10$. It therefore appears that the stability limit for empty clusters of the heavier Group 13–15 elements is attained for species with $n = 10$. The incorporation of a Ni atom into the Sn_9 framework, as in the case of the anion $[Ni@Sn_9Ni(CO)]^{3-}$, leads to only a much smaller expansion of the polyhedron (Figure 2 d) than in the Sn_9Cr cluster.[11] Since the Ni(CO) fragment carries two electrons that can contribute to the framework bonding, it corresponds—according to the isolobal concept—to a Sn vertex atom, and the cluster can be assumed to have the charge distribution $[Ni^0@Sn_9Ni(CO)]^{3-}$. The odd number of electrons implies that we are dealing with a $(2n+1)$-electron, *closo*-type cluster, which is analogous to the well-established oxidized form of the *nido* clusters $[E_9]^{3-}$ (E = Ge, Sn, Pb) with $2n+3$ electrons.[6]

The anion $[Pt@Pb_{12}]^{2-}$ represents the first isolated (soluble) ligand-free cluster of a Group 14 element with $n > 10$ (Figure 2 e).[12] The 12 Pb atoms are arranged around a central Pt atom in the form of a highly symmetrical icosahedron. An orbital analysis reveals only weak interactions between the cluster orbitals and the orbitals of the central atom, thereby suggesting the formulation of the cluster as $[Pt^0@Pb_{12}^{2-}]$. The central Pt atom acts as a template for the electron-precise (according to the Wade rules) Pb_{12}^{2-} cluster and not as an electron donor or acceptor, as observed in other types of filled clusters, such as $[C@Au_6L_6]^{2+}$ and $[Pt@Sn_9Pt]^{2+}$ (Figure 2 p and q).[13]

The Icosahedron

Due to its uniform surface built of equilateral triangles, the icosahedron (Figure 2, **I**) belongs to the so-called platonic bodies. Truncation of the vertices can lead to new polyhedra in which the symmetry is retained. If the truncation results in the formation of equilateral six-membered rings, the polyhedron of C_{60}-fullerene with 60 vertices is generated (Figure 2, **II**). The dual of a polyhedron is formed when the centers of the faces are connected to generate edges. In the case of the icosahedron, this procedure leads to a pentagonal dodecahedron, and vice versa (Figure 2, **III**). The 12 edge-sharing five-membered rings in **III** show a different relative orientation to that of the 12 five-membered rings of the 60-vertex polyhedron in **II**. In an icosahedral cage molecule, the 30 interatomic distances a between the vertex atoms on the surface of the polyhedron are of equal length (Figure 2 e). In contrast, the distances R between these atoms and the center of the polyhedron are $\approx 5\%$ shorter ($R/a = 0.951$).[14] As point groups of icosahedral symmetry do not represent crystallographic point groups, real clusters with 12 vertices present in crystals deviate more or less from the ideal icosahedral symmetry. For an estimation of the volume of distorted polyhedra we propose the deviation from the ideal ratio of the radii $R/a = 0.951$ as a simple criterion (Table 1). The corresponding value, for example, for a polyhedron with cuboctahedral symmetry is $R/a = 1$. In the case of filled icosahedra, the average distances between the central atom and the 12 vertex atoms can be used for R. With the average

Thomas F. Fässler was born in Bad Wald-see/Reute (Germany) in 1959. He studied chemistry and mathematics at the University of Konstanz. In 1988 he received his PhD with Prof. G. Huttner (Heidelberg). After a period of research at the University of Chicago with Prof. J. Burdett, he moved to the ETH Zürich in 1991, where he completed his habilitation in 1997. In 2000 he became Professor at Darmstadt University of Technology, where he also directed the Institute of Inorganic Chemistry in 2001/2002. In 2003 he was appointed Chair of Inorganic Chemistry with Focus on New Materials at the TU München.

Stephan D. Hoffmann was born in 1972 in Königstein (Germany). He studied chemistry (1992–1997) at the Darmstadt University of Technology, where he also received his Ph.D. under the supervision of Professor Johann W. Buchler (2001). He pursued post-doctoral work with Professor Thomas F. Fässler in Darmstadt and since 2003 at the Technische Universität München.

distances of 3.215 Å for d(Pb–Pb) and 3.058 Å for d(Pb–Pt), the ideal value of 0.951 is obtained for the $[Pt@Pb_{12}]^{2-}$ anion.

Main-Group-Element Deltahedra in Salt-like Crystals

In solid phases, more compounds that contain deltahedral main-group-element clusters are known than soluble species. In cases in which cluster units exist exclusively in solid phases, it first has to be ascertained that they can be regarded as isolated units. This is of importance not only for a consideration of the binding within the cluster framework but also with respect to the overall distribution and localization of the electrons. For Zintl phases, an ionic charge distribution is assumed according to the Zintl–Klemm–Busmann concept,[15,16] and the anionic substructures are interpreted by following the $(8-N)$ rule or the Wade rules. The solubility in polar solvents of several Zintl phases that contain Group 14 elements (e.g. K_4Sn_9) supports the concept of ionic character. Sr_3Sn_5 contains *arachno*-type Sn_5^{6-} units, which are not known in solution, however, and the solid exhibits metallic behavior.[17] The charge distribution in many Group 13 element clusters with higher charges cannot be determined unambiguously solely on the basis of structural data. In general, it is not known whether these phases are soluble, and deviations from the expected number of electrons or structures as well as the appearance of different clusters within one compound are quite common. An example is the electron-precise cluster $[Tl_6]^{8-}$, which is found with filled, larger clusters as part of $Na_{14}K_6Tl_{18}Cd$. On the other hand, KTl contains $[Tl_6]^{6-}$ clusters with a smaller number of framework electrons ($2n$ instead of $2n+2$) and features a tetragonally compressed O_h symmetry.[18] In both compounds, direct contacts between the cluster atoms and the alkaline metals have to be taken into consideration, and it is not very likely that these highly charged cages are stable in solution.

It has also been demonstrated for solid phases that polyhedra with triangular faces can be filled as soon as they comprise 10 or more atoms. As shown for the corresponding empty Group 13 element clusters, deviations from the expected number of electrons are quite common. Thus, $K_8In_{10}Zn$ contains the electron-poor cluster unit $[Zn^{2+}@In_{10}^{10-}]$ ($2n$ electrons). The phase $Na_{14}K_6Tl_{18}Cd$ mentioned above contains $[Cd@Tl_{12}]^{12-}$ units (Figure 2 f) and, according to the formula $[Cd^{2+}@Tl_{12}^{14-}]$, can be regarded as an electron-precise centered cluster with an almost ideal icosahedral symmetry. The unit $[Tl^{3+}@Tl_{12}^{14-}]$ observed in $Na_3K_8Tl_{13}$ (Figure 2 g) can be described as an electron-precise cluster only if a formal charge separation is assumed.[18,19] In both cases, the edges of the polyhedra are about 5% longer than the distances between the vertices and the central atoms (Table 1).

Interestingly, a recent publication described a centered *arachno*-type cluster whose structure can be derived from the icosahedral $[Pt@Pb_{12}]^{2-}$ unit by removing two opposite vertices. To date, however, this cluster $[Pd@Bi_{10}]^{4+}$ has been observed only as a component of the solid-phase $Bi_{14}PdBr_{16}$.[19] In the cation $[Pd@Bi_{10}]^{4+}$, there appears to be virtually no interactions between the central Pd atom and the

[a] R is the distance between the vertex atom and the center of the polyhedron; a is the distance between the vertex atoms on the surface of the polyhedra. [b] The ideal value in the icosahedron is 0.951.

skeletal Bi atoms, which are arranged in the shape of a pentagonal antiprism (Figure 2 h). Again the orbital analysis is in agreement with the formula $[Pd^0@Bi_{10}^{4+}]$, and the skeletal cation $[Bi_{10}]^{4+}$ can be regarded as an electron-precise *arachno*-type cluster with a Pd atom in the center. Even when a few vertices are removed, the average Pd–Bi distances remain about 5% shorter than the peripheral Bi–Bi distances ($R/a = 0.951$). In this ionic description, the one-dimensional polymeric string $_\infty^1[Bi_{14}Br_{16}]^{4-}$ acts as a counterion. This charge partition is supported by significantly longer Bi–Br distances *between* the two units than the corresponding distances *within* the anionic unit. A similar situation is found in the well-established *nido* cluster $[Bi_9]^{5+}$.[5] However, the $(2n + 4)$ electron cluster has a *closo*-type structure.

Deltahedra in Intermetallic Phases

The preferred coordination number in packing modes made up by atoms of approximately equal size is 12. This is realized in an ideal way in the variants of close packing of metallic elements, which preferably adopt the cubic (Cu type) and hexagonal (Mg type) close packing. The resulting coordination polyhedra are the cubocthedron (Figure 2 i) and the anti-cuboctahedron (Figure 2 j), respectively. In these entities, the distances between the central atom and the atoms of the surrounding polyhedron are equal to those within the framework of the polyhedron ($R/a = 1$). However, these polyhedra do not belong to the class of deltahedra, as they also contain square planes. According to the notation introduced above, the corresponding structure units can be described as $Cu@Cu_{12}$ and $Mg@Mg_{12}$, respectively.

For binary alloys in which the atoms have different sizes and the components tend to approach close packing, a coordination geometry derived from an icosahedron is generally observed.[20] The cubic Laves phase $MgCu_2$ is an example in which the smaller Cu atom is located in the center

of the heteroatomic deltahedron $Cu@Mg_6Cu_6$, whose structure is shown in Figure 2k. As a consequence of this arrangement the Mg atom is accommodated inside a heteroatomic deltahedron with 16 vertices of T_d symmetry (Figure 2l). If a model is applied in which the Mg as well as the Cu atoms touch each other, an ideal ratio $r(Mg)/r(Cu) = 1.225$ is obtained. The resulting space filling for this arrangement still reaches a remarkable 71% (compare closest packing: 74%).[21]

The coordination polyhedra with 12 vertices described above are found for intermetallic compounds with the ratios of the radii in the range between 1.05 and 1.67. The corresponding value for $r(Pb)/r(Pt)$ in $[Pt@Pb_{12}]^{2-}$ (calculated by using the metallic radii $r(Pt) = 1.373$ and $r(Pb) = 1.750$ Å) was found to be 1.274 and is very close to the value of 1.225 calculated by Laves.

If a model of touching spheres with the metallic radii $r(Pt) = 1.373$ and $r(Pb) = 1.750$ Å is also applied for $[Pt@Pb_{12}]^{2-}$, the distances on the polyhedral surface are calculated as $d(Pb–Pb) = 3.500$ Å and the distances between the Pb atoms and the central Pt atom as 3.123 Å. With the conventional radii as a reference, the Pb–Pt distance is shortened by $\approx 11\%$, with the central Pt atoms slightly too small (5% relative to the standard value). In the isolated dianions $[Pt@Pb_{12}]^{2-}$, the atomic radii appear to be smaller than the metallic radii, owing to a better localization of the electrons than in the metal, and the average distances $d(Pb–Pb)$ and $d(Pb–Pt)$ are 3.215 and 3.058 Å, respectively ($R/a = 0.95$).

Another series of heteroatomic deltahedra that allow close packing of atoms of different sizes has been investigated systematically by Frank and Kasper: In addition to the deltahedra with 12 and 16 vertices (above), the so-called Frank–Kasper polyhedra comprise another two deltahedra with 14 and 15 vertices,[21] and it is therefore conceivable that besides $[M@E_{12}]^{2-}$ there may be many larger, soluble, filled, and ligand-free main-group-element clusters of compositions $[M@E_{14}]^{2-}$, $[M@E_{15}]^{2-}$, and $[M@E_{16}]^{2-}$ that are stable.

Soluble Metalloid and Intermetalloid Clusters

The structure of $[Pt@Pb_{12}]^{2-}$ also shows interesting parallels to the metalloid clusters described by Schnöckel: The central Al atom of the anion $[Al_{77}\{N(SiMe_2)_2\}_{20}]^{2-}$ again has 12 close neighbors in a strongly distorted icosahedral environment,[22] and, as is the case for $[Pt@Pb_{12}]^{2-}$, the central atom has a coordination sphere that neither corresponds to a section of a close packing with a cuboctahedral nor to an anticuboctahedral structure. The distortion of the observed icosahedron can be recognized from the deviation of the two

parallel five-membered rings from planarity (Figure 2m). As a consequence of this deviation, very long Al–Al distances of 3.446 Å appear on the surface of the polyhedron which are more than 25% longer than the shortest ones (2.693 Å). However, the average of the distances on the surface is again about 5.3% longer than the average of those to the interstitial atom. Referring to the term *metalloid* clusters of Group 13 elements,[23] it appears to be appropriate to suggest the term *intermetalloid* clusters for the growing class of metal-centered heteroatomic clusters.[24]

In the meantime, the formation of big clusters could also be demonstrated for As.[25] In the anion $[As@Ni_{12}@As_{20}]^{2-}$ there are, however, strong interactions between the fascinating pentagonal dodecahedron of 20 As atoms and the central $As@Ni_{12}$ cluster (Figure 2n). In this case the As-centered Ni_{12} icosahedron can be regarded as a template for the formation of the As_{20} polyhedron. In contrast to the observations in $[Pt@Pb_{12}]^{2-}$, relatively strong Ni–As interactions contribute to the stabilization of the As framework.

Together with the large cations $[K([2.2.2]crypt)]^{+}$,[26] the anion $[Pt@Pb_{12}]^{2-}$ forms a packing in which the anions are arranged in layers analogous to a closest packing of atoms. These layers are separated by the cations and are aligned congruently along the *c* axis, thereby forming a primitive hexagonal arrangement that is compressed along this axis (Figure 3a and b). This packing mode corresponds to that observed for $[Al_{77}\{Ni(SiMe_2)_2\}_{20}]^{2-}$, which crystallizes with $[Li-I-Li]^{+}$ counterions (Figure 3c and d), and that present in C_{60}^{2-} anions, which in combination with $[K(2.2.2-crypt]^{+}$ cations also form a layer-type aggregation (Figure 3e and f).[27] The observed similarity in the packing modes of large anions of different sizes together with different counterions suggests that the packing can be predominantly explained by repulsive forces between the dianions.

Intermetalloid Clusters in the Gas Phase

Although the structures of a large number of filled main-group-element clusters detected by mass spectrometry have been deduced on the basis of theoretical calculations, there is still a lack of experimental proof.[28] In contrast to gas-phase experiments on bimetallic species, the structures of the clusters discussed above have been proven unambiguously. The experimental structure determination is especially important, as the minor component does not necessarily reside in the center of the cluster, but can—as observed in the anions $[(CO)_3CrSn_9]^{2-}$ and $[(CO)_3WSn_9]^{2-}$—occupy a vertex of the polyhedron. Structure determinations of these electron-precise clusters have proven the presence of isomers in which the transition-metal atoms occupy different vertices of the polyhedra, and NMR spectroscopy experiments have indicated a rapid exchange between these positions in solution.[11] Accordingly, the presence of two transition-metal atoms increases the number of possible isomers. For these cases, the structure of the endohedral Zintl anion $[Ni@Sn_9Ni(CO)]^{3-}$ can serve as an important reference for theoretical predictions of the structures of species with two transition-metal atoms already detected in the gas phase. Although the transition metals in the examples mentioned above bear ligands, it is a safe assumption that the framework of the polyhedron is retained upon the loss of the carbonyl ligands in the gas phase.

Whereas heteroatomic clusters that contain Group 14 elements and alkaline metals have been known in the gas phase for quite some time,[29,30] the corresponding species with main-group/transition-metal atoms are less well investigated.[31] According to theoretical investigations, the bimetallic clusters $[AlPb_{10}]^{+}$ and $[AlPb_{12}]^{+}$, which are very stable in the gas phase, have structures with D_{4d} and I_h symmetry, respectively (Figure 2d and e). Analogously to the endohedral Zintl ions, they can be described as filled, electron-precise *closo* clusters $[Al^{3+}@Pb_{10}^{2-}]$ and $[Al^{3+}@Pb_{12}^{2-}]$.[32]

Endohedral Clusters and Fullerenes

Recently we pointed out the exciting analogy between Zintl ions and fullerides.[33] By including endohedral compounds into this concept, the anion $[Pt@Pb_{12}]^{2-}$ can be taken as further evidence for its validity. Although a larger number of endohedral compounds have been detected in the case of the fullerides, structural proof is rather limited.[34, 35] The comparable size of C_{60} and Pb_{12} allows the incorporation of a metal atom in both cases. The interactions between the central atom and the framework atoms are expected to be small in both cases, but with

Figure 3. The packing of large dianions in the crystal (unit cells in black, distances between the centers of gravity of the clusters in Å). a) and b) $[PtPb_{12}]^{2-}$ with $[K2.2.2crypt]^{+}$ counterions (only K atoms shown); c) and d) $[Al_{77}\{N(SiMe_2)_2\}_{20}]^{2-}$ with $[Li-I-Li]^{+}$ counterions (only the N atoms of the ligand and the I atom of the counterion are shown); e) and f) $[C_{60}]^{2-}$ with $[K2.2.2crypt]^{+}$ counterions (only K atoms shown).

significant contributions in the case of the endohedral anions. The structural analogy mentioned above can be readily rationalized in Figure 2e and o, which have been drawn to scale.

Summary

According to Wade's rules larger clusters that contain Group 14 elements are expected to exist and to be stable. In many cases, these counting rules can also be applied successfully to naked endohedral Zintl ions. For the electron count of these systems, a formal charge separation between the polyhedral framework and the central atom is helpful. Owing to the relatively small charge, the synthesis of larger endohedral intermetalloid clusters built from Group 14 elements should generally be possible, as already demonstrated for the first time by the characterization of the anion $[Pt@Pb_{12}]^{2-}$. The formation of larger clusters starting from the well-established and readily available nine-atom Zintl ions of Group 14 elements seems to be favored if a central atom can be incorporated. The choice of appropriate "template atoms" for the formation of larger clusters may be guided by the species detected in the gas phase, or by the structural features observed in Laves phases or in Frank–Kasper polyhedra. The centered polyanion $[Pt@Pb_{12}]^{2-}$ again illustrates the amazing parallel between deltahedral Zintl ions and fullerenes.

Synthetic Methods

Controlled Microwave Heating in Modern Organic Synthesis

*C. Oliver Kappe**

Angewandte Chemie

DOI: 10.1002/anie.200400655
*A*lthough fire is now rarely used in synthetic chemistry, it was not until Robert Bunsen invented the burner in 1855 that the energy from this heat source could be applied to a reaction vessel in a focused manner. The Bunsen burner was later superseded by the isomantle, oil bath, or hot plate as a source for applying heat to a chemical reaction. In the past few years, heating and driving chemical reactions by microwave energy has been an increasingly popular theme in the scientific community. This nonclassical heating technique is slowly moving from a laboratory curiosity to an established technique that is heavily used in both academia and industry. The efficiency of "microwave flash heating" in dramatically reducing reaction times (from days and hours to minutes and seconds) is just one of the many advantages. This Review highlights recent applications of controlled microwave heating in modern organic synthesis, and discusses some of the underlying phenomena and issues involved.

From the Contents

1. Introduction

High-speed synthesis with microwaves has attracted a considerable amount of attention in recent years.[1] More than 2000 articles have been published in the area of microwave-assisted organic synthesis (MAOS) since the first reports on the use of microwave heating to accelerate organic chemical transformations by the groups of Gedye and Giguere/Majetich in 1986.[2,3] The initial slow uptake of the technology in the late 1980s and early 1990s has been attributed to its lack of controllability and reproducibility, coupled with a general lack of understanding of the basics of microwave dielectric heating. The risks associated with the flammability of organic solvents in a microwave field and the lack of available systems for adequate temperature and pressure controls were major concerns.

Although most of the early pioneering experiments in MAOS were performed in domestic, sometimes modified, kitchen microwave ovens, the current trend is to use dedicated instruments which have only become available in the last few years for chemical synthesis. The number of publications related to MAOS has therefore increased dramatically since the late 1990s to a point where it might be assumed that, in a few years, most chemists will probably use microwave energy to heat chemical reactions on a laboratory scale. Not only is direct microwave heating able to reduce chemical reaction times from hours to minutes, but it is also known to reduce side reactions, increase yields, and improve reproducibility. Therefore, many academic and industrial research groups are already using MAOS as a forefront technology for rapid optimization of reactions, for the efficient synthesis of new chemical entities, and for discovering and probing new chemical reactivity. A large number of review articles[4–13] and several books[14–16] provide extensive coverage of the subject. The aim of this Review is to highlight some of the most recent applications and trends in microwave synthesis, and to discuss the impact and future potential of this technology.

1.1. Microwave Theory

Microwave irradiation is electromagnetic irradiation in the frequency range of 0.3 to 300 GHz. All domestic "kitchen" microwave ovens and all dedicated microwave reactors for chemical synthesis operate at a frequency of 2.45 GHz (which corresponds to a wavelength of 12.24 cm) to avoid interference with telecommunication and cellular phone frequencies. The energy of the microwave photon in this frequency region (0.0016 eV) is too low to break chemical bonds and is also lower than the energy of Brownian motion. It is therefore clear that microwaves cannot induce chemical reactions.[17–19]

Microwave-enhanced chemistry is based on the efficient heating of materials by "microwave dielectric heating" effects. This phenomenon is dependent on the ability of a specific material (solvent or reagent) to absorb microwave energy and convert it into heat. The electric component[20] of an electromagnetic field causes heating by two main mechanisms: dipolar polarization and ionic conduction. Irradiation of the sample at microwave frequencies results in the dipoles or ions aligning in the applied electric field. As the applied field oscillates, the dipole or ion field attempts to realign itself with the alternating electric field and, in the process, energy is lost in the form of heat through molecular friction and dielectric loss. The amount of heat generated by this process is directly related to the ability of the matrix to align itself with the frequency of the applied field. If the dipole does not have enough time to realign, or reorients too quickly with the applied field, no heating occurs. The allocated frequency of 2.45 GHz used in all commercial systems lies between these two extremes and gives the molecular dipole time to align in the field, but not to follow the alternating field precisely.[18,19]

The heating characteristics of a particular material (for example, a solvent) under microwave irradiation conditions

are dependent on its dielectric properties. The ability of a specific substance to convert electromagnetic energy into heat at a given frequency and temperature is determined by the so-called loss factor tanδ. This loss factor is expressed as the quotient tan$\delta = \varepsilon''/\varepsilon'$, where ε'' is the dielectric loss, which is indicative of the efficiency with which electromagnetic radiation is converted into heat, and ε' is the dielectric constant describing the ability of molecules to be polarized by the electric field. A reaction medium with a high tanδ value is required for efficient absorption and, consequently, for rapid heating. The loss factors for some common organic solvents are summarized in Table 1. In general, solvents can be classified as high (tan$\delta > 0.5$), medium (tanδ 0.1–0.5), and low microwave absorbing (tan$\delta < 0.1$).

Table 1: Loss factors (tanδ) of different solvents.[a]

Solvent	tanδ	Solvent	tanδ
ethylene glycol	1.350	DMF	0.161
ethanol	0.941	1,2-dichloroethane	0.127
DMSO	0.825	water	0.123
2-propanol	0.799	chlorobenzene	0.101
formic acid	0.722	chloroform	0.091
methanol	0.659	acetonitrile	0.062
nitrobenzene	0.589	ethyl acetate	0.059
1-butanol	0.571	acetone	0.054
2-butanol	0.447	tetrahydrofuran	0.047
1,2-dichlorobenzene	0.280	dichloromethane	0.042
NMP	0.275	toluene	0.040
acetic acid	0.174	hexane	0.020

[a] Data from ref. [15]; 2.45 GHz, 20°C.

Other common solvents without a permanent dipole moment such as carbon tetrachloride, benzene, and dioxane are more or less microwave transparent. It has to be emphasized that a low tanδ value does not preclude a particular solvent from being used in a microwave-heated reaction. Since either the substrates or some of the reagents/catalysts are likely to be polar, the overall dielectric properties of the reaction medium will in most cases allow sufficient heating by microwaves (see Section 1.2). Furthermore, polar additives such as ionic liquids, for example, can be added to otherwise low-absorbing reaction mixtures to increase the absorbance level of the medium (see Section 2.2.1).

C. Oliver Kappe received his doctoral degree from the Karl-Franzens-University in Graz (Austria), where he worked with Prof. G. Kollenz on cycloaddition and rearrangements of acylketenes. After postdoctoral research work with Prof. C. Wentrup at the University of Queensland (Australia) and Prof. A. Padwa at Emory University (US), he moved back to the University of Graz where he obtained his Habilitation (1998) and is currently associate Professor. In 2003 he spent a sabbatical period at the Scripps Research Institute in La Jolla (US) with Prof. K. B. Sharpless. His research interests include microwave-enhanced synthesis, combinatorial chemistry, and multicomponent reactions.

Traditionally, organic synthesis is carried out by conductive heating with an external heat source (for example, an oil bath). This is a comparatively slow and inefficient method for transferring energy into the system, since it depends on the thermal conductivity of the various materials that must be penetrated, and results in the temperature of the reaction vessel being higher than that of the reaction mixture. In contrast, microwave irradiation produces efficient internal heating (in-core volumetric heating) by direct coupling of microwave energy with the molecules (solvents, reagents, catalysts) that are present in the reaction mixture. Since the reaction vessels employed are typically made out of (nearly) microwave-transparent materials, such as borosilicate glass, quartz, or teflon, an inverted temperature gradient results compared to conventional thermal heating (Figure 1). The very efficient internal heat transfer results in minimized wall effects (no hot vessel surface) which may lead to the observation of so-called specific microwave effects (see Section 1.2), for example, in the context of diminished catalyst deactivation.
Figure 1. Inverted temperature gradients in microwave versus oil-bath heating: Difference in the temperature profiles (finite element modeling) after 1 min of microwave irradiation (left) and treatment in an oil-bath (right). Microwave irradiation raises the temperature of the whole volume simultaneously (bulk heating) whereas in the oil-heated tube, the reaction mixture in contact with the vessel wall is heated first.[38]

1.2. Microwave Effects

Since the early days of microwave synthesis, the observed rate accelerations and sometimes altered product distributions compared to oil-bath experiments have led to speculation on the existence of so-called "specific" or "non-thermal" microwave effects.[21–23] Historically, such effects were claimed when the outcome of a synthesis performed under microwave conditions was different from the conventionally heated counterpart carried out at the same apparent temperature. Today most scientists agree that in the majority of cases the reason for the observed rate enhancements is a purely thermal/kinetic effect, that is, a consequence of the high reaction temperatures that can rapidly be attained when irradiating polar materials in a microwave field. As shown in Figure 2, a high microwave absorbing solvent such as methanol (tan$\delta = 0.659$) can be rapidly superheated to
Figure 2. Temperature (*T*), pressure (*p*), and power (*P*) profile for a sample of methanol (3 mL) heated under sealed-vessel microwave irradiation conditions (single-mode heating, 250 W, 0–30 s), temperature control using the feedback from IR thermography (40–300 s), and active gas-jet cooling (300–360 s). The maximum pressure in the reaction vessel was ca. 16 bar. After the set temperature of 160 °C is reached, the power regulates itself down to ca. 50 W.

temperatures > 100 °C above its boiling point when irradiated under microwave conditions in a sealed vessel. The rapid increase in temperature can be even more pronounced for media with extreme loss factors, such as ionic liquids (see Section 2.2.1), where temperature jumps of 200 °C within a few seconds are not uncommon. Naturally, such temperature profiles are very difficult if not impossible to reproduce by standard thermal heating. Therefore, comparisons with conventionally heated processes are inherently troublesome.

Dramatic rate enhancements between reactions performed at room temperature or under standard oil-bath conditions (heating under reflux) and high-temperature microwave-heated processes have frequently been observed. As Baghurst and Mingos have pointed out on the basis of simply applying the Arrhenius law [$k = A\exp(-E_a/RT)$], a transformation that requires 68 days to reach 90 % conversion at 27 °C, will show the same degree of conversion within 1.61 seconds (!) when performed at 227 °C (Table 2).[18] The very

Table 2: Relationship between temperature and time for a typical first-order reaction.[a]

T [°C]	*k* [s^{-1}]	*t* (90% conversion)
27	1.55×10^{-7}	68 days
77	4.76×10^{-5}	13.4 h
127	3.49×10^{-3}	11.4 min
177	9.86×10^{-2}	23.4 s
227	1.43	1.61 s

[a] Data from ref. [18]; $A = 4 \times 10^{10}$ mol^{-1}s^{-1}, $E_a = 100$ kJ mol^{-1}.

rapid heating and extreme temperatures observable in microwave chemistry means that many of the reported rate enhancements can be rationalized by simple thermal/kinetic effects.

In addition to the above mentioned thermal/kinetic effects, microwave effects that are caused by the uniqueness of the microwave dielectric heating mechanisms (see Section 1.1) must also be considered. These effects should be termed "specific microwave effects" and shall be defined as accelerations that can not be achieved or duplicated by conventional heating, but essentially are still thermal effects. In this category fall, for example 1) the superheating effect of

solvents at atmospheric pressure,[24] 2) the selective heating of, for example, strongly microwave absorbing heterogeneous catalysts or reagents in a less polar reaction medium,[25–27] 3) the formation of "molecular radiators" by direct coupling of microwave energy to specific reagents in homogeneous solution (microscopic hotspots),[26] and 4) the elimination of wall effects caused by inverted temperature gradients (Figure 1).[28] It should be emphasized that rate enhancements falling under this category are essentially still a result of a thermal effect (that is, a change in temperature compared to heating by standard convection methods), although it may be difficult to experimentally determine the exact reaction temperature.

Some authors have suggested the possibility of "non-thermal microwave effects" (also referred to as athermal effects). These should be classified as accelerations that can not be rationalized by either purely thermal/kinetic or specific microwave effects. Nonthermal effects essentially result from a direct interaction of the electric field with specific molecules in the reaction medium. It has been argued that the presence of an electric field leads to orientation effects of dipolar molecules and hence changes the pre-exponential factor *A* or the activation energy (entropy term) in the Arrhenius equation.[21,22] A similar effect should be observed for polar reaction mechanisms, where the polarity is increased going from the ground state to the transition state, thus resulting in an enhancement of reactivity by lowering the activation energy.[22] Microwave effects are the subject of considerable current debate and controversy,[21–23] and it is evident that extensive research efforts will be necessary to truly understand these and related phenomena.[29] Since the issue of microwave effects is not the primary focus of this Review, the interested reader is referred to more detailed surveys and essays covering this topic.[21–23]

1.3. Processing Techniques

Frequently used processing techniques employed in microwave-assisted organic synthesis involve solventless ("dry-media") procedures where the reagents are preadsorbed onto either a more or less microwave transparent (silica, alumina, or clay)[32] or strongly absorbing (graphite)[33] inorganic support, which can additionally be doped with a catalyst or reagent. The solvent-free approach was very popular particularly in the early days of MAOS since it allowed the safe use of domestic household microwave ovens and standard open-vessel technology. Although a large number of interesting transformations with "dry-media" reactions have been published in the literature,[32] technical difficulties relating to non-uniform heating, mixing, and the precise determination of the reaction temperature remain unsolved, in particular when scale-up issues need to be addressed. In addition, phase-transfer catalysis (PTC) has also been widely employed as a processing technique in MAOS.[34]

Alternatively, microwave-assisted synthesis can be carried out in standard organic solvents either under open- or sealed-vessel conditions. If solvents are heated by microwave

irradiation at atmospheric pressure in an open vessel, the boiling point of the solvent (as in an oil-bath experiment) typically limits the reaction temperature that can be achieved. In the absence of any specific or nonthermal microwave effects (such as the superheating effect at atmospheric pressure which has been reported to be up to 40°C)[24] the expected rate enhancements would be comparatively small. To nonetheless achieve high reaction rates, high-boiling microwave-absorbing solvents such as DMSO, *N*-methyl-2-pyrrolidone (NMP), 1,2-dichlorobenzene (DCB), or ethylene glycol (see Table 1) have been frequently used in open-vessel microwave synthesis.[6] However, the use of these solvents presents serious challenges during product isolation. The recent availability of modern microwave reactors with on-line monitoring of both temperature and pressure has meant that MAOS in sealed vessels—a technique pioneered by Strauss in the mid 1990s[35]—has been celebrating a comeback in recent years. This is clearly evident from surveying the recently published literature in the area of MAOS (see Section 2), and it appears that the combination of rapid dielectric heating by microwaves with sealed-vessel technology (autoclaves) will most likely be the method of choice for performing MAOS in the future.

1.4. Equipment

Although many of the early pioneering experiments in microwave-assisted organic synthesis were carried out in domestic microwave ovens, the current trend is undoubtedly to use dedicated instruments for chemical synthesis. In a domestic microwave oven the irradiation power is generally controlled by on/off cycles of the magnetron (pulsed irradiation), and it is typically not possible to monitor the reaction temperature in a reliable way. This disadvantage, combined with the inhomogeneous field produced by the low-cost magnetrons and the lack of safety controls, means that the use of such equipment can not be recommended. In contrast, all of today's commercially available dedicated microwave reactors for synthesis[36–38] feature built-in magnetic stirrers, direct temperature control of the reaction mixture with the aid of fiber-optic probes or IR sensors, and software that enables on-line temperature/pressure control by regulation of microwave power output (Figure 2).

Two different philosophies with respect to microwave reactor design are currently emerging: multimode and monomode (also referred to as single-mode) reactors.[17] In the so-called multimode instruments (conceptually similar to a domestic oven), the microwaves that enter the cavity are reflected by the walls and the load over the typically large cavity. In most instruments a mode stirrer ensures that the field distribution is as homogeneous as possible. In the much smaller monomode cavities, the electromagnetic irradiation is directed through an accurately designed rectangular or circular wave guide onto the reaction vessel mounted at a fixed distance from the radiation source, thus creating a standing wave. The key difference between the two types of reactor systems is that whereas in multimode cavities several reaction vessels can be irradiated simultaneously in multi-

vessel rotors (parallel synthesis), in monomode systems only one vessel can be irradiated at the time. In the latter case high throughput can be achieved by integrated robotics that move individual reaction vessels in and out of the microwave cavity. Most instrument companies offer a variety of diverse reactor platforms with different degrees of sophistication with respect to automation, database capabilities, safety features, temperature and pressure monitoring, and vessel design. Importantly, single-mode reactors processing comparatively small volumes also have a built-in cooling feature that allows for rapid cooling of the reaction mixture with compressed air after completion of the irradiation period (see Figure 2). The dedicated single-mode instruments available today can process volumes ranging from 0.2 to about 50 mL under sealed-vessel conditions (250°C, ca. 20 bar), and somewhat higher volumes (ca. 150 mL) under open-vessel reflux conditions. In the much larger multimode instruments several liters can be processed under both open- and closed-vessel conditions. Continuous-flow reactors are nowadays available for both single- and multimode cavities that allow the preparation of kilograms of materials by using microwave technology (see Section 2.10).[36–38]

2. Literature Survey

2.1. Scope and Organization of the Review

This Review highlights recent applications of controlled microwave heating technology in organic synthesis. The term "controlled" here refers to the use of a dedicated microwave reactor for synthetic chemistry purposes (single- or multi-mode). Therefore, the exact reaction temperature during the irradiation process has been adequately determined in the original literature source. Although the aim of this Review is not primarily to speculate about the existence or non-existence of microwave effects (see Section 1.2), the results of adequate control experiments or comparison studies with conventionally heated transformations will sometimes be presented. The reader should not draw any definitive conclusions about the involvement or non-involvement of "microwave effects" from those experimental results, because of the inherent difficulties in conducting such experiments (see above). In terms of processing techniques (Section 1.3), preference is given to transformations in solution under sealed-vessel conditions, since this reflects the recent trend in the literature, and these transformations are in principle scalable in either batch or continuous-flow modes. Sealed-vessel microwave technology was employed unless otherwise specifically noted. Most of the examples have been taken between 2002 and 2003. Earlier examples of controlled MAOS are limited and can be found in previous review articles and books.[4–16]

2.2. Transition-Metal-Catalyzed C—C Bond Formations

Homogeneous transition-metal-catalyzed reactions represent one of the most important and best studied reaction

types in MAOS. Transition-metal-catalyzed carbon–carbon and carbon–heteroatom bond-forming reactions typically need hours or days to reach completion with traditional heating under reflux conditions and often require an inert atmosphere. The research groups of Hallberg, Larhed, and others have demonstrated over the past few years that the rate of many of those transformations can be enhanced significantly by employing microwave heating under sealed-vessel conditions ("microwave flash heating"), in most cases without an inert atmosphere.[10] The use of metal catalysts in conjunction with microwaves may have significant advantages over traditional heating methods, since the inverted temperature gradients under microwave conditions (Figure 1) may lead to an increased lifetime of the catalyst through elimination of wall effects.[28,39]

2.2.1. Heck Reactions

The Heck reaction, a palladium-catalyzed vinylic substitution, is typically conducted with alkenes and organohalides or pseudohalides as reactants. Numerous elegant synthetic transformations based on C–C bond-forming Heck reactions have been developed both in classical organic synthesis and natural product chemistry.[40] Solution-phase Heck reactions were carried out successfully by MAOS as early as 1996, thereby reducing reaction times from several hours under conventional reflux conditions to sometimes less than five minutes.[41] These early examples of microwave-assisted Heck reactions have been extensively reviewed by Larhed and will not be discussed herein.[10]

Scheme 1 shows a recent example of a standard Heck reaction involving aryl bromides **1** and acrylic acid to furnish
Scheme 1. Examples of Heck Reactions carried out on a 2 and 80 mmol scale.

the corresponding cinnamic acids **2**.[42] Optimization of the reaction conditions under small-scale (2 mmol) single-mode microwave conditions led to a protocol that employed MeCN as the solvent, 1 mol% Pd(OAc)$_2$/P(o-tolyl)$_3$ as the catalyst system, and triethylamine as the base. The reaction time was 15 minutes at a reaction temperature of 180°C. Interestingly, the authors have discovered that the rather expensive homogeneous catalyst system can be replaced by 5% Pd/C (< 0.1 mol% concentration of Pd catalyst) without the need to change any of the other reaction parameters.[42] The yields for cinnamic acid derivative **2a** were very similar when either homogeneous or heterogeneous Pd catalysts were used in the Heck reaction. In the same article[42] the authors also demonstrate that it is possible to directly scale-up the 2-mmol Heck reaction to 80 mmol (ca. 120 mL total reaction volume) by switching from a single-mode to a larger multi-mode microwave cavity (see also Section 2.10). Importantly,

the optimized small-scale reaction conditions could be directly used for the larger scale reaction, thus giving rise to very similar product yields.

In 2002 Larhed and co-workers reported microwave-promoted Heck arylations in the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim]PF$_6$; Scheme 2).[43] Among the variety of possible "green" solvent
Scheme 2. Heck reactions in ionic liquids.

alternatives for catalytic and other reactions, nonvolatile room-temperature ionic liquids have attracted a considerable amount of attention in recent years.[44] Ionic liquids interact very efficiently with microwaves through the ionic conduction mechanism (see Section 1.1) and are rapidly heated at rates easily exceeding $10°Cs^{-1}$ without any significant pressure build-up. Therefore, safety problems arising from over-pressurization of heated sealed reaction vessels can be minimized.[45,46] In the Heck reactions shown in Scheme 2, 4 mol% of PdCl$_2$/P(o-tolyl)$_3$ was used. Full conversions were achieved within 5 (X = I) and 20 minutes (X = Br). Transformations that were performed without the phosphane ligand required 45 minutes. A key feature of this catalyst/ionic liquid system is the recyclability: the phosphane-free system PdCl$_2$/[bmim]PF$_6$ was recyclable at least five times. After each cycle, the volatile product was directly isolated in high yield by rapid distillation under reduced pressure.[43]

The concept of performing microwave synthesis in room-temperature ionic liquids has been applied to 1,3-dipolar cycloaddition reactions,[47] catalytic transfer hydrogenations,[48] ring-closing metathesis,[49] and the conversion of alcohols into alkyl halides.[50] As an alternative to the use of the rather expensive ionic liquids as solvents, several research groups have used ionic liquids as "doping agents" for microwave heating of otherwise nonpolar solvents such as hexane, toluene, THF, or dioxane. This technique, first introduced by Ley et al. in 2001 (see Section 2.9.4),[51] is becoming increasingly popular, as demonstrated by the many recently published examples.[52–60] Systematic studies on temperature profiles and the thermal stability of ionic liquids under microwave irradiation conditions by Leadbeater and Torenius[52,53] have shown that addition of a small amount of an ionic liquid (0.1 mmol mL^{-1} solvent) suffices to obtain dramatic changes in the heating profiles by changing the overall dielectric properties (namely, tanδ) of the reaction medium.

Larhed and co-workers have exploited the combination of [bmim]PF$_6$ and dioxane in the Heck coupling of both electron-rich and electron-poor aryl chlorides with butyl acrylate (Scheme 3).[56] Transition-metal-catalyzed carbon–carbon bond-forming reactions involving unreactive aryl chlorides have represented a synthetic challenge for a long time. Only recently, as a result of advances in the develop-
Scheme 3. Heck reactions of aryl chlorides with air-stable phosphonium salts as ligand precursors. Electron-rich and electron-poor aryl chlorides are equally suitable substrates.

ment of highly active catalyst/ligand systems, have those transformations been accessible.[61] For the Heck coupling shown in Scheme 3, the air-stable but highly reactive [(tBu)$_3$PH]BF$_4$ phosphonium salt described by Netherton and Fu[62] was employed as a ligand precursor using the palladacycle *trans*-di(μ-acetato)bis[*o*-di-*o*-tolylphosphanyl)-benzyl]dipalladium(II)[63] developed by Herrmann et al. as the palladium precatalyst. Depending on the reactivity of the aryl chloride, 1.5–10 mol% of Pd catalyst (3–20% of ligand), 1.5 equivalents of Cy$_2$NMe as a base, and 1.0 equivalent of [bmim]PF$_6$ in dioxane were irradiated at 180°C under sealed-vessel conditions (no inert gas atmosphere) with the aryl chloride and butyl acrylate for 30–60 min. The desired cinnamic esters were obtained in moderate to excellent yields under these optimized conditions (Scheme 3).[56]

A synthetically useful application of an intramolecular microwave-assisted Heck reaction was described by Gracias et al. (Scheme 4).[64] In their approach toward the synthesis of
Scheme 4. Sequential Ugi reactions and Heck cyclizations for the synthesis of seven-membered N-heterocycles.

seven-membered N-heterocycles, the initial product of an Ugi four-component reaction was subjected to an intramolecular Heck cyclization using 5 mol% Pd(OAc)$_2$/PPh$_3$ as the catalytic system. Microwave irradiation at 125°C in acetonitrile for 1 h provided 98% yield of the product shown in Scheme 4. A number of related sequential Ugi reaction/Heck cyclizations were reported in the original publication, also involving aryl bromides instead of iodides.

A very recent addition to the already powerful spectrum of microwave Heck chemistry is the development of a general procedure for carrying out oxidative Heck couplings, that is, the Pd^{II}-catalyzed carbon–carbon coupling of aryl boronic acids with alkenes using Cu(OAc)$_2$ as a reoxidant (100–170°C, 5–30 min).[65]

2.2.2. Suzuki Reactions

The Suzuki reaction (the palladium-catalyzed cross-coupling of aryl halides with boronic acids) is arguably one of the most versatile and at the same time also one of the most often used cross-coupling reactions in modern organic synthesis.[66,67] Carrying out high-speed Suzuki reactions under controlled microwave conditions can be considered almost a routine synthetic procedure today, given the enormous literature precedent for this transformation.[10] Recent examples include the use of the Suzuki protocol for the high-speed modification of various heterocyclic scaffolds of pharmacological or biological interest.[68–74]

A significant advance in Suzuki chemistry has been the observation that Suzuki couplings can be readily carried out using water as the solvent in conjunction with microwave heating.[75–79] Water, being cheap, readily available, nontoxic, and nonflammable, has clear advantages as a solvent for use in organic synthesis. With its comparatively high loss factor (tanδ) of 0.123 (see Table 1), water is also a potentially very useful solvent for microwave-mediated synthesis, especially in the high-temperature region accessible by using sealed vessel technology. Leadbeater and Marco have recently described very rapid, ligand-free palladium-catalyzed aqueous Suzuki couplings of aryl halides with aryl boronic acids (Scheme 5).[75] Key to the success of this method was the
Scheme 5. Ligand-free Suzuki reactions with TBAB as an additive.

use of 1.0 equivalents of tetrabutylammonium bromide (TBAB) as a phase-transfer catalyst. The role of the ammonium salt is to facilitate the solubility of the organic substrates and to activate the boronic acid by formation of [R$_4$N]$^+$[ArB(OH)$_3$)]$^-$. A wide variety of aryl bromides and iodides were successfully coupled with aryl boronic acids by using controlled microwave heating at 150°C for 5 minutes with only 0.4 mol% of Pd(OAc)$_2$ as catalyst (Scheme 5).[75] Aryl chlorides also reacted but required higher temperatures (175°C).

The same Suzuki couplings could also be performed under microwave-heated open-vessel reflux conditions (110°C, 10 min) on a tenfold scale and gave nearly identical yields to the closed-vessel reactions.[76,77] Importantly, nearly the same yields were also obtained when the Suzuki reactions were carried out in a preheated oil bath (150°C) instead of using microwave heating, clearly indicating the absence of any specific or nonthermal microwave effects (see Section 1.2).[76]

The same authors have reported another modification in which, surprisingly, it was also possible to carry out the Suzuki reactions depicted in Scheme 5 in the absence of the palladium catalyst![78,79] These transition-metal-free aqueous Suzuki-type couplings again utilized 1.0 equivalent of TBAB

as an additive, 3.8 equivalents of Na₂CO₃ as a base, and 1.3 equivalents of the corresponding boronic acid (150 °C, 5 min). High yields were obtained with aryl bromides and iodides whereas aryl chlorides proved unreactive under the conditions used. The reaction is also limited to electron-poor or electron-neutral boronic acids. While the exact mechanism of this unusual transformation remains unknown, one possibility would be a radical pathway where the reaction medium, water, provides an enhanced π-stacking interaction as a result of the hydrophobic effect.[67]

The large number of boronic acids that are commercially available makes the Suzuki reaction and related types of coupling chemistry highly attractive in the context of high-throughput synthesis and derivatization. In addition, boronic acids are air and moisture stable, of relatively low toxicity, and the boron-derived by-products can easily be removed from the reaction mixture. Therefore, it is not surprising that efficient and rapid microwave-assisted protocols have been developed for their preparation. In 2002 Fürstner and Seidel outlined the synthesis of pinacol aryl boronates from aryl chlorides bearing electron-withdrawing groups and commercially available bis(pinacol)borane (**3**), using a palladium catalyst formed in situ from Pd(OAc)₂ and imidazolium chloride **5** (Scheme 6, X = Cl).[80] The very reactive N-
Scheme 6. Palladium-catalyzed formation of aryl boronates from electron-rich and electron-poor (hetero)aryl halides.

heterocyclic carbene (NHC) ligand (6–12 mol %) allowed this transformation to proceed to completion within 10–20 minutes at 110 °C in THF by using microwave irradiation in sealed vessels. The conventionally heated process (reflux THF (ca. 65 °C), argon atmosphere) gave comparable yields, but required 4–6 h to reach completion. Dehaen and co-workers subsequently disclosed a complementary approach in which electron-rich aryl bromides were used as substrates (Scheme 6, X = Br) and 3 mol % [Pd(dppf)Cl₂] (dppf = 1,1'-bis(diphenylphosphanyl)ferrocene) was used as the catalyst.[81] A somewhat higher reaction temperature (125–150 °C) was employed to produce a variety of different aryl boronates in good to excellent yields.[81] High-speed microwave-assisted trifluoromethanesulfonation (triflation) reactions of phenols with N-phenyltrifluorosulfonimide (120 °C, 6 min) have also been reported in the literature.[82]

2.2.3. Sonogashira Reactions

The Sonogashira reaction (palladium/copper-catalyzed coupling of terminal acetylenes with aryl and vinyl halides)

enjoys considerable popularity as a reliable and general method for the preparation of unsymmetrical alkynes.[83] General protocols for microwave-assisted Sonogashira reactions under controlled conditions were first reported in 2001 by Erdélyi and Gogoll.[84] Typical reaction conditions for the coupling of aryl iodides, bromides, chlorides, and triflates involve DMF as the solvent, diethylamine as the base, and [PdCl₂(PPh₃)₂] (2–5 mol %) as the catalyst with CuI (5 mol %) as an additive.[84] Gogoll and co-workers later utilized these protocols in a rapid domino Sonogashira sequence to synthesize amino ester **6** (Scheme 7).[85]
Scheme 7. Domino Sonogashira sequence for the synthesis of bis(aryl)acetylenes.

Essentially the same experimental protocol was employed by Vollhardt and co-workers to synthesize *o*-dipropynylated arene **8**, which served as the precursor to tribenzocyclyne **9** through an alkyne metathesis reaction (Scheme 8).[86] In this
Scheme 8. Double Sonogashira reactions under propyne pressure.

case the Sonogashira reaction was carried out in a pre-pressurized (ca. 2.5 atm of propyne) sealed microwave vessel. Double Sonogashira coupling of the dibromodiiodobenzene **7** was completed within 3.75 minutes at 110 °C. It is worth mentioning that the authors have not carried out the corresponding tungsten-mediated alkyne metathesis chemistry under microwave conditions to shorten the exceedingly long reaction times and perhaps to improve the low yield (see

Scheme 16 for a microwave-assisted alkyne metathesis reaction). Additional examples of microwave-assisted Sonogashira couplings in the derivatization of pyrazinones[70] and pyrimidine[87] scaffolds have been reported.

As with the Suzuki reaction, there have been two recent independent reports by the groups of Leadbeater and Van der Eycken[88] that have shown that it is also possible to perform transition-metal-free Sonogashira couplings. Again, these methods rely on the use of microwave-heated water as the solvent, a phase-transfer catalyst (TBAB or polyethylene glycol), and a base (NaOH or Na$_2$CO$_3$). So far these metal-free procedures have been successful for aryl bromides and iodides, and typical reaction conditions involve heating to about 170°C for 5–25 minutes. A recent report by He and Wu describes a copper-catalyzed (palladium-free) Sonogashira-type cross-coupling reaction.[89]

2.2.4. Stille, Negishi, and Kumada Reactions

Microwave-assisted Stille reactions involving organotin reagents as coupling partners were reviewed in 2002.[10] Until recently, very little work was published on Negishi (organozinc reagents) and Kumada (organomagnesium reagents) cross-coupling reactions under microwave conditions. There are two examples in the peer-reviewed literature describing Negishi cross-coupling reactions of activated aryl bromides[90] and heteroaryl chlorides[91] with organozinc halides.

A general procedure describing high-speed microwave-assisted Negishi and Kumada couplings of unactivated aryl chlorides was recently reported (Scheme 9).[92] This procedure
Scheme 9. Negishi and Kumada cross-coupling reactions.

uses 0.015–2.5 mol% of [Pd$_2$(dba)$_3$] as a palladium source and the air-stable [(tBu)$_3$PH]BF$_4$ phosphonium salt (see Scheme 3) as ligand precursor. Successful couplings were observed for both aryl organozinc chlorides and iodides. By using this methodology it was also possible to successfully couple aryl chlorides with alkyl zinc reagents such as *n*-butylzinc chloride very rapidly without the need for an inert atmosphere. The optimized conditions involved the use of sealed-vessel microwave irradiation at 175°C for 10 minutes. Grignard reactions were also carried out successfully by applying the same reaction conditions (Scheme 9). In the same article the authors also describe microwave-assisted methods for the preparation of the corresponding organozinc and magnesium compounds.[92]

In addition to the classical Negishi cross-coupling in which organozinc reagents are utilized, the "zirconium version" involving the coupling of zirconocenes with aryl halides has also been described by using sealed-vessel microwave technology. Lipshutz and Frieman have reported the rapid coupling of both vinyl and alkyl zirconocenes (prepared in situ by hydrozirconation of alkynes or alkenes, respectively), with aryl iodides, bromides, and chlorides (Scheme 10).[93] While aryl iodides required only 5 mol%
Scheme 10. Nickel-catalyzed cross-coupling of alkenyl and alkyl zirconocenes with aryl halides.

Ni/C as a ligand-free heterogeneous catalytic system, the presence of triphenylphosphane as a ligand was necessary to successfully couple aryl bromides (10 mol%) and chlorides (20 mol% ligand). Full conversion was achieved under those conditions within 10–40 min at 200°C using THF as the solvent.

2.3. Transition-Metal-Catalyzed Carbon–Heteroatom Bond Formation

2.3.1. Buchwald–Hartwig Reactions

The research groups of Buchwald[94] and Hartwig[95] have developed a large variety of useful palladium-mediated methods for C–O and C–N bond formation. These arylations have been enormously popular in recent years. A vast amount of published material is available describing a wide range of palladium-catalyzed methods, ligands, solvents, temperatures, and substrates which has led to a broad spectrum of tunable reaction conditions that allows access to most target molecules that incorporate an aryl amine motif.

In 2002 Alterman and co-workers described the first high-speed Buchwald–Hartwig aminations by controlled microwave heating (Scheme 11).[96] The best results were obtained in DMF as the solvent without an inert atmosphere by employing 5 mol% of Pd(OAc)$_2$ as precatalyst and 2,2'-bis(diphenylphosphanyl)-1,1'-binaphthyl (binap) as the ligand. The procedure proved to be quite general and provided moderate to high yields for both electron-rich and electron-poor aryl bromides. Caddick and co-workers were also able to extend this rapid amination protocol to electron-rich aryl chlorides by utilizing more reactive discrete Pd–N-heterocyclic carbene (NHC) complexes or in situ generated palladium/imidazolium salt complexes (1 mol%, Scheme 11).[97]

Independent investigations by Maes and co-workers have described the use of 2-(dicyclohexylphosphanyl)biphenyl as a
Scheme 11. Buchwald–Hartwig amination reactions.

ligand for the successful and rapid Buchwald–Hartwig coupling of (hetero)aryl chlorides with amines under microwave conditions (0.5–2 mol% Pd catalyst).[98] Microwave-assisted palladium-catalyzed aminations have been reported on a number of different substrates, including bromoquinolines,[99] aryl triflates,[100] intramolecular aminations for the synthesis of benzimidazoles,[101] and the coupling of aryl chlorides with sulfonamides.[102]

Direct palladium- or nickel-catalyzed carbon–phosphorous couplings of aryl iodides, bromides, and triflates with diphenylposphane in the presence of a base such as KOAc or diazobicyclo[2.2.2]octane (DABCO) are also reported to result in the rapid formation of triarylphosphanes.[103]

2.3.2. Ullmann Condensation Reactions

A recent survey of the literature on the Ullmann and related condensation reactions has highlighted the growing importance and popularity of copper-mediated C–N, C–O, and C–S bond-forming protocols.[104] Scheme 12 shows two
Scheme 12. Ullmann-type carbon–nitrogen and carbon–sulfur bond formations.

examples of microwave-assisted Ullmann-type condensations from researchers at Bristol–Myers Squibb. In the first example, (S)-1-(3-bromophenyl)ethylamine was coupled with eleven heteroarenes containing N-H groups in the presence of 10 mol% CuI and 2.0 equivalents of K_2CO_3 base.[105,106] The comparatively high reaction temperature (195°C) and the long reaction times are noteworthy. For the coupling of 3,5-dimethylpyrazole, for example, microwave heating for 22 h was required to afford a 49% yield of the

isolated product! The average reaction times were 2–3 h. In the second example, similar conditions were chosen to react mainly aromatic thiols with aryl bromides and iodides to afford aryl sulfides.[107] The same authors have also described the synthesis of diaryl ethers by copper-catalyzed arylation of phenols with aryl halides.[108]

2.4. Transition-Metal-Catalyzed Carbonylation Reactions

Larhed and co-workers took advantage of the rapid and controlled heating made possible by microwave irradiation of solvents under sealed-vessel conditions and reported a number of valuable palladium-catalyzed carbonylation reactions (Scheme 13).[109–113] The key feature of all those proto-
Scheme 13. Palladium-catalyzed aminocarbonylations. Diglyme = diethyleneglycol dimethylether.

cols is the use of molybdenum hexacarbonyl as a solid precursor of carbon monoxide, which is required in carbonylation chemistry. $[Mo(CO)_6]$ liberates enough CO in situ at 150°C, for example, that rapid aminocarbonylation reactions take place (at 210°C, CO is liberated instantaneously). The initially reported conditions used a combination of the palladacycle developed by Herrmann and co-workers (7.4 mol% Pd) and binap as the catalytic system in a diglyme/water mixture and provided the desired secondary and tertiary amides in high yield (Scheme 13).[109] As in many other cases, an inert atmosphere was not required.

Subsequent improvements in the experimental protocol allowed the use of sterically and electronically more-demanding amines (for example, anilines, unprotected amino acids), whereby DBU was used as the base and THF as the solvent for both aryl bromides and iodides.[110] Simple modifications of the general strategy outlined in Scheme 13 enabled the corresponding carboxylic acids[109] and esters[111] to be obtained instead of the amides. Further modifications by Alterman and co-workers have resulted in the use of DMF as a source of CO[112] and the use of formamide as a combined source of NH_3 and CO.[113] The latter method is useful for the preparation of primary aromatic amides from aryl bromides. In both cases, strong bases and temperatures around 180°C (7–20 min) have to be used to mediate the reaction.

A somewhat related process is the cobalt-mediated synthesis of symmetrical benzophenones from aryl iodides and $[Co_2(CO)_8]$ (Scheme 14).[114] Here, $[Co_2(CO)_8]$ is used as a combined activator of the aryl iodide and as CO source. A variety of aryl iodides with different steric and electronic properties underwent the carbonylative coupling in excellent yields when acetonitrile was employed as the solvent. Remarkably, six seconds of microwave irradiation were in

several cases sufficient to achieve full conversion! The use of an inert atmosphere, bases, or other additives were unnecessary. No conversion occurred in the absence of heating, regardless of the reaction time. However, equally high yields could also be achieved by heating the reaction mixture in an oil bath for two minutes.

2.5. Asymmetric Allylic Alkylations

A frequent criticism of microwave synthesis has been that the typically high reaction temperatures will invariably lead to reduced selectivities. This is perhaps the reason why comparatively few enantioselective processes driven by microwave heating have been reported in the literature. For a reaction to occur with high enantioselectivity there must be a large enough difference in the activation energy for the processes leading to the two enantiomers. The higher the reaction temperature, the larger the difference in energy required to achieve high selectivity. Despite these limitations, a number of very impressive enantioselective reactions involving chiral transition-metal complexes have been described. The research groups of Moberg, Hallberg, and Larhed reported on microwave-mediated palladium-[115,116] and molybdenum-catalyzed[117–119] asymmetric allylic alkylation reactions involving neutral carbon, nitrogen, and oxygen nucelophiles in 2000. Both processes were carried out under non-inert conditions and yielded the desired products in high chemical yield and with typical *ee* values of > 98%.

More recently, Trost and Andersen have applied this concept in their approach to the orally bioavailable HIV inhibitor tipranavir (Scheme 15).[120] Synthesis of the key
chiral intermediate **13** was achieved by asymmetric allylic alkylation starting from carbonate **11**. A 94% yield of the product was achieved by employing 10 mol% of the molybdenum precatalyst and 15 mol% of the chiral ligand **12** with 2.0 equivalents of sodium dimethylmalonate as the additive. The reaction was carried out under sealed-vessel microwave heating at 180°C for 20 minutes. Thermal heating under reflux conditions (67°C) required 24 h and produced the same chemical yield of intermediate **13**, albeit in slightly higher enantiomeric purity (96% *ee*).

A similar pathway involving a microwave-driven molybdenum-catalyzed asymmetric allylic alkylation (160°C, 6 min, THF) as the key step was elaborated by Moberg and co-workers for the preparation of the muscle relaxant (*R*)-baclofen.[121] Other enantioselective reactions performed by microwave heating include asymmetric Heck reactions[122] and ruthenium-catalyzed asymmetric hydrogen transfer processes.[123]

2.6. Other Transition-Metal-Mediated Processes

In recent years the olefin metathesis reaction has attracted widespread attention as a versatile carbon–carbon bond-forming method.[124] Among the numerous different metathesis methods, ring-closing metathesis (RCM) has emerged as a very powerful method for the construction of small, medium, and macrocyclic ring systems.[124] In general, metathesis reactions are carried out at room or at slightly elevated temperatures (for example, at 40°C in refluxing CH$_2$Cl$_2$), sometimes requiring several hours of reaction time to achieve full conversion. With microwaves, otherwise sluggish RCM protocols have been reported to be completed within minutes or even seconds.[49,55,71,125–128] In 2003, for example, Efskind and Undheim reported the domino RCM of dienyne **14** with a Grubbs type II catalyst (Scheme 16).[127] While the thermal process (toluene, 85°C) required multiple addition of fresh catalyst (3 × 10 mol%) over a period of 9 h to furnish a 92% yield of product **15**, microwave irradiation for 10 min at 160°C (5 mol% catalyst, toluene) led to full conversion. The authors ascribe the dramatic rate enhancement to the rapid and uniform heating of the reaction mixture and increased catalyst lifetime by the elimination of wall effects.[127]

An interesting ring-closing alkyne metathesis reaction (RCAM) was recently reported by Fürstner et al. (Scheme 16).[128] Treatment of diyne **16** with 10 mol% of the catalyst prepared in situ from [Mo(CO)$_6$] and 4-trifluoromethylphenol at 150°C for 5 minutes led to a 69% yield of cycloalkyne **17**, which was further manipulated into a naturally occurring DNA cleaving agent of the turriane family. Conventional heating under reflux conditions in chlorobenzene for 4 h produced a 83% yield of product under otherwise identical conditions.

The [2+2+1] cycloaddition of an alkene, an alkyne, and carbon monoxide is often the method of choice for the preparation of complex cyclopentenones.[129] Groth and co-workers have demonstrated that such Pauson–Khand reactions can be carried out very efficiently with microwave heating (Scheme 17);[130] 20 mol% of [Co$_2$(CO)$_8$] was suffi-

cient to drive all of the studied Pauson–Khand reactions to completion under sealed-vessel conditions, without the need for additional carbon monoxide. Under the carefully optimized reaction conditions utilizing 1.2 equivalents of cyclohexylamine as an additive in toluene, microwave heating for 5 minutes at 100 °C provided good yields of the desired cycloadducts.[130] Similar results were published independently by Evans and co-workers.[131]

Another important reaction principle in modern organic synthesis is C–H bond activation.[132] Bergman, Ellman, and co-workers have introduced a protocol that allows otherwise extremely sluggish inter- and intramolecular rhodium-catalyzed C–H bond activation to occur efficiently under microwave heating conditions. In their investigations, they found that heating the olefin-tethered benzimidazoles **18** in a mixture of 1,2-dichlorobenzene and acetone in the presence of 2.5–5 mol% [{RhCl(coe)$_2$}$_2$] (coe = cyclooctene) and 5–10 mol% PCy$_3$·HCl provided the desired tricyclic heterocyles **19** in moderate to excellent yields (Scheme 18).[133] Microwave heating to 225–250 °C for 6–12 min proved to be the optimum conditions. The solvents were not degassed or dried before use, but air was excluded by purging the reaction vessel with nitrogen.

2.7. Heterocycle Synthesis

The formation of heterocyclic rings by cyclocondensation reactions is typically a process well-suited for microwave technology. Many of these condensation reactions require high temperatures and conventional reaction conditions very often involve heating the reactants in an oil, metal, or sand bath for many hours or even days. One representative example is the formation of 4-hydroxy-1*H*-quinolin-2-ones of type **22** from anilines and malonic esters (Scheme 20). The corresponding conventional, thermal protocol involves heating the two components in equimolar amounts in an oil bath at 220–300 °C for several hours (without solvent),[136] whereas similar high yields can be obtained by microwave heating at 250 °C for 10 minutes.[137] Here it was essential to use open-vessel technology, since the two equivalents of the volatile by-product ethanol that formed under normal (atmospheric pressure) conditions were simply distilled off and therefore
Scheme 20. Formation of 4-hydroxy-1*H*-quinolin-2-one **22** from aniline **20** and malonic ester **21**.

removed from the equilibrium (Scheme 20).[136] Preventing removal of ethanol from the reaction mixture, by using a standard closed-vessel microwave system, leads to significantly lower yields (Table 3). These experiments highlight the

Table 3: Yields for **22** on microwave heating under closed- and open-vessel conditions (Scheme 20).[a,b]

x [mmol][c]	Solvent [mL]	Yield [%]	p [bar]
1	2	76	3.6
2	2	67	5.3
4	2	60	7.4
1	0.5	91	2.0
2	–	92	[d]
4	–	90	[d]

importance of choosing appropriate experimental conditions when using microwave heating technology. In the present example, scale-up of the synthesis shown in Scheme 20 would clearly only be feasible by using open-vessel technology.[138]

A related cyclocondensation was recently described by Besson and co-workers in the context of synthesizing 8*H*-quinazolino[4,3-*b*]quinazolin-8-ones by Niementowski condensation reactions (Scheme 21).[139] In the first step of this multistep sequence, anthranilic acid derivatives **23** were condensed with formamide (5.0 equiv) under open-vessel microwave conditions (Niementowski condensation).[140] Subsequent chlorination with excess POCl₃, again using open-vessel conditions, produced the anticipated 4-chloroquinazoline derivatives **25**, which were subsequently condensed with **23** in acetic acid to produce the tetracyclic target structures **26**. The final condensation reactions were completed within 20 minutes at reflux (ca. 105 °C) under open-vessel conditions, but not surprisingly could also be performed more rapidly by using sealed-vessel heating at 130 °C. The reaction depicted in Scheme 21 is one of the growing number of examples where not only one, often conventionally difficult to execute transformation has been carried out by microwave synthesis, but several steps in a sequence have been performed by microwave dielectric heating.

Molteni et al. have described the three-component, one-pot synthesis of fused pyrazoles by treating cyclic 1,3-
Scheme 21. Formation of 8*H*-quinazolino[4,3-*b*]quinazolin-8-ones **26** by Niementowski condensation.

diketones with dimethylformamide dimethylacetal (DMFDMA) and a suitable bidentate nucleophile such as a hydrazine derivative (Scheme 22).[141] The reaction proceeds
Scheme 22. Three-component condensation of fused pyrazoles in water.

with initial formation of an enaminoketone as the key intermediate from the 1,3-diketone and DMFDMA precursors, followed by a tandem addition-elimination/cyclodehydration step. Remarkably, the authors were able to perform the multicomponent condensation by heating all three building blocks together with a small amount of acetic acid (2.6 equiv) in water at 220 °C for 1 minute! Upon cooling the reaction, the desired products crystallized directly and were isolated in high purity by simple filtration. Although most of the starting materials are actually insoluble in water at room temperature, at 220 °C water behaves similar to an organic solvent and is therefore able to dissolve many organic materials that are otherwise not soluble in such a polar solvent. It should be emphasized that high-temperature water chemistry at near-critical conditions (ca. 275 °C, 60 bar) has received considerable attention in recent years,[142] and that sealed-vessel microwave heating technology appears to be an ideal tool to rapidly attain this environment.[5,143] Molteni et al. have successfully used other bidentate nucleophiles such as amidines and hydroxylamine for the synthesis of related heterocycles.[141] Numerous reports of the use of DMFDMA as a building block for the rapid synthesis of a large variety of heterocyclic ring systems by MAOS have also appeared.[144–147]

The Bohlmann–Rahtz synthesis of trisubstituted pyridines from β-aminocrotonates and an ethynyl ketone has found application in the preparation of a variety of heterocycles

containing this structural motif.[148] Bagley et al. have developed a microwave-assisted modification of this heteroannulation method, which is best conducted in DMSO at 170 °C for 20 minutes, and provides the desired pyridine derivatives in 24–94 % yield (Scheme 23).[149] A related protocol involving a tandem oxidation/heteroannulation of propargylic alcohols was described by the same authors.[150]
Scheme 23. Bohlmann–Rahtz synthesis of trisubstituted pyridines.

Cycloaddition reactions are clearly very important for the construction of heterocycles, and numerous examples of heterocycle synthesis by controlled microwave heating have been described. For example, nitro alkenes are converted in situ into nitrile oxides by 4-(4,6-dimethoxy[1,3,5]triazin-2-yl)-4-methylmorpholinium chloride (DMTMM) and 4-dimethylaminopyridine (DMAP, Scheme 24).[151] The generated
Scheme 24. Nitrile oxide cycloaddition reactions.

1,3-dipoles undergo cycloaddition with the double or triple bond of an alkene or acetylene dipolarophile (5.0 equiv), respectively, to furnish 4,5-dihydroisoxazoles or isoxazoles. Open-vessel conditions were used and full conversion with very high yields of products was achieved within 3 minutes at 80 °C.

An unusual class of heterocycles are polyketide-derived macrodiolide natural products. The research groups of Porco and Panek have recently shown that stereochemically well-defined macrodiolides can be obtained by cyclodimerization of nonracemic chiral hydroxy esters (Scheme 25).[152] Preliminary experiments involving microwave irradiation demonstrated that exposing dilute solutions of the hydroxy ester (0.02 M) in chlorobenzene to sealed-vessel microwave irradiation conditions (200 °C, 7 min) in the presence of a distannoxane transesterification catalyst led to a 60 % yield of the 16-membered macrodiolide heterocycle. Conventional
Scheme 25. Formation of macrodiolides by cyclodimerization with a distannoxane catalyst.

reflux conditions (ca. 135 °C) in the same solvent (0.01 M of hydroxy ester) provided a 75 % yield after 48 h.

Multicomponent reactions (MCRs) are of increasing importance in organic and medicinal chemistry. In times where a premium is put on speed, diversity, and efficiency in the drug discovery process, MCR strategies offer significant advantages over conventional linear-type syntheses.[153] The Ugi four-component condensation in which an amine, an aldehyde or ketone, a carboxylic acid, and an isocyanide combine to yield an α-acylaminoamide is particularly interesting because of the wide range of products obtainable through variation of the starting materials.[154] The reaction of heterocyclic amidines with aldehydes and isocyanides in the presence of 5 mol % Sc(OTf)$_3$ as a catalyst in an Ugi-type three-component condensation (Scheme 26) generally
Scheme 26. Ugi-type three-component condensation.

requires extended reaction times of up to 72 h at room temperature for the generation of the desired fused 3-aminoimidazoles.[155] Tye and co-workers have demonstrated that this process can be speeded up significantly by performing the reaction under sealed-vessel microwave conditions.[156] A reaction time of 10 min at 160 °C in methanol (in some cases ethanol was employed) produced similar yields of products than the same process at room temperature, but at a fraction of the time.

Another important MCR is the Biginelli synthesis of dihydropyrimidines by the acid-catalyzed condensation of aldehydes, CH-acidic carbonyl components, and urea-type building blocks (Scheme 27).[157] Under conventional conditions this MCR typically requires several hours of heating under reflux conditions (ca. 80 °C) in a solvent such as ethanol. The ideal microwave heating conditions with respect to solvent, catalyst type/concentration, irradiation time, and temperature were rapidly optimized by using the condensation of benzaldehyde, ethyl acetoacetate, and urea as a model reaction.[158] Figure 3 shows the time/temperature optimization profile for the standard Biginelli reaction using 10 mol %
Scheme 27. Biginelli synthesis of dihydropyrimidines through a three-component reaction. Tf = trifluoromethanesulfonyl.
Figure 3. Rapid optimization of reaction time and temperature for the Biginelli condensation of ethyl acetoacetate, benzaldehyde, and urea (Scheme 27) in AcOH/EtOH (3:1) with 10 mol% Yb(OTf)₃ as a catalyst. The optimal conditions (marked in black: 120°C, 10 min) affords the product in 92% yield.

ytterbium triflate in a acetic acid/ethanol (3:1). An optimum yield of 92% of isolated dihydropyrimidine ($R^1 = H$, $Z = O$, $R^2 = Ph$, $E = CO_2Et$, $R^3 = Me$) was obtained by heating the mixture of reactants at 120°C for 10 minutes. The fact that a temperature only marginally higher than the optimal reaction temperature leads to a significantly decreased yield for this transformation[159] underscores the importance of using controlled microwave irradiation conditions with adequate temperature control.

Figure 3 illustrates one of the key advantages of high-speed microwave synthesis, namely the rapid optimization capabilities that are particularly useful if microwave heating is coupled with automation.[158] Recent work by researchers from Arqule and Pfizer has demonstrated how the overall process can be further improved if rapid testing and tuning of reaction conditions involving microwave heating is coupled with statistical experimental design.[160] This is a particularly valuable method if a large number of reaction parameters needs to be considered.

The above-mentioned robotics are also useful for preparing compound libraries through automated sequential microwave synthesis. A diverse set of 17 CH-acidic carbonyl compounds, 25 aldehydes, and 8 urea/thioureas was used for the preparation of a dihydropyrimidine library under the optimized conditions for the Biginelli reaction displayed in Scheme 27. Out of the full set of 3400 possible dihydropyr-

imidine derivatives, a representative subset of 48 analogues was prepared within 12 h by automated addition of building blocks and subsequent sequential microwave irradiation of each reaction vessel in a single-mode microwave reactor equipped with suitable robotics.[158]

In a conceptually different approach, Nüchter, Ondruschka et al. presented the parallel generation of a 36-member library of Biginelli dihydropyrimidines in a suitable multivessel rotor placed inside a dedicated multimode microwave reactor.[161,162] Given the fact that modern multimode microwave reactors can operate with specifically designed 96-well plates under sealed-vessel conditions, the parallel approach offers a considerable higher throughput than the automated sequential technique, albeit at the cost of having less control over the reaction parameters for each individual vessel/well. One additional limitation of the parallel approach is that all reaction vessels during library production are exposed to the same irradiation conditions in terms of reaction time and microwave power, thus not allowing specific needs of individual building blocks to be addressed by varying the time or temperature.

A range of other heterocyclic ring systems synthesized by microwave-assisted cyclocondensation or cycloaddition protocols is shown in Schemes 28 and 29.

2.8. Miscellaneous Solution-Phase Organic Transformations

Since MAOS is becoming an increasingly popular tool for a steadily growing number of researchers, both in academia and industry, it becomes evident that, in principle, all chemical transformations requiring heat can be carried out under microwave conditions. The following literature survey of organic chemical transformations carried out in the solution phase by microwave heating is therefore limited to selected examples that highlight particularly interesting reactions or applications.

2.8.1. Rearrangements

Ley and co-workers have described the microwave-assisted Claisen rearrangement of allyl ether **27** in their synthesis of the natural product carpanone (Scheme 30).[173] A 97% yield of the rearranged product **28** could be obtained by three successive 15-minute irradiations at 220 °C using

toluene doped with the ionic liquid [bmim]PF$_6$ as the solvent. Interestingly, one single irradiation of 45 minutes at the same temperature gave a somewhat lower yield (86%).

A related Claisen rearrangement, albeit on a much more complex substrate was reported by the same research group, again under "pulsed" microwave irradiation conditions. Heating a solution of the propargylic enol ether **29** in dichlorobenzene at 180 °C for 15 minutes resulted in a 71% yield of the desired allene **30** as a single diastereomer, which was further elaborated into the skeleton of the triterpenoid natural product azadirachtin.[174] An 88% yield of product was obtained by applying 15 pulses irradiation of 1 minute duration. No rationalization for the increased yields in these "pulsed versus continuous irradiation" experiments can be given at present. Nordmann and Buchwald recently reported the diastereoselective Claisen rearrangement of allyl vinyl ether **31** to aldehyde **32**.[175] The product was obtained in 80% yield with a diastereomeric ratio of 91:9 by microwave heating at 250 °C for 5 minutes in DMF. Conventional heating at 120 °C for 24 hours provided somewhat higher yields and selectivities (90% yield, d.r. = 94:6).

In their search for synthetic routes to analogues of the furaquinocin antibiotics, Trost et al. have utilized a microwave-assisted squaric acid/vinylketene rearrangement to synthesize dimethoxynaphthoquinone **34**, a protected analogue of furaquinocin E (Scheme 31).[176] Since the conventional rearrangement conditions successfully applied in a closely related series of transformations (toluene, 110 °C) led to incomplete conversion, the reaction was attempted by microwave heating at 180 °C; this afforded an acceptable yield of **34** (58%) after oxidation to the naphthoquinone.

2.8.2. Cycloaddition Reactions

Cycloaddition reactions were among the first transformations to be studied by using microwave heating technology,[3, 7] and numerous examples have been summarized in previous review articles and book chapters.[4–16] Conventional cycloaddition reactions require, in many cases, the use of harsh conditions such as high temperatures and long reaction times, but they can be performed with great success with the aid of
Scheme 31. Rearrangement of a squaric acid derivative to a vinyl-ketene, which further reacts to form the tricyclic product **34**.

microwave heating. Scheme 32 shows two recent examples of Diels–Alder cycloadditions performed by microwave dielectric heating. In both cases the diene and dienophile were
Scheme 32. Examples of Diels–Alder cycloadditions.

reacted neat without the addition of solvent. For the transformation **35**→**36** described by Trost and Crawley, irradiation for 20 minutes at 165 °C (or for 60 min at 150 °C) gave the cycloadduct **36** in near quantitative yield.[177] In the process reported by de la Hoz and co-workers, open-vessel irradiation of 3-(2-arylethenyl)chromones with maleimides at 160–200 °C for 30 minutes furnished the tetracyclic adducts of type **37** along with minor amounts of other diastereoisomers.[178]

Inter- and intramolecular hetero-Diels–Alder cycloaddition reactions of a series of functionalized 2(1H)-pyrazinones

have been studied in detail by the research group of Van der Eycken (Scheme 33).[54,179,180] In the intramolecular series, cycloaddition of alkenyl-tethered 2(1H)-pyrazinones **38** requires 1–2 days under conventional thermal conditions
Scheme 33. Hetero-Diels–Alder cycloaddition reactions of 1H-pyrazin-2-ones.

(chlorobenzene, reflux, 132 °C). The use of 1,2-dichloro-ethane doped with the ionic liquid [bmim]PF$_6$ and sealed-vessel microwave technology at 190 °C enabled the same transformations to be completed within 8–18 minutes.[54] The primary imidoyl chloride cycloadducts were not isolated, but rapidly hydrolyzed by addition of small amounts of water and microwave irradiation (130 °C, 5 min). The overall yields of **39** were in the same range as reported for the conventional thermal protocols.[54]

In the intermolecular series, the Diels–Alder cycloaddition reaction of the pyrazinone heterodiene **40** with ethylene led to the bicyclic cycloadduct **41** (Scheme 33).[54] Under conventional conditions, these cycloaddition reactions have to be carried out in an autoclave at an ethylene pressure of 25 bar before the setup is heated to 110 °C for 12 hours. In contrast, the Diels–Alder addition of pyrazinone precursor **40** with ethylene in a sealed vessel that had been flushed with ethylene before sealing was completed after irradiation for 140 minutes at 190 °C. It was however not possible to further increase the reaction rate by raising the temperature. At temperatures above 200 °C an equilibrium between the cycloaddition **40**→**41** and the competing retro-Diels–Alder fragmentation process was observed (Scheme 33).[54] Only by using a microwave reactor that allowed pre-pressurization of the reaction vessel with 10 bar of ethylene could the Diels–Alder addition **40**→**41** be carried out much more efficiently at 220 °C within 10 minutes.[179]

2.8.3. Oxidations

The osmium-catalyzed dihydroxylation reaction, the addition of osmium tetroxide to olefins to produce a vicinal diol, is one of the most selective and reliable organic transformations. Recent work by Sharpless, Fokin, and co-workers has uncovered that electron-deficient olefins can be converted into the corresponding diols much more efficiently when the reaction medium is kept acidic.[181] One of the most useful additives in this context is citric acid (2.0 equiv), which

in combination with 4-methylmorpholine *N*-oxide (NMO) as the reoxidant for Os^{VI} and K$_2$OsO$_2$(OH)$_4$ (0.2 mol%) as a stable, nonvolatile substitute for OsO$_4$, allows the conversion of many olefinic substrates into their corresponding diols at ambient temperatures. In specific cases, such as for the extremely electron-deficient olefin **42** (Scheme 34), the reaction had to be carried out under microwave irradiation at 120°C to produce the pure diol **43** in 81% yield.[181]
Scheme 34. Osmium-catalyzed dihydroxylation of electron-deficient alkenes.

Another industrially important oxidation reaction is the conversion of cyclohexene into adipic acid. The well-known Noyori method uses hydrogen peroxide, a catalytic amount of tungstate, and a phase-transfer catalyst to afford the clean oxidation of cyclohexene to adipic acid. Ondruschka and co-workers have demonstrated that a modified protocol employing microwave heating without solvent gave comparable yields of the desired product, but in a much shorter time.[182] Rhodium and ruthenium-catalyzed hydrogen transfer type oxidations of primary and secondary alcohols have also been reported recently.[183]

2.8.4. Mitsunobu Reactions

The Mitsunobu reaction is a powerful stereochemical transformation. This reaction is very efficient for inverting the configuration of chiral secondary alcohols since a clean S$_N$2 process is generally observed ("Mitsunobu inversion"). The fact that the Mitsunobu reaction is typically carried out at or below room temperature would suggest that high-temperature Mitsunobu reactions performed under microwave conditions would have little chance of success. It was established in 2001 that Mitsunobu reactions can indeed be carried out at high-temperatures to effect an enantioconvergent approach to the aggregation pheromones (*R*)- and (*S*)-sulcatol (Scheme 35).[184] While the conventional Mitsunobu protocol carried out at room temperature proved to be extremely sluggish, complete conversion of (*S*)-sulcatol to the *R* acetate (S$_N$2 inversion) using essentially the standard Mitsunobu conditions (1.9 equiv DIAD, 2.3 equiv Ph$_3$P) was achieved within 5 minutes at 180°C under sealed-vessel microwave conditions. Despite the high reaction temperatures, no by-products could be identified in these Mitsunobu experiments, and the *R* acetate was formed in >98% *ee*.

An application of these rather unusual high-temperature Mitsunobu conditions for the preparation of conformationally constrained peptidomimetics based on the 1,4-diazepan-2,5-dione core was recently disclosed by the group of Taddei and co-workers.[185] Cyclization of the dipeptide hydroxyhydroxamate **44** under the DIAD/Ph$_3$P microwave conditions
Scheme 35. Mitsunobu reactions. DIAD = diisopropylazodicarboxylate.

(210°C, 10 min) provided the desired 1,4-diazepan-2,5-dione **45** in 75% yield. Standard room-temperature conditions (DMF, 12 h) were significantly less efficient and gave only 46% of the desired compound.

Another microwave-mediated intramolecular S$_N$2 reaction results in the formation of one of the key steps in a recent catalytic asymmetric synthesis of the cinchona alkaloid quinine by Jacobsen and co-workers.[186] The strategy to construct the crucial quinuclidine core of the natural product relies on an intramolecular S$_N$2 reaction/epoxide ring opening (Scheme 36). After removal of the benzyl carbamate (Cbz) protecting group with Et$_2$AlCl/thioanisole, microwave heating of the acetonitrile solution to 200°C for 20 minutes provided a 68% yield of the natural product as the final transformation in a 16-step total synthesis.
Scheme 36. Intramolecular S$_N$2 reaction in the total synthesis of quinine.

2.8.5. Glycosylation Reactions

Glycosylation reactions involving oxazoline donors are generally rather slow and require prolonged reaction times because of the low reactivity of the donors. Oscarson and co-workers have reported the preparation of dimers of *N*-acetyllactosamine linked by alkyl spacers by microwave-assisted glycosylations with oxazoline donors in the presence of pyridinium triflate as a promoter (Scheme 37).[187] Rapid and efficient coupling was achieved in dichloromethane with four different diols using 2.2 equivalents each of the oxazoline donor and pyridinium triflate promotor. Microwave irradiation at 80°C for 20 minutes led to moderate to high yields of the dimers, with yields increased by 12–15% over the conventional process. Fraser-Reid and co-workers recently described related saccharide couplings by employing *n*-pentenylglycosyl donors and *N*-iodosuccinimide (NIS) as
Scheme 37. Microwave-assisted glycosylation reactions.

the promotor in acetonitrile.[31] Various rapid microwave-assisted protection and deprotection methods are also known in the area of carbohydrate chemistry.[188]

2.8.6. Multicomponent Reactions

The Mannich reaction has been known since the early 1900s and has since then been one of the most important transformations to produce β-amino ketones. Although the reaction is powerful, it suffers from some disadvantages, such as the need for drastic reaction conditions, long reaction times, and sometimes low yields of products. Luthman and co-workers have reported microwave-assisted Mannich reactions that employed paraformaldehyde as a source of formaldehyde, a secondary amine in the form of its hydrochloride salt, and a substituted acetophenone (Scheme 38).[189] Optimized
Scheme 38. Examples of Mannich condensations and related reactions.

reaction conditions utilized equimolar amounts of reactants, dioxane as solvent, and microwave irradiation at 180 °C for 8–10 minutes to produce the desired β-amino ketones in moderate to good yields. Importantly, in several examples the reaction was performed both on a 2-mmol scale using a single-mode microwave reactor and also on a 40-mmol scale using a dedicated multimode instrument. As seen with other transformations described earlier (Scheme 1), all the microwave-assisted Mannich reactions studied proved to be "directly scalable": nearly identical yields were obtained on a 2-mmol and 40-mmol scale without the need for reoptimization of the reaction conditions.[189]

The research group of Leadbeater reported a different type of Mannich reaction, which involved condensation of an aldehyde (1.5 equiv) with a secondary amine and a terminal

acetylene in the presence of CuCl (10 mol%) to activate the terminal acetylene (Scheme 38).[58] Optimum yields of propargylamines **46** were obtained by microwave irradiation of the three building blocks with the catalyst in dioxane doped with an ionic liquid at 150 °C for 6–10 minutes. A high-speed microwave approach also exists for the Petasis multicomponent reaction (boronic-Mannich reaction)[190] and for the Kindler thioamide synthesis (the condensation of an aldehyde, amine, and sulfur).[191]

2.8.7. Nucleophilic Aromatic Substitution

An alternative to the palladium-catalyzed Buchwald–Hartwig reactions and the related copper-catalyzed methods for C(aryl)–N, C(aryl)–O, and C(aryl)–S bond formations (Section 2.3) are nucleophilic aromatic substitution reactions. A benzene derivative substituted by a leaving group may be treated, for example, with an amine, but here the benzene derivative must generally also contain an electron-withdrawing group. Such nucleophilic aromatic substitution reactions are notoriously difficult to perform and often require high temperatures and long reaction times. A number of publications report efficient nucleophilic aromatic substitutions driven by microwave heating involving either halogen-substituted aromatic[192,193] or heteroaromatic systems.[72,73,194–196] Scheme 39 summarizes some heteroaromatic
Scheme 39. Nucleophilic aromatic substitution reactions involving halo-substituted N-heterocycles. DMPU = N,N′-dimethyl-N,N′-propylene urea, HMPA = hexamethyl phosphoramide.

systems and nucleophiles along with the reaction conditions that have been developed by Cherng for microwave-assisted nucleophilic substitution reactions.[194–196] In general, the microwave-driven processes provide significantly higher yields of the desired products in much shorter reaction times.

2.8.8. Radical Reactions

There are only a limited number of examples in the literature that involve radical reactions under controlled microwave heating conditions.[197] Wetter and Studer have described radical carboaminoxylations of various nonactivated olefins and difficult radical cyclizations (Scheme 40).[198]
Scheme 40. Radical carboxaminations with malonyl radicals.

The thermally reversible homolysis of alkoxyamine **47** generates the stable radical 2,2,6,6-tetramethylpiperidinyl-1-ol (TEMPO) and a stabilized transient malonyl radical, which subsequently reacts with an alkene to afford the carboaminoxylation product **48**. These radical addition processes take up to three days under conventional conditions (DMF, sealed tube, 135 °C), while the same transformation was complete after microwave heating at 180 °C for 10 minutes in a sealed vessel; higher yields were also obtained in all but one example.

Several other selected examples of microwave-assisted organic transformations are summarized in Schemes 41 and 42.
Scheme 41. Oxidation of thiazolidines,[199] electrophilic nitration,[200] amination,[201] iodination,[87] bromination,[73] and dealkoxycarbonylation reactions.[202] NBS = N-bromosuccinimide.

2.9. Combinatorial and High-Throughput Methodologies
2.9.1. Solid-Phase Organic Synthesis

Solid-phase organic synthesis (SPOS) exhibits several advantages compared with classical protocols in solution. Reactions can be accelerated and driven to completion by using a large excess of reagents, as these can easily be removed by filtration and subsequent washing of the solid support. In addition, SPOS can easily be automated by using appropriate robotics and applied to "split-and-mix" strategies, useful for the synthesis of large combinatorial libraries.[208] However, SPOS also exhibits several shortcomings, as a result of the inherent nature of the heterogeneous reaction conditions; nonlinear kinetic behavior, slow reactions, solvation problems, and degradation of the polymer support, because of the long reaction times, are some of the problems typically experienced in SPOS. A technique such as microwave-assisted synthesis which is able to address some of these issues is therefore of considerable interest, particularly for research laboratories involved in high-throughput synthesis. As far as the polymer supports for microwave-assisted SPOS are concerned, the use of cross-linked macroporous or microporous polystyrene resins has been most prevalent. In contrast to the common belief that the use of polystyrene

resins limits the reaction conditions to temperatures below 130 °C, it has recently been amply demonstrated, both in microwave-assisted SPOS and in the use of polymer-supported reagents and catalysts (see Section 2.9.4), that these resins can withstand microwave irradiation for short periods of time even at temperatures above 200 °C.

Early examples of SPOS under controlled microwave conditions[12] typically involved the use of microwaves in one single step to either attach or cleave material onto or off the resin. A study published in 2001 demonstrated that high-temperature microwave heating (200 °C) can be effectively employed to attach aromatic carboxylic acids to chloromethylated polystyrene resins (Merrifield and Wang) by the cesium carbonate method (Scheme 43).[209] Significant rate
Scheme 43. Attachment of aromatic carboxylic acids to chlorinated polystyrene Wang resin.

accelerations and higher loadings were observed when the microwave-assisted protocol was compared to the conventional thermal method. Reaction times were reduced from 12–48 hours with conventional heating at 80 °C to 3–15 minutes with microwave heating at 200 °C in NMP in open glass vessels. A comparison of the kinetics of the thermal coupling of benzoic acid to the chlorinated Wang resin at 80 °C with the microwave-assisted coupling at the same temperature demonstrated the absence of any microwave effects.

Peptide synthesis has long been one of the cornerstones of solid-phase organic synthesis, and attempts to speed up the rather time-consuming process by microwave heating were made as early as 1992.[210] Erdélyi and Gogoll recently applied controlled microwave irradiation to the synthesis of a small tripeptide containing three of the most hindered natural amino acids (Thr, Val, Ile; Scheme 44).[211]
Scheme 44. Synthesis of a tripeptide. a) deprotection with piperidine at RT; b) coupling reagent, Fmoc-protected amino acid, *i*Pr₂NEt, DMF, MW, 110 °C, 20 min; c) TFA, RT, 2 h. Fmoc = 9-fluorenylmethoxycarbonyl, TFA = trifluoroacetic acid.

A variety of common coupling reagents have been investigated for the synthesis of this rather difficult peptide sequence on standard Rink polystyrene resin. The coupling of the activated amino acids under microwave conditions was completed in a few minutes (1.5–20 min) without the need for double or triple coupling steps as in conventional protocols. Most of the coupling reagents used showed increased coupling efficiency up to 110 °C, with *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate

(HATU) being the most effective, and allowed complete coupling within 1.5 minutes at 110 °C. Decomposition of the reagents was indicated by a color change of the reaction mixtures above this temperature. However, no degradation of the solid support was observed. Furthermore, both LC-MS and ¹H NMR spectroscopic analysis confirmed the absence of racemization during the high-temperature treatment, despite the presence of the diisopropylethylamine base.

The formation of a number of related peptide bonds have been reported under optimized microwave conditions.[212] In fact, specialized equipment dedicated specifically to microwave-assisted solid-phase peptide synthesis is commercially available.[36]

As in solution-phase chemistry (see Sections 2.2 and 2.3), many transition-metal-catalyzed transformations have been conducted successfully on a solid phase by using microwave-assisted techniques. Examples include solid-phase Suzuki-,[213] Stille-,[213] and Sonogashira couplings,[214] Negishi reactions,[92] Mo-catalyzed allylic alkylations,[117] aminocarbonylations,[110] cyanation reactions,[215] trifluoromethanesulfonations,[82] Buchwald–Hartwig aminations,[216] and Cu-catalyzed Ullmann-type C-N arylations.[217]

An interesting example of a transition-metal-mediated microwave-assisted SPOS involving either Cu^II- or Pd^II-mediated cyclizations of 2-alkynylanilides to indoles has been studied by Dai et al. (Scheme 45).[218] The required alkynylanilide precursor **52** was constructed on Rink resin following standard SPOS procedures. The desired cyclization step **52→53** was extremely sluggish under conventional thermal conditions and only partial ring closure was observed (80 °C, 4–5 h). In contrast, dielectric heating with microwaves for 10 minutes at 160 °C in THF in the presence of 20 mol% of [PdCl₂(MeCN)₂] afforded indole **53** (Ar = *p*-CF₃C₆H₄, *n* =
Scheme 45. Pd- or Cu-mediated ring closure of resin-bound 2-alkynyl anilides to indoles.

8) in 75% yield and 94% purity after cleavage. Alternatively, the equivalent Cu^{II}-mediated process (1 equiv of Cu(OAc)$_2$, NMP, 200°C, 10 min) also provided the desired indoles in similar yields and purities. The authors specifically note that no decomposition of the resin was observed even at 200°C.

A related indole synthesis on Rink resin based on the Pd-catalyzed cyclization of propargylamines to iodoanilines was published by Berteina-Raboin and co-workers.[219] In this case, open-vessel microwave technology was used for all the three steps of the synthesis (< 15 min, < 140°C) as well as for the final cleavage reaction, which was carried out at room temperature. Higher yields of final products were achieved in much shorter reaction times by using the microwave protocol as compared to conventional heating.

An interesting multicomponent reaction is the Gewald synthesis of 2-amino-3-acylthiophenes. Earlier reports of the classical Gewald synthesis had described the rather long reaction times required by conventional heating and the laborious purification of the resulting thiophenes. In view of these issues, researchers from Morphochem investigated a "one-pot" microwave-assisted Gewald synthesis on a commercially available cyanoacetylated Wang resin as the solid support (Scheme 46).[220] The overall two-step reaction procedure,

Scheme 47. Preparation of various bicyclic dihydropyrimidinones by cyclative cleavage.

Scheme 46. Gewald synthesis of 2-acylaminothiophenes through a three-component reaction.

including the acylation of the initially formed 2-aminothiophenes, could be performed in less than one hour. This process is an efficient route to 2-acylaminothiophenes which requires no filtration between the two reaction steps. Various aldehydes, ketones, and acylating agents have been employed to generate the desired thiophene products in high yields (81–99%) and in generally good purities.

Kappe and co-workers have reported a multistep solid-phase synthesis of bicyclic pyrimidine derivatives by a Biginelli muticomponent reaction combined with multidirectional cyclative cleavage reactions (Scheme 47).[221] This approach required the synthesis of the 4-chloroacetoacetate resin as the key starting material, which was prepared by microwave-assisted acetoacetylation of hydroxymethyl poly-

styrene resin. In analogy to earlier work,[222] this transesterification was best carried out under open-vessel conditions in 1,2-dichlorobenzene (170°C) to allow the formed methanol to be removed from the equilibrium (see also Scheme 20). This resin precursor was subsequently treated with urea and various aldehydes in an acid-catalyzed Biginelli multicomponent reaction (dioxane, 70°C) to afford the corresponding resin-bound dihydropyrimidinones. The desired furo[3,4-*d*]pyrimidine-2,5-diones were obtained by cyclative release in DMF at 150°C. Pyrrolo[3,4-*d*]pyrimidine-2,5-diones were also synthesized using the same pyrimidine resin precursor, which was first treated with a representative set of primary amines to substitute the chlorine atom. Subsequent cyclative cleavage was carried out at temperatures between 150 and 250°C and led to the corresponding pyrrolopyrimidine-2,5-dione products in high purity. The synthesis of pyrimido[4,5-*d*]pyridazine-2,5-diones was carried out in a similar manner, by employing hydrazines for the nucleophilic substitution prior to cyclative cleavage. A number of related microwave-assisted cyclative-release protocols have been reported.[223,224]

Apart from traditional cross-linked polystyrene resins a number of different supports and formats have been used in microwave-assisted SPOS. These include tentagel resins,[117,213,214,225] cellulose membranes (SPOT synthesis),[226,227] cellulose beads,[228] and glass surfaces.[229] Janda and co-workers have described the use of *Janda Jel* as the support in the solid-phase synthesis of oxazoles (Scheme 48).[230] In this case, resin-bound α-acylamino-β-ketoesters **54** were treated with Burgess reagent to form oxazoles **55**, which were then cleaved from the resin by using a diversity-building amidation reaction. The conditions for the key cyclization step **54**→**55** were carefully optimized with microwave dielectric heating and by monitoring the reaction by on-bead IR spectroscopy. The best conditions utilized 3.0 equivalents of the Burgess reagent and 20 equivalents of pyridine in chlorobenzene (100°C, 15 min). Interestingly,
Scheme 48. Preparation of oxazoles by cyclization of α-acylamino-β-ketoesters.

Scheme 49. Preparation of thiohydantoins on a PEG support. All microwave-assisted steps were carried out under open-vessel conditions.

conventional thermal heating at 80 °C for 4 hours was used for the production of the final library since it provided conversions as high as the 15 minutes microwave run.

One reason why microwave-assisted SPOS has not been as powerful a technique as it perhaps could be is the lack of suitable technology that would allow the combination of sealed-vessel microwave heating and bottom filtration (or related) methods for automated removal of excess reagents or solvents and for performing the required washing steps.[231] Currently such vessel equipment is not generally available, and therefore the advantages of SPOS in conjunction with microwave technology can not be fully exploited. Additional examples of SPOS with controlled microwave heating are found in ref. [232].

2.9.2. Liquid-Phase Synthesis on Soluble Polymer Supports

Besides solid-phase organic synthesis (SPOS) involving insoluble cross-linked polymer supports, chemistry on soluble polymer matrices, sometimes called liquid-phase organic synthesis, has emerged as a viable alternative.[233] Problems associated with the heterogeneous nature of the ensuing chemistry and on-bead spectroscopic characterization in SPOS have led to the development of soluble polymers as alternative matrices for the production of combinatorial libraries. Synthetic approaches that utilize soluble polymers couple the advantages of homogeneous solution chemistry (high reactivity, lack of diffusion phenomena, and ease of analysis) with those of solid-phase methods (use of excess reagents and easy isolation and purification of products). Separation of the functionalized matrix is achieved by either solvent or heat precipitation, membrane filtration, or size-exclusion chromatography.[233]

A variety of successful microwave-assisted transformations involving soluble polymers such as polyethylene glycol (PEG) have been reported since 1999,[234] and most recently by Sun and co-workers using controlled open-vessel microwave conditions.[235,236] In the example shown in Scheme 49 polyethylene glycol of molecular weight 6000 (PEG 6000) was used as a support for the synthesis of a small library of thiohydantoins.[235] In the first step Fmoc-protected amino acids (3.0 equiv) were loaded onto the support by standard peptide coupling with classical DCC/DMAP activation. The coupling was carried out in dichloromethane and required
14 minutes of microwave irradiation under open-vessel reflux conditions. Following deprotection with 10% piperidine in dichloromethane at room temperature, various isothiocyanates (3.0 equiv) were introduced by heating under reflux conditions (7 min), again in the same solvent. The cyclization/traceless cleavage step was completed under mildly basic conditions (K_2CO_3) within 7 minutes and provided the desired thiohydantoins in high overall yield and purity. Although the authors did not report any reaction temperatures apart from "reflux conditions" they noted that control experiments under conventional reflux conditions required significantly longer reaction times, which would indicate the presence of a specific microwave effect (namely, a superheating effect at atmospheric pressure).

2.9.3. Reactions in Fluorous Phases

Tagged fluorous substrates, reagents, catalysts, and scavengers are becoming increasingly popular in organic synthesis, particularly since the advent of high-speed purification techniques such as fluorous solid-phase extraction (F-SPE).[237] The first reports on fluorous synthesis under microwave conditions date back to 1997 and involved Stille coupling reactions with fluorous tin reagents.[238] This was later followed by examples of radical reactions initiated by fluorous tin hydrides.[197] More recently there have been reports on very efficient Pd-catalyzed cross-coupling reactions of perfluoroalkylsulfonates with thiols,[239] and on the use of fluorous-tagged bidentate ligands in microwave-assisted Heck reactions of vinyl triflates with enamides (Scheme 50).[240] F-SPE was used to remove excess reagents or ligands, respectively, in the two cases.

An interesting application of the use of fluorous scavenging in conjunction with microwave synthesis and F-SPE purification was recently illustrated by Werner and Curran[241] in their investigation of the Diels–Alder cycloaddition of maleic anhydride with diphenylbutadiene (Scheme 51). After
Scheme 50. Heck vinylation of enamides in the presence of fluorous-tagged ligands.
Scheme 51. Fluorous dienophiles as diene scavengers in Diels–Alder cycloadditions.

performing a microwave-assisted cycloaddition (160 °C, 10 min) with a 50 % excess of the diene, the excess diene reagent was rapidly scavenged by a structurally related fluorous dienophile under the same reaction conditions. Elution of the product mixture through a F-SPE column with MeOH/H$_2$O provided the desired cycloadduct in 79 % yield and 90 % purity. Subsequent elution with diethyl ether furnished the fluorous Diels–Alder cycloadduct.

2.9.4. Polymer-Supported Reagents, Catalysts, and Scavengers

Apart from traditional solid-phase organic synthesis (SPOS), the use of polymer-supported reagents (PSR) has gained increasing attention from practitioners in the field of combinatorial chemistry.[242] The use of PSRs combines the benefits of SPOS with many advantages of traditional solution-phase synthesis. The most important advantages of these reagents are the simplification of reaction work-up and product isolation, with the former being reduced to simple filtrations. In addition, PSRs can be used in excess without affecting the purification step. Reactions can be driven to completion more easily by using this technique than in conventional solution-phase chemistry.

The combination of MAOS and PSR technology is a rapidly growing field.[243] An early example of microwave-assisted PSR chemistry published by Ley et al. involves the rapid conversion of amides into thioamides by employing a polystyrene-supported Lawesson-type thionating reagent.[51] A range of secondary and tertiary amides was converted within 15 min with 3–20 equivalents of the PSR into the corresponding thioamides in high yield and purity by using microwave irradiation at 200 °C (Scheme 52). These thiona-
Scheme 52. Thionation of amides using a polymer-supported thionation reagent.

tion reactions showed a marked acceleration in the reaction rate compared to classical reflux conditions, with reaction times being reduced from 30 hours to 10–15 minutes. Interestingly, heating at these elevated temperatures caused no damage to the polymeric support. As toluene itself is a less than optimum solvent for absorption and dissipation of microwave energy (see Table 1), a small amount of ionic liquid (1-ethyl-3-methyl-1H-imidazolium hexafluorophosphate) was added to the reaction mixture to ensure an even and efficient distribution of heat.

Isonitriles represent an important class of monomers, and their unique reactivity in MCRs (see for, example, Scheme 26) have made them ideal targets for synthesis. Since the preparation and subsequent purification of the sometimes unstable isonitriles prepared by solution-phase methods is not trivial, a process allowing the rapid generation of isonitriles "on demand" is highly desirable. Two independent routes to isonitriles involving microwave-assisted PSR chemistry were reported in 2002 (Scheme 53).[244–246] In the approach described by Ley and Taylor, a suspension of an isothiocyanate and a polymer-supported 1,3,2-oxazaphospholidine reagent (1.5–3.0 equiv) in toluene was heated under sealed-vessel microwave irradiation conditions at 140 °C. This method enabled the preparation of primary, secondary, tertiary and aromatic isocyanides in high yields and purities.[244] In an alternative method presented by Bradley and co-workers,[245] formamides (which themselves can be efficiently prepared by MAOS)[246] were treated with a sulfonyl
Scheme 53. Preparation of isonitriles by using polymer-bound reagents.

chloride resin (3.0 equiv) and pyridine (50 equiv) in dichloro-methane. The optimum conditions involved heating the mixture at 100 °C for 10 minutes and provided the desired isonitriles in moderate to high yields.[245,246]

Very recently, Porcheddu et al. described an attractive "resin capture and release" strategy for the preparation of libraries of 2,4,5-trisubstituted pyrimidines (Scheme 54).[247]
Scheme 54. Resin capture and release strategy for the solid-phase synthesis of pyrimidine libraries.

The key to the success of the "traceless" synthesis of the pyrimidines is the capturing of β-ketoesters or β-ketoamides on a solid-supported piperazine. Heating a mixture of the piperazine resin, N-formylimidazole dimethyl acetal, and the 1,3-dicarbonyl compound in DMF in the presence of 10 mol % camphersulfonic acid (CSA) at 80 °C for 30 minutes provided resin-bound enaminones in high yields. As in earlier examples described in this Review (see Schemes 20 and 47), it was found to be advantageous to work under open-vessel conditions to allow the removal of the formed methanol from the equilibrium. The desired pyrimidines were then released from the resin by heating the resin-bound enaminones in the presence of 1.0 equivalent of guanidinium nitrates (prepared by a MAOS method) at 130 °C for 10 minutes. A 39-member library of pyrimidines was prepared in excellent overall yields and purities. Related microwave-assisted capture and release strategies have been reported by Turner and co-workers.[248] Some other applications of microwave-assisted PSR chemistry are summarized in Scheme 55.

A truly remarkable combination of polymer-bound reagents, catalysts, and scavengers was used by Ley and co-workers in their total synthesis of the natural product (+)-plicamine (Scheme 56).[254] Microwave dielectric heating was used as the primary means of accelerating a number of slow reactions to maximize the quantities of intermediates that could be progressed through the synthetic sequence. The rapid optimization and screening of reaction conditions permitted by the adoption of automated microwave synthesis was crucial to the successful completion of this synthesis. Further details are found in the original references.[254]

The methodical examination of microwave-assisted scavenging techniques has only been explored recently. An appealing sequence of microwave-assisted synthesis and scavenging was reported by Ellman and co-workers
Scheme 55. Examples of resin-bound reactions: synthesis of 1,3,4-oxa-diazoles using Burgess reagent,[249] Wittig reactions with triarylphos-phanes,[250] catalytic transfer reaction involving formate,[251] O-alkylation with O-alkyl isoureas,[252] and formation of amide bonds with carbodi-imide.[253] HOBt = 1-hydroxybenzotriazole.

(Scheme 57).[255] The authors used microwave heating in the first step of their asymmetric synthesis of α-substituted amines to facilitate the formation of an imine intermediate from chiral 2-methylpropan-2-sulfinamide and an aldehyde precursor. Optimized conditions involved heating the sulfi-namide with the aldehyde (1.2 equiv) in the presence of the Lewis acid and water scavenger Ti(OEt)₄ (2.2 equiv) in dichloromethane at 90–110 °C for 10 minutes. Excess titanium reagent was removed by treatment of the crude mixture with water-saturated diatomaceous earth and subsequent filtration through silica gel. The nucleophilic addition of organomagnesium reagents to sulfinylimines proceeded with high diastereoselectivity at −48 °C. Finally, cleavage of the sulfinyl group with concomitant capture using a macroporous sulfonic acid resin in the presence of catalytic amounts of ammonium chloride (110 °C, 10 min) provided the desired amine tightly bound to the acidic ion-exchange resin. After washing the resin with methanol and dichloromethane, elution with ammonia furnished the chiral amines in high overall yield and purity.

A related, microwave-assisted scavenging process involving the rapid sequestration of amines by a high-loading Wang
Scheme 56. Total synthesis of (+)-plicamine.[243]
Scheme 57. Preparation of chiral amines from sulfinylimines.

aldehyde resin was reported by Messeguer and co-workers,[256] and a systematic kinetic study on microwave-assisted scavenging techniques involving various types of supports was published in 2003.[257]

A recent review has highlighted the growing importance of utilizing immobilized catalysts (namely, nanopalladium species) in conjunction with microwave dielectric heating.[258]

2.10. Scale-Up Problems

It has to be noted that, with very few exceptions, most examples of microwave-assisted synthesis discussed in this Review were performed on a less than 1 g scale (typically 1–5 mL reaction volume). This is in part a consequence of the recent availability of single-mode microwave reactors that allow the safe processing of small reaction volumes under sealed-vessel conditions by microwave irradiation (see Section 1.3).[36,38] While these instruments have been very successful for small-scale organic synthesis, it is clear that for microwave-assisted synthesis to be become a fully accepted technology in the future there is a need to develop larger scale MAOS techniques that can ultimately provide products routinely on a multikilogram scale (or even higher).

Two different approaches to closed-vessel microwave synthesis on a larger scale (> 100 mL processing volume) have emerged that have taken into consideration the physical limitations of microwave dielectric heating.[259] While some research groups have employed larger batch-type multimode[35,42,46,137,189,200,260] or monomode reactors,[261] others have used continuous-flow techniques (multi- and monomode)[59,262] to overcome the inherent problems associated with scaling-up MAOS.

Modern single-mode microwave technology allows the performance of MAOS in very small reaction volumes (0.2 mL).[263] Several authors have reported independently the feasibility of directly scaling reaction conditions from small-scale single-mode (typically 0.5–5 mL) to larger scale multimode batch microwave reactors (10–500 mL) without reoptimization of the reaction conditions.[42,131,137,189,200] In particular, volumes of up to 1000 mL have been reported to be processed successfully in open-vessel environments under microwave conditions.[46] The preferable option for processing volumes of > 1 L seems to be a continuous-flow technique, although here the number of published examples using dedicated microwave reactors is limited.[59,262] At the present time there are no documented published examples of the use of microwave technology for organic synthesis on a production-scale level (> 1000 kg), which is a clear limitation of this otherwise so successful technology.[26]

3. Summary and Outlook

The examples provided in Section 2 of this Review should make it clear that many types of chemical transformations can be carried out successfully under microwave conditions. This

does not necessarily imply that dramatic rate enhancements compared to a classical, thermal process will be observed in all cases,[264] but the simple convenience of using microwave technology will make this nonclassical heating method a standard tool in the laboratory within a few years. In the past, microwaves were often used only when all other options for performing a particular reaction have failed, or when exceedingly long reaction times or high temperatures were required to complete a reaction. This practice is now slowly changing and, as a result of the growing availability of microwave reactors in many laboratories, routine synthetic transformations are also now being carried out by microwave heating.

The benefits of controlled microwave heating, in particular in conjunction with using sealed-vessel systems, are manifold:

- Most importantly, microwave processing frequently leads to dramatically reduced reaction times, higher yields, and cleaner reaction profiles. In many cases the observed rate enhancements may be simply a consequence of the high reaction temperatures that can rapidly be obtained by using this nonclassical heating method, or may result from the involvement of so-called specific or nonthermal microwave effects (Section 1.2).
- The choice of solvent for a given reaction is not governed by the boiling point (as in a conventional reflux setup) but rather by the dielectric properties of the reaction medium which can be easily tuned by, for example, addition of highly polar materials such as ionic liquids.
- The monitoring mechanisms for temperature and pressure in modern microwave reactors allow for an excellent control of reaction parameters (Figure 2), which generally leads to more reproducible reaction conditions.
- The overall process is more energy efficient than classical oil-bath heating, since direct "in-core" heating of the medium occurs (Figure 1).
- Microwave heating can rapidly be adapted to a parallel or automatic sequential processing format. In particular, the latter technique allows for the rapid testing of new ideas and high-speed optimization of reaction conditions (see Figure 3). The fact that a "yes or no answer" for a particular chemical transformation can often be obtained within 5 to 10 minutes (as opposed to several hours in a conventional protocol) has contributed significantly to the acceptance of microwave chemistry both in industry and academia. The recently reported incorporation of real-time, in situ monitoring of microwave-assisted reactions by Raman spectroscopy will allow a further increase in efficiency and speed in microwave chemistry.[265]

Apart from traditional organic and combinatorial synthesis protocols covered in this Review (see Section 2), more recent applications of microwave chemistry include biochemical processes such as a high-speed polymerase chain reaction (PCR),[266] rapid enzyme-mediated protein mapping,[267] and general enzyme-mediated organic transformations (biocatalysis).[268] Furthermore, microwaves have been used in conjunction with electrochemical[269] and photochemical processes,[270] and are also employed in polymer chemistry[271] and material science applications,[272] such as the fabrication and modification of carbon nanotubes or nanowires.[273]

So why isn't everybody using microwaves? One of the major drawbacks of this relatively new technology is equipment cost. While prices for dedicated microwave reactors for organic synthesis have come down considerably since their first introduction in the late 1990s, the current price range for microwave reactors is still many times higher than that of conventional heating equipment.[36–38] As with any new technology, the current situation is bound to change over the next several years, and less expensive equipment should become available. Microwave reactors will then truly have become the "Bunsen burners of the 21st century"[274] and will be standard equipment in every chemical laboratory.

Addendum

Many additional applications of controlled microwave-assisted organic synthesis have appeared in the literature since the submission of the original manuscript. A selection is described below.

A series of air- and moisture-stable [Pd(allyl)Cl(NHC)] complexes with N-heterocyclic carbene ligands has been shown by Nolan and co-workers to catalyze Suzuki–Miyaura cross-coupling reactions of aryl chlorides with boronic acids.[275] This catalytic system is compatible with microwave conditions and rapid couplings were observed within 1.5 minutes at 120 °C. The conventionally heated reactions (60 °C) required several hours to reach completion. The same article also reports on microwave-assisted dehalogenations of aryl chlorides by using the same catalytic system.

Alterman and co-workers have employed a tandem carbonylation/lactonization sequence for the synthesis of phthalides.[276] Optimum conditions involved the use of $[Mo(CO)_6]$ as a solid source of CO, and $Pd(OAc)_2$/dppf as a catalyst (5 mol%) at 180 °C. The microwave-assisted carbonylation/cyclization method was also applied for the synthesis of other scaffolds, such as dihydroisocoumarins, dihydroisoindones, and phthalimides.

Harmata et al. have disclosed an efficient protocol for the Pd-catalyzed N-arylation of enantiopure sulfoximines with aryl chlorides.[277] Optimal results were achieved by using $Pd(OAc)_2$ as the Pd source in combination with *rac*-binap or P*t*Bu$_3$ as ligands under microwave irradiation conditions. The corresponding benzothiazines were obtained with aryl chlorides bearing *ortho*-carbonyl substituents.

Hydrozirconation is a mild method for the selective preparation of functionalized organometallic compounds, and its compatibility with a range of common protecting groups represents a considerable advantage of these species over traditional organometallic reagents. Wipf et al. recently reported that the hydrozirconation of alkynes with $[Cp_2Zr(H)Cl]$ can be greatly accelerated by microwave irradiation.[278] A synthetically useful one-pot method for the preparation of allylic amides was elaborated where an alkyne was first hydrozirconated by microwave irradiation, followed by rapid addition of imines in the presence of dimethylzinc.

Several research groups have reported other high-speed microwave-assisted transition-metal-catalyzed transforma-

tions, such as Suzuki,[279] Heck,[280] Sonogashira,[281] Negishi,[282] and Liebeskind–Srogl reactions,[283] Buchwald–Hartwig aminations,[284] and related reactions.[285]

Bahn and Adolfsson have demonstrated that functionalized 2,5-dihydropyrroles can be obtained by microwave-mediated ruthenium-catalyzed ring-closing metathesis (RCM).[286] The required olefin precursors were conveniently obtained from aza-Baylis–Hillman adducts. Microwave irradiation for 1–2 minutes at 100 °C of a dilute solution of the diene with 5 mol% Grubbs II catalyst in dichloromethane produces the desired dihydropyrroles in high yield. Microwave-assisted enyne-RCM chemistry has been reported by Brown and co-workers.[287]

A simple, high-yielding synthesis of 2,4,5-trisubstituted imidazoles from 1,2-diketones and aldehydes in the presence of ammonium acetate was recently reported by Wolkenberg et al.[288] Alkyl-, aryl-, and heteroaryl-substituted imidazoles were formed in very high yields ranging from 76–99% by utilizing microwave irradiation. Further microwave-assisted alkylation of 2,4,5-trimethylimidazole with benzyl chloride in the presence of base led to the alkaloid lepidiline B in 43% overall yield.

Wellner and co-workers have made extensive use of microwave chemistry in the preparation of cyclic thioureas and guanidines.[289] It was possible to assemble all intermediates and target molecules by MAOS without any need for activation or protecting groups, thus reducing reaction and workup times to a minimum. A variety of other heterocycle syntheses based on microwave protocols have also been published.[290]

A recent publication by the research group of Baran reports the total synthesis of ageliferin, an antiviral agent with interesting molecular architecture.[291] Just one minute (!) of microwave irradiation of sceptrin, another natural product, at 195 °C in water under sealed-vessel conditions provides ageliferin in 40% yield, along with 52% of recovered starting material. Remarkably, if the reaction is performed without microwaves at the same temperature only starting material and decomposition products are observed.

Moody and co-workers have employed a "biomimetic" hetero-Diels–Alder/aromatization sequence for the construction of the pyridine ring in amythiamicin D.[292] The key cycloaddition reaction between the azadiene and enamine component was carried out by microwave irradiation at 120 °C for 12 hours and gave the required 2,3,6-tris(thiazolyl)pyridine intermediate in moderate yield. Coupling of the remaining building blocks then completed the first total synthesis of the thiopeptide antibiotic amythiamicin D.

The synthesis of fully N-differentiated heparin oligosaccharides has been demonstrated by Lohman and Seeberger. One of the many synthetic steps involves the simultaneous installment of an *N,N*-diacetate and *O*-acetyl functionality in a trisaccharide building block.[293] Microwave irradiation of a solution in isopropenyl acetate in the presence of *p*-TsOH at 90 °C for 5 hours led to the desired product in 86% yield. This transformation could not be achieved under a variety of thermal conditions, with only poor yields achieved even after several days.

Vasudevan and Verzal have found that terminal alkynes can be hydrated under neutral conditions in the absence of metal compounds (such as $AuBr_3$) in distilled water.[294] Extension of this methodology led to a one-pot conversion of alkynes into imines (hydroamination).

A recent report by Takvorian and Combs discloses the rapid synthesis of 2-amino-substituted purines by rapid, microwave-assisted nucleophilic aromatic substitution (SN_2Ar).[295] Importantly, the authors also describe the use of small-scale reaction vessels (0.2 mL) for optimization of reaction conditions under optimal reaction concentrations.

Fukase and co-workers have reported the solid-phase synthesis of indol-2-ones (four diversity centers) by a radical cyclization pathway.[296] The key cyclization step was carried out by using Bu_3SnH and azodiisobutyronitrile (AIBN) in DMF under microwave irradiation conditions and provided a small library of 40 compounds. Interestingly, the related radical cyclization in the solution phase was considerably less effective.

A recent publication by Blackwell and co-workers reports the multistep synthesis of a spatially addressed pyrimidine library on planar membrane supports (SPOT synthesis).[297] Microwave irradiation was used to speed up all three steps of the synthesis on the planar support. Importantly, microwave irradiation did not affect the integrity of the cellulose support and the reaction could be easily scaled up by employing other (nonplanar) types of cellulose supports.

A study by Zhang and co-workers describes a new strategy for improving the efficiency of Suzuki coupling reactions by combining rapid microwave synthesis with fluorous separation techniques (F-SPE).[298] The aryl perfluorooctylsulfonate precursors for Suzuki-type couplings were readily prepared from phenols and commercially available perfluorooctylsulfonyl fluoride. Subsequent Suzuki reaction with aryl boronic acids in the presence of a suitable Pd catalyst provided the desired biaryls in high yield. Work-up simply involved filtration of the reaction mixture through a F-SPE cartridge. The same authors have also recently reported on the deoxygenation reactions of aryl perfluorooctylsulfonates.[299]

Lei and Porco have demonstrated the usefulness of a thermally stable polymer-supported anthracene derivative for scavenging dienophiles under microwave conditions.[300] This strategy was used successfully to rapidly sequester reactive dienophiles from reaction mixtures containing Diels–Alder cycloadducts prepared by microwave-assisted Diels–Alder reaction of flavonoid dienes. Diels–Alder reactions under microwave conditions have also been used to modify single-wall carbon nanotubes (SWNT).[301]

Two recent review articles highlight the importance of microwave chemistry for carbohydrate chemistry.[302]

present co-workers for their dedication, enthusiasm, and for their essential contributions to microwave chemistry.

[28] The elimination of wall effects and low thermal gradients (bulk heating) in microwave heated reactions has frequently been suggested to rationalize the outcome of microwave-assisted reactions; for examples, see refs. [5a], [41], [127], [143a], [197].

[29] Related to the issue of microwave effects is the recent concept that simultaneous external cooling of the reaction mixture (or maintaining subambient reaction temperatures) while heating by microwaves leads to an enhancement of the overall process. For published examples, see refs. [30], [31], and [15] (in particular pp. 22–23).

[39] On the other hand, the sometimes extreme reaction temperatures may eventually lead to the decomposition of the metal catalyst and to the deposition of metal black on the inner surface of the reaction vessel. This may lead to arcing phenomena which potentially can lead to the destruction of the reaction vessel. For details on arcing phenomena under microwave conditions, see: A. G. Whittaker, D. M. P. Mingos, *J. Chem. Soc. Dalton Trans.* **2000**, 1521–1526.

[259] One of the main limitations of scaling-up microwave technology is the restricted depth of penetration of microwave irradiation into absorbing materials (solvents or reaction mixtures). At the typical operating frequency of most microwave reactors of 2.45 GHz, the penetration depth depends on the dielectric properties of the medium but is generally of the order of a few centimeters. This means that the microwave energy density inside a large batch reactor (> 1 L volume) may

only be a small fraction of the density on the surface. Therefore, solvents or reagents in the center of the reaction vessel are heated by convection and not by direct microwave dielectric heating. This physical limitation is one of the main reasons for the development of continuous-flow reactors, where the reaction mixture is passed through a relatively small microwave-heated flow cell, thus avoiding problems of penetration depth. On the other hand, continuous-flow reactors with pumping systems may not be appropriate for processing solids, highly viscous liquids, or heterogeneous reaction mixtures.

[264] It should be emphasized that despite the large number of examples presented in Section 2, clearly not all chemical processes are amenable to a high-temperature microwave approach, in particular in those cases where a kinetically controlled pathway leads to the desired product. Also, there may be cases where one of the reagents or substrates is too temperature-sensitive to allow heating to higher than ambient temperatures. The reader should keep in mind that, naturally, the failed examples do not appear in the literarure, which distorts the success rate of microwave synthesis.

Communications

A solvothermal route based on metal(III) trimeric secondary building units (SBUs) is reported along with methods allowing the crystal structures of hybrid organic–inorganic structures to be predicted. The association of a chromium(III) trimeric SBU and 1,3,5-benzenetricarboxylate gives a micro- and mesoporous solid. The simulated crystal-structure solution matches the experimental X-ray pattern. For more information see the Communications by C. Serre, C. Mellot-Draznieks, G. Férey, and co-workers on the following pages.

Communications

A Route to the Synthesis of Trivalent Transition-Metal Porous Carboxylates with Trimeric Secondary Building Units**

Christian Serre,* Franck Millange, Suzy Surblé, and Gérard Férey

Porous solids with either purely inorganic[1] or organic–inorganic hybrid skeletons[2] are currently very topical,[3–7] owing to their applications in ion exchange, gas separation, catalysis, and more recently in hydrogen storage.[8–10] The recent introduction of transition metals in the framework has increased the range of possible applications by exploiting their electronic and magnetic properties.[11–13] However, most hydrothermal or solvothermal syntheses are based on "trial and error" but with some successes with divalent (e.g., Co, Ni, Cu) or trivalent cations (V, Cr),[11,13,14] The most important goal in the field is always to reach a real "design" of hybrid porous solids, that is, the way to obtain tailor-made solids with the required structures and properties starting from well-characterized inorganic and organic species. From this point of view, the number of synthetic routes that use a controlled approach based on secondary building units (SBUs) is still scarce. If some relative successes have been achieved in the past decade with the use of porphyrin building blocks[15] or by the combination of zinc, bypiridine, and SiF_6^{2-} ions,[16,17] then the most efficient synthetic route was developed by Yaghi and co-workers with the use of tetrameric Zn_4O zinc clusters.[18] A few solids were also obtained recently with dimeric[19] or trimeric zinc SBUs.[20–22] Thus, a large number of hybrid solids with pore sizes up to 27 Å and very high surface areas ($\approx 4500\ m^2 g^{-1}$) have been prepared. However, in the cases mentioned above their synthesis conditions are not a complete SBU approach. Soluble monomeric zinc precursors and defined synthesis conditions are used either to allow the formation, with reasonable stability, of these building units in solution prior to the reaction with carboxylate moieties, or to allow the cooperative formation of the building unit in the presence of the carboxylates moieties.

We report herein a new and "controlled SBU" approach for trimeric inorganic species (three metallic octahedra shared by μ_3-O), which keeps the integrity of the inorganic precursor during the formation of the solid. The approach involves acetates of trivalent transition metals (e.g., Fe, Cr, V, Ru, Mn, Co),[23,24] as precursors, which are trimeric. The trimeric acetate building unit is first prepared, then introduced into the reaction media in the presence of the dicarboxylic acid and finally, by increasing the temperature and in the presence of base, a direct exchange between the monocarboxylate (acetate) and the dicarboxylate moieties occurs to produce a 3D solid in which the trimeric SBU remains intact. We also report the successful use of these SBUs in the rational synthesis of two new open-framework iron(III) dicarboxylates. This paper deals with the synthesis, characterization and the structure determination from X-ray powder data of two new 3D open-framework iron(III) dicarboxylates: $Fe^{III}_3O(CH_3OH)_3\{^-O_2C\text{-}(CH)_n\text{-}CO_2^-\}_3\cdot X^-\cdot(CH_3OH)_m$; $X^- = CH_3CO_2^-$, $n = 2$, $m \approx 4.5$ (**MIL-88**; see Figure 1) or $X = Cl^-$ $n = 4$, $m \approx 6$ (**MIL-89**).

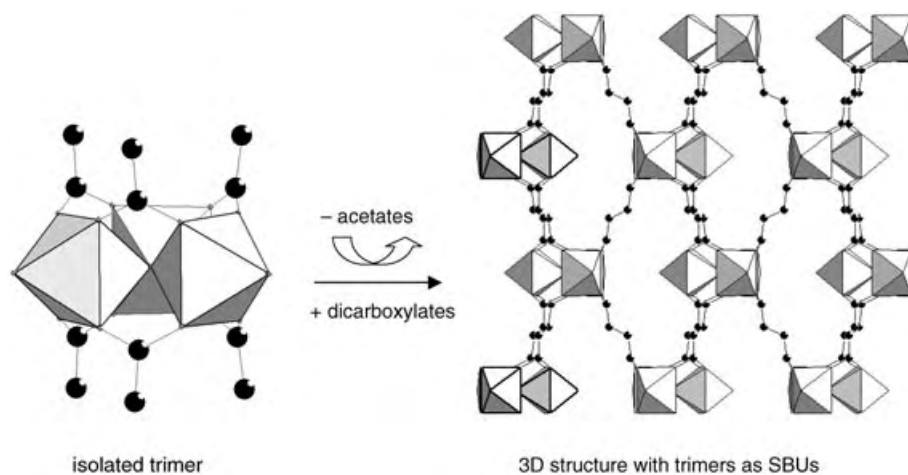
MIL-88 exhibits a 3D structure built up from trimers of iron(III) octahedra linked to fumarate dianions to create a 3D framework (Figure 2). This structure delimits both a 1D pore-


Figure 1. Schematic representation of the synthetic route involving trimeric SBUs with **MIL-88** given as an example.

channel system along the *c* axis (Figure 2 a), which is filled with solvent molecules, and cages, which are filled with acetate groups (Figure 2 b). The free methanol molecules that are present within the pores interact both through hydrogen bonds with oxygen atoms of the inorganic trimers and through Van der Waals interactions with the -CH_3 groups of both the free and bound methanol molecules. It should be noticed that during the determination of the structure, a partial-site occupancy was applied (see Supporting Information) for the disordered free methanol (C(4)-O(6) and C(7)-O(5)) and acetate groups (C(5), C(6) and O(7)).
Figure 2. View of the structure of **MIL-88**: a) along the *c* axis; b) along the *b* axis. Iron octahedra, oxygen and carbon atoms are represented in white, white and black respectively. For a better understanding, free methanol molecules and acetate groups have been removed from (a) whereas carbon atoms from the acetate are in gray in (b).

Figure 3. View of the structure of **MIL-89 ht**: a) along the *c* axis; b) along the *b* axis. Key: Fe octahedra white; O atoms white; C atoms black; Cl atoms gray.

In the case of **MIL-89**, only the structure of the high-temperature form of **MIL-89** labeled **MIL-89 ht** (ht signifies high temperature) or $Fe^{III}_3O(CH_3OH)_3\{^-O_2C\text{-}C_4H_4\text{-}CO_2^-\}_3\cdot Cl^-$ has been determined (see Experimental Section). **MIL-89 ht** also exhibits a 3D structure built up from trimers of iron(III) octahedra. The trimers are related together by *trans, trans* muconate moieties, which ensures the three-dimensionality of the framework (Figure 3); small channels are also present along the *c* axis and are filled with terminal methanol groups and chloride ions. As previously observed for **MIL-88**, a partial occupancy was found for a carbon atom (C(11)) of one terminal methanol molecule (C(11)-O(7)).

In both structures, iron atoms are situated within an octahedral environment of four oxygen atoms from the bidendate dicarboxylates, one $\mu_3 O$ atom, and one oxygen atom from the terminal methanol group. Octahedra are related through the $\mu_3 O$ oxygen atom to form the trimeric building units. Interatomic distances and angles are generally well defined with Fe–O, C–O, and C–C bond lengths within 1.83–2.04, 1.26–1.50, and 1.37–1.40 Å, respectively, for **MIL-88** and 1.88–2.23, 1.27–1.50 A, 1.37–1.48 Å, respectively, for **MIL-89 ht**. Bond-valence calculations indicate that iron atoms in both structures are in a trivalent state. Mössbauer experiments indicate that both solids have only octahedral iron(III) centers in a high-spin state; these results will be reported soon in a full paper with a detailed study of the thermal behavior and the sorption capacities of these solids.[25]

Despite the presence of the same SBUs in both **MIL-88** and **MIL-89 ht**, their structures have significant differences. First, the position of the counteranion (Figure 4): in **MIL-88**, the counterions are disordered acetate groups located at the centre of cages and surrounded by five trimers and six organic chains. **MIL-88** can thus be considered as being built up from successive layers of trimers alternating with acetate groups in the (010) plane; the three-dimensionality is ensured by the fumarate moieties along the *c* axis. In **MIL-89 ht**, the packing of trimers in the (010) plane is much denser and thus the chloride counterion is now located between the layers within the small channels along the *c* axis, delimited by six different alkenes chains and six iron trimers. These differences could come from the presence of free solvent in **MIL-88**, whereas solvent from **MIL-89 ht** has been removed; it is likely that **MIL-89** increases its cell volume when filled with methanol as this phenomenon occurs with **MIL-88** (cell volume increase > 50 %) when filled with methanol. This "breathing" is probably accompanied by a displacement of the anions in both cases; these results will be reported soon.[25]

As described above, two new open-framework iron(III) dicarboxylates have been obtained through the "controlled SBU" approach with retention of the initial trimeric SBU. However, it cannot be proven experimentally whether the trimeric SBU precursor remains intact throughout the synthesis or whether it breaks up and reforms. In the presence of
Figure 4. View of the cages delimiting the anionic moieties in **MIL-88** (a) and **MIL-89 ht** (b). Key: same as that Figure 3 except C atoms from the acetate and Cl atoms are in gray.

terephthalic acid and with the same trimeric SBU precursor under similar solvothermal conditions, a partial destruction of the SBU occurred during the synthesis. The resulting solid, **MIL-85**, was built up from both trimeric SBUs and monomers and even some of the acetate ligands present in the initial precursor were retained.[26] The presence of both trimers and acetate moieties within **MIL-85** indicates that part of the trimeric precursor is probably kept during the synthesis.

Trivalent metal dicarboxylate (**MIL-59**) built up from trimers of octahedra has been reported recently by our group by using a vanadium(III) complex and isophtalic acid under hydrothermal conditions following the "trial and error" method. In this case, a cubic structure with cuboidal cages filled with solvent and chloride ions was observed.[14] This is the only case of trimeric transition-metal carboxylate obtained to date under hydrothermal conditions that exhibit trimeric SBU.

Finally, our method is a new synthetic route that favors the synthesis of open framework transition-metal carboxylates with the trimeric SBUs.

These results show also that despite the presence of identical trimeric SBUs, the structural type in the final solids strongly depends on the nature of the organic linker, thus demonstrating the structural richness of this synthetic route. This successful use of predetermined SBUs in the synthesis of

metal carboxylates also opens the way for the "design" of hybrid solids by using the simulation tool.[27–29] This is also the first SBU route that involves trivalent cations; the number of hybrid solids based on trivalent transition or p-block metals is still scarce.[11–14,30–32]

In addition, as clusters of trimeric metal acetates with various physical properties can be obtained with a large number of transition metals, such as chromium, iron, vanadium, ruthenium, manganese, or cobalt,[23,24] there is a the potential to synthesize open-framework trivalent metal polycarboxylates with different pore shapes and sizes as well as unique physical properties. Several other porous hybrid solids based on these trimeric SBUs with various trivalent cations have been synthesized and will be soon reported, thus enlarging the field of hybrid phases based on trimeric transition-metals SBU.

Experimental Section

Synthesis: The trimeric iron(III) acetate SBU was first prepared according to Dziobkowski et al.[33] Subsequently, iron(III) acetate, fumaric acid ($HO_2C-C_2H_2-CO_2H$; Acros, 99%) or *trans,trans*-muconic acid ($HO_2C-C_4H_4-CO_2H$; Aldrich, 98%), sodium hydroxide (Aldrich, 97%), deionized water, and methanol (Prolabo, 99%) were mixed in the following ratios: 1:3:1.5:50:1000 (based on one trimer). The resulting orange gels were aged at 100°C for 3 days in a teflon-lined Parr bomb and cooled down to room temperature. The light-orange solids are filtered, washed with methanol and acetone, and dried at room temperature.

General analysis: Structure determination of **MIL-89** was carried out only on the high-temperature form **MIL-89 ht**; general analysis was carried out on the room-temperature form that contains free solvent molecules.

Thermal gravimetric analysis (TGA): TGA were performed in air on both solids (**MIL-88** and **MIL-89**) by using a TA-Instrument type 2050 analyzer. The results from both samples showed several weight losses in the range from 273 to 873 K (see the Supporting Information). The residual solid was identified as Fe_2O_3. **MIL-88** exhibits two weight losses of ≈19.5 and 49%, the first within the range of 373–423 K, which corresponds to the departure of the free methanol groups followed by the departure of bound methanol; the second within the range of 673–773 K, which corresponds to the loss of the dicarboxylate and the anionic group. The same behavior is observed for **MIL-89** with two losses of ≈20% and 56%. In the analysis of both samples, Fe_2O_3 crystallizes at higher temperatures. The losses generally agree with the theoretical values (**MIL-88**: free solvent: 17.3%, bound solvent plus organic fraction plus anion: 53.8%; **MIL-89**: free solvent: 20.7%, bound solvent plus organic fraction plus anion: 53.7%). In the case of **MIL-89**, the best matching between observed and calculated TGA losses has been reached for a content of six free methanol groups per trimer of iron octahedra.

Elemental analysis: Iron, carbon, and chlorine contents were determined at the C.N.R.S. Central Laboratory of Analysis of Vernaison (France). Elemental analysis (%) calcd for **MIL-88**: C 31.04, Fe 20.2; found: C 24.0, Fe 21.8, Cl trace. Elemental analysis (%) calcd for **MIL-89**: C 34.9, Fe 18.1, Cl 3.83; found: C 28.12, Fe 20.22, Cl 3.92. The deficit in observed carbon content comes in both cases from the rapid loss of free methanol at room temperature (**MIL-88**: ≈3–4 days; **MIL-89**: <1 day), which automatically decreases the carbon content observed by quantitative analysis.

Density measurements: To avoid problems of free methanol desorption at room temperature, an experiment performed on a fresh sample of **MIL-88** by using a Micromeretics apparatus, Accupyc 1330.

A volumic density of 1.55 g cm^{-3} corresponds reasonably well with the calculated one (1.73 g cm^{-3}).

Infrared spectroscopy: The infrared spectra of the title compounds clearly shows in both cases the presence of the vibrational bands characteristic of the -(O-C-O)- groups around 1550 and 1430 cm^{-1}, thus confirming the presence of the dicarboxylate within the solids. Large bands around 3500 cm^{-1} also confirmed the presence of OH groups in both solids.

Structure determination: All attempts at obtaining single crystals failed in both cases. The powder X-ray diffraction pattern of **MIL-88** was collected on a D5000 (θ-2θ mode) Siemens diffractometer with $\lambda(Cu_{K\alpha1,K\alpha2}) = 1.54059, 1.54439$ Å. In the case of **MIL-89**, due to the rapid evolution of the pattern at room temperature as well as a decrease in the crystallinity (see Supporting Information), a temperature in situ data collection was performed at 373 K by using a D5000 (θ-2θ mode) Siemens diffractometer equipped with an Anton Paar HTK1200 oven. The pattern of **MIL-88** was indexed in the hexagonal space group $P\bar{6}2c$ (no. 196) by using the Dicvol program,[34] with the following cell parameters $a = 11.04(1)$ Å, $c = 14.80(1)$ Å. The pattern of **MIL-89 ht** was indexed in the orthorhombic space group $Pbnn$ (no. 52) with $a = 9.135(1)$ Å, $b = 16.137(1)$ Å, $c = 19.968(1)$ Å. Then, direct methods were realized by using the Expo program to localize the iron atoms and some of the oxygen atoms.[35] Due to poor quality of the data in the case of **MIL-89 ht**, a combination of the Expo and the Cerius programs was used,[36] which allows the manipulation of the whole trimeric building block and based on the position of the iron atoms found by Expo, Cerius allowed us to place the whole inorganic SBU and the first carbon atoms of the muconate moieties at a position compatible with the direct-method findings and the experimental X-Ray diffraction pattern. Finally, free and bound methanol molecules and the anionic counterions were located by successive Fourier difference by using Shelxtl.[37] In the case of **MIL-88**, disorder was present for the methanol groups and for the acetate anion and half occupancies were applied during the refinement. For **MIL-89 ht**, the carbon atom of one of the terminal methanol groups was also placed with a half occupancy. Finally, both structures were refined by using Fullprof[38] and its Winplotr program.[39] Full details of the structure determination are reported in the Supporting Information.

The formula deduced from the structure determinations for **MIL-88** and **MIL-89 ht** are: Fe$^{III}_3$O(CH$_3$OH)$_3${O$_2$C-C$_2$H$_2$-CO$_2$}$_3$·(CH$_3$-CO$_2$)·n CH$_3$OH ($n = 4.5$) and Fe$^{III}_3$O(CH$_3$OH)$_3${O$_2$C-C$_4$H$_4$-CO$_2$}$_3$·Cl. The final agreement factors[40] were satisfactory for **MIL-88**: $R_p = 11.9\%$, $R_{Bragg} = 8.3\%$ and $R_F = 7.7\%$. In the case of **MIL-89 ht**, factors are higher because of the poor quality of the X-ray data ($R_p = 13.7\%$; $R_{Bragg} = 15.6\%$, $R_F = 9.7\%$) and only an approached structure of **MIL-89 ht** is proposed for the moment; better X-ray data will be collected soon on the wet phase by using capillaries to determine more precisely the structure of **MIL-89**. Final Rietveld plots, atomic coordinates, and principal interatomic distances are given in the Supporting Information.

Hybrid Organic–Inorganic Frameworks: Routes for Computational Design and Structure Prediction**

Caroline Mellot-Draznieks,* Julien Dutour, and Gérard Férey

The controlled synthesis of materials with very large pores is an ongoing challenge in the area of materials science. Research into large-pore materials is fueled by their use in catalysis, gas storage, and separation.[1] After intense development of inorganic frameworks in the early 1990s,[2] the subsequent discovery of hybrid porous solids, in which the connection of inorganic moieties is ensured by organic functionalized N-donor or O-donor molecules, paved the way for the rational design of hybrid frameworks.[3–11] A new class of materials has emerged at the crossroads of inorganic materials science and coordination chemistry. Among the most illustrative examples of open frameworks are the zinc carboxylate series by Yaghi, O'Keeffe, and co-workers, and the transition-metal terephthalates that have remarkable methane- and hydrogen-storage properties,[12] together with, for example, a recent series of 3d transition-metal[13a, 14] and rare-earth[15]-based hybrids that exhibit interesting magnetic properties.[13a] The richness of this area lies in the diversity of topologies (from molecular to 3D) and properties, which is conveyed in the wide choice of metal atoms that are available, combined with a virtually infinite choice of organic counterparts (e.g., carboxylates, phosphonates, polyamines).

In the current search for new and interesting hybrid open frameworks, the predictability of the framework architecture and the control of its dimensionality are essential, even if one is confronted with the underlying issue of polymorphism.[6] The possibility of rational design with these types of solids has rapidly emerged through the use of topological and chemical considerations on existing networks.[7] The concept of rational design is rooted in the fact that topochemically selected reactions govern the construction process of the hybrid framework under hydrothermal conditions. Although metal-containing secondary building units (SBUs) may not be isolated, their recurrence in a large number of structures suggests that the targeted inorganic subunit already exits in solution before their condensation into the framework structure and thus may be obtained under appropriate synthetic conditions. For example, this aspect is apparent through the *iso*-reticular synthesis of IRMOFs1–16[12b] derived from the prototypic MOF-5 structure.[12a]

In this context, structural prediction is an important issue. It is crucial to consider how systematic approaches might be computationally developed for producing new hybrid frameworks, with the desire of developing virtual libraries that might be accessible by rational synthesis.

It is worth underscoring here that crystal-structure prediction is now routinely explored in organic chemistry and polymer science,[16, 17] in which candidate structures may be predicted by assembling molecular entities through hydrogen-bond intermolecular interactions. In contrast, such developments have only been recently reported for inorganic crystal structures, which are extremely difficult to predict due to their infinite lattices. Pioneered by Newsam et al. in the field of zeolites,[18] crystal-structure prediction[18–28] and rational design[29–31] are now at work in the field of open frameworks. Due to their ability to cross hypersurface energy barriers and search for low-energy regions, global optimization techniques are intensively used to predict atomic-scale arrangements of infinite lattices and are able to handle the assembly of atoms, ions,[20, 22–25] or predefined building units in three dimensions.[21, 27, 28]

We have introduced the concept of building units for the computational prediction of crystal structures with the AASBU method (automated assembly of secondary building units).[21, 27, 28] This method explores the possible ways of assembling predefined inorganic building units, and focuses on the topology of network-based structures.

Inspired by these recent developments, we present herein the extension of the AASBU method to the realm of hybrid organic–inorganic frameworks and demonstrate its capacity to produce hybrid candidate crystal structures that are built from predefined organic and inorganic counterparts. To our knowledge, no systematic computational strategy has been reported in this field so far.

Indeed, hybrid frameworks offer ideal features for computational developments: although the isolated metal ion, taken alone, lacks directional information, the inorganic unit derived from the metal atom and the organic ligand does (Figure 1). Once the inorganic and organic units are defined, one may assume that there are a limited number of arrangements that are compatible with periodicity and symmetry. With predefined organic and inorganic building units, AASBU simulations are used here to perform their automated assembly in three dimensions, thus exploring the possibilities of connection. The simulations yield a virtual library of candidate hybrid frameworks that are assorted by their space group, cell parameters, and atomic positions.

Our initial efforts were aimed at validating the AASBU approach in the field of hybrid frameworks by simulating existing architectures. In the second instance, we aimed at predicting structures that have not yet been synthesized, both to tackle the issue of polymorphism by limiting the domain of

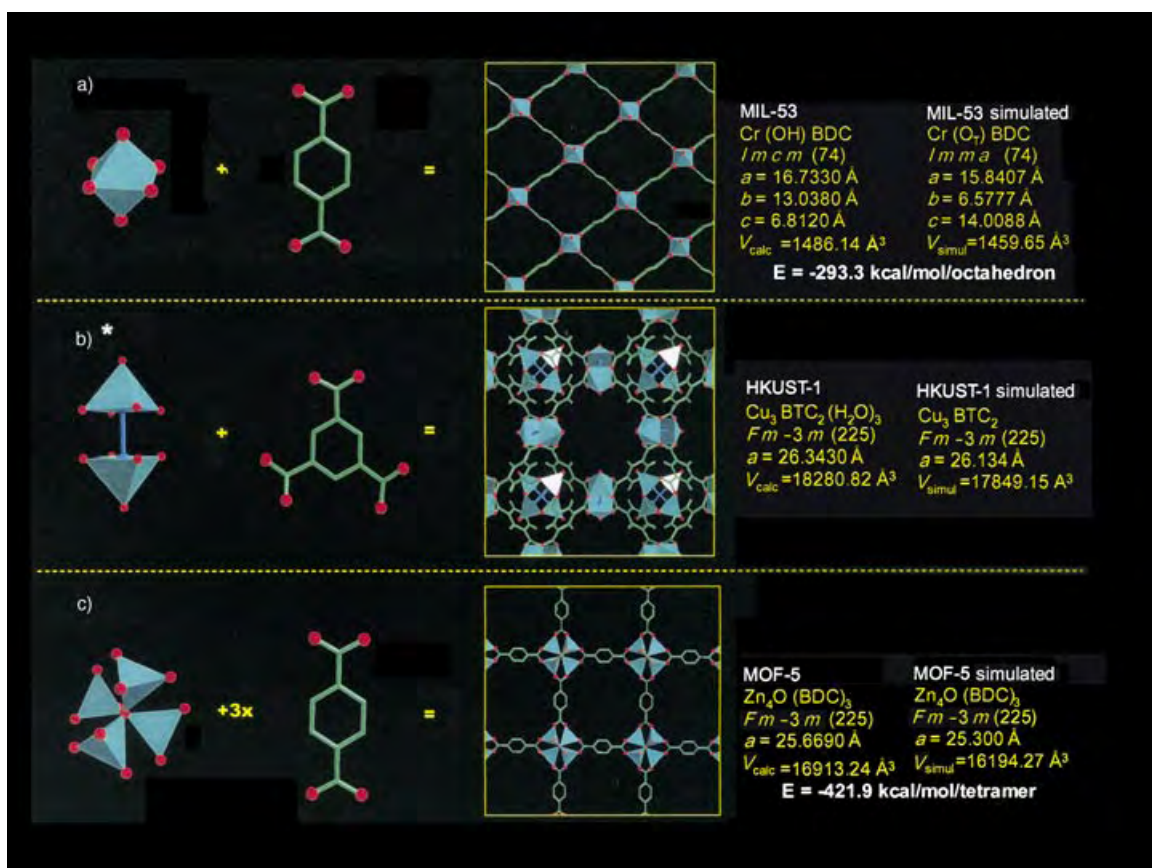

Figure 1. Left: Examples of mono-(a), di-(b), and tetrameric (c) metal clusters and organic carboxylate ligands commonly found in hybrid frameworks. Right: For each organic/inorganic combination, an example of existing very open framework is shown. (∗) The lattice energy of HKUST-1 could not be easily estimated due to the Cu–Cu metal bond and therefore the difficulty of estimating partial charges on Cu atoms.

structures that are possible for a given metal–organic-ligand pair, and to aid the often-difficult task of crystal-structure determination.

In the computational approach that we have developed, the inorganic and organic counterparts may be treated as two different building units, or encapsulated in a single hybrid building block. Both approaches were explored. The preliminary step consists of the elaboration of a suitable library of SBUs, which we directly extracted from known and typical hybrid frameworks (Figure 1). The inorganic unit is modeled by a rigid body, ($\{M_x L_y^{inorg}\}$; M: metal centers; L^{inorg}: ligand atoms of the inorganic units). The organic unit is treated as a flexible body, ($C_n L_m^{org}$; C: carbon skeleton, L^{org}: ligand atoms of the organic units such as oxygen atoms of carboxylate functions). The computational assembly is further controlled through the use of predefined "sticky-atoms": all ligand atoms on both the organic and inorganic units, L^{inorg} and L^{org}, are defined as equally possible linkage points.

The rules that control the possible assembly of the organic and inorganic building units during the subsequent simulation steps are encapsulated in a forcefield that includes "sticky-atom" pairs. They are parameterized on an atom–atom basis by a simple Lennard–Jones expression for the energy of interaction between pairs of atoms i and j, as defined in Equation (1):

$$E_{ij} = \varepsilon_{ij} \left[(r_{ij}^*/r_{ij})^{12} - 2 (r_{ij}^*/r_{ij})^6 \right] \tag{1}$$

The $L^{org} \cdots L^{inorg}$ sticky-atom pairs are those that form the organic–inorganic linkages, parameterized as a highly attractive potential well with a minimum at very short $L^{org} \cdots L^{inorg}$ separations. Similarly, $L^{inorg} \cdots L^{inorg}$ sticky-atom pairs are those that form inorganic–inorganic clusters. A repulsive potential between $L^{org} \cdots L^{org}$ pairs avoids overlapping or connections of organic molecules to one another (Table 1). This potential serves simply to "glue" together organic and inorganic units according to general criteria. The total cost or energy of a given arrangement of organic and inorganic building units in a unit cell, E_{total}, is calculated as the sum over the set of building units of the Lennard–Jones terms [Eq. (1)] that involve

Table 1: Lennard–Jones (L.–J.) parameters used in the AASBU simulations for assembling BDC and octahedral metal centres $\{ML_6\}$.[a]

Atom pairs	L.–J. potential	ε_{ij} [kcal mol^{-1}]	r_{ij} [Å]
$L^{inorg} \cdots L^{org}$	attractive	1000	0.2
$L^{inorg} \cdots L^{inorg}$	attractive	1000	0.2
$L^{org} \cdots L^{org}$	repulsive	1	2.2

[a] The potential parameters that ensure the intramolecular flexibility (bond, angle, torsions) of the organic ligand during the AASBU simulations are given in the Supporting Information.

dissimilar pairs of atoms, plus a term relating to the intra-molecular energy of the flexible organic unit, as defined in Equation (2):

$$E_{organic} = \sum\nolimits_{atoms} (E_{bond} + E_{angle} + E_{torsion}) \text{ with}$$
$$E_{bond} = \frac{1}{2}k_{ij}(r_{ij}-r_o)^2, \; E_{angle} = \frac{1}{2}k_{ijk}(\theta_{ijk}-\theta_O)^2, \; E_{torsion} \quad (2)$$
$$= \frac{1}{2}\sum\nolimits_n B \left(1-d\cos(n\,\varphi_{ijkl})\right)$$

The cost function used here is not an expression of the internal energy of the system, but simply evaluates its degree of connectivity.

Minimal amount of input data is required for a given simulation: the number of organic units per asymmetric unit, the number of inorganic units per asymmetric unit (alternatively the number of hybrid building blocks), and optionally the space group, as in the most general case simulations may be performed in $P1$. The simulations are not constrained by the cell dimensions. The number of independent entities (organic versus inorganic) is the key input parameter restricting the subsequent search within structures that have the desired metal:organic ratio. This method is therefore adequate for searching polymorphs of hybrid frameworks.

The computational steps for generating candidate periodic hybrid structures are performed by using the AASBU method.[27] The main steps are summarized below, further details may be found in reference [27]: 1) periodic trial arrangements of organic and inorganic units are generated by using a simulated annealing Monte Carlo procedure within the imposed space group and the imposed number of organic and inorganic units per asymmetric unit. At this stage, the stored configurations correspond to unconnected organic and inorganic units in 3D space. 2) Each unique arrangement is minimized with respect to the total cost function [Eqs. (1) and (2)]. This is a key step at which the assembly of inorganic and organic units (or alternatively hybrid building blocks) through the predefined linkage points is performed, which possibly leads to periodic connected hybrid arrangements. At this step, the flexibility of the organic unit is crucial to make adequate connections to the inorganic units. 4) Sticky-atom pairs, $L^{org}\cdots L^{inorg}$ and $L^{inorg}\cdots L^{inorg}$, are reduced to a single atom. Realistic predictions of crystal structures are thus produced. The symmetry of each candidate hybrid structure is redetermined by using the Find_Symmetry algorithm.[32]

The AASBU simulation steps were performed by using the Polymorph Predictor of the Cerius2 program.[33] The simulations are left with a list of candidate hybrid structures (space group, cell, atomic positions). A typical calculation requires from around 2 h for "mixing" one simple inorganic unit and one organic molecule per asymmetric unit up to more than 16 h for assembling a more-complex hybrid building block on an Octane SGI R12000 workstation operating at 300 MHz.

As a final step to estimate the stabilities of the hybrid candidates, lattice-energy minimizations were performed on each candidate crystal structure. Short-range interactions were calculated by using the UFF forcefield.[34] The electrostatic contribution was calculated with an Ewald summation by using partial charges obtained from the charge-equilibration method.[35]

With the purpose of demonstrating the viability of our approach in the area of hybrid frameworks, we first focused our efforts on the simulation of existing and well-characterized hybrid frameworks. A limited number of very-large-pore hybrids were chosen as prototypic structures, such as **MIL-53** (M(OH)(BDC), BDC = benzene-1,4-dicarboxylate, M = V^{3+},[36a] Cr^{3+}[36b] or Al^{3+}[36c]), **HKUST-1** ($Cu_3(BTC)_2(H_2O)_3$; BTC = benzene, 1,3,5 tricarboxylate),[37] and MOF-5 ($Zn_4O(BDC)_3$)[12a] (Figure 1), that is, with the specific aim of predicting their full crystal structure by using the related inorganic unit (monomer, dimer, tetrameric respectively) and organic ligand.

A first possible approach consists in computationally assembling independent organic and inorganic units. This mixture approach was explored in the case of the monomeric, trimeric, and tetrameric metal clusters. In the case of the dimeric metal cluster an approach with a hybrid building block is presented below. For example, a series of AASBU simulations were performed with one single octahedron per asymmetric unit, in which the six ligand atoms were possible linkage points, together with one BDC molecule per asymmetric unit in which the four oxygen atoms were defined as possible linkage points thus ensuring a 1:1 metal:organic ratio. Various space groups were sampled: $P1$, $P\bar{1}$, Cc, $Pna2_1$, $P3$, $P\bar{3}$, $P4$, $P\bar{4}$, $P6$, and $P\bar{6}$. The **MIL-53** topology was produced in space group Cc among a list of 54 candidates, with the final high symmetry, $Imma$, in excellent agreement with that of the experimental structure, ($Imcm$)[36c] (See Figure 1a). Interestingly, **MIL-53** belongs to the class of flexible networks that exhibit a very large breathing effect upon water adsorption/removal, which results in important changes in the symmetry and cell size (hydrated: $C2/c$; calcined: $Imcm$).[36c] Interestingly, the simulations performed here in the absence of extraframework species (i.e., water) yield the **MIL-53** topology in its high symmetry form, which is indeed the symmetry of the experimental calcined (water-free) structure.

When this method was adopted for each inorganic and organic units in the required ratio, the expected metal–organic frameworks were generated (Table 2, Figure 1, and Figure 2). An illustrative example was tackled with the tetrameric units found in the prototypic **MOF-5** (Figure 1b).[12a] AASBU simulations were performed by mixing one single tetrameric unit, $\{M_4(\mu_3\text{-}O)(L_3)_4\}$, defined with 12 possible linkage points, and 3 BDC molecules per asymmetric unit, defined with 3×4 possible linkage points. During the simulations steps, only connections between the inorganic unit and the BDC molecules were allowed, while preventing inorganic–inorganic connections with repulsive parameters. The **MOF-5** topology was predicted successfully and appeared in space group $Aba2$, which was ranked the lowest-energy structure among a list of 115 candidates. Indeed, only the first two candidates corresponded to plausible inorganic–organic frameworks: the framework adopts the topology in which $\{M_4(\mu_3\text{-}O)(L_3)_4\}$ tetramers are connected through twelve $L^{inorg}\cdots L^{org}$ interactions to six carboxylates in the octahedral directions to form the expected

Table 2: AASBU simulations of experimentally known hybrid frameworks.

Organic and inorganic units	Organic/inorganic ratio imposed	Initial space group[a]	Predicted structure	Final space group[a]	Ref.
BDC + {ML$_6$}	1:1	*Cc*	**MIL-53**	*Imma*	[36]
BDC + {M$_4$(μ_3-O)L$_{12}$}	3:1	*Aba*2	**MOF-5**	*Fm$\bar{3}$m*	[12a]

Hybrid building-block	Organic/inorganic ratio imposed	Initial space group[a]	Predicted structure	Final space group[a]	Ref.
{M$_6$(BTC)$_4$}[b]	3:2	*C*2	**HKUST-1**	*Fm$\bar{3}$m*	[37]
{M$_6$(BTC)$_4$}[b]	3:2	*Fd$\bar{3}$m*	**MIL-100**	*Fd$\bar{3}$m*	[41]

[a] We make a distinction between the space group as imposed during the AASBU simulations themselves (initial space group) and the space group as obtained from the final symmetry analysis of the simulated structures (final space group). They may be different as arrangements of higher symmetry than that imposed may be produced. [b] The building blocks are built with 12 metal centers (4 trimeric clusters or 6 dimers). However, each dimeric (or trimeric) metal cluster is parameterized to be half-shared with another building block, hence the reported composition of 6 metal centers per building block.
Figure 2. Left: Hybrid building blocks derived from [{Cu$_3$(BTC)$_2$(H$_2$O)$_3$}$_n$].[37] This is an octahedral unit where {Cu$_2$} dimers are placed at the six vertices. The four BTC molecules are placed at four of the eight triangular faces of the octahedron. Right: The expected **HKUST-1** structure was computationally generated by self-assembling the hybrid building block (different colors are used for each building block).

porous cubic structure. The lattice energy minimizations, the simulated cell parameter, and symmetry (25.3 Å, *Fm$\bar{3}$m*) of the first candidate are in excellent agreement with the experimental findings (25.67 Å, *Fm$\bar{3}$m*).

An interesting alternative to the computational mixture of independent organic and inorganic units (see above) is to consider a single hybrid building block and to allow its self-assembly during the subsequent simulation steps. This approach, which has the advantage of being directly inspired by the concept of secondary building blocks used by synthesis chemists for the design of targeted networks, was explored with a paddle-wheel cluster that is known in many complexes[38] and was involved in the synthesis of hybrid frameworks.[7a,37] We started from the SBU proposed by Williams and co-workers in the description of the 3D hybrid framework, **HKUST-1**.[37] As illustrated in Figure 2, the {Cu$_2$} dimers were placed at the vertices of an octahedral unit while being interconnected through BTC molecules placed at four of the eight triangular faces of the octahedron. During

the AASBU simulations, this hybrid building block was allowed to self-assembly by direct edge sharing at the Cu–Cu metal bond. By using two building blocks per asymmetric-unit, we successfully simulated and energy minimized the expected **HKUST-1** structure in the initial space group *C*2, which lead to a crystal structure with the expected symmetry *Fd$\bar{3}$m* and cell parameters (a_{sim} = 26.134 Å/a_{exp} = 26.343 Å).

When compared to the first approach, which mixes independent organic and inorganic units, the hybrid building block inherently contains additional structural information on organic–inorganic connections. While obviously requiring an advanced knowledge of the system under study, this approach should in principle allow a more restricted (i.e., more rapid) production of viable hybrid candidates.

An attractive feature of the simulations is indeed the generation of new topologies. Typically, while assembling one {MO$_6$} octahedron and one BDC molecule (section above), not only the experimentally known **MIL-53** structure was predicted but also a series of not-yet-synthesized topologies ranging from lamellar to 3D extended structures. Figure 3 shows a selection of three hypothetical structures chosen for their serendipitous topological relationships. The three structures derive from the same layer (Figure 3a) and differ only by the degree of "condensation" of the sheets: the stacking of unconnected sheets builds the first structure (Figure 3b), while the second (Figure 3c) shows stacking of dimerized-planes. The third structure has a 3D network (Figure 3d) that results from the infinite stacking of the planes. Another interesting 3D hexagonal structure was produced (Figure 4a), which exhibits large tunnels ($\varnothing$ = 15,6 Å). These candidates illustrate how simulations may be a valuable tool for high-lighting topological relationships.

On the other hand, the number of hybrid structures that contain trimeric metal clusters formed by the assembly of three vertex-sharing octahedra is very scarce.[7b,39] For this reason, our group has recently focused on their chemical condition of existence in hydrothermal synthesis.[40] By using our computational approach to encapsulate the trimeric metal cluster and BDC (or BTC) molecules in a hybrid building block, we simulated a whole series of plausible and very open frameworks.

Figure 4b–c show two hypothetical topologies generated by using a building block that contains BDC and trimeric metal clusters. These topologies represent cubic polymorphs with large cell volumes, 23 579 Å^3 and 64 524 Å^3, and have central cages with an internal diameter of 25 Å, accessible through "four rings" of trimers. A detailed study on this new family of polymorphs will be published elsewhere. [41]

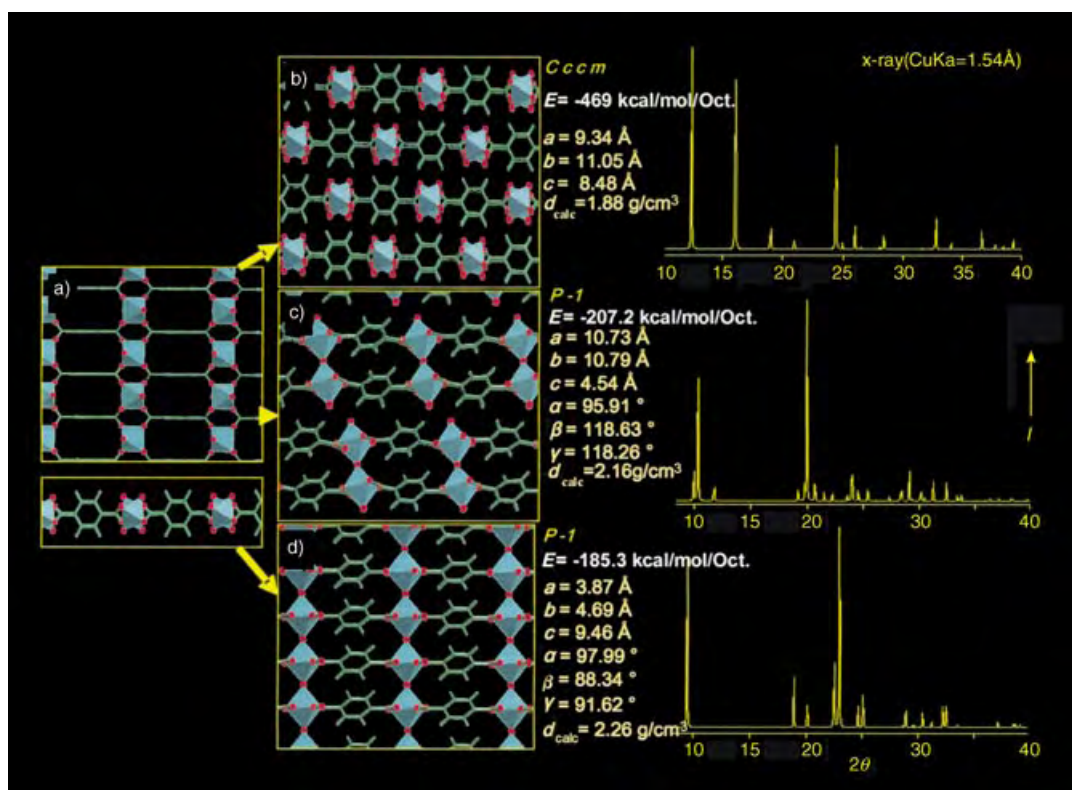
Most interestingly, one of the trimeric BTC-based hybrid polymorph (Table 2) has a giant unit cell and exhibits a


Figure 3. Topological relationships between three simulated hybrids that were obtained by assembling one BDC molecule and one octahedron per asymmetric unit. The three structures are built from the same plane (top and side view in a), which range from lamellar (b and c) to 3D networks (d). *I*: intensity (arbitrary units).
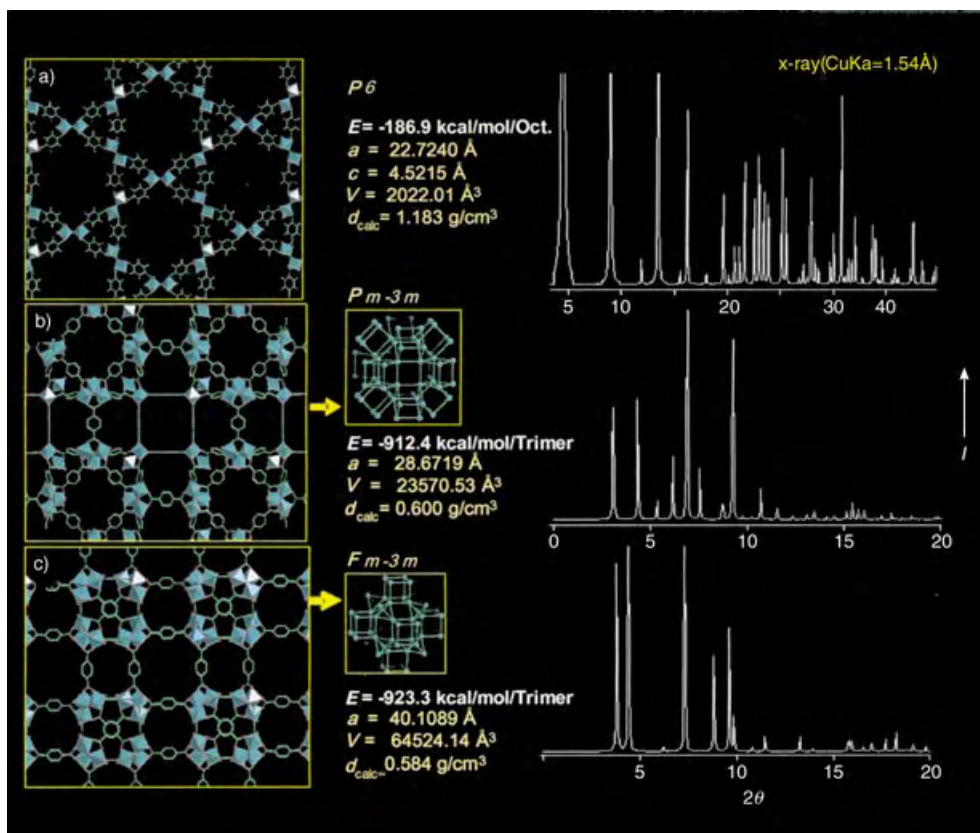

Figure 4. Hypothetical very-open hybrid frameworks, simulated by assembling BDC with a single octahedron (a), and with trimeric metal clusters (b) and (c).

simulated diffraction pattern that exactly matched the experimental pattern of a new phase synthesized in our group, MIL-100. Thus we obtained the solution of its direct-space structure and ensured a valid model for subsequent structure refinement.[42]

In conclusion, this work addresses the computational prediction of hybrid organic–inorganic extended lattices. The production of candidates of crystal structures was successfully performed by direct-space assembly of building units by the AASBU method, either through mixing independent organic and inorganic units or by assembling predefined hybrid building blocks. Hybrid candidates that are compatible with the imposed metal:organic ratios were generated with their cell parameters, space group, atomic positions, along with their simulated diffraction pattern and an estimate of their lattice energies. Since no explicit limit regarding the nature, number, and size of the inorganic and organic units, or hybrid building block is involved, the method offers boundless potential for exploring hybrid frameworks in terms of the topological diversity.

The most appealing development arises from the computer-assisted design of hybrid frameworks. Indeed, in a significant number of systems, it is well-known that controlled synthesis conditions can promote the occurrence of specific building units, which serve to "propagate" the infinite crystal structure. We believe that the computational approach presented herein is valuable to create virtual libraries of viable hybrid polymorphs. Furthermore, AASBU simulations have proven to be, for the first time in the realm of hybrids, a tangible route towards structure solution in direct space.[42] This challenging area is of crucial interest when high quality diffraction data are not available or when very large cell sizes are involved. The development of a structural model in direct space, starting with minimal knowledge such as the metal: organic ratio, is shown to be possible. With such a method in hand, formerly intractable structural problems when using methods based on conventional reciprocal space become feasible in direct space.

We believe this approach serves a step forward in the computational anticipation and structure solution of hybrid frameworks. It should allow one to tackle the issue of polymorphism, while opening up the field of synthesis of new hybrid frameworks and structure solution for compounds that have not yet been characterized.

Molecular gigantism is very topical in inorganic chemistry.[1–5] Inorganic and hybrid nanoporous solids, and keplerates[5] provide illustrations of this trend. Beside its academic interest, this research is motivated by the numerous applications related to this gigantism, such as their use as possible nanoreactors, or in catalysis,[6] gas separation,[7] and gas storage.[8] Besides the systematic chemical search of new systems, two main topological concepts were applied to reach a possible design of porous solids: "scale chemistry"[9] for inorganics and "reticular synthesis from augmented nets"[3, 10, 11] for metal–organic frameworks (MOFs). These two concepts have however limitations: they cannot always provide polymorphs; their topological predictions rapidly lead to complex structures that are almost impossible to solve in the absence of single crystals. We shall prove in the following that, in the domain of MOFs, the introduction of computer simulation beside targeted chemistry of the inorganic moiety push forward these limits. It leads to a new crystalline MOF (**MIL-100**) with a giant cubic cell, the volume of which is close to $380\,000\ \text{Å}^3$. It exhibits a hierarchy of micro- ($\varnothing \approx 6.5\ \text{Å}$) and mesopores ($\varnothing \approx 25\text{–}30\ \text{Å}$) and a large sorption capacity ($3100\ \text{m}^2\,\text{g}^{-1}$).

The dream of the solid-state chemist is the synthesis of "tailor-made" compounds with predicted structures and properties. Forbidden in the case of high-temperature synthesis, which is governed by diffusion processes, the synthesis of tailor-made solids is indeed on the way to being realized in the ever growing domain of MOFs, the synthesis of which gives solids by precipitation of the species from solution. In three main seminal articles,[3, 11, 12] Yaghi, O'Keeffe, and co-workers progressively defined the concept of reticular chemistry with the chemical and topological rules that govern this possible design. This concept starts from the existence in solution of well defined and rigid inorganic and

organic building blocks, which must maintain their structural integrity throughout the construction process of the solid. The proper choice of these inorganic and organic building blocks and their assembly by strong bonding must lead to predetermined ordered structures, reminiscent of the topology of dense structures. Numerous examples in the literature illustrate this concept.[9, 12]

However, one of the limitations of this approach concerns the enumeration of the possible predetermined frameworks accessible from predefined building blocks. So far, what is usually called "design" is the realization of a reasonable expectation of a given structural arrangement. Indeed, the idea of a framework resulting from the connection of building blocks refers only to the most probable organization, based on an initial intuition strengthened by topological symmetry rules.[12] Keeping in mind the principles of reticular chemistry, we applied our new concept to crystal structures of MOFs with the aim of exploring all possible combinations of connections between inorganic and organic building blocks in the system experimentally under study by using original global optimization simulations.[13] This computational approach takes advantage of our previous AASBU method,[14] based on the concept of secondary building units (SBU), to assemble organic and inorganic units. It explores the whole space of configurations with the corresponding cell parameters, space groups, and theoretical atomic coordinates; it classifies the different solutions by their relative energies and therefore gives the most likely arrangements. The validity of the method was first proved by finding hybrid structures that are already known, built from different types of inorganic and organic building units. Moreover, unknown topologies with reasonable relative "energies" appeared during the calculations for all the inorganic and organic building units considered. Finally, the calculated X-ray powder-diffraction pattern for each candidate topology may be directly compared to patterns obtained experimentally, thus allowing the rapid identification of new phases. The efficiency of this method relates to the way that it is carried out, but requires that the inorganic building block be present at an early stage of the reaction.

We recently developed separately the computational[13] and experimental[15] aspects of our concept. Among the best identified inorganic building blocks, our attention focused on the determination of the chemical conditions leading to trimers that are formed by the assembly of three octahedra sharing a common vertex μ_3-O,[15] because known examples are scarce.[3, 16] The conditions used to synthesize the inorganic building units depend on the nature of the cation. Although we initially focused on complexes of Fe^{3+} ions,[15] the search was extended to complexes of Cr^{3+} ions. The combination of Cr^{3+} ions with trimesic acid (benzene-1,3,5-tricarboxylate; BTC) under hydrothermal conditions leads to a new powdered chromium hybrid solid (**MIL-100**).

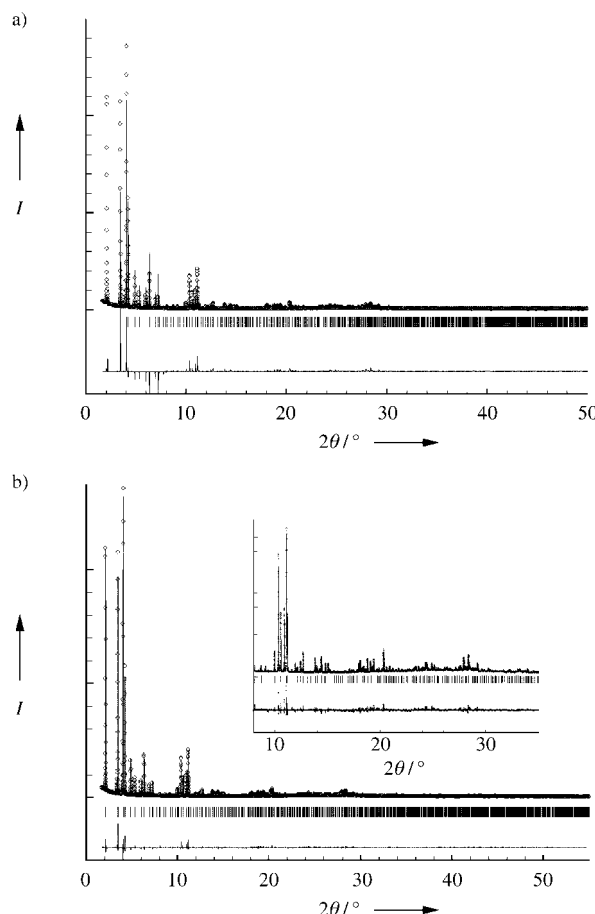
MIL-100 is a highly crystalline and pure green solid, a chromium trimesate of chemical composition $Cr_3F(H_2O)_3O[C_6H_3-(CO_2)_3]_2 \cdot n\,H_2O$ ($n \sim 28$). Its resulting pattern is so complicated (Figure 1) that, in the absence of single crystals, the knowledge of the related structure is ruled out. Consequently, our new simulation method[13] dedicated to the


Figure 1. a) Comparison of the simulated X-ray pattern predicted for **MIL-100** (full lines) with that of the experimental (circles). b) Final Rietveld plot of the as-synthesized **MIL-100**. In both figures, the difference spectrum appears at the bottom. I = intensity.

prediction of MOFs is used to predict candidate crystal structures of **MIL-100**. Candidates polymorphs for the [Cr–BTC] system are simulated as follows. Based on the assumption that there are inorganic trimers (Figure 2a) in the new hybrid **MIL-100**, as highly suggested by our previous results,[15] and that these trimers are linked to the constitutive organic ligand (BTC), possible hybrid building blocks are computationally designed and auto-assembled. Indeed, the arrangement of BTC and inorganic trimers into a large super tetrahedron (ST) was considered as a possible hybrid building block (Figure 2b) and was selected for its compatibility with the chemical composition (metal:organic ratio) of **MIL-100**. The ST is built in such a way that the four vertices of the ST are occupied by the trimers while the organic linker is located at the four faces of the ST. The connection of the ST is established through vertices to ensure a 3D network of "corner-sharing" super tetrahedra. At this stage, three interesting candidates of likely crystal structures were identified and assorted with their full crystallographic parameters together with their simulated X-ray powder patterns. Strikingly, all three candidates are upper homologues of zeotype architectures,[19] that is, MEP, MTN and a new hexagonal type, referred to hereafter as HEX, in which each tetrahedral

Communications

Free water molecules have been omitted for clarity.

center (TO_4), typical of zeolites, is occupied by one super tetrahedron. The corresponding structures, described with more details below (Table 1) illustrate the concept of "scale chemistry".[9] They represent polymorphs with cell volumes in the range 120 000–360 000 $Å^3$. Two of them are cubic (MEP,

MTN; space group $Fd\bar{3}m$, $Pm\bar{3}n$, respectively), the third is hexagonal (HEX, space group $P6_3/mmc$). From this point of view, our computational approach is able to create the potential upper homologues of numerous silicates and zeolites with ST instead of small tetrahedra.

Interestingly, the simulated pattern of the MTN-type hybrid structure matches the targeted experimental pattern of **MIL-100** (Figure 1a), thus yielding the solution of the direct-space structure of the new phase and ensuring a valid model for subsequent structure refinement. The diffraction pattern calculated from the MTN-type computed model corresponds exactly to the position of the Bragg peaks of the new structure. The only difference (Figure 1a) concerns the discrepancy between simulated and experimental intensities; the simulated pattern obtained from the computed model corresponds only to the skeleton whereas the experimental pattern also takes into account the contribution of the occluded species. Owing to the large cell volumes involved, the challenge was then to consider the possibility of a Rietveld refinement of the structure, which required first a very good collection of powder data by using synchrotron radiation (see Experimental Section). Finally, the atomic coordinates and cell parameters of MTN-type model predicted from the simulations were used to perform the Rietveld refinement of the synchrotron diffraction pattern of **MIL-100**. Surprisingly, despite the large number of parameters (67 independent framework atoms, ≈ 170 parameters, in a cell volume of 387 000 $Å^3$), the refinement converges toward good R values and improves the prediction by locating the position of inserted species, which are free water molecules in the case of **MIL-100**. The final Rietveld plot is represented on Figure 1b. The refinement correctly converged towards the general formula $Cr_3F(H_2O)_3O[C_6H_3(CO_2)_3]_2 \cdot nH_2O$ ($n \approx 28$), which is in agreement with the chemical analysis. Extra framework water molecules were localized by using Fourier-difference maps (45 independent water molecules). Full details are given in the Supporting Information.

This is the first time, in the field of hybrid solids, that a rational simulation approach provides a solution of the crystal structure constructed only from topological criteria, which matches the experimental X-ray diffraction pattern of the solid (Figure 1). It is a new method in which conventional direct- or reciprocal-space methods cannot be used in the structure-solution process. The very-

large cell volume involved in our results opens the window to the discovery of numerous new solids with huge potential applications. In the absence of single crystals, such solids could never be tackled before owing to the extreme complexity of the corresponding structures. They now become accessible.

In the supertetrahedra (see Supporting Information), all the bond lengths are in the usual range (1.81–2.18 Å for Cr–O, 1.37–1.64 Å for C–C; 1.23–1.37 Å for C–O). Moreover, valence-bond calculations show that in the trimer the terminal oxygen atom is from a water molecule. The aromatic ring of BTC occupies the center of the faces of the ST. Within the ST, the cage, which has 24 oxygen atoms and carbon 36 atoms and an internal diameter of 6.6 Å. This dimension corresponds to the domain of micropores, in the same range as zeolites.

More interestingly, the corner sharing of the ST delimits a framework with two types of cages (Figure 3), whose dimensions are now typically in the range of mesopores. The smallest cage, which has 20 ST, has an internal diameter of

≈ 25 Å. The polyhedron obtained by joining the centers of the ST is a pentagon dodecahedron (the free opening of the pentagonal windows: (≈ 4.8 × 5.8 Å) being rather small because the terminal water molecules of the trimer point toward the center of the window). The centers of the dodecahedra, are in the (0,0,0) 16c positions of the space group $Fd\bar{3}m$ (origin choice 2). The subnetwork that joins these centers forms corner-linked tetrahedra as in the pyrochlore structure.[17] The dodecahedra share faces and form (see the Supporting Information) infinite linear rodlike chains,[18] which cross orthogonally to each other through common faces to ensure the 3D network. This connection creates larger cavities, which have 28 ST. These cages are centered on the (1/8,1/8,1/8) 8a sites of the space group $Fd\bar{3}m$. The polyhedron determined by the centers of the ST has now 12 pentagonal and 4 hexagonal faces. The aperture of the large hexagonal windows is ≈ 8.6 × 8.6 Å² and the internal diameter becomes close to ≈ 29 Å. In the as-prepared materials, the cavities are occupied only by water molecules. The location of the fluoride counterions within **MIL-100** could not be determined due to the similar diffusion factors of oxygen and fluorine atoms; thus, these anions may be either located in terminal position bound to chromium atoms or within cages as they are in previous structures based on iron trimers.[15]

In inorganic chemistry, such dimensions of pores are mostly reached with mesoporous solids, which, in contrast to the compounds presented herein, have amorphous walls. Thus, **MIL-100** provides the first example of a porous solid with crystalline walls, with a unique hierarchical system of three types of cages of different dimensions. Indeed, this solid may have applications in the domain of adsorption/separation of species.

The two other polymorphs found by our computer simulations have the same relative "energy" cost as **MIL-100** (see Table 1). Both of them have infinite chains of face sharing pentagon dodecahedral cages, already described for **MIL-100**. In the cubic structure ($Pm\bar{3}n$), the corresponding rods cross in three directions of space, thus creating larger cages, this time with 24 vertices instead of 28 and the resulting framework is an upper homologue of zeolite MEP.[19] The topology of the hexagonal polymorph ($P6_3/mmc$), hitherto
Figure 3. Top: Schematic view of the 3D organization of the structure of **MIL-100** with the medium (green) and large (red) cages delimited by the vertex sharing of the ST (the vertices represent the centers of each ST). Bottom: View and dimensions of the two different cages (green, 20 tetrahedra; red, 28 tetrahedra). The medium cages share faces and form interconnected rods (in green) in the interstices of which are located the large cages.

unknown, corresponds to intersecting rods at 60° to each other, and the larger cages are the same as those in **MIL-100**.

The thermal behavior and the sorption properties of **MIL-100** were investigated. First, the thermal gravimetric analysis carried out in air (see Supporting Information) reveals an interesting stability of the title phase up to 275°C. X-ray thermodiffractometry shows that the evacuation of the guests does not affect the topology of the skeleton; only the intensity of some Bragg peaks change, otherwise the pattern fits with that predicted. Second, the title material takes up gases readily. The gaseous N_2 sorption isotherm on the fully evacuated samples (Figure 4) is between type I and IV with
Figure 4. Nitrogen gas sorption isotherm at 78 K for MIL-100 degased overnight at 100°C. P/P_0 is the ratio of gas pressure (P) to saturation pressure ($P_0 = 750$ torr). V is the adsorbed volume ($cm^3 g^{-1}$).

a slight secondary uptake, which is indicative of the presence of both micro- and mesopores. No hysteresis is observed. Using the Dubinin-Raduskhvich equation, we found a pore volume of around 1.16 $cm^3 g^{-1}$ for **MIL-100**. For a monolayer coverage of N_2 (which may not be strictly correct with such large cavities), we estimate the apparent Langmuir surface area to be 3100(40) $m^2 g^{-1}$, which is close to the highest values known.[20]

In conclusion, we have shown from a straightforward example the strength of the combined chemistry–simulation approach for obtaining new materials. The resulting hybrid chromium carboxylate, **MIL-100**, has an eye-catching structure that has a hierarchical pore system (micro: ≈5–9 Å; mesoporous: ≈25–30 Å) with a very-high surface area (≈3100 $m^2 g^{-1}$). While tackling the polymorphism of MOFs by limiting the domain of structures that are possible for a given metal–organic ligand pair, we found that simulations applied to hybrids is a tangible route towards structure solution in direct space. This new approach has the advantage that single crystals are not required for the resolution of the structures, which can be done from Rietveld refinements of powder-diffraction data. This represents a useful tool to bridge a gap because many solids, previously isolated by several groups, were abandoned owing to the lack of single crystals and the complexity of the powder patterns. Incidentally, the results obtained here open a window of opportunity to search for new porous solids with giant pores, which represent the upper homologues of numerous well-known zeolites. This work provides a new example of the possibilities of the concept of "scale chemistry": the increase of the size of the ST generates larger pores, which open the way to new applications for MOF porous solids. Finally, the question may be posed as to whether structures such as **MIL-100** arise from design. The answer is clearly no because in design, one must first imagine something then realize it afterwards. In our approach, the first step does not involve imagination (which is a creative act), but is the result of a computational prediction. For this reason, we prefer to suggest that the label of "simulation assisted chemical structures" (SACS) is the best description for solids obtained by using our method.

Experimental Section

Syntheses and chemical analyses: Metallic chromium (52 mg, 1 mmol; Aldrich, 99%) was dispersed into an aqueous solution of 5M hydrofluoric acid (0.4 mL, 2 mmol). After the addition of 1,3,5-benzene tricarboxylic acid H_3BTC (150 mg, 0.67 mmol; Aldrich, 99%) and H_2O (4.8 mL, 265×10^{-3} mol), the mixture was heated in a hydrothermal bomb at a rate of 20.0°C h^{-1} to 220°C, kept at this temperature during 96 h, then cooled at a rate of 10.0°C h^{-1} to room temperature. The resulting green powder was washed with deionized water and acetone and dried in air. The yield of the reaction was ≈45% based on chromium.

Chemical analyses: These were performed at the National Center of Analysis of the CNRS in Vernaison (France). As the amount of water present in the samples is very sensitive to the temperature (see TGA), only the C:Cr and F:Cr ratios are significant. They agree well with the formula deduced from the structure (C:Cr$_{exp}$ calcd 6.0, found 6.75; F:Cr calcd 0.33, found 0.31).

TGA measurements: A crystalline sample was heated from 25 to 600°C in air at a constant rate of 2°C min^{-1}. Two weight-loss steps

were observed: the first (35% of initial weight) occurred between 25 and 250 °C and is attributed to the loss of guest water molecules (calcd 40%); the second (44% of initial weight) is due to the removal of fluoride ions and the decomposition of the framework and occurred between 275 and 400 °C.

Sorption measurements: Experiments were performed on a Micromeritics ASAP 2010 with nitrogen as the adsorbed gas. **MIL-100** was dehydrated under vacuum overnight at 150 °C.

Crystallographic study: Powder X-ray diffraction data were collected at the high resolution beamline ID31 of the European Synchrotron radiation Source (ESRF), Grenoble (France), from a sample contained in a 1 mm diameter capillary. ID31 beamline receives X-rays from the synchrotron source (which operates with an average energy of 6 GeV and a current beam of typically 200 mA) from an ondulator device. The incident X-ray wavelength was 1.55075 Å. Data collection was performed over the angular range 1–97° 2Θ, with a step 0.005° at 80 K by using a cryostream (cold nitrogen gas blower). Cubic cell, $a = 72.906$ Å (**MIL-100**) with adequate figures of merit was found. Systematic absences were consistent with the space group $Fd\bar{3}m$ (no. 227). After the pattern had been matched, the structure refinement was initiated by using the atomic positions obtained from the simulations. The final agreement factors (Figure 1 b) were satisfactory: $R_p = 5.48\%$, $R_{wp} = 7.61\%$, and $R_{Bragg} = 9.28\%$. For details see the Supporting Information.

The Supporting Information accompanying this paper contains crystallographic and TGA data.

Chemical Control of Valence Tautomerism of Nickel(II) Semiquinone and Nickel(III) Catecholate States**

Hideki Ohtsu and Koji Tanaka*

Transition-metal complexes with dioxolene ligands have been attracting much attention because of their characteristic ligand-localized redox reactions among the three redox states of quinone (Q), semiquinone (SQ), and catecholate (Cat) in addition to metal-centered redox reactions.[1] Interest has especially been paid to interconversion of valence tautomers in the metal–dioxolene framework.[1] Valence tautomers are characterized by displacement of electron density to one redox center or the other, for example, M^{II}-SQ

and M^{III}-Cat compounds, which interconvert by intramolecular electron transfer between the two redox centers. Knowledge gathered for a number of metal complexes with dioxolene[2] and other redox-active ligands[3–5] showing valence-tautomeric behavior greatly aids in exploiting this phenomenon for molecular switching devices.[6] However, neither nickel dioxolene complexes exhibiting interconversion of valence tautomers nor control of valence tautomerism by modification of electron-donor ability of ligands to central metal atoms has been reported so far.

We report herein the synthesis and characterization of nickel(II) semiquinonato and nickel(III) catecholato complexes containing bidentate ligands with modulated nitrogen-donor ability,[7] namely, [Ni^{II}(PyBz$_2$)(tBu$_2$SQ)]PF$_6$ (**1**) and [Ni^{III}(MePyBz$_2$)(tBu$_2$Cat)]PF$_6$ (**2**) as the first example for successful control of valence tautomerism between the Ni^{II}-SQ and Ni^{III}-Cat frameworks by fine-tuning of the donor ability of the bidentate ligands to the nickel ion (Scheme 1).
Scheme 1. Structures of bidentate ligands and dioxolene redox forms.

Scheme 2. Synthesis of **1** and **2**.

Figure 1. ORTEP view of **1**. Hydrogen atoms and counteranion are omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Ni–N(1) 1.858(3), Ni–N(2) 1.918(3), Ni–O(1) 1.860(3), Ni–O(2) 1.843(3), C(1)–O(1) 1.305(5), C(2)–O(2) 1.294(5); N(1)-Ni-N(2) 86.7(1), N(1)-Ni-O(1) 172.8(1), N(1)-Ni-O(2) 93.6(1), N(2)-Ni-O(1) 93.9(1), N(2)-Ni-O(2) 175.1(1), O(1)-Ni-O(2) 86.5(1).

The Ni^{II} semiquinonato complex of PyBz$_2$, **1**, was obtained by mixing PyBz$_2$, tBu$_2$CatH$_2$, and Ni^{II}(ClO$_4$)$_2$·6H$_2$O in a 1:1:1 ratio in acetonitrile and subsequent addition of 2 equivalents of Et$_3$N and 1 equivalents of ferrocenium hexafluorophosphate (FcPF$_6$). The Ni^{III} catecholato complex, **2**, was prepared in a similar manner to **1** by using MePyBz$_2$ in place of PyBz$_2$. Solutions of **1** in CH$_2$Cl$_2$ are blue, whereas those of **2** are brown (see Scheme 2).

The X-ray molecular structure of **1**[8] is shown in Figure 1. The nickel ion in **1** has a tetracoordinate square-planar environment formed by the pyridine N atom, tertiary amine N atom, and the two O atoms of the dioxolene ligand. The C(1)–O(1) and C(2)–O(2) bond lengths of the dioxolene ligand in **1** are 1.305(5) and 1.294(5) Å, respectively. These C–O bond lengths are consistent with those of nickel(II) semiquinonato complexes reported so far.[9] Although many attempts to prepare single crystals of **2** suitable for X-ray structure determination failed, its coordination geometry is safely concluded to be distorted square-planar on the basis of EPR measurements.

The EPR spectrum of **1** in CH$_2$Cl$_2$ at 77 K (Figure 2a) exhibits a sharp isotropic signal with a g value of 2.0066,[10] close to the free-spin value ($g = 2.0023$), which can safely be

Figure 2. EPR spectra of a) **1** (10^{-3} M) and b) **2** (10^{-3} M) in CH$_2$Cl$_2$ at 77 K.

assigned to a ligand-centered radical species composed of low-spin d^8 Ni^{II} ($S = 0$) and the semiquinone ($S = 1/2$) framework. Indeed, the C–O bond lengths of **1** determined by X-ray analysis agree well with those of semiquinone radicals (see

above). In contrast to **1**, an anisotropic signal ($g_\perp = 2.29$, $g_\parallel = 2.20$, $g_{iso} = 2.26$) is observed in the EPR spectra of **2** (Figure 2b).[10] The significantly larger g value of **2** ($g_{iso} = 2.26$) compared with that of **1** ($g = 2.0066$) apparently results from an unpaired electron localized on the metal center. Thus, the electronic structure of **2** is explained by a combination of low-spin d^7 Ni^{III} ($S = 1/2$) and catecholate ($S = 0$). Furthermore, the EPR parameters ($g_\perp = 2.29$, $g_\parallel = 2.20$) provide valuable information about the coordination environment of the nickel(III) ion, which is a distorted square-planar structure with a d$_{z^2}$ ground state.[11] The oxidation states of nickel in **1** and **2** were further confirmed by X-ray photoelectron spectra. The observed binding energy of the Ni $2p_{3/2}$ signals at 854.9 (**1**) and 856.1 eV (**2**) is consistent with oxidation states of Ni^{II} and Ni^{III}, respectively.[12]

Such a drastic difference in the electronic states of **1** and **2** can be ascribed to the steric effect induced by the *o*-methyl group[13–15] in the MePyBz$_2$ ligand. This group weakens the coordination of the pyridine moiety to the nickel ion compared with the unsubstituted PyBz$_2$ ligand. As a result, the dioxolene ligand of **2** binds to the nickel ion more strongly than that of **1**, and this results in the displacement of electron density to form the Ni^{II}-SQ and Ni^{III}-Cat frameworks in **1** and **2**, respectively.

Experimental Section

The complexes were synthesized under nitrogen atmosphere.

1: Ni(ClO$_4$)$_2$·6H$_2$O (0.366 g, 1.0 mmol) was added to a solution of PyBz$_2$ (0.288 g, 1.0 mmol) and *t*Bu$_2$CatH$_2$ (0.222 g, 1.0 mmol) in acetonitrile (20 mL), and triethylamine (0.202 g, 2.0 mmol) was then added to the resulting solution. FcPF$_6$ (0.331 g, 1.0 mmol) was added to the mixture, and the solution was stirred for 2 h at room temperature. After removal of the solvent under reduced pressure, the resulting residue was dissolved in dichloromethane, and ammonium hexafluorophosphate (0.326 g, 2.0 mmol) was added to the solution. The mixture was stirred overnight at room temperature, and insoluble material was removed by filtration. Addition of pentane to the filtrate gradually gave a blue powder that was collected by filtration and recrystallized from dichloromethane/pentane. Yield: 0.380 g (53.4%). Elemental analysis (%) calcd for C$_{34}$H$_{40}$F$_6$N$_2$O$_2$-Ni$_1$P$_1$: C 57.33, H 5.66, N 3.93; found: C 57.14, H 5.62, N 3.90. ESI-MS: *m/z*: 566 [*M*−PF$_6$]$^+$.

Complex **2** was prepared in the same manner as **1** by using MePyBz$_2$ instead of PyBz$_2$. Yield: 0.259 g (35.7%). Elemental analysis (%) calcd for C$_{35}$H$_{42}$F$_6$N$_2$O$_2$Ni$_1$P$_1$·0.5CH$_3$CN: C 57.89, H 5.87, N 4.69; found: C 57.63, H 6.04, N 4.51. ESI-MS: *m/z*: 580 [*M*−PF$_6$]$^+$.

Metallic Nanomagnets Randomly Dispersed in Spherical Colloids: Toward a Universal Route for the Preparation of Colloidal Composites Containing Nanoparticles**

Pedro Tartaj,* Teresita González-Carreño, Maria L. Ferrer,* and Carlos J. Serna

The fabrication of colloids with desired properties has been the aim of many recent investigations.[1] Their modification with metallic nanoparticles is a particularly suitable tool to modulate their optical, catalytic, and mechanical properties.[2] Of special interest for biotechnology and data storage applications, as well as for fundamental studies in the areas of physics and physical chemistry, is the modification of colloids with metallic nanomagnets (MNMs).[3] The properties of these composites in particular, and magnetic composites in general, strongly depend on the size of the nanoparticles, the distance between them, and the nature of the nanoparticle–colloidal matrix interaction.[4] Thus, the development of methods able to fine-tune the size of MNMs, their interparticle distance, and their particle composition (e.g., preparation of multicomponent alloys), while readily modifying the composition of the colloidal matrixes, could help us to produce materials with a highly predictable magnetic response and/or showing unusual magnetic phenomena of interest, for example, in recording applications.[4c] Herein, we report a synthetic route for the preparation of MNMs randomly dispersed in inorganic spherical colloids, which have potential interest in biotechnology.[5] Random distribution, instead of the typical confined distribution obtained in the widely used surface template methods, helps to screen magnetic dipolar interactions.[6] Even though we have focused on the preparation of MNMs randomly dispersed in spherical colloids, the adaptability of the synthetic strategy reported here could allow its use in the fabrication of spherical colloids containing nanoparticles of very different nature and properties.

Aerosol-based processes are convenient routes to prepare nanoparticles randomly dispersed in spherical colloidal matrixes.[7] In fact, we recently reported that α-Fe MNMs dispersed in spherical silica colloids can be produced by heating, in air and H_2, a powder obtained by aerosol pyrolysis of a methanol solution of iron(III) nitrate and tetraethoxysi-

lane.[7c] However, the method fails when trying to obtain MNMs made up of more than one component (alloys) dispersed in colloidal matrixes, because of differences in the solubility of the metallic precursors. Compositional homogeneity at the particle level in aerosol methods is strongly dependent on the solubility of the precursors.[7,8] Specifically, the different solubilities of the metallic precursors during thermal drying (especially at low-volume-packing fractions) result in their sequential precipitation within the colloidal matrix. Thus, at the end of the process, the chemical composition of each individual MNM is not necessarily equal to the average of the alloy (compositional inhomogeneity at the nanoparticle level).

The approach we used to overcome the problem of compositional inhomogeneity, and simultaneously to better control the size of MNMs, was to generate an aerosol from an aqueous sol of ferritin and a matrix precursor (Figure 1). Our
Figure 1. Stepwise fabrication of MNMs randomly dispersed in spherical colloids.

synthetic route is similar to that used for the preparation of mesoporous silica (undoped and doped with gold nanoparticles) and titania materials by aerosol evaporation of sols containing surfactant micelles,[7a, 9] though logically we need to produce nanoparticles not "holes". In this sense, ferritin seems an ideal template for reaching our final goal and, more importantly, ferritin could serve as an ideal model to extend the synthetic strategy to other ferritin-like systems. For example, one can easily deduce that the ability of dendrimers to encapsulate metallic nanoparticles of very different composition (Au, Pt, Pd, Cu, Ag, Ni)[10] could be used for the direct fabrication of colloidal composites containing nanoparticles of very different nature and properties.

Nature has developed a variety of proteins that function as carriers or storage devices for metal components. Of these systems, the iron-storage protein ferritin is one of the most intensively studied.[11] Ferritin consists of a spherical polypeptide shell surrounding a ferrihydrite core. Ferritin can easily be demineralized (apoferritin), to leave an approximately 8-nm internal cavity that can be used as a template for the production of nanomaterials containing elements such as Fe, Mn, U, Co, Ni, and Cr.[11,12] The biological template of ferritin has also been used to prepare CoPt nanometallic alloys of interest in data-storage technology, nanoparticles of Prussian blue ferritin, and very recently to prepare metallic Pd nanoparticles of interest in catalysis.[13] In addition, Lan

et al. demonstrated that it is possible to prepare a sol containing a silica inorganic component and the protein ferritin.[14] However, their final goal was to encapsulate ferritin in a sol–gel-derived silica glass, and not to prepare metallic nanoparticles dispersed in colloidal matrixes with a spherical shape.

Therefore, based on previous work carried out with ferritin, we expected that the internal cavity of ferritin would allow us to confine the various metallic precursors (in the form of inorganic nanoparticles), thus avoiding the problems associated with compositional inhomogeneity in aerosol processes. Besides, if the right matrix is chosen, the particle size can easily be controlled by the particle size of the inorganic component of ferritin. A necessary requirement for the success of the method is the preparation of an aqueous sol of ferritin and the matrix precursor. Simple arguments based on colloid science dictate that both ferritin and the matrix precursor must be equally charged to avoid heterocoagulation. An additional advantage of using ferritin is that its protein cage is remarkably stable, and able to withstand extremes of pH (2–10) and temperature (up to 70 °C).[12] Thus, the high stability of ferritin allows the use of a wide range of experimental conditions to prepare stable sols (that is, compatibility with different matrix precursors).

To probe the reliability of the method in obtaining MNMs of different size and composition dispersed in spherical colloids we used ferritin with its internal cavity fully or partially filled with Fe- and FeCo-containing species. An amorphous silica sol and a crystalline boehmite (AlOOH) sol were selected to probe the versatility of the method in changing the nature of the colloidal matrix. An amorphous silica sol was selected in the first instance because of the several benefits that amorphous colloidal silica matrixes with spherical shape impart to MNMs for applications in biotechnology (colloidal stability, functionality, biocompatibility, and corrosion resistance).[15] The criteria we followed to select a crystalline boehmite sol were based on the different colloidal behavior of boehmite and silica (isoelectric points of ca. 9 and 3, respectively) and the different nature of the initial sol (crystalline versus amorphous).

The aerosol evaporation of a stable aqueous sol containing commercial ferritin[16] and silica (see Experimental Section) led to powders that were heated in air (500 °C, 2 h) to eliminate residual organic matter and hydroxy groups, and finally reduced in H$_2$ atmosphere (700 °C, 10 h) to produce α-Fe MNMs randomly dispersed in silica colloids (Figure 2a). The presence of this phase was confirmed by X-ray diffraction (XRD, see the Supporting Information).[17] The crystallite size estimated from the width of the (110) α-Fe reflection was 5.3 nm, which is similar to the diameter obtained by transmission electron microscopy (TEM; 4–6 nm, Figure 2a). This value is consistent with the expected shrinkage when going from the ferrihydrite (average size of the ferrihydrite core of ferritin is about 7 nm)[11] to the α-Fe phase, by considering the amount of iron in a unit volume of these two phases (that is, no significant interparticle sintering between MNMs on heating).

A similar methodology was used for the preparation of spherical composites with α-Fe MNMs of smaller size (3–
Figure 2. TEM pictures of powders showing random distributions of MNMs in spherical silica colloids: a) from ferritin; b) from Fe-reconstituted apoferritin; c) from FeCo-reconstituted apoferritin. The lower pictures are magnified to enhance the visual resolution of the MNMs (dark spots). The higher concentration of MNMs in (a) reflects the higher number of Fe atoms in commercial ferritin with respect to the reconstituted apoferritin. The pictures were computer-enhanced to improve the MNM contrast.

4 nm, Figure 2b), though in this case we started from an apoferritin reconstituted only with 1000 Fe atoms (for details of reconstitution, see the Experimental Section). The decrease in the size of the α-Fe MNMs was also detected by XRD (see the Supporting Information). Specifically, a decrease from 5.3 to 3.4 nm was estimated from the width of the (110) α-Fe reflection. The volume estimated from the experimental data for a spherical shape (10–35 nm^3, 3–4 nm diameter) is within the margins of experimental error expected for a cubic cluster of 1000 Fe atoms in the α-Fe phase (ca. 12 nm^3). However, the fact that the 1000-atom cluster volume is at the lower limit does not allow us to ignore the possible growth of some nanocrystallites. Finally, FeCo MNMs (Co content ca. 30 mol%; 3–4 nm) dispersed in silica colloids (Figure 2c) were also prepared by using a similar methodology. This particular Co/Fe composition was selected because it has the highest magnetic moment.[18] In this case, apoferritin was reconstituted with 670 Fe atoms and 330 Co atoms (see Experimental Section). Energy-dispersive X-ray (EDX) analyses carried out on the MNMs clearly indicated that the composition of individual nanomagnets was the expected one (Co content of ca. 30 mol% in the FeCo alloy).[19] Thus, we showed the versatility of the method in preparing spherical composites containing randomly distributed MNMs of controlled composition and size. An important point is that the colloids are polydisperse in size (70–400 nm); however, monodispersity can be achieved with aerosol techniques by using differential mobility analyzers.[20]

We also used a crystalline boehmite sol (see Experimental Section) to probe the versatility of the method in changing the nature of the colloidal matrix. Specifically, the use of a boehmite sol (no ferritin added) resulted in a porous matrix (Figure 3a), which was not ideal for stabilizing small MNMs (< 5–6 nm) against corrosion. Thus, the results for boehmite probe the benefit of the confinement effect of ferritin in controlling chemical composition at the nanoparticle level (that is, preparation of multicomponent MNMs) even in porous matrixes. The aerosol evaporation of an aqueous sol of
Figure 3. TEM pictures of powders obtained after aerosol evaporation of an aqueous sol of a) boehmite and b) FeCo-reconstituted apoferritin and boehmite with further heating in air (500 °C, 2 h) and H₂ (800 °C, 10 h).

apoferritin (after reconstitution with 670 Fe atoms and 330 Co atoms) and boehmite, followed by thermal annealing first in air and then in H₂, produced powders made up of FeCo MNMs dispersed in γ-Al₂O₃ colloids (Figure 3b). After the thermal treatment boehmite transformed to γ-Al₂O₃, as evident by XRD analysis. EDX analyses clearly indicate that we were successful in controlling the chemical composition at the nanomagnet level even in a porous matrix. An increase in MNM size was produced when silica was replaced by alumina (ca. 15 nm versus ca. 3–4 nm, Figure 3b and 2c). Thus, no temperature was found that reduced the porosity of the alumina matrix while avoiding sintering between MNMs (small MNMs cannot be stabilized against oxidation). Finally, similar results were obtained in the case of MNMs made up of Fe atoms, which additionally confirmed the benefit of the silica matrixes in providing protection against corrosion.

In summary, metallic nanomagnets (MNMs) of different size and composition randomly dispersed in spherical colloids have been prepared by the aerosol evaporation of an aqueous sol containing mineralized ferritin and a colloidal matrix precursor. Essential to the success of the method is the template effect provided by ferritin. Its internal cavity offers the ideal environment for the encapsulation of multicomponent MNM precursors with the simultaneous control of size. Moreover, the high stability of the ferritin cage allows compatibility with different matrix precursor sols (that is, the nature of the colloidal matrix can be changed). Our results indicate that this synthetic strategy could be extended to other ferritin-like systems, for example, metals encapsulated in dendrimers.

Experimental Section

Aerosol generation: The aerosol device used for the preparation of the spherical composites containing nanoparticles is described elsewhere.[8b] It essentially consists of two furnaces that could be set at different temperatures for drying (first furnace) and thermal decomposition (second furnace). In our experiments we set the temperature of the two furnaces at 400 °C (aerosol evaporation). The aqueous sol containing the ferritin and matrix precursor was atomized at 1.6 mL min⁻¹ with an air pressure of 1.7 kg cm⁻² to give different spherical colloidal composites. The particles obtained were collected with an electrostatic filter (8 kV). Experiments carried out with a freshly prepared sol and a sol aged for 6 h led to similar results, which confirms the reproducibility during the aerosol experiment (typically 2 h).

Ferritin reconstitution: A dispersion of apoferritin (Sigma; 75 mL, 1.46 μM) in NaCl (0.1 M) and 3-(N-morpholine)propanesulfonic acid (MOPS) buffer (50 mM, pH 6.5) was reconstituted by the controlled addition of a deaerated FeSO₄ solution (25 mM, pH 2) at a rate of 0.1 μmol min⁻¹ until completion of the calculated loading of 1000 Fe atoms per unit of protein. The method is similar to that described by Chasteen and co-workers.[11c,d] In our case the rate of addition was slower and reconstitution was restricted to 1000 atoms to assure complete mineralization inside the protein. No iron(III) hydroxide sediment or deposit was found after centrifuging at 4000 rpm (r_{max} = 12 cm, rotor angle = 30°) for 5 minutes and then filtering through a 0.1-μm Millipore filter, which further suggests that the formation of iron(III) hydroxide did not take place outside the protein.

To prepare the FeCo-reconstituted apoferritin, an apoferritin dispersion (75 mL, 1.46 μM) in NaCl (0.1 M) and MOPS buffer (50 mM, pH 6.5) was reconstituted by the controlled addition of a deaerated FeSO₄ solution (25 mM, pH 2) at a rate of 0.1 μmol min⁻¹ until completion of the calculated loading of 670 Fe atoms per molecule of protein. Again following this protocol, we did not find any evidence of the formation of iron(III) hydroxide outside the protein. The dispersion was dialyzed (12-kDa cutoff membrane) against aqueous NaCl solution (0.1 M) to eliminate unwanted ions and then 330 Co atoms per protein unit were added by controlled addition of Co(NO₃)₂ (25 mM, 0.125 μmol min⁻¹) and H₂O₂ (25 mM, 0.125 μmol min⁻¹) to the partially filled apoferritin dispersion (75 mL, 50 mM 3-[(1,1-dimethyl-2-hydroxyethyl)amino]-2-hydroxypropanesulfonic acid (AMPSO) buffer, pH 8.5). The method is a combination of the one reported by Chasteen and co-workers for iron mineralization[11c,d] and that reported by Douglas and co-workers for cobalt mineralization.[12d,e] Since ferritin has more affinity for iron than for cobalt, we added the iron atoms first. In this way, nucleation of cobalt atoms inside the ferritin core was favored by the presence of the Fe-containing nuclei. The high compositional homogeneity of the nanoparticles dispersed in the colloidal matrixes suggests that cobalt was indeed mineralized in the ferritin cores containing iron atoms. To avoid mineralization outside the protein, we only filled the apoferritin with a total of 1000 Fe atoms.

Before mixing with the matrix precursor sol both the Fe- and FeCo-reconstituted apoferritin dispersions were dialyzed against water to avoid excess electrolyte, which can induce coagulation.

Preparation of aqueous sol containing ferritin and silica: Horse spleen ferritin dispersion (2 mL, Sigma Aldrich, type I, 102 mg mL⁻¹) in NaCl (0.15 M) was diluted with water to 96 mL and mixed with a silica sol (2 mL). The clear silica sol stock dispersion was prepared by mixing tetramethoxysilane (2.95 mL, Aldrich, 99%), water (1.4 mL), and HCl (0.04 mL, 0.04 M) at 4 °C with strong agitation for 15 minutes. Use of this procedure to prepare the silica sol allows the amount of alcohol present in the system to be reduced as much as possible, thus avoiding the possible denaturation of the protein ferritin.[14] When reconstituted apoferritin was used instead ferritin, silica sol (2 mL, pH 5.5) was added to reconstituted apoferritin dispersion (75 mL). At this pH value both ferritin (isoelectric point 4–5) and silica (isoelectric point ca. 3) are negatively charged, so heterocoagulation is avoided. The order of addition of the protein, water of dilution, and silica sol was important for the stability of the system. Coagulation of the protein was observed if the silica sol (2 mL) was added to water (96 mL) and followed by ferritin (2 mL).

Preparation of aqueous sol containing ferritin and boehmite: A stable boehmite sol was prepared by following a standard methodology.[21] HCl (final concentration 0.02 M) was added to an aqueous suspension of aluminum isopropoxide (0.25 M, Aldrich) which had been previously heated at 80 °C for 1 h. The vessel was opened at 90 °C for 2 h to allow evaporation of the isopropanol generated from the alkoxide hydrolysis. Finally, the suspension was refluxed at 90 °C

for 16 h to produce a stable sol. For the preparation of the aqueous sol containing apoferritin and boehmite, the reconstituted apoferritin sol (60 mL) was added to boehmite sol (40 mL, 0.25 M). The pH value of the resulting sol was 3.5, which assures compatibility between apoferritin and boehmite. In this case both colloids are below their isoelectric points (that is, positively charged).

The morphology of the powders was examined by TEM (2000 FX2, Jeol). Chemical analyses at the particle level were carried out with an EDX spectrometry analyzer (QX 2000, Oxford Link) integrated in the transmission electron microscope. The different phases present in the solids were detected by X-ray diffraction (XRD, PW1710, Philips).

[16] We did not try to eliminate the inorganic phosphate, because of the small amount of phosphate with respect to iron in native horse spleen ferritin (usually about 5 mol% of the Fe content, Ref. [11a]) and the fact that its presence could even help to stabilize the metallic phase against corrosion (phosphates are routinely used in metallurgy as anticorrosive agents). When the reduction, elimination, or even addition of inorganic phosphate is needed for other systems, protocols can be found in the literature (see for example reference [11b]).

[17] Apart from α-Fe, we expect the formation of a low-crystallinity Fe$_2$SiO$_4$ shell (not observable by XRD) surrounding the α-Fe MNMs, as happens in Fe/silica systems obtained in a similar way (see references [7c] and [15d]). This protective layer imparts stability against corrosion of the metallic component.

[18] R. H. Victora, L. M. Falikov, *Phys. Rev. B* **1984**, *30*, 259.

[19] The Fe and Co atoms form a metallic alloy throughout the range of compositions and we expect, at the end of thermal treatment, the diffusion of Co atoms within the Fe metallic core. In fact, the formation of Fe$_{1-x}$Co$_x$ metallic alloys is reported in the literature by using methods such as ball milling (see for example M. Sorescu, A. Grabias, *Intermetallics* **2002**, *10*, 317 and E. C. Passamani, C. Larica, V. P. Nascimento, *J. Mater. Sci.* **2002**, *37*, 809).

Dipeptides as Microporous Materials**

Dmitriy V. Soldatov, Igor L. Moudrakovski, and
John A. Ripmeester**

The synthesis and characterization of hydrophobic porous frameworks designed for a variety of applications has attracted significant research efforts over the last few years.[1] The key idea in such studies is to design building elements which allow for controllable assembly and disassembly, and which may be extensively replaced and modified to give porous frameworks with various topologies and functions. The natural world often provides excellent examples of how to proceed with the design of materials; for example, the initial experiences with natural zeolites has led to very successful efforts to produce a wide variety of industrially relevant synthetic materials.[2] Recently, supramolecular architectures based upon weaker interactions have motivated a number of studies;[3] polypeptides that can build tubular and helical structures, frequently referred as nanotubes, have attracted considerable attention because of their biological relevancy as ion channels, membrane pores, etc.[4] These naturally occurring and artificially created materials reveal a sophisticated complexity and are often difficult to characterize in detail. Thus, the lower oligomeric peptides, being both simpler model systems and cheaper, would appear to be useful as practical porous materials, especially since some dipeptides demonstrate the ability to host small organic molecules.[5] Moreover, the ability of single crystals of the dipeptides to sustain guest solvent exchange and removal was reported.[5d] Herein we examine the structure and sorption properties of the two closely related dipeptides L-alanyl-L-valine (AV) and L-valyl-L-alanine (VA; Scheme 1), and show that these lower oligomers have considerable promise as novel porous materials. Moreover, the wide variety of amino acids available should allow the assembly of materials with quite diverse structural motifs containing significant void space.
Scheme 1. Dipeptides studied.

The two dipeptides AV and VA are microporous crystalline materials. Hexagonal prisms of the dipeptides were grown from water and characterized by single-crystal X-ray diffraction (XRD) analysis at room temperature (Table 1).[6–8]

Table 1: Single-crystal XRD analysis of guest-free AV and VA.

Compound	AV	VA
temperature [K]	293	293
empirical formula	$C_8H_{16}N_2O_3$	$C_8H_{16}N_2O_3$
formula weight	188.2	188.2
crystal system, space group	hexagonal, $P6_1$	hexagonal, $P6_1$
a [Å]	14.462(2)	14.461(2)
c [Å]	10.027(1)	10.083(1)
V [Å³]	1816.2(4)	1826.1(4)
Z	6	6
total data collected	21480	15948
data unique ($I > 2\sigma(I)$)	2189	1954
refined parameters	142	122
calculated density [g cm⁻³]	1.033	1.027
final $R1$ ($I > 2\sigma(I)$)	0.048	0.057
$wR2$ ($I > 2\sigma(I)$)	0.103	0.116
max peak and hole [e Å⁻³]	+0.17, −0.15	+0.15, −0.14

Both crystals are hexagonal with a $P6_1$ space group and lattice parameters that are nearly identical. Each dipeptide assembles through hydrogen bonds as a 6_1 spiral to form a channel (Figure 1). Mapping out the channel diameter along the z axis (Figure 2) shows that the channels have a smooth, constant-diameter shape similar to that of urea[10] (a well-known and extremely versatile host material) with an average diameter of 5.13 and 4.90 Å for AV and VA, respectively. A feature that distinguishes AV and VA from most other tubulates, however, is that their channels are essentially chiral.[11] The center of the channel is displaced from the 6_1 axis by 0.60 and 1.05 Å for AV and VA, respectively, and rotates around the axis in a right-handed fashion (Figure 3). It should be noted that chiral sorbents are important and challenging targets in crystal engineering. While researchers resort to subtle strategies to induce chirality into novel, artificially created porous materials,[12] the peptides form an endless source of naturally chiral building blocks ideally suited to this task.

Another distinction of the materials studied is the remarkable stability of their porous frameworks. The majority of hosts known to date collapse into a dense form once the stabilizing guest template is removed; only a few may exist in a porous form as a result of their kinetic stability with respect to the dense, thermodynamically stable polymorph.[13] To check for possible polymorphism, AV and VA samples were obtained from different commercial sources, and were

Figure 1. Spiral assembly of AV (left) and VA (right) dipeptide molecules that form a channel (van der Waals dimensions).
Figure 2. Channel diameter (⌀) along the *z* axis in AV (*c* = 10.027 Å), VA (*c* = 10.083 Å), and urea (*c* = 11.017 Å).

Figure 3. The channel shape in AV (left) and VA (right) shown as a set of inscribed disks threaded on a sixfold screw axis. Two *c*-translation periods are shown for each dipeptide.

examined both as received and after recrystallization under a variety of conditions.[6] Only the porous forms of the materials were obtained in every case, as determined by powder XRD (PXRD). This observation reflects the fact that the structural motifs are governed by strongly directional H-bonding interactions rather than close packing. Therefore, dense forms of the materials are not easily obtained, or may not exist at all.

As materials that have permanent void space, it is worthwhile comparing AV and VA with the many varieties of zeolites—a large family of covalently bonded aluminosilicates assembled from a limited number of basic structural units.[14] Zeolites are kinetically stable with respect to the thermodynamically stable dense form, and they are widely used as sorbents, with porosities varying from about 18% (8 cm³g⁻¹) for analcime to about 53% (28 cm³g⁻¹) for faujasite.[2a] The porosity of the dipeptide materials was determined by comparing the density measured by He pycnometry with the density calculated from XRD unit cell measurements.[15] According to these determinations the volume fractions in the materials accessible to He gas were 11.7(3)% and 11.3(2)% for AV and VA, respectively. Similar values (11.4% and 10.4%) were calculated from the XRD

results.[16] Taking into account the much lower density of the dipeptides, the capacity of the materials of about 11 cm³g⁻¹ falls into the range of values observed in practically useful zeolite materials.

A well-utilized property of zeolites is their ability to behave as molecular sieves, that is, they can distinguish between sorbate molecules differing in size as a result of the characteristic apertures that define the access to the internal void space. The channels in AV and VA, with average diameters of 5.13 and 4.90 Å, possess rather minor surface irregularities and are essentially hydrophobic, and therefore may exhibit a molecular-sieving effect. Since the materials

displayed a high affinity towards Xe gas, we used it as the sorbate species to investigate the sorption behavior of the dipeptide materials.

The Xe adsorption isotherms were measured at room temperature for both AV and VA by using a combination of standard volumetric techniques and ^{129}Xe NMR spectroscopy.[17] It is quite remarkable that the two materials with such similar channel sizes show markedly different behavior towards Xe gas (Figure 4). Although the calculated sorption
Figure 4. The sorption isotherms (298 K) of Xe in AV (solid circles) and VA (open circles) crystalline materials. Θ is the Xe/dipeptide molar ratio. The best-fit curves are drawn using a Langmuir equation.

capacities are very similar (0.525(9) and 0.525(8) mol Xe per mol dipeptide for AV and VA, respectively), the sorption constants differ by a factor greater than four (0.120(5) and 0.52(2) bar^{-1} for AV and VA, respectively). The difference, in this case, should be attributable to a tighter binding between the host channel and the guest atom. With a van der Waals diameter of 4.4 Å, a Xe atom can interact more efficiently with the smaller channel in VA (4.90 Å) than with the larger channel of AV (5.13 Å). Although this size difference seems rather minor, it clearly has major consequences, and represents an example of molecular recognition based primarily on size-matching between the host and guest.

The observed sorption capacity implies ideal compositions of AV⊃0.5Xe and VA⊃0.5Xe, that is, three Xe atoms per unit cell, or three Xe atoms per one *c*-translation. Taking the volume of a Xe atom to be 44.6 Å^3, the packing efficiency of the Xe atoms in the channels are 64.6 and 70.4 % for AV and VA, respectively. The total gas storage capacity of the materials is about 60 mLg^{-1}. For comparison, the gas storage capacity of a variety of recently designed metal-organic and organic sorbents is 9–52 mLg^{-1}.[18]

The studied materials showed significant thermal stability, as demonstrated by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) experiments.[19] The dipeptides showed no decomposition, phase transitions, or mass loss up to their melting points of 238 °C (AV) and 213 °C (VA), followed by quantitative evaporation up to 270 °C.

Other potential applications of the current and related materials assembled from lower peptides are connected to their relevance to biological materials. Surprisingly, very few molecules, such as urea, gossypol, and deoxycholic acid, amongst the vast number of compounds utilized as hosts are known to arise from living organisms.[20] Dipeptides may be generated to form the entire family of bioorganic hosts and microporous solids.[5,21] The peptide materials are nontoxic and may be used in biological and medical contexts, such as in chiral recognition/separation or preservation/storage of drugs. Also, they may be extensively utilized to model, for example, transmembrane pores and ion channels,[4d] or the NMR spectroscopic signals of laser-polarized noble gases in proteins and living tissues.[22]

In conclusion, the dipeptides studied in this work have robust porous frameworks with a high capacity and the capability of preferential sorption, even towards chemically inert species such as Xe. Moreover, the new sorbents studied are constructed from natural organic materials and pose no environmental problems. This study suggests that a diverse variety of lower peptides with a propensity for forming frameworks with voids of different geometry should be considered as a promising new class of materials for potential applications where selective sorption/release or gas storage is important.

[6] Crystallizations of AV and VA were performed from distilled water without using a template. Crystals suitable for single-crystal XRD analyses were obtained by evaporation of 0.3 M solutions at 60 °C. PXRD analyses indicated a total correspondence between the bulk products and the samples studied. The same single-crystal phase for each dipeptide, as confirmed by PXRD, was observed for the as-received samples (Sigma and ICN), solid products of fast crystallizations (evaporation in seconds at RT; evaporation over 2 h at 60 °C), very slow crystallizations (evaporation over 2 months at RT), and for crystals exhaustively equilibrated with their supernatant aqueous solutions (8 months at RT).

[7] Single-crystal XRD analyses: Bruker SMART CCD diffractometer, Mo$_{K\alpha}$ radiation ($\lambda = 0.7107$ Å), crystal size $0.5 \times 0.07 \times 0.07$ mm (similar for AV and VA). The structures were solved with the SHELXTL programs (direct methods) and refined with full-matrix least-squares on F^2. CCDC-238397 (AV) and CCDC 238398 (VA) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

[8] Low-temperature crystal structures of the compounds were reported: AV at 150 K (ref. [5d]) and VA at 120 K (ref. [9]).

[14] The diversity of zeolite structures results from the 16 identified "secondary structural units" which must be fitted together to give the combinations of channels and cavities which yield the repeat unit of the zeolite structures; see W. Meier, D. H. Olson, *Atlas of Zeolite Structure Types 2nd ed.*, University Press, Cambridge, **1987**; (the list of the units is given on p 5 therein).

[15] He pycnometry experiments were performed on an AccuPyc 1330 gas pycnometer (Micromeritics). Three samples (from different sources) of each dipeptide were measured several times (10 runs for each) till the results became stable. Typically, the first two measurements gave lower densities presumably because of blockage of the isolated channels by impurities (likely water in trace quantities; from TGA, the mass of possible absorbed sorbates was lower 0.5 %). Average densities found for the "peptide framework body" were 1.169(4) g cm^{-3} and 1.157(3) g cm^{-3} for AV and VA, respectively (27 °C). Calculations performed as described in Ref. [1d] gave the following values (AV/VA): pore volume per unit cell, 212(6)/206(4) Å^3; pore volume fraction, 11.7(3)/11.3(2) %; average cross-section area of the channel, 21.2(5)/20.4(4) Å^2; average diameter of the channel, 5.2(1)/5.1(1) Å.

[16] The channel volumes were calculated from single-crystal XRD results by integration of the spatial figure composed of discs having diameters corresponding to the maximum-sized sphere that could be inscribed in the channel and centered on a given level along the crystallographic z axis.

[17] The intensity of the ^{129}Xe NMR signal in a known amount of material was monitored as a function of gas pressure and compared with that of a standard xenon sample to give the absolute amount of adsorbed xenon. The T_1 relaxation times of adsorbed xenon in the materials studied were found to be in the range of 50 to 80 s and care was taken to set the delays in the NMR experiments sufficiently long to ensure quantitative results. Equilibrium was reached typically in 2 h and the data were highly reproducable both when approaching equilbrium in the sorption or desorption modes. The sorption isotherms were approximated by a Langmuir equation, and the maximum sorption capacity and sorption constants were calculated as described in Ref. [1h].

[19] DSC experiments were run on a TA 2920 calorimeter. Samples of approximately 4 mg were sealed in aluminum pans and heated at a rate of 5 ° min^{-1}. TGA experiments were performed on a TA 2050 analyzer under flow of a N$_2$ at 50 mL min^{-1}. Sample sizes were approximately 8 mg; heating rate 5 ° min^{-1}.

Communications

Are NMR-Derived Model Structures for β-Peptides Representative for the Ensemble of Structures Adopted in Solution?**

*Alice Glättli and Wilfred F. van Gunsteren**

Connecting an NMR observable $\vec{q}^{\,\text{obs}}$, such as an interproton distance derived from nuclear Overhauser effect (NOE) intensity or a ^3J-coupling constant, with the underlying conformational ensemble $\{\vec{r}\}$ is a long-standing problem for the structure determination of peptides, proteins, and other biomolecules in solution.[1–9] In particular, for flexible molecules such as peptides the assumption that all NMR signals originate from the same predominant conformer may not hold.[10–13] In that case conventional NMR structure refinement procedures are not sufficient for the correct interpretation of the experimental data.

Molecular dynamics (MD) simulation can often complement the experimental tools for biomolecular structure determination such as NMR and circular dichroism spectroscopy.[8,9,11,14,15] A sufficiently accurate simulation for comparison with and interpretation of experimental data requires:

1) the choice of the essential degrees of freedom appropriate to model the system of interest and to calculate the desired experimental observable,

2) a physically calibrated force field to describe the interactions along and between the chosen degrees of freedom,

3) equations of motion or a sampling method that generates a Boltzmann-weighted ensemble of conformers, and

4) the knowledge of the relation $\vec{q}(\vec{r})$ between the experimental observable $\vec{q}$ and the molecular structure $\vec{r}$ of the system of interest.

If the molecular model and the atomic interaction function (i.e. the force field) were perfect, and if a simulation could be carried out for an infinitely long time, the generated ensemble would exactly represent the real molecular system and there would be no need to carry out an NMR experiment on the system of interest. Furthermore, the connection

between experimentally measured observables and the underlying conformational ensemble would be perfectly understood, provided that the relation $\vec{q}(\vec{r})$, which connects the experimentally measured observables $\vec{q}$ to a conformation $\vec{r}$, is exactly known. In practice, however, none of these conditions are completely fulfilled. Despite the enormous increase in computation power in recent years, the time required to sample the complete populated conformational space of a biomolecule is still beyond affordable simulation (sampling) for all but the shorter peptides. Additionally, even though current force fields for biomolecules are steadily improving in correctly modeling the structure, dynamics, and energetics of biomolecular systems,[16] they are based on various approximations concerning polarizability, many-body interactions, quantum effects, etc. On the other hand, conventional structure determination makes use of force fields because the number of experimental observables is generally too small to uniquely derive the underlying set of conformations. Here, we compare two methods for the conformational interpretation of the NMR data of a β-hexapeptide (Figure 1):
Figure 1. Chemical formula of the hydroxy β-hexapeptide studied. The peptide is protected by a *tert*-butoxycarbonyl group (N-Boc) at the N terminus and by a carbobenzoxy group (Z) at the C terminus. The hydroxy groups are attached to the C_α atoms and the side chains to the C_β atoms of the backbone.

firstly, conventional structure determination by simulated annealing in vacuo applying NOE distance and dihedral-angle restraints using a simple force field widely employed for structure determination of polypeptides, and secondly, free (unrestrained) MD simulation, which inherently generates Boltzmann-weighted ensembles, using a physically, thermodynamically calibrated force field and explicit treatment of solvent degrees of freedom. We show that the two methods yield rather different results and that the former one may lead to erroneous interpretation of NMR experiments.

The β-hexapeptide under investigation has been suggested by conventional NMR structure refinement to adopt a (P)-2_8-helical conformation in solution[17] (Figure 2), representing the first example of the fourth helical secondary structure element adopted by β-peptides. By forming intramolecular hydrogen bonds, β-peptides adopt secondary structure elements that are very similar to those found in α-peptides and proteins,[18,19] namely left- and right-handed helices (3_{14}-,[20–22] 2.5_{12}-,[23] $10/12$-,[24] and the previously mentioned 2_8-helix[17]), turns, and sheets.[25] Starting from a fully extended conformation, the β-hexapeptide displayed in Figure 1 was simulated in explicit methanol solution at two different temperatures (298 K and 340 K) and at constant pressure (1 atm) using the GROMOS simulation package[26,27] and the GROMOS biomolecular force field (version 45A3[26,28]). For simulation details, see the Supporting Information. The ensembles of structures from the two 100-ns

Figure 2. Superposition of the 20 NMR model structures with lowest energy from the ab initio simulated-annealing structure refinement runs[17] with the 40 upper-bound distance restraints and 12 torsional-angle restraints derived from NMR data at 298 K in methanol.[17] The simulated annealing runs were performed using the X-PLOR program and force field.[29] The model structures suggest that the peptide adopts a (*P*)-2$_8$-helical conformation. The structures are superimposed using the backbone atoms of residues 2–5. The protection groups are omitted for clarity. Color scheme: C = yellow, H = white, N = blue, O = red.

trajectories were analyzed regarding the level of agreement with the NMR-derived data and regarding the conformational space sampled by the peptide in the simulation compared to the one covered by the 20 NMR model structures obtained by standard structure refinement using the program X-PLOR.[29]

In Figure 3 the simulated and the NMR-derived data are compared in terms of 40 NOE distances and 12 ^3J-coupling constants. The average effective violations of the upper-bound distances from all recorded structures in both simulations and from the 20 X-PLOR structures are displayed in Figure 3 A–C. The upper-bound nature of NOE-derived distances implies that only violations with positive values are true violations. Essentially all experimentally observed NOEs are satisfied both in the X-PLOR structures and in the simulations at 298 and 340 K. The ensemble of structures at 298 K marginally violates two interresidue NOE distances: HC$_\gamma$(2)/HC$_\beta$(1) (NOE sequence number 3) and NH(2)/NH(3) (NOE sequence number 16) are both violated by 0.05 nm. The simulation at 340 K violates only one NOE distance (sequence number 3) by 0.03 nm. We also checked whether long proton–proton distances correspond to the absence of measured NOEs, although the latter may have other causes such as fast exchange, a particular overall tumbling time, and extensive spin–spin splitting. The 12 experimentally measured ^3J-coupling constants are compared to the average ^3J-coupling constants calculated for the trajectory structures from the simulations at 298 and 340 K and for the 20 X-PLOR structures using the Karplus relation[30] as shown in Figure 3 D–F. With an average absolute deviation of 0.4 Hz, the average ^3J-coupling constants calculated from the ensemble of structures generated at room temperature agree very well with the experimentally measured values. Only one deviation exceeding 1 Hz, for HN−HC$_\beta$ of residue 1, is observed. The 20 X-PLOR structures agree slightly worse with the experimental values than the simulation at room temperature with deviations of more than 1 Hz for the H-C$_\beta$-C$_\alpha$-H torsions of residues 1 and 4, resulting in an average absolute deviation of 0.6 Hz.

Figure 3. Panels A–C: Average (r^{-6}-averaging) distance violations of the upper-bound distances over all the recorded structures (2×10^5) in the MD simulations at 298 (A) and 340 K (B) and the over the 20 X-PLOR structures[17] (C). The upper-bound distances are inferred from 40 experimental NOE intensities observed in the ROESY NMR spectrum at 298 K.[17] Panels D–F: Comparison of the 12 ^3J-coupling constants (6 HN–HC$_\beta$, 6 HC$_\beta$–HC$_\alpha$) extracted from the one-dimensional ^{1}H NMR spectrum measured at 298 K[17] with the corresponding calculated ^3J-coupling constants averaged over all structures from the MD simulations at 298 K (D) and at 340 K (E) and averaged over the 20 X-PLOR structures[17] (F). The Karplus equation[30] with $a = 6.4$ Hz, $b = -1.4$ Hz, and $c = 1.9$ Hz[40] for ^3J(HN,HC) and with $a = 9.5$ Hz, $b = -1.6$ Hz, and $c = 1.8$ Hz[41] for ^3J(HC,HC) was used. Tables of the experimental NOE upper-bound distances and ^3J-coupling constants, of NOE distance bound violations of the r^{-6}-averaged distances and the calculated ^3J-coupling constants averaged over the X-PLOR structures and the structures from the MD simulations are included in the Supporting Information.

Based on purely geometric criteria, the occurrence of hydrogen bonds in the 20 X-PLOR structures and in the ensemble of structures recorded in the simulations at 298 and 340 K has been determined (Table 1). Interestingly, eight-membered hydrogen-bonded rings (HB$_8$), characteristic for a (*P*)-2$_8$-helix, appear only at very low percentages in the two simulations ($\leq 4\%$), while they are to some extent present in the X-PLOR bundle of structures. This indicates that the suggested (*P*)-2$_8$-helix is only scarcely, if at all, populated in the simulations at 298 and 340 K. The hydrogen-bond analysis also shows that no regular secondary structure is sampled at room temperature, while at elevated temperature the occurrence of four 12-membered hydrogen-bonded rings hints at the formation of a (*P*)-2.5$_{12}$-helix. Additional simulations starting from either a (*P*)-2.5$_{12}$-helix or one of the 20 X-PLOR structure, which are suggested to represent a (*P*)-2$_8$-helix,[17] show the (*P*)-2.5$_{12}$-helical conformation to be stable once the peptide has adopted it, while the X-PLOR structures are rather unstable (see the Supporting Information). In addition to the backbone–backbone hydrogen bonds, various hydrogen bonds between the α-hydroxy hydrogen and carbonyl oxygen atoms are present at the two temperatures. However, hydrogen bonds of the type OH(i)−O(i) (HB$_5$), proposed to

stabilize the (P)-2_8-helical conformation,[17] are observed neither in the simulations nor in the 20 X-PLOR structures.

The results of the conformational clustering analysis over the combined ensembles (10000 structures from each simulation (at 298 K and 340 K) and the 500 copies of each of the 20 X-PLOR structures) are displayed in Figure 4. The conformational clustering analysis groups the structures of the ensembles according to their positional root-mean-square deviation (rmsd) of the backbone (N, C_β, C_α, C) atoms (excluding the first and last residue with the protecting groups) between each other structure favoring the most populated cluster.[31] When a rather stringent rmsd similarity criterion of 0.04 nm is used (Figure 4A), the
Figure 4. Conformational clustering analysis combining the "ensemble" of 500 copies of each of the 20 NMR model structures (i.e. equally weighing each NMR model structure) with the ensembles of 10000 structures each (1 per 10 ps) sampled in the MD simulations at 298 and at 340 K. The plots show the population in percentage per cluster (conformers) and the portion of structures per cluster belonging to the "ensemble" of NMR model structures (black) and to the ensemble of structures generated at 298 K (blue) and at 340 K (red) by unrestrained MD simulation. In order to illustrate the conformational spread of the various ensembles, two different rmsd-similarity criteria are used: A more stringent one of 0.04 nm (A) and the standard criterion for a β-hexapeptide of 0.08 nm (B). With the first criterion a total of 2772 clusters are found, of which clusters 1–20 represent more than 50%, clusters 1–120 more than 75%, clusters 1–625 more than 90%, and clusters 1–1272 more than 95% of the total population. With the second criterion a total of 237 clusters are found, of which clusters 1–4 represent more than 50%, clusters 1–10 more than 75%, clusters 1–28 more than 90%, and clusters 1–51 more than 95% of the total population. For both rmsd criteria, only the populations of the first 60 most populated clusters are shown.

Table 1: Occurrence of intramolecular hydrogen bonds. A hydrogen bond is considered to exist when the donor-hydrogen-acceptor angle is larger than 135° and the hydrogen–acceptor distance is less than 0.25 nm. The hydrogen bonds are grouped according to the type of hydrogen-donor (NH or OH group) and the size (in terms of number of atoms) of the resulting hydrogen-bonded ring (e.g. a hydrogen bond between NH of residue i and C=O of residue $(i-2)$ results in an eight-membered hydrogen-bonded ring, denoted as HB_8). O(0) corresponds to the carbonyl oxygen of the Boc protecting group. Only hydrogen bonds with a population larger than 10% in one of the sets of structures are shown.

| | Occurrence of hydrogen bonds [%] | | |
| | MD simulation | | Refinement |
Donor–Acceptor	298 K	340 K	X-PLOR
NH(i)–O($i-2$) [HB_8]			
NH(3)–O(1)	0	1	20
NH(4)–O(2)	0	1	25
NH(5)–O(3)	2	4	10
NH(i)–O($i-3$) [HB_{12}]			
NH(3)–O(0)	0	30	0
NH(4)–O(1)	0	26	0
NH(5)–O(2)	0	35	0
NH(6)–O(3)	1	18	0
NH(i)–O($i+1$) [HB_{10}]			
NH(2)–O(3)	11	0	0
NH(5)–O(6)	11	1	0
OH(i)–O($i-1$) [HB_7]			
OH(6)–O(5)	0	14	0
OH(i)–O($i-2$) [HB_{11}]			
OH(4)–O(2)	0	8	10
OH(5)–O(3)	1	22	0
OH(6)–O(4)	1	10	0
OH(i)–O($i-3$) [HB_{15}]			
OH(4)–O(1)	1	26	0
OH(5)–O(2)	0	10	0
OH(i)–O($i+2$) [HB_{13}]			
OH(3)–O(5)	38	0	0

three ensembles do not share any part of conformational space; each cluster is populated by members of only one of the three ensembles. With a larger rmsd criterion of 0.08 nm the ensembles slightly overlap at their peripheries (Figure 4B). Cluster 8 represents the only cluster containing structures from all three ensembles (MD at 298 K: 12%; MD at 340 K: 12%; X-PLOR: 76%). Figure 4 also illustrates that the Boltzmann-weighted ensembles generated by free (unrestrained) molecular dynamics simulations bear a much larger conformational variability than the bundle of structures obtained by restrained simulated annealing.

Summarizing, we find that even though the 20 model structures obtained from simulated annealing and the two ensembles generated by free MD simulations show different hydrogen-bond patterns and access different parts of the conformational space of the peptide, they all agree with the available NMR data. First, this indicates that for a given set of experimental observables, depending on the structural properties of a peptide, more than one solution structure is possible. Consequently, a single structure may not be representative for the ensemble of structures in solution.

Second, this study demonstrates that unbiased MD simulation using a thermodynamically calibrated force field reproduces experimental NMR data such as NOE upper-bound distances and ^3J-coupling constants just as well or even better than a set of NMR model structures derived by classical single-structure simulated-annealing refinement techniques using a simple force field in vacuo and the NOE upper bounds and J-value derived torsional-angle values as restraints. The fact that the MD simulations using the GROMOS force field do not need $40 + 12$ restraints to satisfy the NMR data on the peptide demonstrates the accuracy of this force field and of the inclusion of explicit solvent compared to results from the use of the X-PLOR force field in vacuo. Therefore, standard NMR refinement procedures for flexible molecules such as small peptides as well as for proteins should be revised by completing the refinement process with molecular dynamics simulation in explicit solvent with a thermodynamically calibrated force field in order to generate a proper Boltzmann-weighted ensemble of structures. This should lead to a more reliable structural interpretation of the experimentally measured NMR observables. In the present case of the β-hexapeptide the MD simulations show that a (P)-2_8-helical conformation is not stable and therefore probably not representative for the ensemble of solution structures. It cannot be excluded that the finding that the simulation using the GROMOS force field prefers the formation of a (P)-2.5_{12}-helix over a (P)-2_8-helix might be an artifact of the force field. Yet, the simulations agree with the experimental data and the GROMOS force field has very well reproduced experimental findings in previous peptide folding investigations.[11,14,15,31–39] Finally, we note once more that the comparison of modeling or simulation results with experiment should always be done with primary, measured data such as NOE intensities, and maybe distances, or ^3J-values and not only with secondary, derived data such as molecular structures and torsional-angle values in order to avoid spurious conclusions regarding (dis)agreement with experimental data.

Communications

Large Lattice Responses in a Mixed-Valence Prussian Blue Analogue Owing to Electronic and Spin Transitions Induced by X-ray Irradiation**

Serena Margadonna,* Kosmas Prassides, and Andrew N. Fitch

Mixed-valence metal cyanides with general formula $A_x M^{II}_y$-[$M'^{III}(CN)_6$]·$n H_2O$ (where A is an alkali-metal cation, and M and M′ are divalent and trivalent transition-metal cations, respectively) have attracted considerable interest because of their unusual electronic and magnetic properties.[1] In addition to molecular-based ferromagnetic properties with Curie temperatures higher than room temperature,[2–4] the availability of degenerate or quasidegenerate electronic states has made them ideal systems with which to explore switching phenomena at the molecular level.[5] For example, in some of these materials visible-light irradiation at low temperatures can drive optically controlled phase transitions to long-lived metastable states where the optical and/or magnetic properties change dramatically, thereby raising the potential of applications in memory devices and magneto-optical switching.[6–10] Metal-to-metal electron transfer was also induced by X-ray irradiation at very low temperatures in the Prussian blue analogue, $Rb_{1.8}Co_4[Fe(CN)_6]_{3.3}$·$13 H_2O$ with the resulting phase transformation monitored by energy-dispersive syn-

chrotron X-ray diffraction.[11] Herein, we show that X-ray irradiation can also induce interconversion between the ground and excited states in another such compound **1**, over a broad temperature range (between room temperature and 10 K). Depending on the experimental conditions, a variety of internal charge-transfer processes and spin transitions are triggered resulting in either continuous or abrupt phase transformations that are accompanied by large lattice relaxations and can be accurately monitored by high-resolution angle-dispersive synchrotron X-ray diffraction.

$$Rb_{0.7}Mn^{II}_{1.15}[Fe^{III}(CN)_6] \cdot 2 H_2O \quad \mathbf{1}$$
Important information concerning the thermo- and photoinduced magnetization/demagnetization behavior of transition-metal cyanides has been recently obtained by studying the cubic $RbMn^{II}[Fe^{III}(CN)_6]$ system.[12] At room temperature, the Mn^{II} ions are in their high-spin (HS, $t_{2g}^3 e_g^2$, $S = 5/2$) state and the Fe^{III} ions in the low-spin (LS, $t_{2g}^5 e_g^0$, $S = 1/2$) state, and these ions couple antiferromagnetically. Cooling induces a charge transfer from manganese to iron leading to Mn^{III} in the HS ($t_{2g}^3 e_g^1$, $S = 2$) and Fe^{II} in the LS state ($t_{2g}^6 e_g^0$, $S = 0$) and is accompanied by a cubic–tetragonal phase transition, driven by the Jahn–Teller distortion of the $Mn^{III}N_6$ octahedra[13,14] and the appearance of ferromagnetism at approximately 10 K.[15] Green light irradiation at low temperatures induces the reverse electron transfer and the low lying Mn^{II}–Fe^{III} excited state can then be populated.[16] Herein, we report on the internal redox reactions triggered by synchrotron X-ray radiation as a function of temperature and time in the related mixed-valence metal cyanide, **1**. As excited metastable electronic and spin states are populated and evolve with illumination time at different temperatures, the angle-dispersive synchrotron X-ray diffraction technique allows simultaneous complete crystal structure refinements, which leads to the elucidation of the resulting rich phase diagram in unprecedented detail.

We examined the synchrotron X-ray diffraction profiles of **1** collected at 295 K and at 100 and 10 K after cooling in the absence of X-ray illumination. No reflections violating face-centered cubic (*fcc*) extinction rules are evident and the crystal structure remains strictly cubic down to 10 K. Rietveld analysis (Figure 1 a, see Supporting Information) proceeded smoothly with the generic structural model of mixed-valence metal cyanides,[17] comprising a three-dimensional network of $\{Mn(NC)_6\}$ and $\{Fe(CN)_6\}$ octahedra linked by the CN ligands (space group $Fm\bar{3}m$, $a = 10.54314(4)$ Å at 295 K). The $Fe(CN)_6$ vacancy positions (13%) are occupied by H_2O molecules completing the coordination sphere of neighboring Mn^{II} cations while the Rb^+ ions are disordered in the tetrahedral interstices of the framework structure (inset Figure 1 a). The Mn—N and Fe—C bond lengths of the $\{Mn(NC)_6\}$ and $\{Fe(CN)_6\}$ octahedra refine to 2.249(4) and 1.900(5) Å, respectively, consistent with the Mn^{II}-NC-Fe^{III} ground state (GS) assignment of the metal valence states. This result is also in agreement with the magnetic susceptibility data (measured $\chi T = 5.17$ cm³ K mol⁻¹ at 295 K; spin-only value calculated for Mn^{II}(HS, $S = 5/2$)-Fe^{III}(LS, $S = 1/2$), $\chi T = 5.41$ cm³ K mol⁻¹). In contrast to stoichiometric

Figure 1. a) Final observed (blue circles) and calculated (red solid line) synchrotron X-ray powder diffraction profiles ($\lambda = 0.85066$ Å) for **1** at 295 K after 17 min of X-ray illumination. The lower green solid line shows the difference profile and the tick marks show the reflection positions. Two impurity peaks were excluded from the refinement. Inset: Building block of the cubic framework structure of **1**. Alternating {Mn(NC)$_6$} (light violet) and {Fe(CN)$_6$} (dark violet) octahedra are bridged by CN ligands. Pink spheres Rb$^+$ ions, red H$_2$O molecules residing in the Fe(CN)$_6$ vacancies. b)–d) Selected region of representative diffraction profiles showing the evolution of the (200) Bragg reflection with increasing X-ray illumination time. b) 295 K, c) 100 K, d) 10 K. Each curve is labeled with the corresponding illumination time.

RbMn[Fe(CN)$_6$], which is tetragonal at low temperatures[13, 14] after an internal electron transfer to give ferromagnetically coupled Mn^{III}(HS, $S=2$)–Fe^{II}(LS, $S=0$)–Mn^{III}(HS, $S=2$) units, no phase change is observed for **1** down to 10 K. This result can be understood in terms of the disorder associated with the water molecules which fill the Fe(CN)$_6$ vacancies, thereby suppressing the cubic–tetragonal phase transition of stoichiometric RbMn[Fe(CN)$_6$] and is consistent with the temperature dependence of the magnetic data (see Supporting Information), which show 1) a change in χT below 180 K to 4.5 cm^3 K mol^{-1}, implying that the thermally induced charge transfer to give Mn^{III}(HS, $S=2$)–Fe^{II}(LS, $S=0$) occurs only partially ($<20\%$) on cooling, 2) a negative Weiss temperature of -5.4 K implying predominant Mn^{II}–Fe^{III} antiferromagnetic interactions at low temperatures, and 3) the appearance of weak ferrimagnetism below approximately 10 K (coercive field $= 235$ Oe, remnant magnetization $= 240$ cm^3 G mol^{-1}).

We monitored the evolution of the diffraction profiles at various temperatures with increasing exposure time to the X-ray radiation. A striking feature of the data at 295 K is that, although the structure remains cubic, the diffraction peaks continuously shift to higher angles (Figure 1 b), which implies that the material rapidly contracts at a rate of 0.238(3) Å^3 min^{-1} (Figure 2 a) and shows an overall volume

decrease after 150 min of 2.9%. It is remarkable that the lattice contraction at 295 K for the illuminated sample is large enough to produce a cell volume considerably smaller than that of the non-illuminated sample at 10 K (overall volume decrease ca. 0.5%). Rietveld refinements with the same $Fm\bar{3}m$ structural model reveal a monotonic decrease of the Mn−N bond length to 2.203(4) Å after 150 min of exposure of the sample to the X-ray beam (Figure 2 b) at room temperature. This result is consistent with a progressive generation of Mn^{III}-NC-Fe^{II} centers with increased X-ray illumination time and shrinking of the Mn−N bonds upon oxidation of the Mn^{II} centers. In contrast, the iron coordination sphere changes very little upon reduction as expected (in K$_3$[Fe(CN)$_6$] Fe^{III}−C 1.93 Å, and in K$_4$[Fe(CN)$_6$] Fe^{II}−C 1.91 Å[8]). Though there is no unique real-space description of this internal charge-transfer effect, the observation that the width of the diffraction peaks also progressively increases (see Figure 1 b) leads us to describe the observed X-ray induced transformation as the formation of Mn^{III}-NC-Fe^{II} islands which progressively grow in size within a matrix of the original Mn^{II}-NC-Fe^{III} units and with a local structure different from that of the average bulk structure.

The behavior of **1** is even more intriguing when the X-ray irradiation is switched on at 100 K after cooling without illumination (Figure 1 c). The diffraction peaks initially shift continuously to higher angles as at 295 K but, after an incubation period of approximately 20 min, all the diffraction peaks are accompanied by a partner at significantly higher angle, thereby providing the signature of a sudden transformation of the high-temperature structure to an isostructural one (PT-1) with drastically reduced lattice dimensions (Figure 2 a). The fraction of the contracted phase grows rapidly in a very short time and is accompanied by a notable sharpening of the diffraction peaks, which indicates the occurrence of a phase transition in the bulk. The abrupt collapse in the unit cell dimensions ($\Delta V/V \approx -10.3\%$) can be again understood in terms of the X-ray induced internal redox process Mn^{II}(HS)-NC-Fe^{III}(LS)→ Mn^{III}(HS)-NC-Fe^{II}(LS), which occurs even more efficiently at this temperature. This process leads to a large fraction of photoconverted units that exceeds the percolation threshold and thereby a cooperative first-order phase transformation is abruptly triggered. Rietveld refinements (see Supporting Information) indicate that in the contracted phase, the Mn−N bond length further shortens significantly to 2.056(5) Å, while the Fe−C bond lengthens only slightly to 1.920(5) Å (Figure 2 b). We note that the abrupt phototransformation to the collapsed phase is accompanied by the appearance of a small fraction (ca. 5%) of a coexisting minority phase whose lattice

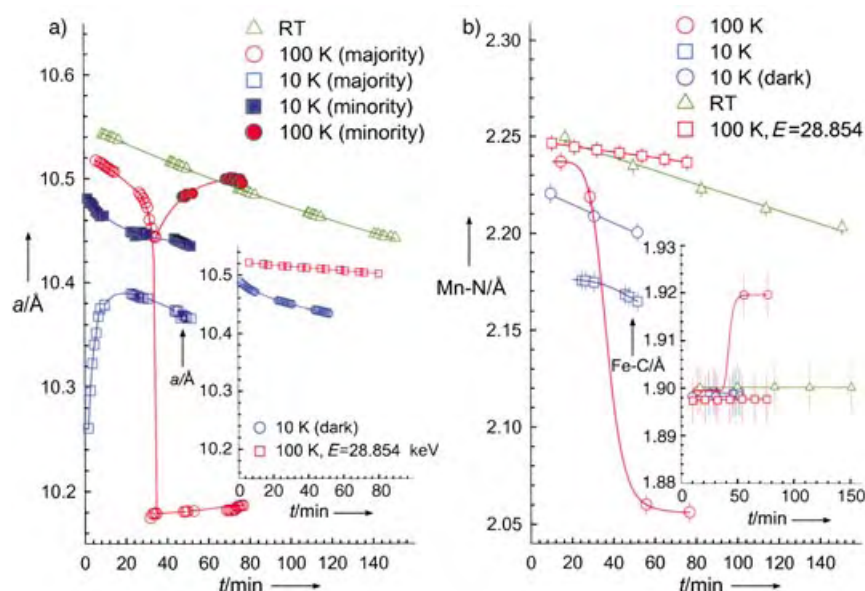
Communications


Figure 2. a) Evolution with increasing X-ray ($E = 14.575$ keV) illumination time of the cubic lattice constant in **1** at different temperatures: 295 K (green triangles), 100 K (red circles), 10 K (blue squares). Open symbols represent the lattice constants of the majority (full symbols the minority) phases at 100 and 10 K. Inset: the time dependence of the lattice constants at 10 K ($E = 14.575$ keV) after cooling in the dark (blue circles) and at 100 K for an incident photon energy of 28.854 keV (red squares). b) The corresponding time evolution of the Mn—N (inset: Fe—C) bond lengths as obtained from Rietveld refinements of the synchrotron X-ray powder diffraction profiles. Symbols are as described in (a).

size rapidly increases and approaches that expected for the untransformed material at this temperature (Figure 2a). Complementary experiments at 100 K with an X-ray beam of energy 28.854 keV were not able to induce the same first-order transition even after 80 min of irradiation and led only to a very slow decrease of the lattice dimensions at a rate of $0.083(2)$ Å^3 min^{-1} (inset Figure 2a). This can be understood by the now significantly reduced (by a factor between about 40–80) energy per unit volume per second deposited at the sample rendering the phototransformation extremely inefficient. This conclusion is also supported by the extracted lattice constant ($a = 10.49667(4)$ Å) being similar to that of the untransformed minority phase at 14.575 keV ($a = 10.4877(7)$ Å). In a complementary series of diffraction experiments at 100 K with a synchrotron X-ray beam of energy 28.850 keV, the first-order transformation to the collapsed phase was also successfully triggered by continuous wave (CW) green laser light illumination ($\lambda = 532$ nm, power $= 50$ mW).[18]

Substantial changes to the diffraction profile of the phototransformed PT-1 material are also observed on cooling to 10 K (Figure 1 d). An extremely rapid phase change sets in as soon as the X-ray light is switched on and the lattice size inflates within the first 10 min by $\Delta V/V \approx +6.3\%$. Apparently the PT-1 phase, which was accessed at 100 K by X-ray irradiation now becomes highly unstable and transforms to a new bulk phase (PT-2) whose lattice constants straddle those of PT-1 and of the non-irradiated phase (GS; see Supporting Information). Undoubtedly, the formation of PT-2 is triggered by the reverse internal redox process, which led to the

formation of PT-1 from GS, namely Mn^{III}-NC-Fe^{II}→Mn^{II}-NC-Fe^{III}. However, both the reduced lattice dimension ($a = 10.36940(6)$ Å) and refined Mn—N bond distance of $2.168(5)$ Å (Figure 2) are inconsistent with a description of the electronic states of the bridging motifs as identical to those of GS, namely Mn^{II}(HS)-NC-Fe^{III}(LS). Additional support for the conclusion that the phototransformed PT-2 phase should not be identified with GS comes from the presence of a co-existing minority phase ($9.9(1)\%$) with a lattice size identical to that of the material when cooled to 10 K in the dark (Figure 2a) and therefore comprising Mn^{II}(HS)-NC-Fe^{III}(LS) units.

To our knowledge, such a sensitivity to X-ray light with facile interconversion between a number of metastable states with differing charge (electronic) and spin (magnetic) states through both continuous (second order) and discontinuous (first order) phase transitions at temperatures ranging from 10 K to room temperature has not been reported for a single molecular system. It is reminiscent of the transitions from an insulating antiferromagnetic to a metallic ferromagnetic state in the Pr$_{0.7}$Ca$_{0.3}$MnO$_3$ manganite[19,20] and from a charge-ordered spin-dimerized to a disordered dimer state in the CuIr$_2$S$_4$ spinel[21] that were driven by X-ray illumination at low temperatures (< 40 K and < 10 K, respectively). Stabilization of the photoinduced states in the manganites has been strongly linked to the structural changes, which accompany the absorption of X-ray photons and the relaxation of the lattice distortion associated with the {Mn^{III}O$_6$} octahedra. This is a similar mechanism to that developed herein for the mixed-valence metal cyanides in which the photoinduced long-range-ordered states at 100 and 10 K are stabilized by the large lattice relaxations after electron removal from the {Mn^{II}(NC)$_6$} octahedra or electron addition to {Mn^{III}(NC)$_6$} octahedra. Moreover, our picture of the inhomogeneous character of the continuous phototransformation at room temperature is also analogous to that proposed for both the manganites and the spinels,[19–21] in which the X-ray induced states are similarly characterized by structural inhomogeneities, as evidenced by the observed peak broadening and gradual evolution in the unit cell dimensions and metal–ligand bond lengths.

In conclusion, the initial results presented herein open the way for the study of the structural relaxations of otherwise inaccessible metastable electronic states of various multi-stable molecular materials following the absorption of photons. In addition, given the energy tunability of synchrotron X-ray light, the kinetics of the phototransformations can be controlled and moved between different time windows even at ambient temperature. We also note the considerably persistent character of the photoinduced transitions. To explain this, we can invoke the large lattice relaxations, which in these materials accompany the internal charge transfer and spin rearrangements (strong electron–phonon

coupling) and need large energies in order to be annealed. Figure 3 summarizes the postulated electronic and spin configurations of the transition-metal ions following the X-
Figure 3. Schematic representation of the postulated electronic and spin configurations of the Mn and Fe ions following the X-ray-induced first-order phase transitions at 100 K in **1** at an incident photon energy of 14.575 keV.

ray-driven first-order phase transition at 100 K. Although the optical and magnetic properties of the two photoinduced bulk states, PT-1 and PT-2 are not probed in the present diffraction experiments directly, we anticipate that both their color and their magnetization should also significantly change. For instance, the color of the material exposed to X-ray light at room temperature changes from light to dark brown. Comparing the magnetic properties, we note that the untransformed material comprises antiferromagnetically coupled Mn^{II}(HS, $S = 5/2$) and Fe^{III}(LS, $S = 1/2$) ions and becomes ferrimagnetic at about 10 K. On the other hand, the exchange coupling between near-neighbor Mn^{III}(HS, $S = 2$) ions in PT-1 is mediated by the Fe^{III}(LS, $S = 0$) degenerate t_{2g} orbitals and is of ferromagnetic nature. As a result, conversion into the phototransformed excited states should be accompanied by drastic changes of the magnetization.

Experimental Section

1 was prepared as a light brown solid by reaction of aqueous solutions of $MnCl_2$ (0.1M), RbCl (1M), and $K_3Fe(CN)_6$ (0.1M) and its stoichiometry established by elemental (Rb:Mn:Fe = 0.72:1.13:1) and thermogravimetric analysis. Temperature- and field-dependent magnetization measurements were performed with a Quantum Design MPMS5 SQUID susceptometer. For the angle-dispersive synchrotron X-ray diffraction measurements, samples were sealed in thin-wall glass capillaries 0.5 mm in diameter. With the sample inside a continuous-flow cryostat, synchrotron X-ray powder diffraction data ($\lambda = 0.85066$ Å, $E = 14.575$ keV, beamsize approximately 2.3×1.4 mm^2) were collected on cooling at 295, 100, and 10 K as a function of illumination time using the high-resolution powder X-ray diffraction beamline ID31 at the European Synchrotron Radiation Facility (ESRF), Grenoble, France. Complementary diffraction data were also collected at 100 K using X-rays with $\lambda = 0.42970$ Å ($E = 28.854$ keV). Data analysis was performed with the GSAS suite of Rietveld analysis programs.

[18] The observed photoinduced effects are of persistent nature. Upon switching off the X-ray beam and warming the sample in the dark to room temperature, the lattice contraction partially survives for many hours (after 10 h, the fraction of the collapsed phase is still about 20%), which implies that the lattice strains accompanying electron transfer are large enough that relaxation does not occur immediately even at room temperature. However, we note that if in the course of warming to room temperature the sample is continuously illuminated by green laser light, the pristine room temperature phase (GS) is completely recovered.

Design of a Conformation-Sensitive Xenon-Binding Cavity in the Ribose-Binding Protein**

*Thomas J. Lowery, Seth M. Rubin, E. Janette Ruiz, Alexander Pines, and David E. Wemmer**

NMR spectroscopy with laser-polarized ^{129}Xe has been used to investigate biomolecular systems, for example, detecting protein cavities in myoglobin, lipoxygenase, lysozyme, and a lipid-transfer protein, through interaction-induced chemical shift changes.[1–4] With the maltose-binding protein (MBP) from *E. coli*[2] and the chemotaxis protein Y[3] the chemical shift of interacting ^{129}Xe was found to respond to the protein conformation because of cavities that change size or shape in different conformers,[3,4] altering the shift of bound ^{129}Xe or the xenon binding affinity. Xenon probing requires no protein derivatization, and exploits simple spectra with no background signals and high sensitivity through optical polarization.[2,3]

It has been estimated that about half of the natural proteins contain cavities of sufficient size to bind xenon,[5] but only a few can be expected to bind xenon in a conformation-sensitive manner. Our studies of the conformation-sensitive xenon binding in MBP[4] led us to attempt to engineer a cavity for conformation-sensitive xenon binding into the ribose-binding protein (RBP), which lacks an intrinsic site of this type.

Periplasmic transport proteins, including MBP and RBP, close around their ligands in a "clam-shell"-like manner as they bind.[6] The ^{129}Xe chemical shift in RBP solutions responds only slightly to this process (Figure 1). Xenon in
Figure 1. Change in ^{129}Xe chemical shift ($\Delta\delta_{Xe}$) with protein concentration (c) for the open (○, solid gray line) and closed (●, solid gray line) conformations of wild-type RBP and for the open (△, black dashed line) and closed (▲, black dashed line) conformations of L19A RBP. $\Delta\delta_{Xe}$ is the difference between the ^{129}Xe chemical shifts of each titration point and the buffer. Insets: a) ^{129}Xe NMR spectrum for 0.64 mM L19A RBP in the open conformation at a chemical shift of 0.83 ppm. b) ^{129}Xe NMR spectrum for 0.69 mM L19A RBP in the closed conformation at a chemical shift of 0.58 ppm. The ^{129}Xe chemical shift and linewidth are sensitive to the conformation of L19A RBP but not to that of wild-type RBP. The source of linewidth sensitivity is under current investigation.

protein solutions exchanges rapidly among all available sites of interaction giving a single observed chemical shift (δ_{obs}), which is an average over all site-specific chemical shifts (δ_i) weighted by their respective binding constants (K_i) [Eq. (1)].[3,7,8]

$$\delta_{obs} = \left(\sum \delta_i K_i\right) c(\text{protein}) \tag{1}$$

The concentration-normalized chemical shift ($\Sigma\delta_i K_i$) values (slopes of the lines) for the open and closed conformations of RBP are (0.7 ± 0.1) and (0.6 ± 0.1) ppm mM^{-1}, respectively, whereas for MBP these are (1.2 ± 0.1) and (2.1 ± 0.1) ppm mM^{-1}.[2] The low sensitivity of the ^{129}Xe shift to the RBP conformation indicates that wild-type RBP does not contain a conformation-sensitive xenon-binding cavity.[3,4] A search of the RBP structures with the program VOIDOO, which identifies internal voids, found a cavity located away from the ligand-binding cleft (Figure 2). Its size, about 50 Å^3, is the same in the open and closed conformations.

Mutating a buried, nonpolar side chain, such as Leu, Ile, or Phe, to a smaller nonpolar side chain, such as Ala, can create a cavity of sufficient size to bind xenon.[4,5,9] Bulky
Figure 2. Cartoon backbone depictions of a) the open, or ligand-free, b) the closed, or ligand-bound, conformation of RBP.[6, 11] Shown in light gray mesh is the surface of the cavity present in wild-type RBP that does not bind xenon; it is located away from the binding site and is the same size in both conformations. The black mesh shows the cavity created by the L19A mutation. Its increased size in the closed conformation is apparent as well as its proximity to bound ribose (with the ring shown by black sticks) and the loops that connect the two domains.

nonpolar side chains in regions that change structure between the two conformers were inspected and six potential sites for mutation were selected for initial screening: L19, L88, F187, F214, I233, and I240. The effect of a change to alanine at each site was evaluated by deleting atoms in the PDB file and calculating the size of the resulting cavity. Two changes produced cavities that differed significantly in size (~ 30 Å^3) between the two conformations, and L19A RBP was selected to test experimentally. The cavity sizes estimated by VOIDOO for the open and closed conformations of L19A RBP are 74 and 102 Å^3, respectively. Smaller cavities can result if residues surrounding a cavity created by mutation relax.[9,10] This was not considered a significant problem in the design process because xenon has been shown to bind to small flexible cavities, increasing the cavity volume by restoring the lining residues to their original positions.[9]

Figure 2 shows that the cavity of L19A RBP is directly below the ribose-binding cleft near loops that serve as a hinge during ligand binding. Of the residues that line the cavity, F15, F16, N64, and D89 make direct contact with ribose in the closed conformation.[11] The proximity of the cavity to functionally critical residues could affect the conformation change and decrease affinity for ribose. The affinities of wild-type and L19A RBP for ribose were measured using isothermal titration calorimetry (ITC) which gave K_d values of (0.11 ± 0.01) μM for wild-type (in agreement with previous work[12]) and (0.30 ± 0.05) μM for L19A RBP. The concentration-normalized ^{129}Xe shifts for open $((1.2 \pm 0.1)$ ppm mm$^{-1})$ and closed L19A RBP $((0.8 \pm 0.1)$ ppm mm$^{-1})$ were determined (Figure 1). The mutation increases the ^{129}Xe shift of the open conformation by 0.5 ppm mm^{-1} and of the closed conformation by 0.2 ppm mm^{-1}, enhancing the discrimination of open and closed conformations.

To verify that xenon binds in the designed cavity, ^{1}H-^{15}N correlation spectra (HSQC) were obtained in the presence

and absence of xenon as done previously for MBP and other proteins.[4, 13] Resonance signals that shift upon xenon addition are primarily from amide protons that line the cavity.[4, 13] ^{1}H-^{15}N HSQC spectra of open and closed wild-type RBP were collected in the presence and absence of 90 mm xenon. The overlayed spectra of wild-type RBP show that 90 mm xenon does not shift signals in either wild-type conformer, indicating that xenon does not bind to the wild-type cavity.[14] In the L19A RBP spectra a subset of the signals shift relative to their wild-type counterparts, reflecting perturbations from introducing the L19A mutation (Figure 3). For both open and
Figure 3. Representative portions of the ^{1}H-^{15}N HSQC spectra for the open (a) and closed (b) conformations of wild-type RBP in the absence of xenon (black), L19A RBP in the absence of xenon (red), and L19A RBP in the presence of 93 (a) or 72 mm (b) xenon (green).

closed L19A RBP specific resonance signals shift with increasing xenon concentration, indicating specific binding.[4] Every signal that shifts with increasing xenon concentration also shifts upon introduction of the L19A mutation, indicating that residues affected by xenon binding are associated with the introduced cavity, verifying creation of a specific xenon-binding site. Several signals affected by xenon binding shift toward the wild-type signals, suggesting that xenon restores these residues to their original environments, as in T4 lysozyme.[9]

The xenon binding affinity was measured by following the change in amide shift with xenon concentration (Figure 4).[4] Five resonance signals that shifted at least ten Hertz in each conformation were fitted as previously described[4] and averaged to give values of (70 ± 30) and $(40 \pm 20)\,\text{M}^{-1}$ for the open and closed conformations, respectively, yielding affinities similar to those for MBP.[4]
Figure 4. The total change in amide ^{1}H chemical shift ($\Delta\delta$) versus xenon concentration (c) for the same resonance signal in the open ($\circ$) and closed ($\bullet$) conformations of L19A RBP. Similar binding curves and fits were obtained for four other resonance signals. The different xenon binding affinity of the open and closed conformations reflects the conformation-sensitive nature of the xenon-binding cavity created by the L19A mutation.

The limiting xenon chemical shifts relative to the shift in buffer, (δ_i) [Eq. (1)], in the xenon-binding cavity were determined by comparing titrations in which the cavity was available and blocked,[4] giving $\delta_{\text{open}} = (7 \pm 3)$ and $\delta_{\text{closed}} = (5 \pm 3)$ ppm. Cavity-induced downfield shifts have been shown to be inversely proportional to cavity volume in proteins, zeolites, and clathrates.[4,15,16] The shift values for the cavity of L19A RBP indicate that it is smaller in the open conformation, as predicted by the design process.

Cavity-creating mutations in T4 lysozyme were shown to decrease the Gibbs energy of unfolding in proportion to the size of the cavity.[11] Urea-induced unfolding of open wild-type and L19A RBP was followed by circular dichroism, and analyzed to give ΔG_u values of (5.8 ± 0.1) and (3.3 ± 0.1) kcal mol^{-1}, respectively. Combining this with ribose affinity measurements from ITC and the calibration from T4 lysozyme[11] gives estimates of 25 Å^3 (open) and 54 Å^3 (closed) for the cavities in RBP, a change of about 30 Å^3 as modeled.[14]

Analysis of the L19A–^{129}Xe interaction shows that the conformational responsiveness arises from both a higher xenon affinity and a larger shift induced by the cavity in the open conformation contributing to the averaged limiting ^{129}Xe chemical shift (δ_{obs}) [Eq. (1)]. The higher xenon binding affinity of the smaller cavity likely arises from increased van-der-Waals contact in the smaller cavity.[9]

We were able to introduce a conformation-sensitive xenon-binding cavity into the ribose-binding protein with a straightforward design process, demonstrating the feasibility of engineering ^{129}Xe NMR reporter sites into proteins of interest for assaying ligand binding or conformation changes. The idea of designed sites for xenon can be further generalized[17] and is being applied to biological problems.

cRGD-Functionalized Polymer Micelles for Targeted Doxorubicin Delivery**

Norased Nasongkla, Xintao Shuai, Hua Ai,
Brent D. Weinberg, John Pink, David A. Boothman,
and Jinming Gao*

Low water solubility, rapid phagocytic and renal clearance, and systemic toxicity represent three major barriers that limit the therapeutic use of many hydrophobic antitumor agents such as doxorubicin (DOXO) and paclitaxel.[1] Various drug-delivery systems, among which polymeric micelles have emerged as a very important system, have been developed to overcome these limitations and deliver various drugs with remarkable in vitro and in vivo success.[2,3] Polymeric micelles are nanoscopic (10 to 100 nm) colloidal particles self-assembled from amphiphilic block or graft copolymers in aqueous media. The hydrophobic core of the micelles is a carrier compartment that accommodates antitumor drugs, and the shell consists of a brushlike protective corona that stabilizes the nanoparticles in aqueous solution.[4] The basic requirements for polymeric micelles in drug-delivery applications include high drug-loading capacity, biodegradability, long blood circulation times, and controllable drug-release profiles. Research on micelles has been greatly advanced in the

[+] These authors contributed equally to this work

past decade.[5–8] However, the ability to achieve high targeting efficiency at the tumor site and associated cells remains a significant challenge for the development of micelle-mediated drug-delivery systems. Although nanosized micelles are known to spontaneously accumulate in tumors with leaky vasculature by an enhanced permeability and retention (EPR) effect,[9] micelles are also observed to accumulate quite significantly in reticuloendothelial sites such as the liver, spleen, and kidney.[10] Consequently, insufficient uptake in tumor sites will decrease the therapeutic effect of the administered drug dose, and nonspecific spreading to healthy tissues will lead to serious side effects and limit the dosage that can be applied. These limitations prevent these drugs from achieving the potential cures that they might otherwise attain.[11]

One strategy to achieve cancer-targeted drug delivery is the utilization of unique molecular markers that are specifically overexpressed in the cancerous tissues. It is well known that tumor endothelial cells show increased expression of

several cell-surface molecules that potentiate cell invasion and proliferation during tumor vascular remodeling and angiogenesis.[12,13] One such molecule is the $\alpha_v\beta_3$ integrin, which plays a key role in endothelial cell survival during angiogenesis.[14] Enlightened by the early discovery that viruses, such as rotavirus and adenovirus, can utilize this receptor to facilitate gene transfer by selective recognition between $\alpha_v\beta_3$ on the targeted cell membrane and the viral surface, researchers have exploited ligands such as the Arg-Gly-Asp (RGD) peptide. In fact, $\alpha_v\beta_3$ was recently used as an endothelial cell target in several therapeutic approaches such as nonviral gene delivery.[15,16]

Unfortunately, ligand-directed delivery of hydrophobic drugs with polymeric micelles has been reported only in a few cases.[17,18] Herein, we develop polymeric micelles that can selectively deliver hydrophobic drugs, such as doxorubicin, to angiogenic tumor endothelial cells with over-expressed $\alpha_v\beta_3$ integrins. To this end, we attached a cyclic pentapeptide c(Arg-Gly-Asp-D-Phe-Lys) (cRGDfK, also referred to as cRGD herein) as an $\alpha_v\beta_3$ ligand to the surface of doxorubicin-loaded poly(ε-caprolactone)-poly(ethylene glycol) (PCL-PEG) micelles. cRGDfK was selected as the targeting ligand since it can selectively bind to the $\alpha_v\beta_3$ integrin with high affinity.[19,20] Although the coupling of doxorubicin to RGD peptides (for example, RGD-4C) was found to be able to target tumor blood vessels,[21] RGD-directed doxorubicin delivery using polymeric micelles has not been reported to date.

The synthesis of the maleimide-terminated block copolymer (MAL-PEG-PCL, $M_n = 5.5$ kD) and preparation of the cRGDfK-functionalized micelles with DOXO loading are outlined in Scheme 1. In contrast to the reported procedure for the polymerization of ε-caprolactone with stannous(II) octoate as a catalyst,[22] the synthesis of MAL-PEG-PCL must be conducted at a lower temperature because of the thermal susceptibility of the maleimide end groups. We found that reaction at 68°C led to PCL segments of the desired molecular weights (for example, 2.4 kD), while reducing the thermal decomposition of maleimide to a negligible level (see the Supporting Information). DOXO-loaded MAL-PEG-PCL micelles were prepared by a solvent-evaporation method.[23] Different amounts of methoxy-terminated MPEG-PCL copolymer were also introduced to control the density of maleimide at the micelle surface, which subsequently controls the cRGD density (5, 16, and 76% of all PEG chains). The typical DOXO loading content (DLC) in the micelle preparations was 3.10 wt%.

Figure 1a shows the ^{1}H NMR spectrum of MAL-PEG-PCL copolymer in CDCl$_3$. Resonances of the PEG methylene protons (mainly at $\delta = 3.64$ ppm) and PCL protons ($\delta = 1.38$, 1.65, 2.31, and 4.06 ppm) were observed. The small triplet at $\delta = 4.2$ ppm was attributed to the proton resonance of the methyleneoxyl group linking the PCL and PEG blocks. The intensity of the integrals for the maleimide vinylic protons at $\delta = 6.74$ ppm confirms that the maleimide group in MAL-PEG-PCL copolymers remained intact, as in the MAL-PEG-OH. These data strongly demonstrated that the desired block copolymers were successfully synthesized. The number-averaged molecular weight of PCL blocks was calculated to be
Figure 1. ^{1}H NMR spectra (600 MHz, 25°C) of a) MAL-PEG-PCL copolymer in CDCl$_3$ and b) cRGD-functionalized, DOXO-loaded micelles in D$_2$O. The inset in (a) shows the proton signal from maleimide groups ($\delta = 6.74$ ppm), and the inset in (b) shows the absence of the maleimide signal and the presence of aromatic protons from the Phe residue in cRGDfK, thus indicating a complete conversion of the maleimide group after cRGD conjugation.

2.4 kD from the integral of the PCL protons at $\delta = 2.31$ ppm versus that of the PEG proton at $\delta = 3.64$ ppm. A postmicellar modification strategy was used to prepare cRGD-functionalized micelles (Scheme 1). The NMR spectrum of the freeze-dried micelles in D$_2$O strongly suggests the formation of the core-shell structure of DOXO-loaded micelles (Figure 1b). The micelle corona (shells) consisting of PEG blocks were solvated to a high degree in D$_2$O and showed clear ^{1}H NMR signals. In contrast, DOXO was loaded inside the solid PCL cores of micelles, and thus the resonances of both the PCL blocks and DOXO molecules were significantly reduced because of their insufficient mobility in D$_2$O. Moreover, successful conjugation of cRGDfK onto the solvated PEG

shells was verified by the resonances of the phenyl protons of cRGDfK at $\delta = 7.4$ ppm and complete disappearance of the maleimide signal at $\delta = 6.74$ ppm (Figure 1 b).

It is well known that the size of nanocarriers plays an important role in cellular internalization process. Before evaluating the cellular uptake of non- and cRGD-functionalized micelles, we studied the size and morphology of the micelles by atomic force microscopy (AFM) and dynamic light scattering (DLS). AFM studies showed that micelles with 76% cRGD attachment had a mean size (43.2 ± 3.9 nm) similar to that of cRGD-free micelles (37.5 ± 2.6 nm). Both unfunctionalized and 76% cRGD-containing micelles appeared to be discrete and round-shaped nanoparticles. Aggregation of micelle particles was not observed. The DLS measurements showed that the size of the cRGD-functionalized micelles was also close to that of the unfunctionalized micelles (20.9 ± 1.7 and 24.4 ± 2.7 nm for non- and cRGD-functionalized micelles, respectively; Figure 2). Two major factors may have contributed to the larger diameter of the micelle determined by AFM measurement. First, the height of the micelle particles was approximately 5 nm by AFM, which is significantly smaller than the diameter of the micelle determined by DLS (20–25 nm). The decreased height in the solid state indicates that particle-flattening events occur during the sample dewetting process on the mica surface, which can increase the apparent particle diameter in the x,y plane for AFM measurement. Second, it is well known

that AFM can give an overestimation of particle size as a result of the AFM tip-broadening effect.[24] The magnitude of the tip dilation effect depends on the height of the object, the ambient humidity, and the size and shape of the AFM tip.[25,26] The morphology reconstruction method can potentially be applied to correct the dilation effect and provide a more accurate determination of the particle sizes.[26]

Finally, we used flow cytometry and confocal laser scanning microscopy to study the uptake of micelles into SLK tumor endothelial cells (derived from human Kaposi's sarcoma) that over-express the $\alpha_v\beta_3$ integrin.[27] We quantified the cellular internalization efficiency of the cRGD-micelles by measuring the increase in fluorescence intensity after the DOXO-loaded micelles had been transported into the cells. Figure 3a shows the percentage of SLK cells with micelle uptake as a function of cRGD density on the polymer micelles after 2 h incubation. We observed a remarkable increase in the uptake of micelles in the cells upon attachment of cRGD molecules to the micelle surface. A higher density of cRGD molecules led to a higher level of cellular internalization of these micelles over the entire cRGD density range (0–76%) examined. A maximum 30-fold enhancement was achieved with 76% cRGD-functionalized DOXO-loaded micelles relative to unfunctionalized DOXO-loaded micelles. It is noteworthy that Kissel and co-workers recently reported that linear RGD molecules attached to DNA/PEI-PEG (PEI = polyethyleneimine) nanocomplexes through PEG spacers did
Figure 2. Size characterization of 0% (a, b) and 76% (c, d) cRGD-functionalized DOXO-loaded micelles by atomic force microscopy (a, c) and dynamic light scattering (b, d).

Communications
Figure 3. a) Percentage of micelle uptake in SLK tumor endothelial cells measured by flow cytometry as a function of cRGD density (0–76%) on the micelle surface. The last bar shows that the cell uptake of 76% cRGD-functionalized micelles is inhibited by the presence of free RGD ligands (9 mM) in solution. b, c) Confocal laser scanning microscopy images of SLK cells treated with 0% (b) and 16% (c) cRGD-functionalized micelles after incubation for 2 h. Cell nuclei were stained blue by Hoechst 33 342 ($\lambda_{ex} = 352$ nm, $\lambda_{em} = 455$ nm) and overlaid with DOXO fluorescent images ($\lambda_{ex} = 485$ nm, $\lambda_{em} = 595$ nm).

This cRGD-directed micelle targeting to $\alpha_v\beta_3$-overexpressed tumor endothelial cells was further demonstrated in a control experiment, in which SLK cells were first incubated with a free AARGDY blocking ligand (9 mM), and then coincubated with 76% cRGD-functionalized micelles (see the Supporting Information). The cellular uptake level of cRGD-functionalized micelles in the presence of blocking ligand was dramatically reduced and became essentially equivalent to that of unfunctionalized micelles (Figure 3a). These data demonstrate that the $\alpha_v\beta_3$ receptor is essential for the uptake of cRGD-functionalized micelles in SLK tumor endothelial cells.

Confocal laser scanning microscopy was then used to characterize and compare the cell uptake and intracellular distribution of cRGD-free and 16% cRGD-functionalized DOXO micelles after incubation for two hours (Figure 3b,c). Significantly increased intracellular DOXO fluorescence intensity was observed with cRGD-functionalized micelles, thus demonstrating again the enhanced cellular uptake by the cRGD-$\alpha_v\beta_3$-mediated endocytosis as shown by flow cytometry. Similar to cRGD-free micelles, cRGD-functionalized micelles were localized in the cytoplasm rather than the nuclei where free DOXO accumulated quickly after membrane diffusion.[8,23] Recently, Maysinger and co-workers detected intracellular localization of modified PCL-PEG micelles (20 to 45 nm) in several intracellular organelles including mitochondria, Golgi apparatus, and acidic organelles such as lysosomes in PC12 and NIH 3T3 cells. They suggested the multiple cytoplasmic-targeting of modified PCL-PEG micelles.[4] On the basis of the $\alpha_v\beta_3$ receptor mediated endocytosis pathway of the cRGD-functionalized micelles, we suggest that in our system the cRGD-functionalized micelles were more likely entrapped in the endosomal compartments. Indeed, as shown in Figure 3b, a large amount of dot-shaped DOXO fluorescence was observed in the cytoplasm of treated cells, which suggests the presence of internalized micelles in the endosomes.[8]

In summary, a very effective $\alpha_v\beta_3$ ligand (cRGDfK) was successfully conjugated to DOXO-loaded PEG-PCL micelles by using a postmicelle modification method. Attachment of the cyclic RGD ligand greatly enhanced internalization of the micelles in tumor endothelial cells that overexpress $\alpha_v\beta_3$ integrins, apparently through receptor-mediated endocytosis. Although preliminary, our results illustrate the tremendous potential of cRGD-functionalized micelles for targeting the tumor neovasculature. To verify this hypothesis, we are conducting in vitro cytotoxicity tests and animal studies with cRGD-functionalized, DOXO-loaded micelles.

not lead to effective targeting to $\alpha_v\beta_3$-expressing cells.[28] We believe the higher affinity of cyclic RGDfK to $\alpha_v\beta_3$ over the linear RGD peptides (>200 times)[19] in our current system has primarily contributed to the higher targeting efficiency by our cRGD micelles.

Polyoxomolybdates

A Molybdenum Crown Cluster Forms Discrete Inorganic–Organic Nanocomposites with Metalloporphyrins**

Akihiko Tsuda,* Eri Hirahara, Yeong-Sang Kim, Hiroyuki Tanaka, Tomoji Kawai,* and Takuzo Aida*

Molybdenum blue (MB), formed by partial reduction of Mo^{VI} in an acidic aqueous solution, is a striking inorganic material due to its vivid blue color. It is a mixture of polyoxomolybdate (POM) clusters consisting of mixed-valent Mo^V and Mo^{VI} centers.[1–3] Although the initial exploration was made more than 200 years ago,[4] the first success in structural analysis of POM clusters was only reported in 1995, when Müller and co-workers isolated a crown-shaped POM cluster and obtained its crystal structure.[5] To date, they have also succeeded in structural determination of large POM clusters with hollow and spherical shapes.[6,7] Despite their interesting potentials in materials sciences, no examples have yet been reported of the utilization of such inorganic nano-objects for the fabrication of discrete inorganic/organic nanocomposite materials. Herein we report that the crown-shaped POM (molybdenum crown cluster; MC), upon mixing with metalloporphyrins having meso-aminophenyl substituents, forms discrete inclusion complexes, where the inorganic cavity of MC can accommodate up to three molecules of the guest compounds, to give spatially isolated metalloporphyrin molecules (Scheme 1).

$$Na_{(32-n)}[(MoO_3)_{176}(H_2O)_{63}(MeOH)_{17}H_n] \cdot$$
$$\approx 600\,H_2O \cdot \approx 30\,MeOH \quad MC$$
MC has a large cavity with a diameter of approximately 2.3 nm.[7] We expected that this cavity can incorporate proton acceptors through a hydrogen-bonding interaction, since a

Scheme 1. Schematic representations of the complexation of molybdenum crown cluster (MC; blue polyhedra) with zinc 5,10,15,20-*tetrakis*(4-aminophenyl)porphyrin (**1**(*p*-NH$_2$)$_{Zn}$; space-filling model: pink Zn, blue N, gray C, white H). Molecular models of MC and **1**(*p*-NH$_2$)$_{Zn}$ are based on X-ray crystallography (see ref. [7]) and MM2 calculation, respectively.

great number of proton-donating μ$_3$-O···H species are concentrated in its inner surface.

MC was prepared according to a literature method,[7] and characterized by means of MALDI-TOF mass spectrometry and scanning tunneling microscopy (STM), along with UV/Vis and IR spectroscopy.[8] The MC, thus obtained, was highly soluble in MeCN to give a clear blue solution, which showed characteristic broad absorption bands at 730 and 1058 nm (Figure 1 a). For the complexation studies with MC, we chose as potential guest molecules zinc complexes of 5,10,15,20-

tetrakis(aminophenyl)porphyrins, such as **1**(*p*-NH$_2$)$_{Zn}$, **1**(*m*-NH$_2$)$_{Zn}$, and **1**(*o*-NH$_2$)$_{Zn}$, and **1**(*p*-NH$_2$)$_{Cu}$, a copper analogue of **1**(*p*-NH$_2$)$_{Zn}$. Compounds **2**$_{Zn}$ having 4-aminobiphenyl groups and **3**$_{Zn}$ bearing 3,5-dihydroxyphenyl groups at the meso-positions were used as references. According to molecular models, **1**(*p*-NH$_2$)$_{Zn}$, **1**(*p*-NH$_2$)$_{Cu}$, **1**(*m*-NH$_2$)$_{Zn}$, **1**(*o*-NH$_2$)$_{Zn}$, and **3**$_{Zn}$ are 2.0, 2.0, 1.8, 1.6, and 1.8 nm in diameter (longer molecular axis), respectively,[9] and smaller than the cavity of MC, whereas compound **2**$_{Zn}$ is much larger (2.8 nm). Compound **3**$_{Zn}$ is different from these complexes, in that it has Brønsted acidic OH functionalities in place of the amino functionalities.

Electronic absorption spectroscopy in MeCN with the five zinc porphyrin complexes indicated that **1**(*p*-NH$_2$)$_{Zn}$ and **1**(*m*-NH$_2$)$_{Zn}$ interact with MC. For example, upon
Figure 1. Absorption spectra (350–850 nm) of a) MC (2.2×10^{-6} M)[10] (inset: 350–1400 nm), and zinc porphyrins, b) **1**(*p*-NH$_2$)$_{Zn}$ (2.4×10^{-6} M), and c) **1**(*o*-NH$_2$)$_{Zn}$ (2.5×10^{-6} M) in the absence and presence of MC (0.5 equiv) in MeCN at 20°C.

titration of **1**(*p*-NH$_2$)$_{Zn}$ which has 4-aminophenyl groups with MC, the Soret-band at 430 nm decreased in intensity with a small blue shift to 427 nm, while a red-shifted shoulder appeared at 440 nm (Figure 1 b). Compound **1**(*m*-NH$_2$)$_{Zn}$ which has 3-aminophenyl groups also showed a spectral change upon titration with MC, a considerable broadening of the Soret band in the longer wavelength region took place.[8] In contrast, **1**(*o*-NH$_2$)$_{Zn}$ bearing amino groups directed towards the porphyrin unit (Figure 1 c) and the larger sized **2**$_{Zn}$[8] hardly showed spectral changes under similar titration conditions. Likewise, the absorption spectrum of **3**$_{Zn}$ having phenolic OH functionalities was virtually unchanged upon addition of MC. These contrasting observations indicate that the complexation of the zinc porphyrins with MC is chemo-,

regio-, and size-selective. Namely, the peripheral amino groups are crucial for the complexation with MC, but they should be oriented away from the porphyrin ring, and such guest molecules should be smaller than the MC cavity. Therefore, MC accommodates $1(p\text{-NH}_2)_{Zn}$ and $1(m\text{-NH}_2)_{Zn}$ inside the cavity through the formation of multiple hydrogen bonds (e.g., $\mu_3\text{-O}\cdots\text{H}\cdots\text{N}$), to give inclusion complexes $[MC\supset1(p\text{-NH}_2)_{Zn}]$, and $[MC\supset1(m\text{-NH}_2)_{Zn}]$, respectively. Copper complex $1(p\text{-NH}_2)_{Cu}$, upon titration with MC, also showed an essentially identical spectral change profile to that of $1(p\text{-NH}_2)_{Zn}$.[8]

To determine the stoichiometry of the complexation, spectroscopic titration of MC with $1(p\text{-NH}_2)_{Zn}$ was conducted in MeCN (Figure 2a), where MC showed stepwise spectral
Figure 2. Spectroscopic titration of MC (2.5×10^{-6} M)[10] with $1(p\text{-NH}_2)_{Zn}$ in MeCN at 20°C. [$1(p\text{-NH}_2)_{Zn}$] = a) 0–2.1×10^{-5} M (overall spectral change), b) 0–0.5×10^{-5} M, c) 0.6×10^{-5}–1.0×10^{-5} M, and d) 1.2×10^{-5}–2.1×10^{-5} M.

changes in response to [$1(p\text{-NH}_2)_{Zn}$]/[MC] at 0–2, 2–4, and 4–10 (Figure 2b–d),[10] with isosbestic points at 1121, 1138, and 1143 nm, respectively. This observation indicates the stepwise formation of 1:1, 1:2, and 1:3 complexes between MC and $1(p\text{-NH}_2)_{Zn}$.[11] Slow evaporation of a concentrated MeCN solution of a 1:3 mixture of MC and $1(p\text{-NH}_2)_{Zn}$ allowed the isolation of $[MC\supset1(p\text{-NH}_2)_{Zn}]$ as a green precipitate, which was subjected to inductively coupled plasma atomic emission spectroscopy (ICP-AES) to give a Mo/Zn ratio of 61.9. This value is in good agreement with that calculated for the 1:3 inclusion complex between MC and $1(p\text{-NH}_2)_{Zn}$ (58.7). According to the crystal structure,[7] the cavity of MC is 1.3 nm deep and large enough to accommodate up to three molecules of $1(p\text{-NH}_2)_{Zn}$ when they are stacked face to face (Scheme 1). Thus, the spectral changes observed for the complexation of $1(p\text{-NH}_2)_{Zn}$ (Figure 1b) and $1(m\text{-NH}_2)_{Zn}$[8] with MC are considered to reflect such a stacking association of these guest molecules in the MC cavity, as well as the proton-donation from their peripheral amino groups.

Ultrahigh-vacuum scanning tunneling microscopy (UHV-STM)[12] (Figure 3) demonstrated that the product upon complexation of MC with $1(p\text{-NH}_2)_{Zn}$ is indeed an inclusion complex $[MC\supset1(p\text{-NH}_2)_{Zn}]$. Thus, a dilute aqueous solution
Figure 3. Left: ultrahigh-vacuum scanning tunneling microscopy (UHV-STM) images and right: scanning tunneling spectroscopy (STS) data on Cu(111) surfaces at 80 K. UHV-STM of a) intact MC (imaging conditions: $I=2.0$ pA, $V_s=1.0$ V), b) a 1:3 mixture of MC and $1(p\text{-NH}_2)_{Zn}$ ($I=2.0$ pA, $V_s=3.0$ V), and c) $[MC\supset1(p\text{-NH}_2)_{Zn}]$ ($I=2.0$ pA, $V_s=1.0$ V). STS differential conductance (dI/dV)–sample bias voltage (V_s) correlations of area (1) an intact MC observed in (a), and areas (2) the shell and (3) the core of $[MC\supset1(p\text{-NH}_2)_{Zn}]$ observed in (c).

of a mixture of MC and $1(p\text{-NH}_2)_{Zn}$ (1:3)[10] was sprayed by the pulse injection technique onto a clear flat Cu(111) surface. The UHV-STM image showed the presence of numerous doughnut-like discrete nano-objects with a diameter of 4–5 nm (Figure 3b), which is consistent with the reported dimension of crystallographically defined MC.[7] Some of these nano-objects in the STM image (Figure 3c) appear to have a filled cavity.[13] By means of scanning tunneling spectroscopy (STS)[14] on one of these filled objects, correlations between differential conductance (dI/dV) and sample bias voltage (V_s) were measured separately for the shell and core parts.[8] As shown in Figure 3, these two parts exhibit different dI/dV–V_s profiles. Although the shell part, as with intact MC, displays a gradual increase in dI/dV with either decreasing or increasing V_s, the core part, in contrast, shows two bands at -0.7 and $+1.6$ V, which are assignable to resonant tunneling currents through the HOMO and LUMO of the guest compound.[15] Since the energy gap of 2.3 eV, thus observed, is consistent with the optical HOMO–LUMO energy gap of $1(p\text{-NH}_2)_{Zn}$ (2.1 eV), it is clear that the object with a filled cavity (Figure 3c) is $[MC\supset1(p\text{-NH}_2)_{Zn}]$.

We also conducted an electron paramagnetic resonance (EPR) study on the inclusion complex of MC with copper porphyrin $1(p\text{-NH}_2)_{Cu}$ ($[MC\supset1(p\text{-NH}_2)_{Cu}]$). MC is diamag-

netic at the ground state, while copper porphyrins are paramagnetic ($S = 1/2$) and generally show anisotropic EPR spectra with two distinct $g_\parallel$ and $g_\perp$ values and hyperfine splittings induced by copper ($I = 3/2$) and nitrogen ($I = 1$) nuclei.[16] In contrast, **1**(p-NH$_2$)$_{Cu}$ alone in MeCN at 103 K displayed an isotropic EPR pattern possibly arising from an irregular aggregation caused by hydrogen-bonding interactions at the peripheral amino groups (Figure 4). On the other
Figure 4. EPR spectra at 103 K in MeCN. a) MC (3.0×10^{-5} M), b) **1**(p-NH$_2$)$_{Cu}$ (3.0×10^{-5} M), c) a mixture of **1**(p-NH$_2$)$_{Cu}$ (3.0×10^{-5} M) and MC (1.0×10^{-5} M).[10]

hand, when **1**(p-NH$_2$)$_{Cu}$ was mixed with MC at a 1:3 molar ratio,[10] the resulting inclusion complex [MC⊃**1**(p-NH$_2$)$_{Cu}$] showed in its EPR spectrum an anisotropic pattern with $g_\parallel$ and $g_\perp$ values of 2.187 and 2.085, respectively, along with sharp hyperfine arising from the copper ($a_\parallel = 19.3$ mT) and nitrogen nuclei. Thus, **1**(p-NH$_2$)$_{Cu}$ is freed from its hydrogen-bonded irregular assembly and incorporated into the MC cavity to form a uniform assembly in the confined nanospace.

In conclusion, we have demonstrated the first example of organic functionalization of doughnut-like molybdenum crown cluster (MC). In its nanocavity MC can accommodate metal complexes of aminophenyl-substituted porphyrins, such as **1**(p-NH$_2$)$_M$ (M = Zn, Cu) and **1**(m-NH$_2$)$_{Zn}$ as a result of hydrogen-bonding interactions, to form discrete inorganic/organic nanocomposite materials. The results indicate a new potential for MC as an inorganic host in supramolecular chemistry and also as an building block for nanoscopic materials science.

Experimental Section

MC, **1**(m-NH$_2$)$_{Zn}$, and **1**(o-NH$_2$)$_{Zn}$ were synthesized according to literature methods,[7,17] while 5,10,15,20-*tetrakis*(4-aminophenyl)-21H,23H-porphine **1**(p-NH$_2$)$_H$ and 5,10,15,20-*tetrakis*(3,5-dihydroxy-phenyl)-21H,23H-porphine **3**$_H$ were obtained from commercial sources. Column chromatography was carried out with Wakogel C-400 or alumina (Merck Ltd.). ^{1}H NMR spectra were recorded in CDCl$_3$ on a JEOL model α-500 spectrometer, where chemical shifts (δ in ppm) were determined with respect to tetramethylsilane (TMS) as internal standard. Electronic absorption spectra were recorded on a JASCO model V-570 spectrometer equipped with a temperature

controller. IR spectra were recorded on a JASCO model FT/IR-610 spectrometer. MALDI-TOF mass spectrometry was performed on a Perceptive Biosystems model Voyager-DE spectrometer with 9-nitroanthracene as matrix. ICP-AES was performed on a Seiko Instruments Inc. model SPS4000 inductively coupled plasma atomic emission analyzer. Ultrahigh-vacuum scanning tunneling microscopy (UHV-STM) was performed on a Unisoku Japan model USM-1200.

Metalation of porphyrins: Typically, a saturated MeOH solution of Zn(OAc)$_2$ or Cu(OAc)$_2$ was added to a CHCl$_3$ solution of a free-base porphyrin, and the resulting mixture was heated under reflux for 1–2 h. After the complete metalation was confirmed by thin layer chromatography (TLC) or MALDI-TOF MS, the mixture was poured into water and extracted with CHCl$_3$. The combined organic extract was washed with water and brine, dried over anhydrous Na$_2$SO$_4$, and then evaporated to dryness. Recrystallization of the residue from THF/hexane gave the corresponding metalloporphyrin in an analytically pure form.

2$_{Zn}$: (1,1′-Biphenyl)-4-nitro-4′-carboxaldehyde (786 mg, 3.5 mmol) and pyrrole (232 mg, 3.5 mmol) were heated in refluxing propionic acid (25 mL) for 3 h. A crystalline precipitate, obtained from the reaction mixture on cooling, was isolated by filtration and washed with water and MeOH. The precipitate (70 mg) and anhydrous SnCl$_2$ (250 mg, 1.1 mmol) were dissolved in concentrated aq.HCl/THF (2:1; 15 mL), and the resulting solution was stirred for 24 h at 50°C. Aqueous KOH was added to the mixture until it turned basic, and the mixture was extracted with CH$_2$Cl$_2$ (4×50 mL). The combined organic extract was dried over anhydrous Na$_2$SO$_4$ and evaporated to dryness. The residue was purified by chromatography on silica gel with CHCl$_3$:MeOH (95:5) as eluent, and a reddish purple fraction isolated was stirred with excess Zn(OAc)$_2$ in CHCl$_3$ for 1 h. The reaction mixture was evaporated to dryness under reduced pressure, and the residue was extracted with CHCl$_3$/water. The combined organic extract was dried over anhydrous Na$_2$SO$_4$ and evaporated to dryness. Recrystallization of the residue from THF/hexane gave **2**$_{Zn}$ (5 mg, 4.7 μmol) as purple powdery substance. MALDI-TOF MS m/z 1040, calcd for C$_{68}$H$_{48}$N$_8$Zn 1040; UV/Vis (CHCl$_3$): $\lambda_{max} = 427$, 522, 559, and 600 nm; ^{1}H NMR (500 MHz, [D$_8$]THF, 25°C): $\delta = 4.61$ (s, 8H, NH$_2$), 6.72 (d, $J = 10.0$ Hz, 8H, bipheny), 7.62 (d, $J = 10.0$ Hz, 8H, bipheny), 7.87 (d, $J = 10.0$ Hz, 8H, bipheny), 8.14 (d, $J = 10.0$ Hz, 8H, bipheny), and 8.88 ppm (s, 8H, pyrrole-β).

handling relative to their radioactive counterparts.[1–3] Combinatorial chemistry is now widely used in the medicinal/ pharmaceutical field and in chemical biology for the discovery of novel biologically active molecules or drug candidates,[4,5] yet the application of this method to fluorescence dyes is only in its infancy. A few early examples include oligopyridines,[6] coumarins,[7,8] oligonucleotides,[9] and conjugated polymers.[10] We previously reported the first combinatorial wide-color-range fluorescent styryl library by solution-phase chemistry and their potential application as organelle-specific probes.[11] Here we report the first solid-phase synthesis of a styryl library and its application as amyloid sensors.

Amyloids result when protein misfolding leads to the formation of ordered secondary structures rich in cross-β-sheets, which are present as fibrillar deposits in tissues.[12] The formation of amyloids has been associated with a large number of protein-misfolding diseases including type II diabetes, Alzheimer's, Parkinson's, Huntington's, mad-cow disease, and others.[13,14] Of the many amyloidoses, Alzheimer's disease (AD) is the fourth leading cause of death in the United States and the most common cause of adult-onset dementia.[15,16] The deposition of β-amyloid (Aβ) aggregates in brain tissue is one of the hallmark characteristics of AD, and the histological staining of the deposits is crucial for the diagnosis of AD.[17] Whereas thioflavin T or S (ThT or ThS) and Congo red (CR) are widely used as detection agents for amyloids, neither of these are considered accurate enough for the quantitative estimation of fibril formation.[18–21] Congo red is not fluorescent (thus the sensitivity is low), whereas ThT (or S) is a blue-emission dye, which often interferes with autofluorescence from tissue or other small-molecule components in the assay system. Therefore, sensor dyes that are more sensitive and assay-friendly which can stain biological tissue have been sought.

The styryl scaffold is formed by a condensation reaction of aldehydes and pyridinium salts, which are widely available commercially and easily prepared starting materials. A series of resins and reaction routes were tested, however, the best results, both in yield and purity, were obtained when 2-chlorotrityl resin **1** (BeadTech Inc., Korea) was used as the first linker-protecting group (Scheme 1). Two different aminoalcohols with 2- or 6-carbon-atom chains were loaded onto the 2-chlorotrityl resin, and the alcohol groups were mesylated for subsequent treatment with picoline moities. Four picoline and three quinoline derivatives were chosen as R^1 building blocks to give solid-supported pyridinium salts **5**. 64 aldehyde R^2 building blocks that contain various functionalities and have various lengths and electron-donating or withdrawing properties are outlined in Scheme 2 (page 6333). Condensation of the solid-supported pyridinium salts **5** and the aldehydes was effectively performed under microwave irradiation. The addition of diluted TFA (1%) then led to the facile release of the final styryl dye compounds **7** from the resin (10 min). All of the synthesized compounds were analyzed by LC/MS, and 320 components were selected based on their purity for further study (average purity: 82%; purity data for individual compounds are available in the Supporting Information). Also, the λ_{max} values of the fluorescence excitation and emission bands of the library compounds

Scheme 1. Solid-phase synthesis of the styryl dyes **7**: a) thionyl chloride, CH_2Cl_2, room temperature, 2 h; b) ethanolamine ($n=1$) or 6-amino-1-hexanol ($n=3$), CH_2Cl_2, room temperature, 3 h; c) methanesulfonyl chloride, NEt_3, CH_2Cl_2, room temperature, overnight; d) pyridine derivative (R^1), NMP, 80–90°C, overnight; e) aldehyde (R^2), pyrrolidine, NMP, 80 W microwave, 6 min; f) TFA (1%) in CH_2Cl_2, 10 min. NMP = N-methylpyrrolidone.

proteins such as Aβ peptides, α-synuclein, and transthyretin, and its rate is highly accelerated under stressful conditions such as elevated temperature or low pH.[23,24] 13 compounds from the 320 compounds in the library were selected based on the observed increases in their fluorescence intensities upon addition of insulin amyloid fibril (relative to the dye or fresh insulin alone; see Figure 1), and their spectroscopic properties are summarized in Table 1. Promisingly, some of the compounds, such as 2C32 and 2C9, displayed dramatic increases in fluorescence intensity (663- and 736-fold) that were much better than the known standard dye ThS (42-fold). The fluorescence of many of the compounds demonstrated a red shift after binding with insulin amyloid fibril (Figure 1) which is a favorable property for the reduction of background signals and also for ratiometric measurements. The longer emission wavelengths of 2C32 and 2C9 may also allow for the screening of blue-green fluorescent inhibitors of amyloid formation, which was not possible with ThS or ThT.

were recorded with a Gemini XS fluorescent plate reader (data available in Supporting Information). The compounds in the library cover practically the whole color range from blue to red. These 320 compounds were tested for amyloid sensing without further purification.

Primary screening of amyloid sensing was carried out with insulin amyloid fibrils generated from fresh insulin which were induced to aggregate at low pH conditions to form a cross-β-sheet secondary structure.[22] (A representative atomic force microscope (AFM) picture of the insulin amyloid fibrils used in this work is provided in the Supporting Information). The formation of insulin amyloids, a characteristic of injection-localized amyloidosis, occurs through kinetic mechanisms that are similar to those for other amyloidogenic

We further tested the 13 selected compounds in synthetic Aβ40 and Aβ42 aggregates. The two Aβ variants, Aβ40 and Aβ42, which differ by truncation at the carboxyl terminus, are the predominant plaque proteins in AD.[25] All of the dyes showed comparable increases in their fluorescence emissions. Interestingly, all of the styryl compounds showed higher sensitivities to fibril Aβ40 than to fibril Aβ42 (Aβ40:Aβ42 = 0.8–3.5), in contrast to ThS (Aβ40:Aβ42 = 0.4). Furthermore, the 13 candidates and ThS were tested for the in vitro staining of fixed AD mouse-brain sections. Images of the amyloid stained with the two most-effective compounds, 2C40 and 2E10, are shown in Figures 2 and 3. As 2C40 displays red
Figure 1. Color changes of the 13 "hit" compounds observed under irradiation with a Blak–Ray 365-nm UV lamp. Each set of 3 samples contains the dye (200 μM) alone in HCl (0.5 mL, pH 1.4; left), with fresh insulin (1 mg mL^{-1}, 0.5 mL, pH 1.4; center), and with insulin amyloid fibrils (1 mg mL^{-1}, 0.5 mL, pH 1.4; right). The dyes are numbered according to the length of the linker (2 or 6), the letter corresponding to R^1 (A–G), and the number corresponding to R^2 (1–64; see Scheme 2).
Scheme 2. Components (linkers, pyridine derivatives R^1, and aldehydes R^2) for the parallel syntheses of the styryl dyes. Bn = benzyl.

fluorescence and 2E10 displays green fluorescence, these compounds may be good complementary-color dye substitutes for ThS (blue). We observed that our new dyes are at least as sensitive as ThS in terms of labeling aggregates and showed 100% colocalization with ThS-labeling in 50 plaques assayed (two brain-slices each). Interestingly, compared to

ThS, which stains the peripheral area of the plaque, our compounds mainly stained the core of the amyloid plaque.

In summary, we have reported the first solid-phase parallel synthesis of a styryl dye library that comprises 320 dye compounds. Through in vitro amyloid screening, 13 new amyloid sensors were identified of which two show outstand-

Improving Quantum Efficiencies of Siloles and Silole-Derived Butadiene Chromophores through Structural Tuning**

Andrew J. Boydston and Brian L. Pagenkopf

Over the last decade, Tamao's *endo-endo* cycloreduction of bis(phenylethynyl)silanes has emerged as a powerful tool for generating 2,5-dilithiosiloles that can be trapped by various electrophiles in situ.[1] The strategy has been used for the construction of various silole-containing monomeric, oligo-meric, and polymeric systems,[2] but a significant structural limitation for cycloreduction is the requirement for arene rings at the alkyne termini. Unfortunately, 3,4-diarylsiloles are virtually non-emissive in solution, exhibiting low quantum efficiencies from 0.1–11 %.[3,4] Their poor lumines-cence has been ascribed directly to effects arising from 3,4-substitution, given that the corresponding unsub-stituted systems consistently show greater emission intensities.[5] The lackluster luminescence of 3,4-diary-lsilole chromophores condemns them to a dark future, which is unfortunate given the ease with which they can be prepared by cycloreduction methods.

We recently observed from silole **1a** a curiously high quantum efficiency of 9 %,[6] and in our studies of conjugated silole oligomers[7] we observed a 20 % quantum efficiency from the silole-capped extended chromophore **2**. The emission intensities of **1a** and **2** suggested that silole luminescence attenuation classically ascribed to the 3,4-diphenyl rings can be circumvented by

manipulation of the C2, C5, and Si substituents. Increased chromophore rigidity often leads to improved luminescence by dually facilitating electron delocalization and minimizing vibrational–rotational events in the excited state.[8] With consideration of the silole nucleus, it seemed likely that increasing steric bulk about silicon and the 2,5-substituents would increase the energy barriers for non-emissive decay processes and ultimately result in increased photolumines-cence. Thus, we explored synthetically practical silole mod-ifications intended to impart "rigidity" to analogues of the parent chromophore **1a**. Herein, we report the structural optimization of a series of siloles ultimately resulting in the first highly luminescent 3,4-diphenylsilole chromophores.

The dimethylsilolene chromophores (**4a** and **5a**) were prepared by Negishi cross-coupling reactions with dibromide **3**[6] (Scheme 1). These new siloles were crystalline solids that were purified by recrystallization from the crude reaction mixtures.
Scheme 1. Synthesis of 1,1-dimethylsilole fluorophores.

For the synthesis of di-*tert*-butylsilolene systems (Scheme 2) we found that isolation of dibromide intermediate **7** was not necessary and good yields were obtained by carrying out the entire reaction sequence from silane **6** through to siloles **1b**, **4b**, or **5b**. As with **4a** and **5a**, this simple process provided the desired siloles as crystalline solids that could be purified by recrystallization from the crude product mixtures.

Chlorosilole **10** was prepared via known intermediate **9**[6] in 72 % overall yield from silane **8** (Scheme 3). Cross-coupling with phenylacetylene provided asymmetric "mixed" silole **11a** in 86 % isolated yield after recrystal-lization. Similarly, bromosilole **12** was used en route to "mixed" silole **11b**.

We found that treatment of the 1,1-dimethylsiloles with Bu₄NF in THF accomplished stereospecific[9] desilylation in nearly quantitative yield after only a few minutes at room temperature (Scheme 4). As can be seen from X-ray crystal structures (Figure 1), the backbone of the chromophore achieves a nearly completely planar orientation upon removal of the silolene moiety and, as expected, the butadiene moiety adopts an *s-trans* conformation. The efficiency and simplicity of this desilylation method provided **1c**, **4c**, and **5c** essentially gratis.[10]

All of the new silole chromophores absorb in the visible region (Table 1) and have moderate molar absorptivities. In comparison with **1a**, siloles bearing larger arenes (**11a**, **4a**, and **5a**) display sequential bathochromic shifts in absorption maxima consistent with having greater electron density.

Scheme 4. Protiodesilylation for synthesis of butadiene chromophores.
Figure 1. X-ray structures of siloles **1c** (left), **4c** (middle), and **5c** (right).

Increasing steric bulk about silicon alone causes a small hypsochromic shift in the absorption maxima (**1a** vs. **1b**, **4a** vs. **4b**, **5a** vs. **5b**, **11a** vs. **11b**). Relative to the least hindered silole **1a**, a hypochromic shift (decrease in absorption intensity) is observed for each of the bulkier systems suggesting a decrease in planarity. In all cases, desilylation causes nearly equivalent hypsochromic shifts (that is, blue shifts) in absorption maxima (**1a**→**1c** $\Delta\lambda_{max} = -66$ nm; **4a**→

4c $\Delta\lambda_{max} = -64$ nm, **5a**→**5c** $\Delta\lambda_{max} = -66$ nm, Table 1) as a result of the loss of butadiene tethering and electronic interactions with the silicon atom. Increasing the size of the alkyl groups on the terminal arenes (i.e. **4c** and **5c** vs. **1c**) also causes longer wavelength absorption maxima and decreased molar absorptivity for the butadienes. Notably, blue emission was obtained from both **4c** and **5c**, which emit with 20% and 25% efficiency, respectively.

These structural modifications resulted in significant stepwise increases in quantum efficiencies (Φ_f) with minimal impact on emission wavelengths (Figure 2, Table 1). Compared with the parent silole **1a** ($\Phi_f = 9$%), emission intensities improved when larger terminal arenes were employed. Replacing a single phenyl group on **1a** ($\Phi_f = 9$%) with a mesityl (**11a**, $\Phi_f = 10$) had a marginal effect, but exchanging both phenyl groups for mesityl groups results in a marked increase in luminescence (**4a**, $\Phi_f = 30$%). Replacing the mesityl groups with triisopropylphenyl groups gave only slight enhancement (**5a**, $\Phi_f = 41$%). Substituting the dimethylsilolene for a di-*tert*-butylsilolene has a greater influence on Φ_f than changes to the terminal arene units. For the parent silole **1a** ($\Phi_f = 9$%), the exchange brought Φ_f to 25% (**1b**). Incorporation of a single mesityl group again lead to only a modest improvement (**11b**, $\Phi_f = 32$%), but when two mesityl groups were used in combination with the di-*tert*-butylsilolene (**4b**) a quantum efficiency of 63% was observed. No further increase was observed, however, with silole **5b** ($\Phi_f = 56$%). To our knowledge, these quantum efficiencies are the highest ever reported for 3,4-diphenylsilole chromophores in solution.

Table 1: Electronic absorption and emission data in solution.

Photoluminescence spectra in CH$_2$Cl$_2$ at room temperature. **4b** (——), **5b** (——), **5a** (——), **11b** (——), **4a** (——), **1b** (——), **11a** (——), **1a** (——), **5c** (——), **4c** (——), **1c** (——). Inset: normalized emission spectra of thin films of **4b** (dashed line) and **5b** (solid line).

Although the solution photoluminescence (PL) efficiency is a good first measure of performance and is paramount in areas such as nitroaromatic detection,[11] the solid-state behavior will more likely dictate the feasibility of deploying these compounds in electronic devices. In this regard, thin-films of **4b** and **5b** were prepared by spin-coating,[12] and their PL spectra examined (Figure 2, inset). Intense green light emission was observed from the thin film of each fluorophore and the emission spectra revealed slight bathochromic shifts in the solid state relative to the solution PL spectra.

In conclusion, simple structural modifications have provided new luminescent silole chromophores with the highest quantum efficiencies for fully substituted monomeric siloles in solution. Importantly, these discoveries welcome siloles prepared by practical cycloreduction methods into the fold of useful fluorophores. The PL intensity was selectively modified without impact on the emission wavelength. This work establishes structure–property relationships that refute the notion that 3,4-disubstituted siloles possess intrinsically low quantum efficiencies, and illustrates enhanced performance through substituent tuning at C2, C5, and Si.

A Reductive-Aggregation Route to [Mn$_{12}$O$_{12}$(OMe)$_2$(O$_2$CPh)$_{16}$(H$_2$O)$_2$]$^{2-}$ Single-Molecule Magnets Related to the [Mn$_{12}$] Family**

Anastasios J. Tasiopoulos, Wolfgang Wernsdorfer, Khalil A. Abboud, and George Christou*

An exciting development in nanoscale magnetic materials occurred in 1993 when [Mn$_{12}$O$_{12}$(O$_2$CMe)$_{16}$(H$_2$O)$_4$] (**1**) was identified as a nanoscale magnet,[1] the first to comprise discrete, (magnetically) non-interacting molecular units rather than a 3D extended lattice (as in metals and metal oxides, for example). This discovery initiated the field of

molecular nanomagnetism and such molecules have since been termed single-molecule magnets (SMMs).[2] They derive their properties from the combination of a large spin (S) and an Ising (easy-axis) magnetoanisotropy (negative zero-field splitting parameter, D). Although several classes of SMMs are now known,[1–10] there is still a need for new examples to improve our understanding of this phenomenon. Efforts along these lines have been concentrated in two directions: 1) development of synthetic routes to new high nuclearity metal complexes,[4,5] and 2) modifications of known SMMs in a controlled fashion.[6–10] The best and most thoroughly studied SMMs to date are members of the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ ([Mn_{12}]) family. A number of [Mn_{12}] derivatives have been prepared in their neutral,[1,6–8] one-electron[6f,9] or two-electron[10] reduced versions with a variety of carboxylate,[6,9,10] mixed carboxylate,[7] and mixed carboxylate/non-carboxylate[8] ligands. In all such modifications, the $[Mn_{12}(\mu_3\text{-O})_{12}]$ core remains essentially the same.

Herein, we report three new developments: 1) a new synthetic procedure in manganese cluster chemistry involving reductive aggregation of permanganate ($[MnO_4]^-$) ions in MeOH/benzoic acid solution; 2) its employment to synthesize NnBu$_4^+$ salts of the new $[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2]^{2-}$ cluster ion, which is a structural derivative of the well studied [Mn_{12}] complexes; and 3) the establishment that this anion is a new SMM.

The synthesis of normal [Mn_{12}] compound **1** consists of the comproportionation reaction between $Mn(O_2CMe)_2\cdot4H_2O$ and KMnO$_4$ in 60% aqueous acetic acid.[11] In contrast, the new synthetic procedure herein is part of a wider investigation of the reduction of $[MnO_4]^-$ in alcohol/carboxylic acid mixtures. The present results were obtained from a MeOH/PhCO$_2$H medium. Thus, addition of $(NnBu_4)MnO_4$ to a methanolic solution of benzoic acid results in the formation of a dark brown solution from which subsequently were obtained essentially black crystals. Recrystallization from CH$_2$Cl$_2$/hexanes results in the formation of two types of black crystals in a total, overall yield of 15%.

Both types of crystals, diamond-like **2a** and needle-like **2b**, were crystallographically characterized. Both contain the same dianion, abbreviated $[Mn'_{12}]^{2-}$.

$(NnBu_4)_2[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2] \cdot 2H_2O \cdot 4CH_2Cl_2$ **2a**

$(NnBu_4)_2[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2] \cdot 2H_2O \cdot CH_2Cl_2$ **2b**

Complex **2a**[12] crystallizes in the orthorhombic space group *Pbca* with its asymmetric unit containing half the $[Mn'_{12}]^{2-}$ cluster and one $[NnBu_4]^+$ ion, as well as one H$_2$O and two disordered CH$_2$Cl$_2$ solvent molecules. The $[Mn'_{12}]^{2-}$ ion of **2a** (Figure 1) contains a central $[Mn^{IV}_4(\mu_3\text{-O})_2(\mu\text{-O})_2(\mu\text{-OMe})_2]^{6+}$ unit surrounded by a nonplanar ring of eight Mn^{III} atoms that are connected to the central Mn$_4$ unit by eight bridging μ_3-O^{2-} ions. The metal oxidation states and their trapped-valence nature were determined by inspection of the Mn–O bond lengths, manganese bond valence sum calculations,[13] and the presence of Mn^{III} Jahn–Teller elongation axes for the manganese atoms in the outer ring. The outer Mn$_8$ ring is very similar to that in normal [Mn_{12}] compound **1**, but **1** has
Figure 1. ORTEP plot (thermal ellipsoids set at 50% probability) of the anion of **2a**. For clarity, the benzoate rings have been omitted, except for the *ipso*-carbon atom of each ring; Mn blue, O red, C gray.

a central $[Mn_4(\mu_3\text{-O})_4]^{8+}$ cubane. The central $[Mn^{IV}_4\text{-}O_4(OMe)_2]^{6+}$ unit of **2a** comprises a planar Mn$_4$ rhombus with two μ_3-O^{2-} ions (O16, O16′), one above and one below the Mn$_4$ plane, and a μ-O^{2-} (O18, O18′) or μ-MeO$^-$ (O24, O24′) ion bridging each edge of the rhombus. The central unit can thus be described either as a face-sharing dicubane unit with two missing vertices, or as two edge-sharing, oxide-capped Mn$_3$ triangular units; tetranuclear complexes possessing a core very similar to this central unit have been observed with manganese,[5a,b] as well as with other transition metals.[14] Peripheral ligation is completed by 16 bridging benzoate groups and two terminal water molecules. All the manganese atoms are six-coordinate with near octahedral coordination geometries.

Complex **2b** crystallizes in the triclinic space group $P\bar{1}$,[12a] and its asymmetric unit consists of a half cluster and two halves of $[NnBu_4]^+$ ions disordered around inversion centers, as well as one disordered H$_2$O molecule and half a CH$_2$Cl$_2$. The structure of the anion of **2b** is essentially identical to that of **2a**, except for some disorder in the peripheral benzoate rings.

For both **2a** and **2b**, there are Jahn–Teller (JT) distortions at the Mn^{III} ions in the outer ring, consistent with high-spin Mn^{III} centers with near-octahedral coordination geometry. The JT distortion takes the form of an axial elongation, with the elongation axes axial to the Mn$_{12}$ disk-like core and thus roughly parallel to each other. Axially elongated Mn–O bonds are typically at least 0.1–0.2 Å longer than the others. However, there is one anomaly: for **2a** (Figure 1), the JT elongated bonds at Mn4 (Mn4–O9 2.074(4), Mn4–O14 2.080(5) Å) are not as long as those found at the other Mn^{III} ions (2.112(5)–2.250(5) Å), and the *trans* bonds Mn4–O7 (1.958(4) Å) and Mn4–O12 (2.060(5) Å) are longer than expected, especially Mn4–O7, which is unusually long for an

Mn-O^{2-} bond (compare Mn−O^{2-} bonds at the other Mn^{III} ions of 1.876(4)–1.905(4) Å). A similar anomalous situation is present at Mn1 of **2b**. This structural feature at manganese atoms Mn4 of **2a** and Mn1 of **2b** is crucial to understanding the magnetic data (see below).

The anions of complexes **2a** and **2b** are remarkably similar to normal [Mn$_{12}$] clusters, such as **1**, with the main difference being the structure of the central cores (Figure 2).
Figure 2. Comparison of the cores of normal [Mn$_{12}$] complex **1** (top) and the anion of **2a** (bottom); Mn^{4+} cyan, Mn^{3+} blue, O red, C gray.

The core of the anions of **2a** and **2b** could be considered the result of partial methanolysis of the central [Mn$_4$O$_4$]$^{8+}$ cubane of **1**, leading to incorporation of two MeO$^-$ bridges and a change in the core structure (although we do not claim that this corresponds to its means of formation in the reaction mixture). Note that complexes **1** and **2** are the smallest nuclearity members of a larger family of [Mn$^{III}_x$,Mn$^{IV}_y$] clusters in which there is an outer Mn$^{III}_x$ ring around a central Mn$^{IV}_y$ core. This family currently comprises normal [Mn$_{12}$] complexes (such as **1**) and **2a/2b** ($x = 8$, $y = 4$), the Mn$_{16}$ cluster [Mn$_{16}$O$_{16}$(OMe)$_6$(O$_2$CMe)$_{16}$(MeOH)$_3$(H$_2$O)$_3$] ($x = 10$, $y = 6$),[4c, 15] and the Mn$_{21}$ cluster [Mn$_{21}$O$_{24}$(OMe)$_8$(O$_2$CCH$_2$-tBu)$_{16}$(H$_2$O)$_{10}$] ($x = 12$, $y = 9$).[16]

The structural similarity between complexes **1** and **2** suggested that **2** might also be an SMM. Thus AC magnetic susceptibility measurements were performed on a polycrystalline sample of **2** (containing both **2a** and **2b**) in the temperature range 1.8–10 K using a 3.5 G AC field oscillating at 5–500 Hz frequencies (ν). These studies revealed two frequency-dependent out-of-phase (χ_m'') AC signals (Figure 3), one in the higher temperature (HT) range of 3–5 K, and a second one at lower temperatures (LT) whose
Figure 3. Plot of χ_m'' versus T for a microcrystalline sample of **2** suspended in solid eicosane at 500 (○), 250 (●), 50 (□), 25 (■), 10 (△), 5 Hz (▲). Inset: Plot of the natural logarithm of relaxation rate, ln(1/τ) versus inverse temperature using the χ_m'' versus T data for the slower relaxing species (higher temperature data). The solid line is a fit to the Arrhenius equation; see the text for the fitting parameters.

peaks clearly occur at temperatures below the operating limit of our SQUID (superconducting quantum interference device) instrument (1.8 K). The LT and HT χ_m'' signals correspond to faster and slower relaxation rates, respectively. The peak of a χ_m'' versus T plot represents the temperature at which the magnetization relaxation rate equals the angular frequency $\omega(= 2\pi\nu)$, and the χ_m'' versus T data at different frequencies (ν) were therefore used as a source of kinetic data to construct an Arrhenius plot (Figure 3, inset) based on the Arrhenius equation in Equation (1), where $1/\tau$ is the relax-

$$1/\tau = 1/\tau_0 \, \exp(-U_{\text{eff}}/kT) \tag{1}$$

ation rate (τ is the relaxation time), $1/\tau_0$ is the pre-exponential factor, U_{eff} is the effective relaxation barrier, and k is the Boltzmann constant. The fit of the data to Equation (1) gave $U_{\text{eff}} = 50.1$ K and $1/\tau_0 = 3.61 \times 10^8$ s^{-1}. This U_{eff} value is smaller than that of normal [Mn$_{12}$] complexes; complex **1**, for example, has a U_{eff} of 60–65 K.

The observation of out-of-phase AC signals suggests that **2** might be an SMM, although such signals by themselves are not proof of an SMM. It is also tempting to assume that the two χ_m'' signals in Figure 3 are due to the two crystal forms, diamondlike **2a** and needlelike **2b**. To confirm whether **2a** and/or **2b** are indeed SMMs, and to assess any difference between the two forms, magnetization versus DC field sweep studies were performed on single crystals of **2a** and **2b** by using a micro-SQUID apparatus.[17] The resulting hysteresis loops are shown in Figure 4, and their coercivities 1) increase with decreasing T at a constant field sweep rate, and 2) increase with increasing sweep rate at a constant T (not shown). This situation is as expected for the superparamagnet-like properties of an SMM.

However, it is clear that the observed properties (hysteresis loops) of **2a** and **2b** are very similar, and this is totally
Figure 4. Magnetization (*M*) versus applied magnetic field ($\mu_0 H$) hysteresis loops for a single crystal (wet with mother liquor) of **2a** (top) and **2b** (bottom) at the indicated temperatures. *M* is normalized to its saturation value, M_s.

inconsistent with the two very different AC signals in Figure 3 and the at-first-glance "obvious" conclusion that the two signals are due to the two crystal forms. In fact, the hysteresis loops of both **2a** and **2b** suggest a mixture of faster relaxing (LT) and slower relaxing (HT) forms, the faster relaxing being responsible for the large decrease in magnetization at zero field, and the slower relaxing being responsible for the subsequent feature at higher fields. The relative proportions of these two features suggest comparable amounts of the LT and HT forms in each crystal, with perhaps a slightly greater amount of the LT, and this situation is again consistent with the relative proportion of LT and HT AC signals shown in Figure 3. Note that the hysteresis studies were performed on wet single-crystals and the AC studies on microcrystals suspended in solid eicosane, and thus not strictly speaking on the same material. Nevertheless, we conclude that 1) complex **2** is a new SMM, 2) the different space groups of diamond-like **2a** and needle-like **2b** lead to only small differences in the magnetic properties of the [Mn₁₂O₁₂(O-Me)₂(O₂CPh)₁₆(H₂O)₂]²⁻ ion, and 3) there are faster and slower relaxing forms of complex **2** that cocrystallize in the same crystal. In fact, the existence of cocrystallized faster and slower relaxing forms of **1** has long been known, with crystals of **1** containing about 5% of the faster relaxing form;[6f] in this respect complex **2** only differs from **1** in the relative amounts of the two forms.

For normal [Mn₁₂] complexes, we have reported elsewhere that crystals of pure faster relaxing forms can be prepared with, for example, *tert*-butylacetate as the carboxylate group.[6d,g] Crystallography on such crystals has allowed the origin of the faster relaxing form to be identified as the

abnormal orientation of one of the Mn^III JT elongation axes, being disposed equatorial rather than axial to the Mn₁₂ disk-like plane, and thus this JT axis points towards a core O²⁻ ion. We have named this "Jahn–Teller isomerism". The same effect is likely to be the origin of the two forms of **2**. Indeed, this phenomenon rationalizes the unusual Mn–O bond lengths at Mn4 for **2a** and Mn1 for **2b**. For **2a**, for example, an approximately equal mixture of a) slower relaxing species with the JT axis at Mn4 in the normal position along the O9-Mn4-O14 axis, and b) faster relaxing species with the JT axis at Mn4 abnormally aligned along the O7-Mn4-O12 axis, will lead to the crystallographic average result that the O9-Mn4-O14 bonds are shorter and the O7-Mn4-O12 bonds are longer than they should be, which is what is seen (similarly for **2b**). We thus feel that the crystallographic data support the conclusion from the magnetic studies that crystals of **2a** and **2b** comprise a mixture of slower and faster relaxing species which result from normal and abnormal orientations, respectively, of a Mn^III JT elongation axis. As with normal [Mn₁₂] complexes, it will require crystallization of pure crystals of the different forms of **2** to allow more detailed study.

In summary, we have developed access to a variant of the [Mn₁₂] family of SMMs by using a reductive-aggregation route. This structurally very similar variant is also an SMM and, like normal [Mn₁₂] complexes, displays both faster and slower relaxing magnetization dynamics that we assign to the presence of Jahn–Teller isomerism. We have in the past obtained many derivatives of [Mn₁₂] complexes, for example, by carboxylate substitution,[6,7] one- and two-electron reduction,[6f,9,10] introduction of non-carboxylate ligands,[8] and similar derivatization of **2** may also prove possible, in which case it is merely the prototype of what could become a large new family of related SMMs.

The control of the relative molecular orientation of redox-active molecules is of great importance for constructing organic conductors and superconductors.[1] Ingenious manipulation of noncovalent interactions such as hydrogen bonding (H-bonding) is an efficient tool for creation of desired molecular arrangements.[2] Thus, a variety of tetrathiafulvalene (TTF) derivatives with H-bonding functionality have been synthesized.[3] However, most of these gave insulating or semiconducting charge-transfer (CT) complexes and salts,[3] while CT salts of ethylenedithio-TTF-CONHMe with inorganic anions solely exhibited metallic behavior.[3c,d] The imidazole ring system has been utilized as an interesting building block for H-bonded CT complexes[4] and assembled metal complexes.[5] Recently, we have designed TTF derivatives substituted with an imidazole moiety, TTF-Im, for exploring molecular conductors with highly ordered molecular aggregation by H-bonding.[6] We report here the first purely organic molecular metal based on the H-bonded CT complex composed of TTF-Im and *p*-chloranil (CHL), in

which the component ratio and electron-accepting ability of CHL are controlled by H-bonding.[7]
In CV measurements, TTF-Im shows the first oxidation potential at −0.06 V vs Fc/Fc⁺, which is close to that of TTF (−0.09 V).[6] Single crystals of TTF-Im were obtained by the vapor diffusion method with hexane/THF.[8] In the crystal structure of TTF-Im, the imidazole moiety is twisted by 15.5(1)° from the TTF skeleton. The imidazole ring forms a one-dimensional chain by N−H···N H-bonding interaction (3.06 Å) along the *a* axis in a zigzag fashion similar to that of imidazole[9] (Figure 1). The TTF-Im molecule uniformly
Figure 1. Stereoview of the crystal packing of TTF-Im, showing N−H···N H-bonding (red), π-stacking columns, and S···S contacts (green) between columns.

stacks and forms a columnar structure parallel to the *c* axis with a face-to-face distance of 3.66 Å. The column is connected by H-bonding and intercolumnar S···S contacts (3.48 and 3.57 Å) along the *a* axis (Figure 1) to give a three-dimensional network.

The CT complex (TTF-Im)₂(CHL) was obtained as black needlelike crystals by diffusion of a solution of TTF-Im and CHL in acetonitrile containing 2 vol% ethanol in an H-shaped tube.[7,10,11] The C=O stretching frequency of 1532 cm⁻¹ in the IR spectrum indicates that the CHL molecule exists as a radical anion.[12] Thus, the ionicity of TTF-Im is estimated to be +0.5.[13] Crystal structure analysis shows that the molecular structure of TTF-Im is nearly planar, with a small dihedral angle of 5.5(1)° between the TTF and imidazole moieties, and the CHL molecule lies on the inversion center (Figure 2). The CHL forms a bifurcated triad with two TTF-Im molecules through double N−H···O H-bonding interactions. Because these H-bonds increase the electron-accepting ability of the CHL molecule, the CHL in the complex is a completely one-electron reduced.[14] Each component molecule forms a uniform stacking column along the *a* axis with interplanar distances of 3.46 Å for TTF-Im and 3.19 Å for CHL. Furthermore, side-by-side S···S contacts

Figure 2. Stereoview of the crystal packing of (TTF-Im)$_2$(CHL). The dashed lines show the intermolecular interactions: N—H···O H-bonding (red) and S···S contacts (green).

between TTF columns (3.51–3.57 Å) along the *b* axis form a two-dimensional donor layer parallel to the *ab* plane. Together with the double H-bonding of CHL, this results in a three-dimensional network of intermolecular interactions in the crystal.

Intermolecular overlap integrals of the HOMO of the donor molecules in the CT complex, calculated by the extended Hückel method, are summarized in Figure 3 a.[15]
Figure 3. a) Packing pattern of the donor molecules; letters indicate intermolecular overlap integrals (s1 = −20.77, t2 = 0.94, t3 = −5.44, t4 = 10.73, t5 = −0.62). b) Energy dispersion, c) density of states, and d) Fermi surface of (TTF-Im)$_2$(CHL), calculated by the extended Hückel method with tight-binding approximation.

Although the strongest overlap integral (s1) was observed along the stacking direction, interactions on the same order of magnitude (t3, t4) were also calculated in the side-by-side directions. The tight-binding approximation gave the energy dispersion, density of states, and Fermi surfaces shown in Figure 3b–d. As shown in Figure 3b, the dispersion affords two bands having a gap of 0.05 eV, the upper one of which is half-filled. The main parts of the Fermi surfaces in Figure 3d exhibit a strongly warped one-dimensional feature. Along with these open surfaces, a hole pocket around point X was derived.

The static paramagnetic susceptibility χ_p of the polycrystalline sample showed nearly temperature-independent behavior in the range of 170–350 K, and its value of $+5.7 \times 10^{-4}$ emu mol^{-1} per (TTF-Im)$_2$(CHL) unit is consistent with Pauli paramagnetism (Figure 4). The χ_p value slightly decreased below 170 K, and after passing through a minimum at 90 K, a strongly temperature-dependent component appeared to increase the total χ_p in the lower temperature region (Figure 4). The magnetic field dependence of the magnetization at 1.9 K revealed that the temperature-dependent part of
Figure 4. Temperature dependence of magnetic susceptibility after correction of Pascal diamagnetism for a polycrystalline sample of (TTF-Im)$_2$(CHL). The inset shows a magnification of the plot.

χ_p is attributed to 1.1 % of nearly isolated $S = 1/2$ spins.[16] No such temperature-dependent contribution was observed above 170 K, and this suggests that the generation of such a component may be associated with the subtle anomaly around 90–170 K.

The ESR spectra of the polycrystalline sample at 296 K showed a single Lorentzian absorption with $g = 2.0068$ (Figure 5). The ESR linewidth ΔB[17] steadily decreased on lowering the temperature (inset to Figure 5) and finally became sharp enough to resolve g anisotropy as $(g_{xx}, g_{yy}, g_{zz}) =$
Figure 5. Temperature dependence of ESR spectra for a polycrystalline sample of (TTF-Im)$_2$(CHL). The inset shows the temperature dependence of ESR linewidth ΔB.[17]

(2.0101, 2.0075, 2.0028), which are characteristic values of TTF$^{\cdot+}$ derivatives. The ESR signal intensity exhibits nearly identical behavior to χ_p at all temperatures. The above results show that the TTF-Im column acts a pathway for electrical conduction. In contrast, no ESR absorption originating from uniformly stacked CHL$^{\cdot-}$ molecules was observed, probably because the short interplane distance of CHL$^{\cdot-}$ (3.19 Å) and the large orbital overlaps induce a strong antiferromagnetic interaction that quenches paramagnetism. Density functional theory calculations gave support to this conjecture. For a pair of CHL$^{\cdot-}$ molecules in the uniform column taken from the X-ray structure, the exchange coupling was calculated to be $2J/k_B = -2677$ K,[18] which results in negligible paramagnetic contribution below 350 K as long as a one-dimensional magnetic chain is considered (Bonner–Fisher model[19]).

The temperature dependence of electrical conductivity for the single crystal along the π-stacking direction confirms metallic behavior down to about 180 K, below which the resistivity increases gradually (activation energy 20 meV; Figure 6). The room-temperature electrical conductivity of
Figure 6. Temperature dependence of electrical resistivity of (TTF-Im)$_2$(CHL) measured by the four-probe method along the long axis (a axis) of a needlelike crystal.

this complex of $\sigma_{rt} = 124$ S cm^{-1} is comparable to those of CT salts of ethylenedithio-TTF-CONHMe[3c,d] and TTF-TCNQ complexes,[20] and 10^4–10^7 orders of magnitude higher than those of CT complexes with organic electron acceptors based on H-bonded TTF derivatives.[3] Clarification of the subtle anomaly in magnetic and electric properties at 90–180 K is the subject of further study.

In conclusion, we have prepared the first purely organic molecular metal based on an H-bonded CT complex. The absence of an abrupt change like the Peierls transition shows that the H-bonding interaction plays a vital role in transport properties by increasing dimensionality. Furthermore, we emphasize the ability of H-bonding interactions to control the electron-accepting ability of CHL and the donor/acceptor ratio by the formation of H-bonded triad of TTF-Im and CHL. We believe that these salient features of H-bonding interactions in purely organic CT complexes demonstrate a new concept for the molecular design of organic conductors.[21]

Photoswitchable Organic Nanoparticles and a Polymer Film Employing Multifunctional Molecules with Enhanced Fluorescence Emission and Bistable Photochromism**

Seon-Jeong Lim, Byeong-Kwan An, Sang Don Jung, Myung-Ae Chung, and Soo Young Park*

Among the various photon-mode molecular memory systems, bistable photoswitching of fluorescence emission is considered to be a promising signaling mode, not only because the fluorescence signals can be readily and sensitively recognized, but also because the small number of photons required for their excitation induce few side effects to spoil the digitalized signals.[1–9] Multifunctional fluorescent (including phosphorescent) molecules combining bistable photochromism with built-in 1,2-bisthienylethene (BTE) units have been successfully investigated with the aim of applications in ultrahigh-density optical memory media, and they show, in principle, reversible and bistable photoswitching.[10–15] The important challenge still remaining unsolved, however, is the general problem of "concentration quenching" in the fluorescence signal, which certainly restricts the application of these multifunctional photochromic molecules to high-density optical memory systems.[16] Herein, we demonstrate an innovative approach to this problem by employing a special class of multifunctional photochromic molecule which shows enhanced fluorescence emission with increasing concentration. It is readily expected that the high storage capability, high sensitivity, and high-contrast on/off signaling ratio are synergetically achieved with this molecule in neat nanoparticles or in a highly loaded polymer film.

Very recently, unconventional fluorescent molecules showing aggregation-induced enhanced emission (AIEE) have been reported by several groups including ours.[17–19] Simple-structured 1-cyano-*trans*-1,2-bis-(4′-methylbiphenyl)-ethylene (CN-MBE) is a typical AIEE molecule that fluoresces strongly in the solid state even though it is virtually nonfluorescent in solution.[19] The multifunctional fluorescent molecule for photoswitchable memory media **1a** was designed and synthesized by replacing one of the end tolyl groups of CN-MBE with the photochromic BTE moiety. Compound **2a**, the non-AIEE analogue of **1a** which lacks

only the CN group, was also synthesized to properly compare the AIEE effect (see Figure 1 for the chemical structures and the Supporting Information for the synthetic details). Compounds **1a** and **2a** were fully identified by ^{1}H NMR spectroscopy, FTIR spectroscopy, MALDI-TOF mass spectrometry, and elemental analysis (analytical data are available in the Supporting Information).

Fluorescent photochromic organic nanoparticles (FPONs) of **1a** were prepared by a reprecipitation method to produce a highly concentrated photon-mode recording medium.[20] Quite uniform and size-tuned nanoparticles of **1a** (see the scanning electron microscopy (SEM) photograph in Figure 1e) were obtained; the diameters of FPONs of **1a** were 40 ± 10, 125 ± 25, 200 ± 50, and 275 ± 75 nm when prepared from THF/water concentrations of 2×10^{-5}, 4×10^{-5}, 1×10^{-4}, and 2×10^{-4} M, respectively (other images are available in the Supporting Information). According to the AIEE principle, FPONs of **1a** showed strongly enhanced fluorescence emission, although they were only weakly fluorescent in a THF solution of the same concentration (ca. 1700 times enhancement, compare (II) with (I) in Fig-

ure 1a). This observation contrasts strikingly with the behavior of conventional analogue **2a**, which shows significant concentration quenching in the nanoparticle (ca. 30 times reduction in fluorescence intensity, compare (VI) with (V) in Figure 1c). Such a totally different fluorescence behavior between **1a** and **2a** (AIEE versus quenching) is most probably related to the different aggregation states in their FPONs. In fact, the UV/Vis absorption spectra shown in Figure 2a,c suggest *J*-type and *H*-type aggregations for **1a** and **2a** FPONs, respectively. The absorption spectra of **1a** FPONs were characteristically red-shifted (Figure 2a) and exhibited Mie light scattering as a result of *J*-type aggregation and nanoparticle formation, respectively. Notably, the absorption maxima of FPONs of **1a** showed a gradual red-shift with increasing nanoparticle size; $\lambda_{max}^{soln} = 360$ nm, $\lambda_{max}^{FPONs} = 371$–382 nm with increasing FPON size of 40–275 nm. Concomitantly, FPONs of **1a** showed strongly enhanced fluorescence emission as shown in Figure 2b ($\Phi_F^{FPONs} = 3.2$–5.1%, $\lambda_{max}^{FPONs} = 485$–493 nm) compared with the isolated **1a** dissolved in THF (2×10^{-4} M, $\Phi_F^{soln.} = 0.002\%$, $\lambda_{max}^{soln} = 461$ nm).[21,22] All of these spectral changes corroborate that the *J*-type aggregation and

The inset graph shows a relative PL intensity modulation of **1a** FPONs (275 ± 75 nm). c),d) UV/Vis absorption and PL spectra of **2a** in THF (2×10^{-5} M) and the colloidal suspension of **2a** FPONs (2×10^{-5} M). e) UV/Vis absorption spectra of **1a** in THF (2×10^{-4} M) and a 20 wt% **1a**-loaded PMMA film. f) PL spectra of the 20 wt% **1a**-loaded PMMA film. The inset graph shows the relative PL intensity modulation of the film.

molecular planarization of **1a** molecules were induced in their FPONs by specific intermolecular interactions.[19,23] In contrast, the UV/Vis absorption spectra of **2a** FPONs were significantly blue-shifted ($\lambda_{max}^{soln} = 360$ nm, $\lambda_{max}^{FPONs} = 329$ nm) as shown in Figure 2c. Moreover, the fluorescence quantum yield of FPONs of **2a** was drastically reduced by 30 times from that of a solution of **2a** in THF (2×10^{-5} M, $\Phi_F^{soln} = 3.4\%$, $\lambda_{max}^{soln} = 439$ nm, $\Phi_F^{FPONs} = 0.1\%$) as indicated in Figure 2d. This blue-shifted UV absorption together with the salient concentration quenching in FPONs of **2a** is attributed to the formation of *H*-type aggregation through strong cofacial π-stacking interactions, which most likely provides a nonradiative decay route.[24,25]

Compounds **1a** and **2a** with open-ring BTE units were converted into **1b** and **2b** with closed-ring BTE units when irradiated with UV light (365 nm, 1.2 mW cm^{-2}). This process was easily monitored by the appearance of new absorption bands in the visible regions ($\lambda_{max}^{1b} = 574$ nm, $\lambda_{max}^{2b} = 570$ nm) as shown in Figure 2a,c (see the Supporting Information for details). Accompanied by this photochromic ring closure, the photoluminescence (PL) intensities of the **1a** FPONs were greatly reduced (compare (IV) with (II) in Figure 1a,b, and see the Supporting Information for details). The fluorescence quantum yields of the FPONs of **1a** in the photostationary state (PSS)[15] were reduced by 16–170 times ($\Phi_F^{FPONs} = 0.20$, 0.09, 0.04, and 0.02% in the PSS, $\Phi_F^{FPONs} = 3.2$, 5.1, 4.1, and 3.4% in the **1a** form with increasing FPON size of 40–275 nm,

respectively).[21,22] However, only a small amount of fluorescence modulation (29% reduction, see the Supporting Information for details) was achieved in a solution of **2a** (2×10^{-5} M, $\Phi_F^{soln} = 2.4\%$ in the PSS, $\Phi_F^{soln} = 3.4\%$ in the **2a** form).

It is known that there are two interconvertible conformations of BTE units: one is a parallel conformation and the other is an antiparallel conformation, of which only the latter allows an electrocyclic ring-closing reaction.[15] Through the ^{1}H NMR spectroscopic study (2×10^{-4} M of CDCl$_3$ solution, 22°C, 300 MHz) it was determined that the parallel and antiparallel conformations of **1a** were equally populated, and also that only about 35% of the **1a** forms were photo-isomerized to the **1b** forms in the PSS under irradiation with 365 nm light.[26,27] An even smaller extent of ring-closing reaction in the PSS is implied for FPONs of **1a**, because the net absorbance of the **1b** form at 574 nm is smaller in FPONs than in solution (see Figure 2a). It is reasonably supposed, therefore, that the photochromic interconversion between the two conformations was suppressed within a FPON (which is essentially a condensed solid state), or that the ring-closing reactions occurred only at the surfaces of the FPONs.[28] Given that the extent of the ring-closing reaction is less than 35%, the experimentally observed extremely large reduction in the fluorescence quantum yield Φ_F (16–170-fold decrease) of FPONs of **1a** in the PSS must be achieved not only by intramolecular energy transfer between the fluorophore and the closed-ring form of BTE, although it is very likely that the 29% reduction of the Φ_F value of the **2a** solution occurs through this intramolecular energy transfer.[2–5,7,8] It is presumed that the condensed-state FPONs also provide an additional quenching event, or intermolecular energy transfer between the unconverted **1a** forms and the neighboring **1b** forms, because of their proximity in FPONs. Consequently, extremely high contrast in the on/off signaling ratio is automatically implemented in the neat FPONs of **1a**, which is an additional advantage to the enhanced fluorescence and high storage capacity of the AIEE molecule.

Moreover, when the FPONs of **1a** in the "off" state were irradiated with visible light (> 500 nm), the PL intensities were perfectly recovered to those of the initial "on" state as a result of the reversible photochromic behavior of the BTE unit. The inset graph in Figure 2b shows a reversible photochromic modulation of relative fluorescence intensity in the suspension of FPONs of **1a** under alternating irradiation with UV and visible light (note the on/off fluorescence intensity ratio > 10).

To produce a more practical photo-rewritable imaging medium we prepared a strongly fluorescent poly(methyl methacrylate) (PMMA; $M_w =$ ca. 120 000) film containing a very high level (20 wt%, ca. 3×10^{-1} M) of **1a** molecules. This polymer film was optically clear and scatter-free, presumably because of the partial miscibility of PMMA and **1a**. The absence of light scattering and detectable aggregate features in the fluorescence-enhanced (FE) SEM image (down to ca. 10 nm scale, see Supporting Information), which are, however, accompanied by distinct *J*-type red-shifted absorption in the film ($\lambda_{max}^{soln} = 360$ nm, $\lambda_{max}^{film} = 372$ nm, see Figure 2e), suggests that the film comprises molecular-scale aggregates of

1a. The presence of molecular-scale aggregates is additionally evidenced by the strong effect of AIEE as the intense blue fluorescence ($\Phi_F^{film} = 5.8\%$, $\lambda_{max}^{film} = 487$ nm versus $\Phi_F^{soln} = 0.002\%$, $\lambda_{max}^{soln} = 461$ nm in 2×10^{-4} M solution) from this polymer film (see Figure 2f).[21,29,30] The AIEE fluorescence from this PMMA/**1a** film was also photoswitched in a bistable manner by alternate UV and visible light irradiation with high contrast ($\Phi_F^{film} = 0.3\%$ in the PSS, $\Phi_F^{film} = 5.8\%$ in the **1a** form, or on/off fluorescence intensity ratio > 19), as shown in the inset graph in Figure 2f. In addition, the practical capability of rewritable fluorescence photoimaging on our AIEE polymer film was investigated by patterned illumination through photomasks. The emblem of Seoul National University was recorded as a first image (Figure 1f), which was subsequently erased and followed by the recording of a second image, the abbreviation of the Molecular Photonics Laboratory (MPL). This successful demonstration of rewritable photoimaging on the polymer film suggests immediate application of **1a** molecules to ultrahigh-density rewritable optical memory media or imaging processes.

In conclusion, we designed and synthesized a special class of multifunctional molecule **1a**, which shows a strongly enhanced fluorescence emission as well as bistable photochromism. High-contrast (> 10) on/off fluorescence switching was successfully implemented in the size-tuned neat nanoparticles of **1a** and also in a PMMA film highly loaded with **1a**.

[20] Preparation of FPONs: All suspensions of FPONs were prepared by the reprecipitation method from THF solution with distilled water. Volume fractions of THF and water were adjusted to 20 and 80%, respectively. See ref. [19] for details.

[21] Fluorescence quantum yields: The fluorescence quantum yields (Φ_F) were relatively calculated using 9,10-diphenylanthracene (DPA) in benzene (see ref. [22]) and in PMMA (see refs. [29,30]) as a standard reference (1×10^{-3} M, $\Phi_F = 83\%$). Through this method, the Φ_F values of FPONs of **1a** were determined as 3.2, 5.1, 4.1, and 3.4% ($\lambda_{max\,em}^{FPONs} = 485, 489, 491$, and 493 nm, $\lambda_{max\,abs}^{FPONs} = 371, 374, 378$, and 382 nm) in the **1a** form, and as 0.20, 0.09, 0.04, and 0.02% in the PSS with increasing FPON size of 40 ± 10, 125 ± 25, 200 ± 50, and 275 ± 75 nm, respectively. It is reasonably considered that the slight reduction of the Φ_F values in 200 ± 50 and 275 ± 75 nm FPONs of **1a** results from the highly increased virtual absorbance values by increased light scattering. In fact, the extent of the apparent absorbance of the FPONs of **1a** at the excitation wavelength, that is at 360 nm, was almost linearly proportional to their suspension concentrations in spite of the inverse proportional relationship between the mean radius and the surface-to-volume ratio of the FPONs.

[26] Determination of the conformational population and conversion rate: A ^{1}H NMR spectroscopic study (2×10^{-4} M of CDCl$_3$ solution, 22°C, 300 MHz) on the **1a** form showed that the parallel and antiparallel conformations were equally populated in solution, as evident by there only being two singlet resonances at $\delta = 1.98$ and 1.91 ppm without any splitting. These signals were assigned as the methyl protons at the 2-positions of the thiophene rings of the **1a** form (see ref. [27]). The conversion rate of about 35% in the PSS was calculated by the integrated ratio between the singlet peaks of methyl protons in the **1a** form and those in the **1b** form, which newly appeared at $\delta = 2.15$ and 2.11 ppm.

Macroscopic Spinning Chirality Memorized in Spin-Coated Films of Spatially Designed Dendritic Zinc Porphyrin *J*-Aggregates**

*Tatsuya Yamaguchi, Tatsumi Kimura, Hiro Matsuda, and Takuzo Aida**

The breaking of chiral symmetry can occur under nonequilibrated conditions.[1–4] Such a spontaneous induction of optical activity from achiral entities has attracted much attention in relation to the origin of chirality in nature. Representative examples can be seen in growth processes of large electrostatic assemblies of achiral chromophoric compounds such as cyanine dyes and porphyrin derivatives in aqueous media.[5] In these cases, the assemblies are considered to adopt helical architectures, where either the *P* or *M* form is selected only accidentally at the initial stage of the self-organization event and develops predominantly in the subsequent stage. Hence, handedness of emerging chirality is unpredictable. Ribó et al.[5c] have discovered, through studies on electrostatic *J*-aggregation of a 4-sulfonatophenylporphyrin in aqueous media, that the sense of such an optical activity can be selected by the spinning direction of vortex stirring initially applied to the solutions. Herein we report an interesting finding that spin-coated films of dendritic zinc porphyrin *J*-aggregates chiroptically memorize the spinning directions. The optical activities of the spin-coated films are thermally stable and preserved up to the melting temperatures of the *J*-aggregates. In contrast with the previous examples,[5] the *J*-aggregates are optically inactive in solution.

Porphyrin *J*-aggregates have attracted attention because of their potential application as nonlinear optical materials.[6] Although several examples of porphyrin *J*-aggregates have been reported, they are formed mostly in aqueous media;[5b,c] however, there are few examples of *J*-aggregation in organic media[7] which occur because of rather weak π-stacking interactions. We found that zinc porphyrins bearing carboxylic acid (-CO_2H) functionalities at the opposite meso positions undergo supramolecular polymerization by dimerization of the -CO_2H groups to give *J*-aggregates in organic media. The *J*-aggregation takes great advantage of a multi-

point π-stacking interaction between the polymeric zinc porphyrin molecules. Our molecular design strategy also includes introduction of [G2] or [G3] dendritic wedges at the residual two meso positions (Gm/n_{acid}, where m is the generation number of the dendritic wedges (2 or 3) and n is the number of benzyl ether units (0—2) in the spacer parts of the dendritic wedges; Scheme 1). The dendritic wedges are essential not only for providing the resulting supramolecular polymers with sufficiently high solubilities but also for steric control over the π-stacking interaction among the polymeric focal cores. For comparison, we synthesized a zinc porphyrin dicarboxylic acid ($G0_{C18}/1_{acid}$) bearing long alkyl chains, and investigated the aggregation behavior of this nondendritic reference as well as those of ester versions Gm/n_{ester}, which were the synthetic precursors of Gm/n_{acid}.

For the synthesis of $G3/1_{acid}$ (Scheme 1), the zinc complex of 5,15-bis(4-methoxycarbonylphenyl)-10,20-bis(4-hydroxyphenyl)porphyrin was treated under alkaline conditions with [G3] poly(benzyl ether) dendron bromide, and the resulting ester ($G3/1_{ester}$) was hydrolyzed with KOH. After neutralization, the reaction mixture was subjected to preparative size-exclusion chromatography (SEC) to isolate $G3/$

1_{acid}. Other dendritic zinc porphyrins such as $G2/0_{acid}$–$G2/2_{acid}$, $G3/0_{acid}$, and nondendritic $G0_{C18}/1_{acid}$ (Scheme 1) were synthesized in a similar manner to the above and unambiguously characterized.[8] As the benzyl ether spacers between the zinc porphyrin unit and the dendritic wedges become longer, the zinc porphyrin core should possess a larger spatial freedom for the π-stacking interaction ($G2/0_{acid} < G2/1_{acid} < G2/2_{acid}$; $G3/0_{acid} < G3/1_{acid}$). On the other hand, the spatial freedom should become smaller as the dendritic wedges become larger ($G3/0_{acid} < G2/0_{acid}$; $G3/1_{acid} < G2/1_{acid}$). In contrast with the case of these dendritic versions Gm/n_{acid}, the zinc porphyrin unit in $G0_{C18}/1_{acid}$ is omitted because of the absence of dendritic wedges.

We found that [G2] dendritic zinc porphyrin dicarboxylic acids such as $G2/0_{acid}$–$G2/2_{acid}$ all form stable *J*-aggregates in CHCl$_3$. For example, the electronic absorption spectrum of a CHCl$_3$ solution of $G2/2_{acid}$ (5 mM) at 25 °C displayed an intense red-shifted Soret band at 453 nm and a blue-shifted band at 413 nm (Figure 1 c) which is characteristic of zinc porphyrin *J*-aggregates. $G2/1_{acid}$ with shorter benzyl ether spacers exhibited a virtually identical absorption spectral profile to $G2/2_{acid}$ (Figure 1 b). Although $G2/0_{acid}$ without
Scheme 1. Structures of the dendritic and nondendritic zinc porphyrin dicarboxylic acids Gm/n_{acid} ($m = 0, 2, 3$, $n = 0–2$) and their esters Gm/n_{ester} ($m = 0, 2, 3$, $n = 0–2$).
Figure 1. CD spectra of thin films of **G**m/n_{acid} ($m=2, 3, n=0$–2) prepared by spin-coating in clockwise (red curves) and counterclockwise (blue curves) spinning directions are also shown; a') **G2/0**$_{acid}$, b') **G2/1**$_{acid}$, c') **G2/2**$_{acid}$, d') **G3/0**$_{acid}$, e') **G3/1**$_{acid}$, f') **G0**$_{C18}$/**1**$_{acid}$.

benzyl ether spacers formed a *J*-aggregate, it displayed a slightly different absorption spectrum, with two red-shifted Soret bands at 451 and 432 nm (Figure 1a). The infrared spectra of solutions of **G2/**n_{acid} ($n=0$—2; 5 mM) in CHCl₃ all showed a carbonyl stretching vibration at 1688 cm⁻¹ arising from a dimeric form of CO₂H, with only a negligibly small shoulder attributable to free CO₂H at 1725 cm⁻¹.[8] Dynamic light scattering (DLS) studies on a dilute solution of *J*-aggregated **G2/1**$_{acid}$ in CHCl₃ (0.05 mM), for example, showed the presence of large assemblies with an average radius of 200 nm.[8] Thus, the zinc porphyrin cores of these dendritic

compounds are hydrogen bonded to one another to form supramolecular polymers. In contrast, their ester versions **G2/**n_{ester} ($n=0$–2) showed a single Soret band at 423 nm (Figure 1a–c; green curves), which is characteristic of non-aggregated zinc porphyrins. Therefore, it is concluded that the *J*-aggregation of zinc porphyrins can be induced in organic media by their hydrogen-bonding interactions. We assume that one-dimensional zinc porphyrin polymers formed by the dimerization of the CO₂H moieties stack up together, through a multipoint π-electronic interaction, to form a large, two-dimensional (2D) sheetlike assembly (Scheme 2). The differ-
Scheme 2. Structures of zinc porphyrin *J*-aggregates with a short, oblique slip (a) and a long, non-oblique slip (b).

ence in the absorption spectral profile between **G2/**n_{acid} ($n=1, 2$) and **G2/0**$_{acid}$ (Figure 1a–c; red curves) is attributable to a difference in the π-stacking geometry of the zinc porphyrin units. Namely, the *J*-aggregates of **G2/1**$_{acid}$ and **G2/2**$_{acid}$ both involve a short, oblique slip of the π-stacked zinc porphyrin units (Scheme 2a), typical of *J*-aggregated tetraarylporphyrin derivatives, since such a geometry can reduce the steric interference from the meso-aryl groups on the zinc porphyrin units.[9] On the other hand, the *J*-aggregate of **G2/0**$_{acid}$, which is devoid of any spacers between the dendritic wedges and the zinc porphyrin core, involves a long, non-oblique slip of the π-stacked zinc porphyrin units (Scheme 2b), possibly because of limited spatial freedom for the π-stacking interaction. The dendritic side chains, which are located presumably on both sides of the 2D sheet, are responsible for the high solubilities of the *J*-aggregates. For reference, the absorption spectral

profile of nondendritic $G0_{C18}/1_{acid}$ in hot $CHCl_3$ (Figure 1 f) was analogous to those of *J*-aggregated $G2/1_{acid}$ and $G2/2_{acid}$, but the compound gradually precipitated on standing at 25 °C.

In contrast with the [G2] dendritic zinc porphyrins $G2/n_{acid}$ ($n = 0$–2), solutions of the one-generation higher systems $G3/0_{acid}$ and $G3/1_{acid}$ (5 mM) in $CHCl_3$ both displayed a single Soret band at 428 nm, similar to their ester versions, thus indicating that their zinc porphyrin cores are not assembled through π-stacking interactions (Figure 1 d,e). Infrared spectroscopic analysis of these compounds showed a considerable amount of free CO_2H groups at 1725 cm^{-1}, along with dimeric CO_2H groups at 1688 cm^{-1}.[8] Therefore, it is likely that the large dendritic wedges attached to the zinc porphyrin core suppress both the hydrogen-bonding and π-stacking interactions. On the other hand, we also found that $G3/1_{acid}$ gives a *J*-aggregate in an apolar solvent such as C_6H_6, where a dimeric form of CO_2H is stable. The electronic spectrum of a solution of $G3/1_{acid}$ in C_6H_6 (5 mM) showed a red-shifted Soret band at 453 nm and a blue-shifted band at 414 nm (Figure 2 b; red
Figure 2. Electronic absorption spectra of solutions (5 mM) of $G3/n_{acid}$ ($n = 0$, 1; red curves) and $G3/n_{ester}$ ($n = 0$, 1; green curves) at 25 °C in C_6H_6; a) $G3/0_{acid}$ and $G3/0_{ester}$ b) $G3/1_{acid}$ and $G3/1_{ester}$ CD spectra of thin films of $G3/n_{acid}$ ($n = 0$, 1) prepared by spin-coating in the clockwise (red curves) and counterclockwise (blue curves) directions are also shown; a') $G3/0_{acid}$, b') $G3/1_{acid}$.

curve), whereas ester $G3/1_{ester}$, under identical conditions, displayed an ordinary Soret band at 429 nm (Figure 2 b; green curve). Infrared spectroscopic analysis of $G3/1_{acid}$ in C_6H_6 (5 mM), in contrast with the case in $CHCl_3$, showed a carbonyl stretching vibration predominantly at 1688 cm^{-1} arising from the dimeric form of CO_2H. These observations again support our hypothesis that the zinc porphyrin units, when polymerized through hydrogen-bonding interactions, have an enhanced capability for π stacking. In contrast, $G3/0_{acid}$, with a sterically encumbered zinc porphyrin core, formed a weak gel in C_6H_6 whose absorption spectrum (Figure 2 a; red curve) was similar to that of non-aggregated $G3/0_{ester}$ (Figure 2 a; green curve).

In the course of the above study we noticed that *J*-aggregated $G2/n_{acid}$ ($n = 0$–2) gave birefringent films when cast from their $CHCl_3$ solutions on to glass plates. Spin-coating of these solutions also resulted in the formation of birefringent films, which showed the presence of rodlike

crystalline particles by polarized microscopy (Figure 3 a–c). The particles from $G2/0_{acid}$ were smaller than those from the other two compounds. Quite interestingly, these films were optically active, although their solutions were silent in circular
Figure 3. Polarized-light micrographs of spin-coated films from solutions of Gm/n_{acid} ($m = 2$, 3, $n = 0$–2) in $CHCl_3$ and solutions of $G3/n_{acid}$ ($n = 0$, 1) in C_6H_6: a) $G2/0_{acid}$, b) $G2/1_{acid}$, c) $G2/2_{acid}$, d) $G3/0_{acid}$, e) $G3/1_{acid}$, f) $G3/0_{acid}$, g) $G3/1_{acid}$; scale bar, 50 µm.

dichroism (CD) spectroscopy. We also found that the spin-coated films displayed a chirality dominance in the statistical distributions that was dependent on the "spinning direction", whereas the cast films did not show any dominance in chirality. For example, when a solution of $G2/2_{acid}$ in $CHCl_3$ (5 mM) was spin-coated in a clockwise direction at 6000 rpm, the resulting film displayed intense CD bands at 413, 440, and 453 nm with positive, negative, and positive signs, respectively (Figure 1 c'; red curve). On the other hand, spin-coating of the same solution in a counterclockwise direction resulted in the appearance of a mirror-image CD spectrum (Figure 1 c'; blue curve). The intensities of the CD bands hardly changed when observed by rotating the samples along an axis perpendicular to the substrate surface,[8] thus indicating a negligibly small contamination with linear dichroism. Furthermore, we prepared 10 samples for each spinning direction and confirmed a

Communications

complete dominance of the emerging chirality sense.[8] Such a spinning direction dependent chirality dominance was also observed for spin-coated films of J-aggregated **G2/1_acid** (Figure 1 b′). As already described, the J-aggregates of **G2/1_acid** and **G2/2_acid** both involve a short, oblique slip of the π-stacked zinc porphyrin units (red curves in Figure 1 b and c, respectively). In sharp contrast, J-aggregated **G2/0_acid**, which is proposed to involve a long, non-oblique slip of the zinc porphyrin π stacks (Figure 1 a; red curve), gave a spin-coated film that exhibited negligibly weak CD bands (Figure 1 a′) in the visible region. Similar weak CD bands resulted when nondendritic **G0_C18/1_acid**, which is J-aggregated in CHCl₃ (Figure 1 f), was spin-coated (Figure 1 f′). These observations indicate the importance of spatial design around the hydrogen-bonded zinc porphyrin chromophores for the emergence of chirality on spin-coating.

One-generation higher **G3/0_acid**, which is not associated through π interactions in CHCl₃ (Figure 1 d) or even in C₆H₆ (Figure 2 a), gave neither birefringent (Figure 3 d, f) nor optically active films (Figure 1 d′, Figure 2 a′) on spin-coating. A nonbirefringent, optically inactive film (Figure 3 e, Figure 1 e′) also resulted when non-assembled **G3/1_acid** in CHCl₃ (Figure 1 e) was spin-coated. In contrast, spin-coating of a solution of J-aggregated **G3/1_acid** in C₆H₆ (Figure 2 b) resulted in the formation of a birefringent, optically active film (Figure 3 g, Figure 2 b′) that exhibited a spinning direction dependent CD response. On the other hand, non-assembled ester versions such as **Gm/n_ester** ($m = 2$, 3, $n = 0$–2) and **G0_C18/1_ester** (Figure 1 a–f; green curves) gave CD-silent films on spin-coating, as expected.

Figure 4 shows a schematic representation of the suggested J-aggregated 2D sheet. This is composed of an offset stacking of hydrogen-bonded dendritic zinc porphyrin polymers (Scheme 2). A helical J-aggregate structure, proposed for the precedent examples,[5b,c] seems unlikely in solutions,

because of a large steric repulsion between the dendritic wedges, along with the one-dimensionality of the backbone polymers. However, such 2D molecular sheets, when transferred to the solid state, are known to role up to form coiled architectures.[4,10] If this happens to the J-aggregated 2D sheet, the zinc porphyrin units are forced to adopt a twisted (chiral) geometry relative to one another, and the assembly can eventually be optically active when the parity of chirality is broken. On the other hand, when a large rotational sheer force is applied to this roll-up event by spin-coating, either a right-handed or left-handed helical coil, depending on the spinning direction, may be selected. In other words, the spin-coated films can chiroptically memorize the macroscopic spinning direction. We found that the chiroptical memory thus fixed is thermally stable. For example, the spin-coated film of J-aggregated **G2/2_acid** still preserved its optically activity when heated at 200 °C for five minutes. Further heating the film up to 260 °C resulted in it losing its birefringence and becoming optically inactive.

In summary, we have demonstrated that spin-coating of hydrogen-bonded dendritic zinc porphyrin J-aggregates gives optically active films, where either of the two enantiomeric forms is selected by the spinning direction. This is the first successful example of the transformation of a macroscopic spinning chirality into a stable supramolecular chirality in the solid state. Extension of this finding to other self-assembling systems and application of the resulting optically active materials to absolute asymmetric synthesis and chiral separation are the challenging subjects worthy of further investigation.
Figure 4. A proposed mechanism for the formation of a chiral zinc porphyrin J-aggregate.

Analytical Methods

Optimization Of "Wired" Enzyme O₂-Electroreduction Catalyst Compositions by Scanning Electrochemical Microscopy**

José L. Fernández, Nicolas Mano, Adam Heller, and Allen J. Bard**

"Wired" enzyme electrodes, comprising enzymes connected electrically through redox polymers, which swell to give electron-conducting hydrogels,[1] are already used in experimental subcutaneously implanted electrodes for the continuous monitoring of glucose in diabetics and may be used in future miniature, microwatt producing, membrane-less biofuel cells.[2] The subcutaneously implanted electrodes comprise, in addition to the "wired" enzyme film that transduces the glucose flux to a current, a glucose flux-controlling membrane, which defines the measurable glucose concentration range, and optionally, a bioinert film.[3] The membrane-less miniature biofuel cells comprise a "wired" glucose oxidase anode, and a "wired" bilirubin oxidase or laccase cathode. Optimizing the performance of these devices requires synthesis and characterization of new redox polymers,[4,5] defining the optimal enzyme–cross-linker–redox-polymer compositions,[6–9] and synthesis and optimization of flux controlling and bioinert membranes. A key parameter,

which is usually explored first, is the polymer/enzyme ratio. An excessive enzyme weight fraction can decrease the current density, because the enzyme, unlike the redox polymer, is an electronic insulator.[10] Furthermore, if the enzyme weight fraction is high enough for the net negative charge of glucose oxidase to balance the positive charge of the redox polymer, an electrostatic adduct that shows poor electronic conductivity precipitates.[6,7] Moreover, when the weight fraction of the redox polymer is excessive, the flux of electrons is reduced, because of the smaller number of enzyme molecules.[11]

The effort and material expended in the optimization process[6,7,11] can be reduced by combinatorial screening techniques[12] exemplified by optimization through scanning electrochemical microscopy (SECM),[13] a technique that has been extensively used for evaluating the activity of enzymatic systems[14,15] and whose utility is demonstrated herein. Because only optimization of an exemplary parameter, the weight fraction of the multicopper oxidase bilirubin oxidase (BOD) or laccase, of a biofuel cell cathode was performed, the study does not provide as yet a fully optimized electrode, for which additional parameters, including the total loading and the weight% of the cross-linker, would have to be defined, along with the thickness of the electrode. The results obtained establish, nevertheless, that SECM screening of compositionally varying arrays of μm-size spot electrodes yields results identical with those obtained with discreet rotating disk electrodes, but much more efficiently in terms of speed and material required.

Ternary mixtures of enzyme, cross-linker, and redox polymer, with compositions ranging from pure enzyme to pure polymer, were prepared from aqueous solutions of BOD from *Trachyderma tsunodae* (8 mg mL^{-1} in pH 7.2 20-mM phosphate buffer) or laccase from *Coriolus hirsutus* (8.6 mg mL^{-1} in pH 5.0 20-mM citrate buffer), and PAA-PVI-[Os(4,4′-dichloro-2,2′-bipyridine)$_2$Cl]$^{1+/2+}$ (8 mg mL^{-1}) or PAA-PVI-[Os(tpy)(dme-bpy)Cl]$^{1+/2+}$ (8.6 mg mL^{-1}), respectively (PAA = poly(1-carboxy-1,2-ethanediyl), PVI = poly(1-imidazolyl-1,2-ethanediyl), tpy = 2,2′:6′,2″-terpyridine, dme-bpy = 4,4′-dimethyl-2′,2-bipyridine). A solution of polyethylene glycol diglycidyl ether at 2 mg mL^{-1} (PEDGE, Polysciences Inc.) was used as the cross-linker. Arrays of spots containing these mixtures were deposited on glassy carbon (GC) plates 15 × 15 × 1 mm (Alfa) by using a piezo-based micro-arrayer, a device similar to that used by Schuhmann and co-workers for micro-patterning of enzymatic biosensors.[15] A commercial piezo-dispenser MicroJet AB-01-60 (MicroFab) with an outlet aperture of 60 μm, that dispenses on-demand picoliter-sized (≈ 100 pL) droplets by application of potential pulses (50 V, 25 μs), was installed onto the head of a digital plotter (Houston Instruments DMP-5) to control its position with a resolution of 100 μm/step. Figure 1 shows the preparation scheme. The dispenser was filled with polymer solution (3 μL), which was dispensed in a programmed number of drops at each site. To test for reproducibility, each composition was prepared in duplicate or triplicate. Thus, the arrays contained 11 rows and two columns of spots. Typically, the first two-spot row contained 10 drops per spot (pure polymer), the next row 9 drops per spot and so on down to and the tenth row with 1 drop per spot. The dispenser was

Communications

Figure 1. Schematic diagram of the preparation of the wired enzyme spot arrays.

emptied, thoroughly rinsed first with ethanol and then with water, and refilled with 3 μL of enzyme solution. Then the plotter positioned the dispenser exactly over the previously prepared polymer spots, and a number of drops of enzyme solution, sufficient for the sum of the enzyme drops and the polymer drops to always equal 10, were dispensed. About 80% of the polymer or enzyme solution used to fill the dispenser can be recovered. After polymer and enzyme were deposited, 3 drops of cross-linker solution were dispensed on each spot. The substrate was maintained under a water-saturated N_2 stream during the complete preparation procedure to avoid the premature evaporation of the spots. To mix the components, the array was then agitated under the water-saturated N_2 stream for 5 min in a Vortex Genie 2 agitator (Fisher), and the array was dried overnight in ambient air. Figure 2 shows an SEM picture of typical arrays and an optical micrograph of an individual spot. The center-to-center distance between the 150–200 μm diameter spots was about 400 μm. Before testing, the arrays were washed with Milli-Q water. The thickness of the spots, estimated by negative feedback mode SECM[13] by using O_2 reduction on Au tips, over a spot and then over the neighboring GC, was 4–5 μm. The weight percent of enzyme (wt.%) at each spot was calculated from the number of drops (or volume fraction) and the concentrations of the polymer, enzyme, and cross-linker solutions used. The wt.% of the cross-linker was fixed at 6.9 for the BOD electrodes and at 6.5 for the laccase electrodes.

The SECM tip generation-substrate collection mode was used to image activity of the arrays.[16] This mode of operation is well suited for imaging activity of surfaces with morphological features since it is relatively insensitive to changes of the tip–substrate distance.[17] SECM images of O_2 reduction activity of the "wired" BOD arrays were obtained in 0.2 M pH 7.2 phosphate buffer, and of the "wired" laccase, in 0.2 M pH 5.0 citrate buffer, as previously described.[16] Briefly, a 25 μm Pt tip situated at 40 μm from the GC surface was scanned in the *xy* plane (parallel to spot rows) at step intervals of 50 μm every 0.2 s while electrogenerating O_2 from H_2O at a constant current. Under these conditions, areas of 5×2 mm can be screened in about 1 h using the SECM (CH Instruments model 900B) with stepper-motor translators. The substrate array potential (E_S) was held at 0.3 and 0.4 V

versus Ag/AgCl (3 M KCl) for BOD and laccase, respectively, where the reduction of O_2 was diffusion controlled.[6, 7] The substrate current (i_S), measured as a function of tip position to produce the SECM image, was larger when the O_2-generating tip passed over a more active spot. Thus, the measure of the electrocatalytic activity of any of the spot electrodes was the magnitude of i_S. Figure 3 presents SECM color-map images obtained for the BOD and the laccase arrays. To establish reproducibility, triplicate experiments were performed. Because of the time-dependent processes, such as diffusion of O_2 into the hydrogel and charge transport through the film, the response times were slower than for metallic electrodes, and individual spots were not well resolved in the direction of the scan (*x*). As a result, the rows of the spots have a smeared, band-like appearance, particularly for the BOD films. Slower scanning can overcome the smearing, at the cost of increased imaging time.
Figure 2. a) SEM photograph of two arrays of redox-polymer–laccase spots made with 6.5 wt.% cross-linker. Each two-dot row corresponds to a particular composition. b) Optical micrograph of the 46.5 wt.% enzyme, 46.6 wt.% polymer, 6.9 wt.% cross-linker "wired" BOD spot, prepared by mixing the component solutions in situ.

In the BOD arrays (Figure 3a), O_2 electroreduction was seen for a 20–80 wt.% BOD range. The largest oxygen reduction reaction (ORR) current (close to the highest expected) was for the 46.5 wt.% BOD spots. With the laccase arrays (Figure 3b), O_2 electroreduction was observed for a 15–70 laccase wt.% range, with a maximum at 46.7 wt.%
Figure 3. SECM images of "wired" enzyme arrays containing spots with different polymer/enzyme ratios. a) BOD (6.9 wt.% cross-linker) in pH 7.2 phosphate buffer, $i_T = -161$ nA (i_T = tip current), $E_S = 0.3$ V versus Ag/AgCl; b) laccase (6.5 wt.% cross-linker) in pH 5.0 citrate buffer, $i_T = -240$ nA, $E_S = 0.4$ V versus Ag/AgCl.

laccase. Figure 4 (solid symbols) summarizes the normalized ORR currents measured for each row as a function of enzyme wt.%. Each point is the average of three values measured from images obtained on three different arrays prepared under identical conditions.
Figure 4. Dependence of the oxygen reduction current (normalized with respect to the highest current) on the enzyme wt.% for a) BOD in pH 7.2 phosphate buffer and for b) laccase in pH 5.0 citrate buffer. Solid symbols = results of the SECM screening, open symbols = results of the rotating disc experiments. 1 mV s^{-1}, 1000 rpm, 1 atm O$_2$, total bioelectrocatalyst loading, 0.26 mg cm^{-2}.

To test the validity of the method, "wired" BOD and "wired" laccase GC rotating-disk electrodes were prepared, as described elsewhere, with different enzyme–polymer ratios.[6,7] Polarization curves were measured by slow potentiodynamic scans (1 mV s^{-1}) in O$_2$-saturated (1 atm) solutions at 1000 rpm in physiological buffer for BOD and in 0.2 M pH 5 citrate buffer for laccase. O$_2$-electroreduction limiting currents were measured five times on each composition for BOD and seven times on laccase. The mean values are plotted in

Figure 4 (open symbols). The results obtained by the two methods were in good agreement. Sample preparation and testing by the SECM screening method required one day, while the preparation and testing of a rotating disk electrode required at least 10 days. The amounts of polymer and enzyme were reduced by a factor of 100 000 in the SECM test.

In conclusion, SECM screening of oxygen electroreduction activity on arrays of "wired" enzyme electrode spots, allows the optimization of a single-variable more rapidly and with less material than optimization utilizing discreet rotating disk electrodes. In the next phase, all parameters of the ORR films on carbon, including total loading, thickness, and weight% of the cross-linker will be optimized.

Asymmetric Synthesis of Highly Substituted β-Lactones by Nucleophile-Catalyzed [2+2] Cycloadditions of Disubstituted Ketenes with Aldehydes**

*Jonathan E. Wilson and Gregory C. Fu**

The development of effective methods for the asymmetric synthesis of β-lactones is an important challenge for a variety of reasons.[1] Numerous biologically active β-lactone-containing natural and unnatural products have been described, including Xenical (tetrahydrolipstatin), an anti-obesity drug developed by Roche.[2,3] Furthermore, β-lactones serve as useful intermediates in an array of fields, including materials science and synthetic organic chemistry.[1,4] The strain of the four-membered lactone provides an opportunity for a range of functionalizations; for example, nucleophiles can react either at the carbonyl group through an addition–elimination sequence or at a C—O single bond through an S_N2 process. Thus, a number of recent total syntheses, such as those of (−)-laulimalide,[5] (−)-malyngolide,[6] and trapoxin B,[7] have exploited enantiopure β-lactones as intermediates.

One attractive route to β-lactones is the overall [2+2] cycloaddition of a ketene with an aldehyde [Eq. (1)]. Chiral

(1)
nucleophiles and chiral Lewis acids have both been shown to catalyze this process, sometimes with outstanding enantioselectivity (the postulated mechanism for the nucleophile-catalyzed cycloaddition is illustrated in Scheme 1).[8–11] To date, all reports of asymmetric catalysis of this transformation have described reactions of ketene itself ($H_2C=C=O$) or of *mono*substituted ketenes. Expanding the scope of such processes to include *di*substituted ketenes would furnish access to α,α-disubstituted β-lactones, an important class of synthetic targets.[12]

Scheme 1. Proposed pathway for the nucleophile-catalyzed enantioselective synthesis of β-lactones from ketenes and aldehydes.

We have been exploring the utility of planar-chiral DMAP and PPY derivatives (for example, **1**) as catalysts for a range of transformations,[13] including an asymmetric Staudinger synthesis of β-lactams that likely proceeds by a pathway analogous to that depicted in Scheme 1 (DMAP = 4-(dimethylamino)pyridine, PPY = 4-pyrrolidin-1-ylpyridine).[14]
We were intrigued by the possibility that these nucleophilic catalysts might also be useful for β-lactone synthesis. This sort of an "extension" from reactions of imines to reactions of aldehydes is not as straightforward as may appear; for example, in the case of cinchona alkaloid-based catalysts, an excellent method for enantioselective β-lactam synthesis from monosubstituted ketenes was reported several years ago,[15] whereas general conditions for β-lactone synthesis from monosubstituted ketenes, which require a Lewis acid co-catalyst, have only been developed very recently.[16] In this Communication, we demonstrate that PPY derivative **1** serves as an effective catalyst for [2+2] cycloadditions of *di*substituted ketenes with aldehydes to furnish the first catalytic asymmetric route to α,α-disubstituted β-lactones.

In our earlier study, we established that **1** catalyzes a Staudinger-type cycloaddition of ketenes with imines to efficiently afford β-lactams with good enantioselectivity (76–98% yield; 81–98% *ee*).[14] However, when we apply these conditions to the corresponding reaction of ketenes with aldehydes, we obtain essentially none of the desired β-lactone [Eq. (2)].

(2)
Interestingly, by lowering the reaction temperature, we can generate the targeted [2+2] cycloaddition product in high yield, and, equally significantly, in high enantiomeric excess (91% yield, 89% *ee*; Table 1, entry 1). Furthermore, the two-

Table 1: Catalytic asymmetric cycloaddition of diethylketene with benzaldehyde.

[a] Average of two runs. [b] Because the product β-lactone could not be separated from a side product, the β-lactone was reduced to a 1,3-diol with diisobutylaluminum hydride (DIBAL-H). TMS = trimethylsilyl.

solvent system that we employed for the synthesis of β-lactams is unnecessary—the formation of β-lactones proceeds in very good yield and *ee* in THF alone (entry 2). It is important to note that the alkaloid-based methods that have proved useful for catalytic asymmetric reactions of *mono*-substituted ketenes are not effective for the illustrated cycloaddition of a *di*substituted ketene (entries 3[10b] and 4[10d]).

Our optimized conditions (Table 1, entry 2) are applicable to a range of [2+2] cycloadditions of disubstituted ketenes with aldehydes (Table 2). Thus, symmetrical ketenes, both acyclic and cyclic, couple with aldehydes with good enantio-selectivity (entries 1–7). Cycloadditions of unsymmetrical disubstituted ketenes generate β-lactones that bear two contiguous stereocenters, one quaternary and one tertiary;[17] we have determined that planar-chiral catalyst **1** preferen-

tially furnishes the *cis* diastereomer (ca. 4.5:1 selectivity) with very good *ee* (ca. 90%; entries 8 and 9).[18]

We have established that these sterically demanding α,α-disubstituted β-lactones can be derivatized through reactions with nucleophiles (Scheme 2). Reagents such as DIBAL-H
Scheme 2. Derivatization of α,α-disubstituted β-lactones.

and hydroxide add to the carbonyl group to furnish a 1,3-diol and a β-hydroxyacid, respectively. Sodium azide, on the other hand, reacts through an S$_N$2 process to generate a β-azidoacid.[19,20] These functionalizations proceed in good to excellent yield with essentially no erosion in enantiomeric excess.[21]

In conclusion, we have established for the first time that a chiral PPY derivative (**1**) can serve as an efficient catalyst for the asymmetric synthesis of β-lactones; this is the only catalyst reported to date that is effective for enantioselective cycloadditions of disubstituted ketenes, which generate α,α-disubstituted β-lactones. Furthermore, we have shown that these β-lactones, in addition to being useful structures in their own right, can be transformed into other important families of enantioenriched compounds. Additional studies of catalytic asymmetric reactions of ketenes are underway.

Large-Scale Synthesis of Micrometer-Scale Single-Crystalline Au Plates of Nanometer Thickness by a Wet-Chemical Route**

Xuping Sun, Shaojun Dong,* and Erkang Wang*

In the past few years metal nanostructures have been the focus of intensive research as a result of their electronic, optical, magnetic, thermal, catalytic, and other properties being distinctly different from their bulk counterparts, and considerable attention, in terms of both fundamental and applied research, has been paid to synthesizing and characterizing metal nanostructures.[1] It has also been demonstrated in nanometer-sized materials that the physical and chemical properties of the structures are closely related to their size and shape.[2] For example, the surface plasmon resonance of metal particles is strongly shape-dependent: the transformation of spherical metal particles into nanometer-sized rods or triangular prisms results in a red-shift and even a split of the corresponding surface plasmon resonance into distinctive dipole and quadrupole modes.[3] A variety of methods have so far been developed to prepare spherical metal nanoparticles,[1d] however, the production of nanostructures by a shape-controlled procedure is still a challenge for materials scientists and there is great interest in developing new methods for fabricating shape-controlled nanoparticles. Many differently shaped nanostructures have been synthesized from metallic Ag by using various chemical approaches, with 1D Ag nanostructures having been fabricated by many research groups.[4] Other Ag nanostructures, such as nanoprisms,[3,5] nanocubes,[6] nanoplates,[7] nanodisks,[8] and nanobelts,[9] have also been fabricated. Much effort has also been made to fabricate Au nanostructures with specific shapes, and many methods have been developed to synthesis 1D Au nanostructures,[10] however, there are very few reports on the synthesis of planar Au nanostructures such as nanodisks[11] and nanoplates.[12] We demonstrate herein a mild wet-chemical route to the large-scale synthesis of micrometer-scale Au nanoplates. In this process $H[AuCl_4]$ is reduced by *ortho*-phenylenediamine in an aqueous medium to form hexagonal single-crystalline Au nanoplates with a preferential growth direction along the Au (111) plane. This result suggests that the molar ratio of *ortho*-phenylenediamine to gold is key to producing Au nanoplates.

The morphology of the precipitate was characterized by scanning electron microscopy (SEM, Figure 1). The lower magnification image (Figure 1 a) indicates that the precipitate consists of a large amount of particles, while the higher
Figure 1. Low magnification (a) and high magnification (b) SEM images of the precipitate. The inset shows that the thickness of a single nanoplate is about 47.7 nm.

magnification image (Figure 1 b) clearly reveals that the particles are micrometer-scale plates, mainly hexagonal in shape. We can conclude from measurements of the distance between two planes of one plate standing against the glass substrate that these plates are nanoplates, tens of nanometers thick (see Figure 1 b, inset). Small quantities of spherical particles are also observed as by-products. The chemical composition of the particles was further determined by energy-dispersive X-ray spectroscopy (EDS). The EDS spectrum obtained from the precipitate only shows the peak corresponding to Au (data not shown), thus indicating that that the particles are pure metallic Au.

Figure 2 shows the transmission electron microscopy (TEM) image (Figure 2 a) of a single Au nanoplate as well
Figure 2. Typical TEM image (a) and corresponding electron diffraction pattern (b) of a single hexagonal Au nanoplate lying flat on a TEM grid.

as the related selected area electron diffraction (SAED) pattern (Figure 2 b) obtained by focusing the electron beam on a nanoplate lying flat on the TEM grid. Interestingly, some patterns are observed on the nanoplate plane. The other four dark dots marked with arrows are spherical Au particles formed as by-products. The SAED pattern reveals that a hexagonal symmetry diffraction spot pattern is generated, thus demonstrating that the Au nanoplate is a single crystal with a preferential growth direction along the Au (111) plane.[13]

The crystalline nature of the nanoplates was further confirmed by recording the X-ray diffraction (XRD) pattern. The XRD pattern (Figure 3) shows sharp peaks correspond-
Figure 3. XRD pattern of the Au products.

ing to the (111), (200), (220), (311), and (222) diffraction peaks of metallic Au, and thus indicates that the precipitate is composed of pure crystalline Au.[14] Note that the ratio of the intensity between the (200) and (111) diffraction peaks is much lower than the standard file (JCPDS; 0.061 versus 0.33). These observations confirm that our nanoplates are primarily dominated by (111) facets, and thus their (111) planes tend to be preferentially oriented parallel to the surface of the supporting substrate.

It is well-known that Au nanostructures dispersed in liquid media usually display a very intense color because of surface plasmon resonance (SPR). Figure 4 shows a photograph and an absorption spectrum of the resulting Au particles sus-
Figure 4. Photograph (a) and UV/Vis spectrum (b) of the Au particles suspended in water.

pended in water. It has been reported that a solution of spherical colloidal Au is red,[15] but interestingly our suspension is gold-yellow in color (Figure 4a). It is also documented that the SPR band of Au nanostructures strongly depends on the size, shape, and aggregation of the nanostructures,[16] and that spherical Au particles show an SPR band at approximately 520 nm that is usually red-shifted to longer wavelengths with increasing particle size.[17] The resulting suspension shows two SPR bands located at about 680 and 925 nm which arise from the longitudinal plasmon resonance of Au particles,[18] thus providing another piece of evidence for the formation of anisotropic Au particles.[17]

We have found in our previous study that H[AuCl$_4$] can be reduced by polyamine-containing polyelectrolytes and dendrimers to form Au nanoparticles.[19] More recently, it has been shown that H[AuCl$_4$] can also be reduced by *ortho*-phenylenediamine to form spherical Au particles with the concurrent formation of poly(*ortho*-phenylenediamine) nanobelts as a result of the oxidative polymerization of *ortho*-phenylenediamine monomers by H[AuCl$_4$].[20] In our present study we also obtained a precipitate of Au nanoplates and belts. Analysis of these belts by SEM shows that they contain C and N, thus indicating that they are oxidative products of *ortho*-phenylenediamine. These belts can be washed away with tetrahydrofuran (THF) to leave purified Au particles.

It is worthwhile mentioning that the quantity of *ortho*-phenylenediamine in the solution is an important factor in determining the morphology of the final Au particles. Control reactions in which excess *ortho*-phenylenediamine was added under otherwise identical conditions only gave isolated or aggregated spherical Au particles. Figure 5 shows typical SEM images of Au products obtained with initial *ortho*-phenylenediamine to gold ratios of of 3:1 (Figure 5a) and 8:1

Figure 5. Typical SEM images of Au particles obtained with an initial *ortho*-phenylenediamine to gold ratio of 3:1 (a) and 8:1 (b).

(Figure 5b), and clearly indicates the formation of aggregated and isolated spherical Au particles, respectively. Other control reactions also gave similar results. These results indicate that the quantity of *ortho*-phenylenediamine in the solution is key to yielding Au nanoplates. We suggest that *ortho*-phenylenediamine molecules serve as a soft template and kinetically control the growth rates of various faces of Au particles by selectively adsorbing on to the crystallographic planes, thus resulting in the formation of large single-crystalline Au nanoplates. However, it is not clear at present how the *ortho*-phenylenediamine molecules influence the growth of different crystal planes of the Au nanoplates, and the detailed mechanism needs further investigation.

In conclusion, we present our preliminary findings that micrometer-sized hexagonal single-crystalline Au nanoplates can be synthesized on a large scale by a mild wet-chemical route, carried out by the chemical reduction of H[AuCl$_4$] with *ortho*-phenylenediamine in aqueous media at room temperature and ambient pressure. Two surface plasmon absorption bands at about 680 and 925 nm are found for these Au nanoplates. The study suggests that the quantity of *ortho*-phenylenediamine in the solution is key to producing Au nanoplates. The importance of the platelet-like gold particles is not restricted to optics; exceptionally interesting materials with unique mechanical properties can be obtained with such colloids.[21]

Experimental Section

H[AuCl$_4$] was purchased from Aldrich and *ortho*-phenylenediamine from Beijing Chem. Co. All reagents were used as received without further purification. The water used was purified through a Millipore system. In a typical experiment, an aqueous solution of 48 mM H[AuCl$_4$] (3 mL) was added to water (5 mL). An appropriate volume of an aqueous solution of freshly prepared *ortho*-phenylenediamine (80 mM) was quickly added to the solution under vigorous stirring at room temperature to obtain a 1:1 molar ratio of *ortho*-phenylenediamine to gold. A large quantity of precipitate was observed several minutes later, which was collected by centrifugation, washed several times with THF and water, then suspended in water. The resulting suspension was used for further characterization.

The samples for SEM and XRD characterization were prepared by placing 100 μL of the suspension on a glass slide, and allowing the solvent to slowly evaporate at room temperature. The sample for the TEM study was similarly prepared by placing a drop of the suspension on a carbon-coated copper grid. The UV/Vis spectra were collected on a CARY 500 Scan UV/Vis/near IR spectrophotometer. The SEM images were obtained on a XL30 ESEM FEG scanning electron microscopy operating at 20 kV. The TEM images were recorded on a JEOL 2000 transmission electron microscopy operating at 200 kV. The XRD pattern was collected on a D/Max 2500 V/PC X-ray diffractometer using Cu (40 kV, 200 mA) radiation.

High-Mobility Air-Stable n-Type Semiconductors with Processing Versatility: Dicyanoperylene-3,4:9,10-bis(dicarboximides)**

Brooks A. Jones, Michael J. Ahrens, Myung-Han Yoon, Antonio Facchetti, Tobin J. Marks,* and Michael R. Wasielewski*

Traditionally, inorganic materials have been the active charge-transporting components in numerous electronic devices. While inorganic materials are ideal for many applications, the rapid development of molecular/polymeric semiconductors for organic field-effect transistors (OFETs) promises materials better suited to inexpensive, flexible, large-area applications, such as displays, RF-ID tags, smart cards, and sensors.[1] To this end, recent advances in p-type organic semiconductors have fulfilled many of the requirements for use in diverse applications;[1c–e,2] however, n-type materials, needed for complementary circuits, continue to present challenges, such as low mobilities, instability in air, poor solubility for efficient film-casting, and large barriers to electron injection.[1b,2]

We have already demonstrated that high-mobility n-type organic semiconductors can be realized by functionalizing oligothiophene cores with electron-withdrawing perfluorinated groups (e.g. DFT-4T and FTTTTF).[3] Furthermore, other research has demonstrated that electron-withdrawing imide substituents afford promising architectures for n-type naphthalene and perylene-based OFET materials (e.g., NDI and PDI).[4] Thus, vapor-deposited and solution-cast films of *N*-fluorocarbon NDI derivatives exhibit air-stable n-type mobilities as high as $0.1 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$, $I_{on}/I_{off} \approx 10^5$, and threshold voltages of approximately 20 V.[4f–h] However, while *N*-alkyl NDI derivatives exhibit comparable or superior electrical performance, they fail to operate in air, possibly because of the less densely packed hydrocarbon tails.[4f] While *N*-alkyl PDI films exhibit outstanding mobilities of approximately $0.6 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$, OFET performance again degrades in air,

DFH-4T   FTTTTF   NDI   PDI

chemical and optical data (Table 1) reveal further depression of the LUMO level of PDI-FCN$_2$ compared to PDI and PDI-CN$_2$, while TGA indicates quantitative sublimation.

For both cyanated PDI materials, a 1:1 mixture of isomers (cyanated at the 1,7 or 1,6 positions) is indicated by NMR spectroscopy, however this characteristic is found to be inconsequential for spectroscopic, electronic structural, and solid-state charge-transport properties (verified by measurements on the pure 1,7 isomer). Single crystals of PDI-FCN$_2$ were grown by sublimation, and the crystal structure (Figure 1) reveals a slightly twisted polycyclic core (torsion angle of about 5°) with slip-stacked face-to-face molecular packing and a minimum interplanar spacing of 3.40 Å.[8] This
devices exhibit very large threshold voltages of around 75 V, and these materials are not known to be solution processable.[4d,i,k] In all instances, the focus of this prior work has been synthetic modification solely of the *N*-substituents. In other studies, microwave conductivity measurements of 1,6,7,12-substituted PDI derivatives demonstrated that modulation of π–π overlap by twisting of the normally flat core can drastically affect carrier mobility;[4c] however, to date functionalization of the PDI core for OFET applications has gone unexplored. Herein we report two core-cyanated PDI derivatives, PDI-CN$_2$ and PDI-FCN$_2$, which exhibit the highest air-

stable n-type OFET carrier mobilities reported to date, in combination with low threshold voltages and substantial processing versatility.

The synthesis of PDI-CN$_2$ was reported elsewhere.[5] This compound exhibits excellent air-stability and solubility in organic solvents, while reduced pressure thermogravimetric analysis (TGA) scans indicate slight (about 2%) decomposition during sublimation. The low-energy LUMO indicated by the first reduction potential, −0.07 V versus the saturated calomel electrode (SCE),[5] suggests improved n-type charge-carrier stability over PDI (−0.43 V vs. SCE).[6,7] Moreover, the results with PDI-CN$_2$-derived OFETs (see below) motivated the synthesis of a new PDI derivative, PDI-FCN$_2$, with additional electron-withdrawing substituents and greater volatility. The new compound was synthesized using modifications of published core cyanation[5] and *N*-fluoroalkylation[4f,j] procedures, and was characterized by NMR spectroscopy, mass spectrometry, optical absorption spectroscopy, photoluminescence, cyclic voltammetry, thermogravimetric analysis, and single-crystal X-ray diffraction. The electro-

Figure 1. Crystal Structure of PDI-FCN$_2$. a) viewed along the unit cell diagonal, showing stacking relationships; fluoropropyl groups deleted for clarity. b) Viewed along the *ab* face diagonal, showing the segregation of arene and fluoroalkyl groups. Note the statistical disorder of the cyano substituents.[10]

motif allows considerable intermolecular π–π overlap, which results in good charge-transport properties (see below). The positions of the disordered cyano substituents suggests that this structural feature does not greatly affect packing.

Top-contact configuration OFETs were fabricated with vapor-deposited PDI films (10^{-6} Torr, 0.2 Å s^{-1} growth), and mobilities determined in the saturation regime by standard procedures.[3] The microstructures and mobilities of the vapor-deposited films are found to be sensitive to substrate temperature during growth (see Supporting Information[9]). Owing to the remarkable air-stability of these materials, all data presented herein were acquired under ambient atmosphere. PDI-CN$_2$-based OFETs display mobilities as high as 0.10 cm^{2}V^{-1}s^{-1}, threshold voltages of approximately 15 V,

and $I_{on}/I_{off}(+100\,V/0\,V) \approx 10^5$, while PDI-FCN$_2$ devices exhibit mobilities as high as $0.64\,cm^2\,V^{-1}\,s^{-1}$, threshold voltages between $-20\,V$ and $-30\,V$, and $I_{on}/I_{off}(+100\,V/-60\,V)$ as high as 10^4. Figure 2 shows current–voltage (I–V) characteristics between source and drain electrodes recorded at different gate biases (V_G) for OFETs of PDI-CN$_2$ and PDI-FCN$_2$ operating in ambient atmosphere. Given the similarities in first reduction potentials for PDI-CN$_2$ and PDI-FCN$_2$, the striking difference in threshold voltages is presumably due to variations in trap densities in the two materials. Devices stored and tested under ambient conditions exhibit negligible degradation in mobility, threshold voltage, or I_{on}/I_{off} over six months.

The microstructure of the vapor-deposited thin films was analyzed by X-ray diffraction (XRD), atomic force microscopy (AFM), and scanning electron microscopy (SEM), with XRD revealing d-spacings in highest-mobility devices of 17.9 Å for PDI-CN$_2$ and 20.3 Å for PDI-FCN$_2$. From a geometry-optimized, computed molecular length of 22.0 Å for PDI-CN$_2$[11] and a crystallographically determined length of 22.8 Å for PDI-FCN$_2$, tilt angles relative to the substrate normal of 55° for PDI-CN$_2$ and 62° for PDI-FCN$_2$ are estimated. These results suggest favorable molecular orientations for source-to-drain electrode charge transport.

AFM and SEM analysis of film morphology confirms polycrystalline topologies with ribbon-like grains (ca. 400–800 nm long, and ca. 100 nm wide).[9] Such large-grained polycrystalline features should promote charge-carrier mobility through efficient π–π intermolecular overlap and minimization of trap sites.[1c,12]

To investigate material versatility for various applications, preliminary studies on bottom-contact OFETs and solution-cast films were performed. Bottom-contact devices are found to display air-stable mobilities from 10^{-3}–$10^{-4}\,cm^2\,V^{-1}\,s^{-1}$. PDI-FCN$_2$ transistors, like many fluorinated organic semiconductors, require alkane thiol treatment of gold electrodes to better match surface energies at the metal/organic interface.[4g] PDI-CN$_2$ devices function without the aid of thiolated electrodes, retaining the ability of PDI to function on unmodified substrates.[4i] Top-contact devices fabricated from drip-cast films are also air-stable and exhibit mobilities of 10^{-3}–$10^{-5}\,cm^2\,V^{-1}\,s^{-1}$. In contrast, solution casting of high-quality films of PDI derivatives not having core functionalization is difficult owing to low solubility in common solvents. While the performance of the vapor-deposited top-contact devices is currently superior to the bottom-contact and solution-cast devices, efforts are being made to optimize device performance in these latter configurations.

One of the unique characteristics of the new PDI systems is the presence of significant charge-carrier densities at $V_G = 0\,V$. Thus, the OFET threshold voltages for these materials are at $V_G = -20\,V$ to $-30\,V$, with the absence of charge carriers then defining the "off" state at $-60\,V$, and classifying these devices as "always on" transistors.[13] This characteristic is documented for very electron-deficient materials, and often attributed to unintentional doping.[14] In some cases, the presence of charge carriers below $V_G = 0\,V$ can be reversed by exposure to an oxidant, and for our devices, I$_2$ vapor increases the threshold voltage to $> -5\,V$ and decreases the I_{SD} at $V_G = 0\,V$ by up to an order of magnitude. Further studies of the nature and origin of the charge carriers are currently underway.

It is thought that ambient stability in n-type organic semiconductors benefits from electron-withdrawing fluorinated substituents, which electronically stabilize the charge carriers as well as promote close packing through fluorocarbon self-segregation. Judging from the present redox potentials, the charge carriers are not expected to be stable with respect to gaseous O$_2$;[15] however, the close-packed fluorine functionalities may help provide a kinetic barrier to oxidation.[1c] The strategic cyanation of PDI produces air-stable N-fluoroalkyl and N-alkyl materials, the air stability presumably reflecting carrier stabilization in the very low-lying LUMOs.

In summary, we report a promising new class of solution processable, cyano-polycyclic n-type organic semiconductors with high carrier mobility and air-stable OFET operation. Notable properties of this family reflect a combination of functionality at the core and imide positions. The cyano functionalities provide solubility for solution processing and stability of n-type charge carriers by lowering the LUMO to resist ambient oxidation. The electron-withdrawing N-functionalities further aid charge carrier stability by further lowering the LUMO energies, but may also induce close molecular packing for increased intermolecular π overlap and

Communications

more efficient charge transport. With the rich chemistry for PDI functionalization available, these derivatives should prove informative for elucidating structure–function relationships in organic n-type electronics.

[8] Single crystals were grown by slow vacuum sublimation. Crystal size: 0.345 mm × 0.106 mm × 0.022 mm. Triclinic, $P\bar{1}$, $Z = 1$. Cell dimensions: $a = 5.2320(14)$, $b = 7.638(2)$, $c = 18.819(5)$ Å; $\alpha = 92.512(5)$, $\beta = 95.247(5)$, $\gamma = 104.730(4)°$, $V = 722.5(3)$ Å^3, $2\Theta_{max} = 57.54$, $\rho_{calcd} = 1.849$ g cm^{-3}. Of 6655 reflections, 3370 were independent ($R_{int} = 0.0967$), 272 parameters, $R1 = 0.0540$ (for reflections with $I > 2\sigma(I)$), $wR2 = 0.1258$ (for all reflections). All diffraction measurements were made on a Bruker SMART CCD diffractometer with graphite monochromated MoKα radiation. Data were collected at 153(2) K and the structure solved by direct methods using SHELXTL. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in idealized positions and not refined. Intensities were corrected for absorption. CCDC-247498 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

An Iridium Difluoroketene Complex: Synthesis and Isolation**

Joseph G. Cordaro, Herman van Halbeek, and Robert G. Bergman*

Dedicated to Professor John E. Bercaw on the occasion of his 60th birthday

Despite substantial research on the chemistry of ketenes, efforts to isolate or characterize the electron-deficient difluoroketene ($F_2C=C=O$) have met with little success.[1] While an early claim of the preparation of $F_2C=C=O$ exists,[2] attempts to repeat this synthesis were not success-

ful.[3] Difluoroketene has been generated transiently by zinc-induced dehalogenation of bromodifluoroacetyl halides, but its formation was only inferred from the isolation of a cycloaddition product with acetone and from the detection of CO and $F_2C=CF_2$, the presumed products of difluoroketene dissociation.[3] Experiments designed to trap [2+2] adducts of cyclopentadiene and fluorinated ketenes generated in situ were successful with methylfluoroketene, phenylfluoroketene, and trifluoromethylfluoroketene, but failed when attempted with difluoroketene.[4] Difluoroketene ethyl trimethylsilyl ketal, a masked variant of difluoroketene, has been employed in organic synthesis as a reagent for making fluoroorganic compounds.[5–7]

In 1998, the generation and IR characterization of difluoroketene in a CO_2-doped argon matrix at 30 K was reported.[8] This highly reactive ketene was also detected in the gas phase by mass spectrometry after ionization of perfluoromethylvinyl ether.[9] However, until now neither the free ketene nor its metal complexes have been obtained on a preparative scale. Herein we report that research on the electron-rich organometallic fragment [Cp*(PMe$_3$)Ir] (Cp* = η^5-C$_5$Me$_5$), has led to the discovery of an isolable difluoroketene complex.

Recently, we reported that upon heating a solution of [Cp*(PMe$_3$)Ir(H){C(O)CF$_3$}] (**1**) in C$_6$D$_6$ at 105 °C, [Cp*(PMe$_3$)Ir(CO)] (**2**) and CF$_3$H were generated in quantitative yield.[10] The proposed mechanism for this elimination involves CF$_3^-$ dissociation from **1** to give the intermediate ion pair **3** (scheme 1). Rapid proton transfer from the iridium carbonyl cation to the CF$_3^-$ ion yields the observed products (Scheme 1).[10] While investigating the mechanism of this transformation, we discovered two different base-induced elimination reactions from **1**.
Scheme 1. Proposed mechanism for CF$_3$H loss from **1**.

Upon vacuum transferring [D$_7$]DMF to an NMR tube containing **1** and a catalytic amount of potassium *tert*-butoxide (0.2 equiv) at −196 °C, only **2**, CF$_3$H, and potassium *tert*-butoxide were detected in quantitative yield, by NMR spectroscopy upon warming to 22 °C. Using [D$_8$]THF as solvent gave similar results. The proposed mechanism for this transformation involves rapid deprotonation of **1** to generate the potassium iridate **4**-K. Elimination of CF$_3^-$ from **4**-K followed by deprotonation of *tert*-butanol, produces **2** and CF$_3$H, which regenerates the base (Scheme 2). Treatment of **1** with a base which would irreversibly deprotonate it, gave an unexpected result.

Compound **1** and 1.4 equivalents of *tert*-butyllithium were dissolved in [D$_8$]THF at low temperature and the subsequent reaction was monitored by NMR spectroscopy as the solution was warmed from −80 to 22 °C. At −80 °C one major species,
Scheme 2. Deprotonation of **1** leading to **2** and difluoroketene adduct **5**.

assigned as the lithium iridate **4**-Li was detected in the ^{19}F NMR spectrum at $\delta = -69.2$ ppm and in the ^{31}P{^{1}H} NMR spectrum at $\delta = -39.9$ ppm. Upon warming, the chemical shifts of all intermediates shifted slightly upfield. At −13 °C only the acyl iridate **4**-Li was detected;[11] at −6 °C new products began to form. As the reaction mixture was warmed above 0 °C, elimination of CF$_3$Li gave iridium carbonyl **2**, and surprisingly, LiF elimination from **4**-Li furnished difluoroketene iridium adduct **5** in a 1:1 ratio (Scheme 2).

Isolation of the difluoroketene adduct **5** was by multiple precipitations and crystallizations from a mixture containing **2** and **5** in a solution of diethyl ether and pentane at −38 °C (ca. 30 %) yield).[12] As a solid at 22 °C under a N$_2$ atmosphere, the difluoroketene adduct **5** showed no signs of decomposition after two weeks. Heating a C$_6$D$_6$ solution of **5** at 75 °C resulted in slow decomposition to **2** and unidentifiable products which contained the {Cp*(PMe$_3$)Ir} fragment.

The characterization of **5** began with heteronuclear NMR spectroscopy experiments on the four NMR active nuclei. The ^{1}H NMR spectrum showed a singlet at $\delta = 1.75$ ppm for the Cp* ligand, and a doublet at $\delta = 1.01$ ppm with $^2J_{H,P} = 10.4$ Hz for the PMe$_3$ ligand. In the ^{19}F NMR spectrum, two inequivalent signals were observed in the region typical of fluorine atoms bound to a sp^2-hybridized carbon atoms. The signal at $\delta = -123.4$ ppm was coupled to both phosphorus and fluorine atoms to give a doublet of doublets with $^2J_{F,F} = 187$ Hz and $^3J_{F,P} = 33$ Hz. The more upfield signal at $\delta = -132.1$ ppm was coupled only to the other fluorine atom with $^2J_{F,F} = 188$ Hz. The ^{31}P{^{1}H} NMR spectrum showed the signals for the PMe$_3$ ligand as a doublet coupled to one fluorine atom at $\delta = -41.6$ ppm with $^3J_{P,F} = 33$ Hz. In the ^{13}C{^{1}H} NMR spectrum, only singlets for the methyl and quaternary carbon atoms of the Cp* ligand at $\delta = 10.0$ ppm and 96.1 ppm, respectively, and a doublet for the PMe$_3$ ligand at $\delta = 18.3$ ppm with $^2J_{C,P} = 42.3$ Hz were found.

The difluoroketene carbon atom signals of **5** were observed in a ^{19}F-detected 2D ^{19}F,^{13}C heteronuclear single- and multiple-bond correlation (HSMBC) experiment.[13,14] This NMR experiment revealed ^{13}C signals at $\delta = 178.0$ and 207.2 ppm, through correlation peaks with each of the ^{19}F signals (see Figure 1), mediated by $^1J_{C,F}$ (320–340 Hz) and $^2J_{C,F}$ (5–10 Hz), respectively. Specifically, the ^{19}F$_a$ signal at −123.4 ppm appeared as a ddd ($^1J_{F_a,C} = 344$, $^2J_{F_a,F_b} = 187$,
Figure 1. The 2D $^{19}F,^{13}C$ HSMBC spectrum of **5** in C_6D_6, recorded at 11.7 T and 19°C. (The 1D ^{19}F NMR spectrum of **5** is displayed at the top.) The HSMBC experiment was carried out using a Bruker Avance 500 spectrometer equipped with a 5 mm ($^1H,X,^{31}P$) triple-resonance probehead with an actively shielded z-gradient coil. The inner (^1H) coil was tuned to the ^{19}F frequency (470.6 MHz), and the outer (X) coil to the ^{13}C frequency (125.8 MHz). The experiment used a gradient-enhanced 2D HMBC pulse sequence without a low-pass filter, allowing for observation of both $^1J_{F,C}$ and $^2J_{F,C}$ mediated correlations in one experiment. No ^{13}C-decoupling was applied during the detection period. For further experimental conditions see ref. [19].

$^3J_{F_a,P} = 34$ Hz) in its correlation peak with the signal at 178.0 ppm, which therefore arises from the CF_2 carbon atom; and as a dd ($^2J_{F_a,F_b} = 187$, $^3J_{F_a,P} = 34$ Hz, $^2J_{F_a,C}$ unresolved, that is, < 10 Hz) in the cross peaks with the CO signal at $\delta = 207.2$ ppm. Analogously, the $^{19}F_b$ fluorine signal at $\delta = -132.1$ ppm appeared as a dd ($^1J_{F_b,C} = 327$, $^2J_{F_b,F_a} = 187$ Hz) in its cross peaks with the CF_2 signal, and as a doublet ($^2J_{F_b,F_a} = 187$ Hz; $^2J_{F_b,C}$ unresolved, that is, < 8 Hz,) in its correlation peaks with the CO signal. All four cross-peak patterns in the 2D spectrum are displaced by the $^2J_{F_a,F_b}$ coupling in both the ^{13}C and ^{19}F dimension. Reported ^{13}C NMR spectroscopic data for the η^2-(C,C) carbon atoms of related phenyl- and diphenylketene iridium complexes were significantly upfield from these values.[15] The downfield resonances for the η^2-(C,C) carbon atoms are likely a result of the deshielding effects of the fluorine atoms.

Solid-state ZnSe attenuated total reflectance (ATR) FTIR spectroscopy of difluoroketene **5** showed strong bands at 1725, 1172, 954, 938, and 837 cm^{-1}. Medium to weak bands were recorded at 1424, 1384, and 1287 cm^{-1}. Using X-ray analysis and isotopic ^{18}O and ^{13}C labeling, Grotjahn and co-workers showed that the IR absorptions for a series of six bisphosphine chloro-iridium and rhodium ketene complexes were dependent on the coordination mode.[15] When the ketene was coordinated through the carbonyl C–O bond an intense IR band, assigned to the C=O stretch, was found between 1632 and 1651 cm^{-1}. Alternatively, when the ketene

was coordinated through the C–C bond, a strong absorption was located between 1728 and 1802 cm^{-1}. Based on these data and the absorption at 1725 cm^{-1} for **5**, the coordination mode of our difluoroketene **5** was inferred to be η^2-(C,C).

Pale yellow pyramidal crystals suitable for X-ray analysis were grown from a concentrated solution of difluoroketene **5** in diethyl ether at −38°C. The ketene adduct crystallized in the C2/c space group with one molecule in the asymmetric unit.[16] Coordination of the difluoroketene to iridium was confirmed to be η^2-(C,C) (Figure 2). An unusually short C–O
Figure 2. ORTEP diagram of **5** (thermal ellipsoids set at 50% probability). Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ir-C11 1.799(9), Ir-C12 1.994(10), Ir-P 2.256(2), C12-F2 1.37(1), C12-F1 1.39(1), C12-C11 1.38(1), C11-O 1.11(1); P-Ir-C11 92.9(3), P-Ir-C12 91.1(3), Ir-C12-C11 61.3(5), Ir-C11-C12 76.6(6), C12-Ir-C11 42.1(4), F2-C12-C11 117.2(9), F1-C12-C11 124.1(8), F1-C12-F2 103.3(8), O-C11-C12 138(1), Ir-C11-O 143.9(9).

bond of 1.11(1) Å for **5** compared to other iridium and rhodium η^2-(C,C)-bound ketene complexes suggests that back-donation from the metal center to the ketene does not elongate the C–O bond.[15,17] However, shorter Ir–C and C–C bonds were also measured, which indicate that the difluoroketene binds more closely than diphenyl- or phenylketene to iridium.[18]

Overall loss of fluoride rather than the CF_3^- ion, when tert-butyllithium is used as the base to deprotonate **1**, may be attributed to reversible CF_3^- loss from iridate **4**. When **1** is deprotonated with KOtBu to give iridate **4-K** and HOtBu, CF_3^- loss followed by protonation to yield CF_3H and **2** is irreversible. However, in the absence of a proton source, F$^-$ loss becomes competitive with CF_3^- loss to give **5** (Scheme 2). Unfortunately, attempts to increase the yield of **5** by adding reagents which might assist in fluoride elimination were unsuccessful.

Difluoroketene iridium complex **5** joins an important group of complexes containing reactive organic fragments that are stabilized by coordination to transition-metal centers. The robust character of adduct **5** is attributed to the donating ability of the electron-rich organometallic fragment that coordinates to the electron-deficient difluoroketene. To our knowledge, this is the first example of a dihaloketene complex and the only structural data available for the difluoroketene fragment in any form.

[11] This intermediate could be trapped with the electrophile MeI, to generate the methyl acyl compound $[Cp*(PMe_3)Ir(Me)\{C(O)CF_3\}]$, see ref. [10].

[12] The synthesis of **5** was achieved on a larger scale as follows: A 250-mL thick-walled, resealable flask equipped with a stir bar was charged with **1** (125 mg, 0.25 mmol) and *tert*-butyllithium (22 mg, 0.35 mmol, recrystallized from pentane at $-38\,°C$ until white). The flask was attached to a vacuum manifold and cooled to $-196\,°C$. THF (10 mL) was vacuum transferred from Na/benzophenone into the flask. The frozen reaction mixture was warmed to $-78\,°C$ and then allowed to warm to room temperature over 15 h. The volatile materials were removed in vacuo to give a reddish-brown residue. Analysis of the crude reaction mixture by NMR spectroscopy revealed a 1:1 mixture of difluoroketene adduct **5** and iridium carbonyl **2** with a small amount of **1**. In a N_2 filled glove box, the crude material was filtered through a pad of silica gel on a medium-pore fitted glass frit eluting with diethyl ether. The resulting orange solution was concentrated in vacuo to 1 mL, layered with pentane, and allowed to stand at $-38\,°C$ for crystallization. Dark reddish-brown clusters of crystals grew after 1 week. The mother liquor was removed by pipette and the solid was washed with pentane. Excess solvent was removed under reduced pressure. Yield: 38 mg (32%) EI HRMS: *m/z* calcd for $C_{15}H_{24}F_2OPIr$ 482.1162 $[M]^+$; found 482.1152.

Polymer–Monomer Pairs as a Reaction System for the Synthesis of Magnetic Fe_3O_4–Polymer Hybrid Hollow Nanospheres**

Yin Ding, Yong Hu, Xiqun Jiang,* Leyang Zhang, and Changzheng Yang

Recently, hollow spheres have attracted increasing interest because of their application in drug delivery,[1–3] cell and enzyme transplantation,[4] gene therapy,[5] separation in biomedicine, and as contrast agents in diagnostics.[6,7] Despite significant advances in the preparation of hollow inorganic or polymeric spheres,[8–11] the construction of nanosized hybrid hollow spheres with both inorganic component and organic polymers as the shells remains a major challenge. Currently, a widely used approach for the synthesis of hybrid micro or submicron hollow spheres is the core-template-based strategy in which the inorganic components are coated on the polymer particles by sol–gel chemistry[12] or layer-by-layer deposition.[13] One advantage of such an approach is that the thickness of the coating layers is controllable. Although successful in the preparation of hollow hybrid spheres, the core-template-based approach faces limitations involving the selection in core composition and nanosized core templates. Furthermore, the core must be removed to create the hollow center. Hence, a core-template-free strategy for the production of hollow hybrid spheres is of particular interest. Previous efforts towards the preparation of hollow hybrid spheres with micrometer dimensions and in the absence of a core template include the assembly of inorganic nanoparticles into hollow spheres by using block copolymers,[14] the

assembly of positively charged polyelectrolytes and negatively charged inorganic nanoparticles,[15] and liquid-phase deposition of inorganic nanoparticles on polymeric capsules.[16] In previous work,[17] we introduced a core-template-free approach to construct nanosized hollow polymeric spheres. The basis of this approach is that the reaction system is composed of water-soluble polymer–monomer pairs containing a cationic polymer and an anionic monomer. Depending on their concentration in aqueous solution, such polymer–monomer pairs can self-assemble to form micelles through electrostatic interactions, and hollow polymeric nanospheres are obtained by the polymerization of the anionic monomers inside the micelles.

As a significant advance in attempts to produce inorganic–organic hybrid hollow nanospheres, we present herein a robust, core-template-free method to prepare magnetic hollow Fe_3O_4–polymer hybrid nanospheres in completely aqueous solution. The preparation procedure is schematically illustrated in Scheme 1. We selected chitosan (CS), which bears amino groups, as the cationic polymer and acrylic acid (AA), which bears acid groups, as the anionic monomer. The CS and AA polymer–monomer pair and Fe_3O_4 nanoparticles stabilized by poly(vinyl alcohol) (PVA) were mixed and formed micelles loaded with Fe_3O_4 nanoparticles; the cores consist of the polyionic complexes of CS and AA (i.e. positively charged protonated CS chains and negatively charged dissociated AA) and the shells consist of protonated CS chains. The formation of CS–AA micelles was confirmed by fluorescent probe, dynamic light scattering (DLS), and transmission electron microscopy (TEM).[17] Initiation of the polymerization of AA with potassium persulfate ($K_2S_2O_8$) followed by cross-linking of the shells with glutaraldehyde (GA) at the end of polymerization led to the formation of magnetic hollow Fe_3O_4–polymer hybrid nanospheres.

The size and morphology of the hybrid spheres were investigated by DLS in aqueous solution, and by TEM and magnetic force microscopy (MFM) in the solid state. The mean-number-average hydrodynamic diameter (D_h) for the synthesized hybrid spheres in aqueous solution was measured to be 76 ± 6.1 nm by DLS and the zeta potential to be 35 ± 2.6 mV by electrophoretic light scattering, suggesting that chitosan molecules with ionized amino groups are at the outermost layer of the hybrid spheres. Figure 1 shows representative TEM images of the synthetic materials. After the addition of Fe_3O_4 nanoparticles (4–6 nm in size) into an aqueous solution of CS–AA followed by polymerization of AA and selective cross-linking of CS at the end of polymerization, spheres with incorporated Fe_3O_4 nanoparticles were formed (Figure 1a). The average diameter of such a structure is 58 ± 11 nm, smaller than that determined by DLS in
Figure 1. a) Direct-view TEM image of the synthesized Fe_3O_4–polymer hybrid nanospheres; b) and c) Direct-view HRTEM images of the synthesized Fe_3O_4–polymer hybrid nanospheres; d) Cut-section TEM image of the Fe_3O_4–polymer hybrid nanospheres after microtomy at room temperature.

aqueous solution as a result of the sample being dry for TEM analysis. The electron-diffraction pattern recorded from these spheres confirms that magnetite nanoparticles with a minor amount of Fe_2O_3 were loaded into the nanospheres. A salient feature of Figure 1a is that these nanospheres have an intense dark circle within the shells of the spheres and dark spots at the surface of some spheres, which suggests that the distribution of the Fe_3O_4 nanoparticles is not concentrated in the core of the spheres. This is confirmed by high-resolution transmission electron microscopy (HRTEM) observation (Figure 1b,c). The lattice fringe planes of Fe_3O_4 nanoparticles arranged in the dark stripe region, indicative of the crystalline region of the Fe_3O_4 particles, are clearly observed inside the shell of the spheres or at the surface of the spheres. The size of the lattice fringe planes of individual Fe_3O_4 nanoparticles is estimated to be 4–6 nm, which corresponds well to the size of Fe_3O_4 nanoparticles used. The occurrence of Fe_3O_4 nanoparticles in the inner shell of the spheres indicates that the magnetic nanoparticles are trapped inside the micelles before polymerization by the interaction of AA and PVA attached to the Fe_3O_4 nanoparticles, as verified by FTIR. The presence of the magnetic nanoparticles the surface of the spheres suggests
Scheme 1. Illustration of the preparation process of hollow hybrid nanospheres.

that partial adsorption of Fe_3O_4 nanoparticles onto the spheres occurs during the reaction process. The most interesting feature of these nanospheres is their hollow interior, as revealed by the TEM image in Figure 1 d obtained by microtomy of a hybrid nanosphere sample at room temperature which had been prepared by depositing hybrid nanospheres on a polyimide sheet followed by embedding in epoxy resin. The image shows the rings of sectioned spheres and the cavity in the interior, thus providing compelling evidence for a hollow sphere structure. Although the Fe_3O_4 nanoparticles are too small to be distinguished, elemental analysis (energy-dispersive spectrometer) provides evidence for the existence of Fe_3O_4 nanoparticles in the hollow spheres.

MFM imaging provides further evidence for the morphology of the hollow hybrid nanospheres and the distribution of magnetite nanoparticles in the nanospheres. As seen from the atomic force microscopy (AFM) image in Figure 2 a, the hybrid nanospheres appear as intact spheres with an average height of 12 ± 2.5 nm and an average width of 47 ± 6.6 nm. In the MFM image (Figure 2 b), a significant magnetic signal
Figure 2. a) AFM and b) MFM images of hollow Fe_3O_4–polymer hybrid nanospheres. Vertical scales (from dark to bright): 0 to 15 nm and $-160°$ to $-206°$, respectively.

from the hollow hybrid nanospheres is detected. The rings, which correspond exactly to the positions of spheres in the AFM image, have diameters of 52 ± 4 nm; the thickness of the circular shells is 15 ± 2 nm. No magnetic signal in the center of the spheres is detected. Moreover, in an additional control experiment, no bright ring was detected in the MFM analysis of Fe_3O_4-free hollow chitosan–poly(acrylic acid) nanospheres. This result indicates again that the magnetite nanoparticles are distributed in the shell wall of the hollow hybrid nanospheres.

We now turn to the formation of the hollow Fe_3O_4–polymer nanospheres. Based on the pK_a values of 4.26 for AA and 4.8 for poly(acrylic acid) (PAA),[18] the conversion of AA monomers inside the micelles into PAA results in some dissociated carboxylic groups becoming protonated carboxylic groups. The original micellar core comprised of positively charged protonated CS and negatively charged dissociated AA gradually disintegrates owing to the polymerization of AA. On the other hand, the residual dissociated carboxylic groups in the produced PAA will interact with the protonated amino groups in CS to form water-insoluble polyelectrolyte complexes between CS and PAA, which causes a decrease in the size of the micelles, as determined by DLS.[17] This process

experiences two kinds of force: The electrostatic attraction between CS and PAA shrinks the spheres, whereas the electrostatic repulsion from the shell tends to expand the spheres. The equilibrium between the two opposing forces results in the formation of the cavity in the center of the nanospheres, with CS–PAA polyelectrolyte complexes as the inner shell and protonated CS chains as the outer shell. As PVA attached to the Fe_3O_4 nanoparticles interacts with PAA by hydrogen bonding (as revealed by the shift of the carbonyl absorption band of PAA from 1753 to 1713 cm^{-1} in FTIR measurements), the Fe_3O_4 nanoparticles should occur in the inner shell where polyelectrolyte complexes between CS and PAA exist. This is confirmed by the TEM image shown in Figure 1 b.

The hollow hybrid nanospheres were calcined as part of our efforts to use these materials. The polymers were removed at elevated temperatures (550°C) under argon for 1 h to afford the completely hollow inorganic nanospheres (Figure 3). The electron-diffraction pattern confirms that these hollow inorganic nanospheres are composed of Fe_3O_4. The diameter and wall thickness of these hollow Fe_3O_4
Figure 3. TEM image of hollow Fe_3O_4 nanospheres produced by calcination of hollow Fe_3O_4–polymer hybrid nanospheres.

nanospheres are 20 ± 2 nm and 5 ± 1 nm, respectively, which are much smaller than those of uncalcined hollow hybrid spheres. Apparently, the hollow Fe_3O_4 nanospheres undergo significant shrinkage during the formation. In contrast to the shrinkage rate (below 30%)[8] of hollow inorganic spheres prepared by colloidal templates, the shrinkage rate is more than 50% in our case. This may be due to the hollow interior of synthesized hybrid nanospheres and the distribution of Fe_3O_4 nanoparticles in the walls of hybrid nanospheres not being compact. Furthermore, the low polydispersity in the size of the hollow Fe_3O_4 nanospheres can be considered as indirect evidence that the synthesized hollow hybrid nanospheres have a relatively uniform size.

In summary, we have illustrated a successful synthesis of hollow Fe_3O_4–polymer hybrid nanospheres by the addition of Fe_3O_4 nanoparticles to an aqueous solution of polymer–monomer pairs composed of the cationic polymer CS and the anionic monomer AA, followed by polymerization of AA and selective crosslinking of CS at the end of polymerization. The process is simple and allows the large-scale preparation of the nanospheres. There is also the possibility of extending this approach to other systems that involve different inorganic nanoparticles and different polymer–monomer pairs.

nisms.[1] Application of such methods to the modification of biomolecules opens interesting new avenues for investigation, with a plethora of potential applications for the end products. In this context, we have focused our efforts on the understanding and development of Pd-catalyzed reactions of nucleosides because these compounds display some unusual reactivities that are often not comparable to simpler molecules. Our contributions to Pd-catalyzed C−N bond formation reactions, as well as the contributions of others, have led to the synthesis of unusual nucleosides that contain entities appended to the exocyclic amino groups of 2′-deoxyadenosine, 2′-deoxyguanosine, and C-8 aryl aminonucleosides.[2–4] Unnatural nucleosides have long since held interest as novel pharmacophores and as probes of biofunction. These types of applications provide added importance to newer methods that lead to modification of nucleosides. For the synthesis of N^6-aryl 2′-deoxyadenosine analogues, the readily available C-6 bromonucleoside **1** has been the substrate of choice, whereas the O^6-benzyl-2-bromonucleoside **2** has been used for the synthesis of N^2-modified 2′-deoxyguanosine derivatives.[4] Although the O^6-arylsulfonate derivatives of purine nucleosides, and particularly those of guanine, are readily available (**3a–c** in Figure 1),[5] the utility of these compounds in Pd-catalyzed transformations has not been explored to date. Purine arylsulfonates, on the other hand, have been used for nucleophilic (S_NAr) displacement chemistry.[5–7] By and large, direct displacement of leaving groups at the C-6 position of purines is possible with good nucleophiles, and amination reactions have been conducted with alkyl amines.[7] There are not many examples of direct displacement reactions with aryl amines, and recently a few examples with bromonucleosides were reported.[8] Among simpler aromatic systems, Pd-catalyzed amination reactions of arene arylsulfonates have been reported recently,[9, 10] and herein we report the first such studies that involve arylsulfonates of nucleosides.

From our recent studies on the Suzuki–Miyaura reactions of **3a**, it was clear that insertion of Pd into the C−sulfonate bond would occur quite readily.[11] However, experience with amination reactions of **1** suggested that the product turnover could highly depend on the nature of the ligand.[3] Therefore, two lines of investigation were initiated: One investigation

was directed towards the determination of conditions that lead to optimal coupling results, whereas the second involved an evaluation of the influence of the sulfonate group on these reactions. For this purpose, sulfonates **3a–c**, which differ in steric factors, were synthesized by known methods.

The supporting ligands chosen for this initial analysis are shown in Figure 2.[12] The choice of these ligands originated from various results that we obtained in previous amination
Figure 2. The ligands that were screened for the amination reactions. Cy = cyclohexyl.

reactions of nucleosides. So far, **L1** and **L4** had been successful for aminations, and **L2** was chosen based upon bite-angle considerations relative to **L1** (**L2** has a bite angle of 110° relative to 93° for **L1**).[13] **L3** has been the preferred ligand for C−C bond-forming reactions of nucleosides and bears the core structure of **L4** and **L5**, a factor that may be useful in an analysis of the structural elements of ligands that can be used for these amination reactions. However, **L3** has so far not been very useful for amination reactions of nucleosides. **L6** and **L7** had not been tested for reactions of nucleosides and were chosen because they contain (Cy)₂P moieties bound to the metal, a factor that we have previously found to be important among the biphenyl-based phosphanes (*tert*-butyl groups in place of cyclohexyl (Cy) groups render the ligands ineffective for amination).[2b]

The representative aryl amine chosen for the optimization experiments was 4-toluidine, and a Pd(OAc)₂/ligand ratio of 1:3 was employed. Based upon our experience with the C−C cross-coupling reaction, sulfonate **3a** was selected for the initial experiments.[11] Parameters that were varied include the ligand, the solvent, and the base; the results of these experiments are summarized in entries 1–6 of Table 1. Certain interesting observations emerge from the data in Table 1. From entries 1 and 2, it becomes apparent that the

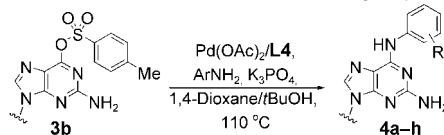
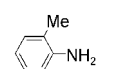
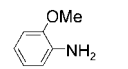
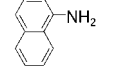
[a] Reaction conditions: **3** (0.1 M in the respective solvent), aryl amine (2.0 equiv), Pd(OAc)$_2$ (10 mol%), **L** (30 mol%), base (1.5 equiv), 110°C. [b] Disappearance of the sulfonate was monitored by tlc. [c] Yields reported are of isolated and purified **4a**. [d] The sulfonate was consumed, but an insignificant amount of product formed. [e] The product was impure after chromatography. [f] The sulfonate was still present in the reaction mixture, and an insignificant amount of product formed.

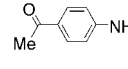
solvent has a significant influence on the reaction which involves **L1** as the ligand. However, this does not appear to be the case with **L4** as the difference in the yields in entries 5 and 6 is only marginal, with the combination of **L4**/K_3PO_4 in 1,4-dioxane producing a faster reaction. **L1** and **L2** produced comparable results which indicate that a change in the bite angle of the ligand does not seem to significantly alter the coupling. As expected, **L3** was ineffective which is consistent with previous aminations at the C-6 position of purine nucleosides.[2b]

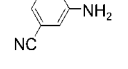
As a reasonable set of reaction parameters had been obtained, the coupling efficiency of the sulfonate **3b** was next studied. Interestingly, this less-hindered sulfonate substrate gave a 10% increase in the yield of **4a** within 30 min (entry 7). Another factor was the importance of tBuOH for the aryl amination; this presented a critical deviation from the amination of simpler arene arylsulfonates. It has been reported that tBuOH is necessary for the amination reaction and reactions in 1,4-dioxane or toluene were very slow.[9] This was not the case here, and although the addition of tBuOH appeared to provide a marginal improvement in yield and product quality, reactions in its presence or absence proceeded rapidly (entries 7 and 8).[14] For this reason, all subsequent reactions were conducted in a mixture of 5:1 1,4-dioxane/tBuOH.


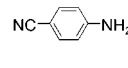


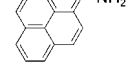












Reaction of the hindered tri(isopropyl)benzenesulfonate **3c** yielded another insight into a plausible steric effect. With this substrate, no product was recovered after 30 min although the sulfonate was consumed (entry 9): This apparently implies that product turnover diminishes with increased alkyl substitution proximal to the sessile C–O bond. With **L5** as the ligand, **4a** was furnished in a yield that was comparable to the yield obtained with **L4**, but the quality of the product was lowered (entry 10). Use of Pd$_2$(dba)$_3$

(5 mol%) and **L5** (30 mol%) led to a significant amount of unconverted **3b** even after 5 h. The use of ligands **L6** and **L7** did not provide any product from the amination step although **3b** was completely consumed in one case. In two cases (entries 2 and 9) in which consumption of the sulfonate occurred and very little product formation was observed, the ^{1}H NMR spectra of the reaction mixtures were analyzed. In both cases, formation of some product (also discernable by tlc) and nucleosidic resonances for another uncharacterized compound were observed. However, no starting material was present as resonances that correspond to the arylsulfonate unit had completely disappeared. No further attempt was made at determining what course these reactions had taken. Finally, to ascertain whether any product formation occurred through a S$_N$Ar displacement mechanism, **3b** was treated with 4-toluidine in the absence of Pd(OAc)$_2$ in the reaction mixture. After 24 h at 110°C, a 12% yield of highly impure **4a** was obtained which clearly indicates that under these conditions, the metal-catalyzed process is the significant contributor to the amination reaction.

These experiments provided a basis for a more detailed analysis of the scope of the amination reaction with respect to the steric and electronic nature of the aryl amine component as well as different catalyst and ligand concentrations. Thus, a series of experiments were conducted using several aryl amines in the presence of different ratios of ligand/Pd. Table 2 provides some interesting insight into these amination reactions. At a catalyst load of 10 mol% Pd(OAc)$_2$ and 30 mol% **L4**, all of the amines that were studied reacted smoothly within 30 min to afford the N^6-aryl-2,6-diaminopurine nucleosides **4a–h**. The electron-deficient amines provided high yields, and the yields obtained with 4-toluidine, 1-naphthylamine, and 2-anisidine were also very good. A lower yield in the reaction of the sterically encumbered 2-toluidine (entry 2) was observed relative to that observed for 4-toluidine (entry 1): this is consistent with a steric influence and is reasonable when the yields obtained with 2-anisidine are also considered (entry 3). Upon lowering the catalyst loading to 5 mol% Pd(OAc)$_2$ and 15 mol% **L4**, the unhindered, electron-deficient amines and 4-toluidine again provided good (although slightly lower) yields. However, a dramatic effect was seen with the *ortho*-substituted amines and 1-naphthylamine (entries 2–4). In these cases, the reactions were incomplete which is consistent with a steric influence. The yield with 2-toluidine was significantly lower than that with the sterically less-hindered 2-anisidine. With 5 mol% Pd(OAc)$_2$ and 30 mol% **L4** (1:6 Pd/ligand), some other differences emerged. All of the reactions, with the

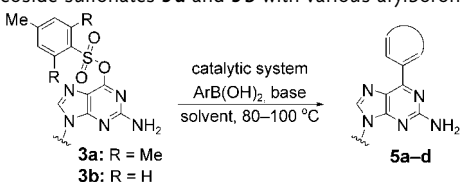
[a] General reaction conditions: **3b** (0.1 M in 5:1 1,4-dioxane/tBuOH), aryl amine (2.0 equiv), K$_3$PO$_4$ (1.5 equiv), 110 °C. [b] Conditions: A: Pd(OAc)$_2$ (10 mol%), **L4** (30 mol%); B: Pd(OAc)$_2$ (5 mol%), **L4** (15 mol%); C: Pd(OAc)$_2$ (5 mol%), **L4** (30 mol%). [c] Disappearance of **3b** was monitored by tlc. [d] Yields reported are of isolated and purified **4a–h**. [e] Incomplete reaction.

exception of 2-toluidine, proceeded to completion with yields that were comparable to those obtained when a higher loading of Pd was used. Therefore, these results suggest that with the exception of highly sterically congested *ortho*-substituted aryl amines, which require 10-mol% Pd(OAc)$_2$, most reactions run successfully at 5-mol% Pd(OAc)$_2$ as long as the ratio of Pd/**L4** ratio is ≈ 1:6. Finally, two reactions of **3b** and 4-toluidine were conducted at 10 and 5 mol% Pd(PPh$_3$)$_4$ in 1,4-dioxane and 1,4-dioxane/*tert*-BuOH, respectively. Both reactions were complete within 30 min to provide a yield of 78–84% of **4a**. In contrast, even with 10 mol% Pd(PPh$_3$)$_4$, the amination of bromonucleoside **1** with 4-toluidine was incomplete after 5 h under the reaction conditions described here and those described previously.[2a] Currently, complexes of **L4**/Pd appear to be generally good for amination reactions of nucleosides.


In light of the results of the amination studies, we reanalyzed the C–C cross-coupling reaction of **3a** and **3b**. In our earlier report on the Suzuki–Miyaura cross-coupling
reaction using **L3**/Pd, **3a** was extensively studied and proved to be a generally good substrate, but one reaction with **3b** indicated that it might be comparable or superior to **3a**, whereas **3c** had again proven less useful.[11] Therefore, the reactions of **3a** and **3b** with selected arylboronic acids were tested in the presence of Pd(OAc)$_2$/**L3** as well as Pd(PPh$_3$)$_4$, which has also found utility for such reactions, under conditions that were previously reported.[11,15] The results of these experiments are summarized in Table 3.

In the presence of 5 mol% Pd(PPh$_3$)$_4$ and K$_2$CO$_3$ in toluene,[15] the reaction of phenylboronic acid with **3b** was incomplete after 5 h; upon prolonged treatment (overnight), **5a** was obtained in 48% yield (entry 1). The replacement of K$_2$CO$_3$ with K$_3$PO$_4$ gave significantly superior yields with a decreased reaction time (entry 2). Little improvement was observed upon increasing the Pd(PPh$_3$)$_4$ load to 10 mol% in 1,4-dioxane (entry 3). However, all of the subsequent reactions were performed at the higher load for comparison with our previous reaction conditions.[11] All of the reactions of **3a** and **3b** gave good yields of the product (Table 3, entries 2–6), but **3a** appeared to be a better substrate. A similar trend was seen for reactions with 2-ethoxyphenylboronic acid (entries 7–10). Reaction of the electron-deficient 4-acetylphenylboronic acid with **3b** produced **5c** in 45% yield (entry 11) with a prolonged reaction time. On the other hand, with sulfonate **3a** the reaction was incomplete (entry 13). This is consistent with previous reports in which electron-deficient arylboronic acids gave low yields of the cross-coupled product with the Pd(PPh$_3$)$_4$ catalytic system.[16] Both **3a** and **3b** gave a comparable yield of the product in the presence of Pd(OAc)$_2$, **L3**, and K$_3$PO$_4$ (entries 12 and 14).[11] With 3-thienylboronic acid, good recoveries of the product were generally observed (entries 15–18), and Pd(PPh$_3$)$_4$ was somewhat superior to Pd(OAc)$_2$/**L3** despite the longer reaction times required and incomplete reaction observed with **3a** (entry 17). The results summarized in Table 3 also show that both **3a** and **3b** can be used for C–C bond-formation reactions, and that the Pd(OAc)$_2$/**L3** system is applicable with a variety of arylboronic acids.

Certain details on the nature of the catalytic systems warrant comment. The Pd(PPh$_3$)$_4$ catalyst shows applicability

for C–C bond-formation reactions and despite low yields with electron-deficient arylboronic acids, it can provide good to high yields when, in combination with K₃PO₄, other boronic acids are used. On the other hand, the biphenylphosphane-based catalysts appear to be more-broadly applicable, but they show some interesting differences. From the results presented in Table 1 and in our previous studies,[2] **L3** appears to be ineffective for the formation of C–N bonds at the C-6 position of purine nucleosides, whereas both **L4** and **L5** produce effective catalysts. However, **L3** is an effective ligand for C–C cross-coupling reactions.[2b, 11] This leads us to speculate about the nature of the ligand–Pd interactions that may contribute to these two different reactions with the same substrate. With **L3**, an intramolecular η¹-arene coordination of the metal has been observed at room temperature.[17] Such interactions or plausible cyclopalladation of the biphenyl entity, as has been reported with the di(*tert*-butyl) analogue,[18] could perhaps provide an active catalyst for the formation of C–C bonds but not for C–N bonds. The prevention of cyclopalladation either through hemilabile heteroatom coordination to the metal in **L4** or the simple blockage of cyclopalladation centers in **L5** could lead to different types of non-cyclopalladated ligand–Pd complexes that display activity for C–N bond-formation reactions.

In summary, we have shown for the first time that an easily prepared arylsulfonate derivative of 2′-deoxyguanosine can be effectively utilized for Pd-catalyzed amination reactions with aryl amines to lead to N^6-aryl-2,6-diaminopurine nucleoside analogues. Furthermore, the results from our studies on amination and C–C cross-coupling reactions seem to indicate a delicate interplay between the nature of the ligand, the substituents on the arylsulfonate, as well as the type of reaction that is conducted, all of which contribute to the success of these reactions.

In Situ Magnetic Resonance Investigation of Styrene Oxidation over TS-1 Zeolites**

Jianqin Zhuang, Gang Yang, Ding Ma, Xijie Lan,
Xiumei Liu, Xiuwen Han, Xinhe Bao,* and
Ulrich Mueller*

As an efficient catalyst for the selective oxidation of various organic substrates,[1] the titanium molecular sieve TS-1 has shown great potential in industry, as it is also environmentally benign. Over the past few decades, the synthesis of TS-1 as well as novel reactions based on it, including the mechanisms of these reactions, have attracted the attention of many researchers from experimental and computational fields.[1–6]

For example, with aqueous H_2O_2 as the oxidant, alkenes are converted into epoxides with high efficiency under mild conditions. With FTIR spectroscopy, Frei and Lin observed the TiOOH species that was determined to be the active site in the oxidation of small olefins.[6] When the reaction was extended to styrene, however, the main product was phenylacetaldehyde (PADH), and only a small amount of epoxide was obtained.[1c,3] Accompanying by-products included benzaldehyde (BADH) from cleavage of the C–C bond and 1-phenyl-1,2-ethanediol (DIOL) from hydrolysis in the presence of water.[3b] Some reports claimed that a synergic effect of TiOOH and a polar solvent (such as water) provided an acidic environment and thus promoted the isomerization or hydrolysis of styrene epoxide.[3,4] However, contrary opinions have been voiced based on the fact that the rearrangement of styrene epoxide is difficult owing to its high stability under the reaction conditions.[5] The oxidation of styrene may instead proceed by a radical mechanism with help from the aromatic π ring. Therefore, PADH might be obtained directly from

styrene, with the formation of styrene epoxide being a competitive process. Kumar et al. used EPR spectroscopy to observe the formation of Ti–superoxo radicals in TS-1 catalysts upon contact with H_2O_2 or urea–hydroperoxide (UHP). The key site was determined to be a Ti–superoxo species such as TiOOH or TiOO·.[4a,6] However, there was no direct evidence for how PADH and styrene epoxide were formed, and the overall reaction is still far from being understood.

In the present work, in situ NMR spectroscopy, one of the most powerful tools for the study of catalytic mechanisms,[7–9] was applied to study the oxidation of styrene over TS-1 zeolites with UHP. The role of the Brønsted acidic sites, the catalytically active sites, and the intermediates of PADH formation were investigated. To supplement the NMR data, EPR spectroscopy was also used. This technique is very sensitive to paramagnetic species with one or more unpaired electrons, and enables the detection of even small amounts of the active sites or reaction intermediates. Through the combination of density functional theory with the gauge-invariant atomic orbital (GIAO) method, the ^{13}C chemical shifts of some key products were calculated. Then, a mechanism for the overall reaction was proposed and verified by subsequent density functional calculations.

Two kinds of TS-1 zeolite samples were used in the study: one without Brønsted acidity (sample **A**) and one with Brønsted acidity (sample **B**). The acidity was confirmed by ^{31}P MAS NMR spectroscopy with trimethylphosphane (TMP) as the probe (see the Supporting Information). When β-^{13}C-enriched styrene was adsorbed on sample **A**, two peaks centered at $\delta = 113.2$ and 128.0–140.0 ppm were observed (Figure 1 A). These peaks correspond to the β carbon atom and the other carbon atoms in styrene, respectively. When styrene was adsorbed on premixed UHP and sample **A**, the conversion of styrene can be observed (Figure 1 B). In addition to the signals of the reactant, two narrow peaks centered at $\delta = 50.2$ and 102.2 ppm appeared. The former is a typical signal for the β carbon atom of styrene epoxide, which is formed by the epoxidation of styrene with UHP.[4a,10] The latter signal is in the range for O-C-O species and assigned to a hemiacetal species **1** bound to framework Ti species of the zeolite. The local structure of the hemiacetal species was optimized by density functional calculations, and then the ^{13}C chemical shift was computed by the GIAO method (see the Supporting Information). The calculated chemical shift of this species is $\delta = 102.7$ ppm, in agreement with the experimental value of $\delta = 102.2$ ppm. In addition, a broad peak at $\delta = 64.0$–68.0 ppm appeared, which can be assigned to a glycol species bound to the framework Ti species. This assumption was confirmed by calculation of the chemical shift at $\delta = 64.7$ ppm for the corresponding structure **2** (see the Supporting Information).
When the sample was heated at 313 K after adsorption, the intensity of the signal for the hemiacetal species increased at the expense of that of styrene (Figure 1 C, D). Meanwhile, the intensity of the signal for the styrene epoxide decreased slightly and, at the same time, a broad peak at $\delta = 64.0$–68.0 ppm appeared. In addition there were two other new peaks: one centered at $\delta = 163.2$ ppm is ascribed to formic acid, arising from further oxidation of styrene, and one at $\delta = 87.0$ ppm is due to an alkoxy group, whose nature needs further investigation. It is important that no signal at $\delta = 200$ ppm corresponding to PADH, the dominant product for styrene oxidation with aqueous H_2O_2, was detected.

Based on these results, it is clear that, with UHP as the oxidant, styrene was mainly converted into the hemiacetal species when catalyzed by TS-1 zeolite without Brønsted acid sites. On the other hand, the concentration of the side product, styrene epoxide, decreases slightly with increasing reaction time (Figure 1 B–D), suggesting that it may be in equilibrium with other minor products. The hemiacetal species are stabilized by the framework of the TS-1 zeolite and thus cannot be released. Therefore, without Brønsted acid sites, styrene could not be converted into PADH.

However, when TS-1 zeolite containing Brønsted acid sites (sample **B**) is used, a different picture is presented. Most importantly, after styrene reacted with a premixture of UHP and sample **B** (Figure 2 C) for 15 min at 313 K, a new peak at around $\delta = 202.0$ ppm appeared. The intensity of the signals for the corresponding species increased as the reaction
Figure 1. The in situ ^{13}C MAS NMR spectra of styrene adsorbed on sample **A** (A), and for the reaction of styrene with a mixture of sample **A** and UHP at 313 K after 0 min (B), 15 min (C), and 45 min (D). The asterisks represent side bands.
Figure 2. The in situ ^{13}C MAS NMR spectra of styrene adsorbed on sample **B** (A), and for the reaction of styrene with a mixture of sample **B** and UHP at 313 K after 0 min (B), 15 min (C), and 45 min (D). The asterisks represent side bands.

proceeded (Figure 2 D, E). On the other hand, the intensity of the signal for the hemiacetal species ($\delta = 102.2$ ppm) increased at first and passed through a maximum at the same time as the depletion of styrene and the formation of PADH, strongly suggesting that the hemiactetal species are intermediates for PADH production. This rules out the previous assumption that PADH results from the rearrangement of styrene epoxide.[4] The intermediate role of the hemiacetal species in the production of PADH is in agreement with the well-documented equilibrium between hemiacetal and acetal, that is, the hemiacetal can be converted into the acetal under acidic conditions.[11] Significantly, the only difference between the two samples is that sample **B** contains Brønsted acid sites; that is, Brønsted acid sites catalyzed the conversion of hemicactal into PADH. Without Brønsted acid sites, PADH is not formed, and the hemiacetal species remains bound to the zeolite framework (Figure 1).

Much to our surprise, if a mixture of sample **A** and UHP is put aside overnight at room temperature and then allowed to react with styrene, no hemiacetal species is formed (Figure 3).
Figure 3. The ^{13}C MAS NMR spectra of styrene upon reaction with a mixture of UHP and sample **A** at 313 K after 0 min (A), 10 min (B), 20 min (C), and 40 min (D). Before the adsorption of styrene, the mixture of UHP and sample **A** was stored at room temperature overnight.

The sole product was a small amount of styrene epoxide ($\delta = 50.2$ ppm). As the reaction proceeded, trace amounts of two other minor products were observed, such as a glycol species at about $\delta = 68.0$ ppm; no aldehyde was detected. This result was completely different from that obtained upon the immediate adsorption of styrene onto the mixture of sample **A** and UHP (Figure 1), implying that the catalytic species responsible for the formation of the hemiacetal had decomposed during the long delay. This interesting phenomenon prompted us to investigate in detail the effect of delay time on the product distribution. Figure 4 depicts the ratio of the
Figure 4. Plot showing the ratio R of hemiacetals to epoxide as a function of delay time before styrene adsorption/reaction. This ratio decreased with an increase in delay time. The intensities of the different species were obtained by integrating the area under corresponding peaks in the ^{13}C MAS NMR spectra.

hemiacetal species to epoxide as a function of delay time. The ratio decreased as the delay time increased, and after a 12-h delay, the hemiacetal species was no longer present (Figure 3).

We also followed the styrene oxidation by in situ EPR spectroscopy. Figure 5a shows the EPR spectra of sample **A** and UHP at room temperature with different delay times. Two distinct signals were observed, which indicated the existence of different Ti^{4+} sites in the mixture. The stronger signal ($g_x = 2.0023$, $g_y = 2.0090$, $g_z = 2.0280$) was assigned to the Ti–superoxo species from the interaction between the framework Ti and UHP. The other weak resonance at $g_z = 2.0200$ was caused by the $(SiO)_2(OH)TiOO^-$ species, that is, the defects in the TS-1 zeolite[12] or the superoxo anion dispersed on extra framework Ti sites.[13] As time went on, the signal at $g_z = 2.0280$ gradually wore off, whereas the signal at $g_z = 2.0200$ remained almost unchanged, indicating that the Ti–superoxo species in the framework Ti sites was not stable and easily quenched. When this result is coupled with that from the NMR experiment, in which the ratio of hemiacetal to epoxide decreased with the delay time, it is clear that production of the hemiacetal species decreased with quenching of the Ti–superoxo species. Thus it is natural to conclude that the Ti–superoxo species was critical in the formation of the hemiacetal species, that is, it represents the active center for the formation of the hemiacetal species. To further support this conclusion, different amounts of styrene were
Figure 5. a) The EPR spectra of sample **A** after interaction with UHP at RT for different lengths of time: A) 0 min, B) 20 min, C) 30 min, D) 45 min, E) 55 min, F) 90 min. b) The EPR spectra of the reaction of sample **A** and UHP with different amounts of styrene: A) 0 mL, B) 0.05 mL, C) 0.10 mL, D) 0.15 mL, E) 0.20 mL, F) 0.25 mL, G) 0.50 mL, H) 0.75 mL.

Scheme 1. The proposed mechanism for the formation of TiOOH and styrene epoxide.

added to the mixture of TS-1 and UHP at 293 K (without delay time). Indeed, the signal at $g_z = 2.0280$ decreased in intensity as the Ti–superoxo species was consumed by the additional styrene, whereas the signal at $g_z = 2.0200$ remained almost intact (Figure 5b). This again proved that the Ti superoxo radical species formed on tetrapodal Ti ions was involved in the oxidation of styrene and is responsible for the formation of the hemiacetal species.

It is generally accepted that the first step in the oxidation by the TS-1/H_2O_2 system is the formation of the TiOOH species, the species responsible for the epoxidation.[1b,2d,14] While the production of the epoxide species was not disturbed by a delay in reaction, it is clear that it is formed at a different active center than the hemiacetal species, the precursor of PADH. This is different from previous studies that suggested that PADH is just the rearrangement product of epoxide.[4] As TiOOH is the precursor for the generation of the Ti–superoxo species (by the reaction TiOOH + HO· → TiOO· + H_2O),[15] the epoxidation and the radical reaction to form the hemiacetal/PADH are competitive processes.

Based on these results and the theoretical calculations (see the Supporting Information), a mechanism for the oxidation of styrene is proposed (Schemes 1 and 2). First, the framework Ti species (which may be distorted[16]) reacts with H_2O_2 to form TiOOH. Second, TiOOH either oxidizes styrene to styrene epoxide or reacts with the OH· radical (generated from the decomposition of H_2O_2) to form the Ti–superoxo radical species. Third, the superoxo species interacts with the C–C double bond of styrene to form a new organic radical **3**, which is immediately converted into another radical **4** through hydrogen transfer from the β-C atom to the α-C atom of the styrene side chain. According to the theoretical calculations this process is thermodynamically favorable (see the Supporting Information). Finally, the OH· radical terminates the chain reactions and form the hemiacetal species (^{13}C MAS NMR signal at $\delta = 102.2$ ppm). Without Brønsted acid sites (as with sample **A**,
Scheme 2. The proposed mechanism for the radical reaction leading to the hemiacetal species and PADH.

Figure 1) the hemiacetal species is stable on the catalyst surface and with Brønsted acid sites (sample **B**) it is converted into aldehyde and then released from the zeolite framework (Figure 2). At the same time, TiOOH is recovered and thus the catalytic cycle is accomplished.

In summary, the mechanism of styrene oxidation by TS-1/ UHP is discussed in detail. It was verified that the Ti–superoxo radical is responsible for the formation of the hemiacetal species, while Brønsted acid sites offer the active centers for the transformation of the hemiacetal species to PADH. Without these Brønsted sites, the hemiacetal species remain stable on the framework of TS-1, and accordingly no PADH is formed. Therefore, styrene epoxide and PADH are formed by two competing processes: PADH does not result from further reaction of styrene epoxide, as previously suggested. Through the combination of experimental results and theoretical calculations, a more reasonable mechanism for styrene oxidation has been proposed.

Experimental Section

The two different TS-1 zeolites with (sample **B**) or without (sample **A**) Brønsted sites were synthesized according to a BASF Aktiengesellschaft patent (WO 01/14251). X-ray diffraction confirmed the MFI structure of both samples. Chemical analysis was performed with a SRS 3400 X-ray fluorescence spectrometer. The overall SiO_2/TiO_2 ratios of these samples are 50 (sample **A**) and 52 (sample **B**).

The acidity in the samples was characterized by ^{31}P MAS NMR spectroscopy of trimethylphosphane (TMP) adsorbed on TS-1 zeolites. The samples were dehydrated by heating at 673 K under vacuum (below 10^{-2} Pa) for 20 h. The adsorption of TMP (Acros Organics) was performed by exposing the dehydrated sample to a saturated vapor pressure at room temperature for 30 min. Each sample was then evacuated for 20 min to remove the TMP physisorbed on the surface. The sample was then filled into an NMR rotor and sealed without exposure to air.

In situ ^{13}C MAS NMR spectra were measured by adsorbing β-^{13}C-rich styrene (Cambridge Co.) on samples **A** and **B** with a homemade device. Before adsorption the samples were dehydrated by heating at 673 K under vacuum (below 10^{-2} Pa) for 20 h and then used directly or mixed with urea–hydroperoxide (Acros Organics) uniformly under N_2. The mixture was evacuated at room temperature for 5 min and styrene was then loaded at -196°C (liquid nitrogen). The sample was evacuated for 20 min to remove physisorbed styrene. Subsequently, it was treated at 313 K for a precisely controlled period of time, and then packed into the rotor.

All NMR spectra were obtained at room temperature on a Bruker DRX-400 spectrometer with a BBO MAS probe using 4-mm ZrO_2 rotors. The ^{31}P MAS NMR spectra with high-power proton decoupling were obtained at 161.9 MHz by using a 2.0-μs pulse, 2-s repetition time, and 1024–2048 scans; the samples were spun at 6 kHz and referenced to 85% H_3PO_4. The ^{13}C MAS NMR measurements were made at 100.6 MHz with high-power proton decoupling by using a 2-μs pulse and 2-s repetition time. For each ^{13}C spectrum, 1600 free induction decays were accumulated with a sample spinning rate of 7 kHz. Adamantane was used as the reference of the chemical shift. The WINNMR program supplied by the instrument manufacturer was employed for spectral deconvolution by using Gaussian–Lorentzian lineshapes.

EPR spectra were recorded on a JEOL ES-EDX3 spectrometer. Prior to the measurements, the samples (100 mg) were dehydrated at 673 K for 2 h under He and then mixed with 30 mg of UHP. The EPR spectra were recorded at room temperature, operating at an X-band frequency of 9.42 GHz and 100 kHz field modulation with a microwave power of 1 mW. The *g* factors were calculated by taking the signal of manganese as standard.

A Bis(thiophosphinoyl)methanediide Palladium Complex: Coordinated Dianion or Nucleophilic Carbene Complex?**

Thibault Cantat, Nicolas Mézailles, Louis Ricard, Yves Jean,* and Pascal Le Floch*

Transition-metal carbene complexes are one of the most widely studied organometallic species because of their high activity in numerous catalytic processes.[1] Most efforts were recently focused on the synthesis of isolable free carbene ligands.[2] However, new and rapid synthetic strategies allowing the generation of new carbenes in the coordination sphere of metals from easily available and cheap precursors have yet to be developed. In this perspective, phosphorus-substituted methane derivatives have attracted the attention of many groups as potential precursors.[3, 4] Besides the particular electronic properties of phosphorus, which markedly differ from that of their nitrogen counterparts, the interest of such derivatives also resides in the possibility of using phosphorus as an anchor for other heteroatoms through oxidation of its lone pair. This approach was elegantly demonstrated by Cavell and co-workers who successfully developed the chemistry of bis(iminophosphorano)methanediide complexes.[5]

As part of a program aimed at exploring the use of thiophosphinoyl ligands in coordination chemistry and catalysis[6] we recently explored the possibility of generating analogous carbene complexes from the bis(diphenylthiophosphinoyl)methane ligand. This work was also motivated by the tendency of thiophosphinoyl ligands to favor coordination of electron-rich metal centers. Furthermore, sulfur ligands were rarely employed as ancillary ligands in carbene chemistry.[7] Herein, we report a new type of pincer ligand featuring a formal "carbenic" atom and two ancillary sulfide ligands.

The new dianion **2** was readily synthesized in quantitative yield through a double deprotonation of the methylene group in **1** using MeLi in toluene at low temperature (Scheme 1) following a similar procedure to that used for the deprotonation of bis(diphenyl-*N*-trimethylsilylphosphinimino)-methane.[8] Formation of **2** was evidenced by vigorous evolution of methane at room temperature and the formation, over two hours, of a yellow turbid mixture. Dianion **2** which is highly

sensitive towards moisture gives rise to a singlet in the ^{31}P NMR spectrum at $\delta = 20.6$ ppm (121.5 MHz, toluene, 25°C, 85% H_3PO_4 as external standard) and was used without purification for further reactions. The reaction of **2** with [(PPh$_3$)$_2$PdCl$_2$] yielded a burgundy red solution and a red precipitate. The ^{31}P NMR spectrum of the new species is highly diagnostic. Indeed the new complex **3** gives rise to an AX$_2$ spin system (δ(A) = 21.5 ppm; δ(X$_2$) = +39.8 ppm, CD$_2$Cl$_2$, 298 K) revealing a symmetrical structure featuring three phosphorus atoms (Scheme 1).
Scheme 1.

After work-up aimed at eliminating the LiCl salt formed and the free PPh$_3$ ligand, complex **3** was fully characterized by NMR spectroscopic techniques (^1H and ^{13}C) and elemental analyses. Though no ^{13}C NMR signal could be recorded for the carbenic carbon atom (as was reported by Cavell and co-workers for some carbene complexes[5g,h]), the absence of methylenic protons was confirmed by both ^1H and ^{13}C NMR spectroscopy. Fortunately, X-ray-quality red crystals of **3** were obtained either from a concentrated CH$_2$Cl$_2$ solution or by diffusion of hexanes into a CH$_2$Cl$_2$ solution of the complex (Figure 1).[9] Complex **3** was found to be remarkably resistant to moisture and it crystallizes with a molecule of CH$_2$Cl$_2$ a situation which already points towards a weak nucleophilic character. The shortest distances between the solvent and the C1 and Pd atoms are 5.0 and 5.9 Å, respectively.
Figure 1. View of one molecule of **3** (thermal ellipsoids set at 50% probability). The hydrogen atoms and cocrystallized CH$_2$Cl$_2$ are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pd1-C1 2.113(2), C1-P1 1.689(2), C1-P2 1.690(2), Pd1-S1 2.3741(6), Pd1-S2 2.3677(6), Pd1-P3 2.3030(6), P1-S1 2.0451(7), P2-S2 2.0424(8); P1-C1-P2 139.2(1), C1-Pd1-S1 80.63(6), S1-Pd1-P3 96.45(2), P3-Pd1-S2 103.78(2), S2-Pd1-C1 80.91(6), C1-Pd1-P3 174.61(6), S1-Pd1-S2 158.42(2).

The structure of **3** definitely establishes the presence of a central tricoordinate carbon atom that is bound to the Pd center and the two PPh$_2$S groups. However, the relatively long C1−Pd separation (2.113(2) Å) rules out the formation of a true double bond (2.005 Å).[7] This bond is shorter than a classical single Pd−C bond (about 2.15 Å). Moreover, even though the overall geometry around the palladium center is square planar, the angle between the Pd−C1 bond and the plane defined by the "carbene moiety" measures 102.0°. Thus in **3**, the metal center seems to be located in a quasiperpendicular plane to the carbene fragment. Similar distortions, but to a lesser extent (angles varying between 0 and 37.7°), were also observed in some of Cavell's complexes.[5e] A striking feature is the very short P−C1 bonds of 1.689(2) and 1.690(2), which are similar to bond lengths found in carbodiphosphoranes and their complexes.[10] These short bonds very likely result from negative hyperconjugation from carbon to phosphorus σ* orbitals. How can this geometry be rationalized? ONIOM calculations were carried out on the real system using the Gaussian 03 set of programs[11] (all phenyl groups were calculated at the MM level and the other atoms at the MQ level of theory).[12] Theoretical data are very similar to those given by X-ray crystallography with the exception of the P−S bond lengths which were found to be slightly longer.

The electronic structure of **3** can be rationalized by looking at the molecular orbital (MOs) which involve the n_p and n_σ nonbonding orbitals on the carbenic center.[13] Owing to the almost perpendicular orientation of the carbene ligand, the sigma bonding MO results from the interaction between the n_p orbital and a metal-centered orbital directed along the Pd−C axis. This doubly occupied MO characterizes a σ Pd−C bond since its antibonding counterpart (the LUMO of the complex) is vacant (Figure 2, right). The n_σ orbital interacts

structure is to consider that the complex results from the interaction between a d^{10}PdL$_3$ fragment and a neutral carbene (Figure 3): an occupied MO of the metal fragment interacts with the vacant n_p orbital, leading to a nearly perpendicular orientation of the carbene ligand (distorted "open book" conformation).[5e] A four-electron interaction develops between the n_σ and d_{xz} orbitals.
Figure 3. A) Usual bonding mode in carbene complexes, B) electronic situation in **3** assuming a d^{10}PdL$_3$ fragment.

Or, one can assume the two electrons of the σ bond to be associated to the carbenic ligand as is usual for electron counting in transition-metal complexes. Then, the whole complex can be described as a d^8 [PdL$_3$]$^{2+}$ metal fragment interacting with a dianionic carbenic center. A further interpretation is found by using the isolobal analogy. The T-shape d^{10}PdL$_3$ fragment is isolobal to CH$_3^-$, so that complex **3** is analogous to the CH$_3$−CH$_2^-$ ion (Figure 4) with a single C−C bond and a lone pair on the pyramidalized methylene moiety.[14]
Figure 4. By the isolobal analogy complex **3** is analogous to the CH$_3$−CH$_2^-$ ion.

The nucleophilic character of the carbenic atom was confirmed by NBO calculations ($q_C = -1.39$ and $q_{Pd} = +0.37$). To demonstrate the presence of a reactive lone pair on this "carbenic" carbon atom, complex **3** was treated with various electrophiles. For example, the reaction with MeI, which was carried out in CH$_2$Cl$_2$ at room temperature, exclusively takes place on the carbon atom. The cationic complex **4** formed was isolated in a quantitative yield (Scheme 2).[15]

This new complex was fully characterized by NMR spectroscopy, elemental analysis, and X-ray crystallography. Orange crystals of **4** were grown by a slow diffusion of hexanes into a dichloromethane solution of the complex (see Supporting Information).[9] Interestingly, we note that the C−Pd bond in **4** (2.146(2) Å) is only slightly elongated with regard to **3** thus confirming the pronounced single-bond character of the C−Pd bond in **3** (2.113(2) Å). Theoretical

Figure 2. HOMO and LUMO of the theoretical structure of **3** as given by DFT calculations.

with the d_{xz} orbital through a π-type overlap. Note that both the bonding and the antibonding combinations are occupied, the latter being the HOMO of the complex (Figure 2, left). Therefore the π interaction does not lead to any π bonding character between the Pd and C1 centers. The bonding picture which emerges from this six-electron four-orbital analysis is that there is: 1) a single (σ) metal–carbon bond involving the n_p orbital on the carbenic center and 2) two nonbonding electron pairs on Pd and C1, the electron pair on the carbenic center is located approximately in the plane of the carbene (n_σ orbital). A way to understand this particular electronic

Communications

Scheme 2.

calculations using the ONIOM method (same level of theory than in **3**) yielded a structure which is very close to that experimentally observed. NBO calculations indicate that the palladium-bound carbon atom still bears a substantial negative charge ($q_C = -1.02$ and $q_{Pd} = +0.36$).

In conclusion, we have developed an easy synthetic access to a new type of nucleophilic "carbene" complex featuring two pendant thiophosphinoyl ancillary ligands. Theoretical calculations indicate that these new species can be either regarded as a coordinated dianion with a strong delocalization of the charge onto the two P–C bonds, or as a nucleophilic carbene complex.

Experimental Section

All experiments were carried out under dry argon or nitrogen atmosphere using distilled and degassed solvents.

3: Two equivalents of MeLi (0.84 mL, 1.6 M in diethyl ether, 1.34 mmol) were added to a solution of **1** (300 mg, 0.67 mmol) in toluene (5 mL) at $-78\,°C$. The mixture was warmed to room temperature and stirred for 2 h leading to the formation of a yellow suspension of **2**. Then [PdCl$_2$(PPh$_3$)$_2$] (470 mg, 0.67 mmol) was added in one portion at room temperature. The resulting mixture immediately turned red and ^{31}P NMR spectroscopy showed the reaction to be complete by indicating the presence of complex **3** and PPh$_3$. Complex **3** and LiCl are poorly soluble in toluene and were isolated by centrifugation. Pure complex **3** was finally obtained in 88 % yield (480 mg, 0.59 mmol) after dissolution in CH$_2$Cl$_2$ (6 mL) followed by filtration to remove LiCl and evaporation of the solvent. Selected data: ^{1}H NMR (300 MHz, CD$_2$Cl$_2$, 25 °C): $\delta = 7.13–7.66$ ppm (m, 35 H; H of phenyl); ^{31}P{^{1}H} NMR (121.5 MHz, CD$_2$Cl$_2$, 25 °C, 85 % H$_3$PO$_4$ as external standard): $\delta = 21.5$ (t, $^3J(P,P) = 14.6$ Hz; PPh$_3$), 39.8 ppm (d, $^3J(P,P) = 14.6$ Hz; PPh$_2$S); ^{13}C{^{1}H} NMR (75.465 MHz, CD$_2$Cl$_2$, 25 °C, CD$_2$Cl$_2$ $\delta = 53.73$ ppm as internal reference): $\delta = 125.4–139.1$ ppm (m; C of phenyl), C-Pd not observed; elemental analysis (%) calcd for C$_{43}$H$_{35}$P$_3$PdS$_2$: C 63.35, H 4.33, found: C 62.97, H 4.05.

4: Complex **4** was obtained by adding MeI (27 µL, 0.43 mmol) to a solution of **3** (350 mg, 0.43 mmol) in CH$_2$Cl$_2$ (10 mL) at room temperature. The mixture was stirred for five minutes and then taken to dryness. Complex **4** was thus isolated in a quantitative yield (100 %, 410 mg, 0.43 mmol). Selected data: ^{1}H NMR (300 MHz, CD$_2$Cl$_2$, 25 °C): $\delta = 1.86$ (dt, $^3J(H,P) = 16.2$ Hz, $^4J(H,P) = 8.6$ Hz, 3 H; CH$_3$), 7.00–8.04 ppm (m, 35 H; H of phenyl); ^{31}P{^{1}H} NMR (121.5 MHz, CD$_2$Cl$_2$, 25 °C, 85 % H$_3$PO$_4$ as external standard): $\delta = 22.8$ (t, $^3J(P,P) = 15.8$ Hz; PPh$_3$), 62.3 ppm (d, $^3J(P,P) = 15.8$ Hz; PPh$_2$S); ^{13}C{^{1}H} NMR (75.465 MHz, CD$_2$Cl$_2$, 25 °C, CD$_2$Cl$_2$ $\delta = 53.73$ ppm as internal reference): $\delta = 20.7$ (pq, $J(C,P) = 5.0$ Hz; CH$_3$), 125.6 (dt, $^1J(C,P) = 48.0$ Hz, $^2J(C,P) = 8.7$ Hz; C-Pd), 127.7–135.4 ppm (m; C of phenyl); elemental analysis (%) calcd for C$_{44}$H$_{38}$IP$_3$PdS$_2$: C 55.21, H 4.00; found: C 55.10, H 3.87.

[12] Theoretical calculations were carried out using the ONIOM (B3PW91[18]/UFF[19]) method implemented in the Gaussian 03 package. All the phenyl groups were considered as the second shell and were calculated using the UFF force field.[18] The carbenic carbon atom, P, S, and Pd atoms were calculated using the B3PW91 functional. A 6-31 + G* basis set was used for H and the 6-311 + G** was used for the carbenic atom, S and P atoms. The quasirelativistic small-core ECP basis set (441/2111/31) developed by Hay–Wadt[20] augmented with a f polarization function of exponent 1.472[21] was used for the Pd atom. The same combination of basis set was chosen for calculation of the theoretical structure of **4** but the 6-31 + G* basis set was used the H atoms of the methyl group.

[13] Molecular orbitals of **3** were calculated at the MQ (B3PW91) level on the ONIOM structure using the 6-311 + G** basis set for the carbenic atom, S, and P atoms and the 6-31G* for all phenyl groups (C and H atoms). Natural bond order (NBO) calculations were performed at the same level of theory for **3**.[22] For the theoretical structure of **4**, the 6-31 + G* basis set was used for calculating the H atoms of the methyl group.

[14] An X-ray crystal analysis of a pyramidalized carbanion has been recently reported: F. Breher, J. Grunenberg, S. C. Lawrence, P. Mountford, H. Rüegger, *Angew. Chem.* **2004**, *116*, 2575–2578; *Angew. Chem. Int. Ed.* **2004**, *43*, 2521–2524.

Cover Picture

Armin de Meijere,* Alexander F. Khlebnikov, Sergei I. Kozhushkov, Kazutoshi Miyazawa, Daniel Frank, Peter R. Schreiner, B. Christopher Rinderspacher, Dmitrii S. Yufit, and Judith A. K. Howard

The rigid helical frameworks of the molecules of (*M*)-(−)-[7]triangulane-1,9-dimethanol associate through hydrogen bonds between their terminal hydroxy groups in supramolecular helices, two of which form a supramolecular double helix. In the cover picture, this is compared with the design by Leonardo da Vinci of a double-spiral staircase. The hydrocarbon (*M*)-(−)-[9]triangulane does not organize itself as a supramolecular double helix. For more information see the Communication by de Meijere et al. on page 6553 ff. The cover picture was created by Dipl.-Chem. Heiko Schill.
History of Science
The 100th anniversary is commemorated of the awarding of the Nobel Prize to Lord Rayleigh and Sir Ramsay for their discovery and characterization of the noble gases. J. M. Thomas describes in his Essay on page 6418 the important stages in the lives of these two great scientists.

Protein Biosynthesis
In vitro and in vivo incorporation of noncanonical amino acids using an expanded genetic code and the perspectives of this method for the synthesis of tailor-made proteins are discussed in the Review by N. Budisa on p. 6426 ff.
Nanoporous Materials
Removal of the coil segments from an ordered rod–coil compound with a honeycomb-like structure to give a perforated crystalline sheet of hexagonally ordered nanopores is described by M. Lee and co-workers in their Communication on page 6466 ff.

Highlights

Chemistry of Odor Perception

The Nobel Price in Medicine this year went to Richard Axel and Linda Buck, who elucidated the molecular basis of the olfactory reception of fragrances and the neuronal preprocessing of information in the olfactory system. From the viewpoint of a chemist, these studies offer fascinating perspectives. For example, they enable an understanding of the perception of odors by transmembrane proteins (see picture).
The kiss of death for a protein is to be labeled with ubiquitin (Ub, see picture). The protein can then be recognized and degraded by the 26S proteasome, an important target in drug research, as it regulates the concentration of certain proteins. Recognition by the proteasome is hindered by two novel proteasome inhibitors, ubistatins A und B, which were identified through a chemical genetic approach.

Essays

Noble gases and Nobel prizes: To mark the 100th anniversary of the awarding of the Nobel Prize to Lord Rayleigh (see picture; right) and Sir William Ramsay (left) for their discovery and characterization of the noble gases, tribute is paid to two scientific greats whose work goes far beyond their prize-winning discovery.

Reviews
Room for one more: The genetic code of life consists of 64 coding units that control the incorporation of no more than 20 canonical amino acids in proteins—enough space remains for codon re-assignments, which render additional, noncanonical amino acids (see picture) translationally active substrates for the protein biosynthesis machinery. This review surveys methods, problems, and perspectives of this genetic code engineering.

Communications

Contents

(−)-Virantmycin (1)

from Curtius rearrangement

desymmetrization with PLE

Stereoselective Synthesis

T. G. Back,* J. E. Wulff ——— **6493 – 6496**

A Stereodivergent Synthesis of Virantmycin by an Enzyme-Mediated Diester Desymmetrization and a Highly Hindered Aryl Amination

Both enantiomers of the antiviral agent virantmycin were synthesized in a sequence of reactions in which the key steps were a highly stereoselective porcine liver esterase(PLE) mediated desymmetrization of a prochiral diester and a

remarkably effective intramolecular aryl amination of an *ortho*-substituted aryl bromide with a highly hindered α-quaternary formamide (see retrosynthetic scheme).

RNA Binding

F.-S. Liang, S.-K. Wang, T. Nakatani, C.-H. Wong* ——————— **6496 – 6500**

Targeting RNAs with Tobramycin Analogues

A library of 4,6-linked analogues of the drug tobramycin with various mono- or diaminosugars attached to the 6-position of the two-ring core has been prepared (see scheme; Bn = benzyl, Tol = *p*-tolyl).

The compounds were screened against different disease-related RNAs, and several of the synthetic analogues showed a high affinity and selectivity toward certain RNA sequences.

Natural Products Synthesis

M. Inoue,* T. Sasaki, S. Hatano, M. Hirama* ——————— **6500 – 6505**

Synthesis of the C-1027 Chromophore Framework through Atropselective Macrolactonization

Long-range steric interactions of the protecting groups of the 1,5-diol were harnessed for the successful atropselective macrolactonization (A) in the synthesis of the C-1027 chromophore framework (see scheme). Subsequent LiN(SiMe$_3$)$_2$/CeCl$_3$-promoted acetylide addition to an aldehyde (B) in the setting of a rigid macrocycle formed the target nine-membered ring system with a highly strained diyne.

Natural Products Synthesis

S. Sakamoto, H. Sakazaki, K. Hagiwara, K. Kamada, K. Ishii, T. Noda, M. Inoue,* M. Hirama* ——————— **6505 – 6510**

A Formal Total Synthesis of (+)-Pinnatoxin A

Powerful dithiane coupling (A) of two fragments and subsequent macrocyclization by ring-closing metathesis (B) produced the entire 27-membered carbocycle of (+)-pinnatoxin A (**1**), a major toxic principle responsible for outbreaks of shellfish poisonings in China and Japan.

Contents
Easy access to axially chiral phthalides
that bear one or two oxymethylene func-
tionalities is provided by an enantioselec-
tive cross alkyne cyclotrimerization in the
presence of the cationic complex [Rh^I{(S)-
H$_8$-binap}]$^+$. The axial chirality is intro-
duced during the formation of the ben-
zene ring with high enantioselectivity.

Plumb line: A series of compounds trans-
[L(PMe$_3$)$_4$W≡Pb(2,6-Trip$_2$C$_6$H$_3$)]$^{n+}$ (n = 0:
L = Br, I; n = 1: L = PhCN, PMe$_3$;
Trip = 2,4,6-iPr$_3$C$_6$H$_2$; see structure of
L = PMe$_3$ derivative) containing W–Pb
triple bonds is reported. Quantum-chem-
ical analyses of the W≡Pb bond in the
plumbylidyne complex [(PMe$_3$)$_5$W≡Pb-
(2,6-Trip$_2$C$_6$H$_3$)]$^+$ confirm the electronic
analogy with Fischer-type carbyne com-
plexes.
Two simple steps, including a new intra-
molecular [4+3] cycloaddition, are
required for the preparation of polycycles
that contain a seven-membered ring from
2-methyleneaziridines (see scheme). The
diene component is introduced by
selective lithiation/alkylation at C3 of the
aziridine ring. Lewis acid catalyzed
cyclization leads to the products in good
yields with stereocontrol.

The complete catalytic cycle of CO oxida-
tion with N$_2$O is shown to occur on Pt$_n^+$
(see scheme); for Pt$_7^+$ it involves six
different elementary reactions. Poisoning
of the catalyst by sequential addition of
CO is observed. The extent of poisoning
can be adjusted with the ratio of N$_2$O and
CO partial pressures.

Dye Aggregates

H. Kashida, H. Asanuma,*
M. Komiyama ———————— **6522 – 6525**

Alternating Hetero H Aggregation of Different Dyes by Interstrand Stacking from Two DNA–Dye Conjugates
Seeing red: Aggregates in which methyl red and naphthyl red moieties are stacked alternately in a DNA duplex have been prepared by hybridization of two DNA–dye conjugates (see picture). A sharp absorption band appears at 478 nm, which is different from that of the individual dyes. A strong CD effect is also induced by the interstrand heterostacking of the dyes.

Reaction Mechanisms　Ⓥ

A. Côté, A. A. Boezio,
A. B. Charette* ———————— **6525 – 6528**

Evidence for the Structure of the Enantioactive Ligand in the Phosphine–Copper-Catalyzed Addition of Diorganozinc Reagents to Imines

Mistaken identity: The active catalyst in the highly selective Cu-catalyzed nucleophilic addition of diorganozinc reagents to *N*-diphenylphosphinoylimines (see scheme) does not contain the bis(phosphine) ligand **1** but rather the hemilabile monophosphine oxide **2**. Ligand **1** is oxidized when it is mixed with either copper(II) or copper(I) triflate. The analogous reaction under nonoxidizing conditions is slower and not enantioselective.

Asymmetric Synthesis

I. Ibrahem, J. Casas,
A. Córdova* ———————— **6528 – 6531**

Direct Catalytic Enantioselective α-Aminomethylation of Ketones

A proline-catalyzed Mannich reaction produces α-aminomethylated ketones in high yield and with excellent *ee* values (see scheme). The Mannich bases resulting from this highly practical one-pot three-component asymmetric reaction are of particular interest, for example, as synthetic building blocks and precursors of pharmaceutically valuable 1,3-amino alcohols.

Oxidations

H. Sundén, M. Engqvist, J. Casas,
I. Ibrahem, A. Córdova* ——— **6532 – 6535**

Direct Amino Acid Catalyzed Asymmetric α Oxidation of Ketones with Molecular Oxygen

A possible prebiotic pathway for the asymmetric incorporation of molecular oxygen into organic compounds involves the amino acid catalyzed reaction of molecular singlet oxygen with ketones. Amino acids and their derivatives mediate the reaction between oxygen and ketones with high efficiency to produce α-hydroxyketones (see scheme).

Contents
The combination of highly compatible metal and enzyme catalysts allows the fastest dynamic kinetic resolution of alcohols ever reported. The use of ruthenium catalyst **1a** (or **1b**) and an immobi- lized lipase results in a highly efficient enantioselective synthesis of acetates in excellent yields at room temperature (see scheme).
Flying to new destinations: Instrument modifications, which give three detection areas (see scheme) in a two-channel detection scheme, extend the achievable duty cycle of a Hadamard transform time-of-flight mass spectrometer (HT-TOFMS) to 100% and effectively converts TOFMS into a continuous detection technique. Beyond the improved signal-to-noise ratio, this advance gives an increase in the data-acquisition rate leading to a higher detection speed.
The golden key: The use of N and N,O ligands for gold(III) complexes leads to stable catalysts that facilitate an efficient synthesis of tetrahydroisoquinolines with substitution patterns difficult to access by classic methods (see picture).
Convenient and direct: 1,4-Dicarbonyl compounds are readily obtained through a one-pot cerium-catalyzed oxidative C—C coupling in the presence of oxygen and subsequent fragmentation. The products are suitable precursors for heterocycles.
Disproportionation of a metastable Ga^I chloride solution and substitution with phosphanides leads to a novel type of metalloid Ga$_{22}$ clusters ([Ga$_{22}$(PtBu$_2$)$_{12}$], see molecular structure, Ga: blue and black, P: gray). The four previously discovered Ga$_{22}$ structural isomers—which in solid-state chemistry would be referred to as different phases—reflect the diverse bonding possibilities in gallium modifications.

(*P*)-(+)-[9]Triangulane
$[\alpha]_D^{20}$ = +909.9

8 steps

—OAc

R *S*
Remarkably high specific rotations, even at 589 nm, are exhibited by the enantiomerically pure σ-[9]helicenes (*M*)-(−)- and (*P*)-(+)-[9]triangulanes (see scheme). This significant power of rotation, which is in very good agreement with calculated values, must be attributed to the rigid helical framework of σ bonds in these formally saturated hydrocarbons.

Communications labeled with this symbol have been judged by two referees as being "very important papers".

News

P. Yang Receives Pure Chemistry Award

The ACS (American Chemical Society) Award in Pure Chemistry is awarded to a young scientist based in North America for fundamental research of exceptional merit and originality in pure chemistry. The recipient for 2005 is Peidong Yang, Associate Professor of Chemistry at the University of California, Berkeley. Born in 1971, Yang completed his BS in Applied Chemistry at the University of Science and Technology of China in 1993. He continued his education in the USA, where he completed his MS and PhD (1997) at Harvard University under the guidance of Charles M. Lieber. Following a period as a post-doctoral fellow in the research group of Galen D.

P. Yang

Stucky at the University of California, Santa Barbara, Yang became Assistant Professor at Berkeley in 1999.

Yang's research is centered on the development of strategies for the rational synthesis and organization of low-dimensional nanoscale building blocks, which can be used to assemble complex architectures with novel electronic and photonic properties. He is particularly interested in the thermal stability, chemical stability, and opto-electronic properties of nanowires. His recent publication on the controlled synthesis of platonic gold nanocrystals in the form of tetrahedra, cubes, octahedra, and icosahedra was highlighted on the cover of *Angewandte Chemie*.[1]

Inorganic Chemistry Award to W. J. Evans

William J. Evans is to receive the ACS Award in Inorganic Chemistry for 2005. Evans completed his BS in 1969 at the University of Wisconsin (USA), with research directed by Donald F. Gaines on penta-borane. After completion of his PhD in 1973 at the University of California, Los Angeles, where he studied metallacarboranes under the supervision of M. Frederick Hawthorne, he undertook postdoctoral research on molybdenum phosphite chemistry with Earl L. Muetterties at Cornell University. Evans then joined the faculty at the University of Chicago in 1975. He was promoted to associate professor there before moving in 1982 to the University of California, Irvine, where he has been ever since as a full professor.

W. J. Evans

Evans embarked on pioneering research into the chemistry of the lanthanide elements at the very beginning of his independent research career. His research program covers many aspects of the chemistry of the lanthanides, actinides, and early transition metals, including synthesis, mechanistic studies, and structural analysis. He is also interested in applications of these metals in organic synthesis, polymers, the development of high-technology materials, and dinitrogen fixation. In his most recent Communication in *Angewandte Chemie* he described the formation of dinitrogen derivatives of lanthanum from organometallic and heteroleptic precursors.[2]

E. Iglesia Receives George A. Olah Award

Enrique Iglesia is the recipient for 2005 of the George A. Olah Award in Hydrocarbon or Petroleum Chemistry, admin-istered by the ACS and awarded to a resident of the USA or Canada who has accomplished outstanding research in the chemistry of hydrocarbons or of petroleum and its products. Iglesia's research focuses on the design, synthesis, and structural and mechanistic characterization of catalysts for chemical reactions important in energy use, petrochemical synthesis, and environmental protection.

Iglesia completed his PhD in chemical engineering at Stanford University (USA) in 1982 under the guidance of Michel Boudart. After gaining eleven

E. Iglesia

years of experience in heterogeneous catalysis and reaction engineering at the Corporate Research Laboratories of Exxon Research and Engineering, he accepted a position as Professor of Chemical Engineering at the University of California, Berkeley in 1993. He is also a Faculty Scientist in the E. O. Lawrence Berkeley National Laboratory of the US Department of Energy, as well as the founding and current director of the Berkeley Catalysis Center. Iglesia has received a number of awards, including two for excellence in teaching from the American Institute of Chemical Engineers. He recently reported in *Angewandte Chemie* on the structural and mechanistic requirements for the activation of methane and its chemical conversion on supported iridium clusters.[3]

The Molecular Basis of Olfactory Chemoreception**

Uwe J. Meierhenrich,* Jérôme Golebiowski, Xavier Fernandez, and Daniel Cabrol-Bass

Dedicated to Professor R. Luft

Chemoreception is the aptitude of living organisms to identify natural or synthetic chemical compounds in their environment and to evaluate their concentration.[1,2] In April 1970, the organic chemist Robert Luft was asked how volatile odorant molecules are perceived by the olfactory system. "*Si vous répondez à cette question*," he replied, "*le Prix Nobel est à vous*".[3] The 2004 Nobel Prize in Medicine was awarded 34 years later to Richard Axel and Linda B. Buck of the Howard Hughes Medical Institute, who deciphered the molecular basis for the perception of odors and the corresponding information preprocessing in the olfactory system. From the viewpoint of a chemist, these studies offer fascinating perspectives.

Olfaction is initiated by a molecular interaction of chemical compounds called odorants with the olfactory neurons located in the epithelium of the nasal cavity. The required molecular properties of odorants were determined

to be a moderate molecular weight, low polarity, a certain water solubility, high vapor pressure, and lipophilicity.[1] The existence of peripheral olfactory receptor (OR) proteins located in the cilia of sensory neurons in the epithelium had been postulated but remained unproven prior to the work of Axel and Buck.[4] Numerous theories had been formulated concerning the mode of interaction between odorant molecules and the olfactory neurons, including the vibrational theory,[5,6] the membrane-diffusion theory,[7] the Piezzo effect,[8] complexation,[9] the polarization theory,[10] the chromatography analogy,[11] the hydrogen-bond-dispersion model,[12] and the tunneling vibrational theory.[13,14]

Since 1949, it had been thought that only the characteristic molecular shape of an odorant determined its odor.[15,16] Based on the identification of a number of different types of anosmia (the lack of a sense of smell), it was concluded that as many (between 7 and 30) specific receptors with the capacity to recognize different molecular shapes must exist. Thus, the existence of an "alphabet" of odor types with corresponding molecular shapes was postulated. The combination of the letters of this alphabet should lead to the perception of a multitude of different odors.[17] Since then, numerous chemical studies have been devoted to the elucidation of structure–odor relationships.[18,19] Despite some success with specific series of molecules and their odors (e.g. musks, ambergris, sandalwood), numerous discrepancies and exceptions remained.[1] Furthermore, it remained impossible to predict the odor of a molecule from its molecular structure. These difficulties are not surprising, as structure–odor relation-

ships are several orders of magnitude more complex than their pharmacological counterparts, structure–activity relationships.[13] More recently, the simplifying "steric theory" of Amoore has evolved into the olfactophore concept. Olfactophores, like pharmacophores, describe the spatial molecular arrangement of interacting groups and were found to be helpful for the computer-aided design of new odorants.[20] Such models were constructed without prior knowledge about the receptor site.

In 1991, Axel and Buck published a study that contributed considerably to our understanding of the molecular basis for the olfactory perception process.[4] To assess the presence of potential receptors in the olfactory epithelium they postulated that OR proteins belong to the family of G-protein-coupled receptors (GPCR). GPCR proteins are embedded in the surface membrane of cells and cross this membrane seven times. They are made up of seven helices, which are joined together by three extracellular and three intracellular loops. These transduction proteins can receive chemical signals outside the cell and transmit them into the interior of the cell. The receptor activates the intracellular G protein, which causes effectors to produce a second signal inside the cell. This second signal causes the cell to react to the original external chemical signal. A simplified schematic representation of the transmembrane protagonists is presented in Figure 1.

Prior to their interaction with transmembrane OR proteins, odorants are thought to be associated with odorant-transport (OT) proteins present in mucus.[21,22] OT proteins belong to a class of carrier proteins present in physiological

[**] This Highlight was written to coincide with the awarding of the 2004 Nobel Prize in Medicine and is dedicated to Prof. Dr. R. Luft, initiator of research on odorants in the late 1960s at the Université de Nice-Sophia Antipolis.
Figure 1. Schematic illustration of odorant binding and signal activation. The transduction mechanism of chemical reception through the cilia is initiated by the binding of an odorant molecule **o** from the gaseous phase **A** to a water-soluble **OT** protein,[21] which transports the odorant to the **OR** protein through the olfactory mucus **M**. Subsequently, the intracellular (**I**) G protein **G** is activated, and this protein in turn activates adenine cyclase **AC**, resulting in an opening of the ion channels located in the cell membrane **C**. The cell is depolarized through the entry of Ca^{2+} ions and leaving of Cl^- ions.

Figure 2. Three-dimensional structure of a complex between the odorant 2-isobutyl-3-methoxypyrazine and a water-soluble OT protein located in the mucus (top).[23] It is assumed that the odorant molecule is transferred to the transmembrane GPCR olfactory receptor (bottom).[22]

fluids. They contribute actively to the transportation of the odorant from the inhaled air stream through the mucus to the cilia of the olfactory neurons.

The basic approach of Axel and Buck was to design probes that could recognize DNA sequences that encode proteins located in the olfactory epithelium. A new class of genes were found that express a previously unknown family of GPCR-type proteins, the so-called OR proteins. The derived molecular structure of an OR protein is depicted in Figure 2 together with a complex of the odorant 2-isobutyl-3-methoxypyrazine with an OT protein.

Gene analysis revealed that the OR proteins had highly variable sequences and that they were only encoded in the olfactory epithelium. From then on, a tremendous number of studies were performed to determine the number and functions of OR proteins.[24,25] By searching the human genome database, Buck and co-workers identified 339 intact OR genes and 297 OR pseudogenes. Sequence comparison led to the classification of the human OR proteins into 172 families.[26] It was shown that a single OR protein can be activated by multiple odorants,[27–31] and that a single odorant can activate several OR proteins.[29] As a consequence, different odorants are recognized by different combinations of receptors, some of which are closely related to one another. Numerous odorants activate distinct sets of OR proteins, even if overlaps between these sets can exist.[29] From these results, the molecular basis for the first steps of olfaction was identified, namely, that olfactory perception proceeds through a *combinatorial* process. Indeed, given the large number of OR proteins, this combinatorial process could permit discrimination between a vast range of chemicals. Buck and co-workers estimated that even if an odorant activated only three receptors (in fact many more are activated), the number of theoretically discriminable odorants should be close to a billion.[29] The biological method of chemical recognition is therefore far removed from the simple "lock and key" analogy. These findings are fully consistent with the potential discrimination of a very large number of chemical compounds with different structures and shapes, as well as distinct odors.

The sequence of the OR proteins was determined indirectly through examination of the DNA sequence. Generally, three-dimensional protein structures can be determined through direct measurements by X-ray crystallography, electron microscopy, and NMR spectroscopy. These techniques are, however, suitable only for water-soluble proteins, and not for GPCR proteins, which require precisely balanced physicochemical conditions for structural and functional integrity. As such conditions are difficult to achieve, new techniques, such as two-dimensional cryomicroscopy, have to be employed to attempt the elucidation of these structures.[32] Therefore, the amount of

Highlights

experimental information available on the three-dimensional structure of GPCR proteins is limited. So far, only the rhodopsin GPCR structure has been determined by direct measurements,[33] and the structures of OR proteins have been derived from rhodopsin-based models.[34] Recent studies started to evaluate the differential responses of a receptor to a broad variety of agonists.[35] Much progress has been made towards understanding the molecular basis of olfactory perception, but many questions remain unanswered because of its combinatorial nature.

The pioneering transdisciplinary studies of Axel and Buck have tremendous implications for flavor and fragrance research. Knowledge about the molecular interactions between OR proteins and odorants can contribute to the evaluation of the interaction of a specific odorant with a given set of OR proteins, a strategy that has already been patented.[36] The combinatorial aspect of information processing in the olfactory bulb and the perception of odor by pattern recognition throw light on the success and failure of previous approaches based on studies of structure–odor relationships and olfactophore modeling. After the confirmation of the three-dimensional OR protein structure, chemists will be in a better position to undertake the rational design of odorants for the activation of specific OR proteins. However, for practical applications, odorants are seldom used as pure compounds, but rather as mixtures, which may be very complex. Thus, the successful application of odorants will always depend on their formulation. The field for the search for new odorants, deodorants, and odor modifiers is wide open.

[21] Until now, the odorant-transport protein was denoted odorant-binding (OB) protein. Herewith, we suggest the label OT protein, because 1. the term "binding" is not specific enough to describe the hydrophobic chemical interaction between odorant and protein, and 2. the term "transport" can describe the processes of inclusion, delivery, and release of the odorant molecule to the OR protein.

A Fatal Affair: The Ubiquitinylation of Proteins

Markus Biel, Veit Wascholowski, and Athanassios Giannis*

The activity, stability, and subcellular distribution of proteins can be modulated by different post-translational modifications. The awarding of the Nobel Prize in Chemistry for 2004 to Ciechanover, Hershko, and Rose pushed ubiquitinylation into the center of scientific attention. Ubiquitinylation is not only a signal for the degradation of unnecessary or defective proteins, but it also plays an important role in complex biological processes, such as cell-cycle control, DNA repair, apoptosis, and immune response.[1]

Ubiquitin (Ub) is a 8-kDa protein made up of 76 amino acids. Usually it is bound to other proteins by an isopeptide bond between its C terminus and a lysine side chain of the protein (Figure 1).[2] The ubiquitin-activating enzyme E1 adenylates the carboxy function of the C-terminal glycine residue of ubiquitin and transfers the activated species to an internal cysteine residue of the enzyme with the formation of a thioester bond. In a second step, Ub is transesterified from E1 to the ubiquitin-conjugating enzyme E2. A ubiquitin ligase E3 then selectively catalyzes its transfer from E2 to the target protein. As ubiquitin itself possesses internal lysine residues (e.g. lysine 48, lysine 63), the enzymatic cascade can be repeated several times to form a chain of Ub units.

Substrate molecules with a single Ub unit may be recognized by proteins that possess special ubiquitin-binding domains. The monoubiquitinylation of his-

tone H2B, which is part of the postulated histone code, serves as a signal for the activation of transcription,[3] whereas the same modification at receptor tyrosine kinases (RTKs) leads to their endocytosis and subsequent transport to the lysosome. Polyubiquitinylated species with Ub chains linked through lysine 63 are responsible for the mediation of nonproteolytic, reversible events,[4] including the modulation of protein properties, such as activity, subcellular distribution, and protein–protein interactions. On the other hand, if polyubiquitin chains are linked through lysine 48, the labeled proteins are recognized by the 26S proteasome and degraded by this 2.4-MDa multisubunit enzyme.[5]

The proteasome is present in both the nucleus and the cytoplasm of a cell and has a cylindrical shape. It consists of a catalytic 20S component, which is closed on both sides by a regulatory 19S component. This 19S unit recognizes and binds proteins with Ub chains that are linked through lysine 48 and forwards them, after cleavage of the ubiquitin chain and unfolding of the structure under ATP hydrolysis, to the catalytic 20S unit. The enzymatic mechanism[6] is not based on the catalytic triad common to most proteases, but on a single, highly conserved N-terminal threonine as the active-site nucleophile. The products of degradation by the proteasome are peptides with a length of 3 to 25 amino acids.

The proteasome has become an interesting target for the development of drugs. Not only does it control gene expression, but it represents a further mechanism for regulating the concentration of certain proteins inside the cell.[7] For example, cycline-dependent kinases (CDKs) are regulators of cell-cycle progression,[8] and their activity depends on cyclines, phosphatases such

as CDC25, and different cellular inhibitors (WAF1, KIP1). The proteasome is responsible for the well-ordered degradation of cyclines and CDK inhibitors. Furthermore, it is linked to the stabilization of CDC25 during cell-cycle progression.[9] The inhibition of proteasome-mediated degradation is an important possibility for the induction of a cell-cycle arrest and is therefore of clinical relevance, for example, in the treatment of malignant tumors. Moreover, ubiquitin–proteasome-mediated degradation is linked to the signaling pathways of p53,[10,11] which serves as a signal for numerous cellular responses, such as DNA repair, cell-cycle arrest, differentiation, and apoptosis, and to the NF-κB family[12,13] of transcription factors (Figure 2).

Until now, proteasome inhibitors have been subdivided into five classes: peptide aldehydes (MG132), peptide vinyl sulfones (NLVS), peptide boronates (bortezomib), peptide epoxyketones (epoxymycin), and β-lactones (PS-519; Scheme 1).[5a,6] They all contain an electrophilic group, which interacts with the threonine residue in the active site of the proteasome. As a result of metabolic instability and lack of enzyme specificity, only two proteasome inhibitors have reached the stage of clinical development: PS-519 (also known as MLN519) influences anti-inflammatory processes,
Figure 2. Cellular signaling pathways linked to the proteasome. Stress (e.g. radiation or chemicals) induces DNA damage and leads to the accumulation of the tumor suppressor p53, which activates gene expression. This process results in the induction of apoptosis. The ubiquitin ligase MDM2 blocks this pathway by ubiquitinylation and subsequent degradation of p53 in the proteasome. Proteasome inhibitors may prevent the destructive degradation of p53 in tumor cells which overexpress MDM2. Moreover, chemotherapy, radiation, viruses, and cytokines lead to the phosphorylation of the inhibitor of NF-κB (IκB) and thus to its degradation. Subsequently, the active NF-κB enhances several signaling pathways, thus ensuring the survival of the cell. Therefore, NF-κB is an important target for antineoplastic drugs.

whereas bortezomib (PS-341, velcade)—now a commercially available drug—shows significant antineoplastic effects in various tumor-cell lines. The
Scheme 1. Selected structures of inhibitors of proteasome degradation.

Highlights

exact mechanism of action and the specificity of each proteasome inhibitor are still under investigation, but much is known about the role of the inhibitors in carcinogenesis, angiogenesis, and metastasis. The biological effects of inhibiting proteasome activity are apoptosis, increased sensitivity to chemotherapy and radiation therapy, and decreased resistance to these therapies.[5a,6,7]

Recently, two new inhibitors of proteasome-dependent protein degradation, ubistatins A and B, were identified by a chemical genetic screen in *Xenopus* extracts.[14] The ubistatins do not bind to the active site of the proteasome, but interact with the ubiquitin–ubiquitin interface of lysine 48 linked ubiquitin chains, thus preventing the recognition of these proteins, which are marked for degradation, by the regulatory 19S unit of the proteasome. The ubistatins therefore form a new class of proteasome inhibitors and belong to the small group of modulators that function by disrupting critical protein–protein interactions.[15]

The experimental basis for this screening system is illustrated in Figure 3. The ubiquitinylation of cyclin B by the E3 ligase APC/C (anaphase-promoting complex/cyclosome) and its subsequent degradation is a prerequisite for exiting mitosis and progression into the next phase of the cell cycle. The use of a cyclin B–luciferase fusion protein allows the identification of compounds that block the degradation of cyclin B and therefore influence cell-cycle progression. Several control experiments were necessary to explore the exact mechanism of action of the most potent compounds. It was found that the ubistatins form specific protein–protein interactions with lysine 48 linked Ub chains and prevent their recognition by the proteasome. Titration experiments monitored by NMR spectroscopy with lysine 48 linked ubiquitin dimers showed that the inhibitors alter the molecular environment of specific hydrophobic sites of the ubiquitin units. Further investigation of these inhibitors in cellular assays may be hindered through their high polarity and low membrane permeability. Nevertheless, these results underline the importance of chemical genetic approaches for the discovery of new lead structures that wouldn't be found by using methods such as structure-based drug design or computer modeling.
Figure 3. Schematic representation of the chemical genetic screen for the identification of ubistatins A and B. The luminescence of luciferase indicates the presence of cyclin B: Compounds that inhibit the degradation of cyclin B lead to continuous luminescence in this test system.

Argon and the Non-Inert Pair: Rayleigh and Ramsay

John Meurig Thomas*

*I*n 1904 two London-based scientists became the first British citizens to be awarded the Nobel prize. Lord Rayleigh, at the Davy–Faraday Research Laboratories of the Royal Institution, won the Physics prize "for his investigation of the densities of the most important gases and for the discovery of argon in connection with these studies"; and Sir William Ramsay of University College, London, won the Chemistry prize "for his discovery of the inert gaseous elements in air, and his determination of their place in the periodic system." The significance of their discoveries, in particular their remarkable joint paper ("Argon, a New Constituent of the Atmosphere", *Philos. Trans. R. Soc. London Ser. A* **1895**, *186*, 187–241) is seen to be even more profound now than it was a century ago. But it must not be thought that these two individuals, like some other scientists who have won the Nobel prize subsequently, were focused upon and conquered just one large problem. On the contrary, these two, in diverse ways, were scientific giants, in ways not revealed by the Nobel citation, and the lessons that present-day practitioners in chemical science may draw from the talents, insights, generosity of spirit, humanity, activity, and achievements of Rayleigh and Ramsay are not only instructive to ponder but inspirational to aspiring young scientists (Figure 1).

Figure 1. Sir William Ramsay and Lord Rayleigh. The picture was taken shortly after the isolation of the first noble gas.

An Outline of Rayleigh's Career

Lord Rayleigh (1842–1919), last of the great British classical physicists, made contributions to every single branch of the physical sciences known in his day. His penetrating insight and prodigious capacity for detailed work enabled him to solve problems previously perceived by his progenitors and contemporaries as intractable as well as to suggest new lines of research that engendered the blossoming of much of 20th (and 21st) century science and technology. No name stands higher in the general esteem of physical scientists, engineers, and applied mathematicians the world over than that of John William Strutt (Third Baron Rayleigh) who was "to the manor born" in rural Essex, some sixty miles from London. No name occurs more frequently in relation to phenomena, principles, and effects with which any student of classical physics must become acquainted than that of Rayleigh. "Rayleigh Scattering" (of electromagnetic waves and the explanation of the blue sky and red sunset), "Rayleigh Waves", "Rayleigh Criterion" (governing resolving power in microscopes and telescopes), "Rayleigh Number" (in convection), "Rayleigh disc" (for measuring the absolute intensity of sound), "Rayleigh Fading and

Rayleigh Distance (terms used in the propagation of electromagnetic waves), "Rayleigh Damping", the "Rayleigh–Jeans Law" (for black body radiation)—these are by no means an exhaustive list of the impact of his work. They reflect but a fraction of the fields and phenomena in which his interests ranged with the most fruitful of results. For example, in 1885 Rayleigh published an article on the propagation of surface acoustic waves. This was a seminal paper that, for modern-day seismologists and earth scientists, is the basis for detecting and pin-pointing the location of distant earthquakes, and for electronic engineers forms that basis for practical delay lines in circuits used in radar and television.

Rayleigh was born John William Strutt at Terling Place in the county of Essex on November 12, 1842. As an infant he exhibited no sign of precocity, and he was almost three years old before he could talk. His schooling was rather fragmentary, short spells first at Eton then at Harrow (two of the premier private schools in the UK) being terminated by ill health. In the autumn of 1857 he was put under the care of Rev. George T. Warner, who took pupils at Torquay where he remained for four years. He entered Trinity College, Cambridge in October 1861 and was soon following the rigorous courses in mathematics given by or Edward J. Routh (of Peterhouse) a phenomenally successful tutor who, in 33 years of teaching produced 27 senior wranglers (the name given to the person who came top in the mathematical tripos examinations). J. W. Strutt was senior wrangler in January 1865. Sir James Jeans, the eminent astronomer and cosmologist, writing some 60 years later, said that *"there still lingers in Cambridge a tradition as to the lucidity and literary finish of his answers in the examination"*. The fine sense of literary style which Strutt displayed even under pressure in the examinations never deserted him. Every paper he wrote—and there were some 450 over a fifty year period—even those dealing with the most abstruse subjects—is a model of clarity and simplicity, and conveys the impression of having been written with effortless ease.

After his triumph in the mathematics examination he took a course on chemical analysis (from George D. Liveing, the newly appointed Professor of Chemistry at Cambridge). This choice of course was partly because young Strutt had a passion for experiment, but chiefly because no course was available in Cambridge dealing with experimental physics—an incredible state of affairs for the University where Newton had studied and taught.[1] In 1866 he was elected a fellow of Trinity College but it was not until 1869 that his first scientific paper appeared bearing the title "On Some Electro-Magnetic Phenomena Considered in Connection with the Dynamical Theory"[2] This paper was a brilliant example of the method and style that its author was to pursue throughout his career. The "dynamical theory" in question was James Clerk Maxwell's monumental work on the electromagnetic field, which Maxwell had cast in terms of complicated mathematical equations that were not readily transparent and fully appreciated by his contemporaries. Strutt elucidated and simplified this recondite theory—almost, as Jeans said later, made it intelligible to the average person. This simplification was done by showing that the intricate processes of the electromagnetic field found practically perfect analogies in such well-understood phenomena as the bursting of a water pipe under sudden pressure. And so, by adding to his towering mathematical skills the capacity for[3] *"understanding everything just a little more deeply than anyone else, and the consequent capacity for exhibiting it in its simplest aspect"*, Strutt began on his extraordinary scientific career, one marked by a catholicity of tastes and an exceptional combination of mathematical power and (later) experimental virtuosity.

Soon after his lucid interpretation of Maxwell's electromagnetic work, there came another major contribution which emerged from his reading the articles of Hermann von Helmholtz on sound. In 1860, Helmholtz had studied the acoustic resonator, now associated with his name. The 28 year old Strutt felt he could improve the mathematical treatment considerably, and this formed his first excursion into acoustics, which led to his classic paper entitled "On the Theory of Resonance"[4] In this major paper he attacked the problem of the oscillations of the air in the mouth of a resonator from the standpoint of energy; and he also introduced the invaluable concept of the acoustic conductivity of an orifice. He significantly extended Helmholtz's results, including (among other novelties) a discussion of coupled resonators. Ruminating over Helmholtz's famous treatise on tone,[5] he realized that there existed no up-to-date book on acoustical problems that provided an adequate mathematical treatment of well-established experimental phenomena.[6] No one had taken the trouble to summarize in a single text the classical memoirs of Euler, Lagrange, D'Alembert, Bernoulli, and other theorists of the eighteenth century.

By that time, 1871 to be precise, he had married Evelyn Balfour, sister of Arthur J. Balfour, the future Prime Minister, and later the author of the Balfour declaration that established a national home for the Jews.[8] Shortly thereafter he was struck by a severe attack of rheumatic fever, which led to his devoting a winter to travel in Egypt and Greece. It was while he was holidaying on a houseboat on the Nile that he drafted—without access to a library—Volume One of his monumental two volume *The Theory of Sound*, in which he examined questions of vibrations and the resonance of elastic solids and gases.[9] But before he left for the Middle East he had, in a two year period, published a dozen other outstanding papers. Arguably one of his most celebrated is entitled: "On the Light from the Sky: its polarization and colour"[10] and it marked the beginning of his concern for the scattering of radiation in general. He arrived, in this paper, at both the intensity and polarization of the scattered light by use of dimensional analysis and properly explained why the sky is blue and the sunset is red.[11] The amplitude of the Rayleigh scattered light is inversely proportional to the square of the wavelength.

In 1873, the year that his father died and when, therefore, he inherited the title of Lord (the Third Baron Rayleigh), he was elected Fellow of the Royal Society (FRS). Taking up residence in the family seat, Terling Place, he built a laboratory adjacent to the manor house. Although his primary interest was (and remained throughout

his life) scientific research, he now found himself compelled to devote a part of his time to the management of his estates. He acquired considerable knowledge of agriculture, which, combined with his general scientific knowledge and acumen led to his practice in estate management being in many regards in advance of its time.

This period saw the commencement of Rayleigh's lifelong interest in psychical research.[13] According to Sir James Jeans,[3] at first Rayleigh expected that investigation would rapidly lead to a definite conclusion, either positive or negative. Apparently he expected the former, in which case he was prepared to throw the greater part of his energies into a study of psychic phenomena. Rayleigh returned to orthodox scientific work when it became clear that no such definite conclusion was being attained.

Professor at Cambridge and at the Royal Institution of Great Britain

In 1879 James Clerk Maxwell, the first occupant of the Cavendish chair of experimental physics at Cambridge, died of intestinal cancer. Rayleigh agreed to serve as the second Cavendish professor for the period 1879–1884. He took his university duties very seriously both with respect to the instruction of students and to the carrying out of a vigorous research program that set about redetermining the values of electrical standards (the ohm, volt, and amp). A classical series of papers resulted from this ambitious project. But after a five-year tenure, he returned to his laboratory at Terling Place. Later he became (from 1887 to 1905) professor of Natural Philosophy at the Royal Institution.[14] In the intervening time, he accepted the secretaryship of the Royal Society, vacated by the resignation of one of his former teachers, Sir George Gabriel Stokes. The duties of such a post were not onerous, and there was no falling off of Rayleigh's output throughout his eleven years of secretaryship.

The tenure of this office gave him the opportunity to discover (in 1891) and rescue from oblivion the valuable memoir in which John J. Waterston[15] in

1846 had anticipated some of the important features of the kinetic theory of gases.

Helping Miss Pockels

An example of Rayleigh's scientific generosity was the support that he gave to some research by Miss Agnes Pockels. In January 1891, after he had published several papers relating to liquid surfaces and surface tension, Rayleigh received a long letter (in German) from Agnes Pockels (1862–1935) of Braunschweig

Figure 2. Agnes Pockels.

(Figure 2). She had read Rayleigh's paper in her brother Friedrich's[16] journals and wanted to tell him of some experiments on surface forces that she had carried out in her kitchen sink. At that time no mechanism for the formal university training of women existed in Germany. So after she completed her education at the Municipal High School for Girls, she came under the tutelage of her scientifically adroit brother. In 1880, while still a teenager, she had begun a series of researches on the effect of oil films on the surface tension of water. To measure surface forces quantitatively, she had suspended a horizontal disk from one arm of a balance scale until the disk just touched the surface of the pure (or contaminated) water. Based on her "surface-balance" work, she sent letters outlining her results to various German scientists, but they displayed little interest in her work. It was her brother who urged her to write to Rayleigh, who

immediately saw that she had achieved several fundamental advances in the surface physics of liquids. Rayleigh then published her paper in *Nature* in 1891, with an introduction by himself commenting on the importance of her work.

This public recognition by a distinguished British scientist brought her instant fame: her later papers, it was alleged,[12] were treated by journals with deferential respect. Professor Voight of the Physical Institute, Braunschweig, offered her laboratory facilities. She later visited illuminati such as Quincke, Ostwald, and Weber, all eminent surface scientists. Irving Langmuir, a later Nobel laureate (1932), adopted essentially her method for measuring surface forces.

The Discovery of Argon[17]

It was at the Royal Institution that Rayleigh largely conducted the work that earned him the Nobel Prize in Physics and brought him his greatest fame. Rayleigh had long been intrigued by Prout's hypothesis that the atomic weights should be integral numbers. If we assign hydrogen to be 1, oxygen should be 16, but it was not quite so. Was the discrepancy real? Rayleigh therefore determined the densities of hydrogen and oxygen; and then he moved on to nitrogen (in 1892). In a letter to *Nature* (submitted September 24 of that year, published September 29) he wrote:[18]

I am much puzzled by some results on the density of nitrogen, and I shall be obliged if any of your chemical readers can offer suggestions as to the cause. According to the methods of preparation, I obtain two quite distinct values. The relative difference, amounting to about one part in 1000, is small in itself, but it lies entirely outside the errors of experiment, and can only be attributed to a variation of the character of the gas.

His two sources of nitrogen had been ordinary air with the oxygen removed by heated metallic copper, and a "lighter" nitrogen obtained by decomposition of ammonia. No illuminating response came at that time from the chemical public, but his colleague at the Royal Institution, Sir James Dewar, said that some of the atmospheric N_2 was in

an allotropic state, such as N_3, just as some oxygen exists as ozone O_3. Rayleigh was skeptical about this; and he continued (for two years) to prepare nitrogen by several methods. Such chemically produced nitrogen was always lighter in density than atmospheric nitrogen. One of Rayleigh's lecture-demonstrations at the Royal Institution was a repeat of some of Henry Cavendish's studies, carried out a century earlier, in which a globe of ordinary air was subjected to electrical sparking so as to consume the oxygen as an oxide of nitrogen (that could be absorbed by potash). In this manner, all of the nitrogen was removed, excect, as Cavendish had noted, a very small residue. In other words, Rayleigh verified the reclusive Cavendish's results that had lain unnoticed in the literature for over 100 years.

Rayleigh expatiated on these puzzling facts in a lecture given to the Royal Society on April 19, 1894. This prompted a member of the audience, William Ramsay, to converse with Rayleigh. By the end of May of that year, Ramsay had shown that nitrogen gas, when repeatedly exposed to heated magnesium (to form the solid nitride) could be made progressively denser. Continuing his experiments through the summer, Ramsay produced in early August a gas, apparently unaffected by further treatment with magnesium (Figure 3). This result led to an exchange of letters. Sir William Crookes examined the gas and reported that it was new and quite distinct from nitrogen. Rayleigh told Ramsay that the residue was neither oxygen nor nitrogen. The two immediately joined forces, and on January 31, 1895 announced to

4th August, 1894

Dear Lord Rayleigh,

I have isolated the gas. Its density is 19.075, and it is not absorbed by magnesium.....

6th August , 1894

Dear Prof Ramsay,–

I believe that I too have isolated the gas, though in miserably small quantities...

Figure 3. The opening sentence of the letters in which Rayleigh and Ramsey report their simultaneous isolation of argon.

the Royal Society the discovery of a new gaseous element, apparently inert chemically, which they called argon (for inert, without work).

Rayleigh and Ramsay's 54-page joint paper gave the density, refractive index, solubility in water, ratio of specific heats (C_p/C_v), and atomic spectrum of the new gas, and they postulated a new zeroth column, for noble gases, in Mendeleeff's Periodic Table. Some scientists argued that so heavy an element could not possibly be a gas. Rayleigh, with aristocratic humor, replied:

…the result is, no doubt, very awkward. Indeed, I have seen some indications that the anomalous properties of argon are brought as a kind of accusation against us. But we had the very best intentions in the matter. The facts were too much for us, and all that we can do now is apologize for ourselves and for the gas.

In the process of isolating argon, Rayleigh designed the refractometer that bears his name, and the Rayleigh modification of the Huygens manometer. Lord Kelvin hailed argon as undoubtedly the greatest scientific event of the year. Specifically, he said:

If anything could add to the interest which we must all feel in this startling discovery, it is the consideration of the way by which it was found—arduous work—commenced in 1882, has been continued for 12 years by Rayleigh, with unremitting perseverance.

When Rayleigh received his Nobel Prize in 1904 the monetary value amounted to some £7700, a huge sum in those days. He donated his money to the University of Cambridge, and it was used to construct a new extension to the Cavendish Laboratory, the so-called Rayleigh Wing. This institution was built using wooden pegs and stone and cement instead of metal nails, to provide a facility better suited for sensitive electrical measurements. (Wilson's cloud-chamber measurements were carried out in this extension. All my present efforts in electron microscopy are also done in the Rayleigh wing). In his later years, honors and responsibilities fell much upon Rayleigh. He was one of the original recipients (1902) of the Order of Merit, and he accepted that Presidency of the Royal Society in 1905 (having earlier declined it).

According to Sir James Jeans:

…his massive, precise and perfectly balanced mind was utterly removed from that of the erratic genius who typifies the great scientist in the popular imagination…The outstanding qualities of his writings were thoroughness and clearness; he made everything seem obvious. Rayleigh died is Essex on 30 June 1919, having been at work on a scientific paper only five days previously…The inscription on his memorial in Westminster Abbey, 'An unerring leader in the advancement of natural knowledge', does not overstate the case.

Sir William Ramsay (1852–1916)

Rayleigh's co-discoverer of argon was born in Glasgow on October 2, 1852. He inherited scientific ability from both his parents; for, whilst his father was a civil engineer of no mean achievement and his paternal grandfather a well-known manufacturer of chemicals used by dyers, his mother was descended from a Scottish family which had produced many medical doctors of note.

As a child he showed remarkable skills with language and, like the polymath, Thomas Young (1773–1829), is said to have read the Bible when he was about four years of age. Brought up in a Calvinistic (Methodist) background he was exposed as a young child to long (and for him rather boring) sermons, during the course of which he acquired aptitude for German and French by reading the Bible in those languages. In his early teens while pursuing a conventional classical education (he was intended for the church) he broke his leg and spent a long convalescent period in bed. To while away the time, his father gave him chemicals with which he experimented. Ramsay later wrote:[19, 20]

I had the misfortune to break my leg at football. During my convalescence I read Graham's chemistry, chiefly, I must admit because I wanted to know how to make fireworks. I remember that my father gave me small quantities of potassium chlorate, phosphorus, sulphuric acid, and some small flasks and beakers and a spirit lamp, and with these I amused myself during several weary months.

Essays

The thought that a young child had access to the potentially explosive mixtures of potassium chlorate and phosphorus in his bedroom fills one with alarm even now!

Young Ramsay attended an elementary (state) school and then proceeded to Glasgow Academy where he quickly revealed his flair for languages. Apart from knowing much of the Bible by heart, he acquired fluency in German and French (later he learned to speak Italian, Norwegian, Swedish, and Dutch and could read several other ancient and modern languages).

At Glasgow University, which he entered in 1866, Ramsay studied classics general literature, logic and mathematics; but after a year he decided to become a chemist. In 1869 he worked for a short while in the laboratory of the chemical supplier Robert Tatlock. At the close of the Franco–Prussian War he went to Heidelberg with the intention of studying under Robert W. Bunsen, but early in 1871 he changed to Rudolf Fittig's laboratory at Tübingen where he obtained the degree of Ph.D. for research on toluic acid (methylbenzoic acid) and nitro-toluic acids. In 1874 he became the assistant to the Professor of chemistry at the University of Glasgow, but in barely six years he became (1880) first, Professor of Chemistry at University College, Bristol, and then, a year later (shortly after his marriage to Margaret Buchanan) its principal. In 1887 he succeeded the renowned organic chemist A. William Williamson as head of general chemistry at University College, London. By the time he left Bristol, Ramsay had established himself as a formidable physical chemist, knowledgeable about critical phenomena, under which liquids and gases are in equilibrium, and dexterous in the design and imaginative use of his own apparatus for handling minute volumes of gases.

The meeting between him and Lord Rayleigh in 1894 after the latter's lecture (on the anomalous density of nitrogen) at the Royal Society marked a major turning point in Ramsay's career. Their joint discovery of argon was soon followed by another of equal importance. It came about after Sir Henry Miers (1858–1947) of the British Museum had suggested that argon might be

identical with an inert gas, supposedly nitrogen, that William Hillebrand (1853–1925), of the United States Geological Survey, had obtained by heating certain uranium containing minerals, such as cleveite (impure UO_3). Ramsay prepared this gas and found that it was not argon, but yet another, new inert gas, identical in its spectrum with the element helium, the presence of which in the sun had been spectroscopically detected during the eclipse of 1868 by Sir Norman Lockyer and Sir Edward Frankland.

Recognizing the remarkable inertness of both argon and helium, Ramsay divined that there must exist a whole related family of such inert elements. He set about, with almost frenetic speed (along with his galvanized collaborators, especially his pupil Morris W. Travers) to search for others (Figure 4); and after many months of hard work using the process of fractional distillation three new inert elementary gases, neon (the new one), krypton (the hidden one), and xenon (the strange one) were all isolated and identified in mid-summer, 1898. These gases were isolated by Ramsay and Travers from one hundred and

Figure 4. Picture by the London cartoonist-Leslie Ward ("Spy" 1851–1922); Ramsey points to the eighth group of the Periodic Table which only contains elements that he discovered and isolated.

twenty tons of air which had been liquefied!

At the turn of the nineteenth and twentieth centuries, Ernest Rutherford and Fredrick Soddy[21] discovered, at McGill University, Montreal, that thorium had associated with it, in minute quantities, a radioactive gas, which they designated thorium emanation. It, too, was chemically inert. In 1903 Soddy joined Ramsay's department at London and began to apply the refined techniques of analysis perfected earlier. The "emanation" gas showed no discharge spectrum, but after a time, the spectrum of helium developed. This was incontrovertible proof of the transmutation of elements, an idea that, in 1903, had been proposed by Rutherford and Soddy. In late 1910, the "emanation", later called radon, was weighed by one of Ramsay's colleagues (Whytlaw-Gray) with a balance of (then) unsurpassed sensitivity. They found that 6.58×10^{-5} cm^3 of radon weighed 6.55×10^{-7} g, and thus they arrived at the atomic weight (222), thereby completing the entire Nobel gas group of the Periodic Table.

Ramsay's Character, Style, and Humanity

Apart from being one of the greatest chemical discoverers—he and Humphry Davy between them discovered 14 of the elements of the Periodic Table—he was gifted with rare scientific insight and imagination, and was the possessor of a most wonderful skill and dexterity in the devising, constructing, and use of apparatus for the delicate and exact investigation of gases. According to one of his greatest protégés, Frederick George Donnan (1870–1956)—of membrane equilibria fame—who succeeded Ramsay as Professor in 1913, he was:

…a man of sanguine and courageous temperament, of tireless energy, and power of instant action, he fearlessly attacked problems the experimental difficulties of which would have dismayed and deterred most men…. Nothing was ever postponed. What an ordinary very active man would do on Monday morning, Ramsay did on Saturday afternoon. He was endowed with extraordinary personal charm, and a most kindly, generous and gentle disposition… An

excellent linguist and musician, a witty and humorous speaker both in public and in private. The quickness and receptivity of his mind were remarkable, so that he was ever the enthusiastic friend and exponent of new advances in science. Thus he was one of the first chemists in England to teach and expound the work of Ostwald, Van't Hoff and Arrhenius with each of whom he could converse in their mother tongue.

Ramsay, like Rayleigh extended his activities in many directions: he found time to write a number of excellent texts on chemistry, was an ardent apostle of reform in converting the University of London into a great teaching University, and served as a member of the Royal Commission on sewage disposal and several other public bodies. Like many other truly great scientists, he could spot winners, two outstanding examples being Fredrick Soddy, Nobel Laureate 1921, and Sir Stafford Cripps, FRS (1889–1952) Statesman, Lawyer, Leader of the House of Commons in Winston Churchill's war-time cabinet, and chancellor of the exchequer in Clement R. Atlee's post-war government.[22] The papers which won Cripps from Winchester a Natural Science Scholarship to New College, Oxford in 1907 were so remarkable that Ramsay, who had been asked to scrutinize, persuaded Cripps to prefer the better equipped laboratories of University College London. This change meant that Cripps was doing advanced research even as an undergraduate. It resulted in Cripps being a part author of a paper on the properties of xenon read before the Royal Society when he was twenty-two.[23]

A Harmonious Partnership

It is fitting that this essay should end with reference to Helmholtz a natural philosopher greatly admired by both Rayleigh and Ramsay. Rayleigh heard Helmholtz give the Faraday Lecture at the Royal Institution in 1881, and it was Helmholtz's pioneering work that stimulated Rayleigh to write his *The Theory of Sound*. During the course of a memorable Friday evening Discourse at the Royal Institution on "*Argon*" in 1895, Rayleigh said:

In what I have to say from this point onwards, I must be understood as speaking on behalf of Professor Ramsay as for myself. At the first, the work which we did was to a certain extent independent. Afterwards we worked in concert, and all that we have published in our joint name, must be regarded as being equally the work of both of us. But, of course, Professor Ramsay must not be held responsible for any chemical blunder into which I may stumble tonight.

These are the very words uttered and written by Rayleigh in the enthralling account that he gave at the Royal Institution.[24] Rayleigh ended his lecture with the following words:

It will be known to many that during the last few months of his life Helmholtz lay prostrate in a semi paralyzed condition, forgetful of many things, but still retaining a keen interest is science. Some little while after his death we had a letter from his widow, in which she described how interested he had been in our preliminary announcement (upon the subject of Argon), and how he desired the account to be read to him again. He added the remark, 'I always thought that there must be something more in the atmosphere'.

[1] Sir George Gabriel Stokes (another senior wrangler), the Lucasian Professor of Mathematics, whom Strutt greatly admired, did carry out some lecture-demonstrations, and he also ran his own laboratory, where, he discovered the phenomenon of fluorescence. The only experimental courses available in Cambridge in the mid-1860s were those in chemistry, mineralogy, and certain biological sciences, a narrowness of choice which Strutt greatly resented.

[11] Dimensional analysis, pioneered as a mathematico-physical tool by Strutt, was later extended by others, notably the Nobel Laureate Percy W. Bridgman[12].

[12] "The Scientific Research of John William Strutt, Third Baron Rayleigh": J. N. Howard, *Proc. R. Inst. GB* **1988**, *60*, 73–86.

[13] One should not be surprised by the fact, for there were other contemporary, great scientists (like William Crookes, inventor of the radiometer and discoverer of the element thallium, and later, like Rayleigh, President of the Royal Society) who were deeply interested in psychical phenomena. That was a widely held view. In fact when the journal *Scientific American* published an editorial in 1920, under the heading "The Future Based on an Analysis of the last 70 Years", it was predicted that whereas the eighteenth century was characterized scientifically by advances in electricity the twentieth century would be equally remembered for advances in psychic research.

[14] The basic duties at the Royal Institution were light: the incumbent was to give each year a course of six Saturday afternoon lectures before Easter, as well as one Friday evening Discourse per annum, the lectures to be illustrated by experiments. In return he would have the year-round use of a laboratory of three rooms in the Royal Institution. The real attraction, it seemed, was that the Royal Institution was wired for electricity (thanks to the effort of the then Director, Sir James Dewar), which his laboratory at Terling was not.

[15] J. J. Waterston (1811–1883) developed the early Kinetic Theory of Gasses and

largely anticipated the theory put forward by R. J. E. Clausius in (1857).

[16] Who is now remembered for his studies of the Pockels effect, used in electro-optical modulators.

[17] Part of this account is based on the excellent Friday Evening Discourse given, at my invitation at the Royal Institution by J. N. Howard during my tenure of the Directorship. See ref. [12] for fuller details.

Prolegomena to Future Experimental Efforts on Genetic Code Engineering by Expanding Its Amino Acid Repertoire

*Nediljko Budisa**
Angewandte
Chemie

Protein synthesis and its relation to the genetic code was for a long time a central issue in biology. Rapid experimental progress throughout the past decade, crowned with the recently elucidated ribosomal structures, provided an almost complete description of this process. In addition important experiments provided solid evidence that the natural protein translation machinery can be reprogrammed to encode genetically a vast number of non-coded (i.e. noncanonical) amino acids. Indeed, in the set of 20 canonical amino acids as prescribed by the universal genetic code, many desirable functionalities, such as halogeno, keto, cyano, azido, nitroso, nitro, and silyl groups, as well as C=C or C≡C bonds, are absent. The ability to encode genetically such chemical diversity will enable us to reprogram living cells, such as bacteria, to express tailor-made proteins exhibiting functional diversity. Accordingly, genetic code engineering has developed into an exciting emerging research field at the interface of biology, chemistry, and physics.

1. Introduction

1.1. Genetic Program and Natural Laws

Life is a continuous interaction of an autonomous self-perpetuating system, composed of organic matter, with its physicochemical environment. Two factors shape this process: first, the deterministic laws of chemistry and physics (Natural laws) and second, the genetic program which determines all biological activities and phenomena. The existence of such a genetic program distinguishes living and non-living matter.[1] In the frame of such a program nucleic acids encode information and proteins replicate it.

The genetic information is defined by a precise sequence, either of bases in nucleic acids, or of amino acids in proteins. The information stored in deoxyribonucleic acid (DNA) may be retained as regulatory DNA, transferred to ribonucleic acid (RNA) and retained as tRNA, rRNA, snRNA, tmRNA etc., "reversed" from messenger RNA (mRNA) back to DNA (by a reverse transcriptase), or further transferred from RNA (through mRNA) to a protein. The "central dogma" of molecular biology, proposed originally by Crick,[2] was the first hypothesis capable of predicting a direction of transfer of genetic information in living beings. It states that "the transfer of information from nucleic acid to nucleic acid or from nucleic acid to protein may be possible, but transfer from protein to protein, or from protein to nucleic acid is impossible." This transfer is governed by the genetic code as a set of rules that precisely relates the sequence of base triplets in nucleic acids (polynucleotides) with a sequence of amino acid residues in proteins (polypeptides). After the elucidation of the triplet genetic code,[3, 4] it became clear how information for linear amino acid sequences was contained in the collinear nucleic acid sequences. That the 20 standard or canonical amino acids are assigned by 61 coding triplet combinations and three termination signals (Figure 1) is now considered as basic biochemical knowledge.

[†] When we are successful in finding a glimmer of light in the dark field of organic nature, which seems to provide us with a comprehensible entry to research in this field, one has always enough reasons to consider himself as lucky, even when one is fully aware of how inexhaustible this matter is.
Figure 1. The structure of the genetic code. Twenty amino acids are encoded by 61 triplet coding units or codons ("sense" codons), while the remaining three codons (UAA, UGA UAU) serve as termination signals in protein translation ("nonsense" codons). The set of 20 canonical amino acids is the result of the evolutionary assignment of coding triplets (codons) or codon families to particular amino acids (below). Note the increased redundancy in coding of strictly polar and apolar amino acids with the highly synonymous quotas for Arg, Ser (XGX codons), Leu and other hydrophobic amino acids (XUX codons). On the other hand, amino acids such as Met (AUG) or Trp (UGG) are assigned with only a single coding triplet.

1.2. What Is Genetic Code Engineering?

Experimental approaches for the expansion of the number of amino acids that can serve as basic building blocks in ribosome-mediated protein synthesis are described

Nediljko Budisa, born 1966 in Sibenik (Croatia), studied chemistry, biology, molecular biology, and biophysics at the University of Zagreb (Croatia). He carried out his Ph.D. work in the laboratory of Robert Huber at the Max-Planck-Institute für Biochemie in Martinsried and defended his Ph.D. thesis in 1997 at the Technical University, Munich. He continued his Postdoctoral work in Martinsried in the laboratories of Robert Huber and Luis Moroder where was been leading a "protein engineering" research team since 2000. He is currently finishing his Habilitation work (started 2001) at the Technical University in Munich.

in the literature under different names. Examples include "expanded scope of protein synthesis",[5] "expanded amino acid repertoire",[6] "expanded genetic code",[7] "tRNA-mediated protein engineering" (TRAMPE),[8] "site-directed non-native amino acid replacement" (SNAAR).[9] All these approaches have in common experimental re-coding, read-through, or changes in meaning of coding triplets in the frame of the existing universal genetic code. In principle, experimental readthrough can be achieved either by the reassignment of evolutionary assigned coding triplets (i.e. sense codons), or by suppression of termination triplets (UGA, UGG, UGU) or non-triplet coding units. In the context of protein expression, this can be achieved by controlling environmental factors (i.e. selective pressure) and/or by supplementation with redesigned translation components. The result of these experimental interventions at the level of the universal genetic code is an increase in its coding capacity by expanding the amino acid repertoire. In other words, the changes in the interpretation of the genetic code lead to the expanded scope of ribosome-mediated protein synthesis. The term "engineering of the genetic code" unifies all these aspects as it strictly refers to experiments aimed at changing the interpretation of the universal genetic code and thus at changing the structure of the code by introduction of novel coding units.

1.3. Terminology of Code Engineering

Engineering of the genetic code can be regarded as a novel interdisciplinary research field. This causes some difficulties in gaining a comprehensive overview of the field. For example, the subdiscipline of genetics brings with it a rather complex terminology. Widely used terms such as "functional genomics" or "proteomics" cover gene actions and interactions for the genome and proteome, reespectively, and include at least four levels of complexity: genes (the genome), messenger RNA (the transcriptome), proteins (the proteome), and metabolism (the metabolome).[10] It becomes even more complicated when other aspects such as post-translational modifications or pharmacological properties are included since each of these research areas uses its own terminology.

There is currently no generally accepted nomenclature for the field of code engineering. A simplified terminology[6] classifies amino acids in two general groups: canonical and noncanonical. Other distinctions include cognate/non-cognate, coded/non-coded, proteinogenic/non-proteinogenic, standard/nonstandard, natural/unnatural/non-natural, special canonical amino acids and biogenic amino acids. Amino acids isosteric or similar to the canonical ones are regarded as analogues or surrogates, and their mode of translation in proteins can be position-specific (directed by reassignments of rare codons and by suppression of termination or frameshifted coding units) or multiple-site (usually directed by reassignments of common coding triplets or codon families in the target sequence).

1.4. Routes towards an Expanded Amino Acid Repertoire

The current methodological developments in the field of genetic code engineering can be divided into two methodologically different, but equally valuable and promising approaches based on different traditions. The first approach, which is based on the use of auxotrophic strains, can be traced back to the classical experiment performed by Cowie and Cohen in 1957.[11] It relies on classical genetics based on breeding, strain construction, and selection of intentionally induced genetic variations in intact host expression cells that are forced to make "mis-incorporations" by environment control and manipulation, that is, by an externally imposed selective pressure. Usual terms used for this experimental approach are codon reassignments and multiple-site mode of incorporation.

The second approach can also be dated back to early experiments performed in an attempt to elucidate the genetic code and to get insights into the process of protein synthesis. The most prominent example is the classical discovery by Chapeville et al.[12] in 1962 which demonstrated that misacylated tRNAs (i.e. tRNAs charged with non-cognate amino acids) are able to participate in peptide bond formation at the ribosome in a fashion consistent with the adapter hypothesis. This discovery can be regarded as the birth of the experimental approaches that use mostly tRNAs with changed identity, usually suppressor tRNAs. By the use of chemically or enzymatically aminoacylated tRNAs the original meaning of coding units is "suppressed" leading to suppression-based methodologies, usually associated with the position-specific mode of incorporation.

1.5. Scope of This Review

The intention of this article is to provide a broader context for discussing the importance of selective-pressure-based methods in the field of genetic code engineering.[6, 13–17] This is indeed necessary due to the lack of recent comprehensive and critical reviews covering this topic. In addition, for a complete overview of this field a critical and systematic review of suppression-based methodologies is also provided. The diversity of topics and themes in chemistry and biology touched by this novel research field will be illustrated through discussions of challenging problems in contemporary biological chemistry. Apart from the attempt to contribute to a clarification of the taxonomic issues, this study will also address possible future research ventures. In this context, it is also important to consider potential global impacts of code engineering on the society.

A great deal of the discussions in this review of code engineering is actually related to the chemistry of *Escherichia coli* which till date, remains the main model microorganism for protein expression in biochemistry. A major task for future experiments is to realize engineering of the genetic code in eukaryotic cells to larger extents, which will certainly provide additional, novel, and exciting insights and concepts. Related fields such as protein modifications, peptide synthesis, recombinantly expressed protein and native ligation,

and in vitro use of chemically misacylated tRNAs will not be addressed since numerous reviews and textbooks are available on these topics.

2. Basic Features and Requirements for Cellular Protein Synthesis

2.1. Chemistry and Metabolism of Canonical and Noncanonical Amino Acids

One of the greatest successes of 19th century biochemistry was the establishment of the nitrogen-balance concept, which is closely related to amino acid metabolism.[18] Only after the advent of radioactive labeling in metabolic studies it became clear that this concept can be understood in terms of a balance between protein synthesis and catabolism. Because of this balance, amino acids are found in living organisms in both their free (modified or unmodified) forms, covalently integrated into peptides and proteins, or conjugated into other structures. Since life is based on protein chemistry, through its evolution on earth, a large variety of organisms has developed idiosyncratic ways of handling amino acids. Therefore, many findings regarding 1) mechanisms of amino acids formation, 2) their chemical nature, and 3) their intracellular transport turnover and discharge properties in *Escherichia coli* apply equally well to mammalian and other cell types.[19] In general, amino acids are either metabolically generated or are imported into tissues by means of active transport.

They may undergo different metabolic pathways serving as substrates for deamination that result in keto acid residues capable of entering the glycolytic pathway at the level of pyruvate or acetyl CoA or alternatively enter the Krebs cycle. In addition, they are both fundamental building blocks for protein synthesis as well as important components in the biosynthesis of numerous bioactive molecules such as nucleic acids, glutathione, nicotinamide sphingosins, porphyrin derivatives, various metabolic cofactors, neurotransmitters, and pigments.[10]

Under the normal physiological conditions and along with the steady state conditions of the growth medium, the amino acid levels in intracellular pools remain constant—oscillations and changes are associated with the cell cycle phase.[20] The transport of amino acids across the plasma membrane is an active process mediated by membrane permeases grouped according to their preference for certain types of amino acids. Living cells inspect many substances that can and do interfere with their metabolism. However transport systems are quite promiscuous and are also not capable of distinguishing between chemically and sterically similar amino acids (and other small molecules) and thus, cells pay the penalty of being penetrated by harmful substances.[19] Therefore, the formation of a pool of noncanonical amino acids is expected to take place just as much as of those of canonical ones.

Because of such a lack of specificity in the cellular uptake mechanisms, a particular cell would treat D- and L-forms in a similar, if not, identical manner and allow the incursion of all kinds of small molecules, which leads to the formation of intracellular pools of β-imino, β-, and γ-amino acids, cyclized

forms etc. Once such substances are present in the cytosol, they may affect a variety of metabolic, synthetic, and other physiological functions. In general, these amino acids have several effectrs: 1) They influence the amino acid biosynthesis, 2) they interact with catabolic enzymes, 3) they act as mechanism-based irreversible enzyme inhibitors, 4) they interfere with the amino acid transport and storage, and finally 5) they act in the translation process by serving as substrates for protein synthesis (i.e. they enter the genetic code).[19,21]

2.2. Why Are There Only 20 Canonical Amino Acids?

Numerum combinationum in terminis etiam numero finitis esse infinitum; si rite omnia expendantur. In ipso immenso combinatorium numero in immensum plures esse combinationes inordinatas, quam ordinatas.

(Careful examination reveals the infinite number of combinations between the finite numbers of terms. In this large number of combinations there are far more without order than with it.)

R. J. Boscovich, *Theoria philosophiae naturalis redacta ad unicam legem virium in natura existentium*, Venetiis, Ex Typographia Remondiana, **1763**, p. 254–256.

Assembling polymeric molecules from building blocks by means of predefined combination rules would certainly lead to combinatorial explosions.[22] The number of the monomeric building blocks is defined, whereas their transient assemblies (i.e. polymers) become entities of great variety, some of which are capable of function. The organized polymeric structures in living beings originate by a self-organization process under nonequilibrium conditions that is facilitated by self-enhancement or cooperativity.[23] These structures are constructed around a template and the choice of their fundamental building blocks is dictated by the need to implement the biological functions carried out by them. In this process of assembly, evolution led to the accumulation of structures/functions on account of their selective advantages. The main questions in this respect are as follows. What basic features should such polymers have? What limits their size, diversity, and complexity?

A few decades ago, Miller and Weber[24] were considering the hypothetical scenario for the independent origin of life on another planet in which proteins would function as catalysts. Which basic building blocks would then be used for the synthesis of the proteins? Applying physicochemical, genetic, and historical argumentation[25] for such a scenario, Miller and Weber concluded that about two-thirds of the basic building blocks would be of the same physicochemical nature as those on earth. According to this concept, amino acids that have adverse effects on protein structure, stability, and function, were excluded from the code. The explanation for the exclusion of other amino acid types that do not violate these rules is most probably historical, such as their unavailability or insufficient evolutionary time to produce them metabolically.[26]

Therefore, the answer to the question as to why only 20 amino acids represent the standard repertoire of the universal genetic code is an evolutionary one. The establishment of this set was certainly a historical process, a sort of "bottleneck" event to which all coding properties could be traced.[27] The establishment of the standard repertoire of 20 amino acids might be depicted either as the "last universal common ancestor",[28] as "progenote" local populations.[29] In other words, in their evolutionary development living beings must have reached a stage when any further amino acid repertoire expansion (i.e. further invasion or reassignments of coding triplets) were not possible without lethal effects. Indeed, genome and proteome complexity of evolutionary advanced eukaryotic cells allows further functional diversification by other means as has been extensively discussed elsewhere.[27]

In this way, the amino acid repertoire of the genetic code can be regarded as conserved. Canonical amino acids as basic monomers of protein structure have a capacity to allow foldable, properly stable, and functionally active structures with well-balanced and optimized sequence compositions, fully integrated into the cell metabolism and bioenergetics. As a result of these evolutionary optimizations, characteristic folds and stable conformations in proteins are largely preserved despite their great variations in their sequences.

In spite of such strict conservation in the code repertoire, it has been possible for decades to substitute, to a certain extent, in the whole proteome one canonical amino acid with a similar noncanonical one by simple experimental design. This procedure foresees simple selective pressure experiments based on the phenotype selection (metabolically engineered cells, e.g., auxotrophs), together with the fermentation conditions and amino acid supply control. Recombinant DNA technology brings these possibilities down to the level of single proteins (see Section 3.4).

Novel "intrinsic" codon reassignments designed experimentally should be chemically plausible. Every amino acid "privileged" for entry in such a "tailored" genetic code must be optimally designed to fulfil the selective requirement, for example, for polarity, hydropathy, molecular volume, isoelectric point, position in the protein structure with optimized codon template. Correspondingly, it was expected that a carefully designed selective pressure experiment should exploit the fact that there is sufficient room for increasing the diversity of the genetic code vocabulary.

2.3. Basic Features of Ribosome-Mediated Protein Synthesis

The genes involved in replication, transcription, aminoacylation and translation are almost universally conserved among the living kingdoms. Protein synthesis, a key step in realizing templated genetic information is performed by ribosomes in all living organisms. These translate the genetic information, previously transcribed from the DNA template to an mRNA (template replica), into the amino acid sequence of a protein. The DNA-replication, RNA-transcription, and protein translation are mutually interdependent processes that are intrinsically coupled with the proper folding of a target protein[6] (see Figure 2).
Figure 2. Flow chart depicting the transmission of genetic information. The accuracy of the translational process depends largely on two successive independent recognition events: 1) selection, activation, and covalent linkage of cognate amino acids with cognate tRNAs (aminoacylation) and 2) noncovalent interactions between charged tRNA with ribosome-bound mRNA (translation in *sensu strictu*). The basic coding is achieved through the conservative mRNA–tRNA codon–anticodon specific base pairing; the meaning of each codon is interpreted through the stringent substrate specificity of aminoacyl-tRNA synthetases (aaRS) in the aminoacylation reaction. Local changes in codon meaning and post-translation modifications provide a means to diversify protein functionality beyond its basic coding.

The protein translation process is shaped by two crucial molecular recognition events: codon–anticodon interaction between tRNAs and mRNAs on the ribosome (translation of the genetic information in *sensu strictu*) and a specific selection of the amino acid substrates by the enzyme actions of the aminoacyl-tRNA synthetases[30] (interpretation of the genetic code). It means that translation of the genetic message relies on interactions between nucleic acids (i.e. base pairing), whereas interpretation of the genetic message relies on the enzyme catalytic actions (i.e. enzyme–substrate interactions)[31] of the aminoacyl-tRNA synthetase (aaRS), and in exceptions on other enzymes as well. In fact, this second recognition event is the tRNA-aminoacylation catalyzed by corresponding enzymes, the aminoacyl-tRNA synthetases, which are highly specific for particular amino acids and their cognate tRNA isoacceptors. Therefore, aaRSs and tRNAs are central players in translation,[32] catalyzing the amino acid activation and accurate biosynthesis of aminoacyl-tRNAs, the immediate precursors for encoded proteins.

Transfer RNA plays a role of an adapter between amino acids and mRNA molecules[2] since it links in a collinear manner the information coded in the nucleotide sequence of mRNA with the amino acid sequence of the corresponding protein. Because of the degeneracy of the genetic code, there are more than forty adapters in *E. coli* alone. The basic architecture of tRNA molecules[33, 34] consists of an acceptor stem capable of being loaded with one amino acid and an anticodon loop which provides complementarity for coding triplets at the mRNA. Such a design predisposes the tRNA molecule to participate in both recognition events crucial for correct translation of a particular mRNA into the target protein sequence.

The original proposal of the adaptor hypothesis postulates that the synthesis of proteins from messenger RNA is possible since each cognate tRNA would be aminoacylated by a unique enzyme.[2] However, it is now well documented that many *Archaea* bacteria possess only 16 of the 20 canonical aaRSs. The absence of particular aaRSs (such as AsnRS and GlnRS) is often compensated in indirect ways, that is, by the recruitment of enzymes of intermediary metabolism.[32] Interestingly, the absence of CysRS is compensated by the dual function of the ProRS (which obviously recognizes both substrates).[35] These surprising findings will most probably be further extended in future genome and proteome mapping among different life kingdoms.

Other features of the translational apparatus include the existence of quality control mechanisms responsible for discrimination between the cognate/noncognate/biogenic amino acid.[36–38] Each tRNA from the cellular pool has its own "identity", which is defined as a sum of properties that enable its recognition through cognate aminoacyl-tRNA synthetase and prevent binding of other enzymes.[39, 40] Similarly, the "identity problem" of amino acids can be faced in the frame of the expanded amino acid repertoire as well. It is conceivable that one amino acid serves as a substrate for two synthetases. The two different tRNA species are then loaded as isoacceptors with the same amino acid and have the same "identity". For example, Tirrell and co-workers[41] clearly demonstrated that norleucine and norvaline are not only substrates for MetRS but also for LeuRS with attenuated editing activity. Similarly, chlorinated and brominated Phe analogues were equally good substrates for engineered PheRS from *E. coli*[42] as well as TyrRS from *M. jannaschii*.[43] Thus, it is reasonable to expect that future experimental manipulations with the intracellular concentrations as well as substrate specificities of aaRS will certainly yield "identity switches" of particular noncanonical amino acids between different coding triplets in the protein translation.

3. Traditional Auxotroph-Based Methods

It is well known from the evolution theory that mutations in living organisms occur spontaneously regardless of their fitness,[1,44] that is, they are random and the environment (selection) acts as a filter to those that are beneficial.[45] The transmission of this strategy from nature into the laboratory facilitates an anthropogenic selection of the phenotype of interest. Rapidly evolving organisms such as viruses, bacteria, protozoa or some organelles or fast growing mammalian cells in culture are usually selected for work in laboratory conditions on very short human time scales. A special class of mutants of bacterial or eukaryotic cells deprived of its own amino acid supply (auxotrophs) can be bred and selected by using methods of classical genetics.[46] The engineering of the genetic code benefits from such cells which are, in fact, either metabolically engineered microorganisms or eukaryotic cells. Cells selected in this way offer an almost ideal platform to affect the selection of the amino acids for protein biosynthesis, that is, to expand its amino acid repertoire. In general, to obtain new amino acids as building blocks for proteins, the selective pressure should be specifically designed for such a compound of interest. Successful experiments include 1) uptake of the noncanonical amino acid, 2) its attachment onto tRNA, and 3) its incorporation into the nascent polypeptide chain.

At the level of the genetic code and genetic message translation, this traditional auxotrophic approach results in sense-codon reassignments, which result in a canonical→noncanonical amino acid substitution in the protein sequence. Substitution experiments were done at the level of the whole proteome.[11] Later, when extra-chromosomal plasmid-directed protein expression systems became available, it was possible to replace amino acids in single target proteins (for example, see refs. [13,17,47–49]).

3.1. Early Experiments

The substitution of canonical amino acids with non-canonical ones is a relatively old approach in protein chemistry.[50,51] The recent revival of these methods can be seen as a renaissance of the pioneering work and ideas from the 1950s and 1960s.[52] Numerous observations and findings from these early studies are still relevant for the development of current methods. In the pioneering work, *Escherichia coli* had still not become a "model" organism for protein expression. Indeed, other microorganisms (*Staphylococcus*, *Bacillus*, *Lactobacillus*, *Salmonella*, *Leuconostoc*) and a variety of eukaryotic cells types (*Saccharomyces*, *Neurospora*, *Tetrahymena*, different carcinoma cell lines such as *HeLa*, hepatocytes, and lymphocytes) were used for incorporation experiments as well.[52]

The initial attempts to introduce variations into the amino acid composition in proteins were made by the fermentation of microorganisms in the presence of structural analogues of amino acids.[53] The basic criterion for one substance to be regarded as an "analogue" was the requirement of having a shape and size similar to those of the naturally occurring molecule without dramatic differences in biophysical properties. Such amino acid analogues that are sterically almost identical to the canonical ones are named isosteres (e.g., Met/SeMet[11] or Arg/canavanine[54]). Modifications that include addition/deletion of one or more methylene group in the side chain (e.g., Met/ethionine[53]) or other groups resulted in homologues of the amino acids. In recent research such amino acids are usually termed as "surrogates" (for examples see Chapter 4).

The first property of such analogues/surrogates observed was their potential to serve as antimetabolites and to penetrate into the amino acid pool of bacteria by the same route as their canonical counterparts. These pools are in dynamic equilibrium with the protein-synthesizing machinery. It was also shown that certain analogues, such as 3-α-indoleacrylic acid, indeed inhibits the endogenous supply (i.e. biosynthesis) of tryptophan.[55] In the context of the fermentation experiments such antimetabolic actions were observed as an emergence of "linear" instead of exponential growth in the cultures supplemented with these analogues.[56] This linear growth was correctly attributed to the incorporation of amino acid analogues into the vital cellular enzymes, which reduces or even abolishes the enzyme function. Almost all documented fermentation experiments with a variety of analogues (except SeMet) reported a linear growth of the culture upon addition of an analogue into the synthetic growth media.[57] These pioneering experiments confirm that the composition of proteins can be influenced by environmental changes, that is, by experimentally imposed selective pressure. Since then, experimental effort has focused towards more specifically defined goals to shed more light on the factors that determine amino acid incorporation into proteins. However, neither these earlier studies nor recent developments in this field, yielded general rules that are capable of predicting which changes will produce translationally active amino acid analogues. To date there are only empirical observations that are concerned with the chemical reactivity, molecular structure, volume, and other properties of the analogues/surrogates.

Nonetheless, these early studies paved the way for more extensive studies of the effects of the exchange of canonical for noncanonical amino acids on the enzymatic and immunological properties of selected proteins. Numerous historical examples of amino acid analogue applications in various fields ranging from microbiology to biomedicine are extensively reviewed elsewhere.[50,51,58]

3.2. The Importance of Cellular Extracts for Early Incorporation Experiments

As early as the beginning of 1950s it had been shown by several investigators that ribosome-mediated protein synthesis does not require the integrity of the cell and can continue after cell disruption.[59] Ribosomes in these cell extracts were programmed with endogenous DNA templates. These systems were invaluable in studies of molecular mechanisms of protein biosynthesis, requirements for protein synthesis, and elucidation of the genetic code. The introduc-

tion of the exogenous messengers as demonstrated by Nirenberg and Matthaei[3,4,60] paved the way not only to unambiguous deciphering of the genetic code, but also to the development of modern cell-free systems with dramatically improved performance. The availability of these cell-free extracts was also important for studying the requirements for protein translation with amino acid analogues/surrogates.

That a large number of amino acid analogues could be activated was well documented, even before a clear picture of the aminoacylation reaction emerged. In these initial experiments, extracts of *E. coli* were used to study the activation of noncanonical amino acids. Norvaline, α-amino-β-chloro-butyric acid, *p*-fluorophenylalanine, Nle, SeMet, and ethionine were activated by *E. coli* extracts.[52] The most important observation in these studies was that the rate of activation does not directly correlate with the translation of amino acid analogues into protein sequences. For example, extracts of a Phe-requiring *E. coli* strain were capable of activating β-2-thienylalanine at the same rate as Phe. On the other hand it is a poor substrate for protein synthesis in intact *E. coli* cells. The lesson from these experiments was obvious: activation of a particular amino acid does not automatically mean that it leads to translational activity. Later, extracts of the microbial auxotrophic strains as working material were replaced with purified aminoacyl-tRNA synthetases (aaRS) and activation was directly tested in ATP-pyrophosphate exchange reactions. By the end of 1970s an impressive number of noncanonical analogues capable of participating in activation reactions were known.[61]

3.3. Proteome-Wide Replacements: An "Unnatural Microorganism"

By the 1950s it was well known that amino acid analogues could be incorporated into the proteins of *E. coli* as well as that those substitutions might result in various biological effects.[52] However, the most important and far-reaching finding was the SeMet-incorporation into proteins made by Cowie and Cohen by use of the Met-auxotrophic *E. coli* ML304d strain.[11] Since the growth rate of the culture was dependent on the external Met supply, it was possible to design a defined synthetic medium in which Met was replaced by SeMet. In such cultures, ML304d cells grow more slowly than in cultures supplied with Met, but the shape of the growth curve was nevertheless exponential. SeMet, when offered as a sole source of replacement for Met, was found to completely and uniformly substitute Met in all cellular proteins retaining exponential growth. In other words, the cellular viability was not dramatically harmed by SeMet replacements and this first "unnatural" organism had similar properties to its Met-containing parental cells.

This landmark experiment by Cowie and Cohen[11] was certainly the first demonstration of proteome-wide substitution of Met residues through selenomethionine. SeMet is one of the few analogues for which a great substitution capacity has been demonstrated. Moreover, the work of Cowie and Cohen[11] is an excellent example of experimentally imposed changes in the interpretation of the genetic code (that is, the

Met→SeMet reassignment for the AUG coding triplet) by use of metabolically engineered cells (Met-auxotrophs). In the following decades, the focus was on the mechanism of the incorporation of SeMet in different cells as well as its role in aminoacylation reactions and protein synthesis. The recent renaissance of SeMet incorporation into proteins was possible only after Hendrickson[62] rediscovered the approach adopted by Cowie and Cohen as an important tool for structural biology. Namely, the replacement of sulfur for selenium in Met residues of proteins was recognized as a very effective anomalous scatterer of X-rays, a main prerequisite for multiwavelength anomalous diffraction (MAD) for solving the phase problem in X-ray crystallography of proteins.[63] The ever increasing number of protein structures resolved by MAD is a clear sign that SeMet proteins are not just another ephemeral trend in biochemical sciences.[64]

A second example of an "unnatural" microorganism was provided by Wong who reported a series[65] of microorganisms capable of intrinsically changing their preference for amino acids. In this experiment, *Bacillus subtilis* QB928 Trp-auxotroph was serially mutated and cultured for many generations in a defined minimal medium containing 4-fluorotryptophan. The resulting *Bacillus subtilis* mutant HR15, which shows a higher preference for 4-fluorotryptophan than for canonical Trp, has been described as the "first free-living organism in the past couple of billion years to have learnt to thrive on a genetic code that departs from the universal code". Unfortunately, an accompanying genotype analysis was not presented and experiments that would reproduce these exciting findings have not been done yet, to the best of our knowledge. Since 4-fluorotryptophan exhibits no characteristic fluorescence at room temperature, related labeled proteins should exhibit "silent" (i.e. suppressed) fluorescence. This was demonstrated in a study of ribosomal proteins isolated from *B. subtilis* HR15, which upon Trp/4-fluorotryptophan replacement lost their fluorescence.[66] The importance of Wong's experiments, however, lies in the fact that he demonstrated the power of genetic selection and the possibility of imposing experimental pressure on the membership mutation of the genetic code, that is, of making a microorganism with a changed genetic code vocabulary.

The approach adopted by Wong to design an "unnatural organism" has recently been revived by Ellington and Bacher. In 2001 they attempted to evolve *E. coli* variants that could survive on 4-fluorotryptophan ((4-F)Trp),[253] the growth-inhibitory properties of which are well known. They hypothesized that a relatively small number of proteins might be adversely affected, and some cells might mutate and emerge through many generations created in a simple serial transfer experiment in a way that (4-F)Trp could be accommodated in the proteome. After continuous evolution for 250 h and 14 serial transfers, the parent strain was adapted to 99% of (4-F)Trp in the medium. Although mutant strains capable of growing on 99.97% of (4-F)Trp in the synthetic medium have been isolated, the evolved strains maintained an absolute requirement for Trp. The authors concluded "that the incorporation of unnatural amino acids into organismal proteomes may be possible but that extensive evolution might be required to reoptimize proteins and metabolism to

accommodate such analogues". In their most recent contribution, Bacher, Bull, and Ellington switched to bacteriophage Qβ as a model system for the generation of chemically ambiguous proteomes.[254] The Qβ phage is a relatively simple model system, defined as a quasi-species since its genome is a weighted average of a large number of different individual sequences. The replication of this phage was examined in *E. coli* Trp-auxotroph in the presence of a series of monofluorinated Trp analogues. Even though the fitness of the phage after 25 serial passages increased substantially, an absolute requirement for traces of L-Trp remained.

Genetic selection was also the tool of choice for ambitious experiments performed by Marliere and co-workers[67] in which the goal was to design "microbial strains with a clear-cut requirement for an additional amino acid that should be instrumental for widening the genetic code experimentally".[68] Mutagenesis/selection cycles that resulted in *E. coli* mutant strains capable of installing translational pathways specific for additional amino acids in vivo, were selected. In this particular experiment, an *E. coli* mutant was grown with a defective thymidylate synthase; thus it lacked an essential enzyme for growth and viability. After the essential arginine codon (for Arg126) in the gene of the thymidylate synthase had been mutated to a leucine-codon, cells were able to grow only in the presence of azaleucine, that is, the activity of this enzyme could be restored only when azaleucine (whose structure mimics leucine, but serves as a functional substitute for arginine) was incorporated at position 126 of the enzyme. In other words, carefully designed selective pressure led to phenotypic suppression that causes Arg compensation with the antibiotic amino acid azaleucine. In the subsequent experiments, Döring and Maliere[69] selected stable bacterial strains with coding triplets that can be read ambiguously. The captured coding signal was the rare isoleucine codon AUA, and cysteine was used as "codon captor" due to the rarity of its codons in genomes. The possibility for total reassignment in *E. coli* by proper selection under experimentally defined pressure was proposed for the rare codon AUA. Most recently Marliere and co-workers[67] constructed an *E. coli* strain with a defective editing function of ValRS (Thr222Pro) capable of overall amino acid replacements by almost 24 % valine with α-amino butyric acid in the cellular proteome.

3.4. Substitutions in Single Target Proteins under Selective Pressure

It is a general rule that nearly all amino acids outside the 20 canonical and metabolic intermediates are toxic (i.e. they do not support cellular growth at all). An exception to this rule is SeMet,[70] and it was shown very early that *E. coli* Met-auxotroph ML304d substitutes completely Met with SeMet in cellular proteins.[11] On the other hand, it was also observed that toxic analogues (fluorinated phenylalanines, norleucine, and canavanine) might serve as substrates in protein synthesis. However, when such toxic analogues are supplied together with their canonical counterparts in the synthetic growth media, usually lower incorporation levels in all cellular proteins can be achieved. For example, the Met

analogue norleucine leads to replacement of only 38 % of the total cellular Met in proteins accompanied by greatly impaired viability of *E. coli* ML304d.[57] More recent experiments have shown that it is possible to replace about 50 % of the total cellular proteins in this way, since one further division of bacterial cells takes place after Met was exhausted in the intracellular pool and extra-cellular medium.[71,72]

The basic problem to overcome to achieve full substitution in target proteins was how to retain the translation capacity and at the same time exclude the metabolic toxicity. The use of auxotrophic mutants of bacteria provided a solution to circumvent toxic metabolic effects. Namely, such cells are suitable for design of successful replacement experiments because preferential incorporation of a noncanonical amino acid over a canonical one can be achieved. A particularly effective approach was to starve host cells of a specific canonical amino acid and to induce the synthesis of a specific protein, with concomitant addition of the analogue to the culture medium. Sykes et al.[73] succeeded in this way in replacing 10 % of all Tyr residues in alkaline phosphatase. Bacteriophage-coded proteins labeled with fluorinated amino acids have been prepared in a similar manner by simultaneous initiation of bacteriophage infection and amino acid analogue addition.[50]

However, the auxotrophic approach for complete labeling of target proteins could be fully generalized to a single target protein only after the introduction of recombinant DNA techniques. Cohen, Boyer, and co-workers[74] found a means to reassemble isolated DNA fragments and genes in new arrangements and to propagate these fragments in living cells. With this method at hand, highly efficient expression systems capable of generating heterologous proteins in large amounts become available. On the other hand, such controlled extrachromosomally encoded protein expression systems provide an excellent platform for the expansion of the amino acid repertoire. In particular, the stringent control of a heterologous gene expression allows the full exercise of selective pressure on the translation apparatus to produce a single substituted target protein in the context of the host cell with an unchanged proteome.

Most importantly, the desired noncanonical amino acids can be incorporated in single target proteins without harmful global effects on the expression host. The basic requirements include: 1) selection of proper cell and expression system, 2) control of fermentation conditions (i.e. environment), 3) selective pressure for the replacement of the amino acid (i.e. the reassignment of the sense-codon(s)) in a single protein.[13] This approach is termed as the selective pressure incorporation (SPI) method since it is based on the principle that the choice of the amino acids for protein synthesis could be conditioned by the control of environmental factors such as amino acid supply and fermentation parameters, that is by an experimentally imposed selective pressure.[6]

The SPI method has been practised under various names by different research groups (e.g. the auxotroph method, media-shift) in the past decade. In the course of this research, a large number of noncanonical amino acids have been incorporated into proteins. The experimental pressure on a selected expression host has been exercized as follows. The

target gene activity is kept silent while the host cells are grown to an appropriate density. After sufficient "healthy" cells are produced, the synthesis of the target protein is induced. From this point on, the host cells serve only as a "factory" to produce the desired recombinant protein. The fermentation in minimal media with growth-limiting concentrations of the native amino acid as natural substrate leads to its depletion in the medium. At this point, the noncanonical amino acid is added and the protein synthesis is induced. As a result of such a pressure on the translation apparatus, the target protein containing exclusively noncanonical amino acid(s) is accumulated. This procedure leads to the arrest of cellular growth, but in the light of a successful expression of target protein variants, this fact is of less importance.[15] Thus, the toxicity can be circumvented in quite a simple and straightforward way. Alternatively, biosynthetic pathways of host cells, as the endogenous supply, can be blocked by intracellular supplementation with proper inhibitors during incorporation experiments.

In fact, the SPI approach as an extension of the heterologous expression is based on the incapability of aaRS, as crucial enzymes in the interpretation of the genetic code, to distinguish between a variety of structurally and chemically similar substrate analogues in the aminoaylation reaction (Figure 3).[6] It enables generally a reassignment of the coding triplets, that is, changes in the interpretation of the genetic code under the experimentally imposed selective pressure in the context of an intact proteome of the host cell. The basic advantages of the SPI method lie in the possibilities

for sense-codon-directed (residue-specific) substitutions, expression and purification of variant proteins at wild-type levels, as well as in the simple, reproducible methodology. For these reasons, SPI is still the method of choice for the production of labeled proteins on a larger scale, for example, for sample-intensive methods of structural biology (such as NMR spectroscopy[73,75] or X-ray crystallography of proteins[63,70,76]) or the production of therapeutic proteins on an industrial scale (Section 7).[14,15,77]

3.5. Enhanced Translation System for the Biosynthesis of Proteins

Selective pressure based methods can be further improved by a manipulation of the activity of particular translation components. For example, Tirrell and co-workers tested a library of nine unsaturated Met analogues for translation activity (Figure 4)[5] in order to introduce the various terminally saturated Met analogues. However, only *trans*-crotylglycine acid (**12**) was incorporated into a model protein. The other Met-surrogate, *cis*-crotylglycine (**17**), was not translationally active in spite of its modest activation capacity. An efficient incorporation (over 90%) of the latter into model proteins has been achieved only after endogenous coexpression of recombinant MetRS.[78] This clearly demonstrates an obvious correlation between activation and translation capacity at least in aaRS (Tyr, Met) without any additional editing function. In this way, a whole repertoire of the Met analogues was incorporated into proteins after
Figure 3. The main routes towards the expanded amino acid repertoire for ribosome-mediated protein synthesis. In the center of these experimental efforts is the tRNA with a changed identity or tRNA aminoacylated with the desired noncanonical amino acid. Such a aminoacylated tRNA can be created either by chemical synthesis (left), or by the use of cognate aminoacyl-tRNA synthetases (aaRS, right). The construction of chemically aminoacylated tRNAs takes advantage of the fact that all tRNAs have a common acceptor sequence (-CCA). Controlled digestion allows the removal of two terminal nucleotides (-CA) in every type of tRNA.[158] The amino acid of interest can be chemically acylated to the dinucleotide p(d)CpA and then attached to the suitably prepared suppressor tRNA by T4 RNA ligase.[166] Such tRNAs can be mainly used for in vitro protein synthesis and only in special cases in vivo. On the other hand, enzyme-mediated aminoacylation can be performed either in vivo or in vitro. Since native aaRS are often promiscuous in their substrate specificity, a rather large number of noncanonical amino acids can be loaded onto cognate tRNAs and translated into the target protein sequences.[6]
Figure 4. Expansion of the coding capacities of AUG and UGG triplets, which are in the genetic code assigned to the canonical amino acids methionine (**1**)[13,76] and tryptophan (**19**),[17,74,75,102–106] respectively. These evolutionary codon assignments make Met and Trp obligatory building blocks in protein synthesis, as they both belong to the first coding level. Experimental reassignments of AUG and UGG coding triplets enable entire libraries of mostly isosteric, noncanonical amino acid analogues and surrogates to serve as substrates for ribosome-mediated protein synthesis, building in this way a second or facultative coding level in the genetic code. Noncoding levels consist of amino acid substrates for which experimental attempts at incorporation were unsuccessful to date. One of the main tasks of code engineering is to "move" translationally inactive amino acids from the noncoding level to coding levels. Most of the translationally active amino acids presented here were incorporated into proteins by the groups of Budisa and Tirrell. Note that translationally active allylglycine, 2-butynylglycine (not shown) as well as norvaline (**9**), norleucine (**3**), homoallylglycine (**11**), and homopropargylglycine (**8**) might serve as substrates for engineered LeuRS as well.[102–106] This novel feature in the translational process ("identity problem") is discussed in detail in the text. Methionine analogues and surrogates: selenomethionine (SeMet, **2**), 2-aminoheptanoic acid (**4**), telluromethionine (TeMet, **5**), *S*-nitrosomethionine (**6**), trifluoromethionine (**7**), ethionine (**10**), *trans*-crotylglycine (**12**), selenoethionine (**13**), azidohomoalanine (**14**), metoxinine (**15**), azidoalanine (**16**), *cis*-crotylglycine (**17**), and trifluoronorleucine (**18**). Translationally active tryptophan analogues and surrogates: 7-azatryptophan (**20**), 4-, 5-, and 6-fluorotryptophan (**21–23**), 5- and 4-hydroxytryptophan (**24** and **25**), 5- and 4-aminotryptophan (**26** and **27**), L-β-(thieno[2,3-*b*]pyrrolyl)alanine (**28**), L-β-(thieno[3,2-*b*]pyrrolyl)alanine (**29**), β-selenolo[2,3-*b*]pyrrolyl-L-alanine (**30**), and β-selenolo[3,2-*b*]pyrrolyl-L-alanine (**31**). The 7-fluorotryptophan, and 4-methyltryptophan are not shown. Translationally inactive Trp analogues and surrogates: 5-cyanotryptohan (**32**), benzothienopenalanine (**33**), azulene (**35**), 1-, 6-, and 7-aminotryptophan (**34**, **36**, **37**), 7-trifluoromethyltryptophan (**38**), and azatryptophan (**39**). The IUPAC names of the compounds are available in the Supporting Information.

fermentation and expression of target proteins in Met-depleted cultures of *E. coli* in which MetRS was overexpressed and the medium supplemented with the analogue at millimolar concentrations.

In addition, this approach can be employed even with synthetases with well documented editing activity, but only if the desired noncanonical amino acid is not a substrate for editing reactions. For example, the leucine analogue trifluoroleucine is about 200-fold less active than leucine in the ATP-pyrophosphate exchange activation assay.[79] Nevertheless, it can easily be incorporated into relatively small coiled-coil proteins under normal expression conditions.[80] On the other

hand, the leucine analogue hexafluoroleucine does not support protein synthesis because it is activated approximately 4000-fold more slowly than leucine. The elevated intracellular concentrations of leucyl-tRNA synthetase proved to be a crucial factor for the incorporation of hexafluoroleucine as a response to the leucine-coding triplets in the mRNA sequence of coiled-coil protein HA1.[81]

It now becomes clear that at least some of the non-canonical amino acids that do not support protein synthesis under conventional expression conditions, can indeed be efficiently incorporated into proteins after the amount of intracellular aaRS is increased in the microbial host.

3.6. Engineering the Catalytic and Editing Function of aaRS

The aminoacylation reaction is one of the main "filters" for the entry of noncanonical/non-cognate amino acids into the genetic code.[38] The "classical" SPI approach simply exploits a "promiscuity" of the wild-type aaRSs to expand the amino acid repertoire.[6] Nevertheless, the number of non-canonical amino acids capable of entering the genetic code by this route is regarded to be relatively small and the range of desired chemical diversity is rather modest when compared to that obtained with the suppression-based methodologies that exploit chemical tRNA aminoacylation. Therefore, the in vivo expansion of the amino acid repertoire by using the SPI approach must profit to a greater extent, if aaRSs of the microbial host would be supplemented or replaced with designed enzymes with changed or relaxed substrate specificity.

Kast and Hennecke[82] reported an engineered mutant of phenylalanyl-tRNA synthetase (PheRS) with a mutation in the binding pocket (Ala294Gly) which charges tRNA^Phe with *p*-chlorophenylalanine. Later, Ibba, Tirrell, and co-workers[42, 83] demonstrated that it was possible to introduce amino acids such as *p*-chlorophenylalanine (**45**) and *p*-bromophenyl-alanine (**52**) into recombinant luciferase and dihydrofolate reductase by using bacterial hosts extra-chromosomally supplemented with this PheRS variant, which exhibits relaxed substrate specificity. A novel mutant of *E. coli* PheRS computationally designed with the additional mutation Thr251Gly further relaxed the substrate specificity. The *E. coli* expression host supplemented with this enzyme was capable of incorporating a whole set of Phe analogues and surrogates such as *O*-acetyltyrosine (**65**), *p*-bromophenylala-nine (**52**), *p*-iodophenylalanine (**46**), *p*-cyanophenylalanine, *p*-ethynylphenylalanine (**66**), *p*-azidophenylalanine (**59**), and 2-, 3-, and 4-azaphenylalanine (**53**, **55**, **56**)[83, 84] into the model protein dihydrofolate reductase (Figure 5).

Aminoacyl-tRNA synthetases without editing activity such as TyrRS are especially attractive targets for substrate-specificity engineering. For example, the mutant Phe130Ser of TyrRS from *E. coli*, whose affinity for 2-azatyrosine (**61**) is elevated, was selected by screening of *E. coli* cells transformed with the mutant TyrRS gene (*tyrS*) harboring plasmids.[85] Similarly, yeast TyrRS-engineering based on the available three-dimensional structure of the enzyme from *Bacillus stearothermophilus*, yielded the mutant Tyr43Gly-

TyrRS which was able to utilize several 3-substituted Tyr analogues as substrates for aminoacylation.[86] Moreover, this yeast Tyr43Gly-TyrRS imported into *E. coli* preferentially recognizes 3-iodotyrosine (**49**) rather than Tyr itself. Schultz and co-workers[87] chose the TyrRS from *Methanococcus jannaschii* to produce a library of its mutants with novel substrate specificity. In this way they selected a mutant with higher specificity for *O*-methyltyrosine (**60**) than for Tyr itself.[88]

A more sophisticated system was reported recently based on combined genetic selection and screening. This system allowed rapid evolution of the substrate specificity of TyrRS from *M. jannaschii*. An antibiotic marker was used in combination with the amplifiable fluorescence reporter to screen for variants with the desired change in amino acid specificity.[43] An advantage of this approach is that the amplifiable fluorescence reporter allows evaluation of aaRS activity and selectivity. In this way, the amino acid binding pocket of a TyrRS from *M. jannaschii* was systematically mutated, which allowed one to select a series of novel TyrRS variants that leads to specific aminoacylation of various Tyr analogues, that is, Tyr-like (or Phe-like) amino acids substituted with different functional moieties such as methoxy,[88] amino,[89] alkenyl,[90] keto,[91] azido,[92] and naphtyl groups[93] as well as substrates with photocrosslinking groups[94](Figure 5).

Another way to achieve a greatly expanded amino acid repertoire for one particular system is the use of synthetases with deleted or attenuated editing activity. Recently, Mursinna and Martinis[95] reported a rational design that led to a blocking of amino acid editing in LeuRS from *E. coli*. In this enzyme a single Thr at position 252 (in the amino acid binding pocket of the editing active site) plays a critical role in the editing reaction; its mutation with bulky amino acids such as Phe or Tyr results in the loss of the editing reaction. Such inactivated LeuRS has the potential to provide an efficient and facile enzymatic synthetic route to generate tRNAs loaded with noncanonical amino acids. Tirrell and co-workers isolated and characterized three LeuRS mutants (Thr252Tyr; Thr252Leu; Thr252Phe) with attenuated editing activity.[41] The LeuRS Thr252Tyr mutant was endogenously overexpressed together with target proteins, which allows the incorporation of the noncanonical amino acids norvaline (**9**) and allylglycine. In addition, noncanonical amino acids described as Met-surrogates were incorporated at the Leu positions of the model protein, for example, homoallyglycine (**11**), homopropargylglycine (**8**, Figure 4), and 2-butynylgly-cine.[41]

Finally, a computational approach for predicting the relative energies of the binding of different noncanonical amino acids into the binding site of aaRS on the basis of crystal structures or homology-derived models represents a useful approach for virtual screening of amino acid analogues. In this context, Goddard et al. reported that the calculated binding energies of some Phe analogues to PheRS correlate well with their translation activities in *E. coli*.[96] Another recently reported example includes a computing procedure termed as the "clash opportunity progressive computational method" for designing mutants of aaRS with higher preference for noncanonical amino acids.[97]
Figure 5. Canonical amino acids Phe and Tyr, encoded with two coding triplets are especially attractive substitution targets for amino acid repertoire expansion. Their "second" coding levels include at least 25 analogues and surrogates. Note that in terms of "identity", many of them can be assigned either as Tyr or Phe analogues, or surrogates, depending on the system in which they were used. For example, *p*-iodophenylalanine (**46**) and *p*-bromophenylalanine (**52**) can be incorporated into proteins either by using *E. coli* cells whose PheRS exhibit relaxed substrate specificity or by using plasmids harboring TyrRS from *M. jannaschii* with novel substrate specificity. Although analogues such as *p*-aminophenylalanine (**57**), *p*-azidophenylalanine (**59**), *p*-benzoylphenylalanine (**62**), and 2-naphthylalanine (**64**) are introduced into model proteins in a response to the termination UGA coding unit by using suppressor tRNA, there is no doubt that they can be translated into proteins in a response to UAU or UAC sense coding triplets by using designed TyrRS and cognate tRNAs (see text for more details). Presented amino acids: tyrosine (**40**), phenylalanine (**41**), *o*-, *m*-, and *p*-fluorophenylalanine (**42–44**), *o*- and *p*-chlorophenylalanine (**51**, **45**), *o*- and *m*-fluorotyrosine (**47**, **48**), *m*-iodo- and *m*-chlorotyrosine (**49**, **50**), 2-, 3-, and 4-azaphenylalanine (**53**, **55**, **56**), 2,6-diazaphenylalanine (**54**), 2- and 3-thienylalanine (**73**, **58**), *O*-methyltyrosine (**60**), 2-azatyrosine (**61**), *O*-allyltyrosine (**63**), *O*-acetyltyrosine (**65**), *p*-ethynylphenylalanine (**66**), *m*-amino- and *m*-metoxytyrosine (**67**, **71**), *m*-hydroxytyrosine (DOPA, **68**), β-fluorophenylalanine (**69**), 3,5-diiodotyrosine (**70**), 3-thienylglycine (**72**), cyclooctatetraenylalanine (**74**), cyclohexylalanine (**75**) (4-boronic acid)phenylalanine (**76**), carboranylalanine (**77**). The IUPAC names of the compounds are available in the Supporting Information.

4. Power and Limits of Selective Pressure: Engineering a "Second" Code

Expansion of the amino acid repertoire, especially in vivo is constrained by general limits imposed by this specific experimental milieu. These limits are metabolic constraints (related to the metabolic toxicity of most of the amino acids outside the canonical 20 as prescribed by the genetic code), proofreading mechanisms in the transmission of genetic information that are providing the fidelity of protein translation, and finally protein folding rules that are closely related to the structure of the genetic code and physicochemical properties of the amino acids. To challenge these constraints and to find means to bypass, change, or modulate aaRSs activities is one of the most fundamental problems of the engineering of the genetic code.

The expansion of the amino acid repertoire as presented in Figure 6 reveals that the postulated universality of the genetic code should not be limited to its first (restricted) part,

but also to its second part (relaxed or second code) which can be experimentally assessed.[6] Three levels in the structure of the genetic code can be postulated (Figure 4 and 5): the first coding level includes canonical amino acids whose entry in the genetic code is obligatory; the second coding level includes noncanonical amino acids whose entry is allowed in the code (i.e. entry is facultative); the third or non-coding level includes all amino acid analogues whose entry in the genetic code by sense-codon reassignments is not allowed (i.e. entry is forbidden) at this level of the method development. In other words, for each amino acid in the standard genetic code table it should be possible to establish or define a whole library of translationally active substances, capable of being incorporated in proteins. The final goal would be to build up an extended structure of the genetic code that would have an additional (i.e. second) coding level with a defined library of translationally active analogues and surrogates for each canonical amino acid. Alternatively, the goal can be defined as an attempt to move amino acids from the non-coding to

Figure 6. The concept of the "second" coding level of the genetic code in the frame of an expanded amino acid repertoire.[6] Canonical amino acids are neither metabolically toxic nor do they undergo proofreading functions. For entry into the genetic code, noncanonical amino acids must fulfil three criteria: they must not be toxic, they should permit proofreading, and they should allow folding of target protein. Additional difficulties might include problems with cellular uptake, metabolic activation, or modification before, or after their charging onto cognate tRNAs. Once such a noncanonical amino acid is reproducibly translated into a protein sequence, it attains full membership in the "second" coding level of the universal genetic code. Proteins expressed in this way that contain noncanonical or artificial amino acids are termed "alloproteins"[121] or "tailor-made" (or custom-made).[204]

coding levels. In Sections 4.1–4.9, a brief overview of eleven amino acids that were targets for replacements.

4.1. Tryptophan

Tryptophan is an attractive target amino acid for replacement since it is the source for almost all of the absorption and fluorescence of proteins. The diverse and rich indole chemistry offers numerous Trp analogues, which can be tested for translation activity. As the rarest amino acid with only about 1% of all residues of globular proteins, Trp provides an almost site-specific intrinsic probe for studying protein structure, dynamics, and function.

The initial attempts to expand the amino acid repertoire for the Trp-coding triplet UGG were reported by Pardee et al. in 1956[98] and by Brawerman and Yčas in 1957.[99] These groups incorporated 7-azatryptophan (**20**) and 2-azatryptophan (**34**) into all proteins of *E. coli*, and incorporated Trp analogues into eukaryotic proteins. Schlesinger reported alkaline phosphatase as the first single enzyme to be labeled with these amino acids in the context of intact cells.[47] Sykes and Ho and their respective co-workers introduced for the first time fluorotryptophan-substituted proteins as tools suitable for ¹⁹F NMR analysis.[73,100] In the last decade Szabo, Ross, and their co-workers[17,101,102] have further extended this repertoire by introducing 5-hydroxyryptophan (**24**) as a useful intrinsic fluorescent probe. Selenophen-and

thienyl-containing Trp analogues have proved to be useful as pharmacologically active substances and markers for X-ray crystallography of proteins.[76,103] One of the most recent advances is the incorporation of aminotryptophan analogues, which opens the possibility to design protein-based sensors (see Section 7).[104,105]

The expanded repertoire for the Trp-coding triplet UGG achieved by the use of the SPI method, currently includes the following translationally active analogues and surrogates (Figure 4): 4-fluorotryptophan (**21**),[66] 5-fluorotryptophan (**22**), 6-fluorotryptophan (**23**), 7-fluorotryptophan, 4-methyl-tryptophan, 7-azatryptopahan (**20**), 4-hydroxytryptophan (**25**),[105] 5-hydroxytryptophan (**24**),[106] 4-aminotryptophan (**27**), 5-aminotryptophan (**26**),[105] L-β-(thieno[3,2-*b*]pyrrolyl)-alanine (**28**), L-β-(thieno[2,3-*b*]pyrrolyl)alanine (**29**),[77] β-selenolo[3,2-*b*]pyrrolyl-L-alanine (**31**), and β-selenolo[2,3-*b*]pyrrolyl-L-alanine (**30**).[76,103]

Although early work suggest that the methylated Trp analogues might be good substrates for tryptophan-tRNA synthetase (TrpRS), and translation machinery,[106] recent experiments indicate that only 4-methyltryptophan is a substrate for native *E. coli* translational machinery.[107] The protonated nitrogen atom of indole obviously has its unique significance in the recognition of Trp and its analogues by TrpRS and translation apparatus in general. This was demonstrated by the synthesis of such analogues in which the imino group was replaced with other heteroatoms (selenium, sulfur, or oxygen); the resulting amino acids were translationally inactive.[77] For example, Trp-like blue amino acid **35** with an azulene ring system is not a substrate for native translation machinery[108] even when it is chemically charged onto tRNA for an in vitro reaction.

To date, there are no reports about the systematic attempts to extend the substrate specificity of TrpRS.[109] It is indeed not difficult to foresee how much additional chemical diversity in proteins could be achieved with such engineered TrpRS at hand. Moreover, attempts to create an orthogonal pair that would use the rare UGG codon would be the most straightforward way to achieve both position-specific and multiple replacements.

4.2. Tyrosine

The experiments of Munier and Sarrazin, in 1962[110] that demonstrated the incorporation of *m*-fluorotyrosine ((3-F)Tyr, **48**) in β-galactosidase mark the beginning of the development of an expanded amino acid repertoire for the Tyr-coding triplets UAU and UAC. In the 1970s, Sykes, Lu, and co-workers[73,111] recorded ¹⁹F NMR spectra of the *lac*-repressor labeled with (3-F)Tyr as well as of alkaline phosphatase from *E. coli*. One decade later, Ring and Huber probed the role of catalytic Tyr in the active site of β-galactosidase by the global replacement of all Tyr side chains with (3-F)Tyr.[112,113] Brooks et al.[114] succeeded in expanding the repertoire of translationally active Tyr analogues by incorporating *o*-fluorotyrosine (**47**) and 2,3-difluoro-tyrosine into ketosteroid isomerase from *Pseudomonas testosteroni*. An early report by Calender and Berg[115] about the

possibility of using L-DOPA (**68**) for incorporation into proteins was not supported by recent experiments[116] (Figure 5).

The investigations into the modification of tyrosyl-tRNA synthetase (TyrRS) from *E. coli* yielded a mutant Phe130Ser-TyrRS capable of introducing the Tyr analogue azatyrosine (**61**) into cellular proteins. Yokoyama and co-workers[86] developed a suppressor tRNA^{Tyr} and a mutant TyrRS that incorporate *m*-iodotyrosine (**49**) into proteins in mammalian cells. The research group of Schultz have evolved a couple of orthogonal *M. jannaschii* TyrRS/tRNA$_{CUA}$^{Tyr} pairs with an impressive wide range of substrate specificity.[43] Amino acids such as *O*-methyltyrosine (**60**), *O*-acetyltyrosine (**65**), *O*-allyltyrosine (**63**), 2-naphthylalanine (**64**), *p*-aminophenylalanine (**57**), *p*-iodophenylalanine (**46**), *p*-bromophenylalanine (**52**), *p*-azidophenylalanine (**59**), *p*-benzoylphenylalanine (**62**) were incorporated into the green fluorescent proteins,[89] glutathione-S-transferase[117] and dehydrofolate reductase[88] as a result of efficient suppression of the UGA termination codon (Figure 5).

Interestingly, a structural homology of TyrRS and TrpRS indicates that the two enzymes can be described as conformational isomers. It remains to be seen whether this feature can be used for a switch or relaxation in their substrate specificity and thus allow an additional expansion of the amino acid repertoire.

4.3. Phenylalanine

Fluorinated phenylalanine analogues were used in the initial incorporation experiments as well as in the last few years mainly for protein NMR spectroscopy. Yoshida[118] found the stability of *Bacillus subtilis* α-amylase remains unchanged upon partial replacement of Phe with *p*-fluorophenylalanine (**44**) but its activity was altered. Conversely, Richmond[52] found that *Bacillus cereus* exopenicillase changed its immunological properties upon substitution with *p*-fluorophenylalanine. On the other hand, for alkaline phosphatase from *E. coli*, replacement of 56% of the Phe groups with *p*-fluorophenylalanine had no detectable effects on stability and activity. More recently, *o*-, *m*-, and *p*-fluorophenylalanine (**42**, **43**, **44**) were systematically incorporated into recombinant proteins or recombinantly produced materials[119] providing them with interesting optical[120] and thermal properties as well as with altered kinetics. Janecek and Rickenberg[121] have shown that β-galactosidase expressed in the presence of the Phe surrogate 2-thienylalanine (**73**) is more labile than the normal enzyme. They also found that this 2-thienylalanine although a substrate for protein synthesis, inhibits permease action, that is, its active transport in the cytosol. This is the reason why incorporation of this analogue is quite poor in auxotrophic strains with intact permease function. More recently, the Phe analogue 3-thienylalanine (**58**) was incorporated into a recombinant periodic protein that forms lamellar crystals comprising regularly folded β-sheets.[122] Koide et al.[123] reported the incorporation of Phe analogues with pyridyl groups in recombinant human epidermal growth factor. These ana-

logues, for example 2-azaphenylalanine (**53**), 3-azaphenylalanine (**55**), and 4-azaphenylalanine (**56**), are protonated in acidic solutions (Figure 5).

The discovery of a bacterial PheRS variant with relaxed substrate specificity by Kast and Hennecke[82] paved the way for further expansion of the translationally active Phe surrogates and analogues. The halogenated analogues *p*-chloro- (**45**), or *p*-bromophenylalanine (**52**) were incorporated into full-length luciferase in vitro.[42] Further redesign of the active site of PheRS and its use for a coexpression in *E. coli* resulted in replacement of Phe residues by *O*-acetyltyrosine (**65**), *p*-aminophenylalanine (**57**), *p*-iodophenylalanine (**46**), *p*-bromophenylalanine (**52**), *p*-azidophenylalanine (**59**), *p*-chlorophenylalanine (**45**), *p*-cyanophenylalanine, *p*-ethynylphenylalanine, (**66**) *p*-azidophenylalanine (**59**), and 2,6-diazaphenylalanine (**54**) in dihydrofolate reductase.[83,124] These designed PheRS variants allow efficient in vivo incorporation of aryl ketone functionality into proteins, which is normally rejected by the cellular translational machinery.[84] Several Phe-based amino acid substrates such as *p*-bromophenylalanine and *p*-iodophenylalanine were incorporated into proteins as a response to the amber stop codon using engineered TyrRS from *M. jannaschii*.[43] In this way, all these amino acids can have a "dual identity" serving as substrates for both systems (Figure 5).

4.4. Histidine

Histidine analogues 1,2,4-triazolyl-3-alanine and 2-methyl-histidine have been successfully incorporated into *E. coli* alkaline phosphatase. The resulting enzyme was inactive since it could not dimerize.[58] The same analogues were incorporated into aspartate transcarbamylase and a mutant phospholipase A2. The products of these modifications differ dramatically from the native enzyme with regard to the activity–pH profiles.[125] In fact, the replacement of His by its noncanonical counterpart 1,2,4-triazolyl-3-alanine yields an enzyme with high activity at acidic pH.[126] A similar effect was achieved by the incorporation of 2-fluorohistidine[127] and 4-fluorohistidine; the pK_a value reduced by approximately 5 pH units.[58] Such a dramatic increase in the acidity of the imidazole ring dramatically alters the activity and properties of the fluorohistidine-containing proteins. This strong effect on pK_a possibly induces a loss in enzymatic activity in many proteins in the physiological milieu making such His replacements with 2-fluorohistidine and 4-fluorohistidine responsible for the toxicity of these substances.[58] These considerations were fully confirmed in the studies of ribonuclease S with semi-synthetically incorporated 4-fluorohistidine.[128] Recently, Ikeda et al. demonstrated the possibility of preparing a versatile set of histidine analogues as efficient substrates for protein synthesis.[129]

His residues are specially attractive for engineering enzyme activity and catalysis since they are often found in the active sites of different enzymes, functioning as catalysts in acid–base and nucleophilic processes. Isosteric replacements in the frame of some canonical amino acids such as Ser/Cys, Thr/Val represent an excellent tool to study the nature of

the catalytic mechanism of residues directly involved in enzyme catalysis. However such replacements are not possible for His side chains. Therefore, engineering of histidyl-tRNA synthetase (HisRS) to extend its substrate specificity will greatly expand the scope and versatility of the enzyme catalysis.

4.5. Leucine, Valine, Isoleucine

Pioneering work by Anker and co-workers demonstrated that 5′,5′,5′-trifluoroleucine was incorporated by bacteria but not by eukaryotic systems. These early results were recently confirmed by Tirrell and Tang[80] who in addition succeeded in incorporating hexafluoroleucine into peptides expressed in vivo.[81] *Lactobacillus casei* dihydrofolate reductase expressed in *E. coli* was substituted with (2S,4S)-5-fluoroleucine to study conformational changes of the protein upon ligand binding with ^{19}F NMR spectroscopy.[130] The translational activity of *threo*-3-hydroxyleucine was reported by Hortin and Boime.[50] More recently, Apostol et al.[131] found that norvaline (**9**) can be incorporated in place of leucine in recombinant proteins. By using the T252Y mutant of leucyl-tRNA synthetase with attenuated editing activity in *E. coli* under conditions of its constitutive overexpression, the noncanonical amino acids norvaline (**9**), norleucine (**3**), allylglycine, homoallylglycine (**11**), homopropargylglycine (**8**), and 2-butynylalanine were inserted efficiently at the leucine sites of recombinant proteins.[41]

The valine analogues 2-amino-3-chlorobutyroneic acid, cyclobutaneglycine, penicillamine, and *allo*-isoleucine have been used to probe the process of membrane transversion of secretory proteins through the endoplasmatic reticulum.[51] However, the extent of their incorporation to date is still unclear. For example, Porter et al.[132] reported that "cyclobutaneglycine is activated by ValRS and forms cyclobutyl-glycyl–tRNA^{Val}, and presumably is incorporated into proteins in lieu of valine". Therefore, additional experiments are necessary to resolve these ambiguities. On the other hand, a recent experiment by Marliere and co-workers unambiguously demonstrated proteome-wide substitution of valine up to 24% by α-aminobutyrate in an engineered *E. coli* strain with attenuated ValRS editing function.[67]

Isoleucine analogues, such as 4-thiaisoleucine, *O*-ethyl-threonine, *O*-methylthreonine, 4-fluoroisoleucine, and *allo*-isoleucine were used in pioneering experiments.[50–52] Novel isoleucine analogues incorporated more recently into a few model target proteins include furanomycin and trifluoroiso-leucine.[133]

The systems for the selection and tRNAs aminoacylation of leucine, valine, and isoleucine evolved in their synthetases additional domains for a "double sieve" discrimination[36] of cognate from non-cognate, noncanonical and biogenic amino acids. Engineered valyl-tRNA synthetase or leucyl-tRNA synthetase with inactivated or attenuated editing function should have a great potential to fill up the second coding levels of leucine, valine, and isoleucine with a large number of analogues, surrogates, or similar amino acids.

4.6. Methionine

Methionine residues in proteins contribute to their structures with both hydrophobic interactions and hydrogen bonding; they are relatively rare (1.5% of all side chains in proteins of known structures), and usually located in positions inaccessible to the bulk solvent with only 15% of all Met residues exposed to the surface.[134] Met (**1**) has always been an attractive replacement target in proteins and peptides because of its facile reversible conversion into a hydrophilic sulfoxide form upon oxidation. Using natural translation machinery in *E. coli* or even yeast and mammalian cells, it was possible to substitute Met residues with SeMet (**2**),[11] Nle (**3**),[49,71,72] ethionine (**10**),[13,52] and even telluromethionine (**5**).[13,135] Honek and co-workers demonstrated the possibility of incorporation of trifluoromethionine (**7**) into phage lysozyme.[136]

A target of the editing activity of the MetRS is the Met metabolic precursor homocysteine.[137] In general, all Met-like amino acids smaller in size than Met itself are edited (with Nle on the border of this size-based exclusion).[138] More recently, Jakobowski showed that *S*-nitrosomethionine (**6**) can be transferred to tRNA^{Met} by MetRS and incorporated into proteins in *E. coli* and in the rabbit reticulocyte system.[139] Removal of the nitroso group from *S*-nitorosomethionine-tRNA^{Met} results in homocysteinyl-tRNA^{Met}, and subsequently, its in vitro incorporation into proteins in place of Met side chains.

The increase in the intracellular MetRS concentration by coexpression experiments in the *E. coli* Met auxotroph CAG18491 and the model protein dihydrofolate reductase[140] allowed further extension of the number of Met-based amino acid analogues and surrogates: homoallylglycine (**11**), homo-propargyl-glycine (**8**), *cis*-crotylglycine (**17**), *trans*-crotylgly-cine (**12**), allyglycine, 2-butynylglycine, 2-aminoheptanoic acid (**4**), norvaline (**9**), and azidohomoalanine (**14**)[141] (Figure 4). Some of these amino acids have a "dual identity", such as norvaline (**9**), 2-butynylglycine, homoallyglycine (**11**), and allylglycine, since they can serve as substrates for both MetRS and LeuRS with attenuated editing activity.[41]

4.7. Proline

Proline is a unique imino acid that has a cyclic side chain with a fixed φ angle, which acts as a classical breaker of both the α-helical and β-sheet structures in water-soluble proteins and peptides. In addition, the rate-limiting step in the slow folding reactions of many proteins involves *cis/trans* isomerization about peptidyl-prolyl-amide bonds.[142] Thus, proline is able to play these important roles due to its unique ring size and geometry. In protein and peptide sequences it is often post-translationaly hydroxylated, but has no similar counterparts among the remaining 19 canonical amino acids. Therefore, proline can be co-translationally substituted only with an expanded amino acid repertoire.

Early reports assigned 3,4,-dehydroproline, 4-thiaproline, 4-selenoproline, *cis*-4-hydroxyproline, *cis*-4-fluoroproline, *trans*-4-fluoroproline, and azetidine-2-carboxylic acid as

potential proline analogues in protein synthesis.[50–52] Recent research confirmed that *cis*-4-fluoroproline, *trans*-4-fluoroproline, difluoroproline, and thiaproline can indeed be incorporated into recombinant proteins.[143] In addition, the proline analogue 3,4-dehydroproline was incorporated in a repetitive periodic protein with lamellar morphology.[144]

In peptide synthesis, pseudoprolines are well known from peptidomimetic studies as serine-, or threonine-derivatized oxazolidines, and cysteine-derived thiazolidines.[145] Chemical aminoacylation of suppressor tRNAs revealed that various proline-based analogues and surrogates that influence the backbone structures of proteins can indeed be incorporated into proteins. They include pipecolic acid, homopipecolic acid, cyclopropylglycine, azetidine-2-carboxylic acid, and hydroxyproline.[146] Although in vivo incorporation of these analogues and surrogates and their derivatives has still not been achieved, there is no doubt that engineering or simple elevation of intracellular levels of prolyl-tRNA synthetase (ProRS) in the context of carefully designed experimental selective pressure, will result in their translational activity.

4.8. Arginine

Canavanine, a very potent toxin from the raw seeds of *Canavalia ensiformis*, is, so far, the only studied analogue of arginine as the substrate for protein synthesis. Pioneering studies from the 1950s and 1960s established that incorporation of canavanine into proteins resulted in altered conformation and disruption of its function.[54] The production of functionally impaired, canavanyl-containing proteins affects cell development and has growth-inhibiting properties. Thus, anticancer and antiviral properties of this substance have been intensively studied.[51]

4.9. Lysine

Lysine residues in proteins play an important role either as targets for chemical derivatization or post-translation modifications. Early studies reported a few analogues of lysine with the potential to be translated into proteins: *S*-2-aminoethylcysteine, 6-*C*-methyllysine, 5-hydroxylysine, *trans*-4,5-dehydrolysine, 2,6-diamino-4-hexanoic acid, 4-oxalysine, 4-selenalysine.[145] However, there are no reports about any recent research in this field. On the other hand, lysyl-tRNA synthetase (LysRS) could be an attractive target for engineering to relax of even exchange its substrate specificity in the desired direction.

The specificity of the aminoacylation reaction (termed as discrimination or *D*-factor) with regards to the 20 canonical amino acids varies considerably among different aaRS in vitro.[137] The highest *D*-factor (between 28 000 and > 500 000) is found for TyrRS, whereas the lowest values (between 130 and 1700) were observed for LysRS. Therefore one of the most important tasks for future experiments is to find out whether this observation of "intrinsically relaxed" LysRS substrate specificity can be generalized for further chemical diversification of the proteins based on lysine-derived analogues and surrogates. In addition, the existence of two unrelated forms of LysRS with the same affinity for lysine but different preferences toward noncanonical amino acids such as thialysine[147] can be also exploited for expanding the lysine-like amino acid repertoire. Since Lys residues in proteins are mainly distributed at surfaces, it is reasonable to expect that LysRS-based orthogonal systems that utilize templates with optimized Lys-codons distributions, would most probably replace complicated suppressor-based approaches for chemical diversification of protein surfaces.[117]

4.10. Metabolic Toxicity and Recruitment of Secondary Metabolism Intermediates for Protein Biosynthesis

Canonical amino acids are like "multi-tasking" substrates perfectly integrated into the fine network of cellular biosynthetic, metabolic, and energetic functions. Their synthesis or uptake has to be regulated, not only to enable protein translation, but also to provide a proper balance of metabolites in the cell. Under normal physiological conditions a small amount of toxic amino acid can be tolerated without gross effects on cellular viability, whereas larger amounts might cause cell death.

The message from these and other similar observations is clear: isosteric amino acids are also physiologically "orthogonal" to canonical amino acids in the sense that they act as antagonists in the given cellular milieu. Such metabolic choices have to be taken into consideration in any attempt to engineer cellular expression hosts for an expanded amino acid repertoire. For these reasons, the simplest approach to proteome-wide substitutions would be to metabolically engineer microbial strains whose simple "nonfunctional" aliphatic amino acids such as alanine, leucine, and valine (which have relatively limited metabolic choices) could be suitable targets for global substitutions, since their replacement would be less harmful. Thus, they are candidates that are most probably the best suited for future noncanonical amino acid translations into the total cellular protein output.

Alternatively, more than 700 biogenic amino acids (among them at least 300 from plants)[148] represent a larger natural reservoir of potential substrates for protein biosynthesis, that is, entry into the genetic code. In organisms of all life kingdoms α-amino acids are the end products of secondary metabolism, intermediates of metabolic pathways, or originate from the metabolism and detoxification of foreign substances.

For years, metabolic engineering has allowed us to generate or design a novel endogenous supply route of substances of interest (vitamins, hormones, metabolic intermediates). In the case of *E. coli* bacterial hosts, it should be possible to generate the desired amino acid from carbon sources. The combination of metabolic engineering and in vivo incorporation of noncanonical amino acids has been demonstrated by Mehl et al.[149] Gene-loci encoding production of *p*-aminophenylalanine (**57**) (*pap*A, *pap*B, and *pap*C) as a metabolic intermediate identified in *Streptomyces venezuele* were "borrowed" and put into *E. coli*. Genes for these enzymes were imported by a low-copy plasmid into *E. coli*,

making this microbe capable of intracellular production of *p*-aminophenylalanine from chorismate. *p*-Aminophenylalanine was incorporated with fidelity and efficiency similar to those of the canonical amino acids by use of a corresponding orthogonal pair. The intracellulary generated *p*-aminophenylalanine pool does not dramatically interfere or compete with the intracellular pools of the canonical amino acids. This expression host supplied with orthogonal components, heterologous target gene, and metabolic pathway is an instructive example of the combination and engineering of components that originate from different species in one unique system.

It is now clear that metabolic engineering of bacterial or any other expression host can be done by two opposite approaches. The first relies on full or partial addition of novel biosynthetic pathways, whereas the second includes knock-out, modulation, or attenuation of the existing biosynthetic supply pathways. For practical purposes, the in vivo expression system in which cells use the desired noncanonical amino acids directly from the growth media is much more advantageous in many cases. On the other hand, the expression of recombinant proteins with *p*-aminophenylalanine in *E. coli* might represent an interesting system for studying the effects of selective pressures on shaping the amino acid repertoire of living cells. Future tighter bridging of natural products chemistry and engineering of the genetic code could lead to a larger scale screening for suitable amino acids as "candidates" for entry into the genetic code from the intermediary metabolism of various species.

4.11. Cellular Proofreading

Under the influence of various selective pressures, living cells evolved molecules of the most efficient size and shape for their function. Basic monomeric protein building blocks having an average size of an amino acid can be divided into 20 unambiguous types apparently fulfilling these criteria. One can speculate that with more building blocks used in protein synthesis, mistakes could be so frequent that they would seriously outweigh the advantage of having more types. There are however, remarkable similarities between the members of the encoded amino acids. Several are isosters (Val/Thr, Cys/Ser), have the same molecular volume (Ile/Val, Pro/Cys), or very similar chemistry (Ser/Thr). Thus, the foremost practical criterion for the distinguishability between them must be their facile differentiation in the recognition process. Indeed, almost perfect discrimination between closely related structures is the hallmark of biochemical systems.[150]

It should always be kept in mind that amino acid activation and tRNA charging are not the only "checked" steps in translation. For example, in the experimental attempts to expand the amino acid repertoire in proteins by using the SPI approach, it was demonstrated that it is possible to incorporate 4-aminotryptophan into the green fluorescent protein (GFP) from *Aequorea*, but not 5-aminotryptophan and 4- or 5-hydroxytryptophan.[104] On the other hand, all these substrates are translationally active, since they could be incorporated into another protein barstar.[105] Other examples are thiaproline, and selenoproline, both of which have been recognized, selected, and loaded onto cognate tRNAs in the aminoacylation reaction, but only thiaproline can be fully translated into target proteins.[14] The reasons for such behavior are still unclear, but certain still unknown editing mechanisms during the ribosomal synthetic cycles or co-translational folding must be at work. To date, studies of co-translational or assisted (i.e. chaperone-mediated) protein folding, as well as ribosome fidelity with various noncanonical amino acids are rare.

The need for a strong discrimination goes beyond the canonical 20 amino acids, since the cellular milieu is full of metabolic intermediates and other biogenic amino acids as well. On the other hand, editing was not evolved against specific features of chemically or sterically similar synthetic amino acids, since living cells never encountered them in their evolution. Such a lack of the absolute substrate specificity of aaRS has been well documented in many systems for decades, and was recognized very early as a route for the expansion of the amino acid repertoire in vivo.

4.12. Protein Folding and the Genetic Code: Are There General Rules for Codon Reassignments?

Amino acid analogues incorporated into proteins using the traditional auxotrophic approach, at the level of the genetic code, represent codon reassignments that occur by obeying a simple "similar replaces similar" rule.[6] In fact, it is well known that experimental or natural codon redefinition occur always among similar amino acids. For example, the Met codon AUG could be reassigned to Ile (noncognate) or Nle (noncanonical) but never to arginine (nocognate) or metoxinine (Figure 7), because this reassignment would be fatal for efficient folding and consequently for the biological activity of the encoded protein structure.[27] In other words, the codon reassignment usually takes place by obeying a simple "similar replaces similar" rule, because disruption of the resulting protein structure is minimized by such modest alterations in the amino acid side chain. In the evolution of proteins, amino acid substitutions are found to occur more frequently between similar amino acids than between dissimilar ones. Sonneborn[151] conceptualized these observations about coding similarities between amino acids with similar physical properties in the form of a "translation-error minimization" theory about the nature of the genetic code. It postulates that the main function of the structure of the genetic code is to maintain the structural stability of globular proteins. From this point of view, the structure of the genetic code is the direct product of natural selection for a system that minimizes phenotypic impact of the genetic error.[152,153]

Therefore, the simplest rule to be obeyed is the general "apolar in—polar out" principle. Namely, the basic architectural pattern for proteins is to fold into tight particles, which have an internal hydrophobic core that is shielded from the surrounding solvent. This binary partitioning of polar and nonpolar amino acids is an intrinsic part of the genetic code. In its structure, these relations are visibly regular: all codons with a central "U" are cognate to amino acids with chemically relatively uniform, hydrophobic side chains ("convergent
Figure 7. Chromatographic mobility of various ninhydrine derivatives of canonical and noncanonical amino acids as a function of their molecular size, polarity, hydrophobicity, and pI values.[220] The elution profiles of Met (**1**, signal c) and its isosteric analogues Nle (**18**, e), SeMet (**2**, f), and metoxinine (**15**, a) as well as of leucine (**78**, d) and its isosteric analogues 5′5′5′-trifluroleucine (**79**, a) and Aza-leucine (**80**, g) were superimposed on the same retention time (t_{Ret}) scale. Since canonical amino acids and their counterparts are almost identical in terms of molecular shape, their separation is based mainly on differences in polarity and pI values. Translational cellular machinery recognizes hydrophobic amino acids Leu and Met as native substrates, whose signals are chromatographically positioned in the "neutral apolar area". Conversely, in the acidic and basic "polar areas" are their isosteric analogues metoxinine (**15**) and azaleucine (**80**), which are not substrates for protein biosynthesis. Namely, hydrophobic and neutral amino acids from the XUX codon family (Val, Ile, and Phe) cannot be globally substituted with these polar amino acids, since it would have an adverse effect on protein folding. Therefore, the positions of the chromatographic peaks revealed which of these noncanonical analogues are allowed to enter into the genetic code.

types"). On the other hand, coding triplets with a central "A" are cognate to amino acids with chemically variable, polar side chains ("divergent types").

Not only is such a chemical order apparent by careful inspection, it can be also quantitatively measured in a simple chromatographic experiment. Woese et al.[154] measured the chromatographic mobility of amino acids on paper in various solvents. The observed mobility correlated with the number of water molecules required for solvation. On this basis, the "polar requirement" index was developed.[155] This index reflects remarkably well the order in the coding table, clearly indicating that the genetic code assigns amino acids to related triplets on the basis of polarity/hydrophobicity. Later studies by Wolfenden and co-workers[156,157] confirmed that the relative distributions of amino acids between surfaces and the interiors of native globular proteins are indeed shaped with a sharp bias imposed by the genetic code.

This is also ture for reassignment or substitution of canonical amino acids with noncanonical ones. The chromatographic mobility test for the series of isosteric canonical and noncanonical amino acids starting with Met and its isosteric analogues Nle, SeMet, and metoxinine (**15**) as well as Leu and its isosteric analogues 5′5′5′-trifluroleucine and azaleucine, is presented in Figure 7. The observed mobility revealed a full agreement between amino acid polarities and their capacities for incorporation into proteins: neutral and hydrophobic (apolar) noncanonical amino acids such as Nle, SeMet, and trifluoroleucine indeed serve as substitution substrates for the

canonical amino acids Met and Leu. On the other hand, their isosteric but hydrophilic (polar) counterparts azaleucine and metoxinine were never successfully incorporated into target proteins. Not surprisingly, Marliere and co-workers[68] used azaleucine as a functional analogue for arginine.

The main lesson from this observation is that novel reassignments of coding triplets are strongly correlated with the biophysical relationships among the sterically similar amino acids. The simple experiments described above teach us also about the existence of a firm boundary between "allowable" and non-permissive amino acids in the genetic code, which can be delineated by simply measuring the differences in their physicochemical properties. In this context, it would be interesting to see if there is a quantitative value (i.e. index) for the possibility of a desired synthetic amino acid to enter the genetic code. Future work in the code engineering field should decide which criteria (e.g., polarity, hydropathy, molecular volume, isoelectric point, position in the genetic code table, and putative protein structure) could be more (or less) important in developing such indices.

5. Suppression-Based Methods

The most common codon reassignment in nature among different organisms occurs from one canonical amino acid to another. For example, vertebrate mitochondria read AUA as Met, whereas in the vertebrate cytosol this codon is assigned to code for isoleucine.[158] On the other hand, according to Osawa and co-workers "central to codon reassignment is the principle that a codon cannot have two assignments simultaneously, because this would be lethal to an organism".[159] However, an exceptional and unique example is the UGA codon that reads for stop, selenocysteine (SeCys), pyrrolysine, Trp, and cysteine.[160] In addition, other examples were identified as well, such as the universal CUG leucine codon, which is translated as serine in some *Candida* species.[161] This coding unit which is capable of assigning a few distinct amino acids was termed a "polysemous codon.[162] Such diversity in the assignment of certain codons in the universal code suggests that it should be possible to experimentally accommodate additional amino acids into proteins.[9]

Traditional approaches based on auxotrophism have only in exceptional cases the capacity to replace amino acids at any chosen position in a protein, as is possible by the use of site-directed mutagenesis. In the case of SeCys insertions, selective pressure during evolution yielded tolerable levels of nonsense suppression. Three-dimensional structural elements of mRNA and a special elongation factor are the crucial elements for local change in the codon meaning. The experimental extension of local changes leads to "an

expanded" genetic code[7] and refers to numerous amino acids experimentally translated into protein sequences by suppression of termination or frameshifted codons.[163] The large variety of chemically or enzymatically aminoacylated suppressor tRNAs able to participate in ribosome-mediated protein synthesis, are the basis for suppression-based methodologies capable of position-specific and multiple-site incorporations of amino acids.

5.1. The Concept of Suppression in Protein Translation

When a nonsense (stop) mutation occurs in the middle of a genetic message, an incomplete polypeptide is released from the ribosome owing to premature chain termination. In many cases incomplete chains have no biological activity, which makes most nonsense mutations harmful for cells. Such harmful effects can be reversed by further changes (supressor mutations) at different genes of mutant tRNAs. These genetic changes might take place in tRNA anticodons, or more rarely in some other tRNA identity elements. Suppressor tRNAs can insert different canonical amino acids in response to the *nonsense* (when one of the three terminator codons appears in mRNA) or *missense* codons (i.e. alteration of one sense codon to another so that different amino acids are determined) or *frameshift* mutation in the parent gene. In this way, the normal functions of these termination or sense codons are suppressed by tRNAs with changed identity.[158]

The existence of suppressor tRNAs raised the question of how they compete with release factors for termination codons especially those for UAG and UGA, which appear quite frequently at the end of genes. In addition, it is still not clear why the UGA and UAG suppressor tRNAs do not generate an unacceptable number of abnormally long proteins.[164] Evidently, there is no advantage for a normal cell to harbor suppressor mutations, even if only a small fraction of proteins would be non-functional. Therefore, suppressions either *nonsense* or *missense* should be regarded as exceptional natural phenomena. The response of a particular suppressor tRNA to a particular nonsense codon (read-through) can vary by as much as tenfold, depending on its location in the mRNA, a phenomenon known as the "context effect". There are also suppressor tRNAs capable of masking the effects of certain frameshift mutations created by the insertion of nucleotides and subsequently to restore a reading frame.[165]

5.2. Chemical tRNA Misacylations and In Vitro Amber (UAG) Suppression Methodology

Lipmann and co-workers demonstrated that misacylated tRNA could be chemically synthesized; they prepared Ala-tRNA^{Cys} by chemical desulfurization (Raney nickel) of Cys-tRNA^{Cys}.[12] Indeed, misacylated tRNA could substitute Cys with Ala at all positions in haemoglobin, which was taken as a model protein. This finding supported the view that fidelity of protein synthesis was controlled largely at the level of amino acid activation and correct tRNA charging by the aaRS. Later, Hecht and co-workers[166] demonstrated the utility of

the misacylated tRNAs for effecting amino acid substitutions at predetermined sites in polypeptides. In this way, it was shown that lysyl-tRNA acetylated at the N$^\varepsilon$-amino group can be incorporated into the rabbit haemoglobin with nearly the same efficiency as the unmodified one.[166] The general method for the preparation of misacylated (either suppressor or normal) tRNAs developed by Hecht and his group has been the subject of numerous reviews.[163,167]

The wide variety of chemically acylated suppressor tRNAs for the terminator codon UAG (Amber codon) are able to participate in the peptide bond formation at the ribosome. Supressor tRNA species containing the anticodon CUA can be prepared either by chemical modification of some commercially available tRNAs (e.g. yeast tRNA^{Phe}) or by runoff transcription of a suppressor tRNA gene. The basic scheme for the chemical aminoacylation of these tRNAs is described in Figure 3. Such tRNAs added in a suitably programmed in vitro translation system contribute directly in ribosome-mediated protein synthesis. In this way, an interpretation step in the flow of the genetic information is efficiently avoided (i.e. in vivo selection, activation, and aminoacylation of desired amino acid). It is therefore not surprising that a wide variety of modified amino acids can indeed participate in protein synthesis.[168] More recently, Schultz,[169] Chamberlin,[170] Sisido[163] and their co-workers, in a series of in vitro experiments using termination or frame-shift suppressor tRNAs, extended the early Hecht approach and demonstrated an extraordinary capacity of the ribosome to allow translation of more than a hundred special non-canonical amino acids (Figure 8).

The in vitro experimental extension of missense or nonsense suppression phenomena for the expansion of the amino acid repertoire was accomplished by chemical mis-acylation of suppressor or cognate tRNAs. Their addition to a translation system programmed with a gene containing nonsense suppression sites results in the incorporation of the special noncanonical amino acid at the corresponding position in the protein. Site-directed incorporation of 3-iodotyrosine into the 16-residue peptide product translated in vitro with a rabbit reticulocyte system was reported by Chamberlin and co-workers.[171] Similarly, by using a nonsense suppressor tRNA from yeast, Noren et al.[7] incorporated several Phe analogues. This position-specific replacement strategy was first postulated by Kwok and Wong,[172] who have shown that *E. coli* PheRS can aminoacylate yeast tRNA^{Phe} with an efficiency of less than 1% of that of *E. coli* tRNA^{Phe}. Thus, the amber suppressor tRNA derived from yeast tRNA^{Phe} was especially suitable for in vitro incorporation experiments with a coupled transcription/translation system based on *E. coli*. These tRNAs insert the desired amino acid efficiently into the β-lactamase; positions were taken that correspond to those of the UAG codon on its mRNA. On the other hand, they were not acylated or deacylated by any of the *E. coli* aaRS present in the cell-free lysate. After the suppression reaction in the Zubay transcription/translation system, 2.8–7.5 µg mL^{-1} of the replaced β-lactamase was produced. which is about 15–20% of the native protein yield (30–45 µg).[7] These successes were possible because four essential requirements for the application of suppression
Figure 8. Some of the translationally active amino acids delivered to the ribosome by chemical aminoacylation of suppressor tRNAs. The large number of synthetic amino acids incorporated into proteins by these approaches demonstrates almost unlimited possibilities for chemical diversifications on protein surfaces. For example, such compounds might be used as markers for hydrophobic/polar interactions, to restrain the protein backbone, to serve as spin labels, or as photoreactive side chains. On the other hand, these amino acids can be packed into the protein core only in exceptional cases. See the reviews by Schultz et al.,[87, 167, 169, 174] Dougherty et al.,[179, 180] and Hohsaka and Sisido.[163] The IUPAC names of the compounds are available in the Supporting Information.

methodology were fulfilled: 1) the suppressible amber (UAG) mutation was generated in the gene of interest by conventional site-directed mutagenesis; 2) the design of an efficient suppressor tRNA was achieved; 3) the suppressor tRNA was chemically acylated, and 4) a suitable in vitro protein synthesis system was available.

5.3. Limits of Suppression-Based Methodologies

The use of misacylated suppressor tRNAs has provided proteins containing various noncanonical amino acids at single predetermined positions. Most of these studies involved a read-through of the UAG codon. The main drawback of all suppressor-based approaches is the limited capacity of chemically misacylated synthetic suppressor tRNA charged with noncanonical amino acids to fully decode (suppress, read-through) nonsense (triplet or quadruplet) codons. This is not surprising since the suppressions are exceptional phenomena that are *context-dependent*, that is, each desired position in a protein sequence cannot be

always suppressed. It has been observed and documented that *release*, that is, intervention of so-called *release factors*, is so effective at some sites that the natural function of the amber stop codon is not suppressed even when the suppressor tRNA is charged with the amino acid that normally appears at that point in the wild-type protein.[173] Other unresolved issues include the stability of mRNA containing terminating codons as well as the stability of protein with noncanonical amino acids.

Therefore, the main bottleneck of this system is not the relatively low yield of the expressed proteins due to the inefficiency of the in vitro system,[169] but the rather low efficiency of the suppression. This parameter depends mainly on the nature of the amino acid to be incorporated into target proteins. For example, Nle can be incorporated into T4 lysozyme with a 100% suppression efficiency, whereas α-methylleucine can be incorporated with only 14%.[174] Unfortunately, suppression efficiencies cannot be reliably predicted, and there are only empirical observations such as read-through being very poor for polar amino acids. By-passing the suppression's "side effects" can at least be in part achieved by the generation of a completely unique quadruplet composed of canonical bases for particular aaRS/RNA pairs with orthogonal function[175] or by choosing non-toxic amino acids such as substituted analogues of aromatic amino acids. More recently, Frankel and Roberts[176] have described a selection approach for identifying coding triplets especially susceptible to suppression. However, the most efficient way to circumvent completely these limits is to switch to the use of sense codons[177, 178] in the context of codon-optimized target gene sequences (Section 5.7).

The generally impaired cellular viability upon in vivo introduction of orthogonal translation components is not the only "side effect" of these experimental interventions. The efficiency of translation can also be substantially reduced, resulting in decreased yields of the desired protein mutants. For example, in rich media, *E. coli* with heterologous wtTyrRS/tRNA$_{CUA}^{Tyr}$ expresses dihydrofolate reductase in yields of 67 mg L^{-1}, whereas by transfer in designed minimal medium, the yield drops by more than 95% to 2.6 mg L^{-1}.[88] Nevertheless, this approach might be useful in those studies where minute amounts of labeled proteins are necessary in the context of the living cells.[179, 180]

It should be always kept in mind that such experiments have been performed with model proteins such as dihydrofolate reductase, streptavidin, luficerase, smaller coiled peptides, lactamase, lysozyme, or GFP, whereas "difficult" proteins such as single-chain antibodies are most probably not permissive of such incorporations at all. In addition, suppression-based approaches that incorporate amino acids, such as ε-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-L-lysine or dansyllysine, might be useful only for the chemical diversification of the protein surfaces.[181] On the other hand, there are a large number of the widely used efficient and much simpler protocols for chemical modifications of the protein surfaces.[117] Therefore, in vitro suppression-based approaches will not be of much use in biological sciences, until currently available protocols for incorporations are considerably simplified.

The identities of amino acids and their nature show a certain correlation with its suppression efficiencies. For example, larger hydrophobic amino acids were incorporated with higher efficiency than smaller or charged ones. Not surprisingly, numerous large polyaromatic amino acids were incorporated in vitro (Figure 8), whereas most of noncanonical amino acids recently incorporated by in vivo suppression are in fact substituted aromatic derivatives of Phe and Tyr (Figure 5). Other factors that might dramatically influence suppression efficiency are polarity, stereochemistry, and amino acid geometry. For example, D-amino acids and β-amino acids are not substrates for translation by nonsense suppression methodologies.[169,174] An interesting question that remains to be tackled is to investigate whether there are correlations between suppression efficiencies, amino acid nature, and the already discussed general rules for codon reassignments.

5.4. In Vitro Frameshift Suppression Methodology

The maintenance of the frame during translation is not absolute and the frameshift mutations can be externally suppressed. Early experiments in the 1960s and 1970s demonstrated that the mutant tRNA in *Salmonella* and yeast with extended anticodons can read non-triplet codons but their read-through efficiency was comparatively low.[158] Recently, it was shown that the efficiency of UAGA quadruplet decoding for a tRNA^{Leu} with engineered $^{3'}$AUCU$^{5'}$ anticodon could be elevated to the range of 20–40%.[182]

An in vitro approach based on frameshift suppressions has been developed by Sisido and co-workers over the last decade.[183] A combination of four base codons AGGN and the corresponding anticodons NCCU was used to examine the scope and possibilities for in vitro frameshift suppression for the incorporation of particular canonical amino acids. Indeed streptavidin was substituted with 2-anthranylalanine by using all combinations of quadruplets: AGGG, AGGA, AGGC, AGGU.[184] The target gene sequence was optimized in a way that its mRNA contains extra downstream stop codons to terminate non-frameshifted products, that is, to abort protein synthesis in the absence of frameshift suppression.[175]

Sisido and co-workers[185] observed that incorporation of certain noncanonical aromatic amino acids is dependent on their adaptability at the active center of the ribosomal A-site. The regularity that emerged from these experiments was that noncanonical amino acids with linearly expanded aromatic groups (e.g. 2-naphtylalanine, *p*-biphenylalanine, (*p*-phenyl-azo)phenylalanine) are more favorable than those with widely expanded or bent aromatic groups (e.g. 9-phenyl-anthrylalanine). The transfer of these components into a cell-free rabbit reticulocyte-based system resulted in essentially the same observations.[184]

The use of quadruplets has aroused great interest because of the possibility of incorporating two or more different amino acids into a single protein. For example, streptavidin mRNA containing CGGG and AGGU quadruplets was translated in the presence of aminoacyl-tRNA$_{CCCG}$ and aminoacyl-tRNA$_{ACCU}$ charged with ε-(7-nitrobenz-2-oxa-1,3-

diazol-4-yl)lysine (CGGG signal in mRNA) and 2-naphthyl-alanine (AGGU signal in mRNA). Sisido and co-workers convincingly showed that the use of quadruplets in vitro protein biosynthesis provides a strategy for the introduction of noncanonical amino acids at several sites in a single protein.[186] Although it was expected that the basic advantage of this strategy should be the circumvention of the competition with the release factors, the rules that govern the different suppression efficiencies for different quadruplets are unclear as well. For example, it was argued that some sites in mRNA cause more frameshifts than others.[187] Therefore, this strategy has been limited both by the overall read-through efficiency of the suppressor tRNAs as well as by the occasional apparent misfolding of nascent proteins containing modified amino acids.

The general aspects related to the limits of anticodon size that would help to identify efficient tRNA suppressors of two-, three-, four-, five-, or even six-base codons have recently been the subject of detailed studies.[188,189] For example it was demonstrated that pentaplets (i.e. five-base codons) are indeed suitable for incorporation of special canonical amino acids into proteins.[189] Extensive examinations performed by Schultz et al. have shown that the translation apparatus indeed permits decoding of codons consisting of three to five bases and that each codon type requires different tRNAs. However, six-base codons are incompatible with the translation machinery and pentaplets cannot be suppressed with the same efficiency as quadruplets. Such limits in codon size are most probably governed by the ribosome itself where the tRNA is a sort of "molecular ruler" that measures codon size during translation.[188]

5.5. Species-Specific Features of Aminoacylation and Orthogonal aaRS/tRNA Pairs

At the level of the interpretation of the genetic code, that is, aminoacylation, orthogonality is defined as a lack of cross-reactivity between heterologous aaRSs and tRNAs with the endogenous synthetases, amino acids, and tRNAs of the natural host. Indeed, the most important requirement for the generation of orthogonal translation components is the strict absence of cross-reactivity with the protein-synthesis apparatus of the host. The tRNA as the carrier of adapter function in translation is the most attractive target for orthogonality engineering. This, however, requires a detailed knowledge of the tRNA identity rules. The rational design of both positive and negative recognition elements of tRNAs is difficult and the experimental results often rely on serendipitous findings. Sometimes it is necessary to search for identity elements outside the anticodon as suitable markers for the design of efficient suppressor tRNA. Nevertheless, the search for orthogonal pairs with in vivo and in vitro suppression methods can be summarized as follows: first, an orthogonal amber suppressor tRNA$_{CUA}$ has to be generated that is capable of incorporating the noncanonical amino acid in response to a UAG codon in the mRNA encoding the protein of interest. Second, an orthogonal aminoacyl-tRNA synthetase has to be designed by using mutagenesis and screening

approaches. Such an orthogonal aaRS should recognize exclusively related orthogonal-tRNA, but not any of the endogenous tRNAs. Finally, a library of mutants of the orthogonal tRNAs and aaRS has to be screened to find orthogonal aaRS/tRNA pairs capable of activating and transferring the desired noncanonical amino acid preferentially over canonical ones.[190]

The first systematic efforts in this direction were made by using the three-dimensional structures of the GlnRS/tRNA$_2$^{Gln} pair from *E. coli* as a starting point to generate several mutant suppressor tRNAs capable of serving as adapters for in vivo protein synthesis.[191] These tRNAs were indeed not substrates for any endogenous aaRSs including GlnRS, which is an important orthogonal component in a nontoxic in vivo aminoacylation system.[192] Parallel attempts to design an orthogonal GlnRS did not yield a mutant enzyme capable of charging orthogonal tRNA better than the native enzyme.[190] Thus, efforts to create an *E. coli* GlnRS/tRNA$_2$^{Gln} orthogonal pair even when heterologues tRNA$_2$^{Gln} from yeast was included, had only limited success.

There are two general difficulties in any attempt to create 21 aaRS/tRNA pairs in the context of a living cell. First, such designed enzymes will selectively be eliminated the living cells due to their redundancy; they can be kept only under experimentally imposed selective pressure. Second, there is the problem to specify which component from the remaining tRNAs and enzymes from the cellular pool directly interferes with the engineered enzyme.[193] For example, RajBhandary and co-workers initially found that the introduction of yeast TyrRS into *E. coli* is lethal, since this enzyme misaylates *E. coli* tRNA^{Pro} with Tyr.[194] Therefore, yeast TyrRS was modified so that it would no longer mischarge the *E. coli* tRNA^{Pro}. Only a mutant (generated by error-prone PCR) with very low rates of misacylation of *E. coli* tRNA^{Pro} could serve as orthogonal aaRS.

The development of orthogonal aaRS/tRNA pairs proved to be very successful when both the components, namely suppressor tRNA and aaRS, were imported from another organism.[195] It is now clear that exploitation of the species-specificity of aminoacylation is the most promising route to design orthogonal pairs. For example, after analysis of biochemical data for the TyrRS/tRNA^{Tyr} pair from a variety of organisms, Wang et al. found that TyrRS/tRNA$_{CUA}$^{Tyr} from *Methanococcus jannaschii* might serve as a valuable orthogonal pair for recombinantly expressed target proteins in *E. coli*.[196] The basis for the orthogonality in the Tyr systems can be derived from fundamentally different modes of recognition of tRNA^{Tyr} by TyrRS in archea/eukarya and eubactera.[197] In this way, a cross-aminoacylation in such a hybrid translation system is not possible. In addition, TyrRS from *M. jannaschii* does not have documented editing mechanisms and its cognate tRNA^{Tyr} can be efficiently transformed into suppressor tRNA without much decline in aminoacylation efficiency.[196] The transfer of amber and ochre supressor tRNAs derived from *E. coli* initiator tRNAs into mammalian COS1 cells was also demonstrated. These tRNAs were not substrates for any mammalian aaRS and their aminoacylation with amino acid analogues opens a perspective for their position-specific insertion in mammalian cells.[198]

5.6. In Vivo Orthogonal aaRS/tRNA Pairs

Chemical aminoacylations are complex experiments, and in vitro expression systems still suffer from low protein yields. This certainly sped up efforts to transfer suppression-based methods to in vivo systems. Although the efforts to create an *E. coli*-based efficient GlnRS/tRNA$_2$^{Gln} orthogonal pair[190] failed, these experiments yielded a methodological breakthrough in the development of an efficient system for positive/negative selection of mutant aaRS enzymes and tRNAs.[43, 88] They also brought into focus other important aspects and issues that should be taken into consideration in host strain engineering. For example, amino acid uptake proved to be a critical issue since it is well known that transport of amino acids into cells is not purely passive. Indeed, most of the translationally active noncanonical amino acids are about the same size as canonical amino acids. Thus, it is not surprising that "exotic" amino acids such as (*p*-phenylazo)phenylalanine are hardly acceptable as substrates for cellular amino acid permease systems. Therefore, the systematic generation of the libraries of cell-permeable amino acids represents an important future research avenue.[199]

Extra-chromosomally controlled heterologous expression systems in microorganisms are especially practical as platforms for expanding the amino acid repertoire because of their easy maintenance, propagation, and handling. These expression systems can be programmed either for position-specific or multiple-site incorporation of noncanonical amino acids by supplementation with additional translation components. These goals can be achieved in the context of living cells only if four basic requirements are fulfilled: 1) the availability of coding units programming the translation of noncanonical amino acids; 2) tRNAs capable of decoding these units, and 3) an enzyme capable of charging the tRNA. 4) Both aaRS and its corresponding tRNA should be free from cross-aminoacylation and compatible with host translation machinery and physiology.[87]

Furter[200] developed for the first time a general approach for the implementation of these criteria for position-specific in vivo incorporation of noncanonical amino acids. The Phe analogue *p*-fluorophenylalanine was incorporated at position 5 as a response to a UGA coding triplet in the mRNA sequence of recombinantly expressed dehydrofolate reductase. This was achieved by introducing yeast PheRS/amber suppressor tRNA^{Phe} into the expression host *E. coli*. There is almost no cross-reactivity between the PheRS from yeast and *E. coli* since identity elements in their tRNAs evolved in a completely different manner. The *E. coli* strain used was a Phe-auxotrophic one and was resistant to *p*-fluorophenylalanine, that is, its PheRS prevents tRNA^{Phe} from being charged with *p*-fluorophenylalanine. In contrast, for yeast PheRS, *p*-fluorophenylalanine is almost as good a substrate as Phe. Thus the system would not be sufficiently defined, since the UGA coding triplet at position 5 of dehydrofolate reductase would be read as both Phe and *p*-fluorophenylalanine. This problem was circumvented by a careful experimental design of the fermentation, resulting in replacement of 64–75% at the amber position 5 in dehydrofolate reductase. This is indeed the first demonstration of the introduction of a new redun-

dant aminoacylation pathway and a new design of the hybrid translation system. When such an expression host is exposed to the efficiently imposed experimental pressure, the noncanonical amino acid is preferentially incorporated over the canonical one.

A further advance was made by the use of the TyrRS/tRNA$_{CUA}^{Tyr}$ orthogonal pair from *M. jannaschii* [196] in the expression host *E. coli* for the position-specific incorporation of *O*-methyltyrosine into dihydrofolate reductase in yields of about 2 mg L^{-1}.[88] This was demonstrated in the case of green fluorescent protein (GFP)[89] as well, where a variety of Tyr analogues were incorporated into the chromophore of this protein. The hybrid translation system with the TyrRS/tRNA$_{CUA}^{Tyr}$ pair from *M. jannaschii* imported into *E. coli* is technically a much more advanced system than the one used by Furter[200] as it is much more stringent. In other words, the orthogonality is almost fully achieved, since amber positions on the mRNA are translated with great fidelity into target proteins with minimal suppression-associated toxic effects. Finally, the use of substituted analogues of aromatic amino acids proved to be advantageous for this system.

It remains to be seen whether these in vivo expression systems can be developed further for use in molecular biology and biochemistry. Limited success in experiments with GlnRS/tRNA^{Gln}[190] poses a dilemma as to whether all synthetase/tRNA systems are generally suited for such design. In addition, the orthogonal synthetase/suppressor tRNA pair for each specific noncanonical amino acid has to be generated through a series of complicated mutagenesis and selection cycles. It is also remains to be clarified whether the in vivo transfer resolves the problems associated with context-dependent suppression phenomena (i.e. the problem of equal suppressability of all positions in a desired protein sequence). The in vivo approach also brings additional difficulties associated with the metabolic toxicity and bioavailability of the desired amino acids, that is, their transfer into the cytoplasm.

5.7. Sense Codon-Dependent Method with Chemoenzymatically Charged tRNAs

The reassignment of sense coding triplets by chemically or enzymatically charged tRNAs might be an attractive alternative to bypass the complications arising from context effects encountered in suppression-based approaches. Takai et al.[177] inactivated tRNA^{Asp} and tRNA^{Phe} within crude S30 extracts from *E. coli* by antisense treatment or by digesting most of the tRNA without essential damage to the ribosomal activity. Using HIV-1 protease as a model protein in RNase-treated cell-free S30 extracts with pre-charged tRNAs, they succeeded in substituting aspartic acid and Phe residues with 2-naphthylalanine and (*p*-phenylazo)phenylalanine, respectively. However they were not able to estimate the specific yield of fully substituted protein, probably because folding of the resulting protein was seriously impaired.

A similar approach by Sisido and co-workers[175, 184] was based on the use of rare codons that can be placed at any position in the target mRNA sequence. Such codon-optimi-

zation of the target gene sequence allows position-specific or multiple-site incorporation of one or more different amino acids. For example, the rarest arginine-codon AGG (which contributes on average to less than 3% of the total tRNA^{Arg} pool) is a suitable binding partner for chemically acylated tRNA$_{CCU}$, which can be used for the incorporation of various photoactive amino acids (*p*-aminophenylalanine, 2-anthrylalanine, 1-naphthylalanine, 2-naphthylalanine, *p*-biphenylalanine).[201]

Sense codon reassignments using externally charged tRNAs should be an interesting approach, since it is based on the use of codon-optimized DNA in the context of in vitro protein synthesis. For example, the canonical amino acid Thr is coded with four coding triplets (Figure 1), with ACA being the rarest codon in *E. coli*. Using sophisticated in vitro systems such as PURE,[202] where addition of all components can be precisely controlled, it should be possible to introduce the desired amino acid either in the position-specific or multiple-site mode. With the help of site-directed mutagenesis, the target DNA sequence can be optimized so that ACA is present only once, twice, etc. in the sequence. The corresponding tRNA (tRNA^{Thr} ($^{3'}$UGU$^{5'}$)) can be enzymatically charged with the desired noncanonical amino acids, while the rest of the tRNA^{Thr} isoacceptors are charged with Thr. Addition of these preacylated tRNAs into the cell-free system devoid of deacylation problems should lead to the desired mode (position-specific, multiple-site) of incorporation.[255] Similarly, Forster et al.[203] combined a purified translation system free of aaRS with chemoenzymatically synthesized cognate tRNAs, which enabled arbitrarily chosen coding triplets to be completely reassigned to noncanonical amino acids in vitro.

Finally, there is a recent report of a successful experiment on the reassignment of coding triplets in the frame of codon families. Tirrell and co-workers[178] used mutant yeast tRNA^{Phe} to reassign one of two degenerate Phe codons to the noncanonical amino acid 2-naphthylalanine. However, this is essentially a missense suppression-based approach and therefore suffers from the "child disease" of all these methodologies: reassignment is incomplete, canonical amino acids are often preferentially incorporated as a response to "reassigned" coding units during translation. For all these reasons, the best approach to achieve full noncanonical amino acid translations might be the use of the codon-optimized DNA/mRNA templates. Such templates would contain rare sense coding units placed in position-specific or multiple-mode sites in a target gene sequences. Therefore, the in vivo or in vitro translation of such codon-optimized DNA/mRNA templates with noncanonical amino acids is most probably the approach that will replace the suppression-based methods to a great extent.

6. Other Aspects Related to an Expanded Amino Acid Repertoire

6.1. In Vitro versus In Vivo Translation for the Extension of the Amino Acid Repertoire

The classical experiments by Chapeville et al.,[12] which clearly demonstrated that misacylated tRNA is capable of

participating in protein synthesis, applied in vitro translation. In fact, cell-free systems with chemically aminoacylated tRNAs demonstrated remarkable ribosome plasticity in terms of the number, as well as the structural, steric, and chemical properties of the amino acids that can be translated into proteins. This chemical diversity can be lost to a great extent on transfer to an in vivo method. A recent example shows that an "orthogonal pair" in an in vivo system derived from the orthogonal system TyrRS/tRNA$_{CUA}^{Tyr}$ from *M. jannaschii* allows mainly the translation of Tyr or Phe analogues (Figure 5). Evidently, to make fairly exotic amino acids such as ε-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-L-lysine, or the biotin derivative **91** (Figure 8), intracellularly bioavailable, experimental intervention for "rational re-design" of many components in the living cell is necessary. The range of the intervention is such that it would require simultaneous remodeling and non-invasive changes for the amino acid transport into cells. Furthermore, ways need to be found to avoid metabolic activation or modifications, as well as to pass translation editing check points of intact cellular physiology.

It should always be kept in mind that protein synthesis by the in vivo gene expression is carried out in cells, which because of their cell walls and membranes form a closed system. The alternative, open system, is represented by in vitro protein synthesis. Thus, the in vitro coupled transcription/translation, which is devoid of the problems associated with the mechanisms of cellular physiological functions, could be optimized as a platform for engineering the genetic code with a significantly wider spectrum than in living organisms.[204] This explains the significant interest in the development of high-yield cell-free translation systems. Various improvements, including optimized batch reactions, addition of chaperones, replenishment of consumable factors, continuous flow or optimization of the relative concentrations of various lysate components, etc. are extensively described in current literature. Therefore, novel generations of even more sophisticated in vitro systems with improved performance in terms of protein yield and control of translation conditions would certainly serve as attractive platforms for the expansion of the amino acid repertoire.

6.2. Site-Directed versus "Statistical" Incorporation

In the early stages of the development of any novel research field, precise terminology cannot usually be formulated because not enough is known to permit such accurate definitions. A pragmatic strategy is to accept provisional, rough terminological characterizations that can provide leverage to the field's first developmental stages with taxonomic refinements emerging as the related facts become clear. In the field of code engineering, the "site-directedness" as a highly desirable feature for the hybrid translation system is a term that demonstrates the confusion that might appear as a consequence of an immature terminology. For example, it was often claimed that the suppression-based read-through methods for noncanonical amino acid incorporation are "site-specific", because it is theoret-

ically possible to insert a suppressible stop-codon at any desired position in the protein sequence. It is most probably not fully correct due to the well known fact that misacylated tRNA must compete with release factors that often result not only in low-suppression efficiency but complete absence of the suppression. In this case it would certainly be necessary to screen for permissible positions that allow a high-level suppression (lowest possible "leakage" of the system). However, it is hard to imagine this approach as "site-directed" in the terms used in routine oligonucleotide-directed DNA mutagenesis experiments.

The term "statistical" incorporation mode (labeling) is likewise not suitable for the following reasons. It is open to discussion whether the reported incorporation for particular amino acids by the use of read-through methods where suppression efficiency is 10%, is "statistical" or "site-directed"; whether the 99% reassignment of a single UGG codon (i.e. Trp substitution) in one particular gene sequence is "statistical" or "multisite" or "site-directed". Such unclear taxonomic considerations might lead to statements like those that selective-pressure incorporation methods has "comparatively little impact on the field of protein engineering".[104] This is indeed misleading when for example the importance of SeMet incorporation into proteins based on the traditional use of auxotrophic strains for structural biology is considered. Also for the design of therapeutic proteins for drug delivery such "multisiteness" might even be a desirable feature of the system (see Section 7). Last but not least, whether SeMet incorporation is "multisite", "statistical", or "site-directed" depends upon the number of AUG codons that can be easily experimentally manipulated by recombinant DNA technology.

To avoid such terminological ambiguities one might simply accept that in naturally occurring proteins the problem of "site-specificity" is solved with the evolutionary optimized appearance of the codon (frequency) in particular sequences. This is especially true for relatively rare amino acids such as Trp, Cys, and Met. In this context, the question of whether one amino acid is "site-directed" or "multisite" incorporated is, in the first place, a matter of codon composition of its coding template. In practice, codon-optimized gene sequences, that is, target gene sequences with controlled codon composition, can be used in incorporation experiments with noncanonical amino acids. Furthermore, one can choose as replacement targets those amino acids that are naturally less abundant such as Trp (1.1%) or Met (1.5%), but which often play crucial roles in protein functionality. Finally there should be numerous protein sequences for which the problem of "multisite" replacements can be circumvented by a simple combination of site-directed mutagenesis and an expanded amino acid repertoire.

6.3. Other Approaches

Experimental intervention at all important levels of transmission of the genetic information might result in the engineering of the genetic code in terms of an expanded

number of amino acids as protein basic building blocks. At the level of the DNA/RNA sequence it is possible to manipulate the nature and lengths of the basic coding/decoding units (i.e. codons/anticodons). The aminoacylation reaction is the interpretation level of the genetic code and therefore the most attractive point for experimental interventions. Since codon–anticodon interactions are insensitive to the nature of the amino acid attached to the acceptor stem of tRNA, the influence of an amino acid charging process is the most obvious way to get novel amino acids into the genetic code. Finally, the ribosome itself can be altered to affect the interpretation of the genetic code. The use of noncanonical nucleotides to form a novel Watson–Crick base pair has already been extensively discussed.[205–207]

Kowal and Oliver[173] explored the use of nonassigned codons in *Micrococcus luteus* to circumvent problems associated with competitions by release factors in suppression-based methods. In this microorganism, six codons are unassigned (or very rarely assigned) allowing one to evaluate the possibility of inserting such codons into the DNA template for either position-specific or multiple-site incorporation of non-canonical amino acids. In vitro reaction in a lysate from *M. luteus* supplied with a plasmid-encoded target gene and *E. coli* tRNAs for unassigned or rare codons led to complete translation.

Besides the engineering of aaRS, specially selected ribozymes capable of transferring amino acids to the 3′-end of specific tRNAs might also provide an additional means of generating aminoacylated tRNAs with noncanonical amino acids.[208,209] However, this methodology at the current level of development suffers from serious shortcomings such as inefficient amino acid transfer, complicated ribozyme construction (which requires chemical methods at least in part), and high concentrations of aminoacylated ribozyme.

Manipulation of the ribosome structure might be another way to expand the genetic code. Little is known about the recognition elements that have to be altered to allow the introduction of versatile chemical functionalities into proteins. For example, Dedkova et al.[210] have shown that the mutations in 23S rRNA in the region of the peptidyltransferase center and the helix 89 led to a conformational change, which diminished the normal mechanisms for discrimination between D- and L-amino acids in the ribosomal A site. Such modified ribosomes might exhibit altered translation properties, a feature that can be exploited for the expansion of the amino acid repertoire. The addition of suppressor tRNA$_{CUA}$ in a cell-free system containing such ribosomes allowed the synthesis of luciferase with D-Met and D-Phe.

Future research should demonstrate whether all these approaches will reach the efficiency of the currently available methodologies for genetic code expansion.

6.4. Future Avenues: Shuttle Orthogonal Pair and Hybrid Translation Systems with Codon Capture

Practical applications either in research or industry will dictate to a great extent current and future development and trends in genetic code engineering. The main focus will be the development of efficient in vitro or in vivo hybrid translation systems, capable of producing elevated levels of tailor-made proteins. The most conceivable way to reach high levels of production of tailor-made therapeutic proteins would be the experimental design of specialized prokaryotic or eukaryotic cells capable of synthesizing protein variants with a high fidelity. Metabolism, bioenergetics, synthetic and supply routes as well as amino acid pools of such cells should be controllable, tightly regulated, and properly balanced. Coupling metabolic engineering with code engineering therefore clearly has a great future.

On the other hand, in vivo expression of tailor-made proteins as tags in mammalian cells is also highly desirable. In this case, the amount of the labeled proteins does not necessarily need to be elevated, since minimal amounts of the tailored protein can easily be detected by fluorescence, for example.[180,211] Finally, the capability to shuttle such systems between cells of different life kingdoms (archea, eubacteria, eukarya) would be of a great advantage. Indeed, a recent report about the use of the orthogonal system TyrRS/ tRNA$_{CUA}$^{Tyr} from *M. jannaschii* in yeast is the first step in this direction.[212]

The initial results on the engineering of the genetic code reveal that new amino acids can be incorporated into the existing repertoire. In most cases, this was readily possible since the goal was not to produce "unnatural organisms", but rather to generate a system that works with an expanded amino acid repertoire. This system is compatible with the translation machinery of the host which serves only as a platform for codon-reassignment experiments. However, currently available methods for the expansion of the amino acid repertoire are characterized by temporal changes termed as read-throughs, suppressions, codon reassignments, etc., which are achieved by changes in the genotype and physiology of the living cells, and by controlled experimental conditions. The goal is, however, permanent reassignments or novel assignments of the coding units that is, codon capture either at the level of the expression system or at the level of the living cell (Figure 9).

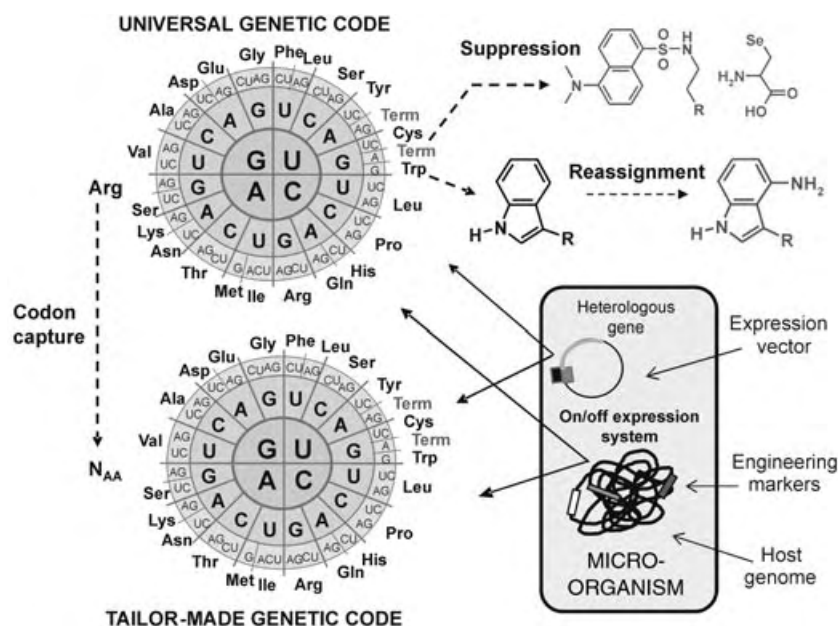
This codon capture should be 1) nonlethal and 2) an intrinsic property of the system. Expression host cells with such a nonlethal codon capture (e.g. an organism without a seriously impaired viability upon an insertion of a novel amino acid in its repertoire) would be the most advanced system to expand the coding capacities of the universal genetic code in vivo. Codon capture can be achieved by a permanent reassignment of coding units in the frame of the existing structure of the universal genetic code. Another and a much more challenging venture is to introduce novel coding units by the generation of novel nucleic acid base pairs. In both cases, the protein translation would be enriched with truly novel canonical amino acids. Such codon capture in an organism with a tailor-made (or target-engineered) genetic code and with an intrinsically expanded amino acid repertoire is the most challenging aspect of future experimental approaches in code engineering.


Figure 9. Codon capture as a vehicle to expand the coding capacities of the universal genetic code. Microorganisms used for genetic code engineering to date, are required to be able to read-through sense, nonsense, and non-triplet coding units, which were reassigned or suppressed, mainly at the level of a single protein and rarely at the proteome-wide level. Alternatively to this temporal re-coding, the existing genetic code can be tailored (or target engineered) with a codon capture. Hereby particular coding units are permanently reassigned, either at the level of the expression system or proteome-wide at the level of a whole living cell. The Arg coding triplets AGA and AGG were chosen as an example for permanent reassignment (codon capture) to a hypothetical novel amino acid (N$_{AA}$). However, any other combination is conceivable as well.

6.5. Is It Possible To Create the "First Autonomous Synthetic Life Form"?

As discussed before, the codon capture should be a nonlethal intrinsic property of an "unnatural" microorganism with a tailor-made genetic code that has an expanded coding capacity. Recent reports about the "first synthetic form of life"[213] with a recombinantly expressed protein, which contains *p*-aminophenylalanine through suppression of the amber termination codon,[149] meets this criteria only partially. Even if *p*-aminophenylalanine is accepted in the proteome of an *E. coli* expression host, which is supplied with a hybrid translation system (i.e. orthogonal components), partially imported metabolic pathways, and the termination stop-codon capture, this only occurs with the aid of an extra-chromosomally placed expression system (Figure 9). Therefore, this "truly unnatural organism"[213] remains what it taxonomically always was, namely *Escherichia coli*. It remains to be seen whether *p*-aminophenylalanine as a "codon captor" of UGA termination signals could invade the genome and the proteome without imperilling the viability of this microorganism.

The first step in this direction would be the invasion of a novel amino acid in the existing repertoire by codon capture. Such cells would be supplied extra-chromosomally or in a compartmental manner with tailored genetic codes. However, one has always to keep in mind the immense complications in these trials. The more we understand the full complexity of

the biological machinery, the clearer it becomes that the components of a living cell interact in so many ways that a change in any key component requires compensatory changes in many others. For example, noncanonical base pairs for an in vivo expansion of the code requires experimental redesign of DNA replication, transcription, editing mechanisms, design of novel tRNA genes, and the necessity for recognition of novel bases and coding units that contain these bases. Similarly, one "rationally" designed orthogonal aaRS/tRNA pair might introduce a massive mutagenesis and finally cell death. Thus, an old principle of continuity expressed by Lucretius as "*Natura non saltus fecit*" ("Nature never makes a leap"), holds true for living organisms as well.

The alterations in the genetic code structure are now a well documented fact in nearly all living beings. For example, each eukaryotic cell is provided with two slightly different code assignment arrangements, but with the same standard amino acid repertoire. This means that one cell can shift one of the 20 canonical amino acids between different codons despite a complex genome encoding a highly complex proteome. The possibility to introduce alternative repertoires into the existing code structure has been described as a "Copernican turn".[27] It postulates that the amino acid repertoire of the genetic code of all living beings is universal and is therefore of prime importance, whereas smaller deviations in codon reassignments are tolerated. Whereas living beings could survive codon reassignments (in the frame of the standard amino acid repertoire), the insertion of a novel amino acid into the existing repertoire is supposed to be harmful or even lethal. In this context, the prime goal of the research field described in this study is to derive new cells with nonlethal codon captures, that is, cells that survive an insertion of a novel amino acid in its repertoire. In this way, an experimental evolution of a "standard" to an "alternative" amino acid repertoire in the genetic code would be fully achievable. Whether and to which extent these cells with nonlethal codon captures and tailored genetic codes derived from natural parent cells can be regarded as a new taxonomic species or subspecies remains to be established.

7. Some Practical Applications of Noncanonical Monomers

7.1. Protein Chemistry in the Era of Genetic Code Engineering

Many interesting noncanonical amino acids contain desirable functional groups such as halogens, keto, and silyl groups, alkenes, or alkynes, could promote considerable functional advantages once incorporated into proteins. The possibility to encode genetically such chemical diversity should enable us to program living cells such as bacteria to do quite sophisticated syntheses with water, salts, and simple

carbon-sources being the only essential external requirements. Therefore, protein chemists will inevitably encounter the challenge of engineering the genetic code in the coming decades. Advances in polymer and peptide chemistry as well as in peptidomimetic chemistry teach us about the potentially vast chemical diversity that can be achieved if these are transferred onto proteins.[214] Indeed, in the foreseeable future the increased demands for proteins with novel properties and functions, or as therapeutic agents, is easy to predict. Thus, the production of such tailor-made, custom-tailored proteins or alloproteins, (Figure 6) by use of programmed templates in metabolically engineered host cells will certainly be one of the main driving forces for the engineering of the genetic code by expanding its amino acid repertoire.

7.2. The Concept of Isomorphous Replacement in Biochemistry

More than two decades ago Wilson and Hatfield[51] described that analogues of canonical amino acids were able to "induce predictable perturbation in protein structure". This is equivalent to the concept of isomorphous replacement in protein X-ray crystallography: a heavy-metal containing analogue can be incorporated in a protein without the occurrence gross changes with regard to the conformation of the molecules in the crystal. This incorporation influences in a predictable way, diffraction patterns of protein crystals, thus enabling their structure elucidation. The most prominent example is the presently routine SeMet incorporation into proteins, which provides selenium as a diffraction label for structure elucidation.[13,63,215] In the meantime, the number of selenium-containing amino acid analogues or surrogates available for this purpose was further increased (Figure 10).[70,76,103,216,217]

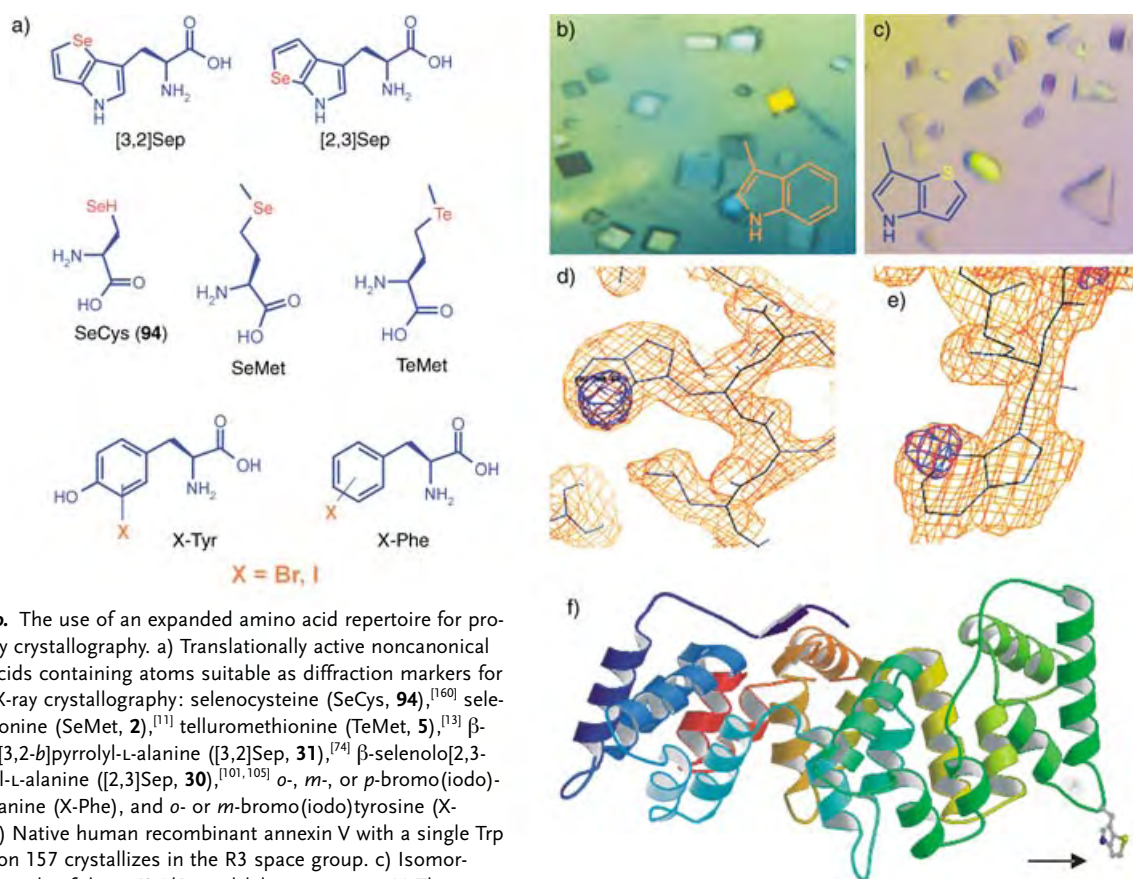
Similarly ^{19}F NMR studies have taken advantage of the extreme sensitivity of ^{19}F chemical shifts to the changes in local environments. This makes ^{19}F NMR spectroscopy a powerful technique as it allows subtle conformational changes and intrinsic dynamic features of proteins to be probed.[75] Furthermore, fluorinated proteins certainly represent potent tools for in vivo ^{19}F magnetic resonance imaging and spectroscopy for diagnostic purposes in medicine due to their biocompatibility. The potentials of amino acid analogues in spectroscopy, protein folding and stability studies, material sciences, and enzymology have been extensively discussed elsewhere.[6,15]


Figure 10. The use of an expanded amino acid repertoire for protein X-ray crystallography. a) Translationally active noncanonical amino acids containing atoms suitable as diffraction markers for protein X-ray crystallography: selenocysteine (SeCys, **94**),[160] selenomethionine (SeMet, **2**),[11] telluromethionine (TeMet, **5**),[13] β-selenolo[3,2-*b*]pyrrolyl-L-alanine ([3,2]Sep, **31**),[74] β-selenolo[2,3-*b*]pyrrolyl-L-alanine ([2,3]Sep, **30**),[101,105] *o*-, *m*-, or *p*-bromo(iodo)-phenylalanine (X-Phe), and *o*- or *m*-bromo(iodo)tyrosine (X-Tyr).[81] b) Native human recombinant annexin V with a single Trp at position 157 crystallizes in the R3 space group. c) Isomorphous crystals of thieno[3,2*b*]pyrrolylalanine-annexin V. This amino acid is a pharmacologically active substance. d) Experimentally determined electron density maps confirmed the complete replacement of the benzyl group of Trp by selenophene units of [3,2]Sep at position 53 in the protein barstar (Figure 11). For this residue the difference Fourier maps (Fo−Fc) are superimposed with 3.5 σ (blue) of the 2 Fo−Fc continuous electron density map at 1 σ (orange). e) Representation as for (d) for the replacement of Trp for [3,2]Sep at position 157 in recombinant human annexin V (Fo−Fc at 3.0 σ and 2 Fo−Fc at 1 σ). f) Structure of human recombinant annexin V with [3,2]Sep at position 157. For both proteins (annexin V and barstar), incorporation of the analogue was fully isomorphous, since their overall fold and structures are practically identical with that of the parent protein.

For a biophysicist, replacements at the level of single atoms or small groups such as H/F, CH$_2$/S/Se/Te represent a type of "atomic mutations".[134,218–220] They cause minimal changes in the local geometry often far beyond the resolution of X-ray and NMR protein analyses, but can often induce significant changes in marginally stable protein structures. In fact, they introduce novel interactions in proteins such as enhanced or decreased polarity and offer the unique possibility to study and understand how these properties are integrated, propagated, and modulated into the cooperatively folded protein structure.

The concept of predictable perturbation or isomorphous replacement can be generally extended from structural biology and biophysics to biomedicine. Some potential applications of the concept will be dealt with in more detail in the following sections.

7.3. DNA Nucleotide Analogues

In addition to protein chemistry, the concept of analogues is widely practiced in other research fields as well. The most prominent example is the observation of the possibility for enzymatic incorporation of dideoxynucleotide analogues (dNTPs) into a growing DNA strand. Sanger and co-workers developed a method based on these experiments that is currently central to almost all current DNA sequencing technologies. The modified dNTPs with detectable reporter groups such as digoxigenin or biotin, fluorochromes or aliphatic side chains covalently attached to the base are able to terminate DNA synthesis mediated by a number of DNA-polymerases.[158]

On the other hand, the same approach could be applied to biomedicine. For example, the human immunodeficiency virus and other retroviruses do not encode specific enzymes required for the metabolism of the purine or pyrimidine nucleosides. Therefore, many of such compounds that exhibit antimetabolic effects or antiviral action that are currently in use, or under advanced clinical trial, for the treatment of HIV infection, belong to different classes of nucleoside/nucleotide analogues that act as reverse transcriptase inhibitors, for example zidovudine (AZT), didanosine (ddI), zalcitabine (ddC), and stavudine (d4T).[221]

Finally, there are attempts to use similar approaches to expand the genetic code through the creation of a 65th codon–anticodon pair from noncanonical nucleoside bases having non-standard hydrogen-bonding or even inter-base hydrophobic interaction patterns. This new DNA base pair would allow an expansion of the information content of DNA by extension of the genetic alphabet with a third base pair.[205,206,222]

7.4. Protein-Based Sensors and "Golden" Fluorescence

Absorbance in the near UV region and fluorescence are intrinsic properties of proteins, which are attributed to the presence of aromatic amino acid residues in the structure; the contributions of these residues to the spectral properties are

additive. The amino acid Trp has been the target for substitution studies for a long time since the mean UV absorbance of proteins is mainly dominated by the its spectral contribution.[120] A recent review by Szabo, Ross, and Hogue[17] details the potential applications of 5-hydroxytryptophan, 7-azatryptophan, and fluorinated Trp analogues for fluorescence spectroscopy. The most recent advances included incorporation of selenium-containing Trp surrogates (for structural biology), and pharmacologically active sulfur surrogates (Figure 10) as well as pH-sensitive aminotryptophan analogues, which open up perspectives for a relatively simple approach for the general design of protein-based sensors (Figure 11).[105]
Figure 11. Replacement of Trp residues in barstar with 4-aminotryptophan converts the pH-insensitive parent protein into a pH-sensitive fluorescent protein. Note that the positions of the fluorescence emission maxima (λ_{max}) are pH-dependent only in (4-NH$_2$)Trp-barstar.

A step further towards the use of aminoindoles was their integration into the chromophore of the green fluorescent protein (GFP) from the jellyfish *Aequoria victoria* (*av*), which has recently become a standard reporter in cellular and molecular biology as well as a model for studies of chromophore photophysics.[223] The *av*GFP chromophore, completely encoded in the amino acid sequence (4-(*p*-hydroxybenzilidene)imidazolid-5-one) is autocatalytically formed in the post-translational reaction of residues Ser 65, Tyr 66, and Gly 67.[224] Chromophore-building residues of *av*GFP are almost ideal models for such substitutions, since the produced effects are immediately observable in the optical properties. Importantly, the placement of any aromatic amino acid in position 66 is crucial for the emergence of a fluorescently active *av*GFP chromophore.[225] The standard amino acid repertoire limits the possibilities to gain altered spectral windows by direct re-design of *av*GFP-chromophore, since only four aromatic rings are available (Phe, His, Tyr, and Trp). It is, therefore, not surprising that despite years of effort on its variations by classical protein engineering approaches, no significantly red-shifted variants of *A. victoria* GFP were found (λ_{max} < 530 nm). Clearly, a further re-design of *av*GFP-chromophores requires an expanded amino acid repertoire.

The mutation Tyr66Trp (e.g. Ser65Thr/Tyr66Trp) leads to enhanced cyan fluorescent proteins (ECFPs) with a characteristic blue-green emission and an indole ring as an integral part of the chromophore. The replacement of the indole ring by an electron-donating 4-aminoindole in ECFP results in a

"gold" fluorescent protein (GdFP) which is, with its Stokes shift of about 100 nm, the most red-shifted *Aequoria* GFP-variant known to date (Figure 12).[104] The GdFP is further charactrized by a dramatically increased thermostability and stability of the monomeric state. It was expressed and purified by using a Trp-auxotrophic *E. coli* strain in the yields similar to that of the parent ECFP ($\approx 30\ \mathrm{mg\,L^{-1}}$ of the culture). This allowed the crystallization of the protein, the elucidation of its structure, as well as the determination of various biochemical and biophysical parameters for the dynamics of the chromophore.

With the *av*GFP variants available to date, however, there is only one pair of proteins, which are excited at the same wavelenth, but which can be detected at two different wavelengths. The design of the GdFP expands these possibilities, since three populations of Trp-auxotrophic *E. coli* cells expressing "cyan", "green", and "gold" fluorescent proteins can be unambiguously detected upon excitation at a single wavelength, clearly opening new ways for multiple labeling applications (Figure 12). It also represents an excellent example of custom-tailored or tailor-made protein.

However, the use of these tailor-made *av*GFPs as fusion tags in mammalian cells is limited, since they need either auxotrophic bacterial strains or bacterial strains that host suitable orthogonal pairs. Therefore, the ideal goal in this particular case would be to provide mammalian cells under investigation with suitable orthogonal pairs or orthogonal translation components to study expression of a larger number of *av*GFP-fusion proteins simultaneously. That requires the development of expressible reporter systems for use in mammalian cells as was recently reported.[198,211,180]

7.5. *Analogues, Isosteres and Surrogates for Biomedicine*

Bioisosteric compounds with nearly identical structures, shapes, and volumes, as well as similar distributions of electrons might affect biochemically associated systems as agonist or antagonists and thereby produce biological properties that are related to each other. Early studies on non-canonical amino acids as antimetabolites which were extensively reviewed by Richmond,[52] Hortin and Boime,[50] Wilson and Hartfield,[51] and Kirk,[58] clearly demonstrated the strong antimicrobial, antimycotic, and antitumor activities of such compounds. However, little attention was paid to these interesting pharmacological properties that might possibly have a great potential in biomedicine.[15] The roles of noncanonical amino acids other than participation in protein synthesis are specific interactions with metabolic and catabolic enzymes (inhibition, activation, modulation) and interference in the process of amino acid biosynthesis, turnover, transport, and storage.

Most of the noncanonical amino acids are toxic; often this toxicity is the result of their conversion into toxic substances by a relatively complex metabolic route. Microorganisms and fungi produce many unusual amino acid containing toxic substances that are physiologically highly active in mammals or other microorganisms, usually in a highly deleterious manner such as cephalosporines or penicillins. Plants are the best chemists among living organisms because of their remarkable capacity to produce a wide variety of secondary metabolites such as alkaloids, terpenes, and tannins to protect themselves from predators, parasites, and infection by viruses. Many novel plant amino acids are structurally very similar to the canonical ones and have the poten-
Figure 12. Top: Single color excitation of differently emitting *av*GFP mutants and variants expressed in bacterial cells and imaged on a standard confocal microscope by using different emission filters. The fluorophores are excited at one wavelength and differ with respect to their emission wavelengths. The experiment shown is an example for in vivo non-invasive multiple labelling: Trp-auxotrophic *E. coli* ATCC49980 cells[102] expressing "enhanced cyan" *av*GFP (ECFP, Ser65Thr/Tyr66Trp), "enhanced green" *av*GFP (EGFP, Phe64Leu/Ser65Thr), and "gold" fluorescent protein (GdFP) are clearly distinguishable upon simultaneous excitation at a single wavelength (457 nm). Bottom: Comparison of normalized fluorescence emission spectra of these *av*GFP classes. The fluorescence of ECFP is characterized by two emission maxima ($\lambda_{max1}=475$ nm; $\lambda_{max2}=506$ nm). The emission maximum of the likewise "classical" mutant EGFP (with Tyr 66 as an integral part of the chromophore) is further red-shifted ($\lambda_{max}=508$ nm).[223] The tailor-made GdFP (with (4-NH$_2$)Trp66 as an integral part of the chromophore) shows the largest red shift ($\lambda_{max2}=576$ nm). RF = normalized fluorescence intensity.

tial to affect deleteriously the metabolism in other organisms. For example, the noncanonical amino acid mimosine causes loss of hair and wool in cattle and sheep grazing on *Leucaena leucocephala* or *Mimosa pudica*, while the numerous selenium. or sulfur-containing amino acids are found in a variety of plants that have wide-ranging toxic effects on grazing animals.[148]

The particularly well-documented toxicity of 3-fluorotyrosine, 3-fluorophenylalanine, and 5-fluorotryptophan is due to the formation of fluoroacetate formed by the dominant Tyr metabolic pathway, which was discovered over 30 years ago.[226–228] The toxic fluoroacetate is the most ubiquitous among the organofluorine compounds and has been identified in more than 40 tropical and subtropical plant species. It is also produced by some microorganisms when grown on media containing fluoride. Whether such a principle can be "borrowed" from nature to kill tumor cells and spare normal ones, is still unknown. Indeed, in drug design for chemotherapy the best way to achieve the specificity of action and selectivity of delivery is to use proteins as delivery vehicles (protein shuttles; Figure 13). For example, it is known that lethal metabolic intermediates such as fluorocitrate and fluoroacetate are formed from 3-fluorotyrosine in mammalian tissues.[58] The same must hold true for tumor cells, if this cytotoxic amino acid would be specifically delivered to them (Figure 14). Free cytotoxic amino acids generally have two choices: 1) the re-incorporation into other proteins (i.e. re-entering protein translation), and 2) the entry into the intracellular metabolism. The cytotoxic action most probably follows the general principle postulated by Pattison that "any compound which can form fluoroacetic acid by some simple biochemical process is toxic".[229]

7.6. Noncanonical Amino Acid Surrogates in the Brain?

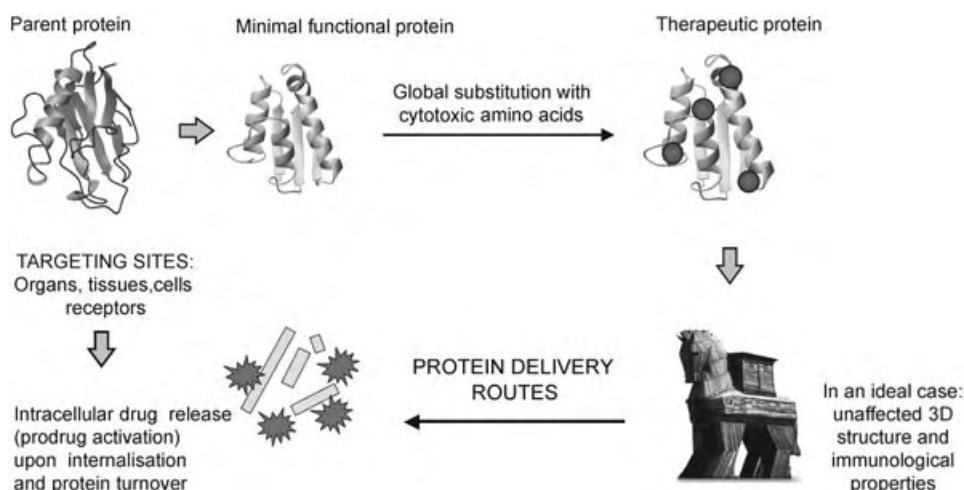
Many surrogates are more active than their parent molecules. A widely known example is the lactose surrogate isopropyl-β-thiogalactoside (IPTG), which is a much stronger inductor of the *lac*-operon than lactose itself. Neuroregulatory amino acids and their derivatives play critical biochemical roles not only in the brain, but also in the whole nervous system. Indeed, numerous neurolologically active substances have amino acids as precursors. The uptake of amino acids into the brain is particularly important for the control of brain functions. The composition of free amino acid pools in the
Figure 14. Human recombinant annexin V isomorphously substituted with the pharmacologically active noncanonical amino acid thiaproline.[14] The overall protein structure is not changed by the replacement. Cytotoxic amino acids, such as thiaproline, that might serve as diagnostic markers, are covalently integrated into the polypeptide as an inactive prodrug and should exert no toxicity during delivery. This approach is expected to introduce as few perturbations as possible in the structural, functional, and immunogenic properties of the protein carrier (e.g. antibodies, cytokines, growth factors, tissue-specific proteins).


Figure 13. Schematic representation of the concept of use of proteins "armed" with cytotoxic amino acids as possible non-invasive carriers for drug delivery.[15] Antibiotic amino acids such as penicillamine, azaleucine, azatyrosine, thiaproline, furanomycin, or strong antimetabolites such as fluorinated amino acids, or canavanine can be incorporated into proteins. Recombinant proteins that contain such pharmaceutically active amino acids are expected to act as specific delivery vehicles "shuttles", "Trojan horses" or even "magic bullets" due to their potential ability for selective delivery and targeting in the human body.

brain differs largely from those of other tissues. The availability (i.e. uptake) and utilization of such amino acids are often the rate-limiting step in the neurological actions of their derivatives. For instance, the administration of large amounts of Trp in rats leads to an increase in the synthesis of the neurohormone 5-hydroxytryptamine (serotonine).[230]

The neurological activity of some noncanonical amino acid analogues, surrogates, and their derivatives has been known for a long time.[231,232] The delivery of such substrates alone or as a part of peptide or protein carriers that pass the blood–brain barrier might provide the brain with novel substances of anthropogenic origin that can exhibit interesting and useful properties.

Relatively well documented "relaxed" substrate specificity of brain enzymes can be exemplified by the nonspecificity of the aromatic amino acid decarboxylase and dopamine-β-hydroxylase, which are responsible for the conversion of a number of Tyr derivatives into analogues of norepinephrine, or the 5-hydroxytryptophan-based serotonine enzymatic system. Furthermore, the storage mechanism between processed (e.g. decarboxylated) canonical amino acids and their amino acid surrogates is nonselective as well.[233] These features might help to modulate synaptic activity by the use of noncanonical amino acid analogues or surrogates because they might enter some of the metabolic pathways of their canonical counterparts and form metabolic derivatives that might displace natural neurotransmitters.

Since neurohormones based on amino acids are responsible for many aspects of neural and brain functions, it is conceivable that the changes in their balance caused by surrogates and analogues released in the brainstream might be responsible even for different consciousness states. In other words, approaching the chemistry of the brain by way of amino acid surrogates should provide an efficient and valuable tool for studying not only the molecular principles of thought, memory, and sensory perception but also might be able to act as effective medicines.[234]

8. The Future of Genetic Code Engineering

8.1. Protein Chemistry and Genetics: History and Current Status

By the end of the 19th century, protein chemists had identified most of the amino acids, which were known to be the main building blocks of all proteins. At the same time, Fischer and Hofmeister[235,236] conceptually solved the problem of amino acid linkages in proteins with the "peptide hypothesis" (i.e. peptide bond concept). The development of a variety of analytical techniques took almost half a century before this hypothesis was fully confirmed with the successful insulin sequencing by Sanger.[237] How amino acids are linked to polypeptide chains was first fully understood only when it had been demonstrated experimentally that RNA templates direct the synthesis of each protein. At this point, the direct connection between intracellular protein synthesis of living matter and its genetic program was clear.

After the unambiguous experimental identification of DNA as the hereditary molecule made by Avery, Hershey,

and Chase,[238,239] biologists, chemists, and physicists directed their interest to DNA. Beadle's "one gene→one protein" concept[240,241] certainly paved the way for the discovery of the regulation of the gene expression by Jacob and Monod.[242] After the genetic code had been deciphered[3,4] further rapid development continued unabated. In the early 1970s almost all crucial concepts of genetics were established and are now an integral part of common biochemical knowledge. The concept "one gene→one protein" certainly does not fit into the current picture of the multidimensionality of a proteome; however, its historical impact is based on the fact that it was used (and still is a common practical guide in laboratory routine) as a working hypothesis leading to important discoveries and developments.

The incorporation of noncanonical amino acids into proteins emerged as a research field as early as the 1950s.[52] However, only after the advent of recombinant DNA technology did it become possible to advance in the direction of an expanded amino acid repertoire. As with the deciphering of the triplet genetic code, organic chemistry and genetics had to work closely together. The new venture is not just a renaissance of old dreams about generating proteins with synthetic amino acids, but is centered on about how to change the universal genetic code experimentally and how affect its evolution.

8.2. Theories on the Genetic Code and Its Engineering

While investigations into the emerging questions about the nature and history of the genetic code evolution were taking place mainly in theoretical biology, research into the possibilities of an expansion of the amino acid repertoire in the genetic code was developed in the field of protein chemistry. The field of molecular evolution in the last few decades was marked by the emergence of a rather large number of studies on the different models for evolution of the genetic code, whose influence on the experimental engineering of the genetic code was rather minimal.

Classical experiments by Miller[25] about the spontaneous prebiotic synthesis of amino acids mark the historical start of the era of the experimental approach to the problem of the origin of life. Regarding the genetic code itself, the vast majority of the contributions deal with theoretical aspects; only a few authors have contributed in both theoretical as well as practical research directions. Recently, Yarus wrote "the immediate future of the code origin appears to be in hands of experimentalists".[243] Wong et al. made historically important contributions to the attempts to expand the amino acid repertoire.[66,172] In addition, Wong postulated the co-evolution theory of the origin of the genetic code, which states that the genetic code expansion took place by the recruitment of precursor amino acids from developing biosynthetic pathways.[244] This means that an expansion of the coding capacities of the existing genetic code can be achieved if host microorganism cells are additionally provided with novel biosynthetic pathways that produce amino acids compatible with their physiology and metabolism. In other words, the amino acid repertoire cannot be freely expanded to maximize

the efficiency of a single function, but must instead co-evolve with the expansion of other cellular metabolic and biosynthetic capacities. Indeed, recent experiments by Mehl et al.[149] seem to confirm such possibilities.

The other hypotheses of the code evolution such as how it was shaped by various selective pressures, its capacity for translation-error minimization and flexibility might indeed serve to certain extents as a good guide or conceptual framework in experimental attempts for code engineering. Taking into account the immense complexity of the biological systems we are dealing with, it should not be a surprise that in spite of the large volume of recent and older literature on the genetic code evolution, there are no generally accepted concepts.

Most probably, we might forever remain agnostic about the exact historical sequence of events in code origin and establishment. The genetic code itself is a product of Darwinian evolution,[44, 245] and Darwinism per se is a historical concept. Therefore, for genetic code engineering, the experiment always remains the ultima ratio to analyze any prediction, hypothesis, or expectation. Even then, the non-resolvable complexities and controversies are often difficult to avoid. For example, the second position of U in the coding triplets, encodes hydrophobic amino acids, that is, the genetic code conserves hydrophobicity against random nucleotide mutations. Not surprisingly, this residue property is also an essential driving force in protein folding. On the other hand, in the context of the standard repertoire, it is often notoriously difficult to characterize a single property such as the hydrophobic nature of Trp.[246, 247] Namely, there are more than forty published hydrophobicity scales in the literature with many cases of contradictions about the hydrophobic/hydrophilic nature of Trp.[248]

8.3. Code Engineering and De Novo Protein Design

The terms "protein engineering" and "protein design" used in numerous contemporary research reports, usually refer to the modification or redesign of pre-programmed protein modules. These are normally identified by pattern recognition or exchange (permutation) among the canonical 20 amino acids. Both these pathways have been selected, shaped, and optimized for billions of years by various selective pressures during evolution. Two fundamentally different approaches have emerged over the last twenty years: 1) A "rational" redesign by site-directed mutagenesis. This method requires knowledge of the three-dimensional structure of the protein or the capacity to predict the effect of exchanges among the canonical 20 amino acids. 2) Random mutational techniques such as DNA shuffling, based on a mutation/selection approach, which imitates the natural selection process.

Unfortunately, despite numerous published studies and experimental observations concerning folding properties of proteins, there are still no general rules for a successful de novo protein design.[249] The rapid progress in structural biology, as reflected by the dramatic increase in the number of resolved three-dimensional structures, was surprisingly of little help in coping with the problems of rational design. Even for genetic code engineering, the availability of three-dimensional structures of all translational components, including that of the ribosome,[250] although spectacular, has until now, contributed only marginally, to enable and teach us how to expand the genetic code experimentally. For example, the recently determined structure of the TyrRS/tRNA$_{CUA}^{Tyr}$ pair from *Methanococcus jannaschii*[251] explained the structural basis for orthogonality—but it was a posteriori, that is, after the novel aaRS substrate specificity had already been established. Although three-dimensional structures are invaluable starting points for design attempts, it is clear that difficult and challenging problems associated with protein rational design as well as code engineering cannot be based solely on such predominantly mechanistic, descriptive, and reductive approaches. One might hope that protein chemistry through code engineering will turn future research trends in biochemical sciences from the currently prevailing dry descriptiveness to a research dominated by conceptual intuition and inventive spirit.

The problem of the de novo design of proteins will not be solved by an expansion of the amino acid repertoire itself. At this stage of the development in the field, many cases are well-documented for which translationally active amino acids exhibit adverse effects on the folding and structural integrity of target proteins. In other words, many interesting non-canonical amino acids simply cannot be accommodated in the existing natural protein scaffolds without their redesign or de novo design. Literally speaking, we are in the same position as those builders from the beginning of dark Middle Ages of Western culture who were borrowing building materials from sophisticated Greek and Roman structures.

8.4. Future Progress and the Global Impact of Code Engineering

Progress in natural science in general, as well as in genetic code engineering in particular, would usually have an impact on society in terms of the novel technical advances and perspectives that it brings. On the other hand, such progress often cannot occur without having an impact on numerous traditional philosophical, religious, and ethical issues. It might cause or catalyze critical re-evaluation, disappearance of the obsolete, and even the emergence of novel ideological, religious, or ethical systems in certain societies. For example, Darwinism offers a frame in which one would see the genetic code as an integral part of cellular chemistry whose function is to increase the survival fitness in a given environment.[45] It also postulates that in the process of the emergence of biologically active natural proteins as well as living organisms, no conscious effort is involved.[252] On the other hand, the engineering of novel functions of artificial proteins or even cells with an expanded amino acid repertoire would be an example of human-made conscious design.

At the more practical level, sound experimental research in coming decades will mainly concentrate on using current knowledge of the basic determinants behind the organization of the present-day genetic code to make it more accessible for further experimental manipulations. The strategy of evolution

will be borrowed from nature to much larger extents than now. Namely, natural selection is a nonrandom process determined by the environment; a sort of statistical bias that increases the probability of otherwise extremely improbable but successful adaptive genetic and phenotypic combinations. This process is highly innovative and teleonomic in its very nature, since the end result of it is improved functional performance in a given environment.

The emergence of such tailor-made (or custom-made) proteins, produced in specialized cells (with target-engineered genetic codes) and intentionally designed for performance in user-defined environments probably mark the start of the "post-proteome" era. Nonetheless, it would always be desirable to refrain from the claim to describe current as well as future progress in the field as "revolutionary"—serendipity and intuition cannot be excluded as important factors for breakthrough discoveries. One more reason always to be sceptical of revolutionary talk is the fact that the only context in which such developments could take place is continuous skilled and dedicated experimental labor. Furthermore, it is hard to imagine that progress anticipated in this way represents a sort of a "paradigm shift". It should be rather taught in terms of a gradual change of concepts and experimental possibilities that are deeply rooted in Mendelian and Darwinian tradition with the necessary requirement for its constant and critical re-evaluation and improvement.

Addendum

Since the submission of this review a series of novel, important, and relevant contributions in this rapidly developing field have appeared.

Proline and phenylalanine analogues and surrogates: The expectation of this study that engineering or a simple elevation of intracellular levels of prolyl-tRNA synthetase (ProRS) will result in a full translational activity of the proline analogues and surrogates such as *trans*- and *cis*-4-hydroxyproline, piperidine-2-carboxylic acid, and azetidine-2-carboxylic acid (Section 4.7) has been fulfilled by Conticello and co-workers.[256] They succeeded in incorporating these amino acids efficiently into recombinant elastin by using Pro-auxotrophic strains with native genomic background activity of ProRS, or Pro-deficient strains supplemented with elevated amounts of native or mutated ProRS expressed under the control of an orthogonal promoter system. Similarly, by using the PheRS mutant with broadened substrate specificity (PheRS-αAla294Gly), Bentin et al. reported the incorporation of large amounts of the photoreactive bicyclic amino acid benzofuranylalanine into a model protein.[257]

Identity problem: An important contribution that fully highlighted the problem of amino acid "identity" (Section 2.3), as a novel feature of the protein translation apparatus was made by Tirrell and Kumar.[258] Therein they fully confirm the hypothesis that there must "be a case when one amino acid is a substrate for two synthetases and subsequently, the isoacceptor from two different tRNA species which are loaded with the same amino acid, that is having the same 'identity'". It is well known (see for example

refs. [259] and [260]) that the fidelity of the aminoacylation reaction is determined not only by the catalytic specificity of aaRS but also by its specific intracellular concentrations in cytosol. In this work, it is explicitly demonstrated how variations of cytosol concentrations of aaRS in bacterial expression hosts can allow a single RNA message to be read in different ways. More specifically, Tirrell, Kumar, and co-workers have shown that the identity of the noncanonical amino acid (2*S*,3*R*)-4,4,4-trifluorovaline can be changed in the protein translation by its assignment either to isoleucine or to valine codons, depending on intracellular levels of the isoleucyl- or the valyl-tRNA synthetase in the bacterial expression host. This is an excellent example of how kinetic knowledge about relative rates of competing aminoacylation reactions could be used to expand the amino acid repertoire.

Bridging the gap between theory and experiment: The results described in reference [254] proved to have implications for the understanding of the origins of alternate genetic codes, favoring the "ambiguous intermediate" hypothesis of Schultz and Yarus.[261,262] Two papers have appeared recently that demonstrate that the community of theoretical biologists concerned with the evolutionary establishment of the genetic code are slowly becoming keen on the experiments of code engineering, continuing in this way a tradition established earlier (see Section 2.2, ref. [27]). Namely, a review by Bacher, Hughes, Wong, and Ellington[263] and a short commentary by Cavalcanti and Landweber[264] elaborated different hypotheses regarding genetic code evolvability in light of the results of novel code engineering experiments.

Other contributions and reviews in the field: In the meantime, Schultz and co-workers have reported the use of orthogonal TrpRS/tRNA^Trp, which is capable of efficient opal suppression for selective incorporation of (5-OH)Trp into proteins in mammalian cells.[265] Another breakthrough from this group is the report of the design and generation of an orthogonal synthetase/tRNA pair derived from archeal tRNA^Lys sequences that are capable of frameshift suppression of the quadruplet codon AGGA.[266] This pair proved to be compatible with the amber-orthogonal system; thus, enabling the simultaneous incorporation of homoglutamine and *O*-methyltyrosine at distinct positions within myoglobin. The most recent reviews by Link et al.,[267] Hahn et al.,[268] as well as by Anthony-Cahill and Maglierly,[269] provide a balanced view on the whole field, whereas specialized reviews have focused on site-specific labeling using chemoenzymatically acylated tRNAs[270,271] and subsequent post-translation chemistry of the resulting proteins.[272]

Noncanonical DNA base pairs: The approach pioneered by Benner and co-workers (1989) on the use of complementary nucleotides to generate novel Watson–Crick base pairs culminated recently in the finding by Yokoyama and co-workers[273] that DNA with unusual base pairs can be transcribed into RNA molecules. The rapid progress in the design and construction of noncanonical base pairs based on research by Benner, Eaton, Kool, Hirao, Rombesberg, Yokoyama, Schultz and their respective groups was recently comprehensively reviewed by Bergstrom.[274]

Communications
Nanoporous crystalline sheet were prepared by self-assembly of roil–coil molecules. Removal of coil segments from the organized structure produced a crystalline layer with a planar nanopore array. The nanoporous solid is capable of entrapping highly nonpolar hexane soluble dyes, such es Nile red, in aqueous solution. For more details see the Communication by M. Lee and co-workers on the following pages..

Supramolecular Crystalline Sheets with Ordered Nanopore Arrays from Self-Assembly of Rigid-Rod Building Blocks**

Myongsoo Lee,* Myoung-Hwan Park, Nam-Keun Oh, Wang-Cheol Zin, Hee-Tae Jung, and Dong Ki Yoon

The design and construction of well-defined nanoporous materials is an area of great interest, because they have broad applications in catalysis, lithography, membrane filtration, and ion-selective membranes.[1–6] Development of such well-defined porous materials requires the rational design of molecular components that are programmed to assemble through noncovalent intermolecular forces. We previously demonstrated that self-assembled structures based on rod building blocks could be manipulated through attachment of flexible parts with different lengths to their ends.[7] Depending on the relative length of the rigid segments, these blocks self-assemble into perforated supramolecular layers with in-plane, ordered coil perforations that are able to self-organize into a three-dimensional (3D) hexagonal superlattice.[8] One can envision that selective removal of coil segments from this ordered structure would provide a novel strategy to generate nanoporous layered materials with in-plane nanopore arrays.

Here we report the preparation of supramolecular crystalline sheets with in-plane nanopore arrays by hydrolysis with aqueous KOH and subsequent removal of coil segments from the perforated layered structure (Figure 1). The synthesis of a self-assembling rod-coil molecule consisting of penta-*p*-phenylene and poly(propylene oxide) was performed in a stepwise fashion starting with esterification of poly(propylene oxide) and 4-bromobenzoic acid, and continuing with Suzuki cross-coupling to generate the rod building block. The rod-coil molecule was characterized by ¹H and ¹³C NMR spectroscopy, elemental analysis, and gel-permeation chromatography (GPC) and shown to be in full agreement with

Figure 1. Preparation of supramolecular porous crystalline sheets by selective removal of coil segments from a perforated layer structure.

the structure presented. The ester linkage grafting the rod and coil segments can be easily cleaved by hydrolysis with alkali metal hydroxide solution.

The rod-coil compound melts into an isotropic liquid at 203°C, as evidenced by differential scanning calorimetry (DSC) and thermal optical polarized microscopy. The TEM image of a microtomed film of the material (stained with RuO$_4$) showed a honeycomblike supramolecular structure with a hexagonal array of light coil perforations in a dark rod matrix (Figure 2a). Small-angle X-ray scattering (SAXS) measurements showed a number of well-resolved reflections, which can be indexed as a 3D hexagonal order (*P*6$_3$/*mmc* space-group symmetry) with lattice constants $a = 12.7$ and $c = 18.0$ nm (Figure 2b).[8] The diameter of a perforation, determined from the lattice constants and density measurements, appeared to be 9 nm, consistent with the TEM analysis.

Wide-angle X-ray diffraction patterns showed three sharp reflections (Figure 3a), that is, the rod segments are packed

Figure 2. a) TEM image of a microtomed film of the rod-coil compound stained with RuO$_4$. b) Small-angle XRD pattern of the rod-coil compound. Inset: SAXS reflections for $q = 1.0$–2.0 nm^{-1} with an intensity scale expansion of $\times 10$.

Figure 3. Wide-angle XRD patterns measured a) before and b) after hydrolysis of the rod-coil compound at 25 °C.

Figure 4. Solid-state ^{13}C NMR spectra of the rod-coil compound a) before and b) after hydrolysis.

into a rectangular lattice (*P2gg* space group) with unit cell dimensions $a = 0.79$ and $b = 0.56$ nm. These results demonstrate that the rod segments crystallize into a perforated layered structure, in which perforations are filled by coil segments, and subsequently the perforations organize into a 3D hexagonal superlattice.

Cleavage of the ester groups followed by selective removal of coil segments in the ordered state is a possible strategy for constructing nanoporous supramolecular crystalline sheets with well-defined pore size. To obtain initial proof of this concept, the thin film with coil perforations was placed in water/methanol containing potassium hydroxide at room temperature to cleave the ester groups grafting the rod and coil segments. Under these conditions, the crystalline layers consisting of rod segments are insoluble and inert. After one week, the rigid and insoluble film was removed from the hydrolysis solution, thoroughly washed with aqueous HCl and methanol, and dried at room temperature under vacuum.

Solid-state ^{13}C NMR spectra of the films showed that the signals associated with the poly(propylene oxide) chain had completely disappeared after hydrolysis (Figure 4). The FT-IR spectrum showed a broad O–H absorption in the region from 3400 to 2400 cm^{-1} and a C=O stretching band centered at 1720 cm^{-1}, which shifts to 1690 cm^{-1} after hydrolysis, indicative of conversion of an ester to a carboxylic acid. These data are consistent with the formation of rigid organic frameworks consisting only of aromatic rod segments by selective removal of the poly(propylene oxide) coils. The resulting film is completely insoluble in water and common organic solvents such as CHCl$_3$, methanol, CH$_2$Cl$_2$, toluene, hexane, and ethyl acetate and does not exhibit any noticeable swelling.

The TEM image of a microtomed film of the hydrolyzed sample stained with RuO$_4$ showed nanopore arrays (Figure 5a), indicative of the formation of nanoholes on hydrol-

ysis. This was also confirmed by atomic force microscopy (AFM) images. The amplitude images of a hydrolyzed film showed an ordered array of circular pores at the positions of the coil perforations (Figure 5b and 5c). The line scan in Figure 5b (inset) shows a pore to pore distance of approximately 12 nm, that is, the fundamental spacing is not changed on hydrolysis. The SAXS pattern exhibited four sharp scattering peaks corresponding to a lamellar structure with
Figure 5. a) TEM image of a hydrolyzed film stained with RuO$_4$. Tapping-mode AFM amplitude images presented as b) two- and c) three-dimensional graphics (250 nm × 250 nm area). d) Small-angle XRD pattern of the hydrolyzed sample.

Communications

a layer thickness of 2.1 nm (Figure 5d), which implies that perforation order is not maintained on removal of the coil segments. Since the length of carboxylic-acid-terminated penta-*p*-phenylene is 2.1 nm, the measured lattice constant indicates that the coil segments are extracted from the perforated layered structure after hydrolysis. These results demonstrate that the crystalline rod layers with in-plane nanopore arrays are stacked into a lamellar structure with a thickness corresponding to the length of a rod, while pore order along the *c* direction is lost on extraction of PPO coil segments. The wide-angle XRD pattern of the hydrolyzed sample revealed the same diffraction pattern but with peak narrowing compared to that of the rod-coil molecule (Figure 3b).[9] These data are consistent with the preservation of the crystal structure within the rod layers, with enhanced crystallinity due to selective etching of the amorphous coil segments from the perforated layers. These results demonstrate that hydrolysis and subsequent removal of the flexible-coil segments in ordered nanostructures formed by rod-coil systems can provide a strategy for constructing nanoporous crystalline materials with uniform pore size.

Remarkably, the nanoporous solid proved capable of entrapping highly nonpolar dyes such as Nile Red in aqueous solution; this is indicative of the presence of nanoholes with hydrophobic interiors. In one experiment, Nile Red was dissolved in hexane and added to an aqueous dispersion of the nanoporous solid. The mixture was treated by ultrasonication for 12 h. After this time, the water subphase turned violet, and the significant decrease in the intensity of the absorption peak corresponding to Nile Red in the hexane phase indicated that dye molecules had been transferred to the aqueous phase (Figure 6). This unique amphiphilic behavior is most probably attributable to hydrophobic and π–π interactions between the hydrophobic interiors of the nanopores and aromatic dye molecules.

In summary, a rod-coil compound in which an ester linkage grafts rod and coil segments exhibited a honeycomb-like supramolecular structure with 3D hexagonal symmetry. Hydrolysis with aqueous KOH and subsequent removal of the coil segments from the ordered structure with in-plane, hexagonally ordered perforations produced a crystalline layer with in-plane nanohole arrays. These results indicate that this approach allows novel, highly ordered nanoporous crystalline sheets to be produced, which potentially have applications as diverse as biomimetic transport membranes,[1d] periodic porous materials,[10] and nanopatterning.[11]

Nanobiotechnology

Reversible Switching of DNA–Gold Nanoparticle Aggregation**

Pompi Hazarika, Bülent Ceyhan, and
*Christof M. Niemeyer**

The utilization of the tremendous recognition properties and functionality of proteins and nucleic acids as building blocks in the "bottom-up" self-assembly of nanometer-scaled functional devices has led, in the past few years, to a new research discipline, descriptively termed as nanobiotechnology.[1] Applications include, for instance, the organization of metal and semiconductor nanoclusters,[2] numerous bioanalytical techniques,[3] as well as biomolecular electronics[4] and nanomechanical devices. In the development of the latter, an increasing number of reports is currently being devoted to the construction of nanomechanical devices from DNA.[5] Examples include the construction of devices from DNA molecules whose functionality is based on conformational changes induced by the binding of intercalators,[6] Co^{3+}-ion-dependent B- to Z-DNA transformation,[7] Mg^{2+}-ion-dependent DNA supercoiling,[8] pH-dependent formation of intramolecular cytosin quartet structures,[9] or by intermolecular hybridization with so-called fueling oligonucleotides.[10–14] In this concept, a given DNA conformation is changed upon hybridization with an effector oligomer, which, in turn, can be removed from the complex by hybridization with a second oligomer. Although various examples have proven the suitability of this approach for switching dye-tagged DNA molecules, to the best of our knowledge, its application to the reversible formation of materials has not been realized yet.

Herein we report the reversible aggregation of DNA-modified gold nanoparticles by taking advantage of two complementary fueling oligonucleotides, F_a and F_d (Figure 1). The base sequence of F_a is comprised of three stretches, a′, b′ (which are complementary to ≈ 23-nm Au nanoparticle-bound 12-mer oligomers a and b, respectively) as well as stretch c′ (which promotes hybridization of F_a and F_d). The transformation cycle starts with state I (Figure 1) in which the DNA nanoparticles are dispersed and reveal a characteristic plasmon absorption maximum at 526 nm (Figure 2). Upon addition of 32 equivalents of oligomer F_a, the particles

Figure 1. Schematic drawing of the reversible aggregation of DNA-modified gold nanoparticles utilizing fueling oligonucleotides F_a and F_d. F_a contains three stretches (a′, b′, and c′, which are complementary to the gold-nanoparticle-bound 12-mer oligomers, a and b). Stretch c′ forms a dangling end in the aggregated particles (state II), which promotes the hybridization of F_a and F_d (intermediate state III).
Figure 2. UV/Vis spectra of nanoparticle aggregation and redispersion. The absorbance maxima at 526 nm and 625 nm indicate the formation of dispersed and aggregated particles, respectively. The fueling oligomers F_a^4 and F_d^4 employed contain a stretch c′ and c that are 4 bases in length. Notably, 2 equivalents of oligomer F_d^4 (with respect to F_a^4) are required to restore the original extinction of the dispersed particles.

aggregate (state II, Figure 1), and, consequently, the plasmon absorption band is damped and shifted towards longer wavelengths (≈ 625 nm; Figure 2). In the next step, oligomer F_d is added; F_d is fully complementary to and hybridizes with F_a, starting at the dangling-end stretch c′ of the duplex DNA that interconnects the nanoparticles. This process, schematically shown as the intermediate state III in Figure 1, leads to the formation of a waste duplex and the redispersion of the nanoparticles. Hence, an increase in absorbance at 526 nm is observed (Figure 2).

Experimental variations revealed that 2 equivalents of oligomer F_d (with respect to F_a) were needed to retain the

extinction of the original nanoparticle solution (Figure 2). It is likely that the excess F_d is necessary owing to a limited accessibility of linking strands F_a within the aggregates and, hence, decreased hybridization kinetics. Additional studies on the influence of the length and base composition of sequence stretch c within the fueling oligomer F_a and F_d showed that four base pairs are sufficient to promote complete removal of the DNA strands that interconnect the particles (see Supporting Information).

To demonstrate the reversible switching of the nanoparticle aggregation, we carried out seven consecutive cycles of aggregation and redispersion by adding fuelling oligomers F_a and F_d, respectively. After each addition, UV/Vis spectra of the samples were recorded (see Supporting Information) and the extinction at 526 nm and 700 nm, which are indicative for dispersed and aggregated particles, respectively, was plotted against the number of steps (Figure 3). The results clearly
Figure 3. Reversible switching of the nanoparticle aggregation. Plot of the extinction measured at 526 nm (black) and 700 nm (gray) versus the number of steps of the addition of either oligomer F_a^4 (even numbers) or F_d^4 (odd numbers). Notably, a high extinction at 526 nm and 700 nm indicates the presence of dispersed and aggregated particles, respectively.

demonstrate the feasibility of using fueling oligomers for the reversible switching of nanoparticle aggregation. Nonetheless, careful analysis of the absorbance maxima observed for the aggregated particles indicated a decrease in the red shift of the plasmon absorption band from 619 nm in cycle 1 to 556 nm in cycle 7 (Supporting Information). As the magnitude of the shift is indicative of the size of the particle aggregates formed,[15,16] this observation suggests that the aggregation efficiency is diminished owing to increasing concentrations of free F_a oligomers.

In conclusion, we have shown that the reversible switching of DNA–gold nanoparticle aggregation can be carried out by the employment of complementary fueling oligonucleotides that contain a short dangling-end sequence for the initiation of strand removal from the aggregates. Further optimization of this concept by variation of temperature, salt concentration, and pH value, by using oligofunctional DNA nanoparticles[17] and, in particular, by careful design of the oligomer sequences[18,19] should pave the way towards nanostructured materials with programmable functionalities for a broad range of applications in nanobiotechnology.

Experimental Section

The preparation of DNA–gold nanoparticle conjugates was carried out as described earlier.[17] The size of the citrate-stabilized gold nanoparticles used was 22.9 ± 5.7 nm. Thiol-modified DNA oligomers (sequence a: 5′-SH-GGT GAA GAG ATC-3′; sequence b: 5′-AAG ACC ATC CTG-SH-3′) were purchased from Thermo Electron, Germany.

To aggregate the DNA-modified particles, generally 32.5 equivalents[20] of oligonucleotide F_a^4 (5′-TAC GCA GGA TGG TCT TGA TCT CTT CAC C-3′) was added to a mixture of DNA–gold nanoparticle conjugates **1** and **2** (each 1.54 nM) in TETBS buffer (0.3 M NaCl, 20 mM Tris-HCl, pH 7.35 containing 5 mM EDTA and 0.05% Tween 20). The solution was incubated for 24 h at room temperature. Subsequently, the aggregates were redispersed by adding oligonucleotide F_d^4 (5′-GGT GAA GAG ATC AAG ACC ATC CTG CGT A-3′; 2.2 equiv with respect to F_a^4), and the solution was incubated for 24 h at 37°C.

For the repeated switching of particle aggregation, seven cycles of aggregation/redispersion were performed as described above with the following amounts of fuelling oligomers: Cycle 1: 32.5 equiv (1.5 pmol) F_a^4 and 73.7 equiv (3.4 pmol) F_d^4; cycle 2: 84.5 equiv (3.9 pmol) F_a^4 and 192.8 equiv (8.9 pmol) F_d^4; cycle 3: 212.3 equiv (9.8 pmol) F_a^4 and 467.9 equiv (21.6 pmol) F_d^4; cycle 4: 511.2 equiv (23.6 pmol) F_a^4 and 1109.0 equiv (51.2 pmol) F_d^4; cycle 5: 1193.5 equiv (55.1 pmol) F_a^4 and 2558.1 equiv (118.1 pmol) F_d^4; cycle 6: 2729.2 equiv (126.0 pmol) F_a^4 and 5796.3 equiv (267.6 pmol) F_d^4; cycle 7: 6138.5 equiv (283.4 pmol) F_a^4. To prevent changes in absorbance due to dilution of the samples, 14 different aliquots of gold nanoparticles were prepared and F_a^4, F_d^4 oligonucleotide solutions were added until a distinct step was reached. In the remaining steps, only buffer was added to these particular samples. After the final addition of either oligomer or buffer solution to all 14 aliquots of the nanoparticle samples, the UV/vis spectra were recorded on a Varian-Cary 100 UV/Vis spectrophotometer.

morphologies that have characteristic dimensions on the nanometer scale.[1] In recent years, efforts to develop supramolecular polymers, that is, macromolecules which consist of monomeric building blocks that are linked together by noncovalent forces, have generated great enthusiasm.[2] A successful design of supramolecular polymers relies on the availability of noncovalent association units that can link various structural modules together. Although strategies that lead to a variety of chains or networks have been reported, association units with reasonable affinity and specificity have only recently become available. The groups of Zimmerman[3] and Meijer[4] have developed self-complementary, quadruply hydrogen-bonded complexes that serve as associating end groups for the construction of supramolecular polymers of high molecular weights. Other polymeric systems that involve supramolecular interactions are also known.[5] Despite the progress made, few hydrogen-bonded supramolecular block copolymers have been reported so far.[5i] Owing to the unavailability of heterodimeric hydrogen-bonded units of sufficient strength and specificity, supramolecular block copolymers that display microphase separation have not been reported. Lohmeijer and Schubert recently reported an exciting example of supramolecular block copolymers by using unsymmetrical metal complexes which were obtained with 30–50% yield after purification (column chromatography).[6]

To ensure microphase separation of designed supramolecular block copolymers and to couple different blocks, ideally, association units that link the different blocks together should exhibit both high stability and high non-self-complementary specificity, and at the same time the linkages should be kinetically reversible. Indeed, this is an unsolved problem. Many metal complexes are highly stable but are kinetically inert, whereas most hydrogen-bonded complexes lack high binding affinities and specificities.

We report herein a new class of supramolecular, AB-type diblock copolymers that rely on hydrogen-bond-enforced association of incompatible polymer chains. In the general structures **1** and **2**, hydroxyl-terminated polystyrene (PS) and poly(ethylene glycol) monomethyl ether (PEG) chains were coupled to two different oligoamide strands. We previously showed that oligoamide strands such as **1'** and **2'** paired into a hexa-hydrogen-bonded heteroduplex with an association constant $K_a > 10^9 \,\mathrm{M}^{-1}$ in chloroform.[7] Thus, mixing the modified PS with the PEG chains in a ratio of 1:1 in a common solvent (chloroform) should also lead to hydrogen-bonded supramolecular diblock copolymers. We also reported that the pairing of oligoamides similar to **1'** and **2'** was accompanied by significant downfield shifts of the signals for the protons of the amide groups: *g* (*g'*), *m* (*m'*), and *t* (*t'*; see structures **1** and **2** for atom labels).[7b] Here, the 1D ¹H NMR spectra of **1'·2a**, **1a·2a**, and **1c·2c** exhibited similar downfield shifts of N−H protons to those of the duplex **1'·2'**[8] which indicates that the PEG and PS strands are linked by intermolecular hydrogen bonds. Results from 2D ¹H NMR (NOESY) studies on **1a·2a** and **1c·2c** revealed interstrand NOEs that are also consistent with the formation of hydrogen-bonded duplexes, that is, the noncovalent coupling of PEG and PS strands.[8]

Communications

1': X = -OCH₃
1a: X = -O-PS ($M_w = 1.7 \times 10^3$)
1b: X = -O-PS ($M_w = 3.2 \times 10^3$)
1c: X = -O-PS ($M_w = 20 \times 10^3$)

2': Y = -OC(CH₃)₃
2a: Y = -O-PEG ($M_w = 350 \times 10^3$)
2b: Y = -O-PEG ($M_w = 2.0 \times 10^3$)
2c: Y = -O-PEG ($M_w = 5.0 \times 10^3$)

Hydrogen-bond-mediated association of the modified PS and PEG chains was further confirmed by gel permeation chromatography (GPC). The **1c·2c** pair, relative to **1c** or **2c** alone, had the fastest elution time (23.00 min), followed by **1c** (23.45 min), and then **2c** (24.99 min; Figure 1a). Upon elution
Figure 1. GPC traces of **1c·2c** (green), **1c** (–•–•–, purple), and **2c** (——, pink) eluted with a) DMF/toluene (10:90, v/v) and b) DMF, both at 60°C. DMF = N,N-Dimethylformamide.

with the polar solvent DMF (Figure 1b), **1c·2c** appeared as two peaks that coincided with the positions of **1c** and **2c** which again confirmed the hydrogen-bonded nature of **1c·2c**. Similar results were obtained from GPC analyses of another duplex, **1b·2b**, and its corresponding constituent blocks **1b** and **2b**.[8]

The above NMR and GPC results clearly establish that PS and PEG strands can indeed be linked through hydrogen bonding. In the bulk phase, under conditions that favor the formation of intermolecular hydrogen bonds, these supramolecular block copolymers may demonstrate properties that are characteristic of typical covalent block copolymers. On the other hand, under conditions that disrupt intermolecular hydrogen bonds, these supramolecular diblock copolymers may dissociate and behave like A/B polymer blends. One of the most important properties of block copolymers involves

microphase separation, which depends on the incompatibility or immiscibility of the two constituent polymer blocks and the volume fraction of the blocks.[1] If the molecular weights of the blocks are low, the constituent blocks are miscible and the corresponding block copolymers will be disordered and therefore not show microphase separation. As their molecular weights increase, the constituent blocks will eventually become immiscible and the corresponding block copolymers will show microphase separation.

According to the method described by Cheng and co-workers,[9] the interaction parameters (χN; 60°C) of the PS and PEG chains in the diblock copolymer architecture were estimated to have values of 2.8, 4.5, 17.3, and 19.8 for **1b·2a**, **1b·2b**, **1c·2b**, and **1c·2c**, respectively. In terms of polymer–polymer interactions in the phase diagram of diblock copolymers,[10] these χN values mean that 1) **1b·2a** and **1b·2b** should exist as disordered hydrogen-bonded block copolymers, which do not exhibit PS/PEG microphase separation owing to their low χN values, 2) **1c·2b** may still be disordered owing to its low PEG volume fraction (9.5%), although it has a reasonably large χN value, and 3) **1c·2c** with its χN value of 19.8 and PEG volume fraction of 20.9% should show microphase separation, which would lead to discontinuous nanoscale PEG domains embedded in the PS matrix. These predictions based on the χN values are fully consistent with results from differential scanning calorimetry (DSC) studies.

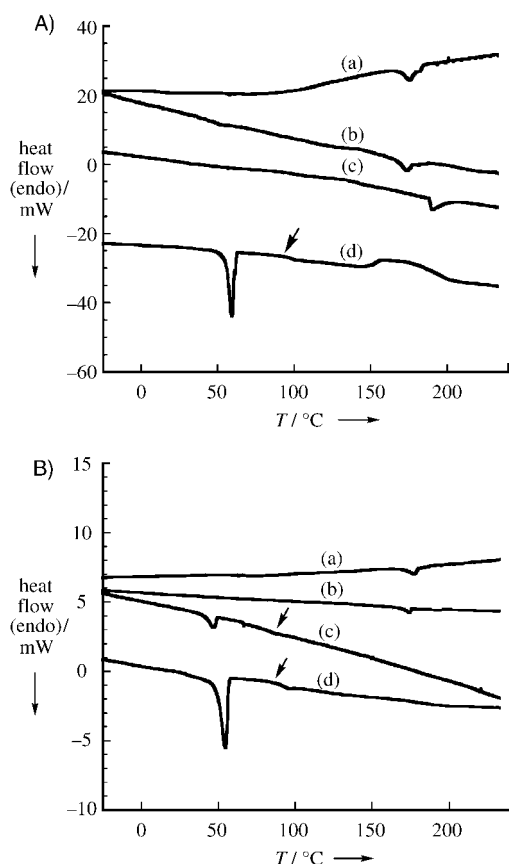
Figure 2 shows the DSC heating diagrams of four PS–PEG pairs, **1b·2a**, **1b·2b**, **1c·2b**, and **1c·2c**. The similar results obtained during the first heating scans for **1b·2a**, **1b·2b**, and **1c·2b** indicate the absence of ordered PEG domains, which suggests that these three duplexes are disordered block copolymers. This is consistent with the above theoretical predictions on **1b·2a**, **1b·2b**, and **1c·2b**. In contrast, the first DSC heating diagram of **1c·2c** revealed a sharp melting peak for PEG near 60°C and a glass transition of PS near 100°C. This heating diagram is very similar to those of ordered, covalent PS–PEG diblock copolymers[9] and suggests that **1c·2c** self-assembles into an ordered morphology. The endothermic peaks observed for **1b·2a** (175°C), **1b·2b** (174°C), and **1c·2b** (190°C) during the first heating scans are likely brought about by the dissociation of the hydrogen-bonded duplex units because a similar peak (192°C) was also observed in the heating diagram of duplex **1'·2'**, which does not carry a polymer chain. The first heating scans of **1c·2c** revealed a broad exothermic peak centered around 179°C, which indicates that the hydrogen-bonded duplex unit of **1c·2c** is in an environment that is very different from those in the three supramolecular pairs that exist in the disordered state. The endothermic peaks were reproduced in the second heating of **1b·2a** (172°C) and **1b·2b** (174°C). The corresponding endo- or exothermic peak was absent in the diagram of **1c·2b** or **1c·2c** during the second heating cycle. Instead, melting peaks of PEG were observed for both **1c·2b** and **1c·2c**, which suggests that the blocks of **1b·2a** and **1b·2b** remain as miscible blends after the hydrogen-bonded duplex unit dissociates at high temperatures. Upon cooling, the two


Figure 2. DSC profiles from the A) first and B) second heating at 5°C min⁻¹ of a) **1b·2a**, b) **1b·2b**, c) **1c·2b**, and d) **1c·2c**. Prior to the second heating, the samples were cooled from 250°C to −50°C at 5°C min⁻¹. Arrows are used to indicate the glass transition from the PS domains of either ordered or macrophase-separated PS/PEG.

Figure 3. Tapping mode AFM image (height) of a film of **1c·2c** by spin-coating from benzene solution. Inset: SEM image of freeze-fractured surface of a sample of **1c·2c**, which had been heated to 250°C and cooled to −50°C at 5°C min⁻¹ (that is, after the DSC experiments).

blocks were linked through hydrogen bonds to form the diblock copolymers from the homogeneous mixtures of the melts. As for **1c·2b** and **1c·2c**, the separated PS and PEG macrophases did not allow the pairing of their hydrogen-bonded duplex units and thus the block copolymers within the timeframe of the cooling cycle. This conclusion is further supported by comparison of the behavior of **1c·2c** with that of a PS/PEG (M_M: 20 000:5000) blend by DSC studies, which revealed significant differences between the two.[8] The first heating scan gave results that were consistent with microphase separation for **1c·2c** and macrophase separation for the PS/PEG blend. After cooling down from the first heating scan, the second heating scan on the same samples led to DSC results that indicated macrophase separation of both samples relative to the original **1c·2c** duplex and the PS/PEG blend.

The microphase separation of **1c·2c** was also confirmed by the AFM image of its spin-coated film from benzene (Figure 3). It was reported that PEG cylinders could be aligned normal to the substrate by spin-coating PS–PEG diblock copolymers from benzene.[11] From the AFM image (Figure 3), the well-dispersed discontinuous PEG domains (dark regions) with an average diameter of 24 nm indicate that the **1c·2c** sample has a typical PS–PEG diblock copoly-

mer-like microphase separation,[11] although it is not clear at this moment whether the PEG domains are vertically oriented cylinders or dispersed spheres. The morphology of a cryogenically fractured surface of the **1c·2c** sample was examined by scanning electron microscopy (SEM) after the DSC experiments, which revealed that the sample had indeed undergone a macroscopic phase separation after the heating and cooling cycles in the DSC analyses. The AFM images of **1c·2c** before and after dipping into a mixture of methanol/water (1:1 v/v) at room temperature for one hour show that the methanol/water-treated sample contains nanoscale local swellings in the PEG domains, which is presumably due to the disruption of the six hydrogen-bonded association units and the swelling of PEG.[8] Furthermore, the AFM image of **1d·2d**, with its higher ratio of PEG relative to that for **1c·2c**, contains enlarged dark regions,[8] which supports our contention that the dark regions in the AFM image of **1c·2c** correspond to microphase-separated PEG domains.

In summary, the supramolecular diblock copolymers described here demonstrate the phase behavior that is typical of diblock copolymers. The perturbation of the hydrogen-bonded duplex units on the phase behavior of the diblock assemblies, such as **1c·2c** and **1d·2d**, with long PS and PEG blocks is surprisingly small. Relative to covalent block copolymers, these supramolecular block copolymers offer unique advantages such as 1) the rapid generation of numerous block combinations, 2) the preparation of block copolymers consisting of blocks that can only be prepared separately by using drastically different methods, 3) the hydrogen-bonded bridging units can be formed or cleaved under mild conditions, and 4) the ability of the designed system to undergo self-repair (or error-correcting). Coupled with the programmable sequence-specificity and high stability of our hydrogen-bonded duplexes, the described strategy can be easily extended to the creation of tri- and multiblock

Communications

copolymers, which will greatly enhance the diversity of the corresponding self-assembled nanoarchitectures.

Four-Stage Amphoteric Redox Properties and Biradicaloid Character of Tetra-*tert*-butyldicyclopenta[*b*;*d*]thieno[1,2,3-*cd*;5,6,7-*c'd'*]diphenalene**

Takashi Kubo,* Maki Sakamoto, Minako Akabane, Yoshinori Fujiwara, Kagetoshi Yamamoto, Motoko Akita, Katsuya Inoue, Takeji Takui, and Kazuhiro Nakasuji*

Dedicated to Emeritus Professor Ichiro Murata on the occasion of his 75th birthday

Phenalenyl-based hydrocarbons possess highly amphoteric redox properties that give low oxidation and high reduction potentials and afford stable multivalent redox species.[1] These
α-position: 1,3,4,5a,6b,8,9,11,12,13a,13d,15
β-position: 2,5,7,10,13,14

compounds have frontier orbitals with a nonbonding molecular orbital (NBMO) character that results from a weak perturbation between singly occupied molecular orbitals (SOMOs) of the phenalenyl radical and the frontier orbitals of a central conjugated system. This perturbation leads to a

small gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). This amphoteric redox property makes the phenalenyl moiety is an important species in redox chemistry. Herein, the synthesis and properties of a new phenalenyl-based conjugated system that has amphoteric redox properties (Scheme 1) and a biradicaloid character originating from a small HOMO–LUMO gap is reported.

The synthetic procedure for **1** is shown in Scheme 2. The key intermediates **3** were obtained as an isomeric mixture of 3,10-, 3,11-, and 4,10-dimethyl compounds by treatment of acenaphthene derivative **2** with sulfur.[2] Isolation of the individual isomers was not carried out as **1** could be prepared from each of them. Bis(propionic acid) derivatives **6** were obtained in three steps. Intramolecular Friedel–Crafts cyclization of the acyl chloride of **6** with AlCl₃ gave diketones **7**, which were reduced and subsequently dehydrated to afford dihydro compounds **9**. Dehydrogenation of **9** with *p*-benzoquinone provided the target compound **1** as black prisms. Compound **1** was found to be stable in the solid state at room temperature even in air. The structure of **1** was confirmed by X-ray cystrographic analysis (see below).

The cyclic voltammogram of **1** gave four reversible redox waves, with two oxidation potentials ($E_2^{ox} = +0.94$ V and $E_1^{ox} = +0.47$ V) and two reduction potentials ($E_1^{red} = -0.53$ V and $E_2^{red} = -0.90$ V; Figure 1. The reversibility of the redox waves indicates the persistency of the mono- and divalent ionic species. Furthermore, the low E_1^{ox} and high E_1^{red} values suggest that the oxidized and reduced species that are generated have high thermodynamic stabilities. The E_1^{sum} value[3a] of 1.00 V is
Figure 1. Cyclic voltammogram (versus saturated calomel electrode) of **1** in CH₂Cl₂ with 0.1 M Bu₄NClO₄ as the supporting electrolyte at room temperature; sweep rate = 100 mVs⁻¹.

comparable to that of pentaleno[1,2,3-*cd*;4,5,6-*c′d′*]diphenalene (PDPL, 0.99 V[3b]), which is the smallest value reported for closed-shell hydrocarbons.[1c] Thus, **1** possesses a high amphoteric redox ability, which indicates that it has a small HOMO–LUMO gap. Such a small gap is also confirmed by the electronic absorption spectrum of **1**, where an extraordinarily low energy band at 800–2000 nm is seen (Figure 2). The band is assignable to a HOMO–LUMO transition, which is consistent with the value of 1520 nm ($f = 0.08$) calculated by time-dependent density functional theory (TD-DFT; RB3LYP/6-31G**) calculations.[4] The low energy band is independent of the sample concentration (5 × 10⁻⁴ and 5 × 10⁻⁵ mol L⁻¹) and the solvent polarity (cyclohexane, tetrahy-

drofuran, dichloromethane, and acetonitrile). Such observations exclude the possibility that the band is an intermolecular charge-transfer (CT) absorption band.

The high amphotericity indicates that **1** should yield cationic and anionic species readily. The ionic redox species of **1** were generated with no difficulties and showed no appreciable decomposition over several weeks at room temperature. The reaction conditions are summarized in Scheme 1. The monovalent radical species **1**·⁺ and **1**·⁻ gave rise to well-resolved ESR signals without detectable changes in the spectra at 183–293 K. The coupling constants of the ring protons are given in Table 1 along with the theoretical

[a] Recorded in CH₂Cl₂ at −70 °C. The *g* value was 2.0045. [b] Recorded in THF at −70 °C. The *g* value was 2.0034. [c] Calculated at the SVWN/6-31G** level and with the McConnell equation ($Q = -2.5$ mT for **1**·⁺ and −2.4 mT for **1**·⁻).

coupling constants calculated by the DFT (SVWN/6-31G**) method and the McConnell equation.[5] The agreement between the experimental and the theoretical hyperfine coupling constants indicates that the unpaired electron is not confined to one phenalenyl moiety (A) but is delocalized over the entire molecule (B).[6] The spin-density calculation indicates that the π spin of **1**·⁺ and **1**·⁻ resides on the two phenalenyl moieties with a similar spin distribution pattern to that of the phenalenyl radical (Figure 3). The similarity of the distribution pattern on two phenalenyl moieties supports the idea that both the HOMO and LUMO of **1** should have a
large contribution from the nonbonding molecular orbital (NBMO) in the phenalenyl radical.

The π-charge distribution of the divalent species **1**²⁺ and **1**²⁻ should closely relate to the π-spin distribution of the monovalent species **1**·⁺ and **1**·⁻. The removal and addition of two electrons in the divalent species occurs in the same molecular orbitals as those of a single electron in the monovalent species, that is the HOMO and LUMO, respectively. The divalent species **1**²⁺ and **1**²⁻ gave rise to only seven signals in the ¹H NMR spectra (two from the *tert*-butyl groups and five from the ring protons; Table 2). This simple ¹H NMR

[a] Compound **1**²⁺ was recorded in D₂SO₄ at room temperature. Compound **1**²⁻ was recorded in [D₈]THF at room temperature. [b] α and β denote the positions shown in the first formula. [c] $\Delta\delta_c = $ ¹³C(**1**²⁺) − ¹³C(**1**²⁻).

spectroscopic pattern reflects the C_2-symmetry of the divalent species. The changes in the ^{13}C NMR chemical shifts of the sp^2 carbon atoms on going from $\mathbf{1}^{2+}$ to $\mathbf{1}^{2-}$ are 744.0 ppm (or 186.0 ppm per electron), which supports the complete generation of the dication and the dianion.[7] The changes observed in chemical shifts for the individual carbon atoms are large at the α position and small at the β position. A similar trend is found with the changes found for the chemical shifts for the phenalenyl species: large (51.8 ppm) at the α position and small (4.9 ppm) at the β position.[8] These NMR spectroscopic studies show that the electronic structures of the phenalenyl cation and anion contribute largely to the divalent species $\mathbf{1}^{2+}$ and $\mathbf{1}^{2-}$, as shown in formula C. Thus, it can be concluded that the high amphotericity of $\mathbf{1}$ results from the NBMO character of its frontier orbitals.

C
A large exchange interaction ($K_{H,L}$) in the frontier orbitals is expected for a compound with a small HOMO–LUMO gap and a large spatial overlap between these orbitals which would lead to a pronounced biradical character.[9] The frontier orbitals in the two phenalenyl moieties in $\mathbf{1}$ have a very similar pattern to the NBMO of the phenalenyl radical, and therefore substantial spatial overlap between the HOMO and LUMO is expected (Figure 4). ESR measurements of solid $\mathbf{1}$ afforded a
Figure 4. HOMO and LUMO of $\mathbf{1}$ as well as the singly occupied molecular orbital (SOMO) of the phenalenyl radical calculated at the B3LYP/6-31G** level.

typical spectra for triplet species ($|D| = 17.2$ mT, $|E| = 3.9$ mT). Furthermore, the temperature dependence of the half-field signal indicated a thermal excitation to the triplet state with an energy gap ($\Delta E_{S\text{-}T}$) of ~5 kJ mol^{-1}. The average distance between the two interacting spins is estimated from the D value to be 5.5 Å, which is smaller than the intramolecular distance between the centers of the two phenalenyl moieties of $\mathbf{1}$ (8.4 Å). This finding suggests that an unpaired

electron is not confined to one phenalenyl moiety but can delocalize on the central thiophene ring. The unpaired electron spin of a triplet state generally broadens NMR resonance signals by thousands of hertz. No signals arising from the ring protons were observed in the ^{1}H NMR spectrum of $\mathbf{1}$ recorded in CD$_2$Cl$_2$. Although a weak and broad signal was recognized between 4 and 9 ppm below $-70\,°$C, sharp signals could not be obtained even at $-90\,°$C (see the Supporting Information). An equilibrium with the thermally accessible triplet state would cause line broadening of the NMR resonance signals. Such a thermal accessibility to the triplet state supports the existence of a small HOMO–LUMO gap and the large exchange interaction ($K_{H,L}$) in $\mathbf{1}$.

The large exchange interaction ($K_{H,L}$) is another fascinating property that describes the ground-state configuration.[10] A configuration interaction (CI) calculation at the CASSCF(2,2)/6-31G(d,p) level afforded an admixture (4%) of the double excitation $^1\Phi_{H,H\rightarrow L,L}$ into the ground configuration $^1\Phi_0$. The singlet diradical index, proposed by Neese and co-workers recently,[11] was estimated to be approximately 35% based on the CI calculation for $\mathbf{1}$. The singlet diradical picture was supported by the DFT calculation at the UB3LYP/6-31G(d,p) level, which afforded an energy lowering of 7 kJ mol^{-1} induced by symmetry breaking of the DFT solution. Fortunately, we obtained two indicative results for the singlet biradicaloid character.

The first indicative result is the X-ray crystal structure showing that $\mathbf{1}$ formed two kinds of dimeric pairs with substantially short nonbonding contacts of about 3.1 Å between each thiophene ring, as shown in Figure 5. The terminal rings were separated by over 4.2 Å because of the steric repulsion between the *tert*-butyl groups and the six-membered rings. The van der Waals contact between carbon atoms only exist within the central dicyclopenta[*b*;*d*]thiophene moieties. The attractive forces leading to dimerization would probably be an intermolecular CT interaction. Therefore, there will be intermolecular delocalization of electrons in the dimer of $\mathbf{1}$.[12] There are two possible explanations for
Figure 5. Crystal structures of $\mathbf{1}$. Top view of the dimeric pair A (a) and B (b), and side view of the dimeric pair A (c) and B (d). Hydrogen atoms are omitted for clarity.

the dimerization of **1** through CT interactions: The first is the attractive forces resulting from electron transfer between occupied and unoccupied molecular orbitals (MOs) in each of the monomers in the dimers. In general, the most important terms are related to an intermolecular HOMO–LUMO interaction; however, with **1** the HOMO–LUMO interaction should lead to no or only slight stabilization of the system because of the orbital symmetry mismatching in the dimeric arrangement described above. In contrast, the next highest occupied molecular orbital (NHOMO)–LUMO interaction should result in the formation of a bonding intermolecular orbital (Figure 6a). The second explanation is an attractive

Singlet Kekulé

Singlet biradical

with a little delocalization to the thiophene ring (see the Supporting Information).

The second indicative result is a cycloaddition reaction of **1** with tetracyanoethylene (TCNE). Mixing a solution of **1** and TCNE in C_6D_6 exclusively afforded a TCNE adduct within 10 seconds in the dark at room temperature (Scheme 3). The

Scheme 3. Reaction of **1** with tetracyanoethylene (TCNE).

b)

Figure 6. Schematic drawing of the molecular orbital interaction of dimeric **1** through electron transfer between occupied and unoccupied molecular orbitals (a), and through the double excitation configuration $^1\Phi_{H,H\rightarrow L,L}$ (b). S and A denote the symmetry of the molecular orbitals.

interaction through the double excitation configuration $^1\Phi_{H,H\rightarrow L,L}$, that is, a singlet biradical contribution. Based on the CASSCF(2,2) calculation of **1**, the occupation numbers of HOMO and LUMO are 1.9 and 0.1, respectively. In this case, a LUMO–LUMO interaction will lead to stabilization of the system because a newly formed "LUMO" of the dimer, which is more stable than the original LUMO, can accommodate at least 0.2 electrons (Figure 6b). In addition, a HOMO–HOMO interaction seems likely to stabilize the system because a newly formed "HOMO" of the dimer would contain only 1.8 electrons. This would suppress a four-electron repulsion that would result from the interaction between fully occupied orbitals. A valence-bond picture is helpful for understanding the singlet biradical structure. The Kekulé form of **1** loses aromatic stabilization in the central thiophene ring, whereas thiophene and phenalenyl radical structures appear in a singlet biradical form of **1**. Therefore, mixing of the singlet biradical configuration with the ground state is promoted. The broken symmetry DFT solution affords a large π-spin population on the phenalenyl moieties
structure of the adduct was confirmed by NMR spectroscopy (^{1}H, ^{13}C, NOESY, HMBC, and HMQC experiments). The reaction may proceed by a stepwise process involving a biradical or a symmetry-forbidden thermal concerted [10+2] process. At this stage the reaction mechanism is still

biradical

[10 + 2] cycloaddition
undetermined. However, discussion of symmetry being "forbidden" or "allowed" becomes meaningless for the concerted reaction of biradicaloid compounds because the double excitation configuration should lower the symmetry-imposed activation energy.[9]

In conclusion, the amphoteric redox compound **1** was prepared by a stepwise synthesis and showed highly amphoteric redox properties. Notably, a singlet biradical character of **1** is suggested by quantum chemical calculations and supported by experimental results. The chemistry of amphoteric redox systems are expected to contribute to investigations

into the solid-state properties of conjugated singlet biradicals, such as crystal packing, magnetism, and electroconductive behavior. Closed-shell conjugated systems based on the phenalenyl radical could lead to conjugated biradicaloid compounds that could be isolated in the air.

Experimental Section

The detailed synthetic procedure for **1** is described in the Supporting Information.

[6] The highly delocalized structure of the charge and the spin suggests that the monovalent radicals **1**$^+$ and **1**$^{\cdot-}$ can be placed in the class III category in the classification of mixed-valence species, which is consistent with the quite large values between the first and the second redox potentials ($E_2^{ox} - E_1^{ox} = 0.47$ V, $E_1^{red} - E_2^{red} = 0.37$ V). The properties of mixed valence compounds depend on the extent of the electronic interaction between the redox centers and its range. The common classification is: small or nonexisting (class I), slight (class II), and strong interaction (class III, including the completely delocalized molecules). See M. B. Robin, P. Day, *Adv. Inorg. Chem. Radiochem.* **1967**, *10*, 247.

[12] In general, the $\pi-\pi$ interactions of aromatic systems is affected by various electronic factors. The well-known attractive forces are derived from electrostatic interactions between electron-deficient and electron-rich sites. However, this interaction is not likely to be effective in the dimeration of **1** because there is only a small overlap of positive and negative charges as found from the Mulliken charge analysis (see the Supporting Information).

Inorganic Electrides

Is Mayenite without Clathrated Oxygen an Inorganic Electride?**

Zhenyu Li, Jinlong Yang,* J. G. Hou, and Qingshi Zhu

With electrons as their anions, electrides have attracted a much interest recently in broad fields of research.[1] Despite their importance both in fundamental science and industrial

applications, traditional organic electrides are stable only at cryogenic temperatures and are air- and water-sensitive. It is therefore interesting and important to explore room-temperature stable inorganic electrides.[2] Existing model systems towards this direction include Na_4^{3+} clusters in the sodalite cage of Na^+Y[3] and alkali metals in the channels of zeolite ITQ-4.[4] Recently, Matsuishi et al.[5] removed the clathrated oxygen ions from the crystallographic cages of mayenite $12CaO·7Al_2O_3$ (C12A7) through a base-metal oxidation process. They suggested that their treatment inject extra electrons in place of the free O^{2-} with a spherical $1s$ wave function of an F^+-like center, and thus produce an inorganic electride.

To gain insight into the electronic properties of this kind of mayenite with removed clathrated oxygen (C12A7:2e⁻) and to verify the electride model, it is important to investigate this material theoretically. Unfortunately, the existing theoretical studies give contradictory conclusions. The first theoretical work by Sushko et al.[6] supports the electride model with localized extra electrons, whereas a recent study by Medvedeva and Freeman[7] reveals that the extra electrons are highly delocalized both in the cavities and in the regions occupied by cations, and thus opposes the electride model. We noticed that both studies do not provide a satisfactory conclusion with respect to the real physical picture of the extra electrons in this novel material. Sushko et al.[6] used an embedded cluster model, which is only suitable for the dilute extra electron limit, and Medvedeva and Freeman[7] used the linear muffin-tin orbital (LMTO) method with a simple atomic sphere approximation, which may not be accurate enough to describe the charge-density distribution in this complex system. Moreover, the geometry was not fully optimized in either of the studies. To clarify this issue, we report herein a careful plane-wave pseudopotential study on the geometrical and electronic structure of this material.

The crystal structure of C12A7, with two formula units per unit cell, is characterized by a positively charged lattice framework $[Ca_{24}Al_{28}O_{64}]^{4+}$ that forms twelve crystallographic cages per unit cell ($I\bar{4}3d$ space group). The remaining two oxygen ions are clathrated in the cages to maintain charge neutrality. We optimized the geometry of C12A7 with its lattice parameter fixed to the experimental value (11.989 Å).[8] As shown in Figure 1, cages with free oxygen inside have a relatively large distortion after optimization, where it can be clearly seen that two opposite Ca atoms at the cage wall are strongly pulled towards the center of the cage. Therefore, after optimization, the cages in C12A7 are no longer identical.

When considering the geometry of the system without clathrated oxygen, one must take special care. In the work of Medvedeva and Freeman,[7] they simply assumed that all cages in C12A7:2e⁻ are identical. But considering the possibility that the extra electrons may be captured in some cages with other cages being kept empty,[5,6] this assumption is far from obvious. In this work, we optimized the geometry of C12A7:2e⁻ from two initial configurations. The first optimization starts from a framework of undistorted cages, and the second starts from the previously relaxed distorted framework, but without clathrated oxygen. Within numerical
Figure 1. Perspective view of a) an undistorted cage and b) a distorted cage in mayenite. There is a clathrated oxygen inside the distorted cage, and the upper and lower Ca (green) at the cage wall are strongly pulled towards the center O (red).

precision, both optimizations led to the same final structure, and the distortion of the second initial geometry finally disappeared. Therefore, the simple assumption of Medvedeva and Freeman[7] turns out to be correct, but it must be emphasized that we can only be confident with the following calculations on electronic structure after such a careful examination of the geometry.

The identical-cage geometry strongly suggests that the picture[5,6] of two types of cages (electron trapping and empty) in C12A7:2e⁻ may be incorrect. We noticed that in the embedded cluster calculation[6] the two quantum-mechanical (QM) cages are geometrically different on account of different classical neighboring cages. This artificial difference between the two QM cages may be the reason that leads to the extra electron being localized in only one of the two cages.

Based on the optimized geometries, we calculated the band structures of C12A7 and C12A7:2e⁻, and the result is shown in Figure 2. For C12A7, there are two very narrow bands below the Fermi level, which mainly come from the p orbitals of the clathrated oxygen, as suggested by Medvedeva and Freeman.[7] Above these two interstitial bands, there is a band manifest (from about 2.0 to 3.8 eV) that corresponds to the cavities. After the clathrated oxygen is removed, the interstitial bands disappear, and the cavity bands become partially occupied by the extra electrons. Because of the disappearance of the distortion, the cavity bands become more degenerate for C12A7:2e⁻.
Figure 2. Band structures of a) C12A7 and b) C12A7:2e⁻. The Fermi energy is at 0. $\Gamma = (0,0,0)$, $M = (1/2,0,0)$, $N = (1/2,1/2,0)$, and $A = (0,0,1/2)$.

Figure 3. a) Isosurface and b) contour map of the charge density of extra electrons in C12A7:2e⁻, and c) contour map of the C12A7:2e⁻ electron-localization function. The isosurface is plotted within a unit cell, and the contour maps are plotted on a profile crossing one cage. The value of the isosurface is 7.0 electrons per unit cell.

To address the validity of the electride model, we calculated the charge density in a 1.5 eV window below E_F, which gives the spatial distribution of the extra electrons. We found that the density is equally distributed in the twelve cages and that most of the charge density is inside the cages (Figure 3 a,b). Although it is still not perfectly localized, our charge density is already different from that of Medvedeva and Freeman.[7] To evaluate the degree of localization quantitatively, we integrated the charge density inside the cage with the ionic radii of Ca, Al, and O set to 0.99, 0.51, and 1.32 Å, respectively. We found that 75% of the extra electron density is distributed in the twelve cages. Although this value is not very high, it is comparable to those of organic electrides. For example, in Cs⁺([15]crown-5)₂·e⁻,[9] a well-studied electride, we determined the ratio of the in-cavity extra electron as 83% by performing a similar analysis. Therefore, our pseudopotential plane-wave calculations show that the extra electrons are generally localized in the cages, and thus support an electride model for C12A7:2e⁻.

Further important theoretical evidence for the electride model comes from the types of chemical bond between the extra electrons and the positively charged lattice framework. Ionic bonding would support the electride model, whereas metallic bonding would lead to the opposite conclusion. Following the seminal work of Silvi and Savin,[10] we used the topological analysis of electron-localization functions

(ELF)[11] to classify chemical bonds rigorously. The key topological character of ELF is its local maxima, namely the localization attractors. There are three types of attractors: bonding, nonbonding, and core. For systems with shared-electron interactions (covalent, dative, and metallic bonds), there is always a point or ring bonding attractor on the bond path, whereas for the unshared-electron interactions (ionic, hydrogen, electrostatic, and van der Waals bonds) there is nothing between the core attractors. A previous study also showed that ELF topological analysis of metallic bonds is characterized by di- or polysynaptic bonding attractors and a tridimensional network of channels.[12] For F or F⁺ centers, which are chemically bonded (ionic type) to the host lattice as a quantum-mechanical subsystem, the ELF topology is characterized by a localization attractor at the vacancy site.[13]

As shown in Figure 3 c, the calculated ELF for C12A7:2e⁻ gives only one localization attractor at the center of the cavity, which is very different from the case of the typical metallic bond,[12] but similar to the ELF topology for F or F⁺ centers.[13] Therefore our ELF topological analysis supports the fact that the extra electrons act as coreless anions, and there is ionic bonding between these anionic electrons and the positively charged host lattice. The electride model of C12A7:2e⁻ is thus also supported by the criterion of the bond type. This new criterion based on powerful ELF topological analysis is much

more conclusive and easy to use than the previous charge-density criterion, which is more frequently used in the literature. In fact, the charge-density criterion may be difficult to apply even for some classical organic electrides that contain delocalized electrons.[1]

Although $C12A7:2e^-$ should be considered as an inorganic electride based on the above discussions, it is very different from the originally suggested electride model.[5,6] The integrated extra electron density within the cavity only approaches 1/3 instead of one electron, and the ELF value of the corresponding localization attractor is also relatively small (about 0.45). Therefore, $C12A7:2e^-$ can be considered as a nonstoichiometric (between extra electrons and cages) electride with only 1/3 of the electron localized in a cage. Accordingly, the chemical formula can be written as $[Ca_{24}Al_{28}O_{64}]^{4+}\cdot(1/3e^-)_{12}$. We point out that before a stoichiometric inorganic electride can be found, it is essential to obtain a stoichiometric ratio between cavities and extra electrons.

In conclusion, by carefully checking the distribution of the extra electron density and the type of bonding between these extra electrons and the host lattice, we obtained a conclusive result on whether mayenite without clathrated oxygen is an electride. This study is useful for pursuing a rigorous definition of electrides in future, and demonstrates that ELF topological analysis may play an important role in this topic. The results presented herein may also shed light on the behavior of a confined electron gas of different topology and suggest new designs for stoichiometric inorganic electrides and related functional materials.

Experimental Section

Computational methodology: Electronic-structure calculations were performed with a pseudopotential plane-wave method within the generalized gradient approximation (GGA) for exchange and correlation. A projector-augmented wave (PAW) pseudopotential[14] for electron–ion interactions and the Perdew–Wang form[15] of the GGA functional were used. A plane-wave kinetic-energy cutoff of 500 eV and a $6 \times 6 \times 6$ Monkhorst–Pack k-mesh were used to calculate the total energy and charge density. The calculations were performed with the Vienna Ab initio Simulation Package (VASP)[16] on an HP RX2600 cluster and an HP superdome server of the USTC-HP Laboratory for High-Performance Computing.

Zn₂[(S)-O₃PCH₂NHC₄H₇CO₂]₂: A Homochiral 3D Zinc Phosphonate with Helical Channels**

Xin Shi, Guangshan Zhu, Shilun Qiu,* Kunlin Huang, Jihong Yu, and Ruren Xu

Chiral metal–organic coordination polymers with open frameworks have attracted much attention because of their potential applications in enantioselective separation and catalysis.[1–4] Such materials are generally prepared by enantioselective synthesis or spontaneous resolution. Spontaneous resolution on crystallization without any chiral auxiliary will result in a racemic mixture of enantiomeric crystals. Moreover, spontaneous resolution is relatively rare and cannot be predicted because its mechanism is not yet fully under-

stood.[4–6] Enantioselective synthesis, however, is a direct and effective method for the synthesis of enantiopure chiral open frameworks by using enantiopure organic building units as reactant precursors.[3,7,8] By enantioselective synthesis, many chiral open frameworks with high thermal stability have been obtained in recent years, and they showed encouraging results in enantioselective separation and catalysis.[9–11]

Some enantiopure organic compounds are good homogeneous catalysts in asymmetric synthesis, for example, (*S*)-proline and its derivatives show highly enantioselective catalysis and afford good yields in many reactions such as α-amination of aldehydes or ketones and aldol, Mannich, and Michael reactions.[12–14] An intriguing idea is to synthesize a porous material with such enantiopure catalysts as building units. The resulting open-framework material might be used as a heterogeneous asymmetric catalyst.

We chose an enantiomerically pure derivative of (*S*)-proline, namely, 1-phosphonomethylproline, as a chiral building unit and successfully prepared a homochiral 3D zinc phosphonate $Zn_2[(S)-O_3PCH_2NHC_4H_7CO_2]_2$ (**1**) with alternately arranged left- and right-handed helical channels. Of particular interest is that the active sites of 1-phosphonomethylproline for asymmetric catalysis—the amino group and the partially uncoordinated carboxylate group—are retained and directed into the channels, in contrast to a recently reported similar metal phosphonate.[16c,d] Many open frameworks constructed from enantiopure phosphonic acids have been reported previously,[11,15,16] but a chiral metal phosphonate containing not only helical channels but also active sites for asymmetric catalysis in achiral channels has not been found so far.

The chiral building unit 1-phosphonomethylproline was prepared by using a modified literature method.[16c] Enantiopure 1-phosphonomethylproline reacts with $Zn(NO_3)_2 \cdot 6H_2O$ in the presence of triethylamine as base under hydrothermal conditions to give the homochiral 3D open framework $Zn_2[(S)-O_3PCH_2NHC_4H_7CO_2]_2$ (**1**; Scheme 1). Compound **1**
Scheme 1. Synthesis of **1**.

crystallizes in the orthorhombic space group $P2_12_12$ (No. 18). It consists of 4,8-nets formed by alternately arranged left- and right-handed helices that are connected through 1-phosphonomethylproline ligands to generate a 3D open framework. Each asymmetric unit contains two unique Zn atoms and two unique P atoms. The Zn atoms adopt tetrahedral geometry by coordination of three phosphonate oxygen atoms and one carboxylate oxygen atom of the ligand, while the other carboxylate oxygen atom is uncoordinated. The 3D framework is based on two crystallographically distinct ZnO_4 tetrahedra and two distinct O_3PC tetrahedra. Each Zn atom shares three vertex oxygen atoms with adjacent P atoms (Zn–

O 1.922(4)–1.978(4) Å), and each O_3PC tetrahedron also shares three oxygen atoms with adjacent Zn atoms. The P–$O_{bridging}$ bond lengths are in the range between 1.501(4) and 1.523(4) Å. The Zn- and P-centered tetrahedra alternate to form 4,8-net sheets by sharing oxygen atoms on the *bc* plane, which are linked by the ligands along the *a* axis to generate a 3D open framework.

Figure 1 shows the framework of **1** viewed along the [100] direction. The structure contains four- and eight-membered
Figure 1. A polyhedral view of the framework along the [100] direction. 4,8-Nets consist of left-handed (A) and right-handed helices (B), which are arranged AA and BB along the *a* axis. 1-phosphonomethylproline ligands are omitted for clarity; Zn yellow, P purple.

rings (7×8 Å, estimated by measuring the distances between the centers of opposite atoms; hereafter, all dimensions are reported in this way), similar to the reported example,[17] which are made of two different helical chains A and B. These chains run along the *b* axis and are arranged AA and BB along the *a* axis, respectively.

The framework of **1** contains two types of microchannels with dimensions of 4×6 and 5×12 Å, seen in a view along the [001] direction in Figure 2. These channels are made of helical chains of the same handedness (either chain A or chain B) and 1-phosphonomethylproline ligands. These helical chains run along the *b* axis and are arranged ABAB along the *c* axis.

Figure 3a shows a view of the framework of **1** along the [010] direction. Three different four-membered-ring channels (left-handed helical, right-handed helical, and achiral channels) and eight-membered-ring channels (7×7 Å) can be seen. Along the *c* axis, left-handed helical channels, achiral channels, and right-handed helical channels alternate. These chiral channels are enclosed by two types of helical chains, as shown in Figure 3b and c. Interestingly, *L*-handed helices consist of Zn1 and P2 atoms, while *R*-handed helices consist of Zn2 and P1 atoms.

Notably, in the structure of **1**, coordination of the 1-phosphonomethylproline ligand to the zinc atom through the phosphonate group and the monodentate carboxylate group leaves a carboxylate oxygen atom uncoordinated and the amino group free, and the functionality of the material is thus
Figure 2. View along the [001] direction. Two types of microchannels with dimensions of 4×6 and 5×12 Å are made of 1-phosphonomethyl-proline ligands and left-handed helical chains (A) and right-handed helical chains (B). The two kinds of chiral chains are arranged ABAB along the *c* axis (Zn yellow, P purple, O red, N blue, C gray).

retained. The uncoordinated carboxylate oxygen atoms and the amino groups with N−H bonds, which are the active sites for asymmetric catalysis, are directed into the achiral six- and ten-membered-ring channels along the [001] direction (Figure 2) and eight-membered-ring channels along the [010] direction (Figure 3a).

Thermogravimetric analysis (TGA) was performed to gauge the thermal stability. No weight loss occurred below 400 °C, which shows that the open framework is stable below that temperature. The presence of active sites for asymmetric catalysis in channels along with the high thermal stability of the homochiral zinc phosphonate open framework promises applications in heterogeneous asymmetric catalysis. Research on asymmetric catalysis is currently underway.

Experimental Section

(*S*)-HO$_3$PCH$_2$NHC$_4$H$_7$CO$_2$H: HCHO (40 mmol, 36% in water) was added dropwise to a mixture of (*S*)-proline (10 mmol), H$_3$PO$_3$ (11 mmol), and HCl (30 mL of a 6.0 M aqueous solution) under reflux. The resultant solution was then heated at reflux for a further 12 h. A white solid was recovered in a yield of 90% after removal of water, and recrystallized from EtOH/propylene oxide. M.p. 257–259 °C. $[\alpha]_D^{25} = -63°$ (*c* = 1.6 in water). Elemental analysis (%): calcd for C$_6$H$_{12}$NO$_5$P (209.14): C 34.44, N 6.69, H 5.74; found: C 34.25, N 6.80, H 5.67. ^{31}P MAS NMR (161.9 MHz, 298 K): δ = 8.7 ppm.

Zn$_2$[(*S*)-O$_3$PCH$_2$NHC$_4$H$_7$CO$_2$]$_2$: Zn(NO$_3$)$_2$·6H$_2$O (0.074 g) and (*S*)-HO$_3$PCH$_2$NHC$_4$H$_7$CO$_2$H (0.053 g) were dissolved in H$_2$O (10 mL), and then triethylamine (0.5 mL) was added while stirring to adjust the pH of the mixture. The mixture (pH ≈ 6) was sealed in a Teflon-lined stainless steel autoclave after stirring for 10 min and heated at 160 °C for 2 d. Colorless block single crystals were filtered off, washed with distilled water, and dried at room temperature to yield **1** (0.079 g, 58%). ^{31}P MAS NMR (161.9 MHz, 298 K): δ = −24.5 ppm. The CD spectrum (Figure 3 of Supporting Information) clearly shows a positive Cotton effect, in agreement with that of the original chiral ligand, which indicates that the chiral ligand retained its original chirality even after the hydrothermal reaction.

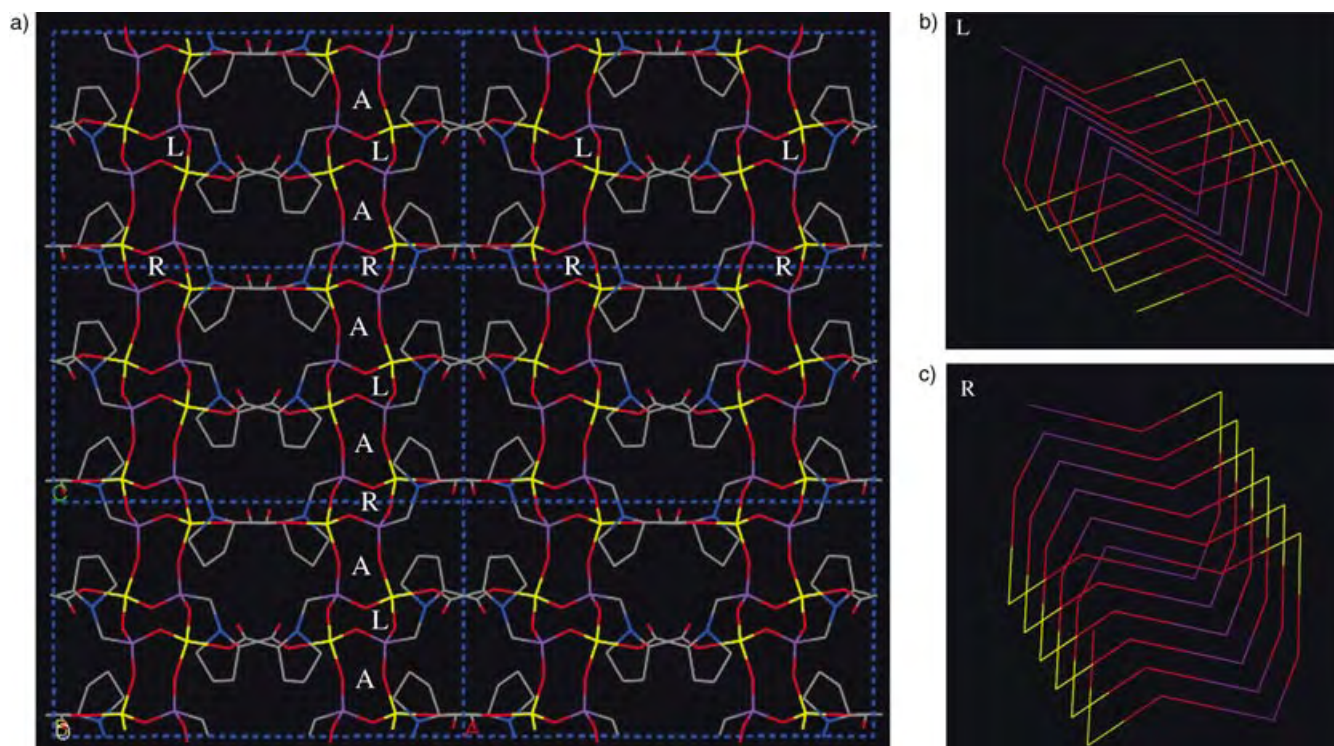
Inductively coupled plasma (ICP) analysis (Perkin-Elmer Optima 3300 DV ICP instrument): Zn 24.08, P 11.45% (calcd: Zn 23.96, P 11.37%). Elemental analysis (Perkin-Elmer 2400 elemental analyzer): C 26.51, H 3.54, N 5.22% (calcd: C 26.45, H 3.70, N 5.14%).


Figure 3. a) The framework viewed along the [010] direction, showing two types of helical channels and achiral channels which are alternately arranged along the *c* axis (A: achiral channel, L: left-handed helical channel, R: right-handed helical channel). b,c) The left-handed (L) and right-handed (R) helical channels (Zn yellow, P purple, O red, N blue, C gray).

Thermogravimetric analysis was performed on a Perkin-Elmer TGA7 unit in air. A weight loss was observed in the 400–450 °C temperature range, which indicated decomposition of the metal phosphonate.

Structure determination: A suitable single crystal with dimensions of $0.58 \times 0.47 \times 0.14$ mm was selected for single-crystal X-ray diffraction analysis. Crystallographic data were collected at 293(2) K on a Bruker-AXS Smart CCD diffractometer using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods[18] and refined by the full-matrix least-squares method against F^2 (SHELXL-97).[19] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms of organic ligands (except H1 and H2) were located geometrically.

Crystal data: $Zn_2[(S)\text{-}O_3PCH_2NHC_4H_7CO_2]_2$ (**1**), $M_r = 544.98$, orthorhombic, space group $P2_12_12$ (No. 18), $a = 18.425(8)$, $b = 9.168(2)$, $c = 10.554(3)$ Å, $V = 1782.7(9)$ Å^3, $Z = 4$, $\mu = 2.929$ mm^{-1}, $\rho_{\text{cald}} = 2.031$ g cm^{-3}, of which 2207 reflections measured, of which 2207 reflections measured, of which 2781 reflections measured, of which 2207 reflections measured, 2781 reflections measured, of which 2207 reflections were unique ($R_{\text{int}} = 0.0424$). The final $wR(F^2)$ was 0.0788 (all data), and $R(F)$ was 0.0523 (all data). CCDC-239389 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

Molecular-Mechanical Switch-Based Solid-State Electrochromic Devices**

David W. Steuerman, Hsian-Rong Tseng, Andrea J. Peters, Amar H. Flood, Jan O. Jeppesen, Kent A. Nielsen, J. Fraser Stoddart,* and James R. Heath*

The dynamics of electrochemically driven, bistable molecular mechanical switches—such as certain nondegenerate, two-station, donor–acceptor [2]catenanes and [2]rotaxanes—have been the subject of numerous experimental investigations[1–3] in the solution phase, in which the general mechanistic details of the redox-activated switching processes are becoming increasingly well understood.[4] These molecular machines may have many technological applications,[5] although few are likely to be liquid-solution-phase based.[6–9] Thus, significant effort has been directed towards understanding and exploiting the bistability of [2]catenanes and [2]rotaxanes in other environments, including both Langmuir–Blodgett (LB)[10, 11] and self-assembled monolayers (SAMs),[12] and in solid-state molecular-switch tunnel junctions (MSTJs).[13–16]

Herein we explore, at a fundamental level, the solid-state application of electrochromic devices by taking advantage of the colorimetric changes that accompany the electrochemically driven switching of certain bistable [2]catenanes and [2]rotaxanes. The molecular switches were immobilized within a solid-state polymer electrolyte, and a microfabricated, planar, three-terminal equivalent of a standard electrochemical cell was used for electrical addressing. The polymer environment significantly slows down certain steps within the molecular-mechanical switching cycle, but the overall mechanism remains unchanged from that observed in other environments. We also find that by varying the molecular structure of the switch, the colorimetric retentions times of

these devices could be controlled over a dynamic range of 10^3 to 10^4 s. The fundamental properties of these devices were quantified through time- and temperature-dependent cyclic voltammetry (CV) measurements. In this way, the kinetic parameters ($\Delta G^{\pm}$, $\Delta H^{\pm}$, $\Delta S^{\pm}$, and E_a) of the rate-limiting step in the switching cycle of the device could be evaluated for several different molecular switches.

Four bistable molecular-mechanical systems[2, 3a, 17, 18]—two [2]catenanes $\mathbf{C1^{4+}}$ and $\mathbf{C2^{4+}}$ and two [2]rotaxanes $\mathbf{R1^{4+}}$ and $\mathbf{R2^{4+}}$—along with appropriate control compounds, were investigated (Figure 1) for electrochromic device applica-
Figure 1. The structural formulas of the two bistable [2]catenanes $\mathbf{C1^{4+}}$ and $\mathbf{C2^{4+}}$ and the two bistable [2]rotaxanes $\mathbf{R1^{4+}}$ and $\mathbf{R2^{4+}}$ investigated within solid-state polymer electrolyte environments. The use of color—namely, red, blue, and green—for certain units and components relates to the graphical representations shown in Figure 2.

tions. Most of these compounds have been studied[2, 3, 19] in the liquid-solution phase by using ^{1}H NMR spectroscopy and temperature-dependent electrochemistry. In addition, the switching cycle of a SAM[12] formed from a [2]rotaxane that is closely related to $\mathbf{R1^{4+}}$ was previously reported. Herein, we present a description of the general switching cycle mechanism that is applicable to all four molecules, followed by a brief description of how certain details of this cycle vary between the four molecules.

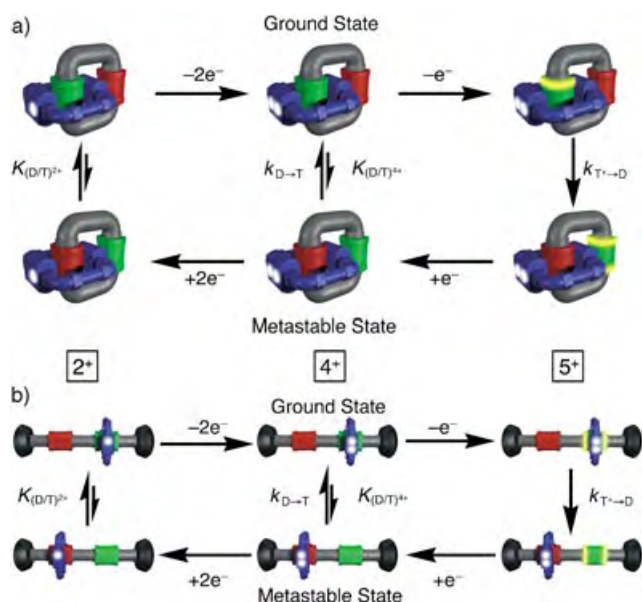
The switching cycle mechanism for the bistable [2]catenanes and [2]rotaxanes is illustrated in Figure 2. There is always an equilibrium ($K_{\mathrm{(D/T)}^{4+}}$) established between the cyclobis(paraquat-*p*-phenylene) (CBPQT^{4+}) ring encircling the tetrathiafulvalene (TTF) site (labeled as the ground-state co-conformer or GSCC) and the dioxynaphthalene (DNP) site (labeled as the metastable-state co-conformer or MSCC).[20] These labels reflect the fact that the equilibrium is most commonly shifted toward the CBPQT^{4+} ring encircling the TTF site. The first oxidation state of the GSCC


Figure 2. The analogous switching cycles for a) the bistable catenanes and b) the bistable rotaxanes, starting from the centrally located ground-state co-conformers. The green and red sites on the ring and dumbbell components refer to the TTF- and DNP-recognition units, respectively. When the TTF unit is oxidized, it is drawn as a highlighted green unit carrying yellow ends. The CBPQT^{4+} ring is modeled as the blue ring encircling the green site with positive charges indicated as white spots. The metastable co-conformers are isomeric (and isoelectronic) with the appropriate ground-state co-conformers.

corresponds to removal of an electron from the TTF site, and is accompanied by a rapidly driven shuttling (Coulombic repulsion) of the CBPQT^{4+} ring to the DNP site with a rate described by the constant, $k_{T+\rightarrow D}$. Upon reduction of the TTF site back to its charge-neutral state, the MSCC is formed. The MSCC and GSCC are readily distinguished from each other by using CV because the oxidation potential of the (bare) TTF unit on the MSCC is approximately 200 mV less[12] positive than that for the GSCC (vs. a Pt reference electrode)—a result that is valid for both the bistable [2]catenanes and the bistable [2]rotaxanes. The return of the MSCC to the GSCC, which is really a recovery of the equilibrium distribution described by $K_{(D/T)^{4+}}$, is thermally activated. This recovery is typically too fast to observe at room temperature in the solution phase.

CV measurements on the bistable [2]rotaxane SAMs[12] revealed that the rate of recovery of the equilibrium distribution was strongly dependent[21] on the physical environment—the rate was much slower for the SAM environment than for the solution phase. For the SAM, it was also demonstrated that the GSCC/MSCC equilibrium distribution may be recovered at least 1000 times faster through the pathway that accesses the two-electron reduction of the CBPQT^{4+} ring to its bis-radical cation, CBPQT$^{2\cdot 2+}$ (Figure 2).[12] This pathway is precisely that proposed originally as the mechanism for "opening" a MSTJ device.[13]

The solid-state polymer environment, which can be considered as a highly viscous solvent, should also affect the rate of recovery of the equilibrium distribution from the

MSCC to the GSCC. There is a long history, dating back to the early work of Kramers,[22] of investigations into molecular-mechanical processes within high-viscosity solvents,[23, 24] although those studies have typically focused on low-amplitude molecular motions with energy barriers of only a few kcal mol^{-1}. Based on the assumption that the large-amplitude, high-energy-barrier motions in our systems follow similar trends, the expectation is that the rate constant for the recovery of the equilibrium distribution will scale as $k = \eta^{-\gamma}$ (η is the solvent viscosity and γ has a value between 0.5 and 0.75).[25]

The molecular switches investigated herein exhibit significant differences from one another that should be reflected in the switching characteristics of the electrochromic devices. **R1**$^{4+}$ and **R2**$^{4+}$ are characterized[3] by very different equilibrium dynamics in solution. **R1**$^{4+}$ contains a simple TTF unit, and the room-temperature affinity of the CBPQT^{4+} ring for this TTF unit over the DNP ring system is 10:1. **R2**$^{4+}$ does not have a simple TTF unit and the CBPQT^{4+} ring has an equal probability for being located on the "quasi-TTF" or the DNP at 298 K, although this equilibrium is temperature-dependent. As chemical constitution impacts the dynamic equilibrium between translational isomers[26] in solution for **R1**$^{4+}$ and **R2**$^{4+}$, we expect a similar situation to pertain within the solid-state polymer environment.

C1^{4+} and **C2**$^{4+}$, on the other hand, are characterized[2, 16] by similar equilibrium dynamics. For both structures, the ground-state equilibrium strongly favors the CBPQT^{4+} ring encircling the TTF unit. However, the molecular-mechanical motion in **C2**$^{4+}$, with its two bulky diazapyrenium units, is significantly more sterically hindered than that in **C1**$^{4+}$, and this constitutional feature is expected, in any environment, to slow the recovery of **C2**$^{4+}$ from the MSCC to the GSCC substantially relative to that of **C1**$^{4+}$.

Figure 3 shows two successive CVs collected from a solid-state polymer device containing **R1**$^{4+}$ as well as measurements
Figure 3. The first and second CVs (298 K, scan rate = 150 mVs^{-1}) of the **R1**$^{4+}$-containing solid-state polymer electrolyte device. The initial scan (gray trace) reveals a weak feature at 115 mV and two oxidation peaks (partially resolved) at 315 and 465 mV. For the second scan (black trace) virtually all the signal corresponding to the feature at 315 mV has shifted to 115 mV. The features at 115 and 315 mV were assigned as the first oxidation state of the metastable and ground-state co-conformers, respectively. A control device that contains only the dumbbell component of **R1**$^{4+}$ reveals two well-separated oxidation peaks at 55 and 355 mV that do not change between the first and second scans.

from a control device containing the dumbbell component of **R1**$^{4+}$. This bistable [2]rotaxane exhibits an equilibrium GSCC/MSCC population of about 10:1 under ambient conditions, similar to that observed in solution at 298 K. The first CV trace reflects this distribution—three oxidation features are recorded at 115, 315, and 465 mV. The relatively weak feature at 115 mV corresponds to the TTF→TTF$^{·+}$ oxidation of the low-abundance MSCC. The feature at 315 mV arises from the TTF→TTF$^{·+}$ oxidation of the GSCC, and the feature at 465 mV is the second oxidation (TTF$^{·+}$→TTF^{2+}) of **R1**$^{4+}$. This second oxidation step is independent of the co-conformer as the CBPQT^{4+} ring encircles the DNP site once the TTF site is singly oxidized. For the second scan, nearly all the integrated current under the 315 mV feature has moved to 115 mV. This assignment is consistent with the control device measurements, which reveal two well-separated oxidation peaks at 55 and 355 mV.

The hysteretic response in the successive CV curves of **R1**$^{4+}$ reflects the slow recovery of the ground-state equilibrium distribution (described by $K_{(D/T)^{4+}}$), and is similar to that observed for the bistable [2]rotaxane SAMs.[12] By varying the time between the first and second CV scans as well as the temperature of the experiment, the various kinetic parameters for relaxation from the MSCC to the GSCC were determined. Figure 4a shows a scan-rate series of (second) CVs. Figure 4b displays a graph of the scan-rate series condensed into a single plot that exhibits an exponential decay. In this case, we have taken into account the rates based on the integrated current of the MSCC oxidation peak at 115 mV relative to the total current of the first-oxidation peaks of the MSCC and GSCC. For all data sets, at least one point was taken at scan rates that were much slower than the measured relaxation times—the $\Delta t = 100$ s in Figure 4b, for example—and that point was fixed in the exponential decay fit. Figure 4c is an Eyring plot of several such series, each collected at a different temperature. From this plot, we can extract the various kinetic parameters that describe the recovery of the ground-state equilibrium distribution. Those parameters, along with the analogous measurements for **C1**$^{4+}$, **C2**$^{4+}$, and **R2**$^{4+}$, are summarized in Table 1. The data for **C2**$^{4+}$ were only collected under ambient conditions, and so only τ_{298} and $\Delta G_{298}^{‡}$ are reported.

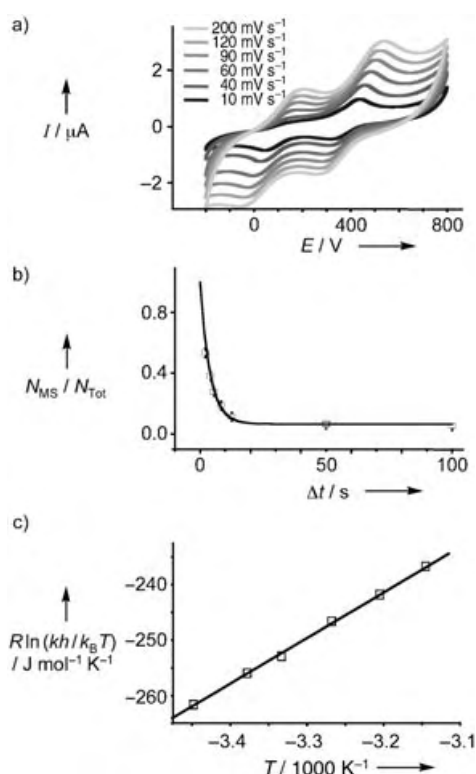
The polymer utilized in this case has a viscosity approximately 10^4 times greater than that of MeCN, which is the commonly used solvent in the investigation of the electrochemical properties of these molecules in solution. Thus, the implication is that the relaxation rates in solution should be between 10^2 and 10^3 times faster than those observed. Thus, under cryogenic conditions, it should be possible to observe the MSCC→ GSCC relaxation in the liquid-solution phase, and we have now confirmed that this prediction does, indeed, hold true. [19]


Figure 4. Experimental data utilized to extract the kinetic parameters of the metastable→ground-state relaxation process of **R1**$^{4+}$ within the solid-state polymer electrolyte environment. a) Representative (second scan) CVs recorded at 296 K at various scan rates. b) The population ratios of the metastable state and the relaxation times fitted to a first-order decay model. c) The temperature dependence of the relaxation kinetics expressed as an Eyring plot.

Table 1: The $1/e$ decay times (τ_{298}) and free energies of activation ($\Delta G_{298}^{‡}$) obtained by using cyclic voltammetry together with the thermodynamic data, obtained after an analysis of variable-temperature cyclic voltammetry studies using the Eyring ($\Delta H^{‡}$, $\Delta S^{‡}$) and the Arrhenius ($E_a^{‡}$) relationships for a series of bistable rotaxanes and catenanes in solution and in a solid-state polymer electrolyte.[a]

Compound	τ_{298} [s]	k_{298} [s^{-1}]	$\Delta G_{298}^{‡}$ [kcal mol^{-1}]	$\Delta H^{‡}$ [kcal mol^{-1}]	$\Delta S^{‡}$ [cal mol^{-1} K^{-1}]	$E_a^{‡}$ [kcal mol^{-1}]

[a] Solid-state polymer data obtained from samples mixed within a polymer matrix (MeCN/PPMA/PC/ LiClO$_4$ ($w/w/w/w$) = 70:7:20:3) at a Pt electrode over a range of temperatures **R1**$^{4+}$ (290–320 K). [b] Self-assembled monolayers of the analogue to **R1**$^{4+}$, bearing a disulfide tether, was characterized by variable-temperature CV to obtain thermodynamic data: $k_{293} = 0.39$ s^{-1}, $\Delta G_{298}^{‡} = 18.0$ kcal mol^{-1}, $\Delta H^{‡} = 17.6 \pm 3.0$ kcal mol^{-1}, $\Delta S^{‡} = -1.4 \pm 10$ cal mol^{-1} K^{-1}, $E_a = 17.7 \pm 2.8$ kcal mol^{-1}.

The viscosity of the polymer matrix changes by approximately a factor of two over the temperature range of these investigations (280–320 K). This trend can certainly impact the measured thermodynamic parameters—most notably $\Delta S^{‡}$. However, τ_{298}, k_{298}, $\Delta G_{298}^{‡}$, and E_a are less sensitive and so it is in the case of these parameters that we have the most confidence. In reference to these values, we find that the MSCC→GSCC relaxation rates, within the polymer environment, are under significant chemical control. In fact, they

varied by more than 1000 times in moving from **R2**$^{4+}$ to **C2**$^{4+}$. This result directly translates into chemical control over colorimetric retention times in these electrochromic devices. In Figure 5, we present a demonstration of such a device
Figure 5. The electrochromic response of the solid-state polymer devices. The working (W), counter (C), and reference (R) electrodes are indicated. a) The device with the working electrode grounded. The green color correlates with the color of the ground-state co-conformer of **R1**$^{4+}$, with the CBPQT^{4+} ring encircling the TTF site. b) After a $+1$ V oxidizing potential has been applied to the working electrode, the color change to red/purple correlates with the translational isomerization having occurred to the metastable state. c) Several seconds after the working electrode has been returned to 0 bias and **R1**$^{4+}$ has relaxed back to the ground-state co-conformer.

containing **R1**$^{4+}$ that was cycled from the green to the red state, and then back to the green state again. This electrochromic device[27] contained substantially higher concentrations of **R1**$^{4+}$ than did other devices discussed herein, but was, in all other ways, identical to them.

In summary, we find that a single mechanistic picture can be applied to describe the electrochemically driven switching cycle of bistable [2]catenanes and [2]rotaxanes in solid-state polymer electrolytes. This mechanistic picture is qualitatively identical to that initially proposed to describe the behavior of a MSTJ device,[13] and is also analogous to that observed for the switching cycle of a [2]rotaxane SAM.[12] We find that the MSCC→GSCC relaxation rate is strongly dependent upon both physical environment and molecular structure. In particular, by varying the molecular structure we could vary

this relaxation rate by more than 1000 times. This variation has interesting implications for controlling the colorimetric retention times (and hence power efficiencies) in solid-state electrochromic devices,[27] and we have demonstrated such a device. Finally, these results suggest that electrochemical measurements[19] on these same molecules in cryogenic solutions should go far toward quantifying how the kinetic parameters that describe the switching cycle are impacted by the physical environment of the molecular switches.

Experimental Section

A three-terminal, microfabricated device, operated as a function of voltage scan rate and temperature, was employed to interrogate the kinetics of electrochemically-induced molecular mechanical switching within a solid-state polymer. The polymer electrolyte matrix was a standard solid-state electrolyte prepared from a solution in MeCN that contained polymethylmethacrylate (PMMA, $M_w = 300\,000$), propylene carbonate, (PC)—as a plasticizer—and LiClO$_4$ (MeCN/PMMA/PC/LiClO$_4$ ($w/w/w/w$) $= 70:7:20:3$). These materials were handled only in flame-dried glassware under an inert atmosphere of Ar. The LiClO$_4$ was purified by fusion under vacuum. The MeCN was dried either by passage through steel columns containing activated alumina under Ar using a solvent purification system (Anhydrous Engineering) or by distillation over CaH$_2$. Finally, the MeCN was deoxygenated prior to use through three freeze/pump/thaw cycles.

The solid-state electrolyte devices were fabricated with traditional CV experiments in mind. A planar three-electrode—working, counter, reference—configuration was implemented, and each electrode consisted of 10 nm of Ti covered with 50 nm of Pt. The electrodes were patterned by using standard lithographic and metal evaporation procedures onto a glass substrate. The fabricated substrates were placed in a glove box under a N$_2$ environment. The electrochemically active species were then combined with the electrolyte and drop cast onto the three electrodes. These devices were allowed to stand for 20 min to facilitate drying, and then were pumped for a further 20 min to a final pressure of 100 mTorr. The working devices were firm to the touch, with a consistency similar to that of a stiff rubber band. The viscosity of similarly prepared polymer electrolytes has been reported,[28] and, at 298 K, it is more than 10^4 times larger than that for the solvent MeCN.

CV measurements were performed in a sealed container on an EG&G VersaStat II Potentiostat with the aid of three electrical feedthroughs and a thermocouple fed back to a hot-plate for thermal control. The key experimental variables were scan rate and temperature and—for a given device—these parameters were varied randomly to avoid the influence of systematic errors.

[20] Previously, we had advocated (M. C. T. Fyfe, P. T. Glink, S. Menzer, J. F. Stoddart, A. J. P. White, D. J. Williams, *Angew. Chem.* **1997**, *109*, 2158–2160; *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 2068–2070) the use of the term "co-conformation" to designate the different three-dimensional spatial arrangements of the components of mechanically interlocked molecular systems. Also, in identifying the ON and OFF states of the bistable [2]catenane employed in the first MSTJ crossbar device,[16] we employed the term "co-conformer" to the two states. See, especially Figure 1 in reference [16]. In other words, in proposing our original mechanism, we appreciated correctly that the ON and OFF states are both isomeric and, of course, isoelectronic.

[21] SAMs of copper catenates have been prepared; however, the electrochemically-triggered circumrotations are either significantly slower than the corresponding motions in solution or completely frozen out; see: L. Raehm, J.-M. Kern, J.-P. Sauvage, C. Hamann, S. Palacin, J.-P. Bourgoin, *Chem. Eur. J.* **2002**, *8*, 2153–2162.

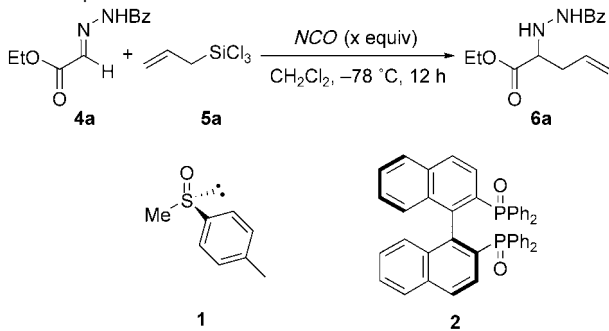
Asymmetric Synthesis

Stereospecific, Enantioselective Allylation of α-Hydrazono Esters by Using Allyltrichlorosilanes with BINAP Dioxides as Neutral-Coordinate Organocatalysts**

*Chikako Ogawa, Masaharu Sugiura, and Shū Kobayashi**


Enantioselective allylation of α-imino esters or their equivalents provides one of the most efficient routes to optically active natural and unnatural α-amino acids. Lectka et al. reported enantioselective allylation of a hemiacetal of a *N*-sulfonyl α-imino ester with trimethyl(2-phenylallyl)silane and related silanes using a chiral Cu[I] catalyst.[1] Jørgensen et al. also reported at almost the same time that the chiral Cu[I] catalyst had lower activity for the reaction with allylsilanes. His group used allylstannanes instead of allylsilanes.[2] However, in both cases, the enantioselectivities obtained were still unsatisfactory, and were dependent on the structure of allylsilanes. Recently, our group also reported that enantioselective allylation of α-hydrazono esters with allyltrimethoxysilanes proceeded smoothly in aqueous media in the presence of a ZnF$_2$-chiral diamine complex.[3] However, also in this case the enantioselectivities obtained were less than 90% *ee*. Furthermore, only a few examples of diastereo- and enantioselective addition of γ-substituted allyl metals to α-imino esters have been reported;[1b,2,4] no *stereospecific,* enantioselective allylation has been attained to date.

Recently, we have found that neutral (uncharged) organic molecules such as *N,N*-dimethylformamide (DMF) and hexamethylphosphoramide (HMPA) mediate allylation of aldehydes[5] and *N*-acylhydrazones[6] with allyltrichlorosilanes. Remarkably, the reactions proceeded without the use of any metal catalyst. These organic molecules coordinate to allyltrichlorosilanes to form hypervalent silicon compounds[7] that react with electrophiles efficiently; thus, we defined these molecules as neutral coordinate-organocatalysts (*NCO*s).[8] Quite recently, we have achieved stereospecific, enantioselective allylation of *N*-acylhydrazones by using chiral sulfoxides as chiral *NCO*s.[9] We have also found that phosphine oxides are effective for the allylation of *N*-acylhydrazones.[10] On the basis of this background, we decided to develop the stereospecific, enantioselective allylation of α-imino ester derivatives.

We selected α-hydrazono esters as α-imino ester surrogates because of their stability compared to the corresponding α-imino esters. Indeed, most α-hydrazono esters are crystalline, easily purified by simple recrystallization, and can be stored for several months at room temperature.[3,11] First, the reaction of α-hydrazono ester **4a** (prepared from ethyl glyoxylate and benzhydrazide) with allyltrichlorosilane (**5a**) was chosen as a model, and several enantiopure catalysts were tested (Table 1). When sulfoxide **1** was used as a chiral

Table 1: Optimization of reaction conditions.

Entry	NCO	x	Conc. [M]	Yield [%]	*ee* [%]
1	1	3.0	0.15	60	23 (*S*)
2	2	0.2	0.30	11	56 (*R*)
3	2	0.4	0.30	38	69 (*R*)
4	2	1.0	0.30	62	96 (*R*)
5	2	1.0	0.05	72	95 (*R*)
6	2	2.0	0.05	91	98 (*R*)

catalyst, the reaction proceeded to afford the desired allylated adduct **6a** in 60% yield but with disappointingly low enantioselectivity (23% *ee*; Table 1, entry 1). Although several reaction conditions were examined using **1**, little improvement of the yield and the selectivity was observed. We then decided to search for other chiral catalysts for this reaction. After screening several catalysts, we found that 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl dioxides (**2**, BINAP dioxides) were promising. When 1.0 equivalent of (*S*)-BINAP dioxide (**2**) was used in the reaction between **4a** and **5a**, the reaction proceeded in dichloromethane at −78°C to give the desired adduct **6a** in 62% yield with 96% *ee* (Table 1, entry 4). Unfortunately, use of smaller amounts of (*S*)-BINAP dioxide gave lower yields and enantioselectivities (Table 1,

entries 2 and 3). The yield and the selectivity were further improved when two equivalents of **2** were used under lower concentration conditions; thus, the desired adduct **6a** was obtained in 91% yield with 98% *ee* (Table 1, entry 6). After the reaction, **2** was recovered almost quantitatively without loss of optical purity. It is noted that the use of chiral phosphine oxides in asymmetric catalysis has been limited,[12] whereas innumerable usage of BINAP has been reported.[13]

We then examined other α-hydrazono esters and allyltri-chlorosilanes, and the results are summarized in Table 2. For

Table 2: Allylation of α-hydrazono esters by using BINAP dioxides.

[a] Compound **3** was used instead of **2**. Reaction time was 15 h.
[b] Reaction time was 6 h.

α-hydrazono esters, larger ester groups gave lower yields, whereas high enantioselectivities were maintained in some cases. For allyltrichlorosilanes, we carefully examined croty-lation using (*E*)- and (*Z*)-crotyltrichlorosilanes. It was exciting to find that the reactions proceeded stereospecifically; (*E*)-crotyltrichlorosilane **5b** gave the *syn* adduct **6e** (Table 2, entry 5), whereas the *anti* adduct **6f** was produced from (*Z*)-crotyltrichlorosilane **5c** (Table 2, entry 6).[14] In both cases, yields were high, and excellent diastereo- and enantioselectivities were obtained. When (*E*)- and (*Z*)-allylic trichlorosilanes, **5d** and **5e**, were employed, both *syn* and *anti* adducts were also obtained stereospecifically, although (*R*)-2,2′-bis(di-*p*-tolylphosphanyl)-1,1′-binaphthyl dioxides (**3**, (*R*)-*p*-tol-BINAP dioxides) as an *NCO* gave better results than **2** (Table 2, entries 7 and 8). It is noteworthy that this is the first example of stereospecific, enantioselective allylation of α-imino ester equivalents. Other allylic silanes **5f** and **5g** also worked well to afford the desired adducts with high enantio-selectivities (Table 2, entries 9 and 10).

The present allylation was successfully applied to the enantioselective synthesis of D-alloisoleucine, an uncommon α-amino acid observed in biologically important peptides;[15] however, there are several reports on enantioselective synthesis of this molecule.[16] Our synthesis is outlined in Scheme 1. The starting material **6e** is an allylated adduct
Scheme 1. Facile synthesis of D-alloisoleucine.

prepared from **4a** and **5b** (Table 2, entry 5). The olefin moiety of **6e** was reduced by using polymer incarcerated Pd (PI Pd)[17] to give **7** in 70% yield. Successive reductive cleavage of the N–N bond of **7** using SmI$_2$,[18] followed by ester hydrolysis gave D-alloisoleucine (quantitative yield for two steps). Thus, D-alloisoleucine has been synthesized from α-hydrazono ester **4a** in four steps in an overall yield of 64%. This efficient synthesis demonstrates the utility of the BINAP dioxide-catalyzed enantioselective allylation reaction for amino acid synthesis.

In conclusion, we have found that BINAP dioxides are excellent chiral neutral-coordinate organocatalysts for the enantioselective allylation of α-hydrazono esters using allyl-trichlorosilanes. The reactions proceeded stereospecifically; (*E*)-allylic silanes gave *syn* adducts, whereas *anti* adducts were obtained from (*Z*)-allylic silanes. This is the first example of the stereospecific, enantioselective allylation of α-imino ester equivalents. Diastereo- and enantioselectivies obtained in this allylation are very high compared to those reported by previous methods. In addition, the present reaction was successfully applied to the efficient synthesis of D-alloisoleu-cine. A drawback of this reaction is the use of two equivalents of BINAP dioxides, but the chiral source could be recovered almost quantitatively without loss of optical purity. Further investigations to reduce the amounts of BINAP dioxides are now in progress.

Stereoselective Synthesis

A Stereodivergent Synthesis of Virantmycin by an Enzyme-Mediated Diester Desymmetrization and a Highly Hindered Aryl Amination**

Thomas G. Back and Jeremy E. Wulff*

(−)-Virantmycin (**1**) is an unusual chlorinated tetrahydroquinoline that was isolated from a strain of *Streptomyces nitrosporeus* in 1980.[1] It was found to possess both strong inhibitory activity against RNA and DNA viruses, and antifungal activity.[2] The initial structure elucidation of virantmycin was reported in the 1980s,[2,3] but not until 1990 was the correct stereochemistry established by NMR methods,[4] and later confirmed by synthesis.[5] To date, racemic syntheses of **1** have been completed by Hill and Raphael,[6] Morimoto, Shirahama et al.,[5,7] and by Steinhagen and Corey.[8] The preparation of the (+)-antipode of the naturally occurring antibiotic has also been reported.[9] Very recently, Kogen et al. achieved the first enantioselective synthesis of (−)-**1** from (*S*)-indoline-2-carboxylic acid.[10] The latter report prompted us to disclose our own efforts in this area, which have resulted in a stereodivergent route to both (+)-**1** and (−)-**1**.

The principal challenge in the synthesis of virantmycin involves the stereoselective construction of the two contiguous stereocenters, which include the quaternary carbon atom at C2. Our plan was to construct the latter center by the desymmetrization of a key intermediate diester **2** by an enzyme-mediated partial hydrolysis. After appending the aryl moiety by a Claisen-like condensation, we envisaged the stereoselective introduction of the amino group to the highly hindered stereocenter by a Curtius rearrangement and ring-closure to complete the tetrahydroquinoline skeleton by an intramolecular aryl amination reaction (Scheme 1).

Diester **2** was readily obtained by sequential alkylation of the enolate derived from dimethyl malonate by using NaH with 5-iodo-2,3-dimethyl-2-pentene[11] and methoxymethyl chloride. Scheme 2 illustrates the desymmetrization of **2**, which was achieved by partial hydrolysis with porcine liver esterase (PLE)[12] to afford the half-ester **3** in 89% yield and 95% *ee*, as determined by integration of the NMR spectrum of the salt formed from **3** and (*S*)-(−)-α-methylbenzylamine.

Scheme 1. Retrosynthesis of (−)-virantmycin (**1**).
Scheme 2. Desymmetrization of diester **2** to generate chiral intermediates **4** and **5**: a) porcine liver esterase (PLE), DMSO-pH 8.0 phosphate buffer (1:4), 7 days, RT, 89%, 95% *ee*; b) cyanuric fluoride, pyridine, dichloromethane, 1 h, 0 °C, 71% for **4** and 75% for **5**; c) 2-(trimethylsilyl)ethanol, 1,3-dicyclohexylcarbodiimide (DCC), *N,N*-dimethylaminopyridine (DMAP), dichloromethane, 3 days, RT, 77%; d) 10% aqueous KOH, methanol, 15 h, 45 °C, 88% (based on 20% of recovered **3**.

Scheme 3. Coupling of diester **6** with chiral intermediate **5**: a) lithium hexamethyldisilazide (LiHMDS), Et₂O, 0 °C, 10 min; then **5**, Et₂O, 1 h at 0 °C→20 h at RT, 63%; b) 10% aqueous NaCl, DMSO, 20 h, 125 °C, 78%; c) NaBH₄, methanol, 2.5 h, 0 °C, 83%; d) pyridinium chlorochromate (PCC), dichloromethane, 3 days, RT, 77%.

The absolute configuration of **3** was assumed to be (*S*) on the basis of earlier studies[12b,c] of PLE-mediated hydrolyses of other β-diesters, and this assignment was confirmed unequivocally by the ultimate conversion of **3** to essentially pure enantiomers of the final products. Thus, half-ester **3** was converted separately into each of the pseudo-enantiomeric acyl fluorides **4** and **5** (Scheme 2),[13] which in turn served as respective precursors of (+)-**1** and (−)-**1**. Acylation of the enolate of diester **6**[14] with **5** afforded triester **7** (Scheme 3), which was subjected to selective Krapcho decarboxylation[15] of the less hindered β-keto ester moiety to furnish **8**. The reduction of the ketone group of **8**, which was required to introduce a hydroxy group to serve as the chlorination site for the final product, resulted in poor stereoselectivity under a variety of conditions. However, the undesired epimer **10** was easily separated from **9** and recycled back to ketone **8** with PCC. The configurations of epimers **9** and **10** were assigned on the basis of NOE experiments conducted on the corresponding β-lactones (Scheme 3).

Alcohol **9** was acetylated and the trimethylsilylethyl ester was selectively removed with fluoride ion. The resulting carboxylic acid was subjected to a Curtius rearrangement

mediated by diphenylphosphoryl azide (DPPA),[16] followed by workup with sodium borohydride, to afford formamide **11** (Scheme 4). The crucial intramolecular Buchwald–Hartwig aryl amination[17] step was then attempted under a variety of conditions, with generally unsatisfactory results. However, we were pleased to discover that the treatment of formamide **11** with [Pd₂(dba)₃] in the presence of the Keay ligand BINAPFu (**12**)[18] under the conditions shown in Scheme 4 resulted in quantitative cyclization to **13**.

The selection of BINAPFu as the Pd ligand of choice was based on model studies of the aryl aminations of other α-quaternary amines (1-adamantylamine and methyl α,α-dimethylglycinate) with methyl 4-bromo-3-methylbenzoate. Other ligands, such as BINAP,[19a] DPPF,[19b] PCy₃,[19c] *o*-biphenyl-PCy₂,[19d] *o*-biphenylP*t*Bu₂,[19d] DPEphos,[19e] MAP,[19f] and IMES hydrochloride[19g] failed to effect coupling or produced very low yields of the corresponding aryl amines under a wide variety of conditions. The successful intramolecular aryl amination of formamide **11** using the BINAPFu ligand is particularly noteworthy because very few examples of aryl aminations of aliphatic amines containing α-quaternary centers are known.[20] BINAPFu is a less strongly donating ligand than other commonly employed bidentate phosphines such as BINAP.[18] Moreover, the reductive elimination steps
Scheme 4. Synthesis of (−)-virantmycin (1) from intermediate 9:
a) *N,N*-dimethylaminopyridine (DMAP), pyridine, acetic anhydride, 3 days, RT; b) 1.0 M tetrabutylammonium fluoride in tetrahydrofuran, 1 h, RT; c) diphenylphosphoryl azide (DPPA), *N,N*-dimethylaminopyridine (DMAP), triethylamine, toluene, 2.25 h, reflux; then NaBH$_4$, tetrahydrofuran, 12.5 h, RT, 84% overall yield for steps a–c; d) [Pd$_2$(dba)$_3$], 12, Cs$_2$CO$_3$, toluene, 6.5 h, 90°C, 100%; e) 0.13 M NaOH in methanol, 24 h, RT, 84%.

Scheme 5. Synthesis of (+)-virantmycin from acyl fluoride 4: a) 10% aqueous KOH, methanol, 20 h, RT; b) NaH, *n*PrSH, HMPA, 4.75 h, RT; c) SOCl$_2$, methanol, 1 h at −10°C→3 h at reflux, 46% overall yield for steps a–c.

of aryl aminations and related Pd-catalyzed coupling reactions are enhanced by weakly coordinating phosphine ligands.[21] It is therefore possible that reductive elimination is the rate-determining step in the present case because of the high degree of steric hindrance associated with coupling an *ortho*-substituted aryl bromide with an α-quaternary amine derivative. The particular efficacy of BINAPFu may be attributed to its ability to facilitate this step.

Deacetylation and concomitant deformylation of tetrahydroquinoline 13 provided the free alcohol 14, which was converted into (−)-1 by the same method used previously by Morimoto and Shirahama[9] in their synthesis of (+)-1 (Scheme 4). The product displayed NMR spectra consistent with the literature[4,6,9] and gave a specific rotation $[\alpha]_D^{20} = -11°$ ($c = 0.13$, chloroform) that compared favorably with that reported for the natural product: $[\alpha]_D^{24} = -11.1°$ ($c = 0.175$, chloroform).[9]

Finally, acyl fluoride 4 was converted into the unnatural antipode (+)-1 by a similar process (Scheme 5), except that the aromatic and aliphatic ester moieties of 15 were converted to the free carboxylic acids in 16 by saponification of the former and dealkylation with sodium propanethiolate of the latter, followed by selective reesterification of the aromatic carboxylic acid and Curtius rearrangement of the remaining aliphatic acid (Scheme 5). Completion of the synthesis was achieved as in the case of (−)-1. The NMR spectra of the product were identical to those of (−)-1 and the optical rotation data $[\alpha]_D^{20} = +13°$ ($c = 0.14$, chloroform), compared

favourably with the literature value $[\alpha]_D^{24} = +11.2°$ ($c = 0.125$, chloroform).[9]

In conclusion, the present method provides a new route to both enantiomers of the antiviral agent virantmycin (1). It employs as key steps a highly enantioselective enzyme-mediated desymmetrization and a remarkably effective intramolecular aryl amination of a hindered α-quaternary aliphatic amine. The procedure is also potentially amenable to the preparation of analogues for the purpose of structure–activity studies.

Targeting RNAs with Tobramycin Analogues**

*Fu-Sen Liang, Sheng-Kai Wang, Takuji Nakatani, and Chi-Huey Wong**

There are growing interests in developing small molecules to specifically target RNA because of the potential therapeutic applications.[1] Aminoglycosides and macrolides, for example, have been known to exhibit antibiotic activities by interacting with the bacterial ribosomal RNA.[2] Recent discoveries of other small molecules that control gene expression in living cells by attenuating RNA activities have shed more light on the promising potential of developing RNA-binding molecules as drugs.[3] Many aminoglycosides have been developed to target not only the bacterial ribosomal RNA 16S A-site, but also other RNA sequences, including the regulatory domains of HIV-1 mRNA, the oncogenic Bcr-Abl mRNA sequence, and the group I intron.[4]

From NMR and X-ray crystallographic studies,[2,5] it is clear that the two-ring cores (rings I and II) of both tobramycin (**1**) and paromomycin (**2**), which are 4,5- and 4,6-linked aminoglycosides, respectively (see Figure 1), sit in the bulges of A^{1408}, A^{1492}, and A^{1493} of the A-site and make very similar contacts with the RNA bases and the phosphate backbones. The surface plasmon resonance (SPR) binding studies of the naturally occurring aminoglycosides with the wild-type or mutant 16S A-site RNAs show that the binding affinity and specificity vary when the compositions or the linking positions of the additional sugar moieties change.[6] Previous studies also suggest that both neamine and nebramine are basic cores for binding to various RNA sequences and for cell permeability.[7] It is possible that by keeping the

two-ring core and changing the carbohydrate unit attached to position 5 or 6 of the core may affect both affinity and specificity.

Most of the aminoglycoside analogues developed to date have been modified by the attachment of various nonsugar moieties to the original aminoglycosides or to the two-ring core through different linkers. Here, we designed and synthesized a new library of 4,6-linked tobramycin analogues with various mono- or diaminosugars attached to the 6-position of the deoxystreptamine ring (Figure 2). With the relatively rigid conformation of the carbohydrate framework, it was hoped that new aminoglycosides with higher binding affinities and selectivities would be found.

The protected nebramine core **5** was derived from tobramycin (**1**; Scheme 1). The amine groups of tobramycin (**1**) were first converted into azides as protecting groups by the diazo transfer reaction.[8] This was followed by benzylation of the alcohol groups to give the fully protected tobramycin derivative **6**. Cleavage of the glycosidic bond between the nebramine core and the third ring was catalyzed by a Lewis acid in the presence of *p*-thiocresol as nucleophile.[9] The advantage of this method, instead of HCl or copper chloride catalyzed cleavage, is that the resulting cleaved third ring can

Figure 3. Thioglycoside building blocks as a) the first donors and b) the second donors. Tol = *p*-tolyl, Troc = trichloroethyloxycarbonyl (CCl$_3$CH$_2$OC(O)-), Bz = benzoyl.

be recovered as a thioglycoside building block and used in library synthesis.

A group of protected monosaccharide building blocks, which contained one or more amine groups, was then selected and synthesized from our thioglycoside building block database (Figure 3). Two sets of building blocks were chosen with significant differences in reactivity as glycosylation donors.[10] The first set, which includes compounds **7**–**17**, contains thioglycoside donors with high reactivity which were designed by the introduction of electron-donating protecting groups (Figure 3 a). The second set, which includes compounds **18**–**29**, contains thioglycoside donors with lower reactivity, tuned by electron-withdrawing protecting groups (Figure 3 b). Thioglycosides **7**–**17** were either directly coupled to the protected nebramine core **5** or were used to assemble disaccharide building blocks with thioglycosides **18**–**29** by *N*-iodosuccinimide (NIS)–TfOH promoted glycosylation (TfOH = trifluorosulfonic acid).[11] After several unsuccessful attempts under different glycosylation conditions, these disaccharide building blocks were found to be relatively inactive. The protecting groups were then changed to benzyl groups to provide higher reactivity toward the nebramine core **5** (Scheme 2). Benzenesulfinylpiperidine (BSP) and Tf$_2$O were used as promoters for these glycosylation reactions (Scheme 3).[12] Stereoisomers at the anomeric positions (α or β linkage) were usually formed in these glycosylation reactions and these were separated by column chromatog-

raphy (silica gel). The number of different protecting groups used was kept to a minimum, with the use of only azido and benzyl groups to simplify the deprotection steps afterward.

Deprotection was completed by first, the reduction of the azido groups with Raney Nickel and anhydrous hydrazine and second, palladium hydroxide catalyzed hydrogenation under acidic conditions to remove the benzyl groups (Scheme 3), to give the tobramycin analogues **32–92** (Figure 4 and Supporting Information). An attempt to remove both groups in one step by hydrogenation in the presence of different palladium catalysts only gave mixtures of incompletely deprotected products probably owing to the poisoning of the catalysts by amines.[13]

The SPR assay was then used to study the binding affinity and specificity of these tobramycin analogues with a number of short RNA sequences (24 to 48 bps), which were identified from sequence-conserved and functionally important regions of several disease-related bacterial, viral, or human RNAs, such as the bacterial ribosomal 16S A-site, *E. coli*. transglycosidase mRNA, Hepatitis C virus (HCV) internal ribosome entry site (IRES) RNAs,[14] HIV frameshift signal,[15] HIV protease mRNA, human oncogenic Bcr-Abl mRNA,[16] and human tyrosine sulfotransferase mRNA (Figure 5). The synthetic compound library as well as commercially available aminoglycosides and

macrolides were first screened at 1 μM against the above RNA molecules. By using tobramycin (**1**) and neomycin B (**3**) as standards, compounds with high binding signals were selected for the determination of dissociation constants (K_d).[17] The K_d values of selected compounds from each RNA screening were determined for all RNA sequences in this study to examine the binding specificity (Table 1).

From the results of the binding assay, several molecules displayed an affinity in the nanomolar range to specific RNA sequences. Whereas all of the selected compounds showed some limited affinity toward the RNAs tested, several compounds exhibited higher affinity to specific RNAs. Tobramycin (**1**) showed a higher affinity to the HIV frameshift signal (0.64 μM, 2–100-fold selectivity); neomycin B (**3**) was more specific to the bacterial 16S A-site and the human tyrosine sulfotransferase mRNA (0.2 μM and 0.3 μM, 8–14-fold); sisomycin (**4**) was selective for the HCV IRES IIId domain (0.26 μM, 5 to > 100-fold); **33** displayed a relatively high affinity to the HCV IRES IIId (0.7 μM, 1.6–5-fold); **34** also showed a high affinity to the HCV IRES IIId (0.25 μM, 1.7–38-fold); **35** was selective for the HIV frameshift signal (0.32 μM, 5.6–

monosaccharide or disaccharide moiety to form analogues of tobramycin. The SPR studies of the interactions of these analogues with certain RNA sequences show that new aminoglycosides can be created to target RNA in a sequence-selective manner. Work is in progress to further study the interactions of selected compounds and RNAs to understand the origin of selectivity and to design better RNA-binding molecules as inhibitors of translational processes in cell-based systems.

Synthesis of the C-1027 Chromophore Framework through Atropselective Macrolactonization**

Masayuki Inoue,* Takeo Sasaki, Suguru Hatano, and Masahiro Hirama*

C-1027 is a chromoprotein enediyne natural product with potent in vitro and in vivo cytotoxicity against a variety of cancer cell lines.[1] It is a member of the subset of enediyne antibiotics that includes neocarzinostatin,[2] kedarcidin,[3] and maduropeptin.[4,5] Each of these agents is composed of protein and small-molecule (chromophore) components, which form a 1:1 complex. The C-1027 chromophore **1**

exerts its potent toxicity by abstracting hydrogen atoms (**2**→**3**) from the backbone of DNA to cleave the double strand.[7] This chemical instability and its complex structure distinguish **1** as a challenging target for total synthesis.[8–11]

The structure of **1** is highly unusual, characterized by a chlorocatechol-containing ansa-bridge, a strained bicyclo[7.3.0]dodecatrienediyne, an appended benzooxazine,[12] and an aminosugar.[13] The synthetic challenge presented by **1** is heightened by the presence of nonbiaryl atropisomerism arising from hindered rotation of the chlorocatechol ring in the ansa-bridge.[14,15] Herein we present the synthesis of the C-1027 chromophore framework through a newly designed atropselective macrocyclization.

Our synthetic strategy is outlined in Scheme 1. The total synthesis of **1** would be attained from its framework **4** by attaching the amino sugar[16] and the benzoxazine, followed by introducing two olefins (C4–C5 and C11–C12).[17] As the nine-membered diyne of **4** could be chemically unstable, as suggested by experiments on a model compound,[18] the macrolactone system would have to be constructed prior to the nine-membered ring.[19] We planned to form this strained nine-membered diyne **4** by LiN(TMS)$_2$/CeCl$_3$-promoted cyclization of **5**.[16,17,19b,20] The highly unsaturated macrocycle **5** was to be synthesized through the coupling of the three fragments **6**, **7**, and **8** in a convergent manner.

The synthesis of the five-membered ring **14** bearing the β-tyrosine moiety was improved from a previously published procedure,[21] and started with the known intermediate **9** (Scheme 2).[22] Nucleophilic addition of vinylmagnesium bromide to enone **9** occurred from the opposite side of the bulky TBS ether to afford tertiary alcohol **10** as the sole isomer.

Scheme 1. Retrosynthesis of the C-1027 chromophore.

Scheme 2. Reagents and conditions: a) CH$_2$=CHMgBr, Et$_2$O, −70→0°C, 83%; b) O$_3$, CH$_2$Cl$_2$/MeOH/pyridine (4:4:1), −80°C; then Me$_2$S, −60°C→RT; c) HC≡CMgBr, toluene, −85°C→RT, 62% (over two steps); d) MsCl, CH$_2$Cl$_2$, −70°C; then DBU, −70°C→RT, 69%; e) TBAF, THF, 0°C, 95%; f) MOMCl, *i*Pr$_2$NEt, (CH$_2$Cl)$_2$, 40°C, 86%; g) **7** (1.1 equiv), CsF, DMF, 75°C, 77%. TBS = *tert*-butyldimethylsilyl; Ms = methanesulfonyl; DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; TBAF = tetrabutylammonium fluoride; MOM = methoxymethyl; DMF = *N,N*-dimethylformamide.

Selective ozonolysis of the terminal olefin of **10** and subsequent reductive workup generated aldehyde **11**. Treatment of **11** with ethynylmagnesium bromide in toluene exclusively produced diol **12** bearing the β-hydroxy group at C8. The stereochemical outcome of the reaction was presumably governed by magnesium chelation and the presence of the bulky iodine, forcing the nucleophile to attack from the

less hindered side of the five-membered chelate **15**. The secondary alcohol of **12** was selectively mesylated with MsCl and Et$_3$N, and the monomesylate was converted into epoxide **13** by the addition of DBU (one-pot reaction). Next, the TBS group of **13** was replaced by a MOM group to give **6** in a two-step sequence. Finally, the β-tyrosine moiety **7**[21] was coupled to **6** by the action of CsF in DMF,[23] leading to adduct **14**.

To evaluate potential strategies for the desired atropselective macrolactonization, substrate **19** was first synthesized (Scheme 3). The tertiary alcohol of **14** was converted into the TMS ether, and the TMS group was also introduced to the terminal acetylene to afford **16**. Sonogashira coupling[24] of **16** with acetylene moiety **8**[19a] in the presence of catalytic [Pd(PPh$_3$)$_4$] and CuI led to **17**. Treatment of **17** with K$_2$CO$_3$ in methanol resulted in simultaneous removal of the acetyl and two TMS groups to produce **18**, and subsequent saponification of the methyl ester of **18** with KOH gave rise to seco-acid **19**.

Macrolactonization of **19** was successfully realized by two methods, but with a non-atropselective outcome. Carboxylic acid **19** was treated with 2,2′-dipyridyl disulfide and PPh$_3$ to give the corresponding thioester, which was heated at reflux in toluene,[25] resulting in the formation of macrolactone **20** and **21** in 50% yield (1:1).[19a] A higher yield of **20** was achieved by the powerful method recently developed by Shiina and co-workers:[26] Treatment of **19** with MNBA and DMAP at 40°C produced macrolactones **20** and **21** (1:1.1 ratio in 65% combined yield). Importantly, the ratio of the atropisomers was unaffected under the two different conditions, and thus the structure of the substrate was likely to be the decisive factor in the selectivity of the reaction. Furthermore, isomerization to enrich the desired atropisomer **20** was unsuccessful. Separate heating of atopisomers **20** and **21** at 160°C in deuterated 1,2-dichlorobenzene for 12 h did not result in isomerization, which suggests that these macrocycles are highly rigid.[27,28] Consequently, selective formation of the desired atropisomer would be possible only by controlling the transition state of the macrolactonization by using an appropriately functionalized substrate.

To examine the effect of substituents of the aromatic ring on selectivity, the OMOM group at C23 of **19** was replaced with OH in the alternative substrate **27** (Scheme 3). First, bis-MOM ether **14** was successfully transformed into mono-MOM ether **22** by treatment with TFA and subsequent reattachment of Boc to the C18 amine. After conversion of phenol **22** into pivaloate ester **23**, TMS groups were introduced at 9-OH and at the C6-methyne to produce Sonogashira coupling substrate **24**. Adduct **25** was then obtained by coupling **24** with **8** in the presence of catalytic Pd^0 and CuI. Deprotection of four protecting groups (two TMS, Ac, and Piv) from **25** with K$_2$CO$_3$ in methanol and subsequent treatment with KOH resulted in seco-acid **27** with the free 23-OH group. Surprisingly, macrolactonization of **27** by using the Corey–Nicolaou thioester method generated solely the undesired atropisomer **28** in modest yield.

From NOESY data and molecular modeling (Macro-Model Ver 8.0),[29] all the macrolactones (**20**, **21**, and **28**) were found to have similar conformations. The structure of **28** is shown as a representative example (Figure 2), in which it can

Scheme 3. be seen that the terminal acetylene and the chlorocatechol are perpendicular to the macrocycle plane. It is evident that the 1,5 hydroxy groups (9-OH and 23-OH) are in spatial proximity, suggesting hydrogen bonding. This hydrogen bonding could also fix the conformation of the transition state (Figure 3), which explains the sole formation of **28** from **27**. In the cyclization of **19**, the larger unfavorable steric
Figure 2. Three-dimensional structure of **28** based on NOESY data (C$_6$D$_6$) and molecular modeling.
Figure 3. Potential hydrogen bonding in the transition state of the macrolactonization reaction.

interaction between the 23-OMOM group and the tertiary 9-OH group could counteract the attractive hydrogen bond, which could be the reason for the nonstereoselective outcome observed. Hence, the atropselectivity of the macrolactonization appears to be controlled by the balance between steric interaction and hydrogen bonding of the substituents at C9 and C23.

From these considerations, placement of a bulky protecting group on the tertiary 9-OH group could force an atropselective macrolactonization to the desired isomer, because both increased steric interaction with the 23-OMOM group and elimination of the hydrogen bond would impose an energetic penalty on the transition state of the unwanted atropisomer. For undertaking an experimental verification of this hypothesis, we designed a new macrolactonization substrate **31**, which bears 23-OMOM and 9-OTES groups (Scheme 4).

As shown in Scheme 4, seco-acid **31** was synthesized from **14** in a route similar to that used for **19**. The TES group was introduced at the tertiary alcohol function of **14**, and the acetylene moiety was transformed to its TMS-protected form **29**. Condensation of **8** and **29** under Sonogashira conditions led to diyne **30**, whose acetate, methyl esters, and TMS group were hydrolyzed with KOH in THF/MeOH/H$_2$O, without affecting the TES ether, giving **31**.

Atropselective macrolactonizaton of seco-acid **31** was effected by using the MNBA method. Upon treatment of **31** with MNBA and DMAP in refluxing CH$_2$Cl$_2$, the desired isomer **32** was formed with 4:1 atropselectivity and isolated in

61% yield.[31] Remarkably, the yield of the desired atropisomer (**32** versus **20**) was doubled by strategic protection of the 9-OH group.

With the desired ansa macrolide **32** in hand, our next focus was to construct the nine-membered diyne ring. Before doing so, the reaction conditions of protecting- and functional-group manipulations were carefully tuned. First, the cyclopentylidene ketal of **32** was selectively removed with TfOH in CF$_3$CH$_2$OH/THF[30] without affecting other acid-labile protecting groups (MOM, TES, MPM, and Boc) to afford 1,2-diol **34**. After conversion of **34** into tris-TES ether **35**, another Boc group was introduced by using (Boc)$_2$O and DMAP to mask the acidic 18-NH proton of **35**, leading to biscarbamate **36**.[32] The primary alcohol at C5 was selectively deprotected by using HF·py to produce **37**, which was oxidized to aldehyde **5** with (COCl)$_2$ and DMSO.

Cyclization of **5** was promoted by a 1:1 mixture of LiN(TMS)$_2$ and CeCl$_3$ in THF from −50°C to room temperature, giving rise to the strained nine-membered diyne **4** as the sole isomer in 30% yield. Thus, this LiN(TMS)$_2$/CeCl$_3$ reagent combination proved to be applicable to the highly complex and conformationally rigid system **5**. The stereochemical structure of **4**, including the newly formed β secondary alcohol, was unambiguously determined by ROESY experiments in [D$_6$]DMSO. The correct atropisomerism of **4** was again confirmed at this stage, indicating the high energy barrier to rotation of the chlorocatechol in all the synthetic intermediates. Diyne **4** slowly decomposed at room temperature, presumably through Cope rearrangement, as
Scheme 4. Reagents and conditions: a) TESCl, imidazole, DMF, room temperature, 98%; b) TMSCl, LiN(TMS)$_2$, THF, −78°C, 87%; c) **8** (1.2 equiv), [Pd(PPh$_3$)$_4$] (20 mol%), CuI (40 mol%), *i*Pr$_2$NEt, DMF, room temperature, 80%; d) KOH, THF/H$_2$O/MeOH (5:1:1), 90%; e) MNBA (2.4 equiv), DMAP (4.8 equiv), CH$_2$Cl$_2$ (1 mM), 40°C, slow addition of **31** over 12 h, 61% (**32**), 15% (**33**), 5% (dimer); f) TfOH, CF$_3$CH$_2$OH/THF (5:1), 65%; g) TESCl, imidazole, DMF, 40°C, 93%; h) (Boc)$_2$O, DMAP, MeCN, 40°C, 100%; i) HF·py, THF, 0°C, 78%; j) (COCl)$_2$, DMSO, Et$_3$N, CH$_2$Cl$_2$, −78°C, 100%; k) LiN(TMS)$_2$ (58 equiv), CeCl$_3$ (61 equiv), THF (1 mM), −50→0°C, 30%. Tf=trifluoromethanesulfonyl, DMSO=dimethyl sulfoxide.

Communications

demonstrated with previously synthesized model compounds.[33]

In conclusion, we achieved the stereoselective synthesis of the C-1027 chromophore framework through atropselective macrolactonization. The key features in this synthesis were 1) strategic protection of a 1,5-diol to attain atropselective macrocyclization, and 2) LiN(TMS)$_2$/CeCl$_3$-promoted acetylide–aldehyde condensation to build the nine-membered diyne ring in a highly unsaturated and heavily substituted macrocycle. Further studies on the total synthesis of the C-1027 chromophore from **4** are currently underway in this laboratory.

[32] Bis-Boc protection of the amine was found to have a dramatic effect on the yield of the nine-membered ring cyclization.[19b]

[33] Cope rearrangement of the nine-membered cyclic 1,5-diyne to the bisallene is considered to be the major decomposition pathway.[18]

www.angewandte.org

chemical and biological aspects of **1** render it an intriguing and challenging target. Indeed, a number of synthetic approaches have been described to date.[4–6] The only total synthesis of **1** was reported by Kishi in 1998,[7] an achievement further highlighted by the determination of the absolute configuration of **1** and the development of a biomimetic intramolecular Diels–Alder reaction to construct the G ring along with the macrocycle. Herein, we describe our own efforts in this area which have culminated in a formal total synthesis of natural (+)-pinnatoxin A.

Our synthetic strategy toward (+)-**1** targeted an optimally convergent route in which two complex fragments (**2** and **3**) were to be constructed, coupled, and elaborated to form the macrocyclic system (Scheme 1). We envisaged assembling **2**

Natural Products Synthesis

A Formal Total Synthesis of (+)-Pinnatoxin A**

*Satoshi Sakamoto, Hayato Sakazaki, Koji Hagiwara,
Kei Kamada, Kento Ishii, Takeshi Noda,
Masayuki Inoue,* and Masahiro Hirama**

In 1995, Uemura and co-workers reported the isolation and characterization of pinnatoxin A (**1**, Scheme 1),[1,2] one of the major toxic principles responsible for outbreaks of *Pinna* shellfish poisonings in China and Japan. The precise biological activity has not been clarified, but **1** has been suggested to be a Ca^{2+}-channel activator.[3] Structurally, **1** features a spiro-linked cyclic imine along with trioxadispiro- and bicycloacetal substructures within a 27-membered macrocycle. The novel

Scheme 1. Retrosynthesis of pinnatoxin A. MOM = methoxymethyl; TES = triethylsilyl; TIPS = triisopropylsilyl; TMS = trimethylsilyl.

and **3** through a dithiane coupling reaction at C25; the polyether macrocycle would then emerge from ring-closing olefin metathesis reaction (RCM)[8] to link C8 and C9, and subsequent EF-ring formation. Ring G was to be constructed by using intramolecular cyclization of epoxy nitrile **4**,[9] which would set the stereochemistry of the C5 quaternary center, as demonstrated in our model studies on simple substrates.[4c,d]

The synthesis of the BCD bisspiroacetal **2** began with previously reported compound **5**[4a] (Scheme 2). Sharpless asymmetric epoxidation[10] of allylic alcohol **5** with (+)-diethyl tartrate provided **6**. Oxidation of alcohol **6** to aldehyde **7** with SO_3·py/DMSO followed by treatment with vinylmagnesium bromide produced epoxy alcohol **8** as a 1:1 diastereomeric mixture. Subsequent reductive opening of epoxide **8** with Red-Al in Et_2O resulted in the formation of 1,3-diol **9** as the major isomer.[11] After protection of **9** as its acetonide, chemo- and enantioselective dihydroxylation of the C15–C16 olefin was realized under Sharpless conditions in the presence of $(DHQD)_2PHAL$,[12] which exclusively produced the desired

Scheme 2. Reagents and conditions: a) *t*BuOOH, Ti(O*i*Pr)$_4$ (0.2 equiv), (+)-DET (0.2 equiv), molecular sieves (4 Å), CH$_2$Cl$_2$, −20°C, 83%; b) SO$_3$·py, Et$_3$N, DMSO, CH$_2$Cl$_2$, room temperature; c) CH$_2$=CHMgBr, THF, −40°C, 74% (over two steps); d) NaAlH$_2$(OCH$_2$CH$_2$OCH$_3$)$_2$, Et$_2$O, −20→0°C; then NaIO$_4$, THF/H$_2$O (1:1), room temperature, 90%; e) 2-methoxypropene, *p*-TsOH, DMF, room temperature, 91%; f) OsO$_4$ (1 mol%), (DHQD)$_2$PHAL (1.5 mol%), K$_3$[Fe(CN)$_6$] (3 equiv), K$_2$CO$_3$ (3.5 equiv), MeSO$_2$NH$_2$ (1 equiv), *t*BuOH/H$_2$O (1:1), 0°C; g) SO$_3$·py, Et$_3$N, DMSO, room temperature, 82% (over two steps); h) CSA (0.1 equiv), MeOH, room temperature, 3 h; then CSA, toluene, room temperature, 2 days, 84% (**12**), 11% (C19-epimer); i) PivCl, CH$_2$Cl$_2$/pyridine (2:1), 0°C→RT; j) TESOTf, 2,6-lutidine, CH$_2$Cl$_2$, 0°C; k) DIBAL-H, THF, −78°C, 75% (over three steps); l) I$_2$, Ph$_3$P, imidazole, THF, room temperature, 91%; m) 1,3-dithiane, *n*BuLi, THF/HMPA (4:1), −78°C, 83%. DET = diethyl tartrate; DMSO = dimethyl sulfoxide; Ts = *p*-toluenesulfonyl; DMF = *N,N*-dimethylformamide; (DHQD)$_2$PHAL = hydroquinidine 1,4-phthalazinediyl diether; CSA = (+)-camphorsulfonic acid; Piv = pivaloyl; Tf = trifluoromethanesulfonyl; DIBAL-H = diisobutylaluminum hydride; HMPA = hexamethylphosphoramide.

1,2-diol **10** without oxidizing the terminal olefin. Then, oxidation with SO$_3$·py converted secondary alcohol **10** into ketone **11**.

The crucial bisspiroacetalization of **11** necessitated fine-tuning of the reaction conditions.[13] First, **11** was exposed to camphorsulfonic acid in methanol at room temperature to remove the acetonide, and then methanol was replaced with

toluene to increase the ratio of the desired isomer **12**. In this way, **12** was selectively generated out of four possible isomers in 84% yield. As depicted in Figure 1, favorable intramolecular hydrogen bonding between free hydroxy groups at C10
Figure 1. Potential intramolecular hydrogen bond in **12**.

and C24 is considered to influence the high selectivity for **12**.[14] Next, the 10-OH and 15-OH groups of **12** were protected as their TES ethers through a three-step sequence to afford **13**, whose 24-OH function was converted into iodide to give **14**. Finally, nucleophilic attack of lithiodithiane at **14** delivered the BCD-ring fragment **2**, suitably functionalized for assembly of the fragments. The configurations of the C16 and C19 stereocenters established during the spiroacetalization were unambiguously determined by NOE experiments at this stage.

Synthesis of the other half of the molecule began with 4,6-*O*-benzylidene-D-glucose (**15**)[15] (Scheme 3). Wittig reaction of **15** with ylide **16**[16] in refluxing THF afforded olefin (*E*)-**17**. The hydroxy groups at C28 and C31 of **17** were selectively protected as TES ethers, and PMBM[17] was introduced to protect the remaining 30-OH to produce **18**. Reduction with DIBAL-H and subsequent protection with MOMCl converted ester **18** into MOM ether **19**. Then, chemoselective hydroboration[18] of the terminal olefin of diene **19** generated alcohol **20**, which was oxidized to aldehyde **21** with SO$_3$·py. Addition of Grignard reagent **22**[4d] to **21** extended the carbon chain corresponding to the A-ring to furnish **23**. The secondary alcohol of **23** was derivatized to mesylate **24**, after which the mesylate was replaced by a nitrile group through the action of Et$_4$NCN to provide **25** after reattachment of the partially cleaved TES groups (1:1 diastereomeric mixture at C5). Replacement of the PMBM group of **25** with the Ms group in two steps and subsequent selective removal of TES from **26** with HF·py resulted in diol **27**.

Stereoselective G-ring formation from **27** was induced by an excess of KN(TMS)$_2$.[4c,d] After treating mesylate **27** with KN(TMS)$_2$ (2.5 equiv) in THF to promote the C30–C31 epoxide formation,[19] additional KN(TMS)$_2$ (1.5 equiv) was introduced to the reaction mixture, giving rise to the desired product **29** as the sole isomer in 72% yield.[20] Not only is the stereoselectivity quite remarkable, but the reactions efficiently install consecutive C5 quaternary and C31 tertiary centers. The selectivity is consistent with cyclization through transition state **28** in which the large branched carbon chain preferentially adopts the equatorial orientation.

Having constructed the G-ring, we turned our attention to stereoselective introduction of the C36-methyl group and

Scheme 3. Reagents and conditions: a) **16** (2 equiv), THF, reflux; b) TESCl, Et₃N, THF, 40 °C; c) PMBMCl, *i*Pr₂NEt, *n*Bu₄NBr, CH₂Cl₂, reflux, 51 % (over three steps); d) DIBAL-H, THF, −78 °C, 89 %; e) MOMCl, *i*Pr₂NEt, *n*Bu₄NBr, (CH₂Cl)₂, room temperature, 95 %; f) 9-BBN, room temperature; then aqueous H₂O₂, aqueous NaOH, 0 °C→RT, 90 %; g) SO₃·py, Et₃N, DMSO, CH₂Cl₂, room temperature, 84 %; h) **22** (2.5 equiv), THF, 0 °C, 85 %; i) MsCl, Et₃N, CH₂Cl₂, 0 °C; j) Et₄NCN, MeCN, 70 °C; k) TESCl, imidazole, DMF, room temperature, 67 % (over three steps); l) DDQ, CH₂Cl₂/pH 7 buffer (20:1), 85 %; m) MsCl, DMAP, pyridine, 40 °C; n) HF·py, 0 °C, 99 % (over two steps); o) KN(TMS)₂ (2.5 equiv), THF, 0 °C; then KN(TMS)₂ (1.5 equiv), 0 °C→RT, 72 %. PMBM = *p*-methoxybenzyloxymethyl; 9-BBN = 9-borabicyclo[3.3.1]nonane; Ms = methanesulfonyl; DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; DMAP = 4-(dimethylamino)pyridine.

elongation of the carbon chain at C6 (Scheme 4). First, 1,3-diol **29** was converted into acetonide **30**, of which stepwise reduction to the alcohol and subsequent protection with TBS afforded **31**. Then, deprotection of the benzylidene acetal of **31** under Birch conditions produced diol **32**, and the secondary alcohol at C29 was quantitatively protected as its TES ether to give **33** in a three-step sequence. Oxidation of the remained primary alcohol of **33** with SO₃·py followed by addition of MeMgBr led to secondary alcohol **34**, which was further oxidized to ketone **35**. Treatment of **35** with the Tebbe reagent[21] resulted in exo olefin **36**. Regio- and stereo-selective hydroboration of diene **36** was realized with 9-BBN to generate **37** with the desired C36-methyl stereochemis-

Scheme 4. TBS = *tert*-butyldimethylsilyl; TBAF = tetrabutylammonium fluoride; PDC = pyridinium dichromate.

try.[22] Primary alcohol **37** was in turn transformed into pivaloyl ester **38**, from which the silyl protecting groups (except TIPS) were removed with TBAF to afford **39**. After selective oxidation of diol **39** with PDC to form aldehyde **40**, the 29-OH group was converted into the TMS ether to afford **41**. Addition of allylmagnesium bromide to the C6 aldehyde of **41** and a subsequent reprotection–deprotection sequence gave **42**. Lastly, introduction of iodine at C26 of alcohol **42** furnished **3**, appropriately functionalized for the next coupling reaction.

The stage was now set for union of the two highly complex structural fragments **2** and **3** and subsequent macrocyclization by RCM (Scheme 5). Lithiation of dithiane **2** with *t*BuLi in THF/HMPA at −78 °C was immediately followed by addition of a precooled solution of iodide **3**,[23] delivering the coupling adduct **43** in 95 % yield based on recovered **3**. After many unsuccessful attempts to effect the macrocyclization of **44**, it was found that the silyl protecting groups proximal to the terminal olefins impeded the RCM reaction, presumably owing to steric shielding of the reaction sites. Therefore, the TES (10-OH) and two TMS groups (6-, 29-OH) were selectively removed with TBAF at 0 °C to produce triol **44**. Gratifyingly, macro-RCM reaction of **44** was enabled by the action of Grubbs catalyst **45**,[24] resulting in the formation of 27-membered carbocycle **46** with the *E* olefin (75 % yield).

Prior to construction of the EF-ring system within the obtained macrocycle, dithiane **46** was transformed into

dimethyl acetal **47** with the Stork reagent ((CF₃CO₂)₂IPh, MeOH).[25] Then, **47** was sequentially subjected to TFA/MeOH and CSA/MeOH,[26] which led to deprotection of the acetonide and silyl protecting groups, and concomitant cyclization of the desired EF-ring of **48** in 71 % yield over the sequence. Notably, the preexisting trioxadispiroacetal moiety was left intact under these acidic conditions.

With the synthesis of the entire macrocyclic structure of **1** completed, the end game for the total synthesis entailed specific functional-group manipulations of the highly complicated molecule. The C10 allylic alcohol of pentaol **48** was oxidized with DDQ to afford α,β-unsaturated ketone **49**,[27] which was converted into ketone **50** by 1,4-reduction of the C8–C9 double bond with the Stryker reagent.[28] The exo methylene group was then introduced at C10 of **50** by Wittig reaction to provide **51**. The Ts and TES groups were sequentially introduced to 1-OH and 28-OH of **51**, respectively, and the 6-OH group was oxidized with Dess–Martin periodinane[29] to give ketone **52**. Displacement of tosylate of **52** with azide generated **53**, which was treated with acid to remove the MOM and TES groups, affording triol **54**. Allylic alcohol **54** was then oxidized to carboxylic acid **55** in a two-step sequence (MnO₂[30] then NaClO₂).

To obtain pinnatoxin A (**1**) directly from **55**, intramolecular aza-Wittig reaction of azide **55** was attempted in the presence of PMe₃.[4d] However, **1** was not detected in the reaction products, and the amine was only obtained through
Scheme 5. Reagents and conditions: a) *t*BuLi (1.9 equiv), **2** (1.7 equiv), THF/HMPA (9:1), −78 °C, 95 % based on recovered **3** (41 %); b) TBAF, THF, 0 °C, 89 %; c) **45** (0.1 equiv), CH₂Cl₂, reflux, 75 %; d) (CF₃CO₂)₂IPh, molecular sieves (3 Å), MeOH/CH₂Cl₂ (20:9), room temperature; e) TFA/MeOH (1:20), room temperature; then CSA, MeOH, room temperature, 71 % (over two steps); f) DDQ, 1,4-dioxane/CH₂Cl₂ (1:1), 40 °C, 67 %; g) [{(Ph₃P)CuH}₆] (0.1 equiv), toluene/H₂O (100:1), room temperature, 64 %; h) Ph₃PCH₃Br, *t*BuOK, THF, 0 °C, 64 %; i) *p*-TsCl, Et₃N, DMAP, molecular sieves (4 Å), CH₂Cl₂, room temperature; j) TESCl, imidazole, CH₂Cl₂, room temperature, 51 % (over two steps); k) Dess–Martin periodinane, CH₂Cl₂; l) NaN₃, DMF, 80 °C, 68 % (over two steps); m) aqueous HCl (2 N)/THF (1:10), 40 °C, 96 %; n) MnO₂, CH₂Cl₂, room temperature; o) NaClO₂, NaH₂PO₄, 2-methyl-2-butene, *t*BuOH/H₂O (4:1), 0 °C; p) PMe₃, THF, 60 °C, 0 % (**1**); q) **56**, toluene, 70 °C, 34 % (over three steps); r) PMe₃, THF/H₂O (10:1), room temperature, 60 %.

hydrolysis of the resultant N=P bond. Therefore, we elected to complete the formal total synthesis of **1** simply by reduction of the C1 azide and esterification of the C34 carboxylic acid. Introduction of *t*Bu to **55** with **56**[31] and subsequent treatment with PMe$_3$ in THF/H$_2$O[32] gave rise to amine **57**, which had been transformed into **1** by Kishi in two steps.[33] Our synthetic **57** showed ^{1}H NMR data that was identical to that provided by Professor Kishi.

In summary, we have reported the formal total synthesis of (+)-pinnatoxin A in a highly convergent fashion. The salient methodologies employed in our successful campaign include 1) stereoselective bis-acetalization to yield the BCD-ring fragment **2** effected by exploiting intramolecular hydrogen bonding; 2) intramolecular alkylation of epoxynitrile **4** to construct the G-ring; 3) powerful dithiane coupling to unify the two halves of the molecule (**2** and **3**); 4) macrocyclization of 27-membered carbocycle **46** by utilizing olefin metathesis reaction; and 5) intramolecular acetalization of the complex macrocycle to construct EF-ring **49**.

[14] Existence of this intramolecular hydrogen bond was suggested from the X-ray analysis of a closely related substrate with free hydroxy groups at C10 and C24.[4a] Furthermore, acidic treatment of a 10-OH-protected substrate resulted in nonselective formation of the desired spiroacetal and its C19-epimer despite the seemingly favorable anomeric effect at C19 of the desired compound.

Communications

cyclotrimerization of terminal alkynes and an electron-deficient alkyne (diethyl acetylene dicarboxylate) catalyzed by the cationic [Rh^I(H$_8$-binap)][9] complex.[10] We anticipated that cross cyclotrimerization of terminal alkynes and electron-deficient 1,6-diynes (bearing a *ortho*-substituted phenyl group and a hydrogen atom at each terminal position) would install the axial chirality during the formation of the benzene rings (Scheme 1).[11–14] Very recently, Gutnov, Heller, and co-work-
Scheme 1. Cationic [Rh^I(H$_8$-binap)]-catalyzed cross alkyne cyclotrimerization to give axially chiral phthalides.

Biaryl Compounds

Enantioselective Synthesis of Axially Chiral Phthalides through Cationic [Rh^I(H$_8$-binap)]-Catalyzed Cross Alkyne Cyclotrimerization**

Ken Tanaka, Goushi Nishida, Azusa Wada, and Keiichi Noguchi*

Axially chiral biaryl compounds are widely found as key structures of effective chiral ligands and biologically active compounds. Therefore, several catalytic enantioselective syntheses of these compounds have been developed to date. These methods are based on three types of asymmetric cross-coupling approaches: 1) cross-coupling of aryl compounds (such as the Kumada coupling,[1] Suzuki coupling,[2] and oxidative coupling[3]), 2) cross-coupling of biaryl ditriflates,[4] and 3) cross-coupling of dinaphthothiophene.[5] In these reactions, the axial chirality is constructed during the formation of the biaryl link, the selective substitution of one of two triflates, and the selective cleavage of one of two carbon–sulfur bonds, respectively.[6, 7]

Cyclotrimerization of alkynes is an attractive method for the synthesis of substituted benzenes, and various transition-metal complexes catalyze this reaction.[8] We recently reported the chemo- and regioselective intermolecular cross

ers reported the synthesis of axially chiral 2-aryl pyridines through the Co^I-catalyzed asymmetric [2 + 2 + 2] cycloaddition of alkynes and nitriles,[15] and Shibata et al. reported the synthesis of axially chiral teraryl compounds through a neutral [Ir^I(Me-duphos)] complex catalyzed asymmetric [2 + 2 + 2] cycloaddition of symmetrical α,ω-diynes and symmetrical monoynes.[16] Herein we describe a highly enantioselective synthesis of axially chiral phthalides by the cationic [Rh^I(H$_8$-binap)] complex catalyzed cross alkyne cyclotrimerization of unsymmetrical α,ω-diynes and unsymmetrical or symmetrical monoynes.[17]

The reaction of 2-methylphenyl-substituted 1,6-diyne **1a** with various terminal monoynes was investigated in the presence of the cationic complex [Rh^I{(S)-H$_8$-binap}]. We were pleased to find that the use of propargyl acetate (**2a**; 5 equiv) furnished axially chiral phthalide (+)-**3aa** in high yield with high enantioselectivity (Table 1, entry 1). Not only

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

2-methylphenyl-, but also 1-naphthyl- (**1b**, Table 1, entry 2), 2-trifluoromethylphenyl- (**1c**, Table 1, entry 3), and 2-chlorophenyl-substituted 1,6-diynes (**1d**, Table 1, entry 4) were suitable substrates in this process. Importantly, the generation of sterically demanding regioisomers **3** was predominant. In the case of **1d**, the use of propargyl alcohol (**2b**) improved the enantioselectivity (Table 1, entry 5).

Interestingly, the use of symmetrical internal monoyne, 1,4-diacetoxy-2-butyne (**2c**; 5 equiv), enhanced the enantioselectivity to yield axially chiral phthalides **3ac–dc** in good yield with excellent enantioselectivity (Table 2, entries 1–4).

5[b]	**1a**	**2d**	(+)-**3dd**	63	>99

[a] Yields of isolated products. [b] Solvent: THF.

In the case of **1d**, the use of 2-butyne-1,4-diol (**2d**) improved the yield and enantioselectivity (Table 2, entry 5). The absolute configuration of the diol (+)-**3dd** was determined to be *R* by an anomalous dispersion method, and that of the diacetate (+)-**3dc** was also determined to be *R* (Figure 1).[18]
Figure 1. ORTEP Diagram of (*R*)-(+)-**3dd** drawn at the 50% probability level. Hydrogen atoms have been omitted for clarity.

The present enantioselective cross alkyne cyclotrimerization was applied to the symmetrical internal diyne **2e**, and the chiral phthalides **5** and **6** were obtained in excellent yield with high enantioselectivity (Scheme 2).
Scheme 2. Cross alkyne cyclotrimerization of **1d** and symmetrical internal diyne **2e**.

In conclusion, we have discovered an enantioselective cross alkyne cyclotrimerization of unsymmetrical 1,6-diynes and both terminal and internal alkynes. This method provides easy access to axially chiral phthalides that bear one or two oxymethylene functionalities. Work toward developing a wide variety of asymmetric reactions in the presence of cationic complexes of Rh^I and modified binap is underway in our laboratory.

Experimental Section

Full procedures and characterization data are given in the Supporting Information. **3ac**: Under an Ar atmosphere, (*S*)-H$_8$-binap (7.9 mg, 0.0125 mmol) and [Rh(cod)$_2$]BF$_4$ (5.1 mg, 0.0125 mmol) were dissolved in CH$_2$Cl$_2$ (1.0 mL), and the mixture was stirred for 5 min. H$_2$ was introduced to the resulting solution in a Schlenk tube. The resulting mixture was stirred for 30 min at room temperature and then concentrated to dryness. The residue was taken up in CH$_2$Cl$_2$ (1.0 mL), and to this solution was added a solution of **1a** (49.8 mg, 0.250 mmol) and **2c** (212.7 mg, 1.25 mmol) in CH$_2$Cl$_2$ (1.0 mL) at room temperature; the vial was rinsed with CH$_2$Cl$_2$ (0.5 mL). The mixture was stirred at room temperature for 3 h. The resulting mixture was concentrated and purified by preparative TLC to furnish (+)-**3ac** (61.7 mg, 0.167 mmol, 67%, >99% ee) as a yellow solid. M.p. 95.0–97.5 °C; $[\alpha]_D^{25} = +17.3°$ (*c* = 0.274, CHCl$_3$); IR (neat): $\tilde{\nu}$ = 1740, 1220, 1020 cm^{-1}; ^{1}H NMR (CDCl$_3$, 400 MHz): δ = 7.60 (s, 1H), 7.22–7.36 (m, 3H), 7.01 (dd, *J* = 7.6 and 1.2 Hz, 1H), 5.33 (s, 2H), 5.29 (d, *J* = 3.2 Hz, 2H), 4.99 (d, *J* = 12.8 Hz, 1H), 4.88 (d, *J* = 12.8 Hz, 1H), 2.17 (s, 3H), 1.98 (s, 3H), 1.97 ppm (s, 3H); ^{13}C NMR (CDCl$_3$, 100 MHz): δ = 170.3, 170.0, 168.6, 147.5, 143.2, 142.6, 135.8, 133.7, 133.2, 129.7, 128.6, 128.5, 125.5, 123.4, 121.5, 68.2, 63.4, 59.8, 20.9, 20.6, 20.0 ppm; HRMS (EI): calcd for C$_{21}$H$_{20}$O$_6$ [M]$^+$: 368.1260; found: 368.1226; CHIRALPAK AS, hexane/*i*PrOH 80:20, 0.8 mL min^{-1}, retention times: 28.6 min (minor isomer) and 30.3 min (major isomer).

Tungsten–Lead Triple Bonds: Syntheses, Structures, and Coordination Chemistry of the Plumbylidyne Complexes *trans*-[X(PMe₃)₄W≡Pb(2,6-Trip₂C₆H₃)]**

Alexander C. Filippou,* Nils Weidemann, Gregor Schnakenburg, Holger Rohde, and Athanassios I. Philippopoulos

Compounds containing a multiple bond between lead and another main-group element are very rare.[1] In fact, only a few diplumbenes, $[Pb_2R_4]$ (R = aryl, silyl),[2] have been isolated to date,[3,4] whereas alkenes are ubiquitous in organic chemistry. Similarly, very few transition-metal plumbanediyl (plumbylene) complexes have been reported,[5] whereas carbene complexes are a common class of organometallic compounds.[6] Other prominent examples of compounds containing transition-metal–lead multiple bonds are the heterocumulenes $[(\eta^5\text{-}C_5H_4R)(CO)_2Mn{=}Pb{=}Mn(CO)_2(\eta^5\text{-}C_5H_4R)]$ (R = H, Me).[7] Two major reasons have emerged from quantum chemical studies for the distinct reluctance of lead to participate in multiple bonding. These are the comparatively low bond energies[8] and the reduced hybridization of its 6s and 6p valence orbitals.[9,10] However, these are not inherent properties of lead, as recently demonstrated by our synthesis of the plumbylidyne complex *trans*-$[Br(PMe_3)_4Mo{\equiv}Pb(2,6\text{-}Trip_2C_6H_3)]$, which features a triply bonded, linear-coordinated lead atom.[11] We have now characterized compounds with tungsten–lead triple bonds. First results of the coordination chemistry of these compounds are also presented, providing experimental evidence for their electronic analogy with Fischer-type carbyne complexes.[12]

Starting materials were the dinitrogen complexes *cis*-$[W(N_2)_2(PMe_3)_4]$ and $[W(N_2)(PMe_3)_5]$[13] and the aryllead(II) halides $[\{Pb(2,6\text{-}Trip_2C_6H_3)X\}_2]$ (X = Br (**1**-Br), I (**1**-I)). Compound **1**-I was prepared by metathetical exchange of **1**-

Br[14] with NaI in diethyl ether. It was isolated in 82% yield as an air-sensitive, bright orange solid, which melts at 222°C and decomposes at 235°C to give an oily, red mass.[15] Compound **1**-I is the first organolead(II) iodide to be structurally characterized.[16] It crystallizes as a centrosymmetric iodide-bridged dimer, which features a Pb_2I_2 parallelogram with a Pb···Pb separation of 4.603(1) Å[17] and two quite different Pb−I bond lengths (2.9499(7) and 3.2764(8) Å) and internal bond angles (84.81(2) and 95.19(2)°; Figure 1). The Pb−C$_{aryl}$ bond length of **1**-I at 2.326(6) Å compares well with those of
Figure 1. DIAMOND plot of the molecular structure of **1**-I in the solid state. Thermal ellipsoids are set at 30% probability. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pb-I 2.9499(7), Pb-I# 3.2764(8), Pb-C1 2.326(6); C1-Pb-I 97.3(2), C1-Pb-I# 115.1(2), I-Pb-I# 84.81(2), Pb-I-Pb# 95.19(2).

1-Br (2.306(13) and 2.329(11) Å).[14] Heating a solution of *cis*-[W(N$_2$)$_2$(PMe$_3$)$_4$] with a stoichiometric amount of **1**-Br or **1**-I in toluene at 100°C was accompanied by a rapid color change from orange to red-brown to afford the plumbylidyne complex **2**-Br and **2**-I, respectively (Scheme 1).[15,18] Compounds **2**-Br and **2**-I were purified by crystallization from pentane and isolated as red-brown, air-sensitive, microcrystalline solids in 66 (**2**-Br) and 58% (**2**-I) yields. Both complexes are very soluble in pentane and decompose upon melting at 195 and 192°C, respectively. The plumbylidyne complex **2**-Br was also obtained in a straightforward manner by the reaction
Scheme 1. Syntheses of the plumbylidyne complexes **2**-X (X = Br, I).

of [W(N$_2$)(PMe$_3$)$_5$] with 0.5 equivalents of **1**-Br in toluene at 100°C (Scheme 1).[15] This reaction provides another example for the aptitude of electron-rich[19] Group 6 metal dinitrogen complexes with a d^6 electron configuration to form triple bonds to lead. Compounds **2**-Br and **2**-I are essentially isotypic (Figure 2).[15] The isostructural, *trans*-configured
Figure 2. DIAMOND plot of the molecular structure of **2**-I in the solid state. Thermal ellipsoids are set at 30% probability. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°] of **2**-I and [**2**-Br]: W-Pb 2.5477(3) [2.5464(5)], W-I 2.8656(4) [W-Br 2.6798(9)], W-P1 2.4776(9) [2.474(2)], W-P2 2.481(1) [2.484(2)], W-P3 2.4663(9) [2.461(2)], W-P4 2.486(1) [2.485(2)], Pb-C1 2.258(3) [2.254(6)]; W-Pb-C1 175.79(8) [177.5(2)], I-W-Pb 177.857(8) [Br-W-Pb 179.05(3)], Pb-W-P1 90.00(2) [90.17(5)], Pb-W-P2 98.17(2) [100.88(5)], Pb-W-P3 89.01(2) [89.17(4)], Pb-W-P4 102.45(3) [102.84(6)].

octahedral complexes have approximate C_2 point group symmetry,[20] and display almost linear W-Pb-C$_{aryl}$ linkages (**2**-Br, 177.5(2)°; **2**-I, 175.79(8)°) and the shortest W−Pb bonds (**2**-Br, 2.5464(5) Å; **2**-I, 2.5477(3) Å) reported to date.[21] In fact, the W−Pb bond lengths of **2**-Br and **2**-I are 0.20 Å shorter than those of the bridged plumbylidyne complex [{W(CO)$_4$}$_2$(μ-Br){μ-Pb(2,6-Trip$_2$C$_6$H$_3$)}] (2.7423(3) and 2.7517(3) Å), which contains a three-coordinate lead center with trigonal-planar geometry,[14] and approximately 0.45 Å shorter than the W−Pb single bonds of the V-shaped tungstenoplumbylene [Pb(2,6-Trip$_2$C$_6$H$_3$){W(η^5-C$_5$H$_5$)(CO)$_3$}] (2.9809(10) and 3.0055(6) Å).[21d] The Pb−C$_{aryl}$ bonds of **2**-Br (2.254(6) Å) and **2**-I (2.258(3) Å) are shorter than those of **1**-Br and **1**-I (Figure 1), or those reported for the plumbylenes [Pb(2,6-Trip$_2$C$_6$H$_3$)R] (R = Me, *t*Bu, Ph: Pb−C$_{aryl}$ 2.272(9)–2.321(3) Å)[14] and metalloplumbylenes [Pb(2,6-Trip$_2$C$_6$H$_3$){M(η^5-C$_5$H$_5$)(CO)$_3$}] (M = Cr, Mo, W: Pb−C$_{aryl}$ 2.278(9)–2.294(4) Å),[21d] and indicate that the triply bonded lead atom uses sp-hybrid orbitals for σ bonding. The composition of **2**-Br and **2**-I was confirmed by elemental analyses and IR, ^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR spectroscopy.[15] The number and relative intensity of the ^{1}H NMR spectroscopy signals of the *m*-terphenyl substituent and the PMe$_3$ ligands suggest an averaged C_{2v} symmetry of the plumbylidyne complexes **2**-Br and **2**-I in solution, and their ^{31}P{^{1}H} NMR spectra in C$_6$D$_6$ showed a singlet for the four chemically equivalent PMe$_3$ ligands, which appears up field (**2**-Br, δ =

−43.6 ppm; **2**-I, $\delta = -53.9$ ppm) of those of the lighter Group 14 element analogues trans-[Cl(PMe$_3$)$_4$W≡E-R] (E = C, R = Me: $\delta_P = -20.8$ ppm, ^1J(W,P) = 285 Hz;[22] E = Ge, R = C$_6$H$_3$-2,6-Dipp$_2$ (Dipp = 2,6-iPr$_2$C$_6$H$_3$): $\delta_P = -31.1$ ppm, ^1J(W,P) = 258 Hz; E = Sn, R = 2,6-Dipp$_2$C$_6$H$_3$: $\delta_P = -30.8$ ppm, ^1J(W,P) = 256 Hz).[23] The ^{31}P NMR signals are flanked by one pair of satellites arising from coupling with the ^{183}W nucleus,[24] the ^1J(W,P) coupling constants (**2**-Br, 257 Hz; **2**-I, 258 Hz) comparing well with those of the ylidyne complexes trans-[Cl(PMe$_3$)$_4$W≡E-R] (E = Ge, Sn; R = aryl, see above). The ^{13}C{^{1}H} NMR spectra of the plumbylidyne complexes **2**-Br and **2**-I display a characteristic downfield-shifted signal for the lead-bonded C$_{ipso}$ atom at $\delta = 270.2$ (**2**-Br) and 267.9 ppm (**2**-I), as do those of the aryllead(II) halides **1**-Br ($\delta_C = 287.9$ ppm)[14] and **1**-I ($\delta_C = 276.7$ ppm).[15]

Electrophile-induced halide abstraction was shown to be a very efficient method for the preparation of cationic Fischer-type carbyne complexes from neutral precursors.[25] Application of this method to **2**-Br and **2**-I was envisaged as an approach to cationic plumbylidyne complexes, given the electronic analogy of **2**-Br and **2**-I with Fischer-type carbyne complexes.[12] In fact, treatment of **2**-Br with Na[B{3,5-(CF$_3$)$_2$C$_6$H$_3$}$_4$][26] and PhCN in toluene afforded the brown benzonitrile complex salt **3**, and bromide abstraction from **2**-Br by Li[B(C$_6$F$_5$)$_4$]·2.5 Et$_2$O[27] in fluorobenzene gave in the presence of PMe$_3$ the olive-green to brown plumbylidyne complex salt **4** [Eq. (1)].[15] Both salts are soluble in THF, and decompose upon melting at 181–182 (**3**) and 149–150 °C (**4**).

$$\text{2-Br} \xrightarrow[\substack{- \text{MBr} \\ (M = \text{Na, Li})}]{+ M[B(Ar_F)_4], + L} \left[L-W\equiv Pb-R \right]^+ [B(Ar_F)_4]^- \quad (1)$$

2-Br

3, L = PhCN, Ar$_F$ = 3,5-(CF$_3$)$_2$C$_6$H$_3$
4, L = PMe$_3$, Ar$_F$ = C$_6$F$_5$

R = 2,6-Trip$_2$C$_6$H$_3$
The structures of the complex cations in **3** and **4** (Figures 3 and 4) reveal the same bonding features of the plumbylidyne ligand as observed in **2**-Br and **2**-I. These are the almost linear coordination geometry at lead (W-Pb-C$_{aryl}$ = 171.7(1) (**3**), 177.5(1)° (**4**)), the short W−Pb triple bonds (2.5520(6) (**3**), 2.5744(2) Å (**4**)), and the comparatively short Pb−C$_{aryl}$ bonds of 2.228(5) Å (**3**) and 2.289(4) Å (**4**). The W−P bond of the trans-disposed PMe$_3$ ligand in **4** is longer (2.565(1) Å) than those of the cis-coordinated PMe$_3$ ligands (2.490(1)–2.513(1) Å), reflecting the trans-influence of the plumbylidyne ligand.[28] ^{1}H, ^{31}P{^{1}H}, ^{19}F{^{1}H}, and ^{13}C{^{1}H} NMR spectroscopic studies corroborated the X-ray structures of **3** and **4**.[15] Thus, the IR spectrum of **3** in nujol displays a characteristic ν(C≡N) band of the benzonitrile ligand at 2171 cm^{-1}, which is at lower wavenumbers than that of free PhCN (ν(C≡N) in nujol = 2230 cm^{-1}) and indicates some tungsten–nitrile back-bonding.[29] In addition, the ^{31}P{^{1}H} NMR spectrum of **3** shows a singlet resonance at $\delta = -36.8$ ppm (^1J(W,P) = 262 Hz) for the PMe$_3$ ligands, which confirms the trans-configuration of the complex cation in **3**. In
Figure 3. DIAMOND plot of the structure of the complex cation in **3**. Thermal ellipsoids are set at 30% probability. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: W-Pb 2.5520(6), W-N 2.099(4), W-P1 2.469(1), W-P2 2.472(2), W-P3 2.493(2), W-P4 2.496(2), Pb-C1 2.228(5), C49-N 1.137(7); W-Pb-C1 171.7(1), N-W-Pb 174.9(1), Pb-W-P1 90.28(4), Pb-W-P2 95.69(4), Pb-W-P3 91.56(4), Pb-W-P4 104.96(4), W-N-C49 179.1(5).
Figure 4. DIAMOND plot of the structure of the complex cation in **4**. Thermal ellipsoids are set at 30% probability. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: W-Pb 2.5744(2), W-P1 2.500(1), W-P2 2.490(1), W-P3 2.513(1), W-P4 2.495(1), W-P5 2.565(1), Pb-C1 2.289(4); W-Pb-C1 177.5(1), Pb-W-P1 87.10(3), Pb-W-P2 93.90(3), Pb-W-P3 88.93 (3), Pb-W-P4 92.93(3), Pb-W-P5 174.87(3).

comparison, the ^{31}P{^{1}H} NMR spectrum of **4** reveals the signal pattern expected for a nonfluxional, square-pyramidal W(PMe$_3$)$_5$ fragment, that is, one doublet at $\delta = -52.1$ ppm (^2J(P,P) = 31 Hz, ^1J(W,P) = 249 Hz) and one quintet at $\delta = -65.6$ ppm (^2J(P,P) = 31 Hz) in the intensity ratio of 4:1.[15] The structures of **3** and **4** are also confirmed by the Pb-C$_{ipso}$ resonance signal in the ^{13}C{^{1}H} NMR spectra at $\delta = 278.7$ (**3**) and 279.1 ppm (**4**). The C$_{ipso}$ signal of **4** is split into a doublet as a result of coupling with the trans-disposed PMe$_3$ ligand (^3J(P,C) = 22 Hz).

The similarity of the plumbylidyne complex [(PMe$_3$)$_5$W≡ Pb(2,6-Trip$_2$C$_6$H$_3$)]$^+$ with the Fischer-type carbyne complexes

Table 1: Results of the bonding analyses of the cation of **4**.

[a] BP86/LANL2DZ; Natural bond orbital analysis of the W−Pb bond: NBO occupancies, bond polarization in %W and %Pb, orbital hybridization, and Wiberg bond index. [b] Natural population analysis. [c] Gibbs free dissociation energy (298.15 K, 1 atm) of the W−Pb bond to the fragments in their relaxed geometries and electronic ground states (zero point energy (ZPE) corrected). [d] Energy decomposition analysis (BP86/TZ2P for Pb, W, and P, and DZP for C and H): Pauli repulsion (ΔE_{Pauli}), electrostatic interaction (ΔE_{elstat}), orbital interaction (ΔE_{orb}), and total interaction energy ΔE_{int} between the fragments [W(PMe$_3$)$_5$] and [Pb(2,6-Trip$_2$C$_6$H$_3$)]$^+$ at their frozen geometries in the complex cation.

[(CO)$_5$M≡C-NEt$_2$]$^+$ (M = Cr, Mo, W) is noticeable.[30] This fact prompted us to study the nature of the W−Pb bond in **4** by various quantum chemical methods. Optimization of the structure of the complex cation at the BP86/LANL2DZ level of theory led to a minimum structure with a W−Pb separation of 2.609 Å and a bond angle at the lead atom of 174.9° in good agreement with the experimental values (Figure 4). Analysis of the electronic charge distribution by the natural bond orbital (NBO) method[31] gives an optimal Lewis structure with a W−Pb triple bond. The W−Pb bond is composed of a σ component that is polarized towards the lead atom, and two nearly degenerate π bonds, which are strongly polarized towards the tungsten center (Table 1). The high polarity of the W−Pb bond is further reflected in the natural population analysis (NPA) partial charges of the Pb (+1.21) and W atom (−1.58) and the Wiberg bond index (WBI) of 1.42 (Table 1), which is slightly lower than that of the model compound *trans*-[Br(PH$_3$)$_4$Mo≡Pb-Ph] (WBI = 1.51).[11] Partitioning of the total interaction energy ΔE_{int} (−410.9 kJ mol^{-1}) between the frozen fragments [W(PMe$_3$)$_5$] and [Pb(2,6-Trip$_2$C$_6$H$_3$)]$^+$ into the attractive Coulomb term ΔE_{elstat} of −352.0 kJ mol^{-1}, the repulsive Pauli term ΔE_{Pauli} of +472.0 kJ mol^{-1}, and the orbital interaction term ΔE_{orb} of −530.9 kJ mol^{-1} affords a covalent character of 60% for the W≡Pb bond.[32] All these results suggest that the W−Pb triple bond of **4** can be reasonably described with the Dewar–Chatt–Duncanson model as a donor–acceptor interaction involving a [PbR]$^+$→ [W(PMe$_3$)$_5$] σ donation and two [W(PMe$_3$)$_5$]→[PbR]$^+$ π back-donations.[33]

Finally, the Gibbs free dissociation energy of **4** to give the fragments [W(PMe$_3$)$_5$] and [Pb(2,6-Trip$_2$C$_6$H$_3$)]$^+$ in their electronic ground states and minimum geometries[34,35] was calculated to be only 149.7 kJ mol^{-1}, which suggests that the complex cation might be useful as a [Pb-R]$^+$ transfer reagent.

Several applications of these compounds in stoichiometric reactions might be envisaged given their structural and electronic analogy with Fischer-type carbyne complexes.

Cycloadditions

A Lewis Acid Catalyzed Intramolecular [4+3] Cycloaddition Route to Polycyclic Systems That Contain a Seven-Membered Ring**

*Gildas Prié, Natacha Prévost, Heather Twin, Stephanie A. Fernandes, Jerome F. Hayes, and Michael Shipman**

Oxyallyl cations are important intermediates in the synthesis of seven-membered rings by way of [4+3] cycloadditions with 1,3-dienes.[1] The products commonly serve as useful templates in organic synthesis.[2] Intramolecular cycloadditions of oxyallyl cations are especially useful for the construction of complex polycyclic systems.[1e,f,3] For example, Harmata and co-workers have used this approach to make aphanamol I, widdrol, and (+)-dactylol.[1e] Less well-studied are 2-amino-allyl cations, which also participate in [4+3] cycloadditions.[4] Interestingly, these *N*-substituted cations appear to have some advantages over the more extensively studied oxyallyl cations. For example, Cha and co-workers have shown that in some situations cycloadditions that involve 2-aminoallyl cations proceed in higher yields and/or with enhanced stereocontrol.[4g] Furthermore, Kende and Huang have shown that asymmetric induction (up to 60% *ee*) is possible in [4+3] cycloadditions that involve 2-aminoallyl cations by incorporating a chiral, nonracemic element into the cation.[4h] Despite these potential benefits, 2-aminoallyl cations are not widely used because methods for their generation are rather limited. Typically, they involve the solvolysis of unstable α-chloro-enamines[4a,d–g] or 2-chloroimines[4c,h] with stoichiometric amounts of silver(ɪ) salts.

As part of a program aimed at exploring the scope and utility of 2-methyleneaziridines **1** in organic synthesis,[5] we realised that these heterocycles might serve as alternative precursors to 2-aminoallyl cations. As methyleneaziridines can be functionalised readily at C3,[5c] we felt that this methodology might be especially useful for the development of intramolecular [4+3] cycloadditions. The general strategy

is depicted in Scheme 1. Lithiation and alkylation of **1** with an appropriately functionalized 1,3-diene is expected to provide direct entry to cycloaddition precursor **2**. Complexation of the nitrogen atom of **2** to a suitable Lewis acid might then
Scheme 1. Proposed Lewis acid catalyzed intramolecular [4+3] cycloaddition of 2-methyleneaziridines.

generate the highly strained and reactive aziridinium ion **3**,[6] which could be expected to undergo fragmentation to Lewis acid complexed 2-aminoallyl cation **4**. Further intramolecular reaction with the appended 1,3-diene would lead to cycloheptenone imine **5**. Thus, in just two synthetic operations, polycyclic systems might be produced from the readily accessible methyleneaziridine **1**. Herein we report our initial studies, which demonstrate the validity of this new approach to seven-membered rings.

A variety of cycloaddition precursors **6–12** were made to probe this chemistry in detail with respect to changes in the 1,3-diene and aziridine components as well as in the nature of the linking tether (Table 1). Lithiation of *N*-benzyl-2-isopropylidineaziridine (*s*BuLi, TMEDA, −78 °C, THF, 5 h) and further reaction with 2-(3-iodopropyl)furan (**13**), 2-(4-iodobutyl)furan (**14**), and 7-iodo-hepta-1,3-diene provided **6** (67%), **7** (71%) and **8** (83%), respectively, after column chromatography. Similarly, reaction of *N*-benzyl-2-cyclohexylidineaziridine with **13**, and separately **14**, gave **9** (61%) and **10** (62%), respectively. We used geometrically pure (*Z*)- and (*E*)-*N*-benzyl-2-ethylideneaziridine,[5d] to produce (*Z*)-**11** (59%) and (*E*)-**11** (71%), respectively, by lithiation and reaction with **13**. Finally, deprotonation and diastereocontrolled alkylation of (*S*)-*N*-(1-phenylethyl)-2-isopropylidineaziridine gave **12** (63%) as a single diastereomer whose relative configuration was assigned by correlation with literature data.[5c]

Initial cycloaddition studies were conducted on furan-tethered aziridine **6**, which bears a three-carbon linking chain between the reaction partners. After some experimentation, it was determined that treatment of **6** with excess BF$_3$·OEt$_2$ (150 mol%) in dichloromethane at room temperature for 16 h yielded tricyclic imine **15** in 67% yield as a single stereoisomer after silica-gel chromatography (Table 1, entry 1). The structure and stereochemistry of **15** were unambiguously confirmed by X-ray crystallography after reduction of the imine from the *Si* face with sodium cyanoborohydride and conversion of the resulting amine

[f] Ring junction stereochemistry confirmed by NOE difference experiments.

into its crystalline hydrochloride salt (data not shown). Significantly, **6** could also be converted into **15** by using just a catalytic amount (10 mol%) of scandium(III) triflate (Table 1, entry 2).[7] Representative procedures are provided in the Supporting Information. Ketone products can be isolated from these reactions by inclusion of an acidic workup step. For example, reaction of aziridine **7** with either BF$_3$·OEt$_2$ or Sc(OTf)$_3$ provided tricyclic ketone **16**, again as a single

diastereomer, after workup with aqueous H$_2$SO$_4$ in methanol (Table 1, entries 3 and 4). The reaction is not limited to electron-rich dienes such as furan. For example, aziridine **8**, which incorporates a simple monosubstituted 1,3-diene, reacts to give **17** as a mixture of diastereomers. In this case, better yields were obtained by heating **8** and BF$_3$·Et$_2$O in 1,2-dichloroethane at reflux for 48 h prior to acidic hydrolysis (Table 1, entry 5). The reaction also accommodates changes in the nature of the structure of the methyleneaziridine component (Table 1, entries 6–10). However, we have been unable to determine if intramolecular cyclo-additions proceed with methyleneaziridines that do not bear carbon substituents on the alkene terminus.[8] Interestingly some stereochemical "memory" is apparent in the cycloaddition of (Z)- and (E)-**11**. Both produce **20** and **21**, but the relative amounts of these two diastereomers is dependent on the alkene geometry in the starting material (Table 1, entries 8 and 9). The assignment of the relative stereochemistry within **20** and **21** was made on the basis of the vicinal coupling constant between 7-H and 8-H (**20**: $J_{7,8} = 5.3$ Hz; **21**: $J_{7,8} = 0.0$ Hz).[9] The conversion of diastereomerically pure **12** into near equal quantities of tricycles **22** and **23** is mechanistically significant as it reveals that the stereochemical homogeneity at C3 of **12** is almost completely lost during the cyclo-addition (Table 1, entry 10).

We propose that the cycloadditions of **6**, **8**, **9**, **11**, and **12** proceed via a compact transition state, with the tethering arm orientating itself *anti* to the bulky Lewis acid complexed amino substituent. This is illustrated for the conversion of (Z)- and (E)-**11** into the major products **20** and **21** via **24** and **25**, respectively (Scheme 2). In support of this hypothesis, it is known that cyclic 2-aminoallyl cations favor compact transition states.[4a] Furthermore, the loss of stereochemical integrity in the conversion of **12** into **22** and **23** is consistent with the formation of a planar 2-aminoallyl cation. To account for the switch in stereochemical outcome in the preparation of **16** (and **19**), an extended transition state may prevail with a longer linking tether.[10] However, in considering the analysis of these reactions, it is important to bear in mind that other mechanistic alternatives cannot be ruled out. For example, the formation of **15–23** might proceed in a stepwise manner by direct nucleophilic attack of the 1,3-diene unit onto the aziridinium cation **3**, followed by subsequent ring closure of the resulting enamine onto the allylic cation derived from the diene.[11] Efforts to obtain direct evidence
Scheme 2. Postulated transition states for the formation of **20** and **21**.

for the involvement of allylic cation **4** have thus far proved unsuccessful.[12]

To conclude, a very concise new entry into a range of polycyclic systems that contain seven membered rings has been devised based on an intramolecular Lewis acid catalyzed [4+3] cycloaddition of methyleneaziridines. Efforts to develop asymmetric variants of this chemistry by using chiral Lewis acid catalysts or chiral, nonracemic methyleneaziridines are currently ongoing in our laboratory.

[6] Protonation and methylation of *N*-substituted methyleneaziridines with HFSO₃/SbF₅ and [Me₂Cl]⁺[SbF₅Cl]⁻, respectively, are known to produce the corresponding methyleneaziridinium cations; see: E. Jongejan, H. Steinberg, T. J. de Boer, *Recl. Trav. Chim. Pays-Bas* **1978**, *97*, 145.

[7] Examples of catalytic [4+3] cycloadditions of allyl cations are uncommon; for a recent example with scandium(III) triflate, see: M. Harmata, U. Sharma, *Org. Lett.* **2000**, *2*, 2703.

[8] Attempts to make substrates that bear two hydrogen atoms on the exocyclic double bond of the methyleneaziridine have been hampered by their lack of stability during silica-gel chromatography. However, preliminary experiments establish that 2-methyleneaziridines do participate in *intermolecular* [4+3] cycloadditions. For example, the reaction of 1-(1-phenylethyl)-2-methyleneaziridine with excess furan (BF₃·Et₂O (1.5 equiv), CH₂Cl₂, room temperature, 16 h; then aqueous AcOH (1M), 2 h) yields 8-oxabicyclo[3.2.1]octan-3-one in 24% yield (unoptimized).

[9] A. M. Montaña, S. Ribes, P. M. Grima, F. Garcia, *Magn. Reson. Chem.* **1998**, *36*, 174.

[10] In the case of **16** (and **19**), it is conceivable that the switch in the preferred diastereomer is not due to a change in the cycloaddition transition state but results from thermodynamic equilibration of the α stereocenter of the ketone during hydrolysis. From labeling experiments, we know that hydrolysis (D₂SO₄/D₂O in CD₃OD) leads to some deuterium incorporation (≈36% D) into **16** at the center α to the ketone.

[11] For recent theoretical studies on [4+3] cycloadditions that support stepwise mechanisms, see: M. Harmata, P. R. Schreiner, *Org. Lett.* **2001**, *3*, 3663; J. A. Sáez, M. Arnó, L. R. Domingo, *Org. Lett.* **2003**, *5*, 4117.

[12] A large downfield shift of the signal for the aziridine methylene group is observed in the ¹H NMR spectrum (400 MHz, CD₂Cl₂) of *N*-benzyl-2-isopropylideneaziridine upon addition of BF₃·Et₂O (150 mol%) which suggests coordination of the nitrogen atom of the aziridine to the Lewis acid. Selected data: uncomplexed: $\delta = 2.37$ ppm (2 H, s); complexed: $\delta = 3.09$ (1 H, s), 2.52 ppm (1 H, s). However, signals for the allylic cation were not observed.

Oxidation

Catalytic Oxidation of CO with N_2O on Gas-Phase Platinum Clusters**

O. Petru Balaj, Iulia Balteanu, Tobias T. J. Roßteuscher, Martin K. Beyer, and Vladimir E. Bondybey**

Herein we report the observation of the full catalytic cycle of CO oxidation with N_2O on cationic platinum clusters for Pt_n^+, $n = 6$–8, in the gas phase studied by Fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometry. Platinum is

the key catalytic metal for a variety of industrial and environmental applications, for example, it catalyzes the oxidation of CO with O_2 in catalytic converters. This reaction has been studied in detail on surfaces.[1] In the present study, N_2O was chosen as oxidant because small platinum clusters can undergo loss of platinum atoms by formation of PtO_2 by reaction with O_2.[2] Gas-phase reactivity studies with bare transition-metal ions and clusters have been a useful tool to elucidate elementary steps in catalysis.[3–6] Irion and co-workers demonstrated the catalytic formation of benzene from ethylene catalyzed by Fe_4^+ in the gas phase,[7] during which collision-induced desorption of C_6H_6 from the cluster was necessary to close the catalytic cycle. Ervin and co-workers demonstrated that the elementary steps of the catalytic cycle of the oxidation of CO with N_2O are possible on anionic platinum clusters.[8–11] Schwarz and co-workers showed that the platinum cation Pt^+ already exhibits catalytic activity, including full cycles of CO and methane oxidation.[12–18] Andersson and Rosén provided strong evidence for catalytic oxidation of H_2 with O_2, forming H_2O on neutral platinum clusters in a flow reactor, albeit without resolving the detailed kinetics of the reaction.[19] Previous studies of gas-phase platinum clusters[1,8–11,19–28] were limited in size range and mass resolution by the use of platinum targets with natural isotope distribution. A laser vaporization source requires only minor amounts of materials, permitting work with isotopically enriched samples.[29] We recently showed that full kinetic information of gas-phase reactions of cationic and anionic platinum clusters with up to 24 atoms can be obtained by using nearly pure ^{195}Pt.[30] This size range is vital for comparison with the reactivities of size-selectively deposited clusters on surfaces, as studied for example, by Heiz et al.[31,32]

When platinum cluster cations in a size range from 5 to 10 are stored in the ICR cell together with a 1:6 mixture of CO and N_2O, for some cluster sizes sequential addition of CO is observed, while for others, a steady state between the bare platinum cluster and its oxides is established. Although Pt_5^+ forms Pt_5O^+ and $Pt_5O_2^+$, it efficiently reacts by attaching CO molecules. Pt_6^+ reaches a steady state with Pt_6O^+, and, to a small extent, $Pt_6O_2^+$ and $Pt_6O_3^+$ are also visible. Pt_7^+ establishes a steady state with Pt_7O^+ and $Pt_7O_2^+$ in a ratio of about 1:2:4. Pt_8^+ behaves somewhat similarly to Pt_7^+, with Pt_8^+ and Pt_8O^+ as dominant species. Pt_9^+ and Pt_9O^+ keep a constant branching ratio, but their intensities decrease, because Pt_9^+ sequentially attaches CO ligands. Pt_{10}^+ efficiently attaches CO without any indication of catalytic activity.

Mass-selection experiments confirm that a steady state is indeed established for the Pt_7^+ group. When Pt_7O^+ was mass selected after 2 s, the constant intensity ratio between Pt_7^+, Pt_7O^+, and $Pt_7O_2^+$ is again established within 3 s after mass selection, which proves that catalytic oxidation of CO takes place, involving the four reactions [Eqs. (1)–(4)]:

$$Pt_7^+ + N_2O \rightarrow Pt_7O^+ + N_2 \tag{1}$$

$$Pt_7O^+ + N_2O \rightarrow Pt_7O_2^+ + N_2 \tag{2}$$

$$Pt_7O_2^+ + CO \rightarrow Pt_7O^+ + CO_2 \tag{3}$$

$$Pt_7O^+ + CO \rightarrow Pt_7^+ + CO_2 \tag{4}$$
After very long reaction delays of 150 s, $Pt_7CO_{8-10}^+$ species are observed to a very small extent. Evidently, by addition of multiple CO molecules, some bare Pt_7^+ ions are removed from the catalytic cycle. To learn more about this process of catalyst poisoning, and to establish the number of CO molecules necessary to quench the oxidation reaction, we changed the experimental conditions in favor of poisoning. A 5:3 mixture of CO and N_2O was used in the ICR cell, and Pt_7CO^+ was mass selected after 1 s. Subsequently, Pt_7CO^+ is (with almost equal probability) either converted back into Pt_7^+, which becomes available for the catalytic cycle described above, or it attaches a second CO molecule to form $Pt_7(CO)_2^+$ [Eqs. (5)–(7)]:

$$Pt_7^+ + CO \rightarrow Pt_7CO^+ \tag{5}$$

$$Pt_7CO^+ + N_2O \rightarrow Pt_7^+ + CO_2 + N_2 \tag{6}$$

$$Pt_7CO^+ + CO \rightarrow Pt_7(CO)_2^+ \tag{7}$$
Mass selection of $Pt_7(CO)_2^+$ under otherwise similar conditions shows efficient addition of further CO molecules, whereas Pt_7CO^+ is barely visible over the full course of the reaction. This observation unambiguously shows that a second CO ligand effectively poisons the cluster, although a minor contribution of CO_2 formation, at most 10% of the efficiency for Pt_7CO^+, cannot be fully excluded. The cluster then presumably adds CO molecules until the surface is fully saturated [Eq. (8)]:

$$Pt_7(CO)_n^+ + CO \rightarrow Pt_7(CO)_{n+1}^+, \ n = 2 - 9 \tag{8}$$
Figure 1 shows the kinetics of the Pt_7^+ catalytic cycle when using a 1:6 mixture of CO and N_2O without mass selection, as this yields the best signal to noise ratio. To decrease the number of fit parameters, we have used the previously published absolute rate constants of Equations (1) and (2).[30] In addition, the rate constant of Equation (6) was taken from the mass selection of Pt_7CO^+. Absolute rate constants and reaction efficiencies of Equations (1)–(7) are summarized in Table 1. As seen in Figure 1, the steady state between Pt_7^+, Pt_7O^+, $Pt_7O_2^+$, and Pt_7CO^+ is established within 5 s. Towards longer reaction times, the intensities slowly decrease, and the poisoned clusters become more and more intense. By extrapolating the exponential decrease of the ions involved in the catalytic cycle, the active lifetime of a cluster in the cycle is estimated to be 750 s. From the reaction rate constants and the intensities of the reactant ions in Equations (3), (4), and (6), one can estimate that each Pt_7^+ cluster converts 0.687 CO molecules into CO_2 per second. Over the lifetime of the cluster in the cycle, this amounts to a total of 515 CO_2 molecules formed.

The full catalytic cycle together with the poisoning mechanism is summarized in Scheme 1. Efficient catalytic conversion of CO into CO_2 is achieved in three different ways, either by CO colliding with the oxide species Pt_7O^+ or $Pt_7O_2^+$ (Equations (3) and (4)), or by N_2O oxidizing preadsorbed CO
Figure 1. Kinetic fit of the Pt_7^+ reactions with a 1:6 mixture of CO and N_2O. Pt_7^+ ● reacts very fast to form Pt_7O^+ ■ and $Pt_7O_2^+$ ▲. The described steady state is established between the three species within 5 s. Pt_7^+ also reacts efficiently with CO to form Pt_7CO^+ ◆, which, in turn, can either revert back to Pt_7^+ ● or can very slowly attach a second CO molecule to form $Pt_7(CO)_2^+$. Additional CO molecules are then attached until the cluster is fully saturated. The final product of CO attachment is $Pt_7(CO)_{10}^+$. The visible $Pt_7(CO)_n^+$ ◀, $n = 2, 8, 9, 10$, are summed together for clarity. Owing to the low intensity of $Pt_7(CO)_2^+$, it was not possible to include it separately in the fit. The gray area denotes the noise level.

Table 1: Absolute rate constants k_{abs} and efficiencies calculated from ADO theory[37,38] for the reactions of Pt_7^+.

Reaction	k_{abs} [10^{-11} cm^3 s^{-1}]	Efficiency [%]
[Eq. (1)]	96.2	154.1[a]
[Eq. (2)]	48.9	78.4
[Eq. (3)]	179.8	287.9[a]
[Eq. (4)]	231.1	370.1[a]
[Eq. (5)]	71.9	115.1[a]
[Eq. (6)]	61.7	98.8
[Eq. (7)]	15.4	24.7

[a] Efficiencies above 100% are obtained because the collision rate is calculated by using a point-charge model, whereas the cluster has a finite size.
Scheme 1. Catalytic cycle of the Pt_7^+ ion in a 1:6 mixture of CO and N_2O. The catalytic cycle is running efficiently between Pt_7^+, Pt_7O^+, $Pt_7O_2^+$, and Pt_7CO^+. Additional CO molecules increasingly poison the cluster. Conversion of $Pt_7(CO)_2^+$ back into Pt_7CO^+ might contribute to a minor extent to the catalytic cycle.

on Pt_7CO^+ (Equation (6)). A minor contribution from $Pt_7(CO)_2^+$ to CO_2 formation is possible, but the absence of $Pt_7(CO)_n^+$ with $n = 3$–7 and the appearance of the $n = 8$–10 species in the mass spectra clearly indicate that CO addition is the only significant process for $n = 3$–9.

If N_2O is present in sufficient excess, the concentration of Pt_7^+ in the steady state is small, and the catalytic cycle runs mostly through Equations (2) and (3) between Pt_7O^+ and $Pt_7O_2^+$. Very few Pt_7CO^+ ions are formed and these are, in turn, almost entirely converted back into Pt_7^+, before attachment of a second or third CO molecule can occur. This gas-phase catalytic cycle thus exhibits a typical characteristic of large-scale catalytic processes: The partial pressures of the reactants can be adjusted to suppress catalyst poisoning.

Our preliminary data for other cluster sizes indicate that the catalytic activity with respect to CO oxidation by N_2O is determined by the reactivity of the bare cluster with N_2O.[30] This seems eminently reasonable: A high reactivity with N_2O shifts the cluster intensities in the steady state in favor of the oxide species and thus hinders the poisoning reaction by sequential CO addition to the bare cluster. For larger clusters, however, the picture becomes more complicated. Owing to their larger surface, adsorption of CO on Pt_nO^+ becomes feasible, presumably at a site that is remote from the oxygen atom. For example, for Pt_{20}^+, it seems that $Pt_{20}OCO^+$ becomes an observable intermediate in the catalytic cycle. Such larger clusters, as well as anionic species, are currently under investigation.

Alternating Hetero H Aggregation of Different Dyes by Interstrand Stacking from Two DNA–Dye Conjugates**

Hiromu Kashida, Hiroyuki Asanuma,* and Makoto Komiyama

DNA is a naturally occurring supramolecule that spontaneously forms a stable duplex with its complementary strand. Recent developments in phosphoramidite chemistry have made it possible to introduce various functional molecules or metal complexes into DNA.[1] In these modified DNA structures, non-natural molecules or metal ions are aligned in an ordered manner and exhibit interesting properties that are rarely found in the monomeric state, such as the "fluorosides" demonstrated by Kool and co-workers.[2]

Dye aggregates are known to exhibit properties that the corresponding monomers do not show. Control of the aggregation is important,[3] especially in the fields of photoinduced electron transfer[4] and enhancement of nonlinear optical properties.[5] Previously, we introduced multiple methyl red moieties into DNA and successfully prepared stable H* and H aggregates that are characterized by a

narrowing of the absorption band as well as hypsochromic shift.[6,7] The number of dye molecules and their orientation are easily controlled by programming the automated DNA synthesizer with the correct sequence. Various aggregates that are impossible to prepare by self-association of dyes are easily programmable through the covalent attachment of dye to DNA (conjugation of dye and DNA). One example of this is a heteroaggregate in which two different dyes are stacked alternately (Scheme 1a). Dye aggregates are conventionally
Scheme 1. Schematic illustration of a) preparation of heteroaggregates and b) modified DNA synthesized in this study.

prepared by the spontaneous self-association of dye monomers,[3] so alternating alignment of two different dyes is very difficult in solution. In our study, dye molecules are introduced into each strand and dye aggregates are prepared by hybridization of these strands. As far as we know, preparation of this type of heteroaggregate has not yet been reported. It is widely known that H aggregation of identical dyes (homo H aggregate) shows both a narrowing and hypsochromic shift of the band because of the strong exciton coupling, as predicted by McRae and Kasha.[8] However, there has been little investigation of whether similar narrowing of the band occurs in heteroaggregation, both from experimental and theoretical viewpoints.

Here, we report for the first time hetero H aggregates, which are difficult to prepare with a conventional method,[3] by the use of two DNA–dye conjugates (Scheme 1a). This heteroaggregate showed a new sharp absorption band that

was different from those of the individual dyes, which indicates that exciton coupling occurs even between the different dyes.

Methyl red and naphthyl red (designated as **M** and **N**, respectively, in Scheme 1b) were introduced into the DNA on D-threoninol linkers from the corresponding phosphoramidite monomers, as reported previously.[6,9] The pK_a values of methyl red and naphthyl red in the single-stranded DNA were 4.1 and 5.8,[9] respectively, as determined from the change of their absorption maxima. At pH 5.0, where all the spectroscopic experiments were conducted, methyl red was neutral whereas naphthyl red was protonated (Scheme 1b). 1,3-Propanediol (**S** residue in Scheme 1b) and dye residues were alternated in the middle of the sequence.[10,11] Aqueous solutions of **MS3A** and **NS3B** exhibited absorption maxima at 462 and 520 nm, respectively (Figure 1).[12] Interestingly, a
Figure 1. UV/Vis spectra of **MS3A/NS3B** duplex (a), single-stranded **MS3A** (c), **NS3B** (d), and simple sum of the spectra of **MS3A** and **NS3B** (b) at 0°C, pH 5.0 (10 mM MES buffer) in the presence of 100 mM NaCl.

new single sharp band appeared at 478 nm when these two strands **MS3A** and **NS3B** were hybridized (Figure 1). A simple sum of the spectra of the single-stranded **MS3A** and **NS3B** solution was very broad and different from the spectrum of the **MS3A/NS3B** duplex (compare the lines in Figure 1). In addition to the new absorption band, a single strong circular dichroism (CD) band with a sharp and symmetrical positive Cotton effect was induced at around 480 nm (Figure 2b). These spectroscopic behaviors demonstrate that methyl red and naphthyl red in the heteroaggregates optically interacted with each other (H band) and had different spectroscopic properties from those in the monomeric states.

This sharp new band became broad on elevating the temperature, and at 60°C, which is higher than the melting temperature T_m of the **MS3A/NS3B** duplex,[13] the spectrum almost coincided with the simple sum of the two individual spectra of **MS3A** and **NS3B** (Figure 2a). This result also supports the hypothesis that the new band is attributed to heteroaggregation. Concurrently, the strong induced CD signal disappeared at 60°C (Figure 2b).

The peak maximum of the heteroaggregates appeared in the middle of those for homoaggregates (H aggregates) of methyl red (**MS3A/MS3B**) and naphthyl red (**NS3A/NS3B**) in

Communications

both UV/Vis and CD spectra (Figure 3). This fact indicates that the new narrow band for the heteroaggregates is an H band derived from exciton coupling among the chromo-

Figure 3. a) UV/Vis and b) CD spectra of heteroaggregates (**MS3A/NS3B**; 2), naphthyl red homoaggregates (**NS3A/NS3B**; 3), and methyl red homoaggregates (**MS3A/MS3B**; 1) at 0°C, pH 5.0 (10 mM MES buffer) in the presence of 100 mM NaCl.

phores.[14–16] This assignment is further supported by the fact that an increase in the aggregation number resulted in a larger hypsochromic shift (see the Supporting Information).[8] To our knowledge, the appearance of an H band from two different kinds of dyes has rarely been reported and is not even predicted in the exciton theory.[17]

Notably, not all combinations of chromophores exhibit a hetero H band. In the case of the methyl red/naphthyl red combination, a new sharp H band appeared. But when **MS3A** or **NS3A** was hybridized with **AS3B** involving azobenzenes in which the absorption maximum was located at 330 nm, no significant optical interaction was observed (Figure 4): the UV/Vis spectrum of either **MS3A/AS3B** or **NS3A/AS3B** almost coincided with the simple sum of that of each strand (see the Supporting Information).[18] A certain degree of spectral overlap between the two chromophores is required to produce a hetero H band.[19]

In conclusion, heteroaggregates in which two dyes are stacked alternately can be prepared by interstrand stacking from two DNA–dye conjugates. Even different dyes can exhibit an H band as a result of aggregation. The present method is applicable to other functional molecules, and

various novel materials can be produced by the attachment of dyes to DNA.[17]

Experimental Section

Synthesis of the modified DNA involving dyes: The modified DNA molecules carrying **A**, **M**, **N**, and **S** residues were synthesized with an automated DNA synthesizer by using the corresponding phosphoramidite monomer prepared according to previous papers,[6,9,20] and conventional ones. All the modified DNA molecules listed in Scheme 1 b were purified by reversed-phase HPLC and characterized by MALDI-TOF mass spectrometry.

MALDI-TOF mass spectrometry: **NS3A**: found m/z 5463 (calcd for [**NS3A**−H]$^+$: m/z 5462); **NS3B**: found m/z 5464 (calcd for [**NS3B**−H]$^+$: m/z 5462); **MS3A**: found m/z 5311 (calcd for [**MS3A**−H]$^+$: m/z 5311); **MS3B**: found m/z 5311 (calcd for [**MS3B**−H]$^+$: m/z 5311); **AS3B**: found m/z 5183 (calcd for [**AS3B**−H]$^+$: m/z 5182).

Spectroscopic measurements: The UV/Vis spectra and CD spectra were measured on JASCO model V-530 and JASCO model J-725 instruments with 10-mm quartz cells, respectively. Both of them were equipped with programmed temperature controllers. The conditions for the sample solutions were: [NaCl] = 100 mM, pH 5.0 (10 mM β-morpholinoethanesulfonic acid (MES) buffer), [DNA] = 5 μM. The T_m value was determined from the maximum in the first derivative of the melting curve, which was obtained by measuring the absorbance at 260 nm as a function of temperature. The temperature ramp was 1.0°C min^{-1}.

[10] Recently, Brotschi and Leumann reported interstrand stacking of bipyridyl C-nucleotides that were consecutively introduced into the DNA. In our design, dye moieties are separated by **S** residues to avoid firm H* aggregation of methyl red moieties in the single-stranded state. See Refs. [6] and [11].

[11] C. Brotschi, C. J. Leumann, *Angew. Chem.* **2003**, *115*, 1694–1697; *Angew. Chem. Int. Ed.* **2003**, *42*, 1655–1658.

[12] Absorption maxima of monomers of methyl red and naphthyl red in the DNA appeared at around 484 and 546 nm, respectively. See the Supporting Information.

[13] The melting temperature of **MS3A/NS3B** was 50.7 °C, as estimated from the change in absorbance at 260 nm as a function of temperature. See the Supporting Information for the actual melting curve.

[14] The possibility of a charge-transfer band is ruled out because the absorption band of the charge-transfer complex usually appears at a longer wavelength than those of individual dyes. See Ref. [15].

[15] S. A. Lee, S. Hotta, F. Nakanishi, *J. Phys. Chem. A* **2000**, *104*, 1827–1833.

[16] The relative alignment of the chromophores will be discussed in detail elsewhere.

[17] Since exciton coupling occurs over very short ranges (within 1.0 nm), our present finding would be applicable to the detection of short-distance interaction.

[18] A contribution of the reduction of the conformers or local polarity change to the band narrowing of **MS3A/NS3B** is unlikely, because significant narrowing was not observed for the combination with **AS3B** involving **A** residues that are structurally similar to **M**.

[19] We attributed the optical inactivity of the azobenzene/naphthyl red or azobenzene/methyl red combinations to the large difference in the absorption maximum, but more detailed analyses are needed.

Evidence for the Structure of the Enantioactive Ligand in the Phosphine–Copper-Catalyzed Addition of Diorganozinc Reagents to Imines[**]

Alexandre Côté, Alessandro A. Boezio, and André B. Charette*

Substantial efforts have been invested recently in the design and development of new chiral ligands for the asymmetric catalytic synthesis of simple chiral building blocks. Among the most effective and popular coordinating groups for chiral ligands are phosphorus-based groups due to their inherent ability to bind strongly but reversibly to several transition metals. However, even though redox processes have been reported between the phosphorus ligand and some transition metals,[1] this potentially harmful process that could lead to important ligand modification has never been highlighted in asymmetric copper-catalyzed reactions. One well-known example is the reduction of Pd^{II} salts into Pd^0 with Ph_3P to produce $Ph_3P=O$ as the by-product.[2] It has also been reported that Cu^{II} salts are reduced by 1,2-bis(diphenylphosphino)ethane to produce several phosphine/phosphine oxide ligands.[3] It is surprising to see that even though Cu–phosphine complexes have been used extensively in asymmetric catalysis (conjugate additions and reduction,[4] nucleophilic addition to ketones,[5] enamines[6] and imines[7]) the in situ oxidation of the ligand has never been observed nor highlighted as the key step for high asymmetric induction. In this communication, we demonstrate that the oxidation of Me-duphos (**1**) by Cu^{II} salts to produce the highly effective monoxide ligand **2** (see Figure 1) is a key event for the high asymmetric induction of the Cu-catalyzed addition of di-

organozinc to *N*-phosphinoylimines. We also report that the efficiency of the oxidation is highly dependent upon the nature of the copper salt and the counterion used in the process.

We recently reported that Cu·**1** is an efficient catalyst for the addition of diorganozinc compounds to imines[8] (Table 1, entry 1). We later disclosed that the replacement of one phospholane group by the hemilabile phosphine oxide (ligand **2**) led to a significant increase of the reaction rate and enantiomeric excesses (Table 1, entry 2).[9]

Table 1: Effect of the order of addition in the Me-duphos-catalyzed reaction.

Entry	Method[a]	Ligand	Conv. [%]	*ee* [%]
1	A	**1**	92	89
2	A	**2**	100	97
3	B	**1**	38	0
4	B	**2**	100	97

[a] Method A: 1) Cu(OTf)$_2$ (6 mol%) and ligand **1** or **2** (3 mol%), 2) addition of Et$_2$Zn (2 equiv); method B: 1) Cu(OTf)$_2$ (6 mol%) and Et$_2$Zn (2 equiv), 2) addition of ligand **1** or **2** (3 mol%).

Although these two reactions appear to differ simply by the selection of the ligand, we were puzzled by the observation that the level of enantiocontrol was greatly dependant upon the order of addition to the reagents. For example, a high level of stereocontrol was observed with both ligands if Cu(OTf)$_2$ was mixed with Me-duphos or bozphos prior to the addition of Et$_2$Zn. In sharp contrast, no enantioselection was observed with Me-duphos if the Cu^{II} salt was initially reduced with Et$_2$Zn (to generate EtCu) followed by the addition of the chiral ligand (Table 1, entry 3). Conversely, the order of addition did not affect the *ee* value of the product if bozphos was used (Table 1, entry 4). One explanation for this behavior is that the Cu·**1** complex is only a precatalyst for the reaction, and it needs to undergo phosphine oxidation to generate the more reactive and selective Cu·**2** complex. To demonstrate whether Me-duphos oxidation is a viable pathway under the reaction conditions, we undertook a systematic spectroscopic investigation of the reaction to identify whether **2** or **3** is formed upon treatment with Cu salts. Unfortunately, the reaction could not be followed by in situ NMR methods due to the presence of paramagnetic Cu^{II}/Cu^0 species and the rapid equilibration and disproportionation between various complexes.

To overcome this problem, we removed the residual Cu salts from the crude reaction mixture by treatment with aqueous KCN under deoxygenated conditions. This is a nice alternative to the use of dithiocatechol dilithium salts, which have been used to scavenge and recover phosphine ligands.[10] Each ligand (**1**–**3**) was submitted to Cu(OTf)$_2$/Et$_2$Zn by the normal or reverse-addition protocol. After a standard KCN workup, the crude mixture was analyzed by ^{31}P NMR

spectroscopy (Table 2). The first striking observation is that significant oxidation (up to 20%) of one of the free phosphine of Me-duphos was observed when the ligand was initally premixed with Cu(OTf)$_2$ (Table 2, entry 2). Conversely,

Table 2: Oxidation of ligands **1**–**3** by Cu(OTf)$_2$.

Entry	Starting ligand	Method[b]	Prod. ratio[c] **1:2:3**
1	**1**	A	96:3:1
2	**1**	B	76:20:4
3	**2**	A	0:98:2
4	**2**	B	0:94:6
5	**3**	A	0:0:100
6	**3**	B	0:0:100

[a] Cu(OTf)$_2$ was purchased from Strem Chemical Inc. [b] Method A: 1) Cu(OTf)$_2$ (2 equiv) and Et$_2$Zn (10 equiv), 2) addition of ligand **1**, **2**, or **3** (1 equiv); method B: 1) Cu(OTf)$_2$ (2 equiv) and ligand **1**, **2**, or **3** (1 equiv), 2) addition of Et$_2$Zn (10 equiv). [c] The ratios were determined by quantitative ^{31}P NMR spectroscopy, and the mass recovery was >70%. See the Supporting Information for details.

inverting the order of addition almost completely suppressed the oxidation of the phosphine (only 3% of bozphos was formed; Table 2, entry 1). The same series of experiments carried with bozphos (**2**) indicated that very little oxidation to give **3** (2–6%) was observed regardless of the order of addition. This is not too surprising since the monoxide should be less prone to oxidation than Me-duphos. The relatively low level of oxidation with procedure A could be attributed to the background oxidation during the workup under a noninert atmosphere and not to a formal oxidation of phosphorus by the in situ formed EtCu.

The next step was to establish whether other species present in the reaction mixture could potentially oxidize Me-duphos to give bozphos (Table 3). CuOTf also led to significant oxidation of Me-duphos (up to 39%; Table 3, entry 2). Conversely, both CuCl and CuOAc led to lower levels of phosphine oxidation, indicating that the nature of the counterion is also important. Since the level of oxidation appeared to be somewhat dependant upon the source of the copper salt used, we began to suspect that the presence of water could accelerate the oxidation process. Indeed, a much higher amount of oxidized product **2** was observed if a

Table 3: Oxidation of **1** with various copper salts.

1 $\xrightarrow[\text{(2 equiv)}]{\text{CuX}}$ **1**+**2**+**3**

Entry	CuX	Source	Prod. ratio[a] **1:2:3**
1	(CuOTf)$_2$·benzene	freshly prepared	75:20:5
2	(CuOTf)$_2$·toluene	commercial	55:39:6
3	CuOAc	commercial	90:8:2
4	CuCl	commercial	96:3:1
5	Cu(OTf)$_2$·2.3 H$_2$O	freshly prepared[b]	52:42:6

[a] The ratios were determined by quantitative ^{31}P NMR spectroscopy. [b] Hydration of commercial Cu(OTf)$_2$ and analyzed by elemental analysis.

partially hydrated form of Cu(OTf)$_2$ was used (Table 3, entry 5). We also noticed that the nature of the phosphine is also very important since the replacement of Me-duphos by PPh$_3$ under the conditions given in Table 3, entry 2 led to about 5% of Ph$_3$P=O.

Plots of the course of the reaction with (Table 1, entries 3 and 4) with different ligands ligand using the reverse-addition procedure are shown in Figure 2. The data strongly suggest
Figure 2. Plot of the course of the reaction with ligands **1–3** (3 mol% ligand/6 mol% Cu(OTf)$_2$). □ = Me-duphos (**1**), ○ = bozphos (**2**), △ = bozphos (**2**) without Cu, × = Me-duphos bisoxide (**3**).

that the ligand **2** is responsible for the highly enantioselective pathway. One striking feature is the difference in the reactivity between complex Cu^I·**1** and Cu^I·**2** in the reaction. This accounts for the observation that high enantioselectivities are obtained even when both complexes are present (Table 1, entry 1). The excellent catalytic activity of bis(phosphine) monoxide complexes has been observed in several reactions.[11–13] Further evidence for the structure of the active catalyst resides in the demonstration that the reaction displays first-order kinetics in catalyst (1:1 stoichiometry ligand:Cu; Figure 3).

In conclusion, this paper highlights the very important observation that this copper–phosphine-catalyzed process
Figure 3. Plot showing that the reaction is first order in catalyst. Ratio bozphos/Cu(OTf)$_2$ = 1:1.

involve an initial phosphine oxidation, leading to a more reactive and selective metal complex.

Communications

highly enantioselective Mannich-type reactions between hydroxyaryl ketones and preformed imines. Jørgensen and co-workers developed direct asymmetric Mannich reactions involving activated ketones as donors which are catalyzed by chiral copper(II) bisoxazoline (BOX) complexes.[12] It was not until recently that researchers demonstrated that amino acid derivatives function as metal-free catalysts for direct asymmetric intermolecular reactions.[13, 14] List et al.,[15] Barbas and co-workers,[16] and we have developed direct organocatalytic asymmetric Mannich reactions of this type that involve ketones as donors.[17] Asymmetric Mannich-type reactions with aldehydes as nucleophiles and preformed α-imino glyoxylate esters as the electrophiles have also been developed.[18] More recently, we developed direct organocatalytic one-pot three-component cross-Mannich reactions.[19] In addition, Jacobsen and Wenzel,[20a] Terada and Uraguchi,[20b] and others have reported excellent organocatalytic asymmetric Mannich-type reactions.[20]

Despite the intense research on the catalytic enantioselective Mannich reaction, there is to our knowledge only one example of a catalytic one-pot three-component α-aminomethylation reaction. In this example, Shibasaki and co-workers demonstrated a catalytic enantioselective reaction between a ketone, amine, and formaldehyde, which furnished the corresponding Mannich base in 16% yield with 64% *ee*.[9] Based on this initial investigation and our recently developed organocatalytic asymmetric α-hydroxymethylation reaction,[21] we became interested in whether organocatalysis could be applied to this transformation. An amino acid catalyzed one-pot three-component reaction would be a more effective and economical process, which would provide a new tool for the α-aminomethylation of ketones [Eq. (1)].

Asymmetric Synthesis

Direct Catalytic Enantioselective α-Aminomethylation of Ketones**

Ismail Ibrahem, Jesús Casas, and Armando Córdova*

The classical Mannich reaction,[1] in which an aminomethyl group is introduced in the position α to a carbonyl function, has found a multitude of applications in organic chemistry.[2] The resulting Mannich bases are of particular interest due to their biological activity as analgesics, antioplastics, and antibiotics, and as synthetic building blocks and precursors of pharmaceutically valuable γ-amino alcohols.[2] However, regardless of the immense importance of this reaction only a few stereoselective α-aminomethylation reactions have been developed.[3] For example, Enders et al. employed enantiomerically pure α-silyl ketones in diastereoselective α-aminomethylation reactions.[4]

Chemists have developed several stoichiometric, indirect, stereoselective Mannich transformations that utilize preformed enol equivalents or imines.[5] More recently, the first successful examples of catalytic asymmetric additions of enolates to imines were reported by Kobayashi and co-workers,[6] which has led to intense research into catalytic indirect Mannich reactions.[7] For example, Hoveyda and co-workers developed an elegant one-pot three-component silver-mediated Mannich-type reaction.[8] Recently, Shibasaki and co-workers reported that heterodimetallic complexes are catalysts for the direct asymmetric Mannich reaction.[9] Shibasaki and co-workers [10] and Trost and Terrell[11] also developed binuclear organozinc complexes that catalyze

(1)

Herein, we disclose one-pot three-component direct organocatalytic Mannich reactions between aqueous formaldehyde and ketones that furnished α-aminomethylated ketones with yields of up to 94% and >99% *ee*. The reactions were catalyzed by proline and its derivatives with excellent chemo- and enantioselectivity.

In an initial experiment we treated cyclohexanone **1a** (2 mmol) with formaldehyde **2** (1 mmol, 36% aqueous solution) and *para*-anisidine (1.1 mmol) in the presence of a catalytic amount of (*S*)-proline (10 mol%) in dimethylsulfoxide (DMSO, 4 mL) at room temperature [Eq. (2)]. The reaction was quenched after 20 h, and α-aminomethylated ketone **3a** was isolated in 90% yield with >99% *ee* by column chromatography using neutral aluminium oxide as the

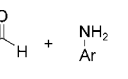
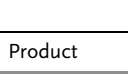
3a: 90% yield, >99% ee

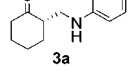
stationary phase.[22] The reactions were also readily performed in *N,N*-dimethylformamide (DMF) and *N*-methylpyrrolidinone (NMP) without decreasing the enantioselectivity.

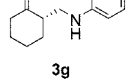
We also performed a catalyst screen using high-throughput chiral-phase high-performance liquid chromatography (HPLC) analyses and found that hydroxyproline derivatives, 5-pyrrolidine-2-yltetrazole, and proline-derived dipeptides catalyzed the α-aminomethylation reactions. For example, *trans*-4-hydroxyproline catalyzed the reaction between ketone **1a**, formaldehyde **2**, and anisidine furnishing **3a** with 90% *ee*.

Next, we performed the corresponding reaction with a set of different aliphatic ketones (Table 1). The reactions were effective, and the corresponding α-aminomethylated ketones **3a–3f** were isolated in high yield with predominantly > 99% *ee*. The reactions proceeded with excellent chemoselectivity, and no aldol adducts could be detected. For acyclic ketones, the reactions were regioselective and the α-aminomethylation occurred predominantly at the methylene carbon atoms of the ketones. For example, α-aminomethylated

Table 1: Proline-catalyzed one-pot three-component direct α-aminomethylation of different ketones.[a]








Entry	Ketone	Product	Yield [%][b]	3:3′	Sel. 3 [% *ee*][c]

[a] Experimental conditions: a mixture of **1** (2 mmol, 2 equiv), **2** (1 mmol), and (*S*)-proline was stirred at room temperature for 16–17 h. The crude product obtained after aqueous workup was purified by column chromatography. PMP = *para*-methoxyphenyl. [b] Yield of the pure products isolated after column chromatography using neutral alumina as the stationary phase. [c] Determined by chiral-phase HPLC analyses. [d] *trans/cis* = 3:1. [e] *ee* of the *trans* isomer.

ketones **3f** and **3f′** were isolated (**3f/3f′** 6:1) in 72% yield for the combined products and with > 99% *ee* for **3f**. The reactions were readily performed on a 10-gram scale in aqueous solvents and in the presence of air without decreasing the yield and the *ee* of the product.

We also examined the variation of the amine component for the catalytic α-aminomethylation reaction. Hence, substituted aniline derivatives were treated with cyclohexanone and formaldehyde in the presence of a catalytic amount of (*S*)-proline (10 mol%; Table 2). In all cases, the reaction furnished the α-arylaminomethylated ketones with > 99% *ee*.

Table 2: Direct catalytic one-pot three-component α-aminomethylation reactions with different aromatic amines.[a]

Entry	Ar	Product	Yield [%][b]	Sel. [% *ee*][c]
1	MeO–C₆H₄–	**3a**	90	> 99
2	I–C₆H₄–	**3g**	45	> 99
3	Br–C₆H₄–	**3h**	71	> 99
4	C₆H₅–	**3i**	92	> 99

[a] Experimental conditions: a mixture of **1** (2 mmol, 2 equiv), **2** (1 mmol), and (*S*)-proline was stirred at room temperature for 16–24 h. The crude product obtained after aqueous workup was purified by column chromatography. [b] Combined yield of products isolated after column chromatography using neutral alumina as the stationary phase. [c] Determined by chiral-phase HPLC analyses.

The α-aminomethylated ketone **3a** was readily reduced with NaBH₄ in situ to give the corresponding monoprotected amino alcohol **4**, which was isolated in 88% yield over the two steps with d.r. (*trans/cis*) 1:1 and > 99% *ee* (Scheme 1). Removal of the *para*-methoxyphenyl (PMP) group under oxidative conditions followed by acetylation afforded the *cis*- and *trans*-diacetylated amino alcohols **5** in 72% yield for the combined products. Optical rotation studies of the *cis* isomer and comparison with published reports revealed that the absolute configuration of the product was *cis*-(1*S*,2*S*)-**5**.[23] As selective reduction of β-amino ketones to both *syn*- and *anti*-1,3-amino alcohols is known, the present procedure is one practical route for the preparation of all of the possible stereoisomers of chiral 1,3-amino alcohols.[24]

Based on the absolute configuration of the product, we propose transition-state model **I** to account for the regio- and enantioselectivity of the α-aminomethylation reaction of unmodified substituted ketones (Scheme 2). Hence, the (*S*)-

Communications

Scheme 2. Transition-state model **I** is evoked to account for the enantioselectivity of the (*S*)-proline-catalyzed reaction.

proline derivative forms an enamine with the ketone that is attacked by the imine from its *si* face, providing (2*S*)-α-aminomethylated ketones. This is in accordance with the transition states of previously reported proline-catalyzed Mannich reactions, in which a *si*-facial attack occurs.[15–19,25]

In conclusion, we have developed a direct catalytic enantioselective method that provides α-aminomethylated ketones in high yield with up to > 99 % *ee*. The reactions were performed without tedious elaboration in wet solvents, were carried out in the presence of air, and could be readily scaled-up. In addition, a high-throughput screen revealed that other proline-derivatives including dipeptides catalyze the reaction with excellent enantioselectivity. To the best of our knowledge, this procedure is the first practical applicable a one-pot three-component catalytic asymmetric α-aminomethylation reaction. Further elaboration of this transformation and its synthetic applications is ongoing in our laboratory.

Experimental Section

Typical experimental procedure (Table 1, entry 1): Ketone **1a** (2 mmol) was added to a vial containing **2** (1 mmol, 36 % aqueous solution) and a catalytic amount of (*S*)-proline (10 mol %) in DMSO (4 mL). After 20 h of vigorous stirring, the reaction was quenched by addition of aqueous NH$_4$Cl, and the aqueous phase was extracted three times with EtOAc. The combined organic layers were dried with MgSO$_4$, which was subsequently removed by filtration. Next, the solvent was removed under reduced pressure, and the crude product mixture was purified by column chromatography using neutral aluminum oxide as the stationary phase (EtOAc/pentane 1:10) to afford α-aminomethylated ketone **3a** in 90 % yield as pale yellow solid. The *ee* value of **3a** was > 99 % as determined by chiral-phase HPLC analysis. **3a**: ^{1}H NMR (CDCl$_3$): $\delta = 1.49$ (m, 2H), 1.67 (m, 2H), 2.10 (m, 2H), 2.35 (m, 2H), 3.05 (dd, $J = 13.3$, 9.3 Hz, 1H), 3.37 (dd, $J = 12.8$, 7.8 Hz, 1H), 3.74 (s, 3H), 6.63 (d, $J = 8.4$ Hz, 2H), 6.77 ppm (d, $J = 8.4$ Hz, 2H); ^{13}C NMR: $\delta = 25.1$, 28.0, 32.3, 42.5, 45.6,

Direct Amino Acid Catalyzed Asymmetric α Oxidation of Ketones with Molecular Oxygen**

Henrik Sundén, Magnus Engqvist, Jesús Casas, Ismail Ibrahem, and Armando Córdova*

Molecular oxygen is fundamental for the existence of complex multicellular life on earth. The initially very small amounts of molecular oxygen is believed to have been formed around 4 billion years ago by the decomposition of CO_2 and water promoted by UV irradiation from the sun.[1] Molecular oxygen can be transferred between its more reactive singlet state ($^1O_2$) and its non-excited triplet state ($^3O_2$).[2] Singlet molecular oxygen ($^1O_2$) plays a significant role in several biochemical processes. For example, it is involved in the development of different diseases and biochemical oxidations.[3,4] Furthermore, chemists have utilized photo- or chemically generated molecular $^1O_2$ as an oxygen source for several synthetic transformations.[1,5] For example, it is used in the formation of allylic hydroperoxides (analogous to the "ene" reaction) and to generate cyclic peroxides (analogous to a Diels–Alder-type reaction). There is a demand in today's society for the development of sustainable chemistry from renewable resources.[6] The content of molecular oxygen in air is 21%, which allows its use in oxidation reactions. Thus, molecular oxygen is one of the ultimate oxidants for oxidation of organic molecules and the development of sustainable chemistry.

Asymmetric reactions that are catalyzed by small organic molecules have received increased attention in recent years.[7] Among several transformations, amine-catalyzed asymmetric epoxidations with dioxirane have been reported.[8] The employment of non-toxic, small organic molecules has the potential for allowing environmentally benign reaction conditions. Based on our previous investigations of organic reactions that are mediated by metal-free organic molecules,[9] we became interested in whether an amino acid would allow the catalytic incorporation of molecular oxygen into ketones [Eq. (1)].[10–11] Moreover, this potential amino acid catalyzed transformation may warrant investigation as a prebiotic pathway for the synthesis of α-hydroxyketones, which are the building blocks of sugars.[12] Herein, we report the unprecedented direct amino acid catalyzed asymmetric incorporation of singlet molecular oxygen into ketones. This α oxidation of ketones with molecular oxygen or air furnished α-hydroxyketones and diols.

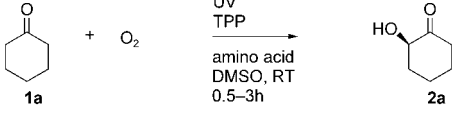
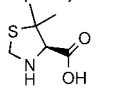
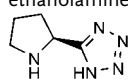
$$(1)$$
In an initial experiment, cyclohexanone **1a** (1 mmol) was added to a vial containing dimethyl sulfoxide (DMSO) (1 mL), L-proline (20 mol%) and tetraphenylporphine (TPP) (1 mol%). A continuous flow of O_2 or air was bubbled through the vial and the reaction was exposed to visible light from a 250-W high-pressure sodium lamp (Scheme 1). To our
Scheme 1. Amino acid catalyzed asymmetric α oxidation of cyclohexanone to give **2a** and in situ reduction to diol **3a**.






delight, complete conversion had occurred after one hour, and the reaction was quenched by aqueous workup. The crude ketone **2a** existed as a mixture of dimeric and oligomeric products. The crude product mixture was purified by silica-gel column chromatography to yield α-hydroxyketone **2a** with 18% *ee*.[13,14] We also performed the reaction with in situ reduction of α-hydroxyketone **2a** with $NaBH_4$ to afford the corresponding optically active *trans*- and *cis*-diols **3a** (*trans*/*cis* = 3:1) in 95% combined yield after silica-gel column chromatography. The enantiomeric excess of the pure *trans*-**3a** diol was determined by chiral-phase GC analyses to be 18% *ee*.

Next, we screened several natural amino acids and their derivatives for their potential in catalyzing the introduction of $^1O_2$ at the α position of **1a** and to improve the stereoselectivity of the reaction (Table 1). We found that several of the amino acids investigated catalyzed the α oxidations with molecular $^1O_2$ with high efficiency and chemoselectivity. The simple amino acids alanine and valine mediated the reaction with the highest stereoselectivity. In fact, this is the first case in which an acyclic amino acid provides higher asymmetric induction than proline and its derivatives in organic solvents. In previously reported direct organocatalytic intermolecular transformations, the catalyst required a cyclic five-membered ring to allow high efficiency and enantioselectivity.[7] However, a higher enantioselectivity was obtained with L-α-methylproline than with L-proline (increase from 18 to 48% *ee* for **2a**). Thus, the presence of a methyl group at the α position of proline significantly increased the stereoselectivity. In contrast, this effect was not observed when comparing valine with α-methylvaline. The asymmetric α oxygenation reactions that were catalyzed by a D-amino acid afforded the opposite enantiomer of **2a** to that obtained in the reactions catalyzed by the corresponding L-amino acid, without affecting the asymmetric induction. Furthermore, amino alcohols, dipeptides, amino acids with amide and amine functionalities, and synthetic amino acid derivatives catalyzed the direct asymmetric introduction of molecular oxygen into

ketones with a similar efficiency to that of the amino acids. However, the amino acid catalysts were superior to the amino alcohols with regards to stereoselectivity. It should be noted that the direct introduction of $^1O_2$ into ketones was also readily catalyzed by glycine and ethanolamine, providing a novel inexpensive entry to α-oxygenated compounds.

We also performed a solvent screen of the L-alanine-catalyzed asymmetric incorporation of molecular oxygen into **1a** in different solvents (Table 2). Direct L-alanine-catalyzed asymmetric α oxidations with $^1O_2$ proceeded smoothly in DMSO, *N*-methylpyrrolidinone (NMP), and *N,N*-dimethylformamide (DMF). In contrast, L-alanine only furnished trace amount of product in MeOH, trifluoroethanol (TFE), and CHCl$_3$. Hence, the best selectivity and efficiency is obtained in the more polar aprotic solvents. We did not observe any significant temperature dependence of the stereoselectivity in DMSO. Furthermore, the reactions were also efficient in aqueous media with air as the molecular oxygen source, which could allow the development of environmentally benign reaction conditions.

Next, we investigated the amino acid catalyzed asymmetric α oxidations with molecular oxygen of various ketones (Table 3). The direct amino acid catalyzed asymmetric α-oxygenation reactions progressed with excellent chemoselectivity and furnished the corresponding α-oxygenated adducts *ent*-**2a** and **2b–e** with good enantioselectivity. For example,

Communications

L-alanine catalyzed the formation of **2c** in 67% yield with 72% *ee*. Furthermore, the amino acid catalyzed reactions with linear acyclic ketones progressed with excellent regioselectivity, and molecular oxygen was asymmetrically incorporated at the most substituted side of the ketone. Moreover, the reactions were readily scaled up and performed on the gram scale. The amino acids were also able to catalyze the asymmetric incorporation of molecular oxygen into unmodified aldehydes.[15] For example, L-α-methylproline furnished (*R*)-2-hydroxy-3-phenylpropanal with 65% *ee*. The direct amino acid catalyzed α oxygenation with molecular $^1O_2$ may be considered as a new, simple, metal-free entry into the synthesis of α-hydroxyketones and diols.

We also tested the amino acid-catalyzed α-oxidations of unmodified ketones with molecular $^3O_2$ as the electrophile in the presence of triethylphosphite.[16] The reactions with molecular $^3O_2$ did not provide the α-hydroxyketone adducts **2** or the diol **3**. Thus, molecular $^1O_2$ is the more reactive electrophile and not $^3O_2$. Moreover, no products were formed in the absence of the amino acid catalysts. We also investigated the possibility of background oxidation by α-hydroperoxide ketone intermediates or another peroxide intermediate that potentially could influence the enantioselectivity of the reaction.[13–14] However, the use of excess (5 equiv) H_2O_2, NaClO, *m*-chloroperbenzoic acid (MCPBA), or oxone as the oxidants for cyclohexanone (1 mmol) in the presence of a catalytic amount of L-proline or L-alanine (20 mol%) in DMSO only provided trace amounts of the diol **3a** after in situ reduction with $NaBH_4$. Furthermore, the L-alanine-catalyzed α oxygenation with $^1O_2$ in the presence of triethylphosphite furnished *ent*-**2a** in 87% yield with 56% *ee*, which is the same *ee* value of *ent*-**2a** obtained without the addition of phosphite (Scheme 2).
Scheme 2. Direct L-alanine-catalyzed introduction of molecular $^1O_2$ to **1a** in the presence of triethylphosphite.

These results indicated that the potential background oxidation by peroxide intermediates was not significant under the set reaction conditions. We were also able to rule out a 1,2-cycloaddition between $^1O_2$ and the catalytic chiral enamine to form a dioxetane intermediate, as no cleavage products from such an intermediate was detected. The stereochemical outcome of the reaction was determined by optical rotation and chiral-phase GC analyses of **2a** and *trans*-**3a**, which revealed that acyclic L-amino acids provided (2*S*)-α-hydroxycyclohexanone *ent*-**2a** and (1*S*, 2*S*)-*trans*-cyclohexane-1,2-diol (*ent*-**3a**). In contrast, L-proline and its derivatives furnished (2*R*)-α-hydroxycyclohexanone (**2a**). The reaction plausibly proceeds through a catalytic enamine mechanism [Eq. (2) and (3)]. Hence, the tentative (2*S*)-α-hydroperoxide intermediate

is formed through proton abstraction by molecular $^1O_2$ from the carboxy group of the acyclic L-amino acids,[14] which provides the sterochemical information, together with addition to the *Re* face of the amino acid derived enamine to furnish (2*S*)-α-hydroxyketone [Eq. (2)]. In the case of α oxygenation mediated by a cyclic L-amino acid, the addition of $^1O_2$ occurs at the *Si* face of the enamine to provide the (2*R*)-α-hydroxyketone [Eq. (3)].

$$(2)$$

$$(3)$$

R' = H, Me
We also established that natural amino acids catalyze the asymmetric incorporation of molecular oxygen into ketones in aqueous buffer. For example, L-alanine catalyzed the direct asymmetric synthesis of *ent*-**2a** in phosphate buffer at 37°C. Moreover, the amino acids mediated the direct catalytic asymmetric α oxidations in air with the sun as the light source. Hence, terrestrial and extraterrestrial amino acids were able to catalyze the introduction of molecular oxygen under prebiotic conditions to form α-hydroxyketones. In fact, the amino acids were able to catalyze the α oxidation of acetone with $^1O_2$ to furnish hydroxyacetone and dihydroxyacetone, which are the building blocks and donors in amino acid catalyzed asymmetric synthesis of sugars under prebiotic conditions.[12a, 17] Thus, the amino acid catalyzed introduction of molecular oxygen may plausibly have served as the first step in their homochirality transfer of their asymmetry to polyhydroxylated compounds, even in the presence of small amounts of oxygen.[12]

In conclusion, we have disclosed the unprecedented ability of amino acids to catalyze the direct asymmetric incorporation of singlet molecular oxygen into ketones. The smallest amino acids alanine and valine catalyzed the transformation with the highest stereoselectivity. The direct catalytic α oxygenations are a novel, inexpensive, operationally simple, and environmentally benign entry to the preparation of α-hydroxyketones and diols. All materials in this process stem from renewable sources, thus allowing a highly sustainable catalytic process. Readily available amino acids allow catalytic asymmetric oxidations with molecular oxygen or air, which has previously been considered to be in the domains of enzymes and chiral transition-metal complexes.

Experimental Section

Typical experimental procedure (Table 1, entry 1): Cyclohexanone (1 mmol) was added to a vial containing TPP (1 mol%) and a catalytic amount of L-alanine (20 mol%) in DMSO (1 mL). A

agrochemicals, flavors, fragrances, and materials. Dynamic kinetic resolution (DKR) is a powerful tool to transform a racemic mixture into one enantiomer.[1] This strategy overcomes the limitation of the maximum 50% yield in a kinetic resolution (KR) by combining it with an in situ racemization of the substrate. Recently the coupling of enzymes and transition metals for the DKR of alcohols has attracted considerable attention.[2,3] In these reactions, in situ racemization by a metal occurs during the enzymatic resolution. The first example was reported by Williams and co-workers who used a rhodium catalyst and a lipase to obtain a DKR of secondary alcohols with moderate efficiency.[4] In 1997 our group reported[5] an efficient DKR process for the synthesis of enantiopure secondary alcohols by the use of ruthenium catalyst **1**[6] in combination with an immobilized lipase. This
method has also been applied to the DKR of different functionalized alcohols, such as hydroxyacid derivatives,[7] hydroxynitriles,[8] azidoalcohols,[9] haloalcohols,[10] hydroxyphosphonates,[11] and diols.[12] Kim, Park, and co-workers have also employed catalyst **1** in the DKR of protected hydroxyacids, diols, and hydroxyaldehydes,[13] and in the asymmetric transformation of ketones and enol acetates to chiral acetates.[14] In general, good yields and enantioselectivities were attained. However, complex **1** suffers from some drawbacks: it is activated at high temperature and therefore a thermally stable enzyme is required. Also, the addition of an appropriate hydrogen source is needed in some cases to prevent ketone formation.

Various ruthenium, rhodium, and iridium complexes are known to catalyze fast racemization of alcohols.[2c,4,5,15,16] Unfortunately, almost all of these catalysts do not work in the DKR of alcohols when combined with the enzyme. Recently, Kim, Park, and co-workers reported that ruthenium catalyst **2** racemizes alcohols within 30 min at room temperature.[17] However, when combined with an enzyme (lipase) in DKR at room temperature, very long reaction times (1.3–7 days) were required, in spite of the fact that the enzymatic reaction (in KR) takes only a few hours.

Very recently we found that complexes **3a–c** catalyze the racemization of chiral alcohols highly efficiently at room temperature after being activated by KOtBu.[18] For example, **3a** (0.5 mol%) racemized (S)-1-phenylethanol within 10 min and resulted in 50% racemization after less than 2 min.

Initial attempts to combine catalyst **3a** (or **3b**) with an enzymatic resolution were unsuccessful and gave either no DKR or led to very long reaction times for the DKR (several days). This was frustrating, as the isolated reactions (racemization and enzymatic resolution) are very fast. Finally, after

some fine-tuning and optimization, we were able to find reaction conditions under which the DKR process has almost the same rate as the kinetic resolution. Herein we report a DKR process (Scheme 1) that is more than two orders of
Scheme 1. DKR of 1-phenylethanol.

magnitude faster than our previous procedures[2,5] and one order of magnitude faster than the hitherto fastest procedure reported.[17] We also provide evidence for the intermediacy of a ruthenium alkoxide complex.

In one experiment a solution of 1-phenylethanol (**4a**) in toluene (0.3 M) was added to a mixture of KOtBu and ruthenium complex **3b**, under an argon atmosphere. After stirring for 5 min, Na$_2$CO$_3$, *Candida antarctica* lipase B (CALB[19]), and isopropenyl acetate were added. After 4 h, only 55% yield of enantiopure (R)-1-phenylethanol acetate (**5a**) was obtained (Table 1, entry 1).[20] Surprisingly, when the

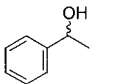
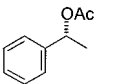
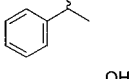
After 4 min CALB (6 mg), Na$_2$CO$_3$ (1 mmol), and isopropenyl acetate (1.5 mmol) were added and the mixture was stirred under an argon atmosphere. [b] Determined by chiral GC. [c] A solution of **4a** in toluene (3.3 mL) was added to a mixture of Ru catalyst and KOtBu. [d] Toluene: 3.3 mL. [e] Yield of isolated product. [f] Under an air atmosphere.

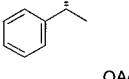
mixture of KOtBu and complex **3b** was stirred for 6 min in toluene before adding the alcohol **4a**, acetate **5a** was obtained in 99% yield with >99% ee in 4 h (Table 1, entry 2). When the concentration of **4a** was increased to 0.5 M, **5a** was obtained after only 3 h in 98% yield (>99% ee) (Table 1, entry 3). Similar results were obtained with catalyst **3a** under the same reaction conditions (Table 1, entry 4). It was observed that the system is very sensitive to molecular oxygen; thus when the reaction was run under an air atmosphere, only 60% yield was attained after 15 h (Table 1, entry 5).

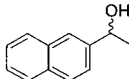
To study the scope of the reaction, a variety of substrates were tested with the reaction conditions used in Table 1, entry 4.[21] For most substrates we obtained the best results when employing 5 mol% of **3a**. The amount of KOtBu needed depends on the substrate and on the amount of CALB employed;[22] therefore it was optimized for each entry. The

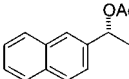
results are summarized in Table 2. Similarly to **5a** (Table 2, entries 1 and 2), the naphthyl derivative **5b** was obtained in 93% yield after 3 h (Table 2, entry 3). The ethyl carbinol **4c** reacts slower with the enzyme and required the use of 40 mg


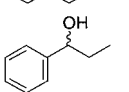


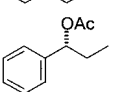


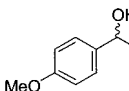


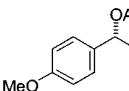


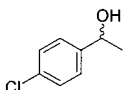


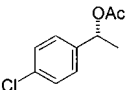


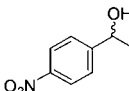


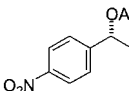


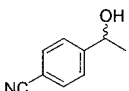


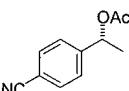


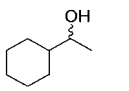


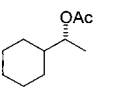


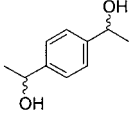


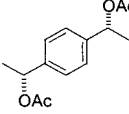












coordination to the ruthenium center. Excellent selectivity and yield were also obtained with the aliphatic substrate **4h** (Table 2, entry 9). DKR of diol **6** is also possible when using 5 mol% of catalyst **3a** at room temperature, although 72 h were needed to attain 93% yield. However, at 50°C enantiopure diacetate **7** was obtained after 10 h in 94% yield (Table 2, entry 10).

The necessity for premixing complex **3a** (or **3b**) with KOtBu in toluene suggests that a new ruthenium complex is formed and this is supported by a color change from yellow to dark red within a few minutes. This intermediate is most likely ruthenium alkoxide **8**, which is crucial for initiating the racemization under DKR conditions. The formation of intermediate **8** is inhibited or slowed down when the substrate alcohol is present in the reaction mixture. A ligand-exchange reaction of **8** with the substrate gives alkoxide **9**, which undergoes β-hydride elimination and forms ruthenium hydride **10** and the oxidized product **11**. Insertion of the ketone into the Ru–H bond produces the racemic alkoxide complex **12**. Alkoxide exchange with *S* alcohol releases *rac* alcohol and regenerates intermediate **9** (Scheme 2).

Alcohol complexes of tungsten, rhenium, and molybdenum have previously been prepared.[23] Recently, Casey et al. observed a Ru–alcohol complex by NMR spectroscopy.[24] Unfortunately, attempts to prepare the alkoxide complex by deprotonation with a base were unsuccessful.[24] The postulated ruthenium alkoxide complex **8** in Scheme 2, would be

Table 2: DKR of various alcohols.[a]

Entry	Alcohol		KOtBu (mol%)	t [h]	Product		Yield [%][b,c]	ee [%][b]
1[d]	OH (1-phenylethanol)	4a	5	3	OAc	5a	98	>99
2		4a	5	3		5a	95 (92)	>99
3	OH (naphthyl)	4b	6.25	3	OAc	5b	93	>99
4[e]	OH (phenyl propyl)	4c	8	17	OAc	5c	92 (90)	>99
5	OH (MeO-phenyl)	4d	7.5	6	OAc	5d	96 (94)	>99
6	OH (Cl-phenyl)	4e	5	6	OAc	5e	93 (91)	>99
7	OH (O2N-phenyl)	4f	5	20	OAc	5f	99 (97)	>99
8	OH (NC-phenyl)	4g	5	20	OAc	5g	98 (95)	>99
9	OH (cyclohexyl)	4h	7	17	OAc	5h	98[f]	>99

[a] Unless otherwise noted, Ru catalyst **3a** (5 mol%), CALB (6 mg), Na₂CO₃ (1 mmol), and KOtBu were stirred in toluene (2 mL) at room temperature for 6 min before adding the alcohol (1 mmol). After 4 min, isopropenyl acetate (1.5 mmol) was added and the mixture was stirred at room temperature under an argon atmosphere. [b] Determined by chiral GC. [c] Yield of isolated product in parenthesis. [d] **3b**: 4 mol%. [e] CALB: 40 mg. [f] Yield determined by ¹H NMR spectroscopy. [g] 50°C.

of CALB and 8 mol% of KOtBu. Although a longer reaction time is needed (17 h), **5c** was obtained in high yield and enantioselectivity (92%, >99% *ee*) (Table 2, entry 4). Electron-rich alcohol **4d** did not significantly change the rate or selectivity of the reaction and gave enantiomerically pure **5d** in 96% yield after 6 h (Table 2, entry 5). Similarly, electron-withdrawing groups on the phenyl ring gave enantiopure acetates in excellent yields. Thus, **5e** was obtained in 93% yield in 6 h (Table 2, entry 6). Despite the prolonged reaction times needed for alcohols **4f** and **4g**, this is the first time that acetates **5f** and **5g** are obtained through DKR (Table 2, entries 7 and 8). A plausible explanation that accounts for the need for longer reaction times is that the nitrogen-containing substituents on the substrates slow down the reaction rate by

easy to observe as it cannot undergo β-hydride elimination. When complex **3a** and KOtBu were mixed in [D₈]toluene in an NMR tube and shaken vigorously, a fine new precipitate of KCl was formed that was allowed to settle. The quantitative formation of a new ruthenium complex was observed by ¹³C NMR spectroscopy. The resonance of the five equivalent quaternary carbons of the cyclopentadienyl ring of **8** is shifted to higher frequency ($\delta = 108.8$ ppm) than that of **3a** ($\delta = 107.1$ ppm) in [D₈]toluene. Similar changes are observed for the resonance of the CO ligands ($\delta = 202.8$ ppm in **8** and 198.0 ppm in **3a**). The resonances of the *tert*-butoxide ligand are also observed ($\delta = 34.3$ and 73.1 ppm), and differ from those of *t*BuOH ($\delta = 31.3$ and 68.2 ppm) and of KOtBu ($\delta = 37.6$ and 66.5 ppm) in [D₈]toluene. Furthermore, when an

Scheme 2. Proposed mechanism for the racemization.

excess of 1-phenylethanol (**4a**) was added to the NMR tube, the formation of acetophenone (**11**) was immediately observed.

In summary, we have developed a highly efficient DKR of secondary alcohols at room temperature that for the first time provides enantiopure products in high yields in very short reaction times. Furthermore, isopropenyl acetate can be employed as the acyl donor, which makes the purification of the products very easy. We have also proven the intermediacy of Ru alkoxides in this process. This mild procedure makes it possible to use sensitive and/or less-thermostable enzymes in future applications.

Experimental Section

Complexes **3a** and **3b** were prepared as described in the literature.[18,25] Toluene was dried over CaH_2 overnight, distilled under argon, and stored over 4-Å molecular sieves. Isopropenyl acetate was washed with saturated K_2CO_3, dried with $CaCl_2$, and distilled under argon. ^1H NMR and ^{13}C NMR spectra of acetates were in good agreement with the data previously reported in the literature.[26]

Dynamic kinetic resolution of 1-phenylethanol (**4a**): A solution of KOtBu (0.5 M in THF; 100 μL, 0.05 mmol) was added to a 10-mL Schlenk flask. The THF was carefully removed under vacuum, and the flask was filled with argon. CALB[19] (6 mg), Na_2CO_3 (106 mg, 1 mmol) and Ru catalyst **3a** (25 mg, 0.04 mmol) were quickly added. The Schlenk flask was evacuated and filled with argon. Toluene (2 mL) was added, and the mixture was stirred for 6 min.[27] 1-Phenylethanol (**4a**) (120 μL, 1 mmol) was then added, and after 4 min isopropenyl acetate (165 μL, 1.5 mmol) was added. After being stirred for 3 h at ambient temperature, the reaction mixture was

filtered and concentrated. Purification by column chromatography (SiO$_2$; pentane/Et$_2$O 98:2) afforded (*R*)-1-phenylethanol acetate (**5a**) as a colorless oil (151 mg, 92 % yield, > 99 % *ee*).

[19] Immobilized and commercially available as Novozym-435.

[20] Under the same reaction conditions, (2-naphthyl)-1-ethanol gave (2-naphthyl)-1-ethanol acetate in 100 % yield but 0 % *ee*.

[21] To avoid opening of the reaction vessel, the order of addition of reagents was changed slightly: Toluene was added to a mixture

of KO*t*Bu, Ru complex, CALB, and Na$_2$CO$_3$. After 6 min the alcohol was added and the mixture was stirred for 4 min. Finally, isopropenyl acetate was added.

[22] To control the water activity, the enzyme was stored in a sealed container with a saturated solution of LiCl for a minimum of 24 h. An excess of KO*t*Bu is needed to consume the water in the reaction mixture. To test this hypothesis, DKR of **4a** was carried out under the same reaction conditions as in Table 1, entry 4, but employing 40 mg of CALB instead of 6 mg. Acetate **5a** was obtained in only 57 % yield after 3 h.

[27] Stirring for 10 min gave essentially the same result but stirring for 1.5 h gave less-reproducible results.

Mass Spectrometry

Continuous Two-Channel Time-of-Flight Mass Spectrometric Detection of Electrosprayed Ions**

Oliver Trapp, Joel R. Kimmel, Oh Kyu Yoon, Ignacio A. Zuleta, Facundo M. Fernandez, and Richard N. Zare*

Time-of-flight mass spectrometry (TOFMS) is a widely used technique that is recognized for offering high analytical performance at a reasonable cost. Development of this technique is ongoing, and advances in areas such as ion optics and ion-detection hardware have pushed the mass resolution and mass accuracy of TOFMS to regimes that are appropriate for the identification of components of complex mixtures.[1] The technique's intrinsic high ion transmission and capability to measure wide mass ranges without scanning, yields high sensitivity and fast spectral acquisition rates. Based on these characteristics, TOFMS seems to be an ideal detector for fast separations of analytes with a broad range of molecular weights.[2] Such applications, which include the in-line separation of pharmaceuticals, peptides, or proteins followed by electrospray ionization, are becoming increasingly important.[3] Unfortunately, the pulsed nature of TOFMS yields inherent losses when analyzing ions emerging from continuous ion sources. Minimization of these losses can be achieved only at the expense of a reduction in the sampled mass range and potentially the mass resolution if the flight path is shortened. In conventional TOFMS, packets of ions are periodically pulsed into the entrance of a field-free drift chamber. To avoid overlap of the recorded flight times, the duration between start pulses is set to be longer than the flight time of the heaviest analyte ion. Ions reaching the entrance of the flight chamber between start pulses are lost. Thus, the ion sampling efficiency (duty cycle) and spectral acquisition speed are directly related to the ratio of the duration of the start pulse to the time between pulses, and these figures of merit decrease as the sampled mass range or flight path are increased.

An ideal detector for capillary and chip-format separations should provide universal detection, sufficient spectral selectivity, and high sensitivity without degrading separation efficiency.[4] If TOFMS is to become the detector of choice for these applications, optimization of its transmission, speed, and efficiency is essential. One approach to improve the duty cycle is to modulate the continuous ion beam of a conventional TOF instrument to receive encoded single-ion packets, for example, by Fourier transform techniques.[5] The mass spectrum is then obtained by mathematical deconvolution and the analyzer duty cycle can be increased to about 25%.

The most widely used strategy for improving the duty cycle of TOFMS is orthogonal extraction (OE).[6] In this TOFMS configuration the fraction of the ion beam that is sampled is proportional to the length of the extraction region in the dimension orthogonal to the field-free flight trajectory. This region tends to be much larger than the sampling volume defined by ion gates used in an on-axis configuration. Thus, OE-TOFMS has a higher duty cycle than conventional on-axis TOFMS. But, because the flight times of ions traversing the extraction region depend on m/z, the duty cycle of OE-TOFMS decreases with m/z. More importantly, the overall performance of OE-TOFMS is still limited by trade-offs between efficiency, mass resolution, and mass range.

In an effort to decouple these figures of merit, we continue to explore a TOFMS strategy based on Hadamard-type, pseudorandom modulation.[7] In this case a finely spaced Bradbury–Nielsen gate (BNG)[8] is used to rapidly modulate (MHz frequency range) a continuous ion beam on and off the axis of detection following a known pseudorandom binary sequence. Encoding sequences are applied to the ion beam by alternating the voltage of this gate between two set limits; a sequence element "1" fixes the gate electrodes at relative ground and allows ions to pass undeflected, while a sequence element "0" shifts the gate electrodes to a deflecting state. The acquired spectrum corresponds to the sum of time-shifted spectra of multiple packets. Knowledge of the encoding sequence allows mathematical deconvolution and recovery of the TOF mass spectrum. The length of the applied encoding sequence is chosen based on the range of flight times (i.e. mass range) being monitored. All encoding sequences contain approximately equal numbers of 1s and 0s (on and off signals), so by detecting all ions of state "1", a one-channel Hadamard transform (HT) TOF mass spectrometer offers a 50% duty cycle, independent of other instrument parameters.

In an attempt to extend the duty cycle of HT-TOFMS to 100% and to increase the overall performance of the technique, for example, the signal-to-noise ratio (SNR), a next generation instrument has been developed as shown in Figure 1a. Improvements include new modulation electronics[9] which integrate the Bradbury–Nielson gate on the driver board to minimize the length of the transmission lines for the amplified modulation sequence for more precise and also faster modulation, and software for simultaneous data acquisition and real-time Hadamard transformation. New focusing optics allow us to obtain a highly focused ion beam with a narrow energy distribution that can be precisely deflected at the BNG with a switching frequency between 5 and 50 MHz corresponding to an encoding element width of

Figure 1. a) Schematic experimental setup of the new HT-TOF mass spectrometer. detector yield no TOF information and contribute to background noise.

Two-channel HT-TOF mass spectrometry involves the simultaneous optimization of paired one-channel HT-TOFMS experiments. Detecting high-quality spectra on the outer channel requires that deflection not only moves ions off the central axis of detection, but also that the deflection is repeatable and well-defined. While the inner channel records the static, focused component of the modulated ion beam, the outer channel detects ions that have undergone a time- and energy-dependent deflection (impulse sweep mode).[10] Optimized conditions for both channels require reducing the kinetic-energy spread of the ions and matching the images of the deflected and undeflected ion-beam modes at the plane of the detector with the detector dimensions.

Images of the deflected and undeflected ion-beam modes were collected for the "0" and "1" modulation states using various optical configurations. The voltages applied to the set of four steering plates (see Figure 1 a) at the entrance of the TOF chamber were scanned to move the ion beam about the three active areas of the detector. Synchronized measurements of total ion current (TIC) were used to generate two-dimensional ion-current plots. These plots represent the convolution of the detector shape and the beam shape. In the situation where the beam cross section is small compared to the detector area, the ion-current plot will have the shape of the beam, and knowledge of the detector dimensions can be used to estimate beam size. These data were used to optimize beam focus and position and to choose appropriate modulation conditions. Figure 2 displays the beam images at optimized conditions. The focused ion beam has dimensions comparable to the inner anode and can be moved vertically between the three active areas. The deflected ion beam has two well-defined centers that exist above and below the focused mode (Figure 2 c and d).

200 and 20 ns, respectively. The deflection angle α of the modulated ion beam (see Figure 1 c) can be controlled by varying the voltage (ΔU) applied to the BNG. With sufficient modulation voltage applied to the BNG two spatially resolved modes of the ion beam can be experimentally observed at the detector plane: a centered, focused beam, and the two deflected ion beam branches that arrive above and below the detector center. To monitor both spatial modes, we have designed and installed a dual-anode multichannel plate (MCP) detector with isolated active charge-collection areas and a mask that is dimensioned to reflect the spatial profile of the modulated ion beam (Figure 1 c).

The maximum duty cycle of a one-channel HT-TOF mass spectrometer is 50%. The experimentally achieved value depends on the percentage of ions entering the mass analyzer that strike the detector and, further, on the fraction of these ions that are modulated on and off of the detector [Eq. (1)] where n_{tot} is the total number of ions entering the mass analyzer, n_t is the number of ions striking the detector in the transmitted mode, and n_{nt} is the number of ions striking the detector (ideally zero) in the non-transmitted mode.

$$\text{duty cycle} = 50\% \left(\frac{n_t}{n_{tot}} \right) \left(\frac{n_t - n_{nt}}{n_t} \right) \tag{1}$$

The first ratio in Equation (1) represents ion-beam clipping, which can result if the ion beam and the detector are not properly aligned. The second ratio describes the deflection efficiency during modulation of the ion beam. The "0"-state ions that are insufficiently deflected and strike the

Figure 2. Two-dimensional images of the position, shape, and size of the temporally and spatially modulated ion beam obtained by *x,y*-steering of the undeflected or deflected ion beam across the two detection anodes. a) Undeflected ion beam detected at the inner anode, b) undeflected ion beam detected at the outer anode, c) deflected ion beam ($\Delta U = 13$ V) detected at the inner anode, d) deflected ion beam at the outer anode.

Subtracting deflected data from the undeflected data collected under identical scanning conditions provides a measure of how many ions are modulated about each detector at a specific beam position and focus. High duty cycle requires that ion current moves between the two channels of detection. Poor alignment or non-ideal deflection yield asymmetry in the data obtained for the two channels. Figure 3 shows an
Figure 3. Net deflection plots of reserpine ($C_{33}H_{40}N_2O_9$) extracted by substracting the vertical cross-sections of the deflected mode from the vertical cross sections of the undeflected mode of the ion beam. The black and gray curves represent the inner and outer detection anodes, respectively.

Figure 4. Spectra of PPG 450 simultaneously collected at the inner (a) and outer (b) anodes of the detector. Spectrum (c) represents the difference of spectrum (a) and spectrum (b) with an experimental improvement of the SNR of 29%. Conditions are 11-bit modulation sequence (2047 elements), 20 MHz modulation frequency, and 30 s acquisition time.

example of such data extracted from vertical cross sections with a modulation voltage $\Delta U = 13$ V applied to the BNG. The changes in the sign and magnitude of the deflection verify that the deflection process is vertical and that the deflected mode of the ion beam has two branches. At the ideal position, the BNG moves the entire ion beam from the inner to the outer anode.

Figure 4 shows deconvoluted spectra of polypropylene glycol (PPG 450) acquired at the inner and outer anodes. The spectrum of the outer anode is inverted owing to the mathematical formalism of the multiplication of the inverse Hadamard matrix (in our experiment a simplex matrix)[11] with the raw spectrum of the outer anode, where each on state of the beam at the inner channel corresponds to the off state of the beam at the outer and vice versa. Similar data were collected for analytes across an m/z range of 200 to 2000 amu, including: caffeine, tetrabutylammonium acetate, *N*-hydroxy-ethyl-*N*,*N*-dimethylbenzylammonium chloride, bradykinin, reserpine, PPG 1000, and gramicidin. In each case, the flight times measured on the two channels were identical, and data subtraction did not require peak matching of the two spectra. At faster modulation and acquisition rates the slight difference in the flight paths to the two channels could require a different procedure to match and calibrate data.

Under ideal conditions the combination of the two channels of data yields an improvement of 41% ($\sqrt{2}$) in SNR over the one-channel experiment (only the inner detector). Experimentally we observe an average SNR improvement of 29%. Small deviations in the beam-detector proportions primarily cause this difference. Two-channel experiments were also carried out with a two-stage reflectron installed. Resolvable ion beamlets were observed in beam-

imaging experiments, but the extension of the flight path (2.2 m) caused a majority of the deflected ions to miss the outer detector at even our lowest deflection voltage ($\Delta U = 13$ V). Thus, the duty cycle on this detector was limited by the beam clipping term in Equation 1. Using current knowledge of the ion-beam dimensions and deflection profiles, appropriately sized detection areas will be designed to detect all ions.

With the implemented instrumental modifications, this two-channel detection scheme extends the achievable duty cycle of HT-TOFMS to 100% and effectively converts TOFMS into a continuous detection technique. Beyond the improved SNR, this advance gives an increase in the data acquisition rate (several thousand full spectra per second). More generally, this work suggests that temporal and spatial encoding of ion beams combined with multichannel detection schemes is a promising strategy for increasing the information density of TOFMS experiments.

Efficient multiplexing enables novel approaches to tandem MS detection. For example, the three spatially defined regions in this experiment (Figure 2) could be used for different MS experiments. It can be envisioned that one of the beams might be used for high-speed HT-TOFMS while the other two ion beams could be transferred into a high-mass resolution ion-trapping instrument, such as a Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR-MS)[12] for MS^n experiments.

Experimental Section

Figure 1 a illustrates the experimental setup of the ESI-HT-TOF mass spectrometer at Stanford University. Ions are produced by an ESI source consisting of three differentially pumped stages. A borosilicate

Communications

glass capillary (0.4 mm i.d., length 124 mm), treated with chlorotri-methylsilane (Fluka) to minimize analyte surface interactions, was used as the transfer line between atmospheric pressure and the first pumping stage. A fused silica capillary, mechanically sharpened and coated with gold was used as spray needle. Analyte solutions were infused into this fused silica capillary at flow rates between 0.1 and 10 $\mu L\,min^{-1}$ by application of back pressure. The typical electrospray conditions were: spray-needle voltage of $+2.4$ to $+3.6$ kV, needle–capillary separation of 5–8 mm, and a spray source temperature of 220°C. The metal front and end cap of the heated transfer capillary were set between $+30$ and $+80$ V. Ions were extracted from the silent zone of the mach disk emerging from the metal spray nozzle with a skimmer (1 mm orifice i.d., $+20$ to $+50$ V). The second pumping stage of the ion source consists of a focusing lens ($+14$ to $+24$ V), a hexapole ion guide (length 21.9 cm, frequency 2.9 MHz, amplitude between 200 and 2500 V; ABB Inc, Pittsburgh), and a focusing exit lens (-2 to -25 V). The ions were accelerated to kinetic energies of 1500 eV by the first segment of a modified Einzel-type lens. Angular spread caused by the acceleration is focused by varying the voltage of the middle lens of the Einzel lens (-420 to -500 V). After the Einzel lens, a Bradbury–Nielsen gate modulates the ion beam. The modulator grid consists of interspersed wire sets positioned normal to the ion beam. The wire sets were made from 20-μm diameter gold-plated tungsten wire and spaced 100 μm apart.[8b] The pseudorandom sequence generator (Predicant Biosciences) is based on a feedback shift register circuit producing variable length sequences between 255 (8-bit) and 16 383 (14-bit) elements. The modulation frequency can be set between 2 and 50 MHz and was kept at 20 MHz for all the experiments reported herein. The low-voltage signals of the binary sequence are transmitted to a driver board which is mounted on a heat sink cooled by a water/Peltier element. The cooling system is rated to dissipate up to 80 W of heat generated during operation. At the driver board the low voltage modulation signal is split into two phases that are 180° out of phase, amplified to voltages between $\Delta U = 13$ and 24 V, and applied to the wire sets of the Bradbury–Nielsen gate, which floats at the flight tube potential (-1500 V). The ion beam passes undeflected when both wire sets are at the same potential, corresponding to the beam "on" state (1). When opposing potentials (between $\Delta U = 13$ and 24 V) are applied to the wire sets, the beam is split into two deflected beams, corresponding to the beam "off" state (0). The effective flight path in the non-reflectron configuration corresponds to approximately 1.1 m. The ions, passing through the slits of mask in front of the detector, are post-accelerated to an energy of 2300 eV before they are detected by a set of multichannel plates (MCPs; Quantar Technology). The MCP signals from the two anodes are amplified and fed into two multi-channel scalers (Turbo MCS, EG&G Ortec, Oak Ridge, TN) for counting purposes. Synchronization of the data acquisition with the modulation electronics is achieved by triggering the start pulse of the data acquisition from the sequence generator at the beginning of the first sequence element. The digitized waveform acquired by the multichannel scaler is transferred to a computer (700 MHz Pentium III-based PC, with 384 MB RAM). Real-time deconvolution and data processing is performed with a program written in Delphi.

Mass calibration was achieved by quadratic regression analysis between the flight times and the known molecular weights of caffeine, polypropylene glycol (PPG 450), bradykinin, and reserpine.

Solvents used for preparing the solutions were reagent grade. Bradykinin, caffeine, reserpine (Sigma), and polypropylene glycol standard (PPG 450, narrow molecular-weight distribution; Scientific Polymer Products) were used as received without further purification. The analytes were dissolved in a water:methanol mixture (70:30 v/v). To improve the electrospray ionization efficiency 10 μL of 50 mM sodium acetate solution were added per mL of sample solutions of bradykinin, reserpine, and polypropylene glycol.

Homogeneous Catalysis

Gold Catalysis: The Benefits of N and N,O Ligands**

A. Stephen K. Hashmi, Jan P. Weyrauch,
Matthias Rudolph, and Elzen Kurpejović*

*Dedicated to Professor Johann Mulzer
on the occasion of his 60th birthday*

The catalysis of organic reactions by gold compounds has been recently shown to be a powerful tool in synthesis.[1,2] When gold(I) compounds are used as precatalysts, ligands such as phosphanes[3–8] or phosphites[9] can be applied. The gold(III) precatalysts are mainly simple halides;[2] other examples include one thioether-containing,[10] one phosphite-containing,[9] and organogold(III)[11] compounds.

For the gold-catalyzed phenol synthesis,[12] AuCl$_3$ usually delivers good results with simple substrates, but with more complicated ones a significant loss of activity is observed. At lower temperature, kinetic studies with our most simple test-substrate **1** (see Scheme 1) showed that the problem with

Figure 1. Reaction of **1** with AuCl$_3$. Reaction conditions: CD$_3$CN, 10 °C, a) 3.3 mol% AuCl$_3$; b) 5.0 mol% AuCl$_3$.

Figure 2. Reaction of **1** with the precatalyst **3**. Reaction conditions: CD$_3$CN, 45 °C, 5 mol% **3**. After 25 h the same amount of **1** was added.

regard to the loss of activity occurs even with as much as 5 mol% of catalyst (Figure 1). With small amounts of catalyst, the conversion remains incomplete.

We have now tested several gold(I) and gold(III) complexes with different ligands as catalysts for this reaction. Gold(I) complexes showed low selectivity and led to several side products. Satisfactory results in terms of activity, long-term stability *and* product-selectivity were obtained only with gold(III) complexes with pyridine derivatives, some of which contained chelating oxygen functionalities. The most interesting complexes were precatalysts **3–6**.[13] The complexes did not suffer deactivation, as shown in Figure 2 for **3**—the activity even holds in a second catalytic run. Unlike with AuCl$_3$, a mechanistically interesting induction period was

observed for **3–6**, clearly proving that here the complexes are precatalysts. This is also the reason for the higher activity in the second run, since the catalytically active species is already present and does not have to be formed in a slow reaction.

With as little as 0.07 mol% of **3** a complete conversion could be achieved; this corresponds to 1180 instead of the usual 20–50 turnovers. The complexes **4–6** are also highly stable catalysts; a comparison of their activity is depicted in Figure 3: the acceptor-substituted pyridine carboxylate **5** is the most reactive one, followed by the unsubstituted **4** and the donor-substituted **6**. Nevertheless, the initial activity of **3**, **4**, and **6** is lower than that of AuCl$_3$. In part, this problem can be solved by switching to dichloromethane/acetonitrile mixtures or even pure dichloromethane (as shown for **3** in Figure 4). In

Figure 3. Comparison of the activities of **4–6** (with test-substrate **1**). Reaction conditions: room temperature, 5 mol% of catalyst, MeCN.
Figure 4. Activity of **3** in the conversion of **1** in different solvents. Reaction conditions: room temperature, 5 mol% **3**, a) CH$_2$Cl$_2$/MeCN = 80:20; b) CH$_2$Cl$_2$/MeCN = 100:0; c) CH$_2$Cl$_2$/MeCN = 90:10.

spite of the slower conversion, these complexes are superior to other transition-metal complexes known to catalyze this reaction (Figure 5).[12c, 14]
Figure 5. Comparison of the activity of **3** with the activities of different transition-metal catalysts (product **2**). Reaction conditions: 5 mol% catalyst, AuCl$_3$: 10°C, MeCN; **3**: 45°C, MeCN; PdCl$_2$: 45°C, MeCN; [{IrCl(cod)}$_2$]: 45°C, MeCN; [Ru$_3$(CO)$_{12}$]: 45°C, benzene; PtCl$_2$: 45°C, MeCN; [{RhCl(cod)}$_2$]: 45°C, MeCN.

The major benefit in preparative terms of using these precatalysts in this reaction is that they enable the preparation of benzoannelated heterocycles with a phenolic hydroxy group in a position which is difficult to achieve by employing classic synthetic methodology.[12d] The most significant targets are antitumor antibiotics from the tetrahydroisoquinoline family,[15] which—with this substitution pattern—are not readily accessible by the Pictet–Spengler or related reactions.[16] As reported previously, with 5 mol% or less AuCl$_3$ no complete conversion could be achieved,[12a] but **6** gave a quantitative conversion of **7a** at room temperature (Scheme 2). And even the Z-protected substrate **7b** (Z = CO$_2$CH$_2$Ph) gave a clean reaction with **6**. With cationic gold(I) complexes we could not achieve the product selectivity reported here.

7a: R = 4-NO$_2$C$_6$H$_4$SO$_2$ **8a** MeCN: 72 h, quantitative, CH$_2$Cl$_2$, 4 h, 95%

7b: R = PhCH$_2$O$_2$C   **8b** 90%
Scheme 2. Conversion of the substrates **7a** and **7b** with the precatalyst **6**.

In conclusion, the development of the gold(III) precatalysts **3–6** represents a first step in catalyst-tuning by ligand design, a major focus of research for most other transition metals. These results provide good evidence for the establishment of significantly more effective gold catalysts.

Experimental Section

Complex **7a** (300 mg, 861 µmol) and complex **6** (15.7 mg, 38.7 µmol; 4.5 mol%) in CH$_2$Cl$_2$ (1.50 mL) were stirred at room temperature for 4 h. The solvent was removed in vacuo, and column chromatography yielded **8a** (284 mg; 95%) .

C—C Coupling

Formation of 1,4-Diketones by Aerobic Oxidative C—C Coupling of Styrene with 1,3-Dicarbonyl Compounds**

*Michael Rössle, Thomas Werner, Angelika Baro, Wolfgang Frey, and Jens Christoffers**

1,4-Dicarbonyl compounds[1] are versatile precursors for the synthesis of various heterocyclic structural motifs, for example, furan,[2] thiophene, and pyrrole derivatives.[3] The conversion of α-halo ketones with enolates represents a classic route to 1,4-dicarbonyl compounds (Feist–Bénary synthesis of furan derivatives).[4] A modern concept utilizes the umpolung of aldehydes, for example, by application of the Stetter reagent[5] or 1,3-dithiane derivatives.[6]

Recently, we reported the cerium-catalyzed α hydroxylation of 1,3-dicarbonyl compounds **1** (Scheme 1).[7] With
Scheme 1. Cerium-catalyzed α hydroxylation of β-oxoester **1a** with O_2 and oxidative C—C coupling with styrene **3**.

respect to economical and ecological considerations, the use of molecular oxygen is superior to other reagents applied in this type of conversion. Based on the assumption of radical intermediates along the hydroxylation pathway, the conversion has been performed in the presence of olefins such as styrene (**3**), and indeed, hydroperoxides **4** were obtained as the major products. Compounds **4** were isolated as hemiacetals such as **4b** with an endoperoxide 1,2-dioxane ring.[8]

Surprisingly, these crystalline endoperoxides have a remarkable stability indicated by defined melting points between 50 and 150°C, but, unfortunately, they were obtained as hardly separable mixtures of diastereoisomers. Thus, purification and characterization are difficult, resulting in a

[*] M. Rössle, Dr. T. Werner, Dr. A. Baro, Dr. W. Frey, Prof. J. Christoffers

restricted application for further synthetic purposes. We were therefore interested in the conversion of 1,2-dioxanes into diastereomerically unique products, either by oxidation, reduction or by disproportionation of the peroxide unit.[9] After considerable experimentation with a number of transition-metal-assisted transformations,[10] we focused our interest on the Kornblum–DeLaMare fragmentation mediated by a pyridine/acetyl chloride system.[11] Owing to the difficult purification of the diastereomeric endoperoxide mixtures, we investigated a sequential one-pot procedure for oxidative C−C bond formation and Kornblum–DeLaMare fragmentation. Herein we report an optimized protocol as the result of these studies.

1,3-Dicarbonyl compounds **1a–h** were converted with styrene (**3**) under CeCl$_3$·7H$_2$O catalysis (10 mol%) in 2-propanol at ambient temperature under an atmosphere of air as the oxidant (Table 1). Under higher partial pressures of O$_2$ the formation of undesired α-hydroxylated products **2** is favored.

Apart from carbocyclic and open-chain β-oxoesters and 1,3-diketones, heterocyclic compounds were also investigated. As can be seen from Table 1, the best result was realized for lactone **5c** (87% overall yield), whereas of cyclohexanone derivative **5e** was obtained in 50% yield. All other substrates, which include lactam **5d** and carbocyclic and open-chain derivatives, were isolated in 62–72% yield. The reaction sequence could also be extended to the seven-membered ring product **5f** (71%). In contrast to α hydroxylations, even the α-unsubstituted substrate **1h** (R′ = H) cleanly reacted in this manner with **3** to give **5h** in 72% yield (Table 1).

To prove the utility of the 1,4-diketones **5** (which bear a quaternary C atom) as building blocks in the synthesis of heterocycles, compound **5a** was treated with liquid NH$_3$. After chromatographic workup, the novel bicyclic 3,4-dihydro-2H-pyrrole derivative **6** was isolated as a single diastereomer in 63% yield (Scheme 2). The molecular structure of **6**
Scheme 2. Interrupted Paal-Knorr reaction of the 1,4-dicarbonyl compound **5a** to pyrrole derivative **6**.

was confirmed by X-ray single-crystal analysis (Figure 1)[12] and can be seen as a product of an interrupted Paal–Knorr pyrrole synthesis. The final elimination of water is inhibited by the quaternary center, and the position of the formed double bond is unexpected for this type of reaction.[4a,b]

Table 1: Formation of 1,4-dicarbonyl compounds **5** by a two-step one-pot reaction consisting of cerium-catalyzed C−C coupling with **3** and subsequent Kornblum–DeLaMare fragmentation.[a]

	Product	Yield [%][b]		Product	Yield [%][b]
5a		71	**5e**		50[c]
5b		62	**5f**		71
5c		87[c]	**5g**		68
5d		72	**5h**		72

[a] See Experimental Section for reaction conditions. [b] Overall yield over two steps. [c] 5 mol% of CeCl$_3$·7H$_2$O.
Figure 1. ORTEP view of 3,4-dihydro-2H-pyrrole derivative **6** drawn at the 50% probability level.

As **3** is partly consumed by polymerization, the reaction was started with the addition of 2 equivalents followed by a further 1 equivalent of **3** after 4 h. The reaction mixture was stirred for a further 20 h, and then all volatile materials were removed under vacuum, leaving a mixture of crude endoperoxides **4**, polystyrene, and cerium-containing materials. This residue was directly treated with a mixture of pyridine (5 equiv) and AcCl (6 equiv) in CH$_2$Cl$_2$ and stirred for 16 h at ambient temperature. Filtration through SiO$_2$ and chromatography gave unique 1,4-diketones **5** in the range of 50–90% overall yield over two steps (Table 1).

In summary, 1,4-diketones **5** are readily accessible in a two-step one-pot reaction in 50–87% overall yields. Our synthetic concept, which may be a valuable alternative to other umpolung strategies, combines an oxidative cerium-catalyzed C−C coupling of 1,3-dicarbonyl compounds **1** with styrene (**3**) and a pyridine/AcCl-mediated Kornblum–DeLaMare fragmentation. A follow-up reaction of **5a** with

NH₃ to afford the new dihydro-2*H*-pyrrole derivative **6** demonstrates that 1,4-diketones **5** are suitable precursors for heterocyclic compounds.

Experimental Section

Typical procedure: Styrene (**3**; 2.0 equiv) and the respective 1,3-dicarbonyl compound **1** (1 mmol, 1.0 equiv) were added to a stirred suspension of CeCl₃·7H₂O (0.1 equiv) in *i*PrOH (0.65 mL/mmol **1**). After 4 h, more **3** (1.0 equiv) was added, and the reaction mixture was stirred for a further 20 h at room temperature. All volatile materials were removed under vacuum, and the residue was suspended in CH₂Cl₂ (2 mL/mmol **1**). Pyridine (5.0 equiv) and acetyl chloride (6.0 equiv) were added at 0°C, and the resulting mixture was stirred for 16 h at room temperature. The reaction mixture was filtered through SiO₂ (petroleum ether/EtOAc 2:1) and subsequently purified by silica-gel column chromatography (petroleum ether/EtOAc 5:1) to give 1,4-diketones **5** as the major products.

Element Modifications

$[Ga_{22}(PtBu_2)_{12}]$: Diversity in the Arrangement of 22 Gallium Atoms—A Unique Case in the Field of Metalloid Clusters?**

Jochen Steiner, Gregor Stößer, and Hansgeorg Schnöckel*

Dedicated to Professor Nils Wiberg on the occasion of his 70th birthday

With the formation of three different Ga_{22} frameworks in metalloid clusters, the element gallium assumes a unique position in the field of metal clusters,[1] since to our knowledge, structural isomers of large metalloid clusters are not known to date for any other metal. Here we report an additional structural variation in the arrangement of 22 gallium atoms, in which for the first time an icosahedral Ga_{12} core is retained despite extensive reduction of the Ga_{22} framework (average oxidation number 0.55). We have previously achieved low oxidation numbers for Ga_{22} clusters only when gallium-centered arrangements were present in the cluster core (oxidation number 0.36, Figure 1): $[Ga_{22}R_8]$ (**1**) with R = SitBu$_3$ (**1a**),[2] Si(SiMe$_3$)$_3$ (**1b**),[3] and Ge(SiMe$_3$)$_3$ (**1c**)[4] as well as $[Ga_{22}R_{10}]^{2-}$ (**2**) with R = N(SiMe$_3$)$_2$;[5] the coordination numbers of the central Ga atoms are 13 for **1** and 11 for **2**. In contrast, in the case of the only previously obtained Ga_{22} cluster with an icosahedral Ga_{22} core (without a central Ga atom), $[Ga_{22}\{N(SiMe_3)_2\}_{10}Br_{10}]^{2-}$ (**3**),[6] the average oxidation number of 0.82 is not very different from that of the GaX starting material. This is also true for the first polyhedral gallium subhalide $[Ga_{24}X_{22}]$ (**4**)[7] (average oxidation number 0.92), which can be viewed as a common precursor (possibly in a slightly modified form, such as $[Ga_{22}X_{20}]$, which is analogous to the well-known $[Al_{22}X_{20}]^{[8]}$) for the numerous

Figure 1. Ball-and-stick representations of the different arrangements of the inner (black) 12, 13, or 14 gallium atoms in the metalloid clusters **1** (1+13), **2** (1+11), **3** (12), **4** (12), and **6** (1+12). The information given in parentheses indicates that, for example, the central Ga atom in **6** is surrounded by 12 Ga atoms in the first coordination sphere.

Ga_{22} clusters (Figure 1). With the $PtBu_2$ ligand used here, as in previous cases such as the metalloid clusters $[Ga_{16}(PtBu_2)_{10}]$ (**5**)[9] and $[Ga_{51}(PtBu_2)_{14}Br_6]^{3-}$ (**6**),[10] we find that the cluster core is linked to the outer shell by additional bonds to bridging P atoms, which facilitates the isolation of unusual Ga_n frameworks. Such clusters have fewer ligands for a given number of metal atoms than clusters with purely terminally coordinated ligands. Therefore, it is possible to achieve a lower oxidation state for the gallium framework.

After slowly heating a metastable solution of GaCl, synthesized by the co-condensation of GaCl with a toluene/diethyl ether (4:1) mixture, from −78 °C to −65 °C and then to −50 °C to induce disproportionation to Ga_n clusters, the metathesis reaction is spontaneous, if at these temperatures, initially only $1/3$ and then $2/3$ of the amount of $LiPtBu_2$ required for full substitution is added as a toluene suspension. Removal of the volatile components under vacuum and washing with pentane yields a dark extract from which large black crystals of $[Ga_{22}(PtBu_2)_{12}]$ (**7**) can be obtained reproducibly within a few days at +60 °C. The crystal structure

analysis[11] of **7** reveals the neutral $[Ga_{22}(PtBu_2)_{12}]$ cluster depicted in Figure 2. The arrangement of the cluster molecules within the crystal corresponds to that of a distorted primitive hexagonal structure with the coordination numbers
Figure 2. Ball-and-stick representation of the Ga_{22} cluster **7**; for clarity, only the bonds from the central phosphorus atom to the α-carbon atom of the tBu groups are shown, the bare Ga atoms are shown in black. The octahedrally arranged P atoms of the bridging phosphanides are drawn as polyhedra (with a view of the parallel triangular faces of the icosahedron and octahedron).

[4+4+8]. The distances between the centers of the clusters are 15.41, 17.62, and 23.62 Å, respectively, for the above-mentioned coordination numbers. The central icosahedral Ga_{12} framework is bound through bridging P atoms to three Ga atoms in each of two neighboring Ga_5 units (see below). These six bridging P atoms enclose the Ga_{12} icosahedron in an octahedron (Figure 2). The six remaining Ga atoms of the icosahedron, which are arranged in a chair conformation, are bound directly to other Ga atoms, which surround the icosahedron in the form of two chainlike fragments. Each of the Ga_5 chains contains two naked Ga atoms and three Ga atoms that are each bound to two $PtBu_2$ groups—one bridging (to the light-colored Ga atoms of the central icosahedron in Figure 2) and one terminal. The ten naked Ga atoms are depicted in black in Figure 2.

The distinctive feature of the $[Ga_{22}(PtBu_2)_{12}]$ cluster (**7**) is that the GaR units surrounding the icosahedral core are bound very tightly to it by the additional bridges. Therefore, they cannot be removed as GaR units like other nonbridging ligands (such as $C(SiMe_3)_3$, $Si(SiMe_3)_3$, and $N(SiMe_3)_2$) under comparable reaction conditions;[12] this prevents further cluster growth (in contrast to the formation of the Ga_{84} cluster, for example). The strong bonds between the $PtBu_2$ ligands and the cluster core on the one hand, and their high reactivity as phosphanide anions on the other, make it possible to take snapshots of the cluster's growth.[13]

Through the stabilization provided by the bridging phosphanide ligands in **7**, an icosahedral Ga_{12} unit has been obtained for the first time whose average oxidation number is strongly shifted toward that of metallic gallium. Figure 3 (left) shows that the arrangement of the 22 Ga atoms of **7** is strongly
Figure 3. Comparison of the gallium substructure in the Ga_{22} cluster (**7**, left) with the corresponding section of the δ-modification of gallium (right).

Table 1: Calculated atomic volumes in icosahedral and body-centered centers of metalloid gallium clusters and element modifications.

	Ox.[a]	Vol. [Å³]/Σ(Atoms)	Vol. [Å³]/Atom
δ-gallium	0	431 (12)	35.92
7	0.55	395 (12)	32.92
3	0.82	377 (12)	31.41
4	0.92	379 (12)	31.58
fcc Ga$^{IV[b]}$	0	501 (13)	38.54
fcc Ga$^{IV[c]}$	0	397 (13)	30.54
8	0.26	462 (13)	35.54
6	0.33	455 (13)	35.00
1b	0.36	484 (13+1)	34.57

[a] Average oxidation state. [b] Volume of the Ga_{13} core extrapolated to standard pressure. [c] Volume of the Ga_{13} core calculated from the lattice constant at 68 GPa.

reminiscent of that of the atoms in δ-gallium[15] (Figure 3, right). The average Ga—Ga distances in the icosahedral substructure of **7** (2.68 Å) are shorter than those in δ-gallium (2.82 Å); this is not unexpected, in respect of the higher coordination number in δ-gallium. In addition, the increase in oxidation number from 0 in δ-gallium to 0.55 in **7** leads to a decrease in the Ga—Ga distances. This influence of the oxidation number on the volume of the icosahedral Ga_{12} cluster could also be confirmed by single-point calculations[16] for **7** and **3**: **3** (oxidation number $+0.82$) 377 Å³ and **7** (oxidation number $+0.59$) 395 Å³. As expected, analogous calculations reveal the volume of the Ga_{12} icosahedron in δ-gallium to be considerably larger, 431 Å³.

Unfortunately, each of the Ga_{22} clusters obtained to date represents only one of many snapshots on the way from the Ga^I species to gallium metal. However, these snapshots demonstrate that this fundamental process of metal formation[17] through disproportionation of metastable solutions is influenced in complex ways by many parameters (e.g. temperature, the type of ligand, the type of donor, and the donor concentration). Similar complexity is certainly expected for the formation of other metals as well. However, since elemental gallium has seven modifications, which are possibly only attained by different reaction paths, the clarification of the formation mechanisms may be exceptionally difficult in this case. Of particular interest here is the question under which conditions the formation of an icosahedral structure as in **3**, **4**, and **7** versus a centered cubic octahedral structure as in **1**, **6**, and $[Ga_{19}R_6]^-$ (R = $C(SiMe_3)_3)$[19] (**8**) is favored. Many experimental and quantum-chemical investigations will be necessary to find an answer to this question. Here, we have initially investigated the volume requirements of the gallium atoms in several Ga_{12} and Ga_{13} units. As a result of such single-point calculations of volume requirements, we have found an approximately linear relationship between atom volume and the corresponding average oxidation state within both the icosahedral Ga_{12} units and the central Ga_{13} units (Table 1).

These calculations, based on the experimentally determined structures of the Ga_{12} and Ga_{13} units, demonstrate that the average atomic volumes of the core gallium atoms differ significantly, depending on the coordination polyhedron.

Whereas an icosahedral arrangement of the Ga_{12} core led to an atomic volume between 35.92 and 31.41 Å³, for cubic octahedral coordination patterns this rose to values ranging from 38.54 to 34.57 Å³. Within both groups, the atoms of the formally zero-valent element modification (fcc- or δ-gallium) assume the maximum volume; as expected, this decreases as the oxidation state of the molecule increases. It is thus the goal of continuing investigations to synthesize molecules whose average oxidation states lie in the range between 0.4 and 0.5. By using identical ligands, slight variations of the reaction conditions could make it possible to obtain both structures (icosohedron or cubic octohedron) with the same ligand shell. This would allow us to determine the influence of the average oxidation state on the arrangements of the cluster cores during formation of the element.

These investigations, which bring the number of different arrangements for 22 Ga atoms in metalloid clusters to four, illustrate the complexity involved in the formation of a bulk metallic phase from precursor salts. The isolation of individual metalloid clusters as intermediates of this process and the determination of their structures is currently the only direct approach to the solution of this fundamental problem. In principle, in situ NMR investigations should be ideal for answering these questions, but for a variety of reasons they often do not achieve this goal: low solubility of the cluster compounds, large half-widths of the gallium signals, and the large number of different gallium atoms in the clusters, which according to calculations result in different NMR chemical shifts (these are mixed-valent compounds, for example, the Ga_{84} cluster[20] contains 42 different Ga atoms; quantum-chemical calculations indicate that these should also have different chemical shifts[21]). Understanding the interactions of the metalloid clusters within the crystal is even more difficult to achieve than knowledge of their structures and mechanisms of formation—as in the case of the unsuccessful interpretation of the electrical conductivity and superconductivity of the Ga_{84} cluster compound.[22, 23]

Experimental Section

LiPtBu$_2$ (1.38 g, 9 mmol) was suspended in toluene (30 mL) at room temperature. In a flask cooled to $-78\,°C$, a 0.32 M Ga^{I}Cl solution (20 mL; 6.4 mmol) in toluene/Et$_2$O (4:1) was slowly warmed to

Communications

−65 °C and the LiPtBu$_2$/toluene suspension (10 mL) was added by pipette. The reaction solution was maintained at −50 °C for 2 h before the remaining ligand suspension (20 mL) was added. The mixture was then warmed to room temperature over 12 h. This resulted in a deep black solution with no residue. The solvent was removed under vacuum and the resulting residue was extracted with pentane.

The deep black pentane extract was filtered to remove the LiCl precipitate and then transferred to a Schlenk flask and heated to 60 °C for 2 h. The mixture was allowed to slowly cool to room temperature, and the Ga$_{22}$ cluster crystallized within a few days as black rhombuses, which could then not be redissolved (yield: 210 mg, 0.064 mmol). It was thus impossible to carry out any NMR spectroscopic or ESI mass spectrometric investigations. Mass spectrometric investigations with the MALDI technique led to unspecific fragmentations.

[13] In a virtual experiment, it is possible to imagine the formation of **7** by the following route: Separation of Ga$_2$X$_4$ units from a subhalide such as the recently described [Ga$_{24}$X$_{22}$] cluster (**4**)[7] could lead to the formation of a hypothetical [Ga$_{22}$X$_{18}$][14] cluster, in which twelve halogen atoms are spontaneously replaced by PtBu$_2$ fragments. Through bridging, six halogen ligands could be removed from the [Ga$_{22}$X$_6$R$_{12}$] cluster formed in this manner and the [Ga$_{22}$R$_{12}$]$^{6+}$ ion could be simultaneously reduced to the neutral [Ga$_{22}$R$_{12}$] cluster (**7**) in the strongly reducing environment.

[14] The hypothetical [Ga$_{22}$X$_{18}$] cluster would have a structure analogous to that of the [Al$_{22}$X$_{20}$] cluster,[8] in which two terminal GaX$_2$ groups would be replaced by GaX groups.

[16] The molecular volumes were calculated with the Guassian 98 program package at the SCF level with a 3-21G* basis set. For this we carried out single-point calculations based on the experimentally determined geometries of the cluster compounds (**1b**, **3**, **4**, **6**, **7**, **8**), as well as δ-gallium and Ga^{IV}; in these calculations, the ICPM solvation model was used to place a shell of uniform electron density (4×10^{-3} e Å^{-3}) around the Ga$_n$ unit. Clusters **5** and **6** have previously been discussed in an analogous fashion.[9,10] a) IPCM: J. B. Foresman, T. A. Keith, K. B. Wiberg, J. Snoonian, M. J. Frisch, *J. Phys. Chem.* **1996**, *100*, 16098; b) Gaussian 98 (Revision A.7), M. J. Frisch, G. W. Trucks, H. B. Schlegel, G. E. Scuseria, M. A. Robb, J. R. Cheeseman, V. G. Zakrzewski, J. A. Montgomery, R. E. Spirocycles

A Convergent Route to Enantiomerically Pure Higher [n−2]Triangulanedimethanol Derivatives and [n]Triangulanes (n ≥ 7)**

B. Christopher Rinderspacher, Dmitrii S. Yufit, and
Judith A. K. Howard*

*Dedicated to Professor Lawrence T. Scott
on the occasion of his 60th birthday*

[n]Triangulanes **1**,[1] that is, hydrocarbons that consist of spiro-annelated (and thereby mutually orthogonal) cyclopropane rings only, with n = 4 (**2**) and n = 5 (**3**) were recently prepared in enantiomerically pure form.[2,3] The extraordinarily high specific rotations of these hydrocarbons (P)-**2**, **3** and (M)-**2**, **3**, which do not bear any chromophore that absorbs above 200 nm, must be attributed to their unique helical σ-bond framework.[4] In the same way as it was proved for the higher π-[n]helicenes with n ≥ 8,[5] the higher (n ≥ 6) σ-[n]helicenes, as these [n]triangulanes with n ≥ 4 may be termed,[6] must be expected to exhibit ever larger specific rotations, at least for a
significant series of derivatives with an increasing number of spiroannelated three-membered carbocycles.

To test this prediction, we set out to prepare higher analogues of **2** and **3** in enantiomerically pure form. In view of the rapidly growing number of possible stereoisomers of these [n]triangulanes with increasing n (e.g., the family of [9]triangulanes consists of four *meso* diastereomers and 16 pairs of enantiomers),[7] a linear strategy to approach any enantiomerically pure continuously helical [n]triangulane with n ≥ 4 would not be feasible (there is only one enantiomeric pair of σ-[6]helicenes and two additional pairs of enantiomeric [6]triangulanes).[7] We therefore conceived a reasonably general convergent strategy, and report herein our first results on its successful application in the synthesis of enantiomerically pure σ-[9]helicenes.

Enantiomerically pure [(1R,3S)-4-methylenespiropentyl]-methanol [(1R,3S)-**5**] and the corresponding enantiomeric acetate (1S,3R)-**6**, which are easily accessible in more than 100-g quantities by enantioselective enzymatic acylation of the racemic alcohol *rac*-**5** with lipase PS,[3,8] were chosen as appropriate starting materials. The addition of dibromocarbene to the double bond in the THP-protected alcohol (1R,3S)-**7** or the acetate (1S,3R)-**6**,[8] adopting a well-established protocol,[9] was followed by deprotection and chromatographic separation to furnish 5,5-dibromodispiro[2.0.2.1]-methanols (1R,3S,4S)-, (1R,3S,4R)-, (1S,3R,4S)-, and (1S,3R,4R)-**8** in 27, 25, 32 and 28% yield, respectively (Scheme 1).

The absolute configuration of all four diastereomers was assigned on the basis of the X-ray crystal-structure analysis[10] of an arbitrarily selected dibromocyclopropane derivative of type **8**, prepared from (1R,3S)-**7**, the known absolute configuration of the starting materials,[8] and comparison of the NMR spectra. THP ethers (1R,3S,4S)-**9** and (1S,3R,4R)-**9** were prepared from the corresponding alcohols with an *anti*-arrangement of their hydroxymethyl and dibromomethylene groups. An improved version of the protocol of Neuenschwander et al.[11] was used for the reductive dimerization of (1R,3S,4S)-**9** and (1S,3R,4R)-**9** to yield mixtures of the diastereomeric bicyclopropylidene derivatives[12] (E)-**10** and (Z)-**10** after cleavage of the resulting THP ethers (Scheme 1). The dimerization probably proceeds via a copper carbenoid generated by treatment of the dibromocyclopropanes **9** with n-butyllithium in the presence of copper(II) chloride. After

Scheme 1. Preparation of enantiomerically pure 5,5′-bis(dispiro[2.0.2.1]-heptylidenemethanol) derivatives (E)-(3S,3′S,4S,4′S,5R,5′R)-, (E)-(3R,3′R,4R,4′R,5S,5′S)-, and (Z)-(3R,3′R,4R,4′R, 5S,5′S)-10. a) DHP, PPTS, CH₂Cl₂, 20 °C, 1.5–5 h; b) CHBr₃, KOH (pellets), TEBACl, CH₂Cl₂, 20–25 °C, 1–3 h; c) MeOH, H₂SO₄, 65 °C, 4 h; d) MeOH, PPTS, 50–65 °C, 2–18 h; e) nBuLi, CuCl₂, −105 to −95 °C, 2 h. DHP = 3,4-dihydro-2H-pyran, PPTS = pyridinium toluene-p-sulfonate, TEBACl = benzyltriethylammonium chloride, THP = tetrahydropyran-2-yl.
chromatographic separation from the corresponding Z isomers, diols (E)-(3R,3′R,4R,4′R,5S,5′S)-10 and (E)-(3S,3′S,4S,4′S,5R,5′R)-10 were obtained in 33 and 23% yield, respectively. These products have the appropriate configurations required for the targeted, continuously helical [9]triangulanes. The assigned E configuration of (3S,3′S,4S,4′S,5R,5′R)-10 was confirmed by X-ray crystal-structure analysis.[10]

Among several attempted cyclopropanations of the diols (E)-(3S,3′S,4S,4′S,5R,5′R)-10 and (E)-(3R,3′R,4R,4′R,5S,5′S)-10 (e.g. with CH₂N₂/Pd(OAc)₂[13] or with CH₂I₂/AlMe₃[14]), only the modified Simmons–Smith-type cyclopropanation[15] according to Shi et al. (with CH₂I₂/ZnEt₂/TFA)[16] applied to (E)-(3R,3′R,4R,4′R,5S,5′S)-10 gave a [7]triangulanedimethanol in moderate yield (28%), which, disappointingly, turned out to have the incorrect configuration (1S,3R,4R,5S,6S,7R,8R,9S)-11 [d-(+)-11] with a horseshoe shape (Scheme 2). Apparently, the cyclopropanation of (E)-10 under these conditions occurs on the sterically less-congested face of the bicyclopropylidene moiety.

Fortunately, though, the old and nowadays rarely applied Gaspar–Roth cyclopropanation protocol (with CH₂N₂/

Scheme 2. Cyclopropanation of enantiomerically pure 1,1′-bis(dispiro[2.0.2.1]heptylidenemethanol) derivatives (E)-(3R,3′R,4R,4′R,5S,5′S)- and (E)-(3S,3′S,4S,4′S,5R,5′R)-10 under different conditions. a) ZnEt₂, CH₂I₂, TFA, 0→20 °C, 5.5 h; b) CH₂N₂ (120–150 equiv), CuCl (30 equiv), 20 °C, 3 h. TFA = trifluoroacetic acid.
CuCl)[17] gave the target (1S,3R,4R,5R,6R,7R,8R,9S)-11 [(P)-(+)-11] and (1R,3S,4S,5S,6S,7S,8S,9R)-11 [(M)-(−)-11] in 26 and 30% yield, respectively, on a 4-mmol scale.[18] However, a large excess of diazomethane and cuprous chloride was required. The absolute configurations of (P)-(+)-11 and (M)-(−)-11 were assigned on the basis of their relative configurations as disclosed by X-ray crystal-structure analyses.[10]

The enantiomerically pure diols d-(+)-11, (P)-(+)-11, and (M)-(−)-11 were transformed into the enantiomerically pure [9]triangulanes d-(+)-14, (P)-(+)-14, and (M)-(−)-14, respectively, in three routine steps for the preparation of triangulanes (Scheme 3).[3] First, the diols were converted into the bis(bromomethyl)[7]triangulanes 12 by treatment with PPh₃·Br₂. Subsequent dehydrobromination of 12 with potassium tert-butoxide gave 1,9-dimethylene[7]triangulanes 13, and cyclopropanation of the latter with diazomethane under Pd(OAc)₂ catalysis[13] furnished the corresponding enantiomerically pure d- [d-(+)-14], (M)- [(M)-(−)-14], and (P)-[9]triangulanes [(P)-(+)-14] in 19, 15, and 30% overall yield, respectively, (≥ 99% ee) after chromatographic separation in the last step.[19]

As expected, both (P)- and (M)-14 exhibit remarkably high specific rotations even at 589 nm: $[\alpha]_D^{20} = +909.9$ (c = 0.96 in CHCl₃) and −890.5 (c = 1.01 in CHCl₃), respectively. The specific rotations increase drastically on going to shorter wavelengths: $[\alpha]_{436}^{20} = +1907.0$, $[\alpha]_{365}^{20} = +3119.4$ ((P)-(+)-14) and $[\alpha]_{436}^{20} = −1866.2$, $[\alpha]_{365}^{20} = −3051.1$ ((M)-(−)-14), indicating that these compounds must exhibit Cotton effects with large amplitudes in the optical rotatory dispersion (ORD)
Scheme 3. Preparation of enantiomerically pure [9]triangulanes *d*-(+)-**14**, (*M*)-(−)-**14**, and (*P*)-(+)-**14**. a) Ph$_3$P·Br$_2$, py, CH$_2$Cl$_2$, −30→20 °C, 5 h; b) *t*BuOK, DMSO, 55 °C, 20 min; c) CH$_2$N$_2$, Pd(OAc)$_2$, Et$_2$O, −5 °C. DMSO = dimethyl sulfoxide.

Figure 1. Section from the crystal packing of (*M*)-(−)-**11** (crystals from Et$_2$O/hexane) with supramolecular double-helical arrangement of hydrogen-bridged molecules as ball-and stick (A) and space-filling models (B). Yellow, blue: cyclopropane spirals; red: hydroxy groups.

curve below 200 nm. DFT calculations at the B3LYP/6-31+G(d,p) level[20–24] for the geometry optimization and time-dependent DFT calculations for determining optical rotations with a triple-ζ basis set (B3LYP/TZVP)[25] for (*P*)-(+)-**14** in the gas phase gave specific rotations of $[\alpha]_D^{20} = 1006.5$, $[\alpha]_{436}^{20} = 2010.7$, and $[\alpha]_{365}^{20} = 3145.5$. These are in excellent agreement with the experimental values over the whole range of wavelengths and thus confirm the strong positive Cotton effect in the ORD curve, which is consistent with a large ellipticity in the CD below 200 nm. In contrast, the enantiomerically pure, but not continuously helical, horseshoe-shaped *d*-(+)-**14** has specific rotations of $[\alpha]_D^{20} = +244.9$ ($c = 1.13$ in CHCl$_3$), $[\alpha]_{436}^{20} = +511.2$, and $[\alpha]_{365}^{20} = +832.0$ only. A comparison of the values of $[\alpha]_D^{20}$ for the now known enantiomerically pure σ-[*n*]helicenes (*P*)-(+)-**14** (+909.9), (*P*)-(+)-**3** (+373.0), and (*M*)(−)-**2** (−192.7)[2,3] indicates a drastic increase in the specific rotation with an increasing number of three-membered rings (see reference [4]). This increase is neither proportional to the relative molecular masses nor to the number of cyclopropane rings.

Another extraordinary feature was observed for the crystal packing of (*M*)-(−)-**11**. In the crystals obtained from a solution in *n*-hexane containing some diethyl ether, the molecules are assembled as supramolecular helices through hydrogen bonds between the terminal hydroxy groups. Two such helices form a supramolecular double helix (Figure 1). A closer look disclosed that Et$_2$O molecules are incorporated in the grooves between two double helices. In spite of being severely disordered in the structure, these solvent molecules apparently play an important role in gluing the double helices together; upon exposing the crystals to air, they rapidly disintegrate into powder, most probably because the Et$_2$O evaporates from the channels. The hydroxymethyl end groups in (*P*)- and (*M*)-**11** apparently are also essential for the supramolecular double-helix formation, as the hydrocarbons (*M*)-**13** and (*M*)-**14** do not form such a packing in their crystals.

Single, double, and even triple helical structures do play very important roles in biology and in polymer chemistry. However for relatively small nonbiological objects, this is not a common phenomenon[26] in that they rarely form single helices,[27] even less frequently double and triple helices.[28]

[18] For unknown reasons, this cyclopropanation on a 4-mmol scale ceased after ≈50% conversion, irrespective of the quantity of diazomethane and CuCl. The product and the starting material had to be isolated as a mixture by column chromatography and together subjected to repeated cyclopropanations until starting bicyclopropylidene had disappeared, as (*P*)-(+)-**11** is readily separable from *d*-(+)-**11**, but not from starting material. These necessary repeated chromatographic purification steps followed by recrystallization from hexane/Et$_2$O/CH$_2$Cl$_2$ decreased the yield significantly. However, on a 0.44-mmol scale the yield was 67%.

[19] All new compounds were fully characterized by spectroscopic methods (^{1}H NMR, ^{13}C NMR, MS), elemental analyses, and, whenever essential, X-ray crystal-structure analyses (see Schemes 1–3 and reference [10]). Physical data for some key compounds: (*M*)-(−)-**11**: Colorless crystals, m.p. 129–131°C (hexane/CH$_2$Cl$_2$/Et$_2$O); $[\alpha]_D^{20} = -660.0$ ($c = 1.04$ in CHCl$_3$); ^{1}H NMR (250 MHz, CDCl$_3$): $\delta = 3.71$ (dd, $J = 6.5$, 11.0 Hz, 2H; CH$_2$O), 3.58 (dd, $J = 7.1$, 11.0 Hz, 2H; CH$_2$O), 1.70 (brs, 2H; 2OH), 1.32–1.42 (m, 2H; Cpr-H), 1.21 (d, $J = 3.9$ Hz, 2H; Cpr-H), 1.16 (dd, $J = 3.9$, 11.0 Hz, 4H; Cpr-H), 1.04 (s, 2H; Cpr-H), 1.00 (d, $J = 3.9$ Hz, 2H; Cpr-H), 0.67 ppm (dd, $J = 4.4$ Hz, 2H; Cpr-H); ^{13}C NMR (62.9 MHz, CDCl$_3$): $\delta = 66.3$ (2CH$_2$), 18.5 (2CH), 18.2, 18.0, 17.4 (2C), 10.4, 9.0 (2CH$_2$), 8.8 (CH$_2$), 8.7 ppm (2CH$_2$). (*P*)-(+)-**11**: Colorless crystals, m.p. 130–131°C (hexane/CH$_2$Cl$_2$/Et$_2$O); $[\alpha]_D^{20} = +673.9$ ($c = 1.92$ in CHCl$_3$). (*P*)-(+)-**12**: Colorless crystals, m.p. 88–89°C (MeOH); $[\alpha]_D^{20} = +527.7$ ($c = 1.25$ in CHCl$_3$); ^{1}H NMR (250 MHz, CDCl$_3$): $\delta = 3.50$ (s, 2H; CH$_2$Br), 3.47 (s, 2H; CH$_2$Br), 1.51–1.60 (m, 2H; Cpr-H), 1.31 (d, $J = 3.9$ Hz, 2H; Cpr-H), 1.25 (d, $J = 4.0$ Hz, 2H; Cpr-H), 1.18 (dd, $J = 7.7$, 4.7 Hz, 2H; Cpr-H), 1.12 (d, $J = 3.8$ Hz, 2H; Cpr-H), 1.03 (s, 2H; Cpr-H), 1.01 (d, $J = 4.1$ Hz, 2H; Cpr-H), 0.75 ppm (t, $J = 4.5$ Hz, 2H; Cpr-H); ^{13}C NMR (62.9 MHz, CDCl$_3$): $\delta = 38.3$ (2CH$_2$), 22.5 (2C), 19.1 (2CH), 18.2, 18.1 (2C), 13.3, 10.4 (2CH$_2$), 9.0 (CH$_2$), 8.1 ppm (2CH$_2$). (*P*)-(+)-**13**: Colorless crystals, m.p. 62°C (MeOH); $[\alpha]_D^{20} = +1302.1$ ($c = 1.17$ in CHCl$_3$); ^{1}H NMR (600 MHz, CDCl$_3$): $\delta = 5.31$ (s, 2H; =CH$_2$), 5.23 (t, $J = 1.9$ Hz, 2H; =CH$_2$), 1.56 (d, $J = 3.7$ Hz, 2H), 1.43 (d, $J = 3.7$ Hz, 2H), 1.39 (d, $J = 7.7$ Hz, 2H), 1.37 (dt, $J = 1.9$, 7.7 Hz, 2H), 1.25 (d, $J = 4.0$ Hz, 2H), 1.15 (s, 2H), 1.08 ppm (d, $J = 4.0$ Hz, 2H); ^{13}C NMR (150.8 MHz, CDCl$_3$): $\delta = 135.7$ (2C), 99.3 (2CH$_2$), 21.9, 18.1, 15.9 (2C), 15.0, 10.7 (2CH$_2$), 8.6 ppm (3CH$_2$). (*M*)-(−)-**13**: Colorless crystals, m.p. 59–61°C (MeOH); $[\alpha]_D^{20} = -1285.4$ ($c = 0.60$ in CHCl$_3$); (*M*)-(−)-**14**: Colorless crystals, m.p. 85–87°C (EtOH); ^{1}H NMR (600 MHz, CDCl$_3$): $\delta = 1.20$ (d, $J = 3.8$ Hz, 2H), 1.17 (d, $J = 3.8$ Hz, 2H), 1.13 (d, $J = 3.8$ Hz, 2H), 1.11 (s, 2H), 1.08 (d, $J = 3.7$ Hz, 2H), 1.06 (d, $J = 3.7$ Hz, 2H), 0.97 (d, $J = 3.8$, 2H), 0.86–0.83 (m, 2H), 0.79–0.74 (m, 4H), 0.70–0.67 ppm (m, 2H); ^{13}C NMR (150.8 MHz, CDCl$_3$): $\delta = 18.1$, 18.0, 17.4, 13.6 (2C), 11.2, 10.3 (2CH$_2$), 9.2 (CH$_2$), 9.1, 4.8, 4.6 ppm (2CH$_2$). (*P*)-(+)-**14**: Colorless crystals, m.p. 85–86°C (EtOH). NMR spectra of compounds (*P*)-(+)-**11**, (*M*)-(−)-**13**, and (*P*)-(+)-**14** were identical to those of their enantiomers.

Cover Picture

Dorothea Fiedler, Robert G. Bergman,* and Kenneth N. Raymond*

A supramolecular metal–ligand assembly catalyzes the [3,3]-sigmatropic rearrangement of enammonium guests in aqueous solution. The cover picture shows the proposed catalytic cycle. The space-restrictive host cavity forces the substrates to bind in a reactive chairlike conformation and thus accelerates the rate of rearrangement. Release and hydrolysis of the rearranged product enable catalytic turnover. For more information, see the Communication by R. G. Bergman, K. N. Raymond, and D. Fiedler on p. 6748 ff.
Noncovalent Interactions
The affinity of a ligand for its receptor depends both on the coordination itself and modification of the noncovalent interactions within the receptor. This phenomenon is described by D. H. Williams et al. in their Review on page 6596 ff.
Polymerization Catalysts
Epoxides and CO_2 undergo copolymerization in the presence of well-defined homogeneous catalysts to produce polycarbonates. The latest developments in this field are summarized by G. W. Coates and D. R. Moore in their Review on page 6618 ff.
Water structure
The previous assumption that water adsorbs in a uniform monolayer on the surface of zinc oxide is disproved by B. Meyer, C. Wöll, and co-workers in their Communication on page 6641 ff. According to the findings a superstructure is formed that consists of partially dissociated water molecules.

The Woodward–Hoffmann Rules …

Figure 1. R. B. Woodward with a Dreiding model of cobyric acid. Copyright: Harvard University Archives.

… **W**ere recognized as groundbreaking immediately upon their formulation, and "many chemists' eyes were opened when they read the original publication by Woodward and Hoffmann in 1965 and the legendary Review in *Angewandte Chemie* in 1969". These are the opinions of contemporary witnesses whom we asked for advice as to whether *Angewandte Chemie* should publish an article by Roald Hoffmann in which he responds to E. J. Corey's claim to have given R. B. Woodward the incentive to develop what quickly became known as the Woodward–Hoffmann rules. In his acceptance speech during the award ceremony for the Priestley Medal, the highest accolade awarded by the American Chemical Society, in Spring 2004, E. J. Corey stated that:

"**O**n May 4, 1964, I suggested to my colleague R. B. Woodward a simple explanation involving the symmetry of the perturbed (HOMO) molecular orbitals for the stereoselective cyclobutene / 1,3-butadiene and 1,3,5-hexatriene/cyclohexadiene conversions that provided the basis for the further development of these ideas into what became known as the Woodward-Hoffmann rules." (published in *Chem. Eng. News* **2004**, *82*(13), 42–44).

The audience/readership was astounded: Were the Woodward–Hoffmann rules not formulated by Woodward and Hoffmann after all? Should they rather be called the Corey–Woodward–Hoffmann rules? It was well known that Havinga, Schlatmann, and especially Oosterhoff had set some very important precedents (see: J. Berson, *Chemical Creativity*, Wiley-VCH, Weinheim, **1999**, pp. 26–31). However, Corey's name had never before been mentioned in this context. As R. B. Woodward (Figure 1) died in 1979 at the age of 62, he can no longer say whether the conversation with Corey on May 4, 1964, enlightened him, gave him a decisive impetus, or merely confirmed his already well-thought-out ideas.

It is most fortunate for the history of science in general and for chemistry in particular that—triggered by E. J. Corey's statement—Roald Hoffmann has penned his memories of that time. Entitled "A Claim on the Development of the Frontier Orbital Explanation of Electrocyclic Reactions", his recollections of the early days of the development of the Woodward–Hoffmann rules and the time leading up to their publication can be read on page 6586 ff. It is unfortunate, but to be respected, that E. J. Corey, whom we of course asked to respond, chose not to say any more on the subject other than reiterating: "I am sure that the statement I made in my Priestley presentation is absolutely true, and at a later time I will present the full story."

For readers who practiced and shaped chemistry in the 1960s and 1970s, Roald Hoffmann's contribution makes compelling reading. For all readers, the article is an opportunity to ponder how new theories develop and how important communication is: both personal, in the form of conversations and correspondence, and formal, from presentations to publications. And how easily the sender and receiver can interpret the same information in a completely different manner. *Angewandte Chemie* is a suitable forum for this contribution: The above-mentioned Review (*Angew. Chem.* **1969**, *81*, 797–869; *Angew. Chem. Int. Ed. Engl.* **1969**, *8*, 781–853), in which

the detailed Woodward–Hoffmann rules were lucidly presented, was published in this journal (see Figure 2). This Review is certainly one of the most-cited publications of *Angewandte Chemie* and, since the launch of the electronic Backfiles, has been one of the most-often downloaded files. Furthermore, the publication of a Correspondence article in a scientific journal has a more lasting character than in a magazine. May it now and in future find many readers and spur them on to reflect carefully on their own behavior.

Dr. Peter Gölitz
Editor

P.S. Another recommended read in this issue is the Essay by Amir Hoveyda, who delves into Primo Levi's literary masterpiece, *The Periodic Table* (page 6592 ff.).

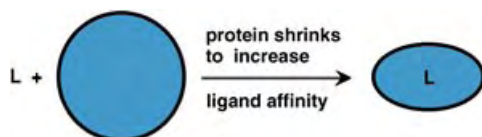
Correspondence

The well-known Woodward–Hoffmann rules explain how the feasibility and stereochemical outcome of pericyclic reactions are governed by the symmetry properties of the molecular orbitals of the reactants and products. Triggered by a recent claim by E. J. Corey, Roald Hoffmann recalls the first steps in the development of this theory.

Essays

In his book *The Periodic Table*, Primo Levi, with touching thoughtfulness, sketched the magic of the elements that make up this world. As with all enduring works of art, *The Periodic Table* is open to numerous interpretations. Another visit, a quarter of a century after its publication, proves to be most rewarding.

Reviews


The strength lies within: This review proposes that receptors and enzymes (shown in blue in the scheme) derive an important contribution to binding their ligands and transition states (respectively) by decreasing their dynamic behavior. Conversely, ligand binding energy is reduced where the binding process increases the dynamic behavior of the receptor protein.

Given the non-renewable nature of synthetic polymers from petroleum feedstocks, there is increasing interest in developing routes to biodegradable polymeric materials from renewable resources. Polycarbonates made from CO_2 and epoxides (see scheme) have the potential to meet these important goals. Reviewed here are well-defined catalysts for epoxide–CO_2 copolymerization and related reactions.

Communications
Half-dissociated: Experimental and computational findings conclude that water forms a highly ordered superstructure on defect-free surfaces of zinc oxide, in which every second water molecule is dissociated (see picture). The results are of general relevance for heterogeneous catalysis.

Light switches: The photon capture area of single fluorescent molecules has been directly measured by switching them "on and off" with light. Stimulated emission of single molecules (see picture) enables the precise control of the excited state population probability of an individual molecule at room temperature.

Giving cells some stick: Osteoblast adhesion to titanium, a common material for implants, is stimulated by coating with an optimized and highly specific nonpeptidic ligand for the αvβ3 integrin (see picture). This new technology is advantageous to conventional coating by peptides or proteins in many practical aspects (selectivity and activity, stability against enzymatic degradation, sterilization, costs).

Different octahedral units form the basis of the structures of the very strong Lewis acids aluminum bromide fluoride (ABF) and aluminum chloride fluoride (ACF) (see picture). A structure model for these phases is established in which the octahedra are linked through μ-bridging fluorine atoms and μ$_3$-bridging X atoms (X = Cl, Br). The bridging of three octahedra by a heavy halogen atom explains the results of NMR and EXAFS analysis.
$(X = Cl, Br)$
Markers by mass: The effect of terpenoids on organisms can be investigated by using DNA adducts as markers. High-resolution MS was used to characterize DNA/α-pinene oxide adducts after enzymatic digestion. The reaction of α-pinene oxide with the N7 position of guanosine leads to cleavage of the N-glycosidic bond and formation of the N7 guanine adducts (see picture).
Impressive tolerance is displayed in the efficient and chemoselective organocatalytic transfer hydrogenation of α,β-unsaturated aldehydes in the presence of a Hantzsch dihydropyridine and a catalytic amount of dibenzylammonium trifluoroacetate (see scheme). Various sensitive functional groups such as the nitro, cyano, alkenyl, and benzyloxy groups survive these reaction conditions.

Contents

A choice selection: A dynamic combinatorial library of oligonuclear coordination compounds is formed from a flexible tris(catechol) ligand with titanium(IV) ions in the presence of lithium carbonate or potassium carbonate. A trinuclear complex (**1**) can be isolated by crystallization from DMF. In contrast, well-defined mononuclear (**2**) compounds are obtained by addition of Na⁺ as a template, and tetranuclear compounds (**3**) are isolated by changing the solvent to DMSO.
Small rings: Only a few methods are known for the synthesis of cyclopropane carbaldehydes and cyclopropyl ketones **2**. In a new, simple route to highly enantioenriched trisubstituted three-membered rings, 4-hydroxy-1-alkenyl N,N-diisopropyl carbamates **1** are treated with NaH, resulting in migration of the carbamoyl group and intramolecular enolate alkylation.
An efficient method for the enantioselective preparation of structurally diverse cyclopropanes has been developed. Sequential homoaldol coupling and activation steps result in a three-carbon homologation of an aldehyde to give a nonracemic, stereochemically rich cyclopropylcarboxaldehyde (see scheme).

The complex macrolide apoptolidinone (**1**) was synthesized in 19 steps (longest linear sequence) from (S)-malic acid. Key reactions include A) two stereoselective aldol reactions, B) a late-stage Grubbs cross-metathesis reaction to install a trisubstituted vinyl boronate, and C) an intramolecular Suzuki–Miyaura reaction.
After all, neat As(N₃)₅ can be isolated: By analogy with AsCl₅, neat As(N₃)₅ was predicted to be a highly unstable compound, and previous attempts at its synthesis had resulted in intense explosions. The successful syntheses and characterization of neat As(N₃)₅ and Sb(N₃)₅ and the crystal structure of the [Sb(N₃)₆]⁻ ion (see picture) are now described.

Hypervalency and secondary bonding are the driving forces behind the rapid absorption of gaseous carbon dioxide by two organotellurium and organotin oxides and the unexpected formation of a unique tellurastannoxane cluster (see structure; dark red Te, black Sn, gray C, light red O). The absorption is reversible with the liberation of carbon dioxide being observed at temperatures between 90 and 145 °C.

Contents
Hold the metal: Upon exposure of acetates **1** to substoichiometric quantities of triphenylphosphane in the presence of **2**, regioselective metal-free allylic substitution occurs through a formal tandem S_N2'–S_N2' substitution mechanism to provide γ-butenolides **3** with high levels of regio- and diastereocontrol (see scheme).
Template-directed processes involving polysaccharide, dextran, and preformed zeolite crystals/nanoparticles are used to prepare elaborate porous frameworks of interconnected filaments of NaY zeolite/silica nanoparticles, as well as macroscopic fibers of crystallographically aligned silicalite nanocrystals (see picture; bar is 5 μm).
Catch a falling star: Peptides from chiral, C^α-methylated α-amino acids (see scheme) found in L enantiomeric excess in meteorites show diastereoselectivity when reacting with racemic proteinogenic amino acids. Accordingly, the prebiotic soup of proteinogenic amino acids may have evolved into a chirally unbalanced system, eventually seeding the homochirality of life.
Removal service: A deletion mutant lacking the Gly600 residue of a prokaryotic squalene–hopene cyclase was prepared. Surprisingly, the mutant cyclase has no enzyme activity for **1** and **3**, but shows a high conversion ratio for **2** (see scheme). Deleting Gly600 alters the specificity from prokaryotic into that of eukaryotic-type cyclases.

R = SiMe*t*Bu₂ — $R = SiMetBu_2$

M = Mg, Ca, Sr
Carbon copies: Alkaline-earth metal (Mg, Ca, and Sr) derivatives **2** of a silagerma-bicyclo[1.1.0]butane-2,4-diide are obtained by the treatment of **1** with magnesium or calcium in THF or by the reaction of the dianion **3** with MgBr₂, CaI₂, or SrI₂ in THF. Such stable derivatives of charged bicyclo[1.1.0]butanes have been elusive species until now.

Sifting through the surface: Permselective core/shell microgels have been prepared by using a labile cross-linker, which can be cleaved stoichiometrically to control the porosity of the shell. Proteins that are smaller than the pore size are allowed to permeate through the shell to bind with the core-bound ligand (arrows; see picture).
no binding   *degradation*   binding
During the biosynthesis of glycopeptide antibiotics of the vancomycin family, several oxidative phenol coupling reactions take place. An oxygenase (OxyB) from the vancomycin producer catalyzes the first of these coupling reactions to a significant extent only when the putative hexapeptide substrate is linked as a thioester to a peptide carrier domain (PCD) derived from the non-ribosomal peptide synthetase (see picture).
Multiple C–C bonds are formed in an unprecedented reaction of an ylide with 2 equivalents of a rhodium-stabilized carbene. The cascade cyclization of the intermediate formed from the three components gives bicyclic pyrrolidine products with excellent diastereoselectivity (see scheme).

O₂ for you: The *trans*-μ-1,2-peroxo Ni₂ dimer **3**, a structural motif unknown previously in nickel coordination chemistry, was produced by reaction of the (tmc)nickel(I) precursor **1** with O₂. Thermal decomposition of **3** in CH₃CN leads to **2**, in which the atoms of the hydroxide ligand derive from O₂ and the hydrocarbon solvent.
(tmc)Ni—O—O—Ni(tmc)

Contents
Independent of the ring size in the aliphatic side chains, peptides made up of $\beta^{2,3}$-cyclic aminoxy acids, novel chiral building blocks of foldamers, adopt uniform secondary structures consisting of rigid β N—O turns and 1.8_9-helix structures (see figure). This contrasts previous results from other groups with cyclic ring-constrained β-peptides.
Central to the design of a new organocatalyst system for aldehyde–aldehyde aldol reactions is the necessity of iminium geometry control during the enamine addition step (see scheme). Significant structural variation in both the aldol donor and aldol acceptor are possible while maintaining high reaction efficiency and enantioselectivity. TFA = trifluoroacetic acid.
Spring-loaded supramolecular chemistry: Pyridine-2-carboxaldehyde reacts with the *m*-phenylenediamine shown in aqueous solution in the presence of Cu^I ions to give a tetracopper(I) grid complex (see structure). This structure is stable in water, but not in any of the organic solvents tried. The strain incorporated into the structure is compensated by a diffuse pressure applied by the hydrophobic effect. R = 2-hydroxyethylcarbamoyl.

The long and the short of it: N···O distances less than 2.8 Å (see picture) have been implicated in determining the 220 nm circular dichroism band intensity in helical peptides. An analysis of helical peptide crystal structures, however, reveals the average experimentally determined hydrogen-bond lengths are 2.978–3.113 Å (α helix) and 2.907–3.211 Å (3_{10} helix).

Can it be < 2.8 Å?
Water-soluble chiral Ru complexes with a β-cyclodextrin unit have been shown to catalyze the reduction of aliphatic ketones (see scheme) with up to 97% *ee* and in good to excellent yields in the presence of sodium formate. The β-cyclodextrin unit is an essential component of the catalyst. It contributes to the unprecedented levels of enantioselectivity observed through the preorganization of the substrates in the hydrophobic cavity.
A new twist of RNA fate: Site-selective chemical functionalization at the C2″−OH group of paromomycin (**1**) afforded a novel analogue with potent inhibitory activity against several bacterial strains, including a multidrug-resistant *S. aureus* (MRSA) strain. X-ray cocrystal-structure determination of the complex with the A site of *E. coli* RNA revealed a new mode of binding in which significant conformational and positional changes had taken place in rings III and IV.
Protecting group chemistry was used to functionalize the channel entrances of zeolite L crystals. This approach is broadly applicable and can be used to obtain a wide range of new zeolite-based materials. The picture shows two microcrystals modified with amino groups at the channel entrances, which reacted further with a red-luminescent head molecule. FG = functionalizing group, prot. = protector.
Get into shape under redox: Rearrangement of [Ru$_4$S$_3$(arene)$_4$] accompanies redox processes and occurs in its reduction of H$^+$ to H$_2$ (see scheme; *Ru* = Ru(cymene)). The [Ru$_4$S$_3$(arene)$_4$]$^{2+}$ ion is so crowded that arene rotation is hindered, which allows the detection of atropisomers.

Contents

Visualizing 3D structures (especially of supported catalysts) by the nondestructive method of electron tomography is best accomplished by high-angle annular dark-field (HAADF) rather than by bright-field (BF) imaging; bimetallic clusters of $[Ru_{10}Pt_2]$ (diameter ca. 0.4 nm), supported on nanoporous silica, are invisible in BF but readily visible in HAADF images (see pictures).
Catalytic containers: A supramolecular metal–ligand assembly $[M_4L_6]$ is utilized as a catalytic host for the unimolecular carbon–carbon bond-forming rearrangement of enammonium cations (see scheme). The restricted reaction space of the supramolecular structure forces the substrate to adopt a reactive conformation upon binding to the interior. The assembly achieves up to 850-fold rate acceleration of the rearrangement.

The editorial staff and the publishers thank all readers, authors, referees, and advertisers for their interest and support over the past year and wish them all a Happy New Year.

Corrigendum

We have become aware of a report by Bergman and co-workers that the abstraction of a methyl group from [Cp$_2$ZrMe$_2$] with B(C$_6$F$_5$)$_3$ leads to an acceleration of the intramolecular hydroamination reaction of an aminoallene substrate relative to the reaction in which only [Cp$_2$ZrMe$_2$] is used (L. Ackermann, R. G. Bergman, R. N. Loy, *J. Am. Chem. Soc.* **2003**, *125*, 11956). We therefore correct our statement on p. 5543 that "alkyl metallocene cations have been used in organic synthesis, but to the best of our knowledge not in hydroamination reactions", with reference to the above-mentioned publication.

In the legends to the Figures 3 and 4 the sweep rates and temperatures have been transposed. The correct values are as follows:

Figure 3: sweep rate 0.001 Ts^{-1} and $T = 0.04$–0.5 K; Figure 4: sweep rate 0.007 Ts^{-1} and $T = 0.01$–0.5 K.

The authors apologize for the error.

A Claim on the Development of the Frontier Orbital Explanation of Electrocyclic Reactions

Roald Hoffmann*

An important discovery took place in the period 1964–1969—it was the elaboration of the complex of ideas known variously as "the conservation of orbital symmetry" or "orbital symmetry control." The stereochemistry and ease (or difficulty) of the elementary steps of many organic reactions found an explanation in the phase relationships of their molecular orbitals.

It was my fortune to collaborate with R. B. Woodward in this story. Our published work consisted of a series of five communications to the Editor of *J. Am. Chem. Soc.* in 1965,[1] a paper in *Accounts of Chemical Research*,[2] and, importantly, a final exposition of the ideas in an article of some length in *Angewandte Chemie*.[3]

Woodward and I used a variety of theoretical approaches in our work—from simple frontier orbital (HOMO/ LUMO) arguments, through orbital correlation diagrams, interaction diagrams, and perturbation theory arguments, to detailed molecular orbital calculations. There were good reasons not to use a single approach—symmetry was a way in to the solution, but its unthinking use would have imprisoned us. Still, there was a leitmotif in our work: orbitals and their symmetries mattered, and so did the number of electrons.

Woodward and I were lucky—we not only rationalized a large, piecewise

puzzling, body of chemistry, but also were able to make predictions that were verifiable by a community eminently capable and interested in probing experimentally the consequences of the theory. Orbital symmetry considerations were expeditiously tested; they were found to be portable and productive. The 1981 Nobel Prize in chemistry was awarded to Kenichi Fukui and me for this work; had R. B. Woodward lived, there isn't the least doubt that he would have shared in this recognition.

E. J. Corey's Public Claim

In his 2004 Priestley Medal address, published in *Chemical and Engineering News*,[4] E. J. Corey writes,

"On May 4, 1964, I suggested to my colleague R.B. Woodward a simple explanation involving the symmetry of the perturbed (HOMO) molecular orbitals for the stereoselective cyclobutene/1,3-butadiene and 1,3,5-hexatriene/cyclohexadiene conversions that provided the basis for the further development of these ideas into what became known as the Woodward–Hoffmann rules."

The same sentence appears in a 2004 *Journal of Organic Chemistry* perspective by E. J. Corey, "Impossible Dreams".[5] This terse reminiscence of a conversation, and a claim of its significance has given rise to considerable discussion and speculation in the community.

Let me recount what I know, remember (and don't remember), and what I infer about the events 40 years ago surrounding this claim. I cannot

speak about the contents of the conversation because I was unaware of it at the time; given that Woodward is no longer alive, we only have Corey's report on it. But in my opinion, the part of E. J. Corey's published statement that reads "*…that provided the basis for the further development of these ideas*" is not right in its characterization of an episode in an important discovery.

Corey's Claim, Made in Prior Conversations or Exchanges with Me on the Subject

In a visit to Cornell in the 1970s, Corey told me that he made my career by telling R. B. Woodward the HOMO explanation in 1964. To my knowledge, this was the first time he made this direct claim to me. I was puzzled, and I think I ignored the comment.

On November 2, 1981, after the Nobel Prize in Chemistry to Kenichi Fukui and me was announced, Corey wrote me a letter stating his claim in substantial detail. The original of this letter is deposited in my papers in the Cornell University Library (available to the public).[6] In the letter Corey recounts a conversation he had with Woodward on the evening of May 4, 1964, in which he told Woodward, who posed the problem of the electrocyclic reactions to him (and who seemed, according to Corey, more interested in geometrical explanations), that the explanation might be found in the symmetry properties of the orbitals involved. Corey continues his account by relating how the next day Woodward appeared in Corey's office and told the same

explanation briefly to Douglas Applequist (a visitor to Harvard that semester) in Corey's presence, as his (Woodward's) "new idea." Corey goes on in his letter to say:

"…the fact is I conceived of the idea, not Bob. In a manner of which few would be capable he pirated the idea, evidently preferring that over my good will. Even more incredible than what Bob did was how he did it."

In his November 2, 1981 letter Corey expressed concern that I would tell the orbital symmetry story in my Nobel Lecture (I had already chosen to talk about something new, the isolobal analogy). And he wanted *me* to tell people of *his*, Corey's, contribution.

This letter, coming at the time that it did, and with such claims, disturbed me greatly. I answered it on November 8, 1981.[6] I said that I would not tell people of Corey's claim—he chose not to do so himself in public (or to Woodward); it would be unfair to Woodward for me to do so then, in 1981, after his death in 1979.

Corey then wrote another letter to me (November 16, 1981)[6] in which he reiterated and escalated his claims, in a manner that I felt as intimidating to threatening. Here are two excerpts from that letter, which convey its tone:

"You cannot deny that despite the possibility of appalling dishonesty at the roots of your collaboration with Bob, you elected to close your mind. The two of you in effect "stonewalled" my contribution so completely that you chose not even to make a perfunctory acknowledgement in your papers."

and

"Roald, please consider that history may not deal leniently in this matter, taking seriously the possibility not only of Bob's dishonesty, but of your own not unwitting participation in the extension of fraud."

In the spring of 1984, I visited Harvard for a semester. During that time Corey and I spoke for a couple of hours on the issue. He then sent me another letter on April 29, 1984[6] in which he gives as the reason that he did not publish his claim in Woodward's lifetime as follows:

"I am amazed that you would think it possible that I would consider doing anything against Harvard, to which I was and am so devoted."

In his first letter to me on November 2, 1981, Corey gave another reason for not writing himself of the way he perceived things had happened:

"I had hoped that Bob himself would do it as he grew older, more considerate, and more sensitive to his own conscience."

To the best of my knowledge, Corey never made an attempt to set the record straight (according to his own perceptions) by speaking of it to Woodward in the 15 years between 1964 and 1979, when Woodward died. Or by publishing his claim. Corey made no public claims, as far as I know, until the statement in his Priestley Medal address in 2004.

Corey did talk to others at Harvard and elsewhere of the matter. In his November 2, 1981 letter to me, Corey writes that he told his story to E. B. Wilson in 1964. And I know he discussed the matter subsequently with Jeremy Knowles. Frank Westheimer and Elkan Blout knew about Corey's claim and agonized over the question for years while composing a memorial notice on Woodward. In the end, despite my objections, Elkan Blout included in his 2001 biographical memoir for Woodward the following sentence: *"In 1964, after a brief discussion with E. J. Corey and others of his thoughts and his chemical results, Woodward was able to formulate his important ideas in this area."*[7]

Scientific and Personal Background to 1964 Events

To set the stage for my recollections of the period, let me recount the story of my relationship with E. J. Corey and R. B. Woodward.

I received my Ph.D. in 1962 with W. N. Lipscomb, Jr. and M. P. Gouterman, and began a Junior Fellowship in the summer of 1962. I was given an office in the basement of Conant Hall, a few doors down from Corey's office in Converse Hall. And I began to learn organic chemistry, applying the extend-

ed Hückel method that a group of us developed in the Lipscomb group to organic molecules. When I finished the first extended Hückel paper on hydrocarbons I sent a preprint (this was early 1963) to the organic chemists at Harvard—Woodward, Corey, Bartlett, and Westheimer—and then set up appointments to see all of them. This was the first time (after five years at Harvard) that I spoke to Woodward about science.

Of the people I saw, Corey responded most positively to my growing interest in organic chemistry. I was down the hall from him, and as busy as he was, he always welcomed me to talk. By telling me of hot subjects—nonclassical carbonium ions and organic photochemistry—he helped draw me into organic chemistry.

I began to go to organic seminars and went to one of the legendary evening Woodward meetings. In the spring of 1964, one of Corey's colleagues from Illinois, Douglas Applequist, visited Harvard for the semester. He gave a course on strained molecules which I listened to with great interest. Applequist and I talked to each other a lot. I was in the midst of discovering for myself the full beauty of organic chemistry.

My Recollections of the Specific Period in 1964

The simple frontier orbital explanation of the stereochemistry of electrocyclic reactions did not originate with me. It was brought to me by Woodward. Let me outline what I have a record of, what I remember, and what I don't recall, concerning my introduction to that frontier orbital explanation. And how my collaboration with Woodward began.

Woodward describes in two lectures the chemical and historical background of the advent of the orbital symmetry rules. In the first, his 1966 Sheffield lecture,[8a] he uses the generic "we"; in his second account, the 1973 Cope Award Lecture (published long after, from a copy of a handwritten text by R. B. Woodward),[8b] there is a direct first person account, as follows:

"I REMEMBER [capitals in the original] *very clearly—and it still sur-*

Correspondence

prises me somewhat—that the crucial flash of enlightenment came to me in algebraic, rather than in pictorial or geometric [all underlining is in original text] form. Out of the blue, it occurred to me that the coefficients of the terminal terms in the mathematical expression representing the highest occupied molecular orbital of butadiene were of opposite sign, while those of the corresponding expression for hexatriene possessed the same sign. From here it was but a short step to the geometric, and more obviously chemically relevant, view that in the internal cyclisation of a diene, the top face of one terminal atom should attack the bottom face of the other, while in the triene case, the formation of a new bond should involve the top (or pari passu, the bottom) faces of both terminal atoms."

In this period I kept a hard-bound notebook. But I did not keep it carefully, with only occasional dates written in. There is in the notebook an April 17 date for a seminar by George Olah, and the next date in the notebook is May 5,

1964 (Figure 1) the day after the Corey and Woodward conversation (as reported by Corey).

The May 5 entry (p. 80; the entire notebook, covering roughly the period March to June 1964, is in the Cornell University Library, collection cited[6]) says "Talk with Woodward and Applequist," and below it contains the stereochemical essence of the four- and six-electron electrocyclic reaction, without orbitals. But clearly orbitals and their phases are in the discussion, because below these reactions I sketch the cyclopropyl to allyl opening and draw the lowest allyl orbital as presumably controlling the disrotatory motion in the cation.

This is the first mention of electrocyclic reactions in my notebook. But I believe I heard of the HOMO symmetry argument earlier (and prior to May 4, the date of the Corey–Woodward meeting) in—I think—a conversation I had with D. E. Applequist, who recounted it as an explanation that Woodward suggested and asked me for my reaction to

it. I have no written record of that early conversation. It must be said, however, that Applequist does not think he had such a conversation with me prior to May 5, 1964.[9]

Returning to my notebook, after some thoughts on cyclopropyl cation, two pages later I sketch out a plan for studying what would later be called con- and disrotatory motion. These preoccupy me for quite a few pages/days (no further dates appear in the notebook until June 9, 1964); the discussion does not focus on orbitals but is "computational". It is pretty well summarized in our first paper. At this point I was still a computational chemist, and even though I used orbitals and perturbation theory, explanations constructed in frontier orbital language were not yet a common part of my work and thought. They quickly became so. In fact, this—a recognition of the force of simple bonding arguments, and their utility in a theory–experiment dialogue—was on a personal level the main consequence for me of the orbital symmetry story.

Here's how Woodward described the beginning of our interaction, in his Cope Award Lecture:

"AFTER a brief false start in extending these ideas, attributable clearly to my gaucherie in the details of quantum chemistry, I very soon realized that I needed more help than was available in my immediate circle, and I sought out Roald Hoffmann… I told him my story, and then, essentially, put to him the question 'Can you make this respectable in more sophisticated theoretical terms?'"[8b]

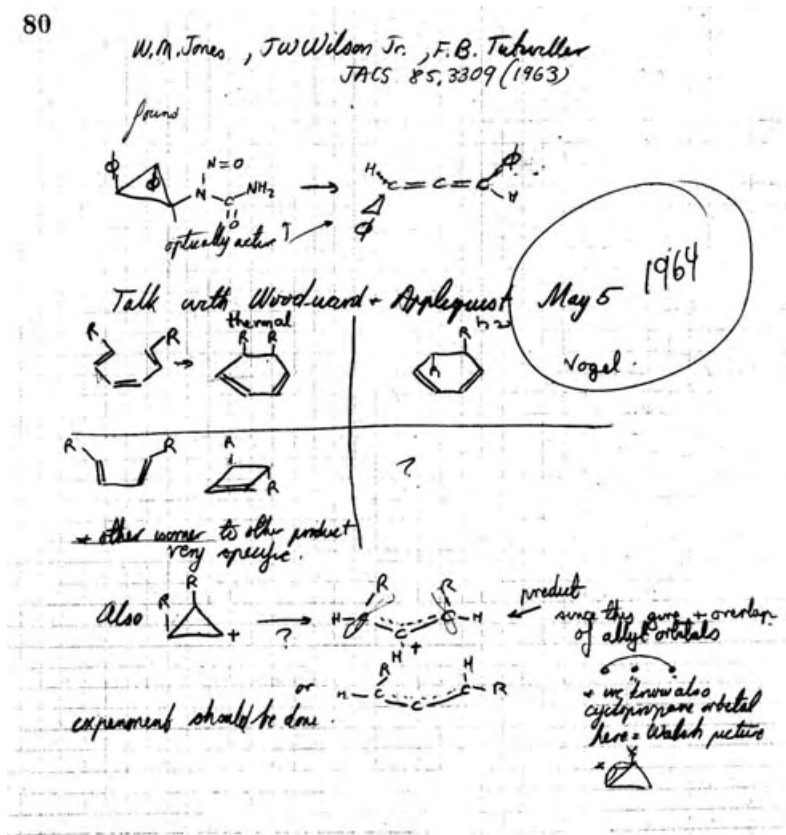
Woodward and I began to talk in that period. An important conversation I recall took place after a seminar by W. von. E. Doering. By that time I had done the calculations and could confirm the ground- and excited-state stereochemical preferences. The electrocyclic reaction paper was submitted on November 30, 1964, and published in the January 20, 1965 issue of the *J. Am. Chem. Soc.*[6a] Then R.B. Woodward and I went on to the rest of our orbital symmetry work. There was a lot to do…


Figure 1. May 5, 1964, entry in Roald Hoffmann's notebook. The year in the date was written in some time later.

Corey's Role in the Orbital Symmetry Story and Woodward's Denial of It

In the letter to me of November 16, 1981, E. J. Corey says that he told me in May 1964 that he had suggested to R. B. Woodward the HOMO explanation for the stereochemistry of electrocyclic reactions, and that Bob had taken over the idea from him. I spoke to Corey often in that period, but I have no recollection of such a conversation; I think Corey's statement would have been so striking (especially the part about Woodward taking the idea from Corey) that I would have remembered it.

Nevertheless, there *was* an idea in my mind then that Corey had a stake in the electrocyclic reaction story; my reconstruction today is that in the late spring and summer of 1964 Corey kept talking to me as if he did have such a role, as if the electrocyclic reaction research were joint work between Corey, Woodward, and me. Eventually, I was sufficiently puzzled by this that I did speak to Woodward. I do not remember when that was; I suspect it was later, in the fall of 1964, when we wrote our first paper.

When Woodward and I spoke of the matter—again, I cannot remember when it was—I asked him directly if Corey had a role in this work. He said "no"—this was our (R.B.W. and R.H.) work.

I did not question Woodward further. In retrospect, I regret not doing so, and I regret not asking Corey more directly to tell me his role in the work. R. B. Woodward was 47, the top synthetic organic chemist in the world. E. J. Corey was 36, a full Professor at Harvard. In May 1964 I was 26, a new Ph.D., a Junior Fellow to be sure, but just starting out in my career.

In the more than a year that I remained at Harvard (I left in June 1965), I kept on talking to Corey and learned a lot from him. I do not remember any cooling of our relationship, though I certainly spent more and more time with Woodward. Corey, in his correspondence with me, disagrees, saying that our previously frequent conversations stopped after I began working with Woodward.

My Perception of What Happened

I have no reason to doubt Corey's statement that there was a conversation between Corey and Woodward on May 4, 1964, even though we have only Corey's account of it.

But, I also do not think that the conversation "*provided the basis for the further development of these ideas into what became known as the Woodward–Hoffmann rules,*" as Corey writes. Here are some factors that go into my reasoning:

a) Woodward had a habit of posing to people problems of great interest. And also of posing such problems as puzzles, even if he had the solution. Specifically, we know that he talked about the electrocyclic conundrum—to H.C. Longuet-Higgins, and Lionel Salem, for instance—as it was taking shape experimentally in the work of others and in the vitamin B_{12} synthesis he was pursuing in collaboration with A. Eschenmoser's group.

b) I think Woodward was perfectly capable of coming up with the frontier orbital explanation by himself. Though he began his career with VB arguments, I found Woodward in 1964 pretty well-versed in MO ideas. Woodward had learned a lot from William Moffitt, around the ferrocene and octant rule stories. Orbital ideas were in the air, the classic Streitwieser and Roberts books widely read, the success of the Hückel rule amply demonstrated. There was also the L. J. Oosterhoff "forerunner" (see below), which Woodward knew about.

One interesting piece of evidence for Woodward's knowledge of molecular orbitals is in a published comment he made after a lecture by Rolf Huisgen in a Welch Foundation Conference in 1961.[10] Woodward draws quite explicitly the orbitals of a vinyl carbene (albeit without phases), and asks "*Do we have specific orbital geometric requirements* [for Huisgen's reaction] *and would they in this case preclude the operation of the mechanism which is so general in many of the cases?*"

My strong feeling is that Woodward had the frontier orbital idea before he spoke to Corey. I think that Corey's coming up with a similar way of thinking about the reaction in that May 4 conversation perhaps might have prompted Woodward to push on, and to ask for my assistance with calculations supporting the frontier orbital approach. For some reason, he was unsure of himself (not a characteristic one normally associated with Woodward…) and needed the support of a theoretical chemist.

Going back to the Corey–Woodward meeting of May 4, 1964, it would not be the first time that two people came away from a conversation with diametrically opposed ideas of what was said.

Crediting Suggestions: Then and Now

Assuming that the contents of the May 4, 1964 conversation were as E. J. Corey reports them, then I think that at best Corey has a claim to a rediscovery of the Oosterhoff orbital argument of 1961. In a paper by E. Havinga and J. L. M. A. Schlatmann, the authors write:

As Prof. Oosterhoff pointed out, another factor that possibly contributes to this stereochemical difference between the thermal and photoinduced ring closure may be found in the symmetry characteristics of the highest occupied π orbital of the conjugated hexatriene system.[11]

The Oosterhoff "forerunner" to the orbital symmetry control ideas is mentioned in a footnote in our first 1965 paper; its role has been discussed by J. A. Berson in his book "Chemical Creativity."[12]

In 1963–1964, E. J. Corey and A. G. Hortmann accomplished the total synthesis of dihydrocostunolide. A crucial step involved a stereospecific electrocyclic reaction. The two papers on the work[13] do not have any reference to an electronic factor in the stereoselectivity. Neither is the Havinga and Schlatmann paper mentioned. The full Corey and Hortmann paper was submitted on August 5, 1965, some months after publication of the first paper by Woodward and me.

Correspondence

The full paper on the dihydrocostu-nolide synthesis provided a place for Corey to state his electronic explanation. It was an opportunity not taken.

Should Corey's suggestion of the frontier orbital explanation for the stereochemistry of electrocyclic reactions have been credited in our first paper and subsequent ones? I can only speak for myself, and from today's perspective. We all make decisions, some easy, some hard, of what to reference/credit in our papers. If the substance of what E. J. Corey reports was said in that conversation with Woodward is true, then I believe it should have been credited. As Oosterhoff's suggestion was. I would be ready today to regret the omission and apologize to Corey for it. But, I am torn… between the conviction with which Corey tells his story in 1981 and today, torn between that and the impossibility of Woodward commenting on the decision today, as well as Woodward's 1964 denial to me of a role for Corey. With Woodward not alive, and no record except Corey's memory for the essence of that conversation, I just cannot say today that the conversation should have been credited.

A Claim Unfairly Made

The matter should have been argued out in 1964, by Corey persisting in telling Woodward of his (Corey's) perception of his contributions. Seventeen years later, Woodward gone, Corey, without publishing his account, wanted *me* to tell others that *his* claim was valid.

People will form their own opinions of Corey's explanation of why he didn't press a public claim (that it would have hurt Harvard, that Woodward would eventually give him credit). Too bad he didn't speak out; had Corey done so in 1964, or in the period 1964–1979, we could have had Woodward's viewpoint.

I believe that E. J. Corey's perception of the consequences of what he told R. B. Woodward is just that—what he, Corey, believes. Based on the arguments I made above, and on what I remember, I don't think that the conversation in question influenced in any significant way the beginning of the orbital symmetry control story. And given that Corey's claim was (and is being) made after Woodward's death—when the claim could have been made for 15 years in Woodward's lifetime—that claim is also deeply and fundamentally unfair.

Essays

Primo Levi's *The Periodic Table.* A Search for Patterns in Times Past

Amir H. Hoveyda*

"
*But all at once it dawned on me that this
Was the real point, the contrapuntal theme;
Just this: not text, but texture; not the dream
But topsy-turvical coincidence,
Not flimsy nonsense, but a web of sense.
Yes! It sufficed that I in life could find
Some kind of link-and-bobolink, some kind
Of correlated pattern in the game,
Plexed artistry, and something of the same
Pleasure in it as they who played it found.*"
Vladimir Nabokov, Pale Fire (Canto Three)

He is not recognized for any contributions to science. He did not receive any scientific accolades, nor was he a university professor. Yet it is likely that Primo Levi will be remembered as a singularly influential chemist of the twentieth century.

A survivor of the world of concentration camps, Levi was trained as a chemist but is admired as a writer and an artist. Levi did not write because he felt that his life would be the stuff of drama that satisfies common curiosities. It was not a wooly relative, a wild whim, or a wily editor, tongue stained with tribal praise that urged him to author books. Writing for Levi was not a distraction from the everyday life—it was life itself.[+]

"I had returned from captivity … was living badly. The things I had seen and suffered were burning inside me; I felt closer to the dead than the living, and felt guilty at being a man, because men had built Auschwitz, and Auschwitz had gulped down millions of human beings, and many of my friends, and a woman who was dear to my heart. It seemed that I would be purified if I told its story. … [By] writing I found peace for a while and felt myself become a man again, a person like everyone else, neither a martyr nor debased nor a saint …"

In his creation *The Periodic Table*, Levi, with touching thoughtfulness, sketched the magic of the elements that make up this world. As with all enduring works of art, *The Periodic Table* is open to numerous interpretations—it rewards us with new vistas upon every re-reading. Levi portrayed the periodic table as a mirror for reflection, through which we might steal a glimpse at the meaning of our existence. Elements in *The Periodic Table* conjure memories, offering fresh notions meant to guide us, at a conscious as well as a subconscious level, in our search to understand Time and the scars that its tyranny leaves on our psyche. Through such meditative explorations we escape the prison of the hours and extend our consciousness beyond the oppressive cage of the immediate present.

The attributes of an element are used by Levi as a metaphor for his discussion in a particular essay; an element can be a nugget hiding a thought or an event that we are made privy to. For Levi, each element is the objects and sensations that cast their mysterious shadows in the writings of Proust: the celebrated Madeleine dipped in a tisane offered by Aunt Leonie

or the musty smell in uncle Adolphe's study. In *The Periodic Table* earthly elements hold ghosts of the past awaiting release initiated by an unexpected meeting, at an unforeseen date, at an unknown location. Reading *The Periodic Table* makes us wonder what do different elements mean to us. What mental reactions do they initiate in our subconscious? What fresh slices of the past have been faithfully sealed for us? We may have been taught as young students, and may now be convinced that Lithium, Europium, Vanadium and Iodine do not belong to the same family in the periodic table. *The Periodic Table* leads us to reconsider. We are encouraged to look again; Ar, Mo and Ir might well be connected in the land of dreams.

On the visible plane, the letter "K" represents potassium. But for Levi, this eleventh letter of our alphabet, unleashed anxieties, fears, sounds and smells of that frightful day when he nearly set his laboratory on fire. Unable to find pieces of sodium, as advised by the procedure that he was to follow for purification of benzene, Levi decided to substitute potassium. He was taught that potassium is

"sodium's twin, but it reacts with air and water even with greater energy. … So I handled my 'half-pea' [of potassium] like a holy relic: I placed it on a piece of dry filter paper, wrapped it up in it, went down into the institute's courtyard, dug out a tiny grave, and buried the little bedeviled corpse …

I took now the empty flask, put it under a faucet, and turned on the water. I heard a rapid thump and from the neck of the flask came a flash of flame directed at the window that was next to the washbasin and the curtain around it caught fire. While I was stumbling

around looking for some even primitive means to extinguish it, the panels of the shutter began to blister and the room was now full of smoke. I managed to push over a chair and tear down the curtains; I threw them on the floor and stomped furiously on them, while the smoke half blinded me and my blood was throbbing violently in my temples.

… In a way it served me right: these are the things that happen to the profane, to those who dawdle and play before the portals of the temple instead of going inside. … [The flask] must have contained, if nothing else the vapor of the benzene, beside of course the air that came in through its neck. But one has never seen the vapor of benzene, when cold, catch fire by itself: only the potassium could have set fire to the mixture, and I had taken out the potassium. All of it?

… I thought of another moral, … and I believe that every militant chemist can confirm it: that one must mistrust almost-the-same (sodium is almost the same as potassium, but with sodium nothing would have happened), the practically identical, the approximate, the or-even, all surrogates, and all patchwork."

Potassium, the over-eager alkali metal represented to Levi the precariousness of life in a world of approximations. After all, one crucial thread that connects arts and sciences is the significance of subtleties. The importance of details is again brought forth in the chapter entitled *Vanadium*. Here, in a letter that Levi receives in response to his queries regarding the quality of a recent shipment of resin that his company had purchased from a German firm, he notices a misspelling. The correspondent, a Dr. L. Müller, writes "beta-naptylamin" in his letter instead of "beta-naphthylamine." Two h's missing; shaped like walking sticks, they lead Levi to a past that he did not necessarily wish to revisit.

"There was a Müller in my previous incarnation, but Müller is a very common name in Germany. … Why continue to think about it? And yet, … I could not quiet a doubt, a kind that refuses to be pushed aside and rasps slightly within you, like termites. Oh, come now, there must be two hundred thousand Müllers in Germany, forget it and think about the varnish …"

Like all dedicated chemists, Levi followed his instinct. He was not about to trust his theory. *"… [T]here is trouble in store for anyone who surrenders to the temptation of mistaking an elegant hypothesis for a certainty: the readers of detective stories know this quite well."* After some deliberation, Levi managed to write to Müller, asking whether he was the man who was his "supervisor" at Auschwitz. Müller was the same man. His written response to Levi set free memories awaiting the right time, the right place to release and render lucid emotions that go far and deep in defining us as individuals. But it was not just memories that emerged from their shell.

"The Müller character was 'entpuppt', he had come out of his chrysalis, he was sharply defined, in perfect focus. Neither infamous nor a hero: after filtering off the rhetoric and the lies in good or bad faith there remained a typically gray human specimen, one of the not so few one-eyed men in the kingdom of the blind."

Much of what we label as the "real world" is the fruit of our imagination; reality frequently coincides with the imaginary world. Our senses become excited about the events that we can only imagine will take place in the future. When we recall the past, what we voluntarily remember, rarely remains unmodified by imagination. It is perhaps natural that once a set of events has occurred, imagination begins to alter memories, and gradually they grow to reflect who we are more than actually what happened. Memories, with time, are molded and remolded like pieces of clay in the hands of a sculptor. Unpleasant visits to relatives are remembered as touching experiences. We renew such visits, and by experiencing the original reality in its refreshed form, we realize the alteration that the persistent force of imagination has imposed on our past. It is for such reasons that an autobiography might be more the fruit of a writer's imagination than an impartial chronicle of events. In reading about Levi's past and his memories as he recalls and relates them, we gain insight about the unique contours of *his* imaginary world. *The Periodic Table* shows that remembering and searching for meaningful patterns in our past can prove to be a

promising gateway that can lead to a better understanding of who we are.

In a few segments such as *Lead* and *Mercury*, Levi speaks to us purely through the magic lantern of his imaginary world. In these stories Levi shows us that truth can be discovered anywhere, in any land, guided by imagination and invention. Through the story in *Lead* Levi deals with the symbiotic relationship between fiction and reality, observation and theory. While reading Levi's stories one wonders: What is the relationship between us the reader and Levi the storyteller? *"The crew chief came from Kriti and was a big liar: he told stories about a country where there lived men called Big Ears …"* If one who tells tales is a liar, then who is the Levi who tells us the story of the crew chief? May we not also find some truth in Levi's other tales? If so, is only what we call "reality" the source of truth? Or can truth be found in our imagination and in our theories, in our stories? Is creativity how we see and interpret the world? Is there only one reality, one truth, one theory?

Levi, like many great artists, viewed everything through myriad dimensions. He cherished the unique power of imagination, but also recognized the freshness that rests within unspoiled facts. Facts were a source of inspiration to Levi. To be able to relate actual events in their original state, however, requires that we keep imagination at bay. Levi wanted his readers to see how *"the boredom of repetitious work was being transformed into nervous gaiety, as when as children you play hide and seek and discover your opponent clumsily squatting behind a bush."* A frank account of struggles to decipher the mysteries of nature had its own unique poetry for Levi; it allowed him to see himself and nature in its own reality, clear from the fog and shifting images of an imaginary world. In the chapter *Silver* Levi confesses:

"… [T]he inadequacy of our preparation, and the need to make up for it with luck, intuition, stratagems and a river of patience. … I wanted to put on display … the strong and bitter flavor of our trade, which is only … a more strenuous version of the business of living. … [T]he stories of solitary chemistry, unarmed and on foot, at the measure

Essays

of man … the chemistry of the founders, who did not work in teams but alone, surrounded by indifference of their time, generally without profit …"

The Periodic Table may make one appreciate that to a large extent scientific papers represent the investigator's account of how a discovery is made. The manner in which we toil as scientists seldom coincides with our ideal world, a world where a total synthesis transpires exactly as we had originally planned it, or where we design that perfect catalyst on a first attempt. Renditions of reality reported by an investigator emanate from processed memory, which in turn is colored by the chronicler's ideals (his dream world). In scientific papers it is the data, it is only the uncompromising hard facts that bear no allegiance to, and remain unaltered by, a researcher's imagination.

One of the more prophetic chapters in *The Periodic Table* is *Zinc*; here, Levi reflected on a subject that is a perennial topic of interest to chemists: impurities. In thinking about this late transition metal, one that "*… they make tubs out of … for laundry, not a veteran covered with glory like copper …*" Levi recalls an early attempt, when as a student he attempted to purify zinc sulfate. The procedure called for sulfuric acid; the acid was first to be diluted. But, as always, certain details needed to be tended to first.

"[A] detail which at first reading had escaped me, namely, that the so tender and delicate zinc … behaves … in a different fashion when it is very pure; then it obstinately resists attack. One could draw from the two conflicting philosophical conclusions: the praise of purity, which protects from evil like a coat of mail; the praise of impurity, which gives rise to changes, in other words to life. I discarded the first, disgustingly moralistic, and I lingered to consider the second, which I found more congenial."

Levi's interpretation is poignant on two levels. It is ironic how as chemists we have become increasingly aware of the positive role that impurities can have on reluctant reactions. Curiously, once their (often unexpected) positive attributes are discovered, such impurities are referred to as additives. Combinatorial chemistry has turned our atten-

tion to the wonders of the chemistry of mixtures. Inorganic and organometallic chemists, in spite of an undying zeal for inert conditions, have provided us with reactive and colorfully impure alloys. Water and air, primordial necessities of life for all creatures on earth, and yet the angel of death to many of our fragile molecular creations, can prove at times to be the indispensable ingredients that push reluctant molecules forward over otherwise indomitable energy barriers.

On a more sublime but sobering level, Levi expanded his journey of self-discovery to include the role of impurities in the larger world, the one outside science:

"In order for the wheel to turn, for life to be lived, impurities are needed, and impurities of impurities in the soil, too, as is known, if it is to be fertile. Dissention, diversity, the grain of salt and mustard are needed: Fascism does not want them, forbids them, … it wants everybody to be the same …"

It was in the same laboratory that young Levi saw a "*small zinc bridge*" that he would negotiate to reach Rita while dispensing with his "*masculine solitude.*" Rita was a quiet, thin, pale and sad but confident fellow student who happened to be "*cooking [his] same dish.*" But Levi was to discover that all objects of desire, upon familiarity, lay bare their blemishes at which time the pleasures of imagination are reduced to their unimpressive, but still lovable, earthly dimensions.

Rita "*got through exams with good marks, but without the genuine appetite that I felt,*" Levi explains. She read Mann's *Magic Mountain* only to discover "*how far Hans would go with Madame Chauchat, and mercilessly skipped the fascinating (for me) … metaphysical discussions between the humanist Settembrini and the Jewish Jesuit Naphtha.*" Levi was disappointed; "*[I]t could even become an essential and fundamental discussion, because I too am Jewish, and she is not …*" Mundane zinc took Levi on a journey of self-discovery. "*I am the impurity that makes zinc react, I am the grain of salt or mustard.*"

But impurities do not rejuvenate by being exclusionary. Impurities are not impurities if they only cling to other impurities.

"… I soon realized that Rita was different from me: she was not a grain of mustard. … For her university was not at all the temple of knowledge: it was a thorny and difficult path which led to a degree, to a job. … All this did not put a distance between us; on the contrary, I found it admirable …

[T]rembling with emotion, I slipped my arm under hers. … I fell into step with her, and felt exhilarated and victorious. It seemed to me that I had won a small but decisive battle against the darkness, the emptiness, and the hostile years that lay ahead."

Through conceiving and writing *The Periodic Table*, Levi explored his personal reality. Levi aimed to unravel mysteries of human behavior and of nature, mysteries that test the limits of our reasoning and imagination. Levi's masterpiece bears tales of his struggles to understand the meaning of his existence and the world surrounding it. In a chapter entitled *Lead* Levi writes:

"This is a difficult thing to explain, but it has already happened more than once that someone, who knows when, coming from who knows where, at some remote time, perhaps before the Flood, finds a vein, does not say anything to anyone, tries by himself to dig out the rock, leaves his bones there, and the centuries pass. My father told me that in whatever tunnel or cave you may dig you find the bones of the dead."

Levi's writing encourages us to search the world in our own way and in our own time. It inspires us to see nature through our eyes, to try and take pleasure in solving her puzzles, anagrams and acrostics. Levi examined—voraciously—ideas, symbols, peoples, eras and kingdoms, songs, anecdotes, mirrored images, revelations, wonders, ruses, incredible tales, endless sufferings.

The Periodic Table invites us to travel the road that, however long and arduous, may be the only means through which we might catch a glimpse of the flicker of light that shines from the depth of a dark abyss. It is an infinite number of small steps, each taken by an instance of recognition that leads us towards the bottom of this unfathomable darkness. Perhaps, it is there that rests the answer to the meaning of it all.

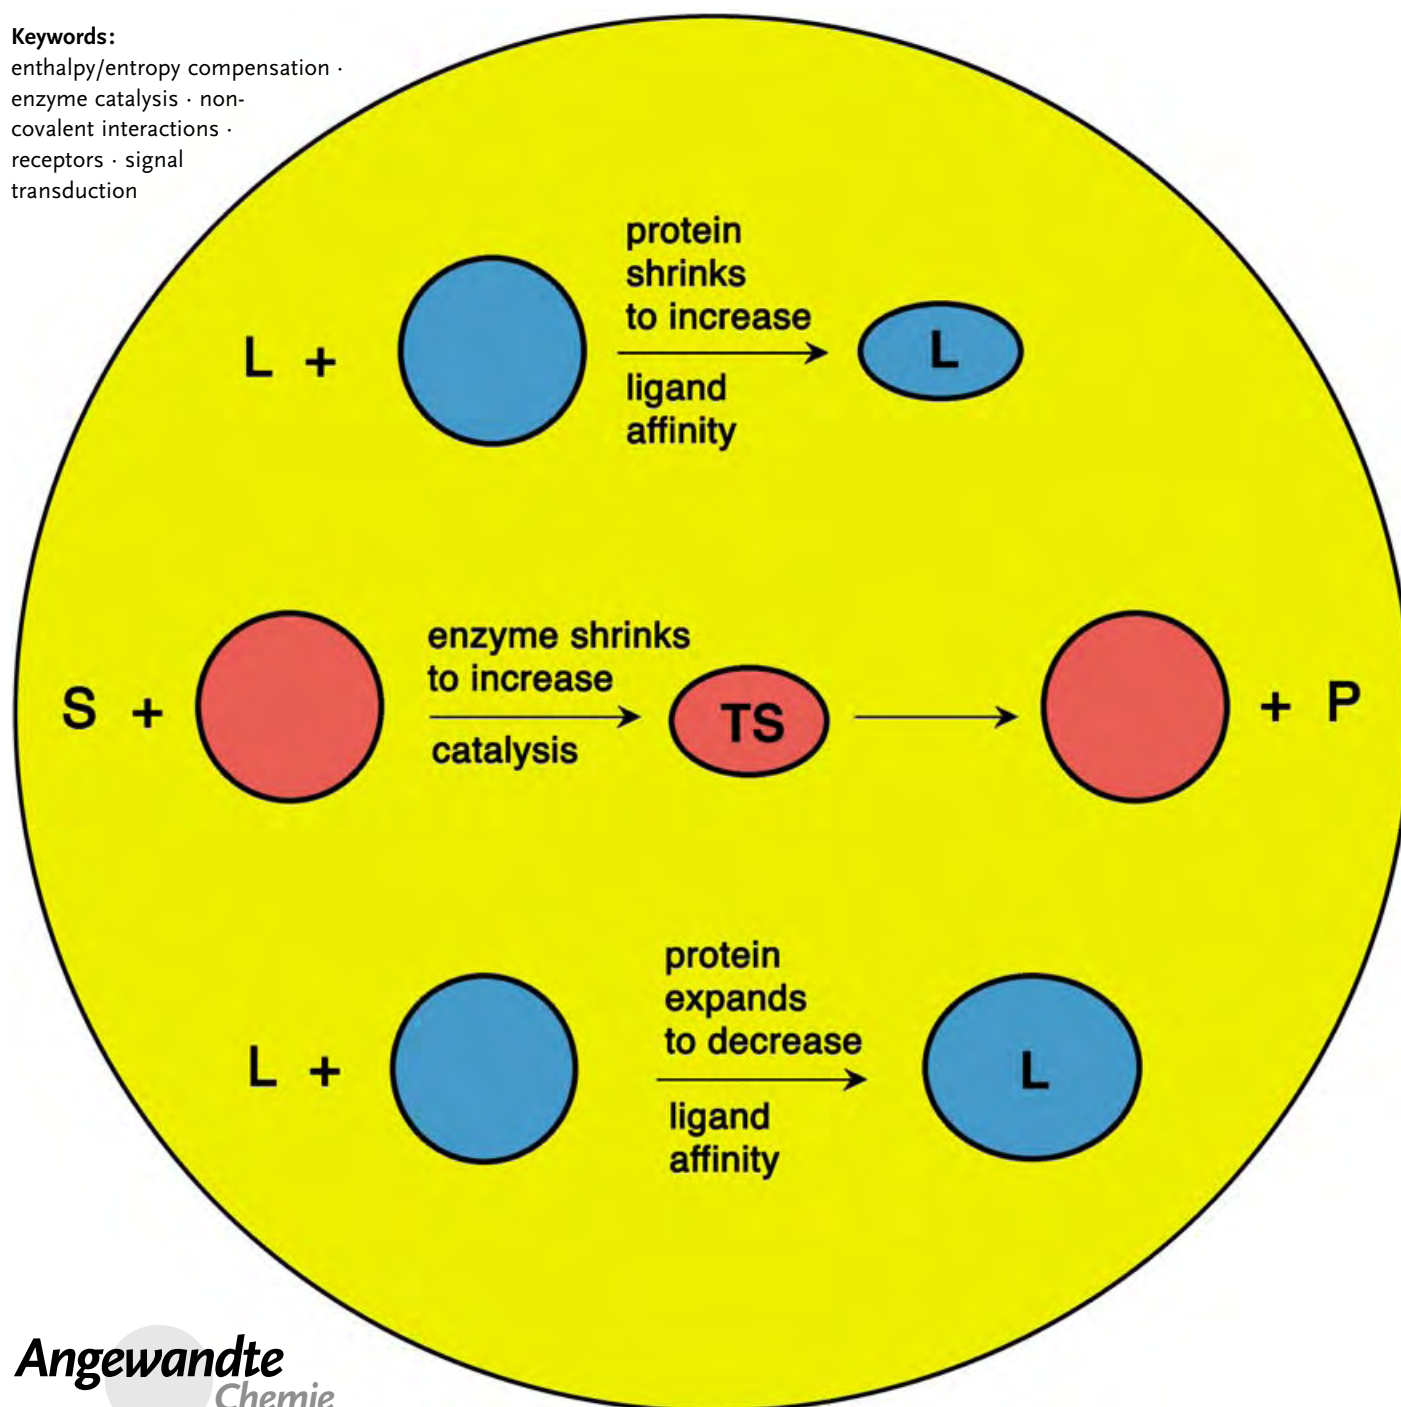
Understanding Noncovalent Interactions: Ligand Binding Energy and Catalytic Efficiency from Ligand-Induced Reductions in Motion within Receptors and Enzymes

Dudley H. Williams,* Elaine Stephens, Dominic P. O'Brien, and Min Zhou

Angewandte Chemie


*N*oncovalent interactions are sometimes treated as additive and this enables useful average binding energies for common interactions in aqueous solution to be derived. However, the additive approach is often not applicable, since noncovalent interactions are often either mutually reinforcing (positively cooperative) or mutually weakening (negatively cooperative). Ligand binding energy is derived (positively cooperative binding) when a ligand reduces motion within a receptor. Similarly, transition-state binding energy is derived in enzyme-catalyzed reactions when the substrate transition state reduces the motions within an enzyme. Ligands and substrates can in this way improve their affinities for these proteins. The further organization occurs with a benefit in bonding (enthalpy) and a limitation in dynamics (cost in entropy), but does not demand the making of new noncovalent interactions, simply the strengthening of existing ones. Negative cooperativity induces converse effects: less efficient packing, a cost in enthalpy, and a benefit in entropy.*

From the Contents

1. Introduction

With the completion of a large part of the sequence of numerous genomes, a frontier research interest has now developed in the field of proteomics. This field is concerned with the more complete identification of proteins (for example, the identification of 1484 proteins from the yeast strain *S. cerevisiae*),[1] with the interactions between these proteins, and with the way that they bind to ligands. The binding constants for these interactions depend on the differences in noncovalent bonding between free and bound states. Insofar as binding constants cannot be predicted, they are poorly understood, and in this sense the molecular basis of biological function is also poorly understood.

In this Review, an approach that treats systems of multiple interactions as the sum of their parts (the additive approach) is first described. It is a very useful approximation. However, in reality, the interactions are often (but not always) greater than the sum of their parts (positively cooperative) or less than the sum of their parts (negatively cooperative). Such cooperative interactions are covered in the second part of the Review. Some consequences for biology are described in Sections 9 and 11–14, with the implications for the understanding of ligand binding energy and enzyme catalysis being particularly important.

1.1. What Is It that Drives a Change?

The Second Law of Thermodynamics states that "in a spontaneous process, the entropy of the universe increases". The simplest description of entropy S is that it is a measure of disorder; thus entropy increases with increasing disorder (more accessible arrangements). The Second Law therefore tells us that in a spontaneous process there will be an overall increase in disorder (increase in S). If the entropy of the universe is S_0 before the change and S_1 after the change, then the overall entropy change is $\Delta S_{overall} = S_1 - S_0$. The more

positive is $\Delta S_{overall}$, the greater is the extent to which the process will occur. In considering the magnitude of $\Delta S_{overall}$ for any process, it is fruitful to divide the entropy change into two parts, namely, the entropy change in the system (what we are studying) and the change in order in the surroundings (the rest of the universe). Since the surroundings are in practice essentially infinite, the change within them is effectively diluted to zero in any finite element, but it is there.

The change in order in the surroundings of the system undergoing change is determined by the change in the enthalpy (exothermic: negative ΔH, endothermic: positive ΔH) of the process, and by the temperature T at which the change occurs. An exothermic process leads to more disorder in the surroundings (by increasing the motion in the surrounding universe). The extent of this increase in disorder is inversely proportional to the temperature. The reason for this latter relationship can be qualitatively understood: surroundings possessing little kinetic energy (low T) become proportionately more random by a given exothermicity than are those possessing more kinetic energy (higher T). Since an exothermic process (ΔH negative) gives a positive contribution to the total entropy change, the increase in entropy from this term is $-\Delta H/T$.

The second part of the entropy change (the change in order within the system undergoing change) is denoted as ΔS_{sys}, and positive values of ΔS_{sys} promote the change. Therefore, taking the two terms together, the propensity for spontaneous change can be quantitated [Eq. (1); for simplicity, the subscript "sys" is normally dropped].

Increase in disorder that occurs in a process $= -\Delta H/T + \Delta S_{sys}$ (1)

It is a consequence of the crucial insights of Boltzmann and Gibbs that we have this relationship. Perhaps confusingly

for generations of students, a new term ($-\Delta G/T$) was coined for this net increase in entropy in a spontaneous process. Thus, $-\Delta G/T = -\Delta H/T + \Delta S$, and leads to the famous Gibbs equation [Eq. (2)].

$$\Delta G = \Delta H - T\Delta S \qquad (2)$$

The Gibbs equation states that ΔG (the free-energy change) is negative for a spontaneous change. Defining ΔG as the *negative* of the total entropy change for a process, multiplied by T, is not so strange as it may at first seem. Early in their careers, physical scientists tend to think in terms of spontaneous change being driven by a release of heat (exothermicity, which means that ΔH is negative). Although this is only one of the determining factors (see above), we therefore have early training to think of a driving force for a spontaneous change in terms of a parameter which has the units of energy and is negative in value. Continuity of thought is encouraged by taking the determinant of spontaneous change (a *positive* entropy change), changing its sign to make it negative, multiplying it by T to give it the units of energy, and calling it "free energy".

Not uncommonly, students are mystified by the spontaneous development of highly ordered organisms, which seems to them inconsistent with the Second Law. It is of course possible because, simultaneous with the development of the ordered organism, the surroundings of the organism are disordered to a greater degree.

Binding affinity can be expressed either in terms of the difference in free energy of free and bound states, or in terms of the equilibrium constant (K), where $\Delta G = -RT\ln K$ (where R is the gas constant and T is the temperature). The more negative ΔG is, the larger is the binding constant. For example, at 300 K, ΔG values of -5.7 and -11.4 kJmol^{-1}

Dudley Williams received his BSc and PhD degrees (in chemistry and organic chemistry, respectively) from the University of Leeds in 1958 and 1961. He subsequently carried out post-doctoral research at Stanford University (US) and in 1964 moved to the University of Cambridge (UK). He is a Fellow of Churchill College and Professor of Biological Chemistry. He was elected a Fellow of the Royal Society in 1983.

Dominic O'Brien received his BSc in Natural Sciences at the University of Cambridge (UK) in 1996. He gained his PhD degree under the supervision of Dudley Williams at the University of Cambridge in 1998 for studying the mode of action and biosynthesis of antibiotics of the vancomycin group. His most recent academic work has been concerned with studies of cooperativity in molecular recognition with Dudley Williams.

Elaine Stephens obtained her PhD under the supervision of Anne Dell at Imperial College, London, for studies of glycoproteins by mass spectrometry. She is currently working on biological applications of mass spectrometry in the Department of Chemistry at Cambridge University.

Min Zhou obtained her BSc and MSc degrees at Nanjing University, China. She is currently a doctoral student at Churchill College, and is studying for her PhD degree under the supervision of Dudley Williams at the University of Cambridge.

correspond to binding constants of 10 and $100\,M^{-1}$, repectively, etc. By using the Gibbs equation to understand binding we can monitor the effects of changes in bonding within the system (ΔH) and changes in the entropy of the system (in terms of $T\Delta S$). Although ΔS, rather than $T\Delta S$, is strictly the change in entropy, experiments carried out at one temperature show that the terms are proportional. $T\Delta S$ has the advantage that its effect upon ΔG can be directly compared with that of ΔH.

1.2. Enthalpy/Entropy Compensation

A key point in what follows is that a decrease in motion implies a decrease in entropy, since it results in fewer accessible arrangements. Consider the formation of a specific noncovalent bond (for example, $\mathbf{A}\cdots\mathbf{B}$ for the transformation $\mathbf{A}+\mathbf{B}\rightarrow\mathbf{A}\cdots\mathbf{B}$). An increase in its strength (which corresponds to an increasing negative contribution to ΔH, and a more favorable binding process) will be accompanied by an increasing restriction in the relative motion of $\mathbf{A}$ and $\mathbf{B}$ in $\mathbf{A}\cdots\mathbf{B}$ (which corresponds to a negative contribution to ΔS, and so unfavorable to binding). This opposing interplay between enthalpy and entropy is known as enthalpy/entropy compensation, and is a fundamental property of noncovalent interactions.[2–4] Importantly, it is not confined to binding in aqueous solution,[5] nor should it be ascribed to errors of measurement.[6] It arises because bonding opposes motion and, also reciprocally, motion opposes bonding. The two effects can be traded off against each other because the strength of noncovalent bonds is, at room temperature, comparable to the thermal energies that oppose them. The idea of enthalpy/entropy compensation is therefore less important in the study of covalent bonds, which are typically too strong to be effectively opposed by thermal motions at room temperature.

2. The Additive Approach

When cooperativity is ignored, contributions of ΔG values to the total free energies of binding may be added together, and contributions of binding constants K are therefore multiplied.

2.1. Costs in the Formation of a Bimolecular Complex ($L+R\rightarrow L\cdots R$)

When a ligand $\mathbf{L}$ binds to a receptor $\mathbf{R}$ it loses some of its translational (t) and rotational (r) motion relative to the receptor. This cost of association is designated as ΔG_{t+r}, and is an adverse entropy term ($\Delta G_{t+r} = -T\Delta S_{t+r}$).[7–9] If the ligand lost *all* its motion relative to the receptor, then the cost of the association at room temperature for a ligand with a mass of a few hundred Daltons is approximately $+57\,kJ\,mol^{-1}$ (opposing binding by a factor of 10^{-10}).[7–9] However, in typical ligand/receptor complexes, the strengths of the noncovalent $\mathbf{A}\cdots\mathbf{X}$ and $\mathbf{B}\cdots\mathbf{Y}$ bonds (Figure 1) are comparable to thermal
Figure 1. Complex formation between a ligand (containing polar functionalities **A** and **B**) and a receptor (containing polar functionalities **X** and **Y**) with exchange of four water molecules to the bulk solvent. (Broken lines indicate hydrogen bonds.)

energies and hence the bonds are highly elastic. Thus, the motional restriction occurring on ligand binding costs much less than $+57\,kJ\,mol^{-1}$ (see Sections 3 and 4).

If a molecule has internal rotations that become more restricted on passing from the free to the bound state, then there is an entropic cost of $-T\Delta S_r = \Delta G_r$ to be paid for each restricted rotation. For example, the ligand shown in Figure 1 (top left) has four internal rotors (indicated by arrows) that allow much internal motion of the ligand prior to binding, but this motion is restricted upon formation of the complex. Binding is opposed by a contribution $4\Delta G_r$, and in the general case by $n\Delta G_r$, where n is the number of restricted rotors.

Complete restriction of an internal rotation has a free-energy cost (ΔG_r) of about $5\,kJ\,mol^{-1}$ at room temperature.[8,9] This value is also too large to be relevant to drug/receptor complexes, again because the energies of the interactions that are restraining the geometry of the complex are comparable to the thermal energies that tend to disrupt it. As a result, the internal rotors, although proscribed from undergoing full rotation, are able to undergo wagging motions in the bound state.

Molecules may bind to their receptors with the introduction of strain, or repulsive atom/atom interactions. Such effects are difficult to explore experimentally. For pragmatism, they are ignored in a simple approach to estimating binding affinities (Section 3), but are relevant in cases of negatively cooperative binding (Sections 6, 9, and 10).

2.2. Energy Benefits in the Formation of the Bimolecular Complex

The formation of a complex is favored when the ligand forms polar interactions to a receptor to give an overall negative change in free energy. The formation of two polar interactions ($\mathbf{A}\cdots\mathbf{X}$ and $\mathbf{B}\cdots\mathbf{Y}$) in water is illustrated in Figure 1. Water molecules which solvate the polar groups $\mathbf{A}$, $\mathbf{B}$, $\mathbf{X}$, and $\mathbf{Y}$ prior to association become part of the bulk water after formation of the complex. These benefits can be semiquantified by including a benefit in the free energy (ΔG_p) for each interaction (which includes the changes in entropy associated with changes in solvent mobility).

The first attempt at a semiquantitation of drug–receptor interactions in terms of the costs and benefits outlined above was by Andrews, Craig, and Martin.[10] We used a similar approach, but applied an additional term to account for the hydrophobic effect.[11]

The hydrophobic effect is classically defined as a benefit to binding that is applicable when binding occurs in water.[12,13] The benefit is a consequence of the removal of hydrocarbon surfaces from exposure to water upon formation of the complex. This effect can be measured by solvent-transfer experiments. For example, if **A** and **B** as well as **X** and **Y** are each separated by three methylene groups (Figure 1), the coming together of the hydrocarbon surfaces (with their concomitant removal from water exposure) will promote binding. The magnitude of the hydrophobic effect is proportional to the surface area of the hydrocarbon that is removed from exposure to water upon formation of the complex and can be estimated in terms of ΔG_h per unit of area A of hydrocarbon buried. The surface area of hydrocarbon that is removed from water exposure in the binding event is readily measured with the aid of computer graphics. Thus, the contribution to binding from the hydrophobic effect is $A\,\Delta G_h$.

The benefit of the removal of exposed hydrocarbon to water upon binding at room temperature derives from the fact that water molecules at hydrocarbon surfaces are more ordered than water molecules in bulk water.[14] Therefore, the hydrophobic effect is normally largely entropy driven at room temperature, although it has a favorable enthalpy component in the special cases where water is expelled from an internalized cavity upon ligand binding.[15]

3. An Equation for the Estimation of Binding Constants

Binding constants in aqueous solution can be estimated from Equation (3), which is derived from the above considerations.

$$\Delta G = \Delta G_{t+r} + n\,\Delta G_r + A\,\Delta G_h + \sum \Delta G_p \qquad (3)$$

ΔG is the observed free energy of binding, $\Sigma\Delta G_p$ is the sum of the free energies of binding for all the polar interactions made in the binding site,[11] and the other terms are as defined in Section 2. Böhm[16a] "trained" a variant of Equation (3) with a set of 45 interactions of experimentally known binding constants from the association of ligands of small molecular weight (66 to 1047 Daltons) with proteins through sets of known interactions (from X-ray structures). He divided the original ΔG_p values into two groups: those involving ionic interactions (ΔG_{ionic}) and those involving hydrogen bonds formed between neutral entities (the term ΔG_p was retained). Since the modified form of the equation has only five types of ΔG contributions and the 45 binding sites involve different combinations of these five types of ΔG contributions, average values for them can be obtained. The values obtained (Table 1) have proved very useful in the pharmaceutical industry.

Table 1: Average values for the parameters of Equation 3.

Parameter	Physical process	Value (kJ mol^{-1})	Factor[a]
ΔG_{t+r}	energy cost of bimolecular association	+5.4	(ca. 10)
ΔG_r	energy cost of restriction of an internal rotor	+1.4	(ca. 2[b])
ΔG_h	benefit of the hydrophobic effect (per Å^2 of buried hydrocarbon)	−0.17 (Å^{-2})	(ca. 1[c])
ΔG_p	benefit of making a neutral hydrogen bond of ideal geometry	−4.7	ca. 7
ΔG_{ionic}	benefit of making an ionic hydrogen bond of ideal geometry	−8.3	ca. 28

[a] Factor by which binding is promoted (opposed) at RT. [b] Per rotor. [c] Upon burial of 33 Å^2 of the hydrocarbon.

The use of the values given in Table 1 resulted in the equation reproducing the binding constants of the training set (which range experimentally from $40\,\mathrm{M}^{-1}$ to $2.5\times10^{13}\,\mathrm{M}^{-1}$) with a standard deviation of 7.9 kJ mol^{-1}, which corresponds to a factor of 24 in binding affinity.[16a] The standard deviation was a factor of 50 in binding affinity for a set of drugs outside the training set. This result represents an impressive outcome for a limited data set, although it should be noted that the inclusion of a larger variety of drug structures (for example, more heavily weighted with heterocyclic structures) somewhat decreased the success of the algorithm.[16b] Several other relatively successful approaches for estimating binding constants have been published since this work, although the physical interpretation of the various terms (and coefficients) in these approaches is less simple.[17,18]

The apparent binding energies obtained for the interactions (Table 1) are in good agreement with those obtained by other approaches, for example, from the mutation of proteins, which are also based on the partitioning of binding-energy contributions.[19–21] Polar interactions (most commonly amide⋯amide hydrogen bonds and ionic interactions) are found to promote binding (negative values of ΔG) moderately in aqueous solution. The reason why the promotion of binding is relatively small is evident from Figure 1: the four hydrogen bonds of the dissociated state are replaced by four hydrogen bonds in the bound state.[19]

The value for the hydrophobic effect is in reasonable accord with the values most commonly found in other studies. It is somewhat larger than those values estimated from the (low) solubility of hydrocarbons in water (0.10–0.14 kJ mol^{-1} per Å^{-2} of the hydrophobic surface buried from exposure to solvent).[22–28] Yet it is smaller than those obtained by the deletion of methyl groups in binding sites, both within proteins or drug/receptor interactions (most frequently in the range 0.18–0.26 kJ mol^{-1} Å^{-2},[20,29–32] although a range extending from 0.06 to 0.64 kJ mol^{-1} Å^{-2} has been reported.[33–38]) Presumably, the large range found in the literature reflects, at least in part, variations in positive and negative cooperative effects.

The localization of the drug at the binding site and restriction of internal rotations upon binding (see Section 2.1) spontaneously emerge from Equation (3) as factors which oppose binding (Table 1, positive values of ΔG_{t+r} and ΔG_r, respectively). The average value $\Delta G_{t+r} = +5.4 \text{ kJ mol}^{-1}$ is remarkably small, and represents only about one tenth of the maximum theoretical entropy loss corresponding to complete immobilization of the ligand (see Section 2). This small value presumably reflects, at least in part, the large residual motion that the drugs can exercise relative to the receptor to which they are bound. The average cost of restricting the rotation of an internal bond in the drugs ($+1.4 \text{ kJ mol}^{-1}$) is slightly less than that found for the formation of crystals from neat liquids that contain internal rotors ($2–3 \text{ kJ mol}^{-1}$).[39] This finding probably reflects the fact that rotations are somewhat less restricted in these binding sites than they are in crystals. Most importantly, the application of the equation gives useful approximate binding constants in many cases.

4. Why is the Adverse ΔG_{t+r} Term Relatively Small?

Given the assumption that the average value of ΔG_{t+r} of $+5.4 \text{ kJ mol}^{-1}$ is representative of drugs as a whole, why is it so small? The stronger the noncovalent bonds that hold the complex together, the larger should be the restriction of overall motion (adverse entropy change, of which ΔG_{t+r} is a measure). To test this hypothesis, it is necessary to examine associations where the entropy change can be put down solely, or largely, to ΔG_{t+r}. Entropy changes arising from changes in solvation must be avoided, or minimized, which precludes the use of data for associations in water or other polar solvents. Additionally, the number of internal rotations that are restricted upon association must be zero, or limited, because interpretation of the entropy change must not be confused by the presence of a significant $n\Delta G_r$ term [Eq. (3)]. In the absence of these effects, the adverse entropy of association will be solely a consequence of, or dominated by, the ΔG_{t+r} term.[40]

The above considerations can be satisfied for simple bimolecular associations of relatively rigid entities occurring in the gas phase ($\mathbf{A} + \mathbf{B} \rightarrow \mathbf{A} \cdots \mathbf{B}$). Binding can only be promoted by a favorable enthalpy of interaction (ΔH), which measures the benefits of noncovalent bonding between the two portions of the complex. Binding can only be opposed by the unfavorable loss in translational and rotational entropy ($T\Delta S_{t+r}$). The anticipated correlation between the heat given out (ΔH) and the order imposed ($T\Delta S_{t+r}$, identical to $-\Delta G_{t+r}$) is shown in Figure 2.[2] There is a limit to the cost in entropy for bond formation in $\mathbf{A} \cdots \mathbf{B}$, which is reached when the bond strength is large compared to thermal energies, and at this point $\delta(\Delta H)/T\delta(\Delta S)$ is very large. However, when bond strengths are comparable to the thermal energy, the restraint is effectively opposed by the motion and $\delta(\Delta H)/T\delta(\Delta S)$ is smaller. Therefore, we can anticipate that the slope of the ΔH versus $T\Delta S$ graph (Figure 2) will increase as the bond strength increases through the "noncovalent region".

Dunitz has indeed shown that a curve closely following the form of Figure 2 can be derived from a semiquantitative
Figure 2. Anticipated relationship between the exothermicity (ΔH) and the cost in entropy ($T\Delta S$) for the complex formation $\mathbf{A} + \mathbf{B} \rightarrow \mathbf{A} \cdots \mathbf{B}$ in the gas phase or in a nonpolar solvent at 298 K (black curve). Under these conditions $-T\Delta S$ is a measure of ΔG_{t+r}. When the relative motion of $\mathbf{A}$ and $\mathbf{B}$ in $\mathbf{A} \cdots \mathbf{B}$ is highly restricted, the entropy costs approach the limiting value of $T\Delta S \approx -57 \text{ kJ mol}^{-1}$. At room temperature the limit is reached at enthalpies corresponding to the formation of a covalent bond. As the $\mathbf{A} \cdots \mathbf{B}$ bond becomes weaker, there is increasing residual motion of $\mathbf{A}$ relative to $\mathbf{B}$. The increasing motion, and the accompanying increase in bond length, is illustrated in the three sets of "dumbbells", which correspond to the green, red, and black points on the curve. The adverse entropy of the association therefore becomes increasingly small.

approach based upon shallow energy wells.[3] For such wells, bond extension and increased dynamics should become important as the depth of the well decreases. This point is illustrated schematically in Figure 2 for decreasingly exothermic associations (green, red, and black points on the curve). The decreasingly exothermic associations not only give rise to "looser" associations, but also to ones that give a less-favorable free energy of binding ($\Delta G = \Delta H - T\Delta S$) for population of the organized state. This last consequence follows because the weakest noncovalent interaction (black point) is, of the three, the one with the most efficient enthalpy/entropy compensation.[3,4]

These conclusions are supported by experimental data. The adverse ΔG_{t+r} term (expressed in terms of $T\Delta S_{t+r}$) decreases as the favorable enthalpy of association is decreased (shallower well).[2,40] The adverse ΔG_{t+r} term is less than 13 kJ mol^{-1} in the cases of weakly exothermic associations (less than 20 kJ mol^{-1}). Put simply, "weak springs" give more residual motion at the binding interface.

A similar relationship should hold for corresponding noncovalent associations in nonpolar solvents because, to a useful approximation, these are like those in the gas phase.

This follows since the favorable entropy of desolvation of the polar groups that interact when the complex is formed should be relatively small. Experimental data for 233 such associations[41] were examined to test this hypothesis.[42] Although 215 of the data points produced a good correlation of the form predicted, 18 appeared anomalous (Figure 3). These 18 data points were subsequently shown to arise because of various kinds of errors.[42].
Figure 3. Enthalpy (ΔH) versus entropy ($T\Delta S$) diagram for the association of macrocycles with neutral molecules in a variety of nonpolar solvents.[41] There are six groups of data points that appear to be inconsistent with the general form of the enthalpy/entropy compensation curve, but all of these are associated with errors[42] (quite understandably arising in a valuable review[41] of large breadth). Three examples of which follow: a) Four data points were transcribed with an incorrect sign for ΔS, thus requiring their transposition from the north-west quadrant to the north-east quadrant). b) Six data points were transcribed in the review with a conversion factor for ΔS that was too large (by a factor of 4.18 Joules/calories), thus requiring their transposition into the general region of the correlation). c) A point that is not an error in transcription was indicated by our experimental value to be erroneous. Given the correction of these errors, and others indicated by the arrows and asterisk,[42] there is agreement between the general forms of Figures 2 and 3.

Many of the points lie in the north-west quadrant (Figure 3) for associations in nonpolar solvents that are less exothermic than 10 kJ mol^{-1}. This is because weakly exothermic associations lead to weakly ordered complexes **A···B** with only a very small cost in entropy. Hence, although the favorable entropy of desolvation will be small for associations in nonpolar solvents, it is large enough in the case of weakly exothermic associations to more than offset the small cost in entropy of the association.

There do not appear to be exceptions among the 233 data points to the general requirements of Figure 2, and the generalization has been used to correct errors in the literature. This last point is important, because unifying concepts are unlikely to emerge when the literature accumulates errors. The idea that forming a more exothermic noncovalent interaction proceeds with a greater cost in entropy (greater restriction in motion) is confirmed.

Collectively, the data for the noncovalent associations occurring in the gas phase and in nonpolar solvents also confirm the conclusion from the training set of drug–receptor data used in conjunction with Equation (3)—noncovalent associations can have relatively small adverse ΔG_{t+r} terms. On average, the drugs in the data set apparently have considerable motions relative to their receptors, that is, they are bound in a relatively dynamic manner.

5. Cooperative Binding Processes: Definitions

The aim in studying binding affinities is to understand the origins of the overall ΔG value in terms of structure. It is evident from the foregoing sections that the changes in the bonding (ΔH) and order ($T\Delta S$) terms for the binding of flexible molecules in aqueous solution are so numerous that the problem is a complex one. A useful approach is to separate the variables so that a deeper understanding can emerge. This has already been achieved at one level by separating the effects of noncovalent bonding in complex formation from those of desolvation (through the examination of complex formation in the gas phase and in nonpolar solvents, see Section 4). Cooperativity between noncovalent interactions has not so far been discussed. It will be seen that its effects upon the bonding (ΔH) and order ($T\Delta S$) terms can be predicted with some confidence, and so another layer of the complexity can be peeled away.

Noncovalent interactions are said to interact with each other in a positively cooperative manner when the binding energy that is derived from them acting together is greater than would be derived from the sum of their acting separately. Conversely, they are said to interact with each other in a negatively cooperative manner when the binding energy that is derived from them acting together is less than would be derived from the sum of their acting separately. Equation (3) was derived to remove part of the problem that arises from cooperativity. Equation (3) is based on the idea that the cost of an association (ΔG_{t+r}) has to be paid only once. It was therefore reasoned that if this adverse term could be factored out from the other free-energy contributions then, to a useful approximation, all the free-energy terms could then be treated additively.

Figures 2 and 3 illustrate the inadequacy of this approach in the general case, since the adverse ΔG_{t+r} term increases as association occurs with stronger bonding. The addition of an extra polar interaction at a binding interface can decrease the local dynamics and thereby increase the favorable free energy of adjacent interactions (see Section 6).[40] It is this gradual switching on of positively cooperative effects, as a result of the interplay between motion and bonding, that precludes rigorous analysis of binding affinities in terms of sums of the parts.

Nevertheless, in many systems (particularly synthetic ones) there may be no significant cooperativity, and in these cases the binding energy will correspond to the sum of the parts. For example, the affinity of polyamines to DNA can be described simply as a function of the number of possible contributions of each ammonium center.[43]

6. Cooperative Binding at a Single Interface

6.1. The Case of Positive Cooperativity

To illustrate how positive cooperativity can arise in a simple system of polar interactions, we consider a receptor that binds ligands **X**, **Y**, and **Z** with affinities ΔG_X, ΔG_Y, and ΔG_Z, respectively (Figure 4). Clearly, binding some combina-
Figure 4. Schematic representation of a receptor that binds ligands **X**, **Y**, and **Z** with affinities ΔG_X, ΔG_Y, and ΔG_Z, respectively. a) Binding of **Z** results in a structure with an intermolecular distance d_0. b) When **Y** and **Z** are connected by a rigid, strain-free linker (**Y**–**Z**) they bind to the receptor with positive cooperativity ($\Delta G_{Y\text{-}Z}$ more negative than $\Delta G_Y + \Delta G_Z$) and there is structural tightening ($d_1 < d_0$). c) If **X** is connected to **Y**–**Z** by a rigid, strain-free linker to form **X**–**Y**–**Z** then further structural tightening will occur ($d_2 < d_1$) leading to a further cooperative enhancement. d) The shorter linker between **Y** and **Z** does not allow both these binding interactions to occur with optimal geometry. **Y**–**Z** binds the receptor with negative cooperativity ($\Delta G_{Y\text{-}Z}$ more positive than $\Delta G_Y + \Delta G_Z$) and there is structural loosening ($d_3 > d_0$).

tion of these ligands, each as separate entities, will result in an overall free energy change that is represented by the sum of the contributions from each individual ligand. Let us now consider the case where **Y** and **Z** are connected by a linker (**Y**–**Z**) (Figure 4b). There is now the benefit of the classic entropic chelate effect to binding described by Jencks and Page.[7–9] That is, if **Y** and **Z** each bound separately with an adverse $T\Delta S_{t+r}$ term of N, then **Y**–**Z** will bind with a cost of less than $2N$. We now add the cooperative effects addressed in this review to this benefit to binding. First, the restrictions in motion that **Y** and **Z** impose on each other when binding as

Y–**Z** will *increase* the exothermicity of the noncovalent bonds that they make with the receptor; that is, there will be structural tightening of the receptor–ligand complex (Figure 4, $d_1 < d_0$). Second, the increased exothermicity associated with this first effect will in turn *reduce* the motions of **Y** and **Z** (in **Y**–**Z**) relative to the receptor. Therefore, these two effects will occur with a benefit in enthalpy and a cost in entropy relative to the situation occurring if there were no positive cooperativity of this nature. Analogous arguments allow us to conclude that if **X** is connected to **Y**–**Z** by a rigid strain-free linker to form **X**–**Y**–**Z** then further structural tightening will occur ($d_2 < d_1$) and lead to a further cooperative enhancement of binding (Figure 4c).

Studies with glycopeptide antibiotics established the reductions in distance modeled in Figure 4a–c.[44] Several peptide ligands, all containing the carboxylate group depicted lower right in Figure 5, were separately bound to the anti-
Figure 5. The binding interaction between the glycopeptide antibiotic vancomycin and the peptide ligand *N*-α-acetyl-Lys-(*N*-ε-acetyl)-D-Ala-D-Ala. Hydrogen bonds are indicated by dotted lines. The binding is also promoted by hydrophobic interactions, notably of the Ala methyl groups to the aromatic rings of the antibiotic. The amide NH proton H^2 discussed in the text is indicated.

biotics. In all cases, a large downfield chemical shift ($\Delta\delta = 1$–3 ppm) of the antibiotic amide NH proton H^2 was observed upon binding of the ligand. A larger limiting downfield shift of this proton indicates a shorter and stronger carboxylate–NH hydrogen bond.[44–46] This hydrogen bond was formed to a higher degree as the number of hydrogen bonds and other motional restrictions adjacent to the carboxylate–NH interaction was increased. The motional restriction of the carboxylate group, afforded by these adjacent motional restrictions, strengthens the hydrogen bonds directly made to the carboxylate group.

The dimers of the glycopeptide antibiotics (Figure 6) exhibit the same effect. The proton resonance H^4 at the dimer interface undergoes a downfield shift when the dimer is formed from the monomer. The extent of this downfield shift
Figure 6. Backbone structure of the dimer of the glycopeptide shown in Figure 5. Hydrogen bonds are indicated by dashed lines. The α-proton H^4 mentioned in the text is indicated. The central four hydrogen bonds at the dimer interface are common to all glycopeptide dimers, whereas the two outer hydrogen bonds can only be made by antibiotics that possess an amino sugar attached to R^6.

increases as additional bonding restraints, more distant from H^4 than the four central hydrogen bonds depicted in Figure 6, are added at the dimer interface. In analogy with the correlation observed between increased downfield changes in the chemical shifts of the α protons of β-strand structures as the interstrand distance decreases,[47,48] these data indicate that remote bonding restraints reduce the interfacial distances in the dimer in the vicinity of H^4.

Thus, structural tightening occurs in the bound state as a consequence of positive cooperativity.[49] Furthermore, thermodynamic measurements indicate that the structural tightening occurs with a benefit in enthalpy (ΔH) and a smaller cost in entropy (in terms of $T\Delta S$).[49]

6.2. The Case of Negative Cooperativity

The model of Figure 4 can also be used to illustrate how negative cooperativity may arise. Consider the case where **Y** and **Z** are rigidly held in a conformation that does not allow both binding interactions to occur with the preferred geometry shown in Figure 4b. This situation could be induced, for example, by introducing a linker between **Y** and **Z** that is too short (Figure 4d). The "pull" of **Y** towards its preferred binding geometry will adversely affect the binding of **Z** by forcing it away from its preferred binding geometry, and vice versa, with the consequence that ΔG_{Y-Z} will be less negative than the sum of $\Delta G_Y + \Delta G_Z$. **Y** binds with negative cooperativity with respect to **Z**, and vice versa. Based on the

arguments presented above, a consequence of this negative cooperativity should be loosening of the interaction of **Z** into its receptor cup (Figure 4d, $d_3 > d_0$), at a cost in enthalpy but with a benefit in entropy.

Studies on the melting of DNA duplexes support the models of negatively cooperative binding. For example, the self-complementary duplex **1** is formed in aqueous solution from its constituent single strands with an exothermicity of -430 kJ mol^{-1}.[50] The magnitude of the exothermicity of duplex formation drops by 220 kJ mol^{-1} upon the introduction of only two mismatches into the sequence (formation of **2** with $X = {}^{m6}G$, namely, methylation at the purine O6 site). This extremely large fall in the exothermicity of duplex formation is associated with a correspondingly dramatic fall in the adverse entropy for duplex formation ($-1164 \text{ J mol}^{-1} \text{K}^{-1}$ for **1** versus $-577 \text{ J mol}^{-1} \text{K}^{-1}$ for **2**).

CGCGAATTCGCG	CGCXAATTTGCG
GCGCTTAAGCGC	GCGTTTAAXCGC
1	**2**

Since the negative cooperativity associated with the introduction of the two mismatches reduces the melting temperature of the duplex, a correction must be made for the heat capacity change upon melting of the DNA.[51–53] After allowing for heat capacity effects, it is found[54] that the introduction of just two mismatches reduces the favorable enthalpy of duplex formation by $123 \pm 53 \text{ kJ mol}^{-1}$. Thus, there is a large reduction in the bonding in the duplex structure, even though formally it involves the removal of only two C=O···HN hydrogen bonds and the introduction of two repulsive C=O···OR$_2$ interactions. Therefore, it appears likely that the introduction of the mismatched T···X interactions in **2** loosens adjacent interactions. A similar calculation for the entropy term indicates that the large reduction in bonding is accompanied by a large increase in the motional dynamics of **2** relative to **1**. There is enthalpy/entropy compensation, with the consequence that the introduction of the two mismatches has a much smaller effect on the relative stabilities ($\Delta\Delta G = 46 \text{ kJ mol}^{-1}$) of the two duplexes than would otherwise be the case.

7. Cooperative Binding over Multiple Interfaces

Although positively or negatively cooperative binding between interactions expressed at the same interface (Section 6) is important, such effects expressed over multiple interfaces are of supreme importance in biology. We first consider the free energy of positively and negatively cooperative binding when expressed over two interfaces.

Figure 7 shows a thermodynamic cycle for the formation of a dimer, which can occur either in the presence, or absence, of a ligand. The dimer can bind two molecules of ligand.[55]

The transformation **A**→**C** represents the free energy of dimerization and **A**→**B** represents the free energy of binding two molecules of ligand to two of monomer. The transformation **C**→**D** represents the free energy of binding two ligands to dimer in the absence of cooperativity, which by
Figure 7. Formation of a fully coordinated dimer from the constituent elements of two ligand molecules (blue) and two antibiotic monomers (red). Vertically arranged species are bound, horizontally arranged species are not bound. Starting from the free components (**A**) the association can occur to give two ligand-bound monomers **B** or a ligand-free dimer **C**. The coordinated dimers may be formed without cooperativity (**D**), with positive cooperativity (**E**), or with negative cooperativity (**F**).

difference between free energy levels **F** and **D** ($\Delta G_{\text{neg.coop}}$) represents the free energy cost of the negative cooperativity.

Suppose the dimerization constant for the formation of a symmetrical dimer is increased by some factor x (for example, 100) by the occupation of both its ligand binding sites (positively cooperative binding, Figure 7). Then the binding constant for each ligand into the two identical binding sites of the dimer must be greater by $\sqrt{x}$ (for example, 10) over binding to the monomer. More generally, if a receptor system is stabilized upon ligand binding, the ligand affinity for the receptor must thereby be increased. This important point is discussed in the general context in Section 11.

definition is therefore the same as the free-energy change for **A**→**B**. The transformation **B**→**D** represents the free-energy change for dimerization of ligand-bound monomer in the absence of cooperativity, and is therefore by definition the same as the free-energy change for **A**→**C**.

If the dimer and ligand interfaces are formed in a positively cooperative manner, then a more stable species **E** is formed instead of **D**. The difference between free energy levels **E** and **D** ($\Delta G_{\text{pos.coop}}$) represents the free energy benefit of the positive cooperativity. If the dimer and ligand interfaces are formed in a negatively cooperative manner, then a less-stable species **F** is formed instead of **D**. The

8. Positive Cooperativity over Multiple Interfaces

8.1. Monomeric Protein Receptors

A structural model[56] to understand this phenomenon of positively cooperative binding is given in Figure 8a, and shows a portion of a protein receptor prior to (top) and after (bottom) binding to a ligand. First consider the free receptor (top): the formation of its two depicted hydrogen bonds is opposed by the relative motions of its two peptide backbones. The internal motions of the chain that is presented to the ligand can be reduced by the formation of hydrogen bonds from it to the ligand (Figure 8a, bottom). Since motion opposes bonding, the restriction of the internal motions of this chain upon ligand binding should result in the strengthening of the hydrogen bonds within the receptor.

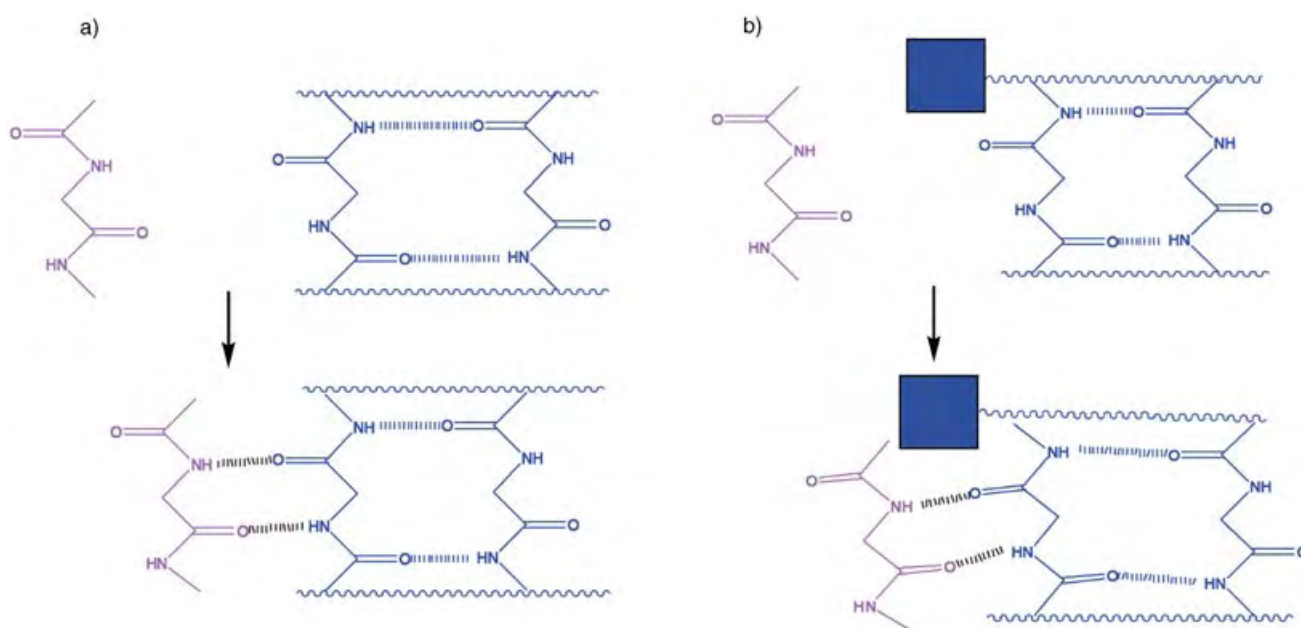
The "damping down" of the motions of the depicted receptor residues upon ligand binding can, in turn, improve noncovalent bonding more deeply within the receptor. Such transmission will result in an improvement in noncovalent bonding at all sites within the receptor that are coupled with


Figure 8. Structural models for positively cooperative binding (a) and for negatively cooperative binding (see text for details).

positive cooperativity to ligand binding. Ligand binding to the receptor is improved because the receptor is stabilized upon ligand binding.

A consequence of improved bonding within a receptor following positively cooperative ligand binding will be a reduced degree of H/D exchange of selected amide NH protons of the receptor (see Section 11).

8.2. Dimeric Receptors

The model of Figure 8a is equally useful in considering the case where the portion in blue represents not a single protein receptor, but rather two peptide chains that can come together through a bimolecular association (the wavy lines are ignored). Under these circumstances, the formation of the blue hydrogen bonds (for example, when a receptor dimer is formed) lead to the presentation of a more organized template to the ligand. For this reason, the cost in entropy in binding the ligand to the dimer will be less than in binding the ligand to the monomer. Molecular dynamics simulations illustrate that this contribution to positive cooperativity is a benefit to entropy.[57]

It must now be considered how the above "templating" advantage of a dimeric over a monomeric receptor structure will cause "knock-on" effects on the structure. Since it is motion that opposes bonding, the presentation of a more-ordered surface (of a dimeric receptor) to a ligand will allow an improvement in interfacial ligand/receptor bonding (Figure 8a). In fact, there will tend to be mutual strengthening of all the hydrogen bonds between the chains in strain-free binding. A consequence of this strengthening of the hydrogen bonds must be to reduce the relative translational motions of the chains, and to further restrict their internal wagging motions, at a cost in entropy.

In summary, positively cooperative binding of a ligand to a dimeric receptor should be beneficial in enthalpy, that is, with a shortening of the noncovalent bonds involved. However, the overall entropy changes cannot be predicted from the model. Strain-free templating of binding gives an entropic benefit, whereas entropy/enthalpy compensation should give an entropic cost. Experiments are required to address this problem.

The structural and thermodynamic features of positive cooperativity expressed over multiple interfaces have been demonstrated experimentally. Dimers of glycopeptide antibiotics of the vancomycin group are typically further stabilized and, without reported exception, become less dynamic when they bind two molecules of the bacterial cell-wall analogues (Figure 9). This reduced dynamic behavior of the dimer receptor system occurs with distance reductions at the dimer interface, as indicated by NMR data.[46] The reduction in the dynamic behavior of the dimeric receptor is greater for strongly binding ligands than for weakly binding ligands.[58] The positive cooperativity is typically associated with a benefit in enthalpy and a cost in entropy.[59] In such cases, the motional restriction that accompanies improved bonding outweighs the benefit in entropy of binding to a more-ordered template.
Figure 9. Peptide backbone of a glycopeptide antibiotic dimer (blue) that is simultaneously bound to two molecules of a bacterial cell peptide precursor analogue (red). The binding of the analogue occurs with positive cooperativity, such that the dimer system is stabilized and shortens the distances marked *a*. The effect affords a benefit in enthalpy and a cost in entropy.

The structural changes occurring upon positively cooperative binding bear analogy to the changes occurring upon cooling a substance. On reducing the temperature of a pure substance, whether liquid or solid, it is universally observed that the change is favorable in enthalpy and adverse in entropy.[60] It is also almost universally observed that reducing the temperature leads to a volume reduction (the ice/water transition is an example of a relatively rare exception). The physical basis for this analogy is evident: both in the exercise of positive cooperativity and in cooling a substance, a reduction in dynamic behavior improves noncovalent bonding and shortens the average noncovalent bond lengths.

9. Negative Cooperativity over Multiple Interfaces—Hemoglobin

Since cooperative binding is a phenomenon of great importance in chemical biology, it might be assumed that a unified definition of the phenomenon would already be in use. This is not the case. For multiple ligand binding sites,[61,62] positively cooperative binding is said to occur when binding ligands are successively bound with increasing affinities. Conversely, negatively cooperative binding is said to occur when binding ligands are successively bound with decreasing affinities.

Importantly, ligand binding can be positively cooperative if the above definition for multiple binding sites is used, while being negatively cooperative if the definition employed here is used (see Section 5). The advantage of the definition of positive cooperativity used in this Review is that it requires that the sets of noncovalent interactions are, when made together, mutually *reinforcing*. Such a condition would seem

to be a mandatory requirement for interactions that are "positively cooperative". We now illustrate the nontrivial consequences of these considerations by reference to the binding of O_2 to hemoglobin.

A structural model to illustrate negatively cooperative binding over two interfaces is given in Figure 8b. Here, the surface chain of the protein receptor must incorporate a structural feature (for example, steric inhibition by the blue square) that inhibits ligand binding to the structure of the isolated receptor. As required for a structurally meaningful definition of "negatively cooperative", the two sets of interactions (the preferred noncovalent interactions at the ligand/receptor interface and those preferred within the receptor) are mutually incompatible. Therefore, when ligand-binding occurs, the ground-state structure of the receptor must be distorted from its preferred geometry (Figure 8b, top) to a state (bottom) in which its internal noncovalent bonding is weakened. Thus, ligand binding that is negatively cooperative should cause receptors to loosen their structures and become more dynamic. Consequently, the extent of H/D exchange of the amide–NH protons of the peptide backbone of the receptor (upon exposure to D_2O) should increase upon ligand binding. In addition, the reduction in bonding efficiency within the receptor upon negatively cooperative ligand binding will make ligand binding less favorable in enthalpy, and more favorable in entropy than would otherwise be the case. Evidence to support these conclusions is presented below.

Hemoglobin, the protein that carries oxygen in the blood stream, exists as a tetramer. The classic work of Monod, Wyman, and Changeux (MWC)[62] allows a deep insight into the changes that occur when O_2 binds to hemoglobin. The initially available form of the tetramer is described as a "tense" (T) form (Figure 10a). The geometry of this form

Figure 10. a) Negatively cooperative binding of O_2 to hemoglobin. In the T state (blue) the hemoglobin is unable to bind O_2 efficiently because the access of the O_2 to the T state is hindered by the plane of the porphyrin ring. The structure of the hemoglobin is therefore distorted (loosened, with a decrease in efficiency of its internal noncovalent bonding) to give the R state (red), which is better able to bind O_2. b) MWC model for the binding of the first molecule of ligand (L) to a tetrameric protein existing in tense (T) and relaxed (R) forms.

does not allow efficient binding of O_2 to it. The initially available T form is distorted to give a more "relaxed" structure (the R form, Figure 10a) to enable O_2 to bind more efficiently. The binding of just one O_2 molecule to the tetramer is envisioned as distorting all four subunits towards the R structure (Figure 10b), so that the subsequently binding O_2 molecules bind with higher affinity. The O_2 binding is therefore defined in the MWC model as positively cooperative. The energy required for the T→R conversion is largely carried out by the first O_2 molecule that binds. Therefore, subsequently binding O_2 molecules have the advantage of accessing a relatively high population of the R state, and bind with greater affinity.[63]

However, in terms of the definition used here, the binding of O_2 to hemoglobin is negatively cooperative. The T state does not allow efficient binding of O_2, and therefore the binding of O_2 distorts it to the R state (Figure 10a). This situation is analogous to the situation shown in Figure 8b.

The negatively cooperative binding does indeed force a loosening of the T state of the tetramer, through the breaking of ionic interactions between subunits.[64] However, and importantly for the structural consequence of negatively cooperative binding developed here, widespread structural changes in the T to R transition seem possible: all non-covalent interactions within a receptor system that are coupled with negative cooperativity to ligand binding should loosen.

To test the above conclusion we determined[65] the change in the dynamic behavior of the (horse) hemoglobin tetramer polypeptide backbone when it binds O_2 by ESI-mass spectrometry. Through the binding of oxygen, a further 7–8 exchangeable amide hydrogen atoms per α chain (5.2–6% of the total number) and a further 16 per β chain (11.4% of the total number) underwent solvent exchange. Thus, complete saturation of the hemoglobin tetramer by O_2 binding results in an increase of 46–48 backbone NH atoms undergoing exchange. The dramatic increase in amide NH exchange is in agreement with the predictions regarding the changes associated with negatively cooperative binding. This increase in dynamic behavior of the amide backbones of the hemoglobin subunits had not been uncovered by previous X-ray studies. Presumably, the changes in dynamic behavior, which are important for an understanding of binding interactions, are masked by crystal-packing forces.

The requirement that negative cooperativity, as exercised on the T state, will be accompanied by enthalpy/entropy compensation (in the sense of a benefit in entropy and a cost in enthalpy) is also satisfied. Thus, as O_2 binding promotes the T to R transition, there should be an uptake of heat by, and increase in disorder within, the hemoglobin tetramer. The following thermodynamic parameters (per subunit) were obtained for the case of O_2 binding to trout hemoglobin:[66] The first O_2 molecule binds with $\Delta H = 0 \text{ kJ mol}^{-1}$ and a favorable $T\Delta S$ term of $+21 \text{ kJ mol}^{-1}$. In contrast, the fourth O_2 molecule binds exothermically ($\Delta H = -32 \text{ kJ mol}^{-1}$) and with a slightly unfavorable entropy term ($T\Delta S = -3 \text{ kJ mol}^{-1}$). The binding of O_2 to the iron atom of hemoglobin in isolation can confidently be assumed to be exothermic. However, since O_2 binding drives the T→R

conversion (Figure 10b), the associated loss in bonding within the hemoglobin structure offsets this exothermic gain. Hence, $\Delta H = 0\ \text{kJ mol}^{-1}$ for O_2 binding starting from the T form is understandable. The favorable $T\Delta S$ term of $+21\ \text{kJ mol}^{-1}$ reflects the loosening of the hemoglobin structure that accompanies its loss of internal bonding. Thus, it may be a useful approximation to isolate the binding event of O_2 to the R form of hemoglobin as being reflected by $\Delta H = -32\ \text{kJ mol}^{-1}$ and $T\Delta S = -3\ \text{kJ mol}^{-1}$. Indeed, O_2 binding *in isolation* should involve only a small adverse entropy change (reflecting the dynamic binding of a ligand of small mass to a receptor). This approximation isolates the thermodynamics of the T→R transition in terms of $\Delta H = +32\ \text{kJ mol}^{-1}$ and $T\Delta S = +24\ \text{kJ mol}^{-1}$. These are plausible numbers for the generation of a structure that is less well bonded and exhibits more dynamic behavior (see the exchange data for horse hemoglobin above for comparison). Additionally, since $\Delta G = \Delta H - T\Delta S$, the T→R transition is $\Delta G \approx +8\ \text{kJ mol}^{-1}$. Thus, at room temperature the free T state of trout hemoglobin should be more highly populated than the free R state by a factor of about 25. Seen in this light, the thermodynamic parameters make physical sense.

Analogous experiments on myoglobin are clearly of interest, since it exists as a monomeric species. In the original classic paper of Monod, Wyman, and Changeux it was assumed that "the subunits of the R form are closer to the conformation of the [hemoglobin] monomer" (cf. myoglobin) and that "myoglobin may be thought of as a relaxed subunit of hemoglobin".[62] According to this assumption, oxygen binds strongly to myoglobin, at least in part, because it does not have to pay the price of the T to R conversion (Figure 10).

However, it is important to recall that the internal structure of the R form has been shown above to be loosened relative to the T state, and this internal loosening must be driven by O_2 binding. Thus, the myoglobin structure might also be loosened internally by O_2 binding. The extent of H/D exchange of the amide protons on the peptide backbone of myoglobin in the absence, and presence, of bound oxygen was determined by ESI-MS. A further 13–15 exchangeable backbone amide hydrogen atoms were exposed to solvent exchange through the binding of oxygen.[56] Myoglobin thus possesses a tight (or "tense") internal structure, and not a relaxed one as originally seemed likely. This conclusion also makes physical sense because, as Perutz commented,[67] it is the binding of O_2 that perturbs the protein structure. Both myoglobin and the T form of hemoglobin bind O_2 with negative cooperativity as defined by the model used here (see Figures 8b and 10a). Consistent with the model, the reduction in binding energy of the O_2 molecule to the T form of hemoglobin is widely spread, not only at the tetramer interfaces, but also among the internal network of noncovalent interactions of each monomeric unit.

The advantages of the negatively cooperative model for O_2 binding to hemoglobin are threefold: 1) it is part of a model for cooperativity (Figure 8) that is consistent with the sense in which the term "cooperativity" is most frequently used. Mutual *enhancement* of compatible sets of interactions is described as *positively* cooperative binding (Figure 8a, for example, as in protein folding[68,69] and crystallization).

Mutual *weakening* of initially incompatible sets of interactions is described as *negatively* cooperative binding (Figure 8b, for example, as in the case of O_2 binding to hemoglobin (Figure 10a)). 2) The model postulates specific structural consequences. For example, since all noncovalent interactions within a receptor system that are coupled with negative cooperativity to ligand binding should loosen, it requires that the internal structure of each hemoglobin subunit be extensively loosened upon O_2 binding (this has been established by H/D exchange experiments[65,70]). 3) The use of the terms T and R states[62] is naturally accommodated, since negatively cooperative binding of O_2 forces a reduction in bonding in the T state (cost in enthalpy) to give the R state which is more dynamic (benefit in entropy).

If the binding of O_2 to hemoglobin were positively cooperative in a structural sense (in terms of noncovalent bonding), then the initial O_2 binding event would represent "normality", and subsequent O_2 binding events would be accompanied by mutual enhancement of noncovalent interactions within the O_2/hemoglobin system. This is not the case. Rather, nature has built the greatest adversity into the first O_2-binding step, where the restriction of access of O_2 to the iron atom is the result of the steric hindrance of the porphyrin ring (Figure 10a). The successively stronger O_2-binding steps that are described as positively cooperative in the Monod, Wyman, Changeux model are in fact successive steps of decreasing negative cooperativity.

Other literature data are consistent with the general properties proposed here for negatively cooperative binding. The binding of the cofactor (6R)-L-erythro-5,6,7,8-tetrahydrobioptrin to the tetrameric recombinant human tyrosine hydroxylase isoform 1 occurs with negative cooperativity.[71] The cofactor-bound form of the enzyme shows, relative to the free form of the enzyme, a decreased resistance to limited tryptic proteolysis—as would be expected from a loosening of the enzyme structure. Additionally, a decreasing incremental affinity is observed for the binding of ligands with one, two, or three carbohydrate units to lectins.[72,73] That is, the binding is negatively cooperative. The ligands with several carbohydrate units coordinate with more positive entropy of binding relative to the analogues with one unit,[74] presumably reflecting the disorder produced in the lectins by the negatively cooperative binding of the second and third carbohydrate epitopes.

Lastly, a decrease in protein stability is induced by ligand binding which increases the flexibility of the protein.[75]

10. Negative Cooperativity that Breaks Interfaces

If the free-energy change associated with negatively cooperative binding were sufficiently large, the free energy of **F** would lie above that of **B** (Figure 7). Under these circumstances, a ligand binds with negative cooperativity to a receptor that is in its dimeric state in the absence of ligand, and thereby induces dissociation of the dimer. Such cases are established,[76] and, indeed, Monod, Wyman, and Changeux[62] considered dissociation of an oligomeric species as the limit of structure loosening.

11. Reduced Dynamics within Protein Receptors as a Source of Ligand Binding Energy

In Sections 7 and 8 it was shown that in the positively cooperative binding of a ligand to a receptor (there a small dimer) the free-energy benefit of the positively cooperative binding is correlated with a tightening (that is, a local volume reduction) within the receptor system. A thermodynamic cycle shows that where a receptor system becomes more stable upon ligand binding it is axiomatic that ligand binding is thereby improved.[55] This conclusion is represented schematically in Figure 11.
Figure 11. Schematic illustration showing that stabilization of a receptor system (oblong) upon ligand binding (blue square) increases ligand binding energy. In the absence of positively cooperative binding (right), the ligand binds without modification (tightening) of the receptor structure. In the presence of positively cooperative binding (left), the ligand binds with overall tightening of the receptor structure. The increase in ligand binding energy arising from positive cooperativity is because of increased stability of the ligand/receptor system. It may in principle be expressed at any of the noncovalent interfaces of the ligand/receptor system.

Has evolution exploited reduced dynamics within protein receptors as a source of ligand-binding energy? Clearly, the search for such effects should be through the examination of systems in which a localized view of noncovalent interactions would seem inadequate in understanding the observed affinities.

The binding of biotin to the streptavidin (STV) tetramer is so remarkably strong ($K = 10^{13.4}\,\mathrm{M}^{-1}$) that it finds widespread use in biology. It is poorly understood and typically found to be an "outlier" in comparison with other affinities.[16,77] Specifically, it is about 1000 times stronger than expected on the basis that the binding should correspond to the sum of the parts.[16,77] We used mass spectrometry to measure the extent of H/D exchange of the amide NH protons in STV both in the absence and presence of biotin. It was found that 22 backbone amide NH protons per STV monomer unit are protected from H/D exchange (RT, pH 8, 2 h) upon binding of biotin.[65] The location of the backbone NH protons protected by biotin binding was obtained from a pepsin digest. The data show that the binding of biotin reduces the solvent accessibility of streptavidin backbone NH protons in much of the structure (Figure 12).

It is noteable that the effects are much more marked in some parts of the structure than in others: thus, the improved packing induced within the receptor upon binding of biotin is not that which might be engendered upon simply carrying out
Figure 12. a) Deuterium incorporation into streptavidin in the absence (■) and presence (♦) of biotin as a function of time t_L. The level of deuterium incorporation in two peptides (43–56 and 59–72) obtained by pepsin digestion was investigated. b) Position of the peptides in a ribbon model of a STV subunit with bound biotin (the figure was prepared with the program MOLMOL[106]). The degree of increased NH protection in the presence of biotin is indicated by color: red >30%, yellow 20–30%, light blue 10–20%, and dark blue <10%.

binding at a higher pressure. Rather, it is exercised only in the parts of the receptor where positively cooperative binding is expressed. It is clear that the binding energy of biotin to streptavidin is widely delocalized. X-ray crystallographic studies of the free and bound tetramer[78–81] do not illustrate the widespread greater dynamic behavior of the free tetramer, presumably because this is damped down by crystal-packing forces. In this respect, we note that liquid to crystal transitions universally occur with improvements in noncovalent bonding that restrict dynamic behavior.

The streptavidin/biotin system provides a clear example where the binding affinity is the property of the whole system, rather than something that can be understood by examination of the ligand/receptor interface. This point is consistent with other, less structure specific, measurements. The effect of biotin binding on the thermal stability of STV has been evaluated by using differential scanning calorimetry (DSC).[79,81] Biotin binding increases the thermally induced denaturation of STV in phosphate buffer from $T_m = 75$ to $112\,°C$. Thus, the biotin/STV system is much more resistant to thermal unfolding than is STV in the absence of biotin, and clearly more stable than is the isolated STV. Additionally, the binding of biotin to STV is remarkably exothermic and adverse in entropy ($\Delta H = -134\,\mathrm{kJ\,mol}^{-1}$ and $T\Delta S = -57\,\mathrm{kJ\,mol}^{-1}$,[81] also reported in another study as $\Delta H = -102\,\mathrm{kJ\,mol}^{-1}$ and $T\Delta S = -26\,\mathrm{kJ\,mol}^{-1}$).[79] All the data satisfy the proposed effects of positively cooperative binding in which ligand binding energy is provided in part because the ligand reduces the dynamic behavior of the receptor. The formation of new noncovalent interactions within the receptor is not required, but simply the strengthening of existing

ones. In this sense, distinct conformational changes are not required.

The above conclusions also receive support from independent findings that an increase in protein stability is induced by ligand binding which reduces the flexibility of the protein.[75] They are also in accord with the long-standing observation of Sturtevant that ligand binding to proteins commonly occurs with a reduction in heat capacity, which is consistent with the loss of many internal vibrational degrees of freedom.[82] Notably, Cooper and Dryden have also concluded[83] that positive cooperativity in ligand binding will induce a "stiffening" in the protein (corresponding to the "tightening" shown here). We note that although the H/D exchange experiments indicate the strengthening of hydrogen bonds, all the binding interactions that are positively coupled to the strength of these bonds will be enhanced.

An additional comment is necessary here. It is widely perceived that if there is a change in structure from the observed state of a free protein to a more packed state upon ligand binding, then there must be a cost in the free energy associated with the structural change of the protein. This idea is incorrect: once the ligand has bound to the protein, a new system (ligand·protein) has been generated. Since the ligand restricts the dynamic motion of the protein in positively cooperative binding (see above data), a more compact state is now the most favored in terms of free energy.

12. Ligand/Receptor Interactions that are Strongly Enthalpy or Entropy Driven

Since positive cooperativity promotes enthalpy-driven binding, and negative cooperativity promotes entropy-driven binding, these relationships can be used plausibly to infer the manner in which drugs are likely to order, or disorder, the receptors to which they bind. The thermodynamic parameters of the binding of 136 drugs to biological receptors has been plotted in a graph of ΔH versus ΔS (Figure 13).[84] Some associations are endothermic by quantities in the region of 30 kcal mol^{-1} (125 kJ mol^{-1}), while at the other extreme, some
Figure 13. Plot of the standard enthalpies (ΔH^0) versus standard entropies (ΔS^0) for the binding equilibria of 136 different ligands to 10 biological receptors, one DNA, and two enzymes. The two dashed lines correspond to the ligand–macromolecule association constants K of 10^4 M^{-1} and 10^{11} M^{-1}. (Reproduced with permission from Ref. [84].)

are exothermic by about 20 kcal mol^{-1} (84 kJ mol^{-1}). The differences in these extremes are massive (ca. 200 kJ mol^{-1}) and can be ascribed to two scenarios:

1) The highly endothermic binding is associated with negative cooperativity and with associated decreased bonding within the receptor (in its drug-bound, relative to drug-free, state). The decreased bonding in the receptor upon binding the drug increases its internal motion, thus accounting for the very favorable positive entropy change ($T\Delta S$ is in the region of 160 kJ mol^{-1} at room temperature).

2) The highly exothermic binding is associated with positive cooperativity, and with associated improved bonding within the receptor (in its drug-bound, relative to drug-free, state). The increased bonding in the receptor upon binding the drug decreases its internal motion, thus accounting for the very unfavorable negative entropy change ($T\Delta S$ is in the region of -47 kJ mol^{-1} at room temperature).

It is of course possible that both positively and negatively cooperative interactions will occur within the same system, and the thermodynamic parameters will then reflect the net effect. Cases where enthalpy/entropy compensation occurs upon ligand binding to proteins have been highlighted, and examples where binding of ligand causes both increases and decreases in flexibility within the same protein are reported.[85] Additionally, we note that we are only able to consider cases where cooperativity acts to loosen or tighten receptor structures. The situation becomes more complex than can be treated here when ligand binding induces the formation of receptor structures that contain new sets of noncovalent interactions within the receptor.

13. Changes in the Aggregation of Receptors in Signal Transduction

The extremes of enthalpy-driven versus entropy-driven binding were interpreted above as reflecting a tightening or loosening of the receptor system. A common feature of cell-signaling pathways is that membrane-bound receptors are induced to change the extent of their aggregation upon binding to the natural ligand (Figure 14).[86] In some cases, agonists (which activate a receptor when they bind to it[87]) induce aggregation of receptors.[86] Such agonist binding should therefore be particularly beneficial in bonding (negative contribution to ΔH) and adverse in entropy (negative contribution to $T\Delta S$). These consequences (although not previously interpreted in this way) are seen in Figure 15 for the binding of agonists (●) to the β-adrenergic receptor.[88]

In other cases agonists induce the dissociation of receptor multimers.[86] Such agonist binding should therefore be relatively adverse in overall bonding and favorable in entropy. These consequences are seen in Figure 16 for the binding of agonists (●) to adenosine A$_1$ and A$_2$ receptors.[89–91]

Antagonists are compounds that bind to such receptors but do not activate them.[87] Therefore, antagonists must avoid induction of the same order of the receptor system that is
Figure 14. The binding of a ligand (red circle) to a receptor (ellipses) in a membrane: a) ligand-free receptor, b), c) receptors with ligands. b) The binding of a ligand induces greater oligomerization ($n > m$) and possibly also closer packing of the oligomers, c) the binding of the ligand induces dissociation of the receptor ($p < m$) and possibly also looser packing of the oligomers. The receptors may be partially bound (as shown in b and c) or fully saturated.
Figure 15. Plots of ΔH versus $T\Delta S$ for the binding of agonists (●), antagonists (○), and partial agonists (▲) to the β-adrenergic receptor.

Figure 16. Plots of ΔH versus $T\Delta S$ for the binding of agonists (●) and antagonists (○) to the a) adenosine A_1 receptor and b) adenosine A_2 receptor.[91]

induced by agonists. Thus, where the agonist induces receptor oligomerization (for example, the β-adrenergic receptor), the antagonist may avoid induction of oligomerization, or even induce the formation of monomeric receptor. Such antagonist binding should therefore be (in comparison to agonist binding) relatively adverse in overall bonding and favorable in entropy. This conclusion is consistent with the data points for antagonist binding to the β-adrenergic receptor (○ in Figure 15).

In contrast, if agonists induce the dissociation of receptor multimers (for example, the adenosine A_1 and A_2 receptors), antagonists may avoid the induction of this dissociation or even induce the formation of receptor oligomers. Such antagonist binding should therefore be (in comparison to agonist binding) relatively favorable in overall bonding and unfavorable in entropy. This conclusion is consistent with the data points for antagonist binding to the adenosine A_1 and A_2 receptors (○ in Figure 16).

Analogous effects are found in numerous systems.[89–91] Thus, agonists and antagonists appear to frequently act differently in their effects on enthalpy/entropy compensation, and in such cases thermodynamic studies can be used to probe the changes in the oligomeric states of receptors upon ligand binding.

14. Volume Reductions within Enzymes can Promote Catalysis

14.1. Benefits of Improved Bonding in Enzyme Catalysis

A reaction of substrate→product (S→P) catalyzed by an enzyme (E) benefits, relative to the reaction in free solution, because the adverse entropy of the reaction in free solution is reduced by the preorganization of the catalytic groups in relation to the substrate [Eq. (4)].[63] Catalysis will also be promoted if the enzyme binds the substrate transition state ($S^\ddagger$) with positive cooperativity.

$$E + S \rightarrow E \cdot S \rightarrow E \cdot S^\ddagger \rightarrow E \cdot P \rightarrow E + P \qquad (4)$$
According to the model presented here, such positively cooperative binding will occur with a cost in entropy (because of reduced dynamics) and a benefit in enthalpy (because of noncovalent bond contractions) within parts of the enzyme structure in the transition state for reaction. The prediction is therefore that this latter cost in entropy will offset the advantage of the preorganization, but that a large benefit in enthalpy should be apparent in enzyme catalysis.

Relevant data are available for the reaction catalyzed by cytidine deaminase.[92] The effect of enzyme catalysis is to increase the reaction rate by 10^{16}, as a result of a benefit in enthalpy ($\Delta\Delta H^\ddagger$) of -84 kJ mol^{-1} and a benefit in entropy

$(T\Delta\Delta S^{\ddagger})$ of only 7 kJ mol^{-1}. From the Boltzmann equation, -5.7 kJ mol^{-1} corresponds to the rate of reaction at room temperature increasing by a factor of 10^1. Thus, the benefit of improved bonding to the enzyme-catalyzed reaction is a factor of about 10^{15}, whereas the benefit from improved order is only a factor of about 10^1 (Figure 17). The data are consistent with catalysis being derived in part by improving the bonds *within the enzyme*, as a consequence of the transition-state structure of the substrate.
Figure 17. Free energy profiles for the uncatalyzed (upper profile, E + S → E + S$^+$ → E + P) and catalyzed (lower profile, E + S → ES → ES$^+$ → EP → E + P) deamination of cytidine (modified from [92] The rate enhancement of the enzyme-catalyzed reaction (10^{16}) is obtained by deconvolution of the free energy benefit of catalysis and arises from overall improvements in bonding (10^{15}) and in order (10^1).

The relative reaction rates of six reactions (enzyme-catalyzed versus noncatalyzed, $k_{cat.}/k_{uncat.}$) have been measured by Wolfenden and co-workers.[93, 94] Strikingly, all the enzyme-catalyzed reactions are greatly accelerated as a result of the large improvement in bonding in the transition state (Table 2). One apparent source of this improved bonding is between the substrate transition state and the enzyme. The additional source proposed here is the strengthening of existing noncovalent bonds within the enzyme.

Table 2: Benefit in enthalpy ($\Delta\Delta H^{\neq}$) between some uncatalyzed and enzyme-catalyzed reactions.[88, 89]

Entry	Enzyme	$\Delta\Delta H^{\neq}$ [kJ mol^{-1}]	$k_{cat.}/k_{uncat.}$[a]
1	chorismate dismutase	−33	10^6
2	chymotrypsin	−66	10^{12}
3	staphylococcal nuclease	−63	10^{11}
4	bacterial α-glucosidase	−80	10^{14}
5	urease	−93	10^{16}
6	yeast OMP decarboxylase	−143	10^{25}

[a] Acceleration of the enzyme-catalyzed reaction relative to the uncatalyzed reaction as a consequence of $\Delta\Delta H^{\neq}$.

14.2. Reduced Dynamic Behavior of Enzyme Transition State Structures

If the above large benefits in bonding do indeed reflect changes within the enzyme to an important extent, rather than simply the formation of strong bonds between the enzyme and the substrate transition state, then enzymes should undergo markedly less H/D exchange when in the

form that binds this transition state. Two recent studies give convincing support to this idea.

Hydrogen/deuterium (H/D) exchange into backbone amide bonds in hypoxanthine-guanine phosphoribosyl transferase (HGPRT) was used to compare the dynamic properties of human HGPRT alone, in forms with bound reactant/product, and in a form with a bound transition-state analogue.[95] It was found that out of a possible 207 amide H/D exchange sites in the enzyme, after 1 h at RT in D$_2$O, HGPRT alone exchanged 160, an equilibrium reactant/product complex exchanged 139, and the transition-state analogue complex exchanged 126 of these amide protons. Thus, the enzyme structure becomes better packed overall to provide binding energy for the reactant/product, and then the packing is improved further to provide even greater binding energy for the transition-state analogue.

Equally striking results are found for the binding of a transition-state analogue to a trimeric purine nucleoside phosphorylase (PNP).[96] The transition-state analogue (immucillin-H) binds to the enzyme extremely strongly ($K_d = 23$ pM) when only one of the three catalytic sites is occupied. Deuterium exchange occurred at 167 slow-exchange sites in 2 h when no ligands were present at the catalytic site. A substrate analogue and product prevented H/D exchange at 10 of these sites. When only one of the three sites of the homotrimer was filled with the transition-state analogue immucillin-H, 27 of the slow-exchange protons were protected from exchange in all of the three subunits. The decisive function of the positively cooperative binding of the transition-state analogue is to reduce the dynamic behavior of the receptor (trimer) system to such a degree that a further 81 backbone NH protons are protected from exchange. The reduction in dynamic behavior occurs almost throughout the trimer,[96] and the binding energy of the transition-state analogue can therefore be derived in a highly delocalized manner.

As in the case of positively cooperative binding of ligands to receptors (Section 11), the improved packing induced within enzyme/substrate transition states is different from that which can be induced by high pressures. Instead, it occurs selectively at those noncovalent interfaces where positively cooperative binding is induced by the substrate transition state (Figure 18).

14.3. Stabilization of the Enzyme in an Enzyme-Bound Intermediate

It can be expected that enzyme-bound intermediates (EBIs) will often bear structural similarities to the transition states for the reaction. Where this is the case, then catalysis should be aided if an EBI has 1) a higher melting temperature (T_m) and 2) a reduced susceptibility to trypsin digestion (relative to the enzyme from which it is formed). These properties have been demonstrated for a haloalkane dehalogenase (DhlA) that catalyzes the hydrolysis of haloalkanes via an alkyl–enzyme intermediate, which is then cleaved by a water molecule that is activated by His 289.[97] When His 289 is replaced by Gln, the mutant enzyme (His289Gln-DhlA)
Figure 18. Improved packing of parts of an enzyme structure upon binding the substrate (S), the substrate transition state (TS), and the product (P). The magnitudes of the size and shape changes are grossly exaggerated to illustrate the principle.

accumulates the alkyl–enzyme intermediate. Both the mutant enzyme and the alkyl–enzyme intermediate generated from it through reaction with 1,2-dibromoethane retain the overall conformation of the wild-type protein. Unsurprisingly, the His289Gln-DhlA mutant is thermally less stable ($T_m = 41\,°C$) than the native enzyme ($T_m = 48\,°C$). However, the alkyl–enzyme intermediate is considerably more thermally stable ($T_m = 51\,°C$) than the His289Gln-DhlA mutant from which it was derived. In accord with the conclusion that higher T_m values reflect less dynamic and more stable structures, a number of trypsin cleavage sites became far less susceptible in the enzyme intermediate than in the enzyme from which it was derived. The stabilization of the enzyme-intermediate structure is consistent with catalytic efficiency being derived in part through reduction in the dynamic behavior of the enzyme-intermediate structure.

15. The General Structural Consequences of Positively Cooperative Binding

We have argued here that when two sets of noncovalent bonds are made in a manner where each can restrict the motion associated with the other, there is a benefit in free energy to the ordered state. This conclusion is consistent with analogous (positively cooperative) changes that occur when the size of a homogeneous system is increased from n to $n + m$ molecules. The classical treatment of this effect was established by Hill.[98] Consider a cluster of n molecules with a repeating geometry in the solid state. As the cluster increases in size, typically 1) the solid becomes thermodynamically more stable and 2) the transition to convert the solid into a liquid becomes sharper.[99,100]

Table 3 shows the case of increasing numbers of layers of N_2 molecules absorbed on a surface.[99] The physical basis for this effect is that as the assemblies increase in size, any given molecule within the solid has other molecules extending out to greater distances that help to hold it in place. In larger

Table 3: Stabilities of N_2 layers as a function of the number of layers.

Number of layers	Melting temperature
2.2	ca. 52 K (very broad)
3.1	56 K (broad)
4.0	58 K (mod. broad)
4.8	61 K (mod. sharp)
infinite	63.14 K (very sharp)

assemblies, any given molecule has reduced dynamic behavior because the other $n-1$ molecules that hold it in place are increased in number. This reduced dynamic behavior means it is better bonded to its immediate neighbors.

The van't Hoff equation [Eq. (5)] requires that the greater the change in the equilibrium constant for a melting process in a given temperature range, the greater must be its enthalpy change.

$$\ln K = -\Delta H / RT + \Delta S / R \qquad (5)$$

Thus, the sharper melting transitions undergone by systems as they increase in size (Table 3) reflect larger enthalpy changes. These larger enthalpy changes derive from two effects: 1) the increased size of the system (for example, 2.2 versus 4.8 layers) and 2) the more effective bonding of each molecule to its neighbors in the larger system. The addition of an extra layer of nitrogen molecules to the system is analogous to the binding of a ligand to a receptor in a strain-free manner. The contractions within such a system as it increases in size are illustrated schematically in Figure 19.
Figure 19. Improved packing and bonding within an ordered system of molecules upon addition of an extra layer.

A corollary of the above argument is that as systems of homogeneous solids become smaller the supramolecular assemblies that behave as an entity become smaller, and their van't Hoff enthalpies of fusion become smaller. It is for this reason that crystals usually exhibit lower (and broader) melting transitions as they are contaminated with increasing amounts of an impurity. In Table 3, the "impurities" are at the boundaries of the N_2 molecules below the surface and the gas above. In biological systems, the water at the surface of a receptor can behave as an "impurity" relative to more positively cooperative binding in the ligand–receptor system.

Consistent with the above generalizations, the incorporation of increasing quantities of cholesterol (as an impurity) progressively reduces the temperature, enthalpy, and cooperativity of the gel-to-liquid-crystalline phase transition of lipid bilayers constituted from phosphatidylserine.[101]

16. Conclusion

An approach in which the simplification is made that noncovalent interactions have characteristic binding energies is useful in the estimation of binding energies. However, in reality each interaction is context-dependent. This context ddependency is associated with enthalpy/entropy compensation.

Enthalpy/entropy compensation, sometimes proposed to be an artifact of experimental error, is a fundamental property of noncovalent interactions (Houk et al. have written a recent summary where either the physical validity or presumed lack of validity of enthalpy/entropy compensation is presented[102]). It occurs in any solid/liquid transition, or when the temperature of any solid or liquid containing noncovalent bonds is changed. It is not only predicted from fundamental theoretical considerations,[2–4] but is also in many experiments far too large to be an artifact arising from errors (see, for example, Figures 13 and 16). In this connection, it should be noted that the uncertainties in the determination of ΔG and ΔH values by calorimetry are not very different.[59]

The correlations presented here between enthalpy/entropy compensation and the changes in dynamic behavior of proteins (as established by H/D exchange) establish the physical nature of a source of enthalpy/entropy compensation in biological systems. The enthalpy well for a local interaction
Figure 20. Relative vibrational levels occupied when the strength of a specified hydrogen bond of the receptor (red) and the coordination of the ligand (blue) are A) not cooperatively coupled, B) are coupled with positive cooperativity, and C) are coupled with negative cooperativity. The enthalpy of the interaction is more favorable (more negative) when it lies more deeply in the well. The asymmetry of the well means that when the interaction lies more deeply in the well its bond length is shorter.

influenced in this way is indicated in Figure 20. Promoting an interaction to lie more deeply in an enthalpy well provides a benefit in enthalpy at a cost in entropy; such a change is positively cooperative since ligands are able to bind better to organized templates. Conversely, inducing an interaction to lie more shallowly in the well gives a benefit in entropy at a cost in enthalpy; such a change is negatively cooperative in the general case since here ligands must distort their receptors, which thereby become more dynamic. When the

enthalpy barrier to breaking an interaction is very small, the available thermal energy will sometimes break the bond (that is, the interaction will be broken by "hopping" out of the well). Thus, when the bonding is extremely weak, the increases in bond length (that are associated with negative cooperativity or the removal of a positively cooperative effect) will also be associated with fraying.[103]

Where ligand binding directly increases the electrostatic polarization of an interaction within the receptor (for example, of a receptor amide/amide hydrogen bond), the well shown in Figure 20 is additionally deepened, thus providing a further source of bond shortening. It is also clearly possible that distortion of a receptor upon ligand binding may occur in such a manner that the well of Figure 20 becomes less deep, and this effect further promotes the bond lengthening associated with negative cooperativity.

The total changes in the free energies in the organized systems (Figure 20) would be determined by summing over all the noncovalent interactions that are influenced in the manner indicated. Note that in a bound state, lying more deeply or shallowly inside a specified well (Figure 20) has the same consequences as lying in a deeper or shallower well (Figure 2).

Thus, evolution can lead to the use of better packing within parts of receptor structures, which occurs upon ligand binding, to aid ligand binding. It is perhaps useful to envision that the ligand causes a "pseudocrystallization" of parts of the receptor.[56] In other cases, the loosening of parts of receptor structures occurs to weaken ligand binding. These changes are most simply represented as in Figures 18 and 21. The occurrence of the volume reductions indicated in Figure 18 and the upper panel of Figure 21 (grossly exaggerated) upon the positively cooperative binding of ligands to proteins is supported by the direct measurement of volume changes
Figure 21. Changes in packing of parts of a receptor structure upon binding its ligand with a) positive cooperativity and b) negative cooperativity. The magnitudes of the size and shape changes are grossly exaggerated to illustrate the principle. The nonsymmetrical induced changes in the shape of the receptor illustrate that cooperativity will typically be exercised more in some parts of the structure than in others. The effects cannot therefore be equated with the ones that would simply be induced by changes in pressure.

occurring in such processes. Thus, it has been reported that decreases in volume (on the order of 1%) occur when *N*-acetyl-D-glucosamine oligomers bind to lysozyme.[104] Importantly, the largest decreases in volume are observed for the ligand that exhibits the highest affinity.

Binding of a small molecule is promoted where the receptor protein shows some or all of the following properties:

1) reduced H/D exchange of the amide protons,[59,87,88]
2) a raised T_m value,[59,73]
3) improved internal bonding and reduced dynamic behavior (more negative values of ΔH and ΔS for ligand binding),[65,81]
4) greater resistance to enzymic digestion and possibly also promotion of the stability of oligomeric forms of the protein.[105]

In the examples cited here, negatively cooperative binding promotes converse effects.[65,71]

Catalytic efficiency is promoted when substrate transition states extensively reduce the dynamic behavior of enzymes. Such a mechanism suggests a reason why enzymes are relatively large structures.

Addendum

It is clearly important to determine whether large binding energies can be provided in the delocalized manner envisioned in this Review. To establish this point, we have recently determined the reduction in the dynamic behavior of glyceraldehyde 3-phosphate dehydrogenase (GAPDH) upon successively binding four molecules of its cofactor (NAD$^+$).[107] We find that in the binding of the first NAD$^+$ to the enzyme tetramer, 60 backbone amide NH protons are protected from H/D exchange, whereas in the binding of the fourth NAD$^+$ molecule, there is no measurable protection of amide backbone NH protons from H/D exchange. The binding constant for the first NAD$^+$ molecule is greater than that for the fourth NAD$^+$ molecule by a factor of about 10^6. Thus, it is clear that the binding constant can, in this case, be increased by a factor of a million because the dynamic behavior of the enzyme/cofactor system is reduced upon binding the first NAD$^+$, but not upon binding the fourth NAD$^+$ molecule.

We have also shown[107] that under circumstances in which streptavidin is concluded to decrease its average amide hydrogen bond length by about 1%, (on decreasing its temperature from 55 to 5°C),[108] its increased stability and reduced dynamic behavior decrease its extent of backbone amide H/D exchange from 99 to 61 (same conditions as reported in Section 11). This experiment, taken in conjunction with the data of Section 11 and the above GAPDH data, suggests that very large ligand binding energies, and increased catalytic efficiencies (of the order of a million-fold), can be derived by decreasing the lengths of the numerous hydrogen bonds of a protein (upon binding a small molecule) by as little as about 1%. It is therefore not surprising that X-ray studies

have not uncovered the structural basis of the effects proposed here.

Discrete Metal-Based Catalysts for the Copolymerization of CO$_2$ and Epoxides: Discovery, Reactivity, Optimization, and Mechanism

Geoffrey W. Coates* and David R. Moore
*M*ost synthetic polymers are made from petroleum feedstocks. Given the non-renewable nature of these materials, there is increasing interest in developing routes to polymeric materials from renewable resources. In addition, there is a growing demand for biodegradable polymeric materials. Polycarbonates made from CO₂ and epoxides have the potential to meet these goals. Since the discovery of catalysts for the copolymerization of CO₂ and epoxides in the late 1960's by Inoue, a significant amount of research has been directed toward the development of catalysts of improved activity and selectivity. Reviewed here are well-defined catalysts for epoxide–CO₂ copolymerization and related reactions.

From the Contents

1. Introduction

Since petroleum resources are predicted to be exhausted within the next century at the current rate of consumption,[1] there is a growing effort to develop new chemical processes using biorenewable resources.[2–4] One such resource of particular interest is CO_2, a nontoxic, nonflammable, naturally abundant C_1 feedstock.[5–8] The reaction of CO_2 with metal complexes has been extensively studied, revealing potential pathways for catalytic reactions.[9–15] However the thermodynamic stability of CO_2 has hampered its utility as a reagent for chemical synthesis; in fact its high stability makes it an ideal medium for many chemical processes.[7,16,17] To overcome this limitation, reactions employing CO_2 with highly reactive reagents have been explored. In particular, the catalytic coupling of CO_2 with heterocycles has received considerable attention over the past 35 years.[18–23] A majority of these publications involve the reaction of CO_2 with epoxides to generate polycarbonates and/or cyclic carbonates (1,3-dioxolan-2-ones) (Scheme 1).
Scheme 1. Alternating copolymerization of cyclohexene oxide (CHO) and propylene oxide (PO) with CO_2.

Aliphatic polycarbonates have potential applications as packaging materials, as well as in the synthesis of engineering thermoplastics and resins, pyrotechnics, and interliners for safety glass.[24–26] Poly(propylene carbonate) (PPC)[+] decomposes uniformly and controllably to cyclic propylene carbonate below 250°C,[27,28] making it particularly useful as a binder for ceramics, adhesives, and propellants.[29] The glass transition temperature (T_g) of PPC is 35–40°C, which hinders its broad utility as a bulk material.[28] Therefore, efforts are being directed to employ aliphatic polycarbonates as additives and pore formers. Clearly one of the most promising applications of PPC is as a mid-segment of polyurethanes.[25] PPCs with high ether linkage content (80% ether) have been reported to exhibit excellent solubility in supercritical CO_2, a rare property for non-fluorinated polymers.[30] Alicyclic polycarbonates, such as poly(cyclohexene carbonate) (PCHC), typically have much higher T_g's (115°C for PCHC) resulting in materials with properties very similar to poly(styrene).[31] PCHC also has a higher decomposition temperature (≈ 300°C), which allows melt-processing.[26] Alicyclic polycarbonates are finding applications in lithographic processes for the construction of microfluidic devices.[32–35] Cyclic carbonates are utilized industrially as polar aprotic solvents, substrates for small molecule synthesis, additives, antifoam agents for antifreeze, and plasticizers.[36,37] The five-membered ring cyclic carbonates (1,3-dioxolan-2-ones) are generally incapable of ring-opening polymerization due to their thermodynamic stability, but do undergo polymerization with partial loss of CO_2 to yield macromolecules with both ether and carbonate linkages.[38] Due to such uses, a number of syntheses of cyclic carbonates have been described over the

[+] A list of frequent abbreviations is given at the end of this Review.

last 30 years. For example, tetraalkylammonium salts, phosphanes, main-group and transition-metal complexes, and alkali metal salts convert epoxides and CO_2 to cyclic carbonates.[20]

The moderate thermal stability and low temperature of thermal deformation of aliphatic polycarbonates, coupled with their high cost (ca. $100 per lb) hamper their widespread use as bulk polymeric materials. More economically viable processes and the synthesis of new types of improved aliphatic polycarbonates would clearly increase the number of applications for these polymers, as well as lower their cost. A significant contributor to the cost of these materials is the low activity of the industrial zinc/dicarboxylic acid catalysts used to polymerize epoxides and CO_2. As a result, a significant amount of recent research has focused on the discovery and development of new catalysts for this process.

There are many parallels between the development of alkene polymerization catalysts and those for CO_2/epoxide polymerization. In each field, the catalysts initially discovered were heterogeneous; subsequent work focused on the empirical optimization to provide higher activity and selectivity for the polymerizations. Eventually, discrete, homogeneous metal complexes were explored in academic laboratories as a way to probe reaction mechanisms. It was envisaged that a detailed understanding of the polymerizations at the molecular level could be applied to the design of improved catalytic systems. In some cases, these new homogeneous catalysts have significant advantages over their heterogeneous counterparts.

Heterogeneous catalysts are the workhorse of many industrial processes. They have many processing advantages over their soluble counterparts, but often contain multiple active sites that result in polymers with broad polydispersity indices (PDIs) and composition distributions. In many cases, only a small percentage of the metal sites are active, and residual catalyst remains in the polymeric product. As a result of these drawbacks, a significant amount of research has been directed toward the development of well-defined, single-site homogeneous catalysts. Homogeneous catalysts are typically of the form L_nMR, where L_n is a set of permanently bound ligands, M is a metal center, and R is an efficient initiation group. These homogeneous catalysts are discrete species, rendering them amenable to precise modification as well as detailed mechanistic studies. Most of the major advances in metal-catalyzed polymerization, including stereoselective[39]

and living[40] alkene polymerization, lactide and lactone polymerization,[41] olefin metathesis,[42] and alkene/CO copolymerization,[43] are the result of progress in homogeneous catalyst design. Homogeneous catalysts are being used to develop unique polymer architectures that lead to new, industrially relevant materials. However, it should be noted that the vast majority of industrial polymerization catalysts are still of the heterogeneous variety.

1.1. Scope of Review

The purpose of this review is to give a thorough account of the CO_2/epoxide polymerization literature,[18–22] with a strong emphasis on single-site homogeneous catalysts and their mechanisms of operation. The review is organized according to the active metal center of the catalyst and although polymerization is the focus, the production of cyclic carbonates is discussed when appropriate. Activities in the form of turnover frequencies (TOFs) are given in mole epoxide converted to product per mole metal per hour (assuming all metal centers are active). The activity of a system is defined on the basis of TOFs as follows: low ($< 5\ TO\,h^{-1}$), moderate ($5–200\ TO\,h^{-1}$), and high ($> 200\ TO\,h^{-1}$). For conformity, CO_2 pressures are reported in atm (1 atm = 14.7 psi = 1.013 bar = 1.013×10^5 Pa).

2. Early Discoveries and Background

In 1969, Inoue and co-workers made the remarkable discovery that a mixture of $ZnEt_2$ and H_2O was active for catalyzing the alternating copolymerization of propylene oxide (PO) and CO_2 (Scheme 1), marking the advent of epoxide–CO_2 coupling chemistry.[44,45] An optimum 1:1 ratio of $ZnEt_2/H_2O$ gave the best yields of methanol-insoluble PPC with an activity of $0.12\ h^{-1}$ (mol of PO converted to polymer per mol Zn per h) at 80°C and 20–50 atm CO_2 (Table 1). On the basis of elemental analysis, the copolymer contained 88% carbonate linkages. Notably, a 1:1 mixture of $ZnEt_2$ and MeOH did not generate an active catalytic species for polycarbonate synthesis. Following this initial lead, Inoue investigated the use of dihydric sources, including resorcinol,[46,47] dicarboxylic acids,[48] and primary amines,[49] in mixtures with $ZnEt_2$ for PO–CO_2 copolymerization. These

Geoffrey W. Coates, born in Evansville, Indiana in 1966, obtained a B.A. degree in chemistry from Wabash College in 1989 and a Ph.D. in organic chemistry from Stanford University in 1994. In his thesis work, under the direction of Robert M. Waymouth, he investigated the stereoselectivity of metallocene-based Ziegler–Natta catalysts. Following his doctoral studies, he was an NSF Postdoctoral Fellow with Robert H. Grubbs at the California Institute of Technology. In 1997, he joined the Department of Chemistry at Cornell University where he is currently Professor of Chemistry.

David R. Moore, born in Hamilton, New Jersey in 1976, graduated from Drew University in 1998 with a B.A. degree in chemistry and subsequently studied organic chemistry under the supervision of Geoffrey W. Coates at Cornell University. His doctoral research focused on the mechanism of alternating copolymerization of epoxides and carbon dioxide using β-diiminate–zinc catalysts. After graduating with a Ph.D. in 2003, he became a research scientist at the General Electric Global Research Center in Niskayuna, New York.

systems showed TOFs of 0.17, 0.43, and 0.06 h^{-1}, respectively (see Table 1).

Following Inoue's discoveries, Kuran and co-workers developed a copolymerization system using ZnEt$_2$ and trihydric phenols, including pyrogallol and 4-bromopyrogal-

lol, that produced PPC with TOFs up to 0.3 h^{-1} at 35°C and 60 atm CO$_2$.[50,51] In general, di- or tri-protic sources and ZnEt$_2$ produced PPC, while monoprotic sources, such as alcohols and secondary amines, only gave propylene carbonate (PC) (Schemes 1 and 2).[52] In an effort to develop more active catalysts, Hattori and co-workers synthesized a heterogeneous catalyst from Zn(OH)$_2$ and glutaric acid. Under 30 atm CO$_2$ and 60°C, the Zn(OH)$_2$/glutaric acid mixture yielded PPC with a TOF of 1.1 h^{-1} ($M_n = 12000$ g mol^{-1}).[53]

While the discoveries of ZnEt$_2$/R(OH)$_x$ and Zn(OH)$_2$/glutaric acid catalysts for epoxide–CO$_2$ coupling marked salient scientific findings, the active species responsible for polymer and cyclic formation remain unknown. Nevertheless, several mechanistic studies indirectly support the theory that multi-site or polymeric catalysts are operative in the alternating copolymerization of CO$_2$ and epoxides.[18,19,52,54–58] In the absence of multiple metal sites (i.e., 1 ZnEt$_2$ + 2 equivalents monohydric source), cyclic compounds are the predominant product of epoxide–CO$_2$ coupling. Epoxide–CO$_2$ copolymerization is generally accepted to proceed by a

coordination–insertion mechanism (Scheme 2). The mechanism includes several prevailing principles:

1) *Mechanism*: The alternating copolymerization of epoxides and CO$_2$ is a two-step process; the insertion of CO$_2$ into a metal alkoxide is followed by insertion of epoxide into a metal carbonate. Hence, most catalysts (polymerization initiators) are metal-alkoxide or metal-carboxylate species that are similar to the putative catalytic intermediates.

2) *Regiochemistry*: In the copolymerization of CO$_2$ and aliphatic epoxides (propylene oxide, etc.), epoxide ring-opening is typically favored at the least-hindered C–O bond, although cleavage is normally observed at both C–O bonds, giving regioirregular polymers.

3) *Stereochemistry*: In the copolymerization of CO$_2$ and alicyclic epoxides, such as cyclohexene oxide (CHO), C–O bond cleavage typically occurs with inversion of configuration at the site of attack (S$_N$2-type mechanism) to give the *trans* ring-opened product.[52,59] To date, there are no reports of catalysts that generate tactic polycarbonates by chain-end control mechanisms, presumably due to the distance between the stereogenic center of the chain end and the active metal center. There are examples of stereocontrol by site-control mechanisms using chiral metal catalysts (see Chapters 5, 7).

4) *Polymer/cyclic product selectivity*: Cyclic species are a common by-product of the copolymerization of CO$_2$ and aliphatic epoxides. Many systems produce predominantly cyclic species,[20] which are thermodynamically more stable than polycarbonates. The percentage of polymer typically increases at lower reaction temperature. Systems can be tuned to favor cyclic-species or polymer formation depending on the catalyst, additives, CO$_2$ pressure, epoxide concentration, and temperature. Formation of cyclic species results from degradation of the growing polycarbonate chain by depolymerization or backbiting.[51] In most cases, cyclic carbonates are thought to be generated by the backbiting of a metal-alkoxide into an adjacent carbonate linkage (Scheme 2).[57]

5) *Ether and dicarbonate linkages*: The presence of ether linkages as a result of consecutive epoxide enchainment can be observed in some aliphatic polycarbonates. Most systems can be tuned to favor CO$_2$ incorporation by catalyst selection, CO$_2$ pressure, epoxide concentration, and polymerization temperature. The enthalpically disfavored consecutive insertion of two molecules of CO$_2$ to give dicarbonate linkages has not been reported.

Scheme 3. Qualitative, ideal free-energy profile depicting alternating copolymerization of propylene oxide and CO_2, as well as potential side-reactions.

These prevailing principles are depicted in a qualitative free-energy profile for the copolymerization of epoxides and CO_2 (Scheme 3).

As observed in early studies, only a few metals are active for the coupling of epoxides and CO_2, including Al, Cr, Co, Mg, Li, Zn, Cu, and Cd.[18,19] Studies have shown that large differences in catalytic efficacy result from the organic frameworks surrounding these metals, especially in the case of zinc. Accordingly, subsequent studies have largely focused on empirical modification of ligands to generate improved catalysts.

3. Aluminum and Manganese Catalysts

In 1978, Inoue developed the first single-site catalysts for epoxide–CO_2 copolymerization based on a tetraphenylporphyrin (tpp) ligand framework, **1a**–**d**.[60] [(tpp)AlCl] (**1a**) and [(tpp)AlOMe] (**1b**) (Figure 1) were found to be living initiators for the homopolymerization of PO and of lactones, including lactide, β-butyrolactone, and ε-caprolactone, as well as for the copolymerization of CO_2 and epoxides and of PO and phthalic anhydrides.[61–67] **1a** and **1b** reacted with PO to form poly(propylene oxide) (PPO) in a living polymerization with PDIs of 1.07–1.15 (Scheme 4). The chloride initiator ring-opened the least hindered C–O bond and generated a regioregular
Scheme 4. Reactivity of aluminum–porphyrin complexes.

PPO. In addition, **1b** copolymerized PO and CO$_2$ at 20°C and 8 atm CO$_2$, giving PPC ($M_n = 3900$ g mol^{-1}; $M_w/M_n = 1.15$) with 40% carbonate linkages over the course of 19 days.[61,64] Although molecular weights were low and reaction times were long, this reaction marked the first example of monodisperse polycarbonates having a narrow PDI.

Similarly to **1a**, [(tpp)AlOR] (**1d**), where R is an oligomer of PO, did not react with CO$_2$. However, upon addition of 1-methylimidazole (MeIm), reversible CO$_2$ insertion was observed. On the basis of ^{1}H NMR studies, MeIm was proposed to bind to aluminum in a *trans* fashion and activate the metal toward CO$_2$ insertion. The addition of ethylene oxide (EO) and CO$_2$ to **1d** catalytically produced cyclic ethylene carbonate (EC).[65] The copolymer of PO and CO$_2$ was synthesized upon addition of ammonium or phosphonium salts. **1a** and 1 equivalent of EtPh$_3$PBr gave PPC ($M_n = 3500$ g mol^{-1}, PDI = 1.09) with a TOF of 0.18 h^{-1} at 20°C and 48 atm CO$_2$. Both EtPh$_3$PBr and Et$_4$NBr were efficient cocatalysts, drastically increasing the percentage of carbonate linkages to >99%. Additionally, cyclic propylene carbonate was produced as a by-product in approximately 20% yield relative to converted PO. **1a**/EtPh$_3$PBr was also active for EO–CO$_2$ and CHO–CO$_2$ alternating copolymerizations producing poly(ethylene carbonate) (PEC) with 70% carbonate linkages, a M_n of 5500 g mol^{-1}, and a PDI of 1.14. Poly(cyclohexene carbonate) was produced with >99% carbonate linkages, a M_n of 6200 g mol^{-1}, and a PDI of 1.06 (TOF = 0.30 h^{-1}; Table 2). Even though this system yields PC, neither EC nor cyclohexene carbonate (CHC) was observed.

Finally, Inoue and co-workers synthesized several AB- and ABA-type block copolymers, incorporating PPO, PPC, and/or poly(PO-*alt*-phthalic anhydride), illustrating the "living" nature of the polymerizations.[67] In 1999, Ree and co-workers also explored metalloporphyrins for PO–CO$_2$ copolymerization. In contrast to Inoue's results, Ree found that **1a** and Et$_4$NBr cocatalyst gave PPC ($M_n = 1900$ g mol^{-1}; $M_w/M_n = 1.10$) with only 75% carbonate linkages at 20°C and 52 atm CO$_2$.[68] Aluminum porphyrins have also been utilized in the exclusive production of cyclic carbonates.[69]

The low molecular weights of polymers produced by {(tpp)Al} catalysts suggest chain transfer, which supports

Inoue's proposal of an "immortal" type polymerization.[60] An immortal polymerization allows for multiple chains to propagate from one metal center, whereas a living polymerization grows only one chain per metal center. Protic sources facilitate chain swapping such that there are more polymer chains than active catalytic sites (Scheme 5). Free chains are
Scheme 5. "Immortal" polymerization of PO using aluminum–porphyrin complexes.

dormant, but continue to grow polymer when exchanged onto the active site. If the chain swapping is more rapid than propagation, polymer chains with narrow PDIs are produced. For example, addition of HCl does not quench the polymerization. Instead, it yields [(tpp)AlCl] which allows for new polymer chains to be initiated (see Scheme 5). [(tpp)AlCl] reinitiates polymerization and grows a new polymer chain in the same "immortal" manner, eventually giving a bimodal polymer distribution. Although no rate studies were reported for the alternating copolymerization of CO$_2$ and epoxides, Inoue showed a second-order dependence on the catalyst for the homopolymerization of δ-valerolactone[70] and proposed a

linear transition-state mechanism incorporating two aluminum–porphyrin complexes for the ring-opening of epoxides.[71]

In 2003, Inoue and co-workers developed a related porphyrin system utilizing manganese as the active metal center.[72] At 80 °C, [(tpp)MnOAc] (**1e**; Figure 1) reacted with CHO and 50 atm CO_2 to produce PCHC (99% carbonate linkages; $M_n = 6700$ g mol^{-1}; $M_w/M_n = 1.3$) with a moderate TOF of 16.3 h^{-1}. In this system, additives such as PPh$_3$, pyridine, or MeIm compromised polymerization rates and decreased the percentage of carbonate linkages. At 80 °C and only 1 atm of CO_2, **1e** catalyzed PCHC formation providing activities of up to 3.3 h^{-1} (95% carbonate linkages; $M_n = 3000$ g mol^{-1}; $M_w/M_n = 1.6$). Finally, the coupling of PO and CO_2 yielded PC, but gave no PPC.

Recently, a salicylaldimine(salen)–aluminum complex, **2a**, was found to be highly active for the cyclization of EO and CO_2 to ethylene carbonate (Figure 2).[73,74] Lewis bases or

Figure 3. Aluminum complexes for the homopolymerization of epoxides and copolymerization of epoxides and CO_2.

Figure 2. Salen catalyst systems (cocatalyst = tetrabutylammonium halide, pyridine, or MeIm) for the synthesis of ethylene carbonate.

quaternary ammonium salts, including pyridine, MeIm, and nBu$_4$NX (X = Cl, Br, I), were utilized as cocatalysts, enhancing rates by up to a factor of five. At 110 °C and in supercritical CO_2 (ca. 150 atm CO_2), a 1:1 mixture of **2a**/nBu$_4$NBr catalyzed the conversion of EO to EC with a TOF of 2220 h^{-1}. Salen-chromium (**2b**) and -cobalt (**2c**) analogs also promoted cyclic-species formation showing rates of 2140 and 1320 h^{-1}, respectively (see Chapters 4, 5). Darensbourg and co-workers have reported AlCl$_4^-$-based complexes that exhibit TOFs up to 50 h^{-1} for the synthesis of propylene carbonate from PO and CO_2.[75]

In 1998, Kuran and co-workers reported an aluminum calix[4]arene, **3**, derived from 25,27-dimethoxy-26,28-dihydroxy-p-$tert$-butylcalix[4]arene and diethylaluminum chloride (Figure 3).[76] Complex **3** was found to be active for the alternating copolymerization of CO_2 with PO or CHO. At 60 atm CO_2 and 35 °C, PPC ($M_n = 5620$ g mol^{-1}) was formed with a TOF of 0.11 h^{-1}. The polycarbonate contained low levels of carbonate linkages, comparable to the PPC made from [(tpp)AlCl] (**1a**) in the absence of quaternary salts. Under the same reaction conditions, **3** converted CHO and CO_2 to PCHC ($M_n = 1930$ g mol^{-1}) with a TOF of only 0.05 h^{-1}. Additionally, cyclic PC and CHC were produced as by-products in 14% and 4% yield with respect to epoxide. Kuran et al. proposed a mechanism involving participation of two aluminum complexes in the alternating copolymerization, although no mechanistic studies were reported. Finally, **3** was active for the homopolymerization of PO and CHO, giving poly(alkene oxides) with fairly narrow PDIs ($M_w/M_n = 1.36-1.51$).

Aluminum alkoxides have also been shown to convert epoxides and CO_2 to polycarbonates. Beckman and co-workers reported several aluminum complexes, including **4**, **5**, and **6** (Figure 3), that reacted with CHO and CO_2 to give PCHC with a maximum TOF of 2.7 h^{-1}.[30,77,78] At 80 atm CO_2 and 60 °C, **4** produced PPC ($M_n = 5000$ g mol^{-1}; $M_w/M_n = 2.89$) with only 22% carbonate linkages and a TOF of 2.0 h^{-1}. These low-carbonate content polymers have shown promise as solubilizers in supercritical CO_2 (scCO_2).[30] As expected, these complexes are also active for the homopolymerization of CHO.

Aluminum complexes are indeed active for the copolymerization of epoxides and CO_2; however, they are plagued by low activities and yield polycarbonates with high percentages of ether linkages. It appears that without additives, current aluminum catalysts do not cleanly generate alternating copolymer. Nevertheless, the "immortal" polymerization of [(tpp)AlX] compounds shows promise for the synthesis of a wealth of unique copolymers with varying levels of carbonate linkages provided the activities can be improved.

4. Chromium Catalysts

Kruper and Dellar discovered that [(tpp)CrX] (**7a,b**; Figure 4) in mixtures with 4–10 equivalents of a Lewis-basic amine cocatalyst (such as MeIm or (4-dimethylamino)pyridine (DMAP)) are moderately active for the cyclization of epoxides and CO_2.[79,80] A wide range of epoxides, including PO, $trans$-2-butene oxide, epichlorohydrin, CHO, and cyclopentene oxide (CPO), were rapidly converted to the corresponding cyclic carbonates. For instance, under 50 atm CO_2 and at 80 °C, **7b** and MeIm converted PO to PC affording a TOF of 158 h^{-1}. **7a** and DMAP catalyzed CHC formation at 50 atm CO_2 and 95 °C, exhibiting activities of 103 h^{-1}. In this case, PCHC was isolated as the major product. Following thermolysis, a 95:5 ratio of $trans$ and cis CHC was observed, suggesting the possibility of dual mechanisms. Unexpectedly,
Figure 4. Chromium–porphyrin complexes for the coupling of epoxides and CO₂.

the conversion of CPO to cyclopentene carbonate gave the *cis* isomer as the exclusive product. To account for this, two mechanistic pathways were suggested: 1) double inversion leading to retention of configuration; and 2) inversion of configuration due to backbiting into a polymer chain. A possible mechanism to explain the double inversion is shown in Scheme 6.
Scheme 6. Proposed mechanism of dioxolanone synthesis using [(tpp)CrCl].

Following this lead, Holmes and co-workers developed [(tfpp)CrCl] (**8**; Figure 4), which showed activities of up to 173 h^{-1} for the alternating copolymerization of CHO and CO₂ at 225 atm CO₂ (scCO₂) and 110°C (Table 2).[81,82] As with complexes **7a** and **7b**, the copolymerization only yielded polycarbonate when **8** was combined with a cocatalyst such as DMAP. The fluorinated aromatic moieties improved catalyst solubility in scCO₂, and consequently increased the yields of PCHC. Similar to aluminum–porphyrin catalysts for epoxide–CO₂ copolymerization, these chromium analogs yielded polycarbonates with narrow PDIs ($M_w/M_n = 1.08$–1.50) and low molecular weights ($M_n = 1500$–9400 g mol^{-1}). Furthermore, the resultant PCHC contained high percentages of carbonate linkages (97%). More recently, polymer supported chromium porphyrins have been found to be active for PCHC production.[83]

Jacobsen and co-workers found [(salen)CrCl] complexes to be highly active in the asymmetric ring-opening of epoxides.[84] This elegant work has since led to many crucial discoveries in the coupling of epoxides with CO₂; in fact the first report of (salen)chromium-mediated epoxide–CO₂ polymerization appeared in a 2000 patent by Jacobsen and co-workers.[85] Nguyen and Paddock reported highly active [(salen)CrCl]/DMAP-based systems, **9a–c** and **10** (Figure 5), for the cyclo-addition of CO₂ and a variety of terminal aliphatic epoxides, including PO, epichlorohydrin, butadiene monoepoxide, and styrene oxide (SO).[86] *Cis*-[(salen)CrCl] (**9a**) was the most efficient catalyst and
Figure 5. Salen–chromium and salen–cobalt complexes for the coupling of epoxides and CO₂.

was approximately twice as active as *trans*-[(salen)CrCl] (**9b**). At 100°C and 7 atm CO₂, **9a** and 1 equivalent of DMAP rapidly converted PO to PC in 1 h, exhibiting a high TOF of 916 h^{-1}. Furthermore, activities were largely dependent on DMAP concentration. Cyclization activities increased when rising DMAP concentrations up to 2 equivalents, but trailed off significantly at higher cocatalyst loadings. Nguyen also reported that cycloaliphatic epoxides such as CHO are copolymerized with CO₂ in the presence of [(salen)CrCl] complexes. Holmes and Mang also reported the conversion of glycidol derivatives to cyclic carbonates using **10**/DMAP.[82] More recently, He and co-workers reported the synthesis of ethylene carbonate using **2b**/cocatalyst mixtures.[73, 74]

Darensbourg and Yarbrough reported that the relatively air-stable complex **10** (Figure 5) is an effective catalyst for the alternating copolymerization of CHO and CO₂.[87] At 80°C

and 60 atm CO_2, compound **10** converted CHO to PCHC with a moderate TOF of 10.4 h^{-1}. Analysis of the polycarbonate showed nearly 100% carbonate linkages, a M_n of 8900 $g\,mol^{-1}$ and a M_w/M_n of 1.2. Based on the TON and lack of cyclic by-product, the PCHC should exhibit a theoretical molecular weight of approximately 35000 $g\,mol^{-1}$. Like the aluminum[60,67] and chromium[79] porphyrin systems, activities increased upon addition of MeIm, such that 5 equivalents MeIm tripled the copolymerization rates to 32.2 h^{-1} (see Table 2). Although complex **10** is chiral, the resultant polymer was completely atactic, as determined by ^{13}C NMR. Additionally, complex **10** catalyzed the coupling of PO and CO_2 to PC and PPC; activities were not specified. At 80°C, cyclic PC is the predominant product, but as the temperature is reduced to 40°C, PPC production becomes a competitive pathway. Finally, silylated aliphatic epoxides, such as 2-(3,4-epoxycyclohexyl)ethyl-trimethoxysilane, and CO_2 can also be copolymerized by salen–chromium complexes and a MeIm cocatalyst.[88] At 80°C and 55 atm CO_2, **9d** (Figure 5) and 2.5 equivalents MeIm catalyzed the formation of the silylated polycarbonate with a TOF of 12.0 h^{-1}.

Subsequent work detailed the intricate energetics of polymer versus cyclic-species formation using compound **10**.[89] In CHO–CO_2 coupling, the activation energies (E_a) for CHC and PCHC formation are 31.8 and 11.2 $kcal\,mol^{-1}$, illustrating markedly higher activation barriers for formation of the cyclic species. The activation barriers for PC and PPC in PO–CO_2 coupling were determined to be 24.0 and 16.2 $kcal\,mol^{-1}$, respectively. The significantly larger E_a for CHC versus PCHC is consistent with the exclusive formation of PCHC, while the slightly larger E_a for PC versus PPC is consistent with the formation of PC during PO–CO_2 copolymerization.

Recently, Rieger and co-workers found that a slightly modified complex, [(salen)CrCl] (**11**), and DMAP cocatalyst rapidly copolymerize PO and CO_2 (TOFs approaching 226 h^{-1}; see Table 2) at 75°C and 35 atm CO_2.[90] Analysis of the PPC revealed molecular weights up to 16700 $g\,mol^{-1}$ (lower than predicted assuming the lack of chain transfer reactions), PDIs as low as 1.38, and carbonate linkages as high as 98%. The DMAP/**11** ratio drastically affected the product distribution in the coupling process. Without DMAP, no conversion to PC or PPC was observed. At 0.5 equivalents DMAP, the maximum ratio of PPC to PC formation (154:34) was observed. Higher DMAP/**11** ratios decreased the proportion of PPC to PC until only PC was observed. For example, when 2 equivalents of DMAP were added, only PC was observed

with a TOF of 602 h^{-1}. Interestingly, cocatalyst was not essential for copolymerization using **10**.[87]

The proposed CO_2–epoxide coupling mechanisms using seemingly similar catalysts **9a**/DMAP, **10**/MeIm, and **11**/DMAP differ considerably. At the current time, there is a lack of agreement regarding the mode of operation of these catalysts. Jacobsen proposed a bimetallic mechanism for the asymmetric ring-opening of epoxides based on the observation that bimetallic catalysts enhanced rates and enantiomeric excesses.[84] Nguyen suggested a bimetallic mechanism for the formation of cyclic species.[86] The *trans* coordination of DMAP to **9a** is proposed to activate CO_2 to give a [(salen)Cr{C(C=O)O$^-$}] species. This intermediate is then proposed to attack PO bound to another salen–chromium complex in a cooperative bimetallic ring-opening process, followed by elimination of the cyclic product.

Darensbourg and co-workers offered a dual CHO–CO_2 copolymerization mechanism for the **10**/MeIm system. Here, initiation occurs by a bimetallic process and propagation operates by monometallic enchainment of epoxide.[87,89] Initiation is accelerated by MeIm, which facilitates chloro-ligand attack on a CHO monomer bound to a second salen–chromium complex (Scheme 7). Subsequent CO_2 insertion
Scheme 7. Proposed CO_2–CHO copolymerization mechanism using **10**/MeIm (P = polymer chain).

into the newly-generated chromium alkoxide generates a chromium carbonate. Because rate studies showed a first-order dependence on both CHO and catalyst, chain propagation was proposed to occur by a concerted epoxide ring-opening that proceeds through a four-membered transition state.

Alternatively, in PO–CO_2 copolymerization using **11**/DMAP, Rieger and co-workers proposed that DMAP coordinates strongly to Cr and facilitates dissociation of the polymer-chain alcoholate and carbonate (Scheme 8).[90]
Scheme 8. Proposed PO–CO₂ copolymerization mechanism for **11**/DMAP catalyst system.

Under sufficient pressures of CO_2, the dissociated carbonate attacks PO-bound **11**/DMAP in a monometallic fashion. Subsequent CO_2 insertion into the newly-formed chromium alkoxide propagates the polycarbonate chain. The anionic nature of the chain-end promotes the degradative backbiting to cyclic propylene carbonate. Therefore, increased stoichiometric amounts of DMAP enhance formation of cyclic product and eventually exterminate copolymer formation.

Owing to similar catalysts and coupling processes, it is unlikely that all of the epoxide ring-opening steps discussed above are occurring simultaneously. Furthermore, no mechanism has accounted for the retention of configuration as reported by Kruper, or the low polymer molecular weights that are indicative of chain transfer or the formation of macrocycles. Studies generally agree that CO_2 reacts with a metal alkoxide and cyclic products are formed by backbiting of a metal alkoxide into an adjacent carbonate linkage. Indeed, detailed mechanistic studies must be performed to delineate the various intermediates and epoxide ring-opening steps involved in these highly active salen–chromium catalysts.

5. Cobalt Catalysts

In 1979, Co(OAc)₂ was reported to copolymerize PO and CO_2 with an extremely low TOF (0.06 h⁻¹).[91] Since this report, few examples of cobalt-catalyzed coupling of epoxides and CO_2 have been found. He and co-workers reported the synthesis of ethylene carbonate using **2c**/cocatalyst mixtures.[73,74] Shi et al. reported that related salen-cobalt com-

plexes such as **12** (Figure 5) can be activated with Lewis-basic amines for the synthesis of propylene carbonate (see Section 7.3).[92] Recently, our group published that salen–cobalt complexes **13a–c** (Figure 5) exhibited moderate activities (up to 81 h⁻¹ with **13a**) for the copolymerization of PO and CO_2.[93] At 25 °C and 55 atm CO_2, **13a** catalyzed the copolymerization to yield PPC with no observable cyclic by-products, 95 % carbonate linkages, a M_n of 15 300 g mol⁻¹, and a M_w/M_n of 1.22. Pressures of 55 atm were essential for polymerization activity as lower pressures (40 atm) significantly hindered the copolymerization. In contrast to copolymerizations using the related salen–chromium catalysts, no heterocyclic additives were necessary. In addition, **13a–c** all showed unprecedented selectivities for PPC formation (>99 % PPC versus PC). (S)-PO–CO_2 copolymerization using enantiomerically-pure **13c** yielded isotactic (S)-PPC (TOF = 71 h⁻¹, >99 % PPC, 99 % carbonate linkages, $M_n = 6900$ g mol⁻¹, $M_w/M_n = 1.58$) with the highest reported level of head-to-tail linkages (93 %). Finally, **13c** exhibited a modest level of selectivity ($k_{rel} = 2.8$) in the kinetic resolution of PO. More recently, a catalyst system comprised of [(tpp)CoCl]/DMAP has been used for the synthesis of a range of dioxolanones from epoxides and CO_2,[94] and **13c**/(nBu)₄NX has been used to resolve racemic propylene oxide by forming PPC with k_{rel} values ranging from 1.1 to 9.0.[95]

6. Lanthanide-Based Catalysts

Yttrium, aluminum, rare-earth metals, and combinations of multiple metal reagents have shown activity for the copolymerization of epoxides and CO_2. For example, PO–CO_2 copolymerization was effected by a rare-earth metal system comprised of yttrium tris[bis(2-ethylhexyl)phosphate], Al*i*Bu₃, and glycerol. The PPC produced contained only 10–30 % carbonate linkages, although molecular weights of up to 476 000 g mol⁻¹ were achieved.[96] This system also exhibited activity for the alternating copolymerization of CO_2 with epichlorohydrin[97] and glycidyl ether monomers.[98] Other rare-earth metal systems consisted of yttrium carboxylates [Y(CO₂CF₃)₃ or Y(CO₂RC₆H₄)₃ where R is H, OH, Me, or NO₂], ZnEt₂, and glycerine.[99–101] The alternating copolymerization of CO_2 and PO yielded PPC with up to 98.5 % carbonate linkages, turnover frequencies up to 2.5 h⁻¹, and molecular weights reaching 100 000 g mol⁻¹. CHO–CO_2 copolymerization produced PCHC with 100 % carbonate linkages, molecular weights of 19 000–330 000 g mol⁻¹, and M_w/M_n's of 3.5–12.5. It must be noted that control experiments indicated that ZnEt₂, but not Y(CO₂CF₃)₃, was essential for polymerization. Finally, ternary catalysts composed of Nd(CO₂CCl₃)₃, ZnEt₂, and glycerol were also reported to copolymerize PO and CO_2.[102]

7. Zinc and Cadmium Catalysts

A variety of metal-based catalysts has shown activity for the coupling of epoxides and CO_2; however, few have exhibited the success associated with zinc-based complexes. Therefore, the majority of the work reported in this field has been performed using complexes with zinc as the active metal center. These catalysts have undergone a renaissance over the past ten years, shifting focus from heterogeneous mixtures to discrete and single-site catalysts which exhibit unprecedented reaction rates and selectivities.

7.1. Heterogeneous Zinc Catalysts

As described in Section 2, the first active species for the alternating copolymerization of epoxides and CO_2 were based on mixtures of: 1) $ZnEt_2$ with an assortment of di- and trihydric sources and 2) carboxylic acids and $Zn(OH)_2$. Subsequent to these groundbreaking discoveries, several companies pursued the commercialization of PPC using these and related catalysts.[103–106] In 1999, Ree et al. reported a variant of the $Zn(OH)_2$/glutaric acid (zinc glutarate) system[53] using ZnO as the zinc source. An optimal activity of 3.4 TO h^{-1} was achieved for PO–CO_2 copolymerization at 60 °C and 25 atm CO_2, which at the time was the highest activity reported for zinc carboxylates (Table 1). Analysis of the PPC revealed a M_n of 210 000 g mol^{-1}, a PDI of 1.3, and a T_g of 38 °C.[107–109] In addition, PO–CO_2 copolymerizations using zinc glutarate have been run in scCO$_2$, a suitable replacement for organic solvents.[110] More recently, polycrystalline[111] and single-crystal[112] zinc glutarate have been studied using X-ray diffraction, which could play an important role in determining the mechanism of this catalyst. Ethylsulfinate capped zinc glutarates have also been reported.[113] They have the potential to reduce the complexity inherent in these systems. Furthermore, terpolymerizations of CO_2, PO, and ε-caprolactone have been performed using zinc glutarate catalysts.[114] PPC has also been synthesized using zinc glutarate produced by an ultrasonic method, giving TOFs up to 7.7 h^{-1}.[29,111] Finally, carboxy-containing polymers, such as styrene and acrylic acid copolymers,[115] and γ-alumina[116] have been used as supports in zinc-catalyzed copolymerization of PO and CO_2.

A soluble counterpart to these systems was reported by Beckman et al., who observed that zinc oxide and a highly fluorinated carboxylic acid derived from a monoester of maleic acid[105] (**14a**; Figure 6) is active for the alternating copolymerization of CHO with supercritical CO_2.[117] The fluorination increased solubility of the catalyst mixture and
facilitated PCHC formation with 8.8 TO h^{-1} at 135 atm CO_2 and 100 °C (Table 2). Additionally, **14b** (Figure 6), a soluble Zn^{II}-based compound, produced PCHC ($M_n = 2150$, $M_w/M_n = 4.4$) with a TOF of only 1.2 h^{-1} at 90 °C and 110 atm CO_2.[77] In 1999, Darensbourg and Zimmer reported that zinc crotonate is a soluble catalyst precursor for this system.[118] This catalyst afforded TOFs of approximately 16 h^{-1} at 80 °C and 55 atm CO_2, yielding PCHC with 84 % carbonate linkages. A promising set of heterometallic catalysts are the double metal cyanide (DMC) catalysts originally reported by Kruper and Smart.[119] Heterogeneous compounds of the form $M_a^1(M^2(CN)_x)_b$ (*a* and *b*: 1, 2, 3; *x*: 4, 5, 6) were active for epoxide–CO_2 copolymerization. DMC catalysts such as zinc hexacyanoferrate(III) converted epoxides, including EO, PO, 1-butene oxide and CHO, to polycarbonates (50–95 % carbonate linkages and PDIs of 2–6) with TOFs of approximately 4 h^{-1}. Chen later reported similar DMC catalysts that exhibited better activities for PO–CO_2 copolymerization.[120] $(PEO)_a Zn(Fe(CN)_6)_b Cl_{2-3b}(H_2O)_c(KCl)_d$ (PEO = polyethylene oxide, *a* (mole ratio chelating atoms/Zn) = 2.2, *b* = 0.50, *c* = 0.76, *d* = 0.20) copolymerized PO and CO_2 at 60 °C and 50 atm CO_2 to give PPC ($M_n = 20 000$ g mol^{-1}) with 9.0 TO per mol zinc per h. To shed light on the origin of activity in DMC catalysts, Darensbourg et al. designed the related homogeneous complex **15**, which was prepared by the reaction of $[\{KCpFe(CN)_2 PPh_2(CH_2)_{1.5}\}_2]$ (Cp = cyclopentadienyl) with ZnI_2 (Figure 7).[121,122] Surprisingly, the coupling of CHO

15
Figure 7. Soluble double metal cyanide complex.

and CO_2 gave predominantly cyclic *cis*-cyclohexene carbonate, a small percentage of low molecular weight polycarbonate was also isolated. Unfortunately, the intrinsic complexity of heterometallic catalysts hampers mechanistic studies, and currently the active species are unknown. Despite these difficulties, the ease of synthesis and inexpensive nature of these materials makes them highly attractive.

7.2. Zinc and Cadmium Phenoxides for Epoxide–CO_2 Coupling

Heterogeneous systems are often marred by poor reproducibility and the production of non-uniform polymers, caused by the presence of many different types of active sites that produce polymer with different activities and selectivities. To address these issues, Darensbourg and Holtcamp reported in 1995 the first discrete zinc complexes

Figure 6. Zinc catalysts for the alternating copolymerization of CHO and CO_2.

for the alternating copolymerization of epoxides and CO_2 (Figure 8).[123] This discovery marks an important step in the development of catalysts for the copolymerization of CO_2 and epoxides. Compound **16a**, which was synthesized from 2,6-diphenylphenol and $Zn[N(SiMe_3)_2]_2$, crystallized as a bis((2,6-

Figure 8. Zinc–bis(phenoxide) compounds for the alternating copolymerization of CHO and CO_2.

diphenyl)phenoxy)zinc complex containing two diethyl ether solvent molecules coordinated to a tetrahedral zinc center. Under 55 atm CO_2 and at 80°C, PCHC (91% carbonate linkages, $M_n = 38\,000$ g mol⁻¹, $M_w/M_n = 4.5$) was produced with a TOF of 2.4 h⁻¹. Additionally, **16a** catalyzed the random terpolymerization of CHO, PO, and CO_2, yielding polycarbonate with approximately 20% propylene carbonate linkages, 70% cyclohexene carbonate linkages, and 10% ether linkages. Approximately the same ratios of PO and CHO incorporation were observed regardless of feedstock composition.

Subsequent work investigated steric influences of N-aryl substituents, including 2,4,6-tri-*tert*-butyl (**16b**), 2,6-di-*tert*-butyl (**16c**), and 2,4,6-trimethyl (**16d**), on CHO–CO_2 copolymerization (see Figure 8).[124] Complex **16d** displayed the highest activities (TOF = 9.6 h⁻¹), thus illustrating that bulky *ortho* substituents were not essential for high copolymerization rates. In the case of **16b**, only 50% carbonate linkages were observed in the resultant PCHC. In line with this result, the zinc phenoxides were also efficient catalysts for the homopolymerization of CHO. Electronic perturbations of the N-aryl *ortho* substituents revealed that electron-withdrawing groups resulted in higher activities for CHO–CO_2 copolymerization: F > Cl > Br.[125] Addition of 2,6-dihalophenols to $Zn[N(SiMe_3)_2]_2$ gave four-coordinate, dimeric zinc phenoxides with coordinated THF solvent molecules. Compound **17a** showed a moderate TOF of 7.6 h⁻¹. Analysis of the PCHC revealed PDIs of 6.0, molecular weights of 42 000 g mol⁻¹, a T_g

of 115°C, and >99% carbonate linkages.[31,125] In general, zinc-bis(phenoxide) compounds catalyzed PO–CO_2 copolymerization at 40°C and PO–CO_2 cyclization at 80°C in unspecified yields. Finally, zinc–bis(phenoxide) catalysts were active for CHO homopolymerization, CHO–CO_2 copolymerization, and CHO–PO–CO_2 terpolymerization, but did not readily react with bulky alicyclic epoxides such as α-pinene and *exo*-2,3-epoxynorbornane. Although no copolymerization activity was observed, X-ray analysis of **18** showed two molecules of *exo*-2,3-epoxynorbornane coordinated to zinc,[126] providing a potential model compound for epoxide-bound intermediates in the polymerization.

Darensbourg et al. proposed that two coordination sites were required for polyether formation, while only one was necessary for copolymer formation.[125,127] To probe this theory, phosphane (PCy₃, PMe₃, etc.) adducts of the zinc phenoxides were synthesized; these have only one open coordination site.[127] Compounds **19a** and **b** (Figure 8) were found to be three-coordinate zinc compounds with a distorted trigonal planar geometry around zinc. While **16b** generated PCHC with only 50% carbonate linkages, **19b** facilitated the formation of PCHC with 100% carbonate linkages, without loss of catalytic activity. Furthermore, **17a**, which possesses only one open coordination site, produced PCHC with essentially 100% carbonate linkages whereas **17b** (the PCy₃ adduct of **17a**) was not active for the copolymerization of CHO and CO_2.

In a related study, Dinger and Scott reported that zinc–phenoxide cluster compounds showed activity for the alternating copolymerization of CHO and CO_2.[128] A variety of solvent-dependent tri-, tetra-, penta-, and hexanuclear compounds were synthesized from tris(3,5-dialkyl-2-hydroxyphenyl)methane derivatives and $ZnEt_2$. For example, compound **20** (Figure 9) catalyzed the copolymerization of CHO and CO_2 to give PCHC with 81% carbonate linkages and a TOF of 1.3 h⁻¹.

L = (tetrahydrofuran)

20
Figure 9. Trinuclear zinc–alkyl catalyst for CHO–CO_2 copolymerization.

Cadmium complexes have not shown significant activities for the coupling of epoxides and CO_2. Nevertheless, cadmium compounds can exhibit organometallic reactivity similar to their zinc analogs and therefore serve as good structural models (Figure 10). Perhaps the most intriguing insight derived from these models came from Darensbourg's discovery of tris(pyrazolylhydroborate)cadmium acetate complexes [(tp)CdOAc] (**21a–c**).[129,130] Complexes **21a** and **b** contain bound PO and CHO and were proposed as possible models for initiation in epoxide–CO_2 polymerization. and co-workers have also synthesized bis(phenoxy) cadmium derivatives as model reagents.[125,126,131–133] Compounds **22a–c** exhibited a distorted tetrahedral geometry around cadmium and illustrated the coordination of epoxides such as CHO and *exo*-2,3-epoxynorbornane. In the absence of coordinating solvents, dimeric three-coordinate cadmium phenoxides were synthesized (**23a,b**). Addition of coordinating solvents, such as THF, regenerated monomeric cadmium phenoxides. Finally, bis(phenoxy) cadmium and [(tp)CdOAc] complexes were not active for epoxide–CO_2 copolymerization; however, they did catalytically convert PO and CO_2 to PC at an unspecified rate.

Although the discrete catalysts above represent an important advance in catalyst design, the active species for the copolymerization remain unclear. Regarding these phenoxide–zinc complexes, one or more ligands are likely to act as polymerization initiators, and thus become the chain-end of the growing polymer chain.

7.3. Discrete Zinc Complexes for Epoxide–CO_2 Copolymerization

Given the success of zinc phenoxide compounds for copolymerization of CHO and CO_2, Darensbourg and co-workers investigated zinc benzoate (**24** and **25**),[134] bis(salicylaldiminato)zinc (**26a–d**),[135] and (dialkylamino)ethyltetramethylcyclopentadienyl (dec) zinc derivatives (**27**)[136] (Figure 11). Zinc benzoate aggregates including compound **24** were synthesized by reaction of $Zn[N(SiMe_3)_2]_2$ with 2,6-disubstituted benzoic acids.[134] Dimeric **24** was converted with pyridine to generate a monomeric complex with three coordinated pyridines (**25**). **24** displayed moderate CHO–CO_2 copolymerization activities (TOF = 7.7 h^{-1}) comparable to those observed with zinc phenoxide compounds. Addi-

tionally, under 55 atm CO_2 at 80 °C, PCHC was generated with essentially 100% carbonate linkages. A number of bis(salicylaldiminato)–zinc complexes (**26a–d**) were synthesized by reaction of $Zn[N(SiMe_3)_2]_2$ with 2 equivalents salicylaldimines.[135] Complex **26a** was the most active catalyst copolymerizing CHO and CO_2 to give PCHC (>99% carbonate linkages, $M_n = 41\,000$ g mol^{-1}, $M_w/M_n = 10.3$) with a TOF of 6.9 h^{-1}. Related zinc–bis(trimethylsilylamido) and zinc–phenoxide complexes have been reported by Chisholm et al.; however, no copolymerization activity was observed.[137] The single-site catalyst [(dec)ZnOAc] (**27**) was synthesized by deprotonation of the dec ligands followed by reaction with $Zn(OAc)_2$.[136] X-ray analysis of **27** revealed a dimeric compound featuring bridging acetates and η^1-coordination of the cyclopentadienyl moiety to zinc. At 30 °C and 40 atm CO_2, **27** exhibited low activity (1.2 TO h^{-1}), and the resultant PCHC possessed 15–20% ether linkages.

Recently, Hampel et al. reported that quinoxaline-derived zinc alkoxide complexes, **28** and **29**, exhibited low activities for CHO–CO_2 copolymerization (Figure 12).[138] At 80 °C and 80 atm CO_2, compounds **28** and **29** showed TOFs of 4.9 and 3.6 h^{-1}, respectively. The PCHC yielded from **28** possessed 97% carbonate linkages, a M_n of 13 500 g mol^{-1}, and a PDI of 4.59.

Binaphthyldiamino (binap) salen-type metal complexes (**12**, **30a,b**) in combination with Lewis basic cocatalysts, including NEt$_3$, DMAP, and pyridine, were reported by Shi and co-workers for the cyclization of terminal epoxides and CO_2 (Scheme 9).[92] At 35 atm CO_2 and 100 °C, **30a**/NEt$_3$ (2 equiv) converts PO to PC with approximately 57 TO h^{-1}.

Figure 12. Quinoxaline-derived zinc phenoxides for CHO–CO₂ copolymerization.

7.4. Pyridine–Zinc Halide Complexes for Epoxide–CO₂ Coupling

Despite extensive research on catalysts for cyclic carbonate synthesis, there are limited reports on catalyst intermediates or reaction mechanisms. Notably, Kim and co-workers addressed both of these issues using pyridinium alkoxy zinc dibromides.[139,140] [(Pyridine)₂ZnBr₂] (**31a**) was found to couple PO and CO₂ to PC with a TOF of 308 h⁻¹ at 100 °C and 35 atm CO₂. [(2-R-pyridine)₂ZnBr₂] (**31a** R = H, **31b** R = Me) reacted with excess PO to provide dimeric pyridinium alkoxy zinc dibromides (**32a** R = H, **32b** R = Me; Scheme 10). Complex **32a** crystallized as a dimeric compound containing a distorted tetrahedral geometry around both zinc centers. Interestingly, PO ring-opening occurred exclusively at the least hindered carbon and only the *meso* dimer crystallized. At 100 °C and 35 atm CO₂, **32a** converted PO and CO₂ to PC with a TOF of 340 h⁻¹, indicating the presence of a slight initiation time as **31a** reacts to form **32a**. A series of [(2-R-pyridine)₂ZnBr₂] (**31a–c**) with varying electronic properties were examined for activity. Electron-donating substituents promoted activity, while electron-withdrawing groups extinguished reactivity (Me > H ≫ Cl), signifying the necessity for Lewis basic pyridine ligands. At 100 °C and 35 atm CO₂, **32b** exhibited an activity for PO–CO₂ cyclization of 530 TO h⁻¹.

In addition to PO–CO₂ cyclization, **32a** and **32b** were active for cyclic ethylene carbonate (EC) production with TOFs of 1200 h⁻¹ and 1450 h⁻¹, respectively. Surprisingly, the reaction of EO with **31a** and **b** resulted in trimeric compounds (**33a** and **b**) containing an alternating zinc and oxygen six-membered ring at the core of the molecule (Scheme 10). Apparently, the sterics of the epoxide determine whether dimeric or trimeric intermediates are formed. Complex **33a** demonstrated activities almost identical to those of **32a** for both PC (327 TO h⁻¹) and EC (1180 h⁻¹), suggesting the same catalytic species. Kim proposed that the dimeric form was the active species for epoxide–CO₂ coupling (Scheme 11). Insertion of CO₂ in **32a** gave zinc

Scheme 9. Proposed catalytic cycle for the cyclization of terminal epoxides and CO₂ using chiral binap salen-type metal catalysts.

Copper complex **30b** and NEt₃ also catalyze the formation of PC with a TOF of 32 h⁻¹. Moreover, catalysts **30a,b** were discovered to transform a variety of terminal epoxides, such as butylene oxide, SO, and epichlorohydrin, to their corresponding cyclic carbonates. Isotope-labeling experiments using *trans*-deuterioethylene oxide derivatives indicated that epoxide ring-opening occurred by nucleophilic attack of a Lewis base (e.g., NEt₃) followed by CO₂ insertion (Scheme 9). Subsequent ring closure produced the *trans*-cyclic carbonate with overall retention of configuration. Although **30a,b** are chiral catalysts, virtually no asymmetric induction was observed.

7.5. Single-Site β-Diiminate Zinc Catalysts for Epoxide–CO₂ Coupling

Our research group discovered a highly active, living epoxide–CO₂ copolymerization system using bulky β-diiminate (bdi) zinc catalysts, such as **36–39**, under low pressures (7 atm CO₂) and temperatures (50 °C) (Figure 14).[143–153]

alkoxide carbonate dimer containing a six-membered ring, that subsequently eliminated PC. Species **32a** was regenerated upon reaction with PO.

Shortly thereafter, Darensbourg et al. illustrated that related pyridine–zinc halide adducts (Figure 13) were catalytically active for CHO–CO₂ copolymerization and cycliza-

Figure 13. Zinc–pyridine complexes for CHO–CO₂ copolymerization.

tion with TOFs as high as 13.5 h⁻¹.[141] 2,6-Dimethoxypyridine reacted with zinc halides to give [Zn(2,6-dimethoxypyridine)₄]²⁺[Zn₂X₆]²⁻ (**34a–c**) while 3-trifluoromethylpyridine reacted with ZnBr₂ to generate (3-CF₃-pyridine)₂ZnBr₂ (**31d**). The order of halide reactivity was Cl ≥ Br > I and the complex with 2,6-dimethoxypyridine was more active than that with 3-trifluoromethylpyridine. At 55 atm CO₂ and 80 °C, PCHC was produced with 80–91 % carbonate linkages, M_n up to 44 000 g mol⁻¹, and broad PDIs. In situ IR studies revealed a first-order dependence on catalyst concentration for polymerization, but an unusual fractional order of 1.5 for CHC formation. It was suggested that both dimeric and monomeric zinc active species accounted for the mixed order in zinc. Kim and co-workers recently reported that pyridine alkoxide ligated zinc acetates **35a–d** (Figure 13) catalyze the copolymerization of CHO and CO₂. Complex **35c** produces PCHC ($M_n = 9500$ g mol⁻¹, $M_w/M_n = 2.5$) with a TOF of 153 h⁻¹. The polycarbonate is unusual in that it has only 63 % carbonate linkages.[142]

Several key design features, including initiating groups, sterics, and electronics, drastically altered the efficacy of the catalysts. To model the growing polycarbonate chain, zinc–acetate (**36**), zinc–methoxide (**37a,b**), and zinc–isopropoxide (**37c,d**) complexes were synthesized as mimics for zinc carbonates and zinc alkoxides (Scheme 12). Zinc acetates were produced from the deprotonated (bdi)Li adducts and Zn(OAc)₂[143,146] or by addition of acetic acid to [(bdi)ZnEt] compounds.[150,151] (bdi)ZnEt was generated by addition of ZnEt₂ to (bdi)H ligands.[143] [(bdi)ZnOAc] compounds crystallized as dimeric compounds with bridging μ,η²-acetates. The reaction of [(bdi)ZnEt] with MeOH provided dimeric [(bdi)ZnOMe] compounds (**37a,b**; **39a,b**).[143,146] Deprotonation of (bdi)H using Zn[N(SiMe₃)₂]₂ gave monomeric, 3-coordinate [(bdi)Zn{N(SiMe₃)₂}] (**38a,b**).[146,154] Subsequent alcoholysis with *i*PrOH yielded [(bdi)Zn(O*i*Pr)] complexes (**37c,d**) that are dimeric in the solid state. (bdi)Zn acetate, methoxide, isopropoxide, and bis(trimethylsilyl)amido complexes were all active for the alternating copolymerization of CHO and CO₂.[143,145,146,149–151] In addition, [(bdi)Zn(O*i*Pr)] complexes were highly active for the living polymerization of lactide,[154,155] ε-caprolactone, and β-butyrolactone.[156] While X-ray crystallography revealed that [(bdi)ZnOAc], [(bdi)Zn(O*i*Pr)], and [(bdi)ZnOMe] compounds were dimeric,

Scheme 12. Synthesis of β-diiminate–zinc complexes.
Figure 15. Monomeric and dimeric [(bdi)ZnOR] complexes.

¹H NMR spectroscopy revealed that the solution states were highly dependent upon sterics.[143,146,151,154] For instance, it was demonstrated that compounds **36a** and **37c** exhibited a monomer⇌dimer equilibrium under appropriate temperatures and concentrations.[143,156] On the other hand, **36b**, **37b**, and **37d** were exclusively dimeric in solution, even at elevated temperatures.[146,156] Concurrently, subtle modifications on the N-aryl *ortho* positions highly influenced polymerization activity. Sterically unencumbered methyl substituents exhibited no polymerization activity, whereas sterically congested ethyl and isopropyl substituents promoted the copolymerization giving TOFs of 431 h⁻¹ and 360 h⁻¹, respectively (Table 2).[151] Furthermore, the unsymmetrical **36c** yielded PCHC (99% carbonate linkages, $M_n = 23300$ g mol⁻¹, $M_w/M_n = 1.15$) with a TOF of 729 h⁻¹. Electronics also played a dramatic role in activity, such that electron-withdrawing cyano substituents enhanced polymerization rates. Complex **36d** produced PCHC (90% carbonate linkages, $M_n = 17900$ g mol⁻¹, $M_w/M_n = 1.15$) with a TOF of 917 h⁻¹ in only 20 minutes. The combination of the unsymmetrical ligand geometries and the electron-withdrawing cyano substituent yielded the most active catalysts reported to date.[149] At 50°C and in only 10 minutes, **39a** and **39b** catalyzed the copolymerization of 1000 equivalents CHO and 7 atm CO₂ to give high molecular weight polymers ($M_n \approx 22000$ g mol⁻¹), narrow PDIs ($M_w/M_n = 1.09$–1.11), and extremely high TOFs of 2170 and 2290 h⁻¹, respectively (see Table 2).

In an attempt to isolate monomeric β-diiminate complexes, Chisholm et al. investigated bulky initiators including *t*BuOH and Ph₃SiOH.[157,158] As expected, monomeric compounds **40** and **41** (Figure 15) were active for CHO–CO₂ alternating copolymerization. Compound **41** also coupled PO and CO₂ to give propylene carbonate in unspecified yield. Unexpectedly, Chisholm's [(bdi)ZnNiPr₂], an analog of our compound **38a**, was not active for the copolymerization, although it readily reacted with CO₂ to generate **42**. Rieger et al. recently showed that an ethyl sulfinate is a viable initiator for the copolymerization.[159] Compound **43** (Figure 15), synthesized by bubbling SO₂ through a [(bdi)ZnEt] solution, was also active for CHO–CO₂ copolymerization. Catalytic activities were comparable to **36a**, indicating
similar active species. From bimodal gel permeation chromatography traces, monomeric and dimeric bdi–zinc species were believed to be active, although no mechanistic studies were conducted. Recently, oligomeric bdi ligands have been generated from 4,4′-methylenedianiline and 2,4-pentanedione. The zinc complexes have shown modest activity for CHO–CO₂ copolymerization (TOF = 11.3 h⁻¹).[160–162]

Yu and Jones recently reported that β-diiminate–zinc catalysts immobilized on silica exhibited moderate activities for CHO–CO₂ copolymerization.[163] Compounds **44**, **45a**, and **45b** (Figure 16) are precursors to the silica-immobilized
Figure 16. Precursors to silica-immobilized bdi–zinc catalysts.

complexes and show activities of 110, 60, and 65 h⁻¹, respectively, under 7 atm CO₂ at 50°C. The resultant polycarbonates exhibited >92% carbonate linkages, molecular weights of 8700–13300 g mol⁻¹, and PDIs of 1.03–1.28. Complexes **45a** and **45b** were supported on mesoporous SBA-15 and controlled-pore glass, but the rates of PCHC formation (TOFs = 5–21 h⁻¹) and percent carbonate linkages (33–78%) decreased. A corresponding drop in molecular weights was

not observed indicating fewer active zinc centers. Finally, based on the activity observed with the silica-supported zinc catalysts, Yu and Jones suggested that the copolymerization proceeded via a monometallic mechanism.[163] High-through-put equipment has been used to screen CHO–CO_2 copolymerization in the presence of β-diiminate–zinc catalysts, but so far this research has been limited to known compounds (**38a,b**).[164]

Morokuma and co-workers performed theoretical studies using the hybrid molecular orbital method ONIOM on the alternating copolymerization of epoxides and CO_2 catalyzed by monomeric **37a**.[165] The rate-determining step of the copolymerization was proposed to be epoxide insertion into a zinc–carbonate bond. Furthermore, in alicyclic epoxides such as CHO, the activation barrier for epoxide ring-opening by a zinc carbonate is drastically reduced due to ring, torsion, and angle strain. By contrast, the study predicted that aliphatic epoxides such as EO could not be copolymerized due to high activation barriers for epoxide ring-opening.

Subtle electronic and steric perturbations to [(bdi)ZnOR] (R = alkyl or acyl) complexes resulted in drastic enhancements in activity for CHO–CO_2 copolymerization.[146,149,151] During the course of these studies, catalysts for PO–CO_2 coupling were also discovered by our research group.[150] PO–CO_2 coupling proved to be highly sensitive on reaction conditions. Both temperature and pressure had a profound effect on product formation. At 50 °C and 20 atm CO_2, unsymmetrical **36e** yielded PC with a TOF of 50 h^{-1}. By simply reducing the temperature to 25 °C, PC formation was suppressed, and the selectivity for PPC/PC was 85:15 with a TOF of 47 h^{-1}. The polycarbonate exhibited > 99 % carbonate linkages, a T_g of 38 °C, a M_n of 43 300 g mol^{-1}, and a PDI of 1.09. Furthermore, ^{13}C NMR spectroscopy revealed a nearly regiorandom copolymer,[166,167] indicating that ring-opening occurred at both C–O bonds. Further modifications of the ligand architecture generated complex **46** (Scheme 13), the
Scheme 13. Unsymmetrical, electron-deficient bdi–zinc complex for the copolymerization of PO and CO_2.

most potent catalyst reported to date for PO–CO_2 copolymerization. Complex **46** copolymerized PO and CO_2 at 25 °C and 7 atm CO_2 to give PPC (> 99 % carbonate linkages, M_n = 36 700 g mol^{-1}, M_w/M_n = 1.13) with a TOF of 235 h^{-1} (Table 2). However, the selectivity for polymer was only 75 %. Increasing the CO_2 pressure to 35 atm favored polymer formation with a selectivity of 93 %, while only moderately attenuating catalytic activity (TOF = 138 h^{-1}). Finally, compound **46** is

highly active for PC formation at high temperatures. At 75 °C, PC is produced with TOFs over 1000 h^{-1}.[168]

Recently, our research group performed mechanistic studies on the [(bdi)ZnOR]-catalyzed copolymerization of CHO and CO_2.[151] Stoichiometric reactions of the copolymerization initiation steps showed that zinc alkoxides insert CO_2, while zinc acetates react with CHO. For example, **37c**, which is a monomeric zinc alkoxide at room temperature ([Zn] = 0.01 M in [D$_6$]benzene) instantaneously reacted with CO_2 to give **47** (Scheme 14). X-ray analysis revealed that **47**
Scheme 14. Insertion reaction of CO_2 with [(bdi)Zn(OiPr)].

crystallized as a μ,η^2-carbonate-bridged dimer. Complex **47** is virtually isostructural to **36a**, suggesting similar reactivity in the copolymerization. Complex **36d** inserted CHO to give **48** over the course of days (Scheme 15). X-ray analysis showed
Scheme 15. Insertion reaction of CHO with [(bdi)ZnOAc].

that **48** is a μ,η^2-acetate-μ,η^1-cyclohexyloxide acetate-bridged dimer in the solid state. Both **47** and **48** serve as model compounds for presumed intermediates in the copolymerization. Due to the expeditious reaction of CO_2 with **37c**, CHO insertion was predicted to be the rate-determining step. To monitor propagation, rate studies were performed on compounds **36a–c** using in situ FT-IR. The kinetic studies revealed a zeroth-order dependence in CO_2 and a first-order dependence in CHO. Hence, insertion of CHO into a zinc carbonate was indeed the rate-determining step. The copolymerization

of CHO (1.98 M in toluene) and 20 atm CO_2 at 50 °C using sterically-unhindered, dimeric **36b** resulted in an order of 1.02 ± 0.03 in [(bdi)ZnOR] concentration (R = alkyl, acyl, or polymer chain). However, under the same conditions, an order in [(bdi)ZnOR] concentration of 1.83 ± 0.04 was determined for **36c**. Therefore, the copolymerization of CHO and CO_2 using **36c** at 50 °C exhibited the following overall rate law: $d[P]/dt = k[\text{epoxide}]^{1.0}[\text{Zn}]^{1.83}$. At lower temperature (30 °C), a decrease in the order in [(bdi)ZnOR] concentration to 1.37 ± 0.02 was observed for **36c**. On the basis of [(bdi)ZnOR] solution studies (R = alkyl or acyl), stoichiometric insertion reactions, and rate studies, a bimetallic mechanism was proposed (Scheme 16a). Sterically
Scheme 16. a) Proposed copolymerization mechanism using bdi–zinc complexes; b) epoxide ring-opening transition state (P = polymer chain).

encumbered bdi–zinc complexes (**36a** and **36c**) ring-open CHO in a bimetallic transition state (Scheme 16b) with a predominantly monomeric ground state. Conversely, sterically unhindered bdi–zinc complexes (**36b**) insert CHO in a bimetallic transition state with a completely dimeric ground state.

7.6. Zinc Catalysts for Asymmetric CHO–CO₂ Copolymerization

There is significant interest in controlling the absolute stereochemistry of ring-opening in epoxide–CO_2 copolymerization for several reasons. First, microstructure directly affects polymer properties.[169] Second, the kinetic resolution of racemic epoxides or desymmetrization of *meso* epoxides by copolymerization is a potential route to valuable chiral

building blocks. CHO, a *meso* molecule, is an ideal substrate for desymmetrization using chiral catalysts.[170] In 1999, Nozaki et al. reported that a 1:1 mixture of ZnEt₂ and (S)-α,α-diphenylpyrrolidine-2-yl-methanol (**49**) was active for stereoselective CHO–CO_2 copolymerization at 40 °C and 30 atm CO_2 (Schemes 17 and 18).[171,172] The polycarbonate
Scheme 17. Asymmetric copolymerization of CHO and CO_2.
Scheme 18. Chiral zinc catalysts for the asymmetric, alternating copolymerization of CHO and CO_2.

exhibited 100% carbonate linkages, a M_n of 8400 g mol⁻¹, and a PDI of 2.2. Hydrolysis of PCHC with base produced the corresponding *trans*-cyclohexane-1,2-diol with 73% enantiomeric excess. ¹³C NMR spectroscopy studies of model polycarbonate oligomers afforded spectral assignments for isotactic dyads (153.7 ppm) and syndiotactic dyads (153.3–153.1 ppm).[173] Finally, ring-opening proceeded by complete inversion of configuration (S_N2 mechanism), hence no *cis*-cyclohexane-1,2-diol was observed.

In a recent report, Nozaki and co-workers isolated presumed intermediates in the asymmetric alternating copolymerization.[174] Reaction of ZnEt₂ and (S)-α,α-diphenylpyrrolidine-2-yl-methanol yielded dimeric **50**, which was structurally characterized by X-ray diffraction studies (Scheme 18). At 40 °C and 30 atm CO_2, **50** catalyzed the formation of isotactic PCHC ($M_n = 11\,800$ g mol⁻¹, $M_w/M_n = 15.7$, TOF = 0.6 h⁻¹) with a slightly lower enantiomeric excess of 49%. When the copolymerization was attempted with **50** and 0.2 to 1.0 equivalents of EtOH, enantioselectivities increased up to 80% *ee*, and better control of molecular weights and PDIs resulted. Compound **51** was proposed to be the active initiating species (see Scheme 18). End-group analysis by MALDI-TOF mass spectrometry revealed in the absence of EtOH signals assignable to the aminoalcohol-initiated polymerization. However, as EtOH addition was

increased from 0.2 to 1.0 equivalents, signals corresponding to the aminoalcohol-derived polycarbonate disappeared as peaks for the EtOH-initiated PCHC emerged. This was further confirmed by end-group analysis using ^{1}H NMR spectroscopy. Finally, mechanistic studies suggest that the dimeric form of the catalyst is in fact the active species.

In 2000, our research group developed C_1-symmetric imine-oxazoline ligated zinc bis(trimethylsilyl)amido compounds for the stereoselective, alternating copolymerization of CHO and CO_2 (Scheme 18).[145] Through multiple electronic and steric manipulations, compound **52** was found to exhibit the highest enantioselectivity (*RR*/*SS* ratio 86:14, 72% *ee*) in the copolymerization. The resultant PCHC exhibited 100% carbonate linkages, a M_n of 14700 g mol^{-1}, a PDI of 1.35, and a T_g and T_m of 120 and 220°C, respectively. Furthermore, stereocontrol was also achieved in the alternating copolymerization of CPO and CO_2, producing poly(cyclopentene carbonate) with a *RR*/*SS* ratio of 88:12 (76% *ee*). As revealed by ^{13}C NMR spectroscopy, the experimental carbonyl tetrad concentrations matched the predicted tetrad concentrations for an enantiomorphic-site control mechanism.[145] The contributions described above represent an important step forward in the production of well-defined, tactic polycarbonates.

8. Summary and Outlook

Over the last decade, significant advances have been achieved in CO_2–epoxide coupling chemistry. Homogeneous catalysts for CO_2–epoxide copolymerization offer significant increases in rate as well as selectivity versus their heterogeneous counterparts. Well-defined, homogeneous catalysts have given new momentum to the field of CO_2 utilization, and have made possible a much deeper mechanistic understanding of these systems. Current catalysts provide reasonable routes to a variety of polycarbonates from inexpensive epoxides, including poly(cyclohexene carbonate), poly(propylene carbonate), and terpolymers of CHO, PO, and CO_2. Moreover, living catalyst systems were found that provide block copolymers and polymers with molecular weights predetermined by monomer/initiator ratios. In addition, both polycarbonates and cyclic carbonates can be synthesized with high selectivities and rates, owing to subtle modification of the catalyst's architecture. Finally, precise control of cyclic carbonates and/or polycarbonate production is achieved by utilizing homogeneous catalysts with appropriate reaction conditions such as pressure, temperature, and cocatalyst additives.

Despite the recent breakthroughs, the future challenges are many. At the current time there are limited applications of epoxide–CO_2 copolymers due to their high cost and low thermal stability. Therefore it will be necessary to develop catalyst systems that are capable of producing these polymers economically. In addition, methods for producing polymers with increased thermal stability are needed. Surprisingly, only Cr, Co, and Zn compounds have shown significant activity for the copolymerization of CO_2 and epoxides. The unusual reactivity of these metals must be further exploited, and other metals such as Mg, Mn, Fe, and Ni should be explored.

Alternative comonomers, including lactones, isocyanates, aziridines, as well as new epoxides, such as limonene oxide and styrene oxide, could be promising reagents in the production of unique copolymers. By utilizing homogeneous living catalysts, there are infinite possibilities of new, exciting copolymer microstructures. Living systems allow for precise control of molecular weights, low PDIs, copolymer synthesis by sequential monomer addition, and the ability to functionalize chain ends. Because only one chain is produced by each metal center in homogeneous catalyst systems, the development of strategies related to Inoue's "immortal polymerization" may lead to more productive systems. Although the enantioselective copolymerization of CO_2 and epoxides has been accomplished, much higher levels of stereocontrol as well as regiocontrol are required for improved physical properties.

Undoubtedly, the future will witness continued research at this exciting interface of inorganic and polymer chemistry to the benefit of both fields. Homogeneous catalysts will lead to epoxide–CO_2 copolymers with unprecedented levels of architectural control, providing many new opportunities in polymer science.

Abbreviations

bdi	β-diiminate
CHC	cyclohexene carbonate

Communications
Contrary to what was previously believed, water molecules do not adsorb intact on the surfaces of zinc oxide, but dissociate by an autocatalytic process and form a complex superstructure consisting of intact water molecules and hydroxy species. For more details, see the Communication by B. Meyer, C. Wöll et al. on the following pages.

Communications

Partial Dissociation of Water Leads to Stable Superstructures on the Surface of Zinc Oxide**

Bernd Meyer, Dominik Marx, Olga Dulub,
Ulrike Diebold, Martin Kunat, Deler Langenberg, and
Christof Wöll**

Understanding wet surfaces and water/solid interfaces is of crucial importance in such diverse fields as corrosion, catalysis, mineralogy, and geology. For H_2O, the delicate interplay between chemical bonding, van der Waals forces, and hydrogen bonding gives rise to complex phenomena such as complete dissociation, partial dissociation at defects, multilayer formation, and wetting.[1] Recently, an intriguing intermediate scenario was advanced, in which the interaction between the water molecules results in a partial dissociation of water on perfect surfaces, leading to superlattices with long-range order.[2–5] In view of possible failures of common theoretical approaches and severe experimental difficulties[5] this proposal has become the subject of a highly controversial debate.[5–9] For a given surface a consistent picture can only be obtained by using a broad array of experimental and computational tools in concert. Applying such a strategy, we unambiguously demonstrate that water forms a simple, unusually stable two-dimensional superstructure on defect-free zinc oxide surfaces. Diffraction (He-atom scattering (HAS), low-energy electron diffraction (LEED)), real-space (scanning tunneling microscopy (STM)), and thermodynamic (He thermal desorption spectroscopy (He-TDS)) data show that water forms a (2×1) superstructure with long-range order that exists up to temperatures close to the boiling point of water. Car–Parrinello ab initio simulations[10] reveal a superlattice in which every second water molecule is dissociated. The unusual thermal stability of this superstructure is a result of a favorable "key–lock" type structural arrangement in conjunction with hydrogen bonding. The computed structure and binding energy are in excellent agreement with those found in the experiment.

Zinc oxide is a material for which significant progress in understanding its surface properties was achieved recently,[11–17] stimulated by its importance for a number of applications ranging from cosmetics and medicine to paints and heterogeneous catalysis. The nonpolar ZnO $(10\bar{1}0)$ surface chosen for the present study is, in contrast to its polar counterparts,[13,16] electrostatically stable and as such now well understood.[12] Briefly, this Wurtzite-type surface consists of layers containing slightly tilted ZnO "dimers", which are formed by three-fold coordinated Zn and O ions. These ZnO dimers, in turn, assemble to form characteristic rows separated by trenches (Figure 1). For the adsorption of
Figure 1. Side and top view of the atomic structure of the molecular adsorbed water monolayer with (1×1) symmetry (left) and the optimized half-dissociated $H_2O/ZnO(10\bar{1}0)$ adsorption geometry (right). The surface unit cells are shown by dashed lines. Zn, O, and H atoms are represented by grey, red, and white spheres, respectively, the O atoms of the water molecules are in blue. In the top views, the atoms in the second surface layer are indicated by lighter colors.

water on this surface one would expect that the oxygen atoms of the water molecules bind to the coordinatively unsaturated Zn ions on the surface. In a previous photoelectron spectroscopy study[18] it was indeed concluded that H_2O chemisorbs at the Zn sites of the ZnO$(10\bar{1}0)$ surface. Since the distance between the Zn sites is fairly large (3.25 Å versus 2.78 Å between H_2O molecules in ice I_h), one would predict the formation of a simple water (1×1) monolayer.

In contrast to this prediction, we find that water on such a ZnO surface forms an ordered superstructure with a (2×1) periodicity. The He atom angular distributions (Figure 2) as well as LEED data clearly show sharp and well-defined half-order diffraction peaks. Also high-resolution STM measurements revealed a (2×1) periodicity of the adlayer. These findings effectively rule out that water is adsorbed on the ZnO$(10\bar{1}0)$ surface as a full monolayer of equivalent H_2O molecules as assumed previously. A (2×1) structure would come about if water would only occupy every other Zn site, with a total coverage of half a monolayer. If the water molecules were separated by two lattice constants, no hydro-

Figure 2. He-atom specular reflectivity of a ZnO(10$\bar{1}$0) surface saturated with water at a temperature of 280 K (solid line) recorded for a heating rate of 1 K s^{-1}. The dashed line shows the corresponding derivative, revealing a desorption maximum at 367 K. Inset: He-atom diffraction patterns for the clean (top) and water-saturated (bottom) ZnO(10$\bar{1}$0) surface recorded along the [01$\bar{1}$0] azimuth. The (2×1) periodicity of the water adlayer is clearly revealed by the prominent half-order diffraction peaks.

gen bonds between the water molecules would be present. However, the STM measurements show that for low water coverages the adsorbates form ordered two-dimensional islands (Figure 3), which implies a strong lateral attraction between adsorbed species. In addition, a quantitative determination of the H$_2$O coverage using X-ray photoelectron spectroscopy (XPS) shows that, at full coverage, the surface
Figure 3. Left: STM image of a ZnO(10$\bar{1}$0) surface after dosing 1 Langmuir of water at room temperature (tunneling conditions: +1.6 V sample bias and 4.7 nA tunneling current). The water molecules form well-ordered two-dimensional islands with a (2×1) periodicity (bright spots) on the ZnO substrate (faint rows). The solid line shows the position where the line profile was taken. Right: Simulated STM images for the (hypothetical) molecular water monolayer with (1×1) symmetry (top) and the half-dissociated H$_2$O/ZnO(10$\bar{1}$0) structure (bottom). The height of the tip above the surface increases from blue through green to red. Bands in the energy range of 1 eV above the band gap are taken into account, mimicking positive sample bias and tunneling into the conduction band.

contains one H$_2$O molecule per surface Zn ion (see Experimental Section), so that a (2×1) structure caused by only every second Zn site being occupied can be ruled out.

Important additional information about the adsorption of water can be gained from the binding energy of the molecules on the surface. The reliable determination of this quantity on metal oxide surfaces is, however, generally hampered by the presence of defects. In fact, most controversies on the question whether water adsorbs in a molecular form or dissociatively on a perfect surface stem from the problem that water may dissociate at defect sites, in particular at oxygen vacancies, which contributes to the overall signal.[1] To rule out contributions of defects, a technique tailored to studying adsorbates on well-defined solid substrates was employed, namely the scattering of thermal energy He atoms. When monitoring the reflectivity of the ZnO(10$\bar{1}$0) surface for thermal energy He atoms as a function of surface temperature (He-TDS) the desorption from perfect areas can be studied exclusively, allowing a precise determination of the adsorbate binding energies.[13] He-TDS has been used previously to detect the desorption of water from oxide surfaces such as MgO[19,20] or of CO and H$_2$ from ZnO surfaces.[13,21] The He-TDS data (Figure 2) reveal a sharp, well-defined desorption maximum close to the boiling point of water at a temperature of 367 K. This corresponds to a binding energy of 1.02 eV, in excellent agreement with a value reported previously.[18] This desorption temperature is astonishingly high. In general, such high desorption temperatures were only observed for a few other metal oxide surfaces for which it is known that water dissociates upon adsorption, for example, the Cr$_2$O$_3$ (0001)[22] and the (2×1) α-Fe$_2$O$_3$(01$\bar{1}$2) surface.[23] It therefore appears to be likely that also on this ZnO surface H$_2$O dissociates, hydroxylating a substrate O atom and adding an OH species on top of a Zn–substrate atom. Such a dissociation may in fact lead to a (2×1) structure. Interestingly, we observed the formation of the (2×1) phase already at temperatures as low as 200 K, a fact which would imply a very low activation energy for dissociation.

The precise value for the binding energy of H$_2$O adsorbed on defect-free regions of the ZnO(10$\bar{1}$0) surface (the coherence length in the He-TDS measurement was of the order of 150 Å) opens the pathway for a *direct* comparison to and validation of theoretical calculations, which then in turn will provide the basis to rationalize the different experimental findings. To this end density functional theory (DFT) calculations were carried out within a periodic slab setup using six to eight ZnO layers. Special care was taken to electrostatically decouple the slabs to suppress artificial interactions.[24] However, applying DFT to subtle molecule/surface interactions is often questionable in view of possible deficiencies for describing hydrogen bonding and van der Waals interactions. Thus, the gradient-corrected Perdew, Burke, and Ernzerhof (PBE) functional used here in conjunction with ultrasoft pseudopotentials and a 25 Rydberg plane wave cutoff (see ref. [12] for further details) was thoroughly tested for the system of interest. It is well known that the PBE functional describes very accurately the equilibrium structure and binding energy of water in isolated dimers and ice I_h.[4,26] However, to probe the reliability of PBE

for water separations and orientations that are relevant here, we have calculated the binding energy of nearest and next-nearest water pairs as they appear in the undissociated (1×1) water monolayer on the $ZnO(10\bar{1}0)$ surface (see below). For these pairs with O−O separations of 3.25 and 5.21 Å, dimer binding energies of 0.085 and 0.011 eV, respectively, were found. This is in astonishing agreement with the results of 0.085 and 0.016 eV of very accurate coupled cluster-type (MC-CEPA[25]) calculations. A similar accuracy was also previously demonstrated to hold for weakly bound molecules and adatoms on small ZnO clusters.[13,14,27] Finally, the structure of bulk ZnO including its low-index surfaces has been calculated reliably within the described DFT/PBE setup.[12] Based on all these gauges, it can be concluded that the PBE functional should capture the relevant interactions.

The adsorption properties of water on the $ZnO(10\bar{1}0)$ surface was studied for various coverages starting from a full monolayer and reducing to 1/2, 1/4, and 1/6 of a monolayer. In a first set of calculations, (1×1), (2×1), (2×2), and (3×2) surface unit cells containing one water molecule were used. This implies that the water molecules are kept equivalent by imposing translational symmetry. Under this constraint, only molecular adsorption of water is found for all coverages with a very similar orientation of the molecules (Figure 1). Dissociative adsorption, which may have been expected from the experimentally observed high desorption temperature, is not stable within this constraint. At a coverage of $^1/_4$ and $^1/_6$ monolayer the H_2O molecules basically do not interact, and the binding energy is 0.94 eV per molecule. It increases to 0.97 and 1.03 eV at half and full coverage, respectively. Despite the molecular adsorption, the binding energies are large and in good general agreement with the experimental value. This unexpectedly strong binding is due to a "key–lock" type interaction between the water molecules and the ZnO surface. The water molecules are stabilized by three different types of attractive interactions to both the substrate and neighboring adsorbate molecules. 1) The O atoms of the water molecules occupy the O sites of a hypothetical next ZnO layer on the $ZnO(10\bar{1}0)$ surface so that the surface Zn ions regain their four-fold tetrahedral coordination as in the underlying bulk, which leads to a strong Zn−O and thus ZnO/H_2O bonding. 2) One of the H atoms forms a hydrogen bond across the ZnO trench of the surface to a neighboring substrate O atom. 3) In the case of a monolayer coverage, a water–water hydrogen bond to a neighboring adwater is formed by the second H atom. Thus, the full monolayer water film is significantly more stable than the half monolayer, in agreement with the XPS and STM data.

Although the key–lock configuration of a full monolayer of molecular water is a low-energy structure, it does not exhibit the (2×1) symmetry observed experimentally. Thus, in a second set of calculations, we explored the possibility that the (2×1) structure appears because of differently oriented water molecules. Two water molecules were randomly displaced in a (2×1) surface unit cell and a structural relaxation was performed. In all cases the adsorbed water molecules moved back toward the (1×1) monolayer structure and none of the modifications yielded an energy per water molecule lower than that obtained for the (1×1) coverage.

This picture changed when we explicitly considered the dynamics of the water molecules in full ab initio Car–Parrinello molecular dynamics (CPMD) simulations.[10] In this approach, the system can evolve to a more stable structure, if there is any, without much bias. We set up slabs with (3×2) and (4×2) surface unit cells containing six and eight water molecules, respectively. Starting from the fully relaxed water monolayer structure with (1×1) symmetry, spontaneous dissociation of a *subset* of water molecules was observed at a simulation temperature of 300 K. After the initial dissociation the structures were stable and no further proton transfers occurred. Since the dissociation starts immediately after the beginning of the CPMD simulations, the activation energy has to be very low, which explains why the (2×1) phase already appears at temperatures below 200 K in the experiment.

Upon further structural optimization, the most stable structure turned out to be a configuration in which every second water molecule is dissociated, leading to a (2×1) superstructure (Figure 1). Interestingly, the undissociated water molecules remain in the stabilizing key–lock position akin to the molecular (1×1) structure described above. The molecules tilt a bit more toward the surface and thereby strengthen the hydrogen bond to their neighboring molecules. In every second water molecule one OH bond is cleaved and the H atom is transferred to a substrate O atom. Thus, two hydroxy groups are formed, one built from an adwater O atom and the second one originating from a substrate O atom. For this half-dissociated (2×1) structure, the overall binding energy per H_2O molecule is found to be slightly, but significantly, increased with regard to that of the molecular (1×1) structure (from 1.03 to 1.13 eV, respectively). This is one of the highest binding energies for water on structurally well-defined solid substrates.[1] It is noteworthy that the interaction between the water molecules themselves "catalyzes" the dissociation reaction. As pointed out above, isolated water molecules do not dissociate on the $ZnO(10\bar{1}0)$ surface. However, calculations show that putting a second water molecule at a neighboring lattice site is already sufficient to trigger the dissociation. Between the two water molecules a hydrogen bond is formed that weakens the already activated OH bond across the ZnO trences in the acceptor molecule. The molecule becomes unstable and the proton is transferred to a substrate O atom without noticeable activation energy.

To investigate if the half-dissociated monolayer structure is consistent with the observations in the STM experiments, STM images for both, the half-dissociated (2×1) and the molecular monolayer (1×1) were calculated by using the Tersoff–Hamann approximation.[28] The experimental STM image in Figure 3 was recorded with a positive sample bias voltage, that is, under conditions where electrons tunnel into the conduction band (i.e. the LUMO). Under these conditions, the clean $ZnO(10\bar{1}0)$ surface is characterized by faint stripes that are attributed to the ZnO dimers (see Figure 1). The bright spots in the (2×1) superstructure of the H_2O islands are in registry with these stripes. The theoretical STM images reveal easily distinguishable differences between the two different adsorbate structures (Figure 3). The pattern

stemming from the half-dissociated superstructure matches the experimental STM image, which is clearly not the case for the molecular adlayer. The bright features in the image of the partially dissociated water layer are due to the OH groups of the dissociated water molecules, with a contrast that is predominantly geometric in nature.

Based on this consistent evidence, it can be concluded convincingly that half of the water molecules on the fully covered perfect $ZnO(10\bar{1}0)$ surface self-dissociate resulting in a well-defined (2×1) superlattice. This superstructure is characterized by long-range order and structural simplicity but in particular by an unusually large stability range extending from 200 K up to the boiling point of liquid water. Transcending the specific case, these findings imply that when ionic materials such as minerals come in contact with water the possibility of water auto-dissociation has *always* to be considered both in experiment and theory— without necessarily invoking defects! This is of particular relevance to heterogeneous catalysis so that a number of reactions, such as methanol synthesis on ZnO or Cu/ZnO in which water is a side product, have to be reanalyzed.

Experimental Section

The measurements were carried out with an ultrahigh vacuum (UHV) molecular beam system that was described in detail in reference [21]. The mixed terminated $ZnO(10\bar{1}0)$ substrates were oriented to within $0.2°$ and polished mechanically. After installation in the UHV chamber the samples were first cleaned by cycles of Ar^+ sputtering (800 V, ≈ 1 µA, 4–12 h, $T = 650$ K). After about 20 preparation cycles the XP spectra revealed contamination levels of less than 0.05 ML for carbon-containing species, and the surfaces exhibited (1×1) diffraction peaks in HAS and LEED. The surface was exposed to water either by backfilling the UHV chamber using a leak valve or by dosing water through a capillary that ended about 5 cm in front of the ZnO substrate.

The STM experiments were carried out in a separate UHV chamber equipped with low-energy He^+-ion scattering, LEED, and an STM operating at room temperature. The sample was prepared by sputtering (1 keV Ar^+, 30 min) and annealing (1000 K, 15 min) cycles. Water was dosed by backfilling the UHV chamber.

Coverage calibration was carried out by ratioing the O1s signal seen for the H_2O monolayer at 533.5 eV to that measured for a (2×1) CO_2 adlayer (with each (2×1) unit cell containing one CO_2 molecule) at the same energy. The intensity ratio $O1s_{OH}/O1s_{CO_2}$ was consistent with the presence of three OH species and one CO_2 molecule per (2×1) unit cell. The activation energy for desorption was determined by using the Redhead formula with the experimental heating rate of $1\,K\,s^{-1}$ and assuming first-order desorption with a preexponential factor of $10^{13} \times 1\,s^{-1}$.

Absolute Optical Cross Section of Individual Fluorescent Molecules**

*Lars Kastrup and Stefan W. Hell**

Besides having revealed transitions masked in the bulk,[1,2] optical spectroscopy of single molecules has enabled the observation of elementary molecular quantum events, such as the absorption and emission of a photon.[3–6] Single photon transitions are quantified by a cross section that can be regarded as the photon capture area of a molecule. Therefore, absolute optical cross sections can readily be measured in the bulk from the decrease (by absorption) or the gain (by stimulated emission) of the number of photons in a beam.[7] Unfortunately, this method is not applicable to individual molecules, because the resulting change in intensity is negligible. If the fluorescence quantum efficiency Q_{em} is known, the molecular absorption cross section can be calculated from the fluorescence emission.[8] However, this method re-introduces the hallmark of ensemble averaging, because Q_{em} is known only from the bulk. As a result, the *absolute* photon capture area of a specific molecule has remained elusive.

Here we report on the measurement of absolute cross sections of stimulated emission at room temperature. No a priori information about the individual molecule is needed. In addition, we demonstrate the instant control of a molecule's excited state by light and thus, as a matter of fact, also the viability of pump–probe experiments[9] with individual molecules at room temperature.

Molecular optical absorption usually takes place from the vibrationally relaxed ground state S_0 to a hot Franck–Condon state S_1^* of the first excited singlet state (Figure 1a). After vibrational relaxation, which occurs on a (sub)picosecond time scale, organic fluorophores emit within a few nanoseconds with a probability given by the fluorescence quantum yield. Alternatively, the $S_1 \rightarrow S_0$ transition can be enforced by light, that is by stimulated emission.[10] Stimulated emission has been employed to probe the temporal evolution of the excited state in a pump–probe fashion, as well as to alter the fluorescence lifetime and anisotropy[11,12] of organic fluorophores in solution. Furthermore, stimulated emission depletion (STED) of the excited state has been introduced in fluorescence microscopy[13,14] to break the diffraction reso-

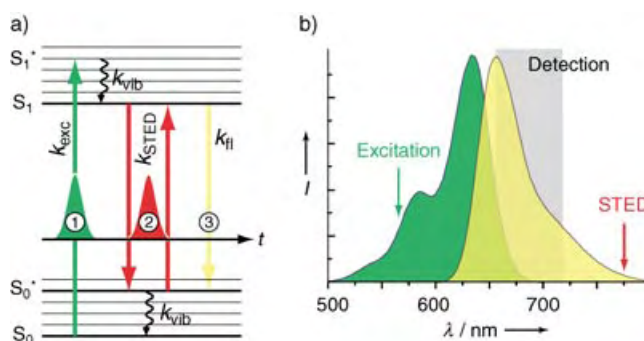

Figure 1. a) Jablonski diagram showing the transitions of the organic fluorophore involved: 1) excitation by the short-wavelength pulse, 2) stimulated emission and re-excitation by the STED pulse, and 3) fluorescence emission. The time axis indicates the succession of the pulses. b) Excitation and fluorescence spectrum of JA 26 showing the excitation and STED wavelengths, and detection regions.

lution barrier,[15,16] but has recently also been used to measure cross sections in the bulk.[17]

We attained single molecule sensitivity with a scanning confocal setup fed by two synchronized pulse trains: a first pulse at a wavelength of $\lambda = 565$ nm for excitation was followed by a red-shifted pulse at $\lambda = 778$ nm for STED, both adapted to the spectrum (Figure 1 b) of the xanthene dye JA 26 (**1**). Efficient STED demands a STED pulse duration τ
of about 15 ps,[13,15] because this is significantly shorter than the nanosecond lifetime of S_1, but much longer than the sub-picosecond vibrational decay of S_0^*. Thus the $S_1 \leftrightarrow S_0^*$ system is effectively depleted.

Figure 2 illustrates the ability of the STED pulse to "switch off" single fluorescent molecules embedded in a poly(vinyl alcohol) film. The image was acquired with constant excitation intensity but with the STED beam intercepted at 250 Hz. The on- and off-periods of 4 ms were about three times shorter than the time span required for scanning the molecule through the focal spot along the x direction. As a result, the molecules appear as diffraction-limited fluorescence spots featuring dark, vertically (y) oriented stripes resulting from the on-times of the STED beam, during which the spontaneous emission is obviously suppressed. Importantly, fluorescence recovers with the interruption of the STED beam. Note that, besides STED, the image of individual molecules exhibits blinking and binary bleaching, as expected for individual molecules.[18] Although depletion requires a much higher laser power than excitation (with pulse peak intensities of up to 1–2 GW cm^{-2}), only a minor increase in photobleaching was observed during the action of the STED beam. In general, the dependence of the photobleaching rate on the STED intensity follows a higher
Figure 2. Stimulated emission of single JA 26 molecules. While scanning a 5×5 µm^2 area in the focal plane (xy) with continuous excitation, the STED beam was periodically interrupted as indicated by the red-black bar above the image. Synchronized with the x scan, stimulated emission is imprinted on the diffraction-limited fluorescence spot left by a molecule in the image: while the STED beam is effective, fluorescence is inhibited and, vice versa, fluorescence recovers within the time resolution of the measurement (i.e. the dwell time of a pixel of 125 µs). This is highlighted in the inset, which displays the fluorescence intensity I of a selected molecule integrated in the y direction. The envelope of the fluorescence trace represents the spatial profile of the excitation spot along the x axis.

power law,[19] that is the photobleaching increases strongly with the pulse peak intensity, but much less so if the power is elevated by extending the pulse duration.

If STED dominates over the other de-excitation channels, the normalized probability of a molecule to fluoresce after an excitation/STED pulse pair depends on the number of photons per unit area in the STED pulse and on the $S_1 \rightarrow S_0^*$ cross section σ_{xy}. Hence, measuring the fluorescence probability as a function of the STED laser power yields the $S_1 \rightarrow S_0^*$ cross section of a specific molecule in absolute terms. This evaluation relies on a three-level photokinetic model (Figure 1a, levels drawn in bold) that applies once the molecule has arrived in the S_1 state. Starting at $t=0$, the STED pulse acts with an intensity I_{STED} for the time span τ of about 15 ps. Besides the spontaneous and stimulated decay of S_1, we also consider (re-)excitation by the STED pulse from S_0^* as well as the vibrational decay of the latter. Singlet–singlet absorption due to the STED pulse may, in principle, occur as well. However, since the subpicosecond decay of the higher singlet states is much shorter than τ (Kashas rule), this mechanism is not expected to affect the efficiency of STED appreciably. Thus, our model is well described by two coupled differential equations. Under the assumption of a rectangular pulse shape, the solution to these equations is straightforward (see Supporting Information).

Further simplifications are obtained if one considers that the fluorescence rate $k_{fl} \approx (4\,ns)^{-1}$ is much slower than the STED rate $k_{STED}(t) = \sigma_{STED}I_{STED}(t)$, which in turn is much slower than the vibrational relaxation $k_{vib} > (10^{12}\,s^{-1})$, that is, $k_{fl} \ll k_{STED} \ll k_{vib}$. If these conditions are fulfilled, the level S_0^* remains virtually unpopulated. Moreover, the probability $P_1(I_{STED})$ of finding a molecule in S_1 after the STED pulse action is solely determined by the number of photons per pulse and unit area rather than by the intensity as a function of time. Hence, the pulse shape is insignificant. Under these conditions, the measured fluorescence follows a monoexponential decay [Eq. (1)]. Here, Δt denotes the integration time,

$$F(I_{STED};\tau) = \Delta t f Q_{em} Q_{det} P_1(0) \exp(-\sigma_{xy} I_{STED} \tau) \qquad (1)$$

Q_{em} is the quantum efficiency of emission, and Q_{det} the detection sensitivity of the instrument. To determine *absolute* σ_{xy} values, Q_{em} and Q_{det} need not necessarily be known, since σ_{xy} is obtained from the simple ratio given in Equation (2).

$$\sigma_{xy} = \frac{1}{I_{STED}\tau} \ln\left[\frac{F(0;\tau)}{F(I_{STED};\tau)}\right] \qquad (2)$$

Higher precision is obtained by fitting the full decay with the exact analytical solution (see Supporting Information) that we actually pursued.

For each measurement, a single molecule was positioned in the overlapping foci of the two beams. Repetitive line scans across the molecule were performed while the STED beam was linearly ramped up from zero to a time-averaged focal power of $\bar{P}_{STED} = 3-10$ mW (Figure 3a and b). After each power ramp, the STED beam was interrupted to verify the
Figure 3. Measurement of saturated depletion of the excited state by stimulated emission of a single molecule. a) Sketch of the linear ramp of the average power $\bar{P}_{STED}$. b) Fluorescence of a single molecule that was repeatedly scanned through the focus in the y direction during the power ramp. Return to $\bar{P}_{STED} = 0$ leads to an instant recovery of the fluorescence intensity I, proving that the decrease in the signal was not due to irreversible photobleaching. c) Profile extracted from the center of gravity of the data shown in b), displaying the decrease and sudden onset of fluorescence intensity I as well as the final bleaching of the molecule.

recovery of the fluorescence. The fluorescence trace along the dotted line in Figure 3b is shown in Figure 3c, which exhibits a largely exponential decrease. A total of 65 traces on different molecules were acquired. Three representative traces are displayed in Figure 4a–c. Fitting with Equation (1)

Figure 4. a–c) Typical fluorescence traces as a function of the average power $\bar{P}_{STED}$ of the STED beam, which demonstrates saturated de-excitation. The curves fitted to the experiment yield the indicated cross sections. d) Histogram of 65 cross sections of individual JA 26 molecules in a PVA matrix. The largest values are attributed to molecules with transition dipole moments parallel to the focal plane. N = number of occurrences.

yields cross sections σ_{xy} of 0.44×10^{-16}, 0.23×10^{-16}, and 0.99×10^{-16} cm^2, respectively, whereas application of the exact solution of the rate equations gives the values 0.53×10^{-16}, 0.26×10^{-16}, and 1.20×10^{-16} cm^2. By varying the parameters entering our model, we estimated the total precision to be about 10%, which is at least comparable, if not superior, to that usually reached in the bulk.

For a molecule that includes an angle θ with the focal plane, only $\sigma_{xy} = \sigma \cos^2 \theta$ of the total cross section σ is effective in optical interactions. Figure 4d shows the σ_{xy} of all the molecules measured. The process of spin coating and arbitrary selection of the molecules is expected to introduce a certain bias in their orientational distribution. Nonetheless, the largest value $\sigma = 1.7 \times 10^{-16}$ cm^2 is an absolute lower limit for the total molecular cross section of JA 26. The molecular orientational distribution is equally required when absolute absorption cross sections are to be determined from ensemble measurements, but in most of these cases, a random distribution can safely be assumed.

Scaling with the ensemble emission spectrum (Figure 1b) or even better with the individual fluorescence spectrum of the molecule, yields the cross section for values other than at 778 nm. If the spectra are mirror symmetric, σ_{xy} allows one to extrapolate the cross section of absorption.[20] This is interesting because there is no purely analogous access to the absolute cross sections of absorption. If Q_{em} and Q_{det} are unknown, the absolute absorption cross sections must be extracted from the saturation of the excitation (see Supporting Information), which is heavily challenged by photobleaching.[21]

In summary, we have demonstrated "instant fluorescence quenching and recovery" of a single molecule by light. The opportunity to *repeatedly* modify the probability of the *same* molecule to be in its excited state should disclose tangible new information. The values of the absolute optical cross sections of a molecular species have been given as a first example.

Recently, novel schemes were proposed to determine the full orientation of the molecular transition dipole moment in space. The synergistic combination with our method may finally also reveal the total radiative decay rate of each molecule in question. In conjunction with an excited state lifetime measurement by time-correlated single photon counting, this information could disclose the non-radiative rates as well, and could thus contribute to the full spectroscopic characterization of individual molecules at room temperature.

Experimental Section

Excitation at $\lambda = 565$ nm of the dye JA 26 was accomplished by a frequency-doubled optical parametric oscillator (APE, Berlin, Germany) which was synchronously pumped by a femtosecond mode-locked titanium:sapphire laser (Coherent, Santa Clara, CA) operating at a pulse repetition rate of approximately 76 MHz. The fundamental mode of the latter was used for stimulated emission depletion at a wavelength of $\lambda = 778$ nm. The laser power was adjusted with two liquid crystals (Cambridge Research & Instrumentation, Woburn, MA). The pulses of both lasers were stretched to 12 ps (excitation) and 15 ps (STED) with gratings and were temporally matched for maximal efficiency of STED. Quarterwave retardation plates ensured circular polarization of the beams which were coupled into a stage-scanning confocal microscope using dichroic beamsplitters (628dclpxr, 720drspxr, Chroma Technology, Rockingham, VT). The collected fluorescence was filtered by a bandpass filter (D680/60, Chroma Technology) and detected by a photon counting module (SPCM-AQR-13-FC, PerkinElmer, Canada). The samples were prepared by spin coating an aqueous solution of the dye JA 26 (~1 nм) containing 0.1% poly vinyl alcohol onto a cleaned glass coverslip and were purged with argon gas.

Biomaterials

Improving Implant Materials by Coating with Nonpeptidic, Highly Specific Integrin Ligands**

*Claudia Dahmen, Jörg Auernheimer, Axel Meyer, Anja Enderle, Simon L. Goodman, and Horst Kessler**

Surface modification for enhanced cell adhesion to improve the properties of the critical interphase between an implant material and the biological tissue is an ongoing issue. Despite considerable improvements there is still a challenge to optimize the following criteria: the efficiency in stimulating cell adhesion, the selectivity for a specific cell type (e.g. osteoblast vs. platelet adhesion), the stability under physiological conditions, the stable covalent attachment to the material, the ease of handling under sterile conditions, and reasonable costs for the coating. Herein we present a new solution to these problems by using anchored nonpeptidic, highly αv-selective integrin ligands to coat titanium, a common implant material.

Osteoblast adhesion can be stimulated by extracelullar matrix (ECM) proteins (e.g. fibronectin, collagen, laminine, and bone sialo protein),[1] their fragments, or by RGD peptides[2] which bind to αvβ3 integrin on osteoblast cells but bind to the platelet integrin αIIbβ3 as well.[3] Selectivity for αvβ3 integrin could be achieved by using optimized cyclic pentapeptides.[4–6] Coating poly(methyl methacrylate) (PMMA) with suitable modified cyclic pentapeptides stimulates osteoblast adhesion in vitro[7] and bone formation in PMMA granulates in vivo (rabbit).[8]

A number of nonpeptidic αv-selective RGD mimics have been developed by us and others[9–12] as potential drugs to treat cancer, osteoporosis, acute renal failure, restenosis, arthritis, and retinopathy.[13–18] Recently the X-ray structure of the αvβ3 head group containing the cyclic peptide cilengitide[5] was reported.[19] Modeling studies on the nonpeptidic αvβ3 ligands elucidated their binding mode.[20] We used this data to identify suitable positions for anchor groups (linkers)

that could be used to attach ligands to the surface without interfering with integrin binding. The guanidine and carboxy groups of the ligand are essential for binding to the integrin subunits α and β, respectively.[21] Therefore we chose the two aromatic rings of our highly αvβ3-selective diacylhydrazine scaffold[10] to position the anchor groups (Scheme 1). By using the AutoDock3 program[22,23] two mimetics with different anchors at R^1 and R^2 were modeled into the X-ray structure of the αvβ3–cilengitide complex[19] after removal of the peptide ligand. The binding modes were identical to those of the anchor-free mimetic ($R^1 = R^2 = H$; Figure 1),[20] and the linkers showed no disturbing interaction with the integrin, hence we synthesized both variants with different linker groups.
Scheme 1. Substituted nonpeptidic diacylhydrazines with possible linker positions R^1 and R^2 for anchoring to surfaces.
Figure 1. Results of the docking studies: Two diacylhydrazine molecules with anchors on the aromatic rings (stylized as yellow spheres) modeled into the crystal structure of the αvβ3 integrin head group.[19]
Scheme 2. Synthesis of R^1 substituted diacylhydrazines on a solid phase. a) NH_4OAc (2 equiv), malonic acid mono-*tert*-butyl ester (1 equiv), EtOH; b) Fmoc-Cl (1.05 equiv), $NaHCO_3$, dioxane; c) TCP-resin, CH_2Cl_2, DIEA; d) 20% piperidine in NMP; e) $COCl_2$ (3 equiv; 1.9 M solution in toluene), sat.$NaHCO_3$, CH_2Cl_2;[24] f) 5-(9-*H*-fluoren-9-ylmethoxy)-1,3,4-oxadiazol-2-(3 *H*)-one (4 equiv), DMF; g) 20% piperidine in NMP; h) 3-(*N*-Fmoc)-aminobenzoic acid (2 equiv), HATU (1.94 equiv), collidine (22 equiv), NMP; i) 20% piperidine in NMP; k) *N,N*′-bis(Boc)guanylpyrazole (10 equiv), CHCl₃, 50°C; l) 20% HFIP in CH_2Cl_2; m) linker molecule (1 equiv), HATU (0.97 equiv), HOAt (1.1 equiv), collidine (11 equiv), DMF; n) 50% TFA, 2% triisopropyl silane,[30] 2% water in CH_2Cl_2. DIPEA = *N,N*-diisopropylethylamine.

Synthesis was performed on solid support (trityl chloride polystyrene resin = TCP-resin) by an Fmoc strategy (Fmoc = 9-fluorenylmethoxycarbonyl) similar to that described elsewhere.[9,10,24] Starting from substituted β-amino acid immobilized on the resin, carbonylated Fmoc-protected hydrazine as the aza-glycine precursor[24] and 3-(*N*-Fmoc)aminobenzoic acid were coupled. Guanidine was successfully incorporated using an excess of *N,N*′-bis(Boc)guanylpyrazole (Boc = *tert*-butoxycarbonyl; Scheme 2). After cleavage (hexafluoroisopropanol (HFIP)/CH_2Cl_2) the resulting Boc/O*t*Bu-protected compound was coupled in solution on position R^1 with two thiol linkers of different length—cysteamine and 6-aminohexanoyl-6′-aminohexanoyl-6″-aminohexanoyl cysteine—and deprotected by trifluoroacetic acid (TFA). Purification was done by reverse-phase (RP) HPLC. The high αvβ3 affinity of all the mimetics, with linkers (**2**, **3**) or not (**1**), was demonstrated in an established IC_{50} assay.[10,25] Whereas the dicarboxy compound **1** is only active for the αvβ3 integrin in the nanomolar range, the linked molecules are biselective

for αvβ3 and αvβ6 integrins (Table 1) as described for other nonpeptides of the diacylhydrazine type.[9]

Steric effects cannot be the reason for the high αvβ3 selectivity of compound **1** as compounds **1–3** are equally

Table 1: Ligand affinities of unanchored (free) nonpeptidic RGD mimetics to different integrins.

	Compound		IC_{50} [nM][a]; inhibition at ligand concentration [nM]			
	R^1	R^2	αvβ3	αvβ5	αvβ6	αIIbβ3
1	COOH	H	16	10^4 (65%)	10^3 (54%)	10^4 (22%)
2	CONH-(CH$_2$)$_2$-SH	H	5.7	200	0.24	3.20×10^3
3	COAhx$_3$Cys[b]	H	0.72	310	2.35	3.15×10^3
4	Cl	CH$_2$NHAhx$_3$-CO-(CH$_2$)$_2$-SH[a]	0.84	245	0.089	4.15×10^3
5[10]	H	H	0.8	n.m.[c]	n.m.[c]	8500
6[10]	Cl	H	0.1	n.m.[c]	n.m.[c]	5500
cyclo(-RGDfK[3-mercaptopropionyl]-)[28]			0.4	n.m.[c]	n.m.[c]	$>10^4$

[a] The data shown represent the mean of at least 2 independent IC_{50} determinations. As previously documented the typical variation in such receptor–ligand inhibition measurements is routinely in the order of the measured value itself.[29] [b] Ahx: 6-Aminohexanoic acid. [c] n.m.: not measured.

sterically demanding. Consistent with our theoretical studies on αvβ5 homology models,[26] the residues Lys180 and Asp252 of the SDL (selectivity determining loop) near the MIDAS region could effect an unfavored reorientation of ligand **1** in the binding pocket through electrostatic interactions with the carboxylate. There are uncharged residues at these positions in the β3 subunit and this could explain the strong impact of the carboxylic group in compound **1** for inhibiting the binding in αvβ5.

R^2-linked compound **4** was synthesized by a combined solution and solid-phase strategy (Scheme 3). *p*-Chlorophenyl-substituted β-alanine was chosen as the C-terminus of the molecule because it is found in very potent αvβ3 integrin ligands.[10] A complete solid-phase strategy could not realized, because after coupling of 3-amino-5-(*N*-Fmoc)aminomethylbenzoic acid stabilized with 4-methylbenzenesulfonic acid the coupling of ε-(*N*-Fmoc)-aminohexanoic acid after Fmoc deprotection (only possible with 2% 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)/2% piperidine in *N*-methylpyrrolidone (NMP)) did not work (probably caused by steric hindrance) even though different coupling reagents have been used. Therefore 3-aminomethyl-5-guanidinobenzoic acid was coupled with 3-(*S*-Trt)-mercaptopropionyl-Ahx-Ahx-Ahx-OH (Trt = trityl) in solution. The product was activated with *O*-(7-azabenzoictriazol-1-yl)-1,1,3,3-tetramethyluroniumhexafluorphosphate (HATU) and coupled on resin-bound 3-(4-chlorophenyl)-3-[(hydrazinocarbonyl)-amino] propionic acid. Cleavage from the resin with HFIP/CH$_2$Cl$_2$, complete deprotection (TFA/CH$_2$Cl$_2$), and subsequent purification by RP-HPLC gave in the integrin ligand **4** that is biselective for αvβ3/αvβ6 with an affinity in the sub-nanomolar range (Table 1).

Substances **2–4** were tested for their cell adhesion properties on surfaces, the thiol linkers enable irreversible immobilization on titanium (an implant material). MC3T3E1 mouse osteoblasts, expressing the αvβ3 integrin,[8] were seeded onto the modified titanium discs (Ti6Al4V, ⌀1 cm), after 1 h the number of adherent cells was measured by detecting the hexaminidase activity.[27] Our study indicates that mouse osteoblasts bind to surfaces coated with compounds **2** or **3** (Figure 2). The plating efficiency was increased up to 42.9% (100 μM compound **3** in coating solution) compared to 9.4% on the unmodified titanium. Compound **3** stimulates cell adhesion as efficiently as the *cyclo*-(-RGDfK[3-mercaptopropionyl]-) peptide.[28] Compound **2** is slightly less potent, probably caused by the significant shorter linker, which makes the integrin ligand less accessible to the integrin. Compound **4**, although having comparable activity in the binding assay of isolated αvβ3

Scheme 3. Synthesis of R^2 substituted diacylhydrazine **4**. a) SO$_2$(NH$_2$)$_2$ (1.2 equiv), SOCl$_2$ (3.6 equiv), sulfalone, 42 h reflux; b) Pd/C, H$_2$, MeOH; c) SC(NHBoc)$_2$ (1 equiv), NEt$_3$ (4 equiv), HgCl$_2$ (1.3 equiv), MeOH; d) Pd/C, H$_2$ 20 bar, 2 M NH$_3$/EtOH, 50°C; e) LiOH (3 equiv), MeOH/H$_2$O; f) 40% aqua.TFA (v/v); g) linker molecule (1 equiv), HATU (1 equiv), HOAt (1 equiv), collidine (10 equiv), DMF; h) HATU (1 equiv); i) 20% HFIP in CH$_2$Cl$_2$; k) 40% TFA, 2% triisopropyl silane,[30] 2% water in CH$_2$Cl$_2$.

Communications
Figure 2. Adhesion of MC3T3 E1 mouse osteoblasts on uncoated and coated titanium surfaces. The mean values of each point given is the result of triplicate determinations, the error bars represent standard deviations. [Pm] = mimic concentration in the coating solution.

integrin (Table 1), yielded no stimulation of osteoblast adhesion when bound to the titanium surface in repeated testing. An explanation could be that in spite of its huge linker the immobilized ligand has an unfavored orientation for integrin binding; the possibility that compound **4** does not immobilize on titanium is unlikely since we have investigated many peptidic derivatives of cyclo(-RGDfK[3-mercaptopropionyl]-) in the past (unpublished data) and all of them coated well on the titanium surfaces (checked by ELISA and cell adhesion assays, data not shown). In the case of the RGD mimic, immobilization could not be directly measured by ELISA because the antibody used recognizes only the cyclic RGD peptide and not the mimetics.

In conclusion, compounds **2** and **3** are the first nonpeptidic αv-selective integrin ligands for surface coating which exhibit a potency for stimulated osteoblast adhesion similar to that of cyclo(-RGDfK[3-mercaptopropionyl]-) when immobilized on titanium. Compounds **2** and **3** are more stable to enzymatic degeneration, pH variations, and heat and their synthesis is much cheaper than that of the cyclic peptide.

Spectroscopic and analytical data for compounds **1–4** are included in the Supporting Information.

Lewis Acids

Amorphous Aluminum Bromide Fluoride (ABF)**

Thoralf Krahl and Erhard Kemnitz*

Dedicated to Professor Gerd-Volker Röschenthaler on the occasion of his 60th birthday

Amorphous aluminum chloride fluoride (ACF; $AlCl_xF_{3-x}$, $x = 0.05–0.3$), which is of high interest for catalytic reactions,[1] was discovered at DuPont in 1992.[2] It exhibits an extraordinarily high Lewis acidity similar to the acidity of SbF_5, and in some cases, has even higher acidity. ACF is prepared by mild fluorination of $AlCl_3$ with chlorofluorocarbons such as $CFCl_3$. However, the fluorination is never carried out to completion; the solid phase always contains some chlorine. The high Lewis acidity is surprising since pure aluminum chloride and phases of aluminum fluorides prepared in other ways are much weaker Lewis acids. We recently reported the investigation of ACF by several spectroscopic methods[3] and presented our initial findings on the structure of this amorphous compound. However, the role of the residual chlorine in ACF is still unclear, but it has been shown that the structures of ACF and $AlCl_3$ differ with respect to the chlorine atoms.

Herein we report on the synthesis of amorphous aluminum bromide fluoride ABF ($AlBr_xF_{3-x}$, with $x = 0.13$), which is very similar to ACF. EXAFS measurements on the Br K edge of ABF enabled a more detailed study of the structure than for ACF. Partially fluorinated samples of $AlBr_3$ with the nominal composition $AlBr_2F$ and $AlBrF_2$ were also investigated. From the analysis of the data measured by ^{19}F MAS NMR spectroscopy and Br K EXAFS, together with that gained during the investigation of ACF,[3] a basic structural model of the compounds ABF and ACF is introduced for the first time.

Solid $AlBr_3$ is built up of discrete Al_2Br_6 molecules,[4a] whereas $AlCl_3$ has a layered structure.[4b] The fluorination of $AlBr_3$ with $CFCl_3$ is highly exothermic and can be performed similar to that of ACF [Eq. (1)] to initially give $CBrCl_3$ and ABF.

$$AlBr_3 + (3-x)\,CFCl_3 \rightarrow AlBr_xF_{3-x} + (3-x)\,CBrCl_3 \qquad (1)$$
The primary reaction product $CBrCl_3$ is not stable in the presence of a very strong Lewis acid such as ABF (see Experimental Section). Thus, it undergoes dismutation and slowly forms CCl_4, CBr_2Cl_2, CBr_3Cl, and CBr_4. These products

have been observed by ^{13}C NMR spectroscopy. ABF is amorphous and shows no reflections in the XRD pattern. During heating, it crystallizes suddenly at 400°C, forms crystalline β-AlF_3 and $AlBr_3$, and looses its very high Lewis acidity.

The Lewis acidity of ABF is very high. It catalyzes the isomerization reaction of 1,2-dibromohexafluoropropane to 2,2-dibromohexafluoropropane at room temperature [Eq. (2)], which requires an extremely strong Lewis acid.[1d]

$$CF_3-CFBr-CF_2Br \rightarrow CF_3-CBr_2-CF_3 \qquad (2)$$
We chose this particular reaction because it can be carried out relatively easily. The acidity of certain Lewis acids has been recently expressed quantitatively by calculation of the fluoride ion affinity (FIA) at the MP2 level of theory. From this point of view, molecular SbF_5 is the strongest Lewis acid with the highest FIA.[5] *Molecular* aluminum chloride and *molecular* aluminum fluoride have just slightly lower acidities. However, the acid strength of *solid* acids such as AlF_3, ACF, and ABF cannot be expressed in such terms, but a ranking of the acid strengths can be done in terms of their reactivity. Reaction (2) requires a highly acidic catalyst; it runs easily at room temperature with the very strong Lewis acids SbF_5, ACF, and ABF but not with the strong acids $AlCl_3$ and $AlBr_3$.

The IR spectrum of ABF (Figure 1) is typical for a network of corner-sharing AlF_6 octahedra,[3] which has the nominal composition of AlF_3. Two intensive bands at around 665 and 350 cm^{-1} are attributed to the valence and deforma-
Figure 1. IR spectrum of ABF ($AlBr_{0.13}F_{2.87}$; CsI pellet).

tion vibrations of the AlF_6 octahedron, respectively. The large width of the band indicates the high degree of amorphicity of ABF. Interestingly, there is no significant difference between the IR spectra of ABF and ACF.[3]

The ^{19}F MAS NMR spectra of ABF, partially fluorinated $AlBr_3$, and ABF exposed to air are given in Figure 2. All spectra show the main signal between $\delta = -160$ and -170 ppm, which is typical for the μ-F atoms of corner-sharing AlF_6 octahedra and is also observed in amorphous and crystalline phases of AlF_3.[3,7] The spectrum of ABF shows an additional weak signal in the region from $\delta = -200$
Figure 2. ^{19}F MAS NMR spectra of a) $AlBr_2F$, b) $AlBrF_2$, c) ABF ($AlBr_{0.13}F_{2.87}$), and d) ABF exposed to air for 18 h.

Figure 3. Measured (a) and simulated (b) ^{19}F MAS NMR spectrum of ABF. The fit (b) is the sum of the components (b1) to (b4). The parameters of the lines are shown in Table 1. b1) Main signal, lines 5 and 6; b2) shoulder, lines 7 and 8; b3) spinning side bands, lines 2, 3, 9, and 10; b4) organic residue, lines 1 and 4; c) difference between (a) and (b). The same scale was used for all components.

[a] The parameters of the Gaussian line fit are given. Only the lines 5 to 8 were considered for relative intensity. (I_{rel}) (s.s.b. = spinning side band).

to −210 ppm. According to the superposition model for the ^{19}F chemical shift, this signal is caused by terminal fluorine atoms bound to only one aluminum atom at a distance of around 1.7 Å (t-F).[6a] The appearance of such types of fluorine atoms has only been observed in ACF before and recently also in alumina fluorinated with $CHClF_2$.[7c] Deconvolution of the ^{19}F NMR spectrum of ABF with the program DMFIT[6b] using Gaussian line shapes and two lines for each of the signals shows that the μ-F:t-F ratio of intensities of the fluorine signals is 92.3:7.7 (Figure 3 and Table 1). The small and narrow signals at chemical shifts of about $\delta = -80$ and −120 ppm can be assigned to the CF_3 and CF_2 groups of the organic residue. The signals of the terminal fluorine atoms disappear when the sample is exposed to atmospheric moisture (Figure 2d), and the structure of ABF changes irreversibly.

The fingerprint region of the X-ray absorption near edge spectra (XANES) of the Br K edge of $AlBr_3$, $AlBr_2F$, $AlBrF_2$, and ABF are shown in Figure 4. The spectra of ABF and $AlBr_3$ differ from each other, whereas the spectra of $AlBr_2F$ and $AlBr_3$ are almost the same. The spectrum of $AlBrF_2$ is a superposition of the spectra of $AlBr_3$ and ABF—a linear combination of both data sets delivers the best fit result at 29% $AlBr_3$ and 71% ABF. From these results, it is evident that the bromine atoms in ABF and $AlBr_3$ differ from each other—the only partially fluorinated compound $AlBrF_2$ contains two different types of bromine atoms: one similar to the bromine in $AlBr_3$ and another similar to the bromine in

ABF. Thus, the measurements confirm that $AlBrF_2$ is a mixture of the two phases, $AlBr_3$ and ABF, and that the remaining bromine in ABF does not derive from unreacted $AlBr_3$.

The FT EXAFS spectra of the Br K edge of $AlBr_3$ and ABF (Figure 5) clearly show that the mean distance between bromine and the surrounding atoms in $AlBr_3$ is smaller than
Figure 4. Br K-edge XANES spectra of a) $AlBr_3$, b) $AlBr_2F$, c) $AlBrF_2$, and d) ABF ($AlBr_{0.13}F_{2.87}$). The dashed lines indicate characteristic features. E_P = photon energy.

Figure 5. Fourier-transformed EXAFS spectra of the Br K-edge of a) $AlBr_{0.13}F_{2.87}$ (ABF) and b) $AlBr_3$. The transformed spectra are not phase-corrected. The original EXAFS function is shown in the insets.
Scheme 1. Structural octahedral units proposed in ABF and ACF (X = Cl, Br). Al atoms in the middle of the octahedra are not shown. The sinuous lines indicate the bond to the next aluminum atom.

that found in ABF, that is the Al—Br bonds lengthen during the fluorination. The long Al—Br distances are surprising, but can be explained with the model established in the following.

The results gained from catalysis studies as well as IR and ^{19}F NMR measurements, and thermoanalysis show that the solid phases ABF and ACF are very similar to each other. Nevertheless, there are some spectroscopic methods, which could only be used with one of the phases (EXAFS for ABF, ESR for ACF[3]). The combination of the results of work on ACF[3] and the work on ABF presented here allows us to propose a simple geometric model for the structure of such compounds. It is assumed that ACF and ABF are built up of the same basic units; the structure is explained with a model based on linked polyhedra.

The following assumptions are made:

1) The aluminum atoms are octahedrally coordinated.
2) Three different types of octahedra are present (see Scheme 1):
2a) $[Al(\mu\text{-}F)_{6/2}]^0$ octahedra (**1**), in which all fluorine atoms link two octahedra,
2b) $[Al(\mu\text{-}F)_{5/2}(t\text{-}F)]^{1/2-}$ octahedra (**2**), in which five fluorine atoms link two octahedra and one fluorine atom is terminal,
2c) $[Al(\mu_3\text{-}X)_{1/3}(\mu\text{-}F)_{5/2}]^{1/6+}$ octahedral (**3**), in which one atom X (Cl or Br) links three octahedra and five fluorine atoms link two octahedra.

To ensure charge balance, the ratio between **2** and **3** must be 1:3. The overall sum formula can be formulated as $[Al(\mu\text{-}F)_{5/2}(t\text{-}F)]\cdot3[Al(\mu_3\text{-}X)_{1/3}(\mu\text{-}F)_{5/2}]\cdot n[Al(\mu\text{-}F)_{6/2}]$, where n is a variable parameter. This formula can be simplified to $Al_{4+n}X(t\text{-}F)(\mu\text{-}F)_{10+3n}$. Substitution of n as $\frac{1}{x}-4$ yields $AlX_x(t\text{-}F)_x(\mu\text{-}F)_{3-2x}$, or AlX_xF_{3-x}. For the ABF investigated in this publication n equals 3.69.

This model can explain the ^{19}F NMR and Br K EXAFS spectroscopic data. The following conclusions can be drawn:

1) The formal charge of the octahedra of type **3** is higher than that of the normal octahedra **1** found in AlF_3. Thus, the

electron deficiency of the central Al atom of **3** is higher than that of the Al atoms in AlF$_3$. Thus, ABF and ACF are more Lewis acidic than AlF$_3$.

2) From $n \geq 0$ follows $x \leq 0.25$. AlX$_{0.25}$F$_{2.75}$ is the limiting composition for a compound called "ABF" or "ACF". This agrees quite well with the value 0.3 both given by duPont[2] and determined by ^{19}F NMR spectroscopy for ACF.[3]

3) The ABF structure investigated contains 7.7% terminal fluorine atoms with chemical shifts between $\delta = -200$ and -210 ppm in the ^{19}F NMR spectrum (Table 1). The amount of *t*-F and Br should be the same. Its formula can then be formulated as AlBr$_{0.13}$(*t*-F)$_{0.22}$(μ-F)$_{2.65}$. The amount of *t*-F is a little higher than that of bromine.

4) The mean distance between a μ_3-bridging halogen atom X and aluminum should be comparatively high. The EXAFS spectra (Figure 5) show clearly that the mean distance of bromine to its nearest neighboring atoms is higher in ABF than in crystalline AlBr$_3$—the μ_2-bridging Br atoms have an Al−Br distance of 2.38 Å and the terminal Br atoms have a Al−Br distance of 2.19 to 2.20 Å.[4a]

5) Al−Br bonds are very sensitive to moisture. During exposure to air, not only are the acidic centers on the surface blocked, but the relevant structural elements explained above are destroyed. The resulting compound can be formulated approximately as Al(OH)$_y$F$_{3-y}$. In the ^{19}F NMR spectrum no signals for terminal fluorine are seen, and the signals are shifted to slightly lower field (Figure 2D). The latter is also observed on comparing the spectra of AlF$_3$ and AlF$_3$·3H$_2$O.[3]

Experimental Section

Solid-state NMR spectra were measured with a Bruker AVANCE 400 MHz spectrometer equipped with a 2.5-mm Bruker MAS probe head at a rotation frequency of 30 kHz and a resonance frequency of 376 MHz for the ^{19}F nucleus.

Measurements of X-ray absorption spectra were carried out at HASYLAB on the beamline X1 (DESY, Hamburg, Germany) in transmission mode. The edge energy of the Br K-shell (13 474 eV) was calibrated with gold foil (Au L$_2$-edge energy 13 733 eV). Samples were mixed with hexagonal boron nitride and pressed into pellets in a dry box.

All preparations were carried out under standard Schlenk conditions. Solvents were dried by condensing over molecular sieves (4 Å) before use. AlBr$_3$ (Reakhim, p.a.), CFCl$_3$ (Fluka, 99.5%), and perfluorooctane (ABCR, 95%) were used for the syntheses. The composition of the samples was checked by Br, C, and F analysis.

Synthesis of ABF: The reaction between AlBr$_3$ and CFCl$_3$ is strongly exothermic and should not be carried out at room temperature. AlBr$_3$ (11.0 g, 41.4 mmol) was placed with a magnetic stirrer in a 250-mL round-bottomed flask equipped with a dry ice condenser. The flask was evacuated and cooled with liquid nitrogen. Six equivalents of CFCl$_3$ (248 mmol) were condensed on the solid. The flask was warmed up to around 200 K (dry ice/2-propanol) and stirred at this temperature for 1 h. The start of the reaction was indicated by the yellow color of the solid. The flask was warmed to room temperature and refluxed for one more hour. The liquid was then evaporated in vacuum, and a fine orange-yellow powder was obtained. The sample had a composition of AlBr$_{0.13}$F$_{2.87}$ and contained 0.8% carbon.

AlBr$_2$F and AlBrF$_2$: The reaction was carried out similarly. Perfluorooctane was added until the solid AlBr$_3$ was totally immersed before the reaction. After mixture had been frozen, the desired amount of CFCl$_3$ (for AlBr$_2$F 1 equiv, for AlBrF$_2$ 2 equiv) was condensed on the solid and then the workup proceeded as described for ABF.

DNA Adducts

Mass Spectrometric Studies of DNA Adducts from a Reaction with Terpenoids**

Wolfgang Schrader,* Sven Döring, and Werner Joppek

The phenomenon of blue haze above forests was described in the 1960s by Went,[1] who correlated the formation of organic aerosols with biogenic plant emissions. Biogenic emissions, especially of mono- and sesquiterpenes, react with atmospheric oxidants to form a large number of products,[2] which are thought to undergo a gas-to-particle conversion to form the organic aerosol. These particles in the atmosphere behave differently than the gaseous compounds, because they absorb or scatter the solar radiation, serve as cloud condensation nuclei, and are involved in multiphase atmospheric chemistry.[3]

In addition to their atmospheric impact, terpenes and terpenoids are considered to be involved in plant–insect interactions.[4] Indoor emissions of terpenes from furniture[5] have been investigated as well as their impact on the nasal and respiratory system, and the risks of respiratory cancer for exposed woodworkers.[6] The implication of terpenes and terpenoids in the generation of chronic pulmonary disease and acute bronchitis is well established.[7] Their impact on the human organism is otherwise still unclear. Even pharmocokinetic data are not specific, and systematic studies on the metabolism have not been reported.[7]

One marker used to observe the impact of xenobiotic compounds on organisms is the formation of DNA adducts, which in theory can lead to tumor development.[8] Studies on DNA damage caused by oxidative stress or other natural compounds are of great interest to scientists.[9] Randerath et al.[10] were studying DNA modifications caused by polycyclic hydrocarbons using a ^{32}P-postlabeling assay when they found a significant number of DNA modifications in control samples from untreated animals. The authors suggested that these adducts arose from indigenous compounds and therefore called them "i-spots". The pattern of these i-spots is dependent on tissue, species, gender, and diet,[11] and the number of i-spots increases with age.[12] Recently, i-spots have been associated with cancer development.[13] Unfortunately, the causes are still not fully understood. Some results indicate that compounds responsible for oxidative stress could cause some of the i-spots,[9] although this does not sufficiently explain the complex pattern of the indigenous DNA modifications. Therefore other chemical compounds must be responsible for these lesions. One source that could have a substantial influence on base-level DNA damage is unsaturated biogenic hydrocarbons, because they are ubiquitous. The only biogenic hydrocarbon that has been investigated in detail with regard to DNA-adduct formation is ethylene.[14] Ethylene metabolizes to ethylene oxide, which is considered a strong carcinogen. Until now, there have been no studies on the impact of unsaturated hydrocarbons with regard to DNA adducts. Here, we report on a new class of xenobiotics and their effect in terms of base-level DNA damage.

Identification of xenobiotics contributing to base-level DNA damage is difficult, because the level is very low (about one adduct per 10^8 nucleotides),[15] which presents a challenge for analytical methods. The most sensitive technique is the ^{32}P-postlabeling assay, which allows detection of one adduct per about 10^8–10^{10} bases.[16] Since the adducts are detected by cochromatography, a synthetic standard is required and unknown adducts cannot be identified.

We have been studying the reactivity of terpenoids tentatively identified as products of the gas-phase ozonolysis of monoterpenes with regard to their reactivity with DNA and DNA constituents in vitro by applying enzymatic digestion followed by mass-spectrometric analysis to characterize the reaction products. Mass spectrometry is not as sensitive as ^{32}P-postlabeling, but the DNA adducts can be detected in small quantities and information about the structure of the adduct molecule can be extracted.[17] For this purpose we use both an ion trap and a Fourier transform ion cyclotron resonance mass spectrometer (FTICR-MS) to study the reaction of α-pinene oxide with calf thymus DNA. While the ion trap MS can be used for fragmentation experiments induced through collision activation (CAD), FTICR-MS provides high-resolution mass data for the reaction products, which can be used to calculate the empirical formulas of the products in complex reaction mixtures.

Enzymatic DNA degradation is a standard tool for the study of these macromolecules. For a better understanding of the reaction, the DNA was digested using two different approaches: with the enzyme nuclease P1 and, alternatively, with a combination of the enzymes benzonuclease with an alkaline phosphatase. While nuclease P1 digests DNA to form mononucleotides, the benzonuclease produces a number of oligonucleotides of different chain lengths. The alkaline phosphatase removes the 5′-phosphates from the oligonucleotides, leading to oligonucleotides composed of n nucleosides and $n-1$ phosphate groups.[17] Because MS provides only mass information about a nucleotide, the sequence specificity cannot be determined. Together, the two approaches provide an overview of possible DNA adducts resulting from the reaction with terpenoids.

Here, we report the first results obtained from the reaction of DNA with α-pinene oxide, an early product of α-pinene oxidation. Epoxides are reactive towards DNA,[17] and their generation, by enzymatic oxidation through the cytochrome P 450, is often the first metabolic step in the removal of insoluble xenobiotics from the organism. A number of strong carcinogens are also activated in this way.[18]

In addition to the DNA experiments we studied reactions of the four mononucleotides with α-pinene oxide in order to compare the results and facilitate the interpretation. The

reaction of α-pinene oxide with DNA leads to a number of different adducts. Although their abundance is rather low, some specific DNA adducts could be detected and characterized. The DNA was detected as mononucleotides after nuclease P1 digestion; besides the not alkylated mononucleotides two adducts were detected. A signal at $m/z = 498$ was recorded for the deoxyguanylmonophosphate (dGMP) adduct and one at $m/z = 482$ for the deoxyadenylmonophosphate (dAMP) adduct. The other two bases did not form adducts under these conditions. MS/MS experiments with these adducts indicate that α-pinene oxide is coupled directly to the nucleobase. Corresponding results from FTICR-MS experiments confirm the findings and make it possible to obtain the empirical formulas of the respective adducts. When the reaction was conducted at 60 °C rather than at 37 °C, the dCMP and dTMP adducts with signals at $m/z = 473$ and 458, respectively, were observed. In comparison, pure mononucleotides showed adduct formation at 37 °C for all four nucleotides.

Spectra of the products of DNA degradation with benzonase and alkaline phosphatase show signals of oligonucleotides with different chain lengths. The most intensive signals were those of the dinucleotides, some of which also formed adducts. A total of seven different adducts with α-pinene oxide were characterized (Figure 1), and they are listed with the mononucleotide adducts in Table 1.
Figure 1. FTICR mass spectrum of enzymatically digested DNA. DNA adducts of α-pinene oxide shown as their dinucleotides are shown; seven of the possible ten dinucleotides are alkylated. The empirical formulas can be calculated from accurate mass determinations.

Table 1: DNA adducts resulting from the reaction with α-pinene oxide.

DNA adduct	m/z	Formula[a]	Accuracy [ppm]
dAMP	482.18072	$C_{20}H_{29}N_5O_7P$	0.6
dGMP	498.17611	$C_{20}H_{29}N_5O_8P$	0.38
dApdC	691.26342	$C_{29}H_{40}N_8O_{10}P$	3.4
dApdT	706.26088	$C_{30}H_{41}N_7O_{11}P$	0.23
dGpdC	707.25712	$C_{29}H_{40}N_8O_{11}P$	1.6
dApdA	715.27209	$C_{30}H_{40}N_{10}O_9P$	0.26
dGpdT	722.25681	$C_{30}H_{41}N_7O_{12}P$	1.6
dApdG	731.26880	$C_{30}H_{40}N_{10}O_{10}P$	2.2
dGpdG	747.26350	$C_{30}H_{40}N_{10}O_{11}P$	1.9

[a] Calculated formulas are based on the negatively charged ions $[M-H]^-$.

MS/MS and MS³ spectra obtained from collision activation revealed that the adduct formation occurs primarily at the purine bases within the dinucleotides. No fragment ion could be detected that would indicate a reaction of α-pinene oxide with a pyrimidine base, while the fragments at $m/z = 286$ and $m/z = 302$ are characteristic for the adenine and guanine adducts, respectively. All the adducts were also characterized by FTICR-MS; the spectra confirmed the results from the ion trap measurements and the empirical formulas of the adducts were also determined (see Table 1). The results indicate that α-pinene oxide reacts with DNA at more or less random positions. The reaction seems to occur primarily with purine bases, while pyrimidine bases are less frequently involved.

In addition to the exocyclic sites in DNA, such as the N2 and O6 positions of guanine, the N7 position of guanine seems to be especially reactive. The FTICR spectrum in Figure 2
Figure 2. FTICR mass spectrum of enzymatically digested DNA showing the mononucleotides and the N7 guanine/pinene oxide adduct.

shows the four unreacted mononucleotides as well as the guanine adduct at $m/z = 302.16225$ (0.6 ppm). The accurate mass measurement led to a formula of $C_{15}H_{20}N_5O_2$, which corresponds to the α-pinene oxide/guanine adduct.

The enzymatic digestion used here should result in mononucleotides or oligonucleotides depending on the enzymes. The α-pinene oxide/guanine adduct in Figure 2 presumably results from reaction at the N7 position of guanosine, because alkylation at this site weakens the N-glycosidic bond, subsequently leading to bond cleavage and removal of the alkylated base from the DNA strand. This effect has been reported previously in studies of styrene oxide alkylation.[19] Reaction at any other position of guanosine would not weaken the N-glycosidic bond and but would lead to either the corresponding mono- or oligonucleotide adduct depending on the enzyme. As a result of the hydrolytic cleavage of DNA, the very viscous reaction solution becomes fluid. A possible reaction mechanism is suggested in Scheme 1. No cleavage products could yet be identified for this hydrolysis of the remaining DNA. In addition to the guanine adduct, an adenine adduct could be found at $m/z = 286.16733$ (0.46 ppm), but the signal has lower intensity.
Scheme 1. The proposed reaction of α-pinene oxide at the N7 position of guanine, which leads to cleavage of the N-glycosidic bond and subsequent formation of the adduct.

The results reported here clearly indicate a reaction between α-pinene oxide and DNA. Although the concentrations used here are higher than in natural circumstances, the aim was to observe DNA adducts and provide sufficient structural information about a new class of xenobiotics that could have an effect on base-level DNA damage.

Experimental Section

Reaction: DNA (4–5 mg) was dissolved in 1 mL triply distilled water, combined with α-pinene oxide (25–100 μL), and then incubated at 37°C for 24–72 h. The reaction mixture was enzymatically digested using a) a combination of benzonase (25 U mg^{-1} DNA; Merck, Darmstadt, Germany) and alkaline phosphatase (1.75 U mg^{-1} DNA; Roche Diagnostics, Mannheim, Germany) or b) nuclease P1 (6 U mg^{-1} DNA; Roche Diagnostics, Mannheim, Germany) and incubated for 24 h at 37°C. The mononucleotides ($c = 1$ mg mL^{-1})

were dissolved in triply distilled water, combined with α-pinene oxide (75 μL), and also incubated at 37°C for 24 h. All reaction mixtures were analyzed without additional purification.

Mass spectrometric detection: A Bruker Esquire 3000 ion trap mass spectrometer was used. The mass range was scanned from $m/z =$ 50 to 2000, and two scans were added for each spectrum. MS/MS and MS^3 experiments were carried out inside the ion trap after the desired ion had been isolated; helium was used as the collision gas. Ions were isolated using a width of 0.5 Da. All samples were dissolved in acetonitrile in a ratio of 1:2 (v/v) and were introduced into the mass spectrometer using the direct-infusion mode with a flow rate of 2 μL s^{-1}. In general, scans were recorded for 2 min and afterwards averaged for a better signal-to-noise ratio. High-resolution mass measurements were obtained from a Bruker APEX III FTICR-MS employing a 7 T magnet. The instrument was equipped with an Agilent electrospray ion source. After ionization ions were stored inside of a hexapole for sampling times between 0.3 and 0.8 s and afterwards transferred to the cyclotron cell. The mass range was scanned from $m/z = 80$ to 2000 with 512k data points. For detection of DNA adducts up to 100 scans were accumulated for a better signal-to-noise ratio.

A Metal-Free Transfer Hydrogenation: Organocatalytic Conjugate Reduction of α,β-Unsaturated Aldehydes**

Jung Woon Yang, Maria T. Hechavarria Fonseca, and Benjamin List*

Hydrogenations of double-bond-containing compounds such as carbonyls, imines, and olefins are crucial for living organisms as well as for the industrial production of chemicals. While chemical hydrogenations require metal catalysts or the use of stoichiometric amounts of metal hydrides, nature typically relies on organic cofactors such as nicotinamide adenine dinucleotide (NADH) in combination with metalloenzymes. Metal-free catalytic hydrogenations of olefins have been unknown both in nature and in chemical synthesis.[1] Herein we disclose a highly efficient and remarkably chemoselective but completely metal-free catalytic transfer hydrogenation of α,β-unsaturated aldehydes.

The hydrogenation of α,β-unsaturated carbonyl compounds is a useful but challenging transformation. As both 1,2- and conjugate reductions readily occur, low selectivity for either of the two pathways is common. Catalytic hydrogenations of α,β-unsaturated aldehydes are possible, but the chemoselectivity is often low, and additional functional groups that are sensitive to hydrogenation conditions such as the benzyloxy, nitro, and nitrile groups are usually not tolerated.[2] Alternative conjugate reductions have been realized with various substrate classes,[3] but a mild, general, highly chemoselective, and catalytic variant that is applicable to α,β-unsaturated aldehydes has not been described.

Reported conjugate reductions of aldehydes are either non-catalytic and require stoichiometric amounts of an (organo)-metallic hydride source,[4] require elevated temperatures,[5] or show only modest selectivity.[6] Clearly, a mild, catalytic, and highly chemoselective variant is highly desirable.

Recently iminium catalysis emerged as a powerful method for the asymmetric catalysis of cycloadditions and conjugate additions to enals and enones.[7] We reasoned that this catalysis strategy might be applicable to the conjugate reduction of α,β-unsaturated carbonyl compounds if a suitable hydride donor could be identified.[8] Such a process would constitute the first metal-free catalytic transfer hydrogenation.

We found that several ammonium salts (5 mol%) readily catalyze the conjugate reduction of *o*-nitrocinnamaldehyde (**3a**) to the corresponding saturated analogue **4a** when the Hantzsch ester **1** (1.1 equiv) is also added at room temperature [Eq. (1), Table 1]. No reduction was observed in the

absence of catalyst after 48 h at room temperature. Cyclic as well as acyclic ammonium salts could be used, and the highest rate and yield was obtained with dibenzylammonium trifluoroacetate (**2a**). Interestingly, this catalyst was introduced in the 1970s by Corey et al. as an efficient catalyst for intramolecular aldol reactions of aldehydes.[9] Under our reaction conditions aldolization did not occur to any measurable extent. In addition to catalyst **2a**, the corresponding pyrrolidinium, morpholinium, and piperidinium salts as well as the Weinreb salt **2b** can be used as catalysts.[10] Ammonium salt **2b** has been used previously in the iminium catalysis of the Diels–Alder reaction.[11]

After identifying an efficient and chemoselective iminium catalyst for the conjugate reduction of enal **3a**, we decided to explore the scope of this new process with a variety of

different aldehydes [Eq. (2), Table 2)]. The reduction works extremely well with a diverse set of unsaturated aldehydes, including substituted aromatic and aliphatic ones, and the

yields exceed 90 % in almost all cases. Both β-mono- and β,β′-disubstituted enals can be reduced, although so far we have been unable to use enals with an additional substituent at the α-position. Besides the carbonyl group of aldehydes and ketones, a variety of functional groups that are sensitive to standard hydrogenation conditions are tolerated in the

process. These include the nitro, nitrile, benzyloxy, and alkenyl functional groups, which all survive the reaction conditions, illustrating the remarkable chemoselectivity of this novel organocatalytic reaction.

In terms of the mechanism we assume the reaction to proceed by the iminium catalysis cycle illustrated in Scheme 1. Accordingly, after an initial reversible formation
Scheme 1. Proposed mechanism of iminium catalysis.

of iminium ion **5** (which effectively lowers the LUMO energy of the substrate), conjugate hydride and proton transfer from dihydropyridine **1** follows. This step generates pyridine **7** along with iminium ion **6**. Hydrolysis then releases saturated aldehyde product **4** and regenerates catalyst **2a**. We suggest the hydride transfer to proceed via transition state **A**.

We are also developing an asymmetric variant of this reaction. For example, treating aldehyde **3i** with dihydropyridine **1** in the presence of catalyst **8** furnished (*R*)-**4i** in good yield and in 81 % *ee* [Eq. (3)].

$$(3)$$
In summary, we have developed the first metal-free catalytic transfer hydrogenation. This novel iminium catalytic conjugate reduction of α,β-unsaturated aldehydes is highly efficient and chemoselective. It requires low catalyst loadings and tolerates various functional groups that are sensitive to the conditions of standard hydrogenations and alternative conjugate reductions. Current work in our laboratory focuses on a) expanding the scope of the reaction even further to include other substrate classes such as ketones and α-substituted α,β-unsaturated aldehydes, b) improving the overall atom economy, potentially by regeneration of the cofactor in situ,[12] c) including the reaction in tandem sequences

Communications

utilizing the presumed enamine intermediate,[13] and d) developing an efficient catalytic asymmetric variant. First results will be reported shortly.

Experimental Section

General procedure for the transfer hydrogenation reaction: Synthesis of aldehyde **4a**: To a solution of *o*-nitrocinnamaldehyde (**3a**, 88.6 mg, 0.5 mmol) and catalyst **2a** (7.8 mg, 0.025 mmol, 5 mol%) in dry THF (2 mL) was added dihydropyridine **1** (140 mg, 0.55 mmol, 1.1 equiv). The reaction mixture was stirred at room temperature for 5 h under argon, after which the solvent was removed and the residue was chromatographed on silica gel (30% diethyl ether/*n*-hexane) to give 84 mg (94%) of **4a** as an oil. All aldehydes **3** and **4** are commercially available or have been described previously, and their analytical data match literature values.

Selecting Different Complexes from a Dynamic Combinatorial Library of Coordination Compounds**

Markus Albrecht, Ingo Janser, Jan Runsink,
Gerhard Raabe, Patrick Weis, and Roland Fröhlich*

*Dedicated to Professor Heinz Balli
on the occasion of his 75th birthday*

Metallosupramolecular chemistry has developed over the last twenty years to an important and still growing field of research.[1] Supramolecular aggregates of different shapes were obtained by the use of well-designed organic ligands in combination with appropriate metal ions or metal complex fragments. Although a series of different approaches have been discussed about how the formation of supramolecular

coordination compounds can be controlled,[2] additional knowledge on the elementary processes of self-assembly is still required.

"Dynamic combinatorial chemistry" is a concept that uses the formation of dynamic combinatorial libraries (or virtual libraries) followed by a selection step which at the end ideally produces only one compound.[3] A dynamic combinatorial library can be either formed by the introduction of labile covalent bonds or by noncovalent interactions between the molecular building blocks.[4] In coordination chemistry it is relatively simple to obtain libraries (mixtures!) of compounds[5] and some examples are known, for which it was possible to select and enhance one species from such a library.[6] However, the selection of different species from the same library was described only in a few cases and still remains a challenge.[7]

Recently we described the formation of the supramolecular tetrahedron $[(1)_4Ti_4]^{8-}$ from the rigid tris(catechol) ligand 1-H$_6$ (Scheme 1). The tetrahedron $[(1)_4Ti_4]^{8-}$ possesses

$[(1)_4Ti_4]^{8-}$ $[(2)M]^{n-}$

dominated by intramolecular hydrogen bonding. In the free ligand, hydrogen bonds are formed between catechol-OH groups and the amide oxygen atom (**A**; Scheme 2) Deproto-
Scheme 2. Comparison of the preferred conformation at catechol amides with that of the corresponding catechol imines.

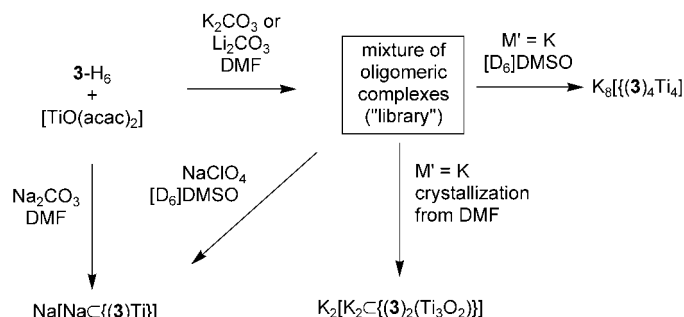
Scheme 1. C_3-symmetric ligands 1-H$_6$–3-H$_6$, which form either tetranuclear $[(1)_4Ti_4]^{8-}$ or mononuclear $[(2)M]^{n-}$ coordination compounds.

a huge internal cavity for guest binding.[8] A few similar molecular tetrahedra from rigid ligands were already known, which, however, did not possess internal cavities.[9] We were interested to test if flexible ligands are also able to form M$_4$L$_4$ tetrahedra.

The well-known flexible tris(catechol) ligand 2-H$_6$ does not form a molecular tetrahedron, instead mononuclear complexes $[(2)M]^{n-}$ are obtained with metal ions.[10–12] The conformation of flexible catechol amide ligands such as 2 is

nation and metal complexation of the ligand leads to rotation of the $C_{catechol}$–C_{amide} bond, and hydrogen bonding occurs between the amide-NH and the catecholato-oxygen atom (**B**). This supports the formation of the mononuclear complex $[(2)M]^{n-}$.[11,13] With catechol imines (e.g. **3**) the orientation of the catechol-C-N spacer moiety is opposite to that of the amides. In the free ligand, hydrogen bonding occurs between the catechol and the imine (**C**); in this case deprotonation and metal complexation lead to repulsion between the electron pairs at oxygen and nitrogen, and the conformation **D** is adopted.[14] The difference in the conformation of coordinated catechol amides (**B**) and catechol imines (**D**) makes the imines superior ligands for the formation of molecular containers, if a huge cavity is desired.[8] The cavity of the corresponding catechol amides will always be smaller. In addition, conformation **E** has to be discussed for the catechol imines. A templating metal ion M′ binds to the internal catecholato oxygen atom as well as to the imine nitrogen atom, thus compensating the repulsion of the free O and N electron pairs.[15]

The tris(catechol) derivative 3-H$_6$ with flexible connecting alkyl units was introduced by Vigato et al. to coordinate as an N$_3$O$_3$-Schiff base ligand to a series of metal ions.[16] We were

interested in using **3**-H$_6$ as an O$_6$ ligand for transition metal ions (e.g. titanium(IV)).[12] In our case, it should be possible to obtain different coordination compounds depending on the coordination mode (**D** or **E**) of the catechol imine unit. A conformation of type **D** should disfavor the formation of a mononuclear transition-metal complex and it is expected that the formation of a molecular tetrahedron is more likely. The conformation **E** with the bound cation M′, which acts as a template and is encapsulated in the cavity of [(**3**)Ti]$^{2-}$, should stabilize the mononuclear complex (Scheme 3)


Scheme 3. Formation of a mixture of titanium(IV) complexes ("library") of ligand **3** from which different coordination compounds can be obtained by selection or separation.

A coordination study of **3**-H$_6$ (1 equiv) with [TiO(acac)$_2$] (1 equiv; acac = actylacetonate) was performed in the presence of lithium, sodium, and potassium carbonate (1 equiv) in DMF. Immediately after removal of the solvent and volatiles in vacuum, ^{1}H NMR spectra were measured in [D$_6$]DMSO (see the Supporting information for the NMR spectra discussed). The spectra show that with lithium and potassium carbonate no defined coordination compounds could be obtained, but mixtures of different species are formed. Similar undefined spectra were obtained by recording the ^{1}H NMR spectrum of the mixture of complexes with potassium cations in [D$_7$]DMF. On the other hand, the use of sodium carbonate results in a nicely resolved NMR spectrum, in which the signal of the imine-hydrogen atom is shifted to $\delta = 8.14$ ppm—this is typical for conformation **E**. Orientation of the proton towards the catecholato oxygen atom (like in **D**) would result in an anisotropic shift and the resonance would be expected at $\delta = 8.5$ ppm or lower.[14] This spectroscopic finding already supports the presence of a mononuclear complex of the type Na$_2$[(**3**)Ti]. The ^{23}Na NMR spectrum shows two signals at room temperature, indicating binding of one of the Na$^+$ ions to the titanium complex [(**3**)Ti]$^{2-}$. The signal of the solvated sodium ion is observed at $\delta = 0$ ppm, that of the other at $\delta = 10.4$ ppm, which is indicative for an O$_x$N$_y$ coordination environment.[17] At low temperature the signal at $\delta = 10.4$ ppm splits into two, a process which is not understood yet. As a hypothesis it is assumed that two diastereomers are formed with a homochiral or heterochiral relation between the sodium and titanium complex units. The epimerization barrier for the titanium(IV) complex can be estimated from ^{1}H NMR measurements in [D$_7$]DMF at variable temperature to be $\Delta G^{\ddagger} = 46.0$ kJ mol^{-1}.

The presence of a mononuclear titanium complex was shown by the X-ray structure analysis of Na[Na⊂{(**3**)Ti}]·3 DMF (Figure 1).[18] Ligand **3** and titanium(IV) form a mononuclear complex in which the imine-nitrogen atoms
Figure 1. Representation of [Na⊂{(**3**)Ti}]$^-$ (a) and [(H$_2$O)-K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}]$^{2-}$ (b) as found in the solid state. c) The central tris(titaniumdioxo) cluster moiety of [(**3**)$_2$(Ti$_3$O$_2$)]$^{4-}$. C: black; O: red; N: green; Ti: yellow; Na: pink; K: blue.

are orientated towards the interior. The cavity seems to be ideal for the uptake of a sodium ion which acts as a template. Lithium or potassium ions are not the correct size for this purpose. However, addition of sodium perchlorate to the mixture of oligomeric complexes, which is formed in the presence of Li$^+$ or K$^+$ ions, results in the quantitative formation of the metallacryptate [Na⊂{(**3**)Ti}]$^-$.[19]

The cavity of [(**3**)Ti]$^{2-}$ is too small for the uptake of K$^+$ ions. However, we were able to crystallize a titanium(IV) complex of ligand **3**, namely K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}], from DMF/diethyl ether in the presence of potassium ions.[18] The complex was formed by K$^+$ templating and possesses two cryptand-type units that are suitable for binding two of the potassium ions. Two ligands **3** coordinate to a tris(titanium-dioxo) cluster[20] from its upper and lower side, respectively. One of the potassium ions coordinates to three imine-nitrogen and three catecholato-oxygen atoms of the first ligand **3** and additionally binds to the central oxygen atom of the Ti$_3$O$_2$ cluster. A second potassium ion binds to three catecholato oxygen atoms of the second ligand **3**, but to only two of the imine nitrogen atoms. In the solid state the coordination sphere at this potassium ion is completed by a water molecule, which functions as a bridge to a further potassium ion. Owing to the templating of the big potassium ions a trinuclear titaniumoxo cluster is stabilized by ligand **3**, providing an appropriate cavity for the template. The five catechol imines, which coordinate through their imine-nitrogen atoms to the potassium ions, possess conformation **E**,

while, as expected, the non-coordinating unit is orientated as shown in **D**.[16]

A few crystals of K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}] (ca. 0.1 mg) were dissolved in [D$_7$]DMF and a ^{1}H NMR spectrum was measured. The resonances of the ethylene units of **3** are not resolved. However, the signals of the aromatic moieties as well as of the imines are very informative. Five of the six imine protons are observed as singlets at δ = 8.49, 8.42, 7.98, 7.60, and 7.56 ppm (1 H each). The sixth -C*H*=N is probably hidden under the peak of the resonance of the DMF proton at δ = 8.06 ppm. The protons of the aromatic groups in K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}] appear at δ = 6.94 (d, *J* = 7.5 Hz, 1 H), 6.81 (d, *J* = 6.9 Hz, 1 H), 6.63 (d, *J* = 7.8 Hz, 1 H), 6.56 (t, *J* = 7.8 Hz, 1 H), 6.49 (m, 2 H), 6.37 (m, 3 H), 6.26 (t, *J* = 7.5 Hz, 2 H), 6.18 (t, *J* = 7.6 Hz, 1 H), 5.98 (m, 5 H), and 5.67 ppm (t, *J* = 8.3 Hz, 1 H). The spectrum shows that K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}] possesses the same low symmetry in solution as was observed in the solid state. Attempts to synthesize K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}] in higher yield by choice of the correct ligand-to-metal stoichiometry did not result in the formation of a specific complex. Therefore K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}] has to be considered as a side product of the reaction of **3** with titanium(IV) ions in the presence of potassium ions and can be separated by crystallization.

The NMR spectrum of a solution of the oligomeric complexes "{K$_2$[(**3**)Ti]}$_n$" in [D$_7$]DMF does not change over a period of several days. However, keeping a [D$_6$]DMSO solution of the mixture for some hours at room temperature, leads to a simplification of the ^{1}H NMR spectrum. Finally, besides the signals for trace amounts of side products, one dominating set of signals can be observed at δ = 8.58 (s, imine-H), 6.86 (d, *J* = 8.1 Hz), 6.27 (t, *J* = 8.1 Hz), and 6.08 ppm (d, *J* = 8.1 Hz). Owing to the high symmetry associated with this spectrum, it can not be assigned to an unsymmetric species such as K$_2$[K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}]. In addition, the signals at δ = 8.6 and 6.85 ppm indicate that an "outward" orientation of the imine-nitrogen atoms occurs (**D**). The imine proton hereby approaches the free electron pairs of the catecholato-oxygen atoms and experiences a low-field shift. A similar effect is observed for the aromatic proton of the catechol unit, which is located close to the imine-nitrogen atom. Owing to the electron pair at the N atom this aromatic proton is shifted to low field. From the orientation of the imine groups and the high symmetry of the compound, we deduce that the complex adopts the structure of a supramolecular tetrahedron K$_8$[(**3**)$_4$Ti$_4$] (Figure 2). Negative-ion FT-ICR-MS (Fourier transform ion cyclotron resonance mass spectrometry) in DMSO shows peaks with the correct isotopic pattern at *m*/*z* 1213.5 {K$_6$[(**3**)$_4$Ti$_4$]}$^{2-}$, 795.6 {K$_5$[(**3**)$_4$Ti$_4$]}$^{3-}$, 783.3 {HK$_4$-[(**3**)$_4$Ti$_4$]}$^{3-}$, 770.6 {H$_2$K$_3$[(**3**)$_4$Ti$_4$]}$^{3-}$, 587.7 {K$_4$[(**3**)$_4$Ti$_4$]}$^{4-}$, and 577.8 {HK$_3$[(**3**)$_4$Ti$_4$]}$^{4-}$, which confirm the presence of the molecular tetrahedron K$_8$[(**3**)$_4$Ti$_4$].

Addition of NaClO$_4$ to a solution of K$_8$[(**3**)$_4$Ti$_4$] in [D$_6$]DMSO leads to a fast transformation of the tetrahedron into the mononuclear compound [Na⊂{(**3**)Ti}]$^-$, which can be nicely monitored by ^{1}H NMR spectroscopy. This shows that this sodium ion stabilized mononuclear titanium(IV) complex is the thermodynamically most stable species in the presented system.
Figure 2. A model of the tetrahedral octaanion [(**3**)$_4$Ti$_4$]$^{8-}$, which was generated by using the Spartan O2 (MMFF) program[21] and graphically represented by using the Schakal 99 progam.

The described results represent a nice example for dynamic combinatorial chemistry, in which a dynamic library of complexes is formed in DMF solution in the presence of potassium ions. From this library three different coordination compounds [Na⊂{(**3**)Ti}]$^-$, [(H$_2$O)K$_2$⊂{(**3**)$_2$(Ti$_3$O$_2$)}]$^{2-}$, or [(**3**)$_4$Ti$_4$]$^{8-}$ can be obtained by addition of an appropriate template, by crystallization, or by equilibration of the mixture in DMSO. Competition experiments show that the mononuclear complex [Na⊂{(**3**)Ti}]$^-$ seems to be the thermodynamically most favored species. For the assembly of a M$_4$L$_4$ complex, sodium ions have to be excluded. We intend to extend this concept further, and to use it for the assembly of other large supramolecular aggregates.

Cyclizations

Synthesis of Stereohomogeneous Cyclopropanecarbaldehydes and Cyclopropyl Ketones by Cycloalkylation of 4-Hydroxy-1-alkenyl Carbamates**

*Rainer Kalkofen, Sven Brandau, Birgit Wibbeling, and Dieter Hoppe**

Only a few methods are known for the synthesis of optically active cyclopropanecarbaldehydes and cyclopropyl ketones by ring-forming reactions.[1–3] Taylor et al.[4] very recently described the synthesis of several racemic, disubstituted cyclopropanecarbaldehydes by intramolecular cycloalkylation of (Z)-4-hydroxy-2-alkenyl N,N-diisopropylcarbamates **1** by activation of the hydroxy group with trifluoromethanesulfonic anhydride (Tf$_2$O; Scheme 1).
Scheme 1. Cyclopropane formation according to Taylor et al. Cb = CON*i*Pr$_2$, Tf = triflate.[4]

We found in our initial studies that this method can be extended to the synthesis of optically active, trisubstituted cyclopropanecarbaldehydes and cyclopropyl ketones **8** starting from compounds **4**, which in turn are readily obtained by enantioselective homoaldol reaction in the presence of (−)-sparteine[5–7] (Scheme 2). According to Taylor et al., the (Z)-anti homoallylic alcohols **4** are converted into the corresponding triflates **5**, which undergo immediate intramolecular attack by the weakly nucleophilic enol carbamate moiety.[8] The substitution step (Scheme 3, Method A) proceeds with complete stereoinversion, leading to a *cis* arrangement of R^2 and R^3 and placing the acyl residue into the *trans* position to both of them via transition state **5**.

Scheme 2. Enantioselective synthesis of 4-hydroxy-1-alkenyl carbamates **4**. **4g–p**: R^1 = Ph, **4a–f**: R^1 = H, R^2, and R^3 in Table 1.

During the course of our work we made a surprising observation: simply treating the homoaldol adducts **4** with sodium hydride furnished the cyclopropanes **8** with excellent diastereoselectivity and complete chirality transfer (Method B, Scheme 3, Table 1). When alcohols **4** and sodium hydride were heated in THF or DMF for several hours, the cyclopropanes **8a–p** formed smoothly with the same efficiency as that observed for Method A. Apparently the N,N-diisopropylcarbamoyl group in alkoxide **6** migrates to the O4 atom,[9] forming the (Z)-enolate **7**, which undergoes cycloalkylation by nucleophilic substitution of the carbamate group with strict stereoinversion. The enolate moiety occupies an *anti* position in transition state **7** in order to avoid steric repulsion with R^2 and R^3. Method B also works well

Scheme 3. Synthesis of highly enantioenriched disubstituted cyclopropanes.

even when a formyl group is generated (Table 1, entries 3 and 5).

The relative configuration of **8h** was confirmed by a single-crystal X-ray analysis.[10] The absolute configuration of the precursor **4** is retained at C3, and the ee values of the products **8** correspond to those of the starting compounds **4** (Table 1). The combination of the cycloalkylation with the (−)-sparteine-mediated homoaldol reaction results in a two-step stereoselective route to cyclopropyl ketones.[11] The N,N-diisopropylcarbamoyl group is required for the activation in the deprotonation step of the homoaldol reaction. Moreover,

through the carbamoyl migration both the nucleophilic and the electrophilic properties of the stable precursors **4** are activated. These features fulfill in an exemplarily manner one demand of modern organic synthesis, namely minimizing the number of steps in a synthetic sequence.[12]

Experimental Section

Synthesis of cyclopropanecarbaldehydes and cyclopropyl ketones:

Method A: A flame-dried flask was charged with **4b** (199 mg, 0.3 mmol, 1 equiv) in 10 mL CH$_2$Cl$_2$ under an argon atmosphere. 2,6-Lutidine (140 mg, 1.3 mmol, 4 equiv) was added by syringe, the solution was cooled to −78 °C, and then freshly distilled triflic anhydride (314 mg, 1.1 mmol, 3 equiv) was injected. The reaction mixture was stirred for 1 h, quenched with 1 mL water, and allowed to warm to room temperature. The mixture was diluted with 25 mL CH$_2$Cl$_2$, the aqueous phase was separated, and the organic layer was washed with saturated NaHCO$_3$ solution (1 × 10 mL). The organic phase was dried over MgSO$_4$ and the solvent evaporated in vacuum. The crude product was purified by flash chromatography on silica gel (diethyl ether/*n*-pentane 1:10).

Method B: To the *anti*-homoaldol adduct **4i** (169 mg, 0.37 mmol, 1 equiv) was added sodium hydride (60% in mineral oil; 20 mg, 0.5 mmol, 1.35 equiv). The flask was placed under argon, THF (2 mL) was injected, and the resulting solution was heated for 14 h at 60 °C. When DMF was used as the solvent the solution was stirred 1 h at room temperature and then heated for 2–12 h at 60 °C (tlc control). For workup 10 mL saturated sodium chloride solution was added. The aqueous phase was separated and extracted with diethyl ether (3 × 25 mL). The combined organic extracts were dried over MgSO$_4$ and the solvents evaporated in vacuum. The crude product **8i** was purified by flash chromatography on silica gel (diethyl ether/*n*-pentane 1:5). For yields and enantiomeric excesses see Table 1.

Cyclopropanes

Enantioselective Synthesis of Cyclopropanes by Aldehyde Homologation**

Christina A. Risatti and Richard E. Taylor

The prevalence of cyclopropane-containing compounds with biological activity, whether isolated from natural sources or rationally designed pharmaceutical agents, has inspired chemists to find novel and diverse approaches to their synthesis.[1] We recently reported an efficient two-step homoaldol/activation sequence that resulted in the isolation of racemic 1,2-disubstituted cyclopropyl aldehydes.[2] Herein we demonstrate the successful preparation of enantiomerically enriched and diastereomerically pure 1,2,3-trisubstituted cyclopropyl aldehydes by asymmetric metalation chemistry. In essence, this two-step procedure provides a three-carbon homologation of an aldehyde to give a nonracemic, stereochemically rich cyclopropyl aldehyde, [Eq. (1)].
Hoppe et al. have elegantly demonstrated that homoaldol adducts are readily available from (E)-butenyl N,N-diisopropylcarbamates **1** through deprotonation with nBuLi/(−)-sparteine complex and transmetalation with Ti(OiPr)$_4$.[3] Condensation with an aldehyde was shown to provide O-enecarbamates **2** with high diastereoselectivity and good enantioselectivity [Eq. (2)].
Carbamate **1** is readily prepared through condensation of N,N-diisopropyl carbamyl chloride with crotyl alcohol in refluxing pyridine. A series of aldehydes were applied to the described homoaldol conditions using the crotyl substrate as a

representative example. Aliphatic aldehydes, including sterically hindered substrates, resulted in high yields of (Z)-homoaldol adducts **3–5** with high *anti* selectivity as expected (Table 1). In addition aromatic aldehydes, including benzaldehyde and tolualdehyde, performed well in the coupling reaction to provide **6** and **7**, respectively (Table 1). In each case, the diastereoselectivity was >95:5 by crude ^{1}H NMR analysis.

Table 1: Trisubstituted cyclopropanes from O-enecarbamates.[a]

Homoaldol adduct	Yield [%]	Cyclopropane	Yield [%], e.r.
3	92	**8a**	91, 93:7
4	85	**9a**	82, 92:8
5	84	**10a**	96, 93:7
6	87	**11a**	92, 83:17
7	89	**12a**	73, 90:10[b]

[a] Reaction conditions: Tf$_2$O, 2,6-lutidine, toluene, −78°C to −50°C.
[b] Two minor diastereomers were also observed in this case (5:1:1 ratio).

Exposure of homoaldol adducts **3–7** to triflic anhydride and 2,6-lutidine provided good to excellent yields of 1,2,3-trisubstituted cyclopropyl aldehydes **8a–12a** (Table 1). In contrast to our previous study[2] these cyclization substrates were more sensitive to the reaction conditions. When our standard activation conditions were employed, in CH$_2$Cl$_2$, multiple products were observed. However, when the reaction solvent was conducted in toluene, the inherent rate and alternative reaction pathways could be reduced such that the reaction was driven toward the formation of the desired cyclopropyl aldehyde products **8a–12a**. The enantiomeric purity of the cyclopropane derivatives was determined by reduction of the aldehyde with lithium aluminum hydride and analysis of the Mosher esters.[4] The observed enantiomer ratios corresponded well with expected enantioselectivity of the starting homoaldol adducts,[3] suggesting the cyclization step proceeds in a stereospecific manner.

The aliphatic systems provided high yields and diastereoselectivity for the cyclopropyl aldehyde products **8a–10a**. In each case, the ring closure takes place with inversion of configuration at the alcohol center.[5] In contrast, reduced diastereoselectivity was observed upon activation of homoaldol adduct **7**. The inductively donating methyl group appears to promote equilibration of the oxonium ion intermediate **13** through the homoallylic cation **14** [Eq. (3)]. Under these conditions no products resulting from elimination were observed.

Communications

(3)

Ideally one would like access to both enantiomers of the cyclopropyl aldehyde products. In fact, Beak et al. have demonstrated that *N*-(*tert*-butoxycarbonyl)-*N*-(*p*-methoxy-phenyl)cinnamyl amine **15** and *N*-(*tert*-butoxycarbonyl)-*N*-(*p*-methoxyphenyl)-3-cyclohexylallylamine **16** undergo asymmetric deprotonation by an *n*BuLi/(−)-sparteine complex [Eq. (4)].[6] However, in this case, transmetalation with Ti(O*i*Pr)₃Cl followed by quenching with an aldehyde furnished the enantiomeric, complementary homoaldol adducts.

(4)

R¹=*p*-methoxyphenyl, R²= Boc

15 R³=Ph
16 R³=cyclohexyl
17 R³=Me
The aldehydes used previously to generate the *O*-enecarbamates were subjected to the Beak homoaldol protocol. To complement the earlier work, the substrates were preformed with crotylamine **17**, and the yields and selectivities corresponded nicely with those observed by Beak for the cyclohexyl and cinnamyl systems. The (*Z*)-*N*-enecarbamates **18–22** were isolated with predominantly *anti* stereochemistry and the diastereoselectivity was >95:5 by crude ¹H NMR analysis (Table 2). Homoaldol adducts **18–22** were activated with triflic anhydride and 2,6-lutidine to provide aldehydes

8b–12b in good to excellent yield. Again, the enantioselectivity of the cyclopropane products corresponded well with the expected enantiomer ratios from the homoaldol coupling, suggesting the cyclization step proceeds with complete stereospecificity.

In this system, cyclization of the aliphatic substrates **18–20** proceeded cleanly in CH₂Cl₂. However, care was taken with the activated aryl systems, and toluene was used as the reaction solvent. It is notable that, in contrast to *O*-enecarbamate substrate **7**, activation of *N*-enecarbamate **22** provided **12b** as a single diastereomer. The iminium ion intermediate, present in solution prior to quenching, is apparently more stable than the corresponding oxonium ion intermediate, and therefore, an equilibrium with its homo-allylic cation is not relevant (Figure 1). Although the method

oxonium ion   iminium ion
Figure 1.

has been applied to 1,2,3-trisubstituted cyclopropyl aldehydes containing a methyl substituent, alternative allylamine derivatives are expected to provide diversely substituted cyclopropanes and broaden the scope of this two-step three-carbon homologation procedure.

In conclusion we have demonstrated the stereospecific cyclization of enantiomerically enriched homoaldol adducts. This chemistry is a remarkably efficient method for the homologation of readily available aldehydes to give non-racemic, stereochemically rich 1,2,3-trisubstituted cyclopropyl aldehydes.[7] Application of this method to the preparation of biologically relevant cyclopropanes is currently underway in our laboratories and will be reported in due course.

Natural Products

Total Synthesis of Apoptolidinone**

Bin Wu, Qingsong Liu, and Gary A. Sulikowski

*Dedicated to Professor Amos B. Smith, III
on the occasion of his 60th birthday.*

Polyketide-derived secondary metabolites have long served as a source of structurally diverse and biologically active natural products.[1] In the course of screening soil microorganisms for cell-specific apoptosis-inducing agents, Hayakawa and co-workers isolated the polyketide natural product apoptolidin (2) from *Nocardiopsis* sp.[2] Apoptolidin induces

apoptolidinone (1) (R = R' = H)   apoptolidin (2)
programmed cell death in E1A-transformed cells but not in normal cells.[2a] Khosla, Salomon, and co-workers later correlated this cell-specific activity to the inhibition of mitochondrial F_0F_1-ATPase by apoptolidin as well as other polyketide natural products.[3] Structurally, apoptolidin features an unsaturated 20-membered macrolide, a six-membered hemiketal, and three hexose sugars.[2b] In 2001 Koert and co-workers reported the synthesis of apoptolidinone (1) and later the same year Nicolaou and co-workers described the total synthesis of apoptolidin.[4–6] The latter total synthesis and other recent work has demonstrated that apoptolidin is a rather labile compound that undergoes a base-induced acyl migration from the C19 to C20 hydroxy group to produce isoapoptolidin,[7] a compound that is less active against

mitochondrial F_0F_1-ATPase.[7a] Although evaluation of the cytotoxicity of select analogues has suggested the three hexose sugars of apoptolidin to contribute significantly to the overall cytotoxicity of **2**,[3c,5e,8] biological evaluation of the aglycone, apoptolidinone (1), has not been reported. We describe herein the total synthesis of apoptolidinone.

Besides the synthetic approach to apoptolidin (2) described by Toshima and co-workers,[6a] all previous synthetic strategies directed towards apoptolidin have relied on a linear approach in which the seco acid was assembled and subsequently subjected to a macrolactonization. To develop a more convergent assembly we retrosynthetically divided apoptolidinone into four fragments (4–7, Scheme 1). We planned to couple the four fragments through a combination of two diastereoselective aldol reactions, a Grubbs cross-metathesis reaction, and an intramolecular Suzuki–Miyaura cross-coupling reaction.

Construction of fragment 4 started from (S)-malic acid (8), which was converted into 3-methoxy-γ-butyrolactone (9) through a known four-step reaction sequence.[9] Reduction of lactone 9 with DIBAL-H afforded lactol 10, which on condensation with 1,3-propanedithiol afforded dithiane 11. Swern oxidation of primary alcohol 11 provided aldehyde 12 in near quantitative yield. A five-carbon unit was introduced to aldehyde 12 by chelation-controlled addition of the Grignard reagent derived from bromide 13 to provide secondary alcohol 14 as a single isomer (Scheme 2). Bromide 13 was prepared from dihydrofuran according to the Kocien-
Scheme 1. Retrosynthetic analysis of apoptolidinone (1). TES = triethylsilyl, TBS = *tert*-butyldimethylsilyl.

ski procedure described by Koert and co-workers in their reported synthesis of apoptolidinone.[4a,10] A solution of 14 in dichloromethane was treated sequentially with iodine, triethylchlorosilane, and imidazole in one pot to provide vinyl iodide 16 in 90% overall yield from 14. The dithiane group of 16 was hydrolyzed efficiently by using the Fetizon–Jurion procedure to provide aldehyde 17 in 68% yield (as well as recovered 16 (19%)).[11]

Homoallylic silyl ether 18 was produced by the asymmetric addition of the diisopropyl tartrate ester derived (Z)-crotylboronate reagent developed by Roush et al.[12] to the pinacol ester of 3-boronoacrolein,[13] followed by silylation (TESOTf, 2,6-lutidine) of the crude crotylation product. The *syn* homoallylic ether 18 (single diastereomer, 80% ee) was

Scheme 2. Synthesis of fragment **4**. a) DIBAL-H, THF, −78 °C; b) 1,3-propanedithiol, BF₃·OEt₂, CH₂Cl₂, 28 °C, 60 % from **9**; c) (COCl)₂, DMSO, iPr₂NEt, −78→0 °C, 98 %; d) **13**, Mg, 1,2-dibromoethane, Et₂O, −78 °C, 68 %; e) I₂, CH₂Cl₂, 0 °C; f) TESCl, ImH, CH₂Cl₂, 28 °C, 90 % from **14**; g) MeI (excess), K₂CO₃, MeCN/pH 7 buffer (4:1), 28 °C, 68 % (plus 19 % recovered **16**); h) **18**, [Pd(Ph₃P)₄], TlOH, THF/H₂O (3:1), 28 °C, 70 %. DIBAL-H = diisobutylaluminum hydride, DMSO = dimethyl sulfoxide, ImH = imidazole.

obtained in 43 % yield over two steps. Suzuki–Miyaura cross-coupling between vinyl iodide **17** and vinyl boronate **18** provided diene **4** in 70 % yield (Scheme 2).[14]

The stereochemical relationship between C19 and C20 (see **20**) was established by a diastereoselective Mukaiyama aldol condensation between aldehyde **4** and enol silane (Z)-**19** (derived from 1,2-butanediol in three steps) to afford ketone **20** as the major product with a 4:1 ratio of isomers (Scheme 3). The assigned C19–C20 relative stereochemistry rested on the observed coupling constant of the aldol product ($J_{19,20} = 3.5$ Hz) and the 1,3-asymmetric induction model proposed by Evans and co-workers for β-methoxyaldehydes.[15] Yamaguchi esterification of **20** with carboxylic acid **5** led to isolation of dienoate **21** in 83 % yield.[16] Kinetic deprotonation (LHMDS, HMPA, THF, −78 °C) of **21** followed by aldol condensation with aldehyde **6**[17] afforded *syn* aldol product **22** as a single isomer in 41 % yield (plus 30 % recovered **21**).[18] After silylation of **22** to give **23** we examined a series of cross-metathesis reactions with propenyl boronate to provide vinyl boronate **25**.[19] The Grubbs second-generation catalyst **24** provided **25** in up to 30 % yield (plus 30 % recovered alkene **23**). Remarkably, this reaction provided **25** as a single isomer that was immediately subject to an intramolecular Suzuki–Miyaura cross-coupling to give macrolactone **3** in 47–60 % yield. Exhaustive desilylation of **3** provided apoptolidinone (**1**) in 61 % yield. Our synthetic apoptolidinone matched, in all respects, the spectral data reported by Koert and co-workers for their synthetic sample.[4a]
Scheme 3. Synthesis of apoptolidinone (**1**). a) BF₃·OEt₂, CaH₂, CH₂Cl₂, −94 °C, 50 % (plus 34 % recovered **4**); b) **5**, 2,4,6-trichlorobenzoyl chloride, Et₃N, DMAP, toluene, −78→28 °C, 83 %; c) LHMDS, THF, HMPA, −78 °C, 2 h; then **6**, THF, 41 % (plus 30 % recovered **21**); d) TESOTf, 2,6-lutidine, CH₂Cl₂, 0 °C, 81 %; e) **24**, isopropenyl pinacol boronic ester (18 equiv), CH₂Cl₂, reflux, 6 h, 30 % (plus 30 % recovered **23**); f) [Pd(Ph₃P)₄], Tl(OEt), THF/H₂O (3:1), 28 °C, 30 min, 60 %; g) HF·py, THF, −10 °C, 12 h; then −5 °C, 5 h, 61 %. DMAP = 4-(dimethylamino)pyridine, LHMDS = lithium hexamethyldisilazide, HMPA = hexamethylphosphoramide, Tf = trifluoromethanesulfonyl.

In summary, apoptolidinone was synthesized from 3-methoxy-γ-butyrolactone (**9**) in 14 steps (longest linear sequence). Key steps of the synthesis include two diastereoselective aldol reactions, a cross-metathesis reaction, and two Suzuki–Miyaura cross-coupling reactions. We anticipate that this synthesis will provide access to modified derivatives of apoptolidin for utilization in studies on the cell-specific cytotoxicity of the parent natural product.[20]

[20] We employed the synthetic route described herein to produce 2–4 mg of apoptolidinone, which is currently undergoing biological evaluation in a side-by-side comparison with apoptolidin itself.

Binary Group 15 Azides

Polyazide Chemistry: Preparation and Characterization of As(N₃)₅, Sb(N₃)₅, and [P(C₆H₅)₄][Sb(N₃)₆]**

Ralf Haiges,* Jerry A. Boatz, Ashwani Vij, Vandana Vij, Michael Gerken, Stefan Schneider, Thorsten Schroer, Muhammed Yousufuddin, and Karl O. Christe*

The binary arsenic and antimony azide species $As(N_3)_3$,[1–3] $[As(N_3)_4]^+$,[4] $[As(N_3)_4]^-$,[4] $[As(N_3)_6]^-$,[4,5] $Sb(N_3)_3$,[3,6] $[Sb(N_3)_4]^+$,[4] $[Sb(N_3)_4]^-$,[4] and $[Sb(N_3)_6]^-$[4] have been reported, and the crystal structures of $As(N_3)_3$,[3] $Sb(N_3)_3$,[3] and $[As(N_3)_6]^-$[4,5] determined.[7] In addition, the Lewis base stabilized species $M(N_3)_5 \cdot LB$ (M = As, Sb; LB = pyridine, quinoline, NH_3, N_2H_4, NH_2CN) are known.[8] However, previous attempts[4] to obtain the neat pentaazides of arsenic and antimony were not successful. Even at low temperatures, attempted syntheses resulted in explosions that were described as "so intense that only pulverized glass remained".[4] Furthermore, $As(N_3)_5$ was predicted[4] to be a "highly unstable compound", based on its analogy to $AsCl_5$.[9] Herein, we communicate the synthesis and characterization of neat $As(N_3)_5$ and $Sb(N_3)_5$, and their conversion into the $[As(N_3)_6]^-$ and $[Sb(N_3)_6]^-$ ions, respectively. We also report the crystal structure of $[P(C_6H_5)_4][Sb(N_3)_6]$.

The reactions of AsF_5 or SbF_5 in SO_2 with excess $(CH_3)_3SiN_3$ result in facile and complete fluoride–azide exchange and yield clear yellow solutions of $As(N_3)_5$ or $Sb(N_3)_5$, respectively, [Eq. (1); M = As, Sb].

$$MF_5 + 5\,(CH_3)_3SiN_3 \xrightarrow{SO_2} M(N_3)_5 + 5\,(CH_3)_3SiF \tag{1}$$
Removal of the volatile compounds (SO_2, $(CH_3)_3SiF$, and excess $(CH_3)_3SiN_3$) results in the isolation of the neat pentaazides.

As expected for highly endothermic, covalent polyazides, $As(N_3)_5$ and $Sb(N_3)_5$ are highly shock sensitive and can explode violently when touched with a metal spatula or by rapid change in temperature (e.g. freezing with liquid nitrogen). $As(N_3)_5$ was obtained as a yellow liquid. Its identity was established by the observed material balance, through ¹⁴N NMR and vibrational spectroscopy, and its conversion with $[N_3]^-$ into the known[4,5] $[As(N_3)_6]^-$ ion. The observed low-temperature Raman spectrum of $As(N_3)_5$ is shown in Figure 1.
Figure 1. Low-temperature Raman spectrum of $As(N_3)_5$.

In contrast to a previous prediction,[4] neat arsenic pentaazide was found to be kinetically stable at ambient temperature, but highly explosive. The presence of covalent azido ligands[1–8,10–14] was confirmed by the observed ¹⁴N NMR shifts of $\delta = -149$ ppm (N_β, $\Delta \nu_{1/2} = 42$ Hz), -160 ppm (N_γ, $\Delta \nu_{1/2} = 96$ Hz), and -282 ppm (N_α, extremely broad) in DMSO solution at 25 °C.

$Sb(N_3)_5$ was obtained as a pale yellow solid. It is even more sensitive than $As(N_3)_5$ and must be handled at reduced temperature. Warming the compound to ambient temperature results in violent decomposition and can cause serious damage. The identity of antimony pentaazide was established by the observed material balance, its Raman spectrum (Figure 2), and its reaction with $[N_3]^-$ to give the $[Sb(N_3)_6]^-$ ion. The calculated and observed vibrational frequencies and intensities for $As(N_3)_5$ and $Sb(N_3)_5$ are listed in Table 1. The agreement between the observed frequencies and those calculated for pentacoordinate trigonal-bipyramidal struc-

[a] Our calculated MP2 minimum energy structures for As(N$_3$)$_5$ and Sb(N$_3$)$_5$ are derived from trigonal bipyramids and are very similar to those obtained at the B3LYP level.[4] [b] Observed Raman intensities are relative intensities; calculated IR intensities [km mol^{-1}] and calculated Raman [Å^4 amu^{-1}].

tures is good. However, it must be kept in mind that distinction between slightly different geometries based on the skeletal modes in these types of polyazido compounds is generally difficult, because the vibrational spectra are complex and not very sensitive to minor changes in the ligand arrangement.

The reactions of As(N$_3$)$_5$ and Sb(N$_3$)$_5$ with ionic azides, such as [PPh$_4$]$^+$[N$_3$]$^-$, produce the corresponding [As(N$_3$)$_6$]$^{-[4,5]}$ and [Sb(N$_3$)$_6$]$^-$ salts, respectively, [Eq. (2); M = As, Sb].

$$M(N_3)_5 + [PPh_4]N_3 \xrightarrow{SO_2} [PPh_4][M(N_3)_6] \qquad (2)$$
Both tetraphenylphosphonium salts were isolated as colorless solids. The [PPh$_4$][Sb(N$_3$)$_6$] salt can also be prepared from the corresponding [SbCl$_6$]$^-$ salt and (CH$_3$)$_3$SiN$_3$ in CH$_3$CN solution. However, the previously published[4] reaction conditions, that is, one single treatment at 25 °C for 24 h, were found insufficient. Even after seven prolonged treatments with large amounts of fresh (CH$_3$)$_3$SiN$_3$ only four of the original six chlorine ligands were replaced by azido groups, as shown by Raman spectroscopy and single-crystal X-ray diffraction studies. Heating to 82 °C in refluxing CH$_3$CN was required to achieve further chloride substitution.

Single crystals of [PPh$_4$][Sb(N$_3$)$_6$] were obtained by recrystallization from CH$_3$CN solution. Because of the presence of a large counterion which serves as an inert spacer and suppresses detonation propagation, these salts are

much less shock sensitive than neat $As(N_3)_5$ and $Sb(N_3)_5$, and are thermally surprisingly stable. Thus, a crystalline sample of $[PPh_4][Sb(N_3)_6]$ could be heated to its melting point at 104–106°C without decomposition.

$[PPh_4][Sb(N_3)_6]$ crystallizes in the monoclinic space group $C2/c$. Its X-ray structure (Figure 3)[15] revealed the presence of
Figure 3. ORTEP drawing of the anionic part of the crystal structure of $[PPh_4][Sb(N_3)_6]$. Thermal ellipsoids are set at 50% probability. Selected bond lengths [Å] and angles [°]: Sb-N1 2.065(2), Sb-N4 2.079(2), Sb-N7 2.085(3), N1-N2 1.220(3), N2-N3 1.120(3), N4-N5 1.222(4), N5-N6 1.127(4), N7-N8 1.222(3), N8-N9 1.128(4); N1-N2-N3 175.1(3), N4-N5-N6 175.1(3), N7-N8-N9 174.7(4), N1-Sb-N4 92.00(9), N1-Sb-N7 88.33(11), N4-Sb-N7 88.45(11), Sb-N1-N2 116.7(2), Sb-N4-N5 116.4(2), Sb-N7-N8 116.6(2).

$[PPh_4]^+$ and $[Sb(N_3)_6]^-$ ions without significant cation–anion interaction. The closest Sb⋯N and N⋯N contacts between neighboring anions are 5.0 Å and 3.2 Å, respectively. The structure of the $[Sb(N_3)_6]^-$ ion is only slightly distorted from perfect S_6 symmetry and is analogous to those of $[As(N_3)_6]^{-,[4,5]}$ $[Si(N_3)_6]^{2-[16]}$ $[Ge(N_3)_6]^{2-[17]}$ and $[Ti(N_3)_6]^{2-,[18]}$ and contrary to that of $[Te(N_3)_6]^{2-}$.[19] The structure of the $[Sb(N_3)_6]^-$ ion consists of an asymmetric SbN_9 unit with three azido groups covalently bonded in a trigonal pyramidal fashion to the antimony center. The remaining three coordination sites at the metal center are occupied by three symmetry related azido groups (symmetry operation $-x + 3/2, -y + 3/2, -z + 1$). All three Sb—N bond of 2.064(2), 2.079(2), and 2.084(2) Å are significantly shorter than the 2.119(4) Å found for $Sb(N_3)_3$.[3]

Further support for the presence of the $[Sb(N_3)_6]^-$ ion is provided by the NMR spectrum. The ^{14}N NMR spectrum in DMSO shows resonances at $\delta = -141$ ppm (N_β, $\Delta\nu_{1/2} = 63$ Hz), -185 ppm (N_γ, $\Delta\nu_{1/2} = 103$ Hz), and -287 ppm (N_α, $\Delta\nu_{1/2} = 580$ Hz), that are characteristic for covalent azides.[1–8,10–14] Our spectrum differs, particularly in the N_γ region, significantly from that previously reported[4] (N_β: $\delta = -141$ ppm, $\Delta\nu_{1/2} = 45$ Hz; N_γ: $\delta = -154$ ppm, $\Delta\nu_{1/2} = 120$ Hz, $\delta = -163$ ppm, $\Delta\nu_{1/2} = 45$ Hz, $\delta = -173$ ppm, $\Delta\nu_{1/2} = 110$ Hz; N_α: $\delta = -244$ ppm, $\Delta\nu_{1/2} = 580$ Hz), for the $[N(C_2H_5)_4]^+$ salt in the same solvent and at the same temperature. We have observed similar shifts and multiple resonances for N_γ ($N_\alpha\delta = -245$ ppm; $N_\gamma\delta = -150$, -160, -168, and -169 ppm) in samples, prepared from $[SbCl_6]^-$, in which chlorine substitution was incomplete, as shown by Raman spectroscopy and

their crystal structures. This result is in accord with our finding that, under the previously reported conditions,[4] the chloride/azide exchange is incomplete.

The observed Raman and IR spectra of $[P(C_6H_5)_4][Sb(N_3)_6]$ are shown in Figure 4, and the observed frequencies and intensities are listed in the Experimental Section.
Figure 4. IR (top) and Raman (bottom) spectra of $[P(C_6H_5)_4][Sb(N_3)_6]$. The bands belonging to the $[Sb(N_3)_6]^-$ ion are marked with asterisks.

Assignments of the observed spectra were made by comparison with those calculated at the MP2/SBK + (d) level of theory and are given in the Experimental Section. The good agreement between the observed and calculated spectra confirms the results from the crystal-structure determination that, in its $[PPh_4]^+$ salt, the $[Sb(N_3)_6]^-$ ion closely approximates ideal S_6 symmetry.

Experimental Section

Caution! *Arsenic and antimony azides are toxic, potentially hazardous, and can decompose explosively under various conditions! They should be handled only on a scale of less than 2 mmol with appropriate safety precautions (safety shields, safety glasses, face shields, leather gloves, protective clothing, such as leather suits, and ear plugs).[3,18,19] Teflon containers should be used, whenever possible, to avoid hazardous shrapnel formation. Rapid changes in temperature of $As(N_3)_5$ and $Sb(N_3)_5$ (whether pure or in SO_2 solution) can result in violent explosions. The manipulation of these materials is facilitated by handling them, whenever possible, in solution to avoid detonation propagation, the use of large inert counterions as spacers, and anion formation which increases the partial negative charges on the terminal N_γ atoms and thereby reduces the N_β–N_γ triple-bond character and the*

*tendency for N₂ elimination. **Ignoring safety precautions can lead to serious injuries!***

All reactions were carried out in Teflon-FEP ampules (FEP = perfluoro ethylene propylene polymer) that were closed by stainless steel valves. Volatile materials were handled in a Pyrex glass vacuum line. All Teflon reaction vessels were passivated with ClF_3 prior to use. Nonvolatile materials were handled in the dry argon atmosphere of a glove box.

Raman spectra were recorded at $-80\,°C$ in the range 4000–80 cm^{-1} on a Bruker Equinox 55 FT-RA spectrophotometer using a Nd-YAG laser at 1064 nm with power levels of 200 mW or less and a 180° geometry. Pyrex melting-point tubes that were baked out at 300 °C for 48 h at 10 mTorr vacuum or Teflon-FEP tubes with stainless steel valves that were passivated with ClF_3 were used as sample containers. IR spectra were recorded in the range 4000–400 cm^{-1} on a Midac, M Series, FT-IR spectrometer using KBr or AgCl pellets. The pellets were prepared inside the glove-box using an Econo press (Barnes Engineering Co.).

^{14}N NMR spectra were recorded unlocked at 36.13 MHz on a Bruker AMX 500 spectrometer using solutions of the compounds in DMSO in sealed standard glass tubes. Neat CH_3NO_2 ($\delta = 0.00$ ppm) was used as the external reference.

The starting materials AsF_5 (Ozark Mahoning) and $[P(C_6H_5)_4]I$ (Aldrich) were used without further purification. $(CH_3)_3SiN_3$ (Aldrich) was purified by fractional condensation and SbF_5 (Ozark Mahoning) by distillation prior to use. Solvents were dried by standard methods and freshly distilled before being used. $[P(C_6H_5)_4]N_3$ was prepared from $[P(C_6H_5)_4]I$ and AgN_3.

$As(N_3)_5$: $(CH_3)_3SiN_3$ (3.91 mmol) was condensed at $-196\,°C$ onto a frozen solution of AsF_5 (0.570 mmol) in SO_2 (1 mL). The reaction mixture was kept at $-25\,°C$ for 30 min and then slowly warmed to ambient temperature over a period of 4 h resulting in a yellow solution. Removal of all volatile material at ambient temperature in a dynamic vacuum resulted in the isolation of a colorless liquid (0.170 g, weight calculated for 0.570 mmol of $As(N_3)_5 = 0.162$ g). The obtained liquid was characterized by Raman and NMR spectroscopy.

$Sb(N_3)_5$: $(CH_3)_3SiN_3$ (4.84 mmol) was condensed at $-196\,°C$ onto a frozen solution of SbF_5 (0.609 mmol) in SO_2 (14 mmol). The reaction mixture was warmed to $-25\,°C$ and kept between $-25\,°C$ and $-15\,°C$ for 10 h resulting in a bright yellow solution. Removal of all volatile material at $-15\,°C$ in a dynamic vacuum resulted in the isolation of an intense yellow solid (0.216 g, weight calculated for 0.609 mmol of $Sb(N_3)_5 = 0.202$ g).

$[PPh_4][M(N_3)_6]$ (M = As, Sb): Neat PPh_4N_3 (0.43 mmol) was added to a cooled solution of $M(N_3)_5$ (0.43 mmol) in SO_2 (15 mmol) at $-64\,°C$. The reaction mixture was kept at $-25\,°C$ and occasionally agitated. After 2 h, all volatiles were removed at ambient temperature in a dynamic vacuum, leaving behind solid $[PPh_4][M(N_3)_6]$. ($[PPh_4][As(N_3)_6]$: 0.285 g, weight calculated for 0.43 mmol = 0.288 g; $[PPh_4][Sb(N_3)_6]$: 0.313 g, weight calculated for 0.43 mmol = 0.307 g). Colorless single crystals of $[PPh_4][Sb(N_3)_6]$ were grown from a solution in CH_3CN by slow evaporation of the solvent in a dynamic vacuum. Raman spectrum of the $[As(N_3)_6]^-$ ion (50 mW, 20 °C): $\tilde{\nu} =$ 2125(4.9)/2085(3.0) ($\nu_{as}N_3$), 1331(0.6)/1269(1.0)/1251(0.6) (ν_sN_3), 666(1.5)/631(0.5) (δN_3), 418(10.0) (ν_sAsN), 379(1.1) ($\nu_{as}AsN$), 278(1.4) (δAsN), 165 (5.0) cm^{-1}. $[Sb(N_3)_6]^-$: IR (KBr): $\tilde{\nu} =$ 3329(mw)/2583(w)/2522(w) (combination bands), 2086(vs)/2016(s) ($\nu_{as}N_3$), 1337(m)/1318(m)/1264(s) (ν_sN_3), 663(m)/580(w) (δN_3), 424(s) cm^{-1} (νSbN). Raman (50 mW, 20 °C): $\tilde{\nu} = 2116(4.1)/2087$ (1.4)/2075(1.1)/2018(0.3) ($\nu_{as}N_3$), 1319(0.5)/1275(0.5) (ν_sN_3), 653(1.4) (δN_3), 412(10.0) (ν_sSbN), 386(1.0) ($\nu_{as}SbN$), 229(2.5) (δSbN), 147 (3.0) cm^{-1}.

Optimizations of all structures were performed using second-order perturbation theory.[20, 21] For the arsenic azides, the Binning and Curtis double-zeta valence basis set,[22] augmented with a d polarization function[23] was used for the arsenic and the 6-31G(d) basis set[24,25] for the nitrogen atoms. For the antimony azides, the Stevens,

Basch, and Krauss (SBK) effective core potentials and the corresponding valence-only basis sets were used.[26] The SBK valence basis set for nitrogen was augmented with a d polarization function[25] and a diffuse s + p shell,[27] whereas only a d polarization function[28] was added to the antimony basis set. Hessians (energy second derivatives) were calculated for the final equilibrium structures to determine if they are minima (positive definite hessian) or transition states (one negative eigenvalue). All calculations were performed using the electronic structure code GAMESS.[29]

Unscaled calculated frequencies (cm^{-1}) and (infrared, km mol^{-1}) and [Raman, Å^{4}amu^{-1}] intensities for the $[Sb(N_3)_6]^-$ ion (C_{2h} symmetry): A_g: 2219 (0) [82], 2200 (0) [48], 1273 (0) [77], 1267 (0) [41], 659 (0) [6.0], 645 (0) [23], 596 (0) [18], 409 (0) [121], 385 (0) [8.8], 236 (0) [5.2], 215 (0) [12], 128 (0) [9.3], 68 (0) [20], 30 (0) [17]; B_g: 2202 (0) [33], 1267 (0) [42], 652 (0) [0.9], 590 (0) [0.1], 549 (0) [0.4], 372 (0) [5.4], 225 (0) [4.6], 128 (0) [8.4], 41 (0) [12], 24 (0) [9.9]; A_u: 2216 (1299) [0], 1268 (171) [0], 659 (5.8) [0], 590 (2.2) [0], 547 (5.8) [0], 424 (135) [0], 257 (122) [0], 195 (9.2) [0], 152 (1.0) [0], 68 (0.3) [0], 36 (1.1) [0], 19 (0.2) [0]; B_u: 2204 (1493) [0], 2193 (914) [0], 1271 (147) [0], 1268 (148) [0], 663 (25) [0], 650 (34) [0], 596 (7.0) [0], 429 (97) [0], 416 (112) [0], 247 (88) [0], 244 (52) [0], 166 (3.5) [0], 79 (4.1) [0], 71 (2.5) [0], 24 (0.5) [0].

Synthesis of *gem*-Difluorocarba-D-glucose: A Step Further in Sugar Mimesis**

Aurélie Deleuze, Candice Menozzi,
Matthieu Sollogoub,* and Pierre Sinaÿ*

Chemical modifications of carbohydrates have been used extensively to understand the origin of the specificity in the recognition processes by sugar-binding proteins in aqueous solution. A classical example is the work by Lemieux, wherein chemoselective removal of hydroxyl groups from oligosaccharides led to the concept of key polar interactions.[1] Along the same lines, the replacement of the endocyclic oxygen atom by a methylene group has provided hydrolytically stable glycoside mimetics called carbasugars, whose biochemical properties have been studied (Figure 1).[2–8] Such a replace-
Figure 1. Glucopyranose and its carbocyclic congeners.

ment has the inherent disadvantage to suppress any possible hydrogen bond formation that involved this electronegative atom. This drawback clearly appeared in the case of carbalactoside, a close mimic of lactoside, which is no longer recognised by a β-galactosidase.[9] A model has shown that the endocyclic oxygen atom (O-5) of the D-galactose moiety is involved in the interaction with hydrogen-donating groups of the active site of the enzyme.[10] One way to circumvent this problem and to enlarge the probing spectrum of carbasugars is to replace the oxygen atom by other hydrogen-bond acceptors. Ideally, to fully understand the role of the endocyclic oxygen requires the two lone pairs to be discriminated so that they can be probed to see which of them, if any, is involved in hydrogen bonding in the active site of the enzyme. Fluorine atoms are not as strong hydrogen-bond acceptors as oxygen, but they still exhibit this property,[11–13] and more interestingly they have been used as reporter groups of the active site of enzymes through ^{19}F NMR spectroscopy.[14] It is therefore foreseeable that

replacement of the endocyclic CH$_2$ group by a CF$_2$ moiety in a carbasugar would constitute a step further in the utilization of this family of sugar mimetics by enhancing their ability to be accepted by enzymes involving O-5 and allowing the study of their complexation by NMR spectroscopy.

We recently reported a novel sugar-to-carbocycle rearrangement promoted by triisobutylaluminum (TIBAL)[15] or Cl$_3$TiOiPr.[16] The proposed key step in this transformation is the opening of the ring to give a carbocationic intermediate. Indeed, this reaction is favored when this putative carbenium species can be stabilized by an electron-donating group (EDG).[17] This is generally applicable to acyclic non-sugar-derived enol ethers (Scheme 1).[18]
Scheme 1. General rearrangement of EDG-substituted vinyl ethers. EDG = electron-donating group, LA = Lewis acid, TIBAL = triisobutylaluminum.

As an example, we recently synthesized a carbasugar with furanyl as the EDG which was easily introduced at the anomeric centre of D-glucose through a glycosylation process. In this synthesis, the anomeric center of the carba congener is derived from the C-5 carbon atom of D-glucose.[19] Given the
Scheme 2. Synthetic strategies for carbasugars through TIBAL-promoted rearrangements. Bn = benzyl.

accessibility of ynopyranosides[20] and the recent results of Harrity and co-workers[21] who showed that dicobalt hexa-carbonyl clusters[22] could act as EDGs in a similar situation, we anticipated that our TIBAL-mediated reductive rearrangement applied to the difluoroalkene **2** might provide a convenient entry to our target molecule **1** (Scheme 2).

Synthesis of the ynopyranose **6**, the precursor of compound **2**, is depicted in Scheme 3. The known[20] *gem*-dibromoalkene **3** was first converted into alkyne **4** through methylation of the acetylenic anion generated in situ. Acetolysis,[23] followed by hydrolysis of the generated anomeric acetate, and oxidation of the hemiacetal afforded the corresponding lactone **5**. Difluoromethylenation according to Motherwell et al.[24] provided the desired *gem*-difluoroalkene precursor **6**.
Scheme 3. Synthesis of the *gem*-difluoro-exo-glucal **6**. Reagents and conditions: 1) a) nBuLi (2.1 equiv), THF, −78 °C, 2 h; b) MeI (6 equiv), THF, −78 °C, 30 min; c) HMPT (4 equiv), −78 °C→RT, overnight, 75 % over three steps; 2) H$_2$SO$_4$ (1 equiv), Ac$_2$O, 0 °C, 3 min, 75 %; 3) MeONa (4 equiv), MeOH, 0 °C→RT, 2 h, 90 %; 4) PCC (3 equiv), 4-Å molecular sieves (3 equiv), CH$_2$Cl$_2$, room temperature, 4 h, 74 %; 5) a) HMPT (5 equiv), THF, −40 °C→RT; b) CBr$_2$F$_2$ (5 equiv), HMPT (5 equiv), THF, RT→reflux, 1 h, 95 %. THF = tetrahydrofuran, HMPT = hexamethylphosphoric triamide, PCC = pyridinium chlorochromate.

As anticipated and much to our delight, the key rearrangement was performed through a two-step one-pot procedure that involved first, the complexation of the alkyne **6** by dicobalt octacarbonyl,[25] followed by the reductive TIBAL-induced rearrangement of **2**.[17] Decomplexation with CAN (ceric ammonium nitrate)[26] of the crude compound **7** afforded alcohol **8** in 75 % yield over three steps and only one purification step by chromatography. The 5a-*gem*-difluoro-carba-α-D-glucopyranose **1**[27] was then easily obtained by controlled reduction of the triple bond, reductive ozonolysis, and debenzylation (Scheme 4). As previously observed,[15] the rearrangement occurs with retention of configuration. The reduction of the putative transient
Scheme 4. Synthesis of the 5a-*gem*-difluorocarba-α-D-glucopyranose **1**. Reagents and conditions: 1) a) [Co$_2$(CO)$_8$] (1.5 equiv), CH$_2$Cl$_2$, room temperature, 2 h; b) TIBAL (5 equiv), toluene, room temperature, 2.5 h; c) CAN (5 equiv), NEt$_3$ (1 equiv), acetone, 30 min, 65 % over three steps; 2) a) Pd/CaCO$_3$, H$_2$, MeOH, room temperature, 4 h; b) O$_3$, CH$_2$Cl$_2$, −78 °C, 5 min; c) NaBH$_4$, CH$_2$Cl$_2$, room temperature, 1 h, 76 % over three steps; 3) Pd/C, H$_2$, MeOH, room temperature, 1 h, 90 %. CAN = ceric ammonium nitrate.

Communications

ketone is stereoselective and is classically explained by the attack of the hydride ion, which is attached to the isobutyl group, on the less-hindered face of the molecule to provide the axial hydroxyl group (Scheme 5).
Scheme 5. Stereoselectivity of the reduction of the transient ketone by TIBAL.

The reduction step described proceeds under steric control, whereas the electronic control admitted in such a case, the Ahn–Eisenstein effect,[28] gives the opposite stereoselectivity. According to this model, the most stable transition-state structure has the axial C–F[29,30] bond in the antiperiplanar position with respect to the forming H–C bond. This model implies, as shown in Figure 2, which depicts the late transition state of the reduction step, a selective attack of the hydride ion to form the equatorial hydroxyl group.
Figure 2. Anh–Eisenstein effect to obtain the axial reduction.

Once again, a one-pot procedure was developed: After reaction of the alkyne **6** with dicobalt octacarbonyl to give cluster **2**, the rearrangement was, this time, induced by Cl$_3$TiOiPr[16] to yield cyclohexanone **10**. The Lewis acid was then quenched with THF, and the ketone was reduced by means of the super hydride. The triple bond in the crude product **11** was decomplexed, and the expected equatorial alcohol **12** was obtained in 73% yield over five steps and only one purification step by column chromatography. The 5a-*gem*-difluorocarba-β-D-glucopyranose **14**[31] was then obtained as described above (Scheme 6).
Scheme 6. Synthesis of the 5a-*gem*-difluorocarba-β-D-glucopyranose **14**. Reagents and conditions: 1) a) [Co$_2$(CO)$_8$] (1.5 equiv), CH$_2$Cl$_2$, room temperature, 2 h; b) TiCl$_3$OiPr (2 equiv), CH$_2$Cl$_2$, −78 °C, 1 h; c) THF (5 equiv), −78 °C, 15 min; d) Et$_3$BHLi (2 equiv), CH$_2$Cl$_2$, −78 °C, 30 min; e) CAN (5 equiv), NEt$_3$ (1 equiv), acetone, 1 h, 73% over five steps; 2) a) Pd/CaCO$_3$, H$_2$, MeOH, room temperature, 1.25 h; b) O$_3$, CH$_2$Cl$_2$, −78 °C, 5 min; c) NaBH$_4$, CH$_2$Cl$_2$, room temperature, 1 h, 78% over three steps; 3) Pd/C, H$_2$, MeOH, room temperature, 1 h, 90%.

The observed stereoselectivity of this reduction process is in sharp contrast to the case in which the fluorine atoms are absent from the molecule. Indeed, when the unsaturated sugar **15**[32] was submitted to the same reaction conditions, only the axial alcohol **16**[15] was obtained in 75% yield (Scheme 7). This result supports the directing role of fluorine in the reduction of the ketone.
Scheme 7. Rearrangement and reduction of **15**. Reagents and conditions: 1) a) TiCl$_3$OiPr (1 equiv), CH$_2$Cl$_2$, −78 °C; b) THF (5 equiv), −78 °C, 15 min; c) Et$_3$BHLi (2 equiv), CH$_2$Cl$_2$, −78 °C, 30 min, 73% over three steps.

In summary, we have synthesized, for the first time, two *gem*-difluorinated carba analogues of α- and β-D-glucopyranoses by using a rearrangement strategy and by taking advantage of the Anh–Eisenstein effect to obtain the β analogue. They are attractive candidates for probing the role of endocyclic oxygen atoms in carbohydrates in sugar–protein interactions. This strategy is currently being extended to other carbohydrates.

Cluster Compounds

Carbon Dioxide Fixation by the Cooperative Effect of Organotin and Organotellurium Oxides

Jens Beckmann,* Dainis Dakternieks, Andrew Duthie, Naomi A. Lewcenko, and Cassandra Mitchell

Dedicated to Professor Alwyn G. Davies

The recent interest in carbon dioxide fixation by organo-metallic species has occurred for two reasons:[1] First, the increasing industrial emission of the "greenhouse gas" CO_2 into the atmosphere has been widely accepted as one of the main causes for global warming and climate changes, and therefore efficient solutions for the recovery of CO_2 are highly sought after. Second, being an inexpensive, nontoxic commodity, CO_2 holds considerable potential as a C_1 feedstock for the preparation of key intermediates required by the chemical industry on a multitonne scale, such as urea and dimethyl carbonate (DMC). In this regard, organometallic complexes play a vital role for the activation of the comparatively inert C–O bonds in CO_2. Whilst a vast variety of transition-metal compounds are able to form complexes with CO_2, main-group organometallic species known to bind CO_2 are rare.[1] Notable exceptions include triorganotin oxides, $(R_3Sn)_2O$, and triorganotin hydroxides, R_3SnOH, which react with gaseous CO_2 to give rise to the formation of polymeric triorganotin carbonates, $(R_3Sn)_2CO_3$ (R = alkyl).[2] Industrially, triorganotin carbonates are used as catalysts for the preparation of organic carbonates from alkyl halides and potassium carbonate.[1c] Di- and triorganotin alkoxides, $R_nSn(OR')_{4-n}$ (R = alkyl, R' = alkyl, aryl; n = 2, 3) react with gaseous or supercritical CO_2 to give di- and triorganotin (alkoxy) carbonates, $R_3Sn(O_2COR')$ and $R_2Sn(OR')(O_2COR')$, some of which produce DMC upon thermolysis.[3]

We have now found that solutions containing of di-*tert*-butyltin oxide, $(tBu_2SnO)_3$,[4] and di-*p*-anisyltellurium oxide, $(p\text{-MeOC}_6H_4)_2TeO$,[5] (Sn/Te ratio = 1:1) readily absorb gaseous CO_2 to produce a unique molecular tellurastannoxane,[6] $[\{(p\text{-MeOC}_6H_4)_2TeOSn(tBu_2)CO_3\}_2]$ (**1**) as an air-stable crystalline material [Eq. (1)]. The formation of this material is rapid (less than 15 min) at room temperature and almost quantitative when the solution is purged with an excess of CO_2. Smaller amounts of the same material were also formed

atom is best described as a distorted trigonal bipyramid, in which two oxygen atoms are situated in the axial positions and two carbon atoms and one oxygen atom occupy the equatorial positions. The distortion seems to originate from the chelating coordination mode of the carbonate.

Taking into account the stereochemically active lone pair, the geometry of the tellurium atom may be described as a distorted octahedron with two carbon atoms mutually *cis* and two oxygen atoms mutually *trans*, and a deficiency in the primary coordination sphere along the vector defined by the two tellurium atoms (Te1···Te1a 4.875(1) Å). The O-Te-O linkage is rather asymmetric (Te1-O1 1.921(2), Te1-O2 2.481(2) Å) as opposed to the O-Te-O linkage in the polymeric parent compound, $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$ (Te1-O1 2.100(2) Å, Te1-O1a 2.025(2) Å). Differences are also found

in the secondary bonding; while $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$ lacks such interactions, two significant intramolecular secondary Te···O bonds are observed for the tellurium atoms of **1**, which involve O4 of the carbonate moiety.[8]

Consistent with the molecular structure established by X-ray crystallography and the pentacoordinate geometry of the tin atoms, the [119]Sn magic angle spinning (MAS) NMR spectrum of **1** shows an isotropic chemical shift at $\delta_{\mathrm{iso}} = -262.4$ ppm, which differs from that of $(t\mathrm{Bu_2SnO})_3$ ($\delta_{\mathrm{iso}} = -84.3$ ppm), which has tetracoordinate tin atoms.[9] The [125]Te MAS NMR spectrum of **1** reveals an isotropic chemical shift at $\delta_{\mathrm{iso}} = 1179$ ppm similar to that of the dimeric $\mathrm{Ph_2TeO}$ ($\delta_{\mathrm{iso}} = 1103/1133$ ppm), but rather different to that of the polymeric $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$ ($\delta_{\mathrm{iso}} = 903$ ppm), which is apparently a reflection of the asymmetric O-Te-O linkage and the presence of secondary Te···O interactions in **1** and $\mathrm{Ph_2TeO}$, as opposed to the rather symmetric O-Te-O linkage and the absence of secondary interactions in $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$.[5] At a MAS frequency of 9 kHz, both the [119]Sn and the [125]Te isotropic chemical shifts were accompanied by a set of spinning sidebands that were indicative for large shielding anisotropies (SA) and utilized for tensor analyses.[10]

For solutions of **1** in $\mathrm{CDCl_3}$, the ^{119}Sn and [125]Te NMR spectra show signals at $\delta = -258.3$ and 1194.3 ppm, respectively, which suggest, by comparison with the respective solid-state NMR chemical shifts, that the molecular structure is retained in solution. Both signals show two identical pairs of satellites giving rise to two $^2J(^{119}\mathrm{Sn}\text{-}\mathrm{O}\text{-}^{125}\mathrm{Te})$ couplings of 113 and 66 Hz, which unambiguously supports the idea that the secondary Te···O interactions also exist in solution.[8] Independent evidence for the configurational stability of **1** in solution stems from osmometric molecular-weight determination in $\mathrm{CHCl_3}$ at 40 °C (1282 Da found, 1301 Da calculated). The presence of the carbonate moiety is evident from the ^{13}C NMR spectra which show a signal at $\delta = 165.4$ ppm (in $\mathrm{CDCl_3}$) and $\delta_{\mathrm{iso}} = 165.6$ ppm (in the solid state), which increases significantly in intensity when using ^{13}C-labeled carbon dioxide for the preparation.

Solutions of $(t\mathrm{Bu_2SnO})_3$ and $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$ were treated separately with gaseous $\mathrm{CO_2}$. While the $(p\text{-}\mathrm{MeOC_6H_4})_2\mathrm{TeO}$ was recovered unchanged, solutions of $(t\mathrm{Bu_2SnO})_3$ also absorb $\mathrm{CO_2}$ to produce $t\mathrm{Bu_2SnCO_3}$ (**2**), albeit at a slower rate than in the formation of **1**. Owing to the virtual insolubility in all common organic solvents, we tentatively assign **2** a polymeric structure, thus acknowledging the fact that all known triorganotin carbonates, $(\mathrm{R_3Sn})_2\mathrm{CO_3}$ (R = alkyl) are also polymeric.[2] This assignment is supported by ^{119}Sn MAS NMR spectroscopy of **2**, which shows an isotropic chemical shift at $\delta_{\mathrm{iso}} = -285.5$.[10]

Applications of organometallic species for the fixation and recovery of $\mathrm{CO_2}$ require the reversibility of the absorption process, preferably at a low temperature to save energy costs.[1] A thermographic analysis of **1** indicates mass loss between 90–145 °C (7.0% found, 6.8% calculated) associated with the liberation of $\mathrm{CO_2}$. It is well known that inorganic bases, such as aqueous KOH also absorb $\mathrm{CO_2}$ from air, however these absorption processes are generally irreversible (e.g. $\mathrm{K_2CO_3}$ is stable up to more than 900 °C).[11] A bulk sample of **1** (300 mg) was heated at 145 °C for 60 min and the

released CO_2 was determined gravimetrically as $BaCO_3$ (recovery 80%). The residual material was free of carbonate by indication of ^{13}C NMR spectroscopy and the related ^{119}Sn and ^{125}Te MAS NMR spectra exhibit signals at $\delta_{iso} = -228.3$ and 834 ppm, respectively, which are significantly different from those of **1** and the starting materials. The residual material was completely soluble in $CDCl_3$ and was used for the reabsorption of CO_2, after which the ^{119}Sn and ^{125}Te NMR spectra of the crude product indicated the renewed quantitative formation of **1**.

In summary, we have demonstrated that solutions of $(tBu_2SnO)_3$ and $(p\text{-}MeOC_6H_4)_2TeO$ (Sn/Te ratio = 1:1) rapidly absorb CO_2 to form an air-stable molecular tellurastannoxane $[\{(p\text{-}MeOC_6H_4)_2TeOSn(tBu_2)CO_3\}_2]$ (**1**) showing significant intramolecular Te···O interactions in both solution and the solid state. In contrast, the absorption of CO_2 by $(tBu_2SnO)_3$ or triorganotin oxo species[2] provides only polymeric organotin carbonates. The desorption of CO_2 occurs at rather low temperatures, which suggests applications of **1** for instance as phase-transfer catalyst[12] or as precursor for the preparation of organic carbonates.[3]

Experimental Section

1: A magnetically stirred solution of $(tBu_2SnO)_3$ (995 mg, 1.33 mmol)[4] and $(p\text{-}MeOC_6H_4)_2TeO$ (1.43 g, 4.00 mmol)[5] in $CHCl_3$ (30 mL), was slowly purged with CO_2 for 15 min at room temperature. The solvent was removed in vacuo and the solid residue recrystallized from CH_2Cl_2/hexane to give colorless crystals. These crystals were dried in vacuum at 50 °C for 1 h to remove cocrystallized CH_2Cl_2. Single crystals suitable for X-ray diffraction were grown from a $CHCl_3$ solution, yield: 2.58 g, 1.98 mmol, 99%. M.p. 198 °C (decomp.) (crystals turn opaque at 120 °C). Elemental analysis (%) calcd for $C_{23}H_{32}O_6SnTe$ (1301.74): C 42.44, H 4.96; found: C 42.39, H 5.03. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 8.02$ (d, $^3J(^1H\text{-}^1H) = 9$ Hz, 8H), 6.92 (d, $^3J(^1H\text{-}^1H) = 9$ Hz, 8H), 3.81 (s, 12H), 1.18 ppm (s, $^3J(^1H\text{-}^{119}Sn) = 109$ Hz, 36H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 165.4$ (CO_3), 161.5 (*p*-C), 133.6 (*o*- or *m*-C), 129.5 ($^1J(^{13}C\text{-}^{125}Te) = 323$ Hz; *i*-C), 114.7 (*o*- or *m*-C), 55.3 (OCH_3), 39.4 ($^1J(^{13}C\text{-}^{119}Sn) = 562$ Hz; CCH_3), 29.3 ppm (CCH_3).

2: A solution of $(t\text{-}Bu_2SnO)_3$ (249 mg, 0.33 mmol)[4] in $CHCl_3$ (20 mL), was slowly purged with CO_2 for 30 min at room temperature. The colorless amorphous precipitate formed was collected by filtration and air dried. Yield: 228 mg, 0.78 mmol, 78%. M.p. 250 °C (decomp.) Elemental analysis (%) calcd for $C_9H_{18}O_3Sn$ (292.97): C 36.90, H 6.19; found: C 36.91, H 6.20.

Complete Chalcogenation of Tin(II) Centers in an Imidotin Cluster**

Tristram Chivers and Dana J. Eisler*

The use of inorganic rings or clusters as precursors to industrially important materials such as inorganic polymers,[1] nanomaterials,[2] or semiconductors[3] represents an active area of contemporary inorganic chemistry. In the latter category the design of suitable precursors for the low band-gap semiconductors SnE (E = Se, Te), which have applications in thermoelectric devices and for optoelectronic materials, is of current interest.[4,5] Suitably chosen complexes containing terminal Sn=E bonds would appear to be candidates for this purpose.[6] In particular, imidotin chalcogenides of the type [(ESnμ$_3$-NR)$_4$] (E = Se, Te) may act as single-source precursors of these binary semiconductors by the energetically favorable elimination of the diazene RN=NR. However, investigations of the reactions of the neutral cluster [(Snμ$_3$-NtBu)$_4$] with chalcogens have revealed that oxidation is limited to one tin(II) center for E = Te (**A**) or two tin(II) centers in the case of E = Se (**B**).[7] To address this synthetic
challenge, we have adopted a strategy that was successful for the generation of the previously inaccessible P–Te ligands [(TePPh$_2$)$_2$N]$^-$ and [Te(NtBu)P(μ-NtBu)$_2$P(NtBu)Te]$^{2-}$.[8] That approach involved the formation of anionic imidophosphorus(III) reagents by metalation with NaH or nBuLi, prior to reaction with tellurium.[8]

Application of this methodology to imidotin cages involves the use of the amido/imido *seco*-cube [Sn$_3$(μ$_3$-NtBu)(μ$_2$-NtBu)(μ$_2$-NHtBu)$_2$] (**1**) reported by Veith et al.[9] We disclose here that the anionic cluster in [Li(thf)$_4$][(thf)LiSn$_3$(μ$_3$-NtBu)$_4$] (**2a**), which is readily generated by dilithiation of **1** with nBuLi, exhibits a dramatic increase in the reactivity of the tin(II) centers towards chalcogens compared to that of the neutral cluster [(Snμ$_3$-NtBu)$_4$]. Complete chalcogenation to give the trichalcogenides

1

2a M$^+$ = [Li(thf)$_4$]
2b M$^+$ = [(thf)Li([12]crown-4)]

3a E = Se, M$^+$ = [Li(thf)$_4$]
3b E = Se, M$^+$ = [(thf)Li([12]crown-4)]
4 E = Te, M$^+$ = [Li(thf)$_4$]
[Li(thf)$_4$][(thf)LiSn$_3$E$_3$(μ$_3$-NtBu)$_4$] (**3a**, E = Se; **4**, E = Te) occurs rapidly under mild conditions and in high yields. The characterization of these imidotin chalcogenides in the solid state by X-ray crystallography and in solution by multinuclear NMR spectroscopy (^{1}H, ^{7}Li, ^{119}Sn, ^{77}Se, and ^{125}Te) is reported.

The reaction of **1** with two equivalents of *n*-butyllithium in THF produces the anionic heterobimetallic cubane **2a** as a solvent-separated ion pair in 40% yield; complex **2b** was prepared from **2a** and [12]crown-4. Wright and co-workers have reported the formation of the related complex [Li(thf)$_4$][Sn$_3$Li(thf)(μ$_3$-NtBu)(μ$_3$-NC$_{10}$H$_7$)$_3$] by the reaction of [(Snμ$_3$-NtBu)$_4$] with three equivalents of C$_{10}$H$_7$NHLi.[10] The ^{1}H NMR spectrum of complex **2a** exhibits two resonances in a 3:1 ratio for the tBu protons, and a single resonance is observed in the ^{119}Sn NMR spectrum; both of these observations are consistent with local C_3 symmetry for the anion in **2a**. The ^{7}Li NMR spectrum of **2a** shows two well-separated resonances, indicating that the [Sn$_3$Li(μ$_3$-NtBu)$_4$] cluster remains intact, even in THF solution.

The reaction of **2a** with slightly more than three equivalents of selenium in THF readily produces the tristannaselone **3a** in essentially quantitative yields within several minutes at room temperature. Complex **3b** was obtained in a similar manner from **2b** and selenium. The tristannatellone **4** can also be synthesized from **2a** and a slight excess of tellurium at room temperature in about 1 h. However, the reaction proceeds more rapidly with gentle heating (20 min, 40°C) to give **4** in 73% yield. The mild reaction conditions necessary to produce the fully chalcogenated complexes **3a**, **3b**, and **4** are in striking contrast to those used to prepare the partially chalcogenated complexes **A** and **B**, which require boiling toluene and long reaction times (24–48 h).[7] Clearly, the negative charge in the anion of **2a** results in a dramatic enhancement of the susceptibility of the Sn^{II} centers towards oxidation. The complexes **3a**, **3b**, and **4** were characterized by multinuclear NMR spectroscopy, elemental analyses and, in the case of **3b** and **4**, by X-ray crystallography.

X-ray structural determinations of **3b**[11] and **4**[12] revealed the presence of three terminal Sn=E bonds in each complex (**3b**, E = Se; **4**, E = Te) (Figure 1 and 2, respectively). For **3b**

Figure 1. X-ray crystal structure of the anion in **3b**; selected bond lengths [Å]: Sn1-Se1 2.397(1), Sn2-Se2 2.391(1), Sn3-Se3 2.386(1). Thermal ellipsoids are shown at the 30% probability level.
Figure 2. X-ray crystal structure of the anion in **4**; selected bond lengths [Å]: Sn1-Te1 2.613(1), Sn2-Te2 2.605(1), Sn3-Te3 2.610(1). Thermal ellipsoids are shown at the 30% probability level.

the Sn=Se bond lengths are nearly equal, with a mean value of 2.391(1) Å, slightly longer than the average Sn=Se bond length of 2.367(1) Å in the structurally related neutral complex **B**.[7] The average Sn=Te bond length of 2.609(1) Å in **4** is significantly longer than the corresponding bond in **A** (2.589(1) Å),[7] and slightly shorter than the distance of 2.618(1) Å observed in the five-coordinate complex [{CH(SiMe$_3$)C$_9$H$_6$N-8}$_2$SnTe].[13] The environments of the four-coordinate Sn^{IV} centers are highly distorted from tetrahedral in both structures, with bond angles in the range 83.6(2)–129.2(1)° in **3b** and 83.4(3)–129.0(2)° in **4**. The tin–nitrogen distances in **3b** and **4** show similar trends. The unique nitrogen center, which caps all three tin atoms, exhibits significantly

longer Sn−N distances (**3b**, 2.174(4)–2.184(4) Å; **4**, 2.15(1)–2.18(1) Å) in comparison to the nitrogen centers that bridge two tin atoms and the lithium atom (**3b**, 2.082(4)–2.105(4) Å; **4**, 2.07(1)–2.12(1) Å).

The solution NMR data for the complexes **3a**, **3b**, and **4** are consistent with the presence of a single species with local C_3 symmetry in each case. For example, the ^{1}H NMR spectra show two resonances in a 3:1 ratio for the N*t*Bu protons, as expected. In the ^{7}Li NMR spectra of the complexes **3a**, **3b**, and **4**, the resonance in the region $\delta = 1.7$–1.8 ppm is shifted significantly from that observed for the parent clusters **2a** or **2b** ($\delta = 2.6$ ppm), and is therefore attributed to the lithium cation that is part of the cubane cluster. For the complexes **3a** and **3b**, nearly identical NMR data were obtained, and so the data obtained for **3a** will serve as an example. The ^{119}Sn NMR spectrum of **3a** shows a single sharp resonance at $\delta = -133$ ppm, with well-resolved ^{77}Se satellites. The magnitude of $^1J_{Sn,Se}$ (3180 Hz) is comparable to the values in the range 2950–3450 Hz found for five-coordinate complexes.[13,14] A single resonance is also observed in the ^{77}Se NMR spectrum, with well-resolved ^{117}Sn/^{119}Sn satellites. The room-temperature ^{119}Sn NMR spectrum of **4** exhibits a single resonance at $\delta = -450$ ppm, which is considerably broader than that observed for **3a** and no ^{125}Te satellites are observed, presumably as a result of chalcogen exchange. Consistently, at 213 K, this resonance becomes sharper, and ^{125}Te satellites can be detected. The value of the $^1J_{Te,Sn}$ coupling (8400 Hz) is consistent with an Sn=Te terminal bond.[13] A single resonance at $\delta = -314$ ppm was observed in the ^{125}Te NMR spectrum of **4**, however poor solubility at low temperature prohibited the observation of well-resolved tin satellites.

The facile chalcogen exchange between clusters can be used advantageously for the synthesis of partially chalcogenated derivatives. Thus, stoichiometric addition of **2a** to solutions of **3a** or **4** results in the rapid and clean formation of the corresponding mono- and dichalcogenated clusters. This approach produces analytically pure products more readily than the direct reaction of **2a** with elemental chalcogens. Details of the synthesis and characterization of the partially chalcogenated complexes will be reported in a full account of this work.

In summary, we have developed a new, high-yield, synthetic route to completely chalcogenated imidotin clusters, which proceeds rapidly under mild conditions. The Sn^{II} centers of the anionic cubane in the solvent-separated ion pairs **2a** or **2b** show remarkable reactivity towards chalcogenation. Furthermore, the dilithio complexes **3** and **4** obtained by this route are potential synthons for the generation of a variety of heterobimetallic imidotin chalcogenides, which may serve as a source of ternary semiconductors by the thermal elimination of the diazene *t*BuN=N*t*Bu.[15]

Communications

referenced to the external standards $(SePh)_2$, $SnMe_4$, and $(TePh)_2$, respectively. The reagent **1** was prepared by modification of the literature procedure.[9]

2a: A solution of **1** (9.00 g, 14.0 mmol) in THF (100 mL) was cooled to −78 °C to form a yellow slurry, and a cold (−78 °C) THF solution (60 mL) of *n*-butyllithium (1.6 M in hexane, 17.5 mL, 28.0 mmol) was added dropwise by using a cannula over 40 min. The resulting clear orange solution was stirred for 30 min at −78 °C, then allowed to warm slowly to room temperature, and stirred for an additional 45 min. The solvent was removed under vacuum and the yellow-orange residue was washed with hexanes (4 × 50 mL). The remaining solid was dissolved in diethyl ether (200 mL) and the solution was concentrated to about 100 mL, resulting in the precipitation of fine yellow crystals of **2a** (5.50 g, 39%). Elemental analysis calcd (%) for **2a** (with loss of one THF) $C_{32}H_{68}N_4Li_2O_4Sn_3$: C 40.76, H 7.27, N 6.79; found: C 40.32, H 7.40, N 6.49; ^1H NMR: $\delta = 1.32$ (s, 27H; N*t*Bu), 1.35 (s, 9H; N*t*Bu), 1.78 (m, 20H; THF), 3.63 ppm (m, 20H; THF); ^7Li NMR: $\delta = -0.62$ (s; $[Li(thf)_4]^+$), 2.63 ppm (s; $[(thf)LiSn_3(NtBu)_4]^-$); ^{119}Sn NMR: $\delta = 538$ ppm.

2b: A solution of [12]crown-4 (0.40 mL, 2.42 mmol) in THF (25 mL) was added to a solution of **2a** (2.50 g, 2.46 mmol) in THF (50 mL) by using a cannula, and the mixture was stirred for 30 min at 25 °C. The solvent was removed under vacuum and the residue was washed with cold diethyl ether (50 mL) to give **2b** as a pale yellow solid (1.88 g, 78%). Elemental analysis calcd (%) for **2b** (with loss of 0.5 THF) $C_{30}H_{64}N_4Li_2O_{5.5}Sn_3$: C 38.38, H 6.87, N 5.97; found: C 38.14, H 6.77, N 6.60; ^1H NMR: $\delta = 1.34$ (s, 27H; N*t*Bu), 1.37 (s, 9H; N*t*Bu), 1.78 (m, 8H; THF), 3.63 (m, 8H; THF), 3.84 ppm (s, 16H; [12]crown-4); ^7Li NMR: $\delta = -0.47$ (s; $[(thf)Li([12]crown-4)]^+$), 2.61 ppm (s; $[(thf)LiSn_3(NtBu)_4]^-$); ^{119}Sn NMR: $\delta = 534$ ppm (s).

3a: A mixture of **2a** (0.600 g, 0.59 mmol) and gray selenium powder (0.160 g, 2.03 mmol) in THF (20 mL) was stirred for 5 min at 25 °C. The resulting deep yellow solution was filtered though a 0.45 μm pore size filter disk, concentrated to about 5 mL, and **3a** was precipitated as a yellow solid (0.720 g, 97%) by the addition of diethyl ether. Elemental analysis calcd (%) for $C_{36}H_{76}N_4Li_2O_5Se_3Sn_3$: C 34.54, H 6.12, N 4.48; found: C 33.74, H 5.86, N 4.58; ^1H NMR: $\delta = 1.47$ (s, 27H; N*t*Bu), 1.57 (s, 9H; N*t*Bu), 1.77 (m, 20H; THF), 3.61 ppm (m, 20H; THF); ^7Li NMR: $\delta = -0.60$ (s; $[Li(thf)_4]^+$), 1.75 ppm (s; $[(thf)LiSn_3(NtBu)_4]^-$); ^{77}Se NMR: $\delta = -174$ ppm (s, $^1J_{119Sn,77Se} = 3185$ Hz, $^1J_{117Sn,77Se} = 3065$ Hz); ^{119}Sn NMR: $\delta = -133$ ppm (s, $^2J_{119Sn,117Sn} = 305$ Hz, $^1J_{119Sn,77Se} = 3180$ Hz).

3b: This complex was prepared similarly from **2b** (0.200 g, 0.21 mmol) and gray selenium powder (0.053 g, 0.67 mmol) and obtained as a yellow solid (0.228 g, 91%). Elemental analysis calcd (%) for $C_{32}H_{68}N_4Li_2O_6Se_3Sn_3$: C 31.72, H 5.66, N 4.62; found: C 31.84, H 5.87, N 4.47; ^1H NMR: $\delta = 1.50$ (s, 27H; N*t*Bu), 1.60 (s, 9H; N*t*Bu), 1.78 (m, 8H; THF), 3.63 (m, 8H; THF), 3.85 ppm (s, 16H; [12]crown-4); ^7Li NMR: $\delta = -0.44$ (s; $[(thf)Li([12]crown-4)]^+$), 1.72 ppm (s; $[(thf)LiSn_3(NtBu)_4]^-$); ^{77}Se NMR: $\delta = -172$ ppm (s, $^1J_{119Sn,77Se} = 3174$ Hz, $^1J_{117Sn,77Se} = 3030$ Hz); ^{119}Sn NMR: $\delta = -133$ ppm (s, $^2J_{119Sn,117Sn} = 312$ Hz, $^1J_{119Sn,77Se} = 3200$ Hz). X-ray quality crystals of **3b** were obtained by slow diffusion of *n*-hexane into a THF solution.

4: A mixture of **2a** (0.600 g, 0.59 mmol) and tellurium powder (0.260 g, 2.04 mmol) in THF (30 mL) was stirred for 20 min at 40 °C. The resulting deep orange solution was filtered though a 0.45 μm pore size filter disk, concentrated to about 5 mL, and diethyl ether (1 mL) was added to give **4** as red crystals (0.600 g, 73%). Elemental analysis calcd (%) for $C_{36}H_{76}N_4Li_2O_5Sn_3Te_3$: C 30.93, H 5.48, N 4.01; found: C 30.79, H 5.61, N 4.07; ^1H NMR: $\delta = 1.52$ (s, 27H; N*t*Bu), 1.62 (s, 9H; N*t*Bu), 1.78 (m, 20H; THF), 3.62 ppm (m, 20H; THF); ^7Li NMR: $\delta = -0.70$ (s; $[Li(thf)_4]^+$), 1.82 ppm (s; $[(thf)LiSn_3\{NtBu\}_4]$); ^{119}Sn NMR (213 K): $\delta = -439$ ppm (s, $^1J_{125Te,119Sn} = 8400$ Hz); ^{125}Te NMR: $\delta = -313$ ppm. X-ray quality crystals of **4** were obtained by slow diffusion of *n*-hexane into a THF solution.

[11] Crystal data for **3b**: 2 ($C_{32}H_{68}N_4Li_2O_6Se_3Sn_3$)·0.5($C_4H_8O$), $M_r = 2459.52$, monoclinic, space group $P2_1/c$, $a = 26.332(5)$, $b = 10.920(2)$, $c = 36.260(7)$ Å, $\beta = 107.51(3)°$, $V = 9943(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.643$ g cm^{-3}, $\mu = 3.731$ mm^{-1}, $T = 173(2)$ K. A yellow platelike crystal ($0.20 \times 0.12 \times 0.05$ mm^3) was coated with Paratone 8277 oil and mounted on a glass fiber. Data were collected on a Nonius Kappa CCD diffractometer by using Mo$_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The structure was solved by Patterson techniques and refined by least-squares calculations (SHELXL-97). Of the 84 930 reflections collected, 22 185 were unique ($R_{int} = 0.071$) and used to refine 891 parameters. Complex **3b** crystallizes with two independent but chemically equivalent molecules in the asymmetric unit. The disorder in the [12]crown-4 unit and the coordinated and lattice-bound THF molecules was treated by using appropriate models. Refinement was carried out on F^2 against all independent reflections and converged at $R_1 = 0.050$ (for 15 995 reflections with $I > 2\sigma(I)$) and $wR_2 = 0.133$ (for all data).

[12] Crystal data for **4**: 6 ($C_{36}H_{76}N_4Li_2O_5Sn_3Te_3$)·0.5($C_6H_{14}$), $M_r = 8429.63$, triclinic, space group $P\bar{1}$, $a = 23.401(5)$, $b = 26.126(5)$, $c = 26.459(5)$ Å, $\alpha = 84.97(3)$, $\beta = 84.26(3)$, $\chi = 83.01(3)°$, $V = 15 929(6)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.758$ g cm^{-3}, $\mu = 3.053$ mm^{-1}, $T = 173(2)$ K. Crystal size : $0.16 \times 0.06 \times 0.06$ mm^3. Data collection, structure solution and refinement followed the procedures outlined above for **3b**. Of the 182 994 reflections collected, 55 941 were unique ($R_{int} = 0.071$) and used to refine 2556 parameters. Complex **4** crystallizes with six independent, but chemically equivalent molecules in the asymmetric unit. Disorder in the cubane and THF molecules was treated by using appropriate models. Refinement converged at $R_1 = 0.071$ (for 35 294 reflections with $I > 2\sigma(I)$) and $wR_2 = 0.177$ (for all data). CCDC-241572 (**3b**) and CCDC-241573 (**4**) contain the supple-

mentary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB21EZ, UK; fax: ($+$44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

Regio- and Stereoselective Construction of γ-Butenolides through Phosphine-Catalyzed Substitution of Morita–Baylis–Hillman Acetates: An Organocatalytic Allylic Alkylation**

*Chang-Woo Cho and Michael J. Krische**

The γ-butenolide ring system ranks among the most ubiquitous structural motifs found in naturally occurring organic molecules.[1] Owing to the prevalence of γ-butenolides, their regio- and stereoselective synthesis has been the focus of intensive effort.[2] In this regard, the use of 2-silyloxy furans as nucleophilic partners in Mukaiyama–aldol-,[3] Mukaiyama–Michael-,[4,5] and Mukaiyama–Mannich-type additions[6] has emerged as an effective strategy. Even broader access to butenolide substructures would be possible through the development of new electrophilic partners amenable to 2-silyloxy furan addition. For example, the use of allylic carboxylates as electrophiles in silyloxy furan addition is unknown and would provide access to γ-butenolides with vicinal stereogenic centers. Herein we disclose that upon exposure of Morita–Baylis–Hillman (MBH) acetates **1a–12a** to substoichiometric amounts of triphenylphosphane (20 mol%) in the presence of 2-trimethylsilyloxy furan, regiospecific allylic substitution occurs to provide the products of *C*-allylation, that is, γ-butenolides **1b–12b** (Table 1). Good to excellent yields, regioselectivities, and diastereose-

lectivities are attained and, in the case of the (−)-8-phenylmenthol ester **14a** (Scheme 3), the absolute stereochemical course of the substitution is controlled.

Recently, a two-step protocol for the amination of MBH acetates mediated by DABCO was reported.[7a,b] A related two-step transformation employing quinidine subsequently appeared.[7c] Following reports of these stoichiometric processes, the DABCO-catalyzed decarboxylative rearrangement of MBH carbamates was demonstrated.[7d] Finally, (DHQD)₂PHAL was recently shown to catalyze regioretentive allylic substitution of MBH acetates when using sodium bicarbonate as a nucleophile.[7e] The corresponding MBH alcohols were produced in 25–42% yield with 54–92% *ee*. As part of a program in nucleophilic catalysis based on phosphine conjugate addition,[8] the first *phosphine-catalyzed* allylic substitution of Morita–Baylis–Hillman (MBH) acetates was reported from our lab.[8e] A key feature of this transformation appears to involve the generation of an electrophile–nucleophile ion pair, which suppresses direct addition of the nucleophile to the less substituted enone moiety of the starting MBH acetate. The enone immediately obtained upon addition of the phosphine may also benefit from activation through internal coordination to phosphorus (Scheme 1). In
Scheme 1. Postulated catalytic mechanism for γ-butenolide synthesis through tandem $S_N2'–S_N2'$ substitution.

our initial study, an acid–base reaction between the leaving group (acetate) and the pronucleophile (4,5-dichlorophthalimide) served to generate the requisite electrophile–nucleophile ion pair. Given the propensity of organosilicon compounds to form hypervalent anions or "ate" complexes,[9] the development of related catalytic C–C bond formations involving electrophile–nucleophile ion pair intermediates derived from enol silane based pronucleophiles was deemed feasible.

To explore this prospect, MBH acetate **1a** (100 mol%) derived from methyl vinyl ketone (MVK) was exposed to 2-trimethylsilyloxy furan (200 mol%) in the presence of triphenylphosphane (20 mol%) in THF solvent (0.3 M) at 0°C. Gratifyingly, the desired product of allylic substitution, γ-butenolide **1b**, was isolated in 88% yield as a single *syn* diastereomer. The regioisomeric substance **1c** was also formed in 9% yield. Withstanding changes in reaction temperature, these conditions proved general across a range

of related MVK-derived MBH acetates **2a–6a**, which bear aromatic, aliphatic, cyclopropyl, vinylic, and acetylenic substituents. All MVK-derived products **1b–6b** were obtained with diastereomeric ratios of ≥ 20:1 (*syn/anti*). Similarly, the corresponding acrylate-derived MBH acetates **7a–12a** provide γ-butenolides **7b–12b** with excellent regioselectivity. Butenolides **7b**, **8b**, **11b**, and **12b**, which bear aromatic, vinylic, and acetylenic substituents, were obtained with excellent diastereoselectivity. However, acrylate-derived MBH acetates **9b** and **10b**, which bear *n*-alkyl and cyclopropyl substituents, respectively, were obtained with lower diastereoselectivities (Table 1).

The high levels of diastereoselectivity attained in these substitutions do not appear to be consistent with an open transition state. It is possible that the high diastereoselectivity arises as a consequence of a mechanism involving *endo*-selective Diels–Alder cycloaddition of the siloxy furan ate complex with the enone obtained upon the addition of the phosphine followed by subsequent Grob-type fragmentation. Structurally related silyloxy furan-enone [4+2] cycloadducts have been isolated. Notably, the high levels of diastereoselectivity observed in the formation of **1b–12b** require that the intermediate phosphine adducts appear as single enone geometrical isomers, irrespective of which mechanism is operative (Scheme 2).[5b]

[a] Procedure: THF (1.6 mL, 0.3 M) was added to a reaction vessel charged with the MBH acetate (0.5 mmol, 100 mol%), 2-trimethylsilyloxy furan (1.0 mmol, 200 mol%), and PPh₃ (0.1 mmol, 20 mol%). The reaction mixture was allowed to stir at 0°C (**1a**, **6a**, **7a**), 25°C (**2a**, **4a**, **5a**, **8a**, **12a**), 50°C (**3a**), or 80°C (**9a–11a**) until complete consumption of starting material was observed, at which point the reaction mixture was adsorbed onto silica gel by evaporation of the solvent, and the product was isolated by silica-gel chromatography. [b] A diastereomeric ratio of > 95:5 indicates that the minor isomer could not be detected by ¹H NMR spectroscopy.
Scheme 2. Alternate mechanisms postulated for the phosphine-catalyzed allylic substitution of MBH acetates to form γ-butenolides.

To control the absolute stereochemical course of this transformation, a chiral auxiliary approach was explored. Whereas (−)-menthol ester **13a** provides the γ-butenolides **13b** and **13c** in good yield, poor levels of asymmetric induction are observed. In contrast, the corresponding (−)-8-phenylmenthol ester **14a** provides the γ-butenolide **14b** in excellent yield and with complete levels of stereocontrol (Scheme 3). The diastereomeric butenolide **14c** was not observed. The stereochemical assignment of **14b**, which is supported by X-ray diffraction analysis, led to the indicated model for stereochemical induction.
Scheme 3. Controlling the absolute stereochemical course of allylic substitution through the use of (−)-8-phenylmenthol ester **14a**.

In summary, upon exposure of MBH acetates **1a–12a** to 2-trimethylsilyloxy furan in the presence of substoichiometric quantities of triphenylphosphine, highly regio- and stereoselective substitution occurs to provide γ-butenolides **1b–12b**. Moreover, as demonstrated by the substitution of MBH acetate **14a**, the absolute stereochemical course of these transformations is controlled through the use of the (−)-8-phenylmenthol ester. Future studies will focus on the development of related transformations, including enantioselective variants of the transformation described herein.

Communications

functional materials with complex architectures. The multi-scale ordering, interlinking, and interfacing of preformed nanoparticles and small crystals can be directed internally by programmed assembly or externally by using a variety of structured organic templates. The former is achieved by self-coding of the inorganic building blocks with information-rich connectors, such as DNA duplexes,[3] antibody–antigen complexes[4] and streptavidin–biotin conjugates,[5] complementary force fields based on electrostatic matching,[6] or shape-directed hydrophobicity.[7] In contrast, preformed nanoparticles can be organized within porous templates such as silica/polymer opals,[8] polymer sponges[9] or perfluorohexane foams[10] to produce ordered macroporous inorganic replicas, or assembled onto polymer beads to form core–shell or hollow microspheres.[11] Inorganic nanoparticles have also been assembled by using miniemulsion droplets,[12] and recent studies involving sonicated water-in-oil emulsions have shown that highly complex spheroids can be assembled from silica/Au nanoparticles.[13]

Exploitation of the above strategies in catalysis and separation science is timely as the chemical synthesis and fabrication of self-supported multifunctional materials with hierarchical porosity, complex formation, and multiscale ordering remains a significant challenge. Recently, nanoslabs of the aluminium-free zeolite, silicalite, were assembled into periodically ordered mesostructures by surfactant templating.[14] Silicalite nanoparticles, about 50 nm in size, have also been organized on extended length scales to produce macroporous architectures by using multicellular bacterial threads,[15] starch sponges,[16] or polyurethane foams,[17] or assembled around latex beads to produce hollow microspheres with hierarchical porosity.[18] Other studies have demonstrated that zeolite crystals several micrometers in size can be organized into 2D arrays by using patterned solid substrates,[19] or arranged into self-supporting complex hollow microspheres by sonication of aqueous dispersions in toluene.[20]

Herein we demonstrate two new routes to the formation of higher-order zeolite materials based on template-directed processes that use the water-soluble polysaccharide, dextran and involve preformed zeolite crystals/nanoparticles as inorganic building blocks. In the first approach, which is based on a recent discovery in the preparation of metal and metal-oxide sponges,[21] centimeter-sized macroporous framework monoliths of interconnected filaments composed of NaY crystals and amorphous silica nanoparticles are prepared by slow thermal processing of dextran/inorganic pastes. The zeolite crystals are embedded in the silica matrix to promote homogeneity in the distribution of active sites within the filamentous framework, and increase the strength of the macroporous monoliths. In the second approach, macroscopic threads of dextran are prepared and used to align linear chains of 100 nm-sized silicalite crystals to produce inorganic fibers with an ordered superstructure of crystallographically oriented prismatic crystals. The silicalite chains, which consist of up to 20 coaligned crystals, are prepared by a novel process involving hydrothermal synthesis in the presence of the cationic polymer, poly(diallyldimethylammonium hydroxide). Our results demonstrate that superstructural ordering of

zeolite crystals within complex macroscopic morphologies can be achieved, and suggest that further development of these proof-of-concept studies should provide a range of novel hierarchical multifunctional materials for potential use in catalysis and separation science.

Open-framework zeolite monoliths were prepared as follows. Dextran ($M_r = 70000$) was dissolved in an aqueous suspension, consisting of 20:1 wt ratio, respectively, of sub-micron-sized NaY zeolite crystallites (size range, 0.7–1 µm) and silica nanoparticles (diameter, 14 nm) to produce a viscous paste that was air dried for two days. Controlled heating of the paste resulted in thermal decomposition of the dextran matrix at around 270 °C with associated outgassing of steam and carbon dioxide to produce an expanded carbon-based foam that served as a template for patterning the thermally induced aggregation of the silica/zeolite particles. Increasing the temperature slowly to 470 °C at a heating rate of 2 °C min⁻¹ resulted in the gradually destruction and removal of the carbon foam, and the formation of an intact inorganic spongelike replica, 1–2 cm in size, that was further heated to 600 °C to remove residual organic constituents.

In general, the above procedure resulted in the preparation of self-supporting replicas that were fragile but sufficiently robust to be handled with care. SEM investigations indicated that the replicas consisted of a continuous open framework of interconnected filaments, about 15 µm in width and 100–150 µm in length (Figure 1). The filaments intersected at distinct three-point junctions to produce open cells that were usually five- or six-sided and 100–300 µm across. Interestingly, the inorganic frameworks exhibited a gradient in pore sizes, with cells produced close to the outer surface of the dextran paste generally larger than those formed deep
Figure 1. SEM micrograph showing open macroporous zeolite/silica framework prepared by dextran templating; scale bar = 100 µm. Inset; high magnification of a single-wall filament showing NaY crystals embedded in a continuous silica matrix; scale bar = 5 µm.

within the matrix. High-magnification images indicated that the filaments were composed of discrete micrometer-sized zeolite crystals embedded within a continuous matrix of condensed silica nanoparticles (Figure 1, inset). Significantly, X-ray diffraction studies showed almost identical reflections for the NaY crystals before and after heating the dextran composites to 600 °C, and BET analysis revealed no corresponding change in the type I isotherm, micropore size distribution, or surface area (650 m^{2}g^{-1}), thus indicating that no degradation in the zeolite structure occurred during formation of the spongelike material.

Interestingly, closed-framework structures were obtained when NaY particles with size distribution of 0.3–0.4 μm were used in combination with colloidal silica solution at a respective weight ratio of 20:1. Under these conditions, the zeolite particles were small enough to stabilize the formation of thin self-supporting NaY/silica films across the 100–300 μm-sized apertures of the cellular framework (Figure 2). The supporting filamentous frame was typically 50 μm in width, whereas the membranes enclosing each cell were only

Figure 2. SEM images of closed cell NaY/silica frameworks. a) Top view showing underlying framework and intact aperture membrane; scale bar = 100 μm. Inset; high magnification image of the ultrathin membrane showing NaY crystals and silica matrix; scale bar = 0.5 μm. b) interior view showing details of closed cell architecture; scale bar = 100 μm.

about 150 nm in thickness. Although the thin inorganic membranes were present throughout the framework monolith, they were very fragile and often split or destroyed when examined by SEM.

The above results indicate that spongelike silica/NaY composites with porosity at both the nano- and macroscale can be prepared by sacrificial dextran templating that involves the in situ formation of thermally induced dextran-derived foams. Other investigations showed that formation of the intact macroporous frameworks depended on the composition of the paste, as well as the heating rates used during thermal processing. For example, by using the above paste composition but with a higher heating rate of 10 °C min^{-1}, samples that contained residual carbon even at 500 °C were produced. Consequently, it was necessary to heat the materials to 650 °C for several hours to prepare carbon-free replicas. However, these conditions resulted in the collapse of the NaY structure, as evidenced by the XRD data, to give frameworks with a low wall porosity of 20 m^{2}g^{-1} (BET analysis). Whereas intact macroporous sponges could be prepared by using silica nanoparticles and dextran alone, significantly, samples synthesized by using NaY and dextran at a low heating rate 2 °C min^{-1} in the absence of silica gave frameworks that were too fragile to be routinely handled. Similar results were also observed when mixtures of dextran and silicalite nanocrystals were used.

Dextran templating was also used to prepare intact macroscopic fibers of aligned silicalite crystals. Significantly, the crystals were preorganized in the form of discrete self-assembled chains (Figure 3a), which were prepared by hydrothermal synthesis in the presence of the water-soluble cationic polymer, poly(diallydimethylammonium hydroxide. The chains were formed in situ within the reaction medium and consisted of prismatic particles that were coaligned with their crystallographic *b* axes parallel to the chain axis, as shown by TEM/electron diffraction analysis (data not shown) and XRD (Figure 4a,b). An aqueous suspension of the chains was mixed with dextran and long fibers up to 20 cm in length were pulled from the mixture, and air-dried. This process resulted in an intact composite fiber that consisted of a densely packed network of silicalite chains oriented preferentially along the morphological long axis, which was subsequently slowly heated to 550 °C to remove the dextran matrix. In general, this procedure resulted in intact inorganic replicas when the precursor threads were a few centimetres in length, whereas longer threads tended to disintegrate into smaller inorganic fibers. In each case, the calcined materials were highly textured and consisted of a superstructure of silicalite crystals. Significantly, materials prepared from dextran/silicalite threads, 20–30 μm in width, were highly ordered with chains of silicalite crystals preferentially aligned along the fiber axis (Figure 3b,c). Corresponding XRD measurements indicated that the silicalite micropore structure was retained after thermal treatment, and that the peak intensity of the (0$\underline{10}$0) reflection was reduced compared to a nonoriented control sample (Figure 4c). The data confirmed that under these conditions, the silicalite crystals within the oriented superstructure were preferentially aligned such that the crystallographic *b* axis was parallel to the fiber direction.

Figure 3. a) As-synthesized ordered chains of silicalite crystals viewed by SEM; scale bar = 1 μm. b) Inorganic fiber with ordered superstructure of silicalite crystals prepared from calcined dextran/silicalite thread; scale bar = 5 μm. c) High-magnification image showing *iso*-oriented texture of prismatic silicalite crystals aligned parallel to the fiber axis; scale bar = 1 μm.
In contrast, the use of thicker dextran/silicalite precursor threads introduced increased levels of particle disorder and macroporous voids in the inorganic replicas, presumably due to enhanced entrapment of gas bubbles and associated disruption of the silicalite chains during thermal processing.

In conclusion, the above results indicate that dextran/inorganic composites can be used for the facile preparation of zeolite materials with higher-order structure, morphology, and porosity. The methods use the ability of dextran to be readily drawn into macrothreads from viscous solutions, or prepared as thick pastes as precursors to thermally induced foams. In both cases, the polysaccharide matrix is used as a sacrificial template to coalign or spatially pattern the zeolite crystals. Removal of dextran by heating the soft macrothreads results in minimal disruption to the constituent silicalite crystals, and the high level of crystal packing induced by the fiber-drawing process, as well as preorganization of the silicalite particles into chainlike assemblies, are sufficient to produce intact fibrous superstructures during sintering. In contrast, thermal decomposition of the pastes gives rise to an open framework of interconnected NaY-containing filaments due to temporary stabilization of CO_2 microbubbles in the lower-density matrix, which induces phase separation and spatial patterning of the zeolite crystals. However, in this case, the level of sintering between zeolite crystals is insufficient to form a self-supporting framework, and a silica "mortar" is required to stabilize the inorganic microfilaments. Interestingly, the presence of silica in association with NaY crystals of relatively small size (300–400 nm) produces intact frameworks in which the individual cell apertures are veiled in a thin micrometer-thick inorganic membrane. Although these structures are very fragile, the ability to prepare both open and closed frameworks of organized zeolite crystals could have interesting applications, for example in high-resolution separation processes. Further work is in progress to extend the above templating procedures to higher-order zeolite architectures with appropriate stability for applications testing and development.

Experimental Section

Preparation of NaY zeolite/silica framework monoliths: NaY zeolite crystals 0.7–1 μm in size were separated from a commercial sample (Aldrich Cat. No. 33, 444-8, SiO_2/Al_2O_3 mole ratio = 5.1; Na_2O wt % = 13) by fractional sedimentation in ethanol by using successive centrifugation at 3000 rpm for 3 min. The BET surface area was 450 $m^2 g^{-1}$ (as supplied) and 610 $m^2 g^{-1}$ (after heating at 2°C min⁻¹ to 600°C). Alternatively, NaY particles with size a distribution of 0.3–0.4 μm were synthesized according to previous methods.[22] An aqueous suspension consisting of NaY and silica particles at a respective weight ratio of 20:1 was prepared by the addition of 0.1 g of submicrometer-sized NaY crystals to 1 mL distilled water, followed by 0.025 g of a 20 wt % colloidal silica suspension (Snowtex C, Nissan Chem. Co., particle size, 14 nm). Dextran (2 g, M_r 70 000) was then dissolved in the suspension to form a viscous solution which was transferred to an open dish and left to air-dry for 2 days. The dried paste was heated to 600°C at a heating rate of 2°C min⁻¹, held at 600°C for 30 min, and then cooled to room temperature in the furnace. Samples were removed and investigated by SEM, XRD, TGA, FTIR spectroscopy and BET analysis (TGA is thermogravimetric analysis).

Preparation of silicalite chains and oriented multichain fibers: Linear chains of prismatic crystals of silicalite-1 were prepared as follows: Tetraethylorthosilicate (TEOS; 16 g, 76.8 mmol) was slowly added to a stirred aqueous solution that contained 1 M tetrapropylammonium hydroxide (TPAOH; 27.32 g, 27.0 mmol) and 20 wt% poly(diallydimethylammonium hydroxide) (PDAC; 10 g, 0.015 mmol). After the reaction had been stirred for 24 h at room temperature, large agglomerates were removed and 10 ml of the resulting cloudy suspension poured into a 20 mL hydrothermal bomb, and placed in a preheated oven at 150 °C and left at this temperature for 24 h. After cooling to room temperature, the white suspension was centrifuged and the supernatant fluid removed, and deionized water added and the precipitate resuspended by shaking. This washing procedure was repeated four times to give suspension 6–7 wt% in solids that slowly sedimented over a period of a few days.

Inorganic macrofibers comprising coaligned chains of silicalite crystals were prepared as follows: 2.0 g of dextran (M_r 70 000) was dissolved in 1 mL of an aqueous suspension containing about 3 wt% silicalite crystals in the form of linear chains to form a viscous solution. Dextran/silicalite threads, often 20–30 μm in width and up to 20 cm in length, were then drawn from the vicsous solution by insertion and slow removal of a spatula tip. The composite threads were air-dried and then heated to 550 °C at 2 °C min^{-1} for 12 h before cooling to room temperature in the furnace. The resulting intact inorganic fibers were removed and investigated by a range of physical methods.

Chirality

Meteoritic Cα-Methylated α-Amino Acids and the Homochirality of Life: Searching for a Link

*Marco Crisma, Alessandro Moretto,
Fernando Formaggio, Bernard Kaptein,
Quirinus B. Broxterman, and Claudio Toniolo**

Growing evidence has recently accumulated on the occurrence of chiral, Cα-methylated α-amino acids with significant ʟ (*S*) enantiomeric excess (*ee*; up to 15%) in carbonaceous chondritic meteorites.[1–3] The amino acids analyzed to date include isovaline (Iva), Cα-methyl norvaline [(αMe)Nva], Cα-

methyl valine [(αMe)Val], C$^\alpha$-methyl isoleucine [(αMe)Ile], and C$^\alpha$-methyl *allo*isoleucine [(αMe)*a*Ile] (Figure 1). In contrast, the α-amino acids lacking the C$^\alpha$-methyl group (including the proteinogenic amino acids) have been found to be
Figure 1. C$^\alpha$-Methylated α-amino acids found in significant L enantiomeric excess in the Murchison and Murray meteorites. Chiral carbon atoms are starred.

racemic within experimental and terrestrial contamination errors.[1–6] As opposed to C$^\alpha$-methylated α-amino acids which are known to resist racemization, proteinogenic amino acids tend to racemize on an evolutionary time scale owing to their weakly acidic C$^\alpha$-hydrogen.[5,7–12] It has been calculated that during just one million years an amount of $\geq 10^{12}$ Kg of organic carbon was delivered by meteorites to the Earth.[1–3] It has been also shown that C$^\alpha$-methylated α-amino acids are generally abundant (10–100 ppm) in meteorites, although the ratios of C$^\alpha$-methylated to C$^\alpha$-nonmethylated α-amino acids (e.g., Iva/Ala) vary significantly (6.8/0.3) between samples. Other potentially chiral organic compounds largely found in meteorites are the α-hydroxy acids. For both classes of compounds (α-amino and α-hydroxy acids) a Strecker-like synthesis from aldehydes and ketones, HCN, water, and ammonia has been proposed.[13] Taken together, these results have suggested that C$^\alpha$-methylated α-amino acids of extraterrestrial origin, delivered by meteorites which heavily bombarded the early Earth, could have been homochirality seeds for life on our planet,[14] which has developed upon proteinogenic amino acids of L-configuration. However, as C$^\alpha$-methylated α-amino acids play a marginal role in contemporary biochemistry, this hypothesis implies that their *ee* values would have been somehow transferred to proteinogenic amino acids.[14] The results reported herein represent an addition to the already postulated mechanisms of chiral transmission between biomolecules, the two most recently published mechanisms involve the stable homochiral Ser octameric cluster[15] and Iva itself[16] as key players. It was also proposed[14] that initially life may have been based on the 3_{10} helix,[17] the typical architecture of peptides rich in C$^\alpha$-methylated α-amino acids,[18,19] rather than on the α helix, the most stable regular secondary structure of proteinogenic amino acids.

Herein we describe the results of a study aimed at determining whether appropriately carboxy-activated, short peptides and long, 3_{10} helical peptides, based on chiral, C$^\alpha$-methylated α-amino acids, can react with proteinogenic

amino acids and favor the incorporation in the sequence of one of their enantiomers over the other. Our investigation focused on L-Iva and L-(αMe)Nva, as they are some of the most abundant and frequently analyzed chiral C$^\alpha$-methylated α-amino acids in terms of *ee* value in meteoritic samples,[1–3] and on L-(αMe)Val, as a representative of the highly sterically hindered subclass of β-branched, C$^\alpha$-methylated α-amino acids which also includes L-(αMe)Ile and L-(αMe)*a*Ile.[1–3]

There is a general agreement on the view that some sort of chemical evolution occurred before the onset of life on Earth, this evolution led to the formation of polymers, or at least oligomers, of amino acids. Therefore, we developed a test system based on homochiral homooligomers of Iva, (αMe)Nva, and (αMe)Val (Figure 2). These peptides are acetylated (Ac) at the N-terminus and activated as 5(4H)-oxazolones (OXL) at the C-terminus. While N-acetylation favors peptide solubilization in organic solvents and prevents
Figure 2. The test system developed for this study. Xxx represents a C$^\alpha$-methylated α-amino acid (R = ethyl: Iva; *n*-propyl: (αMe)Nva; *iso*-propyl: (αMe)Val), while Aaa is a proteinogenic amino acid, either in its free form (Y = OH) or protected as the methyl ester (Y = OCH$_3$). The H-DL-Aaa-Y:Ac-(L-Xxx)$_n$-OXL molar ratio (in acetonitrile or acetonitrile–water mixtures) was 8:1, large enough to ensure thermodynamic rather than kinetic control of the stereochemical outcome of the reaction.

reactivity of the α-amino function, the use of OXL is because they are generated to a significant extent from C$^\alpha$-methylated α-amino acid residues by nearly all activation methods used for peptide-bond formation.[20] In particular, oxazolones are easily produced by intramolecular dehydration of C$^\alpha$-methylated peptides with a free carboxy terminus. Thus, oxazolones represent an almost unavoidable entry to prebiotic peptide formation involving C$^\alpha$-methylated α-amino acids. These peptide oxazolones were allowed to react with a large excess (8 equiv) of the racemate of a representative proteinogenic amino acid or its methyl ester (e.g. H-DL-Val-OH or H-DL-Val-OMe). Formation of the two resulting diastereomeric peptides (differing by the chirality of the incorporated,

C-terminal proteinogenic amino acid) was quantified chromatographically.

Initial experiments were performed in acetonitrile (a good solvent for reaction and HPLC analysis of terminally blocked peptides) with dipeptide oxazolones carrying one C^α-methylated L-residue at the C-terminus and the achiral α-aminoisobutyric acid (Aib, or C^α-methyl alanine), which is abundant in chondritic meteorites,[21] at the penultimate position. Homochiral tripeptides are preferentially formed. Diastereoselection is temperature independent, and is comparable for L-Iva and L-(αMe)Nva while it is significantly higher for L-(αMe)Val (Table 1). By shifting the chiral residue to the penultimate position [for example, Ac-L-(αMe)Val-Aib-OXL] diastereoselection is completely suppressed (data not shown). These results would suggest that the chiral residue within the oxazolone ring is the only one involved in the stereoselection process. However, the related homodipeptide oxazolones behave differently (Table 1). The homochiral diastereoselectivities are temperature dependent and significantly lower than those obtained with the corresponding Ac-Aib-L-Xxx-OXLs, particularly at 30°C and for the L-(αMe)Val oxazolone, thus pointing to a role of the penultimate residue as well in the diastereoselection process. These results can be explained on the basis of the reactant-like nature of the transition state of the step leading to peptide-bond formation through oxazolones,[22] and of the likely occurrence of multiple conformers, differently populated at different temperatures, for the homodipeptide oxazolones. This occurrence of multiple conformers is particularly relevant for the relatively large temperature effect observed for the L-Iva homodipeptide oxazolone. Indeed, two independent molecules are present in the X-ray diffraction structure of Ac-(L-Iva)$_2$-OXL,[23] differing by the signs of the φ,ψ backbone torsion angles at the penultimate residue.

Our investigation of the diastereoselection by the homochiral, homopeptide oxazolones was extended to the pentamer level for L-Iva and L-(αMe)Nva, and to the octamer for L-(αMe)Val (Table 1). For the L-Iva series preferential incorporation of the homochiral proteinogenic amino acid is observed. Diastereoselectivity tends to level off at the tetramer/pentamer level. In the L-(αMe)Nva series the L-selectivity decreases slightly but steadily with increasing peptide length, tending to a preference for the heterochiral

peptide at the pentamer level. For the L-(αMe)Val series reversal of diastereoselection from L to D is found at the trimer level, all longer oligomers giving large heterochiral diastereoselectivities. Along this series the largest variation is observed from trimer to tetramer.

These results led us to the hypothesis that the C^α-methylated residue within the oxazolone ring and the preceding one have opposite effects on diastereoselection. More specifically, the chiral, C^α-methylated residue within the oxazolone ring seems to favor the incorporation of the proteinogenic amino acid of the same chirality, whereas the preceding residue appears to preferentially induce formation of the heterochiral peptide. On this basis, a peptide oxazolone in which the penultimate and the C-terminal residues are of opposite chirality (e.g. L–D) should show an increased selectivity (compared to the L–L sequence) for the D-isomer of the proteinogenic amino acid. Indeed, the reaction of Ac-[L-(αMe)Val]$_2$-D-(αMe)Val-OXL with H-DL-Val-OMe in acetonitrile at 80°C gave a D-selectivity of 42% (not listed in Table 1), significantly higher than the value of 14% obtained for the corresponding all-L trimer. The inversion of chirality at the C-terminal residue in the N-terminal acetylated (αMe)Val tetramer led to a variation of the D-selectivity in the same direction as in the above experiment with the trimer, but of much lower magnitude, from 47% for Ac-[L-(αMe)Val]$_4$-OXL to 50% for Ac-[L-(αMe)Val]$_3$-D-(αMe)Val-OXL (the latter is not listed in Table 1). However, we already noted for the all-L (αMe)Val series a sharp increase in heterochiral diastereoselectivity as the result of main-chain elongation from trimer to tetramer, which suggests the contribution of a conformational effect which may take place at the level of the tetramer.

N-terminal-acylated homotripeptides from Iva, (αMe)Nva, and (αMe)Val fold into β turns,[24] stabilized by an intramolecular hydrogen bond between the NH group of the third residue and the carbonyl oxygen of the acyl group. Consecutive β turns are formed by the higher homologues, giving rise to 3_{10} helices.[19,25,26] The L configurations of (αMe)Nva and (αMe)Val promote the onset of turns and helices with a largely predominant right-handed screw sense. For Iva, the amino acid of this family with the smallest difference in length between the two side chains, the relationship between residue chirality and helical screw

Table 1: Chirality of the incorporated proteinogenic amino acids in the reaction products Ac-Aib-Xxx-D,L-Val-OMe or Ac-(Xxx)$_n$-D,L-Val-OMe from the peptide oxazolones Ac-Aib-Xxx-OXL or Ac-(Xxx)$_n$-OXL and H-DL-Val-OMe in acetonitrile solution at 80°C (or 30°C, in parentheses).[a]

[a] Xxx = L-Iva, L-(αMe)Nva, L-(αMe)Val; the X values (defined as % L−% D, where L and D refer to the chirality of the incorporated proteinogenic amino acid) were determined by HPLC. For the assignment of the eluted peaks each diastereomer was prepared separately and used as a standard. The reported X values are the average of three independent experiments. Reproducibility is within 2%.

sense is somewhat ambiguous.[19,26,27] In an *N*-acylated peptide oxazolone, with the C-terminal residue lacking the hydrogen-bonding donor NH group, the minimal main-chain length required for the formation of a single β turn is four residues.[28] Peptide oxazolones based on C$^\alpha$-methylated residues and longer than tetramers are expected to fold into 3_{10} helices. Indeed, we show herein that in the crystal state the octameric oxazolone Z-[L-(αMe)Val]$_8$-OXL (Z, benzyloxycarbonyl) is folded into a right-handed 3_{10} helical conformation (Figure 3). The three-dimensional structural results reported herein, along with the conformational preferences of C$^\alpha$-methylated peptides[17–19,25–27] (discussed above), support Bada's hypothesis[14] that if these peptides had some role during the origin of biological stereochemistry, then initially life may, at least in part, have been based on a different polypeptide architecture (the 3_{10} helix, instead of the classical α helix promoted by the proteinogenic C$^\alpha$-hydrogen amino acids).

Overall, peptide oxazolones with a longer main-chain length and a bulky side chain (for example, as in L-(αMe)Val) preferentially incorporate a proteinogenic amino acid of the chirality opposite to that of the C$^\alpha$-methylated residues, whereas a shorter main chain and a less bulky side chain in the peptide oxazolone (for example, as in L-Iva) direct the stereoselection towards the proteinogenic amino acid of the same chirality, but with lower efficiency. Such a bimodal distribution of diastereoselectivity is substantially retained in acetonitrile–water mixtures, as indicated by reactions of selected peptide oxazolones with either H-DL-Val-OMe or the racemates of the free amino acids Val, Phe, and Leu (Table 2), the free amino acids being prebiotically more relevant than their methyl esters. Thus, the stereochemical implications of our results are not hampered by addition of water (up to 70%) to the reaction medium. Water, either in bulk or at the interface with organic layers, lipid vesicles, or mineral surfaces, is included in all current models of prebiotic chemical evolution on Earth.[29–32] Acetonitrile itself may be not fully devoid of prebiotic relevance, as its occurrence in comets has been reported.[33]

Prebiotic chemical evolution towards the emergence of peptides is thought to have occurred through a combination of cycles of peptide-bond formation and hydrolysis. A peptide bond between two C$^\alpha$-methylated α-amino acid residues is sterically better protected from hydrolytic cleavage than a bond between a C$^\alpha$-methylated and a proteinogenic amino acid residue. Thus, it is likely that the proteinogenic amino acids incorporated at the C-terminus of C$^\alpha$-methylated peptide chains might have been subsequently released through hydrolysis to a greater extent than those released by the hydrolytic degradation of the fully C$^\alpha$-methylated peptide chains. This process would seem to leave the racemic state of the prebiotic soup unaffected. However, significant epimerization can be expected to occur
Figure 3. X-ray diffraction structure of Z-[L-(αMe)Val]$_8$-OXL. Only oxygen and nitrogen atoms are labeled. The five intramolecular C=O···H—N hydrogen bonds are indicated by dashed lines. The right-handed 3_{10} helix encompasses amino acid residues 1–6. The seventh residue, external to the helix, adopts a conformation with a screw sense opposite to that of the preceding residues. As a result, the oxazolone ring (N8,O7,O8) protrudes out of the helical envelope. Residue 8 is part of the oxazolone ring. The normal to the average plane of the oxazolone ring is nearly perpendicular to the helix axis.

Table 2: Chirality of the incorporated proteinogenic amino acids in the reaction products of selected *N*-acetylated, C$^\alpha$-methylated peptide 5(4*H*)-oxazolones with racemic proteinogenic amino acids or their methyl esters (H-DL-Aaa-Y) in H$_2$O/CH$_3$CN solution.[a]

in between incorporation and release of the proteinogenic amino acids, as a proteinogenic amino acid C-terminal to a peptide chain, upon activation, may undergo cyclization to oxazolone, thus becoming highly prone to racemization.[34] Therefore, the chiral imbalance generated in the prebiotic soup of proteinogenic amino acids by their stereoselective incorporation into the C$^\alpha$-methylated peptides can be retained to an extent which is directly proportional to the occurrence of oxazolone-mediated racemization of the pro-

teinogenic amino acids prior to their cleavage from the C^α-methylated peptide chain. Such a process could have been repeated in cycles, with C^α-methylated peptides providing a stable source of chiral bias. In the long run, the overall result would have been the enrichment of the primordial soup in proteinogenic amino acids of the chirality opposite to that preferentially incorporated by the C^α-methylated peptide chains. If the D-incorporation prevailed, then through amplification mechanisms[35–40] the L-homochirality of life could have emerged.

In summary, our experimental results indicate the possibility that the proteinogenic amino acid homochirality on Earth may have originated from meteoritic C^α-methylated α-amino acids and that the 3_{10} helical structure may have played a significant role in this process, although concurrent or alternative pathways[40–42] leading to the same final scenario are not excluded by the present results.

Communications

Deletion of the Gly600 Residue of *Alicyclobacillus acidocaldarius* Squalene Cyclase Alters the Substrate Specificity into that of the Eukaryotic-Type Cyclase Specific to (3*S*)-2,3-Oxidosqualene**

Tsutomu Hoshino,* Kunio Shimizu, and Tsutomu Sato

The acyclic molecule squalene (**1**) is cyclized into the pentacyclic triterpenes, hop-22(29)-ene (**2**) and hopan-22-ol (**3**; ca 5:1) by squalene–hopene cyclase (SHC) from prokaryotic species (Scheme 1).[1] The polycyclization reaction proceeds with regio- and stereochemical specificity under precise enzyme control to form the 6/6/6/6/5-fused pentacyclic ring system and nine new stereocenters. The polycyclization mechanism is analogous to that of eukaryotic oxidosqualene cyclases (OSCs).[1] SHC folds **1** into the all pre-chair conformation (a product-like conformation) inside the enzyme cavity, which leads to the final hopanyl cation through sequential ring-forming reactions. The proton elimination occurs exclusively from (23*Z*)-Me, but not from the *E*-Me, to form **2**.[1a,2a] A nucleophilic attack by a water molecule on the cation affords **3**.

Recent three-dimensional X-ray crystallographic analyses[3] and site-directed mutagenesis experiments[1a,b] have provided deeper insights into the polycyclization mechanism. Studies with the substrate analogues have also given important information on substrate recognition.[1,2] The reaction cavity is lined with aromatic amino acid residues.[3] Substrate specificity of bacterial SHCs is remarkably broad. Compounds (3*S*)-**4** and (3*R*)-oxidosqualenes **7** undergo the polycyclization reactions to form 3β- and 3α-hydroxyhopenes (**5** and **8**; ca. 1:1) and hopanediols (**6**:**9**; ca. 1:1), respectively, by a similar cyclization mechanism as **1**. Formation of the A-ring of **5** (scheme 1) proceeds by the chair conformation, while that of **8** by the boat structure.[2a]

In contrast to bacterial SHCs, eukaryotic OSCs selectively recognize **4** as the substrate, and never accept **1** and **7**.[1] Figure 1 shows a comparison of the amino acid alignment of some SHCs and OSCs. Gly600 is highly conserved among SHCs, but absent in OSCs.[1a,4] To investigate the role of the G600 from *Alicyclobacillus acidocaldarius*, we constructed the Gly600-deletion mutant (ΔG600 SHC) and then incubated with **1** or a racemic mixture of **4** and **7**. Interestingly, **1** and **7** were completely inert to the mutated cyclase (< 0.2% detection limit), while **4** underwent the cyclization to mono- and tricyclic skeletons which have a 3β-hydroxy group. It is of note that the prokaryotic squalene cyclase could be altered into eukaryotic-type one, the substrate of which is limited to **4**.

The ΔG600 SHC was constructed by using the polymerase chain reaction (PCR), in which oligonucleotide primers were designed in inverted tail-to-tail directions to amplify the
Scheme 1. Polycyclization pathway of squalene (**1**), (3*S*)-**4**, and (3*R*)-oxidosqualene (**7**) into the hopane skeleton.

cloning vector together with the target sequence.[5] One mg each of **1** or the racemic mixture of **4** and **7** was incubated at 40–70°C for 16 h with 1 mL of the cell-free homogenates (ca. 200 μg of the pure mutated SHC). The reaction was quenched by adding 15% KOH/MeOH and the lipophilic products were extracted with hexane. The GC analysis showed that no cyclization products were present in the incubation mixture from **1** (< 0.2% detection limit). On the other hand, six major products were detected in that of the racemate (**4** and **7**; total yield, 32%). The optimum catalytic
Figure 1. Amino acid alignment of some triterpene cyclases. The G598–Y605 alignment of *A. acidocakdarius* SHC corresponds to the G694–C700 sequence of human OSC, and these sequences constitute β-sheet domains.

temperature was 45 °C.[6] The distribution ratios [%] of products **10–15** (Figure 2) was determined to be 11.3:2.9:2.9:3.4:8.6:2.9 and there was 68.0% recovered sub-
Figure 2. Cyclization products of **4** by the ΔG600 mutant.

strate, by the GC analysis. Products **10** and **13–15** were isolated in a pure state by the combination of normal and reverse-phase HPLCs, but separation of **11** and **12** was unsuccessful; column chromatography on SiO_2 impregnated with 5% $AgNO_3$ gave no separation. A mixture of acetates of **11** and **12**, prepared with Ac_2O/py, (Ac = acetyl, py = pyridine) was subjected to a careful column chromatography on SiO_2 (5% $AgNO_3$) which lead to the successful separation of **11** and **12** in part, but a large portion was still mixed.

Structures of all the isolated products as shown in Figure 2 were determined by NMR spectroscopy (¹H, ¹³C, DEPT, COSY 45, HOHAHA, NOESY, HMQC, HMBC).[7] In particular, the H-3 signals of all the products were dd ($J = 10$–12 and 5–6 Hz), characteristic of axial–axial and axial–equatorial spin–spin couplings, thus all the products have a 3β-hydroxy group. Product **10** was identified as achilleol.[8a] Products **11–15** have three allyl methyl groups ($\delta_H = 1.69$–1.88 ppm), which suggests the involvement of a tricyclic ring skeleton. Products **11** and **12** have a podiodatriene skeleton[8b] (podioda-8,17,21-trien-3β-ol for **11** and

podioda-9(11)-17,21-trien-3β-ol for **12**). Compound **11** was recently isolated as an *Arabidopsis* OSC product, and was named thalianol.[8c] Compound **12** is a novel tricyclic triterpene. Product **13** is malabarica-14(27),17,21-trien-3β-ol. Diols **14** and **15** have a similar skeleton to **13** bearing a second hydroxy group at C-14. The NOESY spectra of **13–15** clearly indicated that the stereochemistry at C-13 of **13** and **15** is opposite to that of **14** (13α-H for **13** and **15**; 13β-H for **14**). Production of 3β-hyroxylated skeletons from the racemic mixture, but no formation of 3α-hydroxylated one, indicated that only **4** underwent cyclization, while the enantiomer **7** was unaffected.[2] The recovered epoxysqualene, further purified by normal-phase HPLC (hexane:2-PrOH = 100:2), showed an $[\alpha]_D^{25} = +1.17$ ($c = 0.84$, EtOH), further verifying that 3S-(−)-**4** was selectively converted.[9] Thus, the conversion of **4** by the mutant cyclase was 64%.

Scheme 2 shows the mechanisms for the formation of products **10–15**. (3S)-Oxidosqualene **4** is cyclized into monocyclic cation **16**, then deprotonation from Me-25 yields **10**. Formation of bicyclic cations **17** and **20** guides further cyclization, leading to the 6/6/5-fused tricyclic Markovnikov cations **18** and **21**, respectively. The deprotonation from Me-27 of **18** affords **13** (path *a*). Attack by water on the C-14 cation gives diol **15** (path *b*). Sequential 1,2-shift reactions of hydride and Me-26 of **18** give cation **19** (path *c*). Deprotonation at C-9 of **19** gives **11** and hydride shift of H-9 to C-8 and the proton elimination of H-11 affords **12**. The
Scheme 2. Proposed polycyclization pathways of **4** into **10–15**; see text for details.

alternative route via **21** (path *d*) may be possible, but path *c* would be favorable owing to the antiparallel rearrangement reaction. A water attack on cation **21** gives **14**. Previously we have demonstrated that **21** (13β-H) is a true intermediate, but **18** (13α-H) is a false one.[1a,10a]

The lack of reaction of **1** and **7** suggests that the terminal double bond of **1** and the epoxide ring of **7** may have failed to be in a close proximity to the D374XD376D377 motif,[10b] which is responsible for the initiation of the polycyclization reaction. The specific activity of the mutant enzyme for **4** significantly decreased (ca. tenfold),[6] compared to that of the native SHC, which suggests the looser binding of the epoxide ring of **4** to the mutant enzyme than to the wild-type. The secondary structures of the β-sheet and α-helix domains[3,11] (Figure 1) may be disorganized by the loss of the G600, resulting in inappropriate positioning of F601,[10a] F605,[10c] Y609,[10d,e] and Y612[10d,e] in the reaction cavity, which are crucial for the sequential ring-forming reactions to give the fully cyclized **2**. Residues Y609 and Y612 are important in forming 6/6-fused bicyclic cations **17** and/or **20**,[10d,e] thus monocycle **10** may have accumulated owing to the inappropriate positions of these residues. However, the Phe365, aligned prior to the G600, would still be correctly placed in the reaction cavity, which leads to the formation of **18** and **21** by the stabilization of cations **17** and **20**.[12] The incorrect placement of the F601 and F605 residues, which are essential for the formation of tetra- and pentacycles,[10,12] would interrupt the polycyclization reaction at the tricyclic ring stage, possibly because of the decreased cation/π interaction. A high production (24.2%) of the false intermediate **18** (13α-H)[1a,10a] further indicated that the enzyme structure was disordered in part.

There are a few reports on the altered substrate specificity of the squalene cyclase. A triple mutant of D377C/V380E/V381A,[13] a double mutant of D376C/C435S,[14] and the single mutants[10b,15] of D374N and D376N had no effect on **1**, but all the mutants had a cyclization activity for both enantiomers of **4** and **7**, albeit with significantly lower activity than the wild-type, which indicates that all the mutants had no stereospecificity for the racemic epoxides. The decreased acidity of the DXDD motif by the substitution with Cys or Asn would have led to no reaction for **1** and to a lowered activity for **4** and **7**. In contrast, the ΔG600 mutant selectively accepts **4**, but has no effect on **7**. Thus, the altered substrate specificity of the ΔG600 mutant is completely different from those of the previously reported mutants. The following differences are also noted: The ΔG600 mutant still had the original DXDD motif, and the location of the deleted G600 residue in the reaction cavity is distal from the initiation site of the DXDD motif.[3] The X-ray structure of the wild-type SHC, which was cocrystallized with 2-azasqualene,[3c] shows that the G600 is located in a close proximity to the D-ring formation site of **1**.

Why did the ΔG600 SHC accept only **4**? It is difficult to get a clear answer to this question at the present time, but one possible explanation is as follows. The recent study of the homology modeling of human OSC,[16] based on the crystal structure information of the wild-type SHC,[3] clearly indicates that the β-sheet domain of the OSC, consisting of the G694–C700 sequence (Figure 1), is more loosely packed compared to that of the SHC, which is composed of the G598–Y605 sequence.[16] Thus, the loss of the Gly600 makes the D-ring formation region less compact. The loosely packed domain structure of the mutant cyclase is more flexible, thus, a somewhat free motion of the substrate molecules can be allowed around the D-ring formation sites. The unconstrained motion of the substrates will influence the positions of the substrate heads; the epoxide ring of **4** could be located near to the DXDD motif, but the terminal double bond of **1** and the epoxide ring of **7** failed to have access to the motif. The proposed working hypothesis would agree with the previous reports[10e,17] that the folding conformation and the polycyclization pathway of **1** are directed by the steric bulk size of active sites. However, other factors may be also involved in the alteration of substrate specificity. Further studies are necessary including the X-ray crystallographic analysis and the functional analyses of the related mutants, in order to gain the exact answer for the altered substrate specificity.

In conclusion, this is the first example in which the substrate specificity of prokaryotic cyclase could be successfully altered into that of the eukaryotic-type, which is quite interesting from the evolutionary aspect of squalene cyclases. This study is also indicates how eukaryotic cyclases selectively accept **4**. The rationally engineered mutagenesis of bacterial SHC will lead to further creation of novel eukaryotic-type cyclases.

Experimental Section

A plasmid of pBH, which was a pUC119 derivative having the *Bam*HI-*Hind*III fragment of *shc* gene (1623–1896 nucleotide position),[10b,d] was used as a template. A pair of primers, 5′-TTCCCAGGGGATTTCTACCTCGGC-3′ and 5′-*GGTACC*GGTG-TAGTACGGCTCATCCCAGC-3′, was prepared for deleting a GGG codon of Gly600. The bold of **G** and **A** indicate the silent mutation for creating *Kpn* I site (italics).

The enzyme purification and incubation conditions were carried out according to the published methods.[10b,d]

The hexane extract from the incubation mixture was subjected to column chromatography on SiO₂ with a step-wise gradient elution of hexane→hexane/EtOAc(100:10), to give residual oxidosqualene and **10** in a pure state, but the separation of **11**–**15** failed. Isolation of **14** and **15** was by normal-phase HPLC (hexane:2-PrOH = 100:2). A reverse-phase HPLC eluting with THF/H₂O (55:45) gave **13** in pure state. As a next step, the acetate mixture of **11** and **12**, prepared with Ac₂O/py, was subjected to a careful column chromatography on SiO₂ (5% AgNO₃) by eluting with hexane/EtOAc (100:0.05), leading to the separation of **11** and **12** in part.

NMR spectra were recorded in C₆D₆, the chemical shifts being relative to the solvent peak $\delta_H = 7.28$ and $\delta_C = 128.0$ ppm as the internal reference for ¹H and ¹³C NMR spectra, respectively. The product distribution pattern was monitored by GC. GC-MS and MS spectra were obtained with electronic impact at 70 eV using a DB-1 capillary column (0.32 mm × 30 m), the oven temperature being elevated from 220 to 270°C (3°C min⁻¹). Specific rotation values were measured at 25°C in EtOH. The CD spectra of the ΔG600 and the wild-type SHCs were measured in a solution of 10 mM sodium phosphate (pH 6.0) containing 0.6% Brij 35.

Strained Molecules

The First Bicyclo[1.1.0]butane Dianion of Heavier Group 14 Elements**

Vladimir Ya. Lee, Kazunori Takanashi,
*Masaaki Ichinohe, and Akira Sekiguchi**

The concept of the so-called "non-classical" compounds, which do not follow the generally accepted interpretation of the chemical bonds from the viewpoints of geometry, valency, and hybridization, is a fascinating topic in organic chemistry.[1] Undoubtedly, among such non-classical molecules the highly strained bicyclo[1.1.0]butane and tricyclo[2.1.0.0^{2,5}]pentane, as well as their derivatives, are paramount examples of the most long-standing and attractive challenges for organic chemists (Scheme 1, **A** and **B**, respectively).[2,3] Particularly
Scheme 1. Highly strained non-classical compounds bicyclo[1.1.0]-butane (**A**) and tricyclo[2.1.0.0^{2,5}]pentane (**B**) and bridgehead 1,3- (**C**) and bridging 2,4-dianions (**D**) of **A**.

important is the question of the nature of the bridging bond in both compounds, which has been the subject of theoretical investigations and debates during the last two decades, especially for the derivatives of bicyclo[1.1.0]butane.[2] Experimentally, the chemistry of bicyclo[1.1.0]butane, which has been known since 1959, has been developed, and many representatives of this unusual class of compounds, including their heavy analogues, have been synthesized.[4] However, the stable, charged derivatives (both anionic and cationic) of bicyclo[1.1.0]butanes have remained elusive species until now: neither bridgehead 1,3- (Scheme 1, **C**) nor bridging 2,4-dianions (Scheme 1, **D**) of bicyclo[1.1.0]butane have ever been isolated and characterized.[5] Very recently we have synthesized the $^3\Delta$-1,2,3,4-disiladigermetene **1**,[6] which appeared to be a most promising candidate for reduction to produce the corresponding dianion species. Indeed, by the reaction of **1** with alkali metals, the heavy analogues of the cyclobutadiene dianion were synthesized; their cyclic 6π-

electron system was demonstrated to be non-aromatic.[7] To our surprise, the reduction of **1** with alkaline-earth metals gave a totally different structure with the bicyclo[1.1.0]butane 2,4-dianion skeleton, these compounds were isolated in the form of magnesium, calcium, and strontium salts, whose synthesis and structural characteristics we report herein.

The reduction of **1** with an excess of metallic magnesium or calcium in THF at room temperature resulted in the clean formation of the corresponding magnesium and calcium derivatives of tetrakis(di-*tert*-butylmethylsilyl)-1,3-disila-2,4-digermabicyclo[1.1.0]butane-2,4-diide **2a,b** isolated as highly air- and moisture-sensitive, bright orange crystals (Scheme 2). Of note is that both **2a** and **2b** can be prepared alternatively by the reaction of the dipotassium salt **3**[7] with MX₂ (M = Mg, X = Br; M = Ca, X = I) in THF (Scheme 2). Employing this synthetic approach, we were able to synthesize dianion **2** with strontium as the coordinating counterion, compound **2c**.

Reflecting their symmetrical structure, ^{1}H and ^{13}C NMR spectra of **2a–c** have only two sets of signals for the two kinds of tBu$_2$MeSi substituents. The arrangement of the Si atoms at the bridgehead positions of **2** was clearly evident from the ^{29}Si NMR spectra, which show their very diagnostic greatly upfield-shifted signals: −231.9 ppm for **2a**, −220.2 ppm for **2b**, and −225.2 ppm for **2c**.

Figure 1. Structure of **2a** (ORTEP plot, thermal ellipsoids set at 30% probability; hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Si1-Si3 2.3181(15), Si1-Ge2 2.4911(11), Si1-Ge4 2.4480(11), Si3-Ge2 2.4691(12), Si3-Ge4 2.4523(12), Ge2-Mg1 2.7664(15), Ge4-Mg1 2.6259(14); Si3-Si1-Ge2 61.66(4), Si1-Si3-Ge2 62.62(4), Si1-Ge2-Si3 55.72(4), Si1-Si3-Ge4 61.67(4), Si3-Si1-Ge4 61.86(4), Si1-Ge4-Si3 56.46(4), Si3-Si1-Si5 133.65(6), Si1-Si3-Si7 135.75(7), Ge2-Mg1-Ge4 75.59(4).

2a–c is in complete contrast to our previously reported tricyclo[2.1.0.0²,⁵]pentane analogue, which has an extremely long Ge−C bridging bond,[9] owing to its significant biradical character.

The mechanism for the formation of compounds **2** may involve the initial reduction of the starting material **1** with alkaline-earth metals to form **4**, which has a bicyclo[2.1.0]pentene skeleton (Scheme 3). Valence isomerization to release the inherent strain of **4** might be imag-

Scheme 2. Synthesis of 1,3-disila-2,4-digermabicylo[1.1.0]butane-2,4-diide derivatives **2a–c**. R = SiMetBu$_2$.

The composition of all of the alkaline-earth-metal derivatives **2a–c** was unambiguously established by X-ray crystallography, as shown in Figure 1 for **2a**.[8] With a capping alkaline-earth metal playing a bridge role, bicyclo[1.1.0]butane dianions **2** actually acquire the properties of tricyclo[2.1.0.0²,⁵]pentane derivatives (Scheme 1, **B**). This relationship was clearly demonstrated by consideration of the structural characteristics of the Si₂Ge₂ skeleton of **2**: 1) the Si−Si bridging bonds are a little shortened in comparison with the normal Si−Si bond length, 2.3181(15) Å (**2a**), 2.323(2) Å (**2b**), and 2.3304(15) Å (**2c**); 2) the interplanar angles ϕ (see Scheme 1) are acute: 98.90 (**2a**), 102.30 (**2b**), and 104.90 for (**2c**); 3) bond angles θ are wide: 133.65(6) and 135.75(7) (**2a**), 132.76(9) and 132.89(9) (**2b**), and 128.60(8) and 136.42(8) (**2c**). All of these structural features match the properties of tricyclo[2.1.0.0²,⁵]pentanes (Scheme 1, **B**),[3] in which a small interplanar angle ϕ forces the hybrid orbitals of the bridged atoms towards each other to form short bent C−C bridging bonds. However, such a short Si−Si bridging bond in dianions

Scheme 3. Proposed mechanism of formation of **2**.

ined as the next step, to produce the cyclopentadiene-like compound **5**, which finally undergoes intramolecular cross [2+2] cycloaddition to form tricyclo[2.1.0.0²,⁵]pentane derivatives **2**.[10] Starting from the cyclobutadiene dianion dipotassium salt **3**, the reaction with metal halides MX₂ resulted in the initial formation of **4**, following the isomerization steps described above. Such conclusions are supported by theoretical calculations, which showed that of all the cyclic R₄Si₂Ge₂Mg isomers **4**, **5**, and **2** (R = SiH₃), the tricyclo[2.1.0.0²,⁵]pentane **2** is the most stable compound (0 kcal mol⁻¹), compared with the cyclopentadiene **5** (+12.12 kcal mol⁻¹) and the bicyclo[2.1.0]pentene **4** (+12.39 kcal mol⁻¹).[11]

Experimental Section

2a: The mixture of **1** (96 mg, 0.106 mmol) and excess magnesium (35 mg, 1.44 mmol) in dry oxygen-free THF (2 mL) was stirred for two days at room temperature, during which time the color of the reaction mixture turned from yellow to dark brown. After filtration and evaporation of solvent from the filtrate, recrystallization from hexane–THF gave **2a** as bright-orange crystals (83 mg, 73%). M.p. 205°C (dec.). ^{1}H NMR (400 MHz, [D$_8$]THF, TMS): $\delta = 0.16$ (s, 6H, Me), 0.30 (s, 6H, Me), 1.16 (s, 36H, tBu), 1.19 ppm (s, 36H, tBu); ^{13}C{^{1}H} NMR (100 MHz, [D$_8$]THF, TMS): $\delta = -2.6, -1.6, 22.4, 22.7, 31.4, 31.5$ ppm; ^{29}Si{^{1}H} NMR (79 MHz, [D$_8$]THF, TMS): $\delta = -231.9$ (bridgehead Si), 22.5 and 34.5 ppm (substituent Si).

2c: The mixture of **3** (127 mg, 0.106 mmol) and excess SrI$_2$ (60 mg, 0.176 mmol) in dry oxygen-free THF (2 mL) was stirred for 2 h at room temperature, during which time the color of the reaction mixture turned from dark green to orange. After filtration and evaporation of solvent from the filtrate, recrystallization from THF gave **2c** as bright-orange crystals (95 mg, 74%). M.p. 137°C (dec.). ^{1}H NMR (400 MHz, [D$_8$]THF, TMS): $\delta = 0.14$ (s, 6H, Me), 0.22 (s, 6H, Me), 1.16 (s, 36H, tBu), 1.21 ppm (s, 36H, tBu); ^{13}C{^{1}H} NMR (100 MHz, [D$_8$]THF, TMS): $\delta = -1.9, -1.7, 22.6, 22.9, 32.1, 32.3$ ppm; ^{29}Si{^{1}H} NMR (79 MHz, [D$_8$]THF, TMS): $\delta = -225.2$ (bridgehead Si), 21.1 and 33.6 ppm (substituent Si).

Ligand-Functionalized Core/Shell Microgels with Permselective Shells**

Satish Nayak and L. Andrew Lyon*

Recently the field of nanotechnology has received immense attention, which in part is owed to its potential impact on biotechnology. Nanometric materials find application in many fields such as chemical sensing[1] and biosensing,[2] catalysis,[3] optics,[4] separations,[5] and drug delivery.[6] Nanomaterials offer advantages in such arenas owing to the potential for new or enhanced optical, chemical, mechanical, or electrical properties. Of particular interest is the creation of multifunctional nanoparticles, which contain multiple chemistries such that they interact with their environment in a more-complex fashion. Here we report the synthesis of a well-defined, yet chemically and topologically complex colloidal particle. This structure comprises a porous, thermosensitive hydrogel "core" particle that is modified with a ligand (biotin). This particle is contained within a porous, thermoresponsive hydrogel "shell" that sterically excludes the transport and binding of the protein avidin, for which biotin is a tight-binding ligand. However, by using a cross-linker that can be chemically cleaved in the shell, the ability of avidin to penetrate the particle and bind to the core can be chemically tuned with a high degree of fidelity.

The polymer used in the construction of these particles is mainly composed of poly(N-isopropylacrylamide) (pNIPAm), which is a classic stimuli-responsive polymer.[7] Materials fabricated from pNIPAm are often deemed to be "smart" because they can be tuned to respond to temperature,[8] pH,[9] light,[10] ionic strength,[11] or biomolecules.[12] pNIPAm can be cross-linked into nanoparticles by emulsion or precipitation polymerization processes with good size control over the range 10^{-8}–10^{-5} m.[13] We have developed precipitation polymerization methods to create a class of core/shell hydrogel particles derived from pNIPAm. The specific concept employed for the chemically and topologically complex particles presented herein is shown in Scheme 1. A biotinylated hydrogel core nanoparticle is coated with a hydrogel shell that contains the cleavable cross-linker N,N'-(1,2-dihydroxyethylene)bisacrylamide (DHEA). At the initial cross-link density, the pore size of the shell is too small to allow avidin molecules to pass through to the core where they bind biotin. Upon chemical cleavage of the cross-links, the pore size increases enough to allow avidin to pass through and bind biotin.

We have previously synthesized core/shell hydrogel nanoparticles by a multistage "seed and feed" method, whereby preformed thermoresponsive hydrogel nanoparticles are used as seeds for the addition of either chemically similar or
Scheme 1. A NIPAm/AAc core is biotinylated with biotin hydrazide and EDC, followed by addition of a NIPAm/DHEA shell. The cross-linker density of the shell is such that the pore size is smaller than the avidin–HABA complex which prevents the protein from passing through the shell. Upon treatment with periodate, the DHEA cross-linker degrades which subsequently increases the pore size to allow passage of avidin–HABA complex molecules. The K_d value for avidin–HABA (10^{-6}) is higher than the K_d value for avidin–biotin (10^{-15}). Therefore, HABA is released from avidin when biotin binds to avidin. The binding is detected by UV/Vis spectroscopy. NIPAm = N-isopropylacrylamide, AAc = acrylic acid, EDC = 1-ethyl-3-(3-dimethylaminopropryl)carbodiimide, DHEA = N,N'-(1,2-dihydroxyethylene)bisacrylamide, HABA = 2-(4'-hydroxyazobenzene)benzoic acid.

distinct hydrogel shells.[14] In the present study, the core is predominantly composed of pNIPAm with acrylic acid (AAc) as a minor component (10 mol%). The acid groups are used for attaching biotin to the nanoparticles by carbodiimide coupling (see the Experimental Section in the Supporting Information). These biotinylated cores are then used as seed particles to which a shell is added. The shell also consists of pNIPAm, but it is cross-linked with the cleavable diol cross-linker DHEA. Traditionally, bulk gels that are cross-linked with DHEA have been used for electrophoretic protein

separation.[15] As the vicinal diols in the cross-linker can be cleaved by stoichiometric amounts of sodium periodate, the pore size of the gel can be varied quantitatively by degradation of the cross-linker (Scheme 2). Figure 1 shows the

the absorption spectra of the avidin–HABA complex in the presence and absence of biotinylated core particles. The amount of biotin conjugated to the core particle was determined by titration of the acid groups before and after conjugation. Subtracting the number of moles of acid in the biotinylated sample from that in the non-biotinylated sample reveals that ≈ 160 mg of biotin is conjugated to one gram of core particles. From the avidin–HABA assay, only ≈ 25 mg of biotin was determined to be available for binding to avidin in one gram of core particles. This means that only $\approx 16\%$ of avidin is accessible from the total amount of biotin conjugated to the polymer.

Scheme 2. Structure of the cleavable polymer. Sodium periodate cleaves the 1,2-glycol bond of DHEA through oxidation of the vicinal diols to aldehydes.
Figure 1. Hydrodynamic radius (R_h) of the core/shell particles (●) as a function of the ratio of periodate:DHEA. The R_h of the core is represented by ■. The error bars represent one standard deviation about the average of five separate measurements.

Figure 2. Absorption spectra of avidin–HABA complex in the presence (·····) and in the absence (——) of biotinylated core particles.

variation in the hydrodynamic radius (R_h) of the core/shell particle as a function of cleavage of the cross-links in the shell measured at 25°C (filled circles). The filled squares represent the R_h values for the core. From this we see that the initial R_h value of the core is ≈ 115 nm, whereas that of the core/shell particle prior to the addition of periodate is ≈ 150 nm. Upon addition of periodate to the solution, the shell swells as suggested by the increase in the R_h values of the core/shell particle as a function of periodate concentration. This is expected, as a decrease in the concentration of cross-links in the network should result in a larger equilibrium swelling volume. Ultimately, the R_h value of the core/shell particle increases by ≈ 20 nm following complete cleavage of the periodate cross-links.

To detect the sieving of avidin through the shell we used the colorimetric 2-(4′-hydroxyazobenzene)benzoic acid (HABA) assay.[16] Four equivalents of HABA bind weakly to avidin at the biotin binding site ($K_d = 10^{-6}$ M),[17] and the resultant complex shows an absorption band at $\lambda = 500$ nm. In the presence of biotin, HABA is displaced from avidin ($K_d = 10^{-15}$ M for the avidin–biotin system),[18] and the intensity of the absorbance band at $\lambda = 500$ nm decreases. Figure 2 shows

Figure 3 shows the variation in the absorbance of the avidin–HABA complex at $\lambda = 500$ nm as a function of the ratio of the concentrations of periodate/DHEA for particles with 20, 15, and 2% cross-linked shells. For the 20% cross-
Figure 3. Absorbance of the avidin–HABA complex at $\lambda = 500$ nm as a function of the ratio of periodate:DHEA for 20% cross-linked shell particles (●), 15% cross-linked shell particles (▲), 2% cross-linked shell particles (▼) and biotin-free control particles (■). The error bars represent one standard deviation about the average of three different samples.

Communications

linked shell, the absorbance at $\lambda = 500$ nm remains essentially constant with increasing concentrations of periodate until approximately 70% of the diol groups are cleaved. The absorbance decreases precipitously beyond that concentration which is an indication of the displacement of HABA from avidin by the core-bound biotin. This clearly implies that until $\approx 70\%$ degradation, the pore size of the shell is not big enough to allow the passage of avidin–HABA. At >70% degradation, the pore size becomes large enough to allow avidin–HABA to pass through the shell and bind biotin. Figure 3 also shows the variation in absorbance for control particles that do not have a biotinylated core. No substantial changes in the absorbance are observed for the control samples which further confirms that the changes in the absorbance observed for the biotinylated samples indeed arise from the binding of biotin to avidin. The 15% cross-linked shell shows the same trend as the 20% cross-linked sample, but the decrease in absorbance starts slightly earlier. This is presumably a result of the larger initial pore size in the 15% cross-linked shell relative to that in the 20% cross-linked shell. For 2% cross-linked shells, the absorbance for 0% degradation is already lower than that for the 20% and 15% cross-linked samples, which were treated with a twofold excess of periodate. This result indicates that the pore size for this cross-linking density is so large that it renders the shell permeable and thereby allows avidin to bind biotin in the core without any degradation of the shell. The increased degree of binding also suggests that more biotin molecules are accessible to avidin, as the more-open network structure of the 2% cross-linked shell imposes less steric hindrance to the transport of the protein. Also, further degradation does not lead to any substantial change in the absorbance which indicates that almost all of the biotin molecules are already accessible to avidin prior to any degradation.

To evaluate how a change in the radius of the protein impacts transport through the particle shell, we used an avidin–HRP (horseradish peroxidase) conjugate in which two moles of HRP were conjugated to one mole of avidin. The molecular weight of this conjugate is ≈ 154 kDa (compare to regular avidin: ≈ 66 kDa). Avidin–HRP binds both biotin and HABA with the same affinity as free avidin. Figure 4

shows the change in the absorbance at $\lambda = 500$ nm of the avidin–HRP–HABA complex as a function of the periodate/DHEA ratio for the 20% cross-linked shell particles. No significant decrease in absorbance is observed until an approximately twofold excess of periodate is added to the sample. Again, normal avidin begins to sieve through the shell at $\approx 70\%$ degradation. This indicates that the avidin–HRP complex is too big to sieve through the shell until all of the cross-links are cleaved. Presumably, the excess periodate is needed to drive the reaction in more highly cross-linked (less accessible) regions of the particle shell; the reaction proceeds under stoichiometrically equivalent conditions in free solution.

In conclusion, we have demonstrated the synthesis of complex hydrogel nanoparticles that bind to a protein through both native protein–ligand interactions as well as through steric sieving. These core/shell nanoparticles are formed by a simple "seed and feed" polymerization method, in which the shell has cleavable cross-links. The sieving of proteins through the shell to the core is simply controlled by the manipulation of the pore size of the shell through cleavage of those cross-links. At a particular cross-linker density, only avidin is allowed to sieve through the shell, whereas larger protein structures are excluded from binding. Such nanoparticles could find applications in protein separation processes—the shell could essentially behave as a molecular-weight cut-off membrane to eliminate the binding of macromolecules and assemblies that are larger than the protein of interest. Affinity-based sensors and assays that are required to work in complex biological fluids could also benefit from size-selecting structures. Finally, the specific biotin–avidin ligand/protein system used here has become important for a wide range of surface modification and bioconjugation methods. Thus, one could imagine applying this system to the preparation of a wide range of microgel bioconjugates in which access to the biomacromolecule can be reversibly tuned.
Figure 4. Absorbance of the avidin–HABA complex (●) and avidin–HRP–HABA complex (■) as a function of the percentage of degradation of 20% cross-linked shell particles. The error bars represent one standard deviation about the average of three different samples.

Figure 1. Outline of the biosynthesis of the glycopeptide antibiotic vancomycin. NRPS = non-ribosomal peptide synthetase, PCD = peptide carrier domain.

Enzyme Catalysis

An Oxidative Phenol Coupling Reaction Catalyzed by OxyB, a Cytochrome P450 from the Vancomycin-Producing Microorganism**

Katja Zerbe, Katharina Woithe, Dong Bo Li, Francesca Vitali, Laurent Bigler, and John A. Robinson

During the biosynthesis of vancomycin, three oxidative phenol coupling reactions take place which lead to cross-links between aromatic amino acid side chains in the heptapeptide glycopeptide aglycone (Figure 1).[1] These cross-links constrain the peptide into a conformation that is optimal for binding to a *N*-acyl-D-Ala-D-Ala fragment, which arises during bacterial peptidoglycan biosynthesis.[2] The binding of vancomycin to *N*-acyl-D-Ala-D-Ala inhibits peptidoglycan biosynthesis, an event that is lethal for Gram-positive bacteria.

Important information about the biosynthesis of glycopeptide antibiotics has been revealed through the analysis of biosynthetic gene clusters, in particular those of chloroeremomycin[3] and balhimycin.[4] Gene knockout experiments in the balhimycin producer (balhimycin shares the same aglycone with vancomycin) identified three oxygenase genes (*oxy*A, *oxy*B, and *oxy*C) in the cluster which encode cytochrome P450-like proteins and which are responsible for the three oxidative phenol coupling reactions (Figure 1).[5] These knockout experiments indicated the order in which the

three coupling reactions occur. The first coupling occurs between rings C and D and is catalyzed by OxyB, the second reaction occurs between rings D and E and is catalyzed by OxyA, and the final coupling reaction takes place between rings A and B and is catalyzed by OxyC.[6,7] So far, however, the preferred substrates of OxyA–C and hence at which step in the biosynthesis the coupling reactions occur remain unknown. Our earlier efforts to detect the turnover of the linear heptapeptides **1a** and **1b** by OxyB cloned from the vancomycin producer failed to reveal significant amounts of any product that arises from a phenol coupling reaction.[8] One reason for this failure might be that the phenol coupling occurs in vivo whilst the peptide precursor is still attached as a thioester to a peptide carrier domain (PCD) of the glycopeptide non-ribosomal peptide synthetase (NRPS). The enzyme OxyB might, therefore, be unable to catalyze the coupling of phenols on the free heptapeptide, but rather would require the peptide to be present as a thioester derivative attached to its cognate PCD (as in **2a** and **2b**). Here we report results from experiments with OxyB from the vancomycin producer *Amycolatopsis orientalis* that support this conclusion.

In our hands, it has so far proven difficult to produce **2a** or **2b** in sufficient quantities to perform assays with OxyB. Therefore, we sought to simplify the synthetic problem by synthesizing and testing the derivative **8** (Figure 2). This
Figure 2. Synthetic route to the substrate **8**, and its assay with OxyB. a) PhSH, PyBOP; 95%; b) CoASH, pH 8.5; 50%; c) apo-PCD, phosphopantetheinyl transferase Sfp; 95%; d) OxyB, ferredoxin, ferredoxin–NADP+ reductase, NADPH, in air; e) NH2NH2. PyBOP = (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate.

molecule comprises a hexapeptide **5**, which contains tyrosine in place of *m*-chloro-3-hydroxytyrosine, linked to the sixth PCD from the vancomycin NRPS in *Amycolatopsis orientalis* DSM40040. Although the exact point at which the chlorination steps take place is not yet clear,[9] the coupling reactions of the phenols can occur on non-chlorinated peptide chains.[6] Also, both non-chlorinated linear hexapeptide **10** and bicyclic *N*-methylated hexapeptide **12** have been isolated from *oxy*B and *oxy*C knockout mutants, respectively, although these hexapeptides could conceivably arise by proteolytic degradation of a heptapeptide precursor in the fermentation broth.[5,6]
Of special interest, however, is the recent isolation of both the chlorinated linear and (in particular) monocyclic hexapeptides, **11** and **13**, respectively, from a mutant of the balhimycin producer in which a substantial portion of the *bps*C gene has been deleted.[10] The *bps*C gene is responsible for the condensation of an NRPS-bound hexapeptide with the NRPS-bound seventh amino acid 3,5-dihydroxyphenylglycine. This last result clearly suggests that the corresponding linear hexapeptide linked to the NRPS can act as a substrate for OxyB.

The PCD we chose to produce here comprises 30 residues on the N-terminal side and 52 residues on the C-terminal side of the strictly conserved active site Ser residue.[11, 12] Furthermore, the Cys6 residue was modified to a Ser residue to avoid problems owing to disulfide-bridged dimer formation. This PCD, in its apo-form, was produced in *Escherichia coli* with a His6 tag fused to the N terminus. The engineered apo-PCD was then purified to homogeneity by Ni–NTA (nickel–nitrilotriacetic acid) affinity chromatography followed by anion exchange chromatography. Electrospray ionization mass spectroscopy (ESI-MS) confirmed the expected mass of the protein (m/z: calcd: 11034; found: 11033 ± 1 ([M+H]+)).

The required hexapeptide **5** was synthesized by a concise solid-phase method using Alloc ((allyloxy)carbonyl) chemistry.[13] This hexapeptide could then be converted at its C terminus into the corresponding activated phenylthioester **6** by following a previously reported method (see Figure 2).[14] For this step to work efficiently, it is important that the N terminus is *N*-methylated (as in **6**) because no further protection is then necessary: the *N*-methylamino group does

not react with the thioester under these conditions. Next, the phenylthioester **6** was converted into a coenzyme A (CoA) thioester **7**. The hexapeptide–CoA thioester was then treated with the engineered apo-PCD and the phosphopantetheinyl transferase Sfp from *Bacillus subtilis*.[15] The conversion into the hexapeptide–PCD **8** was followed by reverse-phase HPLC and found to proceed almost quantitatively. After purification by HPLC, the mass of the product **8** was confirmed by ESI-MS (m/z: calcd: 12239; found: 12239 ± 1 ($[M+H]^+$)). Upon treatment of the conjugate **8** with hydrazine, the thioester was cleaved, and the corresponding hydrazide derivative **14** was isolated and characterized by ESI-MS (m/z: calcd: 898.4; found: 898.4 ± 0.2 ($[M+H]^+$)).

14: X = -NH-NH$_2$
15: X = -S-CH$_2$CH$_2$NHAc
An *N*-acetylcysteamine thioester derivative (S-NAC) **15** was also prepared by the direct coupling of *N*-acetylcysteamine to **5** because S-NAC thioesters are frequently used as simpler mimics of CoA and PCD thioesters.

To detect the turnover by OxyB, assays were performed with **8** (80 μM) or other potential substrates in the presence of His$_6$-tagged OxyB[8] (15 μM), an engineered spinach ferredoxin, ferredoxin–NADP$^+$ reductase (0.1 U, Sigma), an NADPH-regenerating system that comprises glucose-6-phosphate (2.5 mM) and glucose-6-phosphate dehydrogenase (1 U, Sigma), and NADPH (1 mM) in HEPES buffer (25 mM, pH 7.0) at 30 °C. When the free peptide **5** was tested in this way, no conversion into a monocyclic product could be detected by HPLC/MS which is consistent with earlier observations with putative free linear heptapeptide substrates (**1a** and **1b**).[8] Following assays with the PCD derivative **8**, the assay mixture was treated directly with excess hydrazine, and the linear open chain and the monocyclic peptides, **14** and **9**, respectively, were analyzed by HPLC/MS. Assays were also performed with **6** and **7**, but these failed to reveal any conversion into a monocyclic product. An assay with **15** revealed a small degree of conversion ($\leq 5\%$) into a new product, whose molecular mass was lower by 2 Daltons (by HPLC/MS). The extent of conversion was too low, however, to allow a full characterization of this product. Assays with the PCD derivative **8**, however, typically showed up to 80% conversion into a new product (see Figure 3) to which we assign the structure **9** (high-resolution positive-ion ESI-MS (APEX Qe FT-ICR mass spectrometer (Bruker Daltonics) equipped
Figure 3. Analysis by HPLC (UV/Vis detection; ——— = 226 nm, ----- = 280 nm) of the products from the conversion of **8** with His$_6$–OxyB (see text for details). The peaks corresponding to linear (**14**) and monocyclic (**9**) products are shown; $*$ = unknown. HPLC conditions: C18 Vydac column (218TP54), solvent A = water + 0.1% TFA, solvent B = MeCN + 0.1% TFA, gradient 5–40% B over 20 min, flow rate: 1 mL min^{-1}. TFA = trifluoroacetic acid, MeCN = acetonitrile.

with a 7 tesla magnet); exact mass calcd for $C_{45}H_{54}N_9O_{11}$: 896.3943 ($[M+H]^+$); found: 896.3938). No conversion of **8** into **9** took place under the assay conditions in the absence of OxyB nor in the absence of ferredoxin and ferredoxin–NADP$^+$ reductase.

ESI-tandem mass spectra (ESI-MS/MS) of **9** and **14** are consistent with the location of a cross-link between rings C and D in the new product **9**. Thus, **14** showed the expected fragment ions b_2, b_3, b_4, and b_5, whereas **9** showed b_2 and b_3 fragments and additional z_3, y_4/z_4, and y_5/z_5 fragments with the expected (-2) masses (Figure 4).

The ^{1}H NMR and 2D COSY, TOCSY, NOESY, and ROESY spectra of **9** allowed a full assignment of the ^{1}H NMR spectrum (see Table 1) and strongly support the proposed connectivity. From 2D spectra, the connectivity of the peptide backbone was established by using standard methods.[16] Also,

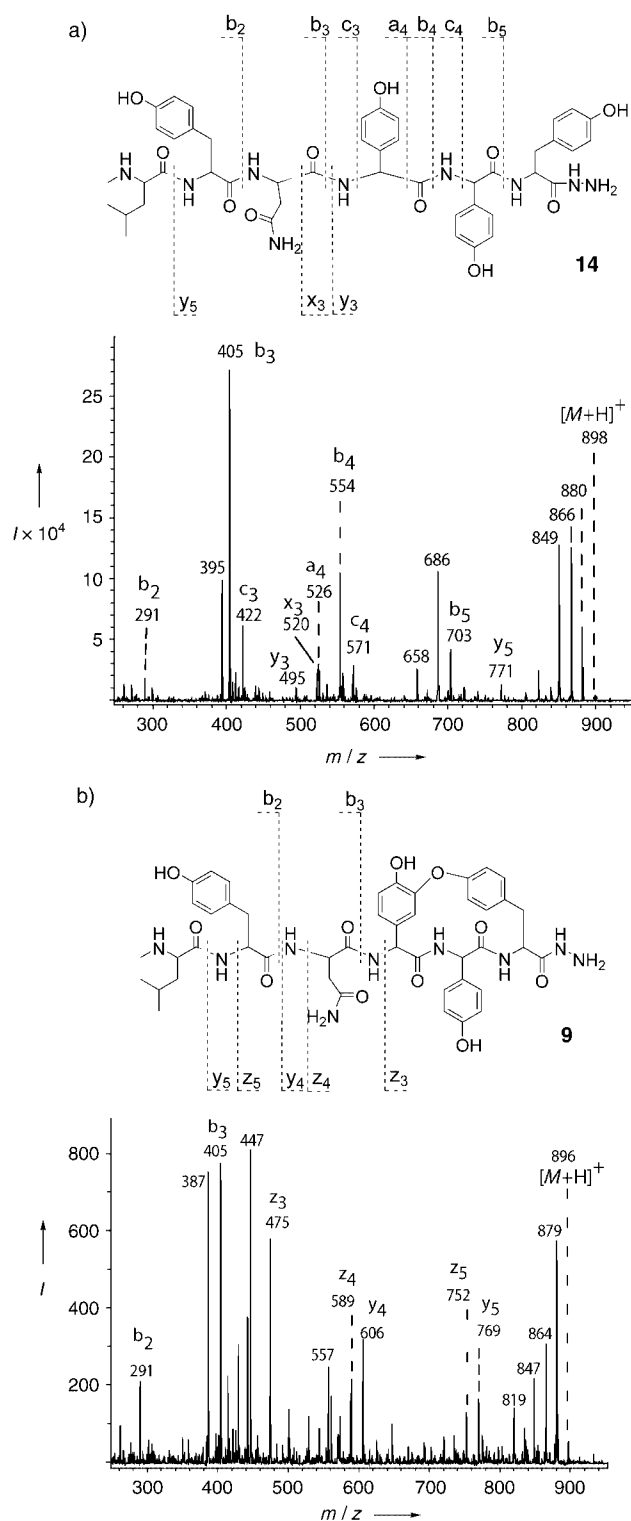

Figure 4. ESI-MS/MS of a) the linear peptide **14** and b) the monocyclic product **9**. The spectra were run on a Bruker ESQUIRE-LC quadrupole ion-trap mass spectrometer. Samples as solutions in MeOH/H₂O (1:2) with 0.05% TFA were introduced through the ES interface at 5 μL min⁻¹. The protonated quasi-molecular ions [M+H]⁺ were selected and subjected to helium gas collision (fragmentation amplitude of 0.9 in the smart fragmentation mode).

the intact connectivity of the side chains of residues 1, 2, 3, and 5 was apparent in the 2D spectra. However, the side chains of residues 4 and 6 in this product had clearly been altered relative to the starting hexapeptide **5** (see Figure 2 for labeling of the rings, residues, and carbon atoms). The proton at C(α) of residue 4 showed NOE connectivities to a singlet peak at δ = 5.95 ppm, which we assign to the hydrogen atom at C(γ1) in the aromatic side chain. This aromatic proton is shifted upfield as expected from its close proximity to the face of the aromatic ring C in residue 6 in **9** (see Figure 2). The proton of the N-H group of residue 4 shows an NOE interaction with the hydrogen atom at C(γ2) in ring D, with the latter hydrogen atom coupling to that at C(δ) to give rise to a doublet-of-doublets. In the case of residue 6, the protons of the aromatic ring C appear as two sets of doublet-of-doublets, which indicates hindered rotation of the aromatic ring and thus renders the two sides diastereotopic as would be expected for **9**. A weak NOE interaction is also observed between the hydrogen atoms at C(γ1) in ring D and C(ε2) in ring C, respectively. At a later stage, we hope to prepare **9** synthetically to prove the identity of this enzymic product by an alternative method, but at this point, the data from MS and NMR spectroscopy experiments strongly support the proposed structure of **9**.

These results provide the first direct evidence that OxyB can catalyze a phenol coupling reaction not on a free peptide but rather on a peptide attached as a thioester to a PCD. A simpler S-NAC thioester mimic, such as **15**, is not sufficient to render the peptide a viable substrate for OxyB. This further suggests that at least the OxyB-catalyzed coupling reaction, and perhaps all of the oxidative phenol couplings during glycopeptide antibiotic biosynthesis, occur whilst the peptide intermediates are attached to cognate PCDs within the NRPS as suggested indirectly by the results from other studies.[10] However, many unanswered questions remain. A key uncertainty is whether the enzyme can also transform heptapeptides such as **2a** and **2b** (and whether this is more efficient), or whether the first phenol coupling reaction occurs preferentially on a hexapeptide (that is, before the last amino acid is added to the chain by the NRPS). Renewed efforts should now be made to prepare and perform assays with heptapeptide–PCD conjugates such as **2a** and **2b**. Evidence from gene knockout experiments suggest already that the biosynthetic enzymes may not have a strict substrate specificity.[10] Clearly, a 3-hydroxy group in residue 6 is not necessary for the coupling reaction that is catalyzed by OxyB to occur. However, the influences of a β-hydroxy group and the chlorine atom in the *m*-chloro-3-hydroxytyrosine residue (compare **2a** and **2b** with **8**) on the rate of the reaction remain to be defined.

Carbenoid Reagents

Stereoselective Synthesis of Bicyclic Pyrrolidines by a Rhodium-Catalyzed Cascade Process**

Ming Yan, Neil Jacobsen, Wenhao Hu,
Luisa S. Gronenberg, Michael P. Doyle, John T. Colyer,*
and Darren Bykowski

The synthesis of complex products by a reaction between multiple components to form several carbon–carbon bonds in one operation is a strategy that has received considerable attention.[1] Often referred to as tandem or cascade processes, these operations are useful for efficient molecular constructions. Ylide chemistry with metal-stabilized carbenes has provided numerous examples of these processes, often in the context of dipolar cycloaddition reactions.[2] We recently reported versatile heterocycle syntheses by reactions of aryl and vinyl diazoacetates with aldehydes and imines catalyzed by dirhodium(II) acetate.[3] These reactions proceed through the generation of an ylide intermediate to produce epoxides, aziridines, dihydropyrroles, and, in select cases, dihydroazepines with a high degree of stereoselectivity. More recently we reported alternative pathways for the highly selective synthesis of dihydropyrrole isomers that are catalyst dependent.[4] During the course of this latter investigation, we obtained the isomeric compounds **2a,b** as minor products formed from two carbene units derived from methyl styryldiazoacetate and one imine (Scheme 1). However, the structure of **2a,b** was not determined. The constitution of these compounds was surprising, as the combination of two carbene units and an imine does not have precedence in diazo chemistry[5] or ylide processes.[1f,6] We now report the structure of this unusual product, the optimization of the reaction conditions to effect the synthesis of such compounds in good yield and selectivity, and the preliminary evaluation of the breadth of applicability of this reaction in synthesis.

The treatment of *N*-benzylidene-*p*-nitroaniline (1.0 equiv) with methyl styryldiazoacetate (1.1 equiv) in the presence of rhodium acetate (1 mol%) in refluxing dichloromethane gave a product mixture that contained two isomeric

of the second isomer was confirmed by NMR spectroscopy to be that of the *trans* diastereomer **2b**.[8] No other isomers of **2** were observed.

Initial investigations focused on reaction stoichiometry and the influence of substituents on the *N*-benzylidene *p*-Z-aniline reagent on product formation in reactions with methyl styryldiazoacetate (2.0 equiv). In these reactions the yield of the bicyclic pyrrolidine was proportional to the number of equivalents of styryldiazoacetate used (up to 2.0 equiv). The

highest yields of the bicyclic pyrrolidine were obtained when Z was H (70% when the benzylidene group was unsubstituted); imines with *para* substituents on the benzylidine moiety were selected for further investigation of substitution effects on the reaction (Table 1).[9]

Variation of the substituents on the benzylidene group had no effect upon diastereoselectivity; however, the yield decreased with imines bearing elec-

tron-donating substituents. Exclusive formation of the *cis* diastereomer of type **8** was observed when *ortho*-substituted imines were used (Scheme 2).
Scheme 2. Exclusive formation of the *cis* isomer in reactions with benzylidene *o*-anisidines.

Our previous investigations are consistent with the initial step being the generation of an azomethine ylide through reaction of the imine with a carbene unit formed by catalytic dinitrogen extrusion from the diazo compound. Initially, we considered the possibility that this ylide intermediate cyclized to form a dihydropyrrole, which then reacted with a second carbene unit to generate the bicyclic pyrrolidine. However,

the exposure of isolated **1** or **9** (formed from benzylideneaniline and methyl styryldiazoacetate) to methyl styryldiazoacetate (1.1 equiv) under the standard reaction conditions failed to produce any quantity of the corresponding bicyclic pyrrolidines, thus ruling out the intermediacy of the dihydropyrrole. Furthermore, *trans* dihydropyrroles are formed with a high degree of selectivity from styryldiazoacetate and *N*-benzylidine *p*-Z-anilines (Scheme 1), whereas the bicyclic products **2–7** are mixtures of *cis* and *trans* isomers and could therefore not be derived from the *trans* dihydropyrrole isomer.

As dihydropyrroles are not intermediates in bicycle formation, an alternative explanation is that the azomethine ylide **10** reacts with a second metal–carbene unit prior to cyclization. Reports by Davies and co-workers have shown that rhodium(II)-stabilized vinyl carbenes are capable of undergoing nucleophilic attack at the vinylogous position.[10] In a similar manner, this mode of nucleophilic addition of **10** to a rhodium(II)-stabilized vinyl carbene would, after the cascade ring closure of **11**, generate the observed products (Scheme 3).

of diastereomers, **3b** was formed with modest enantioselectivity (25 % *ee*).[14]

The potential for using simple, readily accessible starting materials to form stereochemically complex systems in good yields provides a new entry to nitrogen-based heterocycles. Of particular note are the high levels of diastereoselectivity and the promise of future progress in enantioselectivity. Attempts to exploit this reactivity mode in the synthesis of other heterocyclic systems are currently underway.

Scheme 3. Mechanism of formation of bicyclic pyrrolidines.

To evaluate the propensity of the azomethine ylide to add to a second carbene unit rather than cyclize to the dihydropyrrole, we used an excess of the imine relative to methyl styryldiazoacetate. When methyl styryldiazoacetate was added to a tenfold excess of *N*-benzylideneaniline under dilute conditions, the ^{1}H NMR spectrum of the product mixture showed a 39:36:25 ratio of **3a:3b:9**.[11] That the bicyclic pyrrolidine **3** remains the dominant product under conditions which are designed to force cyclization to the dihydropyrrole emphasizes the surprising efficiency of the vinylogous intermolecular reaction. The efficiency of this mode of reactivity was also illustrated upon attempts to trap ylide **10** with a series of dipolarophiles. Similar azomethine ylides have been trapped by electron-deficient olefins and acetylenes in [3+2] cycloadditions.[2a] However, the addition of methyl styryldiazoacetate to imines in the presence of common dipolarophiles of this type, even in significant excess, failed to provide the [3+2] cycloadducts.[12] The formation of bicyclic pyrrolidines was observed in all cases.

We have recently begun to develop an asymmetric variant of this reaction with chiral dirhodium catalysts; in initial investigations *N*-benzylideneaniline and the Davies catalyst [Rh$_2${(*S*)-dosp}$_4$] were used.[13] Although the yield of isolated **3a,b** decreased to 12 % with no significant change in the ratio

Spectroscopic Elucidation of a Peroxo Ni₂(μ-O₂) Intermediate Derived from a Nickel(ɪ) Complex and Dioxygen**

Matthew T. Kieber-Emmons, Ralph Schenker, Glenn P. A. Yap, Thomas C. Brunold, and Charles G. Riordan*

The preparative chemistry and reactivity of Ni$-$O$_x$ intermediates has advanced significantly in the past few years with the identification of a number of new structure types. The most common synthetic approach, reaction of a nickel(ɪɪ) precursor with H_2O_2, has yielded bis-μ-oxo[1–4] and bis-μ-superoxo complexes.[4] An attractive alternate route utilizes the reaction of nickel(ɪ) complexes with O_2. This strategy relies on, and is limited by, the ability to prepare suitable nickel(ɪ) species. We have utilized this latter approach to prepare $[\{(PhTt^{tBu})Ni\}_2(\mu\text{-}O)_2]$[5] (PhTt^{tBu} = phenyltris((*tert*-butylthio)methyl)borate) and the related side-on bound superoxo complex, $[\{PhTt^{Ad}\}Ni(O_2)]$ (PhTt^{Ad} = phenyltris((1-adamantylthio)methyl)borate).[6] During the course of these studies, we considered whether a μ-peroxo Ni$_2$ species was a possible intermediate along the reaction trajectory leading to the bis-μ-oxo dimer. Lacking experimental evidence, a μ-η²,η²-peroxo bridged Ni$_2$ dimer supported by the tris(thioether) borato ligand was evaluated by density functional methods.[7] This hypothetical species was deemed to be of high energy, significantly destabilized ($\Delta H° = 32$ kcal·mol^{-1}) relative to the bis-μ-oxo dimer and, therefore, an unlikely intermediate. Consequently, we turned our attention to macrocyclic tetradentate ligands that coordinate in a planar array, reasoning that such an attribute would render access to the μ-η²,η²-peroxo coordination more difficult. Herein, we report on the successful pursuit of this strategy, which led to the discovery of a Ni$_2$(μ-O$_2$) complex in which the peroxo moiety spans the metals in the μ-1,2 mode.

Addition of dry O_2 to [Ni(tmc)]OTf[8,9] (**1**; tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazadodecane, OTf = [CF$_3$SO$_3$]$^-$) in THF or acetonitrile at room temperature resulted in a color change from pale blue to clover green. The FT-IR spectrum of the paramagnetic product ($\mu_{eff} = 2.7(1)$ μ_B) included a prominent new feature at 3628 cm^{-1} assigned to the $\tilde{\nu}$(O$-$H) mode

of the [Ni(tmc)OH]$^+$ ion. The assignment of a terminal hydroxy species was confirmed by the independent synthesis of [Ni(tmc)(OH)]OTf (**2**) by metathesis of [Ni(tmc)](OTf)$_2$ and KOH. The $\tilde{v}$(O–H) band in the authentic sample of **2** was observed at identical frequency as in the product of the reaction between **1** and O$_2$. Further, the corresponding ^{1}H NMR spectra are nearly indistinguishable (see Supporting Information). The monomeric nature of **2** was established through X-ray diffraction analysis, Figure 1.[10] The geometry
Figure 1. Molecular structure of the cation of **2** derived from an X-ray diffraction analysis. Thermal ellipsoids are set at 30% probability. The hydroxy proton was found in the Fourier difference map.

of the isolated cation is square pyramidal with the amine nitrogen atoms in the basal positions and the terminal hydroxy group in the apical position. The Ni–N bond lengths, which range from 2.116(2) to 2.138(2) Å, are similar to those found for other [Ni(tmc)X]$^+$ species, all of which are high spin, $S = 1$.[9] Compound **2** is the first mononuclear, terminal hydroxy complex of nickel to be defined crystallographically; nonetheless, the Ni–O bond of 1.955(2) Å is consistent with a hydroxy ligand. Further, the hydrogen atom of the hydroxide was found in the difference Fourier map. Isotopic labeling experiments have identified the sources of the hydroxy oxygen and hydrogen atoms in **2**. Addition of ^{18}O$_2$ to **1** generated the [Ni(tmc)(^{18}OH)]OTf isotopomer as characterized by a new $\tilde{v}$(^{18}O–H) band at 3617 cm^{-1} ($\tilde{v}$(^{16}OH)/$\tilde{v}$(^{18}OH) = 1.003; calcd 1.003 for an isolated harmonic oscillator). Oxygenation of **1** in CD$_3$CN resulted in isolation of [Ni(tmc)(OD)]OTf (**2^D**) with $\tilde{v}$(O–D) at 2677 cm^{-1}, identical in magnitude to **2^D** prepared independently, implicating the solvent as the source of the hydrogen/deuterium. The magnitude of the isotopic shift is smaller than anticipated based on reduced-mass considerations for an isolated harmonic oscillator ($\tilde{v}$(OH)/$\tilde{v}$(OD) = 1.355; calcd 1.414).

Low-temperature oxygenation of **1** results in formation of a red intermediate **3**, as indicated by the clean optical progression (isosbestic point at 388 nm, see Supporting Information). In the UV/Vis spectrum, compound **3** is characterized by $\lambda_{max} = 465$ nm (inset Figure 2; $\varepsilon_M = 2100\,M^{-1}\,cm^{-1}$ per nickel). The intermediate has a limited lifetime at –45 °C in acetonitrile, decaying with $\tau_{1/2} = 4$ min. This thermal instability precludes determination of the Ni:O$_2$ stoichiometry by spectrophotometric titration. The proton NMR spectrum of **3** in [D$_3$]acetonitrile shows sharp, paramagnetically shifted resonance signals at 228 K (Supporting Information). Compound **3** is EPR silent between 4 and 77 K. These magnetic data suggest an integer-spin ground state, eliminating the possibility of a 1 Ni:1 O$_2$ adduct, which would have an $S = 1/2$ or $3/2$ ground state. To further elucidate the

molecular structure of **3**, resonance Raman (rR) studies were performed. Excitation of **3** in resonance with the visible absorption band ($\lambda_{ex} = 502$ nm) at 77 K revealed two O$_2$ isotope sensitive features; namely, an intense band at 778 cm^{-1} and a weaker peak at 479 cm^{-1}. These features shift to 735 cm^{-1} and 456 cm^{-1}, respectively, in samples of **3** prepared with ^{18}O$_2$ (Figure 2). The frequency and isotopic
Figure 2. Resonance Raman spectra of **3** at 77 K obtained upon excitation at 502 nm in THF (*); (——) prepared with ^{16}O$_2$, (- - - - -) prepared with ^{18}O$_2$, offset: Δ(^{16}O$_2$ and ^{18}O$_2$) traces. Inset: overlaid optical spectra of **1** (- - - - -) and **3** (——).

red-shift (-43 cm^{-1} ($\tilde{v}$(^{16}O–^{16}O)/$\tilde{v}$(^{18}O–^{18}O) = 1.058; calcd 1.060 assuming an isolated O–O harmonic oscillator) of the dominant 778 cm^{-1} band are consistent with assignment of this band as an intraperoxide stretch.[11–13] The lower frequency mode is ascribed to the $\tilde{v}$(Ni–O) mode associated with this peroxo intermediate, ($\tilde{v}$(Ni–^{16}O)/$\tilde{v}$(Ni–^{18}O) = 1.050; calcd 1.048). The rR excitation profile of the 778 cm^{-1} mode closely parallels the dominant absorption band, which leads to the assignment of this absorption band as a peroxo→Ni^{2+} charge transfer (CT) transition. Together with the magnetic properties, the rR features are indicative of a dimeric μ-1,2-peroxo formulation for **3** (Scheme 1).[14] We favor the *trans* conformation because this core structure is generally adopted by other unsupported peroxo-bridged species. Comparison with vibrational data of other *trans* end-on peroxo dimers lends credence to this assignment. In particular, in [{Cu(tmpa)}$_2$(O$_2$)]$^{2+}$ (tmpa = tris(2-methylpyridyl)amine)) the $\tilde{v}$(O–O) and $\tilde{v}$(Cu–O) stretching vibrations are at 832 cm^{-1} and 561 cm^{-1}, respectively.[12] The frequency of $\tilde{v}$(M–O) vibration

Scheme 1.

Communications
is slightly lower than found in *trans* μ-1,2-peroxo dimers of copper(II) and cobalt(III)[15] which is consistent with a weaker (that is, less covalent) metal–peroxo bonding interaction in the Ni₂ dimer owing primarily to the lower effective nuclear charge of nickel(II) relative to copper(II) and cobalt(III). Also, **3** differs from these other late-transition-metal examples in that the nickel center does not have a ligand *trans* to the peroxo group, as evidenced by the identical optical spectra of **3** in THF and CH₃CN, thus arguing against solvent ligation to the sixth coordination site. This lack of a *trans* axial ligand in **3** eliminates the possibility of mechanical coupling between the Ni−O and Ni−L*trans* stretching motions, which otherwise could lead to a slight upshift of the $\tilde{v}$(Ni−O) vibration. The relative intensities of the Ni−O and O−O vibrational modes, specifically the extreme enhancement of $\tilde{v}$(O−O), strongly suggest that the kinematic coupling between the oxygen-derived modes is substantial. DFT computational studies and a normal coordinate analysis of **3** are underway to elucidate further the nature of the Ni₂(μ-O₂) unit and determine the factors that control the electronic and vibrational characteristics of this new chromophore.

In summary, we have identified a binuclear *trans*-μ-1,2-peroxo Ni₂ dimer, a structural motif unknown previously in nickel coordination chemistry, produced by reaction of a nickel(I) precursor with O₂. This structural assignment of **3** is supported by EPR, NMR, and rR spectral characteristics as well as DFT computations. Thermal decomposition of **3** in CH₃CN leads to **2**, in which the atoms constituting the hydroxide ligand derive from O₂ and the hydrocarbon solvent.

Experimental Section

2: Potassium hydroxide pellets (1.30 g, excess) were added to a slurry of [Ni(tmc)](OTf)₂[16] (380 mg, 0.619 mmol) in THF (≈15 mL). The mixture was stirred for 1 h, resulting in a homogeneous green solution. The mixture was filtered to remove the remaining KOH, and the product was crystallized by diethyl ether vapor diffusion; 81% yield (0.240 g, 0.499 mmol). Green crystals suitable for diffraction analysis were obtained by vapor diffusion of pentanes into a saturated THF solution. Elemental analysis calcd (%) for N₄O₄.₆SNiC₁₅F₃H₃₄.₃ (**2**·(2/3)H₂O): C 36.53, H 7.02, N 11.36; found: C 37.09, H 6.90, N 11.24. FT-IR (Nujol): $\tilde{v}$(OH) 3628 cm⁻¹ (w). Electronic absorption spectrum in MeCN, $\lambda_{max}(\varepsilon_M)$: 409 (41.4), 657 nm (30.1).

2ᴰ: Potassium deuteroxide (KOD) was prepared from the reaction of potassium *tert*-butoxide (1.96 g, 17.5 mmol) with D₂O (5 mL, excess). Excess water and [D₁]*tert*-butanol were removed in vacuo overnight. **2ᴰ** was prepared by a method analogous to that for **2**, using KOD in place of KOH and CD₃CN instead of THF. FT-IR (Nujol): $\tilde{v}$(OD) 2677 cm⁻¹ (w).

[10] X-ray structural analysis for **2**: A single green crystal (0.40 × 0.20 × 0.15 mm) was mounted using Paratone oil onto a glass fiber and cooled to the data collection temperature of 150 K. Data were collected on a Bruker-AXS APEX CCD diffractometer with 0.7107 Å Mo_Kα radiation. Unit cell parameters were obtained from 60 data frames, 0.3° Ω, from three different sections of the Ewald sphere yielding $a = 12.163(4)$, $b = 12.660(4)$, $c = 14.104(5)$ Å, $\alpha = 86.715(6)$, $\beta = 80.626(5)$, $\gamma = 89.312(5)°$, $V = 2139.1(12)$ Å³. 14169 reflections ($R_{int} = 0.0117$) were collected (8939 unique) over $\theta = 2.05$ to 28.02°. No symmetry higher than triclinic was evident from the diffraction data. Solution in the centrosymmetric space group option $P\bar{1}$ yielded chemically reasonable and computationally stable results of refinement. The data-set was treated with SADABS absorption corrections based on redundant multiscan data (G. Sheldrick, Bruker-AXS, 2001) $T_{max}/T_{min} = 1.268$. A molecule was located in a general position while two-half molecules were also located at inversion centers yielding $Z = 2$, and $Z' = 2$. The molecule in general space has a coordinated hydroxide ligand on one metal face and a noncoordinated water molecule on the opposite face. The hydrogen atom on the hydroxy ligand was located from the electron-density-difference map and allowed to refine positionally with a riding isotropic model. The other symmetry unique molecules were assumed to be chemically identical and having water molecules disordered with hydroxy ligands. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were treated as idealized contributions except those on the disordered hydroxy ligands and water molecules which were ignored. Structure factors are contained in the SHELXTL 6.12 program library (Sheldrick, G., Bruker-AXS, 2001). The goodness of fit on F^2 was 1.054 with $R1(wR2)$ 0.0348 (0.0905) for $[I\theta > 2(I)]$ and with largest difference peak and hole of 0.776 and −0.466 e Å⁻³. CCDC-238390 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

Foldamer Structures

β2,3-Cyclic Aminoxy Acids: Rigid and Ring-Size-Independent Building Blocks of Foldamers**

Dan Yang, Dan-Wei Zhang, Yu Hao, Yun-Dong Wu, Shi-Wei Luo, and Nian-Yong Zhu*

The exploration of foldamers having rigid conformations is an area of intensive research.[1] Recently, the research groups led by Seebach and Gellman discovered independently that peptides of β-amino acids can fold into defined secondary structures.[2] One special series of β-peptides, comprising cyclic ring-constrained β-amino acids, which were developed by Gellman and co-workers, form significantly stable helical structures in the solid state, in organic solvents,[3] and even in aqueous solution.[4] Increasing the number of cyclic ring-constrained residues can enhance the helical content of such β-peptides;[5] this approach has become an important and powerful tool for structure–activity studies of the peptides.[5b] Gellman et al. also found that the size of the side-chain rings in the β-peptides has significant impact on the secondary structures. The β-peptides of cyclohexane-containing amino acids prefer to form 14-helix structures, while those of cyclopentane-containing amino acids favor a very different helix, the 12-helix; these conformations result from the different torsional preferences of the C_α–C_β bonds in the cyclic rings of the individual residues.[3b,6] To investigate whether this "ring-size effect" also plays an important role in determining the conformations of our aminoxy peptides, which represent another class of foldamers,[7] we have explored, and report herein, the potential of β2,3-cyclic aminoxy acids, a subclass of β-aminoxy acids in which the α- and β-carbon atoms are part of an aliphatic ring (either a

cyclopentane and cyclohexane unit), to behave as new chiral building blocks for turns and helices.

Compounds **1** and **2**, which are derived from (R,R)-2-aminoxycyclopentanecarboxylic acid, and **3** and **4** derived
from (R,R)-2-aminoxycyclohexanecarboxylic acid, were synthesized by following the standard methods of peptide coupling. Table 1 summarizes the chemical shifts of all the amide protons in ^{1}H NMR spectra (5 mM in CDCl$_3$ at room

Table 1: ^{1}H NMR chemical shifts of the amide NH protons of **1–4** (5 mM in CDCl$_3$ at room temperature).[a,b]

(Table 2). In contrast, the chemical shifts of N-oxy amide protons NH_a of **1–4** are rather upfield (Table 1) and change dramatically upon dilution or addition of $[D_6]DMSO$ (Table 2). These results suggest that the NH_b protons of **1–4** and the NH_c protons of **2** and **4** form intramolecular hydrogen bonds, but that the NH_a protons of **1–4** are not hydrogen-bonded and are solvent accessible. Similar conclusions were drawn from FT-IR spectroscopic studies (see the Supporting Information). This hydrogen-bonding pattern is very similar to that observed in $\beta^{2,2}$-aminoxy peptides and, hence, suggests the presence of a β N–O turn in each peptide, in other words, an intramolecular hydrogen bond between $C=O_i$ and NH_{i+2} to form a nine-membered ring, which is stabilized by an extra hydrogen bond between NO_{i+1} and NH_{i+2} to form a six-membered ring.[8]

Interestingly, the values of the chemical shifts of the NH_c protons of dimers **2** and **4** are much higher than those of the NH_b protons of monomers **1** and **3** (Table 1). In addition, the chemical-shift changes of the NH_c protons of dimers **2** and **4** that are caused by dilution or addition of $[D_6]DMSO$ are much smaller than those of the NH_b protons of monomers **1** and **3**. This observation suggests that hydrogen bonding is enhanced by increasing the number of N–O turns, that is, a cooperative effect exists.

Suitable crystals of **3** and **4** were obtained from $CHCl_3/n$-hexane solutions; their solid-state structures, obtained by X-ray crystallography, are presented in Figure 1.[8] Similar to the $\beta^{2,2}$-aminoxy peptides[9] compound **3** adopts a β N–O turn that is characterized by a nine-membered-ring hydrogen bond between the $C=O_i$ and NH_{i+2} units (O···H distance = 2.20 Å) that is stabilized further by a six-membered-ring hydrogen

bond between the NO_{i+1} and NH_{i+2} units (Figure 1a). The N–O bond is *anti* to the C_α–C_β bond with a dihedral angle $\sphericalangle NOC_\alpha C_\beta$ of 172°. Analogous to the 1.7_9-helix present in $\beta^{2,2}$-aminoxy peptides,[9] the solid-state structure of **4** (Figure 1b) indicates the presence of a well-defined 1.8_9-helix composed of two consecutive β N–O turns with a basic hydrogen-bonding pattern similar to that existing in **3**. In the first N–O turn, the O···H distance in the hydrogen bond between the $C=O_i$ and NH_{i+2} units is 1.93 Å, which reflects the higher acidity of aminoxy amide protons relative to typical amide protons. In the second N–O turn, the O···H distance in the hydrogen bond between the $C=O_{i+1}$ and NH_{i+3} units (2.07 Å) is shorter than that in **3** (2.20 Å); this observation further corroborates the existence of the cooperative effects suggested by the ^1H NMR study.

Since suitable crystals of compounds **1** and **2** for X-ray analysis were not obtained, we utilized computational methods to calculate the most stable conformations of **5** and **6**,[10] which are model compounds for **1** and **3**, respectively (Figure 2). The calculated structure of **6** and the crystal

Figure 2. Pertinent hydrogen bonds present in the most stable conformations of **5** and **6**.

Figure 1. Pertinent hydrogen bonds present in the crystal structures of a) **3** and b) **4**.

structure of **3** are almost superimposable, which strongly supports the correlation between the computational simulation and solid-state structure. The β N–O turn structures are found in the most stable conformations of both **5** and **6**, with little changes in the φ and μ angles but significant changes in the ϕ and θ angles (Table 3). In order to maintain the intramolecular hydrogen bonds of the N–O turns, the tor-

sional angle θ is adjusted accordingly to compensate for the changes in the torsional angle ϕ caused by the difference in ring size. As a result, the relative orientations of the two amide carbonyl groups (C=O$_i$ and C=O$_{i+1}$) are distinct in the most stable conformations of **5** and **6**. This difference is also reflected in the CD spectra of **1–4** (see the Supporting Information).

Figure 3 summarizes the observed nuclear Overhauser effects (NOEs) of compounds **1–4** obtained in 2D-NOESY experiments. All of the 2D NMR experiments were performed using 5 mM solutions in CDCl$_3$ at room temperature,
Figure 3. Summary of NOEs observed for compounds **1–3** (5 mM) and compound **4** (10 mM) in CDCl$_3$ at room temperature (s, strong NOE; w, weak NOE).

except for those for compound **4** (recorded at 10 mM to avoid overlap of the signals of the NH$_a$ and NH$_c$ protons). Compounds **1–4** exhibit very similar NOE patterns: weak NOEs exist between the NH$_i$ and C$_\beta$H$_i$ protons, but strong NOEs exist between the NH$_{i+1}$ and C$_\beta$H$_i$ protons. Moreover, these NOE patterns match well with the corresponding distances between protons of the N−O turns observed in the calculated structure of **5** and crystal structures of **3** and **4** (Table 4). This correlation suggests that, although the ring size of the side chain varies from five to six atoms, to a great extent compounds **1–4** adopt similar N−O turn structures in CDCl$_3$, in contrast to Gellman's β-peptides.

Our β-aminoxy peptides can be considered as analogues of γ-peptides in which the γ-carbon is replaced by an oxygen atom. In fact, nine-membered-ring hydrogen-bonded structures have been observed for several γ-peptides. Dado and

Gellman studied a diamide of an unsubstituted γ-amino acid and found that a nine-membered-ring hydrogen-bonded conformation and a seven-membered-ring hydrogen-bonded conformation are in equilibrium in CH$_2$Cl$_2$ solution.[11] Seebach et al. observed a nine-membered-ring hydrogen-bonded structure for a γ^{2,3,4}-dipeptide in the solid state.[12] However, a γ^{2,3,4}-tetrapeptide was found to form a 2.6$_{14}$-helix (or 14-helix),[12] which is also observed in several other types of γ-peptides.[13] Theoretical calculations on α- and β-aminoxy acids have indicated that the N−O bond has a very strong conformational preference,[7,9b] which contributes to the fact that peptides formed by α- and β-aminoxy acids have a tendency to form hydrogen bonds between adjacent residues.[7,9] On the other hand, β- and γ-peptides have more flexible backbones and tend to form helical structures with hydrogen bonds involving more distant amino acid residues.[2,12,13]

In summary, peptides of β^{2,3}-cyclic aminoxy acids adopt rigid β N−O turns and 1.8$_9$-helix structures. These secondary structures exist independently of the ring size of the aliphatic side chains (either five or six atoms), unlike the case of the β-peptides having cyclically constrained backbones. The strong local conformational control exerted by the β^{2,3}-cyclic aminoxy acids provides a powerful tool that allows the preparation of short peptides having rigid and predictable conformations.

molecular aldol reaction. Almost three decades later, studies by the groups of Barbas[3a] and List[3b] revealed that proline catalysis could be extended to a variety of transformations, including the direct enantioselective aldol reaction[4] between ketones and aldehydes. Recently, our group advanced this proline-catalysis concept to the first example of a direct enantioselective cross-coupling of aldehyde substrates[5] (Scheme 1), a powerful yet elusive aldol variant that had previously only been carried out within the realm of enzymatic catalysis.
Scheme 1. Proline-catalyzed aldehyde–aldehyde aldol reaction.

As part of an ongoing program to develop organocatalysts of broad utility to chemical synthesis, we recently initiated studies towards the identification of simple amines that mimic aldolase type I enzymes while providing complementary function or stereoselectivity to known enamine catalysts (e.g., proline). Herein we describe a mechanism-based investigation that has established imidazolidinones as efficient catalysts for direct and enantioselective aldehyde–aldehyde aldol reactions. More importantly, we demonstrate a new class of enamine catalyst with selectivity parameters that rival or complement benchmark amino acid catalysts (Scheme 2).

In 2001, Houk and Bahmanyar reported a computational study into the transition-state topographies involved in enamine aldol reactions.[6] Besides providing further insight, this study described that secondary enamine additions typically proceed via a late transition state in which the

Organocatalysis

The Importance of Iminium Geometry Control in Enamine Catalysis: Identification of a New Catalyst Architecture for Aldehyde–Aldehyde Couplings**

*Ian K. Mangion, Alan B. Northrup, and David W. C. MacMillan**

In 1971, Hajos and Parrish[1] and Eder, Sauer, and Wiechert[2] independently described the first examples of enantioselective proline-catalyzed reactions in the form of an intra-

Scheme 2. Imidazolidinone-catalyzed aldehyde–aldehyde aldol reaction.

development of the iminium π bond precedes the formation of the carbon–carbon bond. On this basis, we hypothesized that enantiofacial discrimination in enamine additions might be governed, in part, by the ability of an amine catalyst to control iminium geometry during the transition state. Given the success of imidazolidinones as asymmetric catalysts that confer iminium activation and geometry control,[7] we rationalized that amines of type **1** might readily function as enantioselective enamine-aldol catalysts. This hypothesis was further substantiated by the computational model MM3-**2**, which predicts π-facial differentiation of enamine-iminiums derived from **1** on the basis of 1) selective formation of the *E* iminium isomer during the transition state to avoid nonbonding interactions with the bulky *tert*-butyl group, and 2) the benzyl group on the catalyst framework which effectively prevents the *Re* face of the enamine from participating in carbonyl addition.

Initial investigations revealed that the (2*S*,5*S*)-5-benzyl-2-*tert*-butylimidazolidinone catalyst **1** (10 mol %) does, indeed, promote the aldol self-coupling of propionaldehyde to provide the putative aldol adduct **3** in ≥86% yield with 94% *ee* (Scheme 3). Unexpectedly, the initial aldol dimeriza-
Scheme 3. Imidazolidinone-catalyzed aldol reaction: initial results.

tion adduct **3** undergoes rapid formation to the hemiacetal system **4**, a self-termination step that fortuitously protects the product from participation in further aldol processes. To our delight, methanolysis of this aldol hemiacetal product in situ allows direct access to the bench-stable β-hydroxy dimethoxyacetal **5** without loss in enantiopurity or diastereocontrol. Notably, the observed sense of asymmetric induction is in accord with the calculated enamine-iminium model MM3-**2**. In contrast to the proline variant, this enantioselective aldehyde coupling is readily accomplished in a wide variety of solvents,[8] with low dielectric media (e.g., hexane: 90% *ee*; dioxane: 94% *ee*) being generally most efficient. The superior levels of asymmetric induction and efficiency exhibited by the amine salt **1** in Et₂O to afford the dimethoxy-protected aldehyde (2*R*)-**5** in 86% yield with 94% *ee* in one chemical process prompted us to select these catalytic conditions for further exploration.

The ability of imidazolidinone **1** to catalyze enantioselective cross-aldol reactions between non-equivalent aldehydes was examined next. As highlighted in Table 1, addition of α-methylenealdehyde donors by means of a syringe pump to a

variety of formyl acceptors effectively prevents homodimerization while providing the desired cross-aldol products in excellent yields (Table 1, entries 1–10, 58–90% yield). Significant electronic and structural modification in the acceptor component can be realized to incorporate α-alkyl, α-aromatic, and α-oxy functionality (Table 1, entries 1–7, 90–97% *ee*).

Communications

Whereas it has been documented that α-acyloxy-substituted aldehydes are inert to proline catalysis,[9] we have found that these substrates readily participate as electrophilic aldol partners in the presence of amine **1** (Table 1, entry 7, 58% yield, 90% ee).

We next examined the capacity of imidazolidinone **1** to catalyze the homodimerization of α-heterosubstituted aldehydes (Table 1). It has been established that proline catalysis in this venue provides erythrose architecture in one step,[9] a transformation that enables the selective production of mannose, glucose, or allose in only two chemical reactions.[10] As shown in Table 1, entries 8 and 9, exposure of catalyst **1** to α-benzyloxy or α-benzylsulfide aldehydes also provides the erythrose aldol adduct with high levels of enantiocontrol (92–97% ee). In contrast, α-silyloxy aldehydes provide the corresponding threose aldehyde product upon hydrolysis of the corresponding hemiacetal over silica gel (Table 1, entry 10, 4:1 *syn/anti*, 92% ee). As such, we anticipate that the imidazolidinone catalyst will be valuable in the production of hexose carbohydrates that are not available through proline catalysis (e.g. idose, gulose, galactose).[11] More importantly, this result demonstrates the capacity for orthogonal enamine selectivities as a function of amine catalyst architecture.

In summary, we have documented the first asymmetric organocatalytic aldol reaction in the presence of imidazolidinone catalysts. This method allows enantioselective access to β-hydroxy dimethoxyacetals, bench-stable adducts that functionally complement the β-hydroxyaldehyde adducts derived from proline-catalyzed aldol reactions.

The Hydrophobic Effect as a Driving Force in the Self-Assembly of a [2 × 2] Copper(I) Grid**

Jonathan R. Nitschke,* Marie Hutin, and Gérald Bernardinelli

Dedicated to Professor Jean-Marie Lehn on the occasion of his 65th birthday

Grid-type coordination arrays, which consist of a regular array of metal ions sandwiched between two perpendicular sets of parallel ligand molecules, have been shown a great deal of interest in recent years.[1–6] The regular spacing of metal ions and ligands results in a variety of interesting magnetic behaviors,[6–9] and also evokes the possibility of using these complexes as molecular computing elements (quantum-dot cellular automata).[10]

We report herein the preparation of a [2 × 2] copper(I) grid that possesses two novel features. Firstly, the geometry of this grid structure is atypical, not being readily predictable from

the "self-assembly instructions" encoded within the components.[11] The ligands of grids generally cross at perpendicular junctions,[6] which they cannot do in the present structure without distortion. Evidence of this distortion was noted in the crystal structure. Secondly, the self-assembly[4,5,12,13] reaction by which this grid was synthesized took place quantitatively in aqueous solution, but was not observed to occur at all in other solvents. This observation suggests that the hydrophobic effect[14] might play an essential role in directing the self-assembly process.

The mixture of diaminobenzamide **1** (0.024 mmol) with pyridinecarboxaldehyde **2** (0.049 mmol) in D_2O (0.7 mL) under an argon atmosphere gave a complex mixture of products, as observed by NMR spectroscopy. Within five minutes of addition, approximately 30% of **1** and **2** initially present had reacted; possible product structures are shown in Scheme 1. These products were not definitively characterized. However, signals corresponding to at least five distinct aminal and imine products were noted in the ^1H NMR spectrum. These products are capable of interconversion by carbon–nitrogen bond exchange, and thus comprise a dynamic combinatorial library.[15,16] Since diamine **1** may link two molecules of **2**, and **2** may conversely bridge two molecules of **1** in its aminal form,[16] this library could contain a limitless variety of oligomeric and cyclic structures. Our attempts to follow its evolution were hampered by the precipitation of a yellow film over the course of several hours.

The addition of $[Cu(CH_3CN)_4]BF_4$ (0.024 mmol) rapidly brought order to this complex mixture: the presence of Cu^I ions induced the formation of grid structure **3** (Scheme 1) as the unique product, thus templating[17] the formation of the corresponding bisimine ligand from the dynamic library with perfect selectivity. NOESY NMR spectra indicated that the ligand conformation was as shown in structure **3**, and electrospray mass spectra demonstrated it to be tetrameric.

X-ray crystallographic analysis confirmed the presence of this tetrameric structure in the solid state (Figure 1).[18] The complex shows a highly symmetric arrangement around a $\bar{4}$
Scheme 1. Dynamic combinatorial library generated from an aqueous solution of diamine **1** and aldehyde **2**, and the collapse of this library into grid **3** on addition of $[Cu(CH_3CN)_4]BF_4$. Py = 2-pyridyl, R = 2-hydroxyethylcarbamoyl. Shaded spheres represent Cu^I ions.

(S_4) crystallographic axis despite the presence of the flexible hydroxyethyl substituents, which are ordered by hydrogen bonds between neighboring ligands (Figure 1, right). Although they reinforce the grid structure, these hydrogen bonds are not necessary for its formation: 3,5-diaminobenzamide also generated a grid in water when used in place of **1**, despite the fact that it is incapable of forming interligand bonds within a grid-type structure.

Figure 2 shows the coordinate vectors[19] of the ligands present in **3**, which converge at an angle of approximately 60° in an idealized ligand geometry. The coordinate vectors of other ligands in grid complexes lie naturally parallel[1,9] or
Figure 1. Views of the X-ray crystal structure of **3**. The 2-hydroxyethylcarbamoyl (-CONHCH₂CH₂OH) groups have been replaced by purple spheres in the right view for clarity. Each symmetry-equivalent ligand is shown in a different color in the view on the right.

Communications
Figure 2. The coordinate vectors[19] of the ligand present in **3** and of the prototypical grid ligand reported by Youinou et al.[1]

diverge slightly.[3,8] Since the geometry of the grid enforces a parallel arrangement of the ligands, distortion must occur. This distortion is exhibited as: 1) a coordination environment around copper intermediate between tetrahedral (preferred by Cu^I ions) and see-saw (as can be seen in Figure 1, right), 2) an opening of the C_{imine}-N_{imine}-C_{phenyl} angle from an ideal 120° to 127.7°, and 3) a bending (ca. 20°) from planarity of one pyridylimino group on each ligand, thus pushing the copper ions out from the square junctions formed by the ligands (Figure 1, left). These deformations imply the presence of strain, an unusual feature for a quantitatively formed self-assembled structure.

The inference of this strain was supported by the observation that **3** did not appear to be stable in solvents other than water. The formation of **3** was not observed on mixing the precursors of **3** in acetic acid, acetonitrile, acetone, benzene, chloroform, dimethyl formamide, dimethyl sulfoxide, diethyl ether, ethanol, methanol, nitromethane, pyridine, or tetrahydrofuran. When presynthesized **3** was suspended in any of the aforementioned solvents, either it did not dissolve or decomposition was observed. Thus, despite the fact that neither Cu^I ions nor imines are commonly considered to be stable in water, we were able to detect this Cu^I-linked imine complex *uniquely* in that solvent. Our previously described[5,13] aqueous systems were stable in other solvents, and the successes of other research groups with the techniques of ligand-component self-assembly were obtained in nonaqueous solvents.[4,12]

This solvent-dependent stability is likely to be a result of two factors. Firstly, water is a poor ligand for Cu^I ions. The compact donor orbitals of H$_2$O overlap poorly with the diffuse acceptor orbitals of copper(I) ions, which leads to the latter's tendency to disproportionate in aqueous solution. Imine donors, in contrast, are good ligands for Cu^I ions, so much so that this metal will template their formation in water from amines and aldehydes.[13] The disassembly of complex **3** would be facilitated by a solvent that bound strongly to Cu^I ions, and is conversely hindered by the presence of a solvent which does not, thus stabilizing **3** in water. Secondly, non-aqueous solvents would be better able to solvate exposed ligand surfaces, and thus would not force the mixture of species derived from **1**, **2**, and Cu^I ions to collapse into the compact structure of **3**. This structure maximizes the favorable van der Waals interactions, including stacking interactions,[20] between the ligands while minimizing the unfavorable ligand–solvent interactions.

This structure is thus held together through the cooperative interplay of three distinct self-assembly processes: the formation of strong, covalent C=N bonds, as well as weaker, dative N—Cu bonds, and finally the diffuse yet necessary "compression" applied by the hydrophobic effect.[14] The use of the hydrophobic effect as it applies to both metals and ligands represents a new means of control within the field of metallo-organic self-assembly, thus complimenting its use in other contexts.[21] We are continuing to investigate the ways in which an aqueous reaction medium may allow for the construction of new kinds of assemblies, as well as the novel properties that might be engendered by the presence of strain.

Experimental Section

3: Compound **1** (0.0277 g, 0.14 mmol), **2** (0.0303 g, 0.28 mmol), and water (5 mL) were added to a 50-mL Schlenk flask. The flask was then sealed, and the atmosphere was purified of dioxygen by three evacuation/argon-fill cycles. When the solution was homogeneous, [Cu(CH$_3$CN)$_4$]BF$_4$ (0.0446 g, 0.14 mmol) was added, which immediately dissolved to give a violet-black solution. The atmosphere was once more purified of dioxygen by three evacuation/argon-fill cycles, and the reaction was kept at room temperature overnight without stirring. Volatiles were then removed under dynamic vacuum to give **3** in a yield of 0.073 g (99%) as a violet crystalline product, which was pure by NMR spectroscopic analysis. Following the above procedure and starting with a copper concentration of 2.45×10^{-2} M, X-ray quality single crystals (which were also used for the elemental analysis) of **3** were isolated when the solvent was decanted instead of evaporated. ^{1}H NMR (500 MHz, 300 K, D$_2$O, referenced to 2-methyl-2-propanol at 1.24 ppm as the internal standard): $\delta = 9.24$ (s, 8H, imine), 8.22 (d, $J = 1.7$ Hz, 8H, 2,6-phenylamide), 7.94 (d, $J = 7.7$ Hz, 8H, 3-pyridyl), 7.84 (m, 12H, 4-pyridyl, 4-phenylamide), 7.77 (d, $J = 5$ Hz, 8H, 6-pyridyl), 7.26 (dt, $J = 5.5$ Hz, $J = 1.1$ Hz, 8H, 5-py), 3.95 (t, $J = 5.5$ Hz, 8H, hydroxyethylcarbamoyl), 3.74 (t, $J = 5.5$ Hz, 8H, hydroxyethylcarbamoyl); ^{13}C NMR (125.77 MHz, 300 K, D$_2$O, referenced to the methyl groups of 2-methyl-2-propanol at 30.29 ppm as internal standard): $\delta = 168.1$, 160.3, 149.9, 149.0, 147.6, 139.7, 137.6, 129.7, 129.6, 129.4, 118.6, 59.7, 43.1; ESI-MS: $m/z = 436.3$ [CuL]$^+$, 961.2 [Cu$_2$L$_2$+BF$_4$]$^+$, 1484.1 [Cu$_3$L$_3$+2BF$_4$]$^+$, 2009.9 [Cu$_4$L$_4$+3BF$_4$]$^+$; elemental analysis calcd for C$_{84}$H$_{76}$N$_{20}$O$_8$Cu$_4$B$_4$F$_{16}$·H$_2$O·CH$_3$CN: C 47.95, H 3.79, N 13.65; found: C 47.93, H 4.10, N 13.73.

Hydrogen-Bond Lengths in Polypeptide Helices: No Evidence for Short Hydrogen Bonds**

Subrayashastry Aravinda, Saumen Datta, Narayanaswamy Shamala,* and Padmanabhan Balaram*

The 3_{10} helix and α helix are closely related secondary structures observed in polypeptides. The 3_{10} helix is characterized by successive $4\rightarrow1$ (C_{10}) hydrogen bonds ($C_{10} =$ 10 atom hydrogen-bonding ring) of the type $C=O_i\cdots HN_{i+3}$, while the α helix displays a hydrogen bond of the type $C=O_i\cdots HN_{i+4}$ (C_{13}). The α helix is widely distributed in proteins, while the occurrence of segments of 3_{10} helix is very much less frequent.[1] In polypeptides containing $C^{\alpha,\alpha}$ dialkylated residues, α-aminoisobutyric acid (Aib) being the prototype, both the 3_{10} and α helical structures are detected.[2] In homooligomers of Aib, 3_{10} helices are invariably found in crystals,[3] while in heteromeric sequences the precise helical type appears to depend on both Aib content and positioning.[2a,d,4,5] While distinctions between 3_{10} and α helices are possible in the crystalline state, such differentiation becomes difficult in solution.[6] Circular dichroism (CD) has been proposed for distinguishing between 3_{10} and α helix structures by using the ratio of CD bands at 222 nm and 207/208 nm.[7] However, the use of the $[\theta]_{222}/[\theta]_{208}$ ratio has been questioned, suggesting that the distinction between 3_{10} and α helix structures by chiroptical methods may not be readily possible.[8] The conventional interpretation of the CD spectra of helical polypeptides has been further called into question by the careful work of Kemp and co-workers, who have reported the observation of large values of $[\theta]_{222}$, which are inconsistent with those currently accepted for 100% helical structures.[9] Kemp et al. have noted that the 222 nm $n\pi^*$ band has not "been modeled satisfactorily by theory". The widespread use of the CD band intensities at 208 and 222 nm, in estimating helicity values quantitatively and in making qualitative distinctions between helix subtypes, underscores the impor-

tance of relating CD spectral intensities to specific peptide structural features. In addressing this issue, Dang and Hirst[10] have used an improved theoretical method to calculate the 220 nm CD band intensities and have suggested that $[\theta]_{220}$ is extremely sensitive to main-chain hydrogen-bond length. They argue that "shortening from a conventional oxygen–nitrogen separation of about 3.0 Å to 2.8 Å or 2.7 Å is predicted to lead to a sizable enhancement of the intensity at 220 nm", with the effect being most pronounced for α helices and less dramatic for 3_{10} and π helices. These calculations also reveal a dependence of $[\theta]_{220nm}$ on $N\cdots O$ separations in the range 3.0–3.5 Å, a factor which may contribute to the variations in band intensities in model 3_{10} and α helical peptides. With the exception of the Dang and Hirst proposal no testable explanations have been advanced for the observed variation in the 220 nm CD band intensity.

Herein we examine the distribution of hydrogen-bond parameters in high-resolution crystal structures of Aib-containing peptides to assess whether *short* hydrogen bonds are indeed observed in experimental structures. Aib-containing peptides were chosen because of the availability of a large number of accurately determined structures and the occurrence of pure α, 3_{10}, and mixed $3_{10}/\alpha$ helical structures in crystals.

The structure of pBrBz-(Aib)$_{10}$-OtBu (peptide **2**; pBrBz = *para*-bromobenzoyl) provides an example of a complete 3_{10} helix.[3e] The structure of the peptide Boc-Leu-Aib-Val-Ala-Leu-Aib-Val-Ala-Leu-Aib-OMe (peptide **1**; Boc = 1,1-dimethylethoxycarbonyl ($=tert$-butyloxycarbonyl)) determined herein provides an example of a complete α helix over the length of the decapeptide. Figure 1 illustrates the molecular conformations of the two peptides and the distribution of backbone dihedral angles. The parameters for potential hydrogen-bond interactions in the two structures are compared in Table 1. The backbone dihedral angles are given in Table 2. Peptide **1** (α helix) is stabilized by seven intramolecular $5\rightarrow1$ hydrogen bonds while Peptide **2** (3_{10} helix) is stabilized by eight intramolecular $4\rightarrow1$ hydrogen bonds. The data in Table 1 suggests that for the α helix the observed range of $1\rightarrow5$ $N\cdots O$ separation is 2.978 Å to 3.113 Å, while for $1\rightarrow4$ separations in the 3_{10} helix it is 2.907 Å to 3.211 Å. Clearly, none of the observed hydrogen bonds would correspond to the *short* hydrogen bond (2.7 to 2.8 Å) used by Dang and Hirst in their theoretical computation of CD band intensities.[10]

We have classified the hydrogen-bond patterns in the available crystal structures of Aib-containing helical peptides into $4\rightarrow1$ and $5\rightarrow1$ hydrogen bonds by using the following criteria: $N\cdots O$ separation ≤ 3.5 Å, $H\cdots O$ separation ≤ 2.6 Å, $\angle N-H\cdots O \geq 90°$, $\angle C=O\cdots H \geq 90°$, and $\angle C=O\cdots N \geq 90°$.[11] Table 3 summarizes the limits and mean of the hydrogen-bond parameters for the two hydrogen-bond types. Figure 2 summarizes the distribution of the parameters $N\cdots O$ separation and the angles $C=O\cdots N$ and $N-H\cdots O$. In $4\rightarrow1$ and $5\rightarrow1$ hydrogen bonds the mean hydrogen-bond lengths are 3.034 ± 0.109 Å and 3.034 ± 0.118 Å, respectively. This analysis suggests that short hydrogen bonds $N\cdots O < 2.8$ Å are extremely infrequent in polypeptide structures. While our analysis does not exclude the possibility of solvent-induced shortening of

[a] Acceptable hydrogen bonds.

hydrogen bonds as a factor influencing observed CD spectra, there is at present no evidence for such a phenomenon in solution. It may, therefore, be useful to reexamine the factors that contribute to the intensities of the n→π* band in CD spectra of polypeptides. The extensive application of CD methods in estimating helicity in peptides and proteins emphasizes the importance of a rigorous theoretical under-pinning for the analysis of peptide CD spectra. In particular

n→π* band intensities may be influenced by a number of factors. The results herein suggest that short hydrogen bonds may not always be the sole contributing factor. Chiroptical distinctions between 3$_{10}$ and α helical structures must also be tempered by the fact that many sequences can exhibits mixed hydrogen-bonding patterns and can exist in solution as equilibrium mixtures of closely related conformations.

Experimental Section

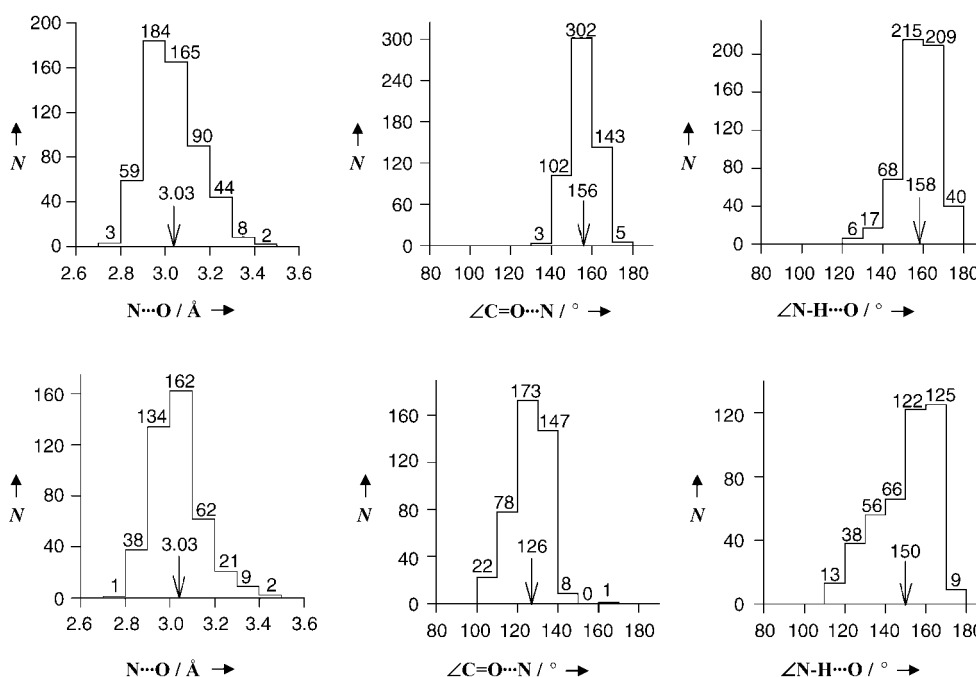
Peptide **1** was synthesized by conventional solution-phase procedures using a segment condensation strategy. Boc groups are used as N-terminal protecting groups and methyl ester as the C-terminal protecting groups. Peptide couplings were mediated by N,N′- dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole.[12] The final step involved a 3+7 coupling. Purification of the peptide was by reverse-phase medium-pressure liquid chromatography (C$_{18}$, 40–60μ), using methanol–water gradients. The peptide was characterized by 500 MHz ^{1}H NMR spectroscopy and MALDI mass spectrometry ([M + Na$^+$]$_{obs}$ = 1089.7; M_{calcd} = 1067.37) Crystals of were grown by slow evaporation of a methanol–water mixture of peptide **1**. X-ray data were collected at room temperature from a dry crystal, on a CAD-4 diffractometer, using Cu$_{K\alpha}$ radiation (λ = 1.5418 Å). ω-2θ scan type was used, with 2θ = 150°, for a total of 7381 independent reflections. The crystal size was $0.2 \times 1.0 \times 0.2$ mm. Space group $P2_12_12_1$, a = 10.791(3), b = 16.632(2), c = 36.068(9) Å, V = 6473(3) Å^3, Z = 4 for chemical formula C$_{52}$H$_{94}$N$_{10}$O$_{13}$, with one molecule per asymmetric unit. ρ_{calcd} = 1.095 g cm^{-3} , μ = 0.064 mm^{-1}, $F(000)$ = 2320. The structure was obtained by direct methods using SHELXS-86.[13a] Refinement was carried out against F^2, with full-matrix least-squares methods using SHELXL-93.[13b] All non-hydrogen atoms were refined isotropically. The R value at the end of isotropic refinement was 0.10. The R value dropped to 0.06 after anisotropic refinement. The hydrogen atoms were fixed geometrically in idealized positions and refined in the final cycle of refinement as riding over the atoms to which they are bonded. The final R value was 0.0418 (wR_2 =


Figure 2. Distribution of N···O separation, C=O···N angles, and N-H···O angles observed in 5→1 hydrogen bonds (top) and 4→1 hydrogen bonds (bottom). N is the number of occurrences in the dataset.

0.113) for observed reflections 5170 with $F_o \geq 4\sigma(|F_o|)$ and 673 variables, where the data to parameter ratio is 7.7:1.0 and $S = 1.038$. The largest difference peak was 0.17 e Å^{-3} and the largest difference hole was -0.25 e Å^{-3}. The standard deviations in bond lengths are approximately 0.004 Å and those of bond angles are approximately 0.3°. CCDC 243105 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: ($+44$)1223-336-033; or deposit@ccdc.cam.ac.uk).

Data base analysis: Out of 407 sequences containing at least one Aib residue retrieved from the Cambridge Structural Database (CSD) (November 2003 release),[14] 393 were linear and 14 were cyclic peptides. For the analysis we have used peptide sequences of length six amino acids and more. 128 sequences were used for hydrogen-bond calculation. All the N–H separations were fixed at 0.86 Å. All the 4→1 and 5→1 hydrogen bonds were calculated. There are totally 555 (α helical) 5→1 hydrogen bonds and 429 (3$_{10}$ helical) 4→1 hydrogen bonds in 128 sequences.

For a list of peptides, CCDC codes and references, used in the hydrogen-bond analysis see the Supporting Information.

Asymmetric Reduction

Enantioselective Reduction of Aromatic and Aliphatic Ketones Catalyzed by Ruthenium Complexes Attached to β-Cyclodextrin**

*Alain Schlatter, Mrinal K. Kundu, and Wolf-D. Woggon**

Molecular recognition of substrates by cyclodextrins is made possible by noncovalent interactions in the hydrophobic cavity of the water-soluble, cyclic sugar oligomers. Inclusion complexes of cyclodextrins[1] and their reactions constitute one of the earliest examples of supramolecular chemistry.[2] As a result of these unique features, cyclodextrins can be used to mediate regioselective reactions[3] and in particular for preparing enzyme models.[4,5]

In this context, the binding properties of β-cyclodextrins have been complemented with chemically reactive subunits,

Communications

either by attaching functional groups such as acid–base catalysts[3] or by linking β-cyclodextrins to metal complexes.[4,5] In most cases superb reactivity and a very high degree of regioselectivity were observed. In contrast, enantioselective reactions with β-cyclodextrin (β-CD) as the only chiral subunit of the catalyst in general gave products with *ee* values well below 50%. For example, the highest enantiomeric excess reported for a product of NaBH$_4$ reduction of an aromatic ketone in the presence of β-cyclodextrin was 24% *ee*.[6] Additives, such as amines[7] or aminoboranes, [8] improved the enantioselectivity, but only at the expense of the yield. We report herein our results on the first ruthenium–arene complexes of β-cyclodextrin-modified amino alcohols and their use in asymmetric hydrogenation reactions of prochiral ketones.

Mono(*O*-6-tosyl)-β-cyclodextrin (**1**, β-CD-Tos) is commercially available and can also be prepared by the tosylation of β-CD on a large scale.[9] The amino alcohol linked β-cyclodextrins **2** and **3** were obtained in good yields as crystalline compounds by the treatment of **1** with an excess of the amino alcohol. [{RuCl$_2$(C$_6$H$_6$)}$_2$] (**4**) was prepared by a literature procedure.[10] The formation of Ru complexes of **2** and **3** (Scheme 1) was shown to be quantitative by ^{1}H NMR
Scheme 1. Synthesis of Ru complexes of the amino alcohol β-cyclodextrins **2** and **3**. The structures of **5** and **6** are tentatively assigned.

spectroscopic studies (600 MHz, D$_2$O). For example, significant chemical-shift changes are observed between **2** and **5**: The doublets assigned to the two H atoms at C6′ of **2** shift downfield by 0.56 ppm, and the triplet assigned to the H atoms at C1 of **2** shifts downfield by 0.49 ppm. The formation of the Ru complex **6** from **3** leads to the following chemical-shift changes: The signals for the two H atoms at C6′ shift downfield by 0.56 ppm and 0.51 ppm, and those for the H atoms at C1 shift downfield by 0.36 ppm and 0.54 ppm.

For catalytic reactions, the Ru complexes were formed in situ and treated with ketones at room temperature under an argon atmosphere in the presence of excess sodium formate as the hydrogen source (Scheme 2). Even with β-cyclodextrin
Scheme 2. Asymmetric reduction of ketones in water.

as the only chiral unit of the Ru complex the alcohol products are formed with remarkable enantioselectivity, predominantly with the *R* configuration (Table 1). Evidently the observed *ee* values correlate with the binding constants of the ketones to β-cyclodextrin,[1] thus reflecting the preorganization of substrates such that *Si* addition of the hydride to the carbonyl group is preferred in the reactive complex.[11]

Table 1: Enantioselective reduction of ketones **7–11** with the catalyst **2+4** (10 mol%).

Ketone	R^1	R^2	Alcohol[a]	Yield [%][b]	ee [%][c]
7	H	CH$_3$	(*R*)-**12**	81	12
8	H	C$_2$H$_5$	(*R*)-**13**	61	6
9	*p*-CH$_3$	CH$_3$	(*R*)-**14**	67	31
10	*p*-Cl	CH$_3$	(*R*)-**15**	93	47
11	*p*-*t*Bu	CH$_3$	(*R*)-**16**	64	47

[a] Absolute configuration based on optical rotation. [b] Yields based on GLC analysis and isolated material. [c] Enantiomeric excess determined by ^{1}H NMR spectroscopy (Eu(tfc)$_3$) (tfc = 3-(trifluoromethylhydroxymethylene)-D-camphorate) and HPLC analysis (chiracel OD-H).

Since it is known from work by other research groups[12] that asymmetric reduction catalyzed by Ru/amino alcohol complexes lacking a cyclodextrin unit is largely dependent on the chirality at the carbinol carbon atom (C2), we prepared **3** by the condensation of (*S*)-(+)-1-amino-2-propanol and β-CD-Tos (**1**). Ligand **3** was isolated in 66% yield as a white solid and was subsequently characterized by high-field NMR spectroscopy, MS(ESI), and X-ray crystal-structure analysis (Figure 1). Initial experiments with the Ru complex of **3**
Figure 1. Structure of ligand **3** derived from X-ray crystal-structure analysis.

revealed a solubility problem in water. To avoid rather dilute conditions the transfer-hydrogenation reactions with **3** were carried out in a mixture of H$_2$O/DMF (3:1; see Experimental Section; DMF = *N*,*N*-dimethylformamide).

When the β-CD derivative **3** was used, the products were obtained with *ee* values of up to 97% and in acceptable yields (Table 2). It is interesting to note that with **3** as a ligand for Ru, acetophenone (**7**) was reduced to (*S*)-**12** with 77% *ee*; in

Table 2: Enantioselective reduction of ketones **7–11** with the catalyst **3+4** (10 mol%).

Ketone	R^1	R^2	Alcohol[a]	Yield [%][b]	ee [%][c]
7	H	CH$_3$	(S)-**12**	90	77
8	H	C$_2$H$_5$	(S)-**13**	63	80
9	p-CH$_3$	CH$_3$	(S)-**14**	69	94
10	p-Cl	CH$_3$	(S)-**15**	77	87
11	p-tBu	CH$_3$	(S)-**16**	51	97

[a], [b], and [c]: see Table 1.

contrast, the Ru complex of (*S*)-1-amino-2-propanol lacking the β-cyclodextrin unit gave **12** in only ≈50% *ee* in favor of the *S* isomer.[13] Since we obtained *R* alcohols by using Ru complexes with ligand **2** and *S* alcohols with ligand **3** our results suggest a clear dominance of the chirality at C2 on the enantioselectivity.

The catalytic system described herein also enables the synthesis of ^{2}H-enriched benzyl alcohols starting from ketones and with sodium [D$_1$]formate as a deuterium source for isotope labeling. Thus, ketones **7**, **8**, and **10** were reduced with 10% of **3+4** and DCO$_2$Na (98% D) in a H$_2$O/DMF mixture (3:1, 500 μL) to give *S* deuterated alcohols **17**, **18**, and **19** in good yields and with enantioselectivities comparable to those observed with HCOONa. High-field NMR (600 MHz) spectroscopic measurements showed that ^{2}H-labeling was as high as >97 atom% (Table 3).

Table 3: Enantioselective reduction of ketones **7**, **8**, and **10** with the catalyst **3+4** (10 mol%) and DCO$_2$Na.

Ketone	R^1	R^2	Alcohol[a]	Yield [%][b]	ee [%][c]
7	H	CH$_3$	(S)-**17**	79	77
8	H	C$_2$H$_5$	(S)-**18**	53	76
10	p-Cl	CH$_3$	(S)-**19**	70	87

[a], [b], and [c]: see Table 1.

Further examples demonstrate the potential scope of the system. α-Ketoesters, such as **20**, are reduced quantitatively to the corresponding *R*-configured alcohols **21** with 57% *ee* (Scheme 3).

Also most promising were first reactions with aliphatic and unconjugated ketones. Thus, ketones **22–28** were reduced under the same conditions as described above to alcohols **29–35** in acceptable yields and with moderate to high enantioselectivity (Scheme 4).
Scheme 3. Reduction of the α-ketoester **20**.
Scheme 4. Enantioselective reduction of aliphatic ketones under the conditions used for the reactions in Table 2.

The reaction mechanism of our transformations seems to resemble that suggested by Noyori and co-workers,[11] since in contrast to **36** the cyclodextrinyl–prolinol–Ru complex **37** was completely unreactive, thus indicating the significance of the N–H group for hydrogen transfer to the carbonyl group (Scheme 5).

Communications
Scheme 5. Suggested hydrogen transfer (*Re* attack) from the Ru–hydride intermediate to geranyl acetone (**26**) encapsuled in β-cyclodextrin (see **36**); the reaction in **37** fails.

In summary, we have synthesized new water-soluble Ru complexes of β-cyclodextrin-modified amino alcohols **2** and **3** to serve as supramolecular catalysts in hydrogen-transfer reactions. Up to 97% *ee* and good to excellent yields were observed. In all cases, β-cyclodextrin plays an important role on the enantioselectivity through preorganization of the substrates in the hydrophobic cavity. This finding is particularly significant in the case of substrates such as **22–28**. Although a number of highly enantioselective Ru-based hydrogen-transfer catalysts are known,[14] including one example that functions in water,[15] none of these systems have been shown to reduce unconjugated ketones.

Experimental Section

Synthesis of **2**: A neat solution of mono(*O*-6-tosyl)-β-cyclodextrin (265 mg, 0.20 mmol) and aminoethanol (960 mg, 15.7 mmol, 80 equiv) was stirred for 12 h at 70°C. Water was then added (1.0 mL), and the resulting yellow solution was added dropwise to acetone (60 mL). The resulting white precipitate (245 mg) was filtered off and recrystallized from water to give pure **2** (140 mg, 59%). MS(ESI): *m/z* 1179 (*M*⁺, 100), 612 ([*M*+Na]²⁺, 72), 1201 ([*M*+Na]⁺, 67); ¹H NMR (600 MHz, D₂O): δ = 4.97–5.02 (m, 7H), 3.79–3.86 (m, 8H), 3.68–3.77 (m, 19H), 3.44–3.50 (m, 13H), 3.33 (dd, *J* = 9.60, 9.60 Hz, 1H), 2.92 (d, *J* = 10.86 Hz, 1H), 2.69 (m, 1H), 2.54 ppm (m, 2H); m.p.: decomposition >275°C.

Synthesis of **3**: A neat solution of mono(*O*-6-tosyl)-β-cyclodextrin (300 mg, 0.23 mmol) and (*S*)-(+)-2-aminopropanol (1.4 g, 18.6 mmol, 80 equiv) was stirred for 12 h at 70°C. Water (0.5 mL) was then added, and the resulting yellow solution was added dropwise to acetone (60 mL). The white precipitate (300 mg) was removed by filtration and recrystallized from water. The white crystals were washed with an ice-cold acetone/water mixture (1:1, 5 mL) to give pure **3** (181 mg, 66%). MS(ESI): *m/z* 1192 (*M*⁺, 100), 618.5 ([*M*+Na]²⁺, 85) 1214 ([*M*+Na]⁺, 78); ¹H NMR (600 MHz, D₂O): δ = 5.00–5.05 (m, 7H), 3.87–3.94 (m, 8H), 3.76–3.85 (m, 19H), 3.48–3.63 (m, 13H), 3.38 (dd, *J* = 9.60, 9.60 Hz, 1H), 3.02 (d, *J* = 10.86 Hz, 1H), 2.79–2.82 (m, 1H), 2.54–2.57 (m, 2H), 1.09 (d, *J* = 6.32 Hz, 3H); m.p.: decomposition >275°C. Crystal data for **3**: C₄₅H₇₇NO₃₅·16H₂O, orthorhombic, *P*2₁, *a* = 12.8092(4) Å, *b* = 19.6407(5) Å, *c* = 26.2645(5) Å, α = 90°, β = 90°, χ = 90°, *V* = 6696.3 Å³, *Z* = 4, ρ_calcd = 1.47, 85399 reflections were measured, *T* = 173 K. Data were collected with Mo_Kα radiation on a Bruker diffractometer (KAP-PACCD and scantype PHIOMEGA).

6 (formed in situ): MS (ESI): *m/z* = 1191 ([ligand **3**]⁺, 100), 1371 ([**6**-Cl]⁺, 11), 1406 ([**6**]⁺, 18); UV/Vis (H₂O): λ_max = 251 nm.

General procedure:[16] Ligand **3** (0.01 mmol) was dissolved in H₂O/DMF (3:1, 0.5 mL), [RuCl₂(C₆H₆)]₂ (**4**, 0.005 mmol) was added, and the resulting mixture was stirred for 1 h at room temperature. HCOONa (1.0 mmol) was then added, and after further stirring for 10 min the ketone (0.1 mmol) was injected. The reaction was usually finished after 24 h at room temperature. The mixture was then extracted three times with hexane (5 mL), the combined hexane extracts were washed with water (6 mL) and dried over Na₂SO₄, and the product(s) were analyzed by GC/HPLC and/or purified by TLC. The *ee* values of the products were determined by HPLC on a chiral phase (chiracel OD-H), GC on a chiral phase (hydrodex 3P), and ¹H NMR/¹⁹F NMR spectroscopic studies of the corresponding Mosher esters.

[16] The concentrations of the catalyst (10 mol%) and formate (excess) were adjusted to give a reasonable reaction time of approximately 24 h. Decreasing the catalyst and/or formate concentration led to unsuitably long reaction times. Preliminary experiments in which Ru–O was replaced by Ru–NTos revealed a sixfold increase in the rate of the reaction, thus allowing for lower catalyst loadings; results will be reported in a subsequent publication.

Drug Design

Antibacterial Aminoglycosides with a Modified Mode of Binding to the Ribosomal-RNA Decoding Site**

Boris François, Janek Szychowski,
Susanta Sekhar Adhikari,
Kandasamy Pachamuthu, Eric E. Swayze,
Richard H. Griffey, Michael T. Migawa,
Eric Westhof,* and Stephen Hanessian*

The past decade has witnessed a phenomenal advance in our understanding of the structure and function of ribosomal RNAs as they relate to the mode of action of clinically relevant antibiotics.[1–6] The aminoglycosides are a group of well-known bactericidal antibiotics.[7] Their widespread use in clinical practice has been curtailed as a result of their oxotoxicity, nephrotoxicity, and susceptibility to enzymatic inactivation;[8] hence the need for careful patient monitoring in a hospital environment.[9] By binding specifically to the bacterial decoding A site, which is responsible for fidelity during protein synthesis by monitoring correct Watson–Crick base pairing between the mRNA codon and the tRNA anticodon, aminoglycoside antibiotics increase the error rate of translation.[10–12] Paromomycin (**1**) has been a benchmark for structural studies owing to its excellent binding affinity for the highly conserved set of nucleotides in the decoding 16S rRNA (A site) region of the 30S subunit of bacterial ribosomes (Figure 1).[13] X-ray crystallographic studies of paromomycin complexed with the 30S subunit of

rRNA from *Thermus thermophilus*[2] as well as with a sequence of oligonucleotides corresponding to the ribosomal A site of *E. coli*[14] have delineated the basis for the molecular recognition.[15]
Figure 1. Structure of paromomycin, its bioactive conformation with relevant nucleotides in the A-site binding domain, and proposed site for diversification (arrow).

Crystal structures[2, 14, 16, 17] have shown that upon binding to the A site the four rings in paromomycin adopt an L shape, which represents its bioactive conformation. Ring I intercalates into the A site and forms two H bonds with A 1408, whereas the invariant ammonium nitrogen atoms of ring II form constant interactions with A 1493, G 1494, and U 1495. The binding of rings I and II force A 1492 and A 1493 to bulge out of the deep/major groove. Rings III and IV interact with the lower stem of the A site mainly through more variable charge and H-bonding interactions with neighboring nucleotides. These hallmark structural events, characteristic of all bioactive aminoglycosides that bind at the A site,[14, 16, 17] are supported by the observed in vivo drug susceptibilities of several ribosomal-RNA mutants.[18]

We reasoned that a structure-based design approach with a chemically modified paromomycin derivative could exploit uncharted areas of the A site, with the possible location of new modes of binding.[19–23] Examination of the crystal structure of the paromomycin complex[14] reveals that the hydroxy group at C2″ of ring III is favorably disposed for appropriate functional diversification (Figure 1). With this objective in mind, the main challenge was to develop methods of regioselective functionalization of the complex polyol system in paromomycin, so as to access the C2″ hydroxy group selectively.

The readily available paromomycin derivative **2**[24] was silylated at C5″ and the product was subjected to O allylation under standard conditions (Scheme 1). Remarkably, after TBS protection of the C5″ hydroxy group, a highly regioselective allylation of the C2″ hydroxy group led to **3** in good yield. Protection of the hydroxy groups on rings II and IV by benzoylation and oxidative cleavage of the allyl group afforded aldehyde **4**. Reductive amination with three representative alkyl amines gave the protected ω-(aminoalkyl) ether analogues **5–7**. Treatment with a catalytic amount of sodium methoxide in methanol afforded the corresponding

polyols. Hydrolysis of the *O*-benzylidene acetal and the TBS ether with aqueous acetic acid, followed by catalytic hydrogenation gave the paromomycin derivatives **8–10**.

The amino ether analogues **8–10** bonded to the 16S rRNA subunit and inhibited bacterial translation/transcription (T/T)[25] with similar potencies. This result was gratifying given our prediction from modeling studies that the C2″ position is suitable for substitution. Most rewarding, however, was that all of the substituted compounds maintained activity against Gram-positive (*S. aureus*) and Gram-negative (*E. coli*) bacteria (Table 1). Whereas in the case of **8** the addition of a

cationic side chain to the paromomycin core afforded a compound with near-identical activity to that of paromomycin, the extension of this chain by one methylene group led to a compound **9** with similar activity against *S. aureus* but diminished activity against *E. coli*. As the binding and T/T activity were largely unaffected, the diminished activity is probably a result of decreased uptake and/or increased efflux by the *E. coli* strain. Most interesting was the 3-(aminomethyl)pyridyl analogue **10**, which was slightly more potent than the parent antibiotic paromomycin against the Gram-positive *S. aureus* strain. Compound **10** was further evaluated against *Streptococcus pyogenes*, *Proteus vulgaris*, and *Klebsiella pneumoniae* strains, and was found to maintain inhibitory activity similar to that of the parent paromomycin.

Extensive studies on the nature of the C2″ tether and of the distal group have led to analogues that exhibit excellent antibacterial activities and interesting structure–activity relationships.[26] Importantly, it might be expected that the incorporation of a large side chain could prevent resistance enzymes from modifying the compounds and rendering them inactive, which is a key element in resistance to aminoglycosides. This hypothesis was partially supported by the activity (MIC 25–50 μM) of **10** against a multidrug- and methicillin-resistant *S. aureus* (MRSA) strain (ATCC BAA-44). This activity is comparable to that observed for the semisynthetic aminoglycoside amikacin, which is modified with an N1 side chain known to combat resistance. In contrast, paromomycin, neomycin, kanamycin, tobramycin, gentamicin, sisomicin, and streptomycin were completely ineffective against MRSA. These results suggest that a C2″ substituent with an aromatic terminal group in 4,5-disubstituted aminoglycosides offers distinct advantages in the fight against the emergence of drug-resistant bacteria. However, it remains to be seen if this type of modification does in fact hinder interaction with one or more resistance enzymes, while allowing strong binding to the target RNA.

Further insight into structure-based design was gathered from X-ray cocrystal data, which revealed a new mode of binding to the decoding A site of rRNA. Crystal structures of **9** and **10** complexed with the same A-site oligonucleotide sequence of *E. coli* RNA as that used for the paromomycin structure were solved at a resolution of 2.6 Å. The two structures are isomorphous and both reveal a normal mode of binding for rings I and II, with the characteristic bulging of A1492 and A1493, and the invariant contacts between the paromamine part (rings I and II) and A1408, or the sugar–phosphate backbone, as shown in Figure 2 for analogue **10**. An important difference is the *direct* contact between the O6 hydroxy group of the deoxystreptamine (DOS) unit and the O4 atom of U1406; the equivalent interaction is mediated by a water molecule in the case of the parent paromomycin.[14] Furthermore, the non-Watson–Crick U1406○U1495 base pair is

Table 1: Activities of C2″-*O*-(aminoalkyl) ether analogues of paromomycin.[a]

[b] Bacterial strains used: *Escherichia coli* (ATCC 25922), *Staphylococcus aureus* (ATCC 13709), *Streptococcus pyogenes* (ATCC 49399), *Proteus vulgaris* (ATCC 8427), *Klebsiella pneumoniae* (ATCC 13883). [c] nd = not determined. MIC = minimum inhibitory concentration.
Figure 2. Top view of the complex between **10** and the A-site RNA oligonucleotide. Adenine residues A 1492 and A 1493 are dark blue, G 1491 is paler blue, A 1408 is pink, and the U 1406 o U 1495 base pair is green. The bridging water molecule between the hydroxy group at C5″ of ring III and N7 of A 1408 is also shown in pink. Note the U o U pair with standard H bonds and the pseudopair of ring I and A 1408.

not bifurcated as in all other aminoglycoside/A-site complexes,[14,16,17] but instead adopts a common geometry with two direct H bonds O4···H−N3 and N3−H···O2[27] (Figure 2).

Rings III and IV of **10** are oriented very differently in the A-site complex with respect to the parent compound paromomycin (and all known 4,5-disubstituted aminoglycosides)[14–16] (Figure 3). In the structure of both analogues **9** and **10**, there is a 40° flip about the β-D-ribofuranosyl linkage to the paromamine unit, which, together with a change in sugar pucker (from C2″-*endo* in paromomycin to C3″-*endo* in **9** and **10**) results in a 90° change in the orientation of ring IV.

The oxygen atom in ring III in **9** and **10** still forms an intramolecular H bond with the amino group at C2′ of ring I, as in the paromomycin complex[14] (Figure 4). However, the hydroxymethyl group at C5″ in **9** and **10** forms a hydrogen
Figure 3. Superposition of paromomycin and **10** complexed to the A site with the DOS rings II superimposed. The left-hand drawing illustrates the 90° rotation of ring IV in **10** relative to that in paromomycin (magenta). The superposition on the right highlights the difference in sugar pucker of ring III from C2″-*endo* in paromomycin (magenta) to C3″-*endo* in **10**.
Figure 4. a) Schematic representation of the contacts between paromomycin and the RNA in the cocrystal with the A-site RNA fragment.[14] b) Schematic representation of the direct and water-mediated contacts observed in the cocrystal of the A-site RNA fragment with **10**.

bond with O6 of G 1491 instead of N7 of G 1491 as in the case of paromomycin. Because of the rotation of ring III, the C5″ hydroxymethyl group forms an additional water-mediated H bond with N7 of A 1408. In fact, the central A 1408 residue forms three (instead of the usual two) H-bonded contacts with the aminoglycoside unit of the two analogues **9** and **10**. The new orientation of ring IV results in a new set of H-bonding interactions. Thus, a network of H bonds links rings I and IV via the C5″ hydroxymethyl group, a water molecule, and A 1408.

The ether chain at C2″ with the distal amino or pyridine group in **9** and **10**, respectively, extends across the deep/major groove of the A site, points into the solvent, and forms no direct contact with the RNA (Figure 4b). Additional contacts are mediated by bridging water molecules that extend in one binding site from the aminoethyl group at C2″ to an oxygen atom of an anionic phosphate in U 1406. These unprecedented conformational changes and new interactions brought about by the presence of the ether chains at C2″ of **9** and **10** result in a compactly folded aminoglycoside structure with unique binding sites (Figure 4b).

We have uncovered a new mode of binding for paromomycin analogues that contain diversely substituted amino-

alkyl ethers at C2″. Cocrystal structures of compounds **9** and **10** with the A site of *E. coli* RNA revealed a new position for the C2″ substituent in the deep/major groove. The orientation of rings III and IV is dramatically changed in the bound conformation, thus resulting in a new set of intramolecular networks of H bonds. The pyridine-substituted aminoethyl ether analogue **10** of paromomycin exhibited potent inhibition of *S. aureus* and promising activity against a panel of resistant bacterial strains, including MRSA. Thus, the introduction of a novel aryl aminoalkyl functionality at C2″ of paromomycin has resulted in the discovery of an excellent first-generation lead compound for the development of new and potent bactericidal aminoglycoside analogues in this series.

Sequential Functionalization of the Channel Entrances of Zeolite L Crystals**

*Stefan Huber and Gion Calzaferri**

Inorganic–organic host–guest systems are of great interest for designing supramolecular devices and machines.[1] We are especially interested in artificial antenna systems that mimic natural photosynthesis. A convenient host is zeolite L, a crystalline aluminosilicate in which corner-sharing SiO_4 and AlO_4^- tetrahedra give rise to one-dimensional channels arranged in a hexagonal structure. The channels have a smallest free opening diameter of 7.1 Å and a channel-to-channel distance of 18.4 Å.[2,3] They can be filled with suitable organic guest molecules, although only guests that can pass through the 7.1-Å opening are able to enter the channels. Pure zeolite L crystals with lengths between 30 and 7000 nm have been synthesized previously.[4].

Due to the channel entrances, the chemical and physical properties of the base and coat of the cylindrical crystals are different. Stopcocks are molecules that can only partly enter the channels. They typically consist of a head, a spacer, and a label, as shown in Figure 1. Only the label and the spacer can enter the channels due to size restrictions,[5] and, depending on the reactivity of the label, they can either be reversibly or irreversibly attached. While fluorescent stopcocks can be used to extract or inject electronic excitation energy from or

Figure 1. a) Schematic picture of a zeolite L crystal loaded with donor dye molecules and modified with acceptor stopcocks at the base. Excitation energy is channeled and focused from inside the zeolite crystal to the outside. b) Enlargement showing details of a channel, the smallest free opening of which is 7.1 Å, and the shape of a stopcock molecule. Only the spacer and label are small enough to enter the zeolite L channels; the head is too big. c) Scanning electron micrographic picture of zeolite L crystals.

into the zeolite L crystals by radiationless Förster-type energy transfer,[6–8] others can be used to block the channel entrances against small molecules such as oxygen or water, or to hinder encapsulated dye molecules from leaving the channels.

Selective functionalization of only the channel entrances is an important topic in the development of highly organized materials, since these molecules are at the interface between the interior of a zeolite L crystal and its surroundings. We describe here a very versatile new five-step reaction principle (Figure 2), which can be summarized as follows:

1) Protection of the functionalizing group with a molecule that is too big to enter the channels of zeolite L. This step is necessary to ensure that the stopcock enters the channels in the desired direction.
2) Adsorption of the reactive stopcock at the channel entrances of the zeolite crystals.
3) Reaction between the adsorbed stopcock and the channel interior, which leads to irreversible fixation. The nature of the bond is not yet known, but water molecules and protons inside the channels seem to play an important role. Therefore, the bond is simply symbolized by a hook in Figure 2.
4) Removal of the protecting group, leaving the crystals with free functionalizing groups at the channel entrances.
5) Coupling of the head bearing the desired property; it can be a fluorescing dye or another molecule.

Since the delicate part of the reaction are steps 1–3, this principle allows us to synthesize a large variety of materials that would otherwise be very difficult to obtain.

This principle was demonstrated to work by functionalizing the channel ends of zeolite L crystals as follows: As a reactive stopcock, 9-fluorenylmethyl carbamate *N*-hydroxysuccinimidyl ester[9–11] (FMOC-NHS) was reacted with (3-aminopropyl)methoxydimethylsilane (APMS) to give **1**
Figure 2. Reaction principle for the irreversible functionalization of the channel entrances of zeolite L crystals. FG: desired group to functionalize the channel ends; protector: the part of the molecule that is too big to enter the channels and that can be removed afterwards; XSi: the group that can penetrate the channels and bind to the zeolite L framework; head: the FG can be further reacted with a head if desired.

(FMOC-APMS). A weighed amount of zeolite L was suspended in *n*-hexane, the number of channel entrances was calculated, and the same amount of **1** was added to the suspension. Knowing the number of channel entrances per milligram of zeolite is very important, since an excess of **1** to channel entrances leads to crystals modified on the whole external surface. The stopcock molecule **1** has a hydrophobic head (FMOC) and a hydrophilic tail (methoxysilane); therefore the tail prefers to penetrate the zeolite L channels, which are hydrophilic, while the hydrophobic head prevents the molecule from entering the channels completely due to the size restriction imposed by the channel openings. The type of reaction between the methoxysilane and the interior of the zeolite channel must be investigated further. Since there are no free silanol groups inside the channels, reactions described for flat surfaces,[12] nanoparticles,[13] and the surface of zeolites[14] are not very probable. However, pentacoordinate silicon oxide compounds are well known,[15a] and pentacoordinate Al^{3+} in zeolite L has been proposed recently.[15b]

The selectivity of the shape dependence of the adsorption was shown by performing the same reaction with FMOC-protected (3-aminopropyl)triethoxysilane (FMOC-APTES). The triethoxysilane group is too bulky to enter the channels of zeolite L under these conditions. Moreover, APTES is known to form clusters in solution, which would also hinder a selective adsorption only at the channel entrances. Therefore, the molecule is expected to adsorb all over the outer surface of the crystals, whereas the smaller stopcock **1** can adsorb selectively at the channel entrances. The same amount of zeolite was used for both modifications and therefore exactly the same amount of FMOC-APMS and FMOC-APTES. Both samples were processed as described in the Experimental Procedure giving NH_2-zeolite L.

The number of amino groups linked to the zeolite L was determined by a quantitative ninhydrin colorimetric reaction, also known as the Kaiser test,[16] and compared to the calculated number of channel entrances. The results showed that essentially 100% of both FMOC-APMS and FMOC-APTES were attached to the zeolite, which means that every zeolite has as many amino groups on the surface as channel entrances for both reactants.

To show the spatial distribution of the amino groups on the zeolite L surface for both samples, the NH_2 groups can be marked with fluorescing dyes. Amino-reactive fluorescing dyes are used by biochemists for protein analysis and are readily available.[17] *N*-Hydroxysuccinimidyl ester (NHS) derivatives, such as dyes **2** (ATTO520-NHS) and **3** (ATTO610-NHS), are well known to react selectively with primary amino groups in high yield, giving an amide bond.
Dye **3** was therefore coupled to the free amino group of APMS- and APTES-modified crystals. Confocal fluorescence microscopy pictures were taken of both, showing the spatial distribution of the fluorescing dye and therefore of the amino groups (Figure 3). The difference between the results
Figure 3. Confocal fluorescence microscopy pictures of zeolite L single crystals. a) Two crystals functionalized with APMS and coupled with the strongly fluorescing dye **3** (top). We also show the relative intensity distribution of one of these crystals (bottom). b) Several crystals functionalized with **3** coupled to APTES (top) and the corresponding relative intensity distribution of one of these crystals (bottom). Both samples are modified with the same amount of dye **3**, therefore the overall fluorescence intensity of the single crystals is similar.

obtained with the monomethoxysilane APMS and the triethoxysilane APTES is striking. The overall fluorescence intensity of single crystals of both samples is about the same, since the same number of amino groups is available, but the distribution of the amino groups on the zeolite surface is completely different: while FMOC-APMS is observed only at the base of the crystals, FMOC-APTES is observed to be present over the whole surface. The only way to explain this is by assuming that the smaller methoxydimethylsilyl group can enter the channels, while the more bulky triethoxysilyl cannot. Control experiments were performed by treating unmodified zeolite L crystals with dye **3**. Since there are no amino groups on the surface, one would expect the dye to be washed away completely. This is indeed the case, and no fluorescence was observed from these samples.

We found that the yield of the reaction between attached amino groups and the reactive dye is mainly determined by the size of the dye and the shape of the crystals. For dyes **2** and **3** we obtained an almost quantitative reaction with the amino groups, and hence full coverage of the channel entrances, when using crystals with a flat base and well-defined shape without any intergrowth, as shown in the SEM picture in Figure 1. The yield decreases to about 10% when zeolite L crystals with a very rough surface are used, indicating the importance of the morphology.

The excitation and emission spectra of **2**, **3**, and the near-IR-emitting dye ATTO680 (**4**) attached to the base of the

2 **3**

zeolite L crystals are shown in Figure 4a. (Note that the structure of **4** has not yet been revealed by the supplier). The excitation and emission spectra of **2** and **3** bound to zeolite L crystals are similar to those recorded for a dilute solution,
Figure 4. a) Excitation (dotted) and emission (solid) spectra of dyes **2** (ATTO520), **3** (ATTO610), and **4** (ATTO680) attached to zeolite L channel entrances. b) Excitation (dotted) and emission (solid) spectra of ATTO680,Ox$^+$-zeolite L. The emission spectrum was recorded when Ox$^+$ was excited selectively at 540 nm. The excitation spectrum was recorded at 720 nm, where essentially only ATTO680 emits.

showing that the dyes are present as monomers. However, the excitation spectrum of **4** is broadened and blue-shifted. Although the structure of **4** is not yet available, we can assume that its dimensions are substantially larger than those of **2** or **3**, allowing electronic interaction between dye molecules located at different channel entrances. This effect is even more pronounced when excitation and emission spectra are measured for a thick layer, in which the chances of intercrystalline electronic interactions between dye molecules bound to different crystals increase.

An additional proof to show that the amino-reactive dye is fixed on the zeolite L crystal can be obtained from energy-transfer experiments. Oxonine-loaded zeolite L (Ox$^+$-zeolite L) is a strongly emitting and stable material that has its emission maximum at 615 nm. The excitation and emission spectra of Ox$^+$-zeolite L were published in ref. [18]. The emission spectrum of Ox$^+$-zeolite L shows a pronounced overlap with the excitation spectrum of ATTO680-zeolite L. This allows Förster-type energy transfer from Ox$^+$ located inside the channels to ATTO680 at the channel entrances in an ATTO680,Ox$^+$-zeolite L sample, if the distance between Ox$^+$ and ATTO680 is in the range of the Förster radius. Therefore, the excitation energy absorbed inside the zeolite L

is transported spatially and focused at the channel entrances. The excitation and emission spectra of an ATTO680,Ox$^+$-zeolite L sample are shown in Figure 4b. Selective excitation of Ox$^+$ causes an important fluorescence of ATTO680 with a maximum at 700 nm; this is obviously due to electronic excitation energy transfer. The ATTO680 is more strongly excited due to energy transfer from Ox$^+$ than by direct excitation at its absorption maximum at 660 nm, as can be seen from the excitation spectrum.

In summary, a new reaction principle for sequential functionalization of only the channel entrances of zeolite L has been developed. The reaction was demonstrated by attaching an aminomethoxysilyl group to the channel openings, which can be further used to selectively bind, for example, fluorescing dye molecules to the base of the crystals. Since amino-reactive fluorescing dyes are readily available, this allows the modification of the base of zeolite L crystals with dyes covering the whole visible and near-IR region. This has important consequences for the preparation of highly efficient antenna materials funneling the excitation energy from inside the zeolite L crystals to the channel ends, or vice versa.[7,8] The amino groups can also be transformed into thiol groups.[19] Such HS-zeolite L crystals are currently under investigation in our laboratory. The reaction principle is not restricted solely to zeolite L or to covalent modification with amino groups, thus opening up options for obtaining a wide range of new, functionalized zeolite-based materials, which otherwise would be very difficult, if not impossible, to obtain.

Experimental Section

Pure zeolite L crystals were synthesized and characterized as described in ref. [4]. The potassium-exchanged form was used for all experiments. The dyes **2–4** were obtained from Fluka and used as received. Confocal microscopy images were taken from zeolite L crystals having a length of about 3 μm; crystals of about 30 nm were used for the energy-transfer experiment. Fluorescence spectra were recorded on an LS 50 B Perkin-Elmer luminescence spectrophotometer, and absorption spectra were measured with a Lambda 900 Perkin-Elmer UV/Vis/NIR equipment. Confocal microscopy was performed with a fluoview FV 300 (Olympus) accessory equipped with an argon-ion laser operating at 488 nm and an He/Ne laser operating at 543.5 nm.

Synthesis of FMOC-APMS (**1**): (3-Aminopropyl)methoxydimethylsilane (APMS, Acros, 97%; 10 μL, 8.7 mg, 0.06 mmol) and was added to 1 mL of CH$_2$Cl$_2$ (dried over CaH$_2$) in a Teflon tube. FMOC *N*-hydroxysuccinimide ester (FMOC-NHS, Fluka, > 98%, HPLC; 30 mg, 0.089 mmol) was dissolved in 1 mL of dry CH$_2$Cl$_2$ and added dropwise to the APMS solution. The reaction mixture was stirred at room temperature and monitored by thin-layer chromatography. After 1 h the reaction was complete, and no more free amine could be detected by a ninhydrin test.

Synthesis of FMOC-APTES: This synthesis was carried out in analogy to that of FMOC-APMS with (3-aminopropyl)triethoxysilane (APTES, Fluka, ≥ 96%, GC; 10 μL, 8.5 mg, 0.053 mmol) instead of APMS.

Synthesis of APMS-zeolite L and APTES-zeolite L: Typically, zeolite L crystals (10 mg) were suspended in 2 mL of *n*-hexane (Merck, p.a.) in a Teflon tube. The number of channel entrances was calculated and 1 equiv of either FMOC-APMS or FMOC-APTES was added to the suspension. After the suspension was sonicated for 20 min to allow the stopcock to adsorb on the zeolite L crystals, it was heated at reflux for 3 h. The suspension was then centrifuged to give

FMOC-APMS-zeolite L or FMOC-APTES-zeolite L. The crystals were suspended in 1 mL of dry DMF containing 0.2 mL of piperidine and stirred for 1 h to remove the FMOC group. After the crystals were centrifuged and washed twice with 2 mL of MeOH, APMS-zeolite L or APTES-zeolite L (NH$_2$-zeolite L) was obtained.

Quantification of NH$_2$ groups bonded to zeolite L: The amine test solution consisted of ninhydrin (Fluka, ~99%, UV; 0.5 g, 2.81 mmol) dissolved in 40 mL of n-butanol and 10 mL of doubly distilled water. A 2-mL aliquot of the test solution was added to 0.05 μL, 0.025 μL, 0.0125 μL, and 0.005 μL (0.3 μmol, 0.15 μmol, 0.075 μmol, and 0.03 μmol, respectively) of APMS, and the solutions were stirred at 100 °C for 35 min. The absorption at 570 nm was measured for all samples against a blank containing ninhydrin solution without APMS, giving a regression line. A weighed amount of typically 1–2 mg of NH$_2$-zeolite L was suspended in 2 mL of the ninhydrin test solution and stirred at 100 °C for 35 min. After centrifuging, the absorption of the solution was measured at 570 nm, and the number of NH$_2$ groups per mg of zeolite L was calculated from the regression line.

Reaction of NH$_2$-zeolite L with an amino-reactive dye: NH$_2$-zeolite L (ca. 5 mg) was suspended in 1 mL of dry acetonitrile (Merck, DNA grade). Triethanalamine (Fluka, >99%, GC; 5 μL, 5.62 mg, 0.038 mmol) was added and the suspension was sonicated for 10 min. The amino-reactive dye (3–4 equiv relative to the NH$_2$ groups) was also dissolved in 1 mL of acetonitrile and added dropwise to the zeolite suspension. The dye-zeolite L was stirred for 1 h then washed twice with 2 mL of MeOH to remove excess dye. The amount of dye bound to the NH$_2$ groups was determined by destroying a known amount of dye-zeolite L with hydrofluoric acid and measuring the concentration of the dye by UV/Vis spectroscopy.

Synthesis of Ox$^+$-zeolite L: Ox$^+$ was synthesized as described in ref. [20] and inserted into zeolite L crystals by ion exchange.[7] Further reaction with ATTO680-NHS ester was performed as described previously for empty zeolite L.

Competing H−H, S−S, and M−M Bond Formation in the "Shape-Shifting" Cluster [Ru₄S₃(arene)₄]²⁺**

Matthew L. Kuhlman and Thomas B. Rauchfuss

Tetrametallic trisulfido clusters[1] mainly adopt the C_{3v} "Roussin Black salt" structure,[2,3] illustrated by the classical anion $[Fe_4S_3(NO)_7]^-$. This motif has recently attracted interest because M_4S_3-like fragments comprise the FeMo cofactor in nitrogenase.[3–5] The only other M_4S_3 structure is the rare C_{2v} capped-butterfly seen in $[Cp_2Mo_2Co_2S_3(CO)_4]$ ($Cp = C_5H_5$; Scheme 1).[2] Herein we describe the character-
Scheme 1. Structures of M_4S_3 cluster cores; M−M bonding can vary; left: C_{3v} Roussin Black salt structure, middle: C_{2v} capped-butterfly, and right: face-capped trigonal prism (this work).

ization of a third M_4S_3 motif; this new cluster is unusual because of its structural dynamics and catalytic properties. In particular, the new M_4S_3 clusters exhibits a previously unobserved competition between S−S and M−M bonding.

Studies on this dynamic property revealed that the new clusters catalyze the reduction of protons to H_2.

We have shown that $[\{(cym)RuCl_2\}_2]$ (cym = 4-*i*PrC$_6$H$_4$Me) reacts with $(Me_3Si)_2S$ to produce trigonal bipyramidal $[(cym)_3Ru_3S_2]^{2+}$.[6] We have found that this simple synthesis also affords the previously unrecognized tetrametallic species $[(cym)_4Ru_4S_3]^{2+}$ (1^{2+}). The distinctive solubility properties of $[(cym)_4Ru_4S_3](PF_6)_2$ (**1**) facilitates its easy isolation in 30% yield [Eq. (1)].

$$2\,[\{(cym)RuCl_2\}_2] \xrightarrow{(Me_3Si)_2S}$$

$$[(cym)_3Ru_3S_2](PF_6)_2 \ (60\%) + [(cym)_4Ru_4S_3](PF_6)_2 \ (\mathbf{1},\,30\%) \qquad (1)$$
In MeCN solution, cluster 1^{2+} is stable at 80°C in the presence of PPh$_3$, and it is stable to UV photolysis.[7]

The reaction stoichiometry leading to 1^{2+} is deceptive: Ru^{II} chlorides are ostensibly converted into the corresponding Ru^{II} sulfides. The ^{1}H NMR data for 1^{2+} indicate low symmetry, which is incompatible with known M$_4$S$_3$ motifs. X-ray crystallographic analysis of **1** revealed that the dication adopts a novel structure, described as a face-capped trigonal prism (Figure 1). An equilateral Ru$_4$ square (Ru–Ru bond 2.81 ± 0.03 Å) is capped by μ_4-S and μ_4-S$_2$ ligands. The crystallographic result shows that 1^{2+} formally arises via an internal reduction of two Ru^{II} to Ru^I concomitant with oxidative coupling of two sulfides to persulfide (S$_2^{2-}$). The 64 electron compound follows the 18 electron rule, although Wade's rules predict a *nido* cluster (9 electron pair/seven vertex).

The crystallographic analysis reveals that the four isopropyl groups are oriented towards the persulfide-containing face of the Ru$_4$ square, which is more spacious than the Ru$_4$S side. A space-filling model indicates steric crowding between the arene substituents,

which would lead to restricted rotation about the ruthenium–arene bonds. Indeed, the ^{1}H NMR spectrum for 1^{2+} is simple at 70°C but becomes complex at lower temperatures as arene rotation is slowed (Figure 2). At −35°C, 13 CH$_3$C$_6$H$_4$*i*Pr signals are resolved (Figure 2b) 14 CH$_3$C$_6$H$_4$*i*Pr signals would be consistent with seven possible atropisomers: (up)$_4$, (down)$_4$, *trans*-(up)$_2$(down)$_2$, *cis*-(up-‖)$_2$(down-‖)$_2$, *cis*-(up-⊥)$_2$(down-⊥)$_2$, (up)$_3$(down), and (up)(down)$_3$, where up and down refer to the orientation relative to the S$_2$ and S faces of the Ru$_4$ square (see Scheme 2). The number of isomers implies that rotation of the S$_2$ ligand is slow on the NMR timescale, such that two *cis*-(up)$_2$(down)$_2$

a)

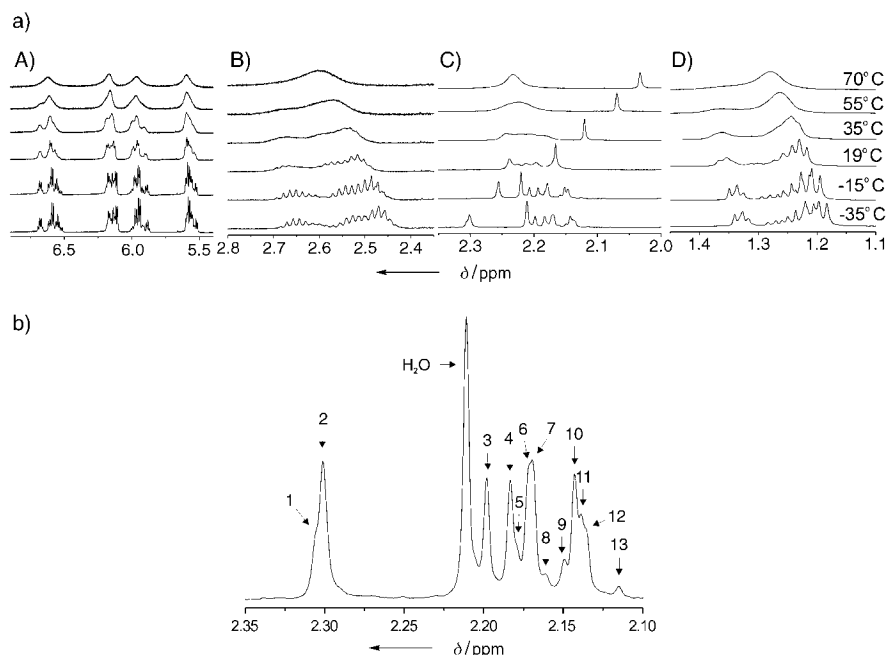
b)


Figure 2. a) Variable temperature ^{1}H NMR spectra ([D$_3$]MeCN) for **1** demonstrating restricted rotation of the cym ligands. A) Aromatic region, B) methyne (isopropyl), C) methyl, and D) methyl (isopropyl) of cym. b) Expansion of the CH$_3$C$_6$H$_4$*i*Pr region for the −35°C spectrum, demonstrating the coexistence of several atropisomers.

Figure 1. Molecular structure of **1**. Thermal ellipsoids are set at 50% probability. Select bond lengths [Å]: Ru1-Ru2 2.782, Ru1-Ru4 2.827, Ru4-Ru3 2.776, Ru2-Ru3 2.848, S1-Ru2 2.352, S3-S2 2.109, S2-Ru2 2.281.

isomers are implicated, those where the cisoid Me groups are parallel (‖; Scheme 2) or perpendicular (⊥) to the S$_2$ unit. Restricted rotation of η^6-arene ligands has rarely been detected in mononuclear complexes[8] and never in a metal cluster. The isomerization barrier could in principle be increased through modifications in the arene ligand.

The cyclic voltammetry (CV) of **1** revealed sequential 1 e$^-$ reductions at −970 and −1270 mV (not shown; all potentials are referenced to the Ag|AgCl couple). A reversible event at 790 mV is assigned to a 2 e$^-$ oxidation. Chemical reduction of 1^{2+} with two equivalents of [Cp*$_2$Co] (Cp* = C$_5$Me$_5$; $E° = 1.73$ versus Ag|AgCl) yielded the neutral cluster [(cym)$_4$Ru$_4$S$_3$] (2^0). The ^{1}H NMR spectroscopy data for this neutral species revealed a 3:1 ratio for the cym signals, which indicates idealized C_{3v} symmetry as expected for the Roussin motif, which was confirmed crystallographically (Figure 3). In contrast to other Roussin-like clusters, the apical metal atom is not connected to the other three metal centers by M–M

A)   B)
Scheme 2. Structures of two atropisomers of **1**, A) the *cis* ∥ isomer and B) the (up)$_3$(down) isomer.
Figure 3. Molecular structure of 2^0 with thermal ellipsoids set at 50% probability. Select interatomic distances [Å]: Ru1···Ru2 3.620, Ru3-Ru2 3.079, Ru3-Ru4 3.059, Ru4-Ru2 3.007, Ru1-S2 2.377, Ru2-S2 2.324.

bonds. Two Ru–Ru bonds are expected in a 68e$^-$ M$_4$ cluster, thus each of the three comparably elongated Ru–Ru bonds within the Ru$_3$ basal plane is consistent with a bond order of 2/3. Compound 2^0 is formally related to the cubane [(cym)$_4$Ru$_4$S$_4$][9, 10] by removal of one sulfur atom and subsequent formation of three Ru–Ru bonds.

The scan-rate dependence of the CV of **1** is consistent with a coupled electrochemical–chemical process. The reduction $1^{2+}\rightarrow1^+$ is fully reversible, but the second reduction is not, hence this event is attributed to the rearrangement to the Roussin-like cluster **2**. At slow scan rates (20 mV s^{-1}), the initially generated 2^+ is fully converted into 1^+, indicated by the event at -970 mV. At faster scan rates (500 mV s^{-1}) separate oxidations are observed for $2^0\rightarrow2^+$ and $2^+\rightarrow2^{2+}$. The
Scheme 3. Pathway for the oxidation of 2^0.

scan-rate dependence suggests that the rearrangement of 2^+ into 1^+ occurs with a half-life of approximately 100 ms. A plausible pathway for rearrangement associated with the oxidation of 2^0 is shown in Scheme 3.

Reflecting its electron-rich character and the robustness of the Ru–S ensemble, 2^0 reacts efficiently with acids, such as HOTf (OTf = [CF$_3$SO$_3$]$^-$), to regenerate 1^{2+}. When this reaction is conducted in CH$_2$Cl$_2$ solution, 1^+(OTf)$_2$ crystallizes in near quantitative yield. Interestingly, this reaction occurs with formation of H$_2$ (^{1}H NMR: $\delta = 4.6$ ppm in CH$_2$Cl$_2$ solution), [Eq. (2)].

$$[(cym)_4Ru_4S_3] + 2\,H^+ \rightarrow [(cym)_4Ru_4S_3]^{2+}\ (100\%) + H_2 \qquad (2)$$

Qualitative experiments suggest that 2^0 is a two-electron reductant since the addition of one equivalent of HOTf precipitates an approximately 50% yield of 1^+(OTf)$_2$. Thus, the implied monohydride intermediate $2H^+$ is apparently more reactive towards HOTf than 2^0. Since 2^0 is capable of reducing protons and 1^{2+} undergoes efficient reduction, a catalytic cycle is apparent, but the CV results were unexpected. Indeed with HOTs a catalytic current that correlates with [HOTs] is observed, but not at the expected potential of approximately $i_{cat} = -1$ V. Instead i_{cat} emerges in the range -0.80 to -0.60 V (Figure 4). The two new reduction events
Figure 4. Voltammograms of 10^{-3} M **1** in 0.1 M Bu$_4$NPF$_6$ MeCN solution. The reductive current at approximately -800 mV can be seen to correlate with the [p-MeC$_6$H$_4$SO$_3$H]. Conditions: scan rate = 100 mV s^{-1}, Pt wire counter electrode, a glassy carbon electrode working electrode, Ag/AgCl reference.

observed in presence of H$^+$ suggest that 1^{2+} forms an electroactive protonated derivative, although we were unable to spectroscopically detect such a species. The two new reduction events not only increase in current with increasing [H$^+$], but shift to a more negative potential with increasing [H$^+$], as seen in catalytic systems.[11,12]

In summary, new M$_4$S$_3$ clusters have been shown to exhibit "shape-shifting", involving redox- and proton-induced conversions between C_{3v} and trigonal-prismatic structures. The parent cationic cluster is further unusual in that its arene

ligands exhibit restricted rotation owing to steric compression. The work underscores the promise of metal sulfide ensembles for hydrogen processing.

Experimental Section

1: A stirred suspension of (4.160 g, 6.8 mmol) of [{(cym)RuCl$_2$}$_2$][13] in warm THF (150 mL) was treated with (2.14 mL, 10.2 mmol) of (Me$_3$Si)$_2$S. The solid slowly dissolved followed by formation of a brown precipitate. The slurry was stirred at 50°C for 1 h. The solid was collected by filtration and washed with THF (20 mL). The dried brown powder was extracted into H$_2$O (100 mL) this solution was treated with KPF$_6$ (2.50 g 13.3 mmol) to precipitate a mixture of [(cym)$_3$Ru$_3$S$_2$](PF$_6$)$_2$ and **1**. After washing this solid with CH$_2$Cl$_2$ to remove [(cym)$_3$Ru$_3$S$_2$](PF$_6$)$_2$, the residue was extracted into acetone, and this solution was concentrated to 5 mL. Addition of Et$_2$O (80 mL) precipitated a brown powder. Yield: 1.34 g (30%). ^{1}H NMR (500 MHz, [D$_3$]MeCN): 1.28 (m, 6H), 2.22 (m, 3H), 2.61 (m, 1H), 6.61 (m, 1H), 6.14 (m, 1H), 5.96 (m, 1H), 5.59 ppm (m, 1H). ESI-MS: m/z 519 ([M^{2+}]). Elemental analysis (%) calcd for C$_{40}$H$_{56}$F$_{12}$P$_2$Ru$_4$S$_3$: C 36.19, H 4.25, N 0; found: C 35.74, H 4.15, N 0.28.

2^0: A solution of [Cp*$_2$Co] (424 mg, 1.29 mmol) in THF (40 mL) was added to a stirred solution of **1** (814 mg 0.61 mmol) in MeCN (130 mL). After 1 h, the solvent was removed in vacuo, and the resulting red powder was extracted with hexane (50 mL). Dark red crystals were obtained upon concentrating and cooling the solution. Yield: 464 mg (65%). ^{1}H NMR (500 MHz, [D$_8$]THF): 1.22 (d, $J =$ 7 Hz, 6H), 1.37 (d, $J =$ 7 Hz, 18H), 1.78 (s, 3H), 2.34 (s, 9H) 2.58 (sept, $J =$ 7 Hz, 1H) 2.78 (sept, $J =$ 7 Hz, 3H) 4.13 (d, $J =$ 6 Hz, 2H) 4.47 (d, $J =$ 6 Hz, 2H) 4.80 (d, $J =$ 6 Hz, 6H) 4.97 ppm (d, $J =$ 6 Hz, 6H). Elemental analysis (%) calcd for C$_{40}$H$_{56}$Ru$_4$S$_3$: C 46.31, H 5.44, N 0; found: C 46.48, H 5.45, N 0.17.

Crystallography: Data was collected at −78°C on a Siemens Platform/CCD automated diffractometer. Data processing was performed with SAINT PLUS version 6.22. Structures were solved using direct methods and refined using full-matrix least-squares on F^2 using Bruker SHELXTL version 6.10. Hydrogen atoms were fixed in idealized positions with thermal parameters 1.5× those of the attached carbon atoms. The data were corrected for absorption on the basis of Ψ-scans. CCDC-244393 and CCDC-244394 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or deposit@ccdc.cam.ac.uk).

The Chemical Application of High-Resolution Electron Tomography: Bright Field or Dark Field?**

John Meurig Thomas,* Paul A. Midgley,*
Timothy J. V. Yates, Jonathan S. Barnard,
Robert Raja, Ilke Arslan, and Matthew Weyland

There are many occasions when chemists need to know detailed information pertaining to the shapes and morphology of minute (nanometer-sized) objects and the topography of nanopores. In characterizing various kinds of electronic devices ranging from quantum dots to quantum wells, in determining the structure of viruses, in visualizing the architecture of supramolecular assemblies inside eukaryotic and prokaryotic cells, and especially in the identification of nanoparticle catalysts supported on high-area nanoporous solids, it is important to know—without recourse to sectioning or other destructive techniques—the precise location, spatial

distribution, and, wherever possible, the elemental composition of such materials.[1]

Like other, well-known forms of tomography (X-ray or positron-emission) electron tomography enables a three-dimensional (3D) picture to be computed (by using proven mathematical procedures) from a series of projected two-dimensional (2D) images taken over as wide a range of angular orientations as possible. The greater the number of distinct 2D images accumulated, the higher is the resolution of the resulting tomogram. Typically, the specimens to be investigated are imaged in a high-resolution electron microscope at a series of angular settings (see Figure 1). From such a series, the tomogram (3D picture) is reconstructed by suitable, so-called "back-projection", as first described by Hart and others.[2–4]

The question arises, however, as to whether the electron tomographic analysis should be performed under so-called "bright-field" (BF) or "dark-field" (DF) conditions. In BF conditions (see Figure 1), in either conventional transmission

Figure 1. a) Bright field (BF) image formation in the TEM (left) and BF and high-angle annular dark-field (HAADF) image formation in the STEM (right). b) Fourier space representation (left) of the series of images, angular sampling θ, maximum tilt α, used to reconstruct a tomogram, such as that of the mesoporous catalyst (right).

(TEM) or scanning transmission (STEM) mode, the forward-scattered beam is used to construct the electron microscopic images (2D) images, whereas in the dark field conditions, it is the beams diffracted through high angles that form the images. BF imaging is the customary procedure, especially in molecular biological contexts; for example in the cryo-electron microscopic, tomographic work of Baumeister et al. a great deal of insight has been gained in visualizing the molecular organization of the cytoplasm using BF-based tomography.[5,6] It has also been used effectively to clarify the

nature of the porosity of zeolites and nanoporous silica and the distribution of finely divided noble-metal catalysts within them.[7–11]

But when attempts are made to extend the resolution of BF electron tomography certain insurmountable, electron-optical drawbacks are encountered. The coherence of the BF signal leads to strong contrast, such as Fresnel contrast, whenever the electron wave encounters a change in refractive index, or diffraction contrast (that produce bend contours and thickness fringes) seen in crystalline specimens. In weakly scattering, noncrystalline samples, these effects are less severe and phase contrast, seen in the image by defocusing, can reveal useful detail. However, phase contrast is highly dependent on the so-called contrast transfer function of the microscope and to reveal very small structures (such as nanoparticles in mesopores, see below) it is necessary to use large defocus values. With large defocus settings, the contrast transfer function oscillates rapidly and direct interpretation of image contrast becomes impossible. For tomography, in which truly 3D samples must be examined, this problem is compounded as identical features at different heights in the specimen can show opposite contrast or no contrast at all. Using small defoci settings will not yield sufficient phase contrast to allow fine detail to be resolved above a support film or substrate, as illustrated later.

High-angle annular dark-field (HAADF) electron tomography, which is readily carried out using a scanning transmission electron microscope (STEM), suffers from none of those drawbacks.[10,12] Electron beams scattered by the specimen to high angles conform closely to Rutherford's scattering law (where the scattered intensity is proportional to Z^2, $Z =$ atomic number of the scattering element) and the process is incoherent, so that the signals accumulated by a HAADF detector (Figure 1) are free from the complications arising from the contrast transfer function, adumbrated above. An authentic image of the internal structure of the specimen is thus recorded, and there are no "missing" atomic spacings (as in BF coherent imaging) arising from purely electron-optical effects. A further advantage with STEM imaging is that specimens can suffer far less beam damage during investigation (which is rather long because several images, typically 70, over an angular span of $+70°$ to $-70°$ of specimen tilt, have to be recorded).

Herein we illustrate, with two examples, the veracity of our statement that HAADF electron tomography is superior to BF electron tomography. In the first example, we focus on the bimetallic nanoparticle catalysts, $[Ru_{10}Pt_2]$, supported on mesoporous silica. Figure 2a shows images of a typical region of mesoporous silica containing this catalyst under BF conditions; and Figure 2b shows precisely the same region of the specimen recorded under HAADF conditions. Whereas under BF conditions the nanoparticles are barely visible, because of the extremely weak phase contrast, under HAADF conditions they stand out clearly because of the high amplitude, atomic number contrast.[13]

Figure 3 shows a series of 3 nm thick slices of the tomogram (derived from images such as that shown in Figure 2b) displayed parallel to the pore axis at intervals of 5 nm—an animation of the top-to-bottom distribution of

Figure 2. a) BF images, taken at three defocus values, of nano-particle-filled mesoporous silica. b) A comparison of BF (left) and HAADF (right) images of identical areas of catalyst: nanoparticles of [$Ru_{10}Pt_2$] invisible in BF are clearly seen in the HAADF image.

Figure 4. a) TEM BF image and b) STEM HAADF image of a Si–Ge multiple quantum well structure. Coherent diffraction effects dominate the BF image. The quantum wells are revealed clearly only in the incoherent HAADF image.

The quintessential conclusion to be drawn from this work is that when electron tomographic resolutions of 3 to 6 nm are deemed adequate, BF imaging suffices. At higher resolutions, and especially in probing nanoparticles of dimension 1 nm or less, it is imperative that HAADF tomography be employed.

Figure 3. An axial projection of a 30 nm thick specimen and five successive 3-nm thick slices through a tomogram of silica-supported [$Ru_{10}Pt_2$]: nanoparticles (red), mesoporous silica (white).

[13] The apparent size of the nanoparticles depends on the precise imaging conditions (e.g. a larger probe size results in a "larger" particle). In reality the [$Ru_{10}Pt_2$] particles are approximately 0.4 nm diameter.

[$Ru_{10}Pt_2$] nanoparticles within the mesoporous silica is in the Supporting Information.

In the second example, we take a section of a Si–Ge multiple quantum-well device, recorded both under BF (Figure 4a) and HAADF (Figure 4b) conditions. Again, the benefits of dark-field imaging are clear. The BF image is dominated by coherent diffraction contrast (bend contours) and the quantum wells are barely visible. In the HAADF micrograph the diffraction contrast has disappeared and the image is dominated by thickness and atomic number contrast—the wells contain 15% Ge. Such an image contrast is ideal for subsequent tomographic analysis.

Communications

Supramolecular Catalysis of a Unimolecular Transformation: Aza-Cope Rearrangement within a Self-Assembled Host**

Dorothea Fiedler, Robert G. Bergman, and Kenneth N. Raymond**

Chemists have long envied the ability of enzymes to manipulate reaction energetics and specificity through steric confinement and precise functional-group interactions. The enormous rate accelerations that enzymes achieve at modest temperatures may be attributed to their high degree of complexity, and the synthetic chemist is hard pressed to create such well-constructed catalytic scaffolds. Yet in this regard, the utilization of supramolecular chemistry may have an advantage: supramolecular self-assembly facilitates the creation of large, complex structures from relatively simple precursors.[1,2] Based on reversible weak interactions, such as hydrogen bonding or metal–ligand interactions, synthetic chemists have generated an array of self-assembled structures, diverse in architecture and composition. Some of these synthetic structures bear an internal cavity, and their interior can provide a new and very specific chemical environment, distinctly different from the exterior surroundings.[3–6] The development of container-like molecules into chemically useful structures is an attractive goal, and their utilization as catalytic reaction chambers can parallel the enzyme function. The rate for a bimolecular Diels–Alder reaction, for example, was reported to be significantly accelerated in the presence of a supramolecular host, owing to the increase of effective concentrations of the two substrates when bound within the same capsule.[7,8] Major challenges are a) to develop supramolecular systems capable of catalyzing unimolecular reactions, and b) to circumvent catalyst inhibition, a problem that frequently occurs when the cavity binds the reaction product more strongly than the substrate.[7,9] We report herein the utilization of a supramolecular metal–ligand assembly that is capable of catalyzing a unimolecular rearrangement. Simply by inclusion into a size- and shape-constrained reaction space these rearrangements are accelerated by up to three orders of magnitude compared to their background rates. Furthermore, the chemical properties of the reacting system provide an effective means of preventing product inhibition, which facilitates catalyst turnover.

Raymond and co-workers have composed supramolecular tetrahedral structures of M_4L_6 stoichiometry through self-assembly of simple metal and ligand components.[10,11] In these assemblies the metal atoms are located at the vertices of the tetrahedron and six bis-bidentate catechol amide ligands span the edges (Figure 1). The tris-bidentate chelation of the metal centers renders them chiral (Δ or Λ), and the
Figure 1. Left: A schematic view of the [G⊂M_4L_6] (G = guest) supramolecular tetrahedral assembly, looking down the C_3-axis. For clarity only one ligand is drawn, the other ligands are represented as sticks. Middle: CAChe model of [NPr$_4$⊂Fe$_4$L$_6$]$^{11-}$, the guest molecule is shown in a space-filling view, the hydrogen atoms are omitted for clarity. Right: The same CAChe model as in the middle, now with host and guest in space filling view. This representation shows that the guest molecule is not exposed to the assembly exterior, but rather is tightly surrounded by the host.

mechanical coupling through the rigid ligands results in the formation of exclusively homochiral assemblies (i.e. $\Delta,\Delta,\Delta,\Delta$ or $\Lambda,\Lambda,\Lambda,\Lambda$). By virtue of the 12^- overall charge, the assemblies are water soluble, yet they contain a flexible hydrophobic cavity of 350–500 Å^3 into which they can bind a broad range of monocationic guest molecules, from alkyl ammonium cations to half-sandwich complexes.[12,13]

In pursuing supramolecular catalysis, a chemical transformation of a cationic substrate, which is compatible with the supramolecular host, needed to be identified. The cationic 3-aza-Cope rearrangement seemed to be the ideal reaction to be carried out in the finite environment of the M_4L_6 assembly. The substrates are ammonium cations (**A**) and should bind to the cavity interior (Figure 2, top). Sigmatropic rearrangement leads to an iminium cation (**B**), which is subsequently hydrolyzed to the corresponding γ,δ-unsaturated aldehyde (**C**).
Figure 2. Top: A general reaction scheme of the 3-aza-Cope rearrangement. Starting from the enammonium cation **A**, [3,3] sigmatropic rearrangement leads to iminium cation **B**, which then hydrolyzes to the aldehyde, **C**. Bottom: ^{1}H NMR spectrum of $[\mathbf{1}{\subset}Ga_4L_6]^{11-}$ (**1**: R^1, R^2, $R^3 =$ H). The observed upfield shift of guest resonance signals illustrates the close contact between host and guest.

Since neutral molecules are only very weakly bound by the supramolecular host, binding of more substrate could occur after the hydrolysis step, enabling catalytic turnover.

We explored a range of enammonium substrates **A**, diverse in size, shape, and substitution pattern (Table 1). All

Table 1: Rate constants for free (k_{free}) and encapsulated (k_{encaps}) rearrangements (measured at 50°C) and their acceleration factors.

Substrate	R^1	R^2	R^3	k_{free} [$\times 10^{-5}$ s^{-1}]	k_{encaps} [$\times 10^{-5}$ s^{-1}]	Acceleration
1	H	H	H	3.49	16.3	5
2	Me	H	H	7.61	198	26
3	H	Et	H	3.17	446	141
4	H	H	Et	1.50	135	90
5	H	*n*Pr	H	4.04	604	150
6	H	H	*n*Pr	1.69	74.2	44
7	H	*i*Pr	H	0.37	316	854

of the substrates were encapsulated by the metal–ligand assembly, which can most easily be monitored by ^{1}H NMR spectroscopy. Shielding by the naphthalene moiety of the ligand scaffold causes an upfield shift of the guest resonances by $\delta = 2$–3 ppm. Enammonium cation **1** (R^1, R^2, $R^3 =$ H), for example, quantitatively yielded the host–guest complex $[\mathbf{1}{\subset}Ga_4L_6]^{11-}$ as confirmed by NMR spectroscopy (Figure 2, bottom) and ES-mass spectrometry. To investigate whether the substrate's reactivity has been altered by encapsulation,

the rates of rearrangement were measured for the free and encapsulated enammonium cations. All rearrangements displayed clean first-order kinetics in buffered solution at 50°C. Remarkably, the encapsulated substrates rearranged faster in all cases (Table 1). Substrate **3**, for instance, experienced 141-fold rate acceleration, once encapsulated by the supramolecular assembly. Even more dramatic is the effect on the isopropyl substituted enammonium cation **7**; binding into the host cavity resulted in a rate increase by a factor of 854. Control experiments with the free rearrangement showed no significant solvent dependence, excluding the possibility that the observed rate enhancement is simply due to the cavity's more hydrophobic environment. The prospect that the host-assembly's negative charge causes the rate acceleration was ruled out by adding salt (2M KCl) in the absence of the assembly, which did not result in a significant change in rate for the free rearrangement.

To elucidate the origin of the observed rate accelerations, the activation parameters were measured. The obtained parameters for the free rearrangement of substrate **3**, for example, are $\Delta H^{\pm} = 23.1(\pm0.8)$ kcal mol^{-1} and $\Delta S^{\pm} = -8$ (±2) e.u. (1 e.u. $= 4.184$ J K^{-1} mol^{-1}). These values compare well with those reported for similar systems,[14] and the negative entropy of activation reflects the highly organized, chairlike transition state required for the rearrangement reaction. The reaction of the encapsulated substrate $[\mathbf{3}{\subset}Ga_4L_6]^{11-}$ gave a very similar value for the enthalpy of activation, $\Delta H^{\pm} = 23.0(\pm0.9)$ kcal mol^{-1}. The entropy of activation, however, differs remarkably by almost 10 e.u., with $\Delta S^{\pm} = +2(\pm3)$ e.u. (see Supporting Information). Comparable effects are observed for the other substrates.[15]

These results imply that the host-assembly selectively binds a reactive conformation of the substrate. The space-restrictive host cavity only allows encapsulation of a tightly packed conformation, closely resembling the conformation of the chairlike transition state. The predisposed conformers, which have already lost several rotational degrees of freedom, are selected from an equilibrium mixture of all possible conformers. Thus the entropic barrier for rearrangement decreases. This effect of preorganization becomes more significant for the larger substrates, which fit more tightly in the host cavity. For example, while an isopropyl substituent at R^2 slows down the rate of the free reaction relative to that of the other substrates, the bulkier R^2 group effects the largest observed acceleration of the encapsulated reaction. Presumably in free substrate **7** the additional steric repulsion between the ends of the alkyl chains reduces the percentage of reactive conformations in free solution even further, therefore decreasing the rate of rearrangement. The encapsulated **7**, however, does not display a similar effect; once squeezed into the cavity, the two pendant alkyl chains are forced to be in close proximity,

and the reaction proceeds at a rate comparable to those of the other encapsulated substrates.

The effect of preorganization into a reactive conformation in the host–guest system is supported by the 2D NOESY spectrum of $[3 \subset Ga_4L_6]^{11-}$ (Figure 3). While the unbound substrate shows no NOEs between the pendant alkyl chains, the encapsulated enammonium cation displays strong dipolar couplings between protons at the two distal ends of the molecule. Assuming a tight, chairlike conformation of the bound substrate, these correlations would be expected.[16]

It is of interest to compare our results with the observations on the enzyme chorismate mutase, which catalyzes the unimolecular Claisen rearrangement from chorismate to prephenate, achieving rate acceleration of a factor of 10^6 relative to the uncatalyzed reaction. Even though this highly complex process is not fully understood, the factors responsible for the enzyme's catalytic efficiency include reduction of both the enthalpic and entropic barrier for rearrangement.[17] It is proposed that a series of functional groups located at the active site stabilize the charge build-up in the transition state, which causes a decrease in enthalpy of activation.[18] In addition, the enzyme binds the substrate in a diaxial, reactive conformation, which lowers the entropy of activation by 11–13 e.u.[19–21] Theoretical studies by Bruice and co-workers on the chorismate rearrangement imply that the efficiency of forming near attack conformers (NACs) in the ground state can be a very important kinetic contribution.[22,23]

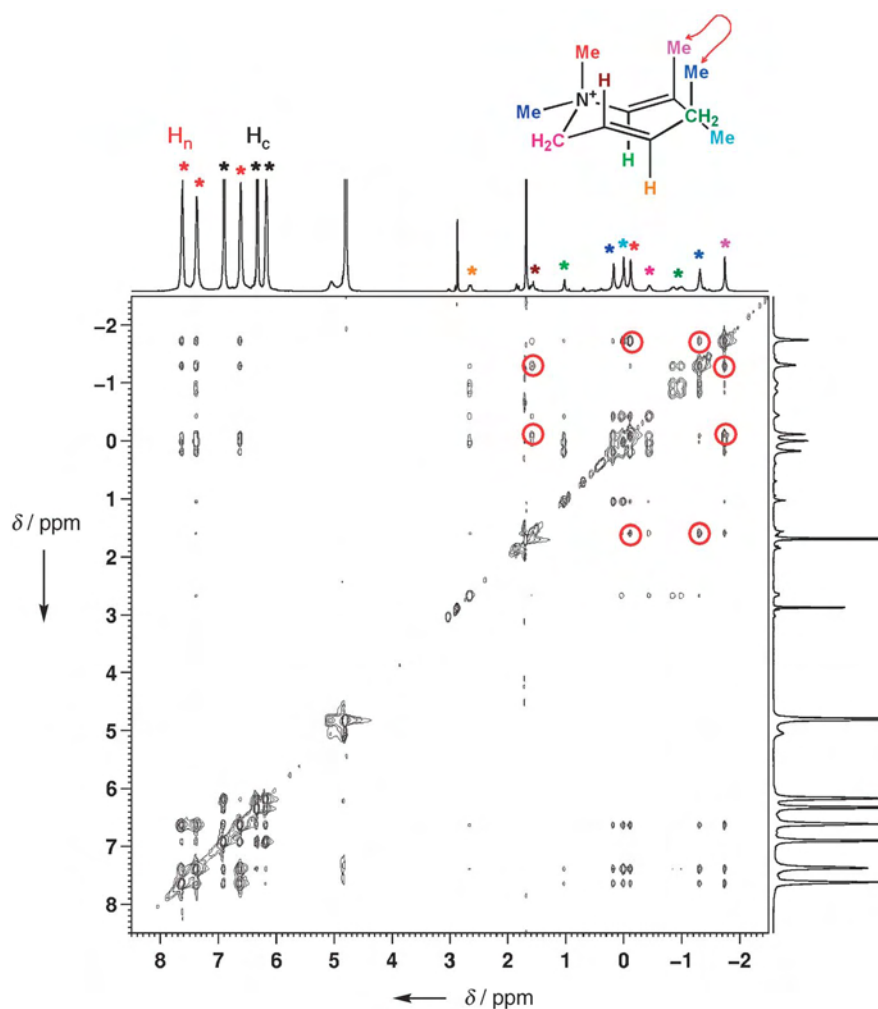
Since the enzyme shows such remarkable catalytic properties, the question arose as to whether the M_4L_6 supramolecular assembly would also be able to mediate the aza-Cope rearrangement catalytically. The stoichiometric experiments had shown that in all cases of the host-mediated 3-aza-Cope rearrangement, the iminium cations **B** hydrolyzed rapidly to the corresponding aldehydes **C**, leaving behind an empty cavity.[24] This property should enable the reaction to be carried out under catalytic conditions. Indeed, carrying out the reaction in the presence of 13 mol% catalyst relative to enammonium substrate revealed truly catalytic behavior of the supramolecular host. Raising the catalyst loading from 13 mol% to 27 mol% to 40 mol% resulted in the expected increases in rate; the observed initial rate constants at 25°C are $k_{13\,mol\%} = 0.64 \times 10^{-4}\,s^{-1}$, $k_{27\,mol\%} = 1.17 \times 10^{-4}\,s^{-1}$, and $k_{40\,mol\%} = 1.80 \times 10^{-4}\,s^{-1}$ (see Supporting Information). The


Figure 3. The 2D NOESY spectrum of $[3 \subset Ga_4L_6]^{11-}$ in a D_2O/MeOD mixture (70:30) recorded at −10°C, mixing time 100 ms. Indicated in red are selected NOEs. The correlation between Me and Me at the two distal ends of the molecule demonstrates the cavity's enforcement of a compressed and folded guest conformation. H_n = naphthyl protons, H_c = catechol protons.

idea of the supramolecular assembly providing a catalytic cavity for rearrangement is further supported by an inhibition experiment with the very strongly binding guest molecule $[NEt_4]^+$. When eight equivalents of $[NEt_4]^+$ were added to the reaction mixtures to block the host cavity, the catalytic activity of the supramolecular host was inhibited. Based on these results, we propose the catalytic mechanism illustrated in Figure 4: 1) A reactive conformation of the enammonium cation binds into the restricted space of the host assembly. 2) The rearrangement proceeds with significant acceleration within the boundaries of the metal–ligand assembly. 3) The rearranged product equilibrates with the bulk solution, and hydrolysis to the corresponding aldehyde enables catalytic turnover by regeneration of the empty assembly that can bind additional substrate.

These findings highlight the ability of container-like molecules to provide size- and shape-defined nanospaces, highly capable of catalysis of unimolecular organic reactions. By binding the substrates in a reactive conformation, the host assembly accelerates the rates of rearrangement by up to
Figure 4. Proposed catalytic cycle for the cationic 3-aza-Cope rearrangement, see text for details.

three orders of magnitude. Release and hydrolysis of the rearranged product generate catalytic turnover. With this, the large potential of supramolecular assemblies as synthetically useful tools in organic chemistry becomes apparent.

– Enantiodivergence in the Reactions of a Highly Enantiomerically Enriched Silyllithium Compound with Benzyl Halides: Control of Inversion and Retention by Selection of Halide
  (C) 1011–1014 [1029–1032]
  DOI: 10.1002/anie.200352700

Strohmeier, G. A. (C) 621–624 [631–634]

Strømgaard, K.
– Chemistry and Biology of Terpene Trilactones from *Ginkgo Biloba*
  (R) 1640–1658 [1670–1689]
  DOI: 10.1002/anie.200300601

Strukul, G.
– Microencapsulated Chloroperoxidase as a Recyclable Catalyst for the Enantioselective Oxidation of Sulfides with Hydrogen Peroxide
  (C) 4097–4099 [4189–4191]
  DOI: 10.1002/anie.200460365

Stucky, G. D.
– Cubic Mesoporous Frameworks with a Mixed Semiconductor Nanocrystalline Wall Structure and Enhanced Sensitivity to Visible Light
  (C) 3037–3040 [3099–3102]
  DOI: 10.1002/anie.200453840
– Micrometer-Sized Spherical Assemblies of Polypeptides and Small Molecules by Acid–Base Chemistry
  (C) 5652–5655 [5770–5773]
  DOI: 10.1002/anie.200460510

Stucky, G. D. (C) 700–704 [718–722]

Studer, A.
– Desymmetrization of Metalated Cyclohexadienes and Application to the Synthesis of Nephrosteranic Acid
  (C) 313–315 [317–319]
  DOI: 10.1002/anie.200352254

Studte, C. (C) 3786–3789 [3874–3877]

Stumpf, H. O.
– A Cu^II Co^II Metallacyclophane-Based Metamagnet with a Corrugated Brick-Wall Sheet Architecture
  (C) 956–958 [974–976]
  DOI: 10.1002/anie.200352604

Stürmer, R. (R) 788–824 [806–843]

Su, J. (C) 5973–5977 [6099–6103]

Su, Z.-M.
– Interlocked and Interdigitated Architectures from Self-Assembly of Long Flexible Ligands and Cadmium Salts
  (C) 5036–5040 [5146–5150]
  DOI: 10.1002/anie.200460758

Su, Z.-M. (C) 2409–2411 [2463–2465]

Suárez, A. (C) 3580–3582 [3664–3666]

Suárez, J. R. (C) 4333–4336 [4433–4436]

Subissati, D. (C) 4767–4770 [4871–4874]

Subramanian, L. R.
– A Versatile Direct Approach to *ortho*-Substituted Azobenzenes from Benzotriazoles
  (C) 1400–1403 [1424–1427]
  DOI: 10.1002/anie.200352782

Sucheck, S. J.
– Dimeric Aminoglycosides as Antibiotics
  (C) 1562–1566 [1588–1592]
  DOI: 10.1002/anie.200353225

Sudhölter, E. J. R. (C) 1352–1355 [1376–1379]

Suematsu, H. (C) 3670–3673 [3756–3759]

Suemune, H.
– Chiral Centers in the Side Chains of α-Amino Acids Control the Helical Screw Sense of Peptides
  (C) 5360–5363 [5474–5477]
  DOI: 10.1002/anie.200460420

Suffert, J.
– A 4-*exo*-dig Cyclocarbopalladation/8π Electrocyclization Cascade: Expeditious Access to the Tricyclic Core Structures of the Ophiobolins and Aleurodiscal
  (C) 2826–2830 [2886–2890]
  DOI: 10.1002/anie.200453773

Sugie, R. (C) 4490–4492 [4590–4592]

Sugimoto, A. (C) 2406–2409 [2460–2463]

Sugisaki, C. (C) 6174–6177 [6300–6303]

Sugiura, K.-i. (C) 707–711 [725–729], 2801–2805 [2861–2865], 3171–3175 [3233–3237], 4763–4767 [4867–4871]

Sugiura, M. (C) 6491–6493 [6653–6655]

Sugiyasu, K. (C) 1229–1233 [1249–1253], 3279–3283 [3341–3345]

Suh, M. P.
– A Robust Porous Material Constructed of Linear Coordination Polymer Chains: Reversible Single-Crystal to Single-Crystal Transformations upon Dehydration and Rehydration
  (C) 2798–2801 [2858–2861]
  DOI: 10.1002/anie.200353494

Sulikowski, G. A.
– Total Synthesis of Apoptolidinone
  (C) 6673–6675 [6841–6843]
  DOI: 10.1002/anie.200461469

Sullivan, T. P. (C) 4190–4193 [4286–4289]

Sultana, A. (C) 3722–3724 [3808–3810]

Sumiya, T. (C) 1112–1115 [1132–1135]

Summerer, D. (H) 1625–1626 [1653–1654]

Sumper, M.
– Biomimetic Patterning of Silica by Long-Chain Polyamines
  (C) 2251–2254 [2301–2304]
  DOI: 10.1002/anie.200453804
– Quaternary Ammonium Groups in Silica-Associated Proteins
  (C) 5933–5936 [6059–6062]
  DOI: 10.1002/anie.200461236

Sun, C. (C) 2106–2108 [2158–2160]

Sun, H.-L. (C) 1374–1376 [1398–1400]

Sun, L.
– An Unusual Cyclization in a Bis(cysteinyl-*S*) Diiron Complex Related to the Active Site of Fe-Only Hydrogenases
  (C) 3571–3574 [3655–3658]
  DOI: 10.1002/anie.200453961

Sun, L. (C) 1006–1009 [1024–1027]

Sun, Q.-Y. (C) 1352–1355 [1376–1379]

Book and Website Reviews

For book reviews authors/editors, book titles, and reviewers are given, for website reviews
subjects and reviewers.

Books

Biography

Enz, C. P.	No Time to be Brief	Kutzelnigg, W.	1457

Encyclopedia/Handbook/Reference Book

Wong, C.-H.	Carbohydrate-Based Drug Discovery	Plettenburg, O., Stilz, U.	3995
Cornils, B., A.Herrmann, W., Schlögl, R., Wong, C.-H.	Catalysis from A to Z	Stürmer, R.	1324
Hessel, V., Hardt, S., Löwe, H.	Chemical Micro-Process Engineering	de Bellefon, C.	6583
Paquette, L. A.	Chiral Reagents for Asymmetric Synthesis	Glorius, F.	1619
McCleverty, J. A., Meyer, T. J.	Comprehensive Coordination Chemistry II	Heinze, K.	3875
Meyers, R. A.	Encyclopedia of Molecular Cell Biology and Molecular Medicine	Kubinyi, H.	4689
Gasteiger, J.	Handbook of Chemoinformatics	Schneider, G.	1761
Rase, H. F.	Handbook of Commercial Catalysts	Cornils, B.	2324
Cornelis, R., Caruso, J., Crews, H., Heumann, K.	Handbook of Elemental Speciation	Karst, U.	5569
Denisov, E. T., Denisova, T. G., Pokidova, T. S.	Handbook of Free Radical Initiators	Fischer, H.	275
Messerschmidt, A., Bode, W., Cygler, M.	Handbook of Metalloproteins	Tuczek, F.	5290
Grubbs, R. H.	Handbook of Metathesis	Dörwald, F. Z.	395
Conn, P. M.	Handbook of Proteomic Methods	Wang, E. W., Bogyo, M. S.	6235
L'Annunziata, M. F.	Handbook of Radioactivity Analysis	Diehl, J. F.	1619
Gauglitz, G., Vo-Dinh, T.	Handbook of Spectroscopy	Popp, J.	2325
Schmid, R. D.	Pocket Guide to Biotechnology and Genetic Engineering	Bornscheuer, U.	1325
Kadish, K. M., Smith, K. M., Guilard, R.	The Porphyrin Handbook	Montforts, F.-P.	5431

Industrial Chemistry

Adams, D. J., Dyson, P. J., Tavener, S. J.	Chemistry in Alternative Reaction Media	Cornils, B.	2195
Mizrahi, J.	Developing an Industrial Chemical Process	Cornils, B.	3099
Aehle, W.	Enzymes in Industry	Cooper, B.	3629
Rogers, R. D., Seddon, K. R., Volkov, S.	Green Industrial Applications of Ionic Liquids	Cornils, B.	274
Hillisch, A., Hilgenfeld, R.	Modern Methods of Drug Discovery	Heinrich, N.	779
Green, M. M., Wittcoff, H. A.	Organic Chemistry Principles and Industrial Practice	Siegel, J. S.	6407

Monograph/Research Report in Analytical Chemistry

Yan, B.	Analysis and Purification Methods in Combinatorial Chemistry	Jung, G.	4552
Gübitz, G., Schmid, M. G.	Chiral Separations—Methods and Protocols	Meierhenrich, U. J.	4252
