the protocols, which had successfully been employed for isocyanide cycloadditions across double bonds,[8] proved inefficient in the case of alkynes. Thus, silver(I) acetate, and gold(I) and copper(I) chlorides gave the isocyanide dimer **10** as the sole product in $>80\%$ yield,[9] whereas no reaction was observed in the presence of zinc halides and scandium(III) triflate. On the other hand, the desired pyrrole **9a**-Me was obtained with an equimolar amount of 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) present, albeit in a poor yield of 17%. Finally, added copper powder (10 mol%) in DMF at 70°C led to the desired product **9a**-Me in 51% yield. These promising results were used as starting points for further optimization.

Under the assumption that the low yield of pyrrole **9a**-Me could be due to the insufficient basicity of DBU, potassium *tert*-butoxide was employed. Indeed, the reaction proceeded cleanly and was complete within 2 h at ambient temperature to give **9a**-Me in 96% yield (Table 1, entry 3). With *p*-toluenesulfonylmethyl isocyanide (TOSMIC, **7b**) under these conditions, the reaction was also efficient and gave the 2-tosylpyrrole **9b**-Me in a 93% yield.

Benzyl isocyanide (**7c**), however, only produced a trace of the 2-phenylpyrrole **9c**-Me along with the unexpected isocyanobenzyl ketone **11** as the major product, which apparently arose by addition of the isocyanobenzyl anion to the carbonyl group of the propiolate **8**-Me and subsequent elimination of methoxide. This type of reaction was not observed with the carbanions derived from methyl isocyanoacetate (**7a**) and TOSMIC (**7b**), and this must have to do with their being softer nucleophiles. This undesired reaction mode could not be completely suppressed by switching to the more sterically encumbered *tert*-butyl ester **8**-*t*Bu. At best, **8**-*t*Bu in the presence of potassium hexamethyldisilazide (KHMDS) at −78°C gave a mixture of **9c**-*t*Bu and **11** in a ratio of 56:44 (Table 1). Switching from potassium to sodium and lithium hexamethyldisilazide led to vastly predominant formation of the formal substitution product **11** again (92 and 96%, respectively), even from the *tert*-butyl ester **8**-*t*Bu and at −78°C. This dependence of the **9c**-*t*Bu/**11** ratio on the nature of the alkali-metal ion is in line with the hard and soft acids and bases (HSAB) principle.[12] As a consequence, cesium *tert*-butoxide was employed, and indeed the ratio **9c**-*t*Bu/**11** increased to 96:4, so that the 2-phenylpyrrole **9c**-*t*Bu could be isolated in 91% yield (Table 1, entry 11).

With this base-mediated cycloaddition of acceptor-substituted methyl isocyanides to acetylenes in hand, our attention was turned to the copper-catalyzed variant (Table 1, entry 2), because it might bring along certain advantages in cost efficiency and compatibility with base-sensitive substrates. In a screening of various copper catalysts,

[a] Reactions were performed on a 0.5 mmol scale. Yields determined by integration of the corresponding peaks in the ^1H NMR spectra with hexamethylbenzene as an internal standard unless stated otherwise. [b] Yield of isolated product. [c] The yield was 91% on a 5 mmol scale. [d] Preactivated nanosize copper powder was used.[11]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

copper(I) benzenethiolate and preactivated nanosize metallic copper powder in dimethylformamide at 85 °C turned out to be equally efficient, providing the pyrrole **9a**-Me in 93 and 92 % yield, respectively (Table 1, entries 12 and 13, respectively). With copper(I) oxide[13] as a catalyst, **9a**-Me was obtained in a slightly lower yield of 78 %, whereas other copper compounds (e.g. copper(I) *n*-hexanethiolate (52 %), benzeneselenide (45 %), and diphenylphosphide (39 %)) gave inferior results. Benzenethiolates of gold(I) and silver(I), as well as copper(I) cyanide and halides gave rise to complex mixtures of products.

The scope and limitations of both the base-mediated and the copper-catalyzed new pyrrole synthesis were tested with a series of different acetylenes and various acceptor-substituted methyl isocyanides (Table 2, Scheme 3). Apparently, quite a number of differently 2,3,4-trisubstituted pyrroles, bearing sulfonyl, dialkoxyphosphoryl, trifluoromethyl, cyano, and secondary amino groups are easily accessible in one step from readily available acetylenes and commercial acceptor-substituted methyl isocyanides. Some of the prepared pyrroles are intermediates in the synthesis of biologically active compounds. Several can also easily be transformed into pyrroles of higher or lower order of substitution according to established protocols.[14,15]

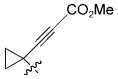
Scheme 3. Preparation of 2,3,4-trisubstituted pyrroles **13** by formal cycloaddition of acceptor-substituted methyl isocyanides to acetylenes. For details see Table 2.

Experimental Section

Synthesis of **9a**-Me under base mediation (method A): To a solution of **8**-Me (620 mg, 5.0 mmol) and **7a** (545 mg, 5.5 mmol) in THF (60 mL) was added dropwise at 20 °C within 1 h a solution of KO*t*Bu (616 mg, 5.5 mmol) in THF (35 mL). The mixture was stirred at 20 °C for 1 h, the reaction was then quenched with AcOH (1 mL), and the mixture concentrated under reduced pressure. The residue was triturated with CH_2Cl_2 (3 × 30 mL) at 20 °C to extract the crude product, which was purified by column chromatography (cyclohexane/ethyl acetate (4:1)) to give **9a**-Me (1.01 g; 91 %) as a colorless solid, m.p. 123 °C. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.83$–0.96 (m, 4H), 2.17–2.27 (m, 1H), 3.76 (s, 3H), 3.82 (s, 3H), 7.43 (d, $J = 3.6$ Hz, 1H), 9.78 ppm (br s, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta = 7.3$ (CH), 8.2 (CH_2), 51.0 (CH_3), 51.45 (CH_3), 116.9 (C), 121.3 (C), 127.5 (CH), 135.4 (C), 161.4 (C), 164.5 ppm (C); IR (KBr): $\tilde{\nu} = 3325$, 3146, 3010, 2951, 1719, 1696, 1541, 1437, 1276, 1199, 1059, 785 cm^{-1}; LRMS (EI): *m*/*z*: 223.1 [M^+]; HRMS (ESI): calcd for $C_{11}H_{14}NO_4$ [M+H$^+$] 224.0923, found 224.0917.



The formal cycloaddition of benzyl isocyanide (**7c**) to *tert*-butyl cyclopropylpropiolate (**8**-*t*Bu) to give **9c**-*t*Bu can be performed by the same protocol except that potassium *tert*-butoxide has to be replaced with cesium *tert*-butoxide.

Synthesis of **13g** by copper-catalyzed formal cycloaddition (method B; Table 2, entry 9): The copper catalyst (preferably preactivated nanosize copper powder (3 mg, 0.05 mmol, 5 mol %), or copper(I) benzenethiolate (9 mg, 0.05 mmol, 5 mol %)) was added to a solution of **7a** (109 mg, 1.1 mmol) and **12f** in DMF (2 mL), and the mixture was vigorously stirred at 70 °C (with preactivated nanosize copper powder) or 85 °C (with CuSPh) for 16 h. The solvent was removed in vacuo (0.05 mbar), and the residue was purified by column chromatography (cyclohexane/ethyl acetate (4:1)) to give pyrrole **13g** (277 mg; 91 %) as a pale yellow solid, m.p. 141 °C. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.22$ (dd, $J = 4.8$, 7.6 Hz, 2H), 1.64 (dd, $J = 5.1$, 7.9 Hz, 2H), 3.67 (s, 3H), 3.81 (s, 3H), 3.87 (s, 3H), 7.40 (d, $J = 3.5$ Hz, 1H), 9.73 ppm (br s, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta = 7.6$ (C), 21.2 (CH_2), 51.2 (CH_3), 51.8 (CH_3), 52,3 (CH_3), 67.2 (C), 94.9 (C), 117.2 (C), 122.5 (C), 127.0 (CH), 129.4 (C), 154.6 (C), 160.4 (C), 163.6 ppm (C); IR (KBr): $\tilde{\nu} = 3298$, 3014, 2954, 2229, 1707, 1559, 1437, 1271, 1196, 1023, 749 cm^{-1}; LRMS (EI): *m*/*z*: 305.1 [M^+]; HRMS (ESI): calcd for $C_{15}H_{16}NO_6$ [M+H$^+$] 306.0978, found 306.0981.

[9] The isocyanide dimer **11** was reported to be formed in the presence of an equimolar amount of AgOAc (see ref. [8c]). The rapid dimerization observed here may be due to the strong influence of the acetylene component on the catalytic activity of Ag^{I}.

[10] Further metal compounds were tested but proved inefficient: CuOTf, $Cu(OTf)_2$, AgOTf, $Yb(OTf)_3$, PdO, Ag_2O, $GaCl_3$, $BF_3{\cdot}OEt_2$, $MgBr_2$, $CoCl_2$.

[11] Commercial nanosize copper powder (Aldrich) was preactivated by heating in vacuo (0.05 mbar) at 150 °C overnight, and was stored under argon. The activity of thus prepared catalyst does not deteriorate within at least two weeks.

Synthesis of Thermolabile Zinc–Pentel Compounds under Kinetically Controlled Reaction Conditions**

Florian Thomas, Stephan Schulz, and Martin Nieger*

Dedicated to Professor Herbert W. Roesky on the occasion of his 70th birthday

Several general reaction pathways have been established for the synthesis of transition metal/Group 15 and main-group metal/Group 15 compounds with the metathesis reaction showing the most potential. Amide, phosphide, and arsenide groups ER_2 (E = N, P, As) can be introduced readily to main-group and transition-metal centers by reaction of metal halides MX_n and the corresponding organolithium compound $LiER_2$. In sharp contrast, the synthesis of metal–antimony and metal–bismuth compounds is rather problematic because of the tendency of lithium stibides and bismuthides $LiER_2$ (E = Sb, Bi) to undergo redox reactions with formation of elemental Sb and Bi. Comparable trends have been observed for dehalosilylation reactions between $E(SiMe_3)_3$ (E = Sb, Bi) and transition-metal halides, which typically yield low-valent compounds such as distibanes and dibismuthanes.[1] Only recently, we reported on reactions of $[\{Me_2AlE(SiMe_3)_2\}_x]$ (E = P, As, Sb, Bi)[2] and Me_3M-dmap (dmap = 4-dimethylaminopyridine; M = Ga, In, Tl), which proceed with Al/M exchange and subsequent formation of the corresponding Group 13/15 heterocycles $[\{Me_2ME(SiMe_3)_2\}_x]$.[3] This novel reaction type generally allows the synthesis of Group 13/15 compounds under kinetic control, as is typical for salt-elimination reactions using organolithium compounds, but does not require redox-sensitive reagents. Consequently, extremely thermolabile compounds such as $[\{Me_2InBi(SiMe_3)_2\}_3]$ and $[\{Me_2TlE(SiMe_3)_2\}_2]$ (E = P, As) could be synthesized and structurally characterized for the first time.[4]

[**] S. Schulz gratefully acknowledges generous financial support from the Deutsche Forschungsgemeinschaft (DFG), the Fonds der Chemischen Industrie (FCI), the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie (BMBF), and Prof. E. Niecke, Universität Bonn. F. Thomas is grateful to the Fonds der Chemischen Industrie for a fellowship award.

To investigate whether this specific transmetalation reaction is applicable only for the synthesis of Group 13/15 heterocycles or if it can be used generally for the synthesis of metal–pentel compounds, we became interested in reactions with organozinc compounds. Consequently, we investigated the reaction of $[\{Me_2AlE(SiMe_3)_2\}_x]$ (E = P, As, Sb) with $[(dmap)_2ZnMe_2]$ (**1**, Figure 1), which was obtained from the reaction of Me_2Zn and two equivalents of dmap in hexane.[5]

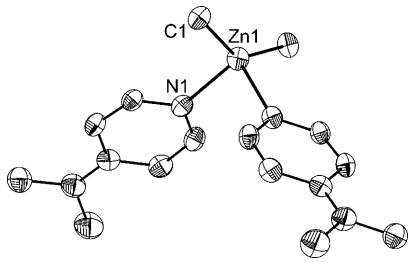

Figure 1. Solid-state structure of **1** (one of two independent molecules, data for the second molecule in square brackets); H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Zn1–C1 2.022(2) [2.023(2)], Zn1–N1 2.177(2) [2.169(2)]; C1-Zn1-C1A 137.2(1) [137.7(1)], C1-Zn1-N1 105.6(1) [104.4(1)], C1-Zn1-N1A 102.3(1) [105.0(1)], N1-Zn1-N1A 97.4(1) [90.9(1)].

The central Zn atom in **1** (crystallographic C_2 symmetry, two independent half molecules in the elemental cell, space group *Pccn*) shows a distorted tetrahedral environment. The Zn–N bond lengths (2.177(2) [2.169(2)] Å) are in between those observed for Me_2Zn adducts with bidentate N-donor ligands (2.20–2.41 Å;[6] coordination number 4) and $[(thf)_2Li\{(NtBu)_3SMe\}\text{-}ZnMe_2]$ (2.137(2) Å), the only structurally characterized Me_2Zn adduct with a threefold-coordinated Zn center.[7]

The reactions of **1** with $[\{Me_2AlE(SiMe_3)_2\}_x]$ (E = P, As, Sb) [Eq. (1a)] and $[(dmap)Al(Me_2)E(SiMe_3)_2]$ with Me_2Zn [Eq. (1b)] occur with Al/Zn exchange and subsequent formation of the desired heterocycle $[\{MeZnE(SiMe_3)_2\}_x]$ (E = P, As, Sb **2**).

$$3/x\,[\{Me_2AlE(SiMe_3)_2\}_x] + 3\,[(dmap)_2ZnMe_2] \xrightarrow[-3\,[(dmap)AlMe_3],\,-3\,dmap]{} [\{MeZnE(SiMe_3)_2\}_3] \quad (1a)$$

$$3\,[(dmap)Al(Me_2)E(SiMe_3)_2] + 3\,Me_2Zn \xrightarrow[-3\,[(dmap)AlMe_3]]{} [\{MeZnE(SiMe_3)_2\}_3] \quad (1b)$$

$[\{MeZnP(SiMe_3)_2\}_3]$ and $[\{MeZnAs(SiMe_3)_2\}_3]$, which have been synthesized previously,[8] were identified by ^1H, ^{31}P, and ^{13}C NMR spectroscopy. Because of the thermolability of **2**, NMR spectra of the reaction solution were recorded directly at −30 °C.[9] Characteristic resonances of $[(dmap)AlMe_3]$ are observed, which is proof of the transmetalation. In addition, resonances arising from the ZnMe and $SiMe_3$ groups with an intensity ratio of 3:18 (^1H NMR) confirm the formation of **2**. Unfortunately, crystals suitable for a single-crystal X-ray analysis have not been obtained to date. However, we obtained single crystals of a rather unexpected compound **3** (Figures 2 and 3) in very low yield (about 4%)

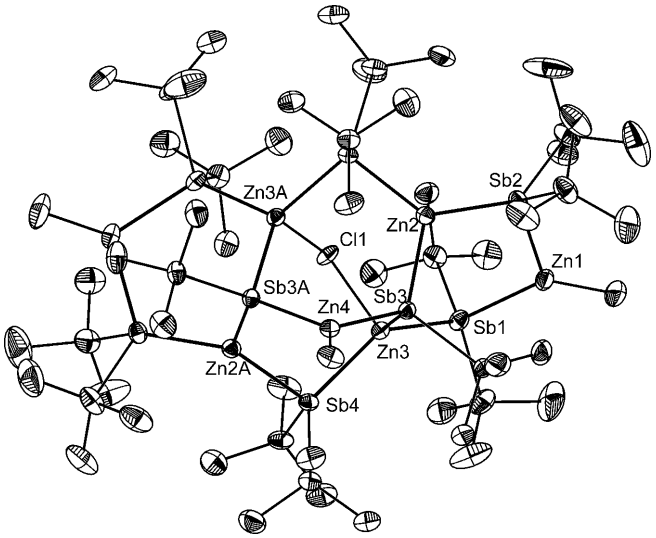

Figure 2. Solid-state structure of **3** (H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Sb1–Zn1 2.644(1), Sb1–Zn3 2.644(1), Sb2–Zn2 2.646(1), Sb2–Zn1 2.656(1), Sb3–Zn2 2.604(1), Sb3–Zn3 2.616(1), Sb3–Zn4 2.629(1), Sb4–Zn3 2.686(1), Sb4–Zn2A 2.604(1), Sb1–Si1 2.542(1), Sb1–Si2 2.553(1), Sb3–Si5 2.544(1), Zn1–C22 1.974(4), Zn4–C23 1.974(5), Zn3–Cl1 2.474(1); Zn1-Sb1-Zn3 118.3(1), Zn1-Sb2-Zn2 110.0(1), Zn2-Sb3-Zn3 90.6(1), Zn2-Sb3-Zn4 117.5(1), Zn3-Sb3-Zn4 109.7(1), Zn2A-Sb4-Zn3 96.8(1), Sb1-Zn1-Sb2 107.2(1), Sb2-Zn2-Sb3 113.6(1), Sb1-Zn3-Sb3 111.0(1), Sb3-Zn3-Sb4 117.9(1), Sb1-Zn3-Sb4 121.5(1), Sb4A-Zn2-Sb2 133.0(1), Sb4A-Zn2-Sb3 113.3(1), Sb3-Zn4-Sb3A 102.5(1), Zn3-Cl1-Zn3A 117.2(1).

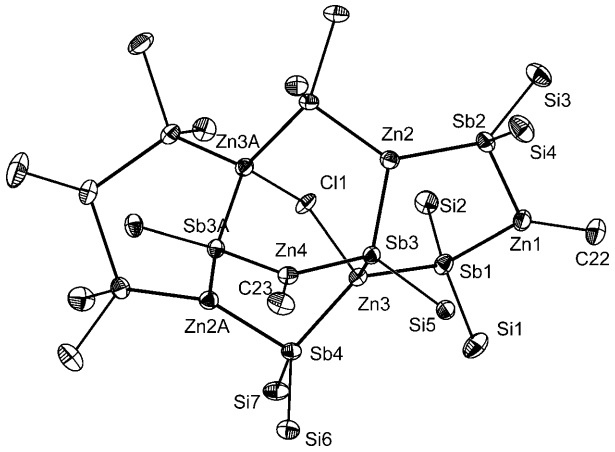

Figure 3. Representation of the central cluster framework of **3**.

from a reaction solution of $[(dmap)Al(Me_2)Sb(SiMe_3)_2]$ and $ZnMe_2$ after storage for six weeks at −30 °C.[5]

The novel cluster **3** contains a central Zn_5Sb_4Cl unit, which is bridged by two additional $ZnSb_2$ moieties. Alternatively, the central framework of **3** can be described as an assembly of three annelated Zn_3Sb_3 rings, in which the outer rings are bridged by a $Sb(SiMe_3)_2$ group (Zn3-Sb4-Zn2A) and a chlorine atom (Zn3-Cl1-Zn3a). Consequently, the central core of **3** is composed completely of six-membered rings. The molecule contains a diadic rotational axis along the atoms Cl1-Zn4-C23. The Sb atoms show distorted tetrahedral coordination spheres, whereas the Zn atoms display different coordination environments. Zn atoms that are bound only to Sb atoms are threefold coordinated, whereas those that are bound to the Cl bridges (Zn3, Zn3A), are fourfold coordinated. The Zn–Sb bond lengths within the heterocyclic Zn_3Sb_3 moieties range from 2.604(1) to 2.656(1) Å. In contrast, the Zn–Sb bond lengths to the bridging $Sb(SiMe_3)_2$ group differ more significantly by about 0.08 Å (Zn2A–Sb4 2.604(1); Zn3–Sb4 2.686(1) Å). These findings as well as the pronounced pyramidalization of Sb4 (sum of bond angles: 312.6° (Zn2A-Sb4-Si6/7 + Si6-Sb4-Si7), 346.6° (Zn3-Sb4-Si6/7 + Si6-Sb4-Si7)) point to rather dative bonding character between Sb4 and Zn3. The endocyclic Zn-Sb-Zn bond angles vary significantly between 90.6(1) and 118.3(1)°, whereas the Sb-Zn-Sb bond angles differ only by 6.4° (107.2(1)–113.6(1)°). The Zn–Cl distance of 2.474(1) Å is rather long, the Zn–C (1.974(5) Å) and Sb–Si bond lengths (2.542(2)–2.577(2) Å) are within typical ranges.

The formation of **3** is attributed to contaminating Cl ions in the Me_2Zn solution used in the reaction with $[(dmap)Al(Me_2)Sb(SiMe_3)_2]$. Apparently these react with $Sb(SiMe_3)_2$ groups in analogy to the reactions of $ZnCl_2$ and ZnI_2 with $E(SiMe_3)_3$ (E = P, As; formation of Me_3SiX, dehalosilylation reaction).[10] Currently, we are investigating the general applicability of this particular reaction type for the synthesis of novel cluster compounds by reaction of defined mixtures of Me_2Zn and $ZnCl_2$ with $[(dmap)Al(Me_2)Sb(SiMe_3)_2]$.[11]

The novel metal-exchange reaction has been extended to the synthesis of Zn–pentel heterocycles. This is a very promising result with respect to the development of a general synthetic pathway for metal–pentel compounds. The reactions can be performed under kinetically controlled reaction conditions at low temperatures. Consequently, previously unknown compounds containing the heaviest Group 15 elements Sb and Bi, as well as novel metal–pentel clusters, might become accessible in the near future.

Experimental Section

1: 4-Dimethylaminopyridine (dmap; 2.44 g, 20 mmol) dissolved in hexane (30 mL) was combined with a 2 M solution of $ZnMe_2$ in toluene (5 mL, 10 mmol) and stirred for 2 h at ambient temperature. The resulting colorless solution was concentrated under vacuum and stored at −30 °C. After 24 h, **1** was obtained as a colorless crystalline solid. Yield: 2.92 g, 8.6 mmol, 86 %. ^{1}H NMR (300 MHz, C_6D_6, 30 °C): $\delta = -0.01$ (s, 6H; $ZnMe_2$), 2.10 (s, 6H; NMe_2), 5.87 (dd, $^3J_{H,H} = 5.3$, $^4J_{H,H} = 1.4$ Hz, 4H; C3-H), 8.21 ppm (dd, $^3J_{H,H} = 5.2$, $^4J_{H,H} = 1.4$ Hz, 4H; C2-H); ^{13}C NMR (75 MHz, 30 °C, C_6D_6): $\delta = -11.9$ ($ZnMe_2$), 36.8 (NMe_2), 105.2 (C3), 147.5 (C2), 153.3 ppm (C4); MS (EI, 15 eV, 100 °C): *m/z* (%): 217 (6) [M^+−dmap], 122 (100) [$dmap^+$], 95 (35) [$ZnMe_2^+$], 80 (56) [$ZnMe^+$].

2: A suspension of $[\{Me_2AlSb(SiMe_3)_2\}_3]$ (0.49 g, 0.5 mmol) in toluene (15 mL) was cooled to −30 °C and then combined with a solution of **1** (0.56 g, 1.5 mmol) in pentane (15 mL). The brownish solution was stirred for 30 min at −10 °C and then stored for 12 h at −30 °C, which resulted in the precipitation of $[(dmap)AlMe_3]$. The solid was removed by decantation, and the remaining solution was concentrated to dryness under vacuum. The resulting waxy solid was dissolved in precooled pentane (10 mL), filtered, and stored for 24 h at −60 °C. Compound **2** was obtained as a colorless, thermolabile, light-sensitive solid. Yield: 0.21 g, 0.21 mmol, 41 %. M.p. 45 °C (decomp). ^{1}H NMR (300 MHz, [D_8]toluene, −30 °C): $\delta = 0.19$ (s, 3H; ZnMe), 0.52 ppm (s, 18H; $SiMe_3$); ^{13}C{^{1}H} NMR (75 MHz,

Models of Putative (AH)G(AH)G Nucleobase Quartets**

Pilar Amo-Ochoa, Pablo J. Sanz Miguel, Patrick Lax, Inés Alonso, Michael Roitzsch, Félix Zamora, and Bernhard Lippert**

The existence of homo(nucleobase) quartets such as those of guanine (G), adenine (A), thymine (T), and uracil (U) in multistranded nucleic acid structures is well-established, and the awareness of the potential relevance of such quartets (also known as tetrads) in biology and medicine is steadily increasing.[1–3] Guanine quartets (G_4) can be formed through the folding of an individual single-stranded oligonucleotide or through the association of either four single-stranded oligo-

nucleotides, two hairpins, or two cyclic oligonucleotides. The exceptional stability of G_4 quartets facilitates the formation of further quartets through stacking. This also applies to mixed nucleobase quartets such as CGCG,[1] TATA,[2a] and even GCAT.[4] Surprisingly, the existence of AGAG quartets is still controversial[5] despite the observation and characterization of four different AG mispair types in nucleic acid structures.[6]

Herein, we report the X-ray crystal structure analyses of two closely related quartets, each with two protonated adenine model nucleobases (9-methyladeninium, 9-MeAH$^+$, "AH") and two 6-oxopurine bases (9-ethylguanine, 9-EtGH, "G" or 9-methylhypoxanthine, 9-MeHxH, "Hx"). Additionally, ab initio calculations for the model quartet consisting of two 9-ethyladeninium and two 9-methylguanine bases are reported which confirm the existence of the quartet observed in the solid-state structure and at the same time, point to the existence of a second variant.

$[\{(9\text{-MeAH})(9\text{-EtGH})\}_2](BF_4)_2$ (**1**) and $[\{(9\text{-MeAH})(9\text{-MeHxH})\}_2](ClO_4)_2$ (**2**) were isolated from an ethanol/water mixture.[7] Figure 1 shows **1** in two perspectives. The

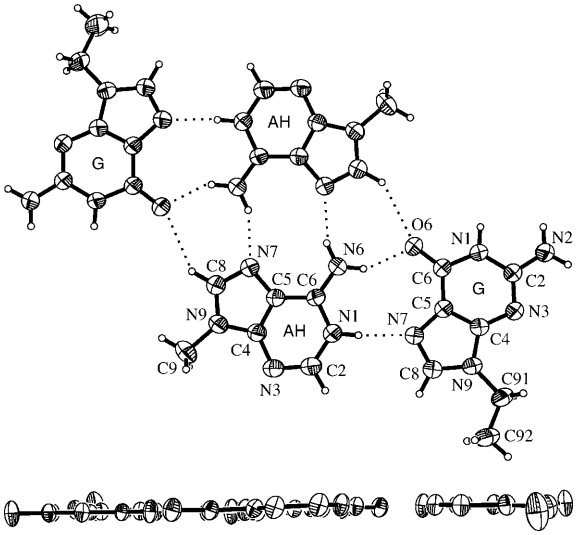

Figure 1. The cationic nucleobase quartet $[\{(9\text{-MeAH})(9\text{-EtGH})\}_2]^{2+}$ (**1**) viewed a) from the top and b) from the side, with atom numbering scheme and eight intramolecular hydrogen bonds between the bases shown. The structure of $[\{(9\text{-MeAH})(9\text{-MeHxH})\}_2]^{2+}$ (**2**) is virtually identical (not shown).

structure of **2** is closely related and is provided in the Supporting Information. Both quartets[8] consist of a central centrosymmetric 9-methyladeninium dimer with hydrogen bonds between the ^{AH}N7 and ^{AH}N6H$_2$ sites. Each of the two 6-oxopurine bases are hydrogen bonded through ^{G}N7 and ^{G}O6 to the ^{AH}N1H and ^{AH}N6H$_2$ sites of adeninium. The distances between the nitrogen and oxygen atoms in the hydrogen bonds NH···N and NH···O of **1** and **2** are listed in Table 1. They are well within the range of distances typically observed in nucleobase pairing motifs, including Watson–Crick base pairs, for example.[9] In **1**, the hydrogen bonds between the G$\cdot$AH$^+$ pairs are shorter than those within the central AH$^+\cdot$AH$^+$ pair. A similar trend is observed in **2**. Moreover, the heteroaromatic ^{AH}CH8 proton of the adeninium ions of

Table 1: Hydrogen-bond lengths [Å] between bases in nucleobase quartets **1** and **2** and in the calculated structure **I**.

Intramolecular hydrogen bonds				
	1	**I**		**2**
^{AH}N7···^{AH}N6	2.860(4)	3.082	^{AH}N7···^{AH}N6	2.842(7)

^{AH}N1···^{G}N7	2.833(4)	2.966	^{AH}N1···^{Hx}N7	2.838(7)
^{AH}C8···^{G}O6	3.350(4)	4.085[a]	^{AH}C8···^{Hx}O6	3.318(8)
Intermolecular hydrogen bonds				
	1			**2**
^{G}N2···^{G}N3	3.008(4)	–	^{Hx}C2···^{Hx}N3	3.284(9)

[a] Average values (max. difference $\pm$0.002 Å).

both **1** and **2** are involved in weak hydrogen bonds to the $^{G/Hx}$O6 atoms of guanine and hypoxanthine, respectively. These contacts, although markedly longer than common NH···N and NH···O hydrogen bonds (Table 1), still clearly qualify for CH···O hydrogen bonds as observed in other nucleobase associations.[10]

Both quartets are almost completely flat; the maximal deviation of individual atoms from the best plane amounts to $\leq$0.03 Å. The base quartets are linked through pairs of hydrogen bonds involving the so-called "sugar edges" of the 6-oxopurines (^{G}N3 and ^{G}N2H$_2$ in **1**, and ^{Hx}N3 and ^{Hx}C2H in **2**) and thus form infinitely long tapes (see Figure 2 and

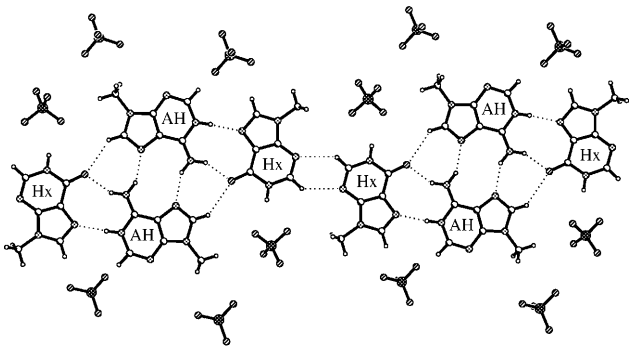

Figure 2. Association pattern of base quartet **2** leading to an infinite tape structure. Structure **1** displays a rather similar arrangement. Perchlorate anions connect adjacent tapes of base quartets.

Supporting Information). The presence of a CH···N contact (in **2**) is noteworthy. Similar hydrogen-bonding patterns and lengths are also realized in Pt^{II} complexes of these nucleobases.[11] Excluding the long hydrogen-bonding contacts between ^{AH}C8H of 9-MeAH$^+$ and ^{G}O6 of the 6-oxopurines in **1** and **2**, the intermolecular separations through ^{AH}N3 and ^{G}N2H$_2$ (**1**), and ^{AH}N3 and ^{Hx}C2H (**2**) are clearly longer than analogous distances observed in other quartet structures, which supports the consideration of **1** and **2** as true base quartets.

The packing of individual tapes in **1** and **2** is different. In both cases the tapes are stacked on top of each other at a distance of $\approx$3.4 Å, to produce stacks. The stacks are slightly inclined (75° in **1**, 77° in **2**) and separated by the tetrahedral counterions (BF_4^- in **1**, ClO_4^- in **2**). Whereas adjacent stacks

are oriented in a parallel fashion in **1**, only every second stack is parallel in **2**. Directly adjacent stacks form angles of 65° with each other in **1** (see Supporting Information). An analysis of the hydrogen-bonding interactions in **2** reveals that with the exception of ^{Hx}C8H, all remaining protons of the two nucleobases not already engaged in hydrogen-bond formation between bases are involved in hydrogen bonds between the quartet and the ClO_4^- anions (the ClO_4^- anions do not display rotational disorder). Specifically, ^{Hx}N1H and ^{Hx}C9CH$_3$ as well as ^{A}C2H and ^{A}C9CH$_3$ of 9-MeAH$^+$ form such contacts, the lengths of which range between ≈3.0–3.4 Å (see Supporting Information).

Formation of the base quartets **1** and **2** can be envisaged as an association of two AH$^+_{anti}$G/Hx$_{syn}$ mispairs[12] (Figure 3). There are two principal arrangements (**I**, **II**) of dimerization, which are interrelated by a simple sliding motion of the two mispairs. In both cases, hydrogen-bonding interactions between donor (Do) and acceptor (A) sites can form, which give rise to favorable secondary electrostatic interactions,[13] even though their distribution is different in the two cases. Arrangement **I** is realized in **1** and **2**. Arrangement **II** combines two of the four possible mispairs between A and G, namely AH$^+_{anti}$G$_{syn}$[12] and A$_{syn}$G$_{anti}$,[14] ignoring the fact that in this second pair, the adenine is likewise protonated. Both mismatches have been shown to be easily accommodated within double-stranded B-form DNA.

By using the Gaussian suite of programs,[15] energy-minimized structures of **I** and **II** (+2 charged each) were calculated and fully optimized (RHF/6-31G* level, see Supporting Information). In all cases, frequency calculations were carried out to confirm that the geometries represented energy minima. Results for **I** and **II** are respectively shown in Figure 4 and Figure 5. Arrangement **I** is slightly less stable than **II** by 23.29 kJ mol^{-1}.[16] Hydrogen-bond lengths in the calculated structure **I** show trends similar to those found in **1** (Table 1), but absolute values are longer in the calculated structure. This applies in particular to the central pair of intermolecular hydrogen bonds between ^{AH}N7 and ^{AH}N6 sites

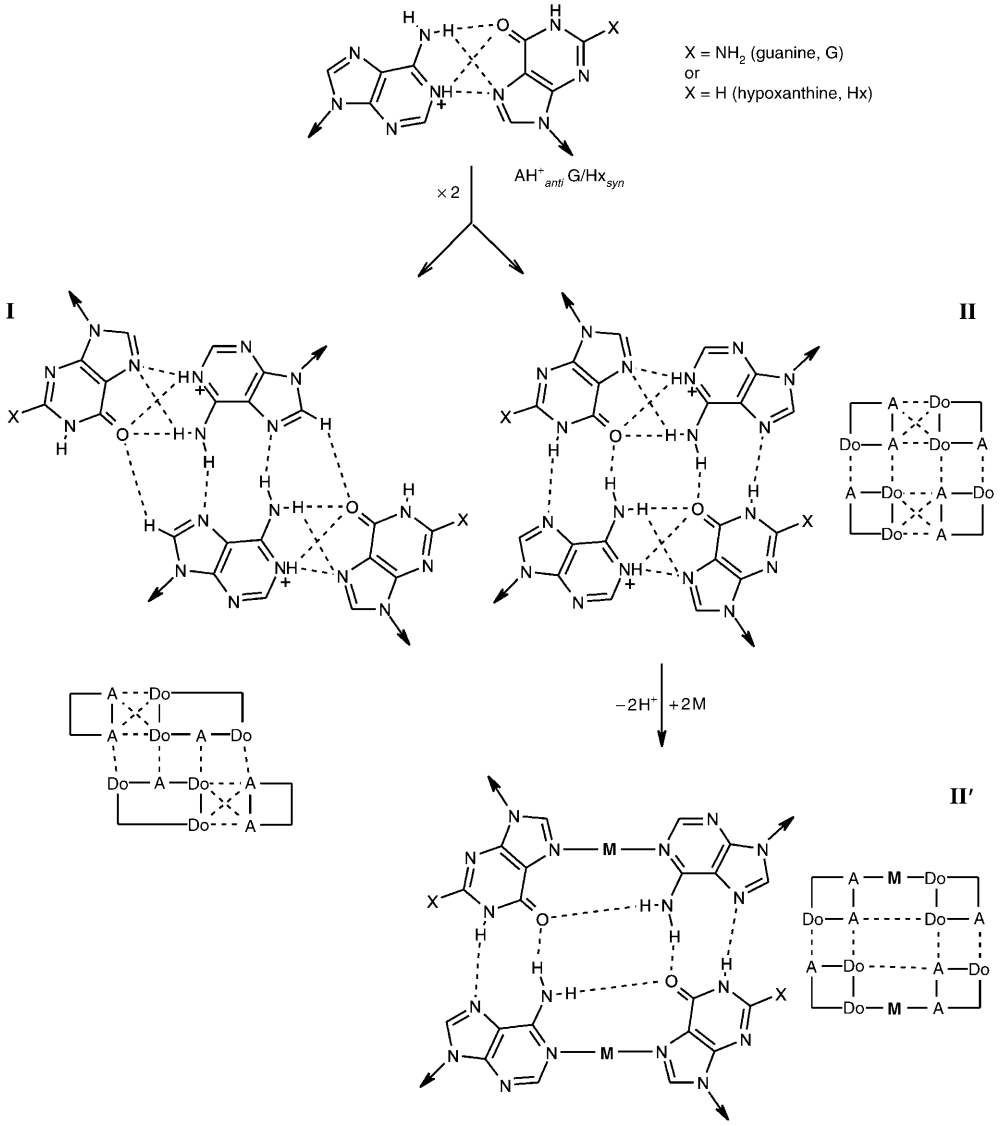

Figure 3. Formal relationship between the AH$^+_{anti}$G/Hx$_{syn}$ mispair (top), base quartets **I** and **II** (middle), and a metal-containing base quartet **II′** (bottom). Favorable secondary electrostatic interactions in hydrogen bonds are indicated by crossed dashed lines.

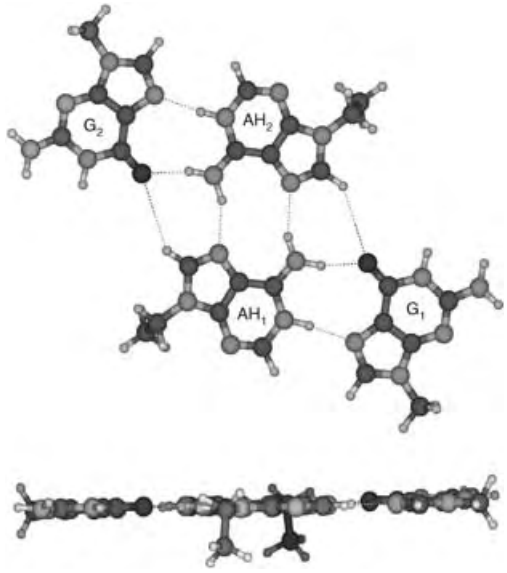

Figure 4. Energy-minimized gas-phase structure (Gaussian) of $[\{(9\text{-EtAH})(9\text{-MeGH})\}_2]^{2+}$ (**I**) with views from top (above) and side (bottom). Calculated hydrogen-bond lengths are listed in Table 1.

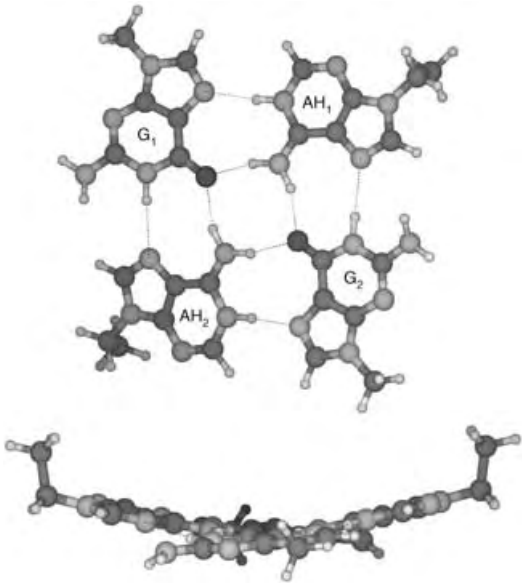

Figure 5. Energy-minimized gas-phase structure (Gaussian) of $[\{(9\text{-EtAH})(9\text{-MeGH})\}_2]^{2+}$ (**II**) with views from top (above) and side (bottom). Calculated hydrogen-bond lengths [Å]: ^{AH_1}N6···^{G_1}O6, 2.877 Å; ^{AH_1}N1···^{G_1}N7, 3.013 Å; ^{AH_1}N6···^{G_2}O6, 2.910 Å; ^{AH_1}N7···^{G_2}N1, 3.212 Å. The other hydrogen bonds are either identical or agree within 0.001 Å. The quartet is slightly saddle shaped, with two guanine bases pointing downward (dihedral angle 12.6°), and the two adeninium ions pointing upward (dihedral angle 20.6°).

of the adeninium bases. In the calculations of **I** and **II**, the combinations of the bases used (9-EtAH$^+$ and 9-MeGH) were applied for a more direct structural comparison with a metal-containing mixed adenine/hypoxanthine quartet which we recently characterized by X-ray crystallography (**II′** in Figure 3).[17] For **II′**, in which the acidic ^{AH}N1 protons of the two adeninium ions are replaced by linear [*trans*-$(NH_3)_2Pt^{II}$] units, the four nucleobases are perfectly planar. The situation in **II′** stands in sharp contrast to the AGAG quartet, which contains neutral bases only. As reported by Gu and Leszczynski[5d] and confirmed by our calculations, the AGAG quartet is V-shaped and far from planar (see Supporting Information). Consequently this quartet has been considered unlikely to play a role in biologically relevant base quartets. Our calculations clearly indicate that protonation of the two adenine bases in AGAG to give (AH)G(AH)G as realized in **II** causes the V-shaped quartet to flatten appreciably (Figure 5). Furthermore, if the four bases in **II** are constrained to coplanarity, the energy penalty is only 4.50 kJ mol^{-1}. This strongly suggests that **II** can be incorporated into a four-stranded structure.

It is less clear how structure **I** fits into a four-stranded DNA. However, the fact that base sextets can be accommodated into a DNA quadruplex[18] implies that a shift from a square **II** to a parallelogram **I** should not present an insurmountable obstacle. Moreover, the central symmetric AH$^+$AH$^+$ pair corresponds to that realized in the double helix of poly(AH$^+$)poly(AH$^+$).[19] Stacking of two of these quartets **I** is feasible, as shown by molecular modeling with HyperChem 6.02 (Figure 6).[20] In this model, the four central adeninium dinucleotides are parallel in alignment and the two layers are rotated by 25°.

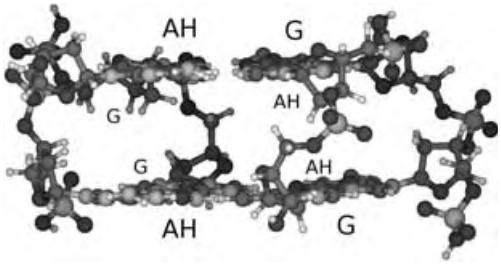

Figure 6. Calculated structure (HyperChem 6.02) of the stacked arrangement of two base quartets (AH)G(AH)G (**I**) joined by phosphodiester bonds between identical bases. Bases closer to viewer are indicated by larger letters.

In conclusion, we have shown that unlike the case for the purine quartet resulting from the dimerization of the neutral $A_{syn}G_{anti}$ pair, the bases that form the purine quartet derived from two $AH^+_{anti}G_{syn}$ pairs are completely (structure **I**) or almost (structure **II**) coplanar. The exocyclic $^{G}N2H_2$ groups are not involved in quartet formation and the hypoxanthine base behaves analogously. How realistic is the protonation of a nucleobase, in this case A, at physiological pH? There is no doubt that protonation equilibria of nucleobases can be significantly disturbed; consequently nucleobase pK_a values can be shifted if favorable hydrogen bonding stabilizes the protonated base.[21] The presence of hemiprotonated cytosine mismatches at physiological pH[1] is yet another example of this principle.

[7] **1** was obtained from a water/ethanol mixture (1:1, 15 mL) solution containing 9-EtGH, 9-MeA (0.21 mmol each) and $Zn(BF_4)_2$ (0.8 mmol) after heating at 80 °C for 24 h, filtration, and keeping the solution for 2 days at 5 °C. Colorless crystals of **1** were obtained in 63 % yield. Elemental analysis for C, H, and N was satisfactory. Colorless crystals of **2** were isolated from a mixture of $HClO_4$ (0.1 mol L^{-1}) in water/ethanol (1:1, 20 mL) containing 9-MeHxH and 9-MeA (0.15 mmol each) after few days at room temperature. The composition of **2** was established by X-ray crystallographic analysis.

[8] Crystal structure data for **1**: $C_{26}H_{34}N_{20}O_2B_2F_8$, $M_r = 832.35$, colorless crystals, triclinic $P\bar{1}$, $a = 8.4649(2)$, $b = 9.1145(2)$, $c = 12.2988(2)$ Å, $\alpha = 95.261(1)$, $\beta = 105.124(1)$, $\gamma = 97.024(1)°$, $V = 901.56(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.161$ Mg m^{-3}, $Cu_{K\alpha}$ radiation, $\lambda = 1.54178$ Å, $\mu = 4.085$ mm^{-1}, $T = 296$ K. 2988 data (2514 unique, $R_{int} = 0.07$, $3.75 < \theta < 70.31°$) were collected on a Bruker SMART 6K CCD area-detector three-circle diffractometer with a Rigaku Rotating Anode by using narrow frames (0.3° in ω) and were corrected empirically (SADABS: G. M Sheldrick, Bruker AXS Inc., Madison, WI, **2000**) for absorption. The raw intensity data frames were integrated with the SAINT program (SAINT + NT Version 6.04, SAX Area Detector Integration Program, Bruker AXS Inc., Madison, WI, **1997–2001**), which also applied corrections for Lorentz and polarization effects. Crystal structure data for **2**: $C_{48}H_{56}N_{36}O_{20}Cl_4$, $M_r = 1595.06$, colorless crystals, monoclinic, space group $P21/c$, $a = 8.804(2)$, $b = 8.193(2)$, $c = 24.008(6)$ Å, $\beta = 102.85(3)°$, $V = 1688.4(6)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.573$ Mg m^{-3}, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $\mu = 0.276$ mm^{-1}, $T = 296$ K. 2946 data (891 unique, $R_{int} = 0.05$, $2.37 < \theta < 26.41°$) were collected on an Enraf-Nonius Kappa CCD diffractometer. Data reduction and cell refinement were carried out by using the programs DENZO and SCALE-PACK (Z. Otwinowski, W. Minor, *Methods Enzymol.* **1997**, *276*, 307). Both structures were solved by standard Patterson methods and refined by full-matrix least-squares methods based on F^2 with the SHELXTL-PLUS (G. M. Sheldrick, Siemens Analytical X-ray Instruments, Inc., Madison, WI, **1990**) and SHELXL (G. M. Sheldrick, SHELXL 97, University of Göttingen, Germany, **1997**) programs. All non-hydrogen atoms in the structures were refined anisotropically. The fluoride ligands in BF_4^- of **1** displayed rotational disorder over five positions. The hydrogen atoms were either included in geometrically calculated positions and refined with isotropic displacement parameters according to the riding model, or found with difference Fourier synthesis, and refined isotropically. CCDC-265600 and CCDC-265403 (**1** and **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Photo-Cross-Coupling Reaction of Electron-Rich Aryl Chlorides and Aryl Esters with Alkynes: A Metal-Free Alkynylation**

Stefano Protti, Maurizio Fagnoni, and Angelo Albini**

Aryl acetylenes are versatile intermediates in organic synthesis in view of the easy derivatization of their triple bonds[1] and find application in molecular electronics.[2] The elective method for the synthesis of these compounds is the Sonogashira reaction, which involves the Pd/Cu-mediated formation of a $C(sp^2)$–C(sp) bond. Despite many efforts to improve this method, the most popular protocol in use today still consists of a mixture of an aryl iodide or bromide, a terminal alkyne, $[PdCl_2(PPh_3)_2]$, an amine, and CuI: the same protocol as introduced many years ago by Sonogashira et al.[3,4]

There has been growing interest into extending the reaction to different aryl precursors; for example, aryl triflates (or nonaflates) were introduced about 20 years ago,[5] and more recently aryl tosylates[6] and aryl boronic acids were also used (in the latter case the presence of air is tolerated).[7] However, the inexpensive aryl chlorides have been employed with success in only a few cases, but necessitated the use of high temperatures.[6,8] The use of a single metal compound is possible, and palladium-free[9] and copper-free[10] protocols have also been investigated for some aryl bromides and iodides. In some cases, copper salts cause an adverse effect on the reaction and do not result in the intended catalysis. Thus, copper can either inhibit the reaction[6] or promote oxidative homocoupling.[11] An effective metal-free reaction is clearly desirable and a step in this direction was recently achieved by using microwave-assisted reactions,[12] although satisfying results have been obtained only in one case, namely the reaction between aryl iodides and phenylacetylenes. The Sonogashira reaction generally involves non-activated terminal alkynes, although tetraalkynyl aluminates[13a] and alkynyl trifluoroborates[13b] make the coupling reaction with aryl halides (or triflates) cleaner. A "sila"-Sonogashira reaction starting from alkynylsilanes has also found limited application.[14]

A radically different approach for the synthesis of aryl acetylenes is presented here, and is based on the use of phenyl cations. In the last few years we have demonstrated that these intermediates (in the triplet state) are obtained smoothly by photolysis of aryl halides substitued with electron-donating groups (for example, chlorophenol[15] or fluoroanilines[16]), aryl sulfonates, and aryl phosphates (for example, methoxyphenyl mesylate or *N*,*N*-dimethylaminophenyl phosphate),[17] and add to alkenes to form an aryl–C bond via a phenonium ion.[15a,18] We surmised that phenyl cations would react with triple bonds to yield β-phenylvinyl cations, or more probably cyclic vinylenebenzenium ions (Scheme 1). The last species have been invoked as intermediates in the thermal solvolysis of styryliodonium tetrafluoroborate[19] and in the photoheterolysis of (*E*)-bromostyrene[20] (Scheme 1).

Scheme 1. Hypothesized photogeneration and reaction of the vinylenebenzenium ion. Ms = methanesulfonyl, Tf = trifluoromethanesulfonyl, EDG = electron-donating group.

The usual literature methods for the generation of vinylenebenzenium ions employ a nucleophilic solvent, usually an alcohol. Under these conditions, addition to form an alkoxystyryl derivative occurred (path a, see Scheme 1 for the case of propyne),[19,21] although proton elimination competed to a variable extent and led either to an aryl alkyne (path b) or an aryl allene (path c). Thus, the choice of the conditions is critical so that the desired elimination occurs to form an aryl alkyne.

In view of the above findings, we studied the photolysis of various precursors of the 4-methoxyphenyl cation, namely, the corresponding chloride (**1a**), mesylate (**1b**), triflate (**1c**), diethylphosphate (**1d**), and fluoride (**1e**; 0.05 M) in the presence of 1-hexyne (**2**, a terminal alkyne), ethynyltrimethylsilane (**3**, a partially silylated alkyne), and trimethylsilylpropyne (**4**, a precursor lacking acetylenic hydrogen atoms; 0.5 M). The results of the irradiation experiments are shown in Table 1.

We were happy to find that cross-coupling with 1-hexyne took place upon irradiation ($\lambda_{exc} = 310$ nm, 36 h) of **1** in 2,2,2-trifluoroethanol (TFE) in the presence of an equimolar amount of base (triethylamine, TEA[22]) to yield 4-(1-hexynyl)anisole (**5**) in more than 60% yield (90% when using

1b[b]		60	75[c]	**7**	75 (14)
1c[b]		60	80[c]	**7**	67
1d		60	80	**7**	50 (10)

[a] Yields of isolated compounds based on consumed aryl halide or ester. The yield of anisole is shown in parentheses, and is not quoted when less than 5%. [b] Reaction sensitized by 0.9 M acetone and buffered by 0.1 M TEA. [c] The consumption of ArX was not increased after prolonged irradiation.

phosphate **1d**). The use of other solvents, such as MeCN or MeCN/H_2O, gave poor yields.

Esters **1b** and **1c** absorbed poorly at 310 nm and underwent a sluggish reaction under these conditions. Acetone (0.9 M) sensitization was adopted and enabled a high conversion to be obtained (>75% in 60 h), provided that the amount of base was doubled (0.1 M). To our knowledge, these are the first examples reported of an alkynylation reaction using an aryl phosphate,[23] a mesylate, or, noteworthy, an aryl fluoride, which is usually an unreactive derivative.

The photoinduced arylation of alkyne **3** by compounds **1** led to the silicon-containing alkyne (*p*-methoxyphenylethynyl)trimethylsilane, **6**).[24] However, arylation of alkyne **4** occurred with elimination of the trimethylsilyl (TMS) group and gave 4-(1-propynyl)anisole (**7**) in a medium to good yield. When this alkyne was used, the aryl derivatives **1** were in part reduced to anisole, except for the case of triflate **1d**.

Aromatic alkynes could not be used conveniently in this procedure because they absorbed a significant fraction of the incident light and underwent photoreactions to give strongly absorbing products. Thus, irradiation of phenylacetylene in TFE led to darkening and clouding of the reaction mixture; under these conditions the consumption of **1a** after 36 h was limited to 37% and the only significant product was anisole (12%).

The generation of phenyl cations from aromatic compounds substituted with other electron-donating groups[25] was then explored by using the readily accessible chlorides **8**–**10** (Table 2). The reaction was successful also in these cases (44–71% yield). However, the use of 4-chlorothioanisole **8** resulted in clouding of the solution during the irradiation, which hindered the complete consumption of the halide and prolonged the required irradiation time. This problem was in part overcome by irradiating at 254 nm. Although 4-chlorophenol gave poor results in the reaction, the *tert*-butyldimethylsilyl-protected derivative **9** gave aryl alkynes in 51–71% yield. The chlorinated benzodioxole **10** reacted in a similar way with 1-hexyne and gave arylated compound **17** in 52% yield after 30 h of irradiation.

Finally, we explored the reaction of **1a** with the propargylic alcohol 2-methyl-3-butyn-2-ol (**18**). In this case, an unexpected route was followed and the *Z*-enone **19** was obtained as the only product (35% yield, Scheme 2).

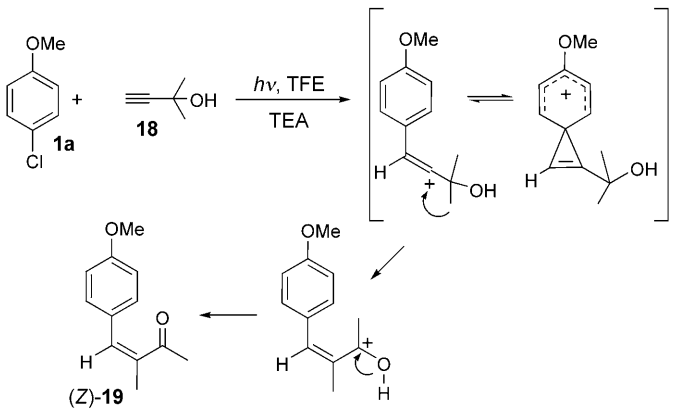

Table 2: Photoinduced synthesis of electron-rich aromatic alkynes.

[a] Yields of isolated compounds based on consumed aryl chloride; the corresponding dehalogenated aromatic compounds (<10%) were identified in the irradiated solutions by GC analysis. [b] Irradiation carried out at 254 nm. Cloudy solutions were obtained after irradiation.

The above results show that aryl alkynes are obtained by reaction of aryl cations with terminal acetylenes or their silylated derivatives. The cations are readily obtained by photolysis of electron-rich aryl esters or aryl halides, with the readily available chlorides being a particularly convenient choice. Furthermore, aromatic compounds bearing an SMe,

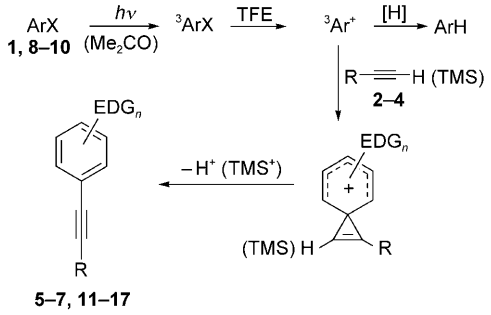

Scheme 2. Addition of the 4-methoxyphenyl cation onto propargylic alcohol **18**.

an *O*-trialkylsilyl (as a protected OH group), or a dioxolanyl group were used for the first time in the generation of aryl cations,[25] thus broadening the scope of the arylation reaction.

Alkynes are known to be less reactive with electrophiles than the corresponding alkenes. However, Mayr et al. reported that 1-hexyne is less reactive by one order of magnitude than 1-hexene in the reaction with $(p\text{-}MeC_6H_4)_2CH^+$ at −70 °C,[26a] but that the difference is reduced at higher temperatures. In some cases the reactivity towards the carbenium ion is similar or even higher than that of alkenes.[26b] In the present case, the reactions involving alkynes **1**–**3** required a longer irradiation time (> 30 h) than alkenes (14 h),[15a] but this can probably be attributed to a stronger filter effect of the product formed (conjugated phenylalkynes versus alkyl benzenes) rather than to a less-efficient reaction. The photolysis requires a polar (preferably a protic) medium for reaction to occur.[27] TFE was found to be the best solvent for the arylation of alkynes, but the same products were formed in lower yields in MeCN, MeOH, MeCN/TFE, and MeCN/H_2O. Among these, MeCN/H_2O (5:1) gave the best results, although reduction of the aryl cations was competitive with the reaction with the alkynes[28] (for example, the reaction between **1a** and **4** gave 34% of **7** and 30% of anisole).

The mechanism of the reaction is outlined in Scheme 3. The vinylenebenzenium ion resulting from the trapping of $^3Ar^+$[29,30] by the alkyne does not undergo solvent addition in TFE (a poor nucleophile),[31] nor indeed in a more nucleophilic medium such as MeCN/H_2O. Rearrangement to yield allenes also does not compete, and the straightforward formation of the alkynes is by far the preferred pathway and involves elimination of the acetylenic hydrogen atom. Of particular note is that deprotonation is the only process observed in the arylation of ethynyltrimethylsilane—to the exclusion of the elimination of the other potential electrofugal group TMS^+.[32] Nevertheless, when the TMS^+ ion is the only leaving group present (as in the case of **4**), this is eliminated and an aryl alkyne is again formed in a good yield,[33] although in this case reduction of the phenyl cation to anisole plays a greater role.[28]

Scheme 3. Mechanism of the photoinduced metal-free formation of aryl alkynes.

A new cationic path was found in the reaction with propargylic alcohol **18**, where a methyl group migrated onto the vinyl cation intermediate (Scheme 2). In this case the driving force is the stability of the α-hydroxy cation formed, and no deprotonation occurred to give an alkyne. Precedents for the migration of a methyl (or a methylene) group adjacent to a vinyl cation have been reported,[34] but examples that lead to an α-hydroxy cation are rare.[35] Moreover, formation of the enone **19** as the *Z* isomer demonstrates a new route to the synthesis of related compounds which are currently accessible by the Rupe or Meyer–Schuster rearrangement.[36]

To summarize, a metal-free protocol for the mild alkynylation of aromatic compounds substituted with electron-donating groups has been developed. The reaction proceeds via a phenyl cation formed by photoheterolysis and allows for the use of a variety of precursors, such as readily available aryl chlorides as well as aryl esters (mesylates or phosphates). Interestingly, aryl fluorides, which are virtually unreactive under metal catalysis in the Sonogashira reaction, could also be used, although the consumption of the reagent was incomplete. Phenylalkynes are obtained in good, although not excellent, yields in TFE. Despite some limitation, this method has distinct advantages over the thermal alternatives, since the reaction is carried out at room temperature, with no need of a sensitive and/or expensive metallic catalyst or of water-free or oxygen-free conditions, and the experimental procedure is quite simple.[37]

The complete H^+ versus TMS^+ selectivity coupled with the successful application to silylated alkynes when no acetylene proton is present is an appealing characteristic of the reaction. The thermal-catalyzed sila-Sonogashira reaction has been exploited to a limited degree up to now, but the use of a silyl derivative may be advantageous for application to complex derivatives where protection is required, as well as making it easier to handle low-boiling alkynes (for example, **4**).[38] Finally, the synthesis of a β-aryl-substituted enone by addition onto a propargylic alcohol opens up yet a new synthetic pathway.

Experimental Section

Typical procedure for the photochemical synthesis of arylalkynes: A solution of an aryl ester or halide (**1**, **8**–**10**, 1.5 mmol, 0.05 M), triethylamine (TEA, 0.05 M), and an alkyne (**2**–**4**, 0.5 M) in TFE (30 mL) was poured into two quartz tubes and purged for 10 min with argon, serum capped, and irradiated with six 15-W phosphor-coated lamps (emission centered at 310 or 254 nm). The photolyzed solution

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was concentrated under reduced pressure and purified by column chromatography (cyclohexane/ethyl acetate as eluant). Acetone (3 mL, 0.9 M) was added to the reaction mixtures involving esters **1b**,**c** and the amount of TEA was increased to 0.1 M.

A Functional Assay for Heparin in Serum Using a Designed Synthetic Receptor**

*Aaron T. Wright, Zhenlin Zhong, and Eric V. Anslyn**

A common objective when developing synthetic receptors is high binding affinity and specificity for an analyte. This aim is challenging when targeting a complex analyte in a competitive crude medium such as serum, urine, or saliva.[1] We report herein the development of a synthetic receptor with high affinity and selectivity in human and equine serum for the clinical anticoagulant heparin.[2]

Two forms of heparin are in clinical use: unfractionated heparin (UFH) with a molecular weight range from 3000–30000 Da, and low-molecular-weight heparin (LMWH) with a mean molecular weight of 5000 Da. Heparin concentration and activity is monitored during surgery, and in postoperative therapy, to prevent complications such as hemorrhaging.[3] Current methods for heparin quantification employ the activated clotting time (ACT), activated partial thromboplastin time (aPTT), chromogenic antifactor Xa assay, electrochemical and piezoelectric assays, and complexation with protamine.[4] Although these are proven methods, they are often arduous, inaccurate, costly, and not always amenable to clinical settings.[5] Recently, an engineered GST fusion protein containing three hyaluronan binding domains from a heparin binding protein was used to accurately measure heparin in plasma at clinically relevant values, but it has not been employed clinically.[6]

Heparin cannot be expressed exactly using a conventional chemical formula. It is a heterogeneous mixture of diverse chain lengths consisting of repeating copolymers of 1→4-linked iduronic acid and glucosamine residues in a semi-random order (Figure 1b). Heparin has the highest anionic charge to mass ratio of any biopolymer, as a result of numerous sulfate and carboxylate functionalities in the biopolymer chain. Its activity occurs by binding to antithrombin III, a naturally occurring protease inhibitor, which accelerates the rate of inhibition of coagulation proteases factor Xa and thrombin by antithrombin III.[7] Clinically administered heparin binds to its natural substrate antithrombin III primarily through cationic ion-pairing interactions with the sulfate and carboxylate groups.[8] Similarly, the cationic protein protamine is an excellent ligand for heparin and is often used for the calibration of aPTT reagents. The highly anionic nature of heparin makes it an ideal target for synthetic receptors that incorporate functional groups for molecular recognition which participate in ion-pairing or other anion-binding interactions.

The design of heparin receptor **1** (Figure 1a) builds upon the successes of synthetic receptors reported previously. For example, we recently created receptor **2** (Figure 2), which incorporates phenylboronic acids and ammonium groups, for the complexation of anionic polysaccharides such as heparin, hyaluronic acid, and chondroitin-4-sulfate.[9] Phenylboronic acids with an *ortho*-aminomethyl group are known to form boronate esters with alcohols in aqueous media, and have been used extensively for the molecular recognition of saccharides.[10] It has been found that these boronate esters have particularly high affinity for anions with closely appended hydroxy groups.[11] Furthermore, ion pairing is anticipated between the ammonium functionalities and the carboxylate and sulfate groups. Receptor **2** had good selectivity for heparin relative to the other anionic polysaccharides. However, because heparin does not consist of a single entity, its concentration must be defined by considering

Figure 2. Previously reported receptor that had insufficient sensitivity to be active and accurate in a biological medium.

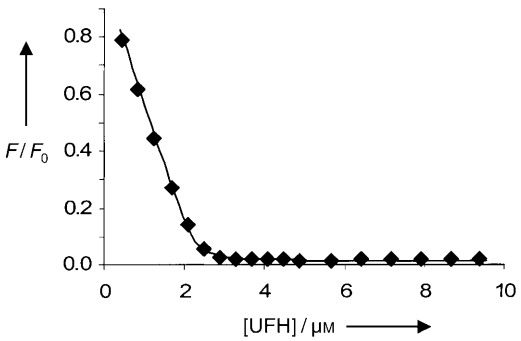

Figure 3. 1:1 binding isotherm for **1** and UFH. The K_a value obtained from the curve was $1.4\times10^{8}\,\text{M}^{-1}$.

various subunits so that a binding constant can be measured. A binding affinity of $3.8\times10^{4}\,\text{M}^{-1}$ was calculated when using a heparin concentration that is defined by the concentration of each disaccharide unit. This affinity was insufficient to allow quantification of heparin in serum at physiologically relevant concentrations. Moreover, although an indicator-displacement assay with **2** gave a dramatic yellow to purple color change in response to heparin,[12] we found that the indicator bound nonspecifically with proteins in crude serum, and thereby skewed the quantitative results.

From the lessons gleaned from the studies using **2**, we designed a second-generation heparin receptor with two goals in mind, both of which are embodied in the structure of **1**. First, the cavity was enlarged to allow the arms containing the boronic acid and ammonium groups to encompass a larger surface of the oligosaccharide, which we predicted would raise the affinity by cooperatively increasing the number of interactions. Second, a fluorescent scaffold was incorporated into the design of the receptor, thereby avoiding the use of an indicator-displacement assay. This new signaling technique should also increase the overall sensitivity of the system. We used 1,3,5-triphenylethynylbenzene as the core unit to satisfy both requirements. However, because of the excellent selectivity previously found for **2** with heparin, we retained the side arms containing the boronic acid and ammonium groups.

An assay for UFH or LMWH in serum requires a binding interaction between **1** and heparin in the nM range. Titrations of **1** with UFH and LMWH in water buffered with 10 mM 2-[4-(2-hydroxyethyl]-1-piperazinyl]ethanesulfonic acid (HEPES) at pH 7.4 were monitored by fluorescence spectroscopy to determine the affinity of **1** for UFH and LMWH. The binding of UFH and LMWH with **1** caused a decrease in the emission intensity, which resulted in a near complete quenching of the receptor's emission. Presumably, the interaction of heparin with **1** leads to conformational restriction of the receptor "arms", thereby modulating the fluorescence—a technique used routinely by Finney and co-workers for creating chemosensors.[13] Titration data at 357 nm was used to generate a binding isotherm, which was analyzed by using a standard 1:1 binding algorithm (Figure 3). As discussed above, the heterogeneous structure of heparin means that one must define a repeating unit with which the receptor interacts. The binding isotherm shown in Figure 3 was achieved by defining the concentration of heparin to be that of four saccharide units (an integral number of saccharides is not required to fit the binding isotherm). The number four supports a stoichiometry where each receptor on average spans four saccharide units along the heparin biopolymer. The calculated association constant between **1** and UFH is $1.4\times10^{8}\,\text{M}^{-1}$. This value corresponds to an increase in affinity of nearly 10^{4} for **1** over **2**, which was gained by increasing the size of the scaffold. It should be noted that the glycosaminoglycuronans hyaluronic acid and chondroitin-4-sulfate did not bind to **1** at low μM concentrations. This result is further evidence for the high selectivity of **1** for UFH and LMWH.

As noted above, several clinical methods (such as aPTT) are calibrated by titration with protamine. Protamine sequesters heparin, thereby lowering its bioavailability to bind antithrombin III. Therefore, if there is a specific binding interaction between heparin and **1** as postulated above, protamine should strip heparin from receptor **1**, thereby restoring the fluorescence. Indeed, fluorescence could be fully reestablished by titration of the complex formed between receptor **1** and either UFH or LMWH with protamine (Figure 4). This observation illustrates that the binding between **1** and heparin is reversible, and acts in an analogous way to that between heparin and antithrombin III.

Our last study targeted the creation of calibration curves for monitoring UFH and LMWH in serum. Heparin is administered intravenously or subcutaneously at therapeutic dosing levels of 2–8 U mL^{-1} (0.8–3.2 μM) during cardiopulmonary surgery and emergency deep venous thrombosis (DVT) conditions to prevent excessive clotting. However, patients are treated at therapeutic dosing levels of 0.2–2 U mL^{-1} (0.08 μM–0.8 μM) in post-operative and long-term anticoagulant care of DVT. Human and equine serums were doped with UFH and LMWH at these dosing levels to simulate monitoring conditions in a clinical setting. A serum sample (32 μL) doped with UFH or LMWH was added to a fluorimeter cell containing a total volume of 1.5 mL HEPES (10 mM) in deionized water. To this was added 2 μL of **1** ($2.24\times10^{-3}\,\text{M}^{-1}$). The fluorescence stabilized over a period of 18 minutes, which contrasts the instantaneous response found

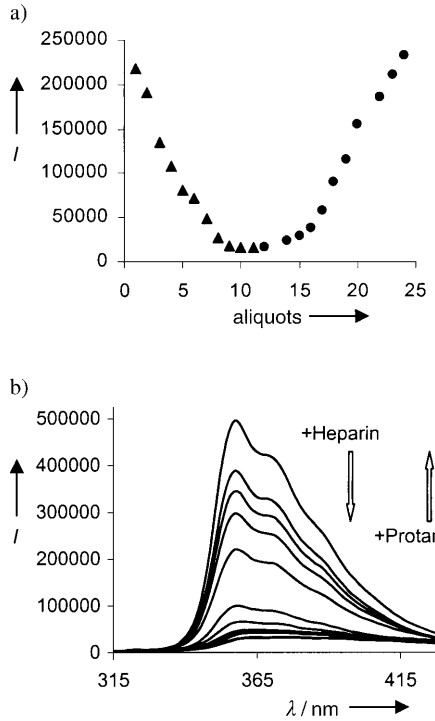

Figure 4. Reversibility of LMWH:**1** binding upon titration with protamine. a) Emission intensity at 357 nm. Dilution was carried out with aliquots of buffered water (HEPES, pH 7.4). First 11 aliquots of heparin were added (▲), and then 12 aliquots of protamine were added (●). The fluorescent emission was reestablished upon titration. b) Emission spectrum of **1** upon addition of LMWH. The addition of protamine reverses the spectrum.

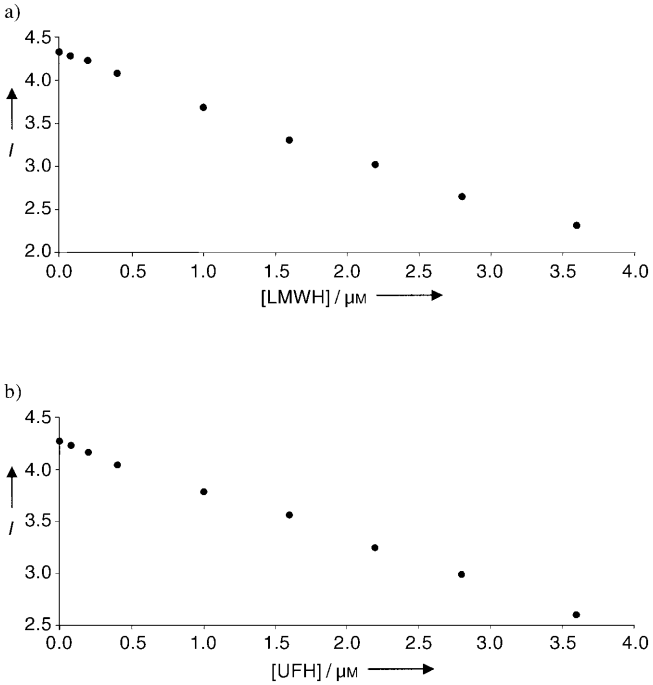

Figure 5. Calibration curves for a) LMWH in human serum and b) UFH in human serum. Conformational changes to **1** upon binding to heparin result in a diminished fluorescence emission. Greater concentrations of UFH and LMWH result in increased fluorescent quenching. The range of detection for both UFH and LMWH was 0–9 U mL^{-1} (0–3.6 μM).

in buffered water, and indicates that the formation of the complex with heparin in serum was slow on the laboratory timescale. This result is potentially a consequence of the kinetics of release of heparin from natural receptors in the sera. Emission spectra were recorded after 18 minutes for each of nine samples with various heparin concentrations to generate calibration curves (355 nM, Figure 5). Increased levels of heparin in serum correlated linearly with lower emission responses for both UFH and LMWH within the range of clinically relevant concentrations, as was observed for the fluorimetric titrations using pure heparin in buffered water. Furthermore, the method worked in both equine and human samples, thus illustrating that the affinity of the synthetic receptor for heparin is independent of the mammalian source, and could potentially be used for either human or veterinary applications.

In summary, we have demonstrated a functional synthetic fluorescent assay for the clinically administered anticoagulant heparin. The synthetic receptor highlighted herein showed remarkable selectivity and affinity for heparin, even in crude serum. The fluorescence emission was used to generate calibration curves for UFH and LMWH in serum at clinically relevant dosing levels (0.2–8.0 U mL^{-1}). These calibration curves allow the heparin concentration in an unknown sample to be determined by comparative analysis of the fluorescence emission. This study demonstrates that synthetic receptors can be created to target very complex bioanalytes, and function successfully in physiological settings.

Modeling the Anodic Half-Cell of a Low-Temperature Coal Fuel Cell**

*Douglas B. Weibel, Roman Boulatov, Andrew Lee, Rosaria Ferrigno, and George M. Whitesides**

Herein we examine the reduction of Fe^{III} ions by subbituminous coal (SBC) having a composition $CH_{0.81}O_{0.22}$ in 5 M H_2SO_4 at 100 °C. The reaction proceeds with a maximum rate constant of 8×10^{-4} cm s^{-1},[1] which is 15–160 times greater than those reported previously.[2,3] We used this reaction in the anode compartment of a prototype of a coal fuel cell that operated at 100 °C and at atmospheric pressure with VO_2^+ as the model oxidant. The cell produced a maximum current (power) density of 5 A (0.6 W) per liter of a slurry of electrolyte and coal, and 100 mA (11 mW) at the scale at which we carried out experiments (19 mL).

Attempts to develop a process for generating electricity directly from the oxidation of coal date back to the late 19th century.[4] Recent work on coal-powered fuel cells has been motivated by two facts: 1) the worldwide reserves of coal significantly exceed those of other fossil fuels,[5] and 2) the environmental benefits of converting coal into electricity directly in a fuel cell rather than by generating steam in turbines have been perceived as significant.[6] The oxidation of carbon electrochemically has a large activation energy (26 kcal mol^{-1}),[7] and proceeds at room temperature at detectable rates only at an overpotential of greater than 1 V.

Two strategies have been used to overcome the intrinsically slow kinetics of the oxidation of carbon in a coal fuel cell. One strategy is to oxidize a carbonaceous fuel (e.g., graphite) electrochemically at high temperatures (> 600 °C)—the majority of recent research on coal fuel cells has been based on this approach.[2,7–9] Molten carbonates are typically used as electrolytes in high-temperature cells; molten hydroxides, borates and silicates, and solid oxides have also been used. One of the most advanced examples of a direct carbon–air fuel cell operated at 630 °C for 500 h with molten KOH/NaOH as the electrolyte, a graphite anode that also served as the fuel, and a Fe–Ti alloy as the cathode at which O_2 was reduced. The cell produced current and power densities of 30 A L^{-1} (270 mA cm^{-2} of anode) and 2.5 W L^{-1} (0.12 W cm^{-2} of anode), respectively.[10] The high operating temperature of this class of cells tends to result in their corrosion, particularly in the presence of oxygen.[10] Other technical problems with these cells include: 1) the high resistivity of molten salts (up to 100 Ω cm);[11] 2) the consumption of carbon by reaction with CO_2 to produce CO;[7] and 3) the clogging of cells by ash and other components of the fuel that are not oxidized.[9] The high resistivity and poor mechanical stability of carbon fuels such as bituminous coal make them impractical as consumable anodes in coal fuel cells—the use of coal slurries in molten electrolytes requires vigorous stirring.[6] Zecevic et al. have argued that high-temperature coal fuel cells cannot be made practical because of these problems.[10]

An alternative strategy for overcoming the slow kinetics of the direct electrochemical oxidation of coal is based on the observation that several transition-metal ions, including Fe^{III}, Sn^{IV}, Cu^{II}, and Ce^{IV}, oxidize coal slurries with an activation energy of 7–16 kcal mol^{-1}, which is significantly lower than that for the direct electrooxidation of coal.[12,13] Although the electrolysis of coal slurries in the presence of transition-metal ions has been studied extensively,[2,3,12,13] we are not aware of any coal-powered fuel cells that use a secondary redox couple (e.g., Fe^{III}/Fe^{II}). This type of cell—in which metal ions would be reduced by the coal and reoxidized at the anode electrochemically—has been considered impractical because of the

slow turnover ($< 7\times10^{-7}$–$2\times10^{-5}\,s^{-1}$) observed under a variety of conditions with all but the strongest oxidants (Ce^{IV} and Br_2).[13]

We found that Fe^{II} ions can be generated by reducing a saturated solution of Fe^{III} ions in 5 M H_2SO_4 (5 mL) with a suspension of SBC (5 g, 70 mesh) at a maximum rate of 4 mM s^{-1};[14] at this rate and temperature, the reaction becomes kinetically suitable for use in a coal fuel cell operating at atmospheric pressure (although problems with the overall conversion of coal to energy remain; see below).

Among the carbonaceous fuels tested, sub-bituminous coal and Kraft lignin were oxidized most rapidly by Fe^{III} ions.[15] The rates of oxidation by Fe^{III} ions decreased in the order: peat, lignite, activated charcoal, anthracite, and bituminous coal. Graphite felt was inert to oxidation by Fe^{III} ions under these conditions. The oxidation of SBC at 100 °C by Cu^{II} ions (0.16 V versus the normal hydrogen electrode (NHE)) and Sn^{IV} ions (0.15 V versus NHE)—both weaker oxidants than Fe^{III} ions (0.72 V versus NHE at 100 °C)—was too slow to be useful.[16]

Up to approximately 0.1 mol of Fe^{III} was reduced to Fe^{II} ions with 1 g of SBC (ca. 100 mesh) at 100 °C in 5 M H_2SO_4.[15] This amount corresponds to approximately 40 % of the electrons available (0.24 mol or 24 kC) from the complete oxidation of 1 g of SBC to CO_2 and H_2O [Eq. (1)].

$$CH_{0.81}O_{0.22} + 1.78\,H_2O \rightleftharpoons CO_2 + 4.37\,H^+ + 4.37\,e^- \quad (1)$$

The reaction between SBC and Fe^{III} ions produced CO_2, traces of CO, and a solid with the chemical composition $CH_{0.58}O_{0.33}$; the mass of this more highly oxidized residue was 75 % of the initial mass of coal. Equation (2) describes the empirical stoichiometry of the oxidation of SBC by Fe^{III} ions under these conditions.

$$CH_{0.81}O_{0.22} + 0.61\,H_2O + 1.62\,Fe^{III} \rightleftharpoons 0.70\,CH_{0.58}O_{0.33} + 0.30\,CO_2 + 1.62\,H^+ + 1.62\,Fe^{II} \quad (2)$$

The rate of reduction of Fe^{III} ions by SBC is given by Equation (3), where $[Fe^{III}]$ is the concentration of Fe^{III} ions (M); m is the mass of coal (g); l is the average "size" of coal particles based on the mesh size of coal (cm);[17] ρ is the density of coal (g cm^{-3});[18] and v is the volume of the reaction mixture (the volume of the solution and the coal, cm^3). In Equation (3) the term $m/l\rho$ is proportional to the total surface area of the coal; for spherical particles the coefficient of proportionality is 0.75.

$$\frac{d[Fe^{II}]}{dt} = k\frac{[Fe^{III}]\left(\frac{m}{l\rho}\right)}{v} \quad (3)$$

The maximum rate of reduction of Fe^{III} to Fe^{II} ions was 4×10^{-3} M s^{-1} at 100 °C in a reaction mixture containing 5 g of SBC (ca. 70 mesh) and 5 mL of a solution of Fe^{III} ions (0.385 M) in 5 M H_2SO_4 (this slurry contained approximately 1:1 electrolyte/SBC (v/v)). The corresponding heterogeneous rate constant k [Eq. (3)] was 8×10^{-4} cm s^{-1}, which is 15–160 times greater than those reported previously for the oxidation of various types of coal by Fe^{III} ions in H_2SO_4 at 100 °C.[2,3]

The kinetic data suggest that the reduction of Fe^{III} ions by SBC under these conditions might provide a method of regenerating Fe^{II} ions in the anodic compartment of a redox fuel cell that uses the Fe^{III}/Fe^{II} couple. To explore this possibility, and to identify some of the limitations of such a cell, we built a prototype of a coal fuel cell. In the anodic chamber, Fe^{III} ions were reduced to Fe^{II} ions by SBC, and Fe^{II} ions were oxidized to Fe^{III} ions electrochemically at a carbon felt anode. The anodic oxidation of the Fe^{II} ions was coupled to the reduction of VO_2^+ to VO^{2+} at the cathode (carbon felt) through an external circuit. We separated the cathodic and anodic compartments with a nafion-112 membrane (Figure 1). VO_2^+ is a more suitable oxidant for academic studies than O_2—the species used in commercial fuel cells—because VO_2^+ is a strong oxidant (the standard potential of the VO_2^+/VO^{2+} couple is only 0.2 V less oxidizing than that of the O_2/H_2O couple) that is reduced much more rapidly than O_2 at carbon electrodes.

VO^{2+} ions accumulated in the cathodic compartment during the operation of the cell. To regenerate VO_2^+ ions, the solution in the cathodic compartment was pumped into a separate vessel where the VO^{2+} ions were oxidized aerobically in the presence of nitrate at 80 °C.[19]

We ran the cell until the desired fraction of electrons (up to 40 %) available from the complete oxidation of SBC to H_2O and CO_2 had been extracted as electric current. We then separated the remaining solid from the electrolyte by centrifugation, and added a fresh batch of SBC. The content of the cathodic compartment was replaced with a regenerated solution of VO_2^+ ions as frequently as necessary to maintain the cathodic potential within 0.1 V. We observed maximum volumetric current and power densities of 5 A per liter of slurry and 0.6 W per liter of slurry, respectively, using 15 mL of 5 M H_2SO_4 saturated with $Fe_2(SO_4)_3$ and 4 g of SBC (ca. 100 mesh; electrolyte/SBC ≈ 4:1 (v/v)). The current/potential curves (Figure 2 a) indicate that the performance of the cell was not limited by the cathodic reaction or by mass transport.

To understand the relative contributions of 1) the reaction between Fe^{III} ions and SBC, 2) anodic oxidation of Fe^{II} ions,

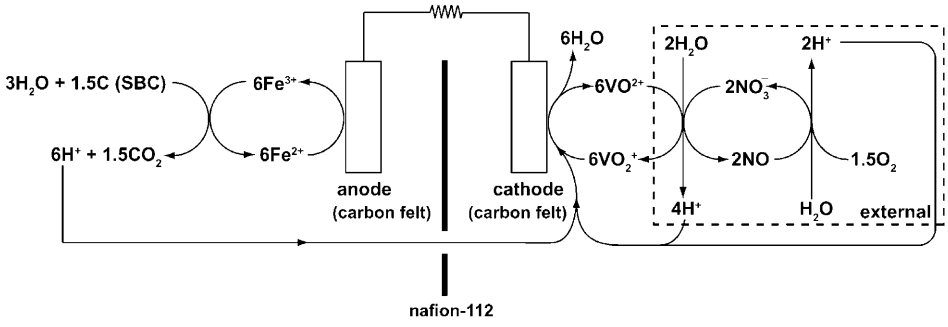

Figure 1. Schematic representation of the coal fuel cell which simplifies the stoichiometry of the reaction between SBC and Fe^{III} ions given in Equation (2).

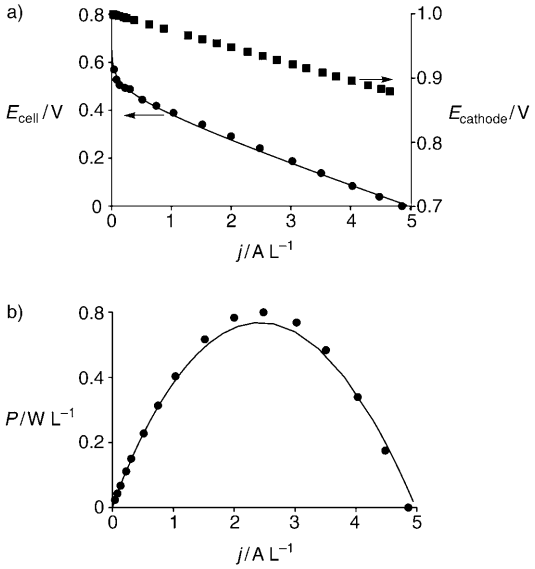

Figure 2. Current and power output of the cell. a) A plot of the potential of the cell E_{cell} (◆, left axis) and the cathodic potential $E_{cathode}$ versus NHE (■, right axis) as a function of the current density j. b) A plot of the power density P as a function of the current density j. The solid lines are fits to Equation (4) using $(km/\rho l) = 0.1\ cm^3\,s^{-1}$, k_{ET}-$S_{an} = 0.01\ cm^3\,s^{-1}$, $v = 0.019$ L, $r = 3.90\ \Omega$. The anodic compartment contained 15 mL of a saturated solution of ferric sulfate in 5 M H_2SO_4 and 4 g of SBC; the cathodic compartment contained 60 mL of a solution of VO_2^+ and VO^{2+} (ca. 1:1) in 5 M H_2SO_4. The temperature of the cell was 100 °C. The arrows indicate the axes corresponding to each plot.

and 3) cell resistance to the performance of the cell at various currents we analyzed the current/potential and current/power data (Figure 2) with a kinetic model in which Fe^{III} ions were reduced to Fe^{II} ions by SBC with a composite rate constant $km/l\rho$, and Fe^{II} ions were oxidized anodically with a rate constant $k_{ET}S_{an}$; the variables k, m, l, and ρ are defined in Equation (3), k_{ET} is the standard heterogenous rate constant[16] for electron transfer between the $Fe^{III/II}$ couple and carbon felt ($> 1\times10^{-5}$ cm s^{-1}, see Supporting Information), and S_{an} is the surface area of the anode (2000 cm^2 for graphite felt with dimensions 13 cm^2 × 0.3 cm).[20] In this model the volumetric current density j [A L^{-1}] is given by Equation (4), where [Fe] is the total concentration of iron (M); v_{an} is the volume of the anolyte (L); E_{cell} is the potential of the cell (V); $E_{cathode}$ is the potential of the cathode (versus NHE, V); $E^{o\prime}$ is the formal potential of the Fe^{III}/Fe^{II} couple under the experimental conditions (0.72 V versus NHE, V); r is the internal resistance of the cell (Ω); F and R are Faraday and gas constants, respectively, and T is absolute temperature (K).

$$j = \frac{1}{v_{an}} \frac{10^{-3} F\,[\mathrm{Fe}]}{\left(\frac{e^{-\frac{0.5F}{RT}(E_{cathode} - E_{cell} - j v_{an} r - E^{o\prime})}}{(k_{ET} S_{an})}\right) + \left(\frac{1+e^{-\frac{F}{RT}(E_{cathode} - E_{cell} - j v_{an} r - E^{o\prime})}}{\left(\frac{km}{T\rho}\right)}\right)} \qquad (4)$$

The fit of experimental current/potential curves to Equation (4) (Figure 2) suggests that at potentials below 0.5 V the performance of this prototype fuel cell is limited primarily by the internal resistance (3.9 Ω, a value corresponding to an areal resistance of 50 Ω cm^{-2}). The carbon felt electrodes were responsible for 95% of this resistance; we estimate the resistance of the nafion membrane and the electrolyte to be less than 0.1 Ω.

At a cell potential between 0.5 and 0.65 V, the rate of the reaction between Fe^{III} ions and SBC limited the current. Our calculations suggest that at the ratio of the area of the anode to the total surface area of SBC used in our experiments $S_{an}/(m/l\rho)$ the electrochemical oxidation of Fe^{II} ions at the anode was not rate-limiting, even at the largest cell potentials.

The open-circuit voltage of our fuel cell was about 350 mV lower than the estimated formal potential of the SBC/O_2 couple.[21] The anodic half-cell was responsible for 150 mV of this overpotential, with the steady-state oxidation of Fe^{II} ions by O_2, hot H_2SO_4, or both being probable side reactions.[22] The cathodic half-cell contributed approximately 200 mV to the overpotential, because we regenerated the catholyte only until its potential reached 1 V (versus NHE). The aerobic oxidation of VO^{2+} is relatively slow, and impractically long times were required to achieve $[VO_2^+]/[VO^{2+}] \gg 1$ that would correspond to more oxidizing potentials. The crossover currents were small (0.5–2 μA cm^{-2} M^{-1}) and contributed little to the overpotential; for example, the loss in a cell comprising two 70-mL compartments separated by a membrane having an area of 13 cm^2 was less than 1 mV per minute when the cell was at open circuit.

As a batch of SBC oxidized, the maximum current density and power produced by the cell decreased as an exponential function of the charge per gram of SBC passed through the cell, because the rate constant for the reaction between Fe^{III} ions and SBC decreased (see Supporting Information).

We ran our prototype fuel cell continuously for 10^3 h (corresponding to the total turnover number of Fe^{III} ions of 10^3) and produced a current that was approximately constant by periodically adding SBC (5 g/100 mL added every 96 h) to the anode compartment and replacing the solution in the cathodic compartment at a frequency that maintained its potential within 0.1 V. The fraction of SBC not oxidized by Fe^{III} ions remained in the anodic compartment during the experiment. We observed no significant degradation in the performance of the cell during this prolonged run.

In summary, we have characterized the kinetics of the oxidation of SBC with Fe^{III} ions at 100 °C and have tested this reaction in a model of the anodic compartment of coal-powered fuel cell. The cell, which contained approximately 4 g of SBC (ca. 100 mesh) and 15 mL of saturated iron sulfate in 5 M H_2SO_4, delivered a maximum current of 100 mA and a power of 11 mW, which correspond to volumetric densities of 5 A L^{-1} and 0.6 W L^{-1}, respectively. It should be possible to lower the internal resistance of our prototype cell to less than 1 Ω and thereby increase the maximum volumetric current and power densities to over 90 A L^{-1} and 7 W L^{-1}, respectively, simply by optimizing the design of the electrodes, provided that limitations of mass-transport can be avoided. These values compare favorably with the maximum current and power densities reported in the literature for high-temperature coal fuel cells: 30 A L^{-1} and 2.5 W L^{-1}.[23]

The conditions described in the manuscript for the oxidation of SBC do not yet form the basis of a practical

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coal fuel cell, because of the small fraction of the enthalpy of SBC that can be converted into electrical power. The reversible electrochemical oxidation of 1 g of SBC with O_2 as the terminal oxidant would produce 24 kC of current at 1 V, which corresponds to 24 kJ of electrical energy. The oxidation of the same amount of SBC by Fe^{III} ions at 100 °C in 5 M H_2SO_4 produces 10 kC of current (40 %); the remaining 60 % of the reducing equivalents are contained in the solid that is oxidized by Fe^{III} ions at a rate below the detection limit of our experiments. At maximal power output, 1.3 kJ of electrical work is extracted from 1 g of SBC (ca. 100 mesh) in our cell; this amount constitutes 5 % of the enthalpy of the aerobic oxidation of SBC. Forty-five percent of the remaining enthalpy resides in the unoxidized solid residue. Ohmic resistance dissipates another 5 % of the enthalpy (1.3 kJ). The remaining losses (ca. 45 %, 11 kJ) arise during the operation of the cell because an equilibrium cannot be maintained between the terminal oxidant (O_2) and the redox couple in the cathodic half-cell (VO_2^+/VO^{2+}) and between the terminal reductant (SBC) and the redox couple in the anodic half-cell (Fe^{III}/Fe^{II}). As a result, the electrolyte in the cathodic compartment is reduced to a greater extent than it would be if it was in equilibrium with O_2, and the anodic compartment is oxidized to a greater extent than it would be if the Fe^{III}/Fe^{II} couple was in equilibrium with SBC. The efficiency of the conversion increases to 7 % (2 kJ) if the cell operates at 10 % of the maximum power output (high potential); in this regime, the currents are low and the irreversible non-electrochemical oxidation of Fe^{II} ions in side reactions dominates the energy losses. The efficiency of converting the enthalpy into electrical power correlates with the power output only as long as the rate of electrochemical oxidation of Fe^{II} ions exceeds the total rate of non-electrochemical processes in which Fe^{II} ions are oxidized, such as oxidation of Fe^{II} ions by air or H_2SO_4.

The primary reason for the inefficient conversion of enthalpy into power is the exponential decrease in the rate constant with the amount of charge extracted from SBC; this relationship indicates that the rapid initial rate of the reaction between SBC and Fe^{III} ions arises from the oxidation of a small fraction of highly reactive functional groups in coal (probably at or near the surface). As these groups are consumed, less-reactive groups at the surface or in the solid core of the particle are oxidized, with an observed corresponding decrease in the apparent rate constant.

Our analysis of Equation (3) suggests that it should be possible (but untested experimentally) to increase the initial rate of oxidation of coal with Fe^{III} ions by: 1) using smaller particles of coal (decreasing l); 2) using a larger ratio of coal to electrolyte (increasing m/v); and 3) using a different carbonaceous fuel or different electrolyte (increasing k). Improvements (1) and (3) may also increase the number of reducing equivalents of SBC extractable by Fe^{III} ions (namely, > 40 %). For example, if, following Equation (3), we assume that using particles of SBC with diameters of 1 μm would increase the initial rate of the reaction 200-fold over that with 200-μm particles (100 mesh)—without affecting how rapidly the rate constant k decays with the amount of charge extracted per gram of SBC—the enthalpy of conversion would be 9 % at maximum power output (17 % at 10 % of the maximum power output). If we assume that the rate constant for oxidation of particles of SBC with diameters of 1 μm with Fe^{III} ions decays 200-fold more slowly than for particles with diameters of 200 μm, the efficiency of converting enthalpy into useable electrical energy would become 18 % at maximum power output (40 % at 10 % of the maximum output).[24] By comparison, the corresponding conversion for an internal combustion engine is about 30 % and for a proton-exchange membrane (PEM) cell is approximately 45 %.[25]

The low efficiency observed in our studies is certainly not inevitable, and can be improved by using a better catalyst for the oxidation of coal than the transition-metal ions screened so far (Fe^{III}, Cu^{II}, Sn^{IV}).

It is possible that the kinetics and extent of oxidation of carbonaceous materials with Fe^{III} ions can be improved by using different fuels. The reactivity of carbon towards the direct electrochemical oxidation in high-temperature coal fuel cells correlates inversely with its degree of crystallinity;[9] a carbon fuel that is more amorphous than SBC may be more reactive to Fe^{III} ions in 5 M H_2SO_4 at 100 °C. If the oxidation of coal by Fe^{III} ions requires the coordination of ferric ions to active sites on the surface of coal, H_2SO_4 may not be the optimal electrolyte—Fe^{III} ions are present in H_2SO_4 primarily as $[Fe(HSO_4)_x]^{(3-x)+}$ complexes and the concentration of coordinatively unsaturated ions available for the oxidation of coal is low.[26]

Ultimately, to be practical, the anodic half-cell based on the transition-metal-catalyzed oxidation of a carbonaceous fuel should be integrated with a (half) membrane-electrode assembly (MEA) for the direct reduction of O_2 at the cathode. This integration would be possible only if MEAs are 1) stable to corrosive electrolytes (e.g., 5 M H_2SO_4 at 100 °C), and 2) have a low permeability to solutes (e.g., H_2SO_4 and the transition-metal ions).

This study does not provide the basis for a practical low-temperature, coal-powered fuel cell—it demonstrates a significant yield of electrons using what is, in essence, a liquid reformer (the $Fe^{III/II}$ component of this system), and provides a benchmark and starting point against which further studies in this area can be compared.

[1] The units of the rate constant are $cm\,s^{-1}$, and arise from the fact that the rate at which Fe^{II} ions are produced is given by $d[Fe]/dt = k[Fe]$(surface area of coal)/(reaction volume) or $[M\,s^{-1}] = k[M][cm^2][cm^{-3}]$. These are the same units used for a rate constant for heterogenenous electron transfer between a redox couple in solution and a solid electrode.

[6] The perceived environmental benefit of converting coal directly into electricity in a fuel cell versus by means of a temperature gradient is the amount of CO_2 released per unit of electrical output. At present, no more than 60 % of the enthalpy of the aerobic combustion of carbon can be converted into electricity as a result of the finite top temperature that can be utilized by turbines. A coal fuel cell can convert all of the enthalpy for the aerobic oxidation of coal thermodynamically into CO_2 because of the positive entropy change upon combustion of C to CO_2.

[15] a) This method of burning coal at low temperature reminds us of prior work on oxidatively removing (namely low-temperature burning) lignin from cellulose using polyoxometalates; see, for example: V. Grigoviev, C. L. Hill, I. A. Weinstock in *Fundamentals and Catalysis* (Ed.: D. S. Argyropoulos), American Chemical Society Symposium Series, Washington, DC, **2001**, pp. 297 – 312; b) lignin, cellulose, and other biomass feedstocks may be particularly attractive fuels in fuel cells because they minimize the emission of CO_2 per unit output of electrical energy.

[16] The standard potential of the $[Fe(H_2O)_6]^{2+}/[Fe(H_2O)_6]^{3+}$ couple is 0.77 V versus NHE: A. J. Bard, L. R. Faulkner, *Electrochemical Methods: Fundamentals and Applications*, Wiley, New York, **2001**, 2nd ed. We measured the formal potential in 25 % H_2SO_4 at 100 °C as 0.57 V versus standard Ag/AgCl, or 0.72 V versus NHE using the potential of the Ag/AgCl reference electrode of 0.15 versus NHE at 100 °C: D. J. G. Ives, *Reference Electrodes, Theory and Practice*, Academic Press, New York, **1961**, p. 189.

[17] Mesh refers to the number of openings per linear inch of a screen. The mesh size of a particle is the mesh screen having the largest openings on which the particle is retained. The mesh size of the American Sieve Series is related to the size of the opening, in cm as: (size in cm) = 2/(mesh size) for mesh sizes above 50, and (size in cm) = (1.5)/(mesh size) for mesh sizes below 40. In kinetic equations, we used the size of the opening in cm as the characteristic size of a particle of coal l because the linear size is not defined for a particle of an arbitrary shape.

[18] The choice of the parameters $m/l\rho$ to represent the accessible surface is discussed in the Supporting Information.

[19] J. T. Kummer, *Inorg. Chim. Acta* **1983**, *76*, L291 – L292.

[20] The measured value for k_{ET} is on the low end of rate constants for electron transfer between the $Fe^{III/II}$ couple and different forms of carbon reported in the literature. See for example, P. Chen, M. A. Frying, R. L. McCreery, *Anal. Chem.* **1995**, *67*, 3115 – 3122.

[21] We were unable to find data in the literature on the standard redox potential of the reaction in Equation (1) or its temperature dependence. We estimated the potential of this reaction at 100 °C from the combustion analysis of SBC, according to the formula: $E_{SBC}(T) = \frac{\Delta G_{combustion}(T)}{nF} - 1.2\ V \approx \frac{LHV}{nF} \approx -0.25\ V$, where the low-heat value (LHV) is the enthalpy of the combustion of coal generating steam and $n = 4.37$.

[22] At open circuit voltage, which corresponds to a potential of the anodic half-cell of about 350 mV versus NHE, the oxidation of Fe^{II} ions by H_2SO_4 becomes thermodynamically favorable at a partial pressure of $SO_2 \leq 600$ Pa (≤ 0.6 % of atmospheric pressure). The aerobic oxidation of Fe^{II} ions is thermodynamically unfavorable at any potential of the cell, but it may be driven by the highly exergonic decomposition of HO_2, which results from reaction between the Fe^{II} ions and O_2. Assuming that the rate of the reduction of the Fe^{III} ions by SBC equals the total rate of oxidation of Fe^{II} ions in side-reactions at open circuit, the apparent first-order rate constant for the non-electrochemical oxidation of Fe^{II} is about 10^{-9} s^{-1} for a reaction mixture containing 1 g of SBC per 4 mL of 5 M H_2SO_4 saturated with iron sulfate at 100 °C.

[23] We cannot compare the sustained current and power output of our cell with similar values reported for high-temperature CFCs. The literature on high-temperature CFCs does not specify the fraction of electrons available from the complete oxidation of fuel in the cell that was consumed while the "sustained" performance of the cell was characterized.

[24] The fraction of oxidizable functional groups that are on the surface of a particle of coal is inversely proportional to the radius of the particle when the groups are distributed homogeneously throughout the particle.

Tailored Catalytic Propene Trimerization over Acidic Zeolites with Tubular Pores**

Johan A. Martens, Wim H. Verrelst, Georges M. Mathys, Stephen H. Brown, and Pierre A. Jacobs*

Oligomerization of short alkenes is applied in large-scale petrochemical processes for a variety of products including liquid hydrocarbon fuels, lubricants, detergent precursors, solvents, and plasticizers.[1–4] Whereas longer-chain linear alkenes result from homogeneous catalytic processes that use transition metal complexes,[5] chain-branched alkenes in the C_6–C_{12} range stem from the oligomerization of C_3 or C_4 alkenes using a fixed bed of silica-supported phosphoric acid (SSPA),[1–4,6] at temperatures and pressures amounting to about 520 K and 12 MPa, respectively.[7,8] Despite drawbacks related to the maintenance of a critical feed hydration level, catalyst clogging, and corrosion problems caused by phosphoric acid leaching, SSPA processes are still widely operated.[1–4] We have now discovered that acidic ZSM-22 zeolite allows the synthesis of propene trimers of intermediate degree of chain branching, suitable as feedstock for oxyfunctionalization processes. The narrow tubular pores of this zeolite impose preferential formation of the slimmer linear and monobranched oligomers. Though the in-time stability of ZSM-22 is similar to that of SSPA, the former catalyst does not present the numerous disadvantages encountered with the latter.

Difficulties in finding a viable substitute for SSPA are not only related to the fact that cheap, impure alkene feedstocks are used, but also to the critical product specification with respect to molecular weight and chain branching of the oligomers. Acidic zeolites through their molecular shape selectivity properties can meet these stringent catalyst requirements. For fuel and lubricant applications, a technology based on ZSM-5 has been developed.[9] More recently, ZSM-57 with its unique lobate pore structure was reported to be a stable and selective dimerization catalyst for C_4–C_6 alkenes.[10] With a ZSM-57-type catalyst, the number of chain branchings (NCB) of the alkene dimers is high and similar to that of processes using SSPA. In oxyfunctionalization processes, olefins with two and especially with three or more chain branchings show decreased reactivity.[11] We now report the advantageous use of ZSM-22 for the synthesis of propene trimers with appropriate low NCB.

Zeolite pore architecture is characterized by the dimensionality and size of the channel system, the latter being determined by the number of oxygen atoms in the ring circumscribing the opening. Candidate zeolite topologies categorized according to micropore architecture were screened in the propene trimerization reaction using a mixture of 12 wt % of propene in propane fed in supercritical state at 6.8 MPa and 473–513 K. Contact time was adapted to reach at least initially a high conversion level. With respect to trimerization yield (Y_{C9}) and limitation of NCB, zeolites with a tubular 10-membered ring (10-MR) channel system devoid of large lobes or intersections outperformed all others (Figure 1, bottom). On the majority of zeolite structure types known today, with intersecting 10-MR channels, side pockets, or pronounced lobes or with 12-MRs,[12] Y_{C9} at high conversion was reduced, while the NCB was close to 2.0 (Figure 1, top), a value typical for SSPA processes.

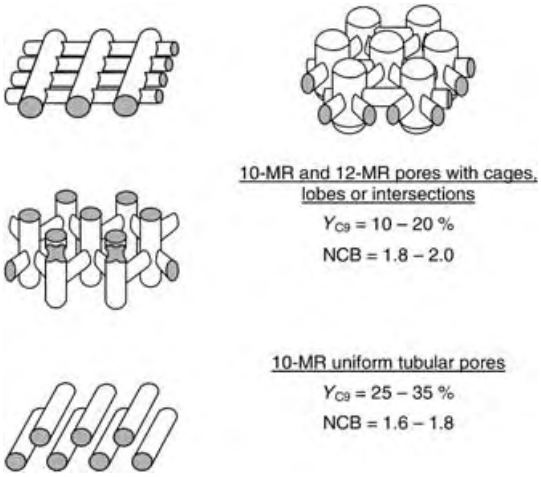

Figure 1. Influence of the micropore system of the acidic zeolite at propene conversions exceeding 80% on propene trimer yield (Y_{C9}) and number of chain branchings (NCB).

Uniform 10-MR tubular pores are encountered in ZSM-22, ZSM-23, SAPO-11 with TON, MTT, and AEL topology, respectively,[12] as well as in the ZSM-48 family of zeolites.[13,14] With ZSM-22, initially all propene was converted. Though the activity showed some decay with time-on-stream, an amount of propene corresponding to 400 times the catalyst weight could be converted easily (see Experimental Section). The three other zeolites showed decreased initial activity, with similar (ZSM-23) or higher rates of decay (ZSM-48 and SAPO-11).

Under the presently used reaction conditions, typical for industrial processes, the tubular 10-MR zeolite catalysts yielded mainly dimers, trimers, and tetramers as reaction products. This is evident from Figure 2, which also clearly

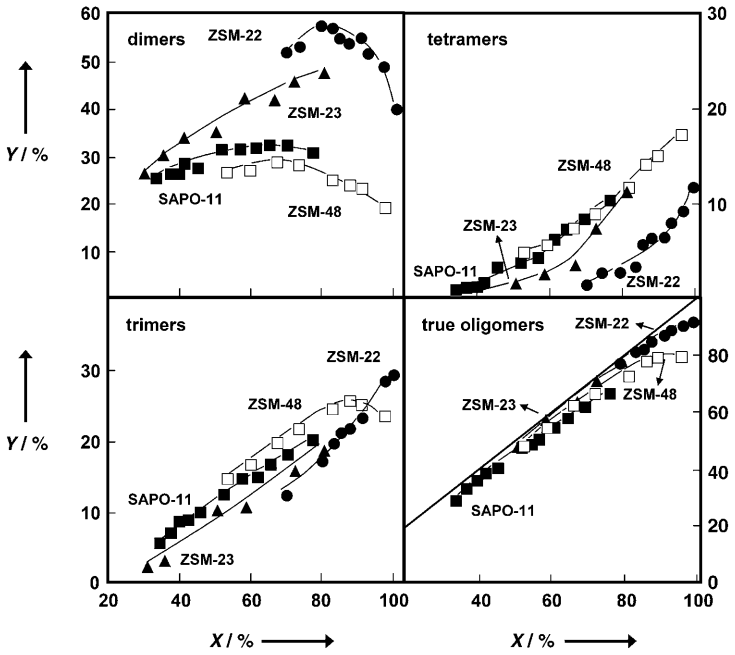

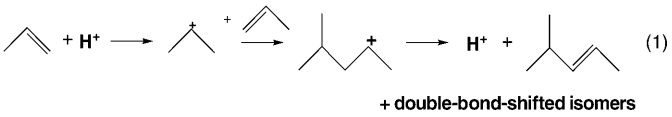

Figure 2. Yield (*Y*) of propene dimers, trimers, tetramers, and of total true oligomers (di- to hexamers, without products with intermediate carbon numbers obtained by cracking and recombination of fragments) against propene conversion (*X*) with ZSM-22, ZSM-23, ZSM-48, and SAPO-11.

indicates that on all four catalysts the true oligomers remain the largest product fraction up to high conversion—for ZSM-23 and ZSM-22 even more pronounced than for SAPO-11 and ZSM-48. Despite the high conversion, also oligomer chain growth was limited. On ZSM-22, the dimer yield peaked at around 80% propene conversion; the trimer yield close to 100% (Figure 2). The highest trimer yields were obtained with ZSM-22. Chain growth was more pronounced on ZSM-23, SAPO-11, and ZSM-48, as noted from the more abundant formation of tetramers and the occurrence of dimer and trimer yield maxima at lower propene conversion.

Given the multitude of possible double-bond and skeletal isomers, the molecular reaction network for propene oligomerization is complex. As double bond positions in the individual dimers were always at equilibrium, selectivity discussions can be limited to the rationalization of the branching of the alkane skeleton obtained after saturation of the double bond. Chain branching was analyzed using gas chromatography with sample hydrogenation (see Experimental Section). In the dimer fraction obtained on ZSM-22 (Figure 3), primary products dominating at low conversion have a carbon skeleton with a methyl branch at C2, as expected for an acid-catalyzed alkylation [Eq. (1)].

(1)

Skeletal isomers with methyl branching at C3 are secondary products obtained by methyl shifts on 2-methyl-

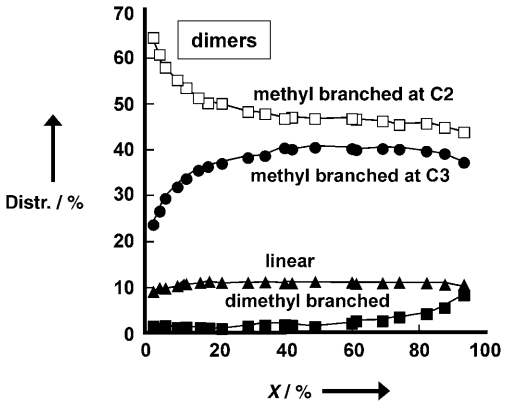

Figure 3. Skeletal distribution of the dimer fraction obtained at increasing propene conversion with ZSM-22.

branched isomers (Figure 3). With ZSM-22, methyl shifts on alkylcarbenium ions were found to be substantially slower than de-branching reactions in which one branch vanishes.[15] Linear dimers observed over the entire conversion range (Figure 3) stem from fast de-branching reactions of 2-methylpentenes. Above 40% propene conversion, linear and methyl-branched dimers are found at equilibrium with ZSM-22 as catalyst (Figure 3). Dimers with dimethyl-branched carbon skeleton were obtained only at high feed conversion. Similar dimers fractions were obtained on the other 10-MR tubular zeolites, except for the more pronounced formation of dibranched dimers on SAPO-11 and ZSM-48.

The NCB in the trimer fractions obtained with 10-MR tubular zeolites is displayed in Figure 4 and compared with that of a typical trimer fraction obtained on SSPA, representative for an oligomerization without any confinement in micropores. The large majority of trimers show a dibranched carbon skeleton (Figure 4), which can be explained by acid-catalyzed oligomerization causing an additional branching upon addition of a novel propene unit to a methyl-branched dimer. Especially with ZSM-23 and ZSM-22, the fraction of

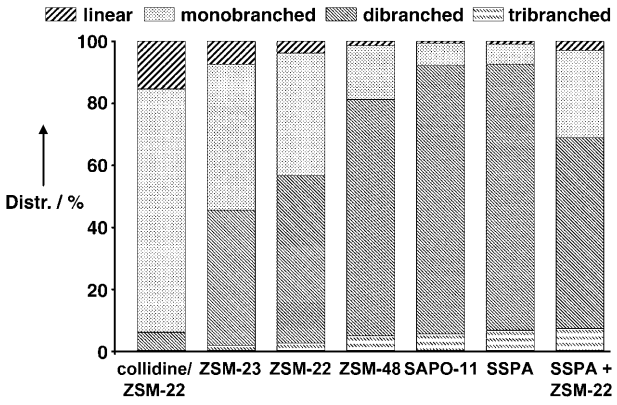

Figure 4. Skeletal distribution of trimer fractions at 30% propene conversion, obtained on collidine-treated ZSM-22, ZSM-23, ZSM-22, ZSM-48, SAPO-11, SSPA, and on successive layers of SSPA and ZSM-22.

trimers with monobranched or linear carbon skeleton is larger than with SSPA. Propene trimers are methyl-branched at carbon positions 3 and 4 (3,4-group isomers) unless the branchings are shifted (2,6-group isomers) or eliminated to give monobranched and linear isomers (monobranched-group isomers).[16] Among the 10-MR tubular pore zeolites the formation of monobranched-group nonene isomers decreases in the series ZSM-23 > ZSM-22 > ZSM-48 > SAPO-11 (Figure 5). The skeletal distribution of the trimer fraction obtained with SAPO-11 is already very similar to that encountered with SSPA (Figure 4).

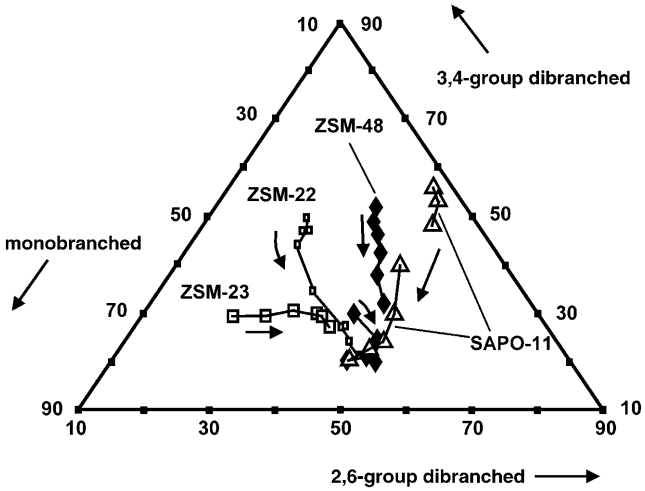

Figure 5. Compositional diagram showing the evolution of the skeletal structures of propene trimers obtained with 10-MR tubular pore zeolites at increasing conversions indicated by the arrows.

Among the known zeolite structure types, those with tubular 10-MRs having a free diameter of around 0.5 nm exhibit the highest heats of adsorption for linear hydrocarbons.[17–22] The free diameters of ZSM-23 pores of $0.45 \times 0.52\ nm^2$ [12] preclude methyl-branched alkanes from entering.[17] The penetration of the same methyl-branched alkanes into the slightly wider ZSM-22 pores with cross sections of $0.44 \times 0.55\ nm^2$ is possible, depending on conditions.[17–20] SAPO-11 belongs to the AEL zeolite family, has a little wider 10-MR of $0.40 \times 0.65\ nm^2$, and readily adsorbs isoalkanes.[21,22] Sorption data on ZSM-48 with its relatively wide 10-MR of $0.53 \times 0.56\ nm^2$ are not available. Catalytic test reactions such as the determination of the constraint index[23] and of the refined constraint index[24] reveal that there is less steric limitation inside SAPO-11 and ZSM-48 pores than inside ZSM-22 and ZSM-23 pores. Thus the observed tendency of debranching of propene trimers in the zeolite sequence of SAPO-11 < ZSM-48 < ZSM-22 < ZSM-23 (Figures 4 and 5) reflects the order of decreasing effective pore width.

The stronger limitation of oligomer chain growth in ZSM-22 compared with ZSM-23 (Figure 2) can be explained as follows: Inside the pores of these two zeolites, the formation of tetramers most likely occurs through propene addition to linear trimers. As ZSM-23 exhibits a stronger tendency to trimer linearization, it shows a more pronounced chain growth. In ZSM-48 and SAPO-11, chain growth can probably also proceed on monobranched trimer chains, explaining why in these zeolites tetramer formation is also more pronounced than in ZSM-22.

As the ZSM-22 crystals are micrometer-sized and the specific external surface area amounts to about $40\ m^2 g^{-1}$, pore mouth sites of ZSM-22 may contribute significantly to catalysis, for example, in catalytic isodewaxing.[25] Acidic sites on the external surfaces and pore mouths of ZSM-22 can be selectively poisoned with collidine (2,4,6-trimethylpyridine), a bulky amine that cannot penetrate the pores of 10-MR zeolites. Whereas the collidine-poisoned ZSM-22 catalyst was about five times less active than the parent sample, the trimer fraction was very rich in monobranched nonenes (80%) and contained a significant amount of linear nonenes (15%) (Figure 4), confirming that catalytic sites located inside the tubular pores are responsible for the formation of monobranched and linear trimers, and that sites accessible to collidine are responsible for the formation of di- and tribranched nonenes. ZSM-22 also shows "coke selectivation" as partially deactivated catalysts were found to be more selective for linear and monobranched nonenes than fresh catalysts, owing to a gradual loss of the contribution of the external sites.

ZSM-22 can be used as hydroisomerization catalyst for converting long-chain *n*-alkanes into mono- and dibranched skeletal isomers,[25] as it establishes the internal equilibrium between the linear alkane, its monobranched isomers, and specific dibranched isomers.[25] This property of ZSM-22 can be exploited to reduce the NCB of the C_9 products obtained from propene oligomerization with SSPA as was shown for the trimer fraction produced in a process with SSPA for which the NCB was reduced from 2.0 to 1.7 during a typical catalytic run (473 K, 6.8 MPa, $W/F_0 = 280\ kg\,s\,mol^{-1}$). The reduction resulted primarily from conversion of dibranched into monobranched and linear nonenes (Figure 4, columns 6 and 7). Tribranched isomers have too little adsorption affinity in pore mouths and are not converted. Dibranched isomers undergo a first de-branching in pore mouths and eventually entire linearization deeper inside the pores.

The ZSM-22 catalysis was also run using feedstock of 50 wt% propene in propane, similar to a process with SSPA. Though with this propene-rich feed, pronounced exothermicity in the catalyst bed was observed, deactivation was minor. Propene conversion remained complete until an amount of propene of at least 400 times the catalyst weight was fed. An incremental increase of catalyst temperature was sufficient to reestablish complete propene conversion. Finally, the experiment was interrupted after the formation of more than 600 kg of oligomer product per kg of catalyst, which is in the range of oligomer yields with SSPA processes. ZSM-22 also brings an important environmental benefit, as it is reusable many times after regeneration and has a much longer lifetime than SSPA which can only be used once. Thus, the use of ZSM-22 in propene oligomerization adds to the sustainability of the petrochemical industry.

Experimental Section

Zeolite samples were synthesized according to published methods: ZSM-22,[26] ZSM-23 was run 4 of reference [27], ZSM-48,[28] SAPO-11[29] was sample S-11/2 of reference [30]. The Si/Al ratio of ZSM-22, -23, and -48 was 42, 44, and 50, respectively. The phase purity was confirmed by XRD and SEM. Gram quantities of as-synthesized zeolite powder were pelletized (0.25–0.50 mm) by compression, loaded in a quartz tube, and calcined, first under flowing nitrogen at 400 °C for 5 h and subsequently under oxygen at 550 °C for 15 h. The samples were exchanged with 0.5 M aqueous NH_4Cl solution and calcined at 400 °C. This procedure resulted in acidic zeolites with more than 99.5 % of the aluminum tetrahedrally coordinated according to ^{27}Al MAS-NMR (signal at 54 ppm against aluminum nitrate reference with a Bruker Avance 400 MHz instrument; spinning frequency of 20 kHz). The FT-IR spectra of the zeolites displayed absorptions at about 3595 and 3745 cm^{-1}, assigned to bridging Al–OH–Si groups with Brønsted acid character and framework-terminating silanol groups, respectively. IR absorption bands at about 3655 cm^{-1}, which are characteristic of hydroxy groups on aluminum atoms that are partially dislodged from the framework and responsible for Lewis acidity, were absent.

The chemical composition of the SAPO-11 material corresponds to $(Si_{0.21}Al_{0.43}P_{0.36})0_2$. The SAPO-11 crystals are composed of 28 % aluminosilicate (AS) and 72 % silicoaluminophosphate (SAP) domains.[30] The catalytic activity of SAPO-11 is mainly due to Brønsted acid sites at the interphase between the AS and SAP domains.

Catalytic experiments in a fixed-catalyst-bed continuous-flow reactor: catalyst pellets of compressed zeolite powder with diameters of 0.25–0.50 mm were loaded in a stainless steel reactor tube with an internal diameter of 9 mm and a length of 300 mm. Empty volume was filled with alumina beads of the same diameter. Reaction conditions: $T = 473$ K; $P = 6.8$ MPa; feedstock: 12 wt % propene in propane; $W/F_0 = 34$ kg s mol^{-1} (W: catalyst weight; F_0: molar propene flow at reactor inlet); liquid feedstock delivered with a liquid mass flow controller (Brooks Instruments). The reactor outlet was sampled online at high pressure using a 4-port HPLC sampling valve (Valco) with an internal volume of 0.1 μL, and analyzed with capillary gas chromatography. Product NCB was determined offline on a gas chromatograph with sample hydrogenation module.

Phosphates

DOI: 10.1002/anie.200501871

The First Structure of a Cerium(IV) Phosphate: Ab Initio Rietveld Analysis of $Ce^{IV}(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$**

Micaela Nazaraly, Gilles Wallez, Corinne Chanéac, Elisabeth Tronc, François Ribot, Michel Quarton, and Jean-Pierre Jolivet*

Since the investigations by König and Alberti in the late 1960s and those by Clearfield in the 1970s, several studies have continued to show that cerium(IV) phosphates (CePs) are interesting inorganic materials for cation exchange, amine intercalation, trapping of radioactive elements, and proton conduction.[1–12] Very recently, cerium(IV) phosphate nanotubes have also been reported.[13] Compared with zirconium, titanium, and tin phosphates, which are well-documented materials used in various fields (ion exchange, intercalation, proton conduction, heterogeneous catalysis, molecular sorption),[14] CePs appear to be much more complex. While the former exhibit two well-characterized lamellar structures, that is, $Zr(HPO_4)_2{\cdot}H_2O$ (α-ZrP)[15] and $Zr(H_2PO_4)(PO_4){\cdot}2H_2O$ (γ-ZrP),[16] based on six-coordinate metal centers, cerium(IV) phosphates appear to adopt several crystalline structures, with P/Ce ratios ranging from 1.1:1 to 3.0:1.[1–12] Despite some efforts and evidences that the structures do not correspond to the α- or γ-ZrP types,[7,9] all these cerium(IV) phosphates structures have remained unknown until now. This lack of information has often made the interpretation of results much more difficult or even impossible. Moreover, in some cases, the chemical composition remains a matter of debate. Indeed, according to its powder X-ray diffraction pattern a unique crystalline compound has, depending on authors, been considered to be $Ce_2O(HPO_4)_3{\cdot}H_2O$, $(CeOH)_2(HPO_4)_3$, $Ce(HPO_4)(PO_4)_{0.5}(OH)_{0.5}$, or $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$.[1a,4a,6,7,9]

This peculiar CeP, which exhibits a P/Ce ratio of 1.5:1 has been described several times in the literature.[1a,3a,4a,6,7,9] A unit cell and possible space groups have even been proposed.[7,9] Moreover, its structure was supposed to be a layered one, even though no amine could be intercalated.[7] However no other structural details were available. As it has been obtained from various cerium(IV) salts (sulfate, ammonium nitrate) or derivatives (hydroxide, oxide) either under reflux or hydrothermal ageing in H_3PO_4 solutions, this crystalline compound seems to exhibit a high degree of thermodynamic stability and, therefore, should offer a relevant first entry in the field of CePs structures. Herein, the structure of $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ is solved by ab initio Rietveld analysis. It consists of $[Ce(PO_4)^+]_n$ slabs bridged by hydrogenphosphate tetrahedra. The chemical nature of the (hydrogen)phosphates is also unambiguously established from the P–O distances and ^{31}P NMR spectroscopy. Importantly, this is the first time a CeP structure is presented.

$Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ was synthesized from CeO_2, H_3PO_4, and H_2O. It consists of crystalline platelets a few microns long in the longest dimension. The compound was found to be monoclinic, with a strong cell elongation along the *a* axis, consistent with the (100) platelet habit of the crystallites. The unit cell parameters were refined from the X-ray powder diffraction data ($a = 21.0142(3)$, $b = 6.55082(7)$, $c = 6.94382(6)$ Å, $\beta = 91.983(1)°$, $V = 955.32(2)$ Å^3) and the results agreed with those reported.[7,9] The structure was solved with the space group *C*2/*c* (No. 15). It can be described as dense $[Ce(PO_4)^+]_n$ slabs, extending parallel to the (*b*,*c*) plane, with cerium atoms on both surfaces (Figure 1). Each cerium atom is connected to four phosphate tetrahedra belonging to the same side and to one phosphate tetrahedron on the opposite surface of the slab. These slabs are bridged by HPO_4^{2-} units and water molecules are also present in the interslab region, which results in eight-coordinate cerium atoms. This structure bears absolutely no resemblance with the α- or γ-ZrP structures.[15,16] The $\{(P1)O_4\}^{3-}$ (slab) tetrahedron is regular (Figure 1), except for the outstandingly small O13-P1-O14 angle (97.1(8)°), which results from the sharing of the O13–O14 edge with a cerium atom. The long P2–O24 distance and the absence of Ce–O24 contact indicate that O24 is the protonated vertex of the $\{H(P2)O_4\}^{2-}$ hydrogenphosphate tetrahedron. The water molecule fills a structural cavity surrounded by eight oxygen atoms of (hydrogen)phosphates and one cerium atom.

Actually, the absence of superstructure peaks indicates some form of disorder in the array of the HPO_4^{2-} and H_2O units. The distances between an HPO_4^{2-} tetrahedron (e.g., the white one (P2) near the center of the cell in Figure 2) and its three closest equivalents (shaded in Figure 2) are too short to allow the occupation of these closest positions. Likewise, the occupation of an HPO_4^{2-} site precludes the presence of a water molecule in the closest H_2O site (d(P2)-O_W) 1.21(1) Å). These two conditions, along with the 50% occupancy of the interslab sites, lead to consideration of two equiprobable sets of alternate HPO_4^{2-} and H_2O units, forming fully ordered zigzags along the *c* axis, shown in different tones in Figure 2. In terms of symmetry, each zigzag still obeys the *c*-mirror axis, but ignores the inversion center and the twofold symmetry. Although neighbor zigzags in the same (*b*,*c*) plane are far enough apart to prevent any overlapping of their sites, the *b* parameter is small and the interactions should be strong

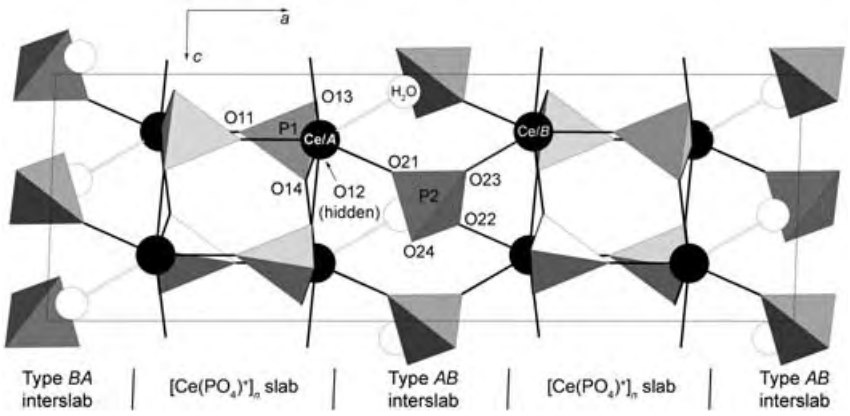

Figure 1. (010) projection of the $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ structure. The random succession of the interslab regions along the stacking *a* axis illustrates the disorder. P–O interatomic distances [Å]: P1-O11 1.543(6), P1-O12 1.518(9), P1-O13 1.52(1), P1-O14 1.53(1), P2-O21 1.50(1), P2-O22 1.51(2), P2-O23 1.52(2), P2-O24 1.61(2). Gray tetrahedra PO_4. The positions Ce/*A* and Ce/*B* are discussed in the text as are the *BA* and *AB* interslab units.

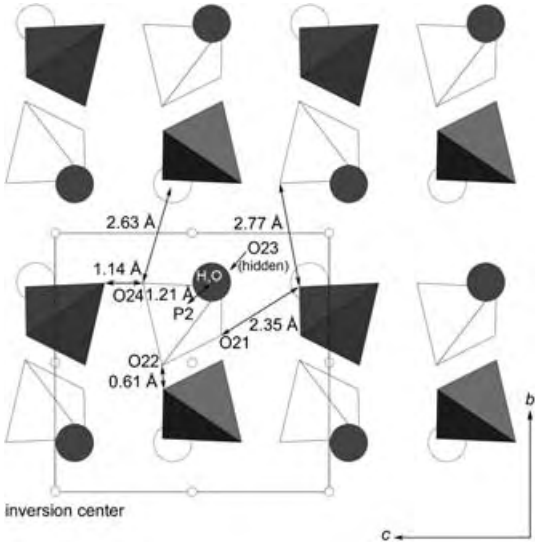

Figure 2. (100) projection of the interslab regions near $x = 1/2$ for the $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ structure. White and shaded units ($H(P2)O_4^{2-}$ tetrahedra and O_w (water oxygen) atoms) represent the two possible and equipropable zigzag models.

enough to keep the structure ordered along the *b* axis (see distances in Figure 2). So, the whole interslab region obeys a *c* symmetry instead of 2/*c*. In contrast, the thickness of the $[Ce(PO_4)^+]_n$ slabs prevents the cerium atom from "seeing" both neighbor layers, thus reducing strongly the ordering interactions along the *a* axis. Indeed, the disorder is likely to affect the stacking axis. The drop of symmetry of the zigzags has repercussions for the cerium atoms. If a pair of cerium atoms that should be equivalent by a twofold symmetry operation is considered for example, Ce/*A* and Ce/*B* in Figure 1, Ce/*A* is linked to atom O21 and the water molecule, while Ce/*B* is connected to atoms O22 and O23 of two different HPO_4^{2-} tetrahedra. Therefore, two different environments must be taken into account for the cerium atoms. They are noted *A* and *B*, hereafter (Figure 3). Note that all cerium atoms on one side of a slab are of the same type, while those facing them on the nearest slab are of the other type. Therefore, each interslab layer has an "*A*" and a "*B*" side, but is randomly either of "*AB*" or "*BA*" type, as shown in Figure 1.

In the course of the Rietveld refinements, attempts were made to measure the effect on the slabs of the disorder in the interslab regions by splitting the cerium atom and the $\{(P1)O_4\}^{3-}$ tetrahedron onto two sites. The cerium atom appeared slightly delocalized along the *a* axis onto two positions, 0.169(5) Å apart, as could be guessed from the two environment types, while the split positions of the P1 and connected oxygen atoms remained very close, but with larger estimated standard deviations (esds). Because this model did not allow correlations between the environment and the position of a slab atom to be established, this model was abandoned. The cerium atom was simply modeled as lying on a single position, with anisotropic harmonic displacement factors, resulting in an *a*-axis elongated thermal ellipsoid (B_{11} 1.27(7), B_{22} 0.10(6), B_{33} 0.12(5), B_{12} 0.1(1), B_{13} 0.04(5), B_{23} 0.10(8) Å^2). Note that the cerium atoms are octacoordinate in both environments (Figure 3), and exhibit

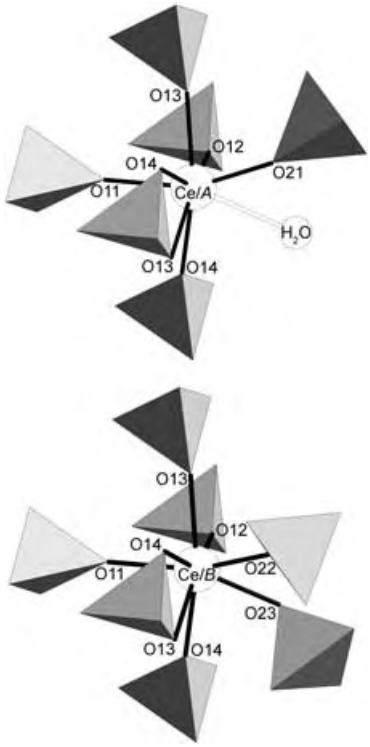

Figure 3. The two possible and equiprobable environments of the cerium atom (top: type *A*, bottom: type *B*) in the $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ structure. Ce–O interatomic distances [Å]: Ce*A*/*B*-O11^{I} 2.235(5), Ce*A*/*B*-O12^{II} 2.206(7), Ce*A*/*B*-O13 2.44(1), Ce*A*/*B*-O13^{III} 2.384(9), Ce*A*/*B*-O14 2.44(1), Ce*A*/*B*–O14^{IV} 2.334(8), Ce*A*-O21 2.22(1), Ce*B*-O22^{V} 2.32(2), Ce*B*-O23^{VI} 2.38(2), Ce*A*-O_w 2.92(2) (with the following symmetry operations: I = 1/2−*x*, 1/2+*y*, 1/2−*z*; II = *x*, 1+*y*, *z*; III = *x*, 1−*y*, 1/2+*z*; IV = *x*, 1−*y*, *z*−1/2; V = 1−*x*, 1−*y*, 1−*z*; VI = 1−*x*, *y*, 1/2−*z*).

nearly equal valences (3.35 and 3.51 for *A* and *B* type cerium, respectively).[17] The slight but non-negligible contribution of the O_W atom in environment *A* accounts for a structural role of the water molecule.

This very same compound, according to its X-ray powder diffraction, has been described in previous works as a cerium(IV) hydroxy(hydrogen)phosphate with the formula $Ce(HPO_4)(PO_4)_{0.5}(OH)_{0.5}$.[4a,6,7] The present structure, and especially the P–O distances, indicate quite clearly that the compound is in fact a cerium(IV) (hydrogen)phosphate hydrate, with the formula $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$. The nature of phosphate units was however confirmed by ^{31}P MAS and CP-MAS NMR spectroscopy (CP-MAS = cross polarization magic-angle spinning), a result of the high sensitivity of such techniques to phosphorus environment.[18,19] The ^{31}P MAS NMR spectrum of $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ (Figure 4) shows three resolved resonance signals at $\delta = -15.7$, -27.3, and -29.2 ppm, with an intensity ratio of 1:1:1. A similar spectrum was previously reported but incorrectly interpreted.[6] Variation of the contact time in ^1H–^{31}P CP-MAS NMR (Figure 4) spectra shows that the signal at $\delta = -15.7$ ppm has a steep magnetization build up, while the two others ($\delta = -27.3$ and -29.2 ppm) have slower ones. From these results it can be inferred that the signal at $\delta = -15.7$ ppm corresponds to a hydrogenphosphate while the others correspond to fully deprotonated phosphates. Accordingly the amount of phosphate is twice the amount of hydrogenphosphate and the formula $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ must be considered. These ^{31}P chemical shifts fall within the regions found for the α- and γ-$M^{IV}P$ structures (M = Zr, Ti) and agree with the generally observed highfield shift of about 10 ppm for the removal of one proton.[19] While there is only one fully deprotonated phosphate environment in the structure, $\{(P1)O_4\}^{3-}$, ^{31}P NMR spectroscopy indicates two similar but different environments. This feature can be related to the occupancy in the interslab region. Indeed, depending on the surface of the slab, that is, corresponding to type *A* or type *B* cerium atoms, P1 has two possible and equiprobable environments which also exhibit different magnetization sources for CP experiments. A P1 atom belonging to a type *A* plane has one $H(P2)O_4$ tetrahedron (P1-O24 3.50 Å) and one water molecule (P1-O_W 3.68 Å) in its near environment, while a P1 atom in a type *B* plane has only one more remote H(P2)O4 tetrahedron (P1-O24 4.07 Å). Accordingly, the signal with the slower magnetization build up ($\delta = -29.2$ ppm) can be assigned to the phosphates in the type *B* planes which have the less-protonated environment.

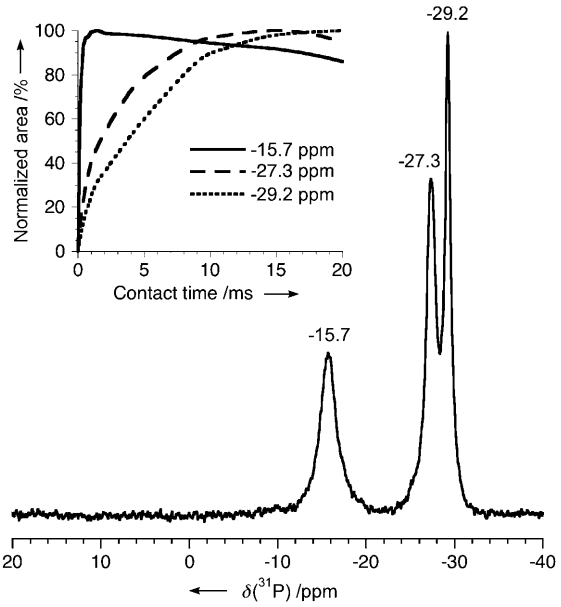

Figure 4. ^{31}P MAS NMR spectrum of $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ ($\nu_{MAS} = 14$ kHz). The inset shows the area of each signal versus the contact time in ^1H–^{31}P CP-MAS NMR experiments.

In conclusion, $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ can be considered to have a layered structure, as previously proposed from sedimentation experiments.[7] However, the bridging hydrogenphosphates hold the slabs tightly together and this simply explains why amine could not be intercalated in such a compound. Of note is that $U_2(PO_4)_2(HPO_4)\cdot H_2O$ and $Th_2(PO_4)_2(HPO_4)\cdot H_2O$, which both exhibit a powder diffraction pattern similar to the one of the homologous compound $Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$ studied here,[9] must have an identical structure to this first reported CeP structure.

Experimental Section

$Ce(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$: Cerium oxide nanoparticles (2.6 g)[20] were dispersed in 1.96 M H_3PO_4 (15 mL; $PO_4/Ce \approx 2.4$). The preparation was then treated hydrothermally at 200 °C for 5 h. The yellow product obtained was collected by filtration, washed several times with distilled water, and dried under a flow of nitrogen.

X-ray powder diffraction (XRD) patterns were recorded on the BM01B line of the European Synchrotron Radiation Facility (Grenoble, France). The instrument parameters were previously refined from a LaB_6 pattern. The powder sample was placed in a 0.3 mm capillary and the data were collected at 293 K, using a wavelength of 0.69947 Å and a Ge(111) rear monochromator. The data were scanned between 4.062 and 55.488° (2θ), with a step of 0.006°, and 1247 reflections were observed. Assuming, as a rule of thumb, a rough 20 $Å^3$ volume per oxygen atom, the number of formula units in the cell was found to be $Z = 4$. Systematic extinctions led space groups *Cc* and *C*2/*c* to be considered, and the structure resolution was initiated with the *Cc*. FullProf.2k[21] was run in profile-matching mode to extract the diffracted intensities and to correct them from absorption. The broadening of the *h*-dependent peaks, resulting from the crystallite shape (platelet), was taken into account when modeling the peaks shapes. The background fitting was made by interpolation between selected points. Eight positions and profile parameters were used. The profile model was a Thompson–Cox–Hasting with anisotropic size and strain effect. A Patterson synthesis performed with Shelx-97[22] allowed the cerium atoms to be located, the other atoms were found by observation of the Fourier maps.[23] The cerium atoms and some of the phosphates appeared to form dense $[Ce(PO_4)^+]_n$ blocks extending parallel to the (*b*,*c*) plane. At this point, the presence of a twofold symmetry between the cerium atoms, as well as between the electron densities became so obvious that the space group was changed for *C*2/*c*. HPO_4^{2-} units and the oxygen atom O_W of the H_2O molecules were found in the interblock spaces, on half-occupied sites in agreement with the stoichiometry and the symmetry (indeed, a joint refinement gave a 0.47(1) occupancy for the interblock sites). To reduce the number of parameters, anisotropic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thermal factors were only used for the cerium atom. A single isotropic displacement factor was used for both phosphorus atoms and an other isotropic displacement factor for all the oxygen atoms. Finally, 44 parameters were refined and gave satisfactory reliability factors ($R_P = 0.060$, $R_{WP} = 0.084$, $R_{Bragg} = 0.055$, $R_{exp} = 0.053$, $R_F = 0.029$, and $\chi^2 = 9.5$).[24] Note that because of the low electron weight of the HPO_4^{2-} unit, the O-P-O angles and P–O distances had to be put under soft constraints, taking those of K_2HPO_4 as reference.[25]

^{31}P MAS NMR spectroscopy was performed at 121.5 MHz on a Bruker Avance 300 spectrometer, using a 4-mm locked Bruker probe. Chemical shifts are quoted relative to 85 % H_3PO_4.

electrochemical oxidation of formic acid on Pt and Pt-group metals, instabilities can cause spontaneous potential and current oscillations under galvanostatic (constant current) and potentiostatic (constant potential) conditions, respectively. The electrooxidation of formic acid is one of the most fundamental electrocatalytic systems and has a great relevance to low-temperature fuel cells; therefore, the mechanism of the oscillations has long been the focus of experimental[3] and theoretical[3b,c,4] investigations.

It is generally accepted that the oxidation of formic acid follows the so-called "dual-pathway" mechanism[5]: one path involves a fast reaction via a reactive intermediate (direct path) and the other path includes a step in which an inhibiting intermediate is formed (indirect path). The reactive intermediate is generally assumed to be a carboxylic acid species (COOH) adsorbed on the surface through the C atom, whereas adsorbed CO produced by dehydration of formic acid has definitely been identified as the poisonous species by in situ IR reflection–absorption spectroscopy (IRAS).[6] The electrochemical oscillations in the oxidation of formic acid have been explained basically in terms of the dual-pathway mechanism: the periodic adsorption and oxidative removal of CO inhibits and accelerates, respectively, the direct path. The ohmic drop (iR, where i is the current and R is the resistance of the electrochemical system) also plays an important role, and current oscillations result from the interplay of chemical and electrical variables.[2,3g,4a,4c] Nevertheless, the details of the oscillations are still controversial[2–4] and further investigations are required.

The identification of the reactive intermediate and probing of the reaction dynamics are essential for a full understanding of the oscillations. Infrared spectroscopy is suitable for this purpose. Honda et al.[7] studied current oscillations by time-resolved IRAS and reported that CO coverage does not change during the oscillations. This result is inconsistent with the general consensus, and these authors proposed a model in which the periodic adsorption and desorption of the OH species ($H_2O \rightleftarrows OH_{ads} + H^+ + e^-$) results in current oscillations. However, the observed current is much larger than that expected from the adsorption and desorption of the OH species. We reexamined the current oscillations by an alternative IR spectroscopy method having a sensitivity higher than that of IRAS, namely, surface-enhanced infrared absorption spectroscopy (SEIRAS) in a Kretschmann-type attenuated-total-reflection (ATR) mode,[8] and found that the reactive intermediate is not COOH but formate (HCOO) adsorbed on the electrode surface through two oxygen atoms. Note that formate is different from the COOH species in molecular structure. On the basis of the results reported herein, we propose a new mechanism of current oscillations that is largely different from those suggested earlier.[3,4]

Figure 1a shows a typical current oscillation pattern observed in 0.5 M H_2SO_4 + 1 M formic acid solution after stepping the electrode potential (E) from 0.05 to 1.1 V versus a reversible hydrogen electrode (RHE, to which all potentials hereafter are referred). The electrode used was a thin ($\approx$50 nm) polycrystalline Pt film deposited on the reflecting plane of a Si ATR prism by an electroless deposition technique.[9] A 30-Ω resistor was connected to the electrochemical system in series for observing the oscillations.[2,3g,4a,4c]

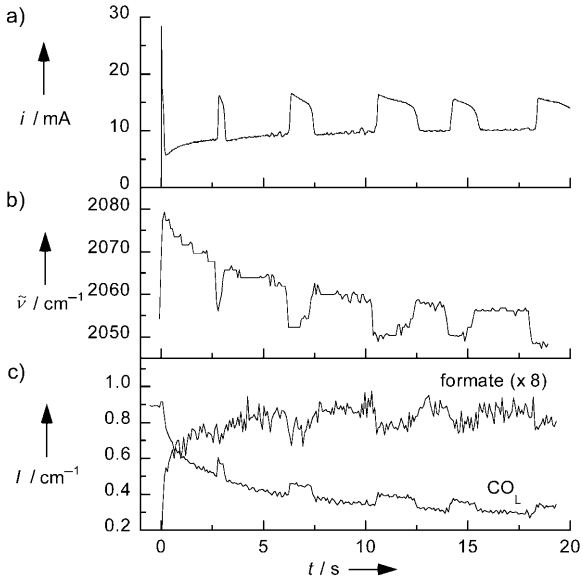

Figure 1. a) Current oscillations observed in the oxidation of formic acid at a constant potential of 1.1 V (RHE) in 0.5 M H_2SO_4 + 1 M HCOOH with a 30-Ω external resistor. b) Peak position of CO adsorbed at an atop site (CO_L). c) Integrated band intensities of CO_L and formate taken from a series of SEIRA spectra acquired simultaneously with the current–time curve.

The high sensitivity of ATR-SEIRAS enabled the time-resolved monitoring of the reaction processes occurring on the Pt electrode during the current oscillations with a time resolution of 80 ms (Figure 2). The spectral data correspond to the 10–15 s region in Figure 1a. A spectrum collected at 0.05 V in the pure electrolyte without formic acid was used as the reference. Other details of the spectral measurements have been described elsewhere.[8–10] Three bands at $\approx$2060, $\approx$1850, and 1320 cm^{-1} change their intensities and/or peak positions periodically. These bands have been assigned, from

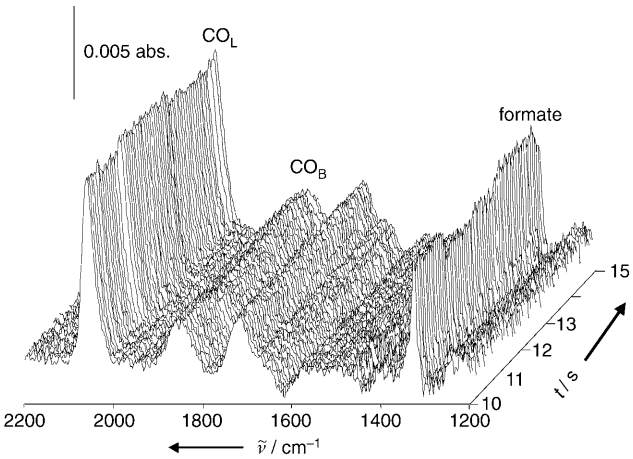

Figure 2. Time-resolved SEIRA spectra of the Pt electrode surface acquired during the current oscillations with a time resolution of 80 ms, which corresponds to the 10–15 s region in Figure 1a. A spectrum of the bare Pt surface collected at 0.05 V in the pure supporting electrolyte without formic acid was used as the reference.

higher to lower, to the stretching modes of CO molecules adsorbed at atop and bridge sites (denoted as CO_L and CO_B, respectively) and to the symmetric OCO stretching mode of formate adsorbed in a bridging configuration (bonded through both oxygen atoms to two Pt surface atoms).[9a] The band at 1720 cm^{-1} corresponds to the C=O stretching mode of formic acid in the bulk solution and thus does not change its intensity. The peak position ($\tilde{\nu}$) of the CO_L band and the integrated intensities (I) of the CO_L and formate bands are plotted in Figure 1 b and c, respectively, as a function of time. The intensity data for CO_B are omitted owing to their negligibly small change. The temporal changes of the spectral features are synchronized with the current oscillations. The CO_L band increases in intensity and decreases in peak position when the current increases (and vice versa), while the change of the formate band intensity is the opposite.

It is well-known that the CO_L band shifts to higher frequencies as the electrode potential increases as a result of the Stark effect and/or electron back-donation from the metal to the $2\pi^*$ orbital of CO.[11] Note that the potential that determines the peak position of the CO vibration is not the externally applied potential E but the potential drop across the double layer, ϕ ($= E - iR$). The peak shift observed during the oscillations can be explained by the change in ϕ; by taking into account the total resistance of the system of 35 Ω (the external resistance of 30 Ω + the measured solution resistance of 5 Ω), ϕ is roughly estimated to be 0.6 and 0.8 V in the high- and low-current states ($i \approx 15$ and ≈ 10 mA), respectively. Consequently, the peak position of the CO_L band is shifted in association with the current oscillations. The global red-shift of the peak position can be ascribed to the gradual decrease of CO_L coverage (nearly proportional to the band intensity, Figure 1 c) through the changes in the dipole–dipole interaction among CO molecules and in the electron back-donation.[11,12]

The temporal changes of the band intensities of CO_L and formate can also be explained by the change of ϕ. The linear-sweep voltammogram shown in Figure 3 a (solid curve) was recorded in the same solution at a sweep rate of 50 mV s^{-1} without the external resistor and by correcting for the ohmic drop arising from the solution resistance (that is, $E = \phi$). The oxidation current is found to be higher at 0.6 than at 0.8 V, which is consistent with the current–time curve (Figure 1 a). Associated with the increase of the potential, the band intensity of CO_L decreases by oxidation and that of formate increases, which is also consistent with the spectral changes observed for the transient from the high-current state to the low-current state. A SEIRAS measurement for a potential step from 0.8 to 0.6 V, which corresponds to the reverse transient from the low-current to the high-current state, showed that the formate band intensity decreases quickly and the CO_L band intensity increases slowly.[13] The slow kinetics of CO formation explains the gradual decrease of the global CO band intensity during the oscillations (Figure 1 c).[14]

It is well-established that formic acid is decomposed to CO_2 through adsorbed formate on Pt in ultrahigh vacuum (UHV) and in the gas phase (CO is also produced by a side reaction).[15] Different from the reaction scheme under these conditions, COOH has long been assumed to be the reactive

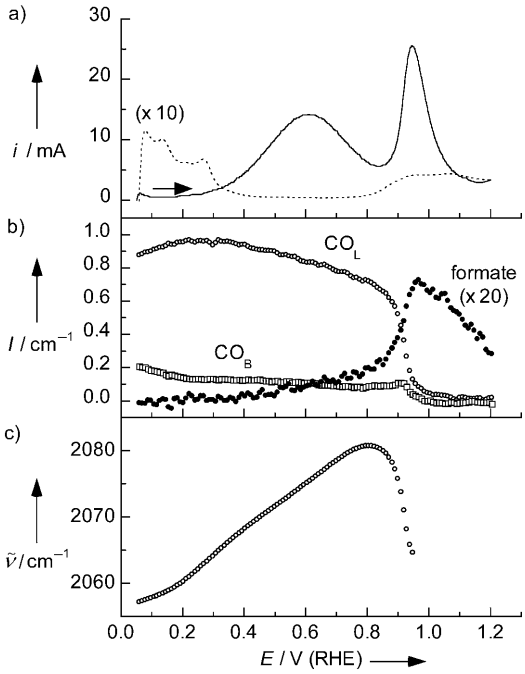

Figure 3. a) Linear-sweep voltammograms for the Pt electrode in 0.5 M H_2SO_4 with (——) and without (-----) 1 M HCOOH recorded at a sweep rate of 50 mV s^{-1} by correcting for ohmic drops. b) Integrated band intensities of CO_L, CO_B, and formate and c) peak position of CO_L plotted as a function of potential. The spectral data were taken from a series of SEIRA spectra acquired simultaneously with the solid-line voltammogram.

intermediate in the electrooxidation of formic acid without any clear experimental evidence. Despite the very high sensitivity of ATR-SEIRAS and very careful examinations, we could not detect any bands corresponding to this species. Instead we observed that formic acid is chemisorbed on the electrode as formate during the oxidation. Adsorbed formate has not been detected by IRAS, as a consequence of the limited mass transfer arising from the thin-layer geometry required for IRAS as discussed in our previous paper.[9b] As shown in Figure 3, the rapid oxidative removal of CO at $E >$ 0.8 V results in sharp increases of the formate band intensity and the oxidation current, which suggests that adsorbed formate is a reactive intermediate. With reference to the well-established reaction mechanism of formic acid oxidation in UHV and the gas phase, the electrooxidation scheme via adsorbed formate is very likely, and quite reasonable. Support for the oxidation via formate was obtained by a quick solution-exchange experiment (from $H^{13}COOH$ to $H^{12}COOH$, or the reverse) at a fixed potential of 0.6 V,[13] which showed that adsorbed formate species are completely replaced by those supplied from the solution within 1 s. The rate is fast enough to explain the observed current. An additional potential-step experiment from 1.5 V, where no carbonaceous species exist on the electrode surface, to 0.6 V showed that adsorption of formate is very fast and saturates within 80 ms (the time resolution used). Therefore, the decomposition of formate to CO_2 is believed to be the rate-determining step. However, isotopic substitution for adsorbed

CO was negligibly slow and thus the indirect path scarcely contributes to formic acid oxidation.

Adsorbed CO can suppress the oxidation of formic acid by blocking vacant sites for formate adsorption. Consequently, the rapid oxidative removal of CO at $E > 0.8$ V leads to an increase of formate coverage and results in a sharp increase of the oxidation current (Figure 3). However, the situation is different in the potential range of 0.6–0.8 V where the current oscillations occur: the oxidation current decreases despite the decrease of CO and the increase of formate. This result indicates that the reaction rate (that is, current) is not a simple function of formate coverage. The suppression of the reaction at $0.6 < E < 0.8$ V, often termed as the negative differential resistance (NDR), plays a decisive role in the oscillation and has been discussed extensively in earlier studies.[2–4] Adsorbed OH species have generally been assumed to cause the NDR. For example, Strasser et al.[3g,4c] proposed that all CO species are oxidized in the NDR region and the adsorption of OH species at vacant sites generated by CO removal block the direct path via COOH formation. This proposal is, however, inconsistent with our data (Figure 3). In addition, the current arising from OH adsorption is not observed at $E < 0.8$ V in the pure supporting electrolyte (Figure 3, dashed curve). Even if the adsorption of OH species could be possible, it would be suppressed by the adsorption of formate.

A hint to help understand the NDR has been given by UHV studies of the decomposition of formate and acetate to CO_2 on transition-metal surfaces.[16] The rate of the decomposition is remarkably slowed down at high formate (or acetate) coverage (θ_f), and once the reaction is initiated the rate is increased *explosively*, which is called surface explosion.[16] The suppression of the reaction before the explosion has been explained by the adsorbed species themselves blocking each other's decomposition by steric hindrance.[16b,c] The necessity for the suppression is high *local* coverage (practically independent of the global coverage).[16b,c] This condition is likely to be fulfilled in the electrooxidation of formic acid, judging by the potential dependence of the CO_L vibrational frequency (Figure 3c). Recalling that the vibrational frequency is a function of both potential and coverage,[11,12] the linear potential dependence up to 0.8 V indicates that CO_L is oxidized without changing the dipole–dipole interactions. This result can be understood by assuming that CO is oxidized to form islands of vacant sites (that is, through a nucleation-and-growth mechanism) and formate is adsorbed at the generated vacant sites (by forming islands of formate).

The rate of decomposition of formate (or acetate) is given by the second-order rate equation (1) by modifying the original rate equation[16] to include CO coverage ($\theta_{CO} = \theta_{CO_L} + 2\,\theta_{CO_B}$).

$$-\frac{d\theta_f}{dt} = k\,\theta_f(1-2\,\theta_f-\theta_{CO}) \qquad (1)$$

The factor 2 of θ_f and θ_{CO_B} arises from the requirement of two vacant sites for the adsorption of these species. The θ_f dependence of the reaction rate is schematically shown in Figure 4 for low and high CO coverages. These plots show that the rate decreases with an increase of CO coverage and also with an increase of θ_f crossing $(1-\theta_{CO})/4$ (the coverage at which the reaction rate is maximal). Formate coverage

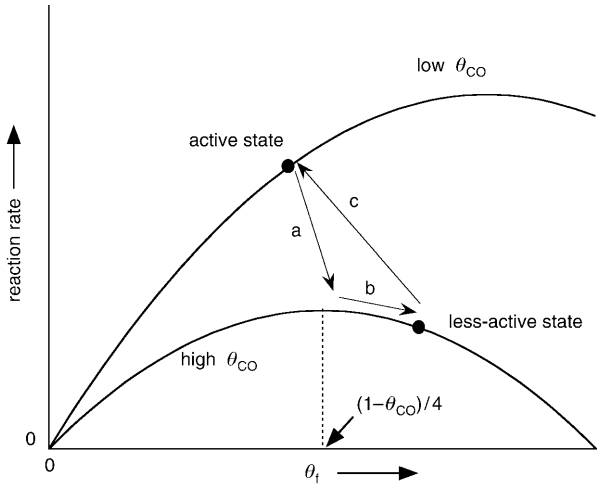

Figure 4. Schematic drawing of the formate coverage (θ_f) dependence of the reaction rate for high and low CO coverages (θ_{CO}) calculated by Equation (1).

increases almost linearly with the potential and CO coverage does not change significantly at $E < 0.8$ V (Figure 3). Therefore, the curves can be regarded as voltammograms by replacing θ_f coverage with potential, although the actual system is more complicated on account of the potential dependence of rate constants and the effect of the diffusion of formic acid.[4] The second-order rate equation (1) can reasonably explain the voltammmetric behavior in the low-potential region (that is, the current peak centered at 0.6 V and the NDR). By using this figure, the current oscillation can be explained as follows. Starting from the active (high-current) state, CO adsorption decreases the reaction rate (a), which results in an increase of ϕ and leads to an increase of formate coverage (b). The increase of formate coverage suppresses formate decomposition and increases ϕ further (that is, autocatalytically) to reach the less-active (low-current) state. Once ϕ reaches a certain high value, both CO oxidation and formate decomposition are accelerated, and the system is shifted to the initial active state (c).

Notably, Wojtowicz et al.[3b] proposed a nonlinear rate equation similar to Equation (1) to explain oscillations in the electrooxidation of formic acid, and they showed mathematically that such nonlinear rate equations are indispensable for oscillations, although the reaction mechanism assumed was totally different from that found herein. A mathematical analysis by the same procedure showed that sustained oscillations are possible in the framework of our new mechanism.[13]

In conclusion, we observed that formic acid is oxidized to CO_2 on Pt electrodes via adsorbed formate and that the decomposition of formate is rate-determining. The result forced us to revise earlier models of current oscillations to include adsorbed formate. The central part of the model proposed herein is that formate species suppress each other's

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

decomposition. Adsorbed CO acts not only as a site-blocking species but also suppresses the decomposition of formate. Coupled with the change in ϕ, the oxidation and formation of CO modify the rate of formate decomposition and lead to current oscillations.

[14] The rate of CO formation decreases as the potential is increased or the oxidation overwhelms the adsorption at high potentials. Consequently, the slow growth of the CO_L band is not observed clearly in the high-current state where ϕ increases gradually with time. Nevertheless, it can lead to the long-term gradual decrease of the global CO_L band intensity.

Preparation of a Hydroperoxo Zinc(II) Intermediate**

*Akira Wada, Syuhei Yamaguchi, Koichiro Jitsukawa, and Hideki Masuda**

Among biological transition-metal ions, in many cases, a Zn^{II} ion serves as a Lewis acid without participating in an electron-transfer reaction. In the late 1960s, it was discovered that copper/zinc-containing proteins (copper zinc superoxide dismutase, CuZn SOD) were capable of catalyzing the disproportionation of a superoxide ion to give molecular oxygen and hydrogen peroxide. The mechanism is considered to progress by alternating reduction/oxidation of the copper atom at the active site (first step, $O_2^{\cdot-} + Cu^{II} \rightarrow O_2 + Cu^{I}$; second step, $Cu^{I} + O_2^{\cdot-} + 2H^{+} \rightarrow Cu^{II} + H_2O_2$).[1,2] As the crystal structure of CuZn SOD indicates an imidazolate-bridged heteronuclear Cu–Zn center at the active site,[3,4] many model complexes that include copper and/or zinc ions have been synthesized and studied to understand the mechanism of disproportionation of superoxide.[5,6] However, these studies have yielded a limited amount of useful information on the formation and physicochemical properties of a metal hydroperoxide intermediate that is suggested in the second step of the SOD reaction.[7]

We have previously synthesized a mononuclear copper(II) hydroperoxide complex by using a new ligand, bis[(6-pivalamido-2-pyridyl)methyl][(2-pyridyl)methyl]amine (H_2bppa).[8] Previous investigations have suggested that copper hydroperoxide complexes tend to decompose in air to generate highly toxic hydroxyl or hydroperoxyl radicals.[9,10] Such a copper hydroperoxide species appears to be unable to release H_2O_2 efficiently with the acceptance of a proton. Thus, it would be very significant to characterize a Zn–OOH species. There is no report for the preparation of a zinc(II) hydroperoxide complex hitherto, although the preparation of a zinc(II) alkylperoxide complex was reported recently.[11] Herein, we describe the preparation and characterization of a Zn^{II}–OOH species by using a tripodal pyridylamine ligand, bis[(6-neopentylamino-2-pyridyl)methyl][(2-pyridyl)methyl]-

amine (H_2bnpa), and we compare the Zn complex with the corresponding Cu–OOH complex.

The initial mononuclear Zn^{II} hydroxide complex, [Zn(H_2bnpa)(OH)]$^+$ (**1**),[12] was prepared from the reaction of the ligand H_2bnpa with [Zn^{II}–OH]$^+$ in methanol/water. The crystal structure obtained from a single crystal of recrystallized **1**-ClO_4 revealed a trigonal-bipyramidally coordinated Zn^{II} with the hydroxide ion in an axial position (see Supporting Information).[12] The coordination of an hydroxide ion was also confirmed by the ^{1}H NMR spectrum of the product, which had a signal from the hydroxide hydrogen atom at 2.04 ppm (singlet) in [D_3]MeCN (see Supporting Information), and by the IR spectrum, which had ν(O-H) stretching vibration at $\bar{\nu} = 3626\ cm^{-1}$.

The reaction of **1** with H_2O_2 (approximately 20 equiv) in [D_3]MeCN solution at 20 °C gave new ^{1}H NMR signals characteristic of a trigonal-bipyramidal Zn^{II} complex, **2** (Scheme 1), which were accompanied by the disappearance

Scheme 1. Synthesis of **2** and **3** from **1**.

of the Zn–OH proton signal and appearance of a new singlet at 7.77 ppm. This signal falls within the range found for protons of HOO^- ions bound to metal centers that were reported previously.[13,14] The intensity of the singlet signal decreased with gradual addition of D_2O ($\approx 6\ \mu L$). Furthermore, upon treatment with D_2O_2, the signal at 7.77 ppm was not detected, although signals associated with the H_2bnpa ligand of **2** were obtained. Thus, these observations allow us to assign the proton signal as a resonance derived from a hydroperoxide ion coordinated to the zinc complex.

The formation of the Zn–OOH species was also monitored by ESI mass spectrometry (see Supporting Information). A solution of **1** in MeCN treated with $H_2{}^{16}O_2$ or $H_2{}^{18}O_2$ afforded prominent positive-ion peak clusters at *m*/*z* 557 or 561, respectively. These observed masses and isotope patterns correspond to the [Zn(H_2bnpa)($^{16}O_2$H)]$^+$ and [Zn(H_2bnpa)($^{18}O_2$H)]$^+$ ions. With D_2O_2 instead of H_2O_2, the peak at *m*/*z* 557 shifts to 560, which suggests that [Zn(D_2bnpa)(O_2D)]$^+$ is generated. These spectroscopic data provide strong evidence for the formation of a mononuclear Zn^{II} hydroperoxide complex, [Zn(H_2bnpa)(OOH)]$^+$ (**2**), in solution. The robust ligation of the hydroperoxide ion to Zn^{II} appears to be stabilized by hydrogen-bonding interactions between the amino hydrogen atoms of **2** and a hydroperoxo oxygen atom. This hydrogen-bonding interaction is confirmed by a larger down-field shift ($\delta = 4.43$ ppm) of the amine proton signals relative to that of free ligand H_2bnpa.

At this stage, it is very important to examine which of the metal hydroperoxide species has higher basicity, Zn^{II}–OOH or Cu^{II}–OOH, because in the second step of the CuZn SOD mechanism, efficient protonation of the hydroperoxide ion is required for rapid liberation of H_2O_2.[3,4,7] To investigate the nucleophilicity/basicity of mononuclear hydroperoxo complexes of Zn^{II} and Cu^{II}, the reaction with CO_2 was carried out according to previously reported procedures.[15] Bubbling CO_2 into an acetonitrile solution of **1** treated with H_2O_2 produced an ESI mass spectrum with a new peak cluster at *m*/*z* 564, whose isotope pattern corresponds to [{Zn(H_2bnpa)}$_2$-(CO_4^{2-})]$^{2+}$ (**3**). Compound **1** reacts with CO_2 to form a species containing {Zn–OCO_2H}$^-$;[16] the resulting change in the ESI spectra (see Supporting Information) implies that the {Zn^{II}–OCO_2H}$^-$ species once formed immediately reacts with the generated peroxide complex **2**, followed by release of water to afford the stable dinuclear zinc complex **3** (see Scheme 1). The formation of **3** observed under very low concentrations of CO_2 is ascribed to an extraordinary high nucleophilicity/basicity of a hydroperoxide ion bound to a Zn^{II} center.

A colorless single crystal of **3**-2ClO_4 suitable for X-ray diffraction analysis was obtained from a THF/Et_2O solution of **2** kept at 0 °C under atmospheric CO_2. As shown in Figure 1, the crystal structure of **3** indicates that the peroxy-

carbonate ion bridges the Zn1 and Zn2 sites, whose coordination environments are distorted octahedral and trigonal-bipyramidal, respectively, in a μ-η^1:η^2 fashion. The two exchangeable coordination sites of the Zn1 center are occupied by the peroxide and carbonyl oxygen atoms of the peroxycarbonate ion in a bidentate fashion with Zn1–O1 and Zn1–O3 bond lengths of 2.002(4) and 2.111(4) Å, respectively, and a O2-C1-O3 angle of 123.1(5)°. The remaining carboxylate oxygen atom of the peroxycarbonate ion is coordinated to the Zn2 site with a Zn2–O4 bond length of 1.987(4) Å.

The O1–O2 bond length is 1.474(5) Å, which is within the range for known metal alkylperoxide complexes (1.36–1.52 Å) and close to that of H_2O_2 (1.49 Å).[17] This bond is slightly longer than those of the previously reported peroxycarbonate metal complexes, $KH(O_2C(O)O)\cdot H_2O_2$ (1.457(2) Å)[18] and $Ph_4P[Fe(quinaldate)_2(O_2C(O)O)]\cdot 1.5\,CH_3OH\cdot 0.5\,(CH_3)_2NCHO$ (1.455(5) Å),[19] which suggests that the peroxy oxygen atoms of the peroxycarbonate ion are derived from hydroperoxide bonded to **2**. For the shortest bond of the peroxycarbonate ligand, C1–O2 (1.320(7) Å) compared with C1–O3 (1.212(7) Å) and C1–O4 (1.290(6) Å), some double-bond character can be assumed. Moreover, as demonstrated by ^{1}H NMR spectroscopic analysis for **2**, the two amine hydrogen atoms stabilize the binding of the peroxycarbonate ion, which is also evidenced by the hydrogen-bond lengths (2.928(8), 2.954(8), 2.884(7), and 3.004(8) Å; see Figure 1). This structure determination is the first of a dinuclear zinc(II) complex with a peroxycarbonate ion in μ-η^1:η^2-coordination mode.

The behavior described above suggests that the hydroperoxo group of complex **2** is nucleophilic towards CO_2. Next, we examined the reactivity of the corresponding Cu^{II} complex with H_2bnpa to compare the nucleophilicity/basicity of the Cu–OOH and Zn–OOH species. However, both $[Cu(H_2bnpa)(OOH)]^+$ and the previously reported complex $[Cu(H_2bppa)(OOH)]^+$ did not show such a nucleophilic reactivity,[8] although the carbonate complex is also generated by the reaction of Cu–OH(H_2bnpa/H_2BPPA) with CO_2. This result suggests lower nucleophilicity/basicity of a hydroperoxide ion bound to Cu^{II}, which is reasonably interpreted in terms of the decrease in electron density on the hydroperoxide oxygen atom due to its stronger binding to Cu^{II} than to Zn^{II}. Thus, only hydroperoxide bound to Zn^{II} may be sufficiently nucleophilic/basic to attract electrophilic molecules such as CO_2.

In summary, we have described the generation, spectroscopic characterization, and reactivity of a novel mononuclear Zn^{II} hydroperoxide intermediate. We have also performed the first X-ray crystallographic characterization of a dinuclear zinc peroxycarbonate complex. A comparison of the electronic and structural properties of the hydroperoxo complexes of Zn^{II} and Cu^{II} may indicate the role of Zn^{II} in the second step of the catalytic cycle of CuZn SOD.

Experimental Section

General: All reagents and solvents were obtained from commercial sources and were used as received unless otherwise noted.

Caution! The perchlorate salts used in this study are all potentially explosive and should be handled with care.

Preparation of **1**-ClO_4: A solution (pH 6.5–7, 300 mL) containing {Zn(OH)} species was prepared by mixing $Zn(ClO_4)_2\cdot 6H_2O$ (178.8 mg, 0.48 mmol) and KOH in methanol/water (1:1). A solution of H_2bnpa (184.3 mg, 0.4 mmol) in a mixture of methanol and water (1:1, 80 mL) was added dropwise to the reaction mixture at room temperature. After 30 min, the solvent was removed in vacuo to leave a white powder. Recrystallization from methanol at 25 °C afforded colorless crystals of $[Zn(H_2bnpa)(OH)]ClO_4$ (0.19 g, 74% yield) suitable for X-ray diffraction measurements (the structure of **1**-ClO_4 is the same as that reported previously, see Supporting Information).[12b]). ^{1}H NMR: see Supporting Information. Elemental analysis (%) calcd for $C_{28}H_{41}N_6O_5ZnCl$: C 52.34, H 6.43, N 13.08; found: C 52.40, H 6.43, N 13.10. MS (ESI) m/z: 541 $[Zn(H_2bnpa)(OH)]^+$.

Preparation of **3**-$(ClO_4)_2$: The treatment of **1** (12.8 mg, 20 μmol) with H_2O_2 in MeCN (0.4 mL) afforded a solution containing **2**. CO_2 dissolved in THF (0.1 mL) was added dropwise to this solution at 0 °C. Crystallization from MeCN/THF/Et_2O in air gave colorless crystals of $[\{Zn(H_2bnpa)\}_2(CO_4)](ClO_4)_2\cdot(CH_3CH_2)_2O\cdot CH_3CN$ (2.63 mg, 38% yield). Elemental analysis (%) calcd for $C_{63}H_{93}N_{13}O_{13}Zn_2Cl_2$: C 52.46, H 6.49, N 12.62; found: C 52.54, H 6.21, N 12.44. MS (ESI): m/z: 564 $[\{Zn(H_2bnpa)\}_2(CO_4)]^{2+}$, 1227 $[\{Zn(H_2bnpa)\}_2(CO_4)(ClO_4)]^+$. ^{13}C NMR (100 MHz, [D$_3$]MeCN, 25 °C, TMS): δ = 207.8 ppm (s, OC(O)OO).

Preparation of $[Cu(H_2bnpa)(OOH)]^+$: The treatment of $Cu(ClO_4)_2\cdot 6H_2O$ (148.2 mg, 0.4 mmol) with H_2bnpa (184.3 mg, 0.4 mmol) and KOH (22.4 mg, 0.4 mmol) in MeCN (0.4 mL) afforded a solution containing $[Cu(H_2bnpa)(OH)]^+$. H_2O_2 (4.0 mmol) was added dropwise to the solution of $[Cu(H_2bnpa)(OH)]^+$ at −40 °C. The mononuclear hydroperoxo copper(II) complex $[Cu(H_2bnpa)(OOH)]^+$ was characterized spectroscopically. UV/Vis (MeCN): λ_{max} = 380 nm (hydroperoxide-to-copper(II) charge transfer transition); ESR: $g_\perp$ = 2.22, $g_\parallel$ = 2.00, $|A_\perp|$ = 94 G, $|A_\parallel|$ = 100 G at 77 K; ESI MS: m/z: 556 $[Cu(H_2bnpa)(^{16}O_2H)]^+$, 560 $[Cu(H_2bnpa)(^{18}O_2H)]^+$; resonance Raman spectra: $\tilde{\nu}$ = 847, 800 cm^{-1} ($\nu(^{18}O\text{-}^{18}O)$); see Supporting Information.

X-ray crystal-structure analysis of **3**-$(ClO_4)_2$: A colorless single crystal suitable for X-ray structure analysis was obtained from a THF/Et_2O solution. Crystal data: $C_{61}H_{90}N_{12}O_{13}Cl_2Zn_2$, M_r = 1401.12, triclinic, space group $P\bar{1}$ (no. 2), a = 13.355(2), b = 26.039(5), c = 10.785(3) Å, α = 101.72(2), β = 98.93(2), γ = 75.39(1)°, V = 3510.5(7) Å^3, Z = 2, ρ_{calcd} = 1.325 g cm^{-3}, μ = 8.26 cm^{-1}, $Mo_{K\alpha}$ radiation (λ = 0.71070 Å), T = 173 K, R_1 = 0.059, R_w = 0.084. CCDC-267192 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Redox Control of Light-Induced Platinum-Cluster-to-Iron Charge Transfer in a Bis(ferrocenylethynyl)-Substituted Hexanuclear Platinum Derivative**

Alberto Albinati, Fabrizia Fabrizi de Biani, Piero Leoni, Lorella Marchetti, Marco Pasquali, Silvia Rizzato, and Piero Zanello**

Placing equivalent redox-active groups as end-caps in molecular arrays is often used to evaluate whether intramolecular electronic communication occurs through organic[1] or metal-containing fragments.[2–9] To this end, ferrocenyl (Fc = [(η-C_5H_5)Fe(η-C_5H_4)]) pendant groups (often as ferrocenylethynyl termini),[3–5] are commonly used because of their chemical robustness, synthetic versatility, and reversible redox properties. They have been attached to mono-[2,3,6,10] or dinuclear[4,7] organometallic and coordination compounds. However examples of metal clusters capped by equivalent ferrocenyl groups are rare. To our knowledge, structurally characterized examples are limited[8a] to the following compounds: $[Mo_6Cl_8(O_2C{-}Fc)_6]^{2-}$, which contains an octahedral core of Mo^{II} centers $\{Mo_6Cl_8\}^{4+}$,[9a] $[Ru_3(CO)_7(\mu_2\text{-S-Fc})_4]$,[9b] $[Cu_3(dppm)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}C{-}Fc)_2]^+$, (dppm = methylenebis-[(diphenyl)phosphine]) with two terminal (Fc-C≡C)$^-$ groups bridging the opposite sides of a triangular Cu^I_3 core in an μ_3-η^1 fashion,[5a] $[M_6(\mu\text{-dppm})_2(\mu_3\text{-}\eta^1\text{-}C{\equiv}C{-}Fc)_4(L)_2]X_2$ (M = Ag, L = CH_3OH, X = BF_4; M = Cu, L = none, X = ClO_4)[5b] and $[Pt_2Au(dppm)_2X(\eta^1\text{-}C{\equiv}C{-}Fc)_2]$.[4a] Electron transfer from, to, or across the cluster-containing spacer, triggered by external stimuli, would make these units promising candidates for the preparation of connector elements in nanoscale switchable molecular devices.[11] Indeed, the utilization of carbonyl

clusters as single-electron tunneling transistors has been reported,[12a] and their employment as molecular capacitors[12b] is also under scrutiny. However, well-documented examples of electron transfer in molecular frameworks containing cluster subunits are exceedingly rare; in all the above-mentioned compounds the metal-cluster spacers do not allow significant electronic communication between the ferrocene units. However, in those derivatives containing one or two ferrocenyl units linked to a hexamolybdate spacer, through π-conjugated arms, a photoinduced charge transfer from the Fc to the polyoxometalate unit was observed,[13] while in a derivative containing a Os_3 core bonded to a viologen-containing acceptor, a photoinduced charge transfer from the triosmium cluster to the acceptor ligand was observed.[11]

Herein, we report the synthesis and structural characterization of $[Pt_6(\mu\text{-}P\textit{t}Bu_2)_4(CO)_4(C{\equiv}C{-}Fc)_2]$ (**1**), in which the hexaplatinum core $[Pt_6(\mu\text{-}P\textit{t}Bu_2)_4(CO)_4]^{2+}$ (hereafter $\{Pt_6\}$) is capped by two ferrocenylethynyl groups, and the results of an electrochemical and spectroelectrochemical study, which shows the presence of photo-electrochemically triggered electron transfer from the $\{Pt_6\}$ core to the peripheral Fc subunits. To our knowledge, this is the first example in which a metallic cluster behaves as electron donor towards a ferrocenium acceptor.

The disubstituted complex **1** was easily prepared from its dichloride precursor $\{Pt_6\}Cl_2$[14] (Scheme 1) and was isolated

Scheme 1. Synthesis of complex **1**.

as a red microcrystalline solid which yielded X-ray quality crystals upon recrystallization from $CHCl_3$ (Figure 1).[15] The structure shows that **1** retains the main structural features which are quite rare for other hexanuclear clusters and that we have found in closely related derivatives.[14,16] The structure consists of a slightly distorted tetrahedral platinum cluster capped, on each of two opposite edges, by a platinum atom linked to a terminally bonded (σ, η^1) ferrocenylethynyl moiety (other possible (π) bonding modes of the alkynyl units are hindered by the bulky phosphido ligands).[16] The ferrocenyl units lie on opposite sides of the plane defined by atoms Pt1, Pt2, Pt3, and Pt6 (Figure 1). Moreover the C_5 ring Cp1–Cp5 is approximately coplanar with the Pt1-Pt2-Pt3 plane (dihedral angle 172(1)°), while the other ethynyl-bound

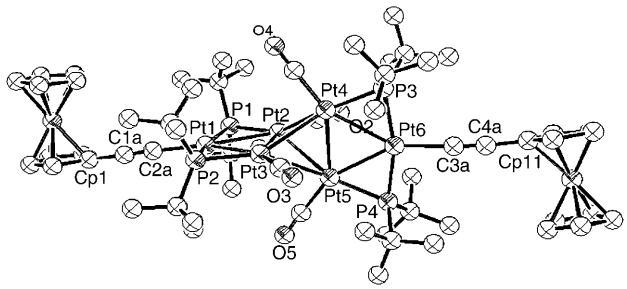

Figure 1. ORTEP view of compound **1**. Thermal ellipsoids set at 50% probability. Selected bond lengths [Å] and angles [°]: Pt1-Pt2 2.7196(5), Pt1-Pt3 2.7196(5), Pt4-Pt6 2.7389(6), Pt5-Pt6 2.7287(5), Pt2-Pt3 2.6875(6), Pt2-Pt5 2.8380(6), Pt2-Pt4 2.8389(5), Pt3-Pt4 2.8421(5), Pt3-Pt5 2.8440(6), Pt4-Pt5 2.6734(5); Pt1-C2a-C1a 178(1), Pt6-C3a-C4a 178(1), C2a-C1a-Cp1 176(1), C3a-C4a-Cp11 173(1).

C_5 ring (Cp11–Cp15) is almost perpendicular to the P4-Pt5-Pt6 plane (dihedral angle 102(2)°).

The structure of **1** is retained in solution, as confirmed by IR and NMR spectra, which show diagnostic signals at the expected positions (IR: $\tilde{\nu} = 2126, 2106$ (ν_{CC}), 2009 (ν_{CO}) cm^{-1}; ^{31}P NMR: $\delta = 333.6$ ppm; ^{195}Pt NMR: $\delta = -4663$ (2 Pt), -2997 ppm (4 Pt)).[14,16]

In CH_2Cl_2 solution the platinum cluster undergoes three reversible, and coulometrically measured, redox processes (Table 1): two slightly separated one-electron reductions

Table 1: Formal electrode potentials (V, vs. SCE) for the redox changes exhibited by $[Pt_6(\mu\text{-}P\textit{t}Bu_2)_4(CO)_4(\eta^1\text{-}C{\equiv}C{-}Fc)_2]$ and related species in CH_2Cl_2.

Compound	$\{Pt_6\}$-centered ox.	Fc-centered ox.	$\{Pt_6\}$-centered red.	
1	+1.26[a,b]	+0.30[a]	−1.50	−1.64
$[Pt_6(P\textit{t}Bu_2)_4(CO)_4(C_2Ph)_2]$[c]	+1.05[a,b]		−1.45	−1.54
Fc-C≡CH[d]		+0.52		

[a] Two-electron process. [b] Peak-potential for irreversible processes. [c] Ref. [18]. [d] Ref. [20].

($E^{\circ\prime} = -1.50$ V and -1.64 V versus saturated calomel electrode (SCE)) and one two-electron oxidation ($E^{\circ\prime} = +0.30$ V).[17] A further, apparently irreversible, two-electron oxidation is also present ($E_p = +1.26$ V) (see Supporting Information).

On the basis of the redox behavior of the parent dication $[\{Pt_6\}(CO)_2]^{2+}$ and its substituted product $[\{Pt_6\}(C_2Ph)_2]$[16b,18] both the two one-electron reductions and the irreversible oxidation are assigned as $\{Pt_6\}$ centered. The reversible two-electron removal event can be reliably assigned to the simultaneous one-electron oxidation of each of the two ferrocenyl units. This simultaneous process does not split into two separated one-electron events, even when a very low-coordinating electrolyte (e.g. $[NBu_4][B(C_6F_5)_4]$) is used.[19] This observation confirms that no electronic (through-space or through-bond) communication between the two ferrocenyl units is allowed by the $\{Pt_6\}$ spacer. The more anodic (irreversible) two-electron oxidation takes place at a potential

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

approximately 200 mV more positive than in the parent complex $[Pt_6(\mu\text{-}PtBu_2)_4(CO)_4(C_2Ph)_2]$. At the same time, the ferrocenyl-centered oxidations occur at a potential approximately 200 mV less positive than in free acetylferrocene.[20] These redox shifts suggest that the acetilyde bridging ligands exert cooperative electronic effects inside the molecular frame.[21]

As shown in Figure 2, the most significant spectroelectrochemical change upon stepwise two-electron oxidation of

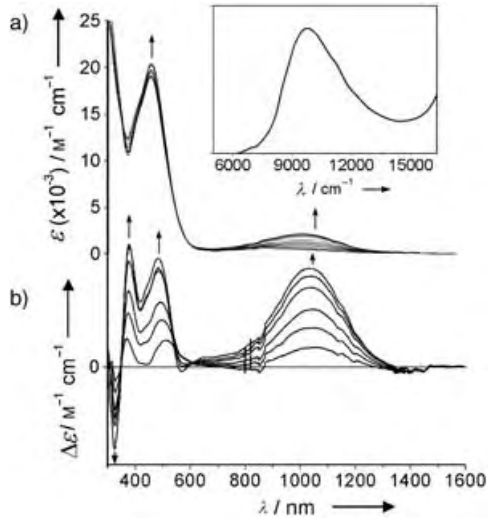

Figure 2. a) UV/Vis/NIR spectra and b) difference spectra recorded upon stepwise oxidation of **1** in an OTTLE cell, CH_2Cl_2/$[NBu_4][PF_6]$ (0.2 mol dm^{-3}) solution. Arrows indicate the change on oxidation. Inset: NIR band in (a) replotted in cm^{-1} to show the asymmetry of this band.

complex **1** is the progressive appearance of a broad band in the NIR region ($\lambda = 1025$ nm; $\varepsilon = 2.1 \times 10^3$ M^{-1} cm^{-1}). Upon exhaustive two-electron oxidation, the UV/Vis region of the spectrum does not change and does not exhibit the typical blue-to-green ferrocenium absorption ($\lambda = 698$ nm for $[FcCCH]^+$)[20]; the solution remains cherry-red. In the stepwise oxidation, the NIR band keeps growing and does not change position or shape even upon removal of the second electron. Such behavior suggests consecutive metal-to-metal charge transfers (MMCT) from the Pt_6 cluster to the peripheral ferrocenium subunits [Eq. (1) and Eq. (2)]

$$\overset{+}{Fc}\text{-}C{\equiv}C\text{-}\{Pt_6\}\text{-}C{\equiv}C{-}Fc \xrightarrow{h\nu} Fc\text{-}C{\equiv}C\text{-}\{\overset{+}{Pt_6}\}\text{-}C{\equiv}C\text{-}Fe \quad (1)$$

$$\overset{+}{Fc}\text{-}C{\equiv}C\text{-}\{Pt_6\}\text{-}C{\equiv}C\text{-}\overset{+}{Fc} \xrightarrow{h\nu} Fc\text{-}C{\equiv}C\text{-}\{\overset{2+}{Pt_6}\}\text{-}C{\equiv}C{-}Fc \quad (2)$$

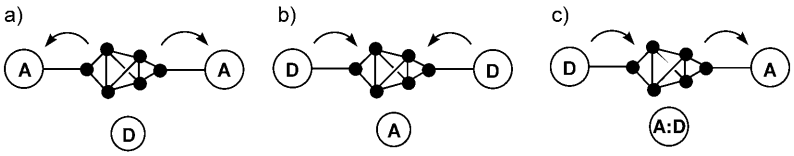
Our preliminary observations show that a band at the same position in the NIR develops upon one-electron oxidation of the corresponding monoferrocenyl complex $[\{Pt_6\}(C{\equiv}C{-}Fc)I]$,[22] giving further support to the assumption that this absorption cannot arise from the interaction between the two ferrocene subunits.

We attempted to check the solvent dependence of the NIR band, but our efforts were frustrated by the impossibility of finding different useful solvents and the pertinent supporting electrolytes. Nevertheless, the change of the supporting electrolyte from $[NBu_4][PF_6]$ to the low-coordinating $[NBu_4][B(C_6F_5)_4]$ maintained unchanged the high-energy bands, but causes a red shift ($\lambda = 1108$ nm) of the low-energy band, thus confirming the sensitivity of the actual absorption to the medium, as expected for a MMCT intervalence transfer (IT) absorption.

As can be seen in the inset of Figure 2, when the spectrum is plotted in cm^{-1}, the asymmetry of the MMCT band becomes evident. Indeed, such a cut-off on the low-energy side of IT absorptions is predicted in the case of sizeable electronic coupling between the states involved in the electron transfer (although different factors, such as vibronic progressions or band overlaps, can cause asymmetry of IT bands).[23]

According to the Hush treatment of dinuclear asymmetric derivatives,[24] the limiting value[25] of the bandwidth at half height ($\Delta\bar{\nu}_{1/2}$) for the IT band of a partially delocalized mixed-valent species is theoretically expected to be given by Equation (3) where the free-energy difference between the initial and the final state after the electron transition, $\Delta G°$, is usually approximated as the separation $\Delta E°$ of the redox potentials of the processes centered on the isolated units involved in the electron transfer. Significantly narrower IT absorptions are expected for a completely delocalized mixed-valent species.

$$\Delta\bar{\nu}_{1/2} = 48\,(\bar{\nu}_{max} - \Delta G^o)^{1/2} \quad (3)$$



On placing the values in Equation (3) it follows that $\Delta\bar{\nu}_{1/2}$ in the present case is given by Equation (4) where $\Delta G° \approx \Delta E° = 4195$ cm^{-1} has been calculated on the basis of the formal electrode potentials of $[\{Pt_6\}(C{\equiv}C\text{-}Ph)_2]^{2+/0}$ and $[HC{\equiv}C{-}Fc]^{+/0}$.[18,20]

$$\Delta\bar{\nu}_{1/2\,theoretical} = 48(9760-4195)^{1/2} = 3580\,cm^{-1} \quad (4)$$

The experimental bandwidth, taken as twice the difference between the band maximum and the half-height point on the high-energy side, is $\Delta\bar{\nu}_{1/2\,experimental} = 4470$ cm^{-1}, which is much larger than the theoretical limiting value of 3580 cm^{-1}. This result suggests that both the singly and doubly oxidized species (the monocation and the dication) can be regarded as valence-trapped systems.

As a final consideration, we underline that compounds that can absorb light in the NIR region may, in principle, be used in optical data-storage devices that are able to read and write through proper diode lasers (that is, operating in the NIR region of the spectrum),[26] in particular when the NIR absorption can be triggered by external perturbations. Even though the intensity of the present NIR transition is too weak[26] for practical applications in data-storage devices, these compounds offer the appealing possibility of easily tuning both the redox capacity of the attached ferrocenyl units and the resulting MMCT NIR absorption. Moreover, the ability of the $\{Pt_6\}$ unit to be both oxidized and reduced[14a] suggests the possibility of building systems in which, based on the proper calibration of redox potentials of the end-cap

[15] Crystal data for **1**·(0.5 $CHCl_3$): $C_{56.5}H_{90.5}Cl_{1.5}Fe_2O_4P_4Pt_6$, M_r = 2293.08. Monoclinic, space group $C2/c$, a = 24.424(2), b = 17.604(1), c = 33.489(2) Å, β = 105.250(2)°, V = 13892(2) Å^3, Z = 8, ρ_{calcd} = 2.193 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 126.10 cm^{-1}, dimensions 0.4 × 0.4 × 0.3 mm^3. 63429 reflections were collected, at 120 K (on a Bruker SMART CCD diffractometer), of which 13675 were unique (R_{int} = 0.0875). An empirical absorption correction was applied using the program SADABS (transmission factors in the range 1.000–0.522). Structure solution was by direct and Fourier methods and refinement by full-matrix least squares on F^2 (programs WinGx vs. 1.70 and SHELX-PC). Isotropic displacement parameters were used for the carbon atoms of the C_5 rings of the Fc units and of the ethynyl moieties; the Pt, Fe, and P atoms, and the remaining carbon atoms were refined using anisotropic displacement parameters. From the difference Fourier maps a solvent molecule (CH_2Cl_2) was found, disordered across a crystallographic inversion center, and its contribution was taken into account. Final agreement factors were R_1 = 0.0403, R_{w2} = 0.0890 for 9178 observed reflections [$I \geq 2\sigma(I)$] and 582 refined parameters; GOF = 1.011. CCDC-272174 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

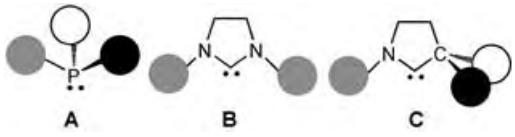
Stable Cyclic (Alkyl)(Amino)Carbenes as Rigid or Flexible, Bulky, Electron-Rich Ligands for Transition-Metal Catalysts: A Quaternary Carbon Atom Makes the Difference**

*Vincent Lavallo, Yves Canac, Carsten Präsang, Bruno Donnadieu, and Guy Bertrand**

The availability of catalysts to perform specific transformations is critical for both industry and academia. Over the years, the success of homogeneous catalysis can be attributed largely to the development of a diverse range of ligand frameworks that have been used to tune the behavior of a variety of metal-containing systems. Advances in ligand design have allowed not only for improvements of known processes in terms of scope, mildness, and catalyst loadings, but also for the discovery of new selective reactions. A good illustration is given by palladium-catalyzed coupling reactions, which are applied to a wide area of endeavors ranging from synthetic organic chemistry to materials science.[1] For these catalytic processes, which represent some of the most powerful and versatile tools available for synthetic chemists, major advances have recently been reported thanks to the use of bulky, electron-rich, phosphines **A** and cyclic diaminocarbenes (N-heterocyclic carbenes (NHCs)) **B** (Figure 1).[2] These ligands stabilize the active catalytic species, and accelerate the important catalytic steps, namely oxidative addition, transmetallation, and reductive elimination. On the other hand, excessive steric hindrance can present some drawbacks for the coupling of bulky reactants.[3] To overcome this problem Glorius and co-workers have successfully developed ligands with "flexible steric bulk" using the conformational flexibility of cyclohexane.[4]



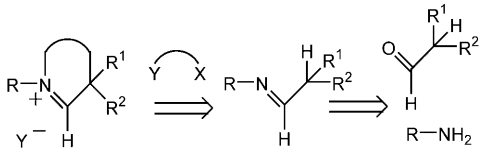


Figure 1. Schematic view of ligands **A**–**C** showing their different steric demands.

Herein we report the synthesis of stable cyclic (alkyl)(amino)carbenes (CAACs) **C** (Figure 1). The replacement of one of the electronegative amino substituents of NHCs **B** by a strong σ-donor alkyl group makes the CAAC ligands **C** even more electron-rich than **A** and **B**. Moreover, owing to the presence of a quaternary carbon atom in a position α to the carbene center, carbenes **C** feature steric environments that differentiate them dramatically from both ligands **A** and **B** (Figure 1), and amplifies flexible steric bulk effect. We show that the peculiar electronic and steric properties of carbenes **C** allow for the synthesis of CAAC-palladium complexes that are highly efficient for the catalytic α-arylation of carbonyl compounds.

Direct detection of singlet alkyl carbene compounds usually requires matrix-isolation conditions or nanosecond time-resolved laser flash photolysis techniques.[5] However, last year we reported that, provided a tertiary alkyl group is bonded to the carbene center, acyclic (alkyl)(amino)carbenes are isolable and, importantly, behave as strong σ-donors toward transition-metal centers.[6] NHCs **B** are more robust and give rise to more active catalysts, when used as ligands for transition metals, than their acyclic counterparts.[7] Therefore it was reasonable to believe that CAACs **C** would also be more stable than their acyclic variants, and would have interesting ligand properties.

The method used to prepare the precursor of acyclic (alkyl)(amino)carbenes, namely the alkylation of the corresponding enamines, is very limited in its scope. Therefore, we have designed a new synthetic approach, which is very versatile (Scheme 1). The choice of R, R^1, and R^2 substituents

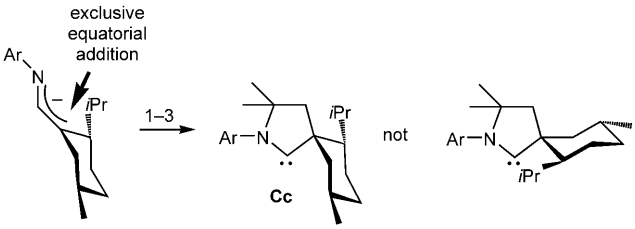
is virtually unlimited (except that R^1 and R^2 cannot be H) and the ring skeleton can be modified at will.

This synthetic strategy was first tested with imine **1a** (Scheme 2) prepared from 2,6-diisopropylaniline and the simplest aldehyde featuring a secondary alkyl substituent, 2-methylpropanal. Deprotonation of **1a** with lithium diisopropylamide (LDA) afforded the aza-allyl anion, which readily induces the ring opening of 1,2-epoxy-2-methylpropane leading to the corresponding alkoxide **2a**. Subsequent treatment with triflic anhydride (TfOTf) at −78 °C gives rise to the triflate derivative, which upon warming to room temperature affords the aldiminium salt **3a** in 58% yield (based on the imine). Lastly, deprotonation with LDA quantitatively affords carbene **Ca** as a white solid (Scheme 2). CAAC **Ca** is perfectly stable at room temperature in the solid state and in solution, for at least two weeks.



Scheme 2. Synthesis of CAAC **Ca**. Ar = 2,6-diisopropylphenyl.

The presence of the tertiary carbon center next to the carbene center offers the possibility of constructing ligands featuring different types of steric environment. Spiro-CAAC **Cb**, readily prepared in a manner similar to that used for **Ca**, but using cyclohexyl carbaldehyde, illustrates how the concept of flexible steric bulk can be incorporated into this ligand family. In fact, compared to the NHCs **B** developed by Glorius and co-workers,[4] the cyclohexane ring of **Cb** is closer to the carbene and to an ensuing metal center, and therefore the effects of the "flexible wing" should be amplified (Scheme 3).

Scheme 3. Flexible steric bulk for a) NHCs (**B**) and b) CAACs (**Cb**). Ar = 2,6-diisopropylphenyl.

In contrast to **Cb**, carbene **Cc** (Scheme 4) exemplifies the rigidity and extreme steric bulk that CAACs can provide to metal centers to which they are bound. As a starting material, we chose the imine **1c** derived from (−)-menthone. The key step of the synthesis is based on the propensity of relatively bulky reactants to approach the cyclohexane moiety from the equatorial direction. This effect is reinforced by the presence of the *iso*-propyl group, and therefore the reaction with the

Scheme 4. Stereoselective synthesis of CAAC **Cc**. 1) Dimethyloxirane; 2) TfOTf; 3) LDA; Ar = 2,6-diisopropylphenyl.

oxirane is completely diastereoselective (Scheme 4). It leads to the diastereomer affording the best protection for the carbene and the ensuing metal center to which it is bound. Moreover, in contrast with **Cb**, the chair conformation is locked. Indeed, the other chair conformation would put both the *iso*-propyl and methyl groups in unfavorable axial positions (even a boat conformation would be highly adverse). It is apparent from the molecular structure, obtained by a single-crystal X-ray diffraction study (Figure 2)[8] that the steric environment of this

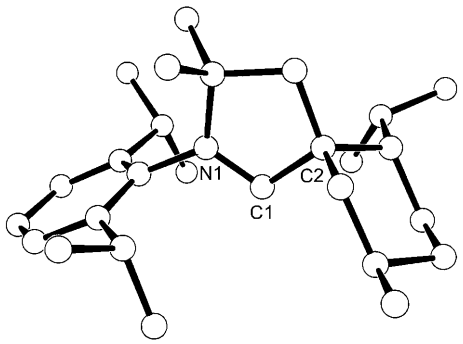


Figure 2. Molecular view of the crystal structure of **Cc**. Selected bond lengths [Å] and angles [°]: N1-C1 1.315(3), C1-C2 1.516(3); N1-C1-C2 106.54(18).

CAAC is very different from that of phosphines (described as a cone) and NHCs (defined as fan-like):[9] the locked cyclohexane moiety constitutes a "wall of protection" not only for the carbene center, but also for a metal if **Cc** is being used as a ligand (Figure 2). It is noteworthy that **Cc** is enantiomerically pure and has been prepared without time-consuming enantio- or diastereoselective separation.

The carbonyl stretching frequencies of *cis*-[IrCl(CO)$_2$(L)] complexes are recognized as an excellent measure of the σ-donor and π-acceptor properties of the ligand L.[10] Addition of half an equivalent of [{IrCl(cod)}$_2$] (cod = 1,5-cyclooctadiene) to a THF solution of carbene **Cc** led to the formation of [IrCl(cod)(**Cc**)], which upon treatment with CO at room temperature afforded *cis*-[IrCl(CO)$_2$(**Cc**)] (**4c**) in high yield. The average value of the carbonyl stretching frequencies for complex **4c** (ν_{av}(CO) = 2013 cm^{-1}) indicates that the donor power of **Cc** is higher than that of electron-rich phosphines (PCy$_3$: ν_{av}(CO) = 2028 cm^{-1}) and even NHC ligands (2017–

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2020 cm^{-1}); only the abnormal C5-bound NHCs are stronger donors (2003 cm^{-1}).[10]

The steric and electronic properties of CAACs should benefit the numerous catalytic processes which require bulky electron-rich ligands at the metal center. As an example of such a process, we chose to study the palladium-catalyzed α-arylation of ketones, discovered concurrently in 1997 by the groups of Buchwald,[11] Hartwig,[12] and Miura.[13] This reaction has not yet been achieved at room temperature with non-activated aryl chlorides; moreover there are no examples with sterically hindered di-*ortho*-substituted aryl chlorides. The use of CAAC ligands **C**, indeed, overcomes these limitations. The [PdCl(allyl)(CAAC)] complexes **5a–c** (Figure 3) were readily prepared in high yields by addition of [{Pd(allyl)(Cl)}$_2$] to the corresponding carbenes **Ca–c**, and isolated as air stable colorless crystals; they can even be purified by column chromatography on silica gel.

Table 1 summarizes the results obtained using complexes **5a–c** for the α-arylation of propiophenone, the classical substrate for the palladium-catalyzed α-arylation of ketones.[11–14] With nonhindered aryl chlorides the superior catalytic activity of CAAC complex **5c** over **5a**,**b** is demonstrated (entries 1–8). A turn over number (TON) of up to 7200 has been obtained at room temperature. This compares extremely favorably with the best TON reported to date: 4200 at 120 °C.[14c] When a di-*ortho*-substituted aryl chloride is used (entries 9–14), no catalytic activity has been observed with **5a** and **5c**, but in marked contrast **5b** is active, even at room temperature. Entries 11 and 13 indicate the thermal stability of the catalyst.

Table 1: Palladium-mediated α-arylation of propiophenone with aryl chlorides.[a]

Entry	Aryl chloride	Catalyst ([mol%])	*T* [°C]	*t* [h]	Yield [%][b]
1	PhCl	**5a** (0.5)	23	70	22
2	PhCl	**5b** (0.5)	23	70	29
3	PhCl	**5c** (0.5)	23	1	100
4	PhCl	**5c** (0.1)	23	1	83
5	PhCl	**5c** (0.01)	23	38	72
6	2-MePhCl	**5a** (0.5)	23	70	0
7	2-MePhCl	**5b** (0.5)	23	36	10
8	2-MePhCl	**5c** (0.5)	23	36	82
9	2,6-Me$_2$PhCl	**5a** (0.5)	23	70	0
10	2,6-Me$_2$PhCl	**5b** (0.5)	23	36	32
11	2,6-Me$_2$PhCl	**5b** (0.5)	70	4	56
12	2,6-Me$_2$PhCl	**5b** (1)	23	16	61
13	2,6-Me$_2$PhCl	**5b** (1)	50	20	81
14	2,6-Me$_2$PhCl	**5c** (0.5)	50	20	0

[a] Conditions: THF (1 mL), NaO*t*Bu (1.1 mmol), propiophenone (1.0 mmol), aryl chloride (1.0 mmol); all reactants (Aldrich) were used as received. [b] Yields as determined by NMR spectroscopy.

The dramatic differences observed in the catalytic activity of complexes **5a–c** can be rationalized by the different steric environments created by ligands **Ca**, **Cb**, and **Cc**. Carbene **Ca** is not sterically hindered enough to favor reductive elimination at room temperature. This step is easily promoted, for relatively small substrates, by the very rigid and bulky **Cc** ligand. However, entry 14 shows that **Cc** gives rise to a catalyst very sensitive to excessive steric hindrance. The molecular structures shown in Figure 3 clearly show that the steric environment around the metal is very similar for **5a** and **5b**, and therefore cannot explain the superior catalytic activity of **5b**. However, in solution, the cyclohexane moiety of **5b** can easily undergo a ring flip, which leads to a steric environment similar to that of **5c**.[15] This flexibility also explains the superiority of **5b** over **5c** in accommodating sterically demanding substrates in the coupling process.

Although the α-arylation of carbonyl compounds has a broad scope of application,[16] very little success has been reported with aldehydes,[17] mostly because of the competing aldol condensation. It was reasonable to believe that this side reaction could be reduced by taking advantage of the mild conditions allowed by CAAC palladium complexes. Indeed, 2-chlorotoluene is coupled with isobutanal with high efficiency at ambient temperature. Using 1 mol% of **5c**, the desired product was obtained after 16 h in 98% yield, and no evidence of aldol condensation products was observed. This is the first example of α-arylation of an aldehyde with an aryl chloride.

In recent years, several different types of stable carbene compounds have been prepared,[18] but only the "pure" σ-donor NHCs, when used as ligands, have led to highly active and robust catalysts,[19] which compete or even surpass their

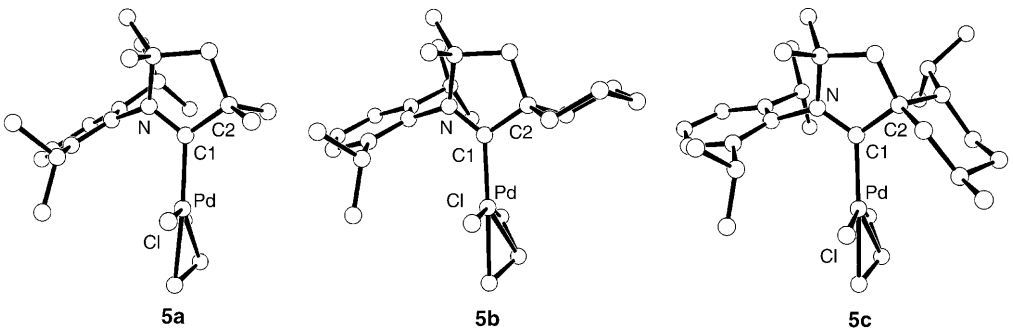

Figure 3. Molecular view of the crystal structures of **5a–c**. bulky, electron-rich phosphine counterparts. It is generally believed that in contrast to NHCs, Fischer-type carbenes would not survive the standard conditions of organometallic catalysis, because of the cleavage of the metal–carbon bond;[20,21] moreover they are regarded as weak σ-donors and good π-acceptors. Our work demonstrates that the readily available CAACs are strong σ-donors, weak π-acceptors, and form highly catalytically active "cyclic Fischer carbene complexes". Their unique steric and electronic properties, in addition to the broad range of structural features possible, which arise as a result of the presence of a tertiary carbon in a position α to the carbene center, makes these carbenes highly desirable as ligands for various catalytic processes, including asymmetric variants.

Experimental Section

All manipulations were performed under an inert atmosphere of argon using standard Schlenk techniques. Dry, oxygen-free solvents were employed. ^{1}H and ^{13}C NMR spectra were recorded on Varian Inova 300, 500, and Brucker Avance 300 spectrometers.

3a,**b**: A solution of LDA (4.66 g, 43.5 mmol) in Et_2O (40 mL) was added at 0 °C to a stirred solution of imine **1a** or **1b** (43.5 mmol) in Et_2O (40 mL). The solution was warmed to room temperature and stirred for 2 h. After evaporation of the solvent under vacuum, the residue was dissolved in Et_2O (80 mL), and 1,2-epoxy-2-methylpropane (4.06 mL, 45.7 mmol) was added dropwise. After stirring for 12 h at room temperature, trifluoromethane sulfonic anhydride (7.68 mL, 45.7 mmol) was added at −78 °C. The solution was warmed to room temperature and stirred for 1 h. After filtration, the residue was washed with Et_2O (80 mL). Extraction of the solid with CH_2Cl_2 (40 mL) afforded **3a**,**b** as white solids. **3a**: 58 %, m.p. 198–200 °C; ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): $\delta = 9.48$ (s, 1H, CH), 7.53 (m, 1H, H_{ar}), 7.34 (m, 2H, H_{ar}), 2.63 (sept, 2H, C*H*CH_3, $J =$ 6.9 Hz), 2.43 (s, 2H, CH_2), 1.68 (s, 6H, CH_3), 1.54 (s, 6H, *C*H_3), 1.35 (d, 6H, CHC*H*$_3$, $J = 6.9$ Hz), 1.17 ppm (d, 6H, CHC*H*$_3$, $J = 6.9$ Hz); ^{13}C NMR (CD_3CN, 25 °C, 75 MHz): $\delta = 192.2$ (CH), 145.6, 133.1, 130.1, 126.6, 122.2 (q, $J = 321.6$ Hz), 85.8, 66.3, 48.8, 30.4, 28.5, 26.3, 26.2, 22.2 ppm. **3b**: 48 %, m.p. 268–270 °C; ^{1}H NMR (CD_3CN, 25 °C, 300 MHz): $\delta = 8.91$ (s, 1H, CH), 7.67 (m, 1H, H_{ar}), 7.52 (m, 2H, H_{ar}), 2.78 (sept, 2H, C*H*CH_3, $J = 6.9$ Hz), 2.53 (s, 2H, CH_2), 1.19–2.11 (m, 10H, CH_2), 1.59 (s, 6H, CH_3), 1.40 (d, 6H, CHC*H*$_3$, $J = 6.9$ Hz), 1.15 ppm (d, 6H, CHC*H*$_3$, $J = 6.9$ Hz); ^{13}C NMR (CD_3CN, 25 °C): $\delta =$ 191.3 (CH), 145.4, 132.9, 130.0, 126.4, 122.2 (q, $J = 321.2$ Hz), 85.0, 53.6, 45.9, 34.6, 30.2, 28.7, 26.1, 25.3, 22.1 ppm.

3c: A solution of the lithium salt of dimethylamine (1.56 g, 30.5 mmol) in THF (40 mL) was added at 0 °C to a stirred solution of imine **1c** (10.00 g, 30.5 mmol) in THF (40 mL). The solution was warmed to room temperature and stirred for 18 h. After evaporation of the solvent and then heating under vacuum at about 200 °C for 10 min, to remove the THF complexed to the lithium, the residue was dissolved in toluene (100 mL). After adding dropwise 1,2-epoxy-2-methylpropane (2.85 mL, 32.0 mmol), the solution was stirred for 12 h at room temperature. Then Tf_2O (5.39 mL, 32.0 mmol) was added at −78 °C and the suspension was allowed to warm to room temperature and stirred for 2 h. After filtration, the oily residue was washed with boiling toluene (90 mL). Extraction of the residue with CH_2Cl_2 (60 mL) afforded **3c** as a white solid, which was recrystallized in CH_2Cl_2/Et_2O at −20 °C. 6.65 g, 41 %, m.p. 258–260 °C; $[\alpha]_D^{23} = -38°$ ($CHCl_3$); ^{1}H NMR ($CDCl_3$, 25 °C, 500 MHz): $\delta = 9.73$ (s, 1H, CH), 7.53 (m, 1H, H_{ar}), 7.34 (m, 2H, H_{ar}), 2.64 (m, 3H, CH), 2.20 (m, 2H), 2.04 (m, 2H), 1.90 (m, 2H), 1.78 (m, 2H), 1.59 (s, 3H, CH_3), 1.55 (s, 3H, CH_3), 1.35 (d, 3H, CHC*H*$_3$, $J = 7.0$ Hz), 1.34 (d, 3H, CHC*H*$_3$, $J =$ 6.0 Hz), 1.21 (d, 3H, CHC*H*$_3$, $J = 6.5$ Hz), 1.17 (d, 3H, CHC*H*$_3$, $J =$ 6.0 Hz), 1.06 (d, 3H, CHC*H*$_3$, $J = 7.0$ Hz), 1.00–1.10 (m, 2H), 0.94 (d, 3H, CHC*H*$_3$, $J = 6.5$ Hz), 0.83 ppm (d, 3H, CHC*H*$_3$, $J = 6.5$ Hz); ^{13}C NMR ($CDCl_3$, 25 °C, 125 MHz): $\delta = 192.64$ (CH), 144.7, 144.5, 131.7, 129.0, 125.6, 125.1, 120.6 (q, $J = 321.6$ Hz), 81.6, 58.5, 52.2, 51.0, 45.4, 34.7, 29.9, 29.5, 29.2, 28.1, 27.1, 26.7, 25.5, 22.8, 22.7, 22.3, 22.2, 22.1, 18.7 ppm.

Ca–Cc: A 1/1 mixture of LDA and iminium salt **3** (5.0 mmol) was cooled to −78 °C and THF was added (30 mL). The suspension was warmed to room temperature and stirred for 30 min. After evaporation of the solvent under vacuum, a solid residue containing the corresponding carbene **C** and LiOTf was obtained and used for the complexation reaction without further purification, except for **Cc**. In this case, the solid residue was extracted with hexane (30 mL), and after evaporation of the solvent under vacuum, **Cc** was obtained as a white microcrystalline solid. **Ca**: ^{13}C NMR ([D$_8$]THF, 25 °C, 125 MHz): $\delta = 304.2$ (C), 145.8, 137.5, 128.0, 123.8, 82.5, 57.7, 50.3, 29.1, 28.9, 27.5, 21.7 ppm. **Cb**: ^{13}C NMR ([D$_8$]THF, 25 °C, 125 MHz): $\delta = 309.4$ (C), 145.8, 137.8, 127.9, 123.6, 81.2, 63.3, 47.7, 35.8, 29.3, 29.1, 26.4, 23.0, 21.5 ppm. **Cc**: 92 %, m.p. 115 °C; $[\alpha]_D^{23} = +113°$ (hexane); ^{1}H NMR (C_6D_6, 25 °C, 500 MHz): $\delta = 7.13$–7.25 (m, 3H, H_{ar}), 3.18 (sept, 2H, C*H*CH_3, $J = 6.9$ Hz), 2.54–2.78 (m, 2H), 2.11 (m, 1H), 1.72–1.97 (m, 4H), 1.41 (dd, 1H, $J = 12.3$ and $J = 3.3$ Hz), 1.11–1.27 (m, 21H), 1.06 (d, 3H, CHC*H*$_3$, $J = 6.9$ Hz), 1.02 (d, 3H, CHC*H*$_3$, $J =$ 6.9 Hz), 0.96 ppm (3H, CHC*H*$_3$, $J = 6.6$ Hz); ^{13}C NMR ([D$_8$]THF, 25 °C, 125 MHz): $\delta = 319.0$ (C), 146.6, 145.7, 138.1, 127.6, 123.8, 123.3, 79.7, 69.4, 53.1, 52.0, 48.0, 36.9, 30.2, 29.8, 29.1, 29.0, 28.6, 27.7, 27.0, 25.4, 24.1, 23.6, 22.8, 21.9, 21.2, 18.7 ppm.

4c: A solution of carbene **Cc** (0.34 g, 0.90 mmol) in THF (5 mL) was added at −78 °C to a stirred THF solution (5 mL) of [{IrCl(cod)}$_2$] (0.27 g, 0.41 mmol). The solution was warmed to room temperature and stirred for 3 h. After evaporation of the solvent under vacuum, the residue was washed with hexane (15 mL), dissolved in THF (5 mL), and carbon monoxide was bubbled through the solution (45 min) at room temperature. After evaporation of the solvent under vacuum, carbene complex **4c** was obtained as a brown powder. 0.42 g, 71 %; ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): $\delta = 7.55$ (m, 1H, H_{ar}), 7.36 (m, 2H, H_{ar}), 2.61–2.76 (m, 3H), 2.38 (d, 1H, $J = 14.4$ Hz), 2.06–2.24 (m, 3H), 1.67–1.95 (m, 6H), 1.64 (s, 3H), 1.60 (s, 3H), 1.36 (d, 6H, CHC*H*$_3$, $J = 6.6$ Hz), 1.19–1.27 (m, 6H), 1.08 (d, 3H, CHC*H*$_3$, $J =$ 6.9 Hz), 0.97 (d, 3H, CHC*H*$_3$, $J = 5.4$ Hz), 0.85 ppm (d, 3H, CHC*H*$_3$, $J = 6.9$ Hz); ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): $\delta = 191.3$ (CO), 190.9 (C), 167.8 (CO), 144.8, 144.6, 132.3, 129.0, 126.1, 125.6, 82.4, 58.7, 58.6, 52.3, 51.1, 45.8, 34.6, 30.4, 30.1, 29.7, 28.6, 27.6, 27.4, 26.6, 23.3, 23.0, 22.9, 22.5, 22.2, 19.4 ppm. IR (CH_2Cl_2): $\tilde{\nu} =$ 2055, 1971 (ν(CO)) cm^{-1}.

5a–c: A solution of carbene **C** (5.2 mmol) in THF (15 mL) was added at −78 °C to a stirred solution of [{Pd(allyl)(Cl)}$_2$] (0.95 g, 2.6 mmol) in THF (15 mL). The solution was warmed to room temperature and stirred for 3 h. After evaporation of the solvent under vacuum, the solid residue was washed with hexane (40 mL). Extraction with CH_2Cl_2 (20 mL) afforded a gray solid, which was recrystallized in THF (**5a**) or hexane (**5b**,**c**) at −20 °C. Carbene complexes **5** were obtained as colorless crystals. **5a**: 71 %, m.p. 162–163 °C; ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): $\delta = 7.27$–7.42 (m, 3H, H_{ar}), 5.05 (m, 1H, H_{allyl}), 4.18 (d, 1H, H_{allyl}, $J = 7.5$ Hz), 3.19 (m, 3H, C*H*CH_3 and 2H_{allyl}), 3.01 (m, 1H, C*H*CH_3), 2.02 (s, 3H, H_{allyl}, CH_2), 1.64 (s, 6H, *C*H_3), 1.23–1.40 ppm (m, 18H, CH_3); ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): $\delta = 267.4$ (C), 146.5, 135.8, 129.1, 125.1, 115.5, 81.5, 76.8, 57.5, 50.5, 48.6, 31.7, 30.6, 29.3, 28.6, 28.1, 27.5, 25.1 ppm. **5b**: 74 %, m.p. 176–178 °C; ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): $\delta = 7.21$–7.63 (m, 3H, H_{ar}), 5.04 (m, 1H, H_{allyl}), 4.18 (d, 1H, H_{allyl}, $J = 7.5$ Hz), 3.29 (m, 1H, C*H*CH_3), 3.15 (m, 2H, H_{allyl}), 2.98 (m, 1H, C*H*CH_3), 2.45 (m, 2H, CH_2), 1.22–2.05 (m, 17H, H_{allyl}, CH_2, CH_3), 1.30 ppm (d, 12H, CHC*H*$_3$, $J = 6.9$ Hz); ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): $\delta = 267.8$ (C), 146.5, 136.3, 129.0, 125.1, 115.6, 80.5, 77.0, 62.9, 48.3, 45.7, 38.8, 37.2, 31.3, 29.5, 28.6, 28.0, 27.0, 25.4, 25.3, 22.9, 22.4 ppm. **5c**: 70 %, m.p. 157–159 °C; $[\alpha]_D^{23} = -1°$ ($CHCl_3$); ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): $\delta = 7.20$–7.38 (m, 3H, H_{ar}), 5.04 (m, 1H, H_{allyl}), 4.21 (d, 1H, H_{allyl}, $J = 7.5$ Hz), 3.70 (sept, 1H, C*H*CH_3, $J = 6.3$ Hz), 3.15 (d,

1H, H_{allyl}, $J = 14.1$ Hz), 2.82–2.98 (m, 4H), 2.32 (m, 1H), 1.70–2.09 (m, 7H), 1.35–1.45 (m, 8H), 1.30 (d, 6H, $CHCH_3$, $J = 6.6$ Hz), 1.29 (s, 3H), 1.20 (d, 3H, $CHCH_3$, $J = 6.9$ Hz), 0.99 (t, 6H, $CHCH_3$, $J = 6.9$ Hz), 0.93 ppm (d, 3H, $CHCH_3$, $J = 6.6$ Hz); ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): $\delta = 272.0$ (C), 148.3, 145.6, 137.5, 129.0, 126.4, 124.7, 114.9, 78.7, 78.0, 67.4, 54.2, 52.0, 51.2, 48.1, 33.7, 33.6, 30.7, 30.1, 29.2, 29.0, 28.6, 28.0, 27.2, 26.0, 25.7, 23.8, 22.4, 20.9 ppm.

α-Arylation procedure: Glass vials were charged under inert atmosphere in the glovebox with NaO*t*Bu (1.1 mmol) in THF (0.5 mL). Then a mixture of the palladium catalyst (see Table 1 for amounts), aryl halide (1.0 mmol) and propiophenone or isobutanal (1.0 mmol) in THF (0.5 mL) was added at room temperature. Then the reaction were stirred at the temperature for the period of time indicated in Table 1. The reactions were quenched with aqueous solution of NH_4Cl and extracted with Et_2O. The organic layer was dried over $MgSO_4$. All compounds were identified by ^{1}H NMR spectroscopy. The reported yields are determined by NMR spectroscopy.

Methyl-Blocked Dimeric α,γ-Peptide Nanotube Segments: Formation of a Peptide Heterodimer through Backbone–Backbone Interactions**

*Roberto J. Brea, Manuel Amorín, Luis Castedo, and Juan R. Granja**

In recent years, considerable effort has been devoted to the synthesis of organic and inorganic nanotubes.[1] Among a number of other nanotube design concepts, self-assembling peptide nanotubes (SPNs)[1–6] have attracted attention for some time because of the probable ease with which they may be endowed with structural and functional properties of interest for applications in biology and materials science.[7] SPNs are formed by stacking cyclic peptides whose amino acid residues have configurations that impart the peptide ring backbone with an essentially flat shape and that orient the C=O and NH groups roughly perpendicular to the ring plane. This allows β-sheet-like hydrogen bonding between antiparallel rings (Figure 1). In particular, SPNs based on cyclic α,γ peptides (α,γ CPs) such as **1a** and **2a**, in which the requisite all-*trans* conformation is achieved by the alternation of (1*R*,3*S*)-3-aminocyclohexanecarboxylic acids (γ-Ach) with D-α-amino acids,[8] hold considerable promise for the design of nanotubes with novel structural and internal cavity properties.

The results reported herein support the possibility of constructing SPNs by using α,γ CPs of type **3**, in which the γ-amino acid is not γ-Ach but (1*R*,3*S*)-3-aminocyclopentanecarboxylic acid (γ-Acp).[9] We show that heterodimerization between γ-Ach-based and γ-Acp-based α,γ CPs is not only possible, but is favored over homodimerization for the compounds used herein. In nature, heterodimerization of peptides is common[10–12] and appears to constitute an economical means toward structural diversity and functional versatility; the same benefits may be expected to accrue from the development of a battery of α,γ CPs that are capable of forming hetero-oligomers with each other. However, whereas in all known natural cases the selectivity for hetero- rather than homodimerization is mainly due to interactions between the side chains of the component monomers, interactions of this kind are not necessary for preferential heterodimerization of the α,γ CPs studied herein. This is fortunate, because it means that the combinatorial advantages of heterodimerization are available without detriment to the possibility of exploiting side chains for other purposes.

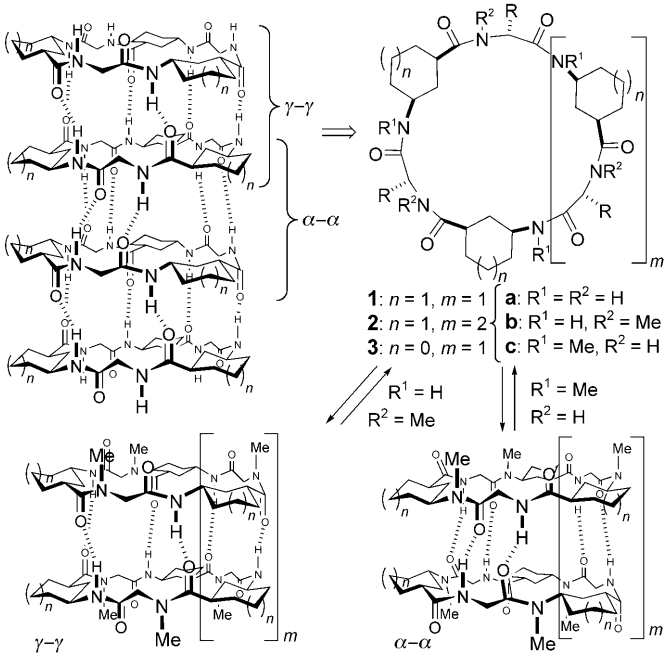

Figure 1. Design for self-assembling peptide nanotubes composed of *cyclo*[(D-Aa-(1*R*,3*S*)-γ-Aa)$_3$-] or *cyclo*[(D-Aa-(1*R*,3*S*)-γ-Aa)$_4$-] units, involving two different (α–α and γ–γ) Hydrogen-bonding patterns (Aa = amino acid). Dimer models of the two hydrogen-bonding patterns are shown at the bottom of the figure. Amino acid side chains have been omitted in the nanotube and dimer structures for clarity.

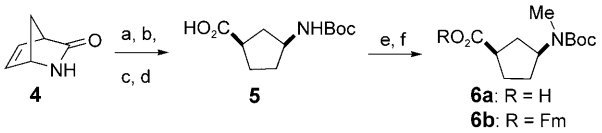
The construction of an SPN from α,γ CPs involves two different sets of β-sheet-like hydrogen bonds: one exclusively involves the NH and C=O groups of the γ-amino acid (γ–γ bonding, Figure 1) and the other, those of the α-amino acid (α–α bonding). In previous work with hexameric and octameric γ-Ach-based α,γ CPs, we found that α–α bonding was stronger than γ–γ bonding.[8] Herein, we accordingly focused on α–α bonding with the preparation of α,γ dimers in which γ–γ bonding was prevented by *N*-methylation of all the γ-amino acids as in **1c**–**3c** to avoid complications that would be irrelevant to this preliminary work.[13]

(1*R*,3*S*)-*N*-Boc-γ-Acp (**5**) was prepared from Vince's lactam (**4**)[14] by hydrogenation, acidic hydrolysis, and *N*-protection (Scheme 1) followed by successive recrystallizations from chloroform containing 0.7 equivalents of (+)-α-phenylethylamine, and was obtained with an enantiomeric purity greater than 97 %[15]. The *N*-methylated amino acid **6a** (^{Me}*N*-γ-Acp) was then obtained by treatment of **5** with sodium hydride and iodomethane in THF, and its fluorenyl-protected ester **6b** by reaction of **6a** with fluorenylmethanol.



The α,γ CP *cyclo*[(D-Leu-(1*R*,3*S*)-^{Me}*N*-γ-Acp)$_3$-] (**7a**, Figure 2) was synthesized by standard procedures and characterized by NMR spectroscopy and mass spectrometry (see Supporting Information). Its ^{1}H NMR spectra in polar and nonpolar solvents (CCl_4, $CDCl_3$, MeOH, DMSO) are well-defined, reflect a high degree of symmetry, and show a $J_{NH,H\alpha}$

coupling constant of 9.4 Hz, which is typical of the all-*trans* backbone conformation required for the flatness of the peptide ring (which, in turn, favors the formation of hydrogen-bonded assemblies such as the SPN shown in Figure 1). In nonpolar solvents, the formation of a dimer ($\mathbf{8}_{7a}$) is reflected by the downfield shift of the NH signal of Leu. The fact that the location of this signal ($\delta = 8.23$ ppm) remains constant at concentrations as low as 1×10^{-4} M, regardless of methanol composing up to 30% of the solvent or heating at 323 K, shows that the association constant for dimer formation must be at least $10^5\,M^{-1}$. FTIR spectra recorded in chloroform display bands at 1626, 1534, and 3304 cm^{-1} which, like analogous bands observed for other all-*trans* cyclic peptides linked by hydrogen bonds in dimers or SPNs,[2,8,13] resemble the amide I, amide II_{II}, and amide A bands typical of protein β sheets.

X-ray crystallography of a colorless prismatic crystal obtained from a solution of peptide **7a** in chloroform by vapor-phase equilibration with hexane confirmed the α–α dimerization of essentially flat, antiparallel rings by means of a β-sheet-like array of six hydrogen bonds with interatomic N···O distances of 2.88–2.98 Å (Figure 3a,b). The drum-shaped dimer has an approximate van der Waals internal diameter of 5.4 Å, and its cavity is occupied by a partially disordered chloroform molecule. The body-centered struc-

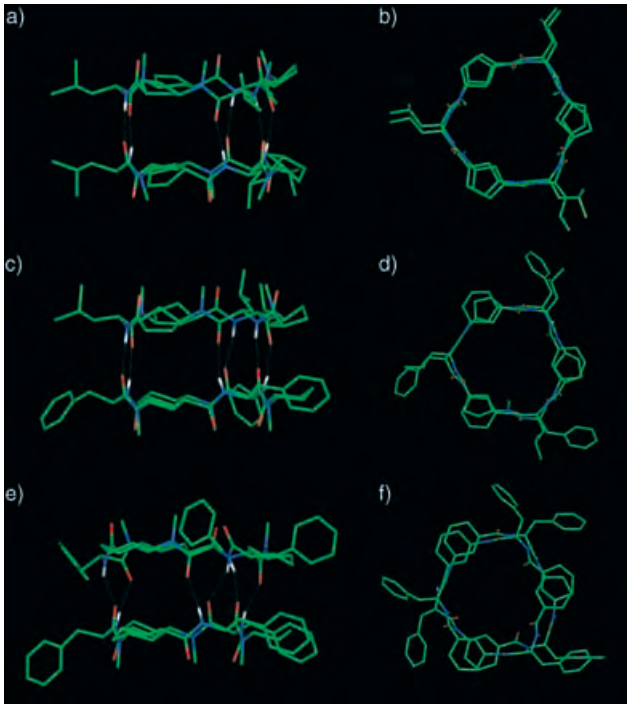

Figure 3. a) Views from the sides (a, c, e) and down the axes (b, d, f) of a,b) homodimers $\mathbf{8}_{7a}$ and e,f) **10**[8a], and of c,d) heterodimer $\mathbf{11}_{7a-9}$ in the solid state; chloroform molecules in the central cavities have been removed for clarity.

ture of the crystal forms channels by stacking the dimers along the crystallographic *a* axis, each dimer making van der Waals contacts with the next through its γ face carbonyl and *N*-methyl groups.

The γ-Ach-based **7a** analogue *cyclo*[(D-Phe-(1*R*,3*S*)-^{Me}*N*-γ-Ach)$_3$-] (**9**) also forms stable homodimers **10** in nonpolar solvents, with an association constant estimated to be at least $10^5\,M^{-1}$, as in the case of **7a** (Figure 2).[8] The possibility of heterodimer formation was confirmed upon the addition of 0.8 equivalents of **7a** to a solution of **9** (2.1 mM) in chloroform, which resulted in the appearance of a new species with a ^{1}H NMR spectrum that did not correspond to either of the possible homodimers. The dimeric nature of the new species, $\mathbf{11}_{\mathbf{7a\text{-}9}}$, was shown by NOE cross-peaks between the signals of $H\gamma_{Acp}$ (at $\delta = 4.92$ ppm) and $H\alpha_{Ach}$ (at $\delta = 2.62$ ppm). Definitive evidence of heterodimerization in the solid state was obtained by X-ray crystallography of the colorless prismatic single crystals recovered from a 1:1 solution of **7a** and **9** in chloroform. As expected, the monomeric cyclic peptides form heterodimers in which the two essentially flat rings are antiparallel, with their α faces linked in β-sheet fashion through six hydrogen bonds with N···O interatomic distances of 2.82–2.90 Å (Figure 3). The dimers stack closely along the *a* axis, each making van der Waals contacts with its neighbor with γ-face carbonyl and *N*-methyl groups. The resulting channel contains two chloroform molecules per unit, one in the cavity of the heterodimer and a second at variable sites between successive dimers.

Notably, the heterodimer $\mathbf{11}_{\mathbf{7a–9}}$ was in fact about 30-fold more abundant than the homodimer if prepared as described above from a mixture of **7a** and $\mathbf{9}$,$\mathbf{8}_{\mathbf{7a}}$ (0.8:1) which at 298 K corresponds to an energy difference of 2.0 kcal mol^{-1}. To determine whether this selectivity was derived from interactions between the side chains of the monomers, we investigated the dimerization of **7a** with *cyclo*[(D-Phe-(1*R*,3*S*)-^{Me}*N*-γ-Acp)$_3$-] (**7b**).[16] If the stability of $\mathbf{11}_{\mathbf{7a–9}}$ were the result of side-chain–side-chain interactions, the potential heterodimer $\mathbf{8}_{\mathbf{7a–7b}}$, in which the side chains are the same as those of $\mathbf{11}_{\mathbf{7a–9}}$ yet not the two backbones, is expected to be at least as stable as is $\mathbf{11}_{\mathbf{7a–9}}$ relative to $\mathbf{8}_{\mathbf{7a}}$. Nevertheless, the ^{1}H NMR spectrum of a 1:1 mixture of **7a** and **7b** in chloroform showed the presence of dimers $\mathbf{8}_{\mathbf{7a}}$, $\mathbf{8}_{\mathbf{7b}}$, and $\mathbf{8}_{\mathbf{7a–7b}}$ in almost equal concentrations, which implies that all three species have similar stabilities. This rules out the possibility of significant interactions between the side chains of opposing rings. Consistent with this conclusion, the addition of 0.9 equivalents of **9** to a solution of **7b** (4.6 mM) in chloroform resulted in the formation of heterodimer $\mathbf{11}_{\mathbf{7b–9}}$ without any observable trace of the homodimer **10**; this shows an even greater difference in stability between hetero- and homodimers than in the case of $\mathbf{11}_{\mathbf{7a–9}}$ and **10**.

The cause of the higher stability of the heterodimers is unclear. However, inspection of the crystal structures of $\mathbf{8}_{\mathbf{7a}}$, **10**[8a] and $\mathbf{11}_{\mathbf{7a–9}}$ (Figure 3) suggests that the heterodimer is more stable through an improved alignment of hydrogen-bond donors and acceptors. This could be due in part to more favorable packing between cyclopentyl and cyclohexyl than cyclopentyl–cyclopentyl or cyclohexyl–cyclohexyl ring packing. This hypothesis is supported by the intradimer distances between CPs in the crystals (see Supporting Information) and by those calculated from the N–H stretch frequencies ($\tilde{\nu} =$ 3304, 3309, and 3300 cm^{-1} in $\mathbf{8}_{\mathbf{7a}}$, **10** and $\mathbf{11}_{\mathbf{7a–9}}$, respectively; see Supporting Information). However, further studies might clarify this issue.

In conclusion, NMR and FTIR spectroscopy and X-ray diffraction data show conclusively that cyclic α,γ hexapeptides containing three γ-Acp units can form stable cylindrical dimers in which antiparallel peptide rings are linked by a β-sheet-like set of six hydrogen bonds. Even greater stability is shown by the heterodimers of these γ-Acp α,γ CPs with γ-Ach α,γ CPs. Potential applications for nanotubes developed from appropriately functionalized α,γ CPs include their use as logic gates, biosensors, catalysts, molecular receptors, and molecule containers.

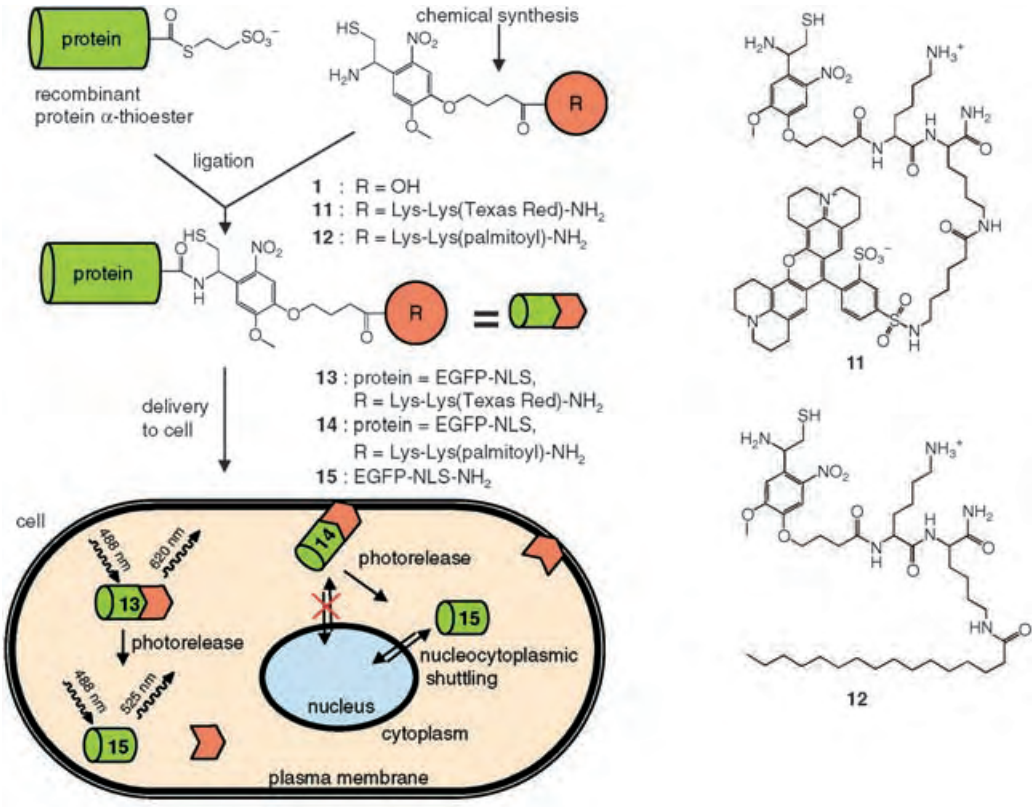
A Ligation and Photorelease Strategy for the Temporal and Spatial Control of Protein Function in Living Cells**

*Jean-Philippe Pellois and Tom W. Muir**

The temporal and spatial regulation of protein function is central to biological processes. Hence, the ability to artificially trigger molecular events in a biologically relevant context is useful for the study of living organisms. By chemically modifying a protein with groups that can respond to an external input such as light, control of protein function inside live cells can in principle be achieved. For instance, peptides or proteins that contain photolabile protecting groups appended to functionalities required for biological activity can be delivered into live cells and activated by UV irradiation at a desired time or location, and a cellular response can subsequently be measured.[1] This can be accomplished within single cells or in the context of whole organisms.[2] Although protein photocaging is a powerful tool to investigate biological systems, this approach has been limited by the difficulties associated with the preparation of the caged protein reagents.



To facilitate the semisynthesis of caged proteins and expand the repertoire of suitable chemical reagents, we report the design, synthesis, and use of a ligation and photorelease (LPR) molecule suitable for the introduction of a light-activatable cleavage site within a semisynthetic protein (Scheme 1). In contrast to previously reported strategies relying on site-specific photochemical cleavage,[3] our LPR approach is based on the ligation of a photocleavable synthetic moiety to the C terminus of a recombinant protein. In principle, the chemical and protein components may influence the properties of one another in the ligated state. Irradiation with light and subsequent photorelease of each element may then lead to the recovery of their respective function. We demonstrate that such chimeric semisynthetic proteins can be efficiently prepared and photocleaved in vitro. We also demonstrate that photocleavage of protein constructs microinjected in live cells can be triggered in a

Scheme 1. Schematic representation of the semisynthesis and applications of protein constructs in which a photoactivatable cleavage site is introduced. A synthetic moiety (e.g. peptide, small molecule) is ligated to a recombinant protein through molecule **1**. The semisynthetic protein is then delivered into living cells where the protein and chemical components can be photoreleased from one another with temporal and spatial control.

dosable manner and that the subcellular localization of a protein can be controlled with light.

The LPR molecule **1** was designed to combine a 2-aminoethanethiol group required for native chemical ligation, an *o*-nitrobenzyl chromophore required for bond cleavage,[4] and a carboxylic acid tether for facile conjugation to amine-containing compounds (Scheme 1).[5] For synthetic purposes, the thiol and amine groups were protected as *S*-*tert*-butyl disulfide and *tert*-butyl carbamate, respectively. The protected molecule was synthesized in seven steps from vanillin (24% overall yield), essentially according to the route developed by Dawson and co-workers for the synthesis of a native chemical ligation auxiliary.[6,7] The product is suitable for solid-phase peptide synthesis (SPPS) using Boc (*tert*-butyloxycarbonyl) or Fmoc (9-fluorenylmethoxycarbonyl) protecting groups. Once deprotected, the 2-aminoethanethiol moiety should be compatible with native chemical ligation and expressed protein ligation (EPL).[8]

The native chemical ligation and photocleavage reactions were characterized using a model α-thioester peptide, Gly-Lys(TAMRA)-Gly-$SCH_2CH_2SO_3Na$ (**7**; TAMRA = 5-carboxytetramethylrhodamine), and a peptide synthesized with **1** at its N terminus, **1**-Lys-Lys(Fl)-NH_2 (**8**; Fl = 6-carboxyfluorescein).[7] The two peptides were incubated in phosphate-buffered saline (PBS), 100 mM 2-mercaptoethanesulfonic acid sodium salt (MESNa; pH 7.5), and the expected product, Gly-Lys(TAMRA)-Gly-**1**-Lys-Lys(Fl)-NH_2 (**9**), was obtained in near-quantitative yield in less than 1 h. Subsequent irradiation of **9** (in 1 mM in PBS, pH 7.5) at 325 nm with a He–Cd laser for 2 s was sufficient for quantitative photolysis and led to the formation of a single N-terminal product, Gly-Lys(TAMRA)-Gly-NH_2 (**10**). The LPR molecule was thus shown to react rapidly with thioesters and to efficiently generate the corresponding amide upon photolysis.[7]

The applicability of our caging strategy was next tested in the context of EPL. The enhanced green fluorescent protein (EGFP) containing the SV40 T-antigen Lys-Lys-Lys-Arg-Lys-Val nuclear localization signal (NLS) at its C terminus was used as a model protein and obtained as the recombinant protein α-thioester (from transthioesterification of an EGFP-NLS-GyrA intein fusion expressed in *E. coli*, see ref. [11]).[9,10] The peptides **1**-Lys-Lys(TR) (**11**) and **1**-Lys-Lys(Palm) (**12**; TR = Texas Red-X, Palm = palmitoyl) were synthesized by SPPS and used as model small molecules. The ligation reactions between the EGFP-NLS α-thioester and peptides **11** and **12** were monitored by reverse-phase HPLC, electrospray mass spectrometry (ES-MS), and sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE) and were complete in less than 12 h (Figure 1a). The products, EGFP-NLS-**1**-Lys-Lys(TR) (**13**) and EGFP-NLS-**1**-Lys-Lys-(Palm) (**14**), were purified and their identity confirmed by ES-MS. Protein **13** is labeled with a fluorophore that can undergo intramolecular fluorescence resonant energy transfer (FRET) with EGFP.[12] Protein **14** is modified with a non-hydrolyzable

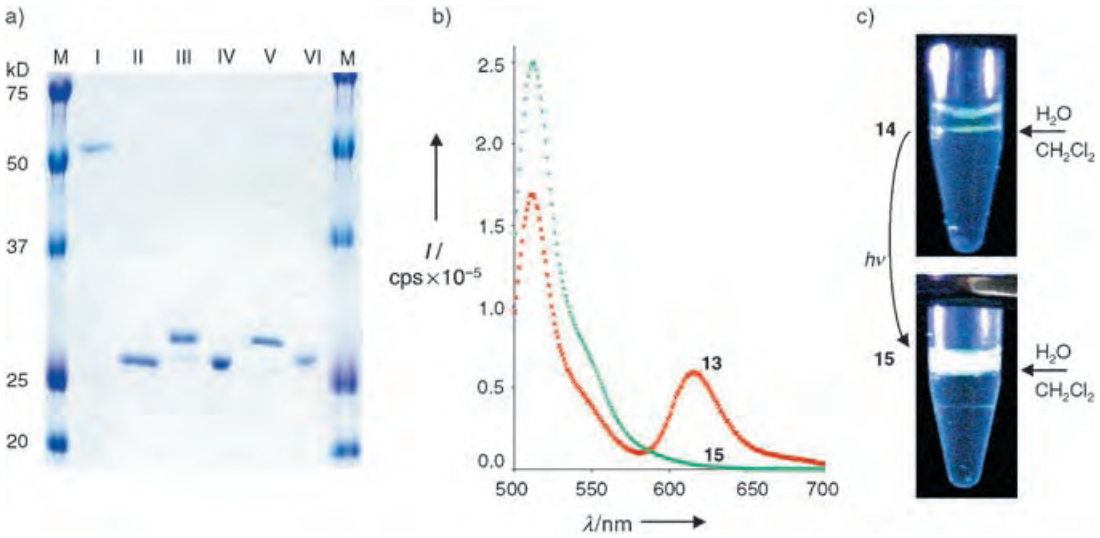

Figure 1. In vitro characterization of the semisynthetic proteins and their photocleaved products. a) SDS-PAGE analysis, Lanes M = marker; I = EGFP-NLS-GyrA-CBD; II = EGFP-NLS α-thioester; III = EGFP-NLS-**1**-Lys-Lys(TR) (**13**); IV = **13** + UV irradiation (**15**); V = EGFP-NLS-**1**-Lys-Lys-(Palm) (**14**); VI = **14** + UV irradiation (**15**). For all samples, UV irradiation was performed with a He–Cd laser at 325 nm for 2 s. Proteins were detected by coomassie staining. b) Fluorescence spectra of protein **13** before and after (→**15**) UV irradiation. Fluorescence excitation was performed at 488 nm. c) Images of test tubes containing protein **14**, before and after UV irradiation, in a two-phase system of water and dichloromethane. An arrow indicates the interface of the two solvents.

lipid, thereby mimicking a widespread post-translational phenomenon found in eukaryotic organisms.[13]

The photocleavage of **13** and **14** was first tested in vitro. Both constructs were irradiated with UV light, and the photolysis products were analyzed by HPLC, ES-MS, and SDS-PAGE. Under the conditions tested, the photolytic conversion was found to be quantitative, with the EGFP-NLS amide **15** (from **13** + UV or **14** + UV) identified as the only proteinogenic product (Figure 1a). The fluorescence spectrum of **13** showed FRET ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 620$ nm) between EGFP and TR with an efficiency of 33%. Protein **13** was used to determine the kinetics and quantum yield of photolysis by using the decrease in FRET intensity as a direct measure of photocleavage between the FRET pair (Figure 1b).[14] Using irradiation at 365 nm and 1 mW cm^{-2}, the kinetics of photolysis was first-order with a half-life of $t_{1/2} = 178$ s and an observed quantum yield of 0.11. Photolysis was quantitative in less than 2 s when a high-intensity laser was used. The behavior of **14** before and after photorelease of the lipid moiety was tested by monitoring the affinity of the protein for a hydrophobic environment. When dichloromethane was added to **14** dissolved in PBS containing 10 mM 3-[(3-cholamidopropyl)dimethylammonio]-1-propane-sulfonate (CHAPS, pH 7.5), the protein localized exclusively at the interface of the two solvents (Figure 1c). Upon irradiation with UV light, the EGFP-NLS moiety was released from the interface and diffused in the aqueous phase.

Protein **13** was microinjected into Hela cells cultured on glass slides and live-cell imaging was performed on a confocal microscope. A FRET signal ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 620$ nm) with an efficiency of 30% was observed accompanied with perfect colocalization of the signals from the green ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 525$ nm) and red ($\lambda_{ex} = 565$ nm, $\lambda_{em} = 620$ nm) channels (Figure 2a). Upon

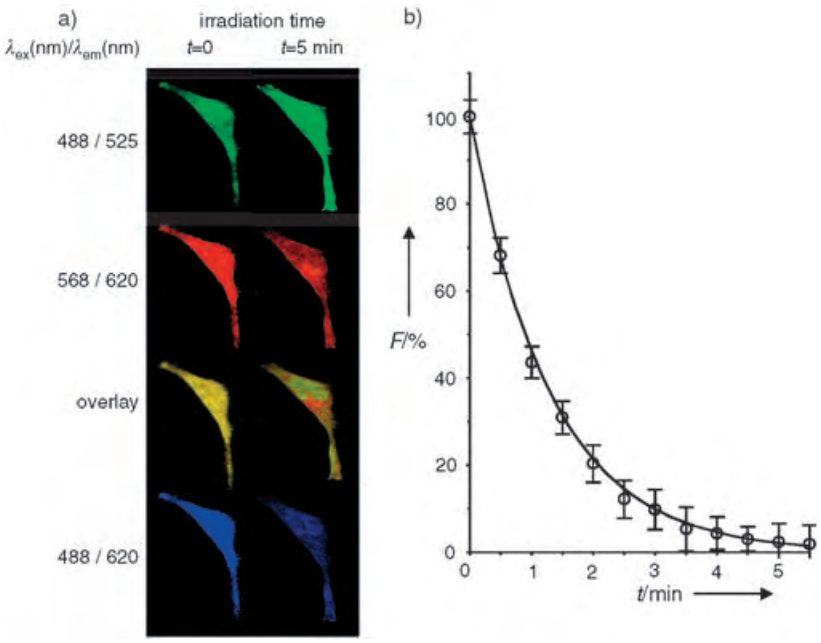

Figure 2. FRET assay. Hela cells were microinjected with **13** and exposed to low-intensity UV light (360 nm) at varying irradiation times. a) Pseudo-color images from confocal microscopy. The fluorescence signal from EGFP ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 525$ nm), Texas Red ($\lambda_{ex} = 568$, $\lambda_{em} = 620$ nm), and FRET between EGFP and Texas Red ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 620$ nm) were recorded before and immediately following UV irradiation. b) Time course of photocleavage. The FRET intensity F (averaged over the cytoplasmic area and normalized at t(irradiation) = 0) is plotted versus time of irradiation, along with an exponential curve of best fit, which yielded a first-order rate constant for photolysis of 1.3×10^{-2} s^{-1}. Error bars represent the standard deviation obtained from the averaging of two experiments.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

irradiation of the whole cell at 360 nm (5 μW), the FRET intensity diminished and EGFP fluorescence inversely increased. The observed kinetics of photolysis was first-order with a half-life of $t_{1/2} = 53$ s (Figure 2b). This demonstrates that photolysis of a protein in a cell can be achieved in a dosable manner with low-intensity UV light.[15] This is especially relevant if different concentrations of a photocleaved species would be expected to trigger different responses. Interestingly, the red and green signals accumulated in different subcellular locations after UV irradiation (Figure 2). These results demonstrate that a protein and a small molecule can be photoreleased from one another, thereby triggering changes in their respective function or localization.

The possibility of photocontrolled cellular localization was further explored with protein **14**. It was expected that the modification of EGFP with a lipid would target the protein to cellular membranes.[16] Indeed, when microinjected in Hela cells, **14** localized with great specificity at the plasma membrane, with less than 6 and 2.5% of the total signal present in the cytoplasm and nucleus, respectively (Figure 3).

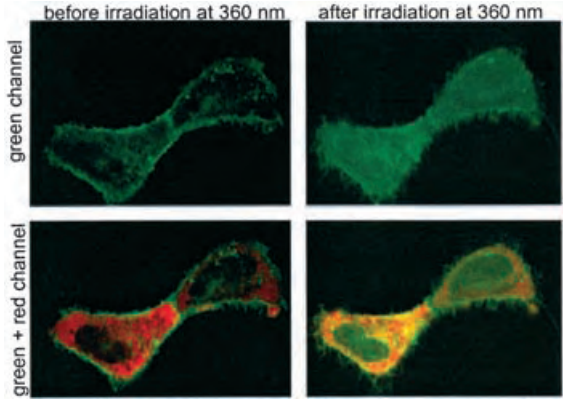

Figure 3. Representative images illustrating the photocontrol of the subcellular localization of a protein. Hela cells were microinjected with **14** and Dextran-TMR (70 kDa). Dextran-TMR was used as a red fluorescent marker that is excluded from the nucleus when injected in the cytoplasm. The images were acquired on a confocal microscope with green ($\lambda_{ex} = 488$ nm, $\lambda_{em} = 525$ nm) and red ($\lambda_{ex} = 568$, $\lambda_{em} = 620$ nm) channels and pseudo-colored. The fluorescence signals were recorded before and immediately following UV irradiation (360 nm).

When the cells were irradiated with UV light, the cleaved product **15** diffused in the cytoplasm and nucleus with respective 11- and 15-fold increases in signal. Even though an NLS was present in the construct, the protein did not accumulate in the nucleus presumably because its low molecular weight (28 kDa) allowed it to diffuse through the nuclear pore complex (NPC).[17] It is therefore interesting to note that the photocaging of a functional lysine present in the NLS sequence might not be sufficient to achieve photocontrol of the nuclear import of a small protein such as EGFP.[18] Indeed, a protein with a molecular weight below the NPC diffusion limit (≈ 40 kDa) might diffuse in and out of the nucleus in both its caged-NLS and uncaged-NLS states. In contrast, using a non-hydrolyzable but photocleavable lipid, EGFP was excluded from the nucleus in the absence of light but underwent free nucleocytoplasmic shuttling after irradiation. Hence, these results raise the possibility of the photocontrol of a protein's activity not by the caging of a critical group required for function but rather by control of its location.[19]

In summary, we have reported the synthesis of a LPR molecule and demonstrated its utility in the synthesis of caged proteins. We demonstrated that a photoactivatable cleavage site can be introduced in a semisynthetic protein containing complex chemical modifications. Furthermore, we showed that photocleavage can be achieved in a dosable manner to generate a controlled amount of cleaved product inside a living cell. Finally, we demonstrated that the localization of an EGFP-NLS construct can be controlled by photochemically releasing a lipid moiety from its C terminus. The chemical diversity that can be introduced by this approach should permit the manipulation of a protein in a variety of ways and the generation of a variety of responses upon photocleavage. Such caging strategies hold potential for the characterization of complex biological processes in their native context, single cells or whole organisms. Direct applications might involve the photoregulation of proteins containing photocleavable localization signals and post-translational modifications.

Lewis Base Promoters in the Pauson–Khand Reaction: A Different Scenario**

Carlos Perez del Valle, Anne Milet, Yves Gimbert,* and Andrew E. Greene*

The Pauson–Khand reaction,[1] a dicobalt octacarbonyl mediated process for joining an olefin and an acetylene to produce a cyclopentenone (Scheme 1), is enjoying increased application in synthesis because of recent improvements that permit a broad range of substrates to be used successfully.[2–5] Spectacular rate and yield increases in both the intra- and intermolecular versions of the reaction have been found to result, in particular, from the addition of Lewis bases,[6] such as amines[3] and thioethers[4] as well as alcohols, ethers, and water.[5]

Although the fundamental role of these Lewis base additives has received little study, it has been widely assumed that they function by accelerating the departure of a second CO ligand from the acetylene cobalt complex to create the requisite vacant site for olefin coordination, and in this way overcome the putative limiting factor.[6] Current reports abound with statements such as "[certain] Lewis bases in low-valent organotransition-metal complexes make the existing ligands labile and produce the reactive complexes"[6b] and "when amines coordinate to low-valent organotransition metals, the existing ligands on the metal become labile".[6a] However, do these spectacular increases really derive from a facilitated departure of a CO ligand to liberate a site for olefin coordination? We questioned this interpretation as it seemed clear that the obligatory loss of the first CO ligand would be energetically the same in the absence or presence of the promoter;[7] the fact that similar temperatures[8] are required for the reaction with and without a promoter being present provides evidence for this reasoning. Moreover, simple Lewis bases, essentially σ donors, should increase backdonation toward the remaining CO ligands by electronic enrichment of the metal, thus making the loss of the second CO ligand at best comparable, if not more difficult.[9] Herein, the prevailing view is shown to be incorrect and a new interpretation based on theoretical studies at the DFT level is outlined.

Yamanaka and Nakamura[10a] and our group[10b] have described the Pauson–Khand reaction pathway at the DFT level. Three particularly important findings resulted: First, the step that requires the most energy (ca. 26.4 kcal mol^{-1}) is decarbonylation,[10c] which occurs at the outset of the reaction (**II**→**III**, Scheme 1); second, equatorial (eq; $\mathbf{IV}_{eq}$) and axial (ax; $\mathbf{IV}_{ax}$) olefin coordination modes are possible (Figures 1 and 2), with the energies of activation for the formation of the cobaltacycle (**VI**) in the range 10.0–14.4 kcal mol^{-1} (the lowest-energy transition state is $\mathbf{V}_{ax}$);[10b] third, the formation of the cobaltacycle is reversible.[11]

In the present study, a CO ligand in complex **II** was replaced with a molecule of water, which occupies a lower-energy equatorial position ($\Delta E = 5$ kcal mol^{-1}, complex $\mathbf{III}_{H_2O}$; Figure 3, blue data).[13] Based on examination of the Co–CO bond lengths in $\mathbf{III}_{H_2O}$, extraction of a second

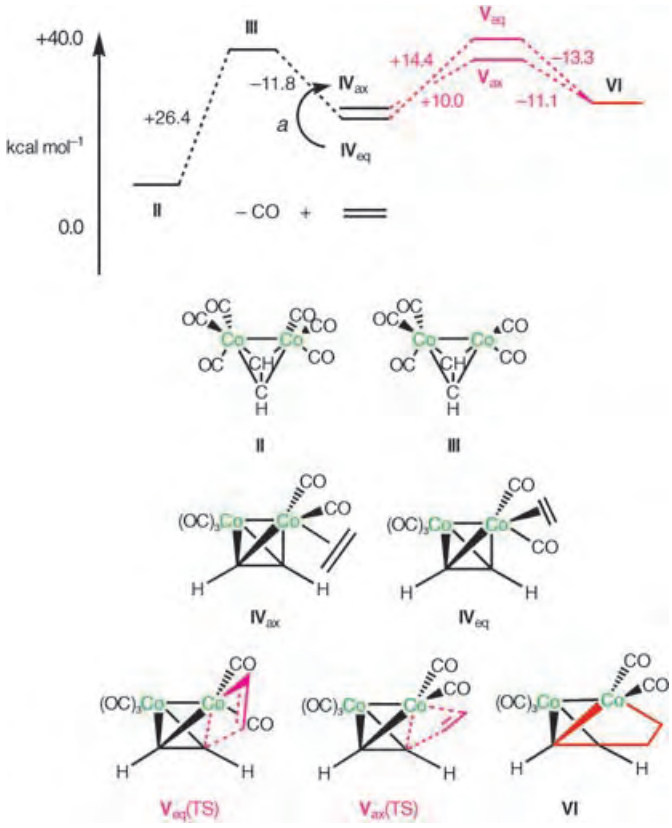

Figure 1. Energy barrier for formation of **VI** without a promoter. *a*) See Figure 2 for the transformation of $\mathbf{IV}_{eq}$ into $\mathbf{IV}_{ax}$. TS = transition state.

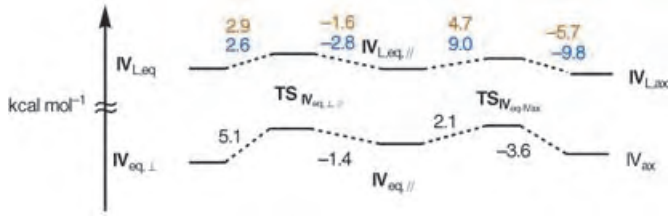

Figure 2. Transformation of $\mathbf{IV}_{eq}$ into $\mathbf{IV}_{ax}$. L = Ligand; ⊥, // are perpendicular and parallel coordination modes, respectively (with respect to the Co–Co axis).

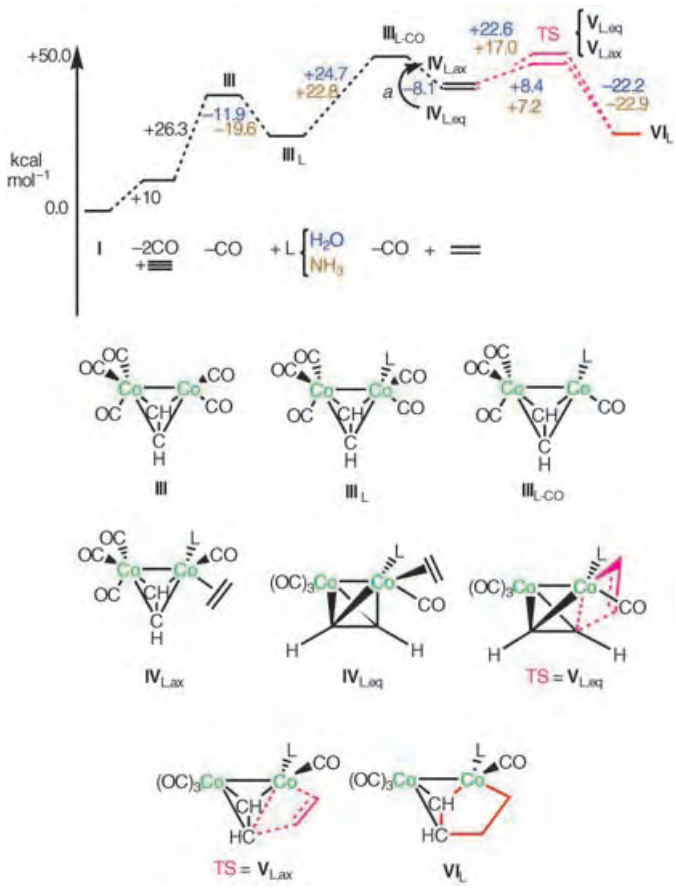

Figure 3. Energy barrier for formation of **VI** with promoter. *a*) See Figure 2 for the transformation of $\mathbf{IV}_{L,eq}$ into $\mathbf{IV}_{L,ax}$.

molecule of CO from $\mathbf{III}_{H_2O}$ was found to engender complex $\mathbf{III}_{H_2O\text{–}CO}$, in which the CO ligand has been lost from the remaining equatorial position on the water-associated cobalt atom (24.7 versus 31.5 kcal mol^{-1} for removal of a CO ligand from the next lowest-energy position, which is in the *trans*-equatorial position on the water-free cobalt atom). It is perfectly clear that water does not facilitate the loss of a second CO ligand, as only 1.6 kcal mol^{-1} separates the loss of the first and second CO ligands.[14] Next, association of complex $\mathbf{III}_{H_2O\text{–}CO}$ with ethylene at the vacant site on the water-associated cobalt atom produced complexes $\mathbf{IV}_{H_2O,ax}$ and $\mathbf{IV}_{H_2O,eq}$ (Figure 3).[15] The former confronts an activation-energy barrier of 8.4 kcal mol^{-1} for the formation of cobaltacycle $\mathbf{VI}_{H_2O}$ via transition-state $\mathbf{V}_{H_2O,ax}$, whereas the latter must overcome an activation-energy barrier of 22.6 kcal mol^{-1} via $\mathbf{V}_{H_2O,eq}$. Thus, it can be assumed that olefin insertion in the presence of water occurs from the axial position with an activation-energy barrier of 8.4 kcal mol^{-1}. This activation-energy barrier is lower than when the water is absent (then the olefin insertion is 10.0 kcal mol^{-1} from an axial position and 14.4 kcal mol^{-1} from an equatorial),[10b,16] but is nevertheless too high to explain the substantial acceleration of the reaction in its presence. A comparison of Figures 1 and 3, however, clearly reveals the remarkable ability of the promoter to stabilize the cobaltacycle: $\mathbf{VI}_{H_2O}$ is more than 22 kcal mol^{-1} lower than the transition state $\mathbf{V}_{H_2O,ax}$. As only 8.4 kcal mol^{-1} is required to reach this transition state in the forward direction, the formation of the cobaltacycle is in essence irreversible[17] in the presence of water. This irreversibility is the major effect of this promoter in the Pauson–Khand reaction.

Ammonia has also been studied at the DFT level to probe the remarkable accelerating effect of amines in the Pauson–Khand reaction, and the results have been found to parallel those obtained above with water as the promoter. Once again, removal of a second CO ligand from the complex ($\mathbf{III}_{NH_3}$) is energetically comparable to removal of the first ligand (Figure 3, brown data). The lower activation energy leading to the cobaltacycle transition state $\mathbf{V}_{NH_3}$ in the forward direction is 7.2 kcal mol^{-1} (Figure 3) and starting from the cobaltacycle $\mathbf{VI}_{NH_3}$, the activation energy is 22.9 kcal mol^{-1}, which effectively makes the insertion, as before, irreversible.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In conclusion, it has been shown for the first time that most simple Lewis base promoters are likely to achieve their dramatic rate effects in the Pauson–Khand reaction by imposing irreversibility on olefin insertion, rather than by facilitating the departure of a CO ligand to create a vacant site for olefin coordination, as previously believed. This discovery may help in the design of new ligands for improved efficacy and/or asymmetric induction in this important transformation.

[7] It is important to point out that there is apparently no pathway (eventually of lower energy) that involves a concerted exchange[12] or direct attack of the promoter on a CO ligand.

[8] For example, the Pauson–Khand reaction of 1-(hept-6-en-1-ynyl)benzene in the presence of cyclohexylamine required 3 days at 25 °C to obtain the expected adduct in 46% yield, whereas at 83 °C, typical thermal conditions, the reaction was complete after 5 min and afforded the adduct in 99% yield.[3b]

[9] Although phosphines and phosphites can be considered Lewis bases, as they coordinate to the metal center through σ donation, the relatively low-energy phosphorus d orbitals, which permit overlap with the metal d orbitals, also make them π acceptors. For this reason, they cannot be treated in the present context as simple Lewis bases. Thioethers, which are also π acceptors although weaker than phosphines, appear from preliminary results to behave as H_2O and NH_3, namely, as pure σ donors (A. Milet, C. Perez del Valle, unpublished results).

[11] Reversibility seems probable on closer examination, although the contrary was assumed[10b] based on earlier work.[1c,10a] This possibility is supported by a subsequent mass-spectrometric study[12] that detected in two separate experiments the insertion product prior to incorporation of any of the CO present and follows from the low CO concentration generally present in the Pauson–Khand reaction medium. (Reversibility does not affect the conclusion given in reference [10b].)

[13] Computational details: All calculations were performed with the Gaussian 98 suite of programs with a restricted B3LYP functional and the LANL2DZ for the Co centers and a D95 split valence basis set for C, O, and H atoms, with an augmentation of d-polarization functions on the C and O atoms. The basis set is denoted as LANL2DZ*; a) Gaussian 98 (Revision A.6): M. J. Frisch, et al. (see the Supporting Information); b) restricted B3LYP functional: A. D. Becke, *J. Chem. Phys.* **1993**, *98*, 5648 – 5652; C. Lee, W. Yang, R. G. Parr, *Phys. Rev. B* **1988**, *37*, 785 – 789; c) LANL2DZ: P. J. Hay, W. R. Wadt, *J. Chem. Phys.* **1985**, *82*, 270–283; d) D95 split valence: T. H. Dunning, Jr., P. J. Hay in *Modern Theoretical Chemistry* (Ed.: H. F. Schaefer, III), Plenum, New York, **1976**, pp. 1 – 28.

[14] This finding is fully consistent with recent calculations (supported by X-ray structure determinations) carried out by Frenking et al. on the octahedral complexes $[M(CO)_6]$ and $[M(CO)_5L]$ (M = Cr, Mo, W; L = H_2O, NH_3). In this investigation, it was shown that replacing a CO ligand with a Lewis base (L) significantly shortens the M–CO bond *trans* to L and slightly shortens those *cis*. On the reasonable assumption that the length of a M–CO bond reflects its strength, the results of Frenking et al. imply that removal of a second CO ligand from $[M(CO)_5L]$ is at best no easier than removal of the first; see: G. Frenking, S. Dapprich, T. Meisterknet, J. Uddin, *Metal–Ligand Interactions in Chemistry, Physics and Biology* (Eds.: N. Russo, D. R. Salahub), Kluwer, Dordrecht, **2000**, pp. 73 – 89.

[15] Pseudorotation[10b] in the equatorially coordinated olefin complex $\mathbf{IV}_{H_2O,eq}$ to give the axially coordinated complex $\mathbf{IV}_{H_2O,ax}$ was determined to be energetically feasible (see Figure 2).

[16] This lowering of the energy of activation is because of a reduction in the gap energy between the highest occupied molecular orbital (HOMO) of the alkyne–$Co_2(CO)_4H_2O$ fragment and the lowest unoccupied molecular orbital (LUMO) of ethylene in $\mathbf{IV}_{H_2O}$ (0.211 versus 0.224 eV in the complex without the promoter, **IV**). As this interaction is involved in the formation of the new C–C bond of the cobaltacycle, it follows that the better overlap in $\mathbf{IV}_{H_2O}$ should translate into a lower activation energy.

A Synthetic Zwitterionic Water Channel: Characterization in the Solid State by X-ray Crystallography and NMR Spectroscopy**

Zhaofu Fei, Dongbin Zhao, Tilmann J. Geldbach, Rosario Scopelliti, Paul J. Dyson, Sasa Antonijevic,* and Geoffrey Bodenhausen*

Bio-inspired supramolecular frameworks are of both fundamental value as models and of practical importance in areas such as materials science, catalysis, and molecular electronics.[1–3] Many of these synthetic materials are constructed from metal ions as connectors and ligands as linkers, and are referred to as coordination polymers.[4] Porous materials are of particular interest, as the nanosized cavities lead to novel phenomena, with applications in separation, storage, and catalysis. In this respect, attempts to generate synthetic water channels that mimic aquaporin water channels[5] have met with some success.[6–10] Here we describe a zwitterionic, helical tube of nanodimensions that to some extent mimics aquaporin, and provide a detailed study of the water incorporated inside the channel over a wide temperature range by solid-state ^{2}H NMR spectroscopy.

Reaction of the carboxy-functionalized imidazolium salt *N*,*N*′-diacetic acid imidazolium bromide[11] with zinc in aqueous solution affords zwitterionic coordination polymer **1** in crystalline form. The structure of **1** was characterized by single-crystal X-ray diffraction at 140 K and is shown in Figure 1. To ensure that the encapsulated water does not undergo any structural changes at ambient temperature, the structure was also determined at 293 K (see Supporting Information). The macrostructure is formed from $ZnBr(H_2O)$ units linked by bridging dicarboxylate anions, which assemble into helical channels and appear to be supported by weak π-stacking interactions between the imidazolium moieties and by intrahelical hydrogen bonds. The strongest hydrogen bonds stem from contacts of the carboxy oxygen atom O2 to H3 and H6 in the next layer. Two molecules constitute a full cycle within the helix with distances between the layers of 6.234 Å. The cavity of the channel is occupied by water molecules, which form a one-dimensional chain with distances between the oxygen atoms of 3.157 Å.

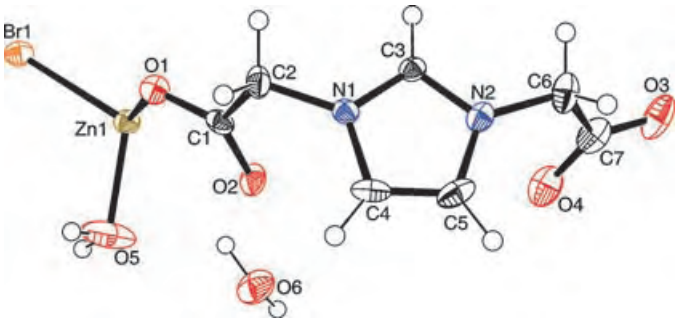

Figure 1. Structure of the asymmetric unit of **1** (ORTEP plot; ellipsoids are drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Zn1–Br1 2.3677(6), Zn–O1 1.977(2), Zn–O4 1.983(3), Zn–O5 2.014(3), C1–O1 1.270(4), C1–O2 1.243(4), C7–O3 1.199(5), C7–O4 1.287(5); O1-C1-O2 124.9(3), O3-C7-O4 126.2(4), Br1-Zn1-O1 109.73(7), Br1-Zn1-O5 111.0(1), Br1-Zn1-O4 114.88(8), O1-Zn1-O5 110.4(1), O1-Zn1-O4 117.1(1), O4-Zn1-O5 92.5(2).

The coordination sphere around the zinc anion in **1** is best described as a distorted tetrahedron with angles between 92.5(2) and 117.1(1)°. Zinc–oxygen bond lengths lie between 1.997(2) and 2.014(3) Å, and both angles and bond lengths are in good agreement with those of comparable zinc dicarboxylate polymers.[12]

The helices are packed in a hexagonal-based array with pronounced interhelical hydrogen bonding (Figure 2b). Each asymmetric unit has five contacts shorter than 3 Å to neighboring helices, which arise from medium-strength interactions from O1 and O3 and weaker contacts from the bromide ligands. The hydrogen atoms H61 and H62 of the encapsulated water molecule are engaged in strong hydrogen

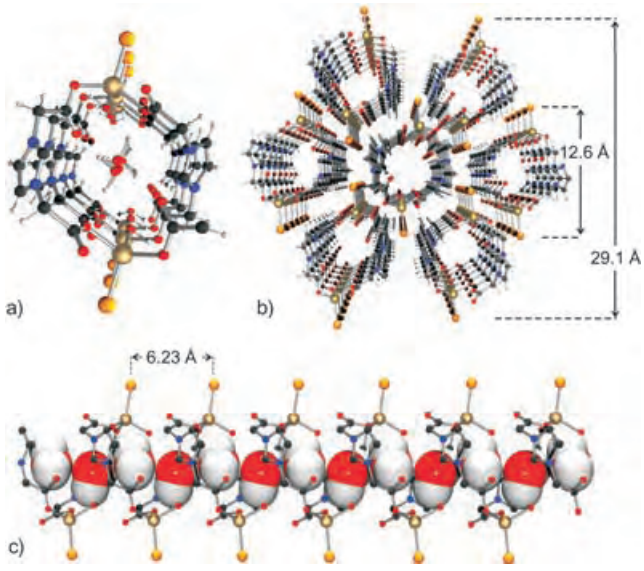

Figure 2. a) View into the helical tube of **1** with the one-dimensional water chain in the center. b) View into the helical tube of **1** with the free water molecules removed for clarity. c) View along the *y* axis showing the encapsulated water drawn with van der Waals radii. Hydrogen atoms on the imidazolium moiety have been omitted for clarity.

bonding to oxygen atoms O2 and O4 on the inner wall of the tube, both of which bear a delocalized negative charge. As a result of these quite strong interactions the oxygen atoms of the water molecules are in relatively close contact and are not bridged by a hydrogen atom. A summary of the more important hydrogen-bonding interactions (< 3 Å) is given in Table 1.

Table 1: Hydrogen-bonding distances [Å] in **1**.

Interhelical contacts		Intrahelical contacts		Contacts from free water	
Br–H2	2.952	O2–H3	2.461	O2–H62	1.728
Br–H4	2.823	O2–H6	2.908	O4–H61	2.194
Br–H6	2.960			O5–H61	2.261
O1–H2	2.405				
O3–H5	2.353				

The inner dimensions of the imidazolium–zinc channel are 5.656 and 6.515 Å between adjacent oxygen atoms O2 and O4, respectively, resulting in a cavity of about 2.656×3.513 Å^2 if van der Waals radii are taken into account.[13]

In the mass spectrum, no evidence of aggregates is observed, and pulsed-field-gradient spin-echo (PGSE) diffusion measurements on **1** in D_2O solution confirmed that **1** exists as a monomer in solution. The estimated diffusion coefficient is 5.65×10^{-10} m^2 s^{-1}, which corresponds to a hydrodynamic radius of about 3.8 Å. This value is in good agreement with that of 3.6 Å for the analogous zwitterionic imidazolium carboxylate (see Supporting Information).

To gain a more comprehensive understanding of the properties of the one-dimensional water chain and to characterize the local mobility of the two different types of water molecules in the helix, **1** was studied by solid-state ^{13}C and ^{2}H NMR spectroscopy. Figure 3 shows the ^{13}C cross-polarized (CP) magic-angle spinning (MAS) NMR spectrum of **1**. Seven nicely resolved resonance signals are associated with seven crystallographically different carbon atoms in the asymmetric unit cell as follows: C1 and C7 at $\delta = 174.07$ and 175.46 ppm; C2 and C6 at $\delta = 53.56$ and 54.78 ppm; C3 at $\delta = 139.67$; and C4 and C5 at $\delta = 125.07$ and 125.77 ppm. The linewidths (full width at half-height, FWHH) of C1 and C7 are only 30 Hz and could be obtained by very accurate

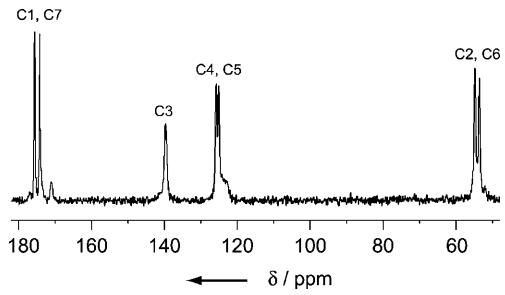

Figure 3. ^{13}C CPMAS NMR spectrum of **1** displays seven resolved resonance signals that are assigned to seven crystallographically different carbon atoms in the asymmetric unit cell. The spectrum is the result of averaging 8000 transients.

adjustment of the magic angle (better than $\pm 0.004°$).[14,15] Such narrow ^{13}C resonances suggest that the helical framework structure of this coordination polymer experiences very little structural disorder, if any.[16] The linewidths of the other carbon atoms are in the range of 50–80 Hz, and are due in part to residual dipolar splittings (or second-order quadrupole–dipole cross-terms) to neighboring ^{14}N atoms.[17–19] The assignment of the chemical shifts of pairs of chemically identical carbon atoms is not feasible from the ^{13}C CPMAS spectrum alone.

Understanding the motional behavior of water molecules that constitute a one-dimensional chain may prove important for the rationalization of various biological processes. To distinguish the two different types of water molecules in **1** and individually examine their motional behavior, they were replaced by D_2O by recrystallization of **1** from heavy water to give the deuterated material **1-D**. The water content of **1-D** amounts to 98% of the theoretical value, as determined by thermogravimetric analysis.

Motional disorder can be readily probed by static and MAS ^{2}H NMR experiments over a wide range of correlation rates, namely, 10^2 s$^{-1} < k < 10^9$ s^{-1}.[20–22] The high-resolution ^{2}H MAS spectra of **1-D** in Figure 4 show three resonances at isotropic chemical shifts $\delta_{iso} = 2.19$, 3.24, and 7.09 ppm. The very narrow resonance at $\delta = 2.19$ ppm (marked with $*$) is assigned to residual [D_6]acetone, which was used in the preparation of **1-D**. This resonance, which in comparison to the other two resonances displays only a center band, makes a negligible contribution to the overall signal. The other two resonances are assigned to water molecules and exhibit different linewidths due to structural disorder of water molecules and/or motional broadening. The considerable difference in the local magnetic fields, reflected in a relatively large difference in isotropic chemical shift, is due to the very different electronic environments of the two types of water molecules. One is coordinated to zinc ($\delta = 7.09$ ppm), whereas the other is located in the middle of the channel ($\delta =$ 3.24 ppm).

Variable-temperature ^{2}H MAS NMR spectra of **1-D** reveal changes in the linewidths of the ^{2}H resonances of both types of water molecules and thus indicate their mobility. Increasing temperature results in line narrowing, and this suggests that both types of water molecules move in the fast motional regime, typically $k \geq 10^7$ s^{-1}.[21–23] Decreasing the temperature leads to line broadening, and the linewidths observed at 246 K for both water resonances are so large that spinning sidebands are barely observable. The rate of the motions in this intermediate regime is typically in the range 10^7 s$^{-1} \geq k \geq 10^4$ s^{-1}. Figure 4b shows a ^{2}H MAS spectrum of **1-D** that was exposed to high vacuum (0.01 mbar) for 4 min. The loss of about 10% of the total amount of water indicates that water molecules can be relatively easily removed from the channel. Both deuterium resonances arising from deuterons of water molecules in Figure 4b are narrower than in Figure 4a. The narrowing of the resonance at $\delta = 3.24$ ppm is more pronounced, most probably due to increased mobility of the free water molecules.

It is expected that water molecules bound to zinc have restricted motional freedom and undergo a reorientational

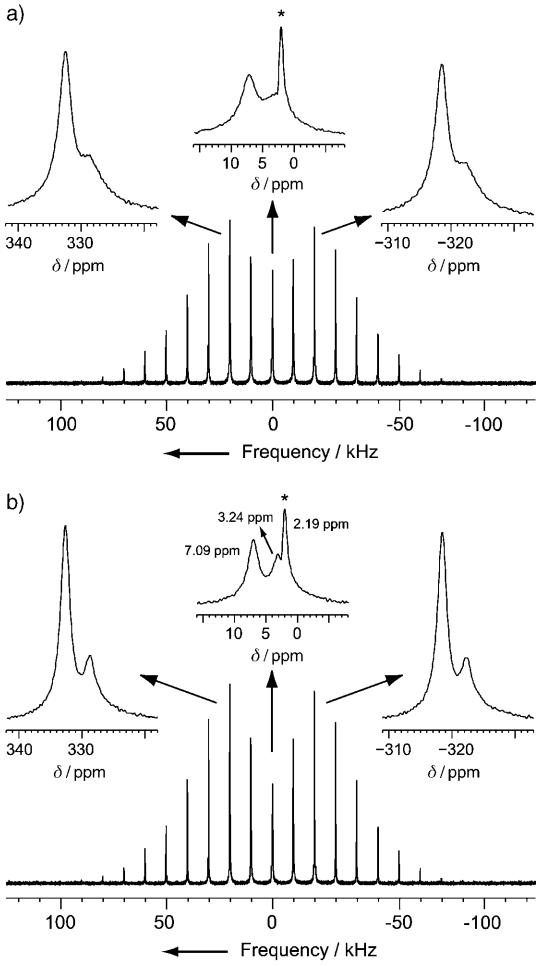

Figure 4. ^{2}H MAS NMR spectra of **1-D**: a) as synthesized and b) treated under high vacuum (0.01 mbar) for 4 min. The center band of (b) displays three resolved signals: two water molecules at $\delta = 7.09$ and 3.24 ppm and a narrow signal at $\delta = 2.19$ ppm (marked with *) originating from traces of [D_6]acetone. The spectra are the result of averaging 640 transients. A line broadening of 10 Hz was applied to both spectra.

motion which is often a 180° flip around the DOD bisector.[24] The free water in the channel, on the other hand, is expected to have more motional freedom, even to the extent of fast isotropic tumbling.[20] Both types of motion lead to averaging of the quadrupolar interaction. The former yields an averaged quadrupolar interaction that is comparable in magnitude to the quadrupolar interaction in the absence of the motion. The latter results in a more pronounced averaging of the quadrupolar interaction, and in extreme cases only a tiny residual quadrupolar interaction is observed. Note that not only reorientation and/or tumbling of the actual deuteron results in averaging of the quadrupolar interaction, but molecular motions of the nearest neighbors can also introduce a time-dependent electric field gradient and hence a time-dependent quadrupolar interaction.

Figure 5 shows the experimental ^{2}H NMR spectra of **1-D** (solid line) recorded at different temperatures under static conditions. They display a complex lineshape resulting from an overlap of several resonances. The narrow resonance at

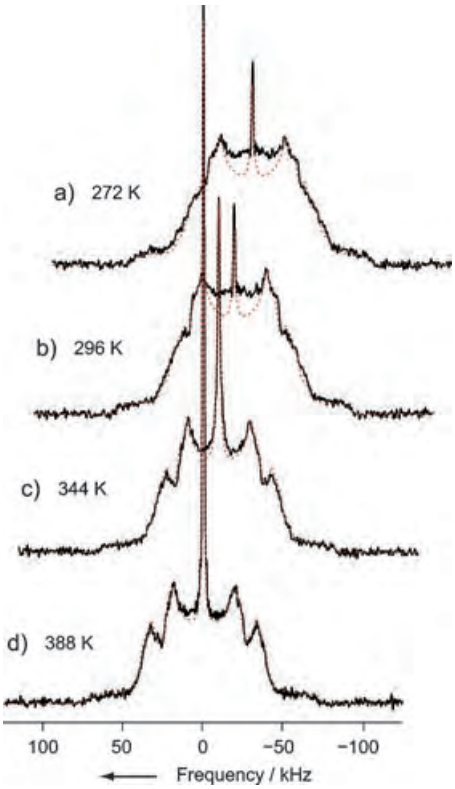

Figure 5. Experimental (solid) and simulated (dashed) static ^{2}H NMR spectra of **1-D** recorded as a function of temperature. The narrow signal at $\delta = 2.19$ ppm in a) and b) purely arises from residual [D_6]acetone. The spectra are the result of averaging 640 transients.

$\delta = 2.19$ ppm in the two spectra at lower temperatures is assigned to traces of [D_6]acetone. This resonance is also present in the spectra recorded at higher temperatures, but here it overlaps with newly formed narrow resonances, as shown in Figure 5c and d. The broad features of the spectra resemble superposition of two deuterium powder patterns. The narrower powder pattern has $\delta_{iso} = 3.24$ ppm, while the broader powder pattern has $\delta_{iso} = 7.09$ ppm, as found from the spectra in Figure 4. They are assigned to free and bound water molecules, respectively. Each powder pattern can be represented by an averaged quadrupolar coupling constant C_Q and an asymmetry parameter η_Q. Simulated spectra obtained by using the averaged quadrupolar parameters listed in Table 2 are in a very good agreement with the experimental spectra (Figure 5). In the absence of motions, C_Q for deuterons of D_2O in solids is typically in the range $240 \geq C_Q \geq 180$ kHz.[25] Evidently, the quadrupolar interaction for the free water molecules is averaged to a greater extent. Bound-water

Table 2: Quadrupolar parameters C_Q and η_Q of **1-D** as determined from static ^{2}H NMR spectra recorded at different temperatures.

T [K]	Bound water ($\delta_{iso} = 7.09$ ppm)		Free water ($\delta_{iso} = 3.24$ ppm)	
	C_Q [kHz]	η_Q	C_Q [kHz]	η_Q
272	98.4	0.14	64.5	0.16
296	96.7	0.12	62.9	0.15
344	96.7	0.09	60.5	0.14
388	96.7	0.09	57.6	0.11

deuterons experience a slight decrease of averaged quadrupolar parameters with increasing temperature, which indicates that there is little change in motional freedom. However, the significant change in C_Q and η_Q for free-water deuterons is indicative of a significant change in motional freedom of these water molecules. Curiously, neither of the two averaged powder patterns corresponds to that which would arise for 180° flips around the DOD bisector, which normally results in averaged values of $\eta_Q \approx 1$.[24]

The intensity ratio of the two powder patterns at lower temperatures is estimated to be 1:1, while at higher temperatures (Figure 5c, d) the intensity of the narrower pattern (free water molecules) decreases by conversion to a newly formed narrow resonance. This "sudden" formation of a new narrow resonance is observed between 336 and 345 K. It has a linewidth typical for water undergoing isotropic motion and cannot result only from an increased rate of motion or deuterium transfer, that is, in the fashion of a proton (deuteron) wire. The observed increase in motional freedom might occur either due to some structural change or to water "rattling" (i.e., diffusing into unoccupied positions) through the channel. A structural change could be expected to result in an increase of motional freedom for *all* free water molecules, but this was not observed. On the other hand, unoccupied water sites represent an opportunity for some water molecules to undergo a translational "hopping" motion. We find that any changes observed in ^{2}H spectra of **1-D** exposed to temperatures in the range from 240 to 390 K are reversible. In samples of **1-D** with 100% water content, where there are no vacant sites in the helix, another very sharp resonance (FWHH of 5 Hz) at $\delta = 5.0$ ppm is observed at 353 K (see Supporting Information). This very narrow resonance is characteristic of water that tumbles very rapidly and was therefore assigned to adsorbed or surface water. It is not clear if these water molecules are released from the channel as a direct consequence of water transport through the channel, as found in other one-dimensional water-channel systems,[26–28] or due to a rather unlikely diffusion process through the "walls" of the nanotubes. In samples with less than 100% water content, water molecules do not appear to leave the tubes when the temperature increases, but move along the vacant sites. The existence of vacant sites was shown to be critical for diffusion processes observed in zeolites containing one-dimensional water channels.[27]

Studies on helical zinc complexes of carboxylic acids have been previously reported,[29,30] including conducting helical polymers,[31] of which zwitterionic polymers are of special interest.[32] In this work, however, the water molecules in the helical channel have been studied by ^{2}H NMR spectroscopy, and it was possible to differentiate the two different types of water molecules. One is assigned to deuterons of free water molecules found in the middle of the channels, while the other corresponds to water coordinated to zinc. Both undergo fast motions ($k \geq 10^7\ s^{-1}$) at room temperature. The quadrupolar interaction of free-water deuterons in **1-D** is scaled to a greater extent, and this indicates different motional behavior than for the bound water molecules. Furthermore, the motional freedom of free water molecules increases with increasing temperature, since the quadrupolar parameters decrease, while they remain the same for the bound-water deuterons. Neither of the two deuterium powder patterns corresponds to simple 180° flips around the DOD bisector. Partial displacement of water molecules from the channel seems to be a process with a low activation energy barrier, since a significant fraction of the water molecules can be removed by short exposure to high vacuum. The change in the motional behavior of a fraction of the free water molecules in **1-D** that occurs between 336 and 345 K results in a dramatic averaging of C_Q. This is most probably due the water "rattling" along the channel, permitted by the existence of vacant water positions, in addition to already existing motional degrees of freedom. Proton (deuteron) transfer can be ruled out as a source of such an observation. The very narrow peak at $\delta = 5.0$ ppm observed at 353 K for **1** without water vacancies is related to water molecules that are delivered to the outside of the channels and have a liquidlike motional behavior. It is likely that these water molecules either diffuse out of the channels or escape as a result of water transfer through the channel. Finally, a possible exchange of deuterons between two different types of water molecules may occur, but on a timescale with a rate constant that is much smaller than the quadrupolar splitting.

It is interesting to compare **1** to other systems that contain water in a confined channel. For example, aquaporin water channels (AQP1) are composed of an hourglass structure with a narrowest constriction of 2.8 Å (Figure 6); the narrowest gap in the channel of **1** is 2.656 Å.

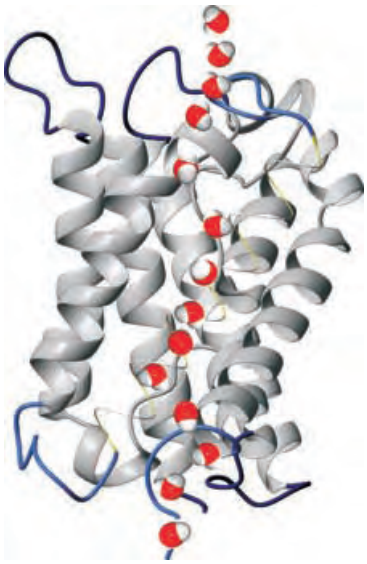

Figure 6. Schematic representation of water flow through an aquaporin channel.

Although **1** resembles an aquaporin channel in that the water molecules form a single file and the diameter of the tube is of approximately the same size as the narrowest part of the pore in the protein, there are also fundamental differences. Owing to the presence of strong hydrogen bonds between the hydrogen atoms of the encapsulated water molecules and oxygen atoms of the inner wall, both water

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrogen atoms point towards the wall of the tube, rather than to neighboring water molecules. In contrast, each water molecule in aquaporin water channels forms one hydrogen bond with the wall of the protein and one with an adjacent water molecule. Furthermore, the water molecules in the aquaporin channel undergo a fliplike motion while passing through the pore. This change in orientation is crucial for proton exclusion and it thereby preserves the electrochemical potential across the cell membrane.[33] Owing to the uniformity of the zwittertube, no comparable conformational change is observed along the chain of water molecules. As the wall of the nanotube consists of zwitterionic residues, interactions between the water molecules are much stronger than in the biological system, where dipole–dipole interactions dominate. This has implications with respect to the efficiency with which the channel can transport water. It was previously demonstrated in carbon nanotubes that the high affinity of water molecules to charged moieties significantly decreases their mobility.[34] While the rate of water transport at room temperature in aquaporin is on the order of one molecule per nanosecond,[35] it is believed to be slower in the zwittertube.

Experimental Section

Synthesis of **1**: A mixture of elemental zinc (1.50 g, 23 mmol) and **2** (2.65 g, 10 mmol) in water (20 mL) was stirred for 10 days at room temperature, after which time no further evolution of hydrogen gas could be observed. The mixture was filtered, and the filtrate concentrated to half of its volume and left at room temperature for seven days to afford big colorless crystals. Yield: 96%. ESI-MS: m/z: 328 $[M-2H_2O]^+$, 344 $[M-H_2O]^+$; ^{1}H NMR (400.1 MHz, D_2O): $\delta =$ 8.68 (s, 1H), 7.36 (s, 2H), 4.80 ppm (s, 4H); ^{13}C NMR (100.6 MHz, D_2O): $\delta = 172.33, 137.18, 123.17, 51.94$ ppm; IR: $\tilde{\nu} = 3150, 3108, 3017, 2950, 1622, 1589, 1565, 1437, 1397, 1298, 1177, 1162, 1101, 971, 765, 681$ cm^{-1}; elemental analysis (%) calcd for $C_7H_{11}BrN_2O_6Zn$ (364.46): C 23.07, H 3.04, N 7.69; found: C 23.11, H 3.07, N 7.75.

Synthesis of **1-D**: A sample of **1** was dissolved in D_2O followed by immediate removal of the solvent at low temperature (2–5 °C) to afford **1-D**. The solid was washed with [D_6]acetone to remove residual water absorbed on the surface. The water content was determined to be 98% of the theoretical value by thermogravimetric analysis and was confirmed by elemental analysis. Unwanted exchange of protons at C3 was observed when the sample of **1-D** was prepared at room temperature with slow evaporation of the solvent. The D3 deuteron of this material results in an additional ^{2}H NMR resonance at $\delta =$ 9.1 ppm (see Supporting Information), which makes interpretation of the NMR spectra more complicated. Similarly, if the reaction of the acid with elemental zinc was carried out in D_2O, unwanted exchange of H2, H3, and H6 is observed.

Crystallography: Single crystals of **1** were measured on a KUMA CCD diffractometer. Data reduction was performed with CrysAlis RED.[36] Structure solution and refinement were performed with the SHELX97 software package;[37] graphical representations of the structures were made with ORTEP32.[38] Structures were solved by direct methods and successive interpretation of the difference Fourier maps, followed by full-matrix least-squares refinement (against F^2). An empirical absorption correction (DELABS)[39] was applied. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms on the imidazolium moiety were placed in their geometrically generated positions and refined with a riding model. Water hydrogen atoms were located on the Fourier map and refined by using the HTAB command with a fixed O–H distance of 0.98 Å and with an additional H···H restraint (1.60 Å) by using the DFIX command in SHELX97.

Crystal data of $C_7H_7BrN_2O_4Zn\cdot 2H_2O$ (**1**): Crystal dimensions $0.19\times0.10\times0.06$ mm^3, monoclinic, space group $P2(1)/n$, $a =$ 9.9025(8), $b = 6.2345(4)$, $c = 19.3319(15)$ Å, $\beta = 99.314(7)°$, $V =$ 1177.76(15) Å^3, $\rho_{calcd} = 2.055$ Mg m^{-3}, $Z = 4$, $\mu = 5.496$ mm^{-1}, $\theta_{max} =$ 3.44 to 25.03, $Mo_{K\alpha}$ radiation ($\lambda = 0.71070$ Å), $T = 140$ K, $F(000) =$ 720, total reflections 6384, independent reflections 1971 ($R_{int} =$ 0.0400), observed data 1677 ($I > 2\sigma(I)$). The final anisotropic full-matrix least-squares refinement on F^2 for 166 variables converged at $R_1 = 0.0271$ and $wR_2 = 0.0636$ with a GOF of 1.061. CCDC-251434 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Solid-state NMR measurements: Spectra were recorded on a Bruker Avance 400 spectrometer equipped with a wide-bore 9.4 T magnet, operating at a Larmor frequency of $\nu_0 = 61.4$ MHz for ^{2}H ($S = 1$) and 100.6 MHz for ^{13}C ($S = 1/2$). Cross-polarized (CP) ^{13}C{^{1}H} MAS NMR spectra were recorded with a standard Bruker 2.5 mm CPMAS probe with a spinning rate of 30 kHz, a ^{1}H radio-frequency (RF) field strength of 85 kHz, a contact time of 1 ms, and a recycle interval of 3 s. The best performance of TPPM proton decoupling during acquisition was obtained with pulse widths of 3.9 μs at 100 kHz ^{1}H RF field and a phase difference between two successive pulses of 35°. The magic angle was adjusted first by minimizing the residual quadrupolar splitting in the rotor-synchronized ^{2}H MAS spectrum of α-oxalic acid [D_6]dehydrate.[12] The subsequent fine adjustment was carried out by maximizing the height of the ST_1-CT shifted-echo signal in a one-dimensional STMAS experiment.[12,15] Static and MAS deuterium spectra were recorded with a Bruker 4 mm MAS probe. A 500 W RF amplifier was used to give a ^{2}H 90° pulse duration of 2.9 μs. The static wide-line deuterium powder patterns were recorded by using "Exorcycled" quadrupolar echo pulse sequence to avoid distortions due to chemical shift anisotropy (CSA).[40] The variable-temperature ^{2}H MAS experiments were performed at a spinning rate of 10 kHz. A recycle interval of 1 s was appropriate for all deuterium resonances. The temperature was calibrated by using $Pb(NO_3)_2$ as a chemical shift thermometer.[41] Chemical shifts are reported in ppm relative to adamantane (high-frequency resonance at $\delta = 38.56$ ppm) for ^{13}C and TMS for ^{2}H. The frequency-domain simulated spectra were produced by a home-written program which does not take finite pulse duration effects into account, and does not include any time dependence of the quadrupolar interaction.[42]

F···H–N Hydrogen Bonding Driven Foldamers: Efficient Receptors for Dialkylammonium Ions**

*Chuang Li, Shi-Fang Ren, Jun-Li Hou, Hui-Ping Yi, Shi-Zheng Zhu, Xi-Kui Jiang, and Zhan-Ting Li**

An essential attribute of biomacromolecules such as proteins and nucleic acids is their accurate control over the noncovalent forces that govern folding and self-assembly processes.[1] In recent years, chemists have been engaged in the development of foldamers,[2] artificial molecules that utilize noncovalent forces to modulate folding or helical structures. Among other noncovalent forces, the O···H–N hydrogen bonding motif has been widely utilized for this purpose,[3,4] a number of pyridine-N···H–N hydrogen-bonded folding architectures have also been developed.[5] Although it has been well established that the fluoride ion acts as a very strong proton acceptor,[6,7] it has been reported that covalently bound fluorine is a very weak intermolecular hydrogen-bonding acceptor.[8,9] We recently found that intramolecular F···H–N hydrogen bonding could be used to promote the stability of hydrazide-based quadruply hydrogen-bonded heterodimers.[10] We envisioned that rationally designed, intramolecular F···H–N hydrogen bonding might provide a novel approach for the formation of new rigid, well-established conformations. Herein, we demonstrate how intramolecular F···H–N hydrogen bonding controls the crescent and helical conformations of aromatic amides to such an

extent that the new foldamers can strongly bind dialkylammonium ions.

The molecular design was based on the recently established three-centered O···H–N hydrogen-bond motif.[11,12] Compounds **1**–**6** were prepared and a comparison of the

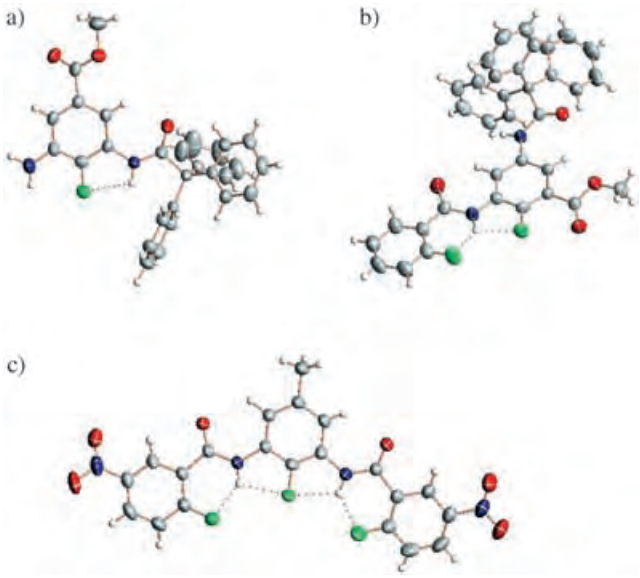
chemical shift of the amide proton in **2**–**6** with that in **1**, which cannot form intramolecular hydrogen bonds (Table 1), reveals a significant downfield shift of their NH signals, suggesting the formation of an intramolecular hydrogen bond in **2**–**6**. Larger changes with respect to **1** are exhibited for **4**–**6** than for **2** and **3**, indicating that the NH protons in **4**–**6** are involved in two hydrogen bonds simultaneously, as observed in the RO-related systems.[11–13]

Numerous attempts to crystallize **2**–**6** were unsuccessful. Given the well-known crystallinity of triphenylmethyl and nitro compounds,[14,15] compounds **7**–**9** were prepared. Crystals of **7**–**9** suitable for X-ray analysis were grown by slow evaporation of a dichloromethane/ethyl acetate solution of **7**–**9**. All three compounds adopt a well-defined planar conformation, which is rigidified by intramolecular F···H–N hydrogen bonds (Figure 1). For **7**, the F···H (amide) distance

Table 1: Chemical shifts (ppm) of the NH signals of **1**–**8**, **10**, and **11a** in $CDCl_3$ (1.0 mM) at 25 °C.[a]

Compound	Chemical shift	Compound	Chemical shift
1	7.78	**6**	8.57 (0.79)
2	8.00 (0.22)	**7**	8.43 (0.65)
3	8.47 (0.69)	**8**	8.88 (1.10)
4	8.83 (1.05)	**10**	8.91 (1.13)
5	8.92 (1.14)	**11a**	9.04 (1.26)

[a] The value in parentheses is the downfield change of the chemical shift relative to that of **1**.



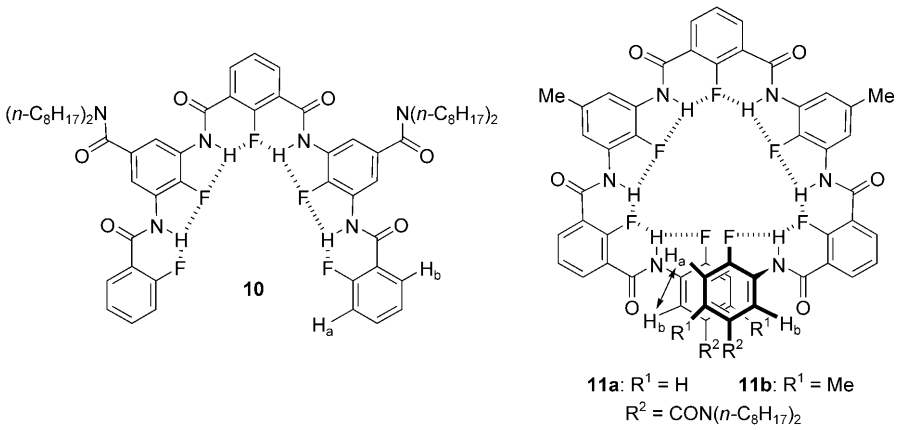


Figure 1. The crystal structures of a) **7**, b) **8**, and c) **9**.

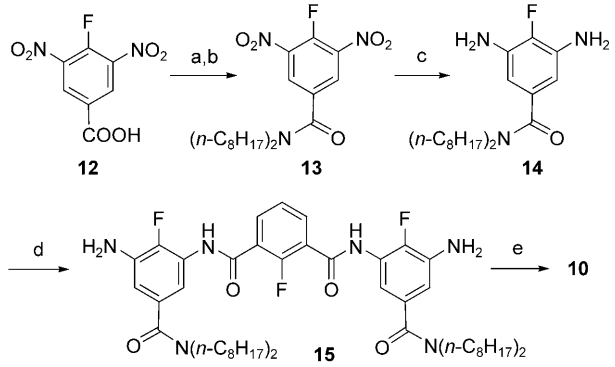
is 2.227 Å, and the F···H–N angle is 106.37°. The fluorine atoms of both **8** and **9** are located in the proximity of the amide hydrogen atom due to the formation of the three-centered hydrogen bonds. The F···H (amide) distance in the six- and five-membered hydrogen bonds is 1.935 and 2.184 Å for **8**, and 1.968 and 2.183 Å for **9**, respectively, and the corresponding F···H–N angles are 135.72 and 107.59° for **8** and 135.98 and 111.21° for **9**. All these values fall in the range considered acceptable for F···H–N hydrogen bonds, namely, the F···HN distance is less than 2.3 Å and the F···H–N angle is greater than 90°.[9a] In contrast, the F···HN distance for the amine group in **7** is 2.385 Å, which is outside the acceptable range given above. In addition, the skeleton of 3-mer **9** adopts a folding conformation.



The three-centered F···H–N hydrogen-bonding motif, which is present both in solution and in the solid state, is an ideal candidate for the construction of foldamers. To explore this possibility, 5-mer **10** and 7-mers **11a** and **11b** (Scheme 1) were synthesized, as shown in Scheme 2 and Scheme 3. Thus, acid **12** was first transformed to amide **13**, which was then reduced to diamine **14**. Treatment of **14** with 2-fluoroisophthaloyl chloride afforded **15**. Finally, reaction of **15** with 2-fluorobenzoyl chloride yielded **10**. For the preparation of **11a**, **16** was first reduced to amine **17**, which was acylated to yield **18**. The latter was then hydrolyzed to acid **19**, followed by a coupling reaction to give **20**. Treatment of **20** with 2-fluoroisophthaloyl chloride afforded **11a** (Scheme 3). Compound **11b** was prepared according to the similar route.

The peaks in the ^{1}H NMR spectrum of **10**, **11a**, and **11b** in $CDCl_3$ are sharp. Their signals have been assigned based on 2D-NOESY and COSY experiments. As expected, their NH signals are also shifted downfield substantially (Table 1) and

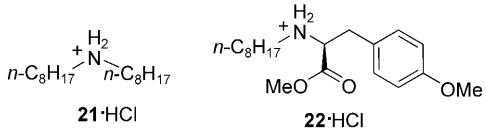
Scheme 1. The structure of crescent **10** and helical **11a** and **11b**. Compound **11b** displayed intramolecular end-to-end NOE values (500 MHz, 2.5 mM in $CDCl_3$ at 25 °C), which support a helical conformation for **11**.



Scheme 2. The synthesis of **10**: a) oxalyl chloride, DMF (cat.), THF, RT, 0.5 h; b) $NH(n\text{-}C_8H_{17})_2$, NEt_3, THF, −10 °C, 1 h, 59%; c) H_2, Pd/C, MeOH/THF, RT, 48 h, 92%; d) 2-fluoroisophthaloyl chloride, NEt_3, CH_2Cl_2, RT, 0.5 h, 33%; e) 2-fluorobenzoyl chloride, NEt_3, CH_2Cl_2, RT, 1 h, 47%.

Scheme 3. The synthesis of **11a**: a) H_2, Pd/C, MeOH/THF, RT, 24 h, 98%; b) 2-fluoro-3-(methoxycarbonyl)benzoyl chloride, NEt_3, CH_2Cl_2, 0.5 h, 91%; c) LiOH, THF/H_2O, RT, 5 h, 98%; d) 2-fluoro-5-methylbenzene-1,3-diamine, EDCI, DMAP (cat.), CH_2Cl_2, RT, 12 h, 45%; e) 2-fluoroisophthaloyl chloride, NEt_3, CH_2Cl_2, RT, 1 h, 55%.

the values are comparable to those of the shorter oligomers **4**, **5**, and **8**. The results indicate that three-centered F···H–N hydrogen bonding also occurs in these oligomers. Moderate NOE values between H_a and H_b of the terminal benzene rings was observed for **11b** (Scheme 1). Because similar NOE values were not revealed for **10** even at the higher concentration of 10 mM, the observed NOE between H_a and H_b in **11b** can only be ascribed to that produced by an end-to-end arrangement, as shown in Scheme 1. This cross-ring NOE strongly supports a rigidified helical conformation of **11b** in chloroform.[4a,b] In contrast, 5-mer **10** is not long enough for its two end benzene units to stack or even to be in close proximity. In principle, a similar NOE might also be displayed in **11a**, but this could not be assigned due to signal overlap for the terminal benzene groups.

Molecular modeling revealed a crescent planar conformation for **10** and a helical conformation for **11a** and **11b**, in which the fluorine atoms converge towards the center of their skeletons creating a polar internal cavity of 6.5 and 6.6 Å diameter, respectively. Such a cavity appears well suited to complex secondary $R_2NH_2^+$ ions in a manner similar to that of dibenzo[24]crown-8.[16] The interactions of **10** and **11a** with symmetrical **21**·HCl were first investigated by means of ESI-MS analysis of their 1:1 solutions (1.0 mM) in chloroform.

Strong peaks for the complexes **10**·**21**·HCl and **11a**·**21**·HCl were observed (Figure 2). The ^{1}H NMR NOESY spectrum also revealed intermolecular a NOE of modest strength for the 1:1 solution of **10** and **21**·HCl as well as **11a** and **21**·HCl in $CDCl_3$ (Scheme 4). These results clearly indicate that strong intermolecular F···H electrostatic interactions or hydrogen bonding also exist between the new F···H–N hydrogen-bonded foldamers and **21**·HCl.[17]

Addition of **21**·HCl to the solution of **10** and **11a** in chloroform remarkably decreased the intensity of the emission for the folding oligomers in the fluorescent spectrum. Similar quenching was not observed when **21**·HCl was replaced with $n\text{Bu}_4\text{N}^+\text{Cl}^-$ under identical conditions. This result rules out the possibility of a salt effect at a higher concentration of ammonium and indicates that the reduction of the emission intensity was caused by the complexation of the folding molecules around the ammonium ion. As an example, the titration spectra of **11a** with **21**·HCl are provided in Figure 3. By fitting the data to a 1:1 binding mode, the association constant K_{assoc} of complexes **10**·**21**·HCl and

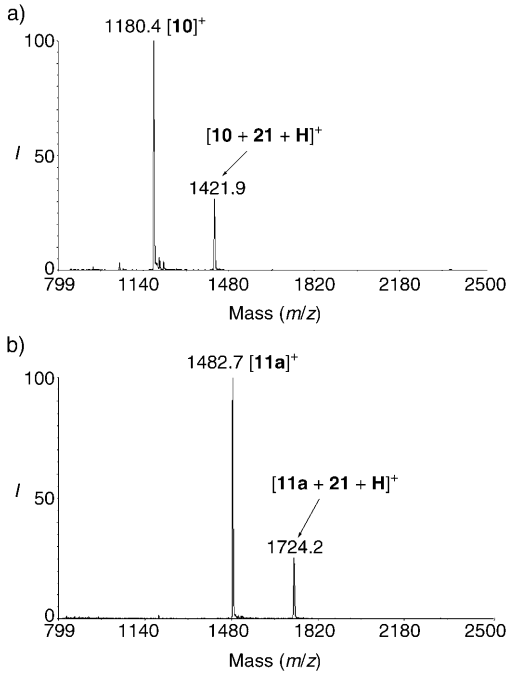

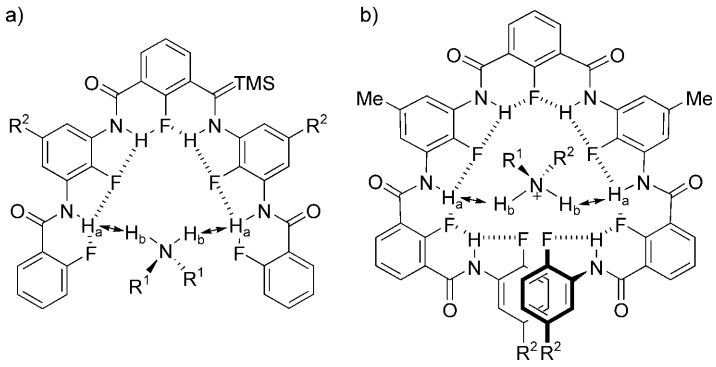

Figure 2. ESI mass spectrum obtained from the 1:1 solution (1.0 mM) of a) **10** and **21**·HCl and b) **11a** and **21**·HCl in chloroform.

Scheme 4. Intermolecular NOE connections revealed by the NOESY spectrum (500 MHz) of the 1:1 solution of a) **10** and **21**·HCl and b) **11a** and **21**·HCl in $CDCl_3$ (4.0 mM) at 23 °C (mixing time: 0.5 s).

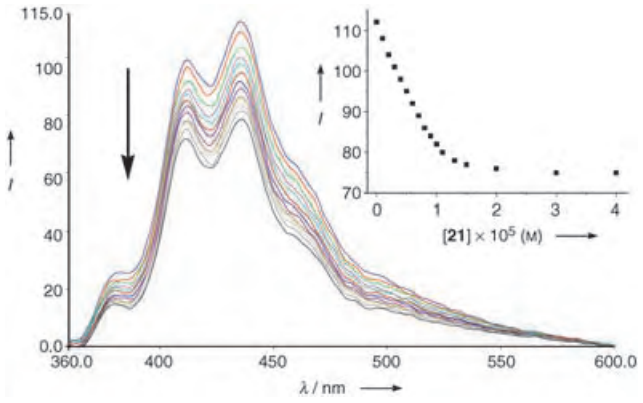

Figure 3. Fluorescent spectra of **11a** (1.5×10^{-5} M, excitation wavelength = 330 nm) in $CHCl_3$ at 25 °C, decreased gradually on addition of **21**·HCl (0 to 4.0×10^{-5} M).

11a·**21**·HCl was determined to be $4.9(\pm0.6)\times10^6$ and $8.1(\pm0.9)\times10^6\,M^{-1}$, respectively.[4b] The 1:1 stoichiometry of the complexes was estimated based on Job plots. The binding constants are considerably larger than that of the complex between dibenzo[24]crown-8 and dialkylammonium ions (ca. $2.7\times10^4\,M^{-1}$ in chloroform),[18] suggesting that highly efficient electrostatic interactions or hydrogen bonding could occur intermolecularly between fluorine and ammonium protons due to the rigidified conformation of the oligomers. By using the same method, the K_{assoc} values for the complexes of **10** with chiral **22**·HCl as well as **11a** with chiral **22**·HCl were determined to be $2.4(\pm0.2)\times10^5$ and $7.3(\pm0.8)\times10^5\,M^{-1}$, respectively. The values are notably lower than those of the respective complexes with **21**·HCl, but still larger than that of the complex between dibenzo[24]crown-8 and dialkylammonium ions.

Given the above strong binding features, chirality induction through complexation of **10** and **11a** with chiral L-tyrosine-derived ammonium **22**·HCl was investigated.[4b,19] The guest molecule itself (**22**·HCl) exhibits a CD signal at about 277 nm. Therefore, induced CD spectra generated from the interaction of **22**·HCl with **10** and **11a** were obtained by subtracting the spectrum of **22**·HCl from that of the complex. Figure 4 shows the typical CD curves of the complexes. Both

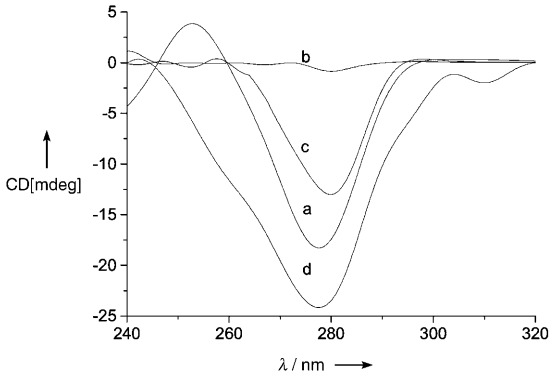

Figure 4. Induced CD spectra of complexes of **22**·HCl (1.0 mM) with a) **10** (1.0 mM), b) **11a** (0.01 mM), c) **11a** (0.05 mM), and **11a** (0.2 mM) in chloroform at 25 °C.

complexes gave rise to negative CD signals, which increased with the increase of the concentration of the foldamers. The intensity of the CD signals decreased on addition of polar methanol in the solvent and vanished in a mixture of methanol and chloroform (1:3 (v/v)), indicating that the signals were generated through intermolecular electrostatic interactions or hydrogen bonding. The different shape of the signals of the two complexes presumably reflects the different binding environments for both complexes.

In conclusion, we have demonstrated that intramolecular F···H–N hydrogen bonds can be utilized to construct a new generation of folding architectures. The new foldamers strongly bind dialkylammonium ions by means of intermolecular electrostatic interactions or F···H–N hydrogen bonding, which can give rise to chiral induction or amplification through complexation with chiral L-tyrosine-derived ammonium ions. It has been proposed that organic fluorine hardly ever accepts hydrogen bonds, the present work reveals that

relatively stable F···H–N hydrogen bonds can be formed, at least, in elaborately designed aromatic amides. This opens new possibilities in supramolecular chemistry. Future work will be aimed at the construction of helical and tubular systems with deeper and larger cavities. It also remains to be shown whether intra- or intermolecular F···H–O hydrogen bonds can be formed in organofluorine molecules.

an ionic lattice can be achieved by replacing some or all of the cation–anion bonding with Lewis base coordination (Scheme 1).[1] In notable cases, the molecular species produced have a close resemblance to the parent lattice.[2] A further strategy is the confinement of a salt lattice within another framework. Recent research has focused on the growth of salt lattices within carbon nanotubes (Scheme 1).[3] Remarkably, novel lattice arrangements can be formed which are different to the bulk materials. A third way by which alkali metal salt lattices can, in theory, be modified is by coordination of the anion (Scheme 1).

This approach is the opposite to the conventional coordination of the cation using a Lewis base and thus can be termed as "inverse coordination".[4] Although there are many examples of anion receptors based on organic frameworks, in these anion receptors interactions are relatively weak compared to the lattice energies of simple metal salts.[5] The obvious candidates for strong anion receptors are inorganic metal hosts. Recent studies by Mulvey[4] and Hawthorne and Zheng[6] have illustrated the power of inverse coordination of this type using macrocyclic hosts.

As part of our studies into the structural and materials properties of p-block-metal phosphides,[7–9] we recently investigated the synthesis of Group 13 anions $[RE(PR)_3]^{4-}$ (E = Al, Ga, In).[10] From the reaction of "$PhPLi_2$"[11] with $MeAlCl_2$ in tetrahydrofuran (THF) the ion-separated compound Li^+-$[\{MeAl(PPh)_3Li_4\}_4(\mu_4\text{-}Cl)(thf)_{12}]^-$ (**1**) was obtained as a crystalline product in 43% yield (first batch; see Scheme 2 and Experimental Section).

Scheme 1. Modification of ionic lattices, as illustrated for the fragmentation of the NaCl-type lattice.

Scheme 2. Synthesis of **1**.

Although **1** was characterized by spectroscopic and analytical investigations, its elaborate structure was not fully apparent until a later low-temperature X-ray study.[12] This study showed that the heterometallic cage anion of **1** has a $[Al_4P_{12}Li_{16}(\mu_4\text{-}Cl)]$ core (Figure 1 a), in which an interstitial Cl^- anion is effectively coordinated by four of the anticipated $[MeAl(PPh)_3Li_4]$ units. Although templating of inorganic cages by halide ions has been seen before,[13] to our knowledge **1** is the first example in which a lattice of a simple binary salt is modified by inverse coordination exclusively of one ion.

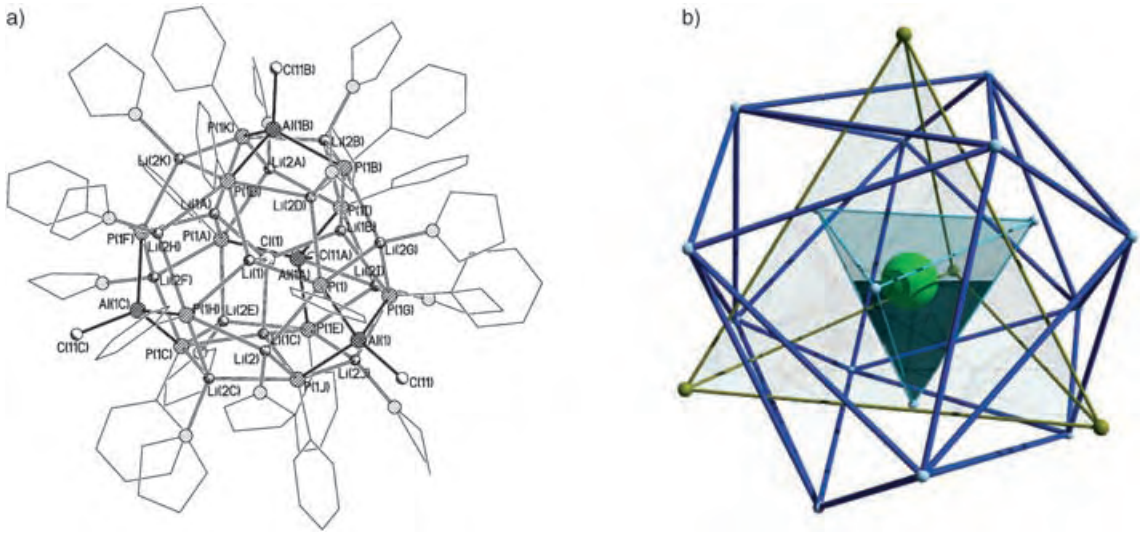

Figure 1. a) Structure of the heterometallic anion of **1**. Selected bond lengths [Å] and angles [°]: Al(1)–C(10) 2.01(2), Al(1)–P(1) 2.461(3), P(1)–Li(1) 2.530(5), P(1)–Li(2) 2.63(1), P(1)–Li(2D) 2.47(2), P(1)–Li(2G) 2.71(2), Li(1)–Cl(1) 2.45(2); P(1)-Al(1)-P(1G) 103.0(1), C(10)-Al(1)-P(1) 115.33(9), Li-Cl(1)-Li(mean) 109.5. Symmetry transformations used to generate equivalent atoms: **A** $x, -y+1, -z+1$; **B** $-x+1, -y+1, z$; **C** $-x+1, y, -z+1$; **D** $-z+1, x, -y+1$; **E** $y, -z+1, -x+1$; **F** z, x, y; **G** y, z, x; **H** $-x+{}^3/_2, -z+1, y+0$; **I** $-x+{}^3/_2, z+0, -y+1$; b) Polyhedral Li (outer shell: blue), Al (gold), Li (inner shell: light blue).

Interestingly, lithium complexes containing the related nitrogen anions $[R'Al(NAr)_3]^{4-}$ (R′ = Et, *n*Bu; Ar = 2-MeO-C_6H_4) adopt the ion-separated arrangements $[Li(thf)_4]^+{}_2$-$[\{R'Al(NR)_3\}_2Li_6]^{2-}$, in which no encapsulation of Cl^- ion occurs even though LiCl was also present as a byproduct in their formation.[10] This difference may reflect the lower ligand bite angle of the $[RAl(NAr)_3]^{4-}$ anions (average N···N distance 2.91 Å) compared to the $[MeAl(PPh)_3]^{4-}$ analogue (P···P 3.85 Å).[14] The tetrahedral $[MeAl(PPh)_3]^{4-}$ anions of **1** are arranged in a supramolecular tetrahedron (gold, Figure 1b), which defines the polyhedral arrangement of Li^+ cations. The twelve phosphorus atoms of the cage are all six-coordinate, each being bonded to four Li^+ cations within the core (Li–P 2.47(2)–2.71(2) Å). The twelve symmetry-related ions Li(1) to Li(1K) (dark blue, Figure 1b) form an outer shell of ions that are each bonded to three phosphorus centers and to the oxygen atom of a thf ligand. The inner sphere of Li ions Li(1) to Li(1C) (light blue, Figure 1b) have a similar tetrahedral environment, but their fourth coordination site is occupied by the central Cl^- anion (Li(1–1C)–Cl(1) 2.45(2) Å) rather than an O atom from thf.

A single, unsolvated Li^+ countercation is present in the lattice of **1** for each of the cage anions (the charge of each anion being −1). Owing to the cubic space group there is inherent uncertainty as to the location of these Li^+ cations, however, their most likely location is midway between cluster anions (along the edges of the cubic unit cell and the central face-to-face diagonals), that is, $^1/_3$ Li^+ occupancy in each of these 24 symmetry-related sites balancing the −8 charge of the 8 anions. Eight anions are depicted in Figure 2.[12] The Li^+ cations loosely bind two cluster anions together through agostic C–H···Li interactions with two pairs of symmetry-related thf molecules (C···Li 2.82–2.84 Å).[15] The resulting zeolite-like structure contains large voids (ca. 17 Å in diameter) and has nearest neighbor Li^+ and encapsulated Cl^- ions separated by 8.76 Å. The absence of further disordered thf molecules or $[Li(thf)_4]^+$ cations in these voids was shown by elemental analysis and ^{1}H NMR spectroscopic studies of bulk samples of **1** (analyzed both before and after exposure to a vacuum). We assume that **1** adopts this open arrangement in order to minimize anion–anion repulsion, while allowing efficient anion–cation interactions between the polyhedra. Clearly, anion–anion repulsion would be significantly greater in the close-packed structure of the original LiCl lattice.

Solid-state ^{6}Li and ^{7}Li magic-angle-spinning (MAS) NMR studies of **1** are consistent with the X-ray study,[16] showing the expected presence of a highly mobile Li^+ cation as a result of its weak coordination. Two resonances are found in the ^{6}Li NMR spectrum at $\delta = 3.8$ ($w_{1/2} = 50$ Hz, 10 Hz line broadening) and 2.2 ppm (very broad). At least two overlapping resonances are apparent in the ^{7}Li NMR spectrum at $\delta = 3.6$ and 0.4 ppm.[17] The ^{7}Li relaxation-assisted separation (2D-RAS) spectrum[18] shows that the peak at $\delta = 0.4$ ppm has a longitudinal relaxation time constant $t_1 = 107$ s, which is consistent with a mobile lithium ion without strong interactions to other nuclei (Li(3)), while the peak at $\delta = 3.6$ ppm has $t_1 = 6$ s. The peak at $\delta = 0.4$ ppm does not appear in a ^{7}Li{^{1}H} CPMAS NMR spectrum, confirming that lithium is not bound strongly to any protons in the crystal. Furthermore, the peak at $\delta = 3.6$ ppm is very broad and likely contains the peaks appearing at $\delta = 3.8$ and 2.2 ppm observed in the ^{6}Li NMR spectrum which are assigned to the cage lithium atoms Li(1) and Li(2). It can be noted that all three Li environments are observed for **1** in solution in THF.

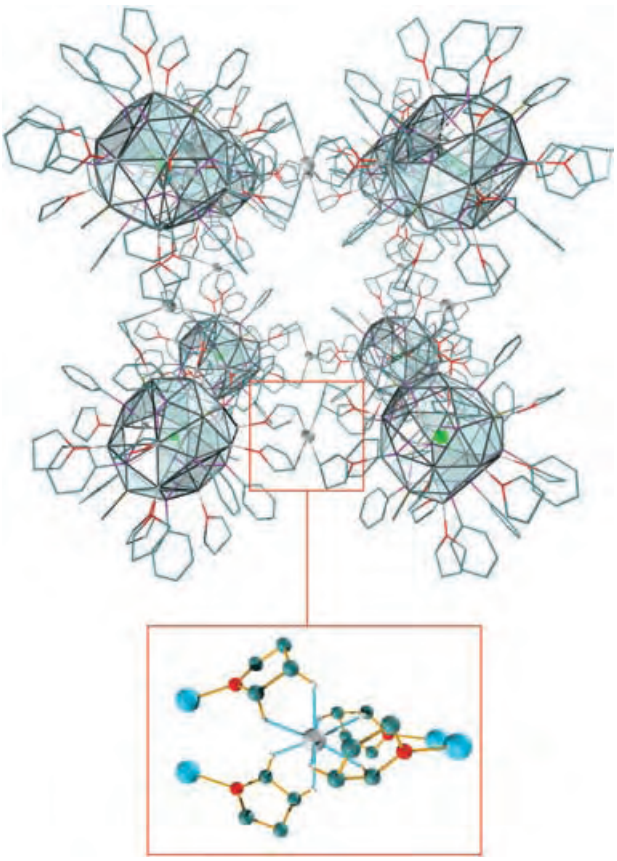

Figure 2. Formation of cube-shaped cavities within the structure of **1**, showing the partial occupancy Li(3) sites between adjacent cluster anions. The insert shows the thf C–H···Li^+ interactions that anchor the Li^+ counterions in the lattice: C···Li 2.81–2.84 Å (H···Li 2.09–2.16 Å).

The structure of **1** dramatically illustrates the concept of lattice modification using inverse coordination of a simple ionic salt. A large expansion of the NaCl-type lattice of LiCl results from the encapsulation of the Cl^- ions within the cages, with a loss of the original close packing of the chloride ion array. This type of structural modification provides a potentially general new strategy for crystal engineering. Such a strategy should lead to a novel approach to fast-ion conductors.[19,20] The generalization of this synthetic approach using inorganic frameworks with building blocks related to the $[MeAl(PPh)_3]^{4-}$ anions in **1** is therefore an exciting prospect both from a theoretical and technological standpoint.[21]

Experimental Section

1: All manipulations were performed under dry, O_2-free argon. *n*BuLi (8.25 mL, 1.60 M in hexane, 13.2 mmol) was added to a stirred solution of $PhPH_2$ (0.66 mL, 6.00 mmol) in diethyl ether (50.0 mL) at −78 °C.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction mixture was allowed to warm to room temperature and stirred for a further 1 h, producing a yellow precipitate, then the reaction mixture was heated at reflux (14 h). The resulting suspension was cooled to −78 °C, and $MeAlCl_2$ (2.00 mL, 1.00 M in hexane, 2.00 mmol) was added. The mixture was allowed to warm to room temperature and then heated at reflux (14 h) to give a yellow solution and white precipitate. After replacing the solvent by toluene (50.0 mL) and filtration (Celite, P4) to remove LiCl, the solvent was removed under vacuum and a yellow precipitate was obtained. Crystallization from THF at room temperature (14 h) led to light yellow cube-shaped crystals of **1** (0.54 g yield, 43 % first batch of crystals); decomp. ca. 210 °C (red) to ca. 270 °C (black solid); IR (Nujol, NaCl), $\tilde{\nu}$ = 3030(w) (C–H aryl stretch), 1570(w) (C=C stretch), 1022(s) cm^{-1}; no P–H stretching band was observed; ^1H NMR (500.2 MHz, 298 K, C_6D_6): δ = 8.3 (m, *m*-CH Ph), 7.22 (q, *p*-CHPh), 0.40 ppm (br s, Me-Al); ^{31}P NMR (202.5 MHz, 298 K, THF/[D_6]acetone capillary, 85 % H_3PO_4/D_2O): δ = −161.8 ppm; ^7Li NMR (194.4 MHz, 298 K, THF/[D_6]acetone capillary, sat. LiCl/D_2O): δ = 2.25 (br s, $w_{1/2}$ = 29 Hz, Li(3)), 1.82 (br s, $w_{1/2}$ = 29 Hz, Li(1)), 0.36 ppm (s, $w_{1/2}$ = 10 Hz, Li(2)); assignments were made solely on the basis of the approximate integration of the spectrum, 1:4:8 ratio of the resonances (theoretical 1:4:12). The ^{31}P and ^7Li NMR solution spectra do not change with concentration or temperature (180–298 K), proving that no fragmentation of the anion of **1** occurs in solution. Solid state MAS-NMR, ^7Li (155.406 MHz, 32 scans, 15-s recycle delay): δ = 3.6 (Li(1) and Li(2)), 0.4 ppm (Li(3)); $^7Li\{^1H\}$ CPMAS (399.87 MHz for ^1H, 4-ms contact time, 8 scans): δ = 3.6 ppm; $^6Li\{^1H\}$ CPMAS (58.89 MHz/399.87 MHz for ^1H, 3-ms contact time, 4096 scans): δ = 3.8 (Li(1)), 2.2 ppm (Li(2)); assignments made on the basis of approximate 2:1 integration. Sixty logarithmically spaced τ values were collected between 0.01 s and 160 s for the RAS spectrum; twenty-four transients were collected for each τ value;[22] elemental analysis (%) calcd for **1**: C 60.0, H 6.8, P 15.0; found (typical): C 59.0, H 7.6, P 12.7.

[11] The dilithiation procedure is the same as that reported previously for a range of other primary phosphines, see: K. Niediek, B. Neumüller, *Z. Anorg. Allg. Chem.* **1993**, *619*, 885. Whether the reaction of $PhPH_2$ with *n*BuLi produces a genuine dilithiate could not be ascertained by NMR spectroscopy owing to the low solubility of the product. Attempts to prepare **1** by stepwise reaction of $MeAlCl_2$ with $PhPH_2$ followed by reaction with *n*BuLi failed. The presence of 2 equivalents of *n*BuLi in the reaction mixture prior to reaction with $MeAlCl_2$ is necessary to prevent an alternative pathway involving P–P bond formation; see: F. García, S. M. Humphrey, R. A. Kowenicki, M. McPartlin, D. S. Wright, *Dalton Trans.* **2004**, 977.
[12] Crystal data for **1**: $C_{124}H_{168}Al_4ClLi_{17}O_{12}P_{12}$, M = 2483.57, cubic, space group $F\bar{4}3c$, Z = 8, a = 35.037(4) Å, V = 43011(9) Å^3, $\mu(Mo_{K\alpha})$ = 0.158 mm^{-1}, ρ_{calcd} = 0.767 $Mg\,m^{-3}$, T = 180(2) K. Data were collected on a Nonius Kappa CCD diffractometer. Of a total of 10442 reflections collected, 1674 were unique (R_{int} = 0.170). The structure was solved by direct methods, and all non-hydrogen atoms of the cluster anion, centered by a chlorine atom at $^1/_2$, $^1/_2$, $^1/_2$ (site symmetry 23), were readily located. The location of the lithium countercation proved more problematic. Initially it seemed possible that a solvated $[Li(thf)_4]^+$ cation might be located in the giant cavity (centered at $^1/_4$, $^1/_4$, $^1/_4$) defined by the cubelike arrangement of the clusters, giving a pseudo-CsCl-type structure. Although there was no significant electron density apparent within the cavity, this might have been explained by a complete randomization of the position of the $[Li(thf)_4]^+$ cation (radius, $r \approx 5$ Å) which is considerably smaller than the cavity ($r \approx 8$ Å, to the closest hydrogen atom). This possibility is ruled out by the elemental analysis, which is consistent with an unsolvated Li^+ cation (with no further THF being present). The only site suitable for a naked cation is at $^1/_4$, 0, 0 (site symmetry −4) which gives reasonable $Li^+\cdots$thf interactions. A lithium atom of occupancy $^1/_3$ was included at this site in the refinement by full-matrix least squares on F^2 with anisotropic displacement parameters assigned to all full occupancy non-hydrogen atoms (G. M. Sheldrick, *SHELX-97*, Göttingen, Germany, **1997**). Relatively high displacement parameters for two carbon atoms indicated some unresolved conformational disorder of the thf ligand. Final R_1 = 0.076 ($I > 2\sigma(I)$) and wR_2 = 0.201 (all data). CCDC 267276 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Hydrogen-Bonded Supramolecular Assemblies as Robust Templates in the Synthesis of Large Metal-Coordinated Capsules**

*Robert M. McKinlay, Praveen K. Thallapally, Gareth W. V. Cave, and Jerry L. Atwood**

The synthesis of large multicomponent spheroid cage structures that offer the possibility of encapsulating numerous molecules is an important theme in supramolecular chemistry.[1] Strategies developed in their construction have mainly relied on self-assembly by means of multiple hydrogen bonds[2] or metal–ligand coordination.[3] Although there are numerous reports[4] of metal coordination to calixarene-based macrocycles, the formation of larger molecular cage structures involving more than two units remains limited.[5]

The bowl-shaped resorcin[4]arene and pyrogallol[4]arene macrocycles lend themselves amenable to the formation of large hexameric cage structures by hydrogen bonding.[6] From a pictorial point of view, substitution of hydrogen atoms for metal ions within these hexameric capsules[6] would result in structural preservation of the hexameric assembly while introducing new variables such as inorganic functionality. Indeed, limited consideration has been given to using pyrogallol[4]arene units as multibranched chelate ligands. Caulder and Raymond have shown the concept of using multibranched chelate ligands in the synthesis of cage structures, however, these structures contain relatively small cavities.[7] Herein we report the formation of a large neutral hexameric coordination cage structure assembled from six pyrogallol[4]arene ligands and twelve Ga^{III} ions.

Treatment of *C*-propyl-pyrogallol[4]arene (Figure 1) with four equivalents of $Ga(NO_3)_3 \cdot H_2O$ in a mixture of acetone and water resulted in the metal-directed self-assembly of $[Ga_{12}(H_2O)_{24}(C_{40}H_{42}O_{12})_6 \subset (acetone)_8(H_2O)_6]$ (**1**; Figure 2). Single-crystal X-ray analysis shows that **1** is assembled from 18 components: 6 pyrogallol[4]arene ligands and 12 Ga^{III} ions.[8] This large "rugby ball" shaped coordination cage is arranged such that the centroids of the six pyrogallol[4]arene ligand components reside on the vertices of a skewed octahedron and encloses approximately 1150 $Å^3$ of space.[9] The cage structure within **1** is held together by four slightly curved six-membered $[Ga_3O_3]$ arrays ($Ga\cdots O_{equatorial}$: 1.886–

2.009 Å, O–Ga–O: 85.18–98.77°, Ga–O–Ga: 137.97–148.07°; Figure 3). All four equatorial positions on each octahedral gallium center are occupied by oxygen atoms from the macrocycle framework, with the axial positions (Ga···O_{axial}

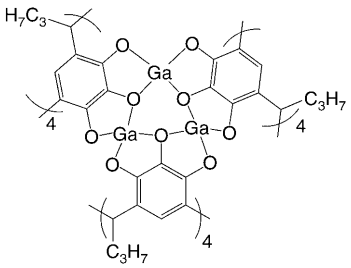

Figure 3. One of the four [Ga_3O_3] six-membered arrays that hold **1** together.

1.924–2.104 Å) occupied by water molecules, twelve of them pointing inwards towards the cavity center. These axial bond distances correspond clearly to Ga···OH_2 coordination rather than Ga···OH bonds.[10] Embedded on the surface of **1** are four water molecules that participate in intermolecular hydrogen bonding with the upper-rim framework of the macrocycle which seals up potential surface voids. Indeed, these surface-coordinated water molecules may be viewed as occupying gates to the interior of the capsule.

The previously reported metal-directed self-assembly of pyrogallol[4]arene macrocycles with four equivalents of Cu^{II} ions resulted in the formation of a large spherical coordination cage $[Cu_{24}(C_{40}H_{40}O_{16})_6]$ (**2**).[11] Each face within the octahedral structure was capped by eight six-membered $[Cu_3O_3]$ planar arrays. In contrast to the Cu^{II} structure **2**, only half of the octahedral faces within **1** are capped with $[Ga_3O_3]$ arrays (Figure 4).

Within the hydrogen-bonded hexameric structure previously determined, there are 24 intramolecular hydrogen bonds, that is, 4 intramolecular hydrogen bonds per macrocycle that seam the capsule together.[6] These intramolecular hydrogen bonds are important for holding and stabilizing each macrocycle into its rigid cone or bowl-shaped conformation. Indeed, within the spherical Cu^{II} coordination capsule **2**, there are 24 intramolecular hydrogen bonds of the type OH···O^- that hold the framework together. However, from a pictorial view, the addition of 12 Ga^{III} metal ions into the hydrogen-bonded hexameric framework results in the substitution of 36 hydrogen atoms. It should be noted that 36 phenol groups, 6 from each macrocycle, remain to participate in hydrogen bonding as determined by ^1H NMR spectral analysis. Therefore, within **1** there are 48 Ga–O coordination bonds, 16 intramolecular hydrogen bonds of the type OH···O^-, 4 intramolecular hydrogen bonds of the type OH···OH, and 16 phenol groups remaining that can participate in intermolecular hydrogen bonding. Thus, the gallium coordination capsule **1** has only a total of 20 intramolecular hydrogen bonds that seam the framework together. A reasonable explanation for the structural difference between **1** and **2** is the loss of four intramolecular hydrogen bonds as a result of Ga^{III} versus Cu^{II}, which has the possibility of

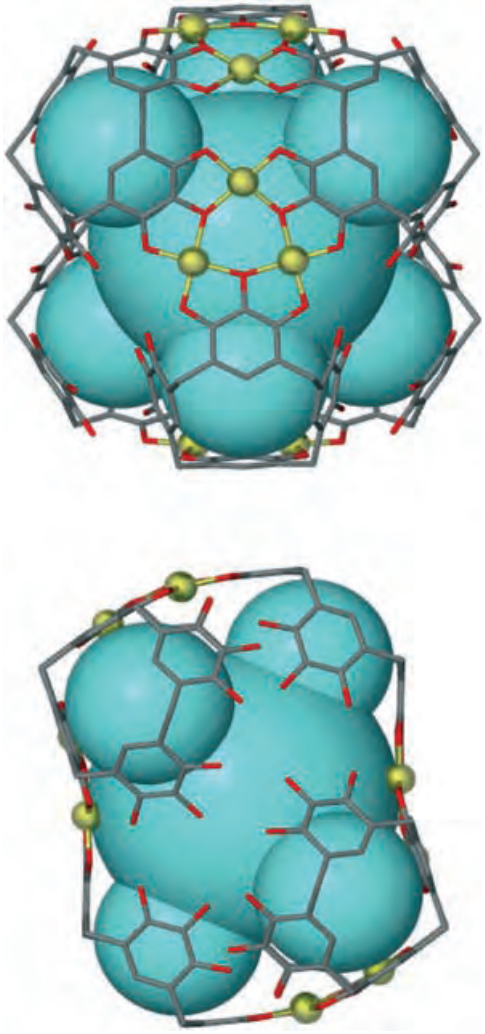

Figure 4. Structure **1** showing half of the octahedral faces capped with [Ga_3O_3] arrays. Axial coordinated water molecules, hydrogen atoms, and alkyl tails removed for clarity.

introducing greater flexibility and decreasing structural rigidity within the cone conformation. This flexibility alters the spherical topology framework found within **2** to a "rugby ball" topology **1**. Since the "rugby ball" topology distorts the remaining phenol framework, further insertion of metal ions is less favored.

The combination of hydrogen bonds and metal–ligand coordination that hold supramolecular cage frameworks together is limited.[12] The advantage of using combinations of noncovalent interactions is a greater degree of freedom and control to build interesting supramolecular assemblies. For example, by alternating the number of intramolecular hydrogen bonds within the metal-coordinated hexameric structure by changing the oxidation state of the metal ion, slightly different structures are formed.

Steric interactions tend to be the main force in organizing guest molecules within large spheroid supramolecular cage assemblies, although there are some exceptions.[13] This implies that many guest molecules within large cavities are highly disordered as determined from X-ray analysis. How-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ever, within structure **1**, the axial metal-coordinated sites from the corresponding Ga^{III} ions are advantageously located orthogonal to the surface framework. These coordination sites have a profound influence on guest arrangements within **1**. Embedded within the large cavity are eight acetone molecules, twelve metal-coordinated water molecules, and six noncoordinated water molecules yielding an effective encapsulation of approximately 66%.[9] The packing coefficient within various molecular recognition systems is calculated to be approximately 55%.[14] The metal-coordinated water molecules within the cavity form hydrogen bonds with each acetone guest molecule. Interestingly, within the asymmetric unit, two axial metal-coordinated water molecules demonstrate evidence of a strong hydrogen bond (O···O 2.501 Å) that connects two neighboring $[Ga_3O_3]$ units together. Furthermore, the metal-coordinated water molecules show hydrogen bonding to each other within each $[Ga_3O_3]$ array (O···O 2.797–2.913 Å). Thus the Ga^{III} geometry is distorted sufficiently away from octahedral symmetry (O_{axial}-Ga-$O_{equatorial}$: 82.85–97.44°).

Found within **1** are two pseudo-linear hydrogen-bonded water $(H_2O)_5$ chains; hydrogen bonds are inferred from short O···O distances. The adjacent O···O distances are 2.711–2.823 Å and the O···O···O angles are 91.01–133.18°. X-ray analysis could not determine the position of hydrogen atoms within the water chain. The free water molecules adjacent to the Ga^{III}-coordinated water molecules also form hydrogen bonds to the phenol groups from the macrocycle framework. The free water molecules within the cavity do not form hydrogen bonds with acetone guest molecules. Within each linear water $(H_2O)_5$ chain, the three non-metal-coordinated water molecules, as a supramolecular entity, in effect act as a bridging ligand by connecting two opposite $[Ga_3O_3]$ arrays within **1** by hydrogen bonding to a metal-coordinated water molecule from each $[Ga_3O_3]$ array (Figure 5). The prevailing

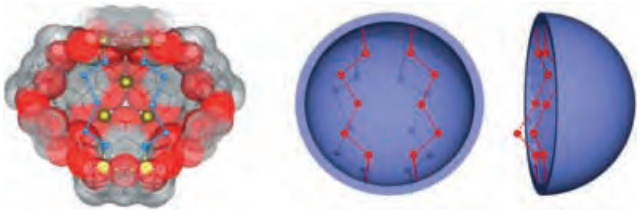

Figure 5. The pseudo-linear hydrogen-bonded water $(H_2O)_5$ chains within **1**. Acetone guest molecules within **1** removed for clarity.

knowledge is that the global minima of hydrogen-bonded water $(H_2O)_n$ clusters with $3 \le n \le 6$ have a general tendency to associate into two-dimensional planar ringlike architectures which is supported by both theoretical and experimental observations.[15] However, it is possible that confined space can offer an alternative environment to enforce different water topologies.

In conclusion, we have demonstrated the synthesis of a large hexameric cage structure stitched together from a combination of metal coordination and hydrogen bonds. Thus, the advantageous structural features from the hydrogen-bonded capsules are preserved while introducing new variables such as inorganic functionality. Indeed, this resulting combination of binding forces has led to architectures that organize the enclosed guest molecules in unique ways.

Experimental Section

Butyraldehyde (11.4 g, 0.16 mol) was added dropwise over a period of 2 h to a solution of pyrogallol (20 g, 0.16 mol) in ethanol (100 mL) and conc. HCl (10 mL) under N_2 gas. The resulting mixture was heated at reflux for 24 h, filtered, washed with water (3 × 500 mL), and recrystallized from methanol. *C*-propyl-pyrogallol[4]arene (14.2 g, 49%) was collected as a colorless powder. ^{1}H NMR (300 MHz, [D_6]acetone): $\delta = 0.95$ (12H, t, $^3J = 7.4$ Hz), 1.32 (8H, sextet, $^3J = 7.4$ Hz), 2.26 (8H, q, $^3J = 7.5$ Hz), 4.37 (4H, t, $^3J = 7.9$ Hz), 7.14 (4H, s), 7.18 (4OH, s), 8.09 ppm (8OH, brs); ^{13}C NMR ([D_6]acetone): $\delta = 13.3$, 20.8, 33.6, 34.9, 113.5, 124.7, 132.6, 139.1 ppm.

Single colorless crystals of **1** suitable for X-ray crystallographic analysis were grown from a sealed container, with a solution of *C*-propyl-pyrogallol[4]arene (0.20 g) in acetone (5 mL) added to a solution of $Ga(NO_3)_3 \cdot H_2O$ (0.28 g) in water (2 mL).[8] Yield: 48%, based on pyrogallol[4]arene ligand. ^{1}H NMR of **1** (300 MHz, CD_3CN): $\delta = 0.98$ (72H, t, $^3J = 7.5$ Hz), 1.29 (48H, m), 2.22 (48H, m), 4.26 (24H, t), 6.89 (12OH + 24Ar, brs), 7.38 ppm (24OH, brs); ^{1}H NMR of **1** (CD_3CN + D_2O): the peak at $\delta = 6.89$ ppm reduces to 24Ar.

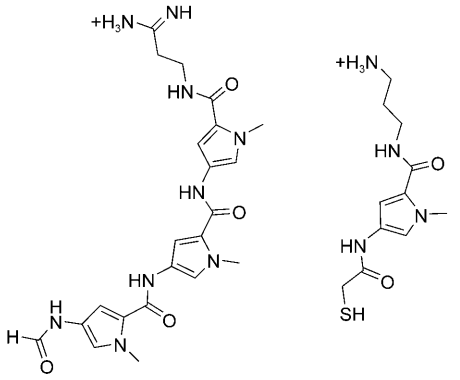
Targeting Nucleic Acid Secondary Structures with Polyamides Using an Optimized Dynamic Combinatorial Approach**

*Sylvain Ladame, Andrew M. Whitney, and Shankar Balasubramanian**

Nucleic acids can adopt a variety of well-defined conformations. DNA exists predominantly as a double-stranded right-handed helix but can also adopt alternative structures such as bulges, hairpins, and four-stranded quadruplexes. Such DNA secondary structures have been identified in genomic DNA and many of these are associated with regulatory mechanisms. DNA secondary structures in regulatory regions are potentially attractive targets for chemical intervention by agents that bind and either block or enhance the binding of transcription factors. Thus far, the most successful approaches for the development of artificial transcriptional repressors have included both small molecules and proteins that recognize RNA or DNA structures. These transcriptional antagonists include oligonucleotides (or oligonucleotide mimics) that recognize the major groove of double-stranded DNA through triple-helix[1] or synthetic pyrrole/imidazole-based polyamides that recognize the minor groove of the DNA double helix.[2] Recently, a small molecule was reported to suppress expression of the oncogene *c-myc* by targeting a proximal four-stranded G-quadruplex DNA secondary structure element.[3]

It is desirable to develop new approaches and new molecules that recognize particular nucleic acid structure(s) with both high affinity and specificity. Dynamic covalent chemistry (DCC) is a reversible exchange process that allows noncovalent interactions to template covalent bond formation.[4] Since its conception, there have been very few examples that have used biologically relevant nucleic acids as a template.[5] We recently reported the use of dynamic covalent chemistry for the generation of G-quadruplex ligands from a small library of nine different species.[6] Herein, we demonstrate the general application of DCC as both a qualitative and quantitative method for the selection and discrimination of ligands that bind distinct nucleic acid structures (quadruplex and duplex DNA).

Distamycin-like polyamides containing *N*-methylpyrrole and *N*-methylimidazole amino acids can bind to the minor groove of double-stranded DNA with an affinity similar to naturally occurring DNA-binding proteins in a sequence-specific manner.[7] During the past decade, extensive work, particularly by Dervan and co-workers, has demonstrated that covalently linking polyamides that contain three pyrrole or imidazole units along a γ-aminobutyric acid turn can lead to a six-heterocycle hairpin that recognizes five base pairs with increased affinity and specificity.[8] More recently, it was shown that distamycin can recognize the G-quadruplex motif.[9,10] Initial studies by NMR spectroscopy and mass spectrometry suggested that distamycin interacts as a dimer with two opposing grooves of a quadruplex with an overall stoichiometry of 4:1.[9] However, recent NMR spectroscopic studies proposed a structurally distinct model in which two distamycin molecules are stacked on the terminal planar G quartet of a quadruplex.[10] Herein, we describe the selection of dimers of pyrrole-based polyamides that bind duplex and/or quadruplex DNA by using an optimized dynamic combinatorial approach. Based on previous studies by ourselves and others, thiol-disulfide chemistry was chosen to mediate the reversible exchange process because it is water-compatible, relatively fast, and pH-controlled.[6,11]



Polyamides **P1**, **P2**, and **P3**, which respectively contain one, two, and three *N*-methylpyrrole heterocycles, were designed to closely mimic the chemical structure of distamy-

P3

aliphatic thiol, and the amidine function at the other terminus of distamycin was replaced by an amino group. Previous studies on distamycin and distamycin analogues suggest that such molecules have the potential to bind quadruplex and duplex DNA as dimers.[7] We set out to optimize the number of heteroaromatic units for binding to each of the two DNA templates. The molecular targets for this study were: 1) a four-stranded intramolecular G quadruplex formed by human telomeric DNA, which is a target under study for anticancer agents,[12] and 2) an A/T-rich duplex DNA sequence identified in the promoter region of the oncogene *c-kit*,[13] which could serve as a site for intervention of transcriptional regulation.

The Fmoc-protected *N*-methylpyrrole monomers were synthesized as previously reported[14] and assembled on a 1,3-diaminopropane-derivatized trityl resin (Merck Biosciences, loading 1.19 mmol g^{-1}) by using standard solid-phase Fmoc chemistry (Fmoc = 9-fluoromethoxycarbonyl). Three distamycin analogues containing either one, two, or three *N*-methylpyrrole units were end-derivatized with *S*-trityl-β-thioacetic acid. Treatment with a solution of TFA/TIS/H_2O (95:2.5:2.5) afforded the desired molecules, which were subsequently purified by HPLC (TFA = trifluoroacetic acid, TIS = triisopropylsilane). The nucleic acid targets used were the intramolecular human telomeric quadruplex formed from the folded deoxyoligonucleotide 5′-biotin-$(GTTAGG)_5$,[15] and an 11-mer duplex DNA formed from 5′-biotin-(CTTTTATTTTG) hybridized with its complementary sequence (also 5′-biotinylated). The experimental design principles were essentially the same as those we reported previously.[6] Briefly, an equimolar mixture of monomers **P1**, **P2**, and **P3** were allowed to react at pH 7.4 in an exchange buffer containing an excess of both oxidized (**G–G**) and reduced (**G**) glutathione. Once equilibrium was reached, the exchange process was stopped by lowering the pH to 2, and the biotinylated target, with associated ligands, was isolated by immobilization onto magnetic streptavidin beads. The DNA was then heat-denatured to release any bound ligands; HPLC was used to identify and quantify each species represented in the dynamic combinatorial library (DCL). Comparison of the DCL composition with that obtained in a parallel control experiment that lacked nucleic acid target enabled the identification of the species that were amplified by the presence of template.

A major limitation of the DCC concept is the possibility for library components to strongly self-associate or to associate with another building block in the absence of template.[11] This effect could mask the template-induced amplification of species that are already present in large quantities in the absence of template.[16] To overcome this intrinsic limitation, we reasoned that a large excess of a competing thiol such as glutathione could be used to drive the thermodynamic equilibrium toward the formation of glutathione conjugates in the absence of target, thus decreasing the presence of stable disulfide adducts of library components. This was expected to sensitize the system toward the detection of amplified species that are otherwise significantly pre-formed in the absence of template.

We initially used reduced glutathione (**G**, 1.5 mM) and oxidized disulfide-bridged glutathione (**G–G**, 0.375 mM) in Tris-HCl buffer (300 mM, pH 7.4), KCl (150 mM), and 100 μM of each monomer to mediate thiol–disulfide exchange. Under such conditions, monomer **P3**, in particular, existed predominantly as the homodisulfide **P3–P3** (representing 73% of the total amount of thiol **P3**) at equilibrium (Figure 1a, blue trace). In such conditions, further amplification of **P3–P3** induced by the addition of DNA target would have been very difficult to observe. Exchange experiments were then carried out with a 10-fold increase in the glutathione concentration (**G**, 15 mM; **G–G**, 3.75 mM) as well as a corresponding 20-fold increase in concentration (**G**, 30 mM; **G–G**, 7.5 mM). The HPLC traces representing the composition of the DCL mixtures at equilibrium are shown in Figure 1a (red and green traces). Elevated glutathione concentrations caused the amounts of **P3** and **P2** glutathione conjugates and free thiols to increase significantly at the expense of both homodisulfides and of heterodisulfide **P3–P2**. For example, whereas the **P3–P3** homodisulfide represented 75% of thiol **P3** at the lowest concentration of glutathione (**G**, 1.5 mM; **G–G**, 0.375 mM) it represented only 15% when the amount of glutathione was increased 20-fold.

Among the conditions tested, the highest glutathione concentrations were optimal for the detection of DNA-template-induced amplification of species containing either

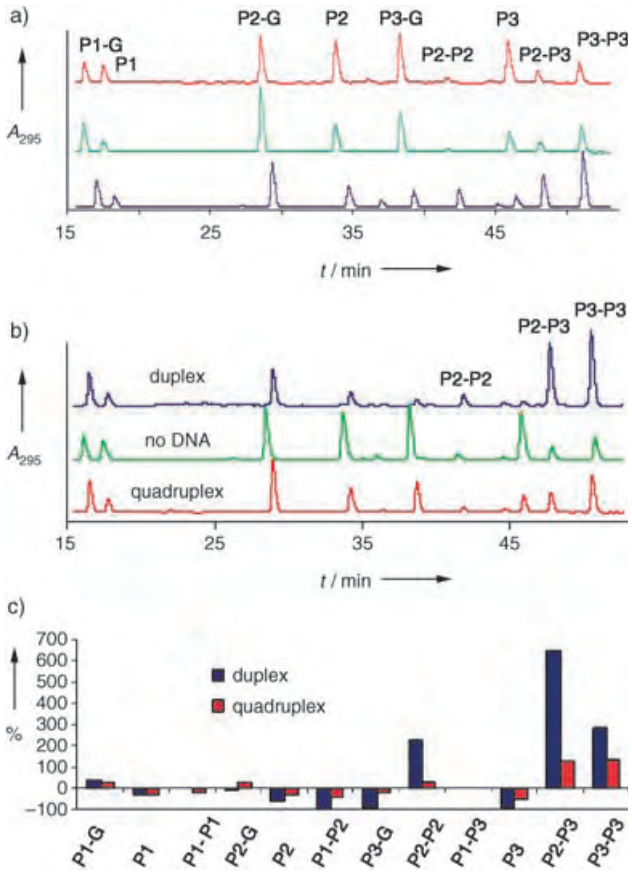

Figure 1. a) HPLC traces showing the component composition at equilibrium after 18 h for exchange experiments starting from **P1**, **P2**, and **P3** as thiols (100 μM each) in Tris buffer (300 mM Tris-HCl pH 7.4, 150 mM KCl) containing different concentrations of glutathione (**G**). From top to bottom: **G** 30 mM + **G**–**G** 7.5 mM, **G** 15 mM + **G**–**G** 3.75 mM, and **G** 1.5 mM + **G**–**G** 0.375 mM; b) HPLC traces showing the component composition at equilibrium after 18 h for exchange experiments starting from **P1**, **P2**, and **P3** as thiols (100 μM each) in Tris buffer (300 mM Tris-HCl pH 7.4, 150 mM KCl) containing **G** (30 mM) + **G**–**G** (7.5 mM) and either in the absence of template or in the presence of quadruplex DNA (100 μM, bottom) or duplex DNA (100 μM, top). c) Histogram showing the percent change in each species of the equilibrium mixture upon introduction of either quadruplex (red) or duplex DNA (blue).

P2 or **P3**. The concept of dynamic combinatorial chemistry strictly requires the system under study to establish equilibrium under the conditions of the selection experiments. To confirm true thermodynamic equilibrium for the disulfide exchange, the experiment was repeated starting from **P1**, **P2**, and **P3**–**P3**, instead of **P1**, **P2**, and **P3** thiol. The same distribution of thiols and disulfides was obtained after 18 h despite the change from initial conditions, which confirms that the system was reversible and under thermodynamic control. Parallel experiments were then carried out with conditions identical to those described above, but in the presence of 100 μM biotinylated quadruplex or duplex DNA. Equilibrium was reached within 24 h and the same distribution of species was observed starting with either all three monomers as thiols or **P1** and **P2** as thiols and **P3** in disulfide form. This confirmed a true equilibration of the system in the presence of template. HPLC traces showing the distribution of every species at equilibrium in the presence of either quadruplex or double-stranded DNA are shown in Figure 1b.

Compared with the experiment carried out in the absence of template, a moderate amplification of disulfides **P2**–**P3** and **P3**–**P3** (130% and 140%, respectively) was observed upon the addition of quadruplex DNA. The quantities of all other DCL species were either unchanged or significantly decreased. Interestingly, substantially greater amplification effects were observed with double-stranded DNA as a template. In the presence of duplex DNA (Figure 1c) the amounts of disulfides **P2**–**P3**, **P3**–**P3** and **P2**–**P2** at equilibrium increased significantly, corresponding to amplifications of 660, 295, and 220%, respectively. These results suggest that homo- and heterodisulfides of **P2** and **P3** are amplified, albeit to varying extents, in the presence of quadruplex and duplex DNA templates. Duplex DNA elicits a much stronger amplification of these selected species than does quadruplex DNA (for example, the increase in **P2**–**P3** is 660% with duplex DNA and 130% for quadruplex DNA), which also suggests that the disulfides of **P2** and **P3** show a much greater affinity for duplexes than for quadruplexes.

Pyrrole polyamides have already been shown to bind A/T-rich duplexes as antiparallel dimers with a very high affinity (K_d values in the nM range). Our results suggest such polyamides bind quadruplex DNA with much lower affinity, in accordance with a comparative NMR spectroscopic study, which showed that both distamycin and netropsin possess a higher affinity for duplex DNA than for quadruplex DNA.[17] To confirm the relative binding of selected species (amplified or not) to both DNA targets, thermal melting studies were carried out under conditions similar to those of the DCC experiments (100 μM DNA, 300 mM Tris-HCl, 150 mM KCl) in the absence or presence of 100 μM selected disulfide ligand (Figure 2). The melting temperature of the duplex alone was found to be 43.5 °C. No stabilization effect was observed upon incubation of DNA with disulfide **P1**–**P1**, which was not amplified. However, addition of either **P2**–**P2** or **P2**–**P3** to the double-stranded DNA produced an increase in the T_m value

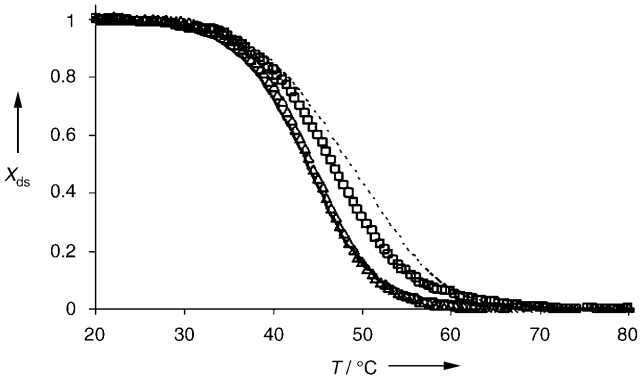

Figure 2. UV/Vis thermal denaturation curves obtained from 100 μM duplex DNA alone (——) and in the presence of either **P1**–**P1** (△), **P2**–**P2** (□), or **P2**–**P3** (••••) at a concentration of 100 μM. Experiments were carried out in duplicate in buffer (300 mM Tris-HCl, pH 7.4 containing 150 mM KCl) in a cuvette with a 1-mm path length. X_{ds} = fraction double-stranded DNA.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to 46.5 °C ($\Delta T_m = +3$ °C) and 48.5 °C ($\Delta T_m = +5$ °C), respectively. No significant shift in melting temperature was observed with quadruplex DNA and either **P1**–**P1** or **P2**–**P3** (data not shown), which may be a consequence of weaker (or less-stabilized) binding. This shows a correlation between the melting temperature values and the level of amplification observed in the DCC experiment, consistent with observations reported previously by Bugaut et al. for the dynamic combinatorial selection of nucleic acid modifications that stabilize DNA duplexes.[5c]

Recently, Poulin-Kerstien and Dervan showed that double-stranded DNA is capable of accelerating the irreversible formation of tandem hairpin dimers.[18] There is also a significant body of work on the use of DNA or RNA as a template for directing chemical reactions, primarily under irreversible conditions.[19] The study reported herein shows that DNA secondary structures (duplex or quadruplex) can also be used as templates that are capable of inducing, under reversible conditions, the formation of ligands that are thermodynamically stabilized through interactions with the DNA. A key feature of our studies is the demonstration that an increase in the concentration of buffering thiol (glutathione) is an effective means to sensitize the dynamic selection process to amplifications of pre-stabilized disulfide species. This may be particularly useful for more complex and larger libraries, in which there is an increased likelihood for mutual recognition between library members. Theoretical studies have demonstrated that the correlation between host–guest binding and amplification could vary from poor (with template in large excess) to good (with substoichiometric template).[20] The optimized dynamic combinatorial approach reported herein could facilitate the detection of only the strongest-binding ligands by preventing the formation of weaker-binding ligands with a large excess of competitor glutathione. This study also suggests that it is possible to compare the level of amplification of the same species obtained in experiments carried out in parallel but with *different* templates. This will be of particular interest for the discovery of DNA-binding ligands that bind selectively and with high-affinity.

Supermolecular Control of Charge Transfer in Dye-Sensitized Nanocrystalline TiO_2 Films: Towards a Quantitative Structure–Function Relationship**

Saif A. Haque, Samantha Handa, Katja Peter, Emilio Palomares, Mukundan Thelakkat, and James R. Durrant*

The attachment of redox or photoactive molecules to solid surfaces is important for the development of many applications. One area of research that is receiving extensive interest at present is the immobilization of molecular dyes on mesoporous nanocrystalline metal oxide electrodes. Such functionalized films are currently under investigation for device applications ranging from solar cells to chemical and biological sensors.[1–6] Recently there has been interest in the use of more complex supramolecular or multifunctional sensitizers to build a range of new applications including heterosupramolecular devices.[7–14] The use of such materials is particularly attractive as it enables the development of electroactive structures that exhibit a remarkable degree of structural organization, improved stability, redox reversibility, and a greater functional diversity.[14–16] A key requirement for the exploitation of such materials in electronic devices is the ability to electrically interface the supramolecular or multifunctional materials to the metal oxide electrode whilst achieving control over key device parameters such as interfacial charge transfer. Such issues have been considered in great detail for molecular-based adsorbates,[17] but are yet to be addressed systematically for functionalized films that comprise more complex, supramolecular or multifunctional sensitizer dyes. This understanding is both of fundamental interest and essential to the design and application of such materials in electronic devices. Herein we address this issue by exploring a class of multifunctional sensitizer dyes that exhibit multistep charge-transfer cascades. We show that by careful design of the "supersensitizer" dye it is possible to modulate the charge-recombination dynamics by five orders of magnitude and achieve remarkably long-lived photoinduced charge separation at a dye/TiO_2 interface. These studies enable us to address the relationship between supermolecular dye structure and interfacial charge transfer and provide an insight into the fundamental processes that govern charge-transfer dynamics at the supermolecular sensitizer dye/TiO_2 interface.

We have used sensitizer dyes in which the dye chromophore is modified by the covalent attachment of secondary electron donors. By introducing such secondary electron-transfer cascades within the dye structure, as illustrated in Figure 1, it is possible to retard the charge-recombination dynamics by increasing the physical separation between the dye–cation moiety and the surface of the TiO_2 surface. Such an approach has been recently adopted, however in all cases reported to date, only simple monomeric electron-donor groups have been employed.[9,14,18] Herein we consider the influence of structure of the electron-donating moiety upon the charge-recombination dynamics. In particular we address the influence of extended π-conjugation within the electron-transfer cascade and the use of polymeric electron-donating units which allows us to address the relationship between supermolecular dye structure and interfacial charge-transfer dynamics. Density functional theory (DFT) ab initio calculations are performed to determine the spatial distribution of the HOMO orbitals of the dyes. These slow charge-recombination dynamics observed herein are shown to be consistent with the increased physical separation of the HOMO orbitals of dye molecules from the TiO_2 surface as indicated by the DFT calculations.

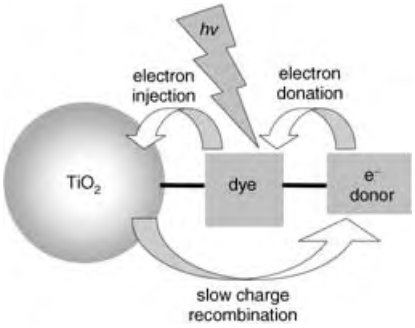

Figure 1. The heterosupermolecular structure and the charge-transfer processes occurring at the dye/TiO_2 interface.

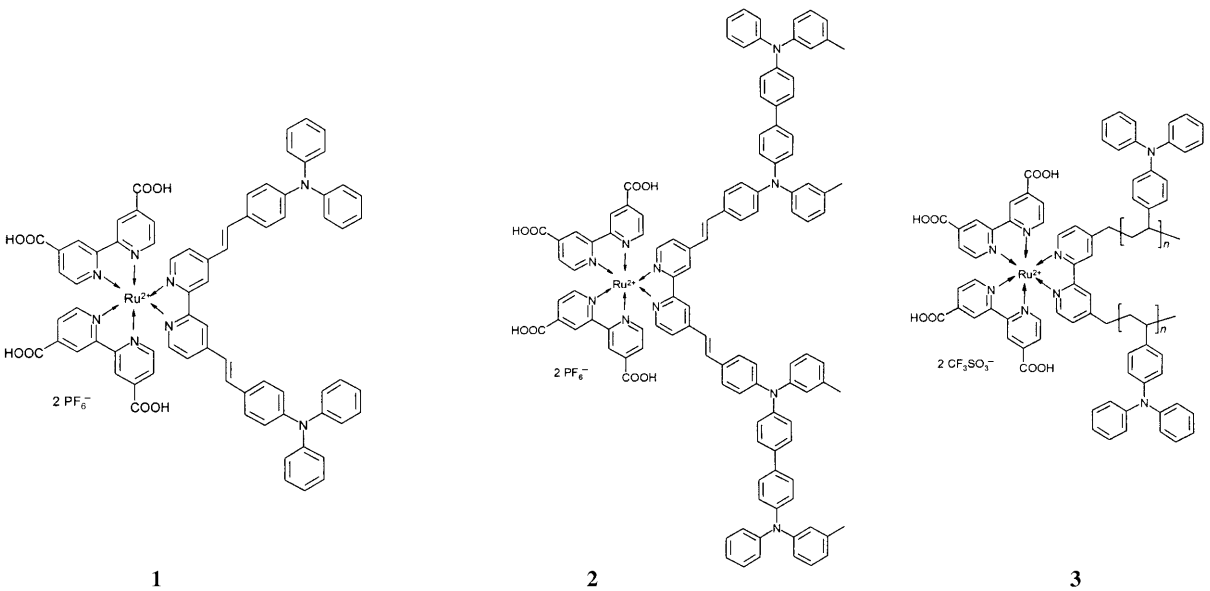

We have employed three bifunctional dyes that differ in the structure of electron-donor component (Scheme 1). Our dyes are built with carboxylated ruthenium (II) polypyridyl chromophores and carry aromatic-amine-based electron-donor groups attached on the 4 and 4′ positions of the bipyridyl (bpy) ligand. Such electron-donor groups are ideal

Scheme 1. The structure of the three dyes employed in this study [Ru^{II}(dcbpy)$_2$(TPAbpy)] (**1**), [Ru^{II}(dcbpy)$_2$(TPDbpy)] (**2**), and [Ru^{II}(dcbpy)$_2$(poly-TPAbpy)] (**3**); dc = dicarboxylate.

for this purpose as they possess low ionization potentials which facilitate the formation of cation radicals, thereby allowing multistep charge transfers. Dyes **1** and **2** comprise low-molecular-weight electron-donating units, namely, triphenylamine (TPA) and *N*,*N*′-diphenyl-*N*,*N*′-bis(3-methylphenyl)-[1,1′-biphenyl]-4,4′-diamine (TPD), respectively. Dye **3** comprises of poly(vinyl triphenylamine) chains (poly-TPA) with approximately 100 repeat units attached to one of the bipyridine units of the Ru^{II} core.[19] Details of the synthesis of these dyes and characterization are provided in the Supporting Information. The attachment of the dyes to the nanocrystalline TiO_2 films was achieved by immersion of the preformed metal oxide electrodes in solutions of the dyes at 25 °C, for 2 h for dyes **1** and **2** and overnight for dye **3**. All three dyes incorporate carboxylate groups (-COOH) to achieve direct binding to the TiO_2 surface. All three dyes were found to result in strong adsorption to the surface of the electrode.

Transient absorption spectroscopy was employed to monitor the charge-recombination dynamics following photo-excitation of the dye. Details of the transient absorption apparatus have been described previously.[20–22] The dye-sensitized films were incorporated into a sealed glass cell and degassed with argon gas prior to transient absorption studies to ensure an anaerobic environment. Experiments employed low excitation energy densities ($\approx 25\ \mu J\ cm^{-2}$ at 430 nm for all three dyes), these excitation densities being selected to ensure matched densities of absorbed photons for the three dyes, this corresponding to approximately 0.5 injected electron per TiO_2 particle.

The recombination dynamics were monitored by observing the decay of the photoinduced cation absorption of the three dyes. Typical data for the dyes are shown in Figure 2 employing a probe wavelength of 850 nm for all three dye/TiO_2 film combinations. The transient absorption traces

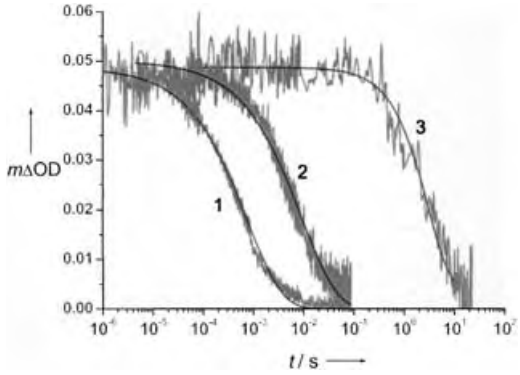

Figure 2. Transient absorption data obtained for nanocrystalline TiO_2 films sensitized with dyes **1**–**3**. The decay kinetics are assigned to the charge recombination of the photo-generated dye cations with the electrons in the TiO_2 [Eq. (2)]. The black lines indicate the fit, see text for details.

shown in Figure 2 follow the formation of the supermolecular-dye cations [Eq. (1)] and their recombination with photo-injected electrons [Eq. (2)].

$$Dye \xrightarrow{h\nu} Dye^* \rightarrow Dye^+ + e^-_{TiO_2} \quad (1)$$

$$Dye^+ + e^-_{TiO_2} \rightarrow Dye \quad (2)$$

The absence of any grow-in of the transient signal is indicative that both the electron injection and arylamine oxidation by the $\{Ru(bpy)_3\}^{3+}$ component of the dye occurs within the time resolution of our apparatus; this result is consistent with previous studies.[23–26] However it is apparent that the recombination dynamics observed for all three dyes differ significantly, with dyes **1**, **2**, and **3** exhibiting recombination half-times ($t_{50\%}$) of 350 μs, 5 ms, and 4 s, respectively. It

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is noteworthy that dye **3**/TiO_2 combination exhibits the longest lifetime reported to date for a dye-sensitized metal oxide film.

We attribute the retardation of the charge recombination observed for dyes **2** and **3** to an increase in the physical separation of dye cation from the metal oxide surface as a result of the multistep translation of the oxidized moiety away from the TiO_2 surface. To support this argument we have performed DFT ab initio calculations to determine the spatial distribution of the HOMO orbitals of **1**–**3**. These calculations were carried out using the Gaussian visualizer with a Gaussian View 3.08 program running on an AMD Athlon 64-bit processor computer. The DFT calculations employed Becke's (B3) three parameter hybrid functional with (LYP) correlation functional (B3LYP). The electronic structures of the complexes were determined using a general basis set with 6-31G(d) for nitrogen, oxygen, and carbon atoms, 6-31G for hydrogen atoms, and an effective core potential basis set LANL2DZ for the ruthenium atoms, full details of which are given in the Supporting Information. The HOMO orbital profiles for the three dyes are shown in Figure 3. The HOMO distribution in $[Ru^{II}(dcbpy)_3]$ dyes without any electron donating groups are centered entirely at the ruthenium core and not on the ligands. However, the HOMO orbitals of **1** are delocalized partially over the bipyridyl group and TPA units.

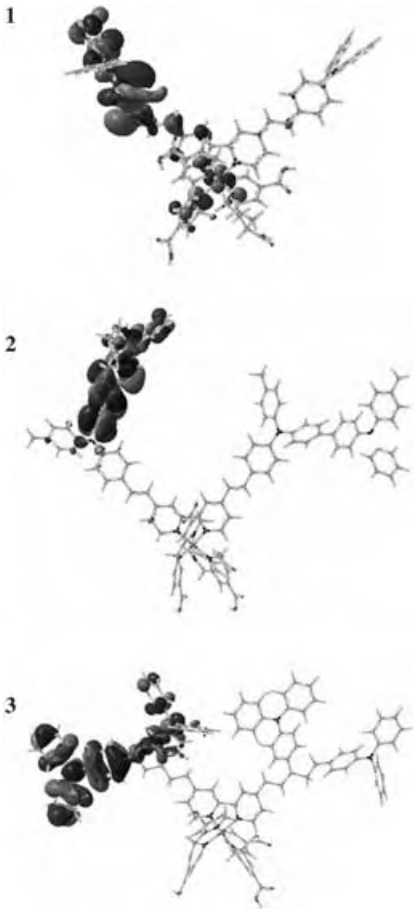

Figure 3. Graphical representation of the HOMOs of dyes **1**–**3** as determined from DFT ab initio calculations.

In contrast, for **2** and **3** the HOMO orbitals are located only on the phenylamine moieties, resulting in an increased separation of the HOMO orbitals from the TiO_2 surface compared to dye **1**. The approximate distances of the excited-state HOMO from the TiO_2 surface, as obtained from these calculations, were 10.8 Å for **1**, 15.6 Å for **2**, and 16.7 Å for **3**.[26] These calculations were complimented by cyclic voltammetry (CV) measurements which indicate a translation of the oxidizing moiety onto the aryl-amine components of the dye and thus further away from the surface of the TiO_2, resulting in an increased physical separation; this result is in agreement with previous CV studies of analogous dyes.[18]

We have recently shown that one of the key factors controlling the charge-recombination dynamics in molecular dye-sensitized nanocrystalline TiO_2 films is the spatial separation of the dye cation from the electrode surface.[17] More specifically we have demonstrated a linear correlation between the logarithm of the experimentally observed charge recombination half-time ($t_{50\%}$) and the spatial separation r of the molecular dye cation from the TiO_2 surface;[17] this is consistent with the expected exponential dependence of electron-transfer rate upon spatial separation ($k_{et} \propto e^{-\beta r}$, where β is the barrier height to electron tunneling and r is the spatial separation) from electron-tunneling theory.[27] Such data for the molecular sensitizers is shown in Figure 4 (points **A**–**E**) with the inclusion of the three supermolecular sensitizers **1**–**3** studied herein. Also included in the same plot is a supramolecular dye rotaxane **5**, based upon cyclodextrin encapsulated azobenzene chromophore and supermolecular dye **4** we have studied previously.[7,9] It is apparent that all

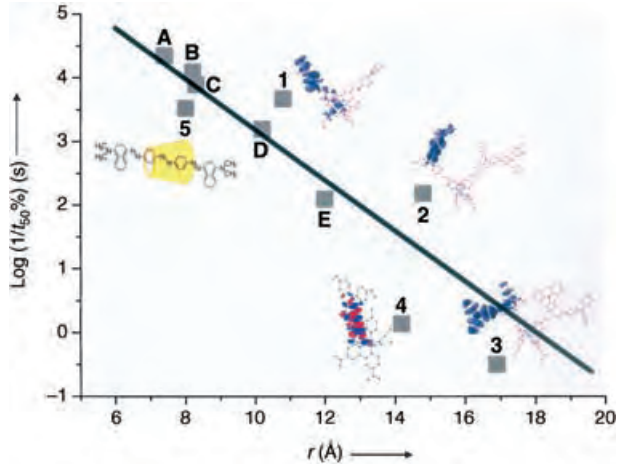

Figure 4. Plot of the logarithm of $1/t_{50\%}$ versus the spatial separation r of the dye cation from the TiO_2 surface for a series of dyes. Letters **A**–**E** represent series of molecular dyes studied previously:[17,29] **A** = [Ru(dcbpy)$_2$Cl$_2$], **B** = [Ru(dcbpy)$_2$(DTC)$_2$], **C** = [Ru(dcbpy)$_2$CN$_2$], **D** = [Ru(dcbpy)$_2$NCS$_2$], **E** = titanium phthalocyanine; DTC = $S_2CHN(C_2H_5)_2$. **1**–**3** are the supermolecular dyes studied herein, **4** is a supersensitizer dye[9] and **5** is a supramolecular dye,[7] both previously studied. The straight line is a linear fit to the experimental data following the theoretical treatment for electron-tunneling theory.[26] The slope of the line is indicative of the barrier height to tunneling $\beta = 0.95 \pm 0.2$ Å^{-1} as determined previously.[17] The influence of the free energy driving force ΔG has been factored into $t_{50\%}$ data shown here to give "free energy optimized" values as previously discussed.[17]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

these five supermolecular dyes **1**–**5** lie reasonably well along the straight line, further indicating that the key parameter controlling the charge-recombination dynamics for the supersensitizers **1**–**4**, and also the supramolecular dye **5**, is the spatial separation of the dye cation from the surface of the electrode. Thus our quantitative relationship for the molecular dyes can be extended to the more complex supermolecular sensitizers. This is the first time such a quantitative relationship has been shown for nanocrystalline metal oxides sensitized with more complex supermolecular or supramolecular sensitizers.[27] Moreover we expect the present findings to have implications for the design of sensitizers for electronic applications such as dye-sensitized solar cells. A key requirement for the efficient operation of such devices is minimization of charge recombination. It is clear from Figure 4 that the more complex "supersensitizers" and in particular dyes **2**–**4**, exhibit considerably slower charge-recombination rates than the more simple molecular dyes. Our results suggest that to achieve a long-lived charge-separated life-time the sensitizer dye can be engineered such that the oxidizing equivalent "hole" resides further away from the TiO_2 surface after charge separation. As such, the use of sensitizer dyes with multistep charge-transfer cascades provides an attractive option for this purpose. Furthermore it is apparent from the data shown in Figure 2 that the temporal shape of the charge-recombination kinetics differs significantly between the three sensitizer dyes. The transient decays in Figure 4 were fitted to a stretched exponential function ($\Delta OD \propto \exp^{-(\omega\tau)}$) with $\alpha \approx 0.4$, $\alpha \approx 0.9$, and $\alpha = 1$ for dyes **1**, **2**, and **3**, respectively, as illustrated by the black lines in Figure 2. This shift is indicative of a transition from more inhomogeneous, transport-limited recombination dynamics to more homogeneous, interfacial electron-transfer-limited recombination dynamics as the spatial separation of the dye cation from the TiO_2 surface is increased, consistent with our previous observations.[7,17,18,28] We note that this shift has potentially important advantages for device optimization as the less dispersive (more mono-exponential) recombination dynamics observed for dyes **2** and **3** offer more potential for precise optimization of the kinetics and energetics of device function.

In summary we have reported a supermolecular dye-sensitized nanocrystalline TiO_2 film in which we are able to achieve a remarkably long-lived (4 s) charge-separated state. Our approach is based upon bifunctional sensitizer dyes. We find that the key parameter that controls charge transfer at the supermolecular-dye/TiO_2 interface is the spatial separation between the cation center of the dye and the electrode surface. More specifically the retardation in charge-recombination kinetics observed for dye **3** compared to dyes **2** and **1** results from a greater physical separation between the dye cation and TiO_2 film surface, which is consistent with the multistep translation of the oxidizing equivalent "hole" away from the surface, and in agreement with our DFT ab initio calculations. We note that the aryl-amine-based electron-donor groups used herein can be expected to electrically interface well with organic hole-transporting materials making our approach attractive for applications in solid-state dye-sensitized solar cells. Moreover, the wetting property of hole conductors may be improved as a result of the matching of the polarity at this interface. We further note that the hybrid integration of multifunctional materials with metal oxide surfaces and the ability of these structures to generate remarkably long-lived charge separation, may also provide a platform for the development of nanostructured optically driven data storage devices. The present findings show that the use of multifunctional dyes provides a versatile approach to the control of interfacial charge transfer.

[26] The spatial separation of the HOMO orbitals from the TiO_2 surface was determined by calculating the geometric distance between the carboxylate groups and each atom of the dye and by weighting this value with the square of the percentage contribution of each atom to the HOMO orbital. The spatial separation from the dye-cation moiety to the electrode surface was also calculated in three alternative ways: 1) by calculating the geometric distance between the carboxylate groups and the "edge" of the HOMO distribution, 2) by calculating the geometric distance between the Ti atom at surface of TiO_2 nanoparticle and each atom of the dye and by weighting this value with the square of the percentage HOMO orbital contribution, and 3) by calculating the geometric distance between the Ti atom at surface of TiO_2 nanoparticle and the "edge" of the HOMO distribution. All four methods yielded almost identical linear dependence of the charge-recombination rate upon spatial separation. We further note that the deviations of the data from the straight line fit in Figure 4 may be due to uncertainties in exact orientation of the anchored dyes on the TiO_2 electrode surface. We also note that for dye **3**, the DFT calculation was performed in a condition where the number of TPA units was 2. This therefore represents a lower limit for the extent of delocalization of the dye cation away from the ruthenium metal center and subsequently from the TiO_2 surface.

Extreme shortening of a C–C bond results from an increase in the s character of the bond orbitals, as is found in hexakis(trimethylsilyl)tetrahedranyltetrahedrane, which is depicted in the cover picture. Although a decade ago nobody assumed that such a derivative could be isolated, in their Communication on page 5821 ff. A. Sekiguchi and M. Tanaka describe the synthesis and characterization of this highly sought after target, which agrees perfectly with theoretical predictions.

Bioorganic Chemistry
In their Review on page 5788 ff., B. F. Cravatt, E. J. Sorensen, and C. Drahl describe the mechanisms and consequences of covalent modification of amino acid residues in the active sites of proteins by small-molecule natural products.

Coordination Polymers
In their Communication on page 5810 ff., M. Lee and co-workers introduce cationic coordination polymers that respond to the type of counteranions bound by undergoing a conformational change. As a result, the solution's bulk properties can be reversibly switched between gel and liquid states.

Coordination Networks
Three different coordination networks from nickel salts, 4,4′-bipyridine, and a V-shaped 4,4′-oxybis(benzoate) ligand are described by E.-B. Wang, Z.-M. Su, L. Carlucci et al. in their Communication on page 5824 ff.

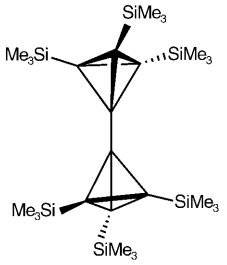
Achiral channels as well as left- and right-handed helical tubes are present in novel lanthanide-organic frameworks prepared under hydrothermal conditions from lanthanide oxides. In the three-dimensional coordination polymers, the Ln atoms (Ln = Eu, Dy, Y, Pr, Nd, Sm, Gd, Tb, Er) are linked by 4,5-imidazoledicarboxylic acid ligands with skew coordination orientation (see picture).

Coordination Polymers

Y.-Q. Sun, J. Zhang, Y.-M. Chen, G.-Y. Yang* ——— **5814 – 5817**

Porous Lanthanide–Organic Open Frameworks with Helical Tubes Constructed from Interweaving Triple-Helical and Double-Helical Chains



Single-chain magnets: A rational approach to decrease magnetic dipolar interactions led to the chain compound $[Dy(hfac)_3\{NIT(C_6H_4OPh)\}]$ (see structure; NIT(R): 2-(4′-R)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide), the first rare-earth-radical-based single-chain magnet. The compound shows slow relaxation behavior, a dynamical crossover resulting from finite-size effects, and a very rich static magnetic behavior.

One-Dimensional Magnets

Molecular Engineering for Single-Chain-Magnet Behavior in a One-Dimensional Dysprosium–Nitronyl Nitroxide Compound

On the short side: Hexakis(trimethylsilyl)tetrahedranyltetrahedrane (see formula) was synthesized by the oxidative coupling of tris(trimethylsilyl)tetrahedranyllithium via a cuprate complex. The exocyclic C–C bond between the two tetrahedrane units is the shortest known C–C single bond (1.436(3) Å) owing to the increased s character of the bond orbitals.

Short C–C Bonds

M. Tanaka, A. Sekiguchi* ——— **5821 – 5823**

Hexakis(trimethylsilyl)tetrahedranyltetrahedrane

Caught in a net: Self-assembly of nickel salts with 4,4′-bipyridine and the long V-shaped 4,4′-oxybis(benzoate) ligand has led to three different coordination networks: a parallel polycatenation of nanotube motifs to give a layered framework (see picture), a 2D→3D polythreaded array involving five polymeric units at a time, and a 3D self-penetrating binodal network with an unprecedented $(4.8^2)(4.6^4.8^4.10)$ topology.

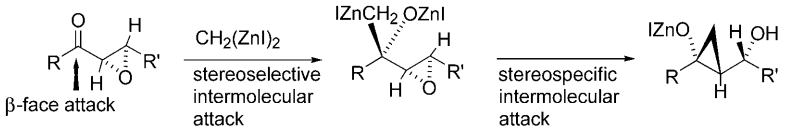
Hypervalent Iodine Reagents

Y. Kita,* S. Matsuda, E. Fujii, M. Horai, K. Hata, H. Fujioka ——— **5857 – 5860**

Domino Reaction of 2,3-Epoxy-1-alcohols and PIFA in the Presence of H_2O and the Concise Synthesis of (+)-Tanikolide

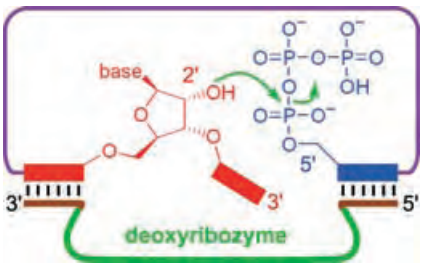


Lactols are prepared by a single operation, in which 2,3-epoxy-1-alcohols are treated with phenyliodine(III) bis(trifluoroacetate) (PIFA) in the presence of H_2O. Thus, an efficient domino three- or four-step sequence has been developed and applied to the concise synthesis of (+)-tanikolide (see scheme).

Diastereoselectivity

K. Nomura, K. Oshima, S. Matsubara* ——— **5860 – 5863**

Stereospecific and Stereoselective Preparation of 2-(1-Hydroxyalkyl)-1-alkylcyclopropanols from α,β-Epoxy Ketones and Bis(iodozincio)methane



A coordinated attack: The reaction of α,β-epoxy ketones with bis(iodozincio)methane produces 2-(1-hydroxyalkyl)-1-alkylcyclopropanols diastereoselectively (see scheme). The reaction proceeds by the coordination and diastereoselective addition of the zinc reagent to the carbonyl group followed by a stereospecific intramolecular attack on the epoxide ring.

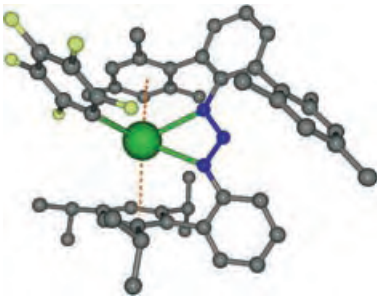
DNA Catalysis

Y. Wang, S. K. Silverman* ——— **5863 – 5866**

Efficient One-Step Synthesis of Biologically Related Lariat RNAs by a Deoxyribozyme

Closing the loop: The artificial 6BX22 deoxyribozyme (in green) synthesizes naturally occurring lariat RNAs in one step from readily available linear RNA substrates. The exquisite site selectivity of this macrocyclization reaction—which can form a 1597-membered ring in 72% yield with <0.1% side products—highlights the utility of catalytic DNA for transformations that are not possible with traditional synthetic methods.

Annulation

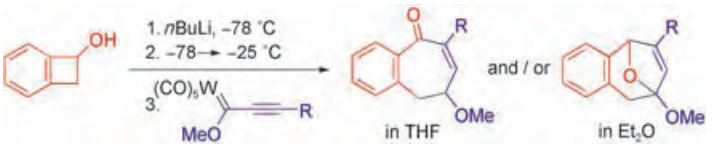


C. P. Davie, R. L. Danheiser* ——— **5867 – 5870**

Stereoselective Synthesis of Highly Substituted Cyclopentenones through [4+1] Annulations of Trialkylsilyl Vinyl Ketenes with α-Benzotriazolyl Organolithium Compounds

Closing the ring: Highly functionalized cyclopentenones are prepared by the reaction of readily available metalated benzotriazole derivatives with trialkylsilyl vinyl ketenes (see scheme; Z = heteroatom substituent). Dienolate intermediates are generated which form the five-membered ring. Most transformations proceed with high stereoselectivity by a mechanism believed to involve stereospecific 4π-electrocyclic ring closure.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

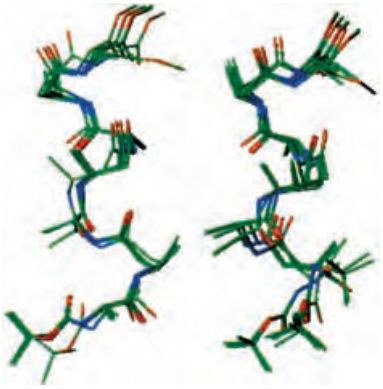


Pentafluorophenyl complexes of the heavier alkaline-earth metals (Ca, Sr, Ba) are stabilized by a novel sterically crowded triazenido ligand. The pendent arene rings of the aryl-substituted triazenide are π bonded to the alkaline-earth metal atoms, thereby suppressing decomposition pathways or ligand redistribution reactions and allowing the isolation of solvent-free derivatives (see picture; Ba: green; N: blue; F: light green; C: gray).

Alkaline-Earth Metal Complexes

S.-O. Hauber, F. Lissner, G. B. Deacon, M. Niemeyer* _____ 5871 – 5875

Stabilization of Aryl–Calcium, –Strontium, and –Barium Compounds by Designed Steric and π-Bonding Encapsulation

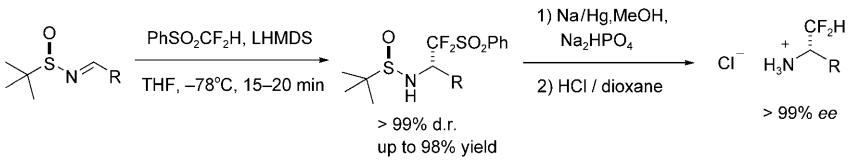


The reaction of alkynyl Fischer carbene complexes with the *ortho*-quinodimethane obtained from lithium benzocyclobuteneoxide leads to the preparation of highly functionalized seven-membered benzocarbocycles (see scheme). The position and the nature of the functional groups in the product are solvent controlled: benzocycloheptenones are selectively formed in THF, whereas benzocycloheptene ketals are exclusively synthesized in diethyl ether.

Synthetic Methods

J. Barluenga,* P. García-García, M. A. Fernández-Rodríguez, E. Aguilar, I. Merino _____ 5875 – 5878

Lithium Benzocyclobuteneoxide as a Precursor of a Vinylogous Enolate: Solvent-Controlled Synthesis of Highly Functionalized Seven-Membered Benzocarbocycles



A new twist: The α/β hybrid dipeptide repeats prepared from alternating C-linked carbo-β³-amino acid and L-Ala residues show a high propensity for mixed helices and produce hitherto unknown right-handed 11/9 and 9/11 helical structures (see picture).

Peptide Helices

G. V. M. Sharma,* P. Nagendar, P. Jayaprakash, P. Radha Krishna, K. V. S. Ramakrishna, A. C. Kunwar* _____ 5878 – 5882

9/11 Mixed Helices in α/β Peptides Derived from C-Linked Carbo-β-Amino Acid and L-Ala Repeats

Nucleophilic (phenylsulfonyl)difluoromethylation of (*R*)-(*N*-*tert*-butylsulfinyl)-aldimines with difluoromethyl phenyl sulfone affords the corresponding products in excellent yields and with high diastereoselectivity (see scheme). The facile and convenient deprotection of both *tert*-butylsulfinyl and phenylsulfonyl groups affords the target α-difluoromethyl amines with high enantiomeric purity.

Synthetic Methods

Y. Li, J. Hu* _____ 5882 – 5886

Facile Synthesis of Chiral α-Difluoromethyl Amines from *N*-(*tert*-Butylsulfinyl)aldimines

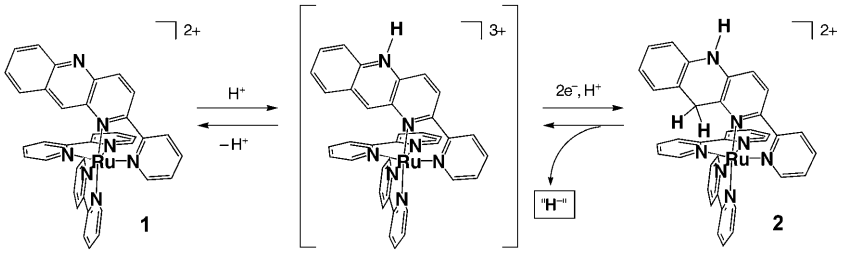
Coordination Modes

M. Tanabe, S. C. Bourke, D. E. Herbert, A. J. Lough, I. Manners* — **5886 – 5890**

Reversible, Strain-Controlled Haptotropic Shifts of Cyclopentadienyl Ligands in [1]- and [2]Metallocenophanes

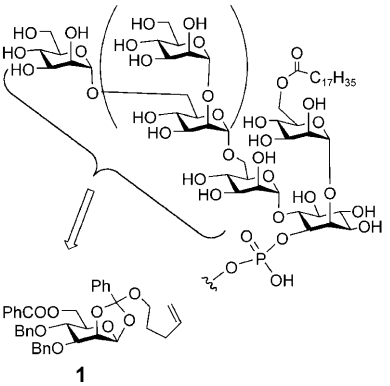


Slipping rings: A reversible shift from η^5-Cp to η^1-Cp and back has been established for ring-strained metallocenophanes (see scheme) and the dependence of the reversibility on the degree of ring strain has been probed. The presence of phosphane ligands has allowed the isolation of novel η^1-Cp ring-slipped Fe and Ru complexes.

Redox Chemistry

T.-a. Koizumi, K. Tanaka* — **5891 – 5894**

Reversible Hydride Generation and Release from the Ligand of $[Ru(pbn)(bpy)_2](PF_6)_2$ Driven by a pbn-Localized Redox Reaction



Electrochemical reduction of $[Ru(pbn)(bpy)_2]^{2+}$ (**1**, pbn = 2-(2-pyridyl)benzo[*b*]-1,5-naphthyridine, bpy = 2,2′-bipyridine) in an acidic solvent gives $[Ru(pbnH_2)(bpy)_2]^{2+}$ (**2**), which releases the hydrogen as "hydride" (see scheme). This catalytic system reduces substrates (for example, acetone) with two electrons and protons from water, and thus operates in a similar way to the NAD^+/NADH redox couple.

Carbohydrate Synthesis

K. N. Jayaprakash, J. Lu, B. Fraser-Reid* — **5894 – 5898**

Synthesis of a Lipomannan Component of the Cell-Wall Complex of *Mycobacterium tuberculosis* Is Based on Paulsen's Concept of Donor/Acceptor "Match"

The perfect match: A mannosidyl *n*-pentenylorthoester **1** is the sole donor and acceptor source for a branched oligomannan array (see picture). An iterative process of regioselective glycosidation of polyol acceptors virtually eliminates the need for protecting-group manipulations, thereby permitting a rapid, high-yielding route to the mycobacterial lipomannan phosphoinositide.

Fluorous Chemistry and Technology—A Symposium Showcases Ever-Broadening Frontiers**

John A. Gladysz*

Only an infinitesimal fraction of publications in chemistry directly spawn new research fields. However, one good case in point is the report by I. Horváth and J. Rábai from 1994 that coined the term "fluorous" and provided the first example of fluorous biphasic catalysis.[1] Fluorous substances are simultaneously hydrophobic and lipophobic, and researchers quickly recognized a variety of useful applications for this phase-orthogonality, which in many cases has the additional benefit of being temperature-dependent. Indeed, biological and physical chemists had been crafting and studying fluorous materials for some time (cloaked in other nomenclature), and they found eager new partners among synthetic chemists who took up the quest for novel recyclable catalysts and reagents, tagging strategies for mixture synthesis and separations, and other objectives.

Today, there are over 800 papers in the literature that contain the word fluorous in the title or abstract. Along the way, a company, "Fluorous Technologies Incorporated" was founded (2000), and a "Handbook of Fluorous Chemistry" has appeared (2004).[2] Clearly, eleven years after the seminal paper, the time for a meeting dedicated to this field had arrived. Accordingly, over 75 scientists from Europe, Asia, and North America made the trek to the scenic venue of Bordeaux in early July. The co-chairmen J.-M. Vincent (University of Bordeaux) and R. H. Fish (Lawrence Berkeley National Laboratory) expertly handled the organizational details. Despite the lure of the vineyards and châteaux, science held the center stage for three exciting days.

The opening talk by I. Horváth (Eötvös Lórand University, Budapest) was both a retrospective and a prospective, and challenged the audience to find ways of addressing the environmental persistence associated with most $(CF_2)_n$-based fluorous compounds. A quest for fluorocarbon-degrading microorganisms was recommended. Subsequent presentations by G. Fontana (Solvay Solexis, Milan) and J. Rábai (Eötvös Lórand University) highlighted new types of oxygen-containing solvents, ponytails, and tags that are more promising in terms of biodegradability, and which have other attractive properties. Nonetheless, a recurrent theme during the entire conference involved fluorous-solvent-free protocols for the recovery of fluorous catalysts and reagents.

One novel approach was reported by P. Pollet (Georgia Institute of Technology; collaborators: C. Eckert, C. Liotta, and P. Jessop). She described the use of CO_2 pressure (sub-supercritical) as a "solubility switch" for fluorous solutes in organic solvents (Figure 1). Furthermore, these "gas expanded" media could desorb fluorous rhodium catalysts from fluorous silica gel, which redeposited upon pressure release. M. Contel (University of Zaragoza; collaborators: J.-M. Vincent and R. H. Fish) and J. A. Gladysz; detailed new thermomorphic catalysts that could be used under homogeneous conditions in alkane, arene, or ether solvents at elevated temperatures, and can be recovered by a simple liquid–solid phase separation at lower temperatures.

Figure 1. Use of CO_2 pressure to homogenize organic (toluene, above) and fluorous (FC-72, below) liquid phases. A colored solute was added to the latter. Note the progressive volume increase. Fluorous solids can be similarly solubilized in organic solvents.

New types of fluorous supports were described, also with the idea of facilitating fluorous-solvent-free procedures. These included fluorous zirconium phosphates (E. Hope, University of Leicester), and garden-variety Teflon tape. Both J. Nishikido (Noguchi Institute, Tokyo) and A. Biffis (University of Padua) reported on fluorous catalysts that had been immobilized on fluorous silica gel (main group or early transition metal Lewis acids and dirhodium complexes); the latter presentation also detailed protocols with fluorous solid ion exchangers.

The use of fluorous tags in discovery synthesis and strategic separations continues to undergo remarkable growth. The state-of-the-art in parallel synthesis was represented in talks by W. Zhang (Fluorous Technologies) and D. Curran (University of Pittsburgh). Attention-getting developments included the emergence of fluorous aryl sulfonates ($ArOSO_2(CF_2)_7CF_3$) as versatile building blocks, and the simultaneous use of fluorous and polyethylene-glycol-like tags[3] that allow two-dimensional separations and enable much more complex libraries to be processed (Figure 2). Fluorous protecting groups can often serve as phase tags, as demonstrated in elegant syntheses of cyclic peptides by S. Takeuchi (Niigata University). Heavy fluorous tags that facilitate oligosaccharide and oligodeoxyribonucleotide syntheses were reported by T. Inazu (Tokai University) and T. Wada (University of Tokyo).

A lecture by W. Bannwarth (University of Freiburg) showed how fluorous tags can be used to immobilize DNA fragments on fluorous silica gel, allowing the facile purification of synthetic oligonucleotides. His data indicated a high potential for the fixation of biomolecules on surfaces by fluorous–fluorous interactions, and applications in molecular biology and proteomics are believed to be just around the corner. Taking the

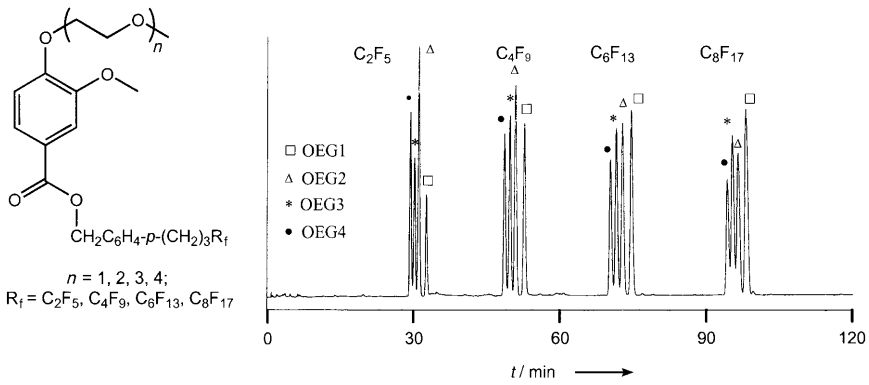

Figure 2. Double demixing of a sample with both fluorous and oligomeric ethylene glycol (OEG) tags on a FluoroFlash PF-C8 HPLC column.

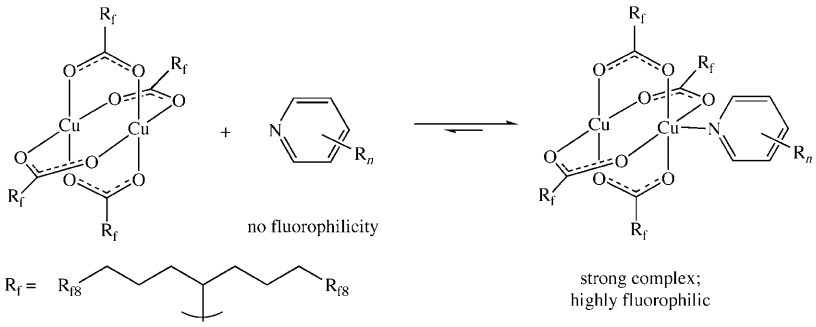
biological interface one step further, K. Hatanaka (University of Tokyo) described fluorous-tagged glycoside primers in which the saccharide chains can be elongated by cellular enzymes. This demonstrates for the first time that fluorous-tagged compounds can be taken up in the cell to participate in the biosynthetic machinery without the need for protection and deprotection steps usually required for chemical oligosaccharide synthesis.



J. Riess (UC San Diego and Alliance Pharmaceutical) then shifted the theme into the clinic—by no means a new venue for fluorous chemistry—and described the search for fluorous ultrasound contrast agents that optimize microbubble lifetime. The physical–biochemical interface was also represented in presentations by M. P. Krafft (Institut Charles Sadron, Strasbourg) and V. Percec (University of Pennsylvania). The former detailed the unique properties associated with phospholipids that contain fluorocarbon–hydrocarbon diblocks, and applications in lung surfactant therapy for neonatal respiratory distress syndrome. The latter featured wedge-shaped building blocks for supramolecular chemistry that contain fluorous domains, and self-assembly processes leading to channels that conduct water and ions.

Additional self-assembly phenomena that involve "halogen bonding" and lead to fluorous solid-state networks were described by P. Metrangolo (Milan Polytechnic; collaborator: G. Resnati). Many other types of phase phenomena received attention, such as design strategies for fluorous gelators, in the lecture of J.-L. Pozzo (University of Bordeaux; collaborator: J.-M. Vincent). B.-J. Deelman (ARKEMA, The Netherlands) reported new theoretical approaches to optimizing fluorophilicities. M. F. Costa Gomes (University of Clermont-Ferrand) explained how thermodynamicists rigorously measure and model phase equilibria, particularly with respect to gas solubilities in fluorous liquids. Differences between nonpolar, polar, and quadrupolar solutes were emphasized. Unusually selective brominations were effected by J. Iskra (Jozef Stefan Institute, Ljubljana) by layering reacting species (substrate and Br_2) on the opposite sides of a fluorocarbon interface, the so-called "phase vanishing" technique. Applications of reversible "phase switching" (Scheme 1) were featured in posters from the J.-M. Vincent research group.

Oxidations with molecular oxygen were also well-represented. K. Pamin (Polish Academy of Sciences, Krakow; collaborator: J. Haber) disclosed new families of fluorous porphyrin catalysts for the oxidation of alkenes, and E. Magnier (University of Versailles), R. H. Fish and M. Contel detailed manganese, cobalt, and copper complexes of cyclic polyamine ligands for the oxidation of alkanes, alkenes, alcohols, and other functional groups. Another approach, relayed by O. Holczknecht (CNR Institute, Milan; collaborator: G. Pozzi), used fluorous derivatives of TEMPO in conjunction with NaOCl or $ArI(OAc)_2$.

Many additional advances in catalysis were reported. One new direction involved the use of fluorous crown ethers and phosphonium salts as phase-transfer catalysts, as recounted by A. Stuart (Leicester). G. Pozzi described highly enantioselective transition metal catalysts based on heavy fluorous chiral nitrogen donor ligands. The lecture of J. Otera (Okayama University) featured fluorous organotin catalysts that are unparalleled for transesterifications and that have a variety of unusual phase properties. G. Vlád (Eötvös Lórand University; collaborator: I. Horváth) detailed improved routes to a variety of fluorous phosphines that see extensive use in catalysis.

At the banquet, I. Horváth and J. Rábai were presented with the first International Award for Fluorous Technologies, in recognition of their groundbreaking contributions noted above. The program concluded with a free-spirited panel discussion. There was unanimous sentiment that fluorous chemistry is a wide-open field that will continue to rapidly grow and expand into new applications. An important message for readers is that there are abundant

Scheme 1. Reversible phase switching: a fluorous dicopper complex that binds pyridines and extracts them into fluorous phases; applications in histamine detection were described.

opportunities for newcomers. The natives are friendly (not to mention hospitable), cooperation abounds, and there is a conspicuous lack of turf battles. For those interested in climbing on board, one opportunity will be the second Symposium, which is scheduled to be held in Kamakura, Japan in July of 2007.

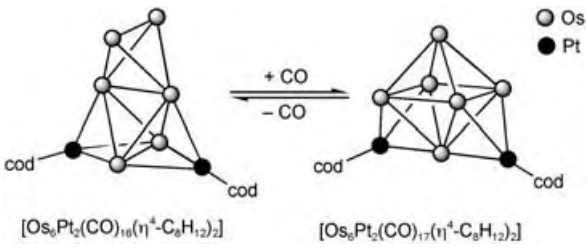
Hydrogen Sponge? A Heteronuclear Cluster That Absorbs Large Quantities of Hydrogen**

Paul J. Dyson and J. Scott McIndoe**

Keywords:
cluster compounds · hydride ligands · hydrogen storage · platinum · rhenium



Clusters offer unique possibilities in reactivity that are not possible with mononuclear complexes, and different to that of nanoparticles and the bulk metallic state.[1] For example, while both mononuclear and cluster species can undergo ligand-substitution reactions by associative, dissociative, or intermediate mechanisms, ligand substitution in clusters can also be driven by metal–metal bond scission/reformation mechanisms (which in fact may be viewed as a special case of an associative reaction).[2] While activation by metal–metal bond scission could conceivably take place at the surface of a nanocluster, such a process would be very difficult to demonstrate experimentally. In contrast, clusters are soluble in common organic solvents and accordingly can be studied in solution by high-resolution spectroscopic techniques in situ.[3] Electronically unsaturated transition-metal carbonyl clusters open up further mechanistic possibilities, providing alternative mechanisms for ligand addition, substitution, and C–X (and other) bond activation, which differ from those of clusters that obey the usual electron-counting rules, that is, the effective atomic number (EAN) rule and the polyhedral skeletal electron pair theory (PSEPT).[4]

A classic example of a low nuclearity (EAN) cluster that contains two electrons less than expected is $[Os_3H_2(CO)_{10}]$. This cluster undergoes addition reactions with, for example, phosphines, to form clusters of formula $[Os_3H_2(CO)_{10}(PR_3)]$. It can also undergo a more complicated addition/Si–H bond activation process with the functionalized phosphine $HMe_2SiC_6H_4CH_2PPh_2$ to afford $[Os_3H(CO)_8(Me_2SiC_6H_4CH_2PPh_2)]$.[5] In both reactions the resulting cluster core comprises a triangle in which all the Os–Os bond lengths are typical of single bonds.

An interesting example of a high nuclearity cluster with two electrons less than the expected number is $[Os_6Pt_2(CO)_{16}(\eta^4\text{-}C_8H_{12})_2]$ (see Scheme 1).[6] The geometry can be described in various ways, but perhaps the simplest way to view the core is as four fused tetrahedra. The addition of two electrons in the form of a CO ligand does not result in a simple transformation, instead a major structural rearrangement takes place, resulting in a cluster with a bicapped-octahedral core. Clusters with excessive electron counts are also known, for example, $[Ni_6(\eta^5\text{-}Cp)_6]$ ($Cp = C_5H_5$) has an octahedral structure but has 90 electrons, four more than expected.[7]

The cationic tetrahedral platinum hydride clusters $[Pt_4H_2(PtBu_3)_4]^{2+}$ and $[Pt_4H(PtBu_3)_4]^{+}$ react rapidly with H_2 to give the heptahydride cluster $[Pt_4H_7(PtBu_3)_4]^{2+}$, in which a Pt–Pt bond has been broken to afford a cluster with a butterfly geometry.[8] This process can be reversed by reaction with ethene.

Very recently Weller and co-workers reported a late-transition-metal cluster that is not just short of two electrons, but deficient by an electron count of 10 (though exactly comparable to the early-transition-metal cluster $[Nb_6Cl_{18}]$).[9,10] The compound in question, $[Rh_6(\mu\text{-}H)_{12}(PiPr_3)_6]^{2+}$, has a regular octahedral geometry in which each vertex has a phosphine ligand and each edge is bridged by a hydride ligand. Now, Adams and Captain have discovered an equally remarkable cluster, $[Pt_3Re_2(CO)_6(PtBu_3)_3]$ (**1**) that is also deficient by 10 electrons, but contains only five metal atoms—three platinum and two rhenium atoms.[11] The cluster was isolated from the reaction of $[Pt(PtBu_3)_2]$ with $[Re_2(CO)_{10}]$ in refluxing octane in 18% yield. The trigonal bi-

Scheme 1. Polyhedral rearrangement observed on the formation of $[Os_6Pt_2(CO)_{17}(\eta^4\text{-}C_8H_{12})_2]$ from $[Os_6Pt_2(CO)_{16}(\eta^4\text{-}C_8H_{12})_2]$ following association of one CO ligand (cod = C_8H_{12}; CO ligands omitted for clarity).

pyramidal geometry presented by this cluster is shown in Figure 1a. The surface of the cluster is decorated with carbonyl and phosphine ligands and the space-filling diagram (Figure 1b) reveals essentially complete encapsulation of the metal core by the ligand sphere.

In the presence of H_2 at room temperature the cluster reacts to form $[Pt_3Re_2(\mu\text{-}H)_6(CO)_6(PtBu_3)_3]$ (**2**). The cluster retains essentially the same geometry, including the original trigonal-bipyramidal core, and the crystal structure of **2** shows that all six of the Re–Pt bonds are bridged by hydride ligands. The hydride ligands were located in the high-quality X-ray structure, and significantly, the Pt–Re bond lengths had considerably lengthened (from an average of 2.648 in **1** to 2.909 Å in **2**).

The 14 valence-electron (VE) complex $[Pt(PtBu_3)_2]$, and the palladium analogue, have been used by Adams and co-workers to produce an array of fascinating new heteronuclear clusters, many with unusual electron counts. In their earlier work they described the reaction of $[Pd(PtBu_3)_2]$ with $[Ru_3(CO)_{12}]$ to afford the remarkable near-planar cluster $[Ru_3(CO)_{12}\{Pd(PtBu_3)\}_3]$ (Scheme 2).[12] The utility of the reactive fragment was further demonstrated in the reaction with $[Ru_6C(CO)_{17}]$ affording $[Ru_6C(CO)_{17}\{Pd(PtBu_3)\}_2]$, which exists as two isomers in the solid state, and with $[Ru(CO)_5]$ yielding the complex $[Ru_2(CO)_9\{Pd(PtBu_3)\}_2]$, a dipalladium adduct of unstable $[Ru_2(CO)_9]$. Subsequently other compounds have been reported including $[Ru_5C(CO)_{15}\{Pt(PtBu_3)\}]$, which consists of two interconverting isomers in solution,[13] and some rhodium–platinum,[14] and iridium–platinum[15] clusters containing up to 12 metal atoms.

Scheme 2. Examples of condensation reactions between the highly reactive 14 VE complexes $[M(PtBu_3)_2]$ (M = Pd or Pt) and various ruthenium carbonyl compounds recently reported by Adams and co-workers (CO ligands omitted for clarity).

Efficient hydrogen production and storage is of considerable importance in a world where cheap and renewable energy source are urgently needed, and although clusters are unlikely to be used for hydrogen storage, they should certainly serve as excellent models for this process. The replacement of nanoclusters in fuel cells by molecular clusters can also be envisaged and it is likely to be clusters such as $[Pd_{28}(CO)_{27}(H_{12})\{Pt(PMe_3)\}\{Pt(PPh_3)\}_{12}]$,[16] $[Pt_4H_8(PPhiPr_2)_4]$,[17] $[Rh_6(\mu\text{-}H)_{12}(PiPr_3)_6]^{2+}$, and $[Pt_3Re_2(\mu\text{-}H)_6(CO)_6(PtBu_3)_3]$ that drive such possibilities forward. The heavy transition metals are of course unlikely candidates for H_2 storage by themselves, setting aside the fact that they are among the most rare and expensive of elements, to meet the US Department of Energy's recommendation for mobile applications of 6% hydrogen by weight,[18] each metal atom alone would have to reversibly absorb many hydrogen molecules. However, the rate and extent of adsorption of H_2 on more promising substrates (light and cheap materials with high surface area, such as carbon) may be increased by using metal particles, which enhance hydrogen storage through hydrogen spillover.[19] Metal nanoparticles with a strong propensity for hydrogen absorption may prove to be useful models and/or precursors for this process. Furthermore, there will certainly be a demand for hydrogen storage beyond mobile applications.

Science follows trends, and not so long ago molecular clusters were in vogue, not just because of their fascinating structures, but also because of their potential to revolutionize catalysis and exhibit novel material properties. While the sheer quantity of publications in this area has certainly decreased from the heights of the late 1980s, fascinating new discoveries continue to be made. Notable synthetic develop-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ments in cluster chemistry include the isolation of a nanosized, three-shelled spherical Pd_{145} cluster;[20] giant polyoxomolybdate wheels,[21] a spectacular, protein-sized Mo_{368} "nanohedgehog",[22] and the exotic inorganic fullerenes $[P_{60}(FeCp^*)_{12}Cu_{25}Cl_{25}(MeCN)_{10}]$[23] ($Cp^* = C_5Me_5$) and $[As@Ni_{12}@As_{20}]^{3-}$.[24] In addition, the employment of clusters as precursors to well defined supported nanoparticles has been elegantly demonstrated.[25] Indeed, part of the renaissance in molecular-cluster chemistry has been driven by the development of nanotechnology; the emphasis in this area of research is on objects whose size is between 0.1 to 100 nm, and the larger molecular clusters fit firmly into the lower end of this range. While nanotechnology is now in fashion, on a scale that molecular clusters never witnessed (metaphorically and in terms of absolute size), in many ways the aspirations remain the same, that is, catalysis, material science, but also in diagnostics and medicine. However, potential biomedical applications of clusters have also been recognized,[26] and it is not unreasonable to assume that as miniaturization continues, a natural regression in size may well mean that clusters fulfill their initial promise in an unexpected context.

It will certainly be interesting to see what Adams and Captain can do with their nascent discovery. The palladium analogue is an obvious target, given that the chemistry of $[Pd(PtBu_3)_2]$ appears to parallel the platinum analogue. The ability of palladium metal to behave as a hydrogen sponge provides further impetus. The cluster **1** uptakes about 75 times its volume of H_2 (about 10% of the efficiency of palladium metal at a stoichiometry of $PdH_{0.6}$, though much of this difference is due to the higher density of Pd—the % hydrogen by weight is 0.33% for **1** compared to 0.56% for $PdH_{0.6}$), and finding a way of making this process reversible will be a key advance. The trigonal bipyramidal cluster **1** should be able to accommodate a further two equivalents of H_2 and still give a satisfactory electron count (and indeed, Adams and Captain found **1** has five low-lying unoccupied molecular orbitals of which three are filled on formation of **2**). Whether the space is available for these four hydride ligands is less obvious—certainly three could occupy the remaining unbridged M–M edges, but the likely position of a fourth is not immediately clear. However, studies by Weller et al. have shown that octahedral rhodium clusters (12 M–M bonds) can possess up to 16 hydride ligands[27] so the possibility of having more hydrogen atoms than edges is certainly feasible. Clusters rich in hydrogen with both terminal and bridging hydride ligands are also known.[17] In such cases, neutron diffraction studies to discern the exact locations of the hydride ligands are desirable. Many questions can be asked about the chemistry of a cluster as unsaturated as **1**. For example, is the oxidative addition of substrates other than hydrogen possible? It is possible to imagine, for example, the oxidative addition or association of different substrates onto the cluster framework followed by recombination in new and different ways to those possible with existing systems.

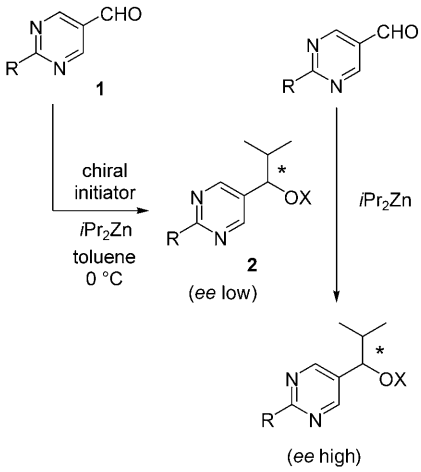
Asymmetric Amplification

DOI: 10.1002/anie.200501742

New Aspects of Soai's Asymmetric Autocatalysis



Joachim Podlech and Timo Gehring*

Keywords:
asymmetric amplification · asymmetric photolysis · autocatalysis · nonlinear effects · zinc

The origin of the homochirality of biomolecules (e.g., amino acids and carbohydrates) is still puzzling. While mechanisms have been found for the formation of enantiomerically enriched biomolecules without the help of enzymes or other chiral biocatalysts, it is still not clear how these generally small enantiomeric excesses could have been amplified under prebiotic conditions.[1] In this context, an example of asymmetric autocatalysis reported by Soai and co-workers in 1990[2] has found ongoing interest. Though was featured in a Highlight back in 1996,[3] significant and stunning improvements since then justify an updated treatise.

In Soai's example heteroaromatic carbaldehydes react with organozinc compounds, and the product serves as an asymmetric catalyst for its own formation (Scheme 1). Soai and co-workers tested a plethora of substrates, and the best results were obtained with 2-(*tert*-butylethynyl)pyrimidine-5-carbaldehyde (**1**).[4] Addition of diisopropylzinc in toluene or cumene at 0 °C led to the nonracemic secondary alcohol **2** even when no source of chirality had been added (15–91 % *ee*). In a series of runs the sense of rotation in the product was randomly distributed.[5]

Similar results were obtained by Singleton et al., but in some experiments they observed a nonrandom distribution of enantiomers even without any chiral inductor added.[6] This has been explained by trace amounts of optically active impurities present but not detectable in the solvents.

Scheme 1. Asymmetric autocatalysis in the formation of secondary alcohols. R = C≡C*t*Bu; X = H, Zn*i*Pr.

Even higher enantioselectivities were obtained when a small amount of product with a small enantiomeric excess was added. Addition of the *S* alcohol **2** (0.8 % with ≈0.00005 % *ee*) led to product **2** with 57 % *ee* (*S* configuration).[7]

Soai et al. observed that not only the product itself but also other chiral sources can be used to induce high selectivities (Figure 1). These chiral sources initiated the formation of product with a small enantiomeric excess, which promoted the faster and more selective formation of further product. Almost every imaginable chiral source has been tested over the last decade:[5] compounds with chiral centers, including chiral alcohols, amines, epoxides, carboxylic esters, and amino acids can be used as chiral initiators. Even an almost negligible asymmetry, as in (*S*)-α-deuterobenzyl alcohol (0.02–0.05 mol %, >95 % *ee*), is sufficient to produce the *R* product with 95 % *ee*.[8]

Furthermore, compounds with planes of chirality (e.g., substituted [2.2]paracyclophanes), with axes of chirality (e.g., [5]- and [6]helicenes and allenes), chiral complexes (K-[Co(edta)·2H$_2$O], edta = ethylenediaminetetraacetate), and crystals with enantiomorphous faces (e.g., sodium chlorate and quartz) were also applicable. The latter used as *d* quartz led to an *S* product with 80–90 % *ee*; *l* quartz

resulted in 84–89% *ee* *R* product.[9] The enantiopurity of product **2** was even higher when the product of a first run was used as catalyst in a second run. Usually after three consecutive runs, the product was obtained with >99.5% *ee*.

A recent publication by Soai et al. describes an especially interesting two-step protocol.[10] A minimal enantiomeric excess (estimated to be about 0.005% *ee*) of the standard product was obtained by asymmetric photolysis of racemic alcohol **2** with *r* circularly polarized UV light. The resulting actually nonracemic alcohol **2** (the authors use the term "cryptochiral" for a non-detectable deviation from the racemate) was used as a catalyst (1%) in the standard reaction to yield the *R* product **2** with 65% *ee*. This result is especially interesting since the enantiomeric excesses of amino acids in meteorites were attributed to a similar photolysis. These amino acids might have been a source for nonracemic organic material in the prebiotic era.[11]

Although the principle of asymmetric autocatalysis is very simple, functional examples are scarce, if not restricted to Soai's system.[5] Autocatalysis occurs when a chiral product acts as a catalyst for its own formation (Figure 2). Nevertheless, the mechanism of the Soai reaction is still not completely understood. The kinetic models presented in literature[12–14,17] considering the formation of catalytically active dimers or higher oligomers[14] are in line with the experimental data, but experimental proof of these proposed intermediates is lacking.

It is obvious that the reaction has to be significantly faster in the presence of the catalyst. But the mechanism for asymmetric autocatalysis should include both the catalysis of the formation of one enantiomer and an inhibition of the generation of the other enantiomer. This inhibition might be possible through removal of the catalyst's minor enantiomer by formation of inactive heterodimers $(R)\cdot(S)$ (or higher oligomers). Similar nonlinear effects have been discussed for dialkylzinc additions in the presence of nonracemic amino alcohols first described by the groups of Noyori[15] and Kagan.[16]

The Soai reaction was obviously not a prebiotic process since the reaction conditions (utilization of highly hygroscopic organometallic compounds) are not very likely in the primordial broth. Nevertheless, one might think of other reactions with greater biological relevance proceeding by means of similar mechanisms. The chemical community is looking forward to further examples of this fascinating type of reaction.

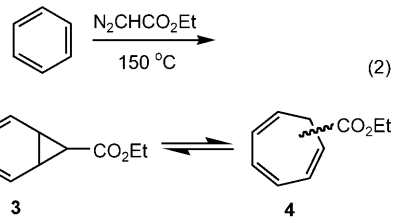
The First Century of Ketenes (1905–2005): The Birth of a Versatile Family of Reactive Intermediates**

*Thomas T. Tidwell**

Keywords:
cycloaddition · history of chemistry · ketenes · reactive intermediates · Wolff rearrangement

Discovery



Organic reactive intermediates[1] are the species involved in multistep organic reactions, and the beginning of the 20th century saw convincing experimental evidence for these entities become available. The discovery by Gomberg in 1900 that triphenylmethyl chloride and zinc formed the stable triphenylmethyl radical (**1**) [Eq. (1)],[2] was widely noted, and Gomberg narrowly missed the award of the Nobel prize for his discovery.[2c] This was quickly followed in 1901 by the demonstration that triphenylmethyl chloride in an ionizing solvent also formed the triphenylmethyl cation **2** [Eq. (1)].[3]

(1)

A carbanion intermediate was suggested by Clarke and Lapworth in 1907 to occur in the benzoin condensation,[4a] and the conversion of **1** or triphenylmethyl chloride with sodium into triphenylmethylsodium was demonstrated in 1914 by Schlenk and Marcus, who studied the ion pairing of the intermediate by measuring the conductivity.[4b] The name carbanion was coined by Wallis and Adams in 1933.[4c]

The intervention of carbenes was inferred to explain the Buchner reaction [Eq. (2)][5a–d] and analogous reactions of diazomethane.[5e] Many examples of stable carbocations, carbanions, and carbon-centered free radicals have been isolated, as have carbenes,[5f,g] which formerly seemed the most unruly of the reactive intermediates.

(2)

These findings combined with an emerging understanding of the theory of organic chemistry incorporating reaction kinetics and stereochemical and structural studies created what came to be known as physical organic chemistry. After decades of work, argument, and controversy the pivotal role of reactive intermediates was well recognized by 1940, marked by the text "Physical Organic Chemistry" by Hammett.[6] As pointed out by Leffler in 1956[1a] reactive intermediates in reactions were assumed "which have not been isolable for direct experimental study" but whose existence could be inferred by comparison to observable species "of the same type as the hypothetical intermediate" and which "have a great variety of degrees of stability, depending upon their structures. The extrapolation to the properties of the hypothetical intermediate is therefore a continuous one." Now with vastly improved methodology many formerly hypothetical intermediates have been observed directly, and even isolated. There are still hold-outs which are too short-lived for observation, or whose preparation has eluded the synthetic skills of the investigators, and these provide a continuing challenge.

Diphenylketene

In 1903 a young instructor (Unterrichts-Assistent) Hermann Staudinger joined the laboratory of Thiele at the Kaiser-Wilhelms-Universität of Strassburg (Strasbourg in French) in the Alsace.[7a] Strasbourg occupies a strategic position on the Rhine River on the border between Germany and France and over the centuries has been part of one or the other, depending on the political and military situation. After the Franco-Prussian war of 1870–1871 it had become part of the new Germany, and the University was endowed with an imposing chemical laboratory (Figure 1), which still stands.[7b] The University is now a prominent center of chemistry in France, the Université Louis Pasteur.

In 1905 Staudinger reported the discovery of the first example of an

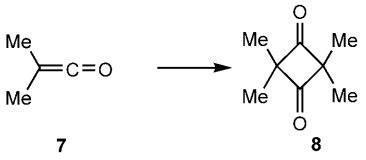
unexpected new family of reactive intermediates, diphenylketene (**6**).[8a] As described later by Staudinger in his scientific autobiography[8b] he was inspired by the work of Gomberg to attempt the preparation of new free radicals. He examined the reaction of α-chlorodiphenylacetyl chloride (**5**) with zinc and was rewarded with the isolation of **6**, the first demonstrated example of these highly reactive organic compounds [Eq. (3)]. Diphenylketene (**6**)

(3)



was obtained as a low-melting-point solid, and so the identity of this species was secure, although ketenes are in general highly reactive, and the existence of some examples is still in doubt.

Staudinger seized the opportunity and pursued the study of ketenes for the next 20 years (Figure 2), after which he

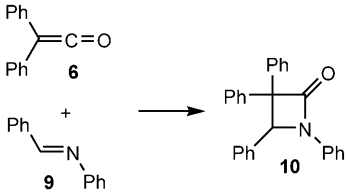


Figure 2. Hermann Staudinger (1881–1965).
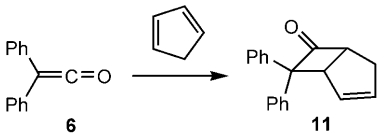
Courtesy of the GDCh (Gesellschaft Deutscher Chemiker (German Chemical Society)).

devoted himself fulltime to the exploration of polymer chemistry, for which he won the Nobel Prize in 1953. Within two years of the initial discovery dimethylketene (**7**) had also been prepared and found to undergo [2+2] dimerization to give the symmetrical cyclobutanedione **8** [Eq. (4)],[9a] and **6** was found to

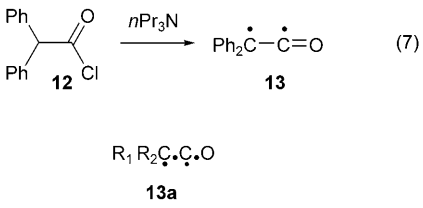


(4)

participate in cycloadditions with the imine **9** to form β-lactam **10** (Staudinger reaction) [Eq. (5)] and with carbonyl

(5)

compounds to form reactive β-lactones.[9b] The reaction of **6** with cyclopentadiene gave a product[9b] that was later proven to be the [2+2] cycloaddition adduct **11** [Eq. (6)]. These discov-



(6)

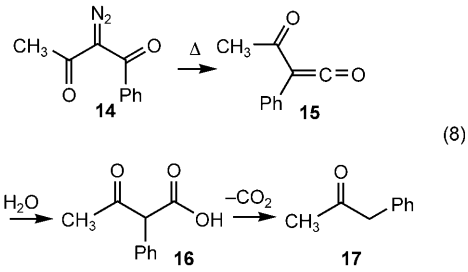
eries were made two decades before the development of the Diels–Alder reaction, and are still mainstays of synthetic organic chemistry. Cycloadditions have remained the most distinctive, useful, and intellectually stimulating aspect of ketene chemistry.

Staudinger, Wedekind, or Wolff

The discovery by Staudinger had, however, been foreshadowed by the investigations of Wedekind, who in 1901 at the University of Tübingen reacted diphenylacetyl chloride (**12**) with nPr$_3$N, and noted the formation of nPr$_3$NHCl. He proposed the formation of the intermediate **13** (this was represented as **13a**) [Eq. (7)], which appears equivalent to ketene **6** but was not isolated or characterized.[10a] Wedekind wrote "Herewith is made the hypothesis,

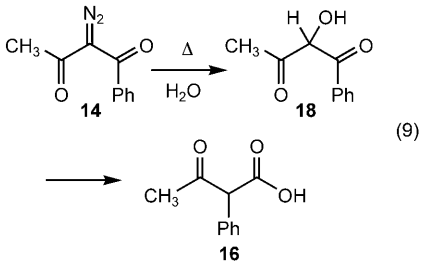
(7)

that the atomic grouping $(R_1.R_2).C_2O.$ is temporarily capable of existence in solution."[10a] This was 15 years before the proposal of the electron pair bond by Lewis, but the idea of the tetravalence of carbon was well established. However, in the next year Wedekind was more equivocal about the existence of the ketene.[10b] This work was known to Staudinger and frequently acknowledged by him,[8a] but Wedekind missed his chance to be recognized as the discoverer of ketenes. He worked in this area for a decade, but there is no mention of this research in his obituary.[10c,d]



Ketenes had also been generated by a completely different route by Ludwig Wolff (Figure 3) at the University of

Figure 3. Ludwig Wolff (1857–1919).
Courtesy of the GDCh.



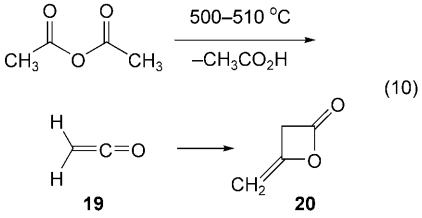
Jena in 1902, by a reaction that became known as the Wolff rearrangement.[11] This involved heating the diazo ketone **14** (formulated at that time as having a cyclic structure) at refux in water to form the ketene **15**. The latter led to the unobserved acid **16**, which underwent decarboxylation to give **17** [Eq. (8)].[11a] Wolff recognized that rearrangement had occurred and that the acid **16** was a key intermediate. But rather than assuming ketene formation, he pro-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(8)

posed that the addition of water occurred to give **18**, which underwent a double migration to form **16**, and cited the analogy of the pinacol and benzilic acid rearrangements [Eq (9)].[11a] The

(9)



proposal of a ketene intermediate in the reaction was made by Schröter in 1909, after ketenes had become well-recognized intermediates.[11c] This reaction was adapted as the Arndt–Eistert reaction for chain elongation, with a proposal for a carbene intermediate,[11d] and was developed for photochemical ketene generation by Horner.[11e,f] The photochemical version of the reaction is particularly valuable for the study of reactive intermediates, as highly reactive ketenes can be generated in various media from the reasonably stable diazo ketones. Addition of water to the ketenes gives observable acid enols as further observable reactive intermediates, which then form the carboxylic acids.

Why is Staudinger and not Wedekind or Wolff credited with the discovery of ketenes? Recognition of priority for discoveries is of intense interest to scientists, but there is no apparent record of dispute between Staudinger, Wedekind, and Wolff. Staudinger was a highly prolific investigator, and with more than 50 papers and a book on ketenes[12a] following his 1905 work in rapid order, his position as the founder of ketene studies has not been challenged. The nature of chemical discovery has been discussed by Berson,[12b] and Staudinger's clear recognition of what he had discovered and extensive further study established him as the founder of the field. Wedekind had correctly identified the structure of the ketene as an unisolated reactive intermediate,[10a] but was not firm in his conviction and missed his opportunity.

Staudinger's further career in the tumultuous development of polymer chemistry, as well as his complex personal life and sometimes outspoken political views, have generated much comment.[12c–e] Wolff has the honor of two well-known named reactions, the Wolff-rearrangement and the Wolff–Kishner reaction, and can be satisfied that every student of organic chemistry still sees his name. Ironically Berson's comments on the need to recognize a discovery were directed at Fittig, Thiele's predecessor and Wolff's supervisor at Strassburg, who had discovered the rearrangement of pinacol with acid, but did not recognize what had occurred, and so the reaction is known as the pinacol rearrangement, an example of the broader class of Wagner–Meerwein rearrangement. As noted above Schröter was the first to formulate the ketene intermediate in the Wolff rearrangement,[11c] and by Berson's criterion Wolff does not deserve credit for the ketene discovery.[12b]

Ketene and Its Dimer: Wilsmore's Contribution

Staudinger was not alone for long in the study of ketenes, for in 1907 from a completely different perspective Wilsmore (Figure 4) prepared $CH_2=C=O$ (**19**) from the thermolysis of acetic anhydride or acetone with a hot platinum wire [Eq. (10)].[13a] The parent

(10)

ketene is a noxious and poisonous gas, and its preparation at University College (London) inspired "The Ketene

Figure 4. N. T. M. Wilsmore (1868–1940). Courtesy of Dr. Andrea Stella.

The Ketene Song

There is a new substance discovered
In a room that's just over the way.
—The inventor's assistant recovered,
Though it was a near squeak, doctors say—.
But though it is ages & ages
E'er the world saw as much as a grain,
Later on you will hear, say the sages,
Of keten again.

It has quite a good constitution
—C twice and H twice and an O—:
And even in weakest dilution
Of its presence you will very soon know.
For the smell of that simple creation
Will grasp at your nose & remain
And hours after you'll sneeze in iration
At ketene again.

It's a simple enough preparation.
You stick in acetic a wire
Which gives the required dehydration
When raised to a red heat or high'r.
Then out comes a torrent of gases
Bearing liquid along in their train:
When this you have trapped ere it passes,
You've keten again

When the O.L. in slumber reposes
And room No 7 is asleep
Dr. Wilsmore, as usual, proposes
To let loose the winds on the deep.
And the sleepers, awakened, grab vainly
After beakers that scatter like rain,
While A and B rage quite insanely
At ketene again.
S.

(A & B were two small research labs, and O. L. refers to the Organic Lab.)

Song", perhaps sung at the occasion of a departmental party.[13b]

Staudinger and Klever shortly thereafter reported the preparation of ketene by the zinc debromination of bromoacetyl bromide.[13c] There was a brisk dispute between Staudinger and Wilsmore as to the priority for this discovery as well as to the purity of Wilsmore's sample of ketene and whether it had the formula $CH_2{=}C{=}O$ or $HC{\equiv}COH$, another possibility noted by Wilsmore. This was resolved in favor Wilsmore and the ketene structure.[13d,e]

The development of ketene chemistry has been bedeviled with controversy, most prominently with the structure of ketene dimer **20** [Eq. (10)], originally suggested by Wilsmore in 1908[14a] to have the acetylketene structure $CH_3COCH{=}C{=}O$. This debate lasted for more than 40 years, and elicited the comment from one worker in the field "The extraordinary chemical behavior of the ketene dimers has lent exceptional interest to that class of substances, and the controversy which has raged for decades over the structures of the compounds is without parallel in the study of small molecules."[14b] This was finally settled definitively by chemical investigations,[14c] electron diffraction,[14d] and X-ray diffraction.[14e] The continual dispute regarding the chemistry of ketenes may be attributed to their extraordinary reactivity and unique structures.

Hurd (Figure 5) was active in the discussion of the structure of diketene, and carried out many studies in ketene chemistry.[15] He modified Wilsmore's procedure for ketene preparation by

Figure 5. Charles D. Hurd (1899–1997). Courtesy of Northwestern University.

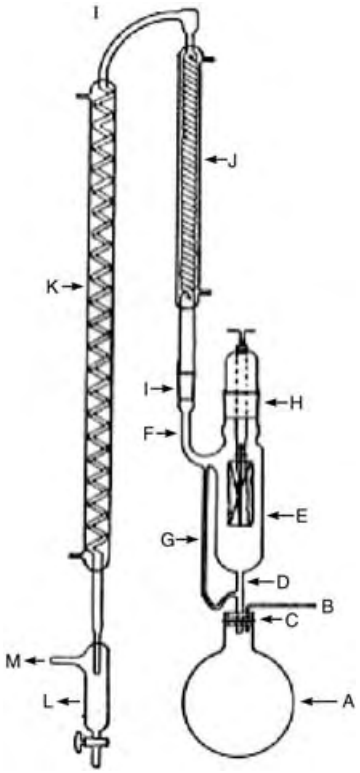

Figure 6. Hurd lamp for ketene preparation (reproduced from Ref. [15e] with the permission of the American Chemical Society).

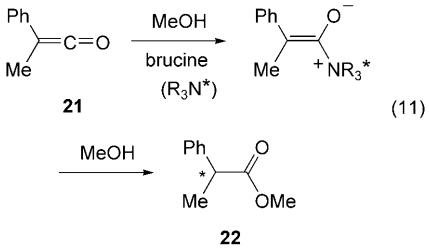
pyrolysis of acetone with the widely used apparatus known as the "Hurd lamp" (Figure 6).[15e] This method was also used for the industrial preparation of ketene for conversion into acetic anhydride.



Asymmetric Reactions

Additions of nucleophiles to unsymmetrical ketenes generate new stereogenic centers, and this led to a long-lasting interest in steroselective reactions of ketenes. In an early study of asymmetric synthesis Richard Weiss at the University of Vienna treated phenyl(4-tolyl)ketene with the optically active alcohol menthol, and after saponification claimed to have obtained an acid with optical activity.[16a] The chirality of the acid arises from the different aryl groups in $Ph(4\text{-}Tol)CHCO_2H$, and the claim that this compound exhibited significant optical activity was improbable and was eventually disproven.[16b,c] Even though this initial effort was not successful, the idea was to prove fruitful, and was later developed by Pracejus (Figure 7) at the University of Rostock

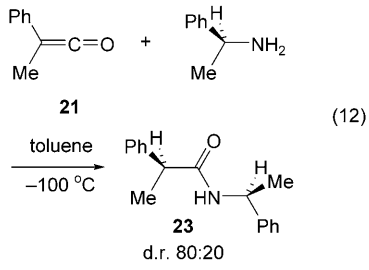


Figure 7. Horst Pracejus (1927–1987). Courtesy of Professor Matthias Beller, Universität Rostock.

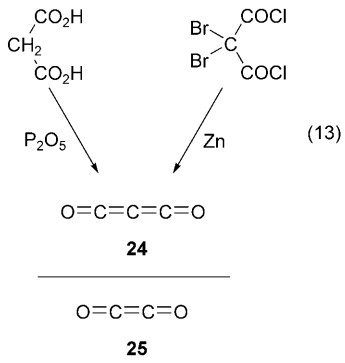
into a practical reaction for aryl(alkyl)ketenes. Pracejus observed significant stereoselectivity in the addition of methanol to phenyl(methyl)ketene (**21**) catalyzed by the chiral base brucine to

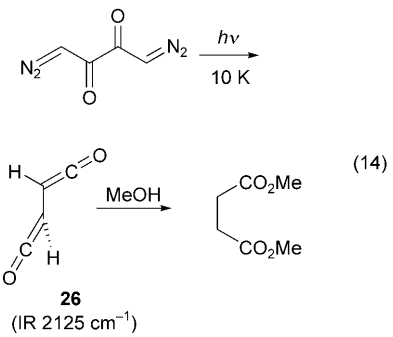
form **22** [Eq. (11)]. Ester **22** is a precursor of α-arylalkanoic acids, which are of major pharmaceutical importance.[16d,e] The Gesellschaft Deutscher Chemiker (German Chemical Society) established the Horst Pracejus Prize for advancement of research in chirality in his honor, first awarded in 1999.



Stereoselective addition of chiral amines to aryl(alkyl)ketenes was also studied by Pracejus,[16f] and reaction of phenyl(methyl)ketene (**21**) with (*S*)-1-phenylethylamine in toluene at −100 °C gave the chiral amide (*S*,*S*)-**23** [Eq. (12)].[16f]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Bisketenes

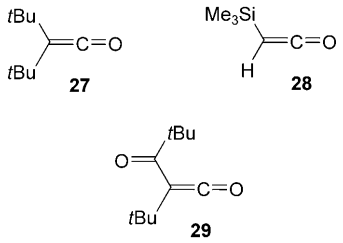


Many types of ketenes have been made, including bisketenes,[17a] that bear two ketene groupings in the same molecule. The first example, carbon suboxide (**24**) was prepared in 1906 by Diels and Wolf by the dehydration of malonic acid [Eq. (13)],[17b] and then in 1908 by

(13)

Staudinger and Bereza by dehalogenation [Eq. (13)].[17c] However, the isolation of further bisketenes proved difficult, and the simplest example, the carbon monoxide dimer **25**, has been the object of continuing theoretical[17d,e] and experimental[17f] examination. Although an energy minimum structure for this molecule has been calculated,[17f] it is still unknown experimentally. It was concluded that this species is an intrinsically short-lived molecule that would rapidly dissociate to CO within a few nanoseconds.[17f]

Staudinger made a sustained effort to prepare other bisketenes, but was unsuccessful in efforts to obtain the linear α,ω-bisketenes, including the 1,2-bisketene **26**.[9b,12a,18a] This was eventually observed in 1982 when it was formed by a double Wolff rearrangement of bis(diazo ketone) in an argon matrix at 10 K. The species was identified by the IR absorption at 2125 cm^{-1}



(14)

and its conversion into the diester with methanol [Eq. (14)].[18b] Surprisingly, such 1,2-bisketenes were shown by computational studies and confirmed by X-ray crystal-structure determination to have twisted, almost perpendicular conformations instead of the typical coplanar structures of 1,3-butadienes.[18c,d]

Substituent Effects

Among the distinctive characteristics of ketenes are their propensity for dimerization and their sensitivity towards hydration, but a notable exception is di-*tert*-butylketene (**27**). This ketene, which was prepared in the

laboratory of Newman (Figure 8) at Ohio State University in 1960,[19a] is

Figure 8. Melvin Newman (1908–1993). Courtesy of Professor J. D. Roberts.

protected by its bulky substituents. Another exception is trimethylsilylketene (**28**), discovered by Shchukovskaya, Pal'chik, and Lazarev in 1965 in Leningrad (now St. Petersburg; Russia) (Figures 9 and 10).[19b,c] Neither of these ketenes is known to dimerize,[19a,b] and both are much less reactive towards

Figure 9. Lidiya L. Shchukovskaya (1926–2002). Courtesy of Dr. Valerij Nikolaev, St. Petersburg State University.

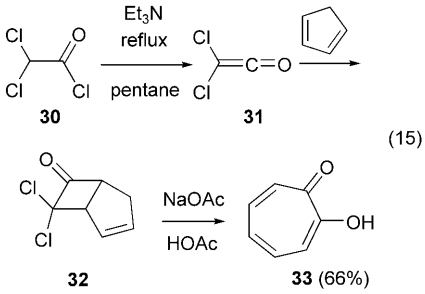


Figure 10. Adrian N. Lazarev (1928–1993). Courtesy of Dr. Valerij Nikolaev, St. Petersburg State University.

water than CH_2=C=O. The stabilization by the trimethylsilyl group in **28** is due to the β-silicon effect and the general tendency of ketenes to be stabilized by electropositive groups through electron donation from ketenyl C–M σ bonds to the in-plane carbonyl π orbital.[19d] The first acylketene was EtO_2CCEt=C=O, also discovered by Staudinger in 1909,[19e] which was only stable at −80 °C, while the crowded example **29**, first prepared in 1978 in Leningrad, appeared to be stable indefinitely as a neat liquid.[19f]

Just as ketenes are stabilized by electropositive groups they are destabilized by electronegative groups. Thus halo ketenes are highly reactive, and despite early efforts directed toward their preparation,[20a–c] were unknown until 1965–1966, when their formation as unobserved intermediates was reported from three different laboratories.[20d–f] Dichloroketene (**31**) was prepared by

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the dehydrochlorination of dichloroacetyl chloride (**30**), and trapped with cyclopentadiene by [2+2] cycloaddition to form bicyclo[3.2.0]pent-2-ene-6-one **32** [Eq. (15)].[20d] Hydrolysis of **32** is a

(15)

simple and efficient method for the preparation of tropolone (**33**) [Eq. (15)].[20d,g] Brady of the University of North Texas (Figure 11)[20e] was a leading pioneer in the development of haloketene chemistry, including fluoro, chloro, and bromo derivatives.

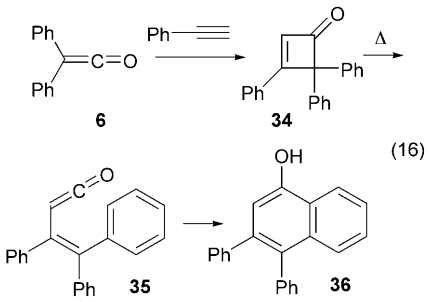

Figure 11. William T. Brady (*1933). Courtesy of Professor Brady.

Cycloadditions

Novel routes to ketenes were found by the reversal of cycloadditions, and these reactions have been extensively exploited in mechanistic studies and in the synthesis of complex molecules. Thus it was discovered by Smith (Figure 12) at the University of Minnesota that cyclobutenone **34**, obtained from [2+2] cycloaddition of diphenylketene with phenylacetylene, undergoes thermal ring opening to the alkenylketene **35**, which gives intramolecular [4+2] cycloaddition with the pendant phenyl group to form **36** (Smith–Hoehn reaction) [Eq. (16)].[21a] Barton (Figure 13) and Quinkert discovered the facile photochemical ring opening of cyclohexadienones to give dienylketenes (Barton–Quinkert reaction).[21b] This process has even been observed with the parent **37**, a tautomer of phenol generated at 77 K, to form **38** [Eq. (17)].[21c]

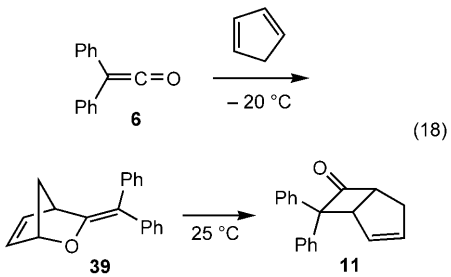
The exquisite stereochemistry observed in the [2+2] cycloaddition of

(17)

ketenes was one of the cornerstones of the development of the rules of orbital symmetry by Woodward and Hoffmann,[22a] and the investigation of these reactions was pursued in many mechanistic studies, particularly by Huisgen (Figure 14) in München (Germany).[22b,c] One of the first examples of the [2+2] cycloaddition of a ketene with a carbon–

Figure 14. Rolf Huisgen (*1920). Courtesy of the Universität München.



carbon double bond was the reaction of diphenylketene (**6**) with cyclopentadiene [Eq. (6)].[9b] Surprisingly it was found by Machiguchi (Figure 15) at Saitama University that the net [2+2]

Figure 15. Takahisa Machiguchi (*1940). Courtesy of Professor Machiguchi.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cycloaddition observed in this canonical process was not the initial reaction in the sequence, but that instead (as observed at low temperature) a [4+2] cycloaddition to carbonyl oxygen formed **39**, which upon warming underwent Claisen rearrangement to **11** [Eq. (18)].[22d]

(18)

Overview

Ketene chemistry in its first 100 years has been a microcosm of organic chemistry as a whole, with useful contributions in synthesis, theory, mechanisms, and practical applications. The major types of ketenes and their typical reactions as described above are now being increasingly applied in new and ingenious ways. Ketenes have always attracted many of the most talented individuals in chemistry, including many Nobel prize winners.[23] Ketenes have found many industrial applications, ranging from the seemingly mundane manufacture of acetic acid and acetic anhydride, to the widespread use of ketene dimers from fatty acids as coatings for paper,[24a] the sophisticated application of the Süs photochemical Wolff rearrangement[24b] for the manufacture of the integrated circuits used in computer chips,[24c,d] and the use of ketenes in the preparation of drug candidates. The unique structural features of ketenes and their high reactivity ensure the vitality of these species in their second century.

Researchers in the post-genome era are confronted with the daunting task of assigning structure and function to tens of thousands of encoded proteins. To realize this goal, new technologies are emerging for the analysis of protein function on a global scale, such as activity-based protein profiling (ABPP), which aims to develop active site-directed chemical probes for enzyme analysis in whole proteomes. For the pursuit of such chemical proteomic technologies, it is helpful to derive inspiration from protein-reactive natural products. Natural products use a remarkably diverse set of mechanisms to covalently modify enzymes from distinct mechanistic classes, thus providing a wellspring of chemical concepts that can be exploited for the design of active-site-directed proteomic probes. Herein, we highlight several examples of protein-reactive natural products and illustrate how their mechanisms of action have influenced and continue to shape the progression of chemical proteomic technologies like ABPP.

1. Introduction

The sequencing of the human genome has transformed the way in which scientists think about biology. However, there is a vast gulf between the wealth of gene sequence information and our knowledge of gene function. Researchers are now confronting the task of understanding the cellular and molecular functions of thousands of predicted gene products. The genome gives rise to the proteome, and it is the combinatorial interactions among proteins that make living organisms so complex at the molecular level. Elucidating the three-dimensional structures and cellular functions of all proteins encoded by prokaryotic and eukaryotic genomes and deciphering the architectures of protein–protein interaction networks of cells and tissues are among the great challenges and opportunities facing new generations of life scientists. To reach this understanding, the development of new technologies and concepts to expedite global analyses of protein function is required.[1] A growing number of research laboratories are exploring biology with chemistry-based strategies that are capable of yielding insight into the role of individual proteins in complex biological systems. The field of chemical synthesis has often played a major role in this process, perhaps most visibly through facilitating the identification of protein targets of bioactive natural products.[2]

For centuries, natural products have been used for medicinal purposes.[3] Life forms that lack immune systems, in particular, biosynthesize natural products of unparalleled structural diversity, some of which modulate biological function with exquisite specificity. It is tantalizing to consider the wealth of secondary metabolites that remains undiscovered. Microorganisms, for example, are a fertile and diverse source for new chemical entities, and researchers are actively developing ways to exploit their metabolic diversity.[4] A provocative subset of biologically active natural products is endowed with electrophilic functional groups that covalently modify nucleophilic residues in specific protein targets. Lipstatin,[5] fumagillin,[6] and microcystin[7] embody the chemistry of the carbonyl group, the epoxide, and the electron-deficient alkene, respectively, and are prominent examples of protein-reactive natural products. These and related secondary metabolites are important because they have yielded insight into the cellular functions of key enzymes. Most natural products that covalently modify proteins possess structural features that render them chemically reactive, whereas others bear latent reactivity; by posing as innocuous substrates, they are activated only by catalytic turnover in their enzyme targets.[8]

Protein-reactive natural products are highly attractive as molecular probes for protein activity profiling experiments, because they provide information about enzyme active sites in complex proteomes. Moreover, the diversity of mechanisms employed by reactive natural products to target enzyme active sites can serve as a valuable guide for the de novo design of affinity agents for the proteomic profiling of specific classes of enzymes. Such activity-based protein profiling (ABPP) endeavors[9] provide a more direct readout of enzyme activity in proteomes, as opposed to inferring this critical parameter from mRNA or protein levels, neither of which reflect the myriad post-translational mechanisms that regulate enzyme function in vivo.[10]

Nature engages protein targets with reactive small molecules in many ways, and the number of natural products that covalently modify proteins is likely very large. In coming to grips with this subject, we have chosen to address selected reactive natural products for which the protein targets are well-characterized, and we have placed particular emphasis on natural products that exert their activities in eukaryotic systems. For a more detailed discussion of classical examples of protein-reactive natural products that target prokaryotic enzymes, such as the β-lactam family of antibiotics, which inhibit peptidases involved in cell wall biosynthesis, the reader is referred to some authoritative review articles.[11] Furthermore, natural products such as DNA-alkylating agents that covalently modify non-protein biomolecules have been extensively reviewed elsewhere, and are not discussed herein.[12] Finally, throughout this review, we attempt to emphasize themes that may be useful in conceiving novel chemical proteomics probes; as will become apparent, the target of natural product action need not be a catalytic nucleophile, or for that matter even an enzyme. Strategies other than the general electrophile–nucleophile interaction offer valuable lessons that may be harnessed by chemical biologists to further expand the proteome space amenable to analysis by ABPP.[13] From the examples below, we hope it is evident that bioactive natural products provide key tools and concepts that can be exploited for the characterization of protein function on a global scale.

2. Natural Products that Target Catalytic Nucleophiles in Enzyme Active Sites

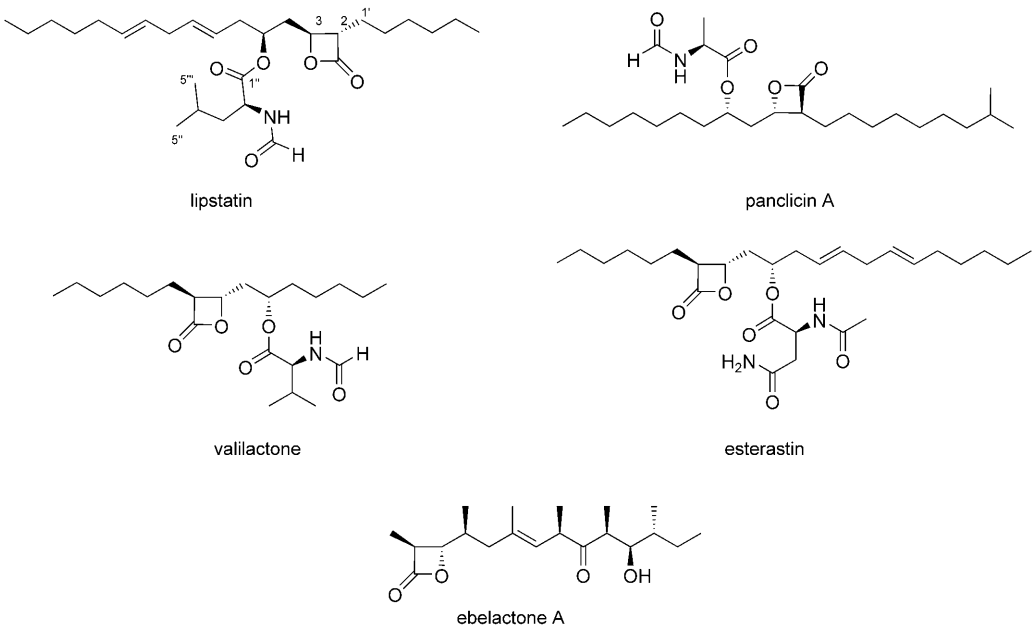
Many natural products have cleverly exploited the catalytic mechanisms of enzymes to elicit selective, covalent inhibition. In this section, we highlight representative natural products that modify key catalytic residues in enzyme active sites.

2.1. Lipstatin

Lipstatin was isolated from *Streptomyces toxytricini* on the basis of its potent, selective, and irreversible inhibition of pancreatic lipase (Scheme 1).[14] The structure of lipstatin was determined by a combination of spectroscopic and chemical methods,[15] and was confirmed by chemical synthesis.[16] Lipstatin features a β-lactone ring with two linear carbon chains of six and thirteen atoms, respectively. The longer of the two is doubly unsaturated and contains an *N*-formylleucine ester side chain. Structural analysis revealed a striking similarity between lipstatin and esterastin, a reported inhibitor of esterase which features a different amino acid side chain, *N*-acetylasparagine.[17] Other members of this β-lactone enzyme inhibitor family include the panclicins,[18] the ebelactones,[19] and valilactone (Scheme 1).[20] The research group of Bacher later found that lipstatin is derived biosynthetically from 3-hydroxytetradeca-5,8-dienoic acid,[21] which forms from a condensation of two mycolic acid[22] components of 14 and 8 carbon atoms, both of which originate from fatty acid catabolism. Protons at the C2 and C3 positions, and one proton at C4 are derived from water.[21c] This is in contrast with the initial assumption that lipstatin had a polyketide origin; early [^{13}C]acetate feeding experiments were inconclusive.[21d] A total synthesis of lipstatin from (*S*)-*N*-formylleucine and dimethyl-(*S*)-(−)-malate was recently described,[23] and there is also a comprehensive body of synthetic work on tetrahydrolipstatin,[16,24] which is obtained by the catalytic hydrogenation of lipstatin.[15]

Pancreatic lipase is the target of lipstatin and its derivatives. This lipase possesses an active-site charge-relay system similar to serine proteases; it features the catalytic triad of His263, Asp176, and Ser152.[25] Pancreatic lipase is responsible for the hydrolysis of dietary triacylglycerols to fatty acids and monoacylglycerols.[26] This catabolic process is critical for proper fat absorption; inhibition of pancreatic lipase activity results in the passage of fats through the stool. Tetrahydrolipstatin limits the absorption of dietary fat by blocking the activity of pancreatic lipase, as well as carboxylester lipase, human milk lipase, and gastric lipase.[22a] Now available under the trade names orlistat or xenical, tetrahydrolipstatin was approved by the Food and Drug Administration in March 1999 and has been successful in helping obese patients lose weight.[26b,27] Obesity affects approximately one third of the U.S. population,[26b] and many problems are thought to stem from this chronic condition, including diabetes mellitus type II. This disease may be prevented or brought under control with an Orlistat regimen.[28]

Tetrahydrolipstatin is also an inhibitor of the thioesterase domain of fatty acid synthase (FAS), an enzyme associated with tumor cell proliferation.[29] Administration of orlistat to prostate tumor cells causes apoptosis; the drug also halts growth of xenograft tumors in mice. Interestingly, it was an



Carmen Drahl obtained her BA in chemistry at Drew University in 2002. She received her MA at Princeton University in the laboratory of G. McLendon. Currently, she is conducting graduate studies at Princeton under the direction of E. J. Sorensen. Her research interests include the synthesis and biological evaluation of reactive natural products. She is the recipient of a Barry M. Goldwater Fellowship, as well as predoctoral fellowships from Eli Lilly and the National Science Foundation.

Benjamin Cravatt studied biological sciences (BS) and history (BA) at Stanford University. He then conducted research with D. Boger and R. Lerner and received his PhD from The Scripps Research Institute (TSRI) in 1996. He joined the faculty at TSRI in 1997 as a member of the Skaggs Institute for Chemical Biology and the departments of Cell Biology and Chemistry. His research group is developing and applying new technologies to elucidate the roles of enzymes in the physiological and pathological processes of the nervous system and in cancer.

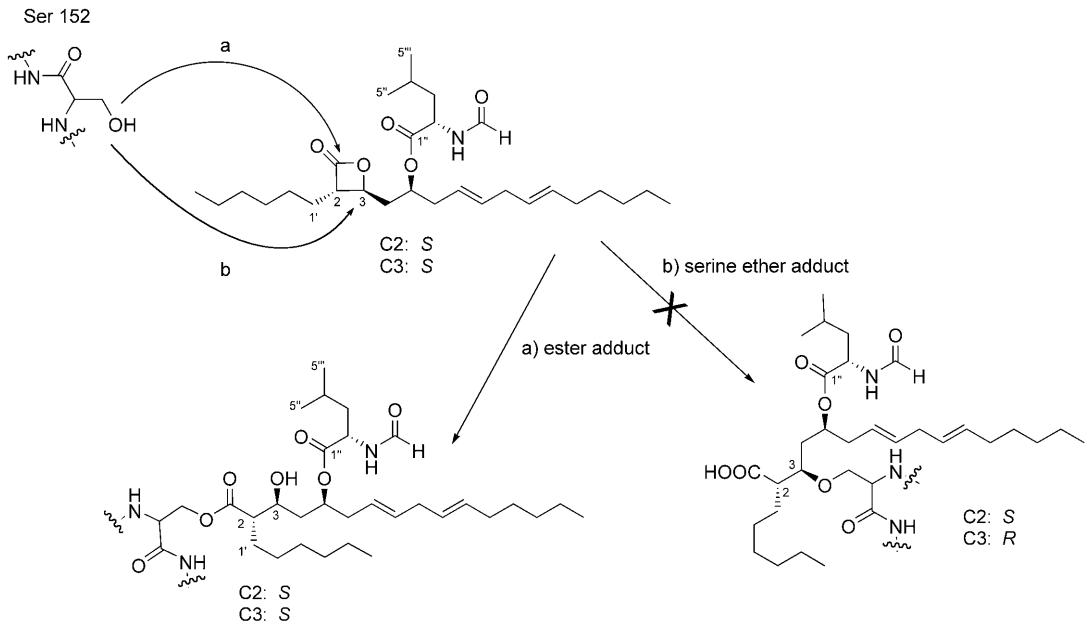
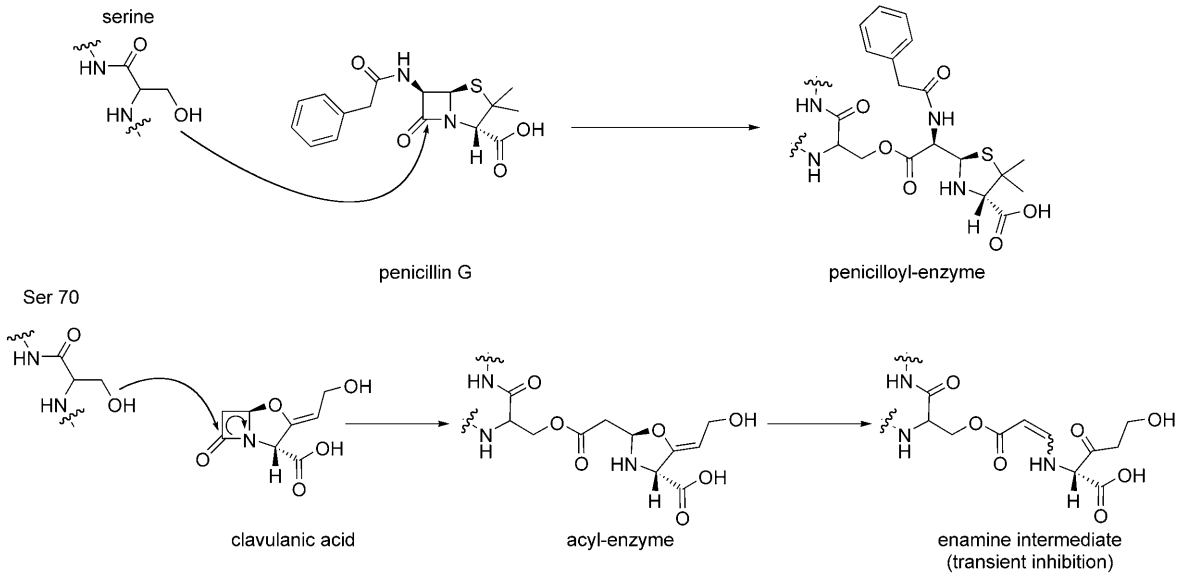
Scheme 1. The lipstatin family of natural products; all members feature a four-membered β-lactone ring.

ABPP screen of prostate cancer cell proteomes with a fluorophosphonate–rhodamine probe that allowed researchers to characterize Orlistat as a FAS thioesterase inhibitor and a potential antitumor therapeutic.[29]

The chemical reactivity of the β-lactone group of tetrahydrolipstatin and its analogues is the basis for their biological effects. The catalytic active-site serine nucleophile of pancreatic lipase attacks the electrophilic β-lactone at the carbonyl carbon C1 to form a β-hydroxy serine ester (Scheme 2, route a).[5,30] Theoretically, attack could also occur at C3 to form a stable serine ether (Scheme 2, route b). Modified tetrahydrolipstatins (as obtained after enzyme attack and following adduct hydrolysis) were synthesized and then compared with the enzyme reaction results. Products with inverted stereochemistry at C3, which would result from nucleophilic attack at this atom, were observed in trace amounts at most. These data support the carbonyl carbon atom as the site of attack.[30] The carbonyl carbon atom may be activated by a hydrogen-bond donor in the active site of the lipase, or the relief of ring strain alone may be sufficient to drive the ring-opening process. In the absence of a water-insoluble substrate and at pH 7.0, the acyl-enzyme intermediate hydrolyzes very slowly to a hydroxy acid that still bears the formylleucine side chain, thus almost completely restoring enzyme activity within 24 hours.[22a,30a]



Erik J. Sorensen received his BA degree from Syracuse University. Under the guidance of K. C. Nicolaou at the University of California, San Diego, he obtained his PhD in 1995 and co-authored the book Classics in Total Synthesis. He subsequently worked as a postdoctoral fellow with S. Danishefsky. In 1997, he began his independent career at The Scripps Research Institute and became associate professor in 2001. In 2003, he moved to Princeton University, where he is the Arthur Allan Patchett Professor in organic chemistry.



This type of reactivity is similar to that of the β-lactam antibiotics, which target peptidases involved in bacterial cell-wall biosynthesis (Scheme 3). The active-site serine nucleophile in the proteins targeted by penicillin is believed to attack the carbonyl carbon of the lactam ring to furnish a ring-opened penicilloyl-enzyme.[31] Clavulanic acid has a more complicated proposed mechanism, but it shares with lipstatin the principal features of inhibition through ring opening and recovery of enzyme activity through the slow subsequent hydrolysis of an enamine.[32]

The simplicity of the reactive motif in the lipstatin family is as instructive as the scaffold that frames it. Many physiological nucleophiles could conceivably react with and open the lactone ring. The long alkyl chains of these natural products presumably direct them toward enzymes with lipid substrates. The reactivation period for pancreatic lipase by hydrolysis of the acyl-enzyme intermediate is interesting, particularly in light of a study that demonstrated a threefold increase in the reactivation rate constant (k_r) in the presence of lipid–water interfaces (k_r increased from 2000 to 6000 min^{-1}).[33] Enzymes found in different environments might therefore have different turnover rates. Part of the noted selectivity of lipstatin may come not only from selective targeting of the small molecule to pancreatic lipase, but also from the selected lack of turnover of the lipase–lipstatin complex. Variation of the scaffold around the reactive β-lactone motif should allow lipstatin-like chemical probes to be redirected to target other lipase enzymes or even other enzyme families altogether.

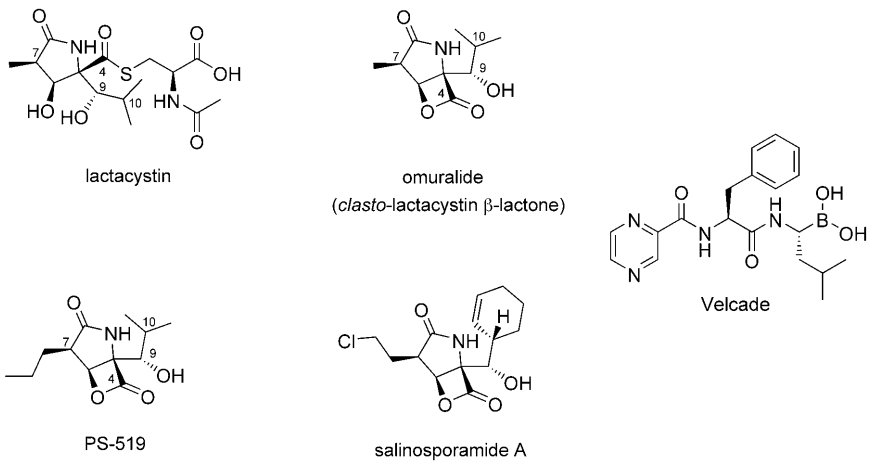
Scheme 2. Two possible mechanisms for the covalent modification of pancreatic lipase by lipstatin. The reaction occurs exclusively at the β-lactone carbonyl group.



Scheme 3. Principal features of β-lactam antibiotic reactivity.

2.2. Lactacystin

Lactacystin (Scheme 4) was isolated by Omura and co-workers from a *Streptomyces* strain in a screen for natural products that induce neurite outgrowth.[34] Its interesting structure was elucidated by X-ray crystallography and NMR spectroscopy,[35] and confirmed by the total syntheses carried out by several research groups.[36] Lactacystin is biosynthesized from three units: leucine, isobutyrate (and/or valine), and cysteine.[37]

Further investigations showed that lactacystin does not mimic nerve growth factor;[38] instead, it reacts specifically with the proteasome, binding covalently to the hydroxy group of the highly conserved N-terminal threonine residue to inhibit the chymotrypsin-like and trypsin-like proteasome activities in irreversible fashion.[38b] The proteasome is an abundant ATP-dependent cellular protease that degrades damaged proteins.[39] With few exceptions, proteasomes act on proteins that are tagged for destruction through the covalent attachment of the small protein ubiquitin.[39] The proteasome consists of a barrel-like core, in which controlled proteolysis takes place. The core is capped at each end by a regulatory protein.[39] The N-terminal threonine residue modified by lactacystin serves as the active-site nucleophile of the proteasome.[38b,40] The proteasome lacks a catalytic triad, but requires a basic group to accept a proton from threonine in

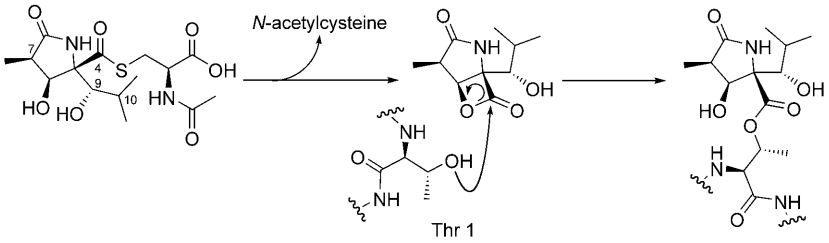


Scheme 4. Lactacystin and related proteasome inhibitors. Velcade is a synthetic inhibitor clinically approved for the treatment of multiple myeloma.

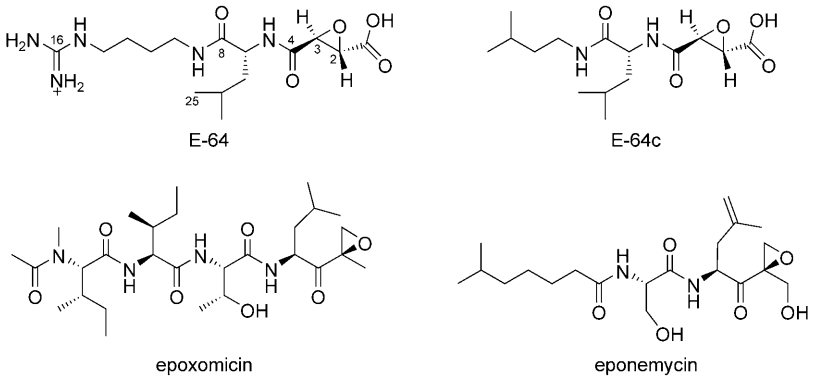
the transition state. This is most likely the job of the α-amino group of Thr 1, which is ideally situated to accept a proton in the crystal structure of the proteasome in complex with lactacystin.[41] Alternatively, the conserved Lys 33 residue may fulfill this role, since mutation of this residue abolishes proteasome activity.[42] Lactacystin inhibits neither the serine proteases trypsin and chymotrypsin, nor the cysteine proteases papain, the calpains, or cathepsin B;[38b] it does, however, covalently inhibit the serine protease cathepsin A.[43] As a fairly selective proteasome inhibitor, lactacystin has proven to be a valuable probe to study the cellular role of the ubiquitin–proteasome pathway.[44]

Different families of proteasome inhibitors have been developed over the years to better understand the ubiquitin–proteasome system. The earliest synthetic inhibitors, the C-terminal peptide aldehydes, showed too little selectivity for the proteasome over serine and cysteine proteases.[40] Certain tripeptides modified at the C terminus by a vinyl sulfone or glyoxal act as mechanism-based inhibitors of the proteasome.[39b,45] Boronic acid peptides (in which the aldehyde pharmacophore has been replaced by a boronate group) are more potent and selective for the proteasome. The flagship boronate compound, PS-341,[40,46] was recently clinically approved for the treatment of multiple myeloma (velcade (bortezomib), Scheme 4). This validates the proteasome as a therapeutic target for at least this type of cancer and potentially other forms as well.[47] Unlike lactacystin, however, Velcade reversibly inhibits the chymotrypsin-like activity of the proteasome.[40] The most clinically advanced lactacystin analogue is PS-519 (Scheme 4), a cell-permeable variant that features an *n*-propyl substitution at C7. This compound is more potent than the natural product and has entered phase II clinical trials for acute stroke.[40,48]

The reactivity of lactacystin is brought about by its latent β-lactone group, termed *clasto*-lactacystin β-lactone or omuralide (Scheme 4).[49] Derivatives that cannot form the β-lactone are inactive. Omuralide is formed in the extracellular fluid from cyclization (lactonization) of lactacystin with loss of the *N*-acetylcysteine leaving group. The resulting omuralide is more cell-permeable than the parent compound,[40,49] and it inhibits proteasome activities 15 to 20-fold faster than lactacystin.[38] Carbon atom C4 of this intermediate lactone is electrophilic and is presumed to undergo attack by the hydroxy group of the catalytic threonine residue[44b] to yield an ester-linked omuralide–proteasome adduct (Scheme 5). The "masking" of the reactive β-lactone in its open thioester form is important, as it may help lactacystin avoid spurious targets. Several research groups have shown that lactacystin labels all active proteasome β subunits.[39b,50] Interestingly, it was

Scheme 5. Lactacystin is lactonized to its cell-permeable, protein-reactive derivative, omuralide, which then covalently inactivates the proteasome.

demonstrated that replacement of the catalytic N-terminal threonine group with serine produced a fivefold increase in the rate of proteasome inactivation by omuralide. This replacement also increased the rate of hydrolysis of the acyl-enzyme intermediate.[51] This result may explain why omuralide and lactacystin inhibit very few serine proteases, as serine–omuralide adducts may undergo rapid hydrolysis to relieve inhibition.[44a] It is instructive to note how the activity and selectivity of lactacystin are exquisitely controlled by intrinsic chemical reactivity.



The structure of the proteasome from *Saccharomyces cerevisiae* co-crystallized with omuralide[41] was determined by X-ray analysis, and confirmed the covalent linkage between the threonine side chain hydroxy group and omuralide. The N-terminal amino group is not modified by the natural product. Omuralide makes four hydrogen-bond contacts with the main chain of the proteasome catalytic subunit. The C9 isopropyl moiety of omuralide projects into a hydrophobic pocket of the proteasome to lend additional binding affinity. Corey and co-workers have shown that replacement of the omuralide C9 isopropyl group with a phenyl group abolishes all activity.[52] Interestingly, salinosporamide A (Scheme 4), a natural product 35-fold more potent than omuralide, possesses a cyclohexene moiety in place of the isopropyl group, yet it shares the bicyclic ring structure of omuralide.[53] Feling and co-workers suggested that this may be indicative of the different ways by which omuralide and salinosporamide A interact with the protea-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some.[53] Corey and co-workers recently reported the first enantiospecific total synthesis of salinosporamide A[54] with a procedure that yields sufficient material to carry out biological analyses of the efficacy of salinosporamide A as a potential anticancer agent. Moreover, congeners of salinosporamide A were recently prepared for the possible treatment of proteasome-mediated disease.[55] It will be interesting to learn whether salinosporamide A has improved upon the delicately balanced chemistry of lactacystin.

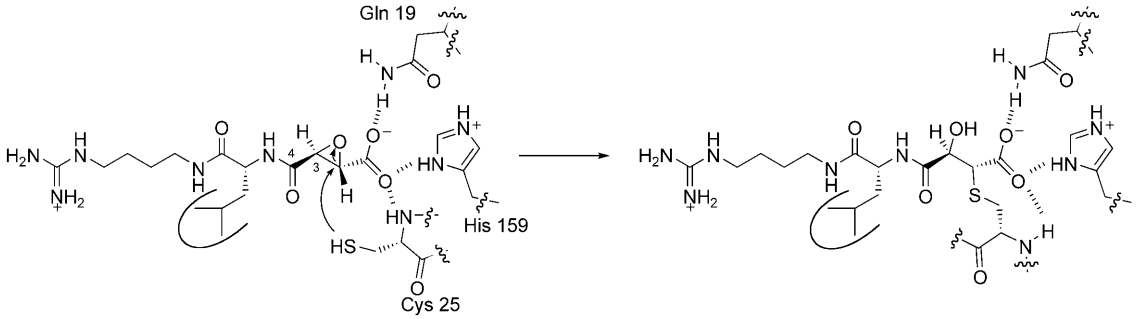
2.3. E-64

In 1978, the Hanada group pursued a specific inhibitor of cysteine proteases to expedite investigation of protease biological functions. They succeeded in isolating a highly potent and irreversible inhibitor, E-64, from the mold *Aspergillus japonicus*.[56] The structure of E-64 was determined principally through classical chemical reactivity testing, IR spectroscopy, and ^{1}H NMR spectroscopy, and was subsequently confirmed by a chemical synthesis of its enantiomer.[57] The structure contains agmatine, the arginine decarboxylation product 1-amino-4-guanidinobutane (Scheme 6). To identify an E-64 pharmacophore, a comprehensive library of derivatives and fragments was synthesized. Both the epoxide and the carboxyl group derived from L-*trans*-(*S*,*S*)-epoxysuccinic acid were found to be indispensable for inhibition of papain.[58] Notably, other peptidyl epoxide natural products that act as covalent inhibitors of the proteasome have also been identified, including epoxomicin[59] and eponemicin[60] (Scheme 6).

Scheme 6. E-64 and other L-*trans*-(*S*,*S*)-epoxysuccinic acid derivatives.

In addition to papain, E-64 is a covalent inhibitor of several other cysteine proteases, including cathepsins B, H, and L, stem bromelain, and ficin.[61] The revelation that the high affinity, active-site-directed reversible inhibitor leupeptin decreased the rate of E-64 binding cemented the idea that E-64 is an active-site-directed inhibitor of cysteine proteases.[61] These proteases exert their catalytic activity with the assistance of an active-site ion pair between cysteine and histidine residues.[62] In papain, these residues are Cys 25 and His 159.[62]

Aberrant cysteine protease activity leads to many disease states. Inflammatory and traumatic processes, muscular dystrophy, Alzheimer's disease, cancer, and cataract formation all have a putative link to cysteine protease dysfunction.[63] In addition, because cysteine proteases are a critical component of the *Plasmodium* life cycle, they are regarded as viable targets for potential antimalarial drugs.[64] In an effort to improve the cell permeability of leads, the agmatine group was replaced with neutral moieties, such as isoamylamine in the case of E-64c (Scheme 6).[65] In 1986, the ethyl ester of E-64c was removed from phase III clinical trials in Japan for muscular dystrophy indications because its efficacy did not meet expectations, and the drug covalently modified proteins of other mechanistic classes.[63d,66] However, by virtue of its inhibition of calpain, this same E-64 derivative has found use in eye drops for the prevention and treatment of cataracts.[67] E-64 is still frequently used to facilitate discovery and classification of newly isolated papain-class enzymes.[68]



Molecular probes for ABPP inspired by the E-64 motif have proven to be of great value for tracking the activities of both animal and plant cysteine proteases in whole proteomes, and in the design and screening of inhibitors for these enzymes.[68a,b] For example, a screen of plant extracts revealed cysteine protease activity for three proteins that had not been previously characterized.[68a] In a comparative screen of mature and senescent leaf extracts, ABPP demonstrated that a change in mRNA transcript levels does not always correlate with protease activity.[68a] In addition, a cell-permeable E-64 probe revealed that increased cathepsin activity is associated with the angiogenic vasculature and invasive fronts of carcinomas.[69] Based on these results, administration of a broad-spectrum cathepsin inhibitor was performed, which impaired tumor growth and invasiveness.

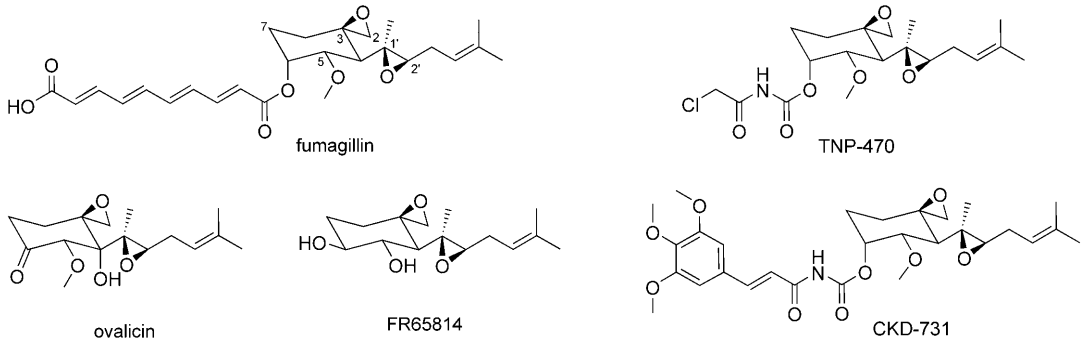
The reaction of the E-64 epoxide with papain was elucidated by ^{13}C NMR spectroscopy.[70] Attack by the catalytic cysteine nucleophile occurs at the epoxide C2 atom.[70,71] Backside attack in S_N2 fashion inverts the configuration at C2 of the product thioether (Scheme 7). The key contacts between cysteine proteases and E-64 that are responsible for situating the inhibitor's epoxide group for regioselective nucleophilic attack have been extensively characterized in a series of crystal structures.[57,71,72] In the structure of the E-64–papain complex, the N-terminal carboxyl group of E-64 is positioned in the oxyanion hole, while the carbonyl group adjacent to the epoxide group interacts with the histidine catalytic base.[71] The mechanistic characterization of the interaction between E-64 and cysteine proteases of the papain class is an excellent example of the power of convergent research efforts in chemical synthesis, classical biochemistry, and structural biology.

3. Natural Products that Target "Non-Nucleophilic" Residues in Enzyme Active Sites

Several natural products inhibit enzymes through the covalent modification of active-site residues that are not essential for catalysis. Although some of these residues appear to perform supportive catalytic roles, they do not

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 7. The active-site cysteine residue of papain attacks the electrophilic epoxide of E-64 in an S_N2 fashion.



participate as nucleophiles directly; other residues seem altogether superfluous for catalysis. In either case, however, covalent modification of these residues results in enzyme inactivation. Herein, we highlight selected examples of natural products that target "non-nucleophilic" residues in enzyme active sites.

3.1. Fumagillin

A 1949 report demonstrated that concentrates of *Aspergillus fumigatus* cultures possessed antibiotic activity against *Staphylococcus aureus*.[73] Tarbell and co-workers characterized the chemical behavior of the active component, fumagillin, including the acid sensitivity of its characteristic spiroepoxide unit.[74] The constitution and stereochemistry of fumagillin were confirmed by X-ray crystallography (Scheme 8).[75] In 1972, Corey and Snider described their elegant studies that culminated in the first chemical synthesis of this natural product.[76] Subsequent work has produced a 26-step synthesis of (−)-fumagillol,[77] the saponification product of fumagillin, and a 13-step racemic synthesis of fumagillol.[78] Fumagillin and its close relatives ovalicin[79] and FR65814 (Scheme 8)[80] possess a rare sesquiterpene carbon skeleton that has been shown by labeling experiments to originate biosynthetically from β-*trans*-bergamotene, which arises from farnesyl pyrophosphate.[81] Other natural products not necessarily in the fumagillin family, but which contain a spiroepoxide moiety include curvularol[82] and FR901464.[83]

Fumagillin and other members of its family target methionine aminopeptidase 2 (MetAP-2), but not the closely related enzyme methionine aminopeptidase 1 (MetAP-1).[6b,84] Methionine aminopeptidases are metalloproteases responsible for co-translational removal of the N-terminal methionine residue in specific protein targets.[6b,85] These enzymes were originally thought to use cobalt as the active-site metal center, but more recent studies indicate that manganese is likely the physiologically relevant cofactor.[86] In the enzyme active site, the metal ions are coordinated by Asp251, Asp262, His331, Glu364, Glu459, and a water molecule.[87] The nucleophilicity of the water molecule is enhanced by coordination to the manganese ion; it attacks the scissile amide bond of the substrate.[88] MetAP-mediated removal of methionine is necessary for post-translational modifications such as myristoylation.[89] A single amino acid residue in MetAP-2, Ala362, confers sensitivity to ovalicin, and a Thr362Ala mutation of the human MetAP-1 gene inserted into yeast results in ovalicin-sensitive yeast colonies.[90]

The connection between inhibition of MetAP-2 and the medicinal utility of fumagillin appears complex and remains unclear.[91] It has been speculated that a connection exists at the level of protein myristoylation.[92] Without removal of N-terminal methionine residues, proteins cannot be myristoylated in vivo, which in turn, could disrupt their localization and function. Therefore, the hypothesis is that fumagillin indirectly causes cell-cycle arrest by interfering with myristoylation, which leads to aberrant subcellular localization of proteins that are not yet identified.[92] Despite a mechanism of action that remains enigmatic, fumagillin is firmly established as a potent antiparasitic agent.[93] During the 1950s, fumagillin was used for treatment of amoebiasis in humans, caused by *Endamoeba histolytica*, and is still used today for Nosema disease in honeybees, caused by the protozoan *Nosema*

Scheme 8. Fumagillin and other protein-reactive spiroepoxides. TNP-470 and CKD-731 are synthetic compounds.

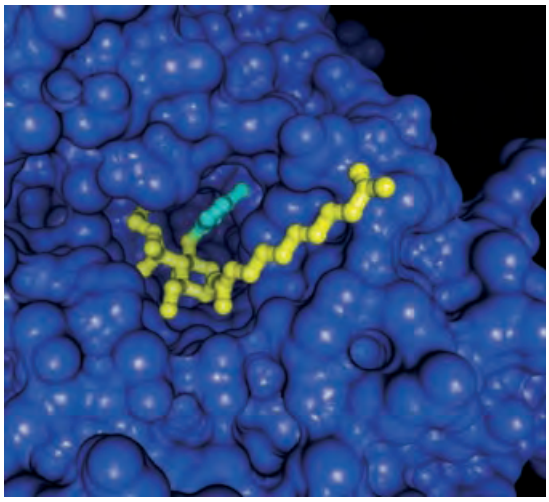
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

apis.[93a,b] More recently, fumagillin has shown efficacy against microsporidial keratoconjunctivitis of the eye, caused by a single-celled fungus.[94] Fumagillin and its semisynthetic derivative TNP-470 (Scheme 8) are the only treatments for microsporidiosis in HIV-positive patients[95] and block the in vitro growth of *Plasmodium falciparum* and *Leishmania donavani*, the organisms that cause malaria and leishmaniasis, respectively.[96] The broad anti-infective activity of fumagillin does not come without a price; it is toxic to mammals which indicates its low selectivity for parasitic over mammalian MetAP-2.[97]

The research group of Folkman stimulated a renaissance of interest in fumagillin with their discovery that this natural product inhibits tumor-induced angiogenesis.[98] TNP-470 is also a promising small-molecule inhibitor of angiogenesis and has progressed into clinical trials as a potential anticancer drug.[99] By using a homology modeling approach from the crystal structure of MetAP-2, Han and co-workers designed CKD-731 (Scheme 8), an analogue that is 1000-fold more potent against endothelial cell proliferation than TNP-470.[100]

New data suggest that MetAP-2 may not be the biologically relevant target of fumagillin, and that MetAP-2 function is not necessary for the growth of endothelial cells.[101] However, this study could not completely rule out a functional role for MetAP-2, because knockdown of the peptidase by siRNA was incomplete. The authors raised the intriguing possibility that another MetAP family member may exist in humans that could also act as a target for fumagillin.[101]

The key reactive motif of fumagillin is its spiroepoxide structure.[6] Removal of the spiroepoxide unit results in a 1000-fold decrease in MetAP-2 inhibition.[84] Fumagillin also possesses a side chain epoxide group; this epoxide was demonstrated to be dispensable for MetAP-2 inhibitory activity.[84] In the X-ray crystal structure of human MetAP-2 complexed with fumagillin, a covalent bond between the imidazole nitrogen ($N^{\varepsilon}2$) of a histidine residue (His231) and the methylene of the spiroepoxide is evident (Figure 1).[87] It has been speculated that His231 acts as a general base during catalysis, as it serves as a nucleophile to open the spiroepoxide ring.[84] It was thought that His231, along with the binuclear metal center, could activate a water molecule for attack at the scissile amide bond, after which another histidine in the active site, His339, could protonate the leaving group.[84] However, the active site geometry in *E. coli* MetAP-2 does not corroborate this proposal.[102] Scheme 9 depicts one model for fumagillin-mediated labeling of MetAP-2.[103] Transition-



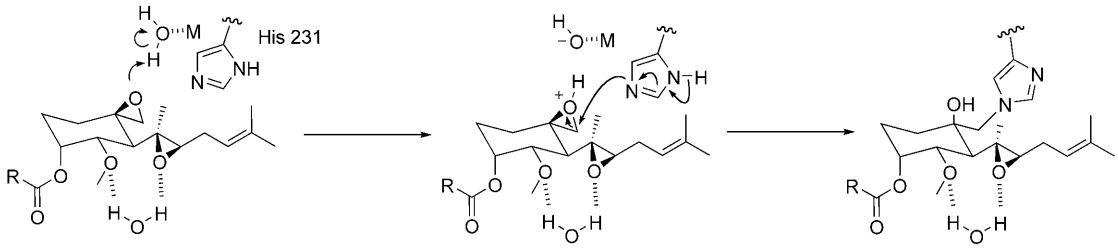


Figure 1. X-ray crystal structure of human MetAP-2 complexed with fumagillin. The covalent bond between C11 of the natural product (yellow) and $N^{\varepsilon}2$ of the active site His231 (cyan) is shown; the rest of the molecular surface of MetAP-2 is colored blue.

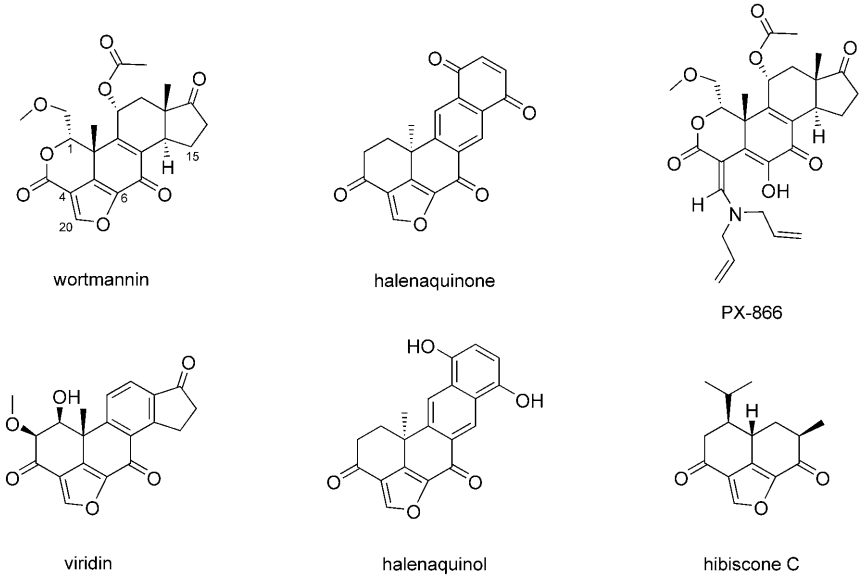
state analogues and crystallographic analysis yielded further insight into the catalytic mechanism of *E. coli* MetAP,[102–104] suggesting that His79 of *E. coli* MetAP (equivalent to His231 of human MetAP-2) actually stabilizes the tetrahedral intermediate that results when the peptide is attacked by an activated hydroxide through direct interaction with the nitrogen atom of the scissile peptide bond. Thus, the histidine residue modified by fumagillin appears to play an important supportive role in catalysis, consistent with the dramatic reduction in enzyme activity observed for a His231Asn MetAP-2 mutant.[84] More generally, fumagillin targeting of MetAP-2, which uses a metal-activated water molecule as the nucleophile for peptide-bond hydrolysis, underscores the remarkable ability of natural products to selectively label the active sites of enzymes that do not themselves engage in covalent catalysis.

3.2. Wortmannin



The antifungal antibiotic wortmannin (Scheme 10) was isolated from *Penicillium wortmanii* and its complex structure was elucidated by chemical degradation and NMR spectroscopic methods.[105] The hallmark of wortmannin is its reactive furan ring, which is fused between C4 and C6 of a steroid

Scheme 9. In one model for MetAP-2 modification by fumagillin, a histidine group in the MetAP-2 substrate binding site is able to open a protonated epoxide. Fumagillin binding is enhanced at low pH.[103]

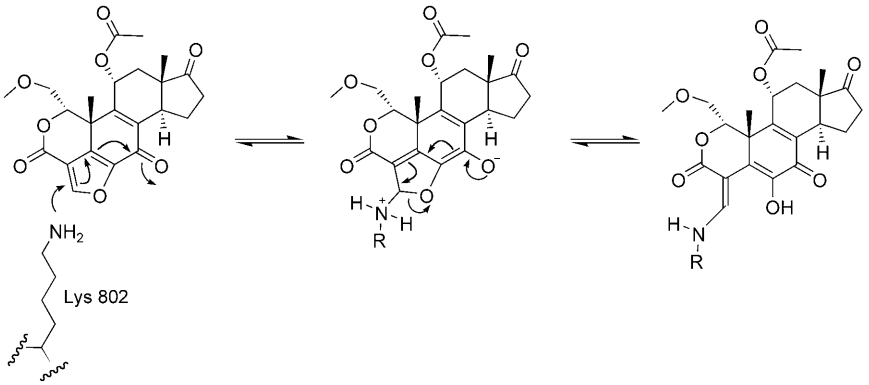
framework.[106] This feature is also found in viridin, demethoxyviridin, the marine-derived pp60$^{v\text{-}src}$ protein tyrosine kinase inhibitors halenaquinone and halenaquinol, and hibiscone C (gmelofuran), which is found in the heartwood of *Gmelina arborea* and the Jamaican Blue Mahoe (Scheme 10).[107]

Scheme 10. The wortmannin family of steroidal natural products. PX-866 was synthesized from wortmannin.



Wortmannin[108] and its structural relative viridin[109] are biosynthesized from the triterpenoid alcohol lanosterol[110] and are potent cell-permeable inhibitors of the lipid kinase phosphatidylinositol 3-kinase (PI 3-kinase). This enzyme is a central component of two major receptor-mediated signal transduction pathways:[111] the G-protein-coupled receptor pathway and the receptor tyrosine kinase pathway. PI 3-kinase phosphorylates at position 3 of the inositol ring of phosphatidylinositol (PtdIns), leading to the production of the second messengers PtdIns-3-phosphate, PtdIns-3,4-bisphosphate, and PtdIns-3,4,5-triphosphate. The precise nature of the PI 3-kinase catalytic mechanism is unknown.[112] In porcine PI 3-kinase, contact with the α- and β-phosphate groups of ATP is mediated by the conserved Lys 833 and Ser 806 side chains, respectively. An early mechanistic model involved deprotonation of the lipid substrate hydroxy group by Asp 946 to generate a nucleophile that attacks the γ-phosphate of ATP. Although mutations of this amino acid abolish activity, the crystal structure of PI 3-kinase indicates that this particular aspartate is not positioned properly for a role as catalytic base. Another residue, His 948, has been offered as an alternative base, but there is no experimental evidence to support this claim.[112b] Alternatively, PI 3-kinase may not possess a base catalyst. Instead, it may operate through a dissociative transition state.[113]

In addition to its well-studied lipid kinase target, wortmannin has been demonstrated to inhibit other serine/threonine kinases, including the mammalian target of rapamycin (mTOR), DNA-dependent protein kinase (DNA-PK),[114] myosin light chain kinase (MLCK), the gentamicin resistance enzyme AAC(6′)-APH(2″), and a membrane-bound PI 4-kinase.[115]

PI 3-kinases are involved in a large number of fundamental cellular processes, including apoptosis, proliferation, cell motility, and adhesion, and have been implicated in the malignant transformation of cells. Increased levels of PI 3-kinase products have been observed in colorectal tumors and in breast cancers.[116] It was also reported that dephosphorylation of PI 3-kinase products suppresses tumor formation.[117] As inhibitors of PI 3-kinase in vertebrates, wortmannin and its structural relatives are considered to have potential as therapeutic agents for the treatment of human neoplasms and other disease states such as diabetes, inflammation, platelet aggregation, atherosclerosis, and osteoporosis. A semisynthetic wortmannin library yielded ten compounds that were advanced to pharmacokinetic and toxicity studies.[118] PX-866 (Scheme 10), a diallylamino wortmannin derivative lacking the furan ring, demonstrated good pharmacokinetics and toxicity and exhibited prolonged inhibition of PI 3-kinase in vivo. This compound also augmented the antitumor effects of the established chemotherapeutic agent cisplatin.[119] It was speculated that loss of the furan ring was redeemed by improved chemical stability or a better fit in the ATP-binding pocket.[118]

Amine nucleophiles react efficiently with the doubly activated and highly electrophilic strained furan ring of wortmannin by attacking C20 to give vinylogous carbamates through an addition–elimination mechanism.[120] Wipf and co-workers recently synthesized a library of 94 C20-substituted semisynthetic wortmannin derivatives by reaction of the natural product with a wide variety of amine and thiol nucleophiles.[118] Wymann and co-workers discovered that this chemistry also occurs in the active site of PI 3-kinase.[121] The ε-amino group of Lys 802 of PI 3-kinase (Lys 833 in porcine PI 3-kinase)[122] attacks C20 of wortmannin which results in furan ring-opening to form a vinylogous carbamate (Scheme 11). This covalent bond-forming event irreversibly inhibits the enzyme. The acid lability of the vinylogous carbamate group complicated efforts to isolate wortmannin-labeled peptides. Fortunately, this group could be reduced with sodium cyanoborohydride to give a considerably more stable amine–wortmannin adduct. ATP, adenine, and FSBA (5′-*para*-fluorosulfonylbenzoyladenosine) each at 1 mM interfered with the alkylation of PI 3-kinase by wortmannin when added before the inhibitor, although substances containing nucleophilic amino acid side chain groups had no effect at the same concentration. FSBA is a derivative of adenine that reacts covalently with nucleophilic amino acids and has been

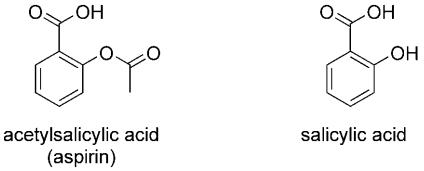
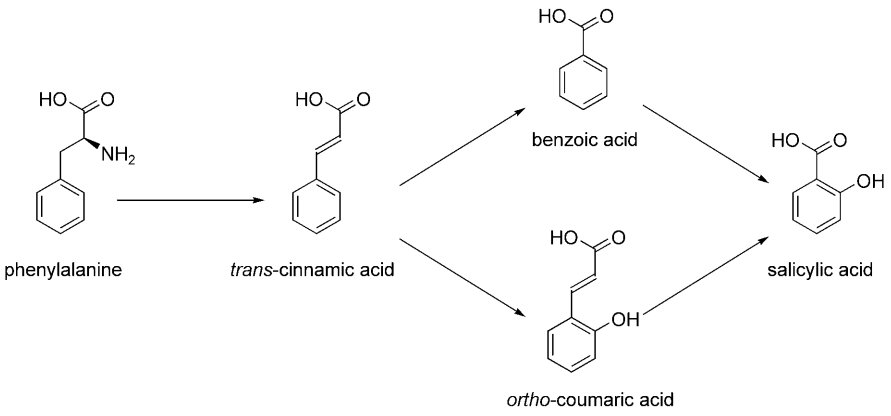
Scheme 11. Lysine 802 in PI 3-kinase opens the doubly activated furan ring of wortmannin by an addition–elimination mechanism to yield a vinylogous carbamate.



used to map nucleotide binding sites.[121] The PI 3-kinase substrate PtdIns-4,5-bisphosphate also effectively competes with wortmannin binding. These findings led Wymann and coworkers to conclude that the wortmannin target site in PI 3-kinase is in a nucleotide binding site in proximity to the substrate binding site. These postulates were confirmed by the X-ray crystal structure of a complex between wortmannin and porcine PI 3-kinase.[122]

The role of Lys 802, as mentioned above, may be the stabilization of the α-phosphate of ATP in the binding pocket, as has been speculated for Lys 72 in protein kinase A (PKA).[121] Lysine 72 anchors the nonlabile phosphate groups of ATP and neutralizes their charges by a salt bridge. Replacement of Lys 72 with Ala in yeast PKA leads to an 800-fold decrease in the V_{max} value.[123] Whereas Lys 72 of PKA and perhaps Lys 802 of PI 3-kinase appear important for enzyme activity, they probably participate in a primarily structural role rather than through direct involvement in catalysis. The protein microenvironment may be responsible for an enhanced nucleophilicity of the targeted lysine; alternatively, the positioning of wortmannin in kinase active sites may preclude productive interactions with catalytic residues. Regardless, the potency of wortmannin should encourage consideration of cofactor binding sites as targets for small-molecule probes. This may expand the menu of proteins amenable to functional proteomic methods like ABPP. Indeed, quite recently, a rhodamine-tagged wortmannin analogue was synthesized and used in proteomic studies to identify mammalian polo-like kinase as an additional target of this natural product.[124] This kinase is an important protein for mitosis that is known to be overexpressed in various human cancers. The wortmannin-based probe successfully detected kinase activity changes due to treatment with drugs and in different stages of the cell cycle. Importantly, these results suggest that wortmannin is a good lead for the development of polo-like kinase inhibitors for cancer therapy.

3.3. Aspirin



In a letter to the Right Honorable George, Earl of Macclesfield and President of the Royal Society, the Reverend Edward Stone wrote on April 25, 1763: "There is a bark of an English tree, which I have found by experience to be a powerful astringent, and very efficacious in curing aguish and intermitting disorders."[125]

Stone was not the first to observe the fever and pain-reducing properties of the extracts of the willow tree. In the year 200 B.C., the Greek physician Hippocrates prescribed willow bark and leaves for pain relief. Willow leaves were described by the Roman Pliny the Elder in his *Natural History*. Today, a modified version of salicylic acid, the active constituent in willow bark, named acetylsalicylic acid or aspirin (Scheme 12),[126] is one of the most widely used remedies in the world.

Scheme 12. Aspirin and salicylic acid, the natural product from which the drug was first synthetically derived.

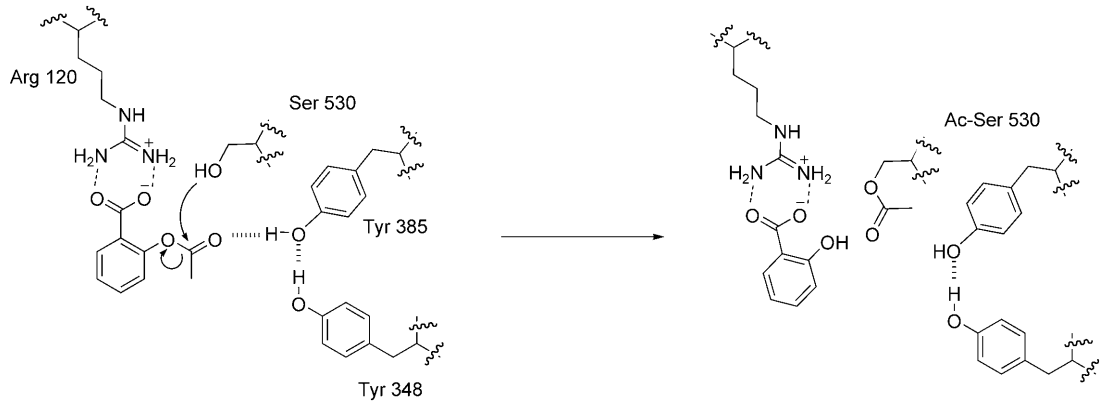
Salicylic acid and structurally related secondary metabolites, the salicylates, are major defensive compounds that are present in nearly all higher plants,[127] and deter the feeding of a variety of herbivores.[127] The biosynthesis of salicylic acid (Scheme 13) may be traced to the phenylpropanoid pathway,[127] which begins with the formation of *trans*-cinnamic acid through the phenylalanine ammonia lyase-catalyzed elimination of ammonia from phenylalanine.[127a] From this point, two pathways are possible, and different plant species may use either or both.[127b] The first involves the removal of a two-carbon unit from cinnamic acid, leading to benzoic acid, followed by *ortho*-hydroxylation to salicylic acid. The second

Scheme 13. Two biosynthetic pathways for salicylic acid in plants.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reverses the order of the two steps, resulting first in *ortho*-coumaric acid. The decarboxylation step is thought to proceed in a fashion similar to the β-oxidation events of fatty acid breakdown.[127] This was supported by studies in which the decarboxylation step in cell-free plant extracts was found to be ATP and CoA-dependent.[128]

In 1860, Hermann Kolbe of Marburg University in Germany carried out a laboratory synthesis of salicylic acid and its sodium salt from phenol, carbon dioxide, and sodium. Kolbe's student, Friedrich von Heyden, established a factory for the bulk production of salicylates in Radebeul, near Dresden. The unpleasant side effect of salicylate, gastric irritation, revealed itself quite rapidly as the drug became widely available. Felix Hoffmann, a chemist at Bayer, ameliorated the problem in 1897 by synthesizing a more easily tolerated derivative, acetylsalicylic acid.[129] Heinrich Dreser, the director of research at Bayer, coined the term "aspirin" from a combination of Spirsäure (salicylic acid) with an initial "a" for acetyl, and a patent was granted in 1899.



For nearly a century, the molecular mechanism of aspirin remained a mystery. However, in 1971, research by Vane indicated that aspirin inhibits prostaglandin biosynthesis.[130] This seminal finding explained both the beneficial properties and side effects of aspirin, and culminated in the awarding of a share of the 1982 Nobel Prize in Physiology or Medicine to Vane.[131] The prostaglandins are paracrine hormones that act on cells proximal to their place of synthesis. A trauma to cells results in an increase in local biosynthesis of prostaglandins, which cause elevated body temperature, inflammation, and pain.[132] Aspirin was found to acetylate and irreversibly inactivate prostaglandin endoperoxide (PGG/H) synthase, also termed cyclooxygenase (COX).[133] In addition, aspirin acetylates human hemoglobin and human serum albumin.[134]

The COX enzyme has two known isoforms, the constitutive COX-1 and the inducible COX-2.[135] COX enzymes catalyze the first two steps in the metabolism of arachidonic acid to prostaglandins. The cyclooxygenase activity incorporates two oxygen atoms into arachidonic acid to produce prostaglandin G_2 (PGG_2). PGG_2 is then subjected to the peroxidase section of these enzymes, which catalyzes a reduction of the hydroperoxy group of PGG_2 to the hydroxy endoperoxide, PGH_2.[133b,136]

It is recognized that aspirin inhibits the cyclooxygenase activity of the COX enzymes, but not their peroxidase activity.[137] Aspirin appears to exert its inhibitory effects by disrupting substrate (arachidonic acid) binding to the cyclooxygenase active site, as the serine residue acetylated by aspirin (Ser530 in COX-1, Ser516 in COX-2) is not critical for catalysis.[133b]

Studies of active-site COX residues have provided insight into the mechanism of COX enzymes, as well as that of aspirin acetylation. The mechanism of acetyl transfer involves several amino acids in the COX active site, including conserved tyrosine and arginine residues (Scheme 14).[138] In 1990, spectral and biochemical studies revealed that Tyr385 is essential for COX-1 cyclooxygenase activity.[139] Structurally, this tyrosine is properly positioned to perform the rate-limiting step of cyclooxygenation: abstraction of the 13-pro-*S* hydrogen atom from arachidonate.[139,140] A Tyr385Phe mutant of COX-2 displays virtually no serine acetylation by aspirin, and a Tyr348Phe mutant displays reduced activity and aspirin acetylation.[141] The latter result confirms the importance of Tyr348, which forms a hydrogen bond to Tyr385 and helps to position the substrate. Arginine 120 of COX-1 is an important residue for both substrate recognition and imparting sensitivity to inhibitors that contain a free carboxylic acid.[142] Analysis of a crystal structure of COX-1 suggests that the guanidino moiety interacts with the arachidonate carboxylate group.[143] Furthermore, reversible inhibitors with a free carboxylic acid, such as flurbiprofen, were ineffective against COX-1 enzymes with a mutation at Arg120.[142,143] The corresponding COX-2 Arg-to-Gln mutant was later found to have a 73% reduction of acetylation of Ser516 in COX-2.[141]

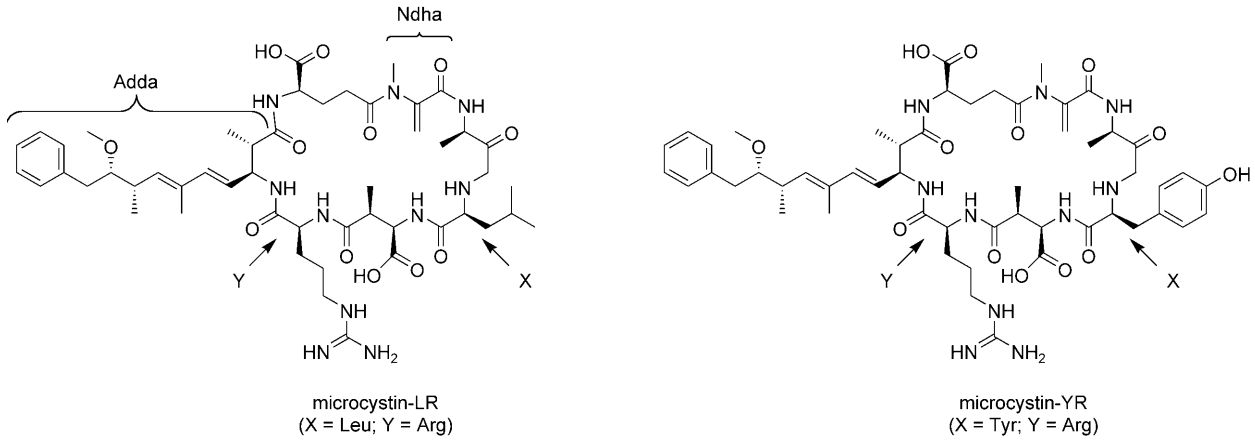
Based on the above experimental data, researchers have described a best possible mechanism for serine acetylation by aspirin (Scheme 14). The amino acid numbering scheme presented in the following paragraph corresponds to COX-1. Initial interaction of the carboxylate group of aspirin with Arg120 stabilizes its location in the substrate-binding pocket. The hydroxy groups of Tyr385 and Tyr348 then act as an extended hydrogen-bonding network. This directs the acetyl group of aspirin toward Ser530, and increases the reactivity of aspirin by stabilizing the developing negative charge of the

Scheme 14. An intricate network of hydrogen bonds and other interactions position aspirin to acetylate Ser530 of cyclooxygenase-1.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tetrahedral addition intermediate. The possibility of transient tyrosine acetylation was excluded by testing the acetylation of a Ser530Ala mutant, for which no *O*-acetyltyrosine was detected.[141] These data are all corroborated by the X-ray crystal structure of COX-1 inactivated by bromoaspirin (bromoacetylsalicylic acid). Bromoaspirin was used so that its location could be identified definitively in a relatively low-resolution (3.4 Å) crystal structure from the presence of the heavy bromine atom. The phenolic oxygen atom of Tyr385 is within hydrogen-bonding distance to the acetyl group.[144]

In summary, an elaborate scheme of hydrogen bonding and ionic interactions serves to position aspirin in the COX active site, increasing its effective concentration and enhancing its reactivity, which leads to the selective acetylation of Ser530. The X-ray structure also lends insight into the inhibitory effect of aspirin acetylation. Ser530 lies in a highly conserved region[133b] along a hydrophobic channel that leads from the surface of the enzyme to the catalytic tyrosine. The aspirin acetyl group extends outward into the channel, perhaps in a manner sufficient to prevent arachidonic acid from reaching the active site.[133b,144]



Finally, it is important to note that salicylic acid also possesses anti-inflammatory effects, but does not itself covalently modify COX enzymes. Discussion concerning the precise mechanism of action of salicylate is ongoing.[145] Thus, the conversion of this natural product to its semisynthetic derivative aspirin had the fortuitous effects of conferring mechanistic irreversibility and anointing principal protein targets for therapeutic intervention.

3.4. Microcystin

Cyanobacteria in the blue-green algae blooms of contaminated drinking water have been the cause of many animal deaths. Beginning in 1878,[146] it became evident that blooms of the genera *Oscillatoria*, *Anabaena*, *Nostoc*, and *Microcystis* in freshwater and marine environments were to blame for related incidents of acute toxicity.[147] The active components, a family of potent hepatotoxins, were isolated and a vigorous research effort initiated toward determining their structure.[148] Although the peptidic nature of the toxins was confirmed in 1959,[149] their amino acid compositions were not determined until many years later.[150] The first complete structure was determined by NMR spectroscopy and MS in 1984,[151] and was soon followed by characterization of other family members.[152] The toxins are cyclic heptapeptides with variable L-amino acid residues at two positions labeled X and Y. They contain an Adda residue, an unusual aromatic β-amino acid featuring an unsaturated alkyl chain (Scheme 15). An unambiguous determination of the configuration of Adda was published in 1988, confirming the structure as (2*S*,3*S*,8*S*,9*S*)-3-amino-9-methoxy-2,6,8-trimethyl-10-phenyl-(4*E*,6*E*)-decadienoic acid.[153] Various names were present in the literature for Adda-containing cyclic peptide natural products, but ultimately the name microcystin was chosen (Scheme 15).[154]

The microcystin family comprises more than sixty members;[155] the vast majority differ in the nature of two variable amino acids, or in the methylation states of the dehydroalanine and/or aspartic acid groups. In naming new microcystins, two letters are appended to abbreviate amino acids at the variable positions. Biosynthetic studies on microcystins were particularly focused on the identification of the origin of the carbon atoms in the Adda unit and the methylaspartic acid residue. Methylaspartic acid originates from acetyl-CoA and pyruvic acid via a methylsuccinic acid intermediate, and the Adda unit derives from acetate; certain methyl groups are methionine-derived.[156] Typically, microcystins are biosynthesized non-ribosomally.[157] Analyses of microcystin synthetase genes have yielded genes for polyketide synthases.[158]

Researchers also sought to understand the molecular nature of the toxicity of microcystins, and not long after the structures of these natural products were revealed, it was determined that they are potent inhibitors of serine/threonine phosphatases 1 and 2A,[7,147b,159] and other less-thoroughly characterized phosphatase family members.[160] Reversible protein phosphorylation is a critical mechanism for the regulation of cellular processes.[161] More than 98% of protein phosphorylation in eukaryotic cells occurs on serine and threonine residues.[160] Serine/threonine phosphatases 1 and 2A (PP1 and PP2A) have been implicated in the regulation of

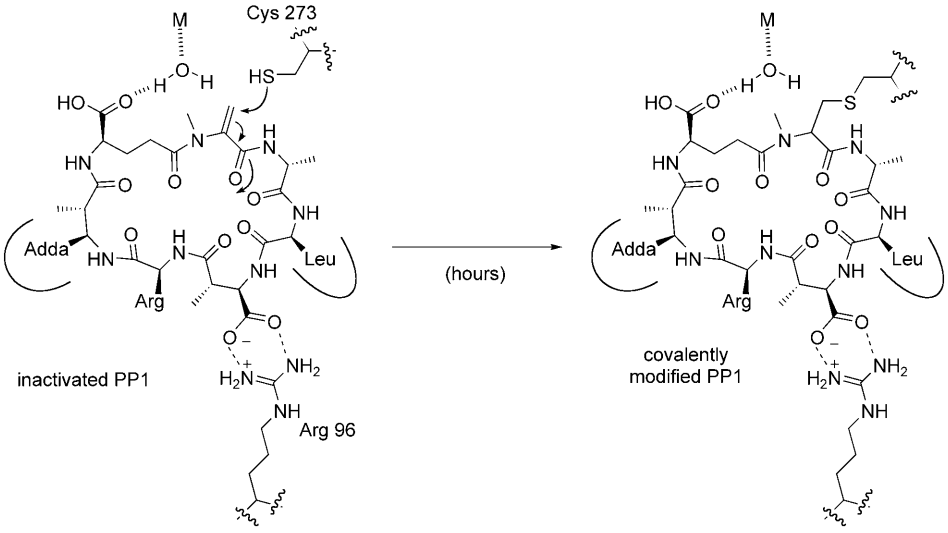
such diverse events as glycogen metabolism, synaptic plasticity, cell-cycle progression, embryogenesis, apoptosis and smooth-muscle contraction.[162] The structures, activities, and inhibition properties of PP1 and PP2A have been reviewed extensively.[163] Significantly, these enzymes do not possess a catalytic nucleophile; instead, they activate a water molecule for catalysis with protein-bound metal ion cofactors.[163]



Indiscriminate inhibition of the many essential functions performed by PP1 and PP2A may contribute to the severe toxicity of the microcystins; between one and two micrograms constitutes a lethal intraperitoneal dose in mice.[147b] Although the broad toxicity of microcystins undermines their potential as therapeutic agents, research groups have synthesized variants and truncated versions of the toxin family to better understand the properties that confer toxicity and specificity.[164] So far, only one total synthesis of a microcystin family member has been completed.[165] These natural products have facilitated the functional characterization of phosphatases and phosphatase–protein complexes in proteomes.[159b,166] A microcystin-LR–rhodamine conjugate reacted with and detected numerous serine/threonine phosphatases in a crude cell lysate sample, and could record changes in phosphatase activity levels.[166] These probes expanded the list of enzyme families amenable to functional proteomic analysis.

Several bioactive natural products, such as leptomycin B,[167] isoavenaciolide,[168] and pironetin[169] have been shown to act as carbon-based electrophiles, similar to the α,β-unsaturated carbonyl element of the methyl-dehydroalanine residue of microcystin. In 1995, two research groups simultaneously published work confirming the conjugate addition chemistry of the dehydroalanine moiety of microcystin with PP1 at Cys 273 near the enzyme C terminus.[7,159a] In PP2A, the analogous Cys 266 is the targeted residue.[159a] The amino acid sequence Ser-Ala-Pro-Asn-Tyr-Cys, which includes the cysteine residue modified by microcystin, is highly conserved in Ser/Thr phosphatases.[7] The covalent linkage between the various microcystins and PP1 is stable to heat and acid. However, covalent binding of microcystin-YR to phosphatases was not observed when the proteins were denatured with sodium dodecyl sulfate prior to the addition of the natural product, indicating that the interaction depends on an intact active site.[7]

Microcystins bind to PP1 with subnanomolar affinity;[170] in the crystal structure of microcystin-LR bound to PP1, the Adda side chain makes contacts with a conserved hydrophobic groove, and the carboxyl group of glutamate and the adjacent carbonyl oxygen atom coordinate the metal-binding site indirectly through water molecules.[171] The leucine side chain of the toxin is situated in a loop of the C-terminal domain; in addition, the carboxyl group of methylaspartate hydrogen bonds to Arg 96, a residue crucial for interactions with phosphate groups on substrates. Hence, access to the active site is completely blocked.

The extensive interactions between microcystins and phosphatase active sites suggest that covalent reactivity contributes only partly to the mode of action of these natural products. Microcystins immobilized to a Sepharose bead through an aminoethanethiol adduct retained inhibitory activity over PP1 and PP2A.[159b] Microcystins-LR, YR, and RR were converted synthetically to their glutathione and cysteine conjugates; both of these thiols reacted with the dehydroalanine group, yet the 1,4-addition products retained a measure of in vivo toxicity ($LD_{50} = 38\ \mu g\,kg^{-1}$ for microcystin-LR; $LD_{50} = 630\ \mu g\,kg^{-1}$ for its glutathione conjugate).[171] Notably, such adducts may not be resistant toward retro-Michael reaction in vivo, and reversible adduct formation may explain the observed biological activity.[172] These results imply that the dehydroalanine residue probably does not play a role in early enzyme–inhibitor interactions.

Mechanistic studies by Craig and co-workers confirmed a two-step mechanism for irreversible inhibition by microcystins (Scheme 16).[173] In the first step, the rapid noncovalent binding and inhibition occurs with all the contacts detailed above. The slower covalent modification of Cys 273 occurs over the course of hours.[173] The tendency for the conjugate addition reaction is likely enhanced by the high

Scheme 16. Microcystin inactivates PP1 prior to the slow covalent attachment to Cys 273. However, the network of noncovalent interactions is essential for a successful conjugate addition.

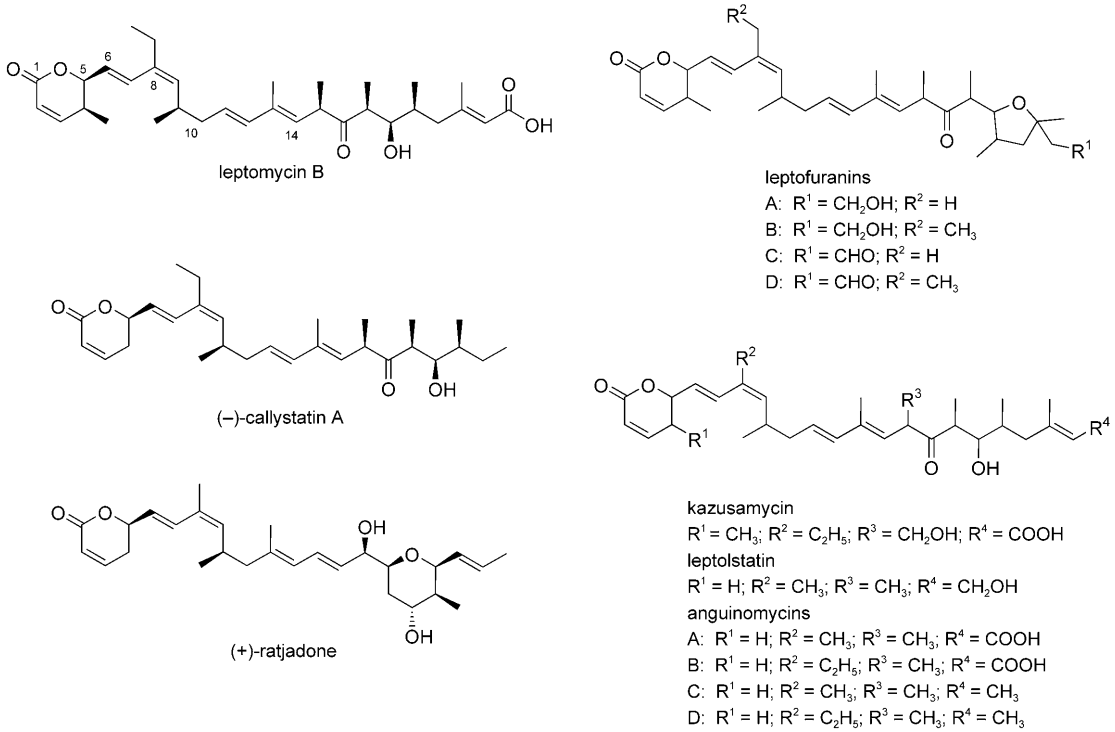
effective concentration of microcystin in the well-folded binding pocket, as evidenced by the control reaction with denatured protein discussed above. It is also not out of the question that the nucleophilicity of the target cysteine may be enhanced in its local protein environment. Regardless, it is important to note that mutagenesis studies have found that Cys 273 is not required for catalysis; in fact, the activity of a Cys 273 Ser mutant is indistinguishable from that of the wild-type enzyme.[174] Thus, microcystins provide a salient example of how an intricate architecture of noncovalent interactions with enzymes can facilitate covalent modification on non-catalytic active-site residues. Notably, similar strategies have been employed to convert tight-binding reversible inhibitors into covalent inactivators of the EGF receptor[175a–c] and p90 ribosomal protein S6 kinase[175d] by the introduction of electrophilic groups in proximity to cysteine residues in the active sites of these proteins.

4. Targeting Nonenzymatic Proteins

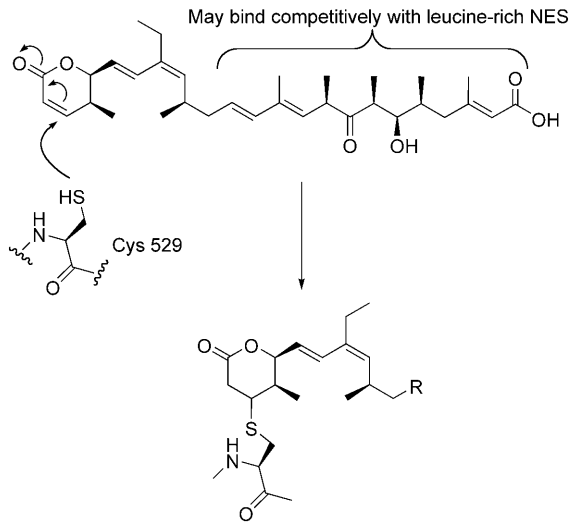


Although most protein-reactive natural products target the active sites of enzymes, there are exceptions. Here, we highlight one such natural product, leptomycin B, which covalently modifies a receptor protein involved in nuclear transport.

4.1. Leptomycin B

A *Streptomyces* strain isolated from soil samples yielded two novel antifungal antibiotics. The active components were purified, isolated, and termed leptomycins A and B.[176] These compounds constitute part of a family of structurally similar natural products, including callystatin A, ratjadone, kazusamycin, anguinomycin, leptofuranin and leptolstatin (Scheme 17).[177] Structures of the leptomycins were determined by NMR spectroscopy, MS, and IR spectroscopy.[178] They feature an unsaturated fatty acid with a terminal δ-lactone ring. Leptomycin B has a polyketide origin; it may be traced back to four acetate units, seven propionate units, and one butyrate unit.[179] Leptomycin B interferes with DNA synthesis stages of the cell cycle,[180] presumably a result of its inhibitory effect on nuclear transport.[181] A nanomolar binding partner for leptomycin B was discovered and named chromosome maintenance region 1 (CRM1).[182] CRM1, also known as exportin 1, is an evolutionarily conserved receptor for the leucine-rich nuclear export signal (NES)[183] of proteins and is an essential mediator of NES-dependent nuclear export of proteins and ribonucleoprotein complexes in eukaryotic cells.[182,184]

In conjunction with CRM1, the protein Rev allows partially processed HIV mRNAs to be transported outside the nucleus for translation, enabling the HIV virus to hijack the cellular protein synthesis machinery.[182,185] Agents like leptomycin B that block the interaction of Rev with nuclear transport proteins have the potential to inhibit HIV-1 replication.[186] Leptomycin B has also been used to accumulate the tumor suppressor p53 in the nucleus.[187] This subcellular localization leads to p53 activation, cell-cycle arrest, and apoptosis. Hence, leptomycin could represent a novel therapeutic approach for HIV and cancer treatment.[187,188]



Leptomycin B binds to CRM1 and covalently modifies Cys 529 in a central conserved region of the protein, which inhibits recognition of the NES; ratjadone was recently found

Scheme 17. The leptomycin family of natural products.

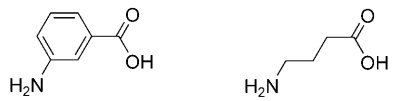
to share this mechanism (Scheme 18).[167,181,186a,189] Researchers found that a single mutation, Cys529Ser, in *Schizosaccharomyces pombe* was sufficient to greatly reduce sensitivity to leptomycin B.[167,190] To determine which portion of the

Scheme 18. The α,β-unsaturated lactone of leptomycin reacts by conjugate addition with Cys529 of exportin.

natural product serves as the pharmacophore, Kobayashi and colleagues performed extensive studies on a series of analogues of callystatin. The α,β-unsaturated lactone was found to be the crucial reactive element.[191] Other research groups reduced the lactone moiety to a saturated analogue[192] or formed a Michael adduct with nitromethane;[185a] both of these events greatly decreased inhibition.[192] Furthermore, *N*-acetylcysteine methyl ester and leptomycin B reacted to give a stable 1,4-addition product, as determined by NMR spectroscopy.[167] All these results lend credence to the idea that leptomycin binds covalently through an attack on its electrophilic α,β-unsaturated lactone function by the thiol group of CRM1 Cys529 (Scheme 18).



The role of Cys529 in CRM1 is not yet clear. This residue does not seem to be necessary for CRM1 to function. The Cys529Ser mutant mediates nuclear export just as effectively as wild-type CRM1, and it is not temperature-sensitive.[167] Moreover, wild-type *Saccharomyces cerevisiae* CRM1 has a threonine in place of cysteine at the analogous position.[167]

It is difficult to speculate further about the nature of the CRM1–leptomycin B interaction, as a structure of the complex has yet to be determined.[188,193] This information is crucial to the development of new drug candidates for the inhibition of nuclear translocation. Leptomycin B itself has a high toxicity profile, as demonstrated in a phase I clinical trial, and was not recommended for further development.[194] Several syntheses of leptomycin B and its relatives have been carried out in an effort to understand the function of this family of compounds.[191a,195] The premise that some of these reagents might selectively shut down transport of specific mRNA molecules is enticing and warrants further research.

In summary, CRM1 is a particularly notable target for a protein-reactive natural product, because this protein is not an enzyme. Despite this, leptomycin B labels Cys529 with exquisite specificity, suggesting that this residue resides in a structured small-molecule binding site. One intriguing possibility is that the central conserved region of CRM1 contains a hydrophobic pocket that is capable of interacting with both leucine-rich NESs and the distinct architecture of leptomycin B in a manner similar to enzyme active sites that bind substrates and inhibitors that often share little structural homology.[167]

5. Summary and Outlook

In this review, we have attempted to highlight the diversity of mechanisms by which natural products engage and covalently modify proteins and protein active sites. The specific compounds discussed are meant to serve as representatives of the different classes of protein-reactive natural products discovered so far, rather than as a comprehensive list. Notably, the reactivity of these natural products is not restricted to a specific type of amino acid, but rather can occur on a range of active-site residues, including serine (lipstatin, aspirin), threonine (lactacystin), lysine (wortmannin), cysteine (E-64, microcystin), and histidine (fumagillin). Moreover, these residues do not need to serve a catalytic function in the target enzyme class (for example, Cys273 in PP1) or, for that matter, to be part of an enzyme active site (as is the case for Cys529 in CRM1). This underscores the creative ability of nature to exploit "spurious" nucleophiles in small-molecule binding sites for the selective modification of proteins. Although all the natural products discussed herein inactivate their cognate protein targets by modifying amino acid residues, other mechanisms of enzyme inhibition are possible. For example, gabaculine (Scheme 19), a rare amino acid

Scheme 19. The natural product gabaculine is a conformationally constrained GABA analogue. GABA = γ-aminobutyric acid.

isolated from the mold *Streptomyces toyocaensis*,[196] inactivates several related aminotransferases by covalently reacting with the enzyme's pyridoxal phosphate cofactor (Table 1).[8c,197]

What lessons might be learned from protein-reactive natural products that could assist in the design of chemical probes for the burgeoning field of activity-based protein profiling (ABPP)?[9] ABPP is a functional proteomic method that aims to develop active-site-directed probes that label many enzymes in parallel, thereby facilitating their collective functional characterization in samples of high biological complexity. The application of ABPP methods has so far enabled the discovery of enzyme activities that are upregulated in diseases like cancer,[69,198] obesity,[199] and malaria;[200] it has also enabled the design of selective inhibitors for these enzymes.[201]

Table 1: Representative protein-reactive natural products and their targets.

Natural product	Target	Labeled residue	Catalytic nucleophile?
lipstatin	pancreatic lipase	Ser 152	yes
lactacystin	proteasome β subunits	Thr 1	yes
E-64	papain (Cys proteases)	Cys 25	yes
fumagillin	MetAP-2	His -231	no
wortmannin	PI 3-kinase	Lys 802	no
aspirin	COX-1	Ser 530	no
	COX-2	Ser 516	no
microcystin	PP1	Cys 273	no
	PP2A	Cys 266	no
leptomycin B	CRM1	Cys 529	no
gabaculine	aminotransferases	PLP cofactor[a]	no

[a] PLP = pyridoxal phosphate.

The profound influence of protein-reactive natural products on the maturation of ABPP can be discerned at several levels. First, and perhaps most clear, many ABPP probes are themselves derivatives of natural products, including biotin/fluorophore-tagged reagents that target cysteine proteases (based on E-64),[68a,b,201b] phosphatases (based on microcystin),[166] and kinases (based on wortmannin).[124] A second class of ABPP probes also borrows a strategy of natural products by modifying conserved catalytic nucleophiles in enzyme active sites. These probes, which include fluorophosphonate and electrophilic ketone reagents for serine[202] and cysteine[203] hydrolases, respectively, typically exhibit a broad target spectrum within a given family of enzymes. Even ABPP probes that incorporate photoreactive (rather than electrophilic) groups could be considered as followers of the precedents set by natural products, as they too exploit class-selective functional groups to bind conserved elements of enzyme active sites.[204] Finally, the principles derived from protein-reactive natural products have also inspired the emergence of a third approach for ABPP that explores the proteome reactivity of structurally diverse libraries of electrophilic agents.[199,205] In this combinatorial, or "nondirected" approach for ABPP, probe libraries have been designed to contain carbon electrophiles, based in large part on the rich diversity of natural products that have exploited this versatile reactive group, to label enzyme active sites (for example, fumagillin, wortmannin, and microcystin). To date, nondirected ABPP efforts have identified active-site proteomics probes for more than 10 mechanistically distinct enzyme classes.[9,199] Remarkably, most of these enzymes lack cognate affinity agents, underscoring the value of nondirected ABPP for the discovery of novel molecular probes of enzyme function.

Looking forward, we anticipate that our understanding of the full spectrum of mechanisms employed by natural products to target protein active sites is still far from complete. Given the central role that natural products have played in the elucidation of the biochemical and cell-biological activities of proteins, we strongly advocate the sustained pursuit of these special pharmacological agents. Their discovery and characterization should continue to offer fascinating insight into the seemingly endless array of small-molecule–protein interactions that occur in nature. The lessons learned from these studies should in turn guide chemical biologists in their efforts to achieve a paramount objective of post-genomic science—the design of selective small-molecule probes for the functional analysis of every protein.

We thank K. Barglow and Dr. E. C. Taylor for critical reading of this manuscript, and Dr. M. H. Bracey for assistance with the generation of figures. This research was supported by the NIH (CA087660), NIGMS (GM065483), a Bristol Myers-Squibb Unrestricted Grant in Synthetic Organic Chemistry, the Skaggs Institute for Chemical Biology, and Princeton University. C.D. gratefully acknowledges predoctoral fellowships from Eli Lilly and the National Science Foundation.

Cationic coordination polymers adopt two distinct conformations in response to the nature of the anions bound. Therefore, a simple exchange of anion type results in a reversible change in the bulk properties of the solution, from liquid to gel and back. M. Lee and co-workers describe the characterization of these polymers in their Communication on the following pages.

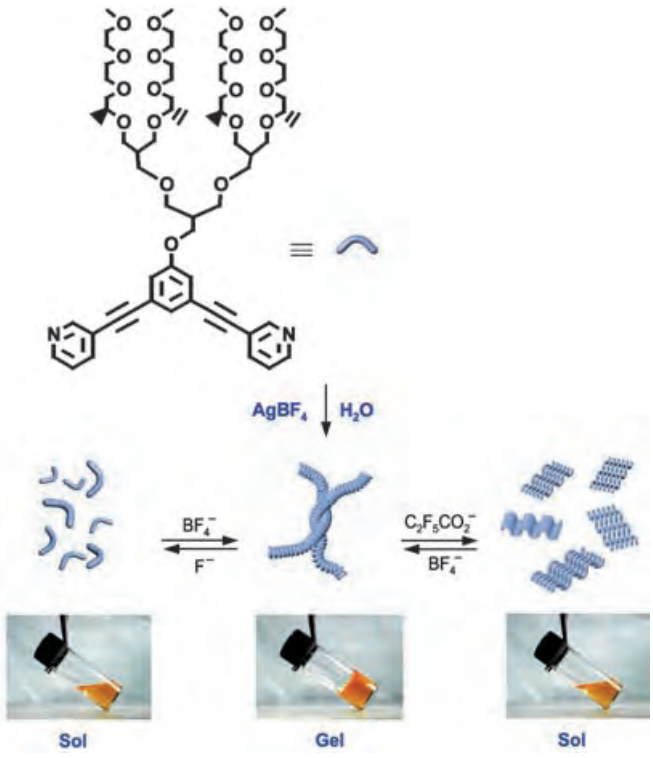
Stimuli-Responsive Gels from Reversible Coordination Polymers**

*Ho-Joong Kim, Jung-Hoon Lee, and Myongsoo Lee**

The design of supramolecular helices that mimic the macromolecular organization observed in biological systems is a topic of great interest.[1] Therefore, considerable effort has been made to introduce helicity into artificial systems.[2] The most widely used strategy for generating supramolecular helices requires a noncovalent motif, which can provide the desired connectivity of the building blocks in a predictable manner.[3] For example, relatively strong directional interactions, such as complexation between bent ligands and transition-metal atoms that adopt a linear coordination geometry can give rise to extended polymeric chains with a helical secondary structure.[4,5] Especially for conformationally flexible ligands, one can envisage the formation of linear coordination chains that can adopt folded or unfolded secondary structures as a function of counteranion binding to cationic polymeric backbones through electrostatic interactions.[6,7] Indeed, a folded helical conformation has been reported to transform directly into an unfolded state in response to external stimuli.[8] These observations led us to investigate whether the secondary structure of cationic coordination chains can interconvert in aqueous solution from a folded helical conformation into an unfolded zigzag conformation in response to a counteranion guest to exhibit a reversible sol–gel transition.[9]

Herein, we report reversible sol–gel interconversion of coordination polymers in aqueous media, from folded helical chains into an unfolded zigzag conformation with counteranion exchange; the process is driven by depolymerization or conformational change (Figure 1). The synthesis of the bent ligands (**1**–**3**) containing hydrophilic dendritic side groups was performed stepwise according to previously reported methods.[10,11] The resulting pyridine ligands were complexed with silver tetrafluoroborate to afford the coordination chains, [Ag-***n***]BF_4, in which ***n*** is one of the ligands, **1**–**3**. All of the analytical data are in full agreement with the chemical structures presented. In the solid state, all of the coordination polymers self-assembled into a hexagonal columnar structure (see Supporting Information), which suggests that the size of the BF_4^- ion is compatible with the internal cavity of the helical columns.

In contrast to [Ag-**1**]BF_4, which precipitates in water, [Ag-**2**]BF_4 and [Ag-**3**]BF_4 form dilute aqueous solutions that undergo spontaneous gelation at concentrations above



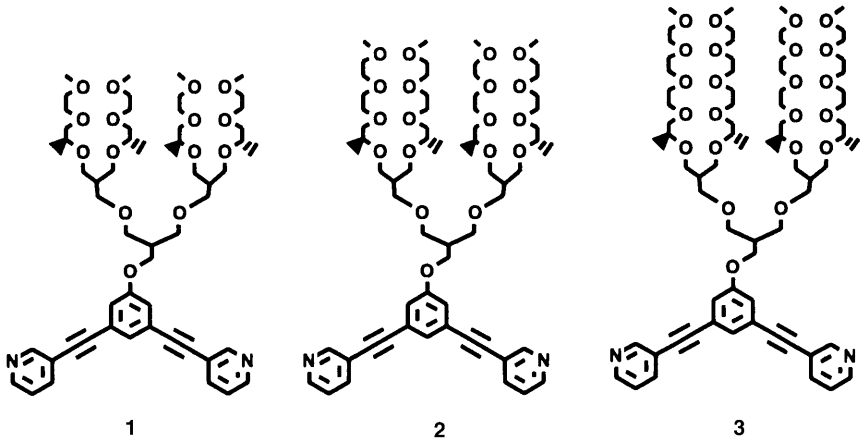


Figure 1. Schematic representation of reversible polymerization and reversible conversion between folded and unfolded conformations of a coordination chain upon counteranion exchange.

2.5 wt%. Upon addition of 1.2 equivalents of tetra-*n*-butylammonium fluoride $Bu_4N^+F^-$ to the gels, which drives the coordination polymers to depolymerize through a strong electrostatic interaction between the Ag^+ and F^- ions, the gels rapidly become a fluid solution. After the addition of 1.2 equivalents of F^- ions, the signals corresponding to aromatic protons in the ^{1}H NMR spectrum of [Ag-**2**]BF_4 show an upfield shift relative to those of the coordination polymer solution (1 wt% in CD_3OD), which indicates that the addition of F^- ions leads to decomplexation of the coordination polymer to give free ligands (Figure 2a). Upon addition of 1.2 equivalents of $Bu_4N^+BF_4^-$, the solution returns to the gel state; thus the polymerization is reversible.

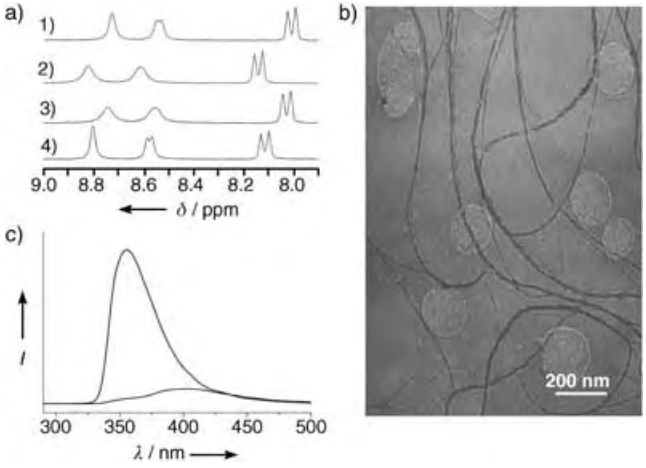

Figure 2. a) ^{1}H NMR spectra (250 MHz, 298 K) in CD_3OD (1 wt%) of 1) **2**; 2) [Ag-**2**]BF_4; 3) [Ag-**2**]BF_4 and 1.2 equiv $Bu_4N^+F^-$; 4) same as (3) after the addition of 1.2 equiv $Bu_4N^+BF_4^-$. b) TEM image of dried gel from [Ag-**2**]BF_4 in H_2O (0.3 wt%) stained with RuO_4. c) Fluorescence spectra of **2** and gel of [Ag-**2**]BF_4 (5 wt% in H_2O; λ_{ex} = 275 nm).

TEM analysis of the gels revealed right-handed helical bundles of elongated fibers with diameters of 6–30 nm, which in turn form an entangled fibrillar network (Figure 2b). The gels reveal a significant Cotton effect in the chromophore of the aromatic unit, which supports the presence of elongated helical aggregates in aqueous solution.[12,13] These results demonstrate that the complexes self-assemble into a helical secondary structure that forms a coiled-coil superstructure, and the fibrous aggregates entangle to form gels. This aggregation of the coordination chains is further supported by fluorescence measurements, which showed a strong red-shift of the emission maximum[14] and a significant decrease in the emission intensity of the gel state relative to that of the ligand (Figure 2c).[15] The formation of the helical secondary structure in aqueous solution can be rationalized by considering supramolecular polymerization through coordination bonding and subsequent binding of counteranions through the *cis*-like conformation of the monomeric units. Molecular models indicate that the size of the BF_4^- ion is compatible with the internal cavity formed by the *cis*-like conformation of the ligands. To maximize electrostatic interactions of the cationic chains with the counteranions, the coordination chains adopt a folded helical conformation, which is responsible for the formation of the entangled fibrillar network.

More importantly, the gels reversibly transform into a fluid solution with counteranion exchange of BF_4^- with a larger ion, $C_2F_5CO_2^-$. Upon addition of 1 equivalent of $Bu_4N^+C_2F_5CO_2^-$ to the [Ag-**2**]BF_4 gel, it transforms rapidly into a fluid solution (Figure 1).[16] CD spectra of the [Ag-**2**]BF_4/$C_2F_5CO_2$ solution shows no Cotton effect (Figure 3a), thus demonstrating the absence of helical aggregation in this condition. The fluorescence spectrum of the gel of [Ag-**2**]BF_4 exhibits an emission maximum at 400 nm, which is indicative of a helical aggregation as described above. However, upon addition of up to 0.8 equivalent of $C_2F_5CO_2^-$ ions, the emission maximum gradually red-shifts (20 nm) with respect

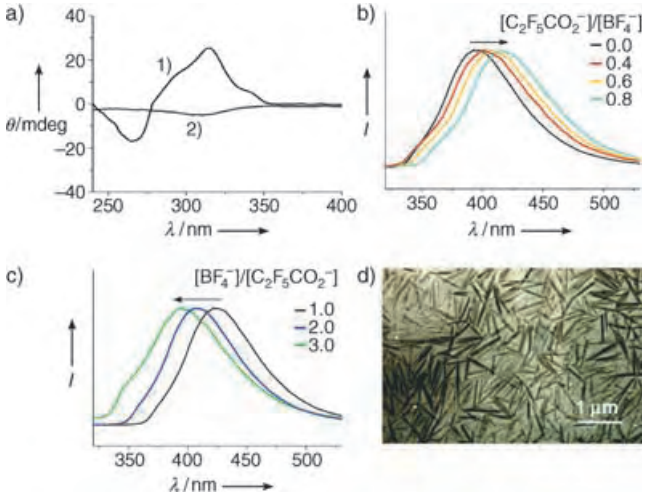

Figure 3. a) Circular dichroism (CD) spectra of: 1) [Ag-**2**]BF_4 (5 wt%); 2) [Ag-**2**]BF_4 (5 wt%) after the addition of 1 equiv $Bu_4N^+C_2F_5CO_2^-$. b) Fluorescence spectra of [Ag-**2**]BF_4 (5 wt%) with increasing amounts of $Bu_4N^+C_2F_5CO_2^-$. c) Fluorescence spectra of a mixture of [Ag-**2**]BF_4 (5 wt%) and $Bu_4N^+C_2F_5CO_2^-$ (1:1) with increasing amounts of $Bu_4N^+BF_4^-$. d) TEM image of [Ag-**2**]$C_2F_5CO_2$ in H_2O (0.3 wt%) stained with RuO_4.

to that observed in the gel state (Figure 3b), thus demonstrating that the chain conformation transforms into a *trans*-like state.[10] It should be noted that the addition of more $C_2F_5CO_2^-$ ions (up to 2 equivalents) did not further change the spectrum. This process was reversed by the addition of BF_4^- ions to give a gel (Figure 3c). Remarkably, TEM images indicate that there is a dramatic change in morphology on replacing BF_4^- with $C_2F_5CO_2^-$ ions. In contrast to that of the gel of [Ag-**2**]BF_4, the TEM image of the homologous complex, [Ag-**2**]$C_2F_5CO_2$, shows discrete ribbonlike aggregates with lengths of 0.7–1.3 μm and widths of 20–40 nm (Figure 3d), which indicates that the size of counteranion has a profound effect on the nanoscale structure and macroscopic properties of the complex. In light of the *trans*-like conformation of the coordination chains as confirmed by fluorescence spectroscopy, we consider these ribbonlike aggregates to be based on a discrete layered structure in which the coordination chains adopt an unfolded zigzag conformation. An inspection of the molecular models indi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cates that the $C_2F_5CO_2^-$ ion is too large for the cavity formed by the *cis*-like conformation of the polymer chains and thus the chain conformation is likely to adopt an unfolded *trans*-like state for efficient binding of the larger counteranion while maintaining close packing of the rigid segments.

We performed ^{19}F NMR spectroscopic experiments to further investigate the role of added $C_2F_5CO_2^-$ ions in the structural change. The ^{19}F NMR spectrum of a D_2O gel of complex [Ag-**2**]BF_4 shows a resonance at $\delta = -151.85$ ppm along with a resonance from a minor isotope at $\delta = -151.80$ ppm, which is downfield with respect to those of free BF_4^- ion (Figure 4). This result suggests that BF_4^- ions

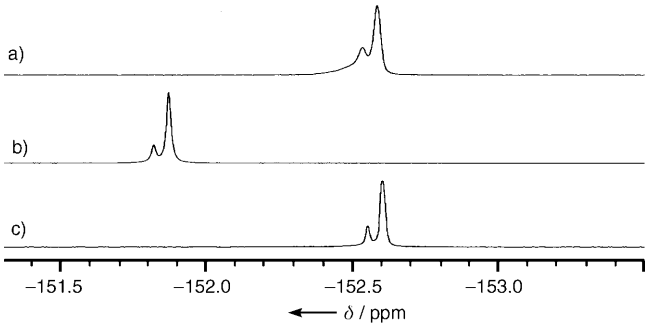

Figure 4. Comparison of ^{19}F NMR spectra in D_2O (470 MHz, 298 K): a) free $AgBF_4$; b) [Ag-**2**]BF_4 (5 wt%); c) [Ag-**2**]BF_4 (5 wt%) after the addition of 1 equiv of $Bu_4N^+C_2F_5CO_2^-$. The chemical shifts were measured as upfield shifts relative to that of $CFCl_3$ as an external standard.

are entrapped within the helical chains.[17] The downfield shift observed for the entrapped anions is due to their coordination to Ag^+ ions. Upon addition of 1 equivalent of $Bu_4N^+C_2F_5CO_2^-$ to the gel of [Ag-**2**]BF_4, however, the signal at $\delta = -151.85$ ppm shifts to -152.60 and the signal from the minor isotope, $\delta = -151.80$ ppm, shifts to -152.55 ppm. These shifts indicate the release of entrapped BF_4^- ions through the modification of the helical conformation. Together with fluorescence spectra, these results demonstrate that this anion exchange triggers release of the entrapped BF_4^- ions with concomitant transformation of the folded helical structure into an unfolded zigzag conformation. Consequently, this conformational change of the coordination chains gives rise to a significant structural change from elongated fibers into discrete ribbonlike aggregates thereby sol–gel interconversion. Therefore, the helical conformation of the coordination chain is most probably the principal driving force for the gelation of the complexes in water.

The results described herein demonstrate that the reversible coordination polymers self-assemble into a helical structure which, in turn, forms an entangled fibrillar network thereby immobilizing the solvent. Remarkably, the aqueous gels were observed to transform rapidly into fluid solutions with counteranion exchange of BF_4^- with F^- or $C_2F_5CO_2^-$, which can be used to trigger reversible sol–gel phase transition. This sol–gel interconversion in response to external stimuli is attributed to depolymerization or transformation of the folded helical conformation into an unfolded zigzag conformation of the coordination chains; there is subsequent structural change from elongated fibers to discrete ribbons with counteranion exchange. These results are a significant example of changing the size of an entrapped guest in a self-assembling system providing a useful strategy to create stimuli-responsive smart nanoscale materials with functions that can be produced at any time on demand.

Porous Lanthanide–Organic Open Frameworks with Helical Tubes Constructed from Interweaving Triple-Helical and Double-Helical Chains**

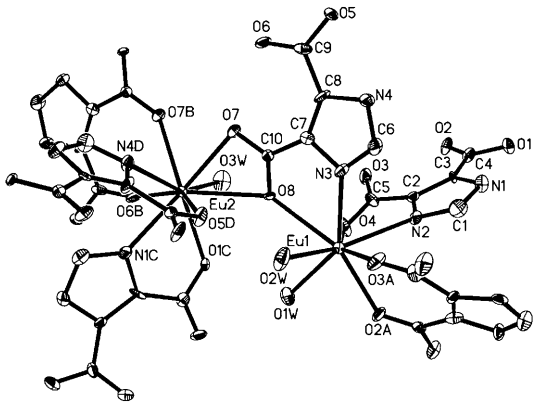
*Yan-Qiong Sun, Jie Zhang, Yong-Mei Chen, and Guo-Yu Yang**

In recent years, the construction of metal-organic coordination polymers has attracted considerable attention in supramolecular and materials chemistry due to the formation of fascinating structures and potential applications as optoelectronic, magnetic, and porous materials.[1] However, most of the work has so far focused on the assembly of the d-block metal-organic open frameworks,[2] while the analogous chemistry of the lanthanides remains less developed.[3] This is attributed to the tendency of the lanthanide ions for high coordination, which favors the formation of condensed structures with[4] or without guest species.[3b,5] To date, no systematic investigation on lanthanide-based porous materials with luminescent properties has been documented.[6] In addition, lanthanide-organic frameworks with channels from which the guest species can be removed and reintroduced reversibly without collapse of the framework are rare.[7]

Among the reported network lanthanide carboxylates, 4,5-imidazoledicarboxylic acid (H_3ImDC), which remains largely unexplored,[8] was chosen as the multidentate ligand for the following reasons: 1) The flexible, multifunctional coordination sites provide a high likelihood for generation of structures with high dimensions. 2) It can be deprotonated to generate H_2ImDC^-, $HImDC^{2-}$, and $ImDC^{3-}$, which allow various, acidity-dependent coordination modes. 3) The skew coordination orientation of the carboxy groups is favorable for constructing a helical structure.

Accordingly, our aim was to synthesize novel lanthanide-organic open frameworks by using the H_3ImDC ligand. Here we report the syntheses, structures, and luminescent and magnetic properties of two novel lanthanide-organic coordination polymers of $[Ln_2(ImDC)_2(H_2O)_3]\cdot 1.625\,H_2O$ (Ln = Eu (**1**) and Dy (**2**)). The structures of **1** and **2** not only display one-dimensional achiral channels, but also contain alternately arranged left- and right-handed helical tubular channels.

White prism crystals of **1** and **2** were obtained by the hydrothermal reaction of Ln_2O_3 and H_3ImDC in water in the presence of HNO_3 at pH 2 and 170 °C. The X-ray crystal structure analyses reveal that **1** and **2** are isostructural and crystallize in the high symmetry tetragonal space group $I4_1/a$.[9] Therefore, only the structure of **1** is described in detail. In the asymmetrical unit of **1**, there are two crystallographically independent Eu^{3+} ions and two unique ImDC ligands with two different coordination modes (Figure 1 and see the Supporting Information). The Eu1 ion (mode **I**, Scheme 1) is eight-coordinate and is described as a dodecahedron (see the Supporting Information): Two imidazole nitrogen (N_{Im}) and four carboxylate oxygen (O_{COO^-}) atoms from three ImDC moieties as well as two terminal water molecules. The coordination geometry for the nine-coordinate Eu2 ion (mode **II** in Scheme 1) is close to that of a tricapped trigonal prism (see the Supporting Information): six O_{COO^-} and two



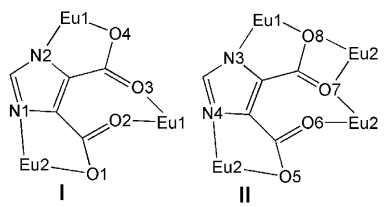


Figure 1. The coordination environments of Eu1 and Eu2 atoms in **1**. Atoms with "A" or "B" in their labels are symmetry-generated.

Scheme 1. Coordination modes of the ImDC ligands in **1**.

N_{Im} atoms from four ImDC units as well as one terminal water molecule. The O7 and O8 atoms in mode **II** are simultaneously coordinated to two Eu^{3+} ions, while the O3 and O4 atoms in mode **I** are not further coordinated (Scheme 1). Thus, the O7/O8 atoms play a key role in the formation of **1** with an open framework. The Eu–O bond lengths range from 2.328(9) to 2.702(8) Å, whereas the Eu–N distances vary from 2.432(11) to 2.572 (10) Å.

The most striking features of **1** are the linkages between the Eu^{3+} ions and the two unusual coordinate modes of the ImDC moieties to form a unprecedented three-dimensional framework with achiral channels and two types of helical tubes with opposite chirality (Figure 2a and see the Supporting Information). The helical tubes of **1** can be understood in terms of two distinct parts: The helical tubular walls and the fillers. Thus, the Eu^{3+} ions linked through four carboxyl groups of two types of ImDC units form the achiral channels and the helical tubular walls that are made of triple-helical chains and double-helical chains (Figure 2b,c and see the Supporting Information). In the structure, the left- and right-handed helical channels, which are made of triple-helical chains, are further weaved by double-helical chains having the reverse orientation to the triple-helical chains to make the tubular walls with opposite chirality (Figure 2b,c and see the Supporting Information). These tubular walls are further linked together by O7 and O8 atoms from mode **II** to form the achiral channels (Figure 2a, and Figures S5 and 6b in the Supporting Information). In addition, the helical channels constructed from the triple-helical chains have a 32-membered ring opening along the [001] direction (Figure 3). In fact, there is no closed 32-membered ring present in the structure. The open 32-membered ring consisting of four repeating O2-C4-O1-Eu2-O7-C10-O8-Eu1 linkages—which are built up from the Eu1 and Eu2 atoms as well as two bridging carboxy groups containing C4 and C10 atoms—gives rise to two types of helical ribbons of three equivalent helical chains with opposite chirality (Figure 2b,c and see the Supporting Information). The separation between the adjacent chains in the helical ribbon is the same as the length of the *c* axis (16.176 Å). The pitch of the helical ribbon running along the *c* axis is three times the length of the *c* axis. In contrast, the double-helical chain consists of two distinct helical chains with a 16-membered ring made of four repeating Eu1-O3-C5-O4 (Eu2-O5-C9-O6) linkages, which are only built up from Eu1 (Eu2) atoms and one carboxy bridge containing C5 (C9) atoms (see the Supporting Information). The shortest Eu···Eu distance, bridged by carboxy groups, is 4.24 Å.

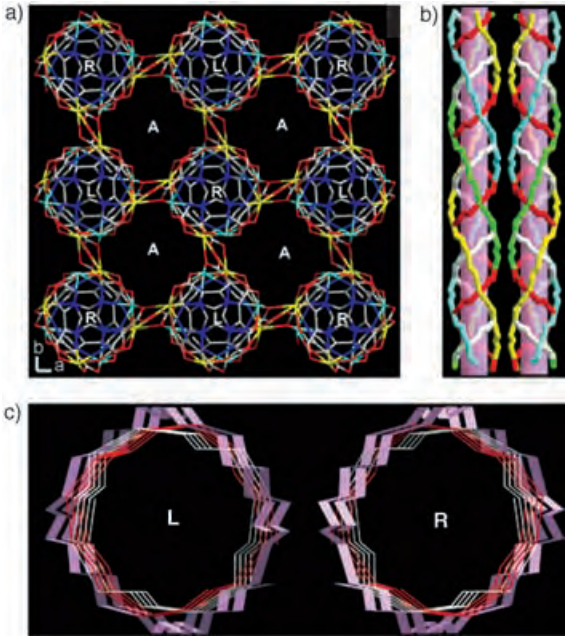

Figure 2. a) The framework of **1** viewed along the *c* axis, showing two types of helical tubular and achiral channels arranged alternately along the *a* and *b* axes. A: achiral channel, L and R indicate the left- and right-handed helical tubular channels. Hydrogen atoms are omitted for clarity. b) View of the helical tubular combination with opposite chirality, constructed from channels of triple-helical chains weaved by double-helical chains with the reverse helical orientation (*b* axis). The triple-helical chains are marked yellow, green, and cyan. The double-helical chains are displayed with red and white helical chains. The imidazole rings are omitted for clarity. c) The helical ribbon representation for the aggregate of triple-helical chains in the helical tube with opposite chirality along the [001] (left) and [00−1] directions (right). The white and red helical chains present two distinct helical chains of double-helical chains weaved across the ribbon.

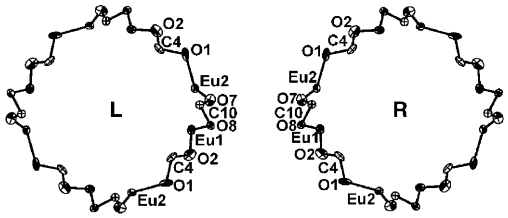

Figure 3. Views of the two types of helical channels containing triple-helical chains in **1** along the [001] (left) and [00−1] directions (right). L and R indicate the left- and right-handed helical channels.

Remarkably, the two types of imidazole rings of the ImDC ligands that act as the fillers are alternately trapped inside the helical tubes and coordinated to adjacent Eu1 and Eu2 atoms from the walls through N_{Im} atoms to form a pair of helical chains with the same helical orientation as the triple-helical chain (see the Supporting Information). The shortest Eu···Eu distance, bridged by an imidazole ring, is about 6.96 Å.

The guest water molecules are suspended in the achiral channels (dimensions 4.58 × 4.58 Å; see the Supporting Information), and the coordinated water molecules point away from the Eu–ImDC hybrid framework and into the achiral channels. There are strong hydrogen bonds between the guests, as well as between the guests and the oxygen atoms from the ImDC moieties and the coordinated water molecules (O···O 2.168(22)–3.344(15) and 2.735(19)–2.976(13) Å, respectively).

Complex **1** displays intense red luminescence (Figure 4a, and see the Supporting Information) and exhibits the characteristic transition of $^5D_0 \rightarrow {}^7F_J$ ($J = 0$–4) of the Eu^{3+}

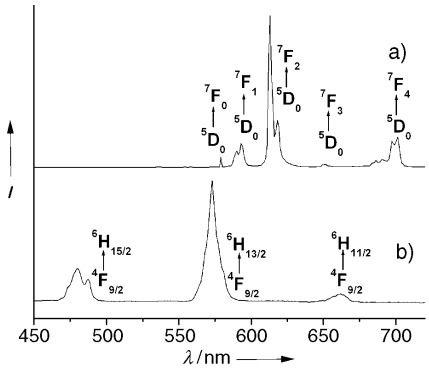

Figure 4. Emission spectra of **1** (a) and **2** (b) in the solid state at room temperature (excitation at 394 and 325 nm for **1** and **2**, respectively). *I* = intensity.

ion with a decay lifetime of 251.2 μs. The appearance of the symmetry-forbidden emission $^5D_0 \rightarrow {}^7F_0$ at 580 nm indicates that the Eu^{3+} ions in **1** occupy sites with low symmetry and have no inversion center,[10] which is further confirmed by the intensity ratio of about 5.5 for $I(^5D_0 \rightarrow {}^7F_2)/I(^5D_0 \rightarrow {}^7F_1)$.[11] This is in agreement with the result of the single-crystal X-ray analysis. Complex **2** is yellow-luminescent in the solid state with typical Dy^{3+} emissions at 480, 573, and 622 nm (decay lifetime 1.21 μs), corresponding to the characteristic emission $^4F_{9/2} \rightarrow {}^6H_J$ transitions of the Dy^{3+} ion ($J = 15/2$, 13/2, and 11/2; Figure 4b and Figure S11b in the Supporting Information). The yellow emission of the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ transition has a stronger intensity than the blue emission of $^4F_{9/2} \rightarrow {}^6H_{15/2}$ for **2**, while the red emission of the $^5D_0 \rightarrow {}^7F_2$ transition is the most intense for **1**, suggesting that the ImDC ligand is suitable for the sensitization of yellow and red luminescence for Dy^{3+} and Eu^{3+}, respectively. With respect to H_3ImDC, the strongest emission peak is located at 490 nm ($\lambda_{ex} = 296$ nm; see Figure S11c in the Supporting Information). The absence of the ligand-based emission in the fluorescence spectra of **1** and **2** suggests that the energy transfer from the ligand to the lanthanide center is very effective and can sensitize the lanthanide emission to a large extent.

The magnetic susceptibilities of **1** and **2** were measured in the temperature range 5–300 K. For **1**, the room temperature value of $\chi_M T$ is 2.77 $cm^3\,K\,mol^{-1}$, slightly less than the value of 3.0 $cm^3\,K\,mol^{-1}$ for two Eu^{3+} ions calculated from the van Vleck equation allowing for population of the excited state with higher values of *J* at 293 K.[3d] As the sample is cooled, $\chi_M T$ continuously decreases due to the depopulation of the Stark levels for a single Eu^{3+} ion, and tends to a value very close to zero as the temperature approaches absolute zero, which indicates a $J = 0$ ground state for the Eu^{3+} ion ($^7F_0$) at the lowest temperature (see Figure S12a in the Supporting Information). The $\chi_M T$ value per molecule of **2** is 30.37 $cm^3\,K\,mol^{-1}$ at room temperature, comparable to the expected value of 28.34 $cm^3\,K\,mol^{-1}$ for two free Dy^{3+} ions with a $^6H_{15/2}$ ground state. As the temperature is lowered, the $\chi_M T$ product increases slightly to a maximum of 31.91 $cm^3\,K\,mol^{-1}$ at about 120 K, and then decreases gradually to 24 $cm^3\,K\,mol^{-1}$ at 5 K, suggesting a dominant ferromagnetic interaction between adjacent Dy^{3+} ions. The fitting above 100 K to Curie–Weiss equation yields a positive Weiss constant $\theta = 7.12$ K, which confirms a ferromagnetic coupling between Dy^{3+} centers (see Figure S12b in the Supporting Information). The further decrease of $\chi_M T$ at low temperature is mainly attributed to the splitting of the ligand field of the Dy^{3+} ion because of strong spin-orbital coupling.[12]

In summary, we have successfully constructed two novel lanthanide metal coordination polymers with an open framework under hydrothermal conditions from lanthanide oxide as the source of lanthanide and multidentate ImDC as a bridging ligand; the synthetic procedure has been well established.[13] The linkages between Ln centers through the ImDC ligands in two unique coordination modes result in a series of unusual lanthanide-organic open frameworks containing not only two types of helical tubular channels with opposite chirality but also achiral channels. To the best of our knowledge, this is the first time lanthanide metal coordination polymers with ImDC ligands have been prepared.

Experimental Section

1 and **2**: A mixture of Ln_2O_3 (0.5 mmol; Eu_2O_3, 0.176 g; Dy_2O_3, 0.187 g), H_3ImDC (1 mmol, 0.156 g), and H_2O (8 mL) in the presence of HNO_3 (0.33 mL 8.4 wt%) in a molar ratio of about 1:2:889:0.92 (pH 2) was sealed in a 30-mL stainless steel reactor with a Teflon liner and heated at 170 °C for 10 days, and then cooled to room temperature. White prismatic crystals of **1** and **2** were recovered by filtration, washed with distilled water, and dried in air.

1: Yield: 60% (based on Eu_2O_3); elemental analysis (%) calcd for $C_{10}H_{11.25}Eu_2N_4O_{12.63}$: C 17.32, H 1.64, N 8.08; found: C 17.31, H 1.63, N 8.14; IR (KBr pellet): $\tilde{\nu} = 1573$, 1389, 1108 cm^{-1}.

2: Yield: 37% (based on Dy_2O_3); elemental analysis (%) calcd for $C_{10}H_{11.25}Dy_2N_4O_{12.63}$: C 16.79, H 1.59, N 7.84; found: C 16.30, H 1.61, N 7.59; IR (KBr pellet): $\tilde{\nu} = 1579$, 1392, 1111 cm^{-1}.

Molecular Engineering for Single-Chain-Magnet Behavior in a One-Dimensional Dysprosium–Nitronyl Nitroxide Compound**

*Lapo Bogani, Claudio Sangregorio, Roberta Sessoli, and Dante Gatteschi**

The discovery of single molecule magnets (SMMs), about a decade ago,[1] opened up a very lively scientific area where still both physicists and chemists join their efforts to better understand and selectively change the magnetic properties of matter.[2] On one side, the interest aroused by these materials is due to the fact that they allow us to directly address questions of fundamental interest,[3] and, on the other side, their proposed applications make them appealing candidates for future devices.[4] The field was further expanded by the discovery, some years ago, of a polymeric compound, [Co(hfac)$_2${NIT(C_6H_4OMe)}][5] (hfac = hexafluoroacetylacetonate; NIT(R): 2-(4′-R)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide), which displays a hysteresis behavior above the temperature of liquid He without undergoing three-

dimensional (3D) magnetic ordering. This slow dynamics of the magnetization was explained with Glauber's model[5] for Ising spin chains and, while the physics underlying these systems is revealing interesting aspects,[6] much effort is devoted to the synthesis of new chain compounds of this kind, known as single-chain magnets (SCMs).[7] The two requirements needed to observe Glauber dynamics, that is, a strong Ising anisotropy and a very low ratio of interchain/intrachain interactions, are difficult to balance, and only a few compounds have been proposed as SCMs up to now.[8]

Rare-earth-radical-based chains are very appealing candidates for SCMs owing to the Ising anisotropy of their metallic centers, and $[Dy(hfac)_3\{NIT(Et)\}]$ (**1**) displays a transition to 3D magnetic order at 4.3 K.[9] However, the interchain interactions are relatively weak, as the shortest metal–metal distances are 10.76 Å, and only through-space (dipolar) interchain interactions are active. It should be possible to further increase these distances by varying the radical, thus determining a passage from 3D order to SCM behavior. This can shed light on the delicate balance between the exchange, structural features, and magnetic anisotropy required for SCM behavior. This idea proved to work well, and we wish to report herein the first complete structural and magnetic characterization of a rare-earth-based SCM synthesized by a rational approach. Frequency-dependent data on a Tb-based compound have been reported in a previous work, but structural evidence was lacking.[10]

The radical $NIT(C_6H_4OPh)$ was an appealing candidate to increase the separation of neighboring chains because it possesses two rather mobile aromatic rings, as spacers, and an

ether group in between that enriches the electron density of these rings. The presence of such electron-rich groups alternating with the electron-poor rings formed when hfac ligands coordinate to a metal center favors stacking interactions along the chain, thus stabilizing the polymeric compound.[11]

The reaction of $[Dy(hfac)_3(H_2O)_2]$ with the $NIT(C_6H_4OPh)$ radical in hot *n*-heptane afforded single crystals of the chain compound $[Dy(hfac)_3\{NIT(C_6H_4OPh)\}]$ (**2**) suitable for X-ray analysis. This compound, whose structure is depicted in Figure 1,[12] consists of chains, parallel to *b*, of octacoordinated $Dy(hfac)_3$ centers connected by radical units, which act as bis-monodentate ligands.

The coordination geometry around the Dy atom is a distorted dodecahedron with triangular faces, where the two radical oxygen atoms occupy the apical positions of two distorted pentagons. The distances between the metal center and these oxygen atoms were found to be very similar to each other (2.329(4) Å and 2.385(4) Å). The stacking interactions between the inner aromatic ring of the spacer and an hfac ligand can be clearly identified,[13] as the distance between the two aromatic planes is 3.75(5) Å and the angle between them

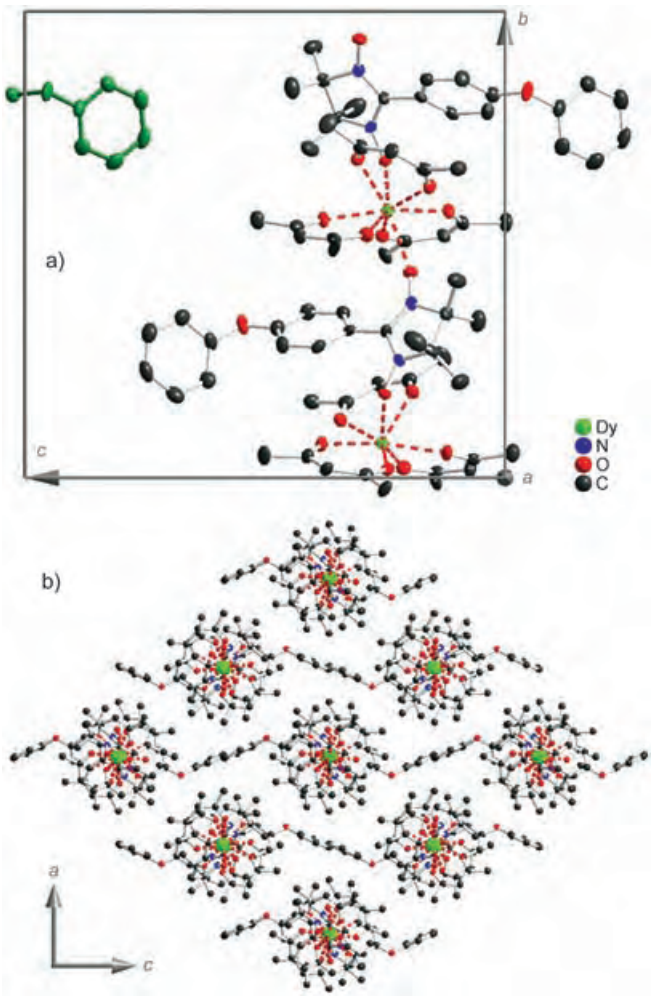

Figure 1. Views of the structure of **2**: a) along the *a* axis, showing the chain structure together with the unit cell. The aromatic tail of the radical of an adjacent chain is also shown (in green); b) along the crystallographic *b* axis, showing the packing of the chains. Ellipsoids are drawn at 50% probability and fluorine and hydrogen atoms have been omitted for clarity.

is 14.6(2)°, in agreement with the situation observed in other metal NIT(R) derivatives.[11] The outer aromatic ring of the spacer, on the other hand, is placed between the chains, with the normal tilted with respect to the inner ring (65.84°) and oriented almost perpendicularly to the chain axis (86.71°). This ring lies isolated in a niche between two other chains, surrounded by the fluorine atoms of four hfac ligands, with a distance of 5.90(5) Å from the centroid of the nearest ligand. In this way, as can be observed from Figure 1, the free volume between the chains is alternatively occupied by the spacers of two different chains, thereby minimizing any weak magnetic interactions between the radicals. Our strategy leads to an increased volume per metal center, which grows from 881 $Å^3$ in **1** to 1001 $Å^3$ in **2** and, more importantly, to a lengthening of all distances between different chains. Analysis of the distances between a chain and the six neighboring ones showed the presence, in both cases, of three couples of equally distant chains. All three distances increase, with the shortest distance between two Dy centers growing from 10.76 to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

11.35 Å, and the next two shortest separations increasing from 11.23 to 11.38 Å and from 11.43 to 14.31 Å. In other words, there is a change from a pseudo-hexagonal arrangement of the chains in **1** to a pseudo-tetragonal one in **2**. Considering the r^{-3} dependence of magnetic dipolar interactions, such changes in the crystal structure, although they may not seem dramatic, reduce the interactions along the shortest distance by 15% and those along the longest distance by up to 49%. This analysis reveals that the engineering of the compound has led to an efficient suppression of interchain interactions independent of the orientation of the magnetic easy axis.

The effect of this crystal engineering strategy on the magnetic properties is evident from Figure 2, in which we show the dc magnetic susceptibility measured for a powder

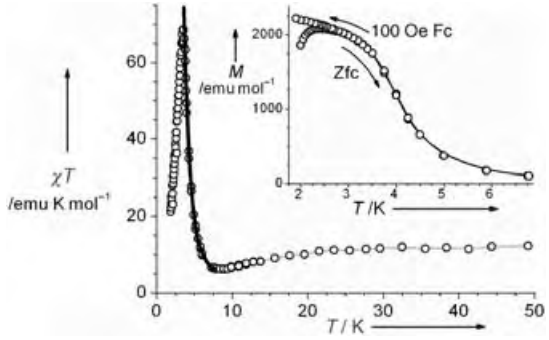

Figure 2. Low-temperature dependence of the χT product from dc magnetic measurements performed in a 100 Oe applied field. The black line represents the calculated curve, as described in the text. In the inset we show the gap that opens up below 2.6 K between the zero-field-cooled and the 100-Oe-cooled curves.

sample. The radicals are $S = 1/2$ isotropic magnetic centers, while Dy^{III}, a $^6H_{15/2}$ ion, is usually treated, at low temperature, as an effective $S = 1/2$ anisotropic center. The high-temperature χT value, 12.2 emu K mol^{-1} at 300 K, is slightly lower than the expected theoretical value for two such noninteracting magnetic centers, but consistent with the data available for **1**.[9] The temperature dependence of χT shows a minimum at 8.6 K and a rounded peak of 68.5 emu K mol^{-1} at 3.6 K, typical of 1D behavior, while the cusp found in the 3D-ordered compound[9] is not observed.

The magnetism of this type of lanthanide–radical chain is characterized by the presence of nearest-neighbor (NN) ferromagnetic metal–radical and next-nearest-neighbor (NNN) antiferromagnetic metal–metal or radical–radical magnetic couplings (J_{Mr}, J_{MM}, and J_{rr}, respectively).[9] The overall behavior at low temperature depends on the ratio between ferro- and antiferromagnetic interactions.[14] The low-temperature powder data of **2** suggest that ferromagnetic interactions dominate. A scaling procedure of the χT data[15] clearly indicates a linear regime characteristic of Ising 1D systems (see Supporting Information). The data between 8.5 and 3.6 K were therefore reproduced with a spin-1/2 Ising model with alternating Landé g-factors (g_r and g_{Dy} for the radical and the Dy centers, respectively) and three exchange interactions. A good agreement ($R = 0.999$) between the calculated and experimental curves in this region was found with the values $g_r = 2.0$, $g_{Dy} = 8.0$ (vide infra), ferromagnetic $J_{Mr} = 19$ K, and antiferromagnetic $J_{rr} = -6.5$ and $J_{MM} = -4$ K. A similar agreement was also observed with other sets of parameters, thereby suggesting a strong correlation between them, with the difference between the ferromagnetic and antiferromagnetic interactions being the key point. Moreover, due to the presence of a strong anisotropy of the magnetization, single-crystal measurements as a function of the orientation will be needed to give a completely reliable set of values.

1D Ising systems are expected to follow Glauber slow dynamics with a thermally activated reversal of the magnetization, $\tau = \tau_0 \exp(\Delta/k_B T)$, where the energy barrier, Δ, depends on the exchange interaction, that is, $\Delta = |J|$ for $S = 1/2$. The ac magnetic susceptibility curves, measured in zero static field, display a frequency-dependent peak for both in-phase χ' and out-of-phase χ'' signals below 4.5 K, as shown in Figure 3, thus indicating the presence of a thermally activated mechanism. A frequency-independent peak at the transition

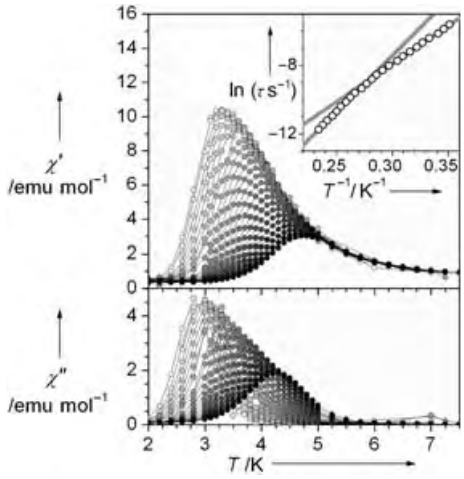

Figure 3. Temperature dependence of the real (top) and imaginary (bottom) components of the ac magnetic susceptibility measured in zero applied field in the frequency range 25 Hz–20 kHz. The inset shows the obtained Arrhenius plot and the crossover.

temperature would be found for a 3D-ordered compound. The dynamic behavior of **2** can be reproduced with the generalized Debye model (Supporting Information) by taking into account a narrow distribution of relaxation times, $\alpha = 0.16$, a value compatible with those observed for other SCMs.[8]

The Arrhenius plot extracted from these data, reproduced in the inset of Figure 3, shows the presence of a crossover between two different activated regimes, both of which give best-fits with physical τ_0 values (5.6×10^{-10} and 1.9×10^{-12} s for the low- and high-temperature regimes, respectively) and two different barriers (42 and 69 K, respectively). The presence of a crossover in the Arrhenius plot of SCMs that halves the Glauber activation barrier due to finite-size effects has been predicted[16] and experimentally observed for systems with a slow relaxation of single monomeric units.[15]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Below 2.6 K, irreversibility effects also appear in static magnetic measurements as a discrepancy between the magnetization curve cooled in zero field and the curve cooled in an applied external field, as shown in the inset of Figure 2. The magnetization curve taken at 1.60 K, depicted in Figure 4, reveals the opening of a hysteresis loop and a very rich magnetic behavior with two different steps, an unprecedented feature in rare-earth polymeric systems. The fact that such steps do not change on varying the field sweep rate indicates that they are associated with static properties. While we cannot totally exclude that the first step around $H = 50$ Oe is due to residual antiferromagnetic interchain interactions, it is interesting to note that the slow relaxation of the magnetization observed above 2 K in zero field also persists above the step. This is consistent with a very "robust" Glauber dynamic regime that is unaffected by possible weak interchain interactions.[17]

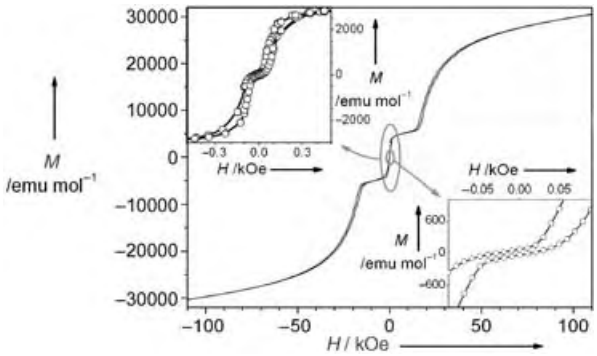

Figure 4. Magnetization curve versus applied field measured at 1.60 K. The nested hysteresis cycles are shown in the two insets.

The step at around $H = 15$ kOe is more difficult to rationalize. The presence of competing NN and NNN interactions could stabilize states that do not correspond to the ferromagnetic alignment of all the spins. A state that has been previously discussed can be described by the spin arrangement …↓↓↑↑↓↑…, in which the red arrows represent Dy magnetic moments and the black arrows represent radical sites.[9] This state has a magnetization corresponding to $(M_{Dy}-M_r)/3$, and is not too far from that observed in Figure 4, assuming that the high-field value tends to $(M_{Dy}+M_r)$, thus providing an average g_{Dy} value of around 8. However, we could not successfully reconcile this picture with the ferromagnetic behavior observed between 4 and 10 K using a simple Ising model; further investigations with single crystals are necessary to clarify this point.

In conclusion, we have prepared and structurally characterized the first rare-earth-radical-based coordination polymer to exhibit SCM behavior, namely [Dy(hfac)$_3${NIT(C$_6$H$_4$OPh)}] (**2**). A critical reconsideration of previously known compounds was a key point to rationally plan the synthesis to enhance the stacking along the chains and to weaken the interchain magnetic interactions. To the best of our knowledge, this is the first successful preparation of an SCM from a material known to undergo 3D magnetic ordering. The chains exhibit all the features of a slowly relaxing system, including a crossover between two Arrhenius regimes, and a hysteresis loop opens below 3 K. The observation of such a crossover in **2**, if due to finite-size effects, would suggest a significant contribution to the barrier coming from the anisotropic building blocks, as the barrier is not exactly halved.[15] This would open the possibility to study the effect of the recently observed dynamics of rare-earth single-ion units[18] when arranged in chains. These dynamic features are accompanied by a very rich static behavior that could be due to the interplay of NN and NNN interactions, with the presence of several low-energy states. Finally, thanks to the synthetic possibilities opened up here, the chemical reactivity of rare-earth metals can now be exploited to study the role of the anisotropy and magnetic multiplicity of the rare-earth ion on the slow dynamics of both monomers and chains.

Experimental Section

Synthesis of **2**: [Dy(hfac)$_3$(H$_2$O)$_2$] (1 mmol) was dissolved in boiling dry *n*-heptane (30 mL). The solution was left to boil for 20 min and then cooled down to 75 °C, whereupon 1 mmol of the crystalline solid radical NIT(C$_6$H$_4$OPh) was slowly added whilst stirring followed by 3 mL of CH$_2$Cl$_2$. The final solution was cooled down to room temperature and was left to stand for about 24 h to give green, needle-like crystals. C$_{34}$H$_{24}$DyF$_{18}$N$_2$O$_9$: calcd C 36.89, H 2.18, N 2.52; found: C 37.10, H 2.50, N 2.79.

Physical measurements: The dc magnetic susceptibility measurements were performed on solid polycrystalline samples with a Cryogenic S600 SQUID magnetometer and were all corrected for the diamagnetic contribution as calculated with Pascal's constants. Magnetization curves with fields over 60 kOe were measured with an Oxford VSM system after inclusion of the sample in grease to prevent orientation of the crystallites. Data were corrected for the magnetism of the grease, which was independently determined at the same temperature and fields. The ac magnetic susceptibility was measured by using a homemade probe operating in the range 20–20 000 Hz.[19] Crystal structure data were collected with an Oxford Diffraction Xcalibur3 diffractometer.

Short C–C Bonds

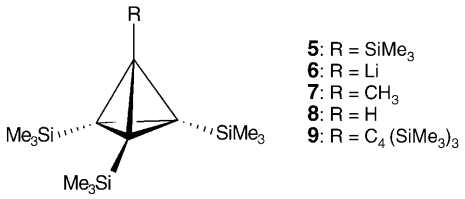
DOI: 10.1002/anie.200501605

Hexakis(trimethylsilyl)tetrahedranyltetrahedrane**

*Masanobu Tanaka and Akira Sekiguchi**

The most important factor for bond shortening is the increase in s character of the bond orbital.[1] In 1988, Eaton and coworkers succeeded in the synthesis and structural characterization of cubylcubane (**1**).[2] The bond length between the

1 **2**: $n=2$, **3**: $n=3$ **4**



two cubane units (1.458 Å) was significantly shorter than the usual carbon–carbon single-bond length (1.54 Å). This bond shortening was attributed to the high s character of the bond orbitals. Later, Ermer et al. synthesized coupled bicyclo[1.1.0]butane derivatives **2** and **3**,[3] in which the corresponding C–C bonds have higher s character than that in cubylcubane. As expected, the linking C–C bond lengths in these coupled bicyclo[1.1.0]butane derivatives are further shortened (1.445 and 1.440 Å). Tetrahedrane is the most strained cage compound with the highest degree of s character in the exocyclic bond. Therefore, the linking C–C bond length in tetrahedranyltetrahedrane (**4**) is expected to be even shorter. Indeed, theoretical studies suggest compound **4** as a candidate for the molecule with the shortest carbon–carbon single bond in a saturated hydrocarbon system.[4] However, treatment of substituted tetrahedranes is extremely difficult because of its high strain and, consequently, high reactivity.[5,6] Until now, no tetrahedranyltetrahedrane derivative has been synthesized.

Recently, we succeeded in the synthesis and characterization of trimethylsilyl-substituted tetrahedrane derivatives.[7,8] Electropositive silyl groups significantly release the inherent ring strain of the tetrahedrane skeleton. For

example, tetrakis(trimethylsilyl)tetrahedrane (**5**) is stable in the presence of air and moisture at temperatures up to 300 °C. We also synthesized and isolated tetrahedranyllithium **6** as a thermally stable compound which is a good precursor for other tetrahedrane derivatives.[8] Indeed, we succeeded in the synthesis of methyl- and hydrogen-substituted tetrahedranes (**7** and **8**, respectively) from tetrahedranyllithium. Surprisingly, tetrahedranes with smaller substituents and hence a lower steric protection were stable in air and at temperatures up to 100 °C. In the ^{1}H NMR spectrum of hydrogen-substituted tetrahedrane **8**, a very large ring C–H coupling constant was observed which is comparable to that of acetylene. From the empirical correlation, we estimated the s character of the ring C–H bond to be 48 %.[8] These results indicate that the C–C link should also have high s character and a very short C–C bond in silyl-substituted tetrahedranyltetrahedrane. Herein, we report the synthesis of hexakis(trimethylsilyl)-tetrahedranyltetrahedrane (**9**) as well as the structural characterization by X-ray crystallography.

Tetrahedrane **9** was synthesized by the oxidative coupling of **6** via a cuprate complex (Scheme 1). First, tetrahedranyllithium **6** was prepared by the reaction of **5** with excess methyllithium in THF, and the ligand of **6** was changed from

Scheme 1. Synthesis of hexakis(trimethylsilyl)tetrahedranyltetrahedrane (**9**).

THF to [15]crown-5 to remove the remaining methyllithium completely. Reaction of **6** with CuCN (0.5 equiv) at −78 °C in THF gave the cuprate complex, which was subsequently oxidized with oxygen at −78 °C. The reaction mixture was purified consecutively by gel-permeation chromatography (toluene) and HPLC (MeOH/*t*BuOMe 1:1) equipped with a recycling system, and finally **9** was isolated as a colorless solid in 3 % yield in a pure form. Several other methods to synthesize **9** by the oxidation of **6** with various reagents such as dichlorodicyano-*p*-benzoquinone, tetracyano-*p*-benzoquinone, $NO^+PF_6^-$, and $(C_6F_5)_3B$ were performed; however, no trace amount of **9** was formed.

Compound **9** was stable in air and up to 200 °C. The most important stabilizing factor can be attributed to the electronic effect of the trimethylsilyl groups, as found in **5**.[7] The ^{1}H, ^{29}Si, and ^{13}C NMR spectra of **9** in [D$_6$]benzene demonstrated its high symmetry. Only one signal was observed for the trimethylsilyl groups in the ^{1}H NMR ($\delta = 0.22$ ppm) and ^{29}Si NMR ($\delta = -2.5$ ppm) spectra, and three signals appeared at $\delta = -18.0$ (ring C–Si), −4.7 (linking ring C), and 0.07 ppm ($SiMe_3$) in the ^{13}C NMR spectrum. The large upfield shift of the ring C atom is typical for tetrahedrane.[7–10] The linking carbon atom shows a remarkably downfield shift relative to that of the silicon-substituted skeletal carbon atom because of the different electronegativities of the Si and C substituents and the high s character of the linking carbon atoms.

The molecular structure of tetrahedranyltetrahedrane **9** was determined by X-ray crystallographic analysis without disorder phenomena. X-ray-quality single crystals were obtained by crystallization from ethanol at 5 °C. As shown in Figure 1,[11] the bulky trimethylsilyl groups sterically

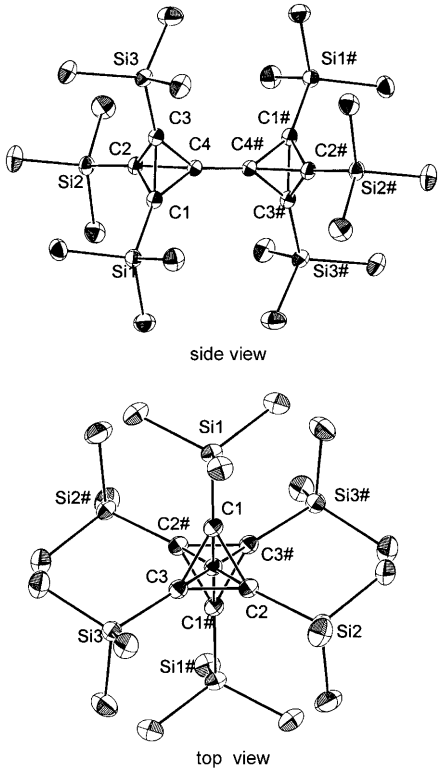

Figure 1. Structure of **9** (ORTEP plot; thermal ellipsoids set at 30 % probability; hydrogen atoms omitted for clarity). protect the tetrahedranyltetrahedrane skeleton, and the two tetrahedrane units have a staggered conformation owing to steric repulsion.

As expected, the linking C–C bond length (1.436(3) Å) is shortened considerably, and this experimental value of the bond length is practically identical to the theoretical one.[4] To our knowledge, this is the shortest noncyclic (unbent) C–C single bond between saturated C atoms observed to date. The calculated s character of the linking C–C bond in **9** at the NBO/B3LYP/6-31G level is $sp^{1.53}$, which supports the suggestion that this shortening arises from the high s character of the bond. When the electronegativity increases (from Si to C), the s character of the exocyclic bond decreases. This electronic effect changes the structure of the tetrahedrane skeleton.[12] Whereas tetrahedrane **5** has a regular tetrahedral structure, the tetrahedrane units in **9** have a distorted tetrahedral structure. The endocyclic C(C)–C($SiMe_3$) bond lengths (C4–C1, C4–C2, C4–C3) in **9** range from 1.483(2) to 1.484(2) Å (average 1.484(2) Å), whereas the endocyclic C($SiMe_3$)–C($SiMe_3$) bond lengths (C1–C2, C1–C3, C2–C3) range from 1.511(2) to 1.528(2) Å (average 1.521(2) Å), which are longer than those of C–C bond lengths of tetrahedrane **5** (average 1.501(4) Å). The endocyclic C($SiMe_3$)–C($SiMe_3$) bond lengths of **9** (average 1.521(2) Å) are somewhat longer than those of **5** (average 1.501(4) Å) and **6**·$(tmeda)_{1.5}$ (average 1.4986(15) Å).

It is interesting to compare the lengths of the endocyclic C($SiMe_3$)–C(R) bond: R = Li for **6** (average 1.5425(15) Å), R = $SiMe_3$ for **5** (average 1.501(4) Å), R = $C_4(SiMe_3)_3$ for **9** (average 1.484(2) Å); certainly, the electronegativity of R affects the structural features of the tetrahedrane skeleton. In the case of the most electropositive Li atom the C($SiMe_3$)–C(Li) bond has a high p character, thus leading to the elongation of the C–C bond, whereas in the case of more-electronegative substituents (from $SiMe_3$ to $C_4(SiMe_3)_3$) the tendency is the opposite: increase in s character and shortening of the C–C bond.

Experimental Section

9: Tetrakis(trimethylsilyl)tetrahedrane (**5**)[7] (53 mg, 0.16 mmol) and a tenfold excess of methyllithium were placed in a reaction tube. Dry oxygen-free THF (3.0 mL) was introduced by vacuum transfer and stirred for 24 h. After the solvent was removed, dry oxygen-free hexane (5 mL) was introduced and the insoluble methyllithium in hexane was filtered through celite in a glove box. [15]Crown-5 (0.03 mL) was introduced as a solution in hexane, and the deposited methyllithium was filtered through celite in a glove box. The solvent was placed in a reaction tube and removed in vacuo. The colorless solid **6** was obtained. CuCN (4.5 mg, 0.05 mmol) was added to the reaction tube and dry oxygen-free THF (4 mL) was introduced by vacuum transfer and stirred at −78 °C for 18 h, and oxygen gas was bubbled in the solution at −78 °C. After the solvent was removed, the reaction mixture was purified by gel-permeation chromatography (toluene) and HPLC (MeOH/*t*BuOMe 1:1) equipped with a recycling system. The solvent was removed in vacuo and **9** was obtained as a colorless solid (2.5 mg, 3 %); m.p. 209–211 °C; ^{1}H NMR (400 MHz, [D_6]benzene, TMS): δ = 0.22 ppm (s, 54 H, $SiMe_3$); ^{13}C{^{1}H} NMR (100 MHz, [D_6]benzene, TMS): δ = −18.0 (C), −4.7 (C), 0.07 ppm ($SiMe_3$); ^{29}Si{^{1}H} NMR (80 MHz, [D_6]benzene, TMS): δ = −2.5 ppm; MS (70 eV, EI): *m*/*z*: 534 [M^+], 461 [M^+−$SiMe_3$), 73 ($SiMe_3$); HRMS: calcd for $C_{26}H_{54}Si_6$: 534.2841; found: 534.2806. The very low yield of **9** is due to the formation of tetrahedrane **5** and hydrogen-substituted tetrahedrane **8**, which were also produced under the reaction conditions together with **9**.

Entangled Coordination Networks with Inherent Features of Polycatenation, Polythreading, and Polyknotting**

Xin-Long Wang, Chao Qin, En-Bo Wang, Yang-Guang Li, Zhong-Min Su,* Lin Xu, and Lucia Carlucci**

The current interest in coordination polymer frameworks not only stems from their potential applications in microelectronics, nonlinear optics, porous materials, and catalysis, but also from their intriguing variety of topologies and entanglement motifs.[1] Interpenetration has been the most investigated type of entanglement, as shown by the two comprehensive reviews by Batten and Robson.[2] More recently, a complete analysis of all the 3D interpenetrated structures contained in the CSD database was also carried out with a rationalization and classification of the topology of the interpenetration.[3] The increasing number of coordination polymers reported in the literature has led to new and more complex types of entanglement being recognized[2b,4,5] in polycatenated, polythreaded, and polyknotted species that are reminiscent of molecular catenanes, rotaxanes, and knots, respectively.

According to Ciani and co-workers,[5] polycatenation differs from interpenetration in that the whole catenated array has a higher dimensionality than that of the component motifs, and that each individual motif is catenated only with the surrounding ones and not with all the others. Polythreaded structures are characterized by the presence of closed loops, as well as of elements that can thread through the loops, and can be considered as extended periodic analogues of molecular rotaxanes and pseudorotaxanes, depending on the "ideal" possibility of being extricated. Polyknotting is typical of self-penetrating nets, that is, single nets having the peculiarity that the smallest topological rings are catenated by other smallest rings belonging to the same net.

Apart from their intrinsic aesthetic appeal, interest in these new families of entangled structures has been heightened by the fact that their resulting overall architectures are more flexible than the usual networks based entirely on coordination bonds[6]—a functional property that has potential applications ranging from drug-delivery vehicles to sensor devices.[7] Therefore, the exploitation of such species not only increases the structural diversity of coordination polymers, but also provides new insights into the relationships between the structure and function of these materials.

We report here three new entangled frames that were obtained from the use of the rigid 4,4′-bipyridine (bpy) and the long V-shaped 4,4′-oxybis(benzoate) (oba) ligands: $[Ni_2(oba)_2(bpy)_2(H_2O)_2]\cdot bpy$ (**1**) is the first example of a polycatenated array of 1D nanotubes, $[Ni_3(oba)_2(bpy)_2(Hoba)_2(H_2O)_2]\cdot bpy\cdot 2H_2O$ (**2**) is a new type of 2D polythreaded architecture involving five polymeric units at a time, and $[Ni(oba)(bpy)]\cdot 2H_2O$ (**3**) is an intriguing self-penetrating 3D net with an unprecedented topology. The magnetic susceptibilities of compounds **1**–**3** were also investigated (see the Supporting Information).

The crystal structure of compound **1**[8] consists of cationic $[\{Ni(bpy)\}_4]^{8+}$ squares (crystallographically equivalent in pairs), with Ni···Ni separations of 11.180(7) and 11.269(5) Å; these square units are joined by anionic oba^{2-} bridges to give one-dimensional nanotubes containing large cubelike boxes of approximate dimensions $11.2\times11.3\times14.9$ Å (Figure 1, top). The two differnt types of nickel(II) centers are coordi-

nated in a distorted octahedral geometry to two oba ligands (one monodentate: Ni-O 1.998(3) and 2.033(3) Å, and one chelate: Ni-O in the range 2.064(3)–2.200(4) Å), two bpy ligands (Ni-N 2.066(4)–2.159(4) Å), and one water molecule (Ni-O 2.045(4) and 2.103(4) Å). A large number of molecular squares have been thoroughly investigated to date,[9] all of which were held together by van der Waals interactions except in one case, in which cationic squares were interconnected by axial chloride bridges into a 3D network.[10] Therefore, to our knowledge, this is the first nanosized tubular structure constructed by the covalent linkage of molecular squares.

The most fascinating and peculiar structural feature of **1** is that each nanotube, which is aligned parallel to the *b* axis, is interlocked in a parallel fashion (along the *a* axis) with the two nearest neighboring ones to give rise to a 2D polycatenated layer (Figure 1, bottom). This kind of entanglement is still quite uncommon and the known examples are based exclusively on infinite 1D molecular ladders.[4,11] Therefore, compound **1**, besides providing a remarkable new structural motif, represents the first example of a 2D array of such motifs polycatenated in a parallel manner. It is also a rare example having both polyrotaxane and polycatenane characteristics[12] and could equally well be considered as formed by interconnected 1D polyrotaxane columns. Free void space is also present within the structure (25.5 % of the crystal volume as calculated by PLATON) which is occupied by guest molecules, with each "box" encapsulating two uncoordinated bpy molecules.

Compound **2** is an extended threaded framework involving 2D coordination layers of square (4^4) topology with dangling ligands. The nodes within the layers are alternately represented by single metal centers (Ni2) of distorted octahedral geometry (Ni-O in the range 2.051(3)–2.119(3) and Ni-N $2\times2.100(4)$ Å), and dinuclear units of Ni1 atoms that are bridged by two pairs of oba carboxylate ligands into a paddle wheel moiety (Ni-O in the range 1.971(3)–1.993(4), Ni-N 2.075(4), and Ni···Ni 2.6174(13) Å). All the nodes are connected through oba and bpy ligands to give a 2D motif with very large rhombic windows (dimensions 12.50×15.00 Å); dangling oba ligands are coordinated in the axial sites of dinuclear nodes only, and disposed in a mutual *anti* orientation with respect to the layer plane (Figure 2a). The layers are stacked in a parallel manner along the [−1 −1 2] direction in an ABCABC sequence at a distance of approximately 5.4 Å. Each dangling arm has an effective length of about 13.5 Å. As result, the dangling oba ligands of each layer are threaded into the rhombic voids of the two adjacent layers above and below, thus every rhombic window of each layer is threaded by only two dangling ligands that come from opposite directions (this is expected considering that the dangling arms reside on the dinuclear nodes only, Figure 2a). Finally, this unique simultaneous threading fashion of five adjacent polymeric motifs gives the novel (2D→3D) polythreaded array observed for compound **2** (Figure 2b).

Polythreaded structures containing finite components are, at present, rare.[5] The few species known include polythreaded 0D rings with side arms that give 1D[13a] or 2D arrays,[13b] as well as molecular ladders with dangling arms

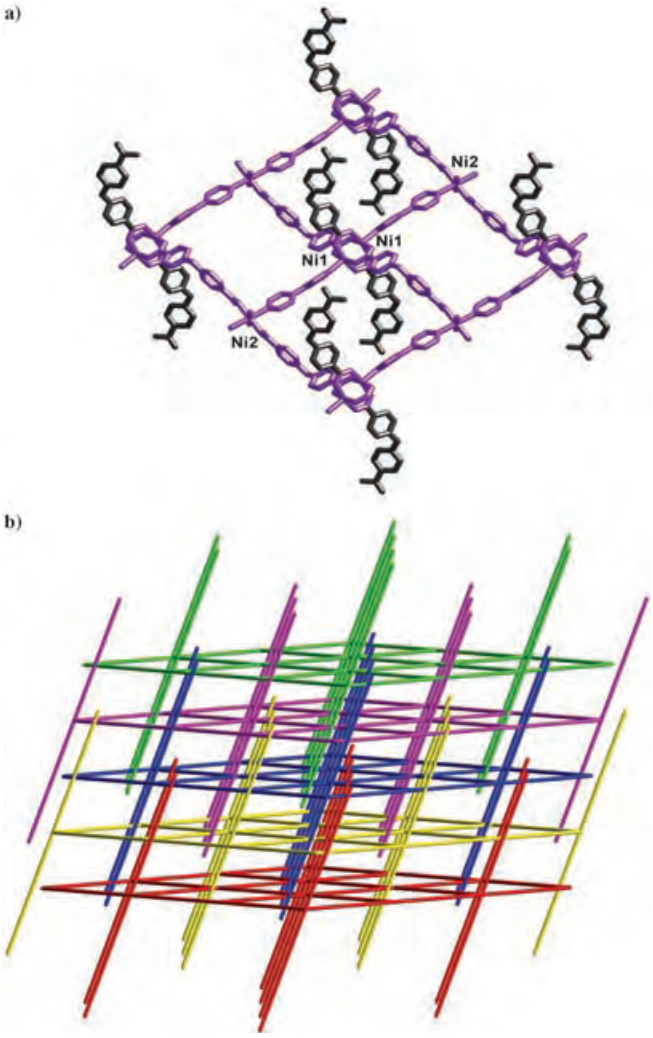

Figure 2. Compound **2**: a) a single 2D square (4^4) layer showing the alternating nodes: single Ni2 atoms and $(Ni1)_2$ paddle wheel units which carry the dangling arms; b) a schematic illustration of the mutual polythreading of five layers.

that result in (1D→2D)[13c] or (1D→3D)[13d] polythreaded arrays. Until now, the only known example of a (2D→3D) polythreaded network assembled from 2D motifs is the complex $[Zn(Hbtc)(4,4'\text{-bpy})]_n$ (btc = 1,2,4-benzenetricarboxylate) reported by us very recently,[14] in which the threading involves the two nearest layers only because of the shorter length of the dangling arms.

The threading observed in **2** is stabilized by two weak interactions: a π–π stacking arising from the aromatic rings of the oba ligands penetrating into the same void (interplanar distance: 3.65 Å, offset: 1.39 Å), and strong hydrogen bonding involving the uncoordinated carbonyl oxygen atoms from a dangling ligand and a coordinated water molecule of a mononuclear metal center on the third nearest neighboring layer (O···O 2.82 Å). When these hydrogen bonds are taken into account, the resulting structure displays a threefold interpenetrated 3D 6-connected net with α-Po (primitive cubic, pcu) ($4^{12}.6^3$) topology. A distorted cubelike unit of the resulting α-Po nets (Figure 3a) shows dimensions of $12.5\times$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

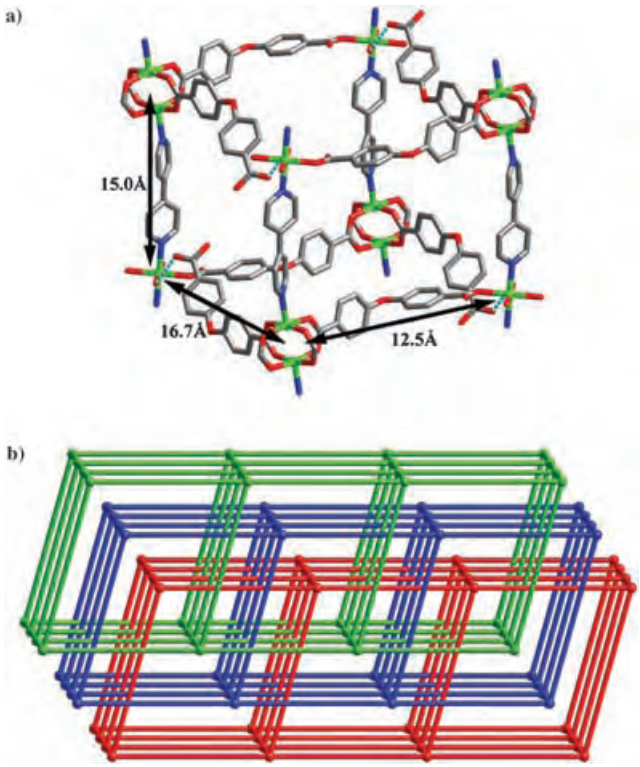

Figure 3. Compound **2**: a) a single distorted cubelike unit of the α-Po net with the relative dimensions 12.5 × 15.0 × 16.7 Å; b) a schematic view of the threefold interpenetrating α-Po network that is formed when H bonds are taken into account.

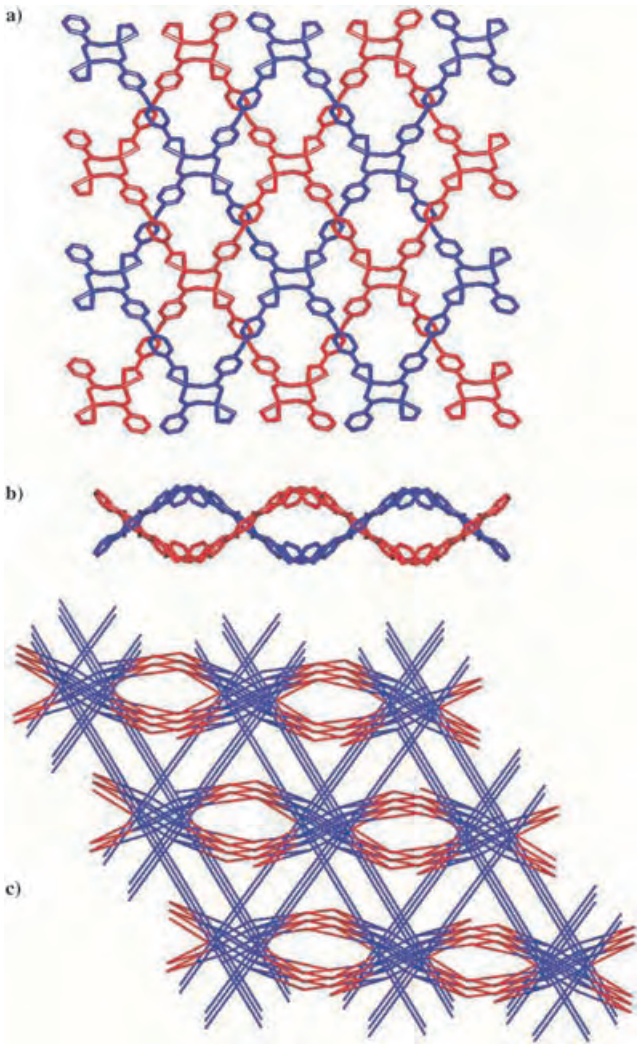

Figure 4. Compound **3**: a) twofold parallel interpenetrating layers of (4.8^2) topology; b) a view down the *c* axis of the twofold interpenetrating layers showing the elliptic-shaped channels; c) a schematic representation of the (3,5)-connected self-penetrating 3D net of (4.8^2)($4.6^4.8^4.10$) topology.

15.0 × 16.7 Å. The three interpenetrating nets of the 3D array originate from layers of A, B, and C type (Figure 3b). An analysis of the topology of interpenetration according to a recent classification[3] reveals that compound **2** belongs to Class Ia (all the interpenetrated nets are generated only by translation and the translating vector is [100] (9.90 Å). The overall entanglement still leaves voids that are occupied by two water molecules and one bpy guest molecule that form an intricate net of H bonds across different layers.

Compound **3** is a new (3,5)-connected 3D self-penetrating network with an unprecedented topology whose structure can be described as follows. First of all, it comprises neutral layers of composition [Ni(oba)]. Within these layers the nickel atoms are coordinated by four oxygen atoms from one chelating and two μ_2-bridging carboxylate ions of oba ligands (Ni-O in the range 2.004(3)–2.162(4) Å) to give dinuclear units that are further extended by bridging oba ligands into 2D layers (Figure 4a). From consideration of the Ni and C atoms of the μ_2-carboxylate groups as nodes, we can see that the layers are comprised of octagonal and rhombic meshes with a 3-connected (4.8^2) topology. The diagonals of the distorted rhombic windows are about 4.3 and 4.4 Å, while the dimensions of the distorted octagonal windows, estimated from the maximum distances between opposite vertices, are about 16.9 × 22.9 Å. The resulting layers are highly undulated as a consequence of the bent geometry of the dicarboxylate ligands and the twisting of its phenyl rings (dihedral angle of ca. 83°). The corrugation of the sheets makes the parallel interpenetration of two such layers possible (the average planes of the layers are coincident) to give a twofold interpenetrated array. Entanglement of layers with (4.8^2) topology are rare compared to layers that show the more common square (4^4) or hexagonal (6^3) topologies, and only few examples are known that include sheets that are interpenetrated in a parallel twofold[15] and threefold[16] manner. These sets of twofold interpenetrated layers generate elliptic-shaped channels running along the *c* axis (Figure 4b) that are populated by the guest water molecules. The twofold layers stack in an ABAB sequence parallel to the plane defined by the (**a**,**b**) and **c** vectors, and are interconnected to the two closest layers (above and below the average plane) through bpy bridges disposed along the crystallographic *a* and *b* axes. Two bpy ligands are *trans*-coordinated to each metal center in an axial position (Ni···N 2.096(3) Å) to give a unique (3,5)-connected 3D framework with an unprecedented (4.8^2)($4.6^4.8^4.10$) topology. In this simplification the 5-con-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nected nodes are the metal atoms and the 3-connected ones are the carbon atoms of the oba ligands bridging the dimetallic unit (Figure 4c).

The network of compound **3** clearly results in self-penetrating since it is generated from linking twofold-interpenetrated sheets. The self-penetration feature is not very common within coordination polymers and only a limited number of self-penetrated nets have been reported to date.[4] A drastic simplification of compound **3** is that it is a 6-connected uninodal net with an unprecedented topology.[17]

In conclusion, although the three compounds described herein were obtained from the same starting building blocks they display quite different structures (ranging from 1D to 3D) and show unusual features of polycatenation, polythreading, and polyknotting. Thus, this study highlights an intriguing feature of coordinative network chemistry in producing rich architectures and topologies.

Experimental Section

1–**3**: A mixture of $Ni(NO_3)_2 \cdot 6H_2O$ (145 mg, 0.5 mmol for **1**–**3**), 4,4′-oxybisbenzoate (129 mg, 0.5 mmol for **1**–**3**), 4,4′-bipyridyl (156 mg, 1 mmol for **1** and **2**; 78 mg, 0.5 mmol for **3**), and water (10 mL) was placed in a 23-mL teflon reactor. After the pH values had been adjusted to 6.5, 5.5, and 7.8 for **1**, **2**, and **3**, respectively, by addition of triethylamine, the mixture was heated at 140 °C for 3 days. Green crystals of **1**–**3** were obtained on cooling the mixture to room temperature at 10 °C h^{-1}.

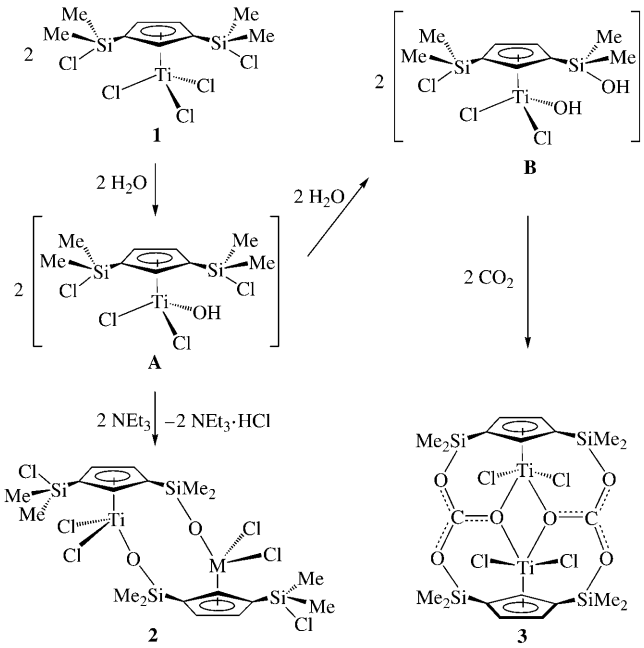
Carbon Dioxide Activation Assisted by a Bis(chlorodimethylsilyl)cyclopentadienyl Titanium Compound**



David Santamaría, Jesús Cano, Pascual Royo, Marta E. G. Mosquera, Tomás Cuenca,* Luis M. Frutos, and Obis Castaño*

A great deal of interest has focused on the role of metal ions as the active centers in the fixation of CO_2 and its transformation.[1] Activation of CO_2 by hydroxo and oxo metal complexes to afford metal hydrogencarbonato and carbonato species, respectively, is related to the function of the carbonic anhydrase metalloenzyme,[2] which catalyzes the physiologically important hydration of CO_2 to hydrogencarbonate [Eq. (1)].

$$\text{[M]-OH or [M]-O-[M]} \xrightarrow{CO_2} \text{[M]-CO}_3\text{H or [M]-CO}_3\text{-[M]} \quad (1)$$

This type of reaction is common for the late-transition metals[3] and is known for main-group organometallic species.[4] Nevertheless, the carbonato derivatives reported for complexes of Group 4–6 metals are synthesized by alternative methods[5] based on reactions of metal precursor compounds with carbonate salts X_2CO_3 (X = K, Bu_4N) and NH_4HCO_3 or by methods that involve the disproportionation of CO_2.

Herein, we describe the use of the bis(chlorodimethylsilyl)cyclopentadienyl titanium(IV) compound **1**,[6] which was reported previously for the in situ activation of CO_2. The carbonato titanium(III) derivative **3** was serendipitously obtained when a dilute solution of **1** in wet toluene was exposed to air for several days (Scheme 1). This reaction proceeded in better yield (43% after purification) when a solution of **1** in toluene was treated with a saturated aqueous solution of CO_2 to give **3**, which was isolated as an analytically pure and highly air-stable diamagnetic orange crystalline solid. However, hydrolysis of **1** carried out in the presence of NEt_3 resulted in no reaction with CO_2 and the μ-oxo titanium(IV) derivative **2** and NEt_3·HCl being obtained (Scheme 1). The reaction of **1** with K_2CO_3 in THF or toluene afforded a mixture of unidentified compounds that did not contain **3**.

Scheme 1. Possible reaction pathways for the synthesis of **2** and **3**.

Hydrolysis of the Group 4 metal/chloro complexes usually proceeds with initial transformation of the metal–chlorine bonds so that intermediate complexes are formed which contain rather uncommon, discrete terminal Group 4 metal–hydroxo bonds.[7] These species subsequently condense to give polynuclear compounds stabilized by μ-oxo bridges.[8] We propose that the carbonato complex **3** results from the in situ formation of intermediate Si–OH/Ti–OH terminal bonds (see **A** and **B** in Scheme 1) and a further insertion reaction of CO_2 with simultaneous reduction to the highly stable titanium(III) compound **3**. This mechanism of formation is consistent with the high stability of **3**, which remains unaltered when left for weeks in air; with the formation of the μ-oxo complex **2** in the presence of a deprotonating agent; and also with the observed stability of **2**, as it did not react with CO_2 to give **3** after several days at temperatures higher than 120 °C.

The ^{1}H NMR spectrum ($CDCl_3$, 25 °C) of complex **3** shows behavior expected for a C_{2h}-symmetric molecule with an A_2B spin system for the cyclopentadiene (Cp) protons and with two resonances of the two nonequivalent methyl groups of the four equivalent {$SiMe_2$} fragments (see Experimental Section). The resonances of the carbon atoms of the two equivalent bridging carbonato ligands are observed in the ^{13}C NMR spectrum as one signal at $\delta = 183.7$ ppm. The IR spectrum shows the characteristic ν(C–O) absorption of the carbonato ligand at 1375 cm^{-1}. The ^{1}H and ^{13}C NMR spectra ($CDCl_3$, 25 °C) of complex **2** show behavior expected for a disymmetric molecule with two resonances for the diastereotopic methyl groups of two equivalent {$SiMe_2O$} fragments rather than the singlet observed for the related symmetrical complex [{$TiCl_2$[μ-($OSiMe_2$-η^5-C_5H_4)]}$_2$][9] reported previ-

ously. The resonances for the $SiMe_2Cl$ protons of **2** appear as two singlets with chemical shifts analogous to those observed for **1** and for $[TiCl_3(\eta^5\text{-}C_5H_4SiMe_2Cl)]$.[9]

The molecular structure of **3**[10] was determined by X-ray diffraction (Figure 1), which indicates a square-base pyramid coordination for the titanium center. The $\{Ti_2O_2\}$ core is planar, with the two carbonato ligands and the four Si atoms also located in a second plane (maximum deviation = 0.0447 Å) with the dihedral angle between the planes at 128°. The Ti–Ti distance (3.2901(9) Å) is longer than that expected for a conventional Ti–Ti bond (ca. 2.68–2.85 Å).[11]

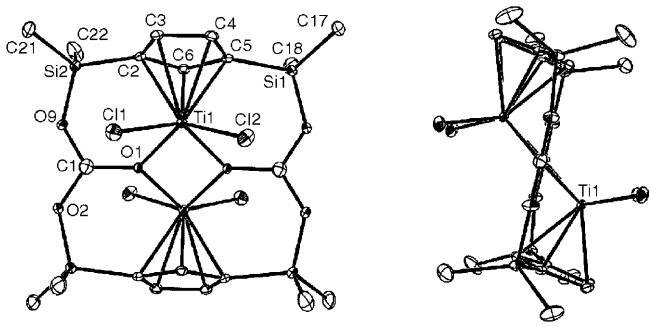

Figure 1. ORTEP view of **3**, with 30% probability ellipsoids. Selected bond lengths [Å] and angles [°]. Ti-Ti 3.2901(9), C1-O2 1.353(3), C1-O9 1.357(3), C1-O1 1.407(3), Ti1-O1 2.0495(14); O2-C1-O9 116.9(2), O2-C1-O1 121.6(2), O9-C1-O1 121.4(2), Cl2-Ti1-Cl1 89.21(3).

To clarify the nature of the $Ti(d^1)$–$Ti(d^1)$ electron coupling and, consequently, the diamagnetism of the molecule, we carried out a theoretical investigation of the electronic properties of **3**. Single-determinant wave functions (Hartree–Fock), as well as DFT methods,[12] failed to explain the stability of the singlet state of this molecule.[13] This fact reflects the importance of the correlation energy in the study of the d^1–d^1 electron coupling. Only by including the correlation energy[14] through the second-order-perturbation method (MP2)[15] is it possible to explain the high stability of the singlet species, which is 57.6 kcal mol^{-1} more stable than the triplet state (49.2 kcal mol^{-1}, as obtained from the X-ray crystal structure), and hence its diamagnetic character. The d^1–d^1 electron coupling basically arose from the in-phase interacting d_{z^2}-like orbitals located in each Ti atom (Figure 2). This in-phase orbital interaction collects almost all of the electronic density between the two Ti atoms,[16] as it is the principal interaction responsible for the spin pairing. Also, minor contributions from the two bridging oxygen atoms increase the strength of the interaction (Figure 2).

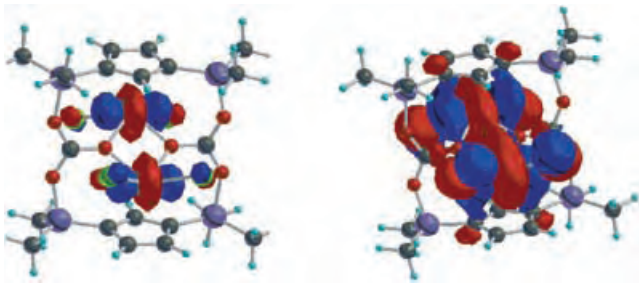

Figure 2. Depiction of the highest-occupied molecular orbitals showing the Ti–Ti in-phase orbital interaction at two different wave-function amplitudes (0.04 and 0.02 (left and right, respectively)). Minor contributions from the two annular oxygen atoms are present.

The Ti–Ti in-phase orbital interaction is strong enough to provide a high stability to the singlet species, as this state is only populated at room temperature. An S_0/T_1 intersystem crossing should not be an efficient path to populate the triplet state, as a result of low spin-orbit coupling[17] as well as the high S_0–T_1 energy gap.

In summary, we have demonstrated that a bis(chlorodimethylsilyl)cyclopentadienyl titanium(IV) derivative can fix CO_2 and transform it into a carbonato ligand with simultaneous reduction to give an air-stable diamagnetic titanium(III) compound. A theoretical investigation of the electronic properties of the molecule demonstrates the high stability of the singlet versus the triplet state and justifies the diamagnetism exhibited by the carbonato complex **3**.

Experimental Section

2: Distilled and degassed water (27 μL, 1.49 mmol) and NEt_3 (0.42 mL, 2.96 mmol) were added to a solution of **1** (0.6 g, 1.48 mmol) in toluene (50 mL). The cloudy reaction mixture was stirred over 24 h at room temperature and then filtered to give a pale-orange solution. The solvent was removed under vacuum and the residue was extracted with hexane. The resulting solution was concentrated to 20 mL and cooled to −35 °C to give a light-orange solid which was isolated by filtration and identified as **2** (0.58 g, 0.827 mmol) 56% yield. Elemental analysis (%) calcd for $C_{18}H_{30}O_2Si_4Ti_2Cl_6$: C 30.92, H 4.32; found: C 30.75, H 4.48; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.55$, 0.60, 0.78, 0.83 (4 s, 4 × 6H, $SiMe_2$), 7.06, 7.19, 7.35 ppm (3 m, 3 × 2H, C_5H_3); ^{13}C NMR (300 MHz, $CDCl_3$): $\delta = 0.2$, 0.6, 2.5, 2.9 (4 × $SiMe_2$), 127.4, 130.7, 134.0 (C_5H_3), 133.7, 135.4 ppm (C_{ipso}, C_5H_3).

3: An excess of distilled and degassed water (67 μL, 3.70 mmol) was added to a pale-yellow solution of **1** (0.3 g, 0.74 mmol) in toluene (200 mL) saturated with CO_2. Formation of the same white solid suspension described above was observed. The reaction mixture was stirred over 42 h at room temperature. After that time, the reaction mixture changed to pale orange. The solvent was removed to give an orange solid that was extracted with a mixture of toluene/pentane and isolated as an orange crystalline solid identified as **3** (0.27 g, 0.086 mmol) 43% yield. Single crystals of **3** suitable for X-ray diffraction studies were grown from a solution of $CHCl_3$. Elemental analysis (%) calcd for $C_{22}H_{32}O_6Si_4Ti_2Cl_{10}$: C 27.67, H 3.38; found: C 27.87, H 3.44; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.51$, 0.60 (2s, 2 × 12H, $SiMe_2$), 6.88 (m, 2H, C_5H_3), 7.88 ppm (m, 4H, C_5H_3); ^{13}C NMR (300 MHz, $CDCl_3$): $\delta = -1.39$, −0.50 ($SiMe_2$), 135.6, 136.5 (C_5H_3), 141.4 (C_{ipso}, C_5H_3), 183.7 ppm (CO_3); IR: $\tilde{\nu} = 3218$, 2961 (C–H (C_5H_3)), 1375 (C=O (CO_3^{2-})), 1262, 1221 (Si–CH_3 ($SiMe_2$)), 834, 800 (Ti-O-Ti), 676 cm^{-1} (Si–Cp ligand).

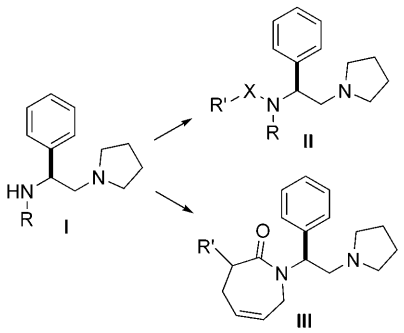
Solid/Solution-Phase Annulation Reagents: Single-Step Synthesis of Cyclic Amine Derivatives



Roland E. Dolle, Calum MacLeod, Blanca Martinez-Teipel, William Barker, Pamela R. Seida, and Torsten Herbertz*

Single-step amine-derivatization chemistry is one of the most powerful and practical streamlined synthetic techniques available to the medicinal and combinatorial chemist. Acylation, sulfonylation, ureidoation, heteroarylation, reductive amination, and alkylation are used extensively to create libraries of amine derivatives.[1] Researchers involved in drug discovery particularly appreciate the importance of such high-throughput chemistries used to create nascent structure–activity relationships (SARs) and to expand the intellectual property field around a novel biologically active lead. Amine derivatization is conveniently carried out in the solution phase with a scavenger resin(s) to assist in the removal of the excess derivatizing reagent and/or product purification.[2] Activated resins have also been developed in which an amine is treated with a resin-bound functional-group-transfer reagent suspended in a suitable solvent.[3a] Following filtration, which removes both the spent and excess reagent, and solvent evaporation, derivatives are generally produced in over 75% purity, which is suitable for biological screening. Examples of this type of reagent are the commercially available carboxyl- and sulfonyl-activated tetrafluorophenol (TFP) resins developed by Salvino et al. for amide and sulfonamide synthesis.[3b]

During the course of a drug-discovery program directed toward the identification of peripherally restricted κ-opioid receptor agonists, we conducted a high-throughput *N*-derivatization campaign for diamine **I**, including the use of TFP resins, to define the SAR in this region of the pharmacophore (**I**→**II**; X = CO, SO_2, HNCO; Scheme 1). In related SAR studies, conformationally restricted analogues **III** were prepared by ring-closing metathesis as the method for the generation of the azepinone ring.[4] In contrast to the hours of labor required to generate acyclic analogues **II** by semi-automated parallel synthesis, the synthesis of cyclic analogues **III** required a multistep sequence and several months of labor. Access to robust reagents to carry out single-step amine annulations would have accelerated the synthesis and biological evaluation of **III** and related heterocyclic analogues. However, there are no generally recognized "off-the-shelf"

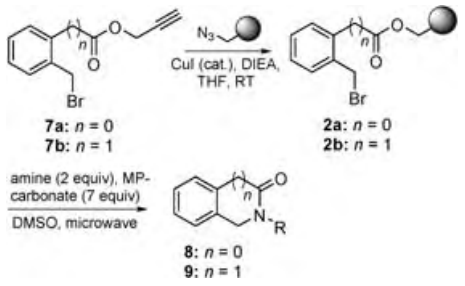
Scheme 1. Amine derivatization leading to κ-opioid receptor agonists.[4]

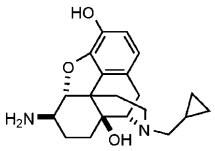
reagents for high-throughput amine annulation. An exploratory chemical-technology program was initiated to address this gap in methodology, and so develop reagents for rapid amine annulation. Approaches were sought to produce monocyclic, bicyclic, spirocyclic, and polycyclic ring systems from primary amines in one step that would be amenable to semiautomated library production in a manner analogous to the acyclic derivatization protocols. The acronym SPAn, derived from solid/solution-phase annulation, collectively refers to the technology, reagents, and products thereof. The first examples of this conceptually new family of SPAn reagents, which yield five-, six-, and seven-membered heterocycles from primary amines, are introduced.

A tandem *N*-alkylation/intramolecular acylation reaction that yields an isoindolinone was selected as the prototypical annulation reaction to be investigated (**1/2**→**3**→**4**; Scheme 2).[5] The results of the initial solution-phase experi-

Scheme 2. Annulation strategy for isoindolinone **4**.



ments with assorted esters **1** and 2,2-diphenylethylamine in a range of solvents under both thermal and microwave reaction conditions were unsatisfactory. As a result, our attention turned to the employment of a cyclorelease strategy[6] and the preparation of resin-bound reagent **2**. The dilemma that immediately surfaced with this approach was the efficient loading of acid **5**. Direct coupling of **5** to Wang resin by employing a range of coupling reagents and reaction conditions resulted in capricious loading, even when **5** was used in large excess. Substantial amounts of lactone **6** formed, which is a testament to the reactivity and instability of this material. In light of this experience and the potential for the troublesome loading of other reactive esters of interest, an alternative method for the generation of the resin-bound reagent was required. The copper(I)-catalyzed 1,3-dipolar cycloaddition of azides and terminal alkynes is a robust ligation method that occurs under very mild reaction conditions.[7] Gmeiner and co-workers recently employed this approach to create new amide-backbone[8a,b] and acrylate-based (REM) linkers[8c] for solid-phase organic synthesis. With this methodology in mind, bromide **7a** (5 equiv; prepared from 2-bromomethylbenzoic acid (1 equiv), propargyl alcohol (3 equiv), *N*,*N*′-diisopropylcarbodiimide (1.2 equiv), and dimethylaminopyridine (cat.) in 48% yield) was added to a suspension of Merrifield azide resin[8a] in dichloromethane followed by the addition of excess diisopropylethylamine (DIEA) and 0.02 equivalents of CuI. The reaction was monitored by single-bead FTIR (disappearance of absorption at 2096 cm^{-1}), and resin **2a** was obtained in good yield (65% as determined by elemental analysis) after 20 hours on an orbital shaker. Importantly, the loading was reproducible (5 runs, 65–70% yield). Subsequent reaction of **2a** with 2,2-diphenylethylamine (2 equiv) in dimethyl sulfoxide (DMSO) with excess MP-carbonate (7 equiv; Polymere Labs) under microwave conditions (150°C for 15 min following a 30-min temperature ramp-up from 25 to 150°C) afforded the desired annulated product **4** in 90% crude purity (UV: $\lambda 1 = 220$ nm; $\lambda 2 = 254$ nm) and 33% yield of the isolated product. It was subsequently found that both the chloro and iodo ester analogues of **2** also load efficiently, but only the iodo resin gave equivalent or higher yields and purity of **4**. For this reason, bromide and iodide were the preferred halogen leaving groups in the SPAn reagents. Unlike **1**, which spontaneously decomposed to **6** and other unidentified materials, the resin-bound reagent **2a** was stable for months when stored at ambient temperature and humidity.



Given the success of this first annulation reaction, the chemistry was expanded to include homologue **2b** and the preparation of a 20-member library of isoindolinones **8** and isoquinolones **9** (Table 1). A range of primary amine substrates was successfully annulated in a single step, including substituted alkyl- **A1**, **A4**; alkylaryl- **A2**, **A9**; heteroarylalkyl- **A3**, **A6–8**; and heterocycloalkylamines **A5** and the sterically demanding 6β-naltrexamine (**A10**). An average yield of 30% and a purity of greater than 90% was obtained following chromatographic purification.

To explore the scope of the SPAn chemistry in terms of ring sizes that may be obtained, iodo esters **10a–d** were synthesized (Scheme 3). Reaction of the resins with a representative amine, phenoxyethylamine (**A1**), under the reaction conditions defined above afforded pyrrolidinone (**11c**; 29%) and piperidinone (**11d**; 24%; Scheme 4). Azetidinone (**11a**) and azepinone (**11b**) were not detected in the crude reaction mixtures. Seven-membered-ring annulation products were obtained, however, provided that a conformational constraint biased the system toward cyclization. For example, reagents **10m–o**, in which the acyl and haloalkyl groups are *ortho*-disposed on an aromatic ring, furnished **11m**, **11n**, and **11o** (21, 23, and 12%, respectively) upon annulation of **A1**.

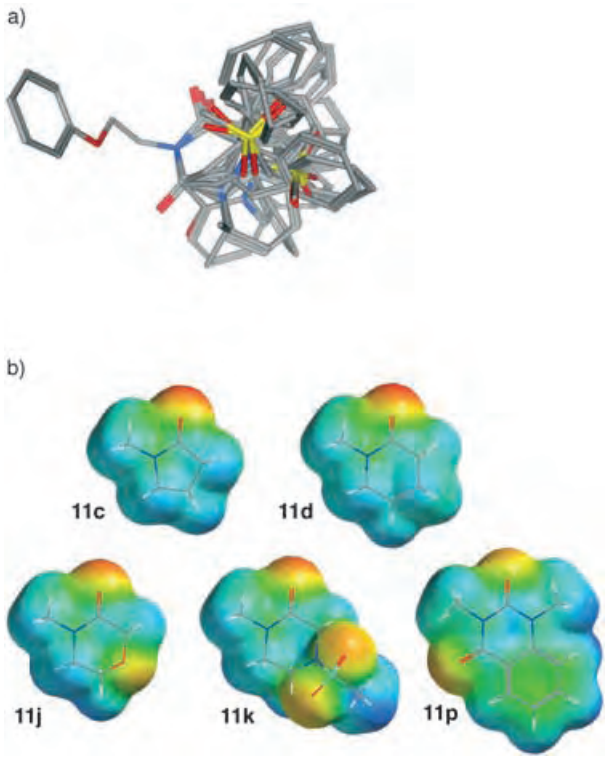
[a] Yield of isolated product, as purified by HPLC.

Scheme 3. Additional selected examples of SPAn reagents.

The introduction of substituents into these reagents adds elements of stereochemical and shape diversity in the annulation products. SPAn reagents **10e–i** with pendent aryl (phenyl) or alkyl (ethyl) groups furnishes substituted pyrrolidinones **11e,f** and piperidinones **11g–i** (**A1**; 23–62% yield). This result is significant for two reasons: First, the chemical reactivity of the SPAn reagents was expanded to include displacement of less-reactive nonbenzylic halogen centers in the tandem alkylation/intracyclization process. Second, the unique three-dimensional disposition of the ring functionalities present in **11e–i** permits a thorough interrogation of biological space. The differential display of the chemical functionalities by the annulation products is ideal for the development of a SAR against a given molecular target. These results are analogous, albeit accentuated by the conformational rigidity of the cyclic derivatives, to SAR information that may be obtained when traditional acyclic derivatization is performed. The swath of chemical space occupied by the SPAn products is assessed visually by examination of the overall topography of all of the annulation products listed in Scheme 4 (Figure 1a). The importance of shape sampling in relation to biological activity is illustrated in the derivatization of 6β-naltrexamine (**A10**) with reagents **2a,b**. The α-phenylpyrrolidinone derivative **8j** exhibits a K_i value of 1.6 nM against the μ-opioid receptor, whereas $K_i =$



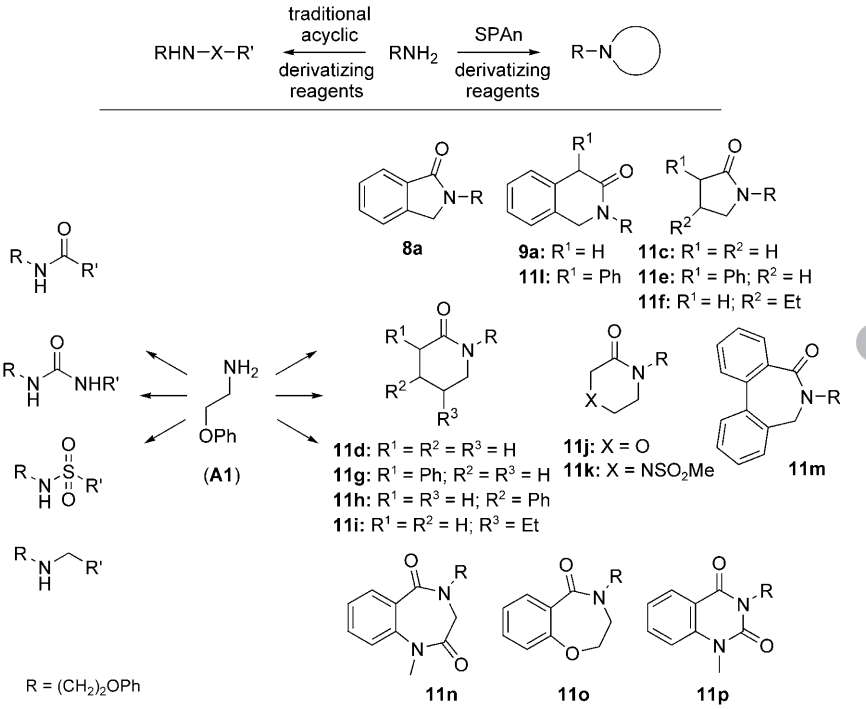


Figure 1. a) The collective topology of SPAn products given in Scheme 4 indicates dense interrogation of chemical space. The phenoxyamide linkage was kept fixed and low-energy conformations of the side chains of **11c–p** were calculated by using the MMFF94x forcefield in the molecular operating environment (MOE; Chemical Computing Group). The structures were aligned with respect to the atoms making up the phenoxyamide linker. b) Graphical comparison of electrostatic potential surfaces of **11c,d** versus **11j,k,p**, as derived from HF/3-21g* calculations by using Spartan '04. The electrostatic potential values range from −67 (red) to 37 kcal mol^{-1} (blue). The phenoxyethyl group is replaced with a methyl group for clarity.

Scheme 4. Use of SPAn reagents for cyclic amine derivatization.

56 nM for the α-phenylpiperidinone derivative **9j** at this receptor. The increase in ring size by a single methylene unit causes a remarkable 35-fold decrease in binding affinity.

Replacement of the methylene carbon atoms in **10b**,**c** by a heteroatom generates reagents **10j**,**k** which afford morpholinone **11j** (**A1**; 29%) and piperazinone **11k** (**A1**; 21%). These cyclic and related heteroatom-containing derivatives **11n–p**, give rise to electrostatic potential (EP) surfaces, distinct from their carbon congeners.[9] This result is again evident upon visual inspection of the EP surfaces generated for **11j**,**k**,**p** and carbon congeners **11c**,**d** (Figure 1b). The complementarity of the EP surface and molecular shape are two mutually inclusive determinants for high-affinity binding. Both of these molecular attributes are readily probed by employing the annulation chemistry.

A new family of reagents for amine derivatization, termed SPAn reagents, enables the single-step conversion of primary amines to cyclic derivatives. The annulation protocol, together with existing protocols for the preparation of amides, sulfonamides, ureas, and other acyclic derivatives in one step (Scheme 4), represents a powerful ensemble for streamlined synthesis. Resin loading, a major obstacle in reagent preparation, was overcome through the 1,3-dipolar cycloaddition reaction of solution-prepared propargyl esters and Merrifield azide resin. The reagents require no further chemical manipulation or activation for their use and display excellent shelf stability. Microwave heating was essential to obtain the annulation products as discrete compounds **11c–p** or in a library format (**2a**,**b**→**8/9a–j**, respectively). Tandem *N*-alkylation/intramolecular acylation is utilized in this report as the annulation manifold to yield heterocyclic lactams. Reagents that afford cycloalkylamines, diazaspirocycles, and other non-lactams have also been developed by us, thus increasing the molecular diversity of the cyclic derivatives obtained. Application of SPAn chemistry in the context of finding new lead compounds and SAR development will be reported subsequently.[10]

Asymmetric Catalysis

DOI: 10.1002/anie.200501478

Highly Regio- and Enantioselective Asymmetric Hydroformylation of Olefins Mediated by 2,5-Disubstituted Phospholane Ligands**

Alex T. Axtell, Christopher J. Cobley, Jerzy Klosin, Gregory T. Whiteker, Antonio Zanotti-Gerosa, and Khalil A. Abboud*

Asymmetric hydroformylation (AHF) is a powerful synthetic methodology that allows conversion of olefins into optically active aldehydes in a single step [Eq. (1)].[1] The aldehyde

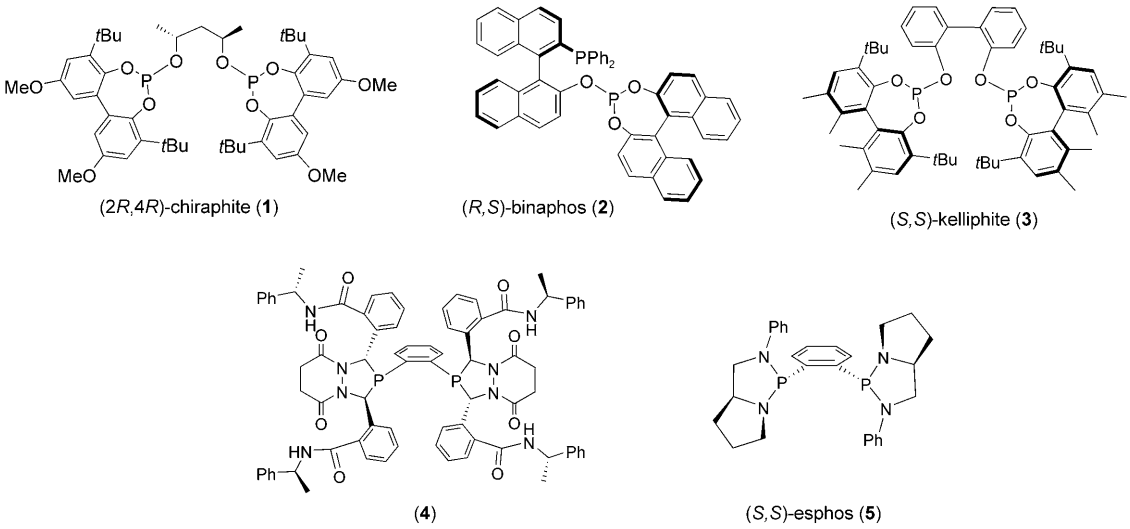
(1)

group is one of the most versatile functional groups and can be readily transformed into a variety of high-value-added chiral chemicals, such as amines, imines, alcohols, and acids.[2] Even though AHF offers great promise to the fine-chemical industry, this reaction has not been utilized on a commercial scale because of several remaining technical challenges; among the most important to overcome are a) low reaction rates at low temperatures for reactions in which good selectivities are usually observed, b) difficulties in controlling the regio- and enantioselectivities simultaneously, and c) limited substrate scope for any single ligand.

The reaction rates of Rh-catalyzed hydroformylations are commonly slower than those of asymmetric hydrogenations that are conducted near ambient temperature. Commercially viable rates in AHF can be achieved at 80–120 °C (turnover rates of several thousand per hour); however, lower regio- and enantioselectivities are usually observed at these high temperatures. Thus, the most desired characteristic of the new generation of AHF ligands should be the ability to produce optically active aldehydes at high temperatures without compromising product selectivity.

Only a few chiral ligands have been successfully applied in AHF reactions (Scheme 1). Among the most effective are (2*R*,4*R*)-chiraphite (**1**)[3] and its analogues,[4] which exhibit enantioselectivities of up to 90 % *ee* for the hydroformylation of styrene at low temperatures; (*R*,*S*)-binaphos (**2**),[5] which shows high enantioselectivities for the hydroformylation of many structurally diverse olefins; (*S*,*S*)-kelliphite (**3**), which is effective for the hydroformylation of allyl cyanide[6] and vinyl acetate;[7] and (*S*,*S*)-esphos (**5**), which displays a high enantioselectivity for the hydroformylation of vinyl acetate.[8] Together with Landis and co-workers, we recently reported[9] the application of diazaphospholane ligands **4** in AHF reactions which showed outstanding hydroformylation rates and very high enantioselectivities for reactions with styrene and allyl cyanide substrates. Diazaphospholane **4** is especially selective for vinyl acetate at 80 °C (96 % *ee*, b/l = 35). This ligand family is structurally related to 1,2-bis(2,5-dialkylphospholano)benzene (duphos; **6**–**8**), 1,2-bis(2,5-dialkylphospholano)ethane[10] (bpe; **9**–**11**), and especially the recently reported (*R*,*R*)-1,2-bis(2,5-diphenylphospholano)ethane ((*R*,*R*)-Ph-bpe; **12**) Scheme 2).[11] The duphos and bpe ligands[12] have been proven to be exceptional ligands for the asymmetric hydrogenation[13] of dehydroamino acids and mono- and disubstituted itaconates, among numerous other applications, but their use has not been reported for AHF reactions.

Herein, we report that **12** is an excellent ligand for the rhodium-catalyzed AHF of styrene, allyl cyanide, and vinyl acetate at high temperatures (80–100 °C). (*R*,*R*)-Ph-bpe (**12**) displays the best regio- and enantioselectivities reported to date for the hydroformylation of styrene and allyl cyanide and the second best for the hydroformylation of vinyl acetate. The reaction rates obtained at these elevated temperatures render this catalytic system amenable to industrial applications.



The hydroformylation reactions were carried out at 80 °C and 1.034 MPa CO/H_2 pressure with substrate/catalyst molar ratios of 5000:1 and a catalyst concentration of 0.37 mM. Phospholane and phosphetane ligands **6**–**16** (Scheme 2) and previously reported ligands **1**–**4** were evaluated under identical conditions for comparison. Active catalysts were prepared by combining $[Rh(acac)(CO)_2]$ (acac = acetylacetonate) with 1.2 equivalents of each bidentate ligand (2.1 equiv for **16**) in toluene followed by pressurizing the resulting solution with syngas (CO/H_2, molar ratio of 1:1). Styrene, allyl cyanide, and vinyl acetate underwent simultaneous hydroformylation under constant pressure, with the gas uptake being monitored continuously. Olefin conversion, together

Scheme 1. Chiral ligands that have been successfully applied in AHF reactions.

Scheme 2. Phospholane and phosphetane ligands.

with the regio- and enantioselectivities of the products, was determined by using gas chromatography on a chiral stationary phase, as previously described.[7] The syngas uptake curves demonstrate that all the phospholane ligands screened exhibited low hydroformylation rates except for **12** (Figure 1). The lowest hydroformylation rates were observed for the ferrocenyl phospholane and phosphetane[14] ligands **13**–**15** (Table 1, entries 12–14). (*R*,*R*)-Ph-bpe (**12**) exhibits an average turnover frequency of 1139 h^{-1}, which is about five times more active than the second fastest phospholane **11** and only about two times slower than **1** and **2**. The most likely reason for the increased activity of **12** compared with the other phospholane ligands is the presence of the electron-withdrawing phenyl rings that reduce the overall basicity of the phosphine moiety. The IR spectroscopic data ν_{CO} obtained for [Mo(CO)$_4${(*S*,*S*)-Me-bpe}], [Mo(CO)$_4${(*S*,*S*)-*i*Pr-bpe}], and [Mo(CO)$_4${(*R*,*R*)-Ph-bpe}] (2012, 2011, and 2015 cm^{-1}, respectively)[15] support the assertion that (*R*,*R*)-Ph-bpe is the least basic phosphine amongst the bpe ligands. It is well established that electron-poor phosphines lead to more active catalysts in Rh-catalyzed hydroformylation.[1a]

The olefin conversion and regio- and enantioselectivity data for the ligands investigated in this study are summarized in Table 1. The olefin conversion data are in close agreement with the syngas uptake curves and clearly demonstrate that **12** exhibits the fastest hydroformylation rates of all the phospholane and phosphetane ligands in this study (Table 1, entry 11 versus entries 6–10 and 12–15). The enantioselectivity data show that bpe and duphos ligands with larger substituents in the 2,5-positions of the phospholane rings (*i*Pr and Ph versus Me and Et) lead to noticeably higher enantioselectivities. Importantly, the selectivities observed for styrene, allyl cyanide, and vinyl acetate are comparable for a given phospholane ligand, thus suggesting the potential for broad applicability of phospholane ligands to a wide range of substrates. Monodentate ligand **16** has a very poor activity and selectivity, which indicates that the bidentate nature of the ligand is necessary for achieving high regio- and enantioselectivities. Phospholane **12** is the most enantioselective ligand in this study giving 94, 90, and 82% *ee* for the

[a] All the reactions were performed at 80 °C in toluene with 1.034 MPa of CO/H_2 (1:1), L/Rh = 1.2:1 (2.1:1 for **16**), substrate/Rh = 5000:1, catalyst concentration of 0.037 mol %, and a reaction time of 3 h.

reactions of styrene, allyl cyanide, and vinyl acetate, respectively.[16] Phospholane **12** is not only the most enantioselective ligand for the hydroformylation of styrene (including previously reported ligands **1**–**4**), but it also gives an unprecedented high regioselectivity (b/l = 45:1). Under identical conditions, **2**, for example, exhibits a significantly lower regioselectivity (b/l = 4.5:1). The ability of a ligand to give high regioselectivities in AHF (high ratio of branched to linear isomers) is a very important attribute as any amount of achiral linear isomer can be regarded as an additional impurity that must be separated from the desired chiral product. To put the regioselectivities of the styrene products into perspective, the amount of the undesired linear isomer formed with (*R*,*R*)-Ph-bpe (**12**) is 2.2 % (b/l = 45:1), whereas with (*R*,*S*)-binaphos (**2**) it is 18.2 % (b/l = 4.5:1; Table 1, entries 11 and 2). Phospholane **12** also gives the highest enantioselectivity (90 % *ee*, b/l = 7.1:1) in the case of the hydroformylation of allyl cyanide. Under the same conditions, diazaphospholane **4** gives a similar enantioselectivity (87 % *ee*) but a noticeably lower regioselectivity (b/l = 4.1:1). For ligands **1**–**4**, only **3** gives a higher regioselectivity for the hydroformylation of allyl cyanide (b/l = 9.9:1), although with a much lower enantioselectivity (68 % *ee*). Phospholane **12** gives the second best enantioselectivity (82 % *ee*) for the hydroformylation of vinyl acetate but with a high regioselectivity (b/l = 340:1) that is unprecedented. The only ligand that shows higher enantioselectivity for the hydroformylation of vinyl acetate is the recently reported diazaphospholane **4** (96 % *ee*, b/l = 37:1).[9]

A second set of hydroformylation reactions was conducted to compare ligand **12** with ligands **1**–**4** using mixtures of neat olefins at 80 °C and 1.034 MPa pressure of syngas with substrate/catalyst molar ratios of 30000:1 and a catalyst concentration of 0.062 mM. At these very low catalyst loadings, the rate of hydroformylation with **12** (an average turnover frequency of 4467 h^{-1}) was virtually identical to those of **1** and **2** and only slower than **3** and **4** (see Figure 2). The regio- and enantioselectivities achieved under these conditions were comparable to those obtained at the substrate/catalyst ratio of 5000:1 (see Table 2).

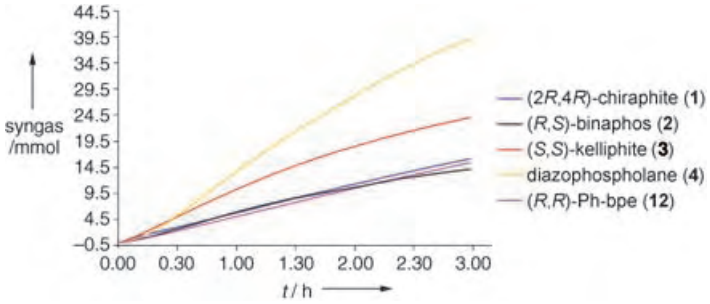

Figure 2. Syngas-uptake curves for reactions were performed with a ratio of olefin/catalyst = 30000:1 (at 80 °C in toluene with 1.034 MPa of CO/H_2 (1:1) and a L/Rh ratio of 1.2:1).

Hydroformylation experiments conducted with the isolated rhodium complex [Rh(acac){(*R*,*R*)-Ph-bpe}], prepared by the reaction of **12** and [Rh(cod)(acac)] (cod = cyclooctadiene), gave identical results to experiments in which the rhodium complex was prepared in situ prior to the hydroformylation reaction. The solid-state structures of **12** and [Rh(acac){(*R*,*R*)-Ph-bpe}] were determined by single-crystal X-ray analysis (Figures 3 and 4).[17]

A preliminary investigation into the reaction conditions (olefin concentration, CO and H_2 pressures, and temperature) reveals that the hydroformylation rate with **12** is first order in olefin concentration, zero order in ligand concentration (ligand/Rh = 1:1–5:1), zero order in H_2 pressure, and negative first order in CO pressure. These observations are consistent with the dissociation of CO from a five-coordinate rhodium dicarbonyl complex as a pre-equilibrium step prior to the rate-limiting insertion of the olefin into the Rh–H bond.[18] Interestingly, the enantioselectivities of all the products were

[a] All the reactions were performed at 80 °C in toluene at 1.034 MPa of CO/H_2 (1:1) with L/Rh = 1.2:1, substrate/Rh = 30000:1, a reaction time of 3 h, and 4.43 mL of a mixture of styrene/allyl cyanide/vinyl acetate/dodecane (1:1:1:0.3 molar ratio).

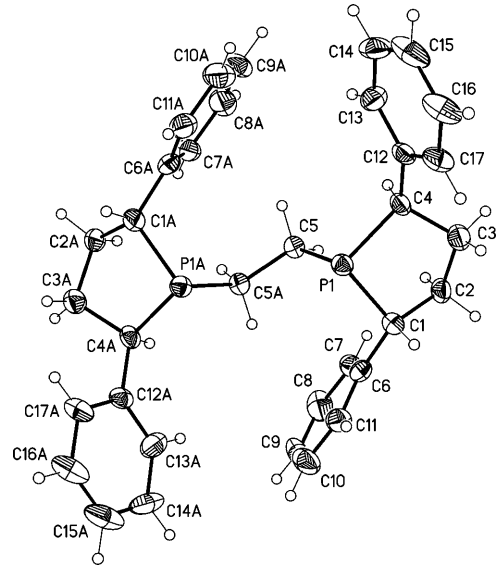

Figure 3. Molecular structure of (*R*,*R*)-Ph-bpe (**12**), with the thermal ellipsoids set at 40% probability.

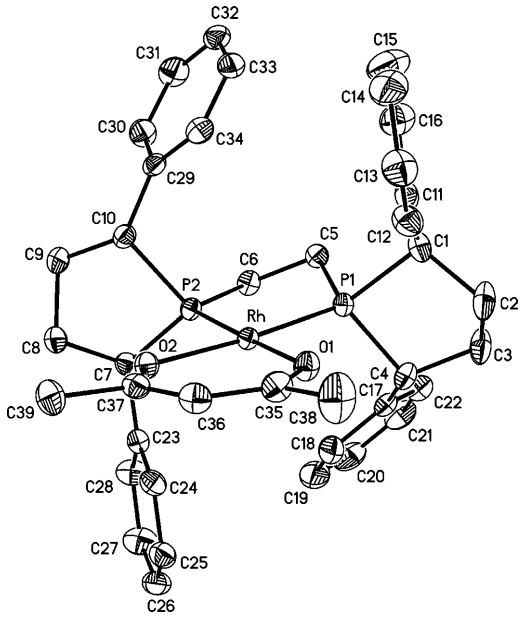

Figure 4. Molecular structure of [Rh(acac){(*R*,*R*)-Ph-bpe}], with the thermal ellipsoids set at 40% probability.

unaffected by variations in the syngas pressure (0.345–3.102 MPa), whereas the regioselectivities were dependent upon pressure, with b/l ratios of 40:1– 45:1 for the styrene products and b/l ratios of 1060:1–155:1 for the vinyl acetate products being observed over these pressures.

In conclusion, (*R*,*R*)-Ph-bpe (**12**) was identified as an excellent ligand for asymmetric hydroformylation which gives state-of-the-art regio- and enantioselectivities for styrene, allyl cyanide, and vinyl acetate, while maintaining commercially viable turnover rates over 4000 h^{-1} at 80 °C. The remarkable ability of phospholane-based ligands **12** and **4** to yield very high enantioselectivities at high temperatures renders these ligands suitable for large-scale industrial applications.

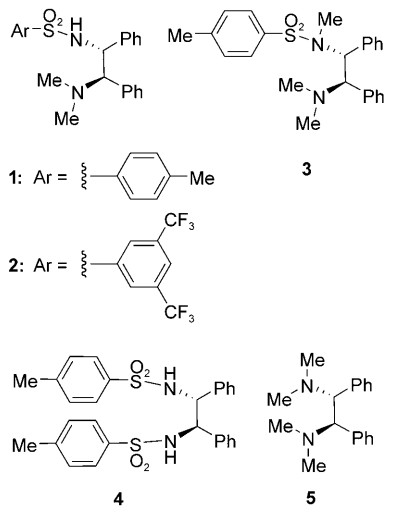
Asymmetric Synthesis

DOI: 10.1002/anie.200501408

Highly Enantioselective Catalytic Thiolysis of Prochiral Cyclic Dicarboxylic Anhydrides Utilizing a Bifunctional Chiral Sulfonamide**

*Takashi Honjo, Shigeki Sano, Motoo Shiro, and Yoshimitsu Nagao**



Asymmetric differentiation between two identical carbonyl groups of prochiral σ-symmetric dicarboxylic acid derivatives by using an enzymatic or a nonenzymatic procedure is a rational and useful strategy for the asymmetric synthesis of biologically active compounds and medicines. The resultant chiral products can be subjected to further so-called "enantioconvergent" and "enantiodivergent" transformations on the basis of latent σ symmetry.[1] Previously, we disclosed remarkable nonenzymatic asymmetric induction methods for various prochiral σ-symmetric dicarboxylic acid derivatives based on highly diastereoselective aminolysis and Dieckmann-type cyclizations using functional heterocycles, such as the C4-chiral 1,3-thiazolidine-2-thiones.[2] Recent efforts in this field have been directed towards the development of methods for the catalytic desymmetrization of prochiral cyclic dicarboxylic anhydrides, such as enantioselective ring opening with methanol and carbon nucleophiles in the presence of a catalytic amount of chiral reagents.[3] We have focused on the development of simple and versatile chiral sulfonamides that are available for various catalytic asymmetric reactions. Very recently, Wang et al. reported highly enantioselective Michael addition reactions catalyzed by a chiral pyrrolidine sulfonamide[4] and Ishihara et al. disclosed an attractive method for the kinetic resolution of racemic alcohols that utilized an L-histidine sulfonamide derivative.[5] Ikariya and co-workers also carried out catalytic enantioselective Michael addition reactions that employed chiral Ru amido complexes.[6] However, to the best of our knowledge, there has been no report of a catalytic asymmetric desymmetrization of prochiral dicar-

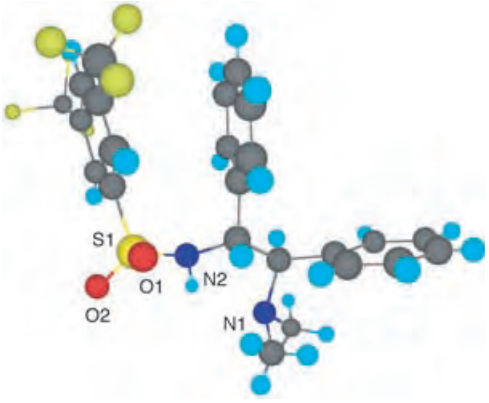
boxylic anhydrides by sulfur nucleophiles. Herein, we describe the highly enantioselective thiolysis of prochiral cyclic dicarboxylic anhydrides with benzyl mercaptan (BnSH) in the presence of a catalytic amount of chiral bifunctional sulfonamide.

First, we inspected the molecular structure of two chiral sulfonamide catalysts **1** and **2** expecting to observe bifunctional catalytic effects, namely, both acid- and base-like properties. The nucleophilicity of the SH group can be enhanced by an amine base, and the electrophilicity of the carbonyl group may be activated by an acidic proton from the sulfonamide moiety.[4,5] On the basis of an X-ray crystallographic analysis of **2** (see below), we envisaged that chiral sulfonamides **1** and **2** would not only show acid- and base-like catalytic functions but may also provide suitable conditions for the enantioselective molecular recognition between a prochiral dicarboxylic anhydride and BnSH based on hydrogen-bonding interactions. Chiral sulfonamides **1** and **2** were readily synthesized as follows: The treatment of (1*R*,2*R*)-*N*,*N*-dimethyl-1,2-diphenyl-1,2-ethanediamine[7] with *p*-toluenesulfonyl chloride or 3,5-bis(trifluoromethyl)benzenesulfonyl chloride in the presence of Et_3N in CH_2Cl_2 afforded the desired products **1** and **2** (89 and 76% yields, respectively).[8] Figure 1 shows the X-ray crystal structure[9] of **2**, in which the three phenyl groups are positioned alongside each other, two of which are organized in a stacked manner,[13] whereas the third occupies a more open position. Thus, the acidic (-SO_2NH-) and basic (Me_2N-) bifunctional groups are located beside each other opposite the phenyl groups and may be suitable for trapping both reactants, namely, the anhydride and thiol moieties, through hydrogen-bonding interactions at the thiolysis site. To verify the bifunctionality of **1** and **2** based on the hypothesis described above, the related chiral compounds **3**–**5** were also synthesized from (1*R*,2*R*)-1,2-diphenyl-1,2-ethanediamine.[8,14]



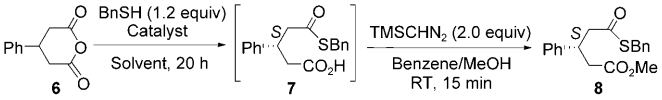


Figure 1. Computer-generated drawing derived from the X-ray coordinates of sulfonamide **2**.

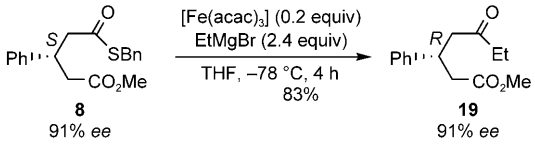
Thus, the asymmetric thiolysis of 3-phenylglutaric anhydride **6** with BnSH (1.2 equiv) was examined in the presence of 10 mol% of chiral catalysts **1**–**5** in toluene at room temperature for 20 h. Then, the resultant crude *S*-benzyl thioester monocarboxylic acid **7** was converted into its methyl ester **8** without isolation of **7** for easy handling to determine the *ee* (Table 1). The desired catalytic asymmetric thiolysis of **6** with 1.2 equivalents of BnSH in the presence of 10 mol% of the bifunctional sulfonamides **1** and **2** smoothly proceeded to afford the chiral product **8** in 78 and 88% yields with 83 and 90% *ee*, respectively (Table 1, entries 1 and 2). However, the thiolysis of **6** with BnSH in the presence of *N*-methyl sulfonamide **3**, containing an *N*,*N*-dimethylamino basic functionality, or bisamino sulfonamide **4**, without an *N*,*N*-dimethylamino group, did not proceed at all (Table 1, entries 3 and 4). In the case of (1*R*,2*R*)-*N*,*N*,*N*′,*N*′-tetramethyl-1,2-diphenyl-1,2-ethanediamine (**5**), the thiolysis proceeded slightly to give **8** in 20% yield with 6% *ee* (Table 1, entry 5). On the basis of the experimental results (Table 1, entries 1–5), we conclude that both the acid catalysis resulting from the sulfonamide proton and the base catalysis resulting from the *N*,*N*-dimethylamino group in the exploitation of catalysts **1** and **2** were equally effected through this facile catalytic and enantioselective thiolysis of **6** with BnSH.

The reaction conditions were optimized with an investigation of the influence of the solvent, reaction temperature, and amount of catalyst **2** on the yield and enantioselectivity of the thiolysis of **6** with 1.2 equivalents of BnSH (Table 1,

Table 1: Investigation of the reaction conditions for the enantioselective thiolysis of 3-phenylglutaric anhydride **6** with benzyl mercaptan in the presence of chiral catalysts.



Entry	Catalyst (mol%)	Solvent	*T* [°C]	Yield [%][a]	*ee* [%][b]
1	**1** (10)	toluene	RT	78	83
2	**2** (10)	toluene	RT	88	90
3	**3** (10)	toluene	RT	NR[c]	–
4	**4** (10)	toluene	RT	NR[c]	–
5	**5** (10)	toluene	RT	20	6
6	**2** (10)	CH_2Cl_2	RT	61	83
7	**2** (10)	MeCN	RT	88	38
8	**2** (10)	THF	RT	87	84
9	**2** (10)	Et_2O	RT	94	92
10	**2** (10)	Et_2O	0	94	92
11	**2** (10)	Et_2O	−30	93	92
12	**2** (5)	Et_2O	RT	95	91
13	**2** (1)	Et_2O	RT	87	87

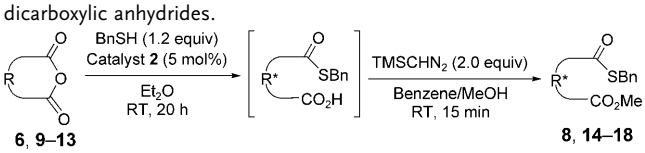
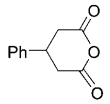
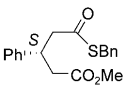
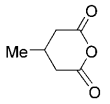
entries 6–13). Among the solvents used (namely, toluene, CH_2Cl_2, MeCN, THF, and Et_2O), Et_2O at room temperature provided the best result, thus giving the chiral product **8** in 94% yield with 92% *ee* (Table 1, entries 2 and 6–9). At reaction temperatures lower than room temperature (0 and −30 °C), the enantioselective thiolysis was almost the same as at room temperature (Table 1, entries 9–11). Interestingly, this catalytic enantioselective thiolysis even proceeded in the presence of 5 and 1 mol% of **2** at room temperature to afford **8** in 95 and 87% yields with 91 and 87% *ee*, respectively (entries 12 and 13). Similar enantioselective thiolysis of **6** with 1.2 equivalents of ethanethiol or thiophenol in the presence of 5 mol% of **2** in Et_2O at room temperature followed by methylation with $TMSCHN_2$ gave the corresponding *S*-ethyl and *S*-phenyl thioesters in 61 and 90% yields with 78 and 16% *ee*, respectively.

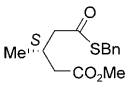


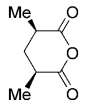
Thus, highly enantioselective thiolysis of prochiral dicarboxylic anhydrides **6** and **9–13** with 1.2 equivalents of BnSH was performed in the presence of 5 mol% of **2** in Et_2O at room temperature for 20 h followed by methylation of the resultant corresponding monocarboxylic acids with $TMSCHN_2$. The corresponding chiral monomethyl esters **8** and **14–18** were efficiently obtained in yields of 87–100% with *ee* values of 83–98% (Table 2). The absolute configuration of the newly formed chiral carbon atom(s) in **8** and **14–18** was determined by conversion[8] into known chiral compounds.[15] Although the detailed reaction mechanism of this catalytic and highly enantioselective thiolysis in the presence of chiral sulfonamides remains unclear, this quite simple catalytic desymmetrization procedure should be a fascinating method for the practical syntheses of chiral synthons (synthetic building blocks). Using the active monothioester character, **8** (91% *ee*) was tentatively treated with 0.2 equivalents of $[Fe(acac)_3]$ (acac = acetylacetonate) and 2.4 equivalents of EtMgBr in THF at −78 °C to give chemoselectively the

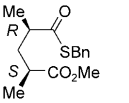


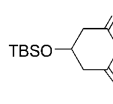


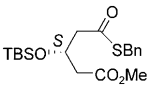


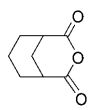


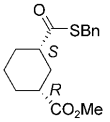


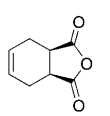


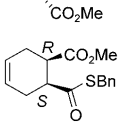












desired chiral ketoester **19** in 83% yield with 91% *ee*.[16]

The chiral monothioesters **8** and **14–18** will be exploited for the asymmetric synthesis of macrocyclic antibiotic drugs and biologically active natural products.[17] Newly designed bifunctional chiral sulfonamides, including **2**, seem to be promising for the development of various catalytic asymmetric induction methods.

Table 2: Catalytic, enantioselective thiolysis of various prochiral cyclic dicarboxylic anhydrides.

Experimental Section

A typical procedure of the catalytic enantioselective thiolysis: Benzyl mercaptan (141 μL, 1.2 mmol) was added to a solution of 3-phenylglutaric anhydride **6** (190 mg, 1.0 mmol) and chiral sulfonamide **2** (25.8 mg, 0.05 mmol) in Et_2O (10 mL) at room temperature. The mixture was stirred at room temperature under Ar for 20 h and treated with 10% HCl followed by extraction with $CHCl_3$. The $CHCl_3$ extracts were dried over $MgSO_4$ and filtered. After evaporation of the filtrate in vacuo, the residue was dissolved in benzene/MeOH (7:2; 9 mL) and a solution of $TMSCHN_2$ in Et_2O (2.0 M, 1 mL, 2.0 mmol) was added. The mixture was stirred at room temperature for 15 min and then evaporated in vacuo to give an oily residue. Purification of the residue by column chromatography on silica gel with EtOAc/*n*-hexane (1:4) afforded compound **8** (312 mg, 95% yield, 91% *ee*) as a white solid (m.p. 34.5–35 °C).

Polynuclear Complexes

DOI: 10.1002/anie.200501327

Two Molecular Tapes Consisting of Serial or Parallel Azido-Bridged Eight-Membered Copper Rings**

Yuan-Zhu Zhang, Hai-Yan Wei, Feng Pan, Zhe-Ming Wang, Zhi-Da Chen, and Song Gao**

The construction of low-dimensional coordination polymers has received intense attention for a long time because of their structural diversity and unusual properties as well as their magneto–structural correlations.[1] Among them, some one-dimensional (1D) expanded chains with exotic topologies have been reported, such as ladders,[2] ropes,[3] and cluster-based chains.[4] They provide an intermediate step from 1D chains towards 2D networks, thus potentially helping the magnetic behavior at the border of 1D to 2D systems to be understood. As a versatile bridging ligand, the azido ion could link two or more metal ions in various modes, for example, μ-1,1 (end-on (EO)), μ-1,3 (end-to-end (EE)), μ-1,1,1, μ-1,1,3, and so forth, thus giving rise to a variety of zero- to three-dimensional polynuclear complexes.[5–9] As far as 1D chains are concerned, many unusual alternating chains with different combinations of these modes have been obtained.[7,8]

However, the synthesis of 1D chains of increasing width is still a big challenge. In our opinion, utilizing the diverse coordination geometry of the copper ion and the versatile bridging modes of the azide moiety might be key to facing the challenge. From the viewpoint of magneto–structural correlation, the azido–copper system might be one of the most complicated systems because of the various bridging modes of the azido ion and the Jahn–Teller effect of the copper ion in an

elongated octahedral or square-pyramidal geometry. Although it has been well stated both theoretically and experimentally that the exchange is ferromagnetic (F) or antiferromagnetic (AF) depending on the angle of Cu-N-Cu for the EO mode,[10] the correlation seems to be open ended for continuous exceptions.[11–12] In addition, to obtain an isolated 1D magnetic chain, a blocking coligand with stereochemical character, as well as an effective bridging ligand, is often needed to reduce the structural dimension and decrease the intermolecular interactions.

2-Benzoylpyridyl (bzp) has been used as a terminal/convergent coligand to form a 1D azido–manganese chain with interchain Mn···Mn distances of 10 Å.[13] We employed this coligand in an azido–copper system on the basis of these considerations and obtained an exotic 1D molecular tape, $[Cu_4(N_3)_8(CH_3CN)_3(bzp)_2]_n$ (**1**), with serial-connected cyclic azido-bridged eight-membered copper rings from the reaction solution of methanol/acetonitrile. Noticing that coordinated acetonitrile molecules might prevent further expansion of the tape, we changed the experimental conditions to 100% methanol as the solvent. Fortunately, we obtained another more interesting molecular tape, $[Cu_5(N_3)_{10}(bzp)_2]_n$ (**2**), with parallel eight-membered copper rings (Scheme 1). Herein, we report the synthesis, structure,[14] and magneto–structural correlations of these copper rings.

Scheme 1. Formation of molecular tapes **1** and **2**.

The single-crystal X-ray determination revealed that **1** consists of neutral 1D azido–copper chains with serial octanuclear repeating units (Figure 1a). There are four crystallographically independent Cu^{II} ions, with each assuming an elongated octahedral geometry; eight nonequivalent azido ligands, five (N5, N8, N11, N20, and N23) which adopt the EO bridging mode and the other three (N14, N17, and N26) which adopt the μ-1,1,1 mode; and three terminal acetonitrile molecules (N2, N3, and N4). For the Cu2 center, three azido atoms (N11, N17, and N20) and one pyridine nitrogen atom (N1) from the bzp ligand are in the basal sites, whereas the oxygen atom (O1) of the bzp ligand and one μ-1,1,1-azido ion are in the apical positions (Cu2–O1: 2.442 Å, Cu2–N14: 2.400 Å). The environment around the other three Cu^{II} ions are similar, with the nonequivalent apical positions occupied by one acetonitrile molecule ($Cu–N_{CH_3CN}$: 2.38–2.43 Å) and one μ-1,1,1-azido ion ($Cu–N_{azido}$: 2.71–2.82 Å)

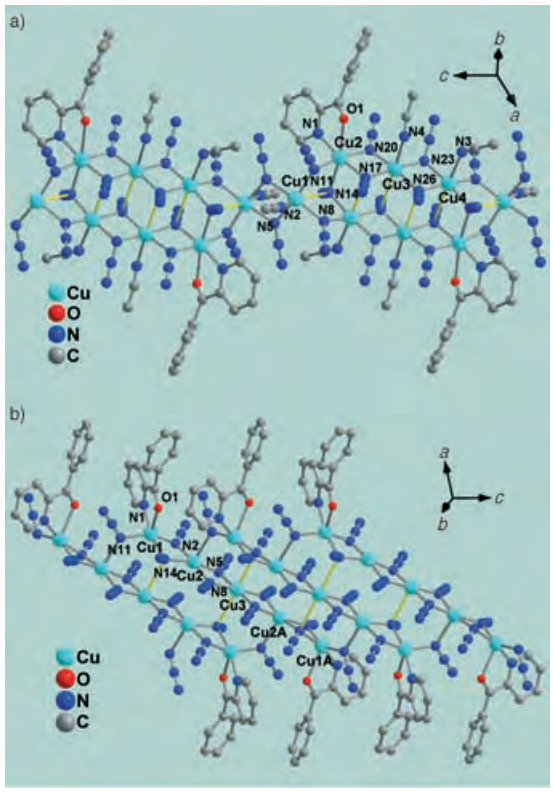

Figure 1. a) The ball and stick structure of the tape **1** with serial cyclic azido-bridged octanuclear copper clusters along the *c* axis (the yellow bonds are approximately 2.8 Å). b) The ball and stick structure of the tape **2** with the parallel linear azido-bridged pentanuclear copper units along the *c* axis (the yellow bonds are longer than 2.65 Å).

and the basal sites furnished by four azido ions ($Cu–N_{azido}$: 1.98–2.03 Å), thus the basal bonds are significantly shorter than the axial ones. Here, the distortion of the basal planes of the octahedral or square-pyramidal Cu^{II} ions could be described by a geometrical parameter τ in accord with the method of Addison et al. with $\tau = |\beta - \alpha|/60$, in which β and α are the bond angles that involve *trans* donor atoms in the basal plane.[15] All the τ values are around 0.05 for the Cu^{II} ions. The Cu-N-Cu angles vary from 82.85 to 102.74°, except for Cu1-N11-Cu2 and Cu1-N8-Cu4A which are 116.78 and 116.38°, respectively, and the dihedral angles ϕ between the basal planes of Cu1 and Cu2, Cu2 and Cu3, Cu3 and Cu4, and Cu4 and Cu1A are 68.9, 1.9, 6.9, and 72.8°, respectively. Thus, a unique centrosymmetric cyclic azido-bridged eight-membered copper ring $[Cu_8(N_3)_{14}(CH_3CN)_6(bzp)_2]^{2+}$ is formed, within which the metal ions are bridged by eight EO azido groups outside, whereas each of the three closest copper ions are bridged by one asymmetric μ-1,1,1-azido ligand inside. The adjacent rings are further linked in a serial mode to an exotic 1D chain by double EO bridges along the *c* axis. The chains of **1** are well isolated as the shortest Cu···Cu interchain distance is 8.3 Å, which is between the Cu2 and Cu2 centers ($-x+1$, $-y+1$, $-z+2$; see the Supporting Information).

The structure of **2** reveals a more interesting neutral azido–copper tape. There are three crystallographically independent Cu^{II} ions (Cu1, Cu2, and Cu3) and five non-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equivalent azido ligands, which include three basal–basal EO azido (N2, N5, and N8) ligands, one basal–apical EO azido (N11) ligand, and one asymmetric μ-1,1,1-azido (N14) ligand (Figure 1b). Both the Cu1 and Cu2 ions are five-coordinate with distorted square-pyramidal geometry (4+1): For the Cu1 center, three azido nitrogen atoms (N11, N2, and N14) and one pyridine nitrogen atom (N1) of the bzp ligand occupy the basal sites, thus leading to significantly shorter Cu–N bond lengths (1.89–1.92 Å), and the oxygen atom of the bzp ligand occupies the apical position (Cu1–O1: 2.27 Å). For the Cu2 center, only the azido ions are involved in the coordination, with the N11A atom at the apical position (Cu2–N11A: 2.275 Å). The values of τ are 0.28 and 0.18 for the Cu1 and Cu2 centers, respectively. The Cu3 ion ($\tau = 0$) lies in the symmetric center with an elongated octahedral geometry furnished by six azido ions, and the apical sites are occupied by two μ-1,1,1-azido (N14) atoms (Cu–N: 2.683 Å, which is much longer than the basal bonds as well as the apical bonds of the square-pyramidal Cu ions). Thus, the five copper ions (Cu1, Cu2, Cu3, Cu2A, and Cu1A) are bridged by double basal–basal EO azides to form a linear unit, in which the dihedral angles ϕ are 25.4° for the Cu1 and Cu2 centers and 5.8° for the Cu2 and Cu3 centers, and the bridge angles are 107.0° (∢ Cu1-N2-Cu2), 104.5° (∢ Cu1-N14-Cu2), and 107.7° (∢ Cu2-N5/N8-Cu3). The intraunit metal distances are Cu1···Cu2: 3.05 Å and Cu2···Cu3: 3.07 Å. The parallel neighboring units are further connected to a tape along the *c* axis through two basal–apical EO azido bridges (∢ Cu1-N11-Cu2B: 118°) and two asymmetric μ-1,1,1-azido bridges with an inter-unit metal distance of Cu1···Cu2B: 3.59 Å. The tapes are well isolated, with the shortest Cu···Cu intertape distance of 8.13 Å occurring between the Cu1 and Cu2 centers ($2-x$, $y-0.5$, $0.5-z$; see the Supporting Information). It is of note that if the weak Cu3–N_{azido} bonds (the yellow bonds in Figure 1b) are omitted, the tape can also be viewed as a 1D chain that consists of parallel eight-membered copper rings (Scheme 1).

The magnetic susceptibilities of **1** and **2** (2–300 K) were measured at 1 kOe on a Quantum Design MPMS XL-5 SQUID system (Figure 2). For **1**, the $\chi_M T$ value per {Cu_4} unit increases gradually on cooling, thus suggesting an overall ferromagnetic coupling between the adjacent Cu^{II} ions, and there is an decrease in $\chi_M T$ below 4 K that may be because of an interchain AF and/or a zero-field splitting (ZFS) effect. The data above 70 K fit well with the Curie–Weiss law ($\chi_M = C/(T-\theta)$), thus giving $C = 1.79\ cm^3 mol^{-1} K$ (which corresponds to four uncoupled Cu^{II} ions with $g = 2.18$) and $\theta = 22.5$ K. No long-range ordering was observed above 1.9 K from the magnetization–temperature (*M*–*T*) curve at 20 Oe and *ac* susceptibilities versus the *T* curves (see the Supporting Information). The observed magnetization curve at 1.9 K is above the calculated Brillouin function for the sum of four isolated Cu^{II} ions ($S = 1/2$) below 50 kOe, thus confirming further the ferromagnetic coupling between the copper ions (see the Supporting Information).

For **2**, the $\chi_M T$ value of 2.2 $cm^3 mol^{-1} K$ at 300 K per {Cu_5} unit decreases gradually on lowering the temperature and reaches a plateau at 1.5 $cm^3 mol^{-1} K$ at 10–20 K (Figure 2b), which is close to the $S = 3/2$ state (it was expected that $\chi_M T =$ 1.875 $cm^3 mol^{-1} K$ at this point; however, the observed value is lower than the expected one, probably as a result of interpentanuclear AF interactions). The $\chi_M T$ value then decreases sharply, possibly because of the interpentanuclear interactions, and/or interchain AF interactions, and/or the ZFS effect as the field-saturation effect has been excluded by the similar decrease found in the $\chi_M T$–*T* curve at the fairly low field of 20 Oe (see the Supporting Information). Fitting the data above 100 K with the Curie–Weiss law gives $C = 2.26\ cm^3 mol^{-1} K$ (which corresponds to five independent spin-only Cu^{II} ions with $g = 2.19$) and a negative θ value of −12 K, thus indicating a net AF coupling among the metal ions. The magnetization value of $2.6 N\beta$ per {Cu_5} unit at 50 kOe and 1.9 K, which is close to and slightly lower than the expected value of $2.9 N\beta$ from the Brillouin function for a $S = 3/2$ system with $g = 2$, also implies a ferrimagnetic-like state in which $S = 3/2$, thus further suggesting the coexistence of antiferromagnetic and ferromagnetic couplings within the pentanuclear subunit. The AF interaction between the subunits was estimated to be −2.4 K by fitting magnetization–magnetic field (*M*–*H*) data by using a modified Brillouin function (see the Supporting Information).

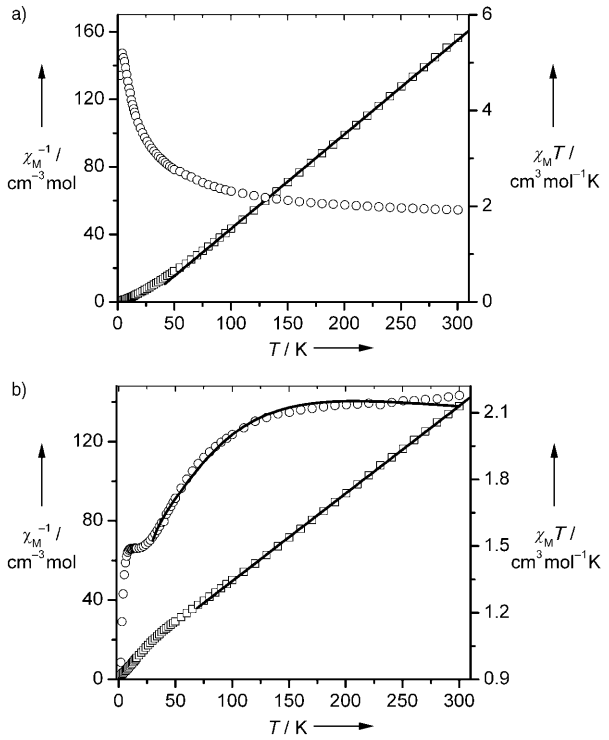

Figure 2. $\chi_M T$ and $1/\chi_M$ versus *T* in an applied field of 1 kOe for a) **1** and b) **2**. The lines are the best fits to the Curie–Weiss law and are an approximate uniform-chain model.

The magnetic behaviors of **1** and **2** can be rationalized on the basis of their structures. The EO bridges in the azido–copper system could be further divided into two types: 1) basal–basal bridges, in which the azido bridges are involved in two basal planes of Cu^{II} ions; 2) asymmetric basal–apical bridges, in which the azido group is located at the apical position of one of the Cu^{II} ions and the basal position of the other. It has been well documented that the exchange is F or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

AF depending on the Cu-N-Cu angle for the basal–basal bridges (the calculated critical angle is 104° and experimentally derived angle is 108°)[10] and that the interaction through the basal–apical bridges is either negligible or weakly F/AF depending on the distortion of the basal planes of the Cu^{II} ions.[12] Taking into account the structure of **1**, interaction through the basal–apical bridges (between the $\{Cu_4\}$ units) is negligible because of very small distortions ($\tau \approx 0.05$). Figure 3 shows the resulting magnetic chain of **1,** in which

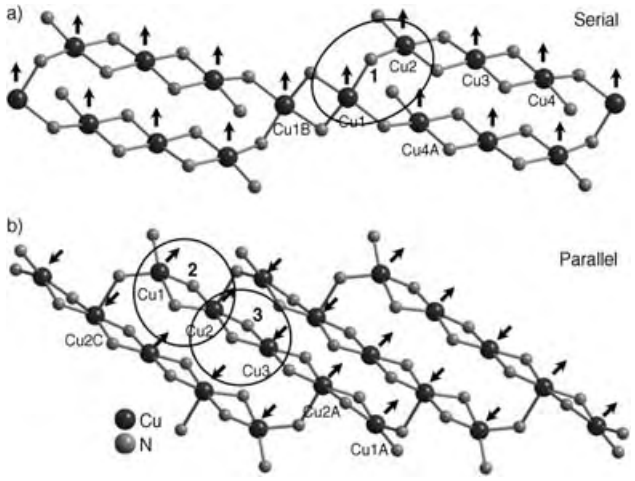

Figure 3. The magnetic chains of a) **1** and b) **2**.

the bridge angles are in the range 98.8–102.7°, except for the ∢ Cu1-N11-Cu2 and ∢ Cu1-N8-Cu4A angles of 116.5° which are anticipated to transmit strong AF coupling. Surprisingly, our magnetic measurements suggest that all the copper ions are F. To understand the unusual F interaction through the Cu1-N11-Cu2 bridges, preliminary theoretical studies were performed for the Cu1–Cu2 "dimer" model **1** formed from **1** (see the Supporting Information) by using the broken-symmetry approach under a DFT framework (DFT-BS).[16,17] The calculated results show that the "local magnetic orbitals" are mainly located at paramagnetic centers (Cu1 and Cu2); describe the distribution of the active spin electrons at each local magnetic center, that is to say, are beside the Cu1 and Cu2 centers, which also contain possible components of bridging and/or terminal ligands; and show that the $d_{x^2-y^2}$ orbitals occupied by nonpaired electrons in the Cu1 and Cu2 ions are located at the basal planes of the Cu1 and Cu2 centers. From the point of view of the molecular orbital theory, the two local magnetic orbitals on the Cu1 and Cu2 ions further constitute the singly occupied molecular orbitals in the triplet state (Figure 4). It is worth noting that the Cu1-N11-Cu2 bridge is different from other usual basal–basal EO bridges because of a large dihedral angle of 68.9° between the basal planes of the Cu1 and Cu2 centers, thus leading no doubt to a small overlap integral (calculated value of 0.0263) between the two local magnetic orbitals on the Cu1 and Cu2 centers. On the basis of the relationship[18] between the exchange constant J and the overlap integral S_{ab} between the local magnetic orbitals of a and b, $J = J_F + J_{AF} = 2K - US_{ab}^2$, in which K is the ferromagnetic contribution and U is the

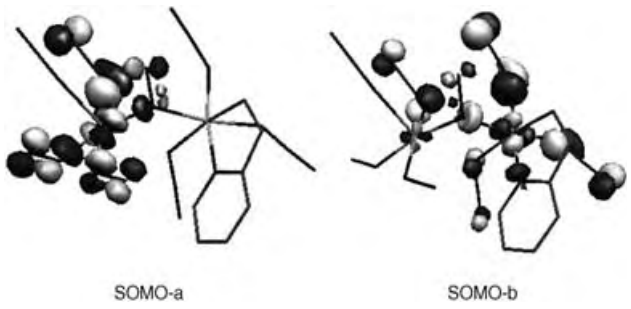

Figure 4. Singly occupied molecular orbitals of model **1** in the triplet state.

charge-transfer energy difference between the covalent and the ionic configurations, the small overlap integral should be responsible for the ferromagnetic interaction between the Cu1 and Cu2 centers. Additionally, we obtained the calculated exchange constant $J = 28.6\ cm^{-1}$ ($H = -2JS_1S_2$), which accounts just for the experimentally ferromagnetic interaction, by using the DFT-BS method.

Figure 3b shows the structure of the magnetic chain of **2**, which is based on the following rational considerations: 1) interactions through the basal–apical bridges that occupy the apical positions of the Cu3 ions (the yellow bonds in Figure 1b) can be safely omitted; 2) the coupling through the Cu1-N11-Cu2C bridges between the adjacent pentanuclear units should be considered as J_1 because the distortion of the basal plane of the Cu1 and Cu2 ions cannot be considered as being small ($\tau \approx 0.18$–0.28); 3) J_2 and J_3 are used to calculate the magnetic exchange interactions for Cu1···Cu2 and Cu2···Cu3, respectively. On the basis of an approximate model,[19] **2** can be treated as a uniform chain with linear pentanuclear $\{Cu_5\}$ as a subunit, for which $H = -2J_2(S_{Cu1}S_{Cu2} + S_{Cu1A}S_{Cu2A}) - 2J_3(S_{Cu2}S_{Cu3} + S_{Cu3}S_{Cu2A})$ (for $\{Cu_5\}$); $H = -2J_1\Sigma S_{p,i}S_{p,i+1}$ (S_p for $\{Cu_5\}$ as a classical system). Fixing $g = 2.19$, the best fitting of the data at 25–300 K gives $J_1 = -1.5$, $J_2 = 112$, and $J_3 = -29\ cm^{-1}$, with $R = 8 \times 10^{-5}$ ($R = \Sigma[(\chi_M T)_{obsd} - (\chi_M T)_{calcd}]^2/\Sigma(\chi_M T)_{obs}^2$). The negative J_1 value of $-1.5\ cm^{-1}$, which indicates AF coupling between the pentanuclear units, is consistent with the estimated value of -2.4 K from the M–H fitting (see the Supporting Information). The theoretical calculations of the "dimer" models of Cu1–Cu2 and Cu2–Cu3 in **2** are also performed by using the DFT-BS approach (see the Supporting Information). The calculated results of $J_2 = 113$ and $J_3 = -22\ cm^{-1}$ reproduced the experimentally derived F and AF characteristics well for Cu1–Cu2 and Cu2–Cu3, respectively. Further inspection of the calculated overlap integrals between the local magnetic orbitals $d_{x^2-y^2}$ on the Cu^{II} ions shows that the small overlap integral (0.0139) between the Cu1 and Cu2 centers and the larger overlap integral (0.136) between the Cu2 and Cu3 centers are responsible for these magnetic coupling characteristics. The large difference might come from three possibilities: 1) using **1**, which has a large ϕ value, as a ferromagnetic reference, the ϕ value of 25.4° between the Cu1 and Cu2 centers in **2**, which cannot be considered as small, might also contribute to the ferromagnetic coupling; 2) the large distortion ($\tau = 0.28$ and 0.18 for Cu1 and Cu2, respectively) also could cause a small overlap between the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

local magnetic orbitals on the Cu1 and Cu2 centers; 3) as the magnetic coupling J often has a strong dependence on the Cu-N-Cu angle θ and as $2J = 4440–41.94\ \theta(cm^{-1})$,[10d] it is evident that the small angles of Cu1-N-Cu2 (104.5 and 107°) would transfer a ferromagnetic interaction more readily than Cu2-N-Cu3 (107.7 and 107.7°). However, it is unclear which is the dominant reason at the present stage.

In summary, we have obtained two exotic 1D molecular tapes with serial and parallel cyclic azido-bridged eight-membered copper rings $[Cu_4(N_3)_8(CH_3CN)_3(bzp)_2]_n$ (**1**) and $[Cu_5(N_3)_{10}(bzp)_2]_n$ (**2**) in solution with methanol, either with or without the addition of acetonitrile. It is of note that the EO bridge in **1**, in which the Cu-N-Cu angle is 116° and $\phi =$ 68.9°, is observed to transmit ferromagnetic interactions and that the central copper center of the linear pentanulear $\{Cu_5\}$ unit in **2** is antiferromagnetically coupled with its neighboring Cu ions and has a ground state S of 3/2. The magneto–structural correlation for a basal–basal EO azido bridge in the azido–copper system is not only dependent on the Cu-N-Cu angle; therefore, more factors should be taken into account, such as the dihedral angle ϕ between the basal planes of the two bridged copper ions as well as the distortion from square-pyramidal to trigonal-bipyramidal geometry for the Cu^{II} ion.

Experimental Section

1: A solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (185 mg, 0.5 mmol) in acetonitrile (15 mL) was mixed with a solution of bzp (92 mg, 0.25 mmol) and NaN_3 (65 mg, 1 mmol) in methanol (15 mL). The resulting solution was kept undisturbed at room temperature. Brown platelike single crystals of **1** were obtained after several days. Yield: 58 mg, 52%. Elemental analysis (%) calcd for $C_{18}H_{18}Cu_4N_{28}O$: C 24.11, H 2.02, N 43.74; found: C 23.73, H 2.14, N 43.14; IR: $\tilde{\nu} = 2046$, 2080, and 2089 (vs) for the azide group and 2262 and 2295 cm^{-1}(w) for CH_3CN.

2: A solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (185 mg, 0.5 mmol) in methanol (15 mL) was mixed with a solution of bzp (92 mg, 0.5 mmol) and NaN_3 (45 mg, 0.7 mmol) in methanol (15 mL). The resulting solution was left at room temperature. Green blocklike single crystals were isolated and brown striplike single crystals of **2** were obtained after 2 weeks. Yield: 18 mg, 24%. Elemental analysis (%) calcd for $C_{24}H_{18}Cu_5N_{32}O_2$: C 26.10, H 1.64, N 40.59; found: C 26.54, H 1.91, N 40.15. IR $\tilde{\nu} = 2052$, 2076, 2095, and 2119 cm^{-1} (v s) for the azide group.

All theoretical calculations were performed by the Amsterdam Density Functional (ADF) program, version 2004.01.[16] The VWN local density approximation,[20] and Operdew nonlocal density corrections[21] are used. The calculations on the magnetic-exchange constant J are based on the broken-symmetry approach developed by Noodleman.[17] The details of the method used for the calculation are described elsewhere.[22] The geometry of the dimer models **1**–**3** was adapted according to the experimentally crystal structure data, in which the bzp ligand was simplified (see the Supporting Information).

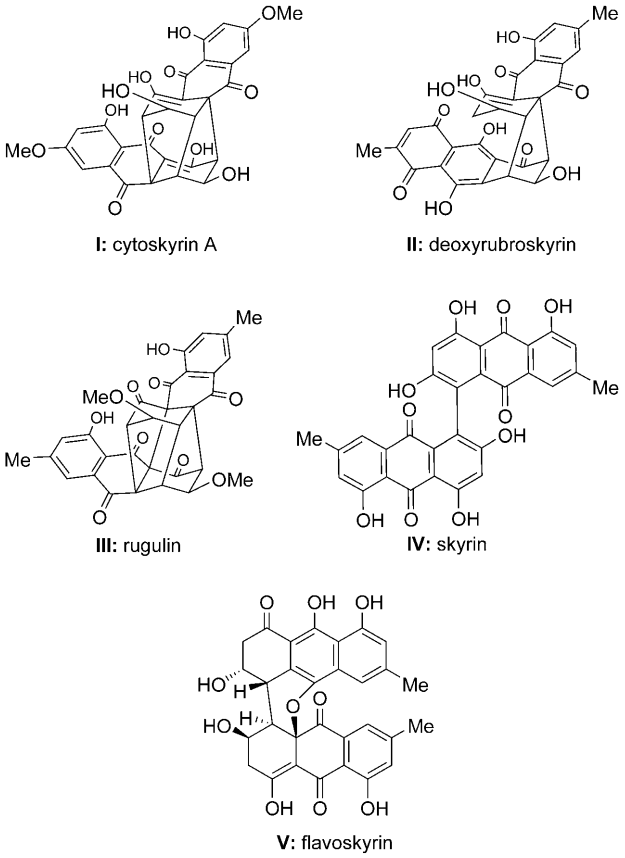
The Cytoskyrin Cascade: A Facile Entry into Cytoskyrin A, Deoxyrubroskyrin, Rugulin, Skyrin, and Flavoskyrin Model Systems**



K. C. Nicolaou, Charles D. Papageorgiou, Jared L. Piper, and Raj K. Chadha*

The collection of naturally occurring compounds shown in Scheme 1 (**I**: cytoskyrin A,[1] **II**: deoxyrubroskyrin,[2a] **III**: rugulin,[3] **IV**: skyrin,[2b,4] and **V**: flavoskyrin[2a]) represents a growing class of natural products often referred to as bisanthraquinones. Notable among them are cytoskyrin A,[1] the newest member of the class whose striking biological activity includes potency down to 12.5 ng mL^{-1} in the biochemical induction assay (BIA), and rugulin, whose structural motif exhibits the highest strain of them all. Isolated from small-scale cultures of the endophytic fungus CR200 (*Cytospora* sp.), which were collected from a branch of a *Conocarpus erecta* tree in the Guanacaste Conservation area of Costa Rica, cytoskyrin A (**I**) presents a challenging synthetic target by virtue of its cagelike structural motif, as do its siblings whose more (**III**) or less (**II** and **V**) enclosed cages are defined by the number of bonds linking their two

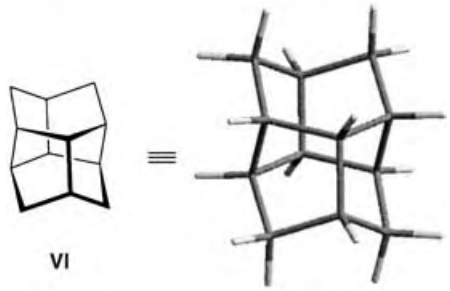
Scheme 1. Naturally occurring modified bisanthraquinones.

Scheme 2. Model systems (**1**–**5**) of the bisanthraquinone natural products rugulin, cytoskyrin, deoxyrubroskyrin, skyrin, and their potential precursor anthraquinone monomer.

anthraquinone monomeric units. Herein we report the construction of model systems for all five natural products **I**–**V**, namely compounds **1**–**5**, respectively, from anthraquinone **6** (Scheme 2) through a stepwise or a cascade sequence of reactions, herein coined the "cytoskyrin cascade".

The present investigations were inspired by the novel molecular architectures of the targeted natural products (Scheme 1) and the work of Shibata and co-workers.[2] To scout possible routes to these intriguing structures, the model systems **1**–**5** (Scheme 2) were selected as initial targets. The complexity of these molecules decreases as we move from **1** (whose anthraquinone units are held together by four carbon–carbon bonds) to **4** (which is cojoined by only one single bond). The origins of **4** can be traced retrosynthetically to **6** through a dimerization process that may or may not proceed via dimer **5**, as shown below.[5] Before we reveal our pathway to these model systems, however, a further comment concerning the cagelike core structure of **1**[6] is in order. This novel core structure presented by the parent $C_{12}H_{16}$ hydrocarbon **VI** (Figure 1), named herein "skyrane", is walled by two slightly distorted six-membered rings (forming the top and bottom of a tilted hexagonal capsule) and four uniformly twisted five-membered rings, leading to a considerably strained architecture. As the bonds are removed one by one from this aesthetically appealing capsule, the strain associated with each daughter molecule is expected to decrease. In terms of a synthetic barrier, however, this trend is counterbalanced



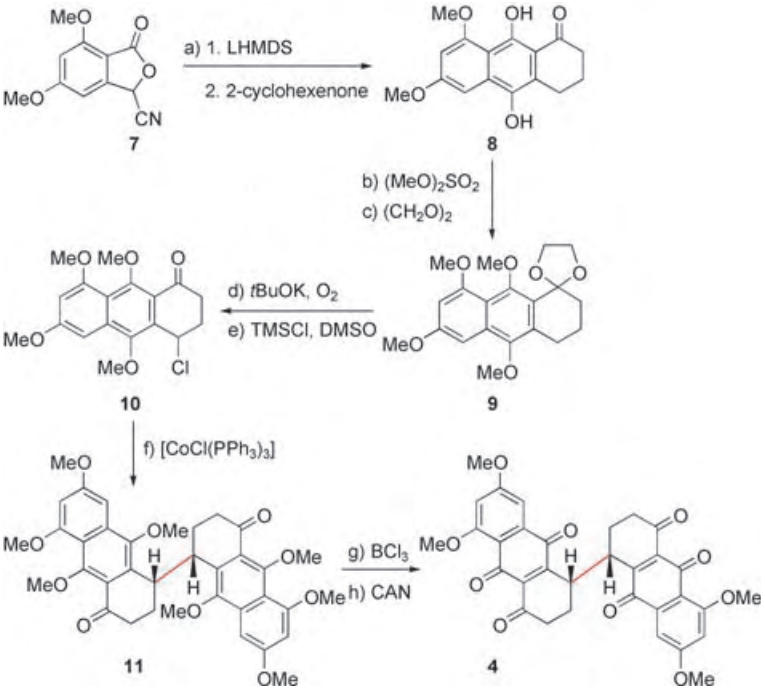


Figure 1. Parent $C_{12}H_{16}$ hydrocarbon, "skyrane".

by entropy: as the cage is being built, proximity should favor the next bond formation.

Scheme 3 summarizes the synthesis of the first model system, bisanthraquinone **4**, through a sequence that features a Hauser annulation[7] to construct the requisite tricyclic system and a radical dimerization to provide the required hexacyclic compound. Thus, treatment of nitrile **7** with LHMDS in THF at −78 °C, followed by addition of 2-cyclohexenone (−78→25 °C) gave crude anthradihydroquinone **8**, which was directly subjected to methylation and dioxolane formation to afford protected compound **9** in 58 % overall yield for the three steps. A subsequent benzylic oxygenation/chlorination sequence then converted **9** into **10** in 57 % overall yield. The anticipated dimerization of **10** was

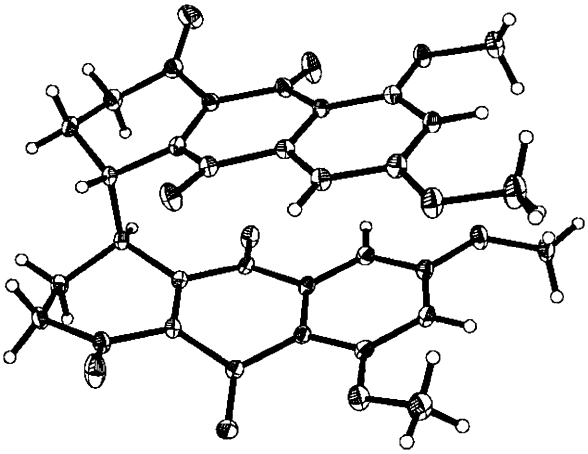
Scheme 3. a) **7** (1.1 equiv), THF, LHMDS (1.5 equiv), −78 °C; then 2-cyclohexenone (1.0 equiv) −78→25 °C, 4 h; b) $(MeO)_2SO_2$ (5.0 equiv), K_2CO_3 (5.0 equiv), acetone, reflux, 12 h; c) ethylene glycol (2.0 equiv), benzene, PPTS (0.2 equiv), reflux, 24 h, 58% over three steps; d) *t*BuOK (6.0 equiv), O_2, DMSO, 2 h; e) TMSCl (2.0 equiv), DMSO, 10 min, 57% over two steps; f) $[CoCl(PPh_3)_3]$ (1.2 equiv), benzene, 25 °C, 3 h; g) BCl_3 (2.2 equiv), CH_2Cl_2, −78→25 °C, 12 h; h) CAN (4.0 equiv), CH_3CN/H_2O 1:1, 10 min, 50% over two steps. CAN = cerium ammonium nitrate; DMSO = dimethyl sulfoxide; LHMDS = lithium hexamethyldisilazide; PPTS = pyridinium *p*-toluenesulfonate; TMS = trimethylsilyl.

performed by exposure to $[CoCl(PPh_3)_3]$[8] in benzene at 25 °C, leading, through radical species, to the desired *dl* dimer (**11**) as the major product (55% yield) accompanied by its *meso* isomer (25%). The two isomers were separated by silica-gel flash chromatography and unambiguously identified through X-ray crystallographic analysis of a later intermediate (see below). The two methyl groups residing on the oxygen atoms nearest to the carbonyl moieties were then selectively cleaved from the major isomer **11** by exposure to BCl_3 in CH_2Cl_2 at −78 °C to furnish the corresponding diphenolic compound, whose oxidation with CAN resulted in the formation of the targeted *dl* bisanthraquinone **4** (50% overall yield for the two steps). Compound **4** crystallized in suitable form for X-ray crystallographic analysis (see ORTEP drawing,[9] Figure 2), which confirmed its stereochemical identity and that of its progenitor, compound **11**.

A second pathway to the bisanthraquinone **4** was devised from monoquinone **6**, obtained in quantitative yield by oxidation of hydroquinone **8** with CAN. Thus, exposure of **6** to catalytic amounts of CSA in CH_2Cl_2 at 25 °C for 1 h resulted in the formation of the flavoskyrin model system **5** (94% yield) through dimerization of the enol form **12** of the starting material (Scheme 4). The same transformation (**6**→**5**) could be brought about by a catalytic amount of a mild base (e.g. iPr_2NEt) in 90% yield. This highly efficient dimerization is presumed to proceed either through a Diels–Alder-type[2e,f]



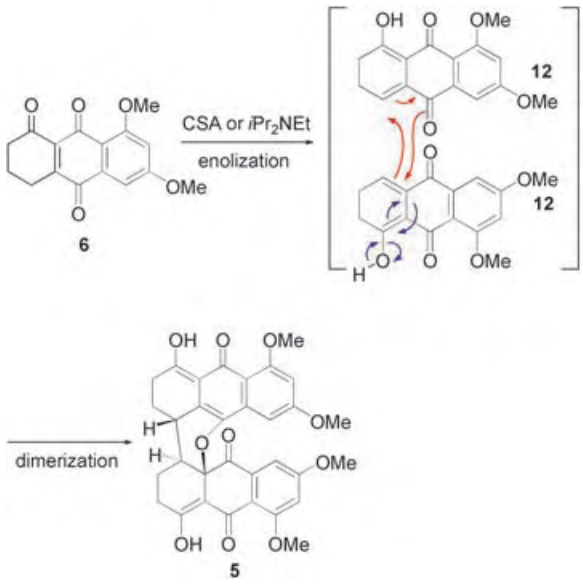


Figure 2. ORTEP drawing of structure **4** (drawn at the 30% probability level).

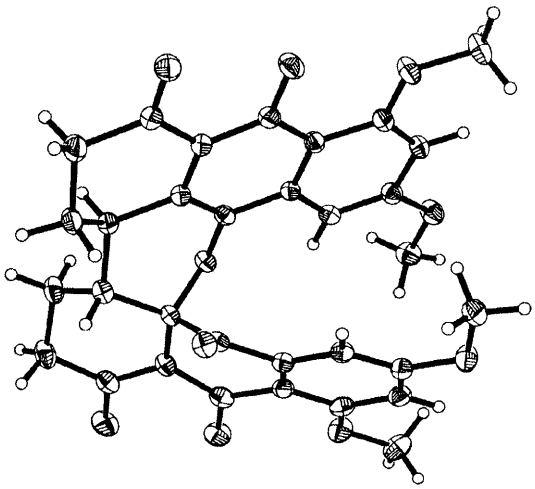
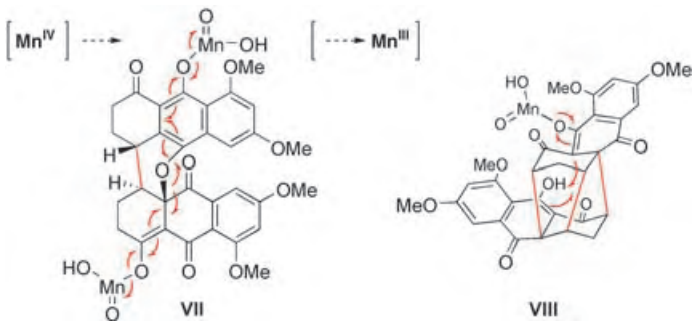
reaction, or through a double Michael reaction, as shown in Scheme 4. The structure of dimer **5** was confirmed by X-ray crystallographic analysis (see ORTEP drawing,[9] Figure 3). Oxidation of **5** with MnO_2 (presumably through the mechanism shown in Scheme 5, structure **VII**) then furnished the desired *dl* bisanthraquinone **4** in 83% yield (Scheme 6). Remarkably, bisanthraquinone **4** was converted into the deoxyrubroskyrin model system **3** in 65% yield simply by exposure to Et_3N (2.0 equiv) in CH_2Cl_2 at 25 °C for 1 h.[2a,e,f] Even more impressive was the conversion of **3** into the cytoskyrin model structure **2** (95% yield), a process that required longer exposure to Et_3N (5.0 equiv) and slightly higher temperature (16 h, 45 °C). This latter transformation (**3**→**2**) could also be accomplished under acidic conditions, albeit in lower yield (PPTS, 2.0 equiv, toluene, 24 h, 100 °C, 65%). Finally, the cytoskyrin-type

Scheme 4. Postulated mechanism for the dimerization of tricyclic quinone **6**, through enolization and a Diels–Alder or double Michael reaction. CSA = (±)-10-camphorsulfonic acid.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim





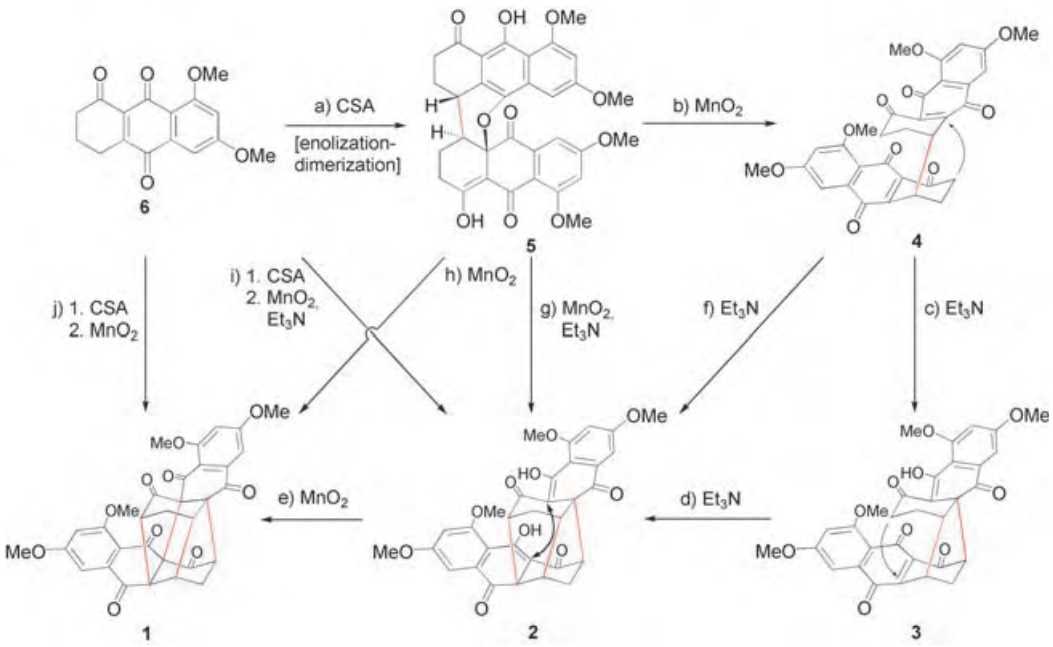


Figure 3. ORTEP drawing of structure **5** (drawn at the 30% probability level).

Scheme 5. Postulated mechanism for the MnO_2 oxidation of compound **5** to **4** (**VII**) and **2** to **1** (**VIII**). This working hypothesis depiction is not based on experimental evidence and is not meant to exclude any other mechanism. The proximity of the Mn=O and enol groups within **VIII** bodes well for an intramolecular interaction between them as part of the mechanism.

compound **2** was transformed into the rugulin-type structure **1** (Table 1) in 95% yield simply by exposure to MnO_2[2a] through an oxidation process that also involved a carbon–carbon bond formation (see Scheme 5, structure **VIII** for a presumed mechanism).

Remarkable as these individual steps may be, they were aesthetically surpassed by the beauty of a number of cascade sequences developed in these studies (Scheme 6). The fact that only a mild base was required to carry out the double Michael reaction leading to **2** (**4**→**3**→**2**; Table 1) and the suspicion that MnO_2 contained such basic species prompted us to attempt this cascade with MnO_2 as the only reagent. Indeed, on exposure to freshly prepared MnO_2 in CH_2Cl_2, compound **5** (Table 1) was transformed into **1** in quantitative yield,[10] through the intermediacy of **4**, then **3**, and finally **2**, all of which were observed by TLC analysis (cascade **5**→**1**; excess MnO_2, 48 h, 45 °C). Interestingly, addition of Et_3N (10.0 equiv) to the starting reaction mixture (**5**, MnO_2) and heating to 45 °C for 20 h resulted in the exclusive formation of **2** (in quantitative yield), with Et_3N apparently inhibiting the last oxidation step (**2**→**1**, presumably through slow deactivation of the MnO_2). Even more impressive was the five-step cascade sequence involving the transformation of the tricyclic monomer **6** into the nonacyclic cytoskyrin model system **2** in 66% yield[10] (cascade **6**→**2**). The latter cascade required treatment of **6** with CSA (0.125 equiv) in CH_2Cl_2 for 1 h at 25 °C, conditions that led to the formation of **5** as indicated by TLC analysis, followed by addition of MnO_2 (excess) and Et_3N (10.0 equiv) and heating to 45 °C with stirring for 36 h, to afford the cytoskyrin model system **2**, through the intermediacy of the fleeting compounds **4** and **3**. This remarkable cascade encompasses an enolization step, followed by a stereoselective dimerization reaction, an oxidation, and finally, an intramolecular double Michael sequence. A similar

Scheme 6. The cytoskyrin cascade: synthesis of flavoskyrin-, skyrin-, deoxyrubroskyrin-, cytoskyrin-, and rugulin-type structures from anthraquinone **6**. All steps can be carried out sequentially in one pot or can be stopped at any stage. Reagents and conditions: a) CSA (0.125 equiv), CH_2Cl_2, 25 °C, 1 h, 94%; b) MnO_2 (10.0 equiv), CH_2Cl_2, 25 °C, 1 h, 83%; c) Et_3N (2.0 equiv), CH_2Cl_2, 1 h, 25 °C, 65%; d) Et_3N (5.0 equiv), CH_2Cl_2, 16 h, 45 °C, 95%; e) MnO_2 (10.0 equiv), CH_2Cl_2, 25 °C, 20 h, 95%; cascade sequences: f) **4**→**2**, Et_3N (5.0 equiv), CH_2Cl_2, 16 h, 45 °C, 95%; g) **5**→**2**, MnO_2 (10.0 equiv), Et_3N (5.0 equiv), CH_2Cl_2, 20 h, 25→45 °C, 100%; h) **5**→**1**, MnO_2 (10.0 equiv), CH_2Cl_2, 48 h, 45 °C, 100%; i) **6**→**2**, CSA (0.125 equiv), CH_2Cl_2, 1 h, 25 °C; then MnO_2 (10.0 equiv), Et_3N (10.0 equiv), 36 h, 45 °C, 66%; j) **6**→**1**, CSA (0.125 equiv), CH_2Cl_2, 1 h, 25 °C; then MnO_2 (10.0 equiv), 88 h, 25 °C, 75%.

experiment in which no Et_3N was added resulted in a six-step cascade transforming **6** to rugulin model system **1** in an impressive 75% yield.

X-ray crystallographic analysis of compound **3**[9] revealed an interesting phenomenon, reminiscent of the classic observation of Ermer with secododecahedrane.[11] As in that case, our initial analysis led to a symmetrical structure (see ORTEP drawing, Figure 4a), an architecture that was contradicted by

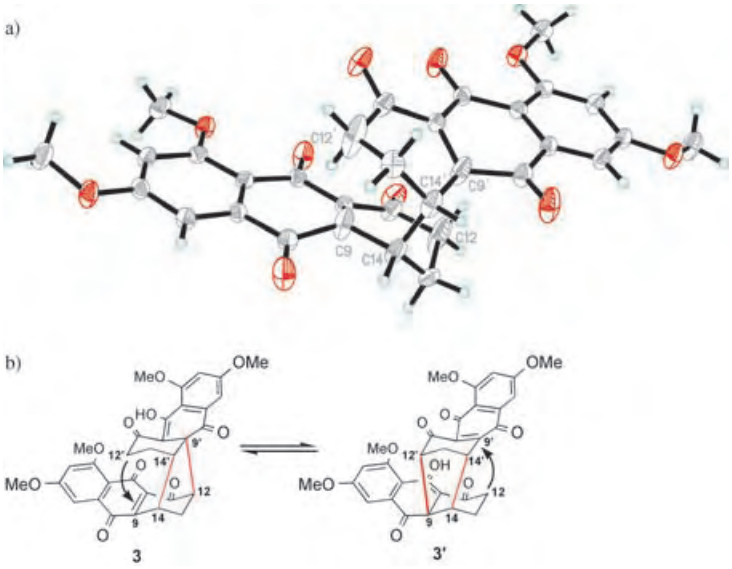

Figure 4. ORTEP drawing of compound **3** (drawn at the 30% probability level) obtained by X-ray crystallographic analysis (using *C*2/*c* space group) at ambient temperature and possible equilibration of **3** and **3′**.

^{1}H NMR spectroscopy, which revealed a nonsymmetrical structure for the molecule.[12] This rare observation may be due to crystal disorder,[13] or dynamic equilibrium involving a two-proton shuttle in which the C12–C9′ bond within **3** breaks as the C12′–C9 bond within **3′** forms (**3**→**3′**, Figure 4b). The structures **3** and **3′** are identical, and X-ray crystallographic analysis reveals an average picture with bond lengths C12–C9′ = C12′–C9 = 2.372 Å and C14–C14′ = 1.56 Å.[14]

The described chemistry provides easy and efficient access to a variety of molecular architectures representing the core structures of numerous natural products, underscoring at the same time the importance of cascade sequences in complex molecule construction. Our experience with the X-ray crystallographic analysis of the deoxyrubroskyrin-type compound **3** should serve as a reminder of the occasional hazards posed by dynamic and/or crystal-disorder phenomena in the solid state and their impact on structure elucidation. While the total synthesis of several members of the bisanthraquinone family of compounds shall now be forthcoming, the gauntlet thrown by skyrane **VI** (Figure 1) is also begging for a solution, a challenge that has not escaped our attention.

[14] The X-ray measurements were initially performed at room temperature and the crystal structure was solved and refined in the centrosymmetric space group *C*2/*c* with $Z = 4$, following the general conventions and statistical analysis of data ($|E^2-1| = 0.91$). Accordingly, the molecules of **3** were observed to reside on (average) crystallographic twofold axes. The distance between the carbon atoms C9 and C12′, however, was as short as 2.37 (2) Å, which was far smaller than the expected van der Waals sum of 3.5 Å. Furthermore, the anisotropic temperature factor ellipsoids of both these atoms were distinctly elongated along their line of separation, suggesting that one Michael addition reaction could have taken place, resulting in bond formation between C9 and C12′ and leading to the nonsymmetrical structure **3**, which could exist in dynamic equilibrium with its identical "regioisomer" (**3**′, Figure 4b). Subsequent crystal structure solution and refinement in the lower noncentrosymmetric space group *Cc*,[15] gave a slightly nonsymmetrical molecular structure with C9–C12′ and C9′–C12 distances of 2.24(2) and 2.52(1) Å, respectively. Interestingly, when the same crystal was subjected to low-temperature X-ray measurements (123 K), these bond lengths diverged even further, as revealed by the values of 1.91(2) and 2.81(2) Å, computed by structure solution and refinement in *Cc*. When the *C*2/*c* space group was used the C9–C12′ distance was approximately the same as the room-temperature distance of 2.37 Å (2). These distances were even more drastically different [1.66(2) and 2.95(2) Å, respectively] in *Cc* when the atoms were refined isotropically. Thus, apparently partial dynamic ordering of the crystal structure occurs on cooling. Interestingly, while both the secododecahedrane[11] and the present examples involve carbon atoms at close proximity to each other, in the former case the X-ray analysis revealed a bond, whereas in the latter case it missed a bond.

[15] We thank Professor O. Ermer for suggesting that we revert to this space group (*Cc*) and for critically reviewing our conclusions regarding this anomalous X-ray crystallographic analysis.

New Iodination Reactions of Saturated Hydrocarbons**

José Barluenga, Esther Campos-Gómez, David Rodríguez, Francisco González-Bobes, and José M. González*

Selective processes that afford functionalized derivatives from the reaction of nonactivated C–H bonds are of current interest.[1] Bromination and chlorination reactions are valuable tools for this purpose with saturated hydrocarbons.[2] However, the related iodination is not so well developed.[3] Herein, we report on new iodination reactions of alkanes under mild thermal conditions. The process relies on the use of the combination of hypervalent iodine, I_2, and trimethylsilyl azide ($TMSN_3$). Furthermore, a related and efficient iodination in water, using H_2O_2 as a convenient source for the oxidant, has also been established.

Hydrocarbons can be iodinated under photochemical conditions by employing $PhI(OAc)_2/I_2/t$BuOH, a process that likely involves the formation of intermediate alkoxyl radicals.[3e] Alternative processes that lead to the development of

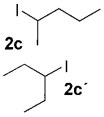
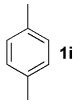
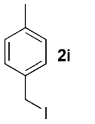
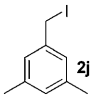
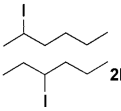
new methodology and involve different types of intermediates as the species responsible for the C–H activation step are of great significance and, overall, might result in new and distinctive synthetic features. Being interested in employing more convenient thermal conditions, we decided to investigate reactions using azide to activate the hypervalent iodine reagent.[4] 1-Acetoxy-1,2-benziodoxole-3(1*H*)-one[5] was chosen as the hypervalent iodine reagent. We expected that a catalytic amount of azide would be able to promote the desired iodination. This assumption was initially validated with cyclohexane (**1a**) as model compound, using $TMSN_3$ as the azide donor (Scheme 1).











Scheme 1. Synthesis of iodocyclohexane **2a** from the thermal reaction of cyclohexane (**1a**) with I_2 promoted by a cyclic λ^3-iodane and catalytic amounts of $TMSN_3$ (Method A, Table 1).

The concentration of the azide is crucial to accomplish the reported iodination. Routinely, to investigate the scope of the iodination (method A),[6] 4×10^{-3} M of azide was used. The results are summarized in Table 1. This novel iodination can be applied to different alkanes, either cyclic or acyclic. Interestingly, for the latter, an improved selectivity is noted.[3e] Now, only secondary positions are iodinated, without significant evidence for related functionalization of the primary ones. Benzylic positions are equally cleanly iodinated. This new reaction provides useful indicators. It relies on a thermal process; moreover, the use of a catalytic amount of azide and the observed selectivity for the iodination of linear hydrocarbons are also significant. Furthermore, this new process is very convenient with regard to the isolation of **2**, as well as the recovery of the reaction by-product. *o*-Iodobenzoic acid can be easily removed and recycled by simple aqueous extraction at proper pH. For the iodination of xylenes, an additional feature is noted. These are very efficient processes, which give rise to an increase in the incorporation of iodine atoms into the organic structure. Now, under proper conditions, most of the I_2 can be successfully used to functionalize the hydrocarbon.[7] On the basis of the formed products, the well-documented chemistry of azidobenziodoxoles, and taking into consideration the above-mentioned features, we propose that the sequence in Scheme 2 offers a feasible mechanistic rationalization for the reported iodinations.

Scheme 2. Proposed mechanism for the conversion of **1** into **2** (Method A, Table 1).

First, the starting acetoxyiodane leads to the formation of the known[5b,c] azidoiodane **A**. Next, interaction with I_2 should render active species, such as the iodanyl radical **B**,[8] a process in which a fraction of iodine acts as an efficient scavenger of azido radicals. The radical **B** would be responsible for the activation of the alkane[9] giving rise to *o*-iodobenzoic acid and a C-centered radical **C**, which then furnishes **2**[10] by trapping iodine.[11]

In an attempt to perform related reactions using simpler reagents we have explored the reaction of alkanes with iodine, aqueous solutions of NaN_3,[12] and H_2O_2 as oxidant.[13] We found that, in the presence of acetic anhydride, an efficient iodination reaction takes place, as depicted in Scheme 3 for

Scheme 3. Synthesis of α-iodotoluene (**2b**) by a C–H functionalization reaction in water (Method B, Table 1).

the functionalization of the benzylic position of toluene. The addition of small amounts of water adjusts the concentration of H_2O_2 and minimizes the formation of by-products (alcohol, acetate).[14]

This new reaction (see Table 1, method B[15] for data concerning the scope), on average, shows improved efficiency with respect to iodine incorporation into the organic precursor, allows an easy isolation of compounds **2**, and retains the selectivity for the iodination of secondary versus primary positions. Accordingly, linear pentane (**1c**) is nicely iodinated; however, the related *n*-hexane (**1k**) fails to react to appreciable extension. Though yet very preliminary, the previously noted differences for the adsorption of *n*-alkanes on the surface of water might account well for the trend in terms of reactivity in a qualitative sense.[16] This approach offers a convenient method to conduct the iodination of a varied and representative set of hydrocarbons in the presence of water.[17] At the same time, this is a very efficient protocol for directly iodinating alkanes, particularly, considering the high percentage of iodine that is typically incorporated into the structure of the hydrocarbon.

Overall, new reactions and significant experimental advances have been achieved for the iodination of hydrocarbons, which is a notoriously difficult reaction. At the same time, new perspectives for the use of well-established cyclic azidoiodanes have been offered by the present study. The examination of the possible reaction paths followed by using different hypervalent iodine reagents is also of interest with regard to investigating alternative reactive combinations based on simpler reagents. Further studies on the scope and implications of the herein reported chemistry are underway in our laboratories.

Experimental Section

Warning: We have not experienced any explosions while conducting our experiments, either using method A or B (so far, we carried out reactions that lead to about 5 mmol of compounds **2**); however, much care should be taken when working with azides, especially when heating them, as they are potentially explosive compounds.

Method A: All reactions were carried out under a positive pressure of nitrogen. In a typical experiment, I_2 (1.1 mmol, 0.28 g) and $TMSN_3$ (10%, 13 μL) were sequentially added to a suspension of 1-acetoxy-1,2-benziodoxol-3(1*H*)-one (1 mmol, 0.31 g) in cyclohexane (25 mL). The resulting mixture was stirred at 60°C (bath temperature) for 15 h. The mixture was allowed to cool and then quenched with aqueous NaOH (5%, 25 mL). The organic layer was distilled under reduced pressure, and excess cyclohexane was recovered. The distillation residue was diluted with diethyl ether (20 mL) and washed with aqueous $Na_2S_2O_3$ (5%, 30 mL), brine (30 mL), and dried over anhydrous Na_2SO_4. The solvent was removed at reduced pressure and the resulting oil was further purified by column chromatography, by using a mixture of hexanes as eluent, to afford cyclohexyl iodide **2a** (0.21 g, 0.91 mmol) as an irritating colorless oil.

Method B: In a typical experiment, Ac_2O (1.2 mL), H_2O (0.5 mL), and NaN_3 (0.20 g, 3 mmol) were sequentially added to a cooled solution (water/ice bath) of I_2 (0.25 g, 1 mmol) in toluene (5 mL). H_2O_2 (30% in water, 0.3 mL) was added and the mixture was vigorously stirred at 40°C for 13 h. The reaction mixture was poured into a saturated solution of $NaHCO_3$ (20 mL) and washed with aqueous $Na_2S_2O_3$ (5%, 15 mL). The organic layer was dried over anhydrous Na_2SO_4, and the excess toluene was recovered by distillation. The yellowish residue was purified by column chromatography, by using a mixture of hexanes as eluent, to afford benzyl iodide **2b** (0.41 g, 1.88 mmol) as a lachrymatory pale yellow oil.

PbTe Nanorods by Sonoelectrochemistry**

*Xiaofeng Qiu, Yongbing Lou, Anna C. S. Samia, Anando Devadoss, James D. Burgess, Smita Dayal, and Clemens Burda**

Size, shape, and compositional control are at the heart of nanochemistry.[1] Herein, we present a novel method that allows control over all three variables in a simple one-step, wet-chemical procedure. One-dimensional (1D) nanomaterials are of great interest for the construction of high-performance thermoelectric (TE) devices. Theoretical calculations indicate that improvement in TE efficiency can be achieved as the diameter of the 1D structures approaches a few nanometers.[2,3] To date, the most successful synthesis of 1D TE materials has been achieved by electrodeposition within alumina templates. A series of Bi_2Te_3,[4,5] $Bi_{2-x}Sb_xTe_3$,[6] $Bi_2Te_{3-y}Se_y$,[7] and $Bi_{1-x}Sb_x$[8,9] nanowires were prepared by using the template-based method. The advantages of the electrodeposition method include high efficiency, ease of control over composition, highly crystalline products, and room-temperature reaction conditions. However, the diameters of the nanowires synthesized by the template method are well above 10 nm. To get into the sub-10-nm regime, one needs to obtain templates with very narrow channel diameters, which is currently the limiting factor of this technique.

However, advances in combining sonochemistry and electrochemistry have provided a new strategy for the synthesis of nanomaterials.[10–13] The synthesis of quite sophisticated 1D nanomaterials has recently been demonstrated[14] to be possible through careful control of the electrochemistry, sonochemistry, and initial composition of the precursor solutions. As observed, the advantage of the sonoelectrochemical method is that it achieves 1D control without any template, thereby practically overcoming the limitation of generating nanorods with diameters below 10 nm. This diameter is the size regime in which TE properties become enhanced and a controlled synthesis can produce technologically relevant nanomaterials. Herein, we report the first synthesis of monodispersed PbTe nanorods that are sub-10 nm in diameter through a sonoelectrochemical technique.

Furthermore, we present the effect of changing the concentration of the coordinating ligand on the resulting composition of the synthesized nanomaterials. Changing the metal/ligand ratio enabled us to tune the composition of the product from pure Te to pure PbTe nanorods.

Lead telluride is the material of choice because of its great potential in high-performance TE devices.[15] Furthermore, it allows the mechanisms that lead to control over the resulting nanorod size and composition to be studied. Basically, the synthesis of PbTe nanorods consists of two steps: First, the electrodeposition of PbTe on the surface of the Ti sonication horn, and second, the dispersion of the PbTe nuclei into solution by pulsed sonication. Control over the electrodeposition process is crucial in obtaining pure and highly crystalline PbTe nanoparticles. Interestingly, we found that the Pb^{2+}/nitrilotriacetic acid (NTA) ratio plays a key role in the synthesis of PbTe nanorods. In contrast to previous studies on the electrodeposition of bulk PbTe,[16] we used a stoichiometric reactant ratio in the synthesis of the nanorods. The introduction of NTA helps to prevent the precipitation of Pb^{2+} ions as $Pb(OH)_2$. Furthermore, electrochemical studies show that NTA acts as more than a coordinating capping agent: it actually determines the final products of the process. The pH value of the solution was monitored during the electrodeposition, and TeO_2 was shown to be sufficiently soluble at $pH < 2$ or $pH > 7$.[16] However, the solubility of NTA was too poor at low pH values to keep the Pb^{2+} ions coordinated and in solution. Therefore, the solution was kept at approximately pH 8 under our experimental conditions, as TeO_2 is dissolved as TeO_3^{2-} ions at this pH value. The overall PbTe reaction equation [Eq. (1)] is (the NTA ligand is omitted for clarity):

$$Pb^{2+} + TeO_3^{2-} + 3\,H_2O + 6\,e^- \rightarrow PbTe + 6\,OH^- \quad (1)$$

Figure 1 shows the cyclic voltammograms of solutions with different NTA concentrations. In this figure, peaks 1, 1′, and 1″ correspond to the reduction of TeO_3^{2-} to Te^{2-} while peaks 2, 2′, and 2″ correspond to the reduction of TeO_3^{2-} to Te^0.[16,17] The potential shifts show that the electrodeposition of PbTe is highly sensitive to the ratio between Pb^{2+} and NTA.

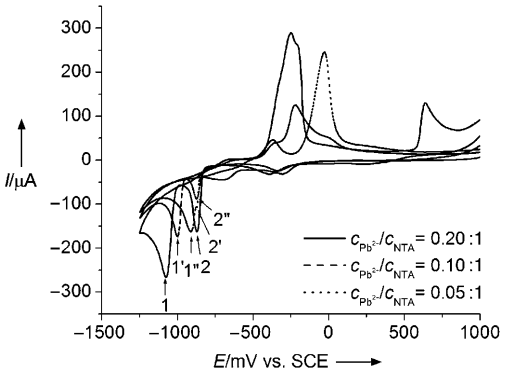

Figure 1. Cyclic voltammogram of the precursor solutions with $c_{Pb^{2+}}/c_{NTA}$ ratios changing from 0.20:1 (solid) to 0.10:1 (dash) then to 0.05:1 (dot). The concentrations of Pb^{2+} and TeO_3^{2-} ions were fixed at 10 mM in all measurements. SCE = saturated calomel electrode.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

At ratios of Pb^{2+}/NTA higher than approximately 0.16:1, the formation of PbTe can be achieved at potentials lower than −1.0 V and only the oxidation peak of PbTe at −0.245 V is observed in the reverse scan. By decreasing the Pb^{2+}/NTA ratio to as low as 0.05:1, peaks 1″ and 2″ almost overlap and the predominant species produced is Te^0, which is proved by the predominant oxidation of Te at −0.029 V during the reverse scan. The precipitation of both PbTe and Te^0 are observed in the intermediate cases in which the Pb^{2+}/NTA ratios are between 0.20:1 and 0.05:1, even when the potential is kept below −1.0 V. Both the oxidation peaks of PbTe at −0.225 V and Te at −0.024 V can be clearly observed in the reverse scan. This tuning of the product outcome was also confirmed by powder X-ray diffraction (XRD) measurements of the isolated nanomaterials. Overall, this observation shows that the Pb^{2+}/NTA ratio controls the nature and concentration of Pb^{2+} ions in solution, which then in turn influences the formation of PbTe.[18] Basically, the PbTe formation predominates when the Pb^{2+}/NTA ratio is high, even at very low concentrations of Te^{2-} ions. However, if the Pb^{2+}/NTA ratio is too low, the thermodynamic solubility constant K_{sp} limits the precipitation of PbTe, which only occurs at relatively high concentrations of Te^{2-} ions. We observed similar phenomena for the synthesis of other semiconductor nanocrystals. These results show that the ratio of metal ion/ligand concentration can be the controlling factor in the redox chemistry involved in the synthesis of semiconductor nanomaterials.

Figure 2 shows the powder XRD pattern of nanorods produced under different Pb^{2+}/NTA ratios. The XRD patterns show that the product exhibits a purely face-centered cubic (fcc) PbTe system ($a = 6.464$ Å; JCPDS card: 78-1905) at a high Pb^{2+}/NTA ratio (a), whereas the product is a purely

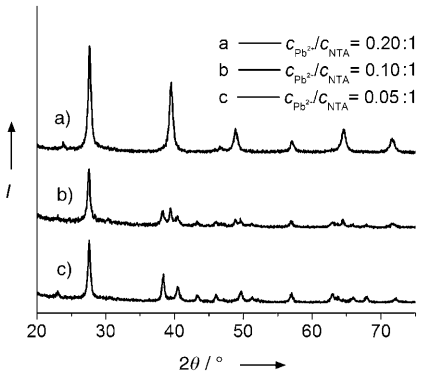

Figure 2. The powder XRD pattern of nanorods synthesized at different Pb^{2+}/NTA ratios. a) Pure PbTe, b) mixture of PbTe and Te, and c) pure Te.

hexagonal tellurium system ($a = 4.457$, $c = 5.927$ Å; JCPDS card: 36-1452) at low Pb^{2+}/NTA ratios of ≤ 0.05:1 (c). The XRD patterns for the products made at intermediate concentration ratios indicate a mixture of PbTe and Te powder. The cyclic voltammetry (CV) and XRD studies together show that the composition of the sample can be controlled by the initial Pb^{2+}/NTA ratio.

Modulation of the morphology is achieved by controlling the current intensity, reagent concentration, reaction time, and ultrasound intensity, as well as the ultrasound pulse on/off ratio. The morphology and crystallinity of the PbTe nanoparticles can be controlled precisely by using the correct sonoelectrochemical conditions.

A transmission electron microscopy (TEM) image of the PbTe nanorods shows a highly uniform nanorod morphology (Figure 3a), in which the nanorods have an average diameter of 7 nm and an aspect ratio of 7. It was found that the reaction time greatly affects the size of the PbTe nanorods and increasing the reaction time yielded larger nanorods with larger aspect ratios. Figure 3c shows the morphology of a PbTe nanorod after reaction for 45 minutes. The resulting nanorod has a diameter of 11.4 nm and a length of 104 nm. Figure 3d shows the nanorod obtained after 1.5 hours, which

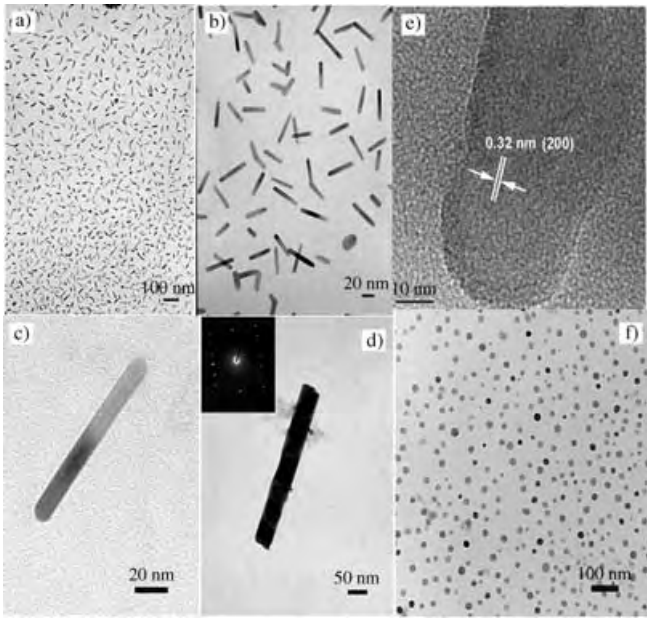

Figure 3. a) TEM image of PbTe nanorods prepared by sonoelectrochemistry at room temperature for 30 minutes. b) Enlarged TEM image of PbTe nanorods prepared under identical conditions. c) TEM image of a nanorod obtained after 45 minutes of reaction. d) TEM image of a nanorod obtained after 1.5 hours of reaction; the inserted selected-area electron-diffraction pattern indicates the single-crystal nature of the shown nanorod. e) HRTEM image of PbTe, a nanorod indicating the (200) lattice plane spacing. f) Spherical PbTe nanoparticles synthesized under a low concentration of Pb^{2+} ions (2 mM).

has a diameter of 43 nm and a length of 370 nm. A high-resolution TEM (HRTEM) study (Figure 3e) shows that the PbTe nanorods are highly crystalline and that the d spacing is 0.32 nm, which indexes to the d(200) planes of the fcc PbTe lattice. This value corresponds exactly to the strongest peak observed in the XRD pattern (Figure 2a). Therefore, the direction of the nanorod growth is perpendicular to the x axis and is along the [001] plane. Figure 3f shows PbTe nanoparticles synthesized under a very low concentration of Pb^{2+} ions (2 mM), and only spherical particles are observed. Increasing the concentration of Pb^{2+} ions causes the spheres to grow and rod-shaped morphologies to be yielded. Such rod growth is likely to occur through Ostwald ripening under the ultrasound cavitation process. Similar growth mechanisms were reported in the thermal synthesis of CdTe nanowires and Ag nanorods.[19,20]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As the XRD results show, the prepared PbTe nanorods exhibit a cubic lattice structure. The crystalline symmetry of the material also affects the ZT value of the TE materials. Cubic space groups yield maximum degeneracy N_v of the band extrema near the Femi level. The ZT value, which is of merit itself, is proportional to the N_v value.[21] Thus, a further enhancement of the TE power can be reached with cubic PbTe nanorods.

In conclusion, we have successfully achieved the synthesis of PbTe nanorods with a diameter in the sub-10-nm regime that are highly uniform, single-crystalline, and pure through a novel sonoelectrochemical method under ambient conditions. The ratio of metal ion/ligand was used to control the purity of the PbTe nanostructures. These very thin and cubic PbTe nanorods are promising building units for future TE devices. Currently, the sonoelectrochemical synthesis of other nanomaterials is being studied to show the usefulness of this procedure for a broad range of synthetic applications.

Experimental Section

The room-temperature synthesis of the PbTe nanorods is based on constant-current electrodeposition accompanied by applied ultrasonic pulses in an aqueous solution that contains lead nitrate (Aldrich, 99.99%), NTA (Aldrich, 99+%), and TeO_2 (Aldrich, 99+%). A VCX-500 ultrasonic processor from Sonics and Materials Inc. (Ti horn, 0.5 inch in diameter, 20 kHz) worked as the ultrasound source and a Harrison 6102 A DC power supply acted as the current source. The solution was sonicated in the presence of a constant current for 0.5–2 h, and a sonication pulse on/off ratio varying from 1:1 to 1:10 was explored for the nanorod synthesis. Highly crystallized and monodispersed PbTe nanorods were produced with current densities of 10 mA cm^{-2}, ultrasound intensities of approximately 25–45%, and a reaction time of 30 min. After the reaction, the resulting brown–black solution was purified by centrifugation, and the precipitate was washed with distilled water and ethanol and then air dried before analysis.

CV measurements were carried out on a BAS CV 50W with a Pt-disc working electrode, Pt-wire counter electrode, and an SCE reference electrode, and the scan rate was 100 mV s^{-1}. The phase purity of products was characterized by a Scintag X-1 Advanced X-ray diffractometer (XRD, 2.4° min^{-1}, $Cu_{K\alpha}$ radiation). The morphology of the PbTe nanorods was analyzed with a transmission electron microscope, JEOL 1200CX (TEM, accelerating voltage: 80 kV). The HRTEM images were obtained on a FEI Tecnai F30 electron microscope by applying an accelerating voltage of 300 kV.

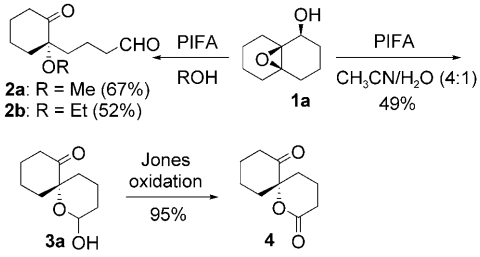
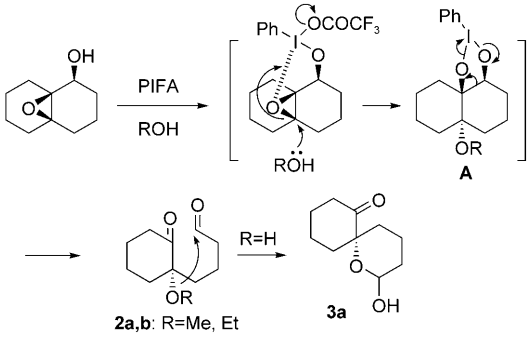
reactions is, therefore, a very attractive subject in the field of synthetic organic chemistry.[1] We present herein an efficient domino reaction in which a three- or four-step sequence occurs in a single operation. Thus, the reaction of 2,3-epoxy-1-alcohols[2] with hypervalent iodine(III) reagents[3] in the presence of H_2O allowed the efficient domino three- or four-step sequence to produce lactols **3** in a single operation (Scheme 1). The reaction was applied to the concise synthesis of (+)-tanikolide.



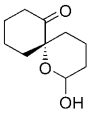
Scheme 1. Domino reaction of 2,3-epoxy-1-alcohols with PIFA in the presence of H_2O.

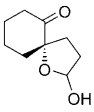


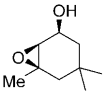
The reaction of bicyclic 2,3-epoxy alcohol **1a** with phenyliodine(III) bis(trifluoroacetate) (PIFA) was examined in the presence of an oxygen-containing nucleophile, an alcohol, or H_2O (when an alcohol was used, it was also employed as the solvent; Scheme 2). A mixture of **1a** (1.0 mmol) in ROH or H_2O/CH_3CN (1:4; 10 mL) was treated with PIFA (1.0 mmol) at 0 °C–RT, with the reaction proceeding smoothly for both nucleophiles. Methoxy keto aldehyde **2a** was obtained in moderate yield from the use of MeOH as the nucleophile, and a similar product **2b** was obtained from EtOH. On the other hand, the lactol **3a** (a mixture of diastereoisomers differing at the acetal position) was obtained from using H_2O. Compound **3a** was converted into the keto lactone **4** by the Jones oxidation.

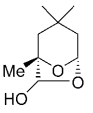
The formation of **2a**,**b** and **3a** from **1a** is rationalized as follows: first, nucleophilic attack of ROH (R = Me, Et, H) on the oxirane ring gave the alkoxy or hydroxy intermediate **A**, whose C–C bond between the two hydroxy groups was cleaved to give keto aldehyde **2a**,**b** in good yield.[4] When H_2O was used as the nucleophile, a further lactol formation occurred to afford **3a** (Scheme 3).

The generality of the lactol formation was examined next by using various types of epoxy alcohols (Table 1). The bicyclic epoxy alcohols **1a**,**b** gave bicyclic keto lactols **3a**,**b** in fairly good yields (entries 1 and 2). The bicyclic dioxaspiro lactols **3c–i** were obtained in good yields from the monocyclic trisubstituted epoxy alcohols **1c–i**.[5] The formation of **3c–i** is rationalized as a further lactol formation between the hemiacetal hydroxy function and the aldehyde (Scheme 4). No further lactol formation was observed in the keto lactols **3a**,**b**, possibly because access to the ketone moieties is more hindered than to the aldehyde moieties.

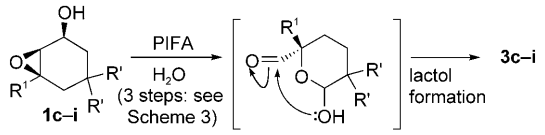








Scheme 2. PIFA treatment of **1a** in the presence of an oxygen-containing nucleophile.



Scheme 3. Plausible reaction mechanism for the formation of **2** and **3**.

The bicyclic keto lactols were converted into the corresponding lactones in two steps. Thus, the reduction of **3e**,**h** with diisobutylaluminum hydride (DIBAH) or the reduction of **3i** of with $NaBH_4$ gave dihydroxy lactols **4e**,**h**,**i**, which were oxidized using Ag_2CO_3/celite[6] to afford the desired lactones **5e**,**h**,**i** in fairly good yields (Scheme 5).

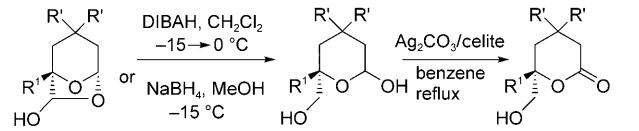


Table 1: Reaction of various 2,3-epoxy alcohols with PIFA in the presence of H_2O.

Entry	Substrate		Product		Yield [%]
1		**1a**		**3a**	49
2		**1b**		**3b**	66
3		**1c** (R^1 = Me)		**3c** (R^1 = Me)	62
4		**1d** (R^1 = Et)		**3d** (R^1 = Et)	74
5		**1e** (R^1 = *n*-$C_{11}H_{23}$)		**3e** (R^1 = *n*-$C_{11}H_{23}$)	72
6		**1f** (R^1 = CH_2CHMe_2)		**3f** (R^1 = CH_2CHMe_2)	67
7		**1g** (R^1 = CH_2Ph)		**3g** (R^1 = CH_2Ph)	72
8		**1h** (R^1 = Ph)		**3h** (R^1 = Ph)	53
9		**1i**		**3i**	65

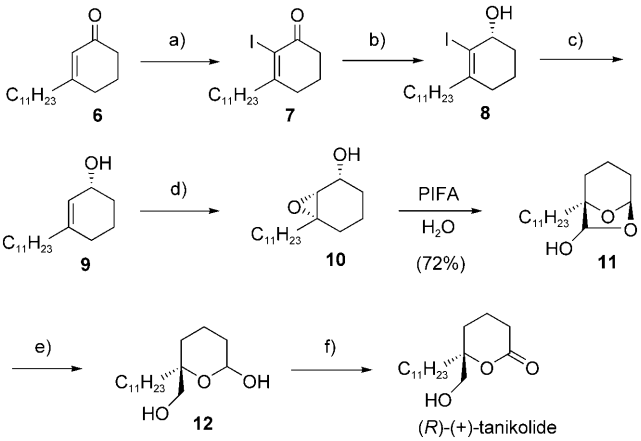
5i (98% over 2 steps)



Scheme 5. Conversion of bicyclic lactols into lactones.

With the general transformation of epoxy alcohols to lactols and lactones now available, the application of this method to the concise asymmetric synthesis of (+)-tanikolide was examined next. (+)-Tanikolide is a γ-lactone metabolite of the marine cyanobacterium *Lyngbya majuscula*, which was collected on Tanikeli Island, Madagascar, in 1999 and shows antifungal activity.[7] The enone **6**[8] was converted into the α-iodo enone **7** in 80% yield by using the procedure developed by Sha and Huang.[9] The asymmetric reduction of **7** with the Corey reagent[10] afforded *R*-allyl alcohol **8** in 93% yield with 98% *ee* (optical purity was 98% *ee*, as determined by HPLC analysis of **9** (chiralcel OD and elution with hexane/*i*PrOH (99:1)). The radical reduction[11] of **8** afforded **9** in 84% yield. The stereoselective epoxidation[12] of **9** gave the *cis*-epoxy alcohol **10**. The treatment of **10** with PIFA gave the lactol **11** in 72% yield. Reduction of **11** with DIBAH gave the hydroxy lactol **12**. Chemoselective oxidation of the lactol hydroxy function with Ag_2CO_3/celite[6] afforded (+)-tanikolide in 57% yield over two steps (Scheme 6). ^{1}H NMR spectroscopic analysis (500 MHz) of the corresponding (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid ester of (+)-tanikolide[13] determined the *ee* value as 98%. Although several synthetic studies of (+)-tanikolide have already been reported,[14] our synthesis provides an alternative approach with few steps and high optical purity.

In conclusion, we have developed a novel transformation of 2,3-epoxy-1-alcohols into lactols in a single operation. The lactone functionality is present in a large variety of biologically active compounds and natural products. As domino reactions can reduce the number of operations in the synthesis of organic compounds, this method opens up a new approach to obtaining optically active lactone compounds and will be very useful in the field of synthetic organic chemistry.

Experimental Section

General procedure for lactol formation (conversion of **10** into **11**): PIFA (281.3 mg, 0.65 mmol) was added to a stirred solution of **10** (175.6 mg, 0.65 mmol) in H_2O/CH_3CN (1:4 (v/v), 6.5 mL) at 0 °C. The reaction mixture was allowed to warm to room temperature and then

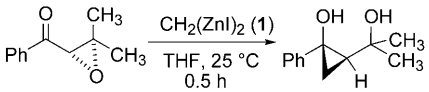
Diastereoselectivity



DOI: 10.1002/anie.200501644

Stereospecific and Stereoselective Preparation of 2-(1-Hydroxyalkyl)-1-alkylcyclopropanols from α,β-Epoxy Ketones and Bis(iodozincio)methane**

*Kenichi Nomura, Koichiro Oshima, and Seijiro Matsubara**

The most common method used to prepare cyclopropane compounds involves the reaction of electrophilic Simmons–Smith-type reagents with alkenes.[1] In contrast to this electrophilic [2+1] reaction, a *gem*-organodimetal compound also has the possibility of participating in a nucleophilic [2+1] reaction because it has two nucleophilic sites on one carbon atom.[2,3] In fact, we have already reported the reaction of bis(iodozincio)methane (**1**) with 1,2-diketone to give *cis*-1,2-cyclopropanediol with high diastereoselectivity.[4] In this transformation, **1** acts as a bidentate Lewis acid and fixes the conformation of the 1,2-diketone in the *s-cis* form.[4c] Thus, a substrate which has two Lewis basic sites may interact at two sites with **1**, and may show some characteristic stereochemical performance during subsequent useful molecular transformations.[5] Following this observation, we treated **1** with α,β-epoxy ketone and found that the reaction resulted in the stereospecific formation of 2-(1-hydroxyalkyl)-1-alkylcyclopropanol.[6]

Treatment of 2-benzoyl-1,1-dimethyloxirane (**2a**) with **1** gives (1*R**,2*R**)-2-(1-methyl-1-hydroxyethyl)-1-phenylcyclopropanol (**3a**) as the sole product (Scheme 1). The stereochemistry of the product was determined by single-crystal X-ray analysis (Figure 1).[7] Other examples of reactions conducted that led to formation of a cyclopropane ring are

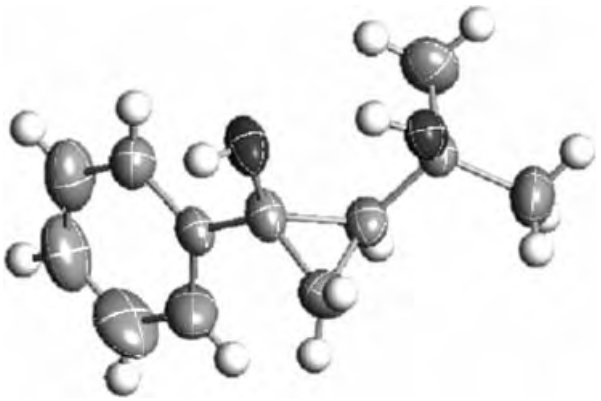

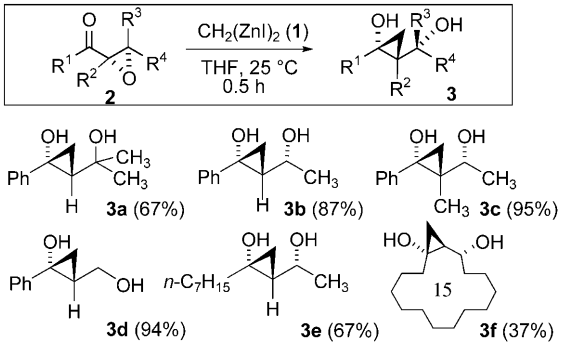

Figure 1. Structure of **3a** as determined by X-ray analysis.

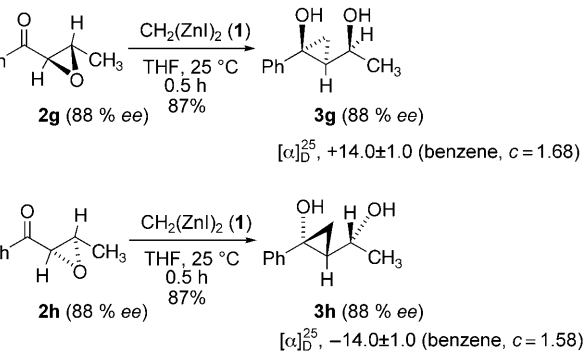
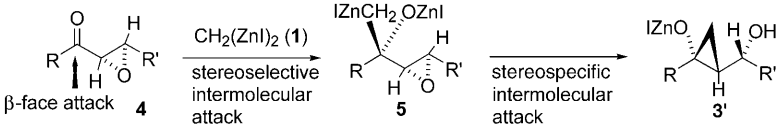
Scheme 2. Preparation of 2-(1-hydroxyalkyl)-1-alkylcyclopropanol **3**.



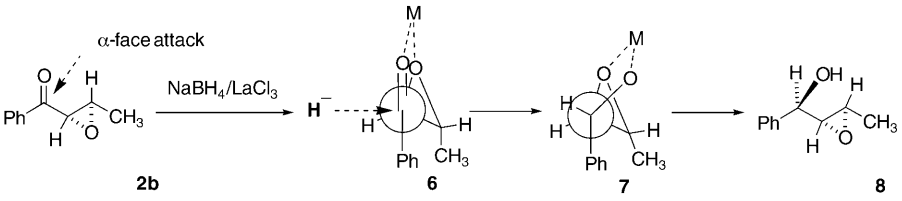
summarized in Scheme 2. In all cases, the reaction yielded a single diastereomer selectively.

An optically active epoxy ketone[8] **2g** was treated with **1** to give (1*S*,2*S*)-2-(*S*-1-hydroxyethyl)-1-phenylcyclopropanol (**3g**) without loss of enantiomeric purity. The reaction involving the enantiomer of **2g** (namely, **2h**) gave the corresponding enantiomer **3h** (Scheme 3).



The diastereoselective formation of cyclopropanol **3** can be explained as follows. The reaction starts with the diastereoselective attack of **1** at the carbonyl group as a consequence of the stereogenic center at the α-carbon atom (Scheme 4).[4,9] This step is followed by stereospecific attack on the epoxide.

The explanation shown in Scheme 4 requires diastereoselective attack to the β face of **4**, which needs to be rationalized, since previous reports concerning the diastereoselective metal-mediated nucleophilic attack to an α,β-epoxy ketone occurred from the α face of **4**.[10]



For example, treatment of **2b** with $NaBH_4/LaCl_3$ resulted in the exclusive formation of *erythro*-epoxy alcohol.[11] The diastereoselective reaction was explained by chelation effects to form intermediate **6**, as shown in Scheme 5. Other metal salts, such as $CaCl_2$, $MnCl_2$, and $ZnCl_2$ as well as $LaCl_3$ showed the same effect. Sato et al reported the preparation of 2-(1-hydroxyalkyl)-1-alkylcyclopropanol from an α,β-epoxy ketone and trimethylstannylmethyllithium.[6] Their results did not reveal any diasteromeric selectivity for trisubstituted oxirane substrates such as **3c**. The major isomers were also postulated to be produced by α-face attack of **4** in the case of disubstituted oxirane substrates (namely, **3a**,**b**,**d**–**f**).[6] In the present cyclopropanation reaction, the addition of **1** cannot be explained by a simple chelation intermediate such as **6**,[6,10,11] because the first nucleophilic attack also occurred by β-face attack on **4**. From our ab initio calculations, we propose that coordination of **1** to 2,3-dioxobutane occurs in a face-to-face arrangement, as shown in Figure 2 (**9**: side view; **10**: bottom view).[4c]

Scheme 3. Preparation of optically active 2-(1-hydroxyalkyl)-1-alkylcyclopropanol from optically active α,β-epoxy ketones and bis(iodozincio)methane (**1**).

Such coordination has two characteristic features: first, the dihedral angle of the diketone part (∢O(1)-C(1)-C(2)-O(2) = 47.7°); and second, the mechanism through which the zinc reagent coordinates to the diketone. A line drawn between the two oxygen atoms of the diketone, and another between the two zinc atoms in the initial complex, cross at almost right angles. In the same way, the nucleophilic attack of **1** on epoxy ketone **2h** can be explained via intermediate **11** (Scheme 6). Attack from the other face via intermediate **13** will be constrained by steric hindrance between **1** and the epoxide ring. Thus, face-to-face coordination will promote attack on the opposite face relative to traditional Cram-chelation intermediates such as **6**.

A cyclic substrate such as **14** or **16** (Scheme 7) will experience some difficulty in differentiating between the intermediate corresponding to **11** and **13** because of steric hindrance of the carbocyclic moiety. Treatment of **14** and **16** with **1**, however, gave the spiro compound with good diastereoselectivity. Figure 3 shows the results of the single-crystal X-ray analysis of the diester obtained from **17a** and 3,5-dinitrobenzoyl chloride.[12]

A derivative of 2-(1-hydroxyalkyl)-1-alkylcyclopropanol is an important intermediate structure of some natural products.[13] In our present method, we report a new diastereofacial selective attack of epoxy ketone by utilizing the Lewis acidity of the dizinc reagent **1**. Bis(iodozincio)-methane (**1**), prepared from diiodomethane and zinc powder, exists as monomeric form without aggregation or a contribution of the Schlenk equilibrium.[14,15] This monomeric structure is crucial when demonstrating its function as an effective bidentate Lewis acid in a stereoselective reaction.

Efficient One-Step Synthesis of Biologically Related Lariat RNAs by a Deoxyribozyme**

*Yangming Wang and Scott K. Silverman**

Lariat RNAs are intermediates in RNA splicing events catalyzed by group II introns and the spliceosome.[1,2] Lariats have a closed RNA loop with a single 2′–5′ linkage and a single-stranded oligonucleotide attached at the 3′-oxygen atom of the branch-site nucleotide (Figure 1 a). Topologically, lariats are a subclass of 2′,5′-branched RNAs, which do not necessarily have the closed loop that is characteristic of lariats. Owing to their special topology, lariat RNAs are difficult to synthesize by any conventional chemical approach such as solid-phase synthesis,[3] and even the simpler 2′,5′-branched RNA core (without the closed loop of a lariat) is a significant challenge.[4] Recently we reported artificial deoxyribozymes (DNA enzymes)[5] that create branched RNAs in $>90\,\%$ yield by catalyzing the intermolecular reaction of an internal 2′-hydroxy group with a 5′-triphosphate.[6,7] Some of these deoxyribozymes are capable of synthesizing branched RNAs of wide sequence composition.[8,9] Lariat products can result from intramolecular branch formation events (that is, macrocyclizations with single linear RNA substrates), as illustrated in Figure 1 b. Apart from using the frequently impractical biological splicing machinery itself, there is no method present for the synthesis of biologically relevant lariat RNAs, which are often several hundred nucleotides in length and have extensive secondary structure[10] that may interfere with loop formation. Indeed, most of our reported branch-forming deoxyribozymes such as 7S11, which is widely useful for branched RNA synthesis,[8] are not useful with biologically derived RNA sequences as substrates (lariat yield typically $<1\,\%$; data not shown). In contrast to these difficulties, we report herein that the 6BX22 deoxyribozyme can create two common classes of biological lariat RNAs efficiently in one step from readily available RNA substrates.

In previous efforts, we used in vitro selection[11] to identify many deoxyribozymes that synthesize branched RNA.[6–9,12]

However, our procedure does not select for the particular ability to create lariats. One-step lariat formation is presumably more difficult than simple branch formation because the incipient RNA loop may clash sterically with the DNA structure, thereby inhibiting catalysis. We surveyed many of the branch-forming deoxyribozymes to determine their lariat-formation capabilities. One of these deoxyribozymes, 6BX22,[12] showed promise in this regard and was examined more carefully. The 6BX22 deoxyribozyme has a specific 39-nucleotide DNA enzyme region embedded between Watson–Crick binding arms, as shown schematically in Figure 1b. It was found to require Mn^{2+}; detectable RNA ligation activity was not observed with Mg^{2+}, Ca^{2+}, Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}, or $[Co(NH_3)_6]^{3+}$ (all as chloride salts at concentrations in the range of 10 μM–10 mM; data not shown). The k_{obs} value for 6BX22-catalyzed branch formation is $\approx 0.07\ min^{-1}$ ($t_{1/2} \approx 10$ min) under standard incubation conditions (Mn^{2+} (20 mM), pH 7.5, 37 °C; see below). The background rate for the analogous DNA-templated reaction (the use of a DNA template that lacks an enzyme region between the DNA binding arms) is much lower; $k_{templated} \approx 4 \times 10^{-7}\ min^{-1}$ [6], which gives a rate enhancement ($k_{obs}/k_{templated}$) of 2×10^5.[13] Therefore, 6BX22 clearly "catalyzes" branch formation. If it merely templated the reaction by increasing the effective substrate concentration, then $k_{obs}/k_{templated}$ would be 1.[5a]

Before studying 6BX22-catalyzed lariat RNA synthesis in detail, we examined the substrate sequence generality of this deoxyribozyme for branch formation. This reaction is simpler than lariat formation because loop closure is not required. The selection procedure in which 6BX22 was identified[12] used RNA substrates that correspond to the conserved branch-site sequences of yeast spliceosomal substrates (Figure 2a), which are common models for understanding RNA splicing.[2] Systematic experiments revealed that sequence changes outside the conserved RNA elements are tolerated well by 6BX22, indicating that this DNA enzyme is general for branch formation with yeast spliceosomal substrates (Figure 2b). Most nucleotide changes within the conserved regions are also tolerated. For example, the branch-site nucleotide itself may be changed from A to C or U with nearly equivalent ligation efficiencies (Figure 2c). A branch-site G is accepted but with diminished yield.

We applied 6BX22 toward the synthesis of three specific representative biological lariat RNAs that are derived from yeast or mammalian spliceosomal substrates, but share no sequence elements outside of the small consensus region. The three RNAs are the 69-nt yeast YBL059W intron with a 51-nt lariat loop,[14] the 130-nt human β-globin IVS1 intron with a 94-nt loop,[15] and the 309-nt yeast actin (ACT1) intron with a 266-nt loop.[16] In each case, a linear 5′-triphosphate substrate was prepared by in vitro transcription with T7 RNA polymerase. By using the linear substrate, the small YBL059W lariat was readily synthesized by 6BX22 in one step and in high yield (Figure 3a). The larger β-globin and ACT1 lariats were also readily prepared (Figure 3b,c). The lariats were formed with k_{obs} values similar to those of the analogous branches, or in the case of β-globin, about sixfold slower (but still with a k_{obs} value that is preparatively useful). Compelling evidence for each lariat structure was provided by several

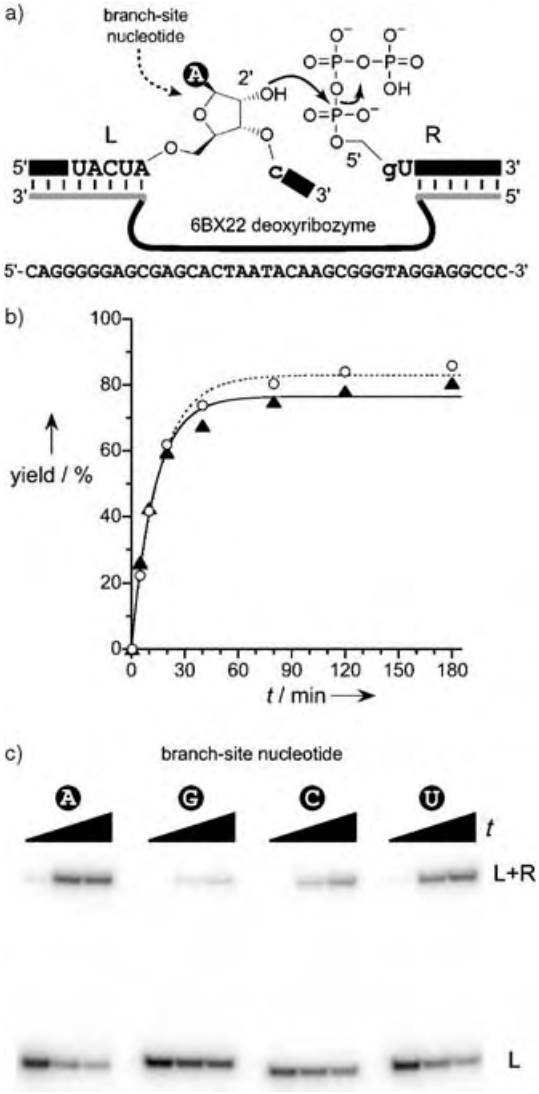

Figure 2. Branched RNA formation by the 6BX22 deoxyribozyme. a) With yeast spliceosomal substrate sequences; the conserved nucleotides are shown explicitly.[2] As demonstrated with the comprehensive experiments shown herein and in the Supporting Information, 6BX22 tolerates nucleotide changes at most of the conserved positions; the sites of tolerance are indicated with uppercase letters. The second nucleotide (U) of the right-hand substrate (R) prefers U, C, or A over G. The sequence of the enzyme region of 6BX22 (the 39 nucleotides not base-paired with the RNA substrates) is given below the structure. The Watson–Crick binding arms of the DNA are shown in light gray. See Experimental Section for full sequences of the left-hand (L) and right-hand (R) substrates. b) Demonstration of the generality of 6BX22 for its RNA substrate sequences; conditions: HEPES (*N*-(2-hydroxyethyl)-piperazine-*N*-(2-ethanesulfonic acid), 50 mM, pH 7.5), NaCl (150 mM), KCl (2 mM), $MnCl_2$ (20 mM), 37 °C. Original RNA sequences that correspond to the core nucleotides of the ACT1 RNA (▲); variant RNA sequences (○, see Experimental Section). For this experiment, $k_{obs} = 0.077 \pm 0.007\ min^{-1}$ (original sequences) and $0.066 \pm 0.004\ min^{-1}$ (variant sequences); errors are standard deviations from exponential curve fits. c) Demonstration of the generality of 6BX22 for branch-site nucleotides ($t = 0$, 0.5, and 1.5 h with 5′-^{32}P-radiolabeled L substrate; 20% PAGE). L+R product yields at $t = 1.5$ h: branch-site A, 71%; G, 5%; C, 33%; U, 64% ($k_{rel} = 1$, 0.085, 0.097, and 0.027, respectively; data not shown). In all cases, partial alkaline hydrolysis of the branched product[6] verified that the site of branching remained unchanged (data not shown).

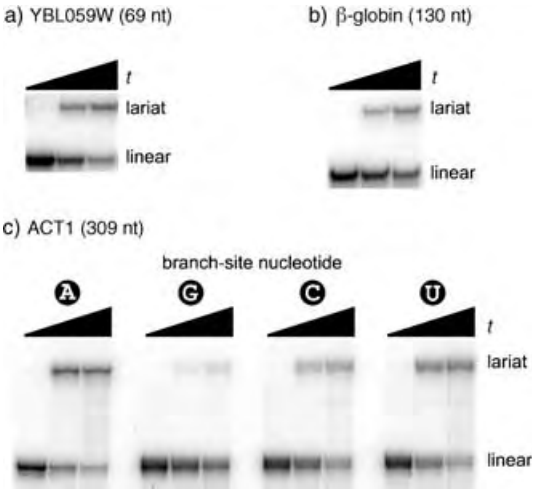

Figure 3. Formation of biologically related lariat RNAs with the 6BX22 deoxyribozyme. a) Synthesis of the 69-nt YBL059W lariat, which has a 51-nt loop (12% PAGE; $t = 0$, 0.5, and 1.5 h). Yield at $t = 1.5$ h: 52%; $k_{obs} = 1.1\ h^{-1}$ (data not shown). b) Synthesis of the 130-nt human β-globin IVS1 lariat, which has a 94-nt loop (8% PAGE; $t = 0$, 2, and 6 h). Yield at $t = 6$ h: 33%; $k_{obs} = 0.17\ h^{-1}$. At $t = 24$ h the yield was ≈50%, but some nonspecific RNA degradation was evident (data not shown). c) Synthesis of the 309-nt ACT1 lariat, which has a 266-nt loop; this was tested with mutants in which the branch-site nucleotide was changed as indicated (6% PAGE; $t = 0$, 0.5, and 1.5 h). Yields at $t = 1.5$ h: branch-site A, 72%; G, 9%; C, 48%; U, 70%. For branch-site A $k_{obs} = 2.8\ h^{-1}$ (data not shown). For the β-globin lariat, disruptor DNA oligonucleotides were required to sequester RNA secondary structure and enable binding of the DNA enzyme to the RNA substrates (Supporting Information). Without disruptors, the β-globin lariat yield was 0.3% at 6 h. A disruptor oligonucleotide was helpful but not absolutely required for ACT1 lariat synthesis, primarily by modestly enhancing the ligation rate (by less than twofold) and by suppressing nonspecific RNA degradation.

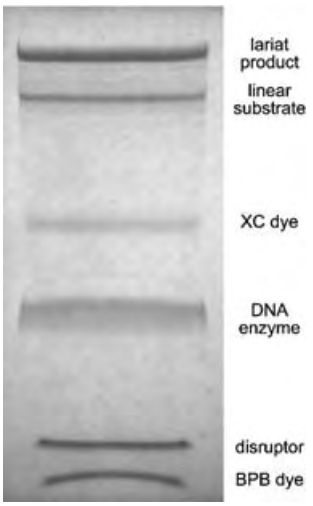

Figure 4. Preparative synthesis of the ACT1 lariat RNA; the image was recorded by UV shadowing of the 6% polyacrylamide gel.

biochemical assays in which the lariat RNA was cleaved with the 10–23 deoxyribozyme[17] and yeast debranching enzyme[18] to generate the predicted pattern of gel bands (Supporting Information). For the β-globin lariat, disruptor DNA oligonucleotides were required to allow the deoxyribozyme to bind productively with its RNA substrates (Supporting Information). For the largest ACT1 lariat, a disruptor helped to prevent RNA degradation, but it was not required for high lariat yield (data not shown).

The yeast ACT1 intron is a particularly common model system for studying spliceosomal RNA processing.[16,19] Artificial synthesis of such lariats without the natural splicing machinery will enable many biochemical experiments, because the sequence requirements of the spliceosome need not be obeyed. For example, the tolerance of 6BX22 toward changes of the branch-site nucleotide during branch formation (Figure 2c) is maintained for lariat synthesis (Figure 3c). Therefore, for the first time, biochemists have access to "real" spliceosomal lariats with mutations at their key branch-site nucleotides. To enable such experiments, preparative-scale (nanomole) synthesis of the ACT1 intron lariat was successfully carried out in high yield (Figure 4).

In summary, we have demonstrated that the 6BX22 deoxyribozyme catalyzes efficient and general one-step lariat synthesis with biological RNAs that are derived from commonly studied yeast and mammalian spliceosomal substrates. The resulting lariats are essentially impossible to synthesize by traditional organic and solid-phase synthesis methods. The only available approach until now has required the use of natural splicing enzymes, which have stringent sequence requirements that impose considerable limitations on the RNA sequences that may be used as substrates. Lariat RNA formation for the YBL059W, β-globin, and ACT1 intron substrates corresponds to the creation of rings with 307, 565, and 1597 atoms, respectively. These DNA-catalyzed macrocyclization reactions succeed without the use of protecting groups despite the presence of hundreds of competitive 2′-hydroxy nucleophiles. This demonstrates an extremely high level of site-selectivity. The reactions also produce very small amounts of side products such as RNA substrate oligomers that are created in large quantity with other deoxyribozymes that synthesize lariat RNAs in low yield.[6] The broadly useful lariat synthesis capacity of 6BX22 is unique in comparison with all of our other deoxyribozymes identified so far, including those such as 7S11, which are quite general for the formation of simpler branched RNAs.[8] The structural basis by which 6BX22—yet none of our other deoxyribozymes—readily tolerates a closed RNA loop in its catalytically active conformation requires further study, as does the mechanism by which 6BX22 achieves its $>10^5$-fold rate enhancement over mere templating. We continue to investigate these fundamental features of catalytic DNA, and we are using synthetic lariats created by 6BX22 to examine key biochemical aspects of RNA splicing.

Experimental Section

Systematic variation of RNA substrate sequences (Figure 2): The original left-hand (L) RNA substrate sequence (which corresponds to that used in the selection procedure[12]) was 5′-GGAAGUCUCAUGUACUAACA-3′. The original right-hand (R) RNA substrate sequence was 5′-GUAUGUUCUAGCGCGGA-3′. Together these

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sequences comprise the "core" of the ACT1 branch. For the experiment shown in Figure 2b, nearly all RNA substrate nucleotides in both L and R were changed by transversions (A↔C and G↔U). In L, changes were made to all nucleotides from the 5′ end through and including UACU. In R, changes were made to all nucleotides after 5′-GU through the 3′ end. In all cases, corresponding transversions were made to the DNA to maintain Watson–Crick complementarity. For the experiment shown in Figure 2c, the L substrate was varied only at the branch-site nucleotide position (UACUAAC). (For experiments with variations at the L substrate UACUA nucleotide and at the R substrate GU nucleotide, see the Supporting Information.) Variation of the 5′-triphosphorylated guanosine (5′-pppG) of the R substrate was not tested. The assays were performed with 5′-^{32}P-radiolabeled L substrate and L/deoxyribozyme/R = 1:3:6, under incubation conditions of HEPES (50 mM, pH 7.5), NaCl (150 mM), KCl (2 mM), and $MnCl_2$ (20 mM) at 37 °C.

Synthesis of the three lariat RNAs (Figure 3): Each linear RNA substrate was prepared by transcription in the presence of α-^{32}P-CTP to give internally ^{32}P-radiolabeled transcript. The assays were carried out under the incubation conditions above and a substrate/deoxyribozyme ratio of 1:2. In all cases, side products (presumably substrate oligomers[6]) were observed in very small amounts: < 3 % yield for YBL059W and β-globin; < 0.1 % yield for ACT1 (data not shown).

Preparative ACT1 lariat synthesis (Figure 4): A sample was prepared that contained 1.0 nmol linear substrate and 1.5 nmol deoxyribozyme plus 2.0 nmol disruptor DNA oligonucleotide (Supporting Information) in HEPES (5 mM, pH 7.5), NaCl (15 mM), and EDTA (ethylenediaminetetraacetic acid, 0.1 mM) in a volume of 150 μL. The sample was annealed by heating at 95 °C for 3 min and then cooling on ice for 5 min. The volume was increased to 200 μL: HEPES (50 mM, pH 7.5), NaCl (150 mM), KCl (2 mM), and $MnCl_2$ (20 mM); Mn^{2+} was added from an aqueous stock solution (1M). The 200-μL solution was incubated at 37 °C for 1.5 h and then mixed with 300 μL low-dye stop solution (80 % formamide, 1 × TBE (tris(hydroxymethyl)aminomethane and boric acid, 89 mM each, pH 8.3), and xylene cyanol and bromophenol blue, 0.0025 % each). The sample was resolved by 6 % PAGE and visualized by UV shadowing; the lariat product was extracted and ethanol-precipitated as described.[7] The isolated yield of lariat RNA product (after gel extraction and ethanol precipitation) was 0.39 nmol starting from 1.0 nmol of linear substrate. This 39 % yield (compared with the 70 % yield observed at the analytical scale without PAGE purification; Figure 3c) reflects losses that are commonly observed during extraction and precipitation of large RNA species from polyacrylamide gels.

[13] If one or more (e.g., 39) random DNA nucleotides are included between the DNA-binding arms in place of the enzyme region, then $k_{templated}$ decreases considerably (data not shown). Therefore, the 6BX22 rate enhancement calculated by using $k_{templated}$ for the DNA template that lacks any enzyme region is a conservative (lower-limit) estimate. Furthermore, as the templated background product is almost certainly linear and not branched RNA[20] (insufficient amounts of this product were available for analysis), the $k_{templated}$ value for the formation of the branched product that 6BX22 actually synthesizes must be lower than the experimentally measured $k_{templated}$ value. This lends further credence to the calculated rate enhancement as a lower-limit estimate.

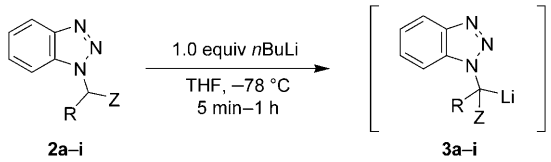
Stereoselective Synthesis of Highly Substituted Cyclopentenones through [4+1] Annulations of Trialkylsilyl Vinyl Ketenes with α-Benzotriazolyl Organolithium Compounds**

*Christopher P. Davie and Rick L. Danheiser**

Cyclopentenones serve as valuable synthetic building blocks and are themselves key features in the structure of a number of prostaglandins[1] and other bioactive natural products. Popular strategies for the construction of this important ring system include the intramolecular aldol reaction, the Nazarov cyclization,[2] the Rautenstrauch rearrangement,[3] and the Pauson–Khand reaction.[4,5] Only a few general [4+1] routes to five-membered carbocycles have been reported to date, one example being the method we developed based on anion-accelerated vinylcyclopropane rearrangements.[6,7] Recently, studies by us[8] and others[9] have led to several new [4+1] approaches to the synthesis of the 2-cyclopentenone ring system. Herein, we report a new variant of our stereocontrolled [4+1] annulation strategy that provides especially efficient access to highly substituted and functionalized cyclopentenones.

As outlined in Scheme 1, our [4+1] annulation strategy is based on the reaction of nucleophilic species with leaving groups ("carbenoid reagents") with trialkylsilyl vinyl ketenes



1a: R = *i*Pr, $R^1 = R^2 = CH_3$
1b: R = *i*Pr, $R^1 = R^2 = (CH_2)_4$
1c: R = Et, $R^1 = R^2 = CH_3$

Scheme 1. Strategy for [4+1] annulation. L = leaving group.

("TAS vinyl ketenes").[8] The utility of vinyl ketenes as versatile intermediates in organic synthesis is now well established.[10] However, vinyl ketenes are rarely isolable species and in most applications are generated as transient intermediates which are trapped in situ in [2+2] cycloadditions. Silyl substituents have the ability to suppress the usual propensity of vinyl ketenes to undergo dimerization and [2+2] cycloaddition reactions, thus opening up new opportunities for useful synthetic transformations. For example, TAS vinyl ketenes participate as electron-rich diene components in Diels–Alder and hetero-Diels–Alder reactions leading to cyclohexenones, phenols, and oxygen and nitrogen heterocycles.[11] In the case of reactions with carbenoid reagents, addition initially furnishes dienolate intermediates, which are believed to undergo ionization and subsequent 4π electrocyclization to generate cyclopentenone rings (see below). TAS vinyl ketenes are readily available through several routes, including the photochemical Wolff rearrangement of α′-silyl-α′-diazo-α,β-unsaturated ketones used for the preparation of **1a–c** in this study.[11a]

The goal of the current investigation was to extend the scope of this [4+1] annulation strategy to include the synthesis of cyclopentenones with a much broader range of substituents at the C5 position. A variety of carbenoid reagents were screened with the aim of identifying new classes of molecules that are competent in the desired transformation and are more readily available than the diazo compounds, sulfur ylides, and stable carbenes previously employed.[8] Among the several classes of compounds examined to date, α-benzotriazolyl organolithium compounds of type **3** were best able to meet our requirements (Scheme 2). Extensive research by Katritzky and co-workers over the past two decades has demonstrated the utility of *N*-substituted benzotriazoles as valuable intermediates for organic synthesis.[12] Benzotriazoles of type **2** bearing a wide range of substituents are either commercially available or readily prepared in one or two steps from inexpensive starting materials and undergo metalation with *n*-butyllithium at −78 °C to provide access to α-benzotriazolyl organolithium derivatives of type **3**. The ability of benzotriazole to function as a leaving group is also well documented and has been exploited by Katritzky and co-workers in the context of numerous useful synthetic transformations.[12]

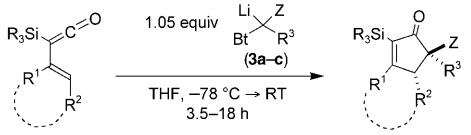
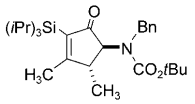
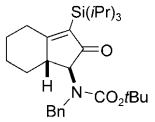
Scheme 3. Demonstration of the feasibility of the [4+1] annulation. Bn = benzyl.

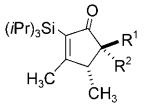
was prepared in 70% overall yield as previously described by Katritzky and co-workers[13] through protection of benzylamine as its *tert*-butyloxycarbonyl (Boc) derivative and reaction of the crude carbamate with one equivalent of benzotriazole and one equivalent of paraformaldehyde in the presence of catalytic *para*-toluenesulfonic acid (toluene, reflux). Metalation of **2a** with *n*BuLi produced the expected organolithium species, which was found to add smoothly to vinyl ketene **1a** at −78 °C in the desired fashion. Upon warming to room temperature, the resulting dienolate intermediate lost the benzotriazole moiety and cyclopentenone **4a** formed in good yield and with greater than 96% selectivity for the *trans*-substituted isomer.

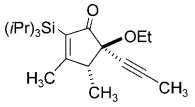
Tables 1 and 2 delineate the scope of the [4+1] annulation. In some cases, the desired cyclopentenone begins to appear at low temperature during the addition of the organolithium reagent, and formation of the five-membered-ring product is completed simply by warming to room temperature (Table 1). This protocol proved effective for annulations that involve carbenoid reagents with strong electron-donor substituents such as amine derivatives (entries 1 and 2) and the combination of an alkoxy moiety and a vinyl or alkynyl group (entries 3 and 4). Each of these reactions was observed to proceed with a preference for the formation of the cyclopentenone with the heteroatom substituent at C5 *trans* to the substituent at C4. This preference is particularly high with small R^3 groups, such as hydrogen or alkynyl moieties. The latter case is synthetically significant, as the products of such reactions (e.g., **7a**) undergo hydrogenation (Scheme 4) to furnish 5-alkyl-substituted cyclopentenones that cannot be produced directly under such mild conditions or with such high stereoselectivity (see below).











Scheme 4. Preparation of 5-alkyl-substituted cyclopentenones.

Attempted annulation with α-benzotriazolyllithium reagents **3d–i** under similar conditions did not lead to the desired cyclopentenones. Control experiments that employed benzotriazole **3d** confirmed that addition to TAS vinyl ketene **1a** proceeds smoothly at −78 °C in the expected manner, but cyclization of the resulting dienolate intermediate does not then occur. We therefore turned to the use of Lewis acids to promote the crucial ionization of the benzotriazole group required for five-membered-ring formation. Extensive screening studies identified $ZnBr_2$ as particularly effective for the desired transformation.[14] Although no reaction is observed upon addition of one equivalent of $ZnBr_2$ to the dienolate solution, efficient cyclization takes place when two or more equivalents of the Lewis acid are added at −78 °C and the reaction mixture is allowed to warm to room temperature. Under these conditions, the desired [4+1] annulation can be achieved with a variety of carbenoid reagents that bear a single heteroatom substituent such as SPh or OMe (Table 2). Cyclopentenone formation is even observed with the aryl-substituted benzotriazole **3g**, although in this case elevated temperatures are required to complete the cyclization.

A notable feature of these [4+1] annulations is the high level of stereoselectivity observed in most of the reactions. Control experiments established that the stereochemical outcome of these [4+1] annulations is not a consequence of thermodynamic control. Specifically, equilibration experiments yielded mixtures of *trans*- and *cis*-substituted cyclopentenones with ratios significantly different from those obtained in the annulation.[15] Thus, it appears likely that the stereochemical course of the [4+1] annulation reflects a mechanism-based kinetic preference for the observed products.

Scheme 5 outlines several alternative pathways to account for the mechanism of the [4+1] annulation. Addition of the carbenoid reagent to the vinyl ketene is predicted to be highly stereoselective because of the shielding effect of the bulky trialkylsilyl group and should result in the formation of the *Z*-enolate **18**. Direct formation of the five-membered-ring product could then result from a concerted process in which ring closure is concomitant with leaving-group departure. An alternative pathway involves ionization to produce oxidopentadienylic cation **20**,[16] which should then undergo rapid conrotatory 4π-electrocyclic closure[17] to generate the cyclopentenone product.[18] Finally, the involvement of cyclopropanone intermediates of type **19** cannot be excluded, particularly in view of the finding that simple silyl ketenes react with diazomethane and trimethylsilyldiazomethane to form mono- and bis(silyl)cyclopropanones.[19]

The stereochemical outcome of the [4+1] annulations that we investigated previously[8] is consistent with a mechanism that involves stereospecific conrotatory electrocyclic closure of a 2-oxidopentadienylic cation. In those prior cases, we suggested that ionization of the dienolate intermediate occurs to generate a cation in which the single C1 substituent is *cis* to the oxy anion to minimize nonbonded interactions. A similar mechanism can account for the reactions reported herein, provided that one assumes that ionization leads to the isomer of intermediate **20** shown in Scheme 5 because of an associative interaction between the heteroatom Z and the metal (M = Zn or Li) in **18** and/or **20**. Alternatively, if cyclization of **18** involves a concerted process, then the stereochemical outcome could reflect a preference for the mode of conrotation from **18** that rotates the leaving group *anti*

to the incipient σ bond and which proceeds via the transition state in which the donor heteroatom occupies an "outside" position ("torquoselectivity").[20]

The vinyl silane moiety incorporated in the [4+1] annulation products provides a useful handle for further synthetic transformations. Of particular interest to us was their conversion into vinyl halides, as a number of naturally occurring 2-halocyclopentenones have recently been found to exhibit potent antitumor activity.[1] In addition, the utility of 2-haloenones in a variety of transition-metal-catalyzed coupling reactions is well documented. With these ends in mind, we investigated the transformations outlined in Scheme 6 to lay

the groundwork for future applications of this annulation methodology. Conversion of α-silyl cyclopentenone annulation products **11a** and **12a** into iodoenone **22** proceeded smoothly by using a modification of the method of Alimardanov and Negishi.[21] Reduction of **22** with nBu$_3$SnH then afforded **23**, and Sonogashira coupling proceeded smoothly to furnish **24** with no detectable epimerization or double-bond migration in either case.

Further studies are underway aimed at the development of asymmetric variants of the annulation reaction and its application in the synthesis of natural products.

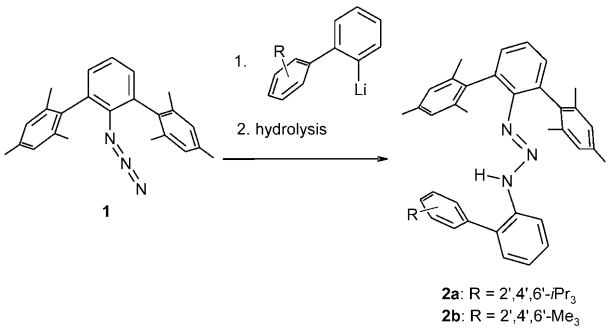
Stabilization of Aryl–Calcium, –Strontium, and –Barium Compounds by Designed Steric and π-Bonding Encapsulation

*Sven-Oliver Hauber, Falk Lissner, Glen B. Deacon, and Mark Niemeyer**

In the last decade a major theme of organometallic chemistry has been the design and development of alternative ligand systems capable of stabilizing monomeric metal complexes while provoking novel reactivity. Exploration of this field is driven by the potential use of these complexes in catalysis and organic synthesis. Examples of monoanionic chelating N-donor ligands that have received much recent attention (Scheme 1) include the β-diketiminate (**I**)[1] and the amidinate

I **II** **III**

Scheme 1. A comparison of some monoanionic chelating N ligands.



(**II**)[2] ligand systems. Much less attention has been given to the closely related triazenides (**III**).[3,4] This may be attributed to the lack of suitable ligands that are sterically crowded enough to prevent undesirable ligand redistribution reactions and allow better control of the electronic and steric properties at the metal center.

Triazenides are weaker donors than the isoelectronic amidinates and the related β-diketiminates, and should induce greater electrophilicity at a bonded metal atom.[5] This is reflected by the results of an NBO (natural bond orbitals) analysis of the energy-minimized structures[6] of the model anions 1,3-diphenyl-1,3-diketiminate ($\mathbf{I_M}$), 1,3-diphenyl-1,3-diazaallyl ($\mathbf{II_M}$), and 1,3-diphenyltriazenide ($\mathbf{III_M}$) (see Supporting Information), which shows an NPA (natural population analysis) charge for the chelating N atoms of −0.54, −0.60, and −0.38, respectively.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

We recently succeeded in the preparation of aryl-substituted, sterically crowded triazenes. Ligands of this type may be synthesized in excellent yields by the reaction of different substituted 2-lithiobiphenyls with the *m*-terphenyl azide **1**, followed by hydrolysis (Scheme 2).

Scheme 2. Synthesis of the triazene ligands **2a** and **2b**.

In a first attempt to test their properties, we have used the obtained triazenes to stabilize pentafluorophenyl compounds of the heavier alkaline-earth metals calcium, strontium, and barium. The heteroleptic pentafluorophenyl triazenides are accessible in tetrahydrofuran as solvent by a convenient one-pot transmetalation/deprotonation[7] reaction from the triazene **2a** (HN_3ArAr'), bis(pentafluorophenyl)mercury, and the corresponding alkaline-earth metal (Scheme 3). After crystallization from *n*-heptane, either the THF-free com-

Scheme 3. Synthesis of **3**–**5**.

pounds $[M(C_6F_5)(N_3ArAr')]$ (M = Sr (**4**), Ba (**5**)) or the solvate $[Ca(C_6F_5)(N_3ArAr')(thf)]$ (**3**) were isolated in good yields. It is remarkable that attempts to replace the pentafluorophenyl substituents by a second triazenide ligand have not been successful so far. Apparently, the steric bulk of the latter prevents further substitution or ligand redistribution and therefore formation of the homoleptic complexes.[8]

Solutions of **4** or **5** in aromatic or aliphatic solvents show considerable thermal stability and can be stored at ambient

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature for months with only minor decomposition. This may be contrasted with the behavior of some related pentafluorophenyl compounds of the di- and trivalent rare earth metals, which are thermally much more labile.[9] Compared to **4** and **5**, solutions of the calcium complex **3** are more sensitive and decompose within weeks at room temperature or within two days at 70 °C. We have not been able to isolate a well-defined decomposition product so far. However, NMR spectroscopic evidence, in particular a ^{19}F NMR signal at $\delta = -72.3$ ppm, points to the formation of a molecular fluoride, presumably [CaF(N_3ArAr′)(thf)], as one of the main products.

Compounds **3**–**5** were examined by X-ray crystallography.[10] The molecular structures of the Ca and Ba derivatives are shown in Figures 1 and 2, respectively, while important structural parameters for all complexes are summarized in Table 1. Despite the relatively large ionic radii of the M^{2+} ions (Ca: 1.14 Å; Sr: 1.32 Å; Ba: 1.49 Å for coordination number four[11]) the size of the η^2-bonded triazenide ligands enforces the formation of strictly monomeric complexes in which the metal atoms possess apparent low coordination numbers of three (**4**, **5**) and four (**3**). It should be noted that the deviation of the metal atoms from the N_3 plane increases in the order Sr (0.406 Å), Ba (0.706 Å), Ca (0.850 Å), while the bite angles

[a] Displacement of M from the N_3 plane. [b] Displacement of M from the C_6F_5 plane. [c] Hapticity of the M···π-arene interaction to the Mes and Trip rings. [d] M···C(arene) distances considered to be bonding. [e] Closest M···F contact.

N1-M-N3 decrease in the order Ca (53.25(18)°), Sr (48.89(17)°), Ba (46.33(10)°).

The average M–N distances to the triazenide ligands (Ca = 2.434, Sr = 2.562, Ba = 2.726 Å) are comparable to those of the amidinates [{PhC($NSiMe_3$)$_2$}$_2$M(thf)$_2$] (M = Ca 2.431 Å,[12a] Sr 2.584 Å[12b]), [{HC(NDip)$_2$}$_2$M(thf)$_n$] (Dip = 2,6-diisopropylphenyl, M = Ca 2.383 Å ($n = 1$), Sr 2.585 Å, Ba 2.728 Å ($n = 2$)),[12d] and [{PhC($NSiMe_3$)$_2$}$_2$Ba(dme)(thf)] (2.779 Å),[12c] which contain five- to seven-coordinate metal atoms, and are longer than those of the four-coordinate homoleptic β-diketiminates [(Dip-nacnac)$_2$M] (Dip-nacnac = (Dip)NC(Me)C(H)C(Me)N(Dip)) (M = Ca 2.379 Å, Sr 2.510 Å, Ba 2.712 Å).[13] Taking into account the apparent lower coordination numbers in the triazenides **3**–**5** the longer M–N bond lengths are most likely a result of the decreased donor ability of the triazenide relative to the amidinate and β-diketiminate ligands and/or a consequence of the additional metal–π-arene interactions (see below). Furthermore, the average Ca–N distance of 2.434 Å in the THF solvate **3** is considerably shorter than the corresponding values found in the eight-coordinate triazenide [Ca{N_3(tol)$_2$}$_2$(dme)$_2$] (av 2.524 Å) (tol = 4-Me-phenyl),[8] which is the only derivative of the heavier alkaline-earth metals currently available for comparison.

Well-defined σ-bonded organometallic compounds of the heavier alkaline-earth metals calcium, strontium, and barium are scarce and are currently restricted to some structurally characterized trimethylsilylmethanides or -benzyls, di- and triphenylmethanides, and acetylides.[14] The heteroleptic pentafluorophenyls **3**–**5** therefore are the first structurally authenticated Ar–Ca, Ar–Sr, and Ar–Ba compounds. The observed M–C distances are toward the short end of the range of M–C bonds reported for other organyls. The Ca–C bond (2.499 Å) is comparable to the value in the four-coordinate alkyl [Ca{CH($SiMe_3$)$_2$}$_2$(dioxane)$_2$] (2.48 Å)[15] but slightly longer than the distance in the two-coordinate compound

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Ca\{C(SiMe_3)_3\}_2]$ (2.46 Å).[16] The Sr–C and Ba–C distances of 2.673(7) and 2.808(5) Å, respectively, seem to be the shortest such bonds reported so far. The deviations of the metal atoms from the least-squares plane defined by the carbon atoms of the bonded C_6F_5 ligands also merit comment. They increase in the order Sr (0.712 Å), Ca (0.797 Å), Ba (1.086 Å). These unusually large displacements are explained by the highly ionic, nondirectional character of the metal–carbon bonds,[6] which is further increased by the electronic influence of the fluoro substituents. As a result, relatively weak intra- or intermolecular forces such as steric repulsion or π-stacking may lead to severe distortions (see Figure S5 in the Supporting Information). It is notable that similar, although even larger, displacements in the range 0.75 to 1.50 Å have been observed for the aryl lanthanides $[Ln(Dpp)_2(thf)_2]$ (Dpp = 2,6-$Ph_2C_6H_3$), which also contain highly polar M–C bonds.[17]

Perhaps the most striking features in the solid-state structures of **3**–**5** are the additional metal–π-arene interactions[18] with the pendent arms of the biphenyl and terphenyl groups in the triazenide ligands. These arene rings apparently compete with THF to bind the M^{II} cations, thus allowing the isolation of solvent-free derivatives.[19] The calcium ion in the THF solvate **3** interacts with only one mesityl (Mes) ring in an η^5 fashion,[20] with Ca···C distances in the relatively narrow range 3.015(7)–3.132(7) Å. In the solvent-free compounds **4** and **5** the metal ions show η^6- or η^5-π-arene interactions to one Mes group and also to the triisopropylphenyl (Trip) ring of the triazenide ligand. The resulting, rather distorted pseudo-tetrahedral coordination of the metal cations is reflected in part by the angles N2-M-C51 (Ca: 112.2°; Sr: 114.8°; Ba: 113.1°) and X1-M-X2 (Sr: 129.5°; Ba: 145.0°), where X1 and X2 define the centroids of the coordinated arene rings and the bidentate triazenido ligand occupies only one coordination site. The importance and specificity of the (N_3ArAr') ligand, and in particular its π-bonding capability, is shown by the failure of a reaction analogous to Scheme 3 between Ca, Sr, or Ba, $Hg(C_6F_5)_2$, and the bulky *N*,*N*′-bis(2,6-diisopropylphenyl)formamidine.[12d] Only decomposition products were obtained, plausibly derived from an unstable $[ML(C_6F_5)]$ species.

A relatively short Sr···F52–C52(*ortho*) contact of 3.076 Å is observed in the solid-state crystal structure of the Sr derivative **4**, which is accompanied by different Sr–C51–C52/C56 angles (105.7(5)° and 139.6(6)°). In contrast, the other pentafluoroaryl derivatives show considerably longer M···F contacts of more than 3.41 Å. To clarify if the metal···arene and metal···fluorine interactions also persist in solution, variable-temperature NMR experiments were performed for the most soluble compounds **4** and **5**. At 298 K, the ^{1}H NMR spectra in [D_{14}]methylcyclohexane show only one set of signals for the Mes substituents, which, however, splits at lower temperatures. Upon warming, coalescence is detected at 238 K (**4**) and 258 K (**5**), with corresponding energy barriers of 49.0 and 53.1 kJ mol^{-1}, respectively. This observation can be interpreted in terms of a hindered rotation around the N1–C1 bond and therefore the persistence of the metal–π-arene interactions in solution. A similar behavior, with a rotational barrier of 54.3 kJ mol^{-1}, was recently observed and confirmed by quantum-chemical calculations for the unsolvated ytterbium thiophenolate [Yb(S-2,6-$Trip_2C_6H_3)_2$].[19] In addition, low-temperature ^{19}F NMR experiments for **4** and **5** show coalescence of the signals of the *ortho*-C_6F_5 fluorine atoms at 218 K and 203 K, with corresponding ΔG values of 39.1 and 34.5 kJ mol^{-1}, respectively. Unfortunately, we have not yet been able to determine which intra- or intermolecular processes are responsible for this fluxional behavior. According to preliminary quantum-chemical calculations (see Supporting Information), the binding energy for the Sr···F interaction in the model complex $[H_2N_3SrC_6F_5]$ is estimated to be only 22.1 kJ mol^{-1} at the MP2 level of theory. DFT calculations for the more sophisticated model compound $[\{(1\text{-}MesC_6H_4)(1\text{-}TripC_6H_4)N_3\}Sr(C_6F_5)]$ ($\mathbf{4_M}$), in which the noncoordinating Mes group in **4** has been replaced by a hydrogen atom, reveal a shorter Sr···F contact (2.881 Å for $\mathbf{4_M}$ versus 3.076 Å for **4**) but weaker π-coordination (av M···C 3.363 Å for $\mathbf{4_M}$ versus 3.210 Å for **4**). Since it is known that DFT methods tend to underestimate weak interactions such as π-arene bonding to electropositive metals,[19] it is plausible that in the real systems **3**–**5** these interactions are actually stronger and dominate over any M···F coordination. As a result, decomposition pathways involving *ortho*-fluoride elimination are effectively blocked.

In summary, we have designed and prepared very bulky aryl-substituted triazenide ligands that have permitted the synthesis of the first structurally characterized aryl compounds of the heavier alkaline-earth metals Ca, Sr, and Ba. Kinetic stabilization in the solid-state and in solution through steric and electronic saturation of the metal centers is achieved by additional π-arene interactions to the pendent aryl substituents. These novel, sterically crowded triazenides may find use as ancillary ligands in catalysis and we are currently exploring this field.

Experimental Section

All manipulations were carried out under strictly anaerobic and anhydrous conditions under argon. The starting materials 2-iodo-2′,4′,6′-triisopropylbiphenyl,[21] 2,4,6,2″,4″,6″-hexamethyl-1,1′:3′,1″-terphenyl-2′-azide,[22] and bis(pentafluorophenyl)mercury[23] were prepared by known procedures.

HN_3ArAr' (**2a**): *n*-Butyllithium (44.4 mmol, 2.5 M hexane solution) was added at 0 °C to a solution of 2-iodo-2′,4′,6′-triisopropylbiphenyl (18.1 g, 44.4 mmol) in diethyl ether (250 mL) and stirring was continued for 2 h. The clear solution of the aryl lithium compound thus obtained was then treated with small portions of 2,4,6,2″,4″,6″-hexamethyl-1,1′:3′,1″-terphenyl-2′-azide (15.8 g, 44 mmol). After warming to ambient temperature and stirring for an additional 12 h, the orange solution was quenched with water (400 mL). The aqueous phase was separated and extracted with diethyl ether (3 × 100 mL). The organic phases were combined, repeatedly washed with water, and dried with Na_2SO_4. Filtration followed by solvent removal in vacuo afforded **2a** as a yellow solid. Analytically pure, pale yellow crystals were obtained by recrystallization from hot acetone. Yield: 25.2 g (39.6 mmol, 89 %); m.p. 174–176 °C; ^{1}H NMR (400.1 MHz, [D_6]benzene): δ = 0.87, 1.00, 1.13 (3 × d, $^3J_{H,H}$ = 6.9 Hz, 3 × 6 H; *o* + *p*-$CH(CH_3)_2$), 2.04 (s, 12 H; *o*-CH_3), 2.18 (s, 6 H; *p*-CH_3), 2.54 (sept, $^3J_{H,H}$ = 6.9 Hz, 2 H; *o*-$CH(CH_3)_2$), 2.69 (sept, $^3J_{H,H}$ = 6.9 Hz, 1 H; *p*-$CH(CH_3)_2$), 6.79 (s, 4 H; *m*-Mes), 6.85–7.14 (m, 7 H; various aryl-H), 7.00 (s, 2 H; *m*-Trip), 8.70 ppm (s, 1 H; NH); ^{13}C NMR (62.9 MHz, [D_6]benzene): δ = 20.9 (*o*-CH_3), 21.1 (*p*-CH_3), 23.8, 24.0, 24.5 (*o* + *p*-$CH(CH_3)_2$), 30.7 (*o*-$CH(CH_3)_2$), 34.5 (*p*-$CH(CH_3)_2$), 121.4, 122.2,

126.8, 128.3, 129.8, 130.8 (aromatic CH), 113.7, 125.6, 134.8, 135.8, 136.1, 137.3, 139.3, 146.2, 147.5, 149.3 ppm (aromatic C). elemental analysis calcd (%) for $C_{45}H_{53}N_3$: C 84.99, H 8.40, N 6.61; found: C 84.88, H 8.41, N 6.64.

[Ba(C_6F_5)(N_3ArAr′)] (**5**): Bis(pentafluorophenyl)mercury (1.07 g, 2.00 mmol) was added at ambient temperature to a stirred mixture of barium ingots (2.5 g, 18.2 mmol) and **2a** (1.27 g, 2.00 mmol) in THF (60 mL). Stirring was continued for 14 h, whereupon the solvent was removed under reduced pressure. The green residue was treated with *n*-heptane, and solid materials were separated by centrifugation. The volume of the resulting deep yellow solution was reduced to incipient crystallization under reduced pressure. Storage in a freezer at −20 °C for several days afforded **5** as a bright yellow, crystalline material. Yield: 1.48 g (1.58 mmol, 79 %); m.p. 144–170 °C (decomp); ^{1}H NMR (250.1 MHz, [D$_6$]benzene): δ = 0.63, 0.78, 1.18 (3 × d, $^3J_{H,H}$ = 6.8 Hz, 3 × 6 H; *o* + *p*-CH(CH_3)$_2$), 2.04 (s, 12 H; *o*-CH_3), 2.19 (s, 6 H; *p*-CH_3), 2.57 (sept, $^3J_{H,H}$ = 6.8 Hz, 2 H; *o*-C*H*(CH$_3$)$_2$), 2.90 (sept, $^3J_{H,H}$ = 6.8 Hz, 1 H; *p*-C*H*(CH$_3$)$_2$), 6.46–7.27 (m, 7 H; various aryl-H), 6.78 (s, 4 H; *m*-Mes), 7.04 ppm (s, 2 H; *m*-Trip); ^{13}C NMR (62.9 MHz, [D$_6$]benzene): δ = 20.8 (*o*-*C*H$_3$), 21.0 0(*p*-*C*H$_3$), 23.1, 24.2, 24.2 (*o* + *p*-CH(*C*H$_3$)$_2$), 30.5 (*o*-*C*H(CH$_3$)$_2$), 33.8 (*p*-*C*H(CH$_3$)$_2$), 116.9, 122.0, 122.0, 123.1, 128.6, 129.0, 129.1, 129.4 (aromatic CH), 128.8, 131.5, 136.6, 137.4, 142.0, 142.4, 148.0, 150.3, 150.6, 152.1 ppm (aromatic C); signals for the C_6F_5 group could not be detected or assigned completely due to signal overlap and their weak appearance; ^{19}F NMR (235.4 MHz, [D$_6$]benzene): δ = −159.0 (m, 2 F; *m*-C_6F_5), −154.2 (tt, $^3J_{F,F}$ = 20.3, $^4J_{F,F}$ = 3.3 Hz, 1 F; *p*-C_6F_5), −113.2 ppm (m, 2 F; *o*-C_6F_5); ^{15}N NMR (40.6 MHz, [D$_6$]benzene): δ = 109.5 (s; -N*N*N-), −69.3, −70.4 ppm (s; -*N*N*N*-); elemental analysis calcd (%) for $C_{51}H_{52}BaF_5N_3$: C 65.21, H 5.58, N 4.47; found: C 64.76, H 5.76, N 4.52.

Details of the preparation and characterization of compounds **2b**, **3**, and **4**, and additional spectroscopic data for **2a** and **5** are given in the Supporting Information.

[6] The Gaussian 03 package (Revision B.01, Gaussian Inc., Pittsburgh PA, 2003) was used for all energy and frequency calculations. The geometries of the molecules were optimized using either density functional theory (DFT) with the functional B3LYP for the model ligands $\mathbf{I_M}$–$\mathbf{III_M}$ (all with implied C_2 symmetry) and the model complex $\mathbf{4_M}$ or second-order Møller–Plesset perturbation theory (MP2) for two conformers of the model compound [$H_2N_3SrC_6F_5$] (C_s symmetry). In each case the GDIIS algorithm with the TIGHT convergence criterion was used. A quasi-relativistic 10-valence-electron pseudopotential was employed for the heavy atom Sr (M. Kaupp, P. von R. Schleyer, H. Stoll, H. Preuss, *J. Chem. Phys.* **1991**, *94*, 1360). The corresponding 6s6p5d valence basis was augmented by one set of f-functions. The basis sets for C, H, N, and F were either 6-311 + G** ($\mathbf{I_M}$–$\mathbf{III_M}$) or 6-31G* ($\mathbf{4_M}$, [$H_2N_3SrC_6F_5$]). All stationary points were characterized by analytical or numerical frequency analyses. The natural bond orbital analysis employed the Gaussian 03 adaptation of the NBO program (E. D. Glendening, A. E. Reed, J. E. Carpenter, F. Weinhold, NBO Version 3.1). For the model complex $\mathbf{4_M}$ the following NPA charges were calculated: +1.728 (Sr), −0.505 (N1), −0.509 (N3), −0.637 (C51).

Lithium Benzocyclobuteneoxide as a Precursor of a Vinylogous Enolate: Solvent-Controlled Synthesis of Highly Functionalized Seven-Membered Benzocarbocycles**

José Barluenga, Patricia García-García, Manuel A. Fernández-Rodríguez, Enrique Aguilar, and Isabel Merino*

The role of Fischer carbene complexes (FCCs) as synthetic intermediates in organic chemistry is today perfectly established,[1] although new patterns of reactivity are still amenable. In this context, we have initiated an exploration of the reactivity of FCCs toward *ortho*-quinodimethanes[2] (*o*QDMs) and reported recently that the reaction of symmetric bistrialkylsilyloxy *o*QDMs, readily generated by thermal ring opening of benzocyclobutenes, with alkynyl FCCs follows a tandem [4+2] cycloaddition/cyclopentannulation sequence that leads to benzo[*b*]fluorenes.[3] Choy and Yang have pointed out that the ring opening of metalated benzocyclobuteneoxides takes place at temperatures as low as −25 °C, thus confirming that such a process is favored by the presence of electron-donating groups on the cyclobutene ring.[4] On the other hand, functionalized seven-membered benzocarbocycles are both important synthetic intermediates and key structural elements in various natural products and/or pharmacologically active compounds, such as terpenes, namely, (−)-presphaerene[5] and barbatusol;[6] alkaloids, for example, dragmacidin E;[7] (−)-colchicine, an antitumour agent;[8] nortriptyline and amitriptyline, which have antidepressant activities;[9] and hamigeran C, which is cytotoxic,[10] among others. We describe herein the preliminary results of the reaction of alkynyl FCCs with *o*QDM **1** prepared by Choy and Yang, thus leading to the preparation of highly functionalized seven-membered benzocarbocycles which have not been previously accessed from FCCs.

In our initial experiment (Scheme 1), benzocyclobutenol **2** was deprotonated with *n*BuLi at −78 °C in THF and the reaction mixture was allowed to reach −25 °C to permit the formation of *o*QDM **1**; subsequently, chromium FCC **3** was added, and the reaction was monitored by TLC. However, rather than the expected [4+2] cycloadduct **5** or benzo[*b*]-fluorene **6**, two benzoheptacarbocycles[11] **7a** and **8a** were isolated as a mixture in low yield, among other products (Table 1, entry 1). As far as we know, this reaction is the first example in which oQDM **1** acts as a four-carbon synthon in a formal [4+3] cycloaddition. We switched to the more stable tungsten FCC **4a** to find that the combined yield of the isolated products, [4+3] cycloadducts **7a** and **8a**, was improved to 65 % (entry 2) under similar reaction conditions. Other solvents (hexane, 1,2-dimethoxyethane, toluene, and dioxane) were then examined but produced either low-yielding mixtures of **7a** and **8a** or no identifiable products.

Table 1: Reaction of **1** with alkynyl carbene complexes **3** and **4** in THF.

Entry[a]	FCC	Metal	R	7	Yield [%][b]	8	Yield [%][b]
1	**3**	Cr	Ph	**7a**	8	**8a**	11
2	**4a**	W	Ph	**7a**	49	**8a**	16
3[c]	**4a**	W	Ph	**7a**	–	**8a**	50
4	**4b**	W		**7b**	71	**8b**	14
5	**4c**	W		**7c**	67	**8c**	30
6	**4d**	W		**7d**	52	**8d**	22
7	**4e**	W	*t*Bu	**7e**	50[d]	**8e**	5[d]

[a] All the reactions were carried out on a 0.5-mM scale for the carbene complex (0.033 M) with 1.5 equivalents of benzocyclobutenol (0.05 M). [b] Yields of isolated product based on the starting alkynyl carbene complexes. [c] Reaction performed in diethyl ether. [d] Products could not be separated; yield estimated by ^{1}H NMR (300 MHz) spectroscopic analysis from a fraction enriched in **7e** after flash column chromatography.

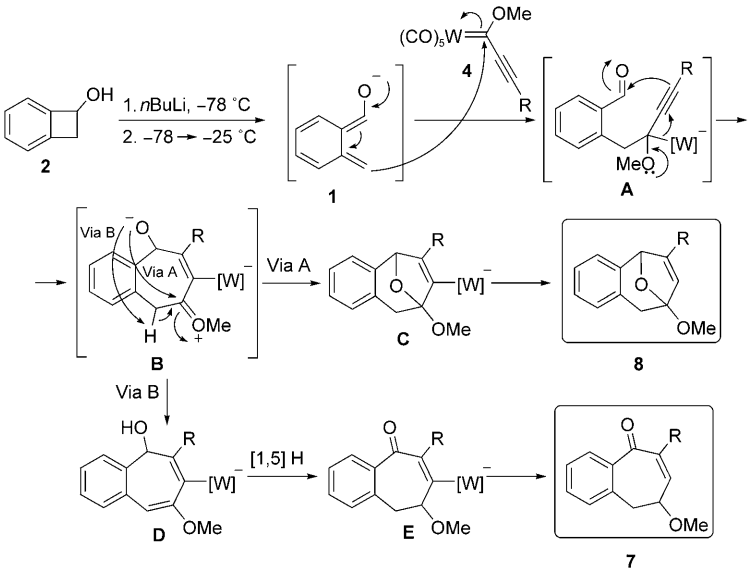
Scheme 1. Reaction of **1** with alkynyl carbene complexes.

Interestingly, the reaction led exclusively to **8a** when performed in diethyl ether (entry 3). Such a strong solvent effect[12] prompted us to consider the possibility of increasing the yield through additives or by variation of the counterion. However, none of the following approaches led to improved results: the addition of different coordinating reagents (*N*,*N*,*N*′,*N*″,*N*‴-pentamethyldiethylenetriamine (PMDTA), [12]crown-4, *N*,*N*′-dimethyl-*N*,*N*′-propyleneurea (DMPU)), the use of different bases (potassium hexamethyldisilazane (KHMDS), NaHMDS, EtMgBr), and transmetalation strategies (BuLi/$ZnCl_2$) in both diethyl ether or THF.

Considering that at this point we had already created conditions that allowed for the selective formation of two differently functionalized benzoheptacarbocycles, we next tried to expand the scope of such transformations by examining of the nature of the substituents of the carbene complex. Thus, carbene complexes **4b–e** were treated with **1** in THF to obtain moderate to good yields of benzocycloheptenones **7** (Table 1, entries 4–7), which were accompanied by small amounts of benzocycloheptene ketals **8** that could be readily separated by flash column chromatography. The best yields were achieved when the R group was a *para*-substituted aromatic moiety (entries 4 and 5), although the reaction also took place selectively for alkenyl- and alkyl-substituted alkynyl FCCs **4d**, **e** (entries 6 and 7).

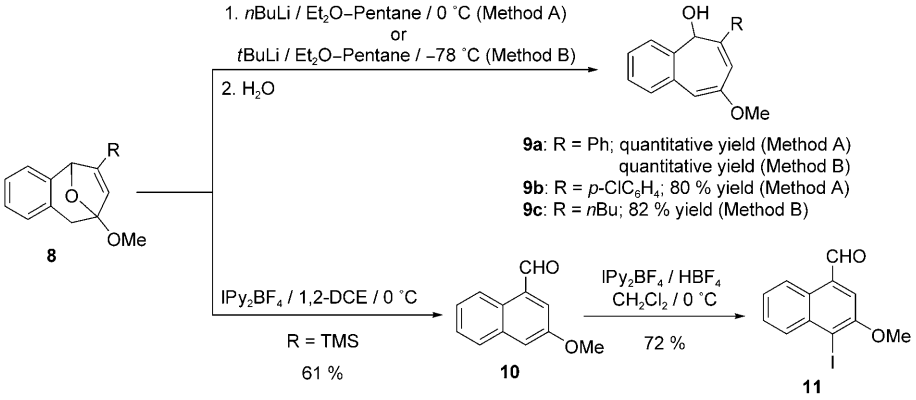


On the other hand, benzocycloheptene ketals **8** were obtained as the unique reaction products, as expected, when carbene complexes **4a–g** were treated with **1** in diethyl ether (Table 2; see also Table 1, entry 3). This reaction was much slower and usually required reaching either room temperature (Table 2, entries 2, 4, and 6) or reflux (entries 5 and 7) to proceed. Again, *para*-substituted alkynylaryl carbene complexes gave the best yields (entries 2 and 3). These reaction conditions tolerate alkenyl (entry 4), alkyl (entries 5 and 6), and silyl (entry 7) groups as substituents in the alkynyl FCC. We also observed that the yield may be improved by performing the reaction at a higher concentration with a higher excess of benzocyclobutenol (Table 2, entry 1 versus Table 1, entry 3).

As a basis for the mechanism, we propose that after the initial deprotonation of benzocyclobutenol **2** at −78 °C, the resulting lithium benzocyclobutenoxide opens to **1** by warming to −25 °C (Scheme 2). Subsequently, *o*QDM **1** would behave as a vinylogous enolate rather than a 1,3-diene, and a nucleophilic attack[13,14] on the carbene carbon of **4** would take place to form intermediate **A**. A 1,2-metal migration,[14] promoted by the methoxy group, would cause simultaneous ring closure to form intermediate **B**. The evolution of **B** could occur by two different routes: In the first (via A), an intramolecular nucleophilic attack would produce the metalated benzocycloheptene ketal **C**, which would account for the formation of **8**, whereas in the second (via B), an intramolecular acid/base reaction would generate the metalated intermediate **D**, thus leading to **E** through a 1,5-hydrogen shift and finally to **7**.

Table 2: Reaction of **1** with tungsten alkynyl carbene complexes **4** in Et_2O.

Entry[a]	FCC	R	8	Yield [%][b]
1[c]	**4a**	Ph	**8a**	70
2	**4b**	MeO	**8b**	56[d]
3	**4c**	Cl	**8c**	86
4	**4d**		**8d**	55[d]
5	**4e**	*t*Bu	**8e**	50[e]
6	**4f**	*n*Bu	**8f**	25[d]
7	**4g**	TMS	**8g**	38[e]



[a] All the reactions were carried out on a 0.5-mM scale for the carbene complex (0.033 M) with 1.5 equivalents of benzocyclobutenol (0.05 M), unless otherwise stated. [b] Yields of isolated product based on the starting alkynyl carbene complexes **4**. [c] Reaction carried out with 5 equivalents of benzocyclobutenol (0.33 M). [d] It was necessary to reach room temperature for the reaction to proceed. [e] It was necessary to reach reflux for the reaction to proceed. TMS = trimethylsilyl.

Scheme 2. Proposed mechanism for the formation of seven-membered benzocarbocycles **7** and **8**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Our preliminary results into the reactivity of benzocycloheptene ketals **8** indicate that it is possible to break the heteroatom bridge of **8** by treatment with *n*BuLi or *t*BuLi to form benzocycloheptadienols **9** in good to excellent yields (Scheme 3); therefore, this breakage acts as a direct entry to a

Scheme 3. Chemical transformations of benzocycloheptene ketals **8**. IPy_2BF_4 = bis(pyridine)-iodonium(I) tetrafluoroborate, 1,2-DCE = 1,2-dichloroethene.

third type of functionalized seven-membered benzocarbocycle. On the other hand, we also observed that ring contraction[15] takes place in **8g** (R = TMS) upon treatment with IPy_2BF_4[16] to give **10** in 61% yield. This apparently simple compound has now been prepared for the first time;[17] thus, by using this approach the difficulties that derived from both the electronic nature and the relative position of its substituents have been overcome. Naphthyl aldehyde **10** could be iodinated with IPy_2BF_4 in acidic medium at the C4 position of the naphthalene skeleton to form **11** in 72% yield (Scheme 3), thus expanding the possibilities for further transformations.

In summary, we have established a new and direct route to seven-membered functionalized benzocarbocycles from tungsten alkynyl FCCs. In this transformation, oQDM **1** prepared by Choy and Yang behaves as a vinylogous enolate which acts for the first time as a four-carbon component in a formal [4+3] cycloaddition. The outcome of the reaction is solvent controlled: selective formation of benzocycloheptenones **7** can be achieved in THF, whereas exclusive synthesis of benzocycloheptene ketals **8** occurs in diethyl ether. The latter compounds can be readily transformed in benzocycloheptadienols **9** by a base-promoted opening of the cyclic ketal moiety. Access to the previously unknown 3-methoxy-1-naphthylcarbaldehyde (**10**) is obtained by a ring contraction of cyclic ketal **8g** promoted by IPy_2BF_4. The exploration of transition-metal-catalyzed (Cu, Rh) nucleophilic ring openings[18] of ketals **8** is currently underway and the results will be reported in due course.

Peptide Helices

DOI: 10.1002/anie.200501247

9/11 Mixed Helices in α/β Peptides Derived from C-Linked Carbo-β-Amino Acid and L-Ala Repeats**

Gangavaram V. M. Sharma, Pendem Nagendar, P. Jayaprakash, Palakodety Radha Krishna, K. V. S. Ramakrishna, and Ajit C. Kunwar**

Oligomers of nonnatural amino acids, which form a variety of secondary structures, have been studied extensively.[1] The impetus for such efforts has invariably been a desire to understand the conformational behavior and to develop these structures into biomolecules with novel properties. The β peptides, a very important class of foldamers, are derived from β-amino acids and exhibit several novel secondary structures.[2–6] The 10/12-mixed helix, unique to β peptides, was discovered by Seebach et al.[4] in β^2/β^3-dipeptide repeats. Theoretical studies by Hofmann and co-workers[7a] and Wu et al.[7b,c] predicted that 10/12 and 12/10 helices are energetically the most favored secondary structures in β peptides in solution. Subsequently, Kessler and co-workers[8] used a cyclic sugar β-amino acid and β-hGly repeats to obtain such mixed helices. In a later study, we demonstrated the presence of robust right-handed 10/12- and 12/10-mixed helices[9] in heterochiral dipeptide repeats from carbo-β^3-amino acid (Caa) residues with "alternating chirality" at the C^β carbon atom. Further studies on peptides with alternating Caa and β-hGly repeats resulted in right- and left-handed 10/12 and 12/10 helices.[10] Although Hofmann and co-workers[11] predicted the existence of mixed helices in homologous α, β, γ, and δ peptides from theoretical studies, the experimental realization of these structures has so far been limited only to β peptides.[4,8–10] From the above studies, it is amply evident that mixed helices invariably resulted from heterodipeptide repeats. However, the α/β-dipeptide repeats reported by Gellman and co-workers[12] showed the coexistence of an

11 helix along with a 14/15 helix, whereas Reiser and coworkers[13] observed a 13 helix in the α/β peptides containing alternate *cis*-β-amino cyclopropane carboxylic acid and L-Ala residues.

Based on the above observations on mixed helices and our own studies on Caa-derived β peptides,[9,10] a hybrid α/β-dipeptide motif was envisaged as a "design control" to identify novel secondary structures. Herein, we report the synthesis of α/β-hybrid peptides from the *S* epimer of Caa[14] and L-Ala, as well as the finding of hitherto unknown and unprecedented 9/11 helices in these peptides by extensive NMR spectroscopy, circular dichroism (CD), and molecular dynamics (MD) studies.

The β peptides **1**–**5** (Scheme 1) were prepared by conventional coupling methods, and structural studies were conducted to analyze their conformational details. All of the peptides (100 μM in methanol) displayed novel CD data with maxima at ≈198 nm along with weaker flat maxima at ≈225 nm; this pattern is distinctly different from the CD profile of a 10/12-mixed helix.

The ^{1}H NMR spectrum of tripeptide **1** displayed downfield shift for two amide protons at δNH = 7.16 and 7.58 ppm, a result that suggests their involvement in hydrogen bonding. Solvent titration studies[15] showed very small chemical-shift changes ($\Delta\delta$NH) of 0.213 and 0.422 ppm for NH(2) and NH(3), respectively, thereby confirming their participation in hydrogen bonding. The observed long-range NOE correlations for C$^\alpha$H(1)/NH(3), C$^\beta$H(2)/NH(3), and NH(2)/NH(3) further support a well-defined structure. Furthermore, the coupling constant values of $^3J_{C^\alpha H/C^\beta H} < 5$ Hz indicate a restricted value of $|\theta| \approx 60°$ for Caa(2). The nondescript $^3J_{NH/C^\alpha H}$ values of 6.8 and 7.5 Hz for Ala(1) and Ala(3), at this stage, prevent us from deducing the structure for **1**. To obtain concrete information for determining the underlying structure in this family, peptides **2** and **3** were investigated.

The ^{1}H NMR spectrum of pentapeptide **2** showed that four of the amide protons (except NH(1)) appear at δNH > 7 ppm, which suggests their participation in hydrogen bonding. The same was further confirmed by solvent titration studies ($\Delta\delta$NH < 0.256 ppm).[15] For Caa(2) and Caa(4), small values of $^3J_{NH/C^\alpha H}$ (< 5.2 Hz) and large values of $^3J_{NH/C^\beta H}$ (9.3 Hz) are consistent with $|\theta| \approx 60°$ and $|\phi| \approx 100°$, respectively. $^3J_{NH/C^\alpha H} = 6.1$ and 5.6 Hz for Ala(1) and Ala(3), respectively, values which correspond to $|\phi| \approx 60°$. To derive the handedness of the structures by NMR spectroscopy, it was crucial to distinguish the resonances of the C$^\alpha$H$_{(pro\text{-}S)}$ and C$^\alpha$H$_{(pro\text{-}R)}$ protons. The NOE correlations for C$^\gamma$H(2)/NH(2), C$^\alpha$H$_{(pro\text{-}S)}$(2)/C$^\delta$H(2), C$^\alpha$H$_{(pro\text{-}R)}$(2)/NH(3), C$^\gamma$H(4)/NH(4), C$^\alpha$H$_{(pro\text{-}S)}$(4)/C$^\delta$H(4), and C$^\alpha$H$_{(pro\text{-}R)}$(4)/NH(5) enabled us to assign these resonances unequivocally and allowed us to deduce a value of about +60° for θ. The distinctive signatures of an 11/9 helix were observed in the ROESY spectrum, in which the NOE correlations for C$^\alpha$H(1)/NH(3) and C$^\alpha$H(3)/NH(5) support an 11-membered hydrogen bond between the CO group of *tert*-butoxycarbonyl (Boc) and NH(3), and between NH(5) and CO(2) (Scheme 1). Similarly, the presence of weak but characteristic NOE correlations for NH(2)/NH(3) and NH(4)/NH(5) are consistent with 9-membered hydrogen bonds between NH(2)–CO(3) and NH(4)–CO(5)

Scheme 1. Structures of α/β-hybrid peptides **1**–**5**; hydrogen-bond interactions are indicated by the arrows.

(Scheme 1). All the distinguishing features discussed above confirm an unprecedented right-handed 11/9/11/9-mixed helix for **2**.

By analogy with the structural information for **2**, the NOE correlations observed in the ROESY spectrum of **1** and the distinct $^3J_{C^\alpha H/C^\beta H}$ and $^3J_{NH/C^\beta H}$ values (for Caa) confirm an 11-membered hydrogen bond between the CO group of Boc and NH(3) and a 9-membered hydrogen bond between NH(2)–CO(3), thereby defining an 11/9 helix. The observation of a helix in a molecule as short as a tripeptide is particularly noteworthy.

Propagation of an exceptionally robust 11/9 helix in heptapeptide **3** was confirmed by NMR spectroscopy, which showed a well-resolved spectrum in the amide region, in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which NH(2)–NH(6) gave $\delta NH > 7$ ppm and small $\Delta\delta NH$ values of 0.262 ppm in the solvent titration studies,[15] which confirmed hydrogen bonding. The $^3J_{NH/C^\alpha H}$ values of 6.1, 5.6, and 5.1 Hz for Ala(1), Ala(3), and Ala(5), respectively, correspond to $|\phi| \approx 60°$. Similarly, for Caa(2), Caa(4), and Caa(6), values of $^3J_{NH/C^\beta H} > 9.3$ Hz and $^3J_{C^\alpha H/C^\beta H} < 5.6$ Hz imply that $|\phi| \approx 100°$ and $|\theta| \approx 60°$. The assignments of the $C^\alpha H_{(pro\text{-}S)}$ and $C^\alpha H_{(pro\text{-}R)}$ resonances for the Caa residues were obtained similarly to those for **2**. Additionally, NOE correlations for $C^\alpha H(1)/NH(3)$, $C^\alpha H(3)/NH(5)$, $C^\alpha H(5)/NH(7)$, NH(2)/NH(3), NH(4)/NH(5), and NH(6)/NH(7) (Figure 1) as well as the information on hydrogen bonding,

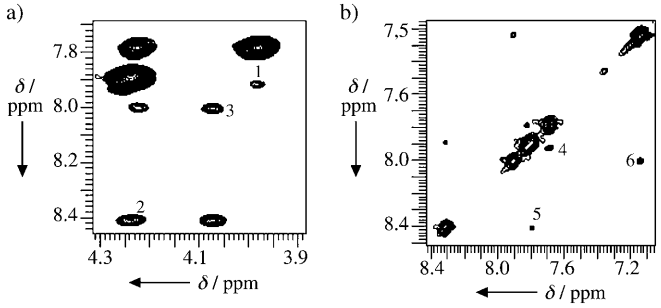

Figure 1. ROESY spectrum of **3**: a) NOE interactions $C^\alpha H(1)/NH(3)$, $C^\alpha H(3)/NH(5)$, and $C^\alpha H(5)/NH(7)$ are marked as 1, 2, and 3, respectively; b) NOE interactions NH(2)/NH(3), NH(4)/NH(5), and NH(6)/NH(7) are marked as 4, 5, and 6, respectively.

confirmed 11-membered hydrogen bonds between NH(3)–CO group of Boc, NH(5)–CO(2), NH(7)–CO(4), and 9-membered hydrogen bonds between NH(2)–CO(3), NH(4)–CO(5), and NH(6)–CO(7) (Scheme 1). The presence of a right-handed 11/9/11/9/11/9 helix and its propagation with the chain length in **3** was evident from all the characteristics described above. The CD profiles of **1**–**3** (Figure 2) showed maxima at around 198 nm and the progressive increase in the molecular ellipticity per residue reflects the enhanced robustness with increasing size of the oligomers.

Similar to our earlier findings with 12/10-mixed helices,[8,9] two possible helical structures (an 11/9 and a 9/11 helix) were

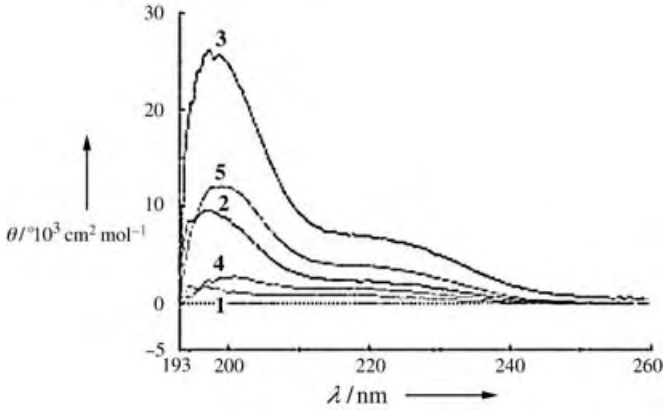

Figure 2. CD profiles of **1**–**5**.

expected in these α/β peptides. Consequently, peptides **4** and **5** were prepared with a Caa monomer at the N terminus to observe the 9/11 helix. The ^{1}H NMR spectrum of **4** showed all the signatures of hydrogen bonding, such as a low-field shift ($\delta NH > 7$ ppm) for two amide protons and small changes of the $\Delta\delta NH$ values in solvent titration studies. Furthermore, the coupling constants and the characteristic long-range NOE correlations for $C^\alpha H(2)/NH(4)$, NH(1)/NH(2), and NH(3)/NH(4) provide compelling evidence for the presence of a unique 9/11/9 helix.

Likewise, a low-field shift ($\delta NH > 7$ ppm) for four amide resonances, and the solvent titration studies ($\Delta\delta H < 0.686$ ppm) confirmed the participation of all the amide groups except NH(2) in hydrogen bonding in **5**. The $^3J_{NH/C^\alpha H}$ coupling constants for Ala(2) and Ala(4) are 4.8 and 5.9 Hz, respectively; these values correspond to $|\phi| \approx 60°$. Furthermore, small $^3J_{C^\alpha H/C^\beta H}$ values for all Caas and distinct NOE correlations for NH(1)/NH(2), NH(3)/NH(4), NH(5)/NH(6), $C^\alpha H(2)/NH(4)$, and $C^\alpha H(4)/NH(6)$ support a propagated right-handed 9/11/9/11/9-mixed helix for **5**. The molecular ellipticity per residue for **5** and the NMR spectroscopic data (larger amide chemical shifts) demonstrate that this helix is more robust than that of **4**.

The $^3J_{C^\beta H/C(4)H}$ values greater than 9 Hz for the Caa residues (except for Caa(1) in **4** and **5**) correspond to $\chi^1(C^\beta H–C^\beta–C(4)–C(4)H) \approx 180°$ in all of the oligomers, as observed in oligomers with 10/12-mixed helices in our earlier study.[9] The $^3J_{C1H/C2H} \approx 4$ Hz, $^3J_{C(2)H/C(3)H} \approx 0$ Hz, and $^3J_{C(3)H/C(4)H} \approx 3$ Hz values for the sugar rings are consistent with a $^3T_2$ sugar pucker, which is similar to that observed earlier. Furthermore, the presence of an envelope conformation for the isopropylidine ring is reflected in the strong $Me_{(pro\text{-}R)}$/C(2)H and $Me_{(pro\text{-}R)}$/C(1)H and the weak $Me_{(pro\text{-}S)}$/C(4)H NOE correlations.

The NOE-restrained MD calculations for **1**–**5** resulted in structures that are in excellent agreement with those obtained above. Volume integrals from the ROESY spectra provided quantitative NOE constraints by using the two-spin approximation. Figures 3 and 4 show a superposition of the 25 lowest-energy structures for **3** and **5**, respectively. For the sake of clarity, the sugar moieties were replaced by methyl groups for the structures in Figures 3 and 4 after the MD calculations. The maximum violations for the NMR-derived constraints for **3** and **5** are 0.25 and 0.33 Å, respectively. The average pairwise heavy-atom and backbone root-mean-square deviations are 0.31 and 0.29 Å for **3**, and 0.58 and 0.47 Å for **5**, respectively. The average dihedral angles of the backbones were derived by excluding the first and last residues. In **3**, the ϕ, θ, and ψ values for Caa are $91 \pm 7°$, $63 \pm 3°$, and $-91 \pm 4°$, respectively, whereas $\phi = -70 \pm 1°$ and $\psi = 135 \pm 2°$ for L-Ala. The corresponding values for **5** are $86 \pm 4°$, $66 \pm 2°$, $-91 \pm 4°$, $-70 \pm 2°$, and $131 \pm 2°$.

In conclusion, our exploratory study on the hybrid α/β-dipeptide repeats resulted in the unprecedented 9/11-mixed helices (9/11 and 11/9). Furthermore, a robust helical structure (11/9) in the shortest α/β tripeptide (L-Ala–Caaβ^3–L-Ala) is a notable feature of the present design. These peptides, in contrast to the reported α/β-mixed peptides derived from cyclic β-amino acids, show a high propensity for

the formation of stable mixed-helical structures. Extrapolation of this study to other α-amino acids will enhance the opportunity of finding not only new secondary structural elements, but also for the introduction of a wide variety of side chains and functionalities to derive desirable properties in this class of peptides.

Facile Synthesis of Chiral α-Difluoromethyl Amines from *N*-(*tert*-Butylsulfinyl)aldimines**

*Ya Li and Jinbo Hu**

Dedicated to Professor George A. Olah

Fluorinated amines are important synthetic building blocks in the design of antimetabolites and drugs because fluorine causes minimal structural changes and maximal shifts in electron distribution.[1,2] Fluorine lowers the basicity of amines and improves oral absorption, suppresses metabolism, and thus increases the bioavailability of a target drug.[3–5] Among the fluorinated amines, α-difluoromethyl amines are of particular interest as the CF_2H functionality is isosteric to a carbinol (CH_2OH) unit and also, as a lipophilic group, it shares much of the dipolar nature of the latter.[6,7] Therefore, α-difluoromethyl amines can be regarded as more lipophilic bioisosteres of corresponding α-aminocarbinols (or β-amino alcohols), which may feature some significant properties within biologically active molecules.

Despite its importance for applications related to life sciences, the synthesis of α-difluoromethyl amines has not been well explored. The few known methods are mainly based on the use of difluoromethyl carbonyl compounds or their imine derivatives as precursors.[8–12] Pey and Schirlin reported the multistep synthesis of α-difluoromethyl amines from substituted malonate esters with CHF_2Cl followed by a Curtius rearrangement.[13] However, the general and efficient asymmetric synthesis of α-difluoromethyl amines still remains a challenge although it has drawn many synthetic endeavors.[9–12,14] The asymmetric hydrogenation of fluorinated imines are usually difficult, and recently Uneyama and coworkers reported that the palladium-catalyzed asymmetric hydrogenation of difluoromethyl imino esters proceeded with poor enantioselectivity (30% *ee*).[9] Hydride reduction of the C=N bond of chiral difluoromethyl β-sulfinyl-*N*-arylimine only gave 82% diastereomeric excess.[10] Difluoropyruvaldehyde *N*,*S*-ketal was synthesized in three steps from difluoroacetic esters and chiral methyl *p*-tolyl sulfoxide in only 72% enantiomeric excess.[11] Conversion of optically pure β-

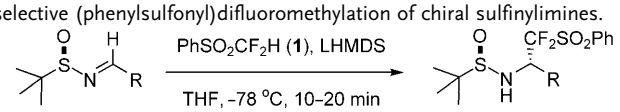
bromo-β,β-difluoroalanine derivatives into corresponding β,β-difluoroalanine products led to a decrease in the optical purity (with 80% *ee*).[14] Funabiki et al. attempted L-proline-catalyzed asymmetric Mannich-type reactions with difluoromethyl aldimine, but prolonged reaction times (7 days) were required and the reactions lacked generality.[12] On the other hand, although Prakash et al. elegantly developed the asymmetric synthesis of α-trifluoromethyl amines using $TMSCF_3$ (TMS = trimethylsilyl) and *N*-(*tert*-butylsulfinyl)aldimines,[15] similar asymmetric synthesis of α-difluoromethyl amines using R_3SiCF_2H and *N*-(*tert*-butylsulfinyl)imines proved problematic due to the low reactivity of R_3SiCF_2H reagents.[16] To the best of our knowledge, there is no synthetic method available for the highly stereoselective synthesis of α-difluoromethyl amines using a direct difluoromethylation strategy. Previously, one of us was involved in the development of difluoromethyl phenyl sulfone (**1**) as a versatile reagent for the selective transfer of difluoromethyl, difluoromethylene, and difluoromethylidene building blocks.[17] Herein, we report the first highly stereoselective nucleophilic difluoromethylation reaction using difluoromethyl phenyl sulfone and *N*-(*tert*-butylsulfinyl)aldimines which has enabled us to efficiently synthesize enantiomerically pure α-difluoromethyl amines through a simple and reliable protocol.



In previous investigations, we found that difluoromethyl phenyl sulfone (**1**) can be used as a convenient difluoromethylating agent for alkyl halides and carbonyl compounds, commonly accomplished through a (phenylsulfonyl)difluoromethylation–reductive desulfonylation strategy.[17d,e] The (phenylsulfonyl)difluoromethyl anion ($PhSO_2CF_2^-$, **2**), generated in situ from **1** and a base such as lithium hexamethyldisilazide (LHMDS) or *t*BuOK, is an excellent nucleophile that can readily undergo addition or substitution reactions with carbonyl compounds, disulfides, and primary alkyl halides.[17] Anion **2**, although difficult to isolate owing to its slow decomposition into difluorocarbene and benzenesulfinate, showed both higher thermal stability and sometimes better nucleophilicity (in the case of alkyl halides) than the trifluoromethyl anion (CF_3^-). Nucleophilic addition reactions between **2** and imines **3** have not been reported, and we envisioned that the reactions would proceed smoothly as a result of the reasonable stability of anion **2** to decomposition and the matched hard-/softness between **2** and imines.[18,19] With these in mind, first we prepared racemic *N*-(*tert*-butylsulfinyl)aldimine **4**[20] as a model compound to test the reaction with difluoromethyl phenyl sulfone (Scheme 1). When LHMDS (2 equiv, dissolved in THF) was added to a solution of aldimine **4** (2 equiv) and $PhSO_2CF_2H$ (1 equiv) in THF at −78 °C, a facile addition reaction occurred and sulfone **1** was quantitatively transformed into product **5** (detected by NMR spectroscopy and TLC) in 15 minutes. More interestingly, analysis of the crude reaction mixture by ^{19}F NMR spectroscopy showed that the reaction proceeded highly diastereoselectively and only

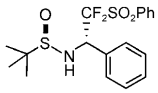
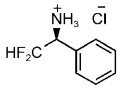
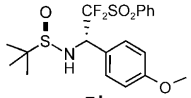
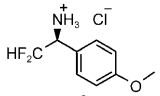
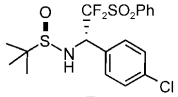
one single diastereomer (racemic) of **5** was formed. The reactant ratio **4**/**1**/LHMDS was further optimized to 1.1:1.0:1.2, and product **5** was isolated in 95% yield as a single diastereomer (racemic). Potassium *tert*-butoxide was also found to be effective for the reaction, however, slightly lower yields (80–85%) of product were obtained.

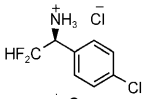


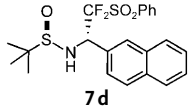


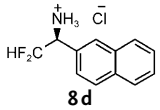


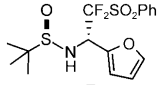


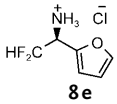


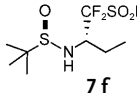


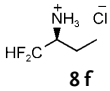


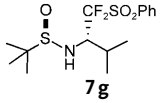


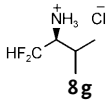


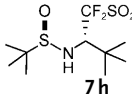


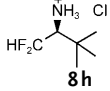












Encouraged by the above results, we predicted that when a homochiral sulfinylimine is subjected to this reaction, enantiomerically pure sulfinamide product could be obtained. The chiral sulfinamide can be further converted into enantiomerically pure α-difluoromethyl amines after deprotection of both *tert*-butylsulfinyl and phenylsulfonyl groups under mild conditions. Therefore, we prepared optically pure (*R*)-(*tert*-butylsulfinyl)aldimines **6**[21] and applied them in this nucleophilic (phenylsulfonyl)difluoromethylation reaction. The optimized reaction conditions as described above were used (**6**/**1**/LHMDS = 1.1:1.0:1.2, −78 °C, 10–20 min), and the results are summarized in Table 1. A variety of structurally diverse (*R*)-(*tert*-butylsulfinyl)aldimines **6** reacted with (phenylsulfonyl)difluoromethyl anion (generated in situ from sulfone **1** and LHMDS) to give the corresponding chiral sulfinamides **7** in excellent yields and with very high diastereoselectivities. Remarkably, the reactions were carried out under basic conditions but were still amenable to sulfinylimines bearing α hydrogen atoms (see entries 6 and 7, Table 1), which is in sharp contrast to their known trifluoromethylation chemistry.[15,18] Prakash et al.[15] and Dolbier and co-workers[18] reported that trifluoromethylation reactions of chiral sulfinylimines (with $TMSCF_3$ or CF_3I/tetrakis(dimethylamino)ethylene) were very sensitive to base (such as CsF), and that sulfinylimines bearing α hydrogen atoms usually gave lower yields. Sterically demanding sulfinylimine **6h** also gave a high yield of product (85%), which is superior to that obtained in the analogous trifluoromethylation reaction.[15,18] In each case as shown in Table 1, the product **7** was obtained as a single diastereomer, as determined by ^{19}F and ^{1}H NMR spectroscopy. Indeed, we observed that the present nucleophilic (phenylsulfonyl)difluoromethylations of sulfinylimines worked even more efficiently than those of carbonyl compounds as previously reported.[17e] The thermal stability, good nucleophilicity, and the softness of the (phenylsulfonyl)difluoromethyl anion generated in situ account for the short reaction times (10–20 min) and excellent chemo- and stereoselectivities. The absolute configuration of sulfinamide **7a** was determined by single-crystal X-ray analysis (see Figure 1a), and the configurations of **7b**–**7h** were assigned by analogy. The sense of diastereoselective induction can be depicted by a nonchelation-controlled addition step to give the Cram products **7** (Figure 1b).[15,18,21b,22]

All of the (phenylsulfonyl)difluoromethylated sulfinamides **7** were selectively deprotected under mild conditions following reported procedures[17,21] to give the corresponding amine salts **8**. Reductive desulfonylation using Na/Hg amalgam followed by acid alcoholysis provided a convenient and facile preparation of **8** from **7**. The results are summarized in Table 2. In all cases, near-quantitative conversions from **7** into **8** (in two continuous deprotection steps) were observed by

Table 2: Preparation of amine salts **8** from **7**.

7 **8**

Entry[a]	Sulfinylimine **7**	Product **8**[b]	Yield [%][c]	$[\alpha]_D^{25}$
1	 **7a**	 **8a**	83	25.4 (c=1.0)[d]
2	 **7b**	 **8b**	96	26.3 (c=0.7)[d]
3	 **7c**	 **8c**	82	24.9 (c=0.5)[d]

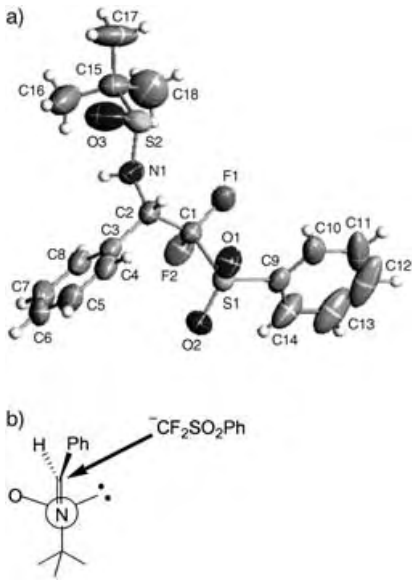

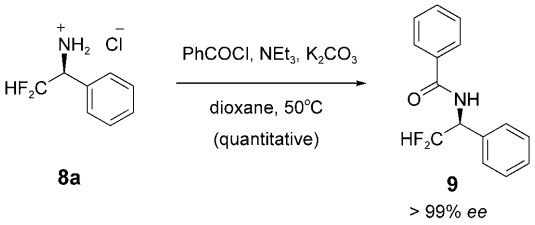

Figure 1. a) X-ray crystal structure of **7a**, and b) depiction of its stereoselective formation.

NMR spectroscopy and the isolated yields of **8** were somewhat affected by the hydroscopicity of the products (see entries 6 and 7, Table 2). To ensure that there was no racemization during the deprotection process, we converted amine salt **8a** into benzamide derivative **9** (Scheme 2). The

Scheme 2. Conversion of amine hydrochloride salt **8a** into chiral benzamide derivative **9**.

high optical purity of **9** (> 99 % *ee*) was determined by chiral HPLC and indicated that the above deprotection procedures are reliable for the preparation of enantiomerically pure α-difluoromethyl amines.

In summary, we have reported the first highly stereoselective and facile synthesis of α-difluoromethyl amines using a nucleophilic difluoromethylation strategy. Nucleophilic (phenylsulfonyl)difluoromethylation of (*R*)-(*N*-*tert*-butylsulfinyl)aldimines with difluoromethyl phenyl sulfone affords the corresponding products in excellent yields and with high diastereoselectivity
(d.r. > 99 %). The facile and convenient deprotection of both *tert*-butylsulfinyl and phenylsulfonyl groups gives the target α-difluoromethyl amines with high enantiomeric purity (*ee* > 99 %). The experimental data reported herein indicate that in a nucleophilic fluoroalkylation reaction, the stability, nucleophilicity, and hard-/softness of a fluorine-bearing carbon nucleophile substantially affect the overall chemical outcome of that reaction. The present synthetic methodology provides a convenient and useful synthetic tool for many applications related to life sciences.

[18] Compared with aldehydes and ketones, imines (even activated *N*-*tert*-butanesulfinyl imines) generally display lower reactivity toward nucleophiles. Thus the stability and nucleophilicity of a proper nucleophile are crucial for its reactions with sulfinyl imines. For example, owing to the lower stability of in situ generated CF_3^- ion, the trifluoromethylation reactions of sulfinyl imines are very sensitive to the precursors of the CF_3^- ion and different reaction conditions. See ref. [15], and for a recent report see: W. Xu, W. R. Dolbier, Jr., *J. Org. Chem.* **2005**, *70*, 4741.

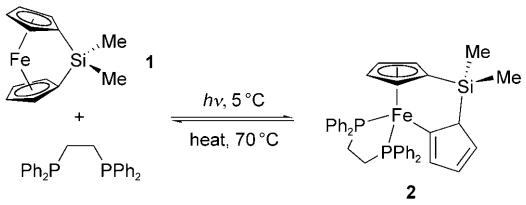
Reversible, Strain-Controlled Haptotropic Shifts of Cyclopentadienyl Ligands in [1]- and [2]Metallocenophanes**



*Makoto Tanabe, Sara C. Bourke, David E. Herbert, Alan J. Lough, and Ian Manners**

Strained rings containing transition-metal elements are of growing interest as a result of their intriguing structures, enhanced reactivity, and ability to function as precursors to high-molecular-weight metallopolymers through ring-opening polymerization.[1–4] Ring-strained metallocenophanes and their analogues have attracted particular attention in this regard and their ring-opened polymeric derivatives exhibit a variety of interesting properties.[3,4] The appreciable ring tilting (α) of the planes of the cyclopentadienyl ligands in ferrocenophanes relative to ferrocene, where the ligands are parallel ($\alpha = 0°$), has been shown to comprise the major contribution to ring strain.[5] Silicon-bridged [1]ferrocenophanes such as **A** ($\alpha \approx 16$–$21°$) have been most well investigated in this area. The moderate ring strain present in **A** has been shown to lead to enhanced reactivity of the bond between the *ipso* cyclopentadienyl (Cp) carbon and the bridging silicon atom. Stoichiometric reactions of **A** with protic regents, for example, lead to facile Si–Cp bond cleavage and to ring-opened species **B**.[6]

In contrast, highly strained, boron-bridged [1]ferrocenophanes ($\alpha \approx 31$–$32°$) have been shown to undergo unexpected ring-opening chemistry involving an Fe–Cp bond on reaction with, for example, $[Fe_2(CO)_9]$ to yield bimetallic species **C**.[7] Very recently, Miyoshi and co-workers have shown that UV-photoirradiation of phosphorus-bridged [1]ferrocenophanes in the presence of a phosphine ligand (e.g., $P(OMe)_3$) leads to a haptotropic shift of a Cp ligand (from η^5 to η^1) to yield the ring-slipped product **D**.[8] Herein, we report some of our initial results from comparative studies of the photolytic reactivity of a range of [1]- and [2]metallocenophanes, which demonstrate that either *reversible* or *irreversible* haptotropic rearrangements from η^5- to η^1-Cp are observed depending on the degree of strain present.

UV-photoirradiation of a slight excess of sila[1]ferrocenophane **1** ($\alpha = 20.8(5)°$)[9] in the presence of 1,2-bis(diphenylphosphanyl)ethane (dppe) in THF at 5 °C led to a haptotropic shift of a Cp ligand from η^5 to η^1 and coordination of the bidentate phosphine ligand to afford [{Fe(η^5-C_5H_4)$SiMe_2$(η^1-C_5H_4)}(dppe)] (**2**) in 90 % yield [Eq. (1)].[10]

(1)

The $^{31}P\{^1H\}$ NMR spectrum of **2** consisted of slightly broad AB doublets at $\delta = 109.4$ and 108.5 ppm[11] with the same coupling constant ($^2J(P,P) = 27.2$ Hz); they were assigned to the diastereotopic phosphine atoms coordinated to the iron center. In the $^{29}Si\{^1H\}$ NMR spectrum, a single broad resonance signal appeared at $\delta = -8.72$ ppm, which is shifted slightly upfield compared to that of **1** ($\delta = -4.6$ ppm).

Figure 1 shows the molecular structure of **2** determined by X-ray crystallography.[12] The photoproduct **2** possesses a

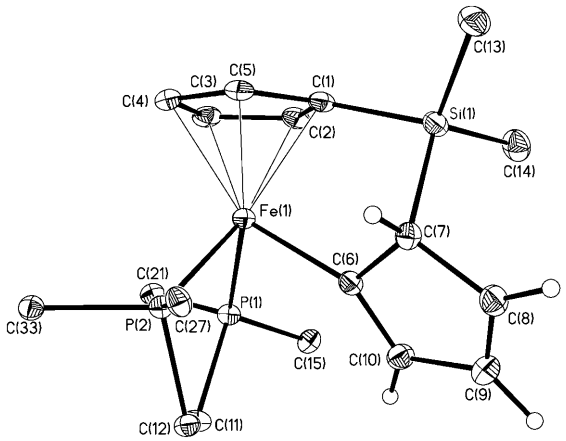

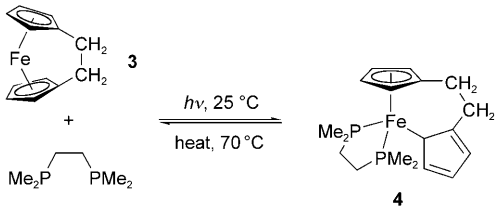

Figure 1. ORTEP drawing of **2** with 30% thermal ellipsoidal plots. Hydrogen atoms are depicted only for the η^1-Cp ring. Phenyl groups of the phosphine ligand are omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe(1)-$Cp_{centroid}$ 1.736(2), Fe(1)-P(1) 2.1543(6), Fe(1)-P(2) 2.1544(6), Fe(1)-C(6) 2.015(2), Si(1)-C(1) 1.862(2), Si(1)-C(7) 1.884(2), C(6)-C(7), 1.524(3), C(6)-C(10) 1.367(3), C(7)-C(8) 1.483(3), C(8)-C(9) 1.343(4), C(9)-C(10) 1.464(3); $Cp_{centroid}$-Fe(1)-C(6) 119.7(9), $Cp_{centroid}$-Fe(1)-P(1) 129.8(9), $Cp_{centroid}$-Fe(1)-P(2) 131.5(9), C(1)-Si(1)-C(7) 99.42(10), Fe(1)-C(6)-C(7) 118.01(16), Si(1)-C(7)-C(6) 100.07(14).

piano-stool geometry around the Fe center. The C(1)-Si(1)-C(7) angle (99.42(10)°) is larger than that of **1** (95.7(4)°),[9] and the angle β (14.0(3)°) of **2**, between the plane of the cyclopentadienyl carbon atoms and the C(1)-Si(1) bond, has decreased significantly (from 37.0(6)° for **1**),[9] indicating that the ring strain is less in **2** than in **1**. The bond lengths for C(6)–C(10) (1.367(3) Å) and C(8)–C(9) (1.343(4) Å) in the σ-bonded Cp ring are shorter than other bond lengths (average 1.490(3) Å), indicating that the double bonds are located in these positions.

All inequivalent proton and carbon signals for the differently coordinated Cp rings were assigned by ^{1}H-^{1}H and ^{1}H-^{13}C COSY NMR spectroscopic methods at −40 °C. Interestingly, one signal in each Cp ring was observed at higher field (δ = 2.82 ppm for η^1-Cp; δ = 3.03 ppm for η^5-Cp). Upon raising the temperature of the solution to 25 °C, all signals in the ^{1}H and ^{31}P{^{1}H} NMR spectra appeared broadened suggesting fluxional behavior around the Fe center.

Remarkably, on heating at 70 °C in [D_6]benzene for 3 h, photoproduct **2** underwent dissociation of the dppe ligand and quantitative retroconversion into **1** [Eq. (1)]. This thermal reaction clearly indicates that, at elevated temperatures, the ring-strained ferrocenophane **1** and dppe are thermodynamically favored compared with the photoproduct **2**. This can be attributed to the greater entropy of the species on the left side of Equation (1) and the enthalpic preference for η^5-Cp coordination. It appears that **2** is metastable at room temperature and that its formation relies on the photoactivation of **1**.

To explore the generality of this surprising reversible reaction, we investigated the analogous chemistry of the ethane-bridged [2]ferrocenophane **3** (α = 21.6(4)°)[13] which has a similar degree of ring strain as **1**. Another ring-slipped Fe complex, [{Fe(η^5-C_5H_4)CH_2CH_2(η^1-C_5H_4)}(dmpe)] (**4**), was obtained from the photolysis of **3** in the presence of 1,2-bis(dimethylphosphanyl)ethane (dmpe) in THF at room temperature [Eq. (2)]. Recrystallization of the crude product from toluene/hexane at −55 °C afforded **4** as dark red crystals in 83% yield.[14] Heating of **4** in [D_8]toluene for 3 h at 70 °C also led to a quantitative reverse haptotropic rearrangement with dissociation of the dmpe ligand.

(2)

Complex **4** was also fully characterized by one- and two-dimensional NMR spectroscopic methods at low temperature and the crystal structure was determined by X-ray diffraction (Figure 2).[12] The piano-stool Fe center, capped by an η^5-Cp

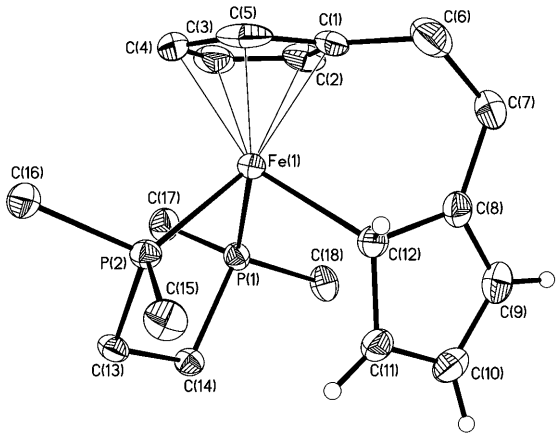

Figure 2. ORTEP drawing of **4** with 30% thermal ellipsoidal plots. Hydrogen atoms are depicted only for the η^1-Cp ring. Selected bond lengths [Å] and angles [°]: Fe(1)-$Cp_{centroid}$ 1.717(5), Fe(1)-P(1) 2.1674(15), Fe(1)-P(2) 2.1776(14), Fe(1)-C(12) 2.201(5), C(1)-C(6) 1.491(8), C(6)-C(7) 1.516(9), C(7)-C(8) 1.512(7), C(8)-C(9) 1.352(8), C(8)-C(12) 1.476(7), C(9)-C(10) 1.428(8), C(10)-C(11) 1.350(8), C(11)-C(12) 1.465(7); $Cp_{centroid}$-Fe(1)-C(12) 120.1(2), $Cp_{centroid}$-Fe(1)-P(1) 125.1(2), $Cp_{centroid}$-Fe(1)-P(2) 128.0(2), C(1)-C(6)-C(7) 111.6(5), C(6)-C(7)-C(8) 113.5(5), C(7)-C(8)-C(12) 124.6(5), Fe(1)-C(12)-C(8) 110.6(3).

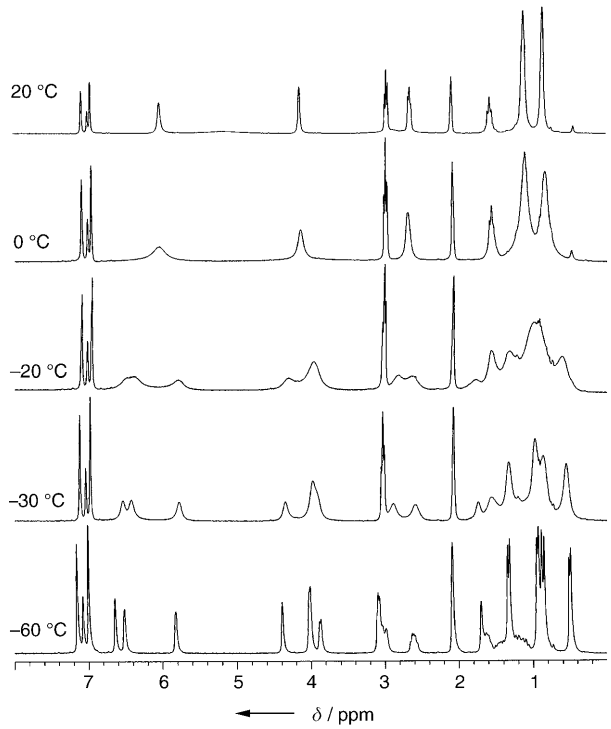
ligand, also possesses a chelating dmpe ligand. The C(1)–C(6) bond was found to lie almost in plane with the η^5-Cp ligand (β = 1.9(3)°), indicating that the structure contains no significant ring strain. The two double bonds in the η^1-Cp ring were located at C(8)–C(9) (1.352(8) Å) and C(10)–C(11) (1.350(8) Å), supported by the conformation around C(12) which is not suited to an sp^2 carbon center. Analysis of **4** in the solid state indicated that the η^1-Cp geometry is a tautomer of that in **2**.

The variable-temperature ^{31}P{^{1}H} NMR spectra exhibited two doublets at δ = 81.0 and 78.9 ppm (^2J(P,P) = 39 Hz) at −40 °C that coalesce to give a single signal at 79.0 ppm upon warming to 20 °C. Figure 3 depicts the ^{1}H NMR spectra of **4**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



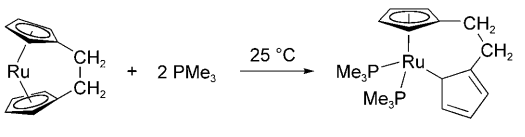


Figure 3. Variable-temperature ^{1}H NMR spectra of **4** between −60 and 20 °C in [D_8]toluene.

between −60 and 20 °C. At −60 °C, eight signals attributed to the two inequivalent Cp rings were observed in the range $\delta =$ 1.70–6.64 ppm. Upon raising the temperature to −20 °C all signals attributable to **4** broadened and coalesced around 0 °C, indicating the same coalescence temperature for both the η^1- and η^5-Cp rings. At 20 °C, two widely broadened signals ($\delta =$ 4.6–5.6 ppm for the η^1-ring; $\delta = 2.8$–3.1 ppm for the η^5-ring; not clearly visible in the spectra) suggest slower fluxional behavior. The fluxional behavior of σ-bonded Cp rings such as that in [Fe(η^1-Cp)(η^5-Cp)(CO)$_2$] has been well studied over the past four decades.[15] The η^1-Cp ring of this species is involved in a fluxional process that consists of successive 1,2-shifts, observable on the NMR time scale, while the η^5-Cp ring signals display no coalescence due to more rapid ring rotation. The dynamic nature of the NMR spectrum of **4** suggests fluxional behavior, which may involve fast successive 1,2-shifts of the η^1-Cp ring and slow coordination mode exchange between the two Cp ligands.

At this point, we investigated the analogous reaction of the more highly ring-strained, ethane-bridged [2]ruthenocenophane **5** which possesses a larger tilt angle of 29.6(5)° by virtue of the larger covalent radius of Ru relative to Fe.[16] When **5** was reacted with excess PMe_3 *without* photoirradiation the new complex [{Ru(η^5-C_5H_4)CH_2CH_2(η^1-C_5H_4)}-(PMe_3)$_2$] (**6**) was formed in a quantitative yield [Eq. (3)].

5 **6** (3)

The solid-state structure of **6** was investigated by single-crystal X-ray crystallography.[12] The molecular structure (Figure 4) and the η^1-Cp ring geometry were similar to that seen for complex **4**. The $Cp_{centroid}$–Ru distance (1.863(3) Å) is longer than the $Cp_{centroid}$–Fe distance in **4** (1.717(5) Å) due to

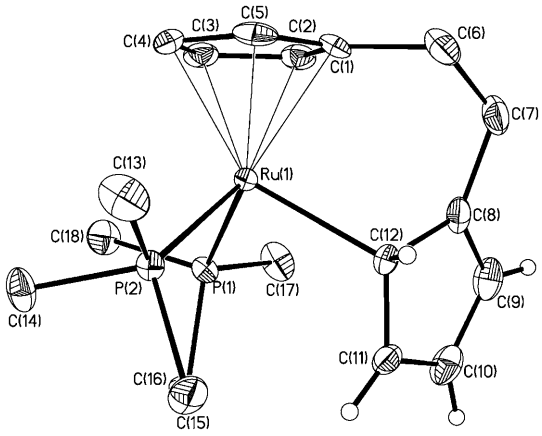

Figure 4. ORTEP drawing of **6** with 30% thermal ellipsoidal plots. Hydrogen atoms are depicted only for the η^1-Cp ring. Selected bond lengths [Å] and angles [°]: Ru(1)-$Cp_{centroid}$ 1.863(3), Ru(1)-P(1) 2.2710(6), Ru(1)-P(2) 2.2719(6), Ru(1)-C(12) 2.275(2), C(1)-C(6) 1.505(4), C(6)-C(7) 1.496(5), C(7)-C(8) 1.508(4), C(8)-C(12) 1.474(3), C(8)-C(9) 1.355(4), C(9)-C(10) 1.425(5), C(10)-C(11) 1.360(4), C(11)-C(12) 1.464(4); $Cp_{centroid}$-Ru(1)-C(12) 117.3(9), $Cp_{centroid}$-Ru(1)-P(1) 124.4(9), $Cp_{centroid}$-Ru(1)-P(2) 123.9(9), C(1)-C(6)-C(7) 112.8(3), C(6)-C(7)-C(8) 114.4(3), C(7)-C(8)-C(12) 126.0(3), Ru(1)-C(12)-C(8) 108.23(16).

the larger size of the ruthenium atom. As expected from the reaction in the absence of UV-photoirradiation, the ring-slipped Ru complex **6** is the thermodynamically stable compound due to the high ring-strain energy of ruthenocenophane **5**. In fact, thermal treatment of **6** in [D_8]toluene (110 °C, 18 h) resulted in no detectable retroconversion to **5**. Similar, irreversible formation of a ring-slipped η^1-Cp complex [{Ru(η^5-Cp)(CH_2CH_2)(η^1-Cp)}(dmpe)] (**7**) was observed with **5** and the chelating diphosphine dmpe.

In summary, ring-strained ferrocenophanes **1** and **3** were found to undergo photochemically and thermally reversible haptotropic shifts (η^5- to η^1-Cp) and the ring-slipped photoproducts **2** and **4** were isolated in the presence of appropriate phosphine ligands. In contrast, the highly ring-strained ruthenocenophane **5** was transformed irreversibly into the analogues **6** and **7** without UV-photoirradiation. We attribute these phenomena to the balance between the release of strain in the [1]- or [2]metallocenophane with the preference for η^5 coordination of the Cp ligand. For **1** and **3**, which possess moderate tilt angles and strain, photoactivation leads to **2** and **4**, which are metastable and retroconvert when heated at 70 °C. In contrast, the highly tilted [2]ruthenocenophane **5** possesses sufficient strain for the more thermodynamically stable species **6** and **7** to be formed irreversibly and without the need for photochemical activation. Currently, we are focusing on the detailed mechanism for the photochemically induced haptotropic rearrangement and the fluxional behavior of ring-slipped Fe and Ru complexes.

Experimental Section

Basic experimental procedures and analytical equipment used were as noted elsewhere.[4b] The ligands dppe and dmpe were purchased from Aldrich, and trimethylphosphine was obtained from Strem. These phosphine reagents were used as received. The photoirradiation experiments were carried out with Pyrex-glass-filtered emission from a 125-W high-pressure mercury arc lamp (Philips). The emission lines of the mercury lamp were as follows: 578.0, 546.1, 435.8, 404.7, 365.0, 334.1, 313.0, and 302.5 nm.

Preparation of **2**: In the absence of light, dppe (359 mg, 0.9 mmol) was added to a slight excess of sila[1]ferrocenophane **1**[17] (242 mg, 1.0 mmol) dissolved in THF (5 mL). The solution was irradiated for 3 h, with stirring, in a cooling water bath at 5 °C. The reaction mixture was evaporated to dryness. Addition of hexane to the red residue followed by filtration allowed for collection of a red solid which was washed with hexane three times (2 mL), and dried in vacuo (517 mg, 90 % based on dppe). Recrystallization from THF/hexane, by slow evaporation, gave dark red crystals suitable for X-ray crystallography. All signals in the ^{1}H and ^{13}C{^{1}H} NMR spectra at 25 °C and −40 °C were characterized by 2D ^{1}H-^{1}H and ^{1}H-^{13}C NMR experiments. ^{1}H NMR (500 MHz, [D$_8$]toluene, −40 °C): $\delta = 7.88$ (br, 2H, Ph-*ortho*), 7.38 (s, 2H, Ph-*ortho*), 7.13–6.99 (Ph, overlapped with solvent), 6.69 (s, 1H, η^1-C$_5$H$_4$, CH=), 6.61 (s, 1H, η^1-C$_5$H$_4$, CH=), 5.33 (s, 1H, η^1-C$_5$H$_4$, CH=), 5.12 (s, 1H, η^5-C$_5$H$_4$), 4.70 (s, 1H, η^5-C$_5$H$_4$), 4.19 (s, 1H, η^5-C$_5$H$_4$), 3.03 (s, 1H, η^5-C$_5$H$_4$), 2.82 (s, 1H, η^1-C$_5$H$_4$, SiCH), 2.59 (br m, 1H, PCH$_2$), 2.17 (br d, 1H, PCH$_2$, ^2J(H,P) = 34 Hz), 1.87 (br m, 1H, PCH$_2$), 1.69 (br d, 1H, PCH$_2$, ^2J(H,P) = 27 Hz), 0.36 (br, 3H, SiCH$_3$), 0.13 ppm (br, 3H, SiCH$_3$); ^{13}C{^{1}H} NMR (75.4 MHz, [D$_6$]benzene, 25 °C): $\delta = 161.5$ (dd, η^1-C$_5$H$_4$, FeC=, ^2J(C,P) = 26, 38 Hz), 147.1 (Ph-*ipso*), 144.7 (η^1-C$_5$H$_4$, CH=), 141.0 (Ph-*ipso*), 140.7 (Ph-*ipso*), 139.5 (Ph-*ipso*), 135.6 (Ph-*ortho*), 134.0 (η^1-C$_5$H$_4$, CH=), 133.3 (η^1-C$_5$H$_4$, CH=), 131.3 (Ph-*ortho*), 129.8 (Ph), 129.1 (Ph), 103.2 (η^5-C$_5$H$_4$-*ipso*), 87.5 (η^5-C$_5$H$_4$), 84.0 (η^5-C$_5$H$_4$), 80.4 (η^5-C$_5$H$_4$), 74.9 (η^1-C$_5$H$_4$, SiCH), 73.6 (η^5-C$_5$H$_4$), 28.6 (dd, PCH$_2$, J(C,P) = 16, 34 Hz), 25.0 (br t, PCH$_2$), 0.11 (SiCH$_3$), −7.92 ppm (SiCH$_3$); ^{31}P{^{1}H} NMR (121.4 MHz, [D$_6$]benzene, 25 °C): $\delta = 109.4$ (d, J(P,P) = 27.2 Hz), 108.5 ppm (d, J(P,P) = 27.2 Hz); ^{29}Si{^{1}H} NMR (79.4 MHz, [D$_6$]benzene, 25 °C): $\delta = -8.72$ (br); MS analysis was not possible, as the sample decomposed in the spectrometer; elemental analysis: calcd for C$_{38}$H$_{38}$FeP$_2$Si (%): C 71.25, H 5.98; found: C 70.95, H 6.00. A solution of **2** in [D$_6$]benzene, heated at 70 °C for 3 h in the absence of light, turned red in color and underwent a quantitative dissociation of the dppe ligand and reformation of the starting material **1**, as observed by ^{1}H NMR spectroscopy. The UV-photoirradiation of **1** with dmpe in THF at room temperature led to a dark red solution. However, a ^{1}H NMR spectrum of the reaction mixture showed the presence of **1** and free dmpe. In contrast, the photoirradiation of **1** with PMe$_3$ in [D$_6$]benzene at room temperature for 5 h afforded the ring-opened polymer [fcSiMe$_2$]$_n$ in 35 % yield ($M_n = 1.3 \times 10^4$, polydispersity index (PDI) = 1.45).[17a]

Preparation of **4**: The ligand dmpe (333 mg, 2.2 mmol) was added to a solution of ethane-bridged [2]ferrocenophane **3**[13a] (212 mg, 1.0 mmol) in THF (30 mL). The reaction mixture was irradiated for 2 h, with stirring at room temperature. The reaction conversion was estimated at 95 % by ^{1}H NMR spectroscopy. All volatile material in the reaction mixture was removed under high vacuum. The resulting material was dissolved in toluene and filtered through a celite-fritted glass disk. Recrystallization from toluene/hexane (10 mL, 4:1) at −55 °C gave dark red crystals (302 mg, 83 % yield). All signals in the ^{1}H and ^{13}C{^{1}H} NMR spectra at 20 and −60 °C were characterized by 2D ^{1}H-^{1}H and ^{1}H-^{13}C NMR experiments. ^{1}H NMR (300 MHz, [D$_8$]toluene, −60 °C): $\delta = 6.64$ (s, 1H, η^1-C$_5$H$_4$, CH=), 6.51 (s, 1H, η^1-C$_5$H$_4$, CH=), 5.82 (s, 1H, η^1-C$_5$H$_4$, CH=), 4.40 (s, 1H, η^5-C$_5$H$_4$), 4.02 (m, 2H, η^5-C$_5$H$_4$ and η^1-C$_5$H$_4$, overlapped signals), 3.87 (d, 1H, η^5-C$_5$H$_4$, ^3J(H,H) = 6.0 Hz), 3.08 (d, 2H, CpCH$_2$, ^3J(H,H) = 6.3 Hz), 3.02 (d, 1H, CpCH$_2$, ^3J(H,H) = 14 Hz), 2.61 (m, 1H, CpCH$_2$, ^3J(H,H) = 6.0 Hz), 1.70 (s, 1H, η^5-C$_5$H$_4$), 1.05–1.70 (4H, PCH$_2$), 1.33 (d, 3H, PCH$_3$, ^2J(H,P) = 7.5 Hz), 0.94 (d, 3H, PCH$_3$, ^2J(H,P) = 6.6 Hz), 0.87 (d, 3H, PCH$_3$, ^2J(H,P) = 10 Hz), 0.51 ppm (d, 3H, PCH$_3$, ^2J(H,P) = 6.6 Hz); ^{13}C{^{1}H} NMR (100.4 MHz, [D$_8$]toluene, −60 °C): $\delta = 157.4$ (η^1-C$_5$H$_4$-*ipso*, CH$_2$*C*=), 143.9 (η^1-C$_5$H$_4$, CH=), 118.2 (η^1-C$_5$H$_4$, CH=), 117.4 (η^1-C$_5$H$_4$, CH=), 94.4 (η^5-C$_5$H$_4$-*ipso*), 81.0 (η^5-C$_5$H$_4$), 80.1 (η^5-C$_5$H$_4$), 79.4 (η^5-C$_5$H$_4$), 56.3 (η^5-C$_5$H$_4$), 31.9 (dd, PCH$_2$, J(C,P) = 27, 14 Hz), 31.7 (Cp*C*H$_2$), 30.8 (Cp*C*H$_2$), 29.7 (dd, PCH$_2$, J(C,P) = 26, 15 Hz), 23.5 (d, PCH$_3$, J(C,P) = 27 Hz), 22.8 (η^1-C$_5$H$_4$, FeCH), 22.1 (d, PCH$_3$, J(C,P) = 25 Hz), 18.2 (d, PCH$_3$, J(C,P) = 9.5 Hz), 8.93 ppm (dd, PCH$_3$, J(C,P) = 4.5, 12 Hz); ^{31}P{^{1}H} NMR (121.4 MHz, [D$_8$]toluene, −40 °C): $\delta = 81.0$ (d, ^2J(P,P) = 39 Hz), 78.9 ppm (d, ^2J(P,P) = 39 Hz); ^{31}P{^{1}H} NMR (121.4 MHz, [D$_8$]toluene, 20 °C): $\delta = 79.0$ ppm; MS(CI, 70 eV): m/z (%): 362 (2.5) [M^+], 212 (100) [M^+−(PMe$_2$CH$_2$)$_2$], 134 (65) [Fe(C$_5$H$_4$CH$_2$)$^+$], 122 (65) [Fe(C$_5$H$_5$) + H$^+$]; elemental analysis: calcd for C$_{18}$H$_{28}$FeP$_2$ (%): C 59.69, H 7.79; found: C 60.04, H 8.01. A solution of **4** in [D$_6$]benzene, heated at 70 °C for 3 h in the absence of light, was quantitatively converted into a mixture of dmpe and **3**, as observed by ^{1}H NMR spectroscopy. Although UV-photoirradiation of the solution of **3** in THF in the presence of dppe at 5 °C led to a slightly dark red color, the ^{1}H and ^{31}P{^{1}H} NMR spectra did not show any photoproducts. The photoreaction with a threefold excess of PMe$_3$ for 3 h in [D$_6$]benzene at room temperature led to polymerization to yield the yellowish insoluble polymer [fcCH$_2$CH$_2$]$_n$ in 66 % yield.[13b]

Preparation of **6**: A fivefold excess of PMe$_3$ (78 μL, 0.76 mmol) was added to a solution of ethane-bridged [2]ruthenocenophane **5**[16] (39 mg, 0.15 mmol) in [D$_6$]benzene (0.5 mL) at room temperature. The reaction mixture immediately turned from yellow to orange in color without UV-photoirradiation. A ^{1}H NMR spectrum of the reaction mixture showed the quantitative conversion into ring-slipped Ru complex **6**. The volatile material was removed under high vacuum to dryness. Recrystallization from hexane by slow evaporation gave orange crystals suitable for X-ray crystallography. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): $\delta = 6.54$ (s, 2H, η^1-C$_5$H$_4$), 5.3–5.7 (br, 2H, η^1-C$_5$H$_4$), 4.10 (s, 2H, η^5-C$_5$H$_4$), 3.89 (s, 2H, η^5-C$_5$H$_4$), 3.00 (t, 2H, CpCH$_2$, ^3J(H,H) = 3.2 Hz), 2.43 (t, 2H, CpCH$_2$, ^3J(H,H) = 3.3 Hz), 1.04 ppm (t, 18H, PCH$_3$, ^2J(H,P) = 3.9 Hz); ^{31}P{^{1}H} NMR (121.4 MHz, [D$_6$]benzene, 25 °C): $\delta = 4.65$ ppm; MS(EI, 70 eV): m/z (%): 410 (19) [M^+], 258 (100) [M^+−2PMe$_3$], 180 (36) [Ru-(C$_5$H$_5$CH$_2$)$^+$]. High-resolution MS for C$_{18}$H$_{30}$P$_2$Ru: calcd 410.086, found 410.087. Compound **6** did not show any retroconversion into ruthenocenophane **5** after 18 h at 110 °C in [D$_8$]toluene (^{1}H NMR).

Preparation of **7**: Excess dmpe (70 μL, 0.42 mmol) was added to a [D$_6$]benzene (0.5 mL) solution of ethane-bridged [2]ruthenocenophane **5** (5 mg, 0.019 mmol) at room temperature. The reaction mixture darkened from yellow to orange-yellow without UV-photoirradiation. A ^{1}H NMR spectrum of the reaction mixture showed quantitative conversion of the [2]ruthenocenophane into the ring-slipped Ru complex **7**. ^{1}H NMR (400 MHz, [D$_6$]benzene, 25 °C): δ = 6.32 (s, 2H, η^1-C$_5$H$_4$), 5.40 (br, 2H, η^1-C$_5$H$_4$), 4.56 (s, 2H, η^5-C$_5$H$_4$), 3.94 (s, 2H, η^5-C$_5$H$_4$), 2.96 (t, 2H, CpCH$_2$, ^3J(H,H) = 6.4 Hz), 2.46 (t, 2H, CpCH$_2$, ^3J(H,H) = 6.4 Hz), 1.61 (m, 4H, PCH$_2$), 1.17 ppm (m, 12H, PCH$_3$); ^{31}P{^{1}H} NMR (121.5 MHz, [D$_6$]benzene, 25 °C): δ = 54.2 ppm. ^{1}H NMR analysis of **7** in [D$_6$]benzene at 70 °C showed no evidence of retroconversion into [2]ruthenocenophane **5**. Partial decomposition of a solution of **7** in [D$_8$]toluene was observed at 85 °C but the remaining ring-slipped compound **7** showed no retroconversion into **5** even at 110 °C after 5 h.

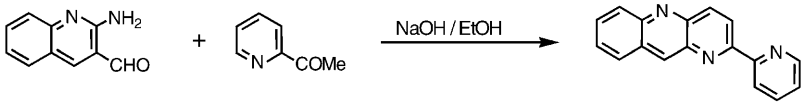
Reversible Hydride Generation and Release from the Ligand of $[Ru(pbn)(bpy)_2](PF_6)_2$ Driven by a pbn-Localized Redox Reaction**

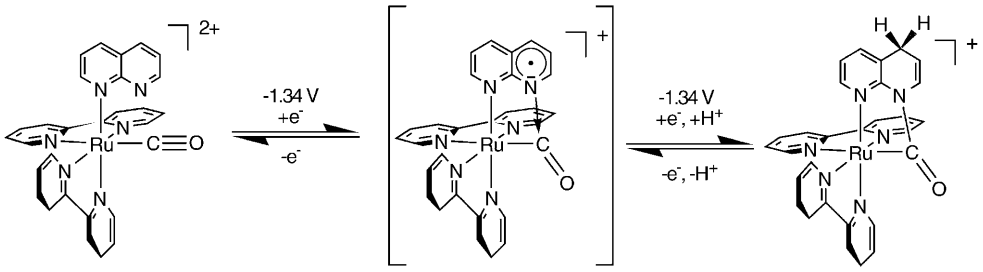
*Take-aki Koizumi and Koji Tanaka**



Metal hydrides such as $LiAlH_4$ and $NaBH_4$ have been widely employed in organic synthesis as fundamental reducing agents, and numerous modified forms have been developed for specific purposes. In biological reactions, on the other hand, the NAD^+/NADH redox couple, in which the oxidized form (NAD^+) with a pyridinium structure is reversibly converted into the reduced form (NADH) with two electrons and one proton, plays a key role in reversible hydride transfer reactions. Chemists have focused much attention on the function of NADH as an *organic hydride*. A number of kinetic studies of the hydride transfer,[1] asymmetric reductions of carbonyl compounds,[2] electron and hydrogen-atom transfer[3] with NADH and its model compounds have been carried out. However, as far as we know, all the reactions so far reported using NAD^+/NADH model compounds are stoichiometric.[2,4]

Recently, we revealed that the electrochemical reduction of *cis*-$[Ru(napy\text{-}\kappa N)(CO)(bpy)_2](PF_6)_2$ (napy = 1,8-naphthyridine) at −1.34 V (versus the ferrocene/ferrocenium (Fc/Fc^+) couple) in H_2O results in bond formation between the noncoordinating N atom of napy and the carbonyl carbon atom as well as the subsequent hydrogenation of the napy ring. Reoxidation of the solution at 0.06 V fully regenerated *cis*-$[Ru(napy\text{-}\kappa N)(CO)(bpy)_2]^{2+}$ (Scheme 1).[5] The reversible formation of a C–H bond in a pyridinium ring by two electrons and one proton (Scheme 1) is in good agreement with the NAD^+/NADH redox couple. This observation has driven us to construct a catalytic system that is able to generate and release hydride ions from a ligand of a transition-metal complex, because until now there has been no report of transition-metal complexes operating in the same way as the NAD^+/NADH system. Herein we describe the synthesis and electrochemical behavior of $[Ru(pbn)(bpy)_2](PF_6)_2$ (**1**, pbn = 2-(2-pyridyl)benzo[*b*]-1.5-naphthyridine, bpy = 2,2′-bipyridine; Scheme 2). The electrochemical reduction of **1** under aqueous acidic conditions induces formation of the hydrogenated product $[Ru(pbnH_2)(bpy)_2](PF_6)_2$ (**2**). We also report the electrochemical reduction of acetone by using complex **1** as a precatalyst.

Scheme 2. Ligands used to form a catalytic system.



2-(2-Pyridyl)benzo[*b*]-1.5-naphthyridine (pbn) was prepared by coupling 3-aminoquinaldehyde[6] with 2-acetylpyridine in ethanol in the presence of NaOH[7] [Eq. (1)]. $[RuCl_2(bpy)_2]$ was treated with two equivalents of $AgPF_6$ in 2-methoxyethanol, followed by addition of one equivalent of pbn to give $[Ru(pbn)(bpy)_2](PF_6)_2$ (**1**) as a red-purple powder [Eq. (2)]. The structure of complex **1** was determined by X-ray crystallographic analysis (Figure 1)[8] and NMR spectroscopy.

(1)

The addition of hydrochloric acid to a solution of **1** in acetonitrile resulted in a dramatic change from orange-brown to green. The UV/Vis spectra show there is a bathochromic shift of the absorption band of the metal-to-ligand charge transfer (MLCT) based on the pbn ligand from 529 to 604 nm. The extent of the decrease in the energy of the π* orbital of pbn upon protonation of the ligand would be larger than that of the dπ orbital of the Ru(II) atom. As a result, the MLCT band of **1** showed a red-shift as a result of a narrowing of the Ru(dπ)–L(π*) energy gap under acidic conditions. A similar green color has been observed in some ruthenium complexes containing quaternary polypyridine-type ligands.[9]

The cyclic voltammogram of **1** measured in MeCN in the presence of 0.1 M Me_4NBF_4 exhibited one reversible (Ru^{II}/Ru^{III}) redox couple at $E_{1/2} = +1.09$ V (versus Fc/Fc^+) and

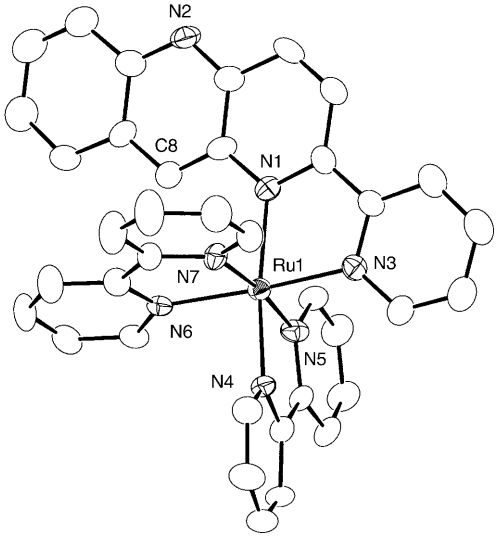

Figure 1. ORTEP drawing of the cationic part of **1** with 50% thermal ellipsoids. Hydrogen atoms are omitted for simplicity. Selected bond length [Å] and angles [°]: Ru1-N1 2.116(5), Ru1-N3 2.051(5), Ru1-N4 2.038(5), Ru1-N5 2.057(6), Ru1-N6 2.082(5), Ru1-N7 2.058(5), N1-Ru1-N3 78.0(2), N1-Ru1-N4 173.1(2); N1-Ru1-N5 98.9(2), N1-Ru1-N6 101.3(2), N1-Ru1-N7 86.4(2), N3-Ru1-N4 95.3(2), N3-Ru1-N5 89.7(2), N3-Ru1-N6 173.9(2), N3-Ru1-N7 95.9(2), N4-Ru1-N5 79.2(2), N4-Ru1-N6 85.5(2), N4-Ru1-N7 96.0(2), N5-Ru1-N6 96.4(2), N5-Ru1-N7 173.0(2), N6-Ru1-N7, 78.0(2).

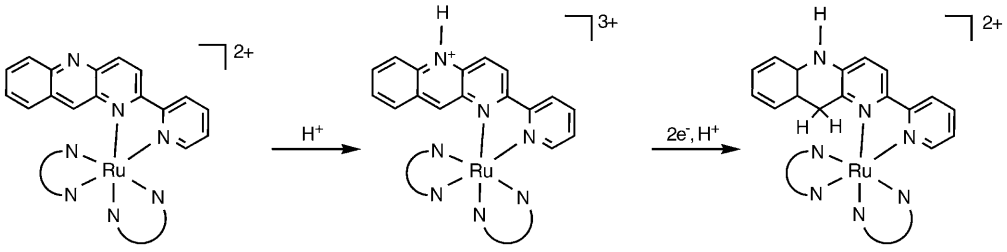


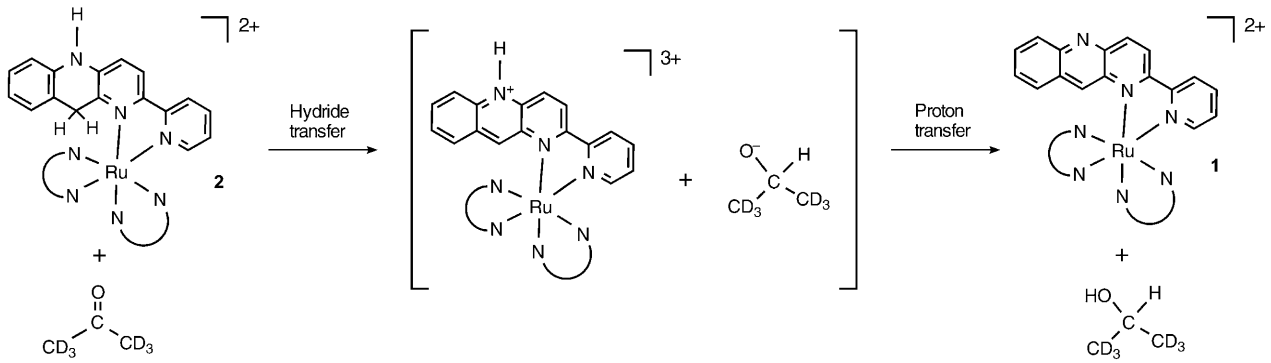
three ligand-based redox processes at $E_{1/2} = -1.03$, -1.65, and -1.92 V. The first of the ligand-based redox processes is assigned to the pbn ligand, and other two waves to bpy redox processes. The first reduction wave appeared at -0.37 V after the addition of 50 equivalents of HCl to the solution. Thus, the protonation of the pbn ligand shifts the redox potentials towards the positive region by approximately 700 mV relative to **1**. The fact that the pbn-based redox reaction takes place reversibly ($\Delta E = 68$ mV) indicates that the radical species generated by the one-electron reduction is stable and does not undergo further reactions, for example, abstraction or dimerization of the H radical by radical coupling.

The potentiostatic electrolysis of **1** in a 1:1 mixture of MeCN and 0.1M AcOH/AcONa buffer solution at -1.14 V (versus Fc/Fc^+) under N_2 consumed electrons corresponding to two electrons per molecule, and then the reaction stopped. The solution turned from red-purple to orange-brown. The ESI-MS spectrum of the resulting solid **2** obtained after drying showed a parent signal at m/z 336.5 with a divalent cation pattern, which is increased by one mass number relative to **1** (m/z 335.5), thus indicating that two hydrogen atoms were added to **1**.

The ^{1}H NMR spectrum of **2** in [D_6]acetone displayed 19 different signals with a total intensity of 27 protons in the aromatic region, which are assigned to two bpy and reduced pbn ligands, including the NH proton. Two characteristic doublets appeared at $\delta = 4.19$ and 3.18 ppm while the singlet peak at $\delta = 8.55$ ppm assigned to the proton on C10 disappeared (Scheme 3).[10]

Dissolving complex **2** in [D_6]acetone resulted in the solution turning from orange-brown to red-orange quite slowly at room temperature. The time-dependent ^{1}H NMR spectrum showed a new signal at $\delta = 3.75$ ppm, which is assigned to the hydrogen atom on the C2 carbon atom of $(CD_3)_2CHOH$. This result indicates that acetone was reduced by **1** to generate 2-propanol, as shown in Scheme 4. Controlled potential electrolysis of **1** (1 mM) was performed in the presence of 0.1M AcOH/AcONa buffer and 0.1M NaCl in an aqueous acetone solution (1:1 v/v, 10 mL) at -1.14 V (versus Fc/Fc^+) with a glassy carbon working electrode. The reaction progressed slowly, and about 20 μmol of 2-propanol formed in 48 h with a current efficiency of approximately 90%. To our knowledge, this is the first example of the electrochemical catalytic reduction of organic molecules by using a NAD^+/NADH model system.

In summary, we have demonstrated the synthesis of a novel ruthenium complex with a ligand that behaves in the same way as the NAD^+/NADH redox couple. We have succeeded in the catalytic reduction of acetone with two electrons and H_2O as a proton source for the first time. The key points of this catalytic system are "hydride" generation and transfer, similar to the function of the NAD^+/NADH redox couple.



Scheme 3. Electrochemical reduction of $[Ru(pbn)(bpy)_2]^{2+}$.

Experimental Section

1: A solution of $AgPF_6$ (60 mg, 0.24 mmol) in $CH_3OCH_2CH_2OH$ (5 mL) was added to a solution of $[RuCl_2(bpy)_2]$ (53 mg, 0.11 mmol)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 4. Mechanism for the reduction of acetone.

in $CH_3OCH_2CH_2OH$ (20 mL) and this mixture was stirred at 70 °C for 2 h. The resulting gray solid was removed by filtration through celite, and then the red-orange filtrate was added to a solution of pbn (28 mg, 0.11 mmol) in $CH_3OCH_2CH_2OH$ (5 mL) and the solution changed immediately from red-orange to red-purple. The reaction mixture was stirred at 70 °C for 12 h. The solution was concentrated to ca. 1 mL and poured into aqueous NH_4PF_6 solution. The reddish purple solid formed was collected and dried in vacuo (92 mg, 88 % yield). Elemental analysis calcd for $C_{37}H_{29}F_{12}N_7OP_2Ru$ (**1**·H_2O): C 45.41, H 2.99, N 10.02; found; C 45.48, H 3.18, N 9.70. ^{1}H NMR (500 MHz, [D_6]acetone): $\delta = 9.15$ (d, J(H,H) = 7.8 Hz, 1 H), 9.09 (d, J(H,H) = 9.3 Hz, 1 H, pbn-H^4), 8.91 (d, J(H,H) = 1.0 Hz, 1 H), 8.90 (d, J(H,H) = 7.8 Hz, 1 H), 8.81 (d, J(H,H) = 9.3 Hz, 1 H, pbn-H^3), 8.71 (d, J(H,H) = 8.3 Hz, 1 H), 8.55 (s, 1 H, pbn-H^{10}), 8.54 (d, J(H,H) = 6.3 Hz, 2 H), 8.47 (d, J(H,H) = 5.4 Hz, 1 H), 8.35 (dt, J(H,H) = 7.8, 1.0 Hz, 1 H), 8.32 (dt, J(H,H) = 7.8, 1.0 Hz, 1 H), 8.27 (dt, J(H,H) = 9.3, 1.0 Hz, 1 H), 8.23 (dt, J(H,H) = 9.3, 1.0 Hz, 1 H), 8.16 (d, J(H,H) = 8.8 Hz, 1 H, pbn-H^6), 8.12 (d, J(H,H) = 4.9 Hz, 1 H), 8.02 (dt, J(H-H) = 7.8, 1.0 Hz, 1 H), 7.99 (d, J(H-H) = 5.4 Hz, 1 H), 7.93 (dt, J(H,H) = 8.3, 1.0 Hz, 1 H, pbn-H^7), 7.85 (dt, J(H,H) = 7.8 1.0 Hz, 1 H), 7.83 (d, J(H,H) = 5.6 Hz, 1 H), 7.67 (dt, J(H,H) = 5.4, 1.0 Hz, 1 H), 7.59 (t, J(H,H) = 7.3 Hz, 1 H, pbn-H^8), 7.56 (dt, J(H,H) = 5.9, 1.0 Hz, 1 H), 7.48 (dt, J(H-H) = 6.3, 1.0 Hz, 1 H), 7.42 (dt, J(H,H) = 7.3, 1.0 Hz, 1 H), 7.33 ppm (d, J(H,H) = 8.3 Hz, 1 H, pbn-H^9). ESI-MS: $m/z = 335.5$ $[M-2PF_6]^{2+}$.

Electrolytic reduction of **1**: Reduction of **1** was performed in a solution of DMF/0.1 M aqueous AcOH/AcONa buffer (1:9, 10 mL) and supporting electrolyte (NaCl, 0.1 M) under controlled potential electrolysis at −1.14 V (versus Fc/Fc$^+$) by using an electrolysis cell consisting of three components: the working (glassy carbon) and counter (platinum plate) electrode compartments were separated by an anion-exchange membrane (AMP). An Ag/Ag$^+$ reference electrode was separated from the working compartment by a luggin capillary. N_2 was bubbled through the solution in the cell for 1 h followed by pre-electrolysis at −1.2 V, then a solution of **1** (19 mg, 20 μmol) in DMF (1 mL) was added. The solution changed from red-purple to orange-brown after about 3 C consumed. After consuming 4.2 C, the solution was transferred to a Schlenk tube, and the solvent was removed by evaporation to give a brown solid. ^{1}H NMR (500 MHz, [D_6]acetone): $\delta = 8.83$ (t, J(H,H) = 7.8 Hz, 2 H), 8.82 (d, J(H,H) = 7.8 Hz, 2 H), 8.68 (s, 1 H, pbnH_2-N*H*), 8.64 (d, J(H,H) = 5.4 Hz, 1 H), 8.52 (d, J(H,H) = 8.3 Hz, 1 H), 8.44 (d, J(H,H) = 8.8 Hz, 1 H, pbnH_2-H^3), 8.17–8.24 (m, 5 H), 8.07 (t, J(H,H) = 7.8 Hz, 1 H), 7.98 (d, J(H,H) = 5.4 Hz, 1 H), 7.84 (d, J(H,H) = 4.9 Hz, 1 H), 7.68 (d, J(H,H) = 5.4 Hz, 1 H), 7.60–7.66 (m, 3 H), 7.52 (t, J(H,H) = 6.8 Hz, 1 H), 7.41 (d, J(H,H) = 8.8 Hz, 1 H, pbnH_2-H^4), 7.33 (t, J(H,H) = 6.3 Hz, 1 H), 7.00 (t, J(H,H) = 7.3 Hz, 1 H, pbnH_2-H^8), 6.71 (d, J(H,H) = 7.8 Hz, 1 H, pbnH_2-H^9), 6.67 (t, J(H,H) = 7.8 Hz, 1 H, pbnH_2-H^7), 6.18 (d, J(H,H) = 7.3 Hz, 1 H, pbnH_2-H^6), 4.19 (d, J(H,H) = 21 Hz, 1 H, pbnH_2-H^{10}), 3.18 ppm (d, J(H,H) = 21 Hz, 1 H, pbnH_2-H^{10}). ESI-MS: $m/z = 336.5$ $[M-2PF_6]^{2+}$.

Electrolytic reduction of acetone: Acetone reduction was performed in a 1:1 solution of acetone/0.1 M aqueous AcOH/AcONa buffer containing **1** (1 mM) and supporting electrolyte (NaCl, 0.1 M) under controlled potential electrolysis at −1.14 V (versus Fc/Fc$^+$) by using an electrolysis cell similar to that used in the reduction of **1**. The analysis of the solution was carried out by sampling 0.1 mL portions from the solution after appropriate intervals of time. Qualitative and quantitative analyses of the product were conducted by using GC-MS and GC, respectively.

[8] Crystallographic data for **1**·acetone: monoclinic, $P2_1/n$ (no. 14), $a = 13.761(10)$, $b = 18.05(1)$, $c = 16.67(1)$ Å, $\beta = 101.558(9)°$, $V = 4056(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.668\ g\,cm^{-3}$, $\mu(Mo_{K\alpha}) = 5.65\ cm^{-1}$, $R1(R_w) = 0.098$ (0.234) for 8963 unique data with $I > 2\sigma(I)$ and 568 parameters. A suitable single crystal for the measurement was mounted on a glass fiber. Data were collected at −100 °C on a Rigaku/MSC Mercury CCD diffractometer by using graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71070$ Å). All data were collected and processed using the Crystal Clear program (Rigaku). All the calculations were carried out by using the teXsan software package.[11] All structures were solved by direct methods and expanded using Fourier techniques. Refinements were performed anisotropically for all non-hydrogen atoms by the full-matrix least-squares method. Hydrogen atoms were placed at the calculated positions and were included in the structure calculation without further refinement of the parameters. CCDC-248968 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[10] We tried to isolate and recrystallize complex **2**. However, good single crystals of **2** were not obtained, since recrystallization of **2** gave a mixture of **1** and **2**. Complex **2** is unstable in air and in solution under inert atmosphere, and slowly changed into complex **1**. ESI-MS analysis showed **2** at first, but the parent signal of **1** gradually appeared with time. Since the recrystallization has not resulted in purification of **2**, the elemental analysis was not completely satisfactory.

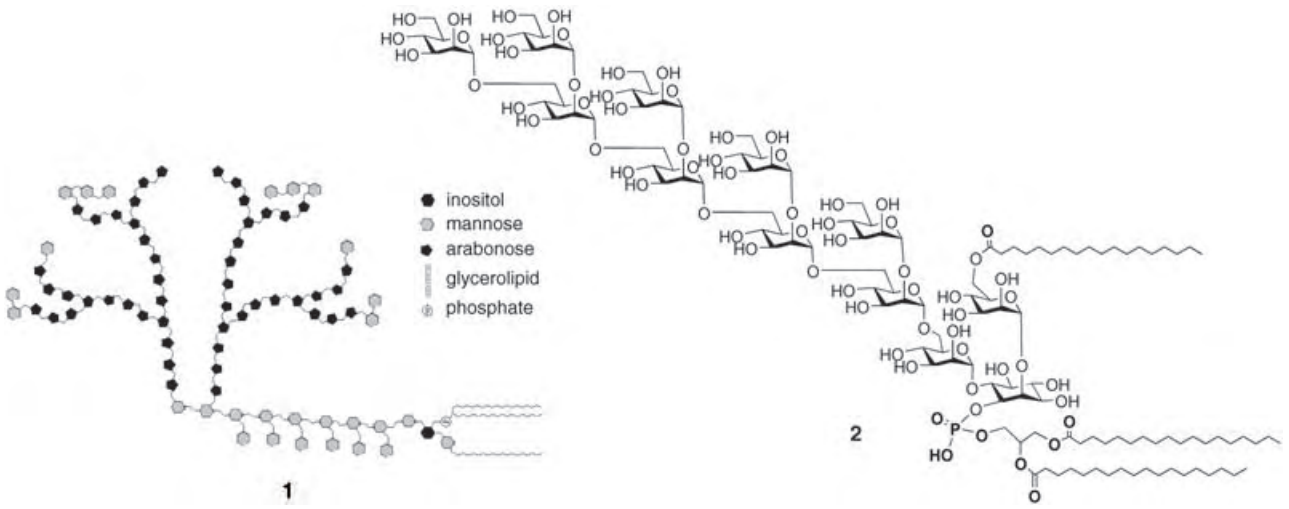
Synthesis of a Lipomannan Component of the Cell-Wall Complex of *Mycobacterium tuberculosis* Is Based on Paulsen's Concept of Donor/Acceptor "Match"**

*K. N. Jayaprakash, Jun Lu, and Bert Fraser-Reid**

The resilience of tuberculosis, evident in the continuing worldwide mortality from this disease,[1] is largely attributable to the dense complex lipoarabinomannan (LAM) capsule that is the major virulence factor of the causative agent *Mycobacterium tuberculosis*.[2] Significant interest stems from recent discoveries showing that LAM exhibits a profound propensity toward immunomodulation,[3] the ability to enhance resistance to various cancers[4,5] and herpes,[6] and a surprising capacity to potentiate HIV antiretroviral drugs.[7] This multifaceted biological profile is matched by its multifaceted architecture,[8] shown as compound **1** by Turnbull



Scheme 1. 1) NaH, BnBr, TBAI, DMF; 2) TBDPSCl, Et_3N, DMAP, CH_2Cl_2; 3) TBDMSCl, imidazole, THF; 4) TrCl, DMAP, Et_3N, py; 5a) TBDMSCl, imidazole, THF, 5b) NaH, BnBr, DMF, 5c) TBAF, THF, 5d) BzCl, DMAP, py; 6) $Yb(OTf)_3$, CH_2Cl_2, O°C; 7) AcOH, H_2O, acetone; 8) NaOMe, CH_2Cl_2, MeOH; 9) CCl_3CN, DBU, CH_2Cl_2. Bn = benzyl, Bz = benzoyl, DMAP = 4-(dimethylamino)pyridine; DMF = *N*,*N*-dimethylformamide; py = pyridine; TBAI = *tert*-butylammonium iodide; TBAF = *tert*-butylammonium fluoride; TBDMS = *tert*-butyldimethylsilyl, TBDPS = *tert*-butyldiphenylsilyl, TCA = trichloroacetyl, Tr = trityl.

et al.[9] Subunits of **1**, which reflect the stages in its biosynthesis, are dispersed throughout the cell wall and are of independent interest. For example, the lipomannan (LM) backbone of **1** exhibits "strong proinflammatory and apoptosis-inducing activity".[10] Herein, we outline a novel synthetic strategy for the assembly of the complex lipomannan domain **2**.

The standard approach to compounds such as **2** normally entails skillful deployment of a bewildering variety of protecting groups.[11] However, a less daunting approach relies on an insight into regioselective glycosidation[12] learned, in part, from the seminal concept by Paulsen of a donor/acceptor "match".[13] This insight can be supported by chemoselective donor activation with Lewis acid salts,[14,15] which is preferable to arming and disarming substrate compounds with protecting groups[16] and other strategies of chemical control.[17]

Thus, the *n*-pentenylorthoester (NPOE) **3a** is readily prepared[18] and can be converted into analogues **3b**–**3f** by using standard procedures (Scheme 1, see page 5894). Lanthanide triflates can then be used 1) to rearrange them into disarmed donors (**3c**→**4a**, **3d**→**4c**, and **3e**→**4f**), and 2) to generate iodonium ion (I^+) from *N*-iodosuccinimide (NIS). However, if $Yb(OTf)_3$ is used for the latter purpose, NPOEs are chemoselectively activated[14,15] without affecting disarmed or armed *n*-pentenyl glycosides (NPGs) such as **4a** and **4b**. Alternatively, the hydrolysis of an NPOE gives a protected mannose (for example, **3d**→**4d**), which opens a facile route to popular trichloroacetimidate donors such as **4e**, which can also be activated by $Yb(OTf)_3$.[15,19]

Scheme 2. 1) NaH, BnBr, TBAI, DMF, 2 h, 98%; 2) PTSA, MeOH, CH_2Cl_2, 89%. NPOE = *n*-pentenylorthoester; NIS = *N*-iodosuccinimide; PTSA = *p*-toluenesulfonic acid; TESOTf = triethylsilyl triflate.

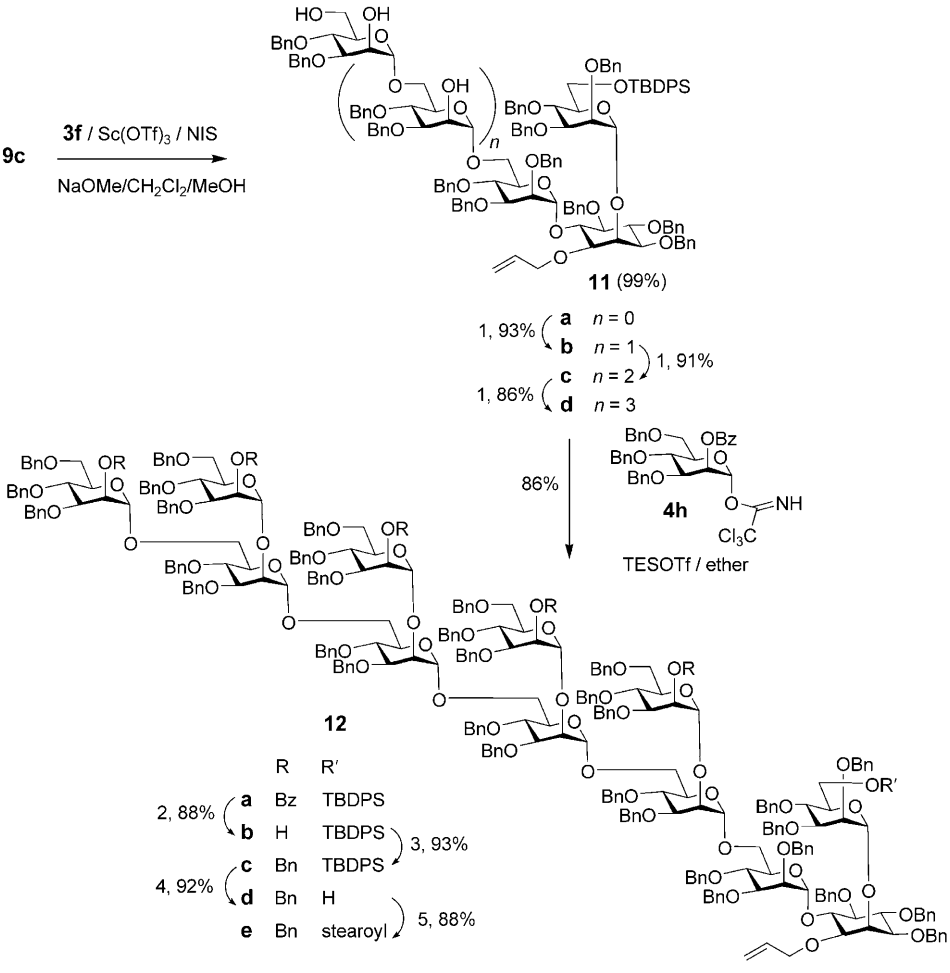
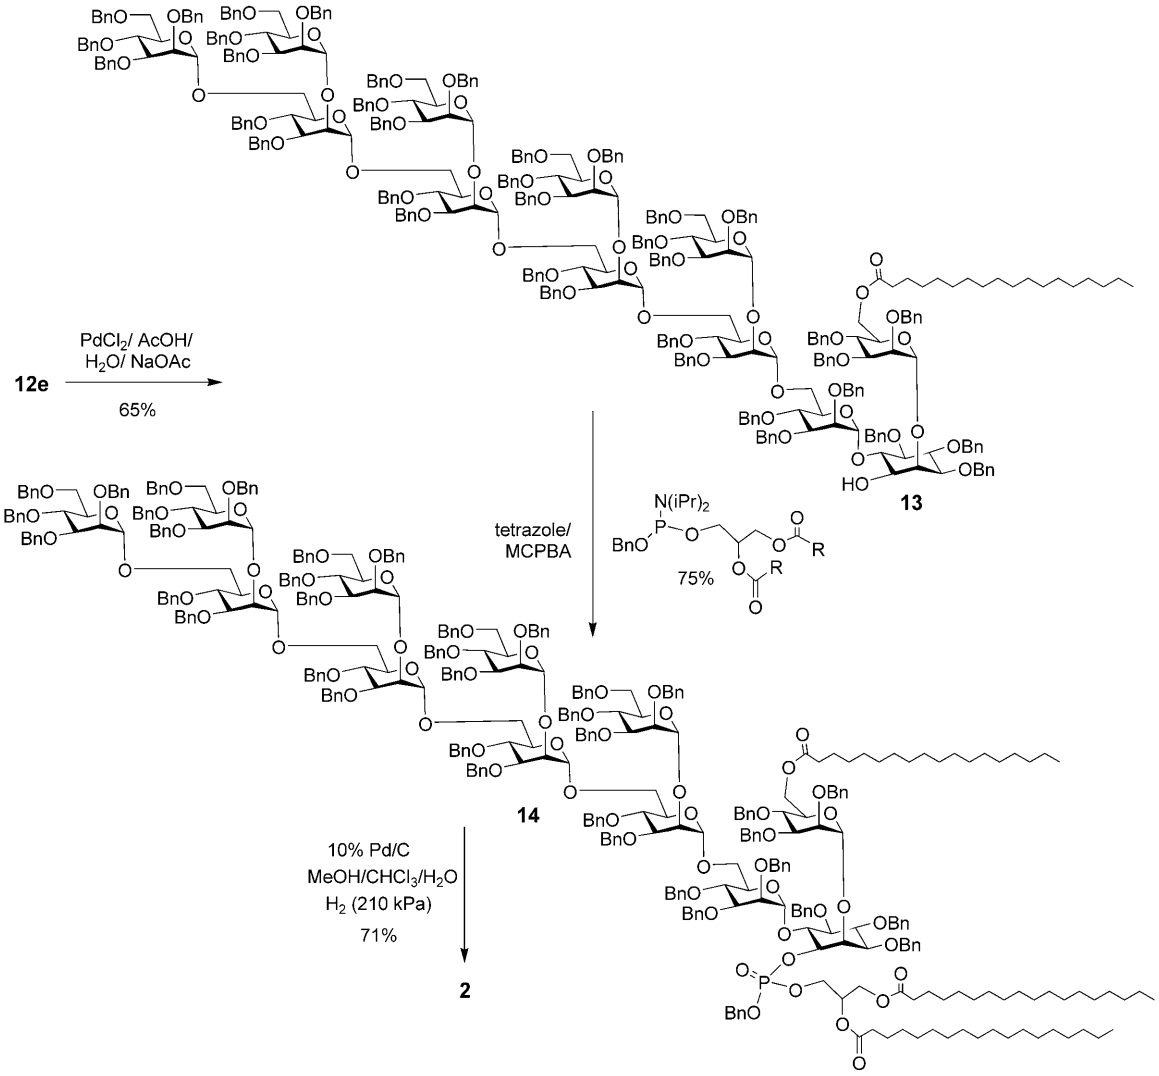
The foregoing salt-based regio- and chemoselectivities are opportune for the formidable challenges presented by compound **2**. The phosphoinositide domain requires the attachment of two mannoside donors, differentiated by O6 protecting groups, to an inositol acceptor diol. Encouraged by the recent success at double differential glycosidation,[15] the known diol **5**[20] was treated with the NPOE **3c** (2 equiv) promoted by $Yb(OTf)_3$/NIS to optimize monoglycosidation, with the confidence that the disarmed NPG **4a** produced by rearrangement would not be activated (Scheme 2).[14] Indeed, **6a** was isolated in 92% yield, and then treated with trichloroacetimidate **4e** (1.5 equiv) by using TESOTf. Compound **7** was obtained in 40% yield, but surprisingly with a selectivity of 1:1 for α/β configurations at the newly formed anomeric center.



This disappointing stereoselectivity (and modest yield) persisted even if the NPOE **3d** was used together with $Sc(OTf)_3$/NIS. The low yields may be rationalized by donor/acceptor studies, supported by the observations of van Boom and co-workers[21] as well as ours,[22] which indicate that a disarmed donor or NPOE is not a good "match" for inositol-2-OH.

A further problem with **7** was that the TBDMS group could not be selectively removed. This forced us to investigate an alternate route that involved the tritylated analogue **8**. Accordingly, pseudodisaccharide **6b**, prepared in 97% yield from diol **5** and excess NPOE **3f**, was treated with armed NPG **4b** and $Sc(OTf)_3$/NIS. The near quantitative yield (94%) of **8**, supports the "match" between the armed donor **4b** and the inositol-2-OH. The material appeared to be homogeneous by TLC, but debenzoylation led to separable products **9a** and **10** in a ratio of 8:1. The ^{13}C NMR spectroscopic data for the anomeric carbon atoms ($\delta = 99.85$ and 98.29 ppm and $\delta = 101.96$ and 98.33 ppm, as indicated in Scheme 2, see page 5895) identified their configurations as αα and αβ, respectively.

Isolation and benzylation of the αα product led to compound **9b** and thus acceptor **9c**. The latter, upon treatment with the O6-benzoylated NPOE **3f** and activation by $Sc(OTf)_3$/NIS followed by debenzoylation, gave pseudotetrasaccharide **11a** in 93% yield (Scheme 3). Iteration of the last two steps, but with $Yb(OTf)_3$ to ensure regioselective glycosidation at the primary hydroxy group, led to triol **11b**, tetraol **11c**, and pentaol **11d**, with excellent yields maintained throughout. The structure of **11d** was supported by resolved signals in the ^{13}C NMR spectra for six anomeric carbons ($\delta = 100.14$, 100.112, 99.83, 99.72, 99.12, 98.25 ppm).



Pentaol **11d** was treated with trichloroacetimidate **4h** (10 equiv) and TESOTf to give the pseudododecasaccharide **12a** in 86% yield. The anomeric signals were merged, but the debenzoylated counterpart, **12b**, displayed seven discrete ($\delta = 102.13$, 101.91, 101.74, 101.29, 101.28, 99.54, 99.32 ppm) and two overlapping sets of two ($\delta = 98.85$, 98.23 ppm) anomeric carbon signals in the ^{13}C NMR spectra, consistent with the 11 pyranoside residues.

Routine high-yielding benzylation and desilylation steps paved the way for installation of the stearoyl ester in **12e** by standard treatment with stearoyl chloride. Palladium-catalyzed deallylation provided **13** (Scheme 4), and the resulting inositol-1-OH cooperated well with our standard phosphoglycero-lipidation protocol[23] involving reaction with the lipidated glyceryl phosphoramidite followed by oxidation with MCPBA.[22a,24] The penultimate product **14** was obtained in 71% yield.

Scheme 3. 1a) **3e**, $Yb(OTf)_3$, NIS, CH_2Cl_2, 1b) NaOMe, MeOH, CH_2Cl_2; 2) NaOMe, MeOH, CH_2Cl_2; 3) NaH, BnBr, TBAI, DMF; 4) TBAF, MS, THF; 5) stearoyl chloride, DMAP, py, CH_2Cl_2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 4. The final steps in the synthesis of **2** from stearoyl ester **12e**. MCPBA = *meta*-chloroperbenzoic acid.

Exhaustive debenzylation of **14** (30 mg) was effected in methanol/chloroform/water solution with palladium (10%) on carbon and hydrogen at 2.1×10^{-5} Pa for 3 h at room temperature. Chromatographic purification (Sephadex column) afforded **2** (10 mg, 71%), which showed eleven anomeric proton signals between $\delta = 4.51$ and 5.02 ppm in the ^{1}H NMR spectra and signals for phosphorus diastereomers at $\delta = 0.61$ and 0.49 ppm in the ^{31}P NMR spectra. Additional confirmation was obtained by MS (for M+2Na: calcd: 2961.4; found: 2961.6). Biological assays on **2** are currently underway and will be reported in due course.
